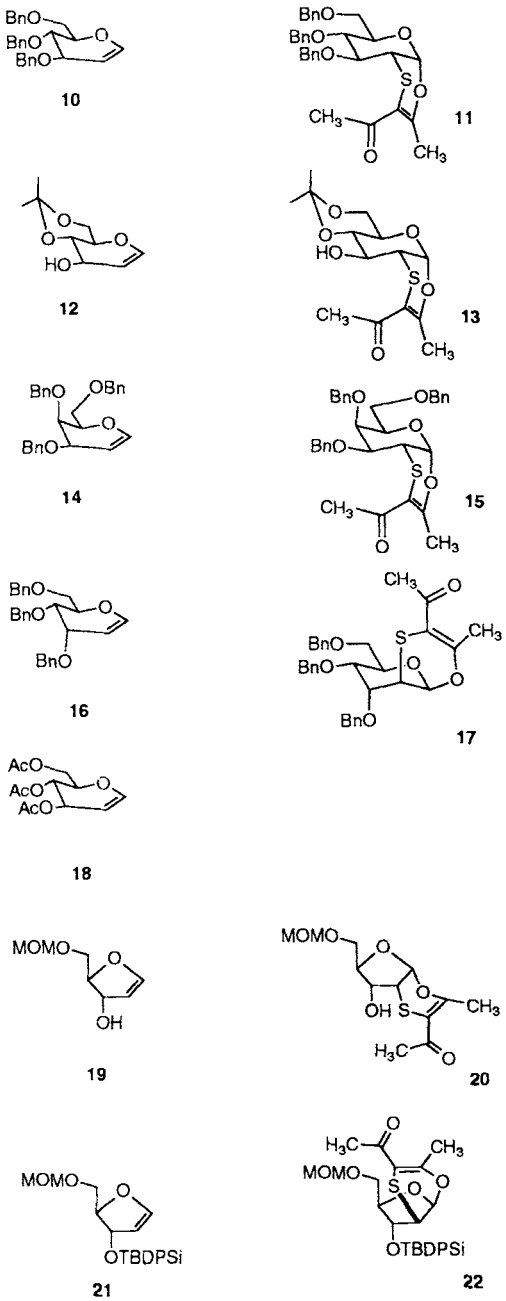
The results of our exploratory work are summarized in Table 1; the corresponding formulas are in Scheme 1. In a typical experiment 3-phthalimidosulfenylpentanedione (**8**) was mixed with a glycal and an equivalent of pyridine or lutidine in CH_2Cl_2 at room temperature. Workup generally afforded pure crystalline products after straightforward chromatographic removal of phthalimide, unreacted glycal, and residual pyridine or lutidine. One interesting feature of the cycloaddition is the qualitative correlation of reactivity with the HOMO–LUMO gap of the reactants.[5] The cycloaddition appears to be a reaction with

Table 1. Results of cycloadditions of diacylthione **9** (LUMO −1.62 eV) to glycals.

Entry	Dienophile [a]	ΔE(HOMO–LUMO) [eV] v [b]	Adduct	Yield [%]
1	**10** (−9.53)	7.91 slow $t_{1/2}$: 3 d	**11**	80
2	**12** (−9.53)	7.91 slow $t_{1/2}$: 3 d	**13**	54
3	**14** (−9.17)	7.55 moderate $t_{1/2}$: 12 h	**15**	73
4	**16** (−9.50)	7.88 slow $t_{1/2}$: 3 d	**17**	68
5	**18** (−9.74)	8.12 no reaction		
6	**19** (−9.39)	7.77 moderate $t_{1/2}$: 1 d	**20**	74 3.6α/1β
7	**21** (−9.35)	7.73 moderate $t_{1/2}$: 1 d	**22**	42 1α/3β

[a] Numbers in parentheses are LUMO energies [eV]. [b] Apparent rate.



Scheme 1. Structural formulas of the compounds listed in Table 1. MOM = methoxymethyl; TBDPSi = *t*-butyldiphenylsilyl.

inverse electron demand, since the smallest differences in energy are between the HOMO of the glycal dienophile and the low-lying LUMO of the heterodiene. Table 1 includes the pertinent energy levels as computed at the AM1 level with the SPARTAN program package.[6] In this reaction the sugar may be either protected or unprotected; however, acetates lower the HOMO of the glycal so that it adds to only very reactive acylthiones (cf. entry 5 in Table 1 and entry 2 in Table 2). The stereochemistry of the adducts conforms with our earlier proposal[7] that the glycal π bond is polarized below the plane except in the allal case (entry 4 in Table 1) where both the polarization and the obvious steric effects direct the cycloaddition above the plane. The NMR spectra of the crude products before chromatography do not give evidence for stereoisomeric adducts [with the exception of furanoid glycals, entries 6 and 7 in

Table 2. Results of cycloadditions of diacylthione **24** (LUMO -2.22 eV) to glycals.

Entry	Dienophile [a]	ΔE(HOMO-LUMO) [eV] v [b]	Adduct [c]	Yield [%]
1	**10** (-9.53)	7.31 moderate $t_{1/2}$: 1 d	**25**	43
2	**18** (-9.74)	7.52 moderate $t_{1/2}$: 1 d	**26**	50
3	**14** (-9.17)	6.95 fast $t_{1/2}$: 1 h	**27**	52
4	**16** (-9.50)	7.28 moderate $t_{1/2}$: 1 d	**28**	50

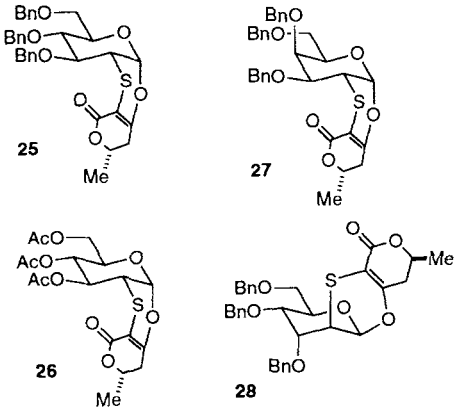
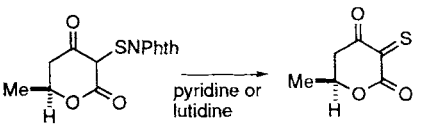


Scheme 2. Structural formulas of the compounds listed in Table 2.

Table 1, and the reaction of diene **30** derived from barbiturate summarized in Equation (g)]. But conclusive proof that no stereoisomeric adducts are formed can be drawn only after comparison of the spectra with those of independently prepared compounds. For entries 2 and 4 in Table 1, the stereochemistry has been confirmed by X-ray crystal structure determinations. Table 2 presents the results obtained with cyclic diacylthione **24**, which is generated in situ according to Equation (f). Since **24**



(f)

23 **24** (-2.22 ev)

has a lower lying LUMO, it is somewhat more reactive than the pentanedione-derived thione. The barbituric acid derived thione **30** affords a 9/1 mixture of α and β adducts in 64% combined yield [Eq. (g)].

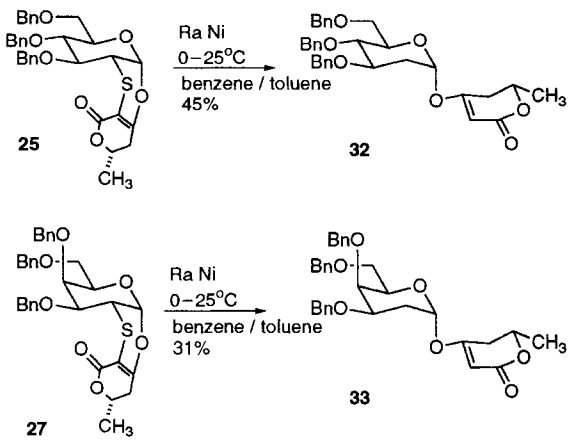
To illustrate our scheme for glycoside synthesis without conventional glycoside chemistry, we have treated cycloadducts **25** and **27** from Table 2 with W-2 Raney nickel at room temperature to yield glycosides **32** and **33** in 45% and 31% yield, respectively (Scheme 3). This conversion is quite sensitive to the age of the



Scheme 3.

catalyst; reduction of the enol ether double bond is a persistent problem.[8] A survey of desulfurization catalysts has not yet been carried out, but it is our goal to obtain yields for the second step at least equal to those of our cycloaddition.

Our cycloaddition concept is an easily accessible approach for highly stereoselective glycosyl transfer and is orthogonal to conventional carbohydrate methodology. Further goals are to employ heterodienes with elements other than sulfur and oxygen at the termini.[9] We are also developing subsequent reactions at the anomeric carbon of our novel cycloadducts.

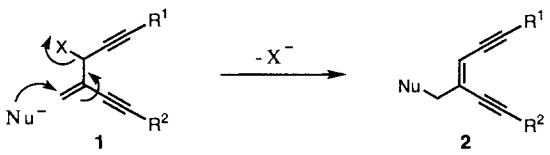
Synthesis of *cis*-Enediynes from 1,5-Diynes by Rearrangement of an Allylic Double Bond**

Wei-Min Dai,* Kin Chiu Fong, Hiroshi Danjo, and Sei-ichi Nishimoto

Until the discovery of the class of enediyne antitumor antibiotics[1, 2] in 1985 and shortly thereafter, the benzenoid diradical derived from the cycloaromatization of enediynes, discovered in 1971–1972,[3] had not received much attention for potential application in biomedical science. During recent years numerous enediynes have been synthesized,[1a] and their ability to damage DNA[4] and kill cancer cells has been demonstrated.[5] Synthesis of pro-enediyne compounds[6] is a new direction of enediyne studies. Introduction of a double bond into 1,5-diynes has been achieved by elimination[7] of mono- or diols under reductive, basic, acidic, or neutral conditions. Oxidation[8a] and photochemical processes[8b] have been also used. In this communication, we report for the first time[9] the synthesis of acyclic *cis*-enediynes **2** from 1,5-diynes **1** by an allylic double bond migration (Scheme 1).



Scheme 1. Synthesis of enediyne **2** from 1,5-diyne **1** by rearrangement of the allylic double bond. Nu = nucleophile.

The enyne aldehydes **5** and **7** were synthesized by the Pd^0-mediated cross coupling reaction of **3**[10] with acetylene derivatives **4** and **6**, respectively (Scheme 2). Addition of $Li-C\equiv CR^2$ to **5** or **7** at −80 °C provided the 1,5-diynes **8a–h** in good yield (Table 1). Formation of the methanesulfonate (mesylate) of **8c** (CH_3SO_2Cl, NEt_3, THF, −80 to 0 °C) was initially attempted. However, only the rearranged allylic alcohol **9c** was isolated. This result suggested that the mesylate was too unstable to be isolated.[11] It decomposed to **9c** after exposure to moisture or aqueous work up. We also noted a set of signals at δ = 5.45 (s) and 5.99 (s), in addition to the signals [δ = 5.19 (s) and 5.99 (s)] of **9c** in the ^{1}H NMR spectrum of the crude product. However, these peaks disappeared after purification by flash column chromatography over silica gel. We suspected that this mysterious compound was the putative allylic chloride formed by attack of chloride ion at the γ position of the mesylate. The chemical yield of **9c** was improved by using $(i\text{Pr})_2\text{NEt}$ and quenching the reaction with aqueous $NaHCO_3$

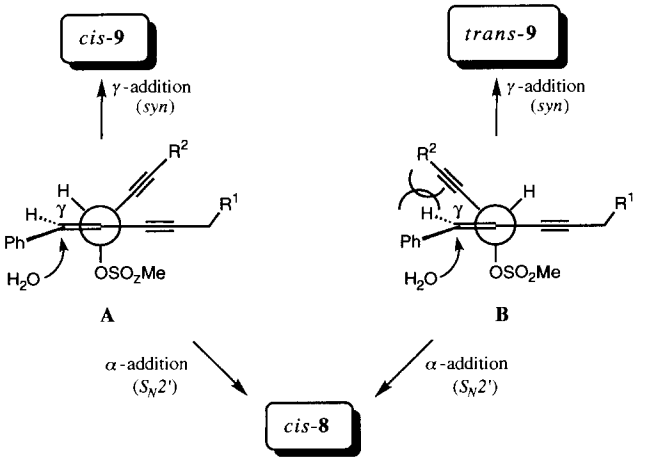
[a] 90:10 mixture of *cis*-**9b** and *cis*-**8b**. [b] 95:5 mixture of *cis*-**9e** and its *trans* isomer. [c] 80:5:10:5 mixture of *cis*-**9g**, *trans*-**9g**, *cis*-**8g**, and *trans*-**8g**.

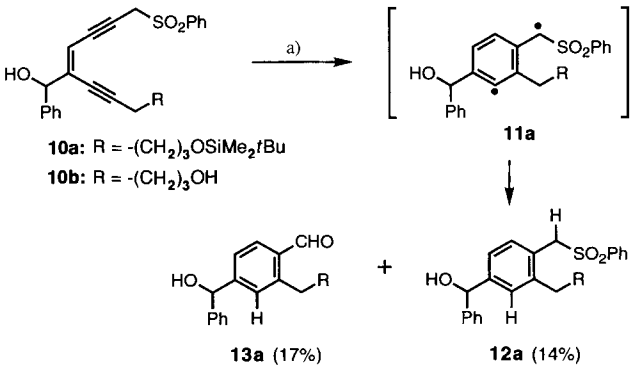
solution at −80 °C. Rearrangement of the allylic alcohols **8** turned out to be a general reaction. Table 1 lists the yields of the eight enediynes isolated. Compounds **9a,c,d,f,h** were formed in the high regio- and stereoselectivity that might be expected for an S_N2' reaction mechanism of *syn* attack[12] at the γ position.[13] The transition state **A** in Scheme 3 illustrates the favorable pathway leading to *cis*-**9**. A similar transition state **B** that would afford *trans*-**9** is destabilized by the strain of the



Scheme 3. Postulated transition states **A** and **B** of the allylic rearrangement. Both transition states can add H_2O at the γ and α positions (S_N2' and S_N2, respectively). The γ addition is shown.

allyl system, which interacts with the acetylene substituent (-C≡CR^2). A small fraction (5%) of *cis*-**9e**, where R^2 is H, was formed through **B**. The *anti* attack of a nucleophile at the α position is also possible.[13] We observed 10% of the α addition product for **8b** that was formed via **A**. In this case the α addition product should be the enantiomer of the starting alcolhol *cis*-**8b**. Only for one substrate, **8g**, were four isomers *cis*-**9g**, *trans*-**9g**, *cis*-**8g**, and *trans*-**8g** isolated; *cis*-**9g** was the major component (80%) (Table 1). Since addition of H_2O to the mesylate could not produce *trans*-**8g** via transition states **A** and **B** either by γ or by α addition, an alternative mechanism involving a stabilized allylic cation might account for the product distribution.[14]

The migration of the allylic double bond causes the chemical shifts of the vinyl and methine protons in **9** to differ significantly from those of **8**. The signals of the vinyl protons in **9a–h** move to high field ($\Delta\delta$ ranges between 0.67 and 0.84), while those for the methine protons (with the exception of those of **9b** and **9g**) shift downfield by $\Delta\delta$ = 0.19–0.45. Nuclear Overhauser effect (NOE) experiments confirmed the configuration of the double bond in **9**. Irradiation at the vinyl proton of **10a** (Scheme 4) gave



Scheme 4. Base-induced cycloaromatization of **10a**. a) Et_3N, degassed benzene/1,4-cyclohexadiene (10:1), 20 °C, 24 h.

8.8% enhancement of the signal for the methine proton but did not affect the the protons of the aromatic ring. Further evidence supporting the *cis* configuration of **9** was provided by a base-induced cycloaromatization (Scheme 4) of the sulfone **10a** prepared by oxidation of **9d** (*m*CPBA, CH_2Cl_2).[15] All these results verified unequivocally the assigned structures for **9**. We examined the DNA cleavage by **10b** with ΦX174 Form I DNA. The agarose gel picture shown in Figure 1 indicated that the proportion of single strand cleavage product (Form II DNA) increased with increasing amount of **10b**. About 40% Form I DNA was converted into Form II DNA at concentration of 5.0 mM (Lane 6).

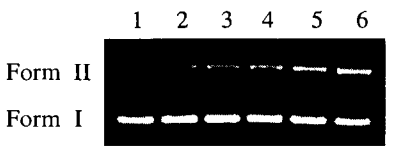


Fig. 1. Results of DNA cleavage by **10b**. ΦX174 Form I DNA (50 μM/bp) was incubated for 72 h at 37 °C with **10b** in TEA buffer solution (pH 8.5) containing 20% DMSO and analyzed by electrophoresis (1% agarose gel, ethidium bromide stain). Lane 1: DNA control without incubation; lanes 2–6: DNA with 0.1, 0.5, 1.0, 2.0, and 5.0 mM **10b**, respectively.

In summary, an efficient synthesis of acyclic *cis*-enediynes has been established for the first time by migration of an allylic double bond into 1,5-diyne. The S_N2' reaction pathway proceeded with remarkably high stereoselectivity to provide the *cis* isomers. Rearrangement of the allylic double bond in the mesylate intermediate of **8** by other nucleo-

philes such as alcohols and thiols were also performed and provided the *cis*-enediynes as major products.

Corrigenda

In the review "Electronegativity and Molecular Properties" by D. Bergmann and J. Hinze (*Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 150–163), Equation (49) should read as follows:

$$D_{AB} = \frac{1}{(1 + |Q_A Q_B|)}\left[\frac{1}{2}(D_{AA} + D_{BB}) + c_3 \frac{(\chi_A - \chi_B)^2}{4(\eta_A + \eta_B)} + c_4 \frac{Q_A Q_B}{d_{AB}}\right] \qquad (49)$$

Furthermore, three corrections are necessary in Table 5: $c_3 = 18.36 \frac{\text{kcal}}{\text{mol eV}}$, $c_4 = -751.98 \frac{\text{kcal Å}}{\text{mol e}^2}$, and the bond dissociation energy of N(te) should be 87.2 kcal mol^{-1}.

In the communication "Single-Chain Polyprenyl Phosphates Form 'Primitive' Membranes" by G. Ourisson et al. (*Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 177–180) the structure of Nile Red was incorrectly given as that of 9-methylanthracene, as in the catalog (Molecular Probes) from which Nile Red was ordered. The excitation and emmission wavelengths given in the communication and correct.

An Orgy of Organic Synthesis

Encyclopedia of Applied Physics. Vols. 1–12, Accelerators to Optics. Edited by *G. L. Trigg*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1991–1995. Hardcover DM 450.00/398.00 (single/set) per volume.—ISBN 1-56081-058-0 (set)

So far, we have reached Volume 12 (Nuclear Waste Management to Optics, Underwater) in this massive undertaking published by VCH and sponsored by the American Institute of Physics, the Deutsche Physikalische Gesellschaft, the Japan Society of Applied Physics, and the Physical Society of Japan. Now we have come more than halfway through the alphabet since Accelerators, Linear first saw the light of day in 1991, and successive volumes of about 600 pages each have provided us with a rich fare of 300 articles, with another 200 to come. I have to declare an interest, for I act as an editorial consultant. However, that has given me some insight into the care and attention to quality that has gone into this enormous work. Each article has been commissioned from an expert or a small team; the outline plan is assessed, as is the final typescript. A cumulative index appears with approximately every third volume, and the final volume will contain the complete index. The index is necessary, partly because in a work spread over so many years and written by so many hands, some articles have to be renamed to let them fall later in the alphabet than they were first expected.

Many articles conclude with a glossary of terms, which is very helpful. They all list the works cited and include a list of further reading. However, I did detect some references to books published in the early 1960s, which suggest a somewhat moribund field (or perhaps author). There is a smattering of colored plates. Some articles conclude with lists of research opportunities and major outstanding problems: few authors can be expected to be so generous with their ideas.

I shall direct part of this review at the content of the *Encyclopedia* that is likely to be of immediate interest to chemists. Most readers of this journal will no doubt wonder anxiously whether "applied physics" might merely include "chemistry" as an article, and leave it at that. That is not the case. Although Volume 3 (Calibration and Maintenance to Collective Phenomena in Solids) does contain Chemical Analysis, Chemical Kinetics, and Chemical Reactions, there is a healthy emphasis on chemistry throughout the twelve volumes currently available. Indeed, of the 300 articles before me, about 30 are unarguably of direct interest to chemists, and many more provide useful peripheral information or contain chemistry buried within. For instance, there are articles on air pollution, atoms, conformational analysis, crystallography, diffraction, electrochemistry, fullerenes, glasses, laser photochemistry, molecules, and nucleic acids.

It must be admitted that some of these articles, particularly those on ostensibly chemical topics contributed by physicists (although a good number of chemists have also contributed), do have a rather physics spin on them. However, that can be viewed as providing a healthy shift in perspective, and affords a way of letting a chemist see how a physicist views the topic. Who knows, the shift in perspective might even stimulate a fruitful shift in a chemist's attitude. On the other hand, the ostensibly physical articles provide a bridge for traveling in the opposite direction: they are moderately succinct summaries of concepts from a wide range of physics, and many of these core topics are essential to a chemist's understanding of instrumentation and the properties of materials and fields. A chemist is much more likely to want this set of volumes for the doorway they provide into applied physics than for the descriptions they give of the more elementary aspects of chemistry. Here the user will be well rewarded, for the articles are up-to-date and cover topics that chemists are likely to want to know about, at least superficially.

I do have some minor criticisms. With well over 500 authors at work, there is inevitably a variability in clarity of exposition. Some authors have been too restricted by the compass of their articles, and too much information, or just too much raw mathematics has been included for it to be readily digestible. On the other hand, some articles are really first class: they give compact, insightful summaries of the state of their topic. Secondly, there is a wide variability in the standard of illustration: some illustrations seem to have been done by amateurs with stencils; others are fine computer graphics; lettering sizes are all over the place.

Half the pleasure of an encyclopedia is in gaining information on the topic of interest; the other half is the luck of serendipitous discovery. These volumes have been slowly spreading along my shelves for about four years, and it is always a pleasure to learn about tuning handbells and their vibrational modes when one should actually be turning up information on nanophase materials (in Volume 11, Mössbauer Effect to Nuclear Structure), or to learn about explosives when I should have been making notes on excitons (in Volume 6, Electronic Circuits to Fusion, Magnetic Confinement).

It would be too much to expect individuals to buy the entire projected 20 volumes or so of the complete encyclopedia, and too frustrating for ownership to extend to no more than one or two favored volumes. An encyclopedia of this breadth is an all-or-none question of ownership. Nevertheless, it is certainly an obligation for libraries to make this span of readily accessible and up-to-date knowledge available to their readers. At the very least, such a work provides a starting point for deeper penetration of the literature; at its best, it provides just enough information to satisfy an immediate need. Libraries should certainly buy this set, and chemistry libraries in particular will find their money well spent.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Classics in Total Synthesis. Targets, Strategies, Methods. By *K. C. Nicolaou* and *E. J. Sorensen*, VCH, Weinheim, **1996**. pp. 798, Paperback DM 78.00—ISBN 3-527-29132-4, Hardcover DM 128.00—ISBN 3-527-29284-5

This very attractive book by Nicolaou—a master of the synthesis of complex molecules—and Sorensen is a hymn of praise to the high art of total synthesis. In this book the classical syntheses are, of course, discussed, like Woodward's reserpine and strychnine syntheses, Corey's and Stork's prostaglandin synthesis, and Woodward's and Eschenmoser's vitamin B_{12} synthesis. Three quarters of the book, however, cover the syntheses of the eighties and nineties. The syntheses are arranged chronologically. The good selection of increasingly more complex natural product syntheses illustrates very well the enormous advances that have been made in the last twenty years. In almost 800 pages the syntheses of about forty significant target molecules are described in a very engaging style. The work of Nicolaou is represented by six syntheses, together with that of other important natural product chemists in the USA, such as Corey, Still, Schreiber, Evans, and Danishefsky. Also interesting are the three industrial syntheses (by Merck, Hoffmann-LaRoche, and Takasago), which, with respect to the academic research, have a different status. For this reason other criteria determined their retrosyntheses.

For every natural product an overview of its biological properties, its significance, and its history is given in a short introduction. Potential problems and difficulties for the total syntheses are already mentioned at this juncture, which considerably facilitates the understanding of the retrosynthesis. Key reactions for the total synthesis are thoroughly discussed in this introduction. For example, in the case of rapamycin (Chapter 31) the Heck reaction, the Suzuki reaction, the Stille reaction, and the Sonogashira reaction are presented in detail. In the case of the palytoxin synthesis by Kishi the $NiCl_2/CrCl_2$-catalyzed coupling reaction is discussed, and in the chapter on zaragossic acid the most important features of the Sharpless dihydroxylation are covered. The reader is familiarized with the mechanism of these reactions as well as with the scope of their application. The retrosynthetic analysis always follows the introduction, and every reaction step is exhaustively discussed and the synthesis strategy presented very clearly. Finally the synthesis is described as it was actually performed. The conditions of the most important key reactions are given in detail, and the stereochemical and mechanistic aspects of these steps are thoroughly discussed. In this section the usefulness of many reagents is briefly explained, with the result that for each synthesis many important concepts and techniques of organic chemistry are covered. Moreover, an appendix on catalytic asymmetric synthesis is offered. This additional information increases the pedagogic value of the book even more and turns it into a valuable organic chemistry textbook. It contains aspects of sugar chemistry, radical chemistry, short but detailed explanations of the Cram–Felkin–Anh and the Baldwin rules, etc. The text is illustrated by many schemes that depict the reactions in excellent diagrams. The whole book is extremely reader-friendly and will without doubt become a best-seller. It is appropriate for undergraduate students as well as for graduate students. In addition it is eminently suitable for a course of special lectures on syntheses of natural products.

In summary, this book can and must be highly recommended. Its content provides an excellent picture of modern natural products chemistry. It will fire many chemists with enthusiasm for total synthesis and organic chemistry. In the light of its overwhelming content, its price of only about 80 DM for the softcover edition is more than reasonable.

Adventures of a Chemist Collector. By *A. Bader*. Weidenfeld and Nicholson, London, 1995. 288 pp., hardcover £ 14.99, $ 25.00.—ISBN 0-297-83461-4

Alfred Bader is a remarkable and compassionate *Mensch* (human being), whose visits with his wife Isabel through the years as roving ambassador for the Aldrich Chemical Company (now Sigma-Aldrich), the world's largest supplier of research chemicals, have made him a familiar figure, welcomed on university campuses and in industrial laboratories alike. In keeping with Bader's genuine interest in people, which is reflected on almost every page, his autobiography, characteristically dedicated to Isabel, is as much concerned with other persons, especially those who have helped or influenced him in his career, as it is with himself.

It is an engrossing and romantic love story; it tells of his love for one woman, Isabel, who finally became his wife after a separation of a third of a century; of his love for what he calls the ABC of his life—art collecting, the Bible, and chemistry, to which he has made so many valuable contributions; of his love for a city, Milwaukee, Wisconsin, to which he has remained faithful despite opportunities to relocate; of his love for a company, Aldrich, which he cofounded at age 27 and with which his name is still synonymous in spite of his unjust and undeserved expulsion as director; and his love of philanthropy and public service, by which he has tried to repay his debt to society and to persons and institutions who have helped him, and for which he received the American Chemical Society's 1995 Charles Lathrop Parsons Award "for his unprecedented innovation, ... for his vision and dedication as a chemist, ... but most of all for his unflagging ambassadorship to the international chemical community, which he has helped to mold into a truly global village".

This volume is also reminiscent of the biblical Book of Job—the saga of a moral, upright man whose triumph over tragedy, injustice, and adversity without bitterness or loss of faith is an inspiring tribute to the resilience of the human spirit.

Alfred Robert Bader was born in Vienna on April 28, 1924, the son of Alfred and Elisabeth Bader (née Serényi). The Baders were middle-class Jews, and the Serényis were devout Hungarian Catholic aristocrats. His father either committed suicide or was murdered two weeks after Alfred, called Bobby as a child, was born. Because his mother was left with almost nothing to support herself, Alfred, and his sister Marion during the extraordinary inflation raging in post-World War I Austria, he was adopted by his paternal aunt Gisela Reich, whom he regarded as his mother ("Muttili"). Although his sister received a strict Catholic upbringing, he was brought up with a love of Judaism, which has served as "a cornerstone of [his] life". He attended the *Sperlgymnasium*, a high school close to his home, from 1934 until July 1938 when, following the *Anschluss*, Jewish students above the age of 14 were not permitted to attend class.

Although the rest of his immediate family remained behind, in December 1938 Alfred emigrated to England with thousands of other Jewish children. He attended the East Hove Senior School for Boys, followed by the Brighton Technical Col-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3507-0784 $ 10.00+.25/0

lege until he turned 16, whereupon he was interned as an enemy alien, first in England and then in a Canadian prisoner-of-war camp. On November 2, 1941, after Martin Wolff, "the first father figure in [his] life", agreed to sponsor him, he was released, and that same month he entered Queen's University at Kingston, Ontario, where he majored in engineering chemistry. Receiving a $ 30 scholarship, he said to himself: "If ever I could, I would establish such scholarships", a promise that he later fulfilled to an extraordinary degree.

Bader obtained practical industrial experience in formulating lacquers during summer jobs at the Murphy Paint Company in Montreal. A $ 50 Scholarship in Public Speaking led him to join the debating society, and he admits: "I have enjoyed public speaking and debating ever since." His experience at Queen's University taught him that "there are two kinds of Christians, those to whom Christianity is just an empty shell and those to whom love, respect and care for neighbors are reality". In 1945 he received his B.Sc. and the medal in chemistry. He then spent an additional year at Queen's, earning an M.Sc. working on fatty acid chemistry.

Although accepted by the University of Zürich and the Eidgenössische Technische Hochschule (ETH), in September 1947 Bader entered Harvard University, because it offered him a fellowship. In only two and a half years he received his Ph.D. for research on naphthoquinones under Louis Fieser's supervision. Rather than accept a junior teaching position at the University of New Brunswick or continue at Harvard, on January 15, 1950, he moved to Milwaukee to work with the Pittsburgh Plate Glass Company (now PPG), which had purchased Murphy Paint, because he "wanted to start [his] own family and that seemed more important to [him] at the time than learning a good deal more chemistry". His starting salary, $ 400 per month, was the lowest received by any Harvard Ph.D. in chemistry. From these humble beginnings Bader was to become an internationally renowned and successful millionaire chemist, collector, and philanthropist.

On July 14, 1949, during a trip from Quebec to Liverpool, England on the S. S. Franconia, Bader met Isabel Overton, daughter of a deeply religious Protestant family from Kirkland Lake, Ontario, and nine days later he proposed to her despite their differences in religion. Isabel accepted a position teaching English and history at a private school for girls at Bexhill-on-Sea, England, and in letter 79 (1950) of the 408 letters that she wrote to Bader, who has preserved and numbered them, she wrote that she did not think their marriage would work and that she would not write to him again or answer any further letters. In the spring of 1950 he met Helen Ann Daniels ("Danny"), a Protestant girl who had converted to Judaism, long before he proposed to her on May 20, 1952. She differed from Isabel in "that she wanted to marry [him] and have a Jewish home and family". The two were married in July, and their two sons David and Daniel were born in 1958 and 1961. In 1975 Bader began having repeated frightening nightmares about Isabel's father. He learned that Isabel had never married, and the two resumed their correspondence. Danny requested a divorce, which took place in 1981. Bader provided for her well, and in 1982 he married Isabel. Danny died of ovarian cancer in November 1989.

On August 17, 1951, Bader and his friend Jack Eisendrath, a Milwaukee attorney, incorporated the Aldrich Chemical Company, named after Eisendrath's fiancée Betty Aldrich. Each of them contributed half the required capital of $ 500. The fledgling company's first product was methylnitrosonitroguanidine (MNNG), which Bader had learned to make while working for his M.Sc. at Queen's. All operations were first carried out in Eisendrath's office and then in a garage rented for $ 25 per month. According to Bader, "the greatest problem every entrepreneur faces is how to find really good employees", and he is proud of the fact that "with one minor exception, no union ever threatened us, and we never had a strike". Realizing that Aldrich could not succeed if it sold only what he knew how to make, Bader decided to combine production with resale, particularly of imports. He began his practice of spending several months every year "travelling in Europe, visiting small and medium-sized chemical companies, inquiring what we might purchase from them". He devotes an entire chapter to these visits, and he states: "Suppliers have been vital to Aldrich. Knowing them personally, understanding them and working with them fueled our growth." He similarly devotes a chapter to "Friends and Competitors".

Most of the sales of the rapidly growing company were for catalog items, and from Aldrich's inception Bader paid special attention to its catalogs and publications, including *Aldrichimica Acta*, which, appearing three or four times per year with its familiar cover usually adorned with an old master painting, has become a collector's item in itself. Aldrich established the American Chemical Society Award for Creative Work in Synthetic Organic Chemistry, and Bader established awards with the Royal Society of Chemistry and the Chemical Institute of Canada. By publication in the *Acta* the prize papers reached an audience greater than that for any chemical journal (by the 1980s more than 200000 copies of each *Acta* issue were distributed worldwide). Aldrich also participated in a number of joint ventures, some successful and some not. These included ALFA Inorganics and Aldrich-Boranes, formed at Nobel laureate Herbert C. Brown's suggestion. Aldrich made its first public stock offering in 1965, and by the late 1960s Bader realized that the greatest growth in chemical research lay in the field of biochemistry. In August 1975 Sigma, the leading supplier of biochemicals, and Aldrich, the leading supplier of organics, merged to form Sigma-Aldrich, with Dan Broida of Sigma as chairman of the board and Bader as president. Today the company employs more than 5000 employees with sales of $ 851 million.

The management styles of Sigma and Aldrich were very different, and Bader's difficulties with his successors at Sigma-Aldrich revolved almost entirely around how to treat people. Sigma-Aldrich's chief executive officer, Tom Cori, the only child of Nobel medicine laureates Carl and Gerty Cori, once told Bader: "Alfred, the problem with you is that you want to be liked, even loved. I don't have a single friend in the world, not one". In contrast, many of Aldrich's suppliers and customers had become Bader's good personal friends. He regarded himself as "a useful link between academics and our company", and he believed that "people are the key to success in every venture".

In May 1991 Bader retired but served as chairman emeritus (without pay beginning in 1992). Matters reached a crisis stage on November 20, 1991, when Cori and David Harvey, the chief operating officer, met with Bader in London and demanded that he sign a letter of resignation. Bader, who had always railed at injustice directed toward others and "enjoy[ed] fights when I know or think I know, I am right", refused. The purported reason for his dismissal was that he was "betting against the company". Although he was the only major stockholder never to have sold any of his Sigma-Aldrich stock, in August 1991 Bader had decided to give 10000 of his 3.66 million shares of stock, a mere 0.33% of his holdings (he is still the largest individual shareholder), to Queen's University. To maximize the gift to his alma mater, instead of selling these

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3507-0785 $ 10.00+.25/0

shares outright he wrote a call option, which he regarded as "betting with the company" because he expected the shares to rise in value. Ironically, that same month Cori, Harvey, and Peter Gleich, the vice-president, sold outright 10000, 7000, and 5000 shares, respectively, much larger proportions (about 10%) of their holdings. Bader's use of an option resulted in Queen's University recovering about $ 60000 more than Cori had received for the same number of shares.

In April 1992 Bader distributed an open letter to chemists detailing what soon became known as "the Sigma-Aldrich affair", which quickly became a *cause célèbre*. Articles appeared in *Chemical & Engineering News*, *Chemistry in Britain*, various newspapers, and even *Forbes*, a respected business magazine. The international chemical community was shocked, and Bader and journal editors received letters of support from all over the world, several of which are reproduced in the book ("I never realized how many friends I had", he wrote). Supporters also telephoned or met with Cori, who refused to relent or discuss the issue.

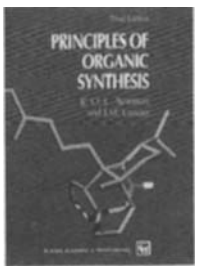
In addition to being justifiably angry, Bader characteristically reacted with sorrow, regret, and concern for the company: "I regard it as a pity that an intelligent, able CEO should have been willing to deprive himself, his team and the company of several more years of effective, valuable help with new products, customer relations, purchasing and other profit and growth producing activities, and that the board supported him." Moreover, although he writes about the present policy of "management by fear", he harbors no enmity for the company, and, with his typical optimism, he predicts for it a rosy future: "I am confident... that Sigma-Aldrich has so many good things going for it, including many very able people, that with some needed reinforcement of top management, it will continue to be a leader in its industry". For several weeks after his dismissal Bader was unable to sleep, but just as the gross injustices of his youth failed to daunt his indomitable spirit, he is well on the road to recovery: "I sleep well now, but once or twice a week I dream that Isabel and I are visiting an old academic friend who is suggesting a new reagent."

Since his childhood years in Vienna, when he bought and sold stamps, Bader has been an inveterate collector. In the middle 1950s he began to "rescue" research samples from various sources that otherwise might have been lost. Eventually this collection, now numbering more than 60000 samples, became known as the Alfred Bader Chemical (ABC) Library (now renamed the Sigma-Aldrich Library)—of immense value for generations of future researchers as well as "a great way to study the history of chemistry". Bader's collection of paintings, first Dutch and Flemish 17th-century and now "biblical subjects by Rembrandt students and truly great works by as yet unidentified artists", is well known. A long chapter details his career as a collector. Another describes 18 of his "trophies of the hunt" in the art world with plates of these paintings; of one of these he writes: "I have spent hundreds of hours studying it in our living room and have often carried it into our bedroom for a last look before putting my arms around Isabel and falling asleep". Separate chapters deal with art collector Efim Schapiro and John Whalley, an artist whom Bader supported. Bader also offers pertinent and amusing anecdotes about his experiences in the art world, including problems involved in donating and appraising paintings.

After his dismissal from Sigma-Aldrich in May 1992, Bader had to move the dozens of paintings hung in the Aldrich offices to his own gallery, and he now spends about a third of his time dealing in paintings, a third writing and lecturing, and a third trying to help chemists, particularly in small companies ("My life's work was to be a chemist helping chemists"). At Queen's University Bader and Isabel recently endowed a Bader Chair in Art History to begin in 1995 and contributed $ 2 million as seed money for an art museum extension. They also established prizes, scholarships, and awards for students in Canada, the United States, Great Britain, and the Czech Republic. In 1986 Bader also established the ACS's Alfred Bader Award in Bioinorganic or Bioorganic Chemistry. He recently donated £ 6 million to Queen's University to purchase and renovate Herstmonceux Castle in Sussex as an international study center. He concludes his copiously illustrated book, which will fascinate not only chemists, business students, art historians, collectors, and Bader aficionados, with a question and an answer that aptly summarize his long career of dedicated service to others: "The one serious problem posed by such a gift is the challenge: what can we do for an encore? But with Isabel's vision, and if the Lord gives us time, we will find other great things to do with our money, which we neither want to use for ourselves nor can take with us."

George B. Kauffman, Laurie M. Kauffman
California State University
Fresno, CA (USA)

Principles of Organic Synthesis. 3rd Edition. By *R. O. C. Norman* and *J. M. Coxon*. Blackie/Chapman and Hall, London, 1993. 811 pp., paperback £ 22.50.—ISBN 0-7514-0126-9



Like the two previous editions (1968 and 1978), this book is intended "for those who have had no more than a brief introduction to organic chemistry". Beginning with the essential concepts of mechanistic theory, Norman and Coxon instruct their readers in the methods and planning of organic syntheses. They deliberately avoid describing the methods used to verify reaction mechanisms, nor do they reproduce experimental details. Exercise problems are included at the end of each chapter.

The first part of the book consists of five chapters dealing with the fundamentals of general chemistry (thermodynamics, chemical bonding, and kinetics), followed by a brief account of the most important types of organic reaction mechanisms, and ending with a discussion of stereochemistry. The second part is much longer, consisting of 17 chapters in which the different types of reaction mechanisms form the starting point for describing synthetic methods based on these mechanisms. Apart from Chapter 22 the material in this part of the book is mainly organized under the various mechanisms, and only to a small extent according to synthetic strategies. Three chapters on the formation of carbon–carbon bonds (using polar organometallic compounds and with acids or bases as catalysts) are followed by chapters on pericyclic reactions and the formation of carbon–nitrogen bonds. Next comes a thoroughly conventional treatment of arene chemistry (electrophilic and nucleophilic substitutions and aromatic diazonium salts), rearrangements, photochemistry, free radicals, oxidation, reduction, and heterocyclic compounds with five- and six-membered rings. In accordance with their importance in modern organic synthesis, compounds of phosphorus, sulfur, silicon, and boron as reagents are treated in a separate chapter, and another is devoted to organometallic compounds of transition elements. These two chapters, together with the final one (Chapter 22), which describes in detail some well-chosen natural products syntheses, form the most topical and interesting part of the book.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3507-0786 $ 10.00+.25/0

On comparing this book with the previous edition which appeared 15 years earlier, it is seen that only one complete new chapter has been added, namely that on transition metal reagents. Also the selection of examples of natural products syntheses in the last chapter has been brought up to date, and the sections on silicon compounds, peptide syntheses, and the preparation of "preformed enolates" using lithium diisopropylamide have been considerably enlarged. By far the greater part of the material has simply been carried over from the previous edition, at least as regards information content, and sometimes even word-for-word. This hardly seems to do justice to the rapid developments that have occurred in synthetic methods in the last two decades. Thus, in common with many other general textbooks, this book mainly provides a survey of classical preparative organic chemistry, structured according to reaction mechanisms. On the other hand, the *principles* of organic synthesis, announced in the title, are scarcely covered. It is only in the accounts of nine examples of natural products syntheses that the reader learns something about the rational planning of a synthesis, at least in rudimentary form. The inadequacy of the treatment is illustrated by the fact that the concept of retrosynthetic analysis does not appear until Chapter 21 (pp. 679–681), where it receives a mere two pages.

The book cannot be said to fully reflect the current state of research. This can be seen, for example, in the treatment of the synthesis of enantiomerically pure compounds. The Sharpless–Katsuki epoxidation merits less than twenty lines of text (pp. 589–590), and the only method given for enantioselective reduction of "symmetrical" (i.e. achiral) ketones is the reaction with pinanyl-9-BBN (pp. 653–654). The diastereoselective (not "enantioselective") alkylation of Davies-Liebeskind enolates is included (p. 572), but other methods such as the Evans aldol method and the asymmetric hydrogenation using Wilkinson catalysts are not mentioned, revealing some lack of balance in the choice of topics. Another very significant shortcoming is that, apart from Chapter 22, there are no references to original publications, and even the suggestions for further reading that were included in the second edition have now been dropped.

The book is unlikely to offer new perspectives to synthetic chemists in universities or industry, but seems more suitable for providing students starting a degree course in chemistry with a readily understandable survey of the repertoire of (mainly classical) synthetic methods.

Ziegler Catalysts. Recent Scientific Innovations and Technical Improvements. Edited by *G. Fink, R. Mülhaupt* and *H. H. Brintzinger*. Springer, Berlin, 1995. 511 pp., hardcover DM 198.00.—ISBN 3-540-58225-8

This book contains an impressive collection of papers presented at an international symposium held in honor of Karl Ziegler. The symposium, entitled "Forty Years of Ziegler Catalysts", took place in September 1993 at the University of Freiburg. The organizers, who have also edited this book, were Professors R. Mühlhaupt of the Materials Research Center in Freiburg, G. Fink of the Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr, and H. H. Brintzinger of the University of Konstanz.

In 1953 Karl Ziegler and his coworkers discovered the "Aufbaureaktion" for the oligomerization of ethene. This subsequently led to the low-pressure process for high-molecular-mass polyethene, using a mixture of aluminum alkyls and titanium tetrachloride as the catalyst. This discovery was the starting point for a period of rapid development in the field of olefin polymerization, providing alternatives to the older high-pressure process for polymerization of ethene, an area of activity that continues up to the present day.

Examples of some of the new developments described in the book are recent results on the nickel-ylide-catalyzed polymerization of acetylene (Storzewski), CO–alkene copolymerization using palladium(II) catalysts (Drent, Chien, and coworkers), and the synthesis of functionalized polymers by ring-opening polymerization (ROMP) reactions (Feast et al.). However, the main themes are the classical Ziegler–Natta catalysis using heterogeneous titanium(III) catalysts and polymerization using metallocene complexes with well-defined molecular structures. In the first article, characteristically entitled "Karl Ziegler—The Last Alchemist", G. Wilke briefly surveys the scientific contributions made by Ziegler and his collaborators and describes the development of the "Aufbaureaktion" for making polyethene. Following the discovery that the oligomerization of ethene was affected by the presence of transition metals (the "nickel effect"), further research led to another success: Giulio Natta and his team discovered that propene could be polymerized stereoselectively using Ziegler catalysts. The contributions of Ziegler and Natta were recognized in 1963 by the award of a Nobel Prize. The second article also presents a historical view; here Heinz Martin, a colleague of Ziegler who worked alongside him for many years, discusses the patenting aspects of Ziegler's work, including the successes and failures that occurred during forty years of Ziegler catalysis. This is followed by an article in which Rolf Mühlhaupt, under the title "Novel Polyolefin Materials and Processes: Overview and Prospects", gives a concise account of developments in the field of Ziegler catalysis and takes the reader up to the current state of knowledge of the relevant science and technology. The comprehensive bibliography with this article helps the reader to seek out the most significant publications on Ziegler catalysis. In the fourth contribution H. Sinn and his coauthors shed some light on the subject of methylaluminumoxanes. Although these compounds have been in use for many years as activators for metallocene catalysts, their structures have still not been fully elucidated.

It would be pointless to try to summarize the contents of every article. It is enough to add that the reader will find here a collection covering the latest developments both in conventional supported catalysts and in metallocenes. The excellent presentations of the individual topics are supported by a detailed subject index and comprehensive bibliographies, which give quick access to the desired information. The book can be thoroughly recommended not only for specialists in metal-catalyzed polymerization but also for everyone with interests in this area.

Electrospray Mass Spectrometry of Biomacromolecular Complexes with Noncovalent Interactions—New Analytical Perspectives for Supramolecular Chemistry and Molecular Recognition Processes

Michael Przybylski* and Michael O. Glocker

The development of "soft" ionization methods in recent years has enabled substantial progress in the mass spectrometric characterization of macromolecules, in particular important biopolymers such as proteins and nucleic acids. In contrast to the still existing limitations for the determination of molecular weights by other ionization methods such as fast atom bombardment and plasma desorption, electrospray ionization (ESI) and matrix-assisted laser desorption have provided a breakthrough to macromolecules larger than 100 kDa. Whereas these methods have been successfully applied to determine the molecular weight and primary structure of biopolymers, the recently discovered direct characterization by ESI-MS of complexes containing noncovalent interactions ("noncovalent complexes") opens new perspectives for supramolecular chemistry and analytical biochemistry. Unlike other ionization methods ESI-MS can be performed in homogeneous solution and under nearly physiological conditions of pH, concentration, and temperature. ESI mass spectra of biopolymers, particularly proteins, exhibit series of multiply charged macromolecular ions with charge states and distributions ("charge structures") characteristic of structural states in solution, which enable a differentiation between native and denatured tertiary structures. In the first part of this article, fundamental principles, the present knowledge about ion formation mechanism(s) of ESI-MS, the relations between tertiary structures in solution and charge structures of macro-ions in the gas phase, and experimental preconditions for the identification of noncovalent complexes are described. The hitherto successful applications to the identification of enzyme–substrate and –inhibitor complexes, supramolecular protein– and protein–nucleotide complexes, double-stranded polynucleotides, as well as synthetic self-assembled complexes demonstrate broad potential for the direct analysis of specific noncovalent interactions. The present results suggest new applications for the characterization of supramolecular structures and molecular recognition processes that previously have not been amenable to mass spectrometry; for example, the sequence-specific oligomerization of polypeptides, antigen–antibody complexes, enzyme– and receptor–ligand interactions, and the evaluation of molecular specificity in combinatorial syntheses and self-assembled systems.

Keywords: macromolecules · mass spectrometry · noncovalent interactions · self-assembly · supramolecular chemistry

1. Introduction

The development of efficient "soft" ionization methods has led to significant advances of mass spectrometry for the direct characterization of macromolecules, particularly important classes of biopolymers such as proteins and nucleic acids.[1–3] Intact molecular ions of higher molecular weight compounds were first obtained in the 1970s by field desorption mass spectrometry (FD-MS).[4] Since the 1980s bombardment by primary particles with energies in the keV range (fast atom bombardment mass spectrometry (FAB-MS) or LSIMS[5]) and ^{252}Cf-plasma desorption mass spectrometry (PD-MS) enabled sensitive and accurate molecular weight determinations of polypeptides and smaller proteins.[6,7] In the past years electrospray ionization (ESI)[8] and matrix-assisted laser desorption-ionization (MALDI)[9] have provided a breakthrough in macromolecular mass spectrometry with the successful analysis of molecular weights greater than 100000 Da. ESI-MS and MALDI-MS have now generally overcome previous limitations in the mass spectrometric analysis of polymers.[10,11]

Although little or no fragmentation of macromolecular ions[12] occurs, soft ionization MS methods have already found broad application in the analysis of primary structures of

biopolymers. Thus, in addition to collision-induced fragmentation and tandem-MS analysis (for example with FAB-MS[13]), the combination with specific chemical (for example enzymatic) degradation reactions has been successfully applied to sequence determinations of proteins.[14] In particular, the direct mass spectrometric analysis of proteolytic peptide mixtures (peptide mapping)[15] has led to numerous applications in structure–function studies of proteins, such as the identification of post-translational modifications with covalent bonds,[16] the determination of epitope sequences in antigen–antibody complexes,[17] and the characterization of isoenzymes[18] and recombinant proteins.[19]

Beyond the elucidation of primary structures, the application of mass spectrometry to the characterization of tertiary structures and supramolecular complexes[20] has previously not been considered feasible. In a few cases dependence of the fragmentation on tertiary structure has been found, for instance the specific fragmentation in FAB mass spectra of α-helical polypeptides[21] and the strong ion suppression effects in PD mass spectra of proteins upon denaturation on the nitrocellulose (NC) sample target,[14a, 22] which indicates that some "native-like" structure is required for obtaining macromolecular ions.[6b] This situation has been changed drastically by the most recent development of electrospray–ionization mass spectrometry. A number of studies by ESI-MS in the last three years have identified supramolecular complexes of biopolymers, as well as specific noncovalent complexes with low molecular weight constituents.[23, 24] In contrast to other ionization methods in which predominantly singly charged ions are produced from liquid (FAB)[7] or solid matrices (PD, MALDI[6, 11]), continuous series of multiply charged macro-ions are obtained by ESI-MS,[8, 25] with distributions of charges characteristic of the solution structure ("charge structure"; see Section 2).[10, 24–26] Moreover, ESI-MS can be readily carried out with aqueous solutions at nearly physiological solution conditions, thus enabling comparison with other methods of structure determination such as NMR spectroscopy.[27]

The direct mass spectrometric characterization of noncovalent macromolecular complexes opens new perspectives for analysis in supramolecular chemistry in which methods with molecular specificity and sensitivity are needed.[28] Unlike other characterization methods, ESI-MS is applicable to relatively impure samples and multicomponent mixtures and is compatible with microanalytical separation techniques.[10] Although the mechanism of ion formation in ESI-MS has not yet been elucidated in detail, a number of different noncovalent interactions (ionic, hydrophobic) have already been successfully characterized. In this article, the results hitherto obtained are discussed primarily in the context of biochemistry and supramolecular chemistry. The current state of the development of the ESI method with regard to the ion formation pathways and their correlation with solution structures is summarized first. In the subsequent sections, applications to noncovalent complexes of biopolymers and synthetic self-assembled complexes are described, followed by a comparison with potential applications of other mass spectrometric methods. Since the development of ESI-MS is still new, this article will not attempt to present an overview; instead, its main goal is to stimulate further evaluation of its analytical potential for the characterization of supramolecular complexes in conjunction with established methods of structure determination.

M. Przybylski

M. O. Glocker

Michael Przybylski, born in 1948 in Berlin, studied chemistry at the University of Mainz and received his PhD in 1975 with H. Ringsdorf with a dissertation on the synthesis and metabolism of polymeric sulfonamides. After two years as visiting research scientist at the National Cancer Institute, NIH, Bethesda, USA, with biochemical studies of antifolate cytostatic agents, he returned to the University of Mainz, where he finished his habilitation in 1985 on the development and bioanalytical application of mass spectrometry for the structure elucidation of natural products and chemotherapeutic agents. Since 1987 he has been Professor of Analytical Chemistry at the University of Konstanz. He was guest professor at the Universities of Odense, Budapest, and Szeged, received the St. Denis research award, and is author of more than 160 original publications. His research areas are the structure and function of lipid-modified peptides and proteins, structure elucidation and degradation of cell surface protens, xenobiotic peptide conjugates, and mass spectrometry of biomacromolecules in which he focuses on mass spectrometric techniques combined with protein-chemical methods for the characterization of tertiary structures, antigenic determinants, and supramolecular complexes.

Michael O. Glocker, born in 1960 in Altheim, studied chemistry at the University of Konstanz and received his PhD in 1990 with J. C. Jochims with a dissertation of nitrilium salts as reactive intermediates. After two years with M. L. Deinzer at the Oregon State University, Corvallis, USA, working on the structure elucidation of macrophage colony-stimulating proteins and natural and chemically modified phytoalexins, he returned to the University of Konstanz in 1992. He is research associate and habilitand at present, received a habilitation stipend from the DFG in 1994, and is author of more than 30 original publications. His research areas are the protein-chemical and mass spectrometric characterization of tertiary structures of proteins and folding pathways mediated by disulfide bridges, and the structure elucidation of natural and recombinant cytokines.

2. Electrospray Mass Spectrometry of Biomacromolecules

2.1. Formation of Macromolecular Ions by Electrospray Ionization

Initial pioneering studies on the electrospray ionization of large molecules were performed more than twenty years ago by Dole et al.[29] However, the development of ESI-MS was initiated only in 1988 with the introduction of efficient ionization sources suitable for quadrupole mass spectrometers.[8, 10, 30] Two types of electrospray ionization sources frequently used in commercial quadrupole mass analyzers are shown schematically in Figure 1. A sample solution is pumped, typically at flow rates of 2–10 $\mu L\,min^{-1}$, through a fused silica microcapillary (often coated with polyimide), whose end is supported in a stainless steel capillary needle. Charged aerosol droplets are electrosprayed by means of an electrical potential (about 2–5 kV) between the needle tip and a cylindrical counterelectrode (nozzle) and dispersed into the ionization region.[10] Gas-phase macromolecular ions of different charges (cations and anions with different charge numbers) are formed by a process formerly referred to as "field-ion evaporation",[31] which leads to the rapid decrease of droplet size ("nanodroplets") and to desolvation. An important parameter for the desolvation of macro-ions is the small (about 10–100 V) potential difference between the nozzle and a second skimmer-type repeller electrode ("declustering" potential ΔCS[10, 23]).

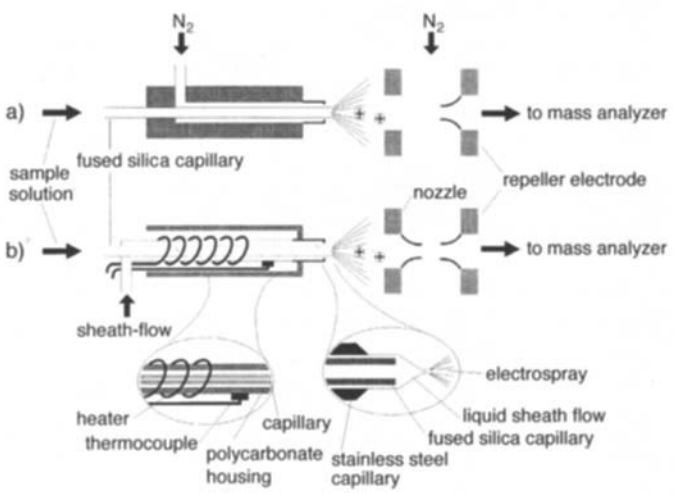

Fig. 1. Schematic representation of electrospray ion sources used in commercial quadrupole mass spectrometers. a) Ion spray source with countercurrent gas (for example, Sciex-API III [30]); b) thermally assisted ESI source without countercurrent gas flow (for example, Vestec A201) [33]. The inserts show a liquid sheath-flow configuration of the inlet capillary (bottom right) [35] and a thermostated capillary heater (bottom left), which controls the temperature of the sample delivery probe to about 20–80 °C [37].

In ionization sources operated at nearly atmospheric pressure and ambient temperature, the desolvation can be assisted pneumatically by ion–molecule reactions by means of a countercurrent flow of an inert "curtain" gas such as nitrogen ("ion-spray" source; Fig. 1a).[30, 32] In a second thermally assisted type of ion source,[33] a nozzle-repeller interface with slight heating of the droplets (typically 40–45 °C) is employed without a countercurrent gas (Fig. 1b). Both ion sources have been used in ESI-MS studies of a wide range of macromolecules and successfully applied to supramolecular complexes. A countercurrent gas was considered to support particularly mild desolvation conditions and has been employed in the majority of studies of noncovalent complexes;[23] however, no advantage of either type of ionization source has yet been demonstrated. An additional coaxial liquid sheath flow through an annular capillary, originally employed to provide suitable interface conditions for online coupling of capillary electrophoresis with ESI-MS,[10, 34, 35, 36] is advantageous for providing specific solution conditions (for example, pH, buffer salts) for the analysis of noncovalent complexes (see Section 2.3). The standard sample delivery probe has been further modified by addition of a thermostated microheater (schematically shown in Fig. 1b).[17c, 24, 37] This probe enables precise temperature control of the inlet capillary to between approximately 20–80 °C and thus provides suitable preconditions to study temperature-dependent equilibria of supramolecular complexes.

Typical features of ESI-MS are illustrated in Figure 2 by the positive ion spectra of bovine ribonuclease A and S, and negative ion spectra of two synthetic oligodeoxyribonucleotides. Acidic aqueous solutions, with an organic cosolvent (for example, 5–10% methanol) to provide stable electrospray conditions, have been widely employed in ESI-MS studies of peptides and proteins.[8, 10, 38] Under these conditions the spectrum of RNase A shows a homogeneous series of multiply protonated molecular ions, with the most abundant $[M+9H]^{9+}$ charge state (Fig. 2a, top). The molecular weight ($M_r = 13682$) is accurately determined from the m/z values for the successive charge numbers.[10, 39] A second ion series of lower abundance is also observed with a mass increment of 98 Da, which is due to a single additional phosphate ion, specifically bound to the S-protein and S-peptide chains of RNase A.[40] The spectrum of RNase S, which comprises the noncovalent complex of the S-protein and S-peptide constituents,[41] in acidic solution (pH 3) shows only the $[M+nH]^{n+}$ ions of the dissociated components; two series of A/B ion doublets (Fig. 2a, bottom) result from the inhomogeneous enzymatic cleavage into the S-peptide (1–19/20) and the S-protein (20/21–124).[42] However, the molecular ions of the intact RNase S complex in aqueous solution at pH 7 have been identified,[43] which is consistent with the known stability of the complex at physiological pH conditions.[44]

In contrast to proteins, oligo- and polynucleotides have mainly been studied by negative ion ESI-MS.[10, 45] The formation of the (formally deprotonated) polyanions is strongly dependent on the counterions present. For example, the spectrum of a 24-mer oligonucleotide recognition sequence of the GCN4 transcriptional activator from yeast,[46] obtained from the purified polyammonium salt,[45] shows a homogeneous series of $[M-nH]^{n-}$ polyanions, indicating complete removal of the ammonium counterions in the desolvation process (Fig. 2b). However, the preparation of homogeneous polyammonium salts is difficult for polynucleotides with increasing chain lengths.[47, 48] The presence of alkali ions leads to the formation of complex molecular ion adducts with strongly decreased sensitivity (see Fig. 2b).[38, 49] Efficient purification techniques to remove contaminating counterions must, therefore, be devel-

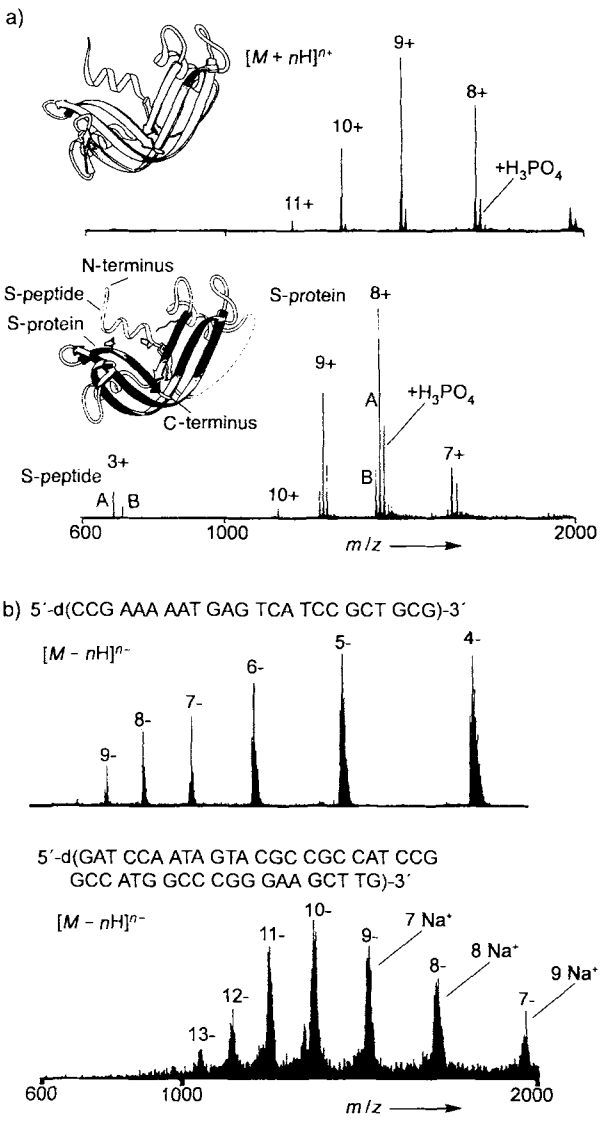

Fig. 2. a) Positive ion ESI mass spectra of bovine RNase A (top; $M_r = 13682$) and RNase S (bottom; $M_r = 11534$) in a mixture of aqueous acetic acid (2%) and methanol (9/1, pH 3). b) Negative ion ESI mass spectra of a synthetic 24-mer oligonucleotide (top, $M_r = 7347$) and a 44-mer (bottom, $M_r = 13504$). Sample solutions of about 0.1 $\mu g \mu L^{-1}$ in acetonitrile: 5 mM ammonium acetate (1/1) (pH 7.5) were introduced through the fused silica inlet capillary with a Harvard microinfusion pump at 4 $\mu L\,min^{-1}$.

oped as a critical step for the analysis of high molecular weight DNA. Accurate molecular weight determinations have so far been limited to sequences of approximately 80 bases.[45, 49]

A qualitative model for the formation of macromolecular ions by electrospray that is compatible with the mechanism discussed by Smith et al.,[23] Fenn,[50] and Röllgen et al.[51] is depicted in Figure 3. The first, generally accepted step in this model is the formation of microdroplets close to the Rayleigh charge limit,[31, 52] which are rapidly reduced to small solvated macro-ions ("nanodroplets"[23]). Coulombic forces in combination with effects of the ESI interface conditions[53] (cf. Fig. 1), analyte charge, temperature, and solvent (solvent proton affinities[54]) have been discussed as major factors influencing the ESI process. A "charge-residue" model, which has not yet been elucidated in detail, has been postulated by Smith et

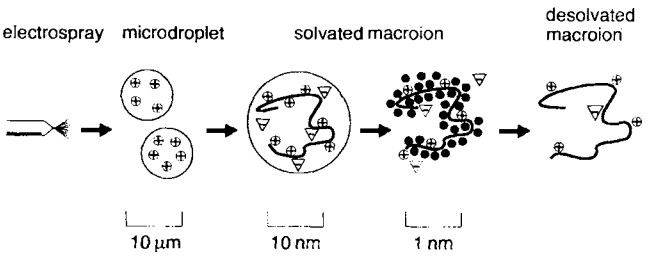

Fig. 3. Schematic representation of macromolecular ion formation from electrosprayed droplets according to the "charge-residue" model of desolvation [23]. ⊕ positive charge sites, ▽ negative charge sites, • solvent molecules. In this example the desolvated ion has a 3 + charge.

al.[23] to explain the formation of desolvated ions. However, direct ion emission from the liquid cone tip (Taylor cone[55]) to which the electrical field is applied has been discussed recently as an alternative mechanism to the original "ion evaporation".[31] This model qualitatively explains the "survival" of noncovalent complexes and is consistent with several features in ESI mass spectra such as remaining specific counterions but removal of other "original" solute components (like NH_3, CH_3COOH).[10, 54, 56] It also appears to be consistent with the observation of charge states and distributions of macro-ions characteristic of structural states in solution (see Section 2.2). Since a rapid adiabatic "cooling" can be assumed to accompany desolvation of charged droplets,[51] the time scale of the ESI process may also suggest that a precondition for observing supramolecular complexes is the maintenance of intact structural elements under kinetically controlled conditions. The still limited experimental approaches to elucidate the ESI mechanism, and their application to the characterization of biomacromolecular structures in solution, are discussed in Sections 2.2 and 2.3.

2.2. Correlation of Charge Structures of Protein Molecular Ions with Tertiary Structures in Solution

Generally, ESI mass spectra show a steady increase of the charge states of ions with increasing molecular weight. The number of charged groups in solution has been found to be a dominant factor determining the maximum charge numbers of macromolecular ions.[10, 38, 57] Initial ESI-MS studies of proteins were mainly carried out with moderately to strongly acidic solutions. Under these conditions, a rough correlation of the number of basic residues (Lys, Arg) with the maximum charge states of protonated ions was observed. However, recent pH-dependent studies provided evidence for a correlation of structural states in solution with the charge distribution ("charge structure"[26]) of multiply protonated molecular ions.[56] As an example, ESI spectra of native hen egg-white lysozyme (HEL) and irreversibly denatured HEL by reduction of disulfide bonds and alkylation are compared in Figure 4. The spectrum of native HEL (Fig. 4a) exhibits a most abundant $[M+9H]^{9+}$ ion and a maximum charge state of 11+, the characteristic charge distribution of the molecular ions showing only little pH dependence.[24, 58] By contrast, the spectrum of the denatured protein shows a significant shift of the ion distribution to higher charge states (Fig. 4b). This result is consistent

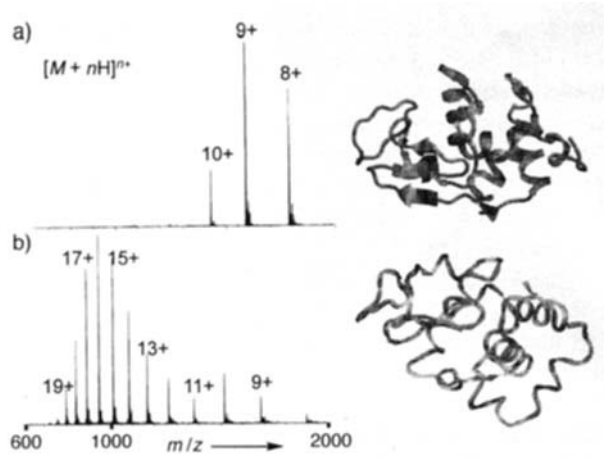

Fig. 4. ESI mass spectra of a) native hen egg-white lysozyme ($M_r = 14307$) and b) DTT-reduced, 4-pyridylethylated lysozyme ($M_r = 15154$) [64]. The structural representations of native and denatured lysozyme were taken from the Brookhaven National Laboratory protein structure data bank. Sample solutions: 0.1 $\mu g \mu L^{-1}$ in a mixture of aqueous acetic acid (2%) and methanol (95/5, pH 3).

with the unfolded, extended surface of the protein as illustrated in Figure 4 by the ribbon diagrams of the tertiary structure.

Similar results have been obtained from comparison of spectra from solutions of native proteins and proteins after denaturation by reduction of disulfide bridges,[10, 59, 60] thermal denaturation,[61] and denaturation induced by solvent changes.[62] Furthermore, they are in agreement with ESI-MS determinations of the extent of deuterium exchange of labile protons, which yield characteristic differences of deuterium incorporation for native and denatured proteins.[58, 63] For example, approximately 50% of the labile H were exchanged for D in the native HEL, but nearly 90% for the reduced protein after 4 hours deuteration in aqueous D_2O.[60, 64] Results of deuterium incorporation for several model proteins are summarized in Table 1 and are in good agreement with NMR data of H/D exchange kinetics of rapidly exchangeable protons.[65] Moreover, ESI-MS studies of exchange kinetics over extended periods, initially carried out by Katta and Chait with bovine ubiquitin,[63] revealed a substantial proportion of slowly exchangeable protons, which is also consistent with NMR data of nativelike protein structures in solution.[65, 66] Additional information on the relationship between solution structures and desolvated molecular ions has been derived from H/D exchange studies of ions from native and denatured proteins in the gas phase, which show opposite reactivities (Table 1). The higher deuterium incorporation for ions of native proteins was explained by Coulomb effects in the compact native structure.[67, 68]

The present model studies clearly indicate that tertiary structure states in solution are reflected in the charge structures of gas-phase molecular ions. However, they do not provide evidence for conservation of tertiary structures in molecular ions in the gas phase.[23] More detailed information about structures of gas-phase macromolecular ions may be derived from charge structures and localization of charge sites on macro-ions by chemical reactions in situ in a reaction system consisting of two ESI capillaries (Y-tube[10, 36]), and by employing the sheath-flow inlet system[36, 69] (cf. Fig. 1). For reactions of proteins with triethylamine or similar bases a significant reduction in the charge numbers on the molecular ions was demonstrated. This observation is well explained by proton transfer; for example, a shift from the 18 + charged ion to a most abundant $[M+9H]^{9+}$ ion was observed for myoglobin.[10, 70]

An alternative approach for probing tertiary structure differences in solution is the comparative ESI-MS analysis of protein derivatives obtained by selective chemical modification.[24, 71] Acylation of lysine- and N-terminal amino groups was used to neutralize basic protonation sites selectively in proteins with known structures, and the extent and sites of partial modifications were identified by molecular weight determinations and mass spectrometric peptide mapping analysis.[60] The charge distributions of molecular ions of partially acetylated RNase A are similar to those of the native protein; in contrast, a significant charge reduction was found upon succinylation.[60] On H/D exchange similar extents of deuterium were incorporated in partially modified and native proteins (see Table 1), and no structural differences between the protein derivatives were detected by ORD/CD spectra.[72] Furthermore, ESI spectra of acetylated myoglobins (Myo) provided the molecular ions of the intact heme–protein complexes under mild desolvation conditions (see Fig. 6). Direct evidence for the conservation of tertiary structures has been recently obtained for partially acylated derivatives of the ion-channel protein porin from *R. capsulatus* by mass spectrometry and X-ray crystallography; a tetrasuccinylated porin was crystallized as an intact trimeric complex isomorphous to the native protein.[73] An example showing that charge structures of molecular ions can reveal even detailed structural differences in solution is the selective modification of arginine residues by 1,2-cyclohexanedione, which yields N^7,N^8-(dihydroxycyclohexanediyne) adducts (DHCH-Arg)[24, 71] (Fig. 5). The DHCH-Arg modification of

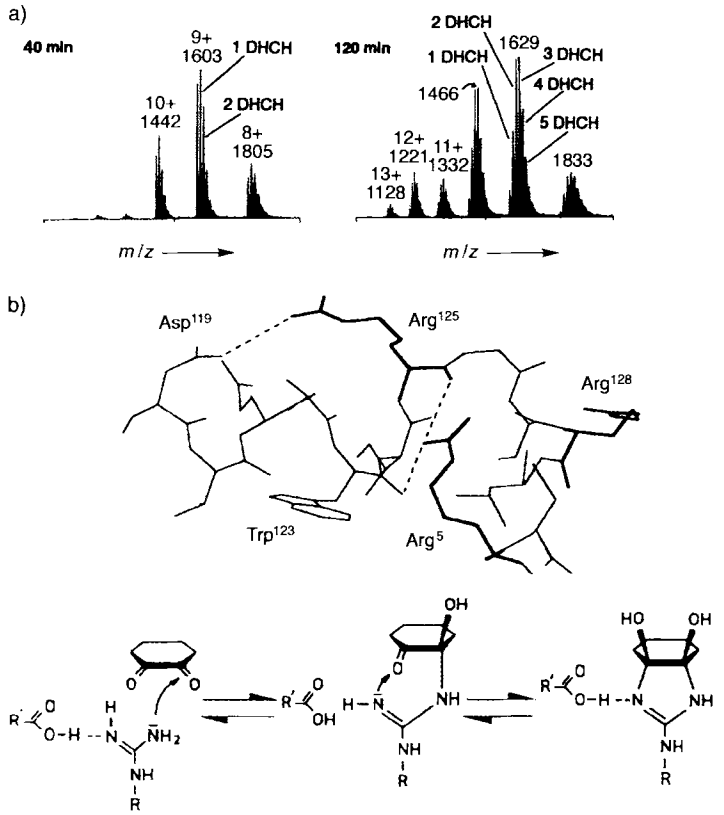

Fig. 5. a) ESI mass spectra of DHCH-Arg-modified hen egg-white lysozyme (HEL); b) tertiary structure of HEL around the Arg-5 and Arg-125 residues and reaction pathway of the arginine modification by 1,2-cyclohexanedione. Native HEL was treated with a 50-fold excess of 1,2-cyclohexanedione in sodium borate (pH 8.5) and protein derivatives isolated at different time intervals [71]. The solvent used for the ESI-MS analysis was a mixture of aqueous acetic acid (2%) and methanol (95/5). From ref. [71].

lysozyme, monitored directly by ESI-MS, showed molecular ion distributions of protein derivatives identical to that of native HEL until four specific Arg residues were modified.[24] All four Arg residues modified under these conditions were found to have suitable intramolecular proton acceptor residues in their microenvironment[71] (shown in Fig. 5b by the partial structures around Arg^5 and Arg^{125} residues). By contrast, ESI spectra of protein derivatives with a higher extent of modification (obtained after extended reaction times) showed additional higher charge-state ions, indicative of gradual unfolding and denaturation (Fig. 5a).

These initial results indicate that further studies probing the effect of defined chemical modifications of structures in solution on electrosprayed molecular ions might be useful. In situ chemical and enzymatic reactions of proteins using the sheath-flow system for delivery of reactant solutions (cf. Fig. 1) can be employed in model studies under conditions similar to those in physiological solutions.[24] An example is the pH-dependent renaturation and formation of the intact heme–protein myoglobin (Fig. 6), one of the first noncovalent complexes detected by ESI-MS.[10, 74] At pH 6, the intact heme–Myo complex is identified by a most abundant $[M+9H]^{9+}$ ion, whereas under increasingly acidic conditions (pH 4) partial dissociation of the complex leads to the doublet series of multiply protonated heme–protein (HP) and apoprotein (AP) ions; at pH 2 only high charge-state ions of AP are observed together with the ion (m/z 616) of the Fe^{III}–porphyrin prosthetic group (Fig. 6a–c). Nearly identical molecular ion distributions were found under comparable solution conditions for the isolated apoprotein. The most abundant peak for the renatured AP was also $[M+9H]^{9+}$ at pH 6 (Fig. 6d–f). In situ reconstitution with a heme–porphyrin solution finally yielded the $[M+9H]^{9+}$ ion of the intact heme–protein (Fig. 6g).

These results and further model studies provide strong evidence for a correlation between charge structures of ions in ESI-MS and solution structures of noncovalent biopolymer complexes.[23, 24] It must be borne in mind that mainly highly charged ions within the mass range of quadrupole analyzers have been studied so far. Thus, the characterization of ions with low charge state (high m/z) and their possible energy differences and higher stabilities of the supramolecular complexes should be interesting in further studies[75, 76] (see Section 3.2); the required ESI sources suitable for time-of-flight and magnetic sector instruments have recently become available.[77]

2.3. Preconditions for the Characterization of Supramolecular Complexes

In addition to the instrumental conditions described in Section 2.1, several analytical preconditions must be fulfilled to enable the direct characterization of supramolecular complexes of biomacromolecules: in particular, specific complexes and unspecific aggregation products must be distinguishable, as well as noncovalent complexes and covalent adducts. The formation of unspecific association products may, in principle, occur in solution or under the electrospray conditions. Corresponding artifact ions (for example, dimeric "cluster ions") are formed with other ionization methods such as FAB-MS and MALDI-MS,[5, 9, 11] but have not been observed by ESI-MS at typical sample concentrations (micromolar solutions).[10] Unspecific association products in ESI spectra of biomacromolecules have been observed with different solution components such as buffers, surfactants, and counterions.[10, 76] The ion abundances of such adducts depend mainly on their relative binding strengths (for example, for hydrophobic interactions in proteins; see Section 3.2 with examples of leucine zipper polypeptides). An analytically relevant example of adducts of lysozyme with sodium dodecylsulfate (SDS) is shown in Figure 7. Adduct ions with up to ten dodecylsulfate anions, leading to a substantial shift of charge distributions and overlapping of protonated molecular ions, have been found at low SDS concentrations.[78] In the light of the broad application of SDS-gel electrophoresis (SDS-PAGE) for protein separation, contamination by SDS and suitable purification techniques are of importance for ESI-MS analyses of proteins. While only little success has been achieved with classical purification techniques (for example, ion-pair extraction),[45, 79] an efficient isolation procedure by direct electroelution from SDS-PAGE has been recently developed for ESI-MS of proteins.[79]

Noncovalent complex formation, for example, between enzyme and specific substrate or inhibitor components, was detected in initial model studies by a specific increase in molecular weight for the complex ions (see Section 3.1).[23]

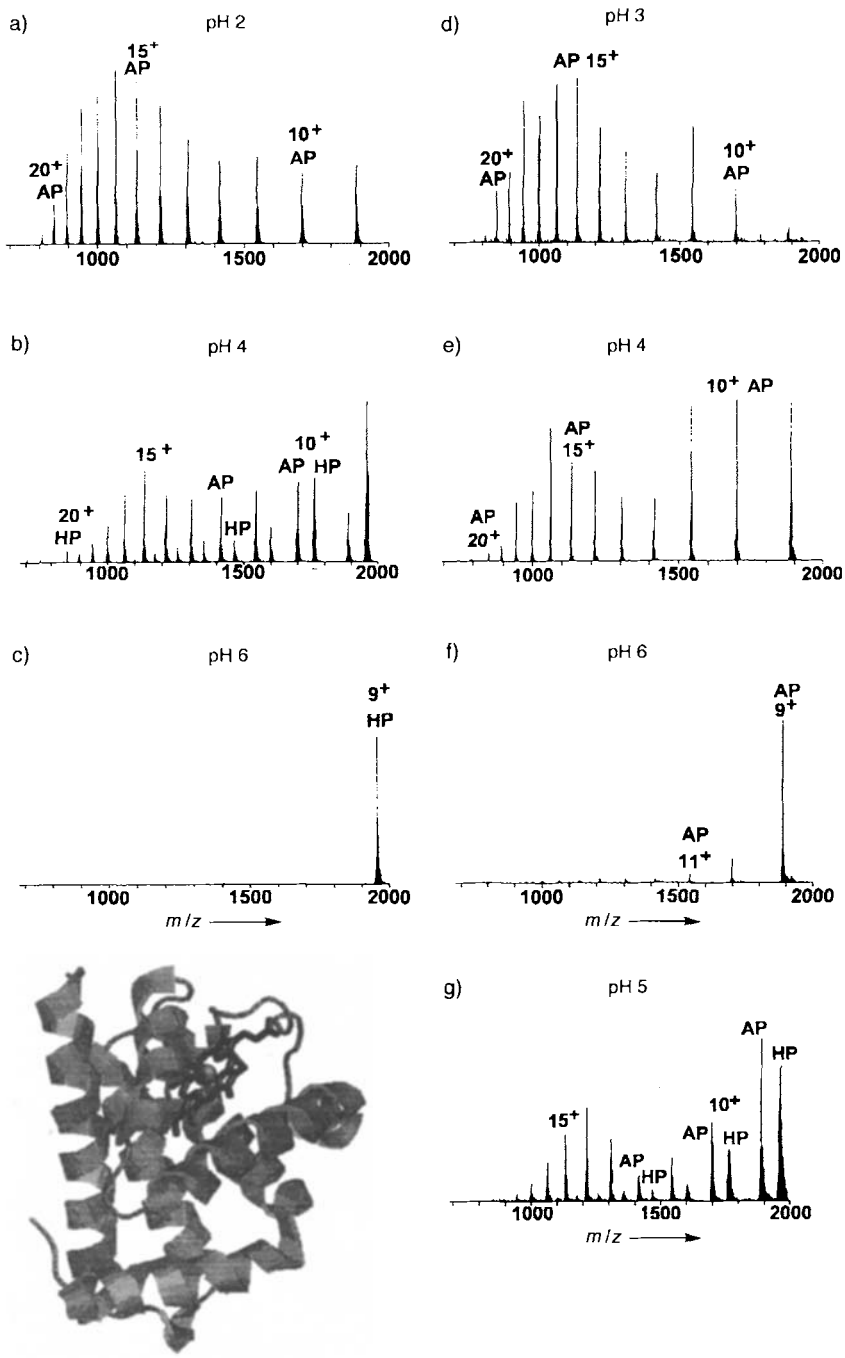

Fig. 6. ESI mass spectra of heme–protein complex of horse heart myoglobin (HP) at several pH values (left) and pH-dependent renaturation of apoprotein (AP, right). a)–c) Spectra after dissociation by acidification with acetic acid/ammonium acetate (5 mM) buffer; d)–f) spectra after renaturation of the apoprotein (ammonium acetate); g) spectrum after reconstitution of heme–myoglobin by addition of heme–porphyrin (pH 5). The solvent used was a mixture of ammonium acetate (5 mM) and methanol (95/5). The representation of the compact tertiary structure of the intact heme–protein (bottom left) was obtained from the Brookhaven National Laboratory crystallographic data base. From ref. [24].

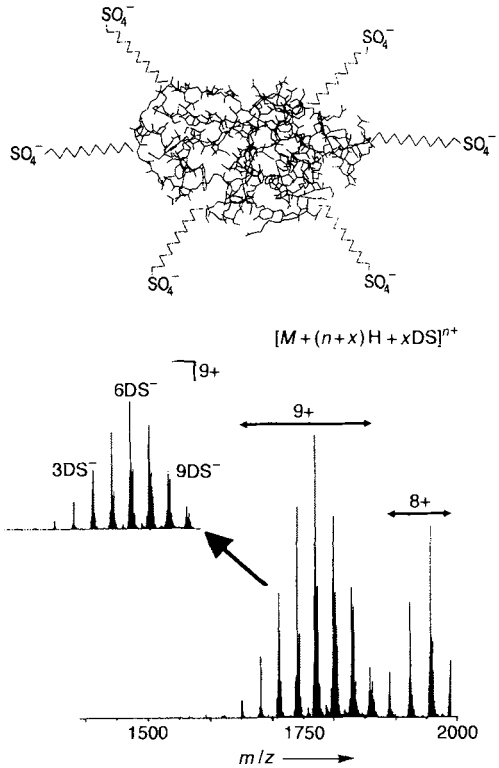

Fig. 7. Top: Structural model of a complex of HEL with six dodecylsulfate ions (DS). Bottom: ESI mass spectrum of dodecylsulfate-contaminated HEL isolated from SDS-polyacrylamide gel electrophoresis by electroelution [79] and expansion of the series of 9+ charged $[M+(n+x)H+xDS]^{n+}$ ions. Solvent: a mixture of acetic acid (2%) and methanol (9/1).

However, the unequivocal distinction between specific noncovalent interaction and covalent binding may be considerably more difficult in analytical applications and may require the detailed characterization of structure and binding mechanism of the complex. The ESI-MS analysis of the complexation of HEL with oligosaccharide substrates and with structural analogs that are inhibitors illustrates this problem.[80] The reaction of HEL with the substrate, hexa-β-(1–4)-*N*-acetylglucosamine (NAG_6), was monitored directly by ESI-MS and revealed the rapid formation (and subsequent disappearance) of the enzyme–substrate complex ions ($M_r = 15542$). During the reaction ions were detected that were attributable to a complex of HEL with the tetraglucosamine hydrolysis product (NAG_4), which binds with a similar affinity to the active hydrolytic site of the enzyme.[81] Competition experiments with several oligosaccharide substrates known to bind at different subsites of the hydrolytic center[72,82] and with a high-affinity inhibitor (oligo-*N*-acetylchitotetraose) provided evidence for the formation of specific noncovalent complexes. Furthermore, the enzyme–substrate complex in this study could be completely dissociated (that is, abundances of complex ions diminished) by using stronger desolvation conditions (increasing declustering potential ΔCS). However, a different behavior was observed in a study of oligosaccharide complexes with a lysozyme mutant in which one of the active-site residues, Asp-52, had been replaced by Ser (D52S-HEL), resulting in a complete loss of enzymatic activity albeit comparable nonproductive substrate binding.[83] The D52S mutant yielded complex ions with the NAG_6 substrate and the NAG_4 product that could not be dissociated by changes of solvent or ion-desolvation conditions (Fig. 8). Based on the molecular

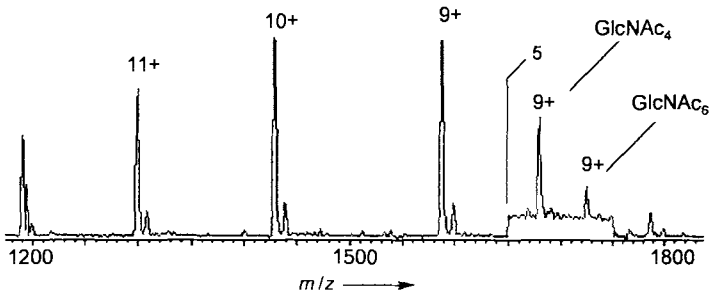

Fig. 8. ESI mass spectrum of adducts of the lysozyme mutant, D52S-HEL with oligo-β-(1-4)-*N*-acetylglucosamine. The expanded peaks are attributable to the $[M+9\,H]^{9+}$ ions of the HEL-$GlcNAc_4$ and HEL-$GlcNAc_6$ adducts. From ref. [83].

weight identified, a covalent complex by formation of a hemiacetal between the Ser-52 residue and the reducing sugar bond of the product (NAG_4) at the active subsite was proposed.[83, 84]

The unequivocal differentiation of noncovalent and covalent macromolecular complexes by molecular weight determination may be difficult with low resolution quadrupole mass analyzers and may require additional chemical studies and/or separation techniques to complement the ESI-MS analysis. The formation of both a noncovalent complex and covalent adducts has been identified in a recent study of the binding of glutathione (GSH) to a recombinant bacterial glutathione-S-transferase (GST) expressed in *E. coli*.[85] ESI spectra of GST after isolation by affinity chromatography on GSH-sepharose in the presence of GSH revealed two major series of molecular ions indicating the addition of two and three GSH molecules to the protein (Fig. 9, center).[86] A substantial part of the bound GSH could not be removed by dialysis; a homogeneous series of $[M+nH]^{n+}$ ions and exact molecular weight of the free enzyme ($M_r = 26\,898$) was obtained only after repeated reduction with dithiotreitol (DTT) and dialysis (Fig. 9, bottom). Mass spectrometric peptide mapping analyses identified the covalent adducts as mixed disulfides (for example, linked through the Cys-138 residue;[16, 86] see Fig. 9, top).

Table 2 summarizes experimental parameters and criteria for the identification of noncovalent complexes and their effects on the ion formation in ESI mass spectra. An essential precondition is a specific or at least predominant stoichiometry of the complex ions in comparison to the ions of the components in solution. The complex formation may be modified by changing the stoichiometry of solution components, and by modification of the ESI-MS conditions (interface temperature; declustering potential).[23] However, further evidence can be obtained by competition experiments with different complex components, and by analysis of the specificity of pH or concentrations changes. Changes of solution conditions may significantly influence the ion formation in ESI spectra, for example, by changes of the charge-state distributions. Equilibria of complex formation have been quantitatively characterized by means of ion abundance ratios in most recent studies (see Section 3.1). Thus at present, comparison with conventional analytical techniques such as ultracentrifugation and native gel electrophoresis is still important for the analysis of noncovalent complexes by ESI-MS.

Several recent studies have demonstrated that the modification of the electrospray conditions for the desolvation of ions and collision-induced dissociation can be effectively used to determine the gas-phase stability of ions of noncovalent complexes and to identify possible artifact products.[10] Important parameters of ESI-MS that affect the conservation of noncovalent complexes are the type of countercurrent gas, the temperature of the ionization chamber, and the residence time of the ion (extraction potential) in the desolvation region.[23, 24] Mild desolvation conditions enable a direct identification of solvent ad-

Criteria indicating the presence of noncovalent complexes	ESI-MS techniques for complex dissociation
specific complex stoichiometry/ equilibrium of complex components	change of solution stoichiometry increase of interface temperature increase of declustering voltage ΔCS
competition of complex components	chemical modification, specific mutation of components
specificity of solution conditions	pH change, change of buffer, concentration change
gas-phase stability of complex ions	increase of declustering voltage, collision-induced dissociation (countercurrent gas)

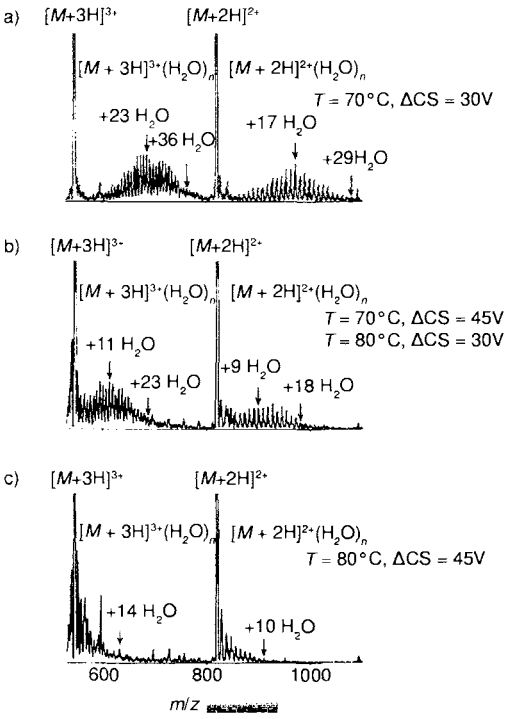

Fig. 10. ESI mass spectra of somatostatin ($M_r = 1638$) and water adducts at different temperatures T and declustering voltages (a–c). The major offscale peaks represent the nonsolvated doubly and triply protonated molecular ions. From ref. [23].

ducts. In one example, up to 40 H_2O molecules were observed in the spectrum of adducts of the polypeptide somatostatin and water under conditions of incomplete desolvation (Fig. 10). These adducts could be dissociated by increasing the ΔCS potential or by increasing the interface temperature.[23, 87] Thus, the lowest possible ΔCS potential appears to provide the mildest conditions for the survival of macromolecular complexes; high ΔCS values (> 100 V) have been shown to induce fragmentation of even covalent bonds.[10, 24]

3. Applications of Electrospray Mass Spectrometry to the Characterization of Supramolecular Complexes of Biomacromolecules

3.1. Protein Complexes with Low Molecular Weight Ligands

The first applications of ESI-MS to the characterization of noncovalent protein complexes with low molecular weight ligands were reported within a short period of time.[23, 88, 89] Examples of complexes with ligands such as enzyme substrates, cofactors, and inhibitors, the protein:ligand stoichiometries, and the charge states of specific complex ions are summarized in Table 3 (see also Figures 6 and 9). The complexes hitherto identified encompass different binding types such as ionic and hydrogen bonds, coordinative binding, and predominantly hydrophobic interactions. Furthermore, the wide range of dissociation constants for complexes of known structures and binding properties (about 10^{-11}–10^{-7} M) suggests a broad potential for applications of ESI-MS.

In most proteins examined so far the molecular weight differences between protein and protein–ligand complexes have been

Table 3. Protein complexes with low molecular weight ligands identified by ESI-MS.

Protein	M_r [a]	Ligand	Complex			Ref.

sufficiently large to enable the unequivocal determination of molecular weights (charge numbers) and complex stoichiometries (see Table 3). However, the accuracy and resolution of the mass determination amenable to quadrupole instruments limit the analysis of high molecular weight proteins (greater than about 50000 Da). Such applications may require high-mass analyzers or instruments providing isotopic resolution (see Section 3.2). Despite these limitations, specific complexes have been identified for a number of model proteins, such as heme–proteins and complexes with oligonucleotide cofactors. Some examples also demonstrated the ability of ESI-MS to characterize more complex binding structures that have not been accessible by conventional methods, such as the complexation of two Zn^{II} ions at two binding sites of the HIV-nucleocapsid polypeptide.[91] An interesting application has been reported by Baca and Kent in studies of synthetic peptide inhibitors of the HIV-1 protease.[92] A synthetic mutant ($Aba^{67}C$, $Aba^{95}C$; see Table 3) of the HIV-protease was shown by the specific molecular ions to form a ternary protease–inhibitor complex comprising two protein subunits and the peptide inhibitor.[95] This result revealed the active, *dimeric* form of the enzyme, which contributes one aspartate residue of each subunit to the catalytic center.[96]

In nearly all protein complexes studied so far, the charge-state distributions of complex ions shift to substantially lower charge (higher m/z) numbers than those observed for the free protein[23] (see Table 3). Corresponding "neutralization" effects have been found for biopolymer complexes, for complexes with low molecular weight ligands, as well as for synthetic supramolecular complexes. For instruments with limited m/z range, this effect may lead to significant problems in the detection of the most abundant complex ions.[24] (see Sections 3.2 and 3.3). As little is known about the effect of complex formation on the charge structure of protein ions from conventional analytical methods, systematic model studies by ESI-MS are required. Furthermore, in some protein complexes with metal ions as ligands it is difficult to identify the oxidation state of the ligand from the charge distribution of complex ions (that is, to ascertain whether the charge state observed was modified under the electrospray conditions).[23, 88] In a study of protein–iron complexes van Dorsselaer et al. obtained exact mass determinations of protonated molecular ions, which identified the Fe^{III}–

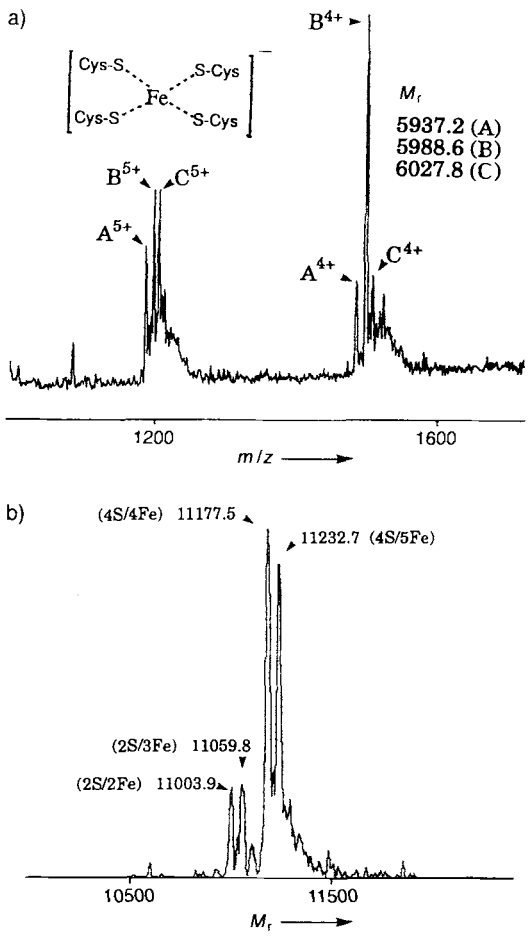

Fig. 11. ESI mass spectrometric identification of protein–iron–cysteine thiolate complexes. a) Spectrum of rubredoxin in H_2O/methanol (1/1). [90].

rubredoxin complex with four cysteine-thiolate ligands and the tetraferritetrathiolatoferredoxin complex (Fig. 11); the charge numbers present in the molecular ions of these complexes clearly reflected the authentic oxidation states in solution.[90] By contrast, oxidation of Fe^{II} to Fe^{III} porphyrin under the ESI-MS conditions has been suggested for the heme–protein complexes of the α- and β-chains of hemoglobin.[88a]

The aim of ESI-MS analyses of protein complexes so far has primarily been the qualitative identification of the specific complex ions. Only a few initial studies of the pH-, temperature-, and concentration-dependence of complex formation have been carried out, as exemplified by the pH-dependent spectra of myoglobin (Fig. 6) and the characterization of the RNaseS complex.[24, 43] The mass spectrometric determination of thermodynamic stabilities and complex formation constants in solution (as estimated by Ogorzalek-Loo et al. for RNaseS[43]) are only at the initial stage. However, first investigations suggest such applications for ESI-MS. For example, the formation constants of crown-ether ([18]crown-6) complexes with alkali metal ions have been directly determined from intensity ratios in the ESI mass spectra of the complex ions and agree well with published data; furthermore, the intensities of the complex ions correlated with the solvation energies of crown-ether complexes.[97a] Likewise, the formation constants for complexes of crown-ether modified peptides with alkali metal ions obtained from the molecular ion intensities in ESI-MS agreed with those obtained by calorimetric methods.[97b] These most recent results indicate that the further development of ESI-MS for the quantitative determination of equilibrium constants for noncovalent complexes is promising, for example, by using crown-ether derivatives for selective "ion-labeling".[97]

3.2. Identification of Supramolecular Protein Complexes

As pointed out in Section 2.3, the identification of supramolecular complexes requires the differentiation of specific complex ions from unspecific noncovalent association. Initial studies on proteins have, therefore, been carried out on dimers of known structure that lead to the formation of specific molecular ions (in contrast to unspecific oligomeric "cluster" ions in FAB and MALDI spectra[5, 11]). The principle for the identification of dimeric complexes by a multiply charged ion series is schematically shown in Figure 12 for a leucine zipper protein. Generally, an oligomer composed of identical polypeptide chains is unequivocally identified by a molecular ion with a non-integer charge number when divided by the number of complex components.[24, 45b] Therefore, all leucine zipper homodimers are characterized by odd charged molecular ions; an identical principle applies to duplex-oligonucleotides from single strands with identical base composition (see Section 3.3).

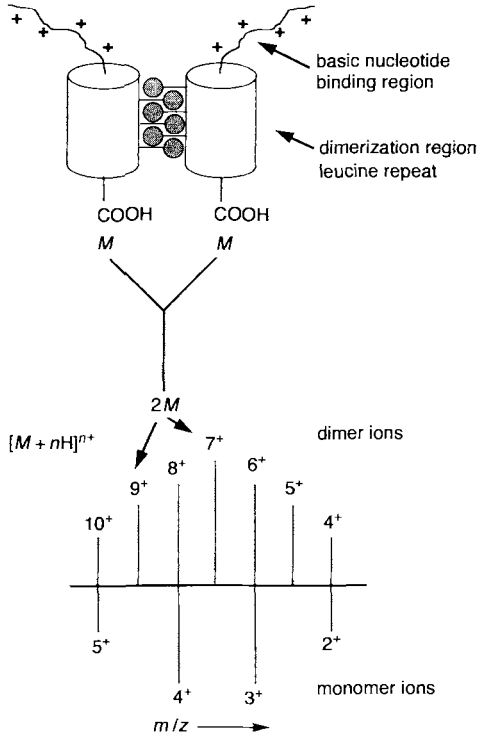

Fig. 12. Schematic structure of leucine zipper polypeptides, and principle of the identification of homodimers by odd-charged $[M + nH]^{n+}$ ion series. The even-charged ions of the dimer are superimposed by the corresponding ions of the monomer (shown downwards) on the m/z scale.

Several classes of leucine zipper proteins have attracted interest recently because of their significance in transcription regulation as well as their structure and specificity in DNA recognition, which has not been elucidated in detail.[98, 99] Leucine zipper structural elements, consisting of regular heptad repeats of leucine residues followed by basic DNA-binding units (see Figures 12 and 13), have been identified in a number of transcription activator proteins[46] and recently in ribosomal RNA-binding proteins.[100] Probably the best known leucine zipper is the GCN4 transcription activator from yeast (GCN4-leucine zipper[46]), which consists of a double-stranded α-helical coiled coil with a 4–3 heptad sequence of hydrophobic and polar residues. Although binding of a specific DNA sequence (palindrome-nucleotide; see Figure 17) has been shown to induce the dimerization and to stabilize the complementary protein conformation,[98, 101] stable dimers of leucine zipper polypeptides have been prepared.[102] Several leucine zipper polypeptides have been characterized by spectroscopic methods (CD, NMR[102, 103]) and the GCN4 sequence by X-ray crystallography.[104] However, since many structural details and general prerequisites for the specificity of protein–nucleotide complexes are still unresolved, the possibility of a direct mass spectrometric characterization has found considerable interest.

First ESI mass spectra of dimeric complexes have been reported by Li et al. for a synthetic leucine zipper peptide.[105] Specific odd-charge $[M+5H]^{5+}$ and $[M+7H]^{7+}$ ions of the dimers could be detected; however, their intensities are low relative to the most abundant even-charged ions of the monomer, which suggests that the stability of the complexes with hydrophobic interactions is low under the ESI conditions. Their identification, however, was ascertained by tandem-ESI-MS analysis upon collision-induced dissociation of the $[M+5H]^{5+}$ ions.[106] Systematic studies based on the sequences of naturally occurring coiled coils have been carried out on a series of synthetic polypeptides containing both leucine zipper dimerization regions and the basic DNA-binding regions.[24, 107, 108] The ESI spectrum of a GCN4 polypeptide at low declustering potential ($\Delta CS \approx 5$–10 V, Fig. 13) displayed an intense peak for the 5+ charged molecular ion of the dimer (M_2) at m/z 1616 ($M_r = 8078$, $(2\times4039+5)/5 = 1616.6$). The ions at m/z 1347 and 1010 can originate from either the monomer or the dimer ($M^{3+}/(M_2)^{6+}$ and $M^{4+}/(M_2)^{8+}$, respectively; see also Fig. 14). The $[M+5H]^{5+}$ ion of the dimer completely disappeared upon dissociation at higher ΔCS (60 V), thus confirming the noncovalent complex; the intensities of the 3+ and 4+ ions of the monomer remained unchanged (Fig. 13, bottom right). In accord with these results, the intensities of the dimeric ion increased at higher concentration (about 100 μM), whereas a change in the temperature of the inlet capillary (30–70 °C) showed only little effect on the monomer/dimer ratio.[108a] Under the conditions employed the dimer could not be formed quantitatively; subsequent studies attributed this to partial dissociation of leucine zipper complexes at the polar capillary surface.[108]

The success of ESI-MS in characterizing supramolecular leucine zipper complexes could be demonstrated in further studies on "coiled coil" polypeptides, one of which ("coil-Ser", see Fig. 14) forms a triple-standed coiled coil according to its crystal structure.[109] Trimeric complexes of "coil-Ser" and related

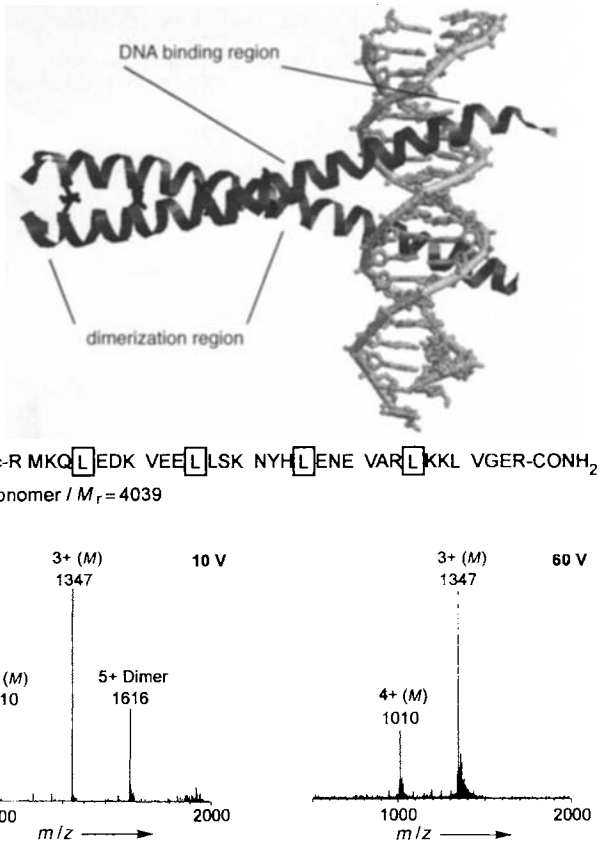

Fig. 13. Bottom: ESI mass spectra of leucine zipper polypeptide GCN4-p1 at 10 V (left) and 60 V (right) declustering voltage. The 5+ charged molecular ion of the homodimer is only observed at ΔCS = 10 V. Spectra were obtained by injection of 5 μL of a 50 μM peptide solution in a solvent mixture of ammonium acetate (2 mM) and methanol (9/1) with pH 6. polypeptides were identified by ESI-MS by their specific $(M_3)^{5+}$ ions, and their presence was confirmed by sedimentation equilibrium analysis.[107] Moreover, the analytical potential of ESI-MS was demonstrated recently by the first identification of homo- and heteromeric complexes in hybridization experiments of polypeptides comprising different sequence variants.[107, 108a] As example, Figure 14 shows ESI mass spectra of an equimolar mixture of two sequence variants (LZ/LZ12A; LA) in which ions characteristic of the heterodimer, AL^{4+}, and both possible heterotrimers, ALL^{5+} and AAL^{5+}, were detected in addition to the homomeric complexes. In contrast to the ESI mass spectra obtained with a quadrupole mass analyzer (Fig. 14a), isotopic resolution and direct assignment of the dimeric and trimeric complex ions was achieved on a double focusing magnetic sector instrument (Fig. 14b).[108a] Thus, the 4+ charged homodimer ion and the 2+ charged monomer were differentiated directly by the mass differences of the isotopic multiplets at m/z 1633 and 1654 ($\Delta m = 0.25$). Likewise, the trimeric $(M_3)^{5+}$ complex ions were ascertained by the correct isotopic distribution ($\Delta m = 0.2$). Under these conditions it was even possible to demonstrate that hybridization of GCN4-polypeptide and "coil-Ser" leucine zippers produced both dimeric and trimeric heteromers,[107] consistent with the results of spectroscopic studies of fluorescence-labeled polypeptides.[110]

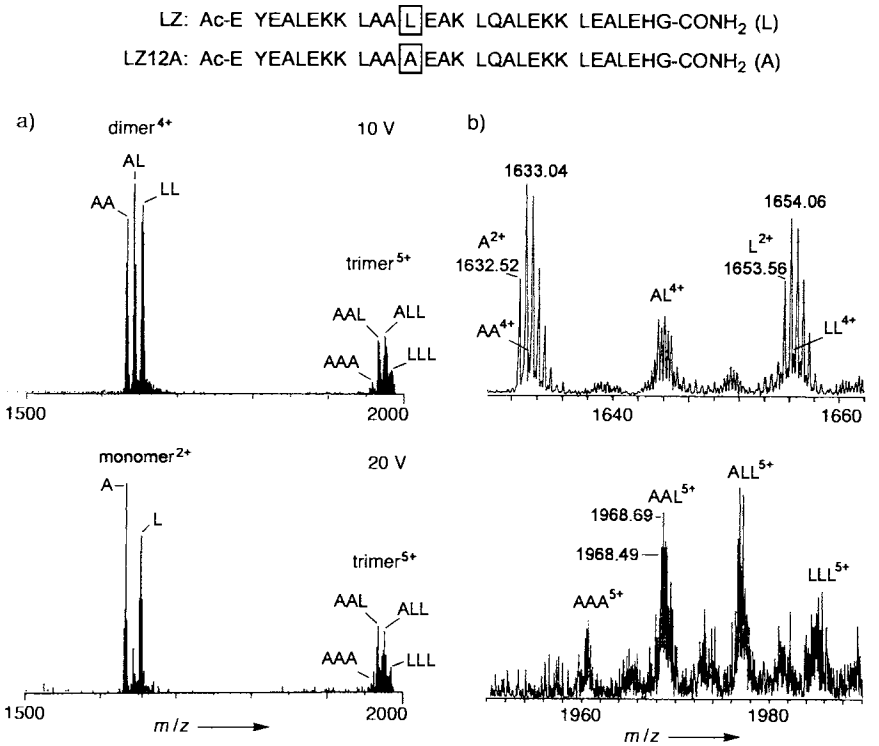

Fig. 14. ESI mass spectra of dimeric and trimeric heteromers obtained from an equimolar mixture (0.1 mM) of peptides LZ and LZ12A [108a]. a) Spectra of dimeric (4+) and trimeric (5+) complexes recorded with a quadrupole mass spectrometer at $\Delta CS = 10$ V (top) and 20 V (bottom). b) Spectrum of dimers (top) and trimers (bottom) on a magnetic sector-field instrument at a mass resolution of about 7000, showing the isotopic resolution for the 4+ and 5+ charged complex ions.

Dimeric complexes of several other DNA- and RNA-binding proteins have been recently characterized by ESI-MS, for instance the RNA-binding autoantigen L7[100] and the nuclear matrix protein SAF-A.[111] A further application has been found in the structure elucidation of the lipid-analogue SP-C protein from lung surfactant, which exerts important biochemical functions in the lung alveolar system.[112–114] A recombinant variant has been developed for the therapy of respiratory distress syndrome.[115] The SP-C protein, which has an extremely hydrophobic α-helical domain (without analogy to the leucine zipper motif) and a palmitoylated N-terminal sequence,[116, 117] was identified by ESI-MS as a specific dimeric complex.[113] This result contributed essentially to the formulation of a structural model for the insertion and stabilization of the palmitoylated SP-C in the lipid alveolar surface layer.[113, 115] In these applications, a considerable problem, particularly for the characterization of complexes with hydrophobic interactions, was the strong tendency of protein complexes to adsorb at the polar fused-silica inlet capillary.[24] Increased stabilities of complex ions and improvements in the characterization of pH- and concentration-dependent equilibria has recently been obtained by using polyacrylamide-coated capillaries,[118] yielding a correlation of ion intensities and stabilities of "coiled coil" polypeptide complexes.[107, 108a] However, a general problem is the decrease in charge numbers for ions of protein complexes relative to the complex components (cf. Section 3.1); for example, the leucine zipper dimers and trimers yielded maximum charge numbers of 5+, while the sum of charge numbers of the monomers is 8+ and 12+, respectively (see Figures 13 and 14). Such charge effects are most characteristic for protein–nucleotide complexes (see Section 3.3), leading to increasing demands on instrumentation (sector or time-of-flight analyzers).[119]

Despite these present limitations, first mass spectra of intact quaternary structures of high molecular weight proteins have been reported. Model studies have been carried out on proteins with a known specific association of subunits in solution, such as dimeric hemoglobin and the tetrameric complexes of avidin and streptavidin, two of the most stable known quaternary structures. A further successful application was the characterization of the cell-recognition lectin, concanavalin A (Con A), with a high-mass quadrupole analyzer[23] (Fig. 15; M_r of the subunit 25500). Abundant ions of the dimer and tetramer with charge states between 14+ and 22+ (m/z region around 4500) were identified from aqueous solution at pH 6.7, in good agreement with the known pH-dependent stability of Con A.[120] At elevated temperature or in acidic solution complete dissociation of the complex into the subunits was established by the appearance of monomer ions at m/z lower than 2000 (charge numbers to about 18+; Figure 15b). Crucial evidence for the specific identification of the quaternary structures in this study was the absence of ions in the spectrum due to nonspecific association products such as trimers and the reversibility of the complex formation upon pH and temperature changes. As expected, the relative decrease of charge numbers is most pronounced for ions of the tetramer, while the denatured monomer shows highly charged ions. Recent studies indicate that ESI time-of-flight instru-

mentation is well suited to determine charge numbers of ions within a broad m/z range for quaternary structures with multiple subunits.[121]

3.3. Characterization of Double-Stranded Oligonucleotides and Higher Order Nucleotide Complexes

Because of the problems in obtaining homogeneous polyanions in the presence of alkali salts, most studies of oligo- and polynucleotides have been carried out with the ammonium salts[45, 49, 122] (cf. Section 2.1; Figure 2b); identical conditions have been applied to the characterization of supramolecular complexes (however, see Figure 18). In the negative-ion ESI mass spectra of DNA and RNA sequences, the $[M - nH]^{n-}$ ions were not significantly pH-dependent from pH 4 to 8.[24, 122a, 123] In contrast to proteins, no clear relation between charge structures of polyanions and structural states in solution has been observed; ion abundances are affected by organic cosolvents and by differences in base composition.[123] However, charge numbers of negative ions are considerably lower for double-stranded complexes than for the complementary single-strand sequences (see Fig. 17). As pointed out in Section 3. 1. for protein complexes, double-stranded oligonucleotides are unambiguously distinguished from isobaric single-strand sequences by the odd-charged duplex polyanions, as illustrated in Figure 16 by an

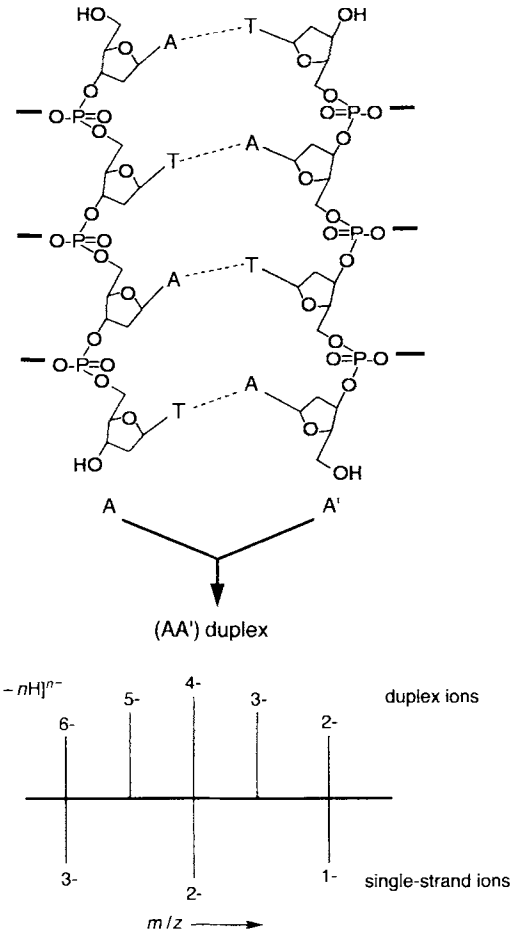

Fig. 16. Scheme illustrating the identification of double-stranded polynucleotides by odd-charged duplex polyanions $[M - nH]^{n-}$ (cf. Fig. 12).

A/T-duplex, while isotopic resolution would be required for the assignment of even-charged complex ions.

First successful investigations of double-stranded synthetic oligonucleotides with conventional quadrupole mass spectrometers have been reported by several authors.[45, 122a] Duplex-specific ions have been identified for self-complementary (isobaric) oligonucleotides, as well as for sequences of different base compositions (see Table 4). ESI mass spectra of the hybridization product of two recognition sequences of the GCN4 leucine zipper (GCN4-U/-L[125]) with a central pseudo-palindromic binding region are illustrated in Figure 17. Among the anions with charges of 8 − to 10 −, the duplex is specifically identified by the $[M - 9H]^{9-}$ ion ($M_r = 14707$; Fig. 17a), whereas the even-charged ions do not enable a direct differentiation because of the small differences in molecular weight in the single-strand sequences ($M_r = 7360$ and 7347; $\Delta m = 13$; see Table 4); however, the quantitative formation of the duplex was ascertained by gel electrophoresis.[45, 126] Analyses of the single-stranded sequences and further model studies also provided evidence for the direct identification of mixtures of duplex and single-strand oligonucleotides.[24, 122b] Thus, the spectrum of the partially dissociated GCN4-U/-L duplex shows the duplex-specific ions (9 −, 11 −), as well as the $[M - nH]^{n-}$ ions of the single-strand sequences with significantly higher *relative* charge numbers (Fig. 17 b). The direct analysis of single-strand/duplex mixtures provides the basis for the determination of duplex melting temperatures by ESI-MS; first model studies have been performed and compared with conventional methods.[127] For the GCN4-U/-L duplex, a melting temperature of 59 °C was obtained with the temperature-controlled sample delivery probe ($T_m = 64$ °C by UV spectroscopic determination).[45a] ESI-MS studies of hybridization products of different synthetic oligodeoxyribonucleotides are summarized in Table 4. For most products studied so far, the molecular weight of the duplex determined by ESI-MS was higher than that calculated

Table 4. Identification of double-stranded oligodeoxynucleotides by negative-ion ESI mass spectrometry.

from the single-strand sequences (without counterions), since the formation of homogeneous $[M - nH]^{n-}$ ion series essentially depends on the purity of the ammonium salts (cf. Section 2.1). As expected, the charges of all oligonucleotide duplex ions are significantly lower than the sum of charges of the single-strand ions. For example, the most abundant duplex ion of a 20-mer hybridization product ($M_r = 12200$[124a]) was observed at m/z 2446 (see Table 4); hence the ions of high molecular weight complexes (found up to m/z 2000) probably represent only a fraction with high charge numbers. Moreover, Light-Wahl et al.[122, 124] suggested that duplex ions with low charge have higher relative stabilities, which may result from the stabilizing effect of remaining counterions.

The results hitherto obtained with double-stranded complexes are encouraging, taking into consideration that little knowledge is yet available about ion compositions and structures in ESI spectra of oligo- and polynucleotides. A number of applications can be envisaged for the characterization of supramolecular complexes for which no specific methods are available at present. Examples are sequence determinations by hybridization products (rather than by mass spectrometric analysis of sequential fragment ions from single-stranded oligonucleotides[128]), the characterization of duplex products of chemically modified nucleotides without the use of radioactive labeling techniques,[129] and the analysis of "antisense" oligonucleotides[130] and intercalation complexes; the characterization of oligonucleotide complexes with actinomycin D and distamycin has been reported recently.[131] Of particular interest should be applications to supramolecular complexes formed by hybridization additional or alternative to the Watson–Crick base pairing, such as Hogsteen complexes and nucleotide-specific triplex structures.[132, 133] That higher-order nucleotide complexes can be studied by ESI-MS has been demonstrated recently by Goodlett et al. with the identification of a quadruplex of the guanine-rich oligonucleotide, d($CGCG_3GCG$) $(dG4)_4$,[134] formed by "quartet" pairing of the central guanine bases, alternative to the intramolecular Watson–Crick base pairing.[135, 136] Negative-ion ESI mass spectra of the complex were obtained in sodium phosphate buffer (required to stabilize the quadruplex by insertion of the alkali metal counterions into the G-base stacks[135]), and under particularly mild desolvation conditions by using sulfur hexafluoride as a sheath gas[137] (Fig. 18). Although the presence of alkali salt caused

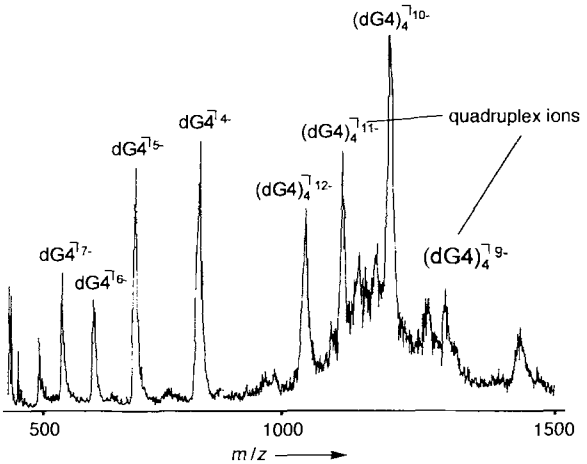

Fig. 18. Identification of the tetramer of 5'-d(CGCGGGGGCG)-3' (dG4) by negative ion ESI-MS. A 0.9 mM solution of dG4 was prepared in 10 mM sodium phosphate (pH 7.6) and 0.1 mM ethylenediamintetraacetic acid (EDTA); spectra were obtained with sulfur hexafluoride as a sheath gas. Ions specific for the quadruplex are labeled $(dG4)_4$. From ref. [134].

considerable peak broademing by multiply sodiated polyanions, unambiguous identification of the quadruplex was obtained by the characteristic *odd-charge* state ions, $(dG4)_4^{11-}$ and $(dG4)_4^{9-}$.

In principle, the successful characterization of supramolecular complexes of proteins as well as oligonucleotides prepares the way for the direct analysis of protein–nucleotide interactions. For protein complexes with mono- and dinucleotides and related cofactors, the conditions of positive-ion ESI-MS of proteins are applicable[89, 93] (cf. Table 3). In studies of the nucleotide-binding region of the elongation factor EF-Tu from *T. thermophilus*,[138] the protein complexes with GDP and GTP were identified as homogeneous $[M + nH]^{n+}$ ion series, and their presence was confirmed by chemical and spectrospopic results.[139] However, protein complexes with high molecular weight DNA and RNA sequences (leucine zipper proteins, EF-Tu/tRNA complex[138]) did not yield highly charged ions.[108a]

Thus, the analysis of protein–nucleic acid complexes with multiple ionic interactions and neutralization by counterions appears to be limited to high-molecular weight ions, so future applications will essentially depend on the development of high-mass analyzers.

4. ESI-MS Characterization of Synthetic Supramolecular Complexes

The synthesis of supramolecular complexes from synthetic self-assembling components and their structural and functional characterization has recently evolved as a most exciting research area.[140–143] A wide range of supramolecular structures such as synthetic helicates, catenanes,[144] and host–guest complexes[145] have been developed, both as model systems for natural self-association processes[146] and as complexes with new supramolecular structures.[147] The isolation and purification of supramolecular complexes often present particular difficulties, and only in a few cases could the complete spectroscopic characterization and crystallographic structure determination be undertaken.[141] Frequently, a major analytical problem is the characterization of reaction pathways leading to the formation of specific complexes in multicomponent mixtures;[148] here mass spectrometric methods have recently found increasing application.[148, 149]

Examples of ESI mass spectra of supramolecular complexes from building blocks of rotaxanes, catenanes, and helicates are summarized in Table 5. For nearly all complexes hitherto analyzed, appropriate electrospray conditions and high ion intensities were obtained with organic (aprotic) solvents. In most cases the charge states of complex ions were derived either from the presence of metal ions[153, 154] or by the formal loss of one or several counterions.[149] Thus, for catenane complexes composed of 4,4′-bipyridyl derivatives and different macrocyclic and aromatic polyether ligands, molecular ions that had lost up to four PF_6^- counterions were detected.[149] The corresponding multiply charged series enables the dimers to be identified by a principle analogous to that applied to the multiply protonated ion series of protein complexes (cf. Section 3.2). Several catenanes and rotaxanes shown in Table 5 have also been successfully analyzed by FAB-MS[149, 150] (see Section 5). Comparative studies of catenanes[155] showed that FAB-MS gives predominantly singly charged ions; thus ESI-MS offers advantages for the analysis of higher molecular weight complexes (greater than 3000 Da). For example, Bitsch et al.[152] detected multicyclic complexes with molecular weights over 7000 Da and containing up to seven interlocked catenane rings by ESI-MS.

Furthermore, ESI-MS has been recently demonstrated as an efficient tool for the direct analysis of mixtures of self-assembling components. For example, double-stranded complexes of oligo-(2,2′-bipyridyl)-ether derivatives were identified with copper(I) ions, whereas triplex helicates are furnished upon insertion of nickel(II) ions.[151] An elegant example has been the ESI mass spectrometric characterization of a polynuclear self-assembly complex of a bis(isoquinoline) (L1) and a hexaphenylhexaazatriphenylene ligand (L2) with $CuPF_6$[149] (Fig. 19). ESI mass spectra of aliquots from an equimolar mixture of the two ligands upon titration with 2.5 equivalents of $CuPF_6$ established the identity of the three-component complex **1** due to the specific triply charged ion $[(L1)(L2)Cu_3^I]^{3+}$ (m/z 616). The composition of the fully assembled complex was ascertained by collisionally activated dissociation and tandem ESI-MS analysis, which yielded fragment ions from the components $[(L1)Cu_2]^{2+}$ (m/z 547) and $[(L2)Cu]^+$ (m/z 753) (Fig. 19b). In addition, protonated ions arising from complexes with one and two Cu^I ions inserted into the "partially capped" complexes (**2** and **3**, respectively) were detected as by-products. The ion intensities of the complex species determined by ESI-MS showed good agreement with the relative amounts deduced from spectrophotometric titration.[156] These results suggest that the formation of supramolecular complexes can be directly analyzed under thermodynamic equilibrium conditions. However, the extent to which the formation of complexes from multicomponent reaction mixtures can be quantitatively analyzed remains to be established in further studies.[148, 157]

5. Comparison of ESI-MS with Other Ionization Methods

The successful development of ESI-MS suggests the potential application of other "soft" ionization MS methods for the analysis of supramolecular complexes. With the exception of a few previous studies such as FAB-MS of polysaccharide–lipid complexes,[158] no systematic investigations of noncovalent interactions with biopolymers have yet been performed by FAB-MS,

Table 5. ESI mass spectrometric identification of supramolecular complexes from synthetic self-assemblying components.

	complex components			supramolecular complex		
complex type	ligand components	metal/counterion [a]	M_r [b]	association	charge state [c]	Ref.
catenane	4,4′-bipyridyl; macrocyclic polyether	–/PF_6^-	2525	dimer	3+	[149]
rotaxane	bis(porphyrin)phenanthroline (spacer); macrocyclic polyether	Cu^I/PF_6^- Au^{III}/PF_6^-	2986	1:1 complex	2+	[150]
helicate	oligo(2,2′-bipyridyl)ether derivative	Cu^I/ClO_4^-	1659	double helicate	3+	[151]
		Ni^{II}/ClO_4^-	2419	triple helicate	6+	
catenane	phenanthroline; (*cyclo*)-oligoacetylene derivative	Cu^I/BF_4^-	4444	pentacatenane	4+	[152]
			5557	hexacatenane	5+	
			6668	heptacatenane	6+	

[a] Metal- and counterion employed in the preparation of the self-assembled complexes. [b] Molecular weights refer to the neutral complexes (including counterions). [c] Most abundant charge states of observed complex ions.

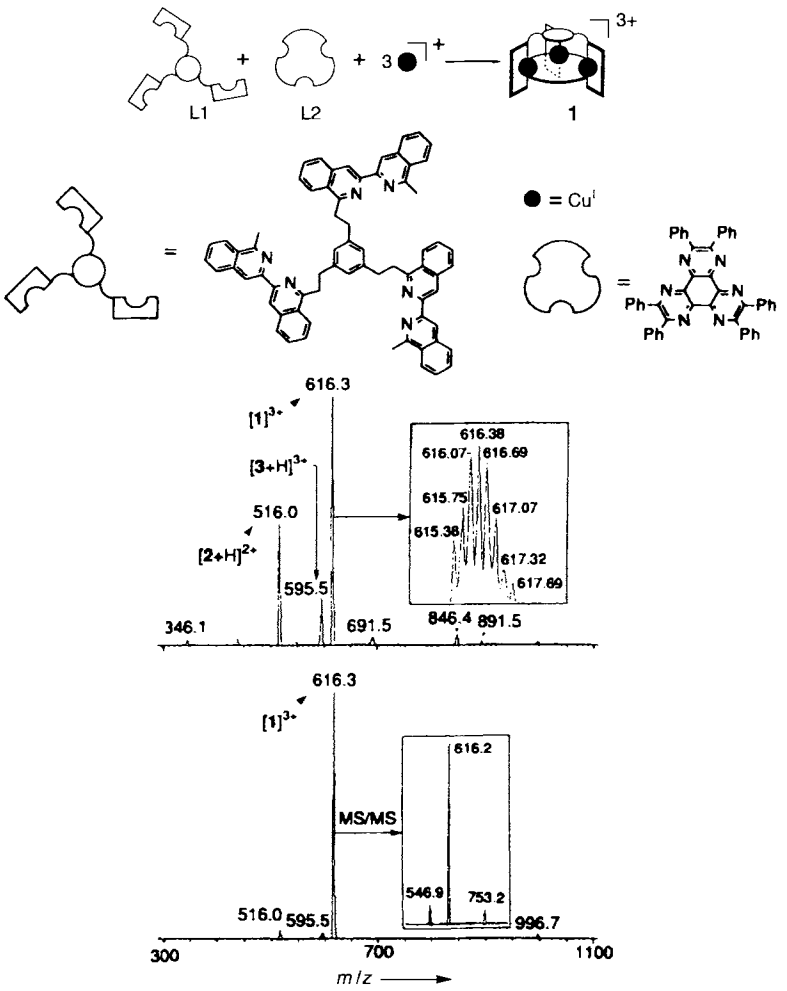

Fig. 19. ESI mass spectrometric identification of the three-component self-assembly complex **1** between tris(bisisoquinoline) (L1) and hexaphenylhexaazatriphenylene (L2) ligands and three Cu^{I} ions. Spectra were recorded of acetonitrile/CH_2Cl_2 (1/1) solutions after titration of an equimolar mixture of L1 and L2 with 2.5 (top spectrum) and 6 equivalents (bottom spectrum) of $CuPF_6$. From Ref. [148].

PD-MS, and MALDI-MS. Comparison of these techniques with ESI-MS on biopolymer complexes with defined structures in solution are difficult, because different sample preparation procedures are used in other ionization methods. Only in FAB-MS are sample solutions used;[5] PD-MS is mainly performed with solid samples, and special conditions are required for solubilization (for example, for the analysis of chemical reactions in situ on the sample target).[7, 15, 159] For nearly all applications of MALDI-MS solid samples were prepared by admixture of a large excess of matrix;[11, 160, 161] no information is currently available about the structural state of macromolecules under these conditions.

A number of synthetic supramolecular complexes such as catenanes and rotaxanes have been identified by FAB-MS in organic solvents (mainly with 3-nitrobenzyl alcohol as matrix).[155, 162, 163] The positive-ion FAB spectra of oligocatenanes from macrocyclic polyethers (cf. Table 5) exhibit abundant molecular cations arising from loss of one of the PF_6^- counterions; ring-opening and elimination of bipyridinium units are the major fragmentaions.[162b] The main limitations for the application of FAB-MS are the limited molecular weight range accessible, the variation of sample concentration by solvent evaporation, and the instability of many coordination complexes in polar solvents. However, first successful studies have been carried out in aqueous solutions with glycerol as matrix.[97, 163, 164] For example, semirotaxane complexes of β-cyclodextrins (β-CD) have been identified in aqueous glycerol solutions through their abundant $[M+H]^+$ ions, as illustrated in Figure 20 by a 1:1 complex of β-CD and 11-aminoundecane-4′-triphenylmethylanilide.[163] Studies of semirotaxanes by ESI-MS for comparison also afforded predominantly the formation of singly charged complex ions.[164] A major obstacle for the analysis of biomacromolecular complexes by FAB-MS is the problem of preparing sample solutions with the same conditions as in physiological solutions. Thus, negative-ion FAB spectra of duplex oligonucleotides did not provide ions indicative of double-stranded products, but only molecular ions of the single-stranded chains and fragments, some of which are sequence-specific;[45] likewise, studies with PD-MS did not yield ions of double-stranded oligonucleotides. However, the recent identification of specific Cu^{II} complexes of the oligopeptide angiotensin[165, 166] by PD-MS from aqueous solution at carefully controlled pH indicates that progress in the analysis of noncovalent complexes by FAB-MS and PD-MS can be expected by improved matrix and sample preparation procedures.[164, 166, 167]

The major problems at present preventing the analysis of supramolecular complexes by MALDI-MS are the harsh, denaturing sample preparation conditions and the formation of unspecific "cluster" ions and matrix adducts.[161, 168, 169] The formation of unspecific adduct ions is illustrated in Figure 21 by UV-MALDI spectra of cytochrome C and an IgG monoclonal antibody,[11] which show ions of dimeric and

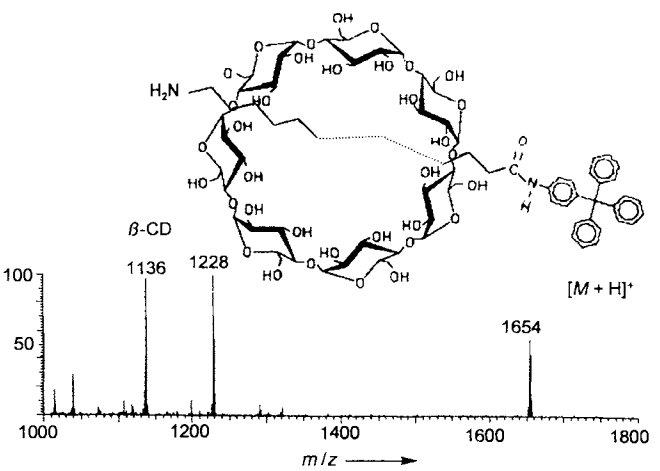

Fig. 20. FAB mass spectrum of the semirotaxane complex of β-CD with 11-aminodecane-4′-triphenylmethylanilide. Solvent: methanol; matrix: 3-nitrobenzyl alcohol [163].

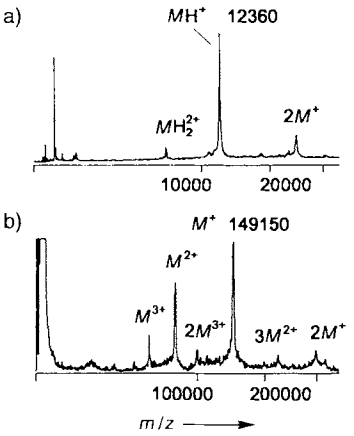

Fig. 21. MALDI mass spectra of a) porcine cytochrome C in 2,5-dihydroxybenzoic acid matrix (337 nm) and b) a mouse IgG monoclonal antibody against a human lymphokine in nicotinic acid matrix (266 nm). From Ref. [11].

trimeric aggregates in addition to the singly and doubly charged molecular ions, without relevance to a quaternary structure. In most cases the samples are incorporated into a strongly acidic matrix with suitable absorption properties (for example, benzoic and cinnamic acid derivatives for UV-MALDI-MS[161, 168]). Under these conditions, complete denaturation of protein structures and dissociation of specific interactions must generally be expected. Accordingly, initial attempts to characterize noncovalent complexes did not yield reproducible results, or yielded only dissociation products (for example, for heme-proteins[169]).[168a, 170] A number of new matrices for UV-MALDI-MS that can be crystallized from aqueous solutions at pH 2–8[171] have recently been developed, but their feasibility for the analysis of supramolecular complexes has not yet been tested. For the characterization of noncovalent interactions, the mild desorption conditions of IR-MALDI-MS with liquid matrices[172] might be more promising than the analysis of solid, crystalline samples. Of particular interest has been the recent observation of multiply charged ion series in IR-MALDI spectra of proteins, for example, of immunoglobuline antibodies.[161] In conclusion, despite single observations of specific complex ions (for example, for the ion channel protein porin[161]), the feasibility of MALDI-MS for supramolecular complexes has not yet been demonstrated. The elucidation of matrix chemistry and desorption mechanism(s) will be of crucial importance for further development.

6. Conclusions and Perspectives

Although introduced only in the past few years as a method for molecular weight and primary structure determination of biopolymers, the ability of ESI-MS to provide information on tertiary structures and specific noncovalent interactions of macromolecules in solution is presently adding a new dimension beyond the characterization of *primary structures* as the classical domain of mass spectrometry. The hitherto successful applications open new perspectives for the direct analysis of supramolecular complexes and molecular recognition processes. Furthermore, they demonstrate that the ESI-mass spectrometric identification of molecular constitution and composition, and of binding specificities of supramolecular complexes provides complementary information to the structure determination by spectroscopic methods and by crystal structure analysis.[173–176]

Considering that for ESI-MS—like other soft ionization methods—little more than qualitative models are available yet on the mechanism of ion formation and transfer from solution to the gas phase, the analytical potential indicated by the present results appears promising.[23, 50, 177] Whereas the detection of electrostatic interactions between charged macromolecules can, in principle, be anticipated,[110, 177] molecular specificity has also been demonstrated with complexes comprising types of binding such as hydrogen-bond and hydrophobic interactions. Moreover, it must be borne in mind that the present investigations have been primarily carried out on ions with high charge states and at low resolution; high-mass ESI-MS instrumentation suitable for the characterization of supramolecular complexes by ions with low charge states has only recently become available.[23, 119] The most recently developed ESI ion-cyclotron resonance (ICR) instruments[178] are particularly promising, especially for the identification of complex ions of high mass *and* at high resolution and for the characterization of gas-phase structures of macromolecular ions. Of primary importance for future applications will be the development of improved sample delivery systems to control the conditions of formation of supramolecular complexes (pH, temperature) in solution and the conditions of desolvation. Although useful correlations between structural states in solution and charge structures of ions in the gas phase have been shown, the structural characterization of gas-phase macromolecular ions is in its infancy, and it is still speculative to postulate a conservation of solution structures. However, first investigations by a combination of ESI-MS and NMR spectroscopy have already provided useful complementary results in the characterization of solution structures, for example, in H/D-exchange studies.[179]

The full potential and limitations of ESI-MS for the analysis of supramolecular complexes cannot yet be evaluated, particularly with regard to the quantitative characterization of equilibria of noncovalent complexes. However, a number of new applications are clearly emerging, for example, the identification of sequence-specific oligomerization products of helical polypeptides,[180] the characterization of antigen-antibody interactions,[181, 182] the characterization of specific enzyme- and receptor-ligand interactions even from complex mixtures such as those obtained from combinatorial peptide syntheses,[183] and the study of specificity in synthetic supramolecular complexes.[184, 185] Further development should stimulate the growing interdisciplinary application of ESI mass spectrometry.

We are indebted to our co-workers for their enthusiasm, ideas, and many discussions throughout the investigations reported in this article: Dr. Detlev Suckau, Dr. Klaus Schneider, Dr. Andrea Schäfer, Dr. Per F. Nielsen, Dr. Michal Svoboda, Dr. Claudia Maier, Dipl.-Ing. Klaus Hägele, Dipl.-Chem. Winfried Fiedler, Dipl.-Chem. Christoph Borchers, Dipl.-Chem. Petra Mayer, Dipl.-Chem. Jürgen Kast, Dr. Kerstin Seidel, Dipl.-Chem. Rainer Schuhmacher, Dr. Wolfgang Weinmann, Dr. Martin Kussmann, Dipl.-Chem. Ingrid G. Kaufmann, Dipl.-Chem. Stephan Witte, Dipl.-Chem. Volker Schnaible, Dipl.-Chem. Andreas Wattenberg, Dipl.-Chem. Martina Schuhmacher, Dipl.-Chem. Marcus Macht, and Dipl.-Chem. Sebastian Bauer. We are grateful to Professors K. P. Schäfer, K. Klemm, A. L. Burlingame, F. W. Röllgen, C. Stürmer, U. Krawinkel, G. Spiteller, M. Speinzl, P. Roepstorff, and W. Welte for helpful discussions, advice, and encouragement, particularly concerning new application areas. Furthermore, we thank A. van Dorsselaer, K. Tomer, M. L. Deinzer, G. Jung, F. W. McLafferty, M. Mák, and R. Frank, for making manuscripts and

many unpublished results available to us. M. P. thanks the state of Baden-Württemberg for support, and particularly Professor B. Penke for his hospitality and many discussions during a guest stay at the A. Szent-György-University, Szeged. We gratefully acknowledge the generous financial support by the Deutsche Forschungsgemeinschaft, Bundesministerium für Forschung und Technologie, Fonds der chemischen Industrie, the European Community within the EU-network "Peptide and Protein Structure Elucidation by Mass Spectrometry", Byk Gulden Konstanz, and Boehringer Mannheim.

A wealth of main group element compounds that resemble olefins, carbenes, and small carbon rings, and yet exhibit their own quite individual chemistry are reported by M. Driess and H. -J. Grützmacher.

Main Group Element Analogues of Carbenes, Olefins, and Small Rings

Matthias Driess* and Hansjörg Grützmacher*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

For a long time methylene ($:CH_2$), ethylene ($H_2C=CH_2$), and cyclopropane [$(CH_2)_3$] were considered as compounds whose higher main group homologues or analogues could not be synthesized. One consequence of the failure of earlier experiments was, for example, the "double bond rule" which was introduced over twenty years ago and is still often quoted. Although it does not dispute the existence of multiple bonding between elements, it states that it leads to very kinetically unstable species. This interpretation of the double bond rule has long since been surpassed due to improved experimental and quantum chemical methods which have allowed the synthesis of main group analogues of methylene, ethylene, and cyclopropane that are kinetically stable in solution and the solid state at room temperature. In the following review recent advances in the synthesis of these compounds will be referenced, and the concepts, which were developed by a systematic study, will be laid out. In doing so, a detailed description of the complex reactivity of the individual classes of compounds will be avoided in order to highlight the basic principles. These can then be used to approximately predict reactivity and characteristics of new compounds. There are significant differences between formally and even structurally analogous compounds with elements from the higher rows as compared to their "lighter" homologues. For example, while every chemist is familiar with the planar D_{2h} symmetrical structure of $H_2C=CH_2$ as the only "significant" isomer, it must be accepted that Sn_2H_4 has four isomers that are separated by very small energy differences. For *cis/trans* isomerism of olefins only the rotation of the C–C double bond needs to be considered, but there are three possible mechanisms for the disilene derivatives $R^1RSi=SiR^1R$. In the last century cyclopropane was considered to be not producible and this provided the impetus for Baeyer's strain theory. Investigations into small silicon cycles, which were discovered much later, show that this theory has more validity for these rings. As a result of the collected data, it is slowly becoming clearer that precisely the carbon compounds once seen as mere models are in reality the "exotic" compounds. Rules with broader applications can be developed by studying the compounds made up of main group elements.

Keywords: carbene analogues · double bond systems · main group element compounds · small rings

1. Introduction

It is the endeavor of every scientist to order his findings and to add to the current body of knowledge. The development of the periodic system of the elements in 1869 by Mendeleev and Meyer is a result of this effort in chemistry and has proven itself as a capable concept of lasting value. From this time comes, for example, the established concept of homologous elements. This defines elements with the same number of valence electrons as forming a family (element group) in which the individual elements and their compounds exhibit similar chemical and physical properties. This "early" periodic system as an ordering principle was based on the experimental methods available at that time. In other words, the capabilities of the systemization were (and have remained) in direct relationship to technical developments and the experimenter's manual skill. The then accepted model led, at the beginning of this century, to attempts to extend the chemistry of the classical main group elements, carbon, nitrogen, and oxygen, to their higher homologues. Investigations were therefore carried out into making silicon analogues of classes of compounds known from organic chemistry such as alkanes, cycloalkanes, and olefins. Despite the decades of continual failure in the search for such compounds, the persistent confidence of many research groups has led to the solution of many synthetic problems. In addition, a symbiotic relationship between experimental and theoretical chemistry has provided an essential improvement in our basic understanding of bonding

theory. However, in applying the homologue concepts, the dramatic changes that occur in character upon replacement of one carbon center with a silicon (semi-metal) or even a tin (metal) center have sometimes been overlooked. Since characteristics of various materials can be analyzed by using an appropriate spectroscopic measurement of energy exchanges, the classical two-dimensional periodic system can be extended to a third dimension to include energy values. For this, L. C. Allen chose spectroscopic electronegativity, χ_{spec}, as a characteristic value for each element. It can be experimentally determined from the atomic ionization potentials and proves itself to be compatible with the electronegativity scales established by Pauling and Allred-Rochow.[1] Based on the three-dimensional periodic system much information including the transition from nonmetals [for example: χ_{spec} 4.193 (F)-2.253 (P)] to "metalloids" B, Si, Ge, As, Sb, Te [χ_{spec} 2.211 (As)-1.916 (Si)] and metals [$\chi_{spec} < 1.824$] is well defined. The significant changes in χ_{spec} that occur upon going from the elements in the second row ($n = 2$) to the homologues in higher rows ($n > 2$) are also clarified. This corresponds to the differences in material character between formally comparable compounds. In addition, this extension of the periodic system provides a physical basis for the long known "diagonal relationship" between elements, which becomes apparent from the similar spectroscopic electronegativities (for example: B (2.051) → Si (1.916) and C (2.544) → P (2.253); compare with the larger difference in the electronegativities $\Delta\chi_{spec}$ for the respective homologous elements Al (1.613) and Si). By using selected main group element compounds analogous to carbenes, olefins, and cycloalkanes, we would like to try and point out the similarities and, more importantly, the differences the homologous substance classes may show.

2. The Concept: The Carter-Goddard-Malrieu-Trinquier (CGMT) Model for Describing Distortions in Multiply Bonded Systems

In the following review molecular compounds of main group elements that are formed from carbene-analogous fragments will be discussed. It is therefore useful to present a model developed by Carter and Goddard III as well as Malrieu and Trinquier, which allows a correlation of the singlet-triplet excitation energy of these fragments with several characteristics of the complete molecule.

In a computational experiment, a molecule $XYE=E^1X^1Y^1$ (E = central atom, X,Y,X^1,Y^1 = arbitrary substituents) with a double bond was homolytically cleaved into two fragments EXY and $E^1X^1Y^1$.[2] In this process, the σ and π bonds, by removal of spin-pairing, were broken and the fragments EXY and $E^1X^1Y^1$ thus exist in a *triplet state* (Fig. 1).

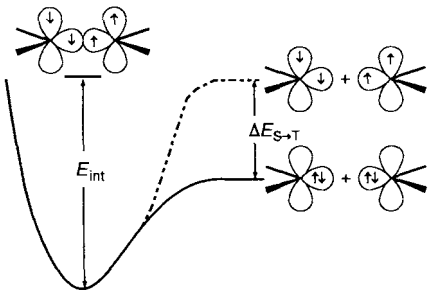

Fig. 1. Schematic representation of the dissociation of a planar, double bond system into two triplet carbene fragments [2a]. E_{int} corresponds to the C=C bond energy for C_2H_4 (172 ± 2 kcal mol^{-1}). $\Delta E_{S\rightarrow T}$ is the singlet-triplet excitation energy of the carbene fragments, which in this case is positive (the fragments have a singlet ground state).

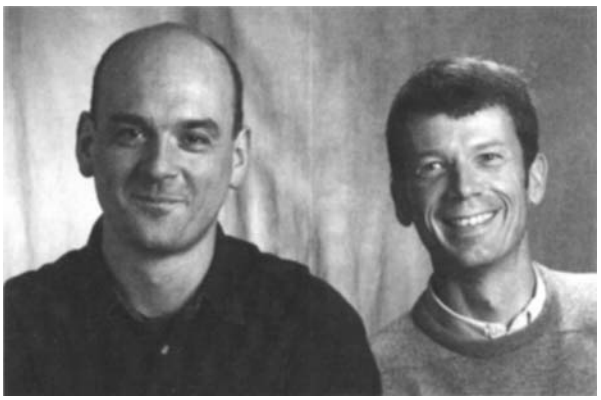
Matthias Driess was born in 1961 in Eisenach/Thüringen, studied chemistry from 1981 to 1985 in Heidelberg, and obtained his Ph.D. in 1988 under the supervision of Professor W. Siebert. After a one-year post-doctoral position with Professor R. West in Madison, Wisconsin (USA), he returned to Heidelberg and started his habilitation in 1990 which he finished in 1993. Since then he has been a Privatdozent at the Anorganisch-chemisches Institut, Heidelberg.

Hansjörg Grützmacher was born in 1959 in Hamburg, studied chemistry from 1978 to 1984 in Göttingen, and obtained his Ph.D. in 1986 under the supervision of Professor H. W. Roesky. After a one-year post-doctoral position with Dr. G. Bertrand at the CNRS-LCC in Toulouse he started his habilitation in 1987 with Professor W. Sundermeyer in Heidelberg which he finished in 1992. In the same year he accepted a position as a C3 professor in Freiburg and in 1995 took up an offer as a distinguished professor at the ETH Zürich.



M. Driess H. Grützmacher

The authors of this contibution have been friends since their habilitation time in Heidelberg and have been mainly involved with main group element compounds and their significance in simple, useful bonding concepts ("chemical rules of thumb"). Both received the ADUC prize for young scientists and were further distinguished with the Ruprecht-Karls-Preis der Universität Heidelberg (M. D.), the Freudenberg-Preis der Akademie der Wissenschaften zu Heidelberg (H. G.), a Winnacker award (H. G.), the Carl-Duisberg-Gedächtnis-Preis der GDCh (H. G.), and a Dozentenstipendium (award) from the Fonds der Chemischen Industrie (M. D.).

In general the *ground state* of these fragments can be either a triplet or a singlet state. By using differently substituted alkenes $XYC{=}C^1X^1Y^1$, Carter and Goddard III showed that the C=C double bond energy E_{TBE} can be obtained from the intrinsic C=C bond energy E_{int} of ethylene (172 ± 2 kcal mol^{-1}) minus the sum of the singlet–triplet excitation energy $\Sigma\Delta E_{S\rightarrow T}$ of the fragments EXY and $E^1X^1Y^1$ [Eq. (a)].

$$E_{TBE} = E_{int} - \Sigma\Delta E_{S\rightarrow T} \qquad \text{(a)}$$

Difluorocarbene CF_2 has a singlet ground state that is about 46.5 kcal mol^{-1} more stable than the triplet state. Thus, E_{TBE} is $172 - 2\,(46.5) = 79$ kcal mol^{-1} and in excellent agreement with the experimentally determined value of 76.3 ± 3 kcal mol^{-1}. Equation (a) is also suitable for estimating the singlet–triplet excitation energy of carbenes from experimentally available double bond energies. EXY fragments with a central atom E from a higher row have a singlet ground state that can be considerably more stable than the triplet state (see below). Since the intrinsic bond energy of the E–E double bond decreases with increasing atomic number, this leads to the curious observation that an E - E double bond can have a lower dissociation energy than an E–E single bond.[3] In other words, the dissociation energy alone is not an appropriate criterion for characterizing a multiply bonded system.

This model from Carter and Goddard III, which correlates the bond energy E_{TBE} with the excitation energy $\Delta E_{S\rightarrow T}$ of the fragment EXY, was extended by Trinquier and Malrieu to enable predictions to be made about the *geometry* of a doubly bonded system depending on the $\Delta E_{S\rightarrow T}$ values of the fragments EXY and $E^1X^1Y^1$. Here the dissociation of a multiply bonded system was not considered. Instead the *combination* of the fragments, as a function of the spin state, was investigated by calculating the total energy of the systems $EXY + E^1X^1Y^1$ as well as the geometric parameters r and θ.[4] The latter describe the E-E^1 distance (r) and the angle (θ) of the two orthogonally placed fragments EXY, $E^1X^1Y^1$ (Fig. 2).

A relative energy scale was plotted on the abscissa, whose origin corresponds to the energy content of two carbene fragments in the *singlet* state. Curve a corresponds to the combination of two carbene fragments with a triplet ground state [$\Delta E_{S\rightarrow T} < 0$]. Curve b represents the combination of two carbene fragments with excited triplet states and is shifted by the value $\Sigma\Delta E_{S\rightarrow T}$ with respect to curve a. The differently shaped curve c results from the interaction of two singlet state carbene fragments. The trace of curves a and b can be described as follows. When the distance r between two separated triplet carbenes is reduced to the equilibrium distance r_{eq}, the system first gains σ bonding energy E_σ as a result of the overlap of the two oppositely positioned spins in the singly occupied p orbitals of the fragments EXY. Thereafter, a tipping action, described by θ, of the fragments away from each other takes place. This leads to a maximal stabilization of the two triplet carbene fragments at an angle $\theta = 0°$. The total energy gain in the resulting "classical" planar doubly bonded system corresponds to the interaction energy $E_{\sigma+\pi}$ which was approximated by Malrieu and Trinquier using experimental or calculated dissociation energies. Another trace is shown by curve c, which describes the approach of two singlet state carbene fragments. There is no observed change in energy in the system upon approaching the distance r_{eq} as there is no bond formation. Furthermore the repulsive interaction due to the unoccupied p orbitals of the fragments in their *trans* orientation with respect to each other is negligible. Only in the second step during which the fragments are tilted is there an interaction. This reaches a maximum at about 45° since the effective electron density from the lone pairs of electrons of the singlet EXY fragments is delocalized in the p(π) acceptor orbitals. This description of a "double bond" as a doubled donor–acceptor bond matches that used by Lappert et al. in 1976.[5] This interaction becomes increasingly destabilized with decreasing angle θ, since the lone pairs of electrons repel each other (two-center–four-electron interaction). The depth of the potential well in curve c also corresponds to approximately half of the interaction energy $E_{\sigma+\pi}$.

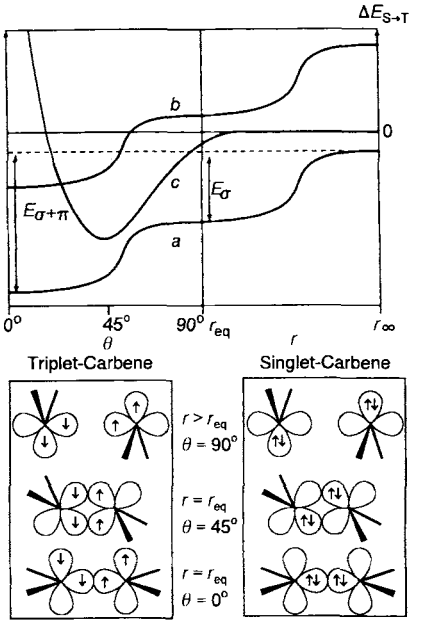


Fig. 2 Schematic interaction diagram of two carbenes or carbene analogues EXY as a function of the positional parameter r (distance) and θ (bending angle) [2b–d]. Curve *a* describes the interaction of two carbene fragments with a triplet ground state. The parallel curve *b* shows the interaction of two carbene fragments with excited triplet states. Curve *c* describes the interaction of two singlet state carbene fragments and has its start at the arbitrarily placed origin of the energy scale ($2\Delta E_{S\rightarrow T}$ (singlet) = 0). For an explanation of $E_{\sigma+\pi}$ and E_σ see text. The orbital interaction of triplet and singlet carbene fragments for different bending angles and distances is shown schematically at the bottom.

The extent of deviation of a doubly bonded system from planarity as well as the vibration energy that must be expended for the *trans* bending of the two fragments EXY and $E^1X^1Y^1$ is dependent on the respective positioning of the curves. In general, the following rules apply: a "classical" planar doubly bonded system is expected according to inequality (b), a "nonclassical"

$$\Sigma\Delta E_{S\rightarrow T} < 1/2E_{\sigma+\pi} \qquad \text{(b)}$$

structure with deviations from planarity according to inequality (c). In other words carbene fragments with a triplet ground state ($\Sigma\Delta E_{S\rightarrow T} < 0$), which form thermodynamically stable double

$$\Sigma\Delta E_{S\rightarrow T} > 1/2E_{\sigma+\pi} \qquad \text{(c)}$$

bonds ($1/2E_{\sigma+\pi} \gg 0$), lead to a coplanar ordering of the fragments. Double bonds that are formed from fragments with a singlet ground state ($\Sigma\Delta E_{S\rightarrow T} > 0$), and whose bond energies $E_{\sigma+\pi}$ are very small, show a nonplanar (*trans*-bent) orientation of the fragments with respect to each other. As we will show, these predictions have been confirmed without exception. The limiting cases in which the sum of the excitation energies $\Sigma\Delta E_{S\rightarrow T}$ is almost as large as half of the bond energy $1/2E_{\sigma+\pi}$ are of interest. Such compounds can adopt different molecular geometries as a result of minor changes (for example, crystal packing and substituent effects).

π-Donor substituents, such as F, OR, or NR_2 groups, stabilize singlet carbene fragments by interaction of the occupied p orbitals (lone pairs of electrons) on the heteroatom with the formally unoccupied p orbitals on the carbene center (Fig. 3).

Fig. 3. Representation of the π* MO of a carbene fragment with π-donor substitution (for example, NR_2, OR, F) which, instead of combining with an unoccupied pπ orbital of a carbene fragment without π-donor sustituents (see Figs. 1 and 2), combines with a second carbene fragment to describe the interaction with an occupied *n*σ orbital. π-Donors cause first an increase in the electron density on the carbene center E and thereby a repulsive interaction upon a lowering of r and second a decrease in the depth of the potential well (compare $E_{\sigma-\pi}$ in Section 2) with variation of $\theta < 90°$; thus this fragment prefers a nonclassical structure [2b].

In addition, the singlet ground state of a carbene can be lowered even further in energy by σ acceptors. This can be explained clearly in the framework of the VSEPR model as a reduction in the X-E-Y angle and an increase in the s character of the lone pair of electrons on the carbene center (see also Section 3). Since the substituents used also influence the dissociation energy of the E–E double bond, inequalities (b) and (c) must be modified. A bent ordering of the π-conjugated fragments would be expected when the relationship (d) is valid,

$$\Sigma\Delta E_{S\rightarrow T} > 1/2E_{\sigma+\pi}\,[1 + (q^1 + q^2)/2] + \alpha q^1 q^2 = f(E_{\sigma+\pi}) \qquad \text{(d)}$$

$$f = 1/2[1 + (q^1 + q^2)/2] + \alpha q^1 q^2 \qquad \text{(d')}$$

in which f is defined according to (d') and where q^1 and q^2 are calculated net charges of the p(π) orbital on the carbene fragments EXY and $E^1X^1Y^1$, respectively, and the proportionality factor α can be estimated to within 200 kcal mol^{-1}. Due to the factor f, the value on the right-hand side of the relationship (d) becomes smaller and the sum of the excitation energy $\Delta E_{S\rightarrow T}$ in π-donor substituted singlet carbene fragments rises simultaneously. The result is, for example, that (partial) fluorination of a doubly bonded system leads to a drastic change in the molecular geometry. This is shown by a comparison of $H_2Si{=}CH_2$ with $F_2Si{=}CH_2$, $H_2Si{=}CF_2$, and $F_2Si{=}CF_2$. Silanediyl H_2Si: has a singlet ground state ($\Delta E_{S\rightarrow T}$ = 21 kcal mol^{-1}) and H_2C: has a triplet ground state ($\Delta E_{S\rightarrow T}$ = −9 kcal mol^{-1}) so that, by assuming a bond energy $E_{\sigma+\pi}$ of about 105 kcal mol^{-1}, inequality (b) is fulfilled and silaethene shows a "classical" planar molecular core. Substitution of hydrogen by fluorine (π-donor) stabilizes the singlet states of the carbene fragments enormously (F_2C: $\Delta E_{S\rightarrow T}$ = 46.5 kcal mol^{-1}; F_2Si: $\Delta E_{S\rightarrow T}$ = 73 kcal mol^{-1}). As a result, the relationship (d) is fulfilled for $F_2Si{=}CH_2$, $H_2Si{=}CF_2$, $F_2Si{=}CF_2$, or even $F_2Si{=}SiF_2$ and no planar molecular structure is expected. A small weakness of the CGMT model must, however, be mentioned. For a given molecular formula, it does not provide a detailed description of the molecular structure associated with a global minimum on the potential energy surface. Therefore, the potential surface must be carefully analyzed by ab initio methods.[6]

The calculation for the E_2H_4 molecules (E = C, Si, Ge, Sn, Pb) provides five minima on the potential surface with the structures **A**–**E** (Fig. 4).

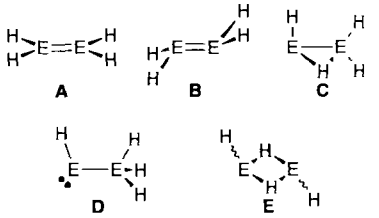

Fig. 4 Possible isomers **A**–**E** for E_2H_4 [6].

For E = C, only the planar, "classic" isomer **A** with C–C double bonding is found as a minimum. One isomer with E=E multiple bonding was also localized as a minimum for E = Si, Ge, and Sn albeit that it is present in the *trans*-bent conformation **B**, which corresponds to the global minimum for E = Si and Ge. No minima representing the conformations **A** or **B** were found for Pb_2H_4. In general, Trinquier showed that a $E{-}E^1$ multiply bonded system, whether it be planar or bent, could only exist when the sum of the singlet–triplet excitation energy is smaller than the bonding energy $E_{\sigma+\pi}$. If instead inequality (e) is valid, the $E{=}E^1$ bond is lost to

$$\Sigma\Delta E_{S\rightarrow T} \geq E_{\sigma+\pi} \qquad \text{(e)}$$

give a more favorable isomer without a direct $E{-}E^1$ connection. Therefore, for example, for the molecules Pb_2H_4 and Si_2F_4, four-membered rings with bridging H and F centers, respectively, are the most stable (isomer **E**) (with $\Delta E_{S\rightarrow T}$ = 37 kcal mol^{-1} for PbH_2[15] and $E_{\sigma+\pi}$ = 50–60 kcal mol^{-1} for Pb=Pb, Equation (e) is fulfilled).[6a]

Except for C_2H_4, the doubly bonded isomer **E** (that can be present in *cis* or *trans* forms which are distinguished by very small energy differences) was found as the local minimum on the potential energy surface of all the heavier homologues and represents the global minimum for Sn_2H_4 and Pb_2H_4. In addition, the carbene-analogous isomer **D** was found as a minimum on the E_2H_4 potential surface for E = Si, Ge, Sn, Pb. For Sn_2H_4 and Pb_2H_4, isomer **C**, in which one hydrogen bridges the E–E single bond, also appears as a local minimum. All four isomers **B**–**E** correspond to minima on the Sn_2H_4 potential energy surface and fall within a narrow range of 10 kcal mol^{-1}![6b]

The CGMT model can also be applied to cumulated multiply bonded systems. If a CO, CS, or an isocyanide group is a constituent of the multiple bond, the relationship (f), in which f' is defined by Equation f', is valid for predicting a bent molecular geometry.[2b] It accounts for the altered acceptor character of the π* orbital of this unit, as compared to a p(π)-acceptor orbital of an electronically unchanged EXY fragment (Fig. 5).

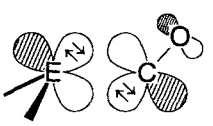

Fig. 5 Schematic interaction of a singlet carbene with CO for $\theta = 45°$ [2b].

$$\Sigma\Delta E_{S\rightarrow T} > E_{\sigma+\pi}\,[3/4 + q^1 + q^2)/8 + \alpha q^1 q^2 = f' E_{\sigma+\pi} \qquad \text{(f)}$$

$$f' = [3/4 + (q^1 + q^2)/8 + \alpha q^1 q^2 \qquad \text{(f')}$$

Using inequality (f) a linear geometry was calculated for ketene $H_2C=C=O$, which is in agreement with experimental results, and a bent structure for $H_2Si=C=O$.

Recently Jacobsen and Ziegler investigated a series of homonuclear doubly bonded systems $XYE=E^1X^1Y^1$ by using density-functional theory (DFT).[3b] In particular they studied the interaction between two triplet fragments ^3EXY and $^3E^1X^1Y^1$. They divided the bonding energy into individual terms that allowed them to separately investigate the steric factors, such as the difference in the geometry of free and bound EXY and $E^1X^1Y^1$ fragments, repulsive interactions of occupied orbitals (Pauli repulsion), and attractive electrostatic interactions of electronic factors (singlet–triplet excitation energies $\Delta E_{S\rightarrow T}$ of the fragments and exchange energy that is released upon formation of two triplet fragments with α and β spins). The essential findings of this bond analysis are that there is indeed multiple bonding between the carbene-analogous fragments with central atoms from higher rows and that the π component of these multiple bonds in molecules with *trans*-bent geometry is of greater importance than in molecules with planar geometry.

The deviation from a planar $XYE=E^1X^1Y^1$ molecule can also be described as a second-order Jahn–Teller distortion. Its importance increases for the higher homologues of ethene due to a smaller energy gap between the HOMO and LUMO.[3b, 5b] Upon *trans*-bending of the central framework, the bonding (p-p)π orbital (HOMO) enters into a stabilizing interaction with the antibonding (p-p)σ^* orbital (LUMO +1) of the $E-E^1$ bond. Simultaneously, the bonding (p-p)σ orbital (HOMO – 2) can mix with the (p-p)π^* orbital (LUMO) of the $E=E^1$ bond and cause destabilization of the (p-p)σ orbital. The interaction of these orbitals becomes stronger the smaller the energy difference between them. In ethene, the destabilization of the bonding (p-p)σ orbital as a result of *trans*-bending is larger than the stabilization of the (p-p)π orbital. Therefore, C_2H_4 remains planar. In contrast, in the higher homologues, which have weaker $E-E^1$ bonds and smaller (p-p)π/(p-p)σ^* orbital energy differences, the reduction of the energy of the bonding (p-p)π orbitals due to *trans*-bending is not compensated for and these molecules are *trans*-bent. Since the GCMT model provides for unrestricted, definitive bonding between carbene-analogous fragments and the double-bonded systems and small rings which are made from them, it will often be referred to in the current article. The following maxims have been formulated:

1) The geometry of a molecule with a multiple bond, defined by the equilibrium distance r_{eq} and the angle θ, which shows deviation from a planar geometry, can be conclusively determined from the singlet–triplet excitation energy $\Delta E_{S\rightarrow T}$ of the fragments formed by bond cleavage. Fragments with a singlet ground state favor *trans*-bent geometries.

2) The stability of the singlet state increases with increasing atomic number at the central atom E in EXY.

3) The dissociation energy of a multiply bonded system is also dependent on the excitation energy $\Delta E_{S\rightarrow T}$ of the fragment. The more stable the singlet state of the fragments EXY and $E^1X^1Y^1$, the lower is the dissociation energy of the doubly bonded system $XYE=E^1X^1Y^1$. It can even be lower than that of the $E-E^1$ single bond energy.

4) The higher the atomic number at the central atom E, the stronger is the deviation of the doubly bonded system from a planar geometry and the longer is the $E=E^1$ bond. This is because the repulsive steric interaction increases with a larger angle θ. It is, however, in general true that *trans*-bending of the fragments of a doubly bonded system with central atoms from the higher rows stabilizes the system to a greater degree than bond lengthening destabilizes it. In other words, the slope of the potential curve is much steeper for the variation of angle θ than for the distance r. With increasing atomic number at the central atom E, the distance r can be varied over a wide range depending on the substituents X and Y. As a result, a discussion of the double bond length has little meaning.

5) The sustituents X and Y display a strong influence on the character of the multiply bonded system. Isolable compounds that contain sterically demanding substituents can only be compared to the compounds EH and EH_2 with limitations. Larger substituents lead to a widening of the X-E-Y angle and therefore to a lowering in the energy of the triplet state as compared to that of the singlet state in the EXY fragment. Consequently, large groups can lead to a flattening in the geometry of an $E=E^1$ doubly bonded system and a shortening of the $E=E^1$ distance (see below for examples).

6) With increasing difference in electronegativity (expressed as the difference in the spectroscopic electronegativity χ_{spec} by Allen)[1] between the central atoms, multiple bonding within a class of compounds for a given central atom E becomes more stable; this means $C=O>C=N>C=C$; $Si=O>Si=N>Si=C$ but $C=O>Si=O$.[7]

7) A multiply bonded system with an $E=E^1$ bond is unstable with respect to an isomer without direct $E=E^1$ bonding when the sum of the singlet–triplet excitation energy of the fragments is larger than the bonding energy $E_{\sigma+\pi}$. A large difference in electronegativity $\Delta\chi_{spec}$ between the central atom E and substituent centers X and Y leads to a preference for isomers with bridging X or Y centers, respectively. This is because the E–X or E–Y bond has increasingly ionic character. A difference in $\Delta\chi_{spec}$ (E,X,Y) of about 0.48 can be estimated as a limiting value. Thus, the boron atoms in the B_2H_2 molecule (which has a triplet ground state!)[7] are connected by a classical B=B double bond. In contrast the most stable isomers of the homologous molecules E_2H_2 with the more electropositive elements E = Al, Ga, In, Tl form four-membered rings with hydrogen-bonded metal centers (see Scheme 10) [$\Delta\chi_{spec}(H,E)\geq 0.544$].

3. The Building Blocks: Carbene-Analogous Fragments with Group 13 to Group 15 Centers

For the directed synthesis of $E-E^1$ multiply bonded systems or the preparation of heterocycles with direct $E-E^1$ bonding by combination of EXY and $E^1X^1Y^1$ fragments, a broad palette of isolable fragments of this kind is desirable.[8] The carbene-analogous fragments with a central atom from the third or higher row ($n>2$) have a singlet ground state. In Figure 6a the singlet–triplet excitation energies $\Delta E_{S\rightarrow T}$ of several HE and H_2E fragments are graphically presented.

Whenever possible, precisely determined, average experimental values from gas-phase investigations were used for the production of Figure 6a or when these values were not available, energies calculated by extensive ab initio methods were used (see

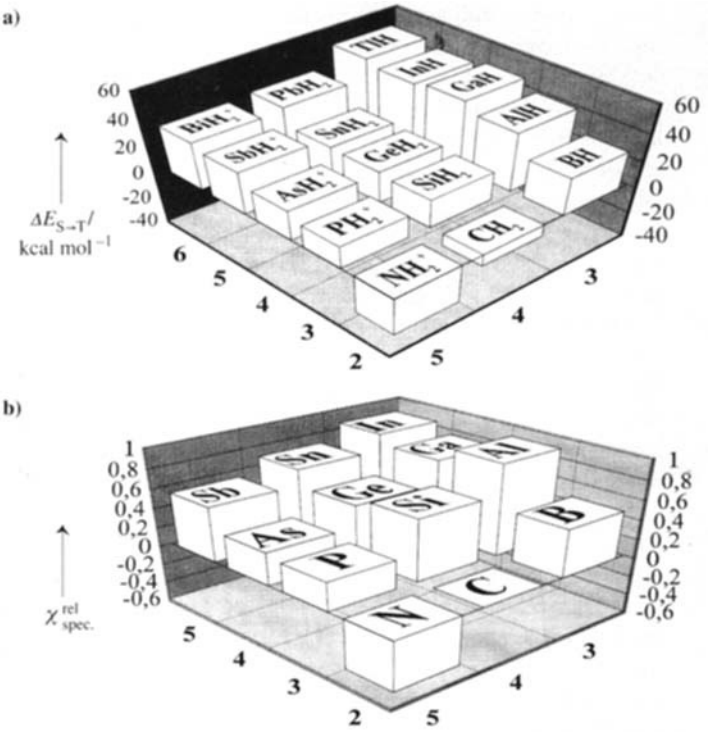

Fig. 6. a) Graphic representation of the singlet–triplet excitation energy $\Delta E_{S\to T}$ [kcal mol^{-1}] for carbene-analogous fragments with central atoms from Groups 13–15: BH (calc.): 27.7 [14a], 31.9 [14b]; AlH (calc.): 42.7 [14a]; GaH (exp.): 49.6 [9]; InH (exp.): 47.0 [9]; TlH (exp.): 50.7 [9]; CH_2 (exp.): -9.0 ± 0.1 [10]; SiH_2 (exp.): 21.0 [11]; GeH_2 (calc.): 23 [3b,15]; SnH_2 (calc.): 24 [15], 23 [3b]; PbH_2 (calc.): 37 [15], 34.2 [3b]; NH_2^+ (exp.): -30.2 [12]; PH_2^+ (exp.): 16.4 [13]; AsH_2^+ (calc.): 22.0 [16]; SbH_2^+ (calc.): 31.0 [16]; BiH_2^+ (calc.): 35.0 [16]. b) Graphic representation of the relative spectroscopic electronegativity χ_{spec}^{rel} based on $\chi_{spec}^{rel}(C) = 0$. The following values for χ_{spec} (in Pauling units [1]) were taken from ref. [1]: B 2.051; Al 1.613; Ga 1.756; In 1.656; C 2.544; Si 1.916; Ge 1.994; Sn 1.824; N 3.066; P 2.253; As 2.211; Sb 1.984.

legend to Fig. 6a). For a better comparison with $\Delta E_{S\to T}$, electronegativity values shown in Figure 6b are given relative to the carbon atom ($\chi_{spec}^{rel}(C) = 0$), that is, relative electronegativities χ_{spec}^{rel} of the main group elements E are graphically portrayed ($\chi_{spec}^{rel}(E) = 2.544 - \chi_{spec}(E)$).[1]

From the listed fragments, only CH_2 and NH_2^+ have a triplet ground state. Within a series of homologous fragments, the value of $\Delta E_{S\to T}$ like that of $\chi_{spec}(E)$ changes drastically upon going from a central atom of the second row to the third row. This jump can be readily explained by the "reluctance to hybridize" shown by elements in the higher rows ($n > 2$). The X-E-Y valence angle of a carbene fragment in a triplet state is larger than that of one in a singlet state ($^3CH_2$: $133.84\pm0.05°$; $^1CH_2$: 100°).[17] As a result, the s contribution in the hybrid orbitals is larger for the triplet state, when such a description is employed for the X–E and Y–E bonds. This assumes an effective hybridization of the s and p atomic orbitals (AO) of the central atom in the framework of the applied mathematical model. For this the comparable, expected values $\langle r \rangle$ (equivalently meaningful as the spatial expansion) of the s and p AOs calculated by quantum mechanics are decisive. Only for elements in the second row do s and p electrons show approximately the same spatial extension because the core electrons occupy the 1s level exclusively. For the elements from the higher rows the *n*p valence electrons ($n > 2$) are spatially separated from the *n*s valence electrons due to Pauli repulsion from the $(n-1)$p electrons in the lower lying shell. Therefore these elements are "reluctant to hybridize".[18, 3a] The H-E-H bond angle in carbene-analogous fragments containing an element E from higher than the second row and with a singlet ground state decreases within a group (for example SiH_2: 92.7°, GeH_2: 91.5°, SnH_2: 91.1°, PbH_2: 90.5°),[15] that is the lone pair of electrons on the central atom E has increasing s AO character.

In view of the hybridization model, the correlation of the spectroscopic electronegativity χ_{spec} with the excitation energy $\Delta E_{S\to T}$ of the fragments EH and EH_2 expressed by the resemblance of the plots shown in Figure 6 can be explained. For electronegative elements E, the energy needed for the s, p hybridization is more than compensated as result of the high E–X valence bond energy E_b. This is because the E–X valence bond energy E_b rises with increasing s AO contribution to the bonding hybrid orbital for electronegative elements ($E_b(C(sp)-H) > E_b(C(sp^2)-H > E_b(C(sp^3)-H)$; but $E_b(Si(sp)-H) \approx E_b(Si(sp^2)-H \approx E_b(Si(sp^3)-H)$).[3a] The valence bond energy E_b is proportional to the ionization potential I_b of the valence orbitals used in describing the bond.[19] These potentials I_b are largest for the more electronegative elements, just as for atomic ionization energies chosen for the calculation of $\chi_{spec}(E)$.

In the past few years several inert carbenes and carbene analogues have been synthesized in which the hydrogen atoms in the compounds shown in Figure 6a have been replaced by bulky organic groups or heteroatoms. As yet, the only carbene analogues, which are monomeric also in the solid state, with a Group 13 element were found in the solid modification of $Tl[C_5(CH_2Ph)_5]$ (**1**)[20a] and in the sandwich compound Tl(1,3-$B_2C_3Me_5$)CoCp (Cp = C_5H_5).[20b] In these compounds the thallium center is η^5 coordinated and can therefore be perceived as a *nido* cluster with $(n + 2)$ core electron pairs according to the Wade–Mingos–Rudolph rules. The same is true for [AlCp*] (**2**) (Cp* = C_5Me_5), [GaCp*] (**3**), [InCp] (**4**), [InCp*] (**5**), [TlCp] (**6**), and [TlCp*] (**7**) which are present as monomers in dilute solutions and/or the gas phase; thus, gas-phase structures of **3**–**7** could be determined.[21, 22] In the crystal, however, many of

	1	2	3	4	5	6	7

R	*t*Bu	$C(SiMe_3)_3$	$C(SiMe_3)_3$

the cyclopentadienides with Group 13 elements with a formal oxidation state of +1 are oligomers (for example $[(AlCp^*)_4]$[23] and $[(InCp^*)_6]$[22]). The alkyl-substituted diyls with Group 13 elements known to date form tetramers in the solid state. Examples include $[(BtBu)_4]$ (**8**),[25] $[\{GaC(SiMe_3)_3\}_4]$ (**9**),[26] and $[\{InC(SiMe_3)_3\}_4]$ (**10**).[27] These clusters with only *n* core electron pairs do not obey the Wade–Mingos–Rudolph rules![28] From these compounds, only the gallium compound **9** dissociates to monomers in dilute solutions or in the gas phase. As a result, it was recently possible to determine the gas phase structure of $[GaC(SiMe_3)_3]$ as the first monomeric alkylgallium(I) compound (Fig. 7).[29] The Ga–C bond is, despite the steric over-

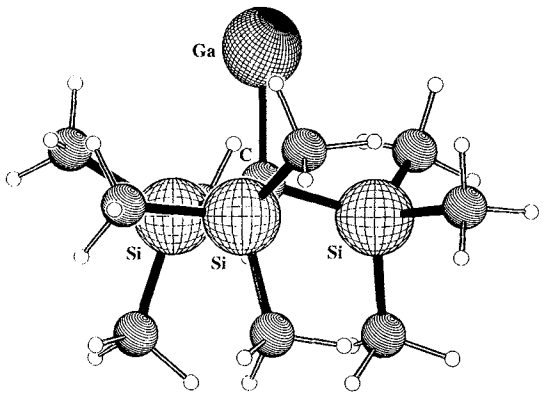

Fig. 7. Structure of monomeric **9** in the gas phase [29]. d(Ga-C) 2.964(17) Å; Ga-C-Si angle 106.2(9)°.

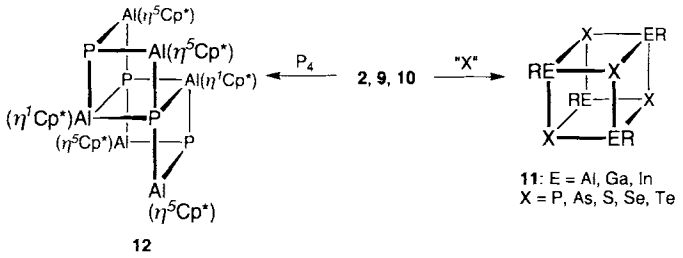
load in monomeric **9**, as expected shorter than that in pentamethylcyclopentadienylgallium (**3**), [**9**: 2.06(2) Å; **3**: 2.405(4) Å]. Since many of the tetrameric clusters $[(RE)_4]$ dissociate readily in solution to the monomers, they are a suitable source of carbene-analogous Group 13 diyls. Thus, Cp*Al (**2**) reacts smoothly with selenium or tellurium to give the heterocubanes **11** (Scheme 1).[30]

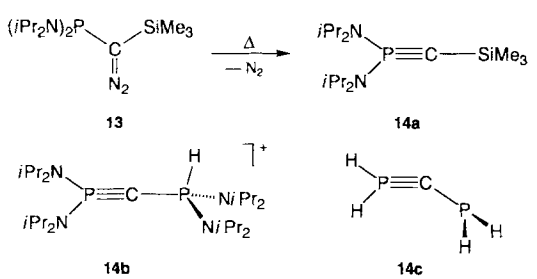


12

Scheme 1. Synthesis of **11** and **12** from **2**, **9**, and **10**.

P_4 reacts with **2** to give the polycyclic cage compound $[(Cp^*Al)_6P_4]$ (**12**) in which the Al centers connected to three phosphorus atoms are η^1 bonded to the Cp* ring, while the Al centers connected to only two phosphorus centers are η^5 bonded to Cp*. In contrast, in **11** all Al centers are η^5 bound to the Cp* groups. The reactions of the gallium (**9**) and indium (**10**) clusters with phosphorus, arsenic, selenium, or tellurium also lead to the heterocubanes **11** ($R = C(SiMe_3)_3$).[32]

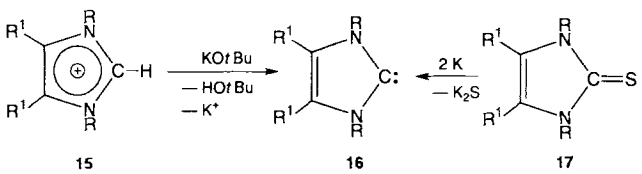
Noteworthy is the synthesis of stable carbenes. Bertrand et al. successfully synthesized the first singlet carbene stabilized by heteroatoms **14** by pyrolysis of the diazo compound **13** (Scheme 2).[33]



Scheme 2. Synthesis of **14a,b,c**.

The structure of compound **14a** has not yet been experimentally determined but it was recently possible to establish the structure of the phosphonium salt $[(iPr_2N)_2P{\equiv}C{-}PH(N\text{-}iPr_2)_2](O_3SCF_3)$ (**14b**).[34] The cation is closely related to **14a** because of the isoelectronic relationship between R_2Si and R_2P^+. In **14b** the $(iPr_2N)P-C$ distance (1.548(4) Å) is shorter than the other P-C distance, which could only be inaccurately determined as 1.605–1.616(5) Å due to disorder of the phosphonium group $[(iPr_2N)_2HP]^+$. The P-C-P angle is about 165° and is, like the P-C distance, in agreement with the value calculated for the $[(H_2N)_2P{\equiv}C\text{-}PH(NH_2)]^+$ ion.[35] Earlier ab initio calculations carried out for $(H_2N_2)P{\equiv}C\text{-}SiH_3$ also showed that the P-C-Si angle of 175.9° is widened in comparison to the structural characteristics described above for singlet carbenes (smaller bond angles at the carbon atom). Therefore these compounds are best described as λ^5-phosphaacetylenes,[36] even though the reactivity of **14a** is very similar to that of a nucleophilic λ^3-phosphanylcarbene.[37] An explanation for the ambivalent reactivity of **14a** as λ^5-phosphaacetylene and λ^3-phosphanylcarbene is offered by theoretical investigations of the diphosphanylcarbene derivative $H_2P{\equiv}C{-}PH_2$ (**14c**), which has not yet been synthesized. The conformation with lowest energy does not have equivalent P-C distances (1.533 Å, 1.765 Å; P-C-P angle 160.5°). As a result, it is considered as a λ^5-phosphaacetylene with polar P^+-C^- multiple bonding. However, the diphosphanylcarbene with equivalent P-C distances (1.719 Å) and considerably smaller P-C-P angle (131.4°) is only 5.7 (SCF) or 14.8 kcal mol^{-1} (MP2) richer in energy. Therefore the ambivalent reactivity of this class of compounds is understandable.[35]

In 1991 Arduengo III et al. extended the investigations on nucleophilic carbenes studied by Wanzlick et al. in the 1960s[38] and reported on the synthesis of the isolable carbenes **16**, in which the carbene center is stabilized by incorporation within an imidazole ring.[39] The synthesis of these compounds is remarkably simple and involves deprotonation of the imidazolium salts **15** with KOtBu or removal of sulfur from 2-thio-imidazolidones **17** with potassium (Scheme 3).[40]

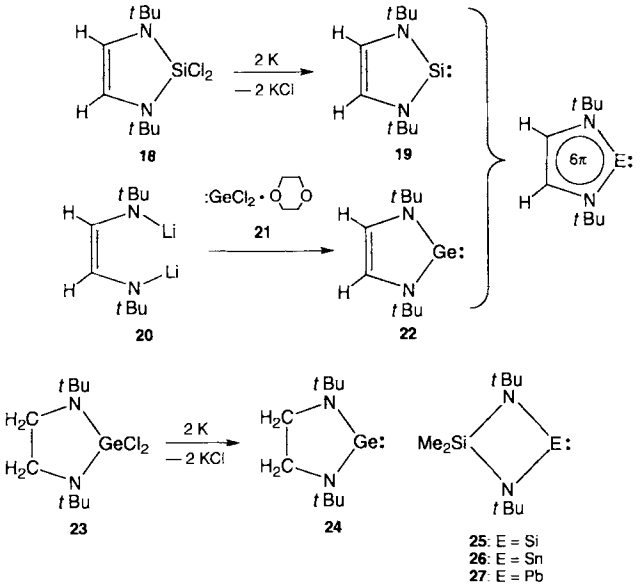


Scheme 3. Synthesis of **16** from **15** or **17**.

The imidazol-2-ylidene **16** has, as expected, a singlet ground state. In the molecular structure determined by single-crystal X-ray crystallography, a small N-C-N angle of about 102° (the corresponding N-C-N angle in **17** is about 109°) and symmetric, relatively long C-N distances (ca. 1.37 Å in **16**, ca. 1.32 Å in **17**) were observed. Reactivity studies prove the nucleophilic character of these carbenes since stable adducts are formed with Lewis acids such as BH_3,[41a] AlH_3,[41b] I^+ ions,[41c] or metal cations.[41d–f] The isolation of a relatively stable triplet carbene was also recently described.[41h]

Inert silicon compounds with a two-coordinate silicon atom (silylenes or silanediyls) have until recently only been studied in

a low-temperature matrix.[8c, 42] They have already been proven to be intermediates in photochemical and thermal decomposition reactions by many trapping reactions.[43] The stable silylene (silanediyl) **19** was also synthesized by a remarkably simple method in 1994. At first glance it is closely related to the above-mentioned stable carbene **16** (Scheme 4).[44]



Scheme 4. Synthesis of **19**, **22**, and **24**.

The germylene (germanediyl) **22** had already been synthesized by a method similar to that for **19** and is also exceptionally stable.[45] The N-E-N bond angles at the C, Si, and Ge centers in **16**, **19** and **22**, respectively, decrease, as expected, in the given order: $102° > 95.4° > 84.8°$. The volatility of the structurally analogous compounds **16**, **19**, and **22** allowed photoelectron (PE) spectra to be recorded. Their interpretation with the help of density function theory (DFT) clarified interesting differences in the electronic bonding behavior.[46] While according to this study in the carbenes **16** the HOMO is represented by the lone pair of electrons on carbon (σ-C), in the silanediyl **19** and in the germanediyl **22** it is described by a π orbital from the imidazole ring that is formed from the out-of-phase combination of the C=C π orbital with the p orbitals on nitrogen and Si or Ge, respectively (Fig. 8). It has to be stressed, however, that ab initio calculations of $(HC)_2(NH)_2C$: give a different orbital ordering which corresponds to the one found for silanediyls or germanediyls.[46b–d]

With increasing atomic number, the ionization from the σ-Si and the σ-Ge orbital, which in **19** and **22** is the HOMO-1, requires increasingly higher energy and the energy difference between the HOMO and HOMO-1 increases [**19**: 8.21 eV, Δ(HOMO − [HOMO-1]) = 1.09 eV; **22**: 8.60 eV, Δ(HOMO − [HOMO-1]) = 1.78 eV]. The silanediyl **19** and the germanediyl **22** owe their unusual stability to cyclic 6π-electron delocalization, a "trick" which has already proven itself in the synthesis of other low-coordinate main group element compounds.[47] This clarifies, in particular, the comparison with the significantly more reactive germanediyl **24**, in which the germanium forms the building block for a saturated five-membered GeN_2C_2 ring,[45] and the silanediyl $Me_2Si(NtBu)_2Si$: (**25**) which could

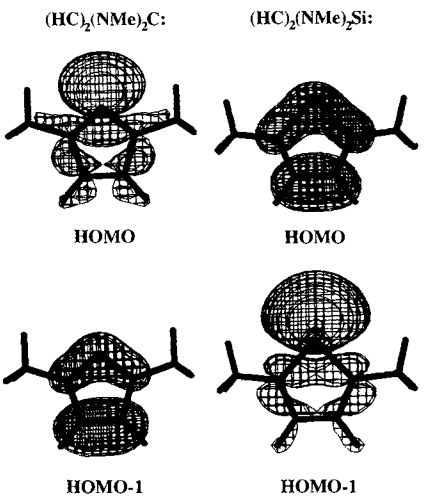


Fig. 8. SPARTAN plots of the HOMO and HOMO-1 for the *N*-methyl derivatives $(HC)_2(NMe)_2C$: (left) and $(HC)_2(NMe)_2Si$: (right) that were calculated with DFT methods as model compounds for **16** and **19** (C. Marchand, H. Grützmacher, unpublished results). The results are in agreement with the reported DFT calculations of **16** and **19** in ref. [46].

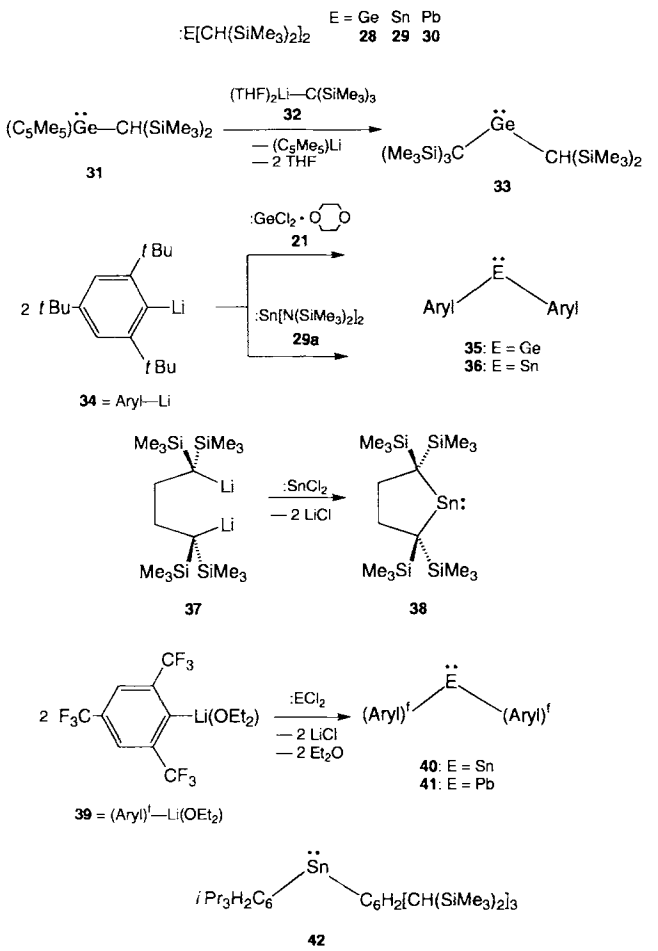
only be detected up to 77 K in a matrix.[42a] In both of these systems such a delocalization is not possible. The synthesis of the saturated cyclic diaminocarbene $(H_2C)(MesN)_2C$:[41g] and $(H_2C)_2(tBuN)_2Si$:[42e] has also been achieved recently. The PE spectra of **19** and **22** were interpreted to indicate the presence of formal Si(0) and Ge(0) chelate complexes with the corresponding diazabutadiene ligands.[46] The homologues **26** and **27**, which could be isolated, are closely related to **25**.[48] By using PE spectroscopy and ab initio calculations, it was also proven for **26** and **27** that the HOMO cannot be described by a σ-Sn or σ-Pb orbital, as would be expected for a singlet carbene analogue. The HOMO is a π-N^+N^- orbital that actually represents the antisymmetric combination of the p orbitals on the nitrogen center.[49] A series of frontier orbitals that deviate from those for a singlet carbene were observed as well for the long known, acyclic, PE spectroscopically investigated amides $[R(Me_3Si)N]_2Sn$: (**29a,b**) and $[R(Me_3Si)N]_2Pb$: (**30a,b**) (**a**: R = Me_3Si; **b**: R = *t*Bu).[50] In these amides the HOMO is described as a b_2 orbital which is essentially an out-of-phase combination of the p orbitals of the lone pairs of electrons on the nitrogen atoms. With these amides, it is therefore not a question of isolobal analogues of singlet carbenes. This analogy has been suggested for **24** and **25** because of their reactivity but it has yet to be proven by PE spectroscopic and quantum chemical investigations.

Alkyl- or aryl-substituted diyls with Group 14 elements are without doubt analogous to singlet carbenes and are significantly more reactive than the above-mentioned aminodiyls **19**, **22**, **26**, and **27**. The synthesis of an isolable monomeric alkyl- or aryl-substituted silanediyl has not been successful but a series of comparable, stable germanediyls, stannanediyls, and plumbanediyls have been isolated and studied in the past few years (Scheme 5).

As early as 1976 Lappert et al. synthesized the alkyl-substituted diyls **28**–**30**; however, they are monomeric only in solution and in the gas phase and dimerize upon crystallization (see below).[54] Therefore the gas phase structures of the germanium and tin compounds were determined.[51] As is expected for dia-



Scheme 5. Synthesis of germanediyls, stannanediyls, and plumbanediyls.

magnetic carbene analogues, the bond angle at the central atom is small (E = Ge: 107(2)°; E = Sn: 97(2)°) and lies within the range observed for acyclic germanediyls and stannanediyls with amino, phenolato, and thiolato substitutents (111–85.4°). Naturally, in the cyclic derivatives the bond angle is smaller (for example 73.2° in **26**; see also the above-mentioned angles for **16**, **19**, and **22**).

The dialkylgermanediyl **33** (C-Ge-C angle 111.3(2)°), which is monomeric even in the solid state, was synthesized by exchange of the η^2-π-bound Cp* group in **31** (C-Ge-Cp* angle 106.9(2)°) with the very sterically demanding $C(SiMe_3)_3$ group.[52] The 2,4,6-tBu$_3$C$_6$H$_2$ group (supermesityl = Mes*) is suitable as a bulky aryl substituent for the synthesis of the diarylgermanediyl **35**, which is inert below 20 °C. Extended heating (> 20 °C) of **35** in solution as well as in the solid state leads to insertion of the germanium atom into a C–H bond of the *ortho*-positioned tBu group and formation of a germa-indane derivative.[53] In contrast, the diarylstannanediyl **36** (C-Sn-C angle 103.6(1)°), which is formed by ligand exchange from the bis(amino)stannanediyl :Sn[N(SiMe$_3$)$_2$]$_2$ **29a** and 2,4,6-tBu$_3$C$_6$H$_2$Li, is also stable under an inert atmosphere even at room temperature. However, isomerization presumably to [(2,4,6-tBu$_3$C$_6$H$_2$)Sn(CH$_2$C-(Me)$_2$-3,5-tBu$_2$C$_6$H$_3$)] also occurs here in solution at 50 °C.[54] The synthesis of the cyclic dialkylstannanediyl **38** (C-Sn-C angle 86.7(2)°), which is monomeric even in the solid state, was only reported recently.[55] The diarylstannanediyl **40** (C-Sn-C angle

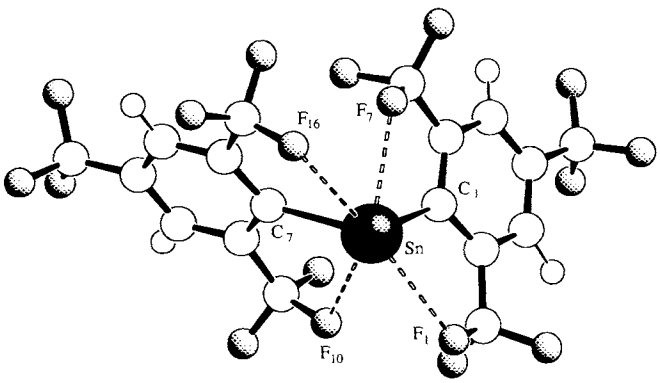


Fig. 9. Molecular structure of **40** in the crystal (yellow modification with monomeric units; Sn–Sn > 6 Å) [56]. Bond lengths [Å] and and angle [°]: Sn–C1 2.278(5), Sn–C7 2.284(5), Sn–F1 2.833(4), Sn–F7 2.663(4), Sn–F10 2.681(4), Sn–F16 2.807(4); C1-Sn-C7 98.3(1).

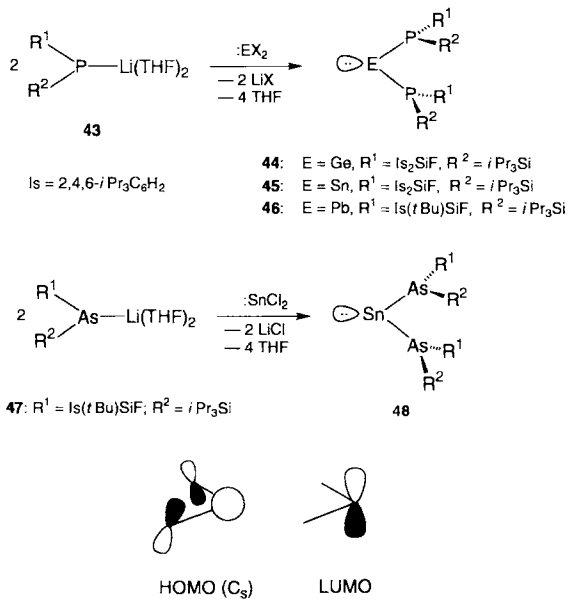
98.3(1)°) and plumbanediyl **41** (C-Pb-C angle 94.5(1)°) are special cases since in these compounds the low-coordinate main group metal centers are protected against oligomerization by metal–fluorine contacts (Fig. 9).[56, 57]

The metal–fluorine distances for **40** are about 25% shorter than the sum of the van der Waals radii and, because of the temperature dependence of the unusually large $^{119/117}$Sn–^{19}F coupling (> 240 Hz), could probably also be stable in solution. The diarylstannanediyl **42** substituted with the sterically demanding 2,4,6-[(Me$_3$Si)$_2$CH]$_3$C$_6$H$_2$ group has until now only been characterized in solution and exists, as expected, as a monomer.[58] An interesting comparison can be made between the above-mentioned amino-substituted diyls **19**, **22**, and **24**–**27** and the structurally characterized phosphanyl- and arsanyl-substituted germanediyls (**44**), stannanediyls (**45**, **48**), and plumbanediyls (**46**) (Scheme 6).[59] The P-E-P and As-Sn-As angles in these compounds also lie in the expected range for singlet carbene analogues (95.0–98.8°).

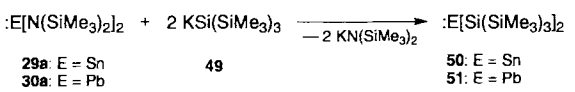
Since the inversion barrier for the pyramidal phosphorus and arsenic center (Σ°(P,As) = 315–320°) is significantly higher



Scheme 6. Synthesis of phosphanyl- and arsanyl-substituted germanediyls, stannanediyls, and plumbanediyls.

than that for the trigonal-planar coordinated nitrogen center ($\Sigma°(N) = 360°$) in the amino-substituted silanediyls, germanediyls, and stannanediyls, the diyls **44**–**46** and **48** are only slightly "stabilized" by π interactions with the lone pairs of electrons on the phosphorus or arsenic centers.

The *ns* atomic orbital of the main group metal center E (E = Ge, $n = 4$; E = Sn, $n = 5$; E = Pb, $n = 6$) provides a larger contribution to the HOMO of the compounds (Scheme 6), which can therefore better considered as (isolobal) analogues to singlet carbenes than as amino-substituted diyls that have an allyl-type HOMO. By the replacement of the electronegative amino with phosphino or arsino substituents the energy difference between the HOMO and the LUMO becomes smaller. Also this σ effect makes the phosphanyl- and arsanyl-substituted carbene analogues more similar to the parent compounds EH_2. This has been proven by the UV/Vis spectra of the intense green and yellow/brown solutions of compounds **44**–**46** and **48**. The lowest electronic excitation energy deviates less from the calculated S_1 transition for the EH_2 molecules (for example SnH_2: 2.50 eV, **45**: 1.92 eV). In contrast, the comparable acyclic aminostannanediyls such as **29a,b** are yellow (S_1: **29a**: 3.18 eV; **29b**: 2.86 eV). The incorporation of the even stronger electron-donating $Si(SiMe_3)_3$ ("hypersilyl") group into stannanediyls and plumbanediyls has been achieved by Klinkhammer and Schwarz (Scheme 7).[60]



Scheme 7. Synthesis of **50** and **51**.

The reaction of the amides :E[N(SiMe$_3$)$_2$] (**29a**: E = Sn; **30a**: E = Pb) with solvent-free KSi(SiMe$_3$)$_3$ in *n*-pentane led to intensively colored solutions [UV/Vis (λ[nm]): 838, 559 (**50**); 1056, 620 (**51**)] from which the stannanediyl **50** and the plumbanediyl **51** were obtained as black crystals. Both compounds are present as monomers in solution but **50** dimerizes in the solid state to give a remarkable distannene (see **87d** in Section 4.1.). The molecular structure of the plumbanediyl **51**, which is also monomeric in the solid state, is shown in Figure 10.

Particularly notable in **51** are the unusually large Si-Pb-Si angles (between 113.6 and 115.7° for four symmetry-independent molecules) that deviate significantly from the smaller angles of other plumbanediyls (**30a**: 103.6(7)°; **41**: 94.5(1)°; **46**: 98.78(4)°). Silyl substitutents destabilize the singlet ground state of a carbene to a greater extent than the first excited singlet state and cause a red shift in this S_1 electronic transition.[61] Moreover, steric interactions restrict the opening of the Si-Pb-Si angle and decrease the HOMO–LUMO energy difference (S_1: 1.17 eV) in **51** further.

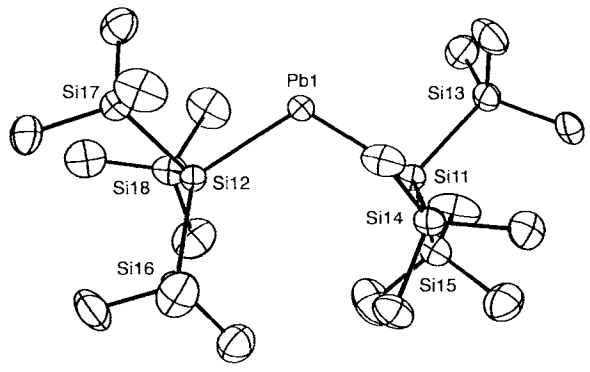


Fig. 10. Molecular structure of **51** in the crystal [60]. Bond lengths [Å] and angle [°] for one of the four symmetry-independent molecules: Pb1–Si11 2.700(3), Pb1–Si12 2.704(3); Si11-Pb1-Si12 113.56(10).

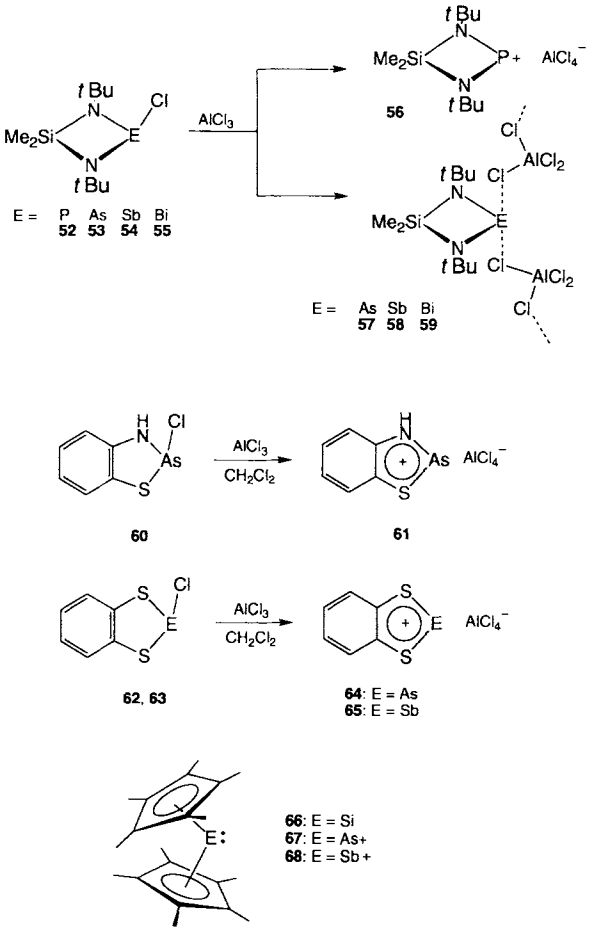
From the cationic carbene analogues H_2E^+ (see Fig. 6) with Group 15 elements (E = N, P, As, Sb, Bi), no stable alkyl or aryl derivatives have yet been described. Nevertheless, the synthesis of divalent, cationic species was possible by applying a few "tricks" which have been mentioned above: a) stabilization by π-donor substituents with nitrogen or sulfur centers, b) stabilization by π delocalization in π-conjugated ring systems, and c) stabilization by cyclopentadienyl groups (Scheme 8).

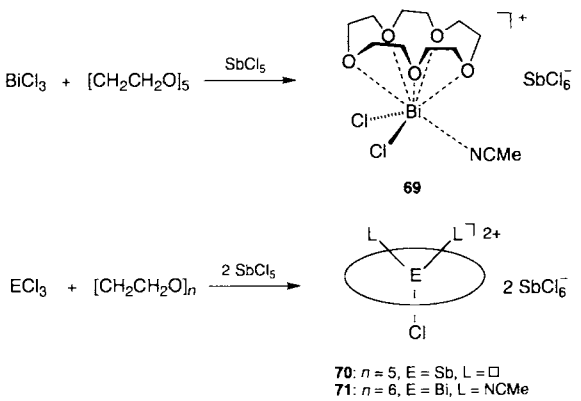


Scheme 8. Synthesis of **57**–**59**, **61**, **64** and **65**. Structures of **66**–**68**.

In this manner Veith et al. used the Me$_2$Si(N*t*Bu)$_2$ ligand system, whose applicability was already proven in the synthesis of the stannanediyl **26**, for the formation of compounds **56**–**59**. These compounds are accessible by chloride abstraction from the derivatives **52**–**55** with $AlCl_3$.[62] However, only the phosphenium salt **56** was proven to be a discrete ion pair in the crystal. In the case of the stibenium and bismuthenium salts **58** and **59** the cations are bridged to the $AlCl_4$ units through a chloride substituent. Compounds **56**–**59** are remarkably soluble in benzene, and, as shown by cryoscopic measurements, are present as monomeric cation–$AlCl_4$ ion pairs or, in the case of

the bismuth compound **59**, as dimeric ion pairs $[\{Me_2Si(NtBu)_2Bi\}_2(AlCl_4)_2]$. The interaction of the *t*BuN units as π donors with the main group element E with a formal electron sextet in the planar heterocycles $Me_2Si(NtBu)_2E$ **26** and **56–59** can be indirectly inferred from the Si–N distances and the N-Si-N angles. It increases in the following order: $Me_2Si(NtBu)_2Sn < [Me_2Si(NtBu)_2Bi]^+ < [Me_2Si(NtBu)_2Sb]^+ \ll [Me_2Si(NtBu)_2P]^+$.

"Stabilized" phosphenium ions, $[XYP]^+$, in which at least one group is X,Y = NR_2, SR, or Cp*, have been well investigated.[63] In contrast, arsenium ions have not been so well studied. The structurally characterized compound **61** was synthesized by Burford et al. (Scheme 8).[64] The low- coordinate arsenic center is bound within a delocalized 10π-electron system. The As–N and As–S distances are very short and the HOMO of the cation is not represented by the lone pair of electrons on arsenic. It is therefore questionable whether this compound, as well as the comparable dithiaarsolium and dithiastibolium salts **64** and **65**, can be described as analogues of singlet carbenes (see also the discussion of the silanediyl **19** and germanediyl **22**). In the cations $[(Cp^*)_2E]^+$ (**67**: E = As, **68**: E = Sb) the E centers are multihapto bound, and, therefore, within the confines of the definition applied here they do not belong to the carbene analogues shown in Figure 6, as is the case for the above-mentioned Cp derivative with Group 13 elements or the silicocene **66**.[65] A possible interesting access to cations with low-coordinate antimony or bismuth centers has been described by Dehnicke et al. (Scheme 9).[66]



Scheme 9. Synthesis of **69**–**71**. L = □ denotes the absence of the NCMe ligands in the case of antimony.

The reaction of $SbCl_3$ or $BiCl_3$ with the strong Lewis acid $SbCl_5$ as chloride acceptor led to the successful complexation of the cations $[BiCl_2]^+$ and $[ECl_2]^+$ in the presence of crown ether. The size of the crown determines the complex formation. Hence, the $[BiCl_2]^+$ complex **69** is obtained with [15]crown-5, while using [18]crown-6 provides the $[BiCl]^{2+}$ complex **71**. In the latter the Bi center is enveloped by a crown ether which has reformed into the shape of a bowl. Two acetonitrile molecules, which are absent in the case of the antimony complex **70**, complete the coordination sphere of the bismuth center in **71** (coordination number 9). It has yet to be tested whether the $[BiCl_2]^+$ or $[ECl]^{2+}$ fragments can be transferred to another substrate in solution.

The numerous carbenes and carbene-analogous fragments presented here provide a broad palette of compounds by which the characteristics of not only symmetrical, but particularly asymmetrical multiply bonded systems $XYE{=}E^1X^1Y^1$ of the main group elements can be studied. It must be taken into consideration that the above-mentioned experimental tricks provide inert compounds with molecular structures that correspond to the expectations for singlet analogues (X-E-Y <120°). They can, however, be electronically very different.

4. The Dimers: Classical and Nonclassical Doubly Bonded Systems

The molecules with the general formula $EE^1XX^1YY^1$ can, in many cases, actually be synthesized by combining the carbene fragments EXY and $E^1X^1Y^1$. Since the isolation of the first diphosphene Mes*P=PMes* by Yoshifuji et al. and the first disilene by West et al. in 1981, many reviews have reported on multiple bonding between elements from the higher rows.[67] Therefore we will only discuss recent advances in order to illustrate the GCMT concept.

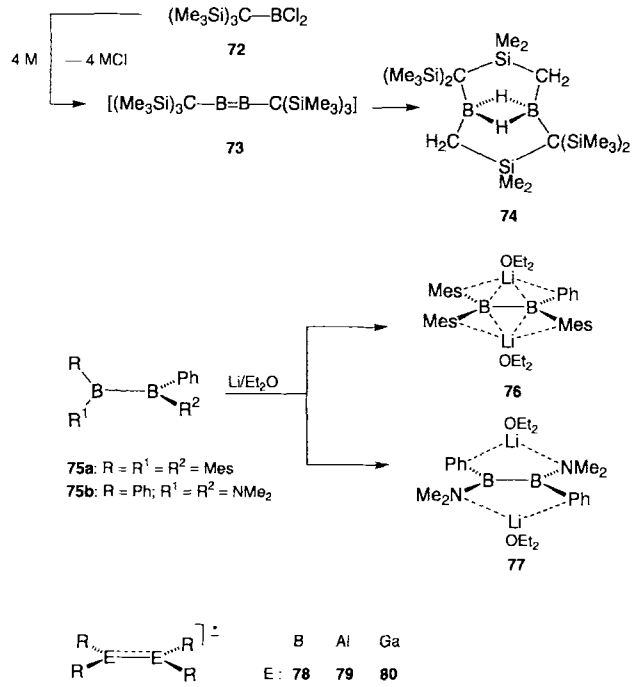
4.1. Compounds with Symmetrical E–E Double Bonds

Within the framework of the GCMT model, application of the inequalities (b)–(e) presented in Section 2 to XE=EX and $X_2E{=}EX_2$ molecules, in connection with the values given in Table 1, allows for the prediction that only diborenes and olefins should contain "classical" molecular structures with "ordinary" σ and (p-p)π bonds as defined by the valence bond model. Choosing a value for $E_{\sigma+\pi}$ is complicated. Several authors quote the dissociation energy ΔE_{TBE} for which data exist from only a few experiments and usually the values must be obtained from calculations. Other authors apply values calculated by quantum mechanics that show some deviations. In each case, the calculated values vary considerably depending on the calculation method. The values that are listed in Table 1, and which form the basis of our discussion, are those that were used by Malrieu and Trinquier and can vary by about ±20%.

As yet a diborene derivative has not been synthesized successfully. Attempts to obtain the diborene **73** by dehalogenation with Na/K alloy of the sterically substituted borane **72** only led to the diborane(6) derivative **74** (Scheme 10).[70]

MO calculations on the parent compound HB=BH show a linear arrangement with a triplet ground state.[71] As a result **73** is a plausible intermediate in the formation of **74**. The calculated B–B distance (1.53 Å) in HB=BH is about 12% shorter than a B–B single bond and therefore reflects the trend observed for carbon compounds (C=C: 1.34 Å; C–C: 1.54 Å).

The two-electron reduction with lithium metal of the diborane(4) compounds **75a,b**, which can be viewed as isoelectronic analogues of ethylene dications, proceeds cleanly to give the diborata dianions **76** and **77**, respectively (Scheme 10).[72] The distinct shortening of the B–B distance by 4.1% and 4.9% in **76** and **77**, respectively, as well as the flattening of the molecular form compared to **75a** and **75b** is attributed to partial B–B π multiple bonding. Despite the evident analogy between



Scheme 10. Synthesis of borane, alane, and gallane derivatives.

Table 1. Sums of the singlet–triplet excitation energies $\Sigma\Delta E_{S\rightarrow T}$, halves of the dissociation energies $1/2\Delta E_{TBE}$ [a], halves of the interaction energies $1/2D^{\circ}$ (0 K) [a], the molecular structures in the electronic ground state, and the designation of the inequalities presented in Section 2. All energies in kcal mol^{-1}; pl = planar, r = ring, f = folded.

Compound	$\Sigma\Delta E_{S\rightarrow T}$	$1/2\Delta E_{TBE}$	$1/2D^{\circ}$	Structure	Inequality
HB=BH	55 [c]		76 [b]	pl	(b)

$H_2Sn=SnH_2$	48	15	41 [a]	f	(c)
$H_2Pb=PbH_2$	74 [d]	5	43 [a]	r	(e)
$H_2Si=CH_2$	12	55	70 [a]	pl	(b)
$H_2Ge=CH_2$	14	43	59 [a]	pl	(b)
$H_2Sn=CH_2$	15	33	50 [a]	pl	(b)
$H_2Pb=CH_2$	28 [d]	23	45 [a]	pl [d] or f	(b, c)
$H_2Ge=SiH_2$	44	22 [e]		f	(c)

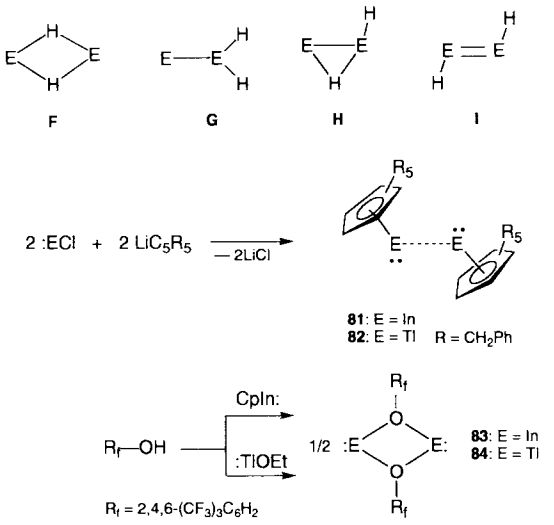
[a] ΔE_{TBE} corresponds to half of the total bonding energy and can partially be obtained from experimentally (C_2H_4, Si_2H_4) determined dissociation energies for the dissociation of $H_2E=EH_2$ into two EH_2 fragments in the ground state. These values were assumed by Malrieu and Trinquier as values for $E_{\sigma+\pi}$ [2b]. The values given in parentheses for $1/2D^{\circ}$ are taken from calculations by Treboux and Barthelat [b] as well as by Jacobsen and Ziegler. They are calculated from half the dissociation energy of the dissociation of a double bond system into two triplet carbene fragments (the so-called snapping energy) and therefore do not correspond to ΔE_{TBE} [3b]. Karnie and Apeloig calculated $\Delta E_{TBE} = E_{\sigma+\pi} - \Sigma\Delta E_{S\rightarrow T}$ and obtained instead of inequality (c) in Section 2 the inequality $\Sigma\Delta E_{S\rightarrow T} > \Delta E_{TBE}$ as a criterion for a *trans*-bent double bond. Thereby, in contrast to experiment and ab initio calculations, a planar structure was predicted for $H_2Si=SiH_2$ and $H_2Ge=GeH_2$ [68]. [b] Values corresponding to the dissociation of HE=EH in the triplet state $^3\Sigma_g^-$, which only for E = B corresponds to the ground state, into two HE fragments in the triplet state ($^3\Pi$) [14a]. [c] We used $\Delta E_{S\rightarrow T}$ = 27.7 kcal mol^{-1} for BH (Treboux and Barthelat) [14a]. Pople and Schleyer give $\Delta E_{S\rightarrow T}$ = 31.9 kcal mol^{-1} [14b]. [d] For PbH_2, a value of 37 kcal mol^{-1} was found for $\Delta E_{S\rightarrow T}$ by Balasubramanian by considering relativistic effects and electron correlation [15]. This is the value which we use. Jacobsen and Ziegler obtained $\Delta E_{S\rightarrow T}$ = 34 kcal mol^{-1} with DFT methods so that $\Sigma\Delta E_{S\rightarrow T}$ = 68 kcal mol^{-1} ($H_2Pb=PbH_2$) and 25 kcal mol^{-1} ($H_2Pb=CH_2$). These authors predict a planar structure for $H_2Pb=CH_2$ [3b]. [e] Ref. [69]. These authors calculate $1/2\Delta E_{TBE}(Si_2H_4)$ = 26 kcal mol^{-1} and $1/2\Delta E_{TBE}(Ge_2H_4)$ = 18 kcal mol^{-1}.

$R_2C=CR_2$ and $[R_2B=BR_2]^{2-}$, any comparative discussion must not ignore the $Li(OEt_2)$ groups bound in the diborata dianion. Therefore, **76** and **77** can also be viewed as diborane(6) derivatives in which the bridging H atoms have been replaced by Li centers. The B–B distances in **76** (1.636(11) Å) and **77** (two halves of symmetry-independent molecules are in the unit cell 1.623(8), 1.631(9) Å) correspond to those calculated for $Li_2B_2H_4$, for which the most stable conformation is planar (B=B: 1.613 Å).[73] The isomer of $Li_2B_2H_4$ in which the Li centers above and below the H_2BBH_2 plane are placed above the B–B bond is 14.9 kcal mol^{-1} higher in energy and has a slightly longer B–B bond (1.629 Å). In the experimentally determined structures of **76** and **77** the Li centers are above and below the R_2BBR_2 plane but are not located over the B–B vector. In each case, the coordination of the Li centers contributes significantly to the stability of these compounds. The attempted twofold reduction of tetraalkyl-substituted diboranes(4) to diborates, in which coordination of the Li centers to aryl carbon or nitrogen centers is impossible, led only to the radical monoanion **78**.[74a] The homologous radical anions **79** and **80** of the corresponding dialane(4) and digallane(4) were recently synthesized and characterized by ESR spectroscopy and, in part, by structural analysis.[74b–e] Also here, attempts to synthesize the dianions were unsuccessful.[74f] Finally, the high thermodynamic stability of the dilithium diborates **76** and **77** was confirmed by calculating the value for the energy released upon dimerization of monomeric $LiBH_2$ units (117.9 kcal mol^{-1}).[73] Consequently these synthetic building blocks, which are of great value in boron chemistry, must be protected by very large substituents.

The values for $\Delta E_{S\rightarrow T}$ and $1/2D^{\circ}$ listed in Table 1 show that, according to inequality (e) and maxim 7 (Section 2), the higher homologues of H_2B_2 should be most stable in an isomeric form without E–E bonding. Also quantum mechanical calculations predict the four-membered ring **F** (Scheme 11) to be the most stable isomer for the molecular formula E_2H_2 (E = Al, Ga, In, Tl).[14a, 75] For E = Al, Ga, and In the isomers **G**, **H**, and **I** were also found as local minima on the singlet potential energy surface. They are increasingly stable in the given order within a relatively narrow energy range of about 25 kcal mol^{-1}. For Tl_2H_2 the calculations provided only the isomers **F** and **G** as minima on the potential energy surface.

Interestingly, Schumann et al. found that in the solid state structures, the cyclopentadienyl derivatives of In(I) **81** and Tl(I) **82** form "dimers" with extremely long E–E distances (3.63 Å) (Scheme 11).[76]

The vectors from the E centers to the center of the C_5R_5 rings (R = CH_2Ph) form an angle θ of 43.5° (E = In) or 48.2° (E = Tl) with the E–E vectors, as expected from the GCMT model. The interaction between the In and Tl centers in **81** and **82**, respectively, is, however, extraordinarily weak and is evidently only observed in solids. This can be ascertained from the yellow color of crystals of **81** and **82**, since crystals in which molecules of **82** exist as monomers without a Tl–Tl interaction (see **1** in Section 2) are colorless.[20] The four-membered rings **83** and **84** with two-coordinate In and Tl centers, which correspond to isomer **F**, were synthesized by Roesky et al. (Scheme 11).[77] These compounds are dimers of the EOR fragments with π-donor substitution and correspond to the structures expected



Scheme 11.

from the GCMT model. The low degree of association is attributed to the *ortho*-positioned CF_3 groups that shield the low-coordinate In and Tl centers (compare the cubic tetramer $[(TlOMe)_4]$[78]).

While a prediction of the molecular form of olefins (planar), digermenes **86a–c** (bent), distannenes **87a–d** (bent), and diplumbenes (ring) is relatively facile with the GCMT model (see Table 1), an evaluation of disilenes such as **85a–i** is difficult because here $\Sigma\Delta E_{S\rightarrow T}$ is on the same order of magnitude as $1/2E_{\sigma+\pi}$ and therefore both planar as well as *trans*-bent structures are possible. Indeed this makes the investigation of such systems particularly exciting, since the electronic and structural character can be varied within a large range by the choice of substituents. Several bonding parameters for the compound classes **85–87** are listed in Table 2.[79]

A comparison of the recently characterized disilenes **85f**[80] and **85g–i**[81] with the previously known compounds **85a–e** shows that disilenes, in agreement with the predictions from the GCMT model, can exist in a planar as well as a weakly bent form. However, no systematic influence of the substituents on the character could be recognized. It must be kept in mind that the energy required to convert $H_2Si{=}SiH_2$, which has a *trans*-bent structure according to extensive ab initio calculations,[3b, 68, 69] to a planar form is very small (<1 kcal mol^{-1}). The observation that the silylated disilenes **85g** and **85i** are bent despite steric strain is contradictory to the theoretical view of SiH_3-substituted compounds held up to now. The observed deviation may be due to hyperconjugative interactions between the Si=Si π bond and σ^* orbitals on the SiR_3 groups, which have a higher group electronegativity. In solution several disilenes including **85a**, **85g,h** are thermochromic. This is attributed to increased thermal occupation of a strongly twisted state ($\varphi >> 0°$; see Scheme 12) by which the longest wavelength absorption band experiences a bathochromic shift.[81]

The digermenes known are, as predicted by the GCMT model, without exception *trans*-bent although also here, as in **85a–i**, the E–E distances and angle θ vary. An even stronger variation of these parameters is observed for the distannenes **87a–d**, which is not surprising due to the decreasing bond strength that accompanies the higher atomic number and the calculated, flat potential energy surface for the lengthening of the E–E distance. At this point, a comparison with the "most crowded known olefin" *Z*-(*t*BuMe$_2$Si)(Me$_3$Si)C=C(*t*BuMe$_2$Si)(Me$_3$Si) is instructive. With a twist angle of $\varphi = 60°$, the C=C bond (1.369 Å) in this compound is lengthened by only about 2% with respect to the reference value (1.34 Å).[82] Olefins can be labeled as molecules with "hard" double bonds, while disilenes, digermenes, and distannenes have "soft" double bonds.[81] Also in agreement with the GCMT model is the average bending angle which increases in the order disilene–digermene–distannene, θ: $4° < 27° < 44°$. It should be mentioned once more that the energy potentials for the bending angle θ and, particularly, for the lengthening of the E=E bond are very flat. As was explained above using Figure 4, several constitutional isomers of the molecule E_2H_4 (E = Si, Ge, Sn, Pb) are localized as minima on the singlet potential energy surface. For Sn_2H_4 there are four isomers (**B–E**) that vary in energy content by a maximum of 10 kcal mol^{-1} since the Sn–H and Sn–Sn bond energies as well as the angle deformation energy are very low. Under this aspect, it is not surprising that a wide range of conformational isomers have been observed for distannenes in the solid state.

The distannene **87a** [83] synthesized in 1976 by Lappert et al. has a Sn–Sn distance (2.77 Å) that lies in the range of a single bond (2.81 Å) and a bending angle θ of 41°. The C-Sn-C angle in **87a** (109.2°) is, as expected from the VSEPR model, slightly

Table 2. Selected bonding parameters for $XX^1E{=}EYY^1$ molecules (E = Si, Ge, Sn). The bending angle θ is the angle that is formed between the XX^1E or YY^1E plane and the E–E bond. The angle φ describes the twisting about the E–E bond [a].

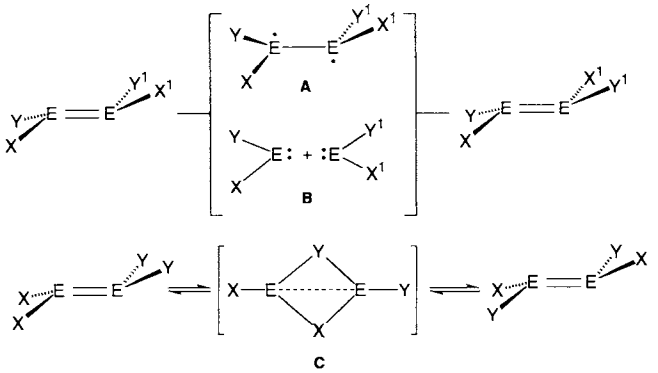
larger than that in the monomer **29** (97(2)°), in which the lone pair of electrons on tin leads to a reduction of the angle. In **87b** the angle θ is 46° and the Sn–Sn distance is increased to 3.63 Å. At most this can be considered as a very weak Sn–Sn interaction, although it can be optically observed. As with the "dimeric" [CpTl] and [CpIn] compounds **81** and **82**,[76] the crystals of **87b** are red, while those of the monomeric stannanediyl **40** are yellow. In a cocrystallizate of the stannanediyl **40** with stannocene [Cp_2Sn] the Sn–Sn distance is even further increased to 4.0 Å, and the crystals of this mixture are orange.[84]

Noteworthy distortions have been observed in the molecular structures of the distannenes **87c**[85] and **87d**[60] (Table 2). In **87c** the two R_2Sn fragments are rotated by an φ angle of 10.6° with respect to one another, the Sn–Sn distance (2.91 Å) is significantly longer than a single bond and both fragments show extremely different bending angles θ. The authors therefore described **87c** as a donor–acceptor complex in which the more strongly pyramidalized Sn center (64.4°) has a negative partial charge and the other less strongly pyramidalized center (21.4°) has a positive partial charge. This description corresponds formally to a dipolar resonance structure $[R_2Sn^+-Sn^-R_2] \leftrightarrow [R_2Sn^- - Sn^+R_2]$ which is by definition not observable. Here one electron from the 5s orbital of one stannanediyl must be promoted to a 5p orbital of the other. This formulation has been discussed by Lappert et al.[5] within the framework of resonance theory and was later used by Pauling for the description of the bonding in olefin-analogous compounds.[86] In **87d** the silylated stannanediyl fragments are strongly rotated with respect to one another ($\varphi = 63.2°$); thus, the authors suggest the possibility of thermal excitation into the triplet state, which is then more stable than the singlet state for olefins rotated by 90°. The Sn–Sn distance (2.82 Å) is shorter than that in **82c**. The bending angle θ in **87d** (28.6°) is smaller than that expected for $H_2Sn{=}SnH_2$ (46–51°).[3b, 87] This is attributed to the silyl substitution, which favors a flattening of the coordination sphere at the Sn center, as well as the sterically demanding $(Me_3Si)_3Si$ groups.

In solution the disilenes, digermenes, and distannenes display varied *cis–trans* isomerization behavior. Three possibilities are shown in Scheme 12.

The classical pathway A in Scheme 12 corresponds to rotation of the E–E bond in which the E=E π bond is broken and the molecule, in a singlet transition state, is rotated by $\varphi = 90°$ about the E–E bond. In addition dissociation into two singlet

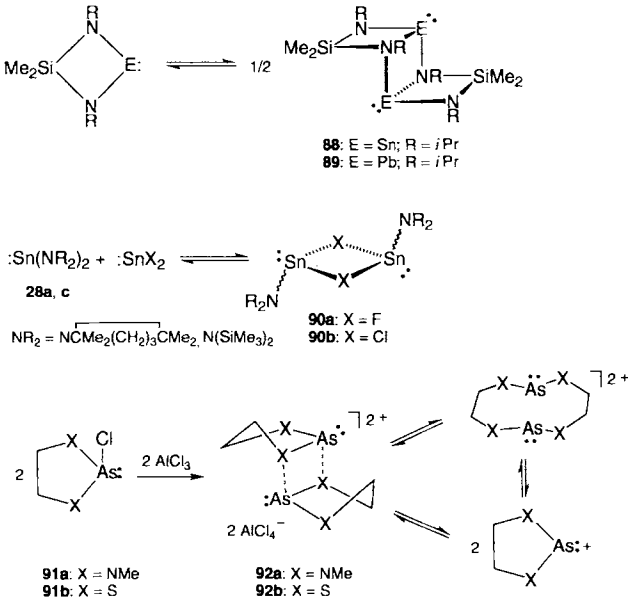


Scheme 12. Isomerizations of disilenes, digermenes, and distannenes.

ER_2 fragments (pathway B) can occur; recombination then provides the *cis* and *trans* isomers. Experimentally, the *cis–trans* isomerization along pathway A has been proven for a series of 1,2-diaryl-1,2-dialkyldisilenes. An activation enthalpy of 25–28 kcal mol^{-1} has been determined for rotation about the Si=Si bond. This is in agreement with the calculated values. The thermal dissociation, on the other hand, requires much more energy (52–58 kcal mol^{-1}) but has been proven recently for the first time for the extremely sterically substituted disilene **85f**.[80] For digermenes only the energetically preferred classical *cis–trans* isomerization by pathway A has as yet been observed. In contrast only dissociation into two stannanediyls has been seen for distannenes. In the case of **87a** and **87c** the monomer–dimer equilibrium has been experimentally proven,[88] while the distannenes **87b** and **87d** evidently exist as monomers in solution.

An interesting alternative to pathways A and B has been suggested by West et al. for tetraaryl disilenes.[89] Isomerization pathway C has a doubly bridged intermediate. The evaluation of the kinetic data provided an activation enthalpy of only 15 ± 2 kcal mol^{-1}. Indeed such a mechanism, a dyotropic rearrangement, is not impossible in light of the many energetically similar E_2H_4 isomers **B**–**E** mentioned in Section 2 (Fig. 4), and consequently, it should be discussed as the preferred "nonclassical" mechanism for digermenes and particularly for distannenes with aryl substitutents.

Doubly bridged structures such as in **88**, **89**,[90] **90a,b**,[91] and **92a,b**[92] are the most stable isomers for dimers of stannanediyls, plumbanediyls, and arsenium ions when they are substituted with heteroatoms bearing lone pairs of electrons (Scheme 13).



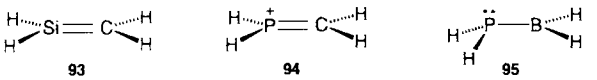
Scheme 13. Synthesis of **88**–**92**.

Owing to the rise in the excitation energy $\Delta E_{S\rightarrow T}$ upon substitution with R_2N, F, or Cl and the weakness of the Sn=Sn or Pb=Pb bond the inequality (e) in the GCMT model is satisfied, and there is no direct E–E bonding in the dimers. In solution the cyclic dimers **88** and **89** as well as **92a,b** are in equilibrium with

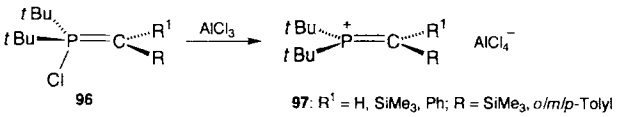
the monomers. This has been proven by trapping reactions.[48, 93] The doubly chloro-bridged **90b**, which is found as *cis–trans* isomers in the solid state and in solution (see the discussion for Figure 4), is a dimer in solution. The fluoro-bridged dimer **90a** is in equilibrium with the trimer $[(R_2N)SnF]_3$. It is noteworthy that to our knowledge no phosphorus analogues of **92a,b** are known. In an unsuccessful search for dications $[R_2P{=}PR^1{}_2]^{2+}$, which are isoelectronic with disilenes, diphosphanes were subjected to electrochemical oxidation reactions. In the case of the amino-substituted diphosphane $(i\mathrm{Pr}_2N)_2P{-}PR_2$ decomposition of even the radical monocation takes place with formation of the phosphenium ion $[(i\mathrm{Pr}_2N)_2P]^+$ and the symmetrical diphosphane $R_2P{-}PR_2$ ($R = i\mathrm{Pr}_2N$, *t*Bu). This finding impressively demonstrates the stability of monomeric, amino-substituted phosphenium ions.[94] In contrast monoamino-substituted disilenes such as $(Me_3Si)_2NMesSi{=}SiMesN(SiMe_3)_2$ are known and are described as having a Si=Si double bond that is less stable than that in aryl- and alkyl-substituted compounds.[95]

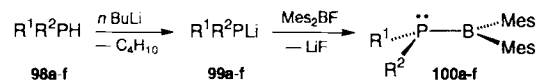
4.2. Compounds with Asymmetrical Double Bonds

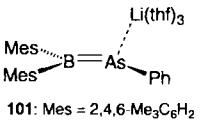
Silaethene **93**,[96] methylenephosphonium ion **94**,[97] and phosphanylborane **95**[98] are isoelectronic but not isostructural



with one another. Methylenephosphonium salts **97a–c** (**97a**: R = H, R′ = $SiMe_3$; **97b**: R = R′ = $SiMe_3$; **97c**: R = R′ = aryl), which are comparable to olefins (Scheme 14), can be synthesized from the di(*tert*-butyl)-*P*-chloro-phosphorus ylides







Scheme 14. Synthesis of **97** and **100a–f**.

96a–c by chloride abstraction with $AlCl_3$. Just as with silaethene **93**, these compounds have a classical molecular framework (Fig. 11) with trigonal-planar coordination at the phosphorus and carbon centers involved in the P=C bond. This bond has a typical length of 1.68 Å which is about 10% shorter than a P–C single bond (≈ 1.85 Å).

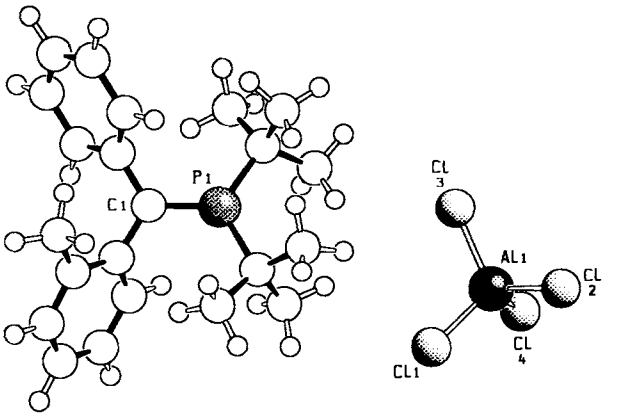


Fig. 11. Molecular structure of **97c** in the crystal [97a]. P1–C1 bond length 1.680(8) Å, shortest cation–anion contact 2.83 Å.

The observed molecular structures of **97c** is as expected by the GCMT model since the following is valid: $\Sigma\Delta E_{S\to T} \approx 7.4\ \mathrm{kcal\,mol^{-1}} < 1/2E_{\sigma+\pi} \approx 25\ \mathrm{kcal\,mol^{-1}}$. The twisting angle φ varies from 11° in **97a** to about 22° in **97c**. The isoelectronic substitution of C^+ in methylenephosphonium ions by a boron center leads to phosphanylboranes such as **100a–f**. These can be synthesized from the phosphanides **99a–f** and Mes_2BF. Although the excitation energy $\Delta E_{S\to T}$ for $[BH_2]^-$ and the bond energy $E_{\sigma+\pi}$ of a B=P bond are not known, it is expected that $\Sigma\Delta E_{S\to T} > 1/2E_{\sigma+\pi}$ is valid since both fragments $[PH_2]^+$ and $[BH_2]^-$ should have a singlet ground state and the P–B bond is weak. As a result the molecular framework in phosphanylboranes should be bent, which has been confirmed by ab initio calculations on **94**[99] and by the experimentally determined molecular structures of **100a–f**.[98] A bond length of 1.93 Å would be expected for a P–B single bond. In the *trans*-bent ground state of $H_2P{-}BH_2$ ($\theta(P) = 70°$; $\theta(B) = 6°$) the calculated B–P distance is 1.901 Å. The flattening of $H_2P{-}BH_2$ requires only 5.9 kcal mol^{-1} (compare the inversion barrier for $PH_3 \approx 38\ \mathrm{kcal\,mol^{-1}}$)[100] and the B–P bond is shortened by about 5% to 1.807 Å. The experimentally determined structures of the differently substituted phosphanylboranes **100a–f** can be considered as conformers with differently pyramidalized phosphorus centers (angle θ) and different degrees of rotation about the B–P bond (angle φ) which are "frozen" in the solid state (Table 3).

The degree to which these parameters influence the B–P bond length can be easily seen. Short distances are found in **100a–c**, in which the sterically demanding substituents flatten the coordination sphere of the three-coordinate phosphorus center, which prefers a pyramidal environment, and therefore forces the

Table 3. Selected structural parameters of phosphanylboranes [98]. The bending angle θ is the angle that is formed between the R^1R^2P plane and the B–P bond. The angle φ describes the twisting about the B–P bond.

	R^1	R^2	d(B-P) [Å]	θ [°]	ϕ [°]
100a	*t*Bu	*t*Bu	1.839	26.9	14.5
100b	*t*Bu	*t*Bu	1.843	8.9	21.8
100c	Mes	Mes	1.839	2.2	2.8
100d	Ph	Ph	1.859	42.1	2.4

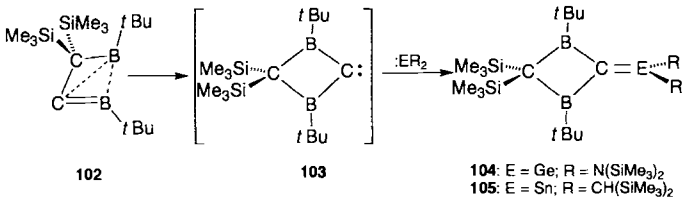
100f	$(Et_2O)Li$	1-Ad	1.823	16.1	13.8

formation of a (p-p) π bond (maxim 5, Section 2). A relatively broad variation in the angles θ (2–27°) and φ (3–15°) can be tolerated without noticeable influence on the B–P distance. Only when bending angles > 40° and twisting angles of more than 20° occur, is there a significant lengthening of the B–P bond.

The lithiated compound **100f** and the analogous (lithio)arsaboraethene **101**[101] are exceptional. They show the shortest B–P and As–P distances, respectively, observed in a molecular compound of this type. Lithium is only weakly bonded to the pnicogen atom, which does indeed have a pyramidal coordination sphere ($\Sigma°(P) = 357.4°$; $\Sigma°(As) = 341.4°$). The carbon atoms that are directly bound to the boron or the pnicogen atom all lie in one plane so that the P=B or P=As double bond is here fully formed. As a result, relatively high rotation barriers ($\Delta G^{\neq} > 20$ kcal mol^{-1}) about the B=E bond (E = P, As) were estimated for these compounds by NMR spectroscopy.

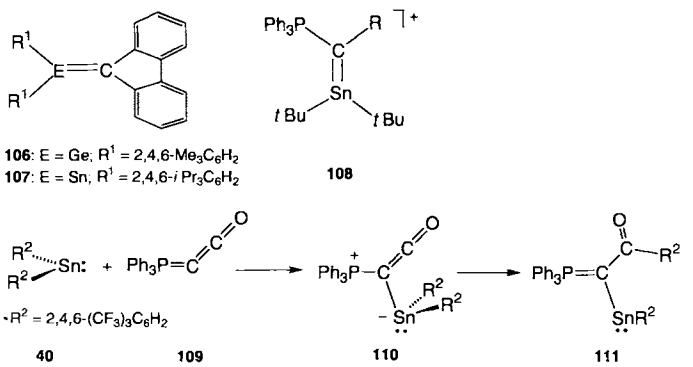
The diborylcarbene **103** can be combined with germanediyls or stannanediyls to form germaethenes and stannanethenes, respectively. Single-crystal X-ray structure analyses were also carried out for **104**[102a] and **105**[102b] (Scheme 15).



102 **103** **104**: E = Ge; R = $N(SiMe_3)_2$
105: E = Sn; R = $CH(SiMe_3)_2$

Scheme 15. Synthesis of **104** and **105** from **102**.

The Ge=C and Sn=C bond lengths (**104**: 1.827 Å; **105**: 2.025 Å) are in good agreement with calculated values (Ge=C: 1.814 Å; Sn=C: 2.063 Å)[87] about 8% and 6%, respectively, shorter than the corresponding single bond lengths (compare the corresponding shortening of about 13% for olefins and about 9% for silaethenes). In **104** and **105** the two carbene-analogous fragments are relatively strongly rotated with respect to each other (**104**: $\varphi = 36°$; **105**: $\varphi = 61°$), and the germanium, the tin, and unexpectedly even the carbon centers are pyramidal (**104**: $\theta(Ge) = 1.7°$, $\theta(C) = 4.8°$; **105**: $\theta(Sn) = 5.0°$, $\theta(C) = 16.0°$). In contrast, the germaethene **106** (Scheme 16) synthesized by Escudié et al. is planar (Ge=C: 1.801 Å)[103] and corresponds to the structure expected from the GCMT model.



106: E = Ge; $R^1 = 2,4,6\text{-}Me_3C_6H_2$
107: E = Sn; $R^1 = 2,4,6\text{-}i\,Pr_3C_6H_2$ **108**

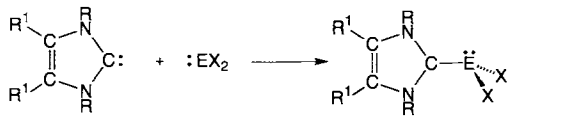
$R^2 = 2,4,6\text{-}(CF_3)_3C_6H_2$

40 **109** **110** **111**

Scheme 16.

The molecular structure of the analogous stannaethene **107**[104] has not yet been investigated. Ab initio calculations at various levels predict a planar structure for $H_2Ge{=}CH_2$ and a planar[3b] (DFT, RHF, or MP2 level) or a slightly more stable bent structure[87] (MCSCF level) for $H_2Sn{=}CH_2$. In general, very little is known about stannaethenes; their existence has been considered plausible mainly as intermediates such as **108**.[105] Reaction of the ketene ylide **109** and the stannanediyl **40** leads to the adduct **110**. Subsequent migration of an aryl group provides the compound **111**.[106] The central Sn–C bond is about 0.1 Å shorter than a Sn–C single bond, and all the substituents of this bond lie in a plane. Thereby at least a few criteria for the presence of a Sn=C multiple bond have been fulfilled.

The synthesis of the carbene adducts **112**[107] and **113a,b**[108] is similar to that of **104** and **105** in that also here a stable carbene is combined with a carbene-analogous fragment (Scheme 17).



16

112: E = Ge, X = I
113a: E = Sn, X = Cl
113b: E = Sn, X = 2,4,6-$i\,Pr_3C_6H_2$

Scheme 17. Synthesis of **112** and **113a,b**.

However, carbene **16** has an energetically low-lying singlet state and is therefore not electrophilic like **103** but rather nucleophilic. It is therefore not surprising that the products **112** and **113a,b** are very different from **104** and **105**. Noteworthy is the strong pyramidalization of the coordination sphere at the main group metal (**112**: $\Sigma°(Ge) = 290°$; **113a**: $\Sigma°(Sn) = 282°$; **113b**: $\Sigma°(Sn) = 309°$) as well as the large extent to which the two halves of the molecule are twisted with respect to one another. In addition, the long Ge–C and Sn–C distances (Ge–C: 2.102 Å; Sn–C: 2.290 Å and 2.379 Å) refute double bond character; thus, these compounds are better described as Lewis acid–base adducts since, as has been proven for **113**, they dissociate to their components in solution. The molecular structures obtained for **112** and **113a,b** can be considered as models for the *least motion* attack of one singlet carbene on another.[107] The combination of two carbene fragments shown schematically in Figure 2 is then only a purely theoretical model.

Special consideration must be given to the fact that it has not yet been possible to synthesize an isolable heteronuclear $XYE{=}E^1X^1Y^1$ multiply bonded system with two Group 14 E and E^1 centers from the higher rows ($n > 2$). These compounds should have especially interesting characteristics. Indeed, the digermasilacyclopropane **114** decomposes thermally (105 °C, 7 h) or photochemically ($\lambda = 254$ nm) to give the dimesitylgermanediyl **116**, the more stable of the two conceivable diyls, and the germasilaethene **115**; however, the latter has not yet been proven since it undergoes spontaneous 1,2-mesityl group migration to form the silylated germanediyl **117** (Scheme 18).

The germanediyls **116** and **117** were proven by reaction with $HSiEt_3$, the trapping reagent typically used for these species.[109] In the meantime, it has also been suggested that tetra-

mesityldigermene $Mes_2Ge{=}GeMes_2$, just like **115**, can thermally or photochemically rearrange to give $MesGe{-}GeMes_3$.[110] As is the case with digermenes, a germasilaethene should also have a *trans*-bent structure.[69, 87] The unsuccessful attempt to make a stable germasilaethene by the above-mentioned method can be explained by a quantum chemical study. This revealed that the rearrangement of a germasilaethene to a silylgermanediyl is an exothermic process with a relatively low activation energy. The same is true for the approximately isoenergetic pair digermene/germylgermanediyl. On the other hand, the thermodynamically favored rearrangement of a germaethene to a germanediyl is blocked by a high activation energy (Scheme 18).[111] The transition state for this rearrangement corresponds to the singly bonded, bridged isomer **C** in Figure 4. The same isomer is found as a local minimum on the singlet potential energy surface for Sn_2H_4 and Pb_2H_4. This example further substantiates the variety of possible isomers on the E_2H_4 potential surface (Fig. 4), which, in turn, makes the experimental search for these isomers exciting and full of promise!

The fragments PH, AsH, SbH, and BiH, which are not shown in Figure 6, are like CH_2, in contrast to the protonated species $[EH_2]^+$, present in a triplet ground state. This observation is simply understood, at least for PH and AsH, by using the qualitative EHT orbital energy level diagram shown in Scheme 19. In contrast to the BH or AlH species with four valence electrons which are present in the singlet ground state (Fig. 6), the π level that lies energetically higher than the nσ orbitals is occupied by two electrons in the six-electron systems PH and AsH. For P and As the magnetic quantum number *l* is still a "good quantum number", which means that the spin-orbit coupling can be ignored. As a result, according to Hund's rule, the more stable state has a maximum total spin $S = 2s + 1 = 3$ (for example $PH(^3\Sigma) \rightarrow PH(^1\Delta) = 21.7\ kcal\,mol^{-1}$).[9] For the higher homologues SbH and, in particular, BiH this simple approximation is no longer valid but these molecules are in the triplet state too.[112] A valence electron configuration in which, from the viewpoint of localized electrons, the central atom has two lone pairs of electrons is avoided. According to the GCMT model, the molecular structures of the higher homologues of the imine $H_2E{=}E^1H$ (E = Si, Ge, Sn, Pb; E^1 = P, As, Sb, Bi) should be planar. That is essentially in agreement with experimental results and ab initio calculations.[113–117] Compounds **120a,b**,[118] **123a–d**,[119] **124** [119b, 120] and **127a,b** [121] were synthesized by thermal elimination of LiCl or LiF, respectively (Scheme 19).

The iminosilane **120a**, phosphasilene **123a** (Fig. 12) and arsasilene **124** are planar ($\Sigma^\circ(Si) = 360^\circ$), as are the longer known phosphagermenes.[67d] The $E{=}E^1$ bonds (Si=N: 1.568 Å; Si=P: 2.062–2.094 Å; Si=As: 2.164 Å; Ge=P: 2.138–2.144 Å) are about 8% shorter than the corresponding single bond lengths.

An exception is the phosphanyl-substituted phosphasilene **127b** whose Si atom is slightly pyramidalized ($\Sigma^\circ(Si) = 356.7^\circ$).[121] While the angles at the phosphorus centers of the Si=P bonds in **123a** and **127b** (112.8°; 104.2°) and the Ge=P bonds in phosphagermenes (102.6°; 107.5°) as well as the angle at the arsenic center in **124** (110.9°) are strongly bent, the nitrogen atom in the *N*-silylated iminosilane **120a** is linearly coordinated (177.8°). This effect is again based on the "reluctance to hybridize" found for the elements phosphorus and arsenic.[116] A parallel is seen in phosphanes and arsanes, which have more

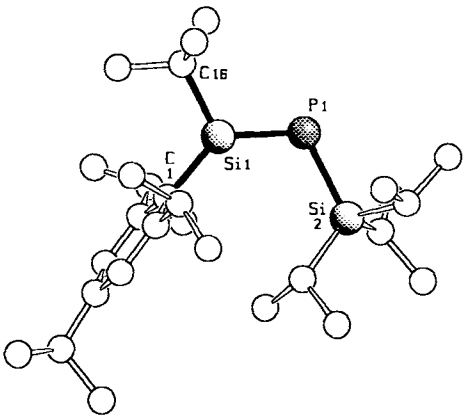

Fig. 12. Molecular structure of **123a** in the crystal [119b]. Bond lengths [Å] and angles [°]: P1–Si1 2.062(1), P1–Si2 2.255(1); Si1-P1-Si1 112.79(4), C1-Si1-C16 113.36(9), C1-Si1-P1 131.99(9), C16-Si1-P1 114.59(7).

strongly pyramidalized structures than amines.[122] The observed deviations from the calculated structures of the parent compounds $H_2Si{=}NH$ (Si-N-H: 122.8°) and $H_2Si{=}PH$ (Si-P-H: 93.7°) are attributed to the replacement of the H atoms with bulky, more electropositive silyl groups (compare NH_3 (pyramidal) and $N(SiH_3)_3$ (planar)).

Calculations of the potential energy surface of H_2SiNH provide a further surprise. The isomeric silylnitrene $H_3Si\text{-}N{:}$ is a local minimum that is 18 kcal mol^{-1} more stable than $H_2Si{=}NH$.[117] The rearrangement of $H_2Si{=}NH$ to $H_3Si\text{-}N{:}$ is, however, hindered by a high energy barrier (60 kcal mol^{-1}). In contrast, $H_2Si{=}PH$ is more stable than the isomeric phosphanediyl $H_3Si\text{-}P{:}$.[117] For the phosphanyl- and arsanyl-substituted germanediyls, stannanediyls, and plumbanediyls shown in Section 3, Scheme 6, the rearrangement in Equation (g) was investigated by quantum mechanical methods.

$$(H_2P)_2E{:} \rightarrow HP{=}E(PH_2)H \quad (E = Si, Ge, Sn, Pb) \qquad (g)$$

It was determined that for E = Si and Ge double bond isomers are favored, while for E = Sn and Pb the carbene-analogues are lower in energy.[59] In all cases the activation energy for the rearrangement process is considerable (30–70 kcal mol^{-1}) and thus allows the directed synthesis of the isomers possible.

The synthesis of thiones **131**[123] (E = Si), **132a**[124] (E = Ge), and **133**[126] (E = Sn), which are monomeric in the solid state, as well as the germaselenones **132b**[125] has clearly shown that by carefully choosing sufficiently bulky ligands and the correct synthetic routes, even the compounds which were only known as oligomers can be obtained as doubly bonded systems (Scheme 20). The E=E^1 distances in these compounds are about 7–10% shorter than the corresponding E–E^1 single bonds.

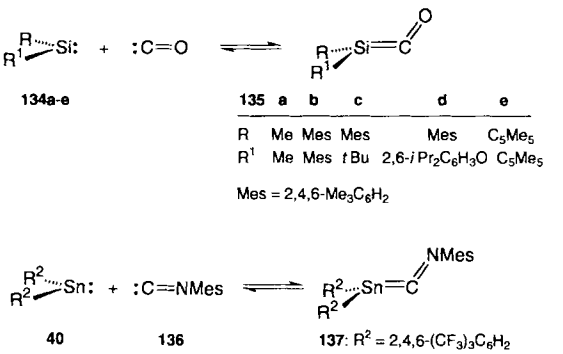
4.3. Cumulated Multiply Bonded Systems

Within the framework of the GCMT model, Inequality (f) (Section 2) is valid for cumulated doubly bonded systems XYE = $(E)_n{=}EXY$. Despite the high excitation energy $\Delta E_{S\rightarrow T}$ for C≡O (≈139 kcal mol^{-1}), the estimation predicts a planar molecular structure for ketene $H_2C{=}C{=}O$ due to the large energy term $f'(E_{\sigma+\pi})$ (for factor f' see [Eq. (f)] in Section 2). Since the H_2Si and C≡O fragments are in a singlet ground state and the Si=C bond is considerably weaker, a *trans*-bent molecular structure is expected for $H_2Si{=}C{=}O$.[2b] Results from ab initio calculations show a Si–C distance of 1.938 Å, which is about 3.5% longer than a Si–C single bond, and an angle θ of 88.6°. The C=O distance (1.137 Å) in the bent molecule is slightly shorter than in free C≡O (1.150 Å); the calculated C≡O stretching frequency is shifted to higher wavenumbers by 8 cm^{-1}.[127] Silanediyl–CO complexes have been experimentally detected in frozen hydrocarbon matrices. Their structures have been controversially discussed [**135a–e**: bent;[128a] **135a**: planar[128b]] (Scheme 21).



Scheme 21. Synthesis of **135** and **137**.

C≡O is very weakly bound in these complexes. As a result, upon melting the matrix, disilenes are obtained as products of the dimerization of silanediyls, which are formed upon decomposition of the silaketenes. Also the silicocene **66** forms a weak complex with C≡O, which has been observed by IR spectroscopy in liquid xenon at 1.5 bar CO pressure.[129] In [Cp*$_2$Si(CO)] and in **135a**, which has been investigated by Arrington et al., the C≡O stretching frequencies appear at significantly lower wavenumbers ($\Delta\nu$(CO) = 78 cm^{-1} and 181 cm^{-1}, respectively) than the calculated values. This is more consistent with the formation of a classical Si=C=O double bond and a linear molecular structure.

The silanediyl–C≡O complexes can be compared to the stannaketenimine **137**. The latter is the only complex of this form that has been characterized by X-ray structure analysis (Fig. 13).[130]

In analogy to the results for $H_2Si(CO)$, the Sn–C distance (2.397(3) Å) in the stannanediyl-isocyanide complex **137** is about 4% longer than the Sn–C distance between the tin atom and the *ipso*-carbon centers of the aryl rings (2.31 Å); the bending angle θ is 153.9(2)° and the C=N stretching frequency of the isonitrile ligand is shifted by 48 cm^{-1} to higher wavenumbers. The dissociation enthalpy (7.07 ± 0.09 kcal mol^{-1}) and entropy (90 ± 1 e.u.)

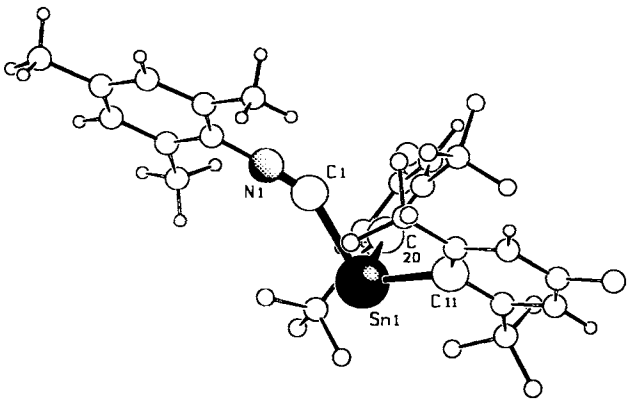


Fig. 13. Molecular structure of **137** in the crystal [130]. Bond lengths [Å] and angles [°]: Sn1-C1 2.397(3), Sn1-C11 2.306(2), Sn1-C20 2.314(3), C1-N1 1.158(3); N1-C1-Sn1 153.9(2), C1-Sn1-C11 104.9(1), C1-Sn1-C20 83.4(1), C11-Sn1-C20 102.6(1).

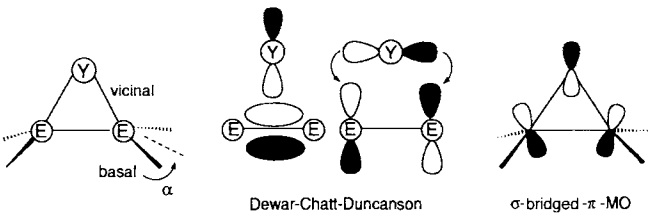
could be determined by temperature-dependent ^{119}Sn NMR spectroscopy. By using these values an equilibrium constant K of 0.33 mol L^{-1} at 298 K was calculated. This indicated that at this temperature about 45% of the stannaketenimine has already decomposed.

The examples discussed in this section prove that the GCMT model is generally suitable for predicting the molecular structure of dimers from carbene-analogous fragments with central atoms from the higher rows. However no ad hoc conclusions can be made about the number of possible conformational isomers and, in particular, their energetic relationship to one another. Here the method of choice has been and remains ab initio calculations. In the next section, we will discuss trimers and strained polycycles that can be constructed from carbene-analogous fragments. Thereby it will be made clear that, in particular, the fragmentation behavior of such rings can be understood and predicted by using the $\Delta E_{S\rightarrow T}$ values that are graphically shown in Figure 6.

5. Heterocyclopropanes: Trimers from Carbene Analogues and Related Heterobicyclo[1.1.0]butanes of the Main Group Elements

Cyclopropanes have something in common with the above-mentioned multiply bonded systems in that their ability to exist was originally disputed.[131] Hence they were always something special. "Acute" angles (60°) are found between the nucleus–nucleus axes that deviate considerably from the "normal" bond angles at the CR_2 groups acting as ring members. This places great angular (Baeyer) strain on the molecules.[132] Moreover, the substituents on the ring members are forced into ecliptic positions from which there is no deviation and thereby cause additional torsional strain.[133] As a result, these small rings are reactive. The C–C single bond in cyclopropane is about 20 kcal mol^{-1} weaker than a normal C–C single bond (84 kcal mol^{-1}).[134] If the electron density of the E–E bond in the small rings $(ER_2)_n$ is experimentally determined within the framework of the available methods and models, the maxima are not found along the nucleus–nucleus bond axes, rather outside of them.[135] Therefore these molecules are described as having bent bonds (banana bonds), and the angles, which include the pathways of maximum electron density (MED) between the nuclei of the ring members, are now 78° in cyclopropane.[136]

The previous sections have shown that in general it is possible to systematically describe the molecular structures and several characteristics of E=E and E=E^1 bonds of the main group elements on the basis of carbene-analogous fragments. This concept can also be applied without restrictions to cyclopropane and its analogues as well as to heterobicyclo[1.1.0]butanes. By doing so the occasionally lower stability or higher reactivity of such systems becomes understandable. Conversely, this concept allows one to predict which electronic structure the carbene-analogous fragments $:ER_2$ must have in order to build a stable ("more stable") heterocyclopropane. This is exemplified in the known series of heterocyclopropanes with Group 14 elements as framework atoms. They can be photolytically and/or thermally broken down to molecules with E=E or E=E^1 double bonds and carbene analogues; thus, they are versatile synthetic building blocks (see Scheme 18 and ref. [67e]). Due to this reactivity, they correspond to the general bond description of mixed E_2Y rings with E and Y as ring members as defined by the Dewar–Chatt–Duncanson model. These can, for example, be described as π complexes from one E=E unit and a carbene analogue Y (Scheme 22).[133c]



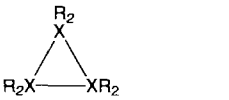
Scheme 22. Bond formation in E_2Y rings.

With increasing electronegativity on Y, a shortening of the basal E–E bond and an increase in the angle α is observed. This is a measure of the leveling of the planarity of the coordination geometry of the basal ring centers. This phenomenon can be summarized as a result of reduced back-bonding from an occupied, symmetry-adapted Y orbital into the π* orbital of the E=E unit. On the other hand, it is possible to explain the molecular structure and stability of three-membered rings by the strong dependence of the total energy on the energy variance of a "σ-bridged π orbital" upon alteration of the molecular shape.[137] Without this arbitrary subdivision into molecular orbitals an analysis of the Laplacian distribution of the total electron density reveals depletion and concentration of charge. Within this mathematical model, a short E–E distance corresponds with a strongly bent path of the valence electron density which can be bent concavely (towards the ring exterior) as well as convexly (towards the ring interior).[138]

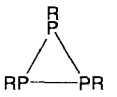
In the following, a comparison of cyclopropane with the homonuclear and mixed heterocyclopropanes that contain carbon, silicon, germanium, tin, lead, and phosphorus as framework atoms will be presented. It will be shown that their description as trimers of carbene analogues provides an explanation for their varying ring strain and reactivity.

5.1. Description of Homonuclear Three-Membered Rings as Formal Trimers of Carbene Analogues: Cyclopropanes Versus Heterocyclopropanes with Si, Ge, Sn, Pb, and P as Framework Atoms

First a few fundamental differences in the molecular characteristics of cyclopropane and analogous homonuclear three-membered rings with Si, Ge, Sn, Pb, and P as ring building blocks will be discussed.[139, 140] Cyclopropanes **138** have been known for a long time. Numerous experimental and theoretical investigations have brought to light that these ring systems are unique in comparison to other three-membered rings. Its olefin-like reactivity is attributed to the relatively large p character of the C–C framework bonds. The unexpectedly low ring strain (**138a** ca. 27 kcal mol^{-1}), which corresponds to that of cyclobutane (C_4H_8 ca. 25 kcal mol^{-1}) despite the small bond angles, is achieved by the six equivalent and particularly strong C–H bonds. They offer compensation for the angle strain, since the strain energy is defined as the difference in the heat of formation between strained and unstrained molecules calculated incrementally. The C–C bonds of the ring, as mentioned above, can be described by the banana bonding orbitals as interpreted by the Coulson–Moffitt model.[141] This is analogous to the formulation of ethene with bent bonds. This description corresponds to that provided by Baeyer in which ethene is perceived as the first representative of strained $(CH_2)_n$ rings.[142]

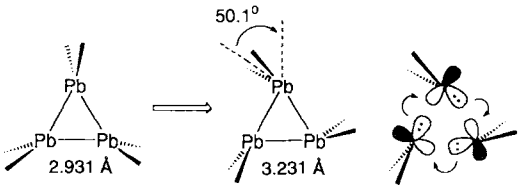


X	R = H	R = Alkyl, Aryl	R = Silyl
C	**138a**	**138b**	**138c**
Si	**139a**	**139b**	**139c**
Ge	**140a**	**140b**	—
Sn	**141a**	**141b**	—
Pb	**142a**	—	—



143: R = H, Alkyl, Silyl

A comparison of cyclopropane **138a** with cyclotrisilane **139a** and other homologues reaffirms that carbon shows "exotic" unprecedented bonding behavior. According to theoretical investigations, carbon forms equivalently strong σ and π bonds as a direct result of its ability to hybridize, an ability not shown by silicon and the other homologues. In addition, the bond strength of the E–E bonds intrinsically decreases, and carbon is clearly more electronegative than its homologues (Fig. 6b).[143, 18, 3a] Consequently, the hypothetical cyclotrisilane **139a**, the cyclotrigermane **140a**, and the cyclotristannane **141a**, which show approximately the same strain energy, are about 10 kcal mol^{-1} more strained than cyclopropane (HF/6-31G*), while the cyclotriplumbane **142a** (ca. 7 kcal mol^{-1} more strained than **138a**) even prefers a structure in which the PbH_2 fragments are rotated in the same direction about the C_3 axis (Scheme 23).



Scheme 23.

This molecule with C_{3h} symmetry is 10 kcal mol^{-1} more stable (MP4/DZ//HF/DZ) than the higher symmetry form with D_{3h} symmetry.[139] The distortion of the hypothetical cyclotriplumbane **142a** from the D_{3h} to C_{3h} structure is evidently based on an intrinsically weak interaction between three $:PbH_2$ particles and has thereby the same origin as the *trans*-bending in nonclassical double bonds.

According to calculations the bonds between the electropositive silicon centers in cyclotrisilanes have a large degree of s-orbital character,[143b] while the bonds to the more electronegative substituents show high p-orbital participation (see the rules from Bent and the VSEPR model). In the case of $(t\mathrm{Bu}_2\mathrm{Si})_3$ (**114b**: R = *t*Bu) an increase in the Si–Si distance of 7%, as compared to the parent compound **139a**, has actually been observed, which leads to a minor destabilization of the three-membered ring. The calculated bonding behavior in cyclotriphosphanes **143** is basically different since the localized lone pair of electrons on the phosphorus atom shows a high degree of s-orbital character and, as a result, the degree of p-orbital participation in the P–P bond is high. Accordingly, experimental and theoretical investigations show that cyclotriphosphanes **143** are about 10 kcal mol^{-1} less strained than cyclopropanes **138**.[145] The low ring strain in **143** is not unexpected since ring strain essentially originates from Pauli repulsion betweeen the geminal E–E bonds which are pushed together by small interior ring angles. A high s-orbital character in these bonds—like in **139**—causes a strongly antibonding σ/σ* delocalization.[146] The ring strain and, as far as is known, the varying reactivity of compounds of the type **138–142** can also be interpreted on the basis of the ground state of the carbene-like $:ER_2$ fragments which can be thought of as forming the three-membered ring. Calculations from Nagase show that the stabilization of three $:EH_2$ particles (E = Si, Ge, Sn, Pb) sharply decreased with increasing atomic number upon formation of the three-membered rings **139a–142a**.[139a] This is attributed to the increased stability of the singlet ground state of the carbene homologues and the decreased E–E bond energy. The much lower thermal stability of hexafluorocyclopropane (**138d**) than **138a** is also attributed to the different ground states of the respective carbenes. Compound **138d** decomposes even at 160 °C into difluorocarbene with a singlet ground state, which is about 46.5 kcal mol^{-1} more stable that the triplet state, and tetrafluoroethene,[147] while **138a** does not isomerize to propene until 400 °C.[148] Ab initio calculations from Nagase have shown that the stability of the three-membered rings with Group 14 elements is increased markedly by substitution, which reduces the singlet–triplet separations $E_{S\rightarrow T}$ for the carbene analogues.[139a] As mentioned above, this is accomplished by electropositive silyl substituents; thus, for example, the singlet–triplet difference in $:SiH_2$ (21 kcal mol^{-1}) is reduced to 4 kcal mol^{-1} in $:Si(SiH_3)_2$. Thereby the cyclotrisilane **139c** has the same ring strain as cyclopropane **138a**! Exceptional reactivity is shown by the cyclotrisilane **139** with $2\text{-}(Me_2NCH_2)C_6H_4$

substituents on silicon. Under thermal stress it does not dissociate into the corresponding disilene and silanediyl but instead forms three silanediyl fragments.[144b]

5.2. Molecular Structures of Selected Three-Membered E_2X Rings (E = Si, Ge, Sn; X = ER_2, NR, O, S, Se, Te) Determined Experimentally

The three-membered rings containing a main group element from a higher row that have been synthesized until now have sterically bulky substituents that hinder decomposition of reactive three-membered rings and formation of thermally favored higher ER_2 oligomers.[67e] The E–E distances *d* and their percentage change Δd(E–E) as a function of the third ring building block X are listed in Table 4.

Table 4. Bond lengths *d*(E E) [Å] and the percentage shortening Δd(E–E) [%] in three-membered E_2X rings.

	X	*d*(E–E)	Δd(E–E)
	R_2Si	2.398 [a]	0
	O	2.227	7.1
	RN	2.230	7.0
	H_2C	2.272	5.3
	S	2.289	4.6
	Se	2.303	4.0
	Te	2.337	2.5
	Cp_2W	2.260	5.7
	R_2Ge	2.558 [a]	0
	RN	2.379	7.0
	H_2C	2.379	7.0
	S	2.383	6.8
	Se	2.398	6.2
	Te	2.435	4.8
	R_2Sn	2.901 [a]	0
	RN	2.709	6.6
	Te	2.827	2.5

[a] Average values for aryl-substituted cyclotrisilanes, trigermanes, and tristannanes (see ref. [67e]).

It must, however, be kept in mind that substituting an ER_2 fragment with X can also result in considerable changes in the steric interactions between the substituents. Therefore the parameters obtained may not be compared with the calculated changes in the parent compound. Hence the E–E bonds given in Table 4, which are used as a reference, are about 2–4% longer in the experimentally investigated, sterically hindered cyclotrisilanes, cyclotrigermanes, and cyclotristannanes $(ER_2)_3$ than in those calculated for $(EH_2)_3$.

The above-mentioned effects become very clear. Electronegative building blocks X such as O and RN lead to a significant shortening of the basal E–E bonds on the same order of magnitude as going from E–E to E=E bonds. For the planar ring $(H_2Sn)_2NH$, in which the difference in electronegativities $\Delta\chi_{spec}$ = 3.066 – 1.824 = 1.242 is very large, a quantum mechanical analysis of the electron density was conducted. The results are shown in Figure 14a as a contour plot.[149]

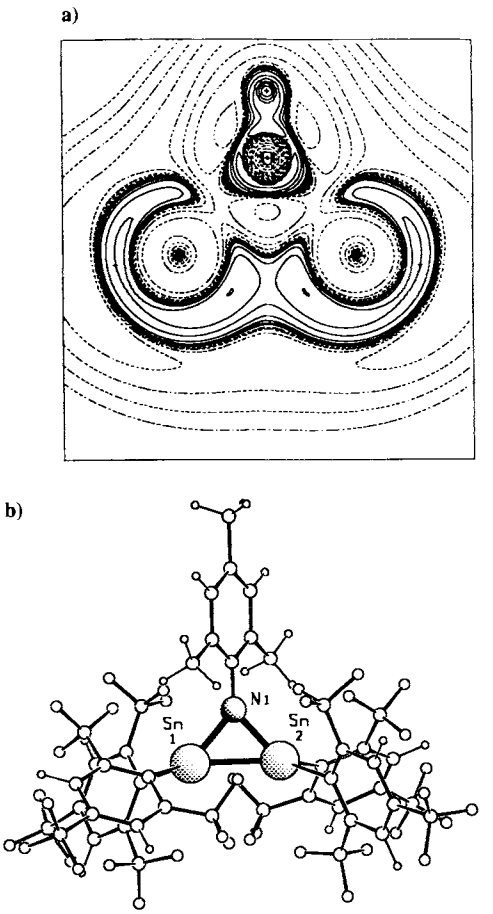


Fig. 14 a) Graphic representation of Laplacian ∇^2 of the electron density of $(H_2Sn)_2NH$ [149]. Solid lines show higher charge density, dashed lines show lower charge density. b) Molecular structure of **152** in the crystal [150]. Bond lengths [Å] and angles [°]: Sn1–Sn2 2.709(2), Sn1–N1 2.079(11), Sn2–N1 2.074(16); Sn1-N1-Sn2 81.4(4), N1-Sn1-Sn2 49.2(4), Sn1-Sn2-N1 49.4(3).

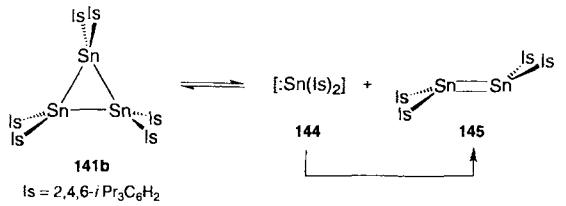
The geometry-optimized, calculated structural data [*d*(Sn–Sn): 2.746 Å; *d*(Sn–N): 2.019 Å] are in good agreement with the results of a single-crystal structure analysis of **152** (Fig. 14b and Scheme 27).[150] The Laplacian distribution clearly shows that azadistanniridines can be viewed as cyclic N-donor-Sn_2-acceptor compounds with a concavely bent Sn–Sn bond. This description is contrary to the Dewar–Chatt–Duncanson formalism in so far as that this would describe the three-membered ring as a complex of one nitrene RN: as an acceptor and a distannene $R_2Sn{=}SnR_2$ as a donor.

5.3. Fragmentation Behavior of Mixed Heterocyclopropanes

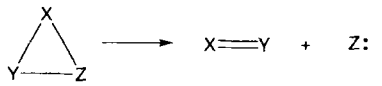
In this section the fragmentation behavior of several selected heterocyclopropanes is presented. The results reveal that the description of the three-membered rings as trimers of carbene analogues is a useful concept for predicting this fragmentation behavior. It explains, for example, the experimental finding that the aryl-substituted cyclotristannane $(Is_2Sn)_3$ (Is = 2,4,6-triisopropylphenyl) **141b** fragments even at 20 °C into [Is_2Sn:] **144** and the corresponding distannane **145** (Scheme 24).[151, 152]



Scheme 24. Fragmentation of **141b** into **144** and **145**.

The analogous [2 + 1]cycloreversion reactions of cyclotrisilanes **139b** and cyclotrigermanes **140b** are also possible by photolysis. This means that these systems are valuable sources of the corresponding $:ER_2$ and $R_2E{=}ER_2$ compounds.

It is expected that fragmentation of a three-membered ring XYZ into the olefin-like molecule X=Y and the carbene-like molecule Z: occurs in such a way as to form the most stable multiply bonded system and carbene analogue (Scheme 25, Table 5).



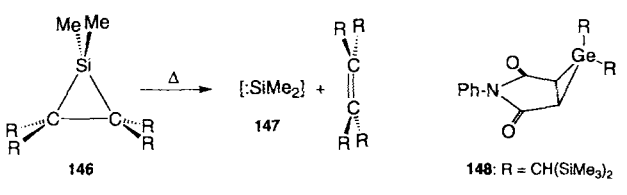
Scheme 25. Fragmentation of heterocyclopropanes. The resulting carbene analogue exists in the singlet state.

Table 5. Fragmentation of C_2E and CE_2 rings. ΔE_{elec} [kcal mol^{-1}] is the change in the electronic energy between the starting material and products. The heterocarbene exists in the singlet state.

	ΔE_{elec}
$SiC_2H_6 \rightarrow H_2C{=}CH_2 + H_2Si:$	47.5
$SiC_2H_6 \rightarrow H_2C{=}SiH_2 + H_2C:$	120.5
$GeC_2H_6 \rightarrow H_2C{=}CH_2 + H_2Ge:$	48.4
$GeC_2H_6 \rightarrow H_2C{=}GeH_2 + H_2C:$	114.8
$Si_2CH_6 \rightarrow H_2C{=}SiH_2 + H_2Si:$	64.7
$Si_2CH_6 \rightarrow H_2Si{=}SiH_2 + H_2C:$	127.2
$Ge_2CH_6 \rightarrow H_2C{=}GeH_2 + H_2Ge:$	48.4
$Ge_2CH_6 \rightarrow H_2Ge{=}GeH_2 + H_2C:$	106.5

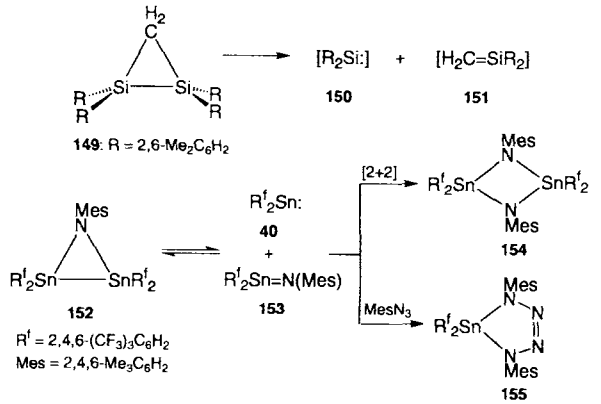
This expectation is supported by ab initio calculations of the fragmentation of C_2E and CE_2 three-membered rings (E = Si, Ge) [140, 153, 154] and is discussed here by using several examples.

Silacyclopropanes such as **146** fragment upon heating into the intermediate silanediyl and the corresponding olefin; the silanediyl **147** can be transferred to another olefin even at 70 °C (Scheme 26).[155, 156]



Scheme 26. Fragmentation of **146** and structure of **148**.

Because of the weaker Ge–C bond and the increased stability of germanediyls, an experimental trick was needed to synthesize a stable germirane. This was recently accomplished by Ando et al. who synthesized the germirane **148**; its stability is attributed to the electron-poor maleinimine group and the weakened C–C π bond in free maleinimine.[157] It has not yet been possible to synthesize a stannirane; moreover, there is still no evidence that this system exists in equilibrium in solution with its components, an olefin and a stannanediyl. By applying the trick used for the synthesis of **148**, namely the destabilization of the decomposition products of the three-membered ring, a stannacyclopropene was obtained as an unsaturated ring with a SnC_2 framework from R_2Sn and a highly strained cyclic acetylene (R = $(Me_3Si)_2CH$).[158] In solution this three-membered heterocycle is in equilibrium with its components, whereas the comparable silacyclopropenes and germacyclopropenes are considerably more thermally stable.[159] The sterically substituted disilacyclopropane **149** is relatively stable and decomposes only photochemically. Here the silanediyl **150** and the silaethene **151** are formed as intermediates which could be identified by trapping reactions (Scheme 27).[160]



Scheme 27. Fragmentation of **149** and **152**.

In contrast, the azadistanniridine **152** decomposes even at room temperature into the stannanediyl **40**, which can be added to mesitylazide in a 2:1 ratio to reform **152**, and the stannanimine **153** (Scheme 27).[150] The stannanimine **153**, unlike **40**, cannot be detected by ^{119}Sn NMR spectroscopy in the presence of **152**; however, it can be isolated in the form of the dimeric diazadistannetidine **154**. With an excess of mesitylazide **153** can be trapped as the tetraazastannole **155**.

While E_2X three-membered rings (E = C, Si, Ge, Sn; X = O, S, Se, Te) with Se and Te as framework atoms are likewise very unstable for E = C because of the relatively strong C=C bond, several stable derivatives for systems with E = Si, Ge, and Sn have been synthesized in the past few years.[67e, 152] The elimination of selenium or tellurium is, however, also a possibility with these three-membered rings, and as a result of the [2 + 1]cycloreversion they provide relatively weak doubly bonded systems. For example, fragmentation of silaphosphatellurane **156**[119] (Fig. 15) or of the isotypical arsenic analogue[119b] in the presence of a cyclophosphanes provides phosphanetellurides and the corresponding free phosphasilene or arsasilene, respectively.[161]

A remarkably different thermal fragmentation is shown by the three-membered ring systems **L** and **M**, which are formed by the [2 + 1]cycloaddition of $E{=}E^1$ bonds (E = Si; E^1 = Si, P, As) to organoazides and diazoalkane derivatives (Scheme 28).[162] The first compound of this type was **157** which was also structurally characterized (Fig. 16).[162c]

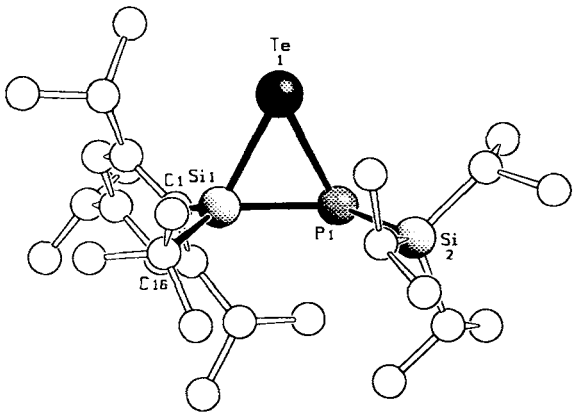


Fig. 15. Molecular structure of **156** in the crystal [119d]. Bond lengths [Å] and angles [°]: Te1–P1 2.524(2), Te1–Si1 2.496(2), P1–Si1 2.235(2); P1-Te1-Si1 52.88(5), Te1-P1-Si1 62.90(6), Te1-Si1-P1 64.22(6), Si1-P1-Si2 123.07(7), Si2-P2-Te1 105.41(7).

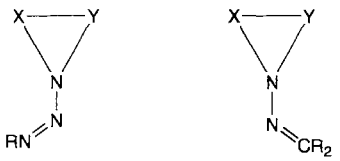

L: X = SiR_2; Y = R_2Si, RP, RAs M: X = SiR_2; Y = R_2Si, RP, RAs

Scheme 28.

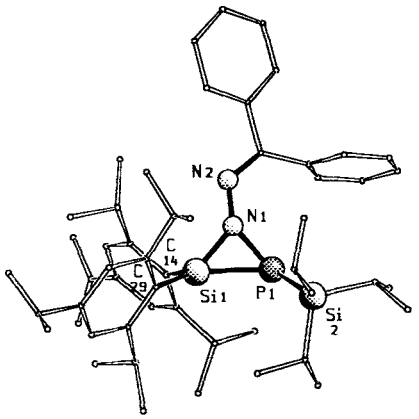

Fig. 16. Molecular structure of **157** in the crystal [162c]. Bond lengths [Å] and angles [°]: P1–Si1 2.237(2), P1–Si2 2.298(2), P1–N1 1.817(3), Si1–N1 1.729(3), N1–N2 1.375(4); Si1-P1-N1 49.2(1), Si1-P1-Si2 112.9(1), P1-Si1-N1 52.7(1), P1-N1-Si1 78.2(1), C1-N2-N1 124.3(2).

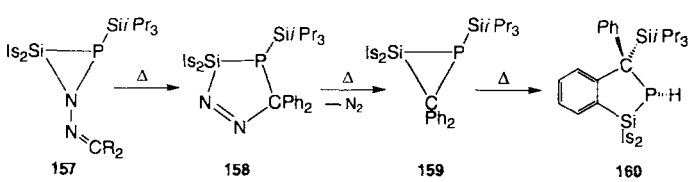
The three-membered ring **157** isomerizes upon heating because of its reactive side chain to give the [2 + 3]cycloadduct **158**. In addition the silaphosphiridine **159** is formed by elimination of N_2. The heterocycle **159** fragments upon heating to 110 °C but not into silanediyl and phosphaalkene but instead goes selectively to the rearrangement product **160** (Scheme 29). This example shows that the reactivity of such three-membered rings can be decisively influenced by bulky organic substituents.

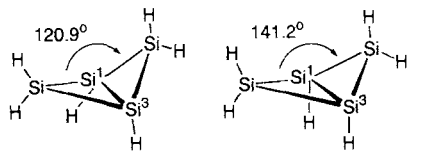


157 **158** **159** **160**

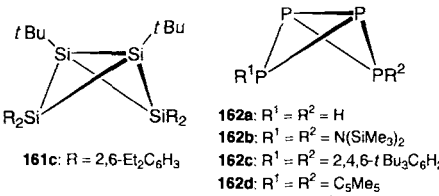
Scheme 29. Fragmentation of **157**.

5.4. Structure and Ring Strain of Tetrasilabicyclo[1.1.0]-butanes and Tetraphosphabicyclo[1.1.0]butanes

The relatively large ring strain in cyclotrisilanes **139** in comparison to cyclopropanes **138** and cyclotriphosphanes **143** has notable consequences for the electronic structures of the corresponding bicyclo[1.1.0]butanes. From ab initio calculations on the parent compound of tetrasilabicyclo[1.1.0]butane it was ascertained that the compound exists in the two forms **161a** and **161b**, which can be referred to as bond stretch isomers. Isomer **161b** is 17 kcal mol^{-1} more stable than **161a** and represents a singlet diradical with an extremely long Si–Si bridgehead bond (2.731 Å in **161b** vs. 2.343 Å in **161a**). The isomers are separated from one another by a very small barrier of 0.12 kcal mol^{-1}.[163]



161a Si^1—Si^3 2.343 Å **161b** Si^1—Si^3 2.731 Å

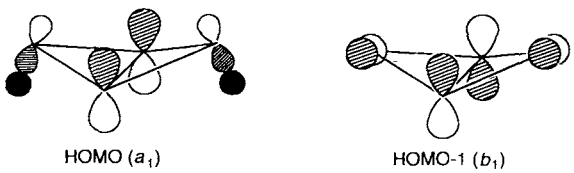


161c: R = 2,6-$Et_2C_6H_3$

162a: $R^1 = R^2 = H$
162b: $R^1 = R^2 = N(SiMe_3)_2$
162c: $R^1 = R^2 = 2,4,6\text{-}t\,Bu_3C_6H_2$
162d: $R^1 = R^2 = C_5Me_5$
162e: $R^1 = H$, $R^2 = SnMe_3$

The molecule evidently rids itself of its high ring strain by bond stretching, that is it prefers a cyclobutane-like structure which in the case of silicon is particularly low in ring strain. Calculation of the strain energy did in fact show that **161** is about 7 kcal mol^{-1} less strained than bicyclo[1.1.0]butane.[164] The structural characterization of the sterically substituted derivative **161c** shows a relatively short Si–Si bridgehead bond (2.373(3) Å); thus, this compound corresponds to the isomeric form **161a**.[165]

In contrast, the tetraphosphabicyclo[1.1.0]butane **162a**, the derivatives (**162b–e**) of which have already been synthesized,[166] has a structure similar to bicyclo[1.1.0]butane.[167] However, in contrast to the latter, **162a** shows scarcely any ring strain.[145c] The P–P bridgehead bond shows a high degree of π character, which is strengthened by the influence of π-donor substituents on the peripheral P atoms. The HOMO has a_1 symmetry and lies only slightly higher in energy than the HOMO-1 with b_1 symmetry (Fig. 17). Compound **162** can therefore



HOMO (a_1) HOMO-1 (b_1)

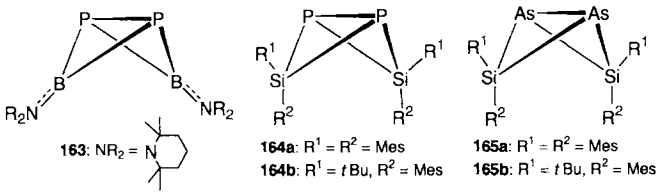
Fig. 17 Graphic representation of the HOMO (a_1) and the HOMO-1 (b_1) in tetraphosphabicyclo[1.1.0]butane **162** [145c].

be formally described as a donor–acceptor complex of P_2 and two phosphanediyl fragments :PR in terms of the Dewar–Chatt–Duncanson model. This is in agreement with the relatively short P–P distance in the P_2 bridge (ca. 2.12 Å); this value lies between that for a P=P (2.00 Å) and a P–P (2.21 Å) bond.

The comparably high stability of the P–P bridgehead bond is lost in this system when the :PR fragments at the peripheral positions are replaced by other carbene-analogous fragments with electropositive central atoms such as boron or silicon. In this case the ordering of the frontier orbitals is reversed and has, as discussed below, a drastic influence on the structure of such systems.

5.5. Mixed Heterobicyclo[1.1.0]butanes with a P_2 and As_2 Bridge

Recently the first B_2P_2-bicyclo[1.1.0]butane derivative **163** was reported; it contains an unusually long P–P bond (2.349(2) Å).[168] This increase in comparison to the P–P bond in diphosphanes and tetraphosphabicyclo[1.1.0]butanes **162b,c** is attributed to the σ-donor character of boron and the ring strain. The hybrid silicon-containing bicycles **164**[169] and **165**[170] with a P_2 or As_2 bridge show, as expected, the same effect.



The strikingly long As–As distance (2.602(3) Å) in **165b** (Fig. 18) is only comparable with that in Realgar As_4S_4 (2.59 Å) (ca. 6% longer than in diarsanes). Ab initio calculations on the parent systems $X_2(SiH_2)_2$ (X = P, As) show that the X–X bond has no diradical character, unlike the case with the tetrasilabicyclo[1.1.0]butanes **161**, but instead, the X atoms are strongly negatively polarized and repel each other.[170]

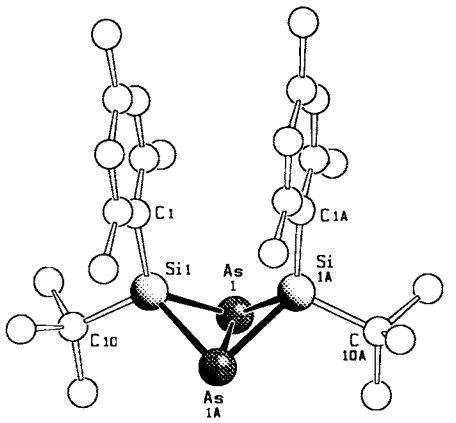


Fig. 18. Molecular structure of **165b** in the crystal [170]. Bond lengths [Å] and angles [°]: As–As 2.602(3), As1–Si1 2.355(3); Si1-As1-Si1A 84.3(1), As1A-As1-Si1 56.5(1), As-Si1-As1A 67.1(1).

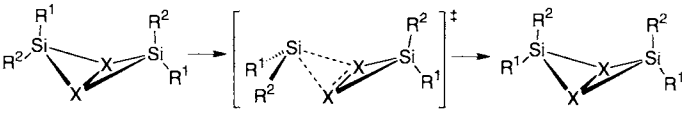
Particularly interesting is the isomerization of the *exo,endo* butterfly molecules **164b*** and **165b*** to the *exo,exo*-configurated compounds **164b** and **165b**, respectively. This gave the first indications of the readiness of these compounds to fragment into silanediyl and X_2Si fragments (X = P, As), and thereby parallels the reactivity seen for the strained three-membered rings with Si framework atoms (Scheme 30).



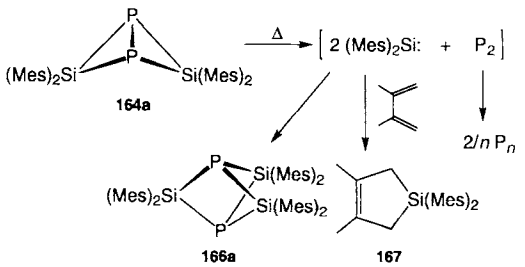
164b* (*exo, endo*): X = P
165b* (*exo, endo*): X = As

164b (*exo, exo*): X = P
165b (*exo, exo*): X = As

Scheme 30. Isomerization of **164b*** and **165b***.

While **164b*** can be converted easily through an inversion of configuration at the silicon center into the *exo,exo* form **164b** by heating (40 °C, 2 h) or irradiation with a lightbulb (200 W, 20 min), the arsenic analogue **165b*** isomerizes significantly slower (7 d irradiation). For energetic reasons the inversion should proceed over a silanediyl–P_2Si complex as transition state. The different behavior of **164b*** and **165b*** is attributed to the unfavorable As–As π interaction in the transition state. Calculations on the isomerization process provided the surprising result that the parent compound $(H_2Si)_2X_2$ (X = P, As) has a relatively high inversion barrier which lies significantly higher in energy than the dissociation limit to H_2SiX_2 and silanediyl (X = P: SCF: 62.5 kcal mol^{-1}; MP2: 71 kcal mol^{-1}). Parent systems and derivatives with bulky substituents are therefore also in this case not comparable with one another[170] (see Maxim 5 in Section 2) since the potential energy surface of the Si_2X_2 framework can be strongly "deformed" by the substituents.

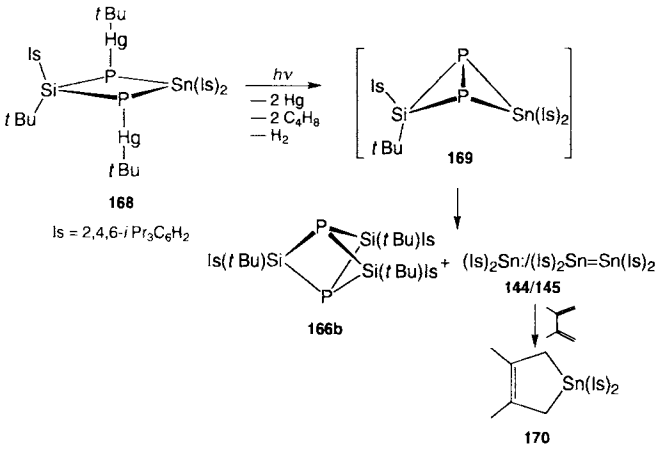
An experimental indication for the extrusion of a silanediyl from the Si_2P_2 bicyclus **164a** is offered by its thermolysis in which the Si_3P_2 bicyclus **166a** and elemental phosphorus are formed.[171] In the presence of a trapping reagent such as 2,3-dimethylbutadiene, thermolysis provides the expected silol derivative **167** (Scheme 31).



Scheme 31. Fragmentation of **164a** and trapping reaction with 2,3-dimethylbuta-1,3-diene.

The readiness of such butterfly molecules to fragment into a carbene-analogous molecule and X_2 (X = P, As) increases, as expected, when silicon is replaced by germanium or tin. It is therefore understandable that after photochemical reductive elimination of Hg from **168**, which has proven to be an excellent method for the synthesis of **164a,b** and **165a,b**,[172] the SiP_2Sn

bicyclus **169** could not be detected. Instead the bicyclus **166b** is formed as the silicon-containing product together with the distannene **145**, which is in equilibrium with the stannanediyl **144**. The latter compounds can be trapped by reaction with 2,3-dimethylbutadiene under formation of the stannole **170** (Scheme 32).



Scheme 32. Fragmentation of **168**.

6. Summary and Outlook

In the current article, an effort has been made to show a correlation between the atomic characteristics of the main group elements (expressed as their spectroscopic electronegativity), the characteristics of reactive fragments HE, H_2E, and $[H_2E]^+$ produced by addition of hydrogen or protons to the elemental atoms, and the characteristics of the compounds constructed from these fragments. In doing so, three classical objects of study in traditional organic chemistry, namely methylene ($:CH_2$), ethene ($CH_2=CH_2$), and cyclopropane [$(CH_2)_3$], were chosen as models for formally analogous main group element compounds. These classical, substance classes with interesting electronic properties have in the past provided us with the now familiar bonding theory, structure chemical concepts, and reactivity principles. Can these ideas be applied to homologous and analogous main group element compounds without further thought? The answer is no. The chemistry of carbon is that of an "exotic" element and is determined by its position in the periodic table. As an element from the second row, it is especially "willing to hybridize" since the element–carbon bond has a high bonding energy which compensates for the considerable "promotion energy" required by this mathematical model. As an element with intermediate electronegativity, carbon almost always forms bonds with high covalent character in molecular compounds (see for example organolithium compounds on the one hand and organofluorine compounds on the other). This characteristic is not seen to such an extent in any other element. A comparison of methylene with the corresponding fragments with main group elements from higher rows already reveals the special position held by carbon. Most of the carbene-analogous fragments have, as a result of their "reluctance to hybridize", a singlet ground state. The ability of carbon to form σ and π bonds of high energy, explains the planarity of olefins. This ability even increases with increasing s orbital participation in the mathematical function used to describe bonding, the valence hybrid orbital. The higher homologues show, within the framework of perturbation theory, an increasing tendency to form *trans*-bent structures. This is a result of a second-order Jahn–Teller distortion.

A concept developed by Malrieu and Trinquier is particularly suitable for predicting the molecular structure of multiply bonded systems of the main group elements. Here the singlet–triplet excitation energies $\Delta E_{S\rightarrow T}$ of the fragments determine the character of the dimers formed from them. Multiply bonded systems have a molecular structure that deviates from planarity or linearity when the sum of the excitation energy $\Sigma\Delta E_{S\rightarrow T}$ is larger than the term $f(E_{\sigma+\pi})$ (with $1/2<f<1$). When $\Sigma\Delta E_{S\rightarrow T}>E_{\sigma+\pi}$ is also valid, a constitutional isomer without direct E–E bonding is predicted for the dimers of the carbene-analogous fragments. Until now no exceptions have been found for the rules derived from the GCMT model. The common ideas taken from carbon chemistry that a "double bond" actually has a higher bonding energy than a single bond or that bond lengths are an analytical criterion for the presence of multiple bonding cannot be transferred to homologous and analogous compounds of the main group elements from the higher rows. Even the preferred bonding theory held up to now of noncylindrical electron density in a double bond, which can be approximated mathematically by a σ and a π bond, is (again) in question for molecules with *trans*-bent structures (see ref.[141c]).

The fragmentation behavior of three-membered rings containing main group elements, in particular, can be advantageously understood and predicted with the concept of describing these cycles as trimers of carbene-analogous fragments. It is almost curious that the observation that Baeyer's strain theory, which was based on the investigations of cycloalkanes, shows more validity for the series of cyclosilanes completed almost 100 years later. Due to the desire to transfer known principles in carbon chemistry to formally analogous main group element compounds, in view of the homologue idea, the uniqueness of the chemistry of the element carbon has been made clear. In the same manner, similar characteristics shown by other compound classes have been recognized. On this basis, fragments such as RE and R_2E can be specifically used for the "design" of molecules with predictable characteristics for many areas of research, for example in materials science where the thermal behavior and fragmentation pattern of precursor molecules plays a large role.

However, there remains much to be done. For example, the search for constitutional isomers of a given molecular formula is particularly exciting. And we think that in this case asymmetrical multiply bonded systems with metalloid main group elements deserve special consideration. For example, it seems that the search for a compound with the formula R_3EE^1 (E = Si, Ge, Sn; E^1 = Al, Ga, In) is worthwhile. The question is will such compounds be "nonclassical" multiply bonded systems $R_2E=E^1R_2$, R-bridged rings and cage compounds, or substituted carbene analogues $:E^1-ER_3$? For several alkoxides such as $Sn(OtBu)_3In$ or $Sn(OtBu)_3Tl$ (R = O*t*Bu) cage structures with three bridging alkoxide groups (not unexpected within the framework of the GCMT model; compare Scheme 11) have been obtained;[178] however, alkyl- or aryl-substituted compounds of this sort have yet to be synthesized. The building

blocks are known (see Section 3), they just need to be "mixed together". Many characteristics of the compounds presented in this article have not yet been investigated. This is especially true for the redox behavior and the related changes in the molecular structure of the (radical) cations and anions in comparison to the corresponding carbon compounds.[173, 174] In addition to an improvement in the bonding theory model, much development in experimental technique is needed.

In conclusion the following must be mentioned: although the chemistry of elements that are "reluctant to hybridize" has been presented here, this behavior must not necessarily apply to the researchers that work in this area. Exactly the attitude "let's see what the neighbors are doing" has allowed this field of research to become what it is, interdisciplinary.

This work was supported by the Deutschen Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie. We thank our mentors Professors. G. Bertrand, G. Huttner, H. W. Roesky, W. Siebert, W. Sundermeyer, and R. West as well as our co-workers Dr. U. Heim, Dr. H. Schönberg, Dr. U. Winkler, and Dipl.-Chem. S. Rell, who participated on several of the projects presented here, for their continual support. We especially thank Dr. H. Pritzkow who conducted almost all of the X-ray crystal structure analyses for us. We thank Dr. U. Fleischer, Prof. G. Frenking, and Prof. R. Janoschek for quantum mechanical calculations, and Mrs. Christina Marchand for her assistance in preparing the figures.

Separation, Characterization, and Fraction Collection in the Nanoliter Domain with Capillary Electrophoresis

Aran Paulus*

In a relatively short time capillary electrophoresis (CE) has advanced to become a new analytical tool with broad applicability. Commercial instrumentation (Fig. 1) has been available

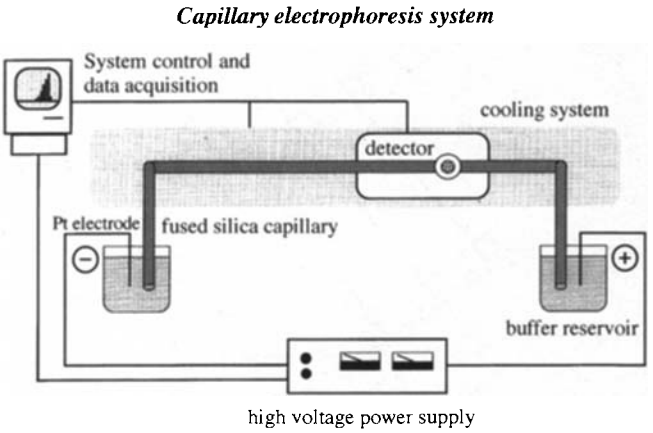

Fig. 1. Schematic representation of a commercial CE instrument. Fused silica capillary: internal diameter 50–100μm, length 20–50 cm; power supply: 0 to ±30 kV; detector: UV- or laser-induced fluorescence; temperature control: 15–60 °C.

only since the end of 1988, but a variety of analytical problems has been solved in capillaries with an inner diameter of 50 to 100 μm and 20 to 50 cm in length. Charged as well as uncharged analytes, inorganic ions, and small organic molecules, as well as complex biopolymers such as peptides, proteins, DNA fragments, and carbohydrates, have been separated by CE under suitable conditions.[1] Especially the extremely high separation efficiency, unparalleled by any other separation technique, added to the appeal of CE. Additional benefits include miniaturization, separation speed, automation, and flexibility in the choice of separation modes.

The majority of CE applications operates with capillaries filled with buffer. By applying an electrical field, an electroosmotic flow (EOF) is generated. In contrast to the parabolic flow profile of a pressure-driven HPLC flow, the EOF is characterized by a plug flow profile, which does not contribute to band broadening and therefore results in higher separation efficiencies. The number of theoretical plates depends only on the diffusion coefficient of the analyte. It can range from several hundred thousand to several million. As the total volume of a CE capillary is a few microliters, the injection volumes are in the order of a few nanoliters. CE has therefore been labeled a nanoseparation technique. The application of an electrical field of 200 to 500 $V\,cm^{-1}$ results in separation times ranging from 5 to 30 min.

The EOF-generated mass transport is supplemented by the electrophoretic mobility. In the presence of an electrical field the electrophoretic mobility causes an additional acceleration or deceleration of the ionic components of the sample according to their charge and mass. The separation mechanism of CE in its simplest form, the capillary zone electrophoresis (CZE), is based on differences in the charge-to-mass ratio of the analytes. Electrophoretic size separations, important for the analysis of DNA fragments and proteins, can be adapted to the CE format by using sieving matrices such as gels or polymer solutions in the capillaries. Capillary gel electrophoresis (CGE) is especially valuable in industrial biotechnology for analysis of recombinant proteins and antisense oligonucleotides because of its high separation efficiency and degree of automation.[2]

Using CZE conditions, neutral analytes would migrate with the EOF. By adding sodium dodecyl sulfate (SDS) to the buffer, micelles are formed, which act like a pseudostationary phase mobilized by the EOF. In the presence of micelles, neutral analytes partition between the aqueous buffer phase and the micellar phase and can thus be separated according to their hydrophobicity.[3] Alternatively, it is possible to fill the capillary with an HPLC stationary phase and to utilize chromatographic interactions with the EOF in the electrical field. This approach is an attractive alternative to microcolumn HPLC and is currently actively pursued as electrochromatography. Compared to HPLC, electrochromatography has its appeal in its high separation efficiencies and miniaturization.[4]

For a number of laboratories, a new analytical technique is only accessible after the introduction of commercial instrumentation. The majority of users will be busy with the solution of practical problems on available machines. However, commercialization also consolidates instrumental standards. Nevertheless, the stormy instrumental development in CE is not yet over, as demonstrated by the literature of the last year. A year ago, the direct coupling of CE with NMR spectroscopy was reported.[5] By using a 5 nL NMR sample cell made of a copper wire

wrapped around the fused silica capillary, NMR spectra with a signal line width of 11 Hz were recorded on-line from CE separations. When these results were published, the author's prophetic comment read: "The described method of miniaturization must be continued to derive a NMR resolution under the described measuring conditions which is close to values attainable by conventional acquisition system." This is exactly what has happened.

In a recent publication, Sweedler at al. report on NMR signal line widths of 0.6 Hz with the same experimental set-up, made possible through a stabilization of the magnetic field around the sample. By flushing the NMR sample compartment with Fluorinert FC-43, a fluid with a magnetic susceptibility between that of copper and heavy water, magnetic field in homogeneities could be suppressed. In this way, the mass sensitivity was improved 130-fold relative to that for conventional 5mm NMR tubes. Even the recording of 2D COSY spectra was possible with the nanoliter NMR sample cell. With an acquisition time of 1 min, 19 ng (56 pmol) sucrose was detected.

Although a direct coupling of NMR with CE is not described in this work, what only two years ago would have sounded impossible now seems feasible: the coupling of a high efficiency separation technique with an information-rich detection method. A CE-band containing picograms of sample migrates within 10 to 20 s passed the detection window. Both acquisition time and sensitivity of NMR spectroscopy are still one order of magnitude off that obtainable with optimal CE with UV detection. Nevertheless, an operational CE–NMR coupling for separation and immediate structural assignment in complex biological and environmental samples is no longer merely a pipe dream.

CE is not limited to separation and characterization of complex sample mixtures. In another paper from Sweedler's group,[7] the miniaturized dimensions of CE have been exploited for nanoliter kinetic assays. Instead of using a capillary, the long sides of two microscope slides were glued together at a distance of 40 μm to form a rectangular separation channel. Each short, open side was immersed in a buffer reservoir. If a capillary to dispense the sample is moved along one open side with the help of a micropositioner, sample injection is continuous and perpendicular to the direction of the separation. The dispenser capillary was filled with 200 nL of a mixture consisting of two amino acids and the derivatization agent naphthalene dialdehyde. Within minutes the reaction yields fluorescent products. Since the reaction is terminated when the reaction partners are separated in the electrical field, the reaction kinetics can be followed as a function of the movement of the dispenser capillary. This approach allows the measurement of rate constants, even if several reaction processes occur simultaneously with a time constant of 1 s in nL volumes. Such a set-up can conceivably be used for tracking biochemical processes such as protein biosynthesis directly in the cellular environment.

An important current instrumental development in CE for further miniaturization and integration of sample pretreatment is microchip CE. In this approach a lithographic process, familiar from microelectronics, is used to fabricate channels into quartz or glass plates. The channel dimensions are similar to those in fused silica capillaries. The advantages of planar or integrated CE include small overall dimensions with short separation channels, the simplicity with which channels can be connected for the integration of sample pretreatment or post separation routines, and the option for multiplexing with several parallel channels. With channels with effective lengths of only 5 cm, a power supply capable of delivering 10 kV is sufficient to generate high electric fields of up to 2000 Vcm^{-1}. Separation efficiency and resolution increase with increasing applied electric field. Since at the same time analysis times decrease, the microchip offers a simple method for fast, highly efficient separations. For example, 5000 theoretical plates per second were achieved in less than 1 min.[9]

Connecting fused silica capillaries for sample pretreatment or transfer of separated sample constituents in subsequent reservoirs introduces dead volumes. Any dead volume in micro columns is detrimental, since the prior separation is destroyed through mixing effects. This problem is circumvented with a microchip: the layout of the lithographic mask (Fig. 2) enables

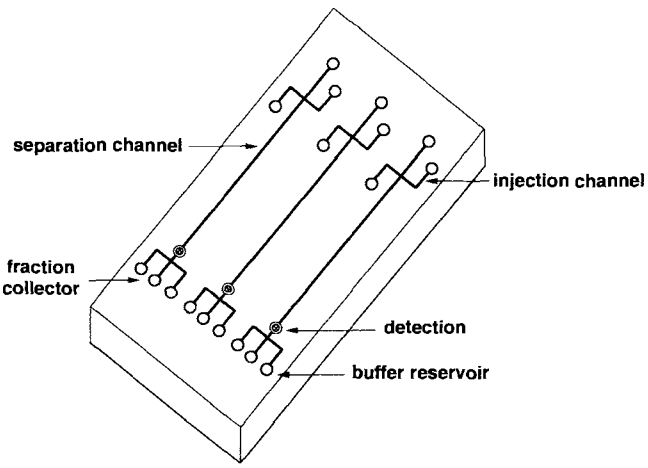

Fig. 2. Schematic representation of a planar integrated CE on a microchip. Channel dimensions: about 10 μm deep, 30 μm wide; length of separation channel: 2 to about 5 cm; chip dimensions: 10 × 5 × 0.5 cm.

any connections to be made without additional dead volumes. Ramsey's group was able to demonstrate the integration of precolumn derivatization of amino acids with phthalaldehyde in a 1 nL reaction volume on a microchip.[10]

The ultimate goal of chemists and biochemists is not only the separation and characterization of complex mixtures, but also, if at all possible, the isolation of a component of the sample for further reactions and investigations. However, in many separation techniques good separations and preparative amounts of samples very often have mutually exclusive criteria. As stated above, it is virtually impossible to handle the nanoliter volumes from CE outside the capillaries. Fortunately, the microchip approach also offers an alternative. C. S. Effenhauser et al. were able to demonstrate a functional picoliter fraction collector.[11] Using a microchip layout with crossing channels after the detection point, the authors separated antisense oligonucleotide mixtures in a polyacrylamide filled channel. By switching the electrical field, they could direct a part of the sample, ideally one component, into a reservoir to separate it from all other components. Single molecule detection is possible today with fluores-

cence detection techniques.[1,2] With that in mind, this combination triggers intriguing possibilities for chemists and biochemists: Single molecules can conceivably be separated, collected, and manipulated on a chip, and possibly even made to undergo chemical reactions. Chemistry with single molecules could soon be reality.

Superlattices, Thin Films, and Materials Design—A Mechanistic Approach

Robert Schöllhorn*

The area of thin films is rapidly developing into a key technology with applications ranging from electronic materials (semiconductors, superconductors, optoelectronics etc.) to chemical sensor systems. A variety of deposition techniques for the preparation of single layers and superlattices is now available, extending from molecular beam epitaxy to chemical vapor deposition. While physicists are focussing their attention on the detection of new quantum phenomena associated with the constrained morphology in nanorange dimensions, it appears that a new avenue is opening here for solid-state chemistry through the controlled synthesis of complex metastable structures. A particularly interesting example in this line is represented by the approach documented in recent work by D. C. Johnson and coworkers which concerns the preparation of new compositionally modulated layered transition metal dichalcogenide structures characterized by the use of a rational synthesis strategy that involves a topological model for kinetic trapping and directed interfacial growth.[1–3]

Superlattices are defined here as multilayer thin films with long-range structural coherence perpendicular to the basal plane which are prepared by time sequential deposition of components. In the area of molecular solids the formation of ordered multilayer systems with complex arrays of subunits has become an established art (for example, Langmuir–Blodgett and polymer films).[4, 5] The deposition of multilayers of metals/alloys,[6] covalent semiconductor materials,[7] and oxometalate superconductors[8] are well known for nonmolecular solids; however, there are only a few reports on other materials. The usual method of preparation is to deposit these phases under conditions that lead directly to the final product.

A different philosophy underlies the approach used by Johnson et al. for the controlled chemical synthesis of complex metastable chalcogenide structures by superlattice precursors. The concept used is based on a two-step process. In the first step a multilayer structure is prepared by modulated sequential deposition of the chemical elements required. This structure is subsequently transformed by low-temperature thermal conversion under defined conditions into a crystalline superlattice compound with compositional modulation. The formation of the heterostructure is not based on conventional epitaxial growth but on kinetic trapping of the desired structure by the specific solid-state reaction mechanism.

Layered transition metal dichalcogenides MX_2 of the CdI_2 or MoS_2 structure type were selected for investigations on this reaction model. These chalcogenides are interesting for several reasons. Their electronic properties vary from insulator to metal and superconductor behavior; charge density waves have been studied extensively with these layered phases.[9, 10] Their topotactic reactivity is exceptional;[11, 12] in terms of application they are of interest, for example as electrode materials for secondary batteries and photoelectrochemical cells, as solid lubricants, and in heterogeneous catalysis. Their physical and chemical properties can be modified by isomorphous replacement of lattice cations and anions.

Experimental investigations were initially carried out on the *binary* Nb/Se system by X-ray diffraction and differential scanning calorimetry; these demonstrated the oriented formation of the binary chalcogenide $NbSe_2$ as a result of the nucleation and growth of the product along the planar interfaces of the modulated precursor phase. The major parameters for reaction control were the diffusion length (layer thickness in the precursor state), the annealing temperature, and the annealing time. With appropriate reaction parameters a variation of the Nb/Se ratio (i.e. metal or chalcogen excess relative to the 1:2 stoichiometry) had no influence on the formation of stoichiometric $NbSe_2$, in spite of the potential competition by neighboring binary phases thermodynamically stable under these conditions. This is in perfect agreement with the assumption of a low-temperature solid-state reaction with kinetic control.

If the mechanism of the interfacial nucleation with oriented crystal growth of kinetic products (Fig. 1) is correct, it should be

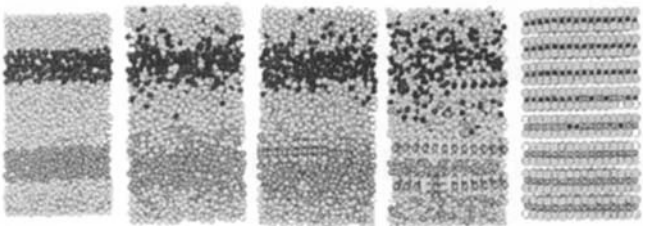

Fig. 1. The reaction pathway for the formation of chalcogenide superlattices: low-temperature thermal transformation of amorphous chalcogenide precursor multilayers, comprising layers of niobium (black spheres) and titanium atoms (gray spheres), each separated by intervening layers of selenium atoms (white spheres) (left), by interfacial nucleation and oriented growth into the desired crystalline product superlattice after annealing (right).

possible to prepare new metastable heterostructures containing ternary compounds with modulated composition perpendicular to the direction of the thin film basal plane. X-ray and DSC studies on the Ti/Nb/Se system in the stoichiometric ratio used for the formation of MX_2 layers demonstrated a persistence of the precursor thin film composition modulation in the course of the low-temperature annealing process and a continuous oriented growth of the product phase. An experiment with a precursor superlattice sequence corresponding to 6(Ti/2 Se)–6(Nb/2Se) yielded a remarkable result: the X-ray pattern of the product phase displayed all of the calculated 62 Bragg reflections of the desired superlattice (Fig. 2). The high quality of the reflections allowed a Rietveld analysis that confirmed the correlation between the precursor heterostructure sequence and the superlattice ordering of the final product. As expected high-temperature annealing of the product phase leads to quantitative conversion into the thermodynamically stable, solid solution phase with short periodicity and identical layer units of the composition $Ti_{0.5}Nb_{0.5}Se_2$.

The novel concept for the controlled low-temperature solid-state synthesis of metastable phases by thin-layer precursors modulated in the nanometer range—characterized by the competition in time windows between short-scale diffusion and heterogeneous interface nucleation with oriented growth of a metastable product phase—has thus been successfully applied by the authors for the controlled preparation of novel transition

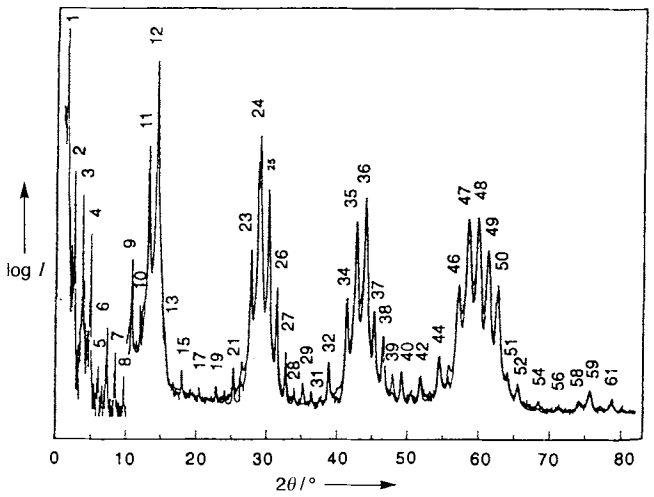

Fig. 2. X-ray diffractogram of a dichalcogenide superlattice with a modulation sequence corresponding to six $NbSe_2$ and six $TiSe_2$ layer units. All 62 Bragg reflections of the desired superlattice are shown.

metal dichalcogenide structures. A new dimension is given here for modifying the interesting physical and topochemical properties of these materials. Transition metal dichalcogenides belong to the category of van der Waals type layered solids; their structural morphology and bonding anisotropy naturally should favor the directed interfacial growth mechanism. A large variety of related layered compounds with similar or more complex layered structures or stoichiometry are known to which this concept could be extended (e.g. transition metal dihalides, phosphorous chalcogenides, sulfide carbides etc.). It seems most likely that this synthesis strategy can similarly be applied to the preparation of metastable framework solids characterized by strongly anisometric structures, such as layer-type perovskites. The limit of application of this concept may be reached with structurally isometric solids, in which coherent directed nucleation and growth at interfaces appears to be less probable. Further aspects of general interest related to this concept are the investigation of dynamic interface processes (in situ diffraction studies), nucleation phenomena, and the transformation mechanisms of amorphous phases in low-temperature solid-state reactions whose investigation with bulk material is frequently problematic.

It is important to note in this context a further line of progress achieved recently concerning modulated materials. Present techniques for the preparation of pristine thin films of nonmolecular solids are based essentially on physical or chemical vacuum techniques in which atoms, molecules or cluster aggregates are deposited from the vapor phase onto solid substrates (i.e. gas/solid processes). A basically different approach is the use of *electrochemical* techniques for thin film preparation (i.e. fluid–solid conversion). There are several advantages associated with this technique: a) the strong tendency of electrochemically deposited materials—including isometric systems—for epitaxial growth, b) the possibility of working with systems not suited for vacuum deposition, c) suppression of interdiffusion between layers (room temperature), and d) precise control of deposition by current density (kinetics) and electrode potential (variable energy scale). Whereas the electrochemical deposition of multilayer systems of metals/alloys and semiconductors[13] has been

well investigated in the last decade, recent work by Switzer and coworkers appears to be the first successful attempt to obtain superlattices from a complex ternary inorganic material by the electrochemical deposition technique.[14]

The major subject of these investigations was the ternary Tl/Pb/O system with a fluorite type structure and a large variation in stoichiometry. By pulsed-current or pulsed-potential deposition from electrolytes with appropriate ionic composition, superlattices with a modulation layer unit thickness of 3 nm could be prepared. X-ray and scanning tunneling microscopy studies confirmed the high quality of the superlattice architecture. The modulation wave lengths were in the order of mean free path dimensions of electrons. The material is a degenerate n-type semiconductor whose high electronic conductivity, which lies in the order of that of metals, is combined with the optical properties of a semiconductor; it is of interest with respect to quantum optical, electronic, and optoelectronic functions.

A further remarkable recent result from the work by Switzer et al. is the pulsed anodic electrodeposition of nanometer-scale modulated "defect chemistry superlattices" of thallium(III) oxide (Fig. 3).[15] The modulation parameters here are intrinsic anion vacancies and cation Frenkel type defects. It could be shown that the defect chemistry of Tl_2O_3 is a function of the applied electrode potential: high overpotentials were found to induce oxygen vacancy defects (Tl_2O_{3-y}), whereas low overpotentials favor excess Tl ions on interstitial sites of the lattice (i.e. $Tl_xTl_2O_3$).

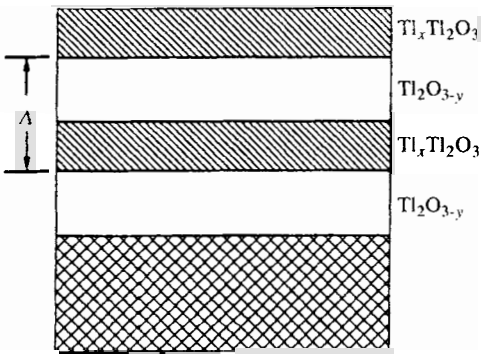

Fig. 3. Scheme of defect modulation in a thallium(III) oxide superlattice obtained by anodic pulsed deposition. Substrate = stainless steel. Λ = Periodicity of layer sequence.

The examples of recent work presented here underline the increasing involvement of chemistry in the area of nonmolecular materials artificially modulated on the nanometer scale, and the potential of low-temperature solid-state processes and controlled materials design. In comparison with the impressive rapid progress in "supramolecular chemistry" it now seems that some keys to doors are becoming available, providing access to a comparable tailoring approach in the domain of nonmolecular solids.

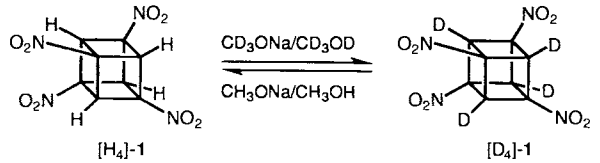
Anions Stabilized by β-Nitro Groups: The Acidity and *ortho*-Metalation of Nitrocubanes—Penta- and Hexanitrocubanes**

Kirill Lukin, Jianchang Li, Richard Gilardi, and Philip E. Eaton*

Nitro groups are powerfully electron withdrawing. On both resonance and inductive scales they are more potent than any other uncharged functionality.[1,2] Anions with α-nitro substituents are highly stabilized by resonance delocalization of charge; an α-nitronate (the *aci*-nitro anion) is 10^{+10} times less basic than a ketone enolate.[3] The acidity of carboxylic acids is increased about one thousandfold by the inductive effect of an α-nitro group.[4] We show here that nitro substituents have a dramatic effect on the acidity and chemistry of cubanes.

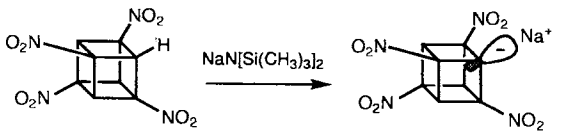
Cubane uses an s-rich orbital to bond substituents. Thus, cubyl hydrogens are more acidic than those on more usual hydrocarbons; for example, cubane is approximately 60000 times more acidic than cyclohexane.[5] Experiments with mono- and 1,4-dinitrocubanes, designed to probe for substituent-enhanced acidity (refer to the effects of amide substituents[6]) were entirely frustrated by the ease with which base destroys these compounds. Not even the simplest exchange reaction could be achieved. If one can use transient colorations as an indicator, single electron transfer mechanisms probably intervened and somehow unraveled the cubane framework; nothing of substance could be isolated. It is possible that an anion was formed, but that β-elimination of nitrite then occurred. Although this happens readily with enolizable β-nitro ketones and the like,[7] elimination of nitrite is much less likely here, for the product would be a cubene. Cubenes are anti-Bredt olefins, highly pyramidalized and difficult to access, but they do give isolable products.[8]

1,3,5,7-Tetranitrocubane (**1**), first made here in 1992 and now much more easily available,[9,10] has four identical hydrogen atoms each surrounded by three nitro groups (the molecule has pseudo-tetrahedral symmetry). The possibility of deprotonating to an anion (**2**) much stabilized by the inductive electron-withdrawing effects (− I effect) of three vicinal (β) nitro groups and, perhaps more importantly, by coordination of the electron-rich oxygen atoms of these groups with the counterion seemed particularly attractive. Indeed, we have found that the acidity of the cubane hydrogen atoms is so enhanced in **1** that their exchange can be effected rapidly even with bases as mild as sodium methoxide in methanol. Thus, reaction of [H_4]-**1** with 0.125 M CD_3ONa in CD_3OD for 45 minutes at room temperature, followed by quenching with hydrochloric acid and extraction with EtOAc, gave [D_4]-**1** in 87% yield. The reverse experiment, that is, reaction of [D_4]-**1** with CH_3ONa in CH_3OH, returned [H_4]-**1**.



[H_4]-**1** [D_4]-**1**

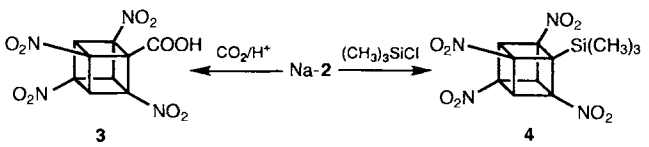
The anion that must intervene in these exchanges exists at only very low concentration in methanolic CH_3ONa. It could not be detected in this milieu by NMR spectroscopy, nor did we have any success trapping it with electrophiles other than acid. However, ^{1}H NMR examination of the reaction of **1** with sodium bis(trimethylsilyl)amide in [D_8]THF at −75 °C showed clearly the formation of the salt Na-**2**: ^{1}H NMR $\delta = 5.54$ (s). This salt is stable for hours at −75 °C, but it decomposes rapidly above −50 °C.



1 Na-**2**

We could estimate the pK_a of **1** from low temperature proton NMR measurements on equilibrium mixtures with various bases. Almost complete metalation (salt formation) occurs in THF with one equivalent of sodium bis(trimethylsilyl)amide, but none with α-lithiobenzyl cyanide. As the pK_a in THF of bis(trimethylsilyl)amine is 25.8[11] and that of benzyl cyanide is 18.7,[12] the pK_a of **1** must be between about 20 and 24.5. We have narrowed this to between 20.5 and 22.5 by noting that **1** is partially converted into its anion by 1.5 equivalents of potassium *tert*-butoxide (the pK_a of *tert*-butyl alcohol in THF is given as 21.6[13]).

The salt of tetranitrocubane can be used to achieve further substitution on the cubane framework. For example, reaction of Na-**2** in THF at −75 °C with carbon dioxide followed by neutralization gave the tetranitrocubane carboxylic acid **3** in 85%



3 **4**

yield (characterized as its methyl ester: ^{1}H NMR: $\delta = 3.84$ (s, 3H), 6.22 (s, 3H); ^{13}C NMR: $\delta = 54.3$ (OCH_3), 67.0 (3C, CH), 72.0, 73.4, 75.2 (3C, CNO_2), 159.9 (C=O)). Quenching **2** with chlorotrimethylsilane gave the tetranitro(trimethylsilyl)cubane **4** in 80% yield (^{1}H NMR: $\delta = 0.16$ (s, 9H), 6.07 (s, 3H); ^{13}C NMR: $\delta = -3.3$ (3C, $SiCH_3$), 67.8 (3C, CH), 71.7, 74.4 (3C, CNO_2), 75.5). These conversions are the first to our knowledge of substitutions by way of "*ortho*-metalations" in which the nitro group activates a β C–H bond and stabilizes the resulting anion.[14]

When a larger excess of sodium bis(trimethylsilyl)amide was used in these reactions, yet more highly substituted cubanes were obtained. Treatment of **1** with five equivalents of base followed by quenching with carbon dioxide and neutralization gave a 70:30 mixture of **3** with **5**, the tetranitro diacid (charac-

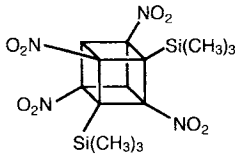
5

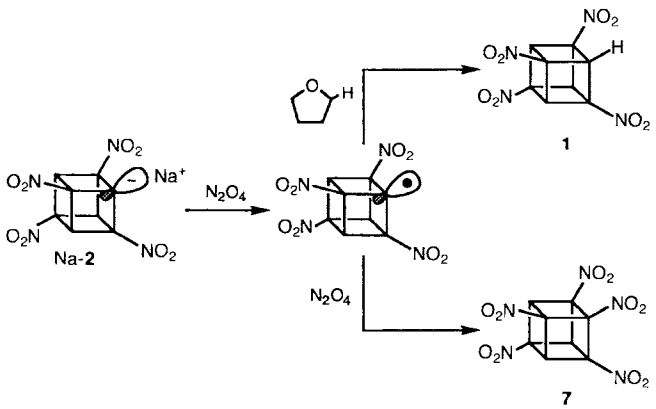


6

terized as its dimethyl ester: ^{1}H NMR: $\delta = 3.90$ (s, 6H), 6.34 (s, 2H); ^{13}C NMR: $\delta = 54.5$ (2C, OCH_3), 66.3 (2C, CH), 72.5 (2C), 74.4 (2C), 76.5 (2C), 159.3 (2C, C=O)). Similarly, the use of three equivalents of base followed by reaction with chlorotrimethylsilane gave a 20:80 mixture of **4** with **6**, the bissilylated product (^{1}H NMR: $\delta = 0.19$ (s, 18H), 6.10 (s, 2H); ^{13}C NMR: $\delta = -3.2$ (6C, CH_3), 67.1 (2C, CH), 72.7 (2C), 75.4 (2C), 75.8 (2C)). We are reasonably certain that **5** and **6** result from sequential anion formations from **3** and **4**. There is no evidence from the low temperature NMR study for dianion formation from **1**.

As anions derived from **1** are trapped effectively with simple electrophiles, we hoped that reaction with electrophilic nitrating reagents would allow us access to more highly nitrated cubanes. Such cubanes are predicted to be powerful, shock-insensitive, high-density explosives.[15] Until now the most highly nitrated cubane known was **1**, obtained from the corresponding tetraacid by oxidation of the derived amine, an approach not applicable to cubanes with vicinal nitro groups.[9, 10]

As best we can determine, there are no firm examples of successful direct nitration of localized (non-resonance-stabilized) organometallic compounds of alkali metals reported.[16, 17] In line with this, we were quite unsuccessful in nitrating salts of **1** with NO_2BF_4, acetyl nitrate, tetranitromethane, amyl nitrate, or similar reagents.[18] However, condensation of excess N_2O_4 into a frozen solution of anion **2** in THF at $-196\,^\circ$C followed by warming produced a 60:40 mixture of 1,2,3,5,7-pentanitrocubane (**7**) and **1**. This strongly suggests that N_2O_4 effects oxidation of **2** to the radical, which then either abstracts a hydrogen atom from the solvent (THF) giving **1** or reacts with N_2O_4 to give **7** (Scheme 1).

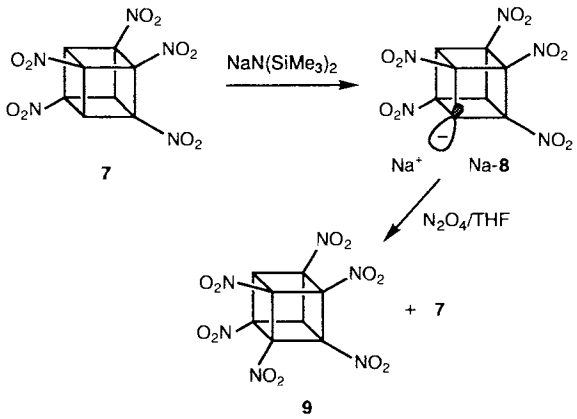


Scheme 1. Reaction of N_2O_4 with Na-**2**.

Pentanitrocubane **7**, the first cubane containing vicinal nitro groups, is colorless and highly crystalline (^{1}H NMR ([D$_6$]acetone): $\delta = 6.43$ (s); ^{13}C NMR: $\delta = 66.5$ ($C_{4,6,8}$-H), 72.8 (C_7-NO_2), 78.8 ($C_{1,3,5}$-NO), 93.0 (C_2-NO_2)). Differential scanning calorimetry (20 °C min^{-1}) indicated a stability similar to earlier polynitrocubanes,[9] decomposition setting in above 250 °C.

The detailed structure of **7** was obtained by single-crystal X-ray analysis.[19] Comparison to that of tetranitrocubane **1**[9] showed that the fifth nitro group in **7**, even though surrounded by three others, causes no significant disturbance in molecular geometry—bond angles and lengths are essentially unperturbed. Molecules of **7** close-pack in the crystal; each oxygen has nine non-bonded O···O contacts shorter than 3.0 Å of which four are between 2.75 and 2.92 Å. This close packing leads to a density of 1.96 gcm^{-3} at 21 °C, a value exceeded by few other CHNO compounds.

Our methodology for nitration of **1** by ortho-metalation can be extended to nitration of pentanitrocubane **7** via its salt Na-**8**. Thus, formation of anion **8** from **7** with sodium bis(trimethylsilyl)amide followed by nitration with N_2O_4 gave a 30:70 mixture of 1,2,3,4,5,7-hexanitrocubane (**9**) and pentanitrocubane **7**, presumably via a radical intermediate (cf. Scheme 1).



The separation of these two polynitrocubanes is very difficult. Nonetheless, we obtained enough of **9** to identify it unambiguously: ^{1}H NMR ([D$_6$]acetone): $\delta = 6.73$ (s); ^{13}C NMR: $\delta = 65.0$ ($C_{6,8}$-H), 78.9 ($C_{1,7}$-NO_2), 83.1 ($C_{3,5}$-NO_2), 91.0 ($C_{2,4}$-NO_2). The assignment was confirmed fully by X-ray analysis of the crystalline bis-acetonitrile solvate of **9**.[20]

[18] Similarly, poor results were obtained with nitrosylating reagents.

[19] Crystal data of **7**: monoclinic ($P2_1/c$), $a = 6.637(3)$, $b = 23.275(14)$, $c = 7.860(5)$ Å, $\beta = 113.21(5)^\circ$, $V = 115.8(11)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.959$ g cm^{-3}. The thin-plate crystal was small ($0.01 \times 0.35 \times 0.40$ mm), leading to a somewhat weak set of diffraction intensities, and thus low precision in the numerical results. Of 1542 collected reflections [$\lambda(Cu_{K\alpha}) = 1.54178$ Å, $T = 294(2)$ K, $\theta/2\theta$ scan mode, $2\theta_{max} = 96^\circ$], 1051 were unique, and 684 with $I > 2\sigma(I)$ were used for refinement. Lorentz, polarization, and absorption corrections (integration, $T_{max} = 0.98$, $T_{min} = 0.72$) were applied to data. The structure was solved and refined using SHELX programs (G. M. Sheldrick, SHELXS86 and SHELXL93, University of Göttingen, Germany). Full-matrix least squares on F^2 refinement varied 218 parameters: atom coordinates and anisotropic thermal parameters for all non-H atoms and isotropic thermal parameters for hydrogen atoms. Final $R = 0.0668$, $wR2 = 0.1647$ with final difference Fourier excursions of 0.294 and -0.302 e Å^{-3} [20b].

[20] a) Crystal data of **9** · 2MeCN: monoclinic, $C2/c$, $a = 13.0102(7)$, $b = 7.7242(6)$, $c = 18.0758(12)$ Å, $\beta = 95.404(7)^\circ$, $V = 1808.4(2)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.676$ g cm^{-3}. The asymmetric unit comprises half of **9** and one acetonitrile molecule; a crystallographic twofold axis passes through the centers of the di- and tetra-substituted faces of the cube. Crystal size $0.36 \times 0.6 \times 0.75$ mm. Of 1567 collected reflections ($\lambda(Cu_{K\alpha}) = 1.54178$ Å, $T = 223(2)$ K, $\theta/2\theta$ scan mode, $2\theta_{max} = 115^\circ$), 1241 were unique ($I > 2\sigma(I)$), and were used for refinement. Lorentz, polarization, and absorption corrections (integration, $T_{max} = 0.65$, $T_{min} = 0.47$) were applied to data. The structure was solved and refined as described above. Final $R = 0.0407$, $wR2 = 0.1062$ with final difference Fourier excursions of 0.278 and -0.186 e Å^{-3}. The indicated precision in the numerical results is about four times higher than that for **7**; the appearance of bonding-electron density peaks in the final electron density map indicated above-average diffraction quality. b) Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-6. Stable Tin and Lead Derivatives of Nitrocubanes: Their Formation and Use in Multiple Functionalization**

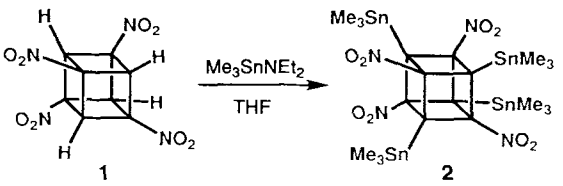
Kirill Lukin, Jianchang Li, Richard Gilardi, and Philip E. Eaton*

The discovery that 1,3,5,7-tetranitrocubane (**1**) is acidic enough to permit preparation of its monosodium salt led us to attempt making polymetallic derivatives with metals forming more covalent bonds.[1]

Trialkyl(amino)stannanes can metalate weak acids such as acetonitrile and cyclopentadiene.[2] The mechanism of such metalations is not known, but we suspect it is not simple. Nonetheless, as the p*K*a of cyclopentadiene is not unlike that of methanol, and we already knew that methoxide in [D_1]methanol was basic enough to effect D-for-H exchange on **1**, it seemed possible that an aminostannane could metalate **1**. Indeed, reaction of **1** with excess (diethylamino)trimethylstannane[3] proved to be very smooth and easily followed by ^{1}H NMR ([D_8]THF, 20 °C). After 15 min, more than 50% of **1** was converted into the monotin derivative ($\delta = 5.94$ (s)). Another singlet ($\delta = 5.99$) corresponding to the ditin compound grew to its maximum (60% yield) in about 1.5 hours. A further singlet ($\delta = 6.05$) for the tritin derivative rose to a maximum (70% yield) after 7.5 h. After 48 hours all signals from cubane hydrogen atoms were gone, and the formation of the tetratin compound **2** was complete. On a preparative scale (0.1 mmol), reaction of **1** with seven equivalents of the base in THF at room temperature for 24 hours resulted in 80% yield of 1,3,5,7-tetranitro-2,4,6,8-tetrakis(trimethylstannyl)cubane (**2**), a stable, white solid, easily purified by column chromatography.[4]



Single-crystal X-ray structural analysis of **2** (Fig. 1) confirmed the assigned structure and revealed disorder amongst the nitro groups.[5] This is noteworthy, as commonly the intermolecular electrostatic interactions amongst highly polar nitro groups of nitro compounds, including other nitrocubanes,[6] result in a high degree of ordering. Apparently the bulky trimethylstannyl groups of **2** serve as 'umbrellas,' distancing the nitro groups of adjacent molecules and thus reducing their interactions. The closest intermolecular approaches of oxygen atoms in **2** are greater than 5.5 Å, whereas in tetranitrocubane **1** each of the four nitro groups is less than 3.0 Å from a nitro group atom on a neighboring molecule in the crystal.

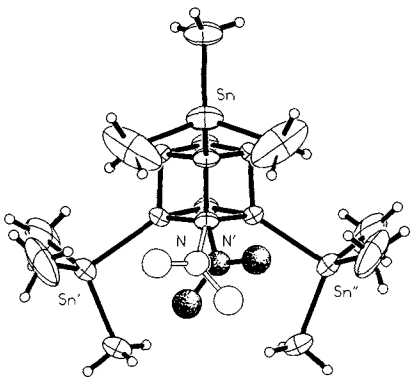


Fig. 1. The molecular structure of crystalline **2**. Anisotropic thermal ellipsoid envelopes are shown at the 25% population density level. For clarity, only one nitro group and the three closest stannyl groups are shown. The observed disorder (55:45) of the nitro groups is illustrated by the shaded (primed) and unshaded constituent atoms.

The general order for the rate of cleavage of carbon–tin bonds with electrophiles is ethynyl > phenyl > vinyl > methyl > butyl and thus correlates apparently with the acidity of the

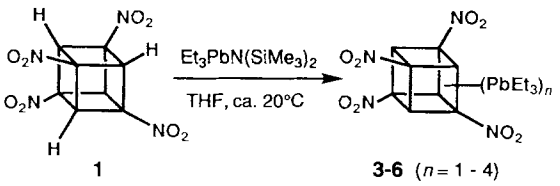
[**] We are grateful to our colleague Prof. Larry Sita for a stimulating conversation about tin amides. We thank Dr. Eric Punzalan for samples of **1**. This work was supported by The U.S. Army Research, Development and Engineering Center (Geo-Centers) and by the Office of Naval Research.

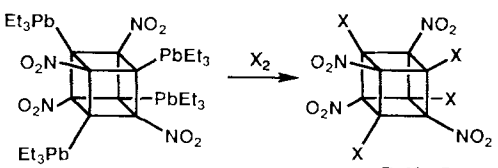
corresponding hydrocarbons.[7] Considering the increased acidity of tetranitrocubane, we quite expected that the cubyl–tin bond in compound **2** would be cleaved first by electrophiles. This is not the case. Reactions of **2** with various electrophiles (e.g. Br_2, $Hg(OAc)_2$, NO_2BF_4) under mild conditions resulted only in cleavage of methyl–tin bonds, leaving the cubyl–tin bonds intact.[8] Attempts to achieve complete cleavage of all carbon–tin bonds in **2** under forcing conditions were unsuccessful. Heating with liquid bromine (5 hours, 50 °C) only resulted in the cleavage of more tin–methyl bonds. We conclude that the tetranitrocubyl group resembles highly electron-deficient groups such as trifluoromethyl and pentachlorophenyl, whose bonds to tin are resistant to electrophiles.[9, 10]

As much of the chemistry of organolead compounds is different from that of other elements of Group IV-A,[11] we examined cubylplumbanes. [Bis(trimethylsilyl)amino]triethylplumbane[12] metalates tetranitrocubane **1** easily. Experiments monitored by NMR spectroscopy showed that the first metalation was much faster than that with the aminostannanes and was complete under comparable conditions after 1 minute at room temperature. Each subsequent metalation was slower, making possible selective synthesis and isolation of **3**–**6**, the four possible lead derivatives of **1**: the yield of the isolated monolead compound **3** was 40%, the dilead compound **4** 65%, the trilead compound **5** 80%, and the tetralead compound **6** 60%.[13] All are white, air-stable solids, somewhat sensitive to light.



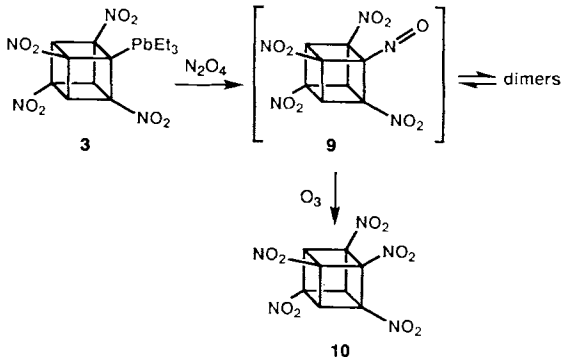
1 **3-6** (n = 1 - 4)

The reaction of the tetralead compound **6** with bromine was followed by ^{1}H NMR spectroscopy. In the beginning the order of cleavage of carbon–lead bonds was like that observed for the carbon–tin bonds in tetranitrocubylstannanes: one ethyl group was cleaved from each lead atom with formation of bromoethane. However, unlike the tin case, the cleavage by bromine continued readily, resulting ultimately in precipitation of lead bromide and formation of 2,4,6,8-tetrabromo-1,3,5,7-tetranitrocubane (**7**), isolated in 65% yield from a preparation on a 20 mmol scale.[14] The structure was confirmed by single-crystal X-ray diffraction analysis.[5, 6] Iodination of **6**, although slower than bromination, produced the corresponding tetraiodotetranitrocubane **8**, isolated in 50% yield.[15]



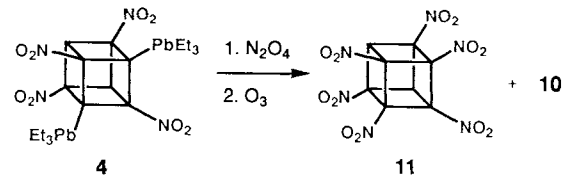
6 **7**; X = Br **8**; X = I

Although nitrodemetalation is a highly desirable reaction for organic synthesis, only a few specialized examples are known,[16] and none proved applicable to conversion of tetranitrocubyl tin or lead derivatives to more highly nitrated cubanes. Nitroso-demetalation has been applied somewhat more generally,[17] but never successfully to the cleavage of all four carbon–lead bonds in a tetraalkylplumbane.[18] Nonetheless, reaction of monolead derivative **3** of tetranitrocubane in dichloromethane at −15 °C with N_2O_4 gave lead nitrate cleanly (75% yield of isolated product; identification by IR spectroscopy). The two new organic products each had one singlet (δ = 6.32 and 6.41) in the ^{1}H NMR spectrum. Although their instability precluded identification, we suggest that they are the geometric isomers of the dimers of nitrosotetranitrocubane (**9**, unseen) and in equilibrium with it. Ozonolysis of the mixture in acetone/dichloromethane (1/5) produced pentanitrocubane **10** (higher than 90% yield by NMR spectroscopy, 70% after isolation), identical to that obtained from nitration of the sodium salt of tetranitrocubane.[1]



3 **9** **10**

Under the same conditions reaction of dilead compound **4** with N_2O_4 followed by ozonolysis gave a 40% yield of an isolated mixture of pentanitrocubane **10**[19] with hexanitrocubane **11** (40:60). The latter was separated by careful crystallization from 95/5 chloroform/acetonitrile and identified by comparison to an authentic sample.[1]



4 **11**

We have so far been unsuccessful in obtaining yet more highly nitrated cubanes from more highly metalated precursors, but our efforts continue, and we expect ultimate success.

Heterometallic Polymeric Cluster Compounds Derived from Tetrathiotungstate and Silver(I): Syntheses and Crystal Structures of $\{[AgWS_4]\}_n[NH_4]_n$ and $\{[W_4Ag_5S_{16}]\}_n[M(DMF)_8]_n$ (M = Nd and La)**

Qun Huang, Xintao Wu,* Quanming Wang, Tianlu Sheng, and Jiaxi Lu

Polymeric transition metal chalcogenides have attracted a great deal of attention because they have many useful properties that are derived from their low-dimensional structures.[1] Tetrathiometalates MS_4^{2-} (M = Mo, W), which are versatile reactants, have been used extensively for the syntheses of a variety of transition metal sulfides, including some polymeric structures.[2] Since the first polymeric M-Ag-S complex (PPh_4)-$AgMoS_4$ (linear chain) was identified by Müller et al. by resonance Raman spectroscopy in 1985,[3] only one report on such polymeric species has appeared.[4] Recently we obtained several W-Ag-S polymeric cluster complexes from the ammonium tetrathiotungstate/silver nitrate system, for example $\{[AgWS_4]\}_n$-$[H_3NC(CH_2OH)_3 \cdot H_2O]_n$[5] (double chain), which has a novel polymeric cluster anion double-chain structure and a hydrogen-bonded chain cation supermolecular structure; thus Ag^+ and WS_4^{2-} can self-assemble in different ways to form polymeric complexes with different configurations. We report herein on the syntheses and structures of polymeric cluster complexes **1**–**3** (DMF = *N*,*N*-dimethylformamide); in **2** and **3**, neodymium(III) and lanthanum(III) cations, respectively, were encapsulated into the one-dimensional W-Ag-S anion polymer.

$\{[AgWS_4]\}_n[NH_4]_n$ **1**

$\{[W_4Ag_5S_{16}]\}_n[M(DMF)_8]_n$ **2**, M = Nd; **3**, M = La

Lanthanoid complexes have many useful properties and have therefore found a large number applications,[6] for example as catalysts and luminescent materials. Lehn described that in the solid state europium(III) and terbium(III) cryptates can convert light energy extremely efficiently.[7] Encapsulation of such lanthanoid complexes into low-dimensional metal sulfides will possibly lead to materials with interesting properties.

The syntheses were all performed at room temperature in air.[8] Complex **1** was obtained by reacting ammonium tetrathiotungstate, silver nitrate, and D,L-valine (1:1:1) in DMF and H_2O. In contrast, complex **2** was produced by reacting ammonium tetrathiotungstate, silver nitrate, neodymium nitrate, and *p*-nitroaniline (2:4:1:2) in DMF and CH_3CN, and complex **3** was synthesized analogously to complex **2** except that lanthanum nitrate was used instead of neodymium nitrate. These three polymeric complexes were all synthesized by self-assembly, which represents an attractive route to molecular materials with novel solid-state properties.[9] In the synthesis of **1**, the addition of amino acid may prevent the formation of a dark AgS precipitate and support the polymerization of W-Ag-S. The above-mentioned syntheses imply that the valence of cation can influence the structure of W-Ag-S polymers obtained in this reaction system; for example, in the syntheses of **2** and **3**, trivalent cations Nd^{III} and La^{III} induced the formation of $[(W_4Ag_5S_{16})^{3-}]_n$ with trivalent anion cluster fragments as cyclic units. It is also expected that divalent and tetravalent cations can induce the formation of new structures of W-Ag-S polymers.

Complexes **1** and **2** were characterized by X-ray single-crystal analyses;[10, 11] the complexes crystallize in the tetragonal $I\bar{4}$ space group and the triclinic $P\bar{1}$ space group, respectively. The linear-chain structure of the anion of **1** is similar to that found in reference [4]; thus only details of the structure of **2** will be given here. However, it should be noted that the W–Ag bond length (2.928(1) Å) in **1** is much shorter than the values found in other W–Ag–S complexes reported previously (e.g. 2.948(1) Å in $\{[AgWS_4]\}_n[MePyH]_n$[4] (py = pyridine), 2.971(2) Å in $[(PPh_3)_3Ag_2WS_4 \cdot 0.8\,CH_2Cl_2]$,[12] and 2.997(2) Å in $[(PPh_3)_4Ag_4W_2S_8]$[13]); this suggests that Ag → WS_4 electron delocalization and much stronger continuous metal–metal interactions are present in this linear chain.[3] The ORTEP drawing of a section of the anion of **2** is shown in Figure 1. This one-dimensional polymeric anion is oriented along the crystallographic *c* axis, and can be regarded as octanuclear cyclic cluster fragments $[W_4Ag_4S_{16}]^{4-}$ linked through Ag^+ ions. In a $[W_4Ag_4S_{16}]^{4-}$

DMF = *N*,*N*-dimethylformamide.

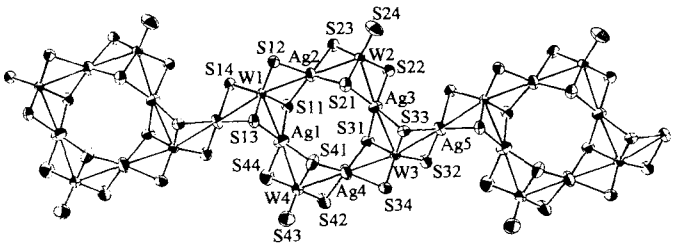

Fig. 1. ORTEP diagram of a section of the crystal structure of the one-dimensional polymeric complex **2** (50% displacement ellipsoids). Selected distances [Å] and angles [°]: W–Ag (av) 2.964(3), W–S_t (av) 2.128(11), W–(μ_2-S) (av) 2.190(9), W–(μ_3-S) (av) 2.248(9), Ag–S (av) 2.542(10); S-W-S (av) 109.4(4), S-Ag-S (av) 109.8(3), W-S-Ag (av) 76.6(3), Ag-S-Ag (av) 104.7(2), W-Ag-W (av) 173.1(1), Ag1-W1-Ag2 88.12(9), Ag1-W1-Ag5a 80.0(1), Ag2-W1-Ag5a 168.0(1), Ag2-W2-Ag3 87.39(9), Ag3-W3-Ag4 86.59(9), Ag3-W3-Ag5 80.53(9), Ag4-W3-Ag5 166.7(2), Ag1-W4-Ag4 88.6(1).

fragment, the W atoms form an approximate square, in which the Ag atoms nearly lie along the edges. The metals (W and Ag) reside in distorted tetrahedral environments; the S-W-S angles range from 106.4(4) to 113.6(5)°, and the S-Ag-S angles from 91.2(4) to 127.7(3)°. Since there are three kinds of sulfur atoms present in the anion, namely, terminal sulfur atoms, μ_2-S atoms, and μ_3-S atoms, the W–S lengths range from 2.123 to 2.268 Å. The mean W–S_t, W–(μ_2-S), and W–(μ_3-S) lengths are 2.128, 2.190, and 2.248 Å, respectively. In comparison, in discrete WS_4^{2-} ions the W–S_t length is 2.177 Å,[2a] whereas in $[WS_4Ag_3(PPh_3)_3\{S_2P(OCH_2CH_3)_2\}]$ the W–S_t, W–(μ_2-S), and W–(μ_3-S) lengths are 2.144(3), 2.217(2), and 2.242(3) Å, respectively.[14] The average W–Ag distance of 2.964 Å in complex **2** is shorter than those in $[(PPh_3)_3Ag_2WS_4 \cdot 0.8\,CH_2Cl_2]$[12] (2.971 Å) and $[WS_4Ag_3(PPh_3)_3\{S_2P(OCH_2CH_3)_2\}]$[14] (3.080 Å), but much longer than that in complex **1** (2.928 Å).

Each Nd^{III} cation in **2** is coordinated by eight DMF molecules; the average Nd–O bond length is 2.43 Å. These simple complex ions $[Nd(DMF)_8]^{3+}$, which function as larger trivalent cations, crystallize with the one-dimensional cluster anions $[(W_4Ag_5S_{16})^{3-}]_n$ from the solution. Figures 2 and 3 show the packing viewed along the *b* and *c* axes, respectively. As shown in Figure 3, the $[Nd(DMF)_8]^{3+}$ ions, which are well separated from each other and from cluster anions, are positioned between the cluster anion chains, and are arranged linearly along these chains. The distance between two neighboring Nd atoms along these chains (i.e. along the crystallographic *c* axis) is 12.608 Å.

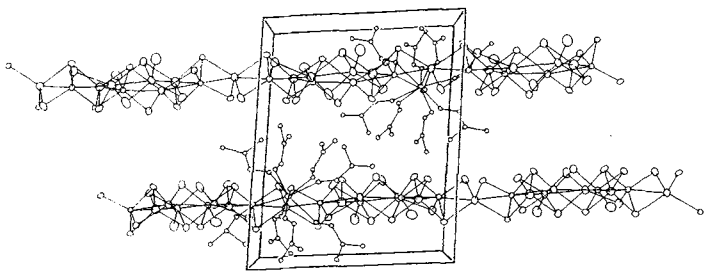

Fig. 2. Packing drawing of **2** viewed along *b* axis.

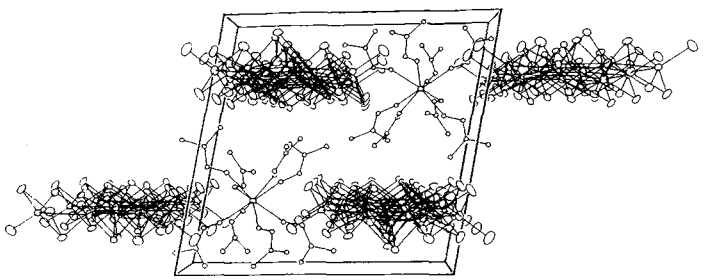

Fig. 3. Packing drawing of **2** viewed along *c* axis.

Experimental Procedure

1: To a solution of $AgNO_3$ (0.17 g, 1 mmol) and D,L-valine (0.12 g, 1 mmol) in H_2O (3 mL) was added a solution of $(NH_4)_2WS_4$ (0.35 g, 1 mmol) in DMF (5 mL). The dark precipitate was filtered off; 0.17 g of orange-red crystals of **1** were obtained by layering the orange-red filtrate with *n*-pentane and methanol.

2: A solution of $AgNO_3$ (0.68 g, 4 mmol), $Nd(NO_3)_3 \cdot 6H_2O$ (0.44 g, 1 mmol), and *p*-nitroaniline (0.28 g, 2 mmol) in CH_3CN (15 mL) was added to a solution of $(NH_4)_2WS_4$ (0.70 g, 2 mmol) in DMF (5 mL). The dark precipitate was filtered off; 0.30 g of red crystals of **2** were obtained by allowing the red filtrate to stand in air for one day.

3: A procedure similar to that for the synthesis of **2** was employed except that $La(NO_3)_3 \cdot 6H_2O$ was used instead of $Nd(NO_3)_3 \cdot 6H_2O$. Allowing the red filtrate to stand in air for one day gave 0.30 g of red crystals of **3**.

All the above complexes gave satisfactory elemental analyses [8].

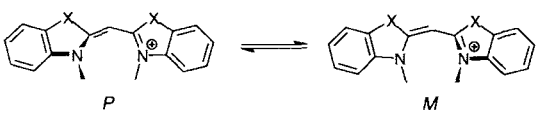
The First C_2-Symmetric, Chiral Monomethine Dye—An Apparent Violation of the Helicity Rule for Optical Rotation**

Lutz Eggers, Volker Buss,* and Gerald Henkel

Dedicated to Professor Fritz P. Schäfer on the occasion of his 65th birthday

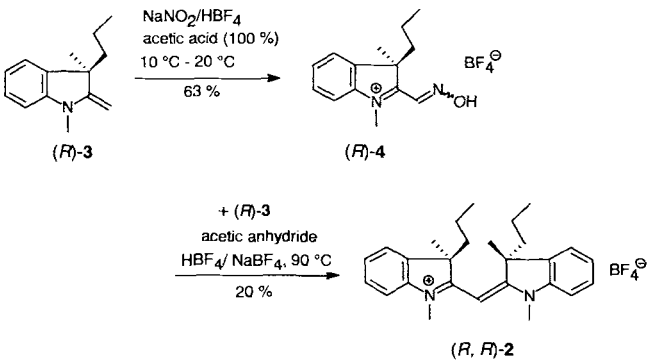
Steric interactions prevent the chromophore in the monomethine cyanine **1**[1] from attaining the planar geometry preferred by conjugated π systems: the X-ray structure of the tetrafluoroborate salt of **1**[2] reveals a twisted *cis,cis* conformation with an angle of 43° between the two indolenine end groups. In solution the two oppositely twisted forms equilibrate rapidly: the barrier to interconversion, determined by dynamic ^{1}H NMR spectroscopy,[3] is 50.0 kJ mol^{-1}.



X = $C(CH_3)_2$ **1**
X = $C(CH_3)C_3H_7$ **2**

In an achiral environment, the two interconverting conformations are enantiomers and cannot be distinguished. Chiral interaction, for example the introduction of a chiral group into the molecule, should remove the degeneracy, converting the oppositely twisted enantiomers into diastereomers, and render them susceptible to chiroptical methods. To this end, we have synthesized the chirally substituted symmetrical monomethine cyanines (*R,R*)-**2** and (*S,S*)-**2** and determined the absolute configuration by X-ray analysis. The observed Cotton effects apparently contradict established rules for optical rotation.

The key intermediates in the synthesis of **2** are the chiral 2-methylene indolines **3**, which were obtained by dimethylation of 2-methyl-3-propylindole[4] and subsequent resolution of the enantiomers with di-*O*-benzoyltartaric acid, a method recently described by Reichardt et al.[5] Reaction with their respective hydroximinium salts **4**[1, 6] yielded both enantiomers of **2**, which after recrystallization from ethanol/diethyl ether proved to be diastereomerically pure[7] (Scheme 1).



Scheme 1. Syntheses of the monomethine (*R,R*)-**2**.

The structure of what turned out to be (*R,R*)-**2** was determined by single-crystal X-ray analysis of the perchlorate (Fig. 1).[8] In the crystal the molecule adopts a twisted *cis,cis* configuration along the conjugated chain of five atoms from N(1) to N(1′). The overall structure is thus very similar to the one reported for **1**.[2]

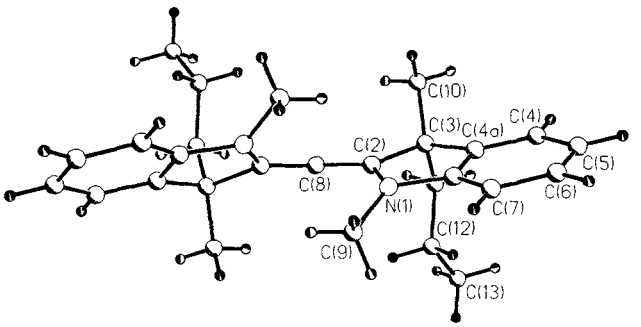


Fig. 1. Crystal structure of (*R,R*)-**2** as perchlorate. Selected bond lengths [pm]: N(1)–C(2) 138.9, C(2)–C(8) 139.0, N(1)–C(7a) 142.7, C(2)–C(3) 152.9. Selected dihedral angles [°]: C(2)-C(8)-C(2′) 129.07, C(2)-C(3)-C(4a) 101.5.

The dihedral angle between the essentially planar indolenine groups and the central plane formed by carbon atoms C(2)-C(8)-C(2′) is 26.8° compared to 21° and 27° in **1**. The out-of-plane deformation of the chromophore is caused by the two *N*-methyl groups that are bent away from each other but still have a nearest H–H distance of only 275.6 pm.

The absolute configuration of the two chiral centers C(3) and C(3′) is identical, which means that the integrity of the chiral center of **3** was conserved throughout the conversion into **2**. There is, of course, another element of chirality present in **2**, namely, the twist of the two indoline rings against each other. The sense of twist in (*R,R*)-**2** is positive: looking along the axis C(2)–C(2′), the front group has to be turned clockwise to eclipse the bonds N(1)–C(2) and N(1′)–C(2′). Consequently a *P*-helical[9] conformation is assigned to this enantiomer in the solid state. In (*S,S*)-**2**, this rotation has to be anticlockwise, so the conformation is *M*.

The UV/Vis spectra of (*R,R*)- and (*S,S*)-**2** are identical, as expected. Position (438 nm) and intensity ($\lg \varepsilon = 4.57$) of the cyanine band resemble that of **1** and other monomethine cyanines.[10] The CD spectra of (*R,R*)- and (*S,S*)-**2** (Fig. 2) exhibit

[**] This work was supported by the Deutsche Forschungsgemeinschaft. For the opportunity to use NMR facilities, we thank Prof. Dr. W. Grahn, Braunschweig.

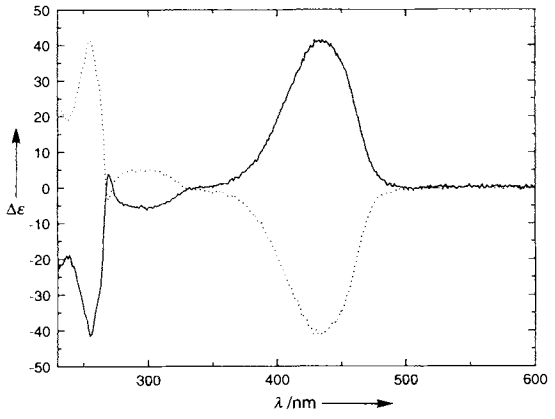

Fig. 2. CD spectra of (*R,R*)-**2** ($c = 4.425 \times 10^{-5}$ mol L^{-1} (····)) and (*S,S*)-**2** ($c = 3.94 \times 10^{-5}$ mol L^{-1} (——)) in ethanol/methanol 4/1 at 23 °C.

perfect mirror symmetry showing that the optical purity of the enantiomers, which were synthesized essentially independently of each other, is very high. The most prominent CD absorption occurs in the region of the cyanine band, where its maximum coincides exactly with the maximum of the UV/Vis band. Another CD absorption around 250 nm is probably due to excitations of the indolenine end groups coupled through the cyanine chromophore.

In solutions of **1**, rapid interconversion (on the NMR time scale[3]) of the enantiomers leads to a racemic mixture of the *P*- and *M*-helical conformation. Likewise, a fast equilibrium between the *M* and *P* form is established in **2**, which for this mixture of diastereomers can, however, never be 1:1. Lower temperatures should shift the equilibrium towards the more stable diastereomer, an effect that should be observable in the CD spectra.

The temperature-dependence of the CD spectra of (*R,R*)-**2** (Fig. 3) shows that this assumption is correct. Lowering the

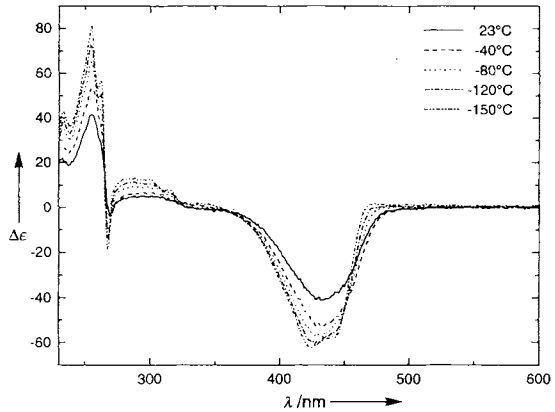

Fig. 3. Temperature-dependent CD spectra of (*R,R*)-**2** in ethanol/methanol 4/1; $c = 4.425 \times 10^{-5}$ mol L^{-1}; temperatures from 23 °C to −150 °C.

temperature to −150 °C increases the amplitudes of all bands by about one half. Analysis of the data in terms of an equilibrium between the *P* and *M* diastereomers[11] fails to converge with meaningful results. Additional data, preferably at elevated temperatures, would probably improve the analysis. However, if as an additional restraint, the two components are assumed to have comparable, but opposite strengths, the model yields a free energy difference of 4 kJ mol^{-1}, but with a correlation coefficient of only 0.85. Whatever the exact numbers, the only plausible interpretation of the spectra is a shift of the equilibrium at low temperature towards the diastereomer with negative rotatory strength at the long-wavelength cyanine band. It is probable, but by no means imperative, that this more stable conformation also corresponds to the structure found in the X-ray analysis for (*R,R*)-**2**, which means that it has a *P*-helically twisted chromophore.

With their delocalized π-electrons constrained to move on a helical path, twisted cyanine dyes are paradigmatic of inherently chiral, open chain π systems, just as the helicenes are for aromatic compounds.[12] For inherently chiral chromophores the sign of the Cotton effect is determined by the screw sense of the transition charge density[13]—which is definitely positive in the case of (*R,R*)-**2**. Does the observed negative rotatory strength for a cyanine with *P*-helical twist violate this rule?

CNDO/S calculations for the chromophore (N(1) to N(1')) of (*R,R*)-**2** with coordinates taken from the X-ray structure show that this is not the case. The calculated rotational strength is -174×10^{-40} cgs units, the experimental value from the integrated area under the CD band at −150 °C is -188×10^{-40} cgs units, a more than satisfactory agreement. The apparent discrepancy with what one would expect on the basis of helical charge movement is resolved by a component analysis. The calculated rotatory strength *R* is the sum of two contributions, $R_\parallel$ corresponding to the component parallel to the helix axis (Fig. 4) and $R_\perp$ to the component perpendicular to this axis

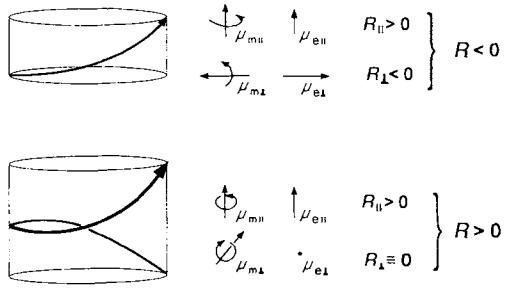

Fig. 4. Rotational strength of electronic charge movement with *P*-helical screw sense and its dependence on helix length. The magnetic moments μ_m are obtained from the charge rotation and the right-hand-rule, the electric moments μ_e from the charge translation. The rotatory strength *R* (that is, the scalar product of these vectors) is positive when the vectors point in the same direction and negative when they point in opposite directions. Top: The positive parallel component of *R* is more than cancelled by the negative contribution of the perpendicular component, leading to an overall negative *R* and negative Cotton effect. Bottom: helix with one complete turn. The perpendicular component is approximately zero because of the (approximately) vanishing perpendicular electric transition moment, leading to a positive *R* and positive Cotton effect.

(which is not the C_2 symmetry axis!). These components are obtained, respectively, as the products of the parallel and perpendicular components of the electric and magnetic transition moments. The calculated values are +3 for $R_\parallel$ and -177×10^{-40} cgs units for $R_\perp$. Because of the much larger contribution of the perpendicular component, the total rotatory strength is negative.[14]

It is evident that the sign and magnitude of the rotatory strength are strongly dependent on the particular structural parameters of the helix. Increasing the twist of the chromophore, which corresponds to a greater turn on the helical path, will lead to a larger parallel component of the electric moment and thus to an increase of the positive contribution to *R*. Likewise, increasing the length of the twisted chromophore will result in a smaller perpendicular component of the electric

transition moment and a decrease of the negative contribution to R. Figure 4 illustrates what happens after one turn of the helix is complete. Because of the very small perpendicular electric transition moment the rotatory strength is now derived exclusively from the parallel component of R, which for a P helix is, of course, positive.

We conclude that the negative rotatory strength of the P-helical cyanine dye (R,R)-**2** is not a violation, but rather a confirmation of the rules that connect the screw sense of helical charge movement with the sign of the observed Cotton effect.

Formation of a Novel μ-Nonasulfido Ligand and Its Degradation into a μ-Disulfido Ligand at a Diiridium Center**

Masayuki Nishio, Hiroyuki Matsuzaka, Yasushi Mizobe, and Masanobu Hidai*

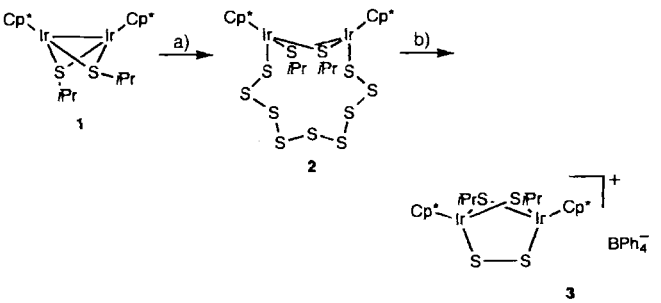
The reactivity of complexes containing two or more metals in close proximity is now attracting significant attention, since activation and reactions of substrates at the multimetallic center in these complexes may lead to novel reactions that are not possible at the monometallic center. We have recently shown that thiolato-bridged diruthenium complexes can undergo unique transformations of various substrates such as terminal alkynes and hydrazines.[1] These studies have subsequently been extended to the preparation of the related thiolato-bridged dirhodium and diiridium complexes. Thereby we have found that the Ir^{II} complex **1**[2] (Cp* = η^5-C_5Me_5) reacts with S_8 to give the dinuclear Ir^{III} complex **2** that contains a novel μ-S_9 ligand. Herein we report on the synthesis and characterization of **2** as well as on its reaction with $NaBPh_4$ that leads to the paramagnetic diiridium μ-S_2 complex **3**.

[Cp*Ir(μ-S*i*Pr)$_2$IrCp*] **1**

[Cp*Ir(μ-S*i*Pr)$_2$(μ-S_9)IrCp*] **2**

[Cp*Ir(μ-S*i*Pr)$_2$(μ-S_2)IrCp*][BPh_4] **3**

Treatment of **1** with excess S_8 (S/Ir ≈ 5) in toluene at room temperature gave an orange precipitate of **2**, which was crystallized from $CHCl_3$/hexane and isolated as an orange crystalline solid in 38% yield (Scheme 1). The structure of **2** was deter-



Scheme 1. Reagents and conditions; a) S_8, toluene, room temperature; b) $NaBPh_4$, CH_2Cl_2/THF, room temperature.

mined by X-ray analysis (Fig. 1).[3] The most remarkable feature of **2** is a unique bridging nonasulfido chain, which is bonded at each end to an Ir atom.

Although polysulfido ligands are ubiquitous in various metal complexes,[4] the nonasulfido ligand is, to our knowledge, that with the longest sulfur chain, and the known examples are limited to the monometallic complexes $[MS_9]^-$ (M = Ag,[5] Au[6]). The present reaction differs significantly from that of the related Ru complexes [Cp*Ru(μ-SR)$_2$RuCp*] with S_8, in which

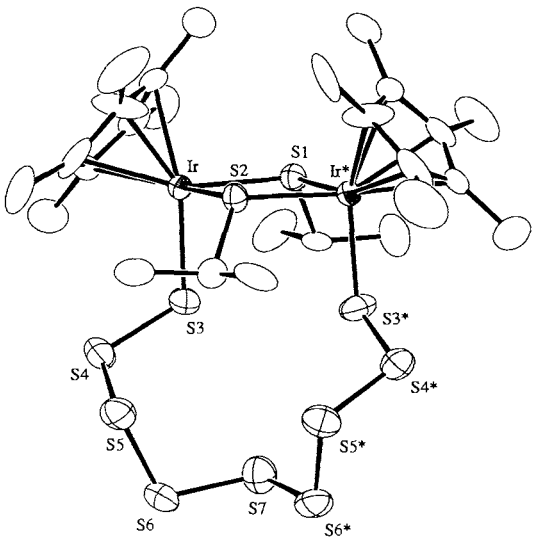

Fig. 1. Crystal structure of **2**. Selected bond lengths [Å], angles [°], and torsion angles [ ]: Ir···Ir* 3.702(1), Ir-S(1) 2.393(4), Ir-S(2) 2.366(4), Ir-S(3) 2.360(4), S(3)-S(4) 2.048(7); S(4)-S(5) 2.062(7), S(5)-S(6) 2.051(6), S(6)-S(7) 2.048(7), Ir-S(3)-S(4) 114.3(2), S(3)-S(4)-S(5) 108.5(3), S(4)-S(5)-S(6) 105.5(3), S(5)-S(6)-S(7) 106.4(3), S(6)-S(7)-S(6)* 109.4(5); Ir-S(3)-S(4)-S(5) 107.7(3), S(3)-S(4)-S(5)-S(6) 84.0(3), S(4)-S(5)-S(6)-S(7) 80.5(4), S(5)-S(6)-S(7)-S(6)* 94.2(4).

the μ-S_2 complexes [Cp*Ru(μ-SR)$_2$(μ-S_2)RuCp*] (R = *i*Pr,[7] *t*Bu[8]) are formed exclusively.

The structure of **2** contains a crystallographically imposed mirror plane that bisects the Ir–Ir vector. The interatomic distance between the two Ir atoms (3.702(1) Å) suggests the absence of any direct metal–metal interaction. The $Ir_2S(1)S(2)$ core is almost planar, and the two *i*Pr groups attached to these sulfur atoms adopt a *cis* configuration. The metrical parameters in the μ-S_9 ligand (S–S distances, 2.048(7)–2.062(7) Å; S-S-S angles, 105.5(3)–109.4(5)°) are not unusual and are comparable to those in S_8[9] and $[MS_9]^-$ (M = Ag, Au). The heptasulfido array from S(4) to S(4)* is bent towards the S(2) thiolato ligand; therefore, the two *i*Pr groups are nonequivalent in the solid state.

In accordance with this structure, the ^{1}H NMR spectrum of **2** recorded at −40 °C exhibits two doublets at δ = 0.83 and 1.16 and two septets at δ = 1.87 and 2.20 assignable to the two *i*Pr groups, together with a singlet at δ = 1.54 for the methyl protons in the Cp* ligands. Upon warming the sample to room temperature, the *i*Pr methyl resonances coalesced to one broad singlet, while the Cp* singlet remained essentially unchanged presumably indicating the fluxional nature of the μ-S_9 ligand at the higher temperatures.

Interestingly, treatment of **2** with $NaBPh_4$ (3 equiv) in CH_2Cl_2/THF at room temperature resulted in the degradation of the μ-S_9 ligand. This was accompanied by the one-electron oxidation of the dimetallic center leading to the formal Ir^{III}/Ir^{IV} complex **3**. The fate of the eliminated "S_7^-" unit could not be clarified. The product **3**, which was isolated as dark green crystals in 44% yield, is paramagnetic; its EPR spectrum (CH_2Cl_2) shows a broad singlet at $g \approx 2.07$. The structure of **3** was confirmed by X-ray analysis.[3] As shown in Figure 2, the cation in **3** has a dinuclear structure, in which two Cp*Ir units are bridged by one S_2 and two S*i*Pr ligands. The Ir(1)Ir(2)S(1)S(2) core in **3** is puckered with a dihedral angle of about 143.1° around the S–S vector, while the Ir(μ-S_2)Ir moiety is essentially planar (Ir(1)-S(3)-S(4)-Ir(2) torsion angle, 0.9(3)°); the Ir–S (disulfido) distances (Ir(1)–S(3), 2.334(3); Ir(2)–S(4), 2.389(4) Å) fall in the expected range for Ir–S single bonds.[10] The S–S distance in the disulfido ligand of 1.997(5) Å is substantially shorter than

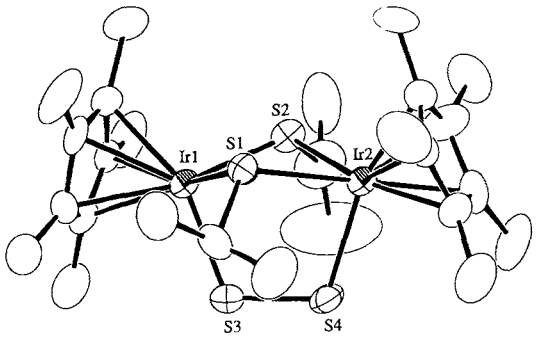

Fig. 2. Crystal structure of the cation in **3**. Selected bond lengths [Å] and angles [°]: Ir(1)···Ir(2) 3.5559(6), Ir(1)-S(1) 2.384(3), Ir(1)-S(2) 2.263(4), Ir(1)-S(3) 2.334(3), Ir(2)-S(1) 2.463(3), Ir(2)-S(2) 2.384(3), Ir(2)-S(4) 2.389(4), S(3)-S(4) 1.997(5); Ir(1)-S(3)-S(4) 108.8(2), Ir(2)-S(4)-S(3) 109.7(2).

that in HSSH (2.055 Å),[9] and comparable to those of η^1:η^1-S_2 ligands in known diruthenium complexes.[7, 11] The distance between the two Ir atoms (3.5559(6) Å) implies the absence of a metal–metal bonding interaction. Since no significant difference is observed in the coordination environment around each Ir atom, it can be assumed that the unpaired electron is delocalized over the two Ir atoms and the μ-S_2 ligand.

Presumably, the degradation involves the heterolytic cleavage of the S–S bond in the μ-S_9 ligand induced by interaction with Na^+. To obtain some insights into this reaction, the redox properties of **2** and **3** were examined by cyclic voltammetry.[12] The cyclic voltammogram of **3** reveals two reversible and one irreversible waves at $E_{1/2}$ = −0.45 and +0.66 V, and E_p = +1.3 V, respectively, assignable to the redox couples $[Ir^{III}/Ir^{III}]/[Ir^{III}/Ir^{IV}]$, $[Ir^{III}/Ir^{IV}]/[Ir^{IV}/Ir^{IV}]$, and $[Ir^{IV}/Ir^{IV}]/[Ir^{IV}/Ir^{V}]$, respectively. In contrast, the cyclic voltammogram of **2** exhibits one irreversible wave at E_p = +0.58 V, assignable to a one-electron oxidation process which appears to correlate with the degradation reaction of the ligand. Thus, the cyclic voltammogram of the oxidation product generated at this potential is essentially similar to that of **3**, showing two reversible waves at $E_{1/2}$ = −0.44 and +0.65 V. This finding strongly suggests that the species generated from **2** by electrochemical oxidation is quite unstable and is rapidly converted into the cation [Cp*Ir(μ-S*i*Pr)$_2$(μ-S_2)IrCp*]$^+$ by degradation of the μ-S_9 ligand.

Experimental Procedure

2: To a solution of **1** (541 mg, 0.672 mmol) in toluene (20 mL) was added S_8 (200 mg, 0.780 mmol), and the mixture was stirred at room temperature for 12 h. An orange solid precipitate was filtered off and dried in vacuo. Recrystallization from $CHCl_3$/hexane gave **2** as an orange crystalline solid (282 mg, 38.4%). C,H analysis: calcd: C 28.55, H 4.05; found: C 28.54, H 4.10.

3: To a solution of **2** (75 mg, 0.069 mmol) in CH_2Cl_2 (20 mL) was added $NaBPh_4$ (70 mg, 0.20 mmol) in THF (15 mL), and the mixture was stirred at room temperature for three days. After removal of the solvent in vacuo, the resulting dark green solid was extracted with CH_2Cl_2. Addition of hexane to the concentrated extract gave **3** as dark green needles (33 mg, 44%). C,H analysis: calcd: C 50.53, H 5.43; found: C 50.00, H 5.58.

The Influence of Substituents on the Formation of Liquid Crystals Induced by Hydrogen Bonds**

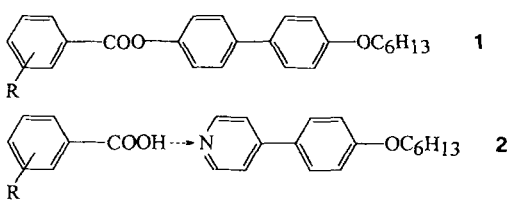
Henry Bernhardt, Wolfgang Weissflog, and Horst Kresse*

Pauling pointed out as early as the late 1930s that the physiological importance of hydrogen bonding exceeds that of any other structural property.[1] Hydrogen bonds are directional and offer one of the most effective ways to selectively influence the properties of organic materials by self-assembly of the building blocks.[2] Hydrogen bonds can also play a very important role in the formation of liquid crystalline phases. Lyotropic liquid crystals are essentially stabilized by the interaction of amphiphilic molecules with protic solvents such as water through hydrogen bonding. Thermotropic liquid crystals are formed by self-assembly of anisotropic, often rodlike molecules. These molecules may be replaced by hydrogen-bonded associates of identical or different components, as is the case for 4-*n*-alkoxybenzoic acids. The characterization of mixed associates formed from 4-substituted benzoic acids was first accomplished by Kresse et al. by dielectric investigations.[3, 4] In the meantime, liquid crystals in which intermolecular hydrogen bonding plays a key role in the formation have developed into an interesting area of research.[5] Associates formed from benzoic acid and pyridine derivatives, which were introduced by Kato, Fréchet et al.,[6, 7] have proven to be very promising examples.

It is also possible to form thermotropic mesophases from molecules whose shape differs significantly from a rodlike form. For instance, there are mesogens that are laterally alkyl- or aryl-substituted or terminally branched to a large extent.[8] So far, our attempts to model such mesogens by associates that are linked by hydrogen bonds have resulted in liquid crystalline aggregates in only a few cases.[9] We report here on the influence of the strength of hydrogen bonds on the induction of liquid crystalline properties by using the simple model system pyridine–benzoic acid as an example.

The formation of a single associate between a carboxylic acid and a pyridine derivative is primarily affected by the acidity of the acid (H donor) and the basicity of the pyridine derivative (H acceptor). When a specific pyridine derivative is used, the strength of the hydrogen bonds is dependent only on the acidity of the respective acid. Thus, we investigated the association behavior of 4-(4-*n*-hexyloxyphenyl)pyridine[10] towards substituted benzoic acid derivatives.

Based on inductive and mesomeric effects, different substituents in various positions of the benzoic acid generally determine not only the strength of the hydrogen bonds, but also the thermal stability of liquid crystalline phases. If the strength of the hydrogen bonds is to be correlated with the mesophase behavior in our pyridine–benzoic acid system, the influence of both steric and polar effects on the mesogenic properties has to be eliminated. Thus, we synthesized the benzoates **1** containing an analogous substitution pattern,[11] and compared their mesophase behavior (Table 1) with that of the corresponding associates **2** formed by hydrogen bonding (Table 2). The stabil-



1 **2**

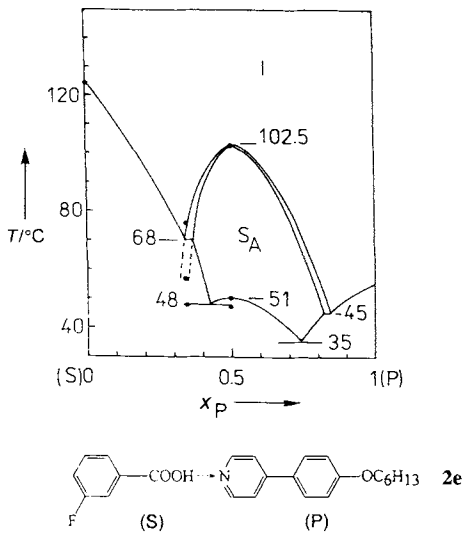
ity of the resulting liquid crystalline state is usually assessed by the clearing temperatures; the nature of the resulting phase types was not considered.

The 1:1 associates **2** were prepared from equimolar amounts of the pure components by fusing, subsequent mixing, and crystallization. The transition temperatures and the phase behavior were determined with a heatable polarizing microscope, and were verified by calorimetric measurements (DSC 7, Perkin-Elmer). The number of suitable benzoic acid derivatives is unfortunately rather low due to the high melting points of many derivatives. Nevertheless, the substituents used allowed the Hammett constant to be varied over a wide range.

A representative phase diagram is shown in Figure 1 for the system 4-(4-*n*-hexyloxyphenyl)pyridine/3-fluorobenzoic acid.



2e

Fig. 1. Phase diagram of 3-fluorobenzoic acid (S) and 4-(4-*n*-hexyloxyphenyl)-pyridine (P).

The formation of a compound in the solid state can be identified by the presence of two eutectic points. In this case mesophases are generally induced by association of two non-liquid crystalline components. The determination of the clearing point of the associate **2d** in the metastable region proved problematic, since the associate could not be supercooled sufficiently. Therefore, a so-called virtual clearing point was determined by linear extrapolation upon admixing of the liquid crystalline compound **3** (K 135 S_A 217 N 218 I) (Fig. 2). This procedure can be justified considering the linearity of the transition temperatures S_A/I in the range $0.25 \leq x_3 \leq 0.75$, which also indicates the chemical similarity of the substance classes **2** and **3**.

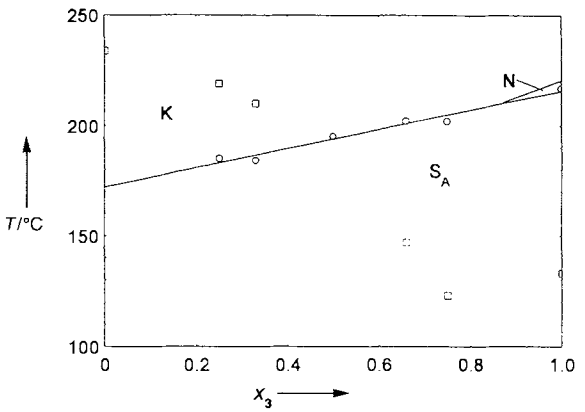


Fig. 2. Determination of the virtual clearing point of the associate **2d** by admixing of compound **3**. The circles indicate the transition temperatures S_A/I and S_A/N, the squares indicate the ends of the melting ranges.

The transition temperatures of the single associates **2a**–**2f** are summarized in Table 2 and can be compared to the mesophase behavior of the corresponding benzoates of 4-*n*-hexyloxy-4′-hydroxybiphenyl **1a**–**1f** (Table 1). The differences in the clearing points of the respective pairs (i.e. $T_{2a} - T_{1a} = \Delta T = -94$ K) were plotted against the Hammett constants σ of the substituents of the benzoic acids (Fig. 3).[12] Because of its large

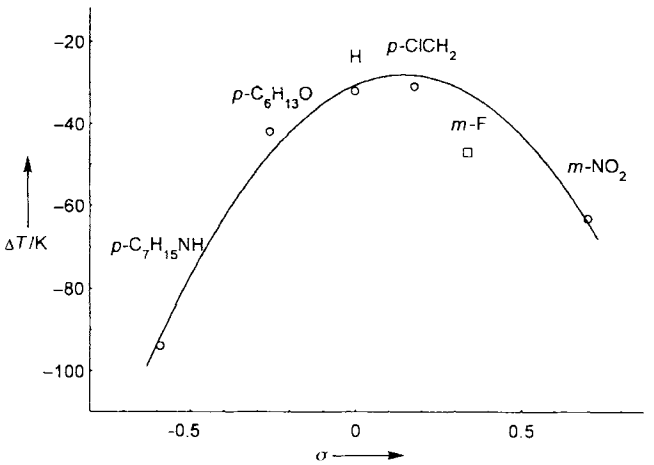

Fig. 3. The clearing point differences ΔT as a function of the Hammett constant and weighted quadratic curve for the substituents indicated by circles.

error, the value for R = *m*-F was not used in the determination of the weighted quadratic curve. Larger differences $|\Delta T|$ indicate a reduced tendency of the associates to form a liquid crystalline state. The investigated system exhibits a maximum of the stability of the liquid crystalline state for weakly electron-withdrawing substituents. An increase in the clearing point differences for small σ values reflects the reduced ability of the acids to make the acidic proton available for hydrogen bonding. Higher σ values lead to stronger hydrogen bonding; however, deviations from the 180° arrangement, no longer meet the steric requirements for the formation of thermotropic mesophases. The increasing charge separation leads to ionic pyridinium salts, which are potentially interesting as lyotropic liquid crystals.

For pyridines of similar basicity, such as 4-alkyl- and 4-alkoxypyridines, esters of 4-hydroxypyridine, and substituted stilbazoles, enantiotropic liquid crystalline associates with 4-*n*-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3508-0875 $ 15.00+.25/0

alkyl- and 4-*n*-alkoxybenzoic acids are known.[6, 7, 13] The substituent constants of the benzoic acids employed deviate only slightly from the optimal value in Figure 3 which suggests that they show a principally identical association behavior. For less basic pyridines, such as isonicotinates, it can be assumed that similar dependencies apply, but the optimal acidity of the respective acid should be shifted in this case. By systematically varying the acidity, it should be possible to find optimal mixing partners for any pyridine derivative. Thus, this method provides a simple way to model covalent liquid crystalline compounds by hydrogen-bonded molecules. The goal of developing novel liquid crystals using hydrogen-bonded associates can be achieved more efficiently by taking electronic substituent effects into consideration.

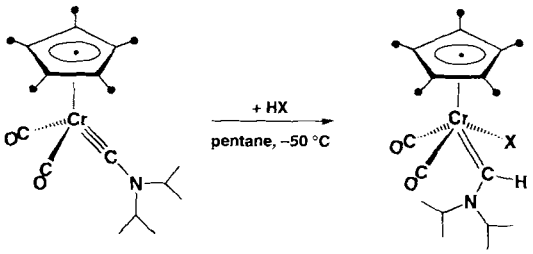
Carbene Complexes of Divalent Chromium**

Alexander C. Filippou,* Dirk Wössner, Bernhard Lungwitz, and Gabriele Kociok-Köhn

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

Numerous mononuclear chromium(0) carbene complexes have been synthesized since their discovery by E. O. Fischer.[1] These compounds have achieved a certain status in organometallic chemistry and in organic synthesis.[2, 3] In comparison, carbene complexes of chromium in higher oxidation states are quite rare. Several Cr^I carbene complexes have been prepared by oxidation of Cr^0 precursors[4] and by transmetalation of $[(tmeda)CrCl_2]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) with $LiCH_2Ph$.[5] In contrast, carbene complexes of divalent chromium have not been described previously, although analogous molybdenum(II) and tungsten(II) complexes are well known.[6] We report here the synthesis, structure, and reactions of the first chromium(II) carbene complexes.

The reaction of **1a**[7] with one equivalent of anhydrous HCl (or HBr) in pentane at −50 °C provided the chromium(II) aminocarbene complexes **2a** and **3** selectively [Eq. (a); the filled

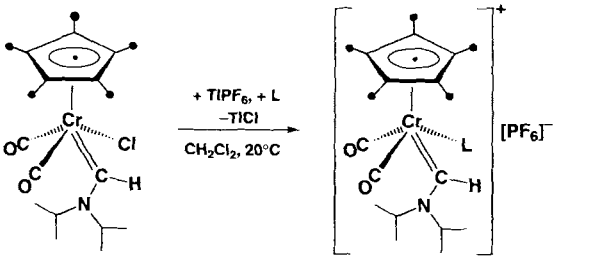


(a)

1a **2a**, X = Cl; **3**, X = Br

circles on the cyclopentadiene ligand represent methyl groups]. These products were isolated as red solids, which decompose on melting at 57 and 47 °C, respectively. In solution below 0 °C they decompose to give a mixture of **1a** and blue, carbonyl-free, paramagnetic products of unknown composition. Complexes **2a** and **3** thus display a significantly lower thermal stability than the analogous tungsten complexes $[Cp^*(CO)_2(X)W{=}C(H)NEt_2]$ ($Cp^* = C_5Me_5$; X = Cl, Br, I) (m.p. 137–150 °C).[6h] The same approach can be used to prepare the red, thermally labile aminocarbene complex $[Cp(CO)_2(Cl)Cr{=}C(H)NiPr_2]$ **2b** from HCl and $[Cp(CO)_2Cr{\equiv}CNiPr_2]$ **1b**.

When the halogeno ligand in **2a** and in **3** is abstracted with $TlPF_6$ in the presence of isocyanides, phosphanes, or phosphites, thermally stable aminocarbene complexes of divalent chromium are obtained, as demonstrated by the selective conversion of **2a** into **4a** and **5** [Eq. (b)], and by the synthesis of the



(b)

2a **4a**, L = EtNC; **5**, L = P(OMe)$_3$

cyclopentadienyl complexes $[Cp(CO)_2(L)Cr{=}C(H)NiPr_2]PF_6$ (**4b**: L = EtNC; **6**: L = *t*BuNC; **7**: L = PMe_3) from **2b**. These compounds also provide access to more electron-rich Cr^{II} carbene complexes by substitution of a carbonyl ligand. For example, the reaction of **4a** with EtNC yields the salt **8** [Eq. (c)]. The cationic Cr^{II} carbene complexes were isolated as yellow (**4a**, **4b**, **5**, **6**, **7**) and brown (**8**), thermally stable solids.

The composition and structures of **2**–**8** were supported by the results of elemental analyses, IR and NMR spectroscopy, and mass spectrometry (Table 1). In the IR spectra of the Cr^{II}

Table 1. Selected spectroscopic data for complexes **2**–**8** [a, b].

2a: m.p. 57 °C (decomp); IR (CH_2Cl_2, −40 °C): $\tilde{\nu}$ [cm^{-1}] = 1942 vs, 1856 vs (CO); 1527 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −15 °C): δ = 1.14 (d, 3H, $CHMe_A$), 1.23 (d, 3H, $CHMe_B$), 1.24 (d, 3H, $CHMe_C$), 1.34 (d, 3H, $CHMe_D$), 1.70 (s, 15H, C_5Me_5); 3.87 (sept., 1H, $CHMe_{A,B}$), 4.24 (sept., 1H, $CHMe_{C,D}$), 11.29 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −15 °C): δ = 9.7 (C_5Me_5), 19.4, 21.3, 24.0, 24.2 (2 × $CHMe_2$), 51.4, 60.7 (2 × $CHMe_2$), 104.1 (C_5Me_5), 260.3 (Cr=C; ^1J(C,H) = 129.5 Hz), 260.5, 263.8 (CO); EI-MS (70 eV): *m/z*: 355 [M^+ − HCl], 327 [M^+ − HCl − CO], 312 [M^+ − HCl − *i*Pr], 299 [M^+ − HCl − 2CO], 284 [M^+ − HCl − *i*Pr − CO], 256 [M^+ − HCl − 2CO − *i*Pr], 214 [M^+ − HCl − 2CO − *i*Pr − MeC(H)=CH_2], 187 [M^+ − HCl − 2CO − *i*Pr − MeC(H)=CH_2 − HCN].

2b: IR (CH_2Cl_2, −40 °C): $\tilde{\nu}$ [cm^{-1}] = 1960 vs, 1875 vs (CO); 1535 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −80 °C): δ = 12.31 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −80 °C): δ = 254.2 (Cr=C; ^1J(C,H) = 135.5 Hz), 258.6, 261.4 (CO).

3: m.p. 47 °C (decomp); IR (THF, −40 °C): $\tilde{\nu}$ [cm^{-1}] = 1944 vs, 1862 vs (CO); 1522 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −50 °C): δ = 11.31 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −50 °C): δ = 258.0 (Cr=C; ^1J(C,H) = 135.7 Hz), 259.8, 262.4 (CO).

4a: m.p. 122 °C (decomp); IR: $\tilde{\nu}$ [cm^{-1}] = 2157 m (C≡NEt); 1971 vs, 1918 s (CO); 1534 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −20 °C): δ = 10.94 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −20 °C): δ = 170.3 ($CNCH_2CH_3$), 245.7, 247.9 (CO), 253.7 (Cr=C).

4b: m.p. 101 °C (decomp); IR: $\tilde{\nu}$ [cm^{-1}] = 2170 m (C≡NEt); 1986 vs, 1933 s (CO); 1537 m ($C_{carbene}$-N); ^1H NMR: δ = 11.75 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR: δ = 166.1 ($CNCH_2CH_3$), 244.9, 246.4 (CO), 249.2 (Cr=C, ^1J(C,H) = 146.0 Hz).

5: m.p. 157 °C (decomp); IR: $\tilde{\nu}$ [cm^{-1}] = 1963 vs, 1901 s (CO); 1528 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −20 °C): δ = 3.72 (d, ^3J(H,P) = 11.0 Hz, 9H, $P(OMe)_3$), 10.46 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR (CD_2Cl_2, −20 °C): δ = 246.3 (d, ^2J(C,P) = 13.6 Hz, CO), 248.9 (d, ^2J(C,P) = 72.9 Hz, CO), 251.0 (d, ^2J(C,P) = 69.5 Hz, Cr=C); $^{31}P\{^1H\}$ NMR: δ = −143.7 (sept., ^1J(P,F) = 717 Hz, PF_6), 183.8 ($P(OMe)_3$).

6: m.p. 59 °C (decomp); IR: $\tilde{\nu}$ [cm^{-1}] = 2144 s (C≡N*t*Bu); 1982 vs, 1928 s (CO); 1537 m ($C_{carbene}$-N); ^1H NMR: δ = 11.91 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR: δ = 167.0 ($CNMe_3$), 244.2, 246.5 (CO), 251.7 (Cr=C).

7: IR: $\tilde{\nu}$ [cm^{-1}] = 1969 vs, 1900 s (CO); 1517 m ($C_{carbene}$-N); ^1H NMR (CD_2Cl_2, −20 °C): δ = 1.55 (d, ^2J(P,H) = 9.6 Hz, 9H, PMe_3), 11.56 (s, 1H, Cr=CH); $^{31}P\{^1H\}$ NMR: δ = 34.8 (PMe_3).

8: IR: $\tilde{\nu}$ [cm^{-1}] = 2144 vs, 2122 s, 2099 m (C≡NEt); 1895 vs (CO); 1509 m ($C_{carbene}$-N); ^1H NMR: 10.94 (s, 1H, Cr=CH); $^{13}C\{^1H\}$ NMR: δ = 179.7, 183.7 (2 × $CNCH_2CH_3$), 254.1 (CO), 263.7 (Cr=C; ^1J(C,H) = 132.7 Hz).

[a] Correct elemental analyses were obtained for **2a**, **3**, **4a**, **4b**, and **5**. [b] IR spectra (Bruker IFS-55 spectrometer) in CH_2Cl_2 at room temperature, if not specified otherwise; NMR spectra (Bruker AM-300 spectrometer) in CD_2Cl_2 at room temperature, if not specified otherwise; the δ_H and δ_C values are relative to the residual signal of the solvent, the δ_P values are relative to 85% H_3PO_4 solution as external standard; the ^3J(H,H) coupling constants in the isopropyl groups are 6.1 Hz; mass spectra: *m/z* values relative to the ^{52}Cr isotope.

aminocarbene complexes an absorption band of medium intensity is observed between 1509 and 1537 cm^{-1} and attributed to the $\tilde{\nu}(C_{carbene}\text{-}N)$ stretching vibration. This indicates the strong π conjugation of the amino group with the Cr–C double bond.[3f, 8] The number and relative intensities of the $\tilde{\nu}$(CO) bands of **2**–**7** and of the $\tilde{\nu}$(C≡NEt) bands of **8** provide evidence for the lateral arrangement of these ligands in the coordination sphere. In the ^1H NMR spectra of **2**–**8** an extremely lowfield singlet (δ = 10.46–12.31) is observed for the proton bound to the carbene carbon.[6c, 9] Accordingly, the carbene carbon resonances of **2**–**8** (δ = 249.2–263.7) are split into a doublet in the proton-coupled ^{13}C NMR spectra. The ^1J(C,H) coupling constants of 129.5 and 146.0 Hz are in the range found for "nondistorted" secondary carbene complexes.[6a–c, 9a]

The crystal structure of carbene complex **4a** was determined by X-ray diffraction (Fig. 1).[10, 11] The Cr–$C_{carbene}$ bond

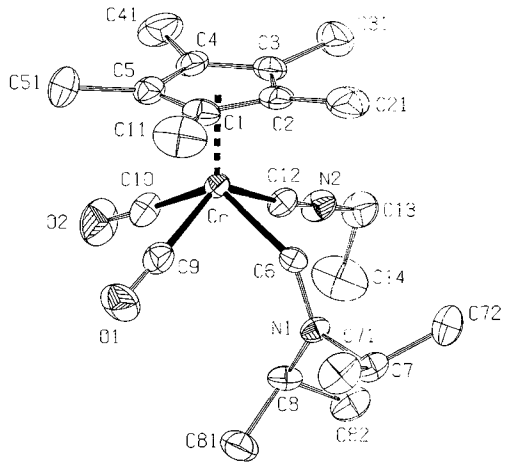

Fig. 1. Crystal structure of the cation in **4a** (PLATON plot). Selected bond lengths [Å] and angles [°]: Cr-C6 203.3(5), Cr-C9 184.4(5), Cr-C10 186.1(5), Cr-C12 198.0(5), Cr-$Cp^*_{centroid}$ 186.12(7), C6-N1 130.4(6), C7-N1 151.9(6), C8-N1 148.7(6), C12-N2 115.1(6); Cr-C6-N1 138.0(3), Cr-C12-N2 174.1(4), C6-Cr-C9 74.9(2), C6-Cr-C10 125.0(2), C6-Cr-C12 80.9(2), C9-Cr-C10 77.3(2), C9-Cr-C12 125.6(2), C10-Cr-C12 78.2(2).

(203.3(5) pm) is somewhat shorter than that found in octahedral Cr^0 aminocarbene complexes[3f] and, as expected, considerably longer then the Cr–$C_{carbyne}$ bond in **1b** (172.8(8) pm). The short $C_{carbene}$–N bond (130.4(6) pm) reflects the double bond character of this bond, which was also evident in the spectroscopic data.[8, 12] The plane of the aminocarbene ligand passing through the atoms Cr, C6, N1, C7, and C8 is almost perpendicular to the Cp* ring plane (dihedral angle between the best planes 85.9(2)°).

Compounds **2**–**8** are the first isolated and characterized Cr^0 aminocarbene complexes. Heteroatom-free derivatives should also be accessible by the route described above, as preliminary results of protonation reactions of chromium phenylcarbyne complexes show. Future studies are aimed to extend this synthetic strategy to Cp-free chromium carbene complexes and to determine their role in chromium-mediated C–C bond forming reactions.[13]

Experimental Procedure

2a: A solution of **1a** (0.355 g, 1.00 mmol) in 20 mL of pentane was cooled to −50 °C, treated by dropwise addition of a 1 M solution of HCl in diethyl ether (1 mL, 1.00 mmol), and stirred for 15 min. A red precipitate formed. The supernatant slightly yellow solution was decanted off and the precipitate washed twice with cold (−50 °C) pentane. Yield: 0.39 g (quantitative), red microcrystalline powder, m.p. 57 °C (decomp).

4a: A solution of **2a** (0.39 g, 1.00 mmol) in 20 mL of CH_2Cl_2 was cooled to −78 °C and treated with EtNC (0.060 g, 0.08 mL, 1.09 mmol) and $TlPF_6$ (0.35 g, 1.00 mmol). The reaction mixture was warmed to 0 °C and stirred for 1 h. The resulting yellow suspension was treated with diethyl ether, the Tl salts were removed by filtration, the filtrate was concentrated to a few mL, and **4a** was precipitated by addition of Et_2O/pentane (1/1). The yellow precipitate was dissolved in a minimum amount of THF and the product precipitated again by addition of Et_2O. Yield: 0.50 g (90%), yellow powder, m.p. 122 °C (decomp).

8: A solution of **4a** (0.265 g, 0.48 mmol) in 20 mL of 1,2-dimethoxyethane was treated with EtNC (0.030 g, 0.04 mL, 0.54 mmol) and heated at 80 °C until the $\tilde{\nu}$(CO) bands of **4a** at 1963 and 1906 cm^{-1} were no longer observed in the IR spectrum of the reaction solution (12 h). The solvent was removed in vacuo, the

residue purified by chromatography on silanized silica gel at −10 °C, and the product eluted with Et_2O/CH_2Cl_2 (5/1). Yield: 0.20 g (72%), brown powder.

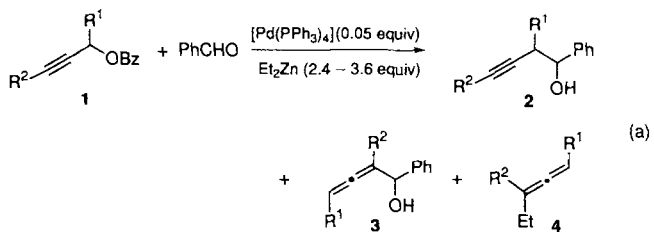
Propargylation of Carbonyl Compounds by Umpolung of Propargylpalladium Complexes with Diethylzinc

Yoshinao Tamaru,* Sachio Goto, Akihiro Tanaka, Masamichi Shimizu, and Masanari Kimura

π-Allylpalladium complexes are versatile intermediates, which serve not only as allylic electrophiles toward hard and soft carbon nucleophiles[1] but also as allylic nucleophiles toward carbonyl compounds.[2] In constrast, the use of propargylpalladium complexes as intermediates is rather limited: Their reaction with hard carbon nucleophiles such as alkyl-, aryl-, ethynylmagnesium and -zinc compounds generally provides allenes;[3] however, their reaction with soft carbon nucleophiles has not been fully elucidated yet.[4] Moreover, to our knowledge, no reports have appeared that indicate that propargylpalladium complexes serve as nucleophiles toward carbonyl compounds. We report here preliminary results that reveal for the first time that propargylpalladium complexes undergo a nucleophilic addition to carbonyl compounds to provide homopropargyl alcohols **2** selectively [Eq. (a)].



(a)

The propargylation of carbonyl compounds proceeded smoothly at room temperature by stirring a solution of a propargylic benzoate **1** (1.2 mmol), a carbonyl compound (1.0 mmol), diethylzinc (2.4–3.6 mmol), and tetrakis(triphenylphosphane)palladium (0.05 mmol) in THF under nitrogen. Results for the reactions with benzaldehyde are summarized in Table 1.[5, 6]

The parent compound **1a** (run 1), 1-substituted compounds **1b–d** (runs 2–7), and the 1,3-disubstituted propargyl benzoate **1h** (run 11) reacted with benzaldehyde to provide homopropargyl alcohols **2** selectively, whereas 3-substituted propargyl benzoates **1e–g** (runs 8–10) reacted to give allenyl alcohols **3** in addition to homopropargyl alcohols **2**. The ratio of **3** to **2** markedly depends on the kind of R^2 substituents, ranging from 72/28 for **3e**/**2e** (R^2 = Me, run 8) to 0/100 for **3g**/**2g** (R^2 = $SiMe_3$, run 10).

Surprisingly, cross-coupling products, ethylallenes **4**, were either not detected at all, or obtained only as minor products (run 6). The propargylation presented here showed poor stereoselectivity: **2b**, **2c**, and **2h** formed as mixtures of the *syn* and *anti* isomers in a ratio of about 1:1.

All the reactions were examined under the conditions specified in footnote [a] in Table 1 and have not been optimized yet. The yields may be improved by modification of the conditions (e.g., 70% in THF alone vs. 90% in a mixture of benzene/THF, run 2 and footnote [d] in Table 1). Propargylic substrates with

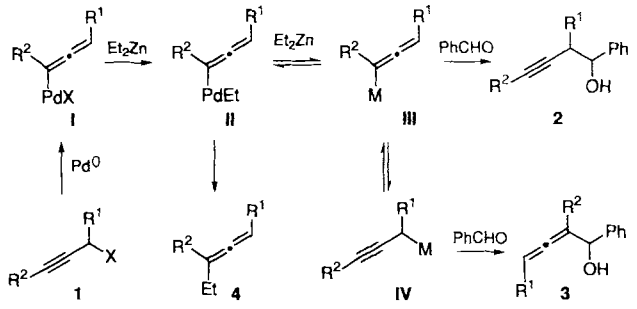
[a] Reaction conditions: **1** (1.2 mmol), benzaldehyde (1.0 mmol), diethylzinc (indicated amount), $[Pd(PPh_3)_4]$ (0.05 mmol) in THF (5 mL) at room temperature under N_2. [b] Yields for the spectroscopically homogeneous products based on the amounts of benzaldehyde used. [c] Mixture of *syn* and *anti* isomers in a ratio of about 1:1. [d] The conditions and yields for a reaction carried out in benzene/THF (5 mL/1.6 mL) are given in square brackets.

various leaving groups other than benzoate can be utilized with similar efficiency (runs 3–5).

The reaction time required for the complete conversion of benzaldehyde (TLC monitoring) ranges from about 10 min (run 5) to 96 h (run 10), and seems to be correlated with two factors: 1) the accessibility of the acetylenic C3 carbon atom to palladium(0), which is restricted by the steric bulk of the R^2 substituent (runs 8–11); 2) the ease of a heterolytic cleavage of the C1–X bond, which depends on the nature of the leaving group X and of the R^1 substituent (runs 2–7).

The present novel palladium-catalyzed propargylation of carbonyl compounds may be rationalized according to Scheme 1, under the assumption that both the transformation of **II** to a mixture of **III** and **IV**[7] and the reactions of these two with benzaldehyde[8] proceed much faster than the reductive elimination of **II** to provide **4**.[3] At present, the metal complex fragment M of **III** and **IV** has not been specified; however, M = ZnX



Scheme 1. Mechanistic rationale for the propargylation and allenylation of benzaldehyde according to Equation (a).

(X = OBz, Br, etc.) is unlikely, judging from the formation of **2b**, **2c**, and **2h** with low stereoselectivity.[9]

The selective formation of the alcohols **2** (runs 1–5, 7, 11) may be attributed to the preponderance of **III** (with C_{sp^2}–M bonding) over **IV** (with C_{sp^3}–M bonding) in the equilibrium shown in Scheme 1. The dramatic change in the ratios of **2**/**3** for the reactions of a series of 3-substituted propargyl benzoates (runs 8–10) may owe its origin to a steric destabilization of **III** for R^2 = Ph and Me groups and to an electronic stabilization of **III** for $R^2 = Me_3Si$.

Extensive studies are in progress to clarify the detailed reaction mechanism and the scope of this technique for the umpolung of propargylpalladium intermediates, which may open new perspectives in organic synthesis.

Experimental Procedure

2b (run 2, Table 1): To a solution of $[Pd(PPh_3)_4]$ (0.05 mmol) and **1b**, X = OBz (1.2 mmol) in dry THF (5 mL) under nitrogen were successively added benzaldehyde (1.0 mmol) and diethylzinc (3.6 mmol, 2 M solution in THF) by syringe. The mixture was stirred at room temperature for 3 h, then diluted with ethyl acetate (40 mL). The mixture was washed successively with 2 M HCl (10 mL), aqueous $NaHCO_3$ (2 × 10 mL), and brine (10 mL). The organic phase was dried ($MgSO_4$) and concentrated, and the residue was purified by flash chromatography on silica gel (hexane/ethyl acetate gradient) to afford 112 mg (70%) of **2b** as a mixture of diastereomers (55:45): B.p. (0.43 Torr): 80 °C; IR (neat): $\tilde{\nu}$ = 3400, 3300, 2110, 1050, 1030 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$, TMS): δ (major isomer) = 1.10 (d, J = 7.0 Hz, 3H), 2.21 (d, J = 2.6 Hz, 1H), 2.80 (d quint, J = 2.6, 7.0 Hz, 1H), 4.51 (br. d, J = 7.0 Hz, 1H), 7.25 - 7.44 (m, 5H); δ (minor isomer) = 1.23 (d, J = 7.0 Hz, 3H), 2.12 (d, J = 2.6 Hz, 1H), 2.89 (d quint, J = 2.6, 7.0 Hz, 1H), 4.74 (br. d, J = 7.0 Hz, 1H), 7.25–7.44 (m, 5H). C, H analysis for $C_{11}H_{12}O$: calcd. C 82.46, H 7.55; found C 82.53, H 7.68.

Chemo- and Diastereoselective Epoxidation of Chiral Allylic Alcohols with the Urea Hydrogen Peroxide Adduct, Catalyzed by Titanium Silicate 1**

Waldemar Adam,* Rajiv Kumar, T. Indrasena Reddy, and Michael Renz

Titanium silicates belong to the class of heterogeneous oxidation catalysts that oxidize a variety of organic compounds with aqueous hydrogen peroxide as relatively cheap oxygen source. Titanium silicate 1 (TS-1), the titanium analog of the ZSM-5 zeolite, can be recycled many times without losing its activity and catalyzes CH insertions,[1] epoxidations,[2] and arene[3] and heteroatom oxidations of amines[4] and sulfides.[5]

The high reactivity of the catalyst can also be a disadvantage, for example, in the product selectivity of epoxidations. For α-methylstyrene only 15% of the epoxide is obtained; the rest undergoes further reactions like epoxide opening and rearrangements.[6] An important aim is the control of diastereoselectivity. In spite of the many investigations in this research field, only little has been reported. Tatsumi et al.[2d] describe the epoxidation of some chiral allylic alcohols, but neglect to comment on the diastereoselectivity. The only known examples are the diastereoselective epoxidation of two cyclic allylic alcohols.[7]

In continuation of our studies on selective catalytic oxyfunctionalizations of organic substrates,[8] we report herein the first diastereoselective epoxidations of acyclic systems and compare their efficiency and diastereoselectivities with relevant known methods. The epoxy alcohols of defined configuration are useful building blocks for oxyfunctionalized natural products.[9]

When, as usually practiced, dilute, aqueous hydrogen peroxide solution is used, migration and/or substitution of the hydroxy group was observed (Scheme 1, path a). These undesirable reactions most likely derive from allyl-stabilized cationic intermediates.[10] If 85% H_2O_2 is employed in the presence of $MgSO_4$, or if it is filtered over this salt prior to use, the desired epoxide **2f** was obtained in 85% yield (Scheme 1, path b). Thus, whereas the presence of water usually makes no difference in epoxidations because TS-1 is known to be hydrophobic, in the case of the allylic alcohols it causes undesirable side reactions. The potentially explosive concentrated hydrogen peroxide can be replaced by the easier to handle and safer, anhydrous crystalline urea adduct of hydrogen peroxide (urea hydrogen peroxide, UHP). The epoxy alcohols were obtained in similarly high yields and high product selectivity (Scheme 1, path c). Only traces of the C–H insertion product, namely the ketone, were detected, and in no case do the above-mentioned troublesome side reactions occur. The allylic alcohols **1** were consumed completely in 12 to 24 h to form the epoxy alcohols **2**, which were isolated in 72 to 95% yields.

To compare the diastereoselectivities of the heterogeneous TS-1 zeolite with those of a homogeneous titanium catalyst in solution, we chose the *t*BuOOH (TBHP) and $Ti(OiPr)_4$ oxidation system (Sharpless epoxidation without tartrate; Scheme 1, path d). The diastereoselectivities of the oxidants UHP/TS-1 and TBHP/$Ti(OiPr)_4$, and for comparison also *meta*-chloroperbenzoic acid (*m*-CPBA) and TBHP/$VO(acac)_2$, are shown in Table 1.

With the UHP/TS-1 oxidant, substrate-specific selectivities are obtained when 1,3-allylic strain (caused by the substituents R^3 and R^4) is present in the substrate. For the allylic alcohol **1f**, for example, the *threo* isomer was obtained essentially exclusively (entry 6, Table 1), while the alcohols **1d** and **1h** also show relatively high *threo* selectivity (entries 4 and 8). Substrates with R^1 and R^3 substituents, for example **1e** and **1g**, still give high *threo* selectivities (entries 5 and 7), which indicates that the R^1 substituent exercises no significant influence on the diastereoselectivity. The allylic alcohol **1b** exhibits no diastereoselectivity (entry 2), like substrates without R^1 and R^3 substituents (**1a** and **1c**, entries 1 and 3).

The substrate **1f** shows a high *threo* selectivity with the oxidant *m*-CPBA (entry 6). In this case, the coordination of the substrate to the peracid through hydrogen bonding is optimal for oxygen transfer when the dihedral angle (O–C–C=C) of the allylic alcohol is 120° (see structure **E**, Fig. 1).[12] The two possible diastereomeric transition states are then energetically sufficiently differentiated by 1,3-allylic strain so that one predominates and one epoxide diastereomer results preferentially.

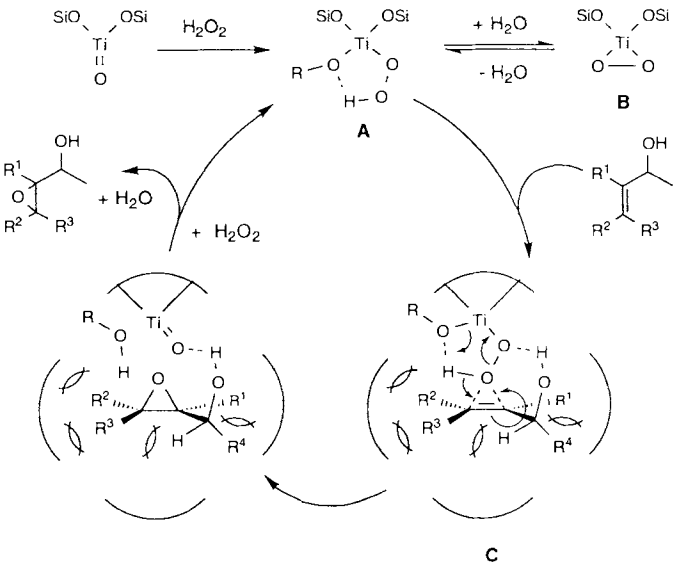
[a] The TS-1 was synthesized by the published procedure with a Si:Ti ratio of about 29 [15], that is, 50 wt% TS-1 represent 2.5 mol% based on the allylic alcohol; all reactions were monitored by TLC to more than 95% conversion; after 12–24 h the oxiranemethanols were isolated in 72–95% yields; traces of the enones were detected in the ^1H NMR spectra of the crude reaction mixture. [b] Carried out by a modified procedure [16]; $Ti(OiPr)_4$ was used in stoichiometric amounts. [c] $VO(acac)_2$ was used in a catalytic amount (0.5 mol%). [d] Diastereomeric ratios (d.r.) of *threo*:*erythro* products determined by ^1H NMR analysis of the characteristic signals in the crude reaction mixture; error ±5% of the stated values. [e] Substrates **1a**–**d**, see ref. [17], substrate **1e** ref. [12]; [f] $CDCl_3$ as solvent.



Scheme 2. Catalytic cycle and structures of the titanium peroxide intermediates **A** and **B** and of the transition state **C** for the oxygen transfer of the UHP/TS-1 oxidant.

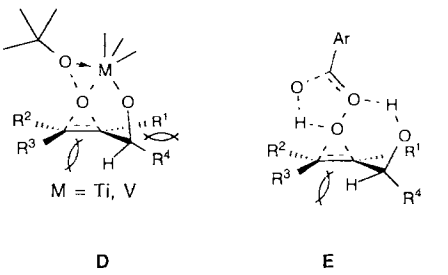


Fig. 1. Transition states for the epoxidations with the oxidants *t*BuOOH/$Ti(OiPr)_4$ or *t*BuOOH/$VO(acac)_2$ (**D**) and *m*-CPBA (**E**).

On the basis of solvent and acid/base effects on the reaction kinetics, the active species for the TS-1 epoxidation is postulated to be similar to peracids (**A**, Scheme 2)[2c, 11, 13] and not to the titanium peroxo complex (**B**, Scheme 2). Consequently, hydrogen bonding between the oxidant and the substrate also operates for the TS-1 epoxidations, and the oxygen is transfered at an optimal dihedral angle of 120° in the allylic alcohol (**C**, Scheme 2). This analogy to the transition state for the oxygen transfer of *m*-CPBA rationalizes the observed identical selectivities; however, the advantage of the UHP/TS-1 oxidant over *m*-CPBA is its catalytic nature (Scheme 2) and the H_2O_2 oxygen source.

As with *m*-CPBA, 1,2-allylic strain is ineffective, as illustrated by substrate **1b**, for which no *erythro* selectivity was obtained with either oxidant (entry 2, Table 1). *Erythro* selectivity would be expected if the dihedral angle were 40°, as it is in the epoxidations of allylic alcohols by the TBHP/$VO(acac)_2$ oxidant (**D**, Fig. 1).[14] The stereochemical probe with both 1,2- and 1,3-allylic strain, namely the alcohol **1e**, which for the vanadium oxidant gives preferentially the *erythro* diastereomer, confirms the similarity between the *m*-CPBA and UHP/TS-1 oxidants in view of the pronounced *threo* selectivity (entries 5 and 7).

Only the substrates **1d** and **1h** (entries 4 and 8), which do not possess *trans* substituents, deviate from this trend. Whereas in the case of *m*-CPBA the *threo* epoxy alcohols are obtained due to the 1,3-allylic strain, the diastereoselectivity for the heterogeneous Ti system drops significantly—surely a zeolite framework effect. We propose that the majority of the molecules will usually react through transition state **C**; however, for *cis* olefins, the sterically less hindered side of the double bond allows additional, less selective attack on the oxygen atom to be transfered in the activated complex. Such unselective possibilities are presumably prevented by steric interactions of the R^2 or R^3 substituents with the zeolite lattice. Alternatively, it is also possible that the less stereoselective Ti peroxo complex **B** is involved in the oxygen transfer, a pathway that is less likely for more sterically hindered substrates such as **1f** and **1g** (entries 6 and 7).

The heterogeneous UHP/TS-1 oxidant differs from the homogeneous TBHP/$Ti(OiPr)_4$ system in several points. A necessary condition for stereocontrolled oxygen transfer in the homogeneous system is coordination of the allylic alcohol to the metal center by means of an alcoholate bond, as suggested by the fact that unfunctionalized olefins are only slowly oxidized and in poor stereoselectivity. Furthermore, the dihedral angle for the TBHP/$Ti(OiPr)_4$ system has to be smaller than 120° because, in contrast to the UHP/TS-1 system, 1,2-allylic strain causes significant *erythro* selectivity (entry 2), but it must be larger than the 40° for the TBHP/$VO(acac)_2$ oxidant because for the stereochemical probe with both 1,2- and 1,3-allylic strain, the latter dominates (entries 5 and 7). Surprisingly, in contrast to the vanadium oxidant, the homogeneous titanium oxidant is very sensitive to 1,3-allylic strain and the *threo* epoxy alcohols are obtained essentially exclusively (entries 4, 6, and 8).

Thus, the heterogeneous UHP/TS-1 oxidant conforms mechanistically to *m*-CPBA, which would be expected in view of the similar active species for the oxygen transfer (cf. transition states **C** and **E**). Hydrogen bonding coupled with 1,3-allylic strain provides the high *threo* diastereoselectivity, as exemplified in substrate **1f**, and 1,2-allylic strain has no significant effect (cf. derivative **1b**). However, mechanistic similarities to the homogeneous TBHP/Ti(O*i*Pr)$_4$ oxidant are also evident, because the latter also displays high *threo* selectivities, but it differs from the UHP/TS-1 oxidant for substrate **1b**, for which TBHP/Ti(O*i*Pr)$_4$ shows significant *erythro* selectivity in view of the greater importance of 1,2-allylic strain. Moreover, besides these mechanistic insights, it should be emphasized that the UHP/TS-1 oxidant is an environmentally acceptable, safe, and mild oxidant for the epoxidation of allylic alcohols. In this way, side reactions that are observed with dilute, aqueous hydrogen peroxide are avoided, and the use of the potentially explosive, concentrated hydrogen peroxide is circumvented.

Experimental Procedure

A solution of 200 mg (2.00 mmol) of the allylic alcohol **1f** in 10 mL acetone was added dropwise to a suspension of 184 mg (2.00 mmol) UHP and 100 mg (50 wt%) TS-1 in 10 mL acetone at room temperature (about 20 °C). The mixture was held at reflux for 20 h, filtered at room temperature through a glass filter, the residue was washed with acetone (2 × 10 mL), and the solvent was removed in a rotoevaporator (35 °C, 20 Torr). The crude product was analyzed by NMR spectroscopy and the *threo*/*erythro* diastereomeric ratio of the sole product was determined to be 95/5 at a conversion of 90%.

Silolyl Anions and Silole Dianions: Structure of [K([18]crown-6)$^+$]$_2$[$C_4Me_4Si^{2-}$]**

William P. Freeman, T. Don Tilley,* Glenn P. A. Yap, and Arnold L. Rheingold*

Silolyl anions [C_4R_4SiR']$^-$ have been the focus of recent experimental[1, 2] and theoretical[3, 4] investigations. These studies are concerned with characterizing the structural and chemical properties of these novel π-electron systems, which may possess some degree of aromaticity. Theoretical studies suggest a significant amount of delocalization for the free $C_4H_4SiH^-$ anion, and NMR data obtained by Hong and Boudjouk for the lithium and sodium derivatives of [$Ph_4C_4Si(t$Bu)]$^-$ in THF indicate some delocalization of the negative charge in the ring.[2] We have recently reported the metal π-complex (η^5-C_5Me_5)Ru[η^5-$C_4Me_4SiSi(SiMe_3)_3$], which appears to have significantly delocalized electron density in the C_4Si ring, as shown by NMR spectroscopy.[5]

After the initial report by Joo and co-workers on the generation of the silole dianion $C_4Ph_4Si^{2-}$, a number of investigations described further properties for such species and their usefulness as intermediates in the synthesis of silole derivatives.[6] Based on somewhat downfield-shifted ^{29}Si NMR resonances, these species appear to have at least some delocalization of negative charge in the five-membered ring.[6b, c] The dilithium derivative [$Li(thf)_2$][$Li(thf)_3$][η^5,η^1-C_4Ph_4Si], recently described by West and co-workers, appears to have a delocalized structure based on the equivalent C–C distances in the C_4Si ring.[6d] Calculations support this view,[6d, 7] and Schleyer et al. have predicted that the "free" silole dianion $C_4H_4Si^{2-}$ would be highly aromatic and form dilithium, disodium, and dipotassium salts with the metals bound in an η^5-fashion to both sides of the ring.[7] Here we report on a silole dianion of the latter type, which is isoelectronic with tetramethylthiophene and has an aromatic $C_4Me_4Si^{2-}$ ring.

Reduction of $C_4Me_4SiBr_2$[8] with three equivalents of potassium in THF gives a solution of dianion **1** (Scheme 1), as deter-

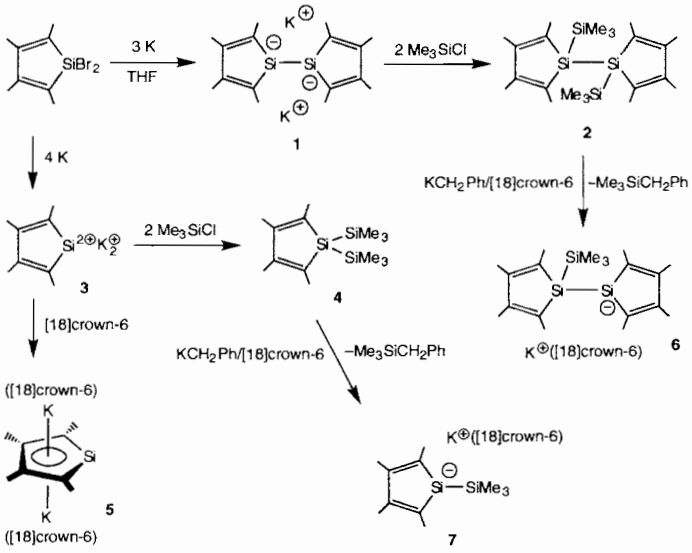

Scheme 1. Synthetic routes to silolyl anions and the silole dianion **5**.

mined by subsequent quenching with Me_3SiCl to produce the tetrasilane **2**. The latter compound was isolated in 60% yield as colorless crystals. A similar reaction sequence was used by Hong et al. to prepare $C_4Ph_4Si(SiMe_3)-Si(SiMe_3)C_4Ph_4$.[6b] Reduction of $C_4Me_4SiBr_2$ with four equivalents of potassium produces THF solutions of dianion **3** (Scheme 1), which was converted to the known[6c] silole **4** by reaction with Me_3SiCl. In the presence of [18]crown-6, this reduction gives complex **5**, which was isolated in crystalline form by slow, gas-phase diffusion of pentane into a solution of **5** in tetrahydrofuran.

Figure 1 provides a view of the molecular structure of **5**.[9] The very slight bond length alternation in the C_4Si ring (C(25)–C(26) = 1.40(1) Å; C(27)–C(28) = 1.38(1) Å; C(26)–C(27) = 1.44(1) Å) is consistent with considerable delocalization of π-electron density. Calculations by Schleyer et al. indicate that $C_4H_4Si^{2-}$ would have even more equivalent C–C distances.[7]

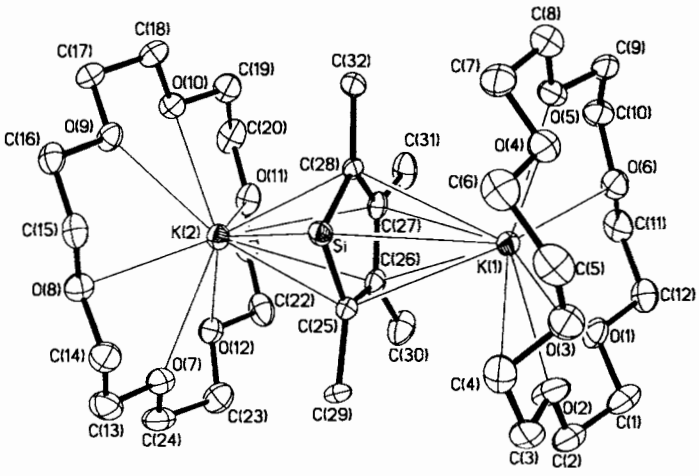

Fig. 1. Molecular structure of **5**. Selected interatomic distances [Å] and angles [°]: C(25)–C(26) 1.40(1), C(26)–C(27) 1.44(1), C(27)–C(28) 1.38(1), Si–C(25) 1.830(8), Si–C(28) 1.851(8), K(1)–C(25) 3.139(8), K(1)–C(26) 2.980(8), K(1)–C(27) 2.986(7), K(1)–C(28) 3.138(7), K(1)–Si 3.387(3), K(2)–C(25) 3.161(8), K(2)–C(26) 3.085(8), K(2)–C(27) 3.060(8), K(2)–C(28) 3.149(8), K(2)–Si 3.364(3); C(25)-Si-C(28) 87.2(4), Si-C(25)-C(26) 113.7(6), C(25)-C(26)-C(27) 112.2(7), C(26)-C(27)-C(28) 114.3(7), C(27)-C(28)-Si 112.6(6).

For comparison, much greater C–C bond length differences have been observed for the siloles $C_4Ph_4SiCl_2$ (1.35(1) Å; 1.54(1) Å),[7] $C_4Me_4SiCl_2$ (1.356(4) Å; 1.515 (6) Å),[6c] and $C_4Ph_4SiMe_2$ (averages: 1.36 Å; 1.51 Å).[10] The Si–C distances in **5** (1.85 (1) and 1.83 (1) Å) are surprisingly close to those observed in the latter silole derivatives (1.83(1),[7] 1.834(3),[6c] and 1.87(1)[10] Å, respectively). The K–C distances range from 2.980(8) to 3.161(8) Å, and are therefore similar to the average K–C bond lengths in $K[C_5H_4SiMe_3]$ (3.00(2) Å)[11] and $K[C_5(CH_2Ph)_5]$ (3.04(4) Å).[12] Each potassium atom is about 0.1 Å closer to the adjacent carbon atoms C(26) and C(27) than to C(25) and C(28). The K–Si distances (3.387(3) and 3.364(3) Å) are longer than the average K–C bond length, by about 0.3 Å. This difference is somewhat less than the difference in covalent radius between carbon and silicon (ca. 0.4 Å).[13] For comparison, the K–Si distances in β-$KSiH_3$ range from 3.56 to 3.86 Å.[14]

We recently reported the synthesis of germolyl anions by nucleophilic cleavage of Si–Ge bonds with benzylpotassium, and the crystal structure analysis of the "free" germolyl anion $[C_4Me_4GeSi(SiMe_3)_3]^-$ which has a highly pyramidalized germanium center.[15] As shown in Scheme 1, this method also works for the synthesis of silolyl anions **6** and **7**. Interestingly, the ^{29}Si NMR resonances for these anions (**6**: $\delta = -53.43$; **7**: $\delta = -41.52$) are shifted upfield relative to the corresponding resonances for the parent siloles (**1**: $\delta = -34.71$; **4**: $\delta = -34.26$). This trend is opposite to that reported by Hong and Boudjouk for the silolyl anions $M[C_4Ph_4Si(tBu)]$ (M = Li, Na) formed from $C_4Ph_4Si(tBu)-Si(tBu)C_4Ph_4$; their ^{29}Si NMR resonances are shifted downfield relative to those of the starting material ($\Delta\delta = 22.5$). The latter observation was interpreted in terms of delocalization of negative charge onto the silolyl anion ring.[2] Based on NMR data, it appears that this is not the case for anions **6** and **7**. The difference between these systems may be attributed to phenyl vs. methyl substitution in the rings, and/or to different degrees of interaction between the alkali metal ion and the silolyl ring. Goldfuss and Schleyer have suggested that η^5 bonding of an Li^+ ion to $C_4H_4SiH^-$ increases delocalization in the C_4Si ring.[4b] Ongoing investigations are intended to address these issues.

Experimental Procedure

2: Tetrahydrofuran (100 mL) was added to a Schlenk flask containing $C_4Me_4SiBr_2$ (0.62 g, 2.3 mmol) and small potassium chunks (0.27 g, 6.9 mmol). After stirring the reaction mixture at room temperature for 10 days, the red reaction solution was cooled to −78 °C, and then Me_3SiCl (1.50 mL, 11.8 mmol) was added. After warming the solution to room temperature, the volatile material was removed, and the resulting colorless oil was extracted into pentane (3 × 40 mL). Concentration and cooling (−78 °C) allowed crystallization of the product in 60% yield. Elemental analysis for $C_{22}H_{42}Si_4$: calcd: C 63.06, H 10.12; found: C 62.89, H 10.24. ^1H NMR (400 MHz, [D_6]benzene): $\delta = 0.13$ (s, 18H, $SiMe_3$), 1.87, 2.12 (s, 12H, CMe). $^{13}C\{^1H\}$ NMR (100.6 MHz, [D_6]benzene): $\delta = -0.61$ ($SiMe_3$), 14.81, 15.74 (*CMe*), 131.83, 150.11 (*C*Me). $^{29}Si\{^1H\}$ NMR (59.6 MHz, INEPT, [D_6]benzene): $\delta = -34.71$ (s, C_4Me_4Si), −13.24 (s, $SiMe_3$).

4: The procedure for the preparation of **2** was followed; however, four equivalents of potassium per equivalent of $C_4Me_4SiBr_2$ were used. The product was isolated as a spectroscopically pure [6c], colorless oil by simply removing the pentane extraction solvent (75% yield). ^1H NMR (400 MHz, [D_6]benzene): $\delta = 0.19$ (s, 18H, $SiMe_3$), 1.84, 2.01 (s, 6H, CMe). $^{13}C\{^1H\}$ NMR (100.6 MHz, [D_6]benzene): $\delta = -0.34$ ($SiMe_3$), 14.65, 15.38 (*CMe*), 130.99, 149.81 (*C*Me). $^{29}Si\{^1H\}$ NMR (59.6 MHz, INEPT, [D_6]benzene): $\delta = -34.26$ (s, C_4Me_4Si), −14.83 (s, $SiMe_3$).

5: Tetrahydrofuran (50 mL) was added to a flask containing $Me_4C_4SiBr_2$ (0.050 g, 1.9 mmol), [18]crown-6 (0.49 g, 1.9 mmol), and small potassium chunks (0.22 g, 5.65 mmol). The solution was stirred for three days, and then the product was crystallized by vapor diffusion of pentane into the red solution of the dianion. Complex **5** formed as red crystals in 5% yield after four days (yield not optimized). Elemental analysis for $C_{32}H_{60}K_2SiO_{12}$: calcd: C 51.71, H 8.15; found: C 49.12, H 7.94. ^1H NMR (400 Mz, [D_6]benzene) $\delta = 2.81$, 3.27 (s, 6H, CMe), 3.47 (broad s, 24H, [18]crown-6).

6: To an NMR tube was added **2** (0.020 g, 0.048 mmol), [18]crown-6 (0.013 g, 0.048 mmol), [D$_6$]benzene (0.3 mL), and KCH_2Ph (0.006 g, 0.05 mmol), and the NMR tube was shaken for 20 minutes. During this time the insoluble benzylpotassium reacts to give an orange solution of the silole anion. ^{1}H NMR (400 MHz; [D$_6$]benzene): $\delta = 0.44$ (s, 9H, $SiMe_3$), 2.08, 2.39 (s, 6H, $C_4\mathit{Me}_4Si-SiMe_3$), 2.33, 2.65 (s, 6H, $C_4\mathit{Me}_4Si^-K^+$), 3.24 (s, 24H, [18]crown-6). $^{13}C\{^1H\}$ NMR (100.6 MHz, [D$_6$]benzene): $\delta = 0.60$ (s, $SiMe_3$), 14.60, 16.45 (s, $C_4\mathit{Me}_4Si-SiMe_3$), 15.71, 18.43 (s, $C_4\mathit{Me}_4Si^-K^+$), 69.95 (s, [18]crown-6), 137.23, 143.80 (s, $C_4Me_4Si-SiMe_3$), 138.49, 149.08 (s, $C_4\mathit{Me}_4Si^-K^+$). $^{29}Si\{^1H\}$ NMR (59.6 MHz, INEPT, [D$_6$]benzene): $\delta = -53.43$ (s, $C_4Me_4\mathit{Si}^-K^+$), -25.47 (s, $C_4Me_4\mathit{Si}-SiMe_3$), -13.49 (s, $C_4Me_4Si-\mathit{Si}Me_3$).

7: To an NMR tube was added **4** (0.010 g, 0.034 mmol), [18]crown-6 (0.009 g, 0.034 mmol), [D$_6$]benzene (0.3 mL), and KCH_2Ph (0.005 g, 0.034 mmol). The tube was shaken for 20 min . The resulting orange solution was identified by NMR spectroscopy as the product **7**. ^{1}H NMR (400 MHz; [D$_6$]benzene): $\delta = 0.57$ (s, 9H, $SiMe_3$), 2.34, 2.67 (s, 6H, $C_4\mathit{Me}_4Si$), 3.20 (s, 24H, [18]crown-6). $^{13}C\{^1H\}$ NMR (100.6 MHz, [D$_6$]benzene): $\delta = 2.50$ (s, $SiMe_3$), 15.55 , 18.34 (s, $C_4\mathit{Me}_4Si$), 70.05 (s, [18]crown-6), 135.76, 149.60 (s, C_4Me_4Si). $^{29}Si\{^1H\}$ NMR (59.6 MHz, INEPT, [D$_6$]benzene): $\delta = -41.52$ (s, $C_4Me_4\mathit{Si}$), -11.00 (s, $SiMe_3$).

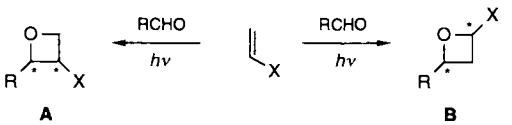
N-Acyl Enamines in the Paternò–Büchi Reaction: Stereoselective Preparation of 1,2-Amino Alcohols by C–C Bond Formation**

Thorsten Bach*

In the Paternò–Büchi reaction of terminal heteroatom-substituted alkenes with aldehydes, oxetanes are formed that carry the substituent X either in the 3- or in the 4-position depending on the regioselectivity of the photocycloaddition (Scheme 1).[1]



Scheme 1. The regioisomeric oxetanes **A** and **B** (1,2- and 1,3-connectivity, respectively, of the groups R and X) that can be formed by the photocycloadditon of an aldehyde to a heteroatom(X)-substituted alkene.

If the electronic properties of the $^3n\pi^*$ state, which is to a large extent responsible for the photochemical reactivity of many carbonyl compounds, are taken into consideration a preference for products of type **A** is expected. The 1,2-connectivity of functional groups in oxetane **A** reflects the nucleophilic character of the carbonyl carbon atom and is thus a hallmark for the photochemically induced reversal of the polarity of the carbonyl group. However, only in a few cases does the reaction of monosubstituted alkenes proceed with sufficient regioselectivity. One example are vinyl sulfides,[2] which, in contrast to the O-analogous vinyl ethers,[3] deliver the photocycloaddition products with good selectivity.

A further problem not yet solved for terminal alkenes concerns the simple diastereoselectivity of the C–C bond formation. Since numerous reactions have been reported that ring-open oxetanes of type **A** at the least substituted C-4 position under retention of the C–C bond formed in the course of the photocycloaddition,[4] the simple diastereoselectivity achieved in the Paternò–Büchi reaction can be transferred potentially to acyclic target molecules.

In view of the importance of 1,2-amino alcohols,[5] for example as enzyme inhibitors,[6] we looked for suitable N-substituted alkenes that may add selectively to carbonyl compounds. Compounds in which the donor activity of the nitrogen atom is reduced are for example N-acylated enamines (enamides), which can be prepared readily from imines **1** [Eq. (a)].[7] The

other compounds under scrutiny *N*-vinyl pyrrolidone (**2d**) and *N*-vinyl acetamide[8] (**2e**) are either commercially available or can be synthesized following published procedures.

Substrates of this kind have not yet been employed in stereoselective Paternò–Büchi reactions. Only studies on heterocyclic enamides[9] and 2-aminopropenenitriles[10] have been reported previously. For our irradiation experiments acetonitrile was found to be the solvent of choice, and benzaldehyde was employed as the carbonyl compound. The photocycloadditions generate the products in very good yields with remarkable regio- and diastereoselectivities [Eq. (b),[11] Table 1]. In the reactions with alkenes **2a** and **2b** one of the four possible isomers was isolated (as a racemic mixture) in diastereomerically pure form. The relative configuration of the products was most readily demonstrated on the oxetanes **3d**/**4d** since there are no rotamers to complicate the NOE studies; thus, the assignment of major and minor diastereoisomer are unambiguous for this particular case. The results of NOE measurements were consistent with the structures of the major diastereoisomers **3c** and **3e** shown in Equation (b). Unfortunately some compounds decomposed at elevated temperature; thus NOE studies on oxetanes **3b** and **4b** which had to be carried out at 373 K remained inconclusive. Based on analogy arguments the relative configuration for the depicted products appears very likely. The amino substituent and the phenyl group in the major diastereoisomer are consequently oriented *cis* to each other.

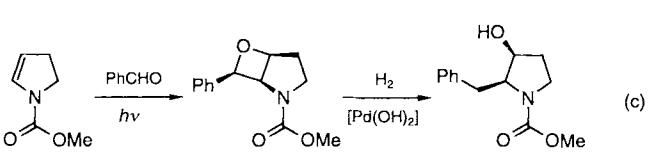
Table 1. Yields, regioisomeric (r.r.) and diastereomeric ratios (d.r.) in the photocycloaddition of benzaldehyde to *N*-acyl enamine **2** carried out in acetonitrile at room temperature [Eq. (b)].

Enamine	R	R^1	*t* [h] [a]	Yield [%] [b]	r.r. [c]	d.r.(**3**:**4**) [d]
2a	Pr	Me	14	70 [e]	>95:5	>90:10
2b	Bn	Me	14	73 [e]	97:3	89:11
2c	Bn	O*t*Bu	14	77 [f]	94:6	87:13
2d		$-(CH_2)_3-$	18	82 [f]	92:8	88:12
2e	H	Me	120 [g]	58 [f, g]	>95:5	79:21

[a] Irradiation time. [b] Isolated yields obtained by using two equivalents of the alkene. [c] Determined by GLC analysis of the crude product. [d] Determined by ^{1}H NMR spectroscopic analysis of the crude product. [e] Yield of pure diastereoisomer **3**. [f] Yield of the diastereomeric mixture **3** and **4**. [g] Slow reaction due to the formation of an amorphous precipitate. The yield relative to converted benzaldehyde is 79%.

The photocycloaddition procedure can also be applied to β-substituted alkenes. The cyclic enamide **5**[12] reacts with benzaldehyde to yield the bicyclic compound **6** [Eq. (c)], whose relative configuration was elucidated by NOE studies. The regioselectivity of the carbonyl attack in this reaction was less pronounced than in the cases described earlier. The yield of desired oxetane **6** was therefore lower than for β-unsubstituted compounds. The facile Pd-catalyzed hydrogenolytic ring opening[13] provides a straightforward access to excellent yields of pyrrolidine derivatives such as **7**, which carry an arylmethyl in the 2-position and a *cis*-oriented hydroxy group in the 3-position. Related natural products of this kind exert antifungal[14] and antibiotic activity.[15]



5 6 (56 %) 7 (94 %)

Further experiments as to the origin of the high regio- and diastereoselectivity are in progress. With regard to regioselectivity possible explanations can be based on previous work[2] as already mentioned. To understand the high degree of simple diastereoselectivity it is appealing to consider the preferred intersystem crossing (ISC) conformations of an intermediate 1,4-triplet biradical.[16] This picture may, however, become more complex if the retro cleavage of a 1,4-biradical can effectively compete with the ring closure step. Temperature-dependent measurements of the simple diastereoselectivity may provide us with additional information related to this issue.[17] Studies concerned with the influence of the aldehyde substrate and with the facial diastereoselectivity of the reaction are under way.

Experimental Procedure

Benzaldehyde (159 mg, 1.5 mmol, 152 µL) and **2** (3.0 mmol) were dissolved in acetonitrile (10 mL) in a quartz tube. This mixture was irradiated for the period of time *t* given in Table 1 (λ = 300 nm; light source: Rayonet RPR 3000). The course of the reaction was monitored by TLC and GLC. Upon complete conversion of the aldehyde the solvent was evaporated in vacuo. The regioisomeric ratio (*r.r.*) was determined by GLC analysis of the crude product mixture, the simple diastereoselectivity (*d.r.*) by ^{1}H NMR spectroscopic analysis. The excess enamide was separated from the desired oxetane by column chromatography (flash chromatography; eluent: cyclohexane/ethyl acetate mostly as a gradient 90/10 to 60/40). A complete separation of the diastereoisomers **3a** and **4a** and **3b** and **4b** was possible by chromatography.

Polybenzoid C_{54} Hydrocarbons: Synthesis and Structural Characterization in Vapor-Deposited Ordered Monolayers**

Markus Müller, Jörg Petersen, Rainer Strohmaier, Christian Günther, Norbert Karl, and Klaus Müllen*

Basic research aimed at developing molecular electronic devices tends to focus more and more on thin—if possible epitaxially ordered—organic films. Such films are produced preferentially under high-vacuum conditions by vapor deposition onto well-characterized substrate surfaces, with careful control of deposition rate, substrate temperature, and film thickness. This development requires organic compounds that vaporize without decomposition, but for applications they must also have a negligible vapor pressure at room temperature, that is, they must have strong intermolecular binding forces. Moreover, suitable molecules must have a shape and symmetry that allows two-dimensional close packing.[1, 2] With the aim of producing adsorbate films composed of molecules that resemble larger sections of graphite layers, we here describe a structure-specific synthesis of the extended polybenzoid hydrocarbons **3** and **13** and report the study of the ordered adsorbate films of **3** by electron diffraction analysis and scanning tunneling microscopy (STM). Evaluation of the shape of larger molecules by ultrahigh-resolution STM and special diffraction methods becomes increasingly important as their characterization by classical spectroscopic methods is impaired by decreasing solubility.

Polybenzoid arenes that can be represented by at least one Kekulé form that consists only of electron sextets as a mesomeric limiting structure[3] can be obtained—as has been described previously—by a cycloaddition–cyclodehydrogenation sequence (Scheme 1).[4] Starting from the ene–diene component **1**, a double intramolecular Diels–Alder cycloaddition and dehydrogenation leads to the phenylene-bridged bistriphenylene derivative **2**, which exists as two rotamers **2a** and **2b**. Therefore the synthesis sequence described[4] must lead to the two isomers **3** and **4** as cyclodehydrogenation products.

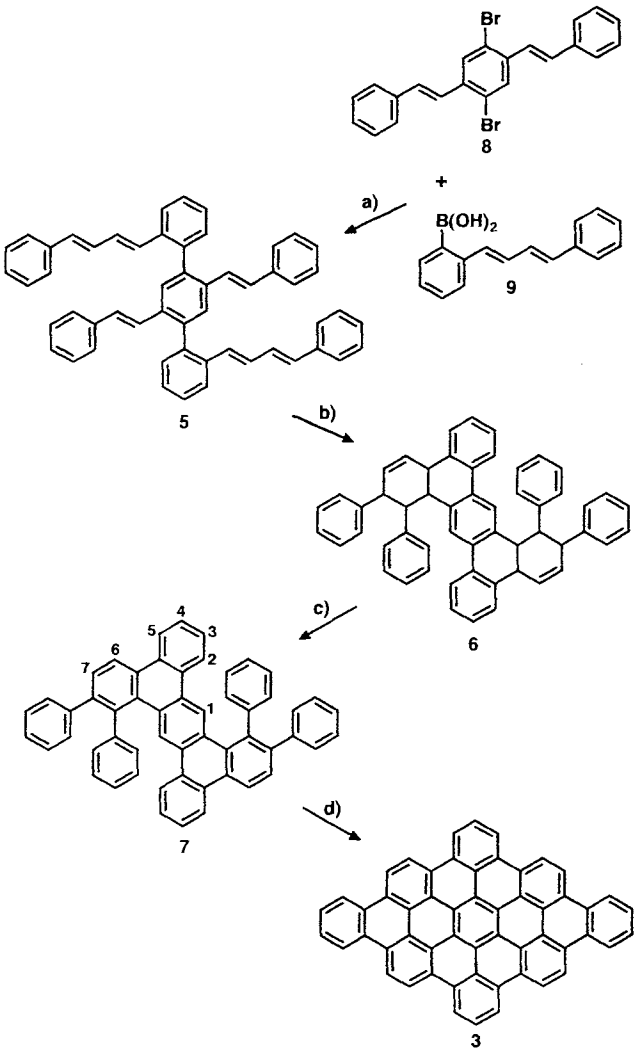
In view of this problem, we decided on a new synthesis route that is structure-specific. If the 1,4-di(2′-iodo-*trans*-styryl)-benzene[4] needed to form the ene–diene component **1** as the central building block is replaced by 1,4-dibromo-2,5-di-*trans*-styrylbenzene (**8**), double hetero-aryl–aryl coupling with **9** leads to the *para*-terphenyl derivative **5**. This opens up a new cycloaddition–cyclodehydrogenation route (Scheme 2) which, in contrast to the earlier route (Scheme 1), no longer permits rotation of the two outer phenyl rings about the central *para*-terphenyl unit after the double intramolecular [4+2] cycloaddition to **6**. Consequently, the formation of a different isomer of the cyclodehydrogenation product **3** is prevented.



Scheme 2. a) Tetrakis(triphenylphosphane)palladium(0); reflux in toluene/ethanol/water mixture (50:25:25 vol%); exclusion of light. b) 135 °C in 1,1,2,2-tetrachloroethane. c) DDQ; 135 °C in 1,1,2,2-tetrachloroethane. d) $AlCl_3/CuCl_2$; room temperature in carbon disulfide. For spectroscopic data see Table 1.

Unlike the ene–diene component **1**, the *para*-terphenyl derivative **5**, which takes part in the double intramolecular Diels–Alder reaction, is not synthesized by aryl–aryl coupling involving zincates, but from boronates, in accordance with the method of Suzuki.[5] Here, the distyrylbenzene **8** is treated with 2-(4′-phenyl-*trans*,*trans*-buta-1′,3′-dienyl)phenylboronic acid (**9**) in 92% yield to form **5**. The formation of **8** proceeds very readily by a double Wittig reaction of benzaldehyde with α,α′-bis(triphenylphosphonio)-2,5-dibromo-*para*-xylene dibromide, and the preparation of the boronic acid **9** proceeds via the known 2′-iodo-1,4-diphenyl-*trans*,*trans*-buta-1,3-diene[4] by lithiation with *n*-butyllithium followed by transmetalation with the trimethyl ester of boric acid.

In the aryl–aryl coupling according to Suzuki to give **5**, no intramolecular [4+2] cycloaddition takes place even after a reaction time of several days in a mixture of toluene, ethanol, and water (50:25:25 vol%) at boiling point (about 100 °C). However, the double intramolecular Diels–Alder reaction of **5** takes place quantitatively in [D_2]1,1,2,2-tetrachloroethane at 135 °C within 1 h (monitored by NMR). On the laboratory scale, the yield for the double [4+2] cycloaddition is 98%. The mixture of isomers of **6** caused by of the formation of eight new chirality centers is not separated. Instead, dehydrogenation of the cyclohexene structures of the crude mixture of **6** formed by the cycloaddition is carried out with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). All the isomers lead to the tetraphenyltetrabenzoanthracene derivative **7** (96% yield).

The oxidative cyclodehydrogenation of **7** is carried out with copper dichloride and aluminum trichloride in carbon disulfide at room temperature (99% yield). The removal of twelve hydrogen atoms can be demonstrated by field desorption (FD) and laser desorption time-of-flight (LD-TOF) mass spectrometry, which show that six new aryl–aryl bonds are formed, with complete planarization of the four phenyl substituents of **7** in the plane of the tetrabenzoanthracene structure. However, unlike the cyclization of **2**, this leads exclusively to the formation of the polybenzoid arene tribenzo-[*hi*,*o*,*uv*]triphenylene[2,1,12,11-*bcdef*]ovalene (**3**)[6] with $D_{2h}(2/mmm)$ symmetry.

The versatility of the cycloaddition–cyclodehydrogenation route described here is shown by the ability to form not only the *para*-terphenyl derivative **5** but also the *para*-terphenyl derivative **10** in which the positions of the styryl and phenylbutadienyl substituents are reversed relative to those in the ene–diene compound **5** (Scheme 3).

The preparation of **10** is also achieved by a double hetero-aryl–aryl coupling of the Suzuki type, in which 1,4-dibromo-2,5-di(4′-phenyl-*trans*,*trans*-buta-1′,3′-dienyl)benzene (**14**) is treated with *trans*-stilbene-2-boronic acid **15**. The formation of the dibromobenzene **14** proceeds in analogy to the synthesis of **8** by the double Wittig reaction of *trans*-cinnamic aldehyde with α,α′-bis(triphenylphosphonio)-2,5-dibromo-*para*-xylene dibromide, and the preparation of the stilbeneboronic acid **15** proceeds in analogy to the synthesis of **9** from 2-iodo-*trans*-stilbene.

Because of its low solubility in the usual solvents, the crude product **10** of the Suzuki reaction is not purified by column chromatography. Instead, it is separated from the inorganic palladium catalyst residues by a Soxhlet extraction with 1,1,2,2-tetrachloroethane, during which the double intramolecular [4+2] cycloaddition of **10** also takes place. The mixture of isomers of **11** is dehydrogenated with DDQ without prior purification (as in the case of the mixture of isomers of **6**), to form the tetraphenyltetrabenzoanthracene derivative **12**, which is then recrystallized several times from 1,1,2,2-tetrachloroethane (53% yield over all reactions).[7]

In the oxidative cyclodehydrogenation of **12** with copper dichloride and aluminum trichloride (98% yield), only eight hydrogen atoms can be removed because of the positions of the four phenyl substituents, so that only four new aryl–aryl bonds are formed, as can be shown by LD-TOF mass spectrometry. As in the synthesis of the arene **3**, the intramolecular Diels–Alder reaction prevents the rotation of the outer phenyl rings of the central *para*-terphenyl unit of **10** after the first cycloaddition stage. The synthesis therefore leads exclusively to the formation of the polybenzoid hydrocarbon **13**, which has $C_{2h}(2/m)$ symmetry.

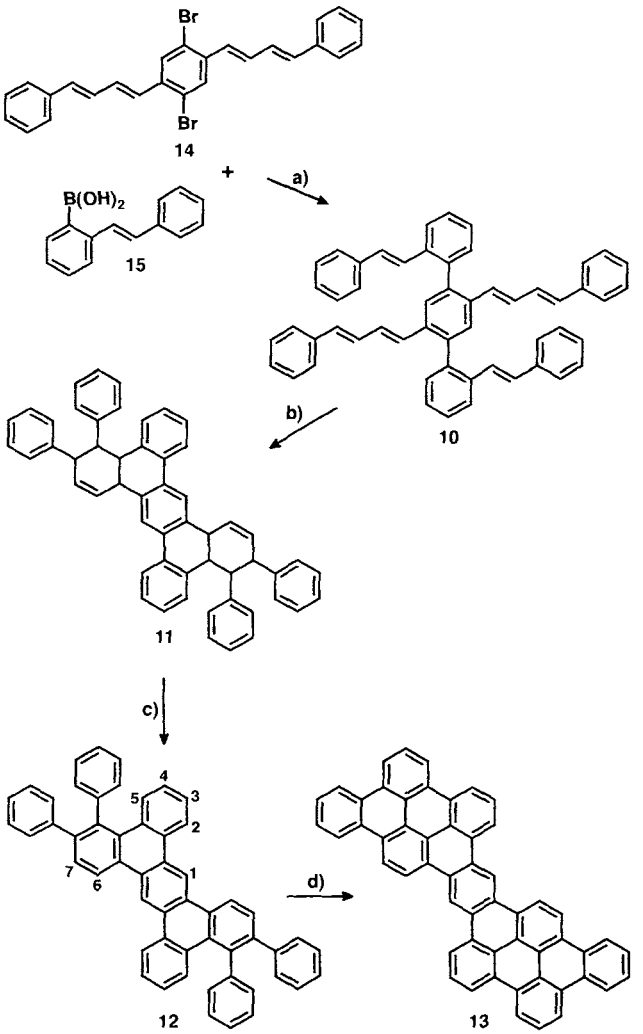

Scheme 3. a) Tetrakis(triphenylphosphane)palladium(0); reflux in toluene/ethanol/water mixture (50/25/25 vol%); exclusion of light. b) 135 °C in 1,1,2,2-tetrachloroethane. c) DDQ; 135 °C in 1,1,2,2-tetrachlorethane. d) $AlCl_3/CuCl_2$; room temperature in carbon disulfide. For spectroscopic data see Table 1.

For structural characterization of **3** and for the production of thin films by vacuum vapor deposition, the crude product was first subjected to a fractionating high vacuum sublimation in a fused silica tube using a temperature step program. At an evaporation temperature of 600 °C, a bright orange, microcrystalline material (maximum crystal size $100 \times 10 \times 1\ \mu m^3$) deposited, which displayed an orange-red fluorescence in high yield when irradiated with UV light.

For investigations by low-energy electron diffraction (LEED), a monomolecular film (approximately 3 Å thick) of **3** was deposited at a rate of 20 $Å\,h^{-1}$ onto a freshly cleaved (0001) surface of a single crystal of the layer chalcogenide MoS_2 (molybdenite) pretreated by heating to 450 °C for about 5 min in ultrahigh vacuum (UHV). Film thickness was monitored by a vibrating quartz balance. Only with very low energy electrons (in the region of 10 eV) could useful electron diffraction diagrams be obtained displaying the very small reciprocal lattice vectors 0.071(3) and 0.105(3) $Å^{-1}$. Taking into account the directions of the latter and their multiplication (induced by the substrate symmetry, with the consequence of multiple domain formation), the very large unit mesh $a = 14.2(5)$ Å, $b = 14.2(5)$ Å, $\gamma = 84.9(1.4)°$ in direct space was derived, with an area of 201 $Å^2$. The appearance of discrete diffraction spots indicates a well-ordered growth of **3** on the MoS_2 substrate. The large unit mesh with an area that corresponds closely to the (estimated) van der Waals area of the planar molecule **3** indicates a close-packed arrangement ($Z = 1$) of molecules that lie flat (cf. Ref. [8]). In situ thermodesorption spectroscopy with detection by mass spectrometry showed that the molecular mass of the molecules that could be resublimed from the monomolecular film was 670 u, in agreement with the formula $C_{54}H_{22}$.

For direct investigation of the molecular size and shape by scanning tunneling microscopy (STM) (see Ref. [2]), a suitably prepared sample was removed from the UHV and scanned in air. The STM images obtained thus clearly showed molecules of rhombic shape and of the expected size (Fig. 1). Here, too, the molecules were found to lie flat on the substrate surface. The intermolecular distances in the STM image are, however, somewhat larger than those that correspond to the close molecular packing concluded from the LEED patterns. One should be aware, however, that the LEED image reflects the dominant packing across a large surface area (about 1 mm^2), whereas the STM image gives very local information. It is known from STM investigations of monolayers of other systems that competition between intermolecular interactions (tending to give close pack-ing) and strongly ordering local interactions with the substrate can lead to more than one structure.[9]

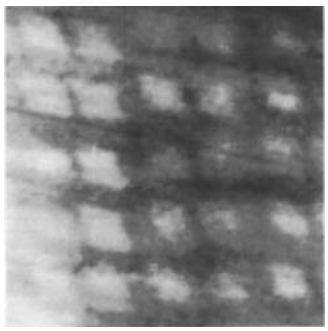

Fig. 1. STM image of a nominally 3 Å thick vapor-deposited layer of **3** on a (0001) face of a MoS_2 single crystal, taken in constant height mode (bias: +1.8 V at the sample; tunneling current: 90 pA; image area: 100 Å × 100 Å). A regular arrangement of rhombic molecules can be discerned.

With the compound **3**, we were successful in synthesizing a large aromatic molecule with remarkable thermal stability, high fluorescence yield, and high symmetry that allows dense surface coverage; these properties render **3** an extremely useful and promising model system for further investigations aimed at the development of a molecular electronics system on the basis of ultrathin epitaxial organic films.

[7] The intermediates previously mentioned had only been characterized by mass spectrometry. Therefore, a thorough investigation by NMR spectroscopy (^1H, ^{13}C, $^1H,^1H$-COSY, $^1H,^1H$-NOESY) of **12** was carried out. Although the number of the signal groups was the same as for the analogous compound **7** in the ^1H NMR spectrum, there was a considerable difference in the chemical shift of comparable signal groups of **7** and **12**.

Copper(I)-Promoted Stille Cross-Coupling of Stannyl Enol Ethers with Enol Triflates: Construction of Complex Polyether Frameworks**

K. C. Nicolaou,* Mitsunobu Sato, Neil D. Miller, Janet L. Gunzner, Johanne Renaud, and Edouard Untersteller

The polyether marine natural products are a remarkable class of compounds whose complexity and structural diversity continue to impress and fascinate synthetic chemists.[1] Their scarcity and striking biological actions dictate their total synthesis and the design, chemical synthesis, and biological evaluation of novel structural analogs. Fundamental to these studies is the development of new synthetic methods for the construction of such systems.[2] Amongst the remaining challenges in this area is a ready access to the unusual bistetrahydropyran systems represented by the ring pairs K–L, O–P, and V–W of maitotoxin[3] (Scheme 1). We report here a highly efficient and practical method for the construction of such units through the copper-promoted Stille cross-coupling of cyclic stannyl enol ethers with cyclic enol triflates.

A potential solution to the synthetic problem posed by the maitotoxin fragments K–L, O–P, and V–W and by other complex natural products would be to cross-couple the glycal partners **I** and **II** and then functionalize the resultant diene **III** appropriately (Scheme 2). Despite the existence of precedent[4] for carbon–carbon bond forming reactions involving Pd^0-catalyzed cross-coupling of stannyl glycals with vinyl or aryl derivatives, the development of a successful procedure for the cross-coupling of appropriate glycal partners proved problematic due to low reaction rates and formation of homodimers[5] (e.g. **IV** and **V**, Scheme 1). As a simple model system, we chose to examine the cross-coupling of enol triflate **1** with trimethylstannyl enol ether **2**. A series of experiments were carried out to optimize reaction conditions for the selective formation of the heterocoupling product **3**. As seen from Table 1 the Pd^0-catalyzed cross-

coupling of enol triflate **1** and stannyl enol ether **2** is best carried out in the presence of CuCl (2.0 equiv) and potassium carbonate (2.0 equiv) in THF at 25 °C giving the desired bisglycal **3** in 80% yield. The role of CuCl was particularly crucial for the success of this reaction.[6] Whether the CuCl acts as a scavenger of free triphenylphosphane ligands or whether a discrete organocuprate is formed as a result of a Sn/Cu transmetalation is open to conjecture.[6a]

Table 1. Conditions for the cross-coupling of **1** with **2** in the presence of a palladium(0) catalyst [a].

Entry	Ratio 1:2	Additives (equiv)			Conditions		Yield [%] [b]
1	1.1				THF	25 °C, 78 h	43

important physical data for compounds **15** and **17** are summarized in Table 3.

We have developed a practical and highly efficient method for the cross-coupling of enol triflates and stannyl enol ethers to afford complex bisglycals, a class of valuable synthetic intermediates.[7] We have, furthermore, demonstrated the applicability of this method to the synthesis of cyclic polyethers through the construction of several complex polyether frameworks, including a fragment related to the NO–PQ system of maitotoxin.[8, 9]

The "Bare" Uranyl(2+) Ion, UO_2^{2+}**

Hans H. Cornehl, Christoph Heinemann, Joaquim Marçalo, António Pires de Matos,* and Helmut Schwarz*

Dedicated to Professor Hubert Schmidbaur on the occasion of his 60th birthday

Uranium has attracted particular attention, not only among scientists, ever since the fateful development of nuclear technology some 50 years ago. The linear uranyl moiety UO_2^{2+} is the leitmotif in the coordination chemistry of this element, and thus both experimental[1] and theoretical[2] methods were extensively employed to study UO_2^{2+} and derived molecules[3] in terms of their structural, electronic, and spectroscopic properties. However, despite the abundant information available on UO_2^{2+} ions in solution and in the solid state, to the best of our knowledge neither the existence nor the basic thermochemical data of isolated UO_2^{2+} ions, unperturbed by the presence of counterions and bulk effects, has been established so far (for the available data[4] on UO_x^{y+} ($x = 0$–2, $y = 1, 2$), see Table 1).[5] We are

Table 1. ΔH_f [kcal mol^{-1}] for UO_x^{y+}.

	U^{y+}	UO^{y+}	UO_2^{y+}	Ref.
$y = 0$	127	6 ± 2	-111 ± 1	[4a]
$y = 1$	270	135	14	[4a]
$y = 2$	544 ± 12	-		[4b]

studying the gas-phase chemistry of f-block elements[6] and here communicate the first experimental observation and thermochemical characterization of isolated UO_2^{2+} ions using two different mass-spectrometric techniques. In addition, we report ab initio calculations of singly and doubly charged uranium dioxide UO_2, which corroborate the deduced thermochemical data and provide information on the underlying electronic structures.

Our first set of experiments involved the generation of UO_2^{2+} by ion–molecule reactions of laser-generated doubly charged atomic uranium cations with various oxygen donors at thermal energies. This was achieved in a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer. Thus, UO_2^{2+} can be generated by the reaction of U^{2+} with molecular oxygen according to the two-step process depicted in Scheme 1. While the

$$U^{2+} \xrightarrow[-O]{+O_2} UO^{2+} \xrightarrow[-O]{+O_2} \boxed{UO_2^{2+}} \xrightarrow[-O_2]{+O_2} UO_2^+$$

Scheme 1.

primary formation of UO^{2+} from U^{2+}/O_2 occurs with collisional efficiency ($k_{obs} = k_{ADO}$, the collision rate calculated from average-dipole-orientation (ADO) theory[7]), the secondary reaction of UO^{2+} with O_2 to yield the uranyl dication UO_2^{2+} is more than one order of magnitude slower ($k_{obs} = 4\%\ k_{ADO}$). In a tertiary step, the so-formed uranyl dications undergo electron transfer with O_2 to yield singly charged uranium dioxide and O_2^+ as the final reaction products ($k_{obs} = 35\%\ k_{ADO}$).

$$U^{2+} \xrightarrow[-CO]{+CO_2} UO^{2+} \xrightarrow[-CO]{+CO_2} UO_2^{2+}$$

Scheme 2.

Oxidation of U^{2+} can also be achieved with carbon dioxide (Scheme 2) or nitrous oxide (Scheme 3). In the case of CO_2, the oxidation stops at the stage of diatomic UO^{2+}. In the U^{2+}/N_2O reaction mixture, both the primary and the secondary reaction proceed at the collisional limit, but the charge transfer decay of UO_2^{2+} is significantly slower ($k_{obs} = 3\%\ k_{ADO}$). Besides the formation of UO^{2+}, the U^{2+}/N_2O reaction also yields singly charged UN^+ [3d, 8] with loss of NO^+, consistent with the lower ionization energy (IE) of NO (IE = 9.3 eV) relative to that of N_2 (IE = 15.1 eV), which is lost as a neutral species in the oxidation pathway.

$$U^{2+} \xrightarrow{+N_2O} \begin{cases} \xrightarrow[80\%]{-N_2} UO^{2+} \xrightarrow[-N_2]{+N_2O} \boxed{UO_2^{2+}} \xrightarrow[-N_2O]{+N_2O} UO_2^+ \\ \xrightarrow[20\%]{-NO^+} UN^+ \xrightarrow{+N_2O} \end{cases}$$

Scheme 3.

The observed reactions allow a "bracketing interval" for $\Delta H_f^\circ(UO_2^{2+})$ to be deduced, since only exothermic or thermoneutral reactions can occur under the experimental conditions chosen. From the U^{2+}/CO_2 reaction, a lower bound of 127 kcal mol^{-1} for the bond dissociation energy (BDE) of UO^{2+} can be derived, which translates into $\Delta H_f^\circ(UO^{2+}) <$ 489 kcal mol^{-1}. Formation of UO_2^{2+} from UO^{2+}/O_2 requires BDE$(OU^{2+}-O) >$ 119 kcal mol^{-1}; thus $\Delta H_f^\circ(UO_2^{2+}) <$ 430 kcal mol^{-1}. Finally, the observed charge transfer between N_2O and UO_2^{2+} yields a lower bound of $\Delta H_f^\circ(UO_2^{2+}) >$ 311 kcal mol^{-1}; thus $\Delta H_f^\circ(UO_2^{2+}) = 371 \pm 60$ kcal mol^{-1}, corresponding to a second ionization energy of 15.4 ± 2.6 eV for uranium dioxide. A noteworthy conclusion from the derived thermochemistry is that both UO^{2+} and UO_2^{2+} are thermodynamically stable dications, that is, the molecular dications lie energetically below the lowest dissociation limits (for UO^{2+}: $\Delta H_f^\circ(U^{2+}) + \Delta H_f^\circ(O) = 604 \pm 12$ kcal mol^{-1}; for UO_2^{2+}: $\Delta H_f^\circ(UO^+) + \Delta H_f^\circ(O^+) = 509$ kcal mol^{-1}, $\Delta H_f^\circ(UO^{2+}) + \Delta H_f^\circ(O) < 549$ kcal mol^{-1}). Thus, metastable decays of the doubly charged species into singly charged fragments by "Coulomb explosions"[9] cannot occur without excitation from the ground state.

In view of the relatively large error bars, the experimentally derived thermochemical data were theoretically cross-checked using the coupled cluster method (CCSD) with a quasi-relativistic ab initio pseudopotential for uranium. The second ionization energy of UO_2 was computed, since via $\Delta H_f(UO_2^+)$ it directly leads to the central thermodynamic quantity $\Delta H_f(UO_2^{2+})$. UO_2^+ is derived from closed-shell UO_2^{2+} (see the MO diagram in Fig. 1) by addition of one electron into either of the uranium-

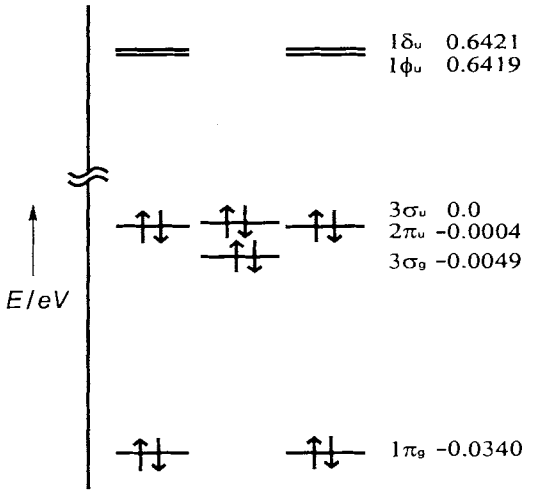

Fig. 1. Hartree–Fock frontier molecular orbital scheme for UO_2^+ and UO_2^{2+}. The occupation shown corresponds to the $^1\Sigma_g^+$ ground state of UO_2^{2+} and the $^2\Delta_u$ and $^2\Phi_u$ states of UO_2^+ arise upon addition of a single electron into either the $1\delta_u$ or the $1\phi_u$ orbital, respectively.

centered nonbonding $1\delta_u$ or $1\phi_u$ orbitals, which have pure atomic 5f character. The remaining frontier MOs are bonding combinations between the uranium 7s, 6d, 6p, and 5f as well as oxygen 2s and 2p atomic orbitals.[10] Calculated U–O equilibrium distances for the low-lying states of UO_2^+ and the $^1\Sigma_g^+$ ground state of UO_2^{2+} are given in Table 2. In the ΛS coupling scheme, UO_2^+ adopts a $^2\Phi_u$ ground state with an adiabatic excitation energy of 0.1 eV to the $^2\Delta_u$ term. The uranium–oxygen distances (Table 2) in the two lowest electronic states of UO_2^+ are 0.06–0.07 Å longer than in the uranyl dication. Upon ionization of UO_2^+ to UO_2^{2+}, the Mulliken charge q(U) of uranium increases by 0.61 e (UO_2^+, $^2\Phi_u$, $q(U) = +2.32$; UO_2^{2+}, $q(U) = +2.93$), less than

Table 2. Optimized U–O bond lengths [Å] for UO_2^+ and UO_2^{2+} as well as calculated [a] vertical energies E_v [eV] for the process $UO_2^+ \rightarrow UO_2^{2+} + e^-$.

	UO_2^+	UO_2^+	UO_2^{2+}
r(U–O)	1.753	1.766	1.697
E_v	15.05	14.63	-

[a] Total energy differences, corrected for spin–orbit effects, which stabilize the lowest electronic states of UO_2^+ by 0.36 eV ($^2\Phi_u$) and 0.20 eV ($^2\Delta_u$), respectively [2c].

the 1.0 e expected from the character of the singly occupied highest molecular orbital of UO_2^+. The associated reorganization of the uranium–oxygen interaction is reflected in the compositions of the bonding molecular orbitals, which acquire more uranium 5f character at the cost of oxygen 2p contributions[10] upon formation of UO_2^{2+} from UO_2^+. The higher partial charge of uranium accounts for the shorter bonds in UO_2^{2+}.

Table 2 lists the calculated second ionization energies for UO_2. Spin-orbit coupling was not included explicitly in the quantum-chemical calculations; however, in the closed-shell species UO_2^{2+} it vanishes in the first approximation. The spin–orbit stabilization of UO_2^+ can be estimated according to Figure 2: The $5f_\phi$ and $5f_\delta$ orbitals split into the $5f_{\phi 7/2}/5f_{\phi 5/2}$ and

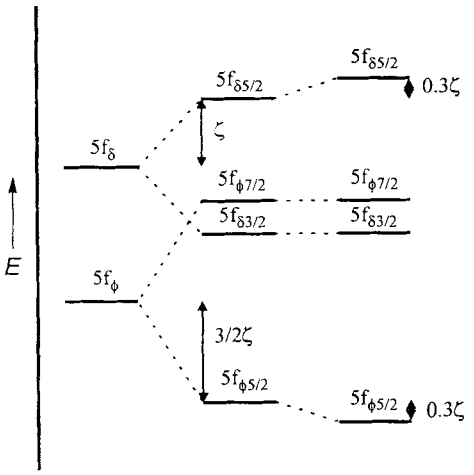

Fig. 2. Spin–orbit effects for $5f_\phi$ and $5f_\delta$ orbitals in UO_2^{2+} according to Ref. [2c].

$5f_{\delta 5/2}/5f_{\delta 3/2}$ pairs, of which the 5/2 components undergo further interaction such that the lowest $5f_{\phi 5/2}$ orbital lies $1.8\zeta(U) = 0.36$ eV lower than the unperturbed $5f_\phi$ level ($\zeta(U)$ is the 5f spin–orbit coupling constant in uranium), while the stabilization of the lowest $5f_{\delta 3/2}$ amounts to $1.0\zeta(U) = 0.2$ eV.[2c] Including this correction, the predicted vertical ionization energies for the ground and first excited state of UO_2^+ are 15.05 eV and 14.63 eV, respectively.[11] Since due to the larger correlation energy in UO_2^+ the calculated ionization energies will be slightly too low, the exact value for the second ionization energy of UO_2 is expected to be in the upper half of the experimentally determined bracketing interval of 15.4 ± 2.6 eV.

In a second, independent mass spectrometric experiment, we observed UO_2^{2+} cations in "charge-stripping" (CS) collisions between singly charged UO_2^+ ions, generated by fast-atom bombardment (FAB),[12] with O_2 targets at 8 keV kinetic energy (laboratory frame). The main products of these energetic UO_2^+/O_2 collisions are the singly charged fragments UO^+ and U^+ arising from collision-induced dissociation (CID) of the parent ion. The uranyl dication, along with the more abundant atomic and diatomic cations U^{2+} and UO^{2+}, is also produced in this event, but the CS process is about a hundred times less efficient than the competing CID channels (Fig. 3). This surprisingly low efficiency is possibly related to the spatially compact nature of the singly occupied molecular orbital of UO_2^+, a hypothesis that is currently under study in our laboratories.[13]

Experimental Procedure

Ion–molecule reactions at thermal energies were studied in Sacavém with an Extrel FTMS-2001 Fourier transform ion cyclotron resonance mass spectrometer, in which U^{2+} ions were generated by laser desorption/laser ionization by focusing the

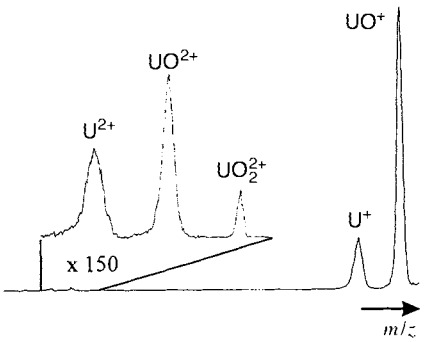

Fig. 3. B(2)-scan "charge-stripping" mass spectrum of UO_2^+ mass-selected by means of B(1) and E(1); oxygen (70% transmission) was used as a collision gas.

beam of a Nd:YAG laser (GCR-11, Spectra Physics, Mountain View, CA; $\lambda = 1064$ nm) onto a pure uranium metal piece, mounted on the solids probe close to the ICR cell. Thermalization of the ions and removal of excess energy was achieved by collisions with argon present at 5×10^{-7} mbar. The reactant gases were admitted to the cell through a leak valve. Reaction pathways were elucidated by MS_2MS and double-resonance techniques. Rate constants k (reported relative to the collision rate k_{ADO} [7]) were derived from the pseudo-first-order decay of the reactant ion and have an estimated accuracy of $\pm 30\%$. The "charge-stripping" experiments were performed in Berlin with a modified VG ZAB-HF AMD 604 four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sectors), which has been described elsewhere [14]. In brief, UO_2^+ ions were generated by fast atom bombardment (FAB) of a suspension of uranyl acetate in sulfolane, accelerated to 8 keV kinetic energy, mass-selected with B(1)E(1), and collided with oxygen (50–80% transmission).

Ab initio pseudopotential (PP) calculations were performed with the quasi-relativistic 60-core electron uranium PP and the associated (12s11p10d8f) [8s7p6d4f] valence basis set by Küchle et al. [15] augmented by two g-type polarization functions (exponents: 1.2649 and 0.5060). A (14s9p4d)/[6s5p3d] atomic natural orbital (ANO) basis set was used for oxygen [16]. Spin-restricted Hartree–Fock computations were followed by spin-restricted coupled-cluster calculations covering all single and double excitations to account for electron correlation (CCSD, [17]) with correlation of all explicitly treated electrons except for the 5s, 5p, and 5d electrons of uranium and the 1s electrons of oxygen), as implemented in MOLPRO94 [18]. The geometries were optimized stepwise by calculating several points close to the minima on the potential energy surfaces (with omission of the g-functions on uranium in the PP calculations). Second ionization energies are not corrected for zero-point vibrational energies.

Combination of the Fe_4S_4 and M-CN-Fe Redox Functions**

Nianyong Zhu, Jürgen Pebler, and Heinrich Vahrenkamp*

The ubiquity of the Fe_4S_4 ferredoxin as an electron-transfer agent in biological systems[1] and its skillful modeling by inorganic chemists[2] have made it a popular object of teaching and research. We became attracted to this compound in the context of our studies on the redox and mixed-valence properties of polynuclear complexes with M-CN-M′ cyanide links,[3] specifically those containing metallocyanides attached to metal clusters.[4] We assumed that the combination of the two redox-active functions, Fe_4S_4 and M-CN-Fe, would lead to new electronic and electron-transfer properties, and herein we report some results of our attempts to verify this assumption.

The target compounds **1** and **2** are easily accessible by using salts of the anionic $[Fe_4S_4Cl_4]^{2-}$ cluster as starting compounds; this is also a suitable reference for physical measurements and structural comparisons.[5] Combination with $[(CO)_5W-CN]^-$ and $[Cp(CO)_2Mn-CN]^-$ ions in CH_2Cl_2 and with [(dppe)-CpFe-CN] (dppe = 1,2-bis(diphenylphosphanino)ethane and $[(Ph_3P)_2CpRu-CN]$ in acetone leads to chloride substitution and formation of the octanuclear $[Fe_4S_4(NC-M)_4]$ cluster ions. Layering their solutions, containing the appropriate counterions, with hexane results in a slow precipitation of **1a,b** and **2a,b** in 80–90% yield. Compounds **1a** and **1b** are stable even at elevated temperatures, while **2a** and **2b** decompose slowly at room temperature.

$(Ph_4P)_2[Fe_4S_4\{NC-W(CO)_5\}_4]$ **1a** $\quad [Fe_4S_4\{NC-FeCp(dppe)\}_4](PF_6)_2$ **2a**

$(Et_4N)_2[Fe_4S_4\{NC-Mn(CO)_2Cp\}_4]$ **1b** $\quad [Fe_4S_4\{NC-RuCp(PPh_3)_2\}_4](SbF_6)_2$ **2b**

The constitutions of **1a** and **1b** were confirmed by X-ray structure determinations. Figure 1 shows the cluster anion of **1a**.[6] The anion is highly symmetrical; a crystallographic twofold axis passes through the centers of two opposing faces of the Fe_4S_4 cube. All bond lengths of the cluster constituents Fe_4S_4 and Fe-NC-W fall within the range known from Fe_4S_4 and Fe-NC-M reference compounds.[2, 3, 7]

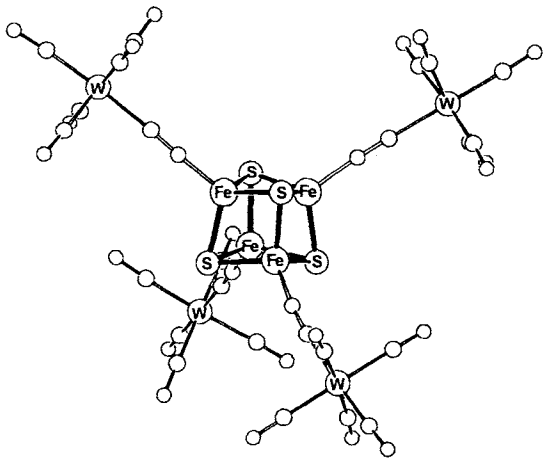

Fig. 1. Crystal structure of the anion of **1a**. Average bond lengths [Å]: Fe–Fe 2.733±0.012, Fe–S 2.275±0.025, Fe–N 1.915±0.005, N–C 1.16±0.005, W–C(CN) 2.143±0.001.

Compounds **1** and **2** are deeply colored, show a characteristic ν(CN) band in the IR spectrum, and their electrochemistry is governed by a reversible one-electron reduction and an irreversible multielectron oxidation (Table 1). Considering the difference of four charge units between the cluster ions **1** and **2**, the difference between their redox potentials is rather small.

[**] This work was supported by the Graduiertenkolleg "Systeme mit ungepaarten Elektronen" and by the Landes-Schwerpunktprogramm "Molekulare Elektrochemie".

The electronic spectra of **1** and **2** (Table 1) differ significantly from those of the reference compounds $[Fe_4S_4Cl_4]^{2-}$[5] and $[Fe_4S_4(SR)_4]^{2-}$.[8] While the intense absorption of the latter in the upper visible or near UV range, assigned to intracore charge transfers,[9] appears in the near UV for **1** and **2** as well, the lower visible or near IR range, which shows only weak features for the reference compounds, is dominated by intense and very broad bands for **1** and **2** (Fig. 2). The UV/Vis absorptions assignable

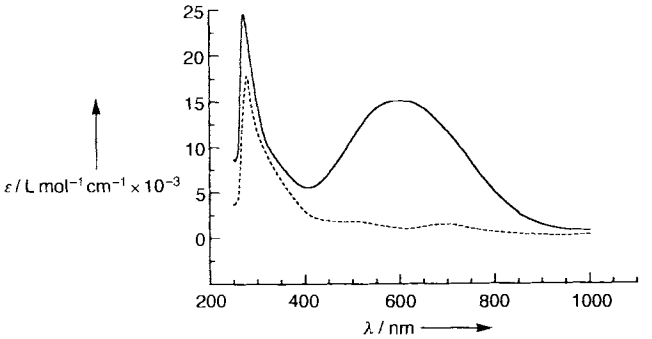

Fig. 2. UV/Vis/NIR spectra of **1b** (—) and $(PPN)_2[Fe_4S_4Cl_4]$ (- - -) in CH_2Cl_2. PPN = bis(triphenylphosphane)iminium.

to the cyanometal units with ε values around 2000 are completely hidden by these bands. We assign the broad bands to intervalence transfer (IT) transitions from the cyanometal unit to the Fe_4S_4 core. This assignment is consistent with the observation that solutions of the trianionic cluster, which is obtained by one-electron reduction of **1a** with cobaltocene, show the IT band at higher energy (466 nm, $\varepsilon = 14000$ L mol^{-1}cm^{-1}).

To further elucidate the electronic nature of the clusters, magnetic measurements were performed for **1a** with a Squid magnetometer. Figure 3 shows the surprising result. At very low tem-

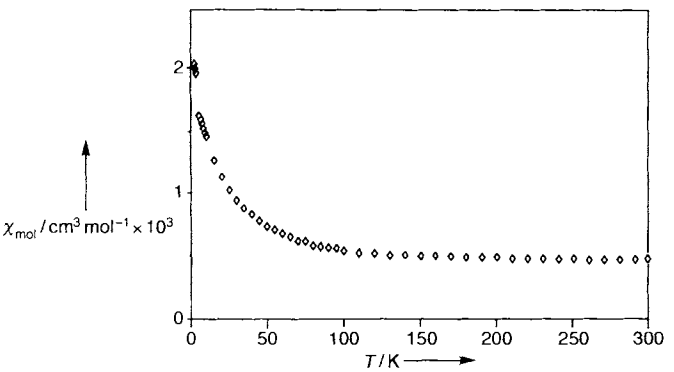

Fig. 3. Temperature dependence of the magnetic susceptibility of **1a**.

peratures an apparent rise of the susceptibility indicates the presence of a paramagnetic impurity that has also been observed in all reference compounds.[5, 10] Between 120 and 300 K, however, χ_{mol} is practically temperature-independent which, to our knowledge, has not been observed for any other synthetic or biological $Fe_4S_4X_4$ derivative. The remaining temperature-independent paramagnetism (TIP) of about 480×10^{-6} cm^3 mol^{-1} lies in the range reported for $[Fe_4S_4Cl_4]^{2-}$ and $[Fe_4S_4(SPh)_4]^{2-}$ ions.[5, 10] If the TIP term is taken as a correction term as has been done for the reference compounds, cluster **1a** and possibly **1b**, **2a**, and **2b** are essentially diamagnetic. In terms of the description of the bonding and the spin–spin interaction for $Fe_4S_4X_4$ species[9, 11] this means that there is very strong antiferromagnetic coupling between the iron atoms with J values well above -300 cm^{-1}. Consequently, the energy gap between the $S' = 0$ ground state and the ladder of excited states is so large that the latter are unaccessible at room temperature.

In accordance with this picture compound **1a** is EPR-silent. Its Mössbauer spectrum recorded at 4.2 K shows a very well resolved doublet with $\delta = 0.333(8)$ mm s^{-1} relative to Fe metal and $\Delta E^Q = 1.06(1)$ mm s^{-1}. These values indicate a delocalized electronic state for the cluster with chemically equivalent iron atoms in the oxidation state +2.5, and the data from the Mössbauer spectrum of **1a** are again very similar to those of other symmetrical $[Fe_4S_4X_4]^{2-}$ compounds.[5, 10, 12]

Thus, while the overall electronic behavior of our new Fe_4S_4 derivatives corresponds to that of known compounds, their strong antiferromagnetic coupling and their intervalence transfer properties pose new questions. It remains to be quantified to what extent the electron-transfer properties of the M-CN-Fe units in **1** and **2** can be exploited, and whether the large separation of the magnetic ground and excited states caused by the cyanometal "ligands" can be related to the preference for the low-spin state caused by cyanide ligands in ordinary complexes.

[7] The possibility of CN inversion, that is the presence of Fe-CN-W links in **1a**, cannot be excluded as we have observed such inversions before and as C and N cannot be distinguished crystallographically.

[5 + 2]Cycloaddition of Cyclic *N*-Phosphino-1-azadienes: Synthesis, Structure, and Reactivity of the First Seven-Membered Iminophosphorane**

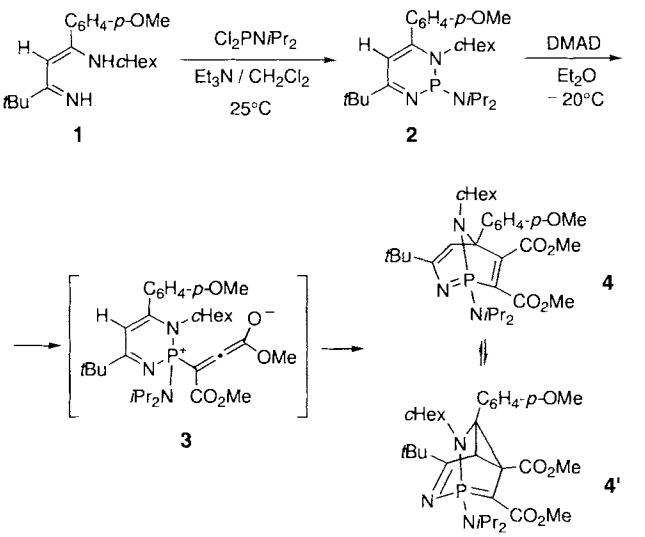
José Barluenga,* Miguel Tomás, Klaus Bieger, Santiago García-Granda, and Rafael Santiago-García

Despite the importance of seven-membered carbocycles, the [5 + 2]cycloaddition reaction has been little developed,[1] and in most cases cationic pentadienyl species are involved.[2] The synthesis of seven-membered heterocycles by 1,5-dipolar cycloadditions is unknown, as far as we are aware;[3] to date only the intramolecular trapping of a vinylthiocarbonyl-*S*-sulfide (1,5-dipole) with an alkene has been reported.[4] The particular chemical properties of phosphorus in compounds led us to investigate α,β-unsaturated *N*-phosphino-substituted imines (*N*-phosphino-1-azadienes) as possible 1,5-dipoles. Our considerations were supported by recent findings in which *N*-phosphino imines[5] and various phosphino 1,3-dipoles[6] were found to react with activated alkenes and alkynes as 1,3- and 1,4-dipoles, respectively. We report herein that 1,2-dihydro-1,3,2-diazaphosphinine **2** actually undergoes [5 + 2]cycloaddition with dimethyl acetylenedicarboxylate (DMAD) leading to novel phospha-heterocycles, as well as on the novel structure and reactivity of these products.[7]

Compound **2** (^{31}P NMR: δ = 57.9) was readily prepared in quantitative yield by condensation of the 4-amino-1-azadiene **1** with dichloro(diisopropylamino)phosphane according to a known procedure (Scheme 1).[8] Treatment of **2** with DMAD in ether at −20 °C afforded a single reaction product (^{31}P NMR: δ = 48.2), which was characterized as the bicyclo[3.2.1]-2,8-diaza-1-phospha-1,3,6-octatriene **4**, and has a new type of iminophosphorane structure.[9] This unprecedented 1,5-dipolar cycloaddition most probably involves nucleophilic attack of the phosphorus center at the electrophilic alkyne, leading to the zwitterionic intermediate **3** followed by 1,7-electrocyclization to give **4** (Scheme 1).

To establish unambiguously the structure of **4**, an X-ray structure analysis was carried out on crystals grown from ether/hexane at −20 °C (Fig. 1).[10] The C4–C6 distance (228.05 pm) is significantly shortened, and the C4-C5-C6 angle (96.1°) as well as the pyramidalization of C7 (sum of angles: 353.9°) suggest an equilibrium between the valence isomers **4** and **4'** in the solid state.[11]

Compound **4** is not thermally stable and rearranges quantitatively (^{31}P NMR spectroscopy) at room temperature in solution (CH_2Cl_2, Et_2O) leading to the new cyclic phosphorus ylide **5** (^{31}P NMR: δ = 56.5) (Scheme 2).[12] Furthermore, we have tested the reactivity of **4** towards electrophiles such as chlorodifluoroacetic acid and methyl iodide. Interestingly, protonation and methylation occurred readily (CH_2Cl_2 at −20 °C) at the carbon adjacent to the phosphorus atom to deliver **6** (E = H) (^{31}P NMR: δ = 46.4) and **7** (E = Me) (^{31}P NMR: δ = 48.5),



Scheme 1. Synthesis of diazaphosphinine **2** and the phosphorus-containing bi- and tricyclic compounds **4** and **4'**, respectively.

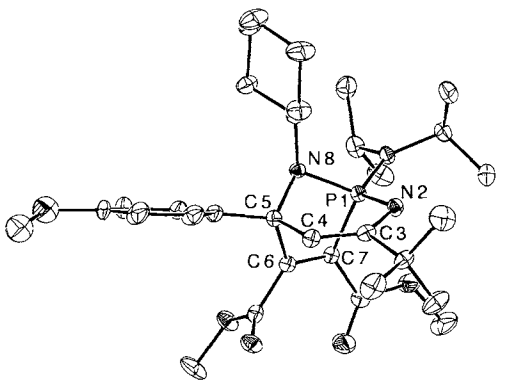


Fig. 1. Crystal structure of **4**. Selected bond lengths [pm] and bond angles [°]: P1–N2 159.7(3), P1–N8 167.8(3), P1–C7 177.2(3), N2–C3 138.7(4), C3–C4 136.6(5), C4–C5 153.2(4), C5–C6 153.5(4), C5–N8 150.1(4), C6–C7 135.1(4); C4-C5-C6 96.1(2), P1-C7-C6 104.6(1), P1-C7-CO, 127.3(2), C6-C7-CO 122.0(3).

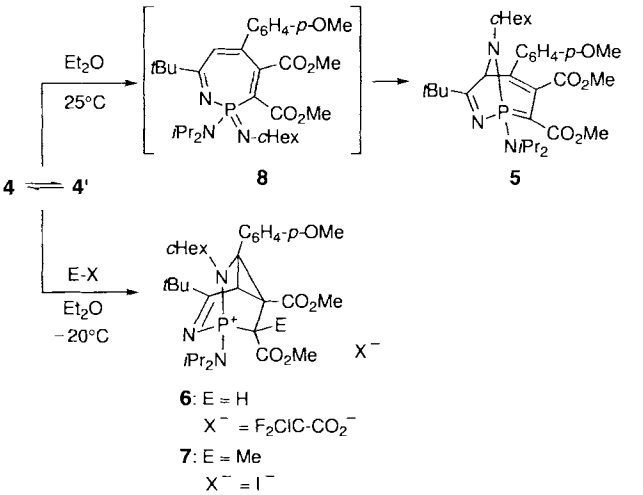

Scheme 2. Formation of phosphorus ylide **5** and phosphonium salts **6** and **7** from **4** and **4'**.

respectively (Scheme 2). These transformations seem to proceed through the valence isomer species **4'**. Thus, the formation of **5** is conceivable by cyclopropane cleavage of **4'** to form intermediate **8**, followed by Michael addition.[13] The trapping reactions of the ylidic carbon atom of **4'** to give the novel phosphonium

[**] This work was supported by DGICYT (Project PB92-1005) and the European Community (Fellowship to K. B.; Contract No. ERBCHBICT941732). The X-ray crystal structure analyses were carried out by S. G.-G. and R. S.-G.

salts **6** and **7** occur stereoselectively, which can be explained easily by the steric hindrance of one of the sides of the molecule by ester and *tert*-butyl groups (see Fig. 1).

Compound **6** cocrystallized in ether together with one molecule of chlorodifluoroacetic acid and the structure was determined by X-ray crystallography (Fig. 2).[10]

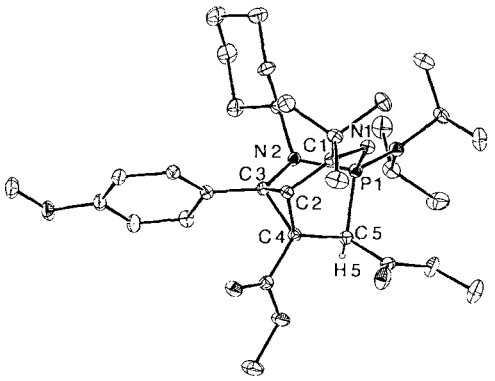

Fig. 2. Crystal structure of **6**. Selected bond lengths [pm] and bond angles [°]: P1–N1 163.9(6), P1–N2 165.8(6), P1–C5 180.9(7), N1–C1 130.8(8), C1–C2 147.6(9), C2–C3 157.4(9), C2–C4 153.4(9), N2–C3 146.3(8), C3–C4 151.7(9), C4–C5 151.3(9); C4-C2-C3 58.4(4); C4-C3-C2 59.5(4); C2-C4-C3 62.1(4).

In summary, we have reported the first [5 + 2]heterocycloaddition of a neutral species, namely a masked phosphorus-containing 1,5-dipole, as well as unusual rearrangements of the resulting bicyclic iminophosphorane. The interatomic distances and angles determined by X-ray structure analysis suggest a norcaradiene–cycloheptatriene type rearrangement **4** $\rightleftharpoons$ **4′** *in the solid state*. Moreover, it is worth noting that all transformations reported here result in the isolation of new, unusual structures (**4**–**7**) in high yields.

Experimental Procedure

Aminoazadiene **1** [14] (4.85 g, 15.4 mmol) was added slowly at 0 °C to a solution of dichloro(diisopropylamino)phosphane (3.12 g, 15.4 mmol) in CH_2Cl_2/NEt_3 (20 mL/5 mL). After the mixture had been stirred for 6 h at 20 °C, the solvent and excess amine were removed under reduced pressure, the residue was treated with ether, and the salts were filtered off. Dihydrophosphinine **2** (^{31}P NMR: δ = 57.9) was obtained as a yellow oil after evaporation of the solvent (6.40 g, 94%) and used without further purification.

A solution of DMAD (0.45 g, 3.2 mmol) in ether (5 mL) was added to a well-stirred solution of **2** (1.41 g, 3.2 mmol) in ether (30 mL) at −20 °C. The mixture was kept at −20 °C for 12 h. Then compounds **4**–**7** were prepared as follows: 1) Evaporation of the solvent at reduced pressure and treatment of the residue with hexane at −20 °C afforded **4** [1.5 g, 80%; ^{31}P NMR: δ = 48.2; m.p. 106–109 °C (decomp)] as yellow-orange crystals. 2) The reaction mixture was left at room temperature for 24 h, the solution was concentrated under vacuum, and the residue crystallized from hexane/ether to afford **5** [1.4 g, 75%; ^{31}P NMR: δ = 56.5; m.p. 134–136 °C (decomp)] as yellow crystals. 3) The reaction mixture was stirred at −20 °C with an excess of chlorodifluoroacetic acid or methyl iodide for 15 min. Removal of solvents and crystallization of the residue from ether gave compounds **6**·ClF_2CCO_2H [1.8 g, 66%; ^{31}P NMR: δ = 46.4; m.p. 115 °C (decomp)] and **7** [1.7 g, 73%; ^{31}P NMR: δ = 48.5; m.p.: 165–170 °C (decomp)] as colorless crystals.

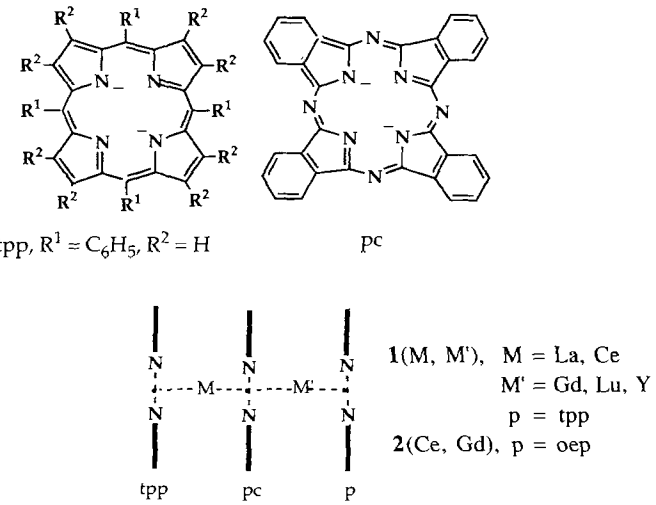
Mixed-Metal Triple-Decker Sandwich Complexes with the Porphyrin/Phthalocyanine/Porphyrin Ligand System**

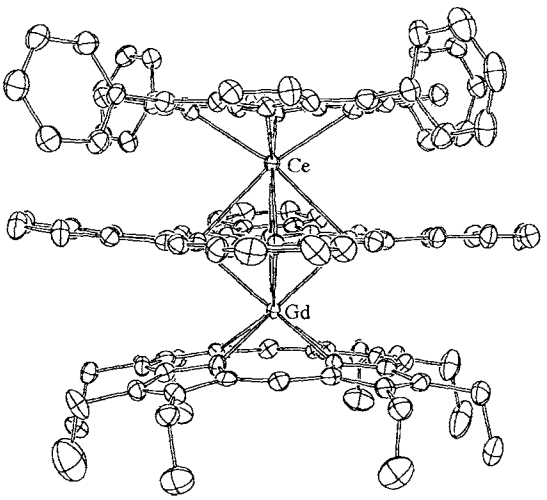
Porphyrin and porphyrin–phthalocyanine double-decker sandwich complexes $[M(p)_2]$ and [M(p)(pc)] can be expanded to symmetric and asymmetric triple-decker sandwich complexes of the form $[M_2(p)_3]$, $[M_2(p)_2(pc)]$, and $[M_2(pc)_2(p)]$ (M = trivalent metal ion; p = porphyrin dianion, pc = phthalocyanine dianion).[1–4] The electronic structures of these triple-decker molecules have been probed by means of the electrochemical, magnetic, and spectroscopic properties of their neutral and one-electron oxidized and reduced states. UV/Vis and electrochemical studies and magnetic susceptibility measurements indicate that upon oxidation of the [(tpp)M(pc)M(tpp)] (tpp = tetraphenylporphyrin dianion) complexes in which no Ce^{III} center is present ($M = La^{III}$, Gd^{III}), the phthalocyanine dianion is preferentially oxidized to the radical monoanion.[5] In contrast, magnetic studies and X-ray photoelectron spectroscopy show that in [(tpp)Ce(pc)Ce(tpp)], one Ce^{III} center is oxidized to Ce^{IV}.[4b]

We have now synthesized and characterized the following mixed-metal complexes: [(tpp)M(pc)M′(tpp)] (**1**(M,M′)), containing no oxidizable metal (M = La, M′ = Y) or one oxidizable metal (M = Ce, M′ = Gd, Lu, Y), and [(tpp)Ce(pc)-Gd(oep)] (**2**(Ce,Gd), oep = octaethylporphyrin dianion). The complex **2**(Ce,Gd) is the first heteronuclear triple-decker sandwich complex with mixed ligands that has been analyzed by a crystal structure determination. The structural formulas of the ligands and a diagrammatic representation of the triple-decker complex is shown in Scheme 1. Electrochemical studies of these mixed-metal sandwich complexes lead to two different linear correlations of the first oxidation potentials with the mean ionic radii of the metals ($[r_i(M) + r_i(M')]/2$) that depend on the presence or absence of an oxidizable Ce^{III} ion.



Scheme 1. Structural formulas of the p and pc ligands and a schematic representation of the triple-decker complexes **1** and **2**.

The synthesis of the heteroleptic, heteronuclear complexes **1**(M,M′) is described in the experimental procedure. However, all attempts to grow suitable crystals of these complexes for X-ray crystal structure analysis failed. Instead we therefore synthesized the Ce^{III}/Gd^{III} derivative with tetraphenylporphyrin, phthalocyanine, and octaethylporphyrin as ligands. This compound yielded crystals of composition **2**(Ce,Gd)·$2C_6H_5Cl$,[6] which contain discrete molecules of **2**(Ce,Gd) (Fig. 1).[7] The triple-decker molecules do not exhibit any bonding interactions with one another nor with the chlorobenzene molecules of solvation. As shown in Figure 1, both the Ce and Gd atoms are



octacoordinated. The outer oep and central pc rings are rotated by an angle of 44.8(4)° relative to their eclipsed orientation. Consequently, the coordination polyhedron of the Gd atom is a slightly distorted square antiprism. In contrast, the outer tpp and central pc rings are almost eclipsed, the rotation angle being only 5.0(1)°. Therefore, the coordination polyhedron of the Ce^{III} ion is a slightly distorted cube. The displacements of the metals relative to the four pyrrole-nitrogen and isoindole-nitrogen mean planes of the macrocycles are as follows: Ce–tpp = 1.330(4), Ce–pc = 1.987(4), Gd–pc = 1.775(4), and Gd–oep = 1.190(4) Å. The outer tetraphenylporphyrin and octaethylporphyrin rings adopt conformations that are domed towards the Gd and Ce cations.[8] The phthalocyanine ring is also domed, with the result that the mean plane of its four isoindole–nitrogens lies closer to the Gd cation than the mean plane through the inner 24 atoms of the ring framework.[8] This particular conformation of the pc ring arises probably both because the ionic radius of Gd^{III} is smaller than that of Ce^{III} and because π–π interactions between the oep and pc are stronger than those between the tpp and pc rings. It had been previously noticed that the π–π interactions in $[Zr(oep)_2]$ were stronger than those in $[Zr(tpp)_2]$.[9–11]

The UV/Vis spectra of all the complexes **1**(M,M′) (M = La, M′ = Y; M = Ce, M′ = Gd, Lu, or Y) and **2**(Ce,Gd) obtained in solution are very similar to each other (see Experimental Procedure) and to the spectra of triple-decker systems with two identical metals **1**(M,M) (M = La, Ce, Pr, Nd, Eu, Gd).[4b]

They are also similar to those displayed by thin films of **1**(Ce,Ce) obtained by sublimation under vacuum.[12] These spectral properties thus confirm that the triple-decker sandwich structures, observed in the solid state for **2**(Ce,Gd) and **1**(Ce,Ce),[4a] are retained in solution for both series of complexes **1**(M,M′) and **1**(M,M). The redox behavior of the mixed-metal complexes **1**(M,M′) was determined by cyclic voltammetry (CH_2Cl_2, 0.1 M NBu_4PF_6). The cyclic voltammograms of these species parallel those of the systems with two identical metals.[4b] All the complexes belonging to the two series **1**(M,M′) and **1**(M,M) undergo three reversible oxidations and two reversible reductions. Moreover, as shown in Figure 2a and 2b, the first oxidation potentials

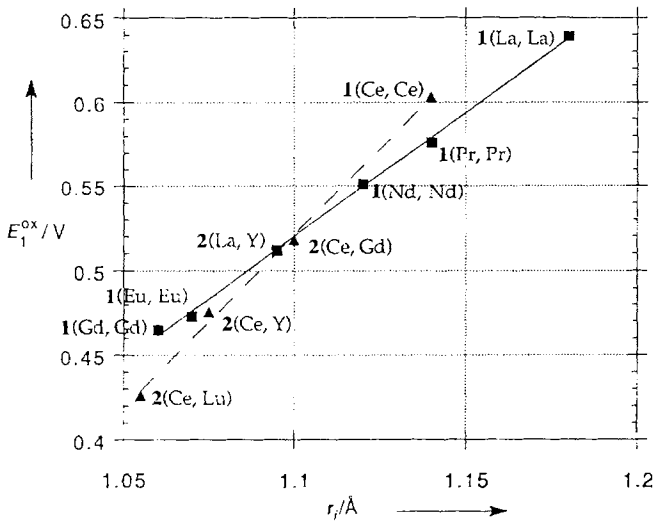

Fig. 2. Correlation between the first oxidation potentials E_1^{ox} of the triple-decker sandwich complexes **1**(M,M′) and **1**(M,M) and the mean ionic radii of M and M′ or the ionic radii of M: ▲ cerium-containing complexes, ■ cerium-free complexes.

(E_1^0) of the mixed-metal complexes **1**(M,M′) examined to date also show a linear correlation with the mean ionic radii of their metal cations. However, as in the complexes containing two identical metal cations **1**(M,M), the slopes of the correlations depend on the presence or absence of a Ce^{III} metal center. These results thus confirm that the presence or absence of an oxidizable Ce^{III} metal ion controls whether the first oxidation occurs at the central atom or the ligand.[4b, 5]

Experimental Procedure

1(M,M′) and **2**(Gd,Ce): A solution of the metal acetylacetonate [M′(acac)$_3$·nH$_2$O] and the metal-free porphyrin H_2p (H_2tpp or H_2oep) (about 0.10 mmol) in 1,2,4-trichlorobenzene was heated at reflux in a three-neck flask for four hours under argon. After cooling, a solid sample (about 0.07 mmol) of a heteroleptic sandwich complex [(tpp)M(pc)] (M = La, Ce) was added, and the resulting mixture was heated at reflux for another eight hours under argon. After cooling, a crude solid was precipitated by addition of pentane. This solid was then extracted several times with dichloromethane. The extracts were combined, and the resulting solution was concentrated under vacuum and then chromatographed on a silica gel column (3/18 cm). Elution with toluene yielded successively some porphyrin H_2p and the olive green triple-decker complex [(tpp)M(pc)M′(tpp)] **1**(M,M′) or [(tpp)Ce(pc)Gd(oep)] **2**(Ce,Gd), which were precipitated by addition of pentane.

1(Ce, Gd): yield 112 mg (79%); correct C,H,N elemental analysis; MS (FAB^+): m/z (%) = 2034 (100) [M^+]; UV/Vis (CH_2Cl_2) λ_{max} [nm] (lgε) = 354 (5.4), 418 (5.6), 490 (5.2), 553 (5.1), 605 (5.1).

2(Ce, Gd): yield 110 mg (81%); correct C,H,N elemental analysis; MS (FAB^+): m/z (%) = 1954 (100) [M^+]; UV/Vis (CH_2Cl_2) λ_{max} [nm] (lgε) = 351 (5.4), 395 (5.3), 420 (5.4), 465 (4.8), 516(5.2), 595 (4.8).

1(Ce, Lu): yield 91 mg (64%). Correct C,H,N elemental analysis; MS (FAB^+): m/z (%) = 2052 (100) [M^+]; UV/Vis (CH_2Cl_2) λ_{max} [nm] (lgε) = 350 (5.5), 413 (5.6), 424 (5.6), 489 (5.3), 558 (5.1), 608 (5.2).

1(Ce, Y): yield 96 mg (70%); correct C,H,N elemental analysis; MS (FAB^+): m/z (%) = 1966 (100) [M^+]; UV/Vis (CH_2Cl_2) λ_{max} (lgε) = 350 (5.5), 415 (5.6), 424 (5.6), 488 (5.3), 558 (5.1), 607 (5.2).

1(La, Y): yield 94 mg (69%); correct C,H,N elemental analysis; MS (FAB^+): m/z (%) = 1965 (100) [M^+]; UV/Vis (CH_2Cl_2) λ_{max} (lgε) = 350 (5.5), 414 (5.6), 424 (5.6), 487 (5.3), 558 (5.2), 607 (5.3); ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, TMS): δ = 10.3 (d, 4H), 9.48 (m, 8H), 8.44 (m, 8H), 8.35 (t,4H), 7.75 (t, 4H), 7.71 (s,8H), 7.51 (t, 4H), 7.37 (t, 4H), 7.11 (t, 4H), 6.94 (s, 8H), 6.84 (t, 4H), 6.57 (d, 4H), 6.30 (d, 4H), 5.48 (d, 4H).

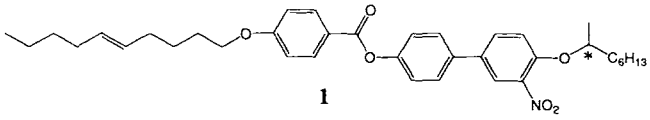
Direct Observation of Enantiomorphous Monolayer Crystals from Enantiomers by Scanning Tunneling Microscopy

Forrest Stevens, Daniel J. Dyer, and David M. Walba*

Pasteur's brilliant observation, using optical microscopy, that crystals of a salt of "racemic acid" actually existed in two enantiomorphous forms[1] not only uncovered the existence of enantiomers, but indeed stimulated the development of modern structural theory. The direct (without resorting to diffraction techniques) observation of supermolecular chirality and the relationship between supermolecular chirality and molecular structure have fascinated chemists ever since. Starting with early studies of the morphology of chiral crystals by optical microscopy, the scale for the observation of chiral supermolecular assemblies has been approaching that of the molecules themselves. McConnell and Weis first recorded the formation of chiral crystalline monolayer domains in Langmuir films of enantiomerically pure lipids by epifluorescence optical microscopy.[2] More recently, chiral monolayers have been observed at molecular resolution by scanning probe microscopy. Thus, chiral symmetry breaking from achiral[3] and racemic[4] molecules has been detected in Langmuir films by atomic force microscopy (AFM), and enantiomorphous monolayer domains from achiral liquid crystal (LC) molecules on graphite have been observed by scanning tunneling microscopy (STM).[5] In related work, amino acids have been spontaneously resolved by crystallization in two dimensions at the air–water interface.[6]

We report here on the molecular resolution STM observation of enantiomorphous images of crystal monolayers grown from pure enantiomers. Furthermore, a racemic mixture of the same molecules produced images of co-existing enantiomorphic domains indistinguishable from those obtained from the enantiomerically pure materials, providing strong evidence for chiral symmetry breaking to give a two-dimensional (2-D) conglomerate. These results suggest a complete 2-D analog of Pasteur's famous system.

The experiments were performed on enantiomerically enriched and racemic biphenylbenzoates **1**. These have one tetra-



1

hedral stereogenic center (indicated by an asterisk). Both enantiomers were prepared in approximately 99% *ee*; the racemate was also prepared.[7] All three compounds were liquid crystalline with a smectic A phase at room temperature.

Each STM sample was prepared by placing a small amount (<1 mg) of the liquid crystal on a freshly cleaved surface of highly oriented pyrolytic graphite. Scanning tips were prepared from mechanically cut 0.025 cm platinum/iridium (80:20) wire. Images were recorded in air at room temperature using a commercially available STM (Nanoscope II, Digital Instruments, Inc.) with tip positive bias.

The images obtained for monolayers of either enantiomer varied somewhat in appearance, probably due to variations in the STM tip. However, by using autocorrelation analysis (see below)[8] the measured unit cell dimensions for all the images obtained were the same within experimental error. Thus, while polymorphism has been observed with similar molecules,[9] enantiomerically pure **1** apparently produces only one monolayer crystal structure.

When the images were of sufficient quality to resolve the molecules, similar structures were always observed, as illustrated in Figure 1 for samples of (*S*)-**1** (Fig. 1A) and (*R*)-**1** (Fig. 1B).

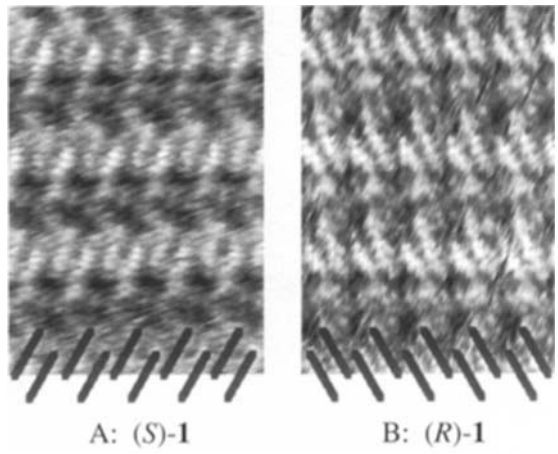

Fig. 1. Enantiomorphous images obtained from (*S*)-1 (A) and (*R*)-**1** (B). The dimensions of the image are 8 nm × 11.5 nm; the gray bars representing the bright regions in the images are 16 Å in length on this scale. These images are raw data, rotated and cropped from the original 15 × 15 nm (400 × 400 data points) scans to aid in the comparison. The scanning parameters were: A: 400 mV, 1 nA; B: 300 mV, 1 nA.

The unit cell dimensions are the same within experimental error, but examination of the images shows that they are clearly enantiomorphous. Images of monolayer crystals grown from both enantiomers exhibit well-defined rows of tilted, rod-shaped bright regions (i.e. areas of enhanced tunneling efficiency), but the bright rods are tilted in opposite directions for the enantiomers.

While the precise mechanisms involved in imaging of organic monolayers overlying conducting surfaces is not known, it is well established that aromatic molecular units image brightly, while aliphatic units are darker.[10, 11] This is the case whether the surface is biased negatively or positively relative to the tip. In the present case the bright regions are approximately 16 Å in length, consistent with the size and shape of the biphenylbenzoate aromatic units. In the monolayers formed from the (*S*) liquid crystal, the cores are tilted about 30° clockwise from the row normal (Fig. 1A), while the monolayers formed from the (*R*) liquid crystal show the cores tilted counterclockwise by a similar amount (Fig. 1B). For the purposes of the present discussion, the image type in Figure 1A, obtained from (*S*)-**1**, will be denoted (+) for clockwise, while that obtained from (*R*)-**1** will be denoted (−) for counterclockwise.

In all cases where monolayer chirality could be resolved, the handedness of the images was coupled to the configuration of the molecules. Out of nine attempts to image (*S*)-**1** six gave monolayer crystals providing images with clearly distinguishable (+) chirality, while in six separate sessions (*R*)-**1** gave discernible (−) images. Hundreds of images were recorded in these sessions, and in no case was observable (+) chirality associated with (*R*)-**1** or (−) chirality associated with (*S*)-**1**. Thus, it can be

stated with a high degree of certainty that molecular chirality is transferred to a chiral supermolecular packing mode, which in turn gives rise to chiral images by STM.

When monolayer crystals are grown from racemic **1**, the formation of a racemic monolayer might be expected by analogy with three-dimensional (3-D) organic crystals, which show some tendency to form racemic crystals rather than conglomerates. However, in a total of eight imaging sessions with racemic **1**, (+) images were observed six times, (−) images were observed seven times, and in four separate cases domain walls between regions of opposite chirality were observed, as illustrated in Figure 2. While Eckhardt et al[4] have used AFM to observe

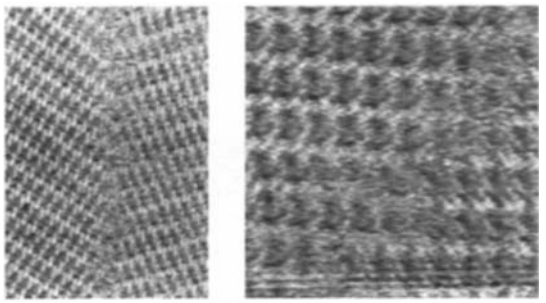

Fig. 2. Co-existing enantiomorphous images obtained from racemic **1**. Image A shows an area of dimensions 27 nm × 38 nm, and image B shows a 15 nm × 15 nm area. These images are raw data, cropped from originals of 50 × 50 nm and 20 × 20 nm, respectively. The scanning parameters were: A: 300 mV, 1 nA; B: 600 mV, 1 nA.

enantiomorphous domains in a racemic material, they did not have access to the corresponding enantiomerically pure material and so could not compare the structures formed by the racemate to structures formed by pure enantiomers, as we have done.

Observation of enantiomorphous domains from the racemic material by STM could result from two different mechanisms: 1) The racemic material could spontaneously resolve into monolayer crystals of pure (*R*) and pure (*S*) material forming a 2-D conglomerate. 2) Both enantiomorphous domains could be composed of racemate—an example of formation of chiral supermolecular structures from "achiral" pairs of enantiomeric molecules. In both cases the enantiomorphous domains represent enantiomeric monolayer crystal structures; in the latter case the enantiomeric domains are composed of mixtures of (*R*) and (*S*) molecules, while in the former case the domains are composed of homochiral molecules (it is not possible to physically separate the domains to measure optical activity in solution, as Pasteur did, to distinguish between these two possibilities). Of course, the crystals formed by these two mechanisms must be diastereomeric.

If resolution occurs and the monolayer crystal domains are enantiomerically pure, the chiral images observed from the racemic material must be identical to those obtained from one or the other of the pure enantiomers. On the other hand, if the monolayer crystals are racemic, the observed images should be different from those of the pure enantiomers, though due to the limits of the STM technique the racemic crystal could fortuitously produce images indistinguishable from those derived from the pure enantiomers.

Autocorrelation was used to calculate unit cells for monolayer crystals grown from enantiomerically pure and racemic **1**. Tip drift often caused "up" scans to be stretched, while "down" scans were compressed, or vice versa. To compensate for this effect, whenever possible consecutive up and down scans were taken and their unit cells averaged. Only these "pair averaged" values were used in the analysis.

Over one hundred pairs of images were analyzed for each material (the two enantiomers and the racemate), and the unit cells from both the pure enantiomers and from the racemate were found to be the same within experimental error.[12] This strongly suggests that the racemate forms a 2-D conglomerate of enantiomerically pure monolayer crystals upon adsorption on graphite—these enantiomerically pure crystals are identical to those obtained from the pure enantiomers. This is similar to the results obtained by Nassoy et al[13] who used grazing incidence X-ray diffraction to show that the unit cells in monolayers of D,L, and racemic myristoyl-alanine were identical. However, they were unable to resolve domains within the racemate or to obtain images of the structures with molecular resolution.

We have used STM to observe monolayers formed by both enantiomers of a chiral material, and the corresponding racemate. The pure enantiomers gave monolayer crystals that produced chiral 2-D images by STM, and enantiomeric molecules delivered enantiomorphic images reproducibly. The racemic material produced monolayer crystals showing both chiralities in two dimensions, and the domains were indistinguishable from images obtained from enantiomerically pure material. This strongly suggests that the racemate forms a 2-D conglomerate of enantiomerically pure monolayer crystals on the graphite surface.

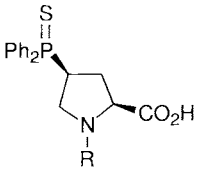
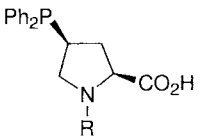
Synthesis of Thiophosphoryl Derivatives of Proline: Building Blocks for Phosphanyl-Substituted Peptides with β-Turns

Scott R. Gilbertson* and Robert V. Pawlick

Natural proteins bind metal atoms for two purposes.[1-3] One is the control and stabilization of protein structure. A number amino acids[4-18] with potential ligands for metals have been incorporated into or at the end of peptide sequences. In these peptides metal complexation has been used to stabilize secondary structure[4-10] or to connect two or more peptides.[11-14] The second role metal atoms play in protein chemistry is based on reactivity of the metal,[19] which may be involved in a variety of reactions such as oxidation, electron transport, protein hydrolysis, and oxygen binding. While much has been accomplished in the use of unnatural amino acids to bind metals to stabilize peptide secondary structure, little work has done in the area of designing and building artificial peptides that contain catalytically active metal systems.[20] For this reason we undertook the development of amino acids that contain phosphanyl groups. The ability to bind transition metals into peptides with phosphanyl groups will make a variety of organometallic chemistry accessible.[21-23] Potentially, peptide structure can then be used to control reactions not usually associated with biological systems such as hydrogenation,[24a] hydroformylation,[25] and cycloisomerization reactions.[26, 27] With a variety of phosphanyl amino acids available one should be able to use metal–phosphane coordination to control peptide structure as well as control reactivity by positioning metals such as rhodium, ruthenium, palladium, and platinum in unique steric environments. In this paper we report on the synthesis of thiophosphorylprolines **1** and **2** by standard peptide coupling methods; their incorporation, along with another phosphanyl-substituted amino acid, into a peptide with a β-turn structural motif; the reduction of the thiophosphoryl group to give the free phosphanes; and the binding of rhodium to this structurally unique ligand.[4, 5, 28] The secondary structures of both the uncomplexed and the metalated peptide were characterized by 2D NMR spectroscopy.



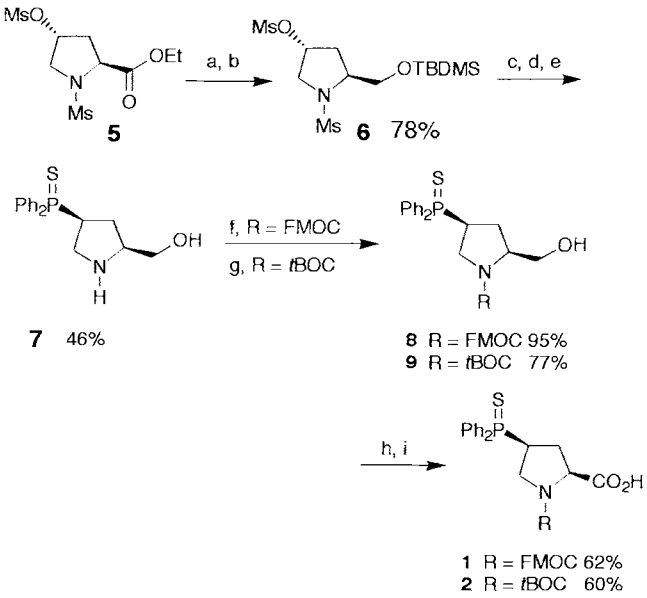
1 R = FMOC
2 R = *t*BOC



3 R = FMOC
4 R = *t*BOC

The original approach to the synthesis of the desired proline derivative was to protect the amino and carboxyl groups of 4-hydroxyproline, convert the hydroxyl group into a good leaving group, and replace this by nucleophilic displacement with a phosphane.[29-31] Our initial attempts using hydroxyproline, in which the ester was protected with a variety of protecting groups, failed. We believe that owing to the high nucleophilicity of the diphenylphosphanide anion, the ester group did not survive the reaction conditions. The next approach attempted was to perform the nucleophilic substitution on a protected hydroxyprolinol and then oxidize the primary hydroxyl group to the carboxlic acid. This route has proven successful despite the potential problem of oxidation of the phosphane sulfide to a phosphane oxide.

Amino acids **1** and **2** were synthesized from readily available 4-hydroxyproline (Scheme 1). Reaction of the ethyl ester of



Scheme 1. a) $NaBH_4$, LiCl, THF/EtOH, 78%; b) TBDMSOTf, lutidine, CH_2Cl_2, 90%; c) Ph_2PNa, THF; d) RedAl, DME, reflux; e) $Na_2S_2O_3$, MeOH, H_2O; f) FMOCOSu, $NaHCO_3$, acetone/H_2O; g) $(BOC)_2O$, $NaHCO_3$, dioxane/H_2O; h) Swern oxidation; i) PDC, DMF.

4-hydroxyproline with two equivalents of methanesulfonyl chloride in triethylamine gave the bis(mesyl) ethyl ester **5**. Compound **5** was reduced to the alcohol and the hydroxyl group was protected by silylation with *tert*-butyldimethylsilyl trifluorosulfonate (TBDMSOTf) to afford **6**. Reaction with sodium diphenylphosphanide displaced the mesylate at the 4-position with inversion of that chiral center.[31] Reaction with sodium bis(2-methoxyethoxy)aluminum hydride (RedAl) in dimethoxyethane (DME) removed both the *N*-mesyl and the silyl group. Treatment with sodium thiosulfate in water/methanol formed the air-stable thiophosphoryl amino alcohol **7**.[32, 33] Reaction with *N*-(9-fluorenylmethoxycarbonyloxy)succinimide (FMOCOSu) yielded the FMOC-protected amino alcohol **8**, whereas reaction with di-*tert*-butyl dicarbonate gave the *tert*-butylcarbonyl (BOC) protected amino alcohol **9**.[34] The remaining reactions in the sequence proceeded smoothly on both the FMOC- and the BOC-protected intermediates. Swern oxidation[35, 36] followed by oxidation with pyridinium dichlorochromate (PDC)[37, 38] provided the desired N-protected thiophosphoryl amino acids **1** and **2** in good yields.

The incorporation of phosphanyl-substituted amino acids into peptides with stable secondary structure is critical to the goal of using peptide secondary structure to control the reactivity of catalytic transition metals. One of the motives for the synthesis of a phosphane-containing proline derivative was to be able to incorporate rhodium and ruthenium atoms into β-turn structural motifs. Recently Imperiali et al. demonstrated that the tetrapeptide Ac-Val-Pro-D-Ser-His-NH_2 shows a significant

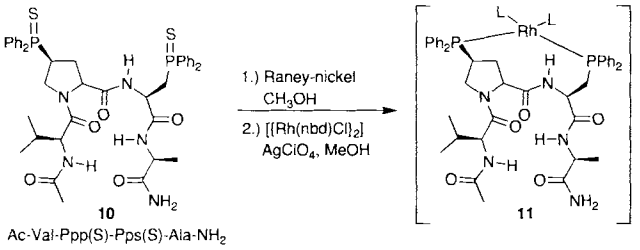
proportion of type II β-turn conformation in DMSO or aqueous solution.[39] Additionally, it has been shown that β-turn structures are favored when a proline residue is in the $i+1$ position.[40] For these reasons we chose to synthesize tetramer **10** (Val-Ppp(S)-Pps(S)-Ala).[41] A second phosphane-containing amino acid, diphenylphosphanylalanine (Pps), is located in the $i+2$ position of the target peptide (Scheme 2).[32] Molecular



Scheme 2. Synthesis of the peptide–phosphane ligand from **10** and formation of the phosphane–rhodium complex **11**. Ppp(S) = 4-(diphenylthiophosphoryl)proline, Pps(S) = diphenylthiophosphorylalanine, Ppp = 4-(diphenylphosphanyl)-proline, Pps = diphenylphosphanylalanine.

modeling indicated that when peptide **10** is in a turn conformation the thiophosphoryl groups are on the same face of the molecule and properly positioned to bind transition metals (see Fig. 1).

The NOESY spectra of **10** in $CDCl_3$ and DMF indicate that the predominate conformation is a type II β-turn. In particular, NOE interactions observed between $d_{\alpha N}(i+1,i+2)$ (A), $d_{NN}(i+2,i+3)$ (B), $d_{N\alpha}(i+2,i+2)$ (C), and $d_{\alpha N}(i+1,i+3)$ (D) are indicative of a type II β-turn structure. Furthermore, interactions E and F between the side chains at positions i (valine) and $i+3$ (alanine) are additional evidence for a β-turn structure. This assignment of secondary structure is supported by a ^3J coupling constant of 5.5 Hz between $(i+2)$NH and $(i+2)\alpha$H.[42] We were moderately surprised the peptide would form a β-turn as its major conformation, given that this secondary sturcture positions the large diphenylthiophosphoryl groups on the same face of the turn structure (Fig. 1). That the structure appears to be a type II β-turn is also interesting; only a limited number of peptides with type II β-turns having L-amino acids in the $i+1$ and $i+2$ positions are known.[43]

Reaction of peptide **10** with Raney nickel converted the thiophosphoryl groups into free phosphanes. The resulting bidentate ligand was then treated with $[Rh(nbd)]^+$ (nbd = norbornadiene), which was generated by reaction of $[\{Rh(nbd)Cl\}_2]$ and $AgClO_4$, to give the rhodium–peptide complex **11** (Scheme 2).

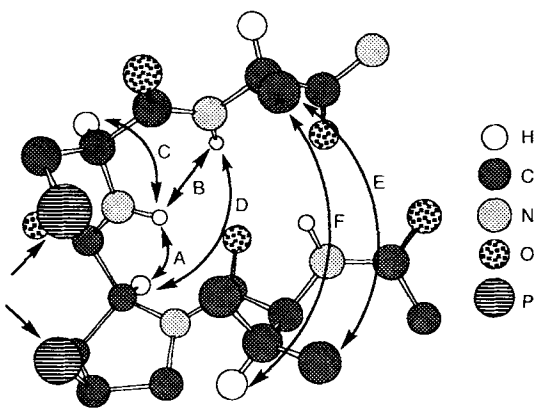


Fig. 1. NOE interactions (double-headed arrows) observed for **10** and **11**: A) $d_{\alpha N}$(Ppp, Pps); B) d_{NN}(Pps, Ala); C) $d_{N\alpha}$(Pps, Pps); D) $d_{\alpha N}$(Ppp, Ala); E) $d_{\alpha\beta}$(Val, Ala); F) $d_{\beta\beta}$(Val, Ala). The phenyl groups of the thiophosphoranes and the protons of the valine and alanine side chains have been omitted for clarity. Note that the two thiophosphoryl groups are located on the same face of the β-turn (arrows).

Metal complexation to the phosphane ligands was easily followed by ^{31}P NMR spectroscopy. Coupling of rhodium (spin = 1/2) to the P atoms of the peptide clearly indicated metal chelation. The NOESY NMR experiments indicated that the rhodium peptide complex **11** has a type II reverse turn structure. As in **10**, NOE interactions A–F (Fig. 1) were observed in **11**.

The ability to incorporate phosphanyl groups into various peptide structures allows for the facile synthesis of a wide variety of phosphane ligands with unique secondary structures. It should now be possible to incorporate phosphanyl groups into virtually any type of peptide structure attainable by peptide synthesis. In principle, a large number of ligands can be synthesized and screened for unique structural characteristics, useful reactivity, and important biological activity. We are currently using commercially available technology to build libraries of ligands and are then screening their reactivity. Phosphanyl-containing peptides might be used to immobilize catalytically active metals in membranes or on surfaces, thus leading to new types of catalyst systems. We are beginning to use this chemistry to synthesize polymer-bound metal ligand systems with the goal of developing well-defined polymer-bound catalysts.

Experimental Procedure

Selected spectroscopic data for **1**, **2**, **10**, and **11**.

1: ^1H NMR (300 MHz, $CDCl_3$): δ = 7.92–7.79 (m, 4H), 7.7–7.63 (m, 2H), 7.59–7.42 (m, 8H), 7.38–7.16 (m, 4H), 4.5–4.36 (m, 2H), 4.34–4.04 (m, 2H), 3.83–3.61 (m, 2H), 3.3 (m, 1H), 2.55 (m, 1H), 2.29 (m, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) (major rotational isomer): δ = 176.5, 154.8, 143.7, 143.3, 141.2, 132.0, 131.6 (d, J(C,P) = 7.1 Hz), 131.3, 131.0 (d, J(C,P) = 9.9 Hz), 128.9 (d, J(C,P) = 11.4 Hz), 127.6, 124.8 (d, J(C,P) = 10.3 Hz), 119.8, 67.9, 59.2 (d, J(C,P) = 10.5 Hz), 47.8 (d, J(C,P) = 31 Hz), 46.9, 38.5 (d, J(C,P) = 60.4 Hz), 30.4; ^{31}P NMR (120 MHz, $CDCl_3$): δ = 44.19 (major rotational isomer), 44.08 (minor isomer); IR (film): $\tilde{\nu}$ = 3060 (br.), 2955 (w), 2881 (w), 1751 (m), 1724 (m), 1706 (s), 1479 (m), 1451 (m), 1436 (s), 1426 (m), 1320 (m), 1170 (m), 1102 cm^{-1} (m); LRFABMS: *m/z* (%): 554 (MH^+, 70), 336 (15), 307 (27), 219 (25), 179 (87); HRFABMS: *m/z* calcd for $C_{32}H_{29}NO_4PS$: 554.1555, found 554.1552.

2: ^1H NMR (300 MHz, $CDCl_3$): δ = 7.91–7.84 (m, 6H), 7.54–7.44 (m, 6H), 4.32 (m, 1H), 3.75–3.65 (m, 2H), 3.33 (m, 1H), 2.55 (m, 1H), 2.29 (m, 1H), 1.41 (s, 9H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 177.1, 157.1, 154.7, 153.3, 131.9 (d, J(C,P) = 4.7 Hz), 131.1 (d, J(C,P) = 17.6 Hz), 131.1 (d, J(C,P) = 17.6 Hz), 131.0 (d, J(C,P) = 13.8 Hz), 131.0 (d, J(C,P) = 15.1 Hz), 128.8 (d, J(C,P) = 12.3 Hz), 81.0, 60.4, 59.0 (d, J(C,P) = 9.9 Hz), 47.3 (d, J(C,P) = 7.5 Hz), 37.7 (d, J(C,P) = 60.3 Hz), 31.5, 28.1, 27.9, 14.1; ^{31}P NMR (120 MHz, $CDCl_3$): δ = 44.13 (major isomer), 43.94, 45.35 (minor isomer); IR (film): $\tilde{\nu}$ = 3055 (br.), 3004 (w), 2981 (w), 2932 (w), 1700 (s), 1696 (s), 1419 (s), 1399 (s), 1159 cm^{-1} (s); LRFABMS: *m/z* (%): 432 (MH^+, 22), 376 (88), 332 (31), 219 (64), 154 (100); HRFABMS: *m/z* calcd for $C_{22}H_{27}NO_4PS$: 432.1398, found 432.1401.

10: ^1H NMR (500 MHz, $CDCl_3$): δ = 8.3 (d, J(H,H) = 5.5 Hz, 1H), 7.91–7.80 (m, 8H), 7.58–7.36 (m, 13H), 6.90 (s, 1H), 6.74 (s, 1H), 5.8 (s, 1H), 4.42 (m, 1H), 4.29 (m, 1H), 4.21–4.18 (m, 2H), 4.1 (dd, J(H,H) = 10.3 Hz, 1H), 3.69 (dd, J(H,H) = 7.3, 9.7 Hz, 1H), 3.37 (m, 1H), 3.26–3.19 (m, 2H), 2.3 (dddd, J(H,P) = 12.1, J(H,H) = 10.5, 9.5, 9.5 Hz, 1H), 2.04 (m, 1H), 1.96 (br. s, 4H), 1.30 (d, J(Me-H,H) = 7.3 Hz, 3H), 0.89 (d, J(Me-H,H) = 6.1 Hz, 3H), 0.86 (d, J(Me-H,H) = 6.7 Hz, 3H), see Table 1 for signal assignment; ^{13}C NMR (75 MHz, $CDCl_3$): δ = 175.4, 172.2, 171.2, 170.9, 170.5, 170.3, 132.6, 132.0, 132.7, 131.2, 131.1, 130.9, 130.8, 131.1, 129.0, 128.9, 128.8, 128.7, 128.6, 128.5, 62.1, 62.01, 56.7, 51.0, 49.2, 48.7, 39.2 (d, J(C,P) = 59.9 Hz), 31.6 (d, J(C,P) = 55.9 Hz), 29.9, 29.5, 22.6, 19.2, 18.2, 16.8; ^{31}P NMR (120 MHz, $CDCl_3$): δ = 42.1, 38.66; LRFABMS: *m/z* (%): 868 ($M+K^+$, 25), 852 ($M+Na^+$, 100), 830 (58); HRFABMS: *m/z* calcd for $C_{42}H_{50}N_5O_5P_2S_2$: 830.2728, found 830.2709.

11: ^1H NMR (500 MHz, $CDCl_3$): for chemical shifts and assignments see Table 2; ^{31}P NMR (120 MHz, CD_3OD): δ = 31.28 (d, J(Rh,P) = 168.8 Hz, 1P), 22.37 (d, J(Rh,P) = 168.8 Hz, 1P); LRFABMS: *m/z* (%): 992 (47), 960 (M^+, 50), 874 (100), 776 (35); HRFABMS: *m/z* calcd for $C_{49}H_{52}N_5O_5P_2Rh$: 960.2890, found 960.2888.

Table 1. Assignment of the ^1H NMR signals of **10** (2D NMR).

Residue	α	β_1	β_2	γ_1	γ_2	δ_1	δ_2	Amide
Val	4.17	1.95	-	0.89	0.86	-	-	6.88

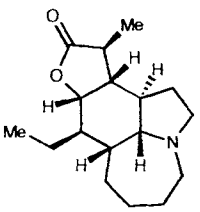
[43] While the number of peptides with type II β-turns having amino acids other than glycine or a D-amino acid in the $i+2$ positon is limited, this type of structure is by no means impossible. There are many well-characterized type II β-turns with L-amino acids in the $i+2$ postion. Since the energy difference between type I and type II turns is small, conformational preferences are sensitive to a number of effects.

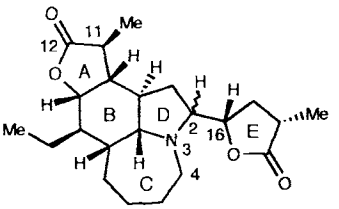
Studies on the Asymmetric Synthesis of *Stemona* Alkaloids: Total Synthesis of (−)-Stenine**

Yoshiki Morimoto,* Maki Iwahashi, Koji Nishida, Yuji Hayashi, and Haruhisa Shirahama

Extracts from the roots and rhizomes of stemonaceous plants (*Stemona* and *Croomia*) have long been used in China and Japan as cough remedies for humans and as anthelmintics for domestic animals. A number of related *Stemona* alkaloids have been isolated from these extracts and their structures have been determined, mostly by X-ray diffraction studies.[1] The most prototypical members of this family of alkaloids are stenine (**1**), tuberostemonine (**2**), and tuberostemonine A (**3**),[2] and of these **2**, in particular, has been shown to possess inhibitory activity



1



2 2α-H
3 2β-H

on the excitatory transmission at the crayfish neuromuscular junction.[3] These pharmacological properties indicate that some of the effects of the crude extracts may be attributable to **2** and that this alkaloid may be a useful tool in the field of neuropharmacology. These and other types of *Stemona* alkaloids have recently been the subject of several studies[4] because of their stimulating structures and prominent physiological activities, and the total synthesis of (±)-stenine (**1**) has already been accomplished by Hart and Chen.[4b] In the course of our investigations into the asymmetric syntheses of these alkaloids, we now report the highly stereocontrolled total synthesis of (−)-stenine (**1**).[5, 6]

The retrosynthetic analysis of these alkaloids is outlined in Figure 1. Recently we developed an efficient synthetic proto-

[**] We thank Prof. M. Haruna (Meijo University) for generously supplying a copy of the ^{1}H NMR spectrum of natural stenine. This work was partly supported by the Saneyoshi Scholarship Foundation and a Grant-in Aid for Scientific Research from the Ministry of Education, Science, and Culture of Japan.

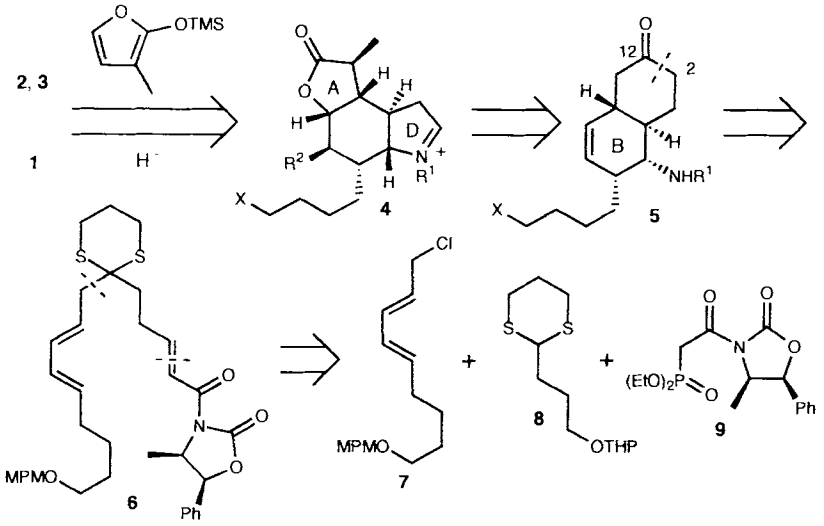

Fig. 1. Retrosynthetic analysis of the *Stemona* alkaloids **1**–**3**. MPMO = 4-methoxyphenylmethyloxy, THP = tetrahydropyranyl; TMS = trimethylsilyl.

col[4i,j] of the D,E ring system, based on the stereoselective addition of 3-methyl-2-trimethylsilyloxyfuran to an *N*-acyliminium ion.[7] In the context of these results, disconnections of the 2,16 and 3,4 bonds designated the iminium ion **4** as a conceivable common intermediate of these alkaloids. It was anticipated that the tricyclic ring system **4** would be prepared from the bicyclic ketone **5** by oxidative cleavage of the 2,12 bond, followed by cyclization of A and D rings. An intramolecular asymmetric Diels–Alder reaction[8] of the (*E*,*E*,*E*)-triene **6**, containing Evans' chiral auxiliary,[9] was considered to be the most efficient method for simultaneously constructing the decalin skeleton and the four stereogenic centers on the B ring in **5**. The desired Diels–Alder precursor **6** was to be assembled, in turn, by convergent coupling of three fragments (dienyl chloride **7**, dithiane **8**, and chiral phosphonate **9**).

We began the synthesis by alkylation of the dithiane **8**[10] with the readily available dienyl chloride **7**.[12] Subsequent removal of the tetrahydropyranyl group provided the alcohol **10**, which was oxidized with SO_3·Py. The modified Horner–Emmons reaction[14] of the resulting aldehyde with the chiral phosphonate **9**[15] afforded the (*E*,*E*,*E*)-triene **6** in good overall yields (Scheme 1). The key reaction—the intramolecular asymmetric Diels–Alder reaction of **6**—proceeded smoothly at −20 °C in the presence of 1.3 equivalents of dimethylaluminum chloride as a Lewis acid to produce the bicyclic compound **11** in good diastereoselectivity and complete *endo* selectivity (**11**: antipode of B ring = 10:1).[9,16] Sequential manipulation of the Diels–Alder adduct **11** (that is, 1) hydrolysis of the 1,3-dithiane, 2) removal of the chiral oxazolidinone,[17] 3) reduction of the resulting thiol ester to aldehyde,[18] and 4) oxidation of the aldehyde with sodium chlorite) furnished the carboxylic acid **13** in high overall yields. The introduction of a nitrogen functionality to **13** to give **14** was carried out by the modified Curtius rearrangement according to the Shioiri's method[19] in the presence of a catalytic amount of copper(I) chloride.[20]

The next stage involved the oxidative cleavage of the 2,12 bond in ketone **14** (Scheme 2). The regioselective enolization of **14** was performed under thermodynamically controlled conditions[16] to predominantly yield the preferred trimethylsilyl enol ether **15** ($\Delta^{2,12}$: $\Delta^{11,12}$ = 6:1). Treatment of **15** with 1.1 equivalents of *m*-chloroperbenzoic acid and subsequent oxidative cleavage of the resulting α-alkoxy ketone with orthoperiodic acid afforded an intermediary carboxylic acid derivative, in situ iodolactonization of which stereoselectively formed the A,B,D ring system **16**. After protection of the hemiacetal in **16**, an appropriately functionalized α-alkoxycarbamate **17** was constructed by stereocontrolled allylation and methylation at the convex side of the molecule by applying Hart's procedure.[4b] Concurrent reduction of the acetal group and of the *p*-methoxybenzyl ether in **17** with an excess of triethylsilane in the presence of boron trifluoride etherate in acetonitrile at 0 °C gave the alcohol **18** in good yield. The allylic group in **18** was converted to an ethyl group by a Lemieux–Johnson oxidation, followed by formation of the dithiolane, and desulfurization with Raney nickel to provide the alcohol **19**, which was transformed to the iodide **20** by using the approach commonly applied for azepane ring formation. Finally, the C ring was constructed by removal of the methoxycarbonyl group with trimethylsilyl iodide,[4b] followed by consecutive intramolecular *N*-alkylation of the corresponding amine in refluxing acetonitrile to afford (−)-stenine (**1**) ($[\alpha]_D^{23}$ = −27.5 (c = 0.523 in MeOH), ref.[2a] $[\alpha]_D$ = −30.2 (in MeOH)). The spectroscopic (^{1}H NMR, ^{13}C NMR, IR) and mass spectrometric data of synthetic

(−)-stenine (**1**) was consistent with the ^{1}H NMR spectrum of natural stenine (**1**) and with the data reported for (±)-stenine (**1**).[4b]

In summary, the highly stereocontrolled total synthesis of (−)-stenine (**1**) has been accomplished, in which the key features are an intramolecular asymmetric Diels–Alder reaction of the triene **6** prepared in a convergent fashion from three readily available components **7**, **8**, and **9** and efficient construction of the tricyclic A,B,D ring system **16**. These concepts are currently being applied to the asymmetric synthesis of tuberostemonine (**2**).

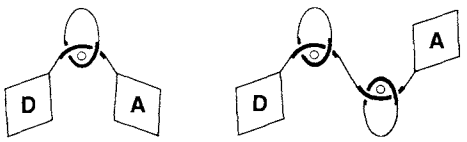
constructing novel structures and topologies such as catenanes[2-4] and rotaxanes.[5] We have recently synthesized a family of porphyrin-stoppered rotaxanes,[6] the prototype of which consists of a central copper(I) complex coordinated to two 2,9-diphenyl-1,10-phenanthroline (dpp) units. One these units is included in a ring and the other is threaded through the ring and bears at its two ends a gold(III) porphyrin acting as an electron acceptor (A) and a zinc(II) porphyrin (electron donor D). Ultrafast photoinduced electron transfer between D (singlet excited state) and A was shown to occur, with a strong superexchange contribution from the central copper(I) complex.[7]



Scheme 1. Representation of a [2]- (left) and a [3]rotaxane (right) with different terminal porphyrin groups, which function as either electron donors (D) or electron acceptors (A).

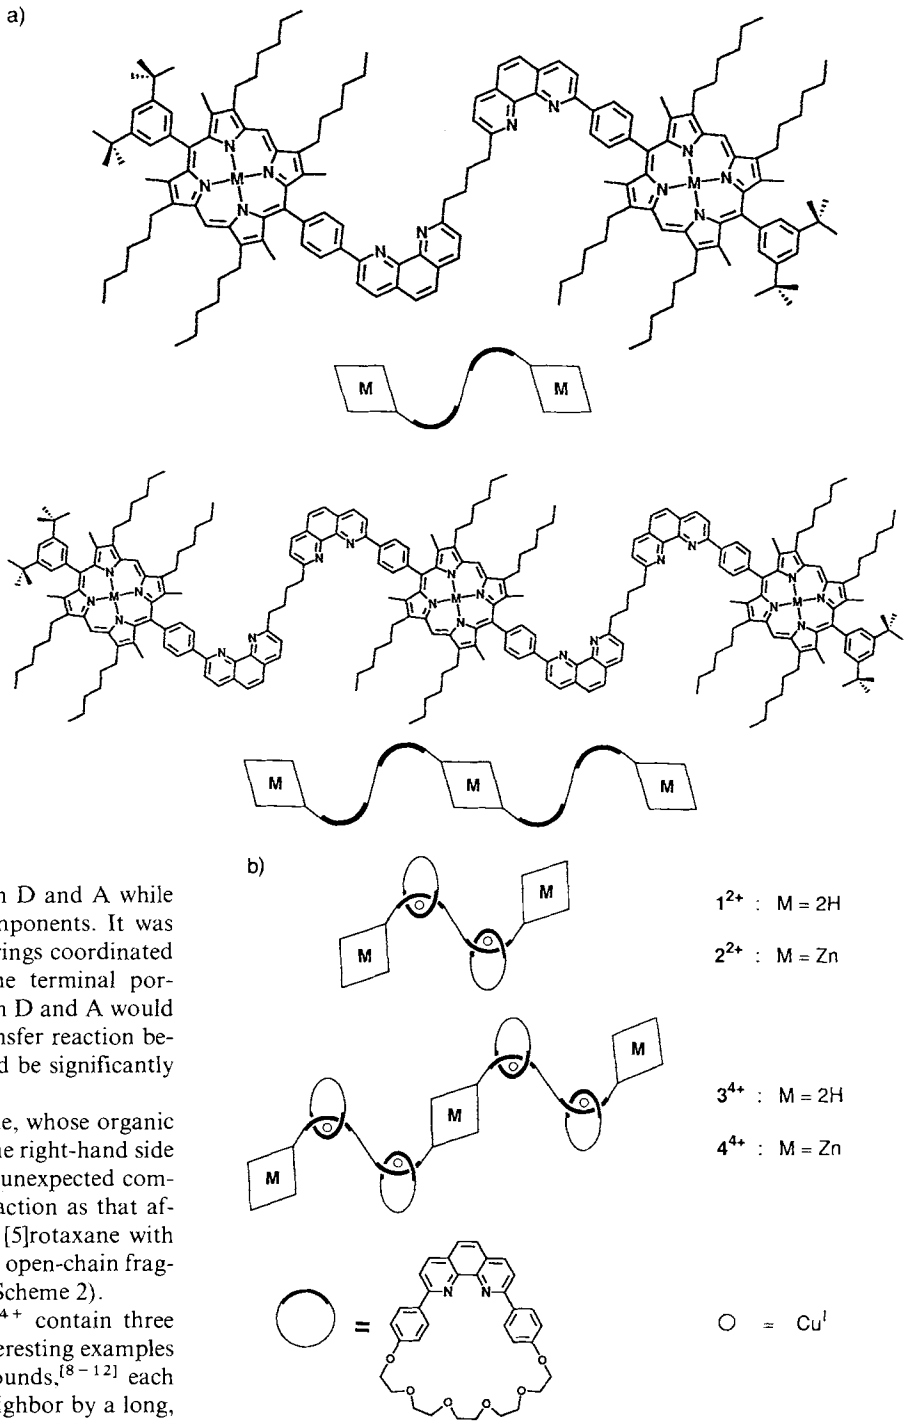
The most straightforward approach to increasing the lifetime of the charge separated state is to increase the distance between D and A while keeping a strong coupling between both components. It was thus hoped that by increasing the number of rings coordinated to Cu^{I} centers and interspersed between the terminal porphyrins, fast forward electron transfer between D and A would still take place, whereas the back electron transfer reaction between the redox products (D^{+} and A^{-}) would be significantly slowed.

We report here the synthesis of a [3]rotaxane, whose organic backbone is indeed similar to that shown on the right-hand side of Scheme 1, as well as the preparation of an unexpected compound obtained in the same condensation reaction as that affording the [3]rotaxane. This compound is a [5]rotaxane with one central and two terminal porphyrins in the open-chain fragment, which is threaded through four rings (Scheme 2).

The strings of the [5]rotaxanes $\mathbf{3}^{4+}$ and $\mathbf{4}^{4+}$ contain three porphyrins but, in contrast to some recent interesting examples of linearly arranged multiporphyrinic compounds,[8-12] each porphyrinic unit is separated from its next neighbor by a long, multifunctional spacer. Noteworthy is the length of the central string. It contains a total of 83 atoms and should be approximately 60 Å long in an extended conformation.

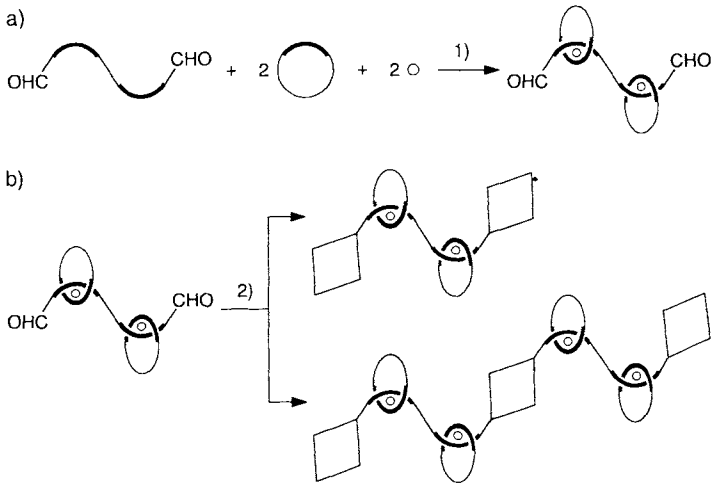
The synthetic strategy is based on the threading of two rings onto the same two-chelate string (Scheme 3). The driving force behind this reaction is the coordination of all the dpp chelates to copper(I) centers.[13] Since appropriate end functions were previously introduced in the string, porphyrinic stoppers can be constructed. As previously shown with similar compounds,[13] the threading step (Scheme 3a) can be quantitative. The second step (Scheme 3b) can involve formation of terminal porphyrins only (upper route) or entail construction of both terminal and bridging porphyrin units (lower route).

1,10-Phenanthroline was treated with the C4-lithiated derivative of 2,2-dimethylpropane-1,3-diyl-protected benzaldehyde[14]



Scheme 2. a) Chemical formulae of the molecular strings constructed in the course of the rotaxane synthesis. b) Schematic representations of the [3]rotaxanes ($\mathbf{1}^{2+}$, $\mathbf{2}^{2+}$) and [5]rotaxanes ($\mathbf{3}^{4+}$, $\mathbf{4}^{4+}$). The porphyrin groups are symbolized by diamonds. Note that the ring used in the threading process is a 30-membered ring.

at 0 °C in THF under argon. Following a classical procedure,[15] after hydrolysis and reoxidation with MnO_2, **5** was isolated in pure form in 71% yield. Compound **6** was obtained by treating **5** with 1,4-dilithiobutane[16] under similar conditions, eventually leading to the dialdehyde **7** after deprotection (73% overall yield from **5**). The difunctional string **7** can be prepared readily on a multigram scale. Macrocycle **8** is one of the most frequently used cyclic building blocks in our group.[17] The threading step



Scheme 3. Synthetic strategy for making porphyrin-stoppered polyrotaxanes. a) The starting dialdehyde molecular string has two phenanthroline units for binding; the macrocycle is also able to bind the metal (small open circle) while being threaded by the string. The threading step (1) is assumed to be spontaneous and will thus not require any additional reagent. b) The porphyrin-forming reaction (2) requires the proper reagents and can, in principle, be directed mostly towards the construction of porphyrins stoppers or of both terminal and bridging porphyrins.

(Scheme 3a) was carried out by first mixing equimolar amounts of $[Cu(CH_3CN)_4]^+PF_6^-$ and **8** and then adding 0.5 equivalents of **7** (CH_2Cl_2/CH_3CN, room temperature). The dication $\mathbf{9}^{2+}$ was obtained quantitatively, as indicated by ^1H NMR spectroscopy. It was treated with the 2,2′-methylenedipyrrole derivative **10**[18] and 3,5-di-*tert*-butylbenzaldehyde (**11**)[19] under experimental conditions analogous to those originally described by Lindsey et al.[20] and also utilized with other copper(I)-containing threaded complexes.[4, 6] The three components, $\mathbf{9}^{2+}$, **10**, and **11**, in a molar ratio of 1:10:8 were treated with CF_3COOH at room temperature in CH_2Cl_2. The porphyrinogen intermediates were reoxidized with chloranil and the final products separated by repeated column chromatography. Compound $\mathbf{1}^{2+}$ was obtained in surprisingly high yield (34%) considering that two porphyrins have to be formed more or less simultaneously. In addition, $\mathbf{3}^{4+}$ was also isolated in pure form (8%) and characterized. The new compounds were characterized by high-resolution ^1H NMR spectroscopy and electrospray mass spectrometry (ES-MS). Figure 1 shows the ES-MS spectrum of a representative product, [5]rotaxane $\mathbf{3}^{4+}$.

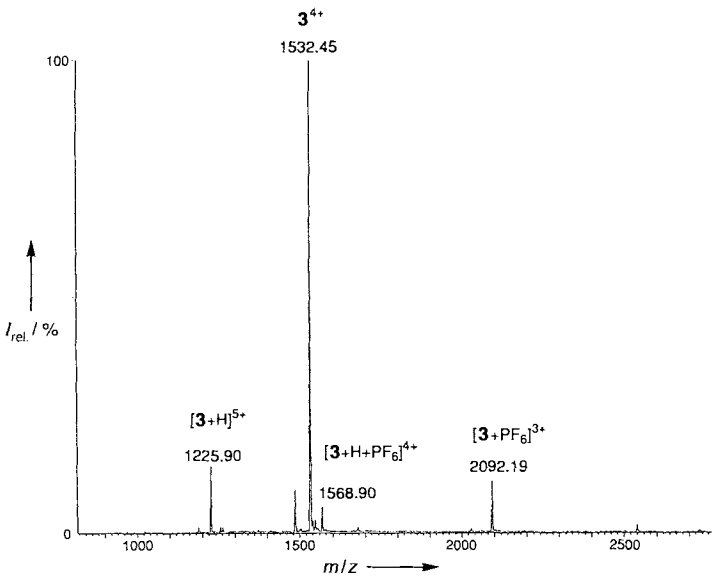


Fig. 1. ES mass spectrum of $\mathbf{3}^{4+}\cdot 4PF_6^-$ (M_r = 6711.78). The spectrum was recorded on a VG BioQ triple-quadrupole mass spectrometer with a m/z range of 4000 (VG Bio Tech Ltd., Altrincham, UK). The accelerating cone voltage (V_c) [21] was set at 20 V to minimize fragmentation. The sample in CH_2Cl_2 was infused in the mass spectrometer with a syringe pump with a continuous flow of 5 μL min^{-1}.

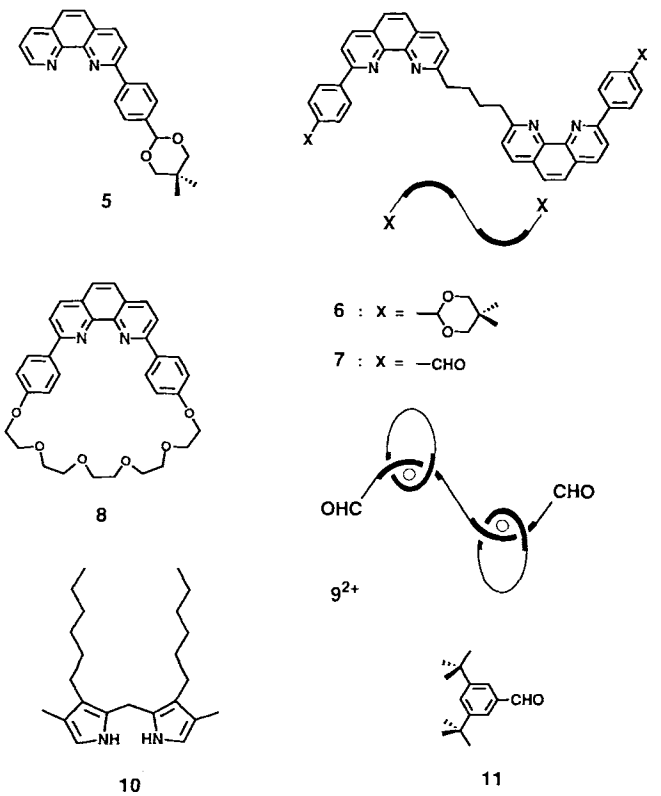

To induce vectorial electron transfer in these polyrotaxanes on irradiation it will be necessary to desymmetrize the molecules and, in particular, to selectively metalate the different porphyrinic sites of each compound. The copper(I) complex subunits are also expected to participate in energy and electron transfer processes. Preliminary emission measurements show that relatively efficient quenching of free-base or zinc porphyrin fluorescence by the copper(I) complex components takes place.

Experimental Procedure

$\mathbf{9}^{2+}$: A solution of $[Cu(CH_3CN)_4]^+PF_6^-$ (2 equiv) in acetonitrile under argon was added by cannula and at room temperature to a stirred solution of **8** (2 equiv) in dichloromethane. The mixture turned orange instantaneously, indicating the formation of $[Cu\cdot\mathbf{8}\cdot(CH_3CN)_2]^+PF_6^-$. The reaction mixture was stirred for 20 min at room temperature, then a solution of bisphenanthroline **7** (1 equiv) in dichloromethane was added. The solution turned dark red immediately. After the solution was stirred for ca. 12 h under argon at room temperature, the solvents were removed under vacuum to afford crude $\mathbf{9}^{2+}\cdot 2PF_6^-$ ($\mathbf{7}\cdot(\mathbf{8})_2\cdot(Cu^+)_2$) in quantitative yield.

$\mathbf{1}^{2+}\cdot 2PF_6^-$ and $\mathbf{3}^{4+}\cdot 4PF_6^-$: A solution of $\mathbf{9}^{2+}\cdot 2PF_6^-$ (0.398 g, 0.18 mmol), **11** (0.32 g, 1.47 mmol), and **10** (0.627 g, 1.83 mmol) in dichloromethane (180 mL) was treated with four drops of trifluoroacetic acid and then stirred overnight at room temperature and under argon. Chloranil (1.39 g, 5.65 mmol) was added and the reaction mixture refluxed for 1.5 h. After cooling, the crude reaction mixture was neutralized with 10% sodium carbonate (80 mL). The resulting organic phase (200 mL) was washed three times with water, stirred for ca. 12 h with 6.5% KPF_6 (200 mL), washed again twice with water, and concentrated to dryness. The residue (1.1 g) was purified by repeated column chromatography on alumina. Elution with

Synthesis of Boron-Rich Lysine Dendrimers as Protein Labels in Electron Microscopy**

Britta Qualmann,* Michael Manfred Kessels,* Hans-Jürgen Musiol, Walter Daniel Sierralta, Peter Wilhelm Jungblut, and Luis Moroder

Currently, interest is growing in the design and synthesis of boron-rich compounds suitable for boron neutron capture therapy of cancer (BNCT)[1] and increasingly also for new electron microscopic techniques like electron energy loss spectroscopy (EELS) and electron spectroscopic imaging (ESI).[2] In all these applications high topical concentrations of boron and reactive handles are required in the molecule for selective conjugation of carborane clusters to molecules that recognize the biological target.

Previous studies clearly revealed the limitations of multiple attachments of small boron-containing molecules to carrier proteins. In the case of antibodies the solubility and immunoreactivity was impaired.[3] Randomly boronated polymers such as poly-D,L-lysine,[4] poly-L-ornithine,[5] dextranes,[6] and starburst dendrimers[7] are inherently heterogeneous and compelled the synthesis of more defined molecules, for example of peptides containing carboranyl amino acids.[8] The main difficulties encountered in this approach derived from the slow and incomplete coupling of carboranyl amino acids at the C- and particularly the N-terminus due to steric hindrance by the bulky 1,2-dicarbadodecaborane moiety. Moreover, both the intermediates and the final products had very low solubilities.[8]

We expected that the handicaps of these linear constructs could possibly be overcome by the use of spherical dendritic molecules built up of lysines (that is, poly-(α,ε-L-Lys)[9]) carrying the carborane clusters at the outer surface. Such lysine dendrimers would offer the advantage of a single acylation step for a multiple attachment of carboranyl amino acids and should ensure quantitative derivatization, since the spherically arranged amino functions of the dendrimers are known to be fully accessible.[10]

Since these carborane-dotted spheres have to be grafted to a defined locus of the carrier protein, for example through the thiol function of antibody fragments (Fab'), the two constructs **A** and **B**, whose structures are shown in Figure 1, were designed to fulfill the following requirements:

1) A boron load high enough to exceed the boron ESI detection limit in biological probes has to be achieved. Though not yet defined for boron, 80 incorporated boron atoms were expected to suffice. This can be obtained with a heptalysine tree (second generation dendrimer), which enables simultaneous incorporation of eight carboranyl amino acids, yielding a dendrimer with 80 clustered boron atoms at its outer sphere. The resulting rather compact, ball-like molecules with a radius of about 12–14 Å, similar to the value of 11.4 Å calculated for the third generation poly-(α,ε-L-Lys),[11] represent marker compounds of defined and homogeneous size and would be most valuable tools in immunocytochemistry based on ESI.[12]

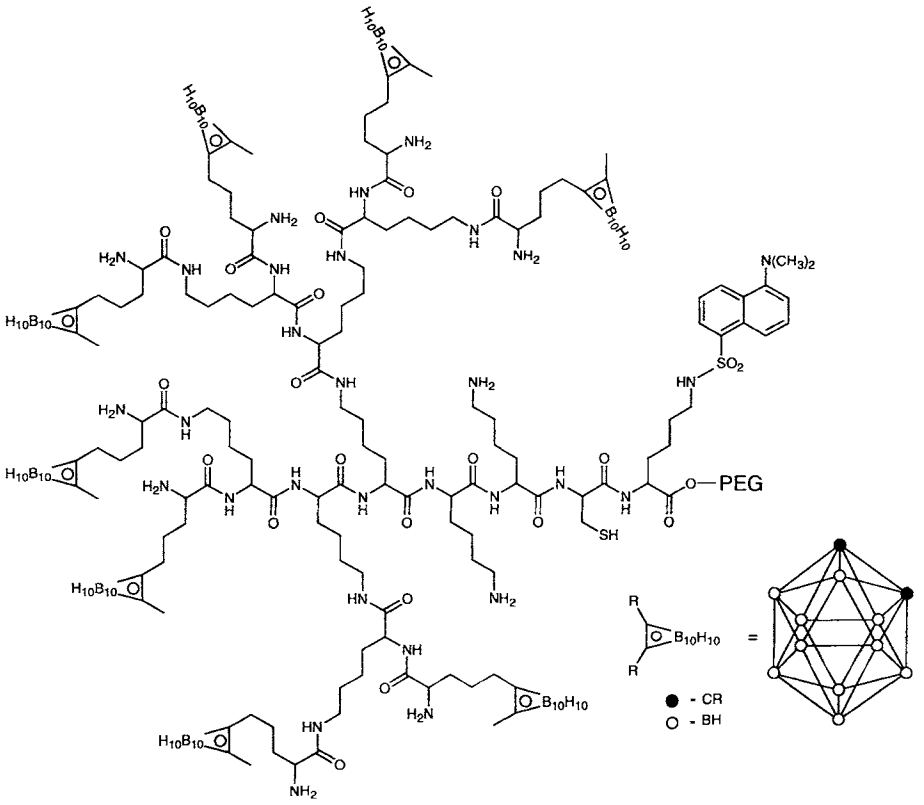

Fig. 1. Structure of the poly-(α,ε-L-Lys) dendrimer **B**. Peptide **A** lacks the polyether moiety at the C-terminus of **B**. PEG = polyethylene glycol (with $\bar{x}$ = 68 glycol units).

2) A reactive handle, like the thiol function of a Cys residue, linked to the terminus of a flexible spacer must be fully accessible to guarantee the selective grafting of the carborane-dotted spheres to defined loci of targeting molecules.
3) A fluorescent probe, in the present case ε-*N*-dansyl-lysine, must be incorporated to allow spectroscopic monitoring of the coupling rate of the boron-rich markers to targeting proteins.
4) The solubility in water must be improved. Increased water-solubility of the hydrophobic boron-rich moiety was expected from the hydrophilic positively charged Lys–Lys spacer and—in the case of peptide **B**—from an additionally attached PEG-tail. Pegylation of peptides is known to strongly enhance the solubility of both protected and unprotected peptides[13] and has recently been found to increase the critical micellar concentration of amphiphiles markedly.[14]

In syntheses of compounds with potential use in BNCT published recently, a dendritic polyalcoholic structure was linked with a single carborane cluster,[15a] or carboranyl groups were introduced into a dendritic micelle;[15b] none of these compounds can be coupled specifically to proteins.

The two peptidic protein marker constructs **A** and **B** presented here were synthesized according to standard procedures of solid-phase peptide synthesis with the Fmoc/*t*Bu strategy (Fmoc = 9-fluorenylmethoxycarbonyl) and using pegylated polystyrene resins. This type of resin was expected to prevent a hydrophobic collapse of the dendrimers by increasing their solvation,[16] and to allow direct generation of the desired compounds with and without the PEG chain. In the final acylation step of the lysine-tree we used (*S*)-5-(2-methyl)-1,2-dicarba-*closo*-dodecaborane(12)-1-yl)-2-amino pentanoic acid[17] (L-MeCBA), for which we have recently developed a highly efficient and convenient new synthesis, as carboranyl amino acid.[18] Cleavage and deprotection of the resin-bound fully protected peptide constructs from TentaGel S-PHB and TentaGel PAP led to compounds **A** and **B** in 88 and 81% yield, respectively. In the HPLC investigation compound **A** showed a dominant product peak of the expected mass according to electron-impact mass spectrometry (EI-MS) (3679.0; calcd. $[M^+]$ = 3679.2 for $C_{139}H_{306}N_{30}O_{22}S_2B_{80}$), which indicates complete incorporation of the eight L-MeCBA residues. For compound **B** HPLC again revealed a main product peak. Mass determinations by FAB-MS (FAB = fast atom bombardment) and EI-MS failed because of the known difficulties encountered in mass spectrometry with pegylated peptides;[19] the spectrum of MALDI-MS (MALDI = matrix-assisted laser desorption/ionization) showed a bell-shaped distribution corresponding to the presence of varying molecular weights of polyethyleneglycol and an apex at 6649.7 Da, which corresponds fairly well with the theoretical value (6675 Da) and is in full agreement with previous MALDI-MS measurements on pegylated peptides.[20]

Compounds **A** and **B** exhibited good solubilities in several polar organic solvents like DMF and alcohols as well as in aqueous organic mixtures, which enabled their conjugation to the thiol group of Fab'. Yields, however, were moderate in the case of **A**, whereas the reaction of compound **B** proceeded smoothly with both 1,4-di-[3'-(2'-pyridyldithio)-propionamido)]butane or bismaleimidohexane as crosslinkers. The high yields of labeled Fab' obtained in the latter case are likely to be due to the good water solubility of marker peptide **B**.

The properties of these two new markers were expected to be superior to those of the sequential polypeptides synthesized by us in previous experiments (the undecapeptide[8c] consisting of alternating racemic carboranyl amino acids and serines as well as a lysine residue for attachment to Fab' through heterobifunctional reagents). In EELS experiments using a Zeiss 902 electron microscope with an integrated energy loss spectrometer, the novel Fab'-(**A**,**B**) conjugates gave sharp signals for the Fab'-**B** conjugate (Fig. 2). The small immunoreagents carrying the antigen-combining site at one end and the boron-rich dendritic marker at the opposite end of the molecule have also been used in immunocytochemical investigations with ESI. First results show high resolution properties[21, 22] and confirm the validity of the new approach in terms of exceeding the detection limits with the 80 boron atom label and of sufficient solubility induced by pegylation of the marker moiety. This innovative approach could represent an interesting route even for the construction of covalently attachable multiple gold or other labels; furthermore, homogeneous functional dendrimers carrying a reactive handle like the constructs described here may be valuable carriers for drug targeting.

Experimental Procedure

Synthesis of **A** and **B**: Fmoc-Lys(Dansyl)-OH [23] was coupled in about 20 h to TentaGel S-PHB or TentaGel PAP (Rapp Polymere, Tübingen, Germany) in DMF

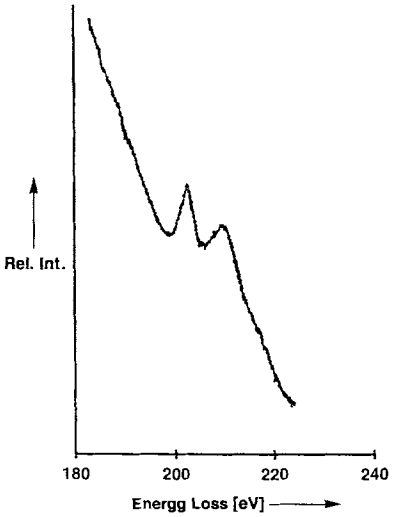

Fig. 2. Electron energy loss spectrum of an immunoprobe containing peptide **B**, adsorbed from an aqueous solution (0.5 mg mL^{-1}) onto nitrocellulose-coated gold grids. The sharp boron absorption edge at an energy loss of 197 eV originates in the element-specific inelastic scattering of outer shell electrons recorded with the electron detector of an energy filter transmission electron microscope (EFTEM) connected to a digital compensation X/Y plotter (Zeiss EM 902, operated at 80 kV; objective aperture 90 μm; spectrometer entrance aperture 100 μm; beam current 30 μA; slit width 1–2 eV; scan speed 1.6 eV s^{-1}; magnification 30000).

by preactivation with O-(7-benzotriazol-1-yl)1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU) (5 min) and addition of 4-dimethylaminopyridine (DMAP). Free hydroxymethylphenoxy linker was capped with acetic acid anhydride. Resin loading was 0.079 mmol g^{-1} TentaGel S-PHB and 0.106 mmol g^{-1} TentaGel PAP as determined spectrophotometrically from the fluorene/piperidine adduct upon Fmoc removal with 20% piperidine in DMF. Chain elongation was carried out with Fmoc-Cys(Trt)-OPfp/HOBt and twice with Fmoc-Lys(Boc)-NCA in DMF with fourfold molar excesses of acylating agents. The lysine tree was constructed by three successive couplings with fourfold molar excesses of Fmoc-Lys(Fmoc)-OH by the TBTU/HOBt/DIEA (1:1:2, DIEA = diisopropylethylamine; HOBt = 1-hydroxybenzotriazole hydrate) procedure [24]. In the case of incomplete couplings (Kaiser's test) reacylation with twofold molar excesses of acylating agents were performed. Finally, Boc-MeCBA-OH [25] was coupled to the dendrimer with HATU/DIEA (1:2, HATU = O-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (PerSeptive Biosystems, Wiesbaden, Germany)) [26] until Kaiser's test was negative. Compound **A** was cleaved from TentaGel S-PHB with 95% aqueous trifluoroacetic acid (TFA) and 2% triethylsilane at room temperature for 2 h, and compound **B** from TentaGel PAP with TFA containing 5% thioanisol and 1% triethylsilane at room temperature for 20 h. The resins were filtered off and the filtrates evaporated to small volumes. The peptides were isolated by precipitation with argon-saturated methyl *tert*-butyl ether/petroleum ether (2:1) (**A**) and additional lyophilization from degassed argon-saturated water (**B**). HPLC was performed on C8 Nucleosil 300; eluent: linear gradient (30 min) from a 5:95 to a 80:20 mixture of CH_3CN and 2% H_3PO_4; flow rate: 1 mL min^{-1}; detection: UV at 210 nm; R_t of **A** = 24.35 min; R_t of **B** = 21.75 min.

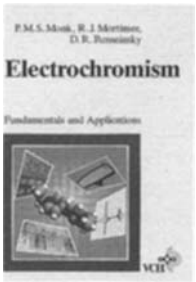
Shocking Colors

Electrochromism. Fundamentals and Applications. By *P. M. S. Monk, R. J. Mortimer* and *D. R. Rosseinsky*. VCH Verlagsgesellschaft, Weinheim, 1995. 216 pp., hardcover DM 168.00.— ISBN 3-527-29063-X

When a compound has two or more redox states with different absorption spectra in the visible region, a color change occurs on oxidation or reduction. The color can be switched by electron transfer, and this behavior is known as electrochromism. This general definition serves as the starting point for the treatment of electrochromic phenomena by Monk, Mortimer and Rosseinsky, three British physical chemists. The task that they address is multifaceted and demanding. On the one hand they aim to establish the fundamentals that enable the reader to understand the striking electrochromic phenomena observed and to interpret the results of spectroscopic and electrochemical experiments on electrochromic compounds, while on the other hand they set out to describe and explain existing or potential technological applications. The book is intended both for those already working in the area and for newcomers. Furthermore, the authors have set out not only to look at the topic from a chemical standpoint but also to serve the needs of physicists, materials scientists, and engineers. Despite having deliberately restricted the literature coverage (the 12 chapters contain slightly over a thousand references), it is almost inevitable that the attempt to fulfill these aims in a book of 200 or so pages encounters problems.



The book is divided into three main parts dealing in turn with the fundamentals, existing applications (electrochromic devices, ECDs), and interesting current work and future developments. Part I ("Introduction") consists of three chapters. First the concept of electrochromism is defined, and its capabilities are compared with those of other related technologies (LCDs, LEDs, etc.), taking as an example the application in a commercial device, an "intelligent" rear-view mirror for cars. Another potential application in the same area is also mentioned: a "smart window". Chapter 1 concludes with various definitions relating to the chemistry, physics, and applications of electrochromic devices.

Chapter 2 contains an introduction to the elementary processes that occur in electrochemical reactions and form the basis of electrochromism. Beginning with a description of the galvanic cell the authors develop the concept of the potential (however, on p. 25 they describe the use of the silver wire pseudo-reference electrode, which in my opinion should be avoided, whereas they ignore reference systems such as that based on ferrocene/ferricinium ion). Voltammetry is then discussed, enabling the potential to be related to the dynamics, kinetics, and charge-transfer processes at an electrode surface. Electrochromic materials are then classified according to the solubilities of the different redox states. The sign convention generally used for the potential in electrochemistry is not simple, but the authors do not exactly clarify it by choosing an example which they themselves describe as "an unusual use, even an abuse". It is, of course, important that the potential E of the working electrode in a voltammetry cell must be related to a reference electrode, but the same does not apply to the voltage increase rate dE/dt (p. 29). It would have been useful to extend the discussion of cyclic voltammograms to include not only dissolved but also adsorbed species, since redox-active particles on the electrode surface play an important role in the later parts of the book. On the whole this chapter seems to be the least successful.

Chapter 3 briefly describes the essential principles and components of an electrochromic device (ECD), including the arrangement of the electrodes, the electrolyte, and the production of electrochromic films. The development of the principles into a practical system is discussed, taking the rear-view mirror mentioned earlier as an example.

Part II ("Electrochromic Systems") consists of seven chapters in which the authors present a survey of the most important classes of substances whose electrochromic properties have been or are being investigated: metal oxides, phthalocyanines, Prussian blue and related compounds, bipyridylium systems, electroactive conducting organic polymers, and various other inorganic and organic materials. These are treated in the style of a review article, with numerous literature references (which according to the preface cover publications up to late summer, 1994). For reasons of space alone many of the results can receive no more than a brief mention. Nevertheless, the authors have managed to provide the reader with a good impression of the enormous variety of electrochromic systems (for example, every optical "redox indicator" is in principle an electrochromic substance, as pointed out on p. 122). Throughout this there are frequent references to the problems in developing such systems into practical ECDs and ways in which these might be solved. Where necessary, references to publications containing contradictory views are juxtaposed, but only rarely are such results critically evaluated. The authors do not conceal the fact that for many of the reaction mechanisms described the details are not yet thoroughly understood, or that many unanswered questions remain with regard to applications.

Part III ("Elaborations") concludes the book with two chapters on polyelectrochromic systems (those with more than two colors) and on photoelectrochromism (where the electrochemical reaction occurs only under the action of light). These discussions also bring in possible future applications, such as electrochromic four-color printing.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

I found relatively few printing errors (examples: on p. XXII the correct abbreviation for the supporting electrolyte tetra-*n*-butylammonium perchlorate is TBAP, not "TPAP"; on p. 28, line 11, and p. 32, line 8, the brackets are incorrectly printed; on p. 31 "Sevcik" should be Ševčic; in Equation (8.1) "+." appears as a superscript; on p. 176, first line of Section 10.1.4, "Würster salts" should be Wurster salts). Here and there it appears that bits of a sentence have been lost, as in "...have performed ellipsometric studies the proton injection into... films..." (p. 64, 11th line from bottom), and in "...thiophene units are chemically bonded rather than by physically mixed" (p. 163, bottom line). In Figure 9.1 some symbols in the margin have been cut off, and on page 177 the formula shows a pyrazole derivative instead of a pyrazoline. A few other inaccuracies or minor faults are the following: in the list of abbreviations it would have been better to keep the entries in strictly alphabetical order (bottom of p. XXII and top of p. XXIII); in the discussion of cyclic voltammograms (p. 32) the term "reversibility" should not be confused with "superimposability"; the unit of the standard exchange current i_0 (pp. 32/33) is given as $\mu A cm^{-2}$, but this unit applies instead to the current *density*; the technique of chronoamperometry mentioned in Table 2.1 is not explained; in Figure 6.1 the potential is given relative to an "SSCE" reference electrode but this is not explained; Figure 8.4 is not referred to in the text; in Section 8.4.2 under the title "Pulsed Potentials" the experiments described instead use "pulses of current"; aniline derivatives (p. 143) are, of course, not heterocyclic compounds, and *o*-toluidine (p. 147) is not an *N*-substituted aniline; Table 9.11 does not give the dihedral angle on which the absorption maximum and the oxidation potential are said to depend.

As to whether this book is suitable for "anyone wishing to enter the field" (consider the targeted readership!), I have to admit to some doubts. To meet the needs of beginners some revision of the foundation chapters in Part I would certainly be necessary, and in Part II the literature would have to be more critically evaluated and classified. On the other hand, the scientist already engaged in work on electrochromic systems, whether in basic research or in applications, will overlook these flaws and the minor errors mentioned above. The latter reader will find in Part II a rich source of references to advanced work.

Chemical Kinetics of Solids. By *H. Schmalzried.* VCH Verlagsgesellschaft, Weinheim, 1995. 433 pp., hardcover DM 298.00.—ISBN 3-527-29094-X

In this latest book H. Schmalzried, author of the successful *Solid State Reactions* (which went to three editions), updates the treatment by including the developments that have taken place in solid state kinetics in recent years. These include important advances in the use of in-situ methods of investigation, an increasing emphasis on the importance of materials science, and a growth in chemists' awareness of the formal theory of nonequilibrium systems and its applications. The author's objective is to give a systematic account of the many different types of solid state processes, and therefore the emphasis is on deriving and explaining the physicochemical concepts, illustrated by appropriate limiting cases, rather than describing a large number of complex reactions. He adopts a phenomenological approach; readers interested in the underlying statistical theory are referred to the relevant literature.

The book can be broadly divided into three parts. The first five chapters present the fundamentals. An introduction is followed by a phenomenological description of the thermodynamics of point defects, taking into account the special characteristics of the crystalline phase with the restrictions imposed on it through the introduction of structure elements (in particular the irregular structure elements of vacant sites and interstitial atoms). Here the author also introduces the chemical potential of the structure elements according to the Schottky model. The special conditions for crystal growth and transport at dislocations and grain boundaries are then described, followed by the fundamentals of irreversible thermodynamics, diffusion, transport in ionic crystals and across phase boundaries, and rate equations for homogeneous reactions. Next the author discusses the relationship between kinetics and dynamics, including the basic essentials of linear response theory, of the transition state, and of the Brownian motion. Here it becomes evident that one should not mistake the work for a textbook; for example, the treatment of irreversible thermodynamics in only three pages can do no more than direct the novice to read up on the subject more fully elsewhere.

The second part consists of ten chapters dealing on the one hand with classical cases of heterogeneous reactions and on the other hand with modern aspects of solid state kinetics. Chapters 6 and 7 treat cases in which the formation of the reaction products increases the spatial separation between the reactants, as for example in the oxidation of metals. Chapter 8 is concerned with solids in a thermodynamic potential gradient, and Chapter 9 with internal reactions. Chapters 10–12 are concerned with reactions at and through phase boundaries, morphology, and phase transformations. Chapter 13 discusses solid state reactions occurring in the presence of radiation, which are important in photographic processes and in the design of nuclear reactors, for example. Chapter 14 deals with the special features of solid state reactions occurring under mechanical stress, and Chapter 15 with the kinetics of certain special solids (silicates, fast ionic conductors, hydrides, layer crystals, polymers).

Finally, Chapter 16 forms an appendix giving an overview of in-situ methods for studying the kinetics of solid state reactions. Here the author addresses the fundamental problem that many of the processes determining the kinetics of the solid state occur at quite high temperatures, whereas measurements are generally carried out ex-situ, i.e., after quenching. The quenching inevitably alters the condition of the system, often introducing a certain amount of ambiguity into the results. Here Schmalzried gives a (brief) description of the capabilities of modern in-situ methods, thereby helping to stimulate their wider use and further development. The list includes thermodynamic methods (thermogravimetry, thermomanometry, thermovolumetry, thermal analysis), electrochemical methods (time- and space-resolved measurements of chemical potentials using miniaturized galvanic cells), nuclear spectroscopic methods (NMR, Mössbauer), electron spectroscopy (UV, VIS, IR, X-ray), and neutron diffraction and scattering. However, rather than giving a detailed introduction to these experimental techniques the author describes examples to show how they can be used for in-situ measurements.

In *Chemical Kinetics in Solids* one is impressed by the breadth of coverage of all relevant aspects of the kinetics of solid state reactions, illustrated by instructive examples (which, as expected, reflect the author's areas of interest to some extent). The length has almost doubled compared with that of *Solid State Reactions*, but nevertheless the treatment remains very succinct and demands thorough concentration from the reader. For the interested newcomer the book offers an excellent insight into the field, with up-to-date lists of references at the ends of the individual

chapters and a well-prepared index, while for the scientist already working in solid state kinetics it is likely to become the standard work of reference.

Monosaccharides. Their Chemistry and their Roles in Natural Products. By *P. M. Collins* and *R. J. Ferrier*. Wiley, Chichester, 1995. 574 pp., paperback £ 22.50.—ISBN 0-471-95343-1

The forerunner of this book was published by Penguin Books Ltd. (Harmondsworth, Great Britain) under the title *Monosaccharide Chemistry*. After a long interval the authors have now brought out this up-to-date monograph on the chemistry of monosaccharides, enlarged to include the whole area of carbohydrates. It is not intended solely for specialists in the field of monosaccharides, but is designed to have a broader appeal to everyone concerned with organic chemistry. Thus, the authors rightly point out that "parts of the book can be looked on as portrayals of modern general organic chemistry with monosaccharides as model systems". To support this they describe the development of carbohydrates chemistry since the 1970s, to which not only carbohydrates chemists but also "mainstream organic chemists" have made fundamental contributions.

A short introduction, in which the authors discuss the contributions made by E. Fischer, Haworth, Hudson and Lemieux to carbohydrates chemistry, is followed by a second chapter of 50 pages dealing with the structural aspects of monosaccharides and their biosynthesis. Although this is intended primarily for chemists about to begin serious work in the field for the first time, it also serves as a useful "refresher course" for those already experienced in carbohydrates chemistry. Chapter 3 then discusses the reactions occurring at the anomeric center of aldoses and ketoses, subdivided into the reactions of free sugars, glycosyl esters, and *O*-protected glycosyl halides. Chapter 4 is concerned with reactions at non-anomeric carbon atoms, beginning with nucleophilic substitutions and ring-opening reactions of oxiranes, followed by the synthesis and reactions of deoxy-, aminodeoxy-, thio-, and deoxyhalogen-sugars. This chapter also covers the chemistry of anhydro-sugars, ring contractions of monosaccharides, branched sugars, dicarbonyl compounds and unsaturated sugars (glycals, 6-deoxy-5-enopyranoses, and "isolated alkenes", i.e. monosaccharides with double bonds at other positions). Chapter 5 is concerned with reactions of the hydroxy groups and the resulting products. First the different reactive properties of the anomeric, primary, and secondary OH groups are described. Other topics discussed here are the kinetic anomeric effect and the selective substitution of hydroxy groups using organotin compounds. The reaction products are classified as ethers, esters (with sub-sections on enzymatic acylation and deacylation reactions, orthoesters, carbonates and their derivatives, sulfonates, chlorosulfonates, sulfites, phosphates, nitrates, borates, boronates, and borinates), and acetals. This chapter ends with a detailed discussion of glycol cleavage. Two chapters cover topics that one would perhaps not expect from the book's title. Chapter 6 deals with the synthesis, structures, and biological functions of oligosaccharides. These are then considered from a different standpoint in Chapter 8 on natural products, which also covers polysaccharides, glycoproteins, proteoglycans, glycolipids, other glycosides (including also nucleosides and their analogs together with nucleotides and nucleic acids), and cyclitols. Chapter 7 describes syntheses of enantiomerically pure "non-carbohydrates" from monosaccharides, with some well-chosen examples (methods using carbohydrates as chiral auxiliaries, and conversion of carbohydrates into other products). The appendix includes a concise survey of the literature on monosaccharides and a very brief note on nomenclature rules, referring to D. Horton's *Tentative Rules for Carbohydrate Nomenclature, Part I*, originally published in 1969 and now superseded by a revised edition (1995). Also included here is a list of trivial names of sugar derivatives, mainly of microbiological origin, and some ^{1}H and ^{13}C NMR data for monosaccharides and their peracetates.

Notable features of the book are the detailed discussions of reaction mechanisms (that of the Ferrier reaction provides a fitting illustration for the dust-cover) and of the unique aspects of the reactions of monosaccharides that result from their structures. In their presentation of structural formulas the authors have unfortunately been more concerned with "economy" than with esthetic quality. Also they have been very sparing in mentioning researchers' names in the text; for example, in Chapter 6.6 on the synthesis of oligosaccharides one would at least have expected a mention of H. Paulsen. This very convenient book contains over a thousand literature citations extending up to 1993, and although these unfortunately do not include authors' names they ensure that it is a valuable reference source. Because of the excellent layout and reasonable price it can also be thoroughly recommended as a student textbook.

What significance the binding of a substrate molecule (dark blue) to the active site of chorimate mutase has for the mechanism of the Claisen rearrangement is reported by Bruce Ganem.

The Mechanism of the Claisen Rearrangement: Déjà Vu All Over Again

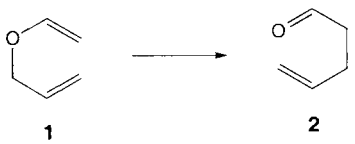
Bruce Ganem*

The great baseball player Yogi Berra, who is quoted in the title, succinctly described what it meant to learn something that others had long ago appreciated. The mechanism by which the enzyme chorismate mutase accelerates the Claisen rearrangement of chorismic acid has for many years perplexed and intrigued chemists and biochemists. Yet classical effects of solvents and catalysts, which were largely ignored by the chemical community, not only provided important clues about the mechanism of the enzyme, but put the Claisen rearrangement in a new perspective. Whereas chorismic acid once seemed exceptional because it rearranged so rapidly under physiological conditions, it is now clear that even allyl vinyl ether rearranges at room temperature in aqueous solution. While the ability of the enzyme to accelerate the rearrangement of chorismate by a factor of 10^6 was once considered extraordinary, catalysis by trivalent aluminum compounds matches, and in some cases exceeds, those rate enhancements. Therefore, it really should not be surprising to learn that Nature has independently evolved several structurally distinct solutions to the design of enzyme catalysts for the rearrangement of chorismic acid.

Keywords: allyl vinyl ethers · Claisen rearrangement · enzymatic catalysis · rearrangements

1. Introduction

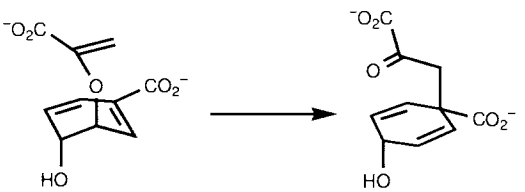
The Claisen rearrangement of allyl vinyl ethers, which was first described in 1912, is the earliest recorded example of a [3,3]-sigmatropic reaction.[1] In its simplest form, the rearrangement is exemplified by the transformation of allyl vinyl ether **1** to 4-pentenal **2** (Scheme 1).[2] Together with its all-carbon counterpart, the Cope rearrangement, these two reactions are pericyclic processes in which, by definition, bond breaking and bond making occur through a cyclic array of interacting orbitals. With their highly ordered transition states, the Claisen and Cope rearrangements are especially useful in creating and controlling new stereocenters. Because the Claisen rearrangement also generates a new carbonyl group, it has become one of the most widely used methods of stereoselective C–C bond formation in synthetic chemistry. Several elegant transformations such as the Johnson orthoester,[3] Eschenmoser amide acetal,[4] and Ireland ester enolate[5] rearrangements rely on the [3,3]-sigmatropic rearrangement of substituted allyl vinyl ethers and variants thereof.



1 **2**

Scheme 1. Claisen rearrangement of allyl vinyl ether **1** to 4-pentenal **2**.

The Claisen rearrangement also enjoys the distinction of being the only example of a pericyclic reaction observed in primary metabolism. Moreover, this biological Claisen is subject to enzyme catalysis.[6] The chorismate ion **3** (Scheme 2), the free acid of which is a key intermediate in the shikimic acid pathway, undergoes a Claisen rearrangement leading to the prephenate ion **4**, the free acid of which is an intermediate in the biosynthesis of phenylalanine and tyrosine. The enzyme chorismate mutase, which is found widely in bacteria, fungi, and plants, catalyzes the rearrangement of **3** to **4** by more than a millionfold.[7, 8]



3 **4**

Scheme 2. Claisen rearrangement of the chorismate ion **3** to the prephenate ion **4**.

It is this apparently unique ability to accelerate a pericyclic reaction that has made chorismate mutases so interesting. Pericyclic processes are thought to proceed by concerted reaction

mechanisms. with simultaneous, but not necessarily synchronous, bond making and bond breaking.[9] While the bonds undergoing chemical change might not necessarily be broken or formed to the same extent at every stage along the reaction coordinate, the changes must occur together in a single kinetic step, and there can be no discrete intermediates. For that reason, pericyclic reactions have always been elusive to study by the usual tools of mechanistic chemists. Interest in chorismate mutases has thus been fueled by the notion that somehow Nature may have gleaned, through evolution, important insights into the rearrangements of allyl vinyl ethers that have otherwise eluded chemists.

In fact, however, the history of research on the aliphatic Claisen rearrangement over the past eighty-odd years has been replete with provocative clues to the mechanism. Appreciable solvent effects and significant levels of catalysis have been reported, although until very recently, these important chemical insights went largely unnoticed in inquiries into the mechanism. The solid-state structure determinations of chorismate mutases from *Bacillus subtilis* (BsCM)[10] and *Escherichia coli* (EcCM)[11] have been instrumental in bringing this area of chemistry into sharper focus.[12]

2. Background

To appreciate the evolution of current thinking about the mechanism of the aliphatic Claisen rearrangement, about the rearrangement of chorismate to prephenate ions, and about the properties of chorismate mutase, some historical background is important. In particular, it is worth reviewing what mechanistic features of pericyclic processes distinguish them from their polar or radical counterparts.

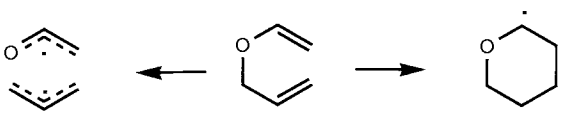
2.1. Sigmatropic Rearrangements

The Claisen rearrangement is a classic example of a [3,3]-sigmatropic rearrangement, one of five categories of pericyclic processes defined by Woodward and Hoffmann.[13] The [3,3]-sigmatropic rearrangement of allyl vinyl ether occurs with a negative activation entropy[14, 15] and negative activation volume.[16] The reaction displays first-order kinetics,[14, 15] and no crossover products are observed.[17] The bond reorganization leading to **2** proceeds through a chair (or chairlike) transition state of contiguous p orbitals,[18, 19] and the stereochemical course of rearrangement is consistent with orbital symmetry rules.

The same hallmarks of a [3,3]-sigmatropic reaction have been noted in the nonenzymatic rearrangement of chorismate ions, including negative activation entropy,[7] first-order kinetics, and chair transition state geometry.[20] Interestingly, the inherent (i. e. uncatalyzed) rate of rearrangement of **3** (H_2O, 75 °C, pH 5) is about 4200 times as fast as that of allyl vinyl ether in dibutyl ether at the same temperature.[21] The mutase-catalyzed rearrangement of chorismate ions also proceeds with a transition state of chairlike geometry,[22] but the entropy of activation in the mutase-assisted process is nearly zero,[8] suggesting that the conformation of the substrate is severely restricted in the enzyme–substrate (E–S) complex.[23] This conformational control undoubtedly contributes to the observed catalysis. The enzyme also lowers the activation enthalpy of rearrangement by about 5 kcal mol^{-1}, which indicates that the protein plays some additional role in catalysis (vide infra).

2.2. Concerted Rearrangements

The Claisen rearrangement is generally regarded as a concerted, but asynchronous, pericyclic process.[9] Secondary deuterium kinetic isotope effects (KIEs) reported by Gajewski on the parent, allyl vinyl ether **1**, indicate that C–O bond breaking proceeds somewhat ahead of C–C bond making, as might be expected in a diradical transition state like **5** (Scheme 3).[24]



5 **1** **6**

Scheme 3. Diradical transition state **5** and diyl transition state **6** for the Claisen rearrangement of allyl vinyl ether **1**.

Bruce Ganem earned a BA degree in chemistry from Harvard College in 1969. In 1972 he received his PhD degree in organic chemistry at Columbia University, then served as a National Institutes of Health Postdoctoral Fellow at Stanford University before joining the faculty of the Department of Chemistry at Cornell in 1974. His broad scientific interests lie at the emerging interfaces of organic and biological chemistry with biochemistry, biotechnology, and molecular medicine. He has held numerous lectureships around the world, and is the author of over 180 scientific papers as well as numerous popular articles about science and science education. He has also served on the advisory or editorial boards of several professional journals.
Profesor Ganem has been the recipient of both A. P. Sloan and J. S. Guggenheim Foundation Fellowships. His awards include the Camille and Henry Dreyfus Teacher–Scholar Award, an Eli Lilly Young Scientist Award, the American Cyanamid Award for the Advancement of the Art and Science of Chemical Synthesis, the Clark Distinguished Teaching Award at Cornell, and the 1996 Arthur C. Cope Scholar Award of the American Chemical Society. He is a member of the Scientific Advisory Board of LeukoSite, and has served as a consultant for American Cyanamid, Cambridge Neurosciences, Cordis Corporation, Ciba-Geigy, Exxon Chemical, Genencor International, Magainin Pharmaceuticals, Parke-Davis Pharmaceuticals, Purdue Pharma, the Teltech Resource Network, and Union Carbide Corporation.

Based on MNDO/3 calculations, however, Dewar has argued that C–C bond formation is more advanced than C–O cleavage, which implies more diyl character (e. g. **6**) in the transition state.[25] Recent ab initio calculations at the MP2/6-31G level indicate a transition structure with appreciable C–O bond breaking (as observed experimentally by Gajewski), but markedly different from Dewar's MNDO calculation.[26]

The nonenzymatic rearrangement of chorismate ions is also a concerted asynchronous rearrangement.[27] Secondary tritium isotope effects using both C5 and C9 double-labeled **3** indicate an asymmetric transition state in which C–O bond breaking is substantially more advanced than C–C bond making. Several ab initio calculations of the uncatalyzed transition structure have been reported,[7, 28] of which the most recent[29] best rationalizes the experimentally observed asychronous bond breaking. An experimental study of kinetic isotope effects on the enzymatic reaction was less revealing: no isotope effect was observed in the mutase-catalyzed rearrangement of C5/C9-labeled **3**.[27] Nevertheless, the catalyzed and uncatalyzed processes might still involve similar mechanisms, since isotope effects on an enzyme-promoted pericyclic process could be masked by some other, earlier, rate-limiting event.

2.3. Solvent and Catalyst Effects

While not an axiom of pericyclic reaction theory, it is generally true that pericyclic processes are, in contrast to most polar and radical reactions, relatively insensitive to solvent.[30, 31] For example, the Cope rearrangement of 1,5-dienes is not influenced by changes in solvent polarity.[32, 33] Also as a consequence of their concertedness, pericyclic reactions are usually not catalyzed by acids, bases, or other agents. Nevertheless, there are exceptions. Certain 1,5-dienes do undergo Cope rearrangement with catalysis by transition metal species.[34, 35] However, the catalyzed processes likely involve transient cyclohexylmetal cations[36] or bis-π-allylmetal complexes,[37] and are thus no longer concerted.[38]

The aliphatic Claisen rearrangement seems to differ from conventional pericyclic processes in its long history of sensitivity to solvents and catalysts. Indeed, both solvent effects and catalysis are more the rule than the exception in Claisen systems. Yet chemists have been reluctant to acknowledge these well-documented reports, perhaps because solvent and catalyst effects seem inconsistent with the mechanistic lore of pericyclic processes. How catalysts might accelerate even the simplest Claisen rearrangements is not known, and the effect of catalysis on reaction mechanism remains poorly understood.[38] At the same time, it should be noted that no evidence has been presented which suggests that accelerated Claisen rearrangements represent anything other than true pericyclic reactions.[39]

This review examines the effect of solvents on the rearrangement of **1** and other aliphatic Claisen systems, including the nonenzymatic rearrangement of chorismate. Known examples of catalysis of aliphatic Claisen rearrangements are also considered. In the case of biological systems, the catalytic sites of two known chorismate mutases are reviewed, as elucidated by recent X-ray diffraction studies on BsCM and EcCM. The clear commonalities that emerge provide the framework for a consistent, coherent mechanistic rationale of solvent and catalyst effects on the aliphatic Claisen rearrangement.

3. Discussion

3.1. Solvent Effects on Claisen Rearrangement Rates

The earliest indications of solvent effects in Claisen processes, detected in allyl aryl ethers almost sixty years ago, set an important precedent for the influence of solvent on aliphatic rearrangements. Kincaid and Tarbell[40] investigated the rearrangement of allyl p-tolyl ether **7** to 2-allyl-4-methyl phenol **8** (Scheme 4). The rate was found to increase with time as concen-

7 8

Scheme 4. Claisen rearrangement of allyl *p*-tolyl ether **7** to 2-allyl-4-methyl phenol **8**.

trations of phenol **8** increased. Measured in separate experiments, the rearrangement of **7** in a 4:1 mixture of **8**:**7** was four times faster than that in neat **7**. Such autocatalysis is not observed in aliphatic Claisen systems because the enol tautomer of the initally formed carbonyl compound is a minor component at equilibrium. To test for simple acid catalysis, both acetic and chloroacetic acids were added; however, no rate enhancements were detected.

In 1958, White et al. measured rate constants for the rearrangement of **7** at 181 °C in five different solvents (Table 1, column 1) and observed a distinct acceleration in solvents of higher polarity.[41] Although no mechanistic rationale was presented, the authors noted that the sevenfold rate difference was comparable in magnitude to that observed in a well-known polar reaction: the N-alkylation of tertiary amines with methyl iodide (Menschutkin reaction) run in benzene/nitrobenzene mixtures.

Appearing jointly with the report by White et al. was an independent study by Goering and Jacobson in which rate constants for the rearrangement of **7** were measured in twelve solvents at 184 °C (Table 1, column 2). A significant solvent effect was observed, with the rearrangement of **7** some 30 times faster in phenol than in decalin.[42] The more rapid rates in hydroxylic solvents led Goering and Jacobson to suggest, for the first time, a correlation with the solvent's hydrogen bonding ability. That idea, though challenged, ultimately provided an important clue to solvent effects in aliphatic Claisen rearrangements.

Twelve years later, the concept that solvents influenced the rate of Claisen rearrangements had still not gained wide acceptance in the chemical community, as was evident from this introduction to a 1970 study by White and Wolfarth:[43]

"The Claisen rearrangement has often been cited as a reaction insensitive to solvent effects, in spite of the fact that early studies indicated that this was probably not so."

White and Wolfarth examined the rearrangement of **7** to **8** at 170 °C both in the gas phase and in 17 solvents of different polarities (Table 1, column 3). A substantial solvent effect leading to a 300-fold variation in rate was observed, with rates generally faster in hydrogen bonding solvents, as had been noted by Goering and Jacobson.[42]

In addition to solvent effects, both the White and Goering groups found that *para*-substituents influenced the rate of allyl phenyl ether rearrangements (Table 2). Twentyfold differences

Table 2. Rate constants k [$10^6 s^{-1}$] for the rearrangement of *para*-substituted allyl phenyl ethers at $T = 181$ °C [46].

Solvent	Substituents in *para* position			
	NO_2	Br	CH_3	OCH_3
tetradecane	2.34	5.98	7.94	28.3
diethylene glycol monoethyl ether	10.3	27.7	44.2	91.6
ethanol/water (28.5%)	90.9	134	233	621

in rate were noted, with electron-donating groups (OCH_3, NH_2) being moderately accelerating and electron-withdrawing groups (NO_2, CN) mildly retarding. Substituent effects on the rates of aliphatic Claisen[2b] and Cope rearrangements[44] have also been observed. Because the effects of substituents in aliphatic and aromatic systems were sometimes contradictory, they have generated much discussion and debate.

It is now evident that the *apparent* effects of substituents in aromatic systems may result from competing phenomena that greatly complicate direct comparisons with corresponding aliphatic systems. First, as has already been noted, aromatic Claisen systems produce phenols that can catalyze the [3,3]-sigmatropic step,[40] thus making every rearrangement subject to a solvent effect. Since *para*-substituents also influence phenolic acidities, the solvent effect is further obscured. Moreover, as Brønsted acids, these phenols would likely also catalyze enolization of the intermediate cyclohexadienone, and it remains unclear whether rearrangement or tautomerization is rate determining in the various solvents studied.

These same substituent effects likely also complicate the interpretation of solvent effects. Although rearrangement rates listed in Table 1 were generally faster in hydrogen bonding solvents, White and Wolfarth maintained that if hydrogen bonding were important, a correlation should be seen between rate accelerations and solvent acid dissociation constants. Yet the rearrangement of **7** in octanoic acid was slower than in *p*-chlorophenol, and rates in aqueous ethanol and in phenol were comparable. Instead, White and Wolfarth found a reasonably good correlation, which they favored in their paper, between rate and solvent polarity, as measured by Kosower's Z-factors.[45]

It should be noted that neither pK_a values nor solvent Z-factors measured at ambient temperature can easily be extrapolated to 170 °C, the temperature at which the kinetic experiments were performed. Thus, even a semiquantitative treatment of the data in Table 1 is not very reliable. Moreover, the fact that a given substituent's effect can vary from 22- to 39-fold in different solvents[46] is more than sufficient to rationalize some of the inconsistencies in the simple hydrogen-bonding model first proposed by Goering and Jacobson.[42] Only the Goering–Jacobson model explains the autocatalysis that Kincaid and Tarbell observed in rearrangements of **7**.

In 1987, the first solvent effects on aliphatic Claisen rearrangements were described in two independent publications. While there was unanimous agreement about the experimental observations, their mechanistic significance has remained open to debate.

Groups at the University of Illinois, Urbana, (Coates) and the University of Pittsburgh, (Curran) collaborated to study the effect of alkoxy substituents on aliphatic Claisen rearrangements,[47] while groups at Indiana University, Bloomington, (Gajewski) and Cornell University, Ithaca, (Carpenter, Ganem) investigated the nonenzymatic Claisen rearrangement of chorismate **3**.[48] Both groups of researchers compared the effect of solvent on the rearrangement of allyl vinyl ether (Table 3, columns 2, 3). While the Illinois/Pittsburgh team found only a modest difference between benzene and methanol, the Cornell groups measured a nearly sixtyfold rate enhancement going from dibutyl ether to 2:1 methanol:water.

Data on four other substituted acyclic allyl vinyl ethers **9**–**12** (Scheme 5) taken from both publications revealed similar solvent effects (Table 3, columns 4–7). For example, two methoxy-substituted allyl vinyl ethers, **9** and **11**, rearranged 18- and 68-fold faster, respectively, in methanol than in benzene. More extensive relative rate data on **12** collected by the Cornell groups displayed a good correlation with Dimroth's solvent E_T values[49] (Table 3, columns 1, 7), just as White and Wolfarth had concluded using a different measure of solvent polarity in the earlier aromatic Claisen studies. This trend was interpreted by

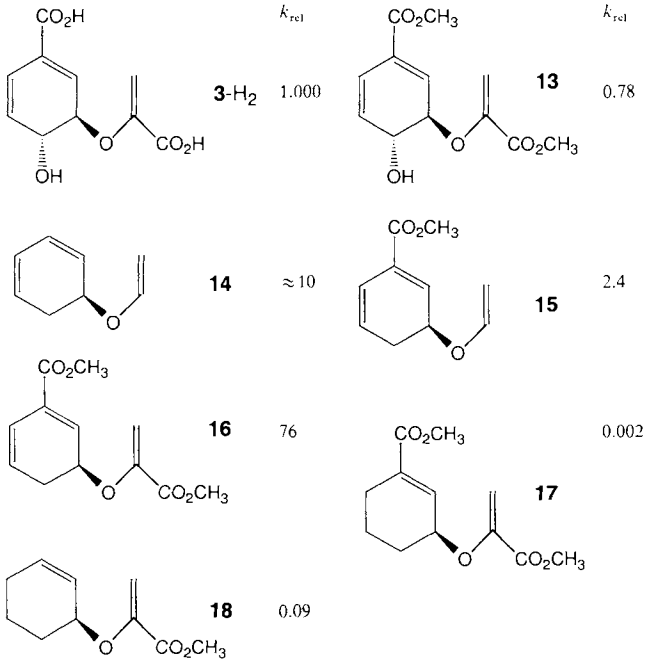
the investigators at Illinois, Pittsburgh, and Cornell as support for a dipolar mechanism in which C–O heterolysis resulted in significant resonance-stabilized ion pair character in the rearrangement transition state.

The thermal rearrangement of chorismate **3**-H_2 the dimethyl chorismate **13**, and five additional chorismate analogs **14**–**18** (Table 4) was monitored in 2:1 $CD_3OD:D_2O$ at 75 °C to obtain the relative rates of rearrangement, and these data were cited by the Cornell researchers as additional evidence in support of a dissociative Claisen process. The observed substituent

Table 4. Relative rate constants k_{rel} for the rearrangement of chorimate analogues [48].



3-H_2 k_{rel} 1.000 — **13** k_{rel} 0.78

18 k_{rel} 0.09

effects, like solvent effects on **9**–**12**, were consistent with C–O bond heterolysis in which the developing carbocation and enolate anion experienced both σ-inductive effects exerted by the hydroxyl and carboxyl groups as well as π-delocalization effects through the disubstituted endocyclic alkene. Several other examples of aliphatic Claisen rearrangements have been reported in which observed rate enhancements could be rationalized by similar inductive and resonance effects.[50–53]

While the 20- to 120-fold solvent-induced rate accelerations for the simple allyl vinyl ethers **9**–**12** were significant, one of the most compelling findings to emerge from the study by the Cornell group was that the rearrangement of dimethyl chorismate **13** was only 18 times faster than that of allyl vinyl ether itself when both rates were measured in a mixture of methanol and water (2/1) at 75 °C. Thus for the first time, it was shown that the rapid rearrangement of chorismic acid, long thought to be an especially facile [3,3]-sigmatropic process, was in very large part attributable to the normal metabolic environment—water.[48] The practical implications and synthetic utility of this finding were quickly acknowledged, and aqueous conditions were soon shown to accelerate several synthetically important Claisen rearrangements.[54,55] Sensitive systems which would not tolerate the high temperature conditions normally required in organic solvents could be rearranged in hot water.

Although the synthetic value of aqueous Claisen rearrangements was universally acknowledged, the specific mechanism by which polar solvents enhanced the rearrangement rate remained unresolved. The Indiana group, led by Gajewski, questioned the dipolar/dissociative mechanism presented by the Pittsburgh/Illinois/Cornell groups. Gajewski argued that neither solvent[45] nor kinetic isotope[24] effects were comparable in magnitude to those observed in reactions proceeding by bona fide zwitterionic structures or tight ion pairs.

As an example, the Indiana group cited the case of a charge-separated cyclopropane opening in which changing the solvent from benzene to DMF increased the rate by 32000.[56] By contrast, the largest solvent rate enhancement in aliphatic Claisen rearrangements was a 200-fold effect on going from cyclohexane to water.[57] For solvolyses where tight ion pair formation was rate determining, typical secondary deuterium kinetic isotope effects approximated 70% of the maximum value.[58] By contrast, the nonenzymatic rearrangement of chorismate displayed only 40% of the maximum KIE.[27] Thus, Gajewski et al. concluded that whatever its structure, the transition state affected by polar hydroxylic solvents accumulated substantially less polar character than well-known zwitterions or tight ion pairs.[57]

In search of an alternative mechanistic rationale, Gajewski attempted to determine the extent to which polar solvent effects were composed of such factors as dielectric effects, solvent cohesive energy densities, hydrogen bond donating effects, and hydrogen bond accepting effects.[59] A solvent rate effect equation was derived which, for the aliphatic Claisen rearrangement, re-

vealed a specific correlation between rate and hydrogen bond donating ability of the solvent. As further evidence against an ionic transition state, secondary deuterium KIEs measured at C4 and C6 of allyl vinyl ether both in *m*-xylene and in $CD_3OD:D_2O$ mixtures indicated that bond breaking was no more extensive in aqueous media than in hydrocarbon solvents.[60]

The importance of solvent hydrogen bonding gained further credence from a Monte Carlo simulation of the effect of hydration on Claisen rearrangements carried out in 1992. Severance and Jorgensen calculated that the transition state for rearrangement of **1** in water was better hydrated than the reactant by 3.85 ± 0.16 kcal mol^{-1}.[61] Consistent with this model, the carbonyl oxygen of the product **2** would be expected to form two hydrogen bonds. The authors suggested that in the transition state, two hydrogen bonds are formed with average strengths of -4.6 kcal mol^{-1} between the oxygen atom of the vinyl ether and two water molecules. By contrast, reactant **1** displayed only a single hydrogen bond with a strength of -3.4 kcal mol^{-1}. Such enhanced hydration could account for a 600- to 700-fold rate enhancement over the Claisen rearrangement of allyl vinyl ether in the gas phase. Moreover, the computed acceleration was not attributable to zwitterionic intermediates, tight ion pairs, or other C–O bond dissociative processes. A recent simulation, modeled at the ab initio level with two explicit water molecules, reached essentially similar conclusions.[62]

A simple physical picture thus emerges for the role of enhanced solvent hydrogen bonding in accelerating the rate of Claisen rearrangements by stabilizing the transition state. Moreover, with hydrogen bonding increasing as the reactant moves towards the transition state, n-π^* conjugation in vinyl ether ground state (Fig. 1) is disrupted.[63] No dipolar or dissociative intermediate need be invoked, thus accommodating the concerns of Gajewski et al. over the magnitude of the observed solvent effects.[59, 60] With remarkable prescience, Severance and Jorgensen forecast that their results would "promote catalyst designs that incorporate two or more hydrogen-bond-donating groups positioned to interact with the oxygen in the transition state." This prediction was to be borne out with startling correctness in the detailed structure investigations of the active site of natural *E. coli* and *B. subtilis* chorismate mutases that were reported shortly thereafter.

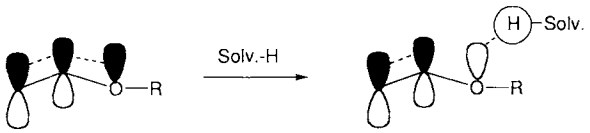

Fig. 1. Disruption of n-π^* conjugation in vinyl ethers by solvent hydrogen bonding which leads to an increase in their ground state energy. Solv. = solvent.

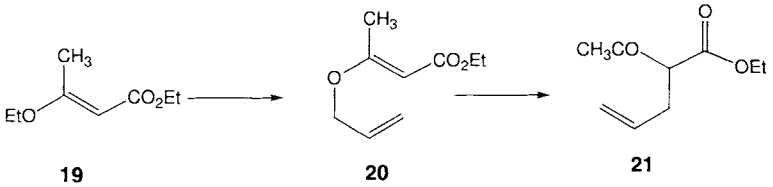
3.2. Chemical Catalysis of the Claisen Rearrangement

"Catalysis of the Claisen rearrangement is as old as the rearrangement itself."[2a] It was Ludwig Claisen himself who discovered in 1912 that when the allyl ether of acetoacetic ester **20** was heated in the presence of ammonium chloride, the salt noticeably enhanced the formation of C-allyl acetoacetate **21** (Scheme 6).[1] Claisen's remarkable discovery was fortuitous:

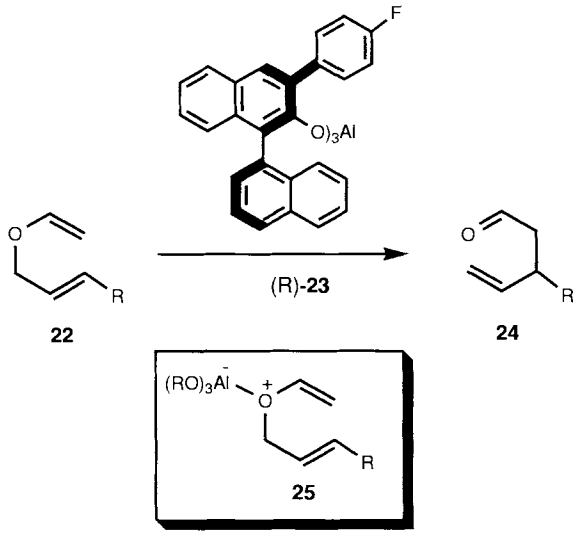


19 **20** **21**

Scheme 6. Formation and rearrangement of *O*-allyl acetoacetate **20**.

NH_4Cl was intended to catalyze the formation of **20** from **19** in an exchange reaction with allyl alcohol. However, as other synthetic approaches to allyl ethers supplanted this method, the use of ammonium chloride gradually disappeared, as did the awareness of its catalytic potential. Nevertheless, the effect of solid NH_4Cl was reinvestigated in several additional aliphatic Claisen rearrangements, and shown to cause a small, but significant, increase in rearrangement rates.[64]

A number of Brønsted and Lewis acids, and even weak acids like silica gel or Celite,[65] have since been reported to accelerate Claisen rearrangements. Developments in this area prior to 1984 have been thoroughly documented in a comprehensive review by Lutz.[38] The most promising synthetic catalysts for regio- and stereospecific rearrangements now appear to be trivalent organoaluminum reagents.[66] Very recently, Yamamoto has developed a chiral aluminum naphthoxide (*R*)-**23** (Scheme 7) that displays a cup-shaped, C_3 symmetric binding cleft whose three *p*-fluorophenyl groups effectively shield one face of the aluminum center. Catalyst (*R*)-**23** is capable of rearranging substituted allyl vinyl ethers **22** to chiral aldehydes **24** at $-78\,^{\circ}C$ with enantiomeric excesses up to 92%.[67] Like other aluminum bis- and tris-phenoxides, complex (*R*)-**23** is thought to function by coordination at the vinyl ether oxygen atom to form **25** (Scheme 7) in what has been termed a "charge-accelerated rearrangement."[38]



22 **24** **25**

Scheme 7. Catalysis of the rearrangement of substituted allyl vinyl ethers **2** to chiral aldehydes **24** by chiral aluminum naphthoxide (*R*)-**23**.

Charge-accelerated rearrangements occur when carbanions or carbocations attached at the allylic positions become more delocalized in the rearrangement transition structure.[68-70] Several examples of such systems reportedly undergo facile Claisen rearrangement. The dramatic rate enhancements seen are rationalized by customary arguments for the stabilization of the transition state.[38] However, zwitterions like **25** are not configured for such charge delocalization, and thus cannot accelerate the rate by lowering the enthalpy of the transition state.

Instead of invoking charge-acceleration effects, an alternative mechanism for Lewis acid catalysis may be drawn by analogy with the aqueous solvent effects heretofore described. Just as enhanced hydration of the transition state accelerated Claisen rearrangements in water, stabilization of the developing lone pairs of electrons by complexation to Lewis acids might also promote the rearrangement. Quantitative differences between the magnitude of solvent-induced and catalyst-induced rate enhancements are difficult to assess at this time, but may involve a combination of ground state and transition state effects. Qualitatively speaking, however, both aqueous solvents and Lewis acid catalysts may be viewed as exerting effects on lone pairs of electrons on oxygen that lower the activation barrier for rearrangement.

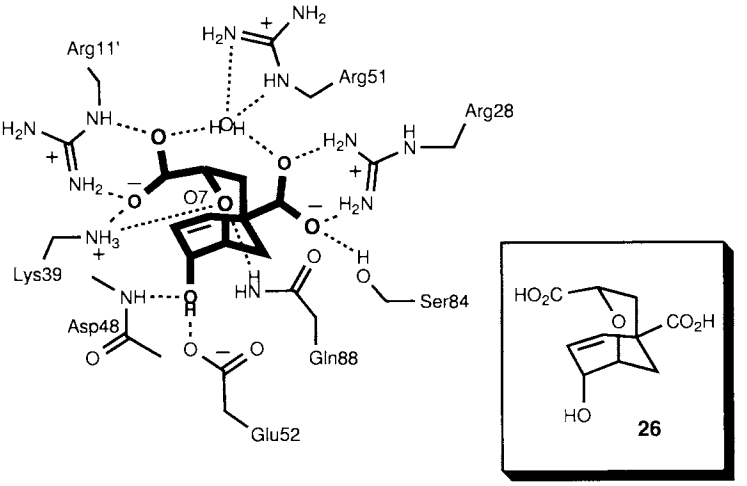


Fig. 2. Amino acid residues of the active site in EcCM, shown complexed to the dianion of the competitive inhibitor **26** (inset).

3.3. Biological Catalysis of the Claisen Rearrangement

How chorismate mutases accelerate the rearrangement of **3** remains an area of continuing debate among chemists and biochemists. Yet as this careful historical analysis of the Claisen rearrangement indicates, clues to the mechanism that were in print for eighty-odd years have largely been ignored by the chemical community. While chorismic acid was long regarded as exceptional because it rearranged so rapidly under physiological conditions, it is now clear that many allyl vinyl ethers, including **1** itself, rearrange at room temperature in aqueous solution. While the ability of the enzyme to accelerate the rearrangement of chorismate ions by a factor of 10^6 was long considered extraordinary, catalysis by trivalent aluminum compounds matches, and in some cases exceeds, those rate enhancements.[67] As with many other chemical reactions, the Claisen rearrangement is subject to a wide range of solvent and catalyst options to promote its rate. Therefore, it was not surprising to discover that Nature has independently evolved structurally distinct solutions to the design of enzyme catalysts for the rearrangement of **3**. Two very different enzymes have already been characterized.

We recently described the 2.2 Å resolution X-ray structure of the N-terminal chorismate mutase domain (residues 1-113) engineered from the bifunctional *E. coli* enzyme chorismate mutase–prephenate dehydratase (P-protein).[111] The structure was solved as a complex with inhibitor **26** (Fig. 2). Monofunctional EcCM has three helical segments (residues 6-42, 49-65, 70-100) which cause the peptide backbone to adopt a figure-4 shape. Coiled-coil and helix-helix interactions between the two longest segments create a catalytically functional, elongated homodimer whose two equivalent, elbow-shaped active sites are highly charged and completely enclosed. Although access to the active site is possible from different directions, as might be expected in the parent bifunctional enzyme, charged Arg, Asp, and Glu side chain residues shield the catalytic region from solvent on different faces of the protein (Fig. 2).

The high-resolution X-ray structure of a comparably-sized (127 residues), monofunctional *B. subtilis* chorismate mutase (BsCM) bound to **26** has also been reported.[110] While the kinetic parameters of EcCM and BsCM are similar, both the amino acid sequence and the secondary structure of BsCM are strikingly different. Standard alignment methods indicate less than 20% similarity in the EcCM and BsCM sequences. In fact, known mutases from different organisms share little sequence similarity. The peptide backbone of BsCM adopts a five-stranded mixed β-sheet containing one α-helix (residues 18-34) and a two-turn 3_{10} helix. BsCM is a symmetric trimer packed to form a pseudo-α,β-barrel; adjacent subunits form three equivalent clefts that constitute the active sites. In striking contrast to EcCM, the active site in BsCM is open and accessible to solvent (Fig. 3).

When the EcCM and BsCM active sites are compared by superimposing the atoms of bound inhibitor **26**, a common mo-

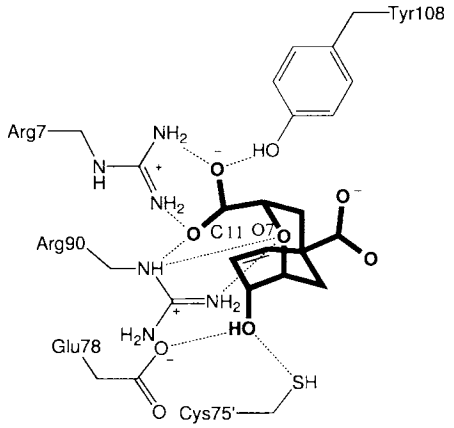

Fig. 3. Amino acid residues of the active site in BsCM, shown complexed to the dianion of the competitive inhibitor **26**.

tif emerges in the highly charged region created by the presence of adjacent, protonated residues (Lys39, Arg11′, Arg51 in EcCM; Arg90, Arg7 in BsCM).[12] This electropositive wall interacts strongly with the left flank of the chorismate ion through an elaborate network of bridging hydrogen bonds involving both O7 and the C11 carboxylate of the enol pyruvate. Besides promoting E–S complex formation through electrostatic effects, the positively charged residues in EcCM and BsCM are thought to orient and lock the chorismate ion in the requisite chair conformer for rearrangement.

At the same time, a lone pair of electrons on the oxygen atom of the vinyl ether of chorismate becomes accessible for hydrogen bonding, and in fact, each enzyme is capable of forming two hydrogen bonds with O7 of the bound inhibitor. These are precisely the hydrogen bonds predicted by Severance and Jorgensen to be important in catalyst design. In the case of EcCM, formation of the E–S complex rotates chorismate into position for hydrogen bonding with Lys39 and Gln88. In the case of BsCM, the oxygen atom of the enol ether group of the chorismate ion likewise forms two hydrogen bonds with Arg90 to promote the pericyclic rearrangement. These hydrogen bonds stabilize the transition state and reduce the activation enthalpy for rearrangement.

Thus a common mechanism is proposed for EcCM and BsCM in which a) adjacent, protonated, active site residues exert conformational control in the chorismate mutase E–S complex, and b) hydrogen bonding between active site residues and O7 of the bound chorismate ion further catalyzes the rearrangement.[12] These mechanistic ideas rationalize all available experimental data on the chorismate mutase reaction, and are consistent with the role of chemical catalysts like Lewis acids and phenols on simple Claisen rearrangements covered in this review.

It seems ironic that chorismate mutase was regarded for so long as being "unique," and that so much mystery and intrigue surrounded the enzyme's ability to catalyze a pericyclic reaction. In retrospect, X-ray structural information on BsCM and EcCM not only provided key clues about the mechanism of chorismate mutases, but also helped substantiate the role of solvent effects on aliphatic Claisen rearrangements. It thus may be worthwhile, in studying the effects of solvent on reactivity, to examine reactions where enzyme-catalyzed counterparts in Nature may provide fresh insight through X-ray crystallographic data. It is hoped that this review will also promote an appreciation of the clear commonalities of mechanism and catalysis that unite the [3,3]-sigmatropic rearrangements of allyl vinyl ethers.

Intermediates in the protonation of a phosphane allyl molybdenum complex can be detected by ^{31}P NMR spectroscopy. For more about the kinetic analysis of protonation mechanisms for hydrocarbon transition metal complexes see the following article by R. A. Henderson.

Protonation of Unsaturated Hydrocarbon Ligands: Regioselectivity, Stereoselectivity, and Product Specificity

Richard A. Henderson*

Understanding the mechanisms of protonation of hydrocarbon ligands is fundamental to a wide range of chemistry including organic synthesis, organometallic chemistry, and even bioinorganic chemistry. Protonation at carbon or metal sites is often slow, with the result that in species containing both types of sites, initial protonation can be at either the metal or the carbon. This has fundamental consequences on the reactivity of hydrocarbon ligands, which are highlighted in this article. In particular, many reactions are apparently the result of a regioselective protonation on the basis of structural analysis of the isolated products. In fact, these products are often formed by an indirect route involving kinetically controlled protonation at the "wrong" site followed by rearrangement to form the thermodynamically controlled, apparently regioselective, product. Other aspects of the protonation mechanisms of complexes containing hydrocarbon ligands are discussed, with an emphasis on the manner in which competitive protonation at metal or ligand can be exploited to select which hydrocarbon is produced and to control the stereochemistry of the hydrocarbon.

1. Introduction

The binding and activation of small molecules at metal sites is an area of research which is of interest to a wide range of chemists—from those involved in the simple stoichiometric reactions of inorganic compounds to those defining the elementary reactions of organometallic homogeneous catalysts, metalloenzymes, and even heterogeneous catalysts. In this article I will concentrate on the protonation of small, unsaturated hydrocarbon residues bound to relatively simple, electron-rich transition metal sites.

The chemistry of carbon residues bound to metal sites has traditionally been considered the domain of organometallic chemists; however, for many years (since the discovery of the cobalt–carbon bond in the vitamin B_{12} coenzyme)[1] it has been appreciated that bioinorganic chemistry can have an organometallic flavor.[2] Clearly in the vitamin B_{12} case, the connection between organometallic and bioinorganic chemistry is based on a structural feature. However, if some of the elementary reactions of metalloenzymes are considered, then further aspects common to organometallic and bioinorganic chemistry become evident. Examples are the 1,2-shifts associated with several types of enzymes, which are initiated by homolysis of the cobalt–carbon bond in the vitamin B_{12} coenzyme;[3] the reduction of carbon dioxide to methane by dihydrogen in methanogenic and acetogenic bacteria containing carbon monoxide dehydrogenase (in anaerobic bacteria a nickel-containing enzyme and in aerobic bacteria a molybdopterin enzyme);[4] and the mono- or dioxygenation of organic molecules by methane monoxygenase[5] and catecholases[6] (iron-containing enzymes). All involve the reaction, or intermediacy, of species containing metal–carbon bonds.

A family of enzymes that are of particular interest (at least to the author!) are the nitrogenases. These enzymes contain iron together with molybdenum or vanadium and transform dinitrogen into ammonia with the concomitant release of some dihydrogen in vivo [Eq. (1)].[7] In vitro the enzyme is capable of

$$N_2 + 8H^+ + 8e^- \longrightarrow 2NH_3 + H_2 \quad (1)$$

transforming a wide range of other small, unsaturated molecules by a sequence of electron and proton transfer reactions. The range of alternative substrates include acetylenes, cyclopropenes, azides, isonitriles, and cyanides. It is worth noting that in several of these a metal–carbon bond must be formed upon binding of the substrate. Of these substrates, the reactions of the nitrogenases with acetylene to form ethene and ethane [Eqs. (2) and (3)], respectively, warrant further comment.

$$C_2H_2 + 2H^+ + 2e^- \longrightarrow C_2H_4 \quad (2)$$

$$C_2H_2 + 4H^+ + 4e^- \longrightarrow C_2H_6 \quad (3)$$

The nitrogenases exhibit a different product specificity in their reactions with acetylene. The molybdenum-based nitroge-

Present address: Nitrogen Fixation Laboratory, John Innes Centre
Norwich Research Park, Colney, Norwich (UK)

nase converts acetylene into ethene exclusively, whilst the vanadium-based enzyme gives predominantly ethene but also some ethane (about 5%). In addition, both nitrogenases exhibit a stereoselectivity in their reactions with acetylene. In the presence of D_2O both enzymes give *cis*-CHDCHD as the exclusive product. The manner in which the enzyme accomplishes such stereoselectivity and product specificity by simple electron and proton transfer reactions was the inspiration of much of our own work in this area.

In this article we shall see that the fundamental mechanistic chemistry associated with the protonation of hydrocarbon residues bound to a transition metal center is a consequence of slow protonation at both metal and carbon sites. Only by understanding the basic mechanistic principles associated with protonation of simple complexes containing hydrocarbon residues can we appreciate how to harness this reactivity to accomplish stereoselective or product-specific reactions.

2. General Considerations on the Rates of Protonation

Throughout this article we shall be concerned with the protonation of unsaturated carbon residues bound to metal sites; consequently it is pertinent to start with a short, entirely general, discussion of the factors that influence the rates of protonation at various sites. This will necessarily be a "broad brush strokes" approach, and the interested reader is referred to specialist reviews of this area for a more detailed discussion.[8–10]

2.1. Rates of Proton Transfer

In general, for the simple process described by Equation (4) there is no chemical barrier for thermodynamically favorable reactions involving attachment of the proton to bases at an O,

$$H^+ + X^- \rightleftharpoons HX \tag{4}$$

N, F, or S site. The rate of the reaction is restricted only by the rate at which the two components diffuse together ($k_{diff} \approx 1 \times 10^{10}\ dm^3\,mol^{-1}\,s^{-1}$). The rate of the reverse reaction is necessarily smaller by a factor dependent on the thermodynamic driving force of the reaction, K_a, (that is, $10^{\Delta pK_a}$). If the forward reaction is not thermodynamically favorable, the rate of the reaction is dependent on the thermodynamic driving force, as given by the Brønsted relationship in Equation (5),

$$k = G_a K_a^{\alpha} \tag{5}$$

where G_a and α are constants. Thus, for the protonation of a series of structurally analogous bases, the curve of the plot of $\log k$ against $\log K_a$ initially has a slope of unity under conditions where the proton transfer is thermodynamically uphill, but levels off to a slope of zero when the proton transfer is thermodynamically favorable.

Exceptions to this general rule occur when there is a considerable change in the structure of the O, N, F, or S acid or base upon proton transfer, and then the rate is slower than the diffusion-controlled limit. For instance, the deprotonation reaction in Equation (6) is a thermodynamically favorable reaction, but

$$^-O_2NNCH_2CH_2NHNO_2 + NH_3 \rightleftharpoons {}^-O_2NNCH_2CH_2NNO_2^- + NH_4^+ \tag{6}$$

the forward rate constant ($k \approx 10^5\ dm^3\,mol^{-1}\,s^{-1}$) is five orders of magnitude slower than the diffusion-controlled limit.[11] This relatively slow rate of proton transfer indicates that there is a significant barrier to removal of the proton from the monoanionic species, which is probably associated with the delocalization of the lone pair of electrons over the NNO_2 residue.

2.2. Proton Transfer at Carbon Sites

We can consider the deprotonation of the CH_2NO_2 residue in nitroethane, as shown in Equation (7), to be the carbon ana-

$$MeCH_2NO_2 + NH_3 \rightleftharpoons MeCHNO_2^- + NH_4^+ \tag{7}$$

logue of the reaction in Equation (6).[12] The rate of this deprotonation is $k = 7 \times 10^{-3}\ dm^3\,mol^{-1}\,s^{-1}$. This example illustrates an entirely general principle: deprotonation of a carbon residue is markedly slower than deprotonation of the "analogous" nitrogen-based residue. This difference between the normal behavior exhibited by O, N, F, or S sites and carbon

Born in 1951 just outside London, Richard A. Henderson studied chemistry at University College London, receiving his PhD in 1976 under the supervision of Martin L. Tobe. After two years as postdoctoral fellow with A. Geoffrey Sykes at the University of Leeds, he moved to the Nitrogen Fixation Laboratory at the University of Sussex in October 1979. His major research interests are in mechanistic inorganic chemistry, in particular the binding of small molecules such as N_2, H_2, RNC, RCN, or unsaturated hydrocarbons to transition metal sites, and their activation towards protonation. More recently his interests have extended to the mechanisms of the reactions of iron–sulfur-based clusters. In 1993 he was the first recipient of the Royal Society of Chemistry Award in Inorganic Reaction Mechanisms.

sites is further emphasized by comparing the rates of the proton transfer reactions shown in Equations (8) and (9).[13]

$$MeCH_2NO_2 + OH \rightleftharpoons MeCHNO_2^- + H_2O \quad (8)$$

$$C_6H_5OH + OH \rightleftharpoons C_6H_5O^- + H_2O \quad (9)$$

Although phenol is a weaker acid than nitroethane, and consequently the thermodynamic driving force is larger for reaction (8), the rate of deprotonation of phenol is diffusion-controlled ($k = 1.5 \times 10^{10}\ dm^3 mol^{-1} s^{-1}$), whereas the deprotonation of nitroethane is much slower ($k = 5.2\ dm^3 mol^{-1} s^{-1}$).

There are two reasons why the rates of proton transfer involving carbon sites are slow. First, with O, N, F, or S sites, proton transfer is preceded by the formation of a hydrogen bond between the sites involved in the proton transfer, and this anchoring of the two sites facilitates the subsequent transfer of the proton. Such hydrogen bonding is much weaker in the case of carbon-based residues. Second, carbon is weakly electronegative, and thus lone pairs of electrons on a carbon atom become delocalized towards more electronegative neighboring atoms. This delocalization involves a change in the electronic structure and in the position of all the nuclei involved, and consequently results in a slow rate of proton transfer.

Clearly, if electronic and structural reorganization factors become less important in the reactions of carbon-based sites the rates of proton transfer can become fast. Thus, in the deprotonation of cyano or disulfano compounds,[14] the rates of proton transfer for thermodynamically favorable reactions are $k \approx 10^7$–$10^8\ dm^3 mol^{-1} s^{-1}$. Although these rates are still at least 100 times less than the normal diffusion-controlled limit, they are significantly faster than those normally observed with carbon-based residues. The rapidity of these reactions indicate that after deprotonation of the conjugate acid the lone pair of electrons resides predominantly on the carbon, rather than being delocalized.

2.3. Proton Transfer at Metal Sites

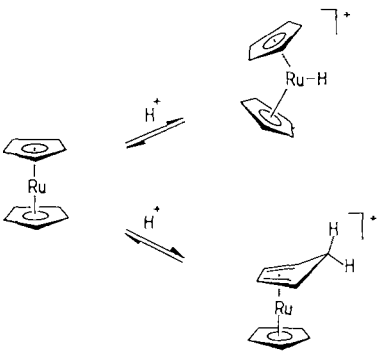
In general, proton transfer to and from metal sites is slow.[10, 15] The origin of this slowness is associated with the significant electronic and structural reorganization that must occur at the metal upon proton transfer. In an extensive series of studies on the rates of deprotonation of hydridic complexes by aniline, a range of reactions exhibiting a variety of thermodynamic driving forces (from exothermic to endothermic) have been studied, and a variety of rate constants have been observed: $[CoH(CO)_4]$ ($k = 1.7 \times 10^6\ dm^3 mol^{-1} s^{-1}$, $\Delta pK_a = -2.3$); $[FeH_2(CO)_4]$ ($k = 5.4 \times 10^4\ dm^3 mol^{-1} s^{-1}$, $\Delta pK_a = +0.8$); and $[OsH_2(CO)_4]$ ($k = 1.0 \times 10^{-2}\ dm^3 mol^{-1} s^{-1}$; $\Delta pK_a = +10.2$).[16] There are two features to note that are typical of proton transfer reactions at metals: first, the rates vary with the thermodynamic driving force of the reaction, and second, the rates never attain the diffusion-controlled limit.

In summary then, although the rates of protonation are usually defined by the rate of diffusion of the two components (the acid and the base), two notable exceptions are the protonation of carbon sites and the protonation of metal sites. Consequently, the difference in the rates of protonation of the ligand and the metal in the complexes containing hydrocarbon ligands may be rather small, and, depending on the system under investigation, either the metal or the hydrocarbon can be the more rapidly protonated site.

3. Regioselective Protonation of Complexes

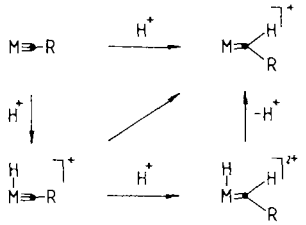
On studying the protonation of unsaturated carbon-based residues bound to metal sites the first pertinent question, in the light of the discussion above, is, "Which site is protonated first: metal or carbon?" This is a question that cannot always be answered by synthetic chemistry. Merely to isolate the product from the reaction of an acid with any particular complex will often result in the identification of the thermodynamically controlled product. What we want to identify is the *initial* site of protonation: the kinetically controlled product. Only if the interconversion of the kinetically controlled and thermodynamically controlled products is slow will it be possible to identify the true initial site of protonation by synthetic chemistry. In order to establish unambiguously which site is protonated first, the reaction must be monitored by a sufficiently rapid method. The most commonly used technique is stopped-flow spectrophotometry, which can study reactions that take longer than about two milliseconds to complete. More conventional, and diagnostic, spectroscopy such as solution IR and multinuclear NMR spectroscopies can be used, but often low temperatures must be employed to slow these reactions sufficiently and ensure that no intermediates have avoided detection.

Protonation at the metal and the hydrocarbon can be completely isolated processes. For instance, the reaction of acids with $[Ru(\eta^5\text{-}C_5H_5)_2]$ results in protonation of the metal as shown in Scheme 1. However, at the same time, H–D exchange of the cyclopentadienyl protons occurs indicating protonation of the hydrocarbon ligands.[17] As the protonation of the metal becomes more extensive (for instance, when stronger acids or higher concentrations of acid are used), the extent of H–D exchange of the ring protons decreases. That is, protonation of the metal and hydrocarbon are competitive processes, and protonation at the metal deactivates the cyclopentadienyl ring towards protonation.



Scheme 1. The reaction of acids with $[Ru(\eta^5\text{-}C_5H_5)_2]$

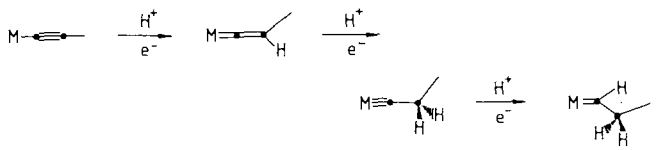
However, a more common situation is that protonation at the metal or the hydrocarbon residue are not mutually independent, because of facile pathways that can transfer the proton from the metal to the carbon. This leads to another pertinent question: "What is meant by a regioselective protonation?" If we consider just the stoichiometry of the reaction and the structure of the product, then (for instance) the conversion of an alkylidyne into an alkylidene, as shown in Scheme 2, is a regioselec-



Scheme 2. The protonation of alkylidyne complexes.

tive protonation. However, if we consider the reaction mechanistically, this apparent regioselectivity could result by three pathways: direct protonation of the carbon atom, protonation of the metal followed by intramolecular migration to the carbon, or protonation of the metal followed by an acid–base catalyzed rearrangement.

We shall see in the examples that follow in this article that true regioselective protonation is rare, and initial protonation at the "wrong" site still allows formation of the product by intramolecular or acid–base catalyzed pathways. We shall also see that no generalization can be made about which site (metal or hydrocarbon) is protonated first. It appears that the energetic barriers to protonation at the metal and a coordinated carbon are rather similar, and which is protonated the faster cannot be defined a priori. In the remainder of this section we shall consider some simple stoichiometric reactions, which together illustrate the sequence of elementary reactions shown in Scheme 3.



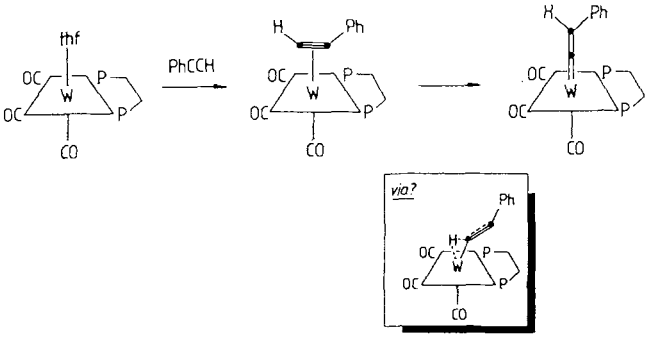
Scheme 3. A typical protonation of an alkynyl ligand to form a vinylidene.

This sequence has been chosen because each step it contains is stoichiometrically very simple, involving the addition of only a single proton, and consideration of the structure of the product would indicate the regioselective addition of a proton. However, studies on each step demonstrate that the interconversions are often mechanistically more complicated, less direct, and certainly less obvious. These studies demonstrate some useful mechanistic principles upon which we shall build in later sections.

The addition of a proton directly to its final residence, whether it be the metal or the carbon, exhibits a simple first-order dependence on the concentration of the acid. In the mechanistic studies that follow, two features are diagnostic of a more complicated mechanism: 1) a complicated rate law, and in particular a complicated dependence on the concentration of acid, and 2) the spectroscopic detection of an intermediate, the kinetically controlled product.

3.1. Protonation of an Alkynyl Ligand to a Vinylidene

This common reaction[18] is typified by the reaction of PhCCH with *fac*-[W(thf)(CO)$_3$(dppe)] (dppe = $Ph_2PCH_2CH_2PPh_2$; thf = C_4H_8O)[19] shown in Scheme 4. After the initial binding of the alkyne to the metal, rearrangement to the isomeric vinylidene complex occurs when the solution is warmed to 50 °C. Despite the prevalence of this transformation, the mechanism has not been studied in detail. However, molecular orbital calculations suggest that because of the importance



Scheme 4. Binding of PhCCH to *fac*-[W(thf)(CO)$_3$(dppe)] and rearrangement to the vinylidene complex.

of π donation from the alkyne, the rearrangement to form the vinylidene is promoted by the unfavorable four-electron, two-center bonding between the alkyne π orbitals and the filled metal d orbitals. Equally, the π complex might rearrange, because the carbon monoxide coligands render the coordinated PhCCH sufficiently acidic for the proton to be released with concomitant formation of the alkynyl species. Subsequent protonation of the alkynyl ligand at the carbon atom remote from the metal generates the vinylidene complex. Certainly, protonation of isolated alkynyl complexes gives vinylidene species, and this reaction has been studied mechanistically.

The rate of protonation of [Ru(η^5-C_5H_5)(CCMe)(PMe_3)$_2$] by [W(η^5-C_5H_5)H(CO)$_3$] shown in Equation (10)[20] is only ten

$$[Ru(\eta^5\text{-}C_5H_5)(CCMe)(PMe_3)_2] + [W(\eta^5\text{-}C_5H_5)H(CO)_3] \longrightarrow [Ru(\eta^5\text{-}C_5H_5)(CCHMe)(PMe_3)_2]^+ + [W(\eta^5\text{-}C_5H_5)H(CO)_3]^- \quad (10)$$

times faster than the rate of proton transfer from this hydrido complex to $PhNH_2$, although the alkynyl to vinylidene reaction is thermodynamically favorable by 1.5 kJ mol^{-1}, whilst the proton transfer to $PhNH_2$ is unfavorable by 1.8 kJ mol^{-1}. This relatively small difference in the rates of proton transfer indicates that, in general, the protonation of the alkynyl complex involves substantial structural and electronic reorganization.

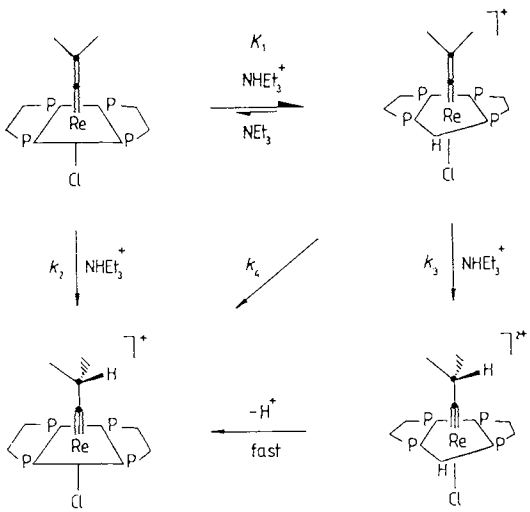
Mulliken population analysis from molecular orbital calculations indicates that the gross atomic charge at the carbon atom remote from the metal is not significantly different for alkynyl and corresponding vinylidene species.[21] Consequently, if protonation of the alkynyl is charge-controlled and occurs at the remote carbon atom, it could be argued that protonation of the vinylidene would also occur at the remote carbon atom to form the alkylidyne. As we shall see in the next example, it is not this simple.

3.2. Protonation of a Vinylidene Ligand to an Alkylidyne

Protonation of vinylidene complexes invariably gives the corresponding alkylidyne in an apparently regioselective protonation of the remote carbon atom.[22] However, mechanistic studies on the reaction of the rhenium complex[23, 24] [Eq. (11)]

$$trans\text{-}[ReCl(CCHPh)(dppe)_2] + NHEt_3^+ \longrightarrow trans\text{-}[ReCl(CCH_2Ph)(dppe)_2]^+ + NEt_3 \quad (11)$$

demonstrate that this transformation can occur by three pathways (Scheme 5).



Scheme 5. Three potential pathways for the protonation of a vinylidene complex to the corresponding alkylidyne complex.

Consideration of this mechanism, assuming that k_2, k_3, and k_4 are the rate-limiting steps and that K_1 is a rapidly established protonation equilibrium, demonstrates that the rate law for the formation of the alkylidyne product is given by Equation (12).

$$k_{obs} = \frac{k_4K_1[NHEt_3^+]/[NEt_3] + (k_3K_1[NHEt_3^+]/[NEt_3] + k_2)[NHEt_3^+]}{1 + K_1[NHEt_3^+]/[NEt_3]} \quad (12)$$

Clearly, the complex acid dependence associated with this mechanism is readily distinguished from the simple first-order dependence on the concentration of acid expected for a direct protonation of the remote carbon site.

The most important feature of this mechanism is that direct, regioselective protonation of the vinylidene ligand (k_2) is slow, whilst protonation at another site, probably the metal (K_1), is rapid. It is important to emphasize that the formation of this hydride is enforced because of the difference in the rates of protonation of the carbon and metal sites. Chemical intuition tells us that this protonation must deactivate the vinylidene towards protonation by decreasing the electron density at the ligand. Nevertheless, formation of the alkylidyne subsequently occurs by both an intramolecular (k_4) and an acid-catalyzed (k_3) pathway .

In experiments with no added NEt_3, the equilibrium K_1 lies far to the right-hand side ($K_1[NHEt_3^+]/[NEt_3] \gg 1$), and the rate law is given by Equation (13). Under these conditions,

$$k_{obs} = k_4 + k_3[NHEt_3^+] \quad (13)$$

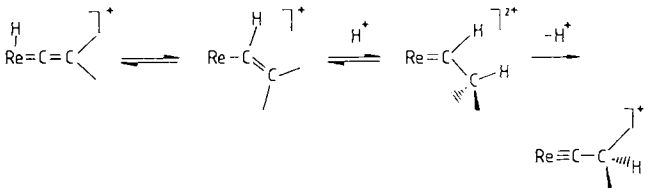
a linear dependence on the concentration of acid is observed, with a finite intercept, and the initial absorbance of the absorbance–time curve is distinctly different from that expected of *trans*-[ReCl(CCHPh)(dppe)$_2$], corresponding to the formation of the hydride within the dead time of the stopped-flow apparatus. Analysis of the data gives $k_4 = 7.3 \times 10^{-2}\,s^{-1}$, $k_4^H/k_4^D = 1.16$, and $k_3 = 9.4\,dm^3\,mol^{-1}\,s^{-1}$, $k_3^H/k_3^D = 1.35$. The acid-independent term in the rate law is associated with an intramolecular migration of the hydride ligand to the remote carbon atom. The isotope effect associated with this pathway is a consequence of the rate-limiting movement of a hydride (deuteride) whose origins are the addition of a proton (deuteron) to the metal.

In the presence of an excess of NEt_3 the position of the equilibrium, K_1, lies to the left-hand side. Consequently, $K_1[NHEt_3^+]/[NEt_3] \ll 1$, and the rate law reduces to that shown in Equation (14). From analysis of the data collected

$$k_{obs} = k_4 + \{k_3 + k_2[NEt_3]/K_1[NHEt_3^+]\}[NHEt_3^+] \quad (14)$$

under these conditions and using the previously determined value of k_4, we can calculate, $k_2/K_1 = 17.6\,dm^3\,mol^{-1}\,s^{-1}$ and $k_3 = 10.5\,dm^3\,mol^{-1}\,s^{-1}$. Furthermore, since we can estimate that K_1 is greater than 4, k_2 is larger than $70.4\,dm^3\,mol^{-1}\,s^{-1}$. The values of k_2 and k_3 both correspond to the protonation of the vinylidene ligand, but the much lower value of k_3 (corresponding to the protonation of the vinylidene ligand in *trans*-[Re(H)Cl(CCHPh)(dppe)$_2$]$^+$) confirms the earlier intuitive conclusion that initial protonation at the metal decreases the basicity of the hydrocarbon residue.

The formation of the alkylidyne complex is associated with a strong thermodynamic driving force, but kinetic factors initially result in the protonation of the "wrong" site—the rhenium center. Subsequently the complex transfers the proton from the metal to the carbon atom by both an acid-catalyzed rearrangement and a pathway (k_4) that appears to be intramolecular. Although the details of the intramolecular route have yet to be defined, it seems unlikely that the proton just "hops" from metal to the remote carbon atom. A more likely mechanism involves rate-limiting intramolecular migration to form a vinyl species, which subsequently protonates to form the corresponding alkylidene (Scheme 6). Subsequent proton loss from the carbon adjacent to the metal produces the alkylidyne complex. This type of acid-catalyzed rearrangement of vinyl species has been observed in the reactions of *trans*-[Mo(η^2-MeCCH)$_2$(dppe)$_2$] (see Section 4.1).



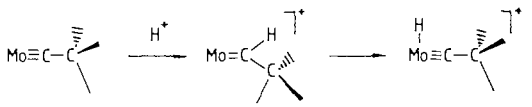
Scheme 6. Proposed mechanism for the intramolecular hydrogen transfer from the metal center to the remote carbon atom of the vinylidene complex, *trans*-[Re(H)Cl(CCHPh)(dppe)$_2$]$^+$.

In discussing this example I have stressed the details of the absorbance–time traces. The importance of establishing that the absorbance change being monitored is that expected for the reaction in question cannot be overemphasized. In addition, the observation that the initial absorbance is different from that of the reactant is indicative of the rapid formation of an intermediate. Even if the initial absorbance change had not been noticed (or, as happens in other systems, is much less marked) the experimenter would be alerted to something having occurred within the dead time of the apparatus by the kinetics of the subsequent step. An acid-independent pathway is very difficult to rationalize in such a stoichiometrically simple protonation reaction!

3.3. Protonation of an Alkylidyne Ligand to an Alkylidene

Protonation of alkylidyne complexes can occur at either the metal or the carbon atom bound to the metal, and the factors that distinguish between protonation of the two sites are rather subtle.[25] For instance, protonation of $[W(CH)L_4Cl]$ gives the hydride $[WH(CH)L_4Cl]^+$ when L_2 is $Me_2PCH_2CH_2PMe_2$ and the alkylidene $[W(CH_2)L_4Cl]^+$ when L is PMe_3.

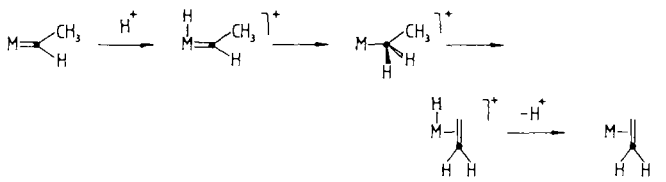
Molecular orbital calculations[26] indicate that the HOMO in alkylidyne complexes may be metal-centered or ligand-centered, or it may be the orbital of the metal–carbon π bond. Calculations of this type also indicate that the alkylidyne residue is always negatively charged, and in particular for the fragment $MoCCH_2tBu$, the build-up of charge is at the carbon atom adjacent to the metal. If the protonation of this residue is frontier orbital controlled, then attack is at the metal (where the HOMO is centered), whereas if the protonation is charge-controlled, attack is at the carbon.[27] Studies on $[Mo(\eta^5\text{-}C_5H_5)(CCH_2tBu)\{P(OMe)_3\}_2]$ indicate that protonation is charge-controlled; the initial site of attack is the carbon atom, and subsequent formation of the hydrido species occurs by an intramolecular hydrogen shift from the alkylidene group as shown in Scheme 7. Studies on $[W(CPh)(CNtBu)Cl(CO)(PMe_3)_2]$, in



Scheme 7. Proposed mechanism for the protonation of $[Mo(\eta^5\text{-}C_5H_5)(CCH_2tBu)\{P(OMe)_3\}_2]$.

which three sites (metal, isocyanide, or alkylidyne) are potentially protonatable, indicates that the alkylidyne is protonated preferentially.[28]

It is worth noting that some alkylidene complexes can undergo rearrangement into the corresponding alkene, and in certain cases this process has been shown to be acid-catalyzed (Scheme 8).[29] The mechanism presumably involves the forma-



Scheme 8. Acid-catalyzed rearrangement of an alkylidene complex to form an alkene complex.

tion of a transient alkyl species, which then undergoes an intramolecular hydrogen migration from the remote carbon atom (β-hydrogen transfer) and subsequent proton release. However such rearrangements are not always acid catalyzed, as for example the intramolecular conversion of $[Re(\eta^5\text{-}C_5H_5)(CHEt)(NO)(PPh_3)]$ into $[Re(\eta^5\text{-}C_5H_5)(\eta^2\text{-}MeCHCH_2)(NO)(PPh_3)]$.[30]

There are two other examples in which apparent regioselective protonation occurs, but mechanistic studies demonstrate that the pathway is complicated. These examples will be discussed in this section, although they do not fall into any of the above headings.

3.4. Protonation of *trans*-$[\overline{Re(CH_2CCPh)Cl(dppe)_2}]$

The reaction of anhydrous HCl with the substituted coordinated allene complex, *trans*-$[\overline{Re(CH_2CCPh)Cl(dppe)_2}]$ gives an η^2-vinyl species in an apparently regioselective protonation as described by Equation (15).[31,32] This reaction exhibits a

$$trans\text{-}[\overline{Re(CH_2CCPh)Cl(dppe)_2}] + HCl \longrightarrow trans\text{-}[\overline{Re(\eta^2\text{-}CH_2CCHPh)Cl(dppe)_2}]^+ + Cl^- \quad (15)$$

simple first-order dependence on the concentration of the complex but a complicated dependence on the concentration of HCl as shown in Figure 1.[33] The complexity of this acid dependence

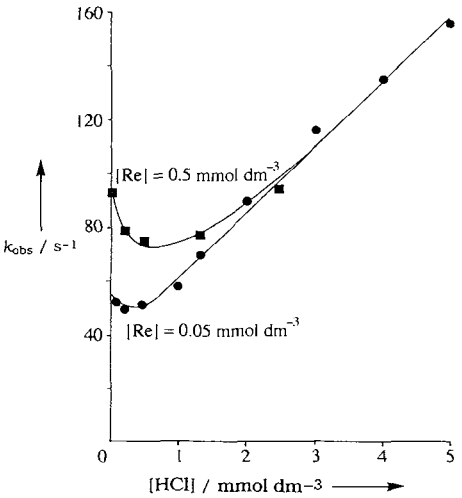


Fig. 1. Dependence of the observed rate constant k_{obs} on acid concentration for the protonation of *trans*-$[\overline{Re(CH_2CCPh)Cl(dppe)_2}]$.

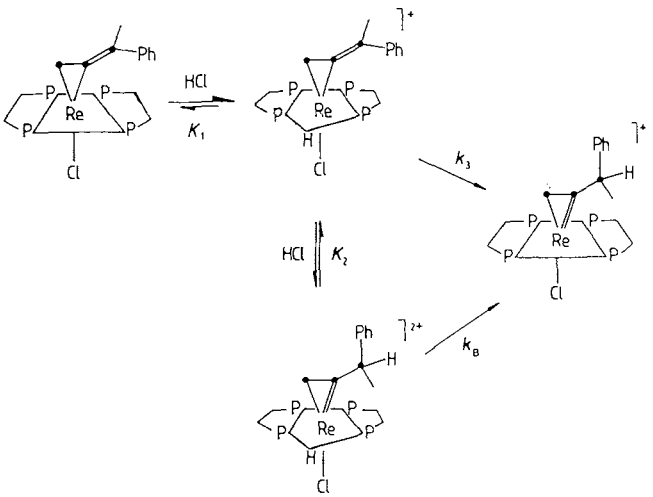
is clearly inconsistent with any trivial mechanism involving direct protonation at the phenyl-substituted carbon atom, but is consistent with the mechanism shown in Scheme 9, in which the first step is the protonation of the metal ($K_1 > 80$; $k_1 \geq 1 \times 10^6\ dm^3\ mol^{-1}\ s^{-1}$) to give the hydrido species



Scheme 9. Proposed mechanism of the protonation of *trans*-$[\overline{Re(CH_2CCPh)Cl(dppe)_2}]$.

$[\overline{Re(CH_2CCPh)}(H)Cl(dppe)_2]^+$, which occurs within the dead time of the stopped-flow apparatus (2 ms). This protonation would appear to be frontier orbital controlled, since extended Hückel calculations[32] indicate that the HOMO of *trans*-$[\overline{Re(CH_2CCPh)}Cl(dppe)_2]$ comprises predominantly the d_{xy}/d_{yz} orbitals on the rhenium atom (54%); the remaining electron density is divided between the phenyl-substituted carbon (36%) and the unsubstituted carbon atoms (10%) of the double bond.

The addition of the proton, albeit at the metal rather than the carbon, means that the stoichiometric requirements of reaction (15) have been met. The subsequent formation of the η^2-vinyl complex is associated with the rate law shown in Equation (16). This rate law describes two pathways: an intramolecular route ($k_3 = 94\ s^{-1}$) and an acid–base catalyzed route. The latter pathway involves rapid protonation of the hydrido complex ($K_2 = 1.37\ dm^3\ mol^{-1}$), followed by rate-limiting deprotonation of the metal by any base present in the system (k_B). The bases present in the system are the solvent (THF: $k_{THF} = 2.7\ dm^3\ mol^{-1}\ s^{-1}$), Cl^- ($k_{Cl} = 2.4 \times 10^4\ dm^3\ mol^{-1}\ s^{-1}$), and even the chloro group in HCl ($k_{HCl} = 3.4 \times 10^4\ dm^3\ mol^{-1}\ s^{-1}$).

$$k_{obs} = {}^{i}k_3 + K_2[HCl]/[Cl^-] \sum_B k_B[B]\}/(1 + K_2[HCl]/[Cl^-]) \quad (16)$$

The intramolecular pathway may be a direct, intramolecular transfer of the hydrogen from the metal to the carbon terminus. Consideration of the X-ray crystal structure of *trans*-$[\overline{Re(CH_2CCPh)}Cl(dppe)_2]$ indicates that in the intermediate $[\overline{Re(CH_2CCPh)}(H)Cl(dppe)_2]^+$ the hydrido ligand may be no more than 1.5–1.8 Å from the phenyl-substituted carbon atom—sufficiently close to permit a reasonably facile transfer.

3.5. Protonation of *trans*-$[W(\eta^2\text{-}C_2H_4)_2(dppe)_2]$

The reaction of an excess of anhydrous HX (X = Cl or Br) with *trans*-$[W(\eta^2\text{-}C_2H_4)_2(dppe)_2]$ gives the pentagonal-bipyramidal hydrido species shown in Equation (17).[34] Protonation

$$trans\text{-}[W(\eta^2\text{-}C_2H_4)_2(dppe)_2] + HX \longrightarrow [WH(\eta^2\text{-}C_2H_4)_2(dppe)_2]^+ + X^- \quad (17)$$

would appear to involve regioselective attack at the metal center. When studied on a stopped-flow spectrophotometer, the reaction clearly occurs in two distinct phases. Typical absorbance–time traces for this reaction, at high and low concentrations of acid, are shown in Figure 2. At all acid concentrations the curves are exponential, and at low concentrations of acid the initial absorbance is that of *trans*-$[W(\eta^2\text{-}C_2H_4)_2(dppe)_2]$, and the final absorbance is that of the hydride product. However, at higher concentrations of acid, although the final absorbance still corresponds to that of the hydride, the initial absorbance is now markedly lower than that of the parent complex, and at intermediate acid concentrations intermediate initial absorbances are observed. The dependence of the initial absorbance on the concentration of HX can be quantified as shown on the left-hand side of Figure 2: this analysis demonstrates that within 2 ms an equilibrium associated with the addition of a single proton to *trans*-$[W(\eta^2\text{-}C_2H_4)_2(dppe)_2]$ is established. However, this proton must have been added to the wrong position, since a further reaction (associated with the exponential decay) is required to form the hydride.

The subsequent formation of the hydrido product occurs by two pathways: one acid-independent and another showing a first-order dependence on the concentration of acid. All of this behavior is consistent with the mechanism shown in Scheme 10.

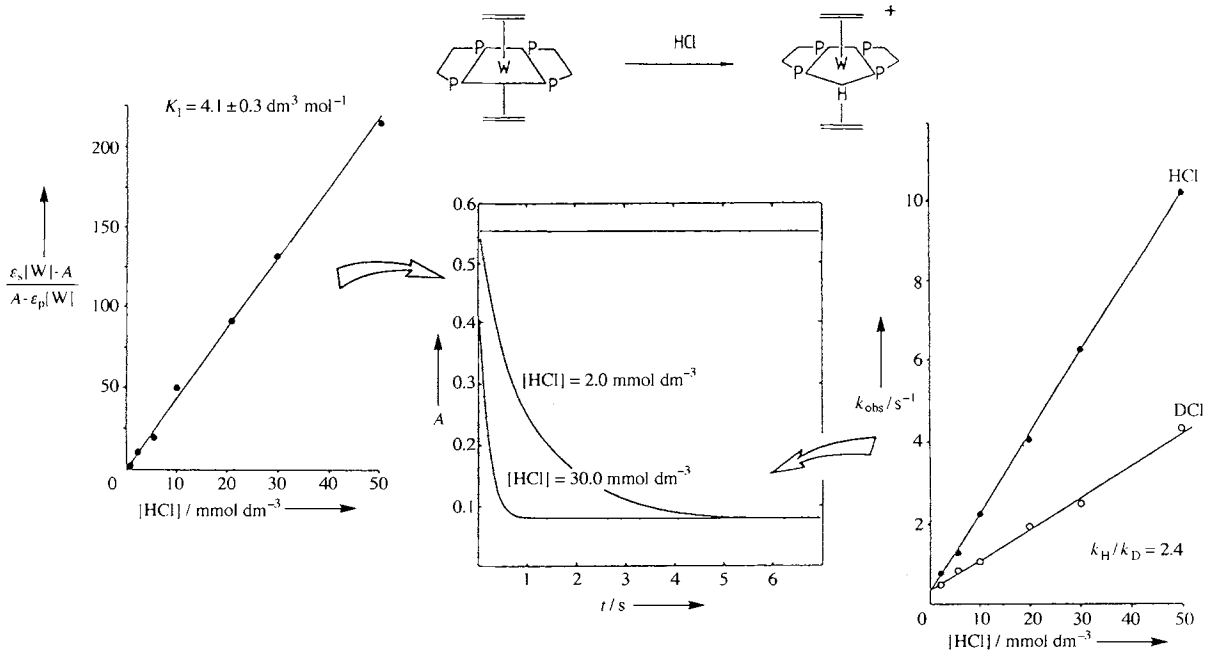


Fig. 2. The protonation of *trans*-$[W(\eta^2\text{-}C_2H_4)_2(dppe)_2]$ (top) and the experimental absorbance–time traces (bottom center). The dependence of the initial absorbance on acid concentration is depicted on the left (ε_s: extinction coefficient of the starting material, ε_p: extinction coefficient of the product, [W]: total tungsten concentration) and the plots of the observed rate constant k_{obs} against acid concentration for HCl and DCl on the right.

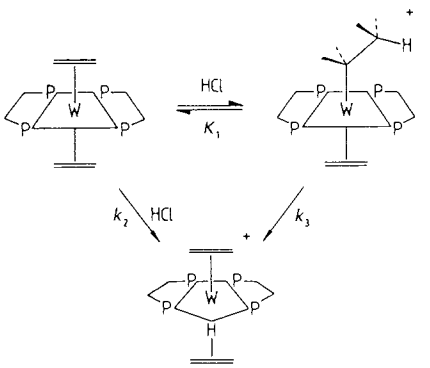

Scheme 10. Proposed mechanism for the protonation of *trans*-[W(η^2-C_2H_4)$_2$(dppe)$_2$].

Thus in a rapid equilibrium the ethene ligand is protonated ($K_1 = 4.1\ dm^3 mol^{-1}$, with HCl), which generates the ethyl species. At low concentrations of acid subsequent rate-limiting intramolecular migration of a hydrogen atom from the remote carbon atom of the ethyl ligand to the metal (β-hydrogen transfer) forms the hydrido product ($k_3 = 0.15\ s^{-1}$). At higher concentrations of acid a further pathway involving direct protonation of *trans*-[W(η^2-C_2H_4)$_2$(dppe)$_2$] at the metal contributes to the reaction. This latter pathway is associated with a significant primary isotope effect ($k_3^H/k_3^D = 2.43$).

Thus, although the stoichiometric equation indicates that the ethene ligands are innocent spectators to the reaction occurring at the metal site, mechanistic studies show that in at least one of the pathways the ethene ligands are intimately involved in transferring the proton to the metal. This noninnocent role for the ethene ligands is confirmed in the studies between *trans*-[W(η^2-C_2H_4)$_2$(dppe)$_2$] and an excess of anhydrous ^{2}HBr. Isolation of the product and its characterization by ^{2}H NMR spectroscopy showed that deuterium was incorporated both at the hydride position and in the ethene ligands.

In *trans*-[W(η^2-C_2H_4)$_2$(dppe)$_2$] the rate of protonation of the coordinated ethene can be estimated as $k_1 \geq 1 \times 10^6\ dm^3 mol^{-1} s^{-1}$, and the rate of protonation of tungsten is $k_2 = 2 \times 10^2\ dm^3 mol^{-1} s^{-1}$. Hence the rate of protonation of the carbon is at least ten thousand times faster than at the tungsten. In the analogous molybdenum system, the ethene is again protonated more rapidly than the metal but now by only a factor of 100. This less marked difference in the molybdenum complex is because the protonation at molybdenum is faster than at tungsten in analogous complexes. Studies on the proton transfer reactions of metal hydride complexes indicate that the rate constant for metal-to-metal proton transfer decreases down a group: Cr > Mo $\gg$ W.

These studies on *trans*-[M(η^2-C_2H_4)$_2$(dppe)$_2$] (M = Mo or W) define unambiguously the more rapidly protonated site. However, this is the exception rather than the rule. For instance, in the closely related propyne complex *trans*-[Mo(η^2-MeCCH)$_2$(dppe)$_2$], the propyne gives the vinyl species *trans*-[Mo(CHCHMe)(η^2-MeCCH)(dppe)$_2$]$^+$ within 2 ms. However, the proton's route to this site cannot be identified. It is possible that the proton adds either directly to the carbon site or binds initially to the metal with subsequent intramolecular migration to the carbon. In the latter case a lower limit for the rate of protonation of the metal can be estimated as $k \geq 1 \times 10^6\ dm^3 mol^{-1} s^{-1}$. This value is much faster than the rate constant for protonation of the metal site in the analogous ethene complex, but is still ten thousand times slower than the diffusion-controlled limit.

The chemistry established in this system is the foundation of the work on product specificity discussed in Section 4.

4. Using Protons as a Means of Product Control

In the discussion so far three general mechanistic principles have emerged for the protonation of complexes containing unsaturated hydrocarbons: 1) The initial site of protonation may not be the final residence of the proton. 2) Protonation can occur at both the metal and the hydrocarbon ligands. 3) Acid-catalyzed or intramolecular rearrangements can, in effect, transfer a proton between the metal and the ligand.

In the remainder of this article we shall see how these mechanistic features, and in particular that protonation can occur either the carbon or the metal, can be used to our advantage—first to control the selective production of alkane, alkene, or alkyne from alkene-based complexes, and second to control the stereochemistry of hydrocarbon products.

4.1. Protonation of *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$]: Formation of Ethene and Ethane

The protonation of *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$] with anhydrous HCl gives mixtures of ethane and ethene together with well-defined metal complexes. A limiting stoichiometric reaction is given by Equation (18); however, as we shall see later,

$$\textit{trans}\text{-}[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2] + 2HCl \longrightarrow \textit{trans}\text{-}[MoCl_2(dppe)_2] + C_2H_4 + C_2H_6 \quad (18)$$

this equation is only valid at relatively low concentrations of acid; at high concentrations of acid other products are formed.[35] Clearly this is a multistage reaction involving, at the very least, diprotonation of one of the ethene ligands, transfer of two electrons from the metal to the protonated ligand, release of one molecule each of ethene and ethane, and the binding of two chlorine atoms to the molybdenum center. This complexity is reflected in the stopped-flow absorbance–time trace for this reaction (Fig. 3). Three distinct stages are evident: an initial absorbance jump, complete within the dead time of the apparatus, is followed by an exponential absorbance decrease and finally an absorbance increase, which is also exponential. This trace is a kineticist's dream that can rapidly become a nightmare in trying to define what elementary reactions are associated with each stage. If we were to come "cold" to this multistage trace, there would be little chance of unambiguously identifying the steps occurring at each stage. However, the previous study on the analgous tungsten complex described in Section 3.5 has identified the characteristic behavior associated with the initial protonation of this type of complex.

The first two stages of the reaction of HCl with *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$] recorded with a stopped-flow apparatus show behavior similar to that observed for the tungsten analogue (Section 3.5): an initial absorbance decrease, complete within

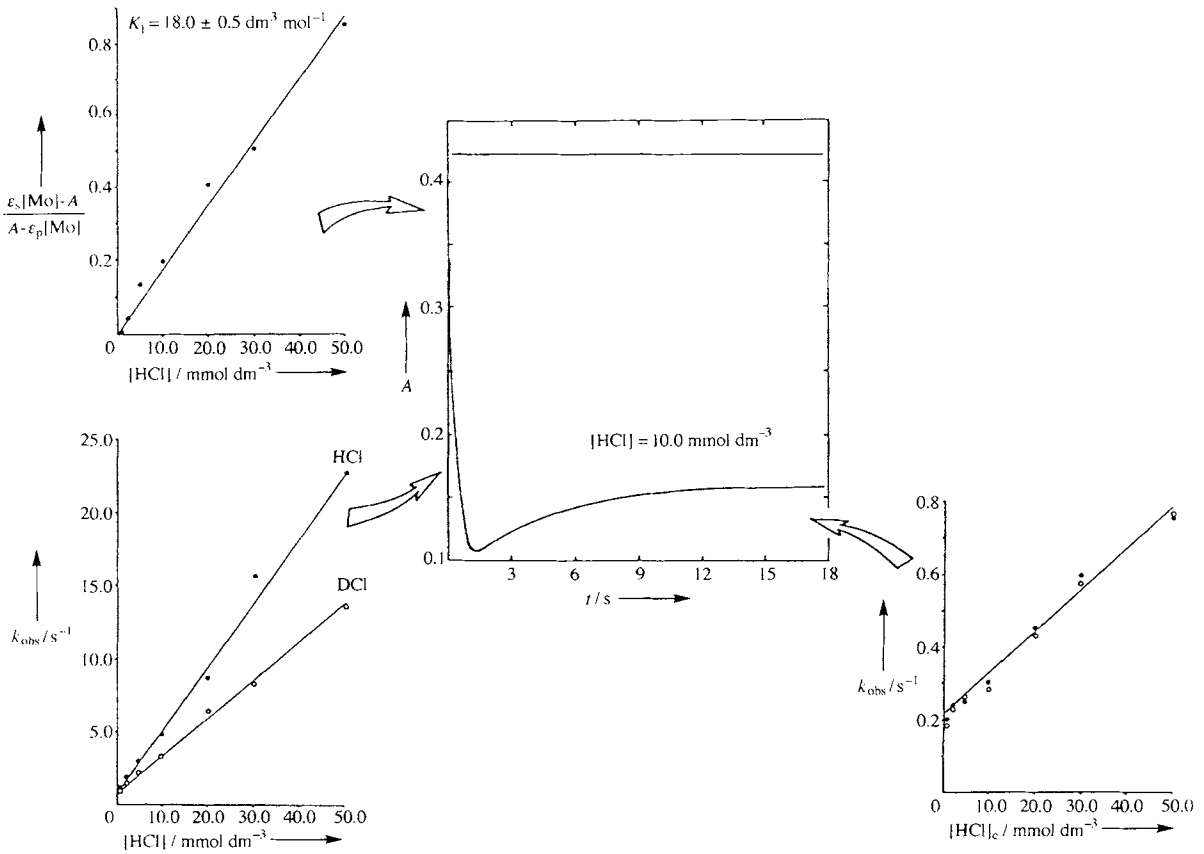

Fig. 3. The protonation of *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$] to form ethene and ethane: the experimental absorbance–time trace and the dependence of the rates of relevant stages of the reaction on acid concentration ([Mo]: total molybdenum concentration, ε_s: extinction coefficient of the starting material, ε_p: extinction coefficient of the product [HCl]$_c$ = [HCl] − [Mo] (corrected acid concentration)).

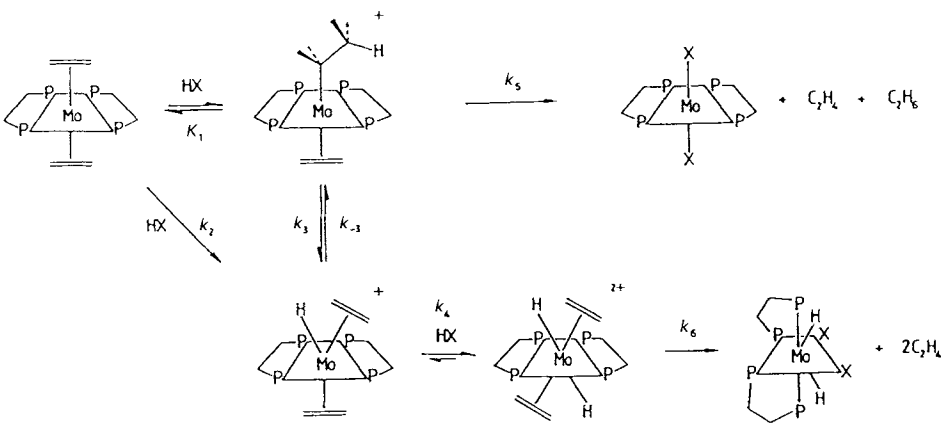
2 ms, whose magnitude depends on the concentration of acid, followed by an exponential decay; the latter process shows a dependence on the concentration of HCl as illustrated in Figure 3.[34] Consequently, we can be confident that these first two phases correspond to the formation of the hydrido species [MoH(η^2-C_2H_4)$_2$(dppe)$_2$]$^+$ by two pathways: 1) rapid protonation of the ethene ligand ($K_1 = 18$ dm^{3}mol^{-1}), followed by intramolecular β-hydrogen transfer from the ethyl ligand to the metal ($k_3 + k_{-3}$) = 0.22 s^{-1}, and 2) direct protonation of the metal in *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$] ($k_2 = 4.6 \times 10^2$ dm^{3}mol^{-1}s^{-1}, $k_H/k_D = 1.64$, Scheme 11). The only difference between this system and the protonation of the tungsten complex is that in this molybdenum system an equilibrium mixture of the parent complex, the ethyl complex, and the hydrido species is produced. This conclusion is consistent with previous work,[36] which showed that in solution [Mo(C_2H_5)(η^2-C_2H_4)(dppe)$_2$]$^+$ is in dynamic equilibrium with [MoH(η^2-C_2H_4)$_2$(dppe)$_2$]$^+$ and that the magnitude of the absorbance changes for these stages depend upon the acid concentration.

A further absorbance increase is observed over the last 20 seconds of the absorbance–time trace, the magnitude and rate of which depends on the concentration of acid. This stage corresponds to the protonation of the equilibrium mixture of *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$], [MoH(η^2-C_2H_4)$_2$(dppe)$_2$]$^+$, and [Mo(C_2H_5)(η^2-C_2H_4)(dppe)$_2$]$^+$ to produce the dihydrido species [MoH$_2$(η^2-C_2H_4)$_2$(dppe)$_2$]$^{2+}$.



Scheme 11. Elementary reactions for the protonation of *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$] to form ethene and ethane.

The kinetics of the third stage exhibits a simple two-term rate law: one term is independent of the concentration of acid and the other shows a first-order dependence on the concentration of acid. Protonation of the equilibrium mixture formed at the end of the second stage disturbs the position of this

equilibrium, and analysis of the kinetics for the third stage reveals that the term independent of the concentration of acid corresponds to $(k_3 + k_{-3})$, that is, to the sum of the rate constants for the equilibrium between $[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$ and $[MoH(\eta^2\text{-}C_2H_4)_2(dppe)_2]^+$. The value of $(k_3 + k_{-3})$ is already known from the analysis of the kinetics of the second stage and is in excellent agreement with the value derived from analysis of the third stage.

The discussion so far presents an internally consistent kinetic model for the early stages of the reaction of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$, and this mechanistic behavior is reconcilable with that of the tungsten analogue. However, the identity of the intermediates has been confirmed by spectroscopic detection, isolation, and characterization. In particular the species formed at the end of the second stage has the same electronic spectrum as that of isolated $[MoH(\eta^2\text{-}C_2H_4)_2(dppe)_2]HCl_2$. However, as is typical of electronic spectra in general, this spectrum consists of rather broad peaks and is not particularly diagnostic. Certainly no structural information about the intermediate can be obtained by this method. A much better identification of the intermediates results from studying the reactions in the probe of an NMR spectrometer.

Figure 4 illustrates the course of reaction (18) as monitored by $^{31}P\{^1H\}$ NMR spectroscopy. In order to detect the intermediates, which at room temperature only have a fleeting exis

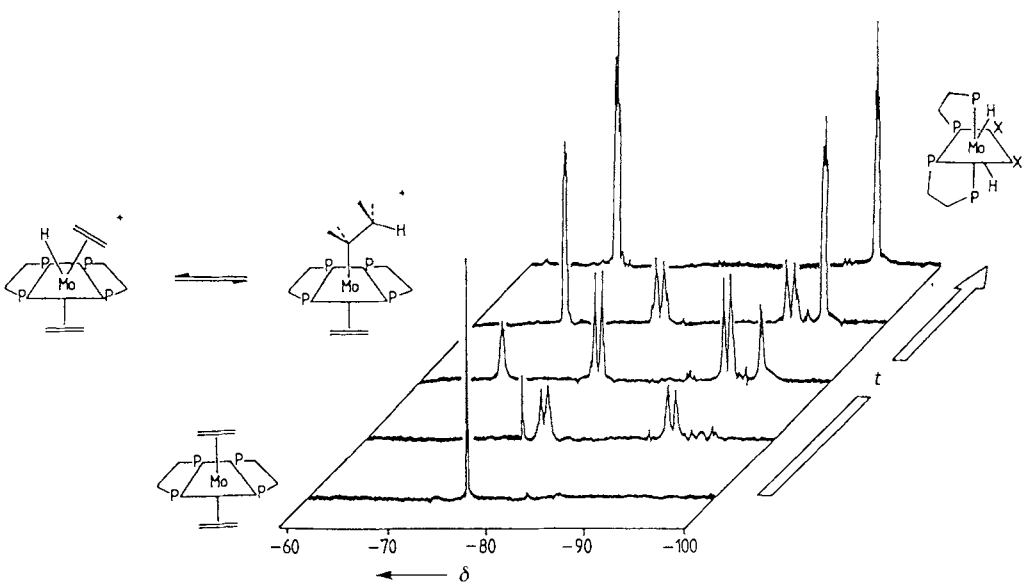


Fig. 4. The time course of the protonation of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$ to form ethene and ethane, monitored by $^{31}P\{^1H\}$ NMR spectroscopy.

tence, the reaction is performed at relatively low concentrations of acid and low temperatures (typically $-80\,^\circ C$). The use of $^{31}P\{^1H\}$ NMR spectroscopy has the advantage that only signals associated with the complex are present, and the other components of the mixture (the acid and solvent etc.) do not complicate the spectrum. The singlet at $\delta = -78$ in the first spectrum of this series is that of the parent complex, *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$. As time passes, this peak decreases in intensity, and a new set of signals appear [$\delta = -80.0$ (d), $\delta = -92.2$ (d); $J_{P,P} = 81.8$ Hz; AA'BB' pattern]. The intensity of this pair of doublets increases, then slowly decreases as, finally, the peaks of one of the products appear. The spectrum that consists of a deceptively simple pair of doublets is that of the equilibrium mixture of $[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$ and $[MoH(\eta^2\text{-}C_2H_4)_2(dppe)_2]^+$ and has been observed in earlier variable temperature studies on this[36] and analogous systems.[37] However, this is the first time this spectrum has been observed for an intermediate in the protonation reactions of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$.

This study confirms the nature of the intermediates at the end of the second stage, which was proposed on the basis of the kinetic analysis. Furthermore, at higher concentrations of acid we observe the expected contribution to the spectrum associated with the presence of $[MoH_2(\eta^2\text{-}C_2H_4)_2(dppe)_2]^{2+}$. The spectrosopic changes are similar to those shown in Figure 4, but now the spectrum of the intermediate is slightly different. It still consists of a pair of doublets, but the chemical shift separation between the doublets is smaller [$\delta = -76.2$ (d), $\delta = -92.2$ (d)], and the doublet separation itself (which is the phosphorus–phosphorus coupling constant, $J_{P,P} = 73.5$ Hz) is about 8 Hz smaller than in the spectrum observed at low concentrations of acid. The spectrum at high acid concentrations is consistent with the presence of a species that is structurally similar to that detected at low concentrations of acid, and the smaller value of $J_{P,P}$ indicates an increased protonation of the metal.[38]

$[MoH(\eta^2\text{-}C_2H_4)_2(dppe)_2]HCl_2$ has been isolated from the reaction mixture at low concentrations of acid by rapid crystallization, but attempts to isolate $[MoH_2(\eta^2\text{-}C_2H_4)_2(dppe)_2]^{2+}$ were unsuccessful, even at high concentrations of acid. The only species isolated was the monohydride, presumably because of the poorer solubility of this species and the rapidity of the monohydride–dihydride protonation equilibrium.

The multiple protonation equilibria shown in Scheme 11 are established within about 20 s. However, the evolution of both ethane and ethene (monitored by GLC) from the reaction mixture has a half-life of about 40 min. The rate of formation of either hydrocarbon is independent of the concentration of acid, but the relative proportions of ethane and ethene depend markedly on the concentration of acid (Fig. 5). Thus at relatively low concentrations of HCl one equivalent each of ethane and ethene are produced. At higher concentrations of acid the carbon mass-balance is maintained, but the proportion of ethane progressively decreases, and the proportion of ethene increases correspondingly until, at $[HCl] \approx 200$ mmol dm^{-3}, two equivalents of ethene are produced.

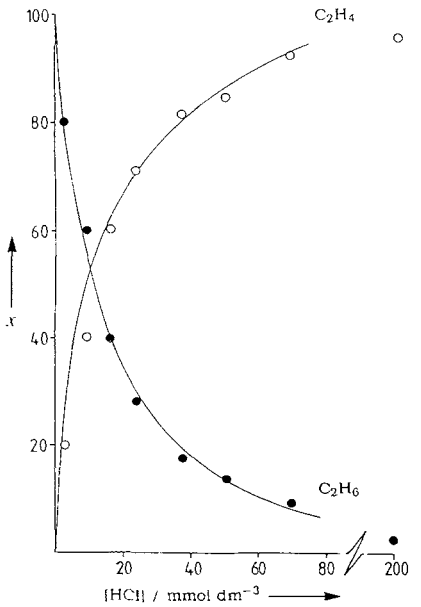

Fig. 5. Dependence of the product distribution on the acid concentration for the protonation of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$.

The mechanism by which these hydrocarbons are formed is shown in Scheme 11. At low concentrations of HCl the predominant species in solution are the complexes of the equilibrium mixture of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$, $[MoH(\eta^2\text{-}C_2H_4)_2(dppe)_2]^+$, and $[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$. Rate-limiting dissociation of the ethene ligand from $[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$, followed by rapid attack of chloride at the metal commits the ethyl ligand to form ethane, presumably by rapid protonation of the ethyl ligand. Thus, under these conditions, one equivalent each of ethene and ethane are produced together with *trans*-$[MoCl_2(dppe)_2]$.

At higher concentrations of HCl further protonation occurs at the metal, and $[MoH_2(\eta^2\text{-}C_2H_4)_2(dppe)_2]^{2+}$ dominates the equilibrium mixture. This further protonation at the metal labilizes both ethene ligands towards dissociation, and thus at high concentrations of acid two equivalents of ethene are produced together with $[MoH_2Cl_2(dppe)_2]$.

The product $[MoH_2Cl_2(dppe)_2]$ has been isolated and characterized. Indeed it is this species whose spectrum is observed in the last spectrum recorded in Figure 4. The product formed at low concentrations of acid, *trans*-$[MoCl_2(dppe)_2]$, has also been isolated and characterized by the common techniques, in particular by its characteristic electrochemical behavior.[39] However, this compound has a d^4 ($S = 1$) configuration and is silent in both EPR and NMR spectroscopy.

The mechanism shown in Figure 3 quantitatively predicts the hydrocarbon product distribution. Since the rate of production of both ethane and ethene is essentially the same, the composition of the hydrocarbon mixture varies with the concentration of HCl according to Equation (19), which has made allowance

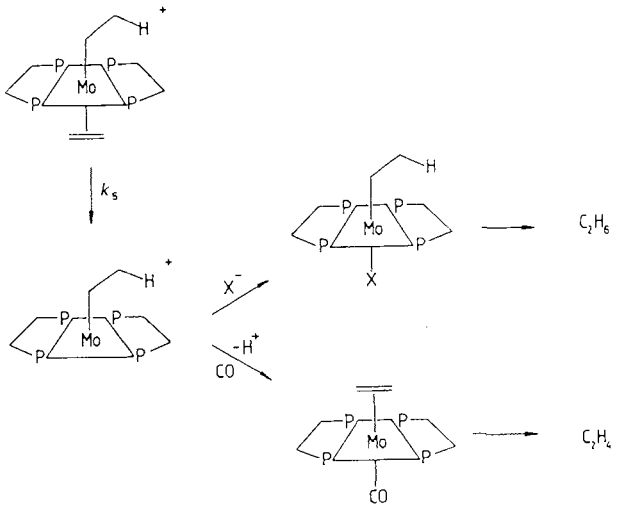
$$\frac{[C_2H_6]}{[C_2H_6]+[C_2H_4]} = \frac{k_3 + k_{-3}}{(k_3 + k_{-3}) + k_4[HCl]} \qquad (19)$$

for the fact that one equivalent of ethene is produced in both pathways. All the elementary rate constants in this equation are known from the kinetic analysis. When the values are substituted into this equation the curves obtained are an excellent fit to the experimental product distribution as shown in Figure 5.

One of the most important aspects of this hydrocarbon product distribution is that it is counterintuitive. After all, in order to produce ethane by the protonation of an ethene ligand, the ethene must be supplied with two electrons and two protons. In a system such as that described here, where the two electrons are already "stored" in the metal, it would seem intuitive that the higher the concentration of acid, the more likely it is that the ethene will protonate, and hence it would be predicted that ethane would be produced preferentially at high concentrations of acid. This is the opposite to the behavior actually observed. However, the observed product distribution is readily understood when it is appreciated that protonation can occur at either the metal or the hydrocarbon, and the site that is protonated defines the hydrocarbon product.

The mechanism in Scheme 11 shows that there is no problem in protonating the ethene in these complexes (indeed it is these ligands which are protonated most rapidly), and when protonated ethane is produced. However, at high concentrations of acid further protonation of the metal occurs and results in the deactivation of the ethene ligand towards protonation and the labilization of the system to the dissociation of ethene.

Just by adding protons the product of the reaction can be controlled. The origin of this control is the sites of protonation: metal or ligand. The product of the reaction can also be controlled after the protonation step by changing the coligands on the complex as illustrated in Scheme 12. Having formed *trans*-



Scheme 12. Controlling the product distribution after the protonation of $[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$ by varying the coligands.

$[Mo(C_2H_5)(\eta^2\text{-}C_2H_4)(dppe)_2]^+$, rate-limiting dissociation of the ethene ligand is usually followed by binding of chloride. However, carbon monoxide can bind preferentially to form *trans*-$[Mo(C_2H_5)(CO)(dppe)_2]^+$. The electron-withdrawing effect of the coordinated carbon monoxide results in proton loss from the ethyl ligand, subsequent release of ethene, and ultimate formation of *trans*-$[Mo(CO)_2(dppe)_2]$. Thus, even at low concentrations of acid the system can be forced to evolve only ethene if the coordination sphere of the complex is perturbed.

Under an atmosphere of dihydrogen the situation is less clear cut, but about 20% of the hydrocarbon released at an HCl concentration of 200 mmol dm^{-3} is ethane, whereas under an atmosphere of argon no ethane is produced under these condi-

tions. It would therefore appear that dihydrogen can also bind to the vacant site generated on dissociation of ethene from $[MoH_2(\eta^2\text{-}C_2H_4)_2(dppe)_2]^{2+}$ to form a species (presumably $[MoH_4(\eta^2\text{-}C_2H_4)(dppe)_2]^{2+}$), which is sufficiently hydride-rich to produce some ethane from this route.

4.2. Protonation of *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$: Formation of Propene and Propyne

The protonation of any alkene other than ethene introduces another potential type of reactivity, which is a consequence of the intramolecular rearrangement possible with higher alkenes shown in Scheme 13. Only one molecule of propene will bind to

Scheme 13. The dynamic equilibrium between $[Mo(\eta^2\text{-}MeCHCH_2)(dppe)_2]$ and $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ illustrating the additional pathway for higher alkenes.

the $\{Mo(dppe)_2\}$ site, and variable temperature NMR spectroscopy has shown that $[Mo(\eta^2\text{-}MeCHCH_2)(dppe)_2]$ is in dynamic equilibrium with $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$.[36] The solid state structure of this complex and the tungsten analogue has been established by X-ray crystallography.[40] The structures are essentially the same, and that of $[WH(\eta^3\text{-}C_3H_5)(dppe)_2]$ is shown in Figure 6. Two important structural features evident

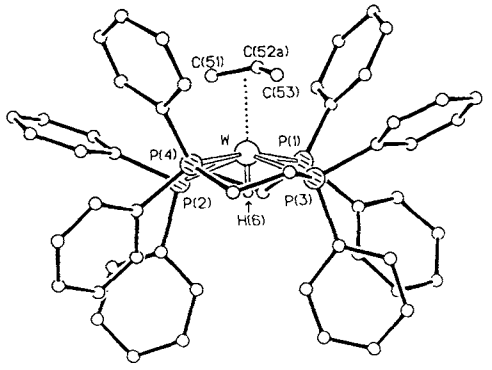


Fig. 6. The crystal structure of $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. Selected bond lengths [Å] and the angle of the allyl group [°]: W-P(average) 2.465 ± 0.007, W-C51 2.372(16), W-C53 2.334(14), W-C52a 2.258(30), C51-C52a 1.35(4), C53-C52a 1.23(4), W-H 1.03(9); C51-C52a-C53 139(3).

from this study are pertinent to the discussion of the reactivity of this complex. First, the hydride (which was located) is *trans* to the allyl group; but, clearly, in solution this hydride must move around the metal surface if it is to transfer intramolecularly to the allyl residue. Second, there is nothing unusual about the geometry of the allyl group: the carbon–carbon bond lengths are typical of an allyl group and the CCC angle is not flattened.

The reactivity that $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ exhibits in its reactions with anhydrous HCl [Eqs. (20) and (21)] led us to look for

$$trans\text{-}[MoH(\eta^3\text{-}C_3H_5)(dppe)_2] + 2HCl \longrightarrow [MoH_2Cl_2(dppe)_2] + MeCHCH_2 \quad (20)$$

$$trans\text{-}[MoH(\eta^3\text{-}C_3H_5)(dppe)_2] + 2HCl \longrightarrow [MoH_2Cl_2(dppe)_2] + H_2 + MeCCH \quad (21)$$

such a distortion in this molecule.[41] At all acid concentrations the same metal product, $[MoH_2Cl_2(dppe)_2]$ is formed. However, the hydrocarbon product is propene at low concentrations of HCl, but propyne at high concentrations of acid. That is, by protonating a complex derived from an alkene we can produce an alkyne!

In order to understand this reaction in more detail it has been studied mechanistically. Before the mechanism is discussed a further structural aspect of the work has to be clarified. The equilibrium between the propene and allyl forms of the molybdenum complex is rapid at 25.0 °C, and thus it is unclear which form is the reactive entity in the protonation reactions. Two-dimensional $\{^1H\text{-}^{13}C\}$ NMR spectroscopy has been used to assign unambiguously the peaks in the ^1H NMR spectrum that are attributable to $[Mo(\eta^2\text{-}MeCHCH_2)(dppe)_2]$ and $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. In this way it was established that at −40 °C the allyl species only is present. At this temperature, the system still reacts with HCl to form propyne at high concentrations of acid. This indicates that the allyl form is the reactive species, and this is confirmed in studies with the tungsten analogue.[42] *trans*-$[WH(\eta^3\text{-}C_3H_5)(dppe)_2]$ is always in the allyl form; even at +40 °C there is no sign of the propene species, and the hydride signal ($\delta = -2.8$, quintet, $J_{H,P} = 35$ Hz) is still well resolved. This complex reacts with anhydrous acid to produce propene at low concentrations of acid and propyne at high concentrations of acid.

A study of the reaction of *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ with an excess of anhydrous HCl on a stopped-flow apparatus shows the same simple behavior under all conditions: an exponential absorbance–time decay.[41] The final absorbance apparently corresponds to that of the product, $[MoH_2Cl_2(dppe)_2]$ (see later discussion), but the initial absorbance is slightly lower than that expected for *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. The difference between the expected and the observed initial absorbance is independent of the concentration of acid. The reaction exhibits a first-order dependence on the concentration of complex and a dependence on the concentration of HCl as described by Equation (22). These simple kinetics are to be contrasted with the

$$k_{obs} = k_3 + k_4[HCl] \quad (22)$$

hydrocarbon product distribution shown in Figure 7, which changes quite dramatically in the acid concentration range over which the kinetics are defined. At low concentrations of acid, propene is the predominant product. At higher concentrations of acid, the carbon mass-balance is maintained, but the proportion of propene decreases whilst the amount of propyne increases proportionately until at $[HCl] > 200$ mmol dm^{-3} propyne is the exclusive product. This behavior is analogous to that observed with the ethene system: the more unsaturated hydrocar-

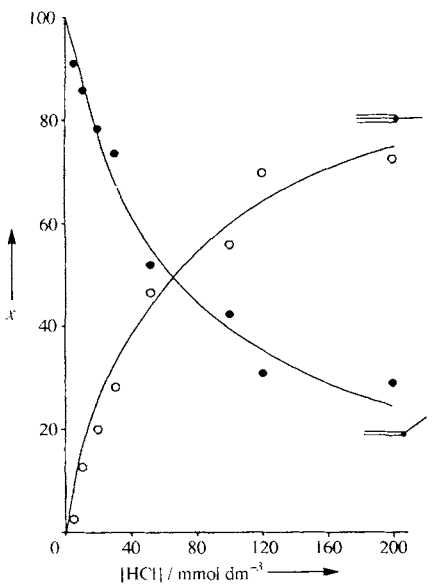

Fig. 7. The dependence of the hydrocarbon product distribution on acid concentration for the protonation of *trans*-[MoH(η^3-C_3H_5)(dppe)$_2$].

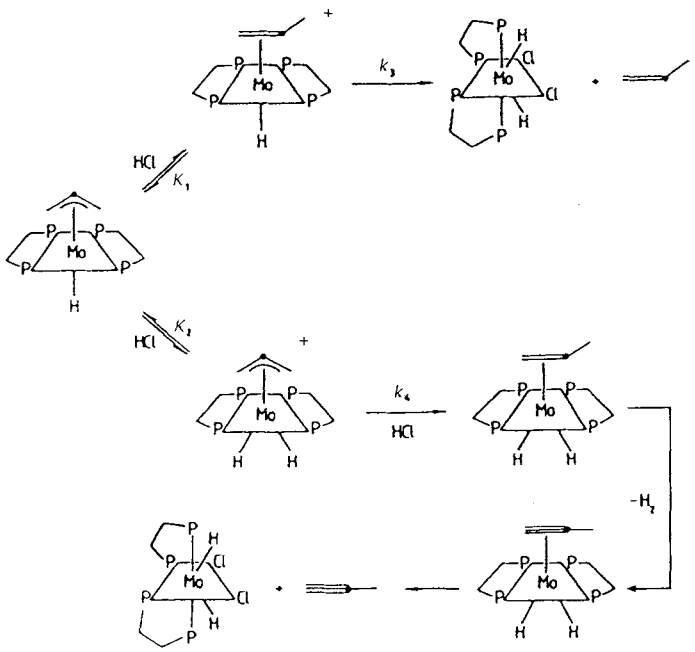
bon is formed only at the higher concentrations of acid. The mechanism of the reaction is shown in the lower portion of Scheme 14. Initial, rapid protonation of *trans*-[MoH(η^3-C_3H_5)(dppe)$_2$] at either the metal or the allyl group produces [MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$ and [MoH(η^2-MeCHCH$_2$)(dppe)$_2$]$^+$, respectively. The cationic propene complex subsequently undergoes rate-limiting dissociation of the propene ($k_3 = 4.3\,s^{-1}$) and ultimate formation of [MoH_2Cl_2(dppe)$_2$].

At low concentrations of acid, any [MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$ formed converts into [MoH(η^2-MeCHCH$_2$)(dppe)$_2$]$^+$, either by an intramolecular migration, or by proton dissociation to reform the parent allyl complex. Hence, under these conditions, one equivalent of propene is formed.

At higher concentrations of acid a further protonation of [MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$ can occur, probably at the allyl group to form [MoH_2(η^2-MeCHCH$_2$)(dppe)$_2$]$^{2+}$ (k_4 = 3.8×10^3 dm^3 mol^{-1} s^{-1}), and this commits the system to the formation of propyne. The important mechanistic point is that this second protonation labilizes the system, not to the loss of hydrocarbon but to the preferential loss of dihydrogen. It seems most likely that the dissociation of dihydrogen generates a coordinatively unsaturated, formally fourteen-electron species, [Mo(η^2-MeCHCH$_2$)(dppe)$_2$]$^{2+}$. In order to counteract this electron deficiency the metal dehydrogenates the coordinated propene to generate the formally sixteen-electron propyne species, [MoH_2(η^2-MeCCH)(dppe)$_2$]$^{2+}$, from which propyne subsequently dissociates. At high concentrations of acid, protonation of [MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$ is faster than dissociation of propene from [MoH(η^2-MeCHCH$_2$)(dppe)$_2$]$^+$, so under these conditions this propene complex converts into [MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$ and one equivalent of propyne is formed.



Scheme 14. Proposed mechanism for the formation of propene and propyne by the protonation of *trans*-[MoH(η^3-C_3H_5)(dppe)$_2$].

The hydrocarbon product distribution that this mechanism predicts is given by Equation (23). The elementary rate and

$$\frac{[\text{MeCCH}]}{[\text{MeCCH}] + [\text{MeCHCH}_2]} = \frac{k_4[\text{HCl}]}{k_4[\text{HCl}] + k_3(K_1/K_2)} \qquad (23)$$

equilibrium constants in this equation are known from the kinetic analysis, except for the ratio K_1/K_2. However, the best fit to the data is obtained when $K_1/K_2 \approx 50$. This is similar behavior to that observed with *trans*-[Mo(η^2-C_2H_4)$_2$(dppe)$_2$]: protonation of the hydrocarbon ligand is more favorable than protonation of the metal.

The details of how the propene and propyne are formed from [MoH(η^2-MeCHCH$_2$)(dppe)$_2$]$^+$ and [MoH_2(η^2-MeCHCH$_2$)(dppe)$_2$]$^{2+}$, respectively, are still not fully understood, and clearly more detail concerning these steps is required. The time course for the production of propene and propyne is shown in Figure 8a.[42] Propene is evolved quantitatively within about two minutes whereas it takes about an hour to produce the propyne quantatively. This indicates that the final absorbance observed in the stopped-flow experiments at high concentrations of acid is not that of [MoH_2Cl_2(dppe)$_2$], but rather corresponds to a precursor whose electronic spectrum is similar to that of the dichloro product. It seems likely that this precursor is [MoH_2(η^2-MeCCH)(dppe)$_2$]$^{2+}$, which slowly evolves propyne. In addition it is clear that dihydrogen evolution precedes propyne evolution consistent with the proposed mechanism.

Intermediates in the propyne-forming pathway have been detected by low temperature $^{31}P\{^1H\}$ NMR spectroscopy (Fig. 8b).[42] The spectra recorded for relatively low concentrations of acid are shown on the right. In the first spectrum the peak in the correct position for *trans*-[MoH(η^3-C_3H_5)(dppe)$_2$] is significantly broadened. This broadening is due in part to the low temperature, but mostly because the spectrum corresponds to the equilibrium mixture of *trans*-[MoH(η^3-C_3H_5)(dppe)$_2$], *trans*-[MoH(η^2-MeCHCH$_2$)(dppe)$_2$]$^+$, and *trans*-[MoH_2(η^3-C_3H_5)(dppe)$_2$]$^+$. As time passes this broad peak slowly decreases in intensity, and the only new peaks that appear are those of the product, [MoH_2Cl_2(dppe)$_2$]. No intermediates are detected under these conditions indicating that only short-lived species are generated on the propene-forming pathway.

At high concentrations of acid the propyne-forming pathway will dominate, and under these conditions at least three intermediates are detectable, as shown on the left of Figure 8b. As the broad peak associated with the protonation equilibria species

decreases in intensity three new sets of signals appear consecutively: the first around the initial peak, the second at high field, and the third at intermediate field. Finally, the peaks attributable to the product $[MoH_2Cl_2(dppe)_2]$ appear. To date we have not been able to identify these intermediates unambiguously, or isolate them, even at low temperatures. However, a noticeable feature of these spectra is the pairs of doublets in the last two sets of signals. This is reminiscent of the spectrum of the intermediates observed in the reaction of *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$, and it is tempting to assign these signals to the species $[MoH_2(\eta^2\text{-}MeCHCH_2)(dppe)_2]^{2+}$ and $[MoH_2(\eta^2\text{-}MeCCH)(dppe)_2]^{2+}$.

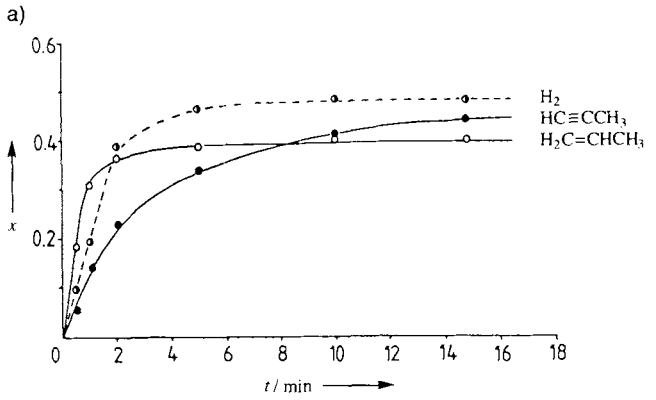
We do not understand the factors which discriminate between the evolution of dihydrogen and the evolution of a hydrocarbon upon protonation of a complex. This is a crucial aspect of the reactivity in the $[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. Recent studies on the reaction of $[MoH_3(CCt\text{Bu})(dppe)_2]$ with anhydrous HCl shown in Equation (24) demonstrate that the rate of coupling of two-hydrogen atoms and the rate of coupling a hydrogen atom with the alkynyl differ by less than a factor of 20.

$$[MoH_3(CCt\text{Bu})(dppe)_2] + 2HCl \longrightarrow [MoH_2Cl_2(dppe)_2] + t\text{BuCCH} + H_2 \quad (24)$$

4.3. Protonation of $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$: Dimerization of an Alkene

One of the major problems in defining the details of the formation of either propene or propyne from *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ is that the two pathways operate simultaneously. It would be advantageous if the formation of one hydrocarbon product could be studied in isolation over a wide acid concentration range. The conversion of the allyl ligand into propyne must involve the removal of the hydrogen atom bound to the central carbon atom. Consequently, protonation of a complex containing a 2-alkylallyl ligand must result only in the formation of the corresponding alkene. With this in mind we attempted to prepare and study the 2-methylallyl analogue of *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$.

The route used to prepare $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ is analogous to that used for all the compounds discussed in this section, and is shown in Scheme 15.[43] Reduction of $[MoCl_4(dppe)]$ by sodium amalgam, in the presence of dppe and under an atmosphere of isobutene gives, after about 18 hours, the labile, orange complex $[Mo(\eta^2\text{-}Me_2CCH_2)_2(dppe)_2]$. This reduction takes place via a bright green intermediate, which can be isolated and shown to be the molybdenum(II), five-coordinate, sixteen-electron species. This complex contains a 2-methylallyl and a hydrido ligand as confirmed by both ^1H and ^{13}C NMR spectroscopy at room temperature. However, it seems that the 2-methylallyl ligand is sufficiently bulky that two sterically demanding dppe ligands cannot be coordinated through all four phosphorus atoms, and hence one of the dppe ligands is only monodentate. $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ undergoes reversible changes in the NMR spectrum when the temperature is varied. Thus, although at 25.0 °C the species is undoubtedly a 2-methylallyl complex, upon cooling an intramolecular,



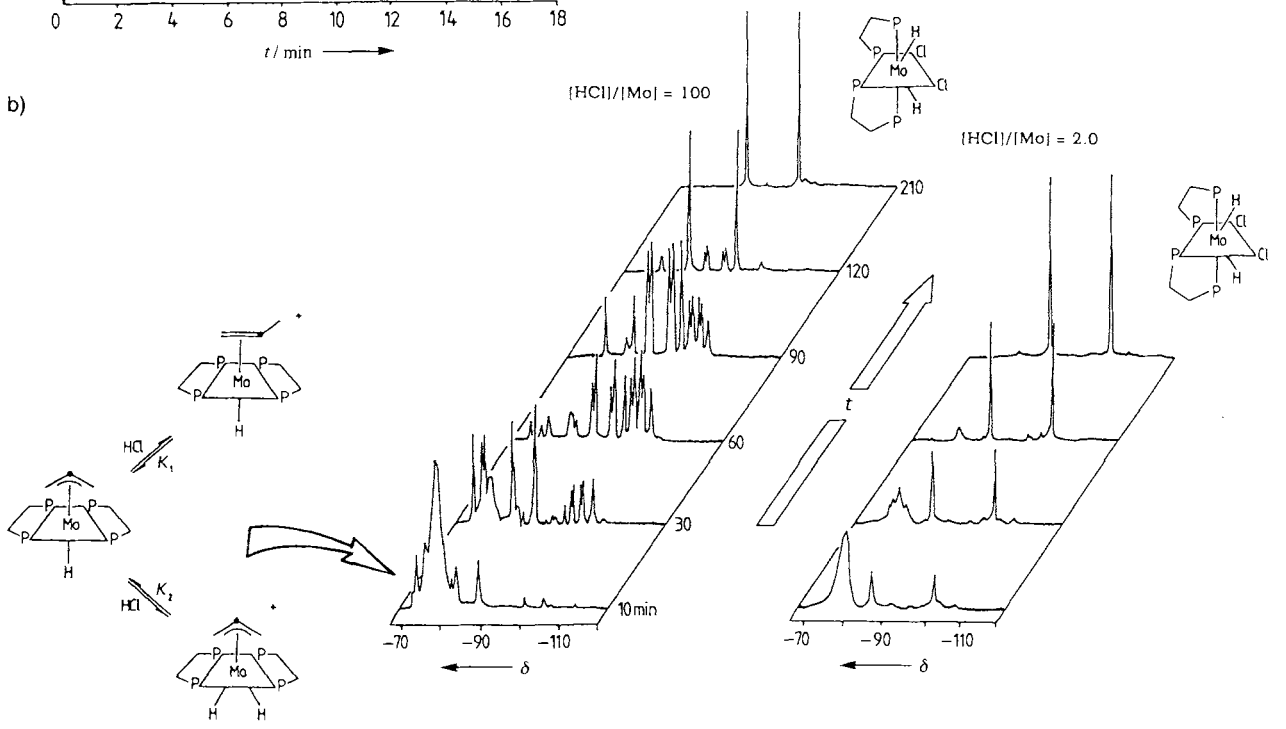


Fig. 8. a) Time course for the evolution of the products in the protonation of *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ (x = moles gas per mole complex; b) time course of this reaction monitored by low temperature $^{31}P\{^1H\}$ NMR spectroscopy for [HCl]/[Mo] = 100 (left) and [HCl]/[Mo] = 2 (right).

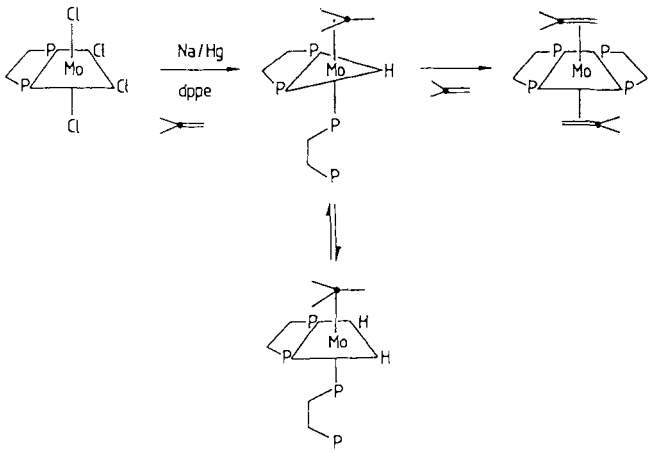

Scheme 15. Synthesis of $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ and its reaction with isobutene to form $[Mo(\eta^2\text{-}Me_2CCH_2)_2(dppe)_2]$.

reversible rearrangement results in the formation of the 18-electron trimethylenemethane dihydrido complex. Parenthetically, it is worth noting that the $\{Mo(dppe)_2\}$ site has been exceptional in demonstrating all the intramolecular rearrangements: alkene/$H^- \rightarrow$alkyl; allyl/$H^- \rightarrow$propene, and trimethylenemethane/$H^- \rightarrow$2-methylallyl.

Protonation of $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ with anhydrous HCl, at room temperature (where it is exclusively in the allyl form) proceeds according to Equation (25). $[MoH_2Cl_2(dppe)_2]$ is a product in all the systems discussed in this section, whilst the hydrocarbon results from the dimerization of isobutene.

$$[MoH(\eta^3\text{-}C_4H_7)(dppe)_2] + 2HCl \longrightarrow [MoH_2Cl_2(dppe)_2] + {}^t BuCH_2C(Me)CH_2 \quad (25)$$

A study of this reaction by the stopped-flow technique shows a single exponential trace with the final absorbance expected for $[MoH_2Cl_2(dppe)_2]$ and an initial absorbance slightly lower than that of the parent complex (Fig. 9). This initial absorbance jump is attributable to the addition of one equivalent of acid, as shown on the left-hand side of Figure 9.

The reaction reflected in the subsequent exponential absorbance–time decay exhibits a first-order dependence on the concentration of complex, but a nonlinear dependence on the concentration of HCl [Fig. 9, right-hand plot; Eq. (26)]. The mechanism of the reaction is shown in Scheme 16. Initial, rapid

$$k_{obs} = \{k_3 + k_4K_2[HCl]\}/(1 + K_2[HCl]) \quad (26)$$

protonation at the metal occurs within 2 ms to form $[MoH_2(\eta^3\text{-}C_4H_7)(dppe)_2]^+$ followed by rate-limiting intramolecular migration of the proton from the metal to the 2-methylallyl ligand ($k_3 = 0.7\ s^{-1}$) produces $[MoH(\eta^2\text{-}Me_2CCH_2)(dppe)_2]^+$. The subsequent steps can not be identified by kinetics, because they occur after the rate-limiting step, but must involve the dimerization of isobutene, and its liberation to form $[MoH_2Cl_2(dppe)_2]$. The complexity of Equation (26) is a consequence of rapid protonation of the pendant phosphorus atom ($K_2 = 52.2\ dm^3\,mol^{-1}$). Consequently the kinetics reflect the reactivity of both $[MoH_2(\eta^3\text{-}C_4H_7)(dppe)_2]^+$ and $[MoH_2(\eta^3\text{-}C_4H_7)(dppe)(dppeH)]^{2+}$ ($k_4 = 2.9\ s^{-1}$). This mechanism (in particular the rate-limiting migration steps) is able to rationalize the following kinetic observations: 1) Rate constants associated with apparently acid-

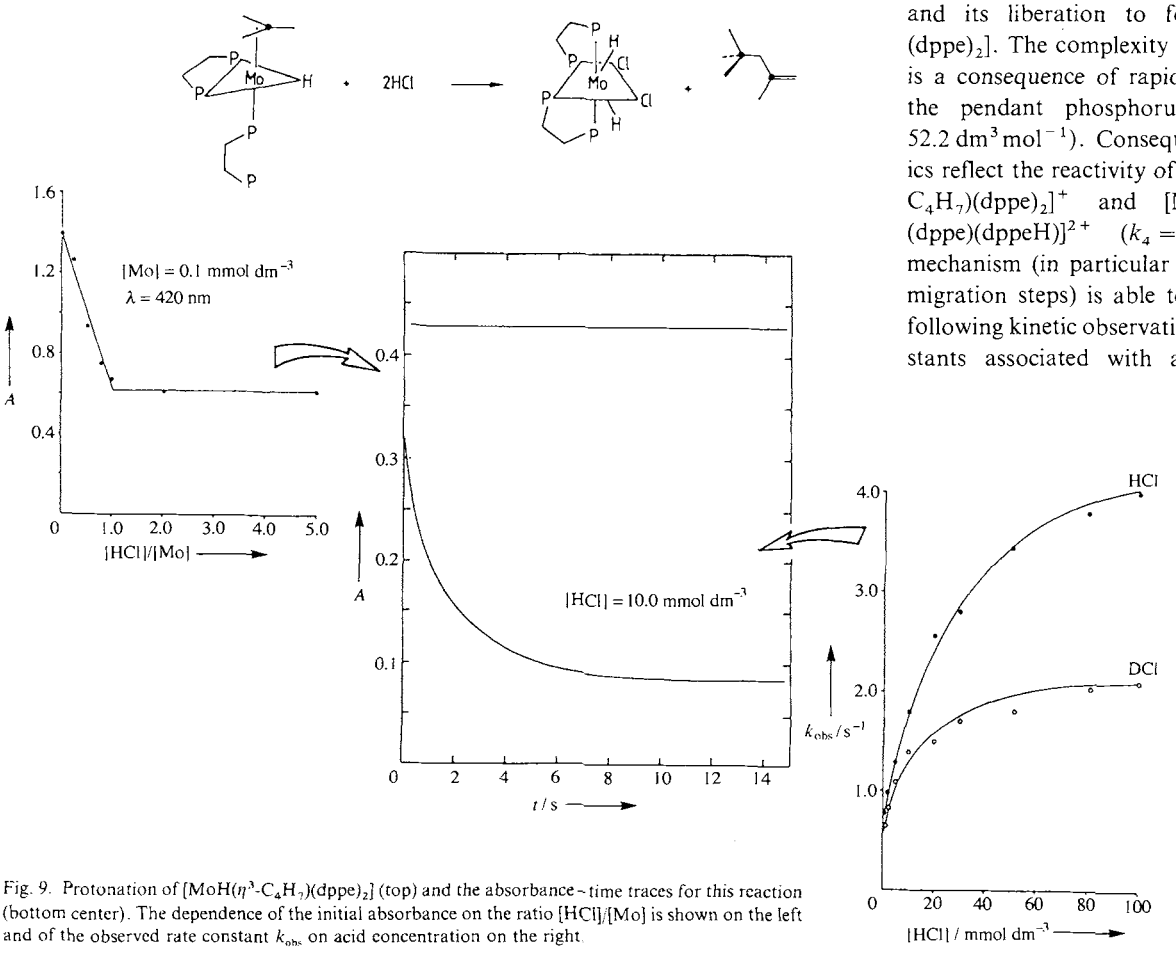

Fig. 9. Protonation of $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ (top) and the absorbance–time traces for this reaction (bottom center). The dependence of the initial absorbance on the ratio [HCl]/[Mo] is shown on the left and of the observed rate constant k_{obs} on acid concentration on the right.

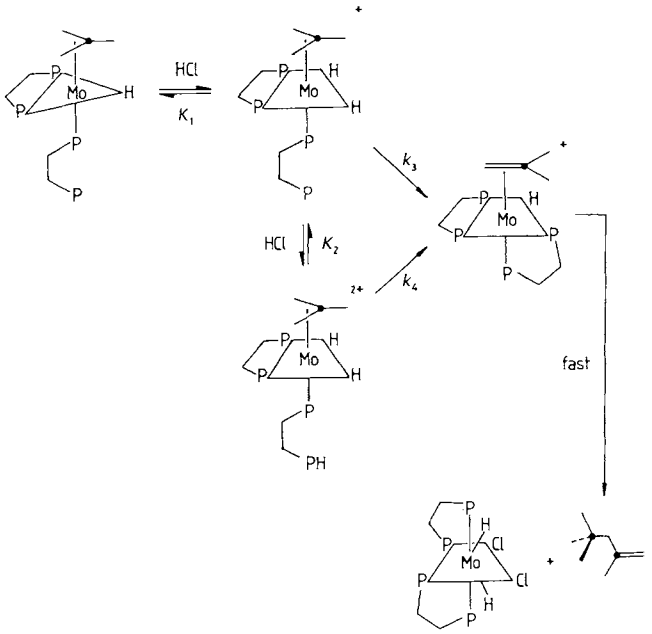


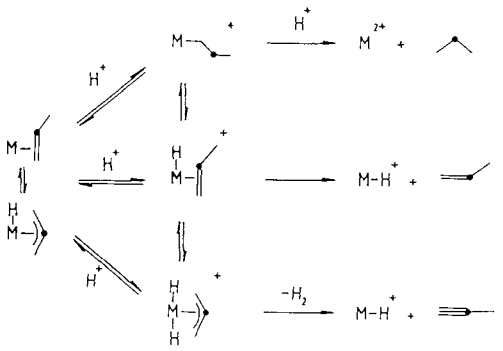
Scheme 16. Proposed mechanism for the protonation of $[MoH(\eta^3\text{-}C_4H_7)(dppe)_2]$ leading to the dimerization of isobutene.

independent steps (k_3 and k_4) exhibit primary isotope effects ($k_3^H/k_3^D = 1.27$, $k_4^H/k_4^D = 1.50$), since these elementary reactions are due to migration of hydrido groups derived from the acid. 2) The initial, rapid reaction consumes one equivalent of acid. 3) As expected, the pendant phosphorus atom is protonated by HCl. An important aspect of the mechanism is that this step is reversible, and thus, towards the end of the reaction, the phosphorus can bind to the metal whilst deprotonated.

The details of the dimerization process are not clear, but it is certainly much faster than the acid-catalyzed dimerization of free isobutene. This indicates that dimerization occurs on the metal site.

4.4. Product Control by Protonation: A Summary

In this section some relatively simple systems have been discussed that when considered together illustrate how the protonation of alkene complexes (or their rearranged analogues) can selectively give alkanes, alkenes, or alkynes as summarized in Scheme 17.



Scheme 17. Protonation of alkene complexes to give alkanes, alkenes, or alkynes, illustrating how selectivity results from protonation at the hydrocarbon or the metal.

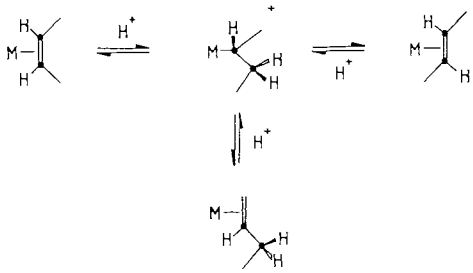
The selectivity is a result of protonation at the hydrocarbon or the metal. Thus, protonation at the coordinated alkene gives the alkyl species, which subsequently reacts further to produce an alkane. However, further protonation of the metal occurs at higher concentrations of acid and this labilizes the system towards the release of alkene.

Alkenes higher than ethene can also rearrange on the metal site to form the allyl hydrido species, and this form is capable of producing alkynes upon protonation, if the protonation at the metal preferentially labilizes the release of dihydrogen to generate a coordinatively unsaturated site capable of dehydrogenating the bound alkene.

At first sight it seems anomalous that no propane is formed in the reaction with *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. The reason for this is probably kinetic: the formation of propane is slow, and the more rapid formation of either the alkyne or the alkene occur preferentially. It would be interesting to study the products of the reaction between DCl and *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$ to establish whether any deuterium is incorporated specifically into the secondary carbon of the propene. This would indicate the transient existence of a propyl species that undergoes intramolecular β-hydrogen or deuterium transfer more rapidly than it can form propane.

4.5. Proton-Catalyzed Isomerization of Alkenes

A reaction which has not been observed in the reactions of alkenes bound to the $\{Mo(dppe)_2\}$ site is the acid-catalyzed rearrangements shown in Scheme 18. In principle, protonation

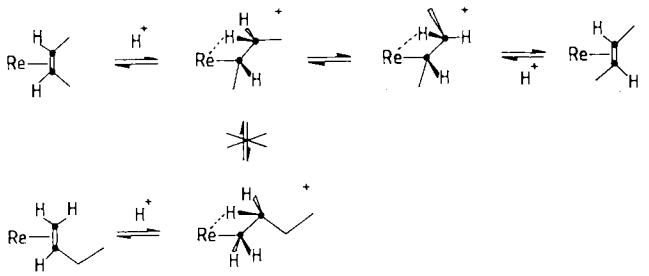


Scheme 18. Acid-catalyzed rearrangements of metal-alkene complexes.

of alkene complexes can give mixtures of *cis*- and *trans*-alkenes together with internal and terminal alkenes via intermediate alkyl species.

Acid-catalyzed *cis*–*trans* isomerization of alkenes bound to rhenium has been observed (Scheme 19).[44] Addition of acid to a solution of the *cis*-2-butene complex $[Re(\eta^5\text{-}C_5H_5)(CO)_2(\eta^2\text{-}cis\text{-}MeCHCHMe)]$ results in the formation of a 45:55 mixture of this *cis*-2-butene complex and $[Re(\eta^5\text{-}C_5H_5)(CO)_2(\eta^2\text{-}trans\text{-}MeCHCHMe)]$ within about 30 min. The proposed mechanism (Scheme 19) involves protonation of the alkene ligand to form the alkyl species, rotation about the carbon–carbon single bond, and deprotonation to generate the equilibrium mixture of alkene complexes.

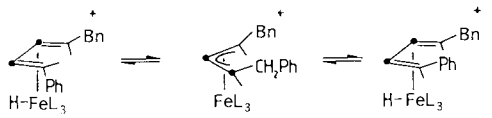
The exact mechanism by which the alkene is protonated (direct attack at the carbon or via a hydrido species) is unknown, but the most important mechanistic feature is the selectivity that



Scheme 19. Isomerization of *cis*-butene on a rhenium center.

shows that both protonation and deprotonation must occur at the same carbon atom: the postulated 2-butyl intermediate does not deprotonate to give the 1-butene complex, and similarly, protonation of the 1-butene complex does not give any 2-butene ligand. This observation can only be rationalized if the two butyl intermediates are different. It has been proposed that the protonation produces an intermediate containing a strong agostic interaction, followed by an "in place rotation" and deprotonation of the agostic alkyl group, which occurs much more rapidly than formation of a free alkyl rhenium intermediate.

A related acid-catalyzed isomerization is the equilibration of coordinated *syn* and *anti* dienes as illustrated for $[Fe(\eta^4\text{-}PhCHCHCHCHBn)(CO)_3]^+$ (Bn = $PhCH_2$) in Scheme 20.[45]



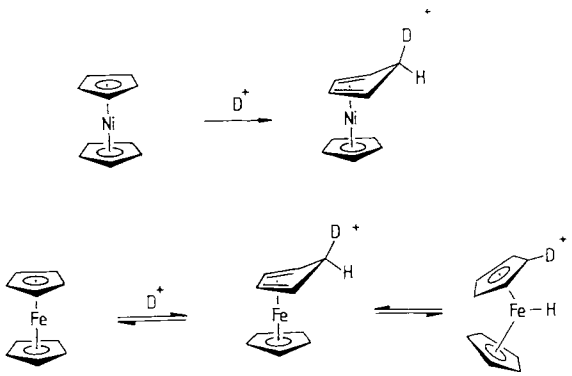
Scheme 20. Equilibration of coordinated *syn* and *anti* dienes at an iron complex. L = CO.

In this example rate-limiting protonation occurs at the metal and is associated with an exceptionally large primary isotope effect ($k_H/k_D = 27$). Intramolecular transfer of the hydrogen from the metal to the diene then forms the allyl species. Subsequent rotation about the carbon–carbon single bond followed by hydrogen migration back to the metal and deprotonation results in equilibration of the *syn* and *anti* isomers.

5. Stereoselective Protonation of Complexes

The addition of protons to coordinated hydrocarbons to produce stereoselective products has been known for some time, especially in the reactions of cyclic polyenes. Thus, as shown in Scheme 21, $[Ni(\eta^5\text{-}C_5H_5)_2]$ is protonated on the cyclopentadienyl ring stereoselectively in the *exo* position.[46] In addition the exchange of ring protons in $[Fe(\eta^5\text{-}C_5H_5)_2]$ involves *exo* attack of a proton at the cyclopentadienyl ring.[47] Subsequently, the *endo* hydrogen transfers to the metal to form $[FeH(\eta^5\text{-}C_5H_5)_2]^+$.

Whether a proton adds directly in *exo* or *endo* position in any particular system cannot be predicted, and examples of both types of addition are known. In many cases there is no clear evidence whether *exo* or *endo* attack has occurred. For instance, the protonation of $[Fe(\eta^4\text{-}C_4H_4)(CO)_3]$ is assumed to involve



Scheme 21. Stereoselective D^+ attack at the pentadienyl ligand in $[Ni(\eta^5\text{-}C_5H_5)_2]$ and in $[Fe(\eta^5\text{-}C_5H_5)_2]$.

endo attack, since the analogous butadiene complex is protonated in this position.[48] Of course, *endo* addition may involve initial protonation of the metal followed by intramolecular migration. However, the intermediacy of a hydrido species is not essential for formation of *endo* product.

Another aspect of stereoselectivity involves the protonation of alkynes to form *cis*- or *trans*-alkenes selectively. We shall discuss this aspect in detail in this section and show how application of the kinetic principles associated with protonation at the metal or the hydrocarbon ligand outlined so far can be employed to control the stereochemistry of the product.

We saw in the Section 3 that the term regioselective is ambiguous in the sense that although the reaction may amount stoichiometrically to a regioselective protonation, the mechanism whereby this product is formed may not involve direct regioselective attack. A similar problem in terminology occurs for the stereoselectivity of products formed by protonation: the stoichiometrically stereoselective product can be formed by a variety of mechanistic pathways.

5.1. Stereoselectivity in the Protonation of Alkynes: Kinetic Control

Consideration of the protonation of a coordinated alkyne reveals that attack can occur at two faces of the alkyne: *exo* to the metal to give a *trans*-vinyl species or *endo* to the metal giving a *cis*-vinyl species.

The fundamental point is that the face of the alkyne to which the proton binds defines the configuration of the vinyl species. Provided the carbon–carbon double bond is maintained upon the addition of the second proton the resulting alkene's configuration will be defined by the position of the initial protonation: *cis*-vinyl gives a *cis*-alkene and *trans*-vinyl gives a *trans*-alkene.

Clearly if the rates of the initial *exo* and *endo* protonations are sufficiently different then a stereoselective alkene will be formed, provided intermediate isomeric vinyl species or the isomeric coordinated alkenes do not equilibrate. Both isomeric vinyl and alkene complexes can equilibrate by protonation to form alkylidene ligands and alkyl ligands, respectively. Rapid rotation about the carbon–carbon single bond in either alkylidene or alkyl ligands prior to proton loss effectively destroys any selectivity (see Section 5.2). In order to avoid this problem the system must be carefully designed.

A question that must be addressed initially is: "Can protonation of a coordinated alkyne occur stereoselectively?" To answer this question the reaction of anhydrous HCl with the symmetrical alkyne PhCCPh bound to the symmetrical site $\{V(\eta^5\text{-}C_5H_5)_2\}$ has been studied [Eq. (27)].[49] The symmetrical nature

$$[V(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-PhCCPh})] + 2\,HCl \longrightarrow [V(\eta^5\text{-}C_5H_5)_2Cl_2] + PhCHCHPh \quad (27)$$

of the entire system ensures that any stereoselectivity observed is a consequence of the rates of protonation and not of the ancillary ligands' "guiding" the proton preferentially to a particular face of the alkyne. Predominantly the *cis*-alkene (85%) is formed with 15% *trans* isomer.

The reaction exhibits a first-order dependence on the concentration of complex, but the dependence on the concentration of HCl is complicated (Fig. 10). This complicated acid dependence

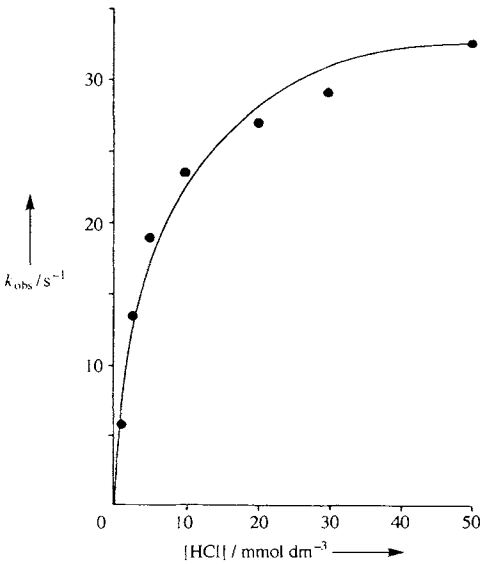


Fig. 10. Dependence of the observed rate constant k_{obs} on acid concentration for the protonation of $[V(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-PhCCPh})]$.

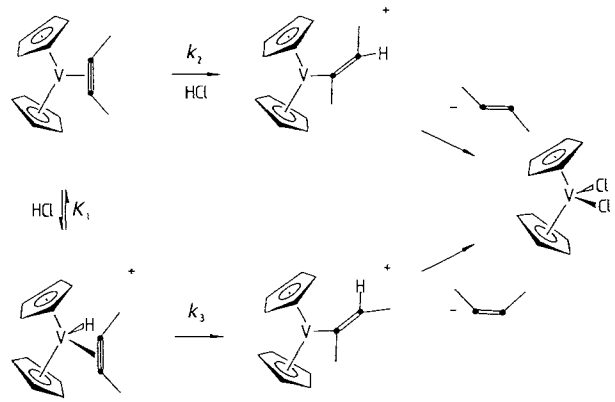
mitigates against simple, direct proton attack at the coordinated alkyne, but rather indicates the mechanism depicted in Scheme 22 with the corresponding rate law shown in Equation (28).

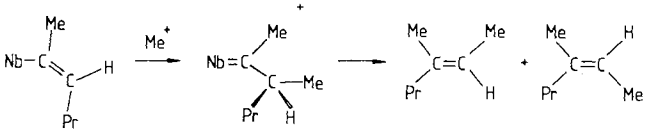
$$k_{obs} = (k_2 + k_3K_1)[HCl]/(1 + K_1[HCl]) \quad (28)$$

The major pathway involves initial, rapid protonation of the metal to give $[VH(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-PhCCPh})]^+$, followed by rate-limiting migration of the hydride to the alkyne necessarily producing the *cis*-vinyl species. In addition, protonation of the alkyne at the face remote from the metal produces the *trans*-vinyl species. Analysis of the data gives $(k_2 + k_3K_1) = 6.2 \times 10^3\ dm^3\,mol^{-1}\,s^{-1}$ and $K_1 = 1.56 \times 10^2\ dm^3\,mol^{-1}$. It seems likely that the carbon–carbon double bond of the vinyl ligand is retained throughout the second protonation, and hence the configuration of the final alkene is defined by the initial site of protonation of the coordinated alkyne.



Scheme 22. Proposed mechanism for the protonation of the symmetrical complex $[V(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-PhCCPh})]$.

Studies on $[Nb(\eta^5\text{-}C_5H_5)_2(CO)(CMeCH\textit{i}Pr)]$ show that protonation of the vinyl species gave an alkene of the same configuration as the vinyl ligand.[50] However, if the second protonation were to occur at the carbon atom remote from the metal, isomerization would result. Methylation of $[Nb(\eta^5\text{-}C_5H_5)_2(CO)(CMeCH\textit{i}Pr)]$ with $MeOSO_2F$ leads to an alkylidene species, which subsequently produces a mixture of alkene isomers (Scheme 23).



Scheme 23. Methylation of $[Nb(\eta^5\text{-}C_5H_5)_2(CO)(CMeCH\textit{i}Pr)]$ with $MeOSO_2F$ leading to a mixture of alkenes.

How then can we design the system so that the vinyl complexes do not protonate at the remote carbon atom and destroy the stereoselectivity? For protonation of vinyl complexes at either the metal or the remote carbon atom, a pair of electrons have to be supplied by the metal, and hence the formal oxidation state of the metal increases by two units. However, since $[V(\eta^5\text{-}C_5H_5)_2(PhCCHPh)]^+$ is a vanadium(IV) complex, protonation at the metal or remote carbon atom is impossible—it can only occur at the vanadium–carbon bond.

This illustrates a general way in which protonation of a complex can be controlled. Protonation of alkyne complexes where the oxidation state of the metal is less than four units from its maximum (that is, greater than +2 for V, Nb, or Ta; greater than +3 for Cr, Mo, or W, etc.) enforces the protonation of the derived vinyl species to occur at the carbon atom adjacent to the metal. In these circumstances, the configuration of the alkene product is always defined by that the vinyl species and hence by the kinetically favored site of protonation of the alkyne ligand.

Further quantitative analysis of the vanadium system in Equation (27) is possible. Since the isomeric alkene product distribution is defined by the rates of formation of the isomeric vinyl species the expression in Equation (29) can be derived,

$$\frac{[cis\text{-PhCHCHPh}]}{[cis\text{-PhCHCHPh}] + [trans\text{-PhCHCHPh}]} = \frac{k_3K_1}{k_3K_1 + k_2} \quad (29)$$

from which $k_2 = 9.3 \times 10^2\ dm^3 mol^{-1} s^{-1}$ and $k_3 = 33.8\ s^{-1}$. Since it can be estimated that $k_1 \geq 1 \times 10^6\ dm^3 mol^{-1} s^{-1}$, it is clear that the difference in the rates of protonation of the metal (to give *cis*-alkene) and alkyne (to give *trans*-alkene) would lead to essentially exclusive formation of *cis*-alkene. However, it is the relatively slow rate of intramolecular migration, together with the reversibility of the protonation at the metal that leads to the poorer stereoselectivity observed experimentally.

The reversibility of the initial protonation is another factor we have to consider in designing systems to give stereoselective alkenes. In certain circumstances, the initial site of protonation would not define the configuration of the product, for instance, if the initial protonation of the coordinated alkyne is reversible, or the favored isomeric vinyl species is protonated only slowly, whilst the minor isomeric vinyl complex protonates rapidly. However, this latter scenario seems unlikely since the isomeric vinyl species are necessarily only distinguished by the substituent on the carbon atom remote from the metal, and consequently one would expect that the rate of protonation of the carbon atom adjacent to the metal would be similar for the two isomers.

The stereoselectivity in $[V(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-}PhCCPh)]$ is controlled entirely by the relative rates of protonation of the metal and the alkyne, and in this highly symmetrical complex the dominant product is the *cis*-alkene.

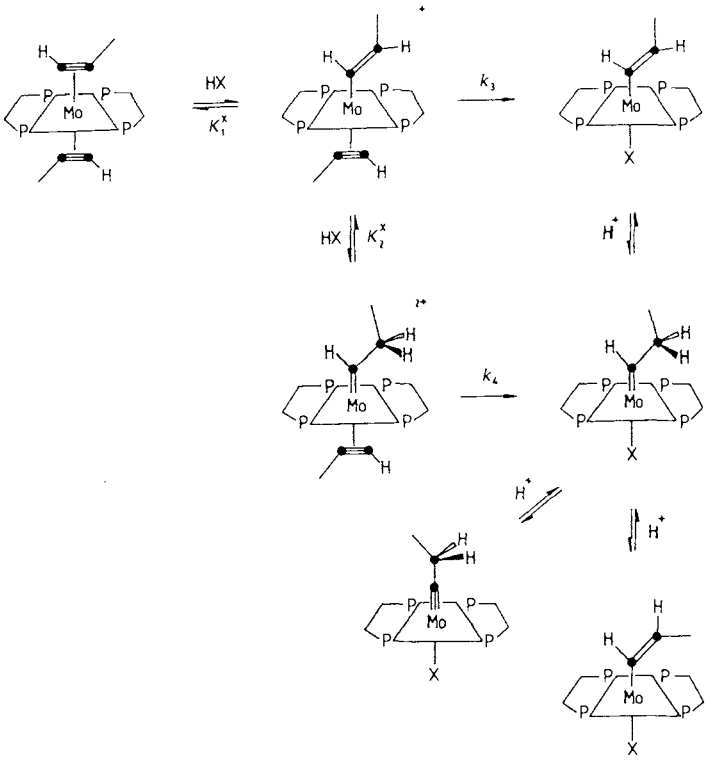
The nitrogenases specifically transform acetylene to *cis*-CHDCHD in vitro by a sequence of electron and proton transfer reactions.[51] Much speculation has centered around how the enzyme accomplishes this stereoselectivity.[7, 52] However, the results from this study indicate that the biological result needs little explanation: the enzyme is merely showing the normal stereoselectivity associated with this type of reaction.

In certain circumstances, stereoselective formation of alkenes by protonation of coordinated alkynes can also be accomplished under conditions of thermodynamic control. The reaction between anhydrous HX (X = Cl, Br, or BF_4) and complexes of the type *trans*-$[Mo(\eta^2\text{-alkyne})_2(dppe)_2]$ gives vinyl and alkylidyne complexes[53, 54] as shown by the examples in Equations (30) and (31), respectively. In both cases the overall stoichiometry

$$trans\text{-}[Mo(\eta^2\text{-}MeCCH)_2(dppe)_2] + HX \longrightarrow trans\text{-}[Mo(CHCHMe)X(dppe)_2] + MeCCH \quad (30)$$

$$trans\text{-}[Mo(\eta^2\text{-}MeCCH)_2(dppe)_2] + HX \longrightarrow trans\text{-}[Mo(CCH_2Me)X(dppe)_2] + MeCCH \quad (31)$$

requires the net addition of one molecule of HX, but clearly for the formation of the alkylidyne, a complex protonation/deprotonation pathway must operate. The mechanistic rationalization of how both types of products can be formed from the same reactants is shown in Scheme 24; the associated general rate law



Scheme 24. Protonation of *trans*-$[Mo(\eta^2\text{-}MeCCH)_2(dppe)_2]$.

is given by Equation (32) if the dissociation of propyne is rate-limiting in both pathways.

$$k_{obs} = \frac{K_1^X[HX]\{k_3 + k_4 K_2^X[HX]\}}{1 + K_1^X[HX] + K_1^X K_2^X[HX]^2} \quad (32)$$

Initial, rapid protonation of *trans*-$[Mo(\eta^2\text{-}MeCCH)_2(dppe)_2]$ forms *trans*-$[Mo(CHCHMe)(\eta^2\text{-}MeCCH)(dppe)_2]^+$ ($K_1^{Cl} = 1.3 \times 10^2\ dm^3 mol^{-1}$) within 2 ms, which can be detected both by electronic spectroscopy and low temperature $^{31}P\{^1H\}$ NMR spectroscopy. Protonation of a propyne ligand decreases the electron density at the metal and consequently labilizes the *trans*-propyne to dissociation ($k_3 = 0.35\ s^{-1}$). Subsequent rapid binding of X^- at the site vacated by MeCCH gives the vinyl product, *trans*-$[MoX(CHCHMe)(dppe)_2]$, and at low concentrations of acid this is the exclusive product-forming pathway.

At high concentrations of acid, protonation of *trans*-$[Mo(CHCHMe)(\eta^2\text{-}MeCCH)(dppe)_2]^+$ to form *trans*-$[Mo(CHCH_2Me)(\eta^2\text{-}MeCCH)(dppe)_2]^{2+}$ can occur ($K_2^{Cl} = 3.0\ dm^3 mol^{-1}$) before dissociation of the propyne ligand. This second protonation further labilizes the *trans*-propyne ligand ($k_4 = 2.58\ s^{-1}$), which is lost in the rate-limiting step. Rapid attack by X^- and proton release from the alkylidene ligand gives either *trans*-$[Mo(CHCHMe)X(dppe)_2]$ (proton loss from the remote carbon atom) or *trans*-$[Mo(CCH_2Me)X(dppe)_2]$ (proton loss from the adjacent carbon atom).

An important mechanistic conclusion is that the product of the reaction (vinyl or alkylidyne complex) is not defined by the site of protonation but is decided by factors that have their influence after the rate-limiting step. Although the alkylidyne species has only been isolated in the reaction with $HBF_4 \cdot OEt_2$,

it seems likely that, irrespective of the acid, the equilibrium mixture of isomeric vinyl complexes, alkylidene, and alkylidyne species shown on the right-hand side of Scheme 24 is present in solution. Which product is actually isolated will depend on the magnitude of the equilibrium constants interconnecting these species, or merely the relative solubilities. It is unlikely that a fluoro ligand favors proton loss from the adjacent carbon atom whilst the chloro or bromo ligand favors proton loss from the remote carbon atom. Rather it seems more likely that the least soluble is product isolated.

The mechanism shown in Scheme 24 has important consequences for the configuration of the vinyl ligand. Irrespective of the initial site of protonation and the resulting configuration of the vinyl ligand in *trans*-[Mo(CHCHMe)(η^2-MeCCH)(dppe)$_2$]$^+$, at high concentrations of acid the reaction proceeds via the alkylidene intermediate *trans*-[Mo(CHCH$_2$Me)(η^2-MeCCH)(dppe)$_2$]$^{2+}$. Free rotation around the carbon–carbon single bond in this intermediate prior to proton loss means that any stereoselectivity introduced at the initial protonation is destroyed. However, *trans*-[Mo(CHCHMe)Br(dppe)$_2$] isolated from this reaction shows partially resolved peaks in the ^{1}H NMR spectrum, which are attributable to the vinyl ligand. Thus, the resonance at $\delta = 10.9$ is a doublet ($J_{H,H} = 8.8$ Hz), and the resonance at $\delta = 9.5$ is a multiplet. In addition the methyl signal at $\delta = 1.15$ is a doublet ($J_{H,H} = 5$ Hz). These coupling constants are consistent with a *cis*-vinyl ligand ($J^{cis}_{H,H} = 6-14$ Hz, $J^{trans}_{H,H} = 11-20$ Hz). Clearly this stereoselective formation of the *cis*-vinyl species cannot reflect a kinetic preference, but must be a consequence of a signifiant difference in the thermodynamic stability or solubility between *trans*-[Mo(*cis*-CHCHMe)Br(dppe)$_2$] and *trans*-[Mo(*trans*-CHCHMe)Br(dppe)$_2$]. That is, the stereoselectivity is thermodynamically controlled.

Thus, at least in principle, stereoselective formation of an alkene by protonation of a coordinated alkyne can be accomplished by thermodynamic control. Protonation of a particular configuration of a vinyl ligand at the carbon remote from the metal generates an alkylidene species, and subsequent deprotonation produces an equilibrium mixture of *cis* and *trans* vinyl species. Further protonation of this mixture will often result in a mixture of isomeric alkenes. However, a specific configuration of an alkene can be produced provided 1) there is a significant difference in the thermodynamic stabilities of the isomeric vinyl species and 2) protonation of the vinyl species to give the alkene is significantly slower than the rate of proton equilibration between the vinyl and alkylidene species.

It is worthwhile just briefly considering the factors that result in a significant difference in the thermodynamic stabilities of the isomeric vinyl species. Clearly the major contributors must be the size of both the vinyl substituent and the coligands of the metal. If both are bulky, one can be reasonably confident that the *trans*-vinyl residue, minimizing unfavorable steric interactions, would be the more stable thermodynamically. However, in the study on *trans*-[Mo(η^2-MeCCH)$_2$(dppe)$_2$] (with a methyl substituent) the *cis*-vinyl ligand is preferred, probably because the methyl group is buried in the surrounding coligand framework.

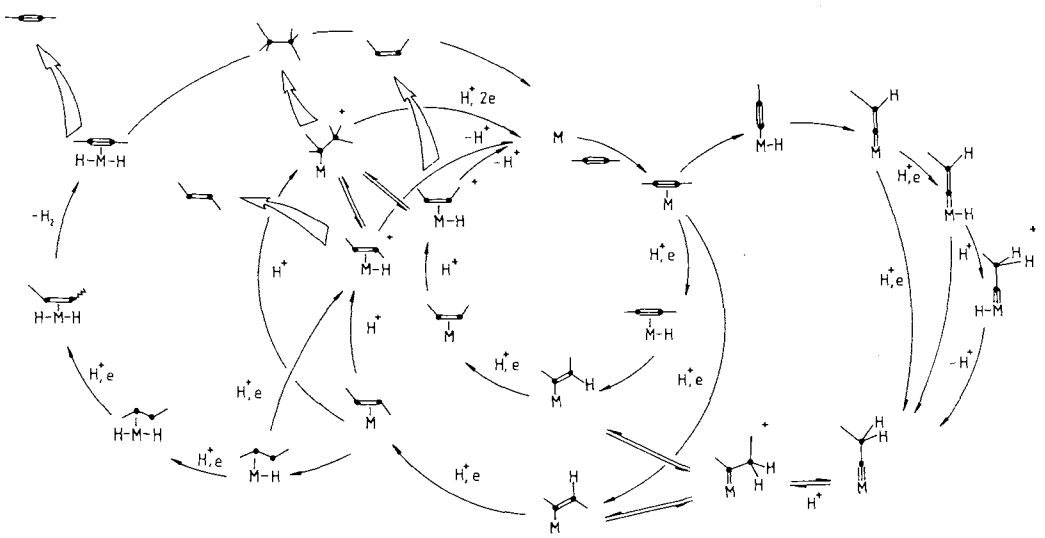
Finally, it should be noted that thermodynamic control of stereochemistry can only operate with alkynes other than acetylene, since the differentiation in stabilities is exclusively a consequence of the substituent on the vinyl ligand.

6. Summary and Outlook

In this review I have highlighted the mechanistic aspects associated with the protonation of unsaturated hydrocarbon residues bound to transition metal sites and emphasized how this reactivity is a natural consequence of having two sites on the same molecule that undergo slow proton transfer reactions. Three key mechanistic principles emerge with which the reactivity of these systems can be understood. 1) Protonation can occur at either the metal or the hydrocarbon ligand. 2) The initial site of attack may not be the final residence of the proton. 3) Transfer of the proton between metal and ligand can occur by intramolecular or acid-catalyzed pathways.

These principles have some important repercussions, the most fundamental of which is that protonation of complexes containing unsaturated hydrocarbons is invariably more complicated than would be imagined from inspection of the structures of the products. Consequently, a reaction can be stoichiometrically regioselective in that the product is ultimately protonated at a single site, though mechanistically the reaction might proceed by several pathways in which the complex is initially protonated at different sites.

An overall picture of the hydrocarbon-evolving transformations discussed in this article is shown in Scheme 25. This dia-



Scheme 25. Overview of all the transformations discussed in this review in which hydrocarbon ligands are released.

gram illustrates how the competitive protonation of metal and ligand can be exploited, first to control the products of the reaction and second, to control the stereochemistry of the products.

The future is still intellectually demanding. Although a lot of synthetic chemistry has resulted in a general understanding of which site is the ultimate residence of the proton, we are still a long way from understanding the mechanistic factors that discriminate between initial protonation of the metal and the hydrocarbon residue. Only if we can understand the kinetic features of this type of reaction can we hope to design complexes whose reactivity and reaction products can be defined prior to their preparation.

Finally, what about catalysis? The diagram in Scheme 25 indicates several cyclic processes established by piecing together the stoichiometric reactions discussed in this article. A feature of all the reactions discussed herein is the formation of well-defined metal-containing products. For instance, $[MoH_2Cl_2(dppe)_2]$ has been isolated from the reaction of HCl with *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$. In a sense, $[MoH_2Cl_2(dppe)_2]$ is "exhausted" since it has supplied electrons to protons, either to form hydride ligands or evolve dihydrogen. However, $[MoH_2Cl_2(dppe)_2]$ can be reduced under an atmosphere of propene to form *trans*-$[MoH(\eta^3\text{-}C_3H_5)(dppe)_2]$,[42] and hence, in principle, we have a catalyst, and a versatile catalyst at that, since by changing the concentration of acid used at each turnover we could selectively produce propene or propyne. Similarly, we can envisage a catalyst that selectively produces ethane or ethene based on *trans*-$[Mo(\eta^2\text{-}C_2H_4)_2(dppe)_2]$. However, in practice, there is a problem in adapting these systems to be truly catalytic because of the preferential reduction of protons to dihydrogen in any system containing an acid and a reductant. A major target in the near future must be finding solutions to this problem. After all, if nature can find ways of minimizing proton reduction in the conversion of acetylene into ethene or ethane by the nitrogenases, so can chemists!

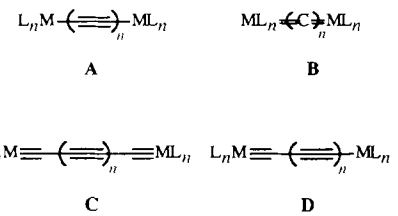
Organometallic "Carbon Chains": They Just Keep Getting Longer!

Uwe H. F. Bunz*

Recently a review by Beck et al.[1] and a Highlight by Lang[2] appeared in this journal in which synthesis, chemistry, and properties of novel, C_n-bridged ($n = 1-5$) homo- and heterobinuclear complexes were discussed. Complexed carbon chains can be considered as "molecular wires"[3] and represent attractive synthetic targets that allow the study of electronic, optical, and electrochemical interactions between two organometallic centers; they can also be considered as sections of the long-sought, one-dimensional carbon modification carbyne (also known as chaoite), stabilized at its ends by metal fragments.[4] Both aspects are of interest in terms of the synthetic chemistry and the materials research.

As shown in Scheme 1, the neutral rods exist in several forms **A**–**D**; those with an uneven number of C atoms occur only in form **B** (cumulene-like) or **D** (carbyne-like). However, compounds of type **A** with an even number of C atoms appear to be more stable. On oxidation of these acetylides, however, the bonding situation can change from **A** to **B** (see below).



Scheme 1. Possible coordination modes of "naked" carbon chains to transition metal fragments.

In the time since the last Highlight[2] the synthesis of linear polyyne derivatives has developed rapidly through the work in the groups of Gladysz,[5] Lapinte,[6] and others;[7] thus, an update appears timely. Gladysz et al. have developed a variable synthetic route to C_n chains supported by two {Re} units ({Re} = Cp*Re(PPh$_3$)NO; Cp* = C_5Me_5).[5c]

Until 1994 only complexes were known that had between one and five C atoms between the organometallic centers. Now representatives of this type are accessible with 8, 10, 12, 16, and 20 C atoms.

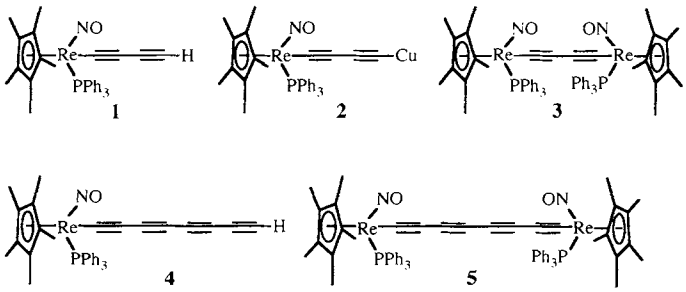
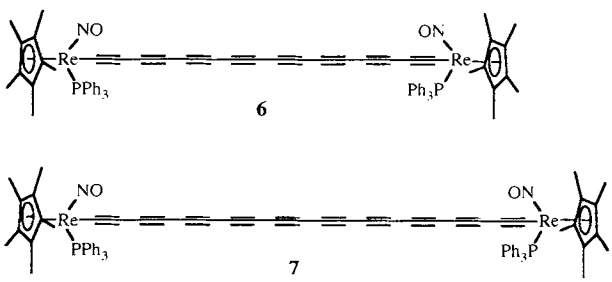
Syntheses

For the construction of acetylides of the form **A** with eight to twenty C atoms Gladysz et al. use a step-growth approach, in which the dimer **5** was obtained in 70% yield starting from (air



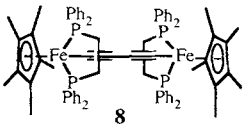
stable!)[5a] **1** by an Eglinton coupling ($Cu(OAc)_2$/pyridine/80 °C).[8a] It is amazing how the Re–C bond is so robust that it survives these comparatively harsh reaction conditions. When **1** was coupled together with the shorter homologue {Re}-C≡C-H by applying Eglinton conditions,[8a] {Re}-C≡C–C≡C–C≡C-{Re} could be isolated in 44% yield. Compound **1** is also useful in another respect. Metalation of **1** with BuLi and subsequent treatment with CuI generated the corresponding cuprate **2**. Reaction of **2** with Br-C≡C–C≡C-SiMe$_3$ in $EtNH_2$ according to a Cadiot–Chodkiewicz protocol,[8b, 9] followed by treatment with K_2CO_3 in methanol yielded the moderately sensitive species **4**. Another Eglinton coupling gave **6** in 70% yield, whereas the Eglinton coupling of {Re}-(C≡C)$_5$-H, which was synthesized analogously, led to the isolation of the decayne **7** in 41%



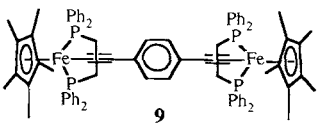
yield with a "naked" C_{20} chain. The polyynes synthesized by Gladysz are the longest organometallic carbon chains prepared to date. The synthesis of bissilyl-protected polyynes with up to 14 triple bonds was described in earlier work by Ingold and Walton;[8b] however, these were never fully characterized.

Whereas Gladysz made extensive use of copper-catalyzed couplings to produce his systems, Lapinte et al. obtained a binuclear complex bridged by a butadiyne unit through a radical dimerization:[6b] oxidation of {Fe}-C≡C-H ({Fe} = Cp*Fe(dppe); dppe = bis(diphenylphosphanyl)ethane) with ferrocenium hexafluorophosphate, led to the dimerization of the radical cation to give $[\{Fe\}=C=CH-HC=C=\{Fe\}](PF_6)_2$. KO*t*Bu reacts in THF with this dication to give the butadiyne complex **8**.

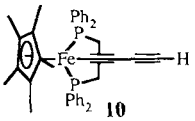
To obtain polyyne units linked to iron centers, $[Cp^*(CO)_2FeI]$ was alkynylated with Li-C≡C-C≡C-$SiMe_3$; photochemical ligand exchange with dppe and desilylation with Bu_4NF gave **10**, which was dimerized in an Eglinton coupling to afford **11** in



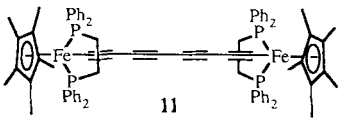
8



9



10



11

80% yield. Copper-catalyzed couplings also function without problems on these compounds, which in comparison to the systems prepared by Gladysz are significantly more sensitive to oxidation. It is pleasing that concepts and reactions known from the chemistry of organic alkynes can be transferred to organometallic chemistry without problems.[8, 9]

Properties

The investigation of *through-space* and *through-bond* redox interactions of organometallic fragments across C_n ligands is of fundamental interest, and the presented organometallic carbon chains are particularly suitable for such a study. The extent of the charge delocalization between the two metal centers and its effect on the bonding in the ligand in (mono)oxidized, formally mixed-valent complexes can be studied by a combination of analytical methods such as cyclic voltammetry, IR spectroscopy, and single-crystal structure analysis.

The electrochemically determined oxidation potentials of the binuclear complexes and their separation in energy as a function of the chain length and the type of organometallic fragment studied are important factors to know. A detailed investigation was made of the C_4 complex **8**, which according to cyclic voltammetry exhibits two one-electron oxidations at −0.675 and +0.045 V. The difference between the oxidation potentials (0.72 V) reveals a strong interaction along the chain between both metal centers in **8**. The radical cation of **8** was obtained in preparative quantities and a single-crystal structure analysis was carried out; **8** has a (crystallographic) inversion center, the C_4 bridge is slightly S-shaped and the C−C bonds with lengths of 1.24(1) and 1.36(1) Å predominantly retain their triple and single bond character, respectively. This somewhat unexpected result (strong electron delocalization without bond length equivalence) was supported by the IR spectroscopic data, which shows a shift of the C≡C stretching frequency to higher wavenumbers in comparison to **8**.

The oxidation product of **3**, $[\{Re\}-C\equiv C-C\equiv C-\{Re\}]^+$, described by Gladysz et al. also shows a strong electronic interaction ($E_1 = 0.11$, $E_2 = 0.64$ V, $\Delta E = 0.53$ V) between the metal centers; however, based on the IR data, for this cation a significant reduction of the bond order in comparison to that of the neutral compound must be concluded, which suggests substantial participation of the cumulene-like resonance formula $[\{Re\}=C=C=C=C=\{Re\}]^+$.

On going from **8** to the longer **11**, oxidations are now found to occur at −0.23 and +0.20 V; the difference between the oxidation potentials in **11** is 0.43 V, and thus almost twice the size as that for the rhenium analogue **5**. However, in **5**, just as in **11**, a significant shift of the C≡C stretching frequencies to lower wavenumbers occurs, which implies a significant participation of the cumulene-like resonance formula in the corresponding radical cations. Whereas **5** and **11** are similar, there are dramatic differences between **8** and **3** (see above) with regard to the bonding mode of the carbon chains that have not yet been fully explained (**A** vs. **B**).

On lengthening the carbon chain in the $\{Re\}-(C\equiv C)_n-\{Re\}$ system, the difference of the oxidation potentials ΔE between the metal centers determined by cyclic voltammetry becomes smaller (C_6: 0.38; C_8: 0.28; C_{16}: 0.1 V), and for the decayne **7** ($n = 10$) it is zero. The two Re centers in **7** are independent from each other, at least with regard to the redox properties, whereas the UV/Vis spectra still show a significant bathochromic shift of the longest wavelength maximum on transition from **6** (C_{16}) to **7** (C_{20}, 54 nm).

The synthesis and evaluation of the properties of these organometallic carbyne units will further help the elementary understanding of distance-dependent electronic interaction processes between metal centers. A study of various organometallic fragments and chain lengths such as, for example, in $(CO)_5Re-(C\equiv C)_n-Re(CO)_5$ is desirable for gaining systematic knowledge of these processes. Recent work by Lapinte et al.,[7d] in which the redox chemistry and physical properties of **9** were investigated extensively, is a step in this direction. The difference between the two oxidation potentials in **9** is 0.26 V, and is thus considerably smaller than in the geometrically similar compound **11**, in which the iron centers lie even further apart.

The following questions need to be answered: a) how large is the maximum interaction between two organometallic centers at a constant length of the C_n bridge that can be achieved by skillful manipulation of the metal fragments, and b) what is the effect of the use of other spacers (phenylene bridges, bicycles, etc.) on the difference between the oxidation potentials. In answering these questions it should be possible to distinguish between through-bond and through-space effects.

The synthesis of **7** and **11** by Gladysz et al. and Lapinte et al., respectively, has opened an area of research that in the near

future will go beyond the synthesis of these aesthetic compounds. The properties and reactions of even longer, naked carbon chains supported by organometallic fragments are eagerly awaited.

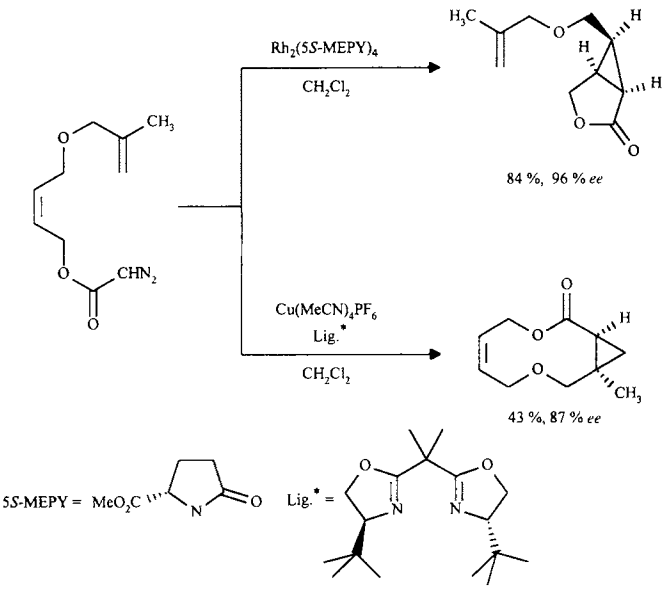
Recent Developments in the Enantioselective Syntheses of Cyclopropanes

Hans-Ulrich Reissig*

The hunt for strained molecules is maintained on the one hand by the competitive ambition to find the most unusual structures and on the other by the enormous synthetic potential of small-ring compounds. Following the general trend of recent years asymmetric syntheses are at the cutting edge of this research.[1] Despite all advances the synthesis of enantiomerically and diastereomerically pure cyclopropane derivatives remains a considerable challenge, especially when particular functional groups are required. The last two years have provided little that is fundamentally new to add to the very elegant procedures based on asymmetric catalysts.[2] In the main, reaction conditions and ligands were optimized, and the scope and limitations were investigated. Most exciting were the new examples from Doyle's group who reported on the enantioselective synthesis of macrocyclic lactones by means of intramolecular carbene additions.[3] Whereas the expected intramolecular cyclopropanation to a bicyclic γ-lactone was observed with a chiral rhodium(II)-MEPY catalyst with 96% *ee* (Scheme 1), with the Evans copper complex containing a bis(oxazoline) ligand the macrocyclic lactone was strongly favored (87% *ee*). Similar, or even higher, regio- and enantioselectivities with astonishingly high yields were also found in other examples. Thus there is now a new strategy, which will certainly find practical uses, for the enantioselective synthesis of macrocycles that are otherwise accessible only with difficulty.



Scheme 1.

Pfaltz's semicorrin copper complexes—a real breakthrough ten years ago—can also be employed for intramolecular [2+1]-cycloadditions (Scheme 2) and achieve between 14 and 95% *ee* depending on the substrate.[4] The related, otherwise very successful, bis(oxazoline) complexes[5] (see above) do not appear to be as effective here though only one example has been investigated.

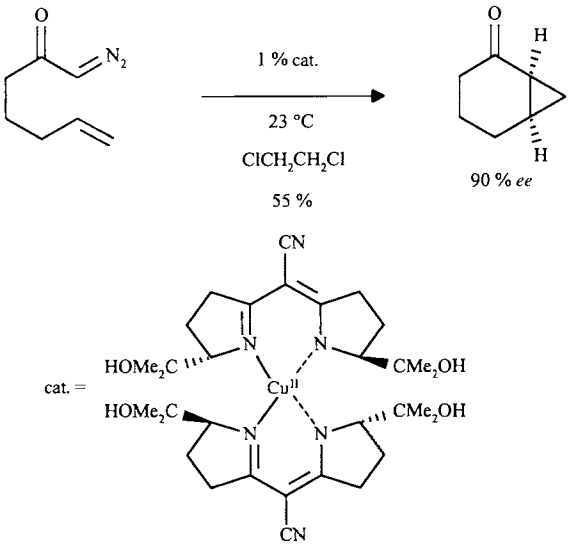
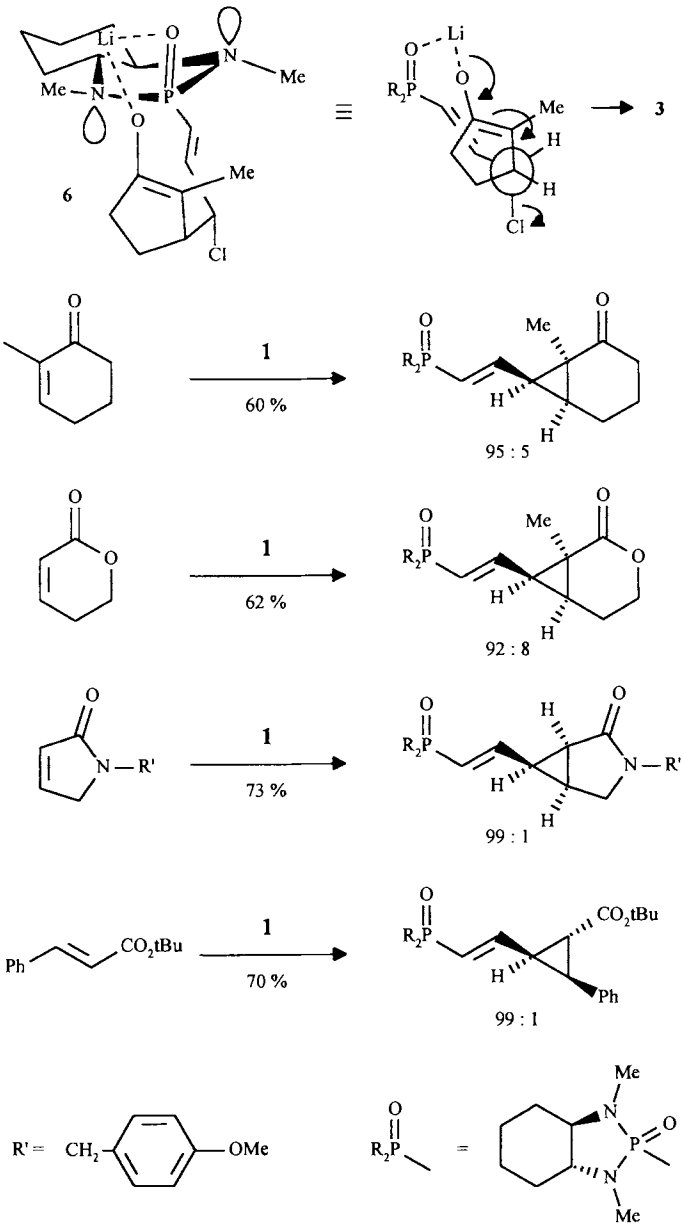


Scheme 2.

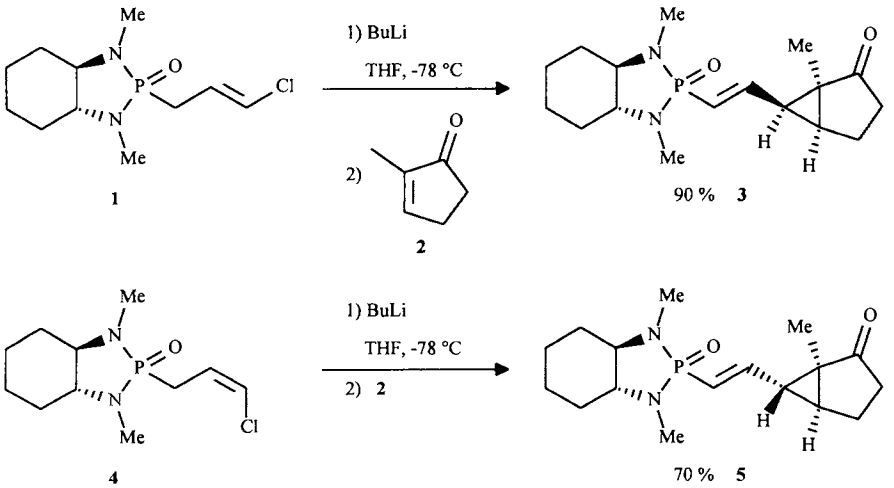
An optically active Co^{III}–salen complex was also employed for enantioselective cyclopropanation.[6] It can, however, be said that the ultimate catalyst system, which reliably delivers both high enantiomeric excess and good *cis/trans* selectivity, and which is also suitable for highly substituted and/or functionalized olefins is still a dream.

Advances, but no breakthroughs, can be seen in the several variants of the Simmons–Smith cyclopropanation.[7] Since enantioselective catalysis is developing only slowly—with respectable individual successes[8]—the auxiliary-controlled procedures are still superior.[9] In general, cyclopropane syntheses controlled by reagent-bound auxiliary groups offer a better guarantee of high enantiomeric purity than those using the more elegant asymmetric catalysts.

A beautiful new example, suitable for the synthesis of highly functionalized cyclopropane derivatives, was recently discovered by the Hanessian group.[10] Whereas in most auxiliary-controlled formal [2+1]cycloadditions[1] the auxiliary group is attached to the olefinic residue, here the chiral information is carried by a chloroallylphosphonic acid amide, such as **1**, which acts as a vinylcarbene equivalent. The reaction of the carbanion derived from **1** with α,β-unsaturated carbonyl compounds such



Scheme 3.

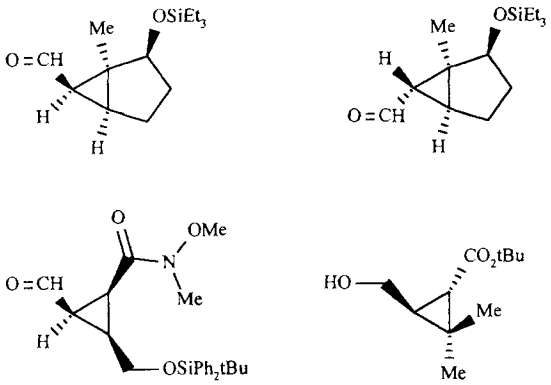


as **2** yields the diastereomerically pure bicyclo[3.1.0]hexanone derivative **3** as the *endo*-isomer (90% yield). By contrast, the reaction between the *cis*-chloroallyl derivative **4** and **2** yields the epimeric bicyclic product **5**. Mechanistically this cyclopropanation is easily understood as resulting from a Michael addition and an intramolecular S_N2 alkylation in which the intermediate **6** could account for the observed diastereoselectivity.

The method seems to be widely applicable as the examples with other cyclic enones, unsaturated lactones, lactams, and *tert*-butyl esters show (Scheme 3). The diastereoselectivities are at least 92:8 and usually much better.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3509-0972 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1996, 35, No. 9

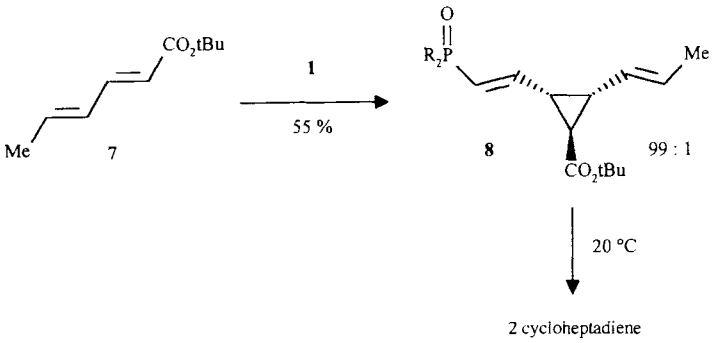
After reduction of the carbonyl group with sodium borohydride and protective silylation of the resulting hydroxy group, the auxiliary is removed by ozonolysis of the alkenylphosphonamide group. By this method, or other obvious sequences, the primary products are converted into a series of enantiomerically pure, interestingly functionalized cyclopropane derivatives (Scheme 4), which should find applications as synthetic building blocks.



Scheme 4.

Nevertheless, ozonolysis of the alkenyl substituents destroys some of the preparative potential of the primary products; as vinylpropanes they would be interesting for many other reactions, for example, for 1,3- and 3,3-sigmatropic rearrangements.[11] It can be inferred from the footnotes of the report[10] that a Cope rearrangement of the primary product **8**, derived from the hexadienoic acid ester **7** and **1**, does actually take place at room temperature with the formation of two isomeric cycloheptadiene derivatives. No details were given about the structure of these compounds. One of the most interesting applications of the method could be the synthesis of enantiomerically pure, highly functionalized cycloheptane derivatives, since divinylcyclopropanes should be obtainable by the appropriate rearrangement of other primary products.

The results described above represent only the classical developments of organic synthesis extended and perfected; however,



a recent publication on antibody-induced cyclopropanation could be the inauguration of what is, in principle, a new path to asymmetric cyclopropane formation (although the example is one with little preparative interest).[12]

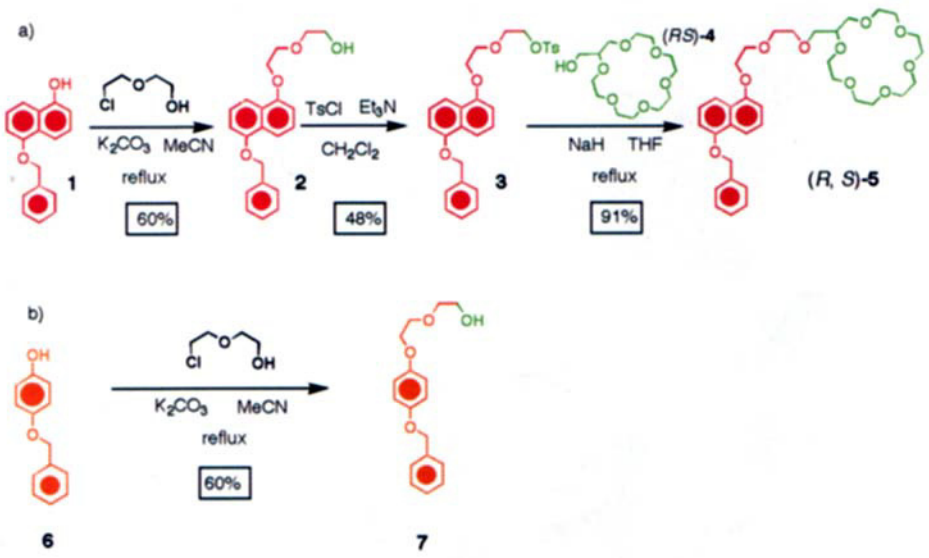
Prototype of an Optically Responsive Molecular Switch Based on Pseudorotaxane**

Masumi Asakawa, Sayeedha Iqbal, J. Fraser Stoddart,* and Nigel D. Tinker

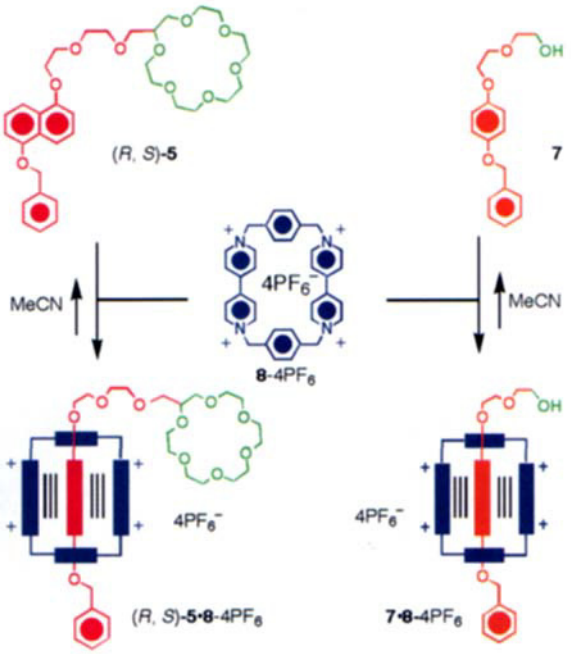
Supramolecular arrays in solution can often be constructed and controlled[1] by a combination of molecular recognition[2] and self-assembly[3] processes. Increasingly, the emphasis is on developing molecular systems that have technological applications in the fields of sensors,[4] devices,[5] and switches.[6] To this end, supramolecular chemistry[7] is playing an increasingly important role.

[2]Pseudorotaxanes[8] and [2]rotaxanes[9] can be assembled from cyclobis(paraquat-*p*-phenylene) as rings and 1,4-dioxy-substituted arenes as threads bearing macrocyclic polyethers at their termini. The [2]pseudorotaxanes can be readily disassembled by the addition of alkali metal cations. Here, we demonstrate how these [2]pseudorotaxanes can be used to produce an optical response on metal binding. The [18]crown-6 derivative (*R*,*S*)-**5**, containing a 1,5-dioxynaphthalene residue, can act (see Scheme 2) both as a host toward alkali metal cations and as a guest toward the tetracationic cyclophane $\mathbf{8}^{4+}$. The binding of (*R*,*S*)-**5** by $\mathbf{8}^{4+}$ can be reduced significantly by the addition of alkali metal cations, such as K^+ ions, which form complexes with [18]crown-6 derivatives.[10] In this manner, we can achieve the unthreading of the [2]pseudorotaxane (*R*,*S*)-**5**·**8**-4PF_6 by chemical means and, at the same time, encourage the self-assembly of the [2]pseudorotaxane **7**·**8**-4PF_6 lacking an [18]crown-6 stopper.

1-Benzyloxy-5-{2-(2-hydroxyethoxy)ethoxy}naphthalene (**2**) has been obtained[11] in 60% yield by the alkylation of 1-benzyloxy-5-hydroxynaphthalene[11] (**1**) with 2-(2-chloroethoxy)-ethanol under basic conditions (K_2CO_3/MeCN) (Scheme 1).[11]



Scheme 1. The synthesis of a) the [18]crown-6 derivative (*R*,*S*)-**5** containing a 1,5-dioxynaphthalene residue and b) the 1,4-dioxybenzene derivative **7**.



(*R*, *S*)-**5**·**8**-4PF_6	MeCN	**7**·**8**-4PF_6
purple	solution color	red/orange
530	λ_{max} / nm	475
910	K_a / M^{-1}	75
4.0	$-\Delta G°$ / kcal mol^{-1}	2.5

Scheme 2. Self-assembly of the [2]pseudorotaxanes **5**·**8**-4PF_6 and **7**·**8**-4PF_6 in MeCN.

The tosylation (TsCl/Et_3N/CH_2Cl_2) of the alcohol **2** afforded **3** (48%), which, with 1.2 molar equivalents of 2-hydroxymethyl-[18]crown-6 ((*R*,*S*)-**4**), gave the [18]crown-6 derivative (*R*,*S*)-**5** in excellent yield (91%). 1-Benzyloxy-4-{2-(2-hydroxyethoxy)ethoxy}benzene (**7**) was obtained[12] by the alkylation of 4-benzyloxyphenol (**6**) with 2-(2-chloroethoxy)ethanol under basic conditions (K_2CO_3/MeCN) in 40% yield.

UV spectrophotometric titrations monitoring the wavelength of the charge transfer (CT) band were employed[13] to evaluate the association constants K_a of the complexation of (*R*,*S*)-**5** and **7** with the tetracationic cyclophane **8**-4PF_6 in MeCN at 25 °C (Scheme 2). Mixing equimolar solutions of (*R*,*S*)-**5** and **8**-4PF_6 in MeCN results instantaneously in a deep purple color with the CT band at 530 nm, which indicates the formation of a [2]pseudorotaxane **5**·**8**-4PF_6. A K_a value of 910 M^{-1}, corresponding to a $-\Delta G°$ value of 4.0 kcal mol^{-1}, was obtained in MeCN at 25 °C with a UV titration method. Mixing equimolar MeCN solutions of **7** and **8**-4PF_6 results instantaneously in a red-orange color with the CT band centered at 475 nm, which indicates the formation of the [2]pseudorotaxane **7**·**8**-4PF_6.

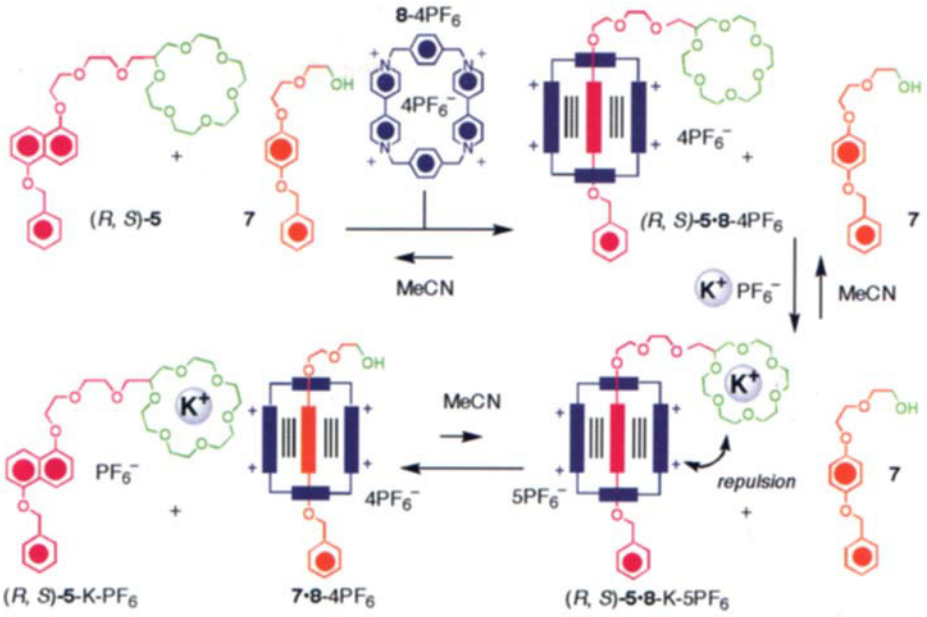
A K_a value of $75\,M^{-1}$, corresponding to a $-\Delta G^{\circ}$ value of 2.5 kcal mol^{-1}, was obtained in MeCN at 25 °C by a UV titration method. The [18]crown-6 derivative (*R*,*S*)-**5**, containing a 1,5-dioxynaphthalene residue, has a greater propensity to bind inside the charged cavity than the 1,4-dioxybenzene derivative **7**. The tetracationic cyclophane is sufficiently small that it cannot slip[14] over the [18]crown-6 polyether residue in (*R*,*S*)-**5**, and hence the formation of the [2]pseudorotaxane **5**·**8**-4PF$_6$ can only occur by the slippage of the tetracationic cyclophane over the benzyl group of (*R*,*S*)-**5**.

Mixing equimolar proportions of (*R*,*S*)-**5**, **7**, and **8**-4PF$_6$ in MeCN results in a deep purple color with the CT band at 518 nm (Fig. 1, trace B), indicating that the tetracationic cyclophane resides mainly around the naphthalene residue of (*R*,*S*)-**5** (Scheme 3). Trace A in Figure 1 corresponds to the CT band observed for the [2]pseudorotaxane (*R*,*S*)-**5**·**8**-4PF$_6$. Addition of 10 mol equivalents of KPF$_6$ to the equimolar solution of (*R*,*S*)-**5**, **7**, and **8**-4PF$_6$ solution in MeCN resulted in a CT at 475 nm (Fig. 1, trace C), and the purple color fades. This trace



Scheme 3. The proposed mode of action of a prototypical optically responsive molecular device.

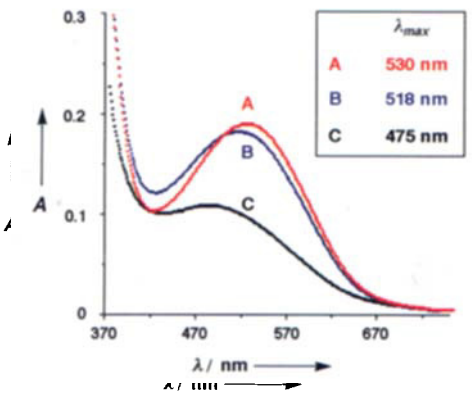


Fig. 1. UV Vis spectra showing the CT bands (concentration: 4.47×10^{-3} M in MeCN) of the[2]pseudorotaxane **5**·**8**-4PF$_6$ (A), an equimolar mixture of **5**, **7** and **8**-4PF$_6$ (B), and an equimolar mixture of **5**, **7** and **8**-4PF$_6$ upon addition of a tenfold excess of KPF$_6$ (C). *A* = absorption.

is almost identical to that found for the [2]pseudorotaxane **7**·**8**-4PF$_6$. Hence, the addition of K$^+$ ions to equimolar solutions of (*R*,*S*)-**5**, **7**, and **8**-4PF$_6$ in MeCN brings about a bathochromic shift of 43 nm.

Apparently, upon addition of an excess of KPF$_6$ to equimolar solutions of (*R*,*S*)-**5**, **7**, and **8**-4PF$_6$ in MeCN an unstable complex (*R*,*S*)-**5**·**8**-K-5PF$_6$ results (Scheme 3). Electrostatic repulsions between the bound K$^+$ ion within the [18]crown-6 terminus of the 1,5-dioxynaphthalene derivative (*R*,*S*)-**5** and the tetracationic cyclophane **8**-4PF$_6$ bring about the disassembly of the metalated complex (*R*,*S*)-**5**·**8**-K-5PF$_6$ to give the metalated derivative (*R*,*S*)-**5**-K-5PF$_6$ and the tetracationic cyclophane **8**-4PF$_6$, which forms the complex **7**·**8**-4PF$_6$ with the neutral 1,4-dioxybenzene derivative **7**. Thus a negative allosteric effect occurs in the complexation of the tetracationic cyclophane and the metal cation with the [18]crown-6 derivative (*R*,*S*)-**5** containing a naphthalene residue, that is, (*R*,*S*)-**5** can bind to either metal cations or the tetracationic cyclophane, but not to both at the same time. Very few cases[15] of negative allosteric effects have been reported.

We have shown that the alkali metal cation acts as a mediator for the negative allosteric effect, since it brings about the disassembly of the tetracationic cyclophane **8**-4PF$_6$ from (*R*,*S*)-**5**·**8**-4PF$_6$, thus enabling the formation of the [2]pseudorotaxane **7**·**8**-4PF$_6$. The net result is that a change in the absorption spectrum (that is, in the optical response) occurs upon addition of metal cations to equimolar solutions of (*R*,*S*)-**5**, **7**, and **8**-4PF$_6$ in MeCN. The development of these self-assembling systems could lead to functioning supramolecular entities that can be readily switched by chemical stimuli to give an optical response.

Experimental Procedure

(*R*,*S*)-**5**: (*R*,*S*)-**4** (64 mg, 0.22 mmol) in dry THF (20 mL) was added over a period of 20 min to a suspension of NaH (10 mg, 40 mmol) in dry THF (50 mL) under reflux. The reaction mixture was heated under reflux for a further 30 min, after which a solution of **3** (100 mg, 0.20 mmol) in dry THF (30 mL) was added over a period of 1 h. The reaction mixture was maintained under reflux for a further 24 h and then allowed to cool down to room temperature before H_2O (10 mL) was added to quench any residual NaH. The solution was then concentrated in vacuo to give a yellow oil, which was partitioned between CH_2Cl_2 and ice cold HCl (10% solution). The organic layer was separated, dried ($MgSO_4$), and concentrated in vacuo to yield a pale yellow oil (117 mg, 91%); FAB-MS: *m/z*: 637 $[M+Na]^+$, 614 $[M]^+$; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.95–7.88 (2H, 2 × d, *J* = 8 Hz), 7.58–7.54 (2H, d, *J* = 8 Hz), 7.48–7.88 (5H, m), 6.89–6.84 (2H, 2 × d, *J* = 8 Hz), 6.75 (2H, s), 4.38–4.32 (4H, m), 4.05–3.90 (2H, m), 3.82–3.78 (2H, m), 3.70–3.55 (23H, m); ^{13}C NMR (75 MHz, $CDCl_3$): δ = 128.6, 127.9, 127.4, 125.2, 114.7, 106.0, 105.8, 78.3, 71.6, 71.3, 71.0, 70.8, 70.6, 70.1, 69.8, 68.0.

(*R*,*S*)-**5**·**8**-4PF$_6$: Mixing equimolar solutions (6.69×10^{-3} M) of (*R*,*S*)-**5** and **8**-4PF$_6$ in MeCN results in the formation of the [2]pseudorotaxane (*R*,*S*)-**5**·**8**-4PF$_6$. FAB-MS: *m/z*: 1737 $[M+Na]^+$, 1592 $[M+Na-PF_6]^+$, 1569 $[M-PF_6]^+$, 1424 $[M-2PF_6]^+$; ^{1}H NMR (300 MHz, CD_3CN): δ = 8.82–8.76 (8H, d, *J* = 8 Hz), 7.90–7.68 (5H, m), 7.63 (8H, s), 7.63–7.58 (8H, d, *J* = 8 Hz), 6.75–6.40 (4H, m), 5.74 (8H, s), 5.20 (2H, s), 4.32–4.28 (2H, m), 4.15–1.11 (2H, m), 3.95–3.91 (2H, m), 3.82–3.88 (2H, m), 3.7–3.30 (25H, m).

7·**8**-4PF$_6$: Mixing equimolar solutions (6.69×10^{-3} M) of **7** and **8**-4PF$_6$ in MeCN results in the formation of the [2]pseudorotaxane **7**·**8**-4PF$_6$. ^{1}H NMR (300 MHz,

CD_3CN): δ = 8.82–8.76 (8H, d, J = 8 Hz), 7.90–7.68 (5H, m), 7.63 (8H, s), 7.63–7.58 (8H, d, J = 8 Hz), 5.74 (8H, s), 5.20 (2H, s), 4.32–4.28 (2H, m), 4.15–1.11 (2H, m), 3.95–3.91 (2H, m), 3.82–3.88 (2H, m).

The miniaturization of a "device" to the molecular level[1–5] is not only of academic interest, but can also contribute to the development of nanotechnology. Progress in constructing molecular devices may have important implications for biomimetic engineering,[6] molecular-based logic,[7] computer technologies,[8, 9] and a variety of sensory techniques.[10, 11] Molecular devices of particular interest are those displaying changes in the relative positions of their component parts – let us call them mechanical molecular machines[12–16]—as a result of the influence of some external stimulus. Here we describe the self-assembly of a novel pseudorotaxane and a very simple molecular machine, which operates by the chemically driven cyclic unthreading and rethreading processes. Pseudorotaxanes are supramolecular (multicomponent) complexes comprising at least one macrocyclic ring threaded by an acyclic component.[17] The [2]pseudorotaxane in this research is $\mathbf{1}^{2+}$ in Figure 1, obtained by self-assembly of the 2,7-dibenzyldiazoniapyrene dication $\mathbf{2}^{2+}$ with the crown ether **3** (Process I, Fig. 1).

When **2**-2PF_6 is added to a solution of **3** in MeCN, the electron-accepting dication $\mathbf{2}^{2+}$ threads itself spontaneously through the center of the macrocyclic ring **3**, which contains two 1,5-dioxynaphthalene electron-donating units. The [2]pseudorotaxane **1**-2PF_6 was characterized by mass spectrometry,[18] ^{1}H NMR spectroscopy, and X-ray crystallography.[19] The mass spectrum of **1**-2PF_6 indicates clearly the loss of one and two PF_6^- counterions from the [2]pseudorotaxane, giving rise to the $[M - PF_6]^+$ and $[M - 2PF_6]^+$ peaks at m/z 1167 and 1022, respectively. Comparison of the ^{1}H NMR spectra (Fig. 2) of the free salt **2**-2PF_6, the crown ether **3**, and the [2]pseudorotaxane **1**-2PF_6 indicates that all the protons undergo very substantial chemical shift changes ($\Delta\delta$ values of up to 0.70). X-ray crystallography reveals that $\mathbf{1}^{2+}$ crystallizes with two crystallographically independent C_i symmetric molecules in the asymmetric unit (Fig. 3). In both complexes, the π-electron-deficient diazoniapyrene component $\mathbf{2}^{2+}$ is sandwiched symmetrically between the π-electron-rich 1,5-dioxynaphthalene rings of **3** (mean interring plane separations 3.48 Å). The 1:1 complex is further stabi-

Ashton, Dr. N. Spencer, and Mr. M. S. Tolley for recording the mass spectra and ^{1}H NMR spectra of the different adducts.

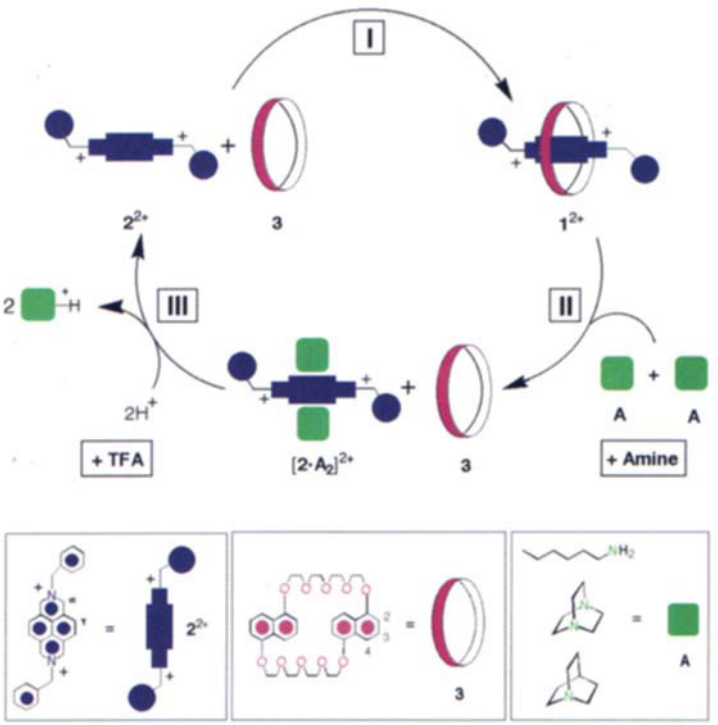

Fig. 1. Top: The chemically driven unthreading and rethreading of the [2]pseudorotaxane 1^{2+} in acetonitrile solution. Bottom: Schematic representations for the 2,7-diazoniapyrene dication 2^{2+}, the crown ether 1,5-dinaphtho-[38]crown-10 **3**, and the amines **A** (hexylamine, diazabicyclooctane (DABCO), and quinuclidine). Identification of the protons associated with 2^{2+} (Greek letters) and **3** (numbers) relate to the ^{1}H NMR assignments in Fig. 2.

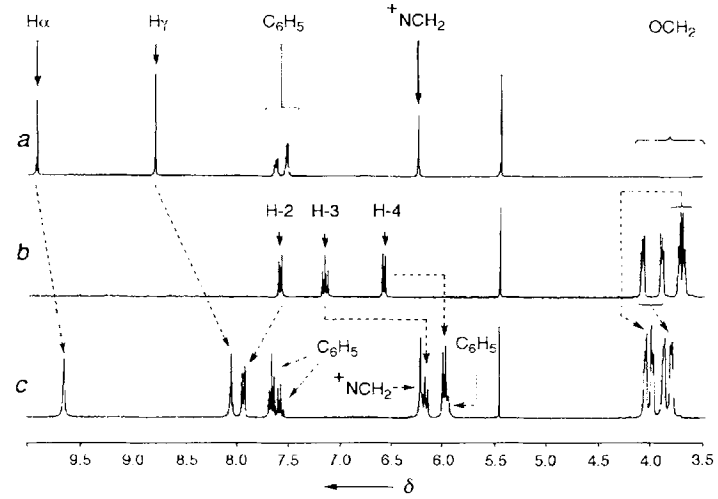

Fig. 2. 300 MHz ^{1}H NMR spectra of CD_3CN samples containing: a) 3.8 mM **2**-$2PF_6$; b) 5.2 mM **3**; and c) 3.8 mM **2**-$2PF_6$ + 3.8 mM **3**.

lized by pairs of C–H···O hydrogen bonds between one of each of the pairs of benzylic methylene protons of 2^{2+} and the central oxygen atoms of the polyether linkages in **3** (mean C···O, H···O distances, and C–H···O angles: 3.33 Å, 2.35 Å, and 176°, respectively). These hydrogen bonds are analogous to those present in the 1:1 complex formed between bis(*para*-phenylene)-[34]crown-10 (BPP34C10) and the 1,1′-dimethyl-4,4′-bipyridinium dication.[20, 21]

The absorption and emission spectra of the separated 2^{2+} and **3** components and [2]pseudorotaxane 1^{2+} are shown in Figures 4 and 5. The interaction between the π-electron donor and the π-electron acceptor leads to noticeable changes in both the

The 2,7-dibenzyldiazoniapyrene dication $\mathbf{2}^{2+}$ forms adducts with aliphatic amines, presumably as a result of a charge-transfer interaction between the electron-accepting[22] $\mathbf{2}^{2+}$ and the electron-donating amine and possibly also hydrogen bonding to the acidic protons at the α-positions in $\mathbf{2}^{2+}$. We have used a variety of amines, including 1,4-diazabicyclo[2.2.2]octane (DABCO), tributylamine, triethanolamine, quinuclidine, 1,6-diaminohexane, and hexylamine. The last one was chosen for further experiments since its adduct is reasonably stable in MeCN solution.

Formation of the adduct between hexylamine and $\mathbf{2}^{2+}$ causes the appearance of a broad CT absorption band (λ_{max} = 595 nm, $\varepsilon = 7000\,M^{-1}cm^{-1}$, trace c in Fig. 4) and a strong and broad emission band (Fig. 5). Titration of an MeCN solution of **2**-$2PF_6$ with hexylamine yielded a Job plot[23] showing the formation of a 2:1 adduct with an association constant (K_a) of the order of $10^8\,M^{-2}$. When the amine used is DABCO, the Job plot suggests that only a species with a 1:1 stoichiometry is formed.

The stability of complexes of the type $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ can be estimated from an experiment (Fig. 6) in which higher concentrations of the amine and the diazoniapyrene dication $\mathbf{2}^{2+}$ are used. When hexylamine **A** (4.4 equiv) is added to a solution of $\mathbf{2}^{2+}$ (5.1 mM) in CD_3CN, the solution turns dark green immediately. The ^1H NMR spectrum is not only considerably more complicated, indicating that several species are present in solution, but it also reveals a substantial loss in intensity of the arene signals. Addition of trifluoroacetic acid (TFA, 4.8 equiv) results in the loss of the intense green color, giving back the pale yellow solution. The spectrum acquired after this chemical transformation gives signals of the individual components $\mathbf{2}^{2+}$ and $\mathbf{HA}^+$ with no appreciable sign of degradation of either species. The cyclical nature of this overall transformation has been shown by repeating this experiment 50 times on the same sample without the appreciable loss of signals corresponding to $\mathbf{2}^{2+}$.

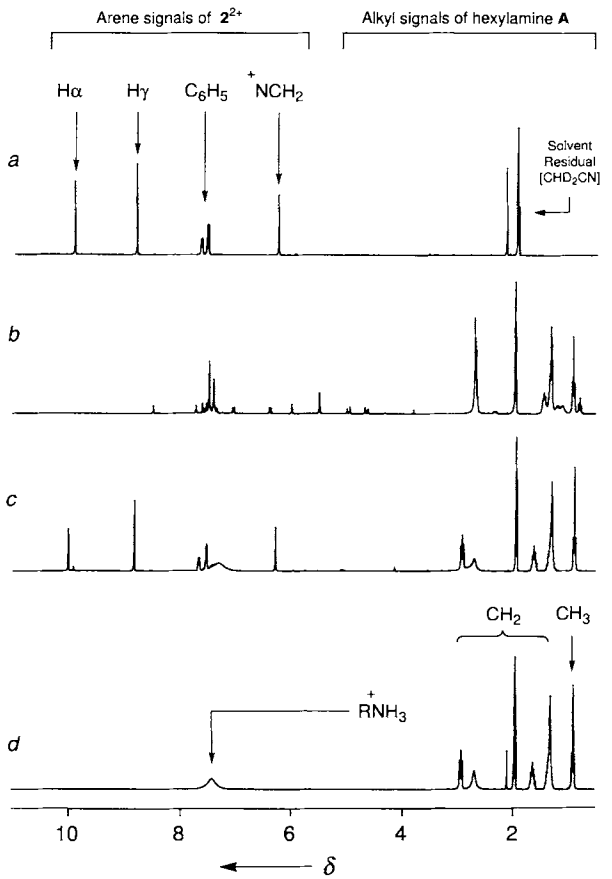

Fig. 6. 400 MHz ^1H NMR spectra of samples containing a) 5.1 mM **2**-$2PF_6$ in CD_3CN; b) after addition of 44 mL (4.4 equiv) of a 0.52 M solution of hexylamine **A** in CD_3CN to solution a); c) after subsequent addition of 64 mL (4.8 equiv) of a 0.37 M solution of TFA in CD_3CN to solution b; and d) addition of 64 mL (1.1 equiv) of a 0.37 M solution of TFA to 44 mL of a 0.52 M solution of hexylamine **A** in CD_3CN.

We have now taken advantage of the chemical affinity of aliphatic amines **A** for $\mathbf{2}^{2+}$ to unthread the component $\mathbf{2}^{2+}$ of the [2]pseudorotaxane $\mathbf{1}^{2+}$ (Process II in Fig. 1). Protonation of the amine disrupts the interactions between **A** and $\mathbf{2}^{2+}$ (Process III in Fig. 1), and so rethreading of $\mathbf{2}^{2+}$ by **3** can occur, making the whole process reversible. These chemically driven cyclic unthreading and rethreading processes exhibited by $\mathbf{1}^{2+}$ can be followed by absorption and emission spectroscopy.

In MeCN solutions containing **2**-$2PF_6$ and **3** (each 6×10^{-5} M), 80% of the species present at room temperature is the [2]pseudorotaxane $\mathbf{1}^{2+}$ (Process I in Fig. 1). Upon addition of hexylamine **A** large spectral changes take place (Figs. 4 and 5). In particular, one can observe a) the appearance of the CT absorption band of the $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ adduct, b) the recovery of the emission band of **3**, and c) the appearance of the emission band of $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$. A more detailed analysis of the absorption spectrum shows also the decrease in intensity of the CT absorption band of $\mathbf{1}^{2+}$. These changes indicate the occurrence of an unthreading process with the formation of the free crown ether **3** and of the adduct $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ (Process II in Fig. 1). After the addition of about 20 equivalents of **A**, no further spectral changes were observed. From the recovery of the luminescence of free crown ether **3** (λ_{max} = 345 nm, Fig. 5), one can estimate that at least 60% of the [2]pseudorotaxane $\mathbf{1}^{2+}$ undergoes unthreading. On the other hand, the increase in absorption due to the formation of $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ (λ_{max} = 595 nm, Fig. 4) indicates that at least 80% of $\mathbf{2}^{2+}$ is present as an amine adduct. The difference in the amount of free **3** and of $\mathbf{2}^{2+}$ complexed by the amine could indicate that a small amount of $\mathbf{1}^{2+}$ gives an amine adduct without unthreading.

The unthreading process can be reversed quantitatively by the addition of TFA to the solution (Process III in Fig. 1), as shown by a) the disappearance of the absorption and emission bands of $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$, b) the decrease of the emission intensity of **3**, and c) the reappearance of the CT absorption band of $\mathbf{1}^{2+}$. The fact that $\mathbf{1}^{2+}$, $\mathbf{2}^{2+}$, **3**, and $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ exhibit characteristic absorption spectra (Fig. 4), and $\mathbf{2}^{2+}$, **3**, and $[\mathbf{2}\text{-}\mathbf{A}_2]^{2+}$ are strongly emitting species (Fig. 5) allows us to follow the threading and unthreading processes in several independent ways. Although the threading/unthreading cycle shows a satisfactory chemical reversibility, its on/off switching response is not complete because, under the experimental conditions, the equilibrium (Process I in Fig. 1) is currently 80% displaced toward the [2]pseudorotaxane. We are striving, by changing the experimental conditions, to improve the efficiency of the system.

In conclusion, we have shown that the unthreading and rethreading of a [2]pseudorotaxane can be induced by chemical stimuli. The described system therefore represents a prototype at the supramolecular level for a simple molecular machine in which the changes in the relative positions of the components can be followed by readily monitorable differences in the absorption and luminescence spectra.

Experimental Procedure

2-$2PF_6$: 2,7-Diazoniapyrene [24] (75mg, 0.36 mmol) was dissolved in Me_2SO (10 mL) and benzyl bromide (2 mL) was added. The reaction mixture was stirred at 60 °C overnight. The product was then filtered and suspended in H_2O/Me_2CO (1/1, 20 mL). NH_4PF_6 (1 g) was added, and the mixture was stirred for 4 h, before being

Efficient Regio- and Enantioselective Mannich Reactions**

Dieter Enders,* David Ward, Johannes Adam, and Gerhard Raabe

The Mannich reaction,[1] in which an aminomethyl group is introduced in the α-position to a carbonyl function, has found a multitude of applications in organic chemistry.[2] The resulting Mannich bases are of particular interest due to their biological activity (for example, analgesic, antineoplastic, and antibiotic effects),[2] as bifunctional synthetic building blocks[2] and as precursors in the preparation of α,β-unsaturated carbonyl compounds[3] and γ-amino alcohols.[4] The introduction of separately prepared iminium salts,[5] and the use of silyl enol ethers,[6] boron enolates,[7] and enamines[8] has so extended the range of application of the reaction that regioselective aminomethylations can even be carried out in aprotic media in good yields.

While some authors have already reported on the stereoselective Mannich reaction,[9] very little is known about the enantioselective variants for the synthesis of β-amino ketones,[10] which is in sharp contrast to the plentitude of publications on its oxa analogue, the enantioselective Aldol reaction.[11] A practical procedure for highly enantioselective α-aminomethylation of ketones is, to the best of our knowledge, not yet available.

We now report an efficient, highly regio- and enantioselective synthesis of Mannich bases, starting from α-silyl ketones (*S*)-**1**, which are accessible by the SAMP/RAMP hydrazone method[12] in good yields (52–60%) and excellent enantioselectivities ($ee \geq 98\%$) (Table 1).

As illustrated in Scheme 1, the α-dimethylthexylsilyl ketones (*S*)-**1** (thexyl = 1,1,2-trimethylpropyl, abbreviated as *t*Hex in Scheme 1) are converted in quantitative yields to the (*Z*)-silyl enol ethers (*S*)-**2** ($Z:E \geq 50:1$) by treatment with lithium diisopropylamide (LDA) and chlorotrimethylsilane (TMSCl) in tetrahydrofuran/hexamethylphosphoric triamide (HMPA) at

[a] Overall yield (four steps) for the isolated α-silyl ketone starting from butanone. [b] Enantiomeric excesses were determined by gas chromatography of the corresponding alcohols by using a stationary phase consisting of β-cyclodextrin/polysiloxane. The alcohols were prepared by the reduction of the α-silyl ketones with $LiAlH_4$. [c] *p*-BrBn = *para*-bromobenzyl.

$-95\,^{\circ}C$. The formation of regioisomeric tetrasubstituted silyl enol ethers was never observed in these reactions. The high selectivity of the deprotonation to the (*Z*)-enolate in the presence of HMPA[13] is a prerequisite for a high asymmetric induction under the assumption that the bulky silyl group diastereofacially directs the introduction of the electrophilic aminomethyl group.

In previous work, the handling of the hygroscopic iminium salts was avoided by the in situ generation of the corresponding iminium ions or similar reactive species by the treatment of aminals or geminal amino ethers in the presence of Lewis acids.[7, 14] In the method described here, the alkylation of the crude silyl enol ether was carried out by reaction with dibenzylmethoxymethyl amine[15] and $BF_3 \cdot Et_2O$ in CH_2Cl_2. Aqueous workup and flash chromatography afforded the desired dibenzylaminomethyl ketones (*S*,*R*)-**3** in excellent yields (94–95%) and high diastereomeric excesses (*de* = 92 to ≥ 96%). The latter were determined by ^1H NMR spectroscopy (Table 2).

The silylated Mannich bases **3** are stable compounds, which show no tendency to epimerize or racemize and can be purified without difficulty by flash chromatography on silica gel. The use of a *tert*-butyldimethylsilyl group rather than the dimethylhexylsilyl group led to a decrease in the diastereoselectivity to as low as 81% in the case of (*S*)-**1a**, although the *Z*/*E* ratio was high and similar to that observed for (*S*)-**1a**.[16] The absolute configuration was determined by the X-ray crystal structure analysis of (*S*,*R*)-**3f** (Fig 1).[17]

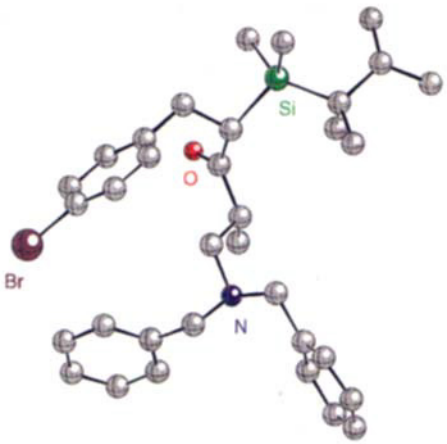

Fig. 1. X-ray crystal structure of (*S*,*R*)-**3f** (ball-and-stick model).

Table 2. α-Dimethylthexylsilyl-β-dibenzylamino ketones (*S*,*R*)-**3** prepared by aminomethylation of the silyl enol ethers (*S*)-**2**.

3	R	Yield [%]	$[\alpha]_D^{20}$ [*c*, benzene]	*de* [a] [%]
(*S*)-**3a**	Me	95	+150.1 (0.4)	92 (≥ 96 [b])
(*S*)-**3b**	Et	95	−113.7 (0.6)	≥ 96
(*S*)-**3c**	*n*Pr	95	−97.6 (0.6)	≥ 96
(*S*)-**3d**	*i*Bu	94	−71.6 (0.5)	≥ 96
(*S*)-**3e**	Bn	94	−80.6 (0.9)	≥ 96
(*S*)-**3f**	*p*-BrBn [c]	95	−32.1 (1.0)	≥ 96

[a] Determined by ^1H NMR spectroscopy (300 MHz). [b] After flash chromatography. [c] *p*-BrBn = *para*-bromobenzyl.

The α-silyl group can be removed readily at room temperature by treatment with nBu_4NF in THF, since the intermediate carbanion is stabilized as an enolate. However, this desilylation is accompanied by an almost complete racemization, the cause of which lies in the formation of basic nBu_4NOH. This problem was solved by the addition of solid NH_4F as a buffer and by carrying out the reaction at low temperatures to control the rate of formation of the base. The enantiomeric excesses (*ee* = 91–97%) of the optically active β-amino ketones (*R*)-**4** thus formed were determined by ^1H NMR spectroscopy (500 MHz) using the chiral cosolvent (*R*)-(−)-9-anthryl-2,2,2-trifluoroethanol (Table 3).

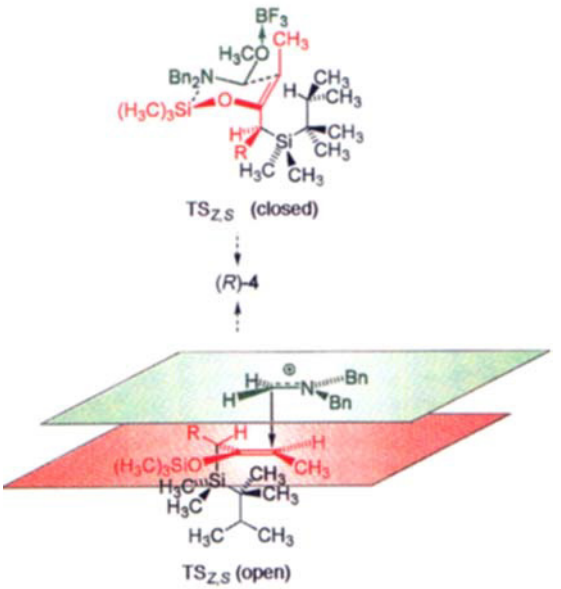
To explain the almost complete diasterofacial selectivity in the formation of (*S*,*R*)-**3**, two transition states can be discussed: On the one hand a cyclic transition state along the lines of the Zimmerman–Traxler model [$TS_{Z,S}$ (closed)][20] can be envis-

Table 3. β-Dibenzylamino ketones (*R*)-**4**, prepared by desilylation of the ketones (*S*,*R*)-**3**.

4	R	Yield [%]	$[\alpha]_D^{20}$ [*c*, benzene]	*ee* [a] [%]
(*R*)-**4a**	Me	96	−8.3 (0.6)	91
(*R*)-**4b**	Et	97	−2.5 (0.7)	93
(*R*)-**4c**	*n*Pr	98	−1.2 (0.5)	93
(*R*)-**4d**	*i*Bu	99	−2.2 (0.4)	94
(*R*)-**4e**	Bn	97	+7.2 (1.1)	97
(*R*)-**4f**	*p*-BrBn [b]	98	+9.7 (0.6)	93

[a] Determined by ^1H NMR spectroscopy (500 MHz) using a solution of (*R*)-**4** (3 mg) and (*R*)-(−)-9-anthryl-2,2,2-trifluoroethanol (10 mg) as chiral cosolvent in C_6D_6 (0.7 mL). [b] *p*-BrBn = *para*-bromobenzyl.

aged, while on the other an open transition state [$TS_{Z,S}$ (open)][21] can also be considered. In both cases the diastereoselectivity is caused by shielding of the Si-side by the bulky dimethylthexylsilyl group. The models lead, via (*S*,*R*)-**3**, to the Mannich bases **4** with *R* configuration at the newly generated stereogenic center (Scheme 2).



Scheme 2. Postulated transition states for the asymmetric Mannich reaction.

To summarize, it has been shown that Mannich bases can be prepared regioselectively in high enantiomeric purity and excellent overall yield by the procedure detailed here. To the best of our knowledge, this procedure is the first practical, generally applicable asymmetric Mannich reaction for the preparation of β-amino ketones. The extension of the method leading to the generation of two new stereogenic centers in the α- and β-positions is currently the object of intensive investigations.[22]

Experimental Procedure

α-Dimethylthexylsilyl ketone (*S*)-**1**: (*S*)-**1** was prepared by successive silylation and alkylation of butanone-SAMP hydrazone with chlorodimethylthexylsilane and an appropriate alkyl iodide or bromide [12].

Silyl enol ether (*S*)-**2**: A solution of LDA (1.1 mmol) in THF (10 mL, freshly prepared from *n*BuLi (0.7 mL of a 1.6 N solution) and diisopropylamine (0.15 mL) was treated with HMPA (2.5 mL) and cooled to −95 °C. To this vigorously stirred solution, a solution of (*S*)-**2** (1 mmol) in THF (1 mL) was added dropwise over a period of 5 min. Finally, TMSCl (1.2 mmol) was added in one portion. After 30 min the reaction mixture was treated with saturated aqueous $NaHCO_3$ solution (10 mL). The product was extracted with *n*-pentane (60 mL), dried over $MgSO_4$, and the solvent removed on a rotary evaporator under reduced pressure. The crude product was immediately used in the next step without further purification.

α-Dimethylthexylsilyl-α′-dibenzylaminomethyl ketone (*S*,*R*)-**3**: Dibenzylmethoxymethylamine (1.15 mmol) [15] was added to CH_2Cl_2 (10 mL) and cooled to −95 °C. The crude product (*S*)-**2**, diluted with CH_2Cl_2 (2 mL) was added dropwise to this solution. After the addition of $BF_3 \cdot Et_2O$ (1.15 mmol), the reaction mixture was allowed to warm to −70 °C. All conversions were complete within 3 h (TLC control). The reaction mixture was worked up by treatment with pH 7 buffer (5 mL), followed by extraction with CH_2Cl_2 (60 mL), drying over Na_2SO_4, removal of solvent on a rotary evaporator under reduced pressure, and flash chromatography (silica gel, diethyl ether/*n*-pentane 1:10).

α-Dibenzylaminomethyl ketone (*R*)-**4**: To a cooled (−70 °C) solution of (*S*,*R*)-**3** (1 mmol) in THF (50 mL) were added sequentially solid NH_4F (1.85 g, 50 mmol) and nBu_4NF (1.2 mL, 1 N solution in THF; 1.2 mmol). The reaction mixture was allowed to warm to room temperature, after which time pH 6 buffer (10 mL) was added and the product extracted with *n*-pentane (90 mL). After the product had been dried over Na_2SO_4, it was purified by flash chromatography (silica gel, diethyl ether/*n*-pentane 1:20).

Correct elemental analyses and satisfactory spectroscopic (NMR, IR) and spectrometric (MS) data were obtained for all new compounds.

[17] Suitable single crystals were obtained by crystallization from methanol at room temperature. The substance crystallizes in the monoclinic space group $P2_1$ (no. 4) with $a = 6.644(6)$, $b = 24.243(2)$, $c = 10.688(1)$ Å and $\beta = 104.0(2)$. With a cell volume of 1670.5 Å^3, $z = 2$ and $M_{calcd} = 592.8$, the density is 1.178 g cm^{-3}. Total number of electrons per unit cell is 632. Enraf-Nonius CAD4-four-circle diffractometer, $Mo_{K\alpha}$ radiation (graphite monochromator, $\lambda = 0.71069$ Å). The structure was solved by using SHELXS86 [18] and refined with XTAL3.2 [19]. The positions of the hydrogen atoms were calculated. 3248 observed reflections [$I > 2\sigma(I)$], 343 parameters refined against F, $R = 0.061$ ($Rw = 0.035$). Maximum residual electron density ± 0.6 e A^{-3}. The absolute configuration of the newly formed stereogenic center in the α-position was determined on the basis of the known configuration in the α'-position. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-11. Fig. 1. Top: Crystal structure of $Ba_4Li_2Si_6$ with the weakly twisted Si_6 rings in the heterographite net $^2_\infty(Li_2Si_6)^{8-}$. The Ba atoms form slightly distorted trigonal prisms. $Ba_4Li_2Ge_6$ also crystallizes in this structure. Bottom: Projection of the $Ba_{10}Ge_7O_3$ crystal structure on its hexagonal base. In this structure, the Ge_6^{10-} anion is planar. The position Ge2 (Ge^{4-}) is statistically only half-filled; thus the O atoms are placed on either one of the two alternative positions (open circles).

Hückel Arenes with Ten π Electrons: Cyclic Zintl Anions Si_6^{10-} and Ge_6^{10-}, Isosteric to P_6^{4-} and As_6^{4-}

Hans Georg von Schnering,* Urs Bolle, Jan Curda, Karl Peters, Wilder Carrillo-Cabrera, Mehmet Somer, Martin Schultheiss, and Ulrich Wedig

Our investigations on the completely intercalated heterographite LiBC ($\cong Li^+ + (BC)^-$)[1] have revealed that very few compounds of this structure type and its derivatives do not meet the valence electron concentration (VEC) of 4 for the heterographite nets $^2_\infty(BC)^-$. A striking example is BaLiSi ($\cong Ba^{2+} + (LiSi)^{2-}$) with a VEC of 3.5.[2] Initially, this phase was described by Gladishevskij[3] as a hexagonal modification of $BaSi_2$, which with a VEC of 5 would fit even less in this family of structures. However, Axel et al.[2] showed later that this modification cannot be prepared from the elements barium and silicon, but that the compound BaLiSi is formed instead by reaction with molten LiCl. It is even more amazing that the recent edition of "Pearson's Handbook"[4] only mentions hexagonal $BaSi_2$! In the present communication we will show that the actual composition of the ternary silicide is $Ba_4Li_2Si_6$ and that an isotypic germanide, $Ba_4Li_2Ge_6$, exists as well.[5, 6] Both compounds form a stuffed derivative of the orthorhombic β-K_4P_6 structure[7] (Fig. 1, top) with complete and ordered heterographite nets $^2_\infty(Li_2Si_6)^{8-}$ and $^2_\infty(Li_2Ge_6)^{8-}$, respectively, but with a VEC of 4.25. The atoms of these nets center the trigonal Ba_6 prisms. The most remarkable structural features are isometric Si_6^{10-} and Ge_6^{10-} rings with 34 valence electrons, isosteric to P_6^{4-} and As_6^{4-},[7, 8], respectively. Both compounds are narrow-band semiconductors ($E_g \approx 80$ meV) and reveal a weak van Vleck paramagnetism.

Systematic investigations into the formation of clathrates in the Na/Ba/Ge ternary system led to the discovery of the new, unusual germanium oxide $Ba_{10}Ge_7O_3$, which formally can be considered as an oxidation product of a barium germanide. This compound was initially discovered as a byproduct in reaction mixtures accidently contaminated with traces of oxygen or moisture. However, it can be prepared in bulk by thermal decomposition of NaGe in the presence of the required amounts of BaO and Ba.[9] In the hexagonal crystal structure (Fig. 1, bottom) Ba atoms form a framework of linked monocapped trigonal prisms and tetragonal bipyramids. These polyhedra are centered either with isolated Ge atoms, with O atoms, or with Ge atoms that belong to six-membered Ge rings.[10] The electron count fulfills the Zintl–Klemm concept with the formal charge distribution according to Ba^{2+}, O^{2-}, Ge^{4-}, Ge_6^{10-}—the latter again reveals a cyclic system with 34 electrons.

In $Ba_4Li_2Si_6$ and $Ba_4Li_2Ge_6$ the six-membered rings are slightly puckered (boat conformation, torsion angle $\pm 4^\circ$, see Fig. 2) like the P_6^{4-} anion in β-K_4P_6.[7] The bond lengths are d(Si–Si) = 238.2 pm (6×) and d(Ge–Ge) = 250.8 pm (2×) and 252.0 pm (4×), whereas the endocyclic bond angles are identical within the standard deviations (119.8–119.9°). The X_6 rings are linked by Li atoms to form a heterographite net (d(Li–Si) = 266–269 pm; d(Li–Ge) = 260–266 pm). The hexagonal AlB_2 type as the assumed structure for $BaSi_2$[3] and BaLiSi[2] is still the prevailing substructure of $Ba_4Li_2Si_6$, and therefore strongly dominates the intensities of the diffraction pattern: $a = 2\,a_{hex}$, $b \cong 2\sqrt{3}\,a_{hex}$, $c = 4\,c_{hex}$. The bond lengths in such a substructure would be d(Si–Si) = d(Li–Si) = 252.4 pm and d(Ge–Ge) = d(Li–Ge) = 257.4 pm, and the shorter homoatomic bond lengths in the real structure of these compounds are thus not a stringent consequence of the crystal structure (d(Ba–Ba) = 436–483 pm, d(Ba–Si) = 340–356 pm. d(Ba–Ge) = 348–358 pm, d(Ba–Li) = 350–360 pm).

Unlike in $Ba_4Li_2Ge_6$, the Ge rings in $Ba_{10}Ge_7O_3$ are planar with significantly shorter Ge–Ge bond lengths (247.5 pm). Due to the simple hexagonal stacking, the 6/*mmm* point symmetry remains in this structure. The Ba–Ge interatomic distances are 337.6 (1×), 355.2 (2×), and 375.3 pm (6×) for the Ge ring atoms and 337.8 (3×) and 357.3 pm (6×) for isolated Ge atoms. The O atoms inside the compressed tetragonal bipyramids are shifted out of their central position towards two alternative neighboring positions, whose occupation is evidently coupled with the order at the statistically half-filled positions of the Ge^{4-} anions. This leads to a distorted tetrahedral (2+2) coordination for the O atoms with Ba–O bond lengths of 257 (2×) and 279 pm (2×).

Bonding within the 34-electron system, for example in the Si_6^{10-} anion, can be elucidated in terms of the Hückel formalism: 24 electrons form six σ bonds and six *n* electron pairs. The remaining ten electrons contribute to the π system and fill three bonding and two antibonding MOs. A more comprehensive approach to analyzing the chemical bonding is the electron localization function (ELF) proposed by Becke and Edgecombe.[11, 12] Based on the total wavefunction of a system, the ELF is a measure of the local effect of the Pauli principle within a fermion system. ELF values fall in the range between 0 and 1. Large ELF values indicate covalent bonds, *n* electron pairs, and core shells.[12]

Within the three-dimensional ELF grid of $Ba_4Li_2Si_6$, the covalent Si–Si bonds, the *n* electron pairs of the Si atoms, and the 1s shells of the Li atoms are denoted by white areas in a two-dimensional section along the mean plane of the six-membered ring, as represented in the isosurface plot of ELF = 0.68 on the left side of Figure 2. This clearly reveals the interaction between the Li and Si atoms. The ELF maxima (attractors) above and below the Si atoms are shifted towards the coplanar Li atoms and therefore indicate a polarization towards the Li atoms. As shown by the dark blue areas between the Li and Si atoms (Fig. 2), there is a distinct separation between the core and the valence regions. The *n* electron pairs of the Si atoms are polarized perpendicular to the ring plane, an effect which is obviously caused by the influence of the Li atoms in heterographite layers next to the ring (Fig. 1). This effect is presumably also responsible for the weak torsion of the six-membered rings because the crystal field symmetry at the Si_6 rings of $Ba_4Li_2Si_6$ is reduced to the point group 222-D_2. The fairly uncommon participation of the *n* electron pairs in the bond region in the Si_6 ring might lead to strong electron fluctuation between the *n* electron pairs and the covalent bonds. Quite instructive is the weighting of the electron density ρ by the ELF, as depicted on the right side of Figure 2, in which two valence electron density isosurfaces ($\rho = 0.05$, $\rho = 0.064$ e au^{-3}) are colored according to the corresponding ELF. It is apparent that the high ELF values of the Si–Si bond are associated with the larger ρ values, whereas the high ELF values of the much more diffuse *n* electron pairs are associated with the significantly smaller ρ values.

The isolated Si_6^{10-} anion can be treated formally as an aromatic system, as indicated in particular by the noncyclindrical symmetry of the ELF distribution along the Si–Si bonds. Unlike isolated unsaturated C–C bonds (e.g. like in ethene), which exhibit two ELF maxima (attractors), one above and one below the plane, the Si_6^{10-} ring, like benzene,[13] does not show this feature.

The X_6^{n-} polyanion with 34 valence electrons, which is analogous to cyclohexene, appears to be particularly stable in Zintl phases containing very electropositive metals. Thus, K_4P_6,

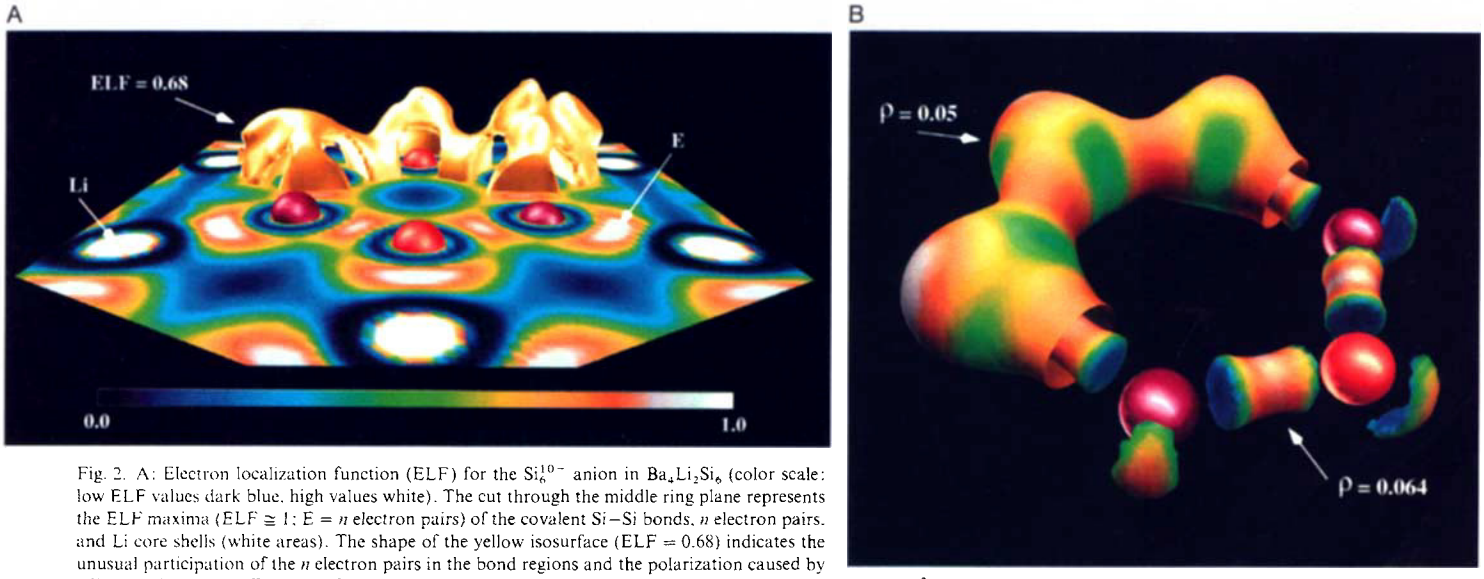

Fig. 2. A: Electron localization function (ELF) for the Si_6^{10-} anion in $Ba_4Li_2Si_6$ (color scale: low ELF values dark blue, high values white). The cut through the middle ring plane represents the ELF maxima (ELF ≅ 1; E = *n* electron pairs) of the covalent Si–Si bonds, *n* electron pairs, and Li core shells (white areas). The shape of the yellow isosurface (ELF = 0.68) indicates the unusual participation of the *n* electron pairs in the bond regions and the polarization caused by adjacent Li atoms. B: Two isosurface representations of the valence electron density ρ (0.05 and 0.064 e au^{-3}) tinted according to the corresponding ELF values (color scale in A). The regions of high ELF values of the diffuse *n* electron pairs lie at lower ρ values than those of the bonds. The Si atoms are in different colors to distinguish the different crystallographic positions.

Rb_4P_6, Cs_4P_6, and Rb_4As_6 are the only stable phases in the corresponding binary systems in which homonuclear polyanions form multiple bonds (the P–P bond length in the three hexaphosphides is 215 pm as opposed to 221 pm for a P–P single bond[7]). This stabilization effect can also be seen in the formation of $Ba_4Li_2Si_6$ and $Ba_{10}Ge_7O_3$ even under very unfavorable conditions: the former in the synthesis of $BaSi_2$ from LiCl fluxes,[3] and the latter as a byproduct in the reactions of oxygen-contaminated starting materials.[9] In this context, the existence of the radical anion P_3^{4-} (analogous to the ozonide anion) is even more remarkable. This anion occurs in the thermally unstable phase K_4P_3,[14] and can be obtained formally by cleaving a P_6^{4-} ring with four additional electrons. Thus, it appears that for the heavier group 14 and 15 elements 10 π electron Hückel arenes such as X_6^{n-} are an alternative to the formation of discrete double bonds.

Thus, it would be worthwhile to reinvestigate thoroughly all of those phases containing graphite or heterographite nets, in which the atoms of the anionic 6^3-net show VEC $\neq 4$.[15] Evidently, the formation of metallic phases can be avoided in a simple manner by variation of the stoichiometric ratio of these atoms or by formation of vacancies: $[Li_2Si_6]^{8-}$ instead of $[Li_4Si_6]^{8-}$; $[\square_2P_6]^{4-}$ instead of $[P_8]^{4-}$. $Al_4\square_2B_6$ instead of AlB_2, for instance, would be a variant containing benzene-analogous anions B_6^{12-} (6 π-electron Hückel arenes).

[15] Since the submission of this communication $Sr_4Li_2Si_6$ has been prepared. The compound also forms orthorhombic crystals ($a = 852.5(1)$, $b = 1481.2(2)$, $c = 1816(2)$ pm, space group *Fddd*) [16]. We are convinced that it is identical to the phase described by Müller et al. [17], $Sr_7Li_4Si_{10} \cong Sr_{4.2}Li_{2.4}Si_6 \approx Sr_4Li_2Si_6$, which was assumed to adopt the AlB_2 structure type with a statistical distribution of Li and Si.

Molecular, Shell-Like Dilithium (Silyl)phosphanediide and Dilithium (Silyl)arsanediide Aggregates with an $[Li_6O]^{4+}$ Core**

Matthias Driess,* Hans Pritzkow, Stefan Martin, Stefan Rell, Dieter Fenske, and Gerhard Baum

Dedicated to Professor Kurt Dehnicke on the occasion of his 65th birthday

Dilithium derivatives of primary amines, phosphanes, and arsanes of the type $[RELi_2]_n$ (R = alkyl, aryl, silyl; E = N, P, As), which are useful nucleophilic building blocks in the element organic chemistry of nitrogen, phosphorus, and arsenic, are molecular aggregates and structurally represent an intermediate between the molecular compounds R_3E and the typical saltlike solid-state compounds Li_3E (lithium pnictides). Their structures, however, have not been well established or are not known, since these compounds have only been obtained as insoluble, X-ray amorphous solids.[1] Recently the decameric dilithium (α-naphthyl) azanediide **1**[2] and the dimeric dilithium phosphanediide-fluorosilane adduct **2**,[3] which are soluble in ether and aromatic solvents, were structurally characterized.

$[(RNLi_2)_{10}(Et_2O)_6] \cdot Et_2O$ $\quad$ $RPLi_2 \cdot 2RF$

1, R = α-$C_{10}H_7$ $\quad$ **2**, R = $SiiPr_2(2,4,6\text{-}iPr_3C_6H_2)$

We have been investigating the synthesis and structure of the dilithium (silyl)phosphanediides and arsanediides **3** which form a spherical cluster framework and are soluble as a result of their easily variable lipophilic shell.[3] Since the degree of aggregation

$[\{R_3SiELi_2\}_n]$ **3**, E = P, As; R = alkyl, aryl

[**] This work was supported by the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Polyedermoleküle") and the Fonds der Chemischen Industrie.

is largely determined by the steric bulk of the triorganosilyl group, we were interested in the reactivity of **3** as a function of cluster size. We have now observed that the double lithiation of the primary silylphosphane **4** and silylarsane **6** in the presence of Li_2O results in the octameric and dodecameric aggregates **5** and **7**, respectively. Surprisingly the cavities of these compounds are filled with an octahedral $[Li_6O]^{4+}$ cluster framework. The compositions of the aggregates have been confirmed by correct elemental analyses.

Compound **5** is formed by the lithiation of **4** with two equivalents of *n*BuLi in the presence of Li_2O in toluene or Et_2O and can be isolated in 69% yield as light yellow crystals. The origin of the incorporated Li_2O has not yet been explained. Since **5** can also be produced in toluene, the hydrolysis product in commercial *n*BuLi solutions, LiOH, could be the potential source for O^{2-}. We have evidence that other Li_2O-free aggregates are formed upon rigorous exclusion of $LiOH/Li_2O$.

$$\underset{\mathbf{4}}{8\,RPH_2} \xrightarrow[-16\,C_4H_{10}]{16\,n\text{BuLi}\,Li_2O} \underset{\mathbf{5}}{[(RP)_8Li_{18}O]}$$

R = *i*Pr$_2$(Mes)Si

$$\underset{\mathbf{6}}{12\,RAsH_2} \xrightarrow[-24\,C_4H_{10}]{24\,n\text{BuLi}\,Li_2O} \underset{\mathbf{7}}{[(RAs)_{12}Li_{26}O]}$$

R = Me$_2$(*i*PrMe$_2$C)Si

A crystal structure analysis of **5**[4] revealed the presence of an aggregate with approximately 422 symmetry (Fig. 1); only the fourfold axis is required crystallographically. The twofold axes

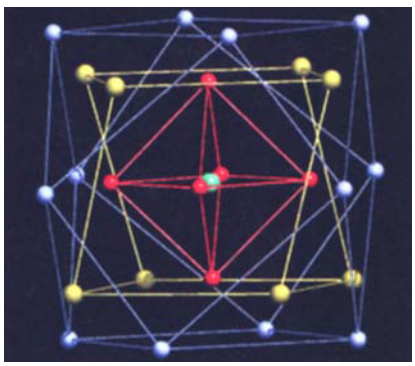

Fig. 1. Representation of the shell-like form of **5** in the crystal. For clarity the silyl groups have been omitted. OLi_6 shell = green, red, P_8 shell = yellow, Li_{12} shell = blue. Selected distances [Å]: Si–P 2.195(2), Li–P 2.39–2.46(1) for outer Li atoms, 2.56(1), 2.58(1) for inner equatorial Li atoms, 2.91(1), 2.93(1) for inner apical Li atoms, Li–O 1.81–1.90(2).

run parallel to *a* and *b* and provide pseudo symmetry. The cluster has eight formal units of dilithium phosphanediide and a Li_2O molecule. The cationic (Li centers) and anionic (P and O centers) building blocks show close packing. The structure is topologically best described as an ionogenic cluster formed by three closed shells and covered by the lipophilic silyl groups (Fig. 1). The eight P atoms comprise a strongly distorted cube, which is surrounded by a Li_{12} cuboctahedral shell and surrounds a Li_6O octahedron.

The Li centers of the Li_{12} shell each sit over an edge of the P_8 cube, whereas the Li centers of the Li_6O cluster are each located over a face. This P_8 partial structure is evidently preferred to the anti-prismatic or the bisdisphenoid ordering which are possible alternatives. An important aspect of this cluster formation is that only twelve of the total sixteen Li centers are placed on the exterior, that is on the edges, of the P_8 framework; thus, the remaining Li ions must be placed in the cavity. These four Li ions are electronically stabilized by binding to the formal O^{2-} ion of Li_2O, thus resulting in a $[Li_6O]^{4+}$ cluster. Sixfold coordination of O^{2-} by metal cations in *molecular* compounds is very unusual and has as yet only been observed in a dilithiomethane–Li_2O aggregate[5] and in a mixed lithium-barium-(*tert*-butoxide)-oxide aggregate.[6]

The Li–P distances to the external Li centers are very similar and lie in the range of 2.39–2.46(1) Å; the Li–P distances for the internal Li centers are 2.56 and 2.58(1), as well as 2.91 and 2.93(1) Å; that is, they correspond with the values observed for lithium phosphanides.[7] The Li–Li distances in the Li_{12} cuboctahedron are longer than 3 Å, and those in the Li_6O framework are significantly shorter (2.63–2.67(2) Å). It has not yet been clarified if these relatively short distances imply bonding interactions, whereas the P–P distances (>4 Å) clearly show that there are no P–P bonds present. The Li–O distances in the $[Li_6O]^{4+}$ aggregate (1.81–1.90(2) Å) are significantly shorter than in solid Li_2O (1.98 Å). In addition, the Li centers of the $[Li_6O]^{4+}$ aggregate are each coordinated by four P atoms.

The filled cluster shows a slight tendency to dissociate in solution. Cryoscopic investigations provided a degree of aggregation of $n \approx 7.7$. Crystals dissolved in benzene show three broad signals ($\nu_{1/2} = 70$–85 Hz) in the ^{31}P NMR spectrum at $\delta = -336.9$, -340.1, and -355.9 in an intensity ratio of 15:15:1. The main signals were assigned to the two different P atoms on the intact cluster, while the remaining weak signal is presumably due to an unknown dissociate. The ^7Li NMR spectrum only shows one broad signal at $\delta = 0.9$ ($\nu_{1/2} = 115$ Hz) that indicates either a fast Li exchange or only minor differences in the δ values for the various ^7Li centers. Because of the limited solubility in toluene no measurements below 0 °C were possible.

A cluster comprising three shells of platonic units is present in **7** which is topologically closely related to **5**. The As centers form a slightly distorted As_{12} icosahedron, in which all of the twenty triangular faces are each capped by a Li center (Fig. 2 left). The twenty Li centers thereby form a pentagondodecahedron as dual polyhedral framework with approximately I_h point symmetry. The remaining four Li cations are found in the cavity of the approximately spherical $[As_{12}Li_{20}]^{4-}$ framework (diameter ca. 8 Å). As in **5**, these Li ions bind to an encapsulated Li_2O molecule leading to formation of a $[Li_6O]^{4+}$ octahedral core. The formation of the approximately O_h-symmetrical cluster in the cavity of the I_h-symmetrical $[As_{12}Li_{20}]^{4-}$ aggregate is very unusual and reflects a "symmetry frustration" which is caused by the stoichiometry. The $[Li_6O]^{4+}$ octahedron is, therefore, tilted with respect to the orientation of the As_{12} icosahedron; a C_3 axis of the octahedron coincides with a C_3 axis of the Li_{20} shell.

The Li–As distances in the $As_{12}Li_{20}$ framework lie between 2.559(9)–2.76(1) Å, and are thus in the range of values obtained for lithium arsanide.[8] The Li–Li distances in the Li_{20} dodecahedron are 2.89(1) and 3.09(1) Å, whereas, like in **5**, the Li–Li distances in the Li_6O framework are significantly shorter (2.52(1)–2.81(1) Å). The large As–As distances (>4 Å) indicate that there are no As–As bonds; the Li–O distances are similar to those in **5**. The Li centers of the Li_6O framework are, as expected, still coordinated to nearby As centers (Fig. 2 right); four Li centers have relatively short distances to three As atoms each, and two Li centers are only close to two As atoms. These distances correspond to those in the $As_{12}Li_{20}$ framework. ^7Li NMR spectra measured at various temperature intervals from

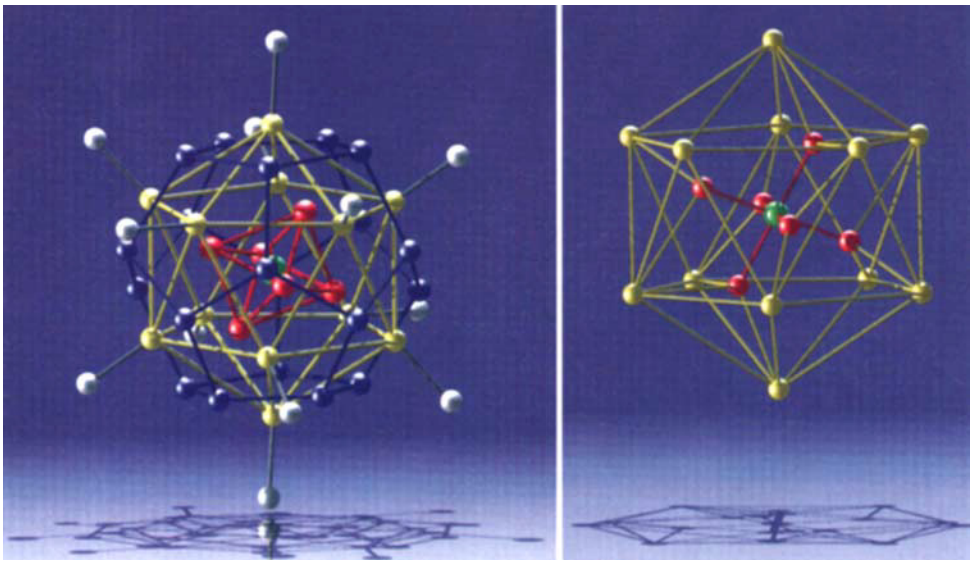

Fig. 2. Left: Representation of the shell-like form of **7** in the crystal. For clarity the organic groups have been omitted. Si = gray, As_{12} shell = yellow, Li_{20} shell = blue, OLi_6 shell = green, red. Selected distances [Å]: Si–As 2.294–2.309(2), Li–As 2.559(9)–2.76(1) for outer Li atoms, 2.55–2.63(1) for inner Li atoms coordinated to two As atoms, 2.60–2.99(1) for inner Li atoms coordinated to three As atoms, Li–O 1.85–1.90(1). Right: connection of the Li_6O octahedron (red, green) with the As centers (yellow).

−40 to 25 °C show that the structure is maintained in solution. The spectra show two sorts of Li in the Li_6O framework and one more sort of Li in the $As_{12}Li_{20}$ framework ($\delta = -1.65$ and -0.66, and 2.05, respectively, in a ratio of 1:2:10). Cryoscopic measurements gave a degree of aggregation of $n \approx 11.8$.

The question of whether other hyperlithiated cluster cations of main group elements such as $[Li_6S]^{4+}$ and $[Li_8C]^{4+}$ can be internally stabilized is currently under investigation.

Experimental Procedure

5: Compound **4** (1.3 g, 4.89 mmol) in toluene (20 mL) was allowed to react with Li_2O-containing *n*BuLi (0.63 g, 9.78 mmol, 2.5 M in hexane) at −50 °C. The yellow solution was slowly warmed to 25 °C and then concentrated in vacuum (10^{-2} Torr) to half its volume. After a few days at 25 °C, light yellow, air-sensitive crystals had formed. Yield: 0.90 g (0.39 mmol, 65%). ^{1}H NMR (300 MHz, C_6D_6): $\delta = 1.20$–1.40 (br. m, 112 H, *i*Pr), 2.11 (s, 12 H, *p*-Me), 2.14 (s, 12 H, *p*-Me), 2.76 (br., 48 H, *o*-Me), 6.72 (s, 16 H, arom. H).

7: Compound **6** (6.0 g, 27.24 mmol) was dissolved in Et_2O (90 mL) and treated with Li_2O-containing *n*BuLi (23.83 g, 54.48 mmol; 1.6 M solution in hexane) at 20 °C. The color of the solution changed upon slow warming to 25 °C from light yellow to orange. An orange-brown solid was obtained upon concentrating the solution in vacuum (10^{-2} Torr). The solid was taken up in toluene (30 mL) and gradually dissolved at 80 °C. Fractional crystallization provided orange-yellow, air-sensitive crystals. Yield: 4.80 g (1.71 mmol; 75%). ^{1}H NMR (300 MHz, C_6D_6): $\delta = 0.68$ (s, 72 H, $SiMe_3$), 1.02 (s, 72 H, CMe_3), 1.06 (d, 72 H, $CHMe_2$, J(H,H) = 6.8 Hz), 2.08 (sept., 12 H, $CHMe_2$, J(H,H) = 6.8 Hz).

Solid-State Coordination Chemistry: Hydrothermal Synthesis of Layered Vanadium Oxides with Interlayer Metal Coordination Complexes**

Yiping Zhang, Jeffrey R. D. DeBord, Charles J. O'Connor, Robert C. Haushalter,* Abraham Clearfield,* and Jon Zubieta*

Layered inorganic oxides constitute a diverse class of materials most of which share the common structural feature of a cationic guest that lies between the anionic oxide layers. The largest number of examples are known for materials composed largely of main group cations like clays, but solids with transition or post-transition elements like the layered double hydroxides[1] and certain alkali metal titanates[2] are known. Layered, and three-dimensional (3-D) oxides, containing both transition and main group metal cations, such as the Zr,[3], V,[4] and Mo[5] phosphates and phosphonates, have also been studied. While many of these solids are noted for their unique characteristic of allowing a wide variety of organic or inorganic chemistries to be performed in the interlamellar region, the closed shell, diamagnetic layers serve mainly as an inert nanoscale scaffolding. In contrast to these diamagnetic layers, several lamellar vanadium oxide solids have been prepared by high-temperature syntheses as well as the intercalation of alkali metal cations,[6a] conductive organic polymers,[6b] and organic cations[6c] between the layers of V_2O_5. A one-dimensional (1-D) metavanadate chain with coordinated $Cu(NH_3)_2$ groups has also been synthesized.[7] We present here a facile, general synthetic route to an entirely new class of layered, mixed-valence vanadium oxides that possess cationic interlayer transition or post-transition metal coordination complexes. The synthesis and structural characterization of **1** (bpy = 2, 2'-bipyridine), **2** (en = ethylenediamine), **3**, and **4**, and preliminary magnetic susceptibility values for **2**–**4** are reported.

$[(bpy)_2Zn]_2[V_6O_{17}]$ **1**, $(en)_2Zn[V_6O_{14}]$ **2**
$(en)_2Cu[V_6O_{14}]$ **3**, $[(en)_2Cu]_2[V_{10}O_{25}]$ **4**

The oxides **1**–**4** are prepared in a single step by the reaction of a precursor containing a transition or post-transition element, the bidentate amine, and V_2O_5 in water at 170 °C, and are isolated as highly crystalline, thin black plates. Since no external reducing agent is employed, the amine presumably serves in this capacity. These materials, $(L_2M)_y[VO_x]$, where L = bidentate amine, M = Cu or Zn, $0.16 \leq y \leq 0.33$ and $2.33 \leq x \leq 2.83$, share common structural features of vanadium oxide layers as well as a six-coordinate interlayer cation with four of the six coordination sites occupied by N atoms from two bidentate amine ligands and two sites from O atoms of the VO layer. The layers are built up in all cases from VO_4 tetrahedra and/or VO_5 square pyramids that are connected by edge- and corner-sharing interactions.

The unprecedented structure of **1**,[8] consists of VO layers, which, when viewed parallel to [100], display a very pronounced sinusoidal ruffling with an amplitude of about 13 Å and a period of about 15 Å (Fig. 1 left). These layers are composed solely of $V^{5+}O_4$ tetrahedra each of which have a terminal vanadyl (V=O) group and share three corners with three neighboring VO_4 units (Fig. 1 right). Within each VO layer there are very large, roughly circular rings, which alternately lie in planes approximately parallel to (011) and (0$\bar{1}$1), defined by fourteen VO_4 tetrahedra with transannular V–V distances of about 13 Å. There are two $Zn(bpy)_2$ moieties per ring, on either side of the

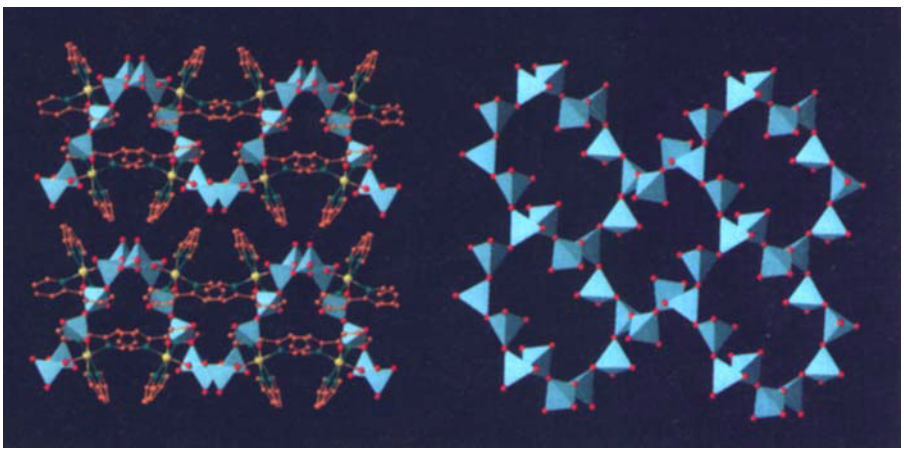

Fig. 1. Crystal structure of **1**; view parallel (left) and perpendicular (right) to the VO layers, illustrating the pronounced sinusoidal ruffling, the presence of the bpy ligands in the troughs, and the 14-ring holes within the layer.

$\bar{1}$ site in the center of the ring, each bonded in a *cis* fashion to two oxygen atoms from two second-nearest neighbor VO_4 groups on opposite sides of the ring. The bpy ligands protrude above and below the mean plane of the V_{14} ring so as to fill the troughs created from the ruffling of the layers with the organic ligands (Fig. 1 right).

The use of en as a bidentate ligand has allowed not only the isolation of new one-dimensional Cu-en-VO materials[9] but several layered solids as well. Two layered examples with en are the isotypic, mixed-valence V^{4+}/V^{5+} vanadium oxides **2**[10] and **3**.[11] Both materials contain Cu or Zn in a very distorted MO_2N_4 octahedral environment consisting of four N donor atoms, which lie approximately in a plane parallel to the VO layers (Fig. 2 left), and two *trans* O atoms from two adjacent layers, coordinated through very long M–O interactions. While this nearly square-planar coordination is not atypical for the Cu center in **3** (four N–Cu distances ≈ 2.03 Å; two O–Cu distances of 2.53 Å), it is highly unusual for the Zn center found in **2** (two N–Zn distances of 2.12 and two of 2.07 Å; two O–Zn

distances of 2.45 Å). The VO layers in oxides **2** and **3** contain infinite zigzag chains of edge-sharing $V^{4+}O_5$ square pyramids running parallel to [010]; their terminal vanadyl groups are oriented in pairs toward opposite sides of the layer, connected together by $V^{5+}O_4$ tetrahedra (Fig. 2 right) giving a layer compostion of $[(V^{5+})_2(V^{4+})_4O_{14}]^{2-}$ according to valence sum calculations.[12] Surprisingly, in spite of the fact that 2/3 of the V atoms are in the oxidation state IV (d^1), the Zn oxide **2** does not give an ESR signal and has an anomolously low magnetic moment according to preliminary magnetization measurements (Fig. 3A), which show that $\chi = M/H$ actually decreases in the range $150 < T < 300$ K. As shown in Figure 3B, the isotypic copper compound **3** also appears to have layers with supressed magnetic moments with $\mu_{eff}(300\ K) \approx 2.2\ \mu B$ ($\mu_{eff} = [8\chi T]^{1/2}$) only slightly greater than that expected ($\approx 1.8\ \mu B$) for the Cu^{2+} ion with $S = 1/2$. Below room temperature, the moment slowly decreases and reaches the value expected for only the Cu^{2+} ion by ≈ 70 K; below this temperature $\chi^{-1}(T)$ is linear (unlike $T > 70$ K) with a θ value near zero, indicative of a paramagnet. The magnetic data for **2** and **3** suggest that either the layers have already undergone an antiferromagnetic transition above room temperature or the spins are paired within states that are delocalized within the layers. However, there is no indication of the characteristic anomaly normally associated with a transition to an antiferromagnetic state.

Changing the reaction conditions in the en-Cu^{2+}-V_2O_5 system gives rise to other vanadium oxides with ligated Cu bound to the layers such as **4**.[4] Like **2** and **3**, oxide **4** has a nearly square-planar $(en)_2Cu^{2+}$ ion bonded to two *trans* oxygen atoms from two adjacent layers (Fig. 4 left), which are formulated as $[(V^{5+})_6(V^{4+})_4O_{25}]^{4-}$ according to charge balance and valence sum calculations. The layers are built up from double strands of infinite corner-sharing strings of edge-sharing trimeric VO_5 square pyramids, which run parallel to [001] and are connected together by VO_4 tetrahedra. The double strands are in turn bridged together by additional VO_4 tetrahedra to create a layer containing ordered voids (Fig. 4 right) with transannular O···O distances of 6 Å. Magnetization data shows that $\mu(300\ K) \approx 5.5\ \mu B$, a value which is below that expected for the six unpaired spins from two Cu^{2+} and four V^{4+} ions. The magnetic moment decreases nearly linearly over the entire range $20 < T < 300$ K, and reaches a value of about 2.8 μB near 10 K, which is the magnetic moment expected for two Cu^{2+} centers each with $S = 1/2$ (Fig. 3C). Note also that below about 15 K, $\chi^{-1}(T)$ is linear with a θ value near zero, consistent with paramagnetism and the pairing of all V^{4+} spins within each layer. Thus the magnetic behavior of **4** resembles that of **3** in that the layers have magnetic moments that slowly decrease over large temperature intervals, with no characteristic anomalies indicative of a phase transition, and appear essentially diamagnetic at very low temperatures.

Thermogravimetric analysis for compounds **1**–**4** shows that the organic component leaves the materials in the 200–300 °C range under N_2 but the residues have not been characterized.

A simple single-step hydrothermal route to a new class of inorganic solid-state materials, which contain amine-ligated transition (or post-transition) metal cations situated between mixed-valence vanadium oxide layers, has been developed. Examination of these layer structures show that they are related both compositionally and structurally to the V_2O_5 starting material. The degree of reduction (V^{4+}/V^{5+}) and condensation (V:O ratio and relative amounts of edge- versus corner-sharing polyhedral connectivities) within the layers is reflected in the charge per volume ratio of the cationic interlamellar coordination complex. The extensive

edge- and corner-sharing of the vanadium-centered polyhedra in these materials strongly influence electron–electron interactions confined within the layers, which gives rise to very unusual magnetic behavior. Many more complexes of this type, in addition to the ones described here, have been prepared,[9] indicating that these materials will constitute a large class of new materials. Combining the well-studied chemistry and properties developed over the last one hundred years for coordination compounds with the heterogeneous nature, stereochemical ridgidity, and potentially variable conductivity of the mixed-valence solid-state oxide layers, suggests that it should be possible to substantially vary the properties of these materials in a relatively straightforward manner.

Experimental Procedure

The syntheses were performed in 23 mL Teflon-lined stainless steel vessels filled to 30–50% at room temperature.

1: A mixture of V_2O_5 (0.312 g), ZnO (0.049 g), H_2O (10 mL), and bpy (0.325 g) in a molar ratio of 1.0:0.35:323:1.2 was heated at 170 °C for 44 h, and then at 200 °C for 90 h. This gave 0.46 g of a solid that was a mixture of brown chunks of **1**, black rods of $VO(VO_3)_6[VO(bpy)_2]_2$, and some unidentified green powder in an approximate ratio of 4:5:1.

2: A mixture of V_2O_5 (0.192 g), ZnO (0.042 g), H_2O (10 mL), and en (0.2 mL) in a molar ratio of 1.0:0.49:524:2.82 was heated at 170 °C for 66 h. This gave 0.187 g (yield 74%) of thin black plates of **2**, which was single phase according to powder X-ray diffraction data.

3: An aliquot of en (0.28 mL) was added to a mixture of water (8 mL), $CuCl_2 \cdot 2H_2O$ (0.17 g) and V_2O_5 (0.181 g) to give a final molar ratio of $CuCl_2 \cdot 2H_2O : V_2O_5 : en : H_2O$ of 1:1:4.2:444. The mixture was heated at 170 °C for 65 h which gave a 73% yield of **3**, which was single phase according to powder X-ray diffraction data.

4: Water (8 mL) was added to a mixture of $CuCl_2 \cdot 2H_2O$ (0.51 g) and V_2O_5 (0.181 g) followed by en (0.45 mL) to give a final molar ratio of $CuCl_2 \cdot 2H_2O : V_2O_5 : en : H_2O$ of 3:1:6.7:444. The resulting mixture was heated at 170 °C for 42 h which gave **4** in about 10% yield mixed with an amorphous black powder in an approximate 1:1 ratio.

$[Os_{10}(CO)_{24}\{Au(PPh_2R)\}_4]$, A Tubular Heterobimetallic Carbonyl–Osmium Cluster

Zareen Akhter, Scott L. Ingham, Jack Lewis,* and Paul R. Raithby

A large number of high nuclearity carbonyl–osmium and –ruthenium clusters have been isolated and characterized in an attempt to understand some of the properties of these compounds.[1] These clusters may be thought to lie at the interface between classical organometallic chemistry and the chemistry involved with metal surfaces. Therefore a thorough understanding of their chemical and electronic properties is of fundamental interest. One of the features that has to date characterized high nuclearity clusters of osmium and ruthenium is the presence of a closely packed array of metal atoms with high intermetal connectivity. The chemical, electronic, and photochemical properties of high nuclearity clusters can be greatly altered by the introduction of polarity within the molecule with the formation of heterobimetallic bonds.[2] To date this has been achieved by the use of redox coupling reactions between anionic carbonyl compounds and cationic metal electrophiles, and the use of mercury and gold fragments has been particularly successful.[3, 4] We now report the synthesis and characterization of a new class of bimetallic osmium–gold clusters in which the metal core has a novel *tubular* geometry, and the metal framework bonding differs from that observed in other osmium–gold systems.

The dianionic cluster $[PPN]_2[Os_{10}(CO)_{26}]$ $\{[PPN]^+ = [N(PPh_3)_2]^+\}$[5] may be readily reduced with K/Ph_2CO in THF to form the highly reduced cluster species. This species is very reactive and hence was generated in situ for further reaction with the electrophilic gold reagents of the type $[Au(PPh_2R)][NO_3]$ (where R = Ph or Me). Purification of the reaction mixture lead to the isolation of the cluster **1** in

$[Os_{10}(CO)_{24}\{Au(PPh_2R)\}_4]$ **1a**, R = Me; **1b**, R = Ph

in 30% yield.[6] The composition of **1** was initially deduced from liquid secondary ion mass spectrometry (LSIMS) and has been confirmed by a single-crystal X-ray structural analysis of **1a** (Fig. 1).[7]

The arrangement of the metal centers of **1a** may be described as two fused octahedra of osmium atoms which share a common edge and possess metal–metal bonding between their apexes. Four gold atoms cap faces of these octahedra in such a way that two adjacent triangular faces are capped at opposite ends of the cluster. However, this is not an accurate description of the osmium metal core geometry, as there appears to be little, if indeed any, metal–metal bonding across the octahedra. These osmium–osmium distances range from 3.286(2) to 3.322(2) Å and have an average value of 3.30 Å (including symmetry related distances), therefore precluding any effective direct overlap of metal orbitals and the formation of metal–metal bonding. Hence a more accurate description would be that the osmium atoms form a *tubular* cluster coordinated to two gold atoms at either end of the tube (Fig. 2). The osmium–osmium bond lengths around the tube range from 2.724(2) to 3.007(2) Å; within this range there appear to be distinctive short, medium, and long bonds. The short distances are found for bonds Os(1)–Os(2) and Os(1)–Os(3), which are 2.730(2) and 2.724(2) Å, respectively. Bonds of intermediate length (2.810(2)–2.853(2) Å) are observed for the bonds Os(2)–Os(3), Os(2)–Os(4), Os(2)–Os(5A), Os(3)–Os(4A), and Os(3)–Os(5), whereas longer metal–metal distances of 3.007(2) and 3.001(2) Å are found for Os(1)–Os(4) and Os(1)–Os(5), respectively. The reason for this apparent lack of consistency in the osmium–osmium bond lengths is unclear; however it seems feasible that the metal orbitals on Os(1) are hybridized in such a manner as to form more effective overlap with the orbitals on Os(2) and Os(3) than with the orbitals associated with Os(4) and Os(5). It is interesting to note that whilst Os(1) appears to form strong metal–metal bonds with its so-called radial orbitals, the tangential orbitals are also used to form significant osmium–osmium bonding. Thus the cluster may be visualized in terms of fused octahedra that are flattened in such a fashion that the axial–axial interactions between Os(2)···Os(3A) and Os(3)···Os(2A) are dramatically increased, with a concomitant decrease in the equato-

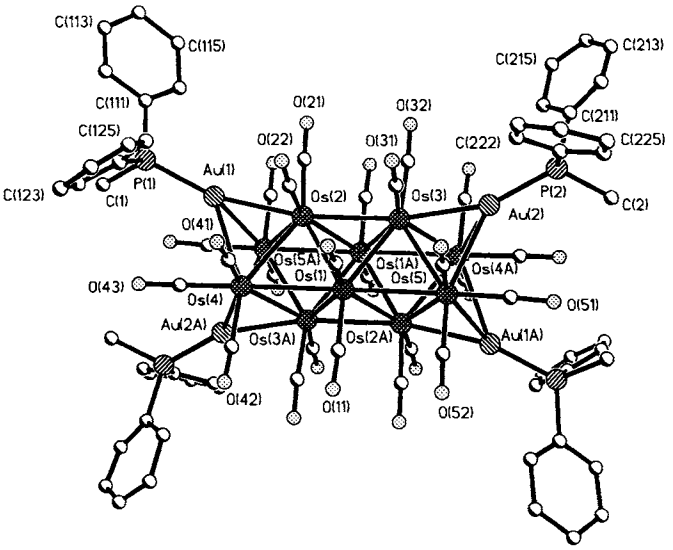

Fig. 1. X-ray crystal structure of $[Os_{10}(CO)_{24}\{Au(PPh_2R)\}_4]$ showing the core as fused octahedra of osmium atoms, which, however, are nonbonded.

rial–equatorial interactions. Indeed, both the axial–axial and equatorial–equatorial pairs of interactions of approximately 4.1 and 2.9 Å, respectively, are considerably different from those expected for an idealized Os_6 octahedron.

The gold atoms of the cluster coordinate in an asymmetric μ_3 fashion, with one strong and two weaker interactions between the gold and the three osmium atoms to which it is attached. Strong interactions are observed between Au(1)–Os(2) and Au(2)–Os(3) (metal–metal distances of 2.711(2) and 2.695(2) Å, respectively). Longer gold–osmium bond lengths are observed for Au(1)–Os(4), Au(1)–Os(5A), Au(2)–Os(4A), and Au(2)–Os(5) (between 2.924(2) and 2.943(2) Å). Hence each of the gold atoms form bonds to two osmium atoms, which are on average 0.23 Å longer than the remaining gold–osmium bond that they form. It is noteworthy that the osmium atoms with which the gold atoms interact strongly have only two carbonyl ligands attached to them and may be considered to be electron-deficient, which results in the formation of strong gold–osmium bonds. The two gold atoms at either end of the cluster are well separated (by 4.324(2) Å).

The X-ray structural determination of **1a** clearly shows that the compound exhibits a highly unusual metal core geometry, in which the osmium atoms form an unprecedented tubular array of osmium atoms. Why this cluster forms such an *open* structure is unclear and is undoubtedly due to a combination of factors. However, reduction of the cluster $[PPN]_2[Os_{10}(CO)_{26}]$ probably directs electron density in metal–metal antibonding orbitals, therefore opening up the metal core of the clusters. Subsequent addition of gold electrophiles results in the retention of these open osmium core geometries.

The cluster **1** has an overall electron count of 132 in the neutral oxidation state. This electron count cannot be obtained by the application of any of the more usual electron counting schemes, such as the Polyhedral Skeletal Electron Pair Theory for condensed polyhedra.[8] This apparent failure of electron counting schemes is not unknown for high nuclearity clusters and is due in part to the greater delocalization of the valence electrons of the metal atoms throughout the cluster as the number of metal atoms increases. The introduction of gold electrophiles to the metal cluster may also contribute to the discrepancy in the electron count, because of increased polarity introduced within the molecule on formation of the heterobimetallic bonds.

Experimental Procedure

A freshly prepared solution of potassium/benzophenone was added to $[PPN]_2[Os_{10}(CO)_{26}]$ (100 mg, 27.0 mmol) [5] dissolved in 50 mL dry, deoxygenated THF. The addition was halted when the starting material had been completely reduced, as determined by IR spectroscopy. This reduction was accompanied by a color change from dark red to brown. The solvent was then removed under vacuum, and the residue suspended in 50 mL dry, deoxygenated CH_2Cl_2. To this suspension was added an excess of the nucleophile $[Au(PPh_2R)][NO_3]$ dissolved in 10 mL CH_2Cl_2. While the mixture was stirred at room temperature for 1 h, the suspension dissolved to yield a red solution. This solution was filtered through a silica pad and the solvent removed at reduced pressure. The residue was purified by thin layer chromatography (eluent: 60% CH_2Cl_2/hexane) to yield the title compound in 30% yield.

Reactions of a Triosmium Cluster Complex with a Side-On-Coordinated Carbene Ligand with Sulfur Compounds Resulting in the Formation of a Thioketone Complex**

Jochem U. Köhler, Jack Lewis,* and Paul R. Raithby

Transition metal clusters with π-coordinated arene ligands have been investigated extensively during the past few years.[1] Cluster compounds in which the arenes adopt a face-capping mode[1] are of special interest, because they are model compounds for the adsorption of arenes on metal surfaces.[2] It is therefore interesting to investigate the reactivity of these face-capping arene ligands. The triosmium carbonyl cluster $[Os_3(CO)_9(\mu_3:\eta^2:\eta^2:\eta^2\text{-}C_6H_6)]$ reacts with nucleophiles such as phenyllithium to form the cyclohexadienyl complex $[PPN][Os_3(CO)_9(\mu_3:\eta^2:\eta^1:\eta^2\text{-}C_6H_6Ph)]$ (**1**, PPN = $[(Ph_3P)_2N]^+$).[3] Recently we synthesized the carbene complex **2**, where the carbene ligand is coordinated side-on to a triosmium nonacarbonyl moiety, obtained by removing a hydride from the cyclohexadienyl

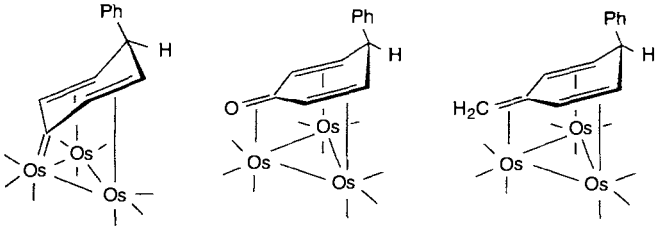
ligand of **1**. The carbene complex **2** can be converted easily into the cyclohexadienone complex **3** in the presence of air and a Lewis base.[4] The carbene carbon atom of complex **2** shows electrophilic behavior as we have shown with the Wittig reagent (triphenylphosphane methanylide). A C–C double bond was formed, as expected, which remains coordinated side-on to one osmium atom of the cluster **4**.[5]

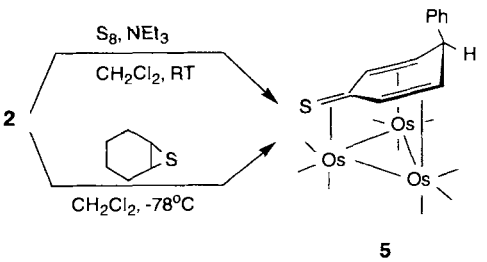


2 **3** **4**

It was of interest to see whether a C=S bond could be formed (analogous to the cyclohexadienone complex **3**) with η^2-coordination. Mononuclear Fischer carbene complexes react with elemental sulfur to form O-methylarylthiocarboxylate, which is no longer coordinated to the metal.[6] Elemental sulfur was added to a solution of the carbene complex **2** in CH_2Cl_2, and the suspension stirred for 45 minutes. No reaction occurred. A Lewis base, NEt_3, was added, and after 45 minutes of stirring at room temperature the thioketone complex **5** was obtained in 72% yield (Scheme 1). We consider that the first step of the reaction, as we proposed in the conversion of **2** into **3**,[4] is a nucleophilic attack by the base with subsequent reaction with sulfur as second step.

The thioketone complex **5** can be also be prepared by the reaction of the carbene complex with cyclohexenesulfide (Scheme 1). This reagent has been used to prepare a η^2-coordinated thioformaldehyde complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(\eta^2\text{-}S{=}CH_2)]^+[PF_6]^-$ from the methylene complex $[(\eta^5\text{-}C_5H_5)Re(NO)(PPh_3)(=CH_2)]^+[PF_6]^-$.[7]

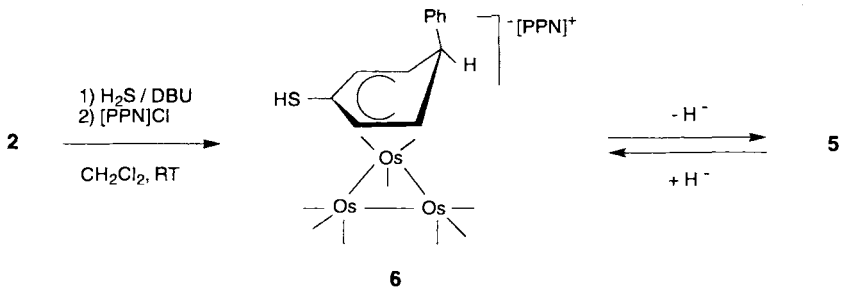
Apart from the signals in the phenyl region, the ^{1}H NMR spectrum of **5** shows three signals at $\delta = 4.74$ (t), 3.84 (dd), and 2.77 (d) (integration 1:2:2), indicating that the cyclohexadienyl ring is still coordinated to the triosmium triangle. The signals are shifted slightly to higher field compared to those of **3**, and the coupling constants are the same as those in **3**. In solution and in air the thioketone complex **5** converts slowly into the cyclohexanone complex **3**. ^{1}H NMR spectra recorded over several days reveal that it is not a direct conversion, as the sulfur is lost initially to form the carbene complex **2**, which then converts into **3**.



Scheme 1. Two ways to prepare the thioketone complex **5** from the carbene complex **2**. RT = room temperature.

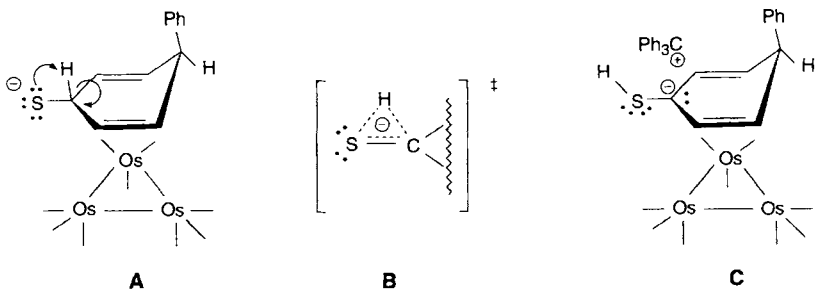
The reactivity of the carbene complex **2** towards H_2S was investigated. The carbene complex **2** dissolved in CH_2Cl_2 did not react with H_2S. However, on the addition of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) to abstract a proton, the color of the solution changed from orange to yellow. In the IR spectrum the carbonyl absorption bands shifted to lower wavenumbers and displayed a pattern typical for anionic triosmium cyclohexadienyl carbonyl cluster complexes (cf. **1** [3]). (A very similar IR spectrum is obtained when DBU itself interacts with the carbene complex (CH_2Cl_2): ν(CO) = 2040 (m), 2035 (sh), 1994 (vs), 1987 (vs), 1958 (m), 1934 (m), 1918 (m) cm^{-1}. This reaction is under investigation.) An anionic thiol complex **6** has been isolated as its PPN^+ salt (Scheme 2). The ^{1}H NMR spectrum is consistent with that of an anionic thiol-substituted cyclohexadienyl triosmium complex (comparable to **1**[3]): apart from the signals assigned to the phenyl groups there are four other signals assigned to the thiol ring at $\delta = 4.96$ (s) (SH), 4.56 (t), 3.93 (d), 2.31 (dd) (integration: 1:1:2:2).

Preliminary protonation of **6** with HBF_4 suggests protonation at the metal core rather than at the thiol group. The thiol group shows H/D exchange in the ^{1}H NMR spectrum on addition of deuterated methanol, as would be expected for the acidic behavior of a thiol group. Nevertheless, when the triphenylmethyl (trityl) cation is used to examine the possibility of a further hydride abstraction from the anionic complex **6**, we were surprised to isolate the thioketone complex **5** (Scheme 2). This implies that, at least formally, a hydride (H^-) has been removed from an acidic thiol group to form a thioketone group. Adding a hydride source ($Li[BHEt_3]$) to a solution of the thioketone complex **5** (which we considered to have an electrophilic center at the carbon of the thioketone group) gave the thiol complex **6**. We propose that the hydride attacks at the carbon of the thioketone group to form a thiolate group (resonance structure **A**, Scheme 3). A proton is then transferred from the carbon (via a transition state **B**) to the sulfur atom. The abstraction of the hydride may be viewed as the reverse of this reaction. We may consider that the trityl cation approaches the carbocycle remote from the metal core and polarizes the cyclohexadienyl ring towards resonance structure **C**. This implies that there is some anionic character at the carbon attached to the thiol group. A proton is then transferred from the acidic thiol group to the more basic carbanionic carbon via transition state **B** and is finally removed as a hydride by the trityl cation.



Scheme 2. Reaction of the carbene complex **2** with H_2S/DBU to form **6** and hydride abstraction with $[Ph_3C][BF_4]$ to form **5**, and back reaction of **5** to **6** with $Li[BHEt_3]$.

The system, therefore, may be considered as having formally an ambivalent thiol group. The acidic thiol group can be converted into a hydride-donating group, and the electrophilic sul-



Scheme 3.

fur in the case of the thioketone can be converted into a nucleophilic group. Similar reactions may open a way to novel ligand reactions in the coordination sphere of trimetallic transition metal clusters.

Experimental Procedure

All reactions were performed under nitrogen with standard Schlenk techniques. Purification on TLC plates (CH_2Cl_2 (40%)/hexane (60%)) and filtrations were carried out under air. The products were stored under nitrogen.

5: a) Reaction of **2** with sulfur in presence of NEt_3: Elemental sulfur (8 mg) and one drop of triethylamine were added to an orange solution of **2** (31 mg) in CH_2Cl_2 (4 mL). The suspension was stirred for 45 min at room temperature and purified by TLC. Complex **5** was obtained as an orange powder (23 mg, 72%). A small amount of **3** was isolated as well. b) Reaction of **2** with cyclohexene sulfide: The orange solution of **2** (36 mg) in CH_2Cl_2 (5 mL) was cooled to $-78\,^{\circ}C$ and treated with cyclohexenesulfide (12 mg, about 3 equiv). The yellowish solution was maintained at $-78\,^{\circ}C$ for 5 min until the color had changed back to orange, and then it was warmed to room temperature. After purification on TLC 31 mg (82%) of **5** was isolated as an orange powder. c) Reaction of **6** with $[Ph_3C][BF_4]$: A solution of $[Ph_3C][BF_4]$ (11 mg, about 1.2 equiv) in CH_2Cl_2 (2 mL) was added dropwise to a yellow solution of **6** (46 mg in 3 mL CH_2Cl_2) at $-78\,^{\circ}C$. After stirring at $-78\,^{\circ}C$ for 5 min the orange solution was warmed to room temperature. The reaction solution was purified by TLC, and **5** (13 mg, 42%) was isolated as a orange powder. Cyclohexadienone complex **3** (5 mg (17%) was isolated as a side product). ^1H NMR (250 MHz, $CDCl_3$): $\delta = 7.1-7.6$ (m, 5H, Ph), 4.74 (t, $^3J(H,H) = 2.5$ Hz, 1H, *CH*-Ph), 3.84 (dd, $^3J(H,H) = 8.0$ Hz, 2.5 Hz, 2H, CH), 2.77 (d, $^3J(H,H) = 8.0$ Hz, 2H, CH); IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2084 (m), 2040 (sh), 2035 (vs), 2010 (m), 1987 (m), 1964 (sh); MS (positive ion FAB): *m/z*: 1014 (as calcd); elemental analysis: found (calcd): C 26.56 (24.85); H 1.21 (0.99).

6: a) Reaction of **2** with H_2S/DBU: A solution of the carbene complex **2** (19 mg) in CH_2Cl_2 (5 mL) was treated with H_2S and stirred for 5 min at room temperature. A solution of DBU·CH_2Cl_2 (1 drop DBU in 1 mL CH_2Cl_2) was added dropwise until the color changed to yellow. The solution was stirred for further 5 min, and [PPN]Cl (13 mg) was added. The solvent was evaporated, and the oily yellow residue that remained was treated with *i*PrOH (3 mL). During this procedure the product formed yellow microcrystals, which were filtered and washed with hexane (2 mL). Yield of **6**: 24 mg (79%). b) Reaction of **5** with $Li[BHEt_3]$: An orange solution of **5** (30 mg) in THF (5 mL) was cooled to $-78\,^{\circ}C$ and treated with $Li[BHEt_3]$ (0.1 mL of a 1.0 M solution in THF). After 5 min a solution of [PPN]Cl (21 mg) in *i*PrOH (2 mL) was added dropwise. The solution was stirred at $-78\,^{\circ}C$ for further 5 min and then warmed to room temperature. The solvent was evaporated, and the oily residue was treated as mentioned above. Yield of **6**: 25 mg (52%). ^1H NMR (500 MHz, $CDCl_3$): $\delta = 7.09-7.65$ (m, 35H, Ph), 4.96 (s, 1H, SH), 4.56 (t, $^3J(H,H) = 2.5$ Hz, 1H, CHPh), 3.93 (d, $^3J(H,H) = 8.2$ Hz, 2H, CH), 2.31 (dd, $^3J(H,H) = 8.3$ Hz, 2.3 Hz, 2H, CH); IR (CH_2Cl_2): $\tilde{\nu}$ [cm^{-1}] = 2044 (m), 1999 (s), 1986 (s), 1959 (m), 1934 (m), 1918 (sh); MS (negative ion FAB): *m/z*: 1015 (as calcd for anion); elemental analysis: found (calcd) C 44.12 (44.04); H 2.68 (2.64); N 0.92 (0.90); P 3.82 (3.99).

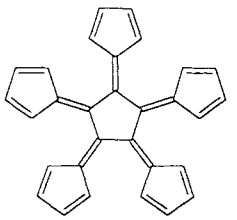
Metalated Tetra- and Penta(cyclopentadienyl)-cyclopentadienyl Compounds: Syntheses by Multiple Pd-Catalyzed Cyclopentadienylations**

Roland Boese, Gabriele Bräunlich, Jean-Pierre Gotteland, Jenn-Tsang Hwang, Carsten Troll, and K. Peter C. Vollhardt*



1

Penta(cyclopentadienylidene)-cyclopentane **1** constitutes the ultimate "fulvaleneradialene"[1] and, as a ligand for transition metals represents a significant target in our efforts to explore the basic chemical behavior of oligo-(cyclopentadienyl) metal compounds.[2] Apart from its potential to anchor rigidly (at least) five metals in close proximity, it also has the correct topography to provide a synthetic entry into metalated semibuckminsterfullerenes[3] or, in the dimeric form of a metallocene, to endohedral metallobuckminsterfullerenes.[4] With respect to the latter, it is noteworthy that a theoretical treatment of C_{60} (and its interactions with metal fragments) views the molecule as derived by an "implosion" of twelve cyclic C_5 units.[5]

We report that metal complexes of **1** and two regioisomers of its lower cyclopentadienyl homologs can be prepared by a remarkably simple and potentially general palladium-catalyzed reaction of iodocyclopentadienyl metal complexes[6] with cyclopentadienide.[7] Extension of this methodology to other substrates should dramatically enhance access to oligosubstituted $(\eta^5\text{-}C_5H_5)M$ systems.[8] Initially, a stepwise approach was sought, starting with the readily available[6e-h] iodocyclopenta-

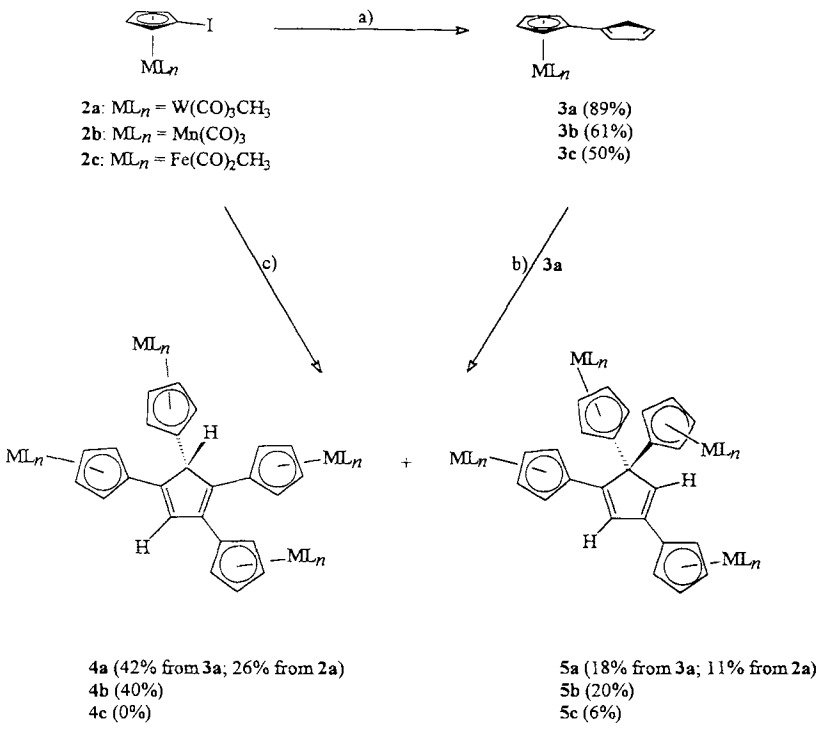

Scheme 1. a) $CpSnBu_3$ (2 equiv), 3% $[Pd(CH_3CN)_2Cl_2]$, THF (THF/DMF, 1:1, for **3b**), 23 °C, 12 h; KF_{aq} workup [11]; b) **2a** (5 equiv), 3% $[Pd(OAc)_2]$, iPr_2NEt (10 equiv), $PhCH_2(Et)_3N^+Cl^-$ (3.3 equiv), DMF, 23 °C, 52 h; c) $CpSnMe_3$ (0.3 equiv), 3% $[Pd(OAc)_2]$, NaOAc (15 equiv), $PhCH_2(Et)_3N^+Cl^-$ (5 equiv), DMF, 23 °C, 52 h.

dienyl complexes **2**, which were subjected to Pd-catalyzed single coupling with tributyl(cyclopentadienyl)stannane[9] to provide **3** as a mixture of 1,3- and 1,4-cyclopentadiene isomers (only the 1,3-isomer is shown in Scheme 1). This method is an improvement over earlier preparations of these compounds, which constitute valuable building blocks on route to (fulvalene)heterodimetal compounds.[10] Surprisingly, an attempt to effect the next step to furnish the tercyclopentadienyl system[2c] by coupling the trimethylstannyl cyclopentadienide of **3a** with **2a** (1 equiv) led instead to the 1,2,4,5-metallocyclopentadienyl-1,3-cyclopentadiene **4a** (9%), in addition to **3a** (20%).[12] The reaction conditions[13] were optimized by varying the ratio of **3a**:**2a** (1:1 to 1:10), the catalyst $[Pd_2(dba)_3]$ (dba = dibenzylideneacetone), the base (NaOAc, K_2CO_3, Na_2CO_3), the ammonium salt $[PhCH_2(Bu)_3N^+Br^-$, $Bu_4N^+Cl^-]$, added ligands (PPh_3), and reaction time (24–56 h). This allowed the isolation of **4a** and its isomer **5a** in 60% combined yield; the two compounds were separated by chromatography on silica gel (hexanes/acetone, 7/3) (Scheme 1, Table 1).[12] The following observations were made during the course of this scrutiny: 1) Complex **2a** decomposed at elevated temperatures (80 °C), thus preempting faster conversions. 2) Bases other than iPr_2NEt gave lower yields but similar product ratios (e.g., NaOAc: **4a**, 28%; **5a**, 12%; K_2CO_3: **4a**, 18%; **5a**, 6%). 3) Changing the catalyst or ammonium salt had little effect. 4) Solvent may influence the yields (e.g., with K_2CO_3, $[Pd_2(dba)_3]$, DMF: **4a**, **5a** 24%; in CH_3CN: 45%). 5) The addition of PPh_3 (0.03 equiv) either completely suppressed the emergence of **5a** (**4a**, 20%) or (0.09 equiv) the reaction altogether. 6) The direct coupling of **2a** to give **4a** and **5a** is also possible simply by using cyclopentadiene as the substrate (e.g., conditions c in Scheme 1, **4a**, 23%; **5a**, 10%). 7) An indication of the potential generality of the reaction is given by the analogous transformations of **2b** and **2c**.[12] Furthermore, the use of these metals also pinpoints some limitations; for instance, the generation of **4b** and **5b** was accompanied by that of the known $[FvMn_2(CO)_6]$ (Fv = fulvalene),[14] highlighting a reductive dimerization route that becomes predominant in the construction of **5c**, whose low yield is due to the presence of the new $[FvFe_2(CO)_4(CH_3)_2]$ (25%).[12] The latter is the only product (80%) when 20% catalyst and 3.3 equivalents of base are employed. 8) Preliminary experiments indicate that heteronuclear couplings are possible. Thus, **2b** (5 equiv) and **3a** resulted under conditions b in Scheme 1 in the so far inseparable mixture of three possible isomers of **5** (20%, 2.5:1:1) as indicated by mass, IR, and ^1H NMR spectral data. Similarly, **2c** and **3a** provided a mixture of one isomer of type **4** and two of type **5** (15%). 9) Attempted interconversion of **4a(b)** and **5a(b)** photochemically or thermally (80–160 °C) led only to decomposition.

The structural assignments of **4** and **5** are based on their distinctive spectral characteristics (Table 1); the most diagnostic are the effects of the plane of symmetry inherent in **5**, which is absent in **4**. The choice of the regiochemical disposition of the central diene unit in **4** (i.e., 1,2,4,5-substitution) is tentative, as the data do not exclude rigorously a tautomeric 1,2,3,5-substitution pattern, but appears justified on steric grounds and is the same as that formulated for 1,2,4,5-tetra-*tert*-butyl-1,3-cyclopentadiene.[15] Unfortunately, crystals of **4** suitable for X-ray analysis could not be obtained, but extensive experimentation eventually furnished such a sample for **5a** by slow diffusion of hexane vapors into a saturated toluene solution (Fig. 1).[16] The molecule is severely sterically encumbered and the central cyclopentadiene is distorted as a consequence. The structure of **5a** and molecular models of **4** also provide a rationale for the reluctance of the latter to undergo further metallocyclopentadienylation in the quest for metalated **1**, even under forcing conditions.

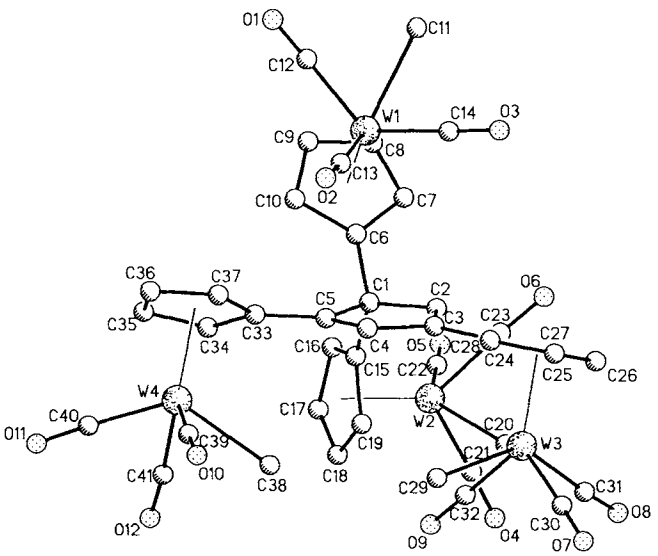

Fig. 1. Molecular structure of **5a**. Selected distances [Å] and angles [°]: C1–C2 1.514(22), C2–C3 1.310(23), C3–C4 1.428(22), C4–C5 1.323(25), C5–C1 1.562(23), C1–C6 1.527(24), C1–C15 1.563(23), C3–C24 1.459(23), C5–C33 1.433(21); C1-C2-C3 112.0(14), C2-C3-C4 107.2(15), C3-C4-C5 114.4(16), C4-C5-C1 105.7(14), C5-C1-C2 100.5(13), C6-C1-C15 108.9(13).

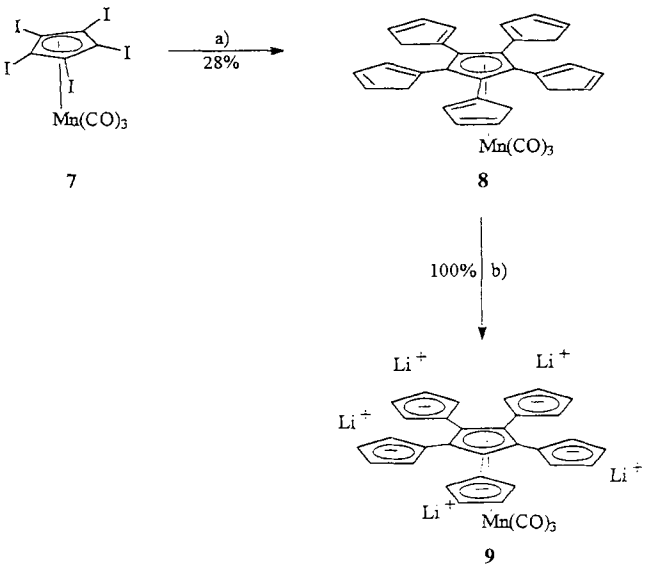
Chemical structural confirmation of **4a** was obtained by deprotonation with NaH (10 equiv) in THF to give the corresponding and, as expected, highly symmetrical orange Na salt **6**, which displays drastically simplified ^1H and ^{13}C NMR spectra (Table 1). Equilibration studies with cyclopentadiene ($pK_a = 15.5$) in 1,2-dimethoxyethane by ^1H NMR spectroscopy allowed the estimation of the pK_a value of **4a** as 14. The anion in **6** could be alkylated with CH_3I or CH_3CH_2I to give an inseparable mixture of 1,2,3,4,5- (minor) and 1,2,4,5,5-substituted cyclopentadiene isomers (^1H NMR), which indicates the nucleophilic reactivity of **6** at least with respect to small electrophiles. Nevertheless, since **1** could not be prepared by fivefold cyclopentadienylation according to Scheme 1, we investigated the hopefully less sterically burdened, inverse strategy given in Scheme 2.

Gratifyingly, treatment of tricarbonyl(η^5-pentaiodocyclopentadienyl)manganese (**7**)[6c] with trimethyl(cyclopentadienyl)stannane[9, 17] resulted in the desired penta(cyclopentadienyl)cyclopentadienyl complex **8** in one step in 28% yield (Scheme 2),[12] as a mixture of 1,3- and 1,4-cyclopentadiene



Scheme 2. a) $CpSnMe_3$ (10 equiv), 30% [$Pd(CH_3CN)_2Cl_2$], DMF, 90 °C, 15 min; b) BuLi (5 equiv), THF, 23 °C, 10 min.

tautomers. The spectral and analytical data are clearly consistent with this formulation (Table 1), and the quantity of signals in the various characteristic regions of the ^{13}C NMR spectrum are indicative of the presence of all eight possible isomers. This mixture is converged to one compound, **9**, on fivefold deprotonation. The high symmetry of **9** is strikingly evident in its NMR data, the nine proton multiplets for **8** simplifying to two AA'BB' "triplets", and the eighty signals discernible for **8** in the ^{13}C NMR spectrum reducing in number to only five in **9**.

The pentaanion in **9** is the first derivative of **1** and as such can be envisioned to function as a starting material for the construction of metalated semibuckminsterfullerenes and a multitude of organometallic clusters with novel topography. Furthermore, the facile multiple cyclopentadienylations reported here open up synthetic routes to a plethora of other oligocyclopentadienyl compounds, assembled around a perhalogenated π core.

Experimental Procedure

8: To complex **7** (1.00 g, 1.20 mmol) and [$Pd(CH_3CN)_2Cl_2$] (100 mg, 0.38 mmol) in freshly distilled DMF (10 mL, from CaH_2) was added $CpSnMe_3$ (2.70 g, 11.8 mmol) and the mixture stirred at 90 °C for 15 min. After the mixture had been cooled to 23 °C, ether (200 mL) was added, the solution washed with H_2O (3 × 100 mL), dried ($MgSO_4$), the solvent removed, and the residue filtered through silica gel (hexanes/ether, 5:1). Subsequent chomatography on silica gel (hexanes/ether, 10:1) gave a yellow fraction containing **8** (176 mg, 28%).

A Novel Heterobimetallic Layered Compound Showing Ferrimagnetism**

Jinkwon Kim,* Jin Mook Lim, Yong-Kook Choi, and Youngkyu Do*

In recent years there has been considerable research into the design of molecular magnetic materials for application in molecular electronic devices such as switches[1-3] and information recording.[4] In a search for new molecular magnetic materials, a variety of chain compounds with a magnetic ground state have been made by connecting two metal ions of unequal spin through an appropriate organic bridging unit such as oxalato,[5-7] carboxylato,[8] or cyano[9] groups. These chain compounds are models for understanding the relationship between molecular structures and magnetic properties. However, this approach toward molecular magnets based on ferrimagnetic chain compounds has some limitations, because the interchain interactions within the crystal lattice are weak. Thus it is important from a practical as well as a theoretical viewpoint to generate a magnetically ordered, two- or three-dimensional heterobimetallic compound by covalently connecting the magnetic centers.[10-13] As intercalated layered materials were recently shown to possess several remarkable properties simultaneously,[14] we directed part of our efforts toward the synthesis of heterobimetallic two-dimensional compounds containing functional branches. We now describe the synthesis, structure, and magnetic properties of compound **1**, (mtm = (bis(methylthio)-methylidene)malonate.

$[MnCu(mtm)_2(H_2O)_2(CH_3OH)_2]_n$ **1**

The reaction of equimolar amounts of MSO_4 and the dicarboxylato ligand mtm in water or alcohol leads to the formation of $[M(mtm)(solvent)_3]_n$ (M = Mn, Cu).[15] The reaction of these chain complexes in a 1:1 ratio in a water/methanol solvent mixture affords the neutral heterobimetallic complex **1**. The IR spectrum of **1** exhibits several bands from 1579 to 1527 cm^{-1} and from 1417 to 1527 cm^{-1}, characteristic regions for $\nu_a(CO_2)$ and $\nu_s(CO_2)$ bands, respectively. This observation suggests that all oxygen atoms of the carboxylato groups in **1** coordinate to metal ions in bridging modes.[16] The molecular structure of **1** established by X-ray diffraction[17] confirms with this expectation (Fig. 1).

The Cu and Mn atoms of the asymmetric unit lie on the crystallographically imposed inversion centers. All the metal atoms of the repeating unit shown in Figure 1 form the (001) plane of the unit cell, four Mn atoms being at the corners and one Cu atom at the center of the plane. The geometry around the Cu atom may be described as octahedral with a large tetragonal distortion due to the Jahn–Teller effect. The equatorial positions are occupied by four oxygen atoms of carboxylato

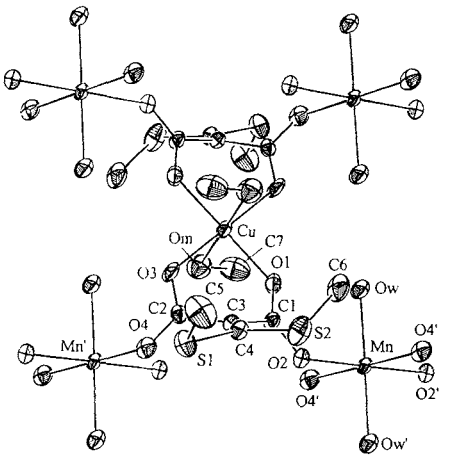

Fig. 1. Structure of the repeating unit of **1** in the crystal (ORTEP diagram, ellipsoids at 50% probability, hydrogen atoms have been omitted for clarity). Primes indicate symmetrically related atoms. Selected bond lengths [Å] and angles [°]: Cu O1 1.970(1), Cu O3 1.949(1), Cu Om 2.482(2), Mn–O2 2.215(1), Mn–O4 2.196(1), Mn Ow 2.185(1); O1-Cu-O3 92.1(1), O1-Cu-Om 85.0(1), O3-Cu-Om 83.7(1), O2-Mn-O4 93.9(1), O2-Mn-Ow 93.4(1), O4-Mn-Ow 94.6(1)

groups with moderate Cu–O bond lengths of 1.949(1) Å and 1.970(1) Å. The axial sites are occupied by two methanol molecules with very long Cu–O distances of 2.482(2) Å. The manganese atom is surrounded by four carboxylato oxygen atoms from four neighboring $[Cu(mtm)_2(CH_3OH)_2]$ units and two water molecules in a somewhat distorted octahedral arrangement. The Cu and Mn atoms are bridged by four carboxylato groups from two mtm ligands in *syn–anti* bonding modes. The separations between neighboring metal ions within the layer are 5.013 Å for Cu···Mn′ along the [110] direction and 5.317 Å for Cu···Mn along the [1$\bar{1}$0] direction.

The crystal packing structure of **1** (Fig. 2) consists of two-dimensional arrays of the $Mn^{II}Cu^{II}$ molecular unit. The resulting neutral sheets are stacked along the *c* axis through the van der Waals interactions between the sulfur atoms of SCH_3 groups that protrude perpendicularly from layers. The interlayer interactions are unique in the sense that the sulfur–sulfur interaction

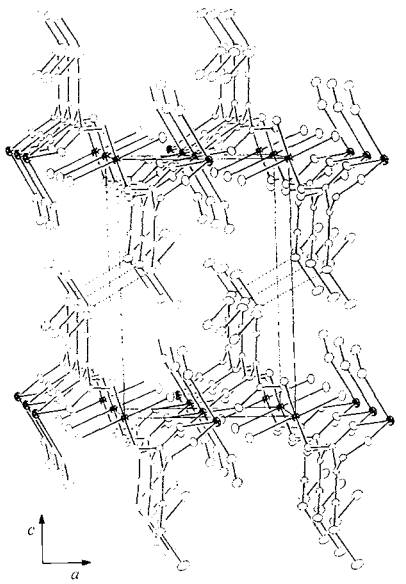

Fig. 2. Perspective view of two neighboring layers of **1**. Dashed lines indicate the shortest sulfur···sulfur interactions.

sites are connected in one dimension along the *b* direction. The shortest interlayer sulfur-to-sulfur distances of 3.479 and 3.554 Å are considerably shorter than the sum (3.60 Å) of their van der Waals radii.[18]

The magnetic behavior of **1** observed by a SQUID magnetometer at a field strength of 0.1 T is depicted as the temperature dependence $\chi_M T$ in Figure 3. The value of $\chi_M T$ remains constant at 4.50 cm^3 K mol^{-1} from room temperature down to about 100 K, and then begins to change smoothly to reach a round minimum at about 25 K (see the inset of Fig. 3), which indicates

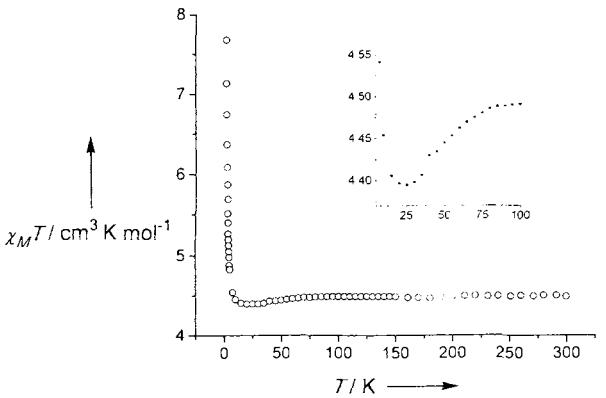

Fig. 3. Temperature dependence of $\chi_M T$ for **1**.

that the adjacent spin centers are antiferromagnetically coupled. These data fit the Curie–Weiss law $\chi = C/(T - \theta)$ with $C = 4.51$ cm^3 K mol^{-1} and $\theta = -0.72$ K. When the temperature is lowered further, $\chi_M T$ increases rapidly and reaches the value of 7.72 cm^3 K mol^{-1} at 1.8 K. The ferromagnetic-like increase of $\chi_M T$ as T is lowered below 25 K is characteristic of a ferrimagnetic material with antiferromagnetic coupling between nonequivalent nearest neighbor spin carriers. Magnetic measurements were made at temperatures as low as 1.8 K in order to characterize the three-dimensional ground state, but no critical temperature (T_c) was observed for **1**. A lower T_c might be expected for **1** considering that the carboxylato bridge in *anti-syn* bonding mode tends to result in a low T_c as seen in several two- and three-dimensional bimetallic systems.[8] The system also does not show hysteresis in field-dependent magnetization measurements (0 to 5 T) at 1.8 K.

The ligand mtm proved to be useful in linking two different metal ions to afford a ferrimagnetic layered compound. In particular the short, one-dimensional S···S interactions between two adjacent MnCu layers suggest that multifunctional layered materials might be made by modifying the alkylthio groups of the mtm ligand.

Experimental Procedure

1: Two separate equimolar mixtures of $MnSO_4 \cdot 5H_2O$ (240 mg, 1 mmol) and K_2mtm (285 mg, 1 mmol) in 10 mL of water and $CuSO_4 \cdot 5H_2O$ (250 mg, 1 mmol) and K_2mtm (285 mg, 1 mmol) in 10 mL of methanol were each stirred for 5 h at room temperature and then filtered. The two filtrates were mixed and allowed to react for 10 h at ambient temperature before filtration. Addition of Et_2O (5 mL) to the filtrate afforded green crystals of **1** in 51% yield (320 mg). Anal calcd. for $C_{14}H_{24}CuMnO_{12}S_4$: C, 26.66; H, 3.80; S, 20.33. Found: C, 26.77; H, 3.79; S, 20.24.

The First Carborane with a Distorted Cuboctahedral Structure**

Narayan S. Hosmane,* Hongming Zhang, John A. Maguire, Ying Wang, Colacot J. Thomas, and Thomas G. Gray

Dedicated to Professor William N. Lipscomb

Nearly 35 years ago, Lipscomb suggested the classical diamond–square–diamond (DSD) mechanism to explain the rearrangement of BH and CH vertices in polyhedral *closo*-boranes and -carboranes.[1] He proposed that conversion of the "carbons adjacent" 1,2-carborane (*closo*-1,2-$C_2B_{10}H_{12}$) involves six simultaneous DSD processes that give rise to a cuboctahedron, which can then collapse to give the "carbons apart" 1,7 isomer (*closo*-1,7-$C_2B_{10}H_{12}$). Diamond–square–diamond processes, or processes that are related to it, have been used in rationalizing a number of isomerizations found in boranes, carboranes, metallaboranes, and metallacarboranes.[2–6] Despite the general acceptance of the DSD process, there is not agreement on the mechanism of the isomerization of the icosahedral carboranes or on the viability of the cuboctahedron as an intermediate.[5, 7, 8] Irrespective of its specific nature, any DSD process will lead to a structure that is more open than the original, and an increase in cage electron density should stabilize such structures.[2, 9]

The two-electron reductions of *closo*-1,2-$C_2B_{10}H_{12}$ and *closo*-1,2-$(CR)_2B_4H_4$ are known to yield the corresponding "carbons apart" *nido*-carborane dianions, in which the cage carbons are on the open carborane faces and are separated by a boron atom.[10, 11] In contrast, the two-electron reduction of the "carbons adjacent" biscarborane (1,2-$C_2B_{10}H_{11})_2$ produces a much less open structure in which two of the triangular faces open to produce four-membered rings, similar to what would arise from a single DSD process.[12] This raises the question as to whether a more open, cuboctahedron-like structure could be stabilized enough for characterization if two more electrons were to be added to the 1,2-carborane precursor by replacing two two-electron BH vertices with two three-electron CR groups, thus giving a total of 28 valence electrons.

The pioneering work of Grimes et al. on Fe and Co metal-mediated oxidative ligand fusion indicates that such substitutions are possible.[13] However, none of the synthesized $(CR)_4B_8H_8$ cages (R is a less bulky Me or Et moiety) showed a cuboctahedron-like structure.[13] Thus, it is clear that in order to produce this type of carborane a different synthetic strategy is warranted. We report herein the synthesis and characterization of the first "carbons apart" tetracarbaborane, $(CSiMe_3)_4B_8H_8$, whose solid-state structure resembles a cuboctahedron.

The reinvestigation of the reaction of anhydrous $NiCl_2$ with the dilithiacarborane *closo-exo*-4,5-[(μ-H)$_2$Li(tmeda)]-1-Li(tmeda)-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$[14] in 1:1 stoichiometry afforded a mixture of two products, the previously reported *closo*-carborane **1**,[14, 15] which was isolated as a colorless liquid by a vacuum distillation at 25 °C, and a white crystalline solid, which was found to be a 1:1 mixture of **2** and **3** (Scheme 1). Fractional crystallization of the solid from a solution of benzene and hexane (1:1) allowed the separation of the two isomers. A neat sample of **2** was found to undergo thermal isomerization at 140–165 °C to yield **3** exclusively. The isomerization reaction showed no indication of reversibility, indicating that **3** is the more stable isomer. This conclusion is supported by ab initio molecular orbital calculations on the model compounds $C_4B_8H_{12}$ with D_{2h} and C_{2v} symmetries, in which the $SiMe_3$ groups are replaced by hydrogen atoms. These calculations show that at the 6-31G*//3-21G* level of theory the C_4B_8 cage with C_{2v} symmetry is more stable than that with D_{2h} symmetry by 124.2 kJ mol^{-1}.[16] As expected, the mass spectra,[17] IR spectra,[17] and elemental analyses (see Experimental Procedure) of **2** and **3** are identical; however, the ^{11}B and ^{13}C NMR spectra[17] are quite different. Isomer **2** exhibits a single peak in the ^{11}B NMR spectrum at $\delta = -30.18$, along with a single cage-carbon resonance in its ^{13}C NMR spectrum at $\delta = -33.32$; isomer **3** shows these resonances at $\delta = -5.57$ and $\delta = -11.41$, respectively. It is evident in the X-ray crystal structure of **2** (Fig. 1) and in a preliminary X-ray analysis of the more stable isomer **3** that while the cage-carbons might be equivalent (**2**) or nearly equivalent (**3**), there are two sets of borons in both isomers. Therefore, the appearances of single resonances in the ^{11}B NMR spectra of both compounds indicate that the C_4B_8 cages of both **2** and **3** are fluxional on an NMR time scale.

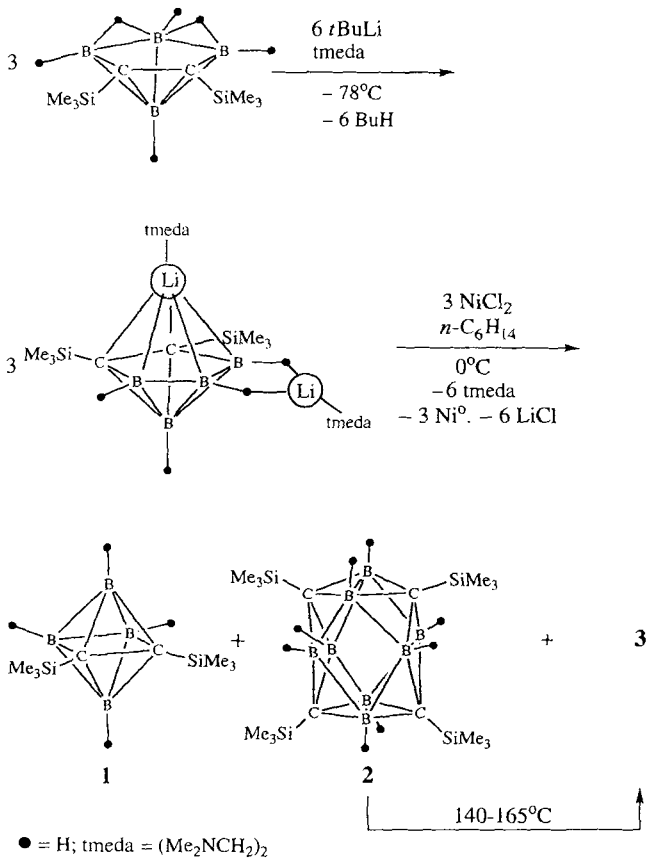

Scheme 1. Synthesis of tetracarbaborane **2** with a distorted cuboctahedral structure.

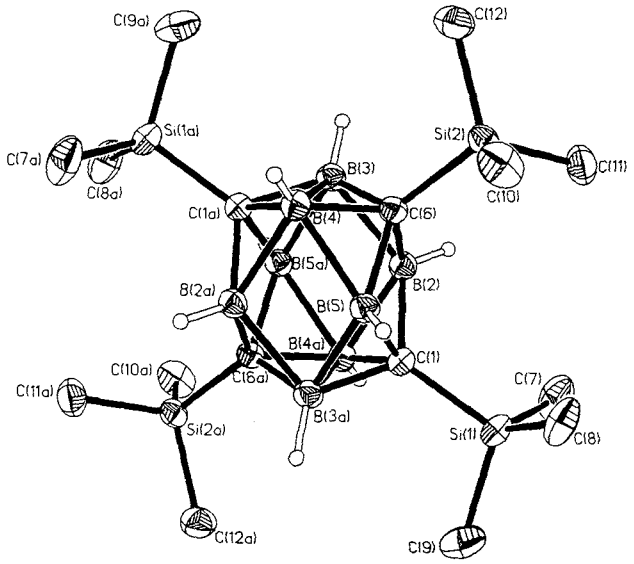

Fig. 1. Crystal structure of **2**. The H atoms of the $SiMe_3$ groups are omitted for clarity. Selected distances [Å] and angles [°]: C(1)-B(2) 1.672(3), C(1)-B(5) 1.685(3), C(1)-B(3a) 1.604(3), C(1)-B(4a) 1.596(3), B(2)-B(3) 1.879(3), B(2)-C(6) 1.682(3), B(2)-B(4a) 1.904(3), B(3)-B(4) 1.798(3), B(3)-C(6) 1.601(3), B(3)-C(1a) 1.604(3), B(3)-B(5a) 1.877(3), B(4)-B(5) 1.893(3), B(4)-C(6) 1.585(3), B(4)-C(1a) 1.596(3), B(4)-B(2a) 1.904(3), B(5)-C(6) 1.670(3), B(5)-B(3a) 1.877(3), B(2)···B(5) 2.192, B(5)···B(2a) 2.161, B(4)···B(3a) 3.072, C(1)···C(6) 2.504; B(5)-B(4)-B(2a) 69.4(1), B(3)-B(4)-B(5) 95.6(1), B(2)-B(3)-B(4) 96.4(1), B(3)-C(6)-B(5) 113.4(1), B(4)-C(6)-B(5) 71.1(1), B(2)-C(6)-B(5) 81.7(1), B(2)-C(6)-B(3) 69.8(1), B(3)-C(6)-B(4) 68.7(1).

Nevertheless, the solid-state structure of **2** (Fig. 1)[18] is that of a distorted cuboctahedron with a D_{2h}-symmetric cage,[19] reminiscent of Lipscomb's proposed intermediate structure.[1] Owing to the heteronuclear nature of the faces, the C_2B_2 rectangular faces are not planar and the B–B distances are not all equal. There are two sets of boron atoms: one of them consists of B(3), B(4), B(3a), and B(4a), and the other of B(2), B(5), B(2a), and B(5a). These could be interchanged by a dual DSD process that produces an intermediate of D_{4h} symmetry.[20]

The data available for **2** and **3** show that their structures are quite different from those of the "carbons adjacent" $(CR)_4B_8H_8$ isomers reported by Grimes et al., in which the cage-carbons are located on the same side of the cage.[13] It is of interest to note that neither **2** nor **3** could be converted to the "carbons adjacent" isomers. Moreover, the use of Grimes's methodology for the oxidative ligand fusion, involving the reaction of $FeCl_2$ with the monosodium salt of *nido*-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_6$ failed to produce the "carbons adjacent" $(CSiMe_3)_4B_8H_8$ isomers. The ^{11}B NMR spectra of the product were the same as those of **3**, thus exemplifying the role of the C(cage)-bound bulky $SiMe_3$ substituents positioned *exo* on the carborane polyhedron in determining the course of the cage fusion reaction.[21] While the mechanism for the formation of the $(CSiMe_3)_4B_8H_8$ isomers is not known, the isolation and structural characterization of **2** demonstrate that the cuboctahedron geometry in carboranes can be stabilized by increasing the total number of valence electrons in a 12-vertex cage to 28 and by introducing steric bulk on the bonding C_2B_3 faces.

Experimental Procedure

A 20.5 mmol sample of *closo-exo*-4,5-[$(\mu$-H)$_2$Li(tmeda)]-1-Li(tmeda)-2,3-$(SiMe_3)_2$-2,3-$C_2B_4H_4$ [14] was allowed to react with 20.8 mmol of anhydrous $NiCl_2$ (2.7 g) in dry benzene (20 mL) at 0 °C for 12 h, during which the color of the solution turned dark brown and some black solid started to precipitate. The heterogeneous mixture was then filtered through a frit in vacuo, the residue was washed with warm benzene (3 × 10 mL), and the washings were collected along with a filtrate. The volatile components of this pale-yellow filtrate were fractionated through a series of traps maintained at 0, −45, −78, and −196 °C, over 2 d. While solvent and tmeda condensed in the trap at −78 °C, *closo*-1,2-$(SiMe_3)_2$-1,2-$C_2B_4H_4$ (**1**) remained in the −45 °C trap (1.2 g, 5.50 mmol, 27% yield). The pale-brown residue that remained in the flask was sublimed at 110–120 °C in vacuo to give a white crystalline solid (1.0 g, 22% yield) at 0 °C. Solution NMR spectra of this substance indicated the presence of isomers **2** and **3** in equal amounts. Subsequent slow recrystallization of this solid from benzene and hexane (1/1) gave colorless plates of **2**: 0.45 g, 1.03 mmol, 10% yield; stable in air; soluble in both polar and nonpolar organic solvents; m.p. 94–95 °C; Anal for $C_{16}H_{44}B_8Si_4$: found (calculated): C 44.16 (44.15), H 10.43 (10.19), B 19.60 (19.85). The mother liquor contained predominantly isomer **3**, as identified by its ^1H, ^{11}B, and ^{13}C NMR spectra. The mother liquor was concentrated to dryness, the white residue was sublimed at 140–165 °C in vacuo over 4 h, and the resulting solid was dissolved in C_6D_6 for characterization. The NMR spectra of this solution unambiguously indicated the presence of **3** only. Vacuum resublimation of this solid at 140–165 °C yielded colorless rectangular (prismatic) crystals of **3**: 0.49 g, 1.13 mmol, 11% yield; stable in air; soluble in both polar and nonpolar organic solvents; m.p. 68 °C; Anal for $C_{16}H_{44}B_8Si_4$: found (calculated): C 44.13 (44.15), H 10.23 (10.19), B 19.71 (19.85)].

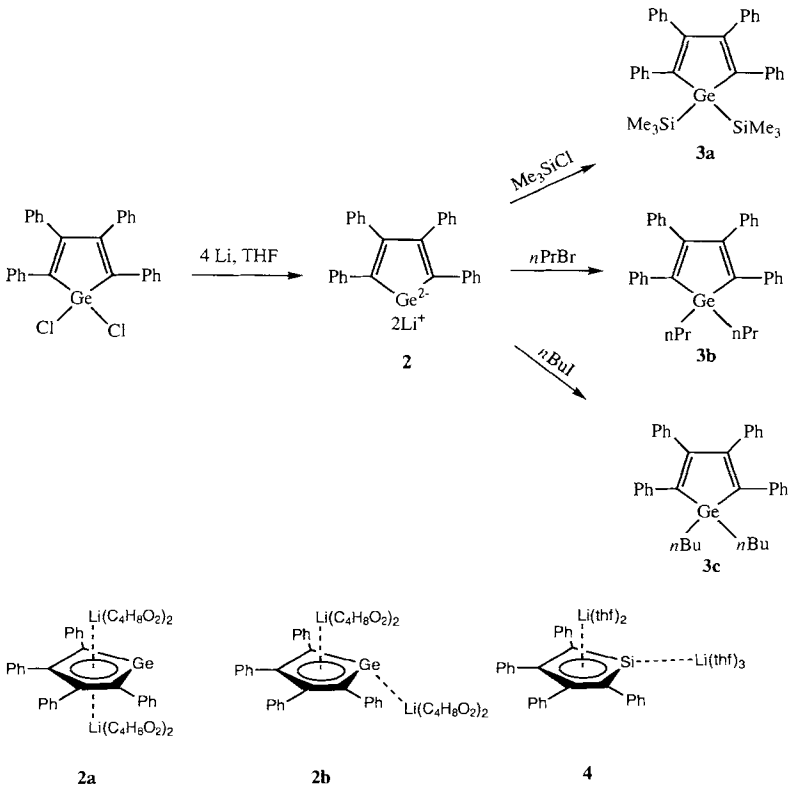
The Dianion of Tetraphenylgermole is Aromatic**

Robert West,* Honglae Sohn, Douglas R. Powell, Thomas Müller, and Yitzhak Apeloig

The anions of siloles and germoles have stimulated a great deal of interest lately.[1-5] Tetraphenylgermole dianions have been studied in THF by Hong and Boudjouk,[6] who proposed a delocalized structure on the basis of the ^{13}C NMR spectrum. On the other hand, Tilley and co-workers have recently reported the X-ray structure of the germole anion, $[(MeC)_4GeSi(SiMe_3)_3]^-$, as its lithium salt **1**.[7] The structure is highly localized; the C–C bond lengths within the five-membered ring vary significantly.



Scheme 1. Synthesis of **2** and **3a–c**.

We now report on the structure of the dilithium salt of the tetraphenylgermole dianion (**2**), which was obtained from 1,1-dichloro-2,3,4,5-tetraphenylgermole (Scheme 1). The dilithium

compound **2** crystallized from dioxane in two structurally distinct forms, depending upon the crystallization temperature. The crystals obtained from dioxane at $-20\,^{\circ}C$ had the composition $Li_2[(PhC)_4Ge]\cdot 5$dioxane (**2a**) and had a reverse-sandwich structure. The two lithium atoms, each coordinated to two dioxane molecules, lie above and below the C_4Ge ring within bonding distance of all five ring atoms (Fig. 1).[8] Crystals of **2** obtained at $25\,^{\circ}C$ had the composition $Li_2[(PhC)_4Ge]\cdot 5.5$ dioxane (**2b**). In **2b** one lithium atom is η^5-coordinated to the ring atoms and the other is η^1-coordinated to the germanium atom (Fig. 2).[9] In both structures the electrons within the ring are highly delocalized, which leads to nearly equal C–C bond lengths. Derivatization of solutions of **2** led to the products **3a**–**3c** (Scheme 1); thus, clearly showing the dianionic character of **2**.

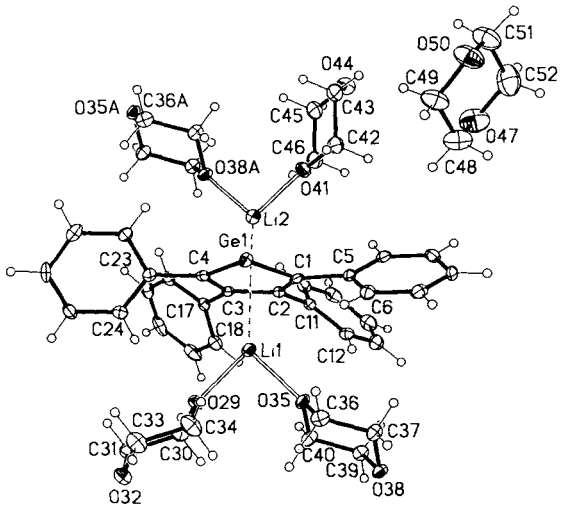

Fig. 1. Crystal structure of **2a**. Selected bond lengths [pm] and angles [°]: Ge1–Li1 273.0(5), Ge1–Li2 268.1(5), Li1–C1 238.0(6), Li1–C2 227.9(6), Li1–C3 228.8(6), Li1–C4 243.5(6), Li2–C1 240.8(6), Li2–C2 229.7(6), Li2–C3 227.8(6), Li2–C4 234.5(6), Ge1–C1 195.7(3), Ge1–C4 195.6(3), C1–C2 142.9(4), C2–C3 144.9(4), C3–C4 143.1(4); C1-Ge1-Li1 58.28(14), C1-Ge1-Li2 60.17(14), C4-Ge1-Li1 59.93(14), C4-Ge1-Li2 58.29(14), Ge1-C1-C2 114.5(2), Ge1-C4-C3 114.3(2), C1-C2-C3 113.7(3), C2-C3-C4 114.0(3), C1-Ge1-C4 83.44(12).

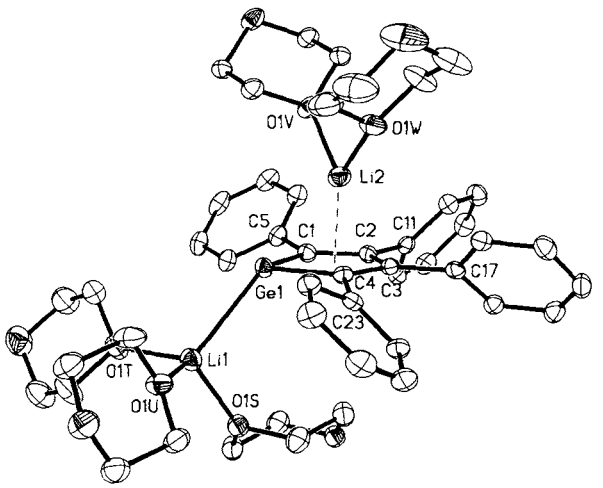

Fig. 2. Crystal structure of **2b**. Selected bond lengths [pm] and angles [°]: Ge1–Li1 261.3(3), Ge1–Li2 265.4(3), Li2–C1 235.9(4), Li2–C2 226.3(3), Li2–C3 230.8(3), Li2–C4 242.3(3), Ge1–C1 193.0(2), Ge1–C4 193.0(2), C1–C2 142.3(2), C2–C3 143.5(2), C3–C4 142.1(2); C1-Ge1-Li1 85.62(7), C1-Ge1-Li2 59.47(8), C4-Ge1-Li1 114.31(9), C4-Ge1-Li2 61.44(8), Li1-Ge1-Li2 174.48(10), Ge1-C1-C2 112.40(12), Ge1-C4-C3 112.59(12), C1-C2-C3 114.77(14), C2-C3-C4 114.62(14), C1-Ge1-C4 85.62(7).

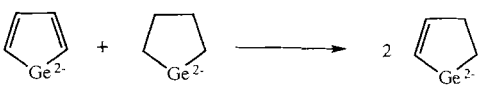
The structure of **2b** is related to that recently published for $Li_2[(PhC)_4Si]\cdot 5$THF (**4**), which also contains η^1- and η^5-coordinated lithium centers.[5] A significant difference between the structures is that in **4** the arrangement at the silicon center is nearly planar, whereas in **2b** the η^1-coordinated lithium center is shifted to the hemisphere anti to the η^5-coordinated lithium center. The angle between the Li–Ge vector and the C-Ge-C plane is 42.9°. Intraring C–C distances for **1**, **2a**, **2b**, and **4** are given in Table 1.

Table 1. Intraring C–C distances for germole and silole anions.

	C1–C2	C3–C4	C2–C3	Ref.
1	136(6)	135(5)	146(6)	[7]
2a	142.9(4)	143.1(4)	144.9(4)	this work
2b	142.3(2)	142.1(2)	143.5(2)	this work
4	144.8(4)	142.6(4)	143.0(4)	[5]

Theoretical calculations provide some insight into the sharp differences between **1** and **2**. MO calculations reported by Tilley et al. for the anion $(H_4C_4GeSiH_3)^-$ gave a small aromatic stabilization energy (ASE) of 5.3 kcal mol^{-1}, and large differences between C–C intraring bond lengths, leading to a low Julg parameter A[10] of 0.53. Our MO calculations[11] for the $(H_4C_4Ge)^{2-}$ ion (Table 2) indicate that the C–C distances within the ring should be nearly identical; the Julg parameter is near 1. An ASE of 13.0 kcal mol^{-1} is predicted from the isodesmic reaction shown in Equation (a).[12] The MO calculations reveal



(a)

Table 2. Calculated bond lengths [pm] and Julg's parameter A for germole anions and dianions.

	C1–C2	C2–C3	C1–Ge	Li–Ge	Li–C1	Li–C2	A
$H_4C_4Ge^{2-}$	139.0	143.5	199.2				0.957
$Li_2(H_4C_4Ge)$	142.5	143.6	200.5	250.7	217.0	210.4	0.997
$Li_2(H_4C_4Ge)\cdot 4H_2O$	142.5	142.2	198.4	273.9	238.6	225.3	1.000
$H_4C_4GeSiH_3^-$ [a]	136.1	148.4					0.532

[a] Data from ref. [7].

that the $Li_2(H_4C_4Ge)$ structure in which both lithium centers are η^5 coordinated is the energy minimum; it is 25 kcal mol^{-1} (at MP2/LANL2DZ) more stable than the isomer in which one lithium center is η^1- and the other η^5-coordinated (see Table 2). Complexation of the dianion by lithium ions further increases the delocalization, as shown by the even larger values of the Julg parameter A predicted for the η^5,η^5-dilithium derivative of the $(H_4C_4Ge)^{2-}$ ion, and likewise for $Li_2(H_4C_4Ge)\cdot 4H_2O$, in which each lithium center is coordinated by two H_2O moleules. Thus both the structure for **1** (localized electrons) and that for **2** (delocalized electrons) are consistent with theory.

We note the good agreement between the experimentally determined geometry for **2a** (Fig. 1) and the calculated geometry for the model compound $Li_2(H_4C_4Ge)\cdot 4H_2O$ (Table 2), including the distances between the plane of the germole ring and the Li centers. Comparison with the calculated geometry of $H_4C_4GeLi_2$ reveals the important role of solvation in controlling the Li–germole ring distance. Thus, d(Ge–Li) and

d(C1–Li) distances in $Li_2(H_4C_4Ge)$ increase by 23.2 pm and 21.6 pm, respectively, upon coordination of two water molecules to each of the η^5-coordinated lithium ions. In contrast, solvation has practically no effect on the intraring distances.

In summary, it appears that anions of Group 14 metalloles (C_4E rings) may have either localized nonaromatic, or delocalized aromatic structures, depending on the nature of the metal E and the substituents. Further structural studies of metallole anions and dianions of this kind with different substituents will be of value in determining the factors leading to "aromaticity" in these substances.

Experimental Procedure

1,1-Dichloro-2,3,4,5-tetraphenylgermole: Diphenylacetylene (26.7 g, 150 mmol) and lithium (1.38 g, 200 mmol) were stirred in diethyl ether (150 mL) at room temperature for 3.5 h. The reaction gave a brown solution and a yellow precipitate. The solution was frozen with a bath of liquid nitrogen, after removal of lithium metal. $GeCl_4$ (25.7 mL, 300 mmol) was added by a syringe in one portion. The mixture was kept at −196 °C for 5 min before the cooling bath was removed, and the solution was allowed to warm up slowly to room temperature, and stirred for 4 h to give a yellow solution. The reaction product was extracted with diethyl ether and obtained as yellow crystals (30 g, 80%) at −10 °C. M.p. 197–199 °C. Selected data; ^{1}H NMR (300.133 MHz, $CDCl_3$): δ = 6.83–6.88 and 7.04–7.21 (br. m, 20H; Ph); $^{13}C\{H\}$ NMR (75.403 MHz, $CDCl_3$ (δ = 77.00)): δ = 149.96, 136.57, 134.66, 132.72, 129.54, 129.50, 128.36, 128.06, 127.68, 127.47; MS(EI): m/z (%): 500 (23) [M^+], 356 (78) [$M^+ - GeCl_2$]. High-resolution MS: calcd. for $C_{28}H_{20}GeCl_2$ 500.0155, found 500.0116.

2: A solution of $Ph_4C_4GeCl_2$ (10.00 g, 20 mmol) in THF (130 mL) was stirred with 4 equiv Li (0.555 g, 80 mmol) for 12 h at room temperature under an argon atmosphere. The color of the solution rapidly changed to a dark maroon. After removal of solvent, the residue, **2**, was extracted with dioxane and filtered. Orange crystals of **2b** were obtained at room temperature. Cooling of the saturated solution to −20 °C produced instead yellow crystals of **2a**. $^{13}C\{H\}$ NMR (75.403 MHz, dioxane (δ = 66.40)): δ = 165.17, 150.07, 143.83, 131.93, 129.19, 128.04, 125.89, 122.03, 119.45.

3a: An excess of trimethylchlorosilane was added slowly to a solution of **2** (20 mmol) in THF (130 mL) at 0 °C. The solution was allowed to warm to room temperature and stirred for 2 h. Then the volatiles were removed under reduced pressure. The residue was extracted with pentane (100 mL) and filtered. Yellow crystals of **3a** (quantitative yield) were obtained after the solution was concentrated and cooled to −10 °C. M.p. 114 °C. Selected data for **3a**: ^{1}H NMR (300.133 MHz, $CDCl_3$): δ = 6.76–6.89 and 6.94–7.10 (br. m, 20H, Ph), 0.16 (s, 18H, $SiCH_3$); $^{13}C\{H\}$ NMR (75.403 MHz, $CDCl_3$ (δ = 77.00)): δ = 151.55, 149.34, 142.40, 140.34, 130.61, 129.53, 127.55, 127.19, 125.54, 124.90, 0.26 ($SiMe_3$); MS(EI): m/z (%): 576 (74) [M^+], 503 (22) [$M^+ - SiMe_3$]. High-resolution MS: calcd. for $C_{34}H_{38}GeSi_2$ 576.1742, found 576.1720.

3b: Yellow crystals, quantitative yield, M.p. 78–80 °C; ^{1}H NMR (300.133 MHz, $CDCl_3$): δ = 6.75–7.10 (br. m, 20H, Ph), 1.45–1.52 (br. m, 4H, CH_2), 1.30 (t, 4H, Ge-CH_2), 0.95 (t, 6H, -CH_3); $^{13}C\{H\}$ NMR (75.403 MHz, $CDCl_3$): δ = 152.28, 143.30, 140.98, 139.65, 130.14, 128.91, 127.80, 127.35, 125.90, 125.31, 18.80, 17.58, 17.37; MS(EI): m/z (%): 516 (100) [M^+], 473 (10) [$M^+ - n$Pr], 429 (69) [$M^+ - 2n$Pr]. High-resolution MS : calcd. for $C_{34}H_{34}Ge$ 516.1882, found 516.1883.

3c: Yellow crystals, quantitative yield, M.p. 148–150 °C; ^{1}H NMR (300.133 MHz, $CDCl_3$): δ = 6.78–7.23 (br. m, 20H, Ph), 1.15–1.39 (br. m, 4H, -CH_2-), 1.00–1.15 (br. m, 4H, -CH_2-), 0.88 and 0.80 (t, 6H, -CH_3), 0.64 (t, 4H, Ge-CH_2); $^{13}C\{H\}$ NMR (75.403 MHz, $CDCl_3$): δ = 151.84, 145.40, 140.74, 139.50, 130.38, 129.46, 127.80, 127.39, 126.01, 125.54, 28.04, 25.01, 15.94, 13.44; MS(EI): m/z (%): 544 (59) [M^+], 429 (28) [$M^+ - 2n$Bu]. High-resolution MS: calcd. for $C_{36}H_{38}Ge$ 544.2197, found 544.2188.

[8] X-ray structure analysis of **2a**: $C_{28}H_{20}GeLi_2 \cdot 5C_4H_8O_2$, M_r = 795.33, triclinic, $P\bar{1}$, a = 9.9864(13), b = 13.573(2), c = 15.881(2) Å, α = 98.190(9), β = 95.827(10), γ = 109.280(9)°, V = 1985.6(4) Å^3, Z = 2, ρ_{calcd} = 1.330 Mgm^{-3}, F(000) = 836, λ = 0.71073 Å, θ = 113(2) K. A yellow single crystal (dimensions 0.40 × 0.40 × 0.10 mm) was mounted under a coating of Paratone-N. Data were collected by the ω scan method in the range of 1.50° ≤ θ ≤ 22.50° on a Siemens P4 diffractometer. Of a total of 5533 reflections, 5177 (R_{int} = 0.0310) were independent. The structure was solved by direct methods with the SHELXS-86 program and refined by the full-matrix least-squares method on using the SHELXL-93 program. $R(F)$ = 0.0370, $R_w(F^2$-all) = 0.0887. There is one lithium cation on each face of the five-membered Ge ring. Each Li is coordinated to two dioxane molecules, both of which are in chair conformations. One of the dioxane molecules that is coordinated to one lithium ion is also coordinated through its other oxygen atom to the lithium ion in another molecule. Thus these groups form infinite chains in the a direction of the crystal. There is also one dioxane molecule in a chair conformation that is not coordinated to any other group. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-16 and CCDC-179-17. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).
[9] X-ray structure analysis of **2b**: $C_{28}H_{20}GeLi_2 \cdot 5.5C_4H_8O_2$, M_r = 927.48, triclinic, $P\bar{1}$, a = 12.7118 (2), b = 13.2702(2), c = 17.2801(3) Å, α = 68.293(2), β = 72.413(2), γ = 62.830(2)°, V = 2377.88(7) Å^3, Z = 2, ρ_{calcd} = 129.5 Mgm^{-3}, F(000) = 980, λ = 0.71073 Å, θ = 133(2) K. An orange single crystal (0.5 × 0.4 × 0.4 mm) was mounted under a coating of Krytox oil. Intensity data were collected by the ψ scan method (1.50° < θ < 22.50° on a Siemens P4 diffractometer equipped with a CCD area detector. From a total of 14703 measured data, 8263 were independent (R_{int} = 0.0291). The structure was solved by direct methods and refined by a full-matrix least squares method on F^2 using the SHELXTL + program. $R(F$-obs) = 0.0312, $R_w(F^2$-all) = 0.0822, S = 1.068 for 8261 data and 596 variables. One lithium ion bonds to a face of the five-membered ring and the other Li ion bonds to the Ge center directly. Dioxanes join the lithium atoms to form an infinite bonded chain [8].
[10] Julg's parameter A is a measure of the deviation of C–C bond lengths from the mean C–C bond lengths in cyclic compounds; A = 1.00 for benzene, 0 for "Kekulé benzene". A. Julg, P. Francois, *Theor. Chim. Acta* **1967**, *7*, 249; S. M. van den Kerk, *J. Organomet. Chem.* **1981**, *215*, 315
[11] Values in Table 2 were calculated by using density functional theory (B3LYP) with the polarized, triply split 6-311G* basis set augmented by diffuse functions (B3LYP/6-311 + G*). All structures were restricted to C_{2v} symmetry; Gaussian 94 was employed [13]. For comparison we calculated the structure of $H_4C_4Ge^{2-}$ at several other levels of theory using different basis sets. The predicted intraring distances and Julg parameters are: HF/6-31 + G* (C,H), ecp28mwb + diffuse (Ge): C1–C2 = 136.7 pm, C2–C3 = 144.7 pm, Ge–C1 = 201.5 pm, A = 0.835; HF/6-311 + G*: C1–C2 = 136.8 pm, C2–C3 = 144.3, Ge–C1 = 199.0, A = 0.856; MP2(fc)/6-31 + G* (C,H), ecp28mwb (Ge): C1–C2 = 142.3 pm, C2–C3 = 141.9 pm, Ge–C1 = 197.8 pm, A = 1.000. We note that RHF theory predicts a more localized structure for the dianion than does DFT theory. However, even at the HF level the structure of the dianion is predicted to be more delocalized than that of the monoanion $H_4C_4GeSiH_3^-$, as shown by the A values. MP2 calculations predict a fully delocalized structure for $H_4C_4Ge^{2-}$.
[12] This value is somewhat smaller than the ASE for the corresponding silole dianion (17.9 kcal mol^{-1} at MP2(fc)/6 + 31G*).

A Trinuclear Organoantimony Cation: Structure of $[Me_2Sb-Sb(Me_2)-SbMe_2][Me_2SbBr_2]$**

Hans Joachim Breunig,* Michael Denker, and Enno Lork

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

Recently we reported on the binuclear adduct $Me_3Sb \rightarrow Sb(Me)I_2$ that contains a remarkably short antimony–antimony bond.[1, 2] In an attempt to prepare polynuclear adducts, we treated distibanes with organoantimony(III) halides.[1] The synthesis of a crystalline compound of the composition $Me_2SbSbMe_2 \cdot 2\,Me_2Br$ has now been accomplished by reacting dimethylantimony bromide with excess tetramethyldistibane. The X-ray structure analysis[3] revealed that instead of an uncharged Lewis acid base adduct the ionic compound **1** was obtained. The formation of **1** can be rationalized as an oxidative

$[Me_2Sb\ Sb(Me_2)\ SbMe_2][Me_2SbBr_2]$ **1**

addition of the electrophile dimethylantimony bromide to a nucleophilic antimony atom of tetramethyldistibane, and transfer of the bromide ion to a second dimethylantimony bromide molecule. Such an addition is unusual since distibanes normally react with electrophilic reagents with fission of the antimony–antimony bond.[4] For example, the reaction of tetraethyldistibane with methyl iodide gives diethylantimony iodide and diethylmethylstibane.[5]

The structure of the ions of **1** is shown in Figure 1. The cation is particularly remarkable. It consists of a chain of three

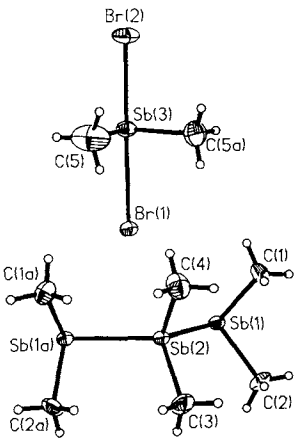

Fig. 1. Structure of **1** in the crystal. Selected bond lengths [pm] and angles [°]: Sb(1)–Sb(2) 282.03(4), Sb(1)–C(1) 215.7(5), Sb(1)–C(2) 216.1(5), Sb(2)–C(3) 212.1(8), Sb(2)–C(4) 213.1(8), Sb(3)–C(5) 213.0(7), Sb(3)–Br(2) 269.99(10), Sb(3)–Br(1) 297.72(9); Sb(1)-Sb(2)-Sb(1a) 116.19(2), C(3)-Sb(2)-C(4) 98.0(4), C(1)-Sb(1)-Sb(2) 92.4(2), C(1)-Sb(1)-C(2) 94.3(2), C(5)-Sb(3)-Br(2) 91.6(2), C(5)-Sb(3)-Br(1) 86.4(2), Br(2)-Sb(3)-Br(1) 176.98(3), C(5)-Sb(3)-C(5a) 96.7(6); dihedral angle C(1)-Sb(1)-Sb(2)-C(4) 8.59 (0.30), C(2)-Sb(1)-Sb(2)-C(5) 4.18 (0.30).

dimethylantimony groups; the two terminal groups are symmetry equivalent. Neither the tetramethyldistibane molecule nor a dimethylstibenium ion can be identified as separate units, as would have been expected for an acid–base adduct. Rather, the cation adopts the structure of a bis(dimethylstibanyl)dimethylstibonium ion. The Sb–Sb bond lengths (282.03(4) pm) are a little shorter than in crystalline tetramethyldistibane (286.2(2)[6] and 283.1(1)[7]) or in the adduct $Me_3Sb \rightarrow Sb(Me)I_2$ (285.9(1)[2]). The coordination of the central antimony atom is almost tetrahedral. The bond angles at the terminal antimony atoms of the chain are close to 90°. Analogous cationic antimony chains have not yet been described in the literature. Little is also known about neutral catenated stibanes like pentamethyltristibane. This chain compound, corresponding to the cation of **1**, has hitherto only been obtained in an equilibrium with polymeric methylantimony and tetramethyldistibane.[8, 9] However, the anion $Sb_3Ph_4^-$ has been characterized by X-ray crystallography, and the Sb–Sb bond lengths in this trinuclear compound are 276.1(1) pm,[10] thus, shorter than the corresponding distances in **1**.

The anion of **1** can be described as a trigonal bipyramid in which the bromine atoms adopt the axial positions and the lone pair of electrons and the methyl groups the equatorial positions. The antimony–bromine distances are 297.7(9) and 270.0(1) pm. These distances are considerably longer than the Sb–Br single bond lengths in solid $MeSbBr_2$ (av 257 pm).[9] The formation and structure of the anion can be explained on the basis of a bonding model[11] in which a Sb–Br σ^* orbital of Me_2SbBr serves as an acceptor orbital for the bonding of a bromide ion. The formation of four bonds by antimony(III) is not common. Related structures have been observed in the ions $[Ph_2SbCl_2]^-$[12] and $[Ph_2SbI_2]^-$.[13]

The arrangement of the ions in the crystal is shown in Figure 2. There are heavy atom contacts between the cations and

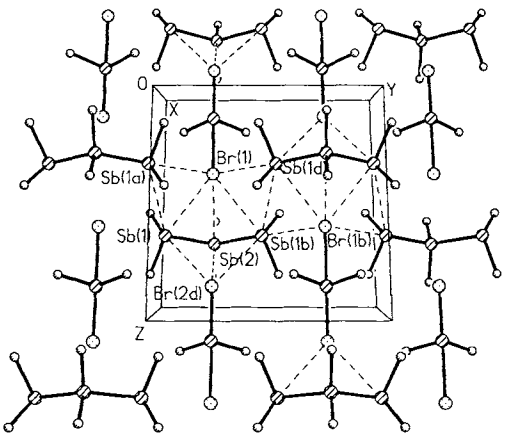

Fig. 2. Unit cell of **1**. Contact distances [pm] between the ions: Sb(1)···Br(1) 385.7, Sb(2)···Br(1) 370.4, Sb(1a)···Br(1) 385.7, Sb(2b)···Br(2) 370.9, Sb(1a)···Br(2) 379.5, Sb(1d)···Br(2) 379.5, Sb(1)···Br(1a) 346.9, Sb(1b)···Br(1a) 346.9, Sb(1)···Sb(1a) 381.5.

anions (Sb···Br 346.9–385.7 pm, Sb···Sb 381.5 pm). Particularly short contacts (Sb(1)···Br(1) 346.9 pm) exist between the terminal dimethylantimony units of two neighboring cations and a bromine atom of the anion. An estimation with the modified[14] Pauling formula[15] gives a bond order of 0.12 for these interactions. Through these weak bonds a $(Br\cdots Sb_3)_x$ zigzag chain is built up in the crystal. Consideration of the interactions between the ions also helps to explain the reactivity of **1**. A slight shift of Br(1) towards Sb(1) and an increase of the distance Sb(1)–Sb(2) corresponds to the transformation of **1** into the starting compounds $Me_2SbSbMe_2$ and Me_2SbBr. Therefore, $[Me_6Sb_3]^+$ should not be considered as an isolated cation.

The solid-state structure of **1** is not preserved in solution in benzene. The ^1H NMR spectrum shows a broad signal at room temperature with a maximum between the frequencies of pure samples of $Me_2SbSbMe_2$ and Me_2SbBr.[1] This pattern corresponds to an exchange of Me_2Sb groups between tetramethyldistibane and dimethylantimony bromide, that is a reversible

formation of **1** from $Me_2SbSbMe_2$ and Me_2SbBr. In the gas phase the components are separated. Mass spectra contain the characteristic signals of $Me_2SbSbMe_2$ and Me_2SbBr.[11] The chemical behavior justifies the description of **1** as an adduct with dative bonds.[16] The observed equivalence of the dimethylantimony groups is attributed to the inability to distinguish between dative and covalent Sb–Sb bonds in **1**. In addition to the reversible dissociation into the starting materials there are irreversible decomposition processes of **1** leading to the formation of Me_3SbBr_2, Me_3Sb, and $(MeSb)_x$. Even the formation of these products can be rationalized by consideration of the results of the structural analysis, since both the reversible and the irreversible decomposition processes may be described as reductive elimination reactions.[17]

Experimental Procedure

All operations were carried out in an argon atmosphere. Dimethylantimony bromide (0.21 g, 0.91 mmol) was added slowly to tetramethyldistibane (0.50 g, 1.65 mmol) [18] through a syringe. After the addition, a small amount of black solid material precipitated together with yellow crystals of **1** (yield 0.18 g, 51.4%). Compound **1** was stable for several days at room temperature when stored under tetramethyldistibane.

[17] Compound **1** can be described as a stibonium ion of the type $[R^1_2R^2_2Sb]X$. Reductive elimination of R^1X gives $R^1R^2_2Sb$. When R^2X is eliminated $R^1_2R^2Sb$ is formed. With $R^1 = Me_2Sb$, $R^2 = Me$ and X = Br (coordinated at Me_2SbBr) the elimination of R^1X describes the reversible decomposition to Me_2SbBr and Me_4Sb_2. The irreversible decomposition of **1** with formation of Me_3SbBr_2 and $MeSb(SbMe_2)_2$ corresponds to the elimination of R^2X. The neutral tristibane gives $(MeSb)_x$ and Me_4Sb_2 on further decomposition.

$Na_{14}K_6Tl_{18}M$ (M = Mg, Zn, Cd, Hg) and $Na_{13.5}Sm_{0.5}K_6Tl_{18}Na$: Novel Octahedral and Centered Icosahedral Cluster Phases Related to the Mg_2Zn_{11}-Type Structure**

Zhen-Chao Dong and John D. Corbett*

Alkali-metal–thallium systems are extremely rich in phases containing thallium cluster anions,[1–7] perhaps because of both the approximate 1:1 ratio between number of atoms and cluster charge in the polyanions and the strong relativistic effect for the element Tl.[6] The use of more than one type of cation has proven to be a powerful means for tuning structural stability because of the increased flexibility for packing the cations and polyanions efficiently, thereby affording effective routes to new clusters not known in the simpler binary systems. Examples are Tl_5^{7-} (approximately D_{3h}) and Tl_9^{9-} (C_{2v}, defect icosahedron) in $Na_2K_{19}Tl_{21}$[4] and $Tl_{13}^{10-}/Tl_{13}^{11-}$ (centered icosahedra) in $Na_4A_6Tl_{13}$ (A = K, Rb, Cs) and $Na_3K_8Tl_{13}$.[6] Subsequently, $Na_{15}K_6Tl_{18}H$, a phase structurally related to $Na_4A_6Tl_{13}$, has been synthesized and shown to contain both Tl_6H^{7-} and $Tl_{12}Na^{13-}$ polyanions.[8] Wade's rules (and extended Hückel calculations) predict 14 skeletal electrons for the closed-shell octahedral Tl_8^{8-} and 26 for either the icosahedral Tl_{12}^{14-} or the centered $Tl_{12}(Na)^{13-}$. The composition $Na_{15}K_6Tl_{18}$ found by X-ray crystallography indicated a one-electron deficiency for the thallium clusters, similar to that for Tl_{13}^{10-}.[6, 7] However, the compound's contradictory Pauli-paramagnetic and ESR-silent properties, as well as the absence of cluster distortions, gave us the first hint that hydrogen was present, which was then verified by the results of subsequent syntheses and and comparisons with the structures of related phases. The amazing stabilization afforded by this small amount of hydrogen (about 0.02 wt%) further suggested a strong electronic drive for closed-shell anion configurations, and therefore opened prospects of further electronic tuning.

The most straightforward modification is the substitution of the centered Na atom within each Tl_{12} icosahedron by a dipositive cation, or partial replacement of exopolyhedral alkali-metal cations by higher valent ions. Of course, the final products are determined not only by electronic and size factors, but also by generally complex matters of phase stability. We report here the successful tuning of the $Na_{15}K_6Tl_{18}H$ phase with retention of the cubic $Pm\bar{3}$ symmetry and the formation of novel (H-free) Tl_6^{8-} (O_h) and M-centered icosahedral $Tl_{12}M^{12-}$ (T_h) clusters. These compounds turn out to be related to the long-known Mg_2Zn_{11}[9] structure and further demonstrate what kind of chemical tuning can be performed to produce new cluster species. Effects of different electron counts on the structures, as well as correlations with properties, are also briefly discussed.

Of the substitutions attempted with Zn, Cd, Hg, Mg, Ca, Sm, Eu, Yb, Ni, Pd, and Pt, only those with Zn, Cd, Hg, Mg, and Sm were successful, according to both X-ray diffraction data (with small lattice shrinkages, Table 1) and energy dispersive analysis by X-ray (EDAX) on several single crystals of each product. Guinier powder patterns for the rest showed no line shifts with

[a] Ref. [8]. [b] Guinier data, $\lambda = 1.540\,562$ Å, $T = 23$ °C. The cell dimensions for $Na_{14}K_6Tl_{18}Cd$ and $Na_{14}K_6Tl_{18}Hg$ are 10.626(3) Å and 10.6308(6) Å, respectively.

respect to the lines for $Na_{15}K_6Tl_{18}H$ (<0.005 Å, about 6 σ), and none of the targeted substitution metals was observed in the EDAX data. Single-crystal studies[10] were carried out for $Na_{14}K_6(Tl_{18}M)$ (M = Mg, Zn) and $Na_{13.5}Sm_{0.5}K_6(Tl_{18}Na)$. The M elements in the former replace the centering Na to give icosahedral $Tl_{12}M^{12-}$ (and regular octahedral Tl_6^{8-}) while the Sm atoms in the latter partially substitute [8.3(8)%] on the exopolyhedral Na3 positions leaving the parent $Tl_{12}Na^{13-}$ but a regular and closed-shell Tl_6^{8-} (Fig. 1). The ascribed closed-

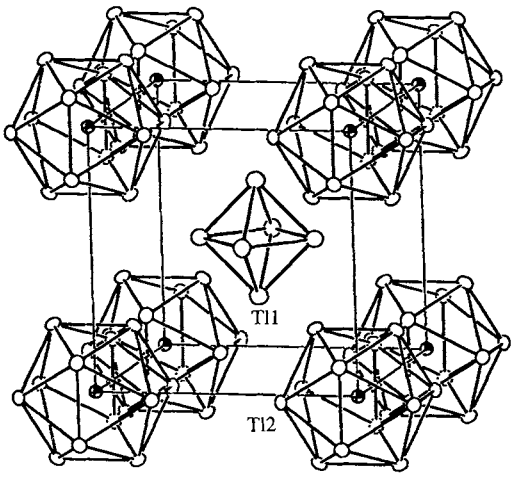

Fig. 1. Arrangement of the discrete Mg-centered icosahedral $Tl_{12}Mg^{12-}$ (T_h) and octahedral Tl_6^{8-} (O_h) anions in the unit cell of $Na_{14}K_6Tl_{18}Mg$ (90% thermal ellipsoids).

shell bonding with M is consistent with the weakly Pauli-paramagnetic property ($\chi_M = 8.5(2) \times 10^{-4}$ emu mol^{-1}) for $Na_{14}K_6(Tl_{18}M)$, where M = Mg, Zn. A Curie–Weiss-type paramagnetism for $Na_{13.5}Sm_{0.5}K_6(Tl_{18}Na)$ ($\mu_{eff} = 0.43(3)\,\mu_B$) is consistent with a trivalent Sm state (electron configuration $4f^5$) and the refined composition (the calculated magnetic moment μ_{eff} for the latter is exactly 0.43 μ_B), because the Sm^{2+} ($4f^6$) would make no contribution to the magnetic moment, because $J = 0$. In parallel with their weak Pauli paramagnetism, these compounds are expected to be poor metals in spite of their closed-shell configurations, as exemplified by the hydride phase ($\partial\rho/\rho\,\partial T \approx 0.34(1)\%\ K^{-1}$, $\rho_{290} \approx 100\ \mu\Omega$ cm). They can therefore be classified as Zintl phases that are incidentally metallic.[6, 11, 12]

It is interesting to notice the small but appreciable dimensional variations between the above phases and $Na_{15}K_6Tl_{18}H$. Lattice constants and important interatomic distances (Table 1) address how delicately different electron counts can affect both the cluster dimensions and the solvation by cations around them. First, the Tl–Tl distance in the octahedron apparently increases slightly (by 0.008(2) Å), from Tl_6H^{7-} to Tl_6^{8-}, although the cells contract (by about 0.05 Å for Mg and 0.02 Å for Zn and Sm), evidently because (polar) covalent bonding from interstitials like hydride usually increases the stabilities of clusters and decreases bond distances when no matrix effects are involved. While cation interactions with icosahedral clusters in these compounds remain basically the same, solvation of Tl_6^{8-} appears slightly stronger than that for Tl_6H^{7-} as judged from the approximately 0.02 Å shorter (Na,K)–Tl distances about the former, consistent with the cluster's higher formal charge. Second, Mg- or Zn-centered icosahedra present shorter center–surface and surface–surface distances with respect to the Na-centered cluster (by about 0.02 Å), presumably from both the stronger coulombic and covalent interactions and from the smaller sizes of Mg and Zn. The Tl–Mg distance of 3.143(1) Å compares very well with that of 3.14 Å reported in MgTl (CsCl type),[13] but the Tl–Zn distance (3.142(1) Å) is considerably longer than the 2.928(1) Å found in the Zn-centered bicapped square antiprismatic $Tl_{10}Zn^{8-}$ ion in $K_8Tl_{10}Zn$.[14] The presence of an undersized Zn atom within the icosahedron is indicated by its relatively large B_{eq} value (4.88 Å^2), and this conclusion is supported by an anomalously large, spherical residual shell (4.3 e Å^{-3} against a background near 1.6 e Å^3) found just 0.02 Å away from the central Zn site in the difference Fourier map. This is consistent with the occurrence of the same $Na_{14}K_6Tl_{18}M$ phase for the somewhat larger Cd and Hg.[15] A 3.14 Å center–surface distance appears to be about the lower limit for a thallium icosahedron.

Also noteworthy is the close structural correspondence of $Na_4K_6Tl_{13}$ (bcc, $Im\bar{3}$)[6] with the present $Na_{14}K_6Tl_{18}M$ ($Pm\bar{3}$), namely, $[(Na_8^{8+})(K_{12}^{12+})][(Tl_{13}^{10-})(Tl_{13}^{10-})]$ vs. $[(Na_8^{8+})(Na_6^{6+})(K_6^{6+})][(Tl_{12}M^{12-})(Tl_6^{8-})]$. The most substantial differences are the replacement of half the icosahedral units related by I-centering with smaller octahedra, and half of the K^+ about the latter by Na^+, and the change from a Tl atom at the center of the icosahedron to M = Mg, Zn, Cd, or Hg. Otherwise, the cation dispositions in the two phases show only slight coordinate shifts that give greater cation–anion interactions with Tl_6^{8-}. A notable contraction of the icosahedra is also observed, the center–surface distance decreasing from 3.22 Å in Tl_{13}^{10-} to 3.14 Å in $Tl_{12}M^{12-}$.

Of particular interest is the close relationship of the $Na_{14}K_6(Tl_{18}M)$ structure to the isotypic Mg_2Zn_{11}[9] (and Na_2Cd_{11}[16]), which can also be structurally formulated as $Zn_{14}Mg_6(Zn_{13}Zn_6)$ with Zn in the center of the icosahedron. Figure 2 shows the alkali-metal cation distributions around the "naked" Tl_6^{8-} (left) and $Tl_{12}M^{12-}$ (right) clusters, while Figure 3 demonstrates how these units are connected into a three-dimensional structure, here as well as for Mg_2Zn_{11} (see below). The linked network shown about the polyhedra in "salt-like" alkali-metal–thallium compounds (Fig. 3) does not imply bonding interactions among the cations, but it does highlight a different zinc substructure in the parent Mg_2Zn_{11}. The larger icosahedral units are held within a cage defined by six zigzag eight-membered rings, while the smaller octahedron is surrounded by twelve five-membered rings. The accompanying shrinkage around the octahedron to preserve suitable bonding interactions results in six extra contacts between pairs of atoms (Na or Zn, represented as gray spheres) that make the former

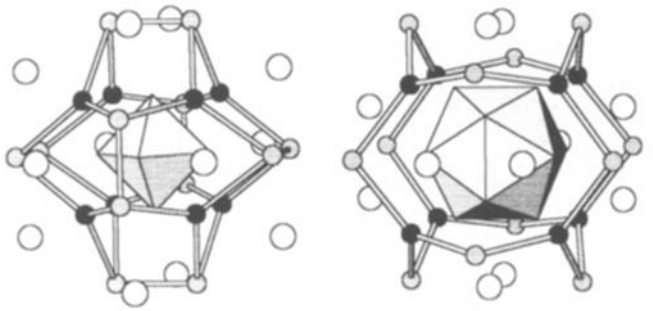

Fig. 2. Environments around the octahedral (left) and icosahedral (right) thallium clusters with the Na sites interconnected to emphasize the relationship to Mg_2Zn_{11}. The *closo*-deltahedra (large circles, and small shaded circles) represent either Tl clusters, K, and the two types of Na atoms in $Na_{14}K_6Tl_{18}M$, or Zn cluster fragments, Mg, and Zn atoms in Mg_2Zn_{11}, respectively.

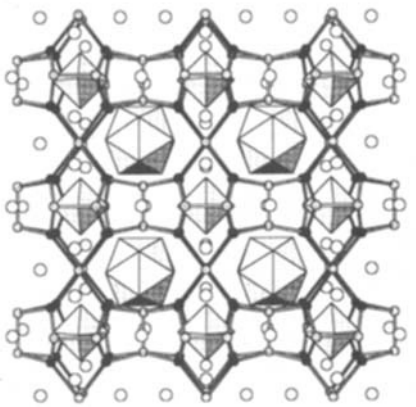

Fig. 3. View of the $Na_{14}K_6Tl_{18}M$ and Mg_2Zn_{11} structures onto [001] showing three different substructures and the interconnections among the cations between clusters. Symbols for the atoms are the same as in Fig. 2.

eight-membered ring bicyclic. Inclusion of isolated cations (represented as open circles for K or Mg) leaves all of the Tl or Zn polyhedra sheathed by 32 atoms functioning in two ways: every triangular face in both polyhedra is capped whereas each vertex is exo-bonded to one atom for the icosahedron but to two Na (or Zn) and two more distant K (Mg) for the octahedron. The eight atoms face-capping the octahedron (black circles) need special attention. These positions, always fully occupied by a single Na or Zn type, are located along the body diagonals in distorted octahedral holes defined by the neighboring polyhedral units, and so demonstrate that the octahedron and icosahedron are the only two interchangeable cluster units with suitable cubic symmetry and comparable environments.

Three different substructures are evident in Mg_2Zn_{11}: the same zinc polyhedra (octahedral Zn_6 and Zn-centered icosahedral Zn_{13}), in the holes a zinc spacer substructure (linked Zn_{14}, like Na), and solvating cations (Mg^{2+}, K^+). It is these different structural functions that afford broad chemical variability through changes in the atom types in the polyhedra, spacers, or cations. While the parent Mg_2Zn_{11} probably represents the highest condensation limit, because the two zinc substructures strongly interact with each other through homonuclear bonding, the present $Na_{14}K_6Tl_{18}M$ phase represents the opposite extreme with isolated polyhedral thallium clusters, well-separated by the solvating alkali-metal cations. Some intermediate degrees of condensation (or bonding polarity) must be also possible and are indeed observed in the isomorphous $Mg_2Al_5Cu_6$ (that is, $[(Al_{14})(Mg_6)][(Cu_{12}Al)(Cu_6)]$)[17] and $Na_2In_5Au_6$ (that is, $[(In_{14})(Na_6)][(Au_{12}In)(Au_6)]$)[18] in which Al or In atoms (in the place of Na) connect Cu or Au octahedra and icosahedra. The nature of the interactions between the linked network and polyhedra undoubtedly undergoes dramatic changes from Mg_2Zn_{11} through $Mg_2Al_5Cu_6$ to $Na_{15}K_6Tl_{18}M$ as the bonding character changes from homonuclear covalent through heteronuclear covalent to predominantly ionic. The last is mechanically the weakest in this series and extremely brittle, but it still has a metallic luster.

The title compounds are examples in which electronic tuning among closed-shell structures is successfully realized. More chemical tuning about this structure type and new octahedral and icosahedral clusters can be expected through appropriate combinations of elements from Groups 1 and 2 and Groups 11–13. In other words, dissection of a structure followed by manipulation of the numbers and types of atoms in a cluster compound may produce new cluster materials with novel properties.

Experimental Procedures

Pure phases of the title compounds were obtained through reactions of stoichiometric amounts of the constituent elements in welded Ta tubing by using the techniques described previously [4]. The surfaces of the Na chunks (99.9%, Alpha) and Tl metal bar (99.998%, Johnson-Matthey) were cleaned with a scalpel in the glovebox before use, whereas the K (99.9%, Baker, sealed under Ar), Mg turnings (99.9%, Aldrich), Zn fillings (99.9%, Fisher), and Sm granules (99.9%, Ames Lab) were used as received. In order to establish that hydrogen interstitials were not involved [8], parallel reactions were run both under vacuum (equilibration at 800 °C for 5 h followed by slow cooling to room temperature) or jacketed by fused silica tubing (equilibration at 500 °C for three days followed by annealing at 250 °C for one week) and with different heating profiles. EDAX studies were carried out on a JEOL 840A SEM with a REBEX DELTA detector with several single crystals of each phase. The single-crystal X-ray diffraction data were collected on a CAD4 diffractometer ($Mo_{K\alpha}$) at room temperature for an angle of 2θ up to 55°. Empirical absorption corrections included ψ-scans and DIFABS [19]. Magnetic susceptibility measurements were made at a field of 3 T over the range of 6–300 K with a Quantum Design MPMS SQUID magnetometer on powdered samples of $Na_{15}K_6Tl_{18}H$ (52 mg), $Na_{14}K_6Tl_{18}Mg$ (47 mg), $Na_{14}K_6Tl_{18}Zn$ (43 mg), and $Na_{13.5}Sm_{0.5}K_6Tl_{18}Na$ (50 mg) in the container type described elsewhere [16]. The raw data were corrected for the susceptibilities of the container and the diamagnetism of the cores [20] as well as for the Larmor precession contributions of the delocalized valence electrons in the clusters, as before [6, 21]. Results are shown in the supplementary material.

A Double Calix[4]arene in a 1,3-*alternate* Conformation**

José-Antonio Pérez-Adelmar, Hervé Abraham, Concha Sánchez, Kari Rissanen, Pilar Prados,* and Javier de Mendoza*

Calixarenes offer attractive possibilities as molecular frameworks for the preparation of highly preorganized, rigid molecular receptors.[1] Double calixarenes, in which the lower rims are linked by suitable spacers (head-to-head), were recently described.[2] Some tail-to-tail (rings linked through the upper rims or *para* positions),[3] and head-to-tail[4] arrangements have also been reported. These structures have received increased attention because they display well preorganized molecular structures, most often in *cone* conformation. However, only a few examples of double calix[4]arenes in 1,3-*alternate* conformation (whose cylindrical shape features a molecular channel) are known, and they all belong to the head-to-head[5] or to the tail-to-tail[6] series. We report herein the synthesis of a 1,3-distal bridged double calix[4]arene in 1,3-*alternate* conformation, the first X-ray crystal structure of such a dimer, and a preliminary NMR study of its complexation with silver(I) ions.

The 1,3-distal O-alkylated derivative **2** was obtained from the parent *p*-H-calix[4]arene **1** (2.2 equiv potassium carbonate, 2.2 equiv 2-ethoxyethyl tosylate, acetonitrile, 2 atm, 130 °C, 74% yield). Reaction of **2** with *N*-bromosuccinimide in 2-butanone gave the dibromo compound **3** as the major component (76% yield after chromatography) and small amounts of the monobromo derivative **4** (1–4% yield). The ^1H[7] and ^{13}C NMR spectra[8] of these compounds indicate that they are in *cone* conformations.

Dibromo compound **3** was then fully O-alkylated under Reinhoudt's conditions (15 equiv cesium carbonate, 12 equiv 2-ethoxyethyl tosylate, DMF, 80 °C)[9] to give **5** as a 92:8 mixture of 1,3-*alternate* and *partial-cone* conformers from which the major 1,3-*alternate* conformer was isolated in 82% yield.

A Double Calix[4]arene in a 1,3-*alternate* Conformation**

José-Antonio Pérez-Adelmar, Hervé Abraham, Concha Sánchez, Kari Rissanen, Pilar Prados,* and Javier de Mendoza*

Calixarenes offer attractive possibilities as molecular frameworks for the preparation of highly preorganized, rigid molecular receptors.[1] Double calixarenes, in which the lower rims are linked by suitable spacers (head-to-head), were recently described.[2] Some tail-to-tail (rings linked through the upper rims or *para* positions),[3] and head-to-tail[4] arrangements have also been reported. These structures have received increased attention because they display well preorganized molecular structures, most often in *cone* conformation. However, only a few examples of double calix[4]arenes in 1,3-*alternate* conformation (whose cylindrical shape features a molecular channel) are known, and they all belong to the head-to-head[5] or to the tail-to-tail[6] series. We report herein the synthesis of a 1,3-distal bridged double calix[4]arene in 1,3-*alternate* conformation, the first X-ray crystal structure of such a dimer, and a preliminary NMR study of its complexation with silver(I) ions.

The 1,3-distal O-alkylated derivative **2** was obtained from the parent *p*-H-calix[4]arene **1** (2.2 equiv potassium carbonate, 2.2 equiv 2-ethoxyethyl tosylate, acetonitrile, 2 atm, 130 °C, 74% yield). Reaction of **2** with *N*-bromosuccinimide in 2-butanone gave the dibromo compound **3** as the major component (76% yield after chromatography) and small amounts of the monobromo derivative **4** (1–4% yield). The ^1H[7] and ^{13}C NMR spectra[8] of these compounds indicate that they are in *cone* conformations.

Dibromo compound **3** was then fully O-alkylated under Reinhoudt's conditions (15 equiv cesium carbonate, 12 equiv 2-ethoxyethyl tosylate, DMF, 80 °C)[9] to give **5** as a 92:8 mixture of 1,3-*alternate* and *partial-cone* conformers from which the major 1,3-*alternate* conformer was isolated in 82% yield.

[**] This work was supported by Dirección General de Investigación Científica y Técnica (DGICYT PB93 0283) and by the Finnish Academy (project no. 8588).

methylene groups in compounds **5**–**8** ranged between $\delta = 33.4$ and 35.4, deviating slightly from the typical value of $\delta = 37$ for calixarenes with 1,3-*alternate* conformations.[8] Reinhoudt et al. found similar deviations ($\delta \approx 35$) for calix[4]arenes whose X-ray structures showed distorted 1,3-*alternate* conformations.[9, 10]

The 1,3-*alternate* conformation of compound **8** was established unambiguously by a single-crystal X-ray structure determination (Fig. 1).[11] The double calix[4]arene **8** has a tubular shape with a cross section of 12 Å and a length of 28 Å (Fig. 1a). The inner diameter of the 1,3-*alternate* calix[4]arene termini varies from 4.1 to 4.5 Å, whereas the separation between nitrogen atoms at the bridges is 4.3 Å. Furthermore, the benzene rings of the terephthaloyl spacers are parallel to each other and separated by 3.3–3.9 Å. Due to the symmetry of **8** the ethoxyethyl arms at the end of the cylinder are twisted by 90° relative to each other in a suitable orientation to "shake hands" with the ethoxyethyl arms of an adjacent molecule. This creates an infinite channel-type structure in the crystal lattice (Fig. 1b). These infinite channels are tightly packed along the *a*-axis; the packing is enhanced by the close contacts of the central ethoxyethyl arms (Fig. 1c). The X-ray structure of **8** is the first reported of a double calix[4]arene in 1,3-*alternate* conformation[14] and shows how these compounds can self-assemble in the solid state as organic zeolite-type structures.

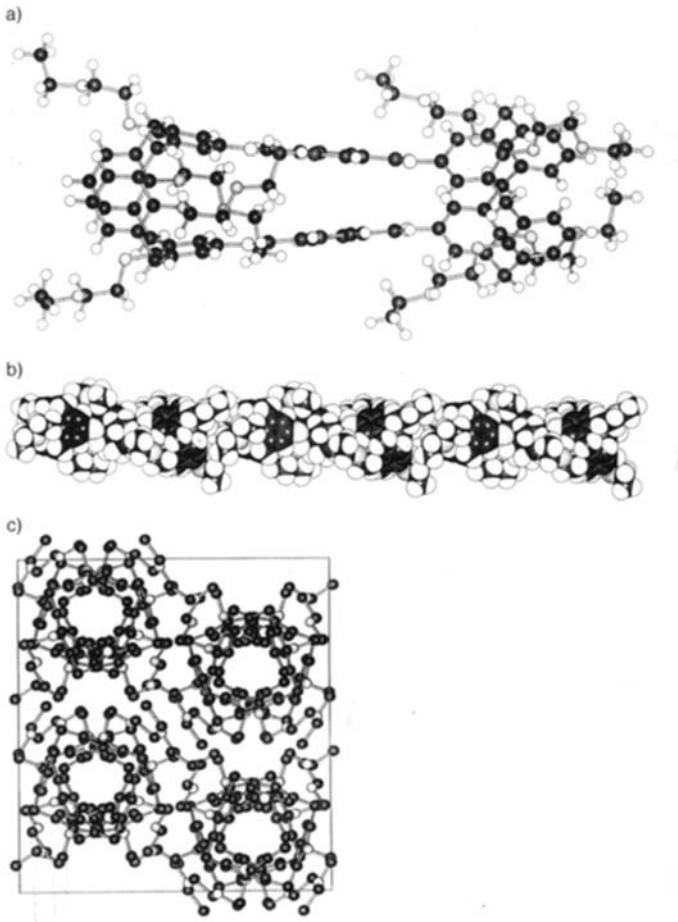

Fig. 1. Crystal structure of **8**. a) Side view. b) Side view of a CPK model of three aligned molecules, showing the tubular structure. c) Top view along the *a*-axis, showing the internal diameter of **8**.

Preliminary ^{1}H NMR experiments revealed that compound **8** shows affinity for silver(I) ions. Addition of increasing amounts of silver(I) triflate caused significant changes in the spectrum (Fig. 2). At room temperature the signals of the imine protons H_A and the protons H_B of the aromatic spacer are shifted significantly downfield, although no new signals appeared. When more than two equivalents of silver(I) had been added, the signals of the calixarene aromatic protons (such as H_C and H_D) shifted as well. Thus, it is likely that two metal ions are complexed initially by the imine nitrogen atoms and then two further cations are complexed at the calixarenes ends by the oxygen-containing chains. At $-80\,^\circ$C new signals appeared upon addition of up to two equivalents of silver(I), corresponding to mixtures of "frozen" species (free ligand, one and two metal atoms). Addition of an excess of the silver salt resulted in a single compound corresponding to the tetranuclear complex. In agreement with the NMR observations, the FAB-MS spectrum of **8** (*meta*-nitrobenzyl alcohol (*m*NBA) matrix) in the presence of an excess of silver(I) triflate shows peaks at *m/z* (%) 2561.1 (0.4) $[(M \cdot Ag \cdot 3AgOTf)^+]$, 2304.2 (3) $[(M \cdot Ag \cdot 2AgOTf)^+]$, 2046.2 (100) $[(M \cdot Ag \cdot AgOTf)^+]$, and 1790.0 (62.4) $[(M \cdot Ag)^+]$.

Addition of small amounts of potassium picrate induced downfield shifts of the signals of the calixarene H_C and H_D aromatic protons. Experiments aimed to study complexation

and/or scrambling of potassium cations at the ends of the dimeric structure in the presence of one or two silver(I) ions, which could block the channel at the central imine binding sites, are currently underway.

Experimental Procedure

8: To a solution of **6** (310 mg, 0.39 mmol) and Ph_3P (246 mg, 2.4 equiv, 0.94 mmol) in dry toluene (150 mL) was added a solution of terephthaldialdehyde (52 mg, 1 equiv, 0.39 mmol) in toluene (10 mL) under Ar. The mixture was stirred at room temperature for 7 d, the solvent was removed in vacuo, and the residue was triturated with diethyl ether and filtered. The filtrate was concentrated to dryness and the resulting solid was triturated with acetonitrile and filtered. Column chromatography (ethyl acetate/hexane, 1:1) afforded **8** (110 mg, 30%). M.p. > 300 °C; ^{1}H NMR (300 MHz, $CDCl_3$): δ = 8.31 (s, 4H, CH=N), 7.58 (s, 8H, ArH), 7.15 (d, J = 7.5 Hz, 8H, ArH), 7.13 (s, 8H, ArH), 6.65 (t, J = 7.5 Hz, 4H, ArH), 4.10–3.93 (m, 24H, OCH_2CH_2O), 3.83–3.80 (m, 8H, OCH_2CH_2O), 3.69 (q, J = 7.0 Hz, 8H, OCH_2CH_3), 3.68 (q, J = 7.0 Hz, 8H, OCH_2CH_3), 3.60 (s, 16H, $ArCH_2Ar$), 1.35 (t, J = 7.0 Hz, 12H, OCH_2CH_3), 1.27 (t, J = 7.0 Hz, 12H, OCH_2CH_3); ^{13}C NMR (75 MHz, $CDCl_3$, Heteronuclear Multiple Bond Correlation (HMBC), Heteronuclear Multiple Quantum Correlation (HMQC)): δ = 157.8 (CH=N), 155.7, 154.2, 145.3, 135.2, 133.9 (ArC), 130.3, 128.3, 122.5, 121.5 (ArCH), 72.3, 72.2, 70.2, 69.9 (OCH_2CH_2O), 66.6 (OCH_2CH_3), 34.5 ($ArCH_2Ar$), 15.2 (OCH_2CH_3); FAB-HRMS (*m*NBA matrix): *m/z*: 1681.8746 [$M^+ + 1$]; calcd. for $C_{104}H_{121}N_4O_{16}$, 1681.8777.

[10] In agreement with this, the spectrum of the isomer of **5** having a *partial cone* conformation shows an AX system (δ = 4.21 and 3.00) for methylene bridges in *syn* orientation and an AB system (δ = 3.62 and 3.72) for those *anti* oriented (HMQC). The corresponding ^{13}C signals appear at δ = 30.4 and 34.2, respectively.

[11] Crystal structure analysis of **8**: $C_{104}H_{120}N_4O_{16}$, M_r = 1682.1, monoclinic, space group $C2/c$ (no. 15), a = 27.029(6), b = 19.612(3), c = 19.540(4) Å, β = 110.63(2)°, V = 9693(4) Å^3, Z = 4, ρ_{calcd} = 1.153 g cm^{-3}, $F(000)$ = 3658, T = 296 ± 1 K. The data were collected from a colorless crystal with dimensions 0.30 × 0.30 × 0.45 mm. Of 6956 collected reflections, 5586 were unique (R_{int} = 0.040), recorded with a SYNTEX $P2_1$ diffractometer using graphite-monochromated $Cu_{K\alpha}$ radiation [λ = 1.5418 Å] and a ω-scan mode to 2θ = 113° (h: −29 → 27, k: 0 → 21, and l: 0 → 21), 3167 reflections with $I > 2\sigma(I)$ were used for refinement. Lp correction, but no absorption correction was applied, $\mu(Cu_{K\alpha})$ = 0.613 mm^{-1}. The structure was solved by direct methods (SHELXS) [12] and subjected to full-matrix refinement [13]. The ratio F_o/(number of parameters) was 5.46, R = 0.121, and R_w = 0.143 for 580 parameters; $w = w'[1.0 - (\Delta F/6\sigma F)^2]^2$, where w' = Chebychev polynomial for F_c with three coefficients (2.79, 3.34, 1.54), S = 1.18, convergence, max. shift/error < 0.08. A final difference map displayed no electron density higher than 0.73 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-20. A Stable Tetraazafulvalene**

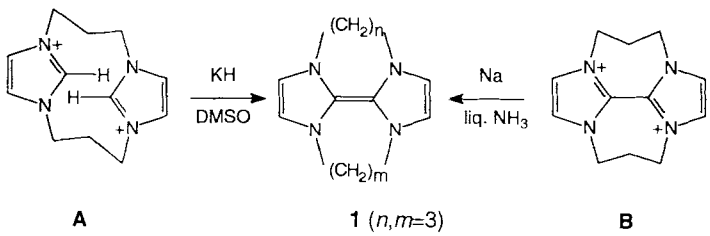
T. Andrew Taton and Peter Chen*

We report the synthesis, X-ray crystal structure, and chemical behavior of the electron-rich olefinic dimer of an *N,N'*-dialkylimidazol-2-ylidene (an Arduengo carbene). The carbenes were recently found,[1] much to everyone's surprise, to be isolable compounds, raising the question as to the C=C bond dissociation enthalpy of the tetraazafulvalene-type dimer of the carbenes. Qualitative theoretical considerations had predicted the bond enthalpy of tetraazafulvalenes to be close to zero, or possibly even negative. In the first thermochemical study of the dimerization of an *N,N'*-dialkylimidazol-2-ylidene, we find the bond dissociation enthalpy of *N,N',N'',N'''*-tetraalkyltetraazafulvalenes to be only slightly greater than zero.

The tetraazafulvalene **1** (n,m = 3) was prepared by two separate routes (Scheme 1). Double deprotonation of the



Scheme 1. Synthesis of **1** (n,m = 3).

doubly bridged bis(imidazolium) dication **A** by treatment with KH in dimethyl sulfoxide (DMSO) or alternatively with $NaNH_2$ in NH_3 afforded **1** rather than the biscarbene **1'** (n,m = 3). Reduction of a doubly bridged biimidazolium dication **B**[2] with sodium in liquid ammonia, evaporation of the ammonia, extraction of the residue with hexane, and finally

[**] The research was supported by the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung. The authors acknowledge the generous assistance of Prof. Dr. Bernhard Jaun (ETH Zürich) and Paul Seiler (ETH Zürich, X-ray structure analysis).

recrystallization of the crude product by slow evaporation yielded pale yellow prisms whose spectroscopic properties[3] are identical to those of **1** ($n,m = 3$) produced by the other route.

The presence of a genuine double bond between the two imidazol-2-ylidene moieties is evident from the ^{13}C NMR chemical shift of central olefinic carbon in **1**. For the carbenes this signal occurs at $\delta = 210-220$, whereas for the tetraazafulvalene **1** ($n,m = 3$) it is found at $\delta = 127.5$. Furthermore, in the X-ray crystal structure[4] of **1** ($n,m = 3$) (Fig. 1) the C–C distance is

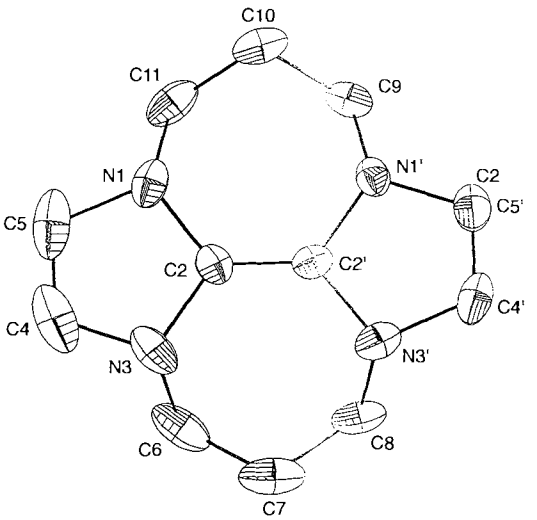

Fig. 1. X-ray crystal structure of **1** ($n,m = 3$). The H atoms are omitted for clarity. Selected distances [Å] and angles [°]: C2–C2' 1.337(5), C2/2'–N1/3/1'/3' 1.429(4) (av), N1/3/1'/3'–C4/5/4'/5' 1.410(6) (av), C4/4'–C5/5' 1.294(9) (av); N1/1'-C2/2'-N3/3' 107.9(3) (av).

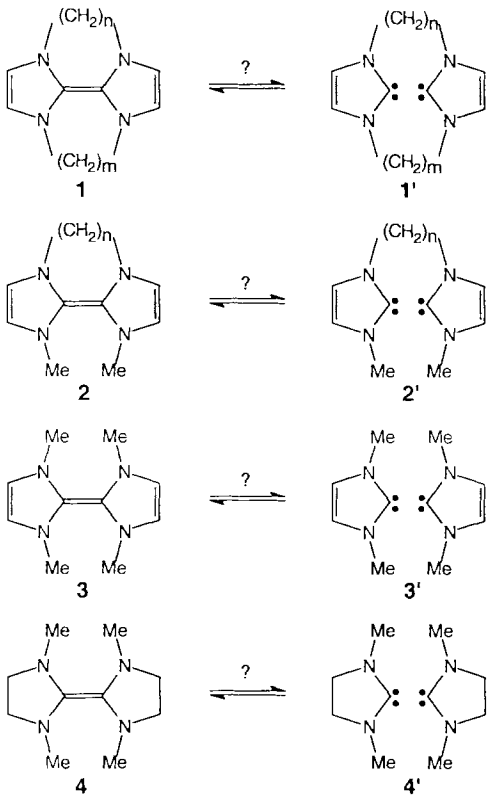
1.337(5) Å, and the central olefinic portion of the molecule close to planar, which is completely consistent with the presence of a bona fide double bond. Although further details of the structure will be discussed in a separate report, one should mention here that the two trimethylene bridges are strongly puckered, permitting considerable flexibility in the molecule. It is noteworthy that in the X-ray structures of the related doubly bridged (also with two trimethylene bridges) bis(benzimidazolone)[5] the two heterocyclic rings are placed face-to-face to minimize steric repulsions, in sharp contrast to **1** ($n,m = 3$). We find **1** ($n,m = 3$) to be stable at room temperature both in solution and in the solid state for days under anhydrous, anaerobic conditions. Furthermore, no change in the ^1H NMR spectrum of **1** ($n,m = 3$) was observed even upon heating to 100 °C in [D_6]DMSO for 15 minutes or more.

Preparation of **1** ($n,m = 4$) by reduction of the corresponding biimidazolium salt in liquid ammonia, extraction, and recrystallization also produced yellow crystals, which, upon warming to room temperature, rapidly changed into a white powder. The powder was identified as the doubly bridged biscarbene **1'** ($n,m = 4$) by its characteristic ^1H NMR spectrum.[6] All attempts to prepare the monobridged tetraazafulvalenes **2** and the unbridged species **3** yielded only the corresponding carbenes **2'** and **3'**

The theoretical prediction of a near-zero or negative bond enthalpy for tetraazafulvalenes is based on a valence-bond promotion energy picture,[7] most recently expounded by Carter and Goddard with ab initio calculations in support.[8] The overall scheme is closely related to valence state arguments from spin-valence theory,[9] the DSSE (= divalent state stabilization



energy) model by Walsh[10] and the valence-bond curve-crossing model by Pross and Shaik.[11] In the Carter and Goddard formulation, the strength of the C=C bond in the formal dimer of a pair of singlet carbenes should correspond to that of a canonical C=C bond (usually that of ethene) minus the sum of the singlet–triplet energy difference for the two carbenes. The singlet–triplet splitting in imidazol-2-ylidenes has been predicted by ab initio calculations[12] to be approximately 85 kcal mol^{-1}, which is the largest value known for any divalent carbon compound other than CO or isocyanides. Accordingly, one expects the bond strength in a tetraazafulvalene to be approximately $[172 - (2 \times 85)] \approx 2$ kcal mol^{-1}. The failure of previous attempts to isolate tetraazafulvalenes has been attributed to the nearly nonexistent bond between the two halves of the molecule. One notes that the tetraaminoethene **4**, which is a formal dimer of imidazolidin-2-ylidene **4'**, has been known for over 30 years,[13] and the dibenzo analogs of **1** ($n,m = 3$) have been recently reported.[5] In these cases, the singlet–triplet energy gap of the carbene is reduced[12] by saturation of the heterocyclic carbene or benzannelation, which increases the strength of the C=C bond in the dimer. However, it is absolutely essential to acknowledge that isolability of either the carbene or its dimer gives no actual information about the C=C bond strength. The surprising preparation and X-ray crystal structure determination of the *N,N'*-dimesitylimidazolidin-2-ylidene[14] related to carbene **4'**, together with the long-known isolability of **4**, underlines the point that isolability only means that a kinetic barrier exists to either dimerization or dissociation. Because we have prepared a series of tetraazafulvalenes that differ only in the number and length of the methylene bridges, and observed the entire range of possibilities from stable dimers, to interconverting dimers and carbenes, to stable carbenes, we can make the following hypothesis. Based on the ready conversion of **1** ($n,m = 4$) to **1'** ($n,m = 4$), we can surmise that the kinetic barrier to dissociation is low enough so that the conversion **1** ($n,m = 3$) to **1'** ($n,m = 3$) would occur if it were thermochemically favorable.

Detailed equilibrium and kinetic studies will be the subject of a future report, but we can already place relatively narrow bounds on the enthalpy of dissociation of the central C=C bond in *N,N',N'',N'''*-tetraalkyltetraazafulvalenes. The problem in determining the enthalpy of C=C bond scission in **1** is similar to that in describing the energetics of intramolecular reactions[15] or of the formation of intramolecular hydrogen bonds in flexible systems.[16] Assuming that the enthalpy of dissociation is approximately constant across the series **1**, **2**, and **3**, the differences in the free energy of dissociation, which is positive for **1** ($n,m = 3$), near-zero or slightly negative for **1** ($n,m = 4$), and more strongly negative for **2** and **3**, should arise principally from differences in the entropy of dissociation. A lower bound of $\Delta H > 0$ is based on the stability of **1** ($n,m = 3$). Given that dissociation is kinetically possible in this case, only a positive ΔH could give a positive ΔG when ΔS for the reaction **1** ($n,m = 3$) → **1'** ($n,m = 3$) is positive. An upper bound on the ΔS value for dissociation of any of the tetraazafulvalenes is $\Delta S < 35\ \mathrm{cal\,mol^{-1}\,K^{-1}}$, which would correspond to the reaction **3** → **3'**. That places, in turn, an upper bound of $\Delta H < 10\ \mathrm{kcal\,mol^{-1}}$ for **1**, **2**, and **3**. Because the ΔH value is actually bracketed by the difference in $T\Delta S$ for the two reactions, **1** ($n,m = 3$) → **1'** ($n,m = 3$) and **1** ($n,m = 4$) → **1'** ($n,m = 4$), and ΔS for **1** ($n,m = 4$) → **1'** ($n,m = 4$) is certainly much less than the upper bound of $35\ \mathrm{cal\,mol^{-1}\,K^{-1}}$, we can estimate with confidence that the bond dissociation enthalpy for an *N,N',N'',N'''*-tetraalkyltetraazafulvalene is $\Delta H = 4 \pm 3\ \mathrm{kcal\,mol^{-1}}$. The exceedingly weak bond is a striking confirmation of the quantitative accuracy of a qualitative theory.

We have prepared and characterized a series of tetraazafulvalenes of varying stability, including one that is isolable at room temperature. Its structure was determined unambiguously by NMR spectroscopy and X-ray crystallography. An estimate of the bond dissociation enthalpy for tetraazafulvalenes agrees very well with expectations from qualitative theory, and confirms the existence of a very weak C=C bond in the formal dimers of singlet carbenes.[17]

Synthesis and Characterization of Bis(chlorin)s from the McMurry Reaction of Formylchlorins**

Laurent Jaquinod, Daniel J. Nurco, Craig J. Medforth, Ravindra K. Pandey, Timothy P. Forsyth, Marilyn M. Olmstead, and Kevin M. Smith*

Arrays of porphyrins linked by rigid spacer groups have become important for the understanding the interchromophore electron-transfer mechanisms responsible for the primary charge separation in photosynthesis[1] and for their potential uses as electronic devices such as conducting polymers (molecular wires),[2] photovoltaic devices,[3] and molecular logic devices;[4] dimers with "face-to-face" or "gable" arrangements are also effective catalysts for the four-electron reduction of dioxygen to water,[5] and the oxidation of organic substrates.[6] Previous work in our laboratories has focused on the synthesis of dimers with ethylene or stilbene linking units through coupling with low-valent titanium (McMurry coupling),[7, 8] as well as through reductive couplings of benzochlorins bearing an acrolein side group.[8] Although these and other porphyrins have proven to be valuable model compounds, we felt that chlorin–chlorin dimers would be a useful step toward the preparation of more biologically relevant model systems. In this paper we describe the reductive coupling of 20-formyl- and 3-formylchlorin derivatives (**1–3**), and some of the unusual

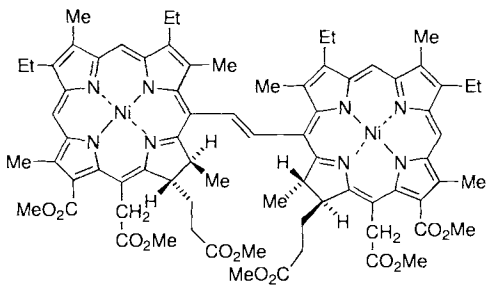
structural and spectroscopic properties of the bis-systems obtained from these reactions.

McMurry coupling of nickel(II) 20-formylmesochlorin-e_6 trimethyl ester (**1**) at room temperature or in 1,2-dimethoxymethane (DME) at reflux led to the production of a single bis(chlorin) in 52% yield.[9] X-ray crystallography (Fig. 1)[10]



4

showed the molecular structure of the dimer to be **4**, in which two crystallographically independent Ni^{II}-chlorin molecules are covalently linked by an ethylene bridge (C=C 1.330(8) Å). To the best of our knowledge, **4** is the first structurally characterized ethene-linked bis(chlorin), though an ethane-linked bis(octaethylchlorin) has been reported.[12] In **4** the nickel-chlorin units are in a *trans* arrangement about the ethylene bridge, with a mean deviation of the porphyrin core atoms from the least squares plane of 0.35 Å and an average Ni-N distance of 1.915 Å. The latter are consistent with the known tendency of nickel porphyrins to favor nonplanar structures with short Ni-N distances.[13, 14] The ^{1}H NMR spectrum of **4** at room temperature shows apparent C_2 symmetry, but upon cooling to 174 K in CS_2/CD_2Cl_2 (3/1) many of the signals broaden and split into two signals of unequal intensity. For the vinyl protons, the downfield signal ($\delta = 7.56$) is favored over the upfield signal ($\delta = 6.28$) by a ratio of 2.1:1 ($\Delta G^{\circ}_{175\,K} = 1.1$ kJ mol^{-1}). The energy barrier for this process estimated from the coalescence temperature of the vinyl protons is $\Delta G^{*}_{223\,K} = 41.6$ kJ mol^{-1}. At present, the most likely explanation for the dynamic behavior exhibited by **4** is restricted rotation about the $C_{meso}-C_{vinyl}$ bonds, with slow exchange between conformations which have the reduced rings on the same side of the dimer (as in the crystal form shown in Fig. 1) and a structure in which both chlorins are rotated 180° about the $C_{meso}-C_{vinyl}$ bond. Other dynamic processes, such as inversion of the nonplanar macrocycles,[15, 16] were considered but could not be used to rationalize the observed dynamic behavior in **4**. Note that in contrast to bis(porphyrins),[17] heating **4** at reflux in deoxygenated boiling acetic acid did not yield significant *cis-trans* isomerization, perhaps because of the steric repulsions present in a dimer with *cis* chlorin substituents.

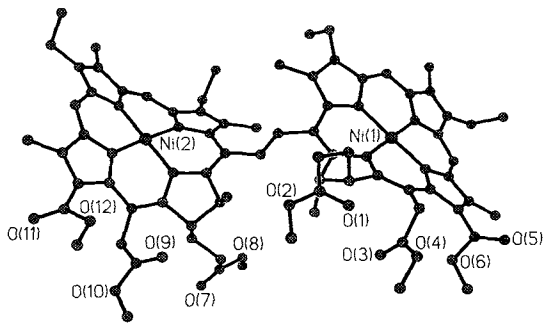


Fig. 1. Molecular structure of *trans*-bis(chlorin) **4**.

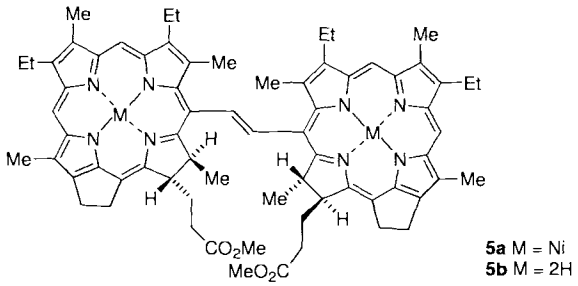
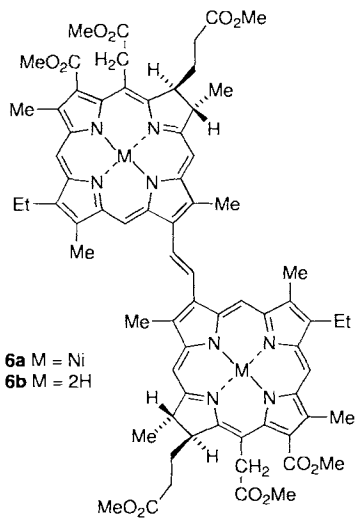
Coupling of the related chlorin, nickel(II) methyl-20-formyl-13^1-deoxomesopyropheophorbidea (**2**) gave the corresponding bis(pheophorbide) **5a** in 72% yield. Variable-temperature proton NMR studies also revealed a dynamic process for this dimer ($\Delta G^{*}_{223\,K} = 41.9$ kJ mol^{-1}). The ratio of the intensities of the signals from the two components is reversed relative to **4**: the upfield vinyl signal ($\delta = 6.57$) is favored over the downfield one ($\delta = 7.61$) by a ratio of 6:1 in favor of the structure in which the chlorin units are rotated by 180° ($\Delta G^{\circ}_{174\,K} = 2.6$ kJ mol^{-1}). Coupling of nickel(II) 3-formyl-3-devinylchlorin-e_6 trimethyl ester[18] (**3**) gave a 67% yield of a bis(chlorin) identified as **6a**, in which the macrocycles are linked by an ethylene bridge at a pyrrole position rather than a *meso* position. Variable-temperature proton NMR studies



5a M = Ni
5b M = 2H



6a M = Ni
6b M = 2H

of **6a** revealed broadening and coalescence of some signals upon cooling, although the nature of the dynamic process was not clear for this bis(chlorin). Interestingly, the behavior of chlorin **3** in the coupling reaction is quite different from that observed for nickel(II) 2-formyl-3,7,8,12,13,17,18-heptaethylporphyrin, which gives a bis(porphyrin carbinol) upon McMurry coupling, rather than an ethylene-linked dimer.[8]

Attempts to demetalate bis(chlorin)s **5a** and **6a** with concentrated H_2SO_4 led to decomposition, so metal-free bis-systems **5b** and **6b** were accessed by performing the coupling reaction in which Zn^{II} is the coordinated metal ion, followed by demetalation of the McMurry product with trifluoroacetic acid (TFA). Previous attempts to couple Zn^{II} porphyrins have led to substantial decomposition.[19] In the present work, the coupling was performed in THF at room temperature in the presence of 3.5 equivalents of pyridine (to prevent any HCl formed during the reduction of $TiCl_3$ from demetalating the acid-labile Zn^{II}-chlorins prior to the coupling). The molecular structure was determined crystallographically (Fig. 2)[10] for the free base **5b** of

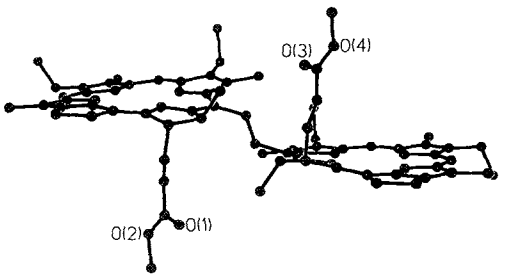


Fig. 2. Molecular structure of metal-free *trans*-bis(chlorin) **5b**.

dimer **5a**, and also shows a *trans* arrangement of the chlorin rings about an ethylene linkage [C=C 1.295(4) Å]. A noticeable difference between the structures of **5b** and the Ni^{II} complex **4** is evident in the increased planarity of the former, where the mean deviation of the macrocyclic core atoms from the least squares plane is only 0.13 Å. Variable-temperature proton NMR studies of **5b** also revealed broadening of some signals upon cooling, although again the nature of the dynamic process is not clear for this system. Treatment of **5b** and **6b** with $[Ni(acac)_2]$ in refluxing chloroform gave nickel complexes **5a** and **6a**.

A striking difference was observed between the bis(chlorin)s linked at a pyrrole position (**6**) and those linked at a *meso* position (**4** and **5**) upon oxidation in refluxing toluene/acetic acid (3/1) in the presence of air. The pyrrole-linked dimer **6a** could not be properly oxidized under these conditions, whereas the *meso*-linked dimer **4** provided the porphyrin–chlorin system **7** in 50% yield, and the *trans*-bis(porphyrin) **8** in 30% yield. Most interestingly, oxidation of **5a** under the same conditions yielded the *cis*-bis(porphyrin) **9** in 80% yield. The molecular structure of **9** (Fig. 3)[10] shows two nonplanar Ni^{II} porphyrins (mean deviation of the porphyrin core atoms from the least squares plane 0.21 Å,

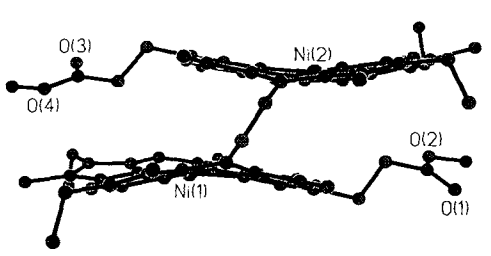

Fig. 3. Molecular structure of *cis*-bis-porphyrin **9**.

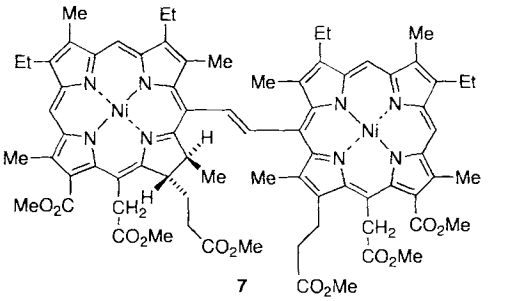
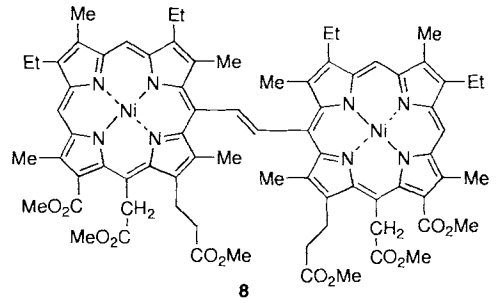
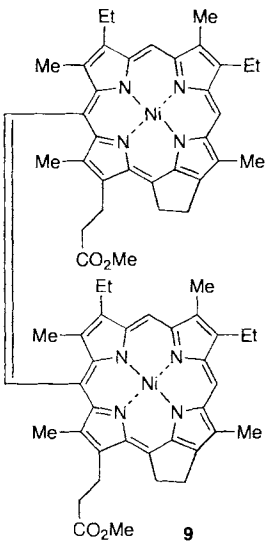




average Ni–N distance 1.925 Å) joined by an ethylene bridge (C=C 1.327(16) Å). No dynamic process was seen for **9** in variable-temperature proton NMR spectroscopy, presumably because the macrocycles cannot rotate about the $C_{meso}-C_{vinyl}$ bond when they are in a *cis* configuration. However, consistent with the molecular structure of **9**, large upfield shifts are seen for the exocyclic ring protons. Finally, the formation of **9** is stereoselective, in contrast to *cis*-octaethyl-1,2-bis-(coproporphyrinyl)ethene ester, which is isolated as a mixture of two atropisomers.[20]



Experimental Procedure

In a typical McMurry coupling reaction, $[TiCl_3(dme)_{1.5}]$ (365 mg, 1.26 mmol) and Zn–Cu couple (335 mg, 4.65 mmol) were added to a dry flask in a dry box. Anhydrous DME (15 mL) was added to the reaction flask, and the resulting mixture was heated at reflux for 2 h under an inert atmosphere. Ni^{II} formylchlorin (0.10 mmol) was added, and the mixture heated at reflux for 3 h. After being cooled to room temperature, the reaction mixture was passed through a short Brockmann Grade III alumina plug with dichloromethane/methanol (10/1) as eluent. The solvents were removed, and the resulting residue was further purified by chromatography on a silica gel column eluted with 5% acetone in dichloromethane. The major green band was then collected and recrystallized from dichloromethane/methanol.

McMurry couplings of Zn^{II}-chlorins were performed in a similar manner except that pyridine (3.5 equiv) was added to the reaction mixture before addition of the Zn^{II} formylchlorin.

UV/Vis data of selected compounds: **4**: λ_{max} (CH_2Cl_2) = 416 (ε = 170000), 458 sh (53600), 648 (51000), 732 sh nm (14000). **5a**: λ_{max} (CH_2Cl_2) = 408 (ε = 119000), 454 sh (57000), 622 (40800), 710 nm sh (11000). **5b**: λ_{max} (CH_2Cl_2) = 416 (ε = 192000), 504 (31400), 550 (15800), 594 (16400), 648 nm (57100). **6a**: λ_{max} (CH_2Cl_2) = 409 (ε = 135600), 500 (10000), 556 (7700), 672 nm (63000). **7**: λ_{max} (CH_2Cl_2) = 420 (ε = 54000), 485 (64300), 588 (19900), 681 nm (30500)). **9**: λ_{max} (CH_2Cl_2) = 397 (ε = 185000), 548 (16000), 588 nm (13700).

[9] All compounds were characterized by UV/Vis and ^{1}H NMR spectroscopy and gave satisfactory mass spectra and elemental microanalyses.
[10] Data collection and structure refinement information (**4**, **5b**, and **9**): Syntex $P2_1$ diffractometer, $\lambda(CuK_\alpha) = 1.54178$ Å, 130(2) K in $\theta/2\theta$ scan mode, $2\theta_{max} = 114°$ (**4**, **9**); for **5b**: Siemens P4 diffractometer with rotating anode, $\lambda(Cu_{K\alpha}) = 1.54178$ Å, 130(2) K in $\theta/2\theta$ scan mode, $2\theta_{max} = 112°$. The structures were solved by direct methods and refined (based on F^2 with all independent data) by full matrix least squares methods (Siemens SHELXTL V. 5.02). Number of parameters: 904 (**4**), 800 (**5b**), 813 (**9**). The NH protons of **5b** were located on a difference map and found to be on rings A and C; all hydrogens were treated as riding. The absolute stereochemistry of **4** and **5b** was correlated with the known absolute stereochemistry of chlorophyll a from which these compounds were derived. The handedness of **9** could not be reliably determined. Reported R values are $R1$ (based on F and observed data) and $wR2$ (based on F^2 and all data). Absorption corrections were performed with XABS2 [11]. T_{min}/T_{max} values: 0.71/0.85 (**4**), 0.84 and 0.94 (**5b**), 0.87 and 0.92 (**9**); m values: 1.27 mm^{-1} (**4**), 0.62 mm^{-1} (**5b**), 1.19 mm^{-1} (**9**). Single crystals of **4** suitable for X-ray diffraction were obtained by slow diffusion of methanol into a solution of **4** in chloroform. A block-shaped green crystal of **4**·0.35 H_2O was selected, dimensions 0.40 × 0.24 × 0.10 mm ($\rho_{calcd} = 1.392$ g cm^{-3}), triclinic, space group $P\bar{1}$, $a = 12.190(2)$, $b = 12.219(3)$, $c = 14.181(3)$ Å, $\alpha = 89.96(2)$, $\beta = 70.300(14)$, $\gamma = 60.780(15)°$, $V = 1700.7(6)$ Å^3, $Z = 1$. Of 4612 reflections measured ($+h, \pm k, \pm l$) 4607 were independent, and 4450 had $I > 2\sigma$, $R_{int} = 0.0145$. Final R factors: $R1 = 0.0425$, $wR2 = 0.1127$, max. residual electron density 0.63 e Å^{-3}. Single crystals of **5b** suitable for X-ray diffraction were obtained by slow diffusion of MeOH into a solution of **5b** in CH_2Cl_2. A needle of **5b**·1.24 H_2O was chosen, dimensions 0.56 × 0.20 × 0.12 mm ($\rho_{calcd} = 1.199$ g cm^{-3}), orthorhombic, space group $P2_12_12$, $a = 25.596(2)$, $b = 13.663(2)$, $c = 17.190(2)$ Å, $V = 6011.5(10)$ Å^3, $Z = 4$. Of 8590 reflections measured ($+h, +k, +l$ and $-h, -k, -l$) 4389 were independent, and 4214 had $I > 2\sigma$, $R_{int} = 0.0294$. Final R factors: $R1 = 0.0439$, $wR2 = 0.1161$, max. residual electron density 0.38 e Å^{-3}. Disorder was encountered in the propyl methyl ester groups. Single crystals of **9** suitable for X-ray diffraction were obtained by slow diffusion of MeOH into a solution of **9** in DMSO. A prismatic crystal of **9**·2 CH_3OH was selected, dimensions 0.42 × 0.14 × 0.06 mm ($\rho_{calcd} = 1.303$ g cm^{-3}), monoclinic space group $P2_1$, $a = 8.789(1)$, $b = 21.406(4)$, $c = 17.295(3)$ Å, $\beta = 96.530(10)°$, $V = 3232.7(9)$ Å^3, $Z = 2$. Of 4841 reflections measured ($+h, +k, \pm l$) 4509 were independent, and 3027 had $I > 2\sigma$, $R_{int} = 0.032$. Final R factors: $R1 = 0.0743$, $wR2 = 0.2097$, max. residual electron density was 0.64 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-19. Oxindigo: Color Deepening, Strong Fluorescence, and Large Stokes Shift by Donor-Substitution

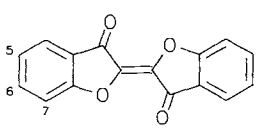
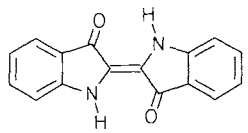
Heinz Langhals* and Barbara Wagner

Oxindigo (**1**)[1, 2] has never attained any technical importance as a chromophore and has been the subject of only few publications in contrast to indigo (**2**), its N-analogue, or to thioindigo,



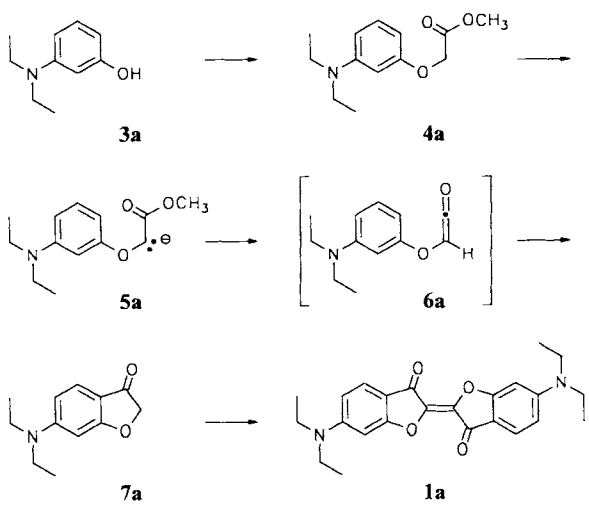
1



2

its S-analogue. This discrepancy is due to its hypsochromic absorption (413 nm in cyclohexane[3]), low coefficient of extinction (13800[3]), lack of fluorescence,[3] and difficult synthesis. We have now discovered that the influence of substituents in the conjugating positions 6 and 6′ is particularly interesting in this respect.

The starting material for oxindigo is coumaranone (benzofuran-2(3H)-one, **7**), which is prepared from **3** and then oxidatively coupled. We sought a new coupling procedure for **7** (Scheme 1), because the synthesis by Fries et al.[1] and Stoermer[2] requires several steps, and the method of Chovin[4] gives other products.[5]



Scheme 1.

The thermal coupling of **7** results in low yields (< 1%) of **1**, whereas the reaction of **3** with atmospheric oxygen under basic conditions produces up to 10% of **1a** with appreciable formation of resin (ethyl chloroacetate and LDA (lithium diisopropylamide), or **3a** to **4a** with KOH in DMSO[6–8] and **4a** to **1a** with

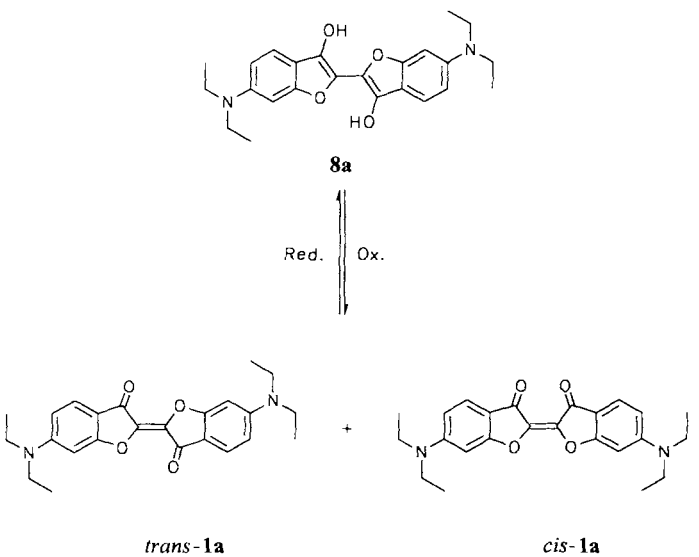
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

LDA). The formation of resin is less pronounced under acidic reaction conditions: for example, the reaction of **3a** with chloroacetic acid chloride and silica gel[9] yields 12% of **1a** under very simple reaction conditions, whilst the reaction of **3a** with bromoacetic acid chloride, $POCl_3$, PCl_3, and $FeCl_3$ yields 20% of **1a**,[10] which is the highest yield of oxindigo and its derivatives yet attained. This latter reaction is a more general synthetic procedure, especially for compounds containing longer alkyl substituent groups at the nitrogen atoms of **3**.

Only the *trans* isomer of indigo (**2**) is obtained by the oxidative dimerization of indoxyl, and special structural requirements[11] are necessary for the preparation of *cis* isomers. In contrast, the analogous preparation of oxindigo compounds also yields *cis* isomers. Traces of *cis*-**1a** are formed in equilibrium with *trans*-**1a** at high reaction temperatures (at reflux in toluene or in DMF at 110 °C), and this yield can be increased to about 50% by lowering the reaction temperature (20–50 °C, kinetic control of the reaction). Another way to prepare *cis*-**1a** is to reduce the more easily prepared *trans*-**1a** to the leuko form (**8a**), which is reoxidized at low temperature to a 1:1 *cis*–*trans* mixture (Scheme 2). The *cis*-**1** isomer may be completely separated



Scheme 2.

from *trans*-**1** by column chromatography. One can reliably distinguish between *cis*-**1** and *trans*-**1** by the carbonyl absorptions in their IR spectra. The *trans* compounds show, as expected, an absorption at 1725 cm^{-1}, whereas a shift to higher wavenumbers (1765 cm^{-1}) is observed for the *cis* compounds because of the interaction of the carbonyl groups, whose dipoles are nearly parallel. (Compare also the corresponding bands of unsubstituted oxindigo[3] and thioindigo.[12])

The UV/Vis spectroscopic properties of **1** are completely changed by the introduction of donor groups into positions 6 and 6'. The unusually large 111 nm bathochromic shift of the absorption to 523.8 nm is striking (see Fig. 1).

The annelation of further rings increases the donor function of the nitrogen atoms by "rigid planarization"; for example the julolidine derivative **1l** exhibits a further bathochromic shift of 34 nm in absorption and fluorescence compared to the value for **1a** (see Fig. 2 and Table 1). The bathochromic shift is less pronounced if the donor function is diminished by phenyl substituents as in **1i**. The spectroscopic data of the methoxy derivative **1k**, which is known,[14] are also in accord with these results.

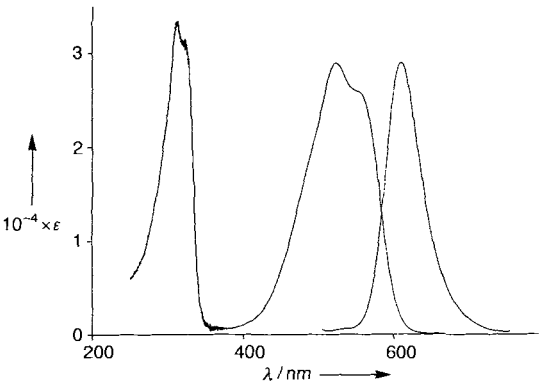


Fig. 1. UV/Vis absorption and fluorescence spectra of *trans*-oxindigo **1a** in $CHCl_3$ (color coordinates [13]: $x = 0.3791$, $y = 0.2169$, $z = 0.4040$ at $T_{max} = 0.1$).

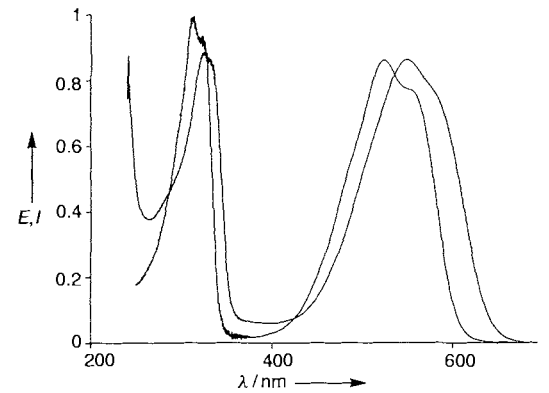

Fig. 2. UV/Vis spectrum of the *trans*-julolidine derivative **1l** (right; color coordinates [13]: $x = 0.2889$, $y = 0.1646$, $z = 0.5472$ at $T_{max} = 0.1$) compared to oxindigo **1a** (left) in $CHCl_3$.

Table 1. Spectroscopic properties of oxindigo derivatives **1** with donor groups in positions 6 and 6'.

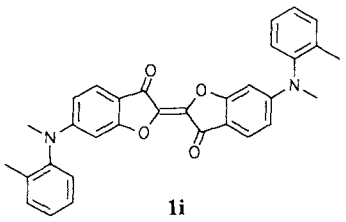
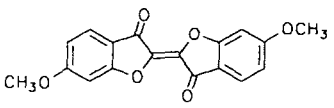
[a] Substituent in positions 6 and 6' of **1**. [b] Absorption maximum in chloroform. [c] Fluorescence maximum in chloroform. Fluorimeter: Perkin Elmer 3000.

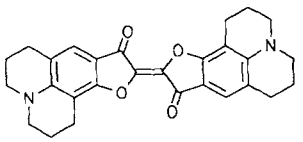
The parent compound, oxindigo, does not fluoresce. However, a strong red fluorescence is induced by the donor groups in **1a** (Fig. 1), which is of interest for fluorescence applications, because of this dye's high color fastness.[15] Dye **1k** also exhibits a strong fluorescence. The effect of the donor groups on



1i



1k



1l

the fluorescence of **1** is exactly opposite to their effect in thioindigo—unsubstituted thioindigo fluoresces strongly, whereas donor groups in positions 6 and 6′ result in a fluorescence quenching.[16] This has been ascribed to an "out-of-phase-conjugation",[16] but the experimental data for oxindigo would seem to contradict this. The remarkably large Stokes shift of 86 nm for **1a** in solution can be taken as an indication of a dynamic process after the electronic excitation. Both the good spectral separation between absorption and fluorescence and the sufficient solubility of the dye are of interest for laser applications.

Although *trans*-**1a** absorbs at remarkably long wavelengths, the absorption of *cis*-**1a**, which forms blue solutions, is at even longer wavelengths (Fig. 3). This behavior is contrary to that of

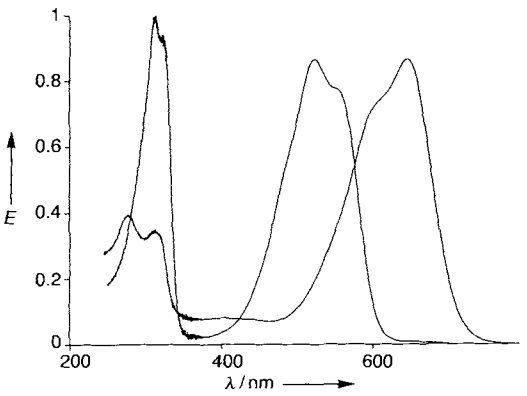


Fig. 3. UV/Vis spectrum of *cis*-**1a** (right; color coordinates [13]: $x = 0.1970$, $y = 0.2300$, $z = 0.5730$ at $T_{max} = 0.1$) compared to *trans*-**1a** (left) in $CHCl_3$.

oxindigo or indigo itself. Whilst *cis*-**1a** does not fluoresce in solution, it exhibits a strong fluorescence in the solid state (see below).

Compound *cis*-**1a** is completely stable as a solid; however, in solution ($CHCl_3$) a photochemical (HPK 125W lamp with yellow filter GG 400, 18 h, see ref. [15]) or thermal[17] transformation into the *trans* isomer takes place. The latter reaction is in contrast to the behavior of unsubstituted oxindigo, which undergoes a thermal decomposition rather than such a transformation,[3] which occurs only photochemically. On the other hand, a photochemical transformation of *trans*-**1a** into *cis*-**1a** is difficult[15]—the strong fluorescence of *trans*-**1a** probably inhibits the reaction through inactivation of the absorbed light.

If the ethyl groups of **1a** are replaced by methyl groups (**1b**), the spectroscopic properties change only slightly. The persistency of the dye, however, is lowered. In contrast, longer alkyl groups at the nitrogen atoms increase the solubility of the dyes without affecting their persistency (for further details see Table 1).

The strong bathochromic shift of **1** by donor groups is satisfactorily supported neither by simple HMO calculations, nor by PPP or by AM1 calculations. This may be attributed to strong intermolecular electrostatic interactions; torsion about the central C=C double bond is less probable as cause both because unsubstituted oxindigo is planar,[18] and because the coefficient of extinction of **1a** is rather high.

The unusually high Stokes shift of **1a** and the differently structured absorption and fluorescence spectra suggest that a relaxation process occurs after the electronic excitation. To gain more insight into this process, quantum mechanical calculations were performed on dye **1b** at the AM1 level (MOPAC). The more stable isomer is *trans*-**1b** with a central C–C bond length of 1.33 Å and a dipole moment of 0.84 D. Isomer *cis*-**1b**, which is also planar, is 1.4 kcal mol^{-1} less stable and has a central C–C bond of 1.34 Å. In the first electronically excited state (**1b**-S_1) the molecule is twisted by 81° (C3, C2, C2′, C3′ angle of torsion) about the central bond which has a length of about 1.37 Å. In this state the molecule has a dipole moment of 12 D. Furthermore, one of the dimethylamino groups is slightly bent out of the π plane (20°).

The relaxation of the planar structure of *trans*-**1b** into the twisted structure of **1b**-S_1 after the electronic excitation can be taken as an explanation both for the large Stokes shift and for the different fine structure of the absorption and the fluorescence spectrum. It may also be the cause for the lack of fluorescence of *cis*-**1b** in solution, because the metastable state **1b**-S_1 might not be reached after the optical excitation. In accord with this concept both the *trans* and the *cis* form exhibit a strong fluorescence in the solid state (*trans*-**1a** 516.5 and 615.8 nm; *trans*-**1l** 666 nm; *cis*-**1e** 722.4, 769.6 and 800 (sh) nm). The *cis* isomers are also of interest for technical applications, because the dyes are very photostable in the solid state and their fluorescence extends far into the NIR region.

Experimental Procedure

trans-**1a**: **3a** (10.0 g, 60.5 mmol) and bromoacetic acid (12.5 g, 90.1 mmol) were allowed to react with $POCl_3$ (7.0 g, 46 mmol), PCl_3 (6.3 g, 46 mmol), and iron(III) chloride (24.6 g, 152 mmol; 24 h, 60 °C). The mixture was worked up with ice, sodium citrate solution, and chloroform, and purified by column separation ($CHCl_3$, silica gel). Yield: 4.0 g of red brown black crystals (19%), m.p. 292 °C. R_f ($CHCl_3$) = 0.70. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2970 (m), 2929 (m), 1727 (s, C=O), 1616 (s, C=C), 1521 (m), 1404 (m), 1354 (m), 1347 (m), 1319 (m), 1277 (m), 1147 (m). UV ($CDCl_3$): λ_{max} (ε) [nm] = 311.4 (34200), 321.8 (31900), 523.8 (29000), 555.2 sh (25800). Fluorescence ($CDCl_3$): λ_{max} = 610 nm. ^1H NMR ($CDCl_3$): δ = 1.23 (t, J = 7 Hz, 12H), 3.44 (q, J = 7 Hz, 8H), 6.55 (d, J = 3 Hz, 2H), 6.69 (dd, J = 3, 9 Hz, 2H), 8.93 (d, J = 9 Hz, 2H). ^{13}C NMR ($CDCl_3$): δ = 12.3, 44.7, 97.3, 105.3, 109.7, 121.3, 128.4, 149.6, 154.2, 159.3. MS (70 eV): m/z (%) = 406 (100) [M^+], 391 (81), 362 (10), 347 (35), 188 (16).

cis-**1a**: **3a** (2.3 g, 14 mmol) in toluene (75 mL) was added in small portions to a LDA solution in cyclohexane/toluene/THF (8 mL, 2 M, −78 °C), and this was then added dropwise to a solution of methyl chloroacetate (1.7 g, 15.5 mmol, −78 °C) in toluene (70 mL). A further portion of the LDA solution (8 mL, 2 M) was added, and the mixture then warmed up (60 °C, 12 h), treated with water (300 mL) and 2 N HCl (pH = 6), extracted (chloroform), washed to neutral (H_2O), and purified by column separation ($CHCl_3$, silica gel). First fraction: 510 mg (10%) *trans*-**1a**; second (blue) fraction: 50 mg blue black crystals (1%; yield of *cis*-**1e** 3%); m.p. 285 °C. R_f ($CHCl_3$) = 0.73. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2960 (s), 2925 (s), 2854 (s), 1763 (m, C=O), 1625 (s, C=C), 1516 (s), 1467 (s), 1455 (m), 1400 (s), 1377 (m), 1352 (m), 1337 (s), 1279 (s), 1070 (s), 795 (m), 717 (m). UV ($CDCl_3$): λ_{max} [nm] = 277.6, 312.5, 609.8 sh, 646.9. ^1H NMR ($CDCl_3$): δ = 1.15 (t, J = 7 Hz, 12H), 3.38 (q, J = 7 Hz,

8H), 6.29 (d, J = 2.5 Hz, 2H), 6.39 (dd, J = 9, 2.5 Hz, 2H), 8.73 (d, J = 9 Hz, 2H). ^{13}C NMR ($CDCl_3$): δ = 22.69, 45.01, 92.84, 105.14, 112.34, 120.75, 129.63, 150.78, 157.40, 169.45. Synthesis of Novel Difluoroprostacyclin Derivatives: Unprecedented Stabilizing Effect of Fluorine Substituents**

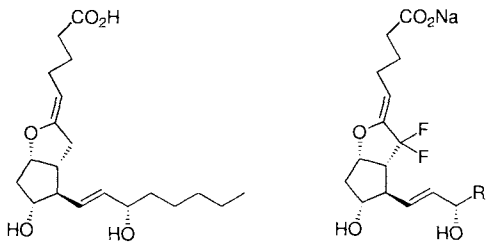
Takashi Nakano, Mayumi Makino, Yoshitomi Morizawa, and Yasushi Matsumura*

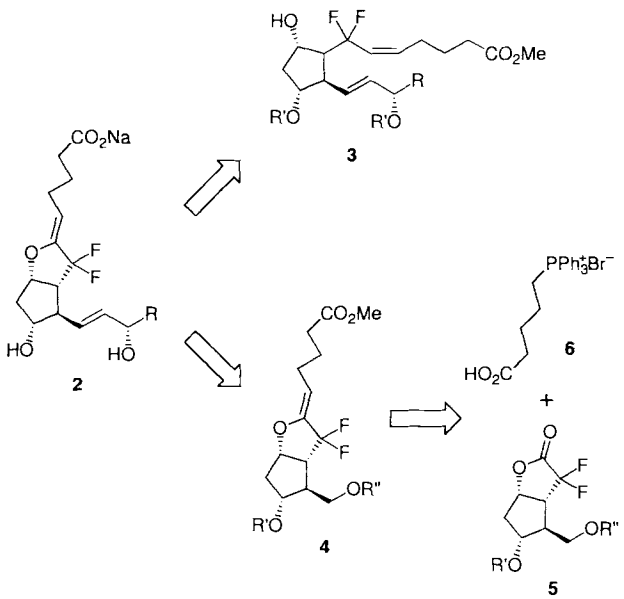
Fluorine has unique physical properties mainly derived from its small atomic size and high electron negativity.[1] Introduction of fluorine into biologically active substances such as steroids,[2] nucleic acids,[3] amino acids, and peptides,[4] as well as prostaglandins and thromboxanes,[5] is regarded as an important strategy in drug design. Prostacyclin (**1**) is a particularly attractive target because of its powerful effects as an inhibitor of platelet aggregation and as a vasodilator in maintaining homeostatic circulation.[6] Despite the pharmacological importance, the inherent instability of **1** limits its therapeutical applicability. Research on new prostacyclin mimetics with reasonable stability and beneficial therapeutic profiles has been a major field of interest for over a decade.[7] Nonetheless, the subject is still far from fully developed. Recent advances in molecular biology including the structural elucidation of prostacyclin receptors[8] require the discovery of more selective agonists to give a better understanding of the precise mechanism of action.



1 **2**

Fluoroprostacyclin derivatives have been targeted by several research groups[9] as potential stable drugs. We are interested in the synthesis of novel prostacyclin mimetics **2**, which have two fluorine atoms at the 7-position. The strong electron-withdrawing effect of the fluorine substituents adjacent to the acid-labile vinyl ether should prevent its hydrolysis. We herein disclose a direct and efficient synthesis of the novel 7,7-difluoroprostacyclin derivative **14** (see Scheme 3), which shows unprecedented stability and potent inhibition of platelet aggregation.[10]

In designing a synthetic plan, we searched for a strategy to construct a characteristic difluorine-substituted vinyl ether employing fluorine-containing building blocks. The conventional route by cyclization of a prostaglandin $F_{2\alpha}$ derivative **3** did not appear promising due to the low reactivity of the electron-deficient double bond bearing two fluorine atoms (Scheme 1). We



Scheme 1. Retrosynthetic analysis of **2**.

approached the challenge by choosing the vinyl ether **4** as a key intermediate. Advantages of this strategy are: intermediate **4** could serve as a useful starting point for the synthesis of a variety of analogs with modified ω-side chains; the α-side chain could be directly assembled by a stereoselective Wittig reaction of difluorolactone **5** and phosphonium salt **6**; and a novel fluorination reaction with the readily available Corey lactone could provide compound **5**.

Electrophilic fluorination is an attractive method to construct fluorinated building blocks simply from rather complicated molecules. Several new electrophilic fluorinating agents have been developed;[11] however, selective difluorination of carbonyl compounds has not received much attention and remains

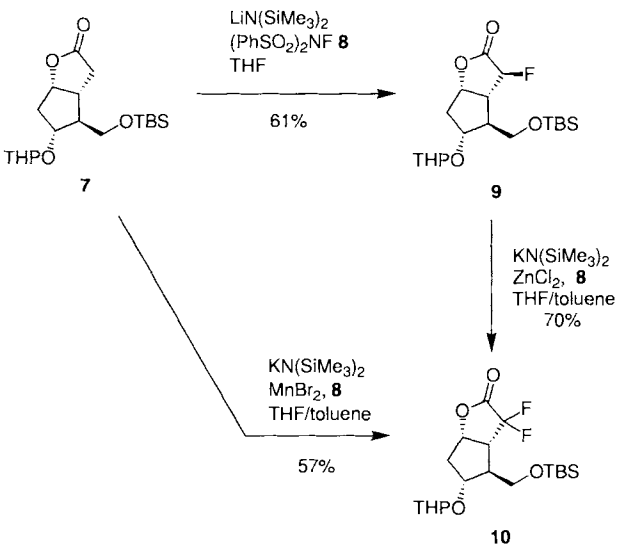
[**] We thank Dr. Arata Yasuda for helpful discussions.

troublesome because of the lack of reactivity of the intermediary α-fluoro enolate.[12] We examined various fluorinating agents and found *N*-fluorobenzenesulfonimide **8**[11h] to be suitable for the reaction. The Corey lactone **7** was treated with lithium *N*,*N*-bis(trimethylsilyl)amide in THF and fluorinated with the sulfonimide **8** at −78 °C to afford monofluorolactone **9** in 61% yield (Scheme 2). The desired difluorolactone **10** could



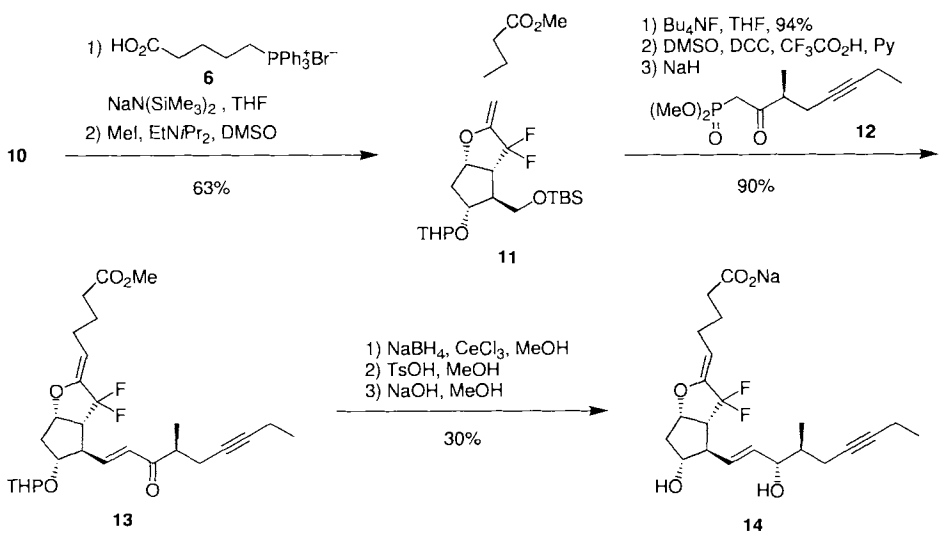
Scheme 2. Synthesis of intermediate **10**. THP = tetrahydropyran, TBS = *tert*-butyldimethylsilyl.

not be obtained in the reaction even when an excess of the base and the sulfonimide **8** were used. On the other hand, fluorination of **9** with reagent **8** after metal exchange with zinc chloride at −78 °C effectively provided the desired difluoride **10** in 70% yield. After many unsuccessful attempts, we found that the fluorination of lactone **7** with **8** in the presence of manganese dibromide gave the desired difluoride **10** directly in 57% yield.

Wittig reaction[13] of the difluorolactone **10** with the phosphonium salt **6** with sodium *N*,*N*-bis(trimethylsilyl)amide in THF at room temperature proceeded smoothly to furnish the vinyl ether **11**, which was obtained as an 87:13 mixture of *Z* and *E* isomers in 63% yield after esterification (Scheme 3). After removal of *tert*-butyldimethylsilyl group with Bu_4NF (94%), Moffatt oxidation to the aldehyde and subsequent Horner–Emmons reaction with the known phosphonate **12**[7c] afforded enone **13** in 90% yield (over two steps). Enone **13** was reduced with $NaBH_4$ in the presence of $CeCl_3$ and the THP group was removed afforded a 1:1 mixture of the (15*S*) and (15*R*) alcohol.[14] The desired more polar (15*S*) isomer was hydrolyzed to provide the carboxylic acid sodium salt **14** as a white solid in 30% yield (over three steps). The (15*R*) isomer could be recovered and converted to **14** by oxidation with manganese dioxide and reduction to the mixture of diastereomeric alcohols.

The stability of **14** in aqueous solution was determined by HPLC. No decomposition was observed in pH 6.5 buffer at 25 °C after 30 days.[15] This is in sharp contrast with natural prostacyclin (**1**), which has very short half-life (76.2 s) under analogous conditions.[16] The high stability of **14** is consistent with the results of a previous study of acid-catalyzed hydration of α-trifluoromethyl vinyl ether in aqueous solution.[17] Protonation of the vinyl ether double bond of **14**, the rate-limiting step in the hydrolysis, should be strongly retarded by the adjacent difluoromethylene group.[18]

The inhibitory activity of **14** on ADP-induced human platelet aggregation in vitro (IC_{50} = 0.07 ng mL^{-1}) is the strongest of all the reported prostacyclin derivatives. In addition, compound **14** was found to be a highly selective prostacyclin agonist with little affinity for various subtypes of the prostaglandin E receptor.[19]



Scheme 3. Synthesis of 7,7-difluoroprostacyclin (**14**). DMSO = dimethyl sulfoxide, DCC = *N*,*N*′-dicyclohexylcarbodiimide, Py = pyridine, Ts = tosyl.

Experimental Procedure

9: To a solution of 1,1,1,3,3,3-hexamethyldisilazane (7.14 mL, 33.8 mmol) in THF (60 mL) was added *n*BuLi (1.66 M hexane solution, 18.7 mL) at −78 °C. The mixture was stirred at −78 °C for 40 min and a solution of **7** (10.0 g, 27.0 mmol) in THF (40 mL) was added. The reaction mixture was stirred at −78 °C for 50 min, and then a solution of **8** (10.7 g, 33.9 mmol) in THF (100 mL) was added. The mixture was stirred at −78 °C for 1 h, poured into saturated $NaHCO_3$, and extracted with EtOAc. The extract was dried, concentrated, and chromatographed on silica gel (hexane/EtOAc 10/1 to 5/1) to give **9** (6.40 g, 61%). ^{1}H NMR ($CDCl_3$): δ = 0.05 (s, 6H), 0.89 (s, 9H), 1.45–2.51 (m, 8H), 2.94 (m, 1H), 3.47–3.87 (m, 4H), 4.63 (m, 1H), 4.92–5.19 (m, 2H); ^{19}F NMR ($CDCl_3$): δ = −178.9 (m).

10: Fluorination of **9**: To a suspension of zinc chloride (25.9 g, 190 mmol) in THF (240 mL) was added a solution of **9** (33.4 g, 86.1 mmol) in THF (240 mL). The mixture was cooled to −78 °C, then potassium *N*,*N*-bis(trimethylsilyl)-amide (0.5 M in toluene, 269 mL) and a solution of **8** (33.9 g, 108 mmol) were added. The mixture was stirred at −78 °C for 1 h and allowed to warm to room temperature. The reaction mixture was poured into saturated $NaHCO_3$ and extracted with EtOAc. The extract was dried, concentrated, and chromatographed on silica gel (hexane/EtOAc 10/1 to 5/1) to furnish difluorolactone **10** (24.3 g, 70%). ^{1}H NMR ($CDCl_3$): δ = 0.06 (s, 6H), 0.88 (s, 9H), 1.25–2.29 (m, 8H), 2.63 (m, 1H), 3.06 (m, 1H), 3.48–3.84 (m, 4H), 4.22 (m, 1H), 4.64 (m, 1H), 5.11 (m, 1H); ^{19}F NMR ($CDCl_3$): δ = −94.3 (m), −115.5 (m); HRMS *m*/*z* calcd for $C_{19}H_{33}O_5F_2Si$ (*M* + 1) 407.2065, found 407.1957.

10: Difluorination of **7**: To a suspension of manganese dibromide (68.7 g, 320 mmol) in THF (500 mL) was added a solution of **8** (101 g, 320 mmol) in THF (500 mL) and the mixture was cooled to −78 °C. To the suspension at −78 °C were added dropwise a solution of **7** (29.6 g, 80 mmol) in THF (200 mL) and a solution of 0.5 M potassium *N*,*N*-bis(trimethylsilyl)amide (800 mL, 400 mmol) in toluene. The mixture was stirred at −60 °C for 2 h then allowed to warm to 0 °C. Saturated $NaHCO_3$ (1000 mL) was added and the mixture was extracted with EtOAc. The extract was dried, concentrated, and chromatographed on silica gel (hexane/EtOAc 10/1) to afford **10** (18.4 g, 57%).

11: To a suspension of **6** (5.45 g, 12.3 mmol) in THF (12 mL) was added sodium *N*,*N*-bis(trimethylsilyl)amide (1 M THF solution, 24.6 mL) at room temperature. The mixture was heated at 70 °C for 1 h, then cooled to room temperature. To the mixture was added a solution of **10** (1.0 g, 2.46 mmol) in THF (8 mL) at room temperature. After stirring for 3 h, the reaction mixture was concentrated, the pH was adjusted to 4, and the mixture was extracted with 50% EtOAc in hexane. The extract was dried and concentrated to give the crude acid, which was dissolved in DMSO (9 mL). To the solution were added *N*,*N*-diisopropylethylamine (1.29 mL) and iodomethane (0.77 mL) at room temperature. The mixture was stirred at room temperature for 18 h, poured into water, and extracted with 50% EtOAc in hexane. The extract was dried, concentrated, and chromatographed on silica gel (hexane/EtOAc 10:1) to afford **11** (757 mg, 63%) as an 87:13 mixture of *Z* and *E* isomers. ^{1}H NMR ($CDCl_3$): δ = 0.05 (s, 6H), 0.88 (s, 9H), 1.25–2.42 (m, 15H), 2.81 (m, 1H), 3.65 (s, 3H), 3.46–3.90 (m, 4H), 4.14 (m, 1H), 4.60–4.78 (m, 3H); ^{19}F NMR ($CDCl_3$): *Z* isomer: δ = −84.1 (m), −116.1 (m); *E* isomer δ = −85.4 (m), −109.7 (d, *J* = 259 Hz); HRMS *m*/*z* calcd for $C_{21}H_{33}O_6F_2Si$ (*M* − *t*Bu) 447.2014, found 447.2001.

13: To a solution of **11** (21.9 g, 43.5 mmol) in THF (300 mL) was added Bu_4NF (1 M THF solution, 66.8 mL) at 0 °C. The mixture was stirred at room temperature for 16 h. After removal of the solvent, the residue was chromatographed on silica gel (hexane/EtOAc 1:1) to give the alcohol (15.9 g, 94%). To the alcohol (9.0 g, 23.1 mmol) in benzene (160 mL) were added DMSO (36 mL), pyridine (2.12 mL), trifluoroacetic acid (0.28 mL), and DCC (14.8 g, 71.7 mmol) at 0 °C. The mixture was stirred at room temperature for 3 h and filtered to remove the precipitate. The filtrate was poured into water and extracted with 15% EtOAc in hexane. The extract was dried and concentrated in vacuo to afford the crude aldehyde. To a suspension of NaH (60% oil dispersion, 1.06 g, 26.5 mmol) in DME (500 mL) was added a solution of **12** (6.57 g, 26.7 mmol) in DME (75 mL) at 0 °C. The mixture was stirred for 1 h, then a solution of the aldehyde in DME (300 mL) was added at 0 °C. The mixture was stirred at room temperature for 30 min, poured into brine, extracted with EtOAc. The extract was concentrated to dryness and chromatographed on silica gel (hexane/EtOAc 4/1) to furnish **13** (10.9 g, 90%). ^{1}H NMR ($CDCl_3$): δ = 1.10 (t, *J* = 7.2 Hz, 3H), 1.19–1.21 (m, 3H), 1.48–2.96 (m, 21H), 3.67 (s, 3H), 3.42–4.15 (m, 3H), 4.60–4.87 (m, 3H), 6.36 (m, 1H), 6.82 (m, 1H); ^{19}F NMR ($CDCl_3$): δ = −84.4 (m), −115.4 (m); HRMS *m*/*z* calcd for $C_{28}H_{38}O_6F_2$ (M) 508.2636, found 508.2573.

14: To a solution of **13** (10.0 g, 19.7 mmol) in MeOH (350 mL) were added $CeCl_3 \cdot 7H_2O$ (11.2 g, 30.1 mmol) and $NaBH_4$ (1.14 g, 30.1 mmol) at −78 °C. The mixture was stirred at −78 °C for 30 min then allowed to warm to room temperature. The mixture was poured into saturated $NaHCO_3$ and extracted with EtOAc. The extract was dried and concentrated to give the crude alcohol (11.0 g). The alcohol was dissolved in MeOH (330 mL), and *p*TsOH·H_2O (0.38 g) was added at room temperature. The reaction mixture was stirred for 1 h, then $NaHCO_3$ (4.4 g) was added. The mixture was concentrated to dryness and chromatographed on silica gel (hexane/EtOAc 1/1 to 1/2) to give the less polar (15*R*) alcohol (3.1 g, 37%), the more polar (15*S*) alcohol (3.3 g, 39%), and a mixture of the isomers (0.4 g). To a solution of the (15*S*) alcohol (0.64 g, 1.5 mmol) in MeOH (22.5 mL) was added 0.1 N NaOH (22.5 mL). The mixture was stirred at room temperature for 13 h, acidified with 0.1 N HCl, and chromatographed on Merck LiChroprep RP-2 (MeOH/H_2O 1/1) to give the acid (507 mg, 82%). The acid was treated with 1 N NaOH to afford the sodium salt **14** as a white powder. IR (KBr): $\tilde{\nu}$ = 3406, 2975, 2938, 1562, 1408, 1300, 1243, 1043, 1017, 971 cm^{-1}; ^{1}H NMR (CD_3OD): δ = 0.97 (d, *J* = 6.8 Hz, 3H), 1.14 (t, *J* = 7.2 Hz, 3H), 1.70–2.78 (m, 15H), 2.63 (m, 1H), 3.89–3.99 (m, 2H), 4.76 (m, 1H), 5.58–5.68 (m, 2H); ^{19}F NMR (CD_3OD): δ = −85.7 (m), −118.7 (d, *J* = 248 Hz); ^{13}C NMR (CD_3OD): δ = 13.1, 14.9, 15.5, 23.0, 25.5, 27.4, 38.7, 40.1, 41.8, 51.3, 52.8, 76.6, 77.8, 78.6, 82.0, 83.5, 102.1, 125.6 (t, *J*(C,F) = 247 Hz), 132.5, 134.9, 150.0, 182.7; HR MS *m*/*z* calcd for $C_{22}H_{29}O_5F_2$ (*M* − Na) 411.1983, found 411.1998.

Charge Transfer Interactions in Dyed Crystals of Aromatic Carboxylic Acids and Their Relevance to MALDI Mass Spectrometry**

Christine A. Mitchell, Scott Lovell, Keith Thomas, Phil Savickas, and Bart Kahr*

Efforts to understand how and why organic molecules enter crystals of aromatic carboxylic acids have suddenly taken on a new urgency in light of matrix-assisted laser desorption/ionization (MALDI) mass spectrometry,[1] a revolutionary process in which analyte molecules, when precipitated with a crystalline acid matrix, are served-up to the gas phase upon irradiation. The success of the MALDI experiment depends critically upon the host–guest interactions, which at this time are poorly understood.[2] We have been systematically studying a large, neglected literature describing crystals, including aromatic carboxylic

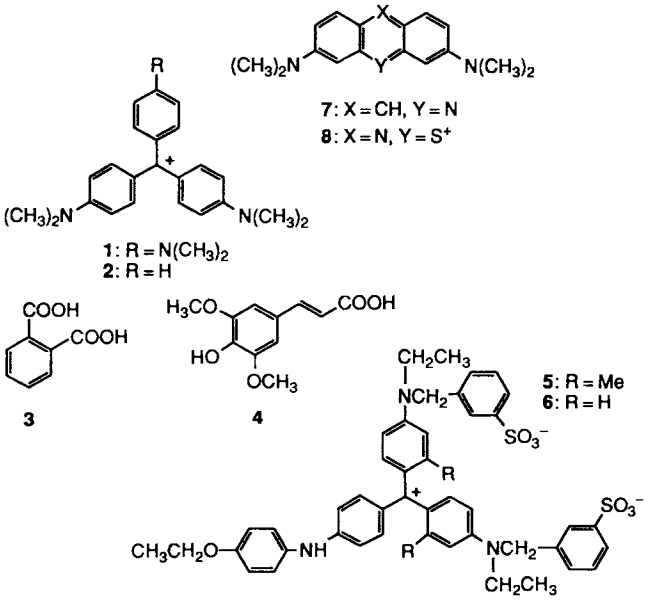
acids, grown from solution in the presence of dyes.[3] Such crystals sometimes display regiospecific patterns of color due to the selectivity of the dye molecules for different crystalline surfaces. In this report we describe the essential role of complex formation in the growth of these mixed crystals, and show how it relates to the contemporary development of MALDI mass spectrometry.

Lehmann first described pleochroic crystals of organic acids grown in the presence of both natural and synthetic dyes,[4] but his experiments are difficult to interpret because he paid little attention to crystallographic directions. Sometime later, Gaubert placed this work on a stronger crystallographic foundation[5] by reporting that Crystal Violet (**1**) and Malachite Green (**2**) color the {021} growth sectors of phthalic acid (**3**) crystals.[6] We grew crystals of **3** from saturated aqueous solutions containing **1** or **2** (0.02 M), as well as dyes **5**–**8**. These



crystals showed characteristic hourglass patterns of coloration resulting from dye inclusion in the {021} growth sectors, in agreement with the previous observations of Gaubert (Fig. 1). We determined, by quantifying the absorption of dissolved mixed crystals, that one dye molecule is included in a colored sector for every $5-15 \times 10^3$ molecules of **3**. The crystals are strongly dichroic for light incident upon the (010) face (Table 1); a maximum absorption was observed when the electric vector made an angle of 45° to [100], the slow vibration direction (Fig. 2).[7, 8]

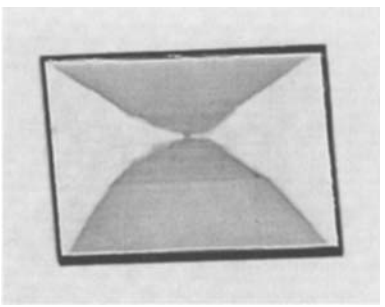


Fig. 1. A mixed crystal (0.7 × 0.5 mm) of **3** and **8** showing its dyed {021} growth sectors and the largest flat faces {010}, viewed in the $-b$ direction.

We determined the X-ray structure[9] of a stoichiometric (1:1) cocrystal of Malachite Green (**2**)·hydrogen phthalate and phthalic acid,[10] which helps to explain the observed dichroism

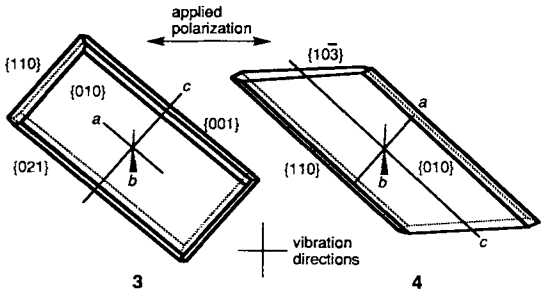

Fig. 2. Morphologies of **3** and **4**. Crystals are oriented with respect to a common set of vibration directions. View is at an angle of 10° from the b axis to emphasize minor facets.

Table 1 Absorption for dyes in phthalic acid crystals and in solution.

in the solid solutions. In this structure the phthalic acid and hydrogen phthalate molecules form a hydrogen-bonded network that may be succinctly described by the graph set $\mathbf{C_2^2(11)S(7)}$.[11] As shown in Figure 3, ion **2** is grossly distorted

from the expected propeller-like ground state geometry,[12] extending its π system in order to accommodate the interaction with hydrogen phthalate. Such charge transfer interactions were previously identified in solution as red shifts in the absorption maxima.[13] Table 1 lists similar red shifts that we observed in solution and in the mixed crystals.

We calculated the electric transition dipole moment (ETDM) in the **2**·hydrogen phthalate complex by applying the INDO/S[14] method to the coordinates from the X-ray structure analysis. Next, we placed the structure of this complex determined by X-ray crystallography, with its attendant ETDM, within a model of the phthalic acid lattice[15] such that the aromatic ring of the hydrogen phthalate in the complex was least squares fit to a phthalic acid ring in the lattice (Fig. 4). We also considered the superposition of a structure in which the COOH functionality at C24 was moved to C26, assuming that it was only necessary to preserve the interaction between **2** and the carboxylate group at C25. The average projection of the ETDMs for the two possible superpositions gave a predicted dichroic ratio of 5.7 with a maximum absorption in the slow vibration direction. Thus, π-complexation of hydrogen phthalate ions with the cationic dyes would serve to orient the chromophore π systems parallel with the (102) planes, yielding absorption anisotropies in reasonable agreement with experiment. Sensibly, the dichroic ratios are greater for the "flat" cations (**7**, **8**) than for the propellers (**1**, **2**, **5**, **6**) because the ETDM is now constrained to lie in the mean molecular plane of the dye, which will adopt a parallel orientation with respect to hydrogen phthalate in the lattice.

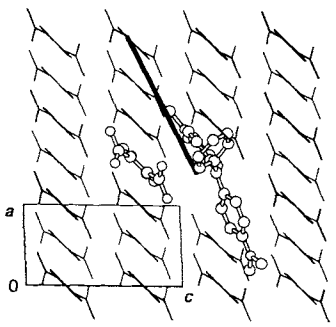

Fig. 4. X-ray structure of Malachite Green incorporated into the phthalic acid lattice, viewed down *b*, such that the complexing hydrogen phthalate ion is superimposed on a phthalic acid molecule in the lattice. The calculated ETDM is indicated as a thick black line.

Recently, researchers attempted to image proteins[16] and oligonucleotides[17] in MALDI host crystals such as sinapic acid (**4**) by first staining the biological molecules with the noncovalent dyes Brilliant Blue G (**5**) and Acridine Orange (**7**), respectively. Since dichroic, facially specific patterns of color were observed only in the presence of the biological molecules, it was reasoned that the proteins and the oligonucleotides carried the dyes into the crystals of **4**. It seemed to us that if crystals of **3** can orient cationic dyes, **4** might produce similar inclusions even in the absence of a biological analyte. We grew crystals of **4** in the presence of **1**, **2**, **5**, **6**, **7**, and **8** under the conditions employed previously by the MALDI researchers (2/1 H_2O/CH_3CN containing 0.1% trifluoroacetic acid at 4 °C).[15] Each dye produced colored crystals of **4** that were dichroic, with the maximum absorptions polarized in the $(10\bar{3})$ planes. No biological cofactors were necessary. Crystals of **4** have a lamellar structure with hydrogen-bonded layers parallel to $(10\bar{3})$, which is the sharpest cleavage plane.[15] It is not surprising, considering our studies with **3**, that dye adsorption occurs on these layers.

The historical literature describes hundreds of other acid/dye solid solutions.[4] We hope that this article will serve to remind researchers of these chemical systems and caution others as to their ubiquity. At the same time, such solid solutions may serve as useful models for the noncovalent interactions that are requisite in forming mixed crystals suited to MALDI mass spectrometry.

Reflections of a True PhD

The Same and Not the Same. By *R. Hoffmann*. Columbia University Press, New York, 1995. 294 pp., hardcover $ 34.95.—ISBN 0-231-10138-4

A popular oratorical strategy especially common in high-brow rhetoric exploits the "tension field" created by one polar extreme acting against another, usually with the speaker clambering up and down like a preacher (in this case) on a Jacob's ladder of subtly linked dichotomies and contradictions in an attempt to make the obvious more memorable. If the orator is gifted at formulating matters with insight, sensitivity, and circumspection, with wisdom and charm, this approach can also provide a source of reflective pleasure. And when has it been otherwise with Roald Hoffmann? His broad background, his dazzling style, his enviably engaged combinatorial memory—these are characteristics that make him a highly regarded and avidly sought spokesperson for all sorts of occasions related to chemistry, or which he himself shows to be chemistry-related. Drawing upon a great many such occasions, and enhancing the effect with a cleverly tailored set of images, Hoffmann has here assembled a skein of information that affords interesting, stimulating, and affirmative reading from beginning to end. The resulting collage is somewhat reminiscent of a series of essays from another chemist: Primo Levi's *The Periodic Table*, which Hoffmann frequently cites in his extensive bibliography. But Levi's work amounts to a veiled autobiography, whereas this is instead a wide-ranging and fervent plea for reflection with respect to chemistry as a discipline. Understanding comes only through enlightened participation. Hoffmann therefore elucidates, in a marvelously uncomplicated way fully accessible to the layman, the actual problems chemists confront amidst the contradictory technical, emotional, moral, and political tensions surrounding their work.

Roald Hoffmann always knows where to find memorable and apt analogies, illustrations, and examples, and many people have contributed enthusiastically to this particular endeavor. Not least among these is the publisher, incidentally, who has produced a deluxe edition the like of which is seldom seen these days on such an occasion: glossy paper and sharp printing, clear diagrams, and faithful color reproductions, presented in a genuine cloth binding! But this handsome piece certainly should not disappear into the bibliophile's bookcase; it should instead be "consumed", and then shared with other chemists. The effort will be richly rewarded!

The content of the book is easily summarized, but characterizing it is more difficult: call it chemistry transformed by a tincture of wisdom into philosophy. Hoffmann's goal is to convey his thoughts directly to an engaged circle of readers, thoughts as they have occurred to him in the course of his life as a theoretical chemist pursuing research, as a graduate adviser, and as a conscientious citizen. Laymen should have no trouble following him, because the reader will quickly become captivated, and there is no let-up. Insightful chemists will affirm the validity of the way Hoffmann analyzes chemistry's methodology, and they will be uplifted by the discovery that their intellectually guided skills are grounded not only in the dissection and unfolding of the multifaceted, but above all in the art of synthesis: joining together, mediating, creating, and recreating. The self-critical scientific reader will also become more acutely conscious of how arrogant it is in a dispute involving concerned environmentalists to demand that a cost/benefit analysis always be undertaken, believing that the world must be run on the basis of a specialist's insights—not unlike Plato's proposed dictatorship over a society made up of minors.

This is one observation among many that are transmuted here by a chemist, drawing upon both chemical experience and political reflection, into a general principle: that only a combination of knowledge and engagement will create an environment in which chemists, too, can introduce their artistry in a harmonious way. Chemistry must therefore direct its educational skills toward those who will themselves never be chemists; indeed, chemical illiteracy is a threat not because it limits our ability to exploit nature, but rather because it prevents us from understanding the principles according to which nature operates. It isolates us from nature, which in compensation acquires a mystical character. That is in turn damaging, because the public becomes incapable of making decisions based on fact with respect to scientific issues. And it is precisely the public and only the public that must make such decisions: not the scientists, who are themselves simply people, neither priests nor politicians. The one chemist among a thousand citizens will continue to learn the necessary skills anyway, but he or she will not be permitted to practice them if the 999 non-chemists fail to understand his/her intentions. This is one of many instances in which awareness of a critical dichotomy leads to increased insight.

Every chemist is familiar with the polarities of analysis and synthesis, left and right, effective and ineffective, equivalent and nonequivalent, natural and unnatural (as well as a host of others), but here these have been refined into productive philosophy. Roald Hoffmann shares this gift with the adepts of old, whose dreams, deeply embedded within us, are still so very alive: the ability of some agent, some catalyst to participate through a keyhole, to ascend immaculately out of a mêlée with the power to turn raw materials into treasure. Are these not still the essential driving forces? Hoffmann makes us acutely conscious of the role of catalysis in the context of the three-way catalyst and of enzymes, but in

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

such a way that we are not deprived of the magic of it all. The magic persists, even if each step along the way can be reconstructed conceptually.

The tragic dichotomy in the deeds and character of the chemist himself is illustrated by a moving sketch of the towering personality of Fritz Haber: rationalist and Don Quixote, world citizen and patriot in both the narrower and the wider sense, career man and visionary, nourisher and destroyer. Haber's fruitful and beneficial ammonia synthesis serves as an elegant starting point for exploring a chemist's activities and thoughts, as well as the leap of genius from paradigmatic routine into the unimagined. Many windows are opened onto the mental universe of the scientist, onto the forces of the mind that guide his or her visions and tools, with a particular chemist serving as an example, but leading to insights that are quite generally valid. We sense the polarities that keep the chemist's world in motion: substances and reactions, discovering and protecting, things and personalities, understanding and feeling, curiosity and power, creative ability and fear, self-control and arrogance, responsibility and exploitation. The crossing-points of various emotions—perceived and unperceived—define the state of the chemist's soul, as they do with all humans, in the contest over the possible, which the chemist seeks in that which holds nature together.

The Janus-faced character of chemistry—its double-barreled quality, its blind spots—is not a new theme, but also not an overly familiar one. Here it becomes a theme for the confessional, at the same time witty and amusing, partly out of personal experience, but with no trace of hubris or hysteria. The chemist as the dull mean—or as the sharp focal point—between a physics obsessed with mathematization and a chaotic biology. Well thought out are the insights so modestly presented on the method of reductionism; beautiful as well are the humility and sense of indebtedness with respect to the humanities which indicate how multidimensional the nexuses are. And the observation that we are tied to linearizing patterns of speech, but at the same time in a desperate search for a "method" of simplification, of enumeration, measurement, and standardization. How easy it all is for chemists, with their conditioned symbolism and the strict conventions of their notation!

Roald Hoffmann's book contains an unimagined treasure trove of thoughts, knowledge, and refinement—from Aeschylus to Zeus, from alchemy to the zodiac, from acetylcholine to xenon tetrafluoride, most of it related to Hoffmann's own scientific efforts or engagements. In effect, it represents the journey of a man out of oppression into freedom, and at the same time his committed gratitude to fate. If the book were to be the subject of an excellent translation it could exert its effect well beyond the bounds of chemistry, and it warrants that opportunity—though the effort might also prove a disappointment, since so much is a function of the marvelous language in which the work is cast, a language the author himself was forced to learn, albeit at an early age.

Resorcinol. Its Uses and Derivatives. (Series: Topics in Applied Chemistry.) By *H. Dressler*. Plenum, New York, 1994. 500 pp., hardcover $ 115.00.—ISBN 0-306-44850-5

The author of this book is obviously a (former) industrial chemist. This becomes apparent in each chapter, on each page, almost even in each sentence, both in its positive and negative aspects.

The introductory chapter is essentially a list of the book's contents, then in only the first seven pages of the second chapter (three of which are filled by full-page reproductions of the IR, ^{1}H NMR—at 60 MHz!—and ^{13}C NMR spectra of resorcinol) we already find four clear references to the author's firm, including the statement that "this plant has had a good record as to the safety and health of its employees for many years". However, as regards the subject of this chapter, entitled "The Properties and Chemistry of Resorcinol", the reader is given insufficient information. For example, Section 2.6 on "Methods of Analysis" consists of just five sentences.

The following ten chapters deal with industrial and commercial aspects of resorcinol in all conceivable variants. The best way to do justice to the book is to list their titles as follows: 3. "Processes for Making Resorcinol", 4. "The Use of Resorcinol in Rubber Compositions", 5. "Resorcinol/Formaldehyde Resins—Adhesives for Wood and Other Nonrubber Applications", 6. "*m*-Aminophenol", 7. "Agricultural Chemicals, Including Veterinary Products", 8. "Pharmaceuticals, Over-the-Counter Medications, and Diagnostic Aids", 9. "The Uses of Resorcinol/Derivatives in Polymers", 10. "Dyes, Fluorescent Chemicals, Optical Bleaches, Laser Dyes, and Imaging/Recording Technologies", 11. "Additives of Many Types", and 12. "Other Uses for Resorcinol".

In each chapter the author strings together innumerable bits of information, mostly at a rather superficial level (examples of the style: "A large number of... were prepared, and shown to be..."; "A preparation of... was patented..."; "A similar patent covered the use of..."). The few cross-references given, although welcome in principle, seem to have been chosen more or less at random. There is hardly any evidence of the mass of information having been critically evaluated or processed in any way, except perhaps in the flow diagrams describing the large-scale manufacture of the basic chemicals resorcinol and *m*-aminophenol (Chapters 3 and 7). In Chapters 3–12 about 90% of the literature references given are patents. Despite the fact that data on tonnages produced and their value are scattered throughout the text, the author evidently felt it necessary to include a separate chapter on these (13. "Selected Business Aspects").

This is followed by a further two chapters (14. "Occurrence in Nature—A Domain of Academic Researchers", 15. "Other Examples of Mostly Academic Work with Resorcinol") which contain about 400 literature references (not patents), compared with the book's total of slightly over 1800. With regard to these two rather unbalanced chapters, the author comments in the introduction: "The placement... near the end of the book is not intended as an indication of the lesser importance of these topics, but rather as an intent to finish with a note of enthusiasm, to show the burst of ideas and the connection to the whole fabric." Here, as in the book as a whole, one would like to believe in the author's good intentions.

At first glance the book appears nicely produced. It contains many structural formulas which aid the reader's understanding, although the choice of these sometimes seems strange. Whereas Chapter 5 contains no chemical formulas at all, those of *m*-fluorophenol and equally simple compounds included elsewhere could surely have been omitted. Most of the formulas are printed in a clear and uniform style, although sometimes they are badly reproduced (e.g., 15-4 and 15-5) and others have been copied without much thought (e.g., 11-44, a [1.1]metacyclophane!). Similar criticisms apply to the black-and-white photographs (some of which are of poor quality, e.g. those showing a lichen-covered rock and a

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3509-1026 $ 15.00+.25/0

minesweeper). Also, surely it should have been possible to find a better ^{1}H NMR spectrum of resorcinol than the badly reproduced version from the Sadtler Catalog!

The book presents, from the standpoint of a chemist engaged in his own special field, of the mainly technical and commercial uses of resorcinol. The question that one must ask is whether it is useful to have a book devoted arbitrarily to a single chemical compound. The reader who feels that it is and decides to buy the book will find that it gives a very comprehensive survey of the relevant patent literature. This is undoubtedly of some value. However, anyone expecting more will be disappointed.

Forschung mit Röntgenstrahlen. Bilanz eines Jahrhunderts (1895–1995). Edited by *F. H. W. Heuck* and *E. Macherauch*. Springer, Berlin, 1995. 682 pp., hardcover DM 98.00.—ISBN 540-57718-1

The idea of publishing a book to mark the centenary of the discovery of X-radiation seems at first sight to be a fairly straightforward undertaking. However, questions arise when one comes to consider what should be included in such a book, and what the reader will expect from the title "Research Using X-Rays"—where should one begin?—and how are the boundaries to be defined? X-radiation is used in such diverse fields as medicine (for both diagnosis and therapy), the natural sciences, engineering and technology, art, and archeology. All these are in fact treated in this book. Obviously such a range could not be covered by a single author, and for that reason this substantial 682-page volume contains 44 articles by different authors.

The book opens with a brief historical outline of the discovery of X-radiation and of the life of Röntgen (which, interestingly, is only taken up to the time when he made the discovery). The first half of the book describes radiological diagnostics as applied to the parts of the body with supporting and movement functions and to internal organs, followed by articles on the applications of X-rays in medico-legal practice, radiotherapy, dosimetry, radiobiology, and veterinary science. It can be seen from this list that F. H. W. Heuck, the editor responsible for the medical part of the book, has been especially concerned to present a balanced and comprehensive picture of the research applications of X-rays in this area. From the standpoint of a layman so far as this field is concerned, I found these articles very interesting. The text, written in a way understandable by the nonspecialist, and the excellent illustrations make this part compelling reading. The articles stimulate one's interest in the medical applications of X-radiation and offer the nonspecialist reader an excellent overview of the subject.

The second half of the book is devoted to the natural sciences and technology. It begins with a historical account of the development of methods for generating X-rays, and of the fundamental knowledge that was gained up to about the mid-1920s. The various methods for detecting X-rays are then described, leading up to the modern CCD (charge-coupled device) camera. Separate chapters deal with applications of X-rays in crystallography, chemistry, and biochemistry, with appropriate examples. These are followed by articles on X-ray diffraction in mixed crystals, noncrystalline metals, and alloys. Additional chapters deal with the technologically important topics of texture determination, elastic stress measurements, and studies of macroscopic structure. These chapters, which are mainly concerned with investigating the structures of materials, are followed by others on X-ray spectroscopy, X-ray microscopy, and measurements on X-radiation from outer space. The book concludes with descriptions of the applications of X-radiation in the fields of art, anthropology, and paleontology.

All the articles are readily understandable, and the text is illustrated by many diagrams and instructive photographs. With only a few exceptions, mathematical formulas have been avoided. It is clear that all the authors have aimed to present their subjects in a way that can be understood by readers who are unfamiliar with the field. Each article also contains a list of material for more advanced reading.

The layout and standard of production of the book are excellent. The editors are to be congratulated on having put together a book which, despite the large number of authors involved, achieves a consistent style and quality. Almost every area of research using X-radiation is covered, and the book provides a very good survey of the subject. It can be recommended for everyone with an interest in the field, and should be available in every university library.

Free-Radical Carbonylations: Then and Now

Ilhyong Ryu* and Noboru Sonoda

Although known since the 1950s, free-radical carbonylation has not received much attention until only recently. In the last few years the application of modern free-radical techniques has revealed the high synthetic potential of this reaction as a tool for introducing CO into organic molecules. Clearly now is the time for a renaissance of this chemistry. Under standard conditions (tributyltin hydride/CO) primary, secondary, as well as tertiary alkyl bromides and iodides can be efficiently converted into the corresponding aldehydes. Aromatic and α,β-unsaturated aldehydes can also be prepared from the parent aromatic and vinylic iodides. If the reaction is carried out in the presence of alkenes containing an electron-withdrawing substituent, the initially formed acyl radical subsequently adds to the alkene, leading to a general method for the synthesis of unsymmetrical ketones. This three-component coupling reaction can be extended successfully to allyltin-mediated reactions. Thus, β,γ-enones can be prepared from organic halides, CO, and allyltributylstannanes. In a remarkable one-pot procedure alkyl halides can be treated with a mixture of alkene, allyltributylstannane, and carbon monoxide in a four-component coupling reaction that provides β-functionalized δ,ε-unsaturated ketones by the formation of three new C–C bonds. The reaction of 4-pentenyl radicals with CO leads to acyl radical cyclization, which provides a useful method for the synthesis of cyclopentanones. Certain useful one-electron oxidations can be combined efficiently with free-radical carbonylations. These findings and others discussed in this article clearly demonstrate that free-radical carbonylation can now be considered a practical alternative to transition metal mediated carbonylation.

Keywords: carbon–carbon coupling · carbon monoxide · carbonylation · radicals · synthetic methods

1. Introduction

As the introduction of carbon monoxide into organic molecules is important in synthesis, many chemists have worked on developing useful and reliable carbonylation reactions. Much of this effort has been centered around the use of transition metals. During the long history of carbonylation chemistry, many industrially important processes have been developed such as the Reppe reaction, the Roelen reaction, and Monsanto's acetic acid synthesis, to name just a few. A wide variety of transition metal complexes can be used to catalyze carbonylation reactions.[1] However, to meet the challenges set by the modern chemical industry, further investigations are needed to obtain new, selective, mild, cheap, and safe carbonylation catalysts.

Transition metal catalysis is not the only means capable of introducing CO into organic compounds. For example, both cationic and anionic species can react with CO to provide carbonyl compounds (Scheme 1).[2, 3] What about the role of free radicals in carbonylation chemistry? Has the potential of free-radical carbonylation been fairly judged? These simple questions initiated our own research into this undeveloped area which began in the late 1980s. Free-radical carbonylation was first investigated in the early 1950s, triggered by the work of Coffman and co-workers, who first documented the peroxide-initiated copolymerization of ethylene and CO.[4] Unfortunately, this type of reaction did not receive much further attention, possibly because some of the initial work employed extremely high CO presssures (> 1000 atm) and kinetic studies were not pursued vigorously. In 1990, however, we reported a highly efficient carbonylation reaction, which takes place in a tin hy-

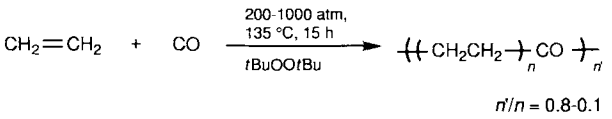
dride mediated radical chain reaction system, to give aldehydes from alkyl halides.[5] This work provided the starting point for us and others to reinvestigate free-radical carbonylation reactions as a synthetic tool. Free-radical carbonylations have long been overshadowed by the successful metal-catalyzed or metal-mediated carbonylations, but now the chemistry appears to be experiencing a renaissance. In this review, we will present the first full coverage of free-radical carbonylation in organic synthesis to date. Extensions of the free radical initiated copolymerization of ethylene and CO, which have also received attention recently in view of the need for degradable polymers, will not be covered here.

2. Early Work

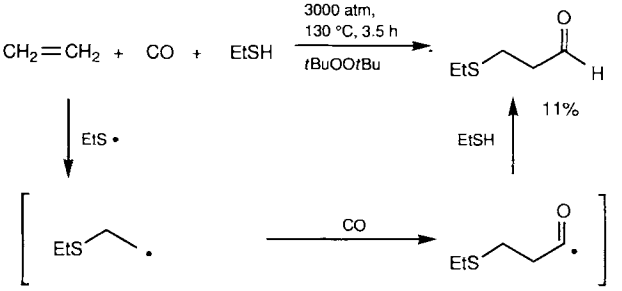
The trapping of carbon monoxide by methyl radical was first reported in 1939 by Faltings.[6] He observed that the reaction of ethane with CO under UV irradiation resulted in the production of acetone. The synthetic applications of free-radical carbonylation truly evolved in the 1950s. In 1952 Coffman, Brubaker, and Hoehn, at DuPont, described the peroxide-initiated copolymerization of ethylene and CO to yield polyketones (Scheme 2).[4]



Scheme 2. Free radical mediated copolymerization of ethylene and CO (1952).

The proportion of CO in the copolymers depended on the ratio of CO/C_2H_4 employed, but the incorporation of CO did not exceed 50% even when CO was used in large excess.[7, 8] The work of Coffman et al. was the first example of efficient addition of radicals to CO, and even more importantly it served as the springboard for the development of radical carbonylation reactions for the preparation of carbonyl-containing compounds other than polyketones.[9]

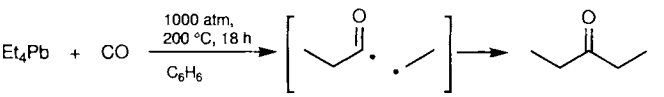
Subsequent work at DuPont aimed at synthesizing aldehydes from an alkanethiol, CO, and ethylene (Scheme 3)[10] or



Scheme 3. Thioformylation of ethylene (1956).

acetylene.[11] Unfortunately, the results were not very promising on account of low yields ($\leq 11\%$) even in reactions conducted under extremely high pressures (up to 3000 atm).

In 1957 Cramer reported that pyrolysis of tetraethyllead at 200 °C under 1000 atm of CO gave diethyl ketone as one of the products (Scheme 4).[12] This reaction was proposed to proceed by the coupling of acyl and alkyl radicals, which was first suggested by Faltings. It was also observed that under similar reaction conditions, α-phenylethyl radicals did not give carbonylated products, presumably due to the stability of the radical.



Scheme 4. Formation of diethyl ketone from tetraethyllead and CO (1957). The yield was not given.

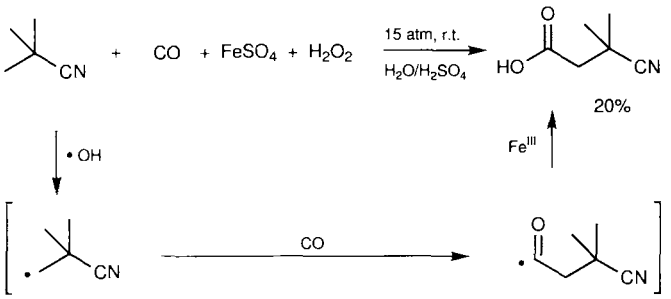
Ilhyong Ryu was born near Nagoya (Japan) in 1951, received his BS in 1973 from Nagoya University, and earned his PhD in 1978 at Osaka University, where he worked under the direction of Noboru Sonoda. After spending a couple of years as a JSPS postdoctoral fellow and a research associate at Osaka University, he became Assistant Professor there in 1987 and was promoted to Associate Professor in 1995. He was a visiting scientist at the University of Ottawa with Professor Howard Alper (1991–1992). He received the Progress Award of Synthetic Organic Chemistry, Japan, in 1990. His current research interests include the development of new synthetic methods by means of reactive intermediates such as either free radicals or organometallic species.

I. Ryu

N. Sonoda

Noboru Sonoda was born in Osaka (Japan) in 1933, graduated from Osaka University in 1956, and obtained his doctorate there in 1961. He became Assistant Professor at Osaka University in 1961 and was promoted to Associate Professor in 1967 and then to Professor in 1973. He served as Dean of the Faculty of Engineering during 1993–1995. He has received many awards for research: the Chemical Society of Japan Award for Young Chemists (1965), the Synthetic Chemistry Award, Japan (1987), the Chemical Society of Japan Award (1990), and the Japan Petroleum Institute Award (1995). His research interests include the development of new synthetic methods based on elements such as sulfur, selenium, tellurium, silicon, and tin, and new carbonylation chemistry.

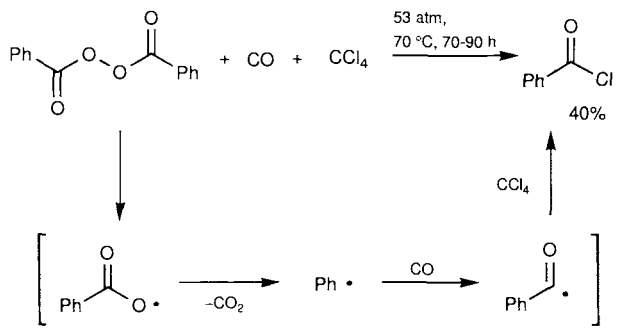
In 1958 Coffman's group and Chiusoli and Minisci independently recorded their efforts to extend the CO trapping reaction to a free-radical carboxylation system. For example, the reaction of *tert*-butyl cyanide with Fenton's reagent ($FeSO_4$, H_2O_2) in the presence of CO yielded β-cyanoisovaleric acid together with the dimer of the starting material (Scheme 5).[13] They



Scheme 5. Free-radical carboxylation with CO at room temperature (r.t.) (1958).

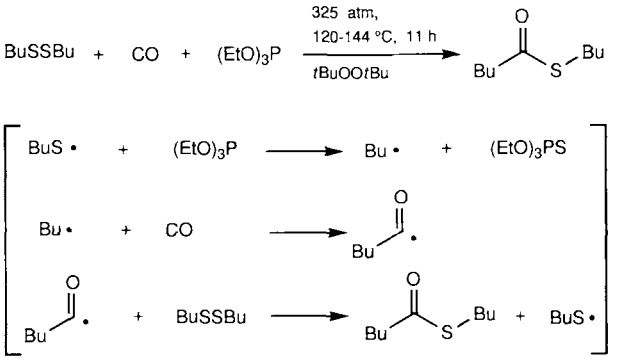
proposed that iron(II) reduces hydrogen peroxide to generate the hydroxyl radical, which abstracts a hydrogen atom from *tert*-butyl cyanide. The resulting radical adds to CO and the acyl radical formed is oxidized by Fe^{III} to give acyl cation, thus regenerating Fe^{II}. The yields of carboxylated products are generally low. Since hydrogen abstraction by the hydroxyl radical from alkanes is not selective, the range of substrates is severely limited. Nevertheless, this work served as a benchmark since it described the incorporation of CO into an "unactivated" C–H bond under remarkably low CO pressures (1–50 atm). Pimeric acid was synthesized from cyclohexanone and CO under similar reaction conditions by β-scission of a cyclohexyloxy radical.[13, 14]

Walling and co-workers also contributed to free-radical carbonylation during the early stages. The decomposition of dibenzoyl peroxide in CCl_4 at 70 °C under 53 atm of CO pressure gave benzoyl chloride in 40% yield (Scheme 6).[15] This product is



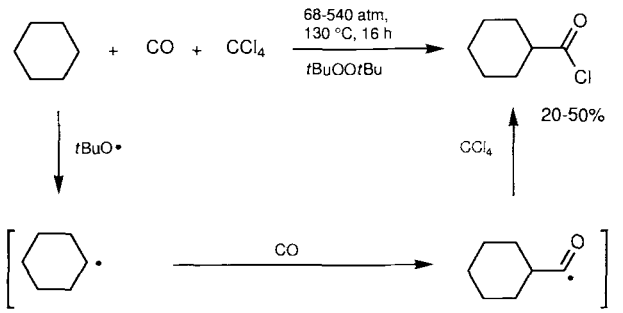
Scheme 6. Carbonylation of Ph' (1960).

thought to result from the addition of phenyl radical, which is generated by the decarboxylation of the initially formed benzoyloxy radical, to CO with subsequent abstraction of chlorine from CCl_4. Interestingly, Walling et al. found that treatment of dibutyl disulfide with CO in the presence of triethyl phosphite afforded *S*-butyl thiovalerate (Scheme 7).[16] Dibutyl sulfide is a by-product of this reaction, but at 325 atm of CO the selectivity for the thioester is very high. Under photolytic conditions the reaction proceeds to some extent even under 1 atm CO. The authors propose the radical chain mechanism shown in Scheme 7, in which disulfide serves not only as a source of butyl radicals but also as a scavenger of acyl radicals.



Scheme 7. Formation of a thioester from a disulfide, triethyl phosphite, and CO (1960).

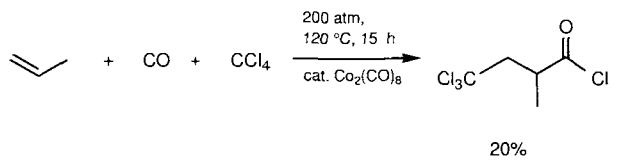
Thaler achieved the conversion of cyclohexane to cyclohexanecarbonyl chloride by subjecting a 2:1 mixture of cyclohexane and CCl_4 to CO under forcing conditions (Scheme 8).[17, 18]



Scheme 8. Preparation of an acid chloride from cyclohexane, CO, and CCl_4 (1966).

The reaction begins by abstraction of hydrogen from cyclohexane by a *tert*-butoxy radical (generated from di-*tert*-butyl peroxide at 130 °C), and the trichloromethyl radical formed in the last step is thought to be the chain carrier. CO pressures of more than 200 atm are required to suppress formation of cyclohexyl chloride.

In 1970 Tsuji and Susuki reported that the reaction of alkenes with CO and CCl_4 in the presence of metal carbonyl catalysts such as $[Co_2(CO)_8]$, $[\{CpFe(CO)_2\}_2]$, and $[\{CpMo(CO)_3\}_2]$ yielded β-trichloromethyl-substituted alkanoyl chlorides (Scheme 9).[19] Carbon tetrachloride served as the solvent and high CO pressures (160–200 atm) were necessary. Although a free-radical mechanism has yet to be verified for the carbonylation step, this reaction is a significant improvement on the original transformation described by



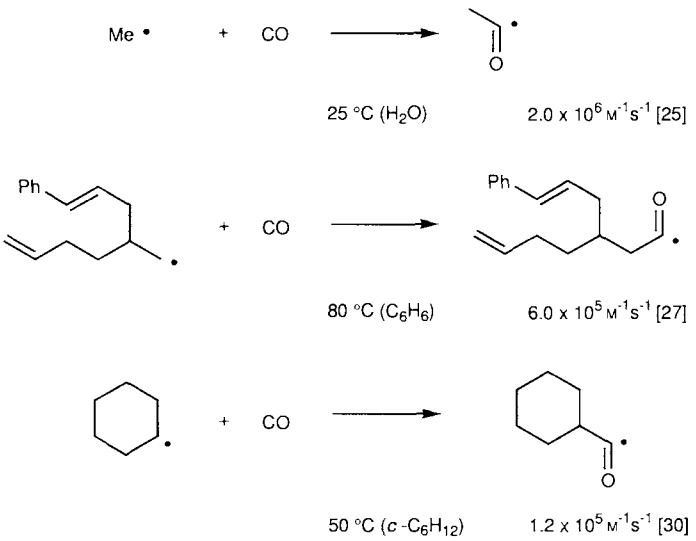
Scheme 9. Carbonylation of propylene with CO and CCl_4 (1970).

Foster et al., which required added peroxide as an initiator and gave poor results.[10]

With the exception of a few studies that were not directed towards preparative applications (see Section 7), the synthetic potential of free-radical carbonylation was mostly neglected until 1990, when our first report appeared.[5] During this period, however, the chemical and physical properties of acyl radicals were largely elucidated.[20] In recent years numerous methods for the formation of acyl radicals, which involve the use of acyl selenides,[21] have modernized and generalized their synthetic applications.[22]

3. Kinetic Studies

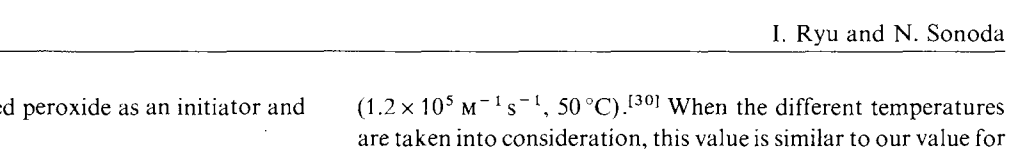
Kinetic information provides the basis for designing and understanding free-radical processes. When we started this research program in the late 1980s, only kinetic data for the gas-phase reaction of methyl and ethyl radicals with CO was available.[23, 24] The lack of useful kinetic data for reactions in solution may be one of the main reasons why free-radical carbonylation long failed to come into its own. However, this all changed with the results of kinetic studies by Bakac et al., by Boese and Goldman, and by us (Scheme 10). The addition of



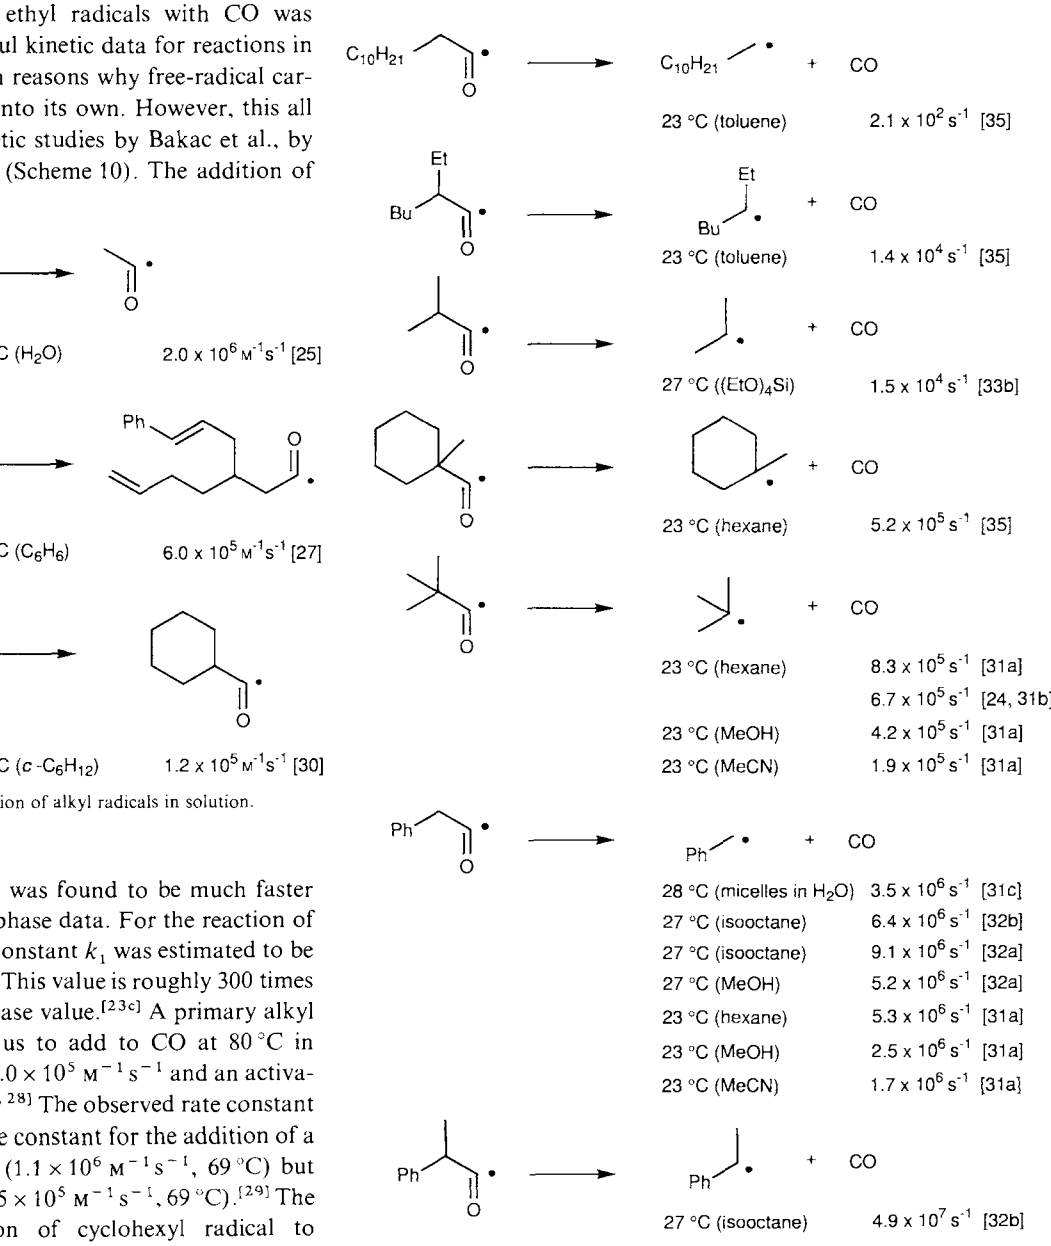
Scheme 10. Rate constants for carbonylation of alkyl radicals in solution.

alkyl radicals to CO in solution was found to be much faster than expected based on the gas-phase data. For the reaction of methyl radical in water the rate constant k_1 was estimated to be $2.0 \times 10^6\ M^{-1}s^{-1}$ at 25 °C.[25, 26] This value is roughly 300 times greater than the reported gas-phase value.[23c] A primary alkyl radical was recently shown by us to add to CO at 80 °C in benzene with a rate constant of $6.0 \times 10^5\ M^{-1}s^{-1}$ and an activation barrier of 6.0 kcal mol^{-1}.[27, 28] The observed rate constant is somewhat smaller than the rate constant for the addition of a primary radical to acrylonitrile ($1.1 \times 10^6\ M^{-1}s^{-1}$, 69 °C) but comparable to that to styrene ($1.5 \times 10^5\ M^{-1}s^{-1}$, 69 °C).[29] The rate constant for the addition of cyclohexyl radical to CO in cyclohexane was reported by Goldman and Boese ($1.2 \times 10^5\ M^{-1}s^{-1}$, 50 °C).[30] When the different temperatures are taken into consideration, this value is similar to our value for the addition of a primary radical extrapolated to 50 °C ($2.7 \times 10^5\ M^{-1}s^{-1}$).

The addition of alkyl radicals to CO is reversible (Scheme 11) and therefore the rate constants for the decarbonylation of acyl radicals (k_{-1}) are useful for the design of free-radical carbonylations. The kinetic parameters for the decarbonylation of pivaloyl and phenylacetyl radicals in solution are well established. For example, at 23 °C the decarbonylation rate constants k_{-1} of pivaloyl and phenylacetyl radicals in hexane are $6.7 \times 10^5\ s^{-1}$[24] ($8.3 \times 10^5\ s^{-1}$[31a]) and $5.3 \times 10^6\ s^{-1}$,[31a] respectively (Scheme 12). The k_{-1} values for the decarbonylation of acyl



Scheme 11. Carbonylation–decarbonylation equilibrium.



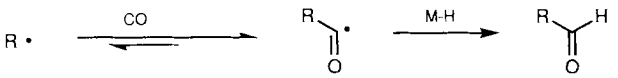
Scheme 12. Rate constants for decarbonylation of acyl radicals in solution.

radicals are solvent dependent,[31a, 32] and the polar nature of acyl radicals is thought to be the origin of the slower rates in polar solvents.

In contrast, the decarbonylation data on secondary and primary acyl radicals are scarce. Some rate constants are known for secondary acyl radicals in solution,[33] but until recently the only available kinetic data for the decarbonylation of primary acyl radicals were measured in the gas phase.[34] In 1995 Chatgilialoglu and Lucarini estimated the approximate rate constants for the decarbonylation of primary, secondary, and tertiary acyl radicals in toluene at 80 °C to be $1.3 \times 10^4\ s^{-1}$, $3.9 \times 10^5\ s^{-1}$, and $1.0 \times 10^7\ s^{-1}$, respectively.[35] Thus the ease of decarbonylation of acyl radicals follows in the order phenylacetyl > pivaloyl > secondary acyl > primary acyl.[36]

4. Free-Radical Formylation: Synthesis of Aldehydes

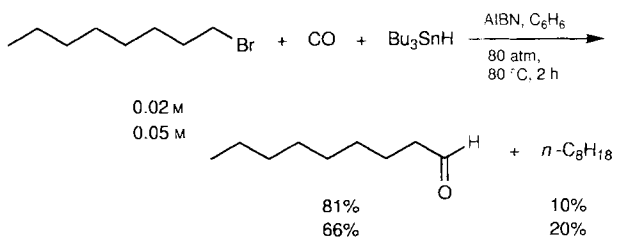
The transformation of organic halides into aldehydes is one of the most useful carbonylation reactions. A versatile transition metal mediated process is the palladium-catalyzed formylation of allyl, benzyl, and aryl halides with CO and a hydrogen donor such as molecular hydrogen, hydrosilanes, formate ions, and tin hydrides.[1, 37] However, the oxidative addition of simple alkyl halides to metal centers is much slower than that of allyl, benzyl, and aryl halides, and the metal-catalyzed processes are useless with the more common halides.[38, 39] Another serious drawback is that the organometallic product of the oxidative addition reaction is often susceptible to β-hydride elimination and subsequent isomerization.[40] Because formylation by free-radical carbonylation proceeds via completely different intermediates (Scheme 13), β-elimination and the accompanying isomerization cannot arise.



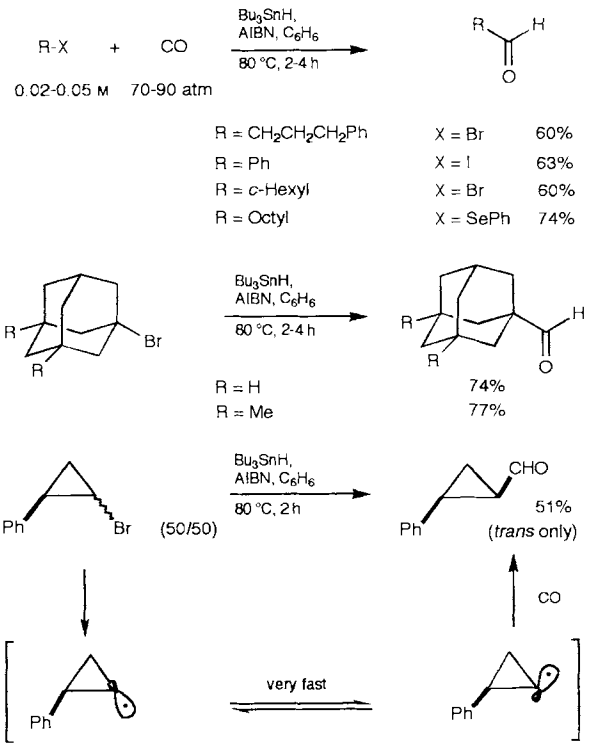
Scheme 13. Concept for free-radical formylation.

In the first attempts at synthesizing aldehydes by free-radical carbonylation (Scheme 3) the marked inefficiency was most likely due to problems with generation of the key alkyl radical, which may hamper the smooth flow of the total free-radical chain system. We believed that this problem could be avoided by employing much more reliable free-radical generation systems like the well-established tin hydride mediated reduction of organohalides.[41] This approach led to a breakthrough. We showed that CO pressures of less than 90 atm can be used for the formylation of alkyl bromides and iodides, when tributyltin hydride and a catalytic amount of 2,2'-azobis(isobutyronitrile) (AIBN) are used.[5] This landmark work marked the first synthetically useful aldehyde synthesis by free-radical carbonylation. Thus, octyl bromide can be formylated to give nonanal in good yield (Scheme 14). Higher dilution conditions have been found to result in better selectivity (formylation vs. reduction).

Scheme 15 illustrates some other examples of free-radical formylation. Secondary alkyl bromides can be formylated successfully, but the efficiency of the reaction of tertiary alkyl bromides varies from substrate to substrate. Thus, 1-bromoadamantane can be formylated smoothly, whereas *tert*-butyl bromide gives pivalaldehyde in relatively low yield. This process is not limited to alkyl halides: aromatic aldehydes can be prepared from the parent iodides.[42] 2-Phenylcyclopropanecarbaldehyde can be prepared from the parent bromide, CO, and tributyltin hydride with high *trans* selectivity. The attack of CO at the least hindered site may account for the selectivity.[43] Selenides can also be used as radical precursors.



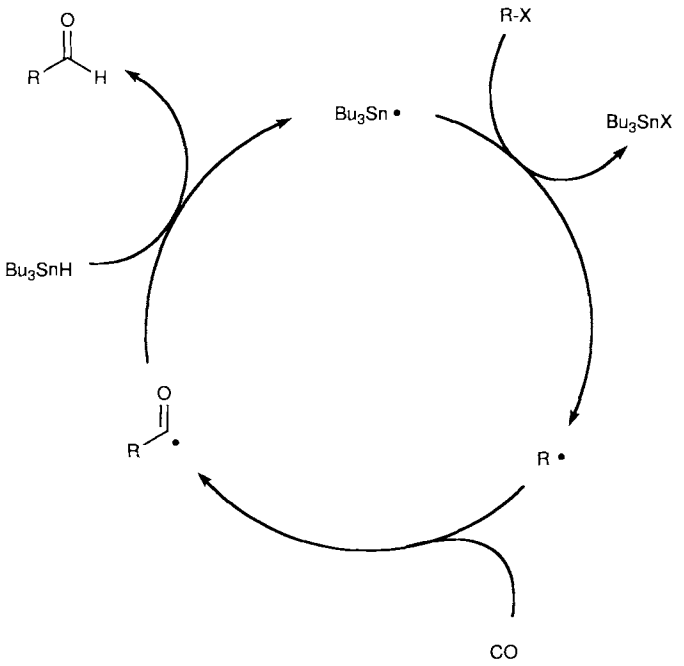
Scheme 14. Free-radical formylation of octyl bromide.



Scheme 15. Free-radical formylation of alkyl halides.

This formylation process can be explained by the free-radical chain propagation mechanism illustrated in Scheme 16. In the initiation step the cyanoisopropyl radical (generated from the decomposition of AIBN) abstracts a hydrogen atom from tributyltin hydride. The resulting stannyl radical abstracts a halogen atom from an alkyl halide furnishing the requisite alkyl radical, which then adds to CO. The resulting acyl radical abstracts a hydrogen atom from tributyltin hydride to give the aldehyde with regeneration of the stannyl radical.

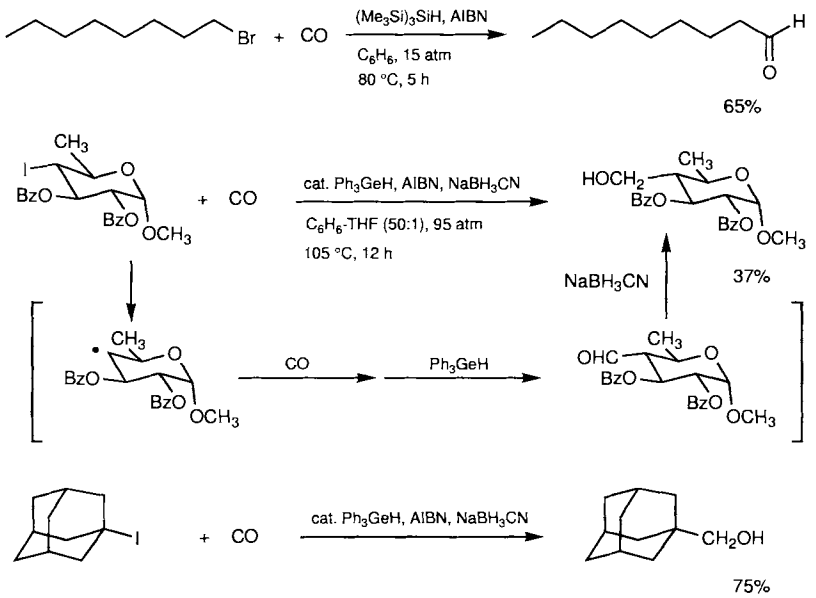
Although alkyl, aryl, and vinyl halides are suitable substrates for free-radical formylations, compounds that yield very stable radicals (i.e. benzyl radical) are not. This is reasonable if one assumes the reverse reaction, decarbonylation of the resulting radicals (see Section 3). Allyl radicals and simple radicals stabi-



Scheme 16. Mechanism for free-radical formylation of RX (R = alkyl, aryl, vinyl).

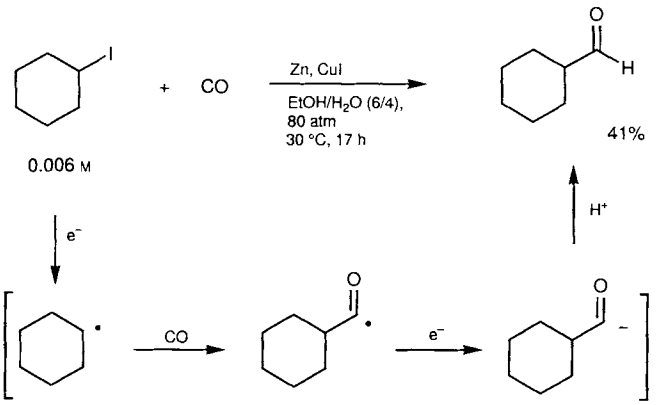
lized by adjacent electron-withdrawing groups like cyano and carbonyl groups or electron-donating substituents like an alkoxy group cannot be formylated under the aforementioned conditions.

In these free-radical formylations, high dilutions of 0.02–0.05 M (for organic halides) and high CO pressures of 70–90 atm are required to force the alkyl radicals to add to CO rather than abstract a hydrogen atom from tributyltin hydride. Other ways to obtain high selectivities for carbonylation over reduction include employing free-radical mediators with reduced hydrogen transfer ability. When we used tris(trimethylsilyl)silane (TTMSS),[44] which reacts with primary alkyl radicals six times slower than tributyltin hydride does, we could reduce CO pressures to below 50 atm (Scheme 17).[45]



Scheme 17. Free-radical formylations mediated by TTMSS and by Ph_3GeH ([RX] = 0.03–0.05 M).

Gupta and Kahne reported that alkyl iodides are converted to the corresponding hydroxymethyl compounds in good yields with catalytic triphenylgermane and sodium cyanoborohydride/AIBN under CO pressure (Scheme 17).[46] Hydroxymethyl compounds are obtained since the free-radical formylation is followed by in situ reduction. Formylation of alkyl iodides can also be conducted with zinc/copper couple in aqueous media (Luche's system) as the reducing agent.[47] Cyclohexyl iodide and 1-iodoadamantane are formylated in moderate yield with this Zn(Cu)/CO system (Scheme 18).[48] Since the one-electron

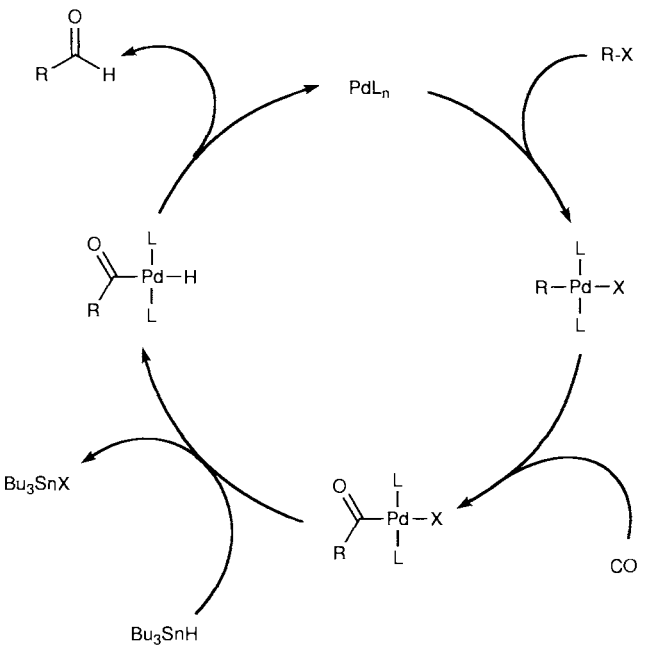


Scheme 18. Free-radical formylation of cyclohexyl iodide mediated by Zn(Cu) couple.

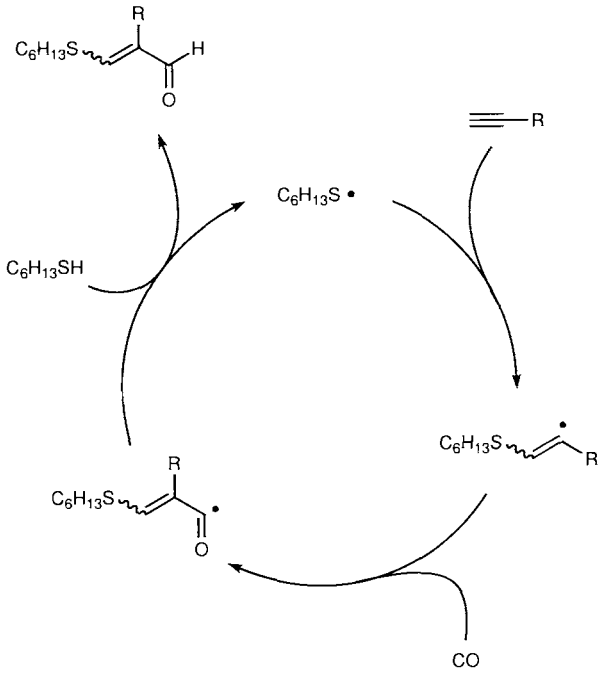
reduction of secondary and tertiary alkyl radicals by zinc is particularly slow, the intermediates add to CO quite smoothly. In contrast, as primary radicals undergo rapid one-electron reduction to the carbanions, the free-radical formylation of a primary alkyl iodide frequently results in a low yield of the aldehyde.

It is interesting to note that a similar formylation catalyzed by palladium(0) complexes also uses tributyltin hydride as a hydrogen source.[37d] Stille and Baillargeon reported that aryl, allyl, and alkenyl halides can be conveniently formylated by tin hydride and CO in the presence of a catalytic amount of $[Pd(PPh_3)_4]$ to yield the corresponding aldehydes. In the proposed mechanism (Scheme 19) the organic halide adds oxidatively to the palladium center to form an organopalladium species. Subsequent CO insertion and reductive elimination then furnish the desired aldehydes. This method is complementary to free-radical formylation, since the latter is not suited to the carbonylation of allylic and benzylic substrates. Conversely, the palladium method is not suited to alkyl halides.

Free-radical formylations are possible not only with organic halides but also with alkynes, 1,6-dienes, and vinylcyclopropanes. The following three examples demonstrate the synthetic potential of these reactions, which are initiated by the addition of heteroatom-centered radicals to unsaturated C–C bonds and therefore inherently lead to heteroatom-substituted aldehydes.

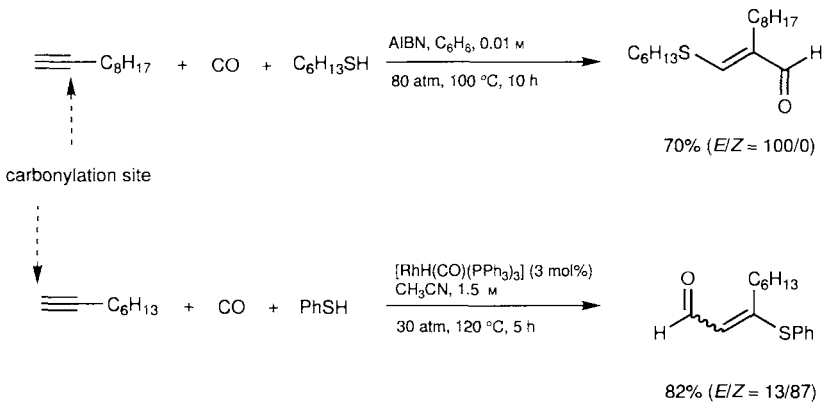


Scheme 19. Mechanism for Stille's Pd-catalyzed formylation of RX (R = aryl, vinyl, allyl).



Scheme 21. Mechanism for Yoshida's thioformylation of alkynes.

Yoshida and co-workers reported that treatment of terminal alkynes with aromatic or aliphatic thiols and AIBN under CO afforded α,β-unsaturated β-thioaldehydes in moderate to good yields (Scheme 20).[49] The formation of exclusively *trans* isomers is due presumably to thermodynamic equilibration. The

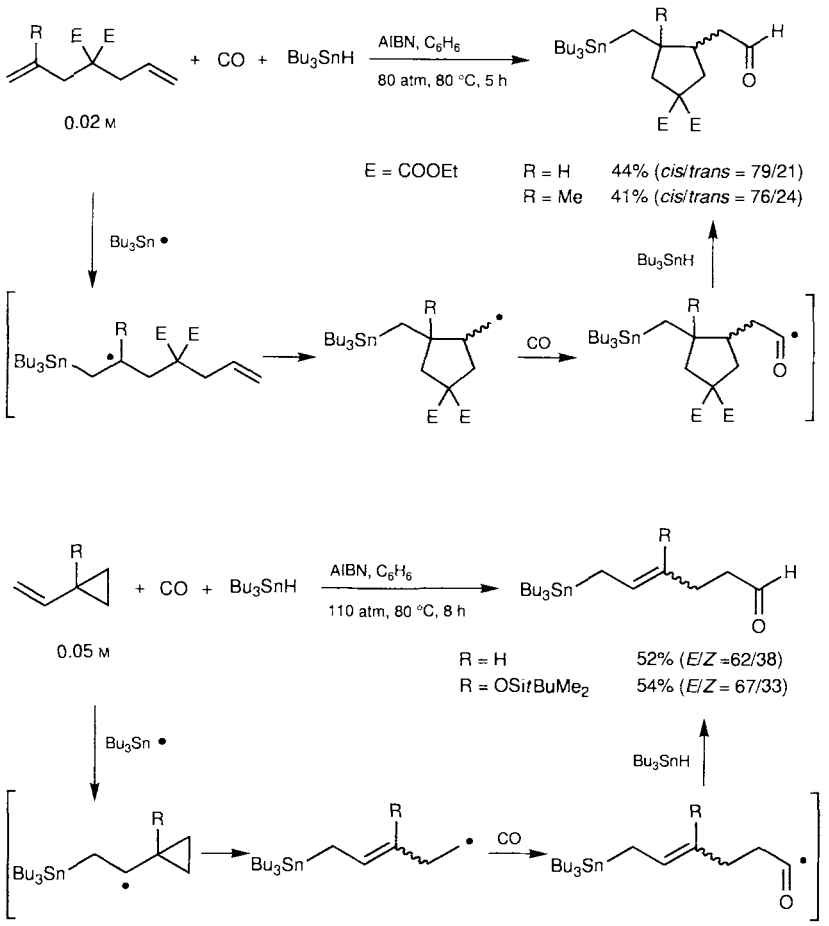


Scheme 20. Two types of thioformylations of alkynes.

reaction follows the mechanism given in Scheme 21. The reactions with alkanethiols gave consistently better results than those with thiophenol. Since alkanethiols have a lower tendency for hydrogen transfer,[50] premature quenching of the vinylic radical prior to reaction with CO is less likely. Thioformylation of alkynes catalyzed by rhodium complexes has been reported recently by Ogawa, Sonoda, and co-workers (Scheme 20).[51] Interestingly, the regioselectivity of the addition to monosubstituted alkynes is the opposite of that in the radical addition.

One of the recent topics in transition metal catalyzed carbonylations is the silylformylation of organic molecules with hydrosilanes and CO;[52] the related stannylformylation has yet to be explored. Free radical based stannylformylation of 1,6-dienes was reported in 1994.[53] In this reaction a 5-*exo*-trig ring closure gives carbocycles having stannylmethyl and formylmethyl groups at adjacent carbons (Scheme 22). The major byproduct of this reaction is the reduced cyclized product.[54] The addition of stannyl radicals to C=C bonds is reversible. Accordingly, in cases where 5-*exo*-trig cyclization of the key radical is relatively slow, as with 1,6-heptadiene, the yields are low as a result of the radical reverting to stannyl radical and the diene. Analogous silylformylation of 1,6-dienes with TTMSS was unsuccessful because the preferred pathway is an intramolecular S_H2-type reaction at silicon.[55] Likewise, stannylformylation of vinylcyclopropanes is accompanied by the ring opening of the cyclopropylmethyl radicals to give γ,δ-unsaturated aldehydes having an allyltin moiety (Scheme 22).[56]

Recently Chatgilialoglu and Lucarini reported some kinetic data for hydrogen abstraction by acyl radicals from tributyltin hydride and TTMSS in nonpolar solvents.[35] At 23 °C a primary acyl radical abstracts hydrogen from tributyltin hydride and TTMSS with rate constants of $4.1 \times 10^5\ M^{-1}s^{-1}$ and $1.6 \times 10^4\ M^{-1}s^{-1}$, respectively. The rates are somewhat slower than those for the analogous hydrogen transfer to alkyl radicals. (For example the rate constant of the reaction of hexyl radical with tributyltin hydride is $1.1 \times 10^6\ M^{-1}s^{-1}$ at 23 °C.[57]) Lusztyk, Ingold, and co-workers also estimated the rate constant for the abstraction of deuterium by propanoyl radical from tributyltin deuteride to be $3.0 \times 10^5\ M^{-1}s^{-1}$ at 23 °C in hexane.[24] The rate constant for the H-abstraction from thiophenol by isopropanoyl radical was



Scheme 22. Stannylformylation of 1,6-dienes and vinylcyclopropanes.

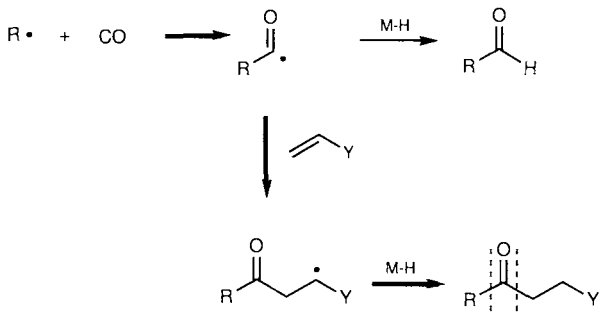
also measured to be 4.4×10^7 $M^{-1}s^{-1}$ at 23 °C in hexane, which is roughly one order of magnitude faster than the corresponding tin hydride reaction.

5. Synthesis of Ketones

As mentioned in the introduction, aside from polyketone synthesis, until recently there were no efficient systems for synthesizing unsymmetrical ketones by free-radical carbonylation. Yet the addition of acyl radicals to alkenes has long been recognized as a useful synthetic method for the preparation of unsymmetrical ketones. In 1949 Kharasch and co-workers reported that the peroxide-initiated chain addition of aldehydes to alkenes yields ketones.[58, 59] A survey of recent examples illustrates the synthetical potential of this ketone synthesis, in which acyl radicals are generated from diverse reagents[60] such as acyl selenides/tin hydride,[60a] acyl tellurides/$h\nu$,[22e] chromium carbene complexes/copper(II),[60b] acylcobalt,[60c, 60e, 22f] and aldehydes/$NO_3^{\cdot}$ radical.[60d] As acyl radicals are nucleophilic, the use of alkenes having an electron-withdrawing substituent facilitates the addition reaction. Kinetic data for reactions in solution indicate that acyl radicals react very rapidly with electron-poor alkenes. Fischer and co-workers have shown that the rate of the addition of pivaloyl radical to acrylonitrile ($k = 5.0 \times 10^5$ $M^{-1}s^{-1}$ at 27 °C) is comparable to that of the analogous reaction of the *tert*-butyl radical ($k = 1.0 \times 10^6$ or 2.4×10^6 $M^{-1}s^{-1}$ at 27 °C).[61] Encouraged by the success of free-radical formylation with tributyltin hydride,[5] we anticipated that the three-component system consisting of RX, CO, and an alkene would lead to unsymmetrical ketones (Scheme 23). The method represents a formal double alkylation of CO, and the transformation is somewhat analogous to Cooke's organotetracarbonylferrate chemistry.[62]

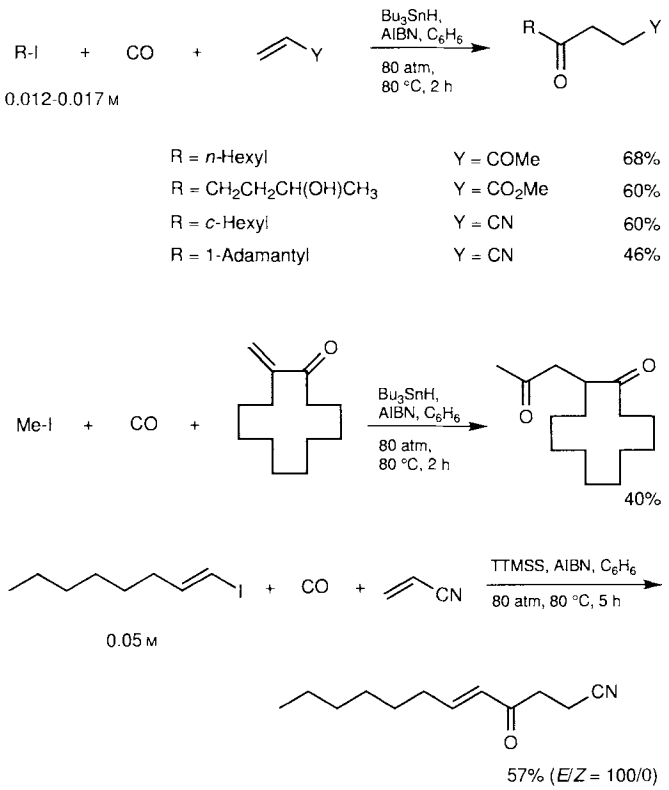
We found that the addition of an alkyl radical to CO could indeed be coupled to the subsequent addition of the resulting acyl radical to an electron-poor alkene to give an unsymmetrical ketone.[63] Competing reactions such as abstraction of hydrogen from tin hydride by acyl radicals to give aldehydes and direct addition of the alkyl radical to the alkene[64] must be supressed. By adjusting the amounts of the alkene and the concentrations ([RI] < 0.02 M) optimal conditions were obtained. Under such high-dilution conditions the ratio of [acyl radical]/[alkyl radical] would be expected to become higher, because the concentration of dissolved CO remains unchanged.

This three-component coupling method has proven to be a general route to a variety of unsymmetrical ketones having diverse functionality. Thus, β-cyano, β-acyl, and β-alkoxycarbonyl ketones can be easily prepared from readily available alkyl halides, functionalized alkenes, and CO (Scheme 24). Styrene can also be used as the alkene component, but the yield of the resulting ketone is rather modest. Reactions conducted with tributyltin hydride require relatively high CO pressures



Scheme 23. Concept for the synthesis of unsymmetrical ketones.

of 70–90 atm to encourage the alkyl radicals to capture CO instead of abstracting a hydrogen atom from tin hydride or adding to alkene; however, lower CO pressures should be sufficient when a radical mediator having poorer hydrogen donating ability is used. With TTMSS as a radical mediator, the three-component coupling reaction of primary alkyl halides can be conducted at CO pressures as low as 20 atm.[45] Nevertheless, even with TTMSS higher CO pressures are required to transform secondary and tertiary alkyl radicals into ketones in good yield. One additional advantage of using TTMSS for the three-



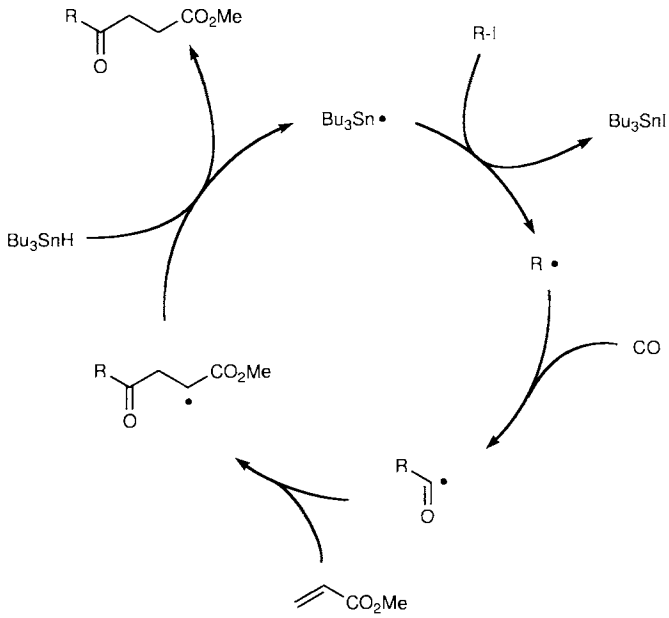
Scheme 24. Representative examples of ketone syntheses.

component coupling is that the reaction can be carried out with only a slight excess of the alkene (generally 1.2 equiv) without a decrease in the yield. This may be because of the slower rate of hydrogen atom abstraction from TTMSS by the acyl radical.[35]

The superiority of TTMSS is further demonstrated by the carbonylation of vinyl radicals (Scheme 24). Vinyl radicals abstract hydrogen from tributyltin hydride considerably faster than alkyl radicals do because of the formation of a strong C–H bond.[65] This often prevents vinyl halides from participating in free-radical carbonylations mediated by tributyltin hydride. For example, the attempted three-component coupling of (*E*)-1-iodooct-1-ene (0.025 M) with CO (80 atm) and acrylonitrile (1.5 equiv) gave 1-octene (45%) as the major product rather than cyanoethyl octenyl ketone (15%). When the same reaction was carried out with TTMSS as the radical mediator, the desired α,β-unsaturated ketone was obtained in 57% yield (Scheme 24).

The chain propagation mechanism of this synthesis of unsymmetrical ketones is illustrated in Scheme 25. This new, efficient synthetic method offers easy access to a variety of structually diverse unsymmetrical ketones, and the use of TTMSS for radical generation increases the versatility of the free-radical carbonylation.

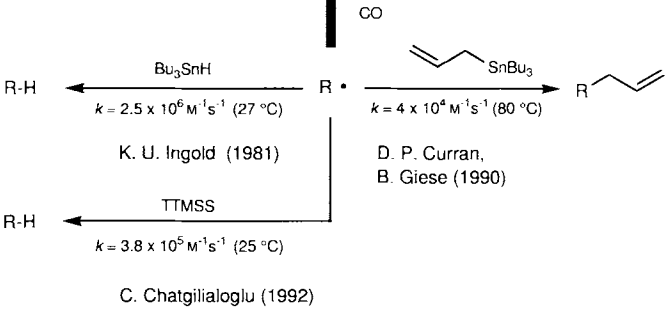
At this point it seems fitting to discuss the efficiency of alkyl radicals in free-radical carbonylations. As discussed in Section 3, the rate constants for the addition of primary and secondary alkyl radicals to CO are large enough for free-radical reactions even at atmospheric pressure, since the values are comparable to the corresponding rate constants for addition of primary alkyl radicals to some reactive alkenes. Nevertheless, high CO pressures are often required for successful free-radical carbonylation. Why? This is mainly because of competing reactions.[66] For example, in the above case of the TTMSS-mediated three-component coupling, competing reactions include direct hydrogen abstraction from TTMSS, addition of the alkyl radicals to alkenes, and even decarbonylation of the resulting acyl radicals. Importantly, free-radical carbonylation in the presence of TTMSS has demonstrated that the reaction with *primary* alkyl radicals is far the more favorable than that of secondary or tertiary alkyl radicals. We consider that this reflects the decarbonylation rates of the corresponding acyl radicals (see Scheme 12).



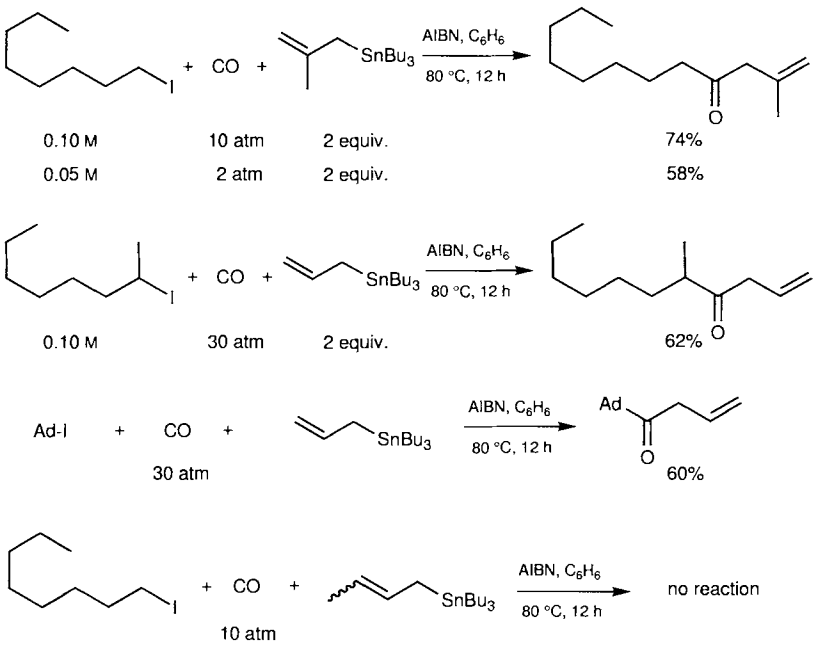
Scheme 25. Radical chain mechanism for the synthesis of unsymmetrical ketones.

Thus, lower CO pressures can be used in the carbonylations of primary alkyl radicals conducted with a slow radical chain mediator. Curran, Giese, and co-workers estimated the rate constant for the addition of primary alkyl radicals to allyltributyltin to be roughly $4 \times 10^4\ M^{-1}s^{-1}$ at 80 C,[67] which is significantly less than the rate of the corresponding H-abstraction from tributyltin hydride (Scheme 26).[57, 65] Thus the direct addition of alkyl radicals to alkenes should not compete with addition to CO. The slow chain propagation of allyltin-mediated process[68, 69] offers valuable insights into the mechanism as well as interesting prospects for synthesis.

The coupling reaction of alkyl iodides, CO, and allyltin yielded β,γ-unsaturated ketones in good yield (Scheme 27).[70, 71] As



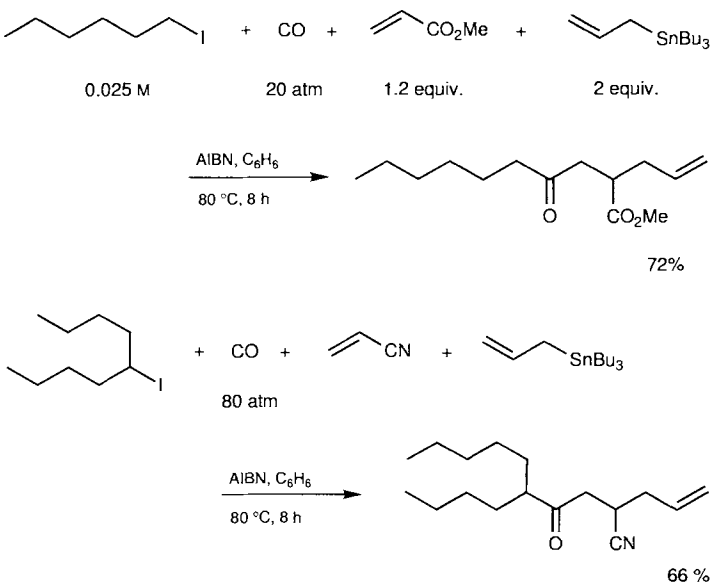
Scheme 26. Rate constants *k* for competing reactions of primary alkyl radicals.



Scheme 27. Allyltin-mediated synthesis of β,γ-unsaturated ketones. Ad = 1-adamantyl.

expected, for the coupling of octyl radical CO pressures of less than 10 atm suffice. In fact, the reaction proceeds efficiently even at 2 atm of CO. For secondary (octyl) and tertiary (adamantyl) radicals, higher CO pressures (30 atm) result in better selectivity for carbonylated products, since the direct S_H2' addition of the alkyl radicals to allyltin is suppressed. Methallyltin can also serve as the alkene component, whereas addition to crotyltin is not possible, presumably due to steric effects.[68]

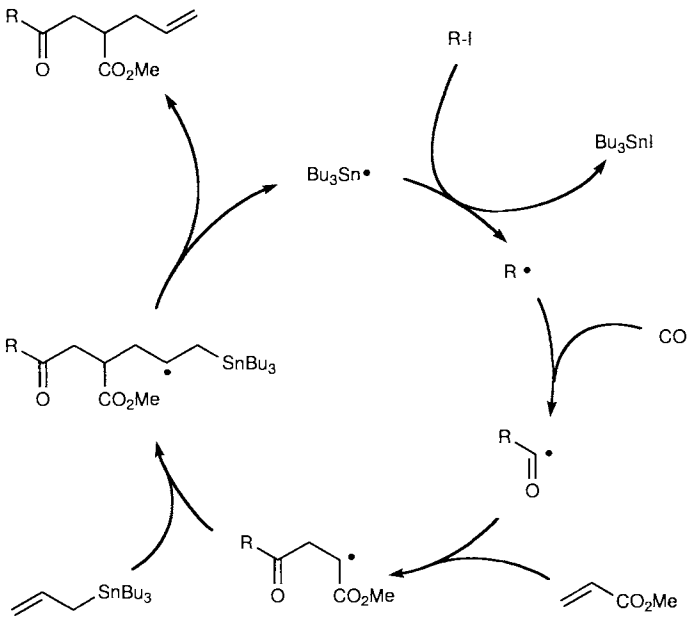
With electron-deficient alkenes, the four-component coupling reaction of alkyl halides, CO, alkenes, and allyltin takes place efficiently. A variety of β-functionalized (cyano, formyl, acyl, and alkoxycarbonyl), δ,ε-unsaturated ketones can be synthesized conveniently in a single operation.[72] Two examples are given in Scheme 28. In free-radical reactions, the efficiency of



Scheme 28. Allyltin-mediated synthesis of functionalized ketones.

chain propagation does not necessarily reflect the number of the steps. This is also true for allyltin-mediated free-radical carbonylations. Even at low concentrations ([RX] = 0.025 M) the four-component reaction gives better yields than the three-component coupling reaction. The undesirable three-component coupling between an alkyl radical, a reactive alkene, and allyltin[73] without incorporation of CO was suppressed by the strict use of nearly stoichiometric amounts of the electron-poor alkene. The four-component coupling reaction can also be applied to vinyl and aryl iodides. Because these substrates have stronger C_{sp^2}–I bonds, higher concentrations ([RX] = 0.1 M) are required.

Scheme 29 illustrates the mechanism of this reaction. The stannyl radical abstracts an iodine atom from alkyl iodide. The resulting alkyl radical adds to CO to form an acyl radical, which then adds to an alkene. An S_H2' reaction with allyltin yields the desired ketone with regeneration of tributyltin radical.



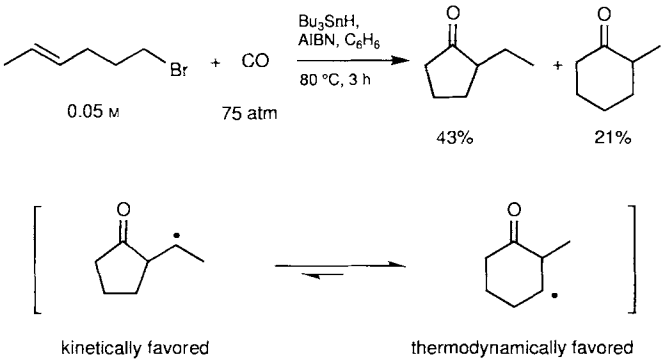
Scheme 29. Radical chain mechanism for the synthesis of functionalized ketones.

6. Synthesis of Cyclic Carbonyl Compounds

It should be possible to combine the concept of free-radical carbonylation with that of radical cyclization to provide access to cyclic ketones. Thus we investigated the (4 + 1) annulation of 4-pentenyl radicals and carbon monoxide with the aim of developing a free-radical carbonylation method for the synthesis of cyclopentanones (Scheme 30).

The reaction of 4-hexenyl bromide, CO, and tributyltin hydride as the free-radical mediator yielded a mixture of 2-ethylcyclopentanone and 2-methylcyclohexanone (Scheme 31).[74] The cyclopentanone results from the addition of the initial rad-

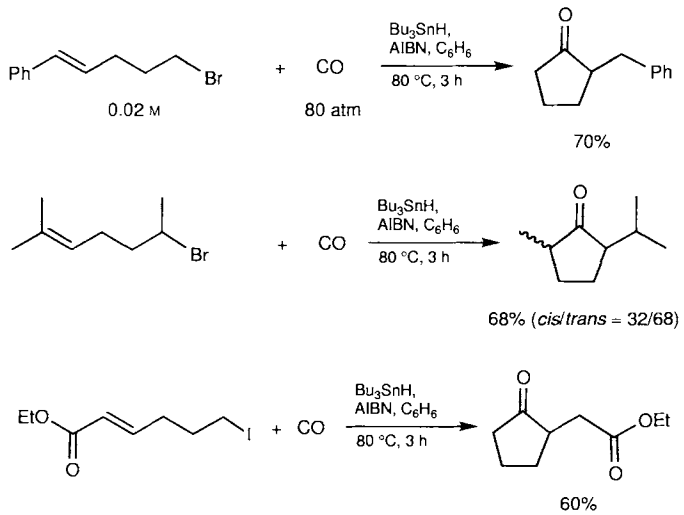
Scheme 30. Concept for carbonylation and cyclization of 4-pentenyl radical.



Scheme 31. Carbonylation and cyclization of 4-hexenyl radical.

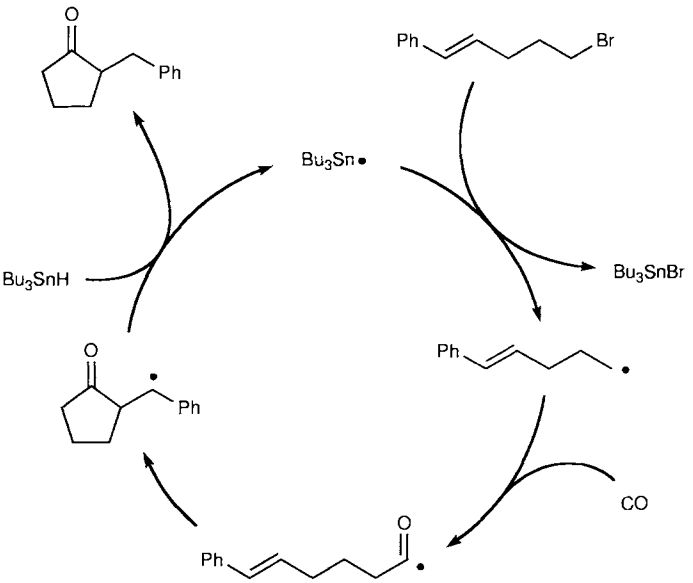
ical to CO to give the 5-heptenoyl radical, subsequent 5-*exo*-trig cyclization, and abstraction of a hydrogen atom.[75] 2-Methylcyclohexanone may be formed by isomerization of the 1-(2-oxocyclopentyl)ethyl radical to the thermodynamically more stable 2-methyl-3-oxocyclohexyl radical. The propensity of the kinetically favored radical to isomerize is somewhat similar to that in the corresponding cyclization of vinyl radicals.[76] However, the two σ radicals undergo 5-*exo* cyclization at different rates. The rate constant for the cyclization of the 5-hexenoyl radical was estimated by Chatgilialoglu and co-workers to be $6.5 \times 10^5\ s^{-1}$ at 80 °C;[77] Beckwith and co-worker showed that the corresponding cyclization of the vinyl radical is much more rapid, roughly $1.2 \times 10^8\ s^{-1}$ at 80 °C.[76a]

With the judicious choice of substituents one can suppress the undesired isomerization. Introduction of dialkyl and phenyl substituents to pent-4-enyl bromide at C-5 led to the selective formation of 5-*exo* cyclization products (Scheme 32). Similarly,



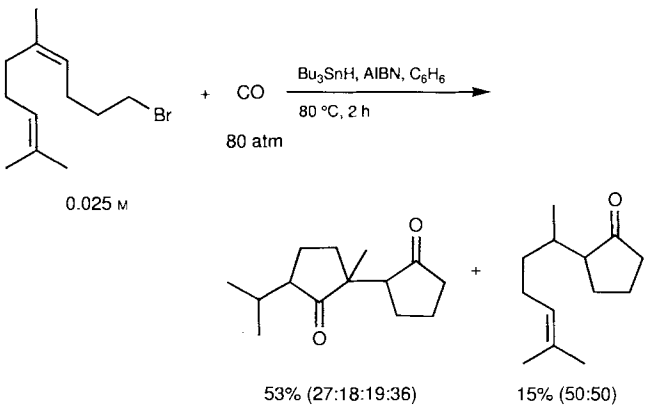
Scheme 32. Synthesis of cyclopentanones.

the reaction of a substrate with terminal carboethoxy moiety resulted in the desired substituted cyclopentanone. The radical carbonylation/cyclization reaction sequence provides a unique and general method for the preparation of cyclopentanones from alkenyl halides and CO.[78] The free-radical chain mechanism is summarized in Scheme 33 with the example of 2-benzylcyclopentanone.



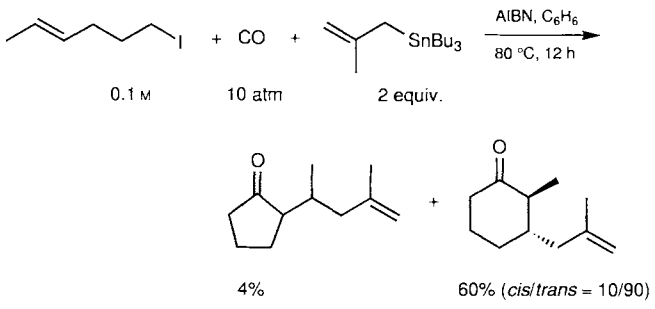
Scheme 33. Radical chain mechanism for the synthesis of a cyclopentanone.

Radical carbonylations can be combined with tandem cyclizations. For example dienyl bromides can be transformed into 1,4-diketones in the presence of a radical initiator, tin hydride, and CO (Scheme 34).[74, 79] In another tandem reaction



Scheme 34. A cascade reaction consisting of carbonylation and tandem cyclization.

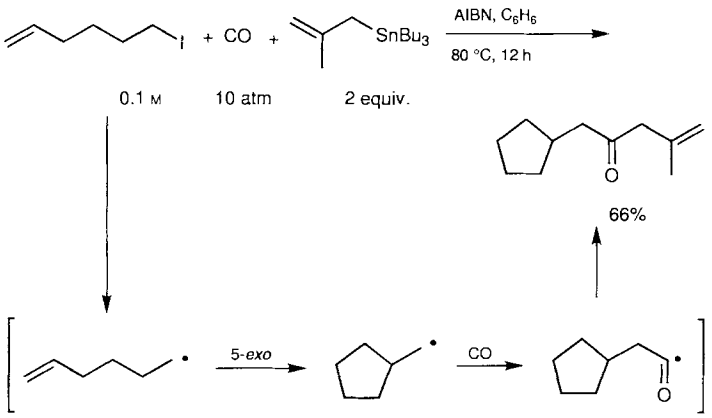
the initially formed cyclic radical is added to allyltributyltin. The reaction of 4-hexenyl iodide with CO (10 atm) in the presence of methallyltin and a catalytic amount of AIBN gave a mixture of five- and six-membered cyclic ketones in the ratio of 6:94 (Scheme 35).[70] This regioselectivity is in stark contrast to that of the carbonylation/cyclization mediated by tributyltin hydride, which gives five-membered ring compounds as the major



Scheme 35. Carbonylation and cyclization with methallyltin.

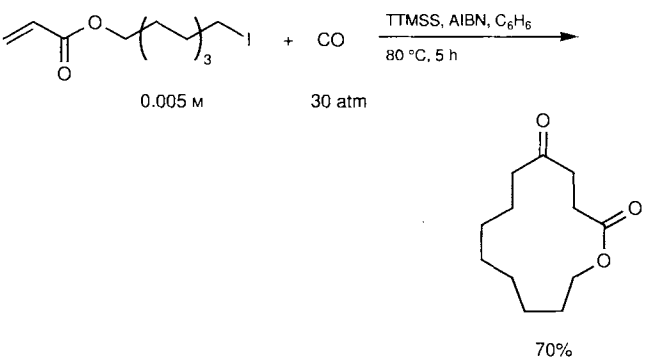
products (cf. Scheme 31). The preferential formation of the six-membered ring products suggests that the allyltin-mediated reaction is thermodynamically controlled.

Unlike the (4 + 1) annulation, (5 + 1) annulation in *exo* mode was not successful, since the addition of the 5-hexenyl radical to CO cannot compete well with rapid cyclization leading to the cyclopentylmethyl radical.[70] Thus in this case cyclization precedes carbonylation and cyclopentylmethyl methallyl ketone is formed as the major product (Scheme 36).



Scheme 36. Cyclization and carbonylation of 5-hexenyl radical.

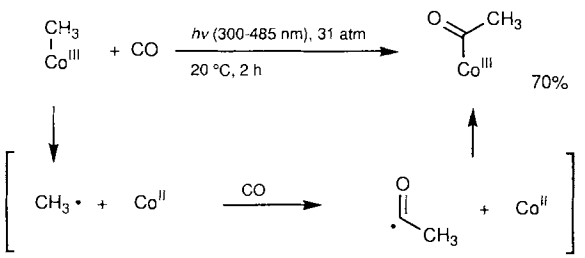
The (*n* + 1) annulation strategy was, however, extended successfully to macrocyclization reactions, where the intramolecular addition takes place with *endo* selectivity.[80] Thus, macrocyclic 4-oxolactones can be conveniently synthesized from alkyl iodides having a terminal acryloxy moiety and CO in the presence of TTMSS (Scheme 37).[81] This (*n* + 1)-type macrocyclization is possible for the formation of ten-membered rings or for larger rings.[82] To our knowledge, there has been no significant work on (*n* + 1)-type macrocyclization by transition metal catalyzed carbonylation.[83]



Scheme 37. Synthesis of a macrocyclic oxolactone by (*n* + 1) annulation.

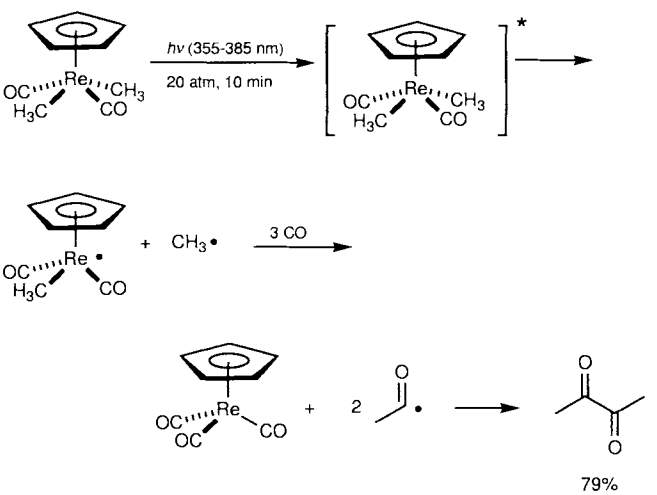
7. Free-Radical Carbonylation Induced by Cleavage of C–M, C–H, and C–C Bonds

In the 1950s it was already suggested that reaction of methyl radical with CO should be exceptionally efficient.[84] The process should have little activation energy due to the inherent instability of the methyl radical. Some examples of the trapping of CO by methyl radical were reported in the 1980s, and more recent kinetic data also indicated that the reaction should be facile.[25] In 1984 Kräutler reported that the irradiation of methylcobalamin with visible light under a CO atmosphere gave acetylcobalamin, and the addition of methyl radical to CO was suggested (Scheme 38).[85] Shortly after this, Bergman and



Scheme 38. Carbonylation of methylcobalamin (abbreviated CH_3–Co^{III}) by UV irradiation.

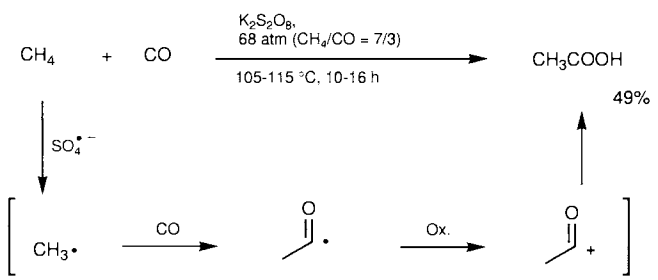
Goldberg reported that UV irradiation of dicarbonyl(cyclopentadienyl)dimethylrhenium under 20 atm of CO pressure yielded 2,4-butanedione.[86] A nonchain radical mechanism is proposed to account for this product. UV irradiation apparently leads to cleavage of the metal–carbon bond, giving the methyl radical. The methyl radical is carbonylated by CO to give acetyl radical, which dimerizes to give 2,3-butanedione (Scheme 39). This work is noteworthy since it emphasizes that free-radical car-



Scheme 39. Photocarbonylation of Bergman's rhenium complex.

bonylation pathways must always be considered when transition metal mediated carbonylations are performed under photolytic conditions.

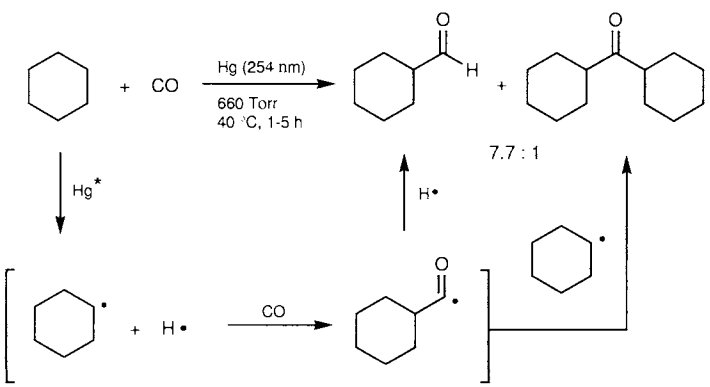
The functionalization of alkanes is a topic of intense interest, and the introduction of CO into unactivated C–H bonds is an important challenge in this very active field.[87] As mentioned in Section 2, the potential of the free-radical carbonylation of alkanes was first demonstrated in the 1950s, but this chemistry attracted renewed attention only recently. In 1992 Sen and Lin reported the carboxylation of methane by CO and peroxydisulfate.[88] Peroxydisulfate, a powerful oxidizing agent[89] which upon mild thermolysis yields $SO_4^{\bullet -}$, is used to generate methyl radical by abstraction of hydrogen from methane (Scheme 40).



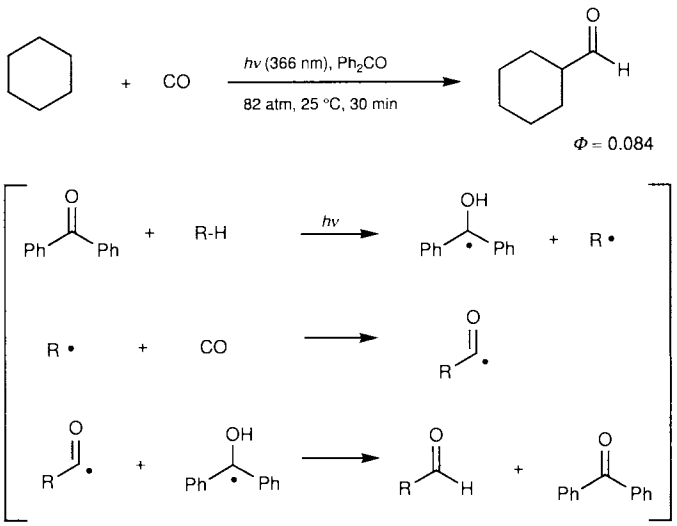
Scheme 40. Synthesis of acetic acid by oxidative carbonylation of methane.

In the next step the methyl radical adds to CO to yield acetyl radical, which is oxidized in situ to give acetic acid. With molecular oxygen as the oxidant, similar carbonylative transformation of short-chain hydrocarbons is effected by catalytic $RhCl_3$[90] and Pd/Cu.[91]

Although the photochemical conversion of alkanes into aldehydes was first achieved in 1987 by Tanaka and co-workers, who used $[RhCl(CO)(PMe_3)_2]$ as the catalyst,[92] the photochemically induced free-radical carbonylation of alkanes was investigated later. In 1991 Crabtree and Ferguson reported the mercury-photosensitized reaction of cyclohexane under CO flow, which gave significant amounts of cyclohexanecarbaldehyde and dicyclohexyl ketone together with uncarbonylated dicyclohexyl (Scheme 41).[93] In 1992 Goldman and Boese reported that aromatic ketones such as benzophenone and 2-trifluoromethylphenyl phenyl ketone photocatalyze the carbonylation of cyclohexane to give cyclohexanecarbaldehyde (Scheme 42).[30]

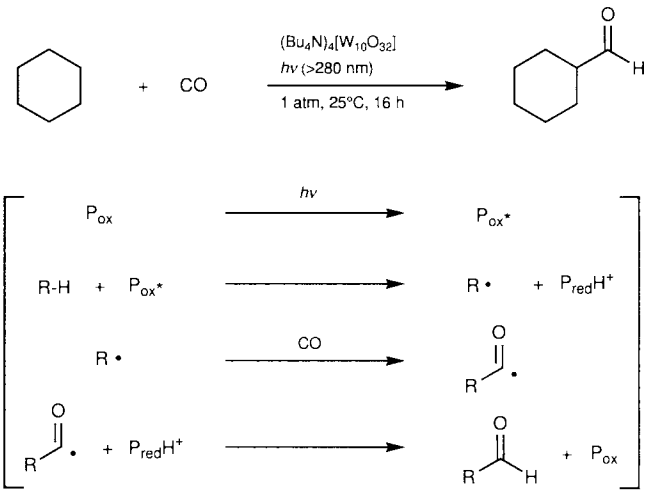


Scheme 41. Hg-photosensitized carbonylation of cyclohexane.



Scheme 42. Photocatalyzed carbonylation of cyclohexane by benzophenone. Φ = quantium yield.

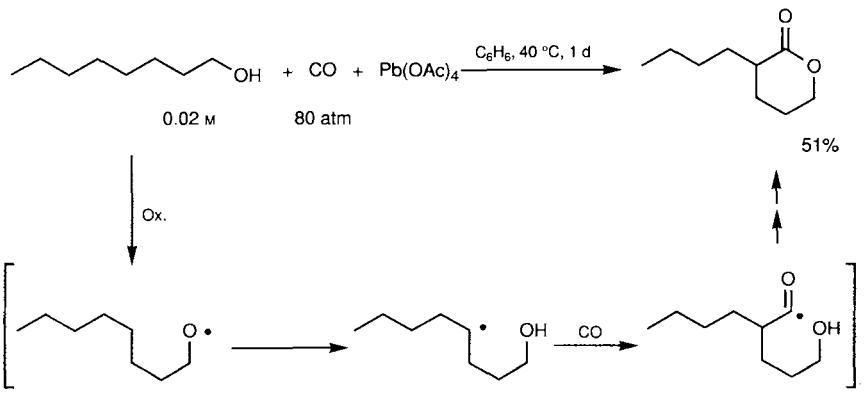
Very recently, Hill and Jaynes found that tetrabutylammonium polytungstate is a good catalyst for the free-radical carbonylation of alkanes under irradiation.[94] For example, the carbonylation of cyclohexane catalyzed by $(Bu_4N)_4[W_{10}O_{32}]$ produced cyclohexanecarbaldehyde with 54 turnovers in 16 h with good selectivity in 8% yield (Scheme 43). The reaction was conducted



Scheme 43. Photocatalyzed carbonylation of cyclohexane by polyoxotungstate. P = catalyst.

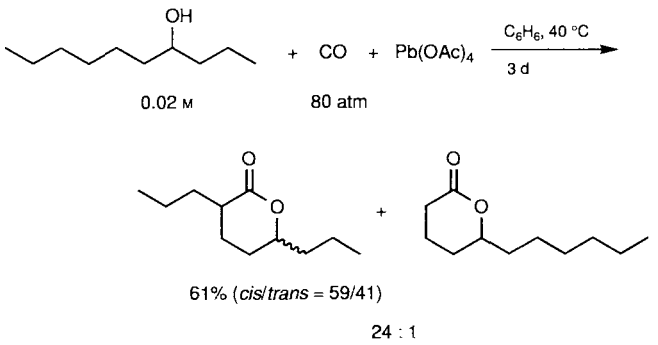
under 1 atm of CO with irradiation from a medium-pressure mercury lamp with a Pyrex filter. Both the turnover levels and the selectivities exceed those of previously reported systems.

These C–H carbonylations are generally not selective for different types of C–H bonds, and only reactions of cyclic alkanes are certain to give uniform products. For this reason we have become interested in the targeted δ-carbonylation of saturated alcohols based on a well-known free-radical reaction, the 1,5-H shift from an alkoxy radical in δ-position.[95] We employed the lead tetraacetate induced oxidation of alcohols[96] to achieve a novel synthesis of δ-lactones from saturated alcohols and CO (Scheme 44).[97] This reaction is quite general for car-



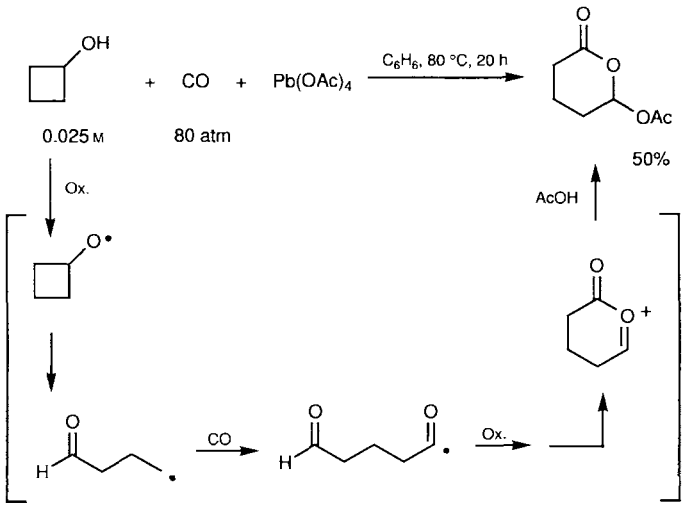
Scheme 44. Carbonylation of 1-octanol induced by lead tetraacetate.

bonylation of primary alcohols and secondary alcohols having primary and/or secondary carbons in δ-position. If an alcohol has both primary and secondary δ-carbons, CO is incorporated preferentially at the secondary position in a 24:1 ratio (Scheme 45). The strategy has been applied to a one-step synthesis of a carpenter bee pheromone starting from commercially available, optically pure (*R*)-(−)-2-hexanol.



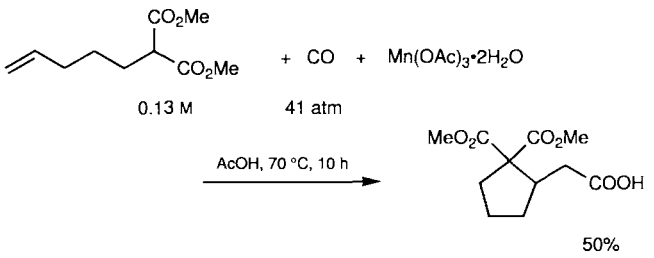
Scheme 45. Carbonylation of 4-decanol induced by lead tetraacetate.

Another approach to generating radicals is the oxidative cleavage of 1-substituted cyclobutanols with lead tetraacetate to give δ-oxoalkyl radicals. Subsequent addition to CO yields acyl radicals, which can be oxidized to afford 5-oxo carboxylic acids.[98] Lead tetraacetate is known to promote decarboxylation of carboxylic acids,[99] but careful examination of the crude reaction mixture by NMR spectroscopy has shown that the primary products are acid anhydrides. In contrast, reaction of 1-unsubstituted cyclobutanols with lead tetraacetate in the presence of CO afforded acetoxy-δ-lactones in moderate yield (Scheme 46).



Scheme 46. Carbonylation of cyclobutanol.

The synthetic potential of a carbonylation reaction with a Mn^{III} oxidizing agent has also been demonstrated by Ryu and Alper.[100] For example, dimethyl (4-pentenyl)malonate, when treated with 2.5 equivalents of manganese(III) acetate dihydrate at 41 atm of CO, yields the desired cyclic carboxylic acid in 50% yield (Scheme 47).



Scheme 47. Oxidative carbonylation with manganese(III) acetate.

8. Summary and Outlook

The rapid development of free-radical methods in the past decade has made a large impact on organic chemistry[101] and motivated us to reexamine the synthetic potential of free-radical carbonylation. As evident in this review, free-radical carbonylations can now be considered to be versatile and promising methods for the introduction of CO into organic molecules. Free-radical carbonylations in combination with tin and silyl radical mediated chain reaction systems offer novel routes to a wide variety of carbonyl-containing compounds.

Free-radical carbonylations have several notable features. An important advantage of free-radical reactions in general is their tolerance of a high level of functionality in the substrates, which makes free-radical carbonylation uniquely suited for the carbonylation of highly functionalized substrates without tedious protection/deprotection sequences. Unlike transition metal mediated methods, which often suffer undesirable side reactions as a result of unstable metal–carbon bonds, a wide range of *alkyl* halides can participate in free-radical carbonylations. A variety of multicomponent coupling reactions with incorporation of CO can be designed based on the abundant kinetic data for free-radical reactions. The combination of free-radical cyclization and carbonylation is a particularly attractive approach for the preparation of cyclic compounds containing a carbonyl moiety. Both reductive and oxidative metal-induced radical reactions can also be utilized in carbonylations. All of the carbonylations described are essentially one-pot reactions performed in an autoclave.

For many years free-radical carbonylation received little attention and thus its full synthetic potential was not probed. Now the opportunity for the facile introduction of CO without the use of transition metals exists and awaits many interesting applications.

The work in Osaka was conducted by an enthusiastic group of graduate students and research staff including Kazuya Kusano, Norio Masumi, Hiroshi Yamazaki, Mitsuharu Hasegawa, Akio Kurihara, Yukihiro Tamura, Kiyoto Nagahara, Hiroshi Fukushima, Hideo Muraoka, Tohru Okuda, Sumiaki Yamasaki, Shinji Tsunoi, Dr. Nobuaki Kambe, and Dr. Akiya Ogawa. We are most thankful to them for their experimental and intellectual contributions. We also thank Professor Mitsuo Komatsu, Dr. Cathleen M. Crudden, and Dr. David C. Falbes for helpful comments. We are grateful to the Ministry of Education, Science and Culture, Japan, for financial support. I. R. thanks the Daicel Chemical Award in Synthetic Organic Chemistry, Japan for partial financial support.

Si–H and C–H Activation by Transition Metal Complexes: A Step Towards Isolable Alkane Complexes?**

Jörg J. Schneider*

The recognition of the fundamental contributions by G. A. Olah on the elucidation of the structure of nonclassical carbocations, in the form of the award of the Nobel prize for chemistry, has recently emphasized the importance of electron-deficient bonds in the understanding of chemical bonding in organic chemistry. In the field of coordination chemistry, the formulation of electron-deficient bonds has been used for some time to describe nonclassical interactions between atoms. Traditional ligands in coordination chemistry such as amines and phosphanes bond to metal centers through their lone pair of electrons. Synergistic bonding effects dominate in the coordination of π-bonded ligands such as alkenes. In the mid-1980s the discovery of dihydrogen complexes having side-on coordination of H_2 gave fresh impetus to transition metal chemistry as well as to the understanding of the interaction of σ-coordinating ligands with transition metals. In the meantime, transiton metal complexes can be obtained with a variety of σ-coordinated X–H fragments, and their mode of bonding can be understood by a common and quite general model. The chemistry of σ-bound silane ligands is particularly varied and well-investigated. These silane ligands enable the investigation of a large range of σ-coordinated metal complex fragments up to complete oxidative addition with cleavage of the Si–H bond and formation of silyl(hydrido) complexes, which has thus also widened our general understanding of the bonding of other σ-bound ligands. Whilst there is a large range of isolable and stable H_2 and SiR_4 complexes available, there are no such alkane analogues known at present. Only when the C–H bond is part of a ligand that is already directly bonded to the transition metal center will the resulting chelate effect stabilize this agostic C-H-M interaction. The complexation of SiH_4, the simplest heavier homologue of CH_4, was achieved recently. This is a further step towards the understanding of the factors which govern σ-complexation of ligands at transition metal centers.

Keywords: C–H activation · complexes with silicon ligands · coordination · methane activation · Si–H activation

1. Introduction

The activation of molecules with σ bonds in the coordination sphere of transition metal is of fundamental interest, particularly with regard to the complexation of hydrocarbons such as methane.[1] As a result of this challenge, the incorporation of molecules with a σ-bonded framework in complexes has developed from what was originally a novel field in the early 1980s to become an important area of research within organometallic chemistry. Nowadays a variety of well-characterized complexes are known that contain σ-coordinated ligands such as (H_2),[2] $(HSiR_3)$,[3] and $(HSnR_3)$.[3] However, comparable stable σ-transition metal complexes of alkanes have not been reported to date.

What is the current level of understanding of the activation and complexation of σ bonds, in particular in H_2, alkanes, and their heavier homologues, the silanes, by oxidative addition at transition metal centers?[4] To what extent can stable SiH_4–transition metal complexes be regarded as having model character for the corresponding CH_4–transition metal complexes? The synthesis, isolation, and structural characterization of the first $M(SiH_4)$ complex **2**[5] [Eq. (a)] was a recent highlight in this area of research. In the following account some of the stages in the development of the transition metal chemistry of σ-bonded ligands will be presented and commented upon.

[**] Abbreviations used: M = transition metal center; (H_2), (CH_4), and $(SiH_4) = (\eta^2\text{-}H_2)$, $(\eta^2\text{-}CH_4)$, and $(\eta^2\text{-}SiH_4)$ respectively, $Cp^* = \eta^5\text{-}C_5Me_5$, INS = inelastic neutron scattering; L = ligand; RHF = restricted Hartree Fock; MP = Moeller–Plesset.

2. σ-Coordinated Dihydrogen and σ-Coordinated Silanes

The simplest ligand that forms exclusively σ complexes with transition metals is the hydrogen molecule H_2. The H–H bond of H_2 always coordinates to a transition metal in a side-on mode.[6] This gives rise to a three-center–two-electron bond, which is comparable to that found in boranes with B-H-B bridges. In analogy to the σ/π bonding formulism for ethene bonding to a transition metal, in H_2 bonding to a transition metal electron density is transferred from an occupied σ_g orbital of the H_2 molecule into an unoccupied metal d_π orbital. By a synergistic interaction, electron density also transfers from an occupied metal d_π orbital into the σ_u^* orbital of the H_2 molecule (Fig. 1). Theoretical investigations,[7] as well as IR,[8a–c] INS,[8d] and Mössbauer[8e] spectroscopic studies confirmed this model of H_2-σ donation and metal(M)-π backbonding. A continual increase of the experimentally obtained intramolecular H–H distances in $M(H_2)$ complexes produce "snapshots" of the oxidative addition of H_2 to a transition metal center.

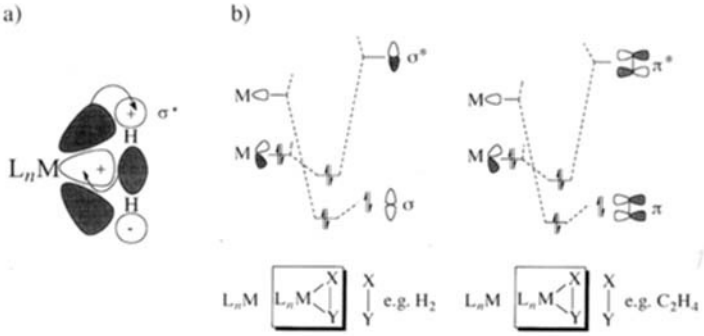

Fig. 1. a) Bonding model for the σ-η^2 side-on coordination of H_2 to a transition metal center; b) comparative representation of the MO interactions in transition metal complexes with σ-coordinating ligands (left) and π-coordinating ligands (right).

At this point the new and surprising results on transition metal free H_2 activation in biosystems should also be mentioned. A hydrogenase found in thermophilic methanogenic archaebacteria is evidently capable of activating H_2 in a catalyzed reaction *without* a redox-active transition metal center.[9] This means that in addition to enzymatic H_2 activation by metal-containing hydrogenases, whose H_2-activating centers contain sulfur and iron or nickel, possibly other modes of H_2 activation occur in nature.

The oxidative addition of a Si–H σ bond is one of the key steps in the mechanism of transition metal catalyzed hydrosilylation.[10] There are numerous examples of the activation of Si–H σ bonds by $M(L_n)$ centers and of complex formation.[3] These reveal that the bonding in silane complexes corresponds to a late step in the oxidative addition to the transition metal center. The ^1H NMR coupling constants and the elongation of the Si–H interatomic distances (from X-ray and neutron scattering investigations) provide a measure of the extent of the oxidative addition in σ-coordinated M-H-SiR_3 complexes (Fig. 2).

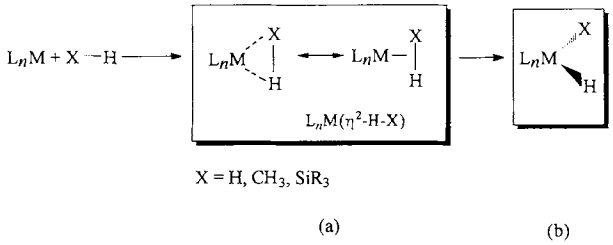

Fig. 2. General scheme for the reaction of a σ-coordinating ligand and a transition metal complex with formation of a side-on σ-η^2 complex (a) and complete oxidative addition of a σ-coordinating ligand to the transition metal complex (b).

3. The C–H Activation of Alkanes

3.1. The C–H Activation of Alkanes by Free Metal Atoms, Metal Oxide Cations, and Metal Clusters

In the case of σ coordination of alkanes to transition metal centers, the weaker basicity, that is the higher electronegativity, of the C–H bond compared to that of the H–H bond has thwarted the successful synthesis and structural characterization of a transition metal stabilized CH_4 complex with methane until now, although both σ bonds have almost equal bond

Jörg J. Schneider was born in 1960 and studied chemistry at the Philipps University in Marburg where he gained his doctorate in inorganic chemistry under C. Elschenbroich in 1986. In 1987/1988, supported by a Fulbright scholarship, he worked as a postdoctoral researcher with K. J. Klabunde at Kansas State University Manhattan/Kansas, USA (two further sojourns there followed in 1991 and 1995). In 1988 he moved to the Max-Planck-Institut für Kohlenforschung at Mülheim an der Ruhr to do further postdoctoral work with G. Wilke, and then remained in Mülheim to start the experimental work for his habilitation in 1989. In 1994 he completed his habilitation in inorganic chemistry at the Universität/Gesamthochschule Essen. In the same year he moved to the Anorganisch-chemisches Institut der Universität/Gesamthochschule Essen as a Heisenberg awardee of the Deutsche Forschungsgemeinschaft. He is currently a lecturer of inorganic chemistry at the University of Essen. His current research focusses on synthesis, structure, and reactivity in organometallic chemistry and on general aspects of high temperature species (atoms and molecules) in synthesis. He is also interested in interdisciplinary research in chemistry, physics, and materials science on which he has recently co-organized two national workshops for graduate students and postdoctoral researchers.

strengths (Me–H: 104.3, H–H: 104.2 ±1 kcal mol^{-1}[11]) and the C–H fragment and the H_2 molecule are isolobal. However, systematic matrix isolation studies of the C–H activation of alkanes by ligand-free transition metal atoms show that even though there is a marked decrease within the group, the reactivity of the transition metal atoms is high (Ru, Os, Rh ≫ Nb, Ta, Mo, Re, Cu, Ag).[12] The crucial factors for the reactivity of all free atoms towards CH_4 were shown to be high M–H dissociation energies and enthalpies of vaporization ΔH_{vap} of the metals. The latter underlines the influence of the kinetic energy of the metal atom in the reactions with CH_4. Ab initio calculations[13] and preparative work on C–H activation with free transition metal atoms[14] confirmed the results from the matrix isolation studies and revealed a particularly high reactivity for the elements Rh and Ru.[15] In the gas phase, the reactivity and selectivity of free transition metal atoms M^0 and ions M^+ towards CH_4 and other alkanes[16] is quite variable and is closely coupled to their electronic configurations and orbital symmetries, as well as to the criteria for spin conservation in these species. Generally, neutral transition metal atoms are less reactive than metal cations in C–H activation. The reason for this is assumed to lie in the $3d^{x-2}4s^2$ ground state electron configuration (x = group number) of neutral atoms which approaches the inert gas character of helium. This means that the charge-induced dipole–dipole interaction with easily polarizable alkanes is distinctly smaller than that for naked metal cations. Precisely this interaction seems to be of crucial importance in the C–H activation of alkanes at transition metal centers in the gas phase, as well as for the differences observed in the reactivity.[16a, 17a] On the basis of ab initio calculations of the gas phase reaction of Pd atoms with CH_4, a complex of type A (Fig. 3) is

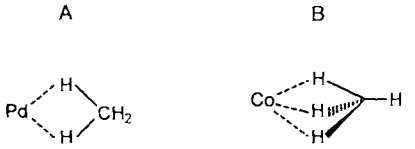

Fig. 3. Intermediates in the C–H activation of methane with Pd atoms in the gas phase (A) [16a,17b] and with Co atoms in solid argon (B) [19].

assumed to be an intermediate[16a, 17a] (A is 4 kcal mol^{-1} more stable by than the reactants Pd_{atoms}/CH_4[18]). Using data from IR matrix-isolation studies, a σ-complex B with C_{3v} symmetry (Fig. 3) is proposed as an intermediate in the oxidative addition of Co atoms with CH_4.[19] The structures A and B are not consistent with the conventional bonding model for σ-H_2 coordination (see above and Fig. 1a). However, interestingly, they are consistent with the results of theoretical calculations of C–H activation of CH_4 with organorhodium complexes (see below and Fig. 6).

In the case of reactions of naked transition metal and transition metal oxide cations with alkanes, there are parallels as well as evident differences in reactivity in the C–H activation of these substrates. Generally, early transition metal oxide cations such as ScO^+, TiO^+, and VO^+ do not react with methane at all. On the other hand, oxide cations of the late transition metals MnO^+ to NiO^+ react very efficiently with methane.[20] The reason for this reduced reactivity of the early metal oxide cations lies in the varying strengths of the M–O bond of these molecules. This bond is particularly strong in the very oxophilic early transition metals and manifests itself in the low reaction efficiency of these transition metal oxide cations with alkanes. The reaction of late transition metal oxide cations with larger alkanes is usually more efficient than that observed with methane; however, this increased reactivity reduces the chemo- and regioselectivity. Additional reaction pathways that may appear, such as the known β-H elimination or even C–C bond activation of the carbon framework of these higher alkanes, may be the cause.[16d, 21] A comprehensive review on the present level of understanding of C–H and C–C activation of alkanes with naked transition metal oxide cations has recently been published by Schröder and Schwarz.[22]

The reactivity of naked metal atom clusters towards CH_4 in the gas phase is size-selective. This was detected for the first time for Pt_2–Pt_{24}; the maximum reactivity occurring for cluster sizes Pt_2–Pt_5.[23a, b] An explanation for the surprisingly high reactivity of such small metal atom clusters is assumed to lie in the low-coordination environment; in contrast larger metal clusters (Pt_6–Pt_{24}) are more highly coordinated and have almost close-packed ordering. In comparative studies of the C–H activation of alkanes in inert gas matrices by free metal atom clusters M_x, the early transition metals were found to be more reactive than the late transition metals.[12] This is consistent with theoretical observations that predict that the activation energy for the dissociative adsorption of alkanes onto metal surfaces increases as the number of d electrons increases.[24]

3.2. Agostic C–H Interactions of Alkanes and Si–H Interactions of Silanes in Transition Metal Complexes

σ-Transition metal alkane complexes of the type $[M(CO)_5(\eta^2\text{-}CH_4)]$ (M = Cr, Mo, W) were detected and characterized spectroscopically as reactive intermediates in alkane/inert gas matrices in the 1970s.[25] Stable, structurally characterized complexes with $(\eta^2\text{-CH})$–M structural elements have only been found to exist so far with agostic bonding;[26] a chelate bridge is responsible for the crucial stabilization of the C-H-M three-center interaction (Fig. 4a). Here the C–H bridge remains close

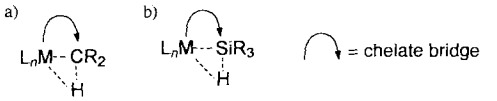

Fig. 4. Agostic interactions in alkane (a) and silane complexes (b).

to the metal center, and the C–H bond is not greatly elongated[2i] (C–H bound: 1.13–1.19 Å, unbound: 1.1 Å), thus preventing complete dissociation and formation of an alkyl(hydrido) complex. In analogy to studies of transition metal complexes with σ-bound silane ligands,[27] an examination of the structural data of transition metal complexes with agostic C-H-M interactions using structural correlation methods[28] has produced a model that describes the approach of the C–H bond towards the metal atom and the stereochemistry during the course of formation of the C-H-M interaction.[2i, 29] Apart from a preliminary stage in which the C–H fragment is more or

less in an end-on orientation ($\sphericalangle$ M-H-C $\approx 150°$), the C–H bond of the alkane approaches the transition metal side-on. Such organometallic complexes with C-H-M interactions have been "arrested" in the early stages of oxidative addition. This is in contrast to compounds with M-Si-H bonds, which, for the most part, do not contain any intramolecular chelate bridges. As a result of the C-H-M interaction, the acidity of the agostically complexed C–H bond increases drastically. In principle, such an intramolecular chelate stabilization should also be possible for Si-H-M interactions (Fig. 4b), and would, of course, lead to the corresponding σ complexes in their early stages of oxidative addition. However, examples of such structures are scarce up to now.[30] If it were possible in future to close this gap with further preparative examples, similar behavior in the coordination of both C–H and Si–H at transition metal centers could certainly be expected.

3.3. C–H Activation of Alkanes in Homogeneous Solution

At the beginning of the 1980s, Bergman, Graham, and Jones and their co-workers in independent work, detected C–H activation reactions of CH_4 and other alkanes in homogeneous solution[31] [Eq. (b)]. Shortly before, Crabtree and Felkin and

$$[(C_5R_5)MLL'] + R'H \xrightarrow{h\nu} [(C_5R_5)ML(R')(H)] + L \qquad (b)$$

R = H, CH_3, R' = CH_3, C_6H_{11}, tBuCH$_2$, Ph
L = CO, $P(CH_3)_3$, L' = CO, H_2, M = Rh, Ir

co-workers had observed the first indications of cycloalkane activation in solution.[32, 33] In the following years Bergman et al. succeeded in detecting conclusively intermediate stages of C–H activation of different alkanes with Ir and Rh complexes.[34] It was frequently the experiments carried out under unconventional, nonclassical conditions, for example in supercritical solvents or in the gas phase, which were of crucial importance for gaining new information on C–H activation. In 1994 it was demonstrated[35] that the photolysis of $[Cp^*Rh(CO)_2]$ in the presence of 2,2-dimethylpropane (neopentane) in liquid krypton produces [Cp*Rh(CO)(Kr)] as an intermediate, which is in equilibrium with the σ-alkane complex $[Cp^*Rh(CO)\{C(CH_3)_4\}]$. These intermediates can be detected *side by side* by IR spectroscopy. The actual end product $[Cp^*Rh(CO)(H)(C_5H_{11})]$ of the oxidative addition reaction of neopentane with the 16 valence electron fragment [Cp*Rh(CO)],[36] arises from an unimolecular reaction [Eq. (c)]. These

$$[Cp^*Rh(CO)_2] \xrightarrow[-CO]{h\nu} [Cp^*Rh(CO)(Kr)] \underset{+Kr,\ k_2}{\overset{+RH,\ k_1}{\rightleftharpoons}} [Cp^*Rh(CO)(RH)] \xrightarrow{k'_2} [Cp^*Rh(CO)(H)(R)] \qquad (c)$$

R = tBuCH$_2$

investigations delivered the first *direct* evidence of an σ-alkane complex as an intermediate in the C–H activation of alkanes. It is worth mentioning at this point that the latest technical developments in apparatus for synthesis in supercritical fluids,[2k] when applied to C–H activations of alkanes, may allow further important advances in this field.

3.4. Heterogeneous C–H Activation of Alkanes

C–H Activation of methane is also known from investigations in heterogeneous phases.[37a–e] For example, the organometallic fragment $[Rh^I(CO)_2]$ exists as an isolated species on oxide surfaces such as Al_2O_3.[37d] On photoactivation there is loss of CO and formation of $[Rh^I(CO)]$. This species can activate CH_4 at temperatures as low as $-40\,°C$,[37e] and cyclohexane at $27\,°C$[37f–h]. The end product of the heterogeneous photochemical C–H activation of CH_4 is the acyl complex $[RhH(CO)(COCH_3)]$, which is formed by migration and insertion reactions of CH_3 into the Rh–CO bond of $[RhH(CO)(CH_3)]$[37e] (Fig. 5). The free coordination site at the Rh center is then filled by a further CO molecule. Such CO insertion reactions have been well documented and represent important key steps in industrial processes, for example the Fischer–Tropsch process,[38a, b] Roelen's hydroformylation,[38c, d, e] or organometallic reactions like the photolytic activation of alkanes with $[RhCl(CO)(PMe_3)_2]$[39] in homogeneous solution.

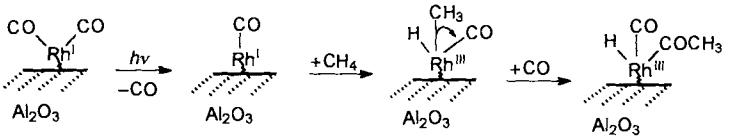

Fig. 5. Reaction scheme for the heterogeneous C–H activation of methane on $[Rh^I(CO)]$ fragments complexed to a surface [37e].

Hitherto, all the known C–H activations at transition metal centers in both homogeneous and heterogeneous phases occur preferentially at primary C–H bonds of alkanes. This gradation in reactivity is contrary to that found for conventional metal-free C–H activations of alkanes with radicals or strong acids[1d, 40] (gradation in reactivity here: *tert*-C-H > *s*-C-H > *primary*-C-H > CH_4), and shows that the environment of the central transition metal center, that is steric effects, have a crucial influence on the reactivity of the C–H activations of alkanes.

3.5. Theoretical Investigations on C–H and Si–H Activation of Alkanes and Silanes

Theoretical studies have accompanied the experimental work on CH_4 and SiH_4 activation on transition metal centers right from the beginning.[41] For intermediates $[L_nRh\cdots(CH_4)]$ of the oxidative addition of CH_4 onto organorhodium complexes, the calculated binding energies, reaction enthalpies ΔH of the total reaction, and the C–H activation energies for the attack of methane by the $[L_nRh]$ fragment, may display strong variations in their absolute values depending on the ab initio procedure used.[41, j, k, 42] However, all the calculations carried out to date gave consistent energy profiles for the C–H activation of CH_4, that is low activation barriers and relatively high reaction enthalpies ΔH, which is consistent with the reactivity of such unsaturated organometallic systems found experimentally. Experimental gas phase investigations of the reaction pathway of the activation of H_2, CH_4 and other alkanes have been carried out using [Cp*Rh(CO)].[34g] In this oxidative addition reaction, the intermediate $[Cp^*(CO)Rh\cdots(CH_4)]$ is formed, which passes through a transition state before transforming into the end

product, a stable methyl(hydrido) complex. Calculations by Morokuma et al. (RHF-MP method) on the H_2, SiH_4, and CH_4 activation at organometallic fragments [Cp*Rh(CO)] and $[RhCl(PH_3)_2]$[39] essentially confirm this reaction pathway.[42b,c] Here, the intermediate of the C–H activation was calculated to have a bidentate structure in which two C–H bonds coordinate simultaneously to the Rh center (Fig. 6). In

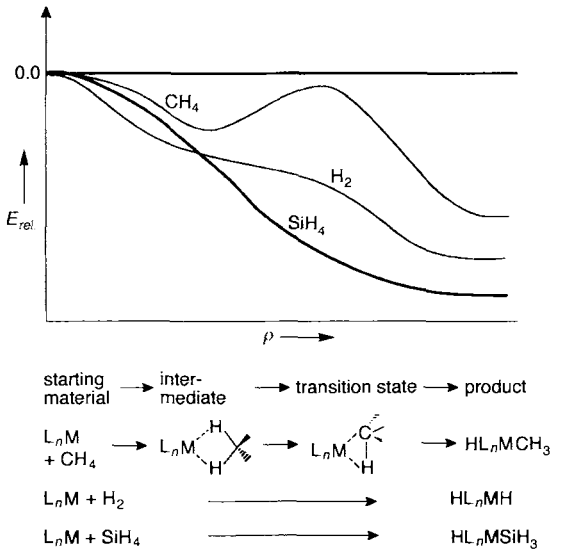

Fig. 6. Reaction profiles for C–H, H–H, and Si–H activation by [Cp*Rh(CO)] and $[RhCl(PH_3)_3]$ according to theoretical investigations [42]. For the structural parameters of the intermediates and the transition states see ref.[42b,c]. ρ = reaction coordinate.

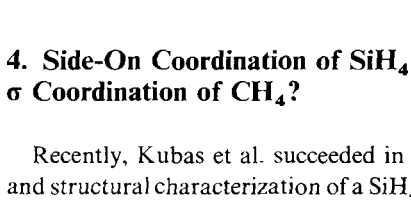
the transition state there is σ-η^2 coordination. Interestingly, calculations on the activation of SiH_4 with both of the above Rh^I complexes gave reaction profiles that did not exhibit a comparable intermediate. The calculated differences in the stabilities of the end products ($HL_nRhSiH_3 > HL_nRhH > HL_nRhCH_3$) of the oxidative additions of H_2, SiH_4 and CH_4 to [Cp*Rh(CO)] and $[RhCl(PH_3)_2]$ correlate well with the $E_{H,Si,C-H}$ ($SiH_4 < CH_2 < CH_4$) and the $E_{H,Si,C-Rh}$ ($SiH_4 > H_2 > CH_4$) bond strengths.[43] This gradation results in a reaction profile for the H–H and the Si–H activation which, in contrast to the C–H activation, only has a downhill gradient without a stable intermediate.

4. Side-On Coordination of SiH_4 as a Model for σ Coordination of CH_4?

Recently, Kubas et al. succeeded in the synthesis, isolation, and structural characterization of a SiH_4 complex [5] by reaction of SiH_4 with the electronically and coordinatively unsaturated 16 valence electron Mo^0 complexes **1**.[44] In the reaction of **1a** ($R = C_6H_5$) or **1b** ($R = i$Bu) with SiH_4, only side-on η^2 coordination is observed both in solution and in the solid state [see Eq. (a)]. Here, the contributions of the ^1H NMR coupling constants of the σ-bound transition metal silane complexes **2** J(Si,bridging-H) and J(Si,H), as well as their differences ΔJ, provide a valuable indication of the extent of the oxidative addition of the SiH_4 ligand at the central Mo atom in **2** in solution (Table 1). Compared to some Mn–silane complexes **5a–c**,[3b]



1 R = Ph (**1a**), *i*Bu(**1b**), Et (**1c**)

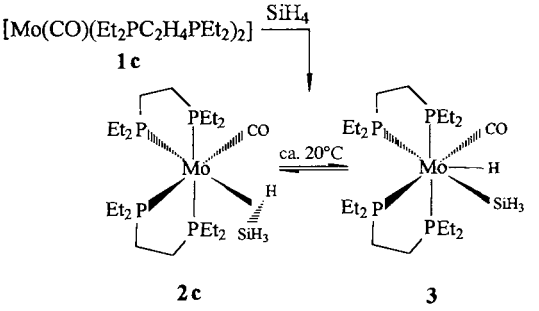
4 R = z.B. Et, Ph; *R = e.g. Ph, n-C_6H_{13}, H*

Table 1. Selected coupling constants J(Si,H) and J(Si,bridging-H) as well as the differences ΔJ [in Hz] of the $Mo(SiH_4)$ and $Mo(H_2SiR_2)$ complexes **2** and **4**, respectively, in comparison with the silylmolybdenum complex **3** and the manganese silane complexes **5a–c**.

Complex	J(Si,H)	J(Si,bridging-H)	ΔJ [a]
$[Mo(SiH_4)CO(Ph_2PC_2H_4PPh_2)_2]$ **2a**	181	50	131
$[Mo(SiH_4)CO(iBu_2PC_2H_4PiBu_2)_2]$ **2b**	163	31	132
$[Mo(SiH_4)CO(Et_2PC_2H_4PEt_2)_2]$ **2c**	164	35	129
$[MoH(SiH_3)CO(Et_2PC_2H_4PEt_2)_2]$ **3**	143	–	–
$[Mo(SiH_3Ph)CO(Et_2PC_2H_4PEt_2)_2]$ **4a**	164, 170	39	131, 1255
$[Mo(SiH_2Ph_2)CO(Et_2PC_2H_4PEt_2)_2]$ **4b**	172	50	122
$[Mo(SiH_3Ph)CO(Ph_2PC_2H_4PPh_2)_2]$ **4c**	187, 194	57	130, 137
$[Cp'Mn(CO)PMe_3(SiH_2Ph_2)]$ **5a** [b]	188	38	150
$[Cp'Mn(CO)PPh_3(SiH_2Ph_2)]$ **5b** [b]	191	43	148
$[Cp'Mn(CO)\{P(OPh)_3\}(SiH_2Ph_2)]$ **5c** [b]	199	45	154

[a] $\Delta J = J(Si,H) - J(Si,bridging\text{-}H)$. [b] $Cp' = \eta^5$-C_5H_4Me.

the value of ΔJ of about 130 Hz for **2a–c** and for **4a–c**[45] is clearly lower. This indicates the presence of η^2-side-on coordinated silane ligands in **2** and **4** in the "early stage" of the oxidative addition. However, for **1c** there is already an equilibrium between the two tautomeric forms **2c** and **3** in solution; thus, both forms are present at room temperature [Eq. (d)]. This ex-



(d)

perimental result indicates a flat energy profile for the activation of SiH_4 by **1**, and is contrary to the theoretical results on Si–H activation obtained by Morokuma et al.; however, it should be kept in mind that his results were obtained with the Rh^I complexes [Cp*Rh(CO)] and $[RhCl(PH_3)]$.[42]

Interestingly, inspection of the electronic situation for the coordination of SiH_4 to the Mo starting complexes **1**, reveals that these complexes exactly fulfil the requirements that Schubert et al. found to be necessary at the beginning of the 1990s for the isolation of stable silane and stannane complexes of Group 6 elements.[46] These results showed that a stepwise increase of the electron density on the metal center due to donor ligands allows the stabilization of σ complexes with silane and stannane ligands. Additionally, the extent of the oxidative addition of

these ligands is directed by factors such as the basicity of the metal center (Cr < Mo < W), the number of phosphane ligands present (Cr, Mo > W), and the electronic situation at the σ-coordinated silane or stannane. In the case of substituted silanes H_xSiR_{4-x}, electron-withdrawing substituents R on the silicon enhance the tendency of σ-Si-H coordination, and increase the activation enthalpy of the reductive elimination of the silane ligand.

Bearing all this in mind, the recent successful σ coordination of SiH_4[5] by means of consequent fine tuning of the electronic situation on both the Mo center and in the ligand sphere of **1** is not quite unexpected; it proves conclusively that such an "optimized" electronic situation at the transition metal center allows the coordination of SiH_4 and thus makes an additional electronic tuning by other ligands on the incoming silicon superfluous. Whether this clearly important step on the way to the coordination of methane can act as a model for the coordination of CH_4 at transition metal centers, as was proposed by Kubas et al.,[4-7] remains to be seen, particularly in view of the electronic differences in the two substrates, CH_4 and SiH_4, and the resulting theoretical and experimental differences for the C–H and Si–H activation at transition metal centers.

5. Final Comments

This account should allow the reader an insight into the comparative C–H and Si–H activation of alkanes and silanes, respectively, at transition metal centers as far as oxidative additions are concerned. Particular consideration has been paid to recent preparative and theoretical results. With respect to the field two recently published review articles by Crabtree[1d, 2j] deserve special attention and will be particularly helpful to the reader.

Completed reactions, that is those that have proceeded to the final oxidative addition of alkanes with transition metals, have already been observed for numerous transition metal atoms and transition metal complex fragments. The σ-transition metal complexes that are formed therein are often only intermediates or transition states on the way to the thermodynamically stable end product, an alkyl(hydrido) complex. In organometallic chemistry it is not rare to find that the high reactivity of a transition metal atom or transition metal complex fragment is associated with a low selectivity or stability of such an intermediate in the corresponding chemical reaction, for example a σ-transition metal complex. This is due in most part to the fact that for highly reactive species there are usually a number of competing reaction channels available. For C–H activation processes this applies in particular to atoms M, complex fragments ML, and highly reactive (unsaturated) complexes ML_n. Therefore, it is necessary to have an accurately tuned electronic and steric situation at the transition metal center to isolate stable σ-alkane complexes as precursors of oxidative additions. For future developments in this field a wide range of ligands with differing electron-directing capabilities and variable spatial requirements will be necessary. They will have to be capable of a) electronic fine tuning of a range of different transition metal centers for σ coordination to the alkane, and b) creating the necessary steric situation at the transition metal center. However, these ligands are probably already largely available. The task facing the organometallic chemist is to find the correct combination of single components—ML fragments and any additional sterically and electron-directing ligands—necessary to obtain complex fragments or complexes that will allow the successful isolation of the first transition metal alkane complexes. Possibly, the use of unconventional preparative methods of synthesis[8c, 25d] will give fresh impetus to the continuation of experimental developments in this area. Moreover, theoretical investigations will continue to be a constant and important partner to the experiments and will aid in understanding the role of the electronic states involved at the transition metal during the C–H activation process.

In summary, inspite of all the successful results obtained so far in the field of C–H activation of alkanes, the understanding of the factors that control the activation of alkanes—and here in particular methane—by transition metals remain a preparative and theoretical challenge.

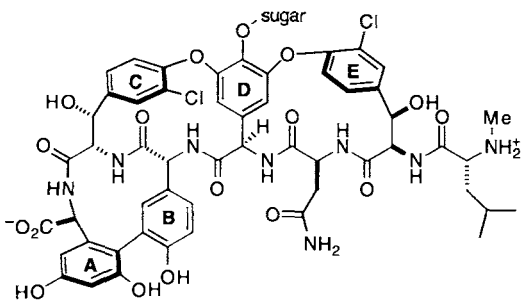
Nucleophilic Aromatic Substitution—A Possible Key Step in Total Syntheses of Vancomycin**

Kevin Burgess,* Dongyeol Lim, and Carlos I. Martinez

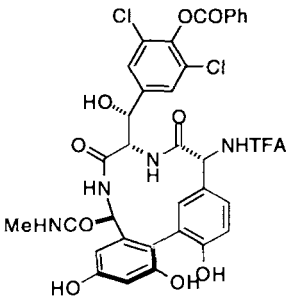
Vancomycin is a natural product with a complicated molecular architecture and clinical significance as an antibiotic for treatment of infections caused by gram positive bacteria. These two attributes have seduced several groups of organic chemists into attempting to prepare this molecule, but no successful synthesis has been reported to date.



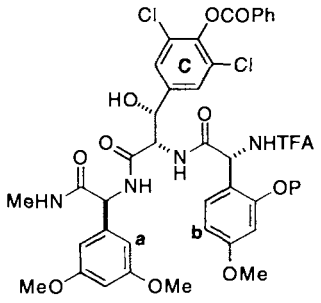
vancomycin

In 1993 there were two reasons to suppose that a total synthesis of vancomycin might be achieved soon.[1] First, the cyclic compound **1** had been prepared;[2] this closely resembles the "southwestern fragment" of vancomycin, which includes the biaryl linkage of rings **A** and **B**. Second, the bicyclic compound **2** had been made;[3] this is closely related to the central region of vancomycin, which incorporates the **C**, **D**, and **E** rings.

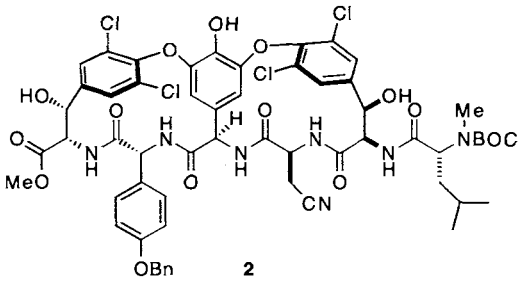
Despite this optimism, it apparently has not been convenient to exploit the syntheses of fragments **1** and **2** in a total synthesis, presumably for the following reasons. Vancomycin has only one chlorine atom on rings **C** and **E**, whereas both *ortho* positions on the corresponding aryl rings of **2** are chlorinated. These extra chlorine atoms were critical for the synthesis of **2**, in which two thallium trinitrate-mediated couplings require both *ortho* phenolic positions to be blocked. Furthermore, the formation of **1**, an oxidative coupling of the carbons marked a and b in structure



1



3
(P = 3,4-dichlorobenzyl)



2

3, required harsh conditions (VOF_3, $BF_3 \cdot OEt_2$, TFA, TFAA, CH_2Cl_2, 0 °C, then Zn) that may not be suitable in the absence of chlorine blocking groups at both *ortho* positions of ring **C** in **3**.

Reduction of a single C–Cl bond to a C–H on a dichlorinated aromatic ring is a challenging transformation. When two such monosubstitutions must be made in a molecule containing two dichlorinated aryl rings in a complex molecular skeleton it is more difficult, and if the chlorine atoms on each ring are inequivalent due to atropisomerism,[4] the task is formidable. No further manipulations of **1** and **2** have been reported, implying that a synthetic stalemate has been reached. Strategies involving dichlorinated **C** and **E** rings may be stymied by the selective dehalogenation problem, and in that case a fresh approach is necessary.

Since 1993, relatively new competitors in the vancomycin synthesis arena have provided an impetus that may have sufficient momentum to bring about its total synthesis. Notably, a series of papers from Zhu and co-workers have focused on intramolecular nucleophilic aromatic substitution (S_NAr) reactions as a means to cyclize peptide-based compounds containing biaryl

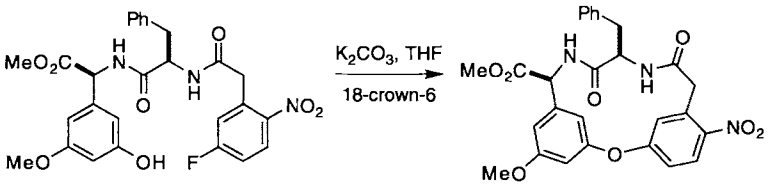
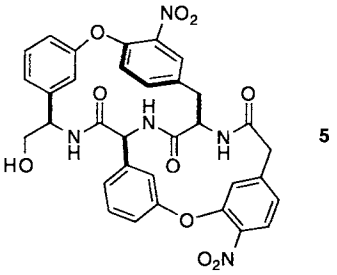
ether linkages. This approach is a notable improvement on Ullmann coupling procedures using aromatic compounds that are not activated to nucleophilic attack. The latter approach had been explored by Boger and co-workers,[5] but the extreme temperatures and prolonged reaction times preclude application of such classical Ullmann couplings in vancomycin syntheses.

The first efforts in this area by Zhu et al. included a synthesis of the 17-membered ring compound K-13 by biaryl ether formation as the ring closure step.[6] Since then, his group has used related reactions to prepare compound **4**, which has a 14-membered ring, then the 14,16 ring fused system **5** similar to that in teicoplanin (a natural product structurally related to vancomycin).[7–9] Model studies in the vancomycin series showed

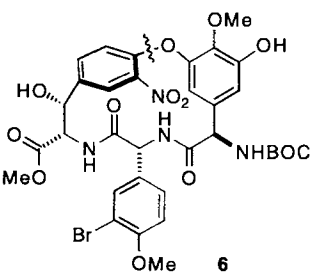


4 71 %

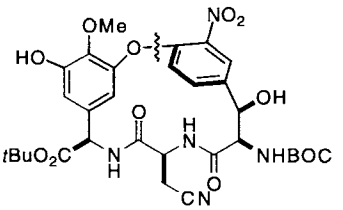


5

that 16-membered peptidic biaryl ethers also could be prepared,[4, 9] an observation that Rao et al. confirmed shortly thereafter.[10] These important studies proved that the ring closure would work even for 16-membered rings of the type found in vancomycin, which had been shown to be difficult to form by other conditions. Moreover, the research by Zhu et al. demonstrated that the cyclization could be performed with minimal racemization at an arylglycine residue within the incipient ring. Indeed, the conditions are sufficiently mild (e.g. K_2CO_3, DMF, 25 °C) that they should be suitable for more complicated substrates. The most recent publication from this group proved that this methodology could be applied to prepare a close analog of the vancomycin **C**-O-**D** ring.[11] Shortly after these studies were published, Boger et al. reported the same type of cyclization method to prepare building blocks for the **C**-O-**D** and **D**-O-**E** rings of vancomycin, compounds **6** and **7**, respectively.[12] The



6



7

intermediate **6** discussed by Boger et al. is notable insofar as it has functionality appropriate for attempted formation of the vancomycin **AB** biaryl fragment.

A total synthesis of vancomycin has not yet been reported. Hurdles that remain include synthesis of the **AB** ring system in such a way that it could be incorporated into the extended product, and coupling of the carbohydrate residues to one of the phenolic oxygen atoms.[13] However, it does seem that the **C**-O-**D**-O-**E** rings of vancomycin, with appropriate chlorine substituents, soon could be synthesized by couplings based on nucleophilic aromatic substitution.

Self-Organized Superlattices of Nanoparticles

Horst Weller*

During the last 50 years, scarcely any field of research in physical chemistry has developed as rapidly as that on nanostructured systems during the last decade. The reason for such avid research arises directly from the dimensions of the ultrasmall solids. With decreasing particle size the ratio of surface to volume increases to such an extent that finally the material properties are much more determined by the surface atoms than by the "classic" lattice atoms. Apart from such surface effects, semiconductors and metals show a drastic change of the electronic structure in the nanometer range, the so-called size-quantization effect, which results from the three-dimensional confinement of electrons and holes within the particles. From the point of view of solid-state physics, the nanoparticles, which are also called Q particles, nanoclusters, nanocrystallites, quantum dots, or artificial atoms, give an impressive example for the quantum mechanical model of a "particle in a three-dimensional box". The chemist may prefer the picture that the overlap of the numerous atomic orbitals in the particles already results in a great number of new states, whereas the energy bands of the macroscopic solid have not yet evolved. It is evident that the optical, catalytic, optoelectronic, magnetic, and electric properties of the particles differ considerably from those of the compact solids. The transition region from molecules to solids is today even described as a new state of matter.

Whereas the first ten years of research were characterized by the investigation of the size-dependent properties of the particles and—as a qualification and precondition for more and more precise measurements—by the development of better and better preparation and characterization methods for monodisperse samples, a new trend of research has recently been established with the aim of arranging individual particles in two- and three-dimensional superlattices and investigating the collective properties resulting from the interaction of the particles. Spectacular results similar to those achieved for the size variation of the isolated particles may be expected.

Ordered superlattices composed of micrometer-sized particles have been known in colloid chemistry for quite a long time; their formation is attributed to the so-called secondary minimum in the potential curves of the colloids. For nanoparticles, this secondary minimum is too small to determine the structure and therefore superlattices can only be formed when the particles are in direct contact through their ligand or stabilizer shells. Opals provide an impressive example for this: the silicon dioxide particles with diameters of about 100–500 nm of which they are composed, form a well-ordered superlattice which is, in fact, the reason for the fascinating interference colors of these precious stones. Up to now, there are only few examples for the crystallization of metal and semiconductor particles. First results have been achieved with iron oxide particles approximately 7 nm in size,[1] followed by investigations of two-dimensional precipitations of gold colloids on carrier foils for electron microscopy.[2–4] Ordered precipitations have also been found in ligand-stabilized Au_{55} and similar clusters.[5, 6] Even more remarkable are the results of a paper recently published by Bawendi et al.[7] who prepared a series of CdSe nanoparticles with diameters between 2 and 6 nm in ordered thin layers as well as in colloid crystals. In both cases crystallization was achieved by slowly removing one component of a solvent mixture, here octane/octanol, thus reducing the solubility of the particles. The alignment of the nanoparticles in a face centered cubic (fcc) superlattice is very clearly shown in high-resolution transmission electron microscope (TEM) images and is supported by X-ray powder diffraction patterns in the narrow- and wide-angle range. These reveal in an impressive way how, as expected, with decreasing particle diameters the superlattice reflections are shifted to higher 2θ values.

Furthermore the authors observed that the fluorescence bands of the crystallized CdSe particles exhibit a long wave length shift in comparison to those in diluted solutions in which the particles are widely separated from each other. In contrast the absorption spectra are identical in both samples. These results are considered to clearly indicate the particle–particle interaction in the superlattice. Similar spectroscopic results have been reported previously for CdS nanoclusters in superlattices.[8] It is certainly incontestable that the fluorescence shift is something to do with the surrounding particles; it remains, however, questionable whether this signifies the formation of collective electronic states, because the change of the ambient dielectric constant or reabsorption might also explain this phenomenon. Therefore further results are eagerly awaited.

The distance between the nanoparticles can be adjusted elegantly by choosing the ligands. This has already been shown for gold particles,[3] and Bawendi et al. have also demonstrated this with the powder diffraction patterns of 4.8 nm crystallites with tributylphosphane oxide, trioctyl phosphane oxide, and hexadecylphosphate as ligands. The distances between the particles change from 0.7 to 1.7 nm.

Unfortunately, Bawendi's nanocluster crystallites measure only few micrometers, so it has not yet been possible to exactly determine the atomic coordinates by single-crystal X-ray diffraction. Such single-crystal data have, however, recently been ascertained for CdS and Cu_2Te nanoclusters and similar compounds with sizes of approximately 1–4 nm. The crystallization and characterization of $[Cu_{146}Se_{73}(PPh)_{30}]$, one of the biggest clusters crystallized up to now, by Fenske et al.[9] is particularly worthy of mention. For semiconductor materials there have recently been remarkable publications on CdS nanoclusters. Following the pioneering work by Dance et al.[10] that led to the crystallization of $[N(CH_3)_4]_2[Cd_{17}S_4(SPh)_{28}]$, Herron et al.[11] succeeded in elucidating the structure of crystallized, electrically neutral $[Cd_{32}S_{14}(SPh)_{36}]\cdot 4DMF$ (DMF = dimethylformamide) nanoclusters, and Vossmeyer et al.[8, 12] reported the corresponding results with $[Cd_{17}S_4(SCH_2CH_2OH)_{26}]$ and $[Cd_{32}S_{14}(SCH_2CH(OH)CH_3)_{36}]\cdot 4H_2O$. All these clusters have a pyra-

midal structure, which is best described as a section of the macroscopic zinc blende lattice (Fig. 1). The superlattice structures, however, vary rather strongly. The corners of the neutral $[Cd_{17}S_4(SR)_{26}]$ clusters are covalently linked through sulfur bridges to give the superlattice, the structure of which is an

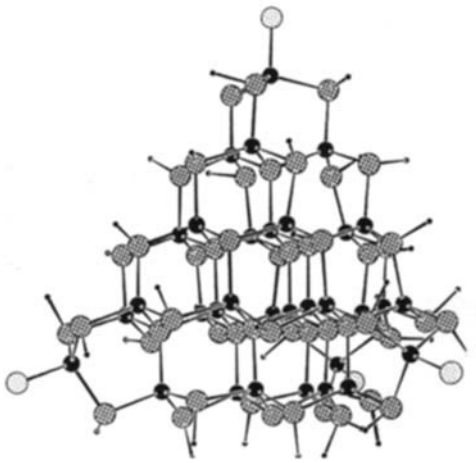

Fig. 1. Structure of the $Cd_{32}S_{14}(SR')_{36}$ nanocluster (● = Cd, ⊛ = S, ○ = H_2O or DMF) [12]. For the sake of clarity the ligands are only indicated. The $[Cd_{17}S_4(SR)_{26}]$ cluster has a very similar structure, the pyramid lacks only the lowest layer of Cd and S, and instead of solvent molecules there are bridging SR groups at the cluster corners. R′ = $CH_2CH(OH)CH_3$ or C_6H_5, R = CH_2CH_2OH.

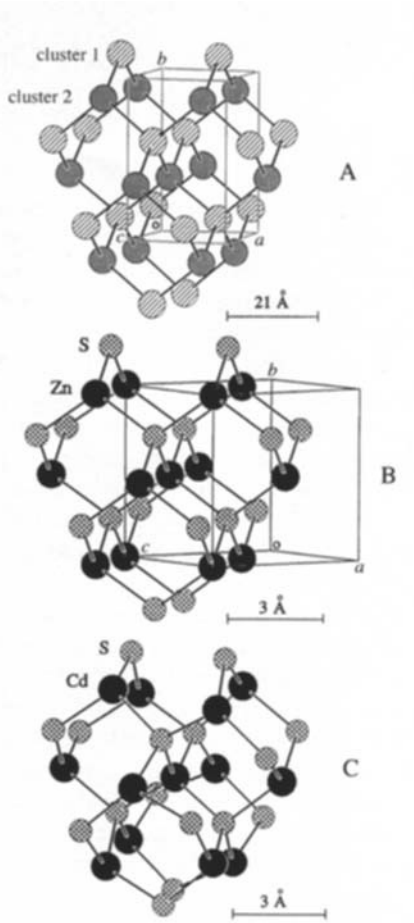

Fig. 2. Section of the $[Cd_{17}S_4(SR)_{26}]$ superlattice (A, each cluster is shown only as a point) and inner structure of the cluster (C); for comparison: zinc blende lattice (B) [8]. The similarity of cluster and superlattice is clearly recognizable. Cluster 1 and cluster 2 in part A of the figure are chemically equivalent, but X-ray crystallographically distinguishable.

enlargement of the inner crystal structure of the individual clusters (Fig. 2). The bigger $[Cd_{32}S_{14}(SR')_{36}]$ clusters form van der Waals type crystals; despite the identical cluster core the superlattices of the latter clusters are totally different. Whereas the thiophenol-stabilized cluster forms a densely packed primitive lattice, the thiopropanol-stabilized cluster forms a rhombohedral lattice in which the clusters build up a double layer structure interspersed with approximately 4 nm cavities filled with water. In addition the absorption bands of both clusters are shifted towards each other by approximately 30 nm in the optical spectra. Evidently, in this range of size the chemistry of the ligands is of importance for the electronic structure of the clusters as well as for their three-dimensional arrangement in the superlattice. Interestingly, the pyramidal structure of the $[Cd_{32}S_{14}(SX)_{36}]$ cluster also occurs in other compounds such as $[Hg_{32}Se_{14}(SePh_3)_{36}]$.[13]

There have been recent reports on a promising attempt at self-organized nanostructuring for gold particles by polymeric and colloidochemical processes. The crux of this method is to prepare the superlattices from colloid phases, here from block copolymer micelles, and to use the micelles as reaction vessel for the preparation of monodispere particles.[14–16] This attempt, that is the control of the synthesis of the particles by host–guest interaction, is not a novel approach, but compared with the present, mostly not very successful attempts, the block copolymer systems offer certain advantages: the polymer structures are sufficiently soft not to be destroyed when the particles are formed—a problem that occurs very often in crystalline inorganic host systems (e.g. zeolites). Furthermore, the block copolymer micelles are exchanged slowly enough to preserve the micelle structure while the particles are precipitated, which is a prerequisite for host–guest systems, but is unfortunately not the case in conventional soap micelles. Block lengths and functionalization of the blocks can be varied rather easily, which is extremely useful for optimizing the materials properties. Figure 3 shows a TEM image of precipitated micelles in the cores of which gold particles have subsequently been generated by reduction. The dense hexagonal packing of the micelles that preforms the resulting superlattice of the gold particles is clearly recognizable.

The examples given illustrate the wide range of variations to be expected when preparing ordered nanocluster materials. In-

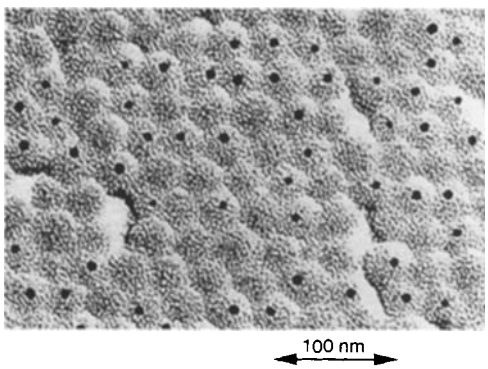

Fig. 3. TEM image of gold particles in polystyrene/poly-4-vinyl pyridine block copolymer micelles. The micelles were loaded with gold salts and precipitated on a carrier net. The reduction of the gold particles was achieved by electron beam; however, other reduction methods are possible [16] (reproduction by kind permission of M. Antonietti and E. Wenz).

cluding the possibility of combining nanoclusters of different size or composition in one superlattice (as can be seen in nature in the case of some opals), it becomes evident how large and varied this field will be in future materials research. It is fascinating to see that it is the self-ordering power of nature that permits the formation of such complex structures and thus at least some of the extremely costly equipment for nanostructuring used today could in future be replaced by the round flask and the beaker. The chemist may even dream of a new structural inorganic chemistry with nanocrystallites serving as building blocks like the atoms in molecular chemistry.[17]

Symmetry-Based Metal Complex Cluster Formation**

Thomas Beissel, Ryan E. Powers, and
Kenneth N. Raymond*

There are examples of non-covalently linked molecular clusters in nature of stunning symmetry and beauty. Two are shown in Figure 1. The 24 individual protein subunits of apoferritin[1, 2] (the elipsoid-shaped subunits on the left of Fig. 1) cluster

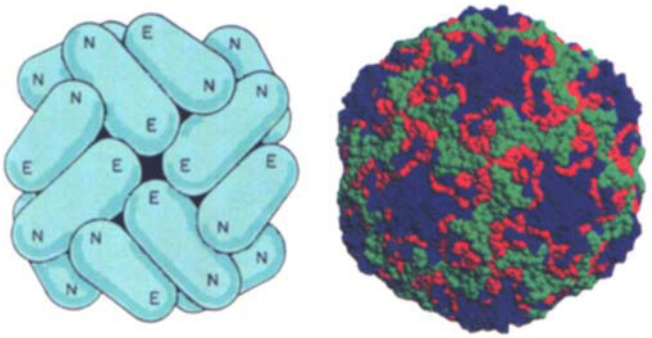

Fig. 1. Models of the apoferritin 24-mer (left) and human rhinovirus 60-mer (right). The view of ferritin is down one of the C_4 axes, the other two C_4 axes of the octahedral cluster are horizontal and vertical, respectively. Along the body diagonal (between three of the elipsoid ends marked N) lies the C_3 axis of the octahedral cluster. The view of the virus is down the C_3 axis, and the regions related by symmetry through the C_2 axis and the C_5 axis are shown in green and blue, respectively.

together to form only this polymeric assemblage (symmetry group O). The approximately spherical cavity can hold over 4000 iron atoms in the form of FeO(OH).[2] When the apoprotein is dissociated into the individual protein subunits and then allowed to reassemble only the highly symmetrical 24-mer of apoferritin forms. Something similar happens with many viruses, in which non-covalently linked protein clusters of virus coats are used to protect the viral nucleic acid. The protein cluster coat of the human rhinovirus (Fig. 1 right)[3] contains 60 protein subunits, which spontaneously assemble to give an icosahedron (symmetry group I). Once again, it is generally true that dissociation and reassembly of the protein coat does not give a random polymer assembly but instead only the highly symmetrical 60-mer.

What is it that leads to the high symmetry of such clusters? What is the relationship of this symmetry to the specificity seen in the formation of a single cluster type with unique cavity size and properties? In each case the individual molecular fragments (the protein subunits) are asymmetric units—the order of the pure rotation groups O and I are 24 and 60, respectively. Can this process be mimicked by using metal–ligand interactions as the driving force? This paper addresses these questions and shows that highly symmetrical clusters can be systematically designed by using the principles of symmetry-driven reactions deduced from natural structures.

In considering the interaction of molecular subunits to make supramolecular assemblages[4] a useful, if extreme, simplification is to consider each intermolecular interaction around the symmetry axis as a molecular lock and key interaction.[5, 6] Such interactions that require different symmetries are incommensurate—they require different stoichiometries at the site of interaction. A useful analogy can be made here with the interaction of incommensurate lattices (Fig. 2). As occurs with some natural

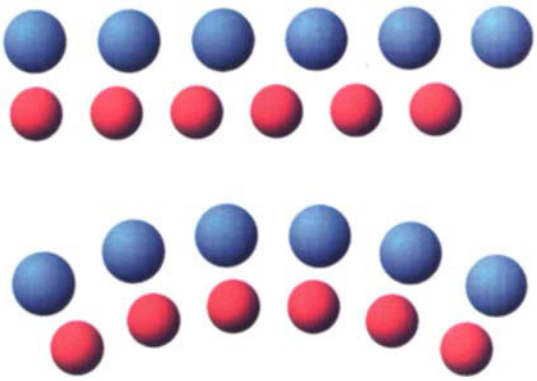

Fig. 2. Lattice 1 (blue) and 2 (red) shown shematically have incommensurate repeat distances (top). If stacked together the lattices must curl in order to remain in register (bottom).

silicates, the superposition of one layer upon another which has a slightly different lattice spacing soon results in a mismatch of the unit cells due to the incommensurate lattice spacings.[7] The two spacings can be kept in register only by curling them, as shown in Figure 2. Similarly, two incommensurate coordination numbers can coexist only by a curvature of the surface lattice of the molecular array.

Consider again the ferritin cluster and its octahedral symmetry. Interaction of the protein subunits at the fourfold axis can be considered as a lock and key interaction in which the lock and key are 90° apart (Fig. 3a). As shown in Figure 3a, this interaction is both a symmetry and stoichiometry requirement: the fourfold symmetry requires formation of tetramers from the monomeric subunit. Similarly the interaction of the protein subunits at the threefold axis can be regarded as a lock and key

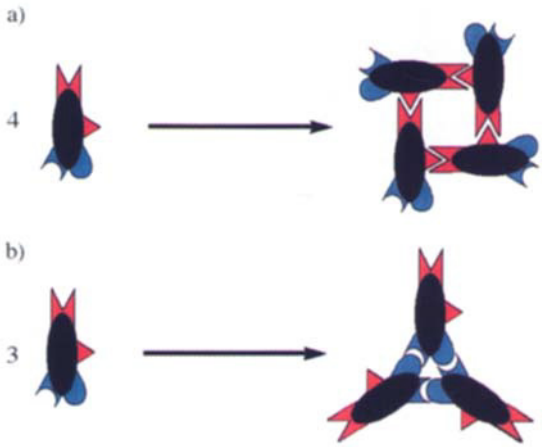

Fig. 3. a) Lock and key interactions that lead to a C_4 symmetric arrangement. b) The same repeating subunit as in a) can lead to a C_3 symmetric arrangement by using a different set of interactions.

[**] Coordination Number Incommensurate Cluster Formation, Part 1. This research was supported in part by the National Institutes of Health, Grant DK32999. T. B. thanks the Alexander von Humboldt-Stiftung for a Postdoctoral Fellowship. We thank Dr. Fred Hollander for his assistance with the structure determination.

interaction in which the lock and key are 60° apart (Fig. 3b). In this case the stoichiometry requirement is to form trimers. The simultaneous satisfaction of these two incommensurate symmetry requirements can only be satisfied by formation of a cluster with octahedral symmetry. In a similar fashion the icosahedral cluster is formed through the combination of incommensurate symmetry number lock and key interactions with fivefold and threefold symmetry, respectively.

The protein–protein interactions described above are formed from many weak interactions. Metal–ligand interactions, which are also highly directional, are much stronger and can be used, instead of many weaker interactions, to direct cluster formation driven by the metal–ligand coordinate bond. Helicates, dimers with molecular D_3 symmetry formed by two pseudo-octahedral metal centers and two bidentate ligands,[8–10] are recent examples of small supramolecular assemblages. The iron complex of the siderophore rhodotorulic acid, and a synthetic hydroxypyridonate analog, are early examples.[11–13] Other examples of spontaneous assembly of metal complex clusters in metal complexes are known,[14–16] however, they seem not to have been designed a priori. It is the goal of this research to *design* such systems, and we present here the most completely characterized of the three types of clusters that have now been prepared.

For simplicity, we begin with the simplest high symmetry polyhedron, the tetrahedron. The pure rotation group T is characterized by incommensurate threefold and twofold symmetry axes. Here the threefold symmetry is induced by using bidentate ligand groups to coordinate to an octahedral metal center. The ligand units are designed to have twofold symmetry, with two bidentate ligand groups, and must be as rigid as possible in order to predispose the coordinating groups to the desired geometry and to prevent geometries which allow a lower stoichiometry.

Hydroxamate ligands were chosen for their high stability and lability with trivalent metals,[17] which provides a strong driving force but also allows formation of the thermodynamically favored cluster over the large number of other intermediate polymers. Molecular modeling[18] was used to design the ligand isophthal-di-*N*-(4-methylphenyl)hydroxamic acid **1** (Scheme 1), which was synthesized by reaction of isophthaloyl dichloride (**A**) with *N*-(4-methylphenyl)hydroxylamine (**B**) (see Experimental Procedure). The reaction of **1** with $[Ga(acac)_3]$ in acetone led to a white microcrystalline precipitate of $[Ga_4L_6]$ (**3**). The dark red compound $[Fe_4L_6]$ **2** was formed in a similar reaction with $[Fe(acac)_3]$. FAB mass spectra and elemental analysis were consistent with the formulation as tetrahedral clustersin both cases.

The 300 MHz ^{1}H NMR spectrum of **3** in CD_2Cl_2 at room temperature shows only six signals, corresponding to the six inequivalent protons of the ligand. This establishes that all six ligands in the cluster are indistinguishable on the NMR time scale. Repeating the synthesis of **3** with excess **1** demonstrates the cooperativity of the cluster formation. The ^{1}H NMR spectrum shows two distinct sets of peaks at room temperature. One set corresponds to the six ligands in the tetrahedron, the other is from the unbound ligand—thus demonstrating no exchange on the NMR time scale.

The solid-state structure[19] of **3** contains two clusters, each of which lies on a special position with $\bar{4}$ symmetry (S_4 an alternative subgroup of the parent T_d group), in which the four metals are separated by an average of 9.0 Å. A space-filling representation of the structure is shown in Figure 4. Figure 5 gives stereo-

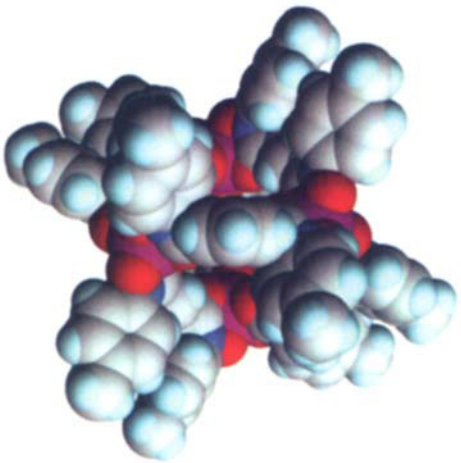

Fig. 4. A space-filling model of **3**, calculated from data from the X-ray structure analysis. View is down the S_4 axis.

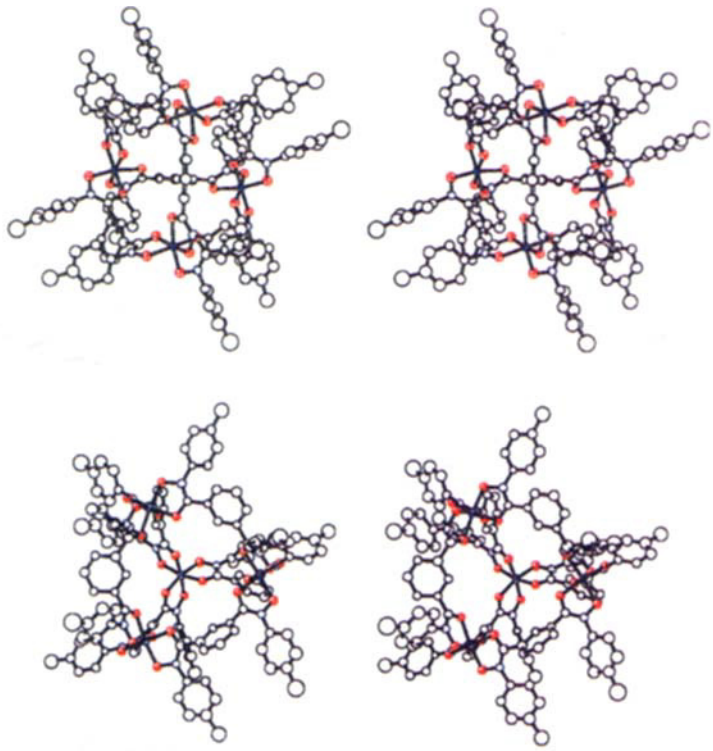

Fig. 5. Stereoviews of **3** looking down the S_4 axis (top) and the pseudo-C_3 axis (bottom).

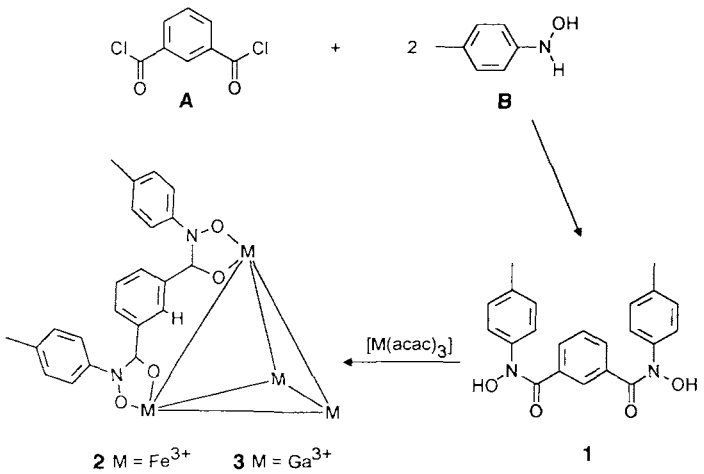

views of the cluster looking down the S_4 axis (top) and the pseudo-C_3 axis (bottom). Each cluster has four crystallographically identical DMF molecules which partially fill the rigid cavity (Fig. 6). The average carbon–carbon distance between the DMF methyl groups within the cluster cavity is 4.0 Å.

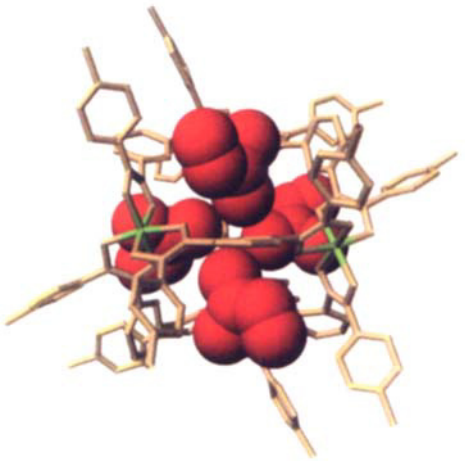

Fig. 6. Stick figure of **3** including a space-filling representation of the absorbed DMF molecules (red).

In summary, the spontaneous assembly of non-covalently linked subunits as seen in the protein clusters of ferritin or viral protein coats has been analyzed in terms of symmetry-driven interactions. The incommensurate coordination numbers for the different lock and key interactions explain the high symmetry (the pure rotation groups *O* and *I*, respectively) seen in these clusters. The unique formation of only one polymer and hence a unique cavity dimension is inextricably linked to the high symmetry. This analysis has been carried forward to the design of supramolecular assemblies based on coordination chemistry interactions. In the first demonstrated design, threefold symmetry at a pseudo-octahedral metal center with bidentate ligands is combined with a rigid ligand system of twofold symmetry to drive formation of a tetrahedral cluster. Both structure and solution experiments indicate that this cluster is the unique product. The success of this *predesigned, symmetry-driven system* supports the explanation of the formation of the highly symmetrical clusters seen in nature. This approach is readily extendible to higher symmetry and larger clusters, studies of which are currently in progress.

Experimental Procedure

1 = LH_2: Pyridine (4 mL, 50 mmol) was added to a solution of **B** (6.1 g, 50 mmol) in dioxane (40 mL). To the resulting mixture, a solution of **A** (5.0 g, 25 mmol) was added dropwise while the temperature of the reaction mixture was maintained below 15 °C. The mixture was then stirred for three hours. The solvents were removed by rotary evaporation and the solid residue was treated with concentrated NH_3/H_2O (100 mL). After the mixture had been stirred for one hour, the white precipitate that had formed was filtered off and then stirred with 0.1 M HCl, filtered, washed with H_2O, and dried. Yield 4.2 g (11 mmol).

B: 4-nitrotoluene (12.00 g, 87.5 mmol) was dissolved in a mixture of NH_4Cl (5.0 g, 93.5 mmol), H_2O (150 mL), and ethanol (150 mL). Zinc (17 g, 260 mmol) was added to the mixture in small portions while the temperature was kept below 10 °C by cooling with an ice/water bath. After the addition of zinc was complete the mixture was stirred for additional three hours and filtered. The precipitate was washed with ethanol, and the combined solvents were reduced by rotary evaporation. The resulting yellow solid was dissolved in diethyl ether, dried with $MgSO_4$, and the ether was removed by rotary evaporation. The yellow residue was washed with hexanes to yield a white, flaky product. Yield 7.3 g (59 mmol).

$[M_4L_6]$ (**2**, M = Fe^{III}, **3**, M = Ga^{III}): A solution of $[M(acac)_3]$ (125 mg, 0.35 mmol) in acetone was added to a solution of **1** (200 mg, 0.53 mmol) and two drops of triethylamine in acetone. The combined solutions were heated to reflux overnight during which time a red microcrystalline precipitate formed. The solid was collected by filtration, washed with a small amount of cold acetone and diethyl ether, and dried. Larger crystals were obtained when DMF was used as the solvent and instead of heating to reflux, the solutions were allowed to stand at ambient temperature for three to five days. Yield: 130 mg (0.05 mmol).

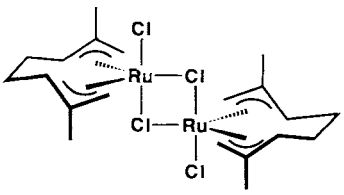
Allylruthenium(IV) Complexes as Highly Efficient ROMP Catalysts**

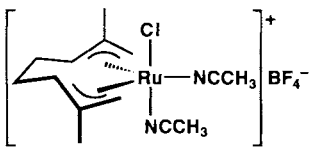
Wolfgang A. Herrmann,* Wolfgang C. Schattenmann, Oskar Nuyken, and Stephan C. Glander

Quite early on, Dolgoplosk et al.[1, 2] recognized the suitability of diazoalkanes as initiators for the catalytic metathesis of olefins. Alkylidene metal complexes prepared from diazoalkanes follow the structural concept developed for olefin metathesis catalysts and have been employed successfully as "tailored" molybdenum and tungsten catalysts.[2-4] Nevertheless, there is continued demand for inexpensive, easy-to-handle catalyst systems. Recently, ruthenium(II) complexes have been preferred for the ring-opening metathesis polymerization.[5] Herein we report for the first time a series of easily prepared and exceptionally active ROMP catalysts of tetravalent ruthenium.

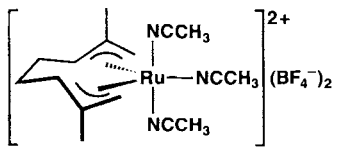
The allylruthenium(IV) precursor complex **1** is obtained from isoprene and commercially available ruthenium(III) chloride.[6] Addition of silver tetrafluoroborate to **1** results in the formation of the cationic complexes **2** and **3**.[7] All of these complexes are



1



2



3

stable in air and in solution for several hours; however, due to their ionic character and the resulting solubility in polar solvents, complexes **2** and **3** are suitable for the precipitation polymerization of norbornene.

Complexes **1**–**3** alone are almost completely ROMP-inactive. However, in the presence of aliphatic diazo compounds, for example commercially available ethyl diazoacetate, these complexes show unusual catalytic activity, with the very short reaction times being particularly noteworthy (Table 1). Polymerization experiments performed at a higher monomer-to-catalyst ratio showed that the activity remains high even over extended reaction times.

With catalyst **3** in the presence of ethyl diazoacetate, turnover frequencies (TOF) above $10^5\ h^{-1}$ have been achieved (Table 2). This unoptimized system exhibits activities not previously attained in the ring-opening metathesis polymerization employing ruthenium catalysts.[5] An important advantage of these novel

3	6/1	99	30 s	1.2×10^5	380×10^3	1.8	31

[a] Yield relative to isolated polymer. [b] TOF = turnover frequency: mol(polynorbornene)/[mol(catalyst) × h]. [c] $\bar{M}_n$: (number average molecular weight) [g mol^{-1}]. [d] PDI: polydispersity index $\bar{M}_w/\bar{M}_n$. [e] Percentage of *cis* double bonds in the polymer (as determined from the ^1H NMR signal intensities of the olefinic protons).

systems is that the degree of polymerization can be controlled by the choice of solvent. Furthermore, the experimental requirements are easily met: the polymerization can be carried out in air and with ordinary, not strictly anhydrous solvents—unacceptable conditions for most tungsten, molybdenum, and rhenium catalysts.

Similarly, the precise structure of the diazoalkane can also be utilized to control the polymerization. Thus, trimethylsilyldiazomethane develops its full activating power only at molar ratios >1/1 (diazoalkane/ruthenium), whereas the use of ethyl diazoacetate leads to an activity maximum at molar ratios <1/1 (Fig. 1). Possibly a metal carbene intermediate is formed which is stabilized through chelating by the carbonyl groups.[8]

The most active catalyst system to date comprises **3** and ethyl diazoacetate. The ring-opening metathesis polymerization of *endo*-dicyclopentadiene (TOF = 1000 h^{-1}) was accomplished

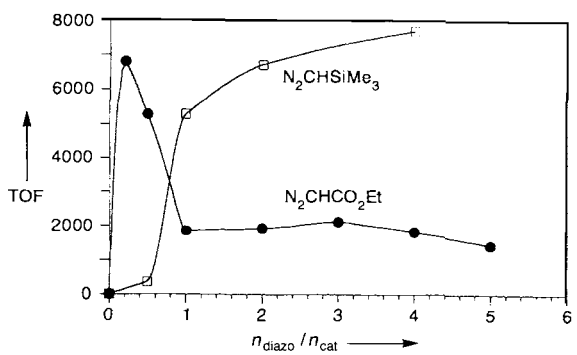

Fig. 1. Dependency of catalyst activity on the ratio diazoalkane/catalyst. TOF = mol(polynorbornene)/[mol(catalyst) × h].

for the first time.[9] The polymerization of cyclooctene with this system resulted in the formation polymers of low molecular weight, whose ethyl ester end-groups could be identified by NMR spectroscopy. The agreement of the molecular weights determined from ^{1}H NMR spectra and GPC data ($\bar{M}_n$ = 30000; PDI = 1.4) proves the presence of a polyoctenamer with defined end-groups, in other words, a telechelic polymer. This supports the notion that the ruthenium complex and diazoalkane initially form a carbene complex that then initiates the polymerization.

Experimental Procedure

In a typical polymerization experiment norbornene (1.50 g, 16 mmol) was dissolved in solvent (12 mL; CH_2Cl_2 or CH_2Cl_2/MeOH). Next, a 10^{-2} M solution (3.2 mL) of diazo compound in CH_2Cl_2 was added. To this mixture was rapidly added a solution of 1.6×10^{-2} mmol of ruthenium complex **2** or **3** in methanol (5 mL) (or 0.8×10^{-2} mmol **1** in 5 mL of CH_2Cl_2). The precipitating polymer was separated from the solution and washed with methanol. At this stage the polymer is usually sufficiently pure. Further purification can be accomplished by dissolving the product in toluene followed by reprecipitation in methanol. The polymer was dried at room temperature under high vacuum (oil pump) until no further change in weight was observed. The yield was determined gravimetrically. The molecular weight distribution was determined by GPC ($CHCl_3$) with polystyrene as standard.

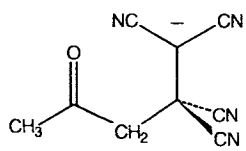
Polymeric Networks of Silver(I) and Copper(I) Ions Linked by an Anionic Acetonyl Derivative of Tetracyanoethylene

Lucia Carlucci, Gianfranco Ciani,*
Davide M. Proserpio, and Angelo Sironi

Many reactions of tetracyanoethylene (TCNE) with metal compounds have been studied in the last few decades,[1] principally because of its ability to form charge-transfer derivatives[2] that are potential conductors and show interesting magnetic properties. The different bonding modes and variable hapticity of TCNE are also of significance for the formation of polymeric networks. Some one-dimensional (1D) coordination polymers with neutral TCNE,[3] and one remarkable two-dimensional (2D) frame, have been described.[4]

We are currently studying the self-assembly of Ag^I cations and polydentate neutral N-donor ligands, and have already reported on interesting 2D and 3D networks, including frames topologically related to the prototypal structures of diamond,[5] α-$ThSi_2$,[6] α-polonium,[7] and $SrSi_2$.[8] The reaction of the potentially tetradentate TCNE with $Ag(CF_3SO_3)$ in H_2O/Me_2CO led to coordination polymer **2**, which unexpectedly contains the anionic acetonyl derivative of TCNE 1,1,2,2-tetracyanopentan-4-one-1-ide, ($AcTCNE^-$; **1**) as ligand. Also in analogous reactions with different silver salts of noncoordinating anions and different solvent systems, no TCNE-containing products were obtained. We report here on **2**, which contains a twofold interpenetrated 2D extended network and on the related Cu^I species **3**, which was



1

[Ag(AcTCNE)] **2**

[Cu(AcTCNE)]·Me_2CO **3**

obtained by reacting $[Cu(MeCN)_4](PF_6)$ with the preformed conjugated acid of **1** (**1**H). Compound **3** exhibits a 3D open zeolite-like framework that belongs to a novel topological type in coordination polymer chemistry.

A complex reaction occurs when a solution of TCNE in acetone is layered over a solution of $Ag(CF_3SO_3)$ in water (molar ratio 1:1). Initially a white powdered material, essentially consisting of AgCN, is precipited (formation of cyanides was reported for other reactions involving TCNE and transition metals[11]). If the reaction solution was left in the dark for a few days, the supernatant solution turned deep orange and elongated pale yellow crystals of **2** formed above the white precipitate.[9] These crystals, which showed IR bands due to the CN and CO stretches of **1**, were suitable for a single-crystal X-ray analysis (see Fig. 1).[11] The synthesis repeatedly gave the same product. However, a fundamental role seems to be played both by the solvent system and by the triflate counterion; attempts to obtain **2** by using other silver salts of noncoordinating anions were unsuccessful.

The structure of **2** consists of 2D infinite undulated nets of hexagonal meshes. These are formed by alternate three-coordinate silver ions and tridentate **1**. Two independent nets of this type interpenetrate to give a layer structure (Fig. 1). The anions

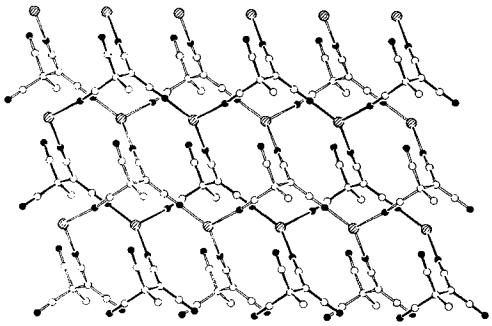

Fig. 1. The twofold interpenetrated layer of **2** (SCHAKAL representation). Only the first carbon atom of the acetonyl groups is shown for clarity. Large hatched circles: Ag; black circles: N; open circles: C.

1 employ the two CN groups bound to the sp^2 hybridized C atom and one CN bound to the sp^3 hybridized C atom for bridging. The Ag^I ions display a distorted trigonal coordination, and show two short Ag–N bonds to the N atoms of the two $C(sp^2)$ nitrile groups (2.114(4) and 2.117(4) Å) and a long one to the N atom of the $C(sp^3)$ nitrile group (2.422(4) Å). The N-Ag-N angles are 146.2(2), 108.1(2), and 105.7(2)°.

The structural type of **2** is rather rare in coordination chemistry. Four classes of interpenetrating 2D networks are presently known, the differences depending on the type of meshes [hexagonal (*h*) or square (*s*)] and on whether the interpenetration occurs in a common plane (type I) or in a mutually perpendicular direction (type II), which results in a 3D array. Complex **2** belongs to class I-*h*, the only previously known compounds of this class are $[AgC(CN)_3]$ (twofold interpenetrated)[12] and a Cd^{II} polymer exhibiting threefold interpenetration described very recently.[13] Very few examples for each of the other classes (I-*s*,[14] II-*h*,[15] and II-*s*[16]) have been reported.

With the aim of accomplishing a more direct and clean synthesis of **2**, we prepared the conjugated acid of **1**, **1**-H, by literature methods.[10] Unfortunately only mixtures that proved difficult to analyze were obtained on reacting **1**-H with a number of silver salts of noncoordinating anions.[17] In contrast, the reaction of $[Cu(MeCN)_4](PF_6)$ with **1**-H in acetone afforded colorless, octahedral crystals of a novel copper(I) 3D polymer **3** that contains **1** as bridging ligand.[18]

The structure of **3** (Fig. 2) consists of a 3D neutral network of four-coordinate copper(I) ions linked by anions **1**. Unlike in **2**, these anions act as tetradentate ligands. The framework resembles a honeycomb with large channels (hexagonal cross-section) extending in the *c* direction. These contain guest acetone molecules. The copper centers reside in distorted tetrahedral environments; the Cu–N bonds and N-Cu-N angles lie in the range 1.938(5)–2.034(5) Å and 103.6(2)–114.3(2)°, respectively. The ability of **1** to coordinate to four metal centers, each attaining an almost tetrahedral geometry, is related to the possibility of free rotation about the $C(sp^2)-C(sp^3)$ bond and to the intrinsic geometry of $C(sp^3)$. Thus, the two planes $C(CN)_2$ are arranged almost perpendicular (dihedral angle of 89.8(2)° in **3** and 82.7(2)° in **2**), and the four CN groups can be considered to be distorted-tetrahedrally oriented (see below).[19]

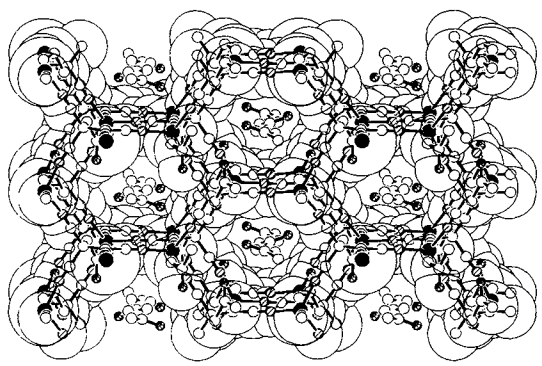

Fig. 2. The structure of **3** (SCHAKAL representation) approximately down the *c* axis. The channels contain acetone molecules. Large black circles: Cu; hatched circles: N; open circles: C; cross-hatched circles: O.

The novel 3D network consists of four-connected (copper atoms) and three-connected (carbon atoms) nodes in the ratio 1:2. However, a more useful topological interpretation can be achieved by replacing the tetradentate anions with their centers (the midpoint of the $C(sp^2)-C(sp^3)$ vector) and connecting them with the copper ions. The resulting fascinating four-connected frame (Fig. 3) belongs to a rare topological type; the shortest circuits starting and ending at each center form squares, hexagons, and octagons in the ratio 2:3:1, hence $4^2 6^3 8$ (specifically net $4^2 6^3 8$-a, according to Wells).[20] Smith, in classifying the framework silicates,[21] cites $(NH_4)LiSO_4$,[22] $RbAlSiO_4$,[23] and the synthetic zeolite Li–A(BW)[24] as examples belonging to this topological type. The prototypal zeolite-like network of **3** may be of interest because of its large channels with an average radius of approximately 4.7 Å, and further studies are in progress to ascertain the possibility of removing or replacing the solvated acetone molecules.

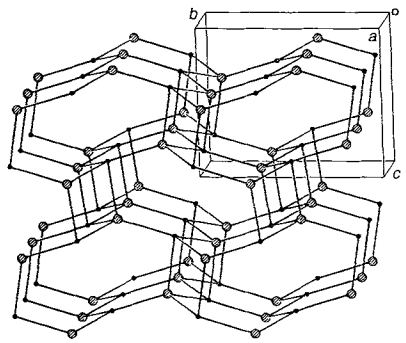

Fig. 3. Schematic view (SCHAKAL representation) of the $4^2 6^3 8$-a network of **3** (large hatched circles: Cu; small black circles: midpoints (C_A) of the $C(sp^2)-C(sp^3)$ bonds of the $AcTCNE^-$ ligands). $\bar{d}(Cu-C_A)$ 4.90(4) Å; C_A-Cu-C_A angle 97–125°; Cu-C_A-Cu angle 80–136°.

The large difference between the structures of the frames in **2** and **3**, in spite of the same stoichiometry, can be related to the higher tendency of Cu^I ions over Ag^I ions to achieve a tetrahedral coordination.

In conclusion, the attempts to obtain novel extended frameworks bridged by the neutral TCNE ligand were unsuccessful. The high reactivity of TCNE, however, led to the unexpected formation of **1**, which exhibits a pronounced tendency to form networks with metal ions. The targeted synthesis of **1** has enabled the preparation of **3**. It is anticipated that this methodology can be extended to other systems with different metal ions and/or with similar polycyano anions.

Experimental Procedure

2: A solution of TCNE (0.130 g, 1.01 mmol) in acetone (3 mL) was layered over a solution of $Ag(CF_3SO_3)$ (0.252 g, 0.98 mmol) in H_2O (3 mL). A white precipitate of AgCN formed immediately. If the solution was left in the dark for 4–5 days, pale yellow elongated crystals of **2** formed above the white precipitate. The mixture was filtered, dried in air, and crystals of **2** were manually separated under a microscope

(yield ca. 15%). The product is air and light stable. A few colorless crystals of **4** were separated successfully from the deep orange mother liquor [9]. Elemental analysis: $C_9H_5AgN_4O$, calcd: C 36.88, H 1.72, N 19.12; found: C 36.10, H 1.83, N 18.84. IR (Nujol): $\tilde{\nu}$(CN) 2251 (w), 2220 (m), 2153 (s), 2127 (s), $\tilde{\nu}$(CO) 1707 (m) cm^{-1}.

3: A solution of TCNE in acetone, acidified with dilute aqueous HCl, was stirred for 24 h. The product (**1**-H), isolated after evaporation of the solution to dryness, was used without further purification. A solution of **1**-H (0.0332 g, 0.178 mmol) in acetone (2 mL) was layered over a solution of $[Cu(MeCN)_4](PF_6)$ (0.0664 g, 0.178 mmol) in acetone (3 mL) under a nitrogen atmosphere in a Schlenk tube. If the reaction mixture was left to stand for a few days, small multifaced colorless crystals of **3** formed. They were filtered off and dried (yield ca. 80%). The product is air stable for days. Elemental analysis: $C_{12}H_{11}CuN_4O_2$, calcd. 46.98, H 3.61, N 18.27; found C 45.95, H 3.40, N 17.95. IR (Nujol): $\tilde{\nu}$(CN) 2258 (vw), 2213 (m), 2162 (s), $\tilde{\nu}$(CO) 1724 (m), 1701 (s) cm^{-1}.

[9] The formation of **1** is somewhat surprising since the addition of acetone (or other ketones) to TCNE, to give the conjugated acid **1**H, is slow and was previously accomplished in the presence of catalysts like HCl, BF_3, or "molecular silver" [10]. The complexity of the overall process is, moreover, confirmed by the further reactions of **1**: we have observed the formation of some small platelike colorless crystals of the novel heterocyclic compound, 6-methyl-2(1H)-pyridone-3,4-dicarboxamide monohydrate (**4**) from the mother liquor. We have characterized **4** by a single-crystal X-ray analysis (see [25]). The formation of **4** from **1** presumably occurs by elimination of one equivalent of CN^- as AgCN and partial hydrolysis of the three remaining nitrile groups to amide groups, followed by ring closure by an internal oxime bond and migration of hydrogen.

Solubilization of NaX Salts in Chloroform by Bifunctional Receptors**

Jurgen Scheerder, John P. M. van Duynhoven, Johan F. J. Engbersen, and David N. Reinhoudt*

Recently, we described bifunctional receptors that are capable of binding and transporting simple salts like KH_2PO_4,[1] CsCl,[2] and NaH_2PO_4.[3] In these bifunctional receptors the (isolated) receptor sites for the anion and cation are covalently linked.[4] Cation complexation did not enhance the anion complexation or vice versa. Now, we report a class of simple, bifunctional receptors that can solubilize NaX salts (X = Cl, Br) in chloroform.[5] In these bifunctional receptors Na^+ complexation is essential for complexation of the anion (positive heterotropic allostery).

Previously we have shown that proper positioning of urea moieties on calix[*n*]arenes ($n = 4$, 6) yields receptors that are capable of binding halide anions exclusively through hydrogen bonding.[6] It has also been established that functionalization of calix[4]arenes with four ethyl ester groups at the lower rim yields ionophores with a high selectivity for Na^+ ions.[7] The combination of these two binding sites on the calix[4]arene skeleton yields molecules that are potential receptors for NaX salts (X = halide). The synthesis of the bifunctional receptors having four ester groups at the lower rim and two or four urea groups at the upper rim is depicted in Scheme 1.

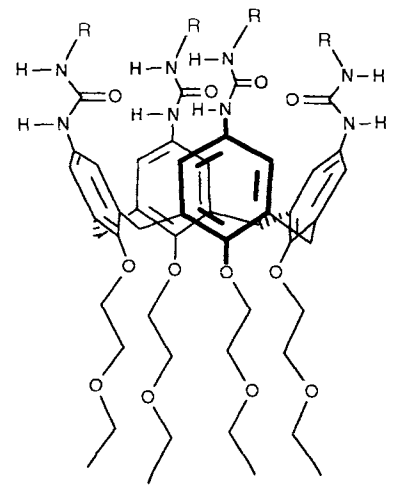
3 X = NO_2
4 X = NH_2

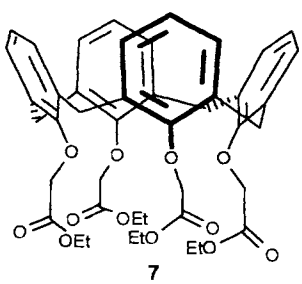
5a, b

Scheme 1. Synthesis of **2** (R = *n*-octyl), **5a** (R = *n*-octyl), and **5b** (R = *tert*-butyl). The labels on the amide protons are used for the assignment of the NMR spectra in Figure 1. RT = room temperature.

Addition of *n*-octylisocyanate to a solution of 5,17-diaminocalix[4]arene tetra(ethyl ester) **1**[3] in $CHCl_3$ gave the di-(*n*-octylureido)calix[4]arene **2** in 44% yield.[8] Reduction of tetranitrocalix[4]arene **3**[9] (Scheme 1) with $NaBH_4/CoCl_2$ in MeOH at room temperature[10] gave the tetraaminocalix[4]arene **4** in 60% yield. Subsequent addition of the appropriate isocyanates to a solution of **4** in $CHCl_3$ at room temperature gave the tetra(ureido)calix[4]arenes **5a,b** in yields of 60 and 36%, respectively.[8] Calix[4]arene **6**, with only an anion binding site, and calix[4]arene **7**,[7] with only a cation binding site, were included as reference compounds (vide infra). Calix[4]arene **6** was synthesized in analogy to **5a,b**, starting from tetrakis-[(ethoxy(ethoxy)]tetranitrocalix[4]arene.[11]



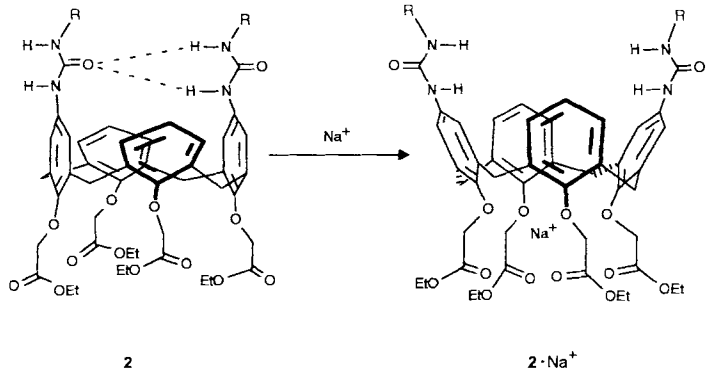
6



7

Calix[4]arene **2** adopts a pinched *cone* conformation in $CDCl_3$ solution at room temperature due to intramolecular hydrogen bonding between the opposite urea moieties.[12] Recently, Rebek and Shimizu[13] reported that tetrakis(benzyloxy)tetra-(*N*-phenylureido)calix[4]arenes form hydrogen-bonded dimers in $CHCl_3$ solution at room temperature.

Upon addition of Bu_4NCl or Bu_4NBr to a 5 mM solution of **2** in $CDCl_3$, no complexation of halide anions was observed. Due to the pinched *cone* conformation of **2**, the anion binding site is blocked (Scheme 2, left). However, complexation of Na^+



2 2·Na^+

Scheme 2. Complexation of Na^+ ions by **2** (R = *n*-octyl).

ions at the lower rim of **2** converts the pinched *cone* conformation into a symmetrical *cone* conformation. Intramolecular hydrogen bonding at the upper rim is not possible in this conformation due to the rigidification of the calix[4]arene skeleton (Scheme 2, right). This is evident from the large downfield shift of the ^1H NMR signal for the aromatic hydrogens of the substituted aromatic rings (ArH) from $\delta = 6.02$ (Fig. 1a) to $\delta = 7.34$ (Fig. 1b).

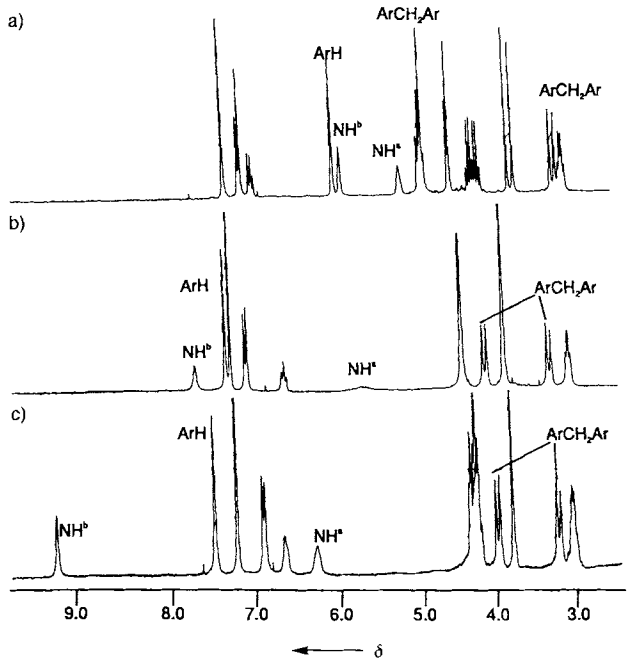


Fig. 1. ^1H NMR spectra of **2** ($CDCl_3$, 5 mM). a) Uncomplexed, b) [**2**·Na]ClO_4, c) [**2**·NaCl]. For NH^a and NH^b see Scheme 1; for ArH and $ArCH_2Ar$ see the text or ref. [14].

The addition of Bu_4NCl and Bu_4NBr to a 5 mM solution of the **2**·Na^+ complex results in a clear downfield shift of the ^1H NMR signals of the urea hydrogens, indicating complexation of the anionic guests through hydrogen bonding.[6] In contrast, the urea hydrogens of **5a,b** are not available for anion complexation due to the formation of a hydrogen-bonded dimer in solution.[14] The addition of Bu_4NBr or Bu_4NCl to a 5 mM solution of **5a,b** in $CDCl_3$ does not result in anion complexation. When **5a,b** is treated with $NaClO_4$, the hydrogen bonding in the dimer is broken, as is evident from the disappearance of the two NMR signals for the aromatic hydrogens and the presence of one signal for these hydrogens.[15] Now the addition of Bu_4NBr or Bu_4NCl to a 5 mM solution of [**5a**·Na]ClO_4 in $CDCl_3$ results in a downfield shift of the signals of the urea hydrogens, indicating hydrogen bonding with the anions. A Job plot[16] indicates a 1:1 stoichiometry for the complex with **5a**, with $K_{ass} \geq 1.0 \times 10^4\ M^{-1}$ for Cl^- and $K_{ass} = 1.3 \times 10^3\ M^{-1}$ for Br^-. The preference for Cl^- ions can be explained by the preference of the "hard" urea hydrogen bond donor for the "harder" hydrogen bond acceptor Cl^-.

The results show that **2** and **5a,b** can simultaneously complex Na^+ and Cl^- or Br^- ions and that cation complexation induces a structural change that is prerequisite for anion complexation. This process resembles a heterotropic allosteric effect.[17] The Na^+ complexation by **5a,b** results in a dissociation of the dimer after which anion complexation can occur.

The bifunctional calix[4]arenes **2** and **5a,b** are capable of solubilizing simple alkali salts in chloroform. The results of the liquid–solid (L–S) extractions[18] of MX (M = Na, K, Cs; X = Cl, Br, I) by **2** and **5a,b** in chloroform are summarized in Table 1. A representative ^1H NMR spectrum of the NaCl com-

Table 1. Percentage of MX complex formed with **2** and **5a,b** after L–S extraction [a].

	2			**5a**			**5b**		
	Na^+	K^+	Cs^+	Na^+	K^+	Cs^+	Na^+	K^+	Cs^+
Cl^-	100	–	–	100	29	–	100	30	–
Br^-	100	16	–	100	62	–	100	75	–
I^-	100	100	–	100	100	–	100	100	–

[a] The concentration of **2** and **5a,b** is 5 mM in $CDCl_3$. See also ref. [18].

plex of **2** is depicted in Figure 1c. Comparison of this ^1H NMR spectrum with that of the free ligand **2** (Fig. 1a) and of [**2**·Na]ClO_4 reveals large downfield shifts of both urea hydrogens and the aromatic hydrogens of the substituted aromatic rings (ArH).

The strong complexation of the NaX salts indicates the strong preference of the receptors for Na^+ ions. Only partial complexation of KX salts is observed, in agreement with the weaker binding of K^+ ions by calix[4]arene tetra(ethyl esters).[7] No complexation of Cs^+ salts is observed, apparently because the Cs^+ ion is too large to fit in the cavity. Although the solubility of the free salts in chloroform is very low and decreases in the order MI > MBr > MCl, the preferential extraction of chloride salts indicates the higher affinity of the urea binding sites for Cl^- ions over Br^- and I^- ions.

Addition of an excess of **2** or **5a,b** to a solution of the salt complexes gives two sets of distinctly separate signals for the complex and the free receptor in the ^1H NMR spectrum. This means that the cation and anion are always complexed to the same molecule and that calix[4]arenes with only a cation or an anion are not present.

The complexation of the salts has also been confirmed by FAB mass spectrometry. When the chloroform solution obtained after L–S extraction of NaCl and NaBr by **5a** is concentrated and the FAB mass spectrum recorded, $[M + Na]^+$ (100%) signals are observed in the positive mode and $[M + Cl]^-$ (100%) or $[M + Br]^-$ (40%) signals in the negative mode. In addition also $[M + Na + Cl]$ (20%) and $[M + Na + Br]$ (20%) signals are present, which clearly proves the salt complexation.

Addition of NaCl or NaBr to a chloroform solution of calix[4]arene **7**, which lacks an anion binding site, did not result in any complexation of Na^+ ions. Addition of NaCl and NaBr to a chloroform solution of calix[4]arene **6**, which lacks the cation binding site, did not result in complexation of Cl^- or Br^- ions. The addition of NaCl or NaBr to a 1:1 mixture of **6** and **7** in $CDCl_3$ did not result in the complexation of Na^+ and Cl^- or Br^- ions. This shows clearly that both the cation binding site and the anion binding site are necessary for the complexation of NaCl or NaBr and that these must be within the same calix[4]arene skeleton.

In conclusion, bifunctional receptors are capable of binding hydrophilic salts MX (M = Na, K; X = Cl, Br, I) in apolar solvents, and the complexation of the cation is essential for anion complexation. Our receptors show a preference for sodium salts with hard anions.[1, 2]

[14] NOESY experiments with **5a,b** reveal through-space connectivities between the aromatic hydrogens of the calix[4]arene skeleton and the $NH^aCH_2CH_2$ and $NH^aCH_2CH_2$ hydrogens of **5a** and the *tert*-butyl hydrogens of **5b**. These connectivities cannot result from through-space interactions within a single molecule since in the same molecule these hydrogens are not close enough [14a]. Consequently, these NOE connectivities must result from intermolecular interactions. Furthermore, the sign of the NOE connectivities is positive, suggesting that slow-tumbling entities with increased molecular mass (≥2000) are present

[14a]. Using the initial rate approximation [14b] and the distance between the equatorial and axial calix[4]arene bridging methylene hydrogens as a reference (1.79 Å) the cross relaxation constants (σ_{12}) for a two-spin system involving two atoms (1 and 2) were determined [14c]. The σ_{12} values are an indication of the degree of aggregation of the two atoms involved [14a]. The σ_{12} values for **5a** and **5b** are -0.7 and -0.2, respectively. The negative σ_{12} values suggest the presence of species with a higher molecular mass. These results support the dimeric structure for **5a,b** proposed by Rebek [13]. a) D. Neuhaus, W. P. Williamson, *The Nuclear Overhauser Effect in Structural and Conformational Analysis*, VCH, Weinheim, **1989**; b) R. R. Ernst, G. Bodenhausen, A. Wokaun, *Principles of Nuclear Magnetization Resonance in One and Two Dimensions*, Clarendon, Oxford, **1987**, pp. 490–538; c) Isotropic tumbling and pure dipole–dipole relaxation is assumed. See K. Wüttrich, *NMR of Proteins and Nucleic Acids*, Wiley, New York, **1986**, Chapter 6.

[15] According to Shimizu and Rebek, Jr. the presence of two signals for the aromatic hydrogens of tetra(ureido)calix[4]arenes **5a,b** results from hindered rotation of the urea moieties around the aryl–urea bond due to hydrogen bonding in the dimer [13]. The fact that upon the complexation of Na^+ by **5a,b** one signal for these hydrogens is present in the ^1H NMR spectra indicates that this hindered rotation is absent and that the dimer is no longer present.

[18] A 5 mM solution (0.5 mL) of **2** or **5a,b** in $CDCl_3$ was stirred with an excess of MX for 24 h. The organic layer was separated and the relative amount of complex formed was determined on basis of the intensities of the ^1H NMR signals for the bridging calix[4]arene methylene hydrogens of the complex and the free ligand.

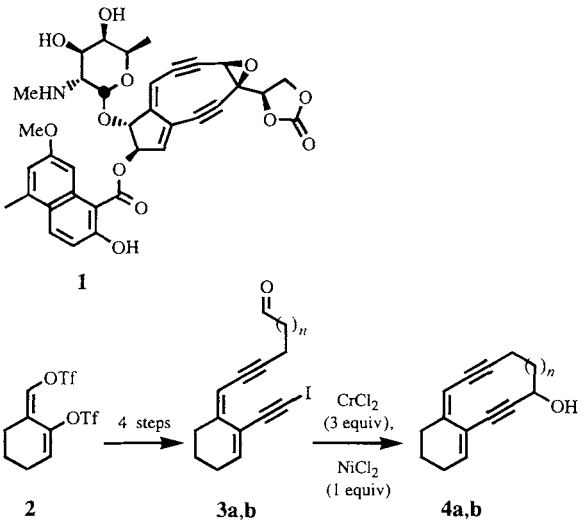
The First Model of the Neocarzinostatin Chromophore with an Epoxide Ring and a Carbonate Moiety**

Matthias Eckhardt* and Reinhard Brückner*

Dedicated to Professor Siegfried Hünig on the occasion of his 75th birthday

Neocarzinostatin is a chromoprotein with exceptionally high antitumor activity.[1] Its chromophore **1** ("NCS") has been established to be its pharmacophore. However, as soon as this compound is separated from the apoprotein, it becomes extremely sensitive towards heat (it is unstable even at room temperature), acid, base, and light. Accordingly, numerous attempts have been made to synthesize dienediyne analogs of **1** that have an in vitro DNA damaging activity comparable to that of the natural product but are hopefully much more stable.[1] In parallel studies analogs of the enediyne anticancer antibiotics esperamycin, calicheamicin, and dynemicin have been sought.[2] In spite of the structural complexity of calicheamicin[3] and dynemicin,[4] their total syntheses either as aglycons or as the fully equipped glycosides found in nature have been achieved. NCS, however, remains an elusive synthetic goal.

In our most recent efforts directed towards the synthesis of NCS analogs we have used bis(enol trifluoromethanesulfonate) **2**[5] ("bistriflate") as a starting material. We found that **2** can be converted into the iodinated dienediyne aldehydes **3a** and **3b** (Scheme 1), and that these compounds cyclize under modified Nozaki–Hiyama conditions to give the dienediyne model compounds **4a** (six-/ten-membered ring system) and **4b** (six-/eleven-membered ring system) of NCS (five-/nine-membered ring system).[6] The cyclized compounds were isolated in quite



Scheme 1. Tf = CF_3SO_2; **a**, $n = 1$; **b**, $n = 2$.

respectable yields of 51% (**4a**) and 54% (**4b**), indicating that the products are fairly stable. This encouraged us to attempt the synthesis of dienediyne models more closely resembling NCS. To limit ring strain we designed a target compound having the tested[6] unnatural six-/eleven-membered rings in the carbon skeleton, but we also incorporated both the epoxide and the carbonate substructure of the natural product in the correct configurations.

Bistriflate **2**[5] and a 1:1 diastereomeric mixture of the enantiomerically pure alcohols **5**[7] were coupled in the presence of catalytic amounts of $[PdCl_2(PPh_3)_2]$ and CuI to provide the monocoupling product **6** and nearly none of its regioisomer (Scheme 2). The technique and selectivity in this reaction parallel those of similar couplings which we described earlier.[5, 6] Although the monocoupling product **6** was isolable, it was usually used in situ in the next step. When the coupling reaction yielding **6** had gone to completion, we added pentynol to the reaction mixture, which still contained the catalytically active Cu and Pd species. A second coupling reaction occurred with cleavage of the remaining triflate moiety. Standard aqueous work-up and purification by flash chromatography on silica gel[8] furnished the biscoupling product **7** in 73% yield.[9] Product **7** is a 1:1 mixture of diastereomers since the precursor alcohol **5** was used as a 1:1 mixture of diastereomers.

Oxidation of diol **7** with the Dess/Martin periodinane[10] afforded ketoaldehyde **8** in 69% yield (Scheme 2).[9] The 300 MHz ^1H NMR spectrum of compound **8** revealed a minor broadened singlet at $\delta = 5.52$ (impurity) besides a dominant broadened singlet at $\delta = 5.45$ (main product). Such signals are typical for the exocyclic olefinic methine protons of monocyclic *Z*-configurated dienediynes like compound **8**.[5b, 6b] The minor signal indicates the presence of 4 mol% of the regioisomeric biscoupling product, a dienediyne ketoaldehyde in which the positions of the two alkyne arms are interchanged. Product **8** was used without further purification; after the next two steps the contaminating regioisomer could no longer be detected by NMR spectroscopy.

The next transformation, a McMurry coupling,[11] is the key step of our synthesis. In this reaction the monocyclic ketoaldehyde **8** was added by syringe pump to a suspension of low-valent titanium freshly prepared from $TiCl_3 \cdot 1.5\,MeOCH_2CH_2OMe$ (DME) and Zn/Cu couple (Scheme 2). This coupling leads chemoselectively to the bicyclic trienediyne **9**,[9] provided the

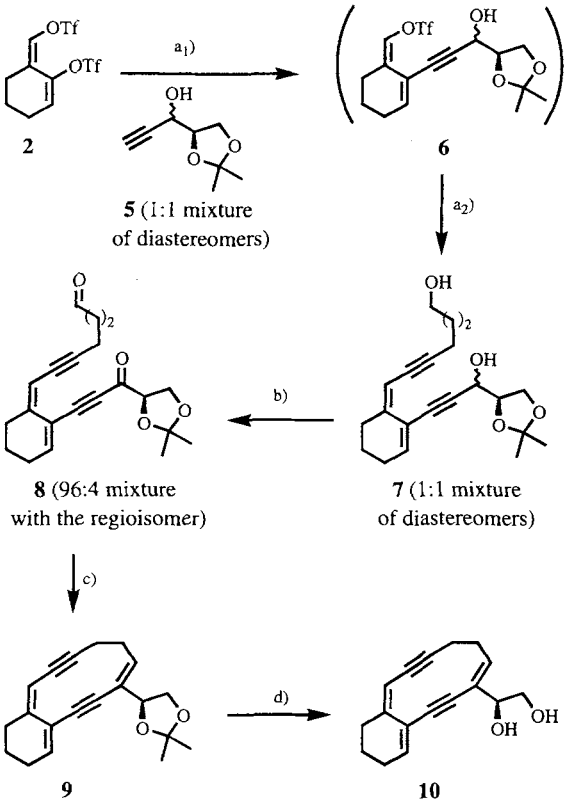


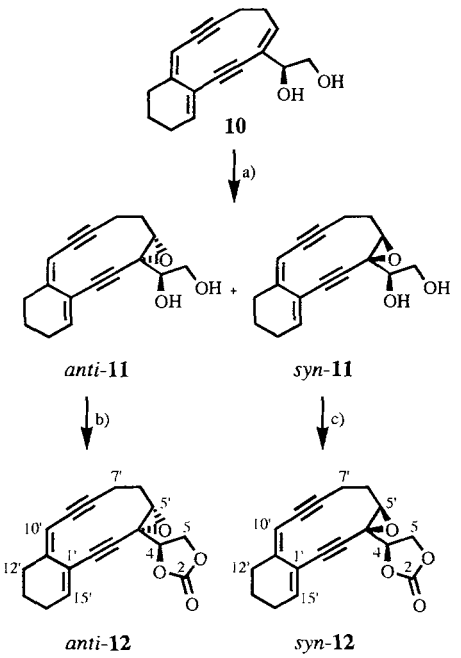
Scheme 2. a_1) Solution of **2** in Et_2O/iPr_2NH (50/17), at room temperature; successive additions of $[PdCl_2(PPh_3)_2]$ (7 mol%), CuI (17 mol%), **5** (1.15 equiv), 4 h; a_2) addition of 4-pentyn-1-ol (1.0 equiv), 18 h; 73% **7**; b) Dess/Martin periodinane (2.6 equiv), a few drops of H_2O, CH_2Cl_2, room temperature, 30 min; 69%; c) DME complex of $TiCl_3$ prereduced with Zn/Cu couple; dropwise addition of **8** ($\approx$0.03 M in DME) at 30–35 °C over 3 h; aqueous workup after another 1 h and purification by flash chromatography on silica gel without complete removal of the eluent; d) conc. HCl in MeOH, room temperature, 4.5 h; 45% yield starting from **8**.

reaction is performed between 30 and 35 °C. The same freshly prepared low-valent titanium reagent effects an intramolecular pinacol coupling of ketoaldehyde **8** if the reaction is conducted at −45 °C. Product **9** was purified by chromatography; however, removal of the eluent initiated its decomposition. Therefore, **9** was used directly in the subsequent reaction, acid-catalyzed removal of the acetonide group through methanolysis (Scheme 2). The trienediynediol **10**[9] was thus obtained in 45% yield based on the ketoaldehyde **8**.

Carbonyl compounds in which the C=O bond is conjugated with a C≡C bond, as in ketoaldehyde **8**, have to our knowledge not been used previously in McMurry reactions.[11] The closest analogy to our coupling **8** → **9** was an intramolecular pinacol coupling of a bisaldehyde of the type H-(O=C)-C≡C-R-C≡C-C(=O)-H;[12] however, an analogous McMurry coupling failed.[12b]

An additional structural feature of ketoaldehyde **8** had to our knowledge[11] never been present hitherto in a McMurry reaction, whether olefination or pinacol coupling: a C–O bond in α-position to the carbonyl group. We had been afraid that substructure O=C-C-OR might be reduced under McMurry conditions to give an enolate rather than the required α-oxygenated ketyl intermediate. Fortunately, this concern was essentially[13] unwarranted.

Our next objective was to epoxidize *one* of the three C=C bonds of the trienediynediol **10** *with stereocontrol* (Scheme 3). The targeted C=C bond is part of both an allylic and a homoallylic alcohol. These circumstances seemed favorable since double bonds of allylic alcohols[14] and of homoallylic alcohols[15] are epoxidized by *t*BuOOH with catalytic $VO(acac)_2$ in preference to other C=C bonds. This is because after the in situ oxidation $V^{IV} \rightarrow V^{V}$ the metal becomes a link between the hydroxyl group and the oxidant and thus directs epoxidation of exclusively the proximal C=C bond. The cyclic transition state also ensures often a high degree of stereocontrol during this attack. The cooperative effect of the OH groups in **10** on treatment with *t*BuOOH/$[VO(acac)_2]$ led to regioselective epoxidation (Scheme 3). However, the stereodirecting effects of the two



Scheme 3. a) *t*BuOOH (>1.5 equiv), $VO(acac)_2$ (>0.6 mol%/30 min), CH_2Cl_2, room temperature, 3 h; 7% *anti*-**11** and 8% *syn*-**11** after separation by repeated flash chromatography; b) $ClC(=O)OCCl_3$ (>2 equiv), pyridine (>10 equiv), CH_2Cl_2, 0 °C, 15 min; 78%; c) same as b); 78%.

OH groups were either very weak or more likely cancelled each other so that we obtained the epoxy diol **11** as a 1:1 *syn*:*anti* mixture.[9] The configurations of these diols were established after they had been separated and converted into the corresponding carbonates *anti*-**12**[9] and *syn*-**12**.[9] The spectra of these compounds (Table 1) were compared with the spectrum of a sample of *syn*-**12**, which had been obtained by a stereochemically unequivocal route (cf. Scheme 4). Only the spectrum of the carbonate derived from diol *syn*-**11** was identical with the reference spectrum.

We tried to epoxidize trienediynediol **10** with greater stereocontrol by using the double stereodifferentiation of the Sharpless asymmetric epoxidation (Scheme 4).[16] The chiral auxiliary was a stoichiometric quantity of D-(−)-diethyl tartrate (DET) so that the complexed oxidant and the allyl alcohol moiety of the substrate formed a matched pair.[16a] However, stoichiometric amounts of the auxiliary, *t*BuOOH, $Ti(OiPr)_4$, and substrate **10** did not react at −23 °C and decomposed slowly at 0 °C.[17] To sidestep this problem diol **10** was silylated at the primary OH group. With only one remaining OH group in *tert*-butyldimethylsilyl ether **13**, reaction under Sharpless conditions resulted in the desired epoxidation with *complete regio- and stereocontrol* giving the silylated epoxide **14**. In the next, one-pot operation the $tBuMe_2Si$ group was removed with

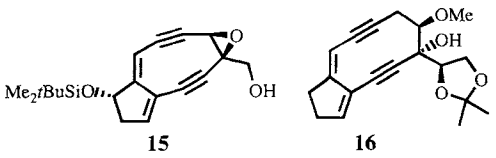
Bu_4NF and the resulting ammonium alcoholate converted into the desired carbonate with diphosgene.[18] The pure carbonate *syn*-**12**[9] (Table 1) was thus available from the McMurry product **9** in 10% overall yield. The configuration of *syn*-**12** is considered established beyond reasonable doubt because the stereoselectivity of the Sharpless oxidation step **13** → **14** cannot possibly deviate from that known from innumerable other applications of this reaction.[16]

Compound *syn*-**12** is a dienediyne analog of NCS (**1**), which is structurally much more closely related to the natural product than many of the earlier analogs. Analog *syn*-**12** has an annulated epoxide ring *and* a cyclic carbonate *both* with the same configuration as the natural product; however, the rings (six-/eleven-membered) in its bicyclic core are larger. The synthesis of analog *syn*-**12** requires only seven steps starting from bistriflate **2** or nine steps starting from formylcyclohexanone.[5, 6]

The known dienediyne analogs closest to NCS are compound **15** from A. G. Myers's lab[19] (five-/nine-membered bicyclic



15 **16**

core structure with an annulated epoxide ring[20]) and compound **18** from the group of Terashima[21] (five-/ten-membered bicyclic core structure with incorrectly functionalized oxygen substituents).

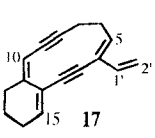
[13] The early fractions of the chromatographic purification of McMurry product **9** delivered up to 10% of the fully deoxygenated bicycle **17**. Its structure was deduced from the appearance of the following olefin signals in the 300 MHz ^1H NMR spectrum ($CDCl_3$): δ = 5.17 (dd, $J(cis)$ = 10.2 Hz, $J(gem)$ = 1.1 Hz, *E*-2′-H), 5.30 (br. s, 10-H), 5.37 (dd, $J(trans)$ = 17.0 Hz, $J(gem)$ = 1.2 Hz, *Z*-2′-H), 6.07 (t, $J(5,6)$ = 8.3 Hz, 5-H), 6.30 (dd, $J(trans)$ = 17.0 Hz, $J(cis)$ = 10.2 Hz,



17

1'-H), 6.33 (td, $J(15,14) = 4.4$ Hz, $^5J(15,10) = 1.1$ Hz, 15-H). Compound **17** could arise from reduction of ketoaldehyde **8** to give the mentioned enolate, subsequent fragmentation into acetone and an enolate containing a negatively charged oxygen atom at the sp^3-hybridized β-carbon, coordination of this oxygen atom to titanium, and elimination of both elements together. This would lead to a ketoaldehyde in which a vinyl ketone would have replaced the originally present dioxolanyl ketone moiety. The last step in the conversion of ketoaldehyde **8** into the oxygen-free cyclized compound **19** would correspond to a McMurry ring closure.

Synthesis, Structure, and Thermolysis of N-Apical 1,2λ^5-Azaphosphetidines with a Pentacoordinate P Center and the First Observation of Their N-Equatorial Pseudorotamers**

Takayuki Kawashima,* Tomokazu Soda, and Renji Okazaki*

In the course of our studies on oxetanes in which a high-coordinate main group element is adjacent to oxygen we achieved the syntheses and isolation of 1,2-oxaphosphetanes,[1] 1,2-oxasiletanides,[2] 1,2-oxagermetanides,[3] and 1,2-oxastannetanides,[4] with pentacoordinate P, Si, Ge, and Sn centers, respectively, as well as 1,2-oxaboretanides with a tetracoordinate B center.[5] These compounds correspond to intermediates of the Wittig,[6] Peterson-type,[7] and boron-Wittig reactions,[8] respectively.

Over 30 years ago Bestmann et al. reported that phosphorus ylides undergo a Wittig-type reaction with Schiff bases in place of carbonyl compounds to give the corresponding olefins,[9] possibly via a 1,2λ^5-azaphosphetidine. We now report the synthesis, crystal structure, and thermolysis of N-apical 1,2λ^5-azaphosphetidines with pentacoordinate P centers as well as the first observation of their N-equatorial pseudorotamers.

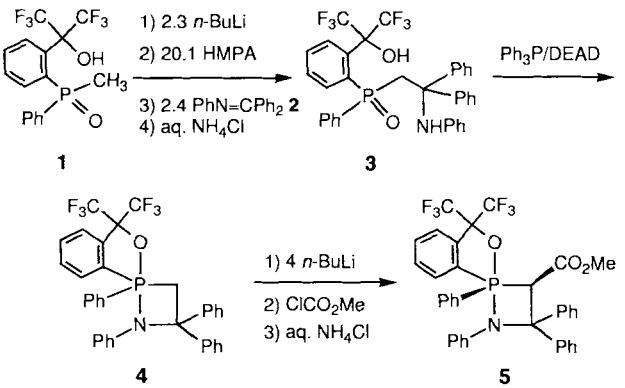
[**] This work was supported in part by a Kurata Research Grant (T. K.) and by a Grant-in-Aid for General Scientific Research (B) (No. 07454160, T. K.) from the Ministry of Education, Science and Culture. We thank Prof. N. Tokitoh of the University of Tokyo for determining the X-ray crystal structure of **4**, as well as Central Glass and Tosoh Akzo Co. Ltd. for gifts of hexafluorocumyl alcohol and alkyllithium compounds, respectively.

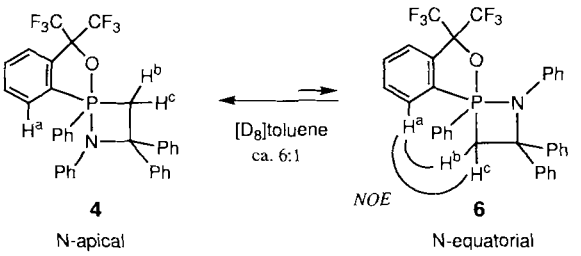
Phosphane oxide **3** was obtained in 44% yield by sequential treatment of methylphenylphosphane oxide **1**, having the Martin ligand,[10] with *n*BuLi, hexamethylphosphoric triamide (HMPA), and *N*-(diphenylmethylene)aniline (**2**) in THF at 0 °C (Scheme 1). Intramolecular cyclization and dehydration of **3**



Scheme 1. Synthesis of compounds **3**–**5**. DEAD = diethyl azodicarboxylate.

with the Mitsunobu reagent[11a] provided 1,2λ^5-azaphosphetidine **4** (colorless crystals from ethanol, 93% yield), which was hydrolyzed on silica gel to give the starting compound **3**. This is the first application of the Mitsunobu reagent to the present type of reaction, although phosphorylation of nucleosides by this method has been reported.[11b] The 3-methoxycarbonyl derivative **5** (11% yield)[12] was prepared from **4** by the same method as that reported for the corresponding 1,2λ^5-oxaphosphetane (Scheme 1).[1b]

In the ^{1}H NMR spectrum of **4**, a downfield shift for the *ortho* proton of the Martin ligand was observed at $\delta = 8.27$, which is a typical feature of compounds with a trigonal-bipyramidal (TBP) structure bearing a polar apical bond.[1a, b, 2, 3, 13] Some other selected NMR data are listed in Scheme 2.



$\delta_P = -29.9$	$\delta_P = -50.9$
H^a: $\delta = 8.27$, $^3J_{HH} = 7.9$ Hz, $^3J_{HP} = 12.1$ Hz	$\delta = 7.64$, $^3J_{HH} = 7.9$ Hz, $^3J_{HP} = 11.6$ Hz
H^b: $\delta = 4.55$, $^2J_{HP} = 21.6$ Hz, $^2J_{HH} = 17.0$ Hz	$\delta = 3.73$, $^2J_{HP} = 7.9$ Hz, $^2J_{HH} = 13.9$ Hz
H^c: $\delta = 4.22$, $^2J_{HP} = 19.6$ Hz, $^2J_{HH} = 17.0$ Hz	$\delta = 3.67$, $^2J_{HP} = 5.6$ Hz, $^2J_{HH} = 13.9$ Hz
$\delta_F = -73.6, -75.5$, $^4J_{FF} = 9.9$ Hz	$\delta_F = -74.2, -75.8$, $^4J_{FF} = 9.3$ Hz

Scheme 2. Selected NMR data of **4** and **6**.

The X-ray crystallographic analysis of **4**[14] (Fig. 1) reveals a distorted trigonal-bipyramidal coordination at phosphorus with apical nitrogen and oxygen atoms, very similar to those of the aforementioned oxa analogues.[1–3] Compound **4** is thus the first example of a pentacoordinate 1,2λ^5-azaphosphetidine.[15] The four-membered ring is similar to that reported for a tetraco-

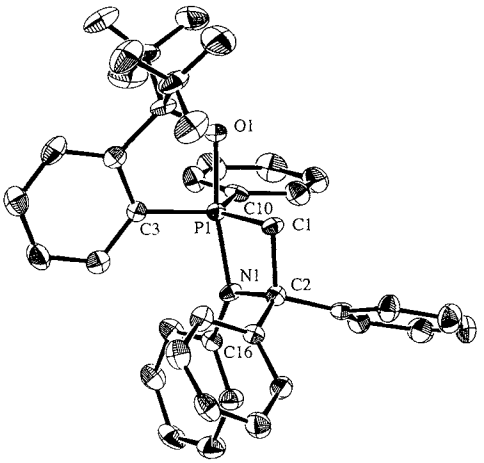


Fig. 1. Crystal structure of **4** (ORTEP, thermal ellipsoids at 30% probability). Selected bond lengths [Å], bond angles [°], and torsion angles [°]: P1-N1 1.798(5), P1-O1 1.796(5), P1-C1 1.818(6), P1-C3 1.816(7), P1-C10 1.822(7), C1-C2 1.542(9), C2-N1 1.486(8); N1-P1-O1 166.9(3), N1-P1-C1 75.1(3), P1-C1-C2 94.3(1), C1-C2-N1 93.1(5), C2-N1-P1 97.5(4), C2-N1-C16 125.4(5), P1-N1-C16 137.1(5), C1-P1-C3 119.9(3), C1-P1-C10 122.5(3), C3-P1-C10 117.5(3); P1-C1-C2-N1 −0.1(5), P1-N1-C2-C1 0.1(5).

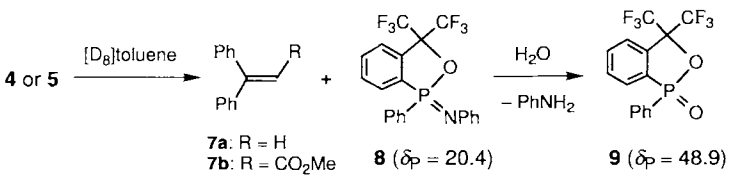
ordinate 1,2-azaphosphetidine,[15c] while the length of the apical P1–N1 bond (1.789(5) Å) is close to those in pentacoordinate 1,3,2-diazaphosphetidines (1.799(2) Å[15e] and 1.782(3) Å[15g]). The bond angle between two apical bonds deviates from 180° by 13.1(3)°. The phosphorus atom is placed in the equatorial plane and the torsion angle P1-C1-C2-N1 is −0.1°, indicating that the four-membered ring is almost planar. Interestingly, the nitrogen atom has trigonal-planar coordination and the plane of the benzene ring on the nitrogen lies in the plane of the four-membered ring. When **4** ($\delta(^{31}P) = -29.9$) was dissolved in [D$_8$]toluene, a further signal was observed at $\delta(^{31}P) = -50.9$, probably due to pseudorotamer **6**, in which the nitrogen atom is equatorial (Scheme 2). In the ^{1}H NMR spectrum the signals of the methylene protons of **6** appeared at a slightly higher field than those of **4** and the coupling constants ($^2J_{H,P}$) are smaller. In the NOE difference spectrum correlations between H^a and H^{b,c} were observed in **6** but not in **4**. The signal of the *ortho* proton in **6** (H^a) is not shifted downfield, indicating that the apical P–C bond is less polar than the P–N bond of **4**. These results can be reasonably interpreted as follows: a) Because the apical P–C bond in **6** is more polar and longer than the equatorial P–C bond in **4**, the shielding effect of the increased negative charge results in upfield chemical shifts and in smaller coupling constants. b) The shorter distances between the protons H^a and H^{b,c} in **6** lead to the observed NOE effects, which are not seen for **4**. This is the first observation of such a pseudorotamer; these compounds are not known for the oxygen analogs, 1,2-oxaphosphetanes.[16] This difference may be related to the difference in electronegativity between nitrogen and oxygen. A similar pseudorotamer ($\delta(^{31}P) = -51.0$) was observed also in the case of **5**.

Heating **4** (200 °C, 5 d) or **5** (100 °C, 18 h) in a sealed tube (Scheme 3) gave quantitatively the corresponding olefin **7a** or **7b**



Scheme 3. Reactions of **4** and **5**.

and iminophosphorane **8**, which was hydrolyzed to the corresponding cyclic phosphinate **9** and aniline. Thus **4** and **5** show Wittig reactivity; in other words, a pentacoordinate 1,2-azaphosphetidine can be regarded as an intermediate of the reaction of phosphorus ylides with Schiff bases. The coexistence of both pseudorotamers experimentally supports the argument that the olefin formation occurs via a C-apical pseudorotamer, which has been proposed in the Wittig reaction.[17]

Experimental Procedure

3: To a solution of **1** (1.002 g, 2.62 mmol) in THF (31 mL) were added at 0 °C *n*BuLi (1.62 M solution of hexane, 3.7 mL, 2.3 equiv) and then after 1 h HMPA (9.2 mL, 20.1 equiv) under argon, and the solution was stirred at 0 °C for 2 h. To the solution was added a solution of **2** (1.632 g, 6.34 mmol, 2.4 equiv) in THF (11 mL) at 0 °C, and the reaction mixture was stirred at 0 °C for 3 h and at −10 °C for 18 h. After usual workup the crude mixture was chromatographed on silica gel to give β-aminophosphane oxide **3** (44% yield) (m.p. 177–179 °C (decomp)); **1** was recovered in 23% yield.

4: To a solution of **3** (301 mg, 0.470 mmol) and Ph_3P (380 mg, 1.45 mmol) in dry benzene (20 mL) was added DEAD (0.24 mL, 1.52 mmol) at room temperature (25 °C) under argon. The reaction mixture was stirred for 45 min. The ^{31}P NMR spectrum of the mixture mainly showed signals at $\delta = -29.4$ and 29.8 due to **4** and Ph_3PO, respectively. After removal of the solvent under reduced pressure, the residue was crystallized from absolute EtOH to give almost pure **4** (272 mg, 93% yield). An analytically pure sample was obtained by recrystallization from CH_2Cl_2/EtOH. Single crystals suitable for X-ray analysis were grown from acetone. **4**: M.p. 258–259 °C (decomp); Anal. calcd for $C_{35}H_{26}F_6NOP \cdot H_2O$: C 65.73, H 4.41, N 2.19; found: C 65.45, H 4.20, N 2.27; HRMS (70 eV): *m/z* (M^+) calcd for $C_{35}H_{26}F_6NOP$: 621.1656, found: 621.1656; ^{1}H NMR (500.1 MHz, $CDCl_3$, 27 °C, TMS): $\delta = 4.22$ (dd, $^2J(H,P) = 19.6$, $^2J(H,H) = 17.0$ Hz, 1H, PCHH'), 4.55 (dd, $^2J(H,P) = 21.6$, $^2J(H,H) = 17.0$ Hz, 1H, PCHH'), 6.41 (d, $^3J(H,H) = 8.1$ Hz, 2H), 6.56 (t, $^3J(H,H) = 7.4$ Hz, 1H), 6.78 (dd, $^3J(H,H) = 7.4$, 8.1 Hz, 2H), 7.15–7.17 (m, 3H), 7.26–7.28 (m, 2H), 7.32–7.40 (m, 10H), 7.52–7.56 (m, 1H), 7.78–7.81 (m, 1H), 7.89–7.90 (m, 1H), 8.27 (dd, $^3J(H,P) = 12.1$, $^3J(H,H) = 7.9$ Hz, 1H); ^{31}P NMR (109 MHz, $CDCl_3$, 27 °C, 85% H_3PO_4): $\delta = -29.4$. Satisfactory ^{13}C and ^{19}F NMR spectra were obtained.

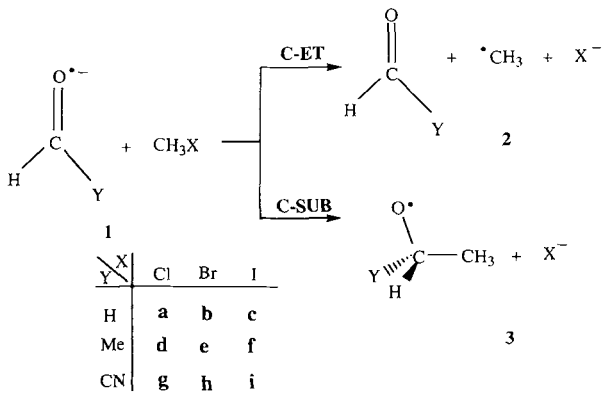
Towards the Definition of the Maximum Allowable Tightness of an Electron Transfer Transition State in the Reactions of Radical Anions and Alkyl Halides**

G. Narahari Sastry, David Danovich, and Sason Shaik*

How tightly bonded can the transition state (TS) of an electron transfer (ET) reaction be before it collapses to a classical TS for a bond-forming reaction? In other words: is it possible to define the minimum allowed separation or the maximum allowed bonding between the reactants of an ET process? These fundamental questions are related to the long-standing interest in the mechanistic dichotomy between ET and nucleophilic substitution (SUB) processes,[1] and to renewed interest in the problem through the recent demonstrations of ET/SUB competitions and mechanistic crossovers in the reactions between radical anions and alkyl halides.[2, 3] The present communication addresses the fundamental questions by using the ET and SUB reactions for combinations of formyl radical anions and methyl halides. We have found that within a distinct range of intermolecular distances the TS is transformed from an ET-TS into a SUB-TS.

Following our recent studies described in ref. [4], we investigated a group of reactions between the substituted formyl radical anions and the methyl halides (systems **1** in Scheme 1). These



Scheme 1. Reactions studied.

systems undergo three types of reactions: O-alkylation, C-oriented electron transfer (C-ET)[4a] to give **2**, and C-alkylation (C-SUB) to give **3**. While the O-alkylation has generally a distinct TS, which has been discussed before,[4] the C-ET and C-SUB reactions are mutually exclusive and exhibit a mechanistic crossover, C-ET → C-SUB, when the substituents on the formyl radical anion and also the halides are varied. This communication focuses on the latter two processes and addresses precisely the fundamental question posed at the outset.

All the calculations were performed with the Gaussian 92 program package.[5] Geometries were gradient optimized and characterized by frequency analysis. Mechanisms were ascertained by following the reaction path, by using the intrinsic reaction coordinate (IRC) technique with internal (non-mass-weighted) coordinates, IRC(internal).[6, 7] Since spin contamination becomes at times significant along the UHF and UMP2 paths,[6b] the study was carried out with ROHF theory,[6a] which is free of spin contamination and gives geometric and energetic results compatible with those of previous studies.[4a] The 6-31G* basis set was used for C, O, H, and N atoms, while for the halides we used the Hay and Wadt effective core potential (ECP)[9] with the LANL1DZ valence basis set augmented with two sets of uncontracted d-type polarization functions (Cl: α_d = 0.150 and 0.375; Br: α_d = 0.232 and 0.600; I: α_d = 0.270 and 0.730). A comparative all-electron study, which was carried out for X = Cl, using the 6-31G* basis set gave virtually identical results with those of the ECP basis set.

An ion–dipole cluster C_R **4**, precedes the transition state **5**, which proceeds either to the ET products **2** or to the C-SUB products **3**. For each pair of reactants in Scheme 1 the C-attack gave only one TS structure (**5**) either of the C-ET or C-SUB variety, but never both. The critical distances for the various C_R and transition state structures are given in Table 1. In the transition from C_R to TS the R_{CO} distance decreases while R_{CX} increases. For case **f** the TS is early and its C–I bond is shorter than that in the cluster but clearly longer than that in the free

[a] Values in the parentheses were obtained with the all-electron 6-31G* basis set. [b] The value in square brackets corresponds to the length of the C–I bond in CH_3I.

reactant, CH_3I. The decrease in R_{CO} promotes the C-ET process (acting to eject the electron from the formyl radical anion), while the increase in R_{CX} is common to both C-ET and C-SUB processes. The IRC(internal) analysis for the C-ET process shows initially a C–C approach followed by C–C recoil. In turn, the C–C recoil is synchronized with C–X bond cleavage; hence this is a dissociative and bonded C-ET process. In contrast, the IRC(internal) analysis for the C-SUB process shows a continuous C–C bond formation synchronized with C–X bond cleavage; hence this is a substitution mechanism. Both types of TSs are connected to cluster C_R in the reverse direction of IRC. Thus, the IRC results for the two processes are distinct and characteristic.

As specified in Table 2, the TS structures for systems **a**–**f** correspond to ET-TS structures. In contrast, systems **g** and **h**, which involve the poorest electron donor, cyanoformaldehyde radical anion, were found to have transition states that correspond to the C-SUB variety, resulting in C-alkylation. Further increase of the acceptor ability of the alkyl halide to X = I in system **i** led to an ET-TS structure even with Y = CN.[6c] Apparently, a mutually exclusive competition exists between the ET and SUB mechanisms along the same C–C–X trajectory of attack, and the entire group of reactions define therefore a mechanistic spectrum with an ET/SUB changeover.

Table 2. Thermochemical quantities [a], entropies of activation [b, c], and α-C^{12}/C^{13} kinetic isotope effects [c, d].

[a] In kcal mol^{-1}. [b] The standard state is 1 M at 298.15 K. [c] The parameters correspond to the process **1** → **5**. [d] Frequencies are scaled by the recommended factor 0.8929 to obtain the thermochemical values. [e] ΔE quantities refer to the process from separated reactants **1** to separated products **2** or **3**. [f] G_{ET} corresponds to the energy difference between the ground state $YHC{=}O^{\cdot -}/CH_3X$ and the charge transfer state $YHC{=}O/CH_3X^{\cdot -}$ at the reactants geometry. [g] Values in parentheses were obtained with the all-electron 6-31G* basis set. [h] $G_{SUB} = G_{ET} + \Delta E_{3\pi\pi^*}(YHC{=}O)$. Note that $\Delta E_{3\pi\pi^*}(YHC{=}O)$ is much smaller for Y = CN than for Y = H, CH_3.

Table 2 also gives the computed energies, entropies of activation, and the α-C^{12}/C^{13} kinetic isotope effects. The activation barriers $\Delta E^{\neq}$ depend on X and Y with the following orders: Cl > Br > I for X, and H < Me ≪ CN for Y. All the TS structures contain C–C bonding, as reflected in large values for the entropy of activation for all the reactions and in normal α-C^{12}/C^{13} isotope effects.[10] Even in the "loosest" TS structure in the group, **5c**, exhibits significant bonding, as implied by the normal α-C^{12}/C^{13} isotope effect.

The mechanistic selection follows from a recent valence bond configuration mixing (VBCM) treatment[11] of the problem in terms of three principal VB configurations, which for brevity may be described by the occupancy of the π_{CO} and π^*_{CO} fragment orbitals of the formyl group, and σ_{CX} and σ^*_{CX} orbitals of the alkyl halide moiety. These are: the reactant configuration ($\pi^2_{CO}\ \pi^{*1}_{CO}\ \sigma^2_{CX}$) the charge transfer configuration ($\pi^2_{CO}\ \sigma^2_{CX}\ \sigma^{*1}_{CX}$) and the substitution configuration ($\pi^1_{CO}\ \pi^{*1}_{CO}\ \sigma^2_{CX}\ \sigma^{*1}_{CX}$). The substitution configuration involves triplet excitation of the formyl moiety from π_{CO} to π^*_{CO} in addition to an electron transfer to the σ^*_{CX} orbital. It is the pairing of the two π electrons of the triplet formyl moiety with the electron in the σ^*_{CX} orbital that is eventually responsible for formation of the new C–C bond in the substitution product. At the geometry of the reactants, the energy of the CT state lies above that of the reactant state by the vertical electron transfer energy gap G_{ET}. The vertical energy gap of the substitution state, G_{SUB}, is obtained by adding the triplet $^3\pi\pi^*$ excitation energy of the formyl moiety to G_{ET}. This triplet $^3\pi\pi^*$ excitation energy for formaldehyde and methyl formaldehyde is much larger than that for cyanoformaldehyde, and therefore the $CN(H)C{=}O^{\cdot -}/CH_3X$ reactant pairs are typified both by a higher lying charge transfer configuration and a more closely lying substitution configuration than the configurations of the corresponding pairs, $H_2C{=}O^{\cdot -}/CH_3X$ and $CH_3(H)C{=}O^{\cdot -}/CH_3X$.

These three configurations cross and mix with each other along the C–C–X trajectory.[11b] Consider first the crossing of the reactant and CT configurations in terms of two key quantities shown in Table 2, the reaction exothermicity ΔE_{ET} and the vertical electron transfer energy gap G_{ET}. A large G_{ET} and weakly exothermic ΔE_{ET} will lead to a tighter crossing point with a small intermolecular distance R_{CC}. In turn, the smaller the C–C distance at the crossing point is, the greater the contribution of the substitution configuration will be, until the point at which its mixing with the reactant configuration prevails and the corresponding structure collapses accordingly to a SUB-TS. This effect of the substitution configuration will become significant for the $CN(H)C{=}O^{\cdot -}/CH_3Cl$ and $CN(H)C{=}O^{\cdot -}/CH_3Br$ pairs; the mixing of the substitution configuration will be enhanced by both the large G_{ET} gaps and the low triplet $^3\pi\pi^*$ excitation energy of cyanoformaldehyde.

Since G_{SUB} depends on G_{ET}, a combination of G_{ET} and ΔE_{ET} variations can serve as the minimum necessary predictor of both the C–C distance at the TS as well as in the mechanistic changeover C-ET → C-SUB . The factor $\alpha = 0.5 G_{ET}/(G_{ET} - \Delta E_{ET})$, derived from the Marcus expression,[12] gives effectively the appropriate combination of G_{ET} and ΔE_{ET} that can gauge the earliness of the TS in terms of its R_{CC} distance. Figure 1 is a plot

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3510-1099 $ 15.00+.25/0

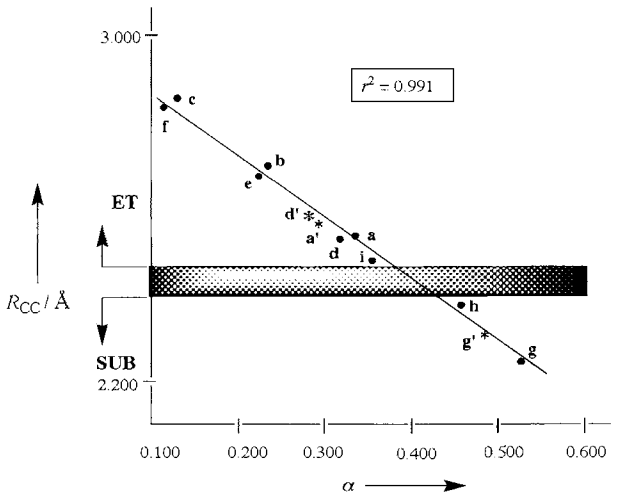

Fig. 1. The variation of C–C distances at the TS as a function of α. Filled circles: results of calculations with the ECP basis set; asterisks: results of calculations with the 6-31G* basis set (systems **a'**, **d'**, and **g'**); gray band: area of mechanistic changeover.

of the R_{CC} distances, calculated for the transition states of the reactions of systems **1**, against the index α. It is seen that the C–C distances in the transition states decrease linearly as α increases; in the ET-TS structures, $R_{CC} \geq 2.481$ Å, while in the SUB-TS structures, $R_{CC} \leq = 2.370$ Å. These two critical values, 2.370 and 2.481 Å, define the mechanistic changeover zone from the C-ET to C-SUB, over a narrow range of approximately 0.1 Å. It follows therefore that the ET/SUB dichotomy characterized by Figure 1 corresponds to two mutually exclusive mechanisms that exhibit a continuous mechanistic spectrum with a narrow changeover zone from C-ET to C-SUB. Thus, while TS earliness is gauged by the Marcus parameter of the ET process, the C-ET → C-SUB mechanistic changeover itself originates in the multiconfigurational nature of the problem, which is characterized by the VB mixing of at least three VB configurations.[11]

We have described here the first structural foundations for the long-sought[1a, b, 3] ET/SUB dichotomy in a set of reactions of radical anions ($A^{\cdot -}$) and alkyl halides (RX). There seems to be a continuous spectrum of distances between the reactants in the ET-TS, and at a certain minimum distance there is a mechanistic changeover to the SUB-TS. Thus, the ET series up to the changeover zone exhibits an ET-TS with variable C–C bonding ranging from weak bonding in cases **c** and **f**, to significant bonding in cases **a**, **d**, and **i**. Of course the choice of the computational method may shift the changeover zone, but nevertheless, the sharpness of the zone indicates that ET-TS structures can indeed be strongly bonded and structurally adjacent to their SUB analogs. The critical zone may of course depend on the nature of the $A^{\cdot -}$/RX family; each family may exhibit its own characteristic changeover zone, and its own point of maximum bonding for the ET-TS.

[6] The term IRC(internal) is used as in ref. [5]. The reaction pathways were examined also by means of IRC with mass-weighted (MW) coordinates [8], IRC(MW). It was found that the energy along the IRC(internal) path is consistently lower than that along the IRC(MW) path in all the cases. Hence the IRC(internal) path qualifies as the path of steepest descent and was therefore used throughout to designate the mechanisms of the reactions. a) At the ROHF level both IRC(internal) and IRC(MW) gave identical mechanistic conclusions for the combinations **a**–**e**, **g**, and **h** with both the 6-31G* and the ECP basis sets (reaction **a** was tested with many other basis sets—6-31 + G*, 6-31G**, 6-311G*, and 6-311G**—all of which led to the same conclusion, an ET mechanism). b) In UHF (for **a**, **c**, **g**) and UMP2/6-31G* (for **a**, **g**), the IRC(internal) path has a rather small spin contamination throughout and leads to the same mechanistic conclusions as the ROHF path. In contrast, the IRC(MW) path passes through highly spin-contaminated regions (for example $\langle S^2 \rangle = 0.875$ for reaction **a**) and produces nonsmooth energy profiles terminating at C-SUB products. For this reason the ROHF level was preferred over the UHF and UMP2 level in the present study. c) For the reaction in system **i** (Y = CN, X = I) the IRC(MW) at the ROHF level gave a nonsmooth profile resulting in C-SUB, while IRC(internal) produced a consistently steeper path and a smooth energy profile leading to ET. As the path of steepest descent starting from **5i** leads to ET products, **5i** was designated as an ET-TS.

[11] a) L. Eberson, S. S. Shaik, *J. Am. Chem. Soc.* **1990**, *112*, 4484. b) Based on Figure 4 in ref. [11a]. The CT state and reactant configurations mix by optimization of the $\pi^*_{CO} - \sigma^*_{CX}$ overlap, while the substitution and reactant configurations mix by optimization of the $\pi_{CO} - \sigma^*_{CX}$ overlap. Hence all three configurations mix along the C···C···X trajectory.

[12] The Marcus expression is given by $\alpha = 0.5(1 + \Delta E_{ET}/\lambda)$, where $\lambda = G_{ET} - \Delta E_{ET}$. Substituting for λ and rearranging leads to $\alpha = 0.5 G_{ET}/(G_{ET} - \Delta E_{ET})$.

and polynuclear complexes[2, 3] has also aroused much attention. This together with our recent efforts on the study of the photophysical and photochemical behavior exhibited by polynuclear d^{10} metal complexes[4, 5] have stimulated the present work. Herein we report on the synthesis and luminescent behavior of a highly novel tetranuclear acetylidocopper(I) complex **1**,

$[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C{\equiv}C)](BF_4)_2$ **1**

which contains an acetylido ligand in both η^1 and η^2 bonding modes. Furthermore, the redox properties in the excited state and the crystal structure have also been determined. Complex **1** is the first structure of a tetranuclear d^{10} metal complex with a μ_4-η^1,η^2-acetylido bridge characterized by X-ray crystallography.

Addition of $[Cu_2(\mu\text{-dppm})_2(MeCN)_2](BF_4)_2$ to a solution of *n*-butyllithium and trimethylsilylacetylene in THF under nitrogen at room temperature results in the formation of **1**, which was isolated as air-stable pale yellow crystals. Complex **1** gave satisfactory C, H analyses, and has been characterized by positive FAB-mass spectrometry, IR and ^{1}H NMR spectroscopy, and by crystal structure analysis.[6]

Figure 1 shows the perspective drawing of the cation in **1**. Complex **1** has crystallographic C_2 symmetry. The four copper atoms are arranged in a distorted rectangular array with the four μ-dppm ligands arranged in a saddlelike configuration. A

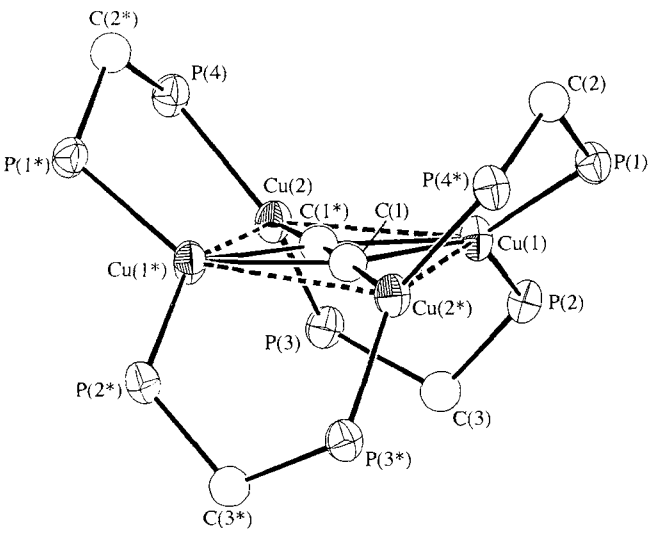

Fig. 1. Perspective drawing of the crystal structure of the cation in **1** with the atomic numbering scheme. Hydrogen atoms and benzene rings have been omitted for clarity. Thermal ellipsoids are shown at the 20% probability levels. Selected bond lengths [Å] and angles [°]: Cu(1)–C(1) 2.13(1), Cu(1)–C(1*) 2.12(1), Cu(2)–C(1*) 1.91(1), Cu(1)–Cu(2) 3.264(2), Cu(1)–Cu(2*) 3.245(2), C(1)–C(1*) 1.26(2), Cu(1)–P(1) 2.273(4), Cu(2)–P(4) 2.236(4), Cu(1)–P(2) 2.270(4), Cu(2)–P(3) 2.230(4); Cu(2)-C(1*)-C(1) 178.2(4), Cu(1)-Cu(2)-Cu(1*) 77.26(6), Cu(2)-Cu(1*)-Cu(2*) 102.60(6), dihedral angle between planes Cu(1)-C(1)-C(1*) and Cu(1*)-C(1*)-C(1) 177.41.

similar configuration has been observed in $[Cu_4(\mu\text{-dppm})_4(\mu_4\text{-S})](PF_6)_2$.[5] The C≡C unit is situated in the middle of the four copper atoms, bridging the four copper atoms in both η^1 and η^2 bonding modes. This represents the first example of a μ_4-η^1,η^2-acetylido-bridged tetranuclear d^{10} copper(I) system. Coordination of this type is also rare in other metal cluster systems.[7] Normal electron counting requires that the C≡C unit acts as a six-electron donor according to the covalent model. While the interaction of the C≡C ligand with each of the Cu_2 units resembles that found in other μ-η^1,η^2-acetylido complexes, best overlap of the two π orbitals of the acetylido ligand with the four copper atoms would require the two Cu_2 units to be orthogonal to each other. However, the π-type bonds from the C≡C unit to Cu(1) and Cu(1*) are close to coplanarity [dihedral angle between Cu(1)-C(1)-C(1*) and Cu(1*)-C(1*)-C(1) is 177.41°]. This may arise as a result of the steric hindrance of the phosphane ligands, which prevents orthogonal geometry for maximum orbital overlap from occurring. A similar type of bonding has also been reported in $[Ru_4(\mu_4\text{-}\eta^1,\eta^2\text{-}C_2)(\mu\text{-}PPh_2)_2(CO)_{12}]$ (**2**).[7a] Unlike in a tetranuclear phenylacetylidocopper(I) complex,[7b] in which true π bonding exists between the C≡CPh unit and the two Cu_2 units arranged in an orthogonal array (dihedral plane 82(1)°), the C≡C bond in **1** (1.26(2) Å) is much shorter than that observed in the phenylacetylide complex (1.38(5) Å),[7b] but comparable to the value of 1.275(11) Å in **2**.[7a] Slightly longer Cu(1)–C(1), Cu(1)–C(1*), Cu(1*)–C(1), and Cu(1*)–C(1*) distances (2.12(1)–2.13(1) Å) have also been observed than the majority of those found in the phenylacetylide complex (1.93(3)–2.18(3) Å).[7b] A Cu(2)-C(1*)-C(1) bond angle of 178.2(4)°, which is close to linearity, is observed. Two of the edges of the Cu_4 unit are shorter than the other two; the copper–copper distances are 3.264(2) and 3.245(2) Å for Cu(1)···Cu(2) and Cu(1)···Cu(2*), respectively. These distances are significantly longer than the sum of van der Waals radii for copper (2.8 Å),[8] which suggests insignificant metal–metal interaction between the four copper atoms. Interestingly, a related tetranuclear M_4 architecture is shown by the $[Pd_4(\mu\text{-}Cl)_2(\mu\text{-dppm})_4]^{2+}$ complex ion.[9]

The electronic absorption spectrum of **1** shows a band at about 262 nm in MeCN, attributable to the intraligand transition of dppm, since free dppm also absorbs strongly in this region. The low-energy absorption at about 374 nm is likely to arise from a $[(C{\equiv}C)^{2-} \rightarrow Cu_4]$ ligand-to-metal charge transfer (LMCT) transition, given the good σ-donating ability of the $(C{\equiv}C)^{2-}$ unit. Upon excitation of complex **1** at $\lambda > 350$ nm at room temperature, intense green and greenish yellow emissions are observed, in the solid state and in solution ($\varphi_{lum} = 0.22$ in acetone), respectively. The photophysical data are summarized in Table 1. The long lifetime of the excited state observed at room temperature in both the solid state and in solution, together with the large Stokes shift suggest that the emission is most likely associated with a spin-forbidden transition from a triplet state. The luminescence of **1** is quenched by pyridinium ion acceptors in an oxidative electron transfer process. The bimolecular rate constants of this quenching are given in Table 2. The reduction potential of the excited state $E^{\circ}(\mathbf{1}^{3+}/\mathbf{1}^{2+*})$ of −1.77 V versus the saturated sodium chloride calomel electrode (SSCE) ($\lambda = 1.39$ eV, and $RT\ln K_{\kappa v} = 0.584$ V vs. SSCE) has been estimated by oxidative quenching studies with a series of structurally related pyridinium ion acceptors, and is indicative of its strong reducing power in the excited state.

4-methyl-*N*-methylpyridinium	−1.49	1.47×10^6

[a] All the cations have hexafluorophosphate counterions except for 3,4-dicyano-*N*-methylpyridinium and 2-chloro-*N*-methyl-3-nitropyridinium which have tetrafluoroborate counterions. [b] Measured against the saturated sodium chloride calomel electrode. [c] k_q' is the rate constant corrected for diffusional effects.

Experimental Procedure

1: To a solution of trimethylsilylacetylene (0.04 mL, 0.30 mmol) in pre-dried, degassed THF (40 mL) under an inert atmosphere of nitrogen, *n*-butyllithium (1.6 M, 0.18 mL, 0.30 mmol) was added at room temperature. A solid sample of $[Cu_2(\mu\text{-dppm})_2(MeCN)_2](BF_4)_2$ (500 mg, 0.43 mmol) was added and stirred at room temperature for 24 h. After evaporation to dryness, the resulting solid was extracted with acetone (3 × 8mL), and the solution was filtered and reduced in volume. Subsequent layering of *n*-hexane into the concentrated solution gave **1** as air-stable pale yellow crystals (yield 200 mg, 46%). ^{1}H NMR (270 MHz, [D$_6$]acetone, 25 °C, relative to TMS): δ = 3.74 (m, 8H; CH_2), 7.00–7.43 (m, 80H; Ph); IR (nujol/KBr): ν[cm^{-1}]: 1057 s, (ν (B–F)); UV/Vis (acetone): λ[nm] (ε_{max}/L mol^{-1}cm^{-1}) = 374 (7420); positive ion FAB-MS: ion cluster at *m/z* 1901 [M^+]. Anal. calcd for $C_{102}H_{88}P_8B_2F_8Cu_4 \cdot H_2O$: C 61.03, H 4.42; found: C 61.13, H 4.45.

[6] a) Crystal Data of **1**: $[(Cu_4P_8C_{102}H_{88})^{2+} \cdot 2BF_4^- \cdot 4(CH_3)_2CO]$, formula weight = 2221.72, orthorhombic, space group *Pccn* (no. 56), a = 21.290(1), b = 23.019(1), c = 22.882(2) Å, V = 11213.7(10) Å^3, Z = 4, ρ_{calcd} = 1.316 g cm^{-3}, $\mu(Mo_{K\alpha})$ = 9.25 cm^{-1}, $F(000)$ = 4576, T = 298 K. A pale yellow crystal of dimensions 0.20 × 0.15 × 0.30 mm mounted inside a capillary glass tube in the presence of some solvent was used for data collection at 25 °C on a Rigaku AFC7R diffractometer with graphite monochromatized $Mo_{K\alpha}$ radiation (λ = 0.71073 Å). ω-2θ scans were used with ω scan angle (0.63 + 0.35 tanθ) at a scan speed of 16.0° min^{-1} (up to four scans for reflections with $I < 15\sigma(I)$). Intensity data (in the range of $2\theta_{max}$ = 45°; h: 0 to 24; k: 0 to 25; l: 0 to 23 and three standard reflections measured after every 300 reflections showed no decay) were corrected for Lorentz and polarization effects, and empirical absorption corrections based on the ψ scan of four strong reflections (minimum and maximum transmission factors 0.925 and 1.000). 8022 reflections were measured, 3357 reflections with $I > 3\sigma(I)$ were considered observed and used in the structural analysis. The space group was determined from systematic absences and the structure was solved by Patterson methods and expanded by Fourier methods (PATTY [6b]) and refinement by full-matrix least squares by using the software package TeXsan [6c] on a Silicon Graphics Indy computer. Only the six heavy atoms (copper and phosphorus) were refined anisotropically. The other 65 non-hydrogen atoms were refined isotropically. 56 hydrogen atoms at calculated positions with thermal parameters equal to 1.3 times that of the attached C atoms were not refined. Convergence for 311 variable parameters by least squares refinement on F with $w = 4F_o^2/\sigma^2(F_o^2)$, where $\sigma^2(F_o^2) = [\sigma^2(I) + (0.012F_o^2)^2]$ for 3357 reflections with $I > 3\sigma(I)$ was reached at R = 0.074 and wR = 0.085 with a goodness-of-fit of 3.00. $(\Delta/\sigma)_{max}$ = 0.04 for the complex cation. Mesoporous Alumina Molecular Sieves**

Stephen A. Bagshaw and Thomas J. Pinnavaia*

The original synthesis of Mobil M41S mesoporous molecular sieves[1, 2] utilized electrostatic interactions between a positively charged surfactant (S^+) and a negatively charged inorganic precursor (I^-) to assemble the mesostructure. The electrostatic assembly process has been verified[3, 4] and extended to include charge-reversed (S^-I^+) and counterion-mediated ($S^-M^+I^-$ and $S^+X^-I^+$; M^+ = metal cation, X^-) pathways.[5–7] We recently demonstrated that mesostructure assembly, at least in the case of silica, can also be achieved through hydrogen bonding interactions between neutral inorganic precursors (I^0) and neutral alkylamine (S^0) or nonionic polyethylene oxide (N^0) surfactants.[8, 9] More recently, Attard et al.[10] have shown that N^0 surfactants in liquid crystalline form function as authentic templates for the synthesis of M41S silicas with hexagonal, cubic, and lamellar structure. Neutral S^0I^0 and N^0I^0 pathways have important advantages over the electrostatic pathways, in part, because most metals form alkoxides or other neutral complexes suitable for hydrolysis and assembly as I^0 precursors. The diversity of compositions of I^0 precursors allows for the synthesis of mesostructured oxides that are difficult or impossible to achieve by electrostatic assembly mechanisms. We describe here the application of the concept of neutral surfactant templating to the synthesis of the first examples of alumina molecular sieves.

High surface area aluminas are especially important industrial catalysts and catalyst supports.[11, 12] Yet, the performance properties of these widely used phases undoubtedly is limited, because they possess only textural porosity and lack the selective framework/confined pore structure characteristic of a molecular sieve. There have been previous attempts to prepare mesostructured forms of alumina by electrostatic assembly pathways,[5–7] but all afforded products that collapsed upon surfactant removal. However, as shown by the present work, N^0I^0 assembly processes provide highly effective pathways to mesoporous alumina molecular sieves.

Three forms of mesoporous aluminas, denoted MSU-1, MSU-2, and MSU-3, were prepared by the hydrolysis of tri-*sec*-butoxyaluminum at ambient temperature in the presence of the nonionic polyethylene oxide surfactants given in Table 1. Typical powder X-ray diffraction (XRD) patterns are shown in Figure 1 for the as-synthesized and calcined forms of MSU-3 alumina prepared from a copolymer surfactant of the type $(PEO)_{13}(PPO)_{30}(PEO)_{13}$ based on polyethylene oxide (PEO) and polypropylene oxide (PPO). Analogous single peak patterns corresponding to large d spacings have been observed for disordered MCM-41,[3, 5] HMS,[8] and MSU-X[9] silicas. However, the reflections for MSU-X aluminas are broader, signifying an even greater degree of structural disorder. Also, the intensities of the XRD lines are substantially larger for the calcined forms of MSU aluminas than for the as-synthesized materials. Analogous changes in XRD intensities have been observed for MCM-41 and HMS silicas.[9] Recent modeling studies by S. D. Mahanti[13] have shown that the removal of the occluded organic template from hexagonal mesostructures enhances the Bragg scattering cross-section. Similar differences in scattering intensities are anticipated for as-synthesized and calcined forms of disordered mesostructures.

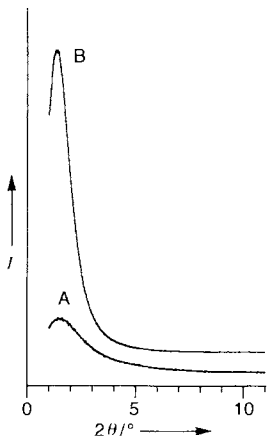

Fig. 1. Powder X-ray diffraction patterns of MSU-3 alumina prepared with Pluronic 64L surfactant: A) As-synthesized sample after air drying at room temperature for 16 h; B) after calcination at 773 K in air for 6 h. The intensity I is in arbitrary units.

PEO-based surfactants are known to adopt spherical to long "wormlike" micellar structures in aqueous solution.[14–16] The pore structures of MSU-X aluminas prepared with these N^0 surfactants reflect the wormlike motif of the micellar structure, as evidenced by the representative transmission electron microscopic (TEM) image (Fig. 2) for a MSU-1 alumina prepared from Tergitol 15-S-9. However, the wormlike channels, though more or less regular in diameter, have no discernible long-range order. That is, the packing of channel system appears to be random, despite the presence of an XRD reflection. In this latter case the regular separation between single channel walls may be giving rise to the XRD reflection. Clearly, the disordered channel system of MSU-X aluminas is in marked contrast to the long-range hexagonal arrangement of channels found for MCM-41[2] and HMS mesostructures.[8]

Fig. 2. TEM image of a calcined (773 K) MSU-1 alumina molecular sieve showing the regular wormlike channel motif, but no discernable long-range channel packing order. The material was prepared by using Tergitol 15-S-9 as the surfactant. The length of the bar corresponds to 60 nm.

Figure 3 provides representative N_2 adsorption/desorption isotherms for a MSU-3 alumina calcined at 773 K. All MSU-X aluminas prepared by using PEO surfactants as templates display a similar broad but well-defined step in the adsorption isotherm at $p/p_0 \approx 0.45-0.8$ and a hysteresis in the desorption isotherm over the same relative pressure range. These features result from the condensation of the adsorbate within the framework-confined mesopores,[17] not from interparticle pores.[18] The lack of textural mesoporosity is indicated further by the absence of a hysteresis loop above $p/p_0 = 0.8$.[8] Some necking of the pore structure is suggested by the sharp curvature in the desorption leg of the hysteresis loop.

Most previously reported studies of mesoporous molecular sieves[1–9] have made use of the Horvath–Kawazoe (HK) model[19] for the determination of pore size distributions from N_2 adsorption isotherms. This model, developed for microporous lamellar carbon materials, assumes the presence of slitlike micropores. Therefore, its applicability to materials with larger,

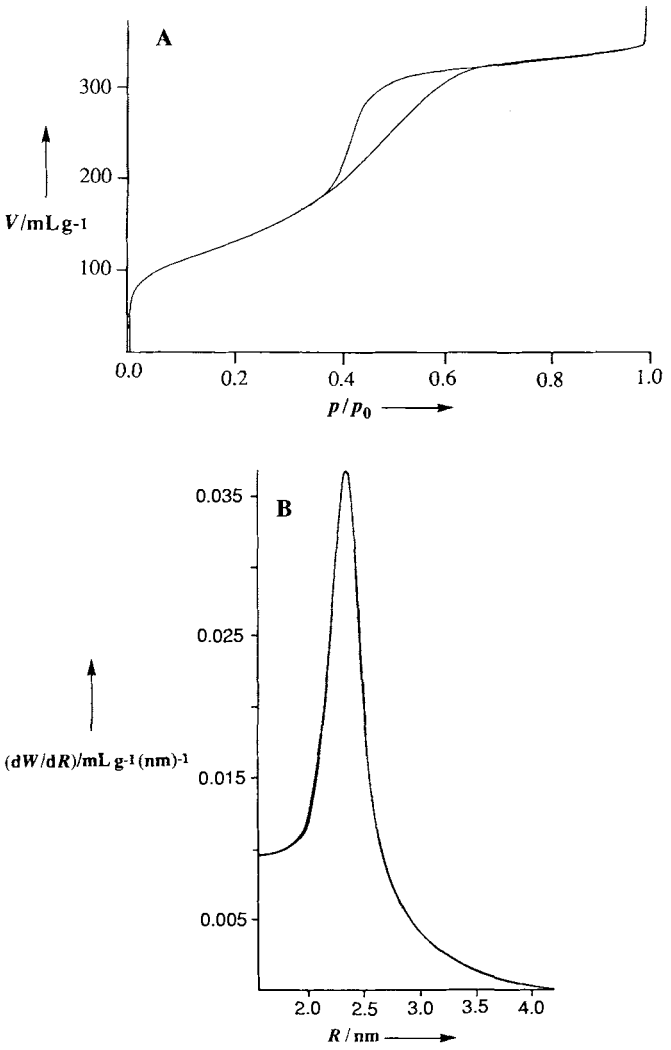

Fig. 3. A) Nitrogen adsorption and desorption isotherms for MSU-3 alumina prepared with the Pluronic 64L surfactant and calcined at 773 K in air for 4 h. The volume of N_2 sorbed is expressed at standard temperature and pressure; p/p_o is the partial pressure of nitrogen in equilibrium with the sample at 77 K. B) Corresponding Barrett–Joiner–Halender pore size distribution determined from the N_2 adsorption isotherm. dW/dR is the derivative of the normalized N_2 volume adsorbed with respect to the diameter of the pores of the adsorbent. Prior to measurement the sample was evacuated at 423 K and 10^{-6} Torr for 16 h.

cylindrical mesopores is likely to be limited. In this report, we have applied in addition to the HK model both the Cranston–Inkley (CI)[20] and the Barrett–Joyner–Halender (BJH)[21] models to the determination of framework pore size. Comparable pore size values were obtained when the CI and BJH models were applied to the N_2 adsorption and desorption branches, respectively. However, HK gave significantly larger pore diameters. For instance, as shown in Figure 3B, the pore distribution determined by the BJH method for MSU-3 alumina is centered at 2.4 nm, whereas the HK model affords a value of 4.8 nm. Measurement of the pores in the TEM image in Figure 2 gave diameters of about 2.6 nm, a value in favorable agreement with the BJH value of 3.3 nm.

Table 1 gives the basal spacings d_{100}, surface areas, pore volumes, and the HK and BJH pore sizes for MSU-X aluminas prepared from different families of PEO-based surfactants. A mesostructure assembly effect is indicated by an increase in both the d spacing and the pore diameters with increasing surfactant size. Since the MSU-X aluminas exhibit similar pore sizes but larger d spacings than MSU-X silicas,[9] we conclude that the channel wall thicknesses is larger for the aluminas than the silicas. This is consistent with the observation that the Brunauer–Emmett–Teller (BET)[18] surface areas of the aluminas calcined in air at 773 K range from 420 to 535 $m^2 g^{-1}$, whereas MSU-X silicas give values twice as large. Nevertheless, the surface areas and pore volumes are substantially larger than those of amorphous and crystalline aluminas[22] prepared by traditional sol–gel or flash-calcination techniques.[23]

The coordination environment of aluminum in MSU-X aluminas was examined by ^{27}Al MAS NMR spectroscopy (MAS = magic angle spinning). Spectra of as-synthesized and calcined MSU-3 alumina (Fig. 4) display three resonance signals, uncorrected for quadrupolar shift, at $\delta = 0$, 35, and 75. These lines are indicative of six-, five-, and four-coordinate metal centers, respectively.[24, 25] In the as-synthesized material the six-coordinate species is dominant, but after dehydration and dehydroxylation at 773 K the four- and five-coordinate centers both increase at the expense of the six-coordinate centers. The presence of five-coordinate aluminum centers is especially noteworthy as they may prove to be of catalytic significance as Lewis acid centers.

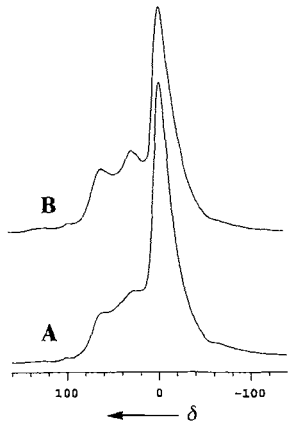

Fig. 4. ^{27}Al MAS NMR spectra of MSU-3 alumina prepared with the Pluronic 64L surfactant: A) As-synthesized sample after air drying at room temperature for 16 h; B) after calcination at 773 K in air for 4 h. The chemical shifts are referenced to external $[Al(H_2O)_6]^{3+}$.

Finally, we note that porous aluminas[26, 27] and aluminates[28] have been prepared previously from alkoxide precursors in the presence of organic pore regulating agents such as methyl cellulose or short-chain quaternary ammonium cations. Although these organic modifiers exhibited structure-directing properties for zeolite syntheses,[29] they afforded aluminas that were X-ray amorphous. Consequently, these earlier alumina synthesis reactions involved modifier encapsulation, but not assembly processes. Alumina aerogels with surface areas near 500 $m^2 g^{-1}$ also have been reported,[30] but the pore structures of these low bulk density materials were purely textural. Because of their thermal stability, high surface area, and multiple aluminum coordination environments, MSU-X alumina molecular sieves offer promising opportunities for new materials applications, particularly as catalysts and catalyst supports.

Experimental Procedure

The synthesis of a representative product, MSU-3 alumina, prepared by using a polyethylene oxide/polypropylene oxide copolymer surfactant illustrates the general procedure for the preparation of a mesoporous alumina molecular sieve. The specific template employed was Pluronic 64L (BASF), a tri-block copolymer with specific stoichiometry $(PEO)_{13}(PPO)_{30}(PEO)_{13}$. A solution containing deionized water (42 mmol) in anhydrous *sec*-butyl alcohol (10 mL) was added very slowly ($\approx$1 mL min^{-1}) to a stirred homogeneous solution containing surfactant (2.1 mmol) and tri-*sec*-butoxyaluminum (21 mmol) in anhydrous *sec*-butyl alcohol (25 mL). The overall reaction stoichiometry, therefore, was 0.1:1.0:2.0 surfactant:Al:water. The resulting gel that formed after stirring for 3 h was diluted with *sec*-butyl alcohol and allowed to react for an additional 16 h. The product was washed with absolute ethanol and dried sequentially at room temperature for 16 h and at 373 K for 6 h. The calcination was carried out by heating to 773 K for 4 h.

XRD patterns were obtained with a Rigaku Rotaflex diffractometer equipped with a rotating anode and $Cu_{K\alpha}$ radiation ($\lambda = 0.15418$ nm). The TEM image was obtained with a JEOL 100CX microscope using an accelerating voltage of 120 kV and a 20 mm objective lens aperture. N_2 isotherms were obtained on a Coulter Om-

Design, Synthesis, and Ion-Transport Properties of a Novel Family of Cyclic, Adamantane-Containing Cystine Peptides**

Darshan Ranganathan,* V. Haridas, K. P. Madhusudanan, Raja Roy, R. Nagaraj, G. B. John, and M. B. Sukhaswami

Cyclic peptides have attracted considerable attention in recent years. Apart from acting as templates in the de novo design[1] of artificial proteins, they serve as useful models[2] for the study of preferences in protein secondary structure and also play a pivotal role in ion transport across biological membranes.[3] Recently, a new aspect has developed: the formation of nanotubes from cyclic peptides.[4]

The problem of delineating conformation in cyclic peptides can be overcome by incorporating rigid units in their framework. The potential of this strategy has recently been shown in the design of conformationally constrained, high-affinity ligands for GPIIb/IIIb receptor proteins[5] and in the development of minimal glucocorticoid receptors models.[6] Thus, it was envisaged that when rigid and simultaneously lipophilic units are incorporated into the cyclic peptide framework, not only would the peptide have the desired conformational constraint but it would also interact with lipid bilayers. These cyclic peptides would thereby effectively and preferentially transport ions across biological membranes.

In this communication we provide the first illustration of this strategy and report on the design and synthesis of a unique family of adamantane-containing[7] cystine cyclic peptides with the general structure cyclo(Adm-Cyst)$_n$ (Adm = 1,3-adamantanedicarbonyl; Cyst = L-cystine dimethyl ester; $n = 2-5$), which were constructed in a single step by the reaction of L-cystine dimethyl ester with 1,3-adamantanedicarbonyl dichloride. Further, members of this class of cyclic peptides have been demonstrated to selectively transport sodium and potassium ions in model membranes.

Treatment of 1,3-adamantane dicarbonyl dichloride with L-cystine dimethyl ester in the presence of triethylamine under high-dilution conditions afforded a mixture of four products with similar TLC behavior, which were separated by chromatography on silica gel with ethyl acetate/benzene (80/20) as eluent. The products were isolated in yields of 55 (**1**), 15 (**2**), 12 (**3**), and 2% (**4**), and were fully characterized by spectroscopic and analytical data (Scheme 1, Table 1)).

The highly symmetrical nature of **1**–**4** was evident from the appearance of only single set of resonances for the cystine and adamantane units in their ^{1}H and ^{13}C NMR spectra.[15] The chemical shifts of the adamantane and cystine protons in **2**–**4** were essentially identical to those of **1**, suggesting that these units adopt similar conformations. The ROESY NMR spectra of **1**–**3** and the very enhanced ROE effect[15] between the NH and the adamantane methylene protons suggests that

Polymer: soluble in DMSO and DMF, insoluble in $CHCl_3$, EtOAc, MeOH; m.p 172–173 °C; thermogravimetric analysis: $T = 250$ °C; ^{1}H-NMR (90 MHz, [D$_6$]DMSO): $\delta = 1.32$–2.37 (m, 14 H), 3.10 (m, 4 H), 3.65 (s, 6 H), 4.60 (m, 2 H), 7.75 (d, $J = 7.0$ Hz, 2 H); IR (KBr): $\tilde{\nu} = 3349$, 2914, 2860, 1750, 1666, 1647, 1562, 1536, 1514, 1441 cm^{-1}

two carbonyl functions are in a *syn-anti* arrangement. The FAB-MS results[15] confirmed that **1**–**4** correspond to the cyclic dimer, trimer, tetramer, and pentamer, respectively, of Adm-Cyst units.[8]

The formation of **1**–**4** containing two, three, four, and five cyclic repeats, respectively, of Adm-Cyst units was rationalized on the basis of further cyclooligomerizations of the initially formed linear Adm-Cyst intermediate (Scheme 1). This notion was supported by the isolation of small amounts (ca. 5%) of linear polymer of the Adm-Cyst unit.

Molecular modeling and energy minimization[9] support the cavitand-like conformation of the 26-, 39-, 52-, and 65-membered macrocycles. The representations of the optimized structures[15] show that while the cavity is hydrophilic, the periphery consisting of repeating adamantane units is largely hydrophobic. This suggests that macrocycles **1**–**4** may harbor metal ions and transport them across membranes. This notion has been demonstrated experimentally.

The capability of compounds **1**–**3** to transport ions across model membranes (small unilamellar vesicles) was evaluated by monitoring the decay of a valinomycin-mediated K^+ diffusion potential[10, 11] and with a chlorotetracycline (CTC)/Ca^{+2} assay.[12, 15] The results show that dimer **1** transports Na^+ in preference to K^+, trimer **2** is more selective towards K^+, and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3510-1106 $ 15.00+.25/0

tetramer **3** shows negligible transport properties for both ions. None of the compounds were able to transport Ca^{+2} ions across the lipid bilayers, as judged by the CTC assay. The macrocycles did not cause the release of entrapped carboxyfluorescein, indicating that the movement of ions across the lipid bilayer was not due to the formation of large pores or detergentlike action.[13] The ion flux may thus be ascribed to a carrier-type of ion-transport mechanism like that of valinomycin.[14]

The cystine cyclic peptides **1**–**4** described here represent a new family of adamantane-containing cyclic peptides, which are capable of transporting Na^+ and K^+ ions across model membranes. This action and their very simple, short synthesis should be incentive for the design of related compounds in this novel class of cyclic peptides.

Experimental Procedure

A solution of freshly prepared 1,3-adamantane dicarbonyl dichloride (2 mmol) in dry CH_2Cl_2 (100 mL) was added dropwise over 0.5 h to a well-stirred solution of L-cystine dimethyl ester hydrochloride (2 mmol) and triethylamine (9 mmol) in dry CH_2Cl_2 (150 mL) at 0 °C. The reaction mixture was stirred at room temperature for 4–6 h and monitored by TLC. The reaction mixture was washed sequentially with ice-cold 2 N H_2SO_4, H_2O, and 5% $NaHCO_3$ (ca. 20 mL each). The organic layer was dried over $MgSO_4$ and concentrated in vacuo. The residue was chromatographed on silica gel with ethyl acetate/benzene (80/20) as eluent to afford macrocycles **1** (55%), **2** (15%) **3** (12%), and **4**(2%), and a small amount (ca. 5%) of a linear Adm-Cyst polymer.

[7] The 1,3-adamantanediyl unit appeared particularly attractive as a low molecular weight, rigid, lipophilic component for fixing the macrocycle in membranes.
[8] Interestingly, metal ion doping experiments with cyclic peptides **1**–**3** indicated a strong tendency for the uptake of alkali metal ions (FAB-MS). The signal intensity for $(1+M)^+$ and of $(2+M)^+$ appeared in the order of $Li^+ > Rb^+ > Cs^+ > K^+ > Na^+$ and for $(3+M)^+$ in the order of $Rb^+ > Cs^+ > K^+ > Na^+ > Li^+$.
[9] The models for macrocycles **1**–**3** were generated with the Biosym program package, version 2.3.5, a Silicon Graphics IRIS Crimson Elan Work Station. The energy minimization was done with INSIGHT and DISCOVER program packages (Biosym Technologies, San Diego, CA), using a consistent valence force field.

[13] Ion transport across membranes can take place either by carriers or by channel formers. The two mechanisms can be easily distinguished by monitoring the release of carboxyfluorescein (CF) trapped in lipid vesicles by fluorescence spectroscopy. Since a channel former leads to the formation of large pores in membranes, the trapped CF leaks out of the vesicles into the bulk medium, which causes a sudden enhancement of its fluorescence intensity due to dilution. Carrier molecules, on the other hand, diffuse through the hydrocarbon region of the membrane and do not cause the escape of CF into the medium, and hence no change in fluorescence is seen. In the present case, the absence of any fluorescence enhancement in the presence of macrocycles **1**–**3** implies that trapped CF is not released, and that ion transport occurs by a carrier-type mechanism, like that of valinomycin.

Directed Synthesis of Stable Hydrogen Polyphosphides: Preparation and Structural Characterization of HP_{11}^{2-} in $(NBnMe_3)_2HP_{11}$ and $(PBnPh_3)_2HP_{11}$ as Well as Its Comparison with the First "Naked" P_{11}^{3-} Ion in $(NEtMe_3)_3P_{11}$**

Nikolaus Korber,* Jörg Daniels, and Hans Georg von Schnering*

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

Recently, the surprisingly stable tetraphenylphosphonium salt of the dihydrogen heptaphosphide $H_2P_7^-$ was isolated and characterized by single-crystal X-ray structure analysis.[1] Even today, very little is known about hydrogen polyphosphides, which are situated between polyphosphanes[2, 3] and polyphosphides.[4] Phosphides and phosphanes with identical phosphorus frameworks (for example, P_7^{3-} [4] and heptaphosphane(3) P_7H_3,[5] both with the nortricyclane cage) are formally related by the Brønsted acid–base concept;[6] however, this formal relationship is difficult to prove experimentally, because the deprotonation of polyphosphanes as well as the protonation of the corresponding polyphosphides both lead to rapid decomposition. Therefore, partially protonated polyphosphides (or partially deprotonated polyphosphanes) are highly reactive species that have rarely been observed in practice. An exception has been a detailed study of the reaction between diphosphane(4) and *n*-butyllithium by Baudler et al., during which several partially lithiated polyphosphanes were detected as highly reactive intermediates by ^{31}P NMR spectroscopy.[7]

In solution, $(PPh_4)H_2P_7$ decomposes as well, yielding undefined higher polyphosphanes; as a crystalline solid, however, it is stable at room temperature and even in air, probably because of the spatial separation of the $H_2P_7^-$ ions by the large cations. $(PPh_4)H_2P_7$ forms in small yields during the reaction of K_3P_{11} with $(PPh_4)Cl$ in liquid NH_3.[1]

[**] The authors are grateful to Dr. W. Hoffbauer for the recording of the solid-state NMR spectra. Bn = benzyl.

Inspired by this serendipitous result, we have investigated possible directed synthetic routes to hydrogen polyphosphides that start from alkali metal polyphosphides. Essential features of such a synthesis are a "soft" protonation of the polyphosphide anions under mild conditions, for example in a solution of liquid NH_3 at low temperatures, and the trapping of the newly formed hydrogen polyphosphide ions with voluminous, noncoordinating cations like quaternary ammonium ions by precipitation as a weakly soluble salt.

We have found that the precise conditions of the protonation reaction were crucial: the simple addition of stoichiometric amounts of the universal acid in the ammonia system (NH_4^+ in the form of halide salts) was unsuccessful. Similarly, the use of urea, which is the ammonia system analogue to carbonic acid, did not produce the desired effect. Only when we employed a reaction that produced the acid in situ were quantitative and reproducible yields achieved. To this end, we used the oxidation of the solvent NH_3 by bromine, which proceeds even at low temperatures (e.g. $-33°C$) according to Equation (a).[8]

$$3Br_2 + 8NH_3 \longrightarrow 6NH_4Br + N_2 \uparrow \qquad (a)$$

Instead of adding bromine directly, it is much more advantageous to use the tribromides Br_3^- of the respective quaternary ammonium cations. Consequently, the halogen generating the acid as well as the quaternary cation that is needed to trap the hydrogen polyphosphide may be added in a simple manner combined in a single reagent.

According to this concept, Cs_3P_{11} and benzyltrimethylammonium tribromide react in liquid NH_3 to yield bis(benzyltrimethylammonium) hydrogen undecaphosphide (**1**), which is surprisingly stable and may even be handled in air for some

$$[N(CH_2C_6H_5)Me_3]_2HP_{11} \quad \mathbf{1}$$

time. HP_{11}^{2-} is the first hydrogen phosphide derived from the pentacyclic cage anion P_{11}^{3-} ("ufosane"),[9] which is built exclusively from fused five-membered rings. The crystal structure[10] confirms the expected cation-to-anion ratio of 2 to 1. The HP_{11}^{2-} anion is located on a twofold crystallographic axis (Fig. 1 top). Although this site symmetry is matched by the symmetry of the phosphorus cage (point group 23-D_3), it is not in agreement with the overall point group symmetry of HP_{11}^{2-}, since the hydrogen atom has to be bound to one of the two symmetry-inequivalent two-bonded phosphorus atoms (P2 and P3). Thus, HP_{11}^{2-} is orientationally disordered with respect to the hydrogen atom, which is difficult to locate by X-ray methods anyway. However, significant distortions of the P_{11} framework permit an unequivocal identification of the phosphorus atom at which the hydrogen atom is located. By the protonation, the atom in question has become a three-bonded phosphorus atom. This should result in longer bond lengths and a larger bond angle with respect to the neighboring atoms.[4] Precisely this is the case for the atom P3, which is situated on the twofold axis (P3–P5 2.196(2) Å compared to P2–P4 2.156(2) Å and P2–P6 2.163(2) Å; P5-P3-P5′ 99.11(8)° compared to P4-P2-P6 96.72(5)°).

Independent evidence for the presence of a hydrogen polyphosphide is provided by the FTIR spectrum, which shows a strong, sharp band at 2245 cm^{-1} assigned to a P–H stretching frequency.

The comparison of **1** with solid $(NEtMe_3)_3P_{11}$ (**2**), which is the first polyphosphide having only quaternary ammonium ions as counter cations, offered further opportunities to confirm our

Selected bond lengths [Å] and angles [°]: P1–P10 2.214(4), P1–P6 2.218(4), P1–P7 2.240(4), P2–P3 2.150(4), P2–P7 2.158(4), P3–P6 2.188(4), P3–P5 2.284(4), P4–P9 2.159(5), P4–P10 2.177(5), P4–P5 2.267(5), P5–P8 2.208(4), P6–P9 2.150(4), P7–P8 2.184(4), P8–P11 2.212(5), P10–P11 2.186(5), P11–H1 1.37(8); P3-P2-P7 96.15(1), P6-P9-P4 95.5(2), P10-P11-P8 98.7(2), P4-P10-P11 94.0(2), H1-P11-P10 105(3), H1-P11-P8 93(3).

results. Recently, some doubts concerning the stability of a compound of this type were caused by a publication by Eichhorn et al., who described the alkylation of P_7^{3-} by tetraalkylammonium ions under very mild conditions.[11] The two-bonded, formally negatively charged phosphorus atoms are evidently very strongly nucleophilic, and cause almost quantitative transfers of alkyl groups from the quaternary ammonium cations, which are known to be rather weak alkylating reagents. In fact, $(PPh_4)_2P_{16}$ was the only example of a polyphosphide with quaternary cations for a long time.[12] Compound **2** can be prepared by simple metathesis in liquid ammonia. It should be mentioned, however, that most of the analogous metathesis reactions with other quaternary ammonium ions are hampered by strong ion-pairing in the solutions, which leads to compounds retaining one or two alkali metal cations per formula unit.[13] The formation of **2** appears to be favored by an especially low solubility. The crystal structure analysis of **2**[14] reveals a further favorable fact: it is the first solid-state structure in which the threefold axis of the ufosane cage corresponds to a crystallographic axis. Therefore, the whole anion is generated by only five symmetry-inequivalent phosphorus atom sites (Fig. 2). A comparison of the bond lengths and angles at the two-bonded phosphorus atom P5 of **2** (P5–P3 2.164(2) Å, P5–P4 2.191(2) Å, P3-P5-P4 95.9(1)°) with the corresponding phosphorus atoms of **1** confirms that the

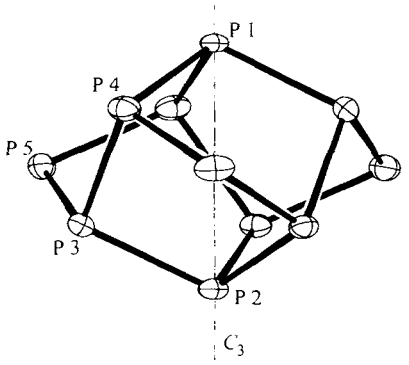

Fig. 2. P_{11}^{3-} in the crystal structure of **2** (ORTEP, 50% probability). Only the enantiomer with the occupancy factor of 87% is shown. Selected bond lengths [Å] and angles [°]: P1-P4 2.239(2), P2-P3 2.243(2), P3-P5 2.164(2), P3-P4 2.190(2), P4-P5 2.191(2); P4-P1-P4 102.0(1), P3-P2-P3 102.8(1), P5-P3-P4 99.7(1), P4-P3-P2 100.8(1), P3-P5-P4 95.9(1).

bonding situation of P3 in **1** (which we believe to be the phosphorus atom where the hydrogen atom is situated) is indeed more similar to that of a three-bonded phosphorus atom; the widening of the P-P-P angle on protonation is particularly significant.

Far more important was the use of **2** as a reference compound in the ^{31}P NMR study of **1**. Since solutions of this hydrogen polyphosphide were again unstable (in analogy to $(PPh_4)H_2P_7$), we had to recur to MAS solid-state NMR spectroscopy (MAS = magic angle spinning). The interpretation of the solid-state NMR spectrum of **1**, which was hampered by rather broad signals and extended overlap of side bands, was greatly facilitated by the comparatively simple NMR spectrum of **2**. Four isotropic signals were observed in the NMR spectrum of **2**, two of which are very close together ($\delta = 174.5$ and 167.9), the remaining signals are at $\delta = -102.3$ and -209.4. The integration of the corresponding signal groups results in a ratio of 6:2:3, which indicates that the two adjoining signals may be assigned to the atoms P3 and P4, which are chemically very similar but crystallographically inequivalent. The signal at $\delta = -102.3$ corresponds to the two atoms on the threefold axis, the signal at $\delta = -209.4$ to the two-bonded atom P5. These assignments helped us to identify the signal of the two-bonded P2 ($\delta = -220$) in the solid-state spectrum of **1**, which displays all the six isotropic signals expected for six crystallographically inequivalent phosphorus atoms. The integration results in a ratio of 2:9 for the signal associated to P2 relative to the remaining signals in the region of three-bonded phosphorus ($\delta = -82, -59, 121, 140, 155$). The latter cannot be separated reliably by integration because of the extended overlap of the side bands. Only the signal at $\delta = 140$ exhibits significant line narrowing following P–H decoupling. It is very probable that this signal can be assigned to the phosphorus atom P3 where the hydrogen atom is situated.

A second synthetic route to hydrogen polyphosphides makes use of large, noncoordinating cations, which are very weak proton donors themselves. A simple example is the benzyltriphenylphosphonium cation, which forms stable benzylidenetriphenylphosphorane upon deprotonation. Accordingly, a second example of a salt of the anion HP_{11}^{2-} was synthesized starting from Cs_3P_{11} and benzyltriphenylphosphonium bromide [Eq. (b)]. Again, a single reagent performs both of the tasks

$$3\,(C_6H_5)_3P^+\text{-}CH_2C_6H_5 + P_{11}^{3-} \longrightarrow \underset{\mathbf{3}}{((C_6H_5)_3PCH_2C_6H_5)_2HP_{11}}\downarrow + (C_6H_5)_3P{=}CHC_6H_5 \qquad \text{(b)}$$

mentioned above: it serves as a proton donor as well as a supply of voluminous cations for the crystallization of the newly formed hydrogen polyphosphide. As was the case with **1**, the distortion of the cage demonstrated by the X-ray data[15] permits the unequivocal identification of the protonated phosphorus atom in **3** (Fig. 1 bottom). Even the position of the hydrogen atom itself was localized and refined (with due caution, because the crystal was of low quality).

Both the synthetic routes described above allow the directed synthesis of hydrogen polyphosphides for the first time. The anions are isolated by the use of quaternary cations as stable solids, offering a convenient access to the chemistry of these species that are highly reactive in solution.

Experimental Procedure

Cs_3P_{11} was synthesized from the elements according to the procedure given in the literature [16] and recrystallized from dry liquid NH_3. All manipulations were carried out under strictly inert conditions. **1**: Cs_3P_{11} (ca. 0.5 mmol) and benzyltrimethylammonium tribromide (Aldrich) were placed into opposite sides of an U-shaped reaction vessel fitted with a glass frit (porosity 3) separating the two sides (molar ratio 1:2). NH_3 (ca. 50 mL) dried over potassium was frozen into the vessel at 77 K. The vessel was allowed to warm slowly to 233 K. After 12 h, **1** formed as red needles of ca. 1 cm length. After the removal of the solvent, CsBr and excess NH_4Br were removed by washing with liquid NH_3 (3 × 20 mL). Yield with respect to Cs_3P_{11}: 94%.

2: Analogous procedure to that for **1**, except that ratio Cs_3P_{11} to ethyltrimethylammonium iodide (Fluka) 1:3. Preparation of single crystals by a longer diffusion path (25 cm). Yield with respect to Cs_3P_{11}: 90%.

3: Analogous procedure to that for **1**, except that ratio Cs_3P_{11} to benzyltriphenylphosphonium bromide (Lancaster) 1:3. Compound **3** formed red ductile crystals, which were mixed with yellow crystals of the benzylidene-phosphorane (identification by X-ray crystal structure analysis). Separation by washing with diethyl ether. Yield: 80%.

Solid-state NMR: Varian Unity 400, ^{31}P frequency 161.419 MHz, spinning frequencies 7–11 kHz, pulse angle 3 ms, 40 (**1**) 240 (**2**) transients, respectively, pause between pulses 120 s, decoupling at 60 kHz, reference 85% H_3PO_4.

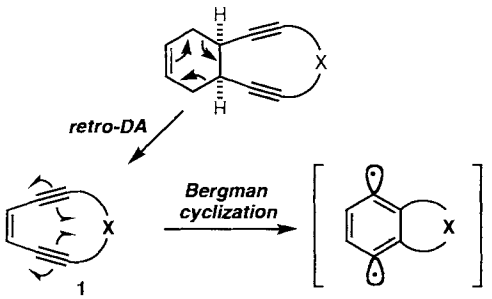
Enediyne Generation by a Retro-Diels–Alder Reaction**

Mark E. Bunnage and K. C. Nicolaou*

The enediyne anticancer antibiotics are potent DNA-cleaving agents with highly unusual molecular architecture and fascinating modes of action.[1] The biological activity of these complex molecules derives from the ability of their 1,5-diyn-3-ene ("enediyne") motif to undergo Bergman cycloaromatization[2] (Scheme 1), thereby generating a highly reactive 1,4-diradical that can abstract hydrogen atoms from the backbone of DNA and thus effect DNA scission.[1] Much recent interest in the enediyne field has focused upon the design and synthesis of simple molecules that utilize the enediyne unit as a "warhead" for damaging DNA.[3]



Scheme 1. General concept for the generation of enediynes by the retro-Diels–Alder reaction and Bergman cyclization of the enediynes.

The propensity of a cyclic enediyne to undergo cycloaromatization and form the reactive 1,4-diradical species depends on the nature of the tether (X) between the two alkyne units (Scheme 1). For example, we have shown that while the simple cyclodecenediyne (**1**) (X = $(CH_2)_4$) spontaneously cyclizes at ambient temperature ($t_{1/2} = 18$ h at 37 °C), the corresponding 11-membered ring congener (X = $(CH_2)_5$) is quite stable.[4] Although ring size has a direct bearing on the stability of a cyclic enediyne, many other factors are known to play an important role.[4] This is exemplified by the naturally occurring enediyne antibiotics such as calicheamicin γ_1^I and dynemicin A, in which the enediyne unit is part of a ten-membered ring but rendered stable by conformational restraints.[5] It is believed that the bioactivation of these molecules leads to a change in conformation of the ten-membered ring such that the triple bonds are brought into closer proximity and the Bergman cyclization is initiated.[1]

In light of the above considerations, the incorporation of an intact enediyne unit into a synthetic sequence could prove problematic, and it would be particularly advantageous to develop a convenient and stable masked form from which the enediyne could be readily liberated when desired. Not only could such a precursor prove useful in the preparation of naturally occurring enediynes but, perhaps more importantly, it should also facilitate the synthesis of enediynes containing alternative tethering groups (X). The generation of reactive enediynes in this manner would constitute a triggering mechanism for the formation of 1,4-diradicals and could thus be of potential application in the development of new prodrugs.

A particularly attractive progenitor for an enediyne is the corresponding 1,5-diyne, which lacks the internal double bond and is thus unable to aromatize. A number of groups have investigated procedures for developing enediynes from stable 1,5-diyne precursors,[6] and strategies for olefin generation based on the reductive activation of anthraquinone,[7] benzylic oxidation,[8] base-induced elimination,[9] photochemical elimination,[10] and the Corey–Winter reaction[11] have all been developed. Nevertheless, a variety of other strategies for introduction of the enediyne olefin component can be envisaged, and we were interested in the application of the retro-Diels–Alder reaction (retro-DA) in this context (Scheme 1).

The utility of the retro-Diels–Alder reaction as a method for alkene synthesis has generally been hampered by the high temperatures required to effect cycloreversion (≫150 °C).[12] Since such temperatures would not be compatible with enediyne generation, we sought to identify a system that could be activated under much less forcing conditions. In 1983 Knapp and coworkers[13] demonstrated that Diels–Alder adducts derived from 9-benzyloxymethoxyanthracene (**2**) undergo facile cycloreversion at 25 °C after removal of the benzyloxymethoxy (BOM) protecting group and deprotonation of the resultant alcohol. This important observation has its origins in the remarkable ability of the oxide anion to accelerate pericyclic reactions (often by factors approaching 10^{17}), as first demonstrated by Evans and Golob[14] in the highly exploited anionic oxy-Cope reaction.[15] Although the oxide anion accelerated retro-Diels–Alder reaction has received only scant attention from synthetic organic chemists,[16] it nevertheless appeared ideally suited for our purposes and we decided to investigate the use of **2** as a platform for the generation of enediynes.

We consequently targeted the 1,5-diyne **3** (Scheme 2) as a key intermediate from which a variety of cyclic enediynes could in

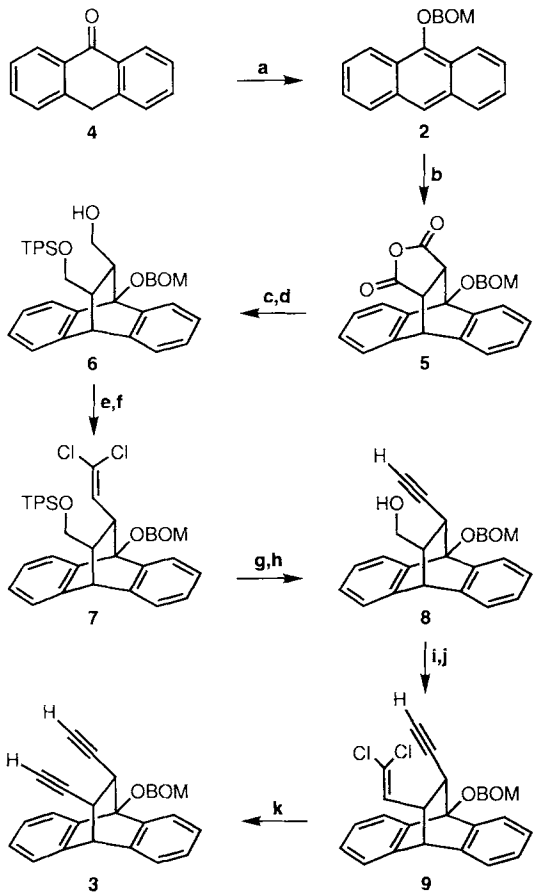
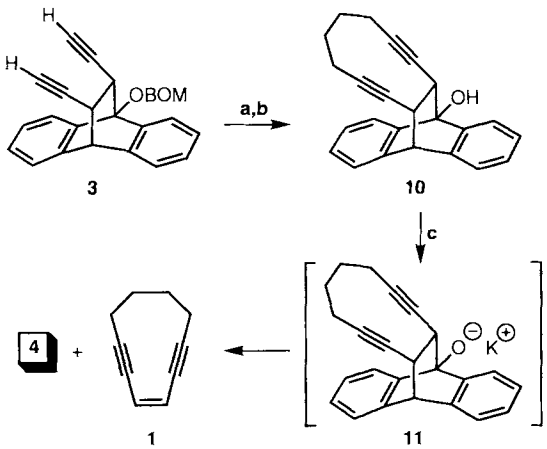


Scheme 2. Synthesis of diyne **3**. Reagents and conditions: a) 1.2 equiv of NaH, THF, 0 °C, 45 min; 1.2 equiv of BOMCl, 1.5 h, 85%; b) 1.0 equiv of maleic anhydride, PhH, reflux, 8 h, 100%; c) 4.25 equiv of $LiAlH_4$, THF, reflux, 12 h, 95%; d) 1.0 equiv of TPSCl, 2.0 equiv of imidazole, 0 → 25 °C, 2.0 h, 63% (+ 25% regioisomer); e) 1.5 equiv of NMO, 0.025 equiv of TPAP, MeCN, 25 °C, 0.5 h, 95%; f) 6 equiv of CCl_4, 3 equiv of $P(NMe_2)_3$, THF, −30 → 0 °C, 1.5 h, 83%; g) 2.1 equiv of *n*BuLi, THF, −78 → 0 °C, 0.5 h, 100%; h) 10 equiv of TBAF, THF, 25 °C, 2 h, 94%; i) 1.5 equiv of NMO, 0.05 equiv of TPAP, CH_2Cl_2/MeCN (9:1), 25 °C, 15 min, 80%; j) 6 equiv of CCl_4, 3 equiv of $P(NMe_2)_3$, THF, −30 °C, 15 min, 84%; k) 3.2 equiv of *n*BuLi, THF, −78 °C, 0.5 h, 45%. BOM = CH_2OCH_2Ph; TPS = *t*$BuPh_2Si$; NMO = 4-methylmorpholine *N*-oxide; TPAP = tetra-*n*-propylammonium perruthenate(VII); TBAF = tetra-*n*-butylammonium fluoride.

tion using the standard Corey–Fuchs procedure[18] was investigated, we obtained superior results by converting the aldehyde to the dichloroolefin **7** with hexamethylphosphorus triamide (HMPA) and CCl_4 in THF at −30 °C (83% yield).[19] Gratifyingly, the transformation of **7** to the desired alkyne occurred in quantitative yield by treatment with *n*-butyllithium, and subsequent desilylation using TBAF cleanly furnished the alcohol **8** (94% yield).

The second alkyne unit was introduced analogously. Thus, oxidation of **8** using TPAP–NMO[17] afforded the corresponding aldehyde in 80% yield. Although rather sensitive, this intermediate aldehyde could be converted, without epimerization, to the dichloroalkene **9** with HMPA/CCl_4 (84% yield). Finally, treatment of **9** with *n*-butyllithium gave the targeted 1,5-diyne **3**[20] in moderate yield (45%).

We were now in a position to investigate whether **3** could function as a platform for the generation of cyclic enediynes. In view of the difficulty in preparing cyclodecenediyne (**1**),[21] and its recognized potential as a DNA-cleaving agent,[4] this enediyne was selected to test the retro-Diels–Alder strategy and, therefore, **10** (Scheme 3) became our next synthetic target. We



Scheme 3. Synthesis of precursor **10** and base-induced retro-Diels–Alder reaction to form enediyne **1**. Reagents and conditions: a) 2.3 equiv of *n*BuLi, 4 equiv of HMPA, THF, −78 °C, 0.5 h; 1.2 equiv of $I(CH_2)_4I$, −78 → 25 °C, 12 h, 52%; b) 10% TFA in MeOH, reflux, 1 h, 94%; c) KH, THF, 25 °C, 30 min, 90%.

principle be generated. The synthesis of **3** commenced with the preparation of **2** through treatment of the sodium salt of anthrone (**4**) with benzyloxymethyl chloride (BOMCl) (85% yield). The Diels–Alder reaction of **2** with maleic anhydride proceeded without difficulty to afford the adduct **5** in quantitative yield, and this was converted to the corresponding 1,4-diol by reduction with $LiAlH_4$ (95% yield). Initial attempts to oxidize this diol to the dialdehyde proved disappointing, and a stepwise strategy for the introduction of the acetylenic groups was pursued. Thus, protection of the diol with *tert*-butyldiphenylsilyl chloride (TPSCl) provided **6** in 63% yield together with 25% yield of the readily separable regioisomeric alcohol. The selectivity in this reaction (ca. 2:1) is presumably a consequence of the BOM protecting group shielding the proximate hydroxyl moiety from attack, possibly by engaging in intramolecular hydrogen bonding. Importantly, the minor alcohol could be recycled easily through desilylation using tetrabutylammonium fluoride (TBAF) (95% yield).

To prepare for the generation of the first alkyne unit, the alcohol **6** was oxidized to the corresponding aldehyde by the TPAP–NMO protocol[17] (95% yield). Although homologa-

first designed **3** with the supposition that the two alkyne moieties would be locked into a *syn* orientation and intramolecular bisalkylation of the dialkynyl dianion with dihaloalkanes would thus be facilitated.[22] This hypothesis was realized, since treatment of **3** with *n*-butyllithium in THF at −78 °C in the presence of HMPA, followed by addition of 1,4-diiodobutane, led smoothly to the desired cyclic 1,5-diyne in 52% yield. Finally, the target alcohol **10** was revealed (94% yield) by removal of the BOM protecting group using trifluoroacetic acid (TFA) in methanol.[23]

Although alcohol **10** proved highly stable under neutral or acidic conditions, deprotonation to form the oxide anion **11** led, as anticipated, to the desired retro-Diels–Alder cycloreversion. Thus, when **10** was treated with potassium hydride in THF at 25 °C, the reaction mixture developed a deep orange color, consistent with the generation of the potassium salt of anthrone, and **1** was generated cleanly (TLC analysis; $R_f = 0.31$ (silica gel, petroleum ether)[4]). Although **1** does undergo Bergman cycloaromatization at ambient temperature, it is stable enough to isolate,[4] and we were able to secure **1** in 90% yield from **10** by preparative TLC on silica gel.

In conclusion, we have demonstrated that the oxide anion accelerated retro-Diels–Alder reaction can be employed for the facile generation of cyclic enediynes from 1,5-diyne precursors. The use of 9-BOM-anthracene (**2**) to mask the double bond of the enediyne offers the advantages of excellent stability towards a variety of synthetic transformations and convenient removal when desired. Although the enediyne precursor is highly stable under acidic or neutral conditions, treatment with base leads to rapid cycloreversion and development of the enediyne. This methodology offers significant scope for the generation of new cyclic enediynes. Precursors such as **11** have potential as novel prodrugs when conjugated to appropriate delivery systems.

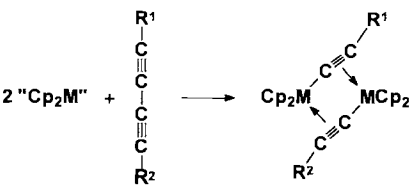
Nickel(0) Complexes of Five-Membered Titana- and Zirconacyclocumulenes as Intermediates in the Cleavage of C–C Bonds of Disubstituted Butadiynes**

Siegmar Pulst, Perdita Arndt, Barbara Heller, Wolfgang Baumann, Rhett Kempe, and Uwe Rosenthal*

Dedicated to Professor Paul Binger on the occasion of his 65th birthday

Oxidative addition to transition metal complexes is known for many compounds with a large variety of bonding types, but C–C single bonds react only very rarely in this manner.[1] Due to the high synthetic potential of the functionalization of hydrocarbons, and because of the significance of catalytic conversions, reactions of this kind are currently enjoying a great deal of attention.[2] Among these reactions, the activation and cleavage of the central C–C single bond in certain 1,4-disubstituted 1,3-butadiynes ($R^1C{\equiv}C{-}C{\equiv}CR^2$) by Os,[3a] Ti,[3b] Zr,[3c] and Ni [3d] complexes has been investigated intensely over the last few years. It is already known that when using "Cp_2Ti" and "Cp_2Zr" the success of the cleavage reaction [Eq. (a)] depends on the influence of the metal[3c] and of the substituents,[4] as well as on the stoichiometry.[5]



(a)

Moreover, in some cases, the cleavage is only successful if suitable heterobimetallic complexes are used instead of homobimetallic complexes. When the substituents R^1 and R^2 are *tert*-butyl groups, only the combination of Ti and Zr leads to the σ-π-acetylide-bridged complex $[Cp_2Ti(\mu\text{-}\eta^1,\eta^2\text{-}C{\equiv}CR)_2Zr\text{-}Cp_2]$,[5] whereas the reaction with solely "Cp_2Ti" or "Cp_2Zr"

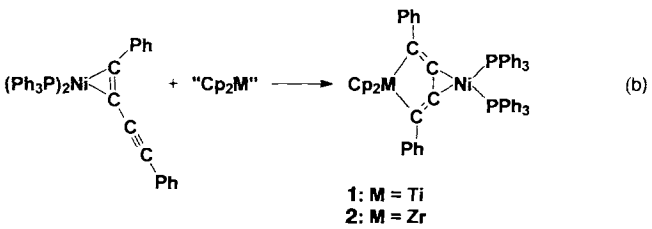
[**] This work was supported by the Max-Planck-Gesellschaft and the Fonds der Chemischen Industrie.

leads to the formation of the five-membered metallacyclocumulenes $[Cp_2M{-}CR^1{=}C{=}C{=}CR^2]$ (M = Ti,[5] M = Zr[6]). The reaction of butadiyne Ni^0 complexes $[(Ph_3P)_2Ni(\eta^2\text{-}R^1C{\equiv}C{-}C{\equiv}CR^2)]$ with metallocenes has also been employed to cleave diynes. This resulted in substituent-dependent "tweezer-like" ($R^1 = SiMe_3$, $R^2 = Ph$) or unsymmetrical σ-π-acetylide-bridged heterobimetallic complexes ($R^1 = R^2 = SiMe_3$); the mechanism of formation remains the subject of speculation as yet.[7]

We report now that in the reaction of the complex $[(Ph_3P)_2Ni(\eta^2\text{-}PhC{\equiv}C{-}C{\equiv}CPh)]$ with "Cp_2Ti" and "Cp_2Zr" without cleavage of the diyne a new type of complex is formed (**1** and **2** respectively), which can be considered as an intermediate in the heterobimetallic cleavage reactions. This is also of theoretical interest from a bonding point of view as a metallacyclocumulene bonded to a Ni(0) complex fragment [Eq. (b)].



(b)

The titanium compound **1**[8] is readily soluble in benzene and THF, but only slightly soluble in *n*-hexane. In the IR spectrum there are no characteristic peaks for complexed C≡C triple bonds in the region of 1900–1600 cm^{-1}. The ^1H NMR [δ_{Cp} = 5.04 (s, 10H)] and ^{31}P NMR [δ = 21.2 (s)] spectra confirm a symmetrical coordination of the butadiyne.

The crystal structure analysis[9] of **1** (Fig. 1) shows that the central double bond of the titanacyclocumulene complex is formally coordinated to the $Ni(Ph_3P)_2$ fragment. This indicates that the compound $[Cp_2Ti{-}C(tBu){=}C{=}C{=}C(tBu)]$[5] really does exist in the form of a cyclocumulene and not in the form of a complex with η^4-bonded butadiyne.[10] Both the metal centers and the C_4 unit between them lie in a single plane and the P1-Ni-P2 plane is twisted at an angle of 35.0° to this (cf. the twist of the P-Ni-P plane in $[(Ph_3P)_2Ni(H_2C{=}CH_2)]$: 3–7°[11]).

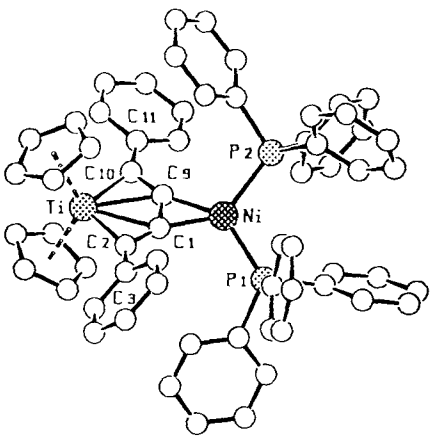


Fig. 1. Selected bond lengths [Å] and angles [°] in **1**: C2-C1 1.316(7), C1-C9 1.419(6), C9-C10 1.334(6), Ni-C1 1.916(5), Ni-C9 1.906(4), Ni-P1 2.227(1), Ni-P2 2.233(1), Ti-C2 2.124(4), Ti-C1 2.325(4), Ti-C9 2.340(5), Ti-C10 2.118(5), Ti-Z1 2.110, Ti-Z2 2.114; C2-C1-C9 137.2(4), C1-C9-C10 135.4(4), C1-C2-C3 134.0(4), C9-C10-C11 132.3(4), C2-Ti-C10 103.7(2), P1-Ni-P2 111.48(5), C9-C1-Ni 67.8(3), C1-C9-Ni 68.6(3), Z1-Ti-Z2 129.36.

Table 1. Selected bond lengths [Å] in **1**, **3**, and **4**.

Bond	1	3	4
Ti-C_α	2.118(5), 2.124(4)	2.252(9), 2.298(10)	2.141(5), 2.172(5)
Ti-C_β	2.325(4), 2.340(5)	2.209(9), 2.213(9)	-
C_α-C_β	1.316(7), 1.334(6)	1.243(13), 1.276(11)	1.369(6), 1.370(6)
C_β-$C_{\beta'}$	1.419(6)	1.339(13)	1.495(6)

Comparison of the data in Table 1 confirms the description of **1** as a titanacyclocumulene coordinated to a Ni^0 compound. The interatomic distances and angles in the TiC_4 unit in **1** are similar to those in the noncoordinated titanacyclocumulene **3**[5] and in the titanacyclopentadiene **4**.[12]

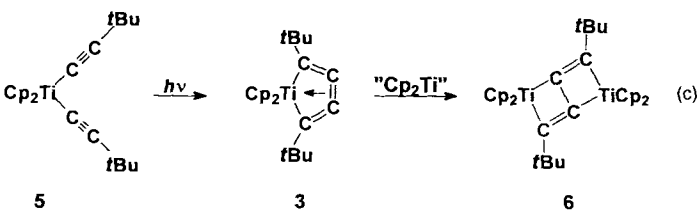
$[Cp_2Ti{-}C(tBu){=}C{=}C{=}C(tBu)]$ **3**

$[Cp_2Ti{-}CPh{=}CPh{-}CPh{=}C(Ph)]$ **4**

The central $C_\beta{-}C_{\beta'}$ bond in **1** (1.419(6) Å) is 0.08 Å longer than that in **3** and thus lies in the range for double bonds in coordinated olefins (cf. $d_{C=C}$ in $[(Ph_3P)_2Ni(H_2C{=}CH_2)]$ 1.43(2) Å[12]). The $C_\alpha{-}C_\beta$ bonds in **1** (1.316(7), 1.334(6) Å) are almost as long as those in **4** (1.369(6), 1.370(6) Å) and the Ti–C_α distances in **1** (2.118(5), 2.124(4) Å) only differ slightly from those in **4** (2.141(5), 2.172(5) Å). Whereas in **3** the Ti–C_β distances (2.209(9), 2.213(9) Å) are shorter than the Ti–C_α distances (2.252(9), 2.298(10) Å), in **1** the situation is the other way around and the Ti–C_β distances (2.325(4), 2.340(5) Å) are about 0.2 Å longer than the Ti–C_α distances.

The zirconocene compound **2** was also synthesized analogously and it displays similar spectroscopic and structural properties.[9, 13] The compounds **1** and **2** can be regarded as coordinated metallacyclocumulenes in which the interaction of the central C=C bond with the Ti atom and the Zr atom[5, 6] is weakened in favor of the interaction with the Ni atom. The isolation of **1** and **2** seems to become possible through the presence of the phenyl substituents on the diyne, because in the case of Me_3Si-substituted butadiynes there is an increased tendency towards activation of the C–C single bond.[3b, 3c, 4]

The significance of the compounds **1** and **2** for the activation of the heterobimetallic C–C single bond lies in that their existence makes the occurrence of metallacyclocumulene intermediates appear probable in the cleavage of butadiynes. Recent investigations also show that in the reverse reaction of the classical combination of acetylide groups with metallocenes to give butadiynes,[10, 14] cyclocumulenes can be identified under photochemical conditions [Eq. (c)].



(c)

Under photochemical conditions complexes of the type $[Cp_2TiR_2]$[15] ($R = CH_3$) and $[Cp_2TiAr_2]$[16] ($Ar = C_6H_5$, $CH_3C_6H_4$) can undergo a typical C–C combination which was also suspected for acetylides in earlier works.[17] On irradiating the complex $[Cp_2Ti(C{\equiv}CtBu)_2]$ **5** with light of the wavelength range 390–450 nm, the course of the reaction as shown in Equation (c) could be unequivocally confirmed qualitatively for the

first time by monitoring concentration profiles characteristic of a consecutive reaction by time-dependent NMR spectroscopic techniques (Fig. 2).

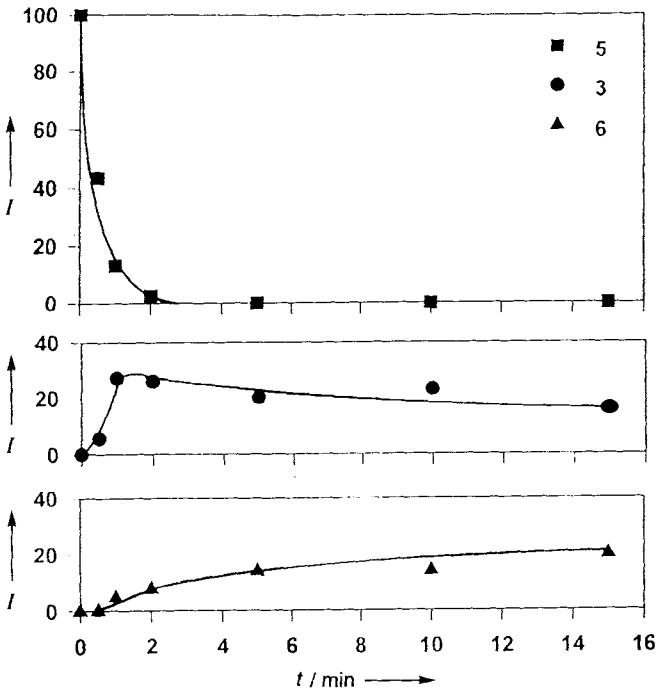


Fig. 2. NMR spectroscopic monitoring of the reaction of **5** to give **6** [see also Eq. (c) and (d)]. Intensities I [%] of the Cp protons of **5** (top), **3** (middle), and **6** (bottom) as a function of time. 0 min: 100% **5**, 0% **3**, 0% **6**; 0.5 min: 43% **5**, 6% **3**, 0% **6**; 1 min: 13% **5**, 27% **3**, 5% **6**; 2 min: 3% **5**, 26% **3**, 8% **6**; 5 min: 0% **5**, 20% **3**, 14% **6**; 10 min: 0% **5**, 23% **3**, 14% **6**; 15 min: 0% **5**, 16% **3**, 20% **6** (total yield 36% with respect to titanium).

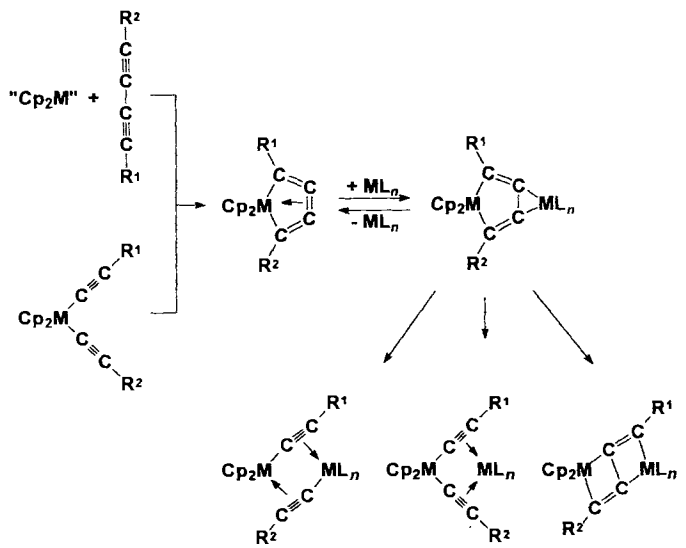
According to this, the σ-bis-acetylide **5** decays very rapidly; the amount of the intermediate **3** formed passes through a maximum. This reacts with "Cp_2Ti" as described[5] to give the binuclear complex **6**.[4] In addition, significant amounts of paramagnetic side products are formed. Both the oxidative addition to metallocene systems and the reductive elimination of butadiynes from metallocene systems can thus be explained by the formation of metallacyclocumulenes and their interaction with a second complex (Scheme 1).



Scheme 1. Formation and reactions of metallacyclocumulenes.

The binuclear complexes formed can then react further in a variety of different ways; the metals, the butadiyne substituents, and the stoichiometry are decisive for the course of the reaction.

Experimental Procedure

All manipulations were carried out under the exclusion of oxygen and moisture.

1: [$(Ph_3P)_2Ni(\eta^2$-PhC≡C–C≡CPh)] (560 mg, 0.71 mmol) in toluene (20 mL) and [$Cp_2Ti(Me_3SiC{\equiv}CSiMe_3)$] (250 mg, 0.71 mmol) in toluene (15 mL) were allowed to react at 40 °C for 4 h. All volatile components were then removed under vacuum and the residue recrystallized from toluene at 50 °C to give dark brown needles of **1**. Yield: 250 mg (36%), m.p. 163–165 °C (decomp.), correct elemental analysis.

2: Dark brown crystals of **2** were obtained analogously to **1** from [$(Ph_3P)_2Ni(\eta^2$-PhC≡C–C≡CPh)] (715 mg, 0.91 mmol) and [$Cp_2Zr(thf)(Me_3SiC{\equiv}CSiMe_3)$] (430 mg, 0.91 mmol) in THF. Yield: 235 mg (25%), correct elemental analysis.

Photolysis of **5**: Six samples of a [D_8]THF solution of **5** (0.04 M) were sealed in NMR tubes and without further cooling irradiated with light of the wavelength range 390–450 nm (HPM-12-Philips 460 W, 1 cm distance) for different periods of time (0.5, 1, 2, 5, 10 and 15 min). NMR spectra were subsequently recorded. The resonances of the protons of the Cp rings in **5**, **3**, and **6** [δ = 6.23 (**5**), 5.05 (**3**), 5.45 (**6**)] in the ^{1}H NMR spectrum ([D_8]THF, quantitative standard C_6H_6) can easily be distinguished from one another.

Formation of Fe^{IV} and Ni^{IV} by Electrochemical and Chemical Oxidation of an Iron-Substituted Nickel(II) Hydroxide: The Direct Two-Electron Step $Ni^{II} \rightarrow Ni^{IV} + 2e^-$**

Peter Axmann, Christina Freire Erdbrügger, Dieter H. Buss and Oskar Glemser*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

Nickel(II) hydroxide crystallizes in the layered structure of brucite. Allmann[1] reported that partial substitution of nickel(II) ions with suitable metal(III) ions results in pyroaurite-type double layered structures of the general formula **1** ($0.2 \leq x \leq 0.4$,

$$\underset{K^{x+}}{[Ni^{II}_{1-x}M^{III}_x(OH)_2]^{x+}}\underset{A^{x-}}{[(X^{n-})_{x/n}(H_2O)_z]^{x-}} \quad \mathbf{1}$$

phase width of the pyroaurite type). The random anionic layers A^{x-} (X = anions of the applied metal salts) are found between the brucite-like cationic layers K^{x+}; the cations in K^{x+} are statistically distributed.[2]

By substitution with Al^{III},[3–5] Co^{III},[4] Mn^{III},[5] and in particular Fe^{III} ions,[6] along with variation of the anion of the metal salt, for example NO_3^-, CO_3^{2-}, SO_4^{2-}, and $SO_4^{2-} + PO_4^{3-}$,[4, 6c, 7] we have been able to improve the electrochemical characteristics of nickel hydroxide with respect to applications as a positive electrode for secondary cells in alkaline electrolytes.[3–7] The molar ratio of Ni^{II}:M^{III} = 4:1 (x = 0.2) was shown to be the best.[3, 8] The substitution with various different M^{III} ions was also successful.[5b]

The remarkable electrochemical characteristics of the Ni/Fe electrode, which we first described,[4, 6] have been confirmed by Delmas et al.[9] During the electrochemical redox process,[10] which is a proton–electron exchange reaction between the pyroaurite-type and γ-NiOOH layers,[11] Faraday yields were found which are larger than the theoretical value for the one-electron step $Ni^{II} \rightarrow Ni^{III} + 1e^-$.[12] This signifies the formation of Ni^{IV} ions.[13] The question of whether the Fe^{III} ions also take part in this electrochemical redox process could be clarified for the first time by studying the Mössbauer spectra[14] of Fe^{III}-substituted pyroaurite-type nickel hydroxides with carbonate as well as sulfate–phosphate ions.[4]

In the following we will present and discuss the results of Mössbauer spectroscopic investigations of the charged and discharged states of an electrode made up of the iron-substituted, carbonate-containing pyroaurite-type nickel hydroxide **2**.[15]

$$[Ni_{4.06}Fe_{0.94}(OH)_{10}]^{+0.94}[(CO_3^{2-})_{0.21}(HCO_3^-)_{0.59}(K^+)_{0.0}\text{-}(H_2O)_{4.66}]^{-0.94} \quad \mathbf{2}$$

The Mössbauer spectrum of the discharged electrode (Fig. 1a) shows two absorption bands. This corresponds to two doublets with isomer shifts δ of +0.34 and +0.44 mm s^{-1},[16]

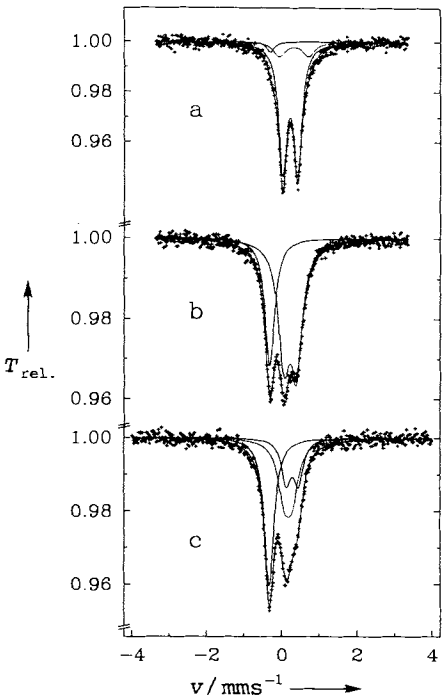

Fig. 1. Mössbauer spectra of an Fe^{III}-substituted pyroaurite-type electrode, v = relative speed between the source and the absorber, T_{rel} = relative transmission. a) Ni/Fe/CO_3 (discharged), b) Ni/Fe/CO_3 (charged), c) NiFe245 (charged); all fits according to model 3 (see text).

which are characteristic for Fe^{III} ions in the high-spin state, as well as to a less intense singlet at $\delta = -0.18$ mm s^{-1}, to whose meaning we will later return. Since both quadrupole doublets show no Lorentz profile, a distribution of quadrupole splittings for the respective isomer shifts must be assumed in order to fit the spectra. This is indicative of different sorts of Fe^{III} ions in slightly varying positions. Similar results were observed with a charged electrode. The quadrupole splittings ΔE_Q presented in Table 1 represent the values at the maxima of the quadrupole distributions.

The typical Mössbauer spectrum of a charged electrode (Fig. 1b) shows signals at $\delta = -0.19, +0.18$, and +0.52 mm s^{-1}. Several interpretation models must be considered.

Model 1: The signals correspond to a doublet and a singlet, both with $\delta = +0.17$ mm s^{-1}; this can be interpreted as low-

Table 1. Mössbauer data for charged and discharged Ni/Fe/CO_3 as well as NiFe245.

Sample	Modell	δ [mm s^{-1}]	ΔE_Q [mm s^{-1}]	Proportion [%]	χ^2
Ni/Fe/CO_3, charged	1	+0.17	0.73	40	1.38
		+0.17	-	60	
	2	+0.52	-	40	1.26
		−0.01	0.37	60	
	3	+0.34	0.34	70	1.13
		−0.19	-	30	
NiFe245	3	+0.40	0.32	23	1.05
		+0.29	≤0.20	37	
		−0.20	-	40	
Ni/Fe/CO_3, discharged	3	+0.34	0.40	82	1.01
		+0.44	0.70	14	
		−0.18	-	4	

spin Fe^{III}. However, with $\chi^2 = 1.38$, this model shows the worst fit of all the alternatives discussed below. This model can be discounted by comparing with the spectrum of another charged electrode with a similar average degree of oxidation but significantly stronger distinction of the signal at $\delta = -0.19$ mm s^{-1} (sample of NiFe245: $\delta = -0.20$ mm s^{-1}, Fig. 1c). The described interpretation can only be applied unter the condition of a strong deviation of the line intensity in the quadrupole doublet. This is highly improbable even with a very large textural contribution.

Model 2: The signals correspond to a doublet at $\delta = -0.01$ mm s^{-1} and a singlet at $\delta = +0.52$ mm s^{-1}. With $\chi^2 = 1.26$ the quality of the fit is better than that for model 1. The isomer shift $\delta = -0.01$ mm s^{-1} is typical for low-spin Fe^{IV}.[17] From a chemical point of view the presence of this state is more probable than the high-spin configuration due to the expected high covalent contribution of the Fe^{IV}–O bond. However, no meaningful explanation can be provided for the singlet. Its isomer shift lies between the typical values for Fe^{III} and Fe^{II} ($\delta = 0.33-0.40$ and 1 mm s^{-1}, respectively), which indicates an increase in electron density on the Fe ion. Such a partial reduction of the Fe^{III} ions is extremely unlikely in the strongly oxidizing γ-NiOOH matrix. Fe^{II} itself is a strong reducing agent in a hydroxide environment. Therefore, this model can also be eliminated.

Model 3: The signals correspond to a singlet at $\delta = -0.19$ and a doublet at $\delta = +0.34$ mm s^{-1}. With $\chi^2 = 1.13$ this model shows the best fit and can be very well applied to the spectrum of the comparison electrode NiFe245 (Fig. 1c): the assignment of two doublets at $\delta = +0.40$ and $+0.29$ mm s^{-1} as well as a singlet at $\delta = -0.20$ mm s^{-1} gives a good fit with $\chi^2 = 1.05$. The signals at $+0.40$ and $+0.29$ mm s^{-1} can be interpreted as high-spin Fe^{III} ions. As described below the singlet at -0.20 mm s^{-1} is from Fe^{IV}. While models 1 and 2 basically require alterations of all the iron ions, in model 3 only a part of the Fe ions are affected. As a result, models 1 and 2 were eliminated and model 3 has been chosen for the basis of the interpretation of the charged electrode.

The measured isomer shift $\delta = -0.19$ mm s^{-1} (Fig. 1b) can, according to literature data, be assigned to high-spin Fe^{IV} ions,[13, 18] which are found in generally about 30% content in the charged Ni/Fe/CO_3 electrodes. The absence of quadrupole splitting indicates approximately undistorted octahedral symmetry of the environment (O_h symmetry of the $Fe^{IV}O_6$ octahedron). The remaining 70% are Fe^{III} ions whose Mössbauer parameters differ only slightly from those of the discharged electrode. In the discharged state small amounts of Fe^{IV} (singlet at $\delta = -0.18$ mm s^{-1}, Fig. 1a) were observed in several different samples. This is probably due to minor amounts of γ-NiOOH which were not accessible during the discharging process because electrical contact was lost to the conducting framework.[19] Noteworthy is the stability of the Fe^{IV} ion in the charged electrode. With $Ni_4Fe/SO_4/PO_4$ samples, no loss of Fe^{IV} was observed even after three months ($T = 290$ K, singlet at $\delta = -0.18$ mm s^{-1}, Fe^{IV} content 23%).[4]

According to the measurements presented, the behavior of the charged electrode is unusual in two ways: 1) The low-spin configuration with two unpaired spins is expected for Fe^{IV}.[20] Unter special condiditions the rarer high-spin configuration can be induced,[20] as in the material investigated here. 2) The high symmetry of the $Fe^{IV}O_6$ octahedron is unusual[21] since d^4 high-spin ions tend to distort their ligand sphere (Jahn–Teller stabilization). This in turn leads to quadrupole splitting of the corresponding signal in the Mössbauer spectrum.[22, 23] In our case a singlet is present. Therefore, the coordination sphere of Fe^{IV} here is not determined by its electron configuration but rather by the γ-NiOOH matrix. This is possible when the distortion of the ligand sphere requires more energy than would be gained by Jahn–Teller stabilization.

The Mössbauer spectra allow for further conclusions. First of all, we can exclude a statistical distribution of the Fe^{IV} ions in the lattice. In this case the Fe^{III} and Fe^{IV} ions would be in similar environments and the Fe^{IV} signal should also show significant quadrupole splitting. Charge delocalization between the nickel ions in varying oxidation states over the total γ-NiOOH lattice would also result in similar environments for the Fe^{III} and Fe^{IV} ions and thereby give rise to signals with comparable quadrupole splitting. This is also not in agreement with the measured Mössbauer spectra.

From this we conclude that domains with local ordering must exist in γ-NiOOH, which force a certain amount of the Fe ions into a regular octahedral corset and simultaneously allow for the transition to the +IV state. How can one imagine this environment to be? In order for the Fe^{IV} ions to have a regular octahedral ligand sphere, the directly adjacent lattice positions must also have O_h symmetry. Within the layer the Fe^{IV} ion can have a maximum of six closest cationic neighbors. In the chosen Ni/Fe molar ratio, these lattice positions are statistically occupied by nickel ions. If we assume that the nickel ions have defined oxidation states, γ-NiOOH with an average degree of oxidation at Ni from +3.0 to +3.3[12] can contain Ni^{III} as well as Ni^{IV} and, as shown here, Ni^{II} in its lattice.

A direct environment of six Ni^{II} ions can be excluded since a fast electron exchange between Fe^{IV} and Ni^{II} would take place. An approximation by which the Fe^{IV} ions are surrounded by six Ni^{III} ions is also not probable. Due to its d^7 configuration, the Ni^{III} ion should be subject to a Jahn–Teller distortion, a situation opposing the formation of a regular environment. In addition, with the given average degree of oxidation the remaining Fe^{III} ions would have environments similar to that of Fe^{IV}. This contradicts the findings from the Mössbauer spectra.

From our point of view the Fe^{IV} ions within the layer must be completely surrounded by Ni^{IV} ions since their d^6 low-spin configuration does not lead to distortion of the ligand sphere (Fig. 2). Use of this domain model also explains the presence of the high-spin state. The high contrapolarizing effect of the Ni^{IV} ions decreases the donor character of the oxygen ions with respect to the Fe ions so that the Fe–O bond has relative ionic character. Simultaneously, the Ni^{IV}–O bonds are sufficiently stabilized, due to their high covalent contribution, to successfully resist distortion of the $Fe^{IV}O_6$ octahedron.

Another possible explanation for the lack of Jahn–Teller distortion in the $Fe^{IV}O_6$ octahedron is presented by the theorem of Höck and Thomas.[24] According to this theorem, a vibronic

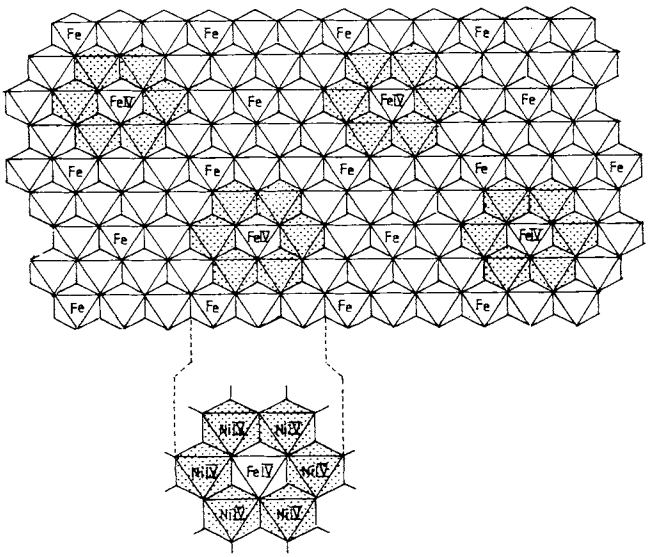

Fig. 2. Domain model for the Fe^{IV} ions in the γ-NiOOH layer.

Jahn–Teller coupling can be suppressed in a strongly electronically delocalized system when the width of the electronic state is larger than the expected ground state splitting. This has been shown for Mn^{III}/Mn^{IV} mixed-oxide crystals[25] and is surely relevant for the domains postulated here.[26]

Such a charge accumulation with seven directly neighboring +IV ions in a layer structure is unusual. However, similar features have been found with ions with significantly higher oxidation states. In the $[TeMo_6O_{24}]^{6-}$ ion,[27] in which the structural unit is derived from CdI_2 and is very similar to the assumed domain structure in γ-NiOOH, the Te^{VI} ion is surrounded by six MoO_6 octahedra. $K_5[I(Mo_6O_{24})]\cdot 5H_2O$ also has a similar structure.[28]

Known data support our ideas for the symmetry of the participating ions. On the basis of Mössbauer and Raman spectroscopic investigations of up to 10 mol% ($x = 0.1$) iron-substituted nickel hydroxide in a charged state, Corrigan et al.[29] assumed that nickel as well as iron ions are present in a highly symmetrical environment. This was confirmed by Kim et al.[30] with X-ray absorption (XAFS) investigations. In contrast to our findings, both groups observed no formation of Fe^{IV}.[31]

Under the assumption of defined charge states, the following is true according to the proposed domain model for the total matrix. In order for all the Fe^{IV} ions to be completely surrounded by Ni^{IV}, the absolute ratio of $Ni^{IV}:Fe^{IV}$ may not be less than 6:1 (limiting case for isolated, intact Ni_6Fe units) (cf. Fig. 2). The Ni^{IV}/Fe^{IV} ratio in the oxidized state of **2** was determined from the Mössbauer spectroscopic, electrochemical, and elemental analytical[15] data.[32–35]

When it is generally assumed that the nickel ions in γ-NiOOH are present in the +III and +IV oxidation states ("$x\,Ni^{IV}O_2\cdot y\,Ni^{III}OOH$"), the Ni^{IV}/Fe^{IV} ratio required for sixfold coordination can not be applied. Almost all of the values obtained from many experiments lie in the range of 2:1 to 4:1. They are therefore not in agreement with the domain model.

The direct two-electron step $Ni^{II} \rightarrow Ni^{IV} + 2e^-$ was postulated relatively early on for the redox reaction in nickel hydroxide.[36] The average degree of oxidation is distributed among the Ni^{II} and Ni^{IV} ions ("$x\,Ni^{IV}O_2\cdot y\,Ni^{II}(OH)_2$"); $Ni^{IV}:Fe^{IV}$ now lies significantly higher than the required 6:1 ratio. Smaller ratios are first expected when the Fe^{IV} content exceeds 40%. However, this high degree of oxidation at nickel could not be achieved electrochemically.

Our experimental results can best be explained by the domain model with the assumption that only Ni^{IV} and Ni^{II} ions are present in the γ-NiOOH phase. This means that the redox process occurs by the direct two-electron step. This is in agreement with the finding that the Mössbauer parameters of the nonoxidized iron ions in γ-NiOOH are barely altered in comparison to the pyroaurite-type starting material. Therefore, there are still mainly Ni^{II} ions in the neighboring positions.

Our arguments are in agreement with investigations by Mansour et al.[37, 38] According to their X-ray absorption measurements (XAFS) of various nickel hydroxides, only two different Ni–O bond lengths, characteristic for Ni^{IV} and Ni^{II}, can be detected. The exclusive presence of Ni in these two oxidation states was also assumed by Greaves et al.,[39] who determined the crystallographic and magnetic structure of Ni_2O_3H from powder neutron diffraction data. Using X-ray data, Wohlfahrt-Mehrens et al.[40] were first to prove that this compound can be formed during electrochemical oxidation in the nickel hydroxide electrode. Thermodynamic considerations of the two-electron step can be found in the paper by Balej and Divisek.[41]

As shown by Mössbauer spectroscopy, the chemical oxidation of a $Ni_4Al_{0.9}Fe_{0.1}$ pyroaurite with peroxodisulfate in 9 M KOH leads to the formation of highly symmetric high-spin Fe^{IV} ions in up to 31% content. An Fe^{IV} content of 35% was achieved in another sample that was electrochemically oxidized.[5b] Therefore oxidized **2** is the first oxidehydroxide produced at room temperature in an aqueous medium showing the γ-NiOOH structure in which both Fe^{IV} and Ni^{IV} are present.

Using Mössbauer spectroscopy and magnetic measurements of iron-substituted γ-NiOOH, Delmas et al.[9] observed the presence of Fe^{IV} in both high- and low-spin states. The samples were prepared by oxidative hydrolysis of the nickelates $NaNi_{1-x}Fe_xO_2$. Noteworthy quadrupole splittings were observed for the respective signals. The given Mössbauer parameters differ significantly from ours. An attempt to fit the spectra of our sample according to the model from Delmas et al.[9] was not successful.

[1] R. Allmann, *Chimia* **1970**, *24*, 99; H. F. W. Taylor, *Mineral. Mag.* **1973**, *39*, 377.
[2] The general structural principle of double-layered compounds with the layered ions $[M^{II}_{1-x}M^{III}_x(OH)_2]^{x+}$ was observed by Allmann [1] to be the structure type of the mineral pyroaurite $[Mg_6Fe_2(OH)_{16}]^{2+}[CO_3^{2-}\cdot 4H_2O]$ with $M^{II}:M^{III} = 3:1$ ($x = 0.25$). This ratio is also shown by other minerals which Allmann assigned to the type pyroaurite. According to C. F. Frondel (*Am. Mineral.* **1951**, *26*, 295) and W. Hofmeister, H. von Platen (*Cryst. Rev.* **1992**, *3*, 3), the double-layer structure of these minerals displays a regular stacking of the layers with ordered cation distribution within the layers in a ratio of $M^{II}:M^{III} = 3:1$ and 2:1, respectively. They have been named "brucitites" by the authors. In precipitated products, neither we or others have observed this superstructure in the X-ray patterns. This may be due to the precipitation methods used, which may be too fast to allow for a definite ordering of the cations (A. Mendiboure, R. Schöllhorn, *Rev. Chim. Mineral.* **1986**, *23*, 819).

[10] Electrochemical investigations were carried out in 9 M KOH with a Cd/$Cd(OH)_2$ counter electrode. The sample was charged for 11 h at 50 mA and discharged at 25 mA to a potential of 0 V vs Hg/HgO. The electrode pellet contained 1.00 g of redox-active material, 0.25 g of graphite, and 0.025 g of Teflon and was pressed in a nickel net.

[12] Examples of Faraday yields [4]: Ni/Fe/CO_3 electrode: $N_{Fe,max} = 131\%$. Ni/Fe/SO_4/PO_4 electrode: $N_{Fe,max} = 130\%$. $N_{Fe,max} = 100\%$ for the theoretical one-electron step $Ni^{II} \rightarrow Ni^{III} + 1e^-$. Participation of Fe in the redox process has not been taken into account here. An average degree of oxidation at nickel of 3.31 was determined from the N_e values [32, 34, 35].

[13] In this article formal charge values such as those describing a bond in its ionic limiting case (complete charge separation) were given for the ions. The actual charge at the metal ions can deviate considerably as a result of covalent bonding contributions (compare also ref. [18]).

[14] The ^{57}Fe Mössbauer spectra were measured ex situ at room temperature in transmission geometry with a ^{57}Co/Rh source with an activity of 25 mCi and an absorber concentration of 3–6 mg cm^{-2}. The speed was calibrated by measuring an α-Fe foil.

[15] Elemental analysis: Ni: 40%, Fe: 8.8%, CO_3: 8%, K: 0.47%. The OH content in the main layer was determined from the number of nickel and iron ions: $n_{OH^-} = 2(n_{Ni} + n_{Fe})$. The IR spectra show a carbonate band ($\tilde{\nu}_{as} = 1480$ cm^{-1}) and a strong hydrogen carbonate band ($\tilde{\nu}_s = 1370$ cm^{-1}), indicating the presence of both anions. Taking into account the potassium ions, the ratio of carbonate to hydrogen carbonate in the interlayer balances the charge of the cationic brucite layer. The water content was found by eliminating all other components. The X-ray structure analysis (hexagonal indexing) provided $a = 3.1$, $c = 23.3$ Å; A. Mendiboure and R. Schöllhorn (*Rev. Chim. Miner.* **1986**, *23*, 819) reported $a = 3.08$, $c = 23.34$ Å for the brucitite with Ni:Fe = 3:1.

[16] The isomer shift δ is given relative to α-iron.

[17] a) G. Demazeau, M. Pouchard, N. Chevreau, J. F. Colombet, M. Thomas, F. Menil, P. Hagenmuller, *J. Less Common Met.* **1980**, *76*, 279: high-spin Fe^{IV} in $Sr_{0.5}La_{1.5}Li_{0.5}Fe_{0.5}O_4(K_2NiF_4)$ at $\delta = -0.19$ mm s^{-1}; b) G. Demazeau, Z. Li-Ming, L. Fournes, M. Pouchard, P. Hagenmuller, *J. Solid State Chem.* **1988**, *72*, 31: for Fe the authors found $\delta = -0.14$ mm s^{-1} in $A^{II}_{0.5}La_{1.5}Li_{0.5}Fe_{0.5}O_4$ (K_4NiF_4-type), which they assigned to the d^4 high-spin state (A = alkaline-earth metals); this result was supported by structural and magnetic data. Further Mössbauer data for low-spin Fe^{IV} ions: c) P. Adler, *J. Solid State Chem.* **1994**, *108*, 275: Sr_2FeO_4: $\delta = -0.017$ mm s^{-1}; d) P. K. Gallagher, J. B. Mac Chesney, D. N. E. Buchanan, *J. Chem. Phys.* **1964**, *41*, 2429: $SrFeO_3$: $\delta = +0.054$ mm s^{-1}; e) M. Takano, N. Nakanishi, Y. Takeda, S. Naka, T. Takada, *Mater. Res. Bull.* **1977**, *12*, 923: $CaFeO_3$: $\delta = +0.073$ mm s^{-1}.

[18] In $SrFeO_3$ the iron is formally in the oxidation state +IV. According to investigations by A. E Bocquet, A. Fujimori, T. Mizokawa, T. Saitoh, H. Namatame, S. Suga, N. Kimizuka, Y. Takeda, M. Takano, *Phys. Rev. B* **1992**, *45*, 1561, the bonding situation in the Fe–O bonds is, as a result of charge transfer, better described by $Fe^{3+}-O^-$ than by $Fe^{4+}-O^{2-}$. According to Demazeau [17a, b], the low-spin state must be assumed for Fe in this compound. The Mössbauer parameters ($\delta = +0.054$ mm s^{-1}) suggest that the extent of back-bonding in $SrFeO_3$ has a greater influence than in the material we describe ($\delta = -0.19$ mm s^{-1}). X-ray photoelectron spectroscopy for chemical analysis (ESCA) would give a more exact description of the bonding situation, but this method is unsuitable for the strongly water-containing hydroxid compounds that we investigated since they decompose in ultrahigh vacuum.

[21] Cf. P. Gütlich, *Top. Appl. Phys.* **1975**, 53. In an O_h-symmetrical ligand field, the fourth electron in the e_g orbital set is delocalized, and like the ligand field it does not contribute to the electronic field gradients at the nucleus.

[22] The Fe^{III} signal for the discharged electrode and the pure starting material (pyroaurite-type) shows quadrupole splitting. The d^5 high-spin configuration should not contribute to quadrupole splitting due to its symmetrically filled sublevels. Therefore, we attribute this splitting to a minor distortion of the octahedron along the C_3 axis, which can occur in the layered structure.

[23] Quadrupole splitting for high-spin Fe^{IV}, see for example [17a]: $\Delta E_Q = 1.10$ mm s^{-1}.

[26] Even under the assumption of low-spin configuration for the ions involved in the cluster, small octahedral distortions of the electronic d states were not registered. This is because strong delocalization would result in the width of this state becoming larger than the relatively small symmetry splittings. An almost regular octahedral symmetry should also here be confirmed by Mössbauer spectroscopy.

[30] S. Kim, D. A. Tryk, M. R. Antonio, R. Carr, D. Scherson, *J. Phys. Chem.* **1994**, *98*, 10269.

[31] Corrigan et al. [29] determined $\delta = +0.22$ mm s^{-1} for Fe^{III}. The values of $\delta = -0.18$ to -0.20 mm s^{-1} that we report correspond unambiguously to Fe^{IV}.

[32] The relative Fe^{IV} content was obtained from the Mössbauer spectra. Based on the iron content in the electrode, as determined by elemental analysis, the portion of iron ions involved in the discharging process $Fe^{IV} + 1e^- \rightarrow Fe^{III}$ (Q_{Fe}) can be determined as follows: 1.00 g of redox-active material contains 0.088 g (8.8%, $n = 1.576 \times 10^{-3}$ mol) of Fe ions. This corresponds to a partial charge of $Q_{100\%,Fe} = nzF = 42.2$ mAh g^{-1} ($z = 1$ and $F = 26803$ mAh mol^{-1}) for complete reaction of $Fe^{IV} + 1e^- \rightarrow Fe^{III}$. If, for example, 30% of the Fe ions, as determined from Mössbauer spectroscopy, participate in the redox process, this corresponds to a value of 12.7 mAh g^{-1} for the electrochemically determined total amount of charge.

[33] The direct galvanostatic determination of the amount of charge for a completely charged electrode is not possible from the charge process. An unmeasureable portion of the charge is lost due to simultaneous electrolyte decomposition with formation of oxygen. For this reason a good approximation of the amount of charge can be obtained from the discharging capacity of the preceeding cycle. In the investigated cycle regions 5–7, consecutive capacity values were nearly the same (deviations < 1%).

[34] To ascertain the portion of nickel ions involved in the discharging process (Q_{Ni}), the value for the Fe^{IV} ions [32] was subtracted from the electrochemically measured total amount of charge ($Q_{Ni+Fe} = 247.0$ mAh g^{-1}) (cf. [33]). In this way a value of $Q_{Ni} = Q_{Ni+Fe} - Q_{Fe} = (247.0 - 12.7)$ mAh g^{-1} = 234.3 mAh g^{-1} was obtained.

[35] Comparing Q_{Ni} to the theoretical capacity value obtained for 100% utilization of the one-electron step $Ni^{III} + 1e^- \rightarrow Ni^{II}$ ($Q_{100\%,Ni}$) provides the average exchanged charge amount per nickel ion as follows: 1.00 g of active material contains 0.40 g (40%, $n = 6.81 \times 10^{-3}$) nickel ions, which corresponds to a charge amount of $Q_{100\%,Ni} = 182.6$ mAh g^{-1} for the theoretical one-electron step. The exchanged charge per nickel ion is then $Q_{Ni}/Q_{100\%,Ni} = 234.3/182.6 = 1.28$, from which an average degree of oxidation for Ni of +3.28 can be determined. The relative content of Ni^{IV} and, under consideration of the analytical Ni/Fe ratio, the absolute Ni/Fe ratio can be calculated from the distribution of the average degree of oxidation on ions in defined charge states.

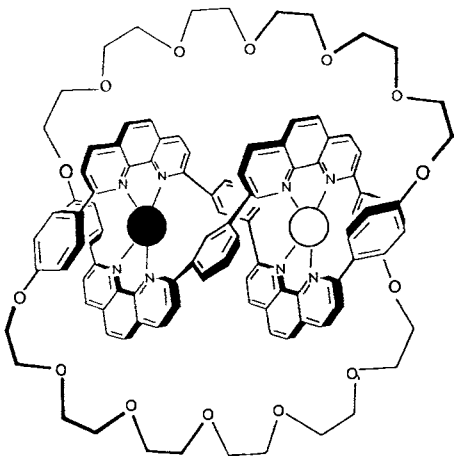
Knotted Heterodinuclear Complexes

Christiane O. Dietrich-Buchecker,
Jean-Pierre Sauvage,* Nicola Armaroli, Paola Ceroni,
and Vincenzo Balzani*

Chemical objects whose molecular graphs display topologically nontrivial properties are of special interest, in relation with mathematics, graphical arts, biology, and molecular sciences in general.[1] Molecular knots exist in nature, either based on DNA or on proteins,[2, 3] but they have also been made recently by chemical synthesis.[4] In particular, the use of the 1,3-phenylene group as a spacer between two 1,10-phenanthroline (phen) units in the copper(I)-templated synthesis allows molecular knots to be prepared on a preparative scale.[5]

We report here that the dicopper(I) knot compound $[1CuCu]^{2+}$ is a surprisingly stable species that can be demetalated in a stepwise manner, first to a monocopper(I) complex $[1Cu]^{+}$ and subsequently to the free knotted ligand **1**. In addition, since the singly demetalated species contains a free coordination site, another metal cation can be introduced to afford the disymmetrical complexes $[1CuZn]^{3+}$ and $[1CuAg]^{2+}$. These



$[1CuCu]^{2+}$, ● = ○ = Cu^{+}
$[1Cu]^{+}$, ● = Cu^{+}, ○ = –
$[1CuZn]^{3+}$, ● = Cu^{+}, ○ = Zn^{2+}
$[1CuAg]^{2+}$, ● = Cu^{+}, ○ = Ag^{+},
1, ● = ○ = –

heterodinuclear species show interesting electro- and photochemical properties, which will also be described herein.

The complex $[1Cu]^{+}BF_4^{-}$ was obtained in quantitative yield by treating $[1CuCu]^{2+}(BF_4^{-})_2$ with a large excess of KCN in CH_2Cl_2/H_2O at room temperature.[6] This complex can be either used as a starting compound for preparing the disymmetrical species, or fully demetalated in refluxing wet CH_3CN to yield the free ligand **1**, which in the presence of protons or metal cations rapidly protonates or remetalates, respectively. The heterodinuclear complexes $[1CuZn]^{3+}$ and $[1CuAg]^{2+}$ were obtained quantitatively after addition of the appropriate metal salt to $[1Cu]^{+}$ at room temperature.[6] ^1H NMR spectroscopy indicates that $[1CuZn]^{3+}$ and $[1CuAg]^{2+}$ contain a helical core analogous to $[1CuCu]^{2+}$. Dinuclear helical complexes of this type containing two different metals have been recently reported.[7, 8] Remarkably, $[1Cu]^{+}$ also displays a helical conformation in spite of its free coordination site. Furthermore, the copper(I) complex subunit of $[1Cu]^{+}$ is even more compact than that in $[1CuCu]^{2+}$ since the release of the first metal ion reduces the conformational strain, allowing better interaction between the remaining copper(I) center and the phenanthroline groups coordinating this center. This is shown by ^1H NMR spectroscopic data which indicate a more pronounced entwining of the ligands, and by the great difficulties associated with trying to remove the second copper(I) ion with CN^{-}.

The decomplexation–recomplexation reactions can be monitored very conveniently by ^1H NMR spectroscopy, as exemplified by the spectra of $[1CuCu]^{2+}$ and $[1CuAg]^{2+}$ in Figure 1, which show the evident loss of symmetry when one of the copper(I) centers is replaced by Ag^{+}.

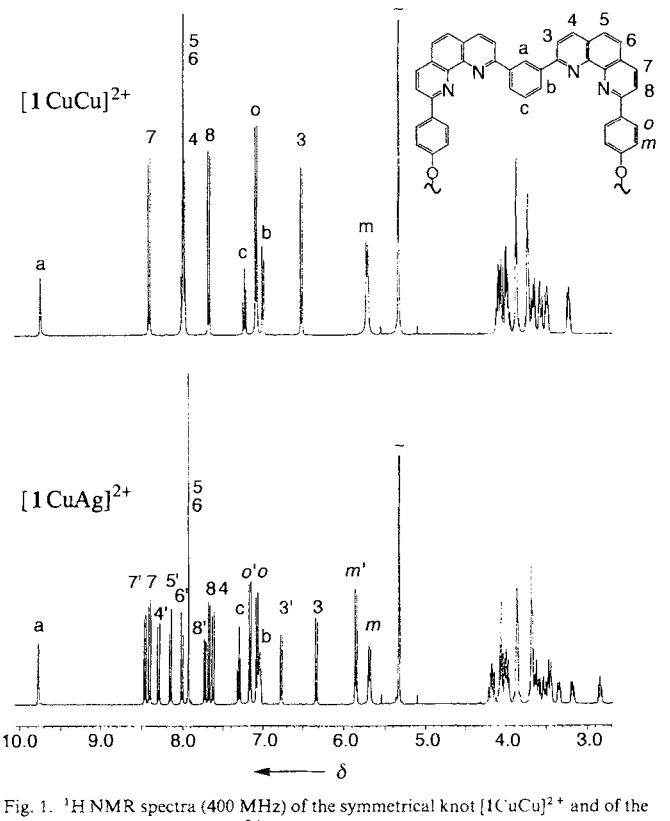


Fig. 1. ^1H NMR spectra (400 MHz) of the symmetrical knot $[1CuCu]^{2+}$ and of the disymmetrical species $[1CuAg]^{2+}$.

The electrochemical data of the complexes have been recorded in CH_3CN. The redox potentials of the Cu^{II}/Cu^{I} couples have been measured against the saturated calomel electrode (SCE), and are all reversible ($\Delta E_p \approx 60$ mV). $[1CuCu]^{2+}$ undergoes two oxidation processes ($[1CuCu]^{3+/2+}$, $E^{\circ} = +0.68$ V; $[1CuCu]^{4+/3+}$, $E^{\circ} = +0.92$ V), whereas $[1CuAg]^{2+}$ and $[1CuZn]^{3+}$ undergo only one oxidation process ($[1CuAg]^{3+/2+}$, $E^{\circ} =$

+ 0.69 V; $[1CuZn]^{4+/3+}$, $E^\circ = +0.90$ V). The $[1CuCu]^{3+/2+}$ and $[1CuAg]^{3+/2+}$ reduction potentials are very similar to those found for other copper complexes containing entwined or interlocked ligands.[9] By contrast, the $[1CuCu]^{4+/3+}$ reduction potential is very high and comparable to the value found for the $[1CuZn]^{4+/3+}$ complex. This reflects the strong electron-withdrawing influence of a divalent metal atom located close to the copper center undergoing the redox reaction. As expected, the presence of a positively charged species substantially destabilizes the divalent state of the copper center and thus shifts the Cu^{II}/Cu^{I} redox potential towards anodic values.

The UV absorption spectra of the novel dinuclear knots $[1CuCu]^{2+}$, $[1CuAg]^{2+}$, and $[1CuZn]^{3+}$ (ligand-centered bands) show very similar features, clearly different from those exhibited by the dicopper knot $[2CuCu]^{2+}$ in which the spacer between the phenanthroline moieties is a $(CH_2)_6$ chain instead of a 1,3-phenylene group.[4c] The mononuclear knot $[1Cu]^{+}$ shows distinct spectral features compared with the dinuclear knots of the same family. Such differences are attributed to the presence of uncoordinated phenanthroline ligands in $[1Cu]^{+}$.

In the visible spectral region all the examined compounds show broad bands due to $Cu^{I} \rightarrow$ phen charge-transfer transitions (Fig. 2). A detailed interpretation of the metal-to-ligand

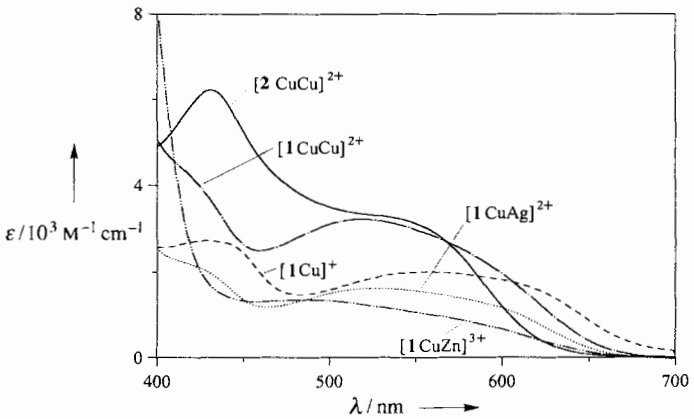

Fig. 2. Electronic absorption spectra in the visible region for the examined compounds in CH_2Cl_2 solution.

charge-transfer (MLCT) bands in Cu^{I} complexes with phenanthroline-type ligands is difficult for several reasons.[10] Nevertheless, some interesting features are apparent from the spectra in Figure 2: a) The intensity of the bands of the compounds containing two Cu^{I} ions is about twice that of the compounds containing only one Cu^{I} ion. b) The spectral features of the complexes of knot **1** are noticeably different from those exhibited by complex $[2CuCu]^{2+}$. c) The spectrum of $[1CuCu]^{2+}$ has exactly the same profile and twice the intensity of the spectrum of $[1CuAg]^{2+}$, which indicates that the coordination environment in the two compounds has substantially the same symmetry. d) The mononuclear complex $[1Cu]^{+}$ has a different spectral profile than the dinuclear $[1CuCu]^{2+}$ and $[1CuAg]^{2+}$ knots; this confirms that the properties of a coordination site are somewhat affected by the presence of a metal in the second coordination site, as inferred from ^1H NMR data (see above).

As is usual for Cu^{I} complexes with phenanthroline-type ligands,[10] the knots investigated herein exhibit a MLCT luminescence in CH_2Cl_2 at room temperature (Table 1).[4c] Noteworthy features are as follows: a) Only one emission band, assigned to the lowest MLCT excited state, is observed; this behavior, and

Table 1. Emission maxima and luminescence properties [a].

Complex cation	λ_{max} [nm] [b]	τ [ns] [c]	Φ_{em} [10^4] [d]	$k_q[O_2]$ [10^{-6} s^{-1}] [e]
$[1Cu]^{+}$	740	120	6	2.6
$[1CuCu]^{2+}$	730	200	9	1.2
$[1CuAg]^{2+}$	725	240	13	1.1
$[1CuZn]^{3+}$	950	11	ca. 0.5	–
$[2CuCu]^{2+}$ [f]	742	210	7	2.5

[a] Deaerated CH_2Cl_2 solution, room temperature. [b] Corrected values of the maximum of the emission band, ± 5 nm. [c] Excited state lifetime, ± 5%. [d] Luminescence quantum yield, ± 20% (uncertainty on relative intensities, ± 5%). [e] Stern–Volmer constant for excited state quenching by dioxygen. [f] From ref. [4c].

the agreement between absorption and excitation spectra all across the UV/vis region, indicate complete conversion of all the upper lying excited states to the lowest emitting MLCT level; this also means that in the compounds containing two distinct chromophoric groups (i.e. $[1Cu]^{+}$, $[1CuAg]^{2+}$, and $[1CuZn]^{3+}$) energy transfer is practically 100% efficient. b) The behavior of $[1CuCu]^{2+}$ and $[1CuAg]^{2+}$ is very similar, which again indicates that the Cu^{I} coordination environment is very similar in the two compounds. c) $[1Cu]^{+}$ shows a shorter excited state lifetime and a smaller luminescence quantum yield than $[1CuCu]^{2+}$, which is consistent with a more rigid structure for the dinuclear complex; this can also explain the difference in the rate constant for the quenching of the excited state by dioxygen in the two compounds. d) The emission band of the $[1CuZn]^{3+}$ complex is strongly red-shifted relative to those of the other complexes; as a consequence (energy gap rule),[11] the radiationless decay of the excited state is faster, which accounts for the shorter lifetime and smaller luminescence quantum yield.

At first sight the decrease in the energy of the lowest $Cu \rightarrow$ phen CT excited state in $[1CuZn]^{3+}$ compared, for example, with that in $[1CuCu]^{2+}$ appear to be contradictory with the Cu^{II}/Cu^{I} reduction potential in $[1CuZn]^{3+}$ (vide supra). In fact, the electrochemical and spectroscopic effects are consistent and can both be explained on the basis of the "conducting" properties of the phenylene spacer. In the ground state, the Cu^{+} ion is more positive in $[1CuZn]^{3+}$, which contains the Cu^{+}-phen-Ph-phen-Zn^{2+} moiety, than in $[1CuCu]^{2+}$, which contains the Cu^{+}-phen-Ph-phen-Cu^{+} moiety, and, as a consequence, oxidation of $[1CuZn]^{3+}$ is more difficult. A more positive Cu^{+} ion should imply a blue shift of the MLCT level; however, it should also be considered that the phen ligand coordinated to Cu^{+} is *much* more positive in $[1CuZn]^{3+}$ than in $[1CuCu]^{2+}$ (i.e. the electron-withdrawing effect of Zn^{2+} is larger on the phen unit coordinated to Cu^{+} than on the Cu^{+} ion). Combination of these two effects leads to a red shift of the MLCT band.

In conclusion, we have synthesized novel knotted heterodinuclear complexes in which the two metal-based components are linked by a 1,3-phenylene spacer. Preparation of these disymmetrical species was made possible by the surprisingly large kinetic inertness of the monocopper(I) complex $[1Cu]^{+}$, which prevents the system from undergoing metal scrambling during the introduction of the second metal center. The presence of a "conducting" spacer leads to electrochemical and spectroscopic properties noticeably different from those of knotted complexes in which the two metal-based components are linked by nonconducting $(CH_2)_n$ spacers.[4c]

Experimental Procedure

Partial demetalation of $[1CuCu]^{2+}$: $[1CuCu]^{2+}2(BF_4^-)$ (132 mg, 0.065 mmol) was dissolved in CH_2Cl_2 (60 mL) and treated with aqueous KCN (400 mg, 6.15 mmol) for 15 h at room temperature. This reaction, monitored by TLC, afforded $[1Cu]^{+}$ (123 mg, 0.065 mmol) after classical work-up and chromatography over alumina

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3510-1120 $ 15.00+.25/0

(quantitative yield, eluent: CH_2Cl_2/EtOH 100/1 to 100/5 v/v). $[1Cu]^+BF_4^-$ ($C_{108}H_{96}N_8O_{14}CuBF_4$): dark brown-red solid. FAB-MS: *m/z*: 1793.5 (calc. for $[1Cu]^+$: 1793.54), 897.3 (calc. for $[1Cu]^+H^+$: 897,2); ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 9.97 (s, $2H_a$), 8.26 (d, $2H_f$, $J \approx 8.3$ Hz), 8.19 (d, $2H'_d$, $J \approx 8.4$ Hz), 8.06 (d, $2H'_c$, $J \approx 8.3$ Hz), 8.01 (d, $2H_g$, $J \approx 8.7$ Hz), 7.90 (d, $4H'_o$, $J \approx 8.8$ Hz), 7.82 (d, $2H_b$, $J \approx 8.7$ Hz), 7.74 (d, $2H'_3$, $J \approx 8.4$ Hz), 7.72 (AB, $4H'_{5,6}$, $J \approx 8.8$ Hz), 7.56 (d, $2H_g$, $J \approx 8.2$ Hz), 7.13 (d, $2H_4$, $J \approx 8.3$ Hz), 6.96 (d, $4H_o$, $J \approx 8.7$ Hz), 6.91 (t, $2H_e$, $J \approx 7.6$ Hz), 6.77 (d, $2H_b$, $J \approx 7.7$ Hz), 6.71 (d, $2H'_b$, $J \approx 7.7$ Hz), 6.69 (d, $2H'_g$, $J \approx 8.4$ Hz), 6.11 (d, $2H_3$, $J \approx 8.3$ Hz), 5.77 (d, $4H'_m$, $J \approx 8.8$ Hz), 5.52 (d, $4H_m$, $J \approx 8.5$ Hz), 4.15–2.41 (m, 48H, OCH_2CH_2O).

Complete demetalation of $[1Cu]^+$: $[1Cu]^+BF_4^-$ (37 mg, 0.02 mmol) dissolved in CH_3CN (30 mL) was treated with aqueous KCN (1.00 g, 15.3 mmol in 20 mL H_2O) at 80 °C for 24 h. The dark brown coloration of the initial solution faded progressively to be pale yellow at the end. After evaporation of the solvents, the crude product was taken up in CH_2Cl_2/H_2O and decanted. After elimination of excess KCN (washing of the organic layer three times with H_2O), a filtration through silica (eluent CH_2Cl_2/MeOH 100:5) afforded $[1HH]^{2+}(BF_4^-)_2$ (33 mg, ca. 0.02 mmol, quantitative yield), which can be converted to **1** by treatment with aqueous K_2CO_3. **1**: $C_{108}H_{96}N_8O_{14}$. Pale yellow glass. ES-MS: *m/z*: 1731.14, 1731.94, 865.85 (calc. for $[1H]^+$ and $[1HH]^+$, respectively: 1731.00, 1732.01, and 866.00, respectively); ^{1}H NMR (CD_2Cl_2, 200 MHz): δ = 8.77 (dd, $4H_b$, $J \approx 7.7$, 1.4 Hz), 8.71 (s, $2H_a$), 8.37 (d, $4H_1$, $J \approx 8.4$ Hz), 8.28 (d, $4H_d$, $J \approx 8.4$ Hz), 8.13 (d, $8H_o$, $J \approx 8.6$ Hz), 8.09 (d, $4H_f$, $J \approx 8.3$ Hz), 7.90 (d, $4H_g$, $J \approx 8.5$ Hz), 7.68 (t, $2Hc$, $J \approx 7.7$ Hz), 7.55 (AB, $8H_{5,6}$, $J \approx 8.8$ Hz), 6.98 (d, $8H_m$, $J \approx 8.8$ Hz), 4.25 (t, $8H_a$, $J \approx 5.5$ Hz), 3.82–3.60 (m, 40H, OCH_2CH_2O).

$[1CuAg]^{2+}(BF_4^-)_2$: To a solution of $[1Cu]^+BF_4^-$ (46 mg, 0.024 mmol, in 10 mL CH_2Cl_2) was added a large excess of $AgBF_4$ dissolved in C_6H_6 (10 mL, 30 mg, 0.153 mmol) at room temperature. After the mixture had been stirred at room temperature overnight a dark green precipitate was formed (oxidation of Cu^I to Cu^{II} by excess silver salt). Upon addition of water (10 mL) the latter copper(II) complex was easily reduced and $[1CuAg]^{2+}(BF_4^-)_2$ was isolated pure after decantation, washing the organic layer with H_2O, drying over $MgSO_4$, and recrystallization from C_6H_6/CH_2Cl_2 (quantitative yield, 50 mg 0.024 mmol). $[1CuAg]^{2+}(BF_4^-)_2$: $C_{108}H_{96}N_8O_{14}CuAg \cdot 2BF_4$): dark red needles. FAB-MS: *m/z*: 1986.4 (calc. for $[1CuAg]^{2+}BF_4^-$: 1985.8), 1791.5 (calc. for $[1Cu]^+$: 1791.9) and 949.7 (calc. for $[1CuAg]^{2+}$: 950.0); ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 9.77 (s, $2H_a$), 8.45 (d, $2H'_f$, $J \approx 8.3$ Hz), 8.40 (d, $2H_f$, $J \approx 8.3$ Hz), 8.29 (d, $2H'_d$, $J \approx 8.3$ Hz), 8.15 (d, $2H'_g$, $J \approx 8.8$ Hz), 7.99 (d, $2H_g$, $J \approx 8.8$ Hz), 7.93 (s, $4H_{5,6}$), 7.72 (d, $2H'_g$, $J \approx 8.2$ Hz), 7.67 (d, $2H_g$, $J \approx 8.3$ Hz), 7.62 (d, $2H_4$, $J \approx 8.3$ Hz), 7.30 (t, $2H_c$, $J \approx 7.7$ Hz), 7.16 (d, $4H'_o$, $J \approx 8.6$ Hz), 7.07 (d, $4H_o$, $J \approx 8.8$ Hz), 7.02–7.05 (m, $2H_b + 2H'_b$), 6.76 (d, $2H'_3$, $J \approx 8.3$ Hz), 6.32 (d, $2H_3$, $J \approx 8.4$ Hz), 5.84 (d, $4H'_m$, $J \approx 8.6$ Hz), 5.68 (d, $4H_m$, $J \approx 8.5$ Hz), 4.20–2.80 (m, 48H, OCH_2CH_2O).

$[1CuZn]^{3+}(BF_4^-)_3$: $Zn(NO_3)_2 \cdot 6H_2O$ (20 mg, 0.067 mmol) and $[1Cu]^+BF_4^-$ (16 mg, 0.008 mmol) were mixed and dissolved in CH_2Cl_2 (10 mL) at room temperature: $[1CuZn]^{3+}$, which was poorly soluble in CH_2Cl_2 as NO_3^- salt, precipitated readily as a brown solid. After subsequent anion exchange by addition of a large excess of $NaBF_4$ to the suspension, the complex $[1CuZn]^{3+}(BF_4^-)_3$ was obtained in CH_2Cl_2. A pure sample was obtained by recrystallization from C_6H_6/CH_2Cl_2 (quantitative yield, 18 mg; 0.008 mmol).

$[1CuZn]^{3+}(BF_4^-)_3$: $C_{108}H_{96}N_8O_{14}CuZn.3BF_4$, brown-orange needles. FAB-MS: *m/z*: 2030.4 (calc.for $[1CuZn]^{3+}(BF_4^-)_2$: 2029.8), 971.2 (calc. for $[1CuZn]^{3+}(BF_4^-)$: 971.5) and 1791.4 (calc. for $[1Cu]^+$: 1791.9); ^{1}H NMR (CD_2Cl_2, 400 MHz): δ = 9.06 (s, $2H_a$), 8.84 (d, $2H'_f$, $J \approx 8.4$ Hz), 8.48 (d, $2H_f$, $J \approx 8.4$ Hz), 8.35 (d, $2H'_d$, $J \approx 8.4$ Hz), 8.30 (s, $4H_{5,6}$), 8.25 (d, $2H_d$, $J \approx 8.4$ Hz), 8.10 (AB, $4H_{5,6}$, $J \approx 8.8$ Hz), 7.94 (d, $2H'_g$, $J \approx 8.4$ Hz), 7.69 (d, $2H_g$, $J \approx 8.3$ Hz), 7.55 (t, $2H_c$, $J \approx 7.7$ Hz), 7.34–7.31 (m, $2H_b + 2H'_b$), 6.75 (d, $2H_3$, $J \approx 8.4$ Hz), 6.74 (d, $2H'_3$, $J \approx 8.4$ Hz), ≈6.0 (br $4H'_m$), 5.74 (br d, $4H_m$), 4.08–3.26 (m, 48H, OCH_2CH_2O).

Bis(diisopropylamino)carbene

Roger W. Alder,* Paul R. Allen, Martin Murray, and A. Guy Orpen

The isolation of stable crystalline imidazol-2-ylidenes by Arduengo and co-workers[1] has aroused great interest. They have shown that derivatives as simple as 1,3,4,5-tetramethylimidazol-2-ylidene (**1**) are stable crystalline solids that show no tendency to dimerize.[2] We are interested in developing these derivatives of diaminocarbene as bases and nucleophilic catalysts, and have recently shown that 1,3-diisopropyl-4,5-dimethylimidazol-2-ylidene (**2**) has a pK_a value of 24 in [D$_6$]DMSO, making it one of the strongest known neutral bases.[3] As an extension of these studies, we started to explore as wide a range of stable diaminocarbene structures as possible. Both imidazol-2-ylidenes and their precursors, imidazolium ions, are aromatic, so aromaticity should not have a first-order effect on the deprotonation. Indeed calculation of the proton affinity (PA) of a range of imidazol-2-ylidenes, dihydroimidazol-2-ylidenes, and acyclic bis(dialkylamino)carbenes, by using the AM1 semiempirical method,[4] showed that PA varied by less than 10 kJ mol^{-1} among similarly substituted examples of these systems (the calculated PAs for **2**, **3**, and **4** are 1066, 1055, and 1063 kJ mol^{-1}, respectively).

This encouraged us to try to generate a diaminocarbene by deprotonation of a suitable amidinium ion, even though it was reported many years ago that *N*,*N*,*N*′,*N*′-tetramethylformamidinium salts are difficult to C-deprotonate.[5] Extensive earlier work by Wanzlick and others[6] showed that 4,5-dihydroimidazol-2-ylidenes were readily generated by a variety of reactions, but apparently always dimerized to give tetraaminoethene derivatives.[7] While our work was in progress however, Arduengo et al.[8] reported the isolation and X-ray crystal structure analysis of the first stable 4,5-dihydroimidazol-2-ylidene **3** by deprotonation of an *N*,*N*′-dimesityl-4,5-dihydroimidazolium ion.

We now report on the isolation of bis(diisopropylamino)-carbene (*N*,*N*,*N*′,*N*′-tetraisopropylformamidinylidene) **4** as a stable solid by deprotonation of *N*,*N*,*N*′,*N*′-tetraisopropylformamidinium chloride **5** with lithium diisopropylamide (LDA) in THF.[9] The formamidinium salt **5** was prepared by reaction of *N*,*N*-diisopropylformamide with phosphorus oxychloride in ether, followed by treatment with diisopropylamine.[10] Reaction of **5** with LDA in THF led to the formation of **4** in 55% yield. Diaminocarbene **4** sublimes readily and is stable under rigorously dry nitrogen, but appears to be significantly more sensitive to oxygen and moisture than other species of this type that we have handled. The X-ray crystal structure of **4** was determined from a crystal grown by sublimation.[11] The structure (Fig. 1) shows that the molecule has approximate C_2

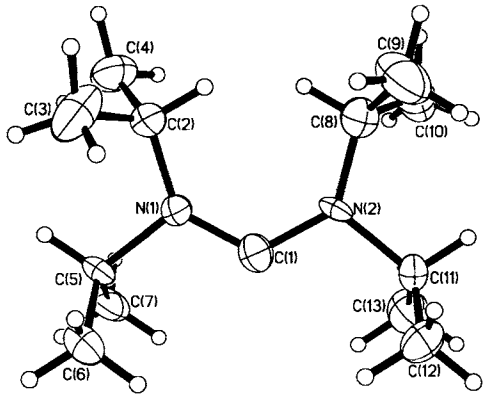

Fig. 1. Molecular structure of **4**. Important bond lengths [Å] bond angles [°] and torsion angles [°]: C(1)-N(1) 1.363(6), C(1)-N(2) 1.381(6), N-CHMe$_2$ (av) 1.492; N(1)-C(1)-N(2) 121.0(5), C(1)-N(1)-C(2) 135.1(4), C(1)-N(1)-C(5) 111.2(4) C(2)-N(1)-C(5) 113.4(4) C(1)-N(2)-C(8) 133.5(4), C(1)-N(2)-C(11) 110.7(4), C(8)-N(2)-C(11) 115.5(4); C(2)-N(1)-C(1)-N(2) −13.7(9), N(1)-C(1)-N(2)-C(8) −10.6(9).

symmetry; the N-C-N angle (121.0°) is much larger than that in any previously studied diaminocarbene derivative (this angle is 104.7° for **3**). The nitrogen atoms are planar, but the C-N-C angles are strongly distorted by the repulsive interactions between the isopropyl groups. The ^{13}C NMR chemical shift of the carbene center at $\delta = 255.5$ is 30–40 ppm downfield of the carbene carbon chemical shifts for imidazol-2-ylidenes, and 10 ppm downfield of that reported for **3**.[8] The further downfield shift for **4** may be related to the increased N-C-N angle.

The ^1H and ^{13}C NMR signals of the *i*Pr groups of **4** are broad at room temperature, and split to reveal two types of *i*Pr groups at −30 °C. The C*H* signals coalesce at −10 °C, leading to a calculated $\Delta G^{\neq}$ of 53 kJ mol^{-1}. Similar behavior was observed for the formamidinium ion precursor **5**, where the coalescence of the C*H* absorptions occurred at +8 °C, $\Delta G^{\neq}$ 55 kJ mol^{-1}. A barrier of 64 kJ mol^{-1} has been reported for the tetramethylformamidinium ion.[12] The fact that the barrier is lower for **5** is understandable in terms of steric destabilization of the ground state relative to the transition state for rotation about a C–N bond. Coalescence of the signals for the *i*Pr groups in **5** must involve rotation about a C–N*i*Pr$_2$ bond, accompanied by rotations about N–*i*Pr$_2$ bonds. In the diaminocarbene **4** interconversion might occur by an inversion mechanism with a linear N-C-N transition state, although AM1 calculations suggest a rotation process will be preferred. However, even if inversion is the observed process, the rotational process must have a higher barrier, and it is therefore clear that there is as much double bond character to the C–N bonds in **4** as those in amidinium ion **5**. Thus, while it is convenient to call **4** a diaminocarbene rather than a formamidinylidene, it would be just as realistic to describe an amidinium ion as a diaminocarbenium ion!

In solutions containing both **4** and **5**, separate NMR signals are seen for these two species, although there is some indication of exchange broadening at higher temperatures. This indicates that proton transfer between **4** and **5** is slow on the NMR time scale. We previously found that proton transfer between **2** and the corresponding imidazolium ion was close to the fast exchange limit at ambient temperature.[3] The slower exchange for **4** is in keeping with the greater steric hindrance in this species. The co-existence in solution of **4** and **5** is interesting from another point of view, since attack of the carbene on the electrophilic carbon atom of the amidimium ion is proposed to be the major route to tetraaminoethenes.[7]

In summary, we have isolated the first acyclic diaminocarbene, and shown that its C–N bonds have substantial double bond character. It will be interesting to discover what minimal steric hindrance is required in these species before dimerization of the carbene sets in, but the preparation of **4** suggests that a wide range of these interesting species can be isolated.

Experimental Procedure

5: Solvents were stored over 3 Å molecular sieves prior to use, and all manipulations were performed under dry nitrogen. Diisopropylformamide (5 mL, 34.5 mmol) in Et_2O (10 mL) was added at 0 °C to a stirred solution of $POCl_3$ (3.2 mL, 34.5 mmol) in Et_2O (25 mL). After the mixture had been stirred for 0.5 h at room temperature, the white precipitate was allowed to settle and the supernatant was removed. The solid was washed with Et_2O (2 × 30 mL), dissolved in dichloromethane (30 mL), and diisopropylamine (4.5 mL, 34.5 mmol) in dichloromethane (10 mL) added dropwise at 0 °C. The solution was stirred at room temperature for 0.5 h, Et_2O (30 mL) added, and the precipitate collected by filtration. The solid, a mixture of the required formamidinium salt and diisopropylammonium chloride (4.4 g), was treated with acetone (30 mL) in which only the formamidinium salt is soluble. After removal of the diisopropylammonium chloride by filtration, Et_2O (30 mL) was added to precipitate the product as a white crystalline solid (2.14 g) which was dried in vacuo over P_2O_5 before use, m. p. 214–220 °C with decomposition. ^1H NMR: (300 MHz, $CDCl_3$): $\delta = 1.49$ (d, 24H), 4.25 (br. s, 4H), 7.60 (s, 1H); ^{13}C NMR (75.45 MHz, $CDCl_3$): $\delta = 22.72$ (br.), 52.0 (br.), 151.05

4: *N*,*N*,*N*′,*N*′-tetraisopropylformamidinium chloride (0.3 g, 1.21 mmol) was added to a solution of LDA (formed by the addition of *n*-butyllithium (0.5 mL, 2.4 M in hexanes) to diisopropylamine (0.21 mL, 1.5 mmol) in tetrahydrofuran at −78 °C). The reaction mixture was allowed to stir at room temperature for 0.5 h by which time complete dissolution had occurred. The solvent was removed under vacuum to give an off-white solid, which was treated with hexane. The supernatant was removed and evaporated under vacuum to give a white solid, which was sublimed at 40 °C/0.2 mm Hg to yield white crystals (0.142 g, 55%), m. p. 51–55 °C. Elemental analysis calculated for $C_{13}H_{28}N_2$: C 73.5, H 13.3, N 13.2%; found: C 73.8, H 13.5, N 13.2; ^1H NMR (500 MHz, [D$_6$]benzene): $\delta = 1.28$ (br., 24H); 3.70 (br., 4H); ^{13}C NMR (125.7 MHz, [D$_6$]benzene): $\delta = 24.2$ (br.), 49.6 (br.), 255.5.

[11] Crystal data for **4**: $C_{13}H_{28}N_2$, $M_r = 212.4$, triclinic, space group $P\bar{1}$ (no. 2), $a = 7.5346(11)$, $b = 8.844(2)$, $c = 12.113(3)$ Å, $\alpha = 110.718(12)$, $\beta = 104.868(12)$, $\gamma = 92.700(9)$°, $V = 721.2(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 0.978$ g cm^{-3}, $\lambda = 0.71073$ Å, $\mu(Mo_{K\alpha}) = 0.57$ cm^{-1}, $F(000) = 240$, $T = 173$ K, crystal size $0.2 \times 0.2 \times 0.2$ mm. All diffraction measurements were made on a Siemens SMART area detector diffractometer, using graphite monochromated $Mo_{K\alpha}$ *X*-radiation. Unit cell dimensions were determined from 89 reflections. Diffracted intensities were measured in a hemisphere of reciprocal space for $3.0 < 2\theta < 45.0$° by 0.3° ω scans, frames observed for 30 s. Crystal decay of about 40% was observed over a period of 13 h. Data collected after about 6 h were discarded because of poor agreement with earlier data. A total of 1259 data were integrated of which 977 had $I > 2\sigma(I)$. No absorption correction was applied. Lorentz and polariation corrections were applied. The structure was solved by direct methods. All non-hydrogen atoms were assigned anisotropic displacement parameters. All hydrogen atoms were located in difference maps and constrained to idealized geometries. Full-matrix least-squares refinement on F^2 of this model using the SHELXL-93 program (SHELXTL version 5.03. Siemens Analytical Xray, Madison WI, 1994) (144 parameters) converged to final residual indices $R1 = 0.084$, $wR2 = 0.198$, $S = 1.15$. Final difference electron density maps showed no features outside the range $+0.26$ to -0.22 e Å^{-3} (cf. methine hydrogen atom peaks 0.39–0.49 e Å^{-3}). Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-26. Structures of XeF_7^- and $Xe_2F_{13}^-$**

Arkady Ellern, Ali-Reza Mahjoub, and Konrad Seppelt*

XeF_6 is an amphoteric solvent; however, it has not been investigated very much, mainly because of its extreme fluorinating power, the difficulties associated with its purification, and because of the extraordinary explosive power of its final hydrolysis product, XeO_3. The conductivity of XeF_6 is found to be $1.45 \times 10^{-6}\ \Omega^{-1}$, which suggests a dissociation into fluoroxenon cations and fluoroxenon anions.[1] Nevertheless, the first preparation of Au^V as $Xe_2F_{11}^+AuF_6^-$ was achieved in liquid XeF_6.[2] The chemistry of the fluoroxenon cations of XeF_6 has been established with the ions XeF_5^+ and $Xe_2F_{11}^+$. In solution and in the melt XeF_6 exists as monomer and tetramer in equilibrium,[3] at low temperatures in solution only the tetramer is observed.[4] Tetrameric and (less often) hexameric units are characteristic for the solid state.[5] Because of the amphoteric character of XeF_6 fluoroxenon anions are expected to exist, and XeF_7^- and XeF_8^{2-} have been described.[6] However, only the structure of XeF_8^{2-} has been confirmed; it is square antisprismatic with no detectable steric activity of the nonbonding pair of electrons.[7]

Little is known about the structure of XeF_7^-. It is formed from CsF and XeF_6 as a yellow solid; however, it readily loses XeF_6, resulting in colorless Cs_2XeF_8. Likewise with NOF the final product is XeF_8^{2-}.[6] By using an excess of the weaker fluoride donor NO_2F crystalline, sublimable $NO_2^+XeF_7^-$ is formed; however, this is always multiply twinned therefore not allowing a single-crystal X-ray structure analysis. XeF_7^- presents an interesting structure, since it contains seven identical ligands and a nonbonding electron pair. This is the only example of such a combination known to date in main group chemistry.

$CsXeF_7$ freshly prepared from CsF and XeF_6 dissolves in BrF_5 to give a lemon yellow colored solution, and crystallizes at 4 °C to give yellow crystals. According to the results of a single-crystal X-ray structure determination the anion has a capped octahedral structure, which is strictly obeyed because of the symmetry constraints of the cubic lattice system (Fig. 1).

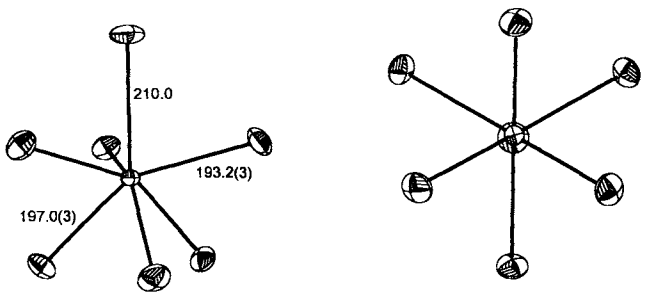

Fig. 1. Structure of the XeF_7^- ion in the crystal of $Cs^+XeF_7^-$ (ORTEP plot, 50% probability). Distances [pm]: Xe–F1 193.2(3), Xe–F2 210.0(6), Xe–F3 197.0(3), Cs···321.7(3), 344.2(4), Cs···F2 3 × 326.5(2), Cs···F3 310.3(3), 341.5(4); angles [°]: F2-Xe-F1 132.2(1), F2-Xe-F3 75.91(1).

In the last few years it has been shown that main group compounds with the coordination number 7 in absence of nonbonding electron pairs always adopt a pentagonal bipyramidal structure (IF_7, TeF_7^-, IOF_6^-, $ROTeF_6^-$, $(RO)_2TeF_5^-$), possibly because this structure has one linear ligand–central atom–ligand arrangement (e.g. I-F-I)—in contrast to all other structural alternatives—to satisfy the high p character of the bonding.[8] Among the comparable transition metal compounds (MoF_7^-, WF_7^-) the capped octahedron is observed;[9] however, not always (ReF_7^-, TeF_7^{2-}).[10–12] The comparison of the capped octahedra of XeF_7^- in $Cs^+XeF_7^-$ with those of MoF_7^- and WF_7^- reveals an important difference. The Xe–F bond to the capping fluorine atom in XeF_7^- is remarkably long (210 pm). Thus, one can assume that this direction in space might also contain the remaining weak influence of the nonbonding electron pair. Whereas the fluorine atoms of the distorted octahedron interact with two cesium ions, the capping fluorine atom interacts with three. This may also explain the length of the bond between xenon and the capping fluorine atom.

Evidently, this C_{3v} structure is not the only geometry the XeF_7^- ion can adopt. The reaction of NO_2F with excess XeF_6 affords $NO_2^+Xe_2F_{13}^-$ as a colorless, sublimable crystallizate. (Once, but so far not reproducibly, $NO^+Xe_2F_{13}^-$ has also been obtained; which has a very similar structure of the anion.[13]) The dinuclear anion $Xe_2F_{13}^-$ (Fig. 2), following XeF_7^-, is evidently a member of a series which would proceed with $Xe_3F_{19}^-$ and $Xe_4F_{25}^-$. However, experimental difficulties have thus far prevented the isolation of these polynuclear anions.

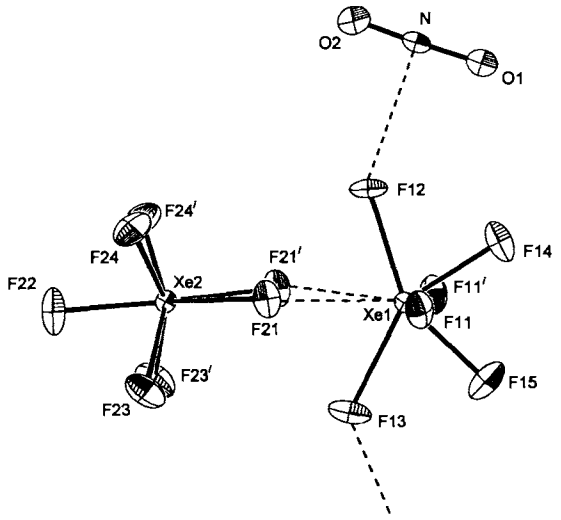

Fig. 2. Structure of a unit $NO_2^+Xe_2F_{13}^-$ in the crystal (ORTEP plot, 50% probability). The crystallographic mirror plane is slightly tilted against the plane of the paper to make symmetry equivalent fluorine atoms visible. Distances [pm]: N···F12 252.2(3), N···F13 247.6(3), Xe1···F21 255.8(3).

The structure of $Xe_2F_{13}^-$ can be separated into a XeF_7^- and a XeF_6 part, if contacts of approximately 255 pm in length are disregarded between F(21) and Xe(1). This view in connection with the long Xe–F bond (210 pm) discussed above is certainly a gross simplification. The XeF_7^- part has a C_{2v} structure as a consequence of lattice symmetry, and the anion has the shape of an ideal capped trigonal prism (Fig. 3). In this case the bond between the capping fluorine atom and the xenon atom is the shortest. The length of the two Xe–F bonds that are opposite to the capping fluorine atom gives the impression that the nonbonding electron pair is located between these long bonds. The structure can also be described as a square pyramidal XeF_5 part with two additional long Xe–F bonds that are pushed away by the nonbonding electron pair. Thus, we conclude that the structure of XeF_7^- is chiefly determined by the lattice symmetry, evidently because energy differences between the different possible geometries of the free anion are marginal.

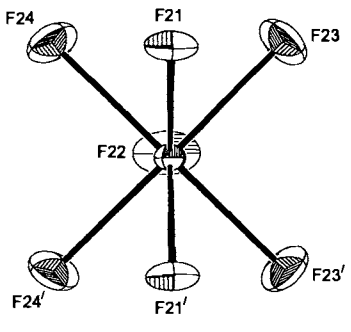

Fig. 3. Capped trigonal prismatic structural unit XeF_7^- in $Xe_2F_{13}^-$. Distances [pm]: Xe2–F21 218.9(2), Xe2–F22 184.2(4), Xe2–F23 190.1(3), Xe2–F24 187.8(3).

The $Xe_2F_{13}^-$ ion holds another surprise—again if the Xe(1)–F(21) contact is not considered—that is, a XeF_6 molecule in a crystalline phase. In agreement with all physical data it is assumed that in the gaseous state XeF_6 has the C_{3v} structure of an octahedron distorted by a nonbonding electron pair. This structure can be interchanged by very small variations of angles into an energetically hardly less optimal C_{2v} structure; the energy barrier between these two structures is very small.[14] In the crystal XeF_6 has a C_{2v} structure with two shorter, two intermediate, and two longer bonds (Fig. 4a). Viewed from a slightly different direction the molecule appears as a distorted C_{3v} structure (Fig. 4b). If one defines the averaged bond angles between opposite fluorine atoms as a measure for the deviation from ideal octahedral symmetry, the angle of 153° for the structures of XeF_6 reveals that it is very distorted (for comparison: IF_6^- 164°, SeF_6^{2-} 172°, and BrF_6^- 180°[15–17]).

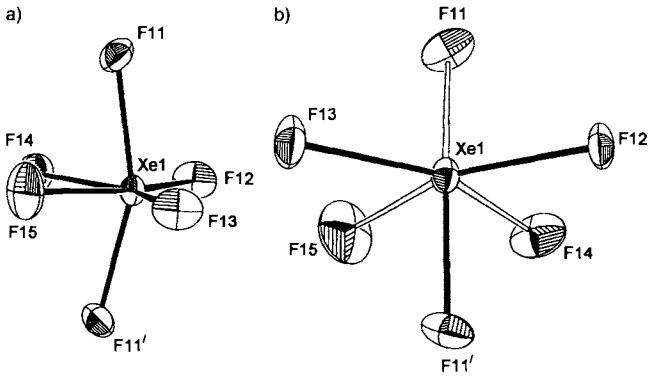

Fig. 4. a) The C_{2v} symmetric XeF_6 molecular unit in $Xe_2F_{13}^-$. b) The same unit as viewed from a slightly different direction to show the approximated C_{3v} structure. Distances [pm] Xe1–F11 188.5(3), Xe–F12 197.2, Xe1–F13 202.1, Xe1–F14 185.5, Xe1–F15 185.6; angles [°]: F11-Xe1-F11′ 157.9(2), F12-Xe-F13 135.2(2), F14-Xe-F15 76.3(2).

Experimental Procedure

$Cs^+XeF_7^-$: An excess of pure XeF_6 [18] was condensed in vacuum (stainless steel system) into a polyperfluoroethene-propene (Teflon FEP) tube on to previously (under exclusion of humidity) powdered CsF. After heating the tube to 40 °C, the excess XeF_6 was pumped off, the crystalline solid was powdered, and again excess XeF_6 was condensed and the procedure repeated. Rapid pumping off of excess XeF_6 afforded a yellow powder of $CsXeF_7$; elemental analysis: found: Xe 34.49, F 34.0%, calcd. Xe 33.46, F 33.4. Raman (solid): $\tilde{\nu}$ = 627.5(10), 555.5(100), 504.5(10), 485(3), 459.5(15), 342(3), 275(3), 207(3) cm^{-1}.

$CsXeF_7$ (ca. 50 mg) was added to a FEP tube, and colorless (Br_2 and BrF_3 free) BrF_5 (3 mL) was condensed onto it. After the tube had been sealed, it was shaken briefly at room temperature to give a clear yellow solution. Discoloration indicated the formation of Cs_2XeF_8. Cooling to 4 °C overnight afforded large yellow crystals.

Crystal structure: A suitable crystal (0.2 × 0.2 × 0.2 mm) was mounted under cooling and in an inert gas atmosphere on an Enraf Nonius CAD-4 cycle diffractometer and measured at −143 °C, a = 896.0(7) pm, $V = 605.7(1) \times 10^6$ pm^3, space group $P2_13$ (No. 198), Z = 8, $2\theta_{max}$ = 70°, $Mo_{K\alpha}$, λ = 71.069 pm, ω scan, 522 measured, 522 independent, 518 used reflections, Lorentz polarization correction, Ψ scan absorption correction, μ = 11.68 mm^{-1}, min/max correction 0.85/1.12. Structure solution was carried out with the program SHELXS 86 [19], refinement with SHELXS 93 [20], 29 parameters, R_1 = 0.035, wR_2 = 0.111, extinction coefficient 0.007(2) [23].

$NO_2^+Xe_2F_{13}^-$: Pure NO_2F [21] and XeF_6 in the molar ratio 1:2 were condensed into a Teflon FEP tube. After the sample had been sealed in vacuum, it was stored at room temperature. Spontaneous sublimation afforded colorless crystals that could be distinguished under the polarization microscope. XeF_6 was optically isotropic, $NO_2^+XeF_7^-$ appeared in the form of square, thin platelets that consist of many, strongly iridescent single crystals, whereas $NO_2^+XeF_{13}^-$ single crystals turn the plane of the polarized light. A single crystal of 0.3 × 0.3 × 0.2 mm dimensions was mounted and measured, as described for $CsXeF_7$, a = 1592.5(3), b = 7543.5(2), c = 864.9(1) pm, β = 94.77(1)°, $V = 1075.8(4) \times 10^6$ pm^3, space group C_2/m (No. 12), Z = 8, $2\theta_{max}$ = 61°, 1732 measured, 1671 independent, 1474 used reflections, DIFABS absorption correction [22], μ = 6.73, min/max correction 6.92/1.12, 97 parameter, R = 0.025, R_2 = 0.068 [23].

Structural Diversity in Alkali Metal Phospholides: A Kalocene-Type Structure

Frédéric Paul, Duncan Carmichael, Louis Ricard, and François Mathey*

The alkali metal derivatives of the cyclopentadienide anions can display four structural forms.[1] Generally, they have bridging η^5-Cp rings incorporated into a polymeric chain, which usually confers low solubility. This structure can be broken down by a donor solvent (Solv) to give monomeric half-sandwich compounds $[CpM(Solv)_n]$. The most interesting structural form, the anionic sandwich complex $[Cp_2M]^-$, has very recently been characterized crystallographically as the lithium compound.[2] A priori, the alkali metal derivatives of phospholide (phosphacyclopentadienide) anions can display the same morphological diversity. However, to date, only lithium tetramethylphospholide, which adopts a half-sandwich structure when crystallized in the presence of tetramethylethylenediamine, has been crystallographically characterized.[3] Some time ago, during a study of a series of flexible tetraphosphole macrocycles,[4] we generated the phospholide anions **2** and **3** in situ by cleavage of one or two P–P bonds of the phosphole tetramer ("P_4") **1** (Scheme 1). As we were interested in the coordination chemistry of these phospholides, we needed precise information on their structures.

2 *trans*-$[K([18]crown\text{-}6)(THF)_2]^+ \cdot 2\ THF$

Scheme 1.

Compound **2** was prepared as previously described[4] and obtained free from traces of the "P_2"Na_2 derivative by recrystallization from 1,2-dimethoxyethane. The structure of its DME adduct $[\mathbf{2}\cdot(DME)_2]$ is shown in Figure 1. As in the tetrameric precursor **1**,[5] the overall structure of $[\mathbf{2}\cdot(DME)_2]$ is highly skewed. The sodium ion (Na1) is η^5-bound to the first phospholyl ring (P1), σ-bound to the second phospholyl (P20), and chelated by one molecule of DME. The 3.172(2) Å separation between Na1 and P11 (cf. 3.001(1) for Na1–P1 and 3.083(2) Å for Na1–P20) suggests a fifth, weak coordination to the neutral

A

phosphorus atom. The simplified representation **A** clearly shows the head-to-tail arrangement of the two phospholyl rings and their η^1-P,η^5-PC_4 bonding mode. Similar coordination modes have been found in some phospholyl–uranium complexes.[6]

The rather short Na1–P20 contact probably reflects a high charge localization of the phospholide anion at phosphorus, as has been predicted by theory.[7] Evidence of high σ-donation from P20 to Na1 is provided by the Na1–phospholyl (P1) distance of 2.569 Å, which is at the high end of the recorded Na–Cp bond lengths (2.40–2.65 Å[11]). $[Cp^*Na(Py)_3]$ ($Cp^* = C_5Me_5$; Py = pyridine), which has three Py donors in the coordination sphere of sodium, has a comparable Na–Cp*(centroid) distance of only 2.40 Å.[8] The influence of the substitution scheme on the structural parameters of the phospholide ring also appears to be significant. For **2**, the relatively small difference in bond lengths ($C_\alpha C_\beta$–$C_\beta C_{\beta'}$) clearly indicates an extensive electronic delocalization throughout the carbon-centered portion of the phospholyl anion. Nonetheless, the P–C separations (1.762(3) and 1.770(3) Å), which are substantially longer than in $[C_4Me_4P][Li(tmeda)]$ (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) (1.750–1.752(2) Å),[3] suggest that phosphorus participates less in cyclic delocalization in **2** than in the tetraalkylphospholide. Thus, it seems possible that extended conjugation between the substituents and the dienic portion of the phospholide may diminish the interaction of the phosphorus with the carbon skeleton of **2**. Such an influence of the substitution pattern on the structural parameters of the phospholide ion is a little unexpected, because calculations suggest that the aromaticity of the parent phospholide anion is only 10% lower than that of Cp^-.[7] However, it has been shown recently that conjugating substituents such as alkynyl groups reduce the degree of aromaticity in the phosphole nucleus.[9] It seems probable that a full understanding of this phenomenon will only be possible from computational analysis.

Compound **3** was prepared in crude form as a yellow precipitate after cleavage of **1** by four equivalents of potassium in DME. Crystals of **3**·2THF suitable for a structural study were obtained by recrystallization from a mixture of THF and [18]crown-6. The X-ray analysis (Fig. 2) shows a double anionic

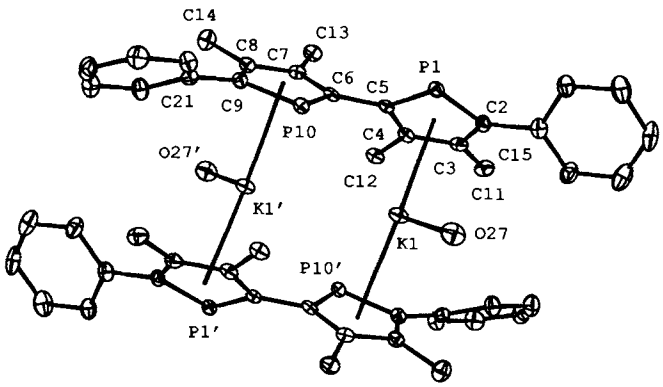

Fig. 2. X-ray crystal structure of the anionic component of **3** (THF adduct). The structure of the cation has been described previously [10] and is not shown. Carbon atoms of the coordinated THF ligand are omitted for clarity. Significant distances [Å] and angles [°]: K1–P1 3.264(1), K1–P10 3.256(1), K1–O27 2.722(3), P1–C2 1.779(4), P1–C5 1.759(3), P10–C6 1.761(4), P10–C9 1.779(4), C2–C3 1.399(5), C3–C4 1.415(5), C4–C5 1.411(5), C5–C6 1.474(5), C6–C7 1.402(5), C7–C8 1.408(5), C8–C9 1.411(5), K–C(α) mean 3.155, K–C(β) mean 3.162, C2-P1-C5 90.8(2), C6-P10-C9 90.8(2).

sandwich related to the previously unknown kalocene anion,[11] which is bent by coordination to THF. Since the structure has a center of symmetry, it is only necessary to discuss the parameters of one P1-K1-P10′ subunit. The two phospholides (P1 and P10′) have a head-to-tail disposition. Their mean planes form an angle of 47°, and the THF molecule is coordinated to the potassium ion on the open side of the tilted sandwich: (P1)centroid-K1-(P10′)centroid = 137.9°, (P1)centroid-K1-O27 = 110.8°, O27-K1-(P10′)centroid = 106.2°. The displacements of the potassium atoms from the phospholyl mean plane (2.855–2.883 Å) are rather large when compared with those in other CpK structures (ca. 2.79 Å).[11] This probably results simply from a relaxation of the K–C distances to accommodate the inherently longer P–K1 separation, which appears to be normal at 3.264(1) Å.[12] Finally, the two 2,2′-biphospholide units unexpectedly adopt a cisoid configuration, and the interaction between the two potassium ions K1 and K1′ is negligible, as shown by their separation of 4.266(2) Å.

From this series of results, it appears that the structural chemistry of alkali metal phospholides is even richer than that of alkali metal cyclopentadienides.

Experimental Procedure

2: Naphthalene (50 mg) was added to sodium metal (1.00 g, 43 mmol) in freshly distilled THF (15 mL) under argon. After five minutes, tetramer **1** (1.00 g, 1.34 mmol) was added. After 2 h the black-green solution was filtered free of sodium with a cannula and treated further with tetramer **1** (0.95 g, 1.28 mmol). The red suspension was then stirred for several hours at room temperature until dissolution of the added tetramer was complete. The solvent was evaporated under vacuum. The red-orange precipitate was washed several times with 20 mL of *n*-pentane and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3510-1126 $ 15.00+.25/0

dried. Yield: 2.75 g, 97% yield of crude air-sensitive red-orange **2**·4THF. Pure **2**·2DME was obtained by slow diffusion of *n*-hexane into a solution of **2** dissolved in DME. $C_{56}H_{64}Na_2O_4P_4$ (red-orange crystals), $M_r = 971.01$, crystal dimensions $0.32 \times 0.32 \times 0.32$ mm, triclinic, $P\bar{1}$ (No. 2), $a = 11.909(1)$, $b = 14.819(2)$, $c = 16.901(2)$ Å, $\alpha = 95.29(1)$, $\beta = 101.23(1)$, $\gamma = 112.58(1)°$, $V = 2654.0$ (1) Å^3, $Z = 2$, $\rho_{calcd} = 1.215$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 2.0$ cm^{-1}, $F(000) = 1028$, $T = 123 \pm 0.5$ K. Final $R = 0.044$, $R_w = 0.065$ for 9550 observed unique reflections with $2\theta_{max} = 60°$ having $F_o^2 > 3.0\sigma(F_o^2)$. Solution by direct methods; 595 variables refined using $\omega(|F_o| - |F_c|)^2$ by full matrix least squares, GOF = 1.19. $(\Delta\rho)_{max,min} = 1.05$ Å^3 in the final difference map [13].

3: Potassium metal (0.91 g, 23.3 mmol) and tetramer **1** (4.00 g, 5.38 mmol) were heated to 70 °C in freshly distilled DME (100 mL) for 12 h. The crude precipitate of air-sensitive pale yellow needles was collected, washed with DME, and dried. Yield of **3**·4DME: 6.30 g, 93%. Crystals suitable for X-ray diffraction were grown by diffusion of hexane into a THF solution containing equimolar amounts of **3** and [18]crown-6. $C_{104}H_{156}K_4O_{20}P_4$ (pale yellow crystals), $M_r = 2006.69$, crystal dimensions $0.20 \times 0.30 \times 0.34$ mm, monoclinic, $P21/n$ (No. 14), $a = 17.445(2)$, $b = 15.783(1)$, $c = 20.382(2)$ Å, $\beta = 102.27(1)°$, $V = 5483.5(2)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.215$ g cm^{-3}, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu = 2.8$ cm^{-1}, $F(000) = 2152$, $T = 123 \pm 0.5$ K. Final $R = 0.056$, $R_w = 0.072$ for 5664 observed unique reflections with $2\theta_{max} = 60°$ having $F_o^2 > 3.0\sigma(F_o^2)$. Solution by direct methods; 595 variables refined using $w(|F_o| - |F_c|)^2$ by full matrix least squares,. GOF = 1.22. $(\Delta\rho)_{max,min} = 0.57$ Å^3 in the final difference map [13].

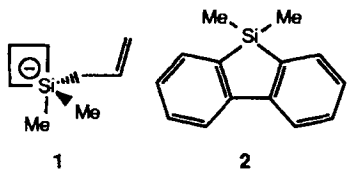
Lithium 2,2′-Biphenyldiyltrimethylsilicate; First Observation of Pentaorganosilicates

Adrianus H. J. F. de Keijzer, Franciscus J. J. de Kanter, Marius Schakel, Robert F. Schmitz, and Gerhard W. Klumpp*

In studies of nucleophilic substitution on silicon and nucleophilic activation of organosilicon compounds,[1] organosilicates with pentavalent silicon bonded to one or several atoms more electronegative than carbon have become very important. By contrast, the addition product of 1,1-dimethylsilacyclobutane and allyl anion, observed in a flowing afterglow experiment, is the only case in which the structure of a pentaorganosilicate (**1**) has been proposed.[2] Otherwise, pentaorganosilicates figure, as yet, only as unproven intermediates in the intramolecular and intermolecular transfer of triorganosilyl groups from neutral to anionic carbon centers. Thus, according to Kumada and co-workers,[3a] the transmetalation of 9,9-diorgano-9*H*,9-silafluorenes such as **2** with organolithiums proceeds via lithium pentaorganosilicates. We now report that we have observed these species at low temperatures by NMR spectroscopy. At higher temperatures they decompose into tetraorganosilane and organolithium. This can result in carbanion exchange between the starting compounds.



1 **2**

Treatment of bromide **3**[4] with *tert*-butyllithium at −80 °C in THF generated a species whose exceptionally high-field ^{29}Si NMR signal ($\delta = -116.9$) was indicative of pentavalent silicon.[5] Apparently, the lithium compound **4** rearranges instantaneously to the title compound **5**,[6] whose composition was deduced from the 8:9 ratio of the intensities of the biphenylene and methyl proton signals.[7] Raising the temperature converts **5** reversibly into methyllithium and 9,9-dimethyl-9*H*,9-silafluorene (**2**), which was identified in situ by comparison of its ^{29}Si ($\delta = 0.6$), ^{1}H, and ^{13}C NMR spectra with those of authentic material. Conversely, cooling THF solutions of methyllithium plus **2** generates **5**, which is the only species present at approximately −100 °C. Cryoscopy indicated that under these conditions **5** is undissociated: After addition of **2** (0.53 mmol) to a solution in THF of Me_4Li_4 (0.14 mmol), the number of particles contained in the solution (0.52 ± 0.01 mmol **5**) corresponded to the amount of **2** that had been added. In the presence of ten equivalents of hexamethylphosphoric triamide (HMPA), which strongly complexes lithium, the splitting of the ^{7}Li NMR signal by ^{7}Li–^{31}P coupling (−120 °C, $\delta(^7Li) = -2.1$,[8] quintet,

$\delta(^{31}P) = 24.1$, 1:1:1:1 quartet, $^2J(^7Li,^{31}P) = 7.5$ Hz[9]) clearly indicated coordination of four HMPA molecules to the lithium ion of **5**. Since a single ^{29}Si NMR signal at -116.2 persisted from -120 to 20 °C, **5**-L_4 (L = HMPA) must be more stable than **2** plus methyllithium throughout the temperature range studied. A single methyl signal and a single set of six phenylene carbon signals in the ^{13}C NMR spectra indicate that stereoisomers of **5**-L_4 (L = HMPA) interconvert rapidly on the ^{13}C NMR time scale, even at -120 °C.

The reaction of butyllithium (1 equiv) with **2** in THF is analogous to that of methyllithium. At -80 °C the ^{29}Si NMR signal of the *Si*-butyldimethyl analogue of **5** is found at $\delta = -113.6$.[10] By contrast, in ether at -80 °C as well as at higher temperatures, neither the methyllithium/**2** system nor the butyllithium/**2** system exhibits a ^{29}Si NMR signal of pentacoordinated silicon. Above -14 °C formation of 9-butyl-9-methyl-9*H*,9-silafluorene[3a] is evident, strongly suggesting, as Kumada and co-workers[3a] had already proposed for the present reaction and for related ones, that **5** and analogues are accessible kinetically also in ether.[11] However, in this solvent, the thermodynamic stability of **5** and its analogues relative to that of **2** plus methyllithium or butyllithium is so low that they cannot be detected. It appears that the stabilities of ate complexes of Group 4 elements depend to a large degree on the strength of complexation of their countercations by the solvent or other Lewis bases. Thus, organofluorosilicates are most stable as the [18]crown-6 potassium salts.[12] The present order of propensity for complexation of the lithium ions and, thereby, stabilization of **5** and analogues, HMPA > THF > ether, applies also to lithium pentaorganostannates.[13] The fact that **5** is present in THF in substantial concentrations suggests to us optimum complexation of the lithium ion, that is the existence of **5**-L_4 (L = THF). This is in accord with known structures of THF-complexed lithium salts[14] and is supported by the value of the reaction entropy in THF. The ratios of the integrals of the NMR signals of the methyl protons of methyllithium, **5**, and **2**, in THF at eleven temperatures (-54 to -9 °C) were used to determine the equilibrium constant K for the reaction $1/4\,Me_4Li_4 + \mathbf{2} \rightleftharpoons \mathbf{5}$, whence $\Delta H = -55 \pm 2$ kJ mol^{-1}, $\Delta S = -225 \pm 6$ J K^{-1} mol^{-1} were obtained. The value of ΔS indicates a strong decrease of the number of particles, as one would expect for the formation of a tetrasolvate,[15] suggesting that actually reaction (a) is occurring.

$$1/4\,Me_4Li_4 \cdot 4THF + 3THF + \mathbf{2} \rightleftharpoons \mathbf{5}\text{-}L_4\ (L = THF) \qquad (a)$$

Any interpretation of the value of ΔH in terms of silicate formation from tetraorganosilanes and carbanions[16] is precluded by the unknown energy contributions associated with the deaggregation of $Me_4Li_4 \cdot 4THF$ as well as with the separation of ions and the complexation of the lithium ion by THF in **5**-L_4 (L = THF).

Chemical shifts of the ^{29}Si NMR signals arising upon treatment of **2** with phenyllithium and *tert*-butyllithium let us conclude that lithium silicates are also formed in these systems, presumably $Li[SiC_{12}H_8Me_2Ph] \cdot 4THF$, $\delta(^{29}Si, -80\,°C) = -112.7$, and $Li[SiC_{12}H_8Me_2tBu] \cdot 4THF$, $\delta(^{29}Si, -80\,°C) = -102.5$, respectively. A similar high-field resonance ($\delta(^{29}Si, -80\,°C) = -102.3$) in the system tetraphenylsilane/phenyllithium/THF–HMPA proves that lithium pentaorganosilicates (here $Li[SiPh_5] \cdot 4HMPA$) are also formed from tetraphenylsilane.

In summary: In THF equilibria are established between various σ-organolithiums and either 9,9-dimethyl-9*H*,9-silafluorene (**2**) or tetraphenylsilane, and the corresponding lithium silicates. The latter can be monitored by NMR spectroscopy at low temperatures and their stability is increased by coordination of HMPA to lithium. To our knowledge these are the first pentaorganosilicates described. Present studies aim at the preparation of lithium pentaorganosilicates from other tetraorganosilanes.

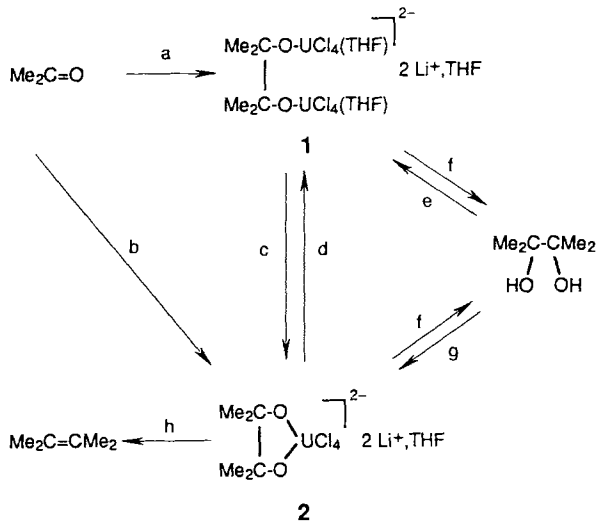
Metallopinacolate Intermediates in the Reductive Coupling of Acetone Promoted by Uranium Reagents

Olivier Maury, Claude Villiers, and Michel Ephritikhine*

Reductive coupling of carbonyl compounds by means of low-valent metal species is an extremely useful reaction in organic synthesis, and many efforts have been made to improve the efficiency and to understand the mechanisms of these processes.[1] A number of titanium systems, prepared from $TiCl_4$ or $TiCl_3$ and various reducing agents under different conditions, have been used for coupling ketones. The nature of the products, diols or alkenes, was found to depend markedly upon the structure of the active titanium species and the experimental conditions.[2] A complete rationale for these results is still lacking.[3] In this context, we thought it of interest to consider the potential of uranium compounds in such transformations. Complexes of uranium and Group 4 elements exhibit strong analogies in structure and reactivity, and highly reactive uranium metal powder was effective in the reductive coupling of aromatic ketones.[4] Moreover, the paramagnetic uranium complexes can be easily identified by their NMR spectra. They often crystallize readily and are therefore valuable auxiliaries in synthetic organic chemistry.[5, 6] We reported that benzophenone could be coupled in the presence of uranium tetrachloride and sodium amalgam. For the first time, the pinacolate intermediate previously postulated was isolated, characterized, and transformed into the corresponding alkene, tetraphenylethylene.[6] Subsequently, we found that aliphatic ketones could also be treated with UCl_4 and Na/Hg or Li/Hg to give pinacols or alkenes in good yields. The reaction of the simplest ketone, acetone, was studied in more detail, and the results reported here provide new insights into the intermediates and elementary steps of the coupling and deoxygenation processes. The influence of the reducing agent in these McMurry-type reactions is also defined.

A solution of acetone in tetrahydrofuran (THF) reacted with UCl_4 and Li/Hg in a molar ratio of 1:1:1 to give the bimetallic pinacolate complex **1** (Scheme 1). The mixture was stirred for 3 h at 20 °C and, after filtration and crystallization, **1** was isolated as a greenish powder in 90% yield. An analogous reaction with the components in a 2:1:2 molar ratio led to the formation of the green mononuclear compound **2**, which was also obtained in almost quantitative yield from **1** and two equivalents of Me_2CO and Li/Hg. Comproportionation of **2** and UCl_4 gave **1**. Unequivocal synthesis of **1** and **2** could be achieved in THF by alcoholysis of the amido(chloro)uranium derivatives $[U(NEt_2)Cl_3(THF)]$ and $[U(NEt_2)_2Cl_2]$[7] with pinacol in the presence of LiCl. Compounds **1** and **2** were characterized by their elemental analyses (C, H, Cl) and their ^1H NMR spectra, which exhibit very shifted paramagnetic signals corresponding to the methyl groups, at $\delta = +108$ and $+26$, respectively.[8]

Other products resulted when sodium amalgam was used in place of Li/Hg. The reaction of acetone with UCl_4 and Na/Hg in the molar ratio of 1:1:1 afforded the neutral metallopinacol **3** as the major product (>60% yield), and NaCl precipitated. When a molar ratio of 2:1:2 was employed, the main product was the neutral metallopinacol **4** in similar yields. Other compounds resulting from aldolization of the ketone were also



Scheme 1. Synthesis, interconversion, and deoxygenation of the metallopinacols **1** and **2**. All reactions in THF at 20 °C except reaction (h) at 65 °C. The coordination of THF molecules in **1** and **2** is not known; in the formulas here written, uranium is hexacoordinate, as most frequently encountered.

$[\{UCl_3(THF)_2\}_2(\mu\text{-}OCMe_2CMe_2O)]$ **3**

$[UCl_2(OCMe_2CMe_2O)(THF)_x]$ **4**

formed and are currently under investigation. These reactions with Na/Hg, which required three days for completion, were much slower than those with Li/Hg. As expected, complexes **3** and **4**, which were synthesized independently by treating $[U(NEt_2)Cl_3(THF)]$ and $[U(NEt_2)_2Cl_2]$ with pinacol, were converted into **1** and **2** by addition of LiCl. The bimetallic compound **3** was characterized by its ^1H NMR spectrum, which showed a broad resonance at $\delta = +126$. The derivative $[\{UCl_3(HMPA)_2\}_2(\mu\text{-}OCMe_2CMe_2O)]$, prepared by replacement of the THF ligands with hexamethylphosphoric triamide (HMPA), gave satisfactory elemental analyses (C, H, N) and its structure was confirmed by X-ray crystallography.[9] Complex **4**, which presumably has a polymeric structure with Cl bridges, is insoluble in organic solvents and could not be purified by extraction or crystallization.

Complexes **1**–**4** are the first metallopinacolate intermediates to be isolated in the reductive coupling of an aliphatic ketone. A bimetallic species similar to **1** and **3** could not be identified in the reactions of benzophenone with the systems UCl_4 and M/Hg (M = Li or Na). However, metallopinacols have been synthesized recently by reaction of dialdehydes and ketoaldehydes with tin hydrides [10] and by treatment of fluorenone with a samarium(II) alkoxide;[11] these complexes are not intermediates in McMurry-type reactions. Not surprisingly, hydrolysis of **1**–**4** led to the immediate and quantitative liberation of pinacol. More interesting is the formation of the alkene product, which, as previously demonstrated,[6] required further treatment of the pinacolato complexes with the reducing agent. In fact, reaction of **1** with one equivalent of lithium amalgam at 20 °C in THF did not afford the alkene but gave after 4.5 h the metallacycle **2** in 85% yield. Since the violet uranium(III) chloride concomitantly formed, $LiUCl_4$ (or $UCl_3 + LiCl$), is precisely that obtained from UCl_4 and Li/Hg, it was not surprising to observe its total conversion into **1** after further addition of one equivalent of acetone (NMR experiments). These results (Scheme 2) confirmed that **1** is an intermediate in the synthesis of **2** and revealed

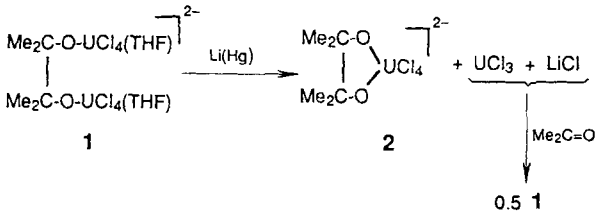

Scheme 2. The role of **1** as an intermediate in the formation of **2**.

two unsuspected points of the reaction mechanism. Firstly, acetone is not involved in the transformation **1** → **2**, which is induced by Li/Hg reduction and generates UCl_3 and LiCl. Secondly, **2** is the true precursor of the alkene, tetramethylethylene. Indeed, **2** was smoothly reduced at 20 °C by Li/Hg to give a not yet identified uranium(III) alkoxide, and complete formation of the alkene could be achieved after the mixture was heated at reflux for 24 h. In agreement with these observations, the reductive coupling of acetone to give pinacol or tetramethylethylene was performed in a one-pot reaction by using the proper quantities of UCl_4 and Li/Hg; the diol was formed by hydrolysis after 8 h at room temperature, whereas the alkene was obtained by heating for 24 h under reflux (quantitative yields by NMR). When the UCl_4 and Na/Hg system was used, the yield of tetramethylethylene did not exceed 10% after 48 h at 65 °C. This difficulty in forming the alkene could be clearly related to the sluggish reduction of the pinacolato intermediate **4**, which was quite inert towards Na/Hg at 20 °C; even after 30 h at 65 °C only about 20% was converted into tetramethylethylene. In contrast, **4** was readily reduced by Li/Hg and transformed completely into the expected alkene after 10 h in refluxing tetrahydrofuran.

We have found that in the reductive coupling of acetone, quite distinct conditions are necessary for both the coupling process leading to the pinacolate intermediates and for the subsequent deoxygenation step giving tetramethylethylene. These differences can be used to achieve remarkable selectivity like that observed with some titanium systems.[1,2] The results also underline the major role of the reducing agent, which determines the structure of the intermediates and is of particular importance in the deoxygenation step. If the first intermediate, a bimetallic species with a bridging $OCMe_2CMe_2O$ ligand, readily reacts with the reducing agent to give a cyclic mononuclear metallopinacol, only this intermediate is transformed under more forcing conditions into the corresponding alkene.

Experimental Procedure

^{1}H NMR (TMS int.): Bruker WP60 (60 MHz). All experiments were carried out under argon (< 5 ppm oxygen and water) using standard Schlenk-vessel and vacuum-line techniques or in a glove box. Solvents were thoroughly dried and deoxygenated by standard methods and distilled immediately before use.

1: A mixture of UCl_4 (354 mg, 0.93 mmol), 1% Li/Hg (640 mg, 0.93 mmol of Li), and acetone (68 μL, 0.93 mmol) in THF (15 mL) was stirred for 3 h at 20 °C. The green solution was filtered and its volume reduced to 5 mL. The green microcrystals of **1** that precipitated upon addition of pentane (10 mL) were filtered off, washed with pentane, and dried under vacuum (464 mg, 90%).

2: By using the same procedure as for **1**, green microcrystals of **2** were isolated in 76% yield from the reaction of UCl_4 (337 mg, 0.88 mmol), 1% Li/Hg (1215 mg, 1.76 mmol of Li) and acetone (102 mg, 1.76 mmol).

3: A mixture of $[U(NEt_2)Cl_3(THF)]$ (253 mg, 0.51 mmol) and pinacol (30.2 mg, 0.25 mmol) in THF (15 mL) was stirred for 2 h at 20 °C. The green solution was filtered and concentrated to dryness, leaving a green powder, which was washed with pentane and dried under vacuum (256 mg, 92%).

4: A mixture of $[U(NEt_2)_2Cl_2]$ (310 mg, 0.68 mmol) and pinacol (81 mg, 0.68 mmol) in THF (15 mL) was stirred for 2 h at 20 °C. The gray precipitate was filtered off, washed with pentane, and dried under vacuum (328 mg).

Molecular Tweezers as Synthetic Receptors in Host–Guest Chemistry: Inclusion of Cyclohexane and Self-Assembly of Aliphatic Side Chains**

Frank-Gerrit Klärner,* Johannes Benkhoff, Roland Boese, Ulrich Burkert, Markus Kamieth, and Ulf Naatz

Simple synthetic receptors with molecular pockets or cavities can act as models for far more complicated biological systems,[1] for example they are important for protein folding or molecular recognition of substrates in enzymatic processes. The study of such receptors should provide information about the stability and structure of receptor–substrate complexes and the noncovalent interactions responsible for their formation. Besides the relatively strong and therefore often dominant hydrogen bonding[1c–h] and the hydrophobic effects[1d,2g] in aqueous solutions, the arene–arene interaction[2] seems to be of some importance. Here we report on syntheses and some supramolecular properties (complex formation and self-assembly) of the novel molecular tweezers[3] **1a–c**, **2**, and **3**, which because of their rigid ribbon-type structure should be execellently preorganized for the formation of complexes with aromatic guest molecules

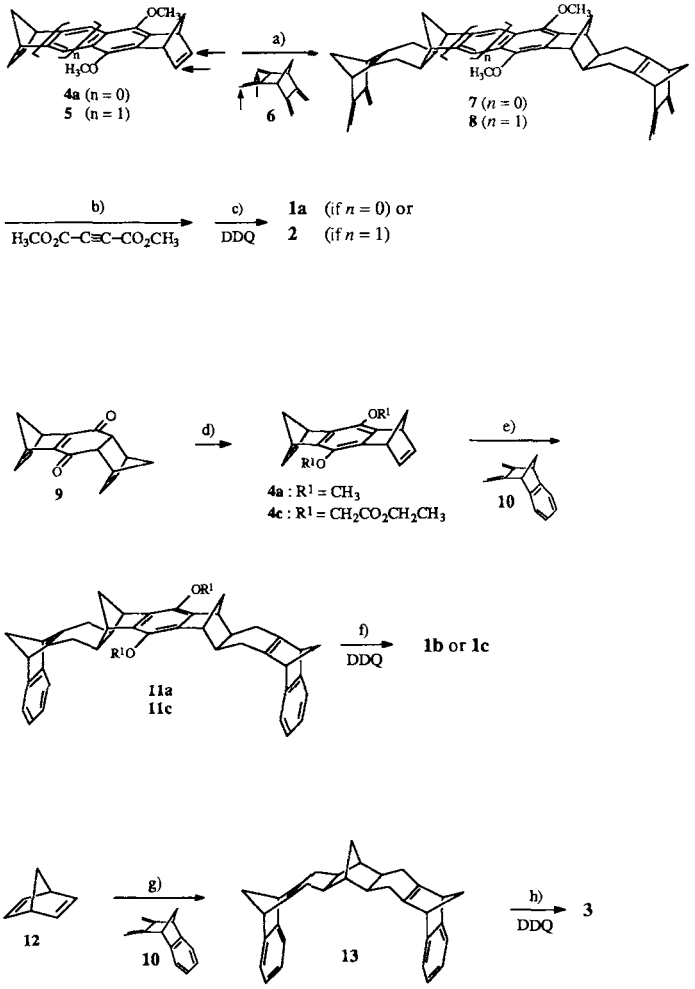
through multiple arene–arene interactions. Furthermore, bond angle distortions, which require little energy, should induce a certain flexibility to these systems allowing the tweezer "arms" to be expanded or compressed in a way comparable to the working principle of mechanical tweezers. Therefore, in their function as receptor they should be able, to a certain extent, to provide a geometrical fit to the structure of the potential substrate.

The key steps in the syntheses of **1a–c**, **2**, and **3** (Scheme 1) are repetitive Diels–Alder reactions[4] which here without exception proceed stereospecifically[5] on the *exo*-face of the bisdienophiles **4a**,[4b] **4c**, **5**,[4b] and **12** and on the *endo*-face of bisdiene **6**[6] or diene **10**.[7] Furthermore Diels–Alder reactions of the resulting bisdienes **7** and **8** with dimethyl acetylenedicarboxylate (DMAD) and subsequent DDQ dehydrogenation (DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone) yield the desired tetraesters **1a** and **2**, respectively, which can be transformed by ester hydrolysis to the water-soluble sodium salts of the corresponding carboxylic acid.[8] Starting with the bisdienophiles **4a**, **4c**, and **12** and the diene **10**, compounds **1b**, **1c**, and **3**, respectively, could be synthesized in only two steps. The high stereoselectivity of the Diels–Alder reaction of diene **10** with norbornadiene **12** was surprising, because **12** does not show complete *exo*-selectivity[9] and, for example, gives a (60:40) mixture of the *syn*- and the *anti*-adduct[10] in the Diels–Alder reaction with 5,6-bismethylenenorbornene as a diene at 140 °C. The bowl-shaped geometry of **1a**, **1c**, and **2** can be seen from the crystal structure analyses (see below).

Preliminary ^{1}H NMR experiments (300 MHz $CDCl_3$, 25 °C) showed that the potential host molecules **1a** and **2** form complexes with 1,4-dicyanobenzene or 1,4-benzoquinone as guest molecules. Addition of **1a** or **2** (c = 0.09 and 0.08 M, respectively) caused an upfield shift of the ^{1}H NMR signals of 1,4-dicyanobenzene (c = 0.02 M, δ = 7.78 → 7.38 or 7.34, $\Delta\delta$ = 0.40 and 0.44, respectively) and 1,4-benzoquinone (c = 0.02 M, δ = 6.79 → 6.64, $\Delta\delta$ = 0.15 with **2**) which indicates that the hydrogen atoms of the guest molecules are located in the magnetic anisotropy regions of the host–arene units.[11] Contrary to these findings the addition of the host fragments **4a** or **5a** did not result in a change of the chemical shifts in the ^{1}H NMR spectra of 1,4-dicyanobenzene or 1,4-benzoquinone. Surprisingly, the structure analysis of **1a** (Fig. 1), crystallized from a (2:1) mixture of cyclohexane and ethyl acetate as colorless rhombic crystals, shows a (1:1) complex of disordered cyclohexane included in the cavity of **1a**. The orientation of the cyclohexane molecule seems to depend on the positioning of the likewise disordered methoxy groups that are pointed towards the cavity. A similar result is apparent from the structure analysis of crystals of compound **2** prepared in the same way. Here also a disordered cyclohexane molecule is included in the cavity of **2**.



Scheme 1. Synthesis of the molecular tweezers **1a–c** and **2**. Reaction conditions and yields. (The thermolyses were performed in pyrex glass ampoules deactivated by $(C_2H_5)_3N$ and sealed under Ar). a) **6** (fivefold molar excess in each case), $(C_2H_5)_3N$ (catalytic amount), toluene, 125 °C, 3.5 d, 66% **7** (m.p. 210 °C decomp.) and 84% **8** (m.p. >300 °C), respectively. b) Dimethyl acetylenedicarboxylate (DMAD) (fivefold molar excess in each case), toluene, 65–70 °C, 21 h, 46% or 51% (1:2) Diels–Alder adduct (n = 0 or 1). c) DDQ (tenfold molar excess in each case), toluene, 115–120 °C, 5 h, 54% **1a** (m.p. >320 °C) or 61% **2** (m.p. >320 °C). d) $(CH_3O)_2SO_2$, NaOH, H_2O, Ar, 25 °C, 2 d, 94% **4a** (m.p. 148 °C); $BrCH_2CO_2CH_2CH_3$, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), KI (catalytic amount), CH_3CN, 70 °C, 24 h, 56% **4c** (m.p. 84 °C). e) **10** (threefold molar excess), toluene, 170 °C, 3 d, 68% **11a**; **10** (fivefold molar excess), $(C_2H_5)_3N$ (catalytic amount), 160–170 °C, 6 d, 65% **11c** (m.p. 124 °C). f) DDQ (1.5-fold molar excess), toluene, 80 °C, 5 h, 44% **1b**; DDQ (twofold molar excess), toluene, 115 °C, 17 h, 43% **1c** (m.p. 246 °C). g) **10** (fourfold molar excess), toluene, 170 °C, 3 d, 60% **13**. h) DDQ (1.5-fold molar excess), toluene, 80 °C, 5 h, 63% **3**.

The geometry of the complex between **1a** and cyclohexane calculated with molecular mechanics (MacroModel: AMBER*)[12] is in good agreement with that derived from the structure analysis. The calculated distance (6.6 Å) between the opposing terminal arene C atoms, that is the tweezer's tips, for example, is well in accord with the experimental result. In the empty tweezer **1a** this distance is calculated to be only 5.6 Å. The

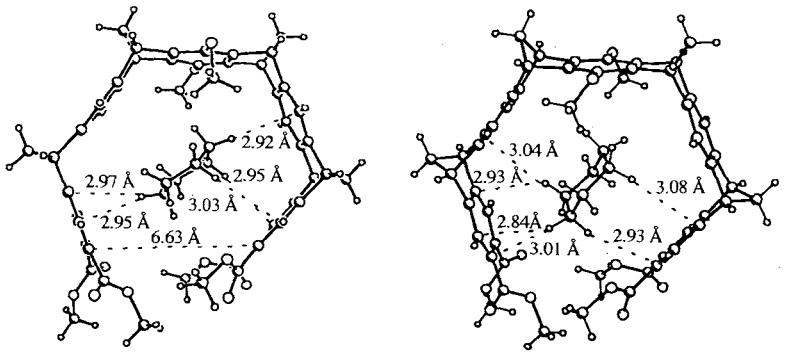


Fig. 1. Crystal structure of the superimposed (1:1) inclusion complex between **1a** and cyclohexane. In both structures the methoxy groups are pointed towards the cavity. The angle of projection between the C atoms of the two OCH_3 groups with the view of O–O axis is 35° in the first case and −55° in the second case. The two cyclohexane rings are twisted by 30° to each other with respect to the C_3 axis.

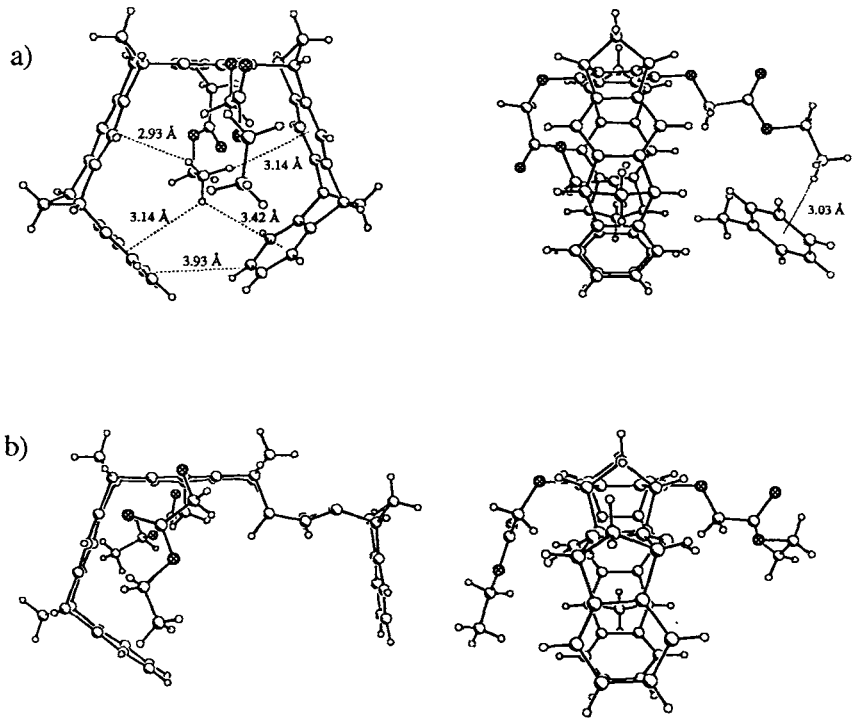

Fig. 2. a) Crystal structure of **1c**. In the side view (top, right) the distance between one methyl hydrogen atom of the extended side chain and the solvent molecule (toluene) is shown. b) Crystal structure of **14c**, the intermediate of the DDQ dehydrogenation **11c** → **1c**.

extra strain energy required for the extension by 1 Å (3 kcal mol^{-1}) is relatively small and can be easily compensated by the attractive noncovalent interactions in the formed complex.[12] For the extension of the corresponding distance in **1b** from 3.8 Å (in the empty tweezer **1b**) to 6.1 Å (in the calculated structure of the complex **1b**/cyclohexane) the extra strain energy is calculated to be 4 kcal mol^{-1}. Corresponding calculations with the tweezer **2** (having a naphthalene spacer unit) show that no change of this distance is necessary for formation of the complex between **2** and cyclohexane.

In the molecular tweezer **1c** a self-assembly of the aliphatic side chains was observed. The first evidence for such a process comes from the unexpected chemical shifts of the OCH_2CH_3 signals in the ^{1}H NMR spectrum of **1c** (Table 1). The upfield shifts indicate that the relevant hydrogen atoms are strongly influenced by the anisotropy of the arene units. The equivalence of the side chains in the NMR spectrum shows that either both side chains are complexed by the arene units in a symmetrical

Table 1. Solvent dependence of the chemical shifts of the OCH_2CH_3 groups in the ^{1}H NMR spectrum of **1c** (300 MHz, 21 °C). The compounds **4c** and **11c** used as references, only show the usual solvent dependence of chemical shifts: $\delta(CH_3) = 1.29$ or 1.23, $\delta(CH_2) = 4.24$ or 4.18 ($CDCl_3$); $\delta(CH_3) = 0.88$ or 0.43, $\delta(CH_2) = 3.85$ or 3.91 ([D_8]toluene).

Solvent	$\delta(CH_3)$	$\delta(CH_3)\delta(CH_2)$
CD_2Cl_2	1.15	4.15
$CDCl_3$	−0.27	3.37
CCl_4	−0.53	3.24
CD_3CN	1.09	4.09
[D_6]acetone	−0.28	3.33
[D_6]benzene	−0.70	3.15
[D_8]toluene	−0.84	3.05

arrangement or that only one side chain is complexed while the other one is free and that there is a rapid exchange between the complexed and the noncomplexed side chain. The results hitherto obtained from low-temperature ^{1}H NMR experiments have not allowed us to make a clear decision[13] between these two possibilities.

The structure analysis of **1c**, however, provides a clear result for the crystalline state (Fig. 2a). Here one side chain is folded and its terminal methyl group is centered in the cavity, whereas the other side chain has an extended conformation. The terminal methyl group of the extended side chain is complexed by a toluene molecule also present in the crystal. A comparison between the structures of **1c** and **14c** (Fig. 2b), an intermediate in the DDQ dehydrogenation **11c** → **1c**, is particularly instructive. Accordingly, the complexation of the side chain with both tweezer arms in **1c** is essential for its folding, whereas the interaction of the side chain with only one tweezer "arm" in **14c** is not sufficient.

The downfield shifts of the OCH_2CH_3 signals observed in the ^{1}H NMR spectra of **1c** in dichloromethane and acetonitrile (Table 1) provide evidence that these small solvent molecules can successfully compete with the one side chain to be included in the cavity of **1c**.[14] Therefore, the chemical shift of the ^{1}H NMR signal of the methyl group seems to be a sensitive probe for the ability of the molecular tweezers to form intermolecular host–guest complexes. The experiments presented here show that even the relatively weak but evidently directed alkane–arene interactions[15] are sufficient for the formation of host–guest complexes and self-assembly, so that they also have to be considered in the explanation of biological systems.

Systematic Separation

Principles and Practice of Modern Chromatographic Methods. By *K. Robards, P. R. Haddad*, and *P. E. Jackson*. Academic Press, London, 1994. 495 pp., hardcover £ 35.00.—ISBN 0-12-589570-4

Chromatographic methods of separation are among the most versatile and powerful tools available to the analyst, especially when combined with detectors of high sensitivity and selectivity. This is reflected in the fact that international book publishers have supplied the market with a wealth of material in this field, including both general treatments and specialist texts. So why do we need yet another book? The authors of this work aim to reach "as wide an audience as possible" ranging, for example, from analytical chemists whose knowledge does not include all the most recent developments in chromatography to scientists who work in fields other than chemistry but need analytical data from chromatography. It is also recommended that the book should be used by undergraduate students; however, this is likely to be no more than wishful thinking in view of the meager treatment of analytical chemistry in many university courses, at least in Germany. The authors have set out to provide a survey of the whole field of chromatography, including modern developments. They have succeeded in this, even though they have not been able to jettison all the unnecessary historical ballast. Inches and psi appear as units in a few places, and the retention factor k is still referred to as the capacity factor k'. On the other hand, topics such as supercritical fluid chromatography have been fully integrated into the text. (However, the less common name ethoxyethane instead of diethyl ether strikes one as curious rather than modern.)

The chapters have the following titles: 1. Introduction and Overview; 2. Theory of Chromatography; 3. Gas Chromatography; 4. Planar Chromatography; 5. High-Performance Liquid Chromatography--Instrumentation and Techniques; 6. HPLC Separations; 7. Supercritical Fluid Chromatography; 8. Sample Handling in Chromatography. HPLC occupies 150 pages, and is thus given considerably more attention than gas chromatography with only 100 pages. Electrophoretic methods are not covered at all.

The practical orientation and experience of the authors is evident in all the chapters, and the whole text is full of valuable advice. In the theoretical chapter, for example, it is pointed out that the quality of a chromatographic system is not determined solely by the resolution and the number of theoretical plates but also depends on factors such as column bleed and the activity of the column. The authors must also be commended for their clear warnings against misplaced faith in the integrity of instruments: "There is a tendency to uncritically accept the output from a computer system." The need for the analyst to use his or her experience in manually checking the data from instrumental measurements is emphasized repeatedly.

How successful have the authors been in their ambition to write an up-to-date survey? Let us take the chapter on gas chromatography as a test example. The first section discusses the carrier gas, including a reference to the pressure programming facility that is provided in some modern instruments. The section on sample introduction describes the currently used techniques, including the main possible sources of error. In accordance with modern practice, the use of a retention gap is recommended. Fourteen pages are devoted to columns, including a mention of high-temperature developments. The practical orientation of the treatment is illustrated by the fact that this section includes detailed descriptions of how to fit a column into the gas chromatograph, and of how to choose a column of the correct dimensions. The treatment of stationary phases which follows provides a good survey of the most commonly used phases. However, the section on "Special Phases" fails to mention liquid-crystalline phases. Chiral phases are included. A short section on the choice of temperature is then followed by a discussion of detectors; those covered here are TCD, FID, ECD, NPD, and FPD detectors. The reader will at first be disappointed to find no mention of other types such as mass-selective detectors, but these appear 20 pages later under "Ancillary Techniques". This section includes a miscellany of topics: derivatization techniques, pyrolysis-GC, head-space techniques, multidimensional GC, high-speed GC, GC-MS, and GC-IR. The atomic emission detector is not mentioned. The description of mass-selective detectors is limited to the detection characteristics; there is no explanation of the functioning of a quadrupole mass spectrometer or of an ion trap. Lastly, however, the authors have not forgotten to include a practically-orientated section on "Performance Tests".

The 50-page chapter on "Sample Handling" contains information that is rarely found in this form in texts on chromatography; it serves as a valuable supplement to the preceding chapters. With the exception of the microwave techniques on which there is currently much research, all the commonly used methods of sample collection and preparation are described in a clear and understandable way. The final chapter then presents eight examples of analytical applications with quantitative calculations, which are discussed in detail.

The reader who works carefully through the 500 pages of this book will gain a wealth of up-to-date knowledge about the use of chromatographic methods. This can then be followed up in greater depth through further reading in more detailed publications, guided by the comprehensive lists of references given in the book.

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

How the understanding of self-assembly in natural systems (e.g. DNA) can be harnessed in the design of self-assembling nanostructures.

Self-Assembly in Natural and Unnatural Systems

Douglas Philp and J. Fraser Stoddart*

Although there are no fundamental factors hindering the development of nanoscale structures, there is a growing realization that "engineering down" approaches, in other words a reduction in the size of structures generated by lithographic techniques below the present lower limit of roughly 1 μm, may become impractical. It has, therefore, become increasingly clear that only by the development of a fundamental understanding of the self-assembly of large-scale biological structures, which exist and function at and beyond the nanoscale, *downwards*, and the extension of our knowledge regarding the chemical syntheses of small-scale structures *upwards*, can the gap between the promise and the reality of nanosystems be closed. This kind of construction of nanoscale structures and nanosystems represents the so-called "bottom up" or "engineering up" approach to device fabrication. Significant progress can be made in the development of nanoscience by transferring concepts found in the biological world into the chemical arena. Central to this mission is the development of simple chemical systems capable of instructing their own organization into large aggregates of molecules through their mutual recognition properties. The precise programming of these recognition events, and hence the correct assembly of the growing superstructure, relies on a fundamental understanding and the practical exploitation of non-covalent bonding interactions between and within molecules. The science of supramolecular chemistry—chemistry beyond the molecule in its very broadest sense—has started to bridge the yawning gap between molecular and macromolecular structures. By utilizing interactions as diverse as aromatic π–π stacking and metal–ligand coordination for the information source for assembly processes, chemists have, in the last decade, begun to use biological concepts such as self-assembly to construct nanoscale structures and superstructures with a variety of forms and functions. Here, we provide a flavor of how self-assembly operates in natural systems and can be harnessed in unnatural ones.

Keywords: molecular recognition · nanochemistry · nanostructures · non-covalent interactions · supramolecular chemistry

1. The Need for Nanochemistry

The creation of nanometer-scale (nanoscale) devices[1–4] has fascinated and inspired the scientific community for more than a quarter of a century. There are no fundamental thermodynamic[5] or quantum mechanical[6] impediments lying in the way of the development of very large scale integrated (VLSI), i.e. nanoscale, electronic architectures. Consequently, the electronics industry is keen to exploit the increased signal processing speeds and lower power consumption VLSI systems offer. The development of a three-dimensional array[7] of switching elements, permitting higher levels of integration, is another primary aim of the industry. These goals, however, conflict with the realization[8] that "engineering down" approaches, in other words a reduction in the size of silicon components below the present 1 μm lower limit, are impractical. For semiconductor devices, difficulties arise as a result of the failure of insulating barriers in the materials used. More specifically, the problems associated with typical insulating barriers in the 0.2 to 1 μm size range include 1) electronic cross-talk between devices as a direct consequence of electron tunneling, 2) quantum mechanical confinement of charge carriers resulting in each device having an energy spectrum dependent on its size, 3) heat dissipation, and 4) the difficulty[9] and cost of fabrication.

Hence, the possibility of "engineering up" from a molecule to functioning electronic devices has become an increasingly attractive prospect.[10–15] The activities associated with this kind of molecular engineering have become synonymous with the quest for molecular electronics. The requirements of molecular electronics demand that we not only provide molecular scale bistable devices (switches), but also the communication infrastructure (input/output) necessary to exchange information with the outside world. Moreover, the switches must be completely controllable, reversible, and readable at the molecular level.[13] It follows that the challenge to the chemist is not only to develop bistable systems (switches), but also to construct the necessary molecular architectures and machineries capable of servicing such systems. To be able to meet these challenges, the chemist must understand and apply[16] the rules of molecular self-organization, self-assembly, and self-synthesis. Fortunately, the chemist is not alone in requiring nanoscale devices. Biological systems display a diverse array of functional nanoscale

structures and devices in the size range 1 to 10000 nm. These structures and arrays are constructed by the self-organization and self-assembly of molecular components, which interact chemically and physically in certain well-defined ways. Indeed, the phenomenon of self-organization may have been responsible[17, 18] for the emergence of life itself. The specificity and precision displayed by biological systems is derived from the highly directed mutual recognition displayed by the components of a structure. Clearly, the ultimate goal for the chemist seeking to match and even emulate the achievements of biological systems in creating and maintaining nanoscale structures is to control the assembly and function of synthetic structures from components with the same precision as that displayed by Nature. This objective can only be achieved by firstly understanding the principles behind the self-organization, self-assembly, and self-synthesis processes exhibited by biological systems.[19, 20]

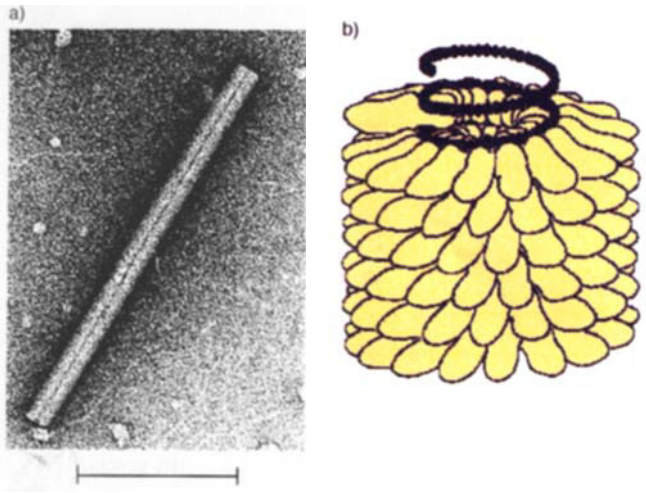

Fig. 1. The tobacco mosaic virus (TMV). a) Electron micrograph, b) schematic representation. The protein subunits are colored yellow (taken from ref. [25]).

2. Self-Assembly in Biological Systems

The tobacco mosaic virus[21] (TMV) is a helical virus particle (Fig. 1), 300 nm in length and 18 nm in diameter, whose self-assembly serves to illustrate many of the features present in self-assembling biological systems.[22–24] The viral particle is composed of 2130 identical subunits, each comprising 158 amino acids, which form a helical sheath around a single strand of RNA, 6390 base pairs (bp) in length. This information illustrates the first point about self-assembling systems—the amount of genetic information required by such structures is remarkably small. If the protein coat of TMV were coded by a single, contiguous gene, then the structure would require a section of RNA approximately 1×10^6 bp long. As 2130 identical subunits capable of self-assembling are utilized to form the protein coat, the complete structure may be coded for in a gene of around 500 bp in length—less than 8% of the total genome.

A further example of the economy in the use of genetic information may be found in the much more complex bacteriophage T4 (Fig. 2).[25] Only 53 out of a total of 135 genes contain information directly related to the construction of this apparently highly complex structure. TMV particles may be dissociated readily into their component parts and then subsequently reassembled accurately in vitro to give totally functional viral particles. In this way, the mechanism of TMV self-assembly has been investigated extensively.[24, 26–28] Under physiological

Douglas Philp was born and educated in and around Glasgow in the West of Scotland. He gained his BSc degree in 1989 from the University of Aberdeen before moving to the laboratories of J. F. Stoddart, first at the University of Sheffield and then at the University of Birmingham. He completed studies toward his PhD in 1992 with a thesis entitled "Self-Assembly in Chemical Systems". He was a Royal Society European Science Exchange Programme Postdoctoral Fellow in the laboratories of Professor François Diederich (ETH, Zürich) before returning to the University of Birmingham in 1994 to take up his current post as a Lecturer in Physical Organic Chemistry. His current research interests focus on the development of self-assembling and self-replicating structures and the application of computational methods in chemistry.

D. Philp

J. F. Stoddart

J. Fraser Stoddart was born and educated in and around Edinburgh in the East of Scotland. He has been Professor of Organic Chemistry at the University of Birmingham since 1990. He was appointed Head of the School of Chemistry there in 1993. Previously, he was a Reader in Chemistry at the University of Sheffield for eight years, where he was also Lecturer from 1970 to 1982. From 1978 to 1981 he was seconded from the University of Sheffield to the ICI Corporate Laboratory in Runcorn. He gained his BSc in 1964, his PhD in 1966, and his DSc in 1980, all from the University of Edinburgh. He was elected to the Fellowship of the Royal Society of London in 1994. He has received many awards, including the International Izatt-Christensen Award in Macrocyclic Chemistry in 1993, and has been a distinguished lecturer in many universities worldwide. Professor Stoddart has published more than 400 communications, papers, reviews, and monographs and has wide-ranging interests in supramolecular science. He is at present developing the transfer of concepts such as self-assembly between the life sciences and materials science.

conditions[24, 26] the protein subunits form a disk-shaped subassembly (Fig. 3a), which is transformed into a helical form (Fig. 3b) by insertion of a loop of RNA into the central hole of the protein disk. Additional protein disks, each corresponding to two turns of the final helix, associate with the growing viral particle (Fig. 3c and d) until assembly is complete. The association of individual subunits into the disk subassembly through noncovalent interactions permits the overall construction process to be dynamic, that is, at or close to equilibrium. As a result, assembly and disassembly of protein subunits is a facile event and the overall self-assembly process is intrinsically error-checking and self-correcting.

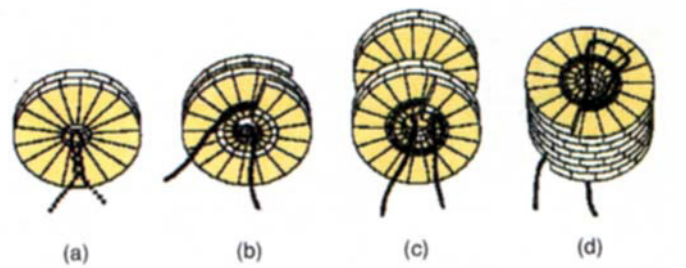

Fig. 3. The self-assembly of the tobacco mosaic virus (taken from ref. [25]).

The assembly of TMV demonstrates the ability of biological systems to construct large, ordered molecular and supramolecular arrays from small, relatively simple subunits by a mechanism of self-assembly. Such processes are responsible for the wide diversity of structure and function observed at both the cellular and subcellular levels in Nature. The evolution of self-assembly pathways in natural systems can be rationalized in terms of the selective advantages conferred upon organisms that utilize such synthetic routes. The common feature of all biological self-assembly processes is the ability to take advantage of many, weak noncovalent interactions between preformed subunits or well-defined subassemblies to guide the formation of a structure. These noncovalent interactions are also responsible for the stability of the final structure. Since self-assembly involves the intermediacy of many weak and reversible interactions, the final structure formed represents a thermodynamic minimum for the system. In addition, owing to the dynamic nature of the assembly process, defective or incorrectly attached subunits are eliminated from the growing structure, ensuring high overall fidelity in the assembly of the final structure. The modular nature of self-assembly processes (Fig. 4), involving the construction of

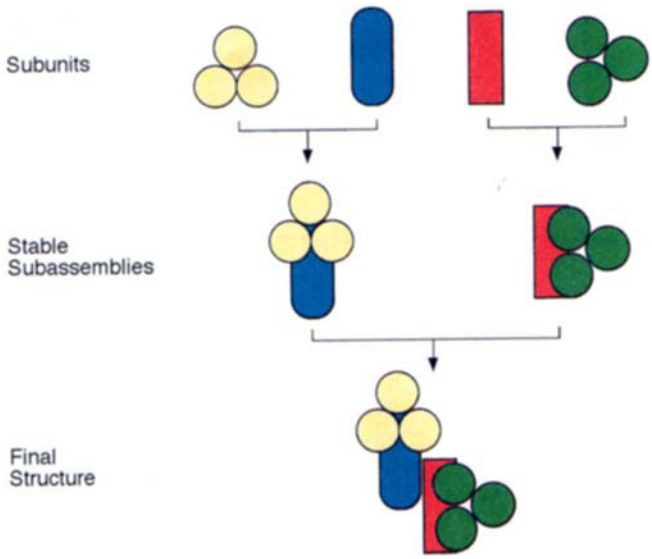

Fig. 4. The modular and convergent nature of biological self-assembly. Subunits aggregate to form stable subassemblies, which in turn form the final structure.

stable subassemblies, which are then carried forward into the final structure, permits great synthetic efficiency; in chemical terms, the synthesis of the final structure is *highly convergent*.[29, 30] The use of several identical subunits within a structure also requires that only a limited set of binding interactions is necessary to form the structure correctly, minimizing the amount of information needed to describe the structure fully. In summary, biological self-assembly processes require assembling subunits to display complementarity in geometric shape and surface electronic properties. The result of this complementarity is a structure stabilized by many, relatively weak, noncovalent bonding interactions, which may be shape-dependent (van der Waals/hydrophobic), or directed (hydrogen bonds/electrostatic interactions), distributed over the whole molecular volume, rather than limited to a few strong, localized covalent bonds. In biological systems, self-assembly pathways utilize both self-assembly in isolation and in harness with the formation of covalent bonds. For these reasons, self-assembly processes fall into two distinct categories, namely strict self-assembly and self-assembly with covalent modification.

2.1. Strict Self-Assembly

The term "strict self-assembly" applies to pathways that produce a final product directly and spontaneously when the correct components are mixed under appropriate conditions. The pathway must be completely reversible and the product should be stable at thermodynamic equilibrium. In addition, the constituent components of the final structure must contain all of the information necessary for correct assembly to occur.

The self-assembly of the DNA double helix from two complementary oligonucleotides is perhaps the most well-known and intensively studied biological paradigm of strict self-assembly. As such, it illustrates many of the salient features of biological self-assembly and, in addition, highlights some of the difficulties associated with the study of self-assembly. An idealized picture of DNA assembly is the contact and recognition of one oligonucleotide strand by another, followed by the propagation of the growing helix by the matching of complementary base pairs. Dynamic assembly and disassembly allow the recovery of the structure from errors in base matching, ultimately leading to correct registration between the two strands, and hence the most stable structure, at thermodynamic equilibrium. In practice, the situation is complicated somewhat by the formation of loops and hairpins, by hydrodynamic effects, and by interstrand penetration.[31] Studies of the nucleic acids $(A)_{17}$ and $(U)_{17}$ have shown that the self-assembly of the double helix is essentially an all-or-nothing process (Fig. 5):[32-34] a certain number

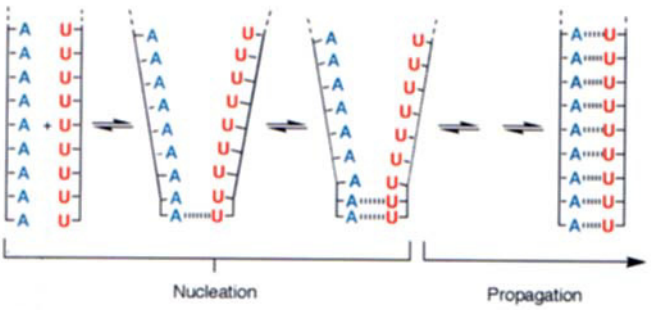

Fig. 5. Nucleation and propagation in nucleic acid self-assembly.

of base pairs are required to form before double helix assembly will occur, but once this particular point is reached, only the fully formed double helix will result. The double helix nucleation structure is believed to consist of three to four base pairs.[32, 34] In terms of its free energy,[35] the formation of a nucleus is unfavorable (Fig. 6). However, additional base pairs formed after nucleation make a large and negative contribution to the overall free energy of double helix formation. Thus, double helix growth proceeds *cooperatively*; base pairing occurs repeatedly, promoting further base pairing until double helix

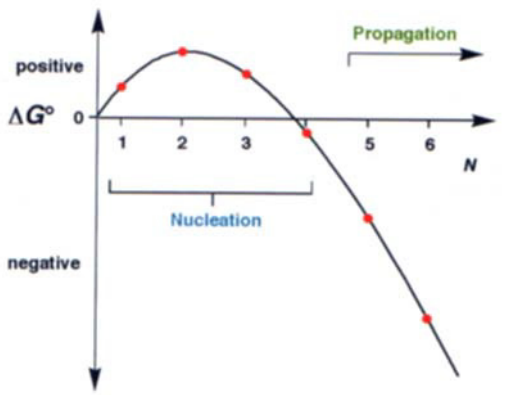

Fig. 6. Free energy profile for the self-assembly of the DNA double helix (adapted from ref. [19]). N = number of base pairs formed.

formation is complete. This pattern of events illustrates a key concept in self-assembly processes: the numerous favorable interactions that occur during the growth of a superstructure can easily overcome the initial unfavorable equilibrium. The favorable noncovalent interactions make up for the entropic price paid to associate the two strands of DNA in solution. Hence, the assembly of a large structure incorporating many noncovalent bonds will be relatively easier than the formation of a small structure incorporating only a few noncovalent bonds.

The study of the folding of ribonuclease, a 124 residue protein containing eight cysteine residues, provides another example of the self-assembly of a thermodynamically stable structure. Native ribonuclease can be reductively denatured[37] to give a random structure carrying eight cysteine SH groups (Fig. 7). When

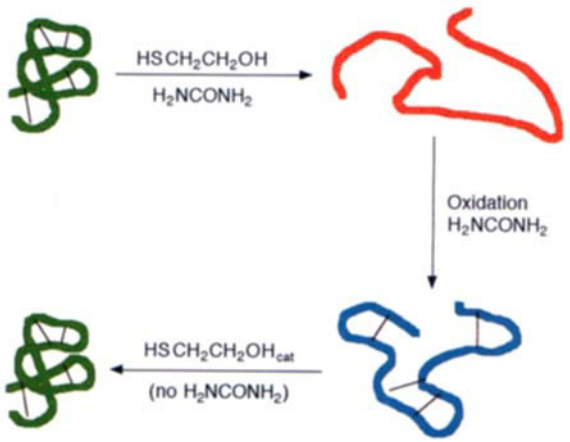

Fig. 7. The folding of ribonuclease. The native structure is colored green, the completely unfolded structure red, and one of the many isomeric, incorrectly folded structures blue.

the protein is reoxidized in the presence of urea (a denaturant), a large number of isomeric disulfide-bonded protein structures are formed. This mixture is essentially enzymatically inactive. Removal of the urea and addition of a catalytic amount of 2-sulfanylethanol, which facilitates disulfide exchange, rapidly regenerates the native structure. These observations demonstrate that, at least in the case of ribonuclease, the native protein structure, under physiological conditions, occupies an energy minimum,[37, 38] and that all of the information necessary for the correct folding of the protein lies in its primary amino acid sequence.

2.2. Self-Assembly with Covalent Modification

Although the folding of ribonuclease could be regarded as an example of self-assembly followed by covalent modification, this category of self-assembly is normally reserved for processes in which the formation of covalent linkages within an assembly is irrevocable and irreversible. Biological self-assembly processes displaying these characteristics fall into three classes:

1. *Precursor Processing*. The preparation of subunits for self-assembly by the covalent processing (Fig. 8) of precursor molecules, or formative processing,[39] is widespread in biological

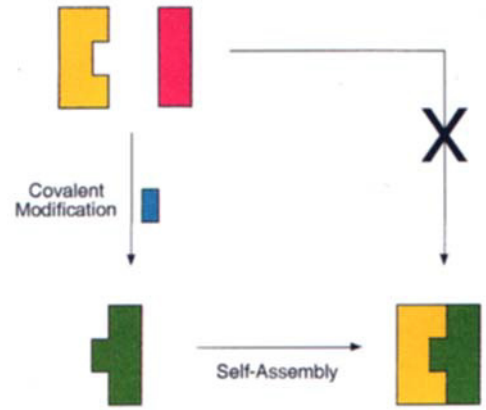

Fig. 8. Structure generation by covalent modification followed by self-assembly. The two subunits (yellow and purple) cannot associate until a covalent modification is performed on one of these subunits (purple to green).

systems. The activation of microtubule assembly by the covalent attachment of GTP to tubulin[40] is an example of such a system (Fig. 9). Microtubules are filamentous assemblies responsible

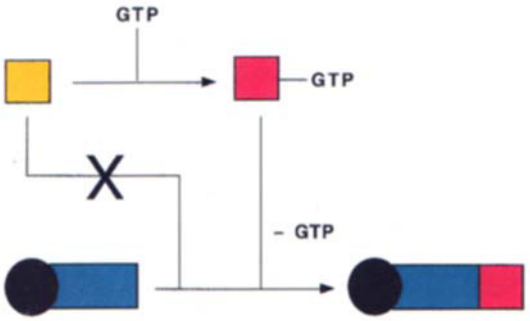

Fig. 9. Microtubule self-assembly. The tubulin subunit (yellow) must be activated by GTP to give an active complex (purple) before it can add to the growing microtubule (blue).

for the movement of vesicles, cellular organelles, and chromosomes (during cell division) through the cytoplasm of the cell. Microtubules are composed of a helical array of alternating protein subunits known as α and β tubulin. They are approximately 250 Å in diameter and of highly variable length. Most microtubules undergo rapid assembly and disassembly from structures known as centrosomes. It transpires that α and β tubulin will only add to the end of the growing chain of the microtubule if they are covalently bound to GTP. The native proteins are completely inactive in promoting the self-assembly process.

2. *Post-Assembly Processing*. Insulin is a mammalian peptide hormone consisting of two covalently linked polypeptide chains—the A chain composed of 21 amino acid residues and the B chain composed of 30 residues. These two chains are linked by two disulfide bridges. Reductive cleavage of these bridges, followed by reoxidation of the tetrathiol does *not* give rise to the native protein; in other words, the two short polypeptide chains do not by themselves contain enough information to assemble correctly the native protein structure. Insulin is, in fact, synthesized by two posttranslational processing steps carried out on a much larger polypeptide, preproinsulin (Fig. 10).[36, 38]

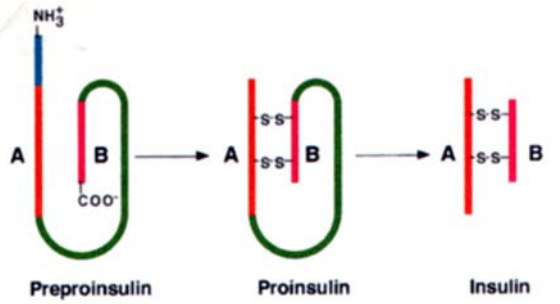

Fig. 10. The posttranslational processing of preproinsulin to form the active hormone, insulin. The signal section is colored blue, the connecting peptide, green.

After cleavage of the signal section, which is used to guide the nascent polypeptide to the correct location within the endoplasmic reticulum, proinsulin is cleaved at two sites in the Golgi complex to give the active hormone in which the A and B chains are linked appropriately by the two disulfide bridges. The generation of insulin from proinsulin serves two functions: firstly, it ensures the correct folding of the protein to form the active tertiary structure, a feat the A and B chains cannot accomplish on their own, and secondly, it permits the storage of insulin as a physiologically inactive precursor.

Self-splicing and self-cleaving RNA structures[41-46] are perhaps the most remarkable examples of post-assembly processing in the biological world. Short stretches of RNA found in a wide range of organisms are capable of performing catalytic processing of themselves after the initial assembly of their structure. The Lucerne Transient Streak Virusoid (LTSV) is a covalently closed loop of RNA, 324 base pairs in length, which infects plant cells. The virus replicates by a "rolling circle mechanism" (Fig. 11). This mechanism requires that the monomeric RNA

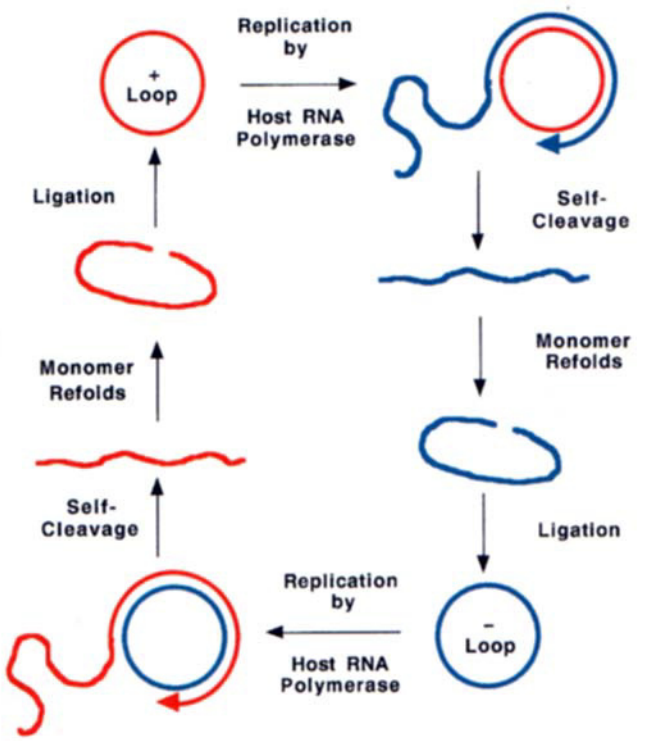

Fig. 11. LTSV replication by a rolling circle mechanism demonstrating catalytic self-excision of RNA strands. The blue loop is capable of cleaving the red polymeric genome into appropriately sized fragments and vice versa.

strand is excised from the growing polymeric RNA molecule produced by this mechanism. Since no cellular enzyme exists to perform this task, and the viral genome is too small to code for such an enzyme, the RNA molecule itself must perform it. In fact, very short strands of LTSV RNA, around 50 base pairs in length, are capable of excising accurately the required monomeric RNA in vitro. Although this remarkable feat of self-assembly followed by self-modification is poorly understood, it is thought to rely upon the catalytic properties of the three-dimensional surface structure of RNA. In essence, RNA is acting as an enzyme. The short stretches of RNA capable of performing this feat have highly conserved sequences, indicating that a sequence-specific three-dimensional structure is involved.

3. *Self-Assembly with Intermittent Processing.* The alternation of self-assembly with pre-assembly or post-assembly covalent processing of subunits or stable subassemblies permits very precise control of the order of events within a biosynthetic pathway. This class of self-assembly is really a fusion of the previous two classes, but offers such fine control over the structure of the final product that it must be considered separately. The best understood examples of this class of self-assembly process are bacteriophage morphogenesis[47] and ribosome assembly.[48] The assembly of ribosomes has been studied extensively in vitro (Fig. 12). It was shown by Nomura in 1968 that a fully functional 30S subunit could be reconstituted in vitro from its constituents, 16S RNA and 21 proteins. The 50S subunit can also be reconstituted in vitro from its constituents, 5S RNA, 23S RNA, and 34 proteins. The significance of these observations is that the assembly of the ribosome must be a self-assembly process; in other words, the components of the ribosome contain all of the information necessary to construct a functional ribosome. In addition, studies on the 30S subunit have shown conclusively that the process occurs in a specific order. A stable intermediate containing the 16S RNA and 15 proteins is isolable when the reconstitution is carried out at 0 °C. It can be converted to a functional 30S subunit by adding the missing proteins and heating to 40 °C. A similar intermediate, containing the two RNAs and 20 of the 34 proteins, is also found in the aggregation of the 50S subunit. This highly programmed assembly route allows the complex ribosomal structure to be assembled with great precision and efficiency.

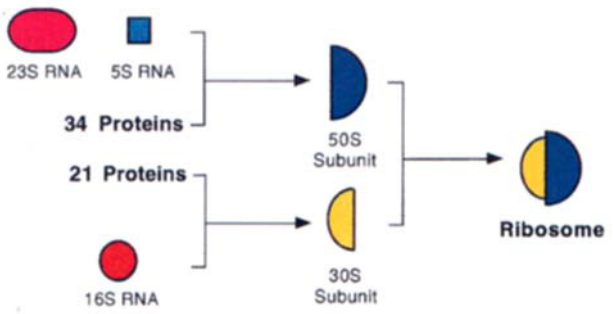

Fig. 12. The self-assembly pathway followed in the construction of a ribosome.

2.3. Lessons to be Learned from Biological Systems

Biological systems point the way forward to chemical systems capable of employing the advantages offered by synthetic routes incorporating self-assembly. The stunning diversity of structure and function found in biological systems, which rely on self-assembly for their genesis, display four common themes for synthetic chemists to exploit:

- Self-assembly processes are economical by virtue of their high convergence.
- Stable, structurally diverse assemblies can be rapidly, accurately, and efficiently synthesized from relatively simple subunits.
- The use of identical subunits within an assembly enables the lexicon of interactions employed to be kept to a minimum, economizing on the amount of information required to describe a structure.
- Molecular recognition by means of many, weak noncovalent bonding interactions leads to a dynamic, reversible, and "intelligent" synthetic pathway, which is self-checking and self-correcting and affords a product representing a thermodynamic minimum.

3. A New Approach to Chemical Synthesis

The science of organic synthesis[29, 30] has, until the present time, been concerned with the construction of assemblies of atoms by the controlled, selective, and sequential formation of covalent bonds. This approach to the generation of large structures has led to syntheses of relatively large molecules such as vitamin B_{12}[49, 50] and palytoxin.[51] The advantages of sequential covalent bond forming techniques lie in their ability to produce arrays of covalently linked atoms in a well-defined and controlled manner. The relative energies of the products may be located far from the global thermodynamic minimum for a particular collection of atoms in a molecule. It follows that the investment of time and manpower necessary to construct assemblies on a nanometer-scale using such an approach must be viewed as prohibitive.[52] Therefore, to construct nanoscale structures, the synthetic chemist must look to novel concepts and new approaches in the search for efficient methods of generating compounds with the desired order and dimensions.[53–58] We can envisage several such approaches:[20]

1. *Covalent Polymerization.* The repetitive reaction of a simple, chemical entity (monomer) with itself under appropriate conditions can give rise to a very large single molecule (polymer). Although this process affords structures that are large in chemical terms ($M_r > 10^5$ Da), the primary molecular constitution is simple and repetitive, and hence this process has limited potential for the controlled generation[59] of three-dimensional structures. Although polymers can produce nanoscale structures as a result of their physical properties, for example phase separation,[60, 61] the approach is limited by the lack of understanding, except in a few cases,[62] of the rules that govern the noncovalent bonding interactions within such polymer systems.

2. *Noncovalent Polymerization or Self-Organization.* Highly organized structures may be formed when many identical mole-

cules aggregate as a direct result of noncovalent bonding interactions. Noncovalent polymerization or self-organization gives rise to a wide variety of supramolecular architectures. Liquid crystals,[63] micelles,[64] monolayers at air–water[65, 66] or air–solid interfaces,[67–69] bilayers,[70] and Langmuir–Blodgett films[71–73] may all be constructed in this manner. However, since the molecules organize themselves, the final structure represents a thermodynamic minimum over which the chemist has only indirect control. Therefore, although self-organization can produce structures of nanometer scale, its application,[74] in isolation from other techniques,[75] is limited by the lack of any precise control.

3. *Self-Assembly*. Biological systems construct and modify functioning nanoscale structures with startling efficiency. It seems logical, therefore, that self-assembly should be the strategy of choice for synthetic chemists wishing to construct nanoscale assemblies. This realization means that the chemist must develop a synthetic regime incorporating the lessons learned from Nature (Fig. 13). In the first instance, sequential

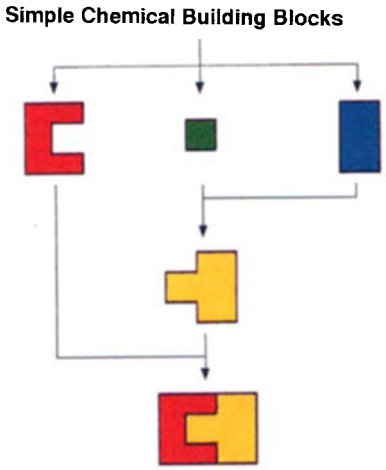

Fig. 13. Synthetic strategy based on self-assembly: conversion of simple building blocks, which can assemble, into complex chemical entities.

covalent synthesis (conventional organic synthesis) has to be used to create subunits which, by relying upon noncovalent bonds, can aggregate with themselves or other synthetic subunits to afford stable, structurally defined supramolecular assemblies. Of paramount importance to this approach is an understanding of the nature of the noncovalent bonding interactions responsible for stabilizing the final assembly. In energy terms, noncovalent bonding interactions are generally several orders of magnitude weaker than covalent bonds. This fundamental feature of bonding means that large areas of complementary surface must be present in the final assemblies in order for them to form stable entities. In addition, the favorable interactions within the superstructure must be sufficient to overcome the entropic penalty that has to be paid for the organization of the assembly's components into an ordered state. Understanding the interactions between noncovalently bonded molecules is crucial to the successful design and synthesis of self-assembling, wholly synthetic structures. Thus, the science of supramolecular[76] or host–guest[77] chemistry is ideally placed to contribute to achieving this goal.

4. Self-Assembly in Chemical Systems

The development of supramolecular or host–guest chemistry in the 29 years since Pederson's discovery[78] of the crown ethers resulted in a diverse array of supramolecular structures. It is not intended in this review to undertake a comprehensive treatment of this field; for this, the reader is directed to numerous reviews[79] and monographs.[80] The number of papers published on self-assembly and self-organization in chemical systems has grown from around 170 in the period 1985 to 1989 to well over 1000 in the period 1990 to 1995. Therefore, in this review, the discussion is limited to an overview of the various types of interactions used by the chemist to create large molecular arrays and how they may be applied to the self-assembly of nanostructures. The reader is directed to the references for a more complete, but still not comprehensive, record of the achievements of chemists in the field of self-assembly.

4.1. Cyclodextrins

The cyclodextrins (CDs) are a series of cyclic oligosaccharides consisting of six or more α-1,4-linked D-glucopyranose rings (Fig. 14).[81, 82] The cyclodextrins are named according to the

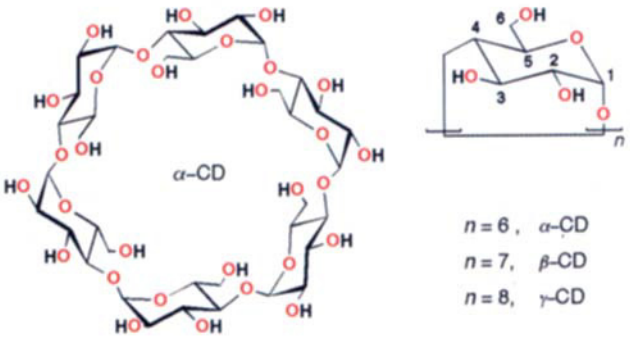

Fig. 14. The chemical structure of the cyclodextrins.

number of glucopyranose rings present: α-CD has six, β-CD has seven, and γ-CD has eight. The most immediately apparent structural feature of the smaller cyclodextrins is the rigid, well-defined cavity resulting from the overall bucket-shape of the molecules (Fig. 15). The open top of the bucket is encircled by the secondary hydroxyl groups at the C2 and C3 positions of the

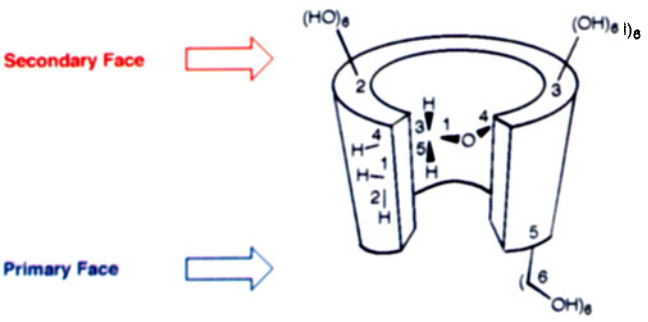

Fig. 15. The gross structure of α-CD.

glucopyranose residues, and the bottom of the bucket is encircled by the primary hydroxyl groups at C6. The interior of the bucket is lined with the oxygen atoms associated with the glycosidic linkages and the hydrogen atoms located at the C3 and C5 positions on the glucose residues. The rigid, relatively hydrophobic cavity of the cyclodextrins gives rise to their voracious appetite for molecular guests of all types. In all cases some part of the guest is bound within the cavity of the cyclodextrin. The precise nature of the binding interactions involved has been the subject of much debate.[81, 83–85] The principal binding interaction in a cyclodextrin–guest complex is most likely a summation of several relatively weak effects, for example van der Waals interactions, hydrophobic binding,[86] and the release of "high-energy water"[81] from the cavity. The contribution from each effect depends on the cyclodextrin, the solvent, and the guest.

Cyclodextrins have been known since 1891, and the first detailed description of their isolation was published in 1903 by Schardinger.[87] Since then, these naturally occurring molecular receptors have been exploited in many ways. Cramer[88] demonstrated that cyclodextrins can form inclusion complexes with a wide variety of substrates. This property was exploited by Bender in his seminal work on enzyme mimics.[89] Their role as catalysts has been further extended and utilized by both Tabushi[90] and Breslow.[91] Cyclodextrins have also been employed as second-sphere ligands in transition metal complexes.[92] Recently, however, the focus of cyclodextrin research has shifted towards their use as ready-made components for the construction of nanoscale structures through self-assembly.[93] The propensity of cyclodextrins to form strong complexes in aqueous solutions with many different types of guests has led to their development as building blocks in the construction of nanoscale devices.

Rotaxanes[94] are a class of molecules in which a dumbbell-shaped component is encircled by a macrocycle; the two components are linked mechanically rather than by a covalent bond. A generally accepted method for the synthesis of rotaxanes is *threading* (Fig. 16).[57] This approach takes advantage of the

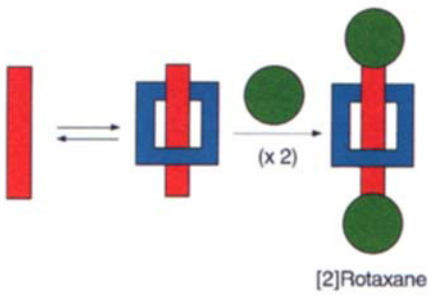

Fig. 16. Schematic representation of the synthesis of a [2]rotaxane by threading.

noncovalent bonding interactions between the rodlike portion of the dumbbell component and a macrocycle. The complex formed between these two species can then be modified with blocking groups to produce the [2]rotaxane. (The prefix [2] indicates the number of mechanically linked components within the molecule.) Clearly, it should be possible to construct rotaxanes by taking advantage of the promiscuous binding properties of cyclodextrins toward guest species of many types. The successful synthesis of a [2]rotaxane, which exploited the binding of α,ω-diaminoalkanes by either α-CD or β-CD, was first reported back in 1981 by Ogino and co-workers.[95] Treatment of such a diaminoalkane with a cyclodextrin yields an inclusion complex, which, after reaction with the cobalt complex $[CoCl_2(en)_2]$ (en = ethylenediamine), yields the [2]rotaxane (Fig. 17). The

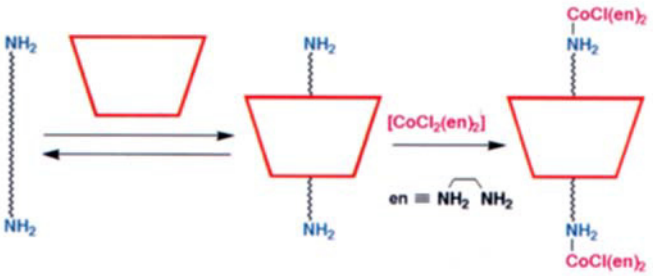

Fig. 17. Cyclodextrin rotaxanes constructed from α,ω-diaminoalkanes and cobalt-based blocking groups synthesized by Ogino and co-workers [95].

terminal metal complexes are apparently too large to permit decomplexation of the diaminoalkane from the cyclodextrin. The concept of utilizing cyclodextrins and metal complexes in the self-assembly of [2]rotaxanes has been described more recently by Wylie and Macartney.[96] In this instance, however, the order of addition of the components—α-CD, 1,1″-(α,ω-alkanediyl)bis(4,4′-pyridylpyridinium) dibromide **1**, and the pentacyanoferrate(II) salt—is unimportant (Fig. 18). Addition of solid $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ to an aqueous solution of the [**1**·α-CD] complex results in rapid formation of the [2]rotaxane **2**. This reaction is demonstrated by the appearance of a metal-to-ligand charge transfer transition in the visible spectrum and the appearance of two sets of ligand proton resonances in the ^{1}H NMR spectrum—a direct result of the end-to-end asymme-

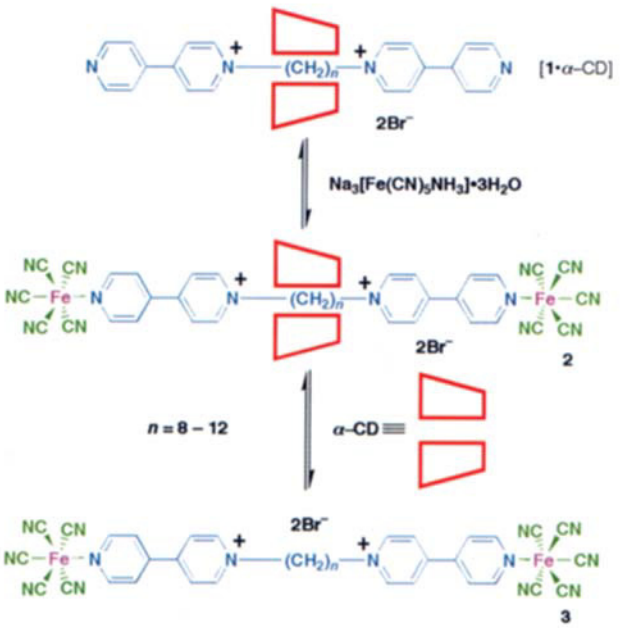

Fig. 18. The cyclodextrin-based [2]rotaxane synthesized by Macartney and co-workers.

try imposed on **1** by the trapped α-CD ring. The [2]rotaxane is also formed by the addition of α-CD to a solution of the bridged dimeric iron complex **3**. This result infers a slow dissociation of the terminal pentacyanoferrate(II) complex, followed by formation of an intermediate semirotaxane, and capping of the free pyridine ligand by reassociation of the pentacyanoferrate(II) complex. The inclusion of the dication within the cavity of α-CD enhances the stability of the coordinate bond between the terminal pyridine ring and the pentacyanoferrate(II) end group. This dissociation precludes the description of this system as a true rotaxane, since the degree of mechanical blocking of dissociation by the terminal groups of the complex is uncertain. It is more appropriate to describe such systems as pseudorotaxanes.[97]

Rao and Lawrence have constructed a "threaded molecular loop" from the bisammonium salt **4** and per-2,6-dimethyl-β-cyclodextrin (DMβ-CD) **5** (Fig. 19).[98] Addition of sodium tetraphenylborate to a solution of the [**4**·**5**] complex results in the precipitation of the [2]rotaxane **6** in 71% yield. ^{1}H and ^{13}C NMR spectroscopic studies confirm the composition of the product. Although FABMS, unsurprisingly, shows only fragment ions, the product **6** can be chromatographed unchanged on cellulose. It is unclear, however, whether the tetraphenylborate anions act as true blocking groups in the [2]rotaxane or simply as counterions. Since ammonium tetraphenylborate salts exist principally as solvent-separated ion pairs in polar solvents,[99] it seems likely that the primary stabilization in the [2]rotaxane **6** is derived from the interaction of **4** and **5**, with little or no contribution from the mechanical capping of the chain termini.

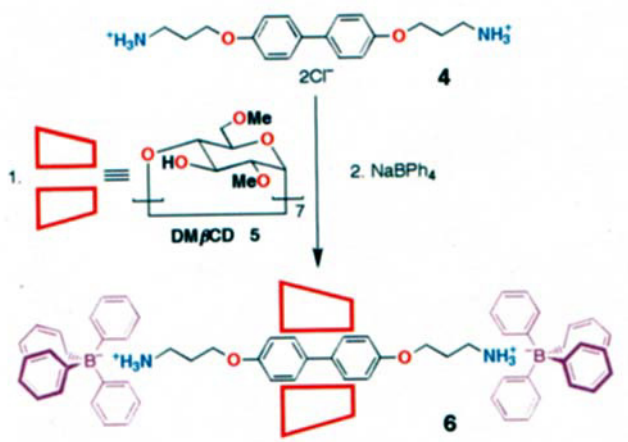

Fig. 19. The threaded molecular loop based on DMβ-CD described by Lawrence and co-workers.

The self-assembly of [2]rotaxanes containing cyclodextrins and covalently attached blocking groups has been reported recently by two research groups. Isnin and Kaifer have demonstrated the self-assembly of asymmetric zwitterionic [2]-rotaxanes incorporating α-CD.[100] Alkyl(ferrocenylethyl)dimethylammonium salts can interact with both α-CD and β-CD (Fig. 20). Termination of the alkyl chain with a carboxylate group provides an attachment point for a blocking group. Although the binding of **7** and **8** by α-CD is pH dependent (K_a(**7**) = 425 M^{-1} (pH 2.6), 71 M^{-1} (pH 8.0)), both are bound in water, and treatment of the complexes [**7**·α-CD] and [**8**·α-CD] with potassium 5-amino-2-naphthalenesulfonate and one equivalent of the coupling reagent 1-ethyl-3-[3-(dimethylamino)-propyl]carbodiimide hydrochloride (EDC) afforded the isomeric zwitterionic [2]rotaxanes **9a** and **10a**, and **9b** and **10b**, respectively. The isomers were separated[101] and the relative orientation of the α-CD component on the asymmetric dumbbell-shaped component of each isomer ascertained. Surprisingly, **9a** and **10a** are stable, whereas their isomers, **9b** and **10b**, unthread slowly.

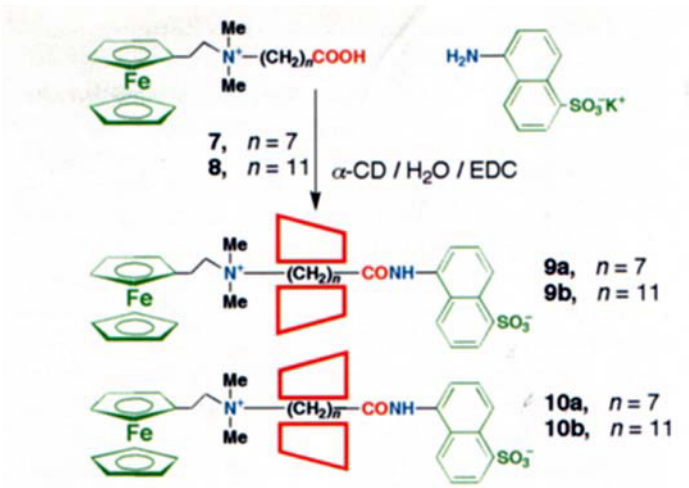

Fig. 20. Isomeric zwitterionic [2]rotaxanes based on α-CD synthesized by Kaifer and Isnin.

Wenz and co-workers[102] have utilized inverse recognition logic to self-assemble a lipophilic [2]rotaxane. Instead of using a hydrophilic cyclodextrin to bind a hydrophobic guest, they designed a lipophilic cyclodextrin that can bind cationic guests in inert organic solvents.[102] Thus, heptakis(3-*O*-acetyl-2,6-di-*O*-butyl)-β-cyclodextrin **11** (Fig. 21) was ob-

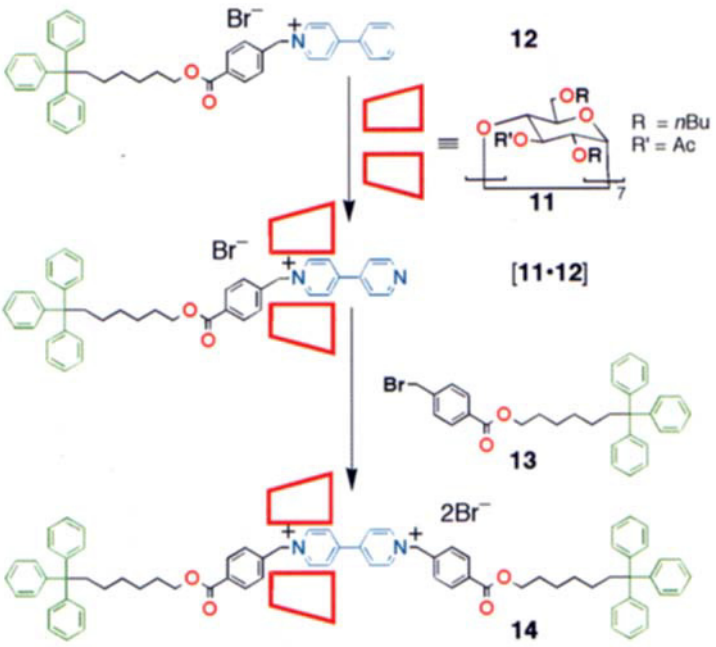

Fig. 21. A lipophilic [2]rotaxane incorporating a chemically modified CD constructed by Wenz and co-workers.

tained by chemical modification of β-CD. The pyridylpyridinium salt **12** was synthesized in nine steps from triphenylmethane. The binding of **12** within the cavity of **11** was demonstrated by ^{1}H NMR spectroscopy, and the association constant was found to be 450 M^{-1} in CD_3CN. The benzylic bromide **13** could then be used to cap the end of complex [**11**·**12**] (Fig. 21). This process affords the [2]rotaxane **14** in 20% yield. The ^{252}Cf plasma desorption mass spectrum of **14** shows a clear molecular ion at m/z 3293 for the intact [2]rotaxane. The ^{1}H NMR spectrum demonstrates that the C_7 symmetry of the cyclic host is maintained in **14**. However, the resonances corresponding to the two CH_2N^+ groups display different signal patterns, one appearing as an AB system and the other as a singlet, illustrating end-to-end asymmetry within the [2]rotaxane.

Polyrotaxanes containing CDs have also been described.[103] Harada and co-workers have reported a polyrotaxane based on poly(ethylene glycol) diamine (PEG-DA) **15**.[104] Polyethylene glycol is known to form an inclusion complex with α-CD.[104] Hence, reaction of 2,4-dinitrofluorobenzene **16** with **15** in DMF solution saturated with α-CD yielded, after extensive purification, the polyrotaxane **17** in 60% yield (Fig. 22). The molecular

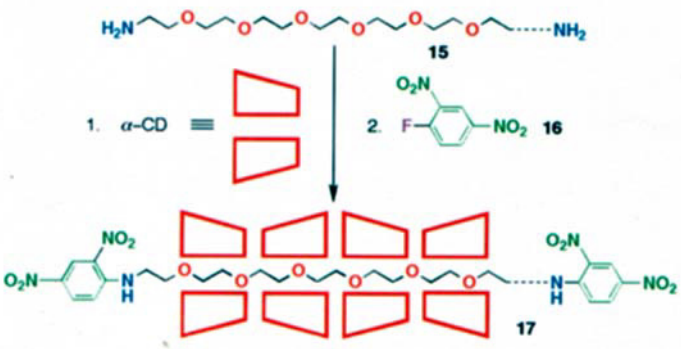

Fig. 22. An α-CD-based polyrotaxane synthesized by Harada and co-workers.

mass of **17** is in the region of 25000 Da, commensurate with the trapping of approximately 22 α-CD beads on the dumbbells. In more recent work Harada et al. have demonstrated the use of a polyrotaxane as a template for the synthesis of a tubular polymer.[105] When the hydroxyl groups of α-cyclodextrin, threaded on to a poly(ethylene glycol) backbone of mass 1450 Da, were allowed to react with epichlorohydrin, the cyclodextrin tori became linked together. Cleavage of the blocking groups with strong base resulted in long tubelike structures with an average molecular mass of 20000 Da.

Wenz and Keller have threaded α-CD with the poly(iminomethylene) chains **18a** and **18b** (Fig. 23).[106] Treatment of **18a** with α-CD gave a product whose ^{1}H NMR spectrum did not change after two hours, whereas the analogous reaction with **18b** required 170 hours to reach equilibrium. The long reaction times are consistent with a stepwise incorporation of the α-CD units: each CD ring must find a chain terminus, and the existing threaded α-CD molecules must shuffle toward the center of the polymer chain to make room for the new rings. Nonspecific reaction of the threaded polymer chain with nicotinyl chloride is expected to trap the CD rings located between the two nicotinamide units on the polymer backbone. This modification should produce a heterogeneous polymer with varying numbers

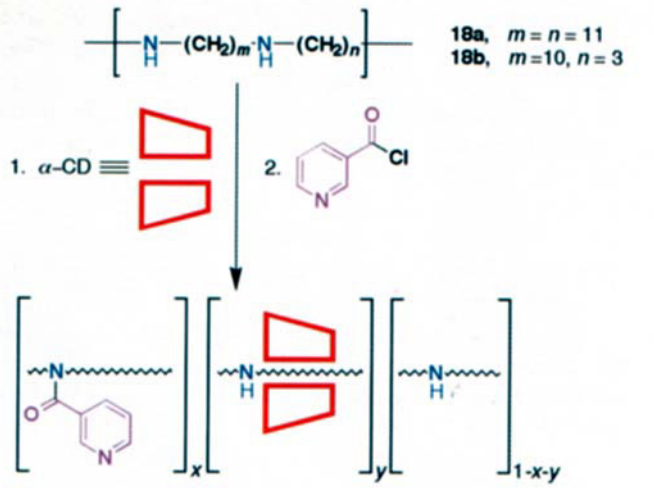

Fig. 23. The α-CD polyrotaxane of Wenz and Keller.

of nicotinyl groups (x), threaded CDs (y), and free polyiminomethylene regions ($1-x-y$) (Fig. 23). Analysis of the product from reaction of [**18b**·(α-CD)$_n$] with nicotinyl chloride revealed a polyrotaxane with a weight-averaged molecular weight of 55000 ± 5000 Da obtained by laser light scattering. The polyrotaxane isolated was shown to possess a degree of polymerization of 55 ± 5 and 37 α-CD rings permanently threaded on to the polymer chain.

The use of CDs as building blocks for the self-assembly of complex molecular architectures has not been restricted to the synthesis of rotaxanes. Lawrence and co-workers have prepared a heme-dependent protein mimic from a tetraarylporphyrin and DMβ-CD by self-assembly (Fig. 24).[107] The protonated te-

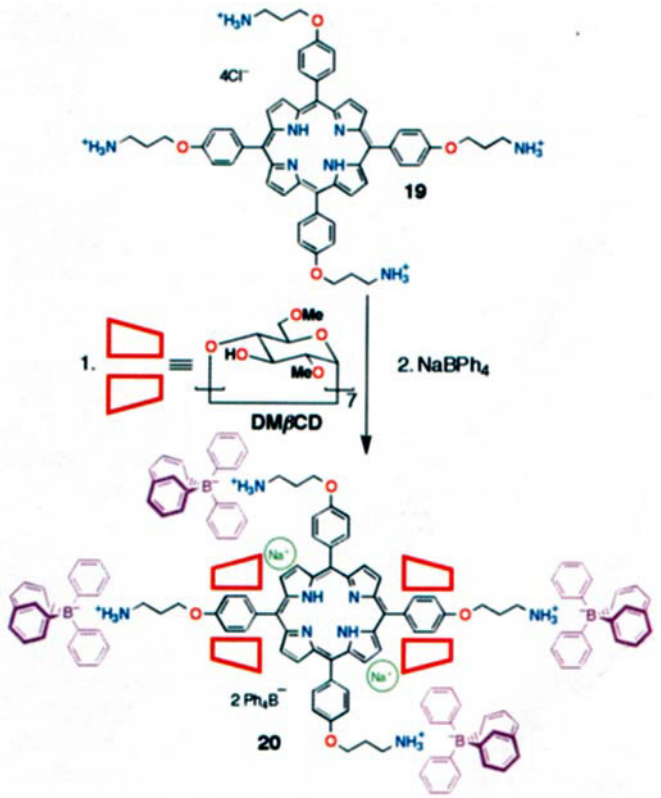

Fig. 24. A self-assembled heme-dependent protein mimic from the group of Lawrence.

traaminoporphyrin **19** forms an inclusion complex on exposure to a tenfold excess of DMβ-CD in aqueous solution at pH 6. The formation of this complex is supported by both a shift in the Soret absorption band of the tetraammonium porphyrin from 444 to 418 nm, and by upfield shifts of the signals for the H3 and H5 protons of DMβ-CD in the ^{1}H NMR spectrum of the complex. The complex is precipitated from aqueous solution by the addition of sodium tetraphenylborate. The precipitation procedure also leads to the incorporation of two Na^+ ions into the structure, which can be removed by complexation with [18]crown-6. Overall, the complete assembly contains eleven components—six tetraphenylborate ions, two Na^+ ions, two DMβ-CDs, and a tetraarylporphyrin—and has a molecular mass of >5000 Da. However, the kinetic stability of this assembly is unlikely to be high since the ammonium tetraphenylborate ion-pairs used as blocking groups are solvent separated[99] in polar solvents.

The synthesis of interlocked or catenated molecules, the catenanes,[108] has fascinated and inspired many scientists for more than 75 years.[109–111] The efficient synthesis of such systems, which has eluded chemists until recently, requires that one ring be threaded by the precursor of the second ring, and that this assembly be held together as the second ring is formed. In other words, one macrocycle must act as a template for the formation of the second macrocycle (Fig. 25). This requirement can be

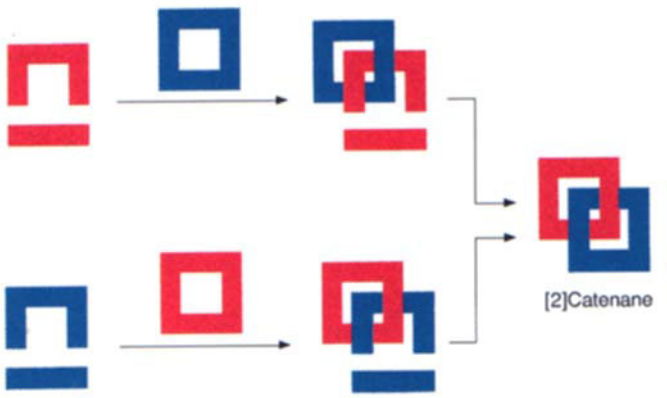

Fig. 25. The assembly of [2]catenanes by different routes. The red ring may be constructed by using the blue ring as the template (top) or vice versa.

fulfilled most easily by exploiting noncovalent bonding between the assembling molecular components. In the first published account of an attempt to synthesize a catenane in 1958, Lüttringhaus, Cramer, Prinzbach, and Henglein[112] endeavored to make use of the weak, noncovalent bonding interaction between α-CD and a series of aromatic guests bearing thiol-terminated alkyloxy substituents. After macrocyclization by oxidative coupling of the thiol groups, they hoped to obtain a catenated α-CD. Although this early attempt was unsuccessful, a number of CD catenanes have now finally been synthesized.[113] DMβ-CD in D_2O binds strongly the diamine **21** incorporating a bitolyl group (Fig. 26). The reaction of **21** with terephthaloyl chloride at 5 °C in 0.01 N NaOH solution in the presence of DMβ-CD affords a mixture of [2]- and [3]catenanes. The [2]catenanes **22** and **23** are produced yields of 3 and 0.8%, respectively, whilst the isomeric [3]catenanes **24a** and **24b** are

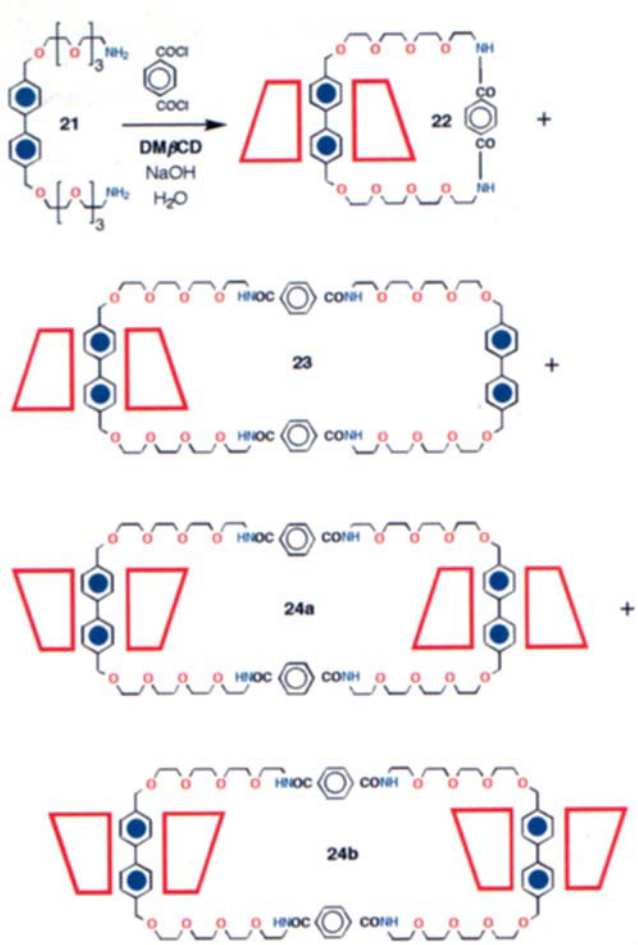

Fig. 26. The first successful synthesis of a series of CD-containing catenanes (facing red quadrilaterals: DMβ-CD).

obtained as an equimolar mixture in 1.1% yield.[114] ^{13}C NMR spectroscopy was used to assign head-to-head or head-to-tail structures to these isomers. The low yields of the catenanes, when compared with the somewhat higher yields for the uncatenated, macrocyclic oligoamides (12% for the bisamide macrocycle and 3% for the tetraamide macrocycle), suggest that the DMβ-CD may be inhibiting the macrocyclizations leading to the catenated species. The single-crystal X-ray structure of **22** reveals that the bitolyl unit is included within the cavity of the CD. Surprisingly, no hydrogen bonding interactions are apparent between the macrocyclic bisamide and the CD torus.

The range of self-assembled structures that can be constructed by utilizing the binding affinities of CDs for very different guests is wide. However, the interaction of CDs with their substrates, although strong, is not directional in other than a general sense. In the next two sections we will highlight the use of noncovalent bonding interactions that are much more directional.

4.2. The Hydrogen Bond

The highly selective and directional nature of the hydrogen bond makes it ideal for use in the construction and stabilization of large noncovalently linked molecular and supramolecular

architectures. Indeed, the biological world is replete with examples of such systems: DNA and protein tertiary structures are amongst the most obvious examples. Hydrogen bonds are formed when a donor (D) with an available acidic hydrogen atom is brought into intimate contact (i.e. a separation less than the sum of the appropriate van der Waals radii) with an acceptor (A) carrying available nonbonding lone pairs of electrons (Fig. 27). Many theoretical approaches to understanding the

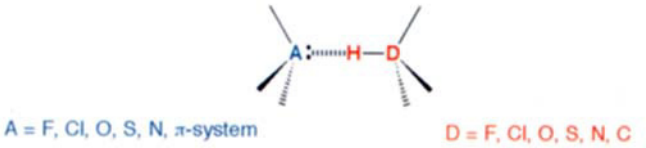

Fig. 27. A hydrogen bond formed between an acidic hydrogen atom (hydrogen bond donor **D** in red) and an appropriate acceptor (**A** in blue).

nature of the hydrogen bond have been advanced,[115] but none are wholly satisfactory in explaining all of the properties of the hydrogen bond. Most likely it involves the summation of several contributions, whereby the importance of each contribution depends on the precise nature of the system involved (Fig. 28). The strength of hydrogen bonds[116] can vary between 1 kcal mol^{-1} for D–H$\cdots\pi$ interactions to 13 kcal mol^{-1} for the Cl–H$\cdots$Cl$^-$ interaction. The geometry of the hydrogen bonds has been studied extensively both by statistical[117] and by X-ray diffraction methods.[118–120] The reader is referred to the literature[121] for a comprehensive survey. Based on X-ray diffraction analyses, certain rules have been proposed for the assembly of superstructures arising from the formation of hydrogen bonds within a system,[122] although many factors influence the nature of the final superstructure.

The use of hydrogen bonding networks to control molecular architectures in the solid state has been exploited by a number of research groups.[92, 123] Etter illustrated the utility of the hydrogen bond as a design element in solid-state organic chemistry.[124] The hydrogen bond directed cocrystallization of diarylureas[125] and acyclic imides[126] with a wide variety of compounds allows the formulation of general rules about the hydrogen bond driven molecular recognition within these molecules. In addition, cocrystallization can be utilized in the investigation of the hydrogen bond preferences of a single compound.[127] 2-Aminopyrimidine **25** (Fig. 29) has two equivalent hydrogen bond donors and two equivalent acceptors. The crystal structure[128] of **25** shows that all donors and acceptors are used in forming continuous chains of hydrogen bonds. However, the addition of either carboxylic acids or dicarboxylic acids can produce four distinct heteromeric structural motifs, depending on the nature of the added carboxylic acid. From the crystal stoichiometries and the patterns shown in Figure 29, rules for hydrogen bond donor and acceptor preferences in this system have been derived.[127]

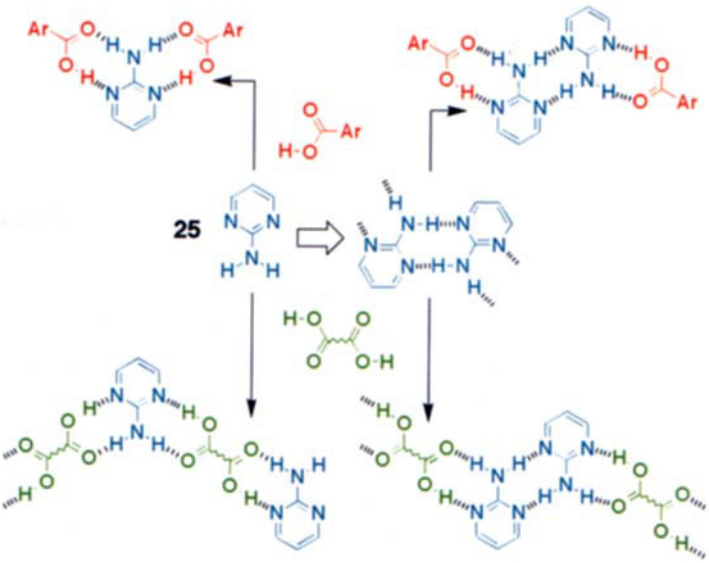

Fig. 29. Cocrystals formed between 2-aminopyrimidine (blue) and carboxylic acids (red) and diacids (green).

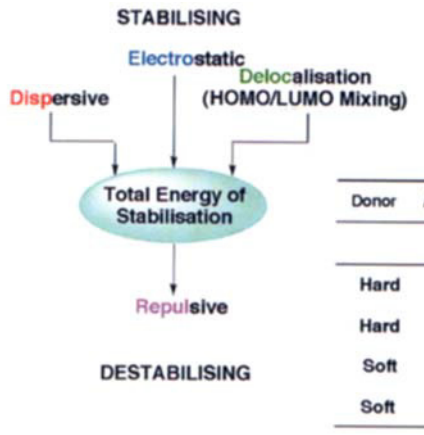
The assembly of long-range solid-state superstructures from simple building blocks directed by hydrogen bond formation has been exploited by Wuest et al.[129–131] The observation[129, 130] that the pyridone dimer can be used to control molecular aggregation led to the design and synthesis of the "tecton" **26** (Fig. 30), which contains a rigid tetraarylmethane core with pyridone units held rigidly at a fixed distance from the core.[131] Crystallization of **26** from a mixture of butyric acid, methanol, and hexane yielded crystals of approximate composition **26**·2C_3H_7COOH. X-ray structural analysis of this crystalline material revealed that the tecton had undergone hydrogen bond directed assembly to form an interpenetrating diamondoid network (Fig. 30), in which the voids are filled by the butyric acid molecules and the interpenetrating networks.[132] Crystallization with different carboxylic acids, for example propionic acid, has given similar results.

Hamilton and co-workers[133] have also demonstrated the controlled assembly of solid-state superstructures, resembling molecular sheets, that rely upon hydrogen bonds. Interestingly, they have



Donor	Acceptor	Interaction Type			
		Electro	Deloc	Disp	Repul
Hard	Hard	++	+/–	–	Similar for all types
Hard	Soft	–	+	+	
Soft	Hard	+	–	–	
Soft	Soft	–	+	+	

Fig. 28. The relative contributions of various types of interactions to the overall strength of a hydrogen bond (table adapted from ref. [261]).

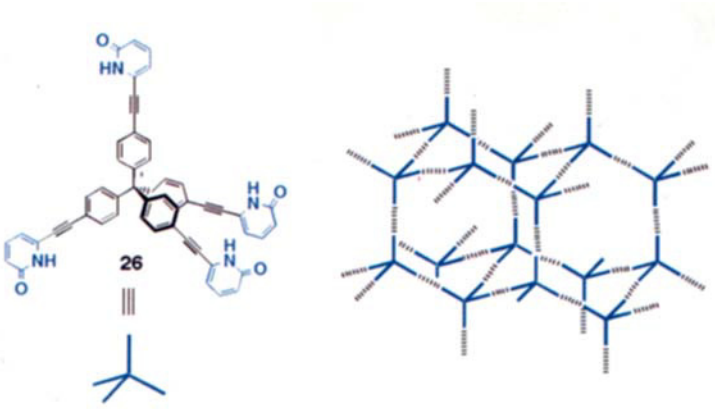


Fig. 30. An interpenetrating diamondoid network arising from hydrogen-bonded tectons (blue) based on the molecular recognition between pyridones.

shown that a conformational change produced by protonation can lead to the self-assembly of solid-state superstructures.[134] 2,6-Diamidopyridine **27** has a parallel arrangement of hydrogen bond donors and acceptors in its free base form (Fig. 31). Protonation at the pyridine nitrogen atom pro-

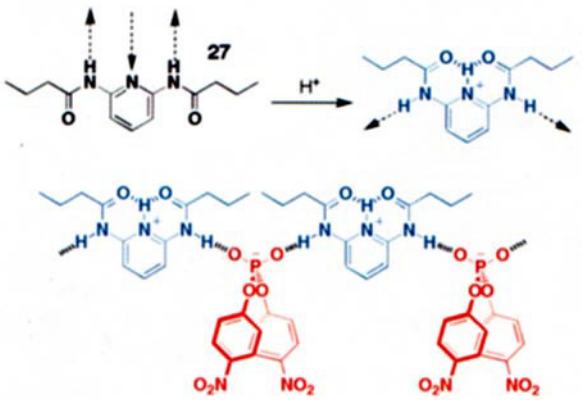

Fig. 31. A conformational change brought about by protonation permits hydrogen bond directed self-assembly to occur.

duces a conformational change: the amide carbonyl oxygen atoms form intramolecular hydrogen bonds and the amide protons are directed outwards. In this conformation, the pyridinium ion can form continuous hydrogen bonded chains with its diaryl phosphate counterions in the solid state (Fig. 31). Hamilton and co-workers have also transferred their design into solution, where (2 + 2) aggregates stablized by a network of hydrogen bonds have been self-assembled successfully.[135] Moreover, they have demonstrated that the aggregation of simple dicarboxylic acids in the solid state is controlled by hydrogen bonding.[136] Six molecules of an appropriately functionalized isophthalic acid form a hexameric aggregate which is stabilized by twelve hydrogen bonds. Hydrogen bonding can also be used to create rodlike structures in the solid state. Crystallization of triamide **28** (Fig. 32) from CH_2Cl_2 and MeOH results in the growth of large rod-shaped crystals up to 1 cm in length![137] X-ray diffraction analysis demonstrates that the triamide molecules form stacks which are stabilized by hydrogen bonds between the three amide NH groups of one molecule and the amide CO groups of the next molecule in the stack.

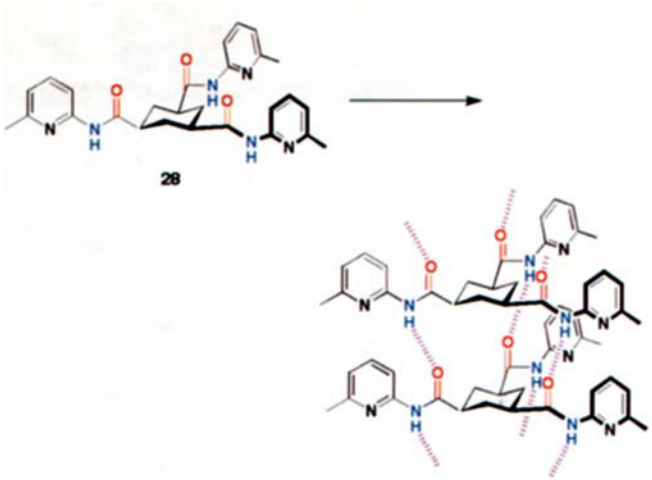

Fig. 32. The hydrogen bond directed self-assembly of molecular rods through hydrogen bonding between amide groups.

Lehn et al.[138] have employed complementary components for the self-assembly of highly ordered strands in the solid state. Cocrystallization of the barbituric acid derivative **29** with the 2,4,6-triaminopyrimidine **30** gives rise to continuous hydrogen-bonded strands (Fig. 33),[138] in which the **A** groups attached to

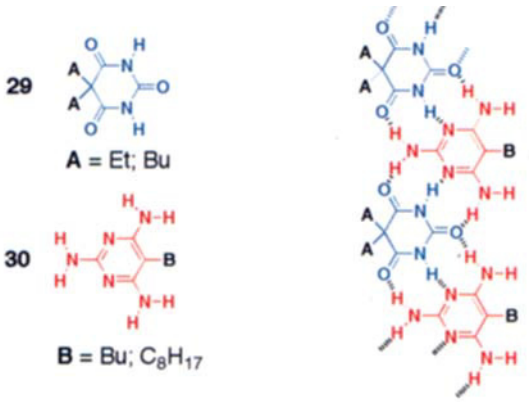

Fig. 33. Cocrystallization of barbituric acid derivatives with triaminopyrimidines forms segregated strands in the solid state through hydrogen bonding.

the barbituric acid nuclei and the **B** groups attached to the triaminopyrimidine nuclei are on opposite sides of the major axis of the hydrogen-bonded strands. The arrangment of side chains could confer specific properties on the cocrystal at the macroscopic level. Such systems open the way for the construction of designed crystal structures for specific applications.

Whitesides and co-workers[139–143] have exploited the strong, multiply hydrogen-bonded lattice formed between cyanuric acid **31** and melamine **32** to construct large, nanometer-scale structures in solution[139, 140] and to direct the assembly of structures in the solid state.[141, 142] Reaction of **31** with **32** gives the insoluble 1:1 complex [**31**·**32**] shown in Figure 34. The linking of three melamine units to a central hub ***H*** (Fig. 35) affords molecule **33**, which is conformationally compatible with the cyanuric acid/melamine lattice. Thus, mixing **33** with three molar equivalents of the alkyl cyanuric acid **34** gives the extremely stable 3:1 complex **35** in $CDCl_3$ solution, which contains one layer of the basic structure of the cyanuric acid/melamine lattice

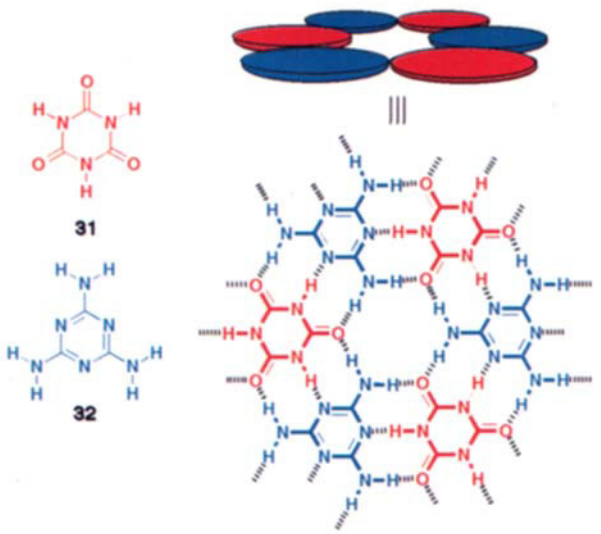

Fig. 34. The stable hexagonal lattice formed between cyanuric acid and melamine.

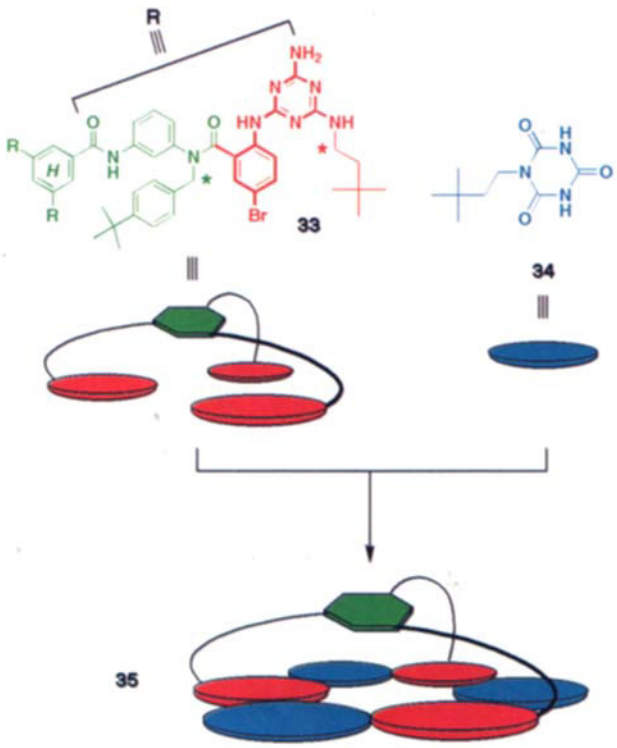

Fig. 35. The hexagonal cyanuric acid/melamine lattice can be transferred into solution. The 3:1 complex between the cyanuric acid derivative (blue) and the hub, which tethers three melamine units, is stabilized by 18 hydrogen bonds.

capped by the trisubstituted benzene hub ***H***. ^{1}H NMR spectroscopy confirms the proposed structure of the 3:1 complex. The two imide NH protons of **33** are in different hydrogen bonding environments and so give rise to separate signals in **35**. In addition, two of the methylene groups of **33** (marked by * in Fig. 35) become diastereotopic in the 3:1 complex, and hence each methylene group gives rise to two separate signals in the ^{1}H NMR spectrum of **35**. NOESY experiments provide further support for the proposed structure. Vapor pressure osmometry (VPO) gives a molecular mass for the species in solution of 2720 Da (c = 2–16 mM), in close agreement with the calculated value of 2733 Da for **35**. The high stability of the complex is a result of two factors: the conformational compatibility of the melamine trimer with the cyanuric acid/melamine lattice, and the preorganization of **33**, namely the connection of the three melamine units to a central aromatic hub ***H***. In subsequent research, Whitesides and co-workers have shown that a bis(cyanuric acid) derivative can aggregate with **33** to form a 3:2 complex of molecular mass > 5500 Da, which incorporates two layers of the cyanuric acid/melamine lattice.[142] Interestingly, cyanuric acid also forms a 1:1 cocrystal with biuret (cyanuric acid is the decomposition product of biuret), which is stabilized by chains of hydrogen bonds running in two directions throughout the crystal lattice.[144] The construction of even larger aggregates is possible using this approach.[145] Mixing the core **36**, containing nine melamine subunits, with an appropriate quantity of the substituted cyanuric acid **37** results in the formation of a single conformation of the decamolecular aggregate **38** (Fig. 36). However, it has not proved possible to deduce by

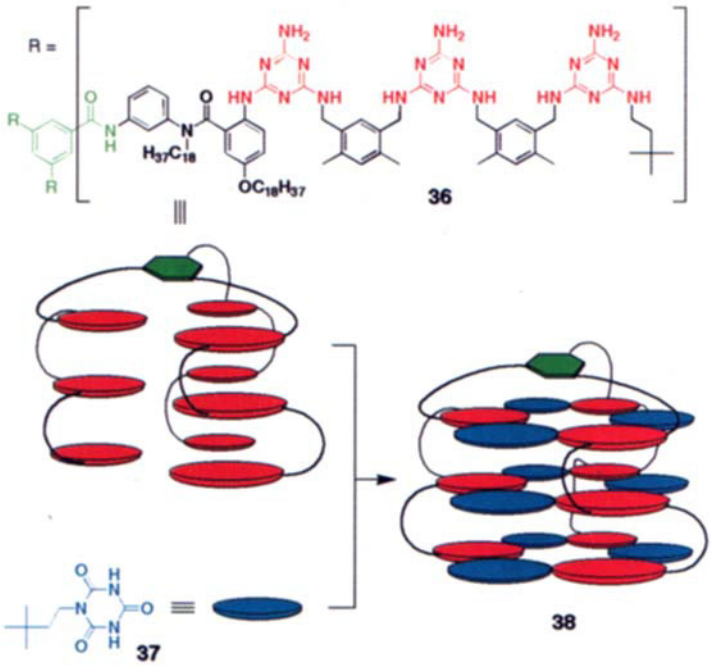

Fig. 36. A triple-decker version of the hexagonal cyanuric acid/melamine lattice can be transferred into solution. The 9:1 complex between cyanuric acid derivative (blue) and the hub, which tethers the melamine units, is stabilized by 54 hydrogen bonds.

NMR spectroscopy which of the many possible conformations is thermodynamically favored and observed. The aggregate **38** contains three layers of the cyanuric acid/melamine lattice, is stabilized by 54 hydrogen bonds, and has a molecular mass in excess of 6000 Da. The successful self-assembly of ten molecules into a single well-defined aggregate, which is stable in solution, demonstrates clearly the power of approaches based on self-assembly for the construction of nanoscale architectures.

Wyler, de Mendoza, and Rebek[146] have extended the range of architectures that have been constructed by hydrogen bond directed self-assembly with the construction of a molecular tennis ball. Molecule **39**, based on diphenylglycouril, is self-complementary and self-associates in solution through the formation of eight hydrogen bonds to form a dimer having an internal cavity (Fig. 37). This dimeric structure is remarkably stable,

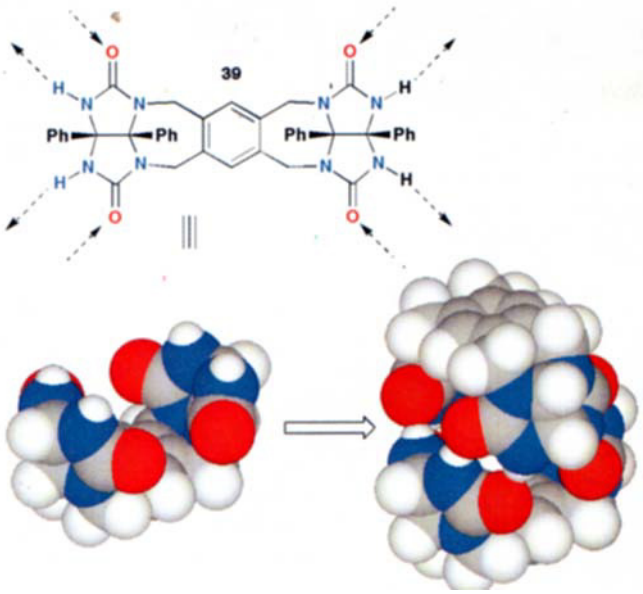

Fig. 37. Self-association of the cyclic bis(urea) derivative through eight hydrogen bonds gives a structure that resembles a tennis ball. The phenyl rings have been omitted from the space-filling representations for clarity.

persisting in $CDCl_3$ containing up to 20% CD_3SOCD_3. The encapsulation of small molecules within these self-assembled cavities has been demonstrated in this system and in others.[147]

Molecular recognition driven by hydrogen bonding can also be used to effect a phase change within a system. Lehn and co-workers have demonstrated the formation of a liquid-crystalline polymer, which is derived from the association of two complementary ditopic components through hydrogen bonds.[148] Mixing equimolar amounts of the complementary, nonmesogenic components **40** and **41** results in the formation of the hydrogen-bonded polymer **42** (Fig. 38), which displays liquid-crystalline behavior from $<25\,^{\circ}C$ up to $200\,^{\circ}C$. The formation of the liquid-crystalline polymer is largely unaffected by the stereochemistry of the components (both the DL and *meso* forms of **40** and **41** give thermotropic mesophases), but the internal

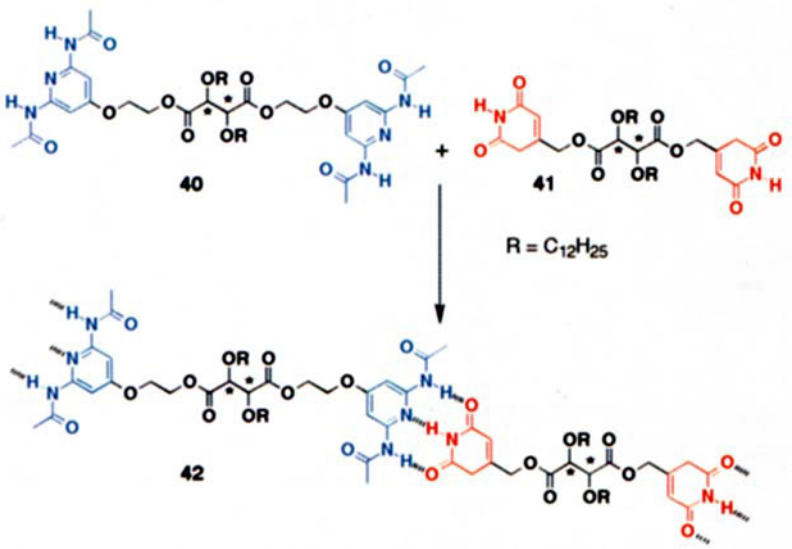

Fig. 38. The formation of a thermotropic liquid crystal by hydrogen bond directed molecular recognition. Compounds **40** and **41** have either DL or *meso* configurations.

structures of the mesophases formed by the stereoisomeric pairs are vastly different. Thus, this system illustrates how the process of self-assembly, through molecular recognition directed by hydrogen bonding, can lead to drastic changes in the physical properties of the system. The formation of a macroscopic mesophase is an expression of microscopic molecular recognition at a macroscopic level. Other systems in which molecular recognition at the microscopic level is manifest in macroscopic physical properties have been reported.[149]

Ghadiri and co-workers have reported the self-assembly of a remarkable series of nanoscale tubules based on cyclic peptides.[150] The basic design utilizes a cyclic peptide whose primary sequence consists of alternating D- and L-amino acids (Fig. 39). Such peptides possess flat "donutlike" conformations in solution. This conformation promotes the face-to-face association of the cyclic peptides into nanoscale tubules, which are stabilized along their length by hydrogen bonding interactions between the amide groups in the peptide backbone. Depending on the conditions, such peptides can be assembled into highly ordered aggregates of nanotubes in the solid state or into transmembrane pores.

Receptors that can catalyze bond-making reactions by forming a superstructure, which converts an intermolecular reaction into an intramolecular one, that is, an artificial enzyme, have been the focus of research by many groups. Kelly et al.[151] have reported the design and synthesis of a "bisubstrate reaction template" **43**, which is capable of a sixfold acceleration in the reaction between the benzylic bromide **44** and the amine **45** (Fig. 40). This rate acceleration is a result of the ability of **43** to bind the two reaction substrates through a network of hydrogen bonds and hold them in place while reaction occurs. The two binding sites in **43** are identical and thus many unproductive ternary complexes may form. Severe product inhibition could also be anticipated in this system since the product will be bound to **43** by no less than six hydrogen bonds. Fortuitously, however, the product precipitates as its HBr salt and is thus removed from the reaction mixture, ensuring at least a modest turnover in the catalytic cycle. The efficacy of this system can be improved by modification of the receptor **43** to reduce the number of nonproductive complexes formed. This goal has been achieved by modification of the right-hand binding site in **43**, resulting in a 12-fold rate enhancement in the second-generation system.[152]

The bisubstrate reaction template described by Kelly et al. is a general case of a catalytic system based on a ternary complex. In such systems two reaction channels exist: an uncatalyzed bimolecular reaction and a catalyzed ternary reaction. When the reaction product can serve as a template for its own formation and, in addition, is capable of conserving and expressing its structure, then the reaction is termed a *self-replication process*. Examples of self-replication have been observed in the nonenzymatic ligation of nucleotides,[153] as demonstrated by the research groups led by von Kiedrowski[154–156] and Orgel.[157, 158]

Minimal models of self-replication in wholly synthetic systems, based on the model shown schematically in Figure 41, have also appeared recently.

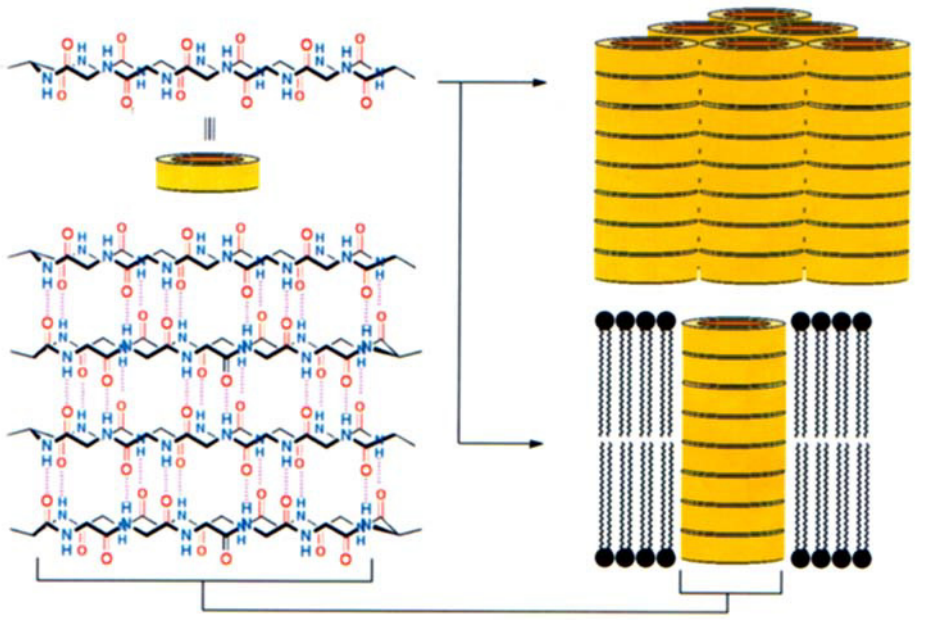

Fig. 39. The self-assembly of cyclic peptides, in which the amino acids have alternating D and L configurations, into tubular superstructures through hydrogen bonding between the amide groups.

Rebek and co-workers[159–161] have built on their experience with molecular receptors based on Kemp's triacid and have developed a self-replicating system.[162] The Kemp's triacid derivative **46** can recognize and bind the adenine derivative **47** to give the complex **48** (Fig. 42).[163, 164] This complex is stabilized, not only by the hydrogen bonding between the imide unit of **46** and the adenine residue of **47**, but also by the $\pi-\pi$ stacking interaction between the adenine base of **47** and the naphthalene moiety of **46**. This assembly is arranged perfectly for the formation of a *cis* amide bond between **46** and **47** by attack of the amino function of **47** on the activated ester of **46**. The *cis* amide linkage in **49** is, however, thermodynamically less stable than the *trans* isomer **50** and isomerization occurs. It opens up two new

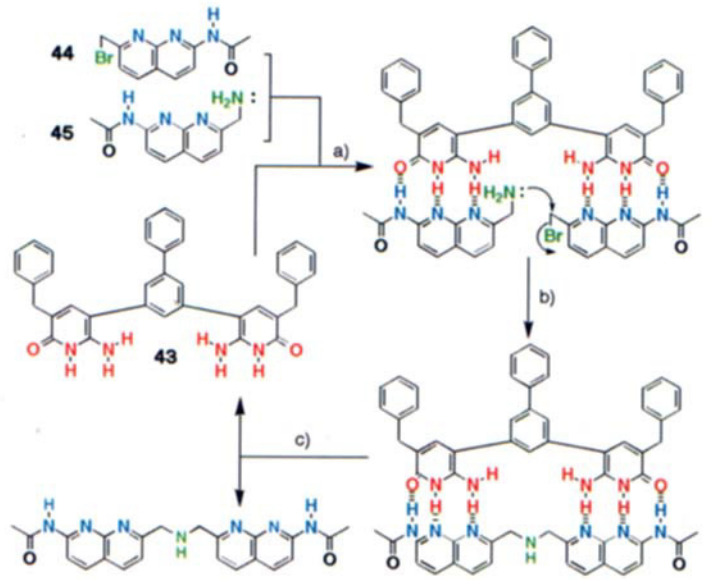

Fig. 40. Rate acceleration through hydrogen bond directed binding of reactants in a bisubstrate reaction template. a) Association, b) reaction, c) dissociation.

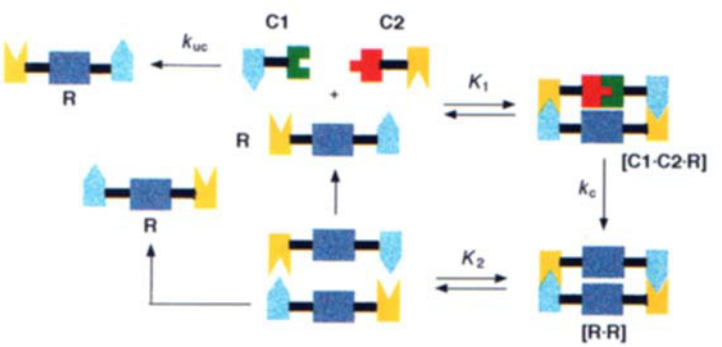

Fig. 41. A minimal model of self-replication. The synthesis of the replicator **R** is accelerated by its binding of components C1 and C2 to form the catalytic ternary complex [C1·C2·**R**]. This autocatalytic cycle is in competition with the uncatalyzed bimolecular reaction.

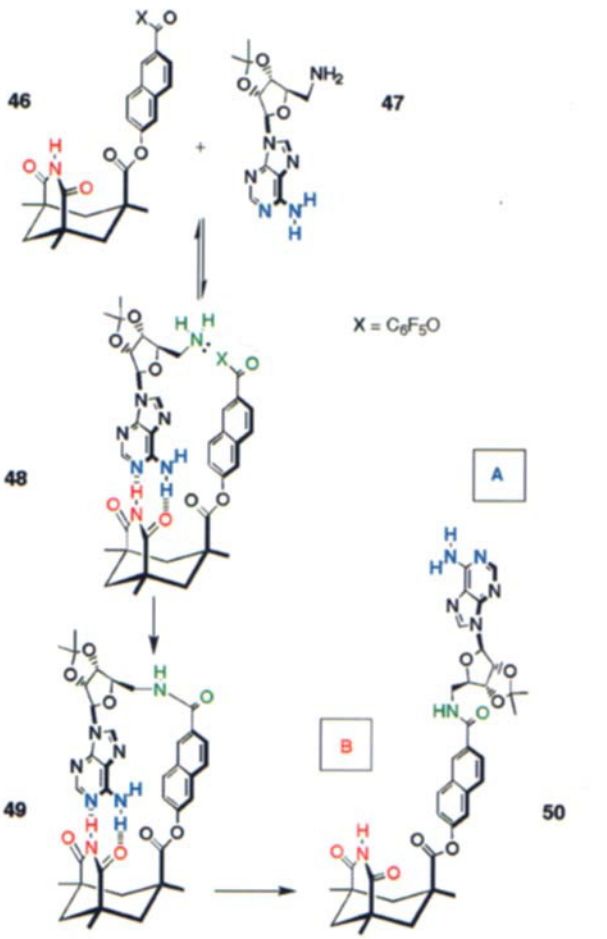

Fig. 42. The construction of a self-replicating system based on adenine recognition, through hydrogen bonding and amide bond formation. Binding sites A and B are available after *cis–trans* isomerization of the amide linkage (**49** → **50**).

binding sites A and B, which are capable of binding **46** and **47**, respectively. The binding of **46** and **47** by **50** is analogous to the formation of the ternary complex containing the bisubstrate reaction template **43**. However, since the product of the reaction between **46** and **47** is ultimately **50**, the formation of **50** must be autocatalytic along this reaction channel. In other words, **50** is self-replicating, when provided with the appropriate components. Since **50** is self-complementary[165] (dimerization constant, $K_D = 630\ M^{-1}$) some product inhibition must occur. Rebek et al. have subsequently identified a sigmoidal rate profile in a related system, demonstrating that the autocatalytic reaction channel is dominant.[166] Competition, reciprocal template effects, and mutation have also been demonstrated in these and other systems,[166, 167] as well as self-replication in systems not based on the Kemp's triacid core.[168]

The condensation of 3-aminobenzamidines and 2-formylphenoxyacetic acids has been exploited[169] by Terfort and von Kiedrowski in the design of a self-replicating system (Fig. 43).

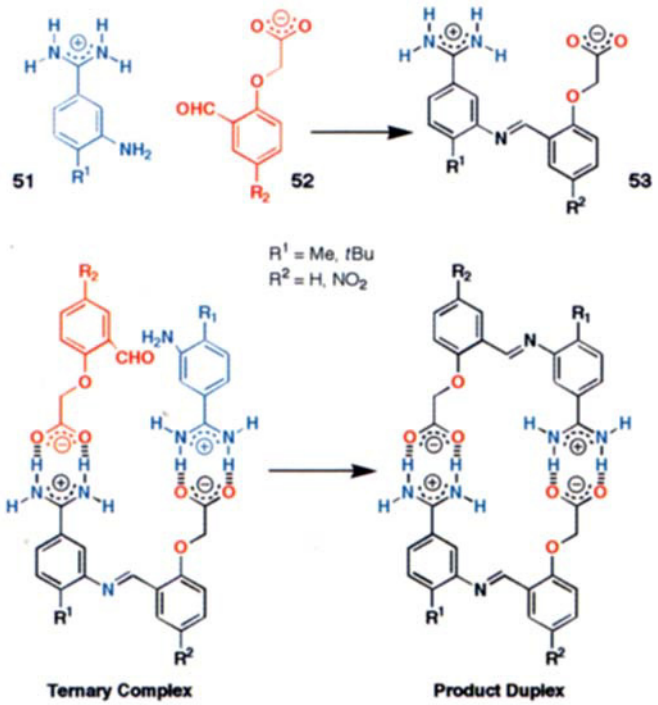

Fig. 43. The construction of a self-replicating system based on carboxylate recognition, through hydrogen bonding and ion pairing, and subsequent imine formation.

By utilizing the same minimal model of self-replication, the amidinium–carboxylate salt bridges formed between **53** and its precursor components, aminobenzamidine **51** and formylphenoxyacetic acid **52**, promote the formation of the central C=N bond of **53** by holding the reactants in close proximity in a ternary complex. Interestingly, kinetic data suggests that in certain cases the ternary complex [**51**·**52**·**53**] is more stable than the [**53**·**53**] duplex. This research indicates that self-replication with exponential autocatalysis can be achieved if the structure of the product can be modified to destabilize the product duplex further with respect to the catalytic ternary complex.[170]

Hunter[171] has designed and synthesized the macrocycle **54** (Fig. 44), which binds *p*-benzoquinone through a combination

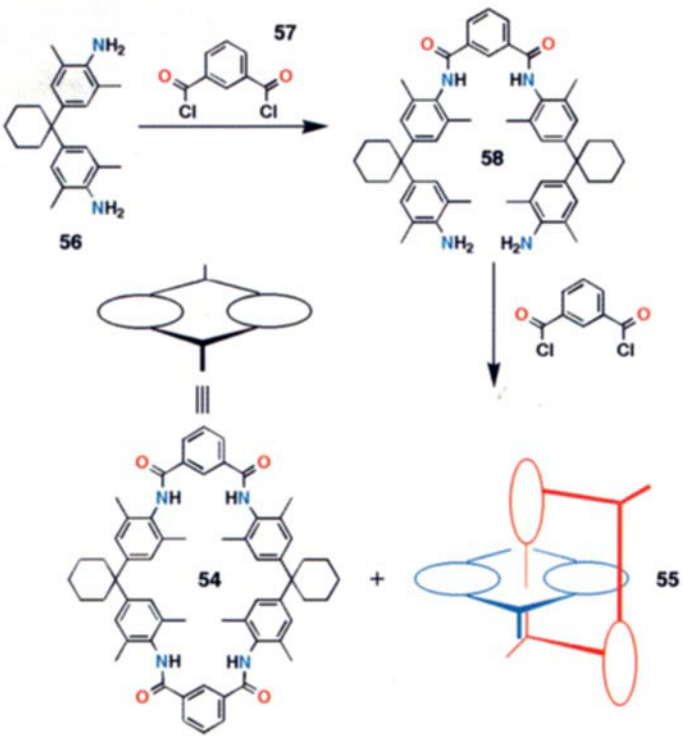

Fig. 44. The synthesis of an amide-based [2]catenane. (The cyclic dimer of **54** is formed as a side-product.)

of hydrogen bonds to the polar amide bridges and CH–π interactions[172] between the acidic hydrogen atoms of the quinone and the arene rings of **54**. In the original synthesis,[171] **54** was prepared in 10% yield by the single-step, high-dilution macrocyclization of the diamine **56** with isophthaloyl chloride **57**. In a modified synthesis,[173] reaction of isophthaloyl chloride **57** with the diamine **58** resulted in three major products: the receptor **54** in 51% yield, a cyclic dimer of **54** in 5% yield, and a product, which was identified as the [2]catenane **55** containing two interlocked units of **54**, in 34% yield. Although the exact mechanism of the self-assembly of **55** is still unclear, the remarkable efficiency of the process dictates that it must involve the complexation of a reaction intermediate with **54** through the hydrogen bonding and π–π interactions that are so effective in the binding of *p*-benzoquinone by **54**. The production of catenated products in such systems is not limited to the use of isophthaloyl chloride.[174] Clearly, a full mechanistic explanation for catenane formation must await complete elucidation[175] of all of the interactions within the system.

In the 29 years since Pedersen's discovery of crown ethers, the binding of ammonium (NH_4^+) and primary ammonium ions (RNH_3^+) by [18]crown-6 and its derivatives through hydrogen bonding interactions has been reported widely.[79] In contrast, studies on the binding of secondary ammonium ions ($R_2NH_2^+$) have been limited to smaller macrocycles such as diaza-[12]crown-4.[176] In principle, enlargement of the complexing macrocycle should provide an environment suitable for the pseudorotaxane-like insertion of the cation through the center of the macrocyclic polyether (Fig. 45). This pseudorotaxane superstructure should be stabilized by hydrogen bonding between the acidic hydrogen atoms of the ammonium group and the oxygen atoms of the crown ether. The realization of this concept

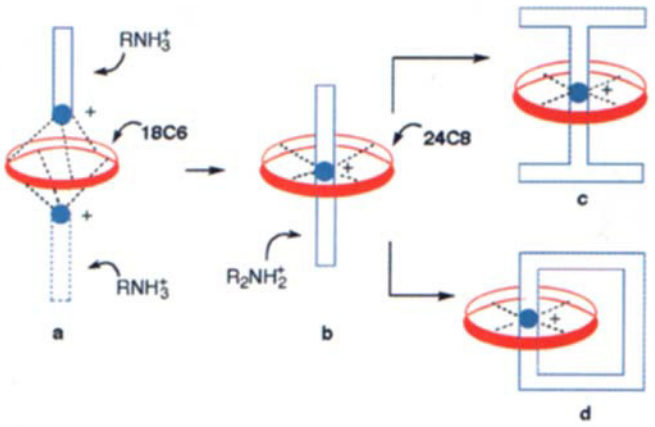

Fig. 45. The progression from a) a complex between a primary ammonium cation and [18]crown-6(18C6) with a "perched" geometry through b) a complex between a secondary ammonium cation and [24]crown-8(24C8) with a pseudorotaxane-like geometry to c) rotaxanes and d) catenanes.

has been described simultaneously by two research groups. We have exploited the recognition between large crown ethers and various dialkylammonium ions to demonstrate that this hypothesis is, in fact, correct.[177] Dibenzo-[24]crown-8 (**DB24C8**) can bind both dibenzylammonium and bis(*n*-butyl)ammonium ions in a pseudorotaxane-like manner (Fig. 46). Interestingly,

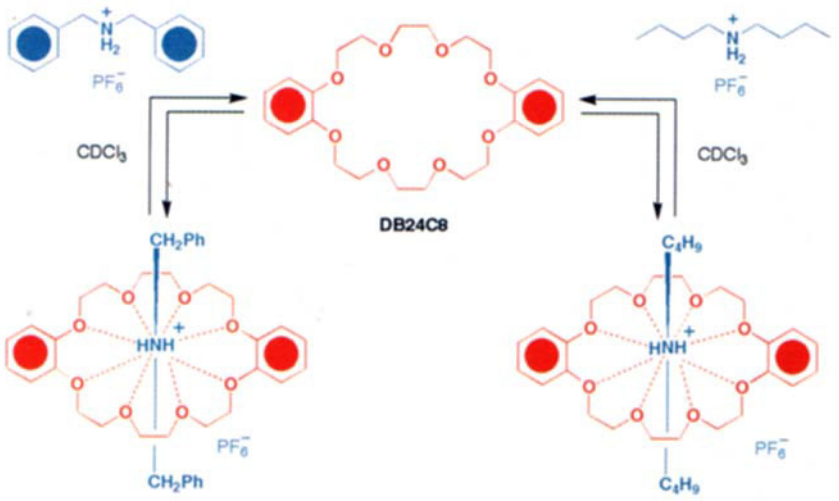

Fig. 46. Dibenzo-[24]crown-8 forms pseudorotaxane-like complexes with both dibenzylammonium hexafluorophosphate and di-*n*-butylammonium hexafluorophosphate.

the exchange of free and bound dibenzylammonium ions is slow on the ^{1}H NMR timescale. This kinetic effect is a result of the large steric barrier encountered by the phenyl rings of the cation when attempting to pass through the **DB24C8** torus, rather than a particularly high binding constant (27000 M^{-1} in $CDCl_3$). This new recognition motif has been extended to the self-assembly of doubly encircled and doubly stranded pseudorotaxanes[177] (Fig. 47). Busch and co-workers have described the synthesis and characterization of a [2]rotaxane based on the recognition of the salts of either 4-(anthracen-9-yl)butylamine or *N*-1-(anthracen-9-yl)methylethan-1,2-diamine by **DB24C8**.[178] The synthesis of the [2]rotaxane proceeded in modest yield

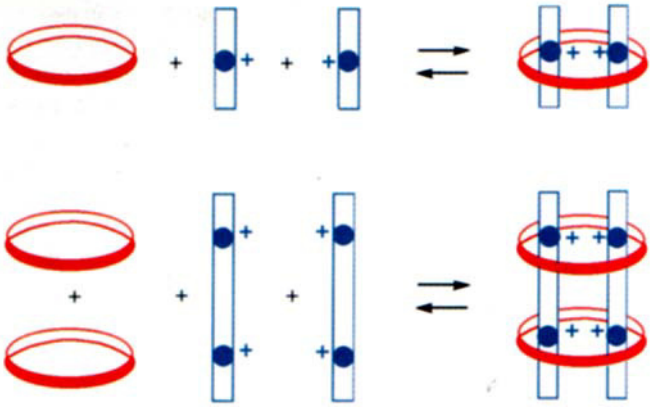

Fig. 47. Secondary ammonium ions can direct the assembly of doubly stranded (top) and doubly encircled (bottom) pseudorotaxanes.

(20%) and the insertion of the ammonium ion through the torus of the **DB24C8** macrocycle has been demonstrated by X-ray crystallography.

4.3. Metal–Ligand Interactions

Metal–ligand interactions have been known and studied since the turn of the century.[179] Werner, building on earlier ideas[180] that metal centers could bind neutral molcules or ligands,[181] introduced the idea of specific metal–ligand geometries in first decade of this century. The stereochemical ideas of Werner were consolidated and expanded on by Lewis and Sidgwick, who introduced the concept of a metal–ligand interaction being the sharing of an electron pair. Later, the idea of chelating and macrocyclic ligands for metal centers emerged.[182, 183] Metal coordination chemistry has many useful features that can be applied to the field of self-assembly. Metal–ligand bonds can be strong, lending stability to a structure, yet kinetically labile, allowing reorganization to occur. Additionally, metal–ligand interactions provide the chemist with a lexicon of well-defined geometries for the design of a wide range of structural forms. One of the earliest examples of molecular self-assembly was provided by the field of metal coordination chemistry.[184–186] In 1960 Curtis reported the one-pot synthesis of a yellow crystalline product from the reaction of $[Ni(en)_3]^{2+}$ (en = ethylenediamine) in dry acetone (Fig. 48). At first this product was assigned incorrectly to a complex of the bisimine species **59**. However, the extreme stability of the complex—it survives boiling acid and alkali—did not support this structural assignment. It was shown subsequently that the yellow product was, in fact, a mixture of the isomeric macrocyclic Ni^{II} complexes **60** and **61**. Although the precise mechanism of this self-assembly process is not clear, it may involve repetitive imine formation with subsequent attack of an acetonyl carbanion on the Ni-coordinated imine; in other words, the Ni^{2+} cation acts as the template[187] around which the macrocycle is assembled.

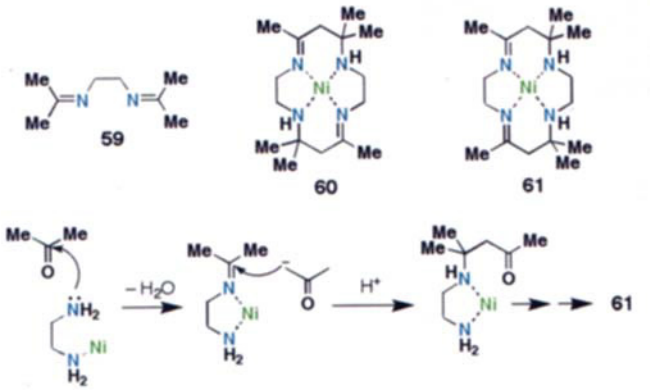

Fig. 48. The self-assembly of a macrocycle around a Ni^{II} ion (Curtis et al. [184–186]).

Sanders and co-workers have extended their earlier investigations of flexible bisporphyrin receptors[188, 189] to utilize the axial ligand site[190] of zinc porphyrins for the directed self-assembly of a diverse array of novel porphyrin-containing macrocycles. Although the macrocyclic porphyrin trimer **63a** can be synthesized by untemplated oxidative coupling of the diacetylenic porphyrin monomer **62a** (Fig. 49),[191] the yield is relatively low (47%) and the crude product contains many other cyclic and acyclic oligomers. If, however, the monomer **62b** is oxidatively coupled in the presence of s-2,4,6-tri-4-pyridyltriazine (**64**), then the amount of cyclic trimer **63b** formed is dramatically enhanced.[192] Surprisingly, bifunctional pyridine ligands such as di-4-pyridylpropane are almost as efficient at

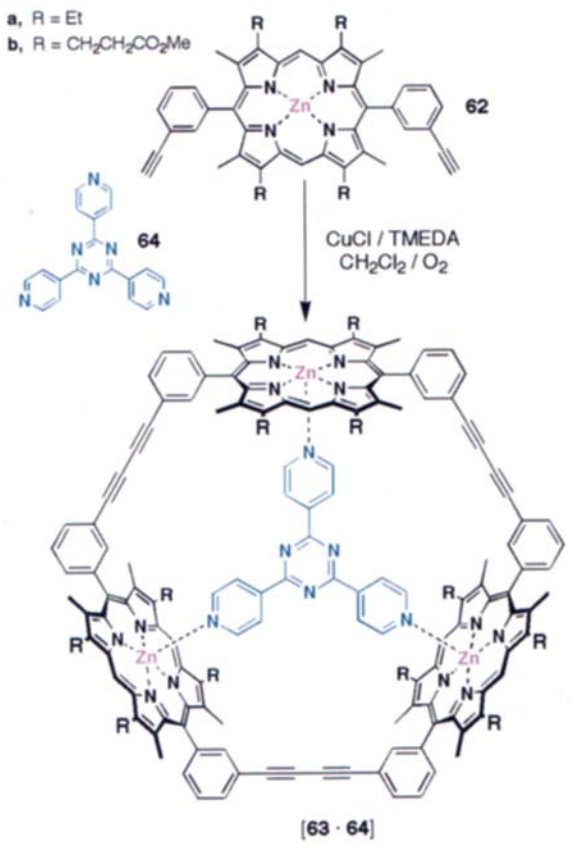

Fig. 49. s-Tripyridyl triazine can act as an efficient template for the formation of a trimeric macrocyclic porphyrin array.

templating the synthesis of **63b**. This observation indicates that **64** acts as a "negative template": it promotes trimer formation passively by inhibiting dimer formation actively. The cyclic dimer can also be synthesized in high yield by employing 4,4′-bipyridine as a "positive template". The attempted template-directed synthesis of an enlarged, platinum-linked cyclic trimer of **62a**, using a chiral aluminium-based ligand designed for the purpose, has also been reported.[193] The multifarious roles of the amine templates within these systems has been further extended by the introduction of the "scavenger template".[194, 195] A scavenger template allows efficient dimerization of singly reactive species in statistical mixtures of unreactive, singly, and doubly reactive species by forcing doubly reactive species to cyclize, thus allowing the singly reactive species to react with themselves. The supermacrocyles formed in these remarkable template-directed syntheses have large internal cavities in which several molecules can be brought together and bound in close proximity. Sanders and co-workers have described the acceleration of an *exo*-selective intermolecular Diels–Alder cycloaddition reaction between a maleimide and a furan derivative, which occurs within the cavity of a cyclic porphyrin trimer.[196] The diene **65** and dienophile **66** can bind in a favorable orientation within the cavity of the trimeric macrocycle **63a** (Fig. 50). The

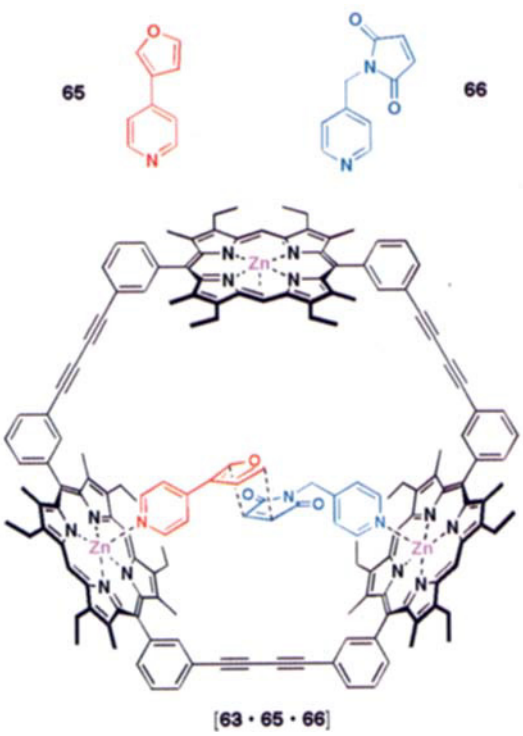

Fig. 50. A trimeric porphyrin array can act as an efficient catalyst for the Diels–Alder reaction between and a furan derivative (red) and a maleimide (blue).

porphyrin trimer acts as a very effective linear template[195] both kinetically, by accelerating the reaction, and thermodynamically, by stabilizing the *exo* product. Trimer **63a** is regarded as a significant step[196] towards the development of artificial enzyme systems as it decouples recognition and orientation of the reactants from the reaction itself. Therefore, it should be possible to bring together a range of substrates within its cavity by rational design changes.

Fujita, Yazaki, and Ogura[197, 198] have exploited metal coordination in the formation of macrocycles of a different kind. When $[M(en)(NO_3)_2]$ (M = Pt, Pd) is treated with bipyridine, a cyclic tetrameric macrocycle **67**—a molecular box—is formed as the thermodynamic product (Fig. 51). The mechanism pre-

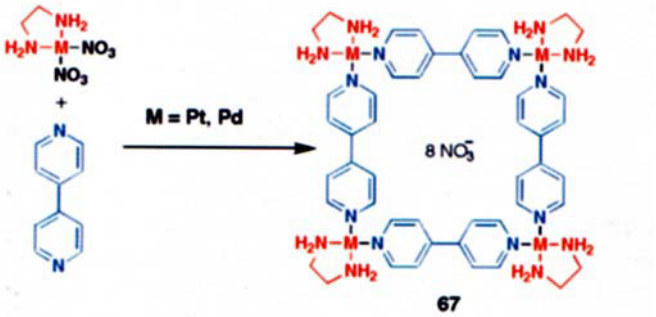

Fig. 51. Tetrameric bipyridine macrocycles are formed readily through metal directed self-assembly.

sumably involves stepwise displacement of the nitrate ligands by bipyridine. Interestingly, in the reaction of the platinum complex, the kinetic product is an oligomeric species which is converted slowly into the thermodynamic, tetrameric product when the reaction mixture is heated at 100 °C. This observation suggests slow exchange within the ligand set around the metal center. In the palladium complex, ligand exchange must be rapid since no oligomeric products are observed by ^{1}H NMR spectroscopy and the thermodynamic product is formed immediately. The macrocycle **67** is capable of binding π-electron rich aromatic guests such as 1,3,5-trimethoxybenzene within its cavity.[199] Other groups have also reported self-assembling molecular boxes based on metal coordination chemistry.[200]

Fujita et al. have extended the concepts used to construct the molecular boxes to the assembly of a wide array of structures[201] such as molecular networks, ladders, and bricks. A spectacular example of the power of these self-assembly processes is the quantitative self-assembly of a [2]catenane from a pair of preformed molecular rings.[202] This synthesis of a [2]catenane exploits the relatively lability of the Pd^{II}–N coordinate bond. When the Pd^{II} complex $[Pd(en)(NO_3)_2]$ **68** is treated with one molar equivalent of 1,4-bis(4-pyridylmethyl)benzene (**69**) in D_2O, the macrocycle **70** is formed initially (Fig. 52). However, as the concentration of the solution is increased, another compound is formed which was shown to have the catenated structure **71** (>90% yield for c(**68**), c(**69**) > 50 mM). Initially, a "double-differential complexation" mechanism was proposed for the assembly of the [2]catenane, in which two molecules of **70** bind each other in their cavities. A control experiment in which the Pd^{II} is replaced by Pt^{II} established that the breaking and reforming of the Pd–N bond is crucial in the efficient formation of the [2]catenane. In the case of Pt^{II}, a kinetic mixture of the [2]catenane together with other products is observed. Dilution of this mixture does not affect the product ratio—the Pt–N coordinate bond cannot be broken under these conditions. However, recent work has shown that a novel "Möbius strip" mechanism, in fact, operates.[202] The different behavior of the Pt^{II} system has been exploited in the assembly of a "molecular lock" based on the [2]catenane struc-

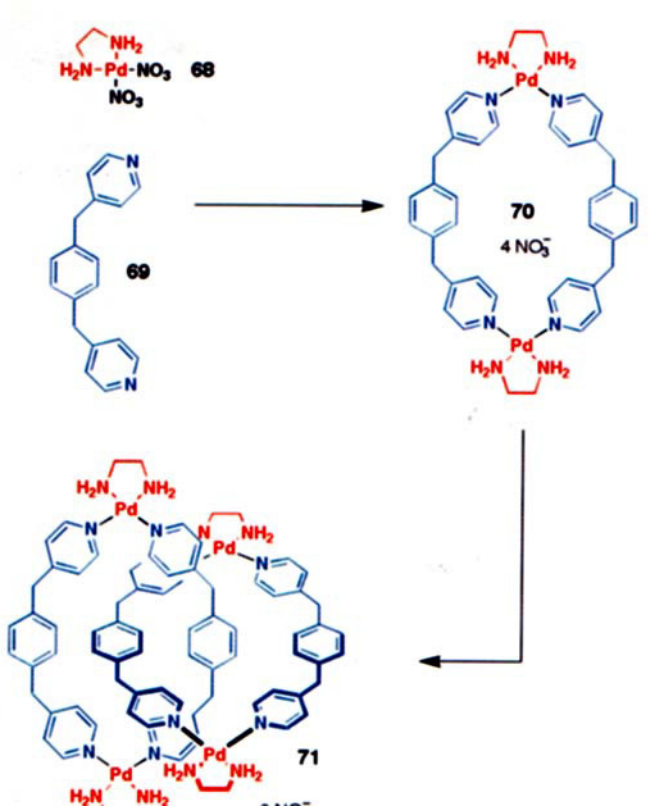

Fig. 52. Metal-directed self-assembly produces first macrocycle **70**. When the concentrations of the appropriate species are increased, [2]catenane **71** forms almost spontaneously and almost quantitatively.

ture **71**.[203] The Pt–N bond in the [2]catenane can only be "unlocked" under certain conditions, and hence the stepwise assembly of the [2]catenane structure can be controlled precisely.

A wide variety of macromolecular biological structures display molecular helicity,[204] for example, the protein α-helix. Lehn and co-workers[205, 206] have described a series of oligobipyridine ligands, which spontaneously order themselves around an appropriate number of Cu^I metal centers to give helical complexes (Fig. 53). These helical species display many of the features normally associated with self-organizing biological systems. The assembly of the helicates shows positive cooperativity;[207] in other words, the binding of the first Cu^I ion facilitates the binding of the second and so on. Hence, their assembly is highly nonlinear, as evidenced by the fact that at all Cu^I concentrations examined only free ligand and fully formed helicate exist in solution. In addition, the binding of the ligands by Cu^I displays self–self selection;[208] that is, given a mixture of ligands, a forming helical species will bind selectively a second ligand of the same size, and thus no overlapping polymeric structures are formed in solution. This phenomenon has been termed the "instructed system paradigm". The assembly of bipyridine ligands carrying pendant nucleoside units around Cu^I centers has also been demonstrated by Lehn et al.[209] In this case, the final structure, a so-called deoxyribonucleohelicate, recalls Pauling's (incorrect) structure for DNA proposed in 1953[210] in that the pyrimidine bases are divergent from the helix core. These systems may have applications as complementary ligands for the selective binding of regions of the DNA

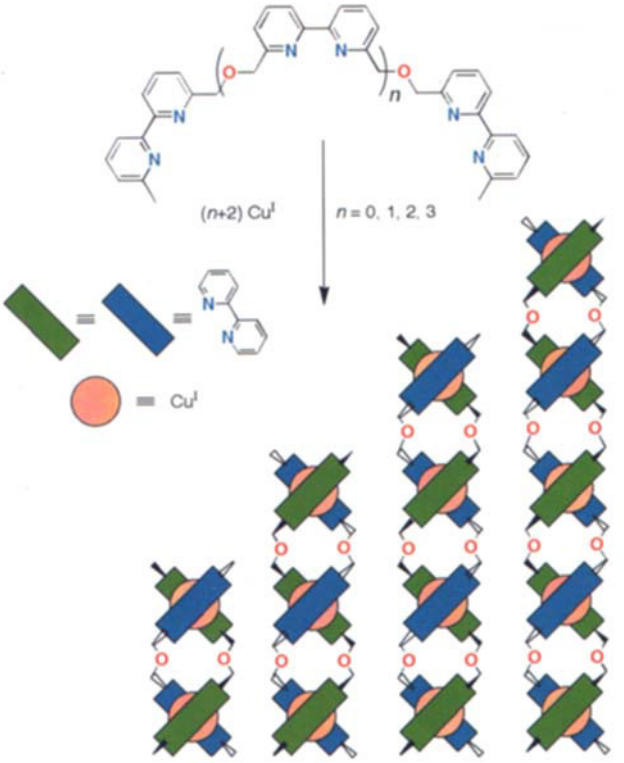

Fig. 53. Cu^{I} ion directed self-assembly of oligobipyridine-based double helices.

double helix, but at the very least they are beautiful examples of the power of self-assembly to create large, unnatural structures in a highly selective and ordered manner. More recently, Lehn and co-workers have reported the self-assembly of triple helices from Ni^{II} ions and oligobipyridine ligands,[211] as well as the spontaneous formation of a cylindrical complex from five ligands and six Cu^{I} ions.[212]

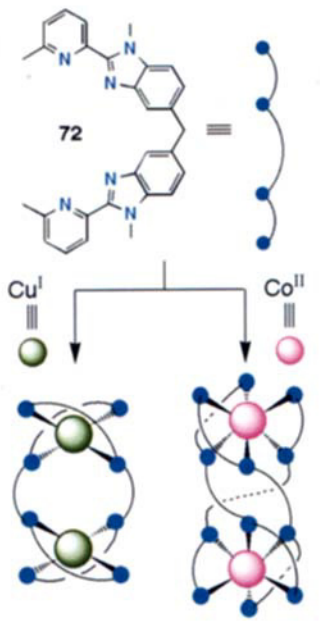

Fig. 54. Different metals instruct the self-assembly of different structures. Ligand **72** can form a double or a triple helical complex depending on the metal ion employed in the self-assembly process.

Constable and co-workers[213–217] have utilized oligopyridine ligands in the self-assembly of both single and double helical metal–ligand complexes with a wide variety of metal centers. The requirements for helix formation in the case of single helices have been elucidated. Helical superstructures arise when the oligopyridine ligands interact with a small, charged center that can impose a clear stereochemical preference on the system.[218] The formation of stereochemically well-defined complexes has been applied by Constable et al. to the efficient template-directed synthesis of the ligands themselves.[219]

By combining pyridine and benzimidazole subunits within the same ligand, Piguet, Bernardinelli, and Williams have been able to self-assemble a wide range of double and triple helices containing both transition metal and lanthanide centers.[220] A degree of control can be exercised over the outcome of these self-assembly processes. When ligand **72** is mixed in a 3:2 ratio with an appropriate source of Co^{II} ions, a dinuclear triple helicate forms spontaneously (Fig. 54).[221] However, the analogous reaction with Cu^{I} ions results in spontaneous formation of a dinuclear double helicate. In this case, the outcome of the self-assembly process is governed by the coordination geometries of the metal centers.

Lehn and co-workers have explored the use of metal coordination for the construction of molecular racks, ladders, and grids (Fig. 55).[222] When ligand **73** is mixed with 1.5 equivalents of $AgSO_3CF_3$, a three-by-three molecular grid self-assembles spontaneously from nine Ag^{I} ions and six ligands (Fig. 56). Analysis of the product by ^{109}Ag NMR spectroscopy indicates that, as expected, there are three types of Ag^{I} ions in the structure in the ratio 4:4:1, corresponding to the metal ions at the vertices, those on the edges, and the single Ag^{I} ion at the center of the grid, respectively.

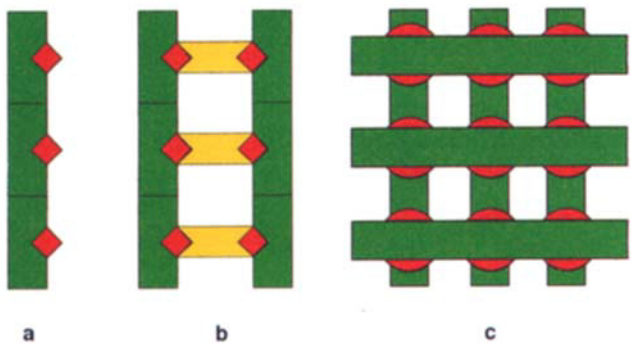

Fig. 55. Rack (a), ladder (b), and grid structures (c).

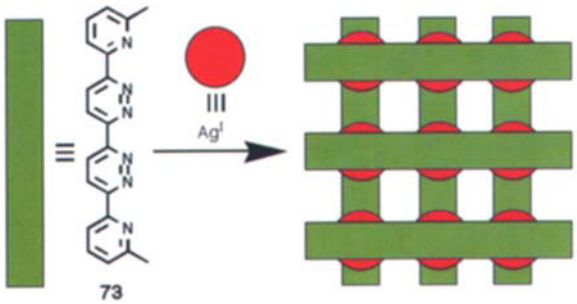

Fig. 56. Nine Ag^{I} cations and six ligands form a molecular grid by self-assembly.

Balzani, Campagna, Denti, and co-workers have described the synthesis and photophysical properties of a series of decanuclear homo- and heterometallic polypyridine complexes incorporating Ru^{II} and Os^{II} metal centers (Fig. 57).[223] These com-

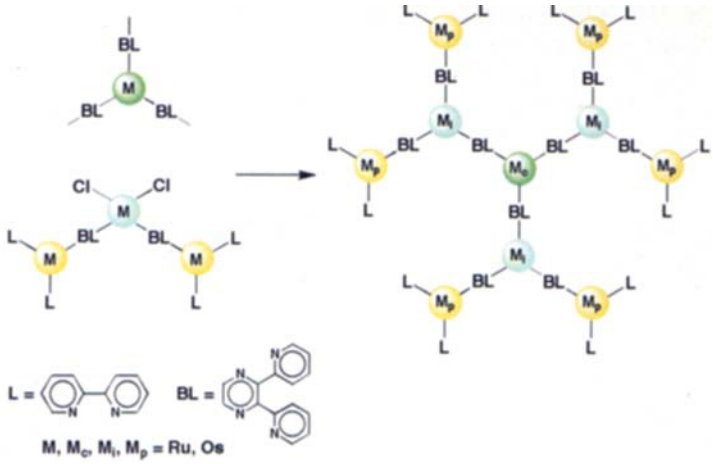

Fig. 57. Energy transfer within the multinuclear dendritic metal complexes is controlled by the identity of the metals and ligands at the various sites within the complex.

pounds have remarkable photophysical properties: when they are irradiated, energy is transferred through the system in a manner predetermined by the nature of the metal in each of the ligand sites. For example, upon irradiation of the complex with $M_c = Os^{II}$, M_i, $M_p = Ru^{II}$, and L = bipyridine, the energy is transferred from the central metal toward the periphery of the assembly.

Sauvage et al. have exploited the coordination geometry of 2,9-disubstituted 1,10-phenanthroline ligands around a Cu^I center to provide the first example of a practical, efficient synthesis of a catenated species (Fig. 58).[224] Sauvage has termed the

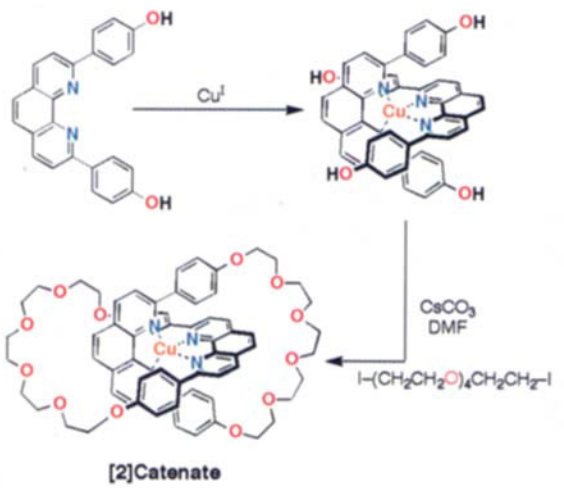

Fig. 58. The interaction between a Cu^I ion and a 9,10-phenanthroline ligand can be used to direct the formation of a [2]catenate.

metalated structures catenates and the corresponding demetalated species catenands (*caten*ane + lig*and*). This research has been extended to encompass both further [2]catenanes containing a variety of metal centers,[225, 226] [3]catenanes,[227, 228] the investigation of higher catenanes by electrospray mass spectrometry,[229] and more recently, [2]rotaxanes containing a Cu^I–phenanthroline core with differentially metalated porphyrin stoppers or with fullerene-based stoppers,[230] and pseudorotaxanes containing several Cu^I centers.[231] Perhaps the most exquisite example of the application of metal–ligand interactions in self-assembly is the synthesis by Sauvage et al. of a molecular trefoil knot.[232] The trefoil knot may be synthesized from a tetrafunctionalized helicoidal complex (Fig. 59), which

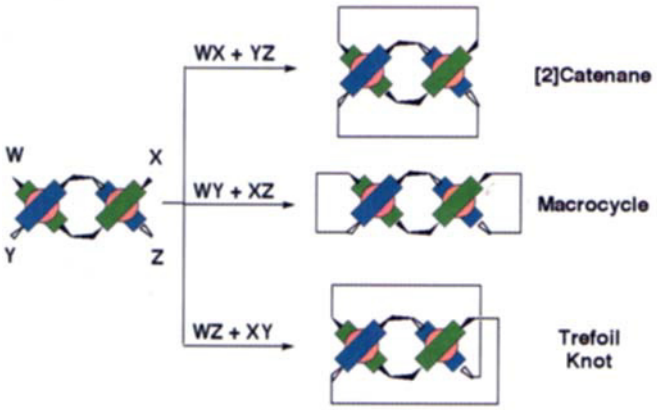

Fig. 59. The possible products of a reaction in which the termini of a double helical complex are linked.

has a number of possible cyclization pathways. In particular, if point W is linked to point Z, and point X to point Y, a trefoil knot results. Other connections produce either macrocyclic or catenated species. Using an extension of their copper–phenanthroline methodology, Sauvage et al. were able to synthesize

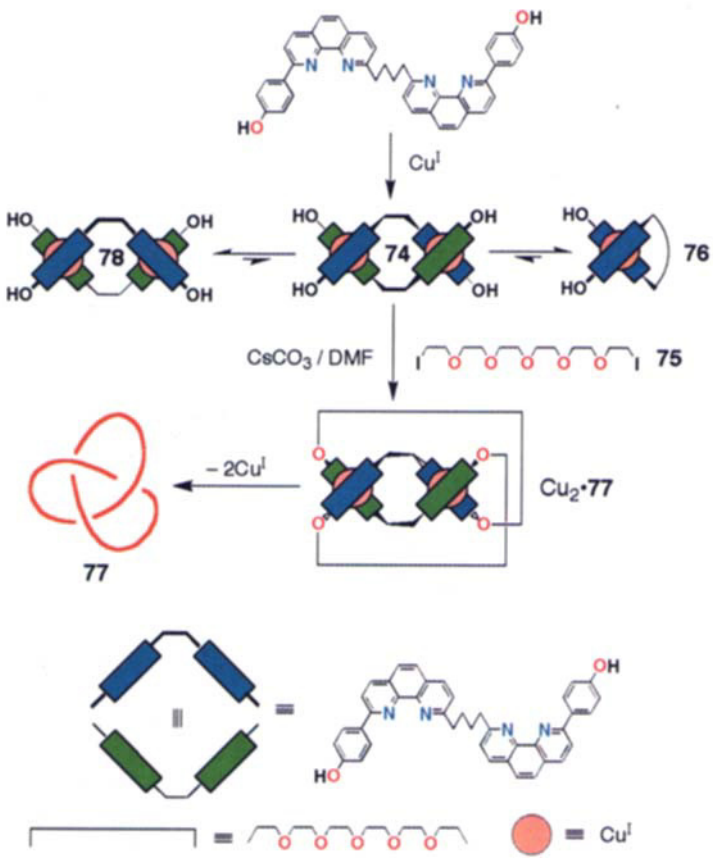

Fig. 60. The double helix formed by two Cu^I cations and a bis(9,10-phenanthroline) ligand can be used to direct the synthesis of a trefoil knot.

trefoil knot **77** in 3% yield from the helical dinuclear Cu^{I} complex **74** and hexaethyleneglycol diiodide **75** (Fig. 60). Although the yield of the trefoil knot appears to be low, it should be noted that the helical dinuclear complex **74** is in equilibrium with the mononuclear Cu^{I} complex **76**, and that the equilibrium lies far to the side of mononuclear complex. In addition, the equilibrium of the helical complex **74** with its face-to-face isomer **78** is also unfavorable (**74**:**78** = 1:10). The effects of these deleterious equilibria can be overcome by the use of a rigid 1,3-substituted phenylene spacer in place of the flexible oligo(methylene)spacer in the original bis(phenanthroline) ligand.[233] The redesigned ligand permits the synthesis of a trefoil knot in a remarkable 30% yield, marking a high point in the synthetic applications of self-assembly.[234]

4.4. Self-Assembling Systems Based on π-Donors and π-Acceptors

The donor–acceptor interactions between π-systems have been known[235] and studied[236] for over 40 years. Although the exact nature of these interactions is still a matter for some debate,[237] they are an important class of noncovalent bonding interactions. The 1,1′-dimethyl-4,4′-bipyridinium dication 79^{2+}, better known as the bipyridinium herbicide paraquat,[238–240] is an extensively studied electron acceptor. It offers a planar π-system in which two positive charges are delocalized[241] as well as a rich and reversible electrochemistry.[242] Unsurprisingly, the dication 79^{2+} forms a wide range of electron donor–acceptor complexes with a variety of electron donors.[243–244] Of most interest in the context of the present research activity are those involving π-donors. Among the species that form relatively weak ($\Delta G^{\circ} < -1$ kcal mol^{-1}) π-donor/π-acceptor complexes with the paraquat dication[245] are aniline, *o*-phenylenediamine, catechol, and hydroquinone. In the crystal structure of the complex formed between hydroquinone **80** and 1,1′-dimethyl-4,4′-bipyridinium diiodide (Fig. 61)[246] the dication and the π-donor have a face-to-face arrangment with a mean separation[247] between the two π-planes of 3.38 Å.

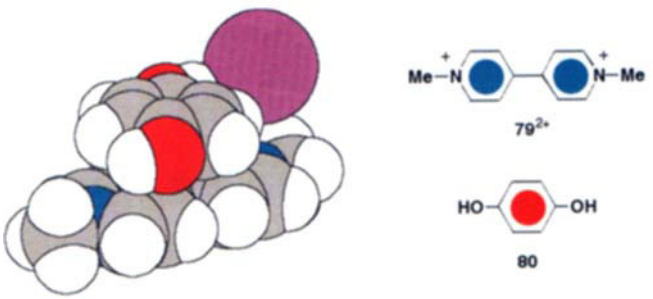

Fig. 61. The X-ray crystal structure of the paraquat diiodide/hydroquinone complex. Note that the second iodide counterion has been removed for clarity.

The bipyridinium herbicides are also capable of forming complexes with macrocyclic π-donors. The dicationic platinum complex 81^{2+} forms a strong complex (K_a = 191000 M^{-1}) with the crown ether dibenzo-[30]crown-10 (**DB30C10**) (Fig. 62).[248] This prompted us to exploit the constitutional similarities between 81^{2+} and the diquat dication 82^{2+} and show that the latter also forms a strong 1:1 complex (K_a = 4100 M^{-1}) with **DB30C10** (Fig. 62).[249] The principal stabilizing interactions in

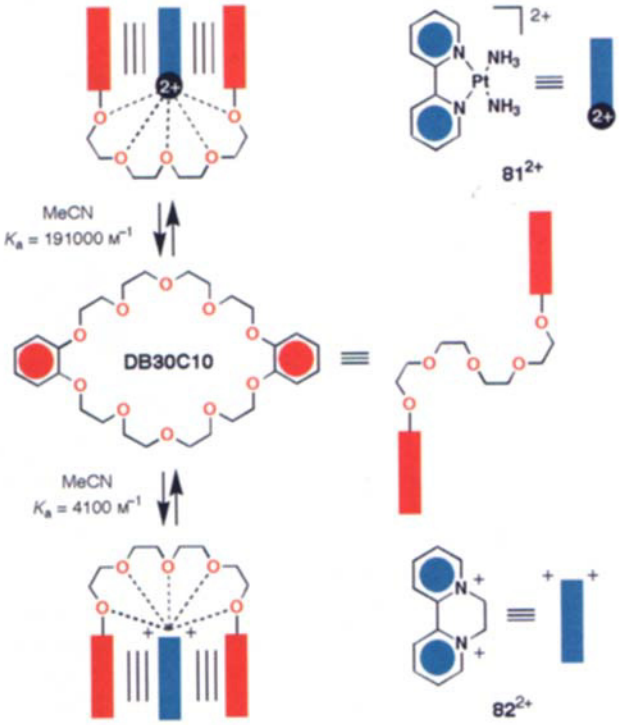

Fig. 62. The binding of $[Pt(bpy)(NH_3)_2]^{2+}$ and the bipyridinium herbicide diquat by **DB30C10**. The counterions have been omitted for clarity. In addition, in the cartoon representation of **DB30C10**, only one of the tetraethylene glycol chains is shown.

the complexes are: 1) the solvation of the positive charge by the oxygen atoms of the polyether chains within **DB30C10** through electrostatic interactions including hydrogen bonding and 2) the π-donor/π-acceptor and charge transfer (CT) interactions between the electron-rich catechol units of **DB30C10** and the electron-deficient π-system in both dications. The CT interaction gives rise to the characteristic orange color of these complexes. Subsequently, we demonstrated that the paraquat dication 79^{2+} can also be bound strongly by bisparaphenylene-[34]crown-10 (**BPP34C10**), a constitutional isomer of the dibenzo crown **DB30C10**.[250–252] **BPP34C10** binds **79**·2PF_6 in acetone solution with a stability constant of 730 M^{-1} for the 1:1 complex (Fig. 63). Furthermore, the X-ray crystal structure of this complex revealed a highly ordered superstructure in which the rod-like 79^{2+} dication is inserted into the cavity of **BPP34C10** centrosymmetrically, such that the methyl groups are positioned on opposite faces of the crown ether in a pseudorotaxane-like manner.[97] The complex is stabilized both by electrostatic interactions, including [C–H···O] hydrogen bonding between the acidic hydrogen atoms of 79^{2+} and the polyether oxygen atoms, and by dispersive forces including CT between the complementary π-systems of **BPP34C10** and 79^{2+}. Like [**82**·**DB30C10**]$^{2+}$, the [**79**·**BPP34C10**]$^{2+}$ complex has a deep orange color as a result of the CT interactions.

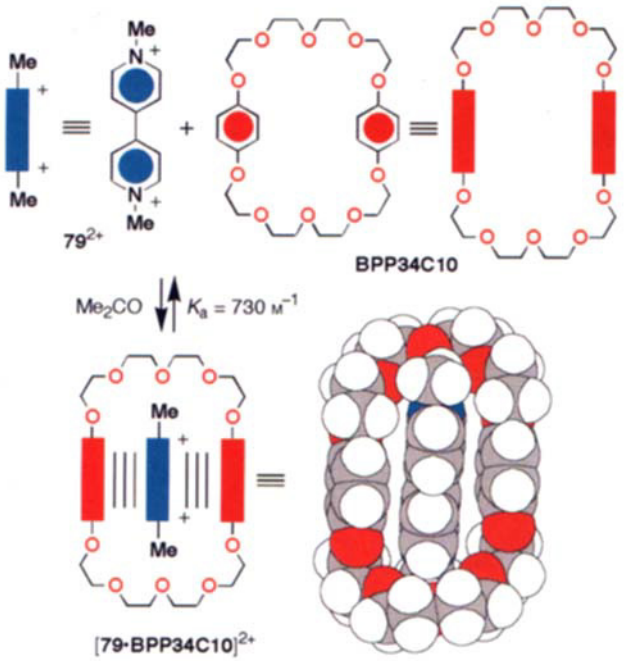

Fig. 63. The complexation of the bipyridinium herbicide paraquat by ***BPP34C10***. The counterions have been omitted for clarity.

Both of these examples illustrate how π-donor/π-acceptor interactions can be used to bind a π-electron deficient *guest* inside a π-electron rich *host*. There is no conceptual or practical reason why the roles of the π-donor and the π-acceptor cannot be reversed to produce a π-electron deficient *host* capable of binding a π-electron rich *guest*. Indeed, this objective has been achieved with the synthesis of the tetracationic cyclophane **83**$^{4+}$ (Fig. 64) as its tetrakis(hexafluorophosphate) salt.[253] This cyclophane, incorporating two π-electron deficient 4,4′-bipyridinium dications, is capable of binding a wide variety of π-electron rich guests within its rigid rectangular cavity. Guests that can be bound include catechol and hydroquinone dimethyl ethers,[254] substituted 1,5-dioxynaphthalene derivatives,[255] aromatic amino acids,[256] tetrathiafulvalene,[257] and derivatives of indole.[258] The X-ray crystal structure of the complex formed between **83**·4PF_6 and 1,4-dimethoxybenzene **84** reveals that the π-electron rich **84** is inserted centrosymmetrically inside the cavity of **83**$^{4+}$ in a pseudorotaxane-like manner (Fig. 64). The principal stabilizing feature in this 1:1 complex is the π-donor/π-acceptor interaction, with no additional stabilization from hard electrostatic interactions such as hydrogen bonding. The absence of efficient electrostatic stabilizing forces is reflected in the low value of the stability constant, namely 17 M^{-1}. Interestingly, there are also weakly stabilizing (<0.3 kcal mol^{-1}) edge-to-face interactions between the electropositive hydrogen atoms on the phenylene ring of **84** and the π-system of the rigid *p*-xylyl unit of **83**$^{4+}$. This type of interaction has been found in widely diverse structures such as in the solid-state structure of benzene and in the crystal structures of proteins rich in aromatic amino acids.[259–261]

The observation that it is possible to bind a π-electron deficient guest within a π-electron rich cavity (e.g. [**79**·**BP34C10**]$^{2+}$) and a π-electron rich guest within a π-electron deficient cavity (e.g. [**83**·**84**]$^{4+}$) strongly suggests the possibility of combining these two supramolecular design features within the same

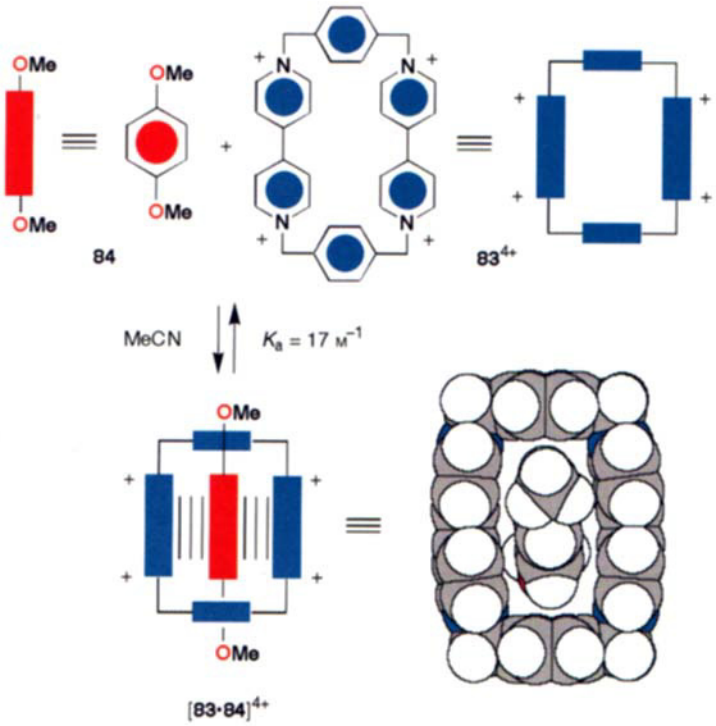

Fig. 64. The complexation of 1,4-dimethoxybenzene by the rigid tetracationic receptor cyclobis(paraquat-*p*-phenylene). The counterions have been omitted for clarity.

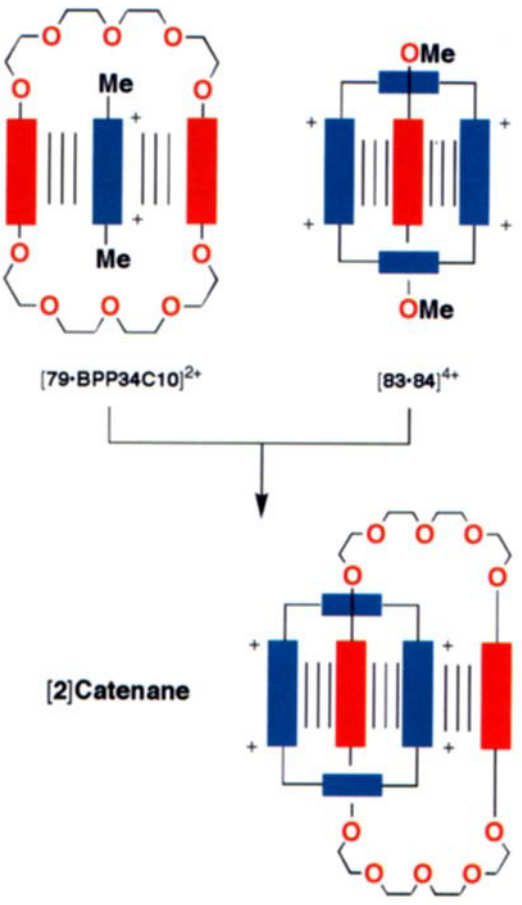

Fig. 65. The emergence of the design of a [2]catenane based on the simple receptor chemistry shown in Figs. 63 and 64.

molecular assembly. This proposition was reinforced by the observation that a continuous π-donor/π-acceptor stack is formed in the solid state when 1,5-dinaphtho-[44]crown-12 crystallizes with two molar equivalents of $\mathbf{79}^{2+}$; one dication is included within the crown ether host and the second is clathrated between adjacent complexes in the crystal.[262] Thus, the design of a [2]catenane emerged quite logically from the supramolecular chemistry of complementary π-donors and π-acceptors (Fig. 65). When the reaction between the bis(pyridylpyridinium) salt $\mathbf{85}^{2+}$ and 1,4-bis(bromomethyl)benzene **86** is performed in acetonitrile at room temperature in the presence of three molar equivalents of the crown ether **BPP34C10**, the [2]catenane **88**·4 PF_6 is formed in 70% yield, following purification and counterion exchange (Fig. 66).[263] This extremely high

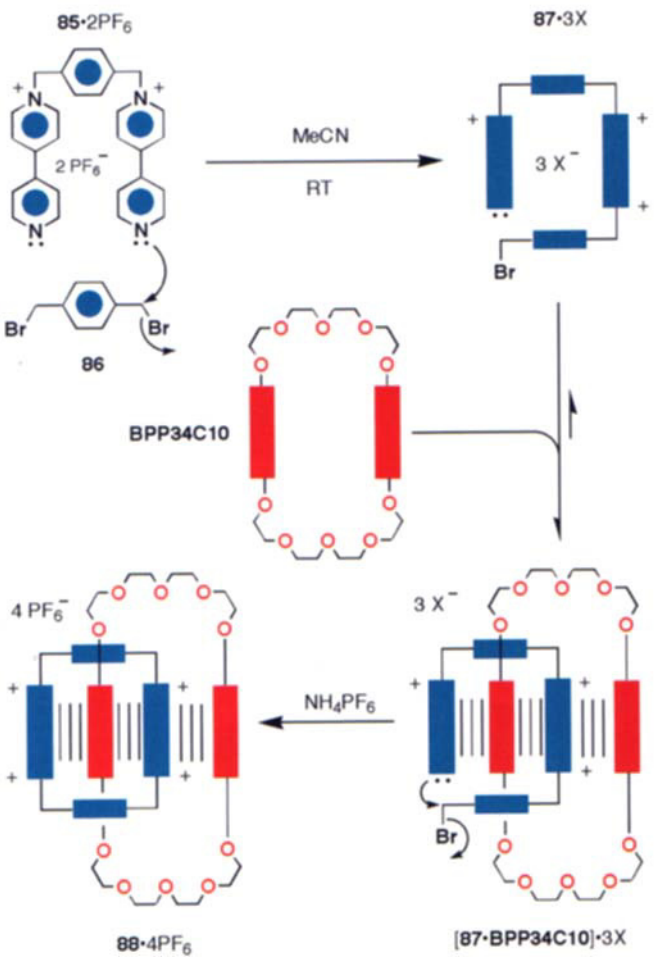

Fig. 66. The self-assembly of a [2]catenane directed by the mutual recognition between appropriately located π-donors (red) and π-acceptors (blue). The critical phase of this reaction scheme is the binding of the paraquat-like tricationic intermediate **87**·3X by **BPP34C10**. RT = room temperature.

yield contrasts starkly with the harsh conditions required and low yields obtained in the synthesis of both the **BPP34C10** and $\mathbf{83}^{4+}$ macrocycles as separate compounds. The mechanism involves initial alkylation of the dication $\mathbf{85}^{2+}$ by 1,4-bisbromomethylbenzene **86** to produce the tricationic intermediate $\mathbf{87}^{3+}$.[264] The 4,4′-bipyridinium component of this trication is then rapidly and strongly complexed by **BPP34C10**. This 1:1 complex will be stabilized by the electrostatic, CT, and π–π stacking interactions between the π-electron rich hydroquinone rings of the crown ether and the π-electron deficient 4,4′-bipyridinium residue of $\mathbf{87}^{3+}$. This intermediate complex $[\mathbf{87}\cdot\mathbf{BPP34C10}]^{3+}$ is ideally disposed to undergo a second ring-closing nucleophilic displacement of bromide ion to form the [2]catenane. The X-ray crystal structure of **88**·4 PF_6·5 MeCN reveals continuous stacks of the [2]catenanes along one of the crystallographic directions such that π-donors and π-acceptors alternate both intra- and intermolecularly[266] with a spacing of 3.5 Å (Fig. 67).[263, 265] Dynamic ^{1}H NMR spectroscopy reveals that the [2]catenane is also highly ordered in solution.[263, 265] Three dynamic processes are observable (Fig. 68). The first is the circumrotation of the neutral **BPP34C10** through the cavity of the $\mathbf{83}^{4+}$ cyclophane (Process I, Fig. 68). This process is relatively high in energy as it involves the disruption of all noncovalent π–π interactions within the [2]catenane, and consequently, at 25 °C this process occurs only 22 times per second. The second process is the pirouetting of the **BPP34C10** around the periphery of the $\mathbf{83}^{4+}$ cyclophane (Process II, Fig. 68). Since this process involves the disruption of only one of the π–π interactions within the [2]catenane, it has a much lower energy barrier than the first dynamic process. As a result, the pirouetting motion occurs 7000 times per second at 25 °C. The third dynamic process observed (Process III, Fig. 68) is the rocking motion of the hydroquinone ring within the cavity of the tetracationic cyclophane. At low temperatures the exchange of the hydroquinone ring protons between the two magnetic enviroments becomes slow on the ^{1}H NMR timescale and two signals arise. At 25 °C, however, this process is extremely fast, occurring 1.6×10^6 times per second. The self-assembly process that forms

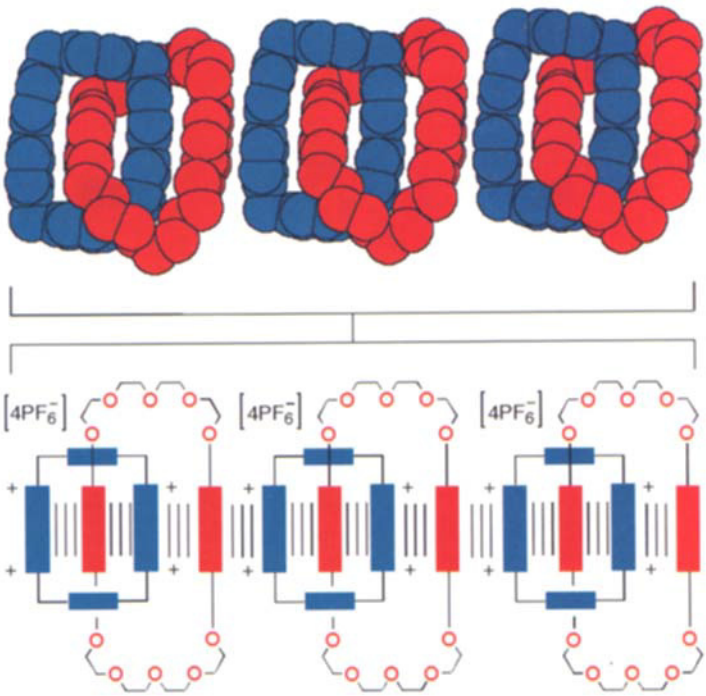

Fig. 67. The mutual recognition between the appropriately located π-donors (red) and π-acceptors (blue), which directs the formation of the [2]catenane, is in action both within the molecule and beyond the molecule in the solid state, where the [2]catenanes form continuous π-donor/π-acceptor stacks.

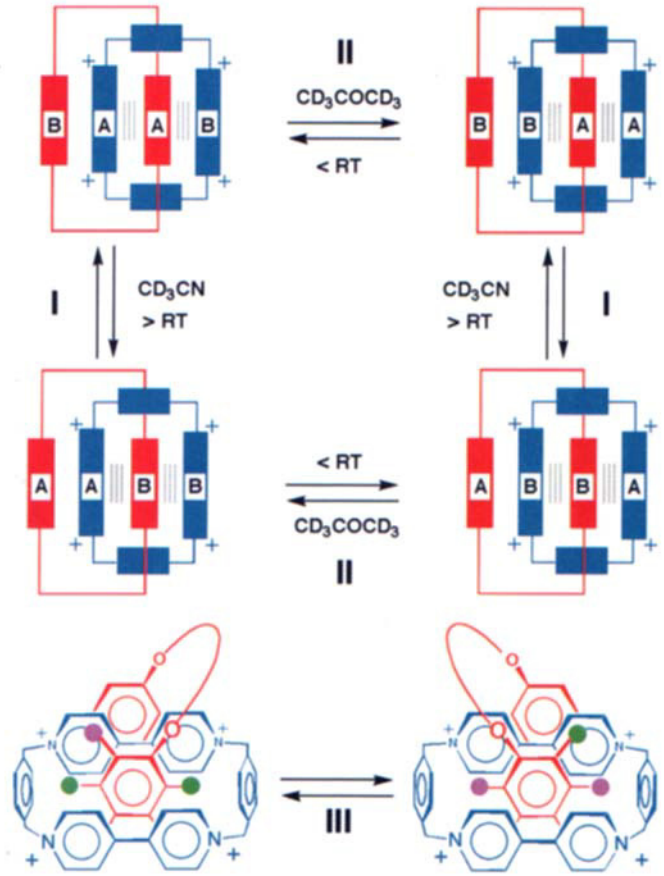

Fig. 68. The three dynamic processes that can occur within the [2]catenane. A detailed commentary is provided in the text.

the [2]catenane **88**·4PF_6 is remarkably robust and can tolerate the incorporation of both other crown ethers[265, 267] and the alteration of the bridging *p*-xylyl unit in the 83^{4+} ring.[265, 268]

To proceed from simple [2]catenane to higher [*n*]catenanes, one or other of the macrocyclic components must be enlarged. Reaction of the expanded crown ether **TPP68C20** with **85**·2PF_6 and **86** in dimethylformamide at room temperature and pressure affords, after appropriate workup, the [2]catenane **89**·4PF_6 in 12% yield (Fig. 69).[269] The dynamic processes characterizing the smaller [2]catenane **88**·4PF_6 also occur in **89**·4PF_6. However, the low-energy process, the pirouetting of the **TPP68C20** around the periphery of the 83^{4+} cyclophane, has a much lower energy barrier as a result of the larger cavity in **TPP68C20** and hence it occurs 28000 times per second at room temperature. The motion of the **TPP68C20** ring through the cavity of the 83^{4+} cyclophane can be observed by variable-temperature ^{1}H NMR spectroscopy. The 83^{4+} cyclophane visits each of the hydroquinone rings in turn as it moves round the perimeter of the **TPP68C20** macrocycle 300 times per second at room temperature—leading us to christen **89**·4PF_6 the "molecular train".[269] When the same catenane-forming reaction is repeated at 10 kbar pressure, the [3]catenane **90**·8PF_6, in which two 83^{4+} cyclophanes have been catenated with the **TPP68C20** macrocycle, is produced in 11% yield (Fig. 70).[269] As in **89**·8PF_6 the 83^{4+} cyclophanes in **90**·8PF_6 move between each of the hydroquinone units in the **TPP68C20** macrocycle. However, dynamic ^{1}H NMR spectroscopy shows that the symmetry

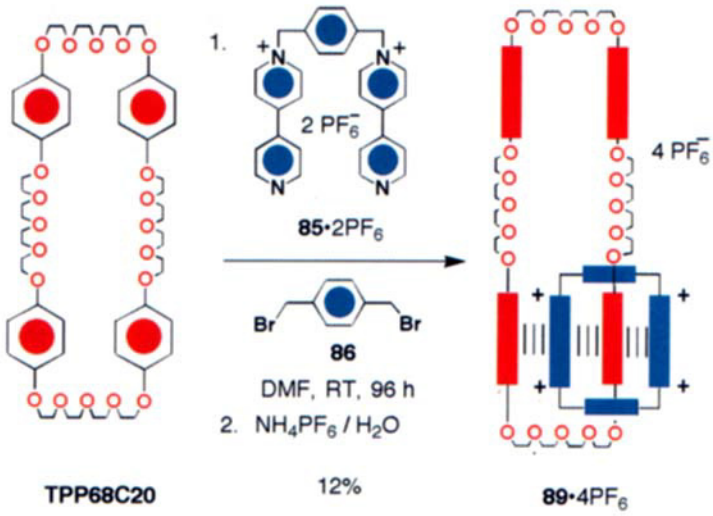

Fig. 69. The synthesis of a [2]catenane that behaves like a molecular train.

of the molecule is maintained. Hence, only the translational isomer[270] in which the 83^{4+} rings are separated by an uncomplexed hydroquinone ring is present in solution: on this "molecular merry-go-round" crashes do not happen.

Molecular modeling indicated that if the *p*-xylyl spacer in 83^{4+} is replaced by a *p*-bitolyl unit, it should be possible to accommodate two hydroquinone rings side-by-side simultaneously within the enlarged cyclophane cavity. The synthesis of this enlarged cyclophane has proven problematic.[271] However, when the dicationic precursor **91**·2PF_6 of the enlarged cyclophane was treated with bis(bromomethyl)biphenyl **92** in the presence of **BPP34C10** or alternatively **1/5DN38C10**, then the [3]catenanes **93**·4PF_6 and **94**·4PF_6 were produced in yields of 20 and 31%, respectively (Fig. 71).[272] Single-crystal X-ray structural analysis confirmed that two hydroquinone rings do indeed sit side-by-side in the 11 × 11 Å cavity of the charged macrocycle, and dynamic ^{1}H NMR spectroscopy showed that the dynamic processes observed in the other catenanes also oc-

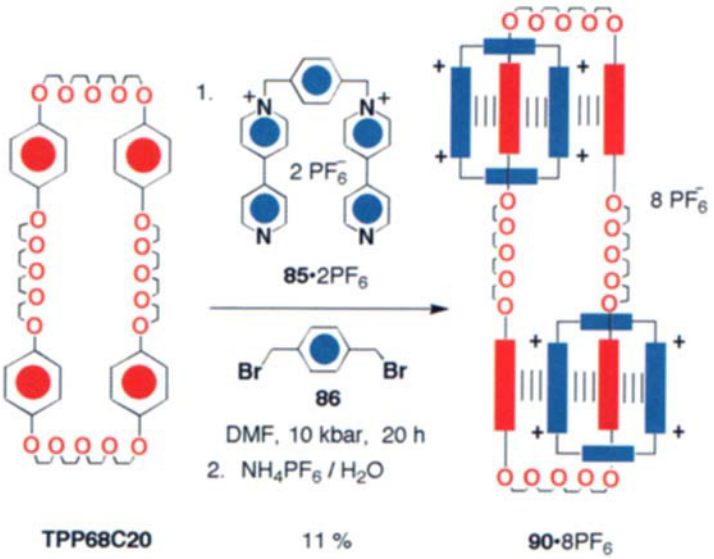

Fig. 70. The synthesis of a [2]catenane that behaves like a molecular merry-go-round.

cur in these new [3]catenanes – the neutral rings circumrotate through the charged ring some 8000 times per second at room temperature.

The successful synthesis by self-assembly of the [2]catenane **89**·4PF_6 and the [3]catenanes **93**·4PF_6 and **94**·4PF_6 suggested to us that it may in fact be possible to construct a [5]catenane by combining these two syntheses. Hence, we anticipated that synthesis of **89**·4PF_6, followed by catenation with **91**·2PF_6 and **92**, could lead to a [5]catenane. Alternatively, we reasoned that it might be possible to synthesize a [3]catenane incorporating **TPP68C20** and the enlarged macrocycle derived from **91**·2PF_6, and subsequently catenate two **83**$^{4+}$ rings in a reaction analogous to that which produces **90**·8PF_6. Unfortunately, all of these expectations were unfulfilled. A reappraisal of the system suggested that the **TPP68C20** macrocycle might be too flexible to allow efficient molecular recognition to occur between it and the forming charged macrocycles. Hence, we decided to explore the use of a crown ether of intermediate size, namely **TPP51C15**, whose ring size is exactly halfway between that of the successful **BPP34C10** and the unsuccessful **TPP68C20**. Thus, reaction of **91**·2PF_6 and **92** in the presence of **TPP51C15** afforded the [3]catenane **95**·4PF_6 in 3.5% yield (Fig. 72).[273] Reaction of **95**·4PF_6 with **85**·2PF_6 and **86** under ultrahigh-pressure conditions afforded both the [4]catenane **96**·8PF_6 in 22% yield and a trace of the [5]catenane **97**·12PF_6. The reluctance of the [4]catenane **96**·8PF_6 to react with further **85**·2PF_6 and **86** was perplexing. This problem was eventually overcome by replacing the hydroquinone units in the crown ether by 1,5-dioxynaphthalene rings. Substitution of **1/5TN57C15** for the **TPP51C15** in the reaction scheme shown in Figure 72 led to the successful synthesis of macroscopic quantities of a [5]catenane, which was dubbed "Olympiadane" (Fig. 73a).[273] Dynamic ^{1}H NMR spectroscopy (Fig. 73b) attests to the high symmetry of this molecule. At 60 °C the ^{1}H NMR spectrum is remarkably simple showing that the motion of all of the catenated rings with respect to each other is fast on the NMR timescale.

The self-assembly of chiral catenated systems is also possible.[274, 275] Reaction of **85**·2PF_6, **98**, and **BPP34C10** in acetonitrile at room temperature for ten days afforded the bis([2]catenane) **99**·8PF_6 in 13% yield (Fig. 74).[274] This system shows remarkable selectivity during self-assembly for the reaction of *para*-related bromomethyl groups within **98**—the only catenated product isolated

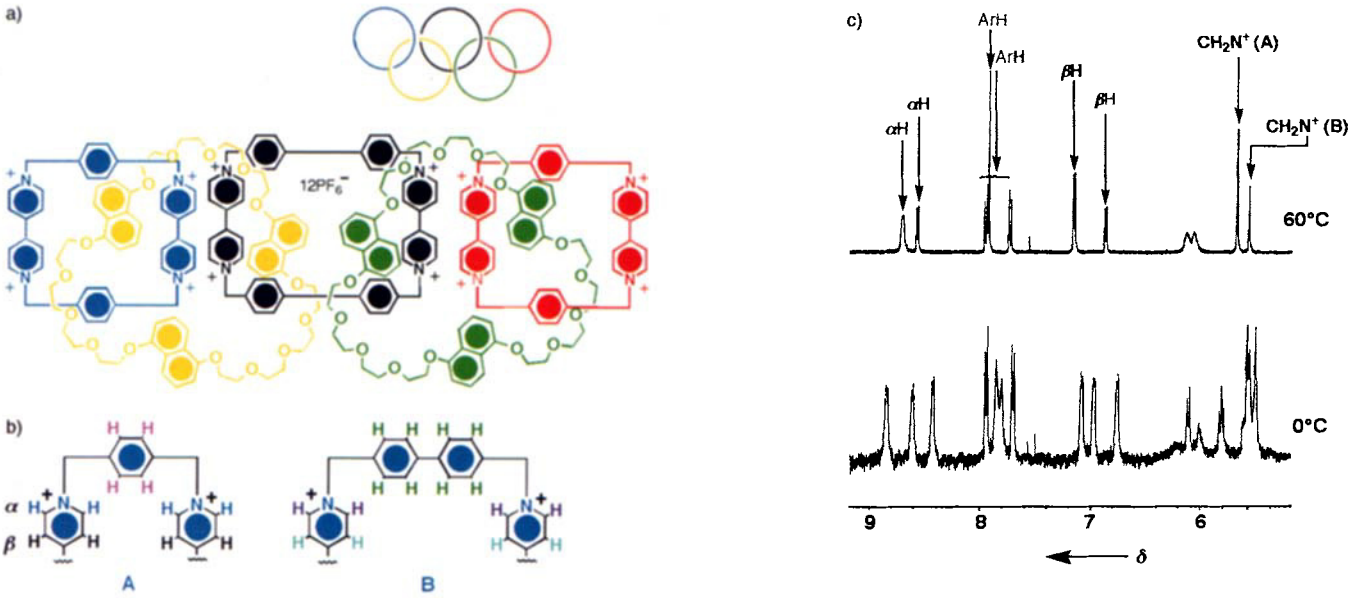

Fig. 73. Olympiadane: a) chemical structure, b) subunits for the assignment, and c) section of the 400 MHz ^{1}H NMR spectra at 0 and 60 °C. The small macrocycles colored blue, black, and red are labeled **A**; the large macrocycles colored yellow and green are labeled **B**.

is **99**·8 PF_6. This molecule has planar chirality, as evidenced by the observation of a highly diagnostic AB system for the four homotopic groups of diastereotopic benzylic methylene protons attached to the central tetrasubstituted benzene core. Interestingly, it is not possible to synthesize **99**·8 PF_6 from the tetracation **100**·4 PF_6 and **86** in the presence of **BPP34C10** (Fig. 74). This highly selective, one-step construction of a chiral bis([2]catenane) from five molecular components demonstrates clearly the power of our synthetic strategy based on self-assembly driven by molecular recognition between complementary π-donors and π-acceptors.

The control of the dynamic processes occurring within the catenated structures has also been investigated. Highly selective translational isomerism can be observed by altering the nature of the π-electron deficient or the π-electron rich component.[276]

Progress has also been made toward the construction of polymeric catenanes with the synthesis and characterization of two bis([2]catenanes) (Fig. 75).[277] In principle a polymeric structure can be achieved by linking π-electron rich components that have been catenated with a dimeric π-electron deficient component (Fig. 75a), or by linking π-electron deficient components that have been catenated with a dimeric π-electron rich component (Fig. 75b). The bis([2]catenanes) **101**·8 PF_6 and **102**·8 PF_6 are protoypes for these two approaches.

The utility of complementary π-donors and π-acceptors is not limited to the construction of catenated structures. [2]Rotaxanes can also be synthesized by self-assembly.[265] In the threading approach (Fig. 76a), the complexed diol is trapped by the addition of silyl ether blocking groups; in the clipping procedure (Fig. 76b), the tetracationic cyclophane is assembled around the dumbbell-shaped template. The successful synthesis of [2]-rotaxanes is not limited to these simple examples containing only one π-donor. Reaction of **85**·2 PF_6 and **86** in the presence of the bis(silyl ether) **103** affords the [2]rotaxane **104**·4 PF_6 in 32% yield (Fig. 77).[278] Since this [2]rotaxane contains two equivalent hydroquinone sites in the threadlike component, the charged ring darts back and forth between the two sites 1800 times per second at room temperature. If the solution is cooled to −50 °C, this shuttling motion ceases and the hydroquinone sites become nonequivalent, as indicated by the ^{1}H NMR spectrum. This type of system has been referred to as a "molecular shuttle". Such molecular shuttles could form the basis for molecular scale devices. Replace-

ment of one of the twohydroquinone rings with another unit of either lesser or greater π-donating ability (colored red and light blue, respectively, in Fig. 78), should, in principle, cause the charged macrocycle to be localized in the ground state. In general, the tetracationic cyclophane will be localized at the site of greatest π-donating ability (a). One can then envisage oxidation of the occupied π-donor to form a radical cation (b), drastically reducing the donating ability of this site to a level below that of the second, poorer π-donor site. Hence, the charged ring would then be expected to move along the thread to the second π-donor site (c). Reversal of the electrochemical cycle should return the system to the starting position, thus effecting an off–on–off switching cycle. Three such systems have been designed and studied.[258, 279, 280] The first system incorporated a hydroquinone ring as the better π-donor and a *p*-xylyl unit as the poorer π-donor (Fig. 79a).[279] Unfortunately, the tetracationic macrocycle partitions itself between the two π-donor sites, with 70% occupation of the hydroquinone site and 30% occupation of the *p*-xylyl site at −30 °C. Such partitioning leads to severe complications for the electrochemical control of the cyclophane position. The second system incorporated within its dumbbell component an indole unit as the better π-donor and a hydroquinone as the poorer π-donor (Fig. 79b).[258] In this case, contrary to our expectations, the tetracationic cyclophane occupied the hydroquinone site preferentially, rendering this molecular shuttle functionally incompetent. In the third-generation system,[280] a tetrathiafulvalene (TTF) unit[281] served as the better π-donor and two equivalent hydroquinone rings as the poorer π-donors within the dumbbell component (Fig. 79c). The position of the tetracationic cyclophane within this system shows an interesting solvent dependency. In CD_3COCD_3 at room temperature the cyclophane is located exclusively on one of the hydroquinone rings. However, in CD_3SOCD_3 the cyclophane partitions itself between the TTF residue and the hydroquinone rings (3:1). The addition of small amounts of D_2O to a CD_3SOCD_3 solution of the [2]rotaxane shifts the equilibrium further in favor of occupation of the

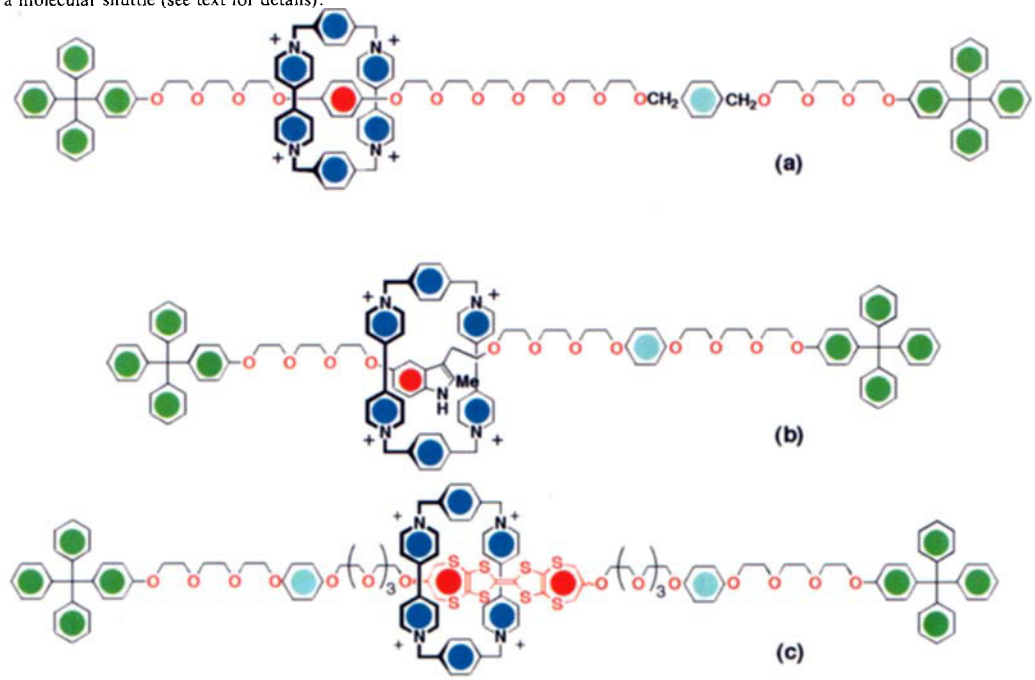

Fig. 79. Three prototypes of controllable molecular shuttles.

TTF residue, thus rendering electrochemical control of this system experimentally feasible.

The synthesis of a chemically and electrochemically switchable molecular shuttle has now been achieved utilizing the same basic design principles.[282] By designating a biphenol residue as the poor π-donor and a benzidine moiety as the good π-donor, control of the position of the tetracationic cyclophane within the molecular shuttle **105**·4PF_6 can be achieved by either chemical or electrochemical means (Fig. 80). In the ground state, the benzidine:biphenol site occupancy is 84:16 in CD_3CN at 229 K. Upon addition of trifluoroacetic acid, the benzidine nitrogen atoms are protonated, and tetracation occupies the biphenol site exclusively. The original site occupancy can be restored by the addition of pyridine to the solution. Electrochemical oxidation of the benzidine moiety, generating the corresponding radical cation, also results in a similar change in site occupancy.

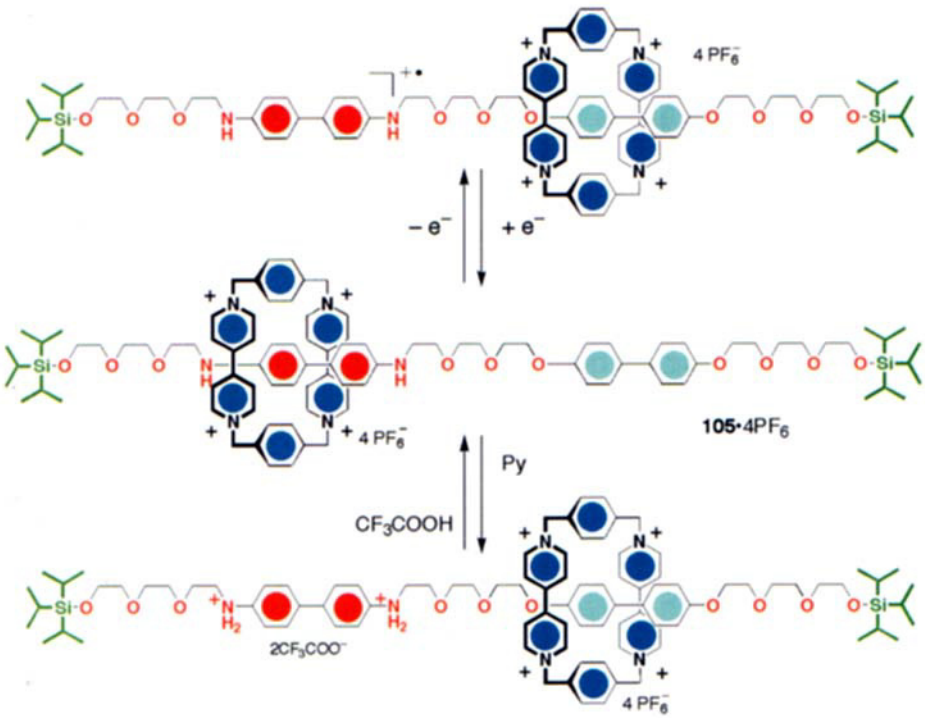

Fig. 80. Electrochemical and chemical control of the translational isomerism in a molecular shuttle based on complementary π-donors and π-acceptors. Py = pyridine.

The redox processes required to drive a molecular shuttle need not be driven electrochemically; photochemical control is also possible. We have demonstrated a simple photochemically driven molecular machine (Fig. 81).[283] When the cyclophane **83**·4Cl and the diol **106** are mixed in deaerated 0.1 M sodium acetate solution, a strong, pseudorotaxane-like complex [**83**·**106**]·4Cl forms, which has a characteristic purple color due to a CT absorption centered on 520 nm. In addition, the fluorescence of the naphthalene ring in **106** is quenched. 9-Anthracenecarboxylic acid, a photosensitizer (**PS**) whose excited state is a powerful reductant, is added and the system is irradiated. Electrons are transferred from **PS** to the [**83**·**106**]·4Cl complex, reducing the $\mathbf{83}^{4+}$ cyclophane to the $\mathbf{83}^{3+}$ radical cation (Fig. 81). To prevent the fast back electron-transfer reaction from $\mathbf{83}^{3+}$ to **PS**, a sacrificial reductant, triethanolamine, is added to reduce **PS** back to its ground state. The interaction between the reduced cyclophane $\mathbf{83}^{3+}$ and **106** is no longer strong enough to hold the complex together, and so dissociation occurs and the fluorescence of the naphthalene ring in **106** reappears. Under the experimental conditions 35% of the pseudorotaxane was unthreaded after 25 minutes of irradiation. The pseudorotaxane can be rethreaded by allowing oxygen to enter the system, whereupon $\mathbf{83}^{3+}$ is promptly reoxidized to $\mathbf{83}^{4+}$ and the [**83**·**106**]·4Cl complex reforms. The ideas demonstrated by this system can be incorporated into molecular shuttles in which the photosensitizer is located in one of the stoppers. A prelude to this type of system is the successful synthesis[284] of a porphyrin-stoppered molecular shuttle.[285]

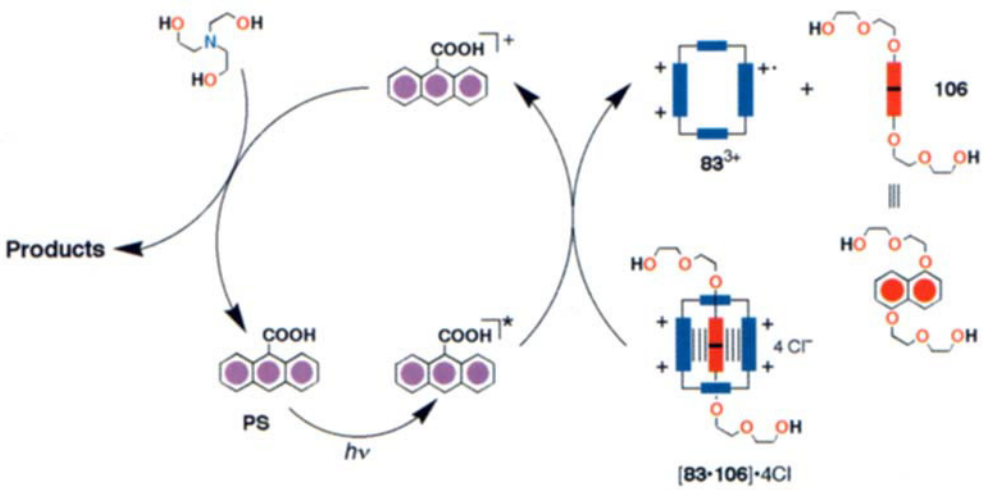

Fig. 81. A simple photochemically driven molecular machine.

The successful control of these supramolecular processes leaves us with three major challenges: firstly, to achieve the control processes in a more facile and selective manner, secondly, to improve the material properties of the compounds we synthesize, and thirdly, to connect our controllable systems to the outside world.

Up to this point we have been concerned with molecular shuttles in which the π-donors have been located in the dumbbell-shaped component and the π-acceptors have been located in the macro-

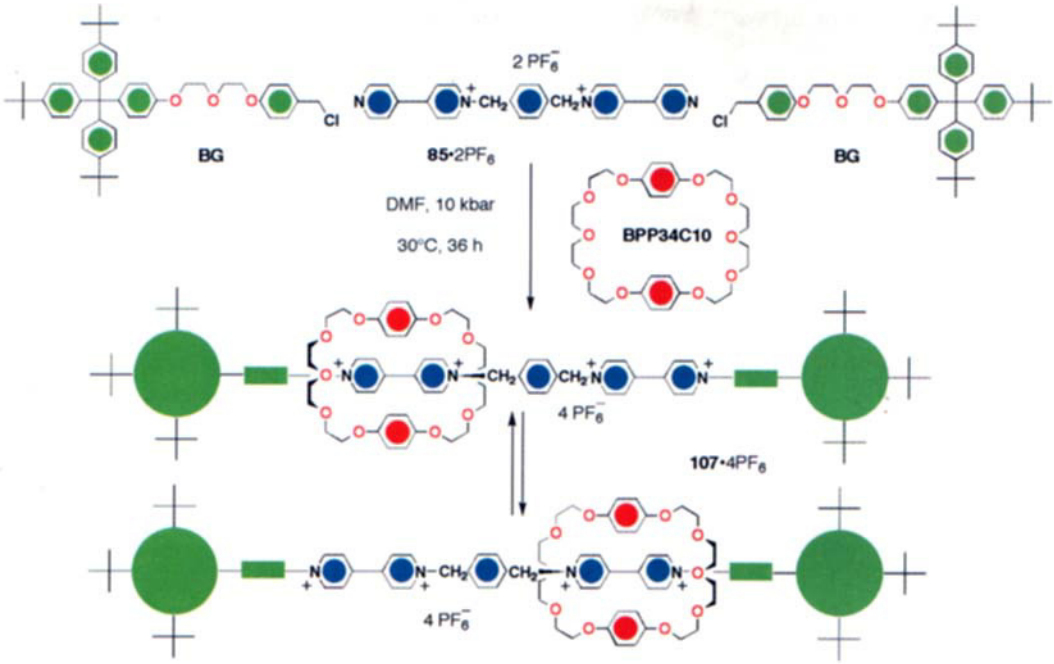

Fig. 82. The self-assembly of a [2]rotaxane, which behaves as a molecular shuttle, directed by complementary π-donors and π-acceptors.

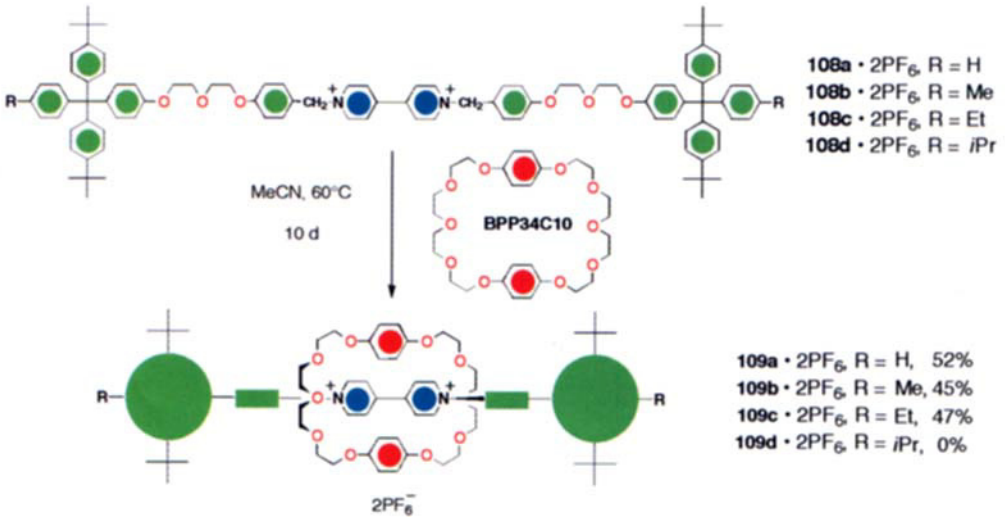

Fig. 84. The syntheses of simple [2]rotaxanes by a slippage route.

cyclic component. There is, of course, no fundamental reason for choosing this design logic; it should be possible to invert the design logic and place the π-donors within the macrocyclic component and the π-acceptors within the dumbbell-shaped component. Thus, reaction of **85**·2PF$_6$ with an appropriately designed blocking reagent **BG** together with **BPP34C10** in stoichiometric amounts affords the molecular shuttle **107**·4PF$_6$ in 23% yield (Fig. 82).[286] Dynamic ^{1}H NMR spectroscopy reveals that the **BPP34C10** macrocycle moves between the two equivalent paraquat sites 340000 times per second at room temperature. The reaction forming **107**·4PF$_6$ seems to show some selectivity since the major product of the reaction is the [2]rotaxane and not the [3]rotaxane in which two **BPP34C10** rings have been incorporated. The observed selectivity depends on the reaction conditions, but is in the region of 10:1 in favor of the [2]rotaxane. Thus, if we wish to obtain a [3]rotaxane incorporating two **BPP34C10** rings, an alternative strategy must be sought. We reasoned that if the large stoppers at the ends of the dumbbell-shaped component were the right size, **BPP34C10** could slip over the stoppers (Fig. 83) at elevated temperatures. The mutual interaction of the π-donors within the crown ether and the π-acceptors within the dumbbell-shaped component then provides a "thermodynamic trap" for the **BPP34C10** macrocycle, raising the activation energy for extrusion of the **BPP34C10**, and so rendering the [2]rotaxanes thus formed stable at room temperature. Hence, heating the dumbbell-shaped compounds **108a**·2PF$_6$–**108d**·2PF$_6$ with an excess of **BPP34C10** in acetonitrile at 60 °C for ten days permitted the isolation of the [2]rotaxanes **109a**·2PF$_6$–**109c**·2PF$_6$ in 45 to 52% yield (Fig. 84).[287] The [2]rotaxane **109d**·2PF$_6$ could not be formed in isolable quantities under these reaction conditions. Examination of the relative rates of slippage revealed that for **108d**·2PF$_6$, slippage was ten times slower than for **109a**·2PF$_6$–**109c**·2PF$_6$. The concept of slippage can be extended to the synthesis of the [3]rotaxanes mentioned above, which are inaccessible by other means. Thus, reac-

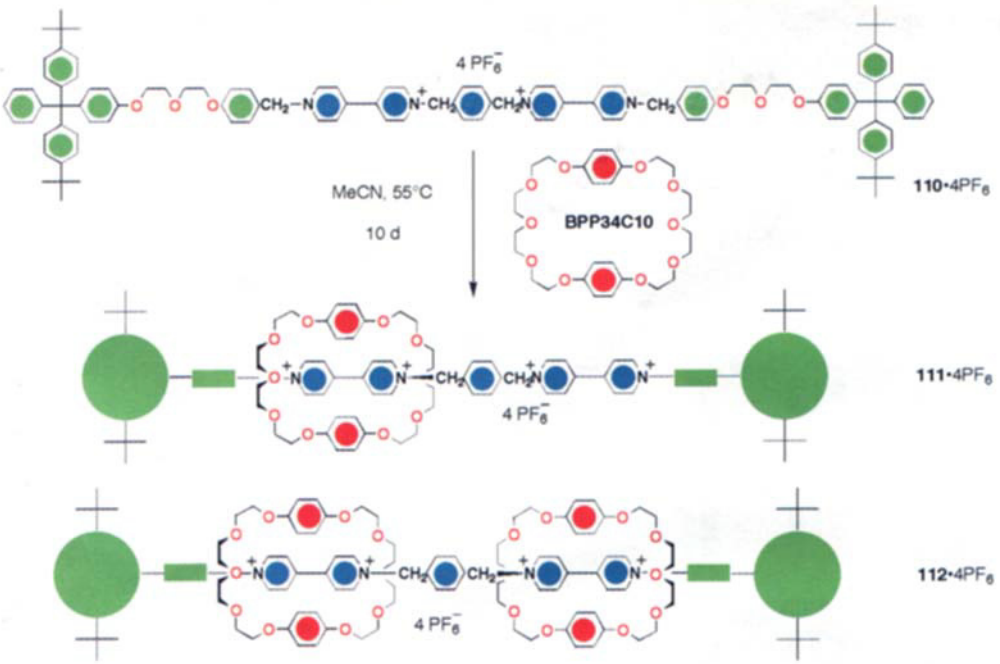

Fig. 85. The syntheses by slippage of [2]- and [3]rotaxanes.

tion of **110**·4PF$_6$ with an threefold excess of **BPP34C10** in acetonitrile at 55 °C for ten days affords both the [2]rotaxane **111**·4PF$_6$ in 31% yield and the [3]rotaxane **112**·4PF$_6$ in 8% yield (Fig. 85).[287] The yields of **111**·4PF$_6$ and **112**·4PF$_6$ could be increased to 20 and 55%, respectively, when a tenfold excess of **BPP34C10** was employed under the same conditions. The ^{1}H NMR spectra of **111**·4PF$_6$ display a temperature dependence commensurate with its properties as a molecular shuttle. In contrast, the ^{1}H NMR spectrum of **112**·4PF$_6$ shows the **BPP34C10** rings to be static and localized on the two paraquat residues as expected. Thus, it can be seen that slippage is an important third method of rotaxane synthesis, which exploits two features fundamental to supramolecular chemistry—size-complementarity (between macrocycle and stoppers) and mutual, noncovalent interactions (as a thermodynamic trap). The slippage approach may be extended to the construction of branched [*n*]rotaxanes (Fig. 86).[288, 289] These systems may be regarded as the first step on the road toward dendritic rotaxanes as well as polyrotaxanes.[289]

For error-checking to be possible in self-assembly processes, the pathways must operate under equilibrium control; in other words, the final assembly is the thermodynamic product for the system. Other methods of selection can operate in systems that utilize intermittent processing. The demonstration of kinetic selection in [2]catenane assembly illustrates this point.[290] In a system in which competing reactions can occur (Fig. 87), the product ratios reflect, not the relative binding efficiencies (*K* or *K'*), for example between the crown ethers and 4,4'-bipyri-

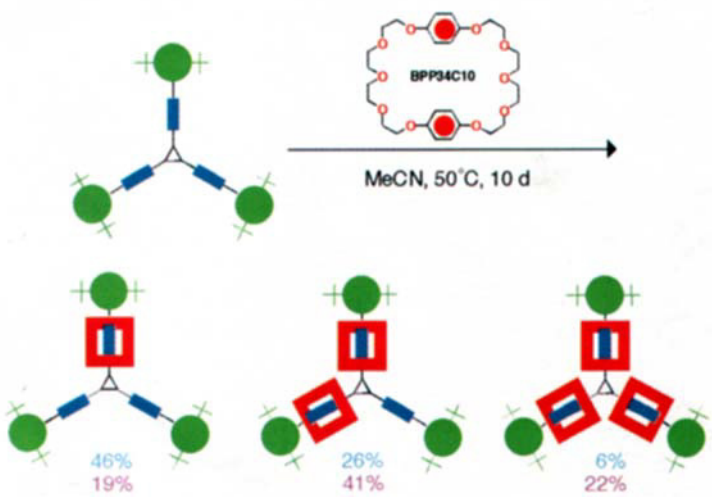

Fig. 86. Towards dendritic polyrotaxanes. The syntheses of branched [2]-, [3]-, and [4]rotaxanes by slippage. The yields in light blue refer to reactions with 2 molar equivalents of **BPP34C10**, those in pink with 15 molar equivalents. In the cartoon representation the formal charges have been omitted for clarity from the blue blocks representing the 4,4'-bipyridinium dications.

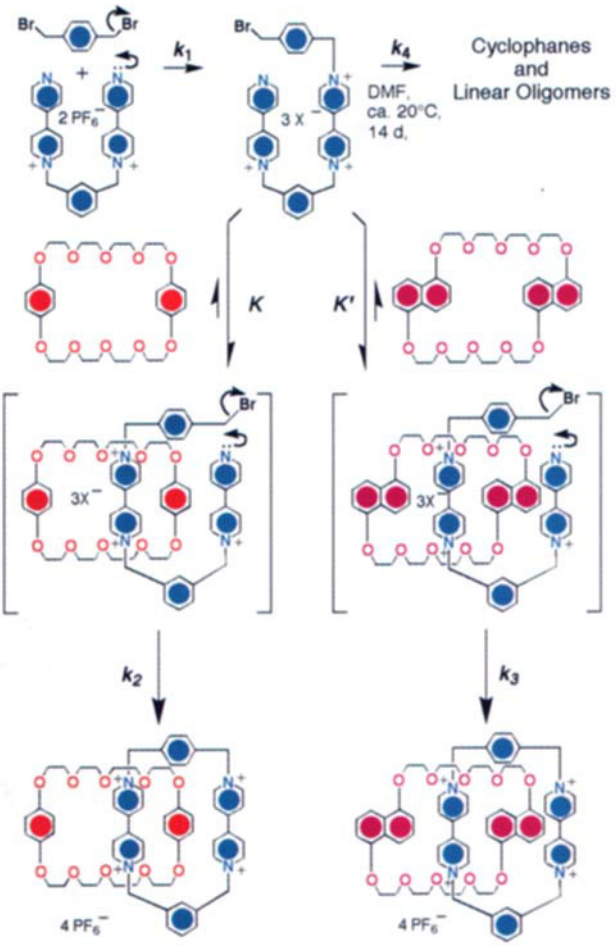

Fig. 87. Kinetic selection in the self-assembly of [2]catenanes. (The products are obained as PF$_6$ salts after ion exchange with NH_4PF_5/H_2O.)

dinium dications, but rather the rate at which the final bond-forming step occurs (k_2 or k_3). In other words, the structure that predominates is selected kinetically, not thermodynamically, during the self-assembly process; Curtin–Hammett type kinetics[291] are operating.

Recently, it has proven possible to combine π-electron deficient and π-electron rich recognition sites within the same molecule to create the self-complementary cyclophane **113**·4PF$_6$ (Fig. 88).[292] The X-ray crystal structure of **113**·4PF$_6$ reveals a

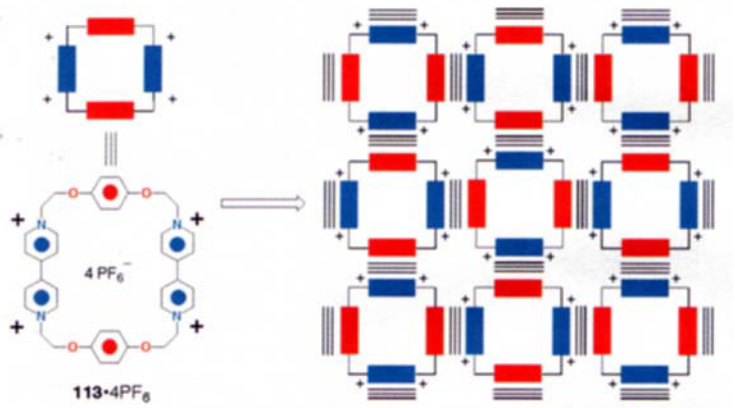

Fig. 88. Schematic representation of the X-ray crystal structure of the molecular mosaic formed by the self-complementary cyclophane **113**·4PF$_6$.

remarkable degree of ordering. The cyclophane itself is almost square and packs in layers in which each cyclophane is rotated 90° with respect to its neighbors. This packing arrangement results in a two-dimensional π-acceptor/π-donor mosaic in the solid state (Fig. 88). Even though adjacent sheets of cyclophanes are separated by counterions and solvent, the cyclophanes are in register and form continuous channels about 1 nm square in the third dimension of the structure. The cyclophane is capable of binding ferrocene,[293] and the crystal structure of this adduct retains the structural features of the free macrocycle. The information present in the self-complementary cyclophane facilitates the efficient self-assembly of a regular three-dimensional supramolecular array in the solid state.

Self-assembling systems based on neutral π-donors and positively charged π-acceptors are particularly easy to design and construct.[294] They give rise to molecular and supramolecular systems with the kinds of physical and chemical properties that make them attractive to work with from the point of view of their forms (for example, depending on the counterion, they are soluble in a wide range of solvents) and their functions (for example, mechanical behavior can be controlled by altering redox properties).

5. The Messages from Self-Assembly

There is no doubt that self-assembly can be utilized to construct a wide diversity of structural types with apparent ease. This situation is a result of the inherent synthetic advantages offered by self-assembly processes.

- Self-assembly can utilize both covalent and *noncovalent* bonding. Hence, noncovalently driven self-assembly can be used to create a primary structure which may be captured and consolidated upon by the subsequent formation of covalent bonds.
- Self-assembly often operates under *equilibrium control*. Thus, a growing structure can reorganize during assembly to maximize complementary surface contacts. The final structure thus represents the thermodynamic minimum for a particular collection of atoms with a given connectivity.
- Self-assembly is, more often than not, a *cooperative* process.
- Self-assembly is *efficient*. A large structure requires a small number of subunit types. Its assembly is *error-checking* and defective recognition features in a subunit are rejected.
- Synthesis is *convergent*. Thus, the synthetic load is significantly lighter.

It follows that, as a synthetic tool, self-assembly has much to offer the chemist.[295] In this review we have met examples in chemical systems of self-assembly that utilize three basic types of interactions. The first type is nonspecific and it operates in the case of the cyclodextrins. This approach has the advantage of being an essentially off-the-shelf model. However, the information content of the system, depending as it does on the hydrophobic effect, is largely nonspecific. The second type is specific and depends upon highly directional interactions such as hydrogen bonding and metal–ligand interactions. These two systems have high information contents as a consequence of the very specific interaction geometries involved. However, the use of such interactions for the construction of large-scale structures requires a high degree of design of the complementary components for the precise matching of hydrogen bonding or the existence of a satisfactory metal–ligand geometry. Self-assembling systems based on interactions between π-donors and π-acceptors fall into an intermediate class. Although they are reasonably specific and hence have a moderate information content and are somewhat directional, they do not require highly regulated design features to function successfully in a self-assembling system.

The establishment of efficient synthetic routes for the construction of nanometer-scale architectures is of paramount importance if the goals of molecular electronics are to be realized. To achieve this aim, the art of chemical synthesis must undergo a profound revolution. Conventional chemical synthesis relies heavily on the use of protecting groups and sophisticated reagents and catalysts to introduce relatively small groups, in terms of molecular mass, in a controlled and stepwise manner. It is difficult to see how this approach can be applied successfully to the construction of mesomolecular systems. Biological systems demonstrate clearly the advantages to be gained by employing what is tantamount to a conceptual leap in synthetic strategy, away from the methods used traditionally in the preparation of small molecular systems, toward construction by self-assembly and self-synthesis. In Nature, processes such as light harvesting, which are apparently very difficult for the scientist to mimic, are accomplished by use of complex systems that are constructed with apparent ease by the processes of self-organization and self-assembly. The research described in this review demonstrates that the chemist, by appropriate choice of noncovalently interacting species, can begin to mimic some of the synthetic strategies so prevalent in Nature. The use of "intelligent substrates", preprogrammed with all of the stereoelec-

tronic information necessary to define molecular recognition within a superstructure, for the assembly of large mesomolecular superstructures such as pseudorotaxanes and double helices or organized molecular assemblies such as catenanes and rotaxanes, demonstrates that self-assembly is a viable synthetic paradigm for the construction of nanometer-scale structures and that there are inherently simple and efficient methods for constructing complex unnatural products without the need for external reagent control or catalysis. At present, the function of the wholly synthetic mesomolecular structures constructed by self-assembly processes is largely unimportant. The development of self-assembly as a viable synthetic paradigm for the efficient construction of nanometer-scale structures and the establishment of the principles governing its use are more important. In any case, the "engineering up" approach to molecular electronic devices requires the construction of not only the devices themselves, but also the infrastructure to serve them—scaffolds to support the devices and a means to connect them to the outside world. Self-assembly offers a synthetic method capable of providing many of these things. It is somewhat ironic that synthetic chemists have developed *wholly unnatural methods* for the synthesis of *natural products*, yet the *wholly unnatural products* required in the quest for molecular electronic devices will be constructed using principles such as self-organization, self-assembly, self-synthesis, and self-replication, which are *natural in origin*.

6. Reflections and Rewards

What has self-assembly to offer to chemists and chemistry in particular, and scientists and science in general? Hopefully, the short commentary[296] that follows will encourage the reader to reflect for a few minutes and then decide that it is actually quite a lot—particularly if the reader is a chemist!

Chemistry can be likened to "language". The atoms are the "letters". The molecules are the "words". Assemblies of molecules make up the "sentences". The sets of assembled molecules or supermolecules are the "paragraphs". The ways in which the molecular assemblies and supramolecular arrays contain and express information are the "chapters". The manner in which this information is conveyed at both a molecular level is the "book". Ultimately, chemistry has to tell a "story". The life sciences are composed of really wonderful chemical "stories". They have been written by nature using "ancient languages".

Chemists are just starting to write their own "stories". They know how to produce the "words". Now, they are learning how to write the "sentences". The "grammar" they will use will be dictated by the nature of the noncovalent bond. The "modern languages" are about to evolve. Materials science and the life sciences will be a beneficiaries. As a discipline, chemistry will be enriched.

There are always many people and organizations it is a pleasure to thank. In particular, we would like to express our gratitude to the University of Birmingham for providing us with contemporary surroundings and a stimulating environment in which to do science. We are indebted to the many funding bodies including the Research Councils in the United Kingdom, European government agencies, the European Community, charities and industrial companies, who have provided the financial support necessary to push our science forward during recent years. None of the research described in Section 4.4 would have been achieved without the contributions of the many talented postgraduate and postdoctoral co-workers whose names appear in the references. Collaboration is right at the heart of scientific discovery. We have been fortunate to have enjoyed many collaborations over the years, but those with Professors Vincenzo Balzani (Bologna), Angel Kaifer (Miami), Helmut Ringsdorf (Mainz), and David Williams (London) have been particularly rewarding. Finally, we would like to thank Professor François Diederich for his critique of an earlier incarnation of the text of this review.

[52] The total synthesis of palytoxin spanned almost 10 years and involved more than 100 researchers. This level of effort was required to produce a compound with a molecular mass of 2680 Da and dimensions an order of magnitude smaller than the 10–100 nm dimensions usually regarded as nanoscale. Clearly, extrapolation of this type of synthetic strategy to a structure with a molecular mass of ca. 10000 Da would be prohibitive both in terms of time and manpower.

[59] Starburst dendrimers are a novel class of highly branched monodisperse polymers with diverse three-dimensional structures, which can be synthesized, divergently or convergently, from multifunctional building blocks by repetitive, near-quantitative reactions. For general reviews of this topic, see: D. A. Tomalia, A. M. Naylor, W. A. Goddard III, *Angew. Chem.* **1990**, *102*, 119; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 138; H.-B. Mekelburger, W. Jaworek, F. Vögtle, *ibid.* **1992**, *104*, 1609 and **1992**, *31*, 1571; G. R. Newkome, C. N. Moorefield, G. R. Barker, *Aldrichimica Acta* **1992**, *25*, 31; D. A. Tomalia, H. D. Hurst, *Top. Curr. Chem.* **1993**, *165*, 193; D. A. Tomalia, *Aldrichimica Acta* **1993**, *26*, 91; J. M. J. Fréchet, *Science* **1994**, *263*, 1710; J. Issberner, R. Moors, F. Vögtle, *Angew. Chem.* **1994**, *106*, 2507; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 2413. For examples of the convergent approach to dendritic macromolecules, see: C. J. Hawker, J. M. J. Fréchet, *J. Am. Chem. Soc.* **1990**, *112*, 7638; K. L. Wooley, C. J. Hawker, J. M. J. Fréchet, F. Wudl, G. Srdanov, S. Shi, C. Li, M. Kao, *ibid.* **1993**, *115*, 9836; K. L. Wooley, C. J. Hawker, J. M. J. Fréchet, *Angew. Chem.* **1994**, *104*, 123; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 82. The growing importance of multiplex and combinatorial methods of synthesis for the rapid generation of libraries of structurally diverse organic compounds should be noted. [97] The name "rotaxane" is derived from the Latin "rota" meaning wheel and "axis" meaning axle [94]. The addition of the prefix "pseudo" indicates that the wheels are free to dissociate from the axle as in a more conventional type of complex. In chemical terms, this means that the components of the pseudorotaxane are held together only be their mutual noncovalent interaction and not (also) by a mechanical feature.

Other groups have prepared similar pseudorotaxane-type structures: J. T. Rademacher, A. W. Czarnik, *J. Am. Chem. Soc.* **1993**, *115*, 3018; S. Matile, T. Hansen, A. Stocker, W.-D. Waggon, *Helv. Chim. Acta* **1994**, *77*, 1087.

[108] The name "catenane" is derived from the Latin word "catena" meaning chain [94]. In chemical terms, such molecules can be viewed as being composed of two or more macrocycles that are connected mechanically but not by any covalent chemical bond. The prefix indicates the number of interlocked components. Thus, a [2]catenane contains two interlocked rings.

[109] For early work on the synthesis of catenanes, see: H. L. Frisch, E. Wasserman, *J. Am. Chem. Soc.* **1961**, *83*, 3789, and references therein. For early work on the configuration and topology of catenanes, see: S. J. Tauber, *J. Res. Natl. Bur. Stand. Sect. A* **1963**, *67*, 591. For an interesting historical footnote, see: D. M. Walba, *New J. Chem.* **1993**, *17*, 618; N. van Gulick, *ibid.* **1993**, *17*, 619.

[110] For reviews and discussions concerning topologically interesting molecules, see: D. M. Walba, *Tetrahedron* **1985**, *41*, 3161; C. O. Dietrich-Buchecker, J.-P. Sauvage, *Bioorg. Chem. Front.* **1991**, *2*, 195; C. Weber, *New J. Chem.* **1993**, *17*, 627; D. M. Walba, T. C. Homan, R. M. Richards, R. C. Haltiwanger, *ibid.* **1993**, *17*, 661; D. B. Amabilino, I. W. Parsons, J. F. Stoddart, *Trends Polym. Sci.* **1994**, *2*, 146; D. B. Amabilino, J. F. Stoddart, *Chem. Rev.* **1995**, *95*, 2725.

[111] Interestingly, catenated structures are relatively common in DNA: B. Hudson, J. Vinograd, *Nature* **1967**, *216*, 647; M. I. Baldi, P. Benedetti, E. Mattoccia, G. P. Tocchini-Valentini, *Cell* **1980**, *20*, 461; S. A. Wasserman, N. R. Cozzarelli, *Proc. Natl. Acad. Sci. USA* **1985**, *82*, 1079. E. Shekhtman, S. A. Wasserman, N. R. Cozarelli, M. J. Solomon, *New J. Chem.* **1993**, *17*, 757.

[118] The poor scattering of X-rays by the hydrogen atom gives rise to large errors (0.05–0.1 Å) for N–H and O–H distances determined by this method. Although, in principle, neutron diffraction can give distances with an accuracy one order of magnitude better, its expense is prohibitive. Instead, X-ray diffraction methods employ a normalization procedure, which fixes the D–H distance at a standard value.

[123] The earliest examples of crystal engineering employing two building blocks that recognize each other, both in a ditopic manner, by complementary hydrogen bonding were found in research carried out in the 1970s and 1980s on the second-sphere coordination of transition metal ammine and aqua complexes by [18]crown-6 and its derivatives. For a discussion of the X-ray crystal structures of $([Cu(NH_3)_4(H_2O)([18]crown\text{-}6)]^{2+})_n(PF_6^-)_{2n}$ and $([Pt(H_2NCH_2CH_2NH_2)(H_2O)([18]crown\text{-}6)]^{2+})_n(PF_6^-)_{2n}$, which form hydrogen bonded chain copolymers in which the transition metal complex and the crown ether alternate to form tubular arrays, see: H. M. Colquhoun, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Chem. Commun.* **1981**, 847, 849; H. M. Colquhoun, D. F. Lewis, J. F. Stoddart, D. J. Williams, *J. Chem. Soc. Dalton Trans.* **1983**, 607. The X-ray crystal structure of $([PhCOCH_2SMe_2([18]crown\text{-}6)]^+)_n(PF_6^-)_n$ provides a rare example of a hydrogen-bonded tubular array in which an *organic cation* replaces the transition metal in a 1:1 polymeric adduct: B. L. Allwood, J. Crosby, D. A. Pears, J. F. Stoddart, D. J. Williams, *Angew. Chem.* **1984**, *96*, 987; *Angew. Chem. Int. Ed. Engl.* **1984**, *23*, 977. For references to other examples, particularly the hydrogen bondined copolymers formed between aqua complexes and [18]crown-6, see ref. [92].

[234] The synthesis of molecular with a rubber glove toplogy has been reported recently, which relied on a combination of Cu^{I}–phenanthroline chemistry and the hook-and-ladder approach: D. M. Walba, Q. Y. Zheng, K. Schilling, *J. Am. Chem. Soc.* **1992**, *114*, 6259. Knotted DNA has also been reported: S. T. Mullins, N. K. Annan, P. R. Cook, G. Lowe, *Biochemistry* **1992**, *31*, 842; N. C. Seeman, J. Chen, S. M. Du, J. E. Mueller, Y. Zhang, T. J. Fu, Y. Wang, H. Wang, S. Zhang, *New J. Chem.* **1993**, *17*, 739.

[235] Molecular donor–acceptor complexes were first noted in 1949 by Benesi and Hildebrand (H. A. Benesi, J. H. Hildebrand, *J. Am. Chem. Soc.* **1949**, *71*, 2703), when they observed an additional band in the electronic spectrum of a mixture of iodine and benzene which could not be attributed to either of the separate components of the system. Subsequently, such complexes were much studied by Mulliken, who proposed a resonance theory description of such complexes (R. S. Mulliken, *ibid.* **1952**, *74*, 811). In Mulliken's model, the complex is viewed as being a resonance between a no-bond structure $\Psi(D\cdots A)$ and a charge transfer state $\Psi(D^{+}\cdots A^{-})$. Later, Dewar proposed a molecular orbital treatment of such complexes in which the mixing of the HOMO of the donor and the LUMO of the acceptor can be treated by perturbation theory (M. J. S. Dewar, A. R. Lepley, *ibid.* **1961**, *83*, 4560).

[236] For reviews, see: R. S. Mulliken, W. B. Person, *Annu. Rev. Phys. Chem.* **1962**, *8*, 107; R. Foster, *Organic Charge-Transfer Complexes*, Academic Press, New York, **1969**; *J. Phys. Chem.* **1980**, *84*, 2135.

[237] See for example: F. Cozzi, M. Cinquini, R. Annuziata, J. S. Siegel, *J. Am. Chem. Soc.* **1993**, *115*, 5330.

[241] An SCF-MO calculation of the charge distribution in the Paraquat dication using the AM1 method reveals that significant positive charge is located at the positions α and γ to the nitrogen atoms, and especially on the hydrogen atoms at the α position. Significant positive charge is also located on the hydrogen atoms of the methyl groups: M. J. S. Dewar, E. G. Zoebisch, E. F. Healy, J. J. P. Stewart, *J. Am. Chem. Soc.* **1985**, *107*, 3902.

[247] The situation in this complex is somewhat complicated by the fact that the iodide counterion also forms a donor–acceptor complex with the Paraquat dication and a continuous hydrogen bonded chain with the phenolic OH groups of the hydroquinone. The fact that the hydroquinone molecule does not position itself to achieve maximum overlap with the Paraquat π-system probably reflects this fact.

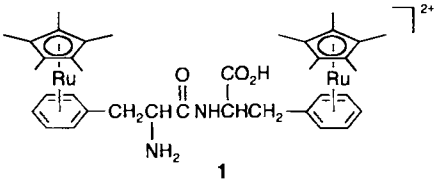
Application of π-Arene–Ruthenium Complexes in Peptide Labeling and Peptide Synthesis

Roland Krämer*

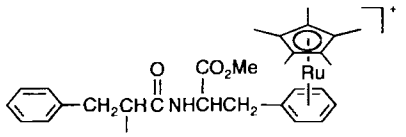
Organotransition metal complexes with biologically relevant ligands have attracted considerable attention in recent years. The term "bioorganometallic chemistry" has been coined to describe the research in this area.[1, 2] The combination of naturally occurring ligands (bioligands) with organometallic compounds with characteristic physical and chemical properties opens interesting perspectives for biochemical and synthetic applications. Examples include the developement of a carbonyl-metalloimmunoassay,[1, 3] the investigation of receptor and enzyme active sites using organometallic-labeled substrates,[1] and the application of organotransition metal complexes with amino acid ligands as enantioselective catalysts.[4] This highlight focuses on some "bioorganometallic curiosities" from the field of [Ru(π-arene)] peptide complexes. In the examples considered herein two characteristics of the π-arene–Ru^{II} interaction play a fundamental role: the remarkable thermal stability of π-arene–Ru bond and the Ru-induced activation of arenes that carry good leaving groups for nucleophilic substitution (S_NAr) reactions.

The facile preparation of [CpRu] sandwich complexes (Cp = η^5-C_5H_5) with aromatic amino acids by reaction of N/O-protected phenylalanine (Phe), tryptophane (Trp), and tyrosine (Tyr) with $[CpRu(MeCN)_3](PF_6)$ was first reported by Moriarty and co-workers.[5] Recently Sheldrick et al. have discovered that this methodology is also applicable to unprotected amino acids[6] and peptides.[7] The [Cp*Ru^{II}] dipeptide complex **1** (Cp* = η^5-C_5Me_5) is obtained readily by reaction of Phe–Phe with two equivalents of $[Cp^*Ru(MeCN)_3](CF_3SO_3)$. The analogous reaction with Trp–Trp affords bis(sandwich) complexes with regioselective η^6-coordination of the six-membered indole ring.

An alternative N/O chelate coordination, which is observed in the reaction of [Cp*Ru] with phenylalanine at room temperature,[6] can be suppressed by applying elevated reaction temperatures. The investigations have been extended to the use of [(η^6-arene)Ru^{II}] fragments as organometallic markers.[8] Sheldrick et al. have also shown that [Cp*Ru]-labeled aromatic amino acids can be incorporated into peptides by using the classic carbodiimide coupling reaction.[7] Thus, reaction of



1

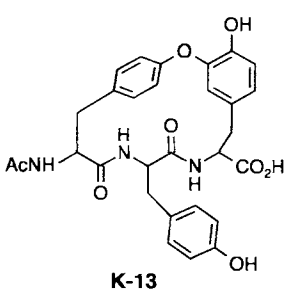


2

[Cp*Ru]-labeled phenylalanine methyl ester with N-protected phenylalanine affords the dipeptide derivative **2** (92%) with specific [Cp*Ru] labeling of the C-terminal Phe residue. The remarkable stability of the η^6-arene–Ru bond is clearly demonstrated by isolation of the intact sandwich complex after removal of the N-terminal protecting group with glacial acetic acid.

The above-mentioned straightforward methods for organometallic labeling of peptides—either by direct attachment of [Cp*Ru] to aromatic side chains or by incorporation of a [Cp*Ru]-substituted amino acid by peptide synthesis—are relevant to biochemical applications. Ruthenocene derivatives that display selective enrichment behavior in tissues are of considerable interest as radiopharmaceuticals (^{97}Ru, ^{103}Ru, ^{106}Ru). For example, radiolabeled ruthenocenylalanine has been applied as a pancreatic imaging agent.[9] In addition, [Cp*Ru] derivatives of bioactive peptides could open new analytical perspectives for the investigation of the substrate binding sites of receptors. [Cp*Ru]-labeled estradiol has already been employed succesfully to gain insights into hormone receptor–substrate interactions.[1]

The next example refers to the utilization of π-arene–Ru^{II} chemistry to the synthesis of important peptide-derived antibiotics. Cyclic biphenyl ethers are structural components of many biologically active peptide derivatives such as the vancomycins and the protease inhibitor K-13. A challenging problem in the synthesis of these compounds is the sensitivity of the amino acid functionality, which is unable to with-



K-13

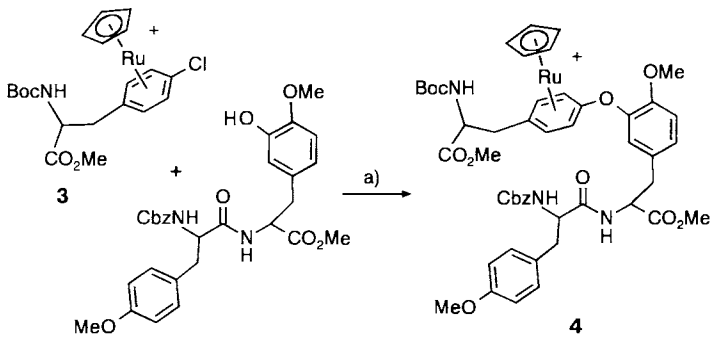
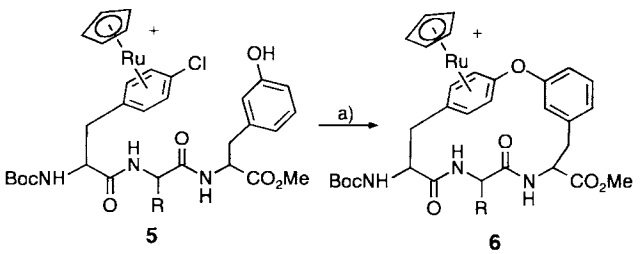
stand the harsh reaction conditions usually required for construction of the diaryl ether linkage. Pearson et al. have reported a formal total synthesis of K-13 in which the diaryl ether coupling is effected under very mild conditions with participation of a ruthenium-activated chloroarene.[10] Nucleophilic substitution (S_NAr)[11] of the chloro substituents in the [CpRu^{II}] derivative of protected *p*-chlorophenylalanine (**3**) by the phenolate function of an isotyrosine dipeptide affords **4** without racemization at the α-C atoms of the amino acid building blocks (Scheme 1).



Scheme 1. Boc = *tert*-butoxycarbonyl. Cbz = carbobenzoxy. a) Sodium 2,6-di-*tert*-butylphenoxide.

The [CpRu] group can be readily photochemically removed; $[CpRu(CH_3CN)_3]PF_6$, which was used for the preparation of **3**, is recovered in 85% yield. Synthesis of the K-13 analogue is completed by deprotection and cyclization of the linear tripeptide **4** by intramolecular coupling of a peptide bond. The low yields in the final cyclization step are a weak point of the reaction sequence.

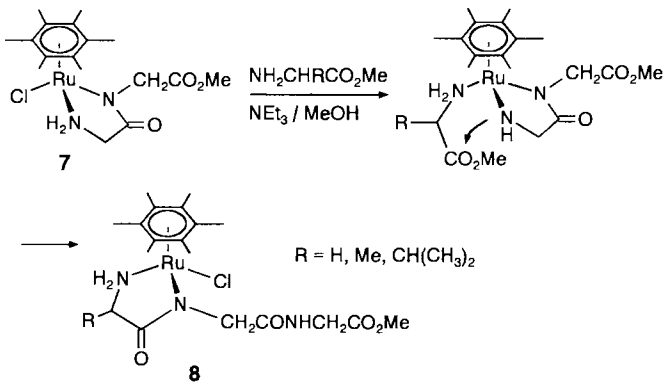
Recently Rich et al. have overcome this problem by an elegant variation of the synthetic route.[12] By coupling of [CpRu(*N*-Boc-*p*-Cl-Phe)]$^+$ with an isotyrosine dipeptide, the tripeptide backbone was constructed *prior* to formation of the aryl ether bond. The linear tripeptide complex **5** is converted to the macrocyclic product **6** by *intramolecular* nucleophilic substitution (Scheme 2). After photolytic removal of the [CpRu] fragment, the 17-membered macrocyclic ring system was isolated in 60% yield!



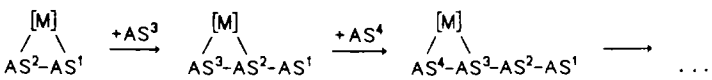
Scheme 2. R = *sec*-butyl, benzyl, 4-(*tert*-butoxy)benzyl. a) Sodium 2,6-di-*tert*-butylphenoxide.

A possible explanation for the surprisingly high yield in the cyclization reaction is an intramolecular preorganization of the electron-poor π-complexed ring and of the electron-rich phenol ring by π-π interactions, which favors formation of the macrocycle over polymerization. The versatility of the approach developed by Rich et al. should facilitate the creation of libraries of cyclic biphenyl ether peptides. Numerous analogues of K-13 and of related antibiotics should be available by varying the N-terminal substituent, the central amino acid, and the C-terminal substituent in a combinatorial fashion during the synthesis.

The final example considered here is a remarkable peptide synthesis in which a π-arene-coordinated ruthenium(II) center directly promotes amide bond formation. The chloro-bridged complex $[\{(\eta^6\text{-hexamethylbenzene})Ru(\mu\text{-Cl})(Cl)\}_2]$ reacts smoothly with peptide esters by formation of *N,N*-chelate complexes.[13] With aromatic amino acids no competitive formation of sandwich complexes is observed. In the glycylglycine methyl ester compound $[(\eta^6\text{-hexamethylbenzene})Ru(GlyGlyOMe)Cl]$ **7**, the dipeptide is coordinated by NH_2 and a deprotonated amide nitrogen atom. On addition of amino acid esters in the presence of base, **7** undergoes a remarkable peptide bond formation reaction that was discovered earlier with related [Cp*M] complexes (M = Rh^{III}, Ir^{III}).[14] The new amino acid is incorporated at the amino terminus of the coordinated peptide chain, and the tripeptide ester complexes **8** are obtained in 80–90% yield.[15] A plausible mechanism involves nucleophilic attack of a metal-bound aminoanion at the carbonyl group of the N-coordinated amino acid ester. The pseudooctahedral $[(C_6Me_6)Ru]$ fragment with three available, facially orientated coordination sites functions as a template.



It has been demonstrated that even longer peptides can be constructed in this fashion (Scheme 3). The tetrapeptide Ser-GlyGlyGly was prepared sequence specifically in a one-pot reaction by successive addition of GlyOMe and SerOMe to a diglycine complex.[14] In some respects this reaction is reminiscent of the action of a ribosome in biological systems, in which peptide bonds are formed by nucleophilic attack of NH_2 at the carboxy group which is esterified with the ribose moiety of a tRNA molecule. Whereas biological peptide synthesis proceeds



Scheme 3. AS: amino acid building block. AS^1: C-terminal amino acid. [M]: organometallic complex fragment.

by incorporation of the new amino acid at the C-terminus of the peptide chain, the peptide synthesis by the metal-based "artificial ribosome" occurs in the reverse direction.

From Oxides to Nitrides: Recent Developments in the Structural Chemistry of Alkali/Alkaline Earth Metal Sub-Compounds

Caroline Röhr*

Almost a hundred years after the discovery of the structurally remarkable rubidium and cesium suboxides and over twenty years since the elucidation of their structures and their thermoanalytical characterization by Simon,[1] this structural chemistry has been extended to the corresponding ternary sodium–barium nitrides in the last few years. The compound $Na_{14}Ba_{14}CaN_6$[2] recently described by Simon and Steinbrenner forms a link between the new subnitrides and the classic suboxides. With a degree of face-sharing of coordination octahedra about O/N never achieved before, the quaternary phase is more than just a new final member in the series of "inverse clusters" of the sub-compounds; it is an important extension of the structural chemistry of this class of compounds, since in this case cations are also present in the saltlike interior of a cluster.

The chemical bonding and the characteristic building units of the structures are similar in the Rb/Cs suboxides and the Na–Ba subnitrides. A remarkable and at the same time special feature of these compounds are clusters comprising face-shared, X-centered octahedra (X = O,N) of the electropositive partners (A) rubidium and cesium, and barium, respectively. The bonds within the octahedra are ionic, whereas between the clusters coordination numbers and interatomic distances occur such as those in metals. Rubidium and cesium as well as barium form the "cluster skin" and act as a link between the ionic and the metallic region. The metallic matrix and thus the composition of the phases can be varied over a wide range in all systems. That compounds with this kind of remarkable bonding also show unusual physical properties (color, low electronic work function, etc.) is as unsurprising as the fact that many of the clusters were detected, for example, also in molten metals.

A special position among the subnitrides is held by the alkaline earth metal nitrides A_2N (A = Ca, Sr, Ba), which crystallize in the anti-$CdCl_2$ type, and thus are the only sub-compounds to exhibit N-centered alkaline earth metal octahedra that are connected not through faces but through six of the twelve edges of the octahedron. All the other suboxides and subnitrides can be arranged according to the increasing linkage of the A octahedra (A = Rb, Cs, Ba, Ca) in the inverse cluster around the anions X ($X = O^{2-}, N^{3-}$) and to the corresponding decreasing ratio A/X (A = number of corners of the octahedra, X = number of centers of octahedra; Table 1, Fig. 1). The series begins at the maximum ratio $A/X = 6$ for discrete $[NBa_6]$ octahedra in $Na_{16}Ba_6N$,[3] which are arranged body-centered cubic and are

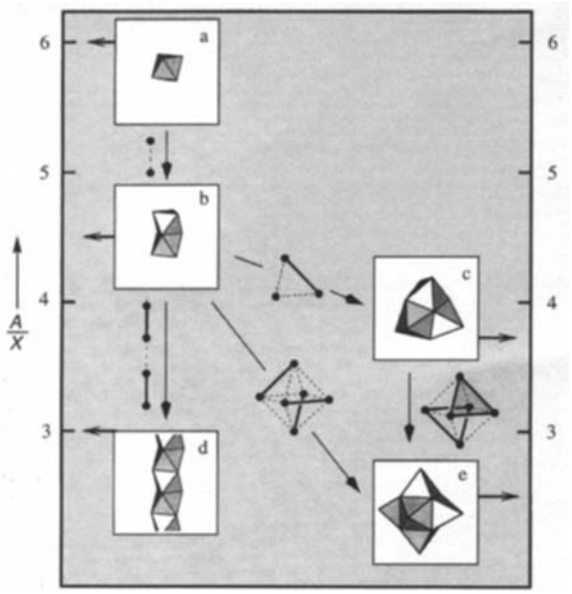

Fig. 1. The clusters in the crystal structures of the suboxides and subnitrides $Na_{16}Ba_6N$ (a), Rb_9O_2 (b), $Cs_{11}O_3$ (c), Cs_3O, $NaBa_3N$, and Na_5Ba_3N (d) as well as $Na_{14}Ba_{14}CaN_6$ (e). *A*: number of corners of octahedra, *X*: number of centers of octahedra.

separated from one another by a large number of sodium atoms. All Rb suboxides show clusters $[X_2A_9]$ comprising two face-sharing octahedra, which in Rb_9O_2[4] are discrete and in Rb_6O[5] are present together with "metallic" rubidium. Units comprising three octahedra condensed through three common faces with a common edge are prevalent in the Cs oxides. These clusters $[X_3A_{11}]$ form the saltlike part in the crystals of $Cs_{11}O_3$,[7] Cs_4O,[8] Cs_7O,[6] (in the latter two again together with additional Cs that does not participate in the construction of the octahedra). The linkage of octahedra each through two opposite faces to give infinite strands occurs both in Cs_3O[10] (which has not been fully characterized by X-ray crystallography) and in $NaBa_3N$[9] and Na_5Ba_3N.[11] The Na atoms in these two compounds are located between the strands of octahedra. With the synthesis of the quaternary nitride $Na_{14}Ba_{14}CaN_6$ Simon and Steinbrenner have achieved the preparation of a "heterocluster" containing both barium (at the cluster periphery) and calcium (in the center of the cluster) for the first time:[2] six octahedrally arranged octahedra $[NBaBa_{4/3}Ca_{1/6}]$ are face-shared in such a way that the calcium ion forms the common corner of all six octahedra and thus in total eight common edges between three octahedra as well as 24 common faces are present per cluster—a cubic close packing with (distorted) octahedra! Alternatively and directly related to the Rb/Cs suboxides, the $[Ba_{14}CaN_6]$ cluster can also be derived from three $[X_2A_9]$ or from two $[X_3A_{11}]$ building units, which clearly shows that this cluster is a new, (provisionally) final member in the series of sub-clusters. As in the other Na–Ba subnitrides, in $Na_{14}Ba_{14}CaN_6$ the clusters, which are arranged face-centered cubic in the crystal, are separated from one another by Na atoms (Fig. 2). If one considers the large variability of the contents A and the crystal structures, for example, of Cs suboxides containing the same cluster, and the possibility of incorporating different amounts of Na between the rigid one-dimensional infinite strands of octahedra in $NaBa_3N$ and Na_5Ba_3N, it appears

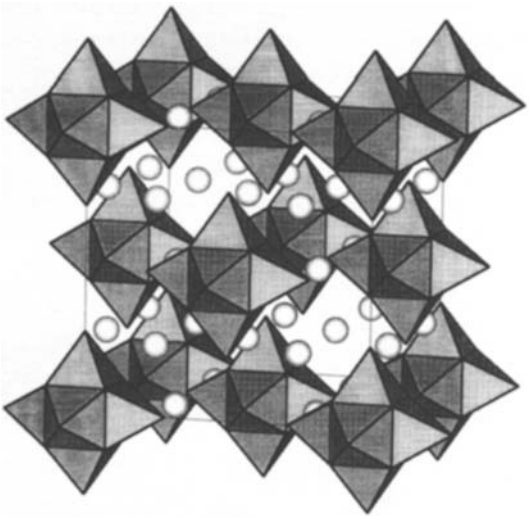

Fig. 2. Section of the crystal structure of the subnitride $Na_{14}Ba_{14}CaN_6$ (octahedra: $[NCaBa_5]$, spheres: Na), which shows the cubic face-centered arrangement of the clusters $[Ba_{14}CaN_6]$.

correct to assume the existence of further stoichiometric phases of the composition $Na_nBa_{14}CaN_6$ ($n = 17, 21, 22$).

A common feature of the suboxides and subnitrides are regions with ionic partial structures in a metal matrix, in which the atoms of the "cluster skin" (for the nitrides to date only Ba and for the oxides only Cs and Rb) play a "mediating role", corresponding approximately to oxidation states between Ba^0 and Ba^{2+}. The bonding becomes clear based on the A–A distances: The edges of the octahedra within the cluster are short and the A–A distances resemble those in electrovalent[*] binary oxides and nitrides; the A–A distances between the clusters are large (interatomic distances as in the metals), and the lengths of the edges of the $[XA_6]$ octahedra on the cluster skin vary with the number of octahedra in which the respective edge participates.

That despite the severe face-sharing of octahedra the N–N distances in $Na_{14}Ba_{14}CaN_6$ are even a little longer than those in the ternary Na–Ba subnitrides is attributed to the displacement of the X atoms from the centers of the A octahedra (away from the common faces of the octahedra towards the cluster periphery) known for suboxide clusters. Consequently, the N–Ca distances are large and the N–Ba distances are small in comparison to the typical distances observed for ionic bonds.

The distribution of the electropositive bonding partners in the crystal structure is interesting, particularly with regard to the quaternary compound. All the results obtained so far indicate that only the large "soft" Ba can form the cluster skin. Although Na and Ca have similar ionic and metallic radii as well as ionization energies, the distribution of elements determined follows the formation of compounds in the binary phases: Ca nitrides are known, Na_3N is unknown. However, binary intermetallic phases are known in the Na–Ba system, but not for Ca–Ba. In the $[Ba_{14}CaN_6]$ cluster Ca occupies the position (the common corner of six coordination octahedra) with the highest positive charge. A similar situation occurs in the mixed Rb–Cs suboxide $Rb_6Cs_5O_3$,[12] in whose structure the lighter homologue prefer-

[*] Compounds are referred to as electrovalent when the valence electrons, in accord with common assumptions, can be attributed unequivocally to specific atoms.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3511-1200 $ 15.00+.25/0

ably substitutes the Cs atoms of the common edge of all three $[OCs_6]$ octahedra of the $[Os_3Cs_{11}]$ cluster.

The nature of the structural units formed in each of the subcompounds is evidently primarily determined by types of atoms that make up the cluster: $[O_3Cs_{11}]$ predominates in the Cs oxides, dimeric $[X_2A_9]$ units are known only in the Rb–O system, and infinite chains of octahedra $^1_\infty[NBa_{6/2}]$ are the characteristic building unit in the Na–Ba nitrides. $Na_{14}Ba_{14}CaN_6$ represents a remarkable subnitride of the Na-Ca-Ba-N system: It contains a new cluster, in which the calcium ion plays an important dual role with respect to the stability both for geometrical reasons (distortion of the octahedra for the extreme face-sharing) and for electronic reasons (first example of a "real" cation (Ca^{2+}) in the saltlike interior of a sub-cluster).

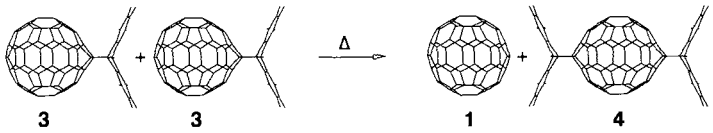
A Topochemically Controlled, Regiospecific Fullerene Bisfunctionalization**

Bernhard Kräutler,* Thomas Müller, Joseph Maynollo, Karl Gruber, Christoph Kratky, Philippe Ochsenbein, Dieter Schwarzenbach, and Hans-Beat Bürgi

Fullerenes, molecular allotropes of carbon,[1, 2] have opened new areas of research at the interface of molecular and solid-state sciences.[3] Exohedral derivatization in solution[5, 6] has recently led to some highly functionalized fullerenes[7–9] in impressively regioselective addition reactions. Crystal engineering[10] and solid-state chemistry could provide an alternative, novel synthetic entry to specific organo-substituted fullerenes. Here we report a highly uniform and topochemically[11, 12] controlled fullerene refunctionalization, which is based on a thermal, intermolecular anthracene-transfer reaction, unprecedented in the solid state. In addition we describe the X-ray structure analysis of the crystalline cycloadduct **2** of C_{60} (**1**) and 1,3-cyclohexadiene.[13] The observed molecular packing in single crystals of **2** stimulated this investigation, as it shows a linear stacking of fullerene and cyclohexene moieties. The approach presented here promises to open new routes in solid-state chemistry.[10]

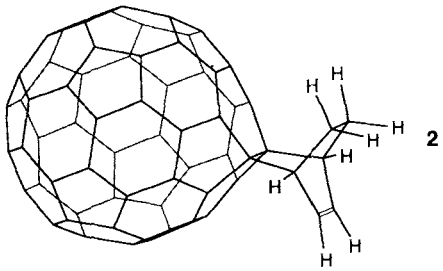
The crystalline 6,6-monoadduct **3** prepared from **1** and anthracene[14–16] undergoes a regiospecific thermal transformation into a solid 1:1 mixture of **1** and the antipodal 6,6-bisanthracene adduct **4**.[15, 16] Heating a deoxygenated sample of



3 **3** **1** **4**

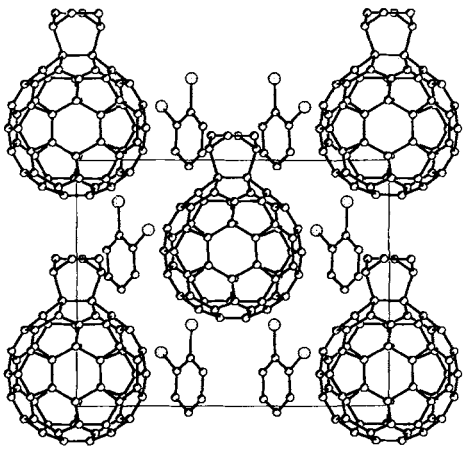
crystalline **3** at 180° C for 10 min afforded 48% each of the fullerene **1** and the antipodal bisadduct **4** (96% conversion; no other components detected). The bisadduct **4**, first described in ref. [15], was isolated and its structure confirmed by NMR spectroscopy and (FAB) mass spectrometry, as well as by single-crystal structure analysis.[17] The relative amounts of **3** and **4** in the reaction mixture were established by ^{1}H NMR spectroscopy (at 500 MHz), and after chromatographic separation the absolute amounts of **1**, **3**, and **4** were determined. The result of the solid-state thermolysis contrasts with that in solution, in which **3** has been noted to decompose to **1** and anthracene.[15] As a control, the monoadduct **3** (76 mM) and anthracene (160 mM) were allowed to react in a carbon disulfide solution at room temperature for 28 days. This led to 52% conversion with 45% yield of a mixture of five bisadducts, about 3% yield of **1**, and the antipodal bisadduct **4** as only a minor product (1.6%).

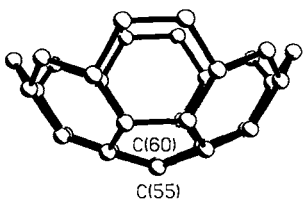
Crystals of the Diels–Alder adduct **2** formed from **1** and 1,3-cyclohexadiene[13] were obtained from a solution of **2** in *o*-



2

dichlorobenzene and analyzed by X-ray diffraction.[18] The crystal lattice with composition $\{\mathbf{2}\cdot 2C_6H_4Cl_2\}$ shows a columnar stacking of molecules of **2** mediated by intermolecular contacts between the convex fullerene surface and the concave cyclohexene moiety (Fig. 1, top). The molecules are arranged such that the part of the fullerene surface recognized by a neighboring cyclohexene moiety is antipodal to its own cyclohexene unit. Note that the fullerene 6,6-bond (C(55)–C(60)) involved in the contact is parallel to the vector between the bridgehead atoms (C(1a) and (C4a)) in the neighboring cyclohexene moiety (Fig. 1, bottom). Similar contacts, two per molecule, have been





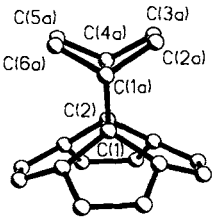


Fig. 1. Top: Crystal packing of $\{\mathbf{2}\cdot 2C_6H_4Cl_2\}$ in the crystallographic *a,b* plane; molecular stacks are parallel to the *b* axis. Bottom: Intermolecular contacts between the convex [60]fullerene (**1**) and the concave cyclohexene receptor moiety, shortest intermolecular distances [Å]: C(55)···C(2a) and C(60)···C(5a) 3.51, C(55)···C(6a) and C(60)···C(3a) 3.53 Å. Due to crystal symmetry the HC=CH and H_2C-CH_2 bonds of the cyclohexene fragment of **2** are disordered.

observed in the bisadduct **4**.[17] Single crystals of **3** were too small for a complete structure analysis; however, it was possible to determine the unit cell constants ($a = 12.8(1)$, $b = 16.9(1)$, $c = 16.6(1)$ Å, $\beta = 94.2(1)^\circ$) and the space group ($P2_1/m$ or $P2_1$). Together, these two observations lead to the conclusion that the molecules of **3** form layers of stacks analogous to those in crystalline **2** (cf. Fig. 1).[19]

The selective thermal transformation of the monoadduct **3** into the fullerene **1** and its antipodal bisadduct **4** is thus suggested to proceed by intermolecular anthracene transfer, in which one molecule of the starting compound acts as an intimate anthracene donor for the neighboring fullerene, which acts as acceptor. The occurrence of this reaction can be rationalized by the specific packing of molecules of **3** in the crystal. There, the crucial 6,6-bonds are properly aligned for anthracene transfer. Such an alignment not only renders the reaction geometrically feasible, but also makes it thermally allowed in terms of orbital symmetry, as a combination of (potentially synchronized) [4 + 2]cycloreversion and [4 + 2]cycloaddition steps.

A second aspect of the transformation of **3** into **1** and **4** in the solid state is the high overall conservation of atomic positions between the starting material and products. Due to their spherical architecture, the fullerene cores undergo only minimal overall deformation in the cycloaddition/cycloreversion reactions. Furthermore, the mode of coaxial alignment, inferred for the crystalline starting material, appears to be carried over to the product state (Fig. 2). Cocrystals of the product components **1** and **4** can be reconstituted from concentrated solutions containing a 1:1 molar ratio of fullerene **1** and the bisadduct **4**. All of the points discussed are in agreement with topochemical control of the anthracene-transfer reaction.

The solid-state reaction reported here not only produces the antipodal bisadduct **4** with high regioselectivity, but it also proceeds with high conversion. Apparently, this reaction is favored both kinetically and thermodynamically in the ordered solid state. Calculated dehydrogenation energies of 1,2-dihydro[60]-fullerenes and of the corresponding antipodal tetrahydro-[60]fullerenes[6] hint at a small enthalpic contribution to the thermodynamic driving force for this reaction. The structural information available shows that the coaxial alignment of the convex fullerene spheres and the concave receptor sites of the diene addends is rigid and restricted in its motion, whereas unsubstituted spherical fullerene molecules often show orientational disorder[20] or reorientational motion.[21, 22] Thus, the increased rotational mobility of the product molecule **1** (but not **4**) in the solid state may stabilize the product state; that is, the highly selective transformation of **3** into **1** and **4** seems to be driven largely by an increase in entropy.

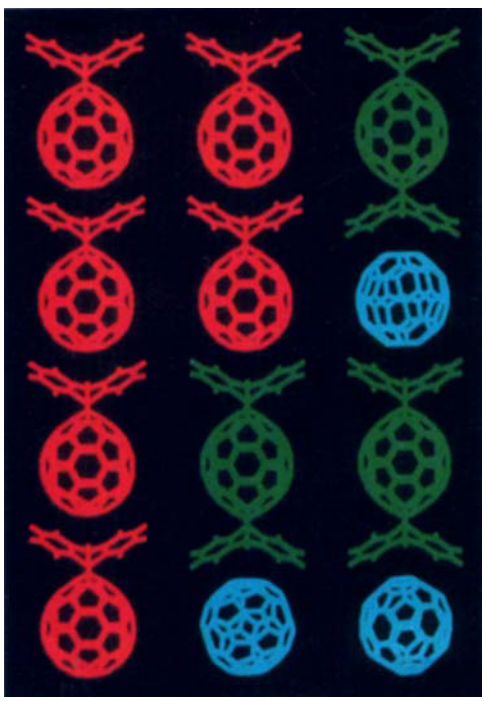

Fig. 2. Schematic description of the anthracene-transfer reaction. A stack of molecules of **3** in the solid state (left) transform into a stack of alternating molecules of **1** and **4** (right).

The results presented here indicate that crystal engineering[10] in combination with topochemical reactions[11] can lead to novel approaches for the preparation of specific fullerene derivatives. Fullerenes, in turn, may serve as versatile scaffolds for the design and for the synthesis of programmed molecular components,[23] which may assemble into useful, ordered solid materials. The exceptional, spherical buildup of fullerenes provides the field of supramolecular chemistry[23] with new structural motifs, which may add a dimension to crystal design[10] and, in this way, contribute fruitfully to new developments in materials science.

many, **1992**). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-29. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: teched(@chemcrys.cam.ac.uk).

[19] From the unit cell volume of **3** (ca. 3595 Å^3) and the space group symmetry, it is probable that the unit cell contains four molecules of **3** and no solvent. With this assumption the calculated density is ca. 1.67 g cm^{-3}, intermediate to those of **2** (1.722 g cm^{-3}) and **4** (1.561 g cm^{-3}). The space group symmetry requires two layers of molecules, one at y and the other at $y+\frac{1}{2}$. The distribution of 1171 intensity measurements with $I(hkl)/\sigma(I) \geq 3$ shows that intensities for $(h+l)$ even are twice as frequent and on average twice as intense as those for $(h+l)$ odd. This indicates a pseudotranslation period of $(a+c)/2$. Within one layer, molecules of **3** must be related by translation along a. This implies that each C_{60} unit of **3** has six nearest neighbors, two at 10.1 Å ($\pm a/2 \pm c/2$), two at 10.8 Å ($\pm a/2 \pm c/2$), and two at 12.8 Å ($\pm a$). These distances are similar to those found in **2**, where they are 10.38 Å between stacks and 12.8 Å within stacks. The former value in **2** is close to the average of 10.45 = (10.1 + 10.8)/2 Å in **3**; the latter value in **2** is almost the same as the value of 12.8 Å in **3**. From these similarities we conclude that layers of **3** show a packing of stacks analogous to that in **2** (see Fig. 1). This conclusion is corroborated by the crystal structure of **4**, which shows linear C_{60}-anthracene$\cdots C_{60}$ motifs and a distance of 12.77 Å between C_{60} centers [17] (vs. 12.8 Å in the postulated linear C_{60}-anthracene$\cdots C_{60}$ motifs of **3**). We thank Dr. F. Pichierri and S. Capelli for help with measurements at the Swiss-Norwegian Beam Line (European Synchrotron Radiation Facility, Grenoble).

Molybdenum Blue: A 200 Year Old Mystery Unveiled

Achim Müller,* Jochen Meyer, Erich Krickemeyer, and Ekkehard Diemann

"This is a substance or group of substances about which there has been much discussion" is a statement we read in an older standard textbook of inorganic chemistry.[1] It refers to an (usually) amorphous blue material that was first mentioned by C. W. Scheele in 1778 and today is known as "molybdenum blue".[2] The first source of information about its composition dates back to J. J. Berzelius in 1826.[3] Since then this material has been the topic of numerous publications,[4, 5] and generations of students and chemists have applied the "molybdenum blue test" as a simple, fast, and sensitive method for a qualitative analysis of molybdenum.[6] However, the constitution of the compound (or compounds) has remained mysterious[7–10] and therefore it is not surprising that most of its remarkable properties could not be explained. We can now show that the anion of the crystalline, blackish-blue compound **1** ($n \approx 350$), prepared recently by us according to a useful strategy[11] for obtaining ever larger clusters,[12] is archetypical for the compounds referred to in the literature as "amorphous molybdenum blue".[13]

$$(NH_4)_{25\pm5}[Mo_{154}(NO)_{14}O_{420}(OH)_{28}(H_2O)_{70}]\cdot nH_2O \quad \mathbf{1}$$

After repeating some general preparation methods as well as analytical test procedures leading to "molybdenum blue", and comparing the properties of the products with those of **1**, significant similarities immediately became apparent (see Fig. 1).[17] In particular, we have studied the reduction of acidified aqueous solutions of molybdates a) with $(N_2H_6)SO_4$, b) with $SnCl_2$, c) with elemental Fe, and d) with elemental Zn[4] as well as e) the photochemically induced reduction with formic acid.[15] Whereas for c) and d) only "amorphous" precipitates with a correspondingly low degree of crystallinity were obtained, we isolated small amounts of a blackish-blue homogeneous material with a higher degree of crystallinity for a) and b). Hence, for the latter it was now possible to obtain spectroscopic data of a homogeneous well-defined compound and compare them with those of the amorphous blue precipitates (of possibly varying compositions). The IR spectra of these compounds are very similar to those of the earlier reported compound **1**,[12] except for a pronounced band at 728 cm^{-1} associated with one of the two stretching vibrations of the {MoNO} group (Fig. 1A). The same

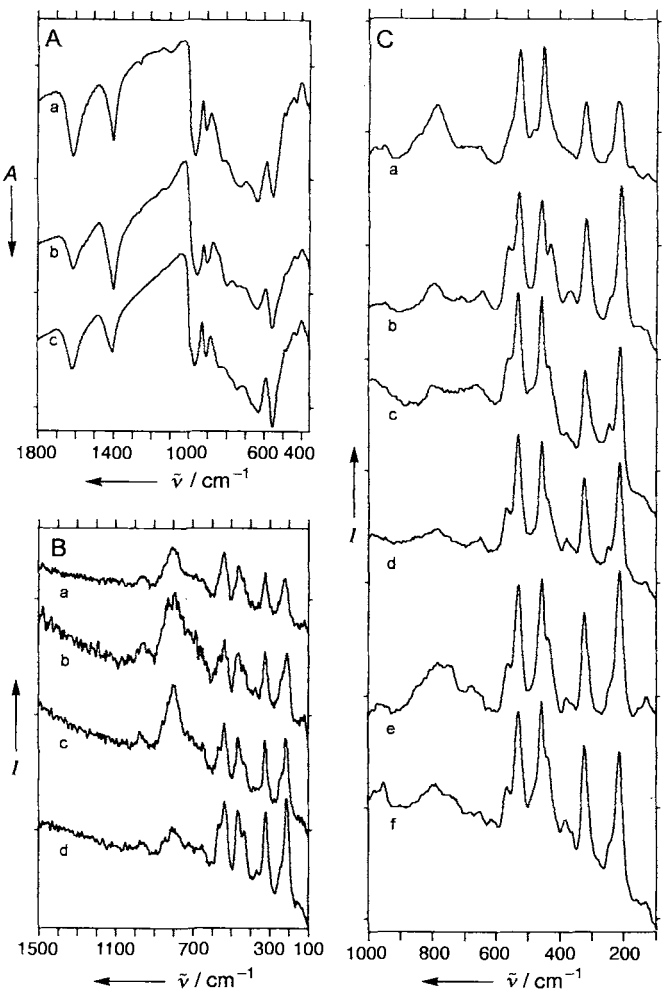

Fig. 1. A) IR spectra (KBr pellet) of **1** (a), of "molybdenum blue" obtained by reduction of molybdate with $(N_2H_6)SO_4$ (b), and $SnCl_2$ (c). B) Solid-state Raman spectra (λ_e = 1064 nm) corresponding to the samples given in A) and of a soluble blue "amorphous" precipitate obtained by reduction with Fe (d). C) Solution Raman spectra (λ_e = 1064 nm) of the products of B), of a molybdate solution (pH 1.4) reduced with Zn (e), and of a molybdate solution (pH 1.4) irradiated with an UV lamp in the presence of formic acid (f).

holds for the corresponding resonance Raman spectra (Nd:YAG laser: $\lambda_e = 1064$ nm; inter-valence-charge-transfer (IVCT) band ≈ 1070 nm), which show a series of five characteristic bands in the region between 900 and 200 cm^{-1} (Fig. 1B). According to a simplified normal coordinate analysis, these bands are assigned to vibrations of $\{(Mo^{V/VI})_mO\}$ fragments ($m = 2,3,4$).[23] Furthermore, the resonance Raman spectra of solutions of "molybdenum blue" obtained by the different given synthetic pathways resemble the corresponding solution spectrum of **1** (Fig. 1C). The differences in the intensity and the shape of one particular band at about 800 cm^{-1} are most probably due to variations in the electron populations of the cluster anions. This band becomes gradually more intense and its half-width decreases upon increasing the degree of reduction (ratio Mo^V/Mo^{VI}) of an acidified (pH 1.4) molybdate solution from 10% to 20%. Above a degree of reduction of 20% this band dominates the spectrum (according to a model calculation it can be assigned to a particular $\{(Mo^{V/VI})_3\mu_3\text{-}O\}$ fragment, in which the IVCT transitions responsible for the resonance effect mainly occur).[23] In addition, the electronic absorption spectra of the reduced molybdate solutions resemble that of **1**; however, the absorbance and to a lesser extent the positions of the absorption maxima vary significantly with the degree of reduction.

Futhermore, Raman spectroscopic investigations[24] show that the dominant species in non-reduced molybdate solutions (pH 1–2) is the large isopolymolybdate $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$ ($\equiv[(MoO_2)_2H_{24}\{Mo_{17}\}_2]^{8-}$),[24, 25] which itself, or the intrinsic $\{Mo_{17}\}$ ($\equiv\{Mo_{17}O_{60}(H_2O)_2\}$) fragment, is considered to act as a template (cf. also ref. [12a]) for the formation of the ring-shaped anions like that of **1**.[12] The greenish by-product of the synthesis of **1**[12a] was identified as the water-insoluble polymeric compound $\{(NH_4)HMo_5O_{16}(H_2O)\cdot H_2O\}_n$, which was also reported to be formed from solutions containing the $[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$ ion.[24]

The X-ray powder diffractograms of the "molybdenum blue" precipitates obtained from different synthetic pathways have almost identical patterns. They show (with the exception of the characteristic sharp reflections of the parts (corresponding to **1**) with the higher degree of crystallinity) only diffuse scattering maxima ($2\theta \approx 26$, 29.5, and 51°; $Cu_{K\alpha} = 154.18$ pm), as usually observed for noncrystalline compounds. However, the intensity pattern corresponds quite well to the envelope of the powder pattern of **1**. This implies that a species at least structurally very similar to the anion of **1** should be present in all these materials.

The results available so far imply that a highly abundant species of "amorphous molybdenum blue" corresponds to a "*molecular* molybdenum trioxide" with a varying degree of protonation and reduction and a (probable) formula of $[(MoO_3)_{154}(H_2O)_{70}H_x]^{y-}$.[23] This formula is derived by replacing the 14 $\{MoNO\}^{3+}$ groups of the anion of **1** by the corresponding number of $\{MoO\}^{4+}$ groups[11] (see also the existence of the comparable cluster pairs $[Mo_{36}(NO)_4O_{108}(H_2O)_{16}]^{12-}$/$[Mo_{36}O_{112}(H_2O)_{16}]^{8-}$[11] as well as $[Mo_6(NO)O_{18}]^{3-}$/$[Mo_6O_{19}]^{2-}$[26]). Interesting in this context is that $MoO_3\cdot 2H_2O$ as well as the homologous oxides CrO_3 and $WO_3\cdot 2H_2O$ are end products of condensation processes caused by acidification. In the present case the formation of neutral polymeric compounds with solid-state structures is prevented by reduction (anion formation).

The knowledge of the basic structure of "molybdenum blue" enables us now to understand for the first time some of its unusual properties:

a) The amorphous character of the predominant part of the obtained samples of molybdenum blue has to be attributed to the difficulties of positioning extremely large anions into a highly ordered crystal lattice. The understanding of the stochastic nature of fluctuations during the nucleation phase of the crystallization process with the help of the Langevin equation[27] presents a fascinating challenge. There are virtually no related investigations in the context of ionic crystals with extremely large ions.

b) The large hydrophilic inner and outer surface built up by the exceptionally large number of H_2O molecules and OH groups as ligands (70 and 28, respectively, in the case of **1**, Fig. 2) explains the high solubility in water,[4] and even (to a lesser extent) in methanol, 95% ethanol, or aqueous acetone.

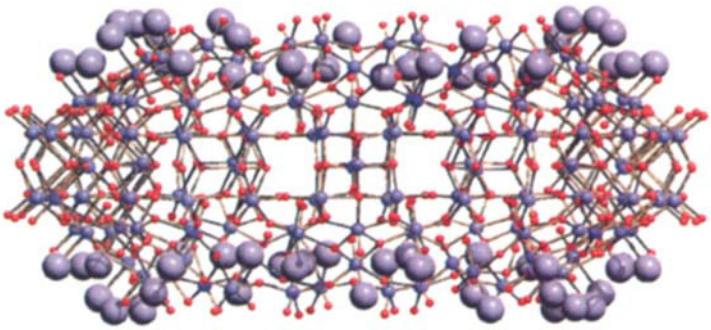

Fig. 2. Ball-and-stick representation of $[(MoO_3)_{154}(H_2O)_{\sim 6}H_x]^{y-}$, derived from **1** by replacing the $\{MoNO\}^{3+}$ by $\{MoO\}^{4+}$ groups (view along the approximated C_2 axis); the 70 H_2O ligands are represented as large gray spheres, the Mo and O atoms as smaller blue and red spheres, respectively.

c) The large surface area is responsible for the high affinity to adsorbents (charcoal, cotton, silk etc.)[28] and models that of solids, for example of mixed-valence transition metal oxides with catalytic activities.[29]

d) The solutions have been described as colloidal (showing a Tyndall effect) with a tendency towards the formation of micelles, but with properties very close to those of "real" solutions.[4, 30] This can be attributed to the size of the anions, and the ability of the species to aggregate, which was recently confirmed by us by dynamic light scattering experiments.[31]

e) The migration of "molybdenum blue" to the anode in an electric field[32] is due to the true anionic nature of the cluster ions and not—as normally in the case of colloids—to nonstoichiometric surface charges.

Other interesting properties are: the nanometer-sized cavity and the corresponding host properties, the high density of states in the HOMO/LUMO region that gives rise to a pseudo-band structure with a narrow band gap resulting in a small-sized semiconductor, the electron-storage properties and the thus related potential suitability as a redox catalyst as well as the remarkable intense color, which, according to resonance Raman investigations, can be attributed to IVCT transitions.

According to the experimental results presented here there is significant evidence that the (anionic) structure of **1** represents the basic structural type of the investigated "molybdenum blue compounds".[13] The high complexity of the molecular system together with its manifold properties may explain the confusion about the nature of this material in literature. With the determination of the structure of **1** and the consistency of its main properties with those reported for "amorphous molybdenum blue", a more than 200 year old mystery has been partly unveiled.

Experimental Procedure

Precipitates of "amorphous molybdenum blue" were obtained from reduced, acidified aqueous solutions of molybdates according to general preparation methods [4,5]. With $(N_2H_6)SO_4$ and with $SnCl_2$ a homogeneous blackish-blue material with a high degree of crystallinity was formed in small amounts that had to be separated mechanically from by-products. All products were stored under inert atmosphere.

Reduction with hydrazinium sulfate: A solution of $(N_2H_6)SO_4$ (0.16 g, 1.2 mmol) in water (8 mL) was added to a solution of $(NH_4)_6[Mo_7O_{24}]\cdot 4H_2O$ (1.12 g, 0.9 mmol) and 50% acetic acid (0.24 mL) in water (12 mL) at 20 °C. 2 mL of the resulting green solution was allowed to stand for about two months (without shaking) in a closed 20 mL test tube for crystallization.

Reduction with tin(II) chloride: A solution of $SnCl_2$ (6.66 mL, 0.025 M; pH 1.4, adjusted with hydrochloric acid) was added to a solution of $(NH_4)_6[Mo_7O_{24}]\cdot 4H_2O$ (10 mL, 0.014 M; pH 1.4) under inert atmosphere. The resulting blue solution was kept under inert atmosphere and allowed to stand for two months (without shaking) for crystallization.

Reduction with elemental iron: Iron powder (5 g, 89 mmol; 150 μm, Merck) was added to a solution of $(NH_4)_6[Mo_7O_{24}]\cdot 4H_2O$ (20 g, 16 mmol) in water (250 mL) in a 300 mL Erlenmeyer flask (wide-necked). Under stirring the pH value was adjusted to 1.0 with 25% hydrochloric acid (colorless precipitate). The mixture was kept at 20° C for 18 h without stirring (Erlenmeyer flask covered with a watch glass). After filtration the solution was kept at 20 °C in a closed test tube for 3 d. The blue precipitate that formed slowly from the deep blue solution was filtered off under an argon atmosphere and dried.

[13] The subject of this article are the blue solutions that can be obtained by (partial) reduction of acidified molybdate(VI) solutions with a large number of different reducing agents (but also by electrolytical [14] or photochemically induced reduction [15]) and that are usually used for a qualitative test for the presence of molybdenum. Solids precipitated from these solutions are known as "amorphous molybdenum blue(s)"—in contrast to blue crystalline oxide–hydrates (prepared from MoO_3 suspensions) and anhydrous blue oxides with typical framework structures [10]. They have also to be distinguished from the "heteropoly blues" with an additional element [16].

[17] In the early publications the stoichiometric composition of the mixed-valence compounds (Mo^V/Mo^{VI}, type III [18]) was normally given as $MoO_{3-x}\cdot nH_2O$ (see Table in ref.[4]). Surprisingly, the real anionic nature of "molybdenum blue" was overlooked in most of the earlier investigations even in those cases where molybdates were used as starting materials and even though the problem of obtaining "electrolyte" or cation-free samples of "molybdenum blue" was sometimes mentioned [3,19] (exceptions [15, 20–22]).

[23] Principally, also the presence of different and larger ring-shaped species (and fragments) with a general composition of $\{(MoO_3)_m(H_2O)_nH_p\}$ cannot be ruled out completely either by powder diffractometry or by IR and Raman spectra *alone*. This corresponds to the general problem of structure determination of amorphous substances (see for instance A. Müller, V. Fedin, K. Hegetschweiler, W. Amrein, *J. Chem. Soc. Chem. Commun.* **1992**, 1795, in the case of a molybdenum sulfide). Both methods together, however, give a strong hint that *mainly* only one kind of those species is abundant. The IR spectra of the very large polyoxomolybdates (type $\{Mo_{36}\}$, $\{Mo_{57}\}$ [11], $\{Mo_{154}\}$ [12]) can be modeled very nicely by superposition of the subspectra resulting from weakly coupled (!) characteristic vibrations of different $\{Mo_mO\}$ fragments ($m = 2, 3, 4$; with the heavy Mo centers preventing (diminishing) coupling. This facilitates the proof of functional groups but complicates, for example, the differentiation of species with different numbers of these base fragments (A. Müller, M. Ohm, H. Bögge, unpublished results).

Stabilization of an Unusual Coordination Geometry at Li^+ in the Interior of a Cryptand-Type Helicate**

Markus Albrecht* and Sirpa Kotila

The metal-directed self-assembly of linear ligands to form triple-stranded helicates proceeds with high stereoselectivity.[1–3] Recently we reported the first example of an achiral *meso*-helicate, which is obtained by self-assembly of three bis(catecholate) ligands with two titanium(IV) ions.[4] We proposed that the stereochemistry of helicate versus *meso*-helicate

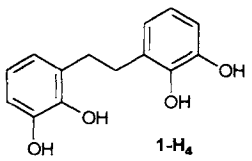
[**] This work was supported by the Fonds der Chemischen Industrie (Liebig Stipendium), the Deutsche Forschungsgemeinschaft, and the Academy of Finland. We thank Dr. H. Röttele (NMR), Mrs. B. Wibbeling (X-ray), Dr. R. Fröhlich (X-ray), and Dr. D. Röttger (CSD search) for their help.

formation depends on the zigzag conformation of the alkyl spacer connecting the ligand moieties. An even number of methylene units should favor the helicate, an odd number the *meso*-helicate structure. To test this assumption we have synthesized a binuclear triple $(CH_2)_2$-bridged titanium(IV) complex.

$Li_4[(\mathbf{1})_3Ti_2]$ is formed quantitatively by self-assembly of three equivalents of 3,3′-ethane-1,2-diylbis(1,2-benzenediol) [1,2-bis(2,3-dihydroxyphenyl)ethane] ($\mathbf{1\text{-}H_4}$)[5] with two equivalents of $[(acac)_2TiO]$ (acac = acetyl acetonate) in the presence of two equivalents of lithium carbonate as base.



1-H$_4$

Only one diastereoisomer can be detected by ^1H NMR and ^{13}C NMR spectroscopy ([D$_4$]methanol), but the spectra do not allow an assignment to the helicate or *meso*-helicate structure.[6] The ^1H NMR spectrum (400 MHz) at room temperature shows the signals of the aromatic moiety at $\delta = 6.46-6.39$ (m, 12H) and 6.29 (dd, $J = 1.4$, 7.4 Hz, 6H) as well as a broad signal at $\delta = 2.80$ (12H) for the protons of the ethylene spacer. When the sample is cooled to 194 K, the signal for the ethylene spacer is split into two multiplets at $\delta = 3.25$ (6H) and 2.31 (6H). Coalescence is observed at 233 K, indicating an energy barrier of $\Delta G^{\neq} = 10.3$ kcal mol^{-1} for the racemization of the two octahedrally coordinated chiral titanium centers.

Figure 1a shows the structure of the tetraanion $[(\mathbf{1})_3Ti_2]^{4-}$ in the crystal.[7] As proposed, the binuclear $[(\mathbf{1})_3Ti_2]^{4-}$ ion possesses the chiral helicate form. Two of the ligands **1** induce a helical turn leading to transfer of chiral information from one titanium(IV) center to the other. The third ligand adopts a more linear orientation (vide infra). This helicate structure indicates the possibility of controlling the stereochemistry in the self-assembly process of achiral components.[8] Simple conformational changes influence the diastereoselectivity in such a way that exclusively one diastereoisomer is formed.

In contrast to the analogous oligonuclear coordination compounds formed from linear nitrogen donors (for example, oligo(2,2′-bipyridine) ligands),[2] the catecholate complexes possess additional lone pairs of electrons at the donor atoms. In the solid state as well as in solution these are capable of binding alkali cations in a cryptand-type fashion.[9,10] Thus, $[(\mathbf{1})_3Ti_2]^{4-}$ encapsulates one of the lithium counterions in its cavity, thereby forcing an extraordinary coordination geometry at this alkali ion (Fig. 1b). The lithium ion bridges the two internal oxygen atoms of the linearly coordinated bis(catecholate) ligand **1**, leading to an O2-Li1-O2* angle of 164.2(5)°. Vacant coordination sites at this Li^+ ion are saturated by two water molecules, which are each fixed in the cavity by hydrogen bonding interactions with the internal oxygen atoms of the two helically orientated ligand strands. The $O10_{water}$-Li1-$O10^*_{water}$ angle is 148.7(6)°. Thus, the tetracoordinate Li1 atom does not adopt the expected tetrahedral geometry. The coordination geometry can be described best as distorted square planar or as trigonal prismatic with one equatorial ligand missing. The free equatorial position is blocked by the ethylene spacer of the linear ligand **1** (Li1···C7(spacer) 2.78(1) Å).

A few rare examples of compounds containing lithium coordinated in a square-planar fashion have been described. Li^+ shows a planar tetracoordinate coordination geometry in porphyrins[11] or phthalocyanines[12] and bis(acetyl acetonate) complexes.[13] In the case of $[\{Li(H_2O)_2\} \subset \{(\mathbf{1})_3Ti_2\}]^{3-}$ the unusual geometry seems to result from constraints of the cavity. The internal oxygen atoms of the Li-binding ligand are 4.01 Å apart. Effective coordination to lithium can only take place if the O2-Li1-O2* angle widens. Steric effects force the water molecules to move outwards. Further stabilization is obtained by the hydrogen bonding interactions of the water. The combination of steric effects with hydrogen bonding stabilization allows the distorted square-planar geometry. Attempts to detect the inclusion of the lithium cation in solution were unsuccessful. ^6Li NMR ([D$_4$]methanol/methanol 1:1, 58.9 MHz) of a sample of $^6Li_4[(\mathbf{1})_3Ti_2]$ at various temperatures (193–300 K) showed only one resonance at $\delta = 0.92$. This indicates that the exchange of encapsulated and solvated lithium ions is fast with respect to the NMR time scale.

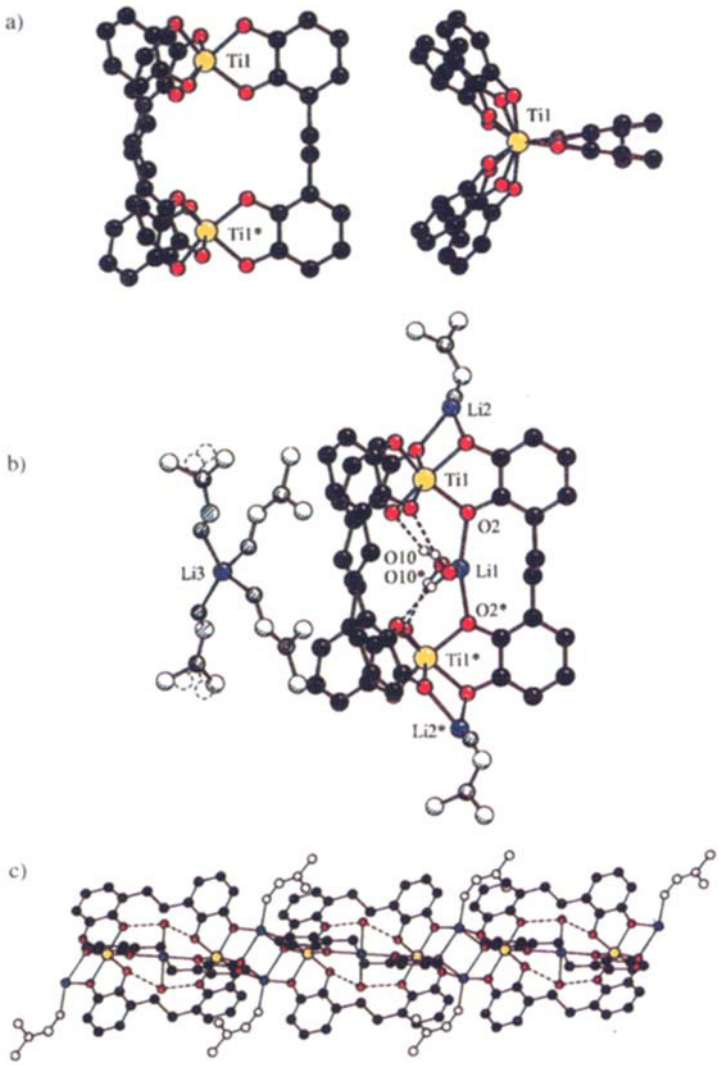


Fig. 1. Molecular structure of $Li_4[(\mathbf{1})_3Ti_2]\cdot 6DMF\cdot 2H_2O$. a) The tetraanion $[(\mathbf{1})_3Ti_2]^{4-}$; side view (left) and view along the Ti–Ti axis (right); b) monomeric unit; c) polymeric structure. Black: carbon, red: oxygen, yellow: titanium, blue: lithium; for clarity only the H atoms forming hydrogen bonds are shown; solvent molecules are not colored; disorder is indicated by dotted lines.

In the crystal, in addition to Li1 two further Li^+ cations are exohedrally bound to external catecholate oxygen atoms at the "ends" of the helicate anion. These two ions form a bridge by interaction with two DMF molecules, resulting in an infinite chain in the solid state (Fig. 1c).[14] Coordination geometries at these two lithium ions are trigonal bipyramidal. The remaining fourth lithium ion is tetrahedrally surrounded by four DMF molecules.

In summary, we have shown that the stereochemistry of the self-assembly processes of achiral components is influenced by small conformational changes of the participating substrates.

Furthermore, the aggregates formed can act as receptors and bind small molecules (water) or ions (Li^+), stabilizing unusual geometries in its cavity. This shows some relevance to the function of enzymes and antibodies that can stabilize the geometry of reaction intermediates by a combination of stereoelectronic effects and hydrogen bonding networks.[15]

Crystal Growth in Zeolite Y Revealed by Atomic Force Microscopy**

Michael W. Anderson,* Jonathan R. Agger, John T. Thornton, and Nicola Forsyth

Zeolites form one of the most important classes of heterogeneous catalyst. Their microporous nature and consequent high surface area impart both high selectivity and high activity. Although well over one hundred zeolite-like compounds can now be synthesized with a wide range of pore geometries their synthesis remains very much a "black art". Generally, zeolites are synthesized from an alkaline aluminosilicate gel that sometimes contains organic cations. At least two main routes to crystallization have been identified: first, gel globules crystallize without transport of material resulting in globular, highly twinned crystals; second, single zeolite crystals grow by transport of nutrient from the gel phase to a growing zeolite crystal. It is the second route that is dealt with in this study.

Novel frameworks are often produced by incorporating large organic cations into the synthesis mixture, but whether these cations act as structure templates or as structure blockers is not well understood. There are a number of examples of syntheses in which the organic molecule fits very snugly into the resulting tunnel structure, for example the tetrapropylammonium ion in ZSM-5, and it is tempting in these cases to think of the molecules as templates. However, often the same structure can be made with other organic molecules or with no organic molecules at all—again ZSM-5 is a good example of a zeolite that can be made with a wide variety of organic molecules or simply in the presence of Na^+ ions.

Zeolite Y (structure designation FAU) is probably the single most important zeolite from a catalytic standpoint, since it is used for the catalytic cracking of petroleum. An interesting recent example of structure-directing through the use of organic molecules is the synthesis of the hexagonal polymorph of zeolite Y (structure designation EMT) in the presence of [18]crown-6 and Na^+ ions.[1] Both FAU and EMT can be constructed by linking sodalite cages (truncated octahedra) through double six-membered rings. The relationship of the sodalite cages is as for zinc blend in FAU and as for wurtzite in EMT. It has been shown[2] that a $[Na([18]crown-6)]^+$ macrocation is located within the oblate cages of EMT into which it sits very snugly. The structure of EMT was originally proposed by Breck[3] and was known as Breck structure six (BSS) but proved elusive to synthesize. The cubic polymorph of zeolite Y on the other hand is extremely easy to synthesize and can be prepared from an aluminosilicate gel containing only Na^+ ions. As EMT and FAU are constructed from the same building units they easily form random intergrowths, and this has been observed in many preparations containing a variety of organic molecules.[4] Like EMT the FAU structure can also be prepared by using a crown ether

([15]crown-5), and it has been shown that by mixing [18]crown-6 with [15]crown-5 controlled intergrowths of the two materials can be prepared.[5-9] A mechanism has been postulated[6,7] in which [18]crown-6 acts to stabilize the EMT structure during crystallization. This mechanism views the crystallization in terms of a layer growth (supported by high-resolution electron microscopy (HREM) of surface growth steps) in which [18]crown-6 decorates a growth layer. This decoration occurs at pocket sites on the growing surface and forces the next growing surface to grow with a mirror symmetry rather than an inversion symmetry to the decorated layer. Such mirror related growth gives EMT rather than FAU structure. The postulation of layer growth was based primarily on electron microscopy which only provides a projected image through the crystal, therefore, although the presence of growth steps was identified, the true morphology of the related terraces circumscribed by these steps was unclear.

Atomic force microscopy (AFM) has recently been used to monitor the surface features in zeolite minerals[10] and also the details of crystal growth of a number of organic[11] and inorganic[12] materials. In this present study we have utilized AFM to scan the surface of crystals of FAU and EMT synthesized by using crown ether templates to reveal the growth face morphology. The crown ether preparations result in relatively large (> 1 mm), defect-free crystals compared with conventional routes for the synthesis of zeolite Y making study by AFM feasible.

Scanning electron micrographs of FAU and EMT samples (Fig. 1) reveal characteristic octahedral and hexagonal crystal

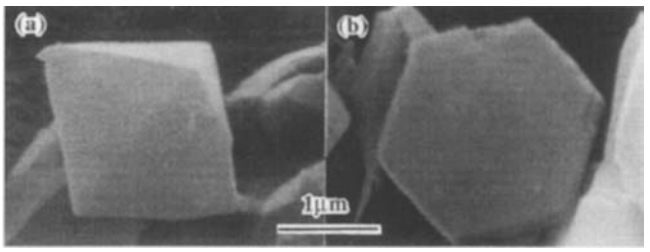

Fig. 1. Scanning electron micrographs of a) a FAU crystal showing octahedral habit with a crystal edge length of about 1 μm and b) an EMT crystal showing hexagonal prism habit with edge length about 1 μm.

morphology, respectively. In FAU the faces of the crystal are all $\{111\}_c$, in EMT the top and bottom faces are $\{001\}_h$ and the side faces are $\{100\}_h$, where c and h depict cubic and hexagonal phases, respectively. Figure 2a shows the AFM image of one of the $\{111\}_c$ faces of FAU. The triangular nature of the face with edge length about 1 μm is immediately apparent. On the crystal surface a host of triangular terraces are observed with the triangles rotated by 60° to the crystal edges. A section analysis (Fig. 2b) reveals that the triangular terraces have a highly uniform thickness of approximately 1.5 nm. This thickness is in very good agreement with the thickness of one faujasite layer of 1.43 nm, calculated crystallographically, (see [110] projection in Scheme 1) and in very good agreement with the step heights observed previously by HREM.[7]

A number of important features are observed in the AFM image of FAU structure: 1) the triangular edges of the terraces are rotated by 60° about $[111]_c$ from the crystal edges; 2) the orientation of all triangular terraces is the same; 3) the spacing between the terrace edges decreases towards the edges of the crystal.

The first feature is at first surprising. One might expect the orientation to be the same; however, the rotated sense of the terraces will result in layer growth which circumvents the whole crystal as illustrated in Scheme 1 in which eight growing terraces

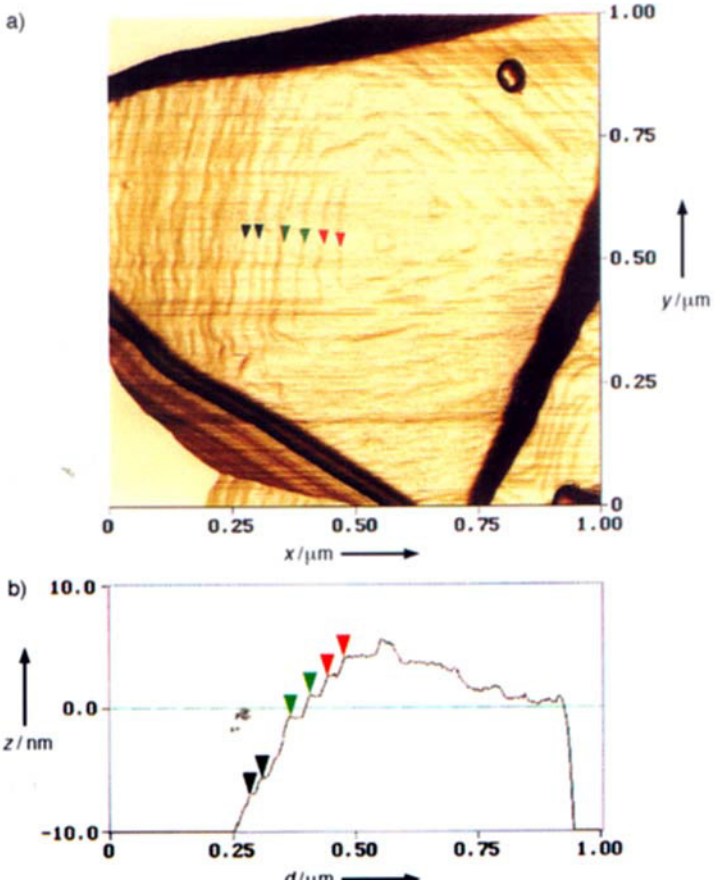

Fig. 2. a) AFM image (TappingMode) of FAU structure showing the $(111)_c$ face. The triangular terraces are growth steps each about 1.5 nm in height. This value was derived from section analysis (b), which shows height and separation of crystal steps (d: lateral shift in the xy plane). The colored arrows correspond to the following step heights and (in parentheses) lateral step separations, respectively: red: 1.5 nm (33 nm); green: 1.7 nm (39 nm); black: 1.4 nm (25 nm).

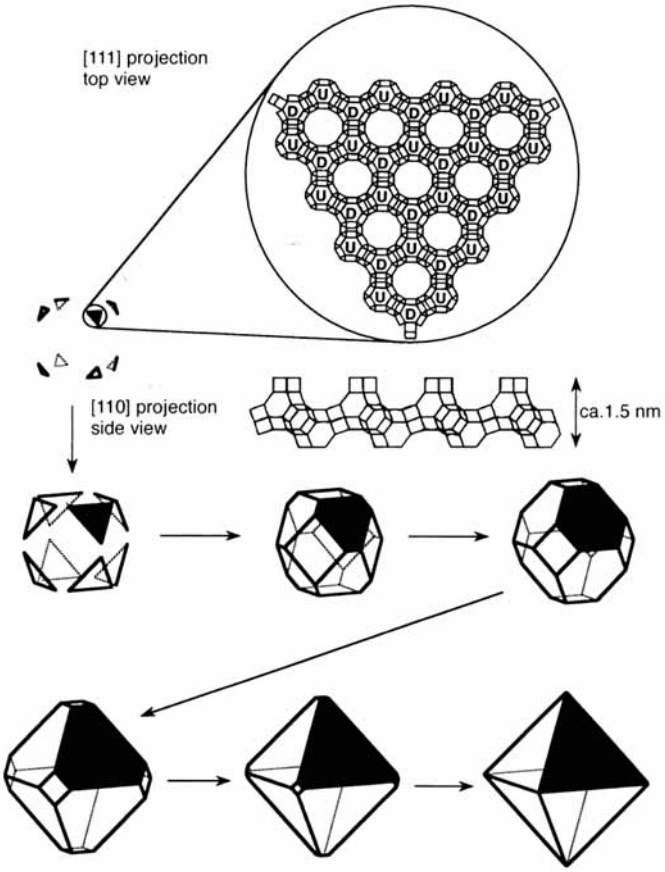
are shown with one highlighted in black. The growing terraces nucleate on the $\{111\}_c$ face and have a triangular appearance, as the [111] projection shows. In these projections vertices represent silicon or aluminum atoms linked by oxygen bridges. The oxygen atoms are not shown for clarity but lie approximately half way along each line. The trigonal symmetry of one faujasite sheet can be seen in the [111] projection where U and D represent up and down, respectively, and indicate displacement of sodalite cage building units. This trigonal symmetry is reflected in the triangular appearance of the growing terraces. As the triangular terraces enlarge they will merge with other growing terraces on other $\{111\}_c$ faces to form the six-sided faces of a truncated octahedron. Such a growth front ensures that the crystal will grow in a uniform manner on all $\{111\}_c$ faces. If the triangular terraces were to grow in the same sense as the crystal faces, each face would in effect grow independently of neighboring faces which might result in more irregular crystals.

The second feature, that is the fact that on any given crystal face, all triangular terraces grow in the same sense is due both to the threefold symmetry of the faujasite layer (Scheme 1) and to the relationship between interconnected layers. A pure cubic faujasite crystal is composed of an ABCABC stacking of faujasite layers. The different layers are shifted laterally to one another but are not rotated. A rotation of one layer by 60° would result in an unfavorable planar fault and the creation of a small amount of EMT structure. For example a layer stacking



Scheme 1. Schematic representation of terrace growth on a $\{111\}_c$ face of a FAU crystal.

ABCAB*ABCABC which is shown with the EMT section in bold and the one rotated B layer highlighted with an asterisk. In order to force this unfavorable rotation between interconnected layers [18]crown-6 must be used as a structure-directing agent.

The last feature, that is the decreasing spacing between terrace edges has been observed previously in HREM images[7] and can be explained in terms of the growth mechanism. If the terraces grow by a terrace-ledge-kink (TLK) mechanism (see Fig. 3 inset), growth rate perpendicular to a growing face is governed by the nucleation time of a new terrace. If it is assumed that this terrace nucleation time is a constant, the terrace number provides a unit measurement of time (the smallest triangular terrace is numbered as one). The size of each terrace will depend upon the time for which it has been growing (that is those with a low terrace number have been growing for the shortest period and will therefore be smallest). If the terraces grow by deposition of nutrient from solution at a kink site (a site with constant area), the area of a terrace will increase at a constant rate. Consequently, a plot of growing time (or terrace number) versus terrace area (or area coefficient, which is the square of any linear parameter of the triangle—we have used the square of the triangle height, h^2) should be linear. Terrace steps will consequently get closer and closer together as the step separation is related to the square root of the terrace area. Figure 3 shows a linear relationship between the terrace growth time (terrace number n) and terrace area coefficient h^2 which is consistent with such a growth mechanism.

It should be remembered that analysis by AFM, as with analysis by HREM, is essentially a "post-mortem" on a crystal following growth. It is not possible to determine whether the surface structure has altered following removal of the crystals from the supernatant solution. Further, it is well known that as

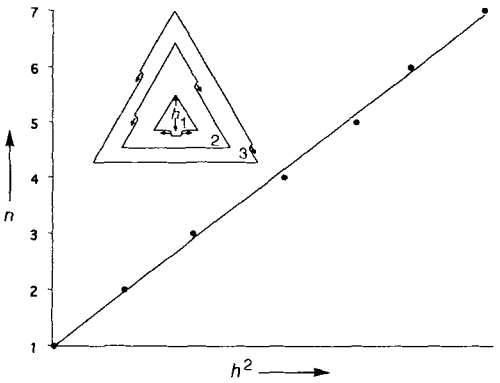


Fig. 3. Linear plot of terrace number n versus area coefficient h^2 (arbitrary units) for growing terraces. The inset shows a schematic representation of kink growth.

the supersaturation of a synthesis medium drops, the first faces to stop growing are the low index faces[13] such as $\{111\}_c$. In FAU, however, the only faces exposed are $\{111\}_c$ and therefore these will all behave in an equivalent manner. The regular nature of the surface terraces coupled with the excellent linear relationship between terrace area and growth time is compelling evidence that these terraces are indeed fundamental units in the growth process and that zeolite Y grows by a layer mechanism. The definitive, yet challenging, experiment will be an in situ AFM study to monitor crystal growth.

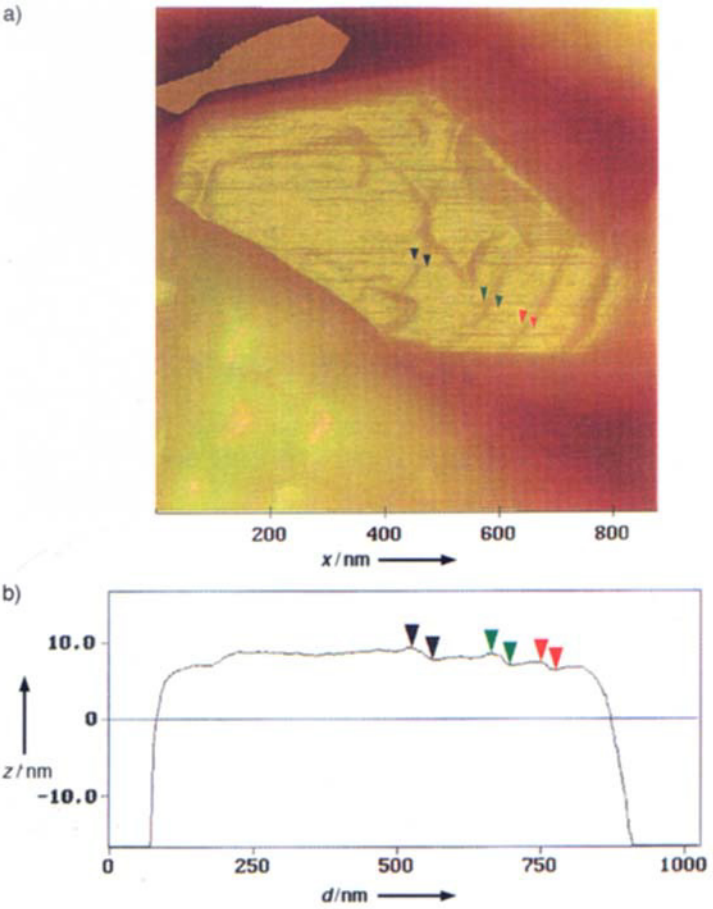

Fig. 4. a) AFM image (TappingMode) of EMT structure showing a partially obscured $(001)_h$ face. These terraces are about 1.5 nm in height, as revealed by the section analysis (b), corresponding to one faujasite sheet (d: lateral shift in xy plane). The colored arrows correspond to the following step heights: red: 1.0 nm; green: 1.5 nm; black: 1.5 nm.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3511-1212 $ 15.00+.25/0

Figure 4a shows the AFM image of one partially obscured $\{001\}_h$ face of EMT. The hexagonal nature of the face with edge length about 0.6 μm is immediately apparent. Though the overall terrace topology on the crystal surface is not as well defined as for FAU, both a hexagonal nature and a diminishing terrace width towards the edge of the crystal are evident. This hexagonal terrace morphology is a consequence of the symmetry generated along the $[001]_h$ direction by the ABAB stacking of faujasite layers. Although individually the A and B layers have threefold symmetry (see Scheme 1) they are rotated with respect to one another by 60° thereby generating a pseudo sixfold axis. Section analysis again reveals that the terraces are approximately 1.5 nm thick and this thickness is highly uniform. The growth terraces of the EMT structure are less well defined than those of the FAU structure which is a reflection of the larger number of defects in EMT than FAU.[7]

Experimental Procedure

The zeolites were synthesized in the system $10SiO_2:1.0Al_2O_3:2.4Na_2O:140H_2O:1.0$ crown ether. The sources of material were 40 wt% colloidal silica (HS-40 Ludox); 40 wt% sodium aluminate solution; [15]crown-5 and [18]crown-6 (Aldrich). Gels were aged for two days at room temperature followed by crystallization in Teflon bottles for eight days at 95 °C.

AFM images were recorded on a Nanoscope Multimode Microscope from Digital Instruments operating in TappingMode. Samples were secured on an adhesive surface to prevent lateral movement. A first order planefit was conducted on the images in the x and y directions to level the crystal terraces, and simulated illumination is used to emphasize the crystal steps. Dark areas around crystal edges are due to the surface topography possessing a greater slope than the side of the tip. Thus, these areas contain information on the tip shape only and do not contain topographical information.

Controlled Assembly of Nanosized Metallodendrimers**

Wilhelm T. S. Huck, Frank C. J. M. van Veggel,* and David N. Reinhoudt*

There is considerable interest in the synthesis of well-defined structures of nanometer dimensions.[1] These structures can be constructed by formation of covalent bonds, but this requires multistep synthesis.[2] Therefore, various other strategies have been developed that rely on self-assembly through noncovalent interactions, for example hydrogen bonds. Whitesides et al.[3] obtained stable rosettelike structures constructed of melamine and barbituric acid units held together by strong hydrogen bonds. The nanotubular assemblies prepared by Ghadiri et al.[4] are another beautiful example of hydrogen-bonded assemblies. Dative bonds to transition metals can also be employed in self-assembly. Lehn et al. have applied the coordination of oligopyridines to transition metals to form triple helices, ladder polymers, and molecular grids.[5] Previously, we have described the self-assembly of small aggregates and ribbonlike polymers using the uranyl cation.[6] In this paper we describe the synthesis of metallodendrimers by controlled assembly.

Dendrimers are attractive, nanosize compounds with very specific architectures.[7, 8]] Dendrimers can be synthesized by following either a convergent or a divergent route,[9] in which an increasing number of new covalent bonds are formed in each generation. A few dendrimers containing transition metals have been reported.[10] Van Koten et al.[11] have used metalated dendrimers as homogeneous catalysts. Balzani and co-workers reported the synthesis of metallodendrimers containing transition metals in every generation, which relied on sequential reactions on the metal centers and protection/deprotection of ligands.[12] In contrast, Achar and Puddephat built dendrimers by oxidative additions to Pt^{II} complexes.[13]

We have recently described the synthesis of large organopalladium spheres by "genuine" self-assembly.[14] Now we report here that we can control this process and use this method for the synthesis of first-, second-, and third-generation metallodendrimers. Our approach is based on controlled assembly of building blocks that contain all the necessary information. We make use of the coordination chemistry of Pd^{II} and have combined in building block **BB-Cl** two kinetically inert tridentate "pincer-type" ligands and one labile coordinating cyano group (Scheme 1). The nucleus $\mathbf{G_0}$ has in this case C_3 symmetry with three Pd centers.

The temporary protection of the metal center by a strongly coordinating Cl^- ion prevents coordination by cyano groups. Further growth of Pd complex $\mathbf{G_0}$ is achieved by replacing the Cl^- ion for a noncoordinating BF_4^- ion, by reaction with $AgBF_4$. Subsequent addition of three equivalents of the protected building block **BB-Cl** yields the next generation dendrimer $\mathbf{G_1}$. By repeating this sequence twice it is possible to build the third-generation metallodendrimer $\mathbf{G_3}$.

The synthesis of **BB-Cl** and $\mathbf{G_0}$ is outlined in Scheme 2. The S-C-S pincer ligand was prepared in seven steps from dihydroxy-

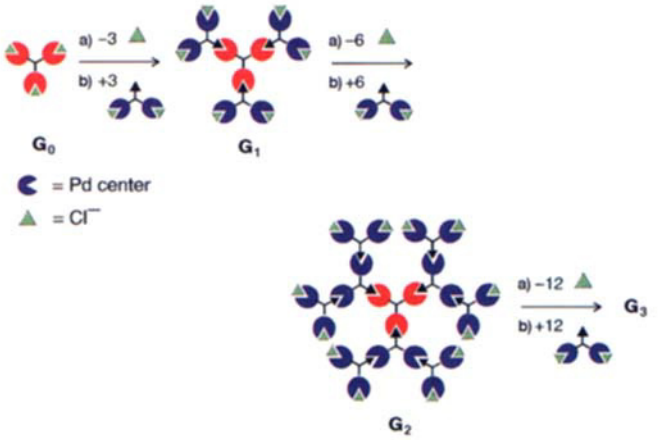

Scheme 2. Synthesis of dendrimer building blocks.

isophthalic acid.[14] The pincer ligands were coupled to a tribromomesitylene spacer to afford the nucleus $\mathbf{L_2}$, or to dibromomonocyanomesitylene to yield the dendrimer building block $\mathbf{L_1}$. Simple cyclopalladation of $\mathbf{L_1}$ and $\mathbf{L_2}$ with $[Pd(CH_3CN)_4(BF_4)_2]$[15] gave in quantitative yield the bis- and trispalladium complexes, which were directly converted into the chloride complexes **BB-Cl** and $\mathbf{G_0}$, respectively, by stirring with aqueous NaCl. The palladation is quantitative and occurs exclusively at the position activated by both S donor atoms, as can be deduced from ^{1}H NMR spectroscopy. A broad singlet at $\delta = 4.4$ for the CH_2S protons reflects the slow conformational interconversion of the five-membered Pd cycle, and the absence of a singlet at $\delta = 6.85$ indicates complete cyclopalladation. After purification by column chromatography (silica gel, eluting with CH_2Cl_2/MeOH 97/3) **BB-Cl** and $\mathbf{G_0}$ were obtained in yields of 70 and 40%, respectively.

Nucleus $\mathbf{G_0}$ was activated by stirring with three equivalents of $AgBF_4$ in CH_2Cl_2/nitromethane (1/1), and three equivalents of **BB-Cl** were added to form the assembly $\mathbf{G_1}$. Repeating the same procedure yielded in a very simple way metallodendrimers $\mathbf{G_2}$ and $\mathbf{G_3}$. These complexes were purified by filtration over hyflo and column chromatography (silica gel reversed phase, eluting with nitromethane) to remove the precipitated silver chloride. The yellow-colored metallodendrimers were obtained as a single fraction in quantitative yield after chromatography. The synthesis of an nth generation metallodendrimer is a one-pot procedure, because intermediate generations need not be isolated. The assembly process is controlled by the repetitive addition of $AgBF_4$ and **BB-Cl**. Dendrimers $\mathbf{G_1}$–$\mathbf{G_3}$ were fully characterized by ^{1}H and ^{13}C NMR and FT-IR spectroscopy,[16] electrospray mass spectrometry (ES-MS), and elemental analysis (Table 1).

The ^{1}H NMR spectra of $\mathbf{G_1}$–$\mathbf{G_3}$ are remarkably simple because of the high symmetry of the nucleus and the similarity of the building blocks. The formation of the desired compounds can be deduced from the ratios of the intensities of the signals of the CH_2CN and CH_2O protons, which is 1:3 for $\mathbf{G_1}$, 3:7 for $\mathbf{G_2}$, and 1:2 for $\mathbf{G_3}$. The signals in the ^{1}H NMR spectrum of $\mathbf{G_3}$ show some broadening, indicating the restricted motion of the inner generations. The ^{13}C NMR spectra show no shifts on going from $\mathbf{G_0}$ to $\mathbf{G_3}$.[17]

Molecular masses were determined by ES-MS. The transformed ES mass spectra (Fig. 1)[18] show signals at m/z 1516.2

Table 1. Selected physical data for $\mathbf{G_0}$–$\mathbf{G_3}$.

$\mathbf{G_0}$: M.p. 164–166 °C; ^{1}H NMR ($CDCl_3$): δ = 7.81 (m, 12H; Ar_5H), 7.39 (s, 3H; ArH), 7.35 (m, 18H; Ar_5H), 6.63 (s, 6H; $Ar_{Pd}H$), 4.93 (s, 6H; CH_2O), 4.53 (br. s, 12H; CH_2S); ^{13}C NMR ($CDCl_3$): δ = 156.5, 150.2, 137.7, 132.3, 131.4, 129.8, 129.7, 109.2, 69.8, 51.7; ES-MS: m/z: 1516.2 $[M-Cl]^+$. Analysis: calcd for $C_{69}H_{57}O_3S_6Pd_3Cl_3 \cdot H_2O$: C 52.78, H 3.79; found: C 52.51, H 3.70.

$\mathbf{G_1}$: M.p. 154–157 °C; ^{1}H NMR (CD_3NO_2): δ = 7.63 (m, 36H; Ar_5H), 7.45 (s, 3H; ArH), 7.40 (s, 9H; ArH), 7.29 (m, 54H; Ar_5H), 6.62 (s, 18H; $Ar_{Pd}H$), 4.93 (s, 18H; CH_2O), 4.49 (br. s, 36H; CH_2S), 3.78 (s, 6H; CH_2CN); ^{13}C NMR (CD_3NO_2, 80 °C): δ = 153.1, 147.0, 145.8, 134.9, 128.3, 127.9, 126.4, 125.8, 106.1, 46.2, 19.8; ES-MS: m/z: 4759.5 $[M-2Cl-2BF_4]^+$. Analysis calcd for $C_{219}H_{177}B_3N_3O_9F_{12}S_{18}Cl_6Pd_9 \cdot CH_3NO_2$: C 51.47, H 3.58, N 1.11, Cl 4.20; found: C 51.99, H 3.74, N 1.33, Cl 4.09.

$\mathbf{G_2}$: M.p. 148–152 °C; ^{1}H NMR (CD_3NO_2): δ = 7.75 (m, 84H; Ar_5H), 7.4 (m, 156H; ArH), 6.75 (s, 42H; $Ar_{Pd}H$), 5.00 (s, 42H; CH_2O), 4.54 (br. s, 84H; CH_2S), 3.89 (s, 18H; CH_2CN); ^{13}C NMR (CD_3NO_2, 80 °C): δ = 153.1, 147.0, 145.8, 134.9, 128.2, 127.9, 126.5, 125.8, 122.8, 106.1, 66.2, 46.2, 19.8; ES-MS: m/z: 11907.0 $[M]^+$. Analysis calcd for $C_{519}H_{426}B_9N_9O_{21}F_{36}S_{42}Cl_{12}Pd_{21} \cdot 2CH_3NO_2$: C 51.99, H 3.62, N 1.29, Cl 3.53; found: C 51.74, H 3.75, N 1.86, Cl 3.16.

$\mathbf{G_3}$: M.p. 139–142 °C; ^{1}H NMR (CD_3NO_2): δ = 7.7 (m, 180H; Ar_5H), 7.5 (m, 336H; ArH), 6.8 (s, 90H; $Ar_{Pd}H$), 5.0 (s, 90H; CH_2O), 4.5 (br. s, 180H; CH_2S), 3.9 (s, 42H; CH_2CN); ^{13}C NMR (CD_3NO_2, 80 °C): δ = 153.1, 147.0, 145.8, 134.9, 128.2, 127.9, 126.5, 125.8, 122.8, 106.1, 66.2, 46.2, 19.8; ES-MS: m/z: 24032 $[M-19BF_4]^+$. Analysis calcd for $C_{1119}H_{918}B_{21}N_{21}O_{45}F_{84}S_{90}Cl_{24}Pd_{45} \cdot 10CH_3NO_2$: C 51.16, H 3.60, N 1.74, Cl 3.22; found: C 51.16, H 3.61, N 2.22, Cl 3.21.

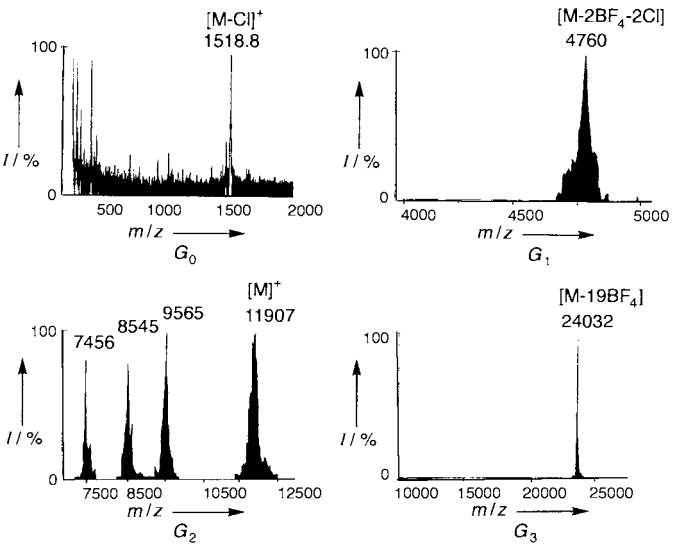

Fig. 1. ES mass spectra for $\mathbf{G_1}$–$\mathbf{G_3}$.

($[\mathbf{G_0} - \mathrm{Cl}]^+$), 4783.5, ($[\mathbf{G_1} - \mathrm{Cl} - 2\,\mathrm{BF_4}]^+$), 11907.0 ($[\mathbf{G_2}]^+$) and 24030.2 ($[\mathbf{G_3} - 19\,\mathrm{BF_4}]^+$). The loss of anions takes place inside the mass spectrometer, generating the multiply charged ions needed for detection and calculation of the molecular weight.[19]

Molecular mechanics calculations[20] were performed on $\mathbf{G_0}$–$\mathbf{G_3}$. The square-planar coordination environment of the Pd centers is well preserved. It is clear that after the second generation the structure of the dendrimer becomes quite entangled (Fig. 2).

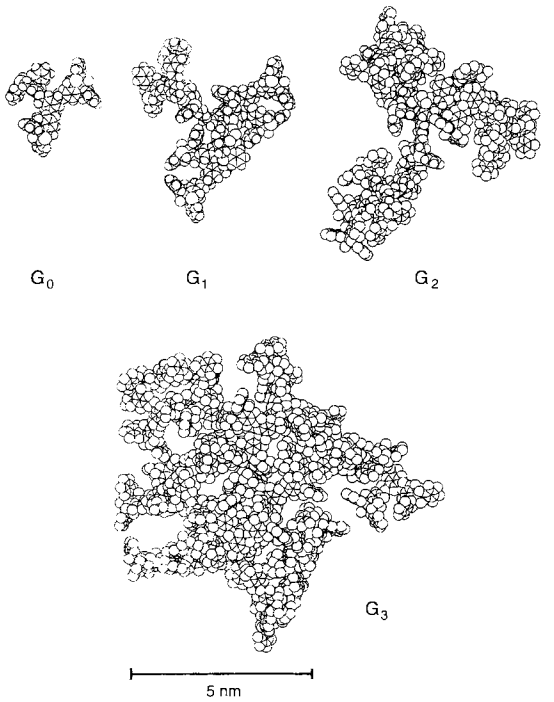

Fig. 2. Optimized structures of $\mathbf{G_0}$–$\mathbf{G_3}$.

We have shown that organometallic structures of nanometer dimensions can now be constructed in a very simple and controlled way. This method of controlled assembly provides a new and versatile tool for dendrimer synthesis. The method allows large variation in the metal in each generation, the coordinating ligands, and the structure of the nucleus.

Molecular Boxes Based on Calix[4]arene Double Rosettes**

Remko H. Vreekamp, John P. M. van Duynhoven, Martin Hubert, Willem Verboom, and David N. Reinhoudt*

The construction of noncovalently bonded, well-defined aggregates has received increasing attention over the last few years. The study of molecular self-assembly is expected to provide information on how interactions between molecular functionalities lead to entities with new shapes and functions. The shapes of recently described ensembles range from boxes[1, 2] and channels[3] to more complex three-dimensional networks and other discrete aggregates.[4–6] Reported molecular boxes based on noncovalent interactions all have rather small cavities, since they result from the dimerization of two molecules with concave structures.[2] Recently we prepared receptors with large hydrophobic cavities by the covalent combination of calix[4]arenes and resorcin[4]arenes.[7] The successful synthesis

of these molecules indicates that calix[4]arene[8] is a suitable molecular building block for the construction of molecular boxes because it offers a rigid concave surface.

In this communication we describe the formation of large self-assembled boxes, which have a "double-rosette structure". The calix[4]arene skeleton[9] serves as a spacer between the two rosettes and as molecular platform that preorganizes the hydrogen bonding groups. This spacer ensures that the centers of the two rosettes are separated by as much as 8.5 Å (based on CPK molecular models).[10] The formation of the hydrogen-bonded rosette is the result of hydrogen bonding between melamine moieties and barbituric or cyanuric acid derivatives. This motif is being studied intensively by Whitesides et al.,[11] and recently Lehn et al. have also used this motif for self-assembly.[12]

We have used three different calix[4]arenes as components for the double rosettes: the dimelamine derivative **1**, upper-rim substituted isocyanuric acid derivative **2**, and the lower-rim substituted isocyanuric acid derivative **3**.[13]

^{1}H NMR titration of **1** with diethylbarbituric acid (BA) in $CDCl_3$ showed several characteristic features (Fig. 1). Very interestingly, already at low concentrations of BA two signals (a, b) were evident at very low field.These resonances, which remain at δ = 14.10 and 13.32 regardless of the **1**:BA ratio, are assigned to the hydrogen-bonded NH protons of BA in the **1**·BA complex. When the amount of barbituric acid is increased, the signal corresponding to the NH_2 protons of free **1** decreases in intensity but remains at the same position. At the same time, signals at δ = 8.37 (c) and 7.43 (d) appear, which correspond to the two secondary amine protons of **1** in the hydrogen-bonded complex. At a ratio of **1**:BA of 1:2 the spectrum is sharp, which indicates the absence of free **1**. The 1:2 ratio is consistent with the double-rosette structure schematically represented in Figure 2. Dilution of this solution did not give rise to changes in the ^{1}H NMR spectrum, indicating that the

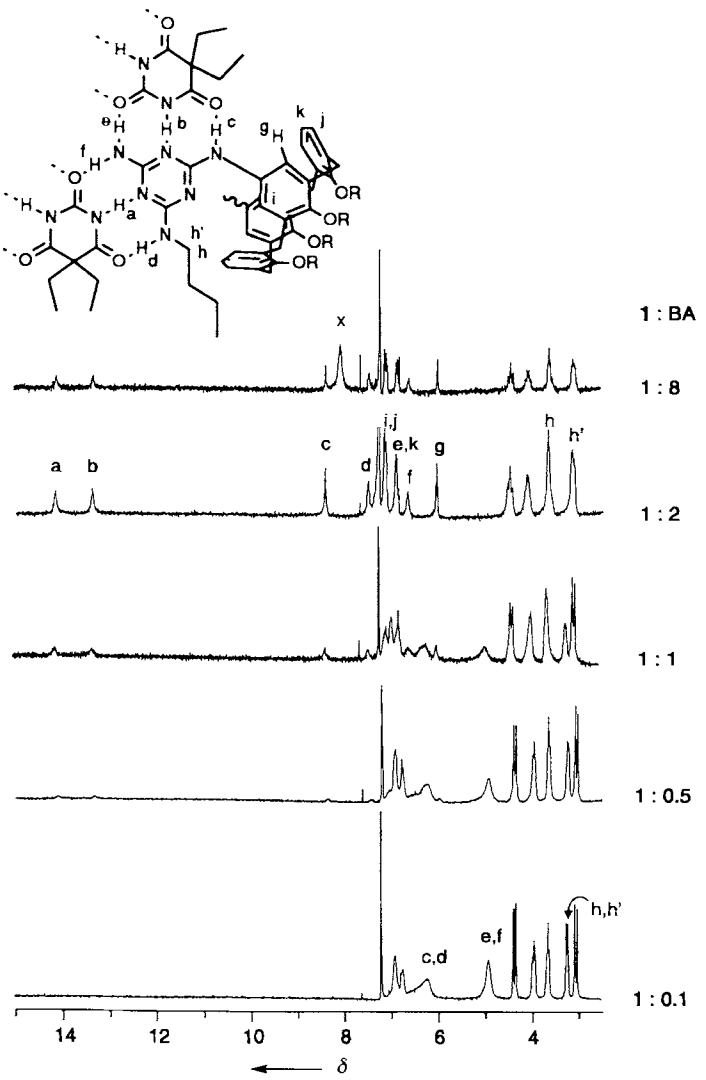

Fig. 1. ^{1}H NMR titration of **1** with BA measured at 400 MHz at ambient temperature. Separate 10 mM solutions of **1** and BA in $CDCl_3$ were mixed in various ratios. x = signal for the free acid.

presence of high-order aggregates is less probable. When more than two equivalents of barbituric acid are present, the signal for the NH protons in free BA is observed alongside the two for the hydrogen-bonded BA. This indicates that exchange between hydrogen-bonded and free BA is slow on the NMR time scale.[15] In the rosette the two NH protons are observed at different chemical shifts as a result of the unsymmetrical substitution of the melamine units. Two signals are observed for both the two NH_2 protons (e, f) and for the two protons of the *n*-butyl chain next to the nitrogen (h, h'), indicating diastereotopicity.[16]

The aromatic protons of the melamine-substituted aromatic ring of calix[4]arene **1** give rise to signals at δ = 7.15 (i) and 6.03 (g). In free **1** these protons display broad signals at δ = 7.05–6.70 and 6.65–6.05, respectively. The resonance at δ = 6.03 is in accordance with a pinched *cone* structure[17] in which the two melamines approach each other.[18]

Titration of **1** with **2** gave similar results. Large downfield shifts are observed for the NH protons (δ = 15.43 and 14.15), free and hydrogen-bonded species do not exchange on the NMR time scale, and a 1:2 ratio is indicated. At ratios beyond 1:2 (i.e. excess **1**) only signals corresponding to the saturated double

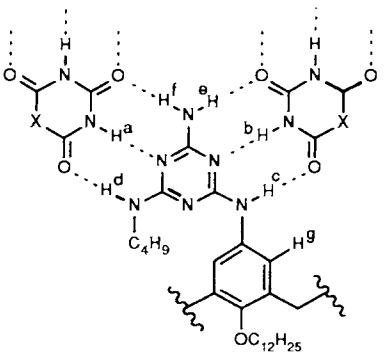
[a] Deviation ±0.1 Å.



rosette and free 1 are observed. No other signals are present at low field, in particular, which means that no intermediate structures such as partly filled double rosettes or linear aggregates exist. This suggests that rosette formation as depicted in Figure 3 is a cooperative process, in which the formation of one rosette preorganizes the remaining units, favoring the formation of the second rosette.

The ^{1}H NMR titration of **1** with **3** was, to a certain extent, similar to that of **1** with BA. The hydrogen-bonded NH protons were observed at slightly higher field ($\delta = 15.17$ and 14.47). At a **1**:**3** ratio of 1:2 the signals of free **1** disappear, indicating the formation of a double rosette.[19]

The distances between the relevant protons in the three double-rosette structures were determined by 2D NOESY experiments (400 MHz) using the initial rate approximation (Table 1).[20, 21] The distances are slightly larger than those obtained from CPK molecular models and molecular modeling of similar hydrogen-bonding motifs,[22, 23] but provide sufficient evidence for the proposed rosette structure.

The above results strongly indicate the formation of rosettes.[24] Further evidence for the formation of the rosettes was derived from build-up curves measured for the NOE interactions between the methylene bridge protons. From these data cross relaxation rates can be derived, the magnitude and sign of which relate to the rotation correlation time τ_c. If the random isotropic tumbling of a spherical molecule/aggregate and the absence of internal motion are assumed, τ_c can be related to the hydrodynamic volume.[23, 25, 26] By using the initial rate approximation, the cross relaxation rates for the methylene bridge protons of the three aggregates together with those for the free **3** and **1** were determined, and from these values the corresponding τ_c values were calculated. Generally, the τ_c values increase as the expected molecular masses of the aggregates increase. Qualitatively a good correlation is present with the curve of the calculated τ_c values (Fig. 4).[27]

The absolute deviations between the calculated and experimental values are most likely caused by the uncertain assumptions regarding density and shape. Assumptions regarding shape are not likely to hold for the somewhat flattened double rosettes. It is known that a greater ellipticity of a molecule leads to a larger effective correlation time, which correlates to a larger apparent molecular weight.[28]

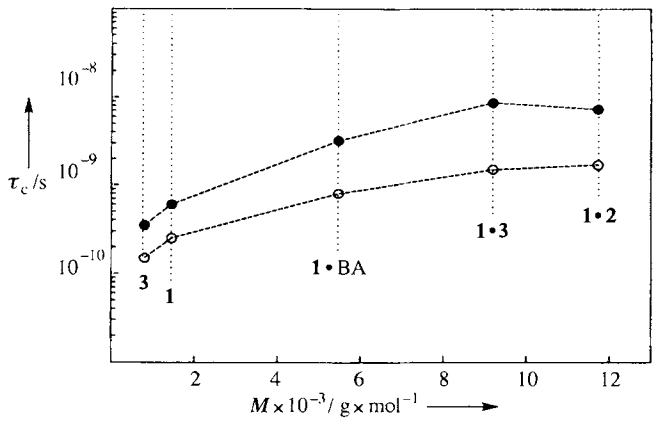


Fig. 4. Rotation correlation times τ_c determined from cross relaxation constants as a function of the molecular weights of the species in question. ● = experimental (400 MHz, 25 mM in $CDCl_3$); ○ = theoretical.

In conclusion, strong indications for the formation of the calix[4]arene-based double-rosette structure from three different combinations of bis(melamine)calix[4]arene and isocyanuric acid derivatives were obtained from ^{1}H NMR titrations and from the distances determined by NOE spectroscopy between the protons involved in hydrogen bonds. The results are in accordance with the expected 1:2 stoichiometry and suggest that the formation of the double rosettes is a highly cooperative process. In addition measurements of cross relaxation rates give further support for the formation of the large entities; the formation of aggregates is reflected by an increase in rotation correlation times. We feel that the determination of cross relaxation rates provides a valuable tool for the characterization of supramolecular structures in general. Future work will focus on complexation of guests, control of the cavity size and openings, and the introduction of chemical functionalities.

[13] Calix[4]arene **1** was synthesized in five steps starting from de-*tert*-butylated calix[4]arene in an overall yield of 19%. The reactions include alkylation of the lower rim, selective nitration of the upper rim [14] followed by reduction to the diamine, and reaction with cyanuric chloride, ammonia, and finally *n*-butylamine. The first four steps of the synthesis of **2** are very similar to those of the synthesis of **1**. Mononitrated de-*tert*-butylated calix[4]arene was reduced to the monoamine. Subsequent reaction with nitrobiuret gave the biuret derivative, which was converted to the isocyanuric acid by treatment with diethylcarbonate to give pure **2** in an overall yield of 22%. The synthesis of **3** started with monoalkylation of *p*-*tert*-butylcalix[4]arene with 2-bromoethylphthalimide. The resulting phthalimido derivative was quantitatively reduced to the monoamine, which was then reacted with nitrobiuret. Subsequent reaction with diethylcarbonate gave the pure monoisocyanuric acid **3**. All new compounds were fully characterized by ^{1}H NMR and ^{13}C NMR spectroscopy, FAB mass spectrometry, and elemental analysis.

[15] From the large difference in chemical shifts for free and complexed BA (Fig. 1) an upper limit for the dissociation rate constant of about 2000 s^{-1} can be estimated. Assuming that the formation rate constant is diffusion limited, an overall binding constant of $\geq 10^5$ M^{-1} can be estimated.
[16] For the assignment of the signals of **1**·BA and the other assemblies discussed in this paper NOE, ROE, and J-correlation spectroscopy were used.
[17] "Pinched" means that two opposite aromatic rings become almost parallel while the other two twist outward and "flatten" the calix.
[18] The rosette is also stable in acetonitrile and toluene; however, addition of > 10% DMSO or MeOH to a $CDCl_3$ solution resulted in slow decomposition.
[19] In this case probably higher aggregates are formed as a result of hydrogen bonding between free **3** and the hydroxyl groups of **3** in the aggregate when more than two equivalents of **3** are present. This was concluded from the appearance of new signals in the ^{1}H NMR spectrum.

[26] The hydrodynamic volume is related to the molecular mass via the density ρ. Equation (a) is used to determine τ_c. This equation expresses the relationship

$$\sigma_{12} = \frac{1}{10}\left(\frac{\mu_0}{4\pi}\right)^2 \frac{\gamma^4\hbar^2}{r^6}\left\{\frac{6\tau_c}{1+4\omega^2\tau_c^2} - \tau_c\right\} \qquad \text{(a)}$$

between τ_c and the cross relaxation constant, σ_{12}, for a two-spin system involving atoms 1 and 2. Isotropic tumbling and pure dipole–dipole relaxation are assumed. μ_0 = dielectric constant, γ = gyromagnetic constant, r = distance between atoms 1 and 2, ω = Larmor frequency.
[27] For these calculations the following values were substituted in the Stokes equation: T = 303 K; η_0 = 0.514 cP.

Binuclear Lanthanide Complexes as Catalysts for the Hydrolysis of Bis(*p*-nitrophenyl)-phosphate and Double-Stranded DNA**

Kaliappa G. Ragunathan and Hans-Jörg Schneider*

The catalysis of phosphate ester hydrolysis is of particular interest from two diametric points of view. The formation and cleavage of these ester linkages in nucleic acids are among the most important molecular functions in living systems. At the same time, as chemical warfare agents phosphate esters are the most disastrous inventions of synthetic chemistry; however, it is often forgotten that as insecticides the related aryl phosphates have saved the lives of millions of people. The present communication addresses the hydrolysis of both kinds of esters catalyzed by binuclear metal complexes.

Recent work in particular by Breslow,[1] Komiyama,[2] Morrow,[3] Chin,[4] and their collaborators has shown that highly charged cations, in particular of lanthanides, can greatly accelerate phosphate hydrolysis.[5] Our own efforts are directed primarily towards the development of ligands that form sufficiently stable complexes and enhance the catalytic activity of these lanthanide complexes.[6] The presence of several metal ions, both in enzymes as well as in synthetic analogs, is known to enhance rates of hydrolysis substantially.[7] In very recent studies with carefully designed binuclear zinc complexes Chapman and Breslow[8] have demonstrated how the catalytic efficiency depends critically on the distance between the metal centers and the conformation of the spacer. However, the rate of hydrolysis[9] for UpU as a DNA model was enhanced only by a factor of 2, and for bis(*p*-nitrophenyl)phosphate (BNPP) the rate enhancement factor was around 12.[8] In other recent reports the application of binuclear complexes having peroxo ligands,[10] zinc complexes for the hydrolysis of dinucleotides,[11] and intramolecular metal complexes[12] for the hydrolysis of phosphonates have been described. With binuclear complexes based on imidazoles, Trogler et al.[13] found a ligand rate factor[9] of only 2 for BNPP hydrolysis; in studies with double-stranded DNA binding but no cleavage was observed. We describe here binuclear lanthanide systems that lead to ligand rate factors[9] of up to 72 for the hydrolysis of BNPP and to dramatic enhancements for the cleavage of plasmid DNA.

Ligands **1**–**4** were synthesized according to literature procedures[14] and treated with two equivalents of Eu^{3+} or Pr^{3+} salts in anhydrous methanol. The complexes with nitrate ions were insoluble in methanol and precipitated immediately from the reaction mixture; the complexes with chloride ions were soluble in methanol and were precipitated by slow addition of acetonitrile. The washed precipitates were generally analytically pure. The elemental analyses and titrations of the complexes with EDTA (the complexes were dissolved in water at pH 2; the pH was then increased to 5.2) indicate that all of the solid complexes contain two metal ions. Unfortunately, the complexes with ligands **1** and **2**, containing the more lipophilic benzene rings, were water-soluble only as nitrate salts, which makes comparison to the more reactive chloride salts with **4** difficult. Nitrates are known to form particularly stable complexes with lanthanides.[15] This might be one explanation for the lower, yet still remarkable rate enhancements for BNPP hydrolysis obtained with Pr^{3+} complexes (Table 1, Scheme 1). The rate enhancement factor of 72 observed with Pr_2^{3+}·**4** indicates that the metal centers should have a certain separation; complexes with ligands **1**–**3** have a smaller distance between the metal binding sites and lead to only moderate rate enhancements at best. In line with the report of Chapman and Breslow[8] such a separation seems to be necessary for simultaneous electrostatic stabilization of the bound phosphate group at one end of the complex and activation of water at the other.[16]

The analysis of the reaction kinetics (van't Hoff method, second-order kinetics) indicates that the catalysis arises from the action of *two* metal ions in the transition state. A plot (Fig. 1) of lg v versus lg [M] at constant ligand concentration, where v is the initial rate (measured at $<10\%$ conversion) and [M] is the metal

Table 1. Summary of the results of phosphate ester and DNA hydrolysis catalyzed by lanthanide complexes.

Macrocycle	F for BNPP [a]		DNA cleavage [% RF II] [b]

	1 [d]	1 [d]	46	42

[a] Efficiency of binuclear complexes for the hydrolysis of BNPP is given as $F = k_{M_2L}/k_M$ from rates at 1 mM [M_2L] and 2 mM [M]; [BNPP] = 3.35×10^{-5} M; $T = 50$ °C; *N*-(2-hydroxyethyl)piperazine-*N'*-propane sulfonic acid (EPPS) buffer (0.01 M), pH 7.0. The hydrolysis was followed by UV-Vis spectroscopy by measuring the increase in absorbance at 400 nm due to the release of *p*-nitrophenol during hydrolysis. [b] Cleavage of double-stranded DNA is given as the percent of the open circular form RF II after correction for the amount of this form in the starting sample of DNA; incubation for 2 h at 37 °C with plasmid DNA (pBR322; concentration 1.95×10^{-5} per base pair), [M_2L] = 1×10^{-3} M or [M] = 2×10^{-3} M; EPPS buffer (0.01 M), pH 7.0. The solutions of the metal complexes were prepared by dissolving the freshly prepared complexes in dimethyl sulfoxide (5% DMSO in the final solution), adding buffer, and adjusting the pH. The macrocyclic polyamines inhibit the migration of DNA in the gel electrophoresis; this was overcome by using ion exchange resins as previously reported [6b]. Densitometry after electrophoresis showed, in double determinations, average deviations of $\pm 2.5\%$. [c] Without ligands. [d] Relative rate = 1; absolute rate k with $EuCl_3$ is 6.0×10^{-3}, with $PrCl_3$ 7×10^{-4} min^{-1}.

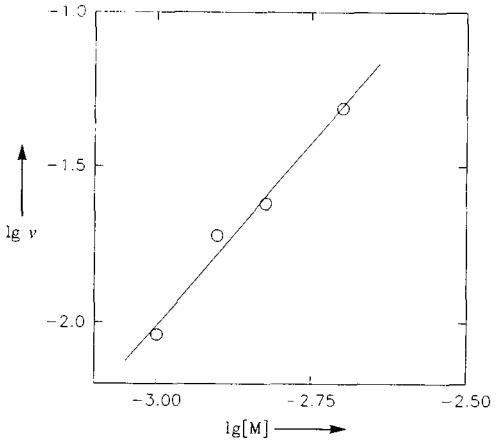

Fig. 1. Plot of lg v (from initial rate v of BNPP hydrolysis at $<10\%$ conversion, [BNPP] $=7\times10^{-5}$ M) versus lg[M], where [M] = [Pr^{3+}] at constant concentration of ligand **4** (1 mM). The concentration of the metal was varied between 1 and 2 mM. Observed slope $=2.3\pm0.2$. For details on the preparation of the metal complexes see text, footnotes in Table 1, and ref. [17].

concentration (between 1 and 2 mM), gives a line with a slope of 2 within experimental error. This treatment neglects the (small) contributions of free metal ions and mononuclear complexes. The van't Hoff plot (Fig. 1) proves that *two* metal ions are involved in the rate-determining step. Spectroscopic or other methods that indicate a 2:1 complex in the solid state or in solution are not conclusive, as the catalytically active complex could be thermodynamically less favorable. Alternative explanations for the observed van't Hoff slope of 2 could be the participation either of two free cations or—even more unlikely—of a single ion complex ML and a free M cation. The first alternative is excluded by the clean first-order reaction observed with uncomplexed lanthanide ions[6a] and by the 72-times slower reaction with the metal cation alone. The second alternative is excluded by the fact that the reaction catalyzed by a 1:1 complex in the presence of an equimolar amount of free Ln^{3+} ions is five times slower than that catalyzed by the 2:1 complex. The 1:1 complex was prepared from equimolar amounts of Ln^{3+} and the ligand in water instead of methanol. The complexes with varying metal content were prepared by mixing L and M in methanol (dried over magnesium methanolate), which was then was removed at 40 °C, and then dissolving the residue in water. The slow rates of complex formation require special conditions in all cases.[17] When EDTA is added (1 mM in the final solution) the reaction rate decreases by about 70% within minutes; with 2 mM EDTA no reaction is observed. This indicates that the complexes are not stable to exchange with EDTA, in line with similar findings by Morrow et al.[18]

Surprisingly, the activity of the complexes of **1**–**4** with plasmid DNA follows the same sequence as that with BNPP, although the nitrophenolate leaving group could lead to a change of mechanism.[19] After the reaction of plasmid DNA with $Pr_2^{3+}\cdot$**4**, electrophoresis and densitometry indicates that single cleavage of form RF I yields 80% of the open circular form RF II (after correction for the RF II form present in the starting material). Visual inspection of the gels shows only form RF II as the cleavage product (Fig. 2). This is to our knowledge the highest proportion of hydrolytic cleavage yet reported for plasmid DNA. In contrast to radical cleavage processes no further cleavage products such as the linear form RF III are apparent in the agarose gels (Fig. 2).[20] That the cleavage occurs by hydrolysis like that with enzymes is furthermore in line with the recent observations of Chin et al.[10] and Komiyama et al.[2b] Even

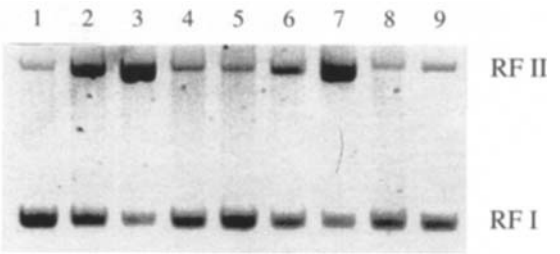

Fig. 2. Electrophoresis gel demonstrating cleavage of double-stranded DNA after 2 h. For conditions see the footnote [b] in Table 1. Lane 1: DNA alone; lane 2: DNA and Eu^{3+}; lane 3: DNA and $Eu_2^{3+}\cdot$**4**; lane 4: DNA and $Eu_2^{3+}\cdot$**2**; lane 5: DNA and $Eu_2^{3+}\cdot$**1**; lane 6: DNA and Pr^{3+}; lane 7: DNA and $Pr_2^{3+}\cdot$**4**; lane 8: DNA and $Pr_2^{3+}\cdot$**2**; and lane 9: DNA and $Pr_2^{3+}\cdot$**1**.

redox-active Ce^{4+} ions act as hydrolytic catalysts. The fact that the rate of DNA cleavage is not accelerated when hydrogen peroxide is added[6b] also speaks against oxidative radical-based mechanisms.

We have shown[6b] that the cleavage of plasmid DNA by lanthanide ions after electrophoretic separation and densitometry is characterized by clean pseudo-first-order rate constants, which then may be used to derive Michaelis–Menten-*type* equilibrium and rate constants K_M and k_{cat}, respectively, from saturation kinetics. We applied the same procedures to study the cleavage of double-stranded DNA with the binuclear complexes prepared from ligand **4**. The observed rates with $Eu_2^{3+}\cdot$**4** and $Pr_2^{3+}\cdot$**4** showed the expected increase with catalyst concentration, but was limited by solubility problems at higher concentrations. The corresponding saturation curve for $Pr_2^{3+}\cdot$**4** (Fig. 3)

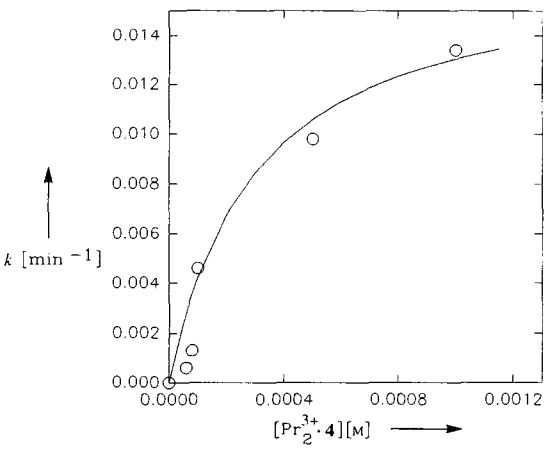

Fig. 3. Saturation kinetics of the cleavage of plasmid DNA by $Pr_2^{3+}\cdot$**4**. The theoretical curve corresponds to $K_M=3.3\times10^{-4}$ M and $k_{cat}=1.7\times10^{-2}$ min^{-1}.

with K_M around 3×10^{-4} M and k_{cat} around 1.5×10^{-2} min^{-1} agree with values found with other lanthanide systems.[6b] The rate constant with $Pr_2^{3+}\cdot$**4** at 37 °C is approximately 2×10^6 times greater than that of the uncatalyzed hydrolysis of double-stranded DNA at 25° and pH 7.0, which was previously determined only very approximately.[21]

In conclusion, binuclear lanthanide complexes can accelerate the cleavage of double-stranded DNA by almost two orders of magnitude over that with metal ions alone. The structure of the ligands, in particular the distance between the metal centers, plays an important role. Unexpectedly, the trends observed with the different ligands are similar for hydrolysis of both activated nitrophenyl phosphates and plasmid DNA. The half-life of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3511-1220 $ 15.00+.25/0

BNPP is reduced from approximately 75 years[22] to as little as 8 min (with $Eu_2^{3+}\cdot$**4** at 50 °C and pH 7.0); that of double-stranded DNA from approximately 2000 years[21] to 50 min (with $Pr_2^{3+}\cdot$**4** at 37 °C and pH 7.0).

Efficient Synthesis of New 2-Cycloalk(en)ylpropanoic Acid Derivatives—Medium and Large Rings as Bioisosteres of Alkylphenyl Moieties?**

Björn Greve, Peter Imming,* and Stefan Laufer

Dedicated to Professor Gunther Seitz on the occasion of his 60th birthday

Ring systems with 9–12 (or 7–14) members are classed as medium-sized rings. They occur less frequently and are more difficult to prepare than five- and six-membered and large rings, and their applicability is restricted.[1] In an evaluation of two standard encyclopedias of chemistry and pharmacy[2] we found only 132 compounds with an eight-, 23 with a nine-, 26 with a ten-, 12 with an eleven-, 28 with a twelve-, and 6 with a thirteen-membered ring. Of these, 81% are natural products and 73% are heterocycles. In medicinal chemistry particular 9–12-membered lactams are of current interest as mimics of β-turns.[3] In this paper we introduce a new approach to the use of medium and large ring systems.

Medium-sized carbocycles can be seen as lipophilic "clusters" and should be bioisosteric to alkylphenyl moieties. In comparison to these they will bind more weakly to electrophilic protein side chains, but because of their conformative flexibility they should display better adaptation to binding domains of proteins.[4] Medium-sized carbocycles also provide a far more versatile framework than phenyl and "normal" rings (five- and six-membered rings) for the regio- and stereodefined attachment of substituents.

To test our concept we prepared compounds that are structurally derived from both arachidonic acid (**1**) (the physiological substrate of cyclo- (COX) and lipoxygenases (LOX)) and inhibitors of these enzymes[5] like 2-(alkylphenyl)propanoic acids (for example ibuprofen (**2**)). In the active site of the enzyme[6] and in solution[7] arachidonic acid adopts a bent conformation as shown. A substrate with a medium-sized ring should at least partly mimic the conformation of **1**.

We have developed a synthetic route to 2-cycloalk(en)ylpropanoic acids of the general formula **3** (MR = medio-/macro-

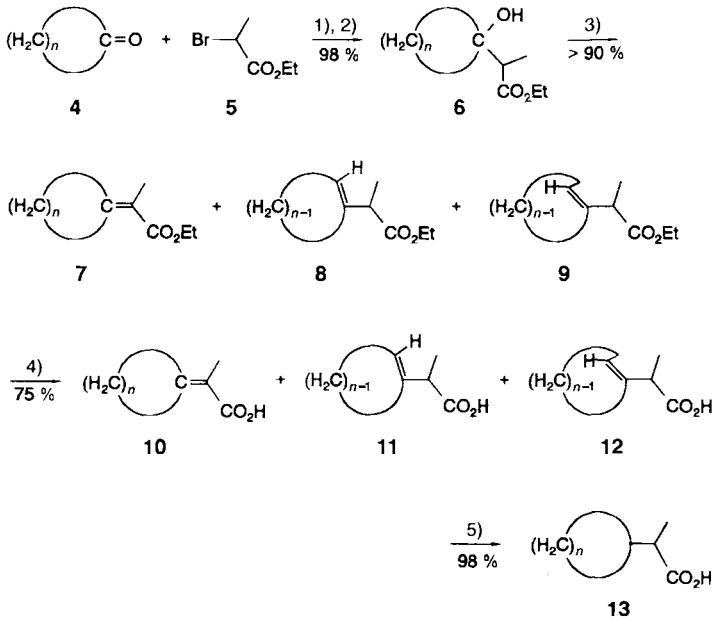
cycle), which leads to the desired compounds in excellent overall yield (Scheme 1). In the first step we treated cycloalkanones **4** with a modified Reformatsky reagent prepared from **5**. (This new type of reagent was developed several years ago.[8])



Scheme 1. Synthetic route to 2-cycloalk(en)ylpropanoic acid derivatives with $n = 4-12, 14$. 1) Zn, THF; CuCN, LiCl; 0/ − 50/0 °C. 2) THF; −78 °C to room temperature, 12 h. 3) *p*-TsOH, toluene; reflux; 48 h. 4) KOH/MeOH; room temperature; 24 h. 5) H_2 (3 bar), 10% Pd/C; 55 °C; 6 h.

Organozinc compounds, which had not been treated with medium-sized and larger cycloalkanones previously, were found to have excellent reactivity towards these ketones. Analogous reactions with other organometallic reagents, including organocerium compounds (where one has to use the more expensive alkyl iodides)[9] were not as satisfactory.

The subsequent water elimination proceeded almost regioselectively in the case of the medium-sized rings, yielding the endocyclic, nonconjugated olefins **8**. The introduction of two sp^2 centers in the ring is energetically more favorable than conjugation with the ester group. Through this, our study proves the applicability of H. C. Brown's I-strain (internal strain) concept,[10] which had been supported theoretically by a force-field analysis.[10b] After hydrolysis we isolated the pure (*E*) esters **11**, and after the final hydrogenation the carboxylic acids **13**.

Pharmacological tests[11] showed interesting differences in activities depending on ring size. Table 1 summarizes the test results. We did not measure significant activities up to a ring size of ten. The derivatives of cycloundecane, cyclododecene, and cyclopentadecene (**13a**, **11b**, and **11c**, respectively) inhibit COX-1 with about twice the activity of aspirin. In contrast to the cyclododecene derivative **11b**, the cycloundecene and cyclododecatriene derivatives, **11a** and **15**, respectively, inhibit 5-LOX more effectively than COX-1. (In the synthesis of **15** from **14**[12] we obtained

the (*E*,*E*,*E*) isomer with 100% *de*.) The almost equal inhibition of both enzymes by the saturated 11-membered and olefinic 15-membered rings **13a** and **11c** makes them promising candidates for the development of "dual action" antirheumatics, a very recent research strategy for the reduction of the gastrointestinal side effects of these drugs.[13] According to present knowledge, a further simultaneous inhibition of COX-2 would be advantageous though not sufficient for the suppression of the symptoms.[14] We thus regard our cyclopentadecene derivative **11c** to be a promising lead for the development of a mimic of arachidonic acid with a (medium) large ring that will have the desired activity profile.

We also prepared the derivatives **16** and **17**, which have a methylsulfonyl instead of a carboxyl function, in a similar fashion. The starting materials were dimethyl sulfone and cyclododeca(die)none. The methylsulfonyl group typical of COX-2 inhibitors[14a] led in our case to a strong decrease in activity towards 5-LOX and COX-1.

In summary, our work has shown for the first time that a differentiated inhibition of enzymes is possible with medium rings of various sizes and degrees of saturation. We propose that unsaturated medium-sized and larger carbocycles are bioisos-

teric to alkylphenyl moieties. This opens up extensive synthetic possibilities and offers a new approach to the rational application of medium-sized and larger carbocycles beyond medicinal chemistry.

Experimental Procedure

All new compounds gave correct analyses or high-resolutaion mass spectra.

6 ($n = 11$): To a suspension of 6.5 g (100 mmol) of zinc (activated with $SiMe_3Cl$ and dibromoethane) in 30 mL of anhydrous THF was added dropwise 9.1 g (50 mmol) of **5** at 0 °C. The ice bath was removed. After excess zinc had settled, the supernatant was transferred dropwise into a solution of CuCN·2 LiCl (50 mmol) in 100 mL of THF at −50 °C. The mixture was warmed to 0 °C, stirred for 30 min, and cooled to −78 °C. Then 8.2 g (45 mmol) of **4** ($n = 11$) was added. The mixture was allowed to warm to room temperature overnight and was worked up as described [8] to yield 12.6 g (98%) of a white solid, which was of sufficient purity for further transformations. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 4.10–4.04 (m, 2H), 3.18 (s, 1H), 2.37–2.32 (m, 2H), 1.62–1.53 (m, 2H), 1.34–1.10 (m, 24H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 178.3, 75.3, 61.0, 45.9, 35.0, 30.9, 27.0, 26.9, 26.6, 23.1, 23.0, 22.62, 22.56, 20.0, 19.6, 14.7, 12.3.

7/**8**/**9** ($n = 11$): A solution of **6** ($n = 11$) in toluene was heated to reflux with a catalytic amount of 4-toluenesulfonic acid for 48 h. After vacuum distillation (104–106 °C/1.8×10^{-2} Torr) we obtained the isomeric olefins in 93% yield. They were purified by chromatography on silica gel eluting with pentane/diethyl ether (8/2). **8**: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 5.21 (t, J = 8 Hz, 1H), 4.08–3.96 (m, 2H), 2.98 (q, J = 7 Hz, 1H), 2.13–1.91 (m, 4H), 1.48–1.10 (m, 22H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 175.1, 138.0, 127.3, 59.9, 43.8, 26.8, 26.3, 25.1, 24.7, 24.6, 24.5, 24.2, 23.8, 22.5, 22.1, 16.6, 13.9.

11b ($n = 11$): We obtained the compound in 74% yield after vacuum distillation (100 °C/1.8×10^{-2} Torr), by stirring 18 mmol of **8** in 18 mL of methanol with 30 mL of a 3 M methanolic KOH solution for 24 h; m.p. 69–70 °C (pentane). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 11.58 (s, 1H), 5.30 (t, J = 8 Hz, 1H), 3.04 (q, J = 7 Hz, 1H), 2.12–1.91 (m, 5H), 1.50–1.12 (m, 18H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 181.8, 137.8, 128.1, 43.9, 27.0, 26.7, 25.4, 24.93, 24.88, 24.87, 24.5, 24.1, 22.7, 16.7.

13b ($n = 11$): A 1 M solution of **11b** in ethyl acetate was hydrogenated for 6 h at 3 bar and 55 °C with 10% Pd/C catalyst. We isolated a 94% yield of a white solid, m.p. 46–48 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 11.04 (s, 1H), 2.45–2.28 (m, 1H), 1.79–1.77 (m, 1H), 1.39–1.18 (m, 22H), 1.03 (d, J = 7 Hz, 3H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 183.4, 42.3, 36.6, 27.1, 25.8, 24.5, 23.9, 23.7, 23.6, 23.2, 23.1, 22.3, 21.3, 13.4.

A Zirconium Bis(porphyrinate) Sandwich Complex with an Appended Quinone**

Gregory S. Girolami,* Christopher L. Hein, and Kenneth S. Suslick*

The development of our understanding of the chemical and physical properties of the photosynthetic reaction center (RC) has been greatly assisted by studies of synthetic analogs. For example, remarkably long-lived charge-separated states have been observed in synthetic porphyrin–quinone tetrads and pentads, and the physiological significance of chromophore orientation and donor–acceptor energetics in reaction centers has been addressed through studies of gable porphyrin dimers and porphyrin–quinone complexes, respectively.[1] The distinctive structural feature of the RC, however, is the closely stacked "special pair" of bacteriochlorophylls that act as the primary photoelectron donor; unfortunately, no model compounds to date feature such a closely spaced cofacial porphyrin dimer as the primary electron donor. Stacked porphyrin macrocycles constrained by rigid organic tethers do not closely resemble the special pair because their mean porphyrin–porphyrin separation is relatively large, typically 5 Å.[1, 2] Much better building blocks for synthetic analogues of the RC are bis(porphyrin) metal sandwich complexes in which the porphyrin–porphyrin separations are about 3 Å.[3] We now describe the first compounds that combine two key structural features present in the reaction center of photosynthetic organisms: a donor consisting of a cofacial arrangement of two porphyrinic macrocycles held about 3 Å apart, and a quinone electron acceptor.

We have previously developed a method to convert the sandwich complex $[Zr(TTP)_2]$ **1** (TTP = 5,10,15,20-tetra(*p*-tolyl)-porphyrinato dianion) to the amine-substituted bis(porphyrin) zirconium species $[Zr(TTP)(TTP\text{-}NH_2)]$ **2**, in which the amine group is attached to a β-pyrrole site on one of the porphyrin rings.[4, 5] In such bis(porphyrin) zirconium species, the two porphyrin rings are cofacial with an N_4 mean plane separation of

2.56 Å; the mean plane separation for all 24 atoms of the porphyrin is 3.28 Å. These strongly interacting porphyrin subunits closely resemble the "special-pair" of chlorophylls in the photosynthetic reaction center, both in their cofacial architecture and spacing and in their electronic properties.[3] Condensation of **2** with 2-(chlorocarbonyl)anthraquinone (**3**) (Scheme 1) in excess pyridine yields the quinone-derivatized bis(porphyrin) complex [Zr(TTP)(TTP-NHCOAQ)] **4** (Fig. 1).[6]

The UV/Vis spectrum of **4** contains a Soret band at 400 nm and several Q bands at 511, 557, and 696 nm; these values are essentially unchanged from those obtained for the parent complex **1** (Fig. 2). Holten et al.[7] have assigned the Q″ band at 511 nm to a charge-resonance state having a wavefunction described as $(A^+B^- + A^-B^+)/\sqrt{2}$, where A and B represent the two porphyrin rings. The absorption at 557 nm is ascribed to a "normal" metalloporphyrin Q band. The lowest energy absorption at 696 nm, called Q′, involves a π-π^* transition that is characteristic of all porphyrin dimers in which the macrocycles are separated by about 3 Å.[7] The anthraquinone unit absorbs strongly at 258 nm, and the features seen are again only slightly altered relative to those of 2-(phenylamidocarbonyl)-anthraquinone (**5**).

The cyclic voltammogram of the quinone-derivatized porphyrin complex **4** contains two oxidation and four reduction waves. The first two reduction waves involve the anthraquinone unit, while the third and fourth involve the bis(porphyrin) π-electron system, as judged from comparisons with the redox potentials of related species (Table 1). The oxidation potential of the porphyrin π-electron system in **4** is approximately 100 mV

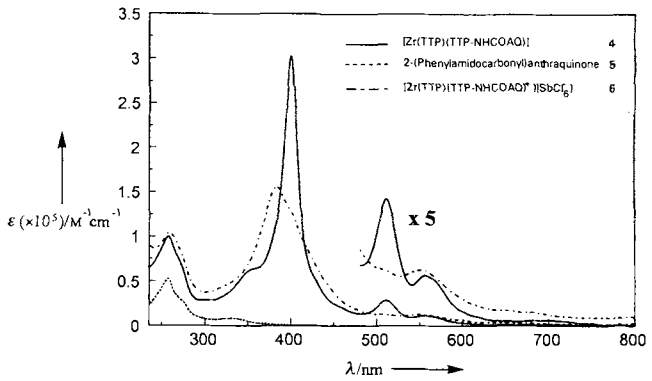

Fig. 2. UV/Vis spectra of complexes **4** and **6** and of quinone **5** in CH_2Cl_2.

Table 1. Electrochemical potentials of the zirconium bis(porphyrinate) sandwich complexes and of the quinone **5** [a].

Porphyrin compound	Porphyrin $Oxid_2$	Porphyrin $Oxid_1$	Quinone $Redn_1$	Quinone $Redn_2$	Porphyrin $Redn_1$	Porphyrin $Redn_2$
1	940	515			−1322	−1674
2	836	432			−1357	−1710
4	947	523	−819	−1265	−1363	−1678
5			−782	−1285		

[a] All potentials measured [mV] in CH_2Cl_2 vs Ag/AgCl. [nBu$_4$NPF$_6$] = 0.1 M. Scan speed = 100 mVs^{-1}. [$FeCp_2$] oxidation occurs at 493 mV under these conditions.

higher than that of the amine-substituted sandwich complex **2**. Furthermore, the reduction potentials for the anthraquinone substituent in **4** are shifted cathodically by about 40 mV relative to those seen for quinone **5**. These changes in the redox potentials suggest that the quinone substituent is electron-withdrawing. The reduction potentials of the porphyrin π-electron system in **4** remain nearly unchanged.

Oxidized dimeric porphyrins exhibit characteristic near-IR absorptions due to electronic transitions between bonding and antibonding molecular orbitals.[8] Treatment of **4** with phenoxathiinylium hexachloroantimonate[9] yields the $SbCl_6^-$ salt **6**

[Zr(TTP)(TTP-NHCOAQ)][SbCl$_6$] **6**

of the double-decker quinone monocation. Both chemical and electrochemical oxidation takes place from the porphyrin HOMO. The near-IR absorption band for **6** occurs at 1096 nm compared to that for $[Zr(TPP)_2]^+$ at 1075 nm.[8] Such electronic transitions are of particular interest since a broad transition (1300 nm) is also found for the special pair of bacteriochlorophyll-b, $[(BChl)_2]^+$.[10] Oxidation of the bis(porphyrin) π-electron system increases the extent of π-π overlap between the two porphyrin rings; consequently, the Soret band of **6** is shifted to higher energy (Fig. 2).[11]

We have also prepared the pyromellitimide-substituted bis(porphyrin) sandwich complex **7** by treatment of **2** with hexylamine and pyromellitic dianhydride (Scheme 2).[12] The mass spectrum confirms the presence of an *N*-hexyl-pyromellitimide group bound to the bis(porphyrin)ziconium core (m/z 1725). The UV spectrum of **7** shows absorptions due to the pyromellitimide substituent at 310 and 320 nm. Porphyrin–pyromellitimide complexes are ideal systems with which to study light-induced charge separation processes because reduced pyromellitimide absorbs strongly at 715 nm, a wavelength at which the bis(porphyrin) subunit is optically transparent.[12]

Until now, models of the photosynthetic reaction center have all relied on monomeric porphyrins as the electron donor. The

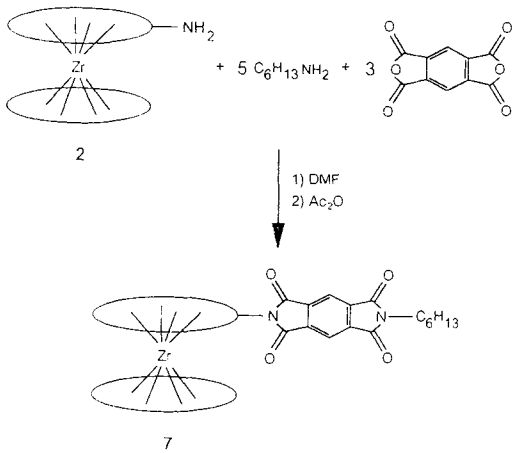

Scheme 2.

two new structural analogs of the reaction center presented here are the first in which an electron acceptor is attached to a porphyrin pair in which the porphyrin planes are held within 3 Å of each other. Comparisons of the electron transfer kinetics and the excited-state lifetimes of **4** and **7** with those of the reaction center are currently under investigation.[13, 14]

Experimental Procedure

4: A solution of **3** (64 mg, 0.24 mmol) in toluene was added dropwise to a suspension of **2** (140 mg, 0.097 mmol) in toluene and pyridine (2 mL), and the resulting mixture was stirred at room temperature for 2 d under Ar. The solvent was removed and the residue was extracted with CH_2Cl_2. The extract was purified by thin layer chromatography on silica plates with toluene as the eluting solvent ($R_f = 0.18$). Product **4** was then recrystallized by slow diffusion of hexane into a toluene solution at 25 °C. Yield : 104 mg (66%). Calcd. for [Zr(TTP)(TTP-NHCOAQ)]: C 79.4, H 4.75, N 7.51, Zr 5.44; found: C 79.2, H 4.66, N 7.59, Zr 5.31. IR (Nujol): $\tilde{\nu} = 1678\ cm^{-1}$ (C=O). UV Vis (CH_2Cl_2): λ_{max} (ε) = 258 (98000), 400 (295000), 511 (28000), 557 (11000), 696 nm (1300). ^1H NMR (CD_2Cl_2, 500 MHz, −80 °C): $\delta = 9.63-9.3$ (8 d, *o*-H), 9.30 (s, pyrr-H adjacent to AQ), 9.0 (br. s amido N-H), 8.74 (s, AQ H1), 8.49 - 8.45 (m, AQ H4-H8), 8.43--8.02 (14 d, pyrr-H), 8.01–7.62 (8 d, *m*-H), 7.88–7.82 (m, AQ H3), 7.09 -6.81 (8 d, *m'*-H), 6.34–5.88 (8 d, *o'*-H), 2.69–2.57 (8 s, *p*-CH_3). FAB MS (8 kV, 3-nitrobenzyl alcohol): *m/z* (%): 1676 (100) [M^+ + H].

6: Phenoxathiinylium hexachloroantimonate (34 mg, 0.064 mmol) was added to **4** (100 mg, 0.060 mmol) in CH_2Cl_2 (75 mL), and the resulting mixture was stirred for 1 h under Ar. The solution was concentrated to about 1 mL and crystals of the salt **6** were obtained by slow diffusion of toluene into the CH_2Cl_2 solution at −78 °C. Yield: 72 mg (60%). Calcd. for [Zr(TTP)(TTP-NHCOAQ)][$SbCl_6$]·0.5 CH_2Cl_2: C 65.2, H 3.92, N 6.13, Zr 4.44, Sb 5.92, Cl 12.1; found: C 64.6, H 4.01, N 6.08, Zr 4.35, Sb 6.01, Cl 11.8. IR (Nujol): $\tilde{\nu} = 1678$ (C=O), 1302 (cation marker band), 1292 cm^{-1} (cation marker band). UV/Vis NIR (CH_2Cl_2): λ_{max} (ε) = 259 (104000), 383 (156000), 554 (12000), 1096 nm (fwhm = 1300 cm^{-1}). EPR (95 K, 1:1 CH_2Cl_2:C-H_n): g = 2.0037, linewidth = 6.41 G. Electrospray ionization MS: 1675 [M^+], 2005, [$M$$SbCl_6^-$].

7: Pyromellitic dianhydride (11 mg, 0.05 mmol) was added to a mixture of **2** (15 mg, 0.01 mmol) and hexylamine (3 mg, 0.03 mmol) in *N,N*-dimethylformamide (DMF) (2 mL). The resulting mixture was heated to reflux for 12 h. The solvent was removed, acetic anhydride (2 mL) was added, and the mixture was allowed to reflux for 1 d. The solvent was removed and the resulting product **7** was purified by thin layer chromatography on silica plates ($R_f = 0.16$). Yield: 1 mg (6%). UV Vis (CH_2Cl_2): λ_{max} (ε) = 310 (117000), 319 (129000), 400 (295000), 511 (27000), 555 (13000), 689 nm (5000). FAB MS (8 kV, 3-nitrobenzyl alcohol): *m/z* (%): 1725 (30) [M^+ + H].

[13] Whereas the fluorescence intensity of [$Zr(TPP)_2$] (**1**) remains relatively unchanged in a range of solvent polarities, excitation of [Zr(TTP)(TTP-NHCOAQ)] (**4**) gives a considerably weaker fluorescence signal with increasing solvent polarity. This suggests that the singlet excited state of **4** undergoes electron transfer to form a charge-separated state (porphyrin$^+$-quinone$^-$). Synthesis and Encapsulation Behavior of New Redox-Active Dimeric Assemblies**

Xavier Garcías and Julius Rebek, Jr.*

Molecular assemblies are suitable systems for the study of recognition phenomena, and self-complementary molecules are advantageous in this regard. These compounds can dimerize through hydrogen bonding,[1] and the dimers present closed-shell capsules capable of surrounding of smaller, complemen-

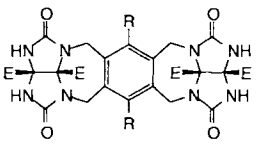
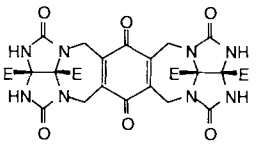
tary guest species.[2] Here we describe systems that feature varied interior linings, and the consequences for the binding of guests are reported.

The new systems are structurally related to the original **1**, but present either electron-rich or electron-deficient surfaces to encapsulated species. Their enhanced solubility in organic media is a consequence of the peripheral ester groups, for example, in **2**.[3] The syntheses follow the methods described earlier: the new hydroquinone **3** was prepared by the condensation of 1,4-bis(acetoxy)-2,3,5,6-tetrakis(bromomethyl)benzene[4] with an excess of the appropriate glycoluril. The corresponding quinone **4** was obtained, without apparent side reactions, through NO_2 oxidation of **3** in CH_2Cl_2.



1: R = H; E = C_6H_5
2: R = H; E = $CO_2(C_2H_5)$
3: R = OH; E = $CO_2(n\text{-}C_4H_9)$



4: E = $CO_2(n\text{-}C_4H_9)$

In organic solvents such as chloroform, both **3** and **4** show the spectroscopic earmarks of well-defined assemblies.[5] Downfield NH resonances ($\delta \approx 9$) and generally sharp NMR signals spectra indicate that the dimeric capsule is the dominant species in solution. Moreover, the dimer **2**, a species closely related in structure, exists as a dimeric capsule in the crystalline state.[6]

In addition to self-assembly into homodimers, disproportionations into heterodimers[7] were observed in mixtures of the hydroquinone **3** and the quinone **4**, or either of these with the capsule **2** (Fig. 1). This behavior is in accord with observations

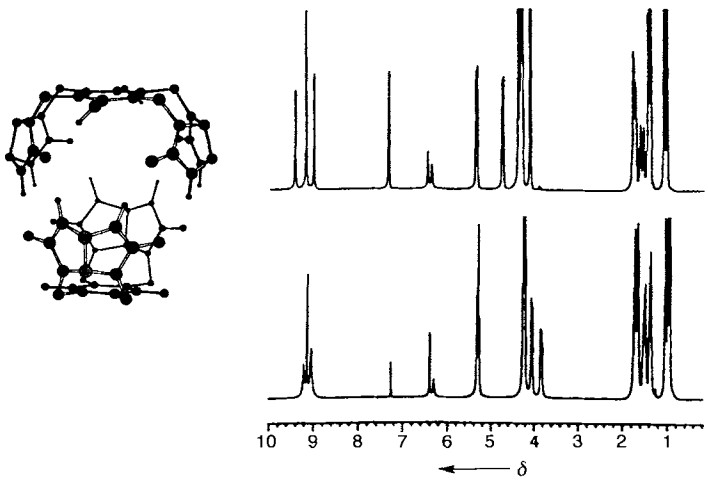


Fig. 1. Left: Energy-minimized [8] structure of the heterodimer **3-4** (glycoluril esters are omitted for clarity). Right: 500 MHz ^{1}H NMR spectra of equimolar mixtures of **2** and **3** (top), and **3** and **4** (bottom).

in our laboratories and elsewhere. The heterodimers present cavities of nearly identical volume to those of the original **1-1** or **2-2** featuring the benzene spacer, but offer a π surfaces with different electron densities to their encapsulated guests.

The encapsulation of small, complementary molecular guests could be observed directly by NMR spectroscopic techniques, and the association constants for the formation of the encapsulation complexes were calculated as described previously.[2] The data are given in Table 1, and the NMR chemical shifts for the signals of encapsulated guests are listed in Table 2. In addition

Table 1. Association constants K_a (M^{-1}, 298 K) for the encapsulation of guests in the dimers **N-N** (**N** = **2**, **3**, **4**). ($K_{a,298}$ = [N-guest.N]/[N-N] × [free guest]).

CF_4	–/ −61.11	–/ −60.24	–/–	–/ −62.48

to methane[9] and ethane, methyl fluoride (CH_3F) and tetrafluoromethane (CF_4) were examined as guests. The studies of the fluorinated methanes were inspired by recent calculations[10] that predict CF_4 to be as well suited as CH_4 as a guest for these capsules. We had, however, been unable to observe the encapsulation of CF_4 by **1** at 298 K by either ^{1}H or ^{19}F NMR methods.[2]

The association constants for the encapsulation of methane and ethane by all of the capsules were similar in magnitude, although the hydroquinone was generally a better host than the quinone. In addition, the upfield shifts observed for guests inside the quinone ($\Delta\delta \approx 0.8$ ppm) were considerably smaller than those for the hydroquinone ($\Delta\delta \approx 1.7$ ppm). This likely reflects the lower anisotropy experienced by guests in the electron-deficient quinone. The fluorinated methanes presented some experimental problems, but CH_3F encapsulated in **2-2** or **3-3** could be directly observed. Figure 2 shows both ^{19}F and ^{1}H NMR spec-

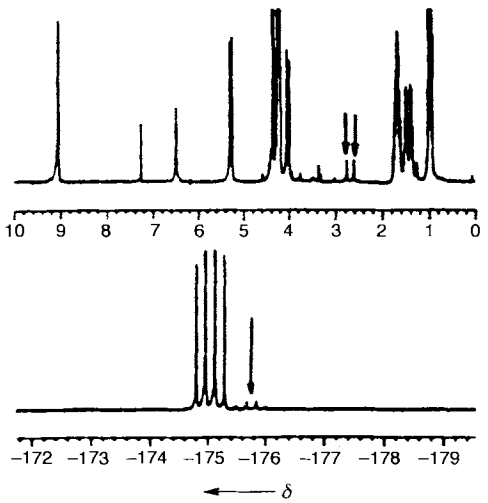

Fig. 2. Top: ^{1}H NMR spectrum (300 MHz) of **3** (28.5 mM) in $CDCl_3$ containing CH_3F (155 mM). Bottom: ^{19}F NMR spectrum (282 MHz) of the same sample. Signals for included CH_3F are marked with arrows.

tra of encapsulated CH_3F in **3**. The encapsulation results in an upfield shift, as expected for a molecule held between two π surfaces. Dimer **4-4** failed to encapsulate CH_3F under similar conditions and an upper limit of $K_{a,298} = 0.3\ M^{-1}$ can be calculated, assuming that no more than 5% of the capsule was occupied.

The ^{19}F NMR spectrum of CF_4 was recorded at high amplitude and 298 K with or without added **1** (Fig. 3a). No new upfield signals for encapsulated CF_4 were observed at this temperature. The low solubility of both **1** and CF_4 may be the cause (the solubility of **1-1** in $CDCl_3$ is only 3 mM). However, a very small peak (0.8% of the signal for free CF_4) could be observed when the temperature was lowered to 273 K (Fig. 3b), but it

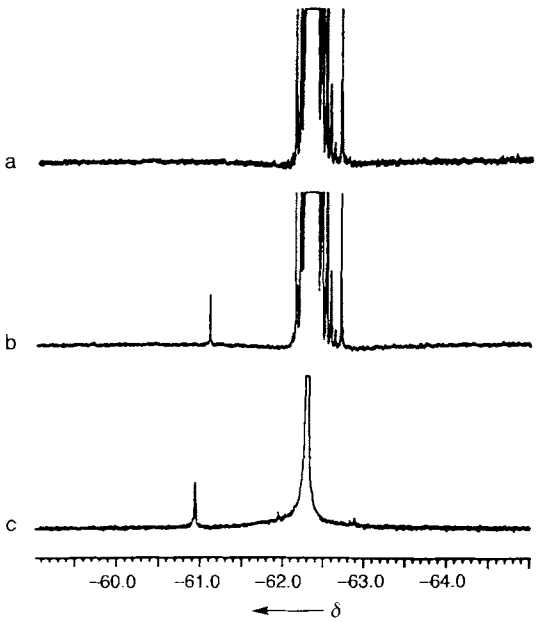

Fig. 3. ^{19}F NMR spectra of **1** in $CDCl_3$ saturated with CF_4 at 298 K (a, 470 MHz) and at 273 K (b, 470 MHz), and of **2** in $CDCl_3$ saturated with CF_4 at 298 K (c, 282 MHz).

appeared downfield of the signal for free CF_4. If this signal represents encapsulated CF_4,[11] the $K_{a,273}$ can be calculated as $2.8\ M^{-1}$. To test the reproducibility of this signal, the more soluble **2-2** was used in $CDCl_3$ saturated with CF_4, with C_6F_6 added as an internal ^{19}F integration standard. Again, the downfield signal was observed only when the capsule was present (Fig. 3c). Integration permits an association constant of $0.7\ M^{-1}$ to be calculated for the encapsulation of this species, presumably CF_4, by **2-2** at 298 K. Similar results were obtained with **3-3**. The association constants for CH_4 are three to four times smaller than those observed for the cryptophanes by Collet et al., who also noted a diminution of affinity when F is substituted for H in chloromethanes.[9]

Why the ^{19}F NMR signal of the encapsulated CF_4 appears downfield of that of free CF_4 ($\delta = -62.48$, referenced to CCl_3F) remains a mystery. It has not been possible to observe this downfield signal for CF_4 in **4-4**, and an upper limit for $K_{a,298} = 0.2\ M^{-1}$ can be calculated if no more than 1% of the CF_4 is encapsulated. Fox et al. have calculated the free energies and suggested that the order of binding affinity to **1-1** should be $CHCl_3 < CF_4 < CH_4$, an order that is confirmed by the experiments described here.[10] The calculations were less successful quantitatively, in that the strength of binding (relative to CH_4) was overestimated for CF_4 and underestimated for $CHCl_3$.

Finally, qualitative evidence for the encapsulation of nitric oxides in **4-4** was obtained. Earlier attempts to bind NO in **1-1** led to decomposition,[2] but the successful oxidation of **3** to **4** with NO_2 suggested the following experiment. Treatment of **3-3** with excess NO_2 in CH_2Cl_2 followed by evaporation of the volatiles gave a solid residue, which was taken up in $CDCl_3$. This solution showed the characteristic NMR spectrum of pure **4-4**. When an equivalent amount of **3-3** was added to this material, only **4-4** was observed by NMR in the solution. Apparently, the $CDCl_3$ solution contained an oxidizing agent—most likely an encapsulated oxide of nitrogen—capable of converting **3** into **4**. The assignment of structure for the encapsulated oxidant awaits further research.[12] In the meantime, we note that many unusual properties of encapsulated guests have been observed in covalent hosts.[13]

Experimental Procedure

NMR experiments: All experiments reported were conducted in spectroscopic grade $CDCl_3$. Methane, ethane, or methyl fluoride were bubbled into a solution of a known weight of the appropiate host at room temperature. The the total volume of the solution was measured and the concentrations of the species (empty/full host and free/included guest) were calculated by integration (^1H and/or ^{19}F NMR). Tetrafluoromethane was bubbled for 15 min into a solution cooled at −40 °C of a known weight of **2**, **3**, or **4**. Hexafluorobenzene (2 μL) was added as internal standard for integration and the tube was sealed while cold. The concentrations of free and encapsulated CF_4 were determined by integration with respect to the C_nF_n. For example, in the case of **2**, the data found were: [**2**] = 42 mg in 0.5 mL = 120 mM; [**2-2**] = 60 mM; $[CF_4]_{total} = 21$ mM; $[CF_4]_{free} = 20.2$ mM; $[CF_4]_{included} = 0.8$ mM; $K_{a,298} = 0.8 \times 10^3/59.2 \times 20.2 = 0.7\ M^{-1}$.

Preparation of **3**: Potassium *tert*-butoxide (1.68 g, 15 mmol) was added all at once to a solution of 5.13 g (15 mmol) of 1,5-bis(carboxybutyl)glycoluril (prepared as described for the corresponding ethyl derivative [3]) in 50 mL of dry DMSO at room temperature. The mixture was stirred until dissolution was complete (about 45 min), then solid 1,4-bis(acetoxy)-2,3,5,6-tetrakis(bromomethyl)benzene [4] (562 mg, 1 mmol) was added, and stirring was continued at room temperature for an additional 2 h. The yellowish mixture was poured into a vigorously stirred solution of 500 mL of 0.1 N HCl. The resulting suspension was filtered by suction, and the solid was washed with water (5 × 100 mL). The white solid was dried and then triturated with hot CH_2Cl_2 (3 × 100 mL) and filtered. The combined filtrates were evaporated yielding 250 mg of crude **3**. After column chromatography (CH_2Cl_2/CH_3OH 98/2), 168 mg (20% yield) of pure material was obtained. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 9.13$ (s, 4H, NH), 6.39 (s, 2H, OH), 5.30 (d, $J = 16.0$ Hz, 4H, benzylic CH), 4.23 (m, 8H, CH_2O), 4.03 (d, $J = 16.0$ Hz, 4H, benzylic CH), 1.75–1.33 (m, 16H, CH_2CH_2), 0.98 (t, $J = 7.3$ Hz, 3H, CH_3), 0.94 (t, $J = 7.3$ Hz, 3H, CH_3); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 165.93$, 165.30, 160.13, 146.20, 128.15, 82.3, 67.12, 37.59, 30.47, 19.20, 19.04, 13.77; HRMS: calcd for $[M+H]^+$ $C_{38}H_{51}N_8O_{14}$ 843.3525, found 843.3519.

Preparation of **4**: Bisglycoluril **3** (42 mg, 0.05 mmol) was treated for 1 h at room temperature with 0.5 mL of a solution of CH_2Cl_2 saturated with NO_2. The solvent was evaporated to obtain a quantitative yield of **4**. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 9.01$ (s, 4H, NH), 5.31 (d, $J = 16.3$ Hz, 4H, benzylic CH), 4.20 (m, 8H, CH_2O), 3.83 (d, $J = 16.3$ Hz, 4H, benzylic CH), 1.76–1.31 (m, 16H, CH_2CH_2), 1.03 (t, $J = 7.3$ Hz, 3H, CH_3), 0.93 (t, $J = 7.3$ Hz, 3H, CH_3); ^{13}C NMR (75 MHz, $CDCl_3$): $\delta = 183.50$, 165.56, 162.21, 158.45, 140.96, 81.94, 75.29, 67.02, 35.28, 30.24, 19.00, 18.85, 13.55; HRMS: calcd for $[M+2H]^+$ $C_{38}H_{50}N_8O_{14}$ 842.3447, found 843.3439.

Self-Complementarity of 7,9-Dimethylguanine: A Base Pair Containing Three Hydrogen Bonds**

Susanne Metzger and Bernhard Lippert*

Molecular recognition of *complementary* molecules through hydrogen bonding is a common feature in biochemistry[1] as well as in supramolecular chemistry.[2, 3] Base pairing according to the Watson–Crick and Hoogsteen scheme[1] and also substrate–receptor recognition[2–4] may serve as examples. Molecular recognition between *identical* molecules is a much less common phenomenon usually restricted to molecules containing "complementary ends".[5] Although many cases of pairwise hydrogen bond formation between identical molecules, including nucleobases,[1] are known, this kind of association should not be referred to as "molecular recognition" since the association constants in solution are low.

With the assumption that at least three hydrogen bonds are required for self-recognition between naturally occurring nucleobases, homo base pairing can be realized between cytosines (partially protonated) and guanines (partially deprotonated) only (Fig. 1). Adeninium base pairs, although known, are difficult to prove in solution. It is well known that cytosines form base pairs at a pH corresponding to their pK_a values (4–5), leading to helical structures in the case of poly(dC), which are sufficiently stable to exist at physiological pH.[6] In the case of guanine, half of the protons at the N1 position must be removed to achieve self pairing (Fig. 1). Considering the high pK_a value of guanine derivatives (9–10) it is not surprising that triple H bonding between guanine nucleobases has not yet been described.

[**] Our work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie (grant for S. M.). We thank Dr. M. Linscheid and C. Siethoff (Institut für Spektrochemie, Dortmund) for recording the ESI mass spectra.

However, in the course of our studies on N7-platinated guanines, we were able to prove the formation of guanine–guanine base pairs by spectroscopic methods and X-ray analysis in two cases (Fig. 2).[7, 8] The acidification of the N1 position ($pK_a = 8–9$) as a consequence of Pt coordination at N7 facilitates base pairing at a pH significantly lower than that required for pairing of the free base.

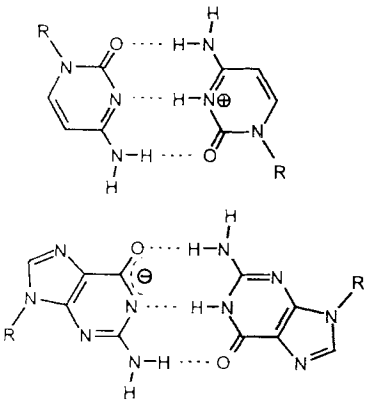

Fig. 1. Partially protonated cytosine ($HC^+\equiv C$) and partially deprotonated guanine ($HG\equiv G^-$).

Using 7,9-dimethylguanine (7,9-DimeG) we have now found a guanine derivative capable of base pairing at pH 7, that is, at physiological pH. 7,9-DimeG can be regarded a model for the naturally occurring 7-methylguanosine, which is known to display a number of biologically interesting functions. Its role as a rare RNA base[9] and as the main product of DNA methylation by carcinogenic and mutagenic agents,[10] its mutagenicity as a consequence of mispairing,[11] and its occurrence in the 5′-cap of mRNA[12] are some of these. 7,9-DimeG is zwitterionic in its neutral form (2-amino-7,9-dimethyl-6-oxodihydropurinium betaine, herbipoline).[13] With a pK_a of 7.19,[13] 7,9-DimeG exists as a 1:1 mixture of its neutral and its cationic form at physiological pH (Fig. 3). Upon titration of an aqueous solution of 7,9-DimeG with an acid HX, a poorly water-soluble precipitate of composition [7,9-DimeGH·7,9-DimeG]X·n H_2O forms in the pH range of 7 ± 1.[14] Attempts to obtain single crystals suitable for X-ray analysis were unsuccessful. IR spectra[15] of the various hydrogen-bonded complexes are almost identical except for anion bands. The electrospray ionization mass spectrum for the complex with $X = ClO_4^-$[16] clearly indicates the existence of a hydrogen-bonded dimer (m/z 359). The poor solubility of [7,9-DimeGH·7,9-DimeG]X in all common solvents does not permit comprehensive characterization of the adduct by NMR spectroscopy.[17] In solutions of the dimer ($X = ClO_4^-$) in DMSO, for example, the maximum concentration is 0.0067 mol L^{-1} (per dimer). Even the choice of a more hydrophobic anion (tetraphenylborate) does not improve solubility because the poor solubility of the neutral 7,9-DimeG is the limiting factor. Attempts to estimate the association constant by a dilution experiment[18] failed, as the $\Delta\delta$ values of the NH_2 signals in the ^1H NMR spectrum ([D_6]DMSO) could be deter-

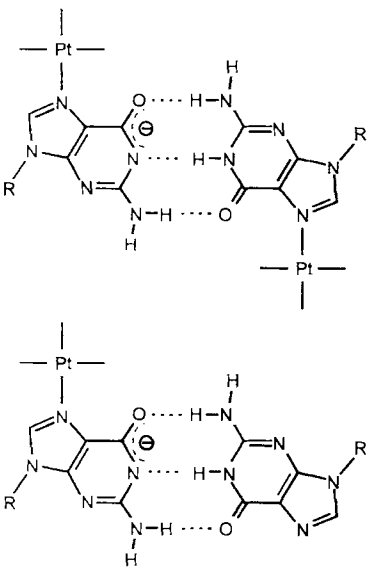

Fig. 2. Guanine–guanine base pairing between two cations of N7-platinated 9-R-guanines and between a cation of N7-platinated 9-R-guanine and neutral, nonplatinated guanine.

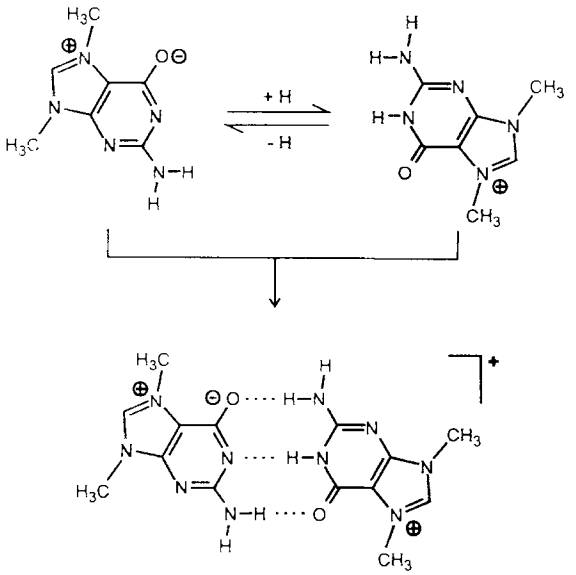

Fig. 3. Acid - base equilibrium of 7,9-dimethylguanine and adduct formation between the two species.

mined for the nonlinear part of the dilution curve only. Nevertheless, the following qualitative conclusions can be drawn from the ^{1}H NMR experiments: First, the upfield shift of the NH_2 signals of the dimer upon dilution significantly exceeds that of the NH_2 signals of 9-ethylguanine (9-EtGH) and 1-methylcytosine (1-MeC) in the same solvent and concentration range.[19] Second, 1-MeC is not capable of replacing 7,9-DimeG from its adduct with 7,9-DimeGH$^+$.[20] Third, for the betaine 7,9-DimeG, no hydrogen bond formation with 1-MeC can be detected in [D$_6$]DMSO, whereas H bonding to 9-EtGH is readily deduced from ^{1}H NMR spectra.[21]

It remains to be clarified if the ability of the rare nucleobase 7,9-dimethylguanine to act as a proton acceptor as well as a proton donor is of relevance to its biological function. In any case, the strong association between 7,9-dimethylguanine and its conjugate acid is exceptional. The positive charge of this base pair is not expected to restrict its occurrence in physiological systems.[22] The high affinity of 7,9-DimeG to guanine may also offer a new strategy for the design of guanine receptors different from conventional ones.[23] Furthermore, it seems feasible that the pK_a value of the N1 proton of guanines may be tuned by substituents at the 7 and 8 positions such that guanine receptors suitable for different pH ranges could be designed.

[14] Preparation: Concentrated aqueous solutions of 7,9-dimethylguanine (ca. 50 mmol L^{-1}) were adjusted to a pH of 7.2 by addition of either $HClO_4$, HNO_3, or HCl, and precipitation was completed by cooling to 4 °C. The colorless solids were filtered off, washed with H_2O, and dried in high vacuum. Yields were between 70 and 85%. C, H, N analyses are in agreement with the proposed compositions (monohydrates for $X = NO_3^-$ and Cl^-; hemihydrate for $X = ClO_4^-$).

[15] The most intensive bands in the C=C stretching region and in the fingerprint region are: 1709.6 (vs), 1684.4, 1617.4, 1592.2, 1576.5, 1560.0 and 786.5, 767.6, 747.5 cm^{-1}, respectively. Spectra were recorded on a FT-IR spectrometer Bruker IFS 28 (32 scans between 200 to 4000 cm^{-1}, KBr). The program Opus, version 2.0 by Bruker, was used for data processing.

[16] MS: *m/z* 359: [7,9-DimeGH·7,9-DimeG]$^+$; *m/z* 180: DimeGH$^+$. Mass spectra were recorded on a Finnigan MAT90 spectrometer using an electrospray source of our own construction at an acceleration potential of +5000 V. 89 scans were recorded in the range of *m/z* 50–800 (scan speed 8.27 s per scan). The solution (H_2O/ methanol) was infused by means of a E540101 pump (TSE) through a 50 µm fused silica capillary (flow rate = 0.5 ML min^{-1}). A sheet flow of methanol (1 µL min^{-1}) was applied for stabilization.

[17] ^{1}H NMR spectra were recorded on a Bruker DRX-400 spectrometer at a frequency of 400.13 MHz in [D$_6$]DMSO without presaturation of the solvent and H_2O signals. The resonance of nondeuterated DMSO was used as internal reference ($\delta = 2.50$).

[18] C. S. Wilcox in ref. [2], pp. 123–143.

[19] Upon dilution of a solution of [7,9-DimeGH·7,9-DimeG]ClO_4 in [D$_6$]DMSO from $c = 6.7$ mmol L^{-1} to $c = 0.42$ mmol L^{-1}, the NH_2 resonance of 7,9-dimethylguanine is shifted upfield by 0.30. The upfield shift of the NH_2 resonance of 9-ethylguanine (9-EtGH) upon addition of an equimolar amount of 1-methylcytosine (1-MeC) in the same concentration range is 0.05 at $c = 6.7$ mmol L^{-1} and 0.0 at $c = 0.42$ mmol L^{-1}. The shift of the NH resonance is $\Delta\delta = 0.1$, as expected. This shift value is twice that of the NH_2 resonance since the NH_2 signal is an average of two protons, one of which is H bonded while the other is not. In the case of [7,9-DimeGH·7,9-DimeG]X this resonance is not observed as a consequence of chemical exchange.

[20] Addition of 1-MeC to a solution of [7,9-DimeGH·7,9-DimeG]ClO_4 in [D$_6$]DMSO does not cause changes in the chemical shifts of any of the two components but leads to clean superpositions only.

[21] Addition of a tenfold excess of 9-ethylguanine to a saturated solution of 7,9-dimethylguanine in [D$_6$]DMSO (c(7,9-DimeG) = 0.36 mmol L^{-1} at 18 °C) results in a downfield shift of the NH_2 resonance of 7,9-DimeG by roughly 0.39 ppm. (7,9-DimeG is expected to exist exclusively in its H bonded form under these conditions.)

[24] Note added in proof (May 2, 1996): After completion of this manuscript we became aware that the results of an X-ray crystal structure determination of a nucleoside analogue, of hemiprotonated 7-methylguanosine (as the iodide salt), have been reported: K. Tomita, *Yakugaku Zasshi* **1989**, *109*, 439–459. The results confirm the existence of the proposed G,G base pair. Neither the title nor the English abstract of this review article provide any indication of this compound. We feel that this is the reason why this work escaped our attention.

Synthesis of Glycopeptides and Lipopeptides by Chemoselective Ligation**

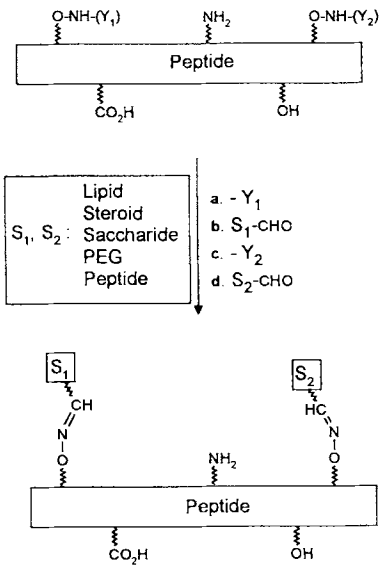
Stefano E. Cervigni, Pascal Dumy, and Manfred Mutter*

An important feature of natural glycoproteins is their structural diversity. Posttranslational glycosylation in eukaryotic cells plays a key role in various phenomena such as protein stabilization against denaturation, intercellular communication processes, and regulation of cell growth.[1] For a better understanding of the contribution of the carbohydrate moieties of glycoproteins in biological processes much effort has been devoted recently to improving the chemical synthesis of glycopeptides as models for glycosylated proteins. Moreover, the glycosylation of peptides is an important tool in drug design for modulating the biological activity and improving the bioavailability and solubility of natural peptides.[2]

The regiospecific chemical synthesis of glycopeptides remains a difficult task due to the weakness of the glycosidic linkage and the need for selective protection of several functional groups.[3] Recent developments in the ligation of unprotected peptide fragments by chemoselective methods[4] have opened new routes to multifunctional peptides and proteins of high complexity. Consequently, numerous applications of this elegant concept have emerged in protein de novo design,[5] for example peptide dendrimers[6] and protein conjugates.[7]

Here we report on a general strategy based on chemoselective formation of oxime bonds[8] for the attachment of unprotected multifunctional peptides to aldehyde-containing compounds such as carbohydrates and lipids. In sharp contrast with other methods applied for the synthesis of glycopeptides,[9] this procedure permits preservation of the cyclic nature of the saccharide unit.[10]

As shown in Scheme 1, amino acids containing selectively addressable amino-oxy functions can be incorporated into the peptide sequence. After the sequential deprotection of the amino-oxy function and subsequent reaction with the aldehyde group of any of a variety of compounds, an oxime bond is formed regioselectively under mild aqueous conditions in a one-pot reaction. This simple method enables the direct linkage of unprotected peptides with free carbohydrates, lipids, and other substrates.



Scheme 1. Strategy for regioselective oxime bond formation. a) and c) Selective deprotection of the amino-oxy functions (Y_1, Y_2: orthogonal protecting groups such as *tert*-butyloxycarbonyl (Boc) and allyloxycarbonyl (Alloc); b) and d) Oxime formation in acetate buffer (S_1, S_2: aldehyde-containing compounds). PEG = polyethyleneglycol.

For example, orthogonally protected peptides were assembled by using standard Fmoc solid-phase chemistry on a Rink amide resin. Subsequently, the N-terminal amino group of the peptide and/or the ε-amino group of lysine were selectively derivatized with differently protected amino-oxyacetyl groups as previously described.[11] After acid treatment the amino-oxyacetyl peptide was reacted with aldehyde groups either on a sugar or lipid to form the corresponding oxime. The reaction was found to occur smoothly, selectively, and independently of the peptide primary sequence.[12] As demonstrated by the preparation of a series of derivatives (**8**–**13**) of the amino-oxyacetylated somatostatin analogue RC-160[13] **1** (Table 1 and

NH_2OCH_2CO-(D)Phe-Cys-Tyr-(D)Trp-Lys-Val-Cys-Trp-NH_2 **1**

Scheme 2), the procedure offers a variety of possibilities for modulating the physical, chemical, and biological properties of peptides.

Table 1. Yields and reaction times of the oxime derivatives of **1**.

Aldehyde	Derivative	*T* [h][a]	Yield [%] [b]
2 glycosone [14]	**8**	5	65
3 glucose	**9**	25	60
4 gentobiose	**10**	75	70
5 maltose	**11**	100	75
6 maltotriose	**12**	120	70
7 decanal	**13**	1	70

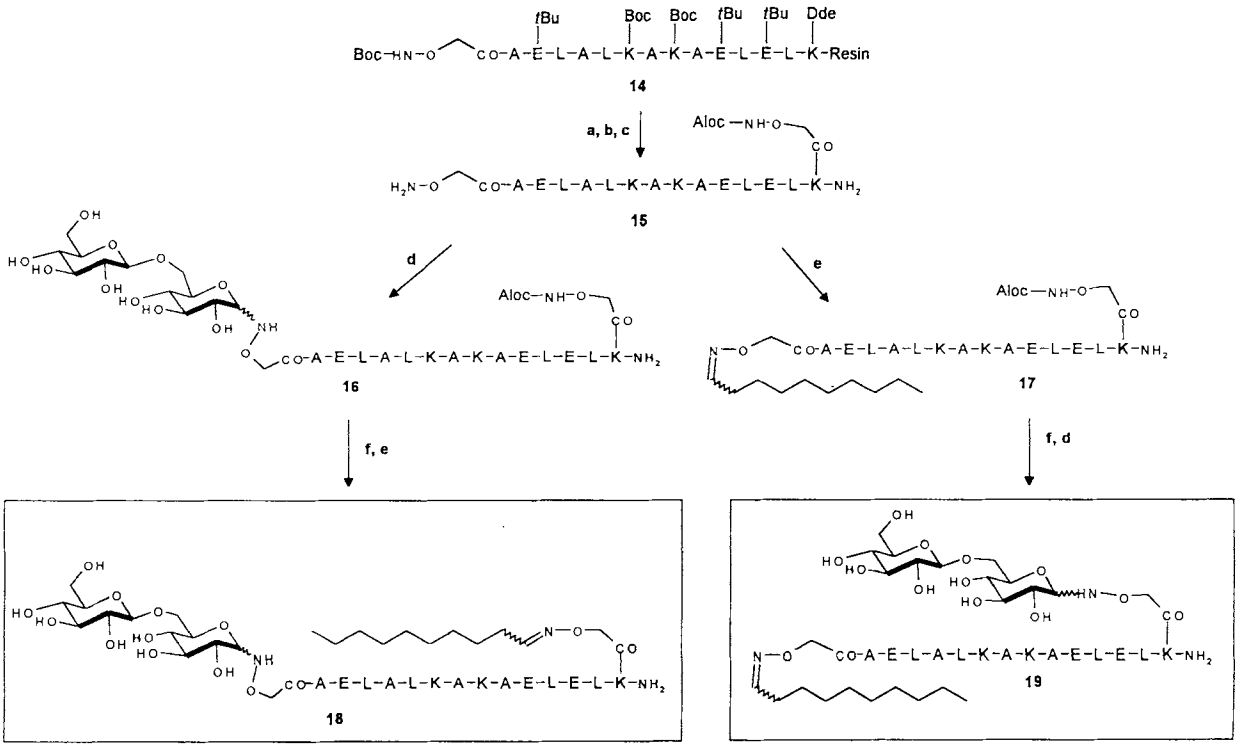

Scheme 3. Chemical pathway for the synthesis of isomeric bis-oxime-containing peptides **18** and **19** (for the sake of clarity only the cyclic form is represented) [10]. a) 3% NH_2NH_2 in DMF; b) Alloc-NHOCH$_2$CO$_2$Su (Su = succinimidyl) in DMF; c) 50% TFA in CH_2Cl_2 (1:1); d) gentobiose **4**, acetate buffer pH 3; e) decanal **7**, acetate buffer pH 3; f) [$(Ph_3P)_2PdCl_2$], nBu$_3$SnH in CH_2Cl_2/AcOH (96:4).

For comparison, the Lys^5(Dde)-protected RC-160 analogue **1a** (Dde = 1-(4,4-dimethyl-2,6-dioxocyclohexylidene)ethyl) was

[H-(D)Phe-Cys-Tyr-(D)Trp-Lys(Dde)-Val-Cys-Trp-NH_2] **1a**

prepared and conjugated to glucosone **2**, gentobiose **4**, and maltotriose **6** by reductive amination[9] with $NaBH_3CN$. Oxime formation leading to the oxime compounds **8**, **10**, and **12** was much faster than the reductive alkylation yielding the corresponding reduced compounds **8a**, **10a**, and **12a**, especially for longer saccharides. With lipid components the chemoselective ligation was even faster and proceeded with remarkably high yields (Table 1). The decreased reactivity of carbohydrates can be explained by the low concentration of the reactive aldehyde form of the reducing sugar in solution. This finding is confirmed by the difference in the reaction times with glucosone **2** and glucose **3**.

To demonstrate the flexibility of the method, two isomeric oxime-ligated glycolipo- (**18**) and lipoglycopeptides (**19**) were prepared (Scheme 3). To this end, we chose an amphiphilic "switch-peptide" designed to undergo solvent-induced conformational changes,[15] and the multifunctional peptide was derivatized with selectively addressable amino-oxyacetyl sites. Removal of Boc/*t*Bu protecting groups of **14** allowed the regioselective attachment of gentobiose (or decanal) to **15** through an oxime bond giving **16** (or **17**). After Pd^{II}-catalyzed cleavage of the Alloc group, **16** was treated with decanal and **17** with gentobiose to provide the oxime-containing lipoglycopeptides **18** and **19** in overall yields of 60 and 65%,[16] respectively.

We have shown that chemoselective oxime bond formation in association with orthogonal protection techniques can be used to attach a variety of compounds such as glycosides and lipids regioselectively to completely unprotected peptides under mild aqueous conditions. In analogy to the posttranslational glycosylation process, the method described above can be considered as a "postsynthetic" modification of unprotected peptides by chemoselective oxime ligation. The approach may be easily extended to any aldehyde-containing compound such as ligands, nucleic acids, and proteins. Its flexibility can greatly facilitate access to more complex targets of pharmaceutical interest. Furthermore, this ligation technique may be applied in combinatorial chemistry and thus extend the potential for creating new chimeric peptide libraries.

Experimental Procedure

Typical procedure for solid-phase peptide synthesis: The linear protected peptide was assembled using *N*α-Fmoc amino acids (3.0 equiv) on Rink amide resin (preactivated with hydroxybenzotriazole (3.0 equiv) and *N*,*N*-diisopropylcarbodiimide (3.0 equiv) in DMF for 15 min) and coupled in the presence of diisopropylethylamine (3.0 equiv) in DMF for 45 min. The Fmoc protecting groups were removed by treatment with piperidine (20% v/v in DMF, 20 min). The amino-oxyacetyl moiety was coupled at the N-terminus of the peptide and/or the ε-amino group of the lysine residue by coupling *N*α-Boc- or *N*α-Alloc- protected amino-oxyacetic acid derivatives. Subsequently, the protected peptide was cleaved from the resin with 50% trifluoroacetic acid in CH_2Cl_2 and the solvent removed under reduced pressure.

Typical conditions for chemoselective ligation: A solution of the amino-oxyacetylated peptide (10 μmol) was dissolved in 2 mL of a 1:1 mixture of 0.1 M (pH 4.0) acetate buffer and CH_3CN and added dropwise to a solution of the carbohydrate or the lipid (100 μmol) in the same buffer. The mixture was acidified to pH 3 with 100 μL of glacial acetic acid, and the coupling reaction was monitored by analytical HPLC. Purification by semipreparative HPLC followed by lyophylization gave the desired glyco- or lipopeptide as a white powder, which was characterized by ESI-MS.

Typical procedure for Aloc cleavage: A solution of the peptide **16** or **17** (15 mg, 0.008 mmol) and [$(Ph_3P)_2PdCl_2$] (2–3 mg) in CH_2Cl_2/4% AcOH (2.5 mL) was treated with nBu$_3$SnH (10 μL, 0.035 mmol) and the reaction was monitored by HPLC. The orange solution was filtered and concentrated in vacuo, and diethyl ether was added. The resulting precipitate was isolated by centrifugation and the

ether phase decanted. The precipitate was washed several times with ether and finally dried to give the deprotected product as a white powder (13 mg, 91%).

The reductive amination was carried out using a modification of a published procedure [13]. In a typical experiment, the protected peptide **1a** (10 μmol) was dissolved in 2 mL of a 10:1 mixture of 0.1 M phosphate buffer (pH 6.0) and CH_3CN. To this peptide solution were added the carbohydrate (200 μmol) dissolved in 2 mL of the same buffer and sodium cyanoborohydride (200 μmol) as a solid. The mixture was stirred at room temperature and progress of the coupling reaction monitored by analytical HPLC. The glycopeptides were purified by semipreparative HPLC and characterized by ESI-MS.

Charge and Potential: Arenes as Oxidants**

Robert Weiss,* Robert May, and Bernd Pomrehn

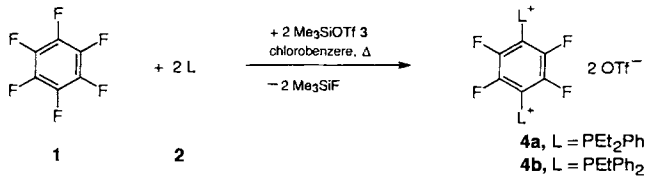
We have shown that the transition from neutral to cationic sets of substituents achieved for both inorganic and organic systems by using the trimethylsilyltriflate-assisted poly(onio) substitution method developed by us leads to a marked increase in their electrophilicities and electron affinities.[1–5] This is attributed primarily to the electrostatic field effects of the cationic substituents. Recently we reported on the first per(onio) substitution of hexafluorobenzene with 4-dimethylaminopyridine (DMAP) as a preliminary highlight of this development.[6] We considered whether the electrostatic activation of the electron affinity of aromatic systems could be raised to such an extent that their "antiaromatic" (LUMO-filled) reduction products would be capable of existing as thermodynamically stable compounds such that their chemical properties could be investigated. This would open up new perspectives in the chemistry even of conventional aromatic compounds.

The protocol for transforming arenes into powerful oxidants by electrostatic activation is based on the fundamental conditions of Coulomb's Law:

1) introduction of the maximum number of onio substituents structurally possible at the organic π-electron system (per(onio) substitution);
2) the use of onium centers of the highest possible electropositivity so as to generate high pole strengths;
3) choice of the shortest possible distances of the positive poles from the organic system.

For a given structural type there is no freedom of choice with criterion 1). However, for criteria 2) and 3) it must be considered carefully whether the use of an element from the first period as an onium center produces a more efficient electrostatic effect than an isoelectronic element from a higher period, because the development of the positive charge of the onium center and its distance from the central system in this comparison are inversely related. Semiempirical calculations show that phosphonio substitutents are far more efficient for our purpose than triorganoammonio substituents.[7] This is consistent with the comparatively higher stability of phosphonium relative to ammonium ylides.

The attempt to achieve per(onio) substitution on hexafluorobenzene (**1**) by the reaction with PR_3/Me_3SiOTf (Tf = trifluoromethanesulfonyl) under a variety of conditions led only to the formation of the 1,4-bis-phosphonio-substituted system **4a,b** (Scheme 1).[8]



Scheme 1. Synthesis of 1,4-bis-phosphonio-substituted benzene derivatives.

Cyclic voltammetric investigations of the salts **4a,b** reveal two quasi-reversible redox steps at remarkably positive potentials (Table 1).[9] In spite of the relatively high electron affinity of **4a,b** these salts are not activated towards further nucleophilic substitution. This in sharp contrast to the analogous substitution of hexafluorobenzene with DMAP, which under autoactivation leads to per(onio)-substituted products.[6] In this case, in

Table 1. Half-wave potentials of the poly(onio)-substituted arenes [a].

Compound [9]	1st Reduction [V]	2nd Reduction [V]

Charge and Potential: Arenes as Oxidants**

Robert Weiss,* Robert May, and Bernd Pomrehn

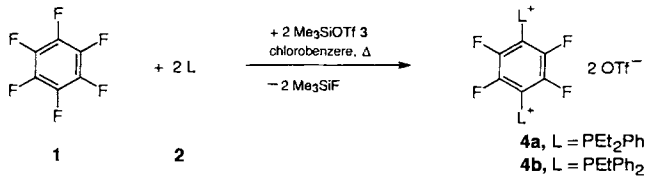
We have shown that the transition from neutral to cationic sets of substituents achieved for both inorganic and organic systems by using the trimethylsilyltriflate-assisted poly(onio) substitution method developed by us leads to a marked increase in their electrophilicities and electron affinities.[1–5] This is attributed primarily to the electrostatic field effects of the cationic substituents. Recently we reported on the first per(onio) substitution of hexafluorobenzene with 4-dimethylaminopyridine (DMAP) as a preliminary highlight of this development.[6] We considered whether the electrostatic activation of the electron affinity of aromatic systems could be raised to such an extent that their "antiaromatic" (LUMO-filled) reduction products would be capable of existing as thermodynamically stable compounds such that their chemical properties could be investigated. This would open up new perspectives in the chemistry even of conventional aromatic compounds.

The protocol for transforming arenes into powerful oxidants by electrostatic activation is based on the fundamental conditions of Coulomb's Law:

1) introduction of the maximum number of onio substituents structurally possible at the organic π-electron system (per(onio) substitution);
2) the use of onium centers of the highest possible electropositivity so as to generate high pole strengths;
3) choice of the shortest possible distances of the positive poles from the organic system.

For a given structural type there is no freedom of choice with criterion 1). However, for criteria 2) and 3) it must be considered carefully whether the use of an element from the first period as an onium center produces a more efficient electrostatic effect than an isoelectronic element from a higher period, because the development of the positive charge of the onium center and its distance from the central system in this comparison are inversely related. Semiempirical calculations show that phosphonio substitutents are far more efficient for our purpose than triorganoammonio substituents.[7] This is consistent with the comparatively higher stability of phosphonium relative to ammonium ylides.

The attempt to achieve per(onio) substitution on hexafluorobenzene (**1**) by the reaction with PR_3/Me_3SiOTf (Tf = trifluoromethanesulfonyl) under a variety of conditions led only to the formation of the 1,4-bis-phosphonio-substituted system **4a,b** (Scheme 1).[8]



Scheme 1. Synthesis of 1,4-bis-phosphonio-substituted benzene derivatives.

Cyclic voltammetric investigations of the salts **4a,b** reveal two quasi-reversible redox steps at remarkably positive potentials (Table 1).[9] In spite of the relatively high electron affinity of **4a,b** these salts are not activated towards further nucleophilic substitution. This in sharp contrast to the analogous substitution of hexafluorobenzene with DMAP, which under autoactivation leads to per(onio)-substituted products.[6] In this case, in

Table 1. Half-wave potentials of the poly(onio)-substituted arenes [a].

Compound [9]	1st Reduction [V]	2nd Reduction [V]
4a	− 0.83 (q)	− 1.46 (q)
4b	− 0.76 (q)	− 1.36 (q)
6	0.04 (q)	− 0.09 (i)
7a	0.03 (r)	− 0.19 (r)
7b	0.14 (r)	− 0.06 (r)
9a	0.60 (r)	− 0.04 (r)
10	0.80 (r)	0.14 (r)

[a] r = reversible, q = quasi-reversible, i = irreversible.

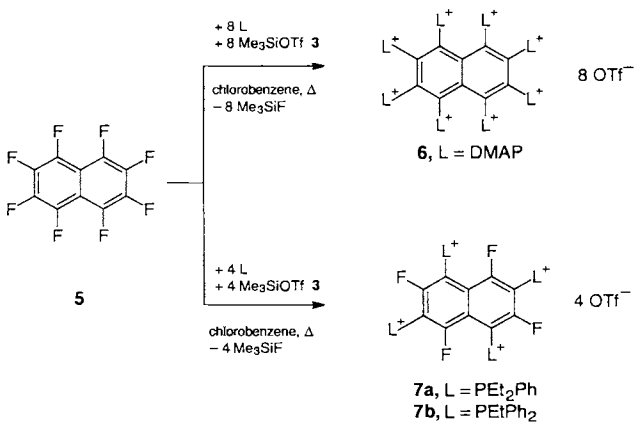
addition to steric effects, electronic effects are probably responsible for the resulting products. According to PM3 calculations the LUMO of **4a,b** is predominantly localized on C atoms positioned α to the phosphonio substitutents, so that the electronic prerequisites for further onio substitution are unfavorable.

The hitherto unknown per(onio) substitution on naphthalene should, because of the larger number of cationic substituents and the inherently higher electron affinity of naphthalene, lead to a further increase of the electron affinity relative to that of the analogous benzene derivatives. By using DMAP/Me_3SiOTf and octafluoronaphthalene (**5**) we achieved per(onio) substitution in the naphthalene system for the first time. The octacationic salt **6** could be isolated as a stable, water-soluble, pale yellow compound in almost quantitative yield (Scheme 2). The replacement



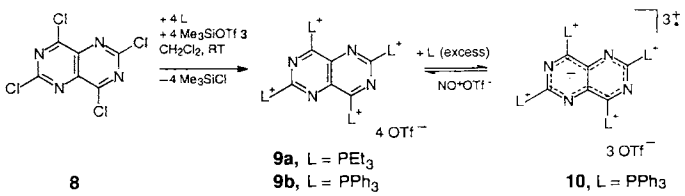
Scheme 2. Octakis- and tetrakis(onio) substitution of octafluoronaphthalene.

of DMAP with tertiary phosphanes led under otherwise identical conditions exclusively to the formation of good yields of the tetrasubstituted products **7a,b**, in which the fluoro and triorganophosphonio substituents alternated along the periphery of the naphthalene core. Investigations into the regiochemistry of the S_NAr reaction at octafluoronaphthalene indicate that substitutions at C-2/C-6 precede those at C-4/C-8.[10] The interplay of steric and electronic factors evidently hinders per(onio) substitution by phosphonio substituents as for the benzene system.

Electrochemical measurements on salts **6** and **7a,b** confirm an unprecedented high electron affinity for benzenoid aromatic compounds (cf Table 1). Remarkably, four triorganophosphonio substituents are as effective in raising the redox potentials as eight pyridinio substituents—an expected trend (see above) in view of the higher capability of phosphonio substituents to stabilize carbanions. The tetraphosphonio-substituted salts **7a,b** represent the ox-forms of a new, completely reversible two-step redox system whose oxidizing power is similar to that of chloranil.[11]

According to PM3 model calculations, replacement of the CF groups by N in salts of the type **7a,b** should lead to an even larger increase in the electron affinity.[7] This could be confirmed experimentally. The reaction of tetrachloropyrimido-[5,5-*d*]pyrimidine[12] (**8**) with four molar equivalents of PEt_3/Me_3SiOTf led smoothly to the formation of the corresponding tetrakis(onio)-substituted salt **9a** (Scheme 3).[13]

The "aromatic" compound **9a** is the ox-form of a completely reversible two-step redox system (Table 1) and, with a half-wave potential of 0.60 V (vs. Ag/AgCl) for the transition ox/sem, has at least the oxidizing power of 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) one of the most powerful organic oxidizing



Scheme 3 Onio substitution of tetrachloropyrimido[5,4-*d*]pyrimidine. RT = room temperature.

agents used in organic synthesis.[11] As a consequence of the increasing positive charge on the phosphorus center when alkyl is replaced by aryl[8b] the intially formed salt **9b**, obtained when PPh_3 is used analogously as a nucleophile, already has such a high electron affinity that it is quantitatively reduced by excess phosphane to the new tricationic radical salt **10**. The latter is a deep green isolable salt that has been fully characterized, including by a high-resolution ESR spectrum. With a strong oxidizing agent such as NO^+ **10** may be reconverted to **9b**. The measured half-wave potential for this conversion of 0.80 V (vs. Ag/AgCl) establishes this compound as the most powerful "aromatic oxidant" known to date. Calculations show that the charge distributions in the antiaromatic red-forms of the polyphosphonio salts **4, 7, 9** are characterized by a maximum charge pairing in terms of the bis-ylidic mesomeric structures **A** and **B/C** (Fig. 1).

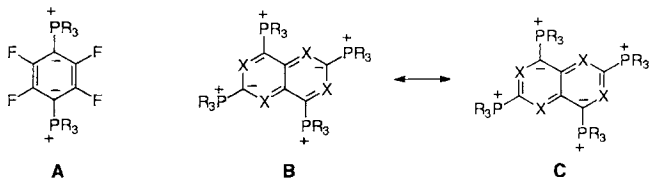


Fig. 1. Bis-ylidic mesomeric structures of the red-forms. X = CF, N.

The position of the pertinent redox potentials and the reversibility of the corresponding reduction steps (cf Table 1) opens up the prospect of generating such systems in a straightforward manner by chemical methods. With the synthesis of the sem-form **10** the first step in this direction has already been taken. Owing to the clear structural analogy with the corresponding quinones we designate the red-forms **A**–**C** as "quinobis-ylides".[14] The controlled reductive generation of suitable representatives of this class of substances is the subject of current investigations.

Experimental Procedure

All reactions were carried out under N_2 and in dried solvents. Correct C, H, N analyses were obtained for all compounds prepared.

4a,b: Compound **3** (2 mmol) and PEt_2Ph or $PEtPh_2$ (2 mmol) were added to a solution of **1** (1 mmol) in chlorobenzene (20 mL) and the solution was stirred under reflux. After 24 h (**4a**; or 72 h for **4b**) the white precipitate was filtered off, washed with Et_2O (5 × 5 mL) and dried for 12 h under high vacuum.

4a: Yield: 99%; ^1H NMR (400.05 MHz, CD_3NO_2/CF_3COOD, 21 °C, TMS): δ = 7.95 (m, 6H; H-2/H-4/H-6, phenyl), 7.80 (m, 4H; H-3/H-5, phenyl), 3.20 (m, 8H; CH_2), 1.38 (dt, $^3J(H,P)$ = 22.21 Hz, $^3J(H,H)$ = 7.56 Hz, 12H; CH_3); ^{13}C NMR (100.5 MHz, CD_3NO_2/CF_3COOD, 21 °C, TMS): δ = 150.27 (dm, $^1J(C,F)$ = – 255.5 Hz; C2/C3/C5/C6, benzene), 137.54 (s; C4, phenyl), 133.61 (d, $^2J(C,P)$ = 9.2 Hz; C2/C6, phenyl), 132.03 (d, $^3J(C,P)$ = 12.8 Hz; C3/C5, phenyl), 121.67 (q, $^1J(C,F)$ = – 319.8 Hz; CF_3), 116.40 (d, $^1J(C,P)$ = 84.5 Hz; C1, phenyl), 109.43 (dm, $^1J(C,P)$ = 84.5 Hz; C1/C4, benzene), 15.65 (d, $^1J(C,P)$ = 49.7 Hz; CH_2), 6.09 (d, $^2J(C,P)$ = 3.7 Hz; CH_3); ^{31}P NMR (161.7 MHz, CD_3NO_2/CF_3COOD, 21 °C, ext. H_3PO_4): δ = 35.53 (s).

4b: Yield: 50%; ^1H NMR (400.05 MHz, CD_3NO_2/CF_3COOD, 23 °C, TMS): δ = 7.99 (m, 12H; H-2/H-4/H-6, phenyl), 7.85 (m, 8H; H-3/H-5, phenyl), 3.54 (m,

4H; CH_2), 1.41 (dt, $^3J(H,P) = 22.70$ Hz; $^3J(H,H) = 7.33$ Hz; 6H; CH_3); ^{13}C NMR (100.5 MHz, CD_3NO_2, CF_3COOD, 23 °C, TMS): $\delta = 150.14$ (dm, $^1J(C,F) = -265.7$ Hz; C2/C3/C5/C6, benzene), 137.83 (d, $^4J(C,P) = 3.6$ Hz; C4, phenyl), 134.82 (d, $^2J(C,P) = 11.1$ Hz; C2/C6, phenyl), 132.14 (d, $^3J(C,P) = 12.9$ Hz; C3/C5, phenyl), 121.71 (q, $^1J(C,F) = -318.0$ Hz; CF_3), 115.80 (d, $^1J(C,P) = 88.3$ Hz; C1, phenyl), 110.65 (dm, $^1J(C,P) = 88.3$ Hz; C1/C4, benzene), 19.36 (d, $^1J(C,P) = 49.7$ Hz; CH_2), 6.94 (d, $^2J(C,P) = 5.5$ Hz; CH_3); ^{31}P NMR (161.7 MHz, CD_3NO_2, CF_3COOD, 23 °C, ext. H_3PO_4): $\delta = 26.71$ (s).

6: Compound **3** (0.80 mL, 4.43 mmol) and **6** (0.605 g, 4.95 mmol) were added to a solution of **5** (0.149 g, 0.55 mmol) in chlorobenzene (20 mL) and the solution was stirred under reflux. After 12 h the yellow precipitate was filtered off, washed with CH_2Cl_2 (4 × 5 mL) and dried for 12 h under high vacuum. Yield: 1.24 g (98%); ^1H NMR (400.05 MHz, CD_3CN, 24 °C, TMS): $\delta = 8.05$ (d, $^3J(H,H) = 7.57$ Hz, 8H; H-2/H-6), 7.83 (d, $^3J(H,H) = 7.57$ Hz, 8H; H-2/H-6), 6.87 (d, $^3J(H,H) = 7.57$ Hz, 8H; H-3/H-5), 6.86 (d, $^3J(H,H) = 7.57$ Hz, 8H; H-3/H-5), 3.24 (s, 24H; CH_3), 3.20 (s, 24H; CH_3); ^{13}C NMR (100.5 MHz, CD_3CN, 24 °C, TMS): $\delta = 157.30$ (s; C4, DMAP), 156.81 (s; C4, DMAP), 142.29 (s; C2/C6, DMAP), 140.42 (s; C2/C6, DMAP), 140.37 (s; C1/C4/C5/C8, naphthalene), 138.49 (s; C2/C3/C6/C7, naphthalene), 131.34 (s; C9/C10, naphthalene), 121.88 (q, $^1J(C,F) = -319.9$ Hz; CF_3), 110.86 (s; C3/C5, DMAP), 110.70 (s; C3/C5, DMAP), 41.80 (s; CH_3), 41.60 (s; CH_3); ^{19}F NMR (470.4 MHz, CD_3CN, 20 °C, C_6F_6): $\delta = -77.9$ (s; CF_3).

7a,b: Compound **3** (2 mmol) and PEt_2Ph or $PEtPh_2$ (2 mmol) were added to a solution of **5** (0.5 mmol) in chlorobenzene (20 mL) and the solution was stirred under reflux. After 48 h the suspension was cooled to −20 °C, the precipitation was completed by the addition of Et_2O (20 mL), and the precipitate was filtered off, washed with Et_2O (5 × 5 mL), and dried for 12 h under high vacuum.

7a: pale yellow powder; yield: 95%; ^1H NMR (400.05 MHz, CD_3CN, 24 °C, TMS): $\delta = 7.85$ (m, 8H; H-2/H-6, phenyl), 7.73 (m, 4H; H-4, phenyl), 7.67 (m, 8H; H-3/H-5, phenyl), 2.85 (m, 16H; CH_2), 1.06 (dt, $^3J(H,P) = 21.73$ Hz, $^3J(H,H) = 7.57$ Hz, 12H; CH_3), 1.01 (dt, $^3J(H,P) = 22.22$ Hz, $^3J(H,H) = 7.32$ Hz, 12H; CH_3); ^{13}C NMR (100.5 MHz, CD_3CN, 24 °C, TMS): $\delta = 167.65$ (dd, $^1J(C,F) = -262.9$ Hz, $^2J(C,F) = 10.1$ Hz; C4/C8, naphthalene), 166.26 (dm, $^1J(C,F) = -270.3$ Hz; C2/C6, naphthalene), 136.82 (d, $^4J(C,P) = 3.7$ Hz; C4, phenyl), 135.99 (s; C4, phenyl), 133.39 (d, $^2J(C,P) = 11.0$ Hz; C2/C6, phenyl), 132.27 (d, $^2J(C,P) = 9.2$ Hz; C2/C6, phenyl), 131.63 (d, $^3J(C,P) = 12.8$ Hz; C3/C5, phenyl), 131.46 (d, $^3J(C,P) = 12.9$ Hz; C3/C5, phenyl), 129.88 (m; C9/C10, naphthalene), 121.92 (q, $^1J(C,F) = -319.9$ Hz; CF_3), 120.01 (d, $^1J(C,P) = 86.4$ Hz; C1, phenyl), 116.31 (d, $^1J(C,P) = 84.6$ Hz; C1, phenyl), 106.46 (m; C3/C7, naphthalene), 102.26 (dd, $^1J(C,P) = 75.3$ Hz, $^2J(C,F) = 19.4$ Hz; C1/C5, naphthalene), 17.78 (d, $^1J(C,P) = 44.1$ Hz; CH_2), 15.40 (d, $^1J(C,P) = 47.8$ Hz; CH_2), 6.64 (d, $^2J(C,P) = 3.7$ Hz; CH_3), 6.11 (d, $^2J(C,P) = 5.5$ Hz; CH_3); ^{19}F NMR (470.4 MHz, CD_3CN, 20 °C, C_6F_6): $\delta = -78.0$ (s, 12F; CF_3), −74.8 (m, 2F; F-4/F-8), −67.9 (m, 2F; F-2/F-6); ^{31}P NMR (161.7 MHz, CD_3CN, 20 °C, ext. H_3PO_4): $\delta = 42.98$ (dd, $^3J(P,F) = 18.4$ Hz; $^3J(P,F) = 8.2$ Hz; P-3/P-7), 35.71 (d, $^3J(P,F) = 6.2$ Hz; P-1/P-5).

7b: pale orange powder; yield: 88%; ^1H NMR (400.05 MHz, CD_3CN, 21 °C, TMS): $\delta = 7.85$–7.62 (m, 40H; phenyl), 3.33 (m, 8H; CH_2), 1.11 (m, 12H; CH_3); ^{13}C NMR (100.5 MHz, CD_3CN, 21 °C, TMS): $\delta = 137.19$ (s; C4, phenyl), 136.69 (s; C4, phenyl), 133.34 (d, $^2J(C,P) = 11.0$ Hz; C2/C6, phenyl), 132.55 (d, $^2J(C,P) = 11.1$ Hz; C2/C6, phenyl), 131.66 (d, $^3J(C,P) = 14.7$ Hz; C3/C5, phenyl), 130.70 (d, $^3J(C,P) = 12.9$ Hz; C3/C5, phenyl), 129.66 (m; C9/C10, naphthalene), 121.92 (q, $^1J(C,F) = -319.9$ Hz; CF_3), 119.10 (d, $^1J(C,P) = 86.4$ Hz; C1, phenyl), 115.57 (d, $^1J(C,P) = 84.6$ Hz; C1, phenyl), 103.72 (m; C3/C7, naphthalene), 101.18 (m; C1/C5, naphthalene), 18.53 (d, $^1J(C,P) = 51.5$ Hz; CH_2), 17.44 (d, $^1J(C,P) = 53.3$ Hz; CH_2), 8.21 (d, $^2J(C,P) = 5.5$ Hz; CH_3), 7.09 (d, $^2J(C,P) = 3.7$ Hz; CH_3); ^{19}F NMR (470.4 MHz, CD_3CN, 20 °C, C_6F_6): $\delta = -78.0$ (s, 12F; CF_3), −69.0 (m, 2F; F-4/F-8), −66.6 (m, 2F; F-2/F-6); ^{31}P NMR (161.7 MHz, CD_3CN, 20 °C, ext. H_3PO_4): $\delta = 32.63$ (d, $^3J(P,F) = 18.2$ Hz; P-3/P-7), 26.07 (d, $^3J(P,F) = 4.1$ Hz; P-1/P-5).

9a: Compound **9** (1 mmol) was suspended in CH_2Cl_2 (30 mL) and **3** (4 mmol) was added. Subsequently, PEt_3 (4 mmol) dissolved in CH_2Cl_2 (10 mL) was added to the mixture. After the mixture had been stirred for 12 h at room temperature, the pale green precipitate was filtered off, washed with CH_2Cl_2 (3 × 5 mL) and dried for 12 h under high vacuum. Yield: 62%; ^1H NMR (399.65 MHz, CD_3CN, 20 °C, TMS): 2.85 (m, 24H; CH_2) 1.29 (m, 36H; CH_3).

10: Compound **9** (1 mmol) was suspended in CH_2Cl_2 (20 mL) and **3** (4 mmol) was added. Subsequently PPh_3 (6 mmol) dissolved in CH_2Cl_2 (20 mL) was added to the mixture. After the mixture had been stirred for 12 h at room temperature Et_2O (100 mL) was added to precipitate a green solid. The solid was filtered off, washed with Et_2O (3 × 5 mL) and dried for 12 h under vacuum. Yield: 69%; UV/Vis (CH_3CN): λ_{max} (ε) = 668 (4870), 614 (5355), %72 (2920), 439 (6330), 382 (8520), 270 (37085), 214 (91945).

A New Mode of Reaction of *tert*-Butylphosphaethyne: Trinuclear Cyclopentadienylcobalt Clusters with P, PS, and PO as μ_3 Complex Ligands**

Jan Foerstner, Falk Olbrich, and Holger Butenschön*

Dedicated to Professor Erwin Weiss on the occasion of his 70th birthday

"Phosphaalkynes correspond to alkynes in all aspects, to nitriles in nothing." This remark by Regitz[1] is substantiated by the results of our investigations of the chemistry of [ω-phosphanyl(ethylcyclopentadienyl)]cobalt complexes. Herein we report on reactions of such complexes with *tert*-butylphosphaethyne that in addition to diphosphete complexes result in the formation of μ_3-phosphido clusters in good yields. The "naked" phosphorus ligand in these clusters can be oxidized with elemental sulfur or with oxygen in the air to give PS and PO ligands, respectively.

The chemistry of phosphaethynes has been investigated intensely in the past few years.[2] In a few cases mononuclear transition metal complexes with a monomeric phosphaethyne ligand have been prepared.[3–5] Because we were able to coordinate alkynes with the [(ω-di-*tert*-butylphosphanyl)ethylcyclopentadienyl]cobalt (Cp'Co) fragment without di- or trimerization,[6, 7] we investigated reactions of Cp'Co complexes with *tert*-butylphosphaethyne. The paramagnetic chloride **1** and the

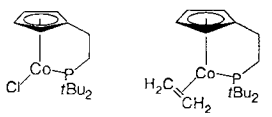
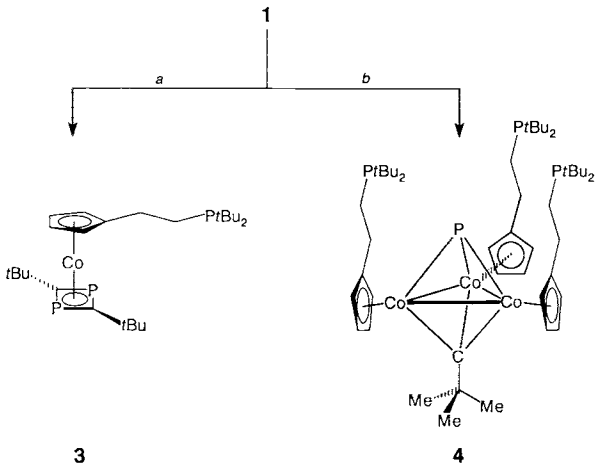
We are indebted to ENRAF-NONIUS for their kind support in performing the X-ray crystal structure analysis. We thank Dr. G. Remberg, Göttingen, and Dr. A. Kornick, Hannover, for mass spectra and helpful discussions.



1 2

ethene complex **2** generated from **1** proved to be good starting materials for Cp'Co complexes: they were applied either in the presence of sodium/amalgam (**1**) or directly (**2**) with a new ligand. The reaction starting with **1** avoids the detour via the ethene complex **2** and usually results in higher yields. Compound **2** should be used as starting material in reactions with ligands (for example arenes) that can undergo side reactions with sodium amalgam.[7]

Treatment of **1** in the presence of sodium amalgam at $-50\,^{\circ}C$ with a threefold molar excess of *tert*-butylphosphaethyne, followed by allowing the mixture to warm up to $-30\,^{\circ}C$ gives the diphosphete complex **3**, in which the "phosphane arm" has been decomplexed, in 71% yield (Scheme 1). A compound analagous



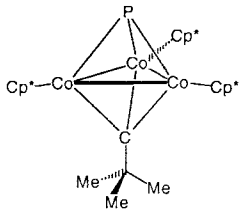
3 4

Scheme 1. a) 3 equiv PC*t*Bu, Na/Hg, THF, $-50 \rightarrow -30\,^{\circ}C$, 4 h, 71%; b) 0.33 equiv PC*t*Bu, Na/Hg, THF, $-50 \rightarrow 20\,^{\circ}C$, 90 min, 85%.

to **3** is obtained by the reaction of cyclopentadienyldi(ethene)cobalt(I) with *tert*-butylphosphaethyne.[8, 9] However, treatment of *tert*-butylphosphaethyne with a threefold excess of **1** at 20 °C leads unexpectedly to the μ_3-carbyne-μ_3-phosphidotricobalt cluster **4** as the sole product in 85% yield. Treatment of **2** with an equimolar amount of *tert*-butylphosphaethyne results in the diphosphete complex **3** (50% yield) together with cluster **4** (5% yield). Such a mode of reaction of *tert*-butylphosphaethyne, which is characterized by a complete breakage of the phosphorus–carbon triple bond and coordination of the phosphorus atom and the carbyne fragment on opposite faces of the tricobalt plane, was hitherto unkown. The quotation of Regitz mentioned at the beginning is confirmed impressively, however, because such reactions of alkynes have been observed at high temperatures (195 °C) and lead to biscarbyne clusters.[10–12] Zenneck et al.[13] and Stone et al.[14] have described compounds that result from cleavage of the P–C bond of *tert*-butylphosphaethyne and subsequent reformation of new P–C bonds.

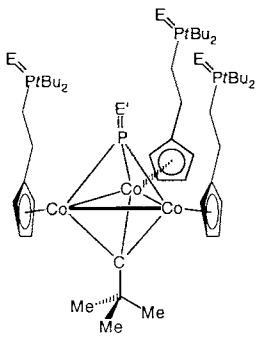
The question of how important is it to start from cyclopentadienylcobalt complexes like **1** or **2** with a phosphanylalkyl substituent for the formation of clusters like **4** was studied by treating common cyclopentadienyl- and pentamethylcyclopentadienylcobalt compounds with *tert*-butylphosphaethyne. The reaction of cyclopentadienyldi(ethene)cobalt with *tert*-butylphosphaethyne for 3 h at 20 °C, followed by evaporation of the solvent, and heating up to 180 °C for 5 min gave no evidence for the formation of a cluster corresponding to **4**.

Treatment of a 1.5 molar excess of $[\{Cp^*CoCl\}_2]$,[15] the dimer corresponding to **1** with pentamethylcyclopentadienyl (Cp*) ligands instead of the Cp' ligand, under the conditions chosen for **1** resulted in a mixture of the diphosphete complex[16] and traces of cluster **5** corresponding to **4** in an overall yield of 57%. When the reaction mixture was heated to 180 °C, **5** was obtained as the only isolated product in 1-2% yield. Thus, the "phosphane arm" promotes the formation of **4** extraordinarily. Possibly in the reaction sequence leading to **4**, initially the originally desired complex with *tert*-butylphosphaethyne is formed, which then reacts further with excess **1** leading to the formation of the tricobalt cluster. Compound **3** does not react with **1** to give **4**, and therefore it is not regarded as an intermediate in the formation of **4**. To date there are only a few μ_3-phosphido clusters known; these have been generated by treatment of phosphorus(III) halides or even P_4 with low-valent transition metal complexes.[17–21]



5 $Cp^* = C_5Me_5$

Preliminary studies on the reactivity were performed by treating the cluster **4** with elemental sulfur. Within 20 min **4** reacts with S_8 in diethyl ether at 20 °C to give the air-stable sulfuration product **6** in 77% yield, in which all four phosphorus atoms have been oxidized (Scheme 2). Compound **6** is one of the very rare complexes with PS as a ligand.[22, 23] In addition to the main product **6**, the phosphorus monoxide complex **7** was separated by column chromatography in low but reproducible yield (1–2%). It is probably generated from incompletely sulfurated product on the chromatography phase silica gel and adsorbed oxygen. This suggests that **4** is initially sulfurated at the phosphorus atoms of the phosphane fragments and then at the phosphido ligand. Oxidation of **4** with oxygen in air leads to the cluster **8**, which is oxidized at all four phosphorus atoms, in good yield (68%). This was characterized by mass spectrometry but decomposes very fast. Compounds **7** and **8** are examples of a rare class of complexes with PO as ligand, first discovered by Scherer et al., which otherwise were only found in interstellar space or as short-lived extremely reactive species.[24–26] The new compounds were characterized by spectroscopy and mass spectrometry (Table 1), and the structure of the PO complex **7** was determined by X-ray structure analysis (Fig. 1).[33]



6: E = E' = S
7: E = S, E' = O
8: E = E' = O

6 + **7** $\xleftarrow{a}$ **4** $\xrightarrow{b}$ **8**

Scheme 2. a) 1. S_8, Et_2O, 20 °C, 20 min; 2. column chromatography on silica gel (petroleum ether/diethyl ether 6:1, red fraction), **6** (77%), elution with diethyl ether (orange fraction) **7** (1–2%). b) 1. Air oxygen, diethyl ether; 2. column chromatography on silica gel, ethyl acetate/ethanol 1:1, red fraction) **8** (68%).

The structure of **7** in the crystal shows a distorted, nearly C_3 symmetrical trigonal bipyramid in which three cobalt atoms Co1, Co2, and Co3 form the base. The phosphorus atom P4 of the PO ligand is located nearly perpendicular above the center of this plane, below which the carbon atom C16 of the *tert*-butylcarbyne ligand is located. The axis comprising the atoms O, P4, C16, and C17 is almost linear (angle O-P4-C16 179.3°,

Distance P4–C16 2.773(4) Å.

P4-C16-C17 179.2°). In the Co_3 plane the Co–Co distances range between 2.459–2.475 Å. The bond lengths Co–P4 are 2.095 Å, the bond lengths Co–C16 1.887 Å. The P4–O distance of 1.489 Å is nearly the same as that found by Scherer in the first P–O complex (1.46, 1.48 Å).[27] A substituted cyclopentadienyl ligand is attached to each Co atom at the periphery of the cluster with the coordinated carbon atoms at about the same distance from the cobalt atom (av Co–C(Cp) 2.084 Å). Remarkably, all three "phosphane arms" point in the direction of the face of the Co_3 plane to which the PO ligand is coordinated. The reason for this might be the steric hindrance of the *tert*-butylcarbyne ligand at the opposite face. An attractive interaction from the O atom to the atoms P1, P2, or P3 was not observed (the shortest distance is 4.643 Å for O–P1).

We have discovered a hitherto unkown mode of reactivity of *tert*-butylphosphaethyne, which in analogy to the reaction of alkynes with cyclopentadienylcobalt complexes leads to μ_3-carbyne-μ_3-phosphidotricobalt clusters with the [ω-phosphanyl-(ethylcyclopentadienyl)]cobalt complexes **1** and **2**, whose phosphido ligand can be oxidized to PS and PO ligands, respectively. The "phosphane arm" in **1** and **2** is evidently needed for the formation of the cluster, since comparable cyclopentadienyl or pentamethylcyclopentadienyl metal complexes form analogous clusters at best in traces. We are currently investigating the role of the "phosphane arm" in the formation of **4**.

Methyl Iodide as a Source of CH_2: Two Routes for Generating 1,1-Disubstituted Butatrienes in the Coordination Sphere of a Transition Metal**

Helmut Werner,* Matthias Laubender, Ralf Wiedemann, and Bettina Windmüller

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

Following the reports on the synthesis of vinylidene complexes of the general type *trans*-[RhCl(=C=CHR)(P*i*Pr$_3$)$_2$],[1] we recently also described an efficient preparative route to the corresponding allenylidene compounds *trans*-[RhCl(=C=C=CRR′)(P*i*Pr$_3$)$_2$].[2] In the course of investigations into the reactivity of these compounds, we have now discovered that the allenylidene unit can be converted by two different pathways into 1,1-disubstituted butatrienes $H_2C{=}C{=}C{=}CRR'$, which because of their lability are otherwise hardly accessible. We note that up to now there is no precedent for the coupling of a CH_2 fragment, generated from CH_2N_2 or CH_3I, with an allenylidene moiety to yield a butatriene. Moreover, allenes can likewise be obtained from allenylidenerhodium complexes.

In contrast to compounds *trans*-[RhCl(=C=CHR)(P*i*Pr$_3$)$_2$] (R = Ph, *t*Bu, CO_2Me), which are inert in the presence of CH_2N_2,[3] complexes **1**–**3**[4] react with excess diazomethane at room temperature within a few minutes.[5] The red or orange butatriene complexes **4**–**6** (Scheme 1), which are only moderately sensitive to air and water, were isolated in nearly quantitative yield. The compositions of **4**–**6** have been confirmed by elemental analysis. The proposed structure shown in Scheme 1 is particularly supported by the ^{13}C NMR spectra (Table 1), which display four signals between $\delta = 180$ and 12 for the carbon atoms of the butatriene ligand. Two of these signals show a relatively large Rh–C coupling and are thus assigned to the C atoms of the butatriene ligand bonded to the metal. The chemical shift of the C^1 resonance as well as the ^1J(CH) coupling constant (161.4 Hz) of **4** indicate a predominant sp^3 character of this carbon atom which implies that the bonding between Rh, C^1, and C^2 is related to that of a metallacyclopropane.

The X-ray crystal structure analysis of **4** (Fig. 1)[6] reveals a distorted square-planar coordination around the central atom;

Table 1. Selected spectroscopic data of complexes **4**–**8** and **12**–**14**, and of the cumulenes **10** and **16** (without data for phosphane ligands, phenyl and *tert*-butyl groups); for assignment C^1–C^4 and H^{exo}, H^{endo} see Scheme 1.

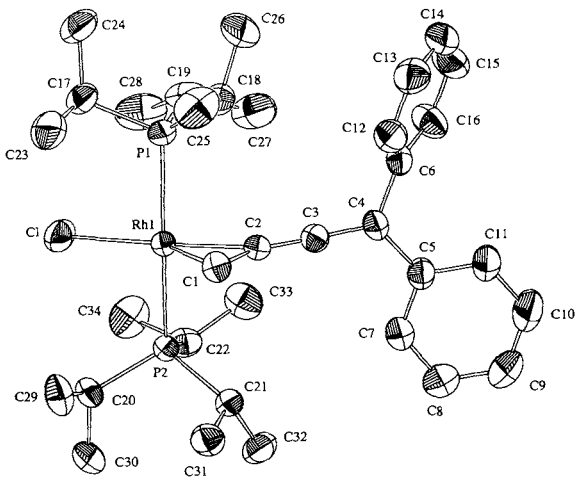

Fig. 1. Molecular structure of **4** (ORTEP plot) in the crystal. Selected bond lengths [Å] and angles [°]: Rh–P1 2.365(1), Rh–P2 2.355(1), Rh–Cl 2.349(1), Rh–C1 2.060(2), Rh–C2 2.063(2), C1–C2 1.408(3), C2–C3 1.272(3), C3–C4 1.335(3); P1-Rh-P2 166.45(2), P1-Rh-Cl 88.16(3), P1-Rh-C1 96.70(7), P1-Rh-C2 90.56(6), P2-Rh-Cl 87.42(2), P2-Rh-C1 94.35(7), P2-Rh-C2 92.89(6), Cl-Rh-C1 144.36(7), Cl-Rh-C2 175.65(6), C1-Rh-C2 40.0(1), Rh-C1-C2 70.1(1), Rh-C2-C1 69.9(1), C1-C2-C3 144.7(2), C2-C3-C4 174.8(2).

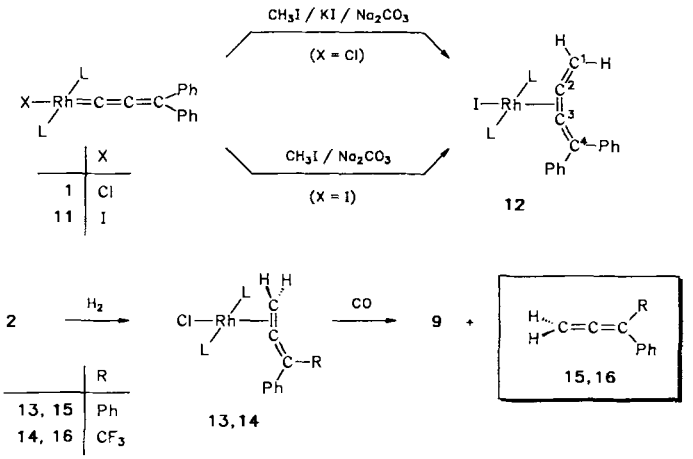
the Cl, Rh, and C1–C4 atoms lie in one plane. The Cl-Rh-C2 axis is almost linear (175.65(6)°), while the P1-Rh-P2 axis (166.45(2)°) deviates somewhat more from linearity. Despite the unsymmetrical coordination of the $C{=}CH_2$ unit to the metal, the Rh–C1 and Rh–C2 bond lengths are nearly identical. This is in contrast to the structurally similar compound *trans*-$[RhCl\{(1,2\text{-}\eta)\text{-}C^1H_2{=}C^2{=}C^3HC^4O_2Et\}(P\mathit{i}Pr_3)_2]$, in which the Rh–C1 and Rh–C2 bond lengths are 2.120(5) and 1.991(5) Å, respectively.[7]

Upon heating in toluene to 80–90 °C for several hours, compounds **4** and **6** rearrange to the thermodynamically more stable complexes **7** and **8**, respectively. The isomerization can easily be monitored by a change of color from red to yellow. In the case of **8**, a mixture of isomers **8a**/**8b** is formed that differ in the relative position of the phenyl and *tert*-butyl groups to the metal center. If the rearrangement of **6** is monitored by ^{31}P NMR spectroscopy, a **8a**:**8b** ratio of about 2:1 is observed initially that after 10 h in toluene at 90 °C changes to 10:1. Under these conditions, a complete conversion of **8b** to **8a** does not occur. Complex **8a** has been isolated analytically pure upon fractional crystallization from acetone (−78 °C) and, by comparison of the ^1H NMR data with those of **8b**, identified as the isomer in which the phenyl group at C^4 is directed towards the metal. The assignment of the signals for the H^{endo} and H^{exo} protons at C^1 follows from the work of Gladysz at al.[8] who assigned the resonances of the CH_2 protons of the allene complex $[C_5H_5Re(\eta^2\text{-}CH_2{=}C{=}CH_2)(NO)(PPh_3)]BF_4$ based on NOE measurements. We note that in all of the previously described 1,1,4,4-tetrasubstituted butatrienerhodium(I) compounds *trans*-$[RhCl\{(2,3\text{-}\eta)\text{-}R_2C^1{=}C^2{=}C^3{=}C^4R'_2\}(PPh_3)_2]$, which were prepared from $[RhCl(PPh_3)_3]$ and corresponding butatrienes,[9] the central C=C bond is coordinated to the metal; the linkage of a terminal $R_2C{=}C$ bond not to rhodium(I) but to platinum(0) was recently reported by Stang.[10]

Similarly to the butenyne complex *trans*-$[RhCl\{(1,2\text{-}\eta)\text{-}PhC^1{\equiv}C^2C^3H{=}C^4HPh\}(P\mathit{i}Pr_3)_2]$,[11] compounds **4**–**8** also react rapidly with CO in benzene at room temperature yielding the carbonyl complex **9**[12] by ligand exchange. Of the butatrienes formed in these conversions, those with CPh_2 and $C(Ph)CF_3$ as the terminal unit are quite labile and undergo secondary reactions. The hitherto unknown compound **10** was characterized by GC/MS and by comparison of the spectroscopic data with those of other butatrienes.[13, 14]

Surprisingly, there is also a second route to convert a metal-bonded allenylidene moiety into a butatriene ligand (Scheme 2).



Scheme 2. L = $P\mathit{i}Pr_3$.

Complex **1** does not react, as we expected, with CH_3I to give a methylrhodium(III) compound. Instead, in the presence of excess Na_2CO_3, a mixture of products is formed, which besides **7** also contains the corresponding iodo derivative **12**.[15] A subsequent reaction of the mixture of products with KI yields **12** almost quantitatively. If compound **11**[2a] is treated with CH_3I and Na_2CO_3 in acetone/THF at room temperature, the butatriene complex **12** can be isolated in 76% yield. As far as the mechanism of formation of **12** is concerned, we assume that in the initial step an oxidative addition of CH_3I at the rhodium center takes place that is followed by an insertion of the allenylidene unit into the $Rh{-}CH_3$ bond. The intermediate $Rh{-}C(CH_3){=}C{=}CPh_2$ then reacts by a β-H shift to give a butatriene(hydrido)diiodorhodium(III) complex, which upon reductive elimination of HI generates the product **12**. Analogous to the first two steps is the formation of $[IrCl(I)\{C(CH_3){=}CH_2\}(P\mathit{i}Pr_3)_2]$ and $[IrI\{C(CH_3){=}CH_2\}\{N(SiMe_2CH_2PPh_2)_2\}]$ from the corresponding vinylidene complexes and methyl iodide;[16] in these cases, however, a subsequent β-H shift does not occur. Preliminary studies indicate that under the same conditions the dideuterated compound *trans*-$[RhCl\{(2,3\text{-}\eta)\text{-}C^1D_2{=}C^2{=}C^3{=}C^4Ph\}(P\mathit{i}Pr_3)_2]$ is formed from **11** and CD_3I. Kinetic studies, now in progress, should provide a more detailed insight into the mechanism of this unexpected reaction.

Compounds **1** and **2** are hydrogenated by H_2 at a different rate. While the reaction of **1** with H_2 in benzene at room temperature is rather slow and completed after 40 h, the corresponding reaction of **2** takes only 30 min. In both cases, the allene complexes **13** and **14** are quantitatively formed by cleavage of the Rh=C double bond.[17] Remarkably, under the chosen conditions no hydrogenation of the allene ligand occurs. Only after increasing the reaction time to 10 days and raising the temperature of the reaction to 60 °C, is the formation of a new rhodium-containing product observed, which according to the NMR data is $[RhH_2Cl(P\mathit{i}Pr_3)_2]$.[18] With regard to the structure of **13** and **14** it is important to note that the ^1H NMR spectra display only one signal for the CH_2 protons, thus confirming the coordination of the *unsubstituted* double bond of the allene to the metal center. A slippage of the $[RhCl(P\mathit{i}Pr_3)_2]$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3511-1238 $ 15.00+.25/0

fragment along the axis of the cumulene, as has been observed for $[Fe(\eta^2\text{-}Me_2C{=}C{=}CMe_2)(CO)_4]$[19] and $[PtCl_2(\eta^2\text{-}Me_2C{=}C{=}CMe_2)]$,[20] could not be detected.

In the same way as for **6** and **8**, on treatment of **13** and **14** with CO (benzene, 10 °C, 1 min) the olefinic ligand can be displaced leading to the 1,1-diphenylallene **15**, which is already known,[21] and the allene derivative **16**, which has been characterized by ^1H, ^{13}C, and ^{19}F NMR spectroscopy (see Table 1).

Imine Substituent Effects on [2+2]Cycloadditions with Ketenes**

Claudio Palomo,* Jesus M. Aizpurua,* Marta Legido, Regina Galarza, Pere M. Deya, Jacques Dunoguès, Jean Paul Picard, Alfredo Ricci, and Giancarlo Seconi

The cycloaddition of imines with ketenes, generated from acid chlorides and tertiary amines, is recognized as one of the most convenient approaches to β-lactams.[1] However, virtually all of the investigations have dealt with the use of non-enolizable imines derived from aldehydes and, therefore, subsequent steps are often required to obtain the desired target product. In fact, ketene-enolizable aldimine cycloadditions, which would generate a wider range of substitution patterns at the C_4 position of the β-lactam ring, have not been viable, because of the instability of the starting imines and the presence of competitive deprotonations. We report herein on our initial findings on the development of this approach to a general asymmetric synthesis of 3-amino-4-alkyl β-lactams. The significance of these compounds as valuable precursors of β-lactam antibiotics, more complex organic compounds, large and medium heterocycles, and amino acid derivatives is apparent.[2] We thought that α-(trimethylsilyl)methyl imines[3] might provide a solution to the above-mentioned problems for two reasons: first, because of the ability of silyl groups to stabilize electron-deficient carbon centers in the β- and/or γ-position[4] and, second, because of the zwitterionic character of the reaction intermediate proposed for this kind of cycloaddition.[5]

[**] This work was supported by the E. U. (Project: SC1 CT 91/0646) and, in part, by Basque Government (Project: PI9386). Grants to M. L. from Spanish Education Ministry and to R. G. from Gobierno Navarro are acknowledged.

The reaction of **1**[6] with **2**[7] resulted exclusively in the formation of β-lactams *cis*-**3** and *trans*-**3** with good to excellent diastereomeric selectivities and, most notably, with complete asymmetric induction at the C_3 position. The results summarized in Table 1 illustrate the efficiency of this method for the

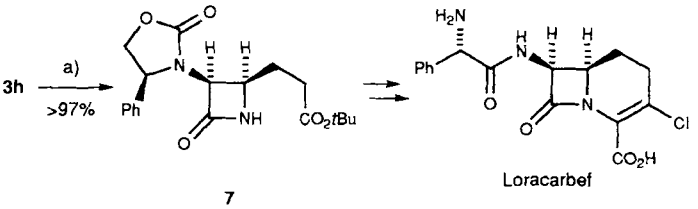
[a] Reactions were conducted on a 10 mmol scale in refluxing benzene or $CHCl_3$; ratio of acid chloride:imine:triethylamine 1.2:1:1.4. [b] The crude imines were used directly. For imine **2a** the *E*:*Z* isomer ratio was 90:10. All other imines showed *E*:*Z* ratios >98:2 as determined by ^1H NMR spectroscopy (300 MHz). [c] Yield of the corresponding mixture of *cis* and *trans* β-lactams. [d] Determined by integration of the doublets at $\delta \approx 4.51$ and ≈ 4.40, which correspond to the *cis*- and *trans*-positioned protons at C3, respectively. [e] Pure compounds crystallized from hexanes/CH_2Cl_2 (10/1). All data recorded in CH_2Cl_2 ($c = 1.0$). [f] Reaction carried out at −78 °C to room temperature overnight. [g] Reaction carried out using a twofold excess of acid chloride and triethylamine.

direct construction of homochiral β-lactams with linear as well as branched chains at the C_4 position. In each case tested, yields were uniformly good when the reactions were carried out in boiling benzene or chloroform, and the use of a twofold excess of acid chloride **1** resulted in a noticeable increase in the yield, particularly when chloroform was used as solvent. Lowering the reaction temperatures led to a decrease in yield with no significant improvement in the ratio of *cis* to *trans* diastereomers. Noteworthy, even the imine **2e** derived from the easily enolizable phenylacetaldehyde, afforded the expected β-lactam, whereas the corresponding *N*-benzyl or *N*-(4-methoxy)phenyl imines gave only enamides and hydrolysis products.[8]

The absolute stereochemistry of the cycloaddition products was established by the conversion of the azetidinone *cis*-**3a** into the known compound **6a** (Scheme 1),[9] and a uniform reaction mechanism was assumed for the other derivatives. Thus, cleavage of the oxazolidinone moiety and subsequent *N*-Boc protection (Boc = *tert*-butoxycarbonyl) of the resulting free amino derivative gave **4a** [syrup, $[\alpha]_D^{25} = +32.8$ ($c = 1.0$ in CH_2Cl_2)] in 72% yield. Subsequent removal of the bis(trimethylsilyl)-methyl moiety by treatment with ammonium cerium(IV) nitrate in acetonitrile/water afforded the corresponding *N*-formyl-β-lactam **5a** in 92% yield. Remarkably, this novel method of deprotection of *N*-[bis(trimethylsilyl)methyl] amides expands considerably their usefulness in synthesis, complementing, as a cationic umpolung, the known fluoride-mediated reactivity of α-amido carbanions.[10] The cleavage of the formyl group from the ring N atom[11] in compound **5a**, which was carried out in a slightly basic medium, afforded **6a** in almost quantitative yield.[12] In addition to this two-step method to remove the *N*-[bis(trimethylsilyl)methyl] substituent from cycloaddition products **4**, we also found that prolonged exposure of β-lactams **3** to ammonium cerium(IV) nitrate in methanol instead of in acetonitrile/water led directly to the corresponding *N*-unsubstituted β-lactams in almost quantitative yields. This is illustrated (Scheme 2) by the synthesis of the loracarbef precursor **7** from **3h**.[13]



Scheme 2. a) $(NH_4)_2Ce(NO_3)_6$, MeOH, 0 °C, 6 h.

In summary, our results help to fill the gap with regard to the unexplained behavior of enolizable aldimines in [2+2]cycloadditions with ketenes[14] and offer for the first time a general asymmetric convergent synthesis to 3-amino-4-alkyl-β-lactams. It is expected that this new methodology for preventing enolization could be extended to further reactions involving zwitterionic species.

Experimental Procedure

Preparation of β-lactams **3**: *C*,*C*-bis(trimethylsilyl)methylamine (1.75 g, 10 mmol) was added to a solution of the corresponding enolizable aldehyde (10 mmol) in dry dichloromethane (10 mL) containing 4 Å molecular sieves. The mixture was stirred at 20 °C and monitored by GC-MS until completion (typically, 30 min). The molecular sieves were filtered off, the solvent was evaporated, and replaced by new dried molecular sieves (3 g) and freshly distilled dry chloroform (30 mL). To this solution, kept under nitrogen, triethylamine (5.6 mL, 40 mmol) and a solution of **1** (4.78 g, 20mmol) in chloroform (10 mL) were added dropwise at 0 °C, and the resulting mixture was heated to reflux for approximately 20 h. After work-up [10b] the corresponding β-lactams **3a–h** were obtained.

Deprotection of the β-lactams **3**: To a solution of the appropriate β-lactam **3** (5 mmol) in dry methanol (40 mL), ammonium cerium (IV) nitrate (10.96 g, 20 mmol) was added at 25 °C, and the suspension was stirred at the same temperature and monitored by TLC. After 6 h, the reaction mixture was taken up in water (50 mL) and extracted with ethyl acetate (3 × 80 mL). The organic layer was washed successively with aqueous $NaHCO_3$ (100 mL, saturated solution), aqueous

aqueous $NaHSO_3$ (3 × 50 mL, 40%), aqueous $NaHCO_3$ (100 mL, saturated solution), and aqueous NaCl (100 mL, saturated solution). Drying and evaporation of solvents yielded quantitatively fairly pure **6**.

[12] A similar transformation sequence was achieved starting from *trans*-**3a** that confirmed the (*S*)-configuration at C3 in all diastereomers obtained. Selected data: **5**: M.p. 156–157 °C, $[\alpha]_D^{25} = -43.4$ ($c = 1.0$ in CH_2Cl_2); **6**: M.p. 182–183 °C, $[\alpha]_D^{25} = +55.0$ ($c = 1.0$ in MeOH).

[13] For a comprehensive review, see: R. D. G. Cooper in *The Chemistry of β-Lactams* (Ed.: M. I. Page), Chapman and Hall, London, **1992**, p. 272.

[14] A semiempirical SCF-MO AM1 theoretical study carried out in our laboratories to establish the dependence of the enamide or β-lactam pathway upon imine nitrogen substituents (CH_3 or $CH(SiMe_3)_2$) was consistent with experimental results, and suggests that the "β-effect" exerted by the two σ HC-$SiMe_3$ bonds is the responible for the chemoselectivity observed. These results will be published in due course.

Lateral Thinking on Organic Textbooks

Aspekte der Organischen Chemie. Band 1: Struktur. Edited by *G. Quinkert, E. Egert* and *C. Griesinger*. Verlag Helvetica Chimica Acta, Basel, 1995. 503 pp., hardcover DM 148.00.—ISBN 3-906390-11-X The English version is planned for later this year (ISBN 3-906390-15-2).

It can be said straight away that this first volume, on structure, in the series *Aspekte der Organischen Chemie* forms an excellent addition to the existing range of textbooks, and it can be recommended both for students and for all involved in the teaching and practice of chemistry. In its approximately 500 pages it offers the reader a view of organic chemistry from a mainly structural standpoint, which cannot be found elsewhere. Many of the topics included, such as the analysis of the crystal structure of diamond and the Prelog catalog of regular tetrahedral structures, are treated didactically for the first time in a structural context. The presentation of the subject matter is esthetically pleasing with a carefully written text, thus helping the reader to understand the more difficult concepts. Nevertheless, the book is not easy reading, and the novice will probably need to use it in conjunction with a more conventional textbook. The intention of the editors and authors is to develop the student's ability for independent learning, for which the excellent bibliographies at the ends of the chapters are a valuable aid. Many of the chapters begin with an interesting historical introduction which provides some light relief. At the beginning of Chapter 8 there is even a short introduction to the ideas of Karl Popper concerning the philosophy of science.

The volume is divided into two parts, with a gray stripe throughout the margin of Part 2 to emphasize the distinction. Part 1 consists of eight chapters which introduce the structural aspects of organic chemistry [constitution, configuration, and conformation (Chapter 2), chirality and symmetry (Chapter 3), molecular topology (Chapter 4)] and discuss examples of their application to specific topics in classical and modern chemistry. Other chapters explain the fundamentals needed for understanding this part of the book. In a very thorough didactic style the book introduces some highly topical areas of research in biological chemistry, thereby bridging the gap between organic chemistry and biology, with special emphasis on the structural analysis of supermolecules and their constituent units. Thus, structural considerations are applied not only to compounds such as carbohydrates and steroids (Chapters 5 and 6) but also to supramolecular structures such as the diamond lattice (Chapter 7). The latter chapter in Part 1 also contains an excellent discussion of the stereostructural aspects of DNA, homo-DNA, and pyranosyl-RNA. Other topics covered include base-pairing, the various conformations of DNA, and antigen and antisense strategies. There is a particularly good description of the conformational analysis of peptides and their secondary structural features, which is probably not treated better in any other book. The setting-up and "tagging" of peptide libraries is also described. Here the authors have taken the bold step of including detailed results from very recent studies. However, they caution that their experimental results, theories, and hypotheses need to undergo a period of expert criticism before being accepted (see Chapter 1: the outline of the book's aims and the overall conclusion). The last chapter of Part 1 discusses the qualitative MO model. The authors then use this model to interpret some conformational observations that cannot be explained on the basis of the classical structure model developed in Chapters 2–6.

Part 2 highlights some important aspects of modern organic chemistry and examines them in detail, and treats some of the topics already mentioned in Part 1 in greater depth. These include the use of information from data banks (Chapter 9), symmetry, point groups, and space groups (Chapter 11), the determination of absolute configuration (Chapter 12), an introduction to NMR spectroscopy (Chapter 13), and aromaticity (Chapter 14). Chapter 15 discusses hydrogen-bonding, which plays an essential role in the formation of supramolecular structures in chemistry and biology. However, the treatment of this topic is not really complete, as it does not include aspects such as secondary electrostatic interactions. Based on the foregoing discussions, the final chapter then deals with base-pairing in biology and chemistry, explaining the basic principles underlying classical and modern molecular biology. The Periodic System is shown inside the front cover of the book and the genetic code inside the back cover. The work provides an excellent demonstration of the interdisciplinary nature of the field and the wide-ranging relevance of organic chemistry. This volume on structure represents a notable advance for the teaching of organic chemistry, and will be of great benefit to students, not least because of the excellent quality of the writing. It is not a textbook in the conventional sense; instead it aims to stimulate thought, and presents organic chemistry in a slightly different and sometimes unusual way. After this first volume of the series we await with interest Volume 2 (reactivity), Volume 3 (synthesis), and Volume 4 (structure determination).

Chiral zirconocenes are good catalysts for a variety of enantioselective reactions. More on the subject can be found in the review by A. H. Hoveyda and J. P. Morken.

Enantioselective C–C and C–H Bond Formation Mediated or Catalyzed by Chiral ebthi Complexes of Titanium and Zirconium**

Amir H. Hoveyda* and James P. Morken

Dedicated to our mentor Professor Stuart L. Schreiber

The development of catalytic processes that effect enantioselective bond formation under mild conditions is an important and challenging task in modern chemical synthesis. In this connection, chiral C_2-symmetric *ansa*-metallocenes (bridged metallocenes) have found notable applications as catalysts. This article discusses the chemistry of this class of chiral metallocene complexes with regard to their utility in catalytic and enantioselective C–C and C–H bond formation reactions. In addition, where applicable, a brief comparison with other related catalytic enantioselective processes is offered. Many of the reactions effected with high levels of enantioselectivity by catalytic amounts of these complexes are of great significance to the preparation of new materials and in the synthesis of therapeutic agents. For example, zirconocene complexes readily catalyze the enantioselective addition of alkylmagnesium halides to alkenes, and cationic zirconocene complexes may promote the highly stereoregulated copolymerization of terminal alkenes. Furthermore, the related chiral titanocenes are involved in an impressive range of useful asymmetric catalytic reactions, including the enantioselective hydrogenation of olefins and reduction of imines or ketones. This review attempts to bring together the practical aspects of the use of [(ebthi)M] complexes of Group 4 transition metals (catalyst synthesis and resolution), outline the manner in which the C_2-symmetric chiral ligands are believed to initiate stereoselective bond formation, and highlight the aspects of this chemistry that are less well understood and require further research.

Keywords: asymmetric syntheses · asymmetric catalysis · enantiomeric resolution · metallocenes · sandwich complexes

1. Introduction

The design and development of catalytic processes that effect bond formation under mild conditions in a highly enantioselective fashion (>90% enantiomeric excess) stands as one of the most important and challenging tasks in modern chemical synthesis.[1] Organometallic systems that possess well-defined three-dimensional structures—metal complexes whose structural integrity in solution can be reliably predicted—offer a particularly attractive option in the design of enantioselective reactions, since the intricacies of substrate–catalyst association can be studied in appreciable detail. Within this context, chiral C_2-symmetric *ansa*-metallocenes, also referred to as bridged metallocenes, have found extensive use as catalysts for enantioselective bond formation.[2] In general, bridged ebti-metallocene dichlorides such as **1**–**3** put forth attractive options for the development of asymmetric reactions because their structures are conformationally constrained and they are relatively easy to prepare. The purpose of this article is to provide a review of the chemistry of these and related chiral metallocene complexes, particularly in relation to their utility in catalytic and enantioselective C–C and C–H bond formation.

2. Chiral, Nonracemic ebthi Complexes of Group 4 Transition Metals: Synthesis and Resolution

2.1. A Historical Perspective

The chiral titanocene derivative **1** was first prepared by Brintzinger and co-workers, as part of their pioneering work in the design and synthesis of configurationally stable Group IV complexes.[3] Their 1982 account describes the preparation of the racemic chiral titanocene, a procedure for separating the chiral complex from the corresponding *meso* isomer, and a method for resolving the racemate as the binaphtholate derivative. In addition, Brintzinger's landmark paper offered the first X-ray crystal structure of a member of this class of C_2-symmet-

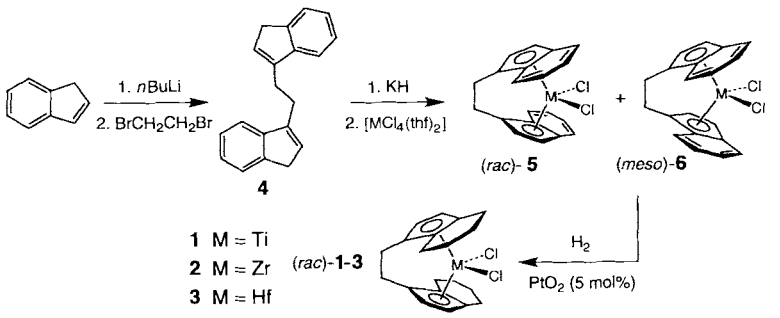
[**] ebthi = ethylenebis(tetrahydroindenyl).

ric metallocenes. A report detailing studies on the zirconocene complex **2** was published by the Brintzinger laboratory in 1985. The synthesis and X-ray crystal structure of the hafnium complex **3** was reported in 1987 by Ewen and Atwood.[4]

Collins and co-workers in 1988 reported a refinement of the original crystal structures of **1** and **2**.[5] In 1995 Piemontesi and Sironi published crystal structures of *rac*- and *meso*-[(ebi)$ZrCl_2$] (ebi = ethylenebis(indenyl);[6] these researchers also disclosed a detailed spectroscopic study of the organometallic complexes, unveiling many of their subtle conformational preferences.

Collins et al.[5] described experimental modifications in the synthesis of zirconocene complexes; the new protocol allowed for improved yields, rendering these organometallic complexes more accessible. Additional modifications of the synthesis route by Buchwald et al. enhanced the efficiency of the catalyst preparation; this included use of KH to deprotonate bis(indene) (Scheme 1) and utilization of a double-dilution technique to complex the bis(indenyl) ligand with [$ZrCl_4(thf)_2$].[7] Interestingly, Buchwald's procedural adjustments also led to the formation of roughly 30% of the corresponding *meso* isomer (2:1 *rac*:*meso*).



Scheme 1. General synthesis scheme for the preparation of chiral metallocenes **1**–**3**.

2.2. General Procedure for Catalyst Preparation

2.2.1. Synthesis of Racemic [(ebthi)M] Complexes

As illustrated in Scheme 1, **4** is produced through alkylation of dibromoethane with the lithium salt derived from indene (*n*BuLi, −78 °C, THF). When the bis(indenyl) dianion is complexed to the solvated metal tetrachloride,[8] *rac*-[(ebi)MCl_2] **5** and *meso*-[(ebi)$ZrCl_2$] **6** form. In principle, **5** (after appropriate enantiomeric resolution) can be used in asymmetric transformations; however, chiral metallocenes **5** are not as readily soluble as the ebthi complexes **1**–**3** and tend to be somewhat less stable than complexes that are formed by hydrogenation of the pendant cyclohexadiene groups. Accordingly, Pt-catalyzed hydrogenation of a mixture of **5** and **6** is typically carried out to afford metallocenes **1**–**3**.[9]

Most recently, Jordan et al. have described a convenient method for the synthesis of *rac*-[(ebi)$ZrCl_2$], in which the *meso* and racemic [(ebi)$Zr(NMe_2)_2$] complexes (prepared by reaction of reaction of **4** with [$Zr(NMe_2)_4$]) undergo rapid equilibration under appropriate reaction conditions.[10] Whereas the initial ratio after two hours is 2:1 (*rac*:*meso*), after 17 hours at 100 °C it is increased to 13:1; subsequent recrystallization of the amido complex affords the desired chiral metallocene in 95% yield. Subsequent treatment with $Me_2NH \cdot HCl$ affords **6** in 69% yield. (The entire operation can be carried out in a single vessel as well.) Most likely, *rac*-[(ebi)-$Zr(NMe_2)_2$] can itself be used for a large number of reactions in which the dichloride is typically employed.

2.2.2. Resolution of Racemic ebthi Complexes

2.2.2.1. Resolution through Mandalate Complexes

Resolution procedures have so far been developed only for the titanium and zirconium metallocenes **1**

Amir H. Hoveyda was born in Tehran in 1959. He received his BA degree from Columbia University in 1981. He then moved to New Haven, where he was a graduate student at Yale University with Professor Stuart L. Schreiber. After receiving his PhD in 1986, he joined Professor David Evans at Harvard as an American Cancer Society postdoctoral fellow. In June 1990 he joined the faculty at Boston College, where he is now professor of chemistry. His research interests are the design and development of new stereoselective reaction methods, organometallic chemistry, the study of reaction mechanisms, asymmetric catalysis, and the synthesis of natural products. His honors include the Young Investigator award of the National Science Foundation, the Pfizer Award in Synthetic Organic Chemistry, a Sloan Fellowship, a Camille Dreyfus Teacher–Scholar Award, and a Johnson & Johnson Focused Award.

A. H. Hoveyda

J. P. Morken

James P. Morken was born in Concord, California, in 1967. He received his BS at the University of California, Santa Barbara, in 1989, after which he joined Professor Hoveyda's research group at Boston College. His graduate work focused on the development of zirconium-catalyzed asymmetric carbomagnesation reactions, for which in 1993 he was awarded a graduate fellowship by the American Chemical Society, sponsored by Glaxo, Inc. Dr. Morken received his PhD in 1995. He is currently an NSF postdoctoral fellow at Harvard University in the laboratories of Professor Stuart L. Schreiber.

and **2**. Two methods for the effective separation of the metallocene enantiomers involve the displacement of the bound chloro ligands with appropriate chiral, nonracemic ligands. Separation of the resulting diastereomers, followed by reinstallation of the chloro ligands, affords the optically pure metallocene dichlorides. The successful procedure illustrated in Scheme 2 calls for the use of *O*-acetylmandelic acid. Diastereomeric mandelate salts **7** and **8** may thus be separated by recrystallization.[11] Treatment of the derived nonracemic mandalates with hydrochloric acid, or formation of the dimethyl metallocene (after treatment with MeLi), followed by the addition of HCl, readily converts **7** and **8** to chiral nonracemic metallocenes **1** and **2**.

2.2.2.2. Resolution through Binaphtholate Complexes

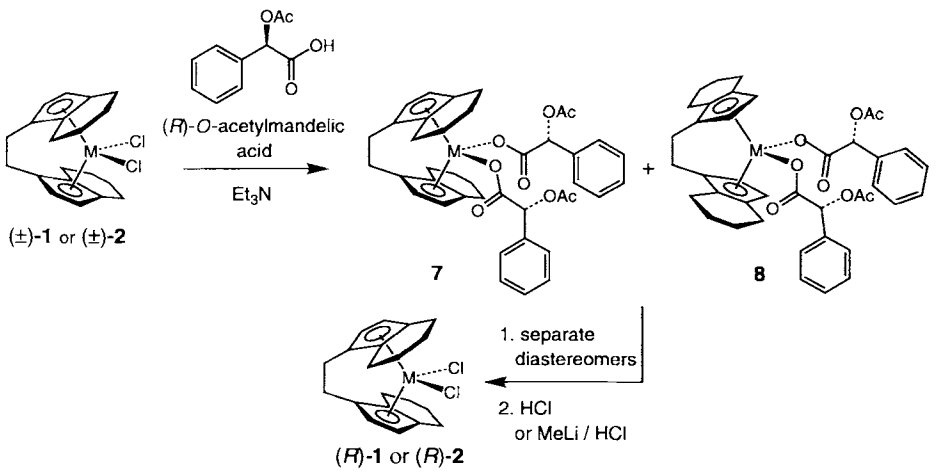
Although the mandelic acid used in the previously mentioned resolution procedure is relatively inexpensive (roughly \$5 per gram), the fractional recrystallization required to separate the diastereomeric derivatives **7** and **8** is somewhat tedious. A more popular procedure for metallocene resolution[3a, 11] relies on the fact that nonracemic binaphtholates (Na[3a] or Li salts[11]) efficiently react with only one enantiomer in the racemic mixture of chiral metallocenes (Scheme 3). Hence, treatment of racemic **1** or **2** with 0.5 equivalents of nonracemic lithium binaphtholate results in the formation of (*R*)-[(ebthi)M(binol)] **9** together with 0.5 equivalents of the unreacted nonracemic metallocene dichloride. The latter may be separated by treatment with silica gel or alumina, since in contrast to the binaphthol derivatives, dichlorides are adsorbed onto these chromatographic supports. Air-stable binaphtholate salts such as **9** are often used directly as precatalysts for various asymmetric processes. Alternatively, these chiral nonracemic metallocene complexes can be converted into the corresponding dichlorides by treatment with HCl. (For the zirconocene **1**, pretreatment with MeLi to form [(ebthi)$ZrMe_2$] is required to separate the free binaphtholate from the metal complex).

3. Stereoselective Reactions with *ansa*-Metallocenes as Reagents

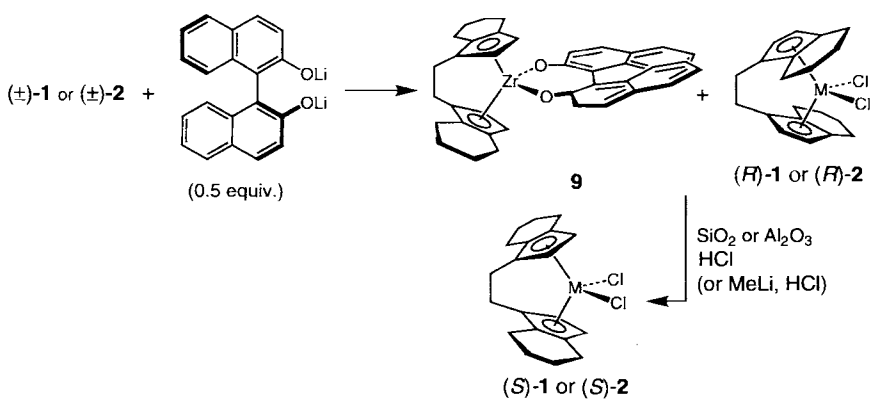
3.1. Enantioselective, Zirconocene-Mediated Synthesis of Allylic Amines

Buchwald and co-workers have reported a procedure that employs metallocene complex **2** for the highly enantioselective preparation of chiral nonracemic allylic amines.[12] Although this protocol requires stoichiometric amounts of the chiral metallocene complex, it offers a reliable and highly enantioselective route towards these important chiral materials. As shown in Equation (a), the net transformation is an asymmetric reductive coupling of an alkyne to the α-carbon of a secondary amine.

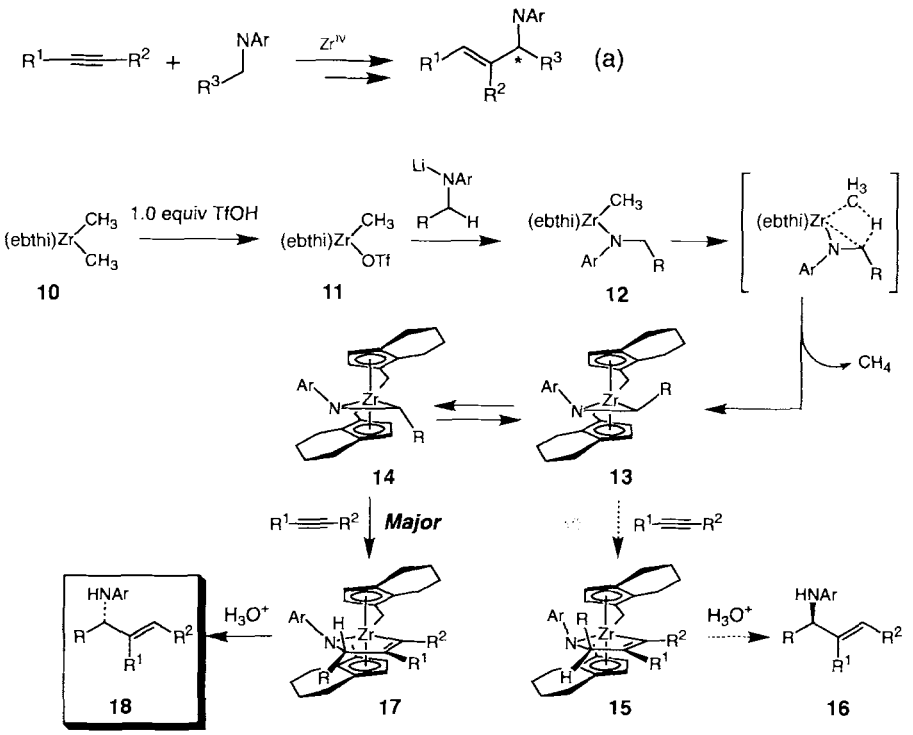
As illustrated in Scheme 4, the zirconocene-mediated synthesis of allylic amines begins with (*S*)-[(ebthi)$ZrMe_2$] **10**, prepared by treatment of binaphtholate **9** (Scheme 3) with two equivalents of methyllithium. Reaction of dimethylzirconocene **10** with one equivalent of trifluoromethanesulfonic acid at −78 °C affords the zirconium methyltriflate **11**, which upon treatment with the appropriate lithium amide is readily converted to **12**. At this point, warming of the reaction mixture to 80 °C results in the formation of the zirconocene–imine complexes **13** and **14**. It is not clear whether β-H abstraction furnishes **13** selectively, or if equilibrium between **13** and **14** is rapidly established at elevated temperatures.[13] In the latter case, the equilibrium should lie on the side of **14**, due to the minimization of steric interactions between the alkyl substituent (R) and the cyclohexyl moiety of the chiral ligand (these steric repulsions likely exist in **13**). Regardless, addition of the alkyne substrate leads to a highly regioselective insertion to provide the five-membered zirconacycle **17**. Subsequent hydrolysis of the metallacyclopentane furnishes the desired allylic amine in excellent enantiopurity (Table 1).



Scheme 2. Resolution of metallocene enantiomers through separation of their diastereomeric mandalate salts.



Scheme 3. Resolution of metallocene enantiomers through separation of their diastereomeric binaphtholate derivatives.



Scheme 4. Buchwald's protocol for [(ebthi)Zr]-mediated enantioselective coupling of alkynes and imines. For R, R^1, and R^2 see Table 1.

Table 1. Zirconocene-mediated enantioselective synthesis of secondary allylic amines.

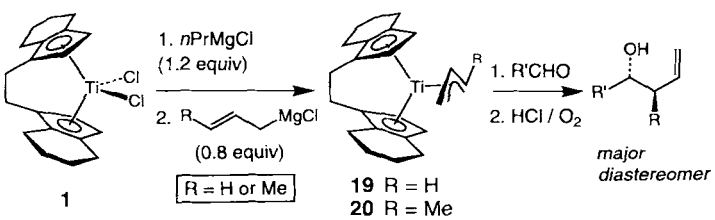
5	Me, O, H	PhNLi, Ph	HNPh, Ph, Me, OH	43 [b]	94

[a] 8:1 mixture of diastereomers. [b] 7:1 mixture of diastereomers.

As the examples in Table 1 illustrate, the zirconocene-mediated synthesis of allylic amines tolerates a variety of functional groups in both the alkyne and amine starting materials. Simple alkyl-substituted alkynes, as well as silylacetylenes, terminal alkenes, and aldehydes, may be employed as substrates. Unsymmetrical alkynes can be used; in cases where the steric bulk of the two alkyne substituents is significantly different, high levels of regiocontrol are observed (entries 2 and 3, Table 1). It is worthy of note that reactions with terminal alkenes (entry 4, Table 1) and an aldehyde substrate (entry 5) occur with useful levels of diastereoselectivity.



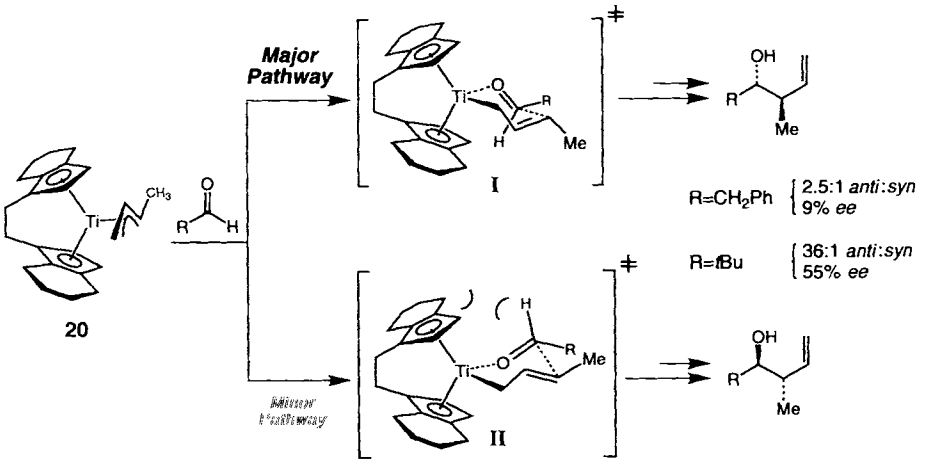
Scheme 5.

3.2. Diastereoselective Titanocene-Mediated Addition of Allylmetal Complexes to Aldehydes

Stereoselective addition of chiral allyl- and crotyltitanocenes to aldehydes, as shown in Scheme 5, has been reported by Collins.[14] Treatment of titanocene dichloride **1** with propylmagnesium chloride, followed by the addition of either allyl- or crotylmagnesium chloride, affords the titanium(III)-π-allyl complex **19** or **20**. Upon subsequent addition of an aldehyde substrate, C–C bond formation takes place, affording the corresponding homoallylic alkoxides (Scheme 5). Workup with anhydrous gaseous HCl, followed by exposure to O_2 results in alkoxide protonation and reoxidation of the titanocene reagent (to **1**). Therefore, chiral titanocene **1**, although required in stoichiometric quantities, can be recovered from the reaction and reused for subsequent transformations.

Whereas excellent diastereoselectivity (40:1 *anti*:*syn*) is achieved in the above addition of allylmetal compounds, with chiral nonracemic metallocenes, C–C bond formation is effected with only moderate levels of enantioselectivity; reaction of pivaldehyde with the crotyltitanocene **20** proceeds with a diastereoselectivity of 36:1 but in 55% *ee* (83% yield). As shown in Scheme 6, other experiments with the crotyl reagent **20** indicate that decreasing the size of the aldehyde substituent results in diminished diastereo- and enantiocontrol in the alkylation.

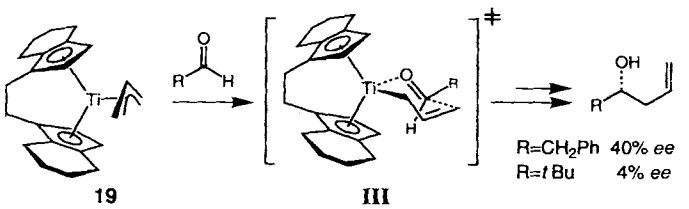
Transition structures **I** and **II** in Scheme 7 have been suggested by Collins to rationalize the observed



Scheme 6. Addition of [(ebthi)Ti(crotyl)] to aldehydes and the related transition state structures proposed by Collins.

trends in stereoselectivity in the Ti-catalyzed additions of allylmetal compounds to aldehydes. It has been proposed that transformations with **20** proceed through a six-membered chairlike transition state structure,[15] in which both the R group of the aldehyde and methyl group adopt the energetically more favorable pseudoequatorial position. The *anti* diastereomer therefore emerges the major product (Schemes 5 and 6). This mechanistic hypothesis offers a rationale for the higher levels of diastereoselectivity that are observed when aldehyde substrates with bulky alkyl substituents are used. Steric repulsion between the aldehyde substrate and cyclohexyl group of the catalyst disfavor transition structure **II** (Scheme 6). It is therefore tenable that allylmetalation of aldehydes with crotyltitanocene **20** proceeds selectively through transition structure **I**.

It is noteworthy that reactions of allyl- and crotyltitanocene reagents with aldehydes have dissimilar stereochemical consequences. The reaction of aldehyde substrates having larger alkyl substituents proceeds with higher levels of relative and absolute stereoselectivity when crotylmetallocene **20** is employed (Scheme 6). However, when allylmetallocene **19** is used (Scheme 7), the more sterically demanding aldehydes provide



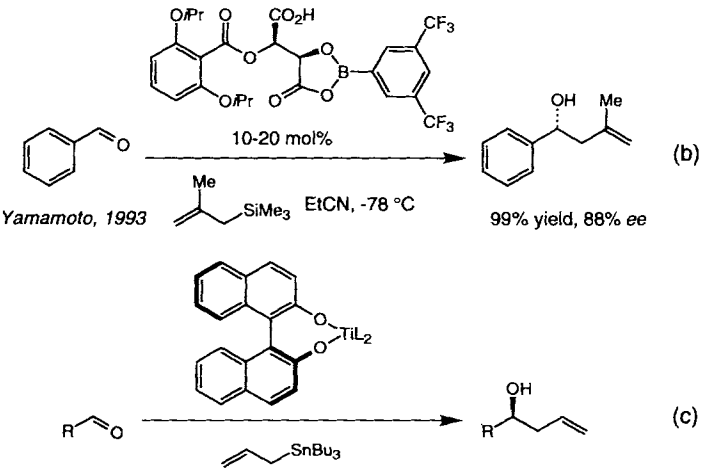
Scheme 7. Addition of [(ebthi)Ti(allyl)] to aldehydes and the related transition state structures proposed by Collins.

inferior levels of stereochemical control. Furthermore, alkylations with **20** generally proceed with higher enantioselectivity than those of **19** (cf. Schemes 6 and 7).

The chairlike transition state structures presented in Schemes 6 and 7 have been invoked by Collins to explain the observed trends in diastereo- and enantioselectivity in reactions of crotyltitanocene **19** and **20** to aldehydes. However, they do not rationalize the stereochemical outcomes observed in alkylations with allyltitanocene **19**. It is plausible that the carbonyl oxygen binds to the metal in such a way that the alkyl group (R) is oriented pseudoequatorially, allowing the reaction to proceed through transition structure **III** (Scheme 7) to furnish the (*R*)-configurated product predominantly. Nevertheless, it is not entirely clear why increasing the steric bulk of the aldehyde should decrease stereoselectivity.

The chiral titanocene-promoted allylation reactions described above are important since, although modest degrees of enantioselectivity are obtained, high levels of diastereoselectivity in the C–C bond forming reactions are detected. In addition, these studies shed light on a variety of subtle interactions between the allylmetal compound and various aldehyde substrates; such principles should prove critical in future developments involving these chiral metallocene complexes. However, as far as stereochemical control in this general class of transformations is concerned, a number of other stoichiometric reactions have been reported that provide outstanding levels of enantioselectivity. Reactions reported by Brown,[16] Mukaiyama,[17] Riediker,[18] Corey,[19] Hafner and Duthaler,[20] Roush,[21] and Hoffman[22] are some notable examples.[23]

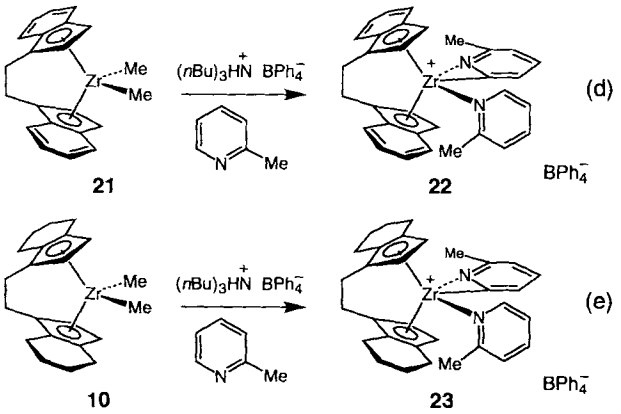
More recently, impressive advances in the area of catalytic asymmetric additions of allylmetal compounds to carbonyls have reported. Procedures put forth by Yamamoto [Eq. (b)][24] and Keck and Tagliavini [Eq. (c)][25] indicate that both



Ti- and B-based chiral Lewis acids can effect C–C bond forming reactions efficiently and with excellent enantioselectivity.

3.3. Stereoselective Alkene Insertion Reactions with Cationic Zirconocene Complexes

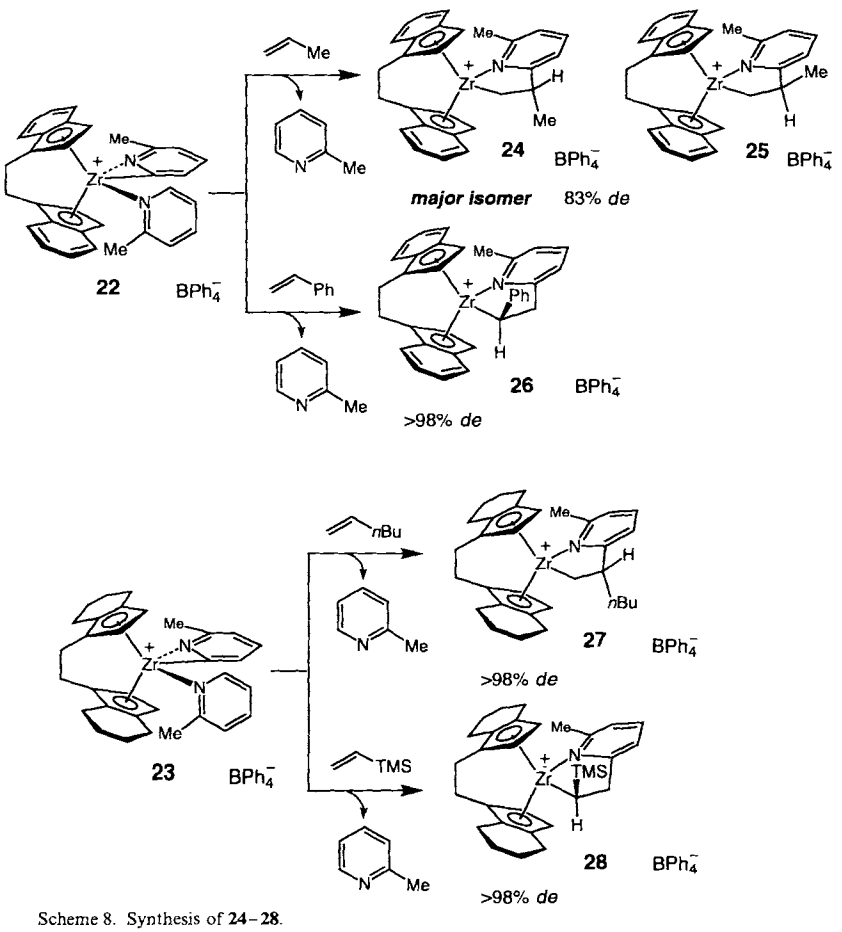
Inspired by the ability of cationic *ansa*-zirconocene complexes to catalyze stereocontrolled olefin polymerization reactions (see Section 4.1.1), Jordan has recently reported the stereoselective insertion of simple alkenes to both [(ebi)Zr(η^2-pyrid-2-yl)] **22** and [(ebthi)Zr(η^2-pyrid-2-yl)] **23**.[26] As shown in Equations (d)



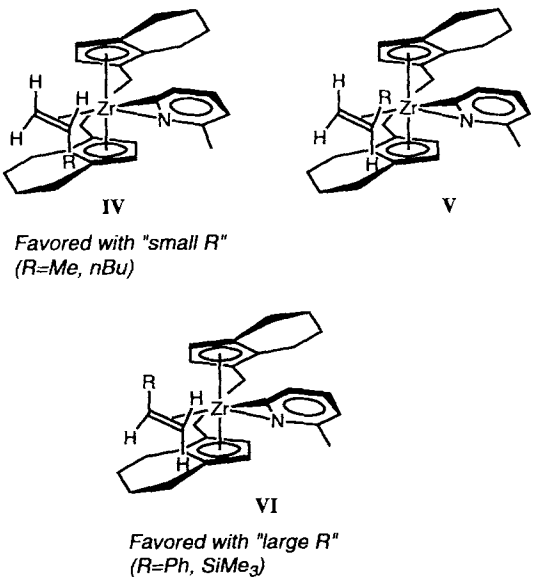
and (e), treatment of *rac*-[(ebi)$ZrMe_2$] **21** and *rac*-[(ebthi)$ZrMe_2$] **10** with $[(n\text{Bu})_3\text{HN}]^+(\text{BPh}_4)^-$ in the presence of 2-picoline affords complexes **22** and **23**, respectively. (The $B(C_6F_5)$ derivatives may also be prepared and are in fact reported to be more convenient to use.) These metallocenes exist as mixtures of isomers which rapidly exchange at 23 °C and are differentiated structurally by the orientation of the η^2-pyridyl ligand ("N-inside" and "N-outside").

When **22** and **23** are treated with a variety of alkene substrates, facile insertion into the azazirconacycle takes place. The resulting azazirconacyclopentanes are formed with various, but generally high, levels of diastereoselectivity, depending on the substituents on the alkene. The cases shown in Scheme 8 are illustrative. Whereas reactions with olefins that bear relatively small substituents (Me or *n*Bu) afford metallacyclopentane isomers **24**, **25**, and **27** selectively, terminal olefins such as styrene or trimethylsilyl vinylsilane with sterically more demanding substituents yield **26** and **28** with high selectivity.

The observed trends in regio- and stereoselectivity have been rationalized by Jordan as resulting from the minimization of steric interactions between alkene substituents and the pyridyl ligand. Scheme 9 illustrates three modes of alkene insertion into **25**. In all the pyridyl complexes the aromatic ring is tilted so as to avoid unfavorable steric interactions with the chiral ebthi group. The coordination mode of structure **IV** is preferred with smaller alkyl substituents: (ebthi)Zr–alkene association occurs such that the less substituted C atom is involved in the C–Zr bond, and pyridyl–olefin interaction leads to the approach of the olefin with the stereochemistry shown (R group towards cyclohexyl group of chiral ligand). In structure **V** steric repulsion between the R group and the pyridyl ligand is proposed to be energetically prohibitive. Accordingly, with groups larger then methyl at the *ortho* position of the pyridyl ligand, structure **IV** is even more preferred, since the resulting larger tilt of the heterocyclic ligand (to avoid the ebthi moiety) increases the severe steric interactions between the pyridyl *ortho* H and the alkene R group in **V**. It thus follows that with smaller *ortho* substituents, selectivity decreases. Additionally, when the R group is large such as *tert*-butyl, steric interactions with the chiral ligand



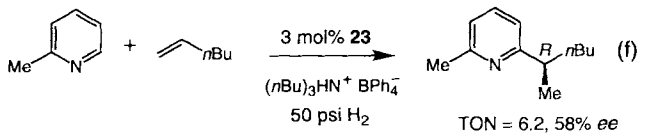
Scheme 8. Synthesis of **24**–**28**.



Scheme 9. Various modes of alkene–metallocene complexation proposed by Jordan for the stereoselective insertion of terminal alkenes into chiral zirconocene–pyridyl systems.

in **IV** lead to reduced stereoselectivity. With alkene substituents such as phenyl or trimethylsilyl, which can stabilize an adjacent partial negative charge on a carbon (developed in the formation of the C–Zr bond),[27] the coordination mode in structure **VI** is favored. However, whereas electronic effects can explain the turnover in the regioselectivity of olefin–metal binding, steric effects between these large alkene substituents and the cyclohexyl unit of the ebthi group provide a plausible rationale for the stereochemical preference of this metal–olefin coordination mode.

As illustrated in Equation (f), the nonracemic complex **23** has been shown to catalyze an asymmetric C–C bond forming reaction. This observation augurs well for future applications of cationic metallocene complexes in the design of catalytic enantioselective reactions.



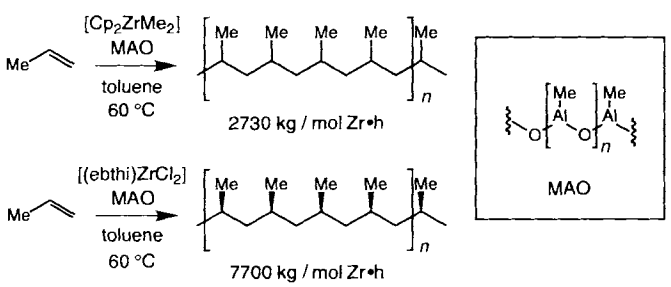
(f)

4. Catalytic Reactions Effected by *ansa*-Metallocenes

4.1. Catalytic Asymmetric C–C Bond Forming Reactions

4.1.1. Asymmetric Polymerization of Propylene

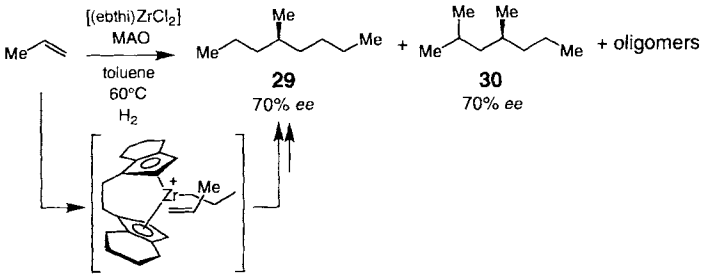
ansa-Metallocenes were initially used by Ewen and co-workers to control tacticity in the polymerization of propylene and butylene. These studies demonstrate that with titanium complexes **5** and **6** (see Scheme 1) product mixtures of isotactic and atactic polymers can be obtained.[28] Kaminsky and Brintzinger reported in 1985 that $[Cp_2ZrMe_2]$ induces the formation of predominantly atactic polymer structures when methylalumoxane (MAO) is used for catalyst activation (Scheme 10).[3c] In contrast, with catalytic $[(ebthi)ZrCl_2]$, polymers of 91% isotacticity and an average of 60 monomers in each isotactic sequence are produced. The activity of the bridged metallocene catalyst was thus demonstrated to be remarkably high: 7700 kg of polypropylene per hour may be produced for every mole of zirconocene; such values correspond to approximately 180000 propene insertions per catalyst molecule per hour.



Scheme 10. Propene is polymerized more efficiently by $[(ebthi)ZrCl_2]$/MAO than by the original catalyst system $[Cp_2ZrMe_2]$/MAO. The top polymer is atactic, the bottom polymer is 91% isotactic.

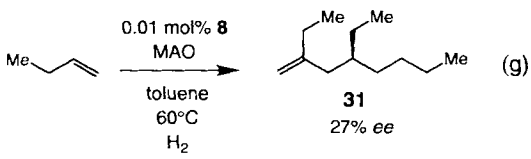
Because isotactic polymers do not have inherent chirality associated with the main chain, efforts have been extended to control the absolute stereochemistry in oligomerization reactions. Oligomers are produced when chain termination steps are facilitated in relation to propagation events;[29] these principles were recently discussed in an excellent review article.[29b] One method of promoting termination steps is to conduct the polymerization in the presence of H_2 gas. It has been proposed that hydrogenation of the intermediate alkyl–metal species effectively inhibits chain growth at the oligomer stage, thus affording a fully saturated product, as well as the corresponding metal hydride.[30] Alternatively, it is possible that addition of hydrogen enhances the relative rate of hydrogenation versus chain growth. If the reaction is conducted at lower alkene concentration, β-hydride elimination may compete with chain propagation and thus lead to the desired short polymers.[31] Indeed, both approaches have been employed in attempts to produce optically pure organic molecules by *ansa*-zirconocene catalysis.

Pino and co-workers demonstrated that when H_2 is introduced into a polymerization reaction with $[(ebthi)ZrCl_2]$/MAO as catalyst, propene oligomers such as **29** are formed with moderate enantioselectivity (Scheme 11).[32] In this process, **29** constitutes only 0.5% (by weight) of the total reaction product, a significant amount, as the system allows for 64000 propene insertions per molecule of catalyst. It is noteworthy that, although the majority (roughly 80%) of the reaction products are high molecular weight polymers, other oligomers obtained (e.g. **30**) exhibit appreciable optical activity as well.



Scheme 11. Synthesis of **29** and **30**.

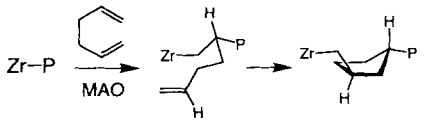
As was previously mentioned, an alternate method for producing oligomers is to reduce alkene concentration in a polymerization reaction, thereby slowing chain propagation relative to β-H elimination. Kaminsky and co-workers have found that polymerization of butene at low substrate concentration results in the desired low molecular weight polymers (e.g. **31**),[31] albeit with low levels of asymmetric induction [Eq. (g)]. Nevertheless, small oligomers do constitute a large percentage of the reaction product (roughly 18% by weight), and low catalyst loadings (0.01 mol% compared to butene) are sufficient for the reaction to proceed efficiently.



(g)

4.1.2. *Asymmetric Cyclopolymerization of Dienes*

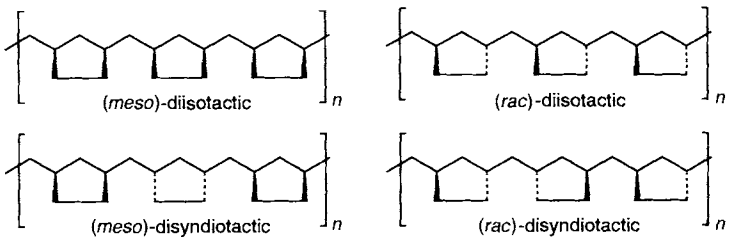
In contrast to the polymerization of terminal alkenes, the cyclopolymerization reaction recently developed by Waymouth and Coates affords isotactic polymers with main-chain chirality.[33] The cyclopolymerization of 1,5-hexadiene depicted in Scheme 12 begins with the insertion of one of the double bonds



Scheme 12. P = polymer.

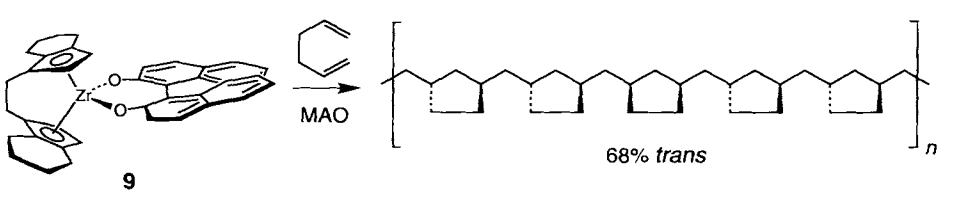
of the diene into the metal–carbon bond of the growing polymer. Insertion of the remaining double bond results in cyclization of the monomer to afford the polymer elongated by one five-membered carbocycle; subsequent insertion steps account for the continued chain growth.

It is worthy of note that of the four types of polymers that can in principle be obtained from a cyclopolymerization reaction, only the (*rac*)-diisotactic product is chiral by virtue of its main-chain stereochemistry (Scheme 13). The other products contain mirror planes within the repeating subunits that make up the polymer.



Scheme 13. Possible stereoisomeric products that may be obtained from cyclopolymerization of 1,5-hexadienes.

Initial studies with the racemic *ansa*-metallocene **9** demonstrated that the predominant product from the cyclopolymerization of 1,5-hexadiene is the chiral (*rac*)-diisotactic polymer;[34a] 68% of the rings in the product have *trans* configuration. Furthermore, optically enriched metallocene catalysts lead to optically active polymers; for the polymer formed with catalyst **9** [Eq. (h)] the molar optical rotation (per monomer unit), $[\alpha]_{405}^{28}$, is +50.1 ($c = 7.8$, $CHCl_3$). Waymouth and Coates therefore concluded that isotactic polymers are the major products in the cyclopolymerization. It is interesting that, although *cis*-configurated rings are present in the polymer structure, the corresponding molar optical rotations (per monomer unit) are considerably higher than that of the model system, *trans*-(1*R*,3*R*)-1,3-dimethylcyclopentane. In this connection, the Stanford researchers suggest that the polymer may adopt conformations in solution that contribute to the observed optical rotation.



(h)

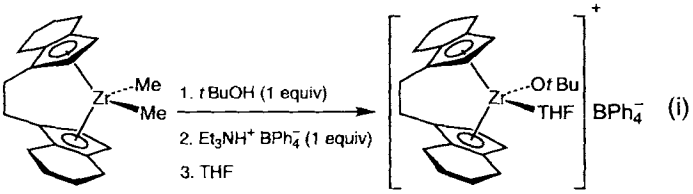
Comparison with Related Catalytic Enantioselective Processes

Stereospecific olefin polymerization reactions catalyzed by chiral metallocene catalysts are particularly important and were recently reviewed by Brintzinger, Fischer, Mulhaupt, Rieger, and Waymouth.[29b] These homogeneous catalysts, alongside enantioselective methods reported by Natta and Farina for polymerization of pentadienes[34] and benzofurans,[35] may be used in highly enantioselective polymerization and cyclopolymerization processes.[36] More importantly, these homogeneous catalytic systems offer unique opportunities in reaction design and engineering, as the polymerization reactions discussed above are effected by a single, well-defined metal complex with a reasonably well understood coordination sphere. In brief, chiral metallocenes have greatly expanded the scope and versatility of the readily accessible types of polymers. Nonetheless, the studies summarized in this section are likely to be the harbinger of other great contributions to the metal-catalyzed enantioselective polymerization reactions.

4.1.3. *Asymmetric Diels–Alder Reactions*

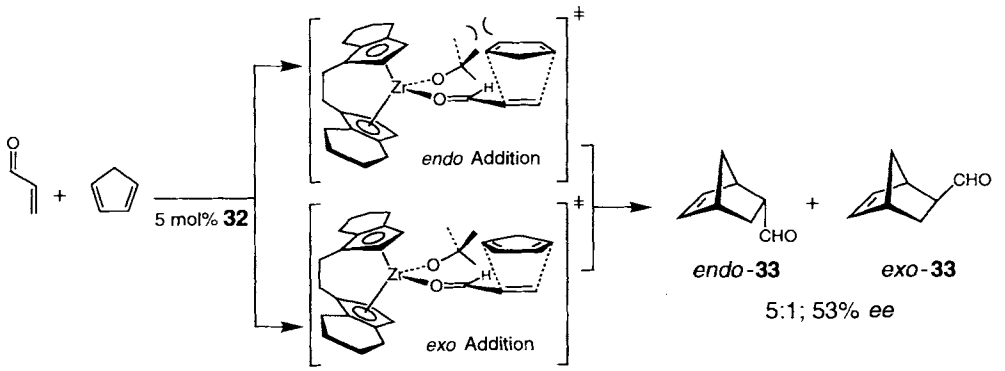
Collins and co-workers have examined catalytic enantioselective Diels–Alder reactions in which *ansa*-metallocene **32** is utilized as a chiral catalyst.[37] The cycloadditions are typically efficient (ca. 90% yield), but proceed with modest stereoselectivity (26–52% *ee*). Collins's studies provide important mechanistic insights that may ultimately be utilized in the design and development of more selective metallocene-based chiral catalysts.

The catalyst used in the asymmetric Diels–Alder reaction is the cationic complex $[(ebthi)Zr(O\text{-}t\text{Bu})(thf)]^+$ **32** [Eq. (i)].



10 32 (i)

Treatment of the dimethylzirconocene **10**[38] with one equivalent of *tert*-butyl alcohol, followed by protonation with one equivalent of $(Et_3NH)(BPh_4)$ results in the formation of the requisite chiral cationic complex **32**, which is used to catalyze the [4 + 2] cycloaddition of acrylate and acrolein derivatives with cyclopentadiene.



Scheme 14. Stereoselective [(ebthi)Zr]-catalyzed [4 + 2] cycloaddition and the corresponding transition state structures proposed by Collins.

In the presence of 5 mol% **32**, the [4 + 2] cycloaddition reaction of acrolein and cyclopentadiene proceeds efficiently to afford **33** in 93% yield and 53% *ee*, as a 5:1 mixture of *endo*:*exo* isomers (Scheme 14). ^{1}H NMR experiments indicate that the preferred orientation for binding between acrolein and the chiral metallocene is as shown in Scheme 14. Accordingly, Collins proposed that acrolein is coordinated to the chiral zirconocene complex so that the vinyl group is oriented away from the bulky alkoxide unit. It is plausible that approach of cyclopentadiene in the *endo* mode (Scheme 14) leads to unfavorable interactions between the diene and the *tert*-butoxy ligand, thus resulting in modest levels of diastereoselectivity (5:1 *endo*:*exo*). Molecular models indicate that any significant steric influence by the chiral ligand on the stereochemical outcome (both absolute and relative) of the cycloaddition is unlikely; the observed low enantioselectivity (53% *ee*) may thus be the result of inefficient asymmetric induction by the chiral ebthi moiety.[39]

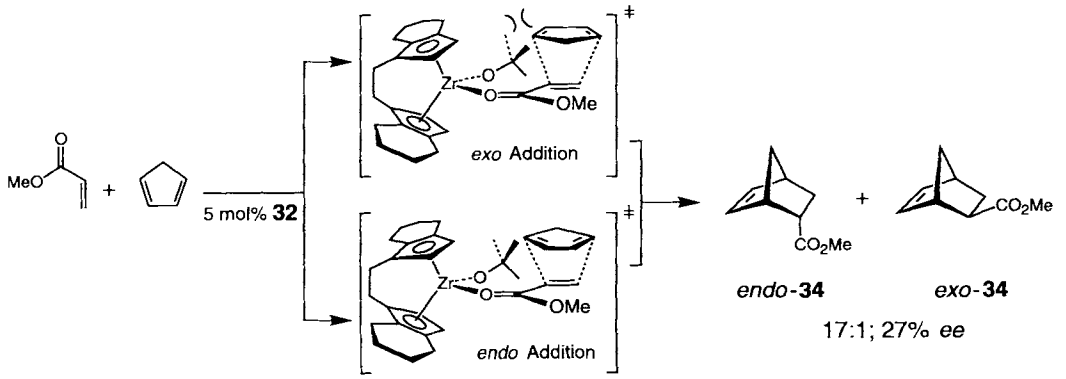
In reactions in which methylacrylate is used as the dienophile (Scheme 15), cycloadditions occur with low enantioselectivity (23% *ee* compared to 53% *ee* with acrolein; the absolute configuration of the major product **34** is opposite to that of **33**), but with significantly higher diastereoselectivity (17:1, *endo*:*exo*). As before, formation of the *endo* isomer may be preferred, since the transition structure that leads to the *exo* isomer should include energetically unfavorable interactions between the diene and the metal-bound *tert*-butoxy group. Higher levels of *endo* selectivity are detected in the reaction of the methyl ester (Scheme 15); this is perhaps because, at least in part, the dienophile π-system is oriented towards the *tert*-butoxy ligand where the steric influence of the bulky substituent is expected to be more pronounced. Collins and co-workers put forth the transition state structures shown in Scheme 15 based on previous reports regarding the preferred stereochemistry of Lewis acid association with carboxylic esters.[40]

Most recently, Collins and co-workers reported on a highly enantioselective catalytic Diels–Alder cycloaddition, in which zirconocene and titanocene bis(triflate) complexes are used as catalysts.[41] Most noteworthy is the influence of the solvent polarity on enantioselectivity. For example, as shown in Scheme 16, with CH_2Cl_2 as solvent and 1 mol% **35** the *endo* product, **36**, is formed in 30% *ee* (30:1 *endo*:*exo*, 88% yield), whereas with CH_3NO_2 as solvent and 5 mol% **35** the enantioselectivity is raised to 89% (7:1 *endo*:*exo*, 85% yield). Extensive ^{1}H and ^{19}F NMR studies further indicate that a mixture of metallocene–dienophile complexes exist in both solutions (ca. 6:1 in CH_2Cl_2 and ca. 2:1 in CH_3NO_2, Scheme 16), and that most likely it is the minor complex isomer that is more reactive and leads to the observed major enantiomer. For example, in NOE experiments when the resonance frequency of H_b in the minor complex is irradiated, 5% enhancement of the signals of the adjacent Cp ring is observed. In contrast, no enhancements are observed when the resonance frequency of H_a in the major complex is irradiated.

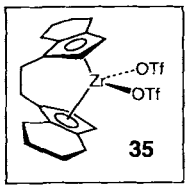
These recent results illustrate, for the first time, that metallocene-based chiral Lewis acids can effectively catalyze [4 + 2] cycloadditions with excellent levels of enantiofacial selectivity. Perhaps more importantly, the reported NMR studies and the observed dramatic solvent effect should pave the way for future endeavors in the rational design of better chiral metallocenes.

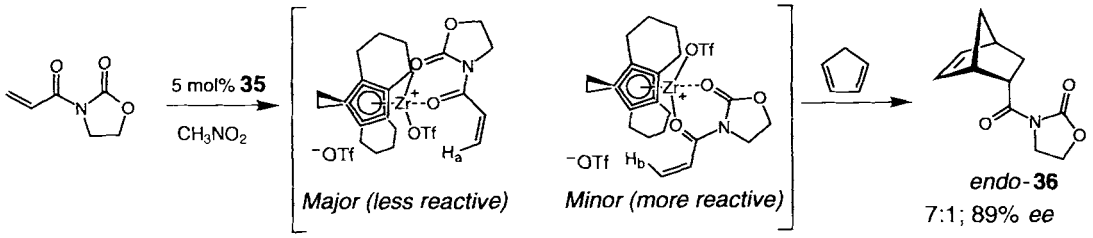
Comparison with Related Catalytic Enantioselective Processes

The cycloaddition reactions catalyzed by titanocene and zirconocene complexes described in this section provide additional useful methods in enantioselective C–C bond forming reactions and offer deeper insights into the inner workings of the [(ebthi)M] class of chiral catalysts. Nonetheless, other catalytic systems can generally be used to carry out these and other similar reactions with better selectivity.[42] Related asymmetric cy-



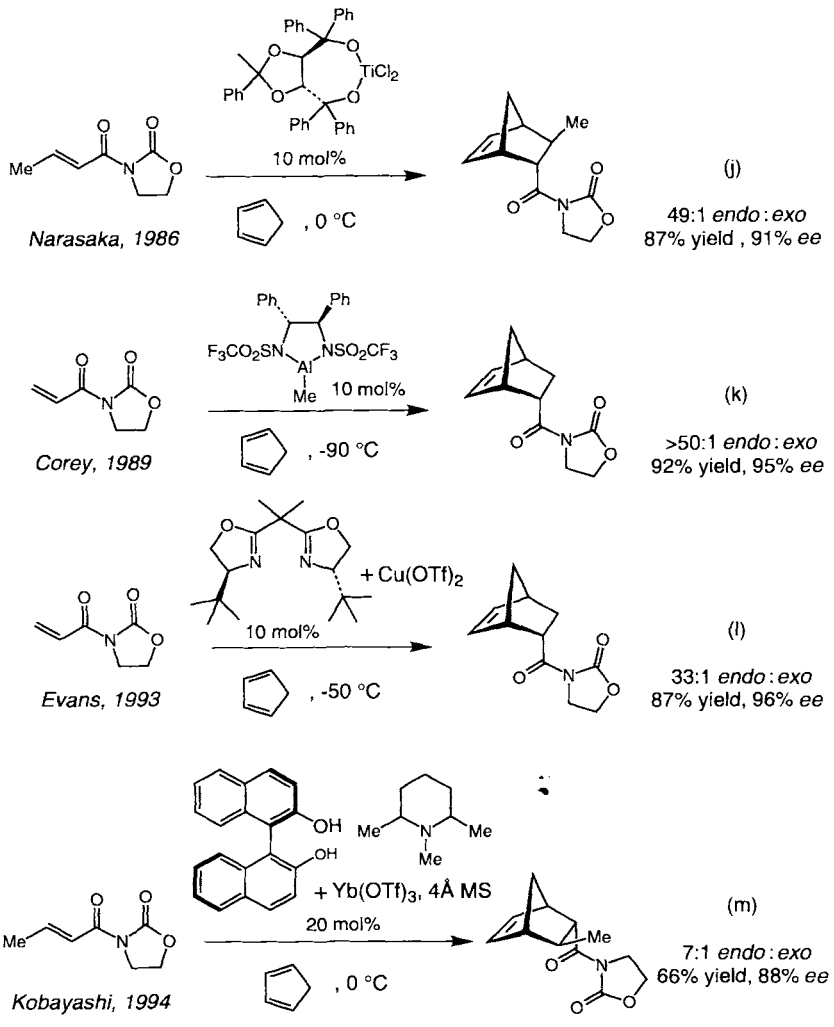
Scheme 15. Stereoselective [(ebthi)Zr]-catalyzed [4 + 2] cycloaddition and the corresponding transition structures proposed by Collins.





Scheme 16. Stereoselective [(ebthi)Zr(OTf)$_2$]-catalyzed [4 + 2] cycloaddition and the corresponding transition structures proposed by Collins.

cloadditions have been reported in which oxazolidinones similar to those in Collins's work serve as dienophiles. For example, Narasaka [Eq. (j)],[43] Corey [Eq. (k)],[44] Evans [Eq. (l)],[45] and Kobayashi [Eq. (m)][46] have described systems that offer similar or frequently even higher levels of relative and absolute stereoselectivity. As further indicated by papers cited in reference [42], asymmetric catalytic [4 + 2] cycloadditions continue to be the subject of extensive investigations in a number of research groups, a fact that reflects the significance of this class of C–C bond forming transformations. However, it should be noted that the enantioselective Diels–Alder cycloaddition is far from being a "generally solved problem". The high enantioselectivities reported in the literature, although extremely important, only concern a specific, relatively small and highly reactive class of dienes and dienophiles.[47] In brief, considering the importance of the [4 + 2] cycloadditions in organic chemistry, future research in this area should continue to provide notable contributions to the field of asymmetric synthesis.



4.1.4. *Asymmetric Carbomagnesation Reactions*

4.1.4.1. *Asymmetric Synthesis through Catalytic Carbomagnesation*

Work in our laboratories in connection to the zirconocene-catalyzed carbomagnesation as a convenient method for selective C–C bond formation has resulted in the development of catalytic processes that are carried out at ambient temperature to afford synthetically useful products with excellent enantiomeric purity. As illustrated in Table 2, in the

Table 2. [(ebthi)Zr]-catalyzed enantioselective ethylmagnesation of unsaturated heterocycles [a].

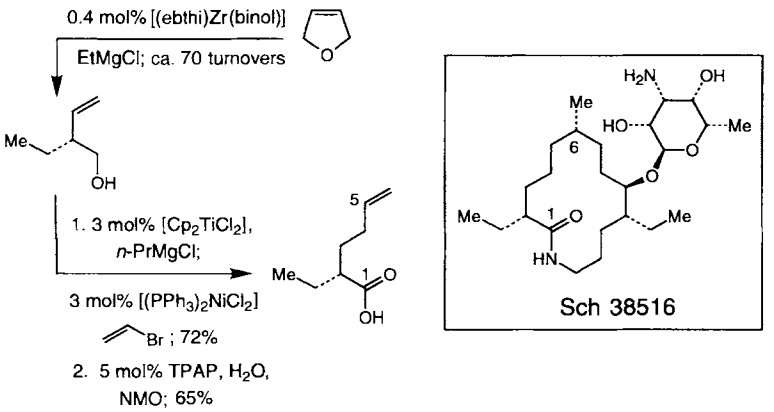
Entry	Substrate	Product	*ee* [%]	Yield [%]
1			> 99	65
2			> 95	75
3			95	73
4			92	75

[a] Reaction conditions: 10 mol% (*R*)-**2**, 5.0 equiv EtMgCl, THF, 22 °C for 6–12 h. Entry 1 with 2.5 mol% (*R*)-**2**.

presence of 2.5–10 mol% nonracemic [(ebthi)$ZrCl_2$] (or [(ebthi)Zr(binol)] and with EtMgCl as the alkylating agent, five-, six-, and seven-membered unsaturated heterocycles undergo facile asymmetric ethylmagnesation.[48]

The rate of ethylmagnesation of the terminal double bonds of the reaction products is sufficiently slower, so that unsaturated alcohols and amines can be isolated in high yield (the second alkylation is not generally stereoselective). Catalytic asymmetric carbomagnesation thus affords nonracemic reaction products that bear a C=C bond and a hydroxyl or amino group, functional groups that are readily amenable to a wide range of subsequent derivatizations.

Within this context, we have recently utilized the stereoselective ethylmagnesation shown in entry 1 of Table 2 as a key step in the synthesis of the aglycon macrolactam of the antifungal agent Sch 38516.[49] As illustrated in Scheme 17, further functionalization of the product of the Zr-catalyzed ethylmagnesation through three subsequent catalytic procedures yields the requisite carboxylic acid unit in >99% *ee*. This synthesis route underlines the utility of the Zr-catalyzed carbomagnesation protocol: the reaction product, since it carries a C=C bond and a hydroxyl group, can be readily functionalized to provide a variety of other nonracemic intermediates.



Scheme 17. Demonstration of the utility of [(ebthi)Zr]-catalyzed ethylmagnesation in the enantioselective synthesis of the aglycon of the macrolactam Sch 38516.

The catalytic cycle that we have proposed to account for the enantioselective ethylmagnesation is shown in Scheme 18. The reaction is initiated by the chiral zirconocene–ethylene complex (*R*)-**37**, formed upon reaction of dichloride (*R*)-**2** with EtMgCl.[50] Coupling of the alkene substrate with (*R*)-**37** leads to the formation of the zirconacyclopentane intermediate **VII**. Reaction of **VII** with EtMgCl affords zirconate **VIII**, which undergoes Zr–Mg ligand exchange to yield **IX**. Subsequent β-hydride abstraction, accompanied by intramolecular magnesium–alkoxide elimination leads to the release of the carbomagnesation product and regeneration of (*R*)-**37**.

An important aspect in the carbomagnesation of six-membered and larger heterocycles is that the intermediate metallacyclopentanes formed preferentially lead to reaction products in which the C–Zr bond is formed at the carbon α to the heterocycle C–X bond. Whether the regioselectivity in the formation of the zirconacycle is kinetically nonselective and rapidly reversible, as is the case when only one regioisomer is active in the catalytic cycle, or whether formation of the metallacycle is kinetically selective (stabilization of electron density upon formation of C–Zr bond by the adjacent C–X bond),[27] has not been rigorously determined. However, as will be discussed below, the regioselectivity with which the intermediate zirconacyclopentane is formed is critical in the [(ebthi)Zr]-catalyzed kinetic resolution of heterocyclic alkenes.

It is plausible that the observed enantioselectivity arises from minimization of unfavorable steric and torsional interactions in the complex formed between (*R*)-**37** and the unsaturated heterocycle (Scheme 18). The alternative mode of addition, illustrated in Figure 1, would lead to costly steric repulsions between the heterocycle and the cyclohexyl group of the chiral ligand.[51] Thus, reactions of

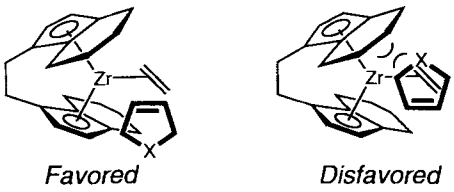


Fig. 1. Substrate–catalyst interactions favor a specific mode of alkene insertion into the zirconocene–alkene complex in carbomagnesation.

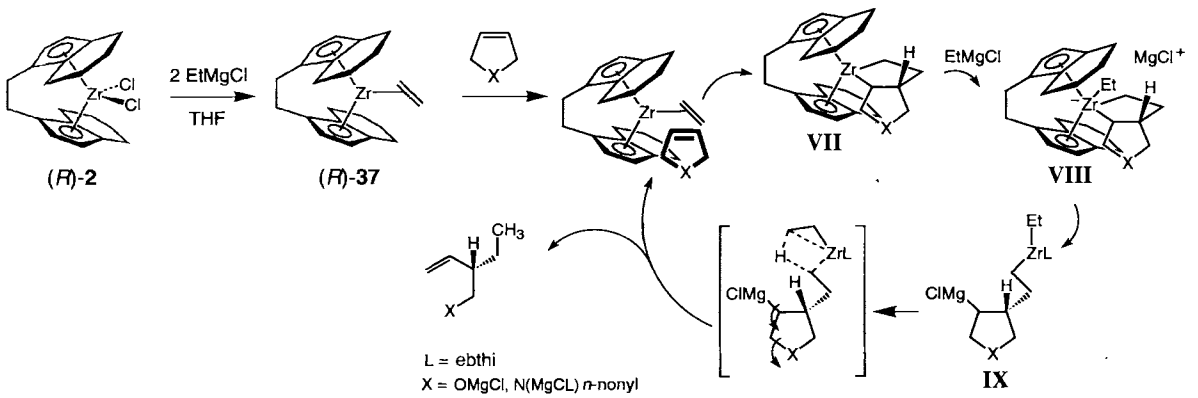

Scheme 18. Catalytic cycle proposed by Hoveyda for the [(ebthi)Zr]-catalyzed ethylmagnesation of unsaturated heterocycles.

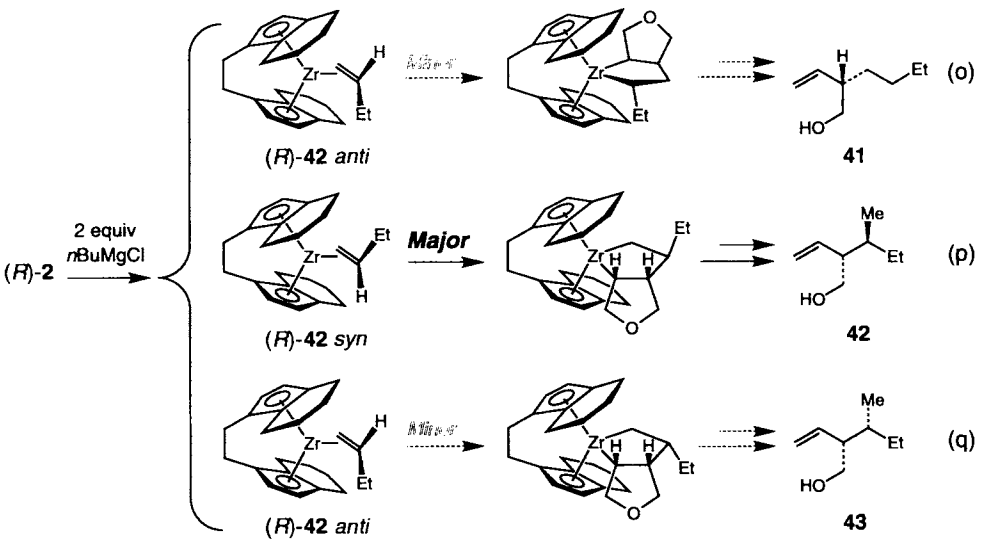
simple terminal olefins under identical conditions result in little or no enantioselectivity. This is presumably because when the alkene carbon that bonds to the zirconium center in **VII** has no substituent, the aforementioned steric interactions are ameliorated and the olefin substrate reacts indiscriminately through both modes of substrate–catalyst binding represented in Figure 1.

As shown in Table 3, reactions in which higher magnesium alkyls are used, namely *n*PrMgCl and *n*BuMgCl, proceed less efficiently (35–40% yield) but with similarly high enantioselectivity (>90% *ee*). Two issues in connection to the data illustrated in Table 3 merit comment. 1) With 2,5-dihydrofuran as substrate, at 22 °C a mixture of branched (**38** and **40**) and *n*-alkyl products (**39** and **41**) are obtained. When the reaction mixture is heated to 70 °C, the branched adducts **38** and **40** become the major product isomers. In contrast, with the six-membered heterocycle, reactions at 22 °C are highly selective (entries 3 and 6, Table 3). 2) With *n*BuMgCl as the alkylating agent, excellent diastereoselectivity is observed as well (entry 6).



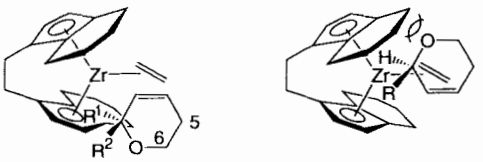
These observations carry significant mechanistic implications. As illustrated in Equations (o) through (q), the zirconocene–alkene complexes derived from the longer chain alkylmagnesium halides present several additional selectivity issues: 1) The transition metal–alkene complex can exist in two diastereomeric forms, (*R*)-**42** *anti* and *syn*, which can lead to the formation of different product diastereomers [cf. Eqs. (o) and (p), and Eqs. (p) and (q)]. The data in Table 3 indicate that the alkylation product arises from the mode of addition shown in Equation (p). 2) As illustrated in Equations (o) and (q), the carbomagnesation process can afford either the branched or the *n*-alkyl product. Insertion of the alkene substrate from the more substituted front of the zirconocene–alkene system affords the branched isomer [Eq. (q)], whereas reaction from the less substituted end leads to the formation of the straight-chain product [Eq. (o)]. The results shown in Table 3 indicate that, depending on the reaction conditions, products derived from the two isomeric metallacyclopentane formation can be competitive.

Detailed studies from our laboratories shed light on the mechanistic intricacies of asymmetric catalytic carbomagnesations and lead to a better understanding of the above trends in regio- and stereoselectivity.[52] Importantly, our mechanistic studies clearly indicate that there is no preference for the formation of either the *anti* or the *syn* [(ebthi)Zr]–alkene isomers (e.g. **42** *anti* vs **42** *syn*); it is only that one metallocene–alkene diastereomer

(*syn*) is more reactive. Our mechanistic studies also indicate that zirconacyclopentane intermediates (**VII** in Scheme 18) do not spontaneously eliminate to give the derived zirconocene–alkoxide; Zr–Mg ligand exchange is likely a prerequisite for the alkoxide elimination and formation of the terminal alkene.

4.1.4.2. Kinetic Resolution through Catalytic Carbomagnesation

The high levels of enantioselectivity obtained in the asymmetric catalytic carbomagnesation reactions (Tables 2 and 3) imply highly organized interactions between the [(ebthi)Zr]–alkene complex and the heterocyclic alkene substrates. It therefore follows that if a racemic mixture of chiral unsaturated pyrans or furans are employed, the resident center of asymmetry may induce different rates of reaction, such that after roughly 50% conversion one enantiomer of the chiral product can be recovered in high enantiomeric purity. Molecular models indicate that with a 2-substituted dihydropyran, as shown in Figure 2, the mode of addition labeled **X** should be significantly favored over **XI** and **XII**, in which the catalyst–substrate complex is destabilized by unfavorable steric interactions.



X **XII**
XI

Fig. 2. Possible modes of association for pyran enantiomers with the [(ebthi)Zr(C_2H_2)] complex. **X**: R^1 = H, R^2 = alkyl. **XI**: R^1 = alkyl, R^2 = H. **XII**: R = alkyl.

As the data in Table 4 indicate, in the presence of catalytic amounts of nonracemic [(ebthi)$ZrCl_2$], a variety of unsaturated pyrans can be resolved effectively to deliver these synthetically useful heterocycles in excellent enantiomeric purity.[53] A number of important issues in connection to the catalytic kinetic resolution of dihydropyrans are noteworthy: 1) Reactions performed at elevated temperatures (70 °C) afford recovered starting material with significantly higher levels of enantiomeric purity than that isolated from processes carried out at 22 °C. For example, the 2-substituted dihydropyran shown in entry 1 of Table 4, when subjected to the same reaction conditions but at room temperature, is recovered after 60% conversion in only 88% *ee* (vs 96% *ee* at 70 °C). Experiments that help establish the mechanistic basis of the above temperature effects are in progress. 2) Consistent with the models illustrated in Figure 2, 6-substituted dihydropyrans (Table 1, entry 2) are not resolved effectively (C5 substituent should not strongly interact with the catalyst structure; see Fig. 2); however, when a substituent at C2 is also present, resolution proceeds with excellent efficiency (entry 3). 3) Dihydropyrans substituted at C5 are resolved with high selectivity as well (entry 4). In this class of substrates, one enantiomer reacts more slowly, presumably because its association with the zirconocene–alkene complex leads to unfavorable steric interactions between the C5 alkyl unit and the coordinated ethylene ligand.

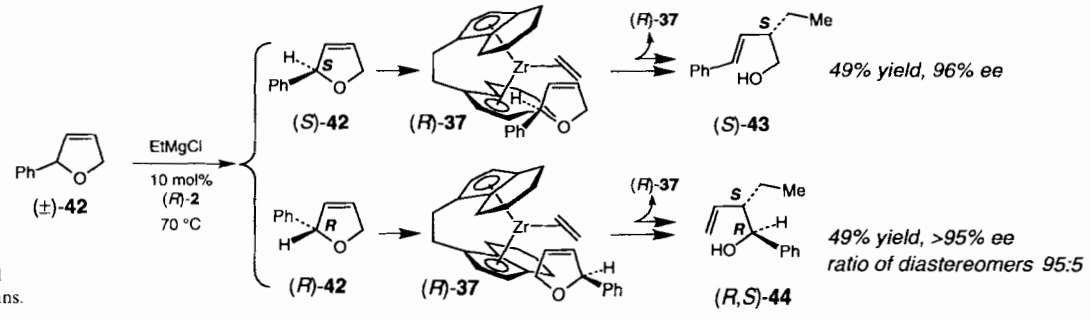
4			58	20	*R*, 99
5		R = MgCl R = TBS	63 61	10 10	*R*, > 99 *R*, 94

[a] Reaction conditions: indicated mol% (*R*)-**2**, 5.0 equiv EtMgCl, 70 °C, THF. Mass recovery in all reactions > 85%. [b] Configuration and *ee* value of recovered alkene.

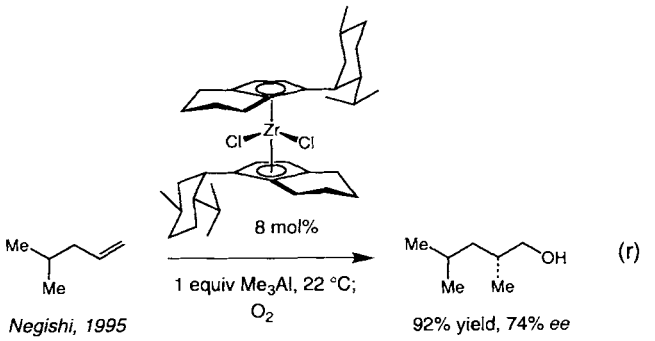
Zirconocene-catalyzed kinetic resolution of dihydrofurans is also possible (Scheme 20).[54] Unlike their six-membered ring counterparts, both of the heterocyclic enantiomers react readily, but through distinctly different reaction pathways, to afford readily separable constitutional isomers in high diastereomeric and enantiomeric purity. A plausible explanation for the difference in the reactivity of dihydropyrans and -furans is that in the latter both olefinic carbons are adjacent to a C–O bond: formation of the C–Zr bond can take place at either end of the π-system. Thus, the dihydrofuran substrate and the [(ebthi)Zr]–alkene complex (*R*)-**37** approach one another so that unfavorable steric interactions are avoided, leading to the formation of readily separable nonracemic products (see Scheme 19).



Scheme 19. [(ebthi)Zr]-catalyzed kinetic resolution of dihydrofurans.

Comparison with Related Catalytic Enantioselective Processes

The zirconocene-catalyzed enantioselective carbomagnesation accomplishes an important and unique task: addition of an alkylmagnesium halide to an alkene to provide a carbometalation product suitable for a variety of additional functionalization reactions (see Scheme 17). Excellent enantioselectivity is obtained in reactions with ethyl-, propyl, and butylmagnesium chloride, and the catalytic resolution processes allow for preparation of a variety of nonracemic heterocycles. Nonetheless, the development of reaction processes for the efficient and enantioselective addition of a larger range of alkyl groups (e.g. methyl, vinyl, phenyl, etc.) to unfunctionalized alkenes remains an important and challenging goal. The reaction described recently by Negishi [Eq. (r)], in which a nonbridged chiral zirconocene[55] is used as catalyst, is an example of research towards this end.[56]



4.2. Catalytic Asymmetric Formation of C–H Bonds

4.2.1. Asymmetric Hydrogenation of Terminal and 1,1-Disubstituted Alkenes

In the last five years much progress has been made in the *ansa*-metallocene-catalyzed hydrogenation of alkenes. Both Zr- and Ti-based catalytic systems have been used for this purpose; terminal and 1,1-disubstituted olefins, as well as trisubstituted alkenes have been used as substrates. By far the most successful hydrogenations involve trisubstituted alkenes, for which enantioselectivities from 83 to 99% *ee* have been reported. In initial studies in this area, carried out by Waymouth and Pino, the polymerization catalyst [(ebthi)ZrX_2]/MAO was used in the presence of H_2 to effect alkene hydrogenation.[29] Pino and Waymouth had recognized that in certain instances olefin polymerization proceeds sluggishly because hydrogenation of the metal–alkyl intermediate is significantly faster than alkene insertion, leading to the formation of hydrogenated monomers in large excess.

Table 5 illustrates the marked difference in reaction efficiency that arises when different metallocene sources are employed in the [(ebthi)Zr]-catalyzed hydrogenation. The mechanism by which MAO converts the zirconium(IV) salts into active zirconium–hydride species remains unclear.[57] However, it has been proposed that when the catalytically inactive zirconium dichloride salt is used, a chlorine atom may form an η^2-bridge between aluminum and zirconium, thus preventing formation of the active cationic metal center.[29]

As was mentioned before, and as illustrated in Table 6, an important prerequisite for efficient cationic [(ebthi)Zr]-catalyzed hydrogenation is that the alkene should not be able to polymerize readily. Whereas with 1-decene as substrate the hydrogenation product is obtained in only 28% yield (Table 6, entry 1; the main product is the polymer), 2-methyl-1-pentene affords 97% of the hydrogenation product (Table 6, entry 3). Interestingly, in a competition experiment, *trans*-2-hexene is hydrogenated much faster than the *cis* isomer (Table 6, entry 4).

Table 5. Hydrogenation of styrene as a function of the zirconium catalyst precursor.

2		2×10^3; 20	94	93
3		2×10^3; 20	100	97
4		10^2; 1	96 4	50 [a]
5		2×10^3; 20	20	20

[a] Combined yield.

Data in Table 7 illustrate that when the nonracemic [(ebthi)Zr] system is used to catalyze the hydrogenation of prochiral alkenes, moderate levels of enantiofacial differentiation are observed (23–65% *ee*). Enantioselective deuteration of pentene occurs in low yield but shows noticeable enantioselectivity (23% *ee*). The same reaction with styrene proceeds in 61% yield and with moderate enantioselectivity (65% *ee*). Hydrogenation of 2-phenyl-1-pentene proceeds in excellent yield (95%) but with poor control of stereochemistry (36% *ee*).

An interesting aspect of these hydrogenations and deuterations of alkenes is that the induced stereochemistry is opposite to that of similar oligomerization reactions. Thus, as the example in Scheme 20 illustrates, the prochiral π-face that is hy-

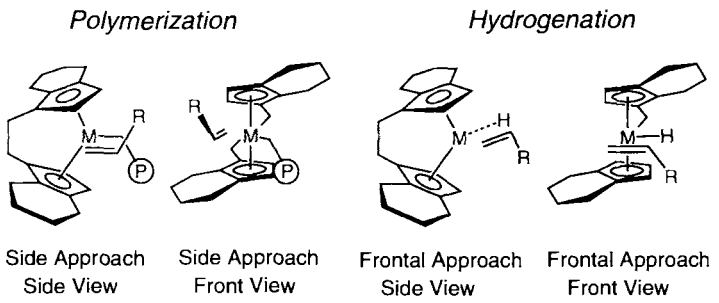
drogenated is opposite to that on which carbon–carbon bond formation takes place in the related polymerization process.

As an explanation Waymouth has suggested that a sterically demanding polymer chain would prefer to associate with the zirconocene catalyst in the manner shown in Scheme 21. That is,

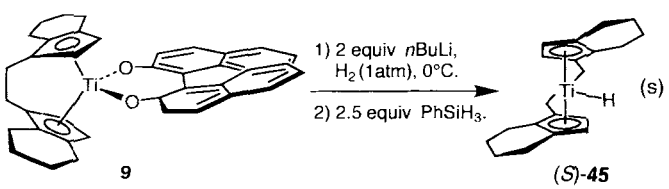


Scheme 21. Transition state structures proposed by Waymouth for the polymerization and hydrogenation of alkenes by [(ebthi)ZrX]/MAO. Ⓟ = polymer chain.

the pendant groups on the alkene substrate may be oriented such that most steric interactions with the ebthi ligand are avoided. This mode of catalyst–substrate interaction necessitates that the reacting alkene approach the [(ebthi)Zr] system side-on in the oligomerization or polymerization processes. In contrast, in the hydrogenation of alkenes the small hydrogen atom may readily adopt the side position below the tetrahydroindenyl ligand, allowing the larger alkene to approach the metal hydride from the sterically more accessible front face (Scheme 21).

4.2.2. *Asymmetric Hydrogenation of Trisubstituted Alkenes*

Hydrogenation of unfunctionalized trisubstituted olefins with bridged titanocene complexes as catalyst precursors has been reported recently by Buchwald and co-workers.[58] Unfunctionalized alkenes are appropriate substrates and excellent levels of enantioselectivity are observed. The active catalyst in these systems is postulated to be chiral titanocene (*S*)-**45**, which is produced by treatment of nonracemic [(ebthi)Ti(binol)] with two equivalents of butyllithium under H_2 atmosphere, followed by the addition of 2.5 equivalents of phenylsilane [Eq. (s)].



As evident in Table 8, hydrogenation of trisubstituted olefins catalyzed by 5 mol% (*S*)-**45** occurs in high yields and >90% *ee*. Aromatic olefins as well as allylic amines and ethers are suitable substrates (entries 4 and 5). Although it is not a stated prerequisite, all substrates reported are alkenes attached to an aromatic ring. Interestingly, *E* and *Z* alkenes react with much different efficiencies under the reported conditions. (*E*)-α,β-Dimethyl-*p*-methoxystyrene is hydrogenated in 48 h to give a 79% yield of the (*R*) enantiomer of the product in 95% *ee* (entry 2, Table 8). However, when a 2:1 mixture of *E*:*Z* alkenes is used as starting material, the reaction requires 146 h to give an 80% yield of the (*R*) isomer in only 31% *ee*.[59]

Table 8. Enantioselective hydrogenation of trisubstituted alkenes with [(ebthi)TiH] [a].

Entry	Alkene	Product [b]	Yield [%]	*ee* [%]
1			91	>99
2			79	95
3			77	92
4			75	95
5			86	94

[a] Reaction conditions: 5 mol% (*S*)-[(ebthi)TiH], 1.38×10^4 kPa (2000 psi H_2), 65 °C, THF. [b] Absolute configuration was determined only for entries 1 and 2.

Transition state structures have been put forth by Buchwald to rationalize the absolute stereochemistry afforded by the [(ebthi)Ti]-catalyzed hydrogenation.[58] In the proposed mechanism the substituent attached to the monosubstituted terminus of the C=C bond appears to control which face of the prochiral alkene reacts preferably. If we assume that the hydride attached to titanium takes the side position beneath the cyclohexyl ring of the ebthi ligand, then the alkene should approach the metal center from the front face of the complex (Ti prefers to bond to the less substituted carbon of the alkene; Scheme 22). Hence, there are two modes of attack for each type of alkene substrate (*E* or *Z*) that could lead to the hydrogenation product; in both instances, one mode of reaction involves interaction of two of the alkene substituents with the large cyclohexyl ring of the catalyst (**XIV** and **XVI**). Because the lower energy path involves an alkene–cyclohexyl interaction (**XIII** and **XV**), there is a reactivity difference between *E* and *Z* alkenes in the hydrogenation reaction.

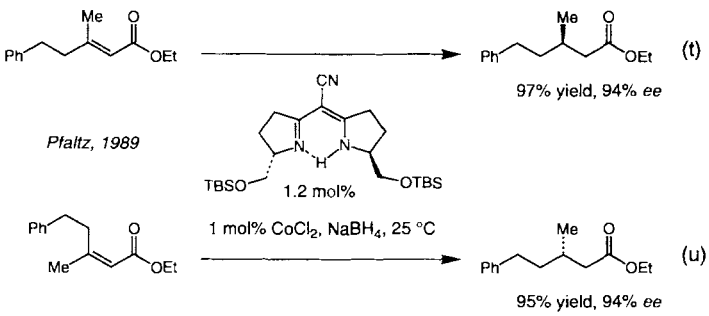
Comparison with Related Catalytic Enantioselective Processes

Significant advances have been made in the area of enantioselective hydrogenation with various rhodium, ruthenium, and cobalt complexes as catalysts.[60] However, similar processes with trisubstituted alkenes as substrates are often nonstereoselective.[61] Therefore, the titanocene-catalyzed hydrogenation of trisubstituted alkenes reported by Buchwald represents the first catalytic transformation that accomplishes this important task with excellent efficiency and enantioselectivity. The development of other new catalytic methods for the hydrogenation of a wider range of olefinic substrates will undoubtedly remain a preoccupation of researchers active in this area. In this context, the highly enantioselective hydrogenation of α,β-unsaturated carbonyl compounds by Pfaltz [Eqs. (t) and (u)] represents a major advance in the field.[62]

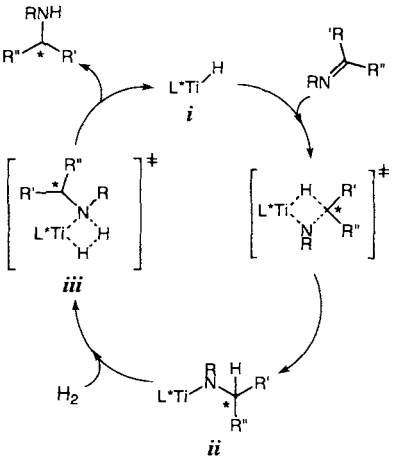


4.2.3. Asymmetric Hydrogenation of Imines

4.2.3.1. Asymmetric [(ebthi)Ti]-Catalyzed Reduction of Imines

Buchwald and co-workers have reported that titanocene **45** is an effective catalyst for enantioselective hydrogenation of imines (Table 9).[63] With 5 mol% of the chiral Ti complex and under 1.38×10^4 kPa (2000 psi) H_2 at 65 °C, imines are reduced to amines in good yield and with 58–98% *ee*.[64a] In the reduction of acyclic imines the selectivity is lower than that obtained with cyclic substrates. This could arise because acyclic imines are often composed of a mixture of *cis* and *trans* isomers; similar to the hydrogenation of alkenes, the two imine isomers might be expected to react through opposite enantiofaces.[64]

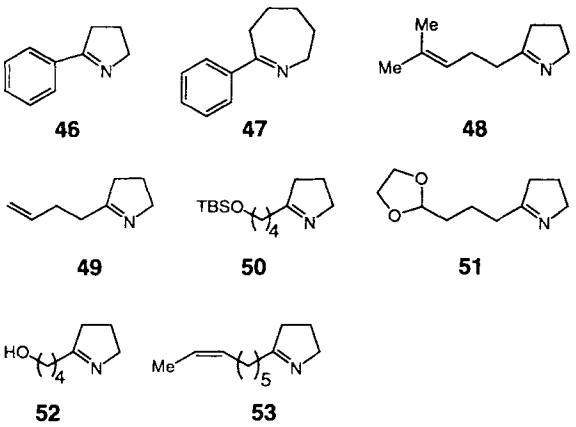
In more recent work, Buchwald has demonstrated that the [(ebthi)Ti]-catalyzed reduction of cyclic imines proceeds notably faster than that of related acyclic substrates.[64b] Kinetic studies indicate that the catalytic cycle shown in Scheme 23



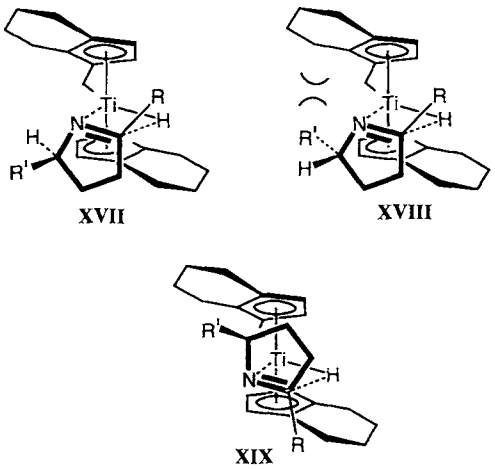
Scheme 23. Proposed mechanism for the [(ebthi)Ti]-catalyzed reduction of imines.

represents a plausible mechanism for the Ti-catalyzed reduction. Specifically, experimental evidence indicates that hydrogenolysis of the Ti–N bond (*ii* → *iii* → *i*) may be the rate-determining step in the titanium-catalyzed reduction of imines.[64c] Buchwald has suggested that when the substrate is a cyclic amine in which the two nitrogen substituents are tethered, the Ti–N bond is generally more accessible to the incoming H_2 molecule and therefore undergoes hydrogenation (*iii* → *i*, Scheme 24) faster than an analogous acyclic system in which the Ti–N bond is effectively more hindered.[65]

Buchwald and co-workers subsequently established that with cyclic imines, 551 kPa (80 psi) H_2 pressure is sufficient for the Ti-catalyzed reduction to proceed smoothly.[64b] Thus, **46**–**53** (Scheme 24) are reduced with 5 mol% **45** [see Eq. (s)] under



Scheme 24. Substrates suitable for [(ebthi)TiH]-catalyzed reduction of imines.



Scheme 25. Transition state models proposed by Buchwald for the [(ebthi)TiH]-catalyzed reduction of cyclic imines. **XVII**: no steric hindrance. **XVIII**: with steric hindrance. **XIX** is not possible.

551 kPa (80 psi) H_2 to yield the desired amines in >70% yield and >98% *ee*. In addition, these workers reported that the more reactive cyclic imines exemplified by **46** are reduced with as little as 1 mol% catalyst. Whereas terminal C=C bonds in the substrate may be hydrogenated along with the imine, di- and trisubstituted C=C bonds are relatively inert under these reaction conditions (ca. 16% of **53** contained the (*E*) alkene and ca. 17% of the substrate was the saturated analog). In the case of hydroxyl-substituted imines, phenylsilane is used for the in situ protection of hydroxyl group; hence hydroxyl imines may be subjected to the catalytic reduction conditions as well (e.g. **52** with excess phenylsilane). Five-, six-, and seven-membered cyclic imines, as well as substrates bearing silylethers, acetals, and protected pyrroles can be utilized in these transformations.

4.2.3.2. Kinetic Resolution through [(Ebthi)Ti]-Catalyzed Reduction of Imines

The catalytic kinetic resolution of chiral imines through the titanium-catalyzed enantioselective hydrogenation reaction has been investigated by Buchwald.[66] As shown in Table 10, when (±)-5-methyl-2-phenyl-1-pyrroline is subjected to the hydrogenation conditions, after about 50% conversion both the recovered starting material and the product in 99% *ee* are obtained (entry 1, Table 10). Whereas pyrrolines substituted at C5 are readily resolved, those carrying substituents at C3 and C4 undergo catalytic resolution less efficiently (cf. entries 1 and 2 to entries 3 and 4).

The proposed transition state structures depicted in Scheme 25, accounting for the reactivity and selectivity patterns observed in [(ebthi)Ti]-catalyzed reduction of imines, are similar to those offered for the catalytic hydrogenation of alkenes (cf. Scheme 22). It has been suggested that in the intermediate in which C–H bond formation occurs, the Ti–H bond is positioned such that it can overlap with the π^* orbital of the imine.[67] That is, bond formation proceeds through a four-centered transition state structure, in which the pyrroline ring is positioned such that steric interactions between the R group attached to the imine carbon and the tetrahydroindenyl ligand are avoided (**XVII** and **XVIII** in Scheme 25). A complex of type **XIX** would be destabilized by interactions between R and the cyclohexyl group of the chiral ligand. Furthermore, it should be preferable that the heterocycle is situated such that the R′ substituent on the stereogenic carbon is oriented away from the catalyst, as in **XVII**. In the transition state structure for the mismatched substrate enantiomer **XVIII**, the R′ group is positioned directly under the cyclohexyl group of the ligand and suffers from unfavorable steric interaction with the cyclopentadienyl ring of the chiral catalyst.[68]

According to the models proposed for the [(ebthi)Ti]-catalyzed reduction of imines, it may be predicted that the C3- and C4-substituted imines should be efficiently resolved under these conditions with equal efficiency. How-

Table 10. [(ebthi)Ti]-catalyzed kinetic resolution of cyclic imines [a].

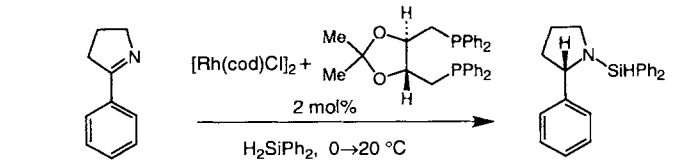
Entry	Substrate	Product	Yield [%] *ee* [%]	Recovered substrate	Yield *ee* [%]
1			34 [99]		37 [99]
2			41 [> 95]		41 [> 95]
3		 *syn:anti 6:1*	42 [> 95]		- [75]
4		 *syn:anti 3:1*	44 [99]		33 [49]

[a] Reaction conditions: 5 mol% (*S*)-[(ebthi)TiH], 551 kPa (80 psi) H_2, 65 °C, THF.

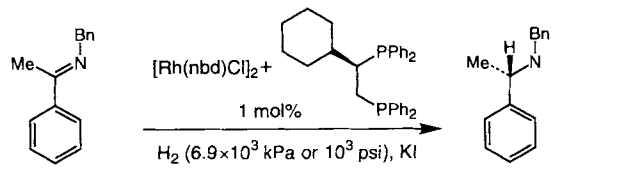
ever, as shown in Table 10 (entry 4), the steric bulk of a phenyl group at C4 is not sufficient to allow effective kinetic resolution, and reduction of a substrate having a benzyl substituent at the C3 site (entry 3) is significantly less selective than that with the corresponding C5-substituted isomers (entries 1 and 2). Thus, it is likely that there are other conformations of the pyrroline ring that allow the alkyl groups at C4 to escape interaction with the ligands of the metal catalyst.

Comparison with Related Catalytic Enantioselective Processes

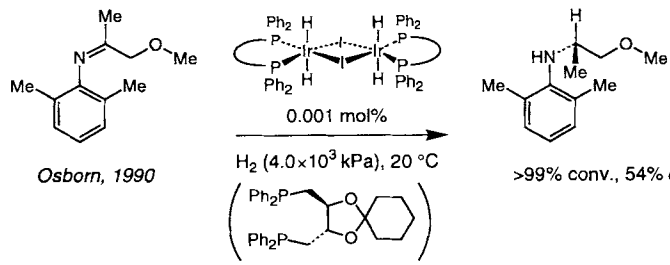
The synthesis of nonracemic amines through reduction of their unsaturated precursors has been the target of a number of important investigations. Procedures described by Brunner and Wiegrebe [Eq. (v)],[69] Fryzuk and James [Eq. (w)],[70] Osborn [Eq. (x)],[71] Spindler [Eq. (y)],[72] and Burk [Eq. (z)][73] offer alternative enantioselective methods. Comparison of this previous work to that described in this section clearly indicates that the [(ebthi)Ti]-catalyzed reduction of imines developed by Buchwald is an important, valuable, and useful addition to the variety of available methods for the reduction of imines.



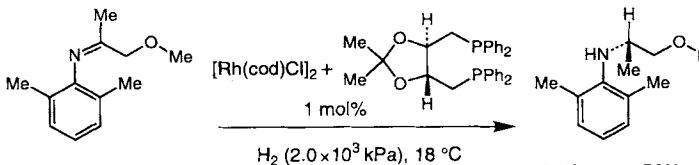
Brunner & Wiegrebe, 1985 — 85% yield, 59% *ee* (v)



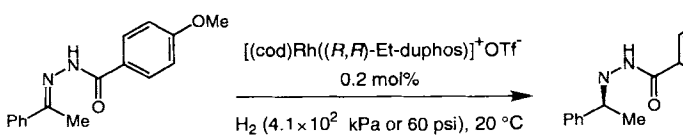
Fryzuk & James, 1988 — >99% yield, 84% *ee* (w)



Osborn, 1990 — >99% conv., 54% *ee* (x)

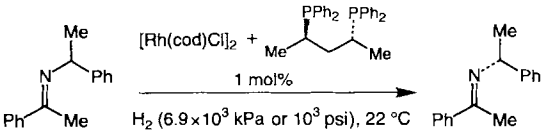


Spindler, 1990 — 77% conv., 56% *ee* (y)



Burk, 1992 — 95% yield, 91% *ee* (z)

In the context of related catalytic kinetic resolution procedures, Lensink reported in 1993 an effective method for the catalytic kinetic resolution of chiral acyclic imines;[74] an example of this process is illustrated below [Eq. (aa)]. Thus, the



Lensink, 1993 — 83% *ee*, 67% conv. (aa)

Rh-catalyzed and the [(ebthi)Ti]-catalyzed resolution methods complement each other in offering convenient routes for the efficient enantioselective syntheses of a variety of chiral imines in nonracemic form.

4.2.4. *Asymmetric Hydrogenation of Enamines*

Buchwald and Lee have reported the [(ebthi)TiH]-catalyzed asymmetric hydrogenation of enamines.[75] The reaction conditions are sufficiently mild that aromatic chlorides, ethers, and trisubstituted alkenes can be considered as compatible functional groups. However, when an aryl bromide is used as a substrate, the the C–Br bond is reduced, presumably by a titanium(III) hydride complex. As shown in Table 11, α-aryl tertiary amines are produced in good yield and with exceptional enantioselectivity. Cyclic tertiary amines are most often employed as substrates; however, acyclic methyl benzyl enamines are suitable starting materials as well (entry 2, Table 11). It is worthy of note that the C=C bond in the cyclohexenyl enamine substrate in entry 3 of Table 11 is not hydrogenated under the reaction conditions.

Transition state models that account for the selectivity observed in the [(ebthi)Ti]-catalyzed asymmetric hydrogenation of enamines have been proposed by Buchwald and are depicted in Scheme 26. It has been suggested that one transition state structure would be significantly favored if the phenyl group rotates out of conjugation with the enamine

C=C bond; as a result the nonbonding pair of electrons on nitrogen could retain their overlap with the olefin π-cloud. Severe A(1,2) allylic strain would exist if both the phenyl π-system and the nonbonding electrons on nitrogen were to remain coplanar with the C=C bond. These conformational considerations lead to the preference for the top transition structure in Scheme 26. Although there is no experimental evidence in support of such conformational tendencies, the above mechanistic paradigm readily accounts for the observed enantioselectivities.

Comparison with Related Catalytic Enantioselective Processes

Catalytic enantioselective methods for the hydrogenation of enamides has been the subject of a number of reports.[76] However, the Buchwald study describes the first examples of asymmetric and catalytic reductions of enamines. Therefore, the [(ebthi)TiH] system has provided the synthetic chemist with a unique tool for the efficient preparation of a variety of nonracemic amines in high enantiopurity.

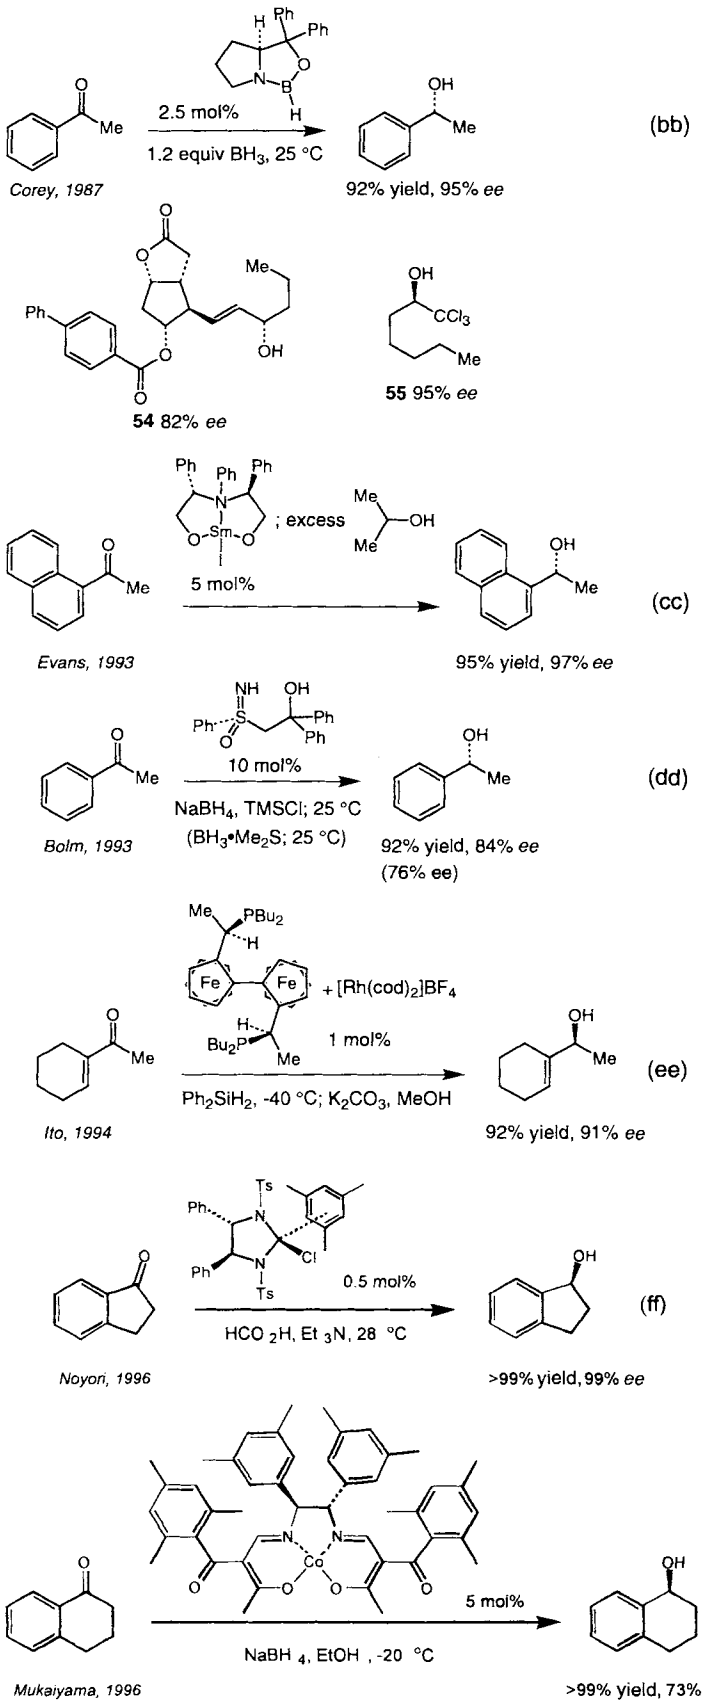
4.2.5. Asymmetric Hydrosilation of Ketones

The development of methods for the enantioselective reduction of ketones has been the subject of intense study in recent years. In general, the reported methods are most effective when the two groups attached to the carbonyl group differ significantly in size. In an effort to extend the scope of this transformation, Buchwald and co-workers have employed the [(ebthi)TiH] complex in the asymmetric catalytic reduction of ketones.[77] Thus, in the presence of polymethylhydrosilane, (*R*)-[(ebthi)TiH] complex (generated from (*R*)-[(ebthi)Ti(binol)] and two equivalents of butyllithium) catalyzes the reduction of various ketones in high yield and with excellent enantioselectivity.

Aryl, methyl, and vinyl ketones are selectively reduced to the corresponding nonracemic secondary alcohols (Table 12). Selectivity is markedly reduced, however, when both of the ketone substituents are aliphatic (entry 4). The selective reduction of cyclohexyl phenyl ketone (entry 5), in which the ketone substituents are of similar size, indicates that electronic effects can play a notable role in controlling stereoselectivity. In connection to the last case, Buchwald suggests that the two substituents may have different effective sizes. The phenyl and carbonyl π-systems may remain coplanar and hence conformationally constrained, whereas the cyclohexyl ring might rotate to avoid costly steric interactions with the chiral ligand. Structures that account for the enantiofacial selectivity in the hydrosilation of ketones are similar to those discussed previously for the hydrogenation of alkenes, imines, and enamines (cf. Schemes 22, 25, and 26).

Comparison with Related Catalytic Enantioselective Processes

Shown below are examples of other highly enantioselective reductions of carbonyl compounds reported by Corey [Eq. (bb)],[78] Evans [Eq. (cc)],[79] Bolm [Eq. (dd)],[80] Ito [Eq. (ee)],[81] Noyori [Eq. (ff)],[82] and Mukaiyama [Eq. (gg)].[83] The Corey method has been utilized in the synthesis of a variety of important target molecules: the prostaglandin precursor **54**,[84] and trichloromethyl alcohol **55**,[85] which is used in the preparation of unnatural amino acids in the nonracemic form, are illustrative.[86] Buchwald's [(ebthi)TiH]-catalyzed method presents a useful complement to other available catalytic methods for the enantioselective reduction of ketones. For example, the hydrosilation procedure reported by Ito [Eq. (ee)] affords the allylic alcohol with enantioselectivity similar to that reported by the MIT group (entry 3, Table 12); however, a subsequent desilylation is required in the Ito method. On the other



hand the cyclohexyl methyl ketone shown in entry 2 of Table 12 is reduced in 80% *ee* by the Ito approach (vs. 24% *ee* by the Ti-catalyzed protocol). The most recent advance reported by Noyori affords outstanding enantioselectivities in a reaction in which the hydride source (formic acid) efficiently reduces the ketone substrate. This is in contrast to the reaction with the more conventional hydride source 2-propanol, which suffers from the reverse process and thus less than ideal conversions.

5. Summary and Outlook

The chemistry described in this article demonstrates that chiral *ansa*-metallocene complexes can be used to effect a number of useful and important catalytic asymmetric transformations in excellent yield and with high levels of enantioselectivity. Because of the direct involvement of the metal center in the bond-forming process, reactions that involve the insertion of a functional group (for example an alkene, imine, enamine, or ketone) into a metal–hydride or metal–carbon bond most often proceed with outstanding regio- and stereoselectivity. However, when bond formation takes place at a site more remote from the transition metal center (as in allylmetalation or Lewis acid catalyzed Diels–Alder reaction), less efficient chirality transfer is observed. Future studies may nonetheless show that in the latter class of transformations alteration of the chiral ligand allows for a higher degree of chirality transfer in metallocene-mediated or -catalyzed reactions.

Although ebthi metallocenes have proven to be effective at promoting a variety of transformations, the equipment required to prepare such catalysts (glovebox and high-pressure hydrogenation apparatus), as well as costs associated with the required metallocene resolution (nonracemic binaphthol costs $45 per gram), may preclude everyday use of these chiral controlling agents in large-scale organic synthesis. In this context, promising advances toward practical syntheses of inexpensive and chiral [(ebthi)MX_2] equivalents may eventually provide more practical alternatives to this powerful class of transition metal catalysts. These organometallic complexes should not only allow for widespread application of the enantioselective and catalytic transformations discussed in this review, they may also be able to effect selective transformations not readily achieved with nonracemic [(ebthi)M] ensembles. Regardless, there is little doubt that the chemistry discussed in this article adumbrates future exciting discoveries in the design and development of useful asymmetric catalytic transformations.

We are grateful to the National Institutes of Health (GM-47480) and the National Science Foundation (CHE-9257580) for generous support of our research in connection to the development of the Zr-catalyzed carbomagnesation reaction. Additional support from Pfizer, Eli Lilly, Zeneca, Glaxo, and Monsanto is also gratefully acknowledged. We are grateful to our co-workers and colleagues Z.-M. Xu, Ahmad F. Houri, Mary T. Didiuk, Michael S. Visser, Charles W. Johannes, Nina R. Horan, and Derek A. Cogan for their important contributions to aspects of the carbomagnesation project described here. We thank Professors Robert Waymouth and Richard Jordan for many useful suggestions and a critical reading of this manuscript, and Professor Steve Buchwald for a helpful discussion.

[51] Kinetic measurements performed in our laboratories [52] indicate that the Zr–Mg ligand exchange (e.g., *i* → *iii* in Scheme 19) is likely the turnover-limiting step. However, formation of the zirconacyclopentane may well be the stereochemistry-determining event in the catalytic cycle. That is, either both metallacycle isomers undergo ligand exchange at the same rate and, therefore, the more predominant metallacycle leads to the final major isomer, or Zr–Mg ligand exchange may be somewhat faster in the minor zirconacycle, but the higher concentration of one intermediate metallacycle may more than compensate for the aforementioned rate difference.

[67] Alkene insertion reactions generally involve a transition state in which the alkene and metal–hydride bond are coplanar. See: R. H. Crabtree in *The Organometallic Chemistry of the Transition Metals*, Wiley, New York **1988**, pp. 148–153.

[68] Buchwald has shown that in the [(ebthi)TiH]-catalyzed reduction of achiral imines, the rate-determining step is hydrogenolysis of the Ti–N bond (Scheme 23). Therefore, insertion of an imine into the Ti–H bond is not necessarily a kinetically significant process. However, the proposed mechanistic arguments, in which the major product stereoisomer is predicted based on the minimization of steric interactions within the [(ebthi)TiH] π-complex, provide a convenient tool for the reliable prediction of stereochemical outcome of the reaction. It is possible that, in fact, enamine or alkene association with the chiral Ti–H complex is the stereochemistry-determining step. In other words, although the Ti–N hydrogenation may be rate-determining, there is little energy difference between the slow steps of the various pathways that lead to enantiomeric products: the predominant product isomer arises from the most abundant transition metal–substrate complex.

A variant of the NaCl structure that according to calculations should be stable at low temperatures or in the presence of included particles

First Step Towards Planning of Syntheses in Solid-State Chemistry: Determination of Promising Structure Candidates by Global Optimization

J. Christian Schön and Martin Jansen*

A method is presented here that allows, in principle, the prediction of the existence and structure of (meta)stable solid compounds. It is based on a set of adjustable modules that are applied to the study of the energy function of the chemical system of interest. The main elements are a set of routines for global optimization and local minimization, as well as algorithms for the investigation of the phase space structure near local minima of the potential energy, and the analysis and characterization of the structure candidates. The current implementation focuses on ionic compounds, for which empirical potentials are used for the evaluation of the energy function in the first stage, and a Hartree–Fock algorithm for refinements. The global optimization is performed with a stochastic simulated annealing algorithm, and the local minimization employs stochastic quenches and gradient methods. The neighborhoods of the local minima are studied with the threshold algorithm. The results of this approach are illustrated with a number of examples: compounds of binary noble gases, and binary and ternary ionic compounds. These include several substances that have not been synthesized yet, but should stand a fair chance of being kinetically stable, for example further alkali metal nitrides besides Li_3N, as well as Ca_3SiBr_2 or $SrTi_2O_5$.

Keywords: computer chemistry · solid-state structures · structure prediction · synthesis planning

1. Introduction and Philosophy

A touchstone for judging the stage of the development of a scientific field is the degree to which it is possible to predict experimental results from basic principles. Considering the main goals of chemistry, namely synthesis and analysis of new compounds, one must ask whether it is feasible to predict the existence of hypothetical compounds under given thermodynamic boundary conditions, and also to develop realistic routes for their synthesis.

Already with respect to the predictability of (meta)stable compounds, dramatic differences exist among the different branches of preparative chemistry. In the molecular chemistry of carbon and some of the other nonmetals, an impressive ability in the design, that is, the prediction of such molecules, has been reached. In addition, a large repertoire of techniques has been developed that allow the systematic planning of specific synthetic routes. As just one of many examples, we mention the "retro-synthesis" technique[1] systematized and developed in the work of Corey;[2, 3] another remarkable approach is the systematic classification of possible reaction sites and paths by Ugi et al.[4]

In preparative solid-state chemistry, however, it is neither possible to predict whether some hypothetical compound can exist at all nor what structure(s) it would exhibit. In most cases, the research is experimental in the classical sense of the word. Of course, the success of such an exploration can be improved through clever choices of starting materials, and appropriate temperature and pressure settings during the synthesis. But a control of the reactions involved that would be sufficient for an a-priori design of a specific synthetic route is not available at this time. The obvious great differences with respect to both the methods and the general approach have caused, for example, Harald Schäfer to remark[5] that a separation of preparative chemistry into the subfields "solid-state chemistry" and "molecular chemistry" were more appropriate than the historically founded one into "organic" and "inorganic" chemistry, and similar sentiments have been expressed by others since.[6]

In Table 1 we have tried to illustrate the complementary, even nearly antagonistic, character of these two subfields through a comparison of the crucial laws and processes pertaining to each. Homogeneous equilibria between molecular starting materials and products dispersed within a solution are compared with the phase equilibria among macroscopically distributed reaction partners in solid-state reactions. From this follows the well-known fact that in homogeneous equilibria all participants in the reaction are present in finite concentrations, while in solid-state reactions the solid starting materials can be used up completely. Thus, with appropriate control of the reaction, only the

Table 1. Comparison of molecular and solid-state chemistry with respect to selected features of reactions within these fields.

Molecular Chemistry	Solid-State Chemistry
homogeneous equilibrium	heterogeneous equilibrium
in equilibrium all reactants are present in finite amounts	reactions may proceed until one of the condensed phases has disappeared, or even until only one remains
low reaction temperatures	high reaction temperatures
kinetic reaction control	thermodynamic reaction control
conservation of molecular framework, reaction at functional groups	destruction of the structure of the starting materials
transport distance: about 5–10 Å	transport distance: about 10^4–10^6 Å
diffusion coefficients: about 10^{-5} $cm^2 sec^{-1}$	diffusion coefficients: about 10^{-10}–10^{-14} $cm^2 sec^{-1}$

pure product can remain in equilibrium as a single condensed phase, in agreement with Gibbs' phase rule.[7]

Already from this observation follows another, usually very clear, difference: since the reactions of molecules dispersed in homogeneous media can be made to proceed with little thermal activation and to involve the opening and closing of only a single or at most very few bonds at a time, these reactions are kinetically controlled to a large degree. In contrast, due to the rather drastic temperature and pressure conditions employed during solid-state reactions, these are usually controlled thermodynamically, and result in a complete reorganization of the structures of the initial compounds. Finally, the actual synthesis techniques strongly reflect the fundamental differences in the conditions for the transport of the atoms involved during the different types of reactions, that is, the distances separating the reactants, the available transport paths, and the diffusion coefficients of the atoms/molecules in the solid or the solution (cf. Table 1).

From this simplified phenomenological comparison, one can draw the conclusion that the regiospecificity of reactions in molecules together with the mainly kinetic control of the reactions constitute an efficient toolbox for planning molecular syntheses, while similar tools are usually not available for solid-state syntheses. One must ask, however, how the molecular chemist can predict whether the final, and also the intermediate, molecules are capable of existing in the first place, and, furthermore, how he can recognize the validity of the proposed reaction steps.

The basis for the understanding of the details of molecular chemistry lies in the hierarchical structure of the participating quantities and the relatively small number of participating atoms. The local environment of an atom within a suggested molecule is dominated by the bonds to the neighboring atoms and to a lesser extent by spatial packing requirements. Since "allowed" local configurations are well-known from experience, both with respect to their geometry and their stability, any presumably stable molecule can be easily constructed by using these local configurations as a system of stable structural increments. On the next level, one can investigate the secondary (topological) structure consisting of rings, chains, or clusters, etc., which again must follow certain simple rules based on size and bonding angle requirements. Finally, in larger molecules or emsembles, the arrangement of secondary structure elements into a higher tertiary or quaternary structure must be considered. This hierarchical approach reflects the fact that the energy function for the kinetically stable molecules usually encountered by the molecular chemist can be described by a sum of local (short-range) interactions. Even up to rather large distortions, this local description appears to remain a valid approximation, and the effects of distortions on the energy of the system are often known and have been accounted for in the models. In the past two decades, such potentials[8, 9] have been implemented successfully in molecular modeling packages that may be seen as a way to "quantify" the intuitive understanding of the molecular chemist.

In contrast, it appears nearly impossible to predict even the existence of stable solid phases with a given fixed composition, not to mention *all* the metastable phases that might exist.[10] Why should Li_3N exist, but not Na_3N or Cs_3N? Why is TiO_2 found in a large number of stable modifications such as rutile,

Martin Jansen, born in 1944 on Pellworm, studied chemistry at the Justus-Liebig-Universität Giessen, where he gained his doctorate in 1973 under the supervision of R. Hoppe. After his habilitation in 1978, he was offered and accepted a professorial chair for Inorganic Chemistry at the Universität Hannover. In 1987 he moved to the Rheinische Friedrich Wilhelms Universität in Bonn. His main research lie in the field of preparative solid-state chemistry, crystal chemistry, materials research, and the structure–property relationship of solids. Among others, he was awarded the Gottfried Wilhelm Leibniz prize and the Otto Bayer prize.

M. Jansen

J. C. Schön

J. Christian Schön was born in Bonn in 1957. He studied physics at the Universität Bonn and at the Massachusetts Institute of Technology, where he received his MS im mathematical physics in 1982, and his PhD in theoretical solid state physics in 1988. Afterwards he undertook postdoctoral studies in applied mathematics at San Diego State University until the end of 1991, where he worked on mathematical models in the areas of materials science and thermodynamics. After being a visitor at the University of Odense (Denmark), he carried out further postdoctoral research in the physics department of Copenhagen University. Since 1993 he has been at the Institut für Anorganische Chemie der Universität Bonn, where he is investigating the energy landscapes of solids, with a particular emphasis on modeling and predicting structures.

anatas, and brookite, while for MgF_2 only one structure has been reliably reported? Indubitably, it is also often possible in solid-state chemistry to estimate whether a suggested structure of a previously unknown compound is reasonable or strange; and a number of empirical rules exist, for example the radius ratio rule,[11-13] the valence electron concentration rule,[14, 15] Pauling's bond valence rules,[13, 16] and the analysis of partial Madelung constants,[17] that help us to pronounce judgement, after the fact. But even with the help of these rules and some empirical information about (formal) ionic charges and ionic radii, or some guidelines about the typical number of bonds a certain atom usually tries to establish, it is very difficult even to derive three-dimensional structures for a hypothetical compound of a given composition. And we are not even addressing the question, which structure might be the thermodynamically stable one (if any exists at all), or whether any of the competing ones might be kinetically stable. Of course, planning a synthesis route is inconceivable without a realistic synthetic target.

That one cannot predict the existence of a solid compound and its structure based on common sense can be seen in the difficulty to write down a simple energy function that—as is the case for an organic molecule—is dominated by a restricted set of local interactions. Of course, for a given existing structure, one can always construct a-posteriori some purely short-range potential containing empirical parameters derived from, for example, certain elastic constants and cell parameters. Because of the way it was constructed, such a potential can be used to justify, but not to predict, the local coordination polyhedra observed.

However, since such a very specific potential cannot be easily transferred even to another polymorphic modification of a given compound, it usually lacks the versatility inherent in the successful potentials used to describe the interactions within molecules. Most "general" forms of effective energy functions need to contain terms that describe long-range interactions, if they are to be of any use in comparing many hypothetical different structures of an unknown compound. However, once such terms are introduced, the simple building blocks one needs to construct consistent structures, in analogy to the visualization of a molecule, become increasingly fuzzy. In addition, we are dealing with practically infinite three-dimensional solids (extended solids), and thus, the number of possible arrangements of simple building blocks such as coordination polyhedra into periodic structures appears to be limitless, not to mention the possibility of amorphous structures and quasi-crystals. Apart from "social" arguments like "each atom of a given type should have the same environment" or "the structure with the higher symmetry should be more prevalent", there appears to be no obvious way to quickly choose among configurations that exhibit the same local structure but are otherwise different.

Nevertheless, the preceding considerations point towards a possible solution of the problems one faces when searching for new solids to synthesize. While it is still impossible to safely predict new and interesting solids by intuition or simple rules alone, with the advent of powerful computers other approaches have become feasible. From a physical point of view,[7] a kinetically stable compound is equivalent to a local minimum on the hypersurface of the potential energy[18] or Gibbs enthalpy of the chemical system, when this minimum is surrounded by energy and/or entropy barriers that are high enough to prevent a decomposition or a transformation into another structure within some (temperature-dependent) "survival time" $\tau_{life}(T)$.[18] Thus, in principle, it is possible to find all the (meta)stable compounds of a given system by studying the corresponding energy hypersurface. At this point, molecular and solid-state chemistry meet again in the sense that the complete range of possible molecules and solid compounds is already present on the energy hypersurface of a given chemical system.[19] Although the main goal of such a detailed study of the energy hypersurface is the recognition of promising synthetic targets and the evaluation of their kinetic stability, the neighborhood structure of the set of local minima may even yield hints for possible synthetic routes.

Since the direct quantum mechanical approach, that is solving the Schrödinger equation for an unknown realistic chemical system, is not yet feasible,[20] we feel that it is necessary to follow a stepwise procedure: first, possible candidate structures are determined with relatively fast but not very accurate methods, and then analyzed with respect to their properties, especially their kinetic and thermodynamic stability. The most promising ones can subsequently be refined by using more advanced and more precise, but also more time-consuming, algorithms. Attempts to implement such a procedure lead directly to the modular approach described in the next two sections.

In Section 4 we present the details of the current implementation, that is, the type of algorithms used, and the type of chemical systems that have been studied so far. Thereafter, we give an overview of the results obtained up to now, followed by a critical discussion of the current procedure. Our method constitutes a new approach to the planning of syntheses in solid-state chemistry; in the final section, we show the links between the method presented and the application of energy minimizations in the field of structure determination and structure refinement in solids, and studies of the energy hypersurface of molecules or clusters.

2. The Elements of the Modular Approach

We have chosen to implement the stepwise procedure described above by splitting it into five modules: input and database, preselector, optimizer, property analyzer, stability analyzer. Each element is devoted to a certain set of tasks, and it may employ algorithms of different degrees of refinement, depending on the stage of the procedure. During the analysis of a chemical system of interest, these modules will be called upon many times, until the most promising candidate structures have been determined.

2.1. Input and Database

The first module consists of two parts. First, there is the database containing as much of the a priori knowledge about the system as can be gleaned from theoretical and/or experimental studies of similar and/or related systems. This can include general properties like ionization energies and electron affinities, effective radii of the participating atoms or ions, and the number of valence electrons. But the database also contains

ranges of allowed parameters in effective potentials, basis sets for ab initio calculations, that is, the quantities necessary to evaluate the energy function within the most useful approximation.

The second part of the module is the traditional input one has to choose for any numerical calculation. Besides fixing the "physical" boundary conditions such as external tensions (e.g. pressure) or electromagnetic fields, we have to decide what the "chemical" boundary conditions should be. Since we can only represent a system of limited size in the computer, it is usually necessary to employ periodic boundary conditions, that is, a simulation cell of arbitrary variable shape containing a possibly fluctuating but nevertheless finite number of atoms is repeated periodically.[21] Evidently, this excludes quasi-crystals and amorphous systems, although one would expect that for very large simulation cells corresponding systems could occur.[22] If the system under investigation is completely unexplored, it might be most useful to impose no further restrictions and to let the subsequent optimization procedures determine which compositions, ionic charges, crystallographic unit cells, etc. characterize the most promising structures. On the other hand, one often has some a-priori interest, for example, in a certain composition, and thus one might want to prescribe fixed ratios of the numbers of different atoms within the simulation cell.

2.2. Preselector

This module represents the "controller" of the structure determination procedure. Like an "expert system", it analyzes the information provided by the other four modules and then decides upon the next step in the procedure. Of course, the general sequence of global and local optimizations, and the analyses of the best local minima is basically fixed. But the choice of initial configurations for the next optimization run(s) and the choice of the parameters of the various algorithms, in particular, is strongly influenced by the outcomes of the previous run(s). Depending on the problem at hand, one may want to program the preselector to follow a fixed schedule, or one may prefer a more dynamic approach. In the latter case, one would also decide (or have the preselector decide on its own), what method to use to evaluate the energy of the system, and how to vary the parameters of the empirical potentials and ab initio algorithms, in order to judge the robustness of the candidate structures.

2.3. Optimizer

The task of this module is rather straightforward. Based on the boundary conditions, initial configurations, and optimization parameters provided by the preselector and input modules, global and/or local optimization algorithms are employed to determine and/or refine local minima of the hypersurface of the potential energy of the system. The lowest local minima are often called sub-optima, since for most difficult optimization problems there is no guarantee that the global minimum can be found during a finite global optimization run.[23–25]

2.4. Property Analyzer

Since the hypersurface of the potential energy contains a very large number of local minima, one can expect that each optimization run will result in a different result. It is thus necessary, to analyze these structures, and to place them into certain structural categories. Furthermore, one might want to identify useful substructures that could serve as the initial configuration of a later optimization run. Finally, we are, of course, interested in the properties of the best structure candidates.[26] The determination and classification of the properties of the candidate structures is the task of the property analyzer module. It must contain algorithms to analyze the geometry of a given structure, and it may include additional algorithms for other properties of interest such as elastic constants.

2.5. Stability Analyzer

This module could have been discussed as part of the previous one, but since it deals with the analysis of the local environment and the kinetic stability of a minimum on the energy hypersurface, it is somewhat different from the usual algorithms that are used to evaluate the properties of a given fixed structure. As was pointed out in Section 2.4, the number of local minima on the energy hypersurface is very large, and this remains true, even after configurations with "similar" structure have been reduced to just one typical structure representative. At a temperature of $T = 0$ K, all these minima could in principle exist. But in most chemical systems, only a small number of (meta)stable periodic structures will actually be accessible synthetically. One criterion that presumably would eliminate many weak candidates, is the kinetic stability of the structure. If the energy barriers around a metastable minimum are too low, even very low temperatures will be enough to provide the activation energy necessary for a phase transformation to a different structure. Therefore, the stability analyzer module consists of algorithms that determine the heights of the energy barriers and the phase space volume near a local minimum.

3. General Aspects of the Search Procedure

Before turning to the specific algorithms we have used for the study of example systems, we would like to outline, how the stepwise procedure might work for an unknown chemical system containing the elements A, B, and C. After all the relevant information about the participating atoms A, B, and C has been placed in the database, the physically reasonable range of parameters for empirical potentials that appear appropriate for the system A/B/C must be estimated, either from general theoretical considerations or empirical data, if, for example, information about binary compounds in the systems A/B, B/C, and A/C is available. Such a range of parameters has to be considered, since even in systems in which a compound is known and potentials have already been parametrized successfully it is far from clear whether the perhaps very specialized shape of the potential is appropriate for the modeling of alternative modifications.

After the external pressure, the initial number of atoms N etc. have been set to some fixed values, the preselector module will create an initial configuration consisting of N atoms with a randomly selected composition $A_nB_mC_l$ ($n+m+l=N$). The atoms are placed at random positions within a simulation cell that is characterized by three cell vectors of random length and orientation. By choosing the empirical potential that allows the fastest evaluation of the energy function, a global optimization is now performed with module 3; the system may be changed, in principle, in all of its aspects as far as the number, identity, state,[27] and location of the atoms, and the size and shape of the simulation cell are concerned. The final results of the global optimization, perhaps including some intermediate configurations, are usually close to but not identical with a local minimum. Thus, a local optimization is performed on each interesting configuration, and the outcomes of module 3 are analyzed in module 4 and classified into structure types. The results are stored, and the global optimization is repeated for different initial configurations until a statistically relevant set of optimized structure candidates has been collected. If the quality of the empirical potentials was not very high, the parameters of the energy function would also be varied to judge the robustness of the structure types observed so far.

Next, the preselector analyzes the observed distribution of local minima with respect to, for example, common compositions, ionic charges, or coordination polyhedra. Based on the results of this analysis, perhaps together with a-priori information about, for example, "characteristic" ionic charges etc., more restricted optimization runs with certain fixed compositions and/or fixed ionic charges, and fixed numbers of atoms can be performed. For each fixed composition etc., global optimizations are performed. Usually at this stage, most runs will result in chemically and physically reasonable structures. If the system is very complex, even now the minimum configurations found may frequently consist of a mixture of only locally (within the simulation cell) optimized structure elements. In this case, it is a good strategy to use these building blocks to construct structure candidates on purely geometric grounds that then could again serve as initial configurations for another set of optimization runs.

While simple empirical potentials can produce many promising structures, the precise values of, for example, their cell parameters or the exact locations of the atoms in the cell are not to be expected. Such details would require performing another optimization round for fixed composition, etc., using a more realistic potential. Preferably, one would want to employ either highly refined (semi)empirical potentials[28–32] or some ab initio method.[33–35] However, it would be very time-consuming to perform a *global* optimization, especially in the latter case. But, since in most cases many promising structure candidates have already been accumulated at this point, one would restrict oneself to essentially *local* minimizations for each structure type, each time using the best representative as initial configuration.

After completion of the optimization stage, the candidate structures with the lowest ground state energy are analyzed with respect to their stability using module 5. The final result of the whole procedure would now consist of an overview of a large number of preferred compositions, and possible structure types and structure elements that would be expected to occur under certain conditions in the system A/B/C, together with estimates of the relative ground state energies and kinetic stability of the most promising ones. The latter information allows the tentative identification of thermodynamically stable and metastable structures.

4. Specific Algorithms

4.1. Construction of Potentials and Choice of Initial Configurations

We have already applied the modular approach to two classes of systems, noble gases[36] and their mixtures,[37,38] and binary[39–42] and ternary[43,44] ionic compounds. The reason for this choice lies in the possibility of employing relatively simple two-body potentials capable of capturing many qualitative and also some semi-quantitative aspects of the energy hypersurface of the compound in the construction of effective energy functions for such test systems. Since one single run of a global optimization procedure typically involves hundreds of thousands or millions of energy evaluations, and it is, in general, necessary to perform hundreds of such runs to acquire sufficient statistics on the distribution of deep-lying minima, any reduction in the number of function evaluations involved in the calculation of the energy is of great importance.

For noble gases, we employ Lennard-Jones potentials [Eq. (a)], for which the parameters ε_{ij} and σ_{ij} are available from experimental and theoretical investigations.[45]

$$V_{ij}(r_{ij}) = \varepsilon_{ij}\left[\left(\frac{\sigma_{ij}}{r_{ij}}\right)^{12} - \left(\frac{\sigma_{ij}}{r_{ij}}\right)^{6}\right] \qquad \text{(a)}$$

The approximate potentials for the description of ionic systems [Eq. (b)] consist of three terms, a damped Coulomb term, $r^{-1}\exp(-\alpha r)$, a repulsive term, r^{-n}, usually $n=12$, and an attractive dispersion term r^{-6}. If the damping factor in the Coulomb term is not present, that is, $\alpha = 0$, the energy function is evaluated by using the summation method suggested by deLeeuw et al.[46]

$$V_{ij}(r_{ij}) = \frac{q_i q_j \exp(-\alpha r_{ij})}{4\pi\varepsilon_0 r_{ij}} + \varepsilon_{ij}^1\left(\frac{\sigma_{ij}}{r_{ij}}\right)^n - \varepsilon_{ij}^2\left(\frac{\sigma_{ij}}{r_{ij}}\right)^6 \qquad \text{(b)}$$

In addition to these two-body terms, the energy function contains one-body terms $E_0(i)$ (the ionization energy or the electron affinity) and $\mu(i)$ (the chemical potential), and the latter is relevant if the number of atoms is allowed to change during the optimization. Thus, the energy function per atom takes the form given in Equation (c).

$$E = \frac{E_{\text{pot}}}{N} = \frac{1}{2N}\sum_{i\neq j} V_{ij}(r_{ij}) + \frac{1}{N}\sum_i E_0(i) + \mu(i) \qquad \text{(c)}$$

This choice has influenced the type of algorithms we employ in the first two modules. The main task in module 1 is the determination of the free parameters in the potential. Three major routes are available, depending on the amount of preknowledge about the system. If the participating atoms have already been studied extensively in the context of molecular studies using ab initio methods, it is sometimes possible to

derive effective two- and three-body potentials based on these theoretical results.[20, 47, 48] Experience shows, however, that so far this path does involve considerable effort, taking months of investigation.[49] Furthermore, the potentials cannot always be transferred with the required (and hoped-for) accuracy from the molecular environment to the one in the solid state.[49] Thus, one is usually forced to fit the parameters to some experimental observations. Here, two options are available: either one may adjust the parameters according to the properties of some known compound(s) of the binary system, for example, bond lengths and elastic behavior, or one may concentrate on the average properties of the participating atoms, for example ionic radii and deformabilities of the ions. The former option is especially useful for the study of ternary systems when the corresponding binary compounds are already known. For the case of binary systems, however, there are two problems. First, if no compound of the system is known beforehand, obviously no fit can be performed. Second, if a compound is already available experimentally, the model can very easily be prejudiced by using only this substance for fitting, and thus suppressing alternative minima of the (true) energy hypersurface. In contrast, the use of "atomic" properties averaged over many different compounds and local atomic environments should result in somewhat more unbiased effective potentials (recently, the use of parameters averaged over many binary compounds has been proposed by Bush et al.[50]). A disadvantage, of course, lies in the lack of specificity of the potential. Because of this possible trade-off between accuracy and generality, the fit procedure is chosen according to the specific circumstances of the calculation. In both cases, but especially when using average atomic parameters, the optimization runs should be repeated by varying the potential about the "best" values chosen originally. Averaged properties of the ions necessary to construct the effective potential have been placed into a databank, while the allowed variation of the parameters mentioned above is performed by the preselector. The fitting to properties of binary compounds has so far not been automated, and is carried out separately for each case. In a number of instances, it is also possible to refer to tabulated values.[29]

For the final analysis of "good" structure candidates, we use the Hartree–Fock type ab initio program CRYSTAL92.[34] Here, too, a certain freedom in the choice of basis sets and pseudo-potential parameters exists, and it is usually necessary to adjust these parameters for each chemical system or even structure candidate.

The current implementation of the preselector creates random initial configurations with as much built-in order and/or restrictions on the type of atoms (enforced composition and/or ionic charges) as desired. Usually, the atoms are placed at positions chosen at random and the volume of the cell is about ten times as large as that expected for a dense packing of all the atoms initially placed into the simulation cell.

4.2. Global and Local Optimization Methods

The availability of a global optimization procedure is of key significance to our procedure. While it is well-known that more and more refined optimization algorithms can be devised based on more and more detailed knowledge of the energy surface of the system, we have so far used only one family of algorithms, which are based on the stochastic simulated annealing algorithm[51] introduced by Kirkpatrick et al.[52] and Cerny.[53] The great advantage of this method lies in the relative ease of implementation and the very general applicability, regardless of the specific optimization problem.

Simulated annealing is based on the Metropolis (Monte–Carlo) algorithm,[54] which implements a weighted random walk through configuration space. Starting from a current configuration i, a neighboring configuration $i+1$ is chosen at random according to a set of rules (the "moveclass"). If the energy E_{i+1} is below or equal to E_i, the move is always accepted, that is, $i+1$ becomes the new current configuration. Otherwise, the move is only accepted with the probability $\exp(-(E_{i+1}-E_i)/C)$, where C is a control parameter of the random walk. Thus during a sequence of such MC steps, the system can climb over barriers of the energy surface. It can be shown that in the long-time limit ($t \rightarrow \infty$) for an ergodic system the probability $p(i)$ of visiting state (= the configuration) i is given by the Boltzmann distribution for the system at a temperature given by $T = C/k_B$.[55] Furthermore, in analogy to the annealing procedure of a real material, we can reduce the control parameter C down to zero, and expect that the system will end up, with a high probability, in some deep-lying minimum. It can be shown that during such a simulated annealing run, an ergodic system will reach the global minimum,[25, 51, 56] at least for $t \rightarrow \infty$.

Clearly, the most important parameters of this optimization procedure are the temperature program, that is, the rule according to which C is decreased to zero, and the moveclass, that is, the selection of the next trial configuration $i+1$ from the current one i. While a considerable effort has been devoted to the development of efficient general temperature programs,[56–64] the choice of a good moveclass still remains an open question, since it is highly dependent on the problem at hand.

For our explorations of the energy landscapes of solids, the best results seem to be gained from a moveclass in which 60–80% of the moves are devoted to movements of single atoms, about 10% each to the change of ionic charges and the addition/removal/exchange of atoms, while the remaining ones should be used to adjust the size and shape of the simulation cell. However, the selection of the moveclass should also take the size of the system, the goals of the current optimization, and the design of the temperature program into account. Often it might even be useful to vary the moveclass as a function of temperature.

As far as the temperature program is concerned, reasonable results have been achieved by using $T_n = T_0 f^n$ ($n = 0 \ldots n_{max}$), with m MC steps between temperature updates. Here, T_0, f, n_{max}, and m should be chosen according to the size of the system, the moveclass, and the objective of the current optimization run. The latter refers to the fact that different strategies have to be chosen, if one wants to find as deep a minimum as possible for a given amount of computer time or whether one tries to gain a general overview of the statistical distribution of local minima and their accessibility.

An extreme option consists of essentially replacing the global optimization with many local optimizations. In this method it is hoped that the initial configurations are chosen such that all

relevant regions of the configuration space are covered. This requires that either the barrier structure is simple enough that quench runs are not always stranded in high-lying minima even when starting from random initial configurations, or that the starting configurations are already so close to the best sub-optima that only some final adjustments are necessary to reach the desired minimum configurations. The latter case applies if realistic initial states are constructed by some special algorithm, or if the initial configurations are based on the results of earlier optimization runs.

We have employed two algorithms for the purpose of local optimization: a stochastic quench, which corresponds to a simulated annealing algorithm with $C = 0$, and a steepest descent algorithm with a line search option.[23] While the stochastic quench can be used with the full moveclass including charge transfer and atom exchange, the gradient descent is only useful when only the cell parameters and the atom positions need to be adjusted.

4.3. Findcell Algorithm

For the purpose of structure element recognition and structure classification, we have constructed the "findcell" algorithm.[65, 66] By using this one can determine whether the simulation cell contains primitive unit cells that can be used to describe either the full structure or substantial regions of the optimal configuration(s). The latter option is of special interest for large simulation cells, since it will often happen that the configurations reached during the optimization contain several distinct regions each showing a distinct but individually viable structure. Each such substructure should then be investigated in detail by using it as the initial configuration of another global or local optimization run. Note that if these substructures exhibit different compositions, their joint appearance may indicate a possible tendency of the system towards phase separation.

If the primitive cell can reproduce the full configuration, the system can then be further classified crystallographically using combinations of already available algorithms.[67–69]

4.4. Threshold Algorithm

The final algorithm we employ is the threshold or lid algorithm.[70] It is an adaptation of the "lid-method"[71] that has been used to classify the local energy landscape of discrete multiminima systems in the neighborhood of a local minimum.[72, 73] Starting from a given local minimum, a sequence of energy lids slightly above the energy of the local minimum is chosen. For each lid value a random walk is performed with the only restriction that no moves above the energy lid are allowed. Periodically, the system is quenched into the nearest local minimum. There will be some value of the lid above which not all of these quenches will return the system to its starting minimum but end up in a different configuration. This lid value gives an upper limit on the height of the energy barrier that separates the starting minimum from other local minima belonging to the newly accessible region of configuration space. Furthermore, the distribution of energies seen during the random walk(s) provides information on the local density of states of the system. Combining the information about energy barriers and local densities of states, we can construct a model of the energy hypersurface that consists of a tree-graph with weighted nodes. This model can then be used to estimate the stability of structure candidates and find their most likely transformation paths into competing structures.

5. Examples

The modular approach has been tested for two types of chemical systems so far: noble gases and ionic compounds. In this section, we will give a short summary of the results and discuss some characteristic examples. Unless explicitly stated otherwise, the initial configurations of the global optimization run were constructed by placing neutral atoms at random positions inside a large simulation cell with cell volume about ten times the volume of all the participating atoms.

5.1. Noble Gases

5.1.1. Lennard-Jones Gas Consisting of Only One Kind of Particles[36]

Since the Lennard-Jones potential has proved to be a very successful approximation for the potential energy of noble gases, we have used a system of atoms interacting through this potential to test the applicability of the simulated annealing algorithm to the problem of finding sub-optima of the energy hypersurface. Up to 36 atoms within the simulation cell were used. The results showed that the best sub-optimal configurations were hexagonal and cubic close-packed arrangements of the atoms. The next best ones were close-packed arrangements with one atom missing in the arrangement, that is, the optimal ones containing one point defect per simulation cell. The remaining runs resulted in strongly distorted or amorphous structures.

To gain a better understanding of this result, we have performed threshold runs for two-dimensional structures (sixteen atoms in the simulation cell) of a Lennard-Jones gas exhibiting one or more point defects.[38, 70] The barrier structure, and the analysis thereof, showed quite clearly that the structure missing one atom per simulation cell from the sites of a close packing constitutes both the deepest side minimum and the most stable one. It is thus no surprise that this structure candidate was the most likely to appear besides the two sub-optima during relatively short or medium length optimization runs in the three-dimensional case.

5.1.2. Binary Noble Gases[37, 38]

While the details of the energy and length scales were irrelevant for the study of a Lennard-Jones gas consisting of a single component, it was necessary to use appropriate values of the parameters ε_{ij} and σ_{ij} for the case of binary noble gases within the Lennard-Jones potential approximation. These values were

taken from experiment as far as available, and corrected or interpolated from theoretical models, depending on whether the values were slightly contradictory or missing, respectively.[45] The number of atoms in the simulation cell was kept fixed at values ranging from 8 to 64. The optimal structures found were refined by using stochastic quench and steepest descent algorithms.

For most of the runs the composition was kept fixed at 1:1.[74] Very long optimization runs were performed, and for the combinations Ne/Ar, Ne/Kr, Ne/Xe, and Ar/Xe the best sub-optimal structures (in 90% of the cases) were found to consist of two regions in the simulation cell, each containing a dense packing of only one component. In contrast, the best configurations (in 90% of the cases) found for the Ar/Kr system showed a close-packed solid solution of Ar and Kr atoms. Finally, Kr/Xe resulted in phase separation in about 50% of the runs, while the remaining 50% resulted in a joint dense packing. These results indicate that Ar and Kr could form a solid solution at low temperatures, in agreement with experiment,[75] while, with the possible exception of Kr/Xe, the other combinations with composition 1:1 would tend to show phase separation instead.

Table 2. Best results of simulated annealing runs for ionic compounds, including a comparison with the observed structures. During the optimization, many additional structures, corresponding to local minima of the energy hypersurface, have been found in these systems.

Input	Structure (calculated)	Structure (observed)
Na/Cl	NaCl structure	NaCl structure
Cs/Cl	CsCl structure	CsCl structure
Li/F	NaCl structure	NaCl structure
Na/F	NaCl structure	NaCl structure
K/F	NaCl/CsCl structure	NaCl structure
Rb/F	NaCl/CsCl structure	NaCl structure
Cs/F	NaCl/CsCl structure	NaCl structure
Ba/O	NaCl structure	NaCl structure
Li/I	NaCl structure	NaCl structure
Sr/O	NaCl structure	NaCl structure
Ni/O	NaCl structure	NaCl structure
Ca/O	NaCl structure	NaCl structure
Mg/O	NaCl structure	NaCl structure
Ca/F	fluorite structure	fluorite structure
Mg/F	rutile structure	rutile structure
Li/O	antifluorite structure	antifluorite structure
K/O	antifluorite strucutre	antifluorite strucutre
Sr/Cl	fluorite structure	fluorite structure
Ca/Cl	$CaCl_3$ structure	$CaCl_2$ structure
Sn/O	rutile structure	rutile structure
Ti/O	rutile structure	rutile structure
Na/O	antifluorite structure	antifluorite structure
Si/O	cristobalite structure, tridymite structure	e.g. tridymite strucutre, cristobalite structure

5.2. Ionic Compounds

The second class of materials chosen as test systems were the (inorganic) ionic compounds. Both binary and ternary compounds have been investigated; the latter including mostly unknown or at least not-yet-synthesized compounds. The general form of the potential was as given in Section 4.1 (see [Eq. (b)]). The effective potential has been constructed by using both $\alpha = 0$, which requires an Ewald summation, and $\alpha > 0$ (= damped Coulomb potential). Average ionic radii and information about the polarizability or "hardness" of the ions were used to establish starting values of the free parameters in the potential, n, ε_{ij}, and σ_{ij}.

In order to test the applicability of the optimization procedure to ionic systems, we have investigated[39] a large number of binary systems using long simulated annealing runs that are expected to reach a very good sub-optimum of the energy hypersurface ($> 10^6$ MC steps). For most of these runs, the composition of the system and the number of atoms in the simulation cell was kept fixed. Initially, electron transfer between randomly chosen pairs of atoms/ions was allowed. Of course, once the preferred ionic charges had been established as part of the global optimization procedure, additional studies of the system using ions with fixed charges were admissible. The results are listed in Table 2. We note that in nearly all instances the best sub-optimum found during the simulated annealing run turned out to be either the structure seen experimentally to be the preferred one or the structure that agreed with the radius ratio rule.

5.2.1. *Binary Systems*

While the above results clearly show that it is possible to determine very good sub-optima of the energy hypersurface of binary ionic compounds using effective potentials based on characteristic atomic quantities, it was felt necessary to investigate in more detail the energy hypersurface of some particular systems. We have chosen NaCl as a representative AB system,[39] and MgF_2, $MgCl_2$, CaF_2, and $CaCl_2$ as AB_2 systems.[41, 42] The parameters in the effective potential were varied slowly from each set of optimization runs to the next to study the robustness of the candidate structures. Each such set of runs consisted of 14 or 20 global optimizations of 10^5 to 3×10^5 simulated annealing steps, the only difference being the initial value of the random number generator. Thus, for each system, several hundred global optimization runs were performed. Since it had already been established during several sets of optimization runs in which charge transfer was allowed that the best sub-optima occurred when the "fully" ionized ions were present (Na^+, Mg^{2+}, Ca^{2+}, F^-, Cl^-), the ionic charges were fixed at these values, and the moveclass consisted of movement/exchange of the ions, and variation of the size and shape of the simulation cell.

Na/Cl

A large number of structure candidates corresponding to local minima of the energy hypersurface were found in the Na/Cl system. They have been listed in Table 3. Two of these structures were judged to be of special interest, the 5-5 variant (Fig. 1) consisting of trigonal bipyramids of Cl^- ions around the Na^+ ions, and a NiAs-type variant. Recently, Martin and Corbett have succeeded in synthesizing an unprecedented monohalide, LaI, exhibiting the NiAs structure type.[76] For each of these variants, the energy barriers separating them from other local minima were determined by using the threshold algorithm. While NaCl in the NiAs-type structure exhibited a barrier in excess of 0.13 eV per atom ($T \approx 1300$ K), the lowest energy barrier for the 5-5 structure was found to be approximately 0.02 eV per atom ($T \approx 200$ K). Thus, the latter structure would not be expected to survive at high temperatures unless it were stabilized

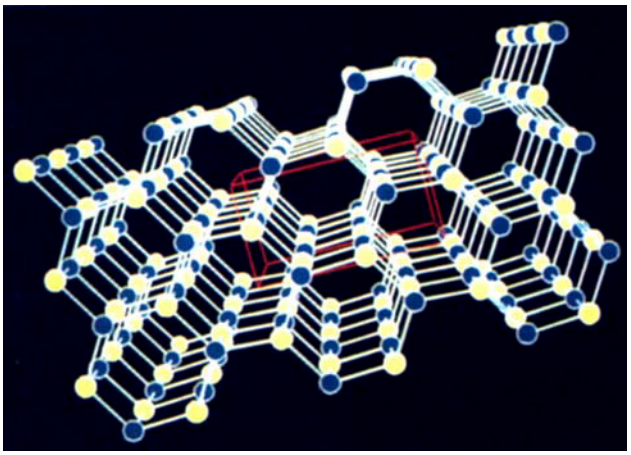

Fig. 1. 5-5 structure of NaCl, consisting of trigonal bipyramids of Cl (blue) about Na (yellow). Ions are not drawn to scale. Average Na–Cl distance is 2.7 Å.

Table 3. Overview of the minima found for the system Na/Cl with composition 1:1. The terms "dense open structures" refer to arrangements of different coordination polyhedra without and with large channels or cavities in the structure, respectively.

Coordination number of Na by Cl	Structure types structure elements	occurrence [%]
4	anti-PtS-structure sphalerite edge-shared tetrahedra	5.5
5	edge-shared trigonal bipyramids	6.8
5	edge-shared square pyramids	3.0
6	NaCl structure	37.2
6	NiAs structure	20.0
6	anti-NiAs structure	4.3
6	other structures	1.8
7	monocapped prisms (Fig. 2)	0.3
8	CsCl structure	0.1
mixed	"dense" structures	12.0
mixed	"open" structures	9.0

in some fashion. In this context, it should be noted that for a set of optimization runs in which large amounts of excess chlorine atoms were present, the 5-5 structure with the excess chlorine located within the channels occurred as the major stable alternative to the phase separation into one region filled with neutral chlorine and a second one containing the standard NaCl structure. Thus, one might expect that in the presence of some third component that could fill the channels in the 5-5 structure, this structure might be stabilized.

Another point to note is the robustness of the deepest local minima with respect to quite large variations of the parameters in the potential. In this context, it was tested, whether there were differences between using a damping factor or an Ewald summation for the electrostatic terms. It was found that the distribution of local minima encountered during the optimizations did not change significantly when using a damping factor ($\alpha > 0$).

To gain some insight with respect to general aspects of the global optimization for large pressures, we have considered pressures of 1, 10, 100, and 10^3 GPa by adding a term pv' to the energy function, where p is the pressure, and v' the volume per atom: $H = E + pv'$. By minimizing the enthalpy H, we have found that for pressures up to 10 GPa, the NaCl structure was the deepest minimum, while above 100 GPa the sevenfold (Fig. 2) and eightfold (CsCl structure) coordinations of Na by

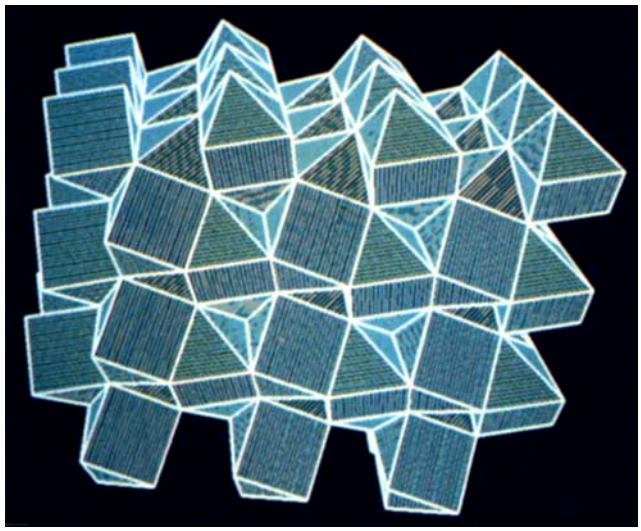

Fig. 2. Structure candidate for NaCl, consisting of face-shared monocapped Cl^- prisms about the Na^+ ions (polyhedral representation).

Cl are preferred compared to the sixfold ones. This agrees qualitatively with the experimental observation that the high-pressure modification of NaCl probably shows a CsCl structure above 29 GPa.[77]

AB_2 Systems

Since layered structures are important variants in AB_2 systems (for example, the CdI_2 and $CdCl_2$ families of structures), it was deemed necessary to always use a Coulomb potential without a damping term. The method chosen to perform the full Coulomb sum was the one suggested by de Leeuw et al.[46] Again, the resulting structure candidates, in general, did not depend on the exact values of the effective potential.

The most common structure types found are summarized in Table 4. We note that these include many commonly found structures like anatas and fluorite, but also layer structures like CdI_2. Although the energies of the latter structure candidates usually are higher than the best sub-optima, it is a pleasant surprise that these layer structures were competitive even in a purely ionic model. One very interesting class of candidate

Table 4. Overview of the most important structure types/elements seen in the systems MgF_2, CaF_2, $MgCl_2$, and $CaCl_2$. The polyhedra listed always refer to the coordination of the cation by the anions. The frequency of occurrence during optimization runs is given in percent.

Structure elements, structure types	MgF_2	$MgCl_2$	CaF_2	$CaCl_2$
(e.g., HgI_2 structure, ZnO_2 substructure of $SrZnO_2$)	0	31	3	4
edge-/corner-shared trigonal bipyramids	6	1	0	0
$CdCl_2$/CdI_2 structure	20	7	5	16
rutile	37	45	9	0
anatas	2	0	0	0
$CaCl_2$ structure	0	0	0	44
other structures based on octahedra	7	10	0	10
edge-/corner-shared prisms	3	0	0	2
edge-/corner-shared monocapped prisms	21	0	15	22
fluorite	0	0	66	0
other structures	4	6	2	2

structures is that in which the cations are surrounded by seven anions forming monocapped prisms. By using the threshold algorithm, it was found that these structures constituted very shallow minima located on a broad saddle of the energy hypersurface between the sixfold and eightfold coordinated structures of the rutile and fluorite type. Also, certain trends among the orientations of, for example, the octahedra in the rutile-type structures could be seen, indicating that $CaCl_2$ should really be more likely to be found in a $CaCl_2$-type structure than MgF_2, whose structure tended to be very close to that of the ideal rutile struture.

Encouraged by these results, we have also applied the effective (ionic) potential to the partly covalent Si/O system. Here, the best sub-optimal structures encountered were the tridymite and cristobalite structures.

AB_3 Systems

Finally several sets of optimization runs were performed for AB_3 systems.[40] We used as examples the alkali metal nitrides Li_3N, Na_3N, K_3N, Rb_3N, and Cs_3N. During the initial (long) runs in which charge transfer was allowed, it was found that in the first two cases the full oxidation states (Li^+, Na^+, N^{3-}) were reached easily, while the latter three did not succeed in completely crossing the barriers on the energy hypersurface separating the configurations with fully ionized from those with the partly ionized building blocks. Both Li_3N and Na_3N exhibited several interesting candidate structures as good sub-optima: the Li_3N structure known to occur in nature and a sheared SrO_3 substructure of the $SrTiO_3$ perovskite structure (both in the cubic and hexagonal variant; see Fig. 3). Based on these results, it appears reasonable to suggest that Na_3N, if it can be synthesized, will crystallize in one of these three structure types.

For the nitrides of the heavier alkali metals, additional optimizations were performed with K^+, Rb^+, Cs^+, and N^{3-} ions for the initial configuration. The observed structures ranged from the ReO_3 structure for Cs_3N and a cubelike variant of the Li_3N structure for Rb_3N and Cs_3N to 11-fold (tetragonal close packing) and 12-fold (like Na_3N) coordinations of the N^{3-} ions by the cations in K_3N. This decrease in the coordination number with increasing size of the cation is reminiscent of the radius ratio rule.

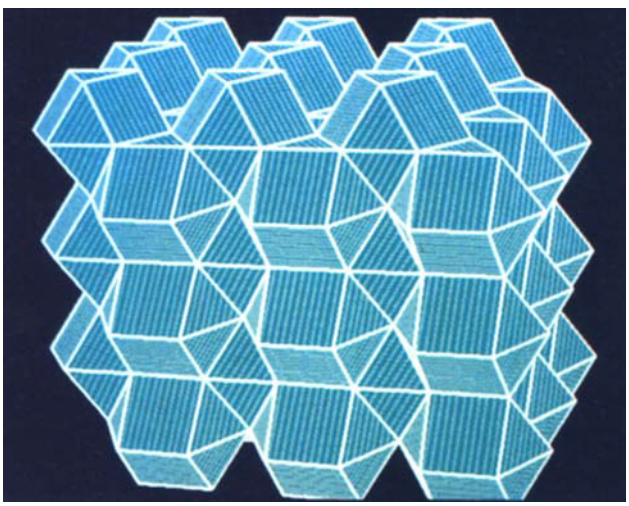

Fig. 3. Sheared SrO_3 substructure of the perovskite structure as a model for the hypothetical compound Na_3N. N^{3-} ions are contained within the fcc arrangement of cuboctahedra formed by the Na^+ ions (polyhedral representaion). Average Na–Na and Na–N distance is about 2.6 Å.

5.2.2. *Ternary Ionic Systems*

When moving from binary to ternary systems, an alternative for the construction of the effective potentials is possible, since in many instances binary compounds of the components are known, and can serve to fit the parameters of the energy function. Even if this option is available, one should still use the less biased approach based on purely atomic parameters for comparison. Since the energy hypersurface of these systems is often rather complex, the optimization runs tend to be quite lengthy.

Ca/Ti/O

To test whether it is possible to find good structure candidates in ternary ionic compounds, we have performed[43] several sets of optimization runs for the system Ca/Ti/O. Of course, there exists a large range of compositions that allow for "full" ionization (Ca^{2+}, Ti^{4+}, O^{2-}) of the system: $Ca_nTi_mO_p$ with $p = n + 2m$. While in binary compounds the composition corresponding to the "fully" ionized case is established nearly automatically during a general global optimization run, a number of equally valid options now exist that correspond to deep local minima separated by rather high energy barriers.

For our test runs, we have chosen besides the simplest one, $n = 1$ and $m = 1$, that is $CaTiO_3$, the three cases $n = 2$, $m = 1$; $n = 1$, $m = 2$; and $n = 3$, $m = 1$. The potential was constructed by using only the average ionic radii, under the assumption that the ions were of medium hardness and the Coulomb potential contained a damping factor.

In half of the relatively short (2×10^5 steps) runs for the case ($n = 1$, $m = 1$), the best sub-optima found were perovskite-type structures, while in only 20% of the runs, the system ended in a configuration without complete ionization ($Ca^{2+}Ti^{3+}O^-(O^{2-})_2$). This agrees well with the experimentally observed[12] structure of $CaTiO_3$, which is considered to be a distorted perovskite-structure. In addition, we estimated the heat of formation from CaO and TiO_2 at $T = 0$ K to be about 130 kJ mol^{-1}. Considering the highly simplified model for the potential energy, this compares reasonably well[78] with the value[79] of 90 kJ mol^{-1} found experimentally under standard conditions. For the other three compositions we have investigated, the best sub-optimal structures also contained fully ionized building blocks. However, so far only some layered structures of Ca_2TiO_4, related to the structure of Ca_2SnO_4,[80] were found to be thermodynamically stable (about 40 kJ mol^{-1}) with respect to dissociation into CaO and TiO_2.

As no calculations using a more refined (for example, Hartree–Fock level) model for the energy were performed for this system, no statement with regard to ferroelectric instabilities can be made, since this would require a more detailed analysis of the covalent aspects of the system.[81]

Sr/Ti/O

The optimizations described for the Ca/Ti/O system were repeated[43] analogously for the Sr/Ti/O system. It was again observed that $SrTiO_3$ should form a pervoskite structure with an enthalpy of formation of about 220 kJ mol^{-1} with respect to the binary compounds (experimental value:[79] 140 kJ mol^{-1} under standard conditions). Possibly stable structure candidates of the composition Sr_2TiO_4 were found, which exhibited strands of edge-sharing TiO_6 octahedra similar to those present in the already known structure.[82] A beautiful structure was found for the composition $SrTi_2O_5$, consisting of layers of SrO_{12} anticuboctahedra interlaced with hexagonal arrangements of TiO_5 trigonal bipyramids (Fig. 4).

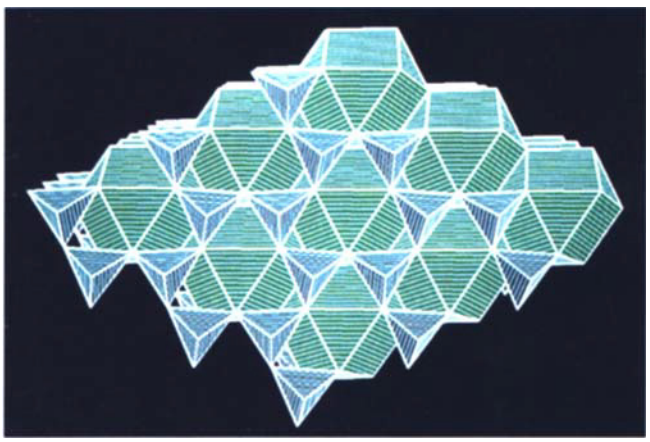

Fig. 4. Structure candidate for $SrTi_2O_5$. The Ti–O substructure consists of corner-sharing trigonal bipyramids (blue) of oxygen about the titanium atoms. The Sr^{2+} ions are located inside the O^{2-} anticuboctahedra (green) between the layers of trigonal bipyramids.

Ca/Si/Br

Apart from the alkali metal nitrides, we have so far only described systems that contain at least one experimentally known compound. Since the goal of our approach is the prediction of unknown solids that might be capable of existence, we need to test the method by applying it to an unexplored system, and subsequently synthesizing the predicted structure candidates. The Ca/Si/Br system appears to be well-suited for this purpose. From the participating components, one would conclude that a hypothetical ternary compound of, for example, the composition Ca_3SiBr_2 should have sufficient ionic character (Ca^{2+}, Si^{4-}, Br^-) to justify the use of the simple potential function for ionic crystals we have been testing so far. Furthermore, the binary components (Ca_2Si, $CaBr_2$) are known, and it is therefore possible to fit the parameters in the two-body potentials to their properties. Last but not least, intensive attempts to synthesize such a ternary compound from this system appear not to have been caried out to date.

During the test runs needed for fitting the parameters, the binary (ionic) compounds proved to be stable local minima. Therefore, we did not precede the long global optimization runs by optimizations involving charge transfer. Instead, the ionic charges were fixed from the outset, and these ions were then, as usual, placed at random positions in a large simulation cell. We have concentrated[44] on the composition Ca_3SiBr_2; each simulated annealing run involved several million optimization steps, in which up to four formula units (24 ions) per simulation cell were used.

The structure candidates belonging to the two best sub-optima found are shown in Figures 5 and 6. The structure in Figure 5 can be derived from a NaCl-type structure, in which the Na sublattice is occupied by the Ca^{2+} ions, while the Cl sublattice contains the Si^{4-} and Br^- ions in such a way that the Si^{4-} ions are as far away as possible from each other while still allowing for a relaxation of the inevitable distortions due to the somewhat different sizes and hardnesses of the Si^{4-} and Br^- ions. In Figure 6, an alternative structure is shown, derived from the CsCl type. Again, the anions occupy the Cl sublattice, while the cations are located on the sites of the Cs sublattice.

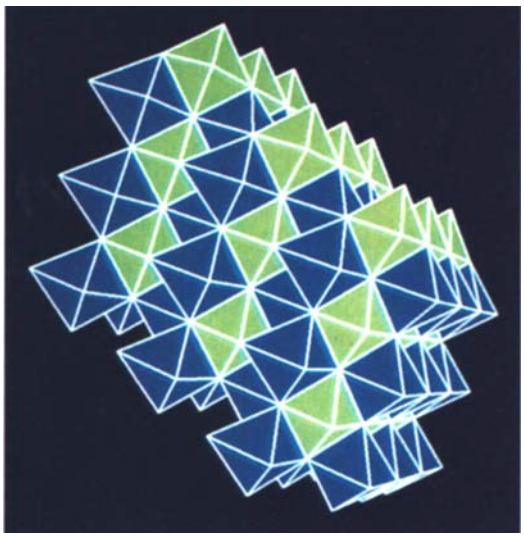

Fig. 5. Structure candidate for Ca_3SiBr_2 based on the NaCl structure. Si^{4+} ions are located within the green octahedra of Ca^{2+} ions, Br^- ions within the blue ones (polyhedral representation). Note the distortions of the octahedra due to the different anion species.

Fig. 6. Structure candidate for Ca_3SiBr_2 based on the CsCl structure. Si^{4-} ions are located within the green cubes of Ca^{2+} ions, Br^- ions within the blue ones (polyhedral representation) Note the distortions of the cubes due to the different anion species

Since no obvious way exists to judge the quality of these structure candidates (at least until the compound has been synthesized!), the ground state energies of these sub-optimal structures were also calculated by using the Hartree–Fock program CRYSTAL92[34] (no global optimization runs). It turned out these ground state energies lie so close together that it was not possible to decide which structure candidate should actually be preferred: E_{HF}(NaCl type) = − 5.15 eV per atom, E_{HF}(CsCl type) = − 5.11 eV per atom compared to E(NaCl type) = − 5.53 eV per atom and E(CsCl type) = − 5.49 eV per atom for the simple potentials.

$Si_3B_3N_7$

The compound $Si_3B_3N_7$ may serve as a final example of a ternary system. So far, it exists only as a kinetically very stable amorphous solid;[83] it is questionable whether it will be possible to ever synthesize a ternary crystalline variant. Although the bonding within this compound is expected to be well-represented by a covalent network, we have applied our usual effective (ionic) potential to the system. After several long global optimization runs, a plausible crystalline structure (Fig. 7) has been found that exhibits the expected coordination of Si^{4+} and B^{3+} by N^{3-} (tetrahedral and trigonal planar environment, respectively). Even each of the N^{3-} ions was surrounded by three cations in an approximately trigonal planar arrangement. It seems that in the case of $Si_3B_3N_7$ already the purely ionic part of the potential is sufficient to generate a structure that is reasonable even in a covalent model.

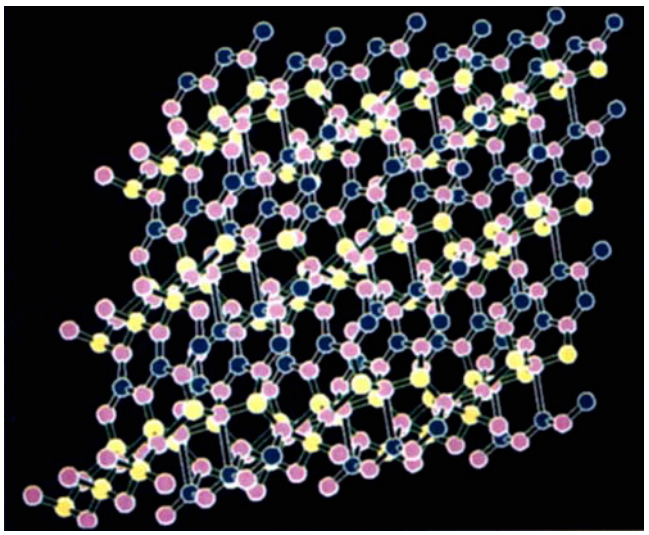

Fig. 7. Structure candidate for crystalline $Si_3B_3N_7$. Si^{4+} ions are represented by yellow spheres, B^{3+} ions by blue spheres, and N^{3-} ions by pink spheres. Nearest neighbors are connected, exhibiting the tetrahedral environment of Si and the trigonal planar one of B. Ions are not drawn to scale.

6. Critical Discussion

The results in the preceding section have shown that the modular approach and our current implementation as described in Sections 2–4 is suitable in general, and already successful in ionic systems, for the determination of reasonable structure candidates of hypothetical compounds, where nothing is known besides the identity of the components and, perhaps, their composition. To gain a better insight into the basic concept of the approach presented, particularly with regard to understanding its strengths and limitations, it is necessary to analyze both the general approach and the implementation chosen.

6.1. Construction of the Energy Hypersurface

The fundamental ingredient to our approach for the prediction of metastable compounds is the assumption that a detailed study of the (potential) energy hypersurface of a chemical system, as a function of atomic/ionic configurations, will yield sufficient information to achieve our goal. This definitely agrees with the basic understanding of classical physical systems for $T = 0$ K, since all configurations that can exist as (meta)stable compounds at $T = 0$ K correspond to local minima of the potential energy of the system.

However, in equilibrium quantum statistical mechanics,[7] only the ground state will be populated at $T = 0$ K, the other local minima are irrelevant. Nevertheless, in most instances of chemical interest, parts of the classical picture still hold in quantum mechanics, as long as one can show that the wave functions corresponding to the classical local minimum configurations have a long lifetime. This is often true, since the energy barriers separating potential energy minima usually are large enough to prevent the decay of a metastable configuration by tunneling. This presupposes, of course, that it is possible to construct such a potential energy surface in the first place.

In general, the eigenfunctions of a solid are complicated functions of both the ionic and the electronic degrees of freedom. Every classical ionic configuration, and its excited states will be a linear combination of many such eigenfunctions. To construct an energy hypersurface (for the electronic ground state) as a parametric function of classical ionic configurations alone, it is necessary that a) the electronic and ionic degrees of freedom can approximately be separated (Born–Oppenheimer approximation[84]), and b) the ionic part of the wave function, in addition, can be separated approximately into well-defined, nearly classical localized particles plus a (negligible) set of zero-point vibrations. Clearly there are some obvious problems: there are many systems in which electron–phonon interactions play an important role in stabilizing or destabilizing an otherwise unstable/stable structure. Thus, both the Born–Oppenheimer approximation and the assumption of negligible zero-point vibrations can lead to errors.[85–87]

Nevertheless, these issues are somewhat beside the point: while structural details (distortions away from a high symmetry, precise dimensions of the unit cell), electronic properties (metal, insulator), and the degree of stability of the compounds may change upon analyzing a given structure in greater detail, we are primarily concerned with the existence and the general structure type of a hypothetical compound. Unless there are reasons to believe that the neglected quantum mechanical effects will destroy or create important local minimum configurations outright, for example superfluidity in liquid helium, the construction of the (potential) energy hypersurface is a good first step.

A much more dubious step is the use of effective potentials instead of using ab initio methods for every energy evaluation. Of course, if a system is studied in great detail using ab inito methods, it is possible to design effective potentials that will provide very good fits to the real potential energy. However, this is very time-consuming, and the additional effort might not be justified by the improvement of the results. Especially, if no a-priori information about the hypothetical compounds is available, it is easy to miss important structure elements that should enter the design of the potential. Furthermore, in many systems the potentials have to involve long-range terms, in order to be sufficiently realistic for global (in contrast to local) optimizations. This requires the use of rather large clusters for ab initio calculations, increasing the time necessary. Because of this problem, we have decided to employ ab initio methods only in later steps of the modular approach, that is, after a first round of optimizations have been performed, and interesting structure candidates have been found. Since then the most important (sub)structures are known, the selective use of first-principle techniques appears to be more efficient as far as computer resources are concerned.[88]

This leaves us with the problem of designing useful effective potentials. We have been guided by the application of basic principles both as far as the expected physics and chemistry of the compound are concerned and with respect to the requirements of efficient global optimization algorithms. First, the potentials have to reflect correctly both the local and the long-range interactions between the atoms/ions: the atoms must not be allowed to overlap too much, and, except through electrostatic forces, they must not interact directly at long distances. Additional terms will enter that reflect the local bonding situation of the atoms, and here usually a selection takes place, depending on whether we want to stress, for example, the covalent, ionic, or metallic character of the hypothetical compound. This first selection is in our opinion the most regrettable approximation in the construction of effective potentials, because it tends to exclude a large variety of possible structures by changing the weight of certain configurations, possibly resulting even in both the elimination of actual minima and the creation of spurious local minima. Nevertheless, we currently see no way of avoiding such a preselection, that is, constructing simple potentials that can describe equally well ionic, covalent, and metallic compounds. Somewhat less critical is the subsequent choice of fit parameters for a given potential, although it can often be a contentious issue[89]—should it be based on (averaged) atomic quantities, (averaged) binary compounds, elastic constants of already-known modifications, etc.?

The advantages and disadvantages of the highly simplified form of our effective ionic potential are quite evident: ease of computation, simple physical and chemical origin of the terms within the potential, simple dependence on atomic quantities based on averaged properties of the atoms within many ionic compounds on the one hand, and lack of quantitative accuracy, use of averaged parameters, restriction to spherically symmetric ions, exclusion of three-body-effects, on the other. Clearly, for a completely unknown (ionic) system full quantitative agreement of a semi-phenomenological with the actual energy hypersurface cannot be achieved purely from knowledge about other systems involving these ions, but requires ab initio calculations instead. Nevertheless, we feel that the simple potential we employ does exhibit the correct qualitative features of the true energy hypersurface and delivers the necessary information for the second round of calculations, which can then be made more precise with the use of more accurate methods. Similarly, since we are registering many good sub-optima, usually exhibiting many different ion coordinations, during the global optimizations, and expect to have included among these the structures actually accessible to the chemist, the use of averaged parameters is not a critical problem. Nevertheless, we feel it is important to vary these parameters slightly to judge which of the local minima found are the most robust ones. In most of the test systems for which the structures of already existing compounds are known, our results indicate that the most robust candidate structures correspond to those that are observed in reality.

The surprising success of the ionic model in reproducing the proper local environment of the atoms within the solid even in some strongly covalently bonded materials is based on the fact that in many instances the optimal or sub-optimal local arrangements within the ionic and the covalent model are identical. This appears to be an expression of a basic rule of crystal chemistry that realistic crystal structures capable of existence tend to be optimized in all relevant aspects, including the contribution of the electrostatic energy in the case of a predominantly covalent solid. The greatest difficulties occur, and the ionic model usually fails, when the covalent bonds result in a poor use of the available space in the structure, for example in the formation of twofold linear coordinations[90] of Cu^+ or Ag^+, or of a square-planar environment with "room" above the plane (e.g. for Ag^{3+}),[91] which in the ionic model would tend to distort into a tetrahedron. Nevertheless, even such coordinations can appear as very good sub-optima under suitable circumstances.[92]

Clearly, it would be interesting to include nonspherical ions or components that can be modeled in such a fashion, for example ions with lone pairs of electrons (Sn^{2+}, transition metal ions) or complex ions ($(O_2^{2-}$, SO_4^{2-}, $O_3^-)$, into the purview of our model potential. Apart from the additional computational effort, there are, in principle, no problems. However, the evaluation of the repulsion between such neighboring ions and also the calculation of the corresponding polarization term could become rather cumbersome. Similarly, the three-body terms usually required for a proper description of covalent bonds add considerably to the time needed for each energy evaluation; and it appears reasonable to eschew their use in the first stages of the optimization, as long as their exclusion does not topple the whole edifice.

6.2. Technical Details of the Algorithms

Once the parameters of the potential have been chosen, the energy of each possible configuration of ions and atoms is determined within the framework of the model. Nevertheless, there are still several open issues and choices left. The most important of these are the boundary conditions (open = cluster, or periodic = crystal), number of atoms in the simulation cell, and the choice of moveclass for the simulated annealing algorithm.

For our purposes, the choice of crystal-like boundary conditions is reasonable, since we are for the most part interested in

(meta)stable crystalline structures. Since we start initially from systems at gaseous densities and allow free variation of the cell, the requirement of periodicity is not very restrictive. A greater problem is the use of fixed numbers of formula units during the optimization. Clearly, if the number of atoms is not allowed to change during a run, only those structures can be found that can be constructed on the basis of some unit cell that contains exactly those atoms. In principle, this problem can be solved by varying the number of atoms arbitrarily during a given run. However, it has often proven to be more efficient to keep the composition fixed during a given run and, instead, to repeat the optimization with all the other promising compositions afterwards. Since this restriction makes the addition and removal of atoms rather awkward, fixing the composition usually implies fixing the number of atoms, too. Therefore, we also need to repeat the runs for a given composition with different numbers of formula units in the simulation cell.[93] Our observations have shown that if, for example, the number of formula units is doubled, the same minima are still present, but that, of course, many additional sub-minima appear. As pointed out in the introduction, the number of possible metastable periodic structures appears to be limitless.

Finally, we have to be aware that the choice of moveclass can, in principle, change the features of the energy landscape. As long as the allowed moves are physical (movements of the atoms, variation of the cell = collective movement of all atoms, charge transfer, etc.) and reasonably complete (no exclusion of physically possible microscopic changes of the configuration), each local minimum found during the optimization will also be a kinetically stable one. Usually this condition is not violated. But if the only goal is to reach the global minimum as fast as possible, it is, of course, useful to try to improve the optimization algorithm by including nonphysical moves, avoiding or eliminating metastable minima in the process. Obviously, for our purposes such a high-efficiency moveclass is a double-edged sword. Thus, we have allowed only those nonphysical moves that remove or exchange whole ions in the simulation cell, since these operations will only lead to the elimination of realistic sub-optima in very special cases.[94]

6.3. Feasibility of the Modular Approach for General Thermodynamic Boundary Conditions

As we pointed out in the introduction, our current investigations are concerned with the prediction of possible (meta)stable structures of a compound at $T = 0$ K and $p \approx 0$ Pa that are characterized by the requirement that they are local minima of the energy hypersurface of the system. Thus, our optimizations are performed with respect to an energy function that is defined in the configuration space, *not* in the thermodynamic space. To address the issue of high-pressure or high-temperature modifications, we have to carefully distinguish between the space of all hypothetical configurations of the chemical system; each configuration is characterized by the number and type of participating atoms, their position vectors, ionic charges, etc., and the usual space of thermodynamic variables, p, T, N_i, etc..

In principle, there is no problem in studying the system under external constraints like pressure p and stationary external electric fields $\boldsymbol{E}$ at $T = 0$ K. Instead of minimizing the potential energy, one now minimizes the enthalpy $H = E + pv'$, or similar extensions of the energy function.[7] A greater practical problem lies in the usually unknown dependence of the parameters of the effective potential on pressure or other external fields. This also holds true for potentials fitted to binary systems, but it can be alleviated somewhat by choosing the parameters to, for example, reproduce measured elastic constants.

The determination of "high-temperature structures" is a much more subtle enterprise. For $T = 0$ K, it is very clear what constitutes a (meta)stable structure: it is the one, and only one, configuration that is associated with a local minimum of the energy hypersurface. In contrast, for $T > 0$ K, equilibrium statistical mechanics tells us that each configuration has a nonzero probability of being present at a given time. This implies that the concept of a single unique configuration that represents the system at $T > 0$ K at all times no longer applies. However, it is often possible to group many of the configurations together according to certain common characteristic properties (e.g. time-averaged structure). If this common quantity is denoted R,[95] it is possible to calculate the probability that the system will be found in some configuration exhibiting property R according to Equation (d).

$$p(R) = \sum_{i \in R} p(i) = \frac{Z(R)}{Z} = \frac{\exp(-F(R)/kT)}{\exp(-F/kT)} \qquad \text{(d)}$$

Here, $Z(R)$ is the partition sum for that region of phase space that is associated with R, and $F(R)$ is defined as the free energy for structure R. Clearly, finding the most likely structure representing the system at temperature T corresponds to finding the minimum of the restricted free energy $F(R)$ with respect to R. While in special cases it is possible to a certain degree to write down analytical expressions for $F(R)$, finding $F(R)$, in general, is very difficult, and we have not yet attempted to adapt our approach to this question.

7. Links with Earlier Studies of the Energy Hypersurface of Complex Systems

As far as we know, the basic concept of our approach, that is the planning of solid-state syntheses through a (as general as possible) determination of possible (meta)stable solid compounds in a chemical system using global and subsequent local optimizations, has not been proposed before. Nevertheless, there are many links to past and present work dealing with, for example, the calculation of the energy of solids or the use of optimization methods to assist in structure determination problems.

In the field of solid-state theory, there is a long tradition of attempts[96] to understand the structure of solids, be they crystalline or amorphous, of macroscopic size or microscopic like clusters. It has always been clear that (meta)stable structures of solids at low temperatures can be identified by determining the minima of the energy hypersurface of the chemical system, apart from certain systems that are dominated by quantum effects. Especially in the early days of solid-state physics,[97, 98] much effort was devoted to the calculation of cohesive energies (ground state energies) of already known compounds,[85] and the derivation of elastic constants by varying the lattice parameters.

With the development of computers and fast algorithms, new tools became available to solid-state theory. A clear path of steady improvement runs from the molecular dynamics studies of Alder and Wainwright,[99] who modeled liquids with hard spheres as building blocks, to ab initio molecular dynamic simulations with the Car–Parrinello algorithm,[35] which are capable of performing local optimizations of the structure of simple solids.[100] This work has been paralleled by developments in the theory of molecules and their structure.[101] It is now standard procedure to employ some local optimization routine during ab initio studies of molecules.

A combination of these two strands of research has come about in the investigation of clusters,[102–128] which can often be viewed either as large molecules or as nanoscopic solids. An early example is the work by Welch et al.[129] in which, in the context of the shell model,[130] local energy minimizations were performed with gradient methods for alkali metal halide clusters containing up to 44 dimers. More recently, for instance, Phillips et al.[131] studied the geometry of NaCl clusters and cluster ions again using a shell model. The global optimization was replaced by a large number of local optimizations with gradient methods; each reasonable initial configuration was generated by adding positive and negative ions in alternating positions of the cluster. Similarly, Rose and Berry[120] have used Born–Mayer potentials and multiple gradient minimizations during molecular dynamics simulations runs to study phase transitions in $(KCl)_{32}$ clusters. Both $(KCl)_n$ and $(LiF)_n$ clusters ($n \leq 15$) have been investigated by Ochsenfeld and Ahlrichs[102] at the SCF (MP2) level by using SCF force field calculations in order to determine local minima. Other work using ab initio density functional calculations together with (relatively short) molecular dynamics simulated annealing runs has been performed by Jones and Seifert[116] for phosphorus clusters ($n \leq 11$). To generate useful starting configurations, they employed simulated annealing with a simple effective potential on the LCAO-trial function level. Of course, this is only a very small sample of the efforts being undertaken in the study of ionic and covalent systems, not to mention the large amount of comparable work on noble gas and metal clusters.

While the clusters studied so far are often too small to really justify being viewed as extended solids, the work on such mesoscopic systems has had a profound effect on the way one approaches the analogous problem of structure optimization in solids. Two difficulties common to these systems have become apparent:[128, 132–134] the number of possible structures of a cluster/solid characterized as local minima of the energy hypersurface is very large, and it is not clear at all how to decide on the best or typical one without studying the energy landscape in great detail. This involves both the calculation of the depth of the local minima, the study of the density of states associated with these minima, and finally the determination of the barrier heights of the saddle points connecting the different structures.

While the importance of the lowest saddle points between two local minima has always been appreciated in the study of molecular reactions,[135–139] this has been perhaps less so when dealing with solids, in which usually only one structure has been considered at a time. The justification for this traditional procedure lies in the kinetic stability of solids, which is related to the idea of broken ergodicity by Palmer,[140] that is, in realistic large systems, it can often happen that at low temperatures thermodynamic equilibrium is not obtained globally. Only for a certain subset of the phase space of the system does the time-average, which is accessible to observation, equal the ensemble average. Thus, the thermodynamic behavior of a solid may depend only on the small region of the energy landscape around some (meta)stable structure.

It has therefore been perfectly reasonable to concentrate on the local environment of some already known or expected interesting structure, and to perform local optimizations of some energy function. Such local optimizations[35, 100, 141, 142] have been performed with varying degrees of restrictions on the number of atoms, symmetry of the structure, and size of the cell parameters. For example, Wentzcovitch and Martins[100] have modeled liquid Li using molecular dynamics techniques; at each step the Kohn–Sham equations were solved. This procedure is thus somewhat more suited to deal with volume changes during the (still rather local) optimization than the original Car–Parrinello algorithm, for which a fictitious electron dynamics has to complement the movement of the ion cores. In this context, one should also mention the modeling of proteins,[143] water,[144] and amorphous structures.[47, 145] In the latter case, one aims for a disordered arrangement of the atoms: thus, instead of finding a good sub-optimum by using some global optimization method, a local minimization is performed, resulting in an amorphous structure.

An interesting application of the use of global optimization methods in the determination of the structures of solids from powder diffraction data has been introduced in recent years by Pannetier, Newsam, Freeman, Catlow, and others.[31, 146–150] In their work, it is generally assumed that some experimental information about the compound is already available, for example, as a X-ray powder diffractogram. Thus, the size and shape of the unit cell, the composition of the compound, the ionic charges, and the number of formula units present in the cell are assumed to be known. It "only" remains to determine the exact positions of the atoms within this cell, a task that often tends to be quite involved, especially if only data from X-ray or neutron powder diffraction experiments are available. Imposing the above constraints, the authors perform global or local minimizations of special cost functions that combine some energy terms based on effective potentials with penalty terms reflecting, for example, Pauling's bond-valence rule[148] or the requirement of an even distribution of ions within the unit cell.[147] If the penalty terms and the effective potential are chosen appropriately,[151] the minimization produces a number of reasonable structure candidates, which then can serve as input either of a structure solving program or a refinement optimization using a more realistic energy function. In the extreme case, the cost function is solely constructed from penalty terms and equals a "figure of merit" that reflects a-priori knowledge of the typical bonding arrangements in the solid.[152, 153]

For example, Pannetier et al.[148] have used a combination of bond-valence and Coulomb terms as cost function to perform simulated annealing optimizations of the positions of the ions within a fixed unit cell of known ion content, for example, for NbF_4 or K_2NiF_4. Similarly, Freeman et al.[147] also used a unit cell for which size, shape, and ion content were known from experiment for their detemination of the structure of TiO_2 poly-

morphs. Using purely repulsive interactions as cost function, initial configurations were created by simulated annealing followed by conjugate gradient. Starting from these configurations, local minimizations were performed by using an empirical potential. Recently, Bush et al.[154] have demonstrated that genetic algorithms as global optimization method can also be used to assist in the determination of the structures of compounds for which only powder diffraction data and the composition of the unit cell are available. Again, an effective cost function similar to the one used by Pannetier et al.[148] was employed during the global optimization.

Alternative approaches[155-159] to understanding or for the determination of structures employ a-priori knowledge about bonding preferences and/or spacial constraints, often assuming a known unit cell, together with bond-valence rules to suggest possible structures. An interesting derivation of covalent structure elements of phosphorus (P_n, $n \leq 70$) using local ab initio optimizations on heuristically constructed network structures has recently been presented by Böcker and Häser.[160]

Our approach parallels the above-mentioned cluster studies in the sense that the basic concept of an in-depth study of the energy landscape is applied to the case of solids on a global scale instead of only very close to a given structure. While one usually considers the difference between cluster and solid to be the number of atoms, we would like to stress the use of periodic boundary conditions versus open boundary conditions in distinguishing between the two views. In this sense, one might consider our simulation cell plus its first shell(s) of neighbor cells as being equivalent to a cluster, that is, the effort required to deal with a cluster of about N atoms should in some way correspond to a calculation of a simulation cell with about $N/27$ atoms. Of course, there are a number of important differences deriving from the periodicity: long-range (e.g. Coulombic) forces have to be treated more carefully, and the free variation of the size and shape of the simulation cell plays a highly important role in the optimization. Together with the variation of composition and ionic charges, this last point is also a crucial step beyond the work on structure determination based on a-priori information about the unit cell of the already synthesized compound, described at the beginning of this section. In our opinion, this freedom during the global optimization is absolutely necessary to reach the goal of being able to plan syntheses in solid-state chemistry.

8. Conclusions

We have presented a method for the prediction of reasonable structure candidates for solid compounds. Thus, the state of planned solid-state syntheses has, in principle, become comparable to the one in the molecular chemistry of carbon and other nonmetals with respect to the formulation of concrete synthetic *targets* for those systems. It is expected that in both fields the further development of effective potentials appropriate for global optimizations will be a major area of future research. However, an important difference still remains: in solid-state chemistry, there is as yet no set of theoretical tools for the detailed design of the synthetic *route* to reach the predicted substance comparable to the aids available in molecular chemistry.

We would like to thank the participants of the structure seminar at the Institut für Anorganische Chemie der Universität Bonn for interesting discussions, and especially Dipl.-Chem. H. Putz and M. Wevers for their contributions. One of us, C. S., would also like to thank the participants of the Telluride Summer Research Center 1993 for useful comments. Funding by the Leibniz program of the Deutsche Forschungsgemeinschaft and by the Pinguin-Stiftung are gratefully acknowledged.

[18] Strictly speaking most of the subsequent discussion deals with those structures that can be stabilized by energy barriers alone, that is, phases that could in principle exist at $T = 0$ K. For those phases that can only exist at high temperatures (e. g. the liquid state), we refer to the discussion in Section 6.3.
[19] The design and synthesis of a new compound correspond to the theoretical and experimental exploration of this energy landscape; thus, a chemist plays a role closer to that of an intrepid discoverer of strange and foreign lands and less to that of a creator of new worlds.

[21] Note that the use of periodic boundary conditions does not imply anything about the final symmetry of the candidate structures.
[22] An alternative is the use of open boundary conditions, that is, the simulation of a cluster. To deal with surface effects, this cluster should be embedded possibly in an effective medium, which reflects the average interaction with the remainder of the solid, .

[74] For several optimization runs, the composition was allowed to vary freely, too. In these cases, the candidate structures were dominated by a close packing of the heavier atoms, while the lighter noble gases tended to be removed from the simulation cell, indicating that phase separation was a very important option for all of these systems.

[78] Note that our energy of formation with respect to the binary compounds is calculated at $T = 0$ K and $p = 0$ Pa, while the experimental value is valid at standard conditions. Since the resulting difference in enthalpy is basically given by the integral over the specific heat, and the contribution from the binary compounds will to a large degree cancel the contribution from the ternary compound, the rough comparison we perform appears to be reasonable.

[88] It is curious to note that the energy differences of the local minima in Ca_3SiBr_2 computed by using the effective potential were actually quite similar to those computed with the Hartree–Fock method (c.f. Section 5.2). This coincidence should not be over-interpreted, of course, nevertheless, their agreement shows that one might expect the optimizations using the simple effective potential to yield at least reasonable qualitative results.

[92] For example, for the quaternary system $Sr_2NiO_2Cl_2$, the best configuration we have found so far shows an A-B-A-layer structure reminiscent of the K_2NiF_4 structure, in which each layer is based on a square O^{2-} lattice with Ni^{2+} filling every other square. Above and below each Ni^{2+} ion, a Cl^- ion is placed, resulting in an elongated octahedron around Ni. The Sr^{2+} ions lie above and below those O^{2-} squares that do not contain a Ni^{2+} ion. Finally, the Cl^- ions "coat" the Sr-Ni-O layer, leading to the NiO_4Cl_2 octahedra, and a O_4Cl_4 coordination of Sr.
[93] One other observation of note is the fact that for the systems with many atoms in the simulation cell the sub-optimal solutions tend to exhibit point defects (cf. Section 5.1). It is possible to "remove" the defects by performing considerably longer optimization runs. However, the effective use of the computer resources becomes quickly an issue, especially, if the optimal candidate structures can already easily be perceived from the sub-optimal structures containing these defects.
[94] Such an instance might be systems that show tendencies to form solid solutions of nearly equal size atoms.
[95] Note that R (sometimes called an order parameter) is usually not a thermodynamic variable like T, p, or V. Its definition is arbitrary and only represents one possible (but very useful if chosen cleverly!) way to partition the configuration space.

Cationic Iridium(III) Complexes: A Step Towards Synthetic Applicability of C–H Activation

John C. W. Lohrenz* and Heiko Jacobsen*

A problem in modern chemistry that still remains only partially solved is the functionalization of unreactive compounds. Here, the activation of C–H bonds in hydrocarbons by transition metals is of central interest.[1] The significance attributed to this question is apparent from the fact that the selective C–H activation was described as a "holy grail of chemistry",[1, 2] and recently an entire issue of the *Journal of Organometallic Chemistry*[3] was dedicated to this topic.

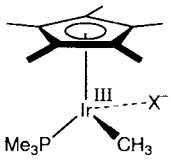
Despite their low reactivitiy C–H bonds are not completely inert, and reactions with selected transition metal complexes have been known for some time in which alkanes can be cleaved successfully. It would be beneficial to be able to use this route to catalytically transform the compounds that occur in large quantities in oil and gas into "valuable" products.

A recent paper by Arndtsen and Bergman,[4] which describes an unusually mild and selective cleavage of C–H bonds in alkanes and arenes by the iridium complex **1a** ([BArf]$^-$ = [B(3,5-

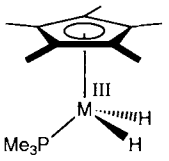
$[Cp^*Ir(PMe_3)(CH_3)(ClCH_2Cl)][BAr_f]$ **1a**

$C_6H_3(CF_3)_2)_4]^-$), is certainly a milestone on the route to efficient C–H activation. Based on this work, herein we wish to take the opportunity to summarize most recent developments in C–H activation by late transition metal complexes.[5]

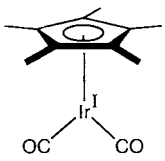
Since the early work in the research groups of Graham,[6] Jones,[7] and Bergman,[8] significant advances in the design of metal complexes have been made. All three research groups employ electronically unsaturated complexes of the late transition metals with vacant coordination sites. The first positive results had been achieved in 1982 by Janowicz and Bergman who utilized the iridium complex **2a**,[8] a compound that mainly activates aromatic C–H bonds. The analogous rhodium complex **2b** was employed by Jones and Feher in 1984 for the oxidative addition to C–H bonds.[7] Activation of methane was achieved for the first time by Graham and co-workers in 1983, who used the iridium complex **3**.[6] As promising as these results



1a $X^- = Cl\text{-}CH_2Cl\ [BAr_f]^-$
1b $X^- = [OSO_2CF_3]^-$
1c $X^- = Cl^-$



2a M = Ir
2b M = Rh



3

were, several significant disadvantages were apparent for all of the systems. First, the catalysts had to be either photochemically or thermally activated, second the presented complexes are quite unselective with respect to the C–H bond to be activated. Finally, so far these complexes can be used in stoichiometric quantities only, and cannot be included satisfactorily in a catalytic cycle.

In the photolysis of compounds **2a,b** and **3**, H_2 or one equivalent of CO are lost, leading to the 16-electron complexes $[Cp^*M(PMe_3)]$ and $[Cp^*Ir(CO)]$, respectively. These, however, could not be observed directly (Scheme 1). In the next step the hydrocarbon oxidatively adds to the metal center. In the initial stage of this process the C–H bond probably coordinates through an agostic interaction to the metal.[9] The product of the addition can be worked up with bromoform, leading to the corresponding bromoalkane.

Indeed, ab initio MP2 calculations[10] on the interaction of the 16-electron model system [CpRh(CO)] with methane revealed a stabilization of the agostic intermediate by $-14.8\ kcal\,mol^{-1}$, which agrees well with the experimental results of Wasserman et al.[9] Furthermore, a moderate activation barrier of $4.1\ kcal\,mol^{-1}$ was obtained for the oxidative addition. Finally, the reaction enthalpy was calculated to be $-30.6\ kcal\,mol^{-1}$. This nicely shows how an activation of hydrocarbons can be achieved by the previously assumed 16-electron intermediates.

Going to the electron-deficient Ir^{III} complex **1b** results in a new class of extremely reactive compounds[11] that are capable of cleaving C–H bonds without prior photochemical activation. The key role of the counterion in the complexes **1** becomes clear when one considers that **1c** with the strongly coordinating chloride ion does not react with benzene below 100 °C, whereas the latter adds quantitatively to the triflate complex **1b** already at

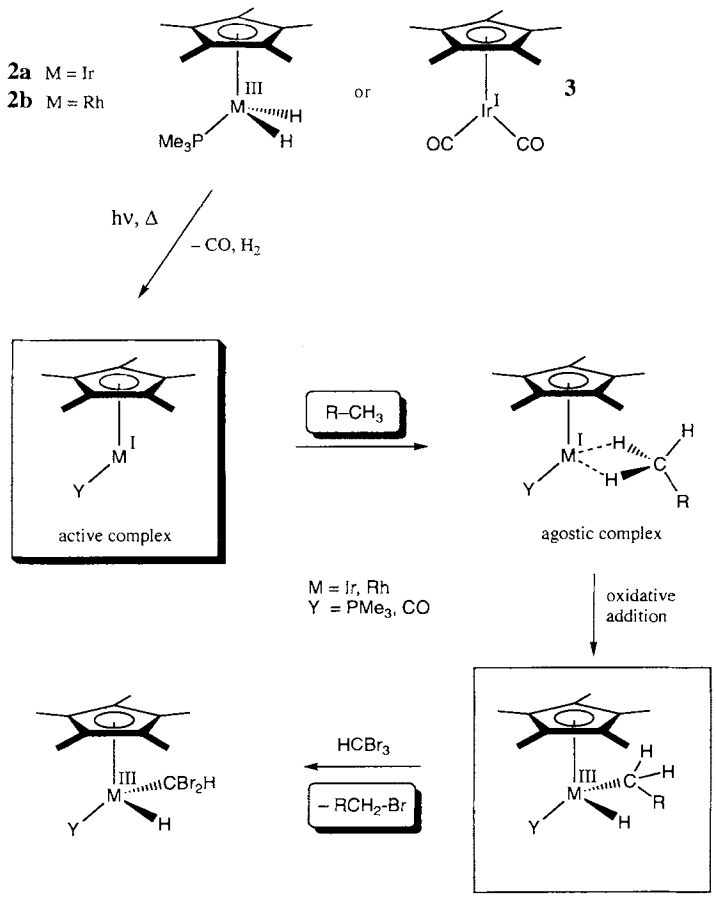
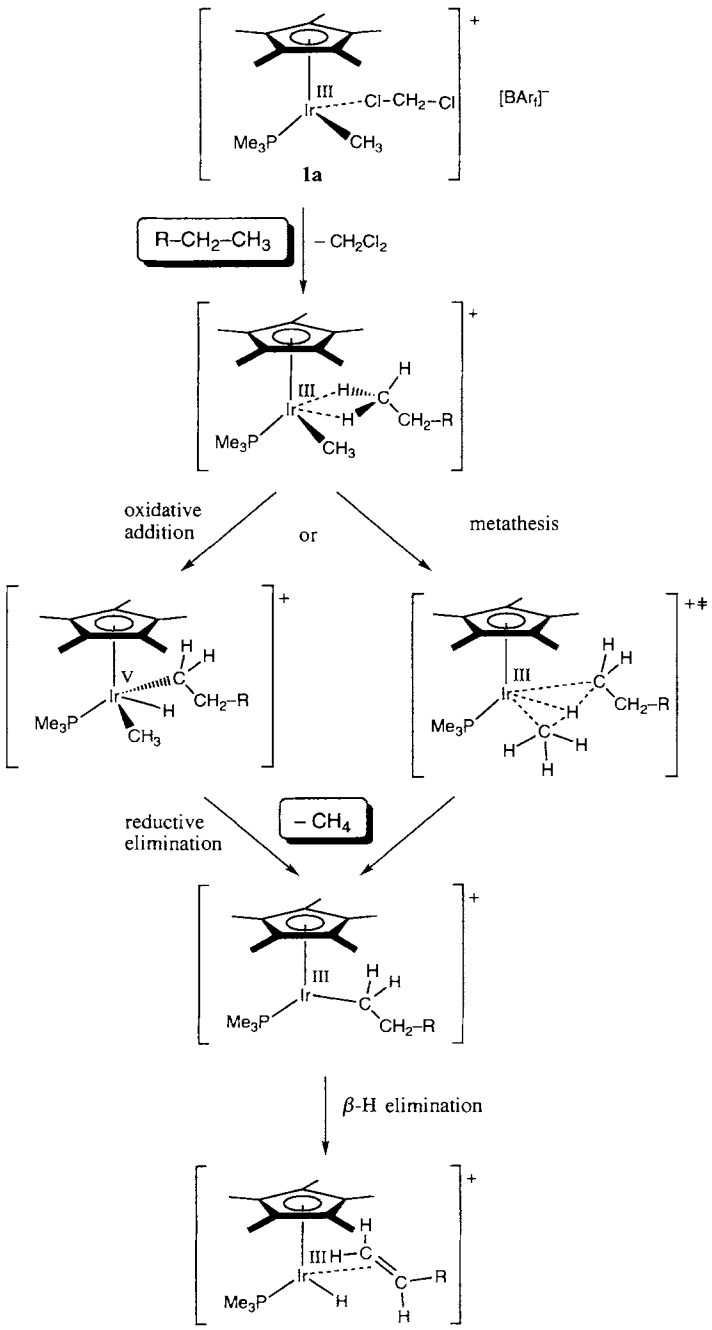


Scheme 1. Mechanism of the C–H activation by complexes **2** and **3**.



Scheme 2. Postulated mechanism of the C–H activation by complex **1a**.

25 °C. These observations suggest that the active species is the free cation formed after dissociation of the counterion.

The reaction of **1a,b** with hydrocarbons leads to the elimination of methane. This indicates the possibility of a reaction by a σ-bond metathesis mechanism, as is also known for complexes of early transition metals (Scheme 2, right branch). Such an interpretation is supported by the fact that the larger electrophilicity of **1a,b** (or to be more precise that of the corresponding cation) makes its chemistry comparable to that of early transition metals.[11] Oxidative addition with subsequent reductive elimination (Scheme 2, left branch), however, cannot be ruled out completely.

The efforts to trap the cationic intermediate led to the very active complex **1a**, in which the triflate ion was replaced by the noncoordinating $[BAr_f]^-$ ion.[4] An X-ray structure analysis revealed that the vacant coordination site of the 16-electron intermediate in **1a** is occupied by a weakly coordinating dichloromethane molecule (Fig. 1). The counterion $[BAr_f]^-$ and a second molecule of dichloromethane have no contacts to the cation. Thus, the dissociated ion pair exists in the crystal.

Compound **1a** reacts with benzene already at −30 °C and activates methane at 10 °C. As assumed by Arndtsen and Bergman, the extremely high reactivity is based on the weak bond between the dichlomethane molecule and the metal center. This could be shown by ^{1}H NMR spectroscopy by a rapid exchange with CD_2Cl_2 at −90 °C.

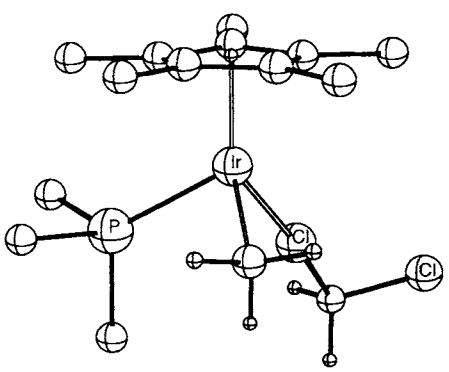


Fig. 1. Structure of **1a**·CH_2Cl_2 in the crystal [4]. The borate counterion and the second dichloromethane molecule do not form contacts to the cation and are therefore omitted.

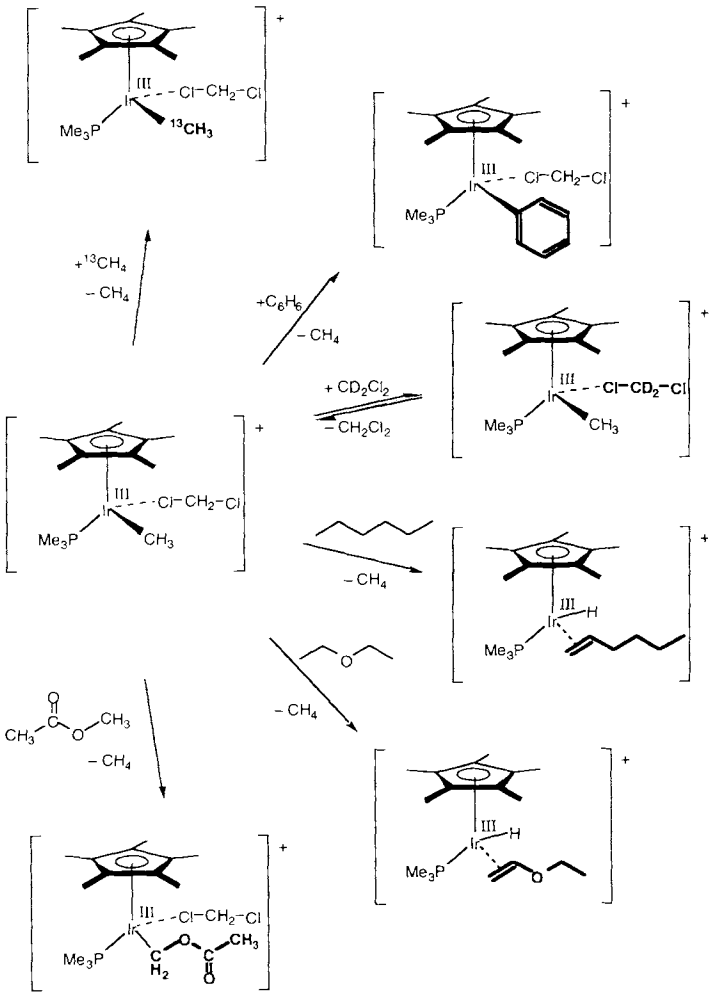

Scheme 3. Reactions of the cation in **1a**.

Selected reactions of the cation in **1a** are given in Scheme 3. Compound **1a** reacts better with primary than with secondary C–H bonds, and in the presence of β hydrogen atoms ultimately leads to olefin complexes. Here, the initial C–H activation step probably is followed by a β-H elimination (Scheme 2). Furthermore, the selectivity of **1a** is shown by the reaction with methyl acetate, in which only the *O*-methyl group reacts. This is remarkable since here a methyl group is activated in the presence of the considerably more acidic protons of an acetyl group. The complex **1a** even tolerates functional groups and thus also enables the targeted cleavage of C–H bonds in "complex" molecules. Diethyl ether, for example, which is still inert toward **1b**, reacts smoothly with **1a** to give the corresponding vinyl ether complex.

The observations outlined in the last section show that the initially described problems of activity and selectivity can be well controlled with complex **1a**. The method developed by Arndtsen and Bergman, however, still requires the complex in stoichiometric quantities. The development of a catalytic process demands in addition the simultaneous activation of an oxidizing agent such as oxygen. For the future, it will be interesting to see whether and how the as yet unresolved problem of *catalytic* C–H activation is mastered.

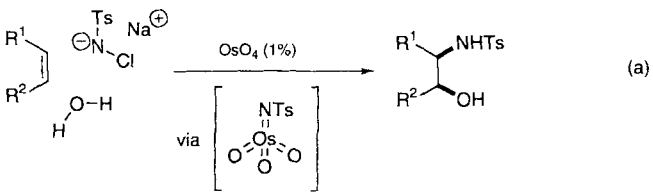
The Sharpless Asymmetric Aminohydroxylation of Olefins

Oliver Reiser*

"The time has come for me to discover something new, but there is so much chemistry out there!" With these words Barry Sharpless closed the Merck–Schuchardt lecture 1995 in Göttingen, Germany.[1] After about 10 years of continuous optimization, the asymmetric dihydroxylation (AD) of olefins had developed into one of the most versatile catalytic asymmetric reactions to date.[2]

An "obvious" extension of the AD process would be the asymmetric transfer of heteroatoms other than oxygen to a C–C double bond. Indeed, the osmium-catalyzed[3] or palladium-mediated[4] aminohydroxylation of alkenes has been known for 20 years. The resulting β-amino alcohols are an important structural element in biologically active compounds as well as the starting point in the design of many chiral ligands. However, to develop this reaction into a catalytic, asymmetric process several problems had to be overcome.

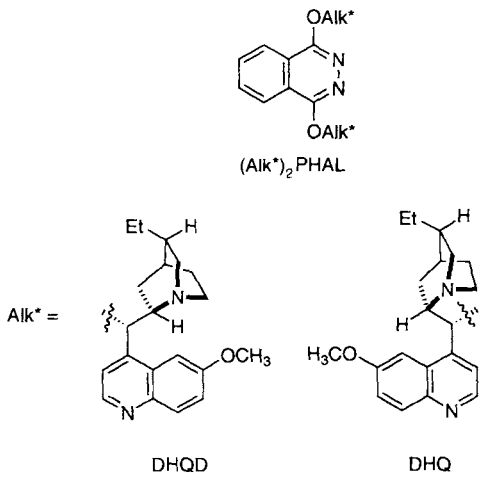
According to the original protocol[3] alkenes can be converted to racemic, N-tosyl-protected β-amino alcohols in the presence of catalytic amounts of osmium tetroxide using Chloramine-T as the nitrenoid source and water as the hydroxyl source [Eq. (a)]. However, unlike the AD process, the aminohydroxylation of unsymmetrical alkenes can lead to two regioisomeric products, which was a drawback in the early stages of its development. Moreover, the direct reaction of osmium tetroxide with the alkene could not be completely surpressed, and diols were sometimes observed as side products.



(a)

Although the first, albeit stoichiometric, example of this asymmetric aminohydroxylation reaction had already been observed in 1980,[5] the discovery of the titanium-catalyzed asymmetric epoxidation (AE)[6] at about the same time probably also "interfered" with an earlier development of today's catalytic asymmetric aminohydroxylation (AA) process.

Since the discovery of the catalytic AD in 1987, there have been numerous attempts in the Sharpless group to render the old catalytic aminohydroxylation process asymmetric.[7] Until recently, the obvious approach of adding the chiral ligands of the AD reaction, but otherwise staying close to the original protocol[3] led to extremly slow catalyst turnover. The present breakthrough[8] was not due to a sudden conceptual insight but rather to the luck of making a number of small changes, all of which had been tried before but never in concert. Suddenly the turnover was decent, diol side products were greatly reduced, and good regioselectivity was seen for the first time.[7] Most exciting of all, the products were obtained with moderate to high enantioselectivities, and with complimentary discrimination of the enantiotopic faces of the alkene by the two ligands, $(DHQ)_2PHAL$ and $(DHQD)_2PHAL$.[9] The same sense of asymmetric induction as in the AD is observed, indicating that the transfer of chirality occurs by a similar pathway. Moreover, due to the highly crystalline nature of the products they can often be raised to enantiopurity by simple recrystallization.



What types of alkenes undergo this reaction (Scheme 1)? In contrast to the AD reaction also strongly electron-poor alkenes are suitable substrates probably due to the greater polarization of the Os=NTs group compared to that of the Os=O group. Thus, acrylates in general give good results in the AA (**5** → **6**), but even dimethyl fumarate (**1**) reacts rapidly—**1** is a very poor AD substrate—to give the 2-hydroxy aspartic acid derivative **2**. Cinnamates **3** can be converted to α-hydroxy-β-amino acids **4**, giving, for example, a most effective entry to the side chain amino acid of taxol.[10] One of the most remarkable effects of the chiral ligand is on the regioselectivity. In the absence of the ligand the cinnamates **3** give roughly equal amounts of the regioiosmers (that is **4** plus its 2-NHTs, 3-OH isomer).[3] *Para*-substitution of the aryl group in **3** by electron-donating or -withdrawing groups is well tolerated, however, *meta*- and, in particular, *ortho*-substitution results in some loss of enantio- and regioselectivity. While most of the reactions to date were carried out with 4 mol%Os/5 mol% ligand, in large scale runs the amount of catalyst required has been successfully reduced by half.

Less electron-poor alkenes like stilbenes (**7** and **9**) are also viable substrates, but the enantioselectivities are generally low-

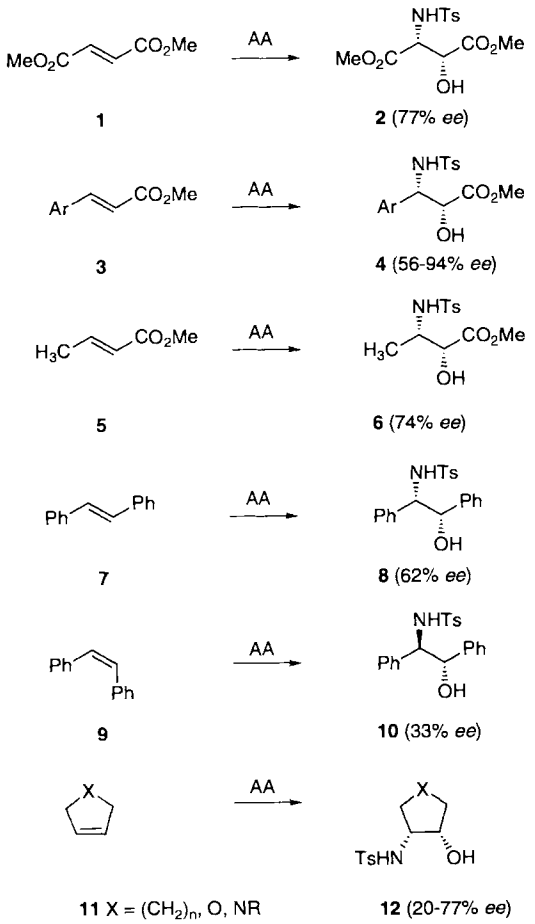
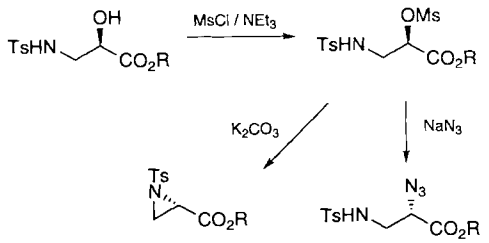


Scheme 1. AA: TsNClNa (3.5 equiv), *t*BuOH/H_2O 1/1 or CH_3CN/H_2O 1/1, room temperature $K_2[OsO_2(OH)_4]$ (4.0 mol%), $(DHQ)_2$-PHAL (5 mol%); $(DHQD)_2$-PHAL leads to the enantiomeric products.

er. Direct comparison of **8** and **10** also indicates, that (*E*)-alkenes are—in analogy to the AD process—better substrates than (*Z*)-alkenes. Nevertheless, it is already clear at this stage that (*Z*)-alkenes, and, in particular, symmetrical (*Z*)-alkenes, are useful substrates in the AA. A *syn*-dihydroxylation of the latter class of olefins leads to *meso* diols and is therefore not suitable in relation of the concept of asymmetric dihydroxylation. Cyclic (*Z*)-alkenes (**11**) ($n = 1, 2$) also have given promising results, and heteroatoms can be present as long as they are not directly attached to the double bond.[7]

1,3-, 1,4-, and 1,5-dienes as well as certain 1-alkenes also have given encouraging results in the AA, but additional regioselectivity and reactivity problems arise with these substrates. Alkenes that seem to be problematic so far are allylic halides, allylic alcohols, and allylic amines, no matter if protected or not. Several allylic acetals have also given poor results.[7]

The products obtained by the AA process can be easily transformed into aziridines or into precursors for α,β-diamino acids (Scheme 2).[7] Moreover, some derivatives like **4** can be deprotected without loss of stereochemical integrity[10] even under the quite harsh conditions (HBr/HOAc/phenol 75 °C) required to remove the N-tosyl group. The recent and exciting introduction of the nitrobenzenesulfonyl group for amine protection,[11] a group combining the virtues of the tosyl group with that of being easily removable, should dramatically advance the chemistry of these and other reactions wherein the purpose is creating new C–N bonds under mild conditions.



Scheme 2. Possible reactions with the product of an AA.

Is it too early to write a "highlight" on this new reaction? Most certainly not! At the present stage of development there are many desirable improvements concerning the range of substrates and the selectivities, as well as optimized reaction conditions. The influence of numerous parameters for the AA process like temperature, solvent, and additives are currently being investigated intensively in the Sharpless group. Also, the openness with which Sharpless et al. is presenting this discovery to the synthetic community is most impressive in that not only short communications but simultaneously full papers with detailed experimental procedures are currently in press. Looking back at the great and successful effort undertaken for the catalytic AD process, one would not be surprised to witness a similar rapid development of this catalytic asymmetric aminohydroxylation process. Moreover, there are already two other oxidative amination processes on the horizon, namely allylic amination of olefins [Eq. (b)] and 1,2-diamination of 1,3-dienes [Eq. (c)].[12] Could these useful, but stochiometric transformations be rendered catalytic and perhaps also asymmetric some day?

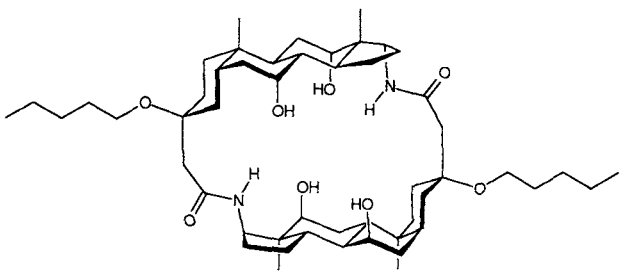
A Steroid-Based Cryptand for Halide Anions**

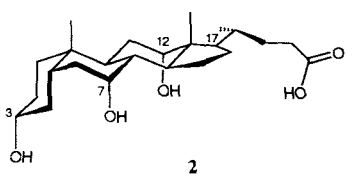
Anthony P. Davis,* John F. Gilmer, and Justin J. Perry

Supramolecular chemistry is founded largely on the early discoveries of the crown ethers and cryptands, *neutral organic molecules* capable of surrounding inorganic cations, binding them through the cooperative action of several preorganized centers, and providing lipophilic exteriors, which promote solubility in nonpolar organic media.[1] The study of anion recognition was a natural extension of this work and has resulted in a variety of elegant and effective systems.[2] However, there are still rather few molecules that may be described in the fullest sense as "anion-equivalents" of crown ethers or cryptands in that they bind inorganic anions using convergent, preorganized functionality mounted on a macrocyclic framework and are a) electrically neutral, b) essentially organic in nature, and c) soluble in nonpolar organic solvents. In order to meet these criteria, a receptor must act either through ion–dipole attraction[2a, b] or through hydrogen-bond donation.[2d–k] While the latter is probably the more potent force, there are few (if any) molecules with good neutral H-bond donor groups that do not also contain H-bond acceptors. The design of multivalent hosts is therefore complicated by a tendency towards intramolecular H-bond formation (which can close the binding cleft or cavity) and intermolecular association (which lowers solubility).

We now report a neutral, macrocyclic organic receptor for halide anions in which these problems are minimized by a lipophilic exterior featuring flexible alkyl chains to maintain solubility in nonpolar organic media and a rigid framework to maintain a binding cavity and limit the possibilities for intramolecular H-bond formation. The new host **1** is conceptually related to the "cholaphanes" reported previously from this laboratory,[3] being a macrodilactam derived from two molecules of the inexpensive steroid cholic acid **2**.[4] However, whereas the cholaphanes surround medium-sized organic molecules, **1** was designed to possess a compact and rigid structure encompassing a much smaller cavity, bordered by a high density of convergent, polar functional groups. In particular, the hydroxyl groups were intended to create an environment mimicking the aqueous solvation of a spherical anion, but preorganized for binding and surrounded by a lipophilic envelope. As a crown ether or cryptand may be thought to provide "preorganized aquation" for a spherical cation, receptor **1** would perform a complementary function for an anion.



1



2

The synthesis of **1** from **2** hinged on replacement of the side chain at C17 with an α-NH_2 group and installation of CH_2CO_2R as a short spacer in the 3α position in addition to the solubilizing β-alkoxy substituent. The early intermediate **3** was prepared by Baeyer–Villiger oxidation[5] of the corresponding 17β-acetyl-5β-androstane, which was obtained from **2** by a degradation sequence developed by Barton and co-workers.[6] The remaining steps are shown in Scheme 1. An apparent cu-

riosity is the oxidation of the C12-OH at the start of the sequence, and its regeneration through a stereoselective reduction on macrocycle **7**. This (somewhat desperate) measure was adopted after we discovered that a 12α-O substituent had a strongly deleterious effect on the azide displacement at C17 (as required for **5** → **6**). Also of note is the regio- and stereoselective application of the "silyl-modified Sakurai" reaction, incorpo-

rating both a spacer in α position and a solubilizing group in β position at C3 during the conversion of **4** to **5**.[7] All the steps in Scheme 1 gave satisfactory yields, the lowest (about 70%) being that of the macrocyclization to form **7**. Despite its congregation of polar groups, the tetraol **1**[8] was found to be highly soluble in chloroform and most other organic solvents.

The prospects for anion recognition by **1** were assessed by molecular modeling. A Monte Carlo search[9] on the receptor revealed a single dominant framework conformation, common to all the structures saved up to 39 kJ mol^{-1} above baseline. The macrocycle possesses an ovoid cavity about 3.3 Å long by 2.2 Å broad, sufficient to accommodate a fluoride and possibly chloride or bromide ion,[10] but too small for significant penetration by chloroform solvent molecules. The cavity is bounded by inward-directed NH groups at the ends of its long axis and CH and OH groups across its breadth, and is closed on one face by a transannular hydrogen bond between the two 7α-OH groups. Although this means that one 7α-OH group may be unavailable for H-bond donation to an enclosed anion, the second may be directed into the cavity as exemplified by the conformation shown in Figure 1 (which is just 2.1 kJ mol^{-1} above baseline).

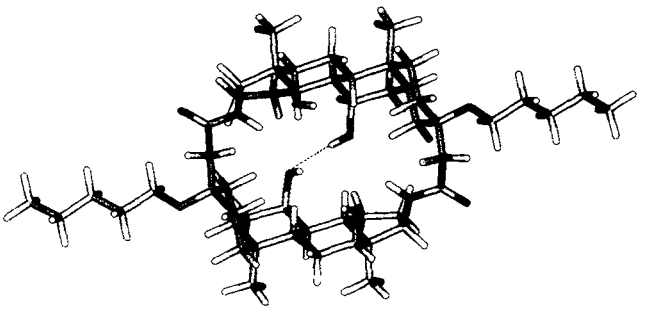

Fig. 1. One of the lower energy conformations of **1** found by computer-based molecular modeling. The macrocycle is viewed from the "C12 face", with the C7–OH···O C7 hydrogen bond (shown as a dotted line) at the base of the cavity. All the conformers located up to 39 kJ mol^{-1} above baseline possessed essentially the same framework conformation, and differed only in torsion angles about the three free OH groups ($1 \times 7\alpha$ and $2 \times 12\alpha$) and the bonds in the pentyloxy groups. The structure shown, which was found at 2.1 kJ mol^{-1} above baseline, is selected to illustrate the possibility of an inward-directed C7–OH (in the bottom left section of the cavity).

The two 12α-OH groups may also rotate inwards to form hydrogen bonds with a guest. The distance between the amide hydrogen atoms (5.6 Å) is probably too great to allow simultaneous formation of two NH···X$^-$ hydrogen bonds. However, as shown in Figure 2, an anion situated towards one end of the cavity can adopt a position about 2 Å from each of four donor hydrogen atoms (one NH, three OH) without significant adjustment of the framework conformation.[11] It should be stressed that Figure 2 is intended to illustrate the general suitability of **1** for halide binding, and does not represent a proposed structure for an actual complex (vide infra).

The recognition properties of **1** towards fluoride, chloride, and bromide anions were studied through NMR titrations employing the tetrabutylammonium salts of the anions in $CDCl_3$. Addition of all three halides resulted in substantial downfield shifts of the signal due to the NH protons on the receptor, consistent with NH···X$^-$ hydrogen bond formation. The shifts could be analyzed in terms of 1:1 binding, giving the association constants (K_a) recorded in Table 1. The macrocycle discriminates quite well between the anions, favoring, not unexpectedly, the smaller and more basic guests, which also gave the larger complexation-induced shifts. The receptor is clearly less potent

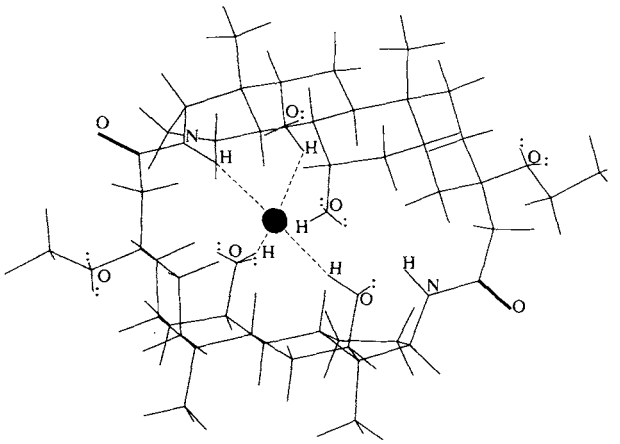

Fig. 2. Modeling H-bond formation to a hypothetical spherical anion within the cavity of **1**. Starting from the conformation in Figure 1, this configuration resulted from manual adjustment of the three OH torsions and anion position, followed by minimization of the receptor with the OH torsions held in place, and return of the anion. The hydrogen bonds (broken lines) range between 1.99 and 2.18 Å.

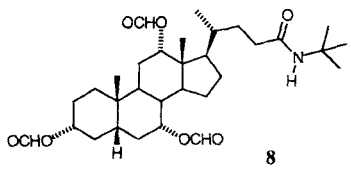
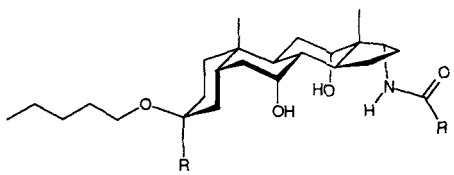
than those employing positively charged binding centers, for which association constants larger than 10^3 are commonly observed even in aqueous media.[12] However the binding constant for fluoride, and the selectivities, compare well with those of earlier neutral organic receptors.[2e, 2j] The H-bond donor groups in **1** are not especially potent by themselves.[13] When the secondary amide **8**, chosen to model the NH groups in **1**,[14] was titrated with tetrabutylammonium fluoride in $CDCl_3$, the observed change in NH chemical shift was small ($\Delta\delta = 0.05$) and essentially linear with concentration. The preorganized arrangement of groups in **1** must therefore be crucial for its effectiveness.



8

It would have been interesting to compare **1** with a "monomeric analogue" of the form **9**. Unfortunately, we were



9

prevented from doing so by our inability to reduce the 12-keto group with the necessary stereoselectivity in acyclic intermediates.[15] However, molecular modeling on the more accessible[16] amido diol **10** suggested that, although its H-bond donor groups are more widely separated than those in **9**, they should be able to act in concert to bind the larger halides.[17] NMR titrations of **10** against tetrabutylammonium chloride and bromide under the conditions used for **1** did indeed provide evidence for 1:1 complex formation. Interesting-

Table 1. Results from ^{1}H NMR titrations of **1** with tetrabutylammonium halides in $CDCl_3$ [a].

Halide	K_a [M^{-1}]	$-\Delta G^0$ [KJ mol^{-1}]	$\Delta\delta$ [b] NH	7β-H	12β-H	17β-H
F^-	3220 ± 350	20.01	1.569	−0.134	−0.27	−0.21
Cl^-	990 ± 80	17.09	0.611	−0.101	−0.168	−0.06
Br^-	250 ± 20	13.68	0.393	−0.13	−0.11	~0

[a] Halides were added to **1** (2–4 mM) in $CDCl_3$ that had been partially dried and deacidified over K_2CO_3. The experiments were performed at 298 K. Binding constants K_a were calculated with an iterative, nonlinear, least-squares curve-fitting programme. Saturation levels of greater than 70% were achieved in all cases. [b] Signal shifts induced by complexation, extrapolated to 100% saturation. Negative values imply upfield movements on addition of the guest.

ly, the limits of the downfield shifts of the NH signal in **10** ($\Delta\delta = 1.15$ and 0.8 for Cl^- and Br^- ions, respectively) were approximately twice those obtained for macrocycle **1**, consistent with our supposition that the amide groups in **1** cannot both participate in binding. However, as expected, the acyclic receptor proved less effective than the macrocycle, binding Cl^- and Br^- with $K_a = 53 \pm 2\ M^{-1}$ and $36 \pm 1\ M^{-1}$, respectively.

A distinctive feature of receptors derived from **2** is the profusion of distinguishable ^{1}H NMR resonances resulting from the low symmetry of the steroidal nucleus.[18] In favorable cases these NMR signals may be used to report on recognition behavior from a variety of positions in the structure. As shown in Table 1, there were several protons apart from the NH which could be followed during the course of the titrations (see also Fig. 3). The signals due to the 7β and 12β *H*COH moved upfield

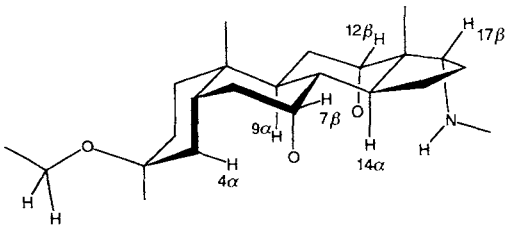

Fig. 3. Section of the structure of **1**, indicating the protons serving, or thought to serve, as NMR probes for complex formation.

in each case, consistent with H-bond donation by OH,[19] which therefore implies that hydroxyl groups in both environments take part in binding.[20] Analysis of this data, where feasible, provided support for the results obtained from the NH signal. The 17β *H*CNH moved upfield on binding to fluoride and chloride, but was unaffected by bromide. In addition to the signals in Table 1, a broad resonance corresponding to three protons from the steroid nucleus moved downfield by about $\Delta\delta = 0.3$ on binding to fluoride. We suspect that these are protons on the interior surface of the host, which are coming into contact with the anionic guest.[21] Our experience with other systems suggests that they may be the 4α-, 9α-, and 14α-H atoms (Fig. 3). A similar but smaller effect was observed on addition of chloride ($\Delta\delta \approx 0.15$). The externally positioned OCH_2 protons were also informative. These nuclei are remote from the expected binding site, but modeling suggests that steric effects should couple their orientations to changes in the conformation of the macrocycle. In **1** they appeared as a complex multiplet, but after binding to fluoride they gave individual signals separated by $\Delta\delta = 0.18$. Similar changes were observed on formation of the chloride complex, but not on addition of bromide. We infer that binding to fluoride and chloride does cause **1** to alter its conformation, whereas its mode of interaction with bromide may be qualitatively different.

Finally, the anion-binding capability of **1** was confirmed by negative-ion LSI-MS. Equal quantities of tetrabutylammonium fluoride and bromide were added to the sample, which was then dissolved in a *p*-nitrobenzyl alcohol matrix. Unexpectedly, it was the bromide complex ($M + Br^-$) that was detected, at 75% the level of the base peak ($M - H^+$). No evidence was found for $M + F^-$. This result is probably due to the nature of the matrix, emphasizing the difficulty of binding fluoride in competition with a protic solvent.

In conclusion, we have designed and synthesized a neutral, lipophilic macrocyclic host molecule with a well-defined cavity, which excludes solvent but is preorganized to bind spherical anions by multiple H-bond donation. NMR studies confirm that it does indeed act as a receptor for halide ions, showing interesting potency and selectivity. Macrocycle **1** joins a select band of neutral molecules that can fairly be termed "anion-equivalents" of crown ethers or cryptands.

22.4 (19-Me), 22.6, 24.1, 26.1, 28.7, 29.5, 29.7, 30.1, 30.6, 31.6, 31.8, 34.4 (C-10), 34.5, 37.5, 38.2, 40.0, 46.2, (C-13), 49.2 (3α-CH_2), 59.6 (C-17), 61.4 (3β-OCH_3), 69.1 (C-7), 74.1 (C-12), 74.5 (C-3), 170.4 (C=O); LSI-MS *m/z* 889 (MNa^+).

[9] Performed within MacroModel V4.0 (Silicon Graphics 4D25TG workstation). See F. Mohamadi, N. G. J. Richards, W. C. Guida, R. Liskamp, C. Caufield, G. Chang, T. Hendrickson, W. C. Still, *J. Comput. Chem.* **1990**, *11*, 440. The search employed 1000 MC steps, the MM2* force field, and GB SA (chloroform) solvation.

[10] At first sight this may seem to be in doubt, given the conventional ionic radii of 1.33, 1.81, and 1.96 Å (diameters of 2.66, 3.62, and 3.92 Å) of fluoride, chloride, and bromide, respectively (Y. Marcus, *J. Chem. Soc. Faraday Trans.* **1991**, *87*, 2995). However, it is questionable whether these figures are relevant to the present circumstances. For example, Farnham et al. (ref. [2f]) record CH···F$^-$ distances of between 1.94 and 2.12 Å. As the standard van der Waals radius for hydrogen (used in our modeling) is 1.2 Å, one might conclude that a radius of about 0.8 Å might be more appropriate for fluoride in a hydrocarbon environment. The figures for chloride and bromide presumably need similar adjustment.

[11] An examination of halide hydrate structures present in the Cambridge Structural Database suggested that "ideal" OH···X$^-$ distances are in the region of 1.75 Å for X = F, 2.3 Å for X = Cl, and 2.4 Å for X = Br.

[12] See, for example, refs. [2a] and [2d]. Very high binding constants (10^6–10^8 M^{-1}) can be obtained with charged receptors operating in nonpolar solvents; see, for example, M. Shionoya, H. Furuta, V. Lynch, A. Harriman, J. L. Sessler, *J. Am. Chem. Soc.* **1992**, *114*, 5714.

[13] M. H. Abraham, *Chem. Soc. Rev.* **1993**, *22*, 73.

[14] The examination of CPK models suggests that the steric environment of the NH in **8** should be roughly similar to that in **1**. It should be noted that the steroidal moiety in **8** serves merely as a convenient appendage, without contributing in any specific way to the value of **8** as a control.

[15] Attempts to separate mixtures of 12α and 12β alcohols were also ineffectual. Our success in reducing **7** to **1** presumably results from steric protection of the steroidal α-face in the macrocyclic structure.

[16] The 3α-amido group was introduced by a double inversion (Mitsunobu reaction followed by azide displacement); cf. A. P. Davis, J. J. Walsh, *J. Chem. Soc. Chem. Commun.* **1996**, 449.

[17] Modeling indicated that the NH and two OH groups in **10** should be able to form H-bonds of 2.5–2.6 Å to a centrally located anion. These figures are not greatly in excess of the "ideal" OH···X$^-$ distances inferred from X-ray crystallography for X = Cl and Br [11]. See also Ref. [20] below.

[18] R. P. Bonar-Law, A. P. Davis, *Tetrahedron* **1993**, *49*, 9845.

[19] C.-Y. Huang, L. A. Cabell, E. V. Anslyn, *J. Am. Chem. Soc.* **1994**, *116*, 2778.

[20] The binding experiments on **10** revealed similar upfield shifts of the *H*COH signals (Δδ between 0.124 and 0.153), supporting our hypothesis that all three H-bond donor groups are involved in halide recognition by this "acyclic analogue" of **1**.

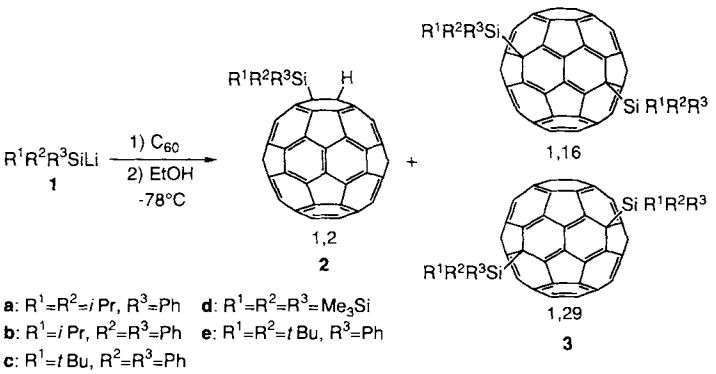
[21] See ref. [2f] for a downfield shift resulting from formation of a CH···F$^-$ hydrogen bond.

Reactions of Silyllithium with C_{60}: Isolation and X-ray Crystallographic Characterization of an Unusual Bissilylated-C_{60} Adduct**

Takahiro Kusukawa and Wataru Ando*

The unique structure of C_{60} and its derivatives have sparked much research activity bridging the disciplines of chemistry, physics, and materials science.[1–5] Recently closed 1,2-, opened 1,6- (5,6-annulenes), and 1,4-adducts have been isolated. Nucleophilic addition to C_{60} is among the most common reaction types in fullerene chemistry.[6] We have reported a few examples of the photochemical formation of silylfullerene derivatives to date.[7] Yet in spite of those developments, the methods available for silylfullerene derivatives is limited, allowing access to only specific patterns of silicon substituents and ring arrangements. However, the use of silyllithium compounds has not previously been reported. Herein we report the isolation of an unusual bissilylated-C_{60} adduct by reactions of bulky substituted silyllithium with C_{60}, whose adduct was characterized by single X-ray crystal analysis.

In earlier work with C_{60} and Ph_3SiLi the formation of a brown precipitate was observed at −78 °C, and when the suspension was quenched with EtOH, only C_{60} was recovered. The analogous reaction with other silyllithium compounds ($Me_2PhSiLi$, $MePh_2SiLi$, $Et_2PhSiLi$, $EtPh_2SiLi$) leads to similar results. On the other hand, diisopropylphenylsilyllithium **1a** reacted with C_{60} under these conditions to produce **2a** (78% yield, based on unchanged C_{60}, for spectroscopic data see Table 1) upon quenching with EtOH (Scheme 1).



a: $R^1=R^2=i$Pr, R^3=Ph **d**: $R^1=R^2=R^3=Me_3Si$
b: $R^1=i$Pr, $R^2=R^3$=Ph **e**: $R^1=R^2=t$Bu, R^3=Ph
c: $R^1=t$Bu, $R^2=R^3$=Ph

Scheme 1. Synthesis of the mono- and disilyl C_{60} adducts **2** or **3**. For spectroscopic data of the products see Table 1. 1,2 etc. represents the type of addition.

The FAB mass spectrum of **2a** exhibits one peak at *m/z* 912–915 for the molecular ion and one for C_{60} at *m/z* 720–723. The ^{13}C NMR spectrum of **2a** displays 30 signals for C_{60} carbon, supporting C_s symmetry for the molecule. One signal has a relative intensity of 4, one a relative intensity of 3, 25 signals have a relative intensity of 2, and three a relative intensity of 1; thus, the number of carbon atoms sums up to 60. Of the 30, two fullerene carbon atoms resonate at δ = 58.87 and 60.94. The signals of all other carbons appear in the region between δ = 130–160.

The partial structure of the fragment bound to the C_{60} moiety derives from the NMR spectroscopic properties for **2a**: The presence of one hydrogen connected to C_{60} is deduced from one doublet at δ = 58.87 and one singlet at δ = 6.93 in the ^{13}C NMR and ^1H NMR spectrum, respectively. The ^{29}Si NMR spectrum of **2a** shows one peak at δ = 5.42, which is assigned to the silicon atoms of **2a**.

The most probable addition pattern for the fullerene moiety is a 1,2-addition.[6c] In the case of a 1,6-addition 60 signals for C_{60} carbon would be expected. The possibility of 1,4-addition can be eliminated by the ^{13}C–^1H COLOC (Correlation Spectroscopy via Long-Range Coupling) spectroscopic method. It was shown that the proton resonance at δ = 6.93 correlates with quaternary carbon (δ = 60.94) on the C_{60}. Under similar conditions, diphenylisopropyl- and diphenyl-*tert*-butylsilyllithium, **1b** and **1c** react with C_{60} to give monoadducts **2b** (80% yield, based on unchanged C_{60}) and **2c** (50% yield, based on unchanged C_{60}), respectively. On the other hand, the reaction of tris(trimethylsilyl)silyllithium **1d** with equivalent amounts of C_{60} at −78 °C give bisadduct **3d** in 69% yield (based on unchanged C_{60}), and monoadduct **2d** could not be detected.

3d: dark red solid; ^{1}H NMR δ = 0.38 (s, 54H); ^{13}C NMR δ = 2.63 (q), 60.88 (s, 2C), 135.02 (s, 2C), 135.76 (s, 2C), 139.36 (s, 2C), 140.06 (s, 2C), 140.62 (s, 2C), 140.82 (s, 2C), 141.83 (s, 2C), 142.49 (s, 2C), 142.71 (s, 2C), 143.30 (s, 2C), 143.66 (s, 2C), 143.81 (s, 2C), 144.37 (s, 2C), 145.20 (s, 2C), 145.66 (s, 2C), 146.00 (s, 2C), 146.14 (s, 2C), 146.22 (s, 2C), 146.25 (s, 2C), 146.38 (s, 4C), 147.09 (s, 2C), 147.43 (s, 2C), 147.90 (s, 2C), 148.75 (s, 2C), 151.55 (s, 2C), 151.67 (s, 2C), 164.76 (s, 2C), 165.71 (s, 2C); ^{29}Si NMR δ = −52.72, −9.95; FAB-MS: m/z: 1215–1218 (M^+)

3e: dark red solid; ^{1}H NMR δ = 1.56 (s, 9H), 1.57 (s, 9H), 7.2–7.4 (m, 3H), 8.0–8.1 (m, 2H); ^{13}C NMR δ = 25.22 (s, 2C), 31.85 (q), 31.89 (q), 65.74 (s, 2C), 127.30 (d), 129.55 (d), 131.66 (s, 1C), 136.40 (s, 2C), 137.11 (d), 138.65 (s, 2C), 139.48 (s, 2C), 140.57 (s, 2C), 141.13 (s, 2C), 141.54 (s, 2C), 141.89 (s, 2C), 141.98 (s, 2C), 142.20 (s, 2C), 143.51 (s, 2C), 143.98 (s, 2C), 144.19 (s, 2C), 145.31 (s, 2C), 145.33 (s, 2C), 145.99 (s, 2C), 146.02 (s, 2C), 146.11 (s, 2C), 146.14 (s, 2C), 146.36 (s, 2C), 146.59 (s, 2C), 146.94 (s, 2C), 147.39 (s, 2C), 147.72 (s, 2C), 148.57 (s, 2C), 150.31 (s, 2C), 152.74 (s, 2C), 162.66 (s, 2C), 165.19 (s, 2C); ^{29}Si NMR δ = 5.22; FAB-MS: m/z: 1159–1162 (M^+).

[a] 500 MHz ^{1}H, 126 MHz ^{13}C, and 60 MHz ^{29}Si NMR spectra in a 1/2 mixture (for all ^{1}H spectra, as well as the ^{13}C and ^{29}Si NMR spectra of **2a**) or 1/1 mixture (all other spectra) of $CDCl_3/CS_2$; J values in Hz.

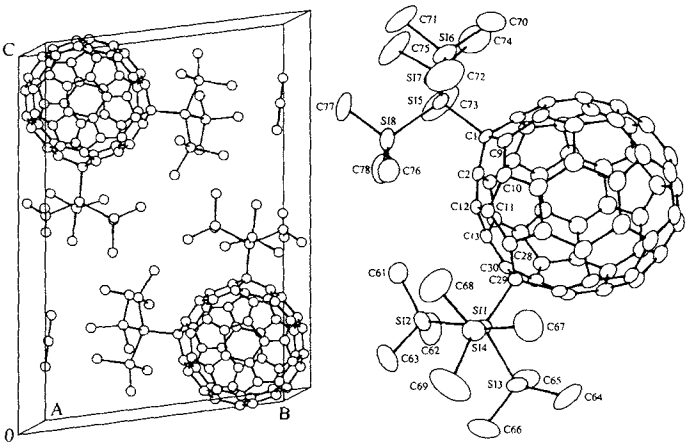

Fig. 1. X-ray crystallographic characterization of **3d**·CS_2. Left: arrangement in the unit cell. Right: Crystal structure of one of the two enantiomorphic molecules in the unit cell. The ellipsoids represent 50% probability.

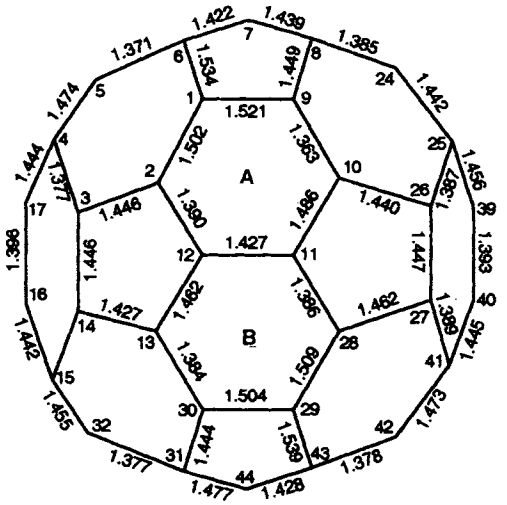

Fig. 2. Bond lengths [Å] in **3d** and selected bond angles [°]: C2-C1-C6 121.9, C2-C1-C10 109.1, C6-C1-C10 117.3, C1-C2-C3 123.2, C2-C3-C4 110.2, C3-C4-C5 124.0, C4-C5-C6 120.6, C1-C6-C5 117.2, C1-C6-C7 122.0, C5-C6-C7 108.9, C6-C7-C8 123.3, C7-C8-C9 109.7, C8-C9-C10 124.3, C1-C10-C9 120.4. The standard deviation in the last digit is 7–8 Å.

The FAB mass spectrum of **3d** exhibits one peak at m/z 1215–1218 for the molecular ion), as well as one for C_{60} at m/z 720–723. The ^{13}C NMR spectrum of **3d** displays 29 signals for all quaternary carbon atoms, of which one fullerene carbon atom resonates at δ = 60.88. All other signals appear in the region between δ = 135–165. Symmetry arguments support the 1,6-addition or 1,4-addition to C_{60}; however addition of the bulky substituent [$(Me_3Si)_3Si$] is unfavorable for 1,6-addition. In order to obtain information of the structure for **3d**, we carried out the X-ray crystallographic analysis.[8]

Compound **3d** crystallized in the triclinic space group $P\bar{1}$, with two enantiomorphic molecules of **3d** and two CS_2 molecules in the unit cell (Fig. 1, left). The crystal structure of **3d** is shown in Figure 1 (right), and selected bond lengths and angles are given in Figure 2.

The C–C bond lengths C12–C2, C9–C10, C11–C28, and C30–C13 are within 1.363(7)–1.390(7) Å, which are close to the C–C double bond length. The bond angles at the fullerene C atoms excluding the bonds in rings A and B, are 107.3(4)–109.2(4)° in the pentagons and 118.3(4)–121.5(5)° in the hexagons, values which are within the normal range. The length of the C_{60} skeleton, excluding the bonds in rings A and B, range from 1.371(7) to 1.474(8) Å (Fig. 2). The structure of **3d** is a new type of addition mode to the C_{60}.

Relative stabilities of the dihydrofullerenes (given as the energy of formation from C_{60} and H_2) were reported by Dixon et al., who determined them with semiempirical calculations:[9] 1,2 (776.1 kcal mol^{-1}) > 1,4 (780.0 kcal mol^{-1}) > 1,16 or 1,29 (791.6 kcal mol^{-1}) > 1,6 (794.5 kcal mol^{-1}). Accordingly, our new bissilylated-C_{60} (**3d**, 1,16 or 1,29 addition) is about 15.5 kcal mol^{-1} more unstable than the 1,2 form, but 2.9 kcal mol^{-1} more stable than the 1,6 adduct. Additions of two $(Me_3Si)_3Si$ groups at the 1,2 (6,6 addition) and 1,4 positions are unfavorable because of the steric hindrance, so the two $(Me_3Si)_3Si$ groups might be bound to the 1,16 (or 1,29) positions.

Di-*tert*-butylphenylsilyllithium **1e** also reacts with C_{60} to give bisadduct **3e** in 72% yield (based on unchanged C_{60}). The structure of the adduct **3e** was determined in a similar manner by use of NMR techniques.

The UV/Vis absorption spectrum of **2a–2c** shows absorption at 416–417 nm and 444–445 nm in toluene. On the other hand, bisadducts **3d** and **3e** show broad absorption at 520 nm–600 nm.

The formation of **3** poses a question on the mechanism of the addition of silyllithium to C_{60}. The structure of **3** resulted from the introduction of two organosilyl groups at the 1,16 or 1,29 positions of the two six-membered rings. Considering the bisadduct formation by Grignard reagents,[6e] we initially proposed that the formation of **3** involved radical processes. To clarify the mechanistic pathway of the formation of **3**, we examined the photochemical reaction (254 nm) of $[(Me_3Si)_3Si]_2$ with C_{60}, which did not give the bisadduct **3d**. From these findings, the $(Me_3Si)_3Si$ radical is probably not be involved in the formation of **3**. Further studies are in progress in order to establish the mechanism of this interesting addition reaction.

Experimental Procedure

A solution of the silyllithium compound (**1a**-**1e**, 138.9 μmol) in THF (1.7 mL) was added by syringe to a solution of C_{60} (138.9 μmol) in dry toluene (120 mL) at −78 °C over 30 min. After the addition, the solution was quenched with EtOH and warmed to room temperature. The solvent was evaporated, and the residue purified by gel-permeation chromatography (Jaigel 1H and 2H columns, Japan Analytical Industry Co. Ltd.; eluent toluene), to afford the adducts **2a**-**2c**, **3d**, and **3e**.

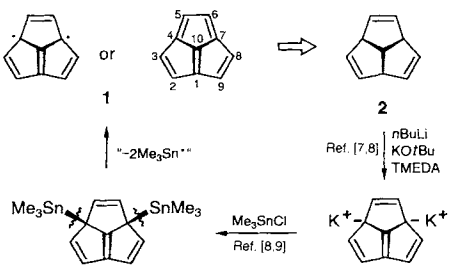
The Long Elusive Acepentalene—Experimental and Theoretical Evidence for its Existence**

Rainer Haag, Detlef Schröder, Tosja Zywietz, Haijun Jiao, Helmut Schwarz,* Paul von Ragué Schleyer,* and Armin de Meijere*

In 1964, Woodward et al. proposed triquinacene (**2**) as a logical precursor to the still elusive acepentalene (**1**, Scheme 1).[1] The nowadays easily accessible $C_{10}H_{10}$ hydrocarbon **2**[2, 3] has the same carbon skeleton as **1**, but contains only three isolated double bonds, and therefore is far less strained. Introduction of two additional double bonds into triquinacene **2** would result in the highly strained acepentalene **1**, which, like cyclobutadiene and pentalene, is an antiaromatic species.[4, 5] The Hückel molecular orbital (HMO) theory predicts that, on the assumption of a D_{3h} symmetric geometry, the $C_{10}H_6$ hydrocarbon **1** has a triplet diradical ground state.[4a] However, Jahn–Teller distortion to a lower symmetry singlet is possible. In addition, the angle strain of the three widened C,C,C angles on the three outer bridgeheads disfavors a planar geometry of **1**. After all, the aromatic acepentalene dianion $\mathbf{1}^{2-}$, which is formed by treatment of **2** with a superbasic mixture,[6] has a curved molecular surface.[7, 8]

Several disubstituted dehydrotriquinancenes with four double bonds have been synthesized, but none of them has been transformed successfully into **1**.[3, 5] The bis(trimethylstannyl)-dihydroacepentalene **3**, which was obtained by trapping the dianion $\mathbf{1}^{2-}$ with trimethyltin chloride (Scheme 1),[8] is a stable species (under inert atmosphere), despite the strain due to the central bridgehead–bridgehead double bond.

The slight elongation of the carbon–tin bond (X-ray analysis)[8b, 9] suggests that compound **3** might serve as a particularly good precursor for the fully unsaturated acepentalene **1**. How-



Scheme 1. Pathway for the generation of acepentalene **1**.

ever, attempts to cleave off both trimethyltin substituents from **3** homolytically (either thermally or photolytically) to generate acepentalene **1** have not been successful.[8b, 10a]

Neutralization–reionization mass spectrometry (NRMS) is a potential approach to the neutral acepentalene **1**.[11] In such experiments, appropriate precursors are ionized in the ion source of a mass spectrometer and subjected to double collision: The fast moving ions are neutralized in the first collision, the remaining ions are deflected, and the beam of neutrals is reionized in the second collision event.

Electron or chemical ionization of bis(trimethylstannyl)-dihydroacepentalene **3** in the positive ion mode does not lead to an intense $[C_{10}H_6]^{\bullet+}$ signal, and tin-containing cations prevail in the mass spectrum. Further, the integrity of the acepentalene skeleton is not guaranteed in the radical cation, because cationized hydrocarbons are known to undergo extensive structural rearrangements.[12] In contrast, negative-ion chemical ionization (NICI)[13] of **3**, with N_2O as the reagent gas, affords large amounts of the acepentalene anion radical, $[C_{10}H_6]^{\bullet-}$. The high yield of $[C_{10}H_6]^{\bullet-}$ points to a relatively high electron affinity[14] of neutral **1** (see below). A significant electron affinity of the acepentalene skeleton was already indicated by a previous study of the tribenzo derivative.[15]

The $[C_{10}H_6]^{\bullet+}$ ion radical formed by reionization of the intermediate neutral molecule **1** is observed in the NR mass spectrum of $\mathbf{1}^{\bullet-}$ (Fig. 1). This process is quite efficient and reionized neutral **1** is the base peak in the NR spectrum. In addition, the observation of $[C_{10}H_6]^{\bullet+}$ demonstrates that neutral **1** is stable for at least 1 μs, which is the time scale of the NR experiment. The intrinsic stability of **1** is further demonstrated by elongating the flight time of the neutral in the NR experiment by a factor 8: This hardly changes the features of the NR mass spectrum and reionized **1** is the predominant base peak.[10b]

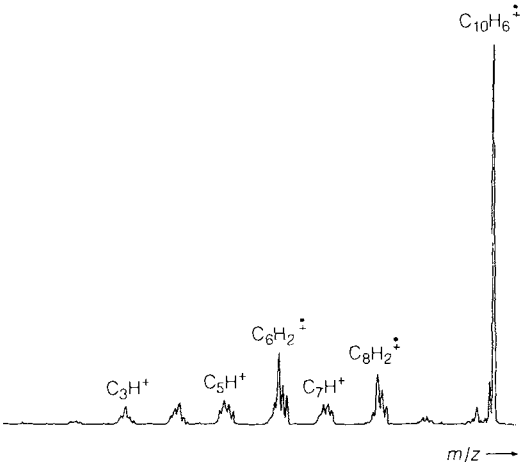

Fig. 1. Neutralization–reionization mass spectrum of $[C_{10}H_6]^{\bullet-}$ generated by chemical ionization of **3** with oxygen (each 80% transmission) in both collision cells.

The generation of the neutral hydrocarbon by collisional electron detachment from the corresponding anion radical is also advantageous in that structural rearrangements are much less likely to occur in this process[16, 17] than in the neutralization of cationic species. The absence of rearrangements is further supported by the finding that $[C_{10}H_6]^{\bullet-}$ undergoes neither unimolecular nor collision-induced fragmentation (except for electron detachment), even though potential fragments exhibit positive electron affinities (for example, acetylide anions).[14] Although mass spectrometry cannot prove structures directly, the fragmentation pattern in the NR spectrum is consistent with the connectivity of the acepentalene skeleton, for example, predominant losses of ethyne and oligoyne fragments (C_2H_2, C_4H_2, C_6H_2 etc.).

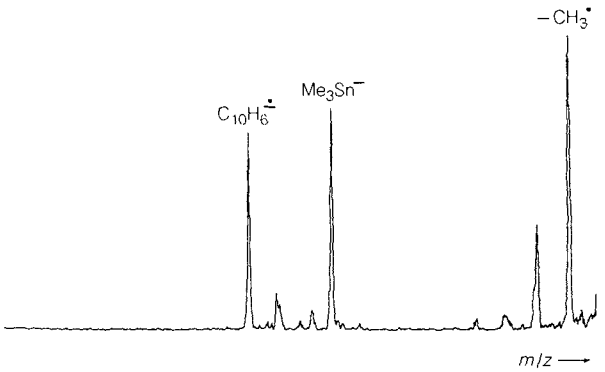

Fig. 2. Collisional activation mass spectrum of $[\mathbf{1}/SnMe_3]^-$ (He, 80% transmission).

Collisional activation (CA) of $[\mathbf{1}/SnMe_3]^-$ is another approach to generate neutral **1**. $[\mathbf{1}/SnMe_3]^-$ is also generated by NICI of **3** with N_2O in a simple substitution process of **3** with $O^{\bullet-}$ [reaction (a)] in which rearrangements are unlikely to occur. In the CA mass spectrum of $[\mathbf{1}/SnMe_3]^-$ (Fig. 2) two competing processes [reactions (b) and (b')], which only differ in the placement of the negative charge in the products, become apparent.

$$\mathbf{3} + O^{\bullet-} \longrightarrow [\mathbf{1}/SnMe_3]^- + MeSn^{\bullet} \quad (a)$$

$$[\mathbf{1}/SnMe_3]^- \longrightarrow Me_3Sn^- + C_{10}H_6 \quad (b)$$

$$[\mathbf{1}/SnMe_3]^- \longrightarrow [C_{10}H_6]^{\bullet-} + Me_3Sn^{\bullet} \quad (b')$$

According to Cooks's kinetic method,[18] the near unit ratio of the Me_3Sn^- and $[C_{10}H_6]^{\bullet-}$ ions implies that the electron affinities (EAs) of both fragments are comparable. While $EA(Me_3Sn^{\bullet})$ has not been determined yet,[19] $EA(Me_3Sn^{\bullet}) \approx 1.5$ eV can be estimated from the available literature data for silicon, germanium, and tin compounds.[14] This value agrees well with the calculated value for **1** (1.8 eV, see Table 1). Also note that the competition of reactions (b) and (b') implies that fragmentation of $[\mathbf{1}/SnMe_3]^-$ leads to neutral **1** in its electronic ground state (see below).

These experimental data can be compared with the results of density functional theory computations on acepentalene.[20] The Becke3LYP/6-31G* optimized structural parameters for singlet $\mathbf{1}(S_0)$ and triplet acepentalene $\mathbf{1}(T_0)$ are given in Figure 3. At Becke3LYP/6-31G*, $\mathbf{1}(T_0)$ and $\mathbf{1}(S_0)$ are energy minima (NIMAG = 0). The C_s symmetric $\mathbf{1}(S_0)$ shows the localized single and double bond lengths expected for a singlet antiaromatic species. In contrast, $\mathbf{1}(T_0)$ is C_{3v} symmetric and has a

Table 1. Calculated total [Hartree] and relative [kcal mol^{-1}] energies as well as ZPVE (kcal mol^{-1}) for **1** (C_s, singlet), **1** (C_{2v}, singlet), **1** (C_{3v}, triplet), and $\mathbf{1}^{\bullet-}$ (C_s).

Species (point group)	Becke3LYP/ 6-311 + G* [a]	ZPVE [b, c]	E_{rel}
1 S_0 (C_s)	−384.57448	74.14 (0)	0.0
1 S_0 (C_{2v})	−384.56280	73.90 (1)	7.5
1 T_0 (C_{3v})	−384.56943	73.45 (0)	3.9
$\mathbf{1}^{\bullet-}$ (C_s)	−384.63873	73.59 (0)	−40.8 [d]

[a] Single-point energies using Becke3LYP/6-31G* geometries. [b] Becke3LYP/6-31G* values, scaled by 0.97. [c] Number of imaginary frequencies, in parentheses. [d] This corresponds to EA $\mathbf{1}(S_0) = 1.8$ eV.

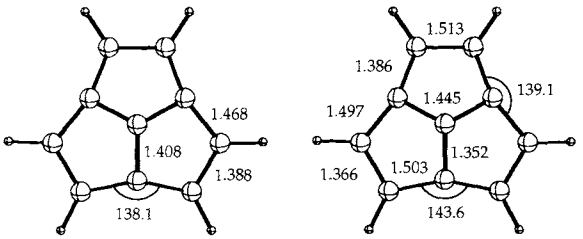

Fig. 3. Bond lengths [Å] and bridgehead C,C,C angles [ ] for **1** (C_{3v}, triplet, left) and **1** (C_s, singlet, right).

delocalized π system. The bond lengths, compared to the **1**(S_0) state, show partial equalization of formal single and double bonds. This is supported by the computed natural atomic charges and Wiberg bond indices.[21]

Table 1 summarizes the total and relative energies for **1**(T_0, C_{3v}), **1**(S_0, C_s), **1**(S_0, C_{2v}) and $\mathbf{1}^{\bullet-}(C_s)$. In contrast to the HMO results,[1a] the C_s singlet acepentalene **1**(S_0) is 3.9 kcal mol^{-1} lower in energy than the triplet state at the Becke3LYP/6-311 + G*//Becke3LYP/6-31G* + ZPVE (Becke3LYP/6-31G*) level. The singlet state is stabilized by Jahn–Teller distortion, which is typical for almost all antiaromatic compounds.[22] The inversion of the S_0 state proceeds via a C_{2v} transition structure with an associated barrier of 7.5 kcal mol^{-1} (Table 1).

Experimental Procedure

The experiments were performed with a modified VG ZAB HF AMD 604 four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sectors), as described previously [23]. The anion radical of acepentalene, $[C_{10}H_6]^{\bullet-}$, was generated by chemical ionization (CI) of **3** with N_2O as electron-moderating and reagent gas [24]. For the CA spectra, $[C_{10}H_6]^{\bullet-}$ was mass-selected with B(1)E(1) at a mass resolution of $m/\Delta m = 3000$, collided with helium [80% transmission], and the products were analyzed with B(2). In the NR experiments [11], mass-selected $[C_{10}H_6]^{\bullet-}$ collided with oxygen (80% transmission) in the first of two collision cells in the field-free region preceding B(2). Subsequently, all remaining ions were deflected by charging an electrode to a potential of 1000 V. The beam of fast neutrals proceeded to the second collision cell in which oxygen (80% transmission) was present as reionizing gas. The cations formed were analyzed by scanning B(2) in the positive ion mode. The occurrence of a "recovery signal" for the reionized neutral $C_{10}H_6$ demonstrates that the neutral must be stable for at least 1 μs, since it survived the flight between the two collision cells (distance 10 cm). Longer flight times for the neutrals were achieved by using a collision cell for neutralization located after the end of E(1) such that the distance between the neutralization and reionization chambers was about 80 cm [25]. All spectra were accumulated and processed on-line with the AMD/Intectra data system; 5 to 15 scans were averaged to improve the signal-to-noise ratio.

[20] Geometry optimizations and frequency calculations were carried out at the Becke3LYP/6-31G* level by using the Gaussian 94 [25] program package. Stationary points were characterized to be energy minima with no imaginary frequencies (NIMAG = 0) or to be transition structures having only one imaginary frequency (NIMAG = 1). Natural atomic charges (NAC) and bond orders (Wiberg bond index, WBI [27]) were derived from the natural bond orbital analysis (NBO) of Reed et al. [28]. Single-point energies were obtained at the Becke3LYP level with the 6-311 + G* basis set with the Becke3LYP/6-31G* geometries.
