4.5. The Influence of Stabilizing Neutral Ligands and the Anionic Ligands *t*BuO$^-$ and PhS$^-$ on Reactivity and Selectivity

Is it possible to increase the stability of thermolabile alkyl transition metal reagents by means of complexation with neutral ligands without any excessive loss of reactivity and selectivity? This question was posed in the case of Me_2Co, which decomposes at −40 °C in Et_2O or THF (see Scheme 3). The complexes **70**[71] (isolated, stable up to 20 °C) and **71**–**73** (prepared in situ from the corresponding known dichlorides[73–75] and two equivalents of MeLi) in Table 5 exhibited a considerably lower reactivity than Me_2Co itself in reactions with benzaldehyde and quinoxaline carried out in Et_2O; this corresponds to the observation that the nucleophilicity of Me_2Co in Et_2O is higher than in the more basic solvent THF. A better

Table 5. Comparison of the reactivity of the complexes **70**–**73** with Me_2Co. Reaction conditions: Et_2O, −78 to 20 °C in 18 h.

n Equiv reagent	Substrate	Product	Yield [%]
2 Me_2Co	benzaldehyde	1-phenylethanol [53b]	90
2 [$Me_2Co(PMe_3)_2$] **70**			52
2 [$Me_2Co(PEt_3)_2$] **71**			23
1 Me_2Co	quinoxaline	2-methylquinoxaline [53d]	26 [a]
1 [Me_2Co(dppe)] **72** [b]			2
1 [$Me_2Co(py)_2$] **73**			1

[a] Under optimum conditions 53% (Scheme 31). [b] dppe = 1,2-bis(diphenylphosphino)ethane.

yield than that from Me_2Co was, however, obtained when [$Me_2Co(PEt_3)_2$] (**71**) was allowed to react with ethyl benzoate (see Scheme 28), probably because of the higher thermal stability of **71**. Compounds **71** and [$Me_2Co(py)_2$] (**73**), both of which are stable at −10 °C, were studied with respect to selectivity: compound **71** showed itself to be completely unselective in competition experiments with benzaldehyde/acetophenone and heptanal/3-pentanone,[53b] and the cheleselectivity of **73** is much lower than that of Me_2Co[53d] (see Scheme 24).

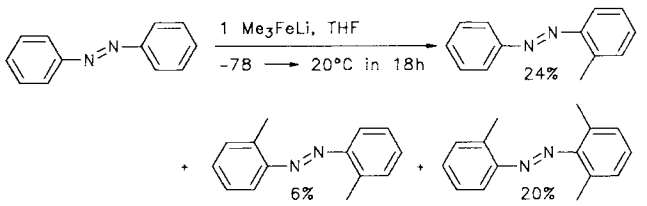
The hetero-ate complexes $RFe(OtBu)_2Li$,[53a] $RFe(SPh)_2Li$,[53a] $R_2Fc(OtBu)_2Li_2$,[53f] and $R_2Fe(SPh)_2Li$[53f] (R = Me, *n*Bu) have only been the subject of preliminary studies and will thus only be mentioned in passing: while the methyl complexes were generally much less favorable with respect to both reactivity and selectivity than the methyl-homo-ate complexes prepared according to Scheme 1, the *n*-butyl complexes were found to be superior to the corresponding homo-ate complexes, indicating a greater thermal stability. Two 1:1 reactions with 2-cyclohexenone (**51**) (THF, −78 °C, 1 h, rising to 20 °C in 45 min) are used as examples: *n*BuFe(OtBu)$_2$Li reacted predominantly (3-*n*-butylcyclohexanone (79%), *n*-butylcyclohex-2-enol (15%)) and *n*BuFe(SPh)$_2$Li[53a] solely by 1,4-addition (3-*n*-butylcyclohexanone (71%)). Alkyl–Co^{II} complexes with *t*BuO$^-$ or PhS$^-$ as ligands were less effective than the analogous Fe complexes.

5. Reactions with Other Substrates

5.1. *ortho*-Methylation of Azobenzene and 4-Dimethylaminoazobenzene

A small amount of *ortho*-methylation product is formed in each case when Me_3FeLi is allowed to react with benzalaniline and benzonitrile (see Schemes 30 and 32, respectively). The formation of these compounds, which certainly involves the intermediate formation of a cyclometalation product (cf. ref. [76]), is by no means surprising, since the postulated mechanisms involve an intermediate that can be considered a suitable precur-

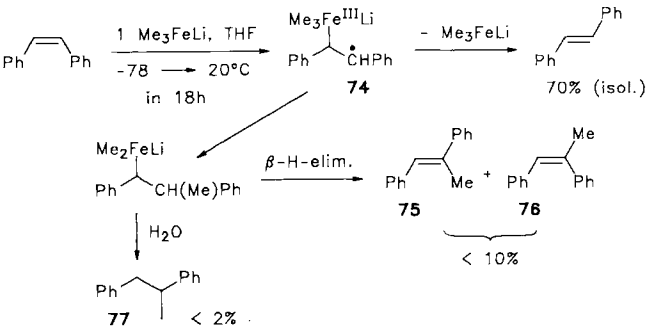
sor for *ortho*-methylation. *ortho*-Methylation was the sole reaction observed when Me_3FeLi was allowed to react with *azobenzene* (Scheme 38) or *4-dimethylaminoazobenzene*.[17a, 77] *In the case of the latter substrate the ortho*-methylation of the dimethylamino-substituted (and thus electron-richer) benzene ring occurs to a lesser extent than that of the other benzene ring. An explanation of this result is presented in reference [77]. MeLi, which reacts by an alternative mechanism, *ortho*-methylates 4-dimethylaminobenzene preferentially at the dimethylamino-substituted ring.[77]



Scheme 38. See also ref. [77].

5.2. Addition to C–C Double and C–C Triple Bonds

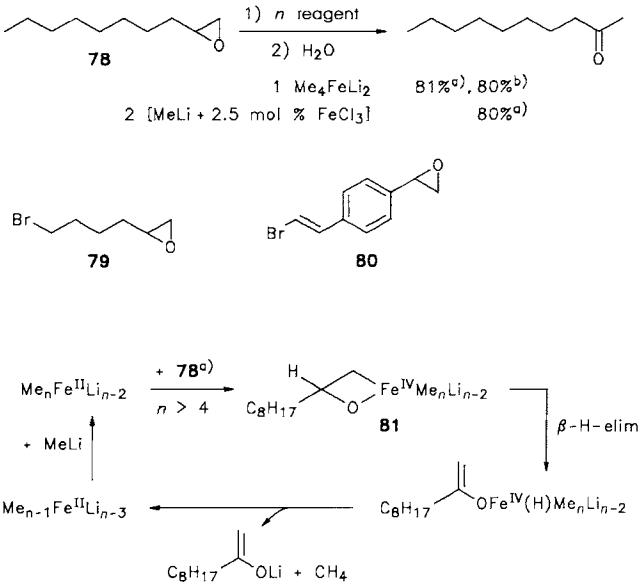
(*Z*)-Stilbene and tolane (as examples of substrates with a nonpolarized C–C multiple bond) were allowed to react with one molar equivalent of Me_3FeLi.[17a] The main reaction of *(Z)-stilbene* was its rearrangement to (*E*)-stilbene, making the presence of the radical **74** (and thus a one-electron oxidative addition) very probable. The formation of the by-products **75**–**77** can easily be explained, as shown in Scheme 39. Under the conditions given in Scheme 39, small amounts of several products were obtained from *tolane* (recovered in 65% yield), the most predominant of these were identified by GLC-MS coupling as **75** and **76**. When methyl phenylpropynoate, a substrate with a polarized C–C triple bond, was allowed to react with one equivalent of Me_3FeLi (THF, −78 to 20 °C in 18 h) the main product was methyl (*E,Z*)-2-methylcinnamate (66%) with a *Z*/*E* ratio of 67:33[17a] (for comparison the corresponding reactions with other ate-complexes: with Me_3MnLi *Z*:*E* = 4:96;[17d] with Me_2CuLi according to ref. [78] 100% *Z*-selectivity, but according to ref. [17a] *Z*:*E* = 75:25).



Scheme 39. Products formed from (*Z*)-stilbene and Me_3FeLi and mechanistic rationale for their formation [17a].

5.3. Regiospecific Epoxide Rearrangement

Terminal aliphatic epoxides can undergo rearrangement to aldehydes when treated with Lewis acids.[79] Their rearrangement to give methyl ketones, which has previously been carried out with $Co_2(CO)_8$ or noble metal catalysts (for a survey see ref. [46]), also occurs in high yields when Me_4FeLi_2, Me_3FeLi, or the catalytic systems [RLi +2.5 mol% $FeCl_3$] (R = Me, *n*Bu)[17g, p, 46] are used (for an example see Scheme 40). Alkylating ring opening, the main reaction when alkyl derivatives of Cu^I and Ti^{IV} react with epoxides, is not observed. Me_4CoLi_2 and Me_4NiLi_2 also cause terminal aliphatic epoxides such as **78** to rearrange to methyl ketones, but the yields are lower (ca. 30%) because of the occurrence of side reactions. The following order of the electrophilicity towards Me_4FeLi_2 was determined by means of competition experiments with two substrates carried out in analogy to Scheme 8: 1-alkenyl bromides > ketones > terminal epoxides > alkyl bromides. Thus, this reagent reacts with **79** in a highly selective manner at the epoxide group (78% rearrangement) and with **80** at the vinyl bromide group (90% cross-coupling).[46] The aromatic epoxides styrene oxide and α-methylstyrene oxide are converted by Me_4FeLi_2 into product mixtures.[46] The mechanism formulated in Scheme 40, which involves the ferraoxetane **81**, was postulated for the catalytic rearrangement of 1-decene oxide (**78**) with [MeLi +2.5 mol% $FeCl_3$].[46] The stoichiometric rearrangement with Me_4FeLi_2 or Me_3FeLi probably occurs in an analogous manner.



Scheme 40. Rearrangement of terminal epoxides with Fe reagents [46]. a) Et_2O, −78 to 20 °C in 18 h; b) Et_2O, −78 °C 45 min.

6. Summary and Future Prospects

Alkyl derivatives of Cu^I, Mn^{II}, Ti^{IV}, and Ce^{III} have well-established uses in organic synthesis; the nonstabilized alkyl derivatives of Fe^{II} and Co^{II} as well as the alkyl-cyano-ferrates, -cobaltates, and -nickelates whose chemistry is discussed above form

a welcome addition to the arsenal of mild, selective alkylation reagents for organic electrophiles (Table 6 gives a summary of favorable applications). Such compounds are clearly superior to the alkyl–Cu^{I} and alkyl–Mn^{II} reagents (the reactivities of which are comparable) in several respects. These observations, as well as some unexpected reactions (Schemes 31, 32, and 40) point (in comparison with alkyl derivatives of Cu^{I} and Mn^{II}) to an increased willingness to undergo oxidative addition with electrophiles. Depending on the reactivity of the substrates this can apparently be either a *two-electron oxidative addition* (for organic halides that are not S_N1-active; see Scheme 13, 18, and 34) or a *one-electron oxidative addition* (for unsaturated compounds that can stabilize unpaired electrons, see Schemes 37A and 39). It is not surprising that alkyl derivatives of Fe^{II} are particularly willing to tolerate the oxidative addition of electrophiles, since the stability of the divalent oxidation state of the elements Mn, Fe, Co, and Ni is at its lowest for Fe.[8] The cyanide ligands of the cyano-ate complexes of Fe, Co, and Ni prevent β-H-elimination subsequent to the oxidative addition of alkyl halides and thus facilitate cross-couplings with these substrates in high yields. As far as Fe-catalyzed alkylations (in principle long-known) is concerned (see Section 3.7), the extremely high selectivity and the nature of the active species has been recognized.

Table 6. Alkyl complexes of Fe, Co, Ni, Cu, and Mn that can be recommended as reagents for C–C bond formation reactions with the given organic electrophiles (*n*Oct = *n*-octyl)

Substrates	Reaction type	Reagents
1-alkenyl halides		
Hal = Br	cross-coupling	Me_4MLi_2 (M = Fe, Co), nBu_4FeLi_2, $nOct_2Fe$, $Me_2Fe(CN)_2Li_2$
Hal = Br	cheleselective cross-coupling	Me_4FeLi_2, R_4MnLi_2 (R = Me, *n*Bu)
Hal = Cl	cross-coupling	Me_4MLi_2 (M = Fe, Co), Me_3CoLi
Hal = F	cross-coupling	Me_4CoLi_2
1-bromo-4-phenyl-1,4-butadiene	cross-coupling	Me_4CoLi_2
1-alkenyl triflates	cross-coupling	Me_4FeLi_2
acyl chlorides	cross-coupling	alkyl-Mn^{II} reagents, Me_2M (M = Fe, Co), nBu_2Fe, nBu_3FeLi
1-halogenonaphthalenes		
Hal = Br	cross-coupling	$Me_3M(CN)_2Li_3$ (M = Fe, Co)
Hal = Cl	cross-coupling	$Me_3Co(CN)_2Li_3$
Hal = F	cross-coupling	$Me_4Co(CN)_2Li_4$
bromobenzene	cross-coupling	$Me_3Co(CN)_2Li_3$
1-alkynyl halides (Hal = Br,Cl)	cross-coupling	$MeCo(CN)_2Li$, Me_4FeLi_2
alkyl halides (Hal = Br, Cl)	cross-coupling	alkyl-Cu^{I} reagents, $Me_nFe(CN)_2Li_n$ (n = 2–4), $R_4Ni(CN)_2Li_4$ (R = Me, *n*Bu)
gem. dichloroalkanes	methylenation	Me_4FeLi_2
allyl halides (Hal = Br, Cl)	cross-coupling without rearrangement	Me_4MLi_2 (M = Fe, Co) al well as alkyl-Fe- and alkyl-Co-reagents with functional groups in the alkyl groups (see Scheme 4)
4-*tert*-butylcyclohexanone	equatorial-diastereoselective addition	Me_2Fe, Me_3FeLi, nBu_2Fe
conjugated enones	1,4-addition	alkyl-Cu^{I} reagents
PhCOOEt	substitution	Me_2CuLi
	substitution +addition	Me_4CoLi_2

An appropriate continuation of the investigations described above[80] would involve the extension of the chemistry of the cyano-ate complexes of Fe, Co, and Ni, which have so far only been subjected to reaction with organic halides, to include unsaturated organic compounds, the exploration of the potential of alkyl derivatives of these metals as mild alkylating reagents for electrophilic heteroarenes, and the question as to whether super-ate complexes—possibly in combination with chiral anionic ligands—of Mn, Co, and Ni can function as highly selective alkylation catalysts.

I thank those co-workers (their names can be found in the list of references) who were members of the highly effective team that worked with great personal initiative on the research group's last project (either nerved by failures or inspired by successes) and who did not let the gas chromatographs get cold even during the Institute's holiday periods! Those who were involved in the project thank the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie for financial support.

[69] The alkyl–Ce^{III} reagents (RLi or RMgHal + $CeHal_3$) described by T. Imamoto (*Pure Appl. Chem.* **1990**, *62*, 747–752, and references therein) behave more like Category A reagents (ready addition to enolizable ketones because of their low basicity, as for alkyl–Ti^{IV} compounds; 1,2-addition to conjugated enones) than category B reagents (nBuCeI$_2$ reacts with 4-iodoacetophenone not by cross-coupling but at the keto group to give 4-I-$C_6H_4C(OH)(CH_3)C_4H_9$ in 93% yield; no cross-coupling reactions with other aryl halides or with 1-alkenyl halides are known). However, their ready addition to esters and amides of carboxylic acids as well as to nitriles demonstrates a behavior that is untypical of category A reagents.

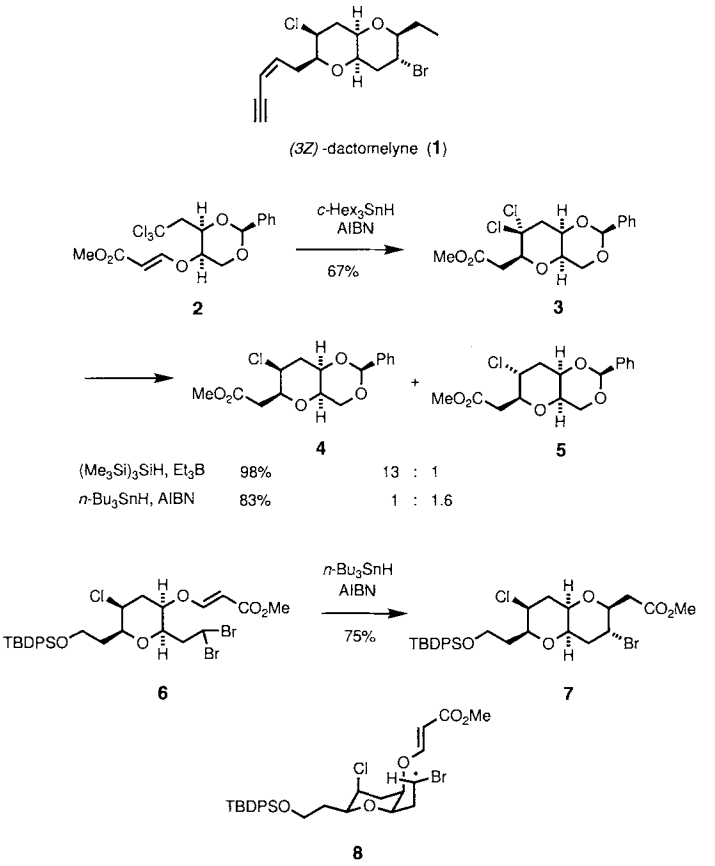
Radical Reactions as Key Steps in Natural Product Synthesis

Ulrich Koert*

Radical reactions have developed into indispensable methods in organic synthesis[1] and are often used as key steps in the construction of complex natural products. Impressive demonstrations are found in the following examples taken from the current literature: the synthesis of dactomelyne by Lee et al.,[2] that of camptothecin by Curran et al.,[3] and of 7-deoxypancratistatin by Keck et al.,[4] and the approaches towards aspidospermidine by Murphy et al.[5] and pseudopterosin A by Schmalz et al.[6]

The total synthesis of the marine natural product (3*Z*)-dactomelyne (**1**) requires the elaboration of the *cis*-linked pyranopyran skeleton and the stereoselective introduction of halogen atoms on the tetrahydropyran rings. Lee et al.[2] solved this problem by using β-alkoxyacrylates twice as radical acceptors. Radical cyclization of the trichloro compound **2** afforded the bicyclic product **3**. The selective monodehalogenation of the dichloro compound **3** giving **4** was accomplished with a radical reaction as well. Important for the desired stereoselectivity was the use of the silane $(Me_3Si)_3SiH$. Stannanes like nBu$_3$SnH gave the other epimer **5** as the major product. The highlight of the synthesis was the construction of the second tetrahydropyran ring and simultaneous stereoselective introduction of the bromo-substituted stereocenter: the radical reaction of β-alkoxyacrylate **6** with nBu$_3$SnH gave exclusively the desired bicyclic product **7**. The authors propose the chairlike transition state **8** to explain the observed stereoselectivity. The bicyclic product **7** was converted in a few steps into the target compound (3*Z*)-dactomelyne (**1**).



The potent antitumor agents camptothecin (**11**) and its derivatives are currently the targets of extensive synthetic activities.[7] A major contribution to this research area came from the laboratory of D. P. Curran[3] in Pittsburgh with a total synthesis of camptothecin relying on radical chemistry. In the key step of this synthesis the iodoalkyne **9** was allowed to react with phenyl isonitrile to provide the target compound **11**. In this radical cascade reaction, an excellent example of a "sequential reaction",[8] the simultaneous construction of the B- and C-rings of camptothecin was accomplished. The mechanism for radical reaction is best explained by the transformation of the structurally less complex bromoalkyne **12** into the tetracyclic compound **16**. First, a trimethylstannyl radical produced from hexamethyldistannane attacks the C–Br bond of compound **12**.

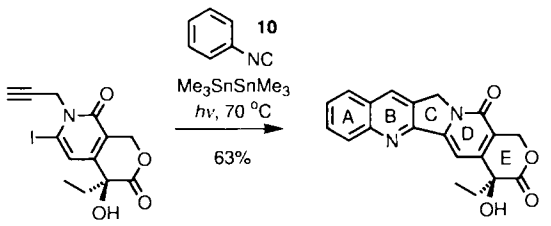
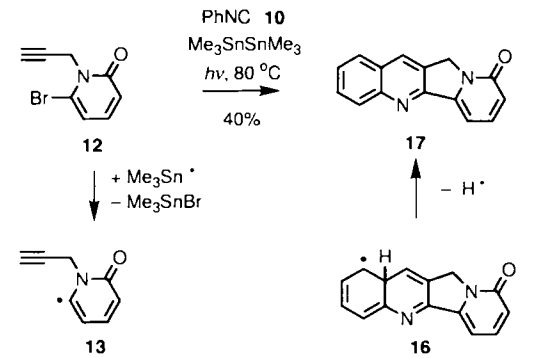
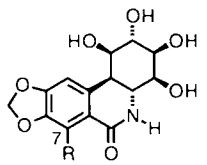
Fax: Int. code +(6421)288-917

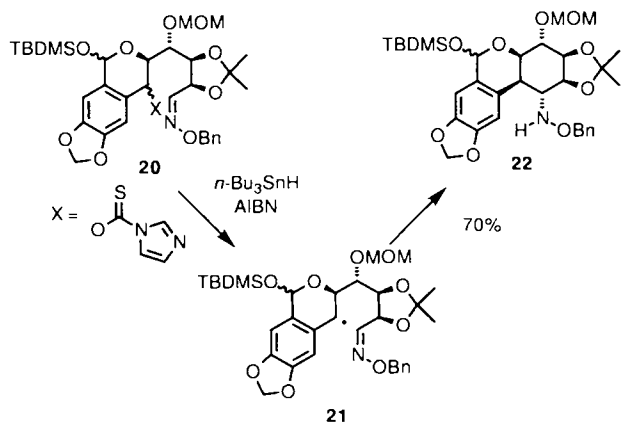
The resulting pyridone radical **13** reacts intermolecularly with isocyanide **10** to yield the radical intermediate **14**. An intramolecular attack of the radical center in **14** on the alkyne functionality leads to radical **15**. Finally, the A-ring is attacked by the radical center in **15** leading to **16**, which rearomatizes to yield the desired compound **17**.

The alkaloid pancratistatin (**18**) isolated from *Amaryllidaceous* plants displays promising antineoplastic and antiviral activity.[9a] The 7-deoxy compound **19** exhibits both better therapeutic properties and decreased toxicity.[9b] The group of G. E. Keck[4] successfully completed the total synthesis of 7-deoxypancratistatin (**19**) using a radical reaction as a key step. Here, the radical precursor **20** was treated with nBu$_3$SnH to yield the benzyl radical **21**, which reacted further by a 6-*exo* cyclization affording the cyclohexylamine **22**. Important for the excellent stereoselectivity of this step was the conformational control dic-



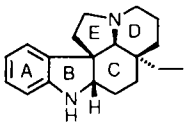


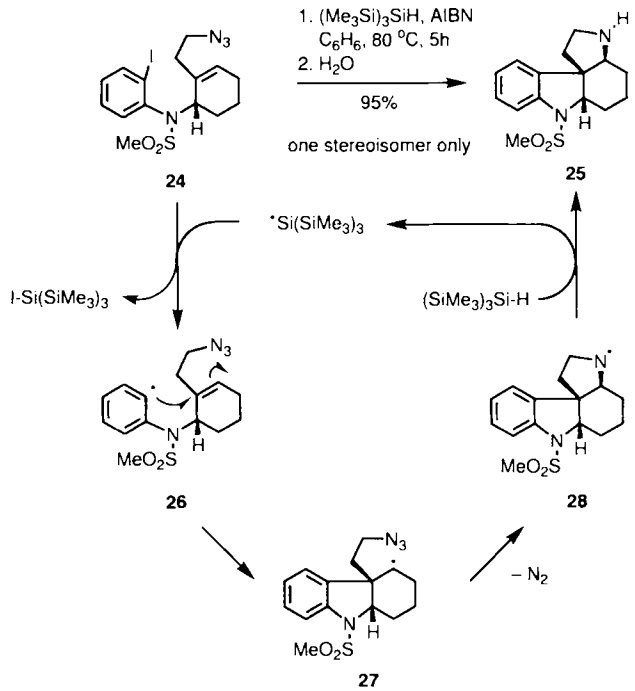




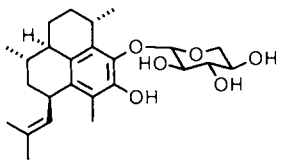
tated by the *tert*-butyldimethylsilyl (TBDMS) protected six-membered lactol ring. Compound **22** was then transformed in few standard steps into the target compound **19**.

J. A. Murphy et al.[5] were able to show the synthetic potential of radical reactions in a short and efficient synthesis of the ABCE ring system of aspidospermidine (**23**). They used a tandem radical cyclization to directly convert the aryl iodide **24** into the tetracycle **25**. The mechanism of this reaction sequence was rationalized as follows: A silyl radical produced from $(Me_3Si)_3SiH$ attacks the aryl iodide bond in **24** forming the aryl radical **26**. Intramolecular attack of the radical center in **26** on the double bond then affords the alkyl radical **27**. Lastly, addition of this alkyl radical to the azide function followed by loss of N_2 gives the observed product **25** via the N-radical intermediate **28**. The high stereoselectivity and the excellent yield of this tandem radical cyclization is noteworthy.

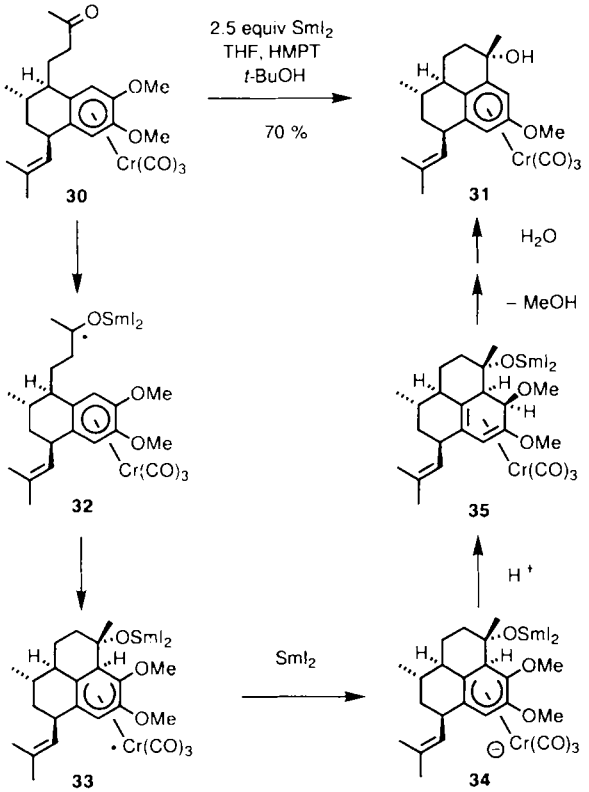




New perspectives are opened by the combination of radical reactions with organometallic chemistry, as was demonstrated recently by the group of H.-G. Schmalz at the TU in Berlin.[6] In the course of synthetic studies towards pseudopterosin A (**29**) and related compounds they succeeded in the SmI_2-induced cyclization of the arenetricarbonylchromium complex **30** to give the tricyclic pseudopterosin scaffold **31**. The authors propose the following mechanism for this reaction: In the first step the ketyl radical **32** is produced, which adds to the arene ring to give **33**. A second transfer of one electron by SmI_2 affords the anionic η^5 complex **34**. Subsequent protonation yields η^4 complex **35**, from which the final product **31** is obtained after elimination of methanol and hydrolytic workup. It should be noted that the pendant trisubstituted double bond does not lead to any side reactions.



pseudopterosin A (**29**)



The present selection of natural product syntheses with radical reactions as key steps demonstrates the extraordinary potential applications of modern radical chemistry. However, one limitation is evident: four out of the five reaction sequences presented involved an intramolecular cyclization reaction.[10] Intermolecular radical bond formations with high yields and stereoselectivities are still very rare in the total synthesis of bioactive compounds. One exception is the camptothecin synthesis by Curran et al. However, progress in acyclic stereoselection of radical reactions[11] should soon help to formulate new solutions for these synthetic challenges.

Enantioselective Catalytic Hydrogenation

Judith Albrecht and Ulrich Nagel*

Enantioselective catalysis is one of the most important tools in asymmetric synthesis.[1, 2] With its assistence biologically active substances can be prepared in enantiomerically pure form—this purity can be a crucial factor with pharmaceutical products. In the field of crop protection the use of enantiomerically pure compounds provides irrefutable advantages for both economic and ecological reasons.[3, 4]

Enantioselective transition metal catalyzed hydrogenation has an important place among the methods of asymmetric synthesis. A large range of substrates can be enantioselectively hydrogenated in this way, which is extremely important for the preparation of natural and also nonnatural amino acids, because it enables the directed synthesis of all possible amino acid derivatives from the many prochiral enamides and ketones. Recently great progress has been made in this field. Very high *ee* values are achieved, and even sterically demanding substrates like β,β-disubstituted enamides are able to be hydrogenated in good optical yield.[5, 6]

Since the beginning of the 90's Burk et al. have been exploring the development of novel electron-rich phosphane ligands that give powerful catalysts for enantioselective hydrogenation on complexation with rhodium.[7] The ligands they use each contain two phospholanes *trans*-substituted in 2,5 position, whose

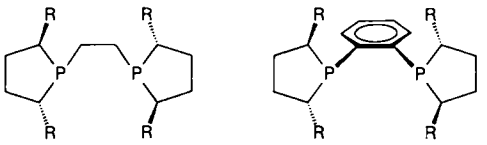
phosphorus atoms are linked together through different groups as backbone. The carbon atoms adjacent to the phosphorus atoms are chiral and in these catalysts are situated in the immediate vicinity of the rhodium atoms (Scheme 1).



BPE DuPHOS

Scheme 1. The bisphospholane ligands BPE and DuPHOS; R = Me, Et, *n*Pr, *i*Pr (to give Me-, Et-, *n*Pr-, and *i*Pr-BPE or -DuPHOS).

Initially the phospholanes were synthesized by derivatization of homochiral 1,4-diols with mesyl chloride. The dimesylates were then transformed into the 2,5-disubstituted phenylphospholanes with dilithiumphenylphosphide. The phenyl group was cleaved with pure lithium metal, and the resulting lithium phosphide could then be converted into the bridged system with 1,2-dichloroethane, ethyleneglycoldi-*p*-tosylate, or 1,3-dichloropropane. The yields with this synthetic route were moderate and depended strongly on the purity of the lithium metal.[8]

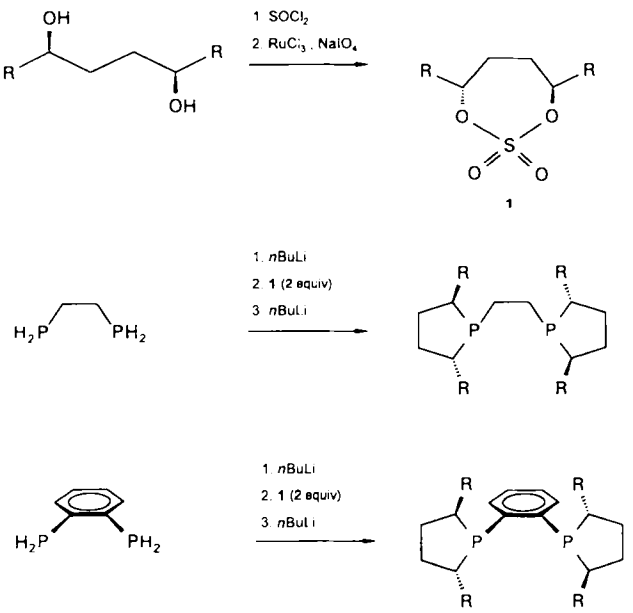
A later optimized synthesis also starts from the 1,4-diols. They are then converted into cyclic sulfates with thionyl chloride on mediation of ruthenium chloride and sodium periodate. The sulfates are transformed with dilithiumbis(phosphido)-ethane into bis(phospholanyl)ethane ligands (BPE) or with dilithium-1,2-bis(phosphido)benzene into a bis(phospholanyl)-benzene (DuPHOS) ligand. Ring closure to form phospholanes is achieved by addition of *n*BuLi[9] (Scheme 2).

The differently substituted BPE and DuPHOS rhodium complexes were applied in the hydrogenation of *N*-acetyl enamines. Of the BPE ligands, the ethyl-substituted derivative gave the highest *ee* values (93% for methyl α-acetylaminocinnamate and 98% for methyl α-acetylaminoacrylate). Higher enantioselectivities were achieved with the DuPHOS ligands. Under optimized conditions some systems afforded *ee* values of over 99%. In particular the sterically demanding *n*Pr-DuPHOS gave *ee* values of 99.8% (enantiomer ratio 1000:1).

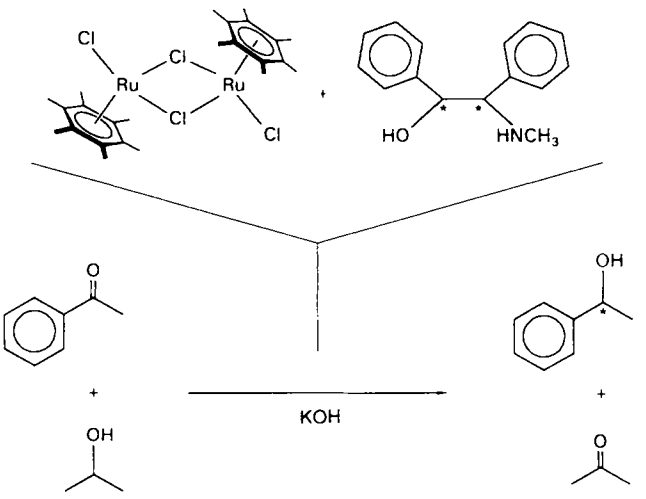
In all enantioselective hydrogenations the ability of the substrate to form a chelate ring with the catalyst is extremely important. For this reason the enantioselective reductive amination of ketones is always particularly difficult, because these compounds usually do not have a structure suitable for the required chelation. Burk et al. circumvent this problem by reversible derivatization. The ketones are converted into *N*-acetylhydrazones, whose structures resemble those of enamides.[10] The C–N double bond can then be hydrogenated by *n*Pr-DuPHOS–rhodium with *ee* values almost as high as those for C–C double bonds of enamines. The *N*-acetylhydrazines obtained thus can either be transformed into the free hydrazines by acid hydrolysis or into amines by treatment with samarium diiodide. In this way a large number of ketones can be reductively aminated.[11]

To hydrogenate prochiral ketones to the corresponding chiral alcohols, Noyori et al. have developed ternary catalyst systems from $[RuCl_2(binap)(dmf)_n]$, a chiral diamine, and KOH.[12, 13] By this route methyl(1-naphthyl)ketone can be hydrogenated to 1-(1-naphthyl)ethanol with $[RuCl_2(binap)(dmf)_n]$, 1,2-diphenylethyldiamine, and KOH in the ratio 1:1:2 in 2-propanol (substrate:catalyst = 500:1, 4 bar H_2, 28 °C, 6 h) in greater than 99% yield with 97% *ee*.

Other sources of hydrogen can be used instead of elemental hydrogen gas. In transfer hydrogenations a secondary alcohol has been employed as hydrogen donor. Noyori et al. have also made advances in this field. They use a catalyst system from $[RuCl_2(\eta^6\text{-mesitylene})]_2$, *N*-(*p*-toluenesulfonyl)-1,2-diphenylethylenediamine, and KOH in 2-propanol. At room temperature acetophenone can be reduced in 15 h with this complex prepared in situ (substrate:catalyst = 200:1) to 1-phenylethanol in 95% yield with an optical purity of 97%.[14] Catalyst systems with a β-amino alcohol as auxiliary are faster, as shown by the reduction of acetophenone to 1-phenylethanol under otherwise identical conditions with $[RuCl_2(\eta^6\text{-hexamethylbenzene})]_2$, 2-methylamino-1,2-diphenylethanol, and KOH within as little as 1 h in 94% yield and 92% *ee* (Scheme 3).[15]



Scheme 2. Synthesis of BPE and DuPHOS ligands.

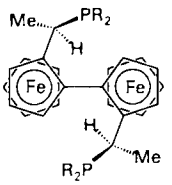


Scheme 3. Transfer hydrogenation of acetophenone.

The *N*-acetylhydrazones used by Burk et al. are ketone derivatives, and their structures therefore correspond to those of the β,β-disubstituted *N*-acetylaminoacrylic acids. This and the finding that both the (*E*)- and the (*Z*)-enamides are hydrogenated with almost the same enantioselectivity by the BPE and DuPHOS complexes prompted them to investigate the ability of the phospholane ligands to enantioselectively hydrogenate β,β-disubstituted *N*-acetylaminoacrylic acids.[5]

Attempts to use the ligands Et-, *n*Pr-, and *i*Pr-DuPHOS, which were most successful for the *N*-acetyl enamines, gave unsatisfactory results: the *ee* values were 74, 45, and 14%, respectively. In supercritical CO_2 as solvent[16] they improved to 90%. The use of supercritical CO_2, however, puts a greater demand on the hydrogenation apparatus than conventional conditions, since it must be able to withstand high pressures. The temperature must also be precisely controlled, because in supercricital systems merely a small temperature difference can lead to enormous effects.

The *trans* chelate ligands developed by Ito et al. are also used for enantioselective hydrogenation of β,β-disubstituted *N*-acetylaminoacrylic acids.[6] These ligands fall into the class of TRAP ligands (Scheme 4, TRAP = 2,2″-bis[1-(dialkylphosphanyl)-ethyl]-1,1″-biferrocene), with which good *ee* values are achieved. Methyl α-*N*-acetylamino-β,β-dimethylacrylate can be hydrogenated with Bu-TRAP at a catalyst:substrate ratio of 1:1000 in 24 h (15 °C, 1 bar H_2) to form the corresponding propane carboxylic acid in 88% *ee*.



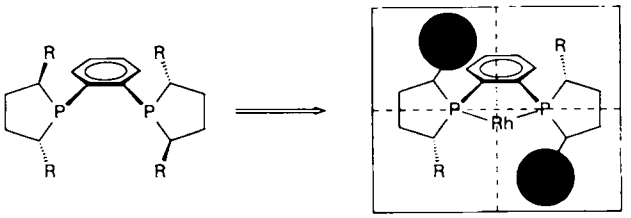
Scheme 4. Ito's TRAP ligand.

Further progress in the hydrogenation of β,β-disubstituted *N*-acetyl enamines was made with the sterically less hindered Me-DuPHOS–rhodium catalyst. In this system an *ee* value of 92% was obtained.[5]

The best enantioselectivities till now have been reached with the Me-BPE ligand. With this ligand a large variety of β,β-disubstituted *N*-acetyl enamines were hydrogenated with very high *ee* values of over 99% in some cases. For a catalyst:substrate ratio of 1:500 under mild conditions (25 °C, 6 bar H_2) β-methyl- and β-ethylphenylalanine derivatives could be prepared from the corresponding β,β-disubstituted *N*-acetylaminoacrylates in 12–24 hours with optical yields of 99.4 and 99%, respectively.

The Pr-DuPHOS ligand is one of the best ligands for the hydrogenation of sterically less congested substrates, whereas for the sterically more demanding β,β-disubstituted compounds the ligand Me-BPE is the better choice. The astoundingly different behavior of derivatives of these catalysts is hard to predict, yet because of the opportunities for variation in the synthesis of the bisphospholanes, the broadest possible tailoring of the ligands to a problem at hand is assured.

An old but graphic picture to explain the enantioselectivities with different ligands is that of the blocked quadrants[17] (Scheme 5). The rigid benzene ring in the backbone of the



Scheme 5. Blocked quadrants.

DuPHOS ligands blocks two diagonally oriented quadrants at the metal atom through the substituents on the phospholane ring. The bulkier the substituent and the more rigidly it is held in its position, the better the quadrants are blocked. For most of the sterically less hindered substrates like β-monosubstituted acetylaminoacrylic acids the optimum is reached with the *n*Pr-DuPHOS ligand. The ligand in the catalyst may not be so bulky that the binding of the substrate is overly restricted. Thus the *ee* values for hydrogenations with the bulkier *i*Pr-DuPHOS–rhodium catalyst decrease.[9]

In the case of the tetrasubstituted acrylic acids the rigid DuPHOS ligands block both diagonally oriented quadrants so severly that the larger space requirements of these substrates cannot be accommodated. Here the more flexible Me-BPE ligand with its smaller methyl groups performs better.

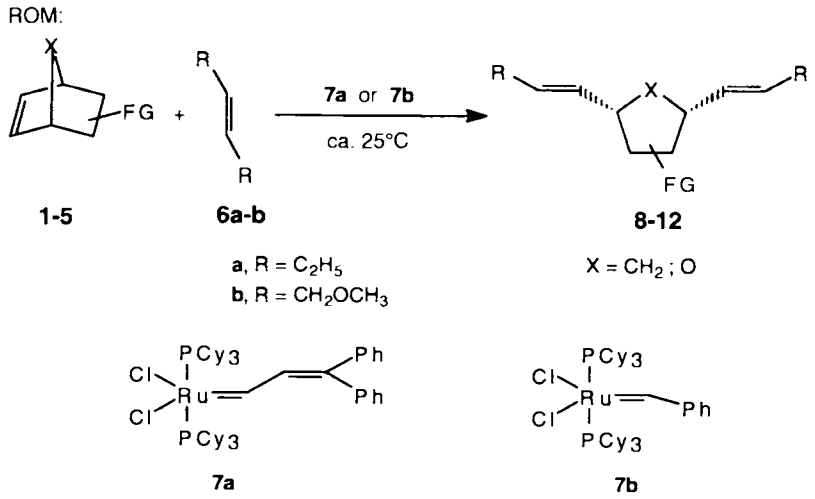
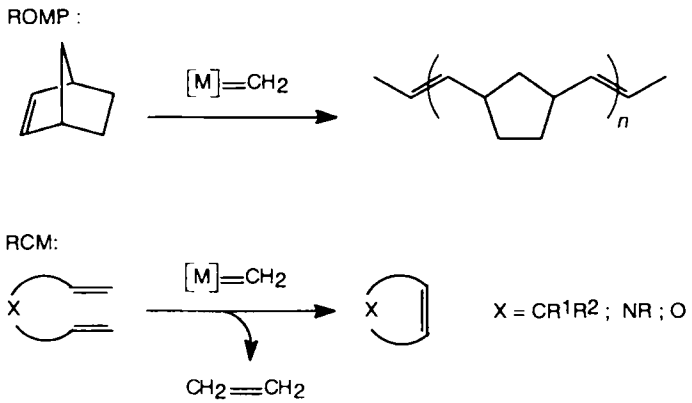
Synthesis of Highly Substituted Cyclopentane and Tetrahydrofuran Derivatives by Crossed Olefin Metathesis**

Matthias F. Schneider and Siegfried Blechert*

The metathesis of olefins, a reaction which has been known for many years, is the metal-catalyzed exchange of the alkylidene groups of two olefins.[1] This synthetically very interesting reaction has very often been employed in the past in ring-opening metathesis polymerization (ROMP).[2] More recently, many reports have been published about the use of ring-closing metathesis (RCM) for the synthesis of carbo- and heterocycles (Scheme 1).[3] The mechanism of such C–C coupling proceeds by [2+2]-cycloadditions and reversions of metal-alkylidene complexes.[4] With the discovery of novel catalysts[5] capable of tolerating a wider range of functional groups, olefin metathesis is becoming increasingly important.



Scheme 2. Crossed olefin metathesis. Top: synthesis of **8**–**12** from **1**–**5** and **6a,b**. FG = functional group. For conditions and results, see Table 1. Bottom: ruthenium catalysts used. Cy = cyclohexyl.



Scheme 1. Ring-opening methathesis polymerization (ROMP) and ring-closing methasis (RCM) with metal complex catalysts. [M] = metal complex fragment.

Mixed olefin metatheses, in which two different olefins are employed in a bimolecular C–C bond forming reaction, appears particularly exciting to us. We wanted to trap the intermediate from a ring-opening with a second alkene. In this way the production of monomers would be possible.

A crossed metathesis was recently described which involved the reaction of cyclobutene derivatives with monosubstituted alkenes.[6] With symmetrical olefins the reaction led exclusively to polymers. We now wish to report the successful crossed ring-opening metatheses (ROM) of functionalized bicycles with symmetrical olefins (Scheme 2).[7]

[**] This work was funded by the Fonds der Chemischen Industrie.

We utilized the ring strain of norbornene derivatives as the driving force for the ring opening. To avoid polymerization we carried out the reactions in dilute solution (max. 0.1 M) and with a tenfold excess of *trans*-3-hexene (**6a**). The ruthenium complex **7a**[8] was used as catalyst. The course of the reactions was followed by gas chromatography. The results are listed in Table 1.

The yields are high, with the exception of **11**. Because of the relatively high volatility of **8a**, **9**, and **10**, yields were determined by gas chromatography with octadecane as internal standard. The conversion of the crude products into less volatile substances led to similar yields (for example, the conversion of **9** into the diol with $LiAlH_4$ and subsequent workup: 94% over two steps). The lower yield obtained from the ring-opening of the β-lactam **4** is apparently due to the competitive formation of oligomers detectable with ^1H NMR spectroscopy and mass spectrometry. In this case the polymerization cannot be avoided by use of higher dilution. As expected, the double bond in the newly formed olefins does not always have the same conformation. Mixtures of all-*trans* and *cis*-*trans* products are formed. In every case, the major product is the all-*trans* compound. In the case of **11a** a small amount of the all-*cis* olefin was also detected.

After the successful reaction with *trans*-3-hexene (**6a**), we investigated reactions with the diacetate of *cis*-2-butene-1,4-diol. The desired reactions did not take place with this substrate. Consistent with other experiments we have carried out, the catalyst **7a** apparently does not tolerate allylic acetates or carbonates. However, reactions with *trans*-1,4-dimethoxy-2-butene (**6b**) were successful, as shown by examples with **8b** and **12b**.

These ring openings are not restricted solely to norbornene derivatives. The Diels-Alder adduct **5**, readily accessible from furan, can be used in crossed olefin metathesis, yielding products in high yield (see Table 1, **12a,b**).

The reactions described above proceed by cycloadditions and cycloreversions. The conformation of the olefin should therefore influence the course of the reaction. The use of *cis*-3-hexene

[a] Benzene. [b] CH_2Cl_2. [c] 10 equiv *cis*-3-hexene **6c**. [d] 1.5 equiv *cis*-3-hexene **6c**. Isomer ratio cannot be determined unequivocally. BOC = *tert*-butoxycarbonyl. TBDMS = *tert*-butyldimethylsilyl.

6c provided confirmation of this supposition. The reaction with **1**, under otherwise identical conditions as those described for **6a**, proceeded significantly more rapidly. After 3 h the conversion of **1** was essentially complete. The maximum yield was achieved after 5 h. In contrast, the required reaction time for **6a** was 19 h. The isomer ratio was essentially unchanged by the use of *cis*-3-hexene **6c**.

By capitalizing on the higher rate of reaction of **6c** and by use of the new ruthenium catalyst **7b**[5] we could also almost totally suppress the competing oligomerization found in the ring opening of the β-lactam **4**. Thus, the yield could be more than doubled to 73%.

The use of a smaller excess of the trapping olefin is desirable for worthwhile preparative use of ring opening metathesis. This was possible with a revised experimental methodology. The catalyst **7b** and only 1.5 equivalents of **6c** were added to CH_2Cl_2. Bicycle **1**, dissolved in CH_2Cl_2, was then slowly added over 4 h. The yield of 75% thus achieved is acceptable.

A mechanism for crossed olefin metathesis appears plausible in which the ring opening proceeds via a carbene complex of the acyclic olefin. A subsequent reaction of the cyclopentyl-substituted carbene complexes with the trapping olefin should lead to product and to renewed formation of the catalytically active carbene complex.

Bicycles **1**–**5** containing diverse substituents, many of which are enantiomerically pure, are easily accessible. The process described should therefore offer attractive possibilities for the preparation of highly substituted five membered rings.

Experimental Procedure

A typical procedure for ring opening metathesis can be illustrated with **8a**: All metatheses are carried out under an atmosphere of argon. Benzene or dichloromethane can be used as solvent. Ruthenium catalyst **7a** (5.2 mg, 5.6 μmol, 2 mol%) are dissolved in CH_2Cl_2 (2 mL). *trans*-3-Hexene **6a** (240 mg, 2.8 mmol) dissolved in CH_2Cl_2 (1 mL), and **1** (60 mg, 0.28 mmol) dissolved in CH_2Cl_2 (3 mL) were then added. The resulting mixture is allowed to stir at room temperature for 19 h. The reaction can be monitorred by gas chromatography. After complete conversion the solvent is removed under reduced pressure.

The crude product is purified by column chromatography (Kieselgel, Et_2O:isopentane = 1:9). Compound **8a** (70 mg, 0.238 mmol, 85%) is obtained as a colorless oil.

Variation of the metathesis with 1.5 equivalents of trapping reagent: ruthenium catalyst **7b** (14 mg, 16.6 μmol, 6 mol%) and **6c** (34 mg, 0.42 mmol) are dissolved in CH_2Cl_2 (6 mL). A solution of 58 mg (0.276 mmol) **1** in 12 mL CH_2Cl_2 is added to this solution over a period of 4 h by syringe pump, and the mixture is stirred for 13 h at room temperature. Yield: 75%.

All new compounds have been unequivocally characterized by spectroscopy. The structural determination was accomplished by two dimensional NMR spectroscopy and by NOE experiments. Spectroscopic data for (*E,E*)-**8a**: ^{1}H NMR (400 MHz, $CDCl_3$): δ = 5.51 (2H, dt, J = 15, 6 Hz), 5.40 (1H, ddt, J = 15, 7.5, 1 Hz), 5.22 (1H, ddt, J = 15, 8.5, 1 Hz), 3.65 (3H, s), 3.61 (3H, s), 3.25 (1H, dd, J = 10, 8.5 Hz), 3.04–2.91 (1H, m), 2.99 (1H, dd, J = 10.5, 8.5 Hz), 2.67 (1H, ddt, J = 10.5, 10.5, 7.5 Hz), 1.99 (4H, dq, J = 7.5, 6 Hz), 1.56–1.40 (1H, m), 0.95 (3H, t, J = 7.5 Hz), 0.92 (3H, t, J = 7.5 Hz); ^{13}C NMR (50.32 MHz, $CDCl_3$): δ = 174.7 (C), 173.4 (C), 133.9 (CH), 133.0 (CH), 129.9 (CH), 128.1 (CH), 52.3 (CH_3), 52.0 (CH), 51.7 (CH_3), 51.3 (CH_3), 47.1 (CH), 44.4 (CH), 39.2 (CH_2), 25.3 (CH_2), 13.7 (CH_3); IR (CCl_4): $\tilde{\nu}$ = 2964, 1736, 1436, 1199, 1169, 969 cm^{-1}. A Versatile New Preparation of Cyclopropylamines from Acid Dialkylamides**

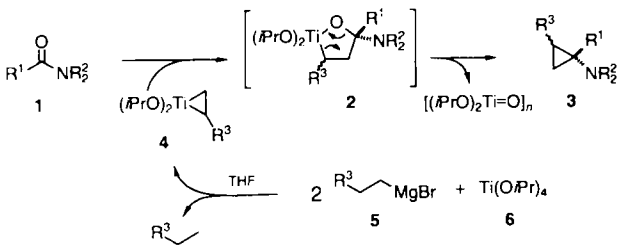
Vladimir Chaplinski and Armin de Meijere*

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

Not only has the cyclopropane ring established its role as a particular functional group[1] and as a part of valuable "composite functionalities"[2] in organic synthesis; it has also become indispensable as a skeleton or substituent in a variety of biologically active compounds.[3] Among the most important precursors for such compounds are cyclopropylamine and substituted cyclopropylamines, yet only a few methods exist for their preparation.[4] Our completely different approach to aminocyclopropanes from acid dialkylamides, which appears to have a wide potential, complements existing methodology and substantially broadens the range of easily accessible derivatives.

The facile preparation of cyclopropanols from alkyl carboxylates and ethylmagnesium bromide (EtMgBr) in the presence of titanium tetra(2-propanolate)[5] [Ti(O*i*Pr)$_4$] was the force behind the idea to transform carboxylic acid dialkylamides **1** to cyclopropylamines in an analogous way. Indeed, when *N*,*N*-dimethylacetamide was treated analogously to an ester[5b] with 2.1 equivalents of EtMgBr in the presence of 0.2 equivalents of Ti(O*i*Pr)$_4$, and the reaction mixture worked up appropriately, 1-dimethylamino-1-methylcyclopropane (**3a**) was obtained, but in poor yield ($\leq 30\%$).

The yield was significantly improved when a stoichiometric amount (1 equivalent with respect to **1**) of Ti(O*i*Pr)$_4$ was employed (Scheme 1 and entry 1 in Table 1). The method is equally



Scheme 1. Synthesis of cyclopropylamines. For conditions and further details see Table 1.

applicable to acid *N*,*N*-dibenzylamides, but at elevated temperature[6] yields 1-alkyl-1-dibenzylaminocyclopropanes **3b–d** (entries 2–4), from which primary cyclopropylamines can be obtained by catalytic hydrogeneration.[7] Higher homologues of alkylmagnesium bromides give 1,2-dialkylsubstituted cyclopropylamines **3e–h** in moderate yields (35–51%, entries 5–8).

This demonstrates that the titanacyclopropane **4**, which is assumed to form by β-hydride elimination from a dialkyloxo-di(propan-2-olato)titanium intermediate initially formed from two equivalents of alkylmagnesium bromide **5** and titanium tetra(2-propanolate) **6**,[5,9] can add across the C=O double bond of an acid amide to give an amino-substituted titanaoxacyclopentane (**2**). Because of the oxophilicity of titanium and the poor leaving characteristics of the dialkylamino group, this intermediate apparently cycloreverts, probably aided by the attack of the donor solvent THF on titanium, to yield the aminocyclopropane **3** and an oligomeric titanium species, which is eventually solvolyzed to TiO_2. This must be the reason why yields of **3** drop drastically when substoichiometric amounts of Ti(O*i*Pr)$_4$ are employed.

It is remarkable that the titanacyclopropane **4** readily attacks the weakly electrophilic carbonyl group of an *N*,*N*-dialkyl-

amide.[10] That accepted, however, it is not surprising that *N,N*-dialkylformamides react more rapidly than higher acid amides. The procedure can be drastically simplified for formamides (entries 9–12 in Table 1) and yet gives better yields (69–74%). Although with two bulky isopropyl groups the reaction required heating under reflux for 3 days, the sterically congested cyclopropyldiisopropylamine **3m** was obtained from diisopropylformamide[11] in 76% yield, and even *N,N*-di-*tert*-butylformamide,[12] when treated with a threefold excess of the reagent at elevated temperatures for an extended time, gave cyclopropyldi-*tert*-butylamine (**3n**), the most highly congested tertiary amine known to date,[13] albeit in low yield. A competition experiment disclosed that the cyclopropanation of dibenzylformamide proceeds more rapidly than that of *tert*-butyl acetate. Dialkylformamides can also be cyclopropanated with reagents generated from β-substituted ethylmagnesium bromides and $Ti(OiPr)_4$, but the 2-alkyl-1-dialkylaminocyclopropanes **3o, p** are obtained with no or low diastereoselectivity only (entries 15, 16 in Table 1).

Experimental Procedure

General procedure for the cyclopropanation of acid *N,N*-dialkylamides: To a suspension of the alkylmagnesium bromide (50 mmol, 25% excess) in THF (200 mL, cooled to −78 °C) was added $Ti(OiPr)_4$ (20 mmol in 10 mL of THF) under nitrogen through a steel cannula. After the mixture had been stirred for 2 min, the dialkylamide (20 mmol in 10 mL of THF) was added, and the mixture allowed to warm to 20 °C. It was stirred for an additional 3 h before volatile amines (with boiling points close to that of THF and isopropyl alcohol together with THF were distilled from the reaction mixture, without adding water, under reduced pressure (100 Torr) into a cold trap (−78 °C). Addition of a solution of hydrogen chloride in ether precipitated the hydrochloride of the cyclopropylamine. The crystals were collected and recrystallized from $CHCl_3/Et_2O$.

Amines with higher boiling points (containing one or two benzyl, isopropyl, or cyclopropyl groups in addition to the newly formed cyclopropane ring) were isolated by first adding saturated ammonium chloride solution (150 mL) and water (50 mL), then filtering the solution to remove the any precipitate that may have formed, and extracting it with ether (3 × 50 mL) after the solution had been made basic (pH > 11) with 15% sodium hydroxide solution. The combined ethereal extracts were washed with saturated sodium chloride solution, dried over $MgSO_4$ or K_2CO_3, and concentrated under reduced pressure (amines with C_8–C_{11} were first converted into nonvolatile salts with hydrogen chloride solution). Large amounts were purified by distillation.

Simplified procedure for the transformation of dialkylformamides: To a solution of dialkylformamide (5 mmol) in THF (30 mL) was added $Ti(OiPr)_4$ (5.5 mmol) and then at ambient temperature within 20 s a 2.85 M ethylmagnesium bromide solution in ether (12.5 mmol, 4.4 mL). On warming to 45 °C the mixture turned black, and ethane was evolved. After the mixture had been stirred for an additional 10 h, it was treated with 15 mL of saturated ammonium chloride solution, filtered if necessary to remove precipitated TiO_2, and the filtrate extracted with ether (3 × 20 mL). The combined ethereal extracts were washed with 20 mL of sodium chloride solution, dried over K_2CO_3, and concentrated.

A Step-Growth Approach to Metal-Capped One-Dimensional Carbon Allotropes: Syntheses of C_{12}, C_{16}, and C_{20} μ-Polyynediyl Complexes**

Tamás Bartik, Berit Bartik, Monika Brady, Roman Dembinski, and J. A. Gladysz*

The three-dimensional and two-dimensional carbon allotropes, diamond and graphite, have been known since antiquity. However, the one dimensional carbon allotrope, which would consist of sp hybridized carbons, remains by comparison only exigously described. Over the last thirty years several syntheses have been claimed.[1, 2] Recently mixtures of lower (C_{16}–C_{28}) and higher (C_{75}–C_{150}) oligomers have been prepared by novel synthetic techniques with various organic endgroups.[3–6] These reports foreshadow many fascinating properties, the precise delineation of which requires samples that are homogeneous in chain length.

We have sought to prepare compounds in which elemental carbon chains span two transition metals. We previously isolated dirhenium μ-polyynediyl complexes of the formula $[\{Re^*\}(C\equiv C)_n\{Re^*\}]$ (n = 2, **C4**; 3, **C6**; 4, **C8**; $\{Re^*\} = (\eta^5\text{-}C_5Me_5)Re(NO)(PPh_3)$) from coupling or cross-coupling reac-

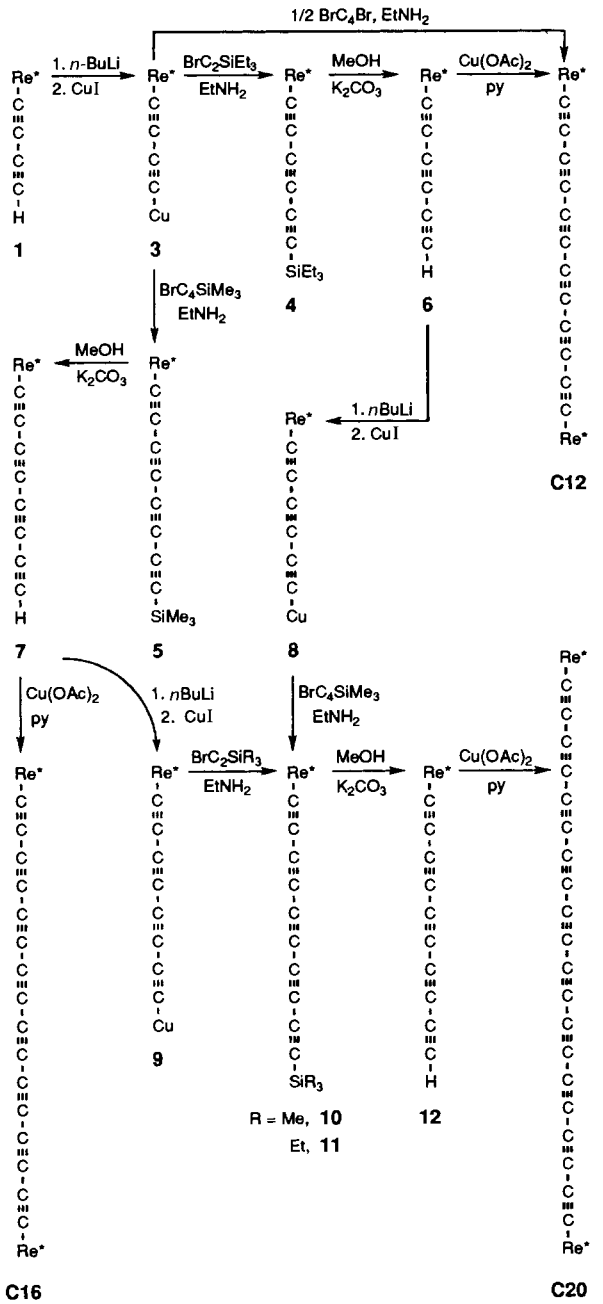
[**] We thank the National Science Foundation for support of this research.

tions of the corresponding [{Re*}(C≡C)$_n$H] species ($n = 1, 2$).[7] In this communication, we detail new step-growth chain extension methodology that leads to analogous complexes with up to twenty-carbon bridges. This strategy appears to carry no upper bound for chain length and should allow access to a complete family of well-defined oligomers.

The racemic butadiynyl complex [{Re*}(C≡CC≡CH)] (**1**; Scheme 1) was treated with *n*BuLi in THF (1.1 equiv, −45 °C) to generate the previously reported C_4Li complex [{Re*}(C≡C–C≡CLi)] (**2**).[8] Then CuI was added (− 20 °C). The sample was warmed and kept at room temperature for a short time. IR and ^{31}P NMR spectra showed broad signals indicating complete conversion to a new complex or mixture of complexes. These were presumed to have the empirical formula [{Re*}(C≡CC≡CCu)] (**3**; Scheme 1).[9]



Scheme 1. Syntheses of [{Re*}(C≡C)$_n${Re*}] [n = 6 (**C12**), 8 (**C16**), 10 (**C20**)]; {Re*} = (η^5-C_5Me_5)Re(NO)(PPh_3); py = pyridine.

Under suitable conditions copper-substituted and bromine-substituted alkynes couple to 1,3-diynes.[10] However, to our knowledge such "Cadiot-Chodkiewicz" protocols have not been applied in metal coordination spheres. Thus, solutions of **3** were treated with excess $EtNH_2$ (− 20 °C). Then $BrC{\equiv}CSiEt_3$[11] or $BrC{\equiv}CC{\equiv}CSiMe_3$[12] (1.0–1.1 equiv) were added. Workup gave the analytically pure C_6Si and C_8Si complexes [{Re*}(C≡CC≡CC≡CSiEt$_3$)] (**4**) and [{Re*}-(C≡CC≡CC≡CC≡CSiMe$_3$)] (**5**) in 51–77% yield after crystallization. Complexes **4** and **5** exhibited spectroscopic properties similar to those of lower homologs reported earlier.[7] However, IR spectra showed additional $\nu_{C\equiv C}$ bands.[9b]

Reactions of **4** and **5** with K_2CO_3/CH_3OH gave the corresponding C_6H and C_8H complexes [{Re*}(C≡CC≡CC≡CH)] (**6**) and [{Re*}(C≡CC≡CC≡CC≡CH)] (**7**) in 91–98% yield after workup. These were moderately air-sensitive as solids, and more air-sensitive in solution (**7** > **6**). Subsequent reactions with $Cu(OAc)_2$ (1.0 equiv, 50 °C) in pyridine gave the μ-dodecahexaynediyl and μ-hexadecaoctaynediyl complexes [{Re*}-(C≡C)$_6${Re*}] (**C12**) and [{Re*}(C≡C)$_8${Re*}] (**C16**) in 71–67% yield. Key properties are summarized below.

"Second generation" chain extensions of **6** and **7** were investigated. Reactions with *n*BuLi and CuI similar to those above were presumed to generate the C_6Cu and C_8Cu species [{Re*}(C≡CC≡CC≡CCu)] (**8**) and [{Re*}-(C≡CC≡CC≡CC≡CCu)] (**9**). Treatment of **8** with excess $EtNH_2$ and then with $BrC{\equiv}CC{\equiv}CSiMe_3$, as described for **3** above, gave the analytically pure $C_{10}Si$ complex [{Re*}-(C≡CC≡CC≡CC≡CC≡CSiMe$_3$)] (**10**) in 51% yield. Similar reactions of **8** and $BrC{\equiv}CC{\equiv}CSiEt_3$[13] or **9** and $BrC{\equiv}CSiEt_3$ gave the triethylsilyl analog **11** in 24–26% yields.

Reaction of **11** and K_2CO_3/MeOH gave a $C_{10}H$ complex, [{Re*}(C≡CC≡CC≡CC≡CC≡CH)] (**12**), which was partially characterized. The crude sample was treated with $Cu(OAc)_2$ in pyridine as described above. Workup gave the μ-icosadecaynediyl complex [{Re*}(C≡C)$_{10}${Re*}] (**C20**) in 41% yield. Finally, a more convergent chain extension route was probed. The C_4Cu species **3** was treated with excess $EtNH_2$ and then the *di*bromide $BrC{\equiv}CC{\equiv}CBr$.[14] Workup gave **C12** in 45% yield.

The sp carbon chains in **C12**, **C16**, and **C20** are by far the longest tether between two metals to date.[7, 8, 15, 16] All three compounds are microcrystalline or amorphous powders and show only slight decomposition after one week in air at room temperature. When heated they decompose (above 100 °C) without melting or explosion. Mass spectra exhibit strong molecular ions. Correct microanalyses have been obtained for **C12** and **C16**, but not yet for **C20**. Solubilities are high in CH_2Cl_2 and THF but low in hexane. In solution **C20** is noticeably more labile than **C12** or **C16**.[16]

Some physical properties of **C12**–**C20** should asymptotically approach those of a one-dimensional sp carbon allotrope. For example, ^{13}C NMR spectra show Re*C*≡*C* signals at $\delta = 127$–114. Interestingly, the remaining signals cluster in the narrow range of $\delta = 68$–63 (Fig. 1). Similar trends occur in mixtures of oligomers with organic endgroups, reported by Lagow.[3] Also, the colors of solutions deepen from red (**C12**) to black cherry (**C16**) to brown-black (**C20**). Accordingly, UV/Vis spectra exhibit progressively red-shifted bands of markedly increasing intensities, as illustrated in Figure 2. Some have molar extinction coefficients of well over 100000 $M^{-1}cm^{-1}$. Importantly, PES and MO studies of metal ethynyl and butadiynyl complexes[17] suggest that the HOMOs of **C12**–**C20** likely have appreciable metal d *and* (C≡C)$_n$ π character.

Cyclic voltammograms of **C4**–**C8** show two chemically reversible one-electron oxidations under suitable conditions.[7b]

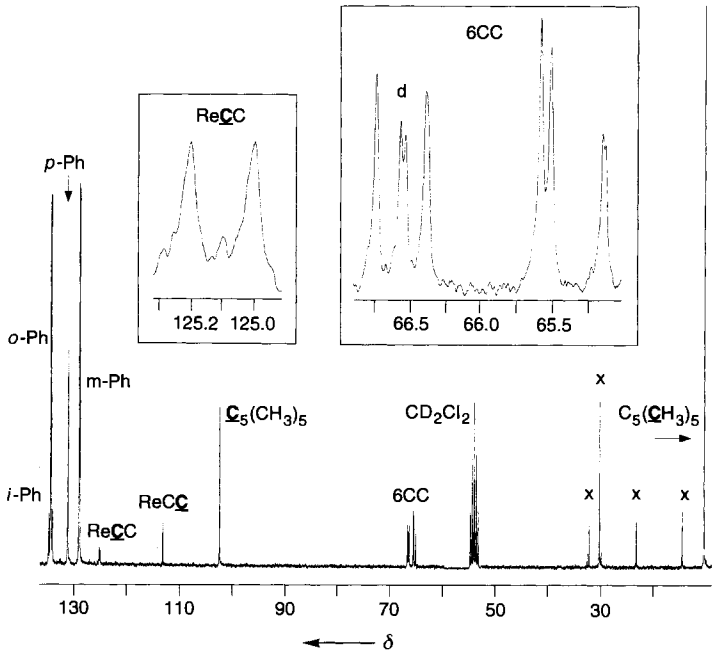


Fig. 1. ^{13}C NMR spectrum of **C16** (75 MHz, CD_2Cl_2, 20 °C) and expanded sp carbon region (insets); x = solvent impurities; d = doublet.

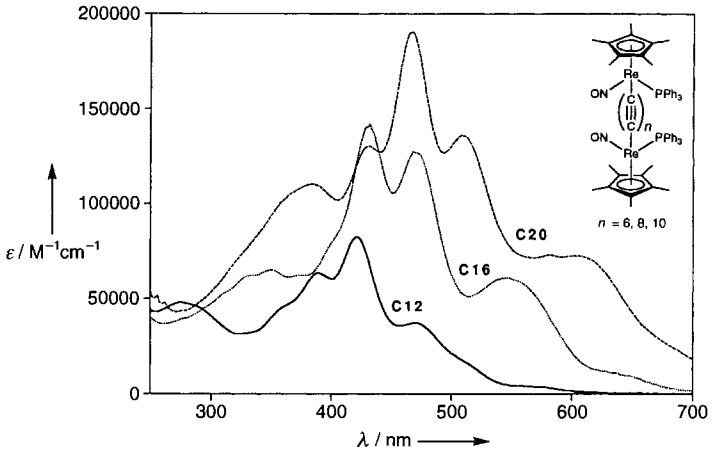

Fig. 2. UV/Vis spectra of **C12**, **C16**, and **C20** (CH_2Cl_2, ambient temperature).

Table 1. Cyclic voltammetry data [a].

Compound	$E_{p,a}$ [V]	$E_{p,c}$ [V]	E^0 [V]	ΔE [mV]	i_a/i_c [b]
C4	0.15	0.06	0.11	90	1
	0.68	0.59	0.64	90	1
C6	0.24	0.17	0.20	70	1
	0.62	0.55	0.58	70	1
C8	0.37	0.30	0.34	70	>1
	0.66	0.59	0.62	70	>1
C12	0.60	0.52	0.56	80	≫1
	0.79	0.69	0.75	100	≫1
C16	0.70	0.64	0.67	60	≫1
	0.79	0.73	0.76	60	≫1
C20	0.80	0.67	0.74	130	⋙1

[a] The first line shows the potential of the first oxidation, and the second line that of the second oxidation. **C20** undergoes only one oxidation (see text). $7-9\times10^{-5}$ M in 0.1 M $Bu_4N^+BF_4^-/CH_2Cl_2$ at ambient temperature, Pt working and counter electrodes, ferrocene standard, potential vs. Ag wire pseudoreference; scan rate 100 mVs^{-1}. p = potential. a = anode. c = cathode. [b] Improved reversibility is generally seen at lower temperatures.

These generate monocations and dications, which have been isolated in the C_4 series. Data acquired under identical conditions with **C12**–**C20** are summarized in Table 1. Some striking trends are evident. For example, as the carbon chain lengthens, the first oxidation potential becomes thermodynamically less favorable (**C4** vs. **C16**, $\Delta E^\circ = 0.56$ V). The second potential varies by a smaller amount (**C4**/**C6** vs. **C16**, $\Delta E^\circ = 0.12/0.18$ V). Consequently, the E° values approach each other, and with **C20** they merge to give a single—presumably two-electron—oxidation. This signifies the chain length at which the two rhenium atoms start to behave independently, at least in a redox sense.

The final step in each synthesis of **C12**–**C20** can be viewed as "convergent". However, especially for **C20**, a number of iterative steps are required. Importantly, many ways can be envisioned to optimize or combine the individual steps, or to employ longer building blocks. In summary, we have shown that it is possible to rationally synthesize metal-capped oligomers of sp carbon atoms that are homogeneous in chain length. Additional properties of the title compounds, and syntheses of analogs, will be reported in the near future.

Photochemically Induced Metathesis Reactions of Tetradehydrodianthracene: Synthesis and Structure of Bianthraquinodimethanes**

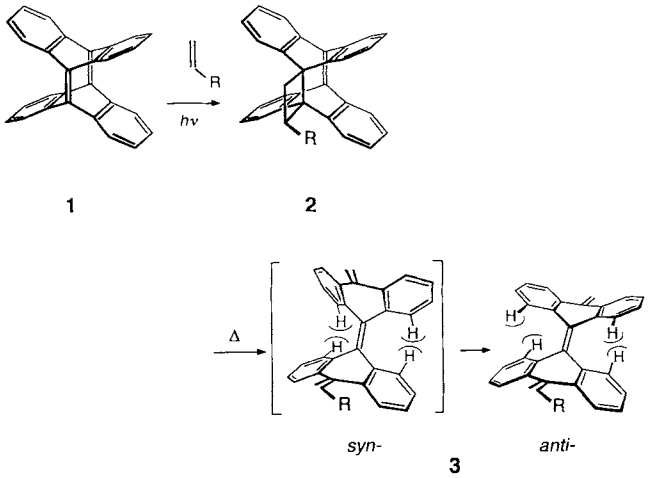
Stefan Kammermeier and Rainer Herges*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Photochemical [2+2] cycloadditions[1] with subsequent [2+2] cycloreversion in the sense of an overall metathesis reaction often lead to interesting products that are otherwise difficult to prepare.[2] With the example of 5,12:6,11-di[1,2]benzenodibenzo[*a*,*e*]cyclooctene[3] (9,9′,10,10′-tetradehydrodianthracene, ethylene*super*phane;[4] **1**), we demonstrate that this concept of two-step (photochemical and thermal) metathesis can be used to synthesize spherically deformed, polycyclic, aromatic hydrocarbons.

The highly strained, but stable diene **1** contains two bridgehead double bonds 2.42 Å apart,[3] which are *syn*-pyramidalized.[5] The unusual configuration (pyramidalization, through-space interaction) gives rise to a decrease in the $\pi-\pi^*$ gap, which is mainly due to a lowering of the LUMO.[6] Consequently, the reactivity of the double bonds towards electrophilic[7] and (even more pronounced) towards nucleophilic[8] reagents should be enhanced. Therefore **1** should be particularly reactive towards electron-rich alkenes in cycloadditions. As part of our investigations into the reactivity of **1** we performed photochemical [2+2] cycloadditions with a number of alkenes and cycloalkenes. Compound **1** gives three absorption bands in the UV range above 200 nm: 282 ($\varepsilon = 1270$), 270 ($\varepsilon = 2500$), and 233 nm ($\varepsilon = 10\,700$). The longest wavelength band can probably be attributed to the symmetry-forbidden $\pi-\pi^*$ transition and therefore to the excited state that correlates with the [2+2] cycloadducts.

Ethene adds photochemically (benzene, 150 W Hg high-pressure lamp, quartz, room temperature, 90 min) to **1** forming a very strained but isolable cyclobutane derivative **2a** in 32% yield (Scheme 1). Upon heating (toluene, 90 °C, 30 min) a cycloreversion[9] takes place to give the previously unknown, unsubstituted bianthraquinodimethane **3a** (yield 57%).[10, 11] Because of the repulsion between the *peri*-hydrogen atoms the bianthraquinoid systems cannot adopt a planar conformation. In contrast to bianthrone, which avoids this steric hindrance by distorting to a (more stable) *anti*-pyramidalized or a (less stable)



Scheme 1. Metathesis of tetradehydrodianthracene **1** with acyclic alkenes; **a**, R = H; **b**, R = Me. Important data of compounds **2a**, **3a**, and **3b** are given in Table 2.

twist conformation,[12] bianthraquinodimethane **3a** has, according to our calculations[13] at different levels of theory, an *anti*- and a *syn*-pyramidalized form as conformational minima. The twist conformation in this case is not a minimum. As expected, the *anti*-pyramidalized form (C_{2h} symmetry) is more stable than the *syn* isomer (C_{2v} symmetry).[6] At the highest level of theory applied the energy difference is 9.35 kcal mol^{-1} (Table 1). Presumably the *syn*-pyramidalized bianthraquinodimethane **3a**, which is formed upon thermochemical ring opening of **2a**, immediately changes pyramidalization to give the more stable *anti*-conformation (Scheme 1).

Table 1. Absolute electronic energies E_{tot} of both isomeric forms of the unsubstituted bianthraquinodimethane **3a** calculated at different levels of theory.

Level of theory	E_{tot} [Hartree]		ΔE
	anti-Isomer	*syn*-Isomer	[kcal mol^{-1}]
HF/3-21G	−1141.27370	−1141.25725	10.32
HF/6-31G*	−1147.68297	−1147.66766	9.60
Becke3LYP/6-31G*//HF/6-31G*	−1155.21041	−1155.19551	9.35

The product of the photochemical [2+2] cycloaddition with propene (**2b**) is not stable under our reaction conditions (see above). The thermochemical [2+2] cycloreversion giving **3b** (yield 53%) proceeds so fast that the cyclobutane intermediate could not be detected. This agrees with observations that the [2+2] cycloreversion of cyclobutanes is accelerated by alkyl substituents.[9] A rough estimation of the Gibbs activation energies[14] predicts that in our case the methyl group lowers the barrier of activation for the [2+2]cycloreversion by at least 5.5 kcal mol^{-1}. This is substantially more than in the cyclobutane parent system (1.3 kcal mol^{-1}).[9]

With cycloalkenes as reaction partner (toluene:cycloalkene = 5:1, 150 W Hg high-pressure lamp, quartz, room temperature, 120 min) cyclophane-like bridged bianthraquinodimethanes **5a** and **5c**–**e** (Scheme 2) were formed. In this case as well, the cyclobutane intermediates **4** could not be isolated. A by-product in all reactions is bianthryl (probably formed by hydrogen transfer from the cycloalkene to one of the double bonds of **1** and subsequent electrocyclic ring opening[15]). The cyclophane-like bridged bianthraquinodimethanes **5a** and **5c**–**e** are fixed by the alkane chain in the usually less stable *syn*-pyramidalized form. Moreover, the X-ray analysis of **5d** (Fig. 1)[16]

Scheme 2. Metathesis of tetradehydrodianthracene **1** with cycloalkenes. Important data of the product **5** are given in Table 2.

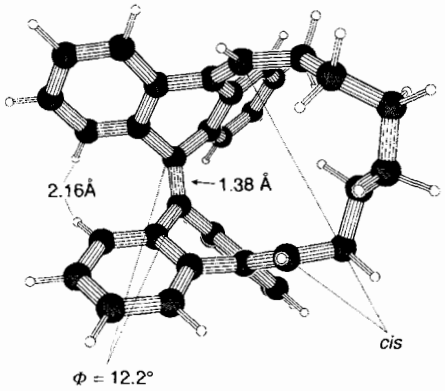

Fig. 1. Crystal structure of **5d**. Φ = pyramidalization angle at the olefinic carbon atoms.

proves that the aliphatic chain is *cis* with respect to both quinoid double bonds (C_s symmetry). The stereochemistry of the cycloalkene (*cis*) is preserved in both steps of the metathesis reaction.

The central pyramidalized double bond of **5d** in the X-ray structure is 1.38 Å long, and the pyramidalization angle is 12.2°. Both anthracenediylidene units are not planar but are bent outwards to resemble a roof. The central six-membered rings thus have a boat conformation. The distance between the *peri*-hydrogen atoms facing each other from the two anthracene units is only 2.16 Å. This is substantially less than the sum of the van der Waals radii. There is, however, no twist in the central double bond to compensate for the repulsive interaction.

Surprisingly, addition of cyclohexene to **1** is not observed. However, norbornene, which contains a conformationally fixed cyclohexene and norbornadiene, undergoes a metathesis reaction in relatively high yields.[17] NOE experiments with the metathesis product show that the addition proceeds in *exo* position.

The multiple addition of **1** to cyclic polyenes should be of interest for the generation of extended polyaromatic systems consisting of several bianthraquinodimethane units. The first step of such a metathesis reaction can be successfully performed by irradiation of **1** in benzene[18] (150 W Hg high-pressure lamp, quartz, room temperature, 4 h). In contrast with **5d**, in the ring-opened product **6** (yield 25%, Table 2), the unsaturated bridging chain has *trans* conformation with respect to both quinoid double bonds. The resulting C_2 symmetry[19] of **6** is verified by a strong NOE effect between the inner *peri*-hydrogen atoms that are spatially very close (in **5d** this distance is only 2.16 Å, see Fig. 1). If **6** had C_s symmetry (*cis* conformation of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3504-0418 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1996, 35, No. 4

the bridging chain), such a NOE effect could not be observed, because the facing hydrogen atoms would be magnetically equivalent. Presumably the *trans* product is preferred during metathesis on thermodynamic grounds. According to AM1 calculations[20], the *trans* form is about 9 kcal mol^{-1} less strained than the *cis*-bridged isomer.[21] In solution at room temperature the metathesis product **6** is in a rapidly established equilibrium with about 5–10% of an isomer or conformer that can be completely separated by HPLC (Silicagel Grom-sil, Si 100, 5 µ, column 250 × 20, petroleum ether:dichloromethane = 2:1). However, after a few minutes the original equilibrium again is restored. Because of the small amounts and its instability the less concentrated isomer could not be characterized.

In compound **6** the completely conjugated π system with 14 electrons in the perimeter is formally suitable for subsequent cycloadditions. In contrast to normal arenes, the p orbitals are not orthogonal to a common nodal plane but approximately perpendicular to the surface of a cylinder ("beltlike" conjugation). The repeated addition of **1** to **6**, as well as the dimerization or cyclic oligomerization of **1**, are further worthwhile avenues that we are currently pursuing. This could lead to beltlike molecules, which are interesting targets in view of the topical expanding field of research on molecular cavities and graphitic tubes.

[14] Eyring's equation was used for estimation of the activation parameters. The half-life for **2b** at 85 °C is 200 min (determined by NMR spectroscopy), which corresponds to a free energy of activation of 26.6 kcal mol^{-1}. The half-life for **3b** at 20 °C should be less than 10 min. An upper value for the free energy of activation of 21.1 kcal mol^{-1} can thus be derived.

[15] M. M. Weinshenker, F. D. Greene, *J. Am. Chem. Soc.* **1968**, *90*, 506.

[16] The *R* value of our X-ray structure analysis is only 0.103 because of the thermal flexibility of the alkane chaines. The topology of the structure, however, can be unambiguously derived from the data.

[17] Besides the low ring strain, symmetry grounds are most probably also responsible for the unusually low reactivity of cyclohexene. Presumably the C_2 conformation of the ground state is not favorable for an addition, because the transition state of the cycloaddition should have C_s symmetry according to the Woodward–Hoffmann rules. Thus, during the reaction an energetically unfavorable conformational transition of the cyclohexene ring from C_2 to C_s symmetry must take place. This explanation concurs with the fact that norbornene, which can be viewed as a C_s-fixed cyclohexene, reacts smoothly. All other reactive cycloalkenes have (at least local) C_s symmetry with respect to the π plane of the double bond. A remarkably low reactivity of cyclohexene towards cycloadditions for the series of cycloalkenes was also found by other groups. See, for example, T. Hierstetter, B. Tischler, J. Sauer, *Tetrahedron Lett.* **1992**, *33*, 8019–8022; A. Hassner, H. W. Pinnick, J. M. Ansell, *J. Org. Chem.* **1978**, *43*, 1774–1776; K. Ziegler, H. Froitzheim-Kühlhorn, *Liebigs Ann.* **1954**, *589*, 157.

[18] With copper(I) triflate as catalyst, irradiation times are shorter and the yields are somewhat higher: R. G. Salomon, J. K. Kochi, *Chem. Commun.* **1972**, 559–560; *Tetrahedron Lett.* **1973**, 2529–2532.

[19] The *cis* configuration of the hydrogen atoms at both double bonds in the bridging unit was deduced from the vicinal coupling constant ^3J(H,H) of 8.9 Hz. The coupling constant ^3J(H,H) of 9.0 Hz can be assigned to the coupling of the two quinoid hydrogen atoms and the neighboring vinyl H atoms.

[21] In the metathesis products **5a** and **5c–e** the *cis*-annelation is favored on thermodynamic grounds, according to AM1 calculations. Compound **5d**, which was shown to be *cis*-bridged by X-ray analysis, is 6.3 kcal mol^{-1} more stable than the corresponding *trans* isomer.

Structural Characterization of a Tris-Agostic Lanthanoid–H–Si Interaction**

William S. Rees, Jr.,* Oliver Just, Herbert Schumann,* and Roman Weimann

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

As speed and area efficiency demands in silicon-based electronic circuitry reach near-theoretical limits, attention is turning toward the potential for optical communication, computation, and connection. One approach to overcome the intrinsic direct band gap of silicon is to capitalize on the rich electronic manifold inherent in rare earth elements (Ln).[1] The initial work in

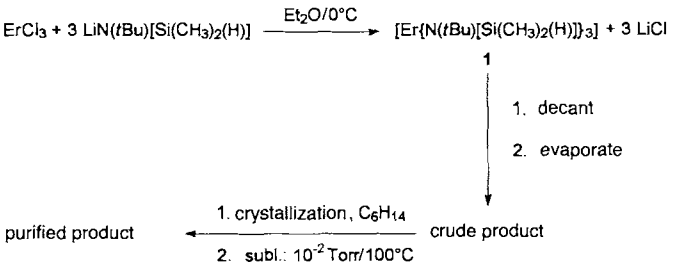
this area[2] was followed by results of rare earth element doped lattices grown by chemical vapor deposition (CVD).[3] As one component of research in the area of designed dopant sources for CVD use, previous success had been garnered by employing metal amide compositions for nitrogen doping of ZnSe.[4, 5] Thus, it was of interest to explore the potential of $Ln(NR_2)_3$ compounds as dopants in epitaxial semiconducting layers. Following preliminary fruition in this field,[6] a demand for Ln amide sources with higher vapor pressures emerged.[7] During the search for such materials, a novel interaction of Si–H and erbium was observed for one of these precursors. The present report contains details related to what is, to the best of our knowledge, the initial finding of what is attributed to be a tris-agostic interaction for a lanthanoid element.

The seminal reports of lanthanide tris(amide) compounds[8] relied on the well-known bis(trimethylsilyl) moiety popularized by decades of success in Bradley's group.[9] Subsequent structurally characterized examples include the dysprosium and erbium tris[bis(trimethylsilyl)amide] entries.[10] It was unsurprising that the metal centers in these compounds were observed to be three-coordinate, due to the rather large effective cone angle of $N[Si(CH_3)_3]_2^-$ as a ligand, coupled with its electron-donating properties to the electropositive Ln^{3+} ion. As a consequence of this rarity of coordination number three for lanthanides, it was of interest to probe the boundaries of utilizing less spacially demanding, and concomitantly less electron-donating, substituents on the nitrogen atom.

The first step in such a progression was the preparation of $[Er\{N(t\text{Bu})[Si(CH_3)_3]\}_3]$, pseudoisosteric with $[Er\{N[Si(CH_3)_3]_2\}_3]$, yet electronically perturbing to the Er^{3+} ion. The vapor pressure data for these two compounds were compared ($[Er\{N(t\text{Bu})[Si(CH_3)_3]\}_3]$: vapor pressure $p = 10^{-3}$ Torr/120 °C and $[Er\{N[Si(CH_3)_3]_2\}_3]$: $p = 10^{-4}$ Torr/140 °C) and then attention was turned toward the selective replacement of substituents at the silyl subunit. During the present investigation, independent publications of the structural characterization of five-coordinate yttrium and neodymium[10] compounds $[ML_3L'_2]$, as well as a four-coordinate neodymium[11] derivative occurred (L = amido ligand; L' = neutral coordinated THF). The vapor pressure of $[Er\{N(t\text{Bu})[Si(CH_3)_2(H)]\}_3]$ (**1**), synthesized according to Scheme 1, was observed to be surprisingly high in comparison



Scheme 1. Synthetic route to **1**.

with other known examples of compounds of this class. Additionally, the melting point was seen to deviate substantially from the values evaluated previously for a range of derivatives.[12] Thus, the search for the origin of these properties compelled a crystallographic characterization of the compound.

The structure[13] of compound **1** is depicted in Figure 1. Remarkably, all the *tert*-butyl groups are present on the same face of the N_3 plane, while there is a uniform rotation of each $Si[(CH_3)_2(H)]$ subunit which places all six methyl groups toward the periphery of the opposing hemisphere of the molecule. This rotation presumably is dictated by the interaction between the three silyl hydrogen atoms and the erbium center, as no indication of structure-influencing intramolecular forces was found in the unit cell. In 1983 Brookhart and Green[16] coined the term agostic to describe interactions of this type. Since then, several examples have been reported[17] for transition metals and C–H as well as N–H units. Very recently $\eta^2(H_2)$[18] and η^2(Si-H) interactions[19] with transition elements have been observed; a rigorous comparison of agostic and η^2 interactions presently is unwarranted, based on available data. To our knowledge, no earlier publications describe potential interactions between lanthanide elements and Si–H units, either originating from inter- or intramolecular coordination.

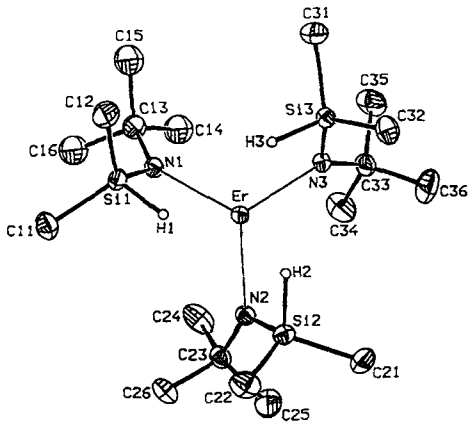


Fig. 1. ZORTEP plot [15] of the structure of **1** in the crystal (thermal ellipsoids are scaled to the 30% probability level). Selected interatomic distances [pm] and angles [°] (standard deviations are given in parentheses): Er–N1 220.6(2), Er–N2 220.6(2), Er–N3 220.6(2), Er–H1 232(3), Er–H2 241(3), Er–H3 237(3), N1–Si1 168.9(3), N1–C13 147.6(4), N2–Si2 169.1(3), N2–C23 146.3(4), N3–Si3 168.6(3), N3–C33 147.5(4), Si1–H1 141.1(3), Si2–H2 146.1(3), Si3–H3 148.1(3); N1-Er-N2 118.97(9), N1-Er-N3 114.60(9), N2-Er-N3 116.85(9), Er-N1-Si1 99.34(11), Si1-N1-C13 126.2(2), Er-N1-C13 133.6(2), Er-N2-Si2 99.85(11), Si2-N2-C23 126.9(2), Er-N2-C23 133.1(2), Er-N3-Si3 99.73(11), Si3-N3-C33 127.1(2), Er-N3-C33 133.1(2).

As can be gleaned from an examination of the interatomic distance and angle data of homoleptic tris(amido)lanthoid derivatives (Table 1), compound **1** has substantially shorter M–N contacts (220 pm). Furthermore, the N-M-N interatomic angles of 116° ± 2° are, in comparison to the corresponding average angle of 111° ± 3° in the four-coordinate entity $[Nd\{N(C_6H_5)[Si(CH_3)_3]\}_3](THF)$, considerably closer to the

Table 1. Interatomic angles [°] and distances [pm] involving M–N interactions for homoleptic lanthanide tris(amide) compounds.

Compound	M–N Distances	MN_2 Angles
$[Er\{N(t\text{Bu})[Si(CH_3)_2(H)]\}_3]$ [a]	Er-N1 220.6(2)	N1-Er-N2 118.97(9)

predicted value of 120° for a VSEPR-optimized three-coordinate structure (VSEPR = valence shell electron pair repulsion). This value is approximated for other homoleptic tris(ligand) lanthanide derivatives with sterically demanding ligands.[20] Additionally, the dihedral angles lie around 0° [H(*n*)-Si(*n*)-N(*n*)-Er; $n = 1$: 2.5(13)°; $n = 2$: −4.6(11)°; $n = 3$: −0.1(11)°]; a consequence of the above-mentioned rotation of the dimethylsilyl groups. This further reinforces the concept that the structural motif of compound **1** is dominated by the controlling influence of the tris-agostic Er-H-Si interactions.

The IR data given in Table 2 also support the presence of the Er-H-Si interactions. A comparison of the Si–H vibrational frequencies in free HN(*t*Bu)[Si(CH$_3$)$_2$(H)] and in the complex

Table 2. IR spectroscopic data for compounds with metal–Si–H interactions and representative values for non-interacting systems.

1 reveals the expected shift (253 cm^{-1}) to long wavelength.[21] The well-documented difficulty in obtaining precise NMR data on lanthanide compounds has hampered an examination of the ^2J(Si,H) coupling constant for the silyl-bound hydrogen atoms present in compound **1**. Such a probe of the "unstretched" Si–H character is restricted in the present case.[22] The Si–H interatomic distances (141–148 pm) are, however, within the range of values found for rather rare unstretched complexes, as compared to the typical stretched complexes.[22a] Presumably such an observation is predominately attributable to the influence of a d^0 metal center. In such instances, the possibility of back donation is eliminated, and all indications favor the highly unusual unstretched case. Furthermore, compound **1**, unlike the CH(SiMe$_3$)$_2^-$ unit, cannot be discussed in terms of γ-C-H-Ln versus β-Si-Me-Ln interaction.[23] Examples of Ln-N-Si-Me also have been reported,[24] as well as other γ-agostic or β-methyl interactions;[25] however, the tris-agostic M-H-Si interaction described here appears to be unique.

In conclusion, the tris-agostic Si–H–Er interaction in the solid-state structure of **1** is a possible source of the origin of the observed high vapor pressure and low melting point.

Experimental Procedure

An aliquot of $ErCl_3$ (0.91 g, 3.35 mmol) was suspended in Et_2O (40 mL) and stirred at 0 °C for 1 h. Freshly synthesized LiN(*t*Bu)[Si(CH$_3$)$_2$(H)] (1.38 g, 10.07 mmol) in Et_2O (60 mL) was added dropwise with rapid stirring. The mixture was allowed to warm to ambient temperature and the resultant pink solution was stirred overnight. Subsequently, the clear ether phase was decanted and evaporated. The residue from the ether solution was extracted with hexanes (50 mL). The resultant solution was filtered and its volume reduced in vacuum to 20 mL. Pink crystals of compound **1**, obtained from this solution after three days at −80 °C, were washed three times with cold (−78 °C) hexane and dried at 20 °C and 10^{-2} Torr. Subsequent sublimation at 100 °C and 10^{-2} Torr yielded an air-sensitive, pink powder. Yield = 0.78 g (42%); m.p. 48 °C; ^{13}C NMR (100.569 MHz, C_6D_6, 22 °C, Si(CH$_3$)$_4$ relative to residual C_6D_5H): δ = −227.12 (s, *C*(CH$_3$)$_3$), −127.75 (s, C(*C*H$_3$)$_3$), −8.99 (s, Si(*C*H$_3$)$_2$); ^{29}Si NMR (79.4521 MHz, C_6D_6, 22 °C, external standard: Si(CH$_3$)$_4$): δ = 429 (s, *Si*(CH$_3$)$_2$(H)); MS (EI, 70 eV, 156 °C): *m/z* (%): 559 (6.6) [M^+ + 1], 558 (17.5) [M^+], 543 (20.7) [M^+ − Me], 528 (1.0) [M^+ − 2Me], 501 (2.0) [M^+ − *t*Bu], 499 (2.7) [M^+ − Si(CH$_3$)$_2$(H)], 485 (2.4) [M^+ − N[Si(CH$_3$)$_2$(H)]], 428 (3.5) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)]], 427 (4.7) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − (H)], 412 (21.7) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − (CH$_3$)(H)], 397 (9.8) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − (CH$_3$)$_2$(H)], 369 (12.8) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − [Si(CH$_3$)$_2$(H)]], 355 (8.0) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − N[Si(CH$_3$)$_2$(H)]], 298 (2.4) [M^+ − N[*t*Bu][Si(CH$_3$)$_2$(H)] − N[*t*Bu][Si(CH$_3$)$_2$(H)]], 130 (6.5) [N[*t*Bu][Si(CH$_3$)$_2$(H)]$^+$], 116 (100) [[*t*Bu][Si(CH$_3$)$_2$(H)]$^+$], 73 (20.3) [N[Si(CH$_3$)$_2$(H)]$^+$], 59 (38.1) [[Si(CH$_3$)$_2$(H)]$^+$].

[12] A slight increase in vapor pressure for the purified product **1** versus the crude product **1** was noted. One potential source for the observation of a depression in the vapor pressure in the crude product is the presence of 'ate' complexes. Recently such species have been isolated in this laboratory by reacting $ErCl_3$ with three equivalents of LiN{(*t*Bu)[Si(CH$_3$)$_3$]} and crystallizing the reaction product from Et_2O. Details of crystallographic characterization of the obtained [Li(Et$_2$O)$_3$][Er{N(*t*Bu)[Si(CH$_3$)$_3$]}$_3$Cl] will be reported separately. It is noted that the formation of such 'ate' species appears to be irreversible, that is, once formed, they resist successful removal of LiCl and subsequent conversion to a neutral, homoleptic lanthanide tris[(silyl)(alkyl)amide] species.
[13] X-ray crystal structure analysis data: $C_{16}H_{48}N_3Si_3Er$, M_r = 534.10 g mol^{-1}, monoclinic, space group $P2_1/n$, a = 11.128(2), b = 14.430(3), c = 17.943(3) Å, β = 90.73(2)°, V = 28.810(9) Å^3, Z = 4, ρ_{calcd} = 1.231 g cm^{-3}, crystal size 0.33 × 0.53 × 0.4 mm^3, number of reflections for lattice parameters = 25 (19.5° ≤ 2θ ≤ 26.6°), T = 185 K, μ = 3.041 mm^{-1}, F(000) = 1100. Data collection and correction: Enraf-Nonius CAD-4 diffractometer, $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), graphite monochromator, aperture 2.5 mm, scan time variable, max. 45 s, scan angle (0.93 + 0.35 tanθ)°, scan technique ω-2θ, range 2° < 2θ < 48°, *hkl* boundaries: −12 ≤ *h* ≤ 12, 0 ≤ *k* ≤ 16, 0 ≤ *l* ≤ 20, total number of measured reflections: 4971, unique reflections: 4346 (R = 0.0227), observed reflections with [|F_o| ≥ 4σ|F_o|]: 4340, corrections: Lorentz, polarization, absorption (DIFABS: correction factors: min. 0.917, max. 1.164). Solution and refinement: structure solution by Patterson method, full-matrix least-squares refinement, 236 parameters refined. The methyl groups in the *t*Bu moiety attached to nitrogen N1 were found to be disordered over two sites (C14–C16/C141–C161), each occupying a population parameter of 0.5. The disordered carbon atoms and the agostic hydrogen atoms H1, H2, H3 each were refined with isotropic, whereas all other non-hydrogen atoms were refined with anisotropic, thermal parameters. All hydrogen atoms were calculated in idealized positions (C–H 96 pm, U_{iso} = 0.08 Å^2, final residue value R_1 = $\Sigma(|F_o| - |F_c|)/\Sigma|F_o|$ = 0.0190, R_2 = $[\Sigma_w(|F_o| - |F_c|)^2/\Sigma_w(|F_o|^2)]^{1/2}$ = 0.0417

($w = 1/\sigma^2(F_o)$), Goof = $[\Sigma_w(|F_o| - |F_c|)^2/(n-p)]1/2 = 1.051$, $\Delta\rho$(max./min.) = max. 0.404 e Å^{-3} and min. -0.300 e Å^{-3}. All refinements were performed by using the SHELXL-93 program system [14]. Further details of the crystal structure investigation are available on request from the Fachinformationszentrum Karlsruhe GmbH, D-76344 Eggenstein-Loepoldshafen (Germany) on quoting the dispository number CSD-404714.

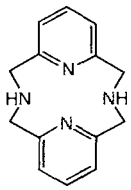
Eight-Coordinate Iron(II) and Iron(III) Ions in Complexes with Distorted Dodecahedral FeN_8 Environments: Synthesis and Structures of Bis(2,11-diaza[3.3](2,6)pyridinophane)iron Complexes**

Welf O. Koch, Adriana Barbieri, Michael Grodzicki, Volker Schünemann, Alfred X. Trautwein, and Hans-Jörg Krüger*

The classical coordination chemistry of iron is dominated by four-, five-, and six-coordinate metal ions, while coordination numbers higher than six are only occasionally encountered in discrete molecules.[1] To our knowledge, only four complexes with eight-coordinate iron ions have been confirmed by X-ray structure determinations: three with an iron(II)[2–4] and one with an iron(III) ion.[5] The formation of these compounds is strongly dependent on the type of ligands used in the synthesis and is confined 1) to bidentate ligands (nitrate,[5] 1,8-naphthyridine = napy[2]) with small chelate bites, which render four-membered chelate rings with the metal ion, 2) to tetradentate ligands (O_4-[12]ane),[3] which form sandwich-like complexes, and 3) to octadentate ligands,[4] in which the backbone of the ligand is specially designed for the encapsulation of the central metal ion by all eight donor atoms. In these studies, only neutral nitrogen or oxygen donor atoms were found to coordinate iron(II) ions, while the coordination of iron(III) ion was restricted to anionic oxygen donors. The ligand donor atoms are generally arranged in the form of a distorted square prism or a distorted dodecahedron.



L-N_4H_2

We utilized derivatives of the tetraazamacrocyclic ligand 2,11-diaza[3.3](2,6)pyridinophane L-N_4H_2.[6] In eight-coordinate iron complexes that contain tetraoxocyclododecane[3] or tetraazacyclododecane derivatives[4] as ligands all donor atoms of the macrocyclic ring lie in a plane. This cannot occur in L-N_4H_2-containing complexes because of the ligand's rigidity due to the pyridine rings and its preference to assume a boat–boat conformation upon coordination.[6] With this ligand all four nitrogen donors are arranged in a rhombus which is bent along the shorter diagonal (= $N_{py}-N_{py}$ axis). This arrangement also occurs in dodecahedral coordination geometries; thus, utilization of two molecules of L-N_4H_2 per metal ion was considered to be a promising route to the synthesis of complexes with eight-coordination at the central ion. We report here on the synthesis and structures of iron complexes of the type $[Fe(L\text{-}N_4H_2)_2]^{n+}$.

The reaction of two equivalents of L-N_4H_2 with iron(II) perchlorate in methanol under a nitrogen atmosphere and subsequent metathesis with sodium tetraphenylborate yields a yellow precipitate, which after recrystallization in acetonitrile/ether analyzes correctly for a complex of the composition **1**.

$[Fe(L\text{-}N_4H_2)_2](BPh_4)_2 \cdot Et_2O$ **1**

As a solid and even in solution, **1** is not oxygen-sensitive. Its cyclic voltammogram (Fig. 1) displays an oxidative electron transfer reaction at +385 mV vs. SCE[7] which approaches electrochemical reversibility ($\Delta E_p = 70$ mV and $i_{pc}/i_{pa} \approx 1$ at all scan rates, $i_p/v^{1/2}$ = constant). The electrolysis of a solution of **1** in acetonitrile at an applied potential of +590 mV vs. SCE

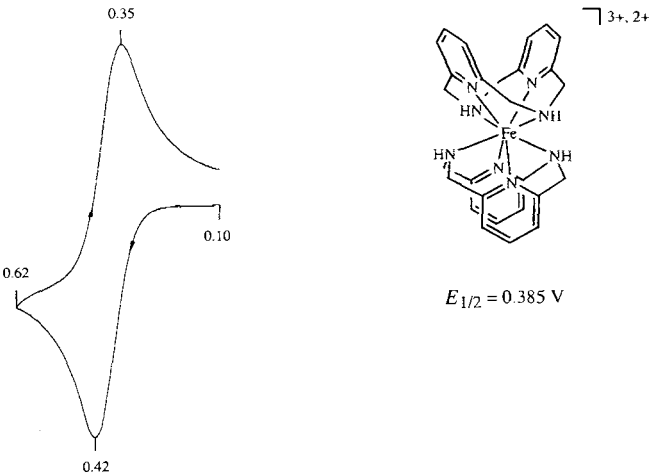


Fig. 1. Cyclic voltammogram (50 mV s^{-1}) of $[Fe(L\text{-}N_4H_2)_2]^{2+}$ at a Pt foil electrode in acetonitrile at 25 °C; peak potentials and half-wave potential vs. SCE are indicated.

renders a pale yellow solution after a total transfer of 1.00 e^- per molecule of **1**. Re-reduction of the iron(III) species at +190 mV accounts for 96% of recovery of the initial iron(II) complex, indicating that the oxidized species is sufficiently stable to warrant a bulk preparation. However, attempts to synthesize the iron(III) complex directly from iron(III) perchlorate and the free ligand or alternatively by chemical oxidation of complex **1** have failed. The iron(III) complex was eventually obtained by bulk electrolysis of **1** in acetonitrile at +590 mV vs. SCE and isolated as **2**. Magnetic susceptibility measurements at room temperature revealed that complexes **1** and **2** contain high-spin iron.

$[Fe(L\text{-}N_4H_2)_2](ClO_4)_3$ **2**

Complexes **1** and **2** could be obtained as single crystals; their structures were determined by X-ray diffraction[8] (Fig. 2). In both complexes the iron ion is coordinated by all nitrogen

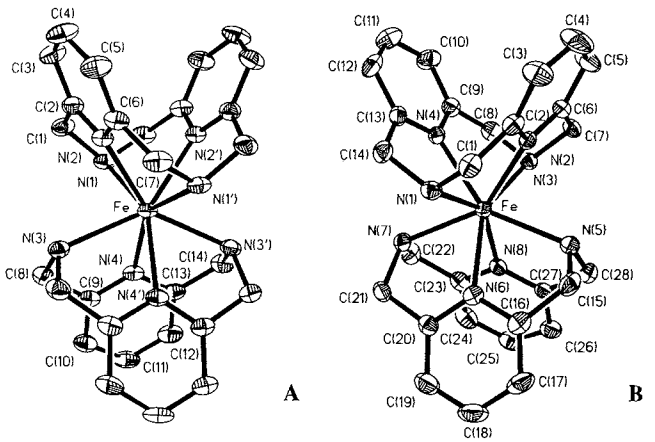

Fig. 2. Crystal structures of the $[Fe(L\text{-}N_4H_2)_2]^{2+}$ (**A**) and $[Fe(L\text{-}N_4H_2)_2]^{3+}$ ions (**B**) showing thermal ellipsoids at 50% probability and the atom numbering schemes. Selected distances [Å] and angles [°]: **A** (the primed and unprimed atoms are related by a twofold rotation axis): Fe–N(1) 2.372(2), Fe–N(2) 2.290(2), Fe–N(3) 2.392(2), Fe–N(4) 2.305(2); N(1)-Fe-N(2) 71.67(6), N(1)-Fe-N(3) 82.46(6), N(1)-Fe-N(4) 78.99(6), N(1)-Fe-N(1') 133.34(8), N(1)-Fe-N(2') 71.23(6), N(1)-Fe-N(3') 116.48(7), N(1)-Fe-N(4') 146.12(6), N(2)-Fe-N(3) 78.86(6), N(2)-Fe-N(4) 140.26(6), N(2)-Fe-N(2') 73.09(9), N(2)-Fe-N(3') 146.23(6), N(2)-Fe-N(4') 121.86(7), N(3)-Fe-N(4) 71.10(7), N(3)-Fe-N(3') 133.20(9), N(3)-Fe-N(4') 71.51(6), N(4)-Fe-N(4') 72.38(9). **B**: Fe–N(1) 2.290(3), Fe–N(2) 2.211(3), Fe–N(3) 2.325(3), Fe–N(4) 2.218(3), Fe–N(5) 2.299(3), Fe–N(6) 2.236(3), Fe–N(7) 2.313(3), Fe–N(8) 2.218(3); N(1)-Fe-N(2) 72.8(1), N(1)-Fe-N(3) 136.9(1), N(1)-Fe-N(4) 74.0(1), N(1)-Fe-N(5) 114.1(1), N(1)-Fe-N(6) 77.3(1), N(1)-Fe-N(7) 82.3(1), N(1)-Fe-N(8) 145.1(1), N(2)-Fe-N(3) 73.2(1), N(2)-Fe-N(4) 74.6(1), N(2)-Fe-N(5) 76.2(1), N(2)-Fe-N(6) 121.3(1), N(2)-Fe-N(7) 146.0(1), N(2)-Fe-N(8) 139.6(1), N(3)-Fe-N(4) 72.1(1), N(3)-Fe-N(5) 82.1(1), N(3)-Fe-N(6) 144.4(1), N(3)-Fe-N(7) 114.21(9), N(3)-Fe-N(8) 76.49(9), N(4)-Fe-N(5) 145.4(1), N(4)-Fe-N(6) 140.5(1), N(4)-Fe-N(7) 76.6(1), N(4)-Fe-N(8) 120.0(1), N(5)-Fe-N(6) 71.9(1), N(5)-Fe-N(7) 136.4(1), N(5)-Fe-N(8) 73.8(1), N(6)-Fe-N(7) 73.2(1), N(6)-Fe-N(8) 73.3(1), N(7)-Fe-N(8) 71.7(1).

donors of the two ligand molecules; thus, the metal ions in both complexes are unambiguously eight-coordinate. The coordination geometries are best described as distorted dodecahedrons. Instead of a torsional angle of 90° between both ligand moieties, as is required in an ideal dodecahedral geometry (D_{2d} symmetry), the angle found is only 70°. Hence, the overall structures of both complexes approach D_2 symmetry.

In complex **1**, the average $Fe-N_{py}$ and $Fe-N_{amine}$ bond lengths are 2.298 ± 0.008 and 2.382 ± 0.010 Å, respectively; which are about 0.1 Å larger than those observed in octahedral high-spin iron(II) complexes with $L\text{-}N_4H_2$ ligands.[6] Upon oxidation, the Fe–N bond lengths decrease to 2.221 ± 0.014 and 2.307 ± 0.018 Å, respectively, which are also considerably longer than those found in six-coordinate high-spin iron(III) complexes.[6] The substantial decrease in Fe–N bond lengths upon oxidation is a clear sign of metal-centered oxidation. The N_{py}-Fe-N_{py} and N_{amine}-Fe-N_{amine} angles, defined by the Fe–N bonds to the same ligand moiety (72.7° and 133.3° for **1** and 73.9° and 136.6° for **2**), hardly change upon oxidation of the iron ion. As in octahedral iron complexes containing this ligand, the metal ion is not placed on the intersecting line of the least-squares planes of those pyridine rings belonging to the same ligand unit. The angles included by these planes are only 46° for **1** and 55° for **2**.

The only Mössbauer study, to our knowledge, carried out on discrete high-spin eight-coordinate iron(II) complexes involved the complex $[Fe(napy)_4]^{2+}$, where $\Delta E_Q = +4.54$ mm s^{-1} constitutes one of the largest quadrupole splittings ever found for an iron(II) compound.[9] The Mössbauer spectra of **1** as a solid and in rapidly frozen acetonitrile solution were recorded at 4.2 K. Both spectra consist of a doublet with an isomer shift $\delta_{IS} = 1.24(1)$ mm s^{-1} (relative to α-Fe at 300 K) and a quadrupole splitting $\Delta E_Q = 3.05(1)$ mm s^{-1}, indicating that in solution the same distorted dodecahedral coordination geometry of the iron ion is present as in the crystalline solid. An additional measurement of **1** as a solid at 150 K in a field of 4 T $\perp \gamma$ documented the asymmetry parameter η and the sign of the electric field gradient: $\eta = 0.1(1)$, ΔE_Q (150 K) $= -3.02(1)$ mm s^{-1}.

Molecular orbital calculations in local spin density approximation by the SCC-Xα method[10] using the experimentally determined atomic positions of the cation in **1** yield $\Delta E_Q = -3.30$ mm s^{-1} and a small asymmetry parameter ($\eta = 0.14$). The direction of the main component V_{zz} of the electric field gradient tensor coincides with the bisectors of the angles N(2)-Fe-N(2') and N(4)-Fe-N(4') (cf. Fig. 2, **A**). Taking this direction as the molecular z axis, the Fe(3d) shell occupation of the high-spin ground state for the iron(II) complex is approximately $(d_{z^2})^2(d_{x^2-y^2})^1(d_{xz})^1(d_{xy})^1(d_{yz})^1$.[11] In conclusion, the results of the Mössbauer investigations show that a large quadrupole splitting ($\Delta E_Q \geq 4$ mm s^{-1}) is not a general property of the eight-coordinate iron(II) ion but reflects the particular electronic structure of a high-spin iron(II) complex. On the one hand, complex **1**, which contains an eight-coordinate iron(II) ion, yields a quadrupole splitting ΔE_Q of about 3 mm s^{-1}, whereas, on the other hand, five-coordinate iron(II) porphyrin complexes with anionic axial ligands, exhibit ΔE_Q values of ≥ 4 mm s^{-1}.[12]

For the first time, eight-coordinate iron ions have been established in a pair of iron complexes with identical ligand environments. These complexes differ only in the oxidation state of the metal ion. Compound **2**[13] is the first eight-coordinate iron(III) complex with a neutral donor atom set. In contrast to $[Fe(napy)_4]^{2+}$ and $[Fe(NO_3)_4]^-$ ions with four-membered chelate rings, only five-membered chelate rings are found in **1** and **2**. The current study has demonstrated that the use of the ligand $L\text{-}N_4H_2$ provides a systematic way to synthesize complexes with eight-coordination at the central ion. An extended investigation with other metal ions, especially with those of the first transition metal row, is currently in progress.

While some of the previously reported eight-coordinate iron complexes change their coordination environment on dissolution,[9b, 14] complexes **1** and **2** are stable and maintain their coordination geometry in solution. They are, therefore, well suited for a detailed investigation of the electronic properties of eight-coordinate iron ions.

Experimental Procedure

1: Under an atmosphere of pure nitrogen a solution of $[Fe(H_2O)_6](ClO_4)_2$ (91 mg, 0.25 mmol) in methanol (15 mL) was added to a solution of L-N_4H_2 (120 mg, 0.5 mmol) in methanol (30 mL). The mixture was heated to reflux and then cooled again to room temperature before it was treated with a solution of sodium tetraphenylborate (171 mg, 0.5 mmol) in methanol (15 mL). The reaction mixture was subsequently heated to reflux for a short time, and the resulting yellow precipitate was collected by filtration under air and washed twice with small amounts of methanol. Recrystallization by ether diffusion into a solution of the complex in acetonitrile afforded **1** (249 mg) as analytically pure, large yellow crystals (80% yield). Anal. calcd. for $C_{80}H_{82}B_2FeN_8O$: C 76.93, H 6.62, N 8.97; found: C 76.90, H 6.77, N 9.08. Magnetic moment $\mu = 4.89\ \mu_B$.

2: Over a period of 7.5 h, **1** (290 mg, 0.23 mmol) was electrolyzed at +590 mV vs. SCE in acetonitrile (60 mL) containing tetrabutylammonium perchlorate (4.1 g) as supporting electrolyte. The electrolysis was carried out at a platinum net electrode with a PAR Model 273A Potentiostat/Galvanostat controlled by the Model 270 Research Electrochemistry Software. After the passage of 96.6% of the theoretical amount of electrons, the resulting pale-yellowish solution which contained already partially precipitated product was stored at −30 °C overnight. The precipitate was isolated by filtration and washed with copious amounts of ethanol and ether. Ether diffusion into a solution of the solid in acetonitrile yielded pale-yellow crystals of the composition $[Fe(L\text{-}N_4H_2)_2](ClO_4)_3 \cdot MeCN$. Since the acetonitrile molecule in the crystal lattice is quite volatile, the solid was kept under vacuo for one day rendering 137 mg of analytically pure product (71% yield). Anal. calcd. for $C_{28}H_{32}Cl_3FeN_8O_{12}$: C 40.29, H 3.86, N 13.42; found: C 40.07; H 3.87; N 13.24. Magnetic moment $\mu = 5.54\ \mu_B$.

Warning: Perchlorate salts are potentially explosive and should be handled with care [15]. Since the solid does explode upon grinding, such procedures, if they are absolutely necessary, should only be carried out with small amounts of complex!

[11] In more detail the local spin density calculation renders the occupation numbers $d_\uparrow^{4.99} d_{z^2\downarrow}^{0.97} d_{x^2-y^2\downarrow}^{0.11} d_{xy\downarrow}^{0.15} d_{xz\downarrow}^{0.14} d_{yz\downarrow}^{0.15}$. The d_{z^2} orbital is almost nonbonding for both spin directions, while the occupation numbers of the other four "spin-down" Fe(3d) orbitals reveal some covalent contributions from the Fe–N bonds, resulting in a reduction of the electric field gradient arising from the d_{z^2} orbital alone. These results emphasize that the cation in complex **1** cannot be compared with the $[Fe(napy)_4]^{2+}$ ion, for which a positive quadrupole splitting is found and in which the d_{xy} orbital is the doubly occupied molecular orbital [9c]. Detailed molecular orbital calculations are currently under way to elucidate the differences in electronic structure between the two eight-coordinate iron(II) complexes.

Transition Metal Stabilized Al^I and Ga^I Complexes; Structure of $[(CO)_5Cr-Ga\{(CH_3)(tmeda)\}]$**

Markus M. Schulte, Eberhardt Herdtweck, Gabriele Raudaschl-Sieber, and Roland A. Fischer*

The chemistry of low-valent Al and Ga compounds, pioneered by Schnöckel et al.[1] and Uhl et al.[2], is currently undergoing rapid development. Recently, high-vacuum co-condensation techniques have been employed to obtain compounds such as E^IX (E = Al, Ga; X = Cl, Br) as metastable solutions that were subsequently used in synthesis.[1] E–E bonds are a typical structural feature of E^IR systems in the solid-state (R = halogen, alkyl, η^5-C_5R_5).[1, 2] We report here on the first transition metal stabilized Al^I and Ga^I complexes that do not contain E–E bonds and on some of the applications of these volatile precursors in MOCVD processes (MOCVD = metal organic chemical vapor deposition) for the deposition of intermetallic thin films.

Equimolar amounts of Cl_2ER (E = Al, Ga; R = Cl, alkyl) and $K_2[Cr(CO)_5]$ react in THF according to Scheme 1 to give the anionic species $K[(CO)_5Cr-E(Cl)(R)]$, which could be isolated after salt metathesis as solvent-free Ph_4P or PPN salts (PPN = $Ph_3P{=}N{=}PPh_3$). If the THF is replaced successively by CH_2Cl_2, the potassium salts eliminate the second equivalent

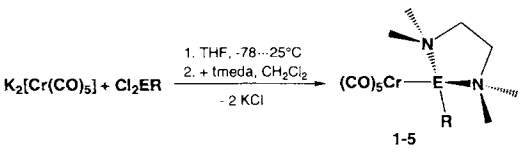
of KCl. In this way, $[(CO)_5Cr-Ga(Cl)(thf)_2]$ was obtained. In contrast, Cl abstraction from the respective Ph_4P or PPN salts was achieved only with $Tl[PF_6]$. Addition of a bidentate Lewis base to solutions of the potassium species in CH_2Cl_2 leads to the formation of compounds **1**–**5** (Scheme 1), which crystallize as



Scheme 1. **1**–**3**: E = Ga; **4**,**5**: E = Al; **1**: R = Me; **2**, **4**: R = Et; **3**, **5**: R = Cl.

colorless to yellow cubes or prisms from concentrated CH_2Cl_2 solutions (yields >90%). The Ga compounds, in particular, are quite air and moisture stable, even for longer periods of time, whereas the related Ga^{III} complexes[3] $[L_nM-GaR_2(Do)]$ (Do = donor ligand) decompose instantaneously. Thus, Raman spectra on the single crystals could be recorded without any special precautions.[4]

Only for In have complexes structurally analogous to **1**–**5** been confirmed by X-ray crystallography ($[(CO)_5Cr-In-Br(thf)]$[5] and $[\{HB(3,5\text{-}Me_2pz)_3\}In-M(CO)_n]$ (M = Fe, $n = 4$; M = W, $n = 5$; 3,5-Me_2pz = 3,5-dimethylpyrazolyl)).[6] The former is polymeric in the solid state (intermolecular In···Br–In contacts). The X-ray structure analysis of **1**[7] (Fig. 1) exemplifies the monomeric structure of the compounds

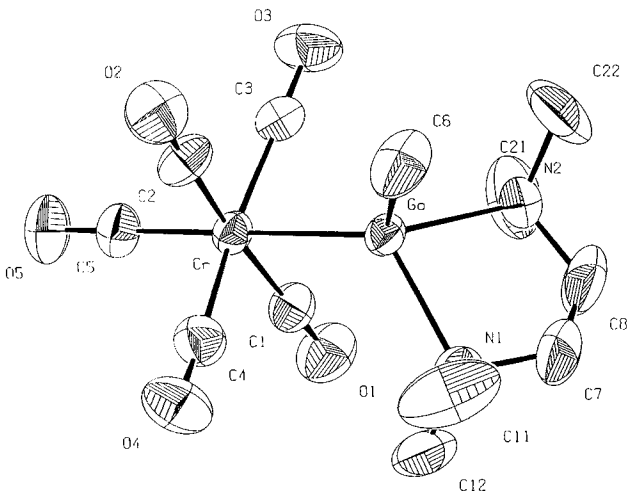


Fig. 1. Structure of **1** in the crystal (ORTEP plot). Hydrogen atoms were omitted for clarity. Selected bond lengths [pm] and angles [°]: Ga–Cr 247.85(11), Ga–N1 217.3(5), Ga–N2 217.4(5), Ga–C6 198.4(6), Cr–C1 186.9(6), Cr–C2 183.9(6), Cr–C3 186.8(6), Cr–C4 186.0(6), Cr–C5 184.7(6); Cr-Ga-N1 120.6(1), Cr-Ga-N2 119.8(2), Cr-Ga-C6 122.5(2), N1-Ga-N2 82.32(19), N1-Ga-C6 101.6(2), N2-Ga-C6 101.6(3), Ga-Cr-C1 89.3(2), Ga-Cr-C2 85.3(2), Ga-Cr-C3 84.7(2), Ga-Cr-C4 85.4(2), Ga-Cr-C5 179.4(2).

reported herein. This is considered to be responsible for their volatility. The Cr–Ga bond (247.8(2) pm) in **1** is unprecedented for molecular compounds.[8] The description of **1**–**5** as Al^I and Ga^I systems is supported by the structural analogy to the In^I systems. Additional evidence is provided by the vibrational spectra. The IR absorptions in the ν(CO) range lie between 1880 and 2030 cm^{-1} and are shifted to significantly *higher* energies than those of the anionic intermediates (1830–1990 cm^{-1}). An analysis of the ν(CO) force constants by using the "CK" approximation[4] confirmed the analogy of **1**–**5** with neutral $L(CO)M^0$ complexes (L = phosphine, arsine). The fragments $[E(R)(tmeda)^0]$ are isolobal to PR_3 and AsR_3 (R = alkyl, Cl) and are regarded as potent σ donors; however, some π-acceptor capabilities are evidently still present (similar to PCl_3). In this sense the bonding in these M–E systems is similar to that in donor-stabilized transition metal silylene complexes.[9] A description of **1**–**5** as complex $M-E^{III}$ contact ion pairs, under the assumption of strongly negatively polarized 18-electron $(CO)_5M^{2-}$ fragments and twofold positively charged $ER(Do)_2^{2+}$ units, appears inappropriate, even when the group electronegativities of the $(CO)_nM$ fragments (which are about 4) are taken into consideration.[10] The exchange of the basic ligand TMEDA by N-base ligands with conjugated π-electron systems (bipyridine, diazabutadiene) gave intense metal–ligand charge-transfer bands in the UV/Vis spectra.[11] In contrast to some E^{III} complexes, it is also remarkable that the metal–metal bonds are preferred over isocarbonyl structures M–C=O–E (E = Al, Ga),[12] and that **1**–**5** are stable to heterolytic bond dissociation in coordinating solvents such as THF and CH_3CN.[3] The ^{27}Al NMR resonances ($\delta = +156$ for **5**) are shifted to higher field compared to those of the Al^{III} complexes $[L_nM-AlR_2(Do)]$ ($\delta = +200 \pm 10$).[12] Qualitatively, this is consistent with the results of ab initio calculations for solvated Al^ICl.[13] Also the mass spectra of complexes **1**–**3**, which volatilize at 110–130 °C and 10^{-3}–10^{-4} Torr without decomposition, show unexpected effects compared to the spectra of the E^{III} complexes. After loss of TMEDA, a series of complex fragments $[(CO)_mMGaR]$ ($m \leq n$) containing an intact M–Ga bond are observed. In contrast, cleavage of the M–Ga bond is preferred for all Ga^{III} complexes $[L_nM-GaR_2(Do)]$. These complexes react cleanly with halogens X_2 by oxidative M–E bond cleavage to give $[(CO)_5M(X)]^-$ and $[(X)(R)E(tmeda)]^+$. Because $[(CO)_5M(X)]^-$ can be described as a Lewis acid base adduct of X^- to the 16-electron fragment $(CO)_5M^0$, the assumption of an oxidation $E^I \rightarrow E^{III}$ is plausible. A selective functionalization of the E–Cl units is possible. Thus, **3** and **5** could be converted smoothly with LiH and $LiBH_4$ into the corresponding hydrides and boranates, respectively.

MOCVD experiments with the Cr–Ga complex **2** were carried out in an isothermal horizontal, hot-wall reactor (10^{-3} Torr, 250 °C).[14] Ex situ analysis (atomic absorption spectroscopy (AAS), scanning electron microscopy–energy-dispersive X-ray analysis (SEM-EDX), and X-ray photoelectron spectroscopy (XPS), Fig. 2) of the resulting metallic, shiny,

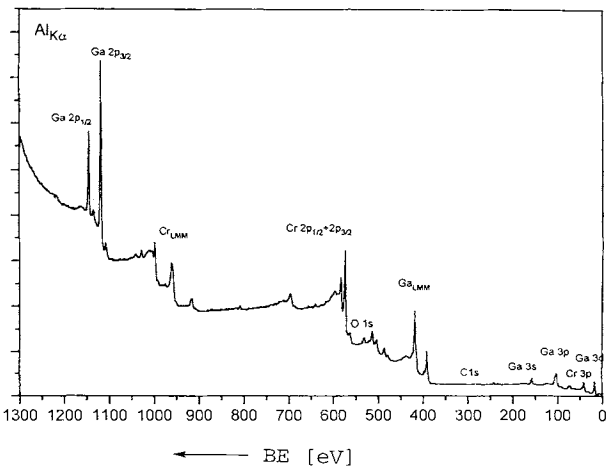

Fig. 2. X-ray photoelectron spectra of a typical CrGa film grown on SiO_2 (BE = bonding energy); quantative XPS analysis (at.% ± 2): Ga 38, Cr 36, O 11, C 15. SEM-EDX of the same sample (at.% ± 0.1): Ga/Cr = 1.06.

thin films (ca. 1.5 μm thickness; quartz, Si substrates) show the exact metal stoichiometry of 1:1.[15] Thus, compound **2** allows precise control of the stoichiometry even at low substrate temperatures. This result is in accord with previous findings made for the Ga^{III} systems $[L_nM-GaR_2(Do)]$: precursors with GaR_2 units loose GaR_3 (stable against pyrolysis) under mild deposition condtitions to give Ga-deficient films.[16] In this sense the monoalkylated precursors with a $Ga^{I}R$ fragment are far superior to the dialkylated systems with $Ga^{III}R_2$ units. The analysis of the volatile exhaust gases (in situ mass spectrometry, GC/MS and NMR spectroscopy after condensation of the gases) revealed the presence of the unfragmented base ligand. The only hydrocarbon species observed was ethene, which supports a β-H-elimination mechanism.

In conclusion, it is anticipated that the results with the model systems **1**–**5** will have ramifications for the development of improved single-source precursors for the MOCVD of relevant intermetallic phases[17] particularly for III/V semiconductors.

Experimental Procedure

1: A suspension of $K_2[Cr(CO)_5]$ (2 mmol) in THF was added to a solution of Cl_2GaCH_3 (2 mmol) in THF at −78 °C. After the mixture had been stirred for 2 h at 25 °C, TMEDA (1 equiv) was added, and the mixture was stirred for an additional hour. The THF was then exchanged for CH_2Cl_2. After filtration and concentration to 20 mL, **1** crystallized at −30 °C. (yellow cubes, 770 mg, yield 98%). Compounds **2**–**5** were obtained in an analogous manner.

Selected physical data: **1**: Yellow cubes (m.p. 119 °C, subl. 110 °C, 10 − 3 Torr). ^{1}H NMR (399.78 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = -0.01$ (s, 3H, $GaCH_3$), 2.52 (s, 6H, NCH_3), 2.79 (s, 6H, NCH_3), 2.87 (m, 4H, NCH_2, AA'BB'); ^{13}C NMR (100.53 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 6.3$ (q, ^1J(C,H) = 120 Hz, CH_3), 47.7 (q, ^1J(C,H) = 138 Hz, NCH_3), 48.9 (q, ^1J(C,H) = 139 Hz, NCH_3), 57.8 (t, ^1J(C,H) = 139 Hz, CH_2N), 227.9 (CO), 231.6 (CO). IR (CH_2Cl_2, [cm^{-1}]): ν(CO) = 2013 (vs), 1920 (s), 1884 (vs). CI-MS (isobutene) *m/z* (%): 392 (3) [M^+] (correct isotope pattern), 377 (2) [$M - CH_3^+$], 276 (11) [M − tmeda$^+$], 248 (4) [M − tmeda − CO$^+$], 117 (100) [tmeda + H$^+$]. Correct C, H, N, Cr, and Ga analysis.

5: Yellow prisms. ^{1}H NMR (399.78 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 2.86$ (s, 6H, NCH_3), 2.91 (s, 6H, NCH_3), 3.09 (m, 4H, NCH_2, AA'BB'). ^{13}C{^{1}H} NMR (100.53 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 48.3$ (NCH_3), 49.6 (NCH_3), 57.5 (CH_2N), 228 (CO). ^{27}Al{^{1}H} NMR (104.17 MHz, CD_2Cl_2, 25 °C, {[Al(H$_2$O)$_6$]$^{3+}$ external}) $\delta = 156$ ($F_{1/2} = 4680$ Hz). IR (CH_2Cl_2, [cm^{-1}]): ν(CO) = 2015 (s), 1926 (vs), 1876 (vs). Correct C, H, N, Al, and Cr analysis.

Synthesis of a Stable Hexagonally Packed Mesoporous Niobium Oxide Molecular Sieve Through a Novel Ligand-Assisted Templating Mechanism**

David M. Antonelli and Jackie Y. Ying*

Although recent efforts have suggested that it should be possible to synthesize mesoporous materials from transition metal oxides by molecular self-assembly of organic templating agents and inorganic oxides,[1, 2] to date there has been no report of this technique successfully generating such materials which could maintain a stable mesoporous structure upon removal of the organic micelles. Mesoporous materials, such as the aluminosilicate-based MCM-41,[3, 4] have pores with diameters in the 20–100 Å range; in contrast, the pore diameters in zeolites are less than 15 Å. Mesoporous oxides have potential application as solid electrolyte devices, as sorbents, and in catalytic processes where high surface area, fast diffusion, and large pore sizes are necessary for high performance. The synthesis of a stable mesoporous transition metal oxide should provide heterogeneous catalysts suitable for methane oxidation, NO_x decomposition,

[**] This work was supported by the National Science Foundation (CTS-9257223, CTS-9411901, and DMR-9400334). The authors acknowledge Dr. A. Nakahira for his assistance with the transmission electron microscopy and Dr. T. Sun for helpful discussions.

hydrodesulfurization, photocatalytic decomposition of organic halides, and solid acid catalysis. Recently we described the synthesis of Ti-TMS1, the first hexagonally packed mesoporous transition metal oxide, by using a modified sol–gel method in conjunction with phosphate surfactants and titanium alkoxides.[5, 6] One of the important features of this synthesis route was the use of acetylacetone to slow down the condensation of the titanium alkoxide precursor sufficiently to allow the Ti centers to interact with the phosphate head groups on the micellated surfactant molecules. This material, however, underwent partial collapse of the mesostructure during template removal by calcination, yielding surface areas of about 200 $m^2 g^{-1}$.

Herein we describe the synthesis of the niobium oxide molecular sieve (Nb-TMS1), an ultrahigh surface area, hexagonally packed mesoporous transition metal oxide material which is the first such material *completely* stable to surfactant removal. The synthesis of this material was achieved through a novel approach by using the condensation of an organometallic precursor in which the propagating niobium alkoxide moiety is chemically linked through a Nb–N bond to a long-chain amine surfactant molecule. The initial reaction between the amine and $Nb(OEt)_5$ was conducted in the absence of water to ensure that an interaction between the Nb and the surfactant was established prior to condensation. This new approach thus obviates the use of acetylacetone and other chelating agents to control the condensation reaction. Covalent binding of the surfactant to the inorganic phase contrasts to already established routes which employ hydrogen bonding[8] or coulombic forces[1–4] to achieve the desired interaction.

Previous efforts to synthesize hexagonally packed mesoporous oxides have focused on a liquid-crystal templating mechanism involving the adjustment of pH, inorganic precursor, and surfactant head group to achieve an optimal electrostatic charge balance between the organic and inorganic phases during the assembly process.[7] Although claims have been made that such a route should provide a general method for synthesizing mesoporous materials of desired composition by judicious choice of the synthesis parameters, most efforts have led to formation of layered phases. The hexagonally packed mesoporous oxides of tungsten, antimony, lead, and iron derived by such an approach were found to be thermally unstable.[7] High surface areas and well-defined porosities could not be maintained in these systems upon surfactant removal, unlike the case of alumina-[10] or silicate-based systems.[3]

When a solution of niobium(v) ethoxide $Nb(OEt)_5$ (5.0 g) in ethanol (10 mL) was treated with tetradecylamine (0.25–1 equivalents), a new amino(ethoxy)niobium complex was obtained. The reaction of $Nb(OEt)_5$ with donor ligands such as amines is well documented.[9] When this solution was further treated with water (10–20 mL), a rapid reaction ensued, giving a white gelatinous precipitate. If this gel was aged at 100–180 °C for seven days, a white powder (Nb-TMS1) was obtained with a characteristic hexagonal X-ray powder diffraction (XRD) pattern (Fig. 1a) similar to those recorded for MCM-41 with the exception that the (110) and (200) peaks are not well resolved. The transmission electron micrograph (TEM) of Nb-TMS1 shown in Figure 2a also confirms the nature of this material as structurally analogous to MCM-41. While regions of local disorder do exist, the general arrangement of the pores is hexagonal. Prior to our reports[5, 6] and this paper, early transition metal alkoxides have only been used to dope MCM-41, for example 1% Ti in either MCM-41,[8] or its alumina-based analogue.[10]

The surfactant was best removed from Nb-TMS1 by careful treatment with $EtOH/HNO_3$ at 40 °C and pH = 1–2 followed

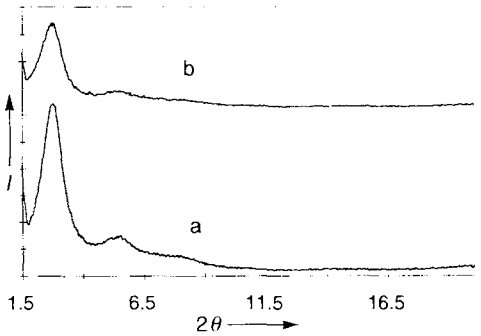

Fig. 1. a) XRD pattern of Nb-TMS1 synthesized with tetradecylamine (I = intensity in arbitrary units, 2θ is measured in degrees). The d spacing for the (100) reflection appears at 34 Å, which is slightly smaller than the value of ≈35 Å observed for as-synthesized MCM-41 made with trimethyltetradecylammonium bromide, possibly reflecting the greater degree of extension of the trimethylammonium head group over the amine head group for the same alkyl chain length. The (110), (200), and (210) reflections appear between 4° and 7° for 2θ as expected; however, the (110) and (200) peaks are not well resolved. This effect was observed previously in samples of MCM-41 and Ti-doped MCM-41, and has been attributed to the small particle size and/or the regions of local disorder where the nanometer-sized tubes are not stacked in a perfectly hexagonal array [8, 10]. b) XRD pattern of the same sample of Nb-TMS1 after $EtOH/HNO_3$ washes, which demonstrates that although the peaks are not as intense, the overall hexagonal structure was maintained after the successful surfactant removal.

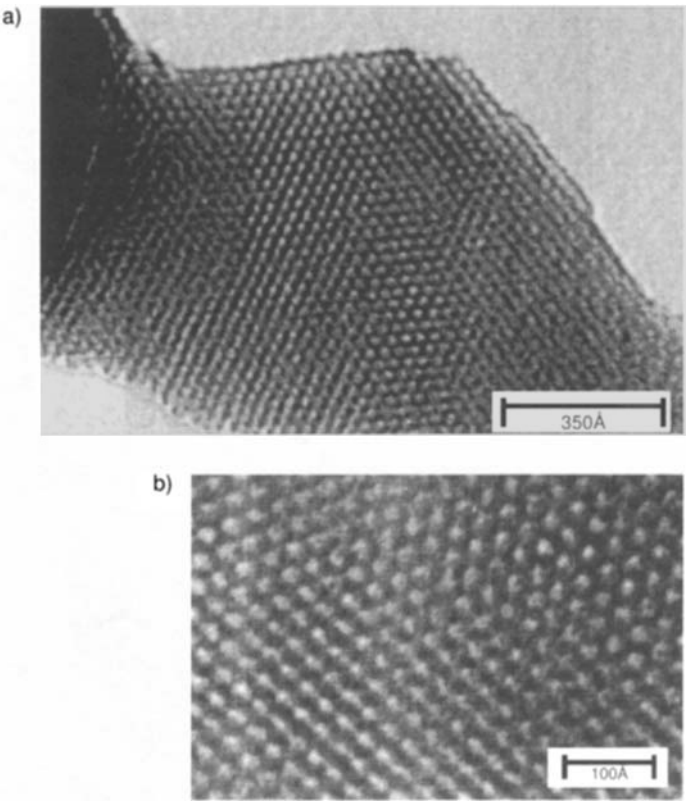

Fig. 2. High-resolution TEM images of the as-prepared Nb-TMS1 synthesized by using tetradecylamine a) prior to and b) after treatment with $EtOH\ HNO_3$. a) The pores are hexagonally packed, with an opening of about 27 Å and wall thickness of about 8 Å. The sum of these numbers agrees well with the value of about 35 Å calculated for the hexagonal repeat distance, a_o ($a_o = 2d_{100}/3^{1/2}$), from XRD. In general, the hexagonally ordered domains are about 100 nm, while samples of MCM-41 may have domain sizes on the micron level. Regions consisting of randomly packed cylindrical pores also exist. b) The pores are hexagonally packed, with an opening of about 25 Å. This pore size is in excellent agreement with the value of 27 Å as measured by N_2 adsorption, although direct comparison between pore sizes obtained from the BJH method (BJH = Barrett–Joyner–Halenda) and those obtained by TEM or XRD are not always valid due to the nature of the method.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3504-0427 $ 15.00+.25/0

by extensive washing in ethanol. This process led only to a slight reduction of the XRD peak intensity (Fig. 1b). Treatment with HNO_3 at pH values lower than 1 led to reduction of the intensity of the X-ray pattern without loss of the high surface area or narrow pore size distribution. We attribute this to decreased size of the crystal domains. In general, samples made at lower surfactant-to-metal ratios (about 1:2 to 1:3) showed the greatest stability towards acid treatment at lower pH values, as measured by XRD peak intensities. The TEM of surfactant-free Nb-TMS1 (Fig. 2b) confirms that we have synthesized a structural analogue of hexagonally packed mesoporous MCM-41. After acid washing, this material retains only a small amount of surfactant and surface nitrate, as determined by photoacoustic IR spectroscopy. There is also evidence of Nb–OH groups, indicating that this material is partially hydrated. This result is consistent with EDAX studies (EDAX = energy dispersive analysis by X-rays) which show that this material contains slightly less Nb and more O than pure Nb_2O_5. Elemental analysis of these samples further supports the nature of this material as hydrated Nb_2O_5. The BET surface area of a typical sample Nb-TMS1 synthesized from tetradecylamine and washed in the manner described above was 434 $m^2 g^{-1}$. This value agreed well with that for samples of MCM-41 (about 1000 $m^2 g^{-1}$) with similar d spacings, after corrections for the molar weight ratio between $NbO_{2.5}$ and SiO_2 (132.9/61). The N_2 adsorption–desorption isotherms of Nb-TMS1 (Fig. 3a) presented only slight hysteresis. The pore size distribution of this material (Fig. 3b) showed one narrow peak at 27 Å.

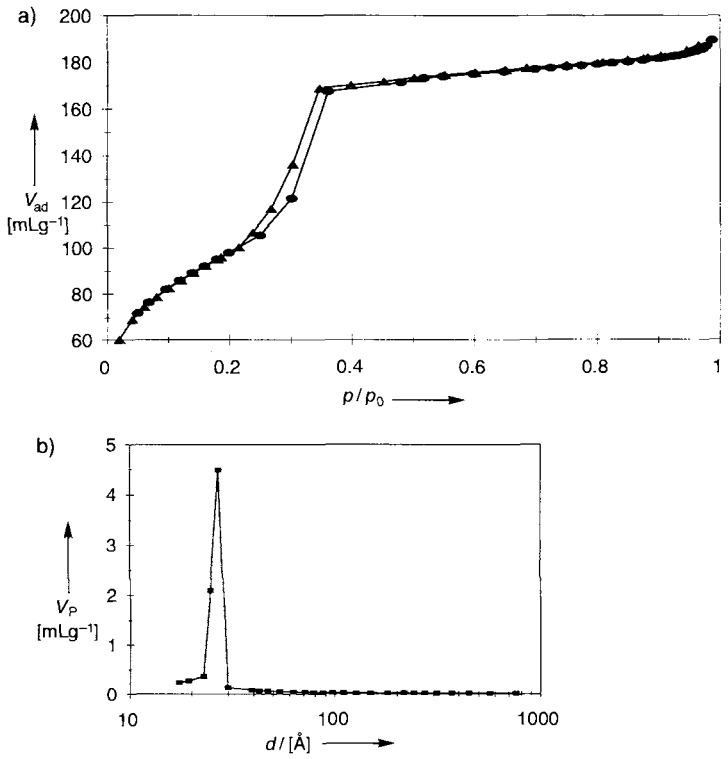

Fig. 3. a) The N_2 adsorption(●) – desorption(▲) isotherms (V_{ad} = volume N_2 adsorbed, p/p_0 = relative pressure of N_2) for heat-treated (400 °C, 2 h) Nb-TMS1 synthesized with tetradecylamine and washed three times with EtOH/HNO_3 at 40 °C. The isotherms display the sharp incline at values of p/p_0 in the range which is typical of other mesoporous materials studied (0.2 to 0.4) [12,13]. b) BJH pore size (d = pore diameter, V_p = pore volume) distribution of the same Nb-TMS1 sample, illustrating the narrow pore opening range, centered at 27 Å. The N_2 adsorption data of this sample prior to heat treatment was nearly identical to that shown apart from the fact that the surface area decreased from 434 to 380 $m^2 g^{-1}$ and the pores decreased in size by about 1 Å after heat treatment.

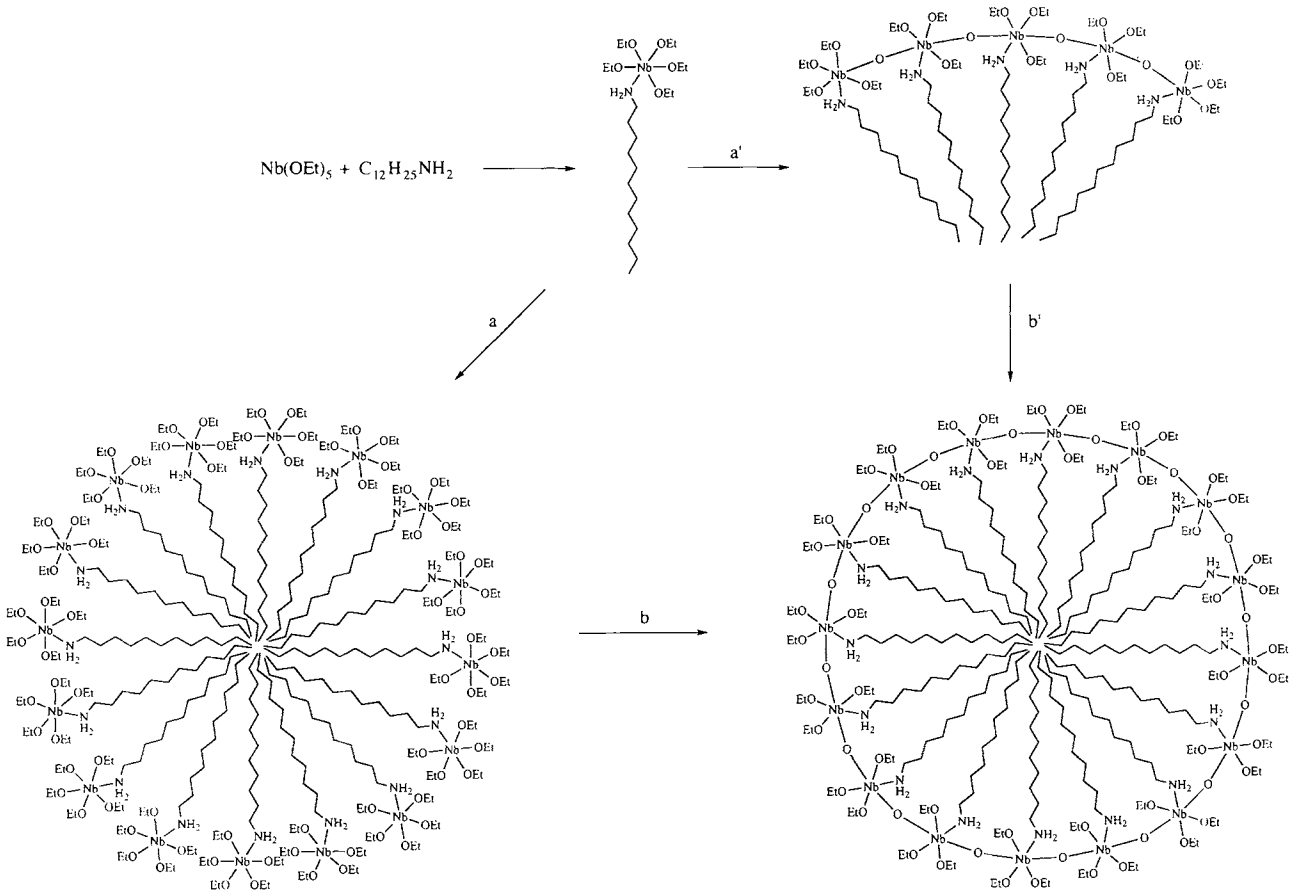
We have also tried other methods for surfactant removal. Washing the as-synthesized sample with ethanol produced materials with surface areas of about 5 $m^2 g^{-1}$. This is in contrast to recent results[10] which showed that amine surfactants could be removed from samples of silica- and alumina-based mesoporous materials by stirring them in ethanol at room temperature. This finding demonstrates that the amine surfactant was more strongly bonded to the inorganic wall in Nb-TMS1 than in the silica- and alumina-based systems where hydrogen bonding has been invoked to explain the self-assembly process.

The thermal and hydrothermal stability of surfactant-free Nb-TMS1 was studied with N_2 adsorption. This revealed that this material retains mesoporosity, crystallinity, and high surface area to at least 400 °C, a temperature that is well above those previously reported by other researchers for the as-synthesized mesostructured W, Sb, Pb, and Fe oxide materials.[2,7] These results indicate that the Nb-TMS1 synthesized by this novel approach would be very attractive as a high surface area catalytic material with thermal stability and uniform pore sizes. As a transition metal oxide with variable oxidation states, Nb-TMS1 would also offer additional unique catalytic properties not possible in the conventional alumina- or silicate-based MCM-41 systems.

The route to Nb-TMS1 described in Scheme 1 is novel in that the surfactant is covalently bonded to the metal atom in the precursor and possibly throughout the entire aging process. Our new mechanism contrasts to that proposed for the synthesis of MCM-41, where a covalent ligand interaction between the tetraalkylammonium surfactant head group and the Si center is neither present nor possible. In the formation of MCM-41, it has been proposed that the surfactant phase acts as template for the assembly of the inorganic phase either by preformed micelles[11] or electrostatic charge matching between the silicate oligomers and the individual surfactant head groups.[1,2,7] In the synthesis of Nb-TMS1, such a mechanism is not feasible since the surfactant is not soluble in water under the synthesis conditions applied. We propose instead that the Nb–N bond present in the precursor remains intact during at least the initial phase of the synthesis. This is supported by solution and solid-state MAS ^{15}N NMR studies conducted on ^{15}N-labeled samples of the dodecylamine niobium ethoxide precursor in [D_8]toluene and Nb-TMS1 synthesized from ^{15}N dodecylamine. The presence of substantial line broadening (about 450 Hz), attributable to the ^{93}Nb quadrupole (I = 9/2), in both the $^{15}N\{^1H\}$ NMR spectrum of the precursor complex in [D_8]toluene and the $^{15}N\{^1H\}$ MAS NMR spectrum of Nb-TMS1 is strong evidence of a N–Nb bond in both substances. The difference of the chemical shifts of 6.40 ppm between the precursor complex (δ = − 351.13) and free dodecylamine (δ = − 357.53) in [D_8]toluene is virtually identical to the difference of 5.96 ppm between solid Nb-TMS1 (δ = − 361.96) and solid dodecylamine (δ = − 367.92). This suggests that the nitrogen nucleus in Nb-TMS1 has remained bonded to Nb throughout the course of the synthesis process. Furthermore, addition of niobium ethoxide to an alcohol/water solution of dodecylamine led only to formation of amorphous materials. This emphasizes the importance of forming the bond between the metal and the head group prior to exposure to water. Also, while the organic phase in samples of MCM-41 prepared with amine surfactants at neutral pH can be removed by stirring in ethanol for one hour, little if any surfactant is removed from Nb-TMS1 under these conditions. This further supports that Nb–N bonds may well be intact in the as-synthesized material.

The strong interaction between the micelle head groups and the inorganic precursor molecule provided by our ligand-assist-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3504-0428 $ 15.00+.25/0



Scheme 1. Schematic representation of two possible synthesis pathways for Nb-TMS1 under a ligand-assisted templating mechanism. In pathway 1, the organometallic precursor self-assembles in ethanol prior to hydrolysis (a). The micellar array thus formed holds the Nb-containing head groups in place during subsequent condensation (b). Although alcohol can disrupt micelle formation, this phenomenon is largely dependent on concentration of the surfactant and the dielectric constant of the medium [14–16]. Due to the high concentrations of the niobium precursor used in the synthesis of Nb-TMS1 and the polar nature of ethanol, micelle formation is possible. Although the niobium head group is not hydrophilic, we think that because of ethoxy exchange with the free ethanol in the solvent, it would prefer to occupy regions of the solution rich in ethanol, while the hydrophobic tail groups would tend to cluster together. Evidence for this is that ethoxo complexes are usually soluble in ethanol, while long-chain hydrocarbons are not. In pathway 2, the self-assembly step (b') occurs only after sufficient propagation of the alkoxide hydrolysis and polycondensation (a'). The self-assembly of polymers containing hydrophobic and hydrophilic regions during chain growth has been noted before. Although the niobium head group is initially hydrophobic, the hydrolytic replacement of ethoxo groups with hydroxo and oxo groups may have given rise to progressively more hydrophilic head group assembly in forming the final mesostructure depicted.

ed templating approach is unique. It has enabled us to synthesize the first mesoporous transition metal oxide, Nb-TMS1, which has excellent thermal stability. We have further applied this methodology to prepare mesoporous oxides of Ti, Zr, Ta, Ce, and Y, and it has great potential to be general to a myriad of related mesoporous materials constructed from transition metal, lanthanide, and actinide oxides. Availability of such materials with well-defined hexagonally packed mesoporous structures of high thermal stability will greatly advance a variety of catalytic and other applications. The ability to intentionally vary the pore size of such material through varying surfactant chain lengths and addition of swelling agents will offer increased selectivity in reactions involving large molecules. The new possibility of generating transition metal oxide based systems with ease of dopant introduction will further provide attractive compositional control for tailoring catalytic materials characteristics.

Experimental Procedure

The X-ray powder diffraction data were recorded on either a Siemens D-5000 θ-θ diffractometer with $Cu_{K\alpha}$ radiation and a scintillation detector at 2.2 kW or a Rigaku RU-300 θ-2θ with a rotating anode using $Cu_{K\alpha}$ radiation at 10 kW. High-resolution transmission electron microscopy (TEM) images and electron diffraction patterns were obtained on a JEOL 2010 transmission electron microscope operated at 200 kV. Samples were prepared by sonication in 2-propanol and suspension on carbon-coated copper grids. N_2 adsorption data were collected on a Micromeritics ASAP 2000 Sorption Analyzer.

In a typical procedure, tetradecylamine (1.68 g, 7.87 mmol) was dissolved in niobium(v) ethoxide (5.0 g, 15.74 mmol). The solution was stirred until homogeneous and ethanol (5 mL) was added. Water (15 mL) was then added and the mixture was stirred, which caused the immediate precipitation of a white solid. This mixture was then left overnight at ambient temperature and further aged at 80 °C, 100 °C, and 180 °C for 1, 1, and 7 days, respectively. The product was collected by suction filtration and washed with three 50 mL portions each of water, ethanol, and ether. After drying in a vacuum oven at 100 °C, the surfactant was removed by treatment with 70% nitric acid at pH 1–2 in ethanol for 1–12 hours at room temperature, followed by stirring in ethanol for 12–24 hours. Materials prepared in this manner have pore sizes of about 27 Å and surface areas of 400 to 600 $m^2 g^{-1}$ with an XRD (100) peak centered at a d value of 31 Å.

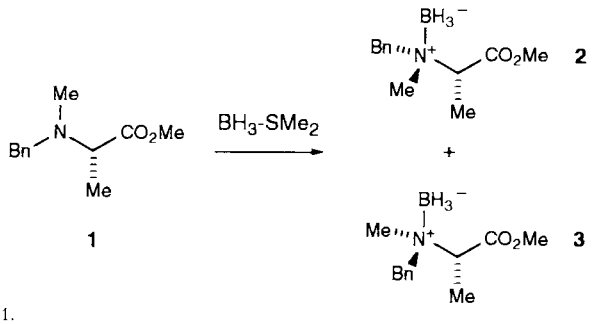
Chiral Borane–Amine Adducts in Asymmetric Synthesis: Alkylation of Alanine Derivatives

Vincent Ferey, Loïc Toupet, Thierry Le Gall, and Charles Mioskowski*

Current interest in the α-methyl-α-amino acids stems from their use as conformational modifiers in peptides and as components of biologically active peptides.[1] Hence, in recent years, various synthetic approaches to this class of compounds have been developed.[2, 3] Herein we present a method that allows the enantioselective synthesis of α-methyl-α-methylamino esters **4** (see Scheme 2) from methyl (*S*)-*N*-benzyl-*N*-methylalaninate. This approach does not rely on a chiral auxiliary reagent, but is based on the self-regeneration of the stereogenic center.[4] The key reaction, the α-alkylation of an enolate containing a chiral borane–amine moiety,[5–7] proceeds with up to 82% *ee*.

Amino ester **1** (90% *ee*)[8] was prepared from L-alanine methyl ester in two steps: N-benzylation (PhCHO, $NaBH_4$, 80%) and N-methylation (HCHO, HCO_2H, MeOH, 86%) (Scheme 1). Treatment of **1** with BH_3–SMe_2 in THF (Table 1, entry 1) led to a mixture of diastereomeric borane–amino ester adducts **2** and **3**, which were separated by column chromatography. Their structures were established unambigously by a single-crystal X-ray analysis of the less polar diastereomer **2** (Fig. 1).[9] Interestingly, in the solid state, the C2 proton in **2** is antiperiplanar with respect to the bulkier substituent on the nitrogen atom, the benzyl group.

We later noticed that the two diastereomers equilibrate in THF at room temperature, and then we conducted the complexation in other solvents (Table 1). We found that, in hexane, it



Scheme 1.

Table 1. Formation of borane–amino ester adducts from **1** (Scheme 1).

Entry	Solvent	Equiv borane	*T* [°C]	Time [h]	Ratio **2**/**3**	Yield [%]
1	THF	1.1	0	1	46/54	64 [a]
2	3:1 hexane:CH_2Cl_2	1.05	0	1	53/47	[b]
3	toluene	1.05	0	1	60/40	[b]
4	hexane	0.95	20	6	90/10	62 [c]
5	hexane	0.95	20	24	95/5	78 [d]

[a] Combined yield of diastereomers **2** and **3** after chromatographic separation. [b] Yield not determined. [c] Combined yield of diastereomers **2** and **3** (isolated as a solid). [d] Yield of diastereomer **2** after recrystallization.

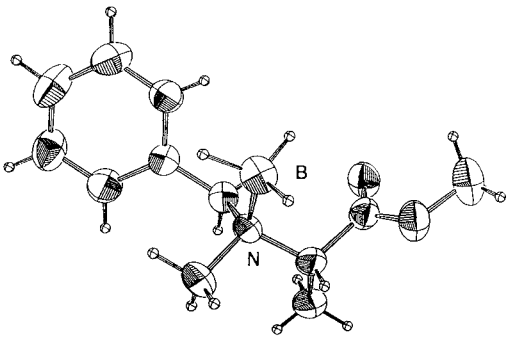


Fig. 1. Crystal structure of the borane–amino ester adduct **2**.

was possible to obtain selectively diastereomer **2**, which crystallized during the reaction, in good yield (Table 1, entry 5). This phenomenon can be described as an asymmetric crystallization-induced disequilibrium,[10] a principle previously applied to the synthesis of enantiomerically pure borane–amine complexes with a chiral boron atom.[11]

The diastereomer **2** was alkylated with various halides (Scheme 2; Table 2, entries 1–5). Potassium hexamethyldisilazide (KHMDS) was employed as base when benzylic or allylic electrophiles were used. Under the same conditions, other non-activated halides did not react with the enolate even at 0 °C. In these cases lithium diisopropylamide (LDA) was used and hexamethylphosphoric triamide (HMPA) (2 equiv) was added prior to the introduction of the electrophile. When the reaction was complete, the reaction mixture was hydrolyzed with a saturated aqueous NH_4Cl solution, which led to compounds **4**. The products were then purified by column chromatography. The yields were generally good; however, compound **4d** was obtained from pentyl iodide in only 50% yield. The enantiomeric excesses were determined by ^1H NMR spectroscopy of **4** or of alcohols **5** (obtained by reduction of **4** with diisobutylaluminum hydride) in presence of [Eu(hfc)$_3$]. The values given are corrected for 90%

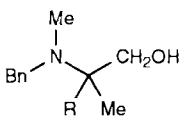
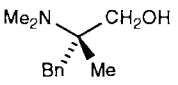
4	$CH_3(CH_2)_4I$	LDA	**2**	**4d**	+4.5	50	68 [d]
5	MeO_2CCH_2Br	LDA	**2**	**4e**	−3	82	80 [c]
6	$PhCH_2Br$	KHMDS	**3**	**4a**	−27	66	68 [c]
7	$CH_2{=}CHCH_2Br$	KHMDS	**3**	**4c**	−2	66	40 [d]
8	$CH_3(CH_2)_4I$	LDA	**3**	**4d**	−3.5	50	36 [d]

[a] See Experimental Procedure for details; all products have been fully characterized. [b] Enantiomeric excesses were determined from the ^1H NMR spectrum of **4** or of alcohol **5** in the presence of $[Eu(hfc)_3]$. The values given are corrected for 90% optical purity of the starting material **1**. [c] Enantiomeric excess determined with amino ester **4**. [d] Enantiomeric excess determined with amino alcohol **5**.

optical purity of the starting material **1** used. Thus, the *ee* values observed for the alkylation reactions of **2** range from 68 to 82%.[12] The main enantiomer in **4a** was shown to have *S* absolute configuration by chemical correlation with the known alcohol **6**.[14]



5

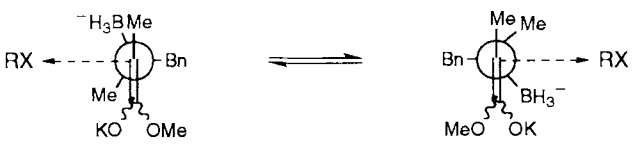


6

Alkylation reactions were also performed with diastereomer **3** (which contained 5% of diastereomer **2**). As expected, the optical rotations of the products of these reactions are of opposite sign to those of the corresponding compounds obtained from **2** (Table 2, entries 6–8). However, the *ee* values of the products were lower than expected in this case, probably because **3** epimerizes partially, at the chiral nitrogen center, under the reaction conditions.[15]

Isolation and separation of the diastereomeric borane–amine intermediates formed in the alkylation reactions could have, in principle, provided a means for improving the enantiomeric excesses of the final products; however, all attempts to isolate the intermediates in the reaction of **2** with benzyl bromide failed. Moreover, no borane–amine adducts were obtained in the reaction of compound **4a** with BH_3–SMe_2. Steric crowding on the nitrogen atom probably prevents formation of a stable adduct.

A Felkin model of the transition state[16] can be used to explain the stereochemical outcome of the reactions. If one assumes that the incoming electrophile RX attacks *anti* to the benzyl group, the larger substituent on nitrogen, two conformations **A** and **B** can be adopted by the enolate derived from diastereomer **2**. Experimental results are in agreement with predominant alkylation through transition state **A**, which should be favored on the basis of steric and electronic effects: BH_3 is larger than the methyl group, and the two negative charges localized on the boron atom and on the carboxylate function are far from each other. This explains the exceptionally high enantiomeric excesses observed here for the alkylation of an acyclic α-amino ester derivative.



A B

The application of the optically active adducts of chiral amines and borane in synthetic organic chemistry has until now been limited to the enantioselective reduction of ketones and ketone derivatives,[17] to the enantioselective hydroboration of alkenes[18] and, via their corresponding amine–boryl radicals, to the kinetic resolution of carbonyl compounds.[7c] In our new application for borane–amine adducts in asymmetric synthesis a temporarily chiral, quaternary nitrogen atom serves to induce the enantioselective formation of a carbon–carbon bond.

Experimental Procedure

2, 3: To a solution of amino ester **1** (10 g, 48.3 mmol) in THF (150 mL) was added dropwise at 0 °C BH_3–SMe_2 (5.31 mL, 53.1 mmol). The reaction mixture was stirred for 1 h at 0 °C before the solvent was removed by evaporation. The ^1H NMR spectrum of the crude product showed that the ratio of the two diastereomers **2** and **3** was 46:54. Purification by column chromatography (silica gel, hexane/CH_2Cl_2 (3/2)) afforded 2.267 g of borane–amino ester **2**, 2.51 g of a mixture of the two diastereomers, and 2.047 g of borane–amino ester **3** (combined yield of **2** and **3**: 64%).

2: Colorless solid, m.p. 77 °C; $([\alpha]_D^{23} = -68.4$ ($c = 1.9$ in CH_2Cl_2)); ^1H NMR ($CDCl_3$): $\delta = 1.15$–2.20 (m, 3H), 1.58 (d, $J = 7.1$ Hz, 3H), 2.79 (s, 3H), 3.63 (q, $J = 7.1$ Hz, 3H), 3.72 (s, 3H), 4.08 (d, $J = 12.3$ Hz, 1H), 4.22 (d, $J = 12.3$ Hz, 1H), 7.30–7.50 (m, 5H); ^{13}C NMR ($CDCl_3$): $\delta = 13.8$, 44.1, 51.8, 64.1, 65.2, 127.6, 128.7, 131.2, 132.6, 171.6; ^{11}B NMR ($CDCl_3$): $\delta = -10.0$ (br q, $J = 95$ Hz); IR: $\tilde{\nu} = 3009$, 2954, 2416, 1743, 1452, 1433, 1221, 1166, 1114, 866, 748, 700 cm^{-1}; elemental analysis calcd. for $C_{12}H_{20}BNO_2$: C 65.19, H 9.12, B 4.89, N 6.33; found: C 64.93, H 9.11, B 5.05, N 6.28.

3: Colorless solid, m.p. 92–93 °C; $[\alpha]_D^{23} = -63.2$ ($c = 1.9$ in CH_2Cl_2)); ^1H NMR ($CDCl_3$): $\delta = 1.15$–2.15 (br m, 3H), 1.59 (d, $J = 7.1$ Hz, 3H), 2.56 (s, 3H), 3.76 (s, 3H), 3.79 (q, $J = 7.1$ Hz, 3H), 3.99 (d, $J = 12.2$ Hz, 1H), 4.39 (d, $J = 12.2$ Hz, 1H), 7.30–7.55 (m, 5H); ^{13}C NMR ($CDCl_3$): $\delta = 13.1$, 46.1, 51.9, 61.6, 65.8, 127.7, 128.7, 131.2, 132.6, 170.7; ^{11}B NMR ($CDCl_3$): $\delta = -10.5$ (m); IR: $\tilde{\nu} = 2958$, 2379, 1740, 1451, 1397, 1211, 1176, 1087, 858, 743, 699 cm^{-1}; elemental analysis calcd. for $C_{12}H_{20}BNO_2$: C 65.19, H 9.12, B 4.89, N 6.33; found: C 65.08, H 9.21, B 4.85, N 6.31.

Selective preparation of **2**: To a solution of amino ester **1** (300 mg, 1.45 mmol) in hexane (8 mL) was added dropwise at room temperature BH_3–SMe_2 (0.135 mL, 1.375 mmol). After 5 min a white precipitate began to separate. Stirring was continued for 24 h, then the reaction mixture was filtered. The solid was washed with a little hexane, then dried in vacuo. The ^1H NMR spectrum showed that the ratio of the two diastereomers **2** and **3** was 95:5. Recrystallization from hexane/CH_2Cl_2 (3/1) afforded 225 mg of **2** (78%).

Alkylation of **2** using KHMDS: A cooled solution of **2** (50 mg, 0.23 mmol) in toluene (0.5 mL) was added to a solution of KHMDS (0.545 mL of a 0.5 M solution in toluene, 0.27 mmol) in THF (3 mL) at −78 °C. The reaction mixture was stirred for 15 min at −23 °C then cooled to −78 °C; benzyl bromide (0.041 mL, 0.34 mmol) was added by syringe. The reaction mixture was stirred for 2 h at −78 °C then allowed to warm to 0 °C over 2 h. Saturated aqueous NH_4Cl (2 mL) was added, resulting in the formation of a white precipitate, which was dissolved by adding 2 mL of H_2O. The aqueous phase was extracted with CH_2Cl_2 (5 × 10 mL); the combined organic layers were washed with brine, dried over $MgSO_4$, then concentrated to dryness. Purification of the residue by column chromatography (silica gel, hexane/ethyl acetate (98/2)) afforded 52 mg of amino ester **4a** (78%).

Alkylation of **2** using LDA/HMPA: A fresh solution of LDA was prepared by adding 1.3 M *n*-butyllithium in hexane (0.577 mL, 0.75 mmol) to diisopropylamine (0.115 mL, 0.818 mmol) in THF (3 mL) at 0 °C, and stirring at this temperature for 15 min. A cooled solution of **2** (150 mg, 0.68 mmol) in toluene (0.5 mL) was added to the LDA solution cooled at −78 °C. The reaction mixture was stirred for 15 min at −23 °C then cooled to −78 °C. HMPA (0.237 mL, 1.364 mmol) was added rapidly, followed by methyl bromoacetate (0.097 mL, 1.023 mmol), dropwise. The reaction mixture was stirred for 2 h at −78 °C then allowed to warm to 0 °C over 2 h. Saturated aqueous NH_4Cl (2 mL) was added, resulting in the formation of a white precipitate, which was dissolved by adding some H_2O. The aqueous phase was extracted with diethyl ether (5 × 10 mL); the combined organic layers were washed

with brine, dried over $MgSO_4$, then concentrated to dryness. Purification of the residue by column chromatography (silica gel, hexane/ethyl acetate (98/2)) afforded 155 mg of amino diester **4e** (82%).

Heterobimetallic Hydroxy Complexes: $[Re_3(CO)_9(\mu_2\text{-}OH)_3(\mu_3\text{-}OH)]^-$ as a Novel Tripodal Ligand**

Wolfgang A. Herrmann,* André Egli, Eberhardt Herdtweck, Roger Alberto, and Franz Baumgärtner

Hydroxy and alkoxy complexes of transition metals have recently received renewed interest in terms of applications both in catalysis and—as precursors of metal oxides—in material science.[1–3] Hydroxy groups frequently bridge two or three metals, thus leading to oligomeric structures.[4] A notable example is the cubane-type rhenium cluster **1**, which forms from

$[Re_4(CO)_{12}(\mu_3\text{-}OH)_4]$ **1**

photolysis of the parent rhenium carbonyl complex $[Re_2(CO)_{10}]$ in water.[5] Hardly any chemistry has as yet unfolded for compounds of this type because of their perfectly closed structures. If it were possible, however, to remove a $[Re(CO)_3]^+$ corner from **1**, the resulting new anionic Re_3 cluster should display a rich coordination chemistry provided a) no redox instability is associated with this structure, and b) metal ions of the correct size are introduced as reaction partners.

The tetraethylammonium salts of **2** and **3** are easily accessible from $[N(C_2H_5)_4]_2[ReBr_3(CO)_3]$.[6] Both hydroxyrhenates were isolated from aqueous solution at room temperature after simply adding 1.33 equivalents of alkali hydroxides for **2** and more than 1.5 equivalents for **3** (Scheme 1). Whereas the dinuclear **3** exhibits triply hydroxy-bridged $[Re(CO)_3]^+$ moieties, the trinuclear **2** is an incomplete cubane-type structure missing one rhenium corner. The perfect cubane **1** does not form this way in alkaline aqueous solution.

$[Re_3(CO)_9(\mu_2\text{-}OH)_3(\mu_3\text{-}OH)]^-$ **2**

$[Re_2(CO)_6(\mu_2\text{-}OH)_3]^-$ **3**

The hydroxymetalate **2** acts as a novel tripodal ligand for a wide range of metals. Thus, divalent manganese and copper form the heterobimetallic, electroneutral complexes **4a** and **4b** in near quantitative yields as fully air- and water-stable crystalline compounds.[7]

$[MRe_6(CO)_{18}(\mu_3\text{-}OH)_8]$ **4a** ($M = Mn^{II}$), **4b** ($M = Cu^{II}$)

A single-crystal X-ray diffraction study of the Re_6Mn complex **4a** (Re^I/Mn^{II}) revealed a "double-cubane" type structure, in which the common corner is occupied by the divalent metal ion.[8] The average Mn–O distance of 2.177(7) Å agrees well with common Mn^{II}–O lengths and particularly with the bond lengths in the related homonuclear complex $[Mn_7(CO)_{18}(\mu_3\text{-}OH)_8]$ (av.: 2.169(2) Å).[9] The Re–O distances are slightly longer (2.157(8)–2.212(9) Å, av. 2.182(8) Å) than in the free ligand **2** (2.146(6)–2.174(8) Å),[6] but they are still shorter than in the closed cubane **1** (2.207(8) Å,[10] 2.159(26)–

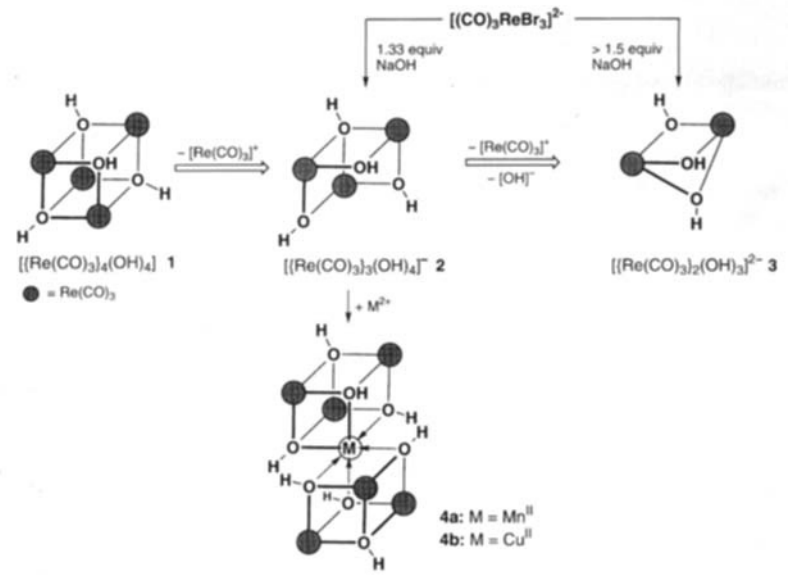

Scheme 1.

2.224(27) Å[11]). The central manganese atom shows an unusual geometry in that it resembles a trigonal prism more than an octahedron (see Fig. 2, left).

A space-filling model reveals the hydrophobic shell resulting from the 18 peripheral carbonyl ligands. However, the intermolecular alignment that depends on hydrogen bonds between the hydroxy ligands and cocrystallized water molecules shows clearly that this shell is upset by the hydroxy groups of the complex. Thus, the twisted core geometry can be rationalized from these peripheral interactions between hydroxy and carbonyl ligands. Those hydroxy groups not engaged in coordination with the manganese center are not captured by water but rather by ether molecules, derived from the preparation of the complex.[7] This results in a layered arrangement in the crystal, assembled from parallel rods of the complex. The space between the layers is occupied by the ethyl groups of ether molecules (Fig. 1, left).

With respect to the Re–O distances (2.151(10)–2.225(9) Å, av. 2.187(10) Å), the copper complex resembles the manganese derivative. However, the coordination sphere of the Cu^{II} center is an octahedron with tetragonal distortion (Fig. 2, left). The bond lengths differ as much as 0.44 Å, ranging from 1.992(9) to 2.428(10) Å.

Like its manganese analogue, the copper complex compound exhibits a layered arrangement in the crystal (Fig. 1, right). However, **4b** crystallizes with only two water molecules per complex (in contrast to six in **4a**), which form hydrogen bonds with the μ_3-OH ligands of one flank of the complex. The μ_3-OH ligands of the other flank form very weak hydrogen bonds to the μ_3-OH ligands of a second and third complex. As in **4a**, the layers are coated with diethyl ether molecules. In contrast to **4a**, the complexes are rotated around the copper ion within the layer plane, which probably facilitates hydrogen bonding. Though the differences in layering of the complexes might arise from different coordination geometries of the heterometals, this suggestion is merely speculative.

The characteristics of **2** as organometallic, tridentate, ligand binding through oxygen bears a certain resemblance to those of silsesquioxanes[12–15] and ligands of the type $[CpCo\{P(O)R'R''\}_3]^-$.[16,17] As opposed to the π-donor properties of the latter, **2** and silsesquioxanes are pure σ-donors, and both form cubane-type structures. However, the hydroxy groups of **2** are not deprotonated upon coordination.

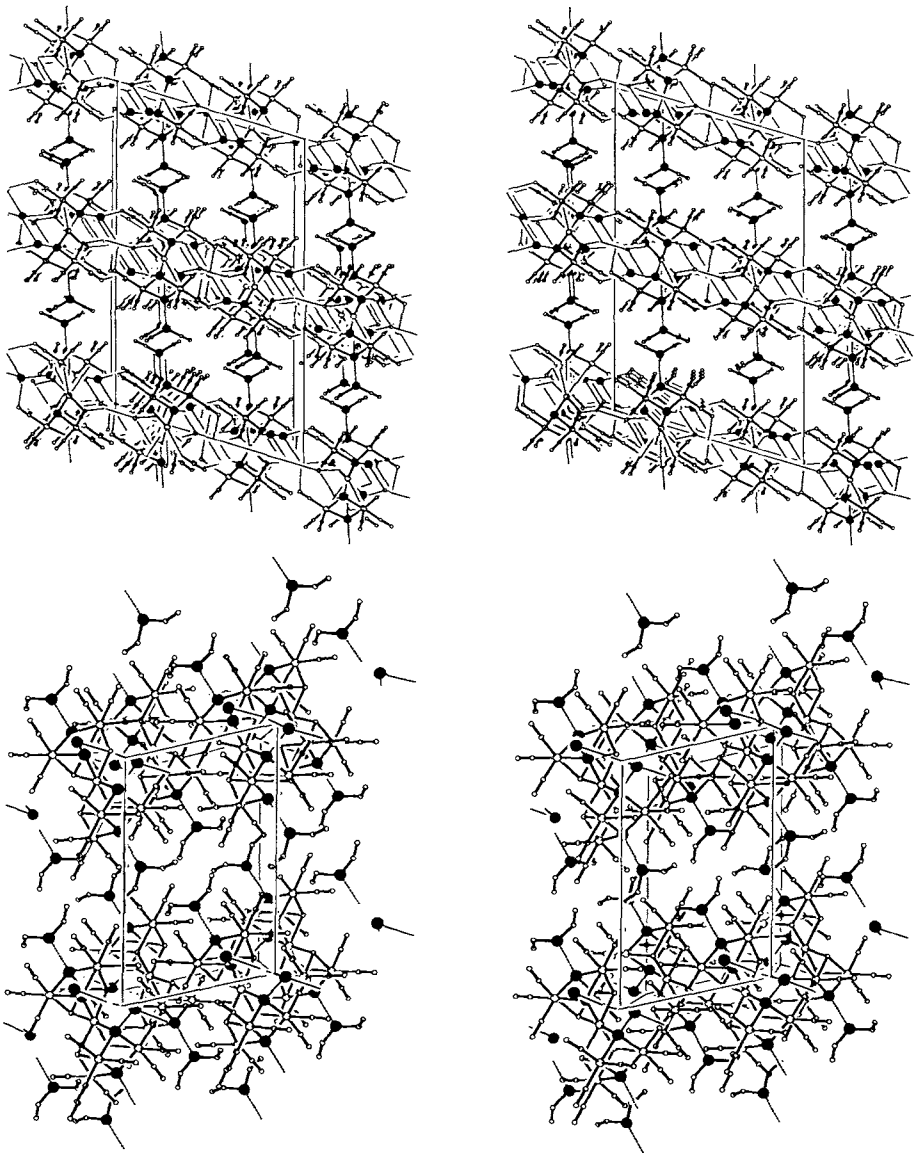

Fig. 1. The layered arrangement of the complex compounds **4a** (left) and **4b** (right) in the crystal (PLUTON drawing). The views are directed between the layers. Dotted lines indicate hydrogen-bridged O···O bonds with 2.59 Å < D–H···A < 2.80 Å.

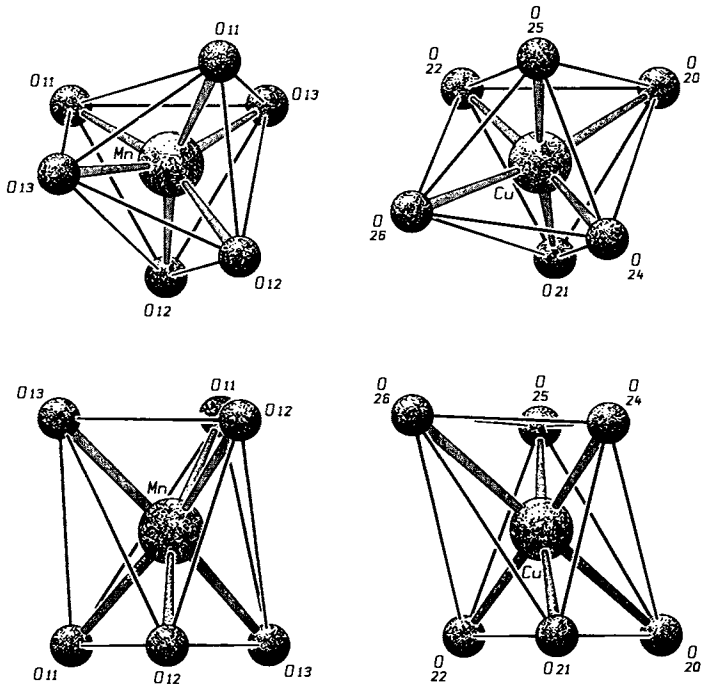

Fig. 2. Comparison of the Mn^{II} and Cu^{II} coordination sphere of **4a** and **4b** (SCHAKAL drawing).

The very different coordination geometries of **4a** and **4b** demonstrate that the new organometallic ligand **2** combines tridentate complexation with a highly flexible core geometry. In addition, the notably different bond lengths and the ability to complex hard as well as soft metal centers illustrate the potential of hydroxymetalates in coordination chemistry.

[7] Since the formation of the trinuclear unit takes time, the ligand solution should be prepared several hours before complexation of the second metal M. For this purpose NaOH (1 M solution, 133 μL) is suspended in 2 mL of an aqueous solution of $[N(C_2H_5)_4]_2[ReBr_3(CO)_3]$ (77 mg, 0.1 mmol). The latter compound can be prepared either from $[Re_2(CO)_{10}]$ [6] or perrhenate (R. Alberto, R. Schibli, A. Egli, P. A. Schubiger, W. A. Herrmann, G. Artus, U. Abram, T. A. Kaden, *J. Organomet. Chem.* **1995**, *492*, 217–224). Compounds **4a**, **b** are prepared by the addition of a solution of the appropriate metal salts (0.0166 mmol) in water (0.5 mL) to the ligand solution. The reaction solution is then extracted with diethyl ether (5 mL). After separation of the phases, the ether is removed in vacuo. IR (KBr): **4a**: ν(CO) 2031, 1926, 1898; **4b**: ν(CO) 2024, 1905 cm^{-1}. An excess of the metal salts decreases the yield of 1:2 complexes. Analysis by IR spectroscopy of the residue from the aqueous phase of **4a**, which was evaporated to dryness, displayed a significant shift of the carbonyl stretching bands to lower wavenumbers (2014 (A_1) and 1875 cm^{-1} (E)). The dependence on the stoichiometry suggests formation of 1:1 complexes. The shift in wavenumbers might be caused by anions coordinated to the manganese center.
[8] Crystallographic data for $C_{18}H_8MnO_{26}Re_6 \cdot 6H_2O \cdot 2(C_2H_5)_2O$ (**4a**): $M_r = 2068.7$, monoclinic, $C2/c$ (No. 15), $a = 2980.1(4)$, $b = 1010.8(1)$, $c = 1781.7(2)$ pm, $\beta = 106.74(1)^\circ$, $V = 5139.5(11) \times 10^6$ pm^3; $Z = 4$; $\rho_{calcd} = 2.674$ $g\,cm^{-3}$, $F_{000} = 3772$, $\mu = 144.0$ cm^{-1}. Data were collected on a STOE IPDS diffractometer with graphite monochromator, $\lambda(Mo_{K\alpha}) = 0.71073$ Å. For general details about the data collection see Ref. [19]. During data collection no decay was observed, absorption correction [20], and correction for extinction effects were applied. From 16916 collected data, 1333 were rejected because of negative intensities and 303 because of systematic absences. After merging ($R_{int} = 0.088$) 4349 from 4350 unique data ($I > 0.0\sigma(I)$) were used in the final refinement. The structure was solved with direct methods and refined by full-matrix least-squares calculations, with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were calculated in ideal positions except for those located at the solvent water and the ether molecules. Refinement was concluded with $R1 = 0.060$ and $wR2 = 0.115$; SHELXL weights. Synthesis and Structure of a Bridging Germylidyne Complex: A Stable Germyl Cation**

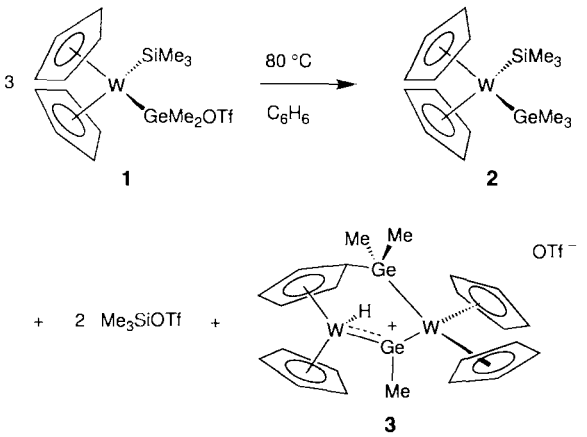
Lisa K. Figge, Patrick J. Carroll, and Donald H. Berry*

The isolation of three-coordinate silicon cations, R_3Si^+, have been the subject of many recent reports.[1, 2] However, analogous germanium cations have not been described. In a related vein, Ogino, Tobita and co-workers have isolated a cationic diiron complex bridged by a germanium center. This germanium center is substituted with one alkyl group and a Lewis base[3a] and can be viewed as a base-stabilized germyl cation. We now report the synthesis and structure of a germanium-bridged tungsten dimer, which formally contains a base-free dimetalated germyl cation (germylium ion).

Thermolysis of $[Cp_2W(SiMe_3)(GeMe_2OTf)]$ (**1**)[4] in a solution of benzene at 80 °C results in the formation of three new products, trimethylsilyl triflate ($Me_3SiOSO_2CF_3$), $[Cp_2W(SiMe_3)(GeMe_3)]$ (**2**), and the dinuclear compound **3** [Eq. (a)]. Interestingly, the reaction also occurs when the solid is heated at 80 °C in the absence of a solvent.



Trimethylsilyl triflate was identified by ^1H and ^{19}F NMR spectroscopy and compared with an authentic sample. The tungsten germyl silyl complex **2** has previously been synthesized independently.[4] The dimeric compound **3** has been isolated in good yield (93% of theoretical) as a bright orange powder, which is moderately soluble in acetonitrile. The ^1H NMR spectrum (in CD_3CN) exhibits three singlets for the intact Cp rings and three broad multiplets for the substituted C_5H_4 ring. The resonance for the remaining C_5H_4 proton is obscured by the Cp signals. Two singlets correspond to the nonequivalent methyl groups of the $C_5H_4GeMe_2$ fragment and a singlet at $\delta = 1.73$ to the methyl group on the germanium bridging the two tungsten centers, more than 1 ppm downfield from the $GeMe_2$ resonance. A singlet corresponding to the tungsten hydride is observed at $\delta = -10.8$ ($^1J_{W,H} = 79.9$ Hz). Significantly, both this hydride chemical shift and tungsten coupling constant are normal for tungstenocene hydrides (cf. **4**,; see below), which indicates that there is no nonclassical Ge···H–W interaction between the three-coordinate germanium atom and the tungsten hydride.

Although the identity of **3** could not be conclusively established by ^1H NMR, the structure of **3** has been unambiguously determined by single-crystal X-ray diffraction methods.[5] The structural analysis reveals a dinuclear compound with one normal Cp_2W unit and second tungsten (W2) with one intact Cp ring and one germanium-substituted Cp ring (Fig. 1). The tungsten hydride observed in the ^1H NMR spectrum was located in the structure at a chemically reasonable position (W–H = 1.53 Å), but did not refine satisfactorily. There is no indication of any interaction between the hydride and the three-coordinate germanium (Ge1···H = 2.80 Å). The germanium on the ring has two methyl groups and is bonded to one of the tungsten metal centers. The second germanium in the structure bridges the two tungsten centers and has only a single methyl substituent. The triflate counterion is totally dissociated; the closest contact to the three-coordinate germanium is 3.707(8) Å.

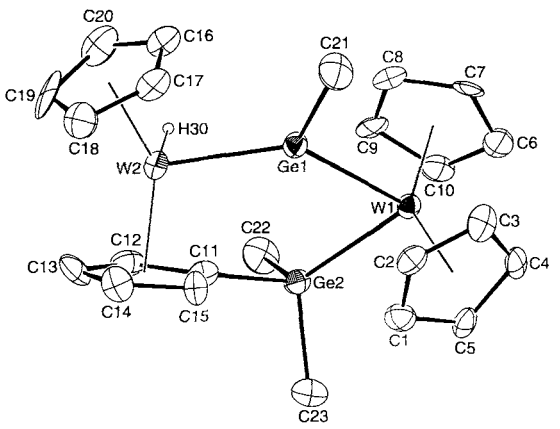


Fig. 1. Crystal structure of **3** (ORTEP drawing showing 30% probability thermal ellipsoids). The hydrogen atoms and the triflate ion have been omitted for clarity. Selected bond lengths [Å] and angles [°]: W1–Ge1 2.583(2), W1–Ge2 2.605(2), W2–Ge1 2.487(2), Ge1–C21 2.001(18); W1-Ge1-C21 108.9(6), W2-Ge1-C21 121.2(6), W1-Ge1-W2 129.9(1).

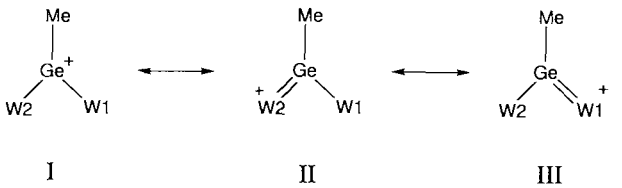
The geometry about the three-coordinate germanium atom Ge1 is planar (angle sum 360.0°), and it lies only 0.009 Å above the plane defined by the two tungsten centers and the methyl substituent. The tungsten–germanium bond length from W1 to the four-coordinate germanium atom Ge2 is comparable to the W–Ge single bond in $[Cp_2W(SiMe_3)(GeMe_2Cl)]$.[4] In addition, the bond between W1 and Ge1 is also typical of a W–Ge single bond. However, the W2–Ge1 distance is significantly shorter at 2.487(2) Å.

Three possible resonance structures for the bonding about the three-coordinate germanium center are shown in Scheme 1. Structure I depicts the case in which the cationic charge is localized on germanium. In structures II and III, the charge is delo-



Scheme 1. The three possible resonance structures to describe the bonding about the three-coordinate germanium atom.

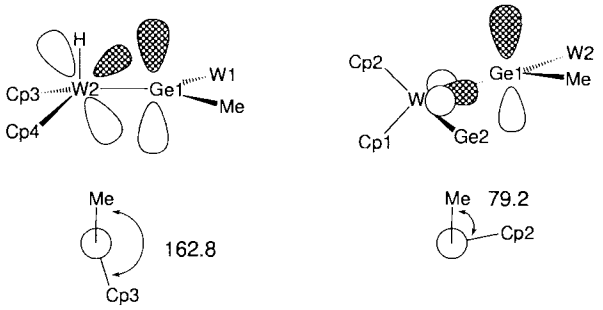
calized onto the tungsten centers by π-back bonding to the germanium atom. Although delocalization of the charge to both tungsten centers is possible, the presence of one normal and one short W–Ge distance suggests that only W2 is involved in back bonding. The valence orbitals in bent Cp_2M complexes lie in the equatorial plane between the Cp ligands.[7] Therefore, maximum π-bonding is achieved when the acceptor orbital on germanium is also located in the equatorial plane.

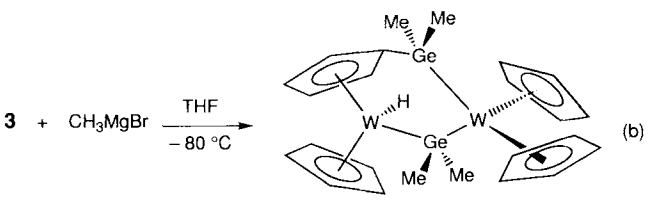
Scheme 2 illustrates the relative orientation of each tungsten center to the bridging three-coordinate germanium, as determined in the crystal structure. The two Cp rings on



Scheme 2. The relative orientation of each tungsten center to the bridging three-coordinate germanium atom (Ge1).

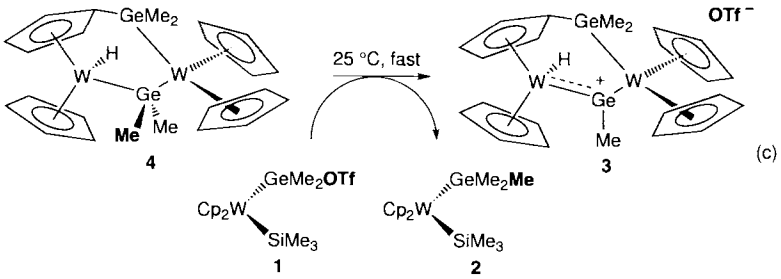
W2 and the two substituents on Ge1 (W1 and C21) are nearly eclipsed (dihedral angle Cp3-W2-Ge-C21 = 162.8°) This positions the p-orbital on germanium coplanar with a tungsten valence orbital of π-symmetry (with respect to the W–Ge bond), and π-back bonding from the d^2, 18-electron tungsten center should be possible. On the other hand, the rings on W1 are nearly perpendicular to the substituents on Ge1 (dihedral angle Cp2-W1-Ge-C21 = 79.2°); thus only minimal overlap should be possible with the π-symmetry orbital. This is consistent with the normal W1–Ge1 and short W2–Ge1 distances observed in the structure. Once again it should be stressed that although the W2–H30 bond also lies in the plane of the Ge p-orbital, the spectroscopic parameters are typical of an unperturbed tungsten hydride and appear to preclude a bridging or nonclassical interaction with the germanium atom.

Some insight into the formation of **3** has been gained from the following experiments: Treatment of a suspension of **3** in THF with CH_3MgBr yields a soluble dimeric product, tentatively assigned as **4** on the basis of ^1H NMR [Eq. (b)].



4

Although **4** decomposes in solution over hours and has not been isolated as a pure compound, treatment of **4** with **1** at room temperature leads to the rapid formation of **2** and precipitation of **3** [Eq. (c)].



Thus **1** is capable of abstracting a methyl group from the dimetalated $GeMe_2$ unit in **4**, and this seems a probable final step in the formation of **3** from **1**. Our group has recently reported an intermolecular methyl group migration in a related tungsten germyl silyl complex,[4] and, in addition, Tilley and Grumbine have directly observed a comparable intermolecular migration in the reaction of $[Cp^*Ru(PMe_3)_2(SiMe_3)]$ with the stable silylene complex, $[Cp^*Ru(PMe_3)_2(SiPh_2)]^+$.[8]

The process by which **4** is formed from **1** remains obscure, but could involve dimerization and rearrangement of the neutral germylene complex formed by 1,2-elimination of Me_3SiOTf from **1**. Alternatively, the stepwise intermolecular elimination of Me_3SiOTf could also achieve the same end. Activation of Cp ring carbon atoms is a well-documented process often associated with metallocene dimerization.[9]

Compound **3** bears some relation to the cationic base-stabilized bridging germylidyne, and analogous silylidyne complexes, reported by the Ogino group.[3] Tilley and Grumbine have also reported a neutral bridging silylidyne complex, $[(CO)_4Os\{Si(S\text{-}p\text{-}Tol)\}RuCp^*(PMe_3)_2]$, in which a Si(STol) group bridges the two metals.[10] Similarly, **3** can be viewed as a cationic complex with germylidyne bridges.

Other important examples of two- and three-coordinate germanium centers stabilized by transition metals include dimetalated cumulenes of the type M=E=M)[11] (for example, $[Cp'(CO)_2Mn{=}Ge{=}MnCp'(CO)_2]$[11a]) and the "inidene" complexes extensively studied by Huttner et al.[12] The anionic inidene complex $[Cp'(CO)_2Mn{\cdots}Ge(I){\cdots}MnCp'(CO)_2]^-$ is of particular note, as it bears the strongest structural resemblance to **3**. One apparent difference is that the inidenes are generally viewed as having a rather electron-rich main group element (for example Ge^0) which undergoes π-bonding to satisfy the electron count at the metal centers. On the other hand, the three-coordinate germanium atom in the cation of **3** is clearly electron deficient; hence the π-backbonding from the 18-electron tungsten center serves to delocalize the positive charge. This difference has chemical consequences: the methyl germanium center in **3** is electrophilic and reacts with the methyl Grignard compound to yield **4**, whereas the structure of $[Cp'(CO)_2Mn{\cdots}Ge(I){\cdots}MnCp'(CO)_2]^-$ suggests the iodide is best depicted as an anion weakly coordinating to a Ge^0 center.

Experimental Procedure

3: Compound **1** (290 mg, 0.45 mmol) was placed in a glass bomb, which was evacuated and placed in an 80 °C oil bath for 48 hours. The pale yellow powder became bright orange. The volatiles (trimethylsilyl triflate) (0.050 g, 0.22 mmol, 75% of theory) were removed under vacuum, and the orange powder was washed with petroleum ether to remove $[Cp_2W(SiMe_3)(GeMe_3)]$ (0.068 g, 0.134 mmol, 90% yield). Yield of **3**: 136 mg (93%). C,H anal. calcd for $C_{24}H_{29}W_2Ge_2O_3F_3S$: C, 29.80; H, 3.02; found: C, 29.92; H, 2.71. ^1H NMR (200 MHz, CD_3CN, 303 K): δ = 5.88 (m, 1H, C_5H_4Ge), 5.30 (m, 1H, C_5H_4Ge), 5.17 (m, 1H, C_5H_4Ge), 4.91 (s, 5H, Cp), 4.75 (s, 5H, Cp), 4.59 (s, 5H, Cp), 1.73 (s, 3H, GeMe), 0.48 (s, 3H, $GeMe_2$), 0.44 (s, 3H, $GeMe_2$), −10.80 (s, 1H, WH; $^1J(W,H)$ = 79.9 Hz).

4: A THF solution (7 mL) of **3** (30 mg, 0.031 mmol) was cooled to −80 °C and a 3.0 M solution of CH_3MgBr (0.030 mmol) in diethyl ether (10 μL) was added. The reaction was warmed to room temperature and stirred for 10 minutes. The volatiles

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3504-0436 $ 15.00+.25/0

were removed under vacuum to yield a yellow solid. ^{1}H NMR (200 MHz, C_6D_6, 303 K): 4.95 (m, 1H, C_5H_4Ge) 4.14 (s, 5H, Cp), 4.12 (s, 5H, Cp), 3.96 (s, 5H, Cp), 3.21 (m, 1H, C_5H_4Ge), 0.77 (s, 3H, GeMe), 0.75 (s, 3H, GeMe), 0.62 (s, 3H, GeMe), 0.61 (s, 3H, GeMe), −11.32 (s, 1H, WH; ^1J(W,H) = 81.7 Hz). Two additional C_5H_4Ge resonances are believed to be obscured by the other Cp resonances or the large residual THF resonance.

Reaction of **4** with **1**: Immediately following the isolation of **4**, the solid was dissolved in C_6D_6 (0.5 mL) and filtered. This solution was added to an NMR tube containing **1** (16 mg, 0.025 mmol). The tube was sealed under vacuum. Immediately after addition a bright orange precipitate forms. The ^{1}H NMR indicates that only **2** and **1** (in excess) are present in solution.

[5] X-ray structure analysis of **3**: $C_{24}H_{29}W_2Ge_2SF_3O_3$ (M_r = 967.43), orange crystals, crystal dimensions 0.05 × 0.03 × 0.04 mm; monoclinic, space group $P2_1/n$ (no. 14), a = 8.8533(2) b = 15.9110(4), c = 18.2630(5) Å, β = 93.666(1)°, V = 2567.35(10) Å^3, Z = 4, $\mu(Mo_{K\alpha})$ = 113.89 cm^{-1}, T = 235 K, $F(000)$ = 1808.00. A total of 18150 reflections were measured over the ranges $4 \le 2\theta \le 50°$, $0 \le h \le 10$, $-18 \le k \le 18$, $-21 \le l \le 21$ on a Rigaku/MSC RAXIS IIc image plate area detector with graphite monochromated $Mo_{K\alpha}$ radiation. The *hkl* data were extracted using the bioTex software package [6a] and subsequent data reduction and solution of the structure was accomplished with the teXsan [6b] package. Cell constants were refined in bioteX using a total of 14366 reflections. Thus eight variables (a, b, c, three orientation angles, and the mosaicity) were refined using 14366 experimental observations. This technique is typical for data sets collected with an area detector, but this large overdetermination results in extremely small esd's for the cell constants. The actual errors are probably somewhat higher due to the uncertainty in $\lambda(Mo_{K\alpha})$. The intensity data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied [6c]. A total of 4533 reflections were independent, and 3086 reflections with $F^2 > 3\sigma(F^2)$ were used for all calculations. The structure was solved by direct methods and 317 parameters refined based on F, minimizing the quantity $\sum w(|F_o| - |F_c|)^2$ with $w = 1/\sigma^2(F)$. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were included as constant contributions to the structure factors and were not refined. The hydride on tungsten was located, but could not be refined. Final agreement factors of R_1 = 0.0491, R_2 = 0.0508, and GOF = 1.755 were obtained. Further details of the crystal structure investigation may be obtained from the Director of the Cambridge Crystallographic Data Center, 12 Union Road, GB-Cambridge CB2 1EZ (UK), on quoting the full journal citation.

The First Recombinant Hydroxynitrile Lyase and its Application in the Synthesis of (*S*)-Cyanohydrins**

Siegfried Förster, Jürgen Roos, Franz Effenberger,* Harald Wajant, and Achim Sprauer

Dedicated to Professor Manfred Regitz on the occasion of his 60th birthday

Recently we have reported comprehensively on syntheses and reactions of optically active cyanohydrins.[1] That overview points out that the hydroxynitrile lyase isolated from bitter almond (PaHNL) [EC 4.1.2.10] catalyzes the enantioselective addition of hydrocyanic acid to aldehydes to give (*R*)-cyanohydrins with high optical purities. Because of the very broad substrate range and the easy availability of the enzyme, this procedure is the simplest approach to (*R*)-cyanohydrins.

The conditions for the enzyme-catalyzed preparation of (*S*)-cyanohydrins are, however, essentially different. The application of hydroxynitrile lyase from *Sorghum bicolor* (SbHNL) [EC 4.1.2.11] as catalyst proved so far to be the most successful method for the enantioselective addition of HCN to aldehydes, yielding (*S*)-cyanohydrins.[2, 3] Although this enzyme is now available from Sorghum seedlings in larger amounts for preparative applications, this source is insufficient for technical processes. In addition to the problems of availability, the limited substrate range of SbHNL, which accepts only aromatic and heteroaromatic but not aliphatic aldehydes as substrates, is a severe disadvantage for the application of this enzyme.[2] The (*S*)-hydroxynitrile lyase from *Hevea brasiliensis*, recently applied in the preparation of (*S*)-cyanohydrins, accepts aliphatic aldehydes as substrates but also has the disadvantage of more difficult accessibility.[4]

In view of the disadvantages of both (*S*)-hydroxynitrile lyases used in organic synthesis to date, we were interested in developing an (*S*)-HNL that shows a broad substrate range and can easily be obtained in large amounts by genetic engineering. Investigations with the cloned SbHNL[5] have so far shown that its functional expression requires complex posttranslational processing.[5b] For this reason enzymatically active SbHNL will not be able to be produced genetically in the foreseeable future.

Better results should be obtainable with a hydroxynitrile lyase isolated from *Manihot esculenta* (MeHNL) [EC 4.1.2.37],[6] which is serologically distinct from the other hydroxynitrile lyases.[7] It not only promises more convenient conditions for the functional expression but also more flexibility of substrate range, as first synthetic applications of the natural enzyme have shown.[7] We have now overexpressed the in pQE4 cloned MeHNL-gene (pQE4-MeHNLwt)[7b] in *E. coli* M15[pREP4] cells.[7b]

Activity measurements of lysate of transformed M15[pREP4] cells (M15-MeHNL) show an HNL activity of 0.5 units per milliliter of culture, whereas no activity could be detected in the lysate of untransformed cells.[7b]

[**] Enzyme-Catalyzed Reactions, Part 23. This work was supported by the Bundesministerium für Bildung und Forschung and by the Fonds der Chemischen Industrie. Part 22: F. Effenberger, S. Heid, *Tetrahedron Asymmetry* **1995**, *6*, 2945–2952.

The M15-MeHNL cells were disrupted at pH 5.4 and then treated with benzonase. MeHNL was purified by anion exchange chromatography on Q-Sepharose FF. After ultrafiltration the activity of the purified recombinant MeHNL was 900 U mL^{-1}. An 80 L M15-MeHNL culture with 150–200 g wet weight yields approximately 40000 U of recombinant MeHNL. The same quantity of enzyme from plant material would require 100–200 kg of dried cassava leaves. Thus, for the first time an (*S*)-hydroxynitrile lyase has become available in large quantities in a simple way. The biochemical properties of the recombinant MeHNL and MeHNL isolated from *Manihot esculenta* are identical.[7b]

Although the first experiments to determine the catalytic potential of the MeHNL isolated from cassava leaves demonstrated a broad substrate range, the achieved optical yields of the (*S*)-cyanohydrins obtained were unsatisfactory.[7a]

With the recombinant enzyme, available now in sufficient amounts and with 25 times higher specific activity than the natural enzyme, we have investigated the enantioselective addition of hydrocyanic acid to several aldehydes (Scheme 1, Table 1) and ketones (Scheme 2, Table 2). To achieve the highest possible optical purity, diisopropyl ether was chosen as solvent.[1] Although cellulose (Avicel or cellulose P100 PSC) has proved to be very suitable as supporting material for the reactions with PaHNL and SbHNL,[1,8] the reactions with the recombinant MeHNL on cellulose support gave only moderate optical yields.[9] However, by using nitrocellulose as support, which possesses a higher affinity for proteins than cellulose, the enantioselectivity is high in most cases (Tables 1 and 2).

[b] Determined by gas chromatography on β-cyclodextrin phases after acetylation with acetic anhydride or saponification to carboxylic acid and subsequent esterification to methyl ester, or by gas chromatography of diastereomeric (*S*)-MPTA esters (MPTA = α-methoxy-α-trifluoromethylphenyl acetic acid) [1,9]. [c] Comparison with Ref. [11]. [d] Yield determined by ^{1}H NMR spectroscopy.

Table 1 shows that MeHNL exhibits a similar broad substrate range as (*R*)-hydroxynitrile lyase from bitter almond: that is, not only aromatic and heteroaromatic but also aliphatic aldehydes are accepted as substrates. Even the sterically very demanding pivalaldehyde (**1d**) reacts highly enantioselectively.

The enzyme-catalyzed enantioselective addition of HCN to ketones was established for PaHNL,[10a] as well as for hydroxynitrile lyase from *Linum usitatissimum*.[10b] Both enzymes catalyze the formation of (*R*)-ketone cyanohydrins. The synthesis of (*S*)-ketone cyanohydrins catalyzed by an (*S*)-hydroxynitrile lyase has not yet been published. (*S*)-Ketone cyanohydrins have been recently prepared from racemic ketone cyanohydrins by enantioselective transcyanation with (*R*)-hydroxynitrile lyase PaHNL.[11]

In Table 2 our results of the MeHNL catalyzed preparation of (*S*)-ketone cyanohydrins (*S*)-**4** are summarized. As expected, in the reactions of alkyl methyl ketones the optical yields of the products obtained improve with increasing size of the alkyl group.[10a] While branching in the β-position of the alkyl substituent has no disadvantage on the enantioselectivity (**4e**), a bulky substituent in the α-position to the carbonyl group (**4f**) decreases the optical purity. MeHNL accepts even an aromatic ketone such as acetophenone as substrate (Table 2).

Experimental Procedure

Overexpression of MeHNL in *E. coli*: The coding region of the MeHNL gene was amplified from oligo(dT) primed first strand cDNA with PCR (forward primer: GCA GGG CCG GAT CCC ATT TCC AAA ATG GTA ACT GCA CA; rewind primer: GCA GGG CCG GAT CCA CAC AAC GTG GAA CTC TCC CAT ATT;

underlined sequences correspond to position 16–39 and 933–910 of the MeHNL gene published) [6b] and cloned in the correct reading frame in the pQE4 expression vector (Quiagen). The resulting expression plasmid pQE4-MeHNLwt was transformed in *E. coli* M15[pREP4] cells for overexpression (M15-MeHNL).

An overnight culture (2 mL) of a single colony of M15-MeHNL in LB medium containing ampicillin (100 $\mu g mL^{-1}$) and kanamycin (25 $\mu g mL^{-1}$) was used to inoculate an 8 L culture that was then grown for 12 h at 37 °C. This culture was used to inoculate a 100 L fermenter (Bioengineering). The M15-MeHNL cells were grown at 30 C for 1 h and expression of recombinant MeHNL was induced by adding isopropyl-β-D-thiogalactosid (IPTG) to a final concentration of 1 mM. The cells were grown for an additional 3.5 h and concentrated to about 7.5 L by cross-flow concentration (Maxisette system) with a 0.3 μm membrane (0.46 m^2) (Filtron). To remove the remaining LB medium the cells were centrifuged for 10 min at $10000 \times g$. The resulting pellet was resuspended in 2 L sodium acetate buffer (50 mM, pH 5.4), and the cells were disrupted by high-pressure homogenization (500 bar, 3 cycles; Rannie-APV MiniLab). To destroy chromosomal DNA the crude lysate (total amount of MeHNL 40000 U, spec. activity 2.8 $U mg^{-1}$) was digested with benzonase (Merck) (final concentration of 5000 $U L^{-1}$) for 1 h at room temperature. After centrifugation at $130000 \times g$ for 1 h MeHNL was enriched to a spec. activity of 12 $U mg^{-1}$ by anion exchange chromatography. A Q-Sepharose FF 100/1200 column was equilibrated in 20 mM sodium acetate, pH 5.7 (buffer A) and bound proteins were eluted with a 7200 mL linear gradient of 0–1 M NaCl in buffer A at a flow rate of 50 mL min^{-1}. MeHNL eluted after 450 mL salt gradient.

Enzyme-catalyzed preparation of (*S*)-cyanohydrins: The support (50 mg nitrocellulose) was soaked in 3 mL sodium citrate buffer (0.02 M, pH 3.3) for 30 min. After decanting, centrifuging (30 min, $5700 \times g$), and drying under high vacuum (5 h), a concentrated solution of MeHNL (900 $U mL^{-1}$, amounts as in Tables 1 and 2) was added dropwise. After 15 min the enzyme-charged support was centrifuged (at −5 °C, 30 min, $3650 \times g$) and transferred to a flask. Diisopropyl ether (5 mL), substrates **1** or **3** (0.3–0.4 mmol) and HCN (100 µL, 2.6 mmol) were added, and the mixture stirred at room temperature for the time given in Tables 1 and 2. The support was filtered off and washed with diethyl ether. The combined filtrates were dried, and solvent and unchanged starting materials (**1a–g**, **3a–f**) distilled off. Thus pure aldehyde cyanohydrins (*S*)-**2a–j** (Table 1) and ketone cyanohydrins (*S*)-**4a–f** (Table 2) were isolated. To obtain compounds (*S*)-**2k–o** and (*S*)-**4g** in pure form it was necessary to convert them into acetates or trimethyl silyl ethers for the separation from unchanged starting materials. The yields obtained correspond to those determined by ^1H NMR spectroscopy (Tables 1 and 2).

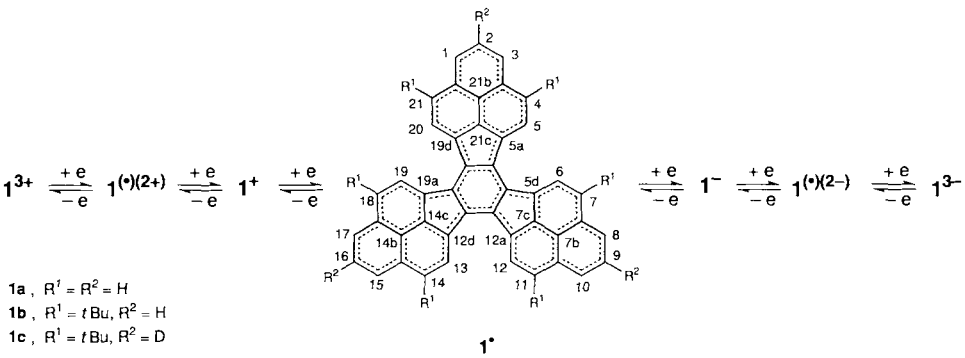
Hexa-*tert*-butyltribenzodecacyclenyl: A Six-Stage Amphoteric Redox System

Takashi Kubo, Kagetoshi Yamamoto, Kazuhiro Nakasuji,* Takeji Takui, and Ichiro Murata

Some organic compounds[1] show amphoteric redox behavior, that is the numerical sum (E^{sum}) of oxidation potential (E^{ox}) and reduction potential (E^{red}), $E^{sum} = E^{ox} + (-E^{red})$, is very small. These compounds are oxidized or reduced easily by an electron transfer. Recently we synthesized the four-stage amphoteric redox hydrocarbons bearing two phenalenyl units, which are crucial for the amphoteric redox behavior. To study the properties of higher amphoteric hydrocarbons, we designed the tribenzodecacyclenyl **1a**, which contains three phenalenyl units. Compound **1a** is expected to behave as a six-stage amphoteric redox compound (Scheme 1)[2] and to readily generate super-charged species such as the trication and trianion. We now



Scheme 1. Six-stage amphoteric redox behavior of **1**•.

report the synthesis of **1b**, the hexa-*tert*-butyl derivative of **1a**, and the properties of **1b**•, $\mathbf{1b}^{3+}$, and $\mathbf{1b}^{3-}$.

The starting material, 2,5,8,11,14,17-hexa-*tert*-butyldecacyclene (**2**),[3] was formed directly by Friedel–Crafts alkylation of decacyclene (Scheme 2).[4] The bromination of **2** furnished an isomeric mixture of the tribromides **3** in 76% yield,[5] which were converted to tris(propionic acid) derivatives **7** by the usual method (only one isomer is shown in Scheme 2). Friedel–Crafts cyclization of **7** gave the triketones **8**, which were reduced and subsequently dehydrated to afford trihydro compounds **10**.[6] The dehydrogenation of **10** with *p*-benzoquinone or *p*-chloranil provided the neutral monoradical species **1b**• as an air-sensitive brown solid (Scheme 2).

The ESR signal of **1b**• was observed, but lack of resolution prevented the determination of the hyperfine coupling (hfc) constants. However, the ESR spectrum of the deuterated compound **1c**• gave hyperfine structure,[7] from which two hfc constants were obtained, 1.43 G (6H), 0.47 G (6H). The hfc

constants of the hydrogen atoms H-2, H-9, and H-16 in **1b**• were determined by a computer simulation. Assignments of hfc constants $a_H\mu$ to protons in the position μ were based on a HMO-McLachlan calculation ($\lambda = 1.2$)[8] of the spin density of **1a**•. The hfc constants and the calculated spin densities are listed in Table 1. The linear relationship between the hfc constants

stants and the theoretical values for the spin densities suggests that the unpaired electron delocalization is not confined to one phenalenyl unit but is operative over the entire C_3 symmetric molecule.

The cyclic voltammogram of **1b**• measured in dichloromethane exhibited six reversible one-electron redox waves (Fig. 1). The electrochemical data of **1b**• and related hydrocarbons bearing two phenalenyl units are summarized in Table 2. The sum of the redox potentials E_1^{sum} of **1b**• is substantially smaller than those reported so far for hydrocarbons. Such a small E_1^{sum} value can be explained in terms of the electronic stability of three redox states of the phenalenyl unit owing to the delocalization of the generated charges or the unpaired electron over the molecules.

The trication **1b**$^{3+}$ was obtained as a dark green solution by dissolving **1b**• in concentrated D_2SO_4 or as dark green needles[9] by treating **1b**• with three equivalents of tris(4-bromophenyl)aminium hexachloroantimonate. The trianion **1b**$^{3-}$ was generated as a red purple solution[10] by the reaction of the trihydro compound **10** with a potassium mirror in a sealed degassed tube at −78 °C for a week. The ^{1}H and ^{13}C NMR chemical shifts of **1b**$^{3+}$ and **1b**$^{3-}$ are given in Table 1. The total ^{13}C chemical shift change ($\Sigma\Delta\delta_C$) of the sp^2 carbon atoms on going from **1b**$^{3+}$ to **1b**$^{3-}$ is 1041.63 (or 173.61 per electron), which supports the idea of the presence of the trication and the trianion, respectively.[11] The shift changes ($\Delta\delta_C$) are large for the C atoms at positions α^1, α^2, and α^3, which correspond to the α positions of the phenalenyl,[12] but small for the C atoms at other positions except for the central benzene ring. This finding suggests that the phenalenyl units contribute largely to the stability of both triply charged species.[13]

The most striking feature is that the signals of the protons at the position β^2 of **1b**$^{3-}$ unexpectedly appear at lower field than the signals of the corresponding protons of **1b**$^{3+}$, in spite of the shielding effect caused by the three negative charges. The ^{13}C chemical shifts of the C atoms at position β^2 reveal that the electron density at the position β^2 is slightly larger in **1b**$^{3-}$ than in **1b**$^{3+}$. These findings clearly suggest the effect of a diamagnetic ring current in **1b**$^{3-}$. Ring currents of **1b**$^{3+}$ and **1b**$^{3-}$ were calculated by London–McWeeny's method.[14] For **1b**$^{3+}$, the phenalenyl unit causes a weakly diamagnetic effect and the

An Intramolecular Base-Catalyzed Proton Transfer in 1,3-Bis(4-fluorophenyl)triazene

Ferdinand Männle and Hans-Heinrich Limbach*

Proton transfer processes are elementary steps in many acid- and base-catalyzed organic and biochemical reactions.[1–6] Because of their complexity, simple model compounds are required if the proton motion is to be followed experimentally, for example, by NMR spectroscopy or other fast reaction techniques. Model systems are also important for the theoretical treatment of proton transfers.[7–10] Whereas several model systems for double proton transfer within or between neutral molecules have been devised,[11–13] only a few model systems involving degenerate single proton transfer processes, which are coupled to charge transfer and therefore to solvent reorientation, are currently available. Recently, in the conjugated porphyrin monoanion[14] an intramolecular single proton transfer that is characterized by a high activation barrier was observed. In contrast, the barrier for proton transfer is very low in hydrogen-bonded complexes formed by acetic acid and pyridine at low temperatures in organic solvents.[15] Here we introduce a model system that lies between these two extremes: bis(4-fluorophenyl)[1,3-$^{15}N_2$]triazene (**1**, Fig. 1) dissolved in an aprotic solvent together with a base such as trimethylamine (**2**). The NMR experiments described below show that the intramolecular proton transfer in **1** occurs only in the presence of **2**. Therefore, **2** acts as catalyst carrying the mobile proton of **1** from one nitrogen site to the other, as illustrated in Figure 1a.

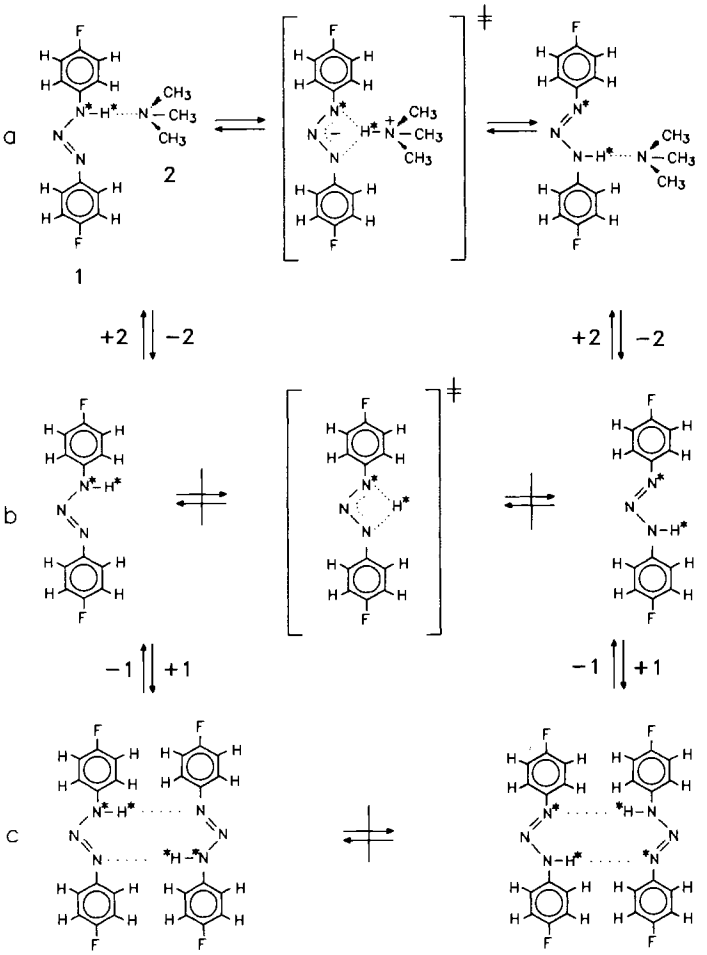

Fig. 1. Proton transfer pathways for 1,3-bis(4-fluorophenyl)[1,3-$^{15}N_2$]triazene (**1**): a) intramolecular proton transfer, catalyzed by trimethylamine; b) hypothetical intramolecular uncatalyzed proton transfer; c) intermolecular double proton transfer in hypothetical cyclic dimers of **1**.

The ^{1}H NMR spectra of sealed samples of **1** in deuterated ethyl methyl ether that are carefully prepared with well-established vacuum techniques to exclude water and other acid or basic impuritites do not show any sign of proton mobility. The partial room-temperature ^{1}H NMR spectrum of such a sample is shown in Figure 2a. The signal of the mobile proton of **1** is split into a doublet by scalar coupling with a single ^{15}N nucleus of **1** ($^1J_{N,H}$ = 93.5 Hz), which indicates that the mobile proton is localized at a single nitrogen site. More precisely, potential

intramolecular proton jumps (Fig. 1b), intermolecular double proton transfer in a hypothetical dimer (Fig. 1c), and intermolecular proton exchange catalyzed by impurities as discussed previously[16–19] are slow on the NMR time scale. This also applies if a small amount of trimethylamine (**2**) is added before recording the spectrum at 137 K (Fig. 2c). Due to enhanced hydrogen bond formation the proton signal shifts to low field. However, if the temperature is increased to 248 K, a triplet can be observed, indicating a scalar coupling to both ^{15}N atoms ($^1J_{N,H}$ = 47 Hz). In the absence of **2** this doublet–triplet transition does not occur. The observation of this triplet verifies that a fast intramolecular proton transfer according to Figure 1a is mediated by **2**. Intermolecular proton exchange would lead to a doublet–singlet transition.[13] Since only one signal was observed for the mobile proton of **1**, the hydrogen-bond exchange between solvated monomeric **1** and its 1:1 complex with **2** is fast on the NMR time scale. The same proton therefore shuttles frequently between the two nitrogen sites of **1**, whereas a different base molecule (**2**) catalyzes each jump.

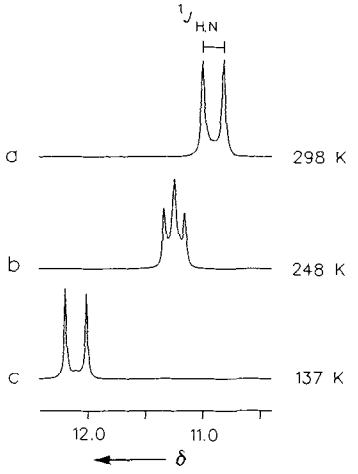

Fig. 2. a) ^1H NMR (500 MHz) signal of the mobile proton of a 0.1 M solution of **1** in [D_8]ethyl methyl ether, at 298 K. b),c) Corresponding signals at 248 and 137 K at the same concentration of **1**, but with 0.02 M trimethylamine (**2**) added.

During the proton carrier process the proton must be temporarily transferred from **1** to **2**—this creates a contact ion pair. The properties of the contact pair ensure that proton transfer to the initial or second nitrogen site of **1** is faster than the dissociation of the contact ion pair that would lead to intermolecular proton exchange. This finding is plausible, because the free energy of dissociation of the contact ion pair is enormous in a solvent with a low dielectric constant as a result of the Coulomb interaction. By contrast, the dissociation energy of the molecular 1:1 complex between **1** and **2** is minimal, leading to the fast hydrogen bond exchange mentioned above.

The uncatalyzed intramolecular proton transfer of **1** is understandably slow, since no intramolecular hydrogen bond is present. Furthermore, **1** does not form cyclic dimers in which a double proton transfer could take place according to Figure 1c, as is the case with the related diarylamidines.[13] This observation can be rationalized, because **1** is planar, and the associated steric repulsion between the aromatic protons within a dimer hinders the approach of the two molecules and the formation of strong hydrogen bonds.

In conclusion, in an aprotic but not necessarily apolar solvent, bases such as trimethylamine are capable of picking up mobile protons at one molecular site and carrying them rapidly to another site. The transfer occurs faster than the dissociation of the intermediate contact ion pair. The system diaryltriazene/trimethylamine therefore is an interesting model for further experimental and theoretical studies of proton carrier processes, which could perhaps contribute to the understanding of the mechanisms of enzyme reactions.

Regioselective Palladium-Catalyzed Hydrostannylation of Unsymmetrical Oxabicyclic Alkenes**

Mark Lautens* and Wolfgang Klute

Hydrometalation reactions are widely used for the generation of stereochemically defined organometallic compounds. Transition metal catalysts have been shown to accelerate the hydroboration,[1] hydrosilylation,[2] and hydroalumination of alkenes.[3] Significant control of the regio-, stereo-, and enantioselectivity has been achieved.

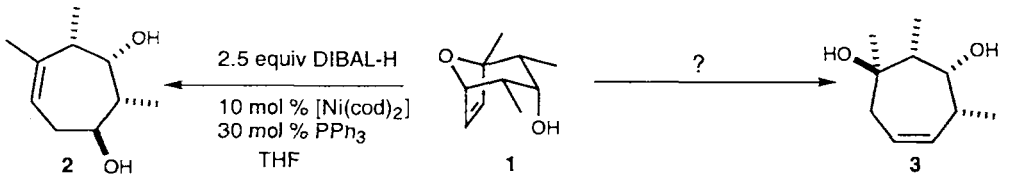
We are interested in demonstrating the utility of oxabicycloheptenes and -octenes as precursors to functionalized and synthetically useful cycloalkenols.[4] We reported that nickel-catalyzed hydroalumination–elimination of bridgehead-substituted substrates such as **1** occurs regioselectively affording the secondary alcohol **2**.[5] Methodology that would selectively lead to the regioisomeric tertiary alcohol **3** would be equally useful. We



now report a two-step procedure that accomplishes this goal by a regioselective palladium-catalyzed hydrostannylation and organolithium-induced elimination.

Addition of trialkyl- or triaryltin hydride to multiple bonds has typically been achieved under radical conditions.[6] However, there are several recent reports of Pd- and Rh-catalyzed hydrostannylation of enones[6] and triple bonds,[7] and a single example with an allene[8] and a conjugated double bond.[9] To our knowledge simple alkenes have not been examined to date.

Our initial investigations focused on the feasibility of a Pd-catalyzed hydrostannylation of the unsymmetrical oxabicycloheptene **4**. To determine the reactivity of the alkene in the absence of a catalyst, **4** and tributyltin hydride were stirred for 16 h at room temperature. (Scheme 1, step a; Table 1, entry 1).

Table 1. Dependence of the regioselectivity of the Pd-catalyzed hydrostannylation of **6** on the ligand:metal ratio.

Entry	Catalyst	*t* [h]	Yields [%] [a]

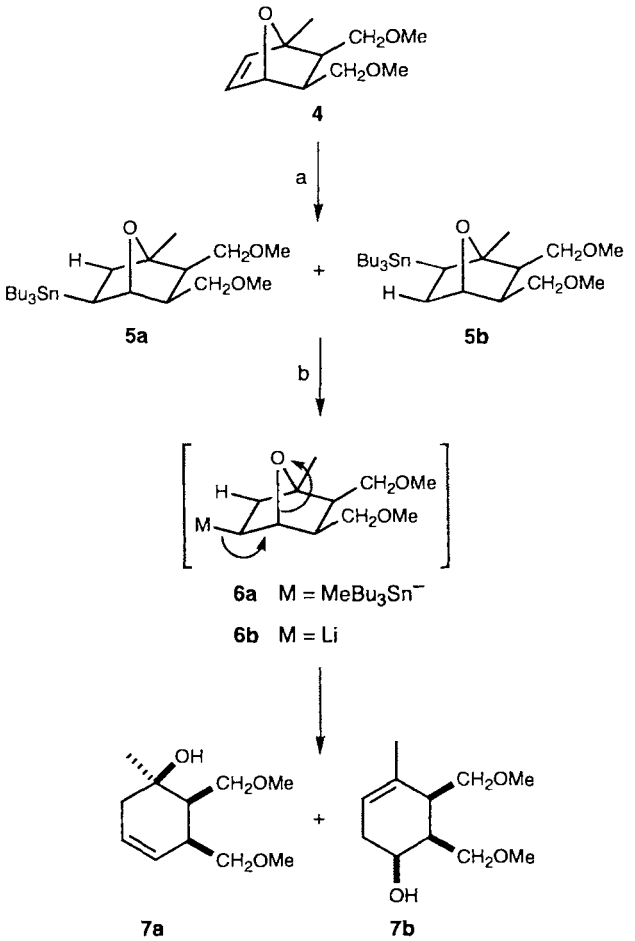
[a] Yield of isolated product. [b] Determined by capillary gas chromatography on a Chiraldex β-TA column; for an authentic sample of **7b**, see Ref. [5a, 15]. [c] 90/10 mixture by ^{1}H NMR spectroscopy. [d] Galvinoxyl = [2,6-di-*tert*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene)-*p*-tolyloxy, free radical. [e] Addition over 2 h, then stirred for 14 h.

A 90:10 mixture of stannanes **5a** and **5b** was formed; the major isomer arose from addition of the tributyltin moiety to the sterically less encumbered carbon.[10] Addition of galvinoxyl failed to inhibit this reaction, which suggests that a polar pathway might be important (entry 2).[7b, 11]

In the presence of a catalytic amount of $[Pd_2(dba)_3]$ (dba = dibenzylidene acetone), the rate of reaction was much faster, and all the starting material was consumed in less than 2 h (entry 3). Addition of a phosphane ligand improved the chemical yield of the hydrostannylated product and the regioselectivity (entries 4 and 5).[10, 12] Increasing the ligand-to-metal ratio from 2.25:1 (entry 4) to 11.75:1 led to a slight improvement in the ratio of **5a** to **5b**[10] (entry 5), but this increase was insufficient to justify using a such a large amount of the ligand. Most other substrates gave acceptable levels of selectivity with a Ph_3P:Pd ratio of 2.5:1. We observed that tributyltin hydride rapidly decomposes to Bu_6Sn_2 and H_2 in the presence of the Pd catalyst, and so a solution of tributyltin hydride was added slowly by syringe pump over 2 h to a solution of the substrate and catalyst.[7c] Yields in excess of 90% were obtained under the optimized conditions.

The correlation between regioselectivity and ligand-to-metal ratio is best explained by a mechanism of the hydrostannylation that involves a hydropalladation followed by a reductive elimination



Scheme 1. a) See Table 1; b) 1.5 equiv MeLi, THF, room temperature, 10 min.

with formation of the carbon–tin bond. Higher selectivity would be expected upon increasing the steric bulk of the catalyst.

Transmetalation of simple tetraalkylstannanes with an organolithium typically leads to equilibrium mixtures when the basicities of the organolithium derived from the alkyl stannane and the organolithium reagent used to promote the transmetalation are similar. However, by coupling the transmetalation step to an elimination reaction it was possible to obtain excellent yields of **7a**, **b** upon treatment of **5a**, **b** with methyllithium (Scheme 1, step b).[13–15] The elimination probably proceeds

directly from the ate complex **6a**, although dissociation to the secondary organolithium species **6b**, which then undergoes elimination, is also possible.

The scope of the hydrostannylation–elimination sequence was demonstrated by carrying out reactions with a variety of bridgehead-substituted oxabicyclo[3.2.1]octenes (Table 2). In all cases the tributyltin moiety was delivered preferentially to the sterically less crowded carbon of the bicyclic system and subsequent elimination gave the tertiary alcohol. The selectivity was typically greater than 95:5 except for the hydrostannylation of the hydroxymethyl-substituted bicycle, where a 75:25 mixture was obtained (entry 2a). However, following protection of the free alcohol as a silyl ether, the selectivity improved dramatically (entry 2b, TBS = *tert*-butyldimethylsilyl). A larger excess of triphenylphosphane and addition of tributyltin hydride over 6 h was required for a substrate bearing an amide at the bridgehead in order to obtain the product in high yield (entry 3). Finally, an N-benzoyl-protected azabicyclooctene efficiently undergoes hydrostannylation and elimination to furnish the amidocycloheptene (entry 5, Bz = benzoyl).

The difference in regioselectivity for the palladium-catalyzed hydrostannylation and nickel-catalyzed hydroalumination is intriguing, and further studies are underway to understand the factors controlling the reaction pathway.[5a, 14] One possibility is that a hydrometalation is occurring in one system, whereas a metallometalation dominates in the other. Experiments designed to differentiate these two pathways are in progress. As a consequence of this difference in regioselectivity, access to the complementary series of ring-opened products has now been achieved.

Experimental Procedure

5a: A solution of tributyltin hydride (200 mg, 0.68 mmol) in dry toluene (1 mL) was slowly added by syringe pump to a solution of **4** (1.3 mg, 0.309 mmol), $Pd_2(dba)_3$ (5.7 mg, 6.2 μmol), and triphenylphosphane (7.6 mg, 29 μmol) in toluene (4 mL). During the addition the color of the solution changed from yellow to brown. The solvent was evaporated, and the residue purified by flash chromatography (EtOAc:hexanes = 1:9) yielding 143.4 mg (0.293 mmol, 95%) of **5a** as a colorless oil. ^1H NMR (400 MHz, $CDCl_3$) δ = 4.26 (s, ^3J(H,Sn) = 68.2 Hz, 1H), 3.39 (m, 1H), 3.20–3.32 (m, 3H), 3.30 (s, 3H), 3.26 (s, 3H), 2.25 (dt, ^3J(H,H) = 9.4, 4.3 Hz, 1H), 2.08 (q, ^3J(H,H) = 7.0 Hz, 1H), 1.90 (dd, ^3J(H,H) = 11.7, 9.5 Hz, 1H), 1.40–1.55 (m, 8H), 1.37 (s, 3H), 1.27 (sex, ^3J(H,H) = 7.3 Hz, 6H), 0.74–0.89 (m, 15H); ^{13}C NMR (100 MHz, $CDCl_3$) δ = 85.6, 81.6, 71.4, 70.5, 58.7, 58.4, 51.2, 47.4, 43.0, 29.2, 27.6, 27.5, 18.0, 13.7, 8.6; HRMS: *m/z* calcd for M^+ 490.2469, found 490.2470.

7a: A solution of **5a** (88.9 mg, 0.182 mmol) in dry THF (2 mL) was treated at room temperature with a solution of methyllithium (0.3 mL, 0.42 mmol) in ether. After 10 min the reaction was quenched with NH_4Cl, extracted four times with ethyl acetate, and the combined organic phases were washed with saturated brine and dried over Na_2SO_4. The solvent was evaporated, and the residue purified by flash chromatography (EtOAc:hexanes = 1:4). Compound **7a** was obtained as colorless crystals (32.6 mg, 0.163 mmol, 89%). M.p. 37–38 °C; ^1H NMR (400 MHz, $CDCl_3$) δ = 5.67 (dq, ^3J(H,H) = 9.9, 3.7 Hz, 1H), 5.47 (dq, ^3J(H,H) = 9.8, 2.2 Hz, 1H), 4.64 (s, 1H), 3.62 (dd, ^3J(H,H) = 9.5, 8.4 Hz, 1H), 3.49 (dd, ^3J(H,H) = 9.9, 7.0 Hz, 1H), 3.37 (s, 1H), 3.36 (s, 1H), 3.35 (s, 3H), 3.33 (s, 3H), 2.65 (ddt, ^3J(H,H) = 11.9, 5.9, 2.9 Hz, 1H), 2.08–2.24 (m, 3H), 1.21 (s, 3H); ^{13}C NMR

(100 MHz, $CDCl_3$) δ = 126.5, 126.1, 72.8, 71.6, 70.2, 59.0, 58.9, 43.7, 39.4, 38.2, 27.5; HRMS: *m/z* calcd for M^+ 200.1412, found 200.1407.

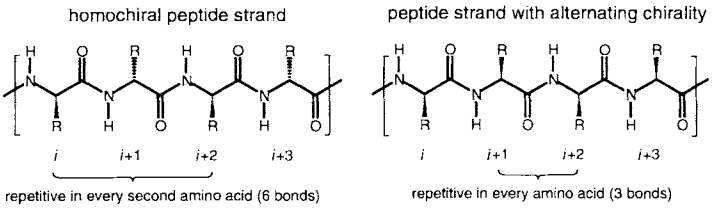
Pairing Properties of Alanyl Peptide Nucleic Acids Containing an Amino Acid Backbone with Alternating Configuration**

Ulf Diederichsen*

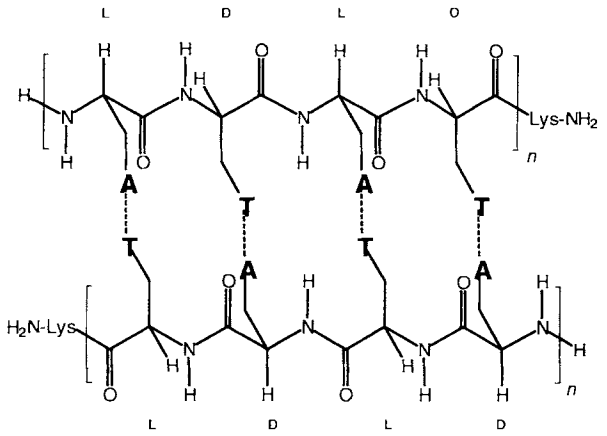
Peptide nucleic acids (PNAs) contain a peptide or polyamide backbone and side chains that are substituted with the nucleobases of DNA or RNA.[1] This class of biomolecules gained importance because of its antisense or antigene potential.[2] In a PNA backbone isomorphous to DNA and RNA, six bonds of the sugar phosphate backbone correlate in terms of their length to two amino acids. Therefore, the repeating unit of a potential antisense PNA is built of an amino acid pair[3] containing a base-substituted and a proteinogenic amino acid.[4] If possible, the pairing complex adopts a conformation with an idealized distance for base pair stacking of about 3.5 Å. This might be achieved by modulating the pitch of a double strand through helicalization.[5] By keeping the distance between base pairs constant, the shortening of the backbone results in an unwinding of the helix until the linear double strand is reached; this is the case when the distances of the base pairs and the backbone between consecutive repeating units is identical. A PNA with a regular peptide strand in β-sheet conformation fulfills the prerequisites for a linear pairing complex except that the consecutive side chains are oriented antiperiplanar (Scheme 1). By using



Scheme 1. An antisense PNA isomorphous to DNA needs six backbone bonds for a repetitive unit like in a pair of amino acids. A PNA strand with alternating configuration and β-sheet conformation is repetitive in every side chain.

alternating configurations of the amino acids an orientation of all side chains on the same side of the β-sheet can be achieved,[6] and thus a PNA repetitive in every monomeric unit is obtained. Taking an alanyl PNA with alternating sense of chirality as an example, we now introduce new PNA–PNA pairing complexes based on recognition of the bases adenine and thymine.

The PNA model described in Scheme 2 was regarded as a working hypothesis at the start of our project: A regular alanyl



Scheme 2. Model of a linear pairing complex between the enantiomeric alanyl PNA oligomers H-(AlaA-AlaT)$_n$-Lys-NH_2 and H-(AlaA-AlaT)$_n$-Lys-NH_2. AlaA = β(adenine-9-yl)alanine, AlaT = β(thymine-1-yl)alanine, D-configurated amino acids are underlined. There is a specificity of the double strand pairing with antiparallel strand orientation and homochiral base pair connectivity. The C-terminal lysine amide was added for solubility reasons.

peptide strand, whose side chains are β-substituted by the nucleobases adenine and thymine, is repetitive when adopting a β-sheet conformation, and when the amino acid units have alternating configuration. A double strand formed by base pairing is characterized by colinear strands and orthogonal planes of base pairs with a distance of 3.5 Å. Further structural features are lack of charge repulsion, parallel/antiparallel strand orientation, and hetero-/homochiral base pair connectivity. We synthesized

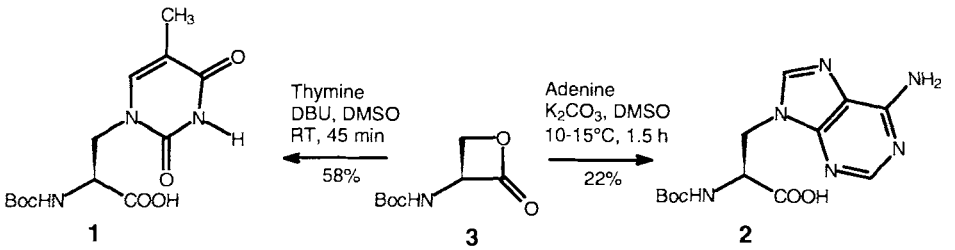
[**] This work was supported by the Fonds der Chemischen Industrie with a Liebig fellowship. I am grateful to Professor H. Kessler for generous support and Professors A. Eschenmoser, A. Vasella, and C. Leumann for the opportunity to measure the UV and CD spectra, and for the characterization of the oligomers by MALDI-TOF-MS.

PNA oligomers to determine their pairing stabilities and to identify double strands based on A–T or A–A, T–T pairing.

The enantiomerically pure amino acids *N*-Boc-thyminylalanine **1** and *N*-Boc-adeninylalanine **2**[7] used for oligomerization were prepared as described by Eschenmoser and Lohse.[8] Nucleophilic ring opening of *N*-Boc-serine-β-lactone **3**[9] with the bases thymine and adenine provided amino acids **1** and **2**, respectively, with an enantiomeric purity of >98% (HPLC of amino acid dimers) (Scheme 3). The PNA oligomers were obtained by solid-phase synthesis on a MBHA-polystyrene (MBHA = 4-methylbenzhydrylamine) resin loaded with L- or D-lysine(Z)-OH (Z = benzyloxycarbonyl) in yields of >98% when HATU (HATU = *O*-(7-azabenzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate)[10] was used as the coupling reagent. After cleavage from the resin the PNA oligomers were purified by HPLC (RP-C18), isolated in yields of 11–25%, and characterized by ^{1}H NMR spectroscopy and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF-MS).



Scheme 3. Synthesis of the base-substituted L-alanyl monomers **1** and **2** by ring opening of L-serinelactone **3** (taken from the thesis of Lohse [8] with kind permission of A. Eschenmoser). RT = room temperature; DBU = 1,8-diazabicyclo[5.4.0]-undec-7-ene; DMSO = dimethyl sulfoxide.

The expected pairing of oligomers in a double strand was investigated by temperature-dependent UV spectroscopy. Cooperative depairing of a double strand, which is based on hydrogen bonds and base stacking, can be recognized as a sigmaoidal increase of the UV absorption A_{rel} with increasing temperature (hyperchromicity), as known from DNA melting curves. All the curves described herein were measured under identical conditions (0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7); prior to heating, the samples were kept at 0 °C for 30 minutes until the absorption remained constant. On cooling, the starting absorption was achieved for each of the cooling curves; however, the pairing process occurred only below 5 °C. The melting curve of the oligomer H-(AlaA-AlaT)$_4$-Lys-NH$_2$ (D-configurated amino acids are underlined) has two cooperative transitions at T_m = 14 °C and 25 °C (Fig. 1) indicating that in addition to self-pairing in the double strand there seems to be a second coordination. The equimolar mixture of this oligomer H-(AlaA-AlaT)$_4$-Lys-NH$_2$ with the enantiomeric compound H-(AlaA-AlaT)$_4$-Lys-NH$_2$ yields a temperture-dependent UV spectrum in which the melting temperature is T_m = 31 °C. The pairing of enantiomeric oligomers is more stable than self-pairing of one enantiomer and exhibits almost doubled hyperchromicity (Fig. 1). The nonlinear dependence of the absorption on the temperature below 20 °C, which is indicative of additional associations, has been observed particularly in melting curves of A/T alternating octamers. The CD spectra of the oligomer H-(AlaA-AlaT)$_4$-Lys-NH$_2$ and the enantiomeric oligomer each show the depairing process at about T_m = 14 °C (Fig. 2). This suggests that the pairing complex is highly symmetrical, because the curves measured at 0 °C have a lower Cotton effect, while the intensity increases at 10 and 25 °C. The formation of a pairing complex of A/T alternating octamers at lower temperatures is further supported by a comparison with the CD spectrum of the single-stranded (UV absorption is temperature independent) tetramer H-(AlaA-AlaT)$_2$-Lys-NH$_2$ (Fig. 3). Whereas at 0 °C there is an obvious difference between the curves of octamer and tetramer, at 60 °C, when oligomer H-(AlaA-AlaT)$_2$-Lys-NH$_2$ is destacked and H-(AlaA-AlaT)$_4$-Lys-NH$_2$ is depaired, the CD curves are very similar.

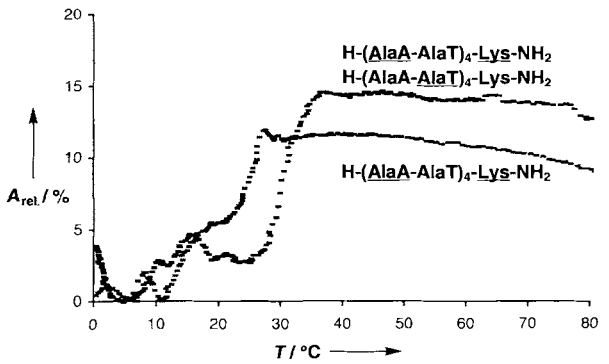


Fig. 1. Melting curves of H-(AlaA-AlaT)$_4$-Lys-NH$_2$ (6 mM) and an equimolar mixture of the enantiomeric oligomers H-(AlaA-AlaT)$_4$-Lys-NH$_2$ and H-(AlaA-AlaT)$_4$-Lys-NH$_2$ (3 mM each, 260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

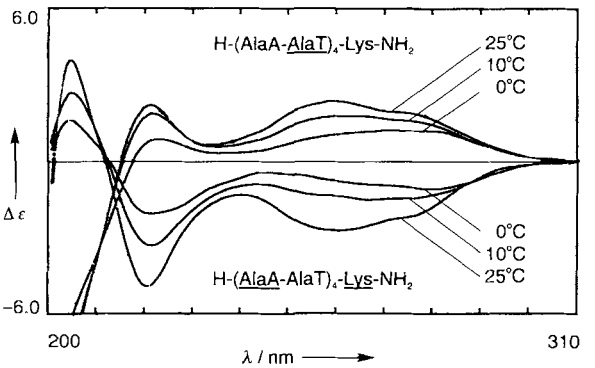

Fig. 2. CD spectrum of the oligomers H-(AlaA-AlaT)$_4$-Lys-NH$_2$ and H-(AlaA-AlaT)$_4$-Lys-NH$_2$ measured independently (6 mM, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

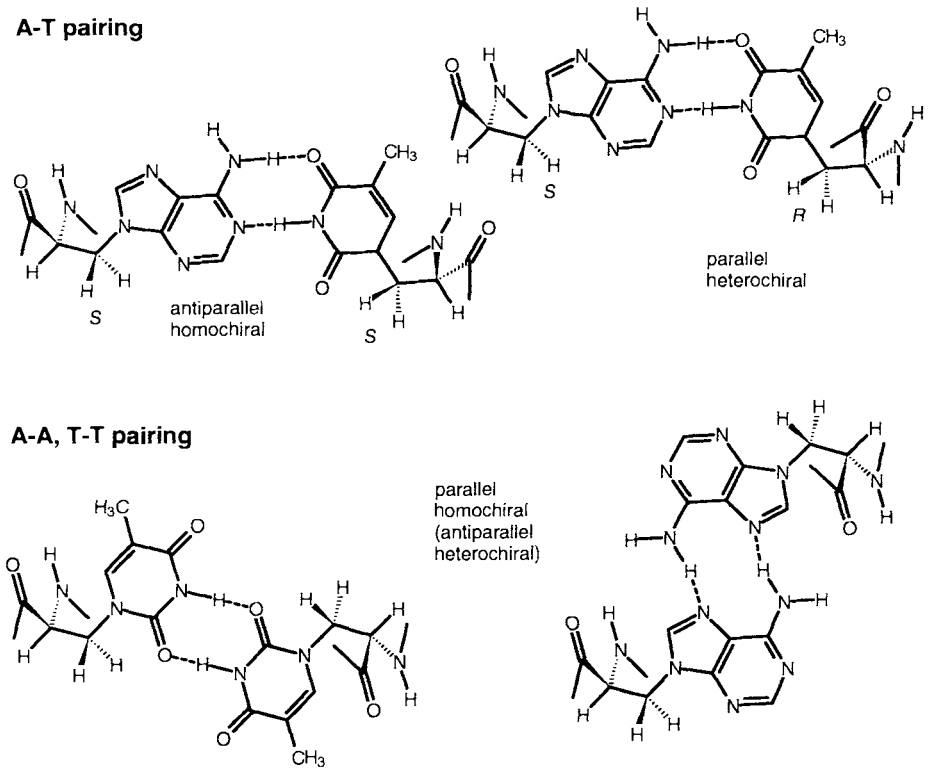
In principle, pairing of A/T alternating oligomers is possible either by formation of A–T or A–A, T–T base pairs. Simple model studies suggest that an A–T Watson–Crick pairing alanyl PNA forms a complex with antiparallel strand orientation and homochiral base pair connectivity (Scheme 4). Switching one strand to get a parallel pairing complex does not change the geometry but inverts the configuration at C-α (heterochiral base pair connectivity). The A–A, T–T pairing type is formed by parallel (antiparallel) strand orientation and homochiral (heterochiral) base pair connectivity, regardless of the pairing mode. Furthermore, the model shows that the strands of the self-pairing oligomer H-(AlaA-AlaT)$_4$-Lys-NH$_2$ are oriented parallel for both pairing modes, or in contrast, antiparallel in the case of the pairing complex with the two enantiomers. Although the base pairs are orthogonal to the strand the model suggests selectivity of strand orientation. The higher stability observed for the complex of the mixture of enantiomers is consistent with antiparallel strand orientation. With charge separation of the lysine side chains protonated at pH 7 and an additional A–T base pair, antiparallel strand orientation should be the preferred option.



Scheme 4. According to simple model studies, self-pairing in the A–T mode is only possible with parallel strand orientation and the pairing of enantiomeric strands requires antiparallel strand orientation. Formation of double strands with A–A and T–T base pairing is an interesting alternative, because both base pairs described need comparable backbone distances and are C_2-symmetrical.

The oligomers H-(AlaA-AlaA)$_3$-Lys-NH$_2$ and H-(AlaT-AlaT)$_3$-Lys-NH$_2$ have also been synthesized with the intention of forming an A/T pairing complex. H-(AlaT-AlaT)$_3$-Lys-NH$_2$ does not form pairing complexes as indicated by the temperature independence of the UV absorption and the CD curves (not shown). The melting curve of the H-(AlaA-AlaA)$_3$-Lys-NH$_2$ oligomer (Fig. 4), however, indicates two cooperative transitions at melting temperatures of T_m = 9 and 31 °C. Model studies suggest formation of a double strand and further coordination of one or two energetically equivalent adenine hexamers; the latter is possible only by formation of hydrogen bonds with every second adenine. The pairing mode of this adenine self-pairing is currently under investigation. The possibility of correlating an adenine hexamer with a stable complex, which has a nucleobase specificity, has to be interpreted as an indication of a β-sheet conformation of the peptide strand. The repetitive backbone conformation[11] of a 3_{10}-helix has to have 3.0 amino acids per turn. Therefore, a PNA with alternating configuration would only be repetitive in every seventh amino acid. Deorganization of a stable conformation like a peptide helix also is unlikely to be the reason for the melting curves we observed, because in this case there should be no difference between the melting curve of one enantiomeric A–T octamer and the racemic mixture.

The temperature-dependent UV spectrum of an equimolar mixture of oligomers H-(AlaA-AlaA)$_3$-Lys-NH$_2$ and H-(AlaT-AlaT)$_3$-Lys-NH$_2$ (Fig. 5) shows there is no reorganization of the adenine self-pairing double strand on addition of a thymine hexamer. The melting temperature of T_m = 31 °C as well as the hyperchromicity remain unchanged. Therefore, the A–A pairing is more

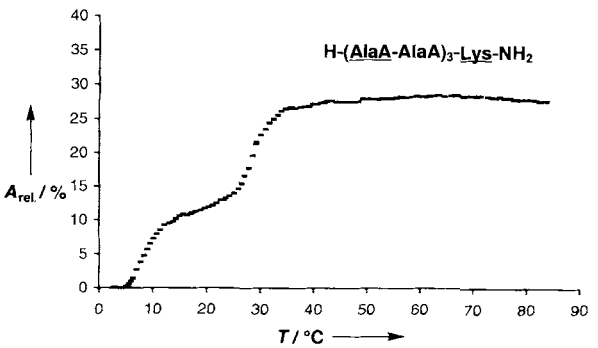


Fig. 4. Melting curve of H-(AlaA-AlaA)$_3$-Lys-NH$_2$ (17 mM, 260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

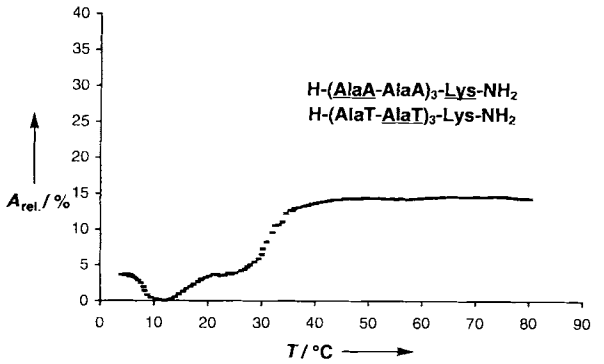

Fig. 5. Melting curve of an equimolar mixture of H-(AlaA-AlaA)$_3$-Lys-NH$_2$ and H-(AlaT-AlaT)$_3$-Lys-NH$_2$ (each 6 mM, 260 nm, 0.1 M NaCl, 0.01 M Na_2HPO_4/H_3PO_4, pH 7).

stable than the A–T mode. The addition of H-(AlaT-AlaT)$_3$-Lys-NH$_2$ only results in a hypochromicity at the lower melting temperature of the self-pairing oligomer H-(AlaA-AlaA)$_3$-Lys-NH$_2$.

The CD spectrum of an equimolar mixture of oligomers H-(AlaA-AlaA)$_3$-Lys-NH$_2$ and H-(AlaT-AlaT)$_3$-Lys-NH$_2$ differs very little from that of the hexamer H-(AlaA-AlaA)$_3$-Lys-NH$_2$ alone (not shown) and can be interpreted as the sum of the single measurements. This again points to the higher stability of the A–A pairing compared with A–T.

Alanyl peptide nucleic acids with alternating configuration of the amino acids form defined pairing complexes, the nature of which is dependent on the kind and sequence of the nucleobases. The rules known for pairing of DNA are not valid for the PNA complexes discussed herein since A–A turned out to be more stable than A–T. Model studies indicate the presence of a linear pairing complex; thus, because of the linearity and the uncharged peptide backbone, the dimer or higher complexes are likely to be more closely packed and formation of unnatural base pairs is possible. Future investigations, for example with 7-carbaadenine which can only form Watson–Crick base pairs, are required to determine the pairing modes. Furthermore, experiments to determine the conformational parameters with multidimensional NMR spectroscopy are planned.

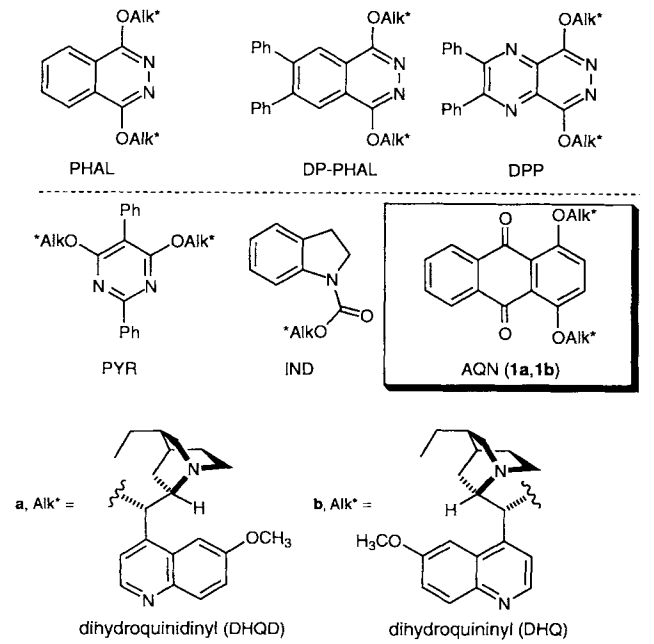
A New Ligand Class for the Asymmetric Dihydroxylation of Olefins**

Heinrich Becker and K. Barry Sharpless*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The catalytic asymmetric dihydroxylation (AD) of olefins using and dihydroquinidine (DHQD) or dihydroquinine (DHQ) derivatives as ligands has become a useful and reliable transformation in organic synthesis.[1] High regio- and stereoselectivity for a broad range of substrates are the most outstanding characteristics of this reaction. To date, over 500 different ligands have been tested in our group and a few superior structural types have been identified (Scheme 1). Ligands based on phthalazine (PHAL) such as (DHQD)$_2$PHAL and (DHQ)$_2$PHAL,[2] along with their recently developed analogs



Scheme 1. Ligands used in the asymmetric dihydroxylation.

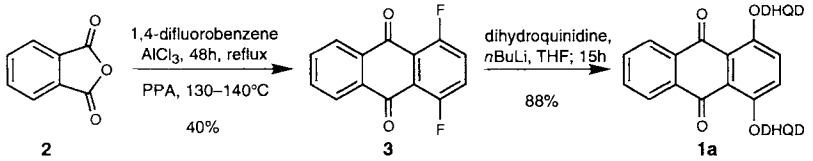
[**] This work was supported by the National Institutes of Health (GM 28384), the W. M. Keck Foundation, and the Fonds der Chemischen Industrie (postdoctoral fellowship for H. B.). We are very grateful to Prof. A. Paul Krapcho for inspiring us to prepare this new ligand class. We thank Paul Richardson for performing the reaction with allyl tosylate (Table 1, entry 5), and Koenraad Vanhessche for permission to include many of his unpublished results in the tables for comparison.

having diphenyl having diphenylphthalazine (DP-PHAL) and diphenylpyrazinopyridazine (DPP) cores,[3] are the most general and lead to high enantioselectivities with most olefins. Ligands based on pyrimidine (PYR) have been found superior for sterically congested olefins (especially terminal olefins).[4] *cis*-1,2-Disubstituted olefins can usually not be dihydroxylated with satisfactory enantioselectivities; however, stereoselectivities in the 70–90% range have been realized for several types of *cis*-1,2-disubstituted olefins.[1a, 5] Despite the recent improvements in ligands for the AD reaction,[3, 5] some important types of olefins, for instance the ubiquitous vinyl compounds, cannot be dihydroxylated reliably with good results.

In this paper we introduce 1,4-bis(dihydroquinidinyl)anthraquinone $(DHQD)_2AQN$ **1a** and 1,4-bis(dihydroquininyl)-anthraquinone $(DHQ)_2AQN$ **1b** (Scheme 1) as a new set of ligands for the AD reaction, which have properties complementary to those of known ligands. The new ligands are easily prepared by nucleophilic substitution of 1,4-difluoroanthraquinone (**3**) with the lithium salt of dihydroquinidine or dihydroquinine in THF at room temperature (Scheme 2). 1,4-Difluoroanthraquinone is obtained by Friedel–Crafts reaction of phthalic anhydride (**2**) and aluminum trichloride in 1,4-difluorobenzene followed by cyclization with polyphosphoric acid (PPA).[6, 7]

The new anthraquinone ligands lead to excellent results in the AD reactions of many allylically substituted terminal olefins. In reactions with the new AQN ligands, most examples of this important class of olefins (Table 1, entries 1–5) can now be dihydroxylated with satisfying enantioselectivities, making a variety of small chiral nonracemic building blocks easily available.[8, 9] Also, reactions of olefins containing multiple halogen atoms (Table 1, entries 6–8; Table 2, entry 16) show significant improvement. The increase in enantioselectivities for terminal olefins with aliphatic substituents (Table 1, entries 10–13) and di- and tri-substituted olefins (Table 2, entries 14–18) is moderate in reactions with the AQN ligands. For sterically congested olefins (Table 1, entries 8 and 13) the pyrimidine-based ligands are still superior. Olefins with aromatic substituents (Table 2, entries 19–24) are usually not dihydroxylated with competitive enantioselectivities in AD reactions with the new ligands; however, the results with indene and allylbenzene (Table 2, entries 23 and 24, respectively) are the best yet for these substrates.

The frequently observed decrease in *ee* values upon changing from DHQD to DHQ ligands is also found for the anthraquinone ligands; in most cases the decrease is moderate. Use of the less expensive quinidine- and quinine-derived ligands instead of their dihydro analogs is possible, but a decrease in *ee* values usually results.[10] The new ligands not only lead to better enantioselectivities, the AD reactions are also faster for certain substrates. For example, 1-decene reacts with OsO_4 about 10% faster in the presence of $(DHQD)_2AQN$ than in the presence of $(DHQD)_2PHAL$.[11]



Scheme 2. Synthesis of $(DHQD)_2AQN$ **1a**. $(DHQ)_2AQN$ **1b** can be prepared analogously (see Experimental Procedure).

In summary, the new anthraquinone-based ligands lead to superior enantioselectivity in the asymmetric dihydroxylation of *almost all* olefins having only aliphatic substituents.[1,2] As these ligands are easy to prepare, their use constitutes an important extension of the AD methodology. The enantioselectivities and rates of reaction for terminal olefins, the most common and most useful class of olefins, show significant improvement. Except in reactions of olefins with aromatic or sterically demanding substituents, the new ligand pair $(DHQD)_2AQN$/$(DHQ)_2AQN$ is now the ligand of choice for the AD reaction.

Experimental Procedure

For general experimental conditions see "Supporting Information" to ref.[3]. Typical procedure for the asymmetric dihydroxylation reactions and workup at 1 mmol scale: $(DHQD)_2AQN$ (8.6 mg, 0.01 mmol, 1 mol%), $K_3Fe(CN)_6$ (990 mg, 3 mmol), K_2CO_3 (420 mg, 3 mmol), and $K_2OsO_2(OH)_4$ (1.4 mg, 0.004 mmol, 0.4 mol%) were dissolved in *tert*-butyl alcohol/water (5 mL of each) at room temperature. For 1,2-disubstituted and trisubstituted olefins $CH_3SO_2NH_2$ (95 mg, 1 mmol) was added. The solution was cooled to 0 °C and the olefin was added. The mixture was stirred at 0 °C, usually for ca. 12 h. In the workup $Na_2S_2O_5$ or Na_2SO_3 (0.8 g) was slowly added and the suspension was warmed to room temperature with vigorous stirring. Ethyl acetate (ca. 20 mL) was added, and the aqueous layer was further extracted with ethyl acetate (2 × 5 mL). If $CH_3SO_2NH_2$ was used the combined organic layers were washed with ca. 20 mL of 2 M aqueous NaOH. The combined organic layers were dried over $MgSO_4$ and then concentrated. The crude product was purified by flash chromatography on silica gel to afford the diol in yields of 65–90%.

Optical rotations of the diols and methods for the determination of enantiomeric excesses: All optical rotations (EtOH, abs.) are given for the products from the reaction of the olefin with $(DHQD)_2AQN$. The *ee* values of the diols or their derivatives were determined by HPLC using Chiracel columns (except for entry 17 in Table 2). Abbreviations used: PMBz = *para*-methoxybenzoyl, IPA = isopropyl alcohol, Bz = benzoyl, NBA = nitrobenzyl alcohol. Entry 1: $[\alpha]_D^{23} = +8.8$ ($c = 1.32$); (bis-PMBz), OD-H, 10% IPA/hexane, 1 mL min^{-1} [retention times: 14.6 min (*S*), 28.0 min (*R*)]; Entry 2: $[\alpha]_D^{23} = +5.9$ ($c = 1.50$); bis-PMBz, OD-H, 10% IPA/hexane, 1 mL min^{-1} [15.3 min (*S*), 30.8 min (*R*)]; Entry 3: $[\alpha]_D^{23} = +5.0$ ($c = 1.10$); diol, OD-H, 5% IPA/hexane, 0.75 mL min^{-1} [22.0 min (*S*), 24.4 min (*R*)]; Entry 4: $[\alpha]_D^{23} = +5.9$ ($c = 1.10$); diol, AD, 10% IPA/hexane, 1 mL min^{-1} [26.8 min (*R*), 29.1 min (*S*)]; Entry 5: $[\alpha]_D^{23} = +14.1$ ($c = 1.30$); bis-PMBz, OD-H, 30% IPA/hexane, 1 mL min^{-1} [38.0 min (*R*), 53.4 min (*S*)]; Entry 6: $[\alpha]_D^{23} = +4.2$ ($c = 1.01$); bis-PMBz, OD-H, 10% IPA/hexane, 1 mL min^{-1} [11.1 min (*S*), 20.7 min (*R*)]; Entry 7: $[\alpha]_D^{23} = -11.7$ ($c = 0.94$); bis-PMBz, OD-H, 10% IPA/hexane, 1 mL min^{-1} [7.4 min (*S*), 16.0 min (*R*)]; Entry 8: $[\alpha]_D^{23} = -23.4$ ($c = 1.02$); bis-PMBz, OD-H, 10% IPA/hexane, 1 mL min^{-1} [9.6 min (*S*), 14.0 min (*R*)]; Entry 9: $[\alpha]_D^{23} = -4.0$ ($c = 1.13$); bis-PMBz, OD-H, 40% IPA/hexane, 0.75 mL min^{-1} [14.8 min (*R*), 45.6 min (*S*)]; Entry 10: $[\alpha]_D^{23} = +14.7$ ($c = 1.04$); bis-PMBz, OD-H, 5% IPA/hexane, 0.75 mL min^{-1} [12.4 min (*R*), 16.6 min (*S*)]; Entry 11: $[\alpha]_D^{23} = +15.8$ ($c = 0.91$); bis-PMBz, OD-H, 5% IPA/hexane, 0.75 mL min^{-1} [13.0 min (*R*), 17.3 min (*S*)]; Entry 12: $[\alpha]_D^{23} = +17.8$ ($c = 0.95$); bis-PMBz, OD-H, 5% IPA/hexane, 0.70 mL min^{-1} [14.4 min (*R*), 20.6 min (*S*)]; Entry 13: $[\alpha]_D^{23} = -4.8$ ($c = 0.96$); bis-Bz, OF, 2.5% IPA/hexane, 0.8 mL min^{-1} [12.9 min (*R*), 17.6 min (*S*)]; Entry 14: $[\alpha]_D^{23} = +38.6$ ($c = 0.96$); bis-PMBz, AD, 5% IPA/hexane, 0.7 mL min^{-1} [18.2 min (*S,S*), 21.7 min (*R,R*)]; Entry 15: $[\alpha]_D^{23} = +12.5$ ($c = 1.01$); bis-PMBz, OD-H, 10% IPA/hexane, 0.5 mL min^{-1} [14.2 min (2*S*,3*R*), 18.4 min (2*R*,3*S*)]; Entry 16: $[\alpha]_D^{23} = -20.1$ ($c = 1.12$); bis-PMBz, AD, 10% IPA/hexane, 1 mL min^{-1} [13.7 min (*S,S*), 16.9 min (*R,R*)]; Entry 17: $[\alpha]_D^{23} = +39.5$ ($c = 1.14$); diol, GLC, CDX-B, 125 °C isotherm [10.0 min (*S*), 10.2 min (*S*)]; Entry 18: $[\alpha]_D^{23} = +2.9$ ($c = 0.99$); mono-Bz, OD-H, 1% IPA/hexane, 1 mL min^{-1} [22.6 min (*R*), 24.3 min (*S*)]; Entry 19: $[\alpha]_D^{23} = -31.9$ ($c = 1.00$); diol, OB-H, 10% IPA/hexane, 0.5 mL min^{-1} [14.3 min (*R*), 18.1 min (*S*)]; Entry 20: $[\alpha]_D^{23} = -4.4$ ($c = 0.96$); bis-Bz, OD-H, 2.5% IPA/hexane, 1 mL min^{-1} [18.4 min (*R*), 22.3 min (*S*)]; Entry 21: $[\alpha]_D^{23} = -1.7$ ($c = 1.05$); diol, AD, 10% IPA/hexane, 0.5 mL min^{-1} [17.4 min (*S,S*), 20.7 min (*R,R*)]; Entry 22: $[\alpha]_D^{23} = -9.9$ ($c = 0.99$); cyclic carbonate, AD, 2.5% IPA/hexane, 1 mL min^{-1} [22.7 min (1*R*,2*S*), 26.0 min (1*S*,2*R*)]; Entry 23: $[\alpha]_D^{23} = +24.1$ ($c = 1.12$); diol, OK, 10% IPA/hexane, 0.8 mL min^{-1} [11.7 min (1*R*,2*S*), 14.4 min (1*S*,2*R*)]; Entry 24: $[\alpha]_D^{23} = +22.9$ ($c = 1.05$); cyclic carbonate, OD-H, 10% IPA/hexane, 1 mL min^{-1} [31.8 min (*R*), 35.4 min (*S*)].

3: A mixture of **2** (5.00 g, 33.8 mmol), $AlCl_3$ (18.0 g, 135 mmol), and 35 mL of 1,4-difluorobenzene was heated at reflux for 48 h. The excess (ca. 25 mL) 1,4-difluorobenzene was removed by distillation and 200 mL of 1 N aq. HCl was added slowly. The mixture was extracted with CH_2Cl_2 (1 × 300 mL, 3 × 100 mL). The combined organic layers were dried by filtration through cotton. The solvent was evaporated and the residue was taken up in 20 mL of $CHCl_3$. Hexane (50 mL) was added and the mixture was cooled to 0 °C, then to −20 °C. The resulting precipate was filtered and dried in vacuo, then 25 mL of polyphosphoric acid was added and the mixture was heated to 130–140 °C for 2 h. The black mixture was poured on to ca. 200 g of ice and then allowed to warm to room temperature with stirring. After neutralization with solid K_2CO_3, the mixture was extracted with CH_2Cl_2 (4 × 100 mL). The combined organic layers were dried by filtration through cotton and concentrated in vacuo. The crude product was filtered through a 5 × 10 cm column of basic alumina (Act. I) eluting with CH_2Cl_2. It was then purified by flash chromatography (4 × 15 cm column of silica gel, hexane/ethyl acetate 2/1, then 1/1) to afford 3.31 g (13.5 mmol, 40%) of **3** as slightly yellow solid. M.p. 220–223 °C; FT-IR (KBr): $\tilde{\nu}$ = 3087 (m), 3051 (w), 1683 (s), 1590 (m), 1472 (m), 1416 (m), 1335 (m), 1258 (s), 1171 (m), 722 (s), 567 (m) cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 7.45–7.50 (m, 2H), 7.80 (dd, J = 5.8, 3.3 Hz, 2H), 8.24 (dd, J = 5.8, 3.3 Hz, 2H); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 121.6, 124.6 (dd, ^2J(C,F) = 20 Hz, ^3J(C,F) = 14 Hz), 127.0, 133.2, 134.3, 156.2 (dd, ^1J(C,F) = 268 Hz, ^4J(C,F) = 4 Hz), 180.6; ^{19}F NMR ($CDCl_3$ [$CFCl_3$], 375 MHz): δ = −180.4 (t, $J \approx 7$ Hz); MS (FAB$^+$/nitrobenzyl alcohol (NBA)/CsI) calculated for $C_{14}H_6F_2O_2$ (MH^+), 245.0414; found, 245.0410.

$(DHQD)_2AQN$ **1a**: A solution of dihydroquinidine [13] (3.35 g, 10.25 mmol, 2.5 equiv) in dry THF was cooled to −50 °C and 6.4 mL (10.25 mmol, 2.5 equiv) of 1.6 M *n*BuLi in hexane was added slowly over 10 min. The solution turned slightly red at the end of the addition. It was stirred for 15 min, warmed to 0 °C, and then **2** (1.00 g, 4.10 mmol) was added as a solid. The reaction mixture was warmed to room temperature, stirred for 18 h, warmed to ca. 40 °C, and stirred for another 2 h. For reactions conducted on a larger scale, the THF was removed in vacuo at this point. Ethyl acetate (200 mL) was added along with sat. aqueous $NaHCO_3$ solution (100 mL). The aqueous phase was extracted with ethyl acetate (2 × 100 mL), and the combined organic layers were dried with $MgSO_4$. After removal of the solvent in vacuo, the raw product was purified by flash chromatography on silica gel (4 × 15 cm, $CHCl_3$ + 5% MeOH + 0.5% NH_4OH) to afford 3.107 g (3.625 mmol, 88%) of $(DHQD)_2AQN$ **1a** as yellow solid. M.p. 152–157 °C; $[\alpha]_D^{23} = -487$ (c = 1.10, $CHCl_3$); UV (MeOH): λ_{max} = 415 nm (ε = 5260), λ_{max} = 335 nm (ε = 11030); FT-IR (KBr): $\tilde{\nu}$ = 2934 (s), 2871 (m), 1669 (s), 1620 (m), 1508 (m), 1463 (m), 1260 (s), 1243 (s), 1030 (m) cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 0.84 (t, J = 7.3, 6H), 1.25–1.77 (m, 14H), 2.41 (br s, 2H), 2.40–2.81 (m, 8H), 3.24 (br s, 2H), 3.92 (s, 6H), 5.87 (br s, 2H), 6.65 (s, 2H), 7.36 (dd, J = 9.4, 2.2 Hz, 4H), 7.49 (d, J = 4.2 Hz, 2H), 7.79 (dd, J = 5.7, 3.3 Hz, 2H), 8.02 (d, J = 9.4 Hz, 2H), 8.22 (dd, J = 5.8, 3.3 Hz, 2H), 8.65 (d, J = 4.5 Hz, 2H); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 12.1, 24.5, 26.5, 27.2, 37.8, 50.2, 51.0, 55.7, 60.3, 81.0 (br), 100.7 (br), 119.1 (br), 120.4, 122.0, 123.4, 126.2, 126.5, 132.0, 133.3, 134.3, 143.0, 144.6, 147.6, 151.2, 158.0, 182.9; MS (FAB$^+$/NBA/CsI) calculated for $C_{54}H_{56}O_6N_4$ (MH^+), 857.4278; found, 857.4242.

$(DHQ)_2AQN$ **1b**: The synthesis is analogous to that of **1a**. Dihydroquinine [13] (3.35 g, 10.25 mmol, 2.5 equiv), 1.6 M *n*BuLi in hexane (6.4 mL, 10.25 mmol, 2.5 equiv), and **3** (1.00 g, 4.10 mmol) afforded 2.967 g (3.462 mmol, 84% yield) of $(DHQ)_2AQN$ **1b** as a yellow solid. M.p. 177–180 °C; $[\alpha]_D^{23} = +579$ (c = 1.18, $CHCl_3$); FT-IR (KBr): $\tilde{\nu}$ = 2954 (m), 2931 (s), 2871 (m), 1669 (s), 1621 (m), 1509 (m), 1461 (m), 1262 (m), 1243 (s), 1005 (m) cm^{-1}; ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 0.80 (t, J = 7.3 Hz, 6H), 1.14–1.44 (m, 8H), 1.59 (br s, 2H), 1.92 (br s, 2H), 2.05 (br s, 2H), 2.35–2.61 (m, 6H), 3.05 (dd, J = 13.4, 10.0 Hz, 2H), 3.23 (br s, 4H), 3.92 (s, 6H), 5.95 (br s, 2H), 6.61 (br s, 2H), 7.32 (br s, 2H), 7.37 (dd, J = 9.2, 2.5 Hz, 2H), 7.43 (d, J = 4.5 Hz, 2H), 7.79 (dd, J = 5.7, 3.3 Hz, 2H), 8.03 (d, J = 9.2 Hz, 2H), 8.28 (dd, J = 5.7, 3.3 Hz, 2H), 8.64 (d, J = 4.5 Hz, 2H); ^{13}C NMR ($CDCl_3$, 100 MHz): δ = 12.1, 20.9, 25.6, 27.7, 27.8, 37.6, 43.5, 55.8, 58.9, 60.0, 80.4 (br), 100.6 (br), 118.7 (br), 120.6, 122.0, 123.4, 126.2, 126.4, 132.1, 133.3, 134.3, 142.8, 144.6, 147.6, 151.0, 158.2, 182.7; MS (FAB$^+$/NBA/CsI) calculated for $C_{54}H_{56}O_6N_4$ (MCs^+), 989.3254; found, 989.3286.

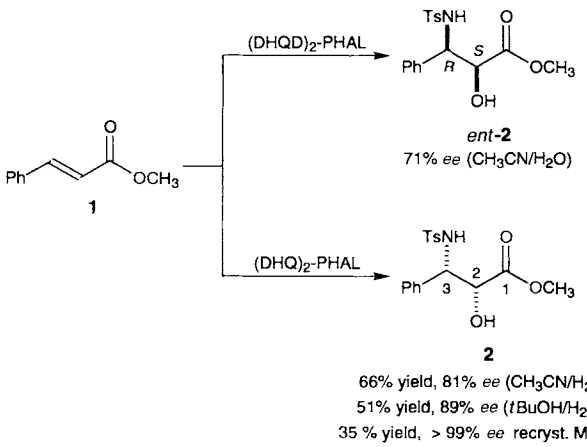
[10] When quinidine- or quinine-derived ligands are used, the operative ligands are the corresponding tetraols.
[11] Reactions with pseudo-first-order rates were conducted in *t*BuOH at 25 °C with concentrations of OsO_4, olefin, and ligand of 0.0002 M, 0.002 M, and 0.002 M, respectively. The rates were determined by monitoring the formation of the osmate ester at $\lambda = 680$ nm using a Cary 4 spectrophotometer. The rates are: $(DHQD)_2PHAL$/1-decene: $0.95 \times 10^{-2}\ s^{-1}$; $(DHQD)_2AQN$/1-decene: $1.10 \times 10^{-2}\ s^{-1}$; $(DHQD)_2PHAL$/styrene: $3.30 \times 10^{-2}\ s^{-1}$; $(DHQD)_2AQN$/styrene: $1.03 \times 10^{-2}\ s^{-1}$.
[12] Recently the DPP ligands have been found to be excellent for the AD reaction of olefins with aromatic substituents. See ref.[3].
[13] Dihydroquinidine and dihydroquinine were obtained from their hydrochloride or hydrobromide salts as described in the "Supplementary Material" to ref.[2a]. The ligands are available from Aldrich.

Catalytic Asymmetric Aminohydroxylation (AA) of Olefins**

Guigen Li, Han-Ting Chang, and K. Barry Sharpless*

Dedicated to the memory of Fèlix Serratosa

The β-hydroxyamino group is frequently found in biologically active molecules. We report here that this important unit can now be synthesized directly from olefins in enantiomerically enriched form. The new osmium-catalyzed asymmetric process is exemplified by the synthesis of the enantiomers of the taxol side chain (**2** and *ent*-**2**) from methyl cinnamate (**1**) (Scheme 1).



Scheme 1. $K_2OsO_2(OH)_4$, 4%; $(DHQ)_2$-PHAL or $(DHQD)_2$-PHAL, 5%; TsNClNa·3H$_2$O, 3 equiv; CH_3CN/H_2O or *t*BuOH/H_2O, v/v = 1/1; room temperature, 3 h, 0.07 M olefin. See preceding communication for details on the ligands $(DHQ)_2$-PHAL and $(DHQD)_2$-PHAL.

[**] This work was supported by the National Science Foundation (CHE-9296055), the National Institutes of Health (GM 28384), PPG Industries, Sepracor Inc., Merck Research Laboratories, and the W. M. Keck Foundation. We thank Dr. Pui Tong Ho for many helpful discussions. K. B. S. is extremely grateful to Professor Tohru Fukuyama of Rice University for communication of his sulfonamide deprotection discovery[8] and generously suggesting we try it in our earlier osmium-[5] and selenium-catalyzed[9] processes. Taking his advice led us to encounter, serendipitously, these long-sought conditions for achieving catalytic turnover in the AA.

This *catalytic* asymmetric aminohydroxylation (AA) is obviously a close relative of the catalytic asymmetric dihydroxylation (AD).[1] In fact, the *stoichiometric* variant was first reported in 1980 as a footnote in the initial report on the stoichiometric asymmetric dihydroxylation process.[2] However, our studies on both the AD and AA reactions, which were at first only stoichiometric transformations, were pushed aside by rapid developments in the titanium-catalyzed asymmetric epoxidation process (AE), also discovered in 1980.[3] Ever since the development of the *catalytic* AD in 1987,[1a] we have tried to render the AA *catalytic*. Success was very limited[4] until recently when several adjustments in the reaction conditions led to useful catalyst turnover rates. The new process otherwise relies on a simple combination of the phthalazine ligands of the AD reaction and the conditions of the old, but efficient, osmium-catalyzed aminohydroxylation from the 1970s.[5] Other than the asymmetric induction, the most dramatic effect of the cinchona alkaloid ligand is on the regioselectivity. In the original study with methyl cinnamate (**1**),[5a] in which no ligand was used, the C-3 sulfonamide isomer **2** and its C-2 regioisomer were produced in a 2:1 ratio. In the present system this ratio is improved to $\geq 5{:}1$.[6] The reaction of ethyl crotonate (Table 1, entry 2) benefits from this same ligand effect (cf. ref.[5b]). Another positive effect of the ligand is its ability to suppress formation of the diol by-product, which in the absence of the ligand is substantial in this new system.

Table 1 reveals that the process in its present form leads to only modest enantioselectivities (33–81% *ee*). On the other hand, the first report on the catalytic AD reaction did not look much better (20–88% *ee*),[1a] and this new process offers considerably more variables for optimization. Even the present results are useful since hydroxysulfonamides tend to be highly crystalline; enantiomeric purity near 100% can often be reached by recrystallization. This is the case for the derivative of the taxol side chain, **2**, which can be deprotected by treatment with 33% HBr in acetic acid for 10 hours at 75 °C to give the enantiomerically pure α-hydroxy-β-amino acid in 77% yield.[7] While the core functionality of toluenesulfonamide derivative **2** survives these strongly acidic conditions, many compounds would not. Indeed, the notorious problems associated with deprotection of sulfonamides are a serious concern for this AA process. Fortunately, a recent breakthrough from the Fukuyama group[8] promises to make sulfonamide protection for nitrogen extremely popular.[9–11] In any case, the strongly acidic conditions successful for deprotection of the precursor of the taxol side chain indicate that more molecules than previously imagined may tolerate the old "brute-force" approach for hydrolysis of aromatic sulfonamides.

Initial experience has been largely with CH_3CN/H_2O as solvent (procedure 1, Table 1), but *t*BuOH/H_2O is also a good solvent system (procedure 2, Table 2) and both are worth trying with new substrates. For the examples given in Table 2, the products are insoluble in *t*BuOH/H_2O and for *trans*-stilbene, the starting material is also insoluble. In these cases, the reported yields and *ee* values are for the product isolated by direct filtration of the reaction mixture (no workup, not even reduction with sulfite). The products are almost pure by NMR and HPLC analysis. Another virtue of this approach is that the toluenesulfonamide by-product remains in the mother liquor. In procedure 1, the excess $TsNH_2$ can be difficult to remove.

Mechanistic studies on the AA are underway and we have evidence[12] that there is more than one catalytic cycle, which is reminiscent of the AD process when *N*-methylmorpholine *N*-oxide (NMO) is the oxidant.[13] For the present, we eschew further speculation on the mechanism except to note four key

Table 1. Catalytic asymmetric aminohydroxylation in CH_3CN/H_2O (1/1) (see procedure 1 in the Experimental Procedure).

Entry	Substrate	Product [a]		*ee* Values [%] $(DHQ)_2$-PHAL [b]	*ee* Values [%] $(DHQD)_2$-PHAL [c]	Yield [%]	*t* [h]	M.p. [°C] [b]	$[\alpha]_D^{25}$ [b]
1	 **1**	 **2**	F	81 (99)	71	64	3	154–155	+19.8 ($c = 0.50$)
2		 **3**	F	74	60	52	1.5	oil	−20.3 ($c = 1.25$)
3		 **4**	F	77 (93)	53	65	3	140–141	−7.9 ($c = 0.63$)
4 [d]		 **5**	P	62 (99)	50	52	14	167–168	−15.9 ($c = 0.43$)
		 **6**	F						
5		 **7**	⟨	33 (99)	48	48	3	227–228	+53.0 ($c = 0.11$)
6				45 (99)	36	64	6	117–119	+1.8 ($c = 0.60$)

[a] All absolute configurations have been determined (see Experimental Procedure). [b] Numbers in parentheses are *ee* values after recrystallization from methanol. (In some cases [7] it is the mother liquor that is enantioenriched when the racemate crystallizes preferentially.) The melting points and optical rotations (in 95% ethanol) are for the samples with the highest *ee* values listed in the $(DHQ)_2$-PHAL column of Table 1. [c] The *ee* values in this column are for the products that are enantiomeric to those in the Product column. [d] CH_3CN/H_2O (4/3) was used as the solvent.

facts. 1) The AA process is obviously an asymmetric version of the catalytic aminohydroxylation process discovered twenty years ago.[5a] 2) The ligand suppresses the formation of the diol by-product. 3) The ligand leads not only to enantioselectivity, but in some cases also accelerates catalytic turnover (ligand-accelerated catalysis, LAC[14]).[15] 4) The ligand influences the regioselectivity, sometimes strongly so. The latter effect is perhaps fortunate for reactions of unsaturated carbonyl compounds such as cinnamate and crotonate (Table 1, entries 1 and 2). The ligand steers the nitrogen center to the β-carbon atom producing a class of amino acids (e.g. **2** and **3**), which are useful in the synthesis of peptidomimics.

Table 2. Catalytic asymmetric aminohydroxylation in *t*BuOH/H_2O (1/1) (see procedure 2 in the Experimental Procedure).

Substrate	Product	*ee* Values [%] $(DHQ)_2$-PHAL	Yield [%]	*t* [h]
	 **2**	82 (89 [a])	60 (51 [a])	3
	 **5**	64 (99 [b])	78 (50 [b])	3
	 **6**	50	57	2.5

[a] In this case, one-half of the olefin was added at the beginning of the reaction and the rest was added in portions over 45 min starting one hour later. [b] The minor enantiomer was completely removed by two triturations with ethyl acetate leaving a 50% yield of enantiopure (*S*,*S*)-**5**.

Two features of this AA process are surprising: 1) Even strongly electron-deficient olefins such as dimethyl fumarate (Table 1, entry 3) react rapidly and with good *ee* values,[16] whereas in the AD reaction dimethyl fumarate reacts extremely slowly and with less than 40% *ee*. 2) *cis*-Disubstituted olefins appear to be promising substrates, even symmetrical compounds which of course give achiral *meso* diols in the AD. Although the enantioselectivities are low for *cis*-stilbene and cyclohexene (Table 1, entries 5 and 6, respectively), AA reactions of heterocyclic *cis* olefins have exceeded 77% *ee*.[17]

For the *trans*-disubstituted olefins examined here the face selection rule follows that for the AD reaction; that is, with the olefin drawn as in Scheme 1, $(DHQD)_2$-PHAL directs addition to the β-face and $(DHQ)_2$-PHAL directs addition to the α-face. For *trans* olefins it is now the DHQ series that generally gives higher *ee* values (Table 1, entries 1–4), the inverse of the situation for the AD reaction.[1] Another trend, which fits our current speculation on the mechanism,[18] is that with electronically unsymmetrical olefins the nitrogen becomes attached to the carbon

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3504-0452 $ 15.00+.25/0

atom distal to the strongest electron-withdrawing group (Table 1, entries 1 and 2).

In summary, the asymmetric aminohydroxylation (AA) of olefins is now an effective catalytic process. Much work lies ahead to establish the scope and utility of the reaction, but it should already prove useful in research laboratories. The AA shares with the AD three desirable features. The first is simplicity: only catalytic amounts of both osmium and chiral ligand are required; the reactions are performed at close to room temperature with commercially available reagents and are not influenced by water or oxygen; and the products can often be isolated by filtration of the crude reaction mixture. The second feature is the crucial functional group transformations AA and AD provide: under essentially neutral conditions and with great reliability an olefin undergoes *cis*-vicinal addition of two heteroatoms.[19] Last but not least is scope: like the AD, the AA has no requirement for auxiliary functional groups.

Experimental Procedure

General procedure: All reagents and solvents were purchased from commercial sources and used as received unless stated otherwise. Stoichiometries are calculated based on the purities reported by the manufacturer (*trans*-stilbene: 96%; Chloramine-T trihydrate: 98%). $K_2OsO_2(OH)_4$ should be mauve colored rather than brown/black and should be dry for the best yields and *ee* values (the hygroscopic nature of the salt affects the amount of osmium available). All new compounds gave satisfactory spectroscopic analyses (^{1}H NMR and IR spectroscopy, HRMS). Enantiomeric excesses were determined by HPLC using Chiracel columns (Daicel Chemical Industries) and isopropyl alcohol/hexane (v/v) mobile phases; the retention time of the major enantiomer from the $(DHQ)_2$-PHAL reaction is in italics. The vicinal hydroxysulfonamides derived from AA reactions using $(DHQ)_2$-PHAL as the chiral ligand were correlated to compounds of known absolute configuration by HPLC.

Procedure 1: Ethyl (2*R*,3*S*)-*N*-(*p*-toluenesulfonyl)-3-amino-2-hydroxybutanoate (**3**): To a stirred solution of $(DHQ)_2$-PHAL (0.11 g, 0.14 mmol, 5 mol%) in 20 mL of acetonitrile and 20 mL of water, in any convenient-sized glass vessel or vial, were added *trans*-ethyl crotonate (0.32 g, 2.8 mmol), Chloramine-T trihydrate (2.42 g, 8.4 mmol, 3 equiv), and $K_2OsO_2(OH)_4$ (41.6 mg, 0.112 mmol, 4 mol%). As the reaction proceeded to completion over the course of about 90 min at room temperature, the color of the solution changed from yellow to pale green, then deep green, and finally back to yellow (for entry 3 in Table 1, the yellow color remains throughout). After addition of aqueous sodium sulfite (1.0 g in 15 mL H_2O), the phases were separated and the aqueous phase was extracted with ethyl acetate (3 × 15 mL). The combined organic extracts were washed with brine, dried over $MgSO_4$, and concentrated to dryness to give the crude product, which also contains the *p*-toluenesulfonamide by-product produced upon the reduction of the excess Chloramine-T. Flash chromatography (hexane/$CHCl_3$/MeOH (6/4/1)) of this material provided 0.44 g (52% yield, 74% *ee*) of **3** as a clear oil eluting before the *p*-toluenesulfonamide impurity. When the 3 equiv of Chloramine-T was replaced with 1.5 equiv of Chloramine-T and 1.5 equiv of Et_4NOAc, comparable results were obtained and the amount of *p*-toluenesulfonamide by-product formed was reduced. This can greatly simplify product isolation, especially when the product and the toluenesulfonamide have similar chromatographic mobilities. Nonchromatographic methods for removing the $TsNH_2$ will be described elsewhere.

Procedure 2: (1*S*,2*S*)-*N*-(*p*-Toluenesulfonyl)-2-amino-1,2-diphenylethanol (**5**): To a solution of $(DHQ)_2$-PHAL (2.20 g, 2.80 mmol, 5 mol%) in *t*BuOH (100 mL) and water (100 mL) in a 500 mL Erlenmeyer or round-bottomed flask were added in order, *trans*-stilbene (10.5 g, 56.0 mmol), Chloramine-T trihydrate (48.4 g, 0.168 mol, 3.0 equiv), and $K_2OsO_2(OH)_4$ (0.824 g, 2.24 mmol, 4 mol%). The reaction flask was immersed in a room-temperature water bath and the slurry stirred for 2.5 h. Over the course of the reaction, the color changed from brown to deep green and then to yellow as the stilbene slurry became a hydroxysulfonamide slurry. The product was isolated by filtration and the crude solid was washed once with cold (ca. 5 C) *t*BuOH:H_2O (1 1, 15 mL) to yield 16.1 g of **5** (78% yield, 64% *ee*, pure by NMR spectroscopy and HPLC). Trituration of this product twice with ethyl acetate (2 × 15 mL) at room temperature in a sintered glass funnel left crystals of enantiomerically pure **5** (10.3 g, 50% yield, >99% *ee*, m.p. 166–167 °C). See ref. [20] for analogous solid-to-solid AD procedures.

Analysis of enantiomeric excesses: **2**: Chiralcel OG, 30% *i*PrOH/hexane, 1 mL min^{-1}; 21.8 min (2*S*,3*R*), 28.3 min (2*R*,3*S*). **3**: Chiralcel OD-H, 15% *i*PrOH/hexane, 1 mL min^{-1}, 7.5 min (2*S*,3*R*), 13.4 min (2*R*,3*S*). **4**: Chiralcel OG, 30% *i*PrOH/hexane, 1 mL min^{-1}, 16.7 min (2*S*,3*S*), 21.8 min (2*R*,3*R*). **5**: Chiralcel OD-H, 15% *i*PrOH/hexane, 1 mL min^{-1}, 16.2 min (1*S*,2*S*), 26.0 min (1*R*,2*R*). **6**: Chiralcel OD-H, 15% *i*PrOH/hexane, 0.5 mL min^{-1}, 18.5 min (1*S*,2*R*), 22.1 min (1*R*,2*S*). **7**: Chiralcel OG, 15% *i*PrOH/hexane, 0.5 mL min^{-1}, 28.5 min (1*S*,2*R*), 34.4 min (1*R*,2*S*).

Correlation of the absolute configurations: (2*R*,3*S*)-**2**: Authentic (2*R*,3*S*)-**2** was synthesized from *N*-benzoyl-(2*R*,3*S*)-3-phenylisoserine methyl ester (taxol C13 side chain[20]) [6 N HCl, reflux (methyl ester and *N*-benzoyl groups removed); $SOCl_2$, methanol (esterification); TsCl, K_2CO_3, acetone/water (1/1) (*N*-sulfonylation)] [HPLC: vide supra]. (2*R*,3*S*)-**3**: (2*R*,3*S*)-**3** was converted to *N*-tosyl-(2*S*)-alanine methyl ester [6 N HCl (hydrolysis); $RuCl_3/H_5IO_6$ (oxidative cleavage); $SOCl_2$, methanol (esterification)] [HPLC: Chiralcel OD-H, 15% *i*PrOH/hexane, 1 mL min^{-1}, 16.1 min (2*R*), 17.0 min (2*S*)]. (2*R*,3*R*)-**4**: (2*R*,3*R*)-**4** was converted to its *N*-tosyl-(2*R*,3*R*)-2-oxazolidinone derivative, which was also independently synthesized from (1*S*,2*S*)-**5** [carbonyl diimidazole, CH_2Cl_2; $RuCl_3$, H_5IO_6 (oxidative degradation of the phenyl groups)[21]; $SOCl_2$, methanol (esterification)] [HPLC: Chiralcel OD-H, 15% *i*PrOH/hexane, 1 mL min^{-1}, 26.0 min (1*R*,2*R*), 47.2 min (1*S*,2*S*)]. (1*S*,2*S*)-**5**: An authentic sample of (1*S*,2*S*)-**5** was synthesized from (1*R*,2*S*)-**6** [CrO_3, H_2SO_4 (oxidation of alcohol to ketone); DIBAL-H reduction gave a 4:1 mixture of (1*R*,2*S*)-**6** and (1*S*,2*S*)-**5**] [HPLC: vide supra]. (1*S*,2*R*)-**6**: An authentic sample of (1*R*,2*S*)-**6** was synthesized from (1*R*,2*S*)-2-amino-1,2-diphenylethanol [TsCl, K_2CO_3, acetone/water] [HPLC: vide supra]. (1*S*,2*R*)-**7**: *N*,*N*′-Ditosyl-(1*R*,2*R*)-diaminocyclohexane was synthesized from (1*S*,2*R*)-**7** [SO_2Cl_2, Et_3N, EtOAc; NaH (cyclic sulfamidate formation); NaN_3 (opening); H_2, Pd/C (azide reduction); TsCl, K_2CO_3, acetone/water (1/1)] and compared to the compound derived from authentic (1*R*,2*R*)-diaminocyclohexane[22] [HPLC: Chiralcel AS, 20% *i*PrOH/hexane, 1 mL min^{-1}, 23.2 min (1*R*,2*R*), 32.3 min (1*S*,2*S*)].

[6] In fact, at an early stage (ca. 5% conversion) of the reaction with methyl cinnamate this ratio is >20:1 and the enantiomeric purity of the major regioisomer (**2**) is about 95% *ee*. Both regio- and enantioselectivity drop continuously as the reaction proceeds. This is tentatively attributed to intrusion of a "second cycle" (see refs.[12,13]).

[7] G. Li, K. B. Sharpless, *Acta Chem. Scand.*, in press. This paper describes a one-third mole scale synthesis of the precursor of the taxol side chain based on the solution-to-solid AA of methyl cinnamate (procedure 2, Table 2, but with only 2.5 mol% ligand and 2.0 mol% osmium catalyst). See also ref. [22].

[15] The ligand, in this case $(DHQ)_2$-PHAL, substantially accelerates the rate of catalysis for the α,β-unsaturated ester substrates (Table 1, entries 1–3). However, for stilbene and the remaining entries in Table 1 the catalysis is faster in the absence of ligand—an example of the more common phenomenon of LDC (ligand-decelerated catalysis)[14]. It is too early to speculate on the origin of these opposite effects of the ligands.

[16] Despite their electron deficiency, reactions of α,β-unsaturated carbonyl compounds are among the fastest to date in the catalytic AA.

[17] A. Houri, K. B. Sharpless, unpublished results.
[18] In the AA the putative organometallic intermediate (see mechanistic section of the AD review [1b]) can be either an oxametallacycle or an azametallacycle. The AA results to date suggest the azametallacycle is preferred, especially for substrates like methyl cinnamate and ethyl crotonate (entries 1 and 2 in Table 1).

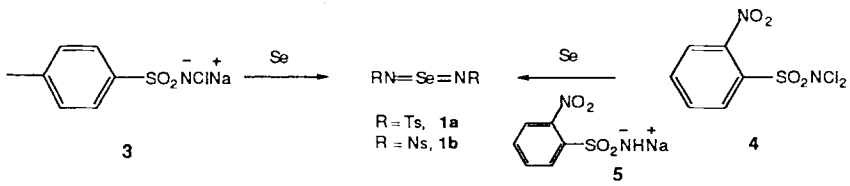

Scheme 2.

Allylic Amination and 1,2-Diamination with a Modified Diimidoselenium Reagent**

Milan Bruncko, Tinh-Alfredo V. Khuong, and K. Barry Sharpless*

Allylic amines and 1,2-diamino-3-alkenes are compounds of great interest[1] predominantly for the synthesis of natural products,[2] medicinal agents,[3] and amino and 1,2-diamino carboxylic acids.[4] Several methods for allylic aminations have been developed,[5] but these require severe reaction conditions or several sequential reactions. Many of the methods employ alkenes that have already been functionalized at the allylic position.[6] The recently published discovery of a simple method for deprotection of nitro-substituted benzenesulfonamides by Fukuyama et al.[7] encouraged us to return to selenium chemistry. We report here on a modification and significant improvement in a method for the allylic amination of olefins utilizing diimidoselenium reagents.[8]

Diimidoselenium compounds **1** have been shown to react in a manner similar to selenium dioxide (Scheme 1).[9] Oxidation of an allylic position in alkenes using SeO_2 proceeds by an ene reaction followed by [2,3]sigmatropic rearrangement, and **1** can effect allylic amination by an analogous pathway. The in situ synthesis of selenium reagent **1a** involves treatment of sodium

[**] This work was supported by the National Institutes of Health (GM 28384), Merck Research Laboratories, and the W. M. Keck Foundation. This research was made possible by the exciting discovery of a superior alkylation/deprotection strategy for amines by Fukuyama et al.[7]. We are deeply indebted to him for encouraging us to try it in our old selenium-mediated allylic aminations.

N-chloro-*p*-toluenesulfonamide (Chloramine-T) (**3**) with elemental selenium in dichloromethane under anhydrous conditions (Scheme 2).[10] Due to the poor solubility of both of these reagents the overall reaction is slow (24–48 h). Subsequent deprotection of the amino function of the allylic amines by removal of the *p*-toluenesulfonyl group requires harsh conditions that are incompatible with many other functionalities. Replacement of the insoluble Chloramine-T (**3**) with a more reactive and entirely soluble dichloramine derivative such as **4** results in a substantial process improvement (Scheme 2). Reagent **4** is very reactive. Therefore we have developed two procedures for allylic amination with **1b**. For reactions on less than a 10 mmol scale all reagents (Se, **4**, **5**) are mixed and dichloromethane is added quickly. For larger scale reactions a solution of **4** in dichloromethane is added to the suspension of selenium and sodium sulfonamide **5**. By these modifications, the whole process can be accomplished in one pot in less than three hours.

The reaction of the selenium reagent **1b** with different alkenes was investigated, and the results are summarized in Table 1. Allylic amination of the simple terminal olefin 1-hexene (Table 1, entry 1), provided the 2-nitrobenzenesulfonyl derivative **6a** in 51% yield. This yield is slightly lower than that ob-

Table 1. Allylic amination of alkenes[a].

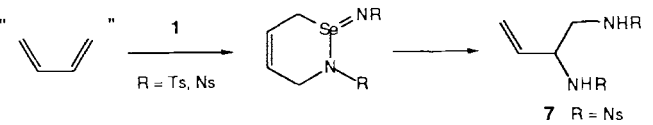
Entry	Alkene	Product	Yield [%] [b]
1		 **6a**	51 (54) [c]
2		 **6b**	21
3		 **6c**	64 (74) [c]
4		 **6d**	39 [d]
5		 **6e**	59

[a] For reaction conditions see the Experimental Procedure. [b] All yields were determined by isolation of products. [c] Numbers in brackets correspond to yields obtained with the tosyl reagent [8]. [d] 2.1:1 mixture of diastereomers.

tained with the selenium reagent prepared from Chloramine-T. Treatment of two equivalents of methylenecyclohexane (Table 1, entry 3) with one equivalent of **1b** afforded the 2-nosylamido product **6c** in 64% yield. With the opposite proportions, two equivalents of **1b** and one equivalent of the same substrate (Table 1, entry 4), the 2,6-bis(nosylamido) product **6d** was obtained as a 2.1:1 mixture of diastereomers in 39% yield. An acyclic substrate such as 1,5-hexadiene nevertheless afforded the

mono-substituted nosylamido product **6b** (Table 1, entry 2), even when the amount of **1b** was increased to two equivalents. 1-Phenylcyclohexene (Table 1, entry 5) provided 6-nosylamido product **6e** in 59% yield as a single regioisomer. A trace amount (<5%) of a product of an allylic chlorination and subsequent hydrolysis at the 6-position was observed.[11] Allylic chlorination with *N*-chlorosuccinimide and catalytic selenium has been described previously.[12] Attempts to achieve allylic amination of substrates such as 1-phenyl-3,4-dihydronaphthalene and 1,4-cyclohexadiene using the diimidoselenium reagent were unsuccessful.

1,3-Dienes react with **1a** by a Diels–Alder reaction and subsequent [2,3]sigmatropic rearrangement to give *cis*-1,2-diaminoalkenes (Scheme 3).[10] The reaction of cyclopentadiene with **1b** affording **7a** (Table 2, entry 1) proceeds in much higher yield than the analogous reaction with **1a**. The reaction of 1,3-cyclohexadiene (Table 2, entry 2) with **1b** was more complex,



Scheme 3.

providing not only the expected diamino product **7b** (29%) but also a series of selenium-containing by-products and/or by-products formed after allylic amination. The diamination

Table 2. Formation of 1,2-diamino-3-alkenes from 1,3-dienes according to Scheme 3[a].

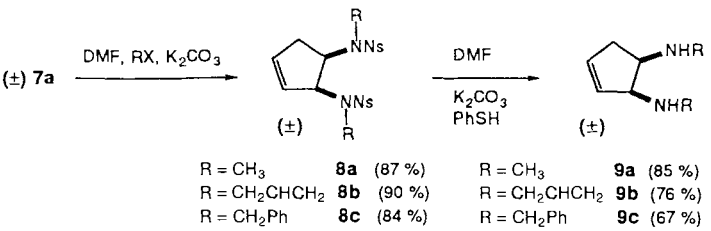
Entry	Diene	Product	Yield [%] [b]
1		 (±)-**7a**	65 (40) [c]
2		 (±)-**7b**	29 (37) [c]
3		 **7c**	46 (68) [c]
4		 **6g**	7 [d]

[a] For reaction conditions see the Experimental Procedure. [b] All yields were determined by isolation of products. [c] Numbers in brackets correspond to yields obtained with the tosyl reagent[10]. [d] Only the product of allylic amination was isolated.

product **7c** (Table 2, entry 3) was isolated in 46% yield along with the product of allylic monoamination **6f** (17%) in the reaction of **1b** with 2,3-dimethyl-1,3-butadiene. With this diene the tosyl reagent provided only the vicinal diamine product.[10] This difference in reactivity can be explained by the higher electrophilicity of **1b**.

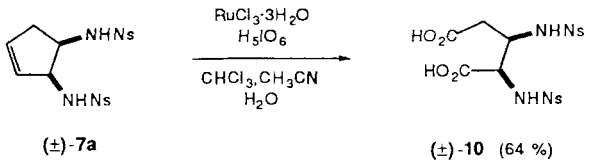
To study the influence of electron-withdrawing groups on the reactivity of **1b**, 1,3-dienes such as methyl 1,3-cyclohexadiene-1-carboxylate, ethyl sorbate, and methyl furoate were examined. However, the allylic amination of methyl 1,3-cyclohexadiene-1-carboxylate with **1b** (Table 2, entry 4) gave the precursor **6g** of (±)-gabaculine[12b, 6b, 13] in very poor yield (7%). The electron-withdrawing substituent apparently renders these 1,3-dienes quite inert under the standard reaction conditions.

To demonstrate the utility of this method, functionalized 1,2-diaminocyclopent-3-enes **9a–c** were synthesized (Scheme 4). The advantage of nitro-substituted benzenesulfonyl residues as protecting groups for amino functions, which were recently introduced by Fukuyama et al.,[7] lies in the ease of deprotection. Dimethyl (**8a**), diallyl (**8b**), and dibenzyl derivatives (**8c**) were prepared in excellent yields by treatment of **7a** with alkyl halides in DMF and in the presence of K_2CO_3. Removal of the nosyl protecting group in **8a–c** proceeded in the presence of thiophenoxide in DMF, via the Meisenheimer complexes, to provide the secondary vicinal diamines **9a–c** in good yields (Scheme 4). Under the same conditions sulfonamide **6e** was also deprotected.



Scheme 4. DMF = dimethylformamide.

A further application of these methods is the preparation of amino acids by the oxidative cleavage of the double bond in the aminated or diaminated products. For example, this was accomplished by oxidation of **7a** with periodic acid and a catalytic amount of $RuCl_3 \cdot 3H_2O$.[14] Dicarboxylic acid **11** was isolated as a white crystalline solid in 64% yield (Scheme 5).



Scheme 5.

In conclusion, we have described a modified and improved procedure for allylic amination of olefins and 1,2-diamination of 1,3-dienes that employs nosyl protecting groups on the intermediate diimidoselenium compound.

Experimental Procedure

Allylic aminations and 1,2-diaminations:

A) General procedure for reactions on scales less than 10 mmol: Dry 2-nitrobenzene-*N*,*N*-dichlorosulfonamide **4** (1.084 g, 4 mmol), sodium 2-nitrobenzenesulfonamide **5**[15] (1.838 g, 8.2 mmol), selenium (0.332 g, 4.2 mmol), and molecular sieves 3Å were placed into a flame-dried flask under nitrogen, and dry dichloromethane (20 mL) was quickly added. The reaction mixture was stirred for 3 h at room temperature. Alkene or diene (8 mmol) was added to the white slurry and the reaction mixture was stirred for another 16–48 h. The reaction mixture was poured into 5% NaOH/ethyl acetate (100 mL/100 mL) and stirred for 20 min. The organic layer was separated, washed with another portion of 5% NaOH (100 mL), and dried over $MgSO_4$. The solvent was removed in vacuo and the brown residue purified by flash column chromatography (silica gel, ethyl acetate/hexane 10–40%).

B) General procedure for reactions on scales over 10 mmol: Dry sodium 2-nitrobenzenesulfonamide **5** (9.19 g, 40 mmol), selenium (1.66 g, 21 mmol) and molecular sieves 3Å were placed into a flame-dried flask under nitrogen, and dry dichloromethane (80 mL) was added. A solution of 2-nitrobenzene-*N*,*N*-dichlorosulfonamide **4** [15] (5.42 g, 20 mmol) in dichloromethane (40 mL) was added dropwise by syringe or cannula. The reaction mixture was stirred for 3 h at room temper-

ature. Alkene or diene (3.3 mL, 2.64 g, 40 mmol) was added to the white slurry and the reaction mixture was stirred for another 16–48 h. The workup was the same as that described above.

6a: 51% yield of the oily product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 0.87 (t, ^3J = 7.3 Hz, 3H), 1.30–1.39 (m, 2H), 1.47–1.56 (m, 2H), 3.93 (quint, ^3J = 7.5 Hz, 1H), 4.86 (dt, ^3J = 10.3 Hz, ^4J = 0.9 Hz, 1H), 4.97 (dt, ^3J = 17.1 Hz, ^4J = 1 Hz, 1H), 5.33 (d, ^3J = 8.6 Hz, 1H), 5.51 (ddd, ^3J = 7, 10.3, 17.2 Hz, 1H), 7.67–7.72 (m, 2H), 7.79–7.83 (m, 1H), 8.04–8.07 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 13.40, 18.39, 37.48, 57.24, 116.06, 125.05, 130.85, 132.62, 133.37, 134.62, 137.13, 146.71. FT-IR (neat): $\tilde{\nu}$ = 3336, 1537, 1411, 1355, 1167 cm^{-1}. HRMS-FAB: calcd for $C_{12}H_{16}N_2O_4SCs^+$: 416.9885; found: 416.9869.

6b: 21% yield of the oily product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 2.29–2.34 (m, 2H), 4.05–4.10 (m, 1H), 4.98 (dt, ^3J = 10.4 Hz, ^4J = 1 Hz, 1H), 5.04 (s, 1H), 5.06 (s, 1H), 5.07–5.11 (m, 1H), 5.41 (d, ^3J = 8.2 Hz, 1H), 5.57–5.68 (m, 2H), 7.69–7.73 (m, 2H), 7.82–7.86 (m, 1H), 8.06–8.11 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 39.86, 56.54, 116.48, 119.32, 125.20, 130.87, 132.32, 132.70, 133.39, 134.81, 136.63, 147.69. FT-IR (neat): $\tilde{\nu}$ = 3338, 1538, 1410, 1346, 1168 cm^{-1}. HRMS-FAB: calcd for $C_{12}H_{14}N_2O_4S + H^+$: 283.0753; found: 283.0792.

6c: 64% yield of the oily product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.30–1.57 (m, 4H), 1.60–1.67 (m, 1H), 1.72–1.83 (m, 1H), 1.87–1.96 (m, 1H), 2.18 (dt, ^3J = 4.8, 14 Hz, 1H), 3.92–3.99 (m, 1H), 4.59 (s, 1H), 4.71 (s, 1H), 5.52 (d, ^3J = 8.6 Hz, 1H), 7.67–7.72 (m, 2H), 7.77–7.80 (m, 1H), 8.03–8.07 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 23.69, 26.97, 33.40, 35.10, 56.99, 107.80, 124.97, 130.47, 132.67, 132.71, 133.39, 134.38, 146.83. FT-IR (neat): $\tilde{\nu}$ = 3343, 2932, 1538, 1444, 1356, 1167 cm^{-1}. HRMS-FAB: calcd for $C_{13}H_{16}N_2O_4SNa^+$: 319.0728; found: 319.0737.

6d: 39% yield of a mixture of diastereomers (2.1:1 ratio by NMR). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.56–1.67 (m, 6H), 4.13–4.17 [3.93–3.98] (m, 2H), 4.83 [4.90] (s, 2H), 5.49 [5.55] (d, ^3J = 8 [8.4] Hz, 2H), 7.69–7.73 (m, 4H), 7.83–7.86 (m, 2H), 7.98–8.02 [8.04–8.08] (m, 2H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 20.19 [24.36], 33.57 [34.89], 55.34 [56.55], 111.39 [106.45], 125.66 [125.17], 131.03 [130.30], 132.94 [132.99], 133.66 [133.55], 133.89 [134.58], 144.25 [146.90], 147.61 [147.50]. FT-IR (neat): $\tilde{\nu}$ = 3330, 2938, 1537, 1421, 1357, 1165 cm^{-1}. HRMS-FAB: calcd for $C_{19}H_{20}N_4O_8S_2Cs^+$: 628.9777; found: 628.9759.

6e: 59% yield of the oily product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.69–1.81 (m, 3H), 2.03–2.23 (m, 3H), 4.43 (br s, 1H), 5.44 (d, ^3J = 5 Hz, 1H), 6.04 (dd, ^3J = 2.8, 4.8 Hz, 1H), 6.87–7.02 (m, 5H), 7.60–7.70 (m, 3H), 8.07 (d, ^3J = 7.6 Hz, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 16.27, 25.40, 30.75, 50.83, 125.73, 126.18, 126.89, 127.88, 130.58, 131.70, 132.81, 133.04, 134.02, 136.13, 139.36, 146.76. FT-IR (neat): $\tilde{\nu}$ = 3358, 2931, 1539, 1403, 1354, 1168 cm^{-1}. HRMS-FAB: calcd for $C_{18}H_{18}N_2O_4SCs^+$: 491.0042; found: 491.0055.

6g: 7% yield of the oily product. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 2.50 (ddd, ^3J = 7.9, 18.2 Hz, ^4J = 2.4 Hz, 1H), 2.75 (dd, ^3J = 5.6, 18.2 Hz, 1H), 4.27–4.34 (m, 1H), 5.50 (d, ^3J = 8.9 Hz, 1H), 6.00 (dd, ^3J = 5.1, 9.4 Hz, 1H), 6.20 (dd, ^3J = 5.5, 9.3 Hz, 1H), 7.05 (dd, ^3J = 5.5 Hz, ^4J = 2.4, 1H), 7.75–7.79 (m, 2H), 7.87–7.90 (m, 1H), 8.18–8.21 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 28.64, 47.44, 51.89, 125.57, 126.26, 130.38, 130.55, 131.79, 133.03, 133.17, 133.68, 135.10, 147.35, 166.53. FT-IR (neat): $\tilde{\nu}$ = 3285, 1706, 1537, 1436, 1354, 1262, 1166 cm^{-1}. HRMS-FAB: calcd for $C_{14}H_{14}N_2O_6SNa^+$: 361.0470; found: 361.0482.

7a: 65% yield, m.p. 158–159 °C (dichloromethane/pentane). ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 2.23–2.31 (m, 1H), 2.46–2.53 (m, 1H), 4.17 (q, ^3J = 6.6 Hz, 1H), 4.45 (d, ^3J = 6.5 Hz, 1H), 5.44–5.48 (m, 1H), 5.68 (br s, 1H, NH), 5.84–5.86 (m, 1H), 5.98 (br s, 1H, NH), 7.70–7.75 (m, 4H), 7.83–7.86 (m, 2H), 8.05–8.10 (m, 2H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 37.43, 54.85, 60.22, 125.58, 128.94, 130.50, 130.67, 132.98, 133.06, 133.73, 133.79, 133.83, 134.14, 147.64, 147.77. FT-IR (KBr): $\tilde{\nu}$ = 3358, 3309, 1535, 1418, 1350, 1160 cm^{-1}. Correct elemental analysis.

7b: 29% yield. ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.67–1.73 (m, 2H), 1.98–2.16 (m, 2H), 3.78–3.85 (m, 1H), 4.07–4.13 (m, 1H), 5.21–5.26 (m, 1H), 5.57 (d, ^3J = 9 Hz, 1H, NH), 5.73 (d, ^3J = 8.8 Hz, 1H, NH), 5.76–5.81 (m, 1H), 7.68–7.77 (m, 4H), 7.82–7.86 (m, 2H), 8.03–8.06 (m, 1H), 8.07–8.10 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 22.26, 25.53, 52.35, 52.48, 124.43, 125.46, 125.52, 130.32, 130.51, 131.87, 132.98, 133.10, 133.69, 133.88, 134.06, 134.43, 147.61, 147.67. FT-IR (neat): $\tilde{\nu}$ = 3339, 1536, 1413, 1351, 1166 cm^{-1}. HRMS-FAB: calcd for $C_{18}H_{18}N_4O_8S_2Cs^+$: 614.9620; found: 614.9640.

7c: 46% yield of the crystalline product; m.p. 114–117 °C; ^{1}H NMR ($CDCl_3$, 400 MHz): δ = 1.43 (s, 3H), 1.52 (s, 3H), 3.33 (dd, ^3J = 7.2, 12.8 Hz, 1H), 3.50 (dd, ^3J = 6, 12.8 Hz, 1H), 4.93 (d, ^4J = 1.2 Hz, 1H), 5.00 (s, 1H), 5.66–5.71 (m, 2H), 7.66–7.76 (m, 4H), 7.79–7.84 (m, 2H), 7.94–7.99 (m, 1H), 8.08–8.12 (m, 1H). ^{13}C NMR ($CDCl_3$, 400 MHz): δ = 18.71, 22.96, 49.91, 62.20, 114.81, 125.16, 125.45, 130.67, 130.83, 132.66, 132.98, 133.59, 133.63, 133.87, 134.94, 143.49, 147.58, 147.80. The Scent of Success?

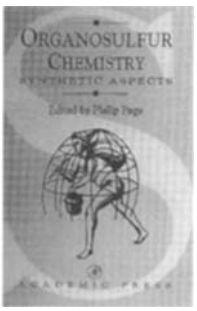
Organosulfur Chemistry. Synthetic Aspects. Edited by *P. Page*. Academic Press, London, 1995. 277 pp., hardcover £ 55.00.—ISBN 0-12-543560-6

In almost every area of organic chemistry, from asymmetric synthesis and catalysis, through heterocyclic and dyestuffs chemistry and the synthesis and modification of natural products, to supramolecular and macromolecular chemistry, we find sulfur in a remarkably wide variety of oxidation states, coordination numbers, and bonding situations. Few other elements compare with the ability of sulfur, either in elemental form or as any of its many simple compounds, to become incorporated into organic substrates when activated thermally, chemically, or photolytically. Organosulfur chemistry is particularly well suited as an aid to fulfilling the objectives of the synthetic chemist. On the one hand sulfur compounds in the form of electrophiles, nucleophiles, or free radicals can facilitate reactions in which sulfur acts in an enabling role, while on the other hand there are many organosulfur compounds that have valuable properties in their own right. In accordance with the important role of sulfur in organic chemistry, there exist a great many monographs, specialist journals, and review articles covering the field. The book reviewed here is concerned primarily with synthetic aspects, while also dealing with some bioorganic and pharmaceutical applications of sulfur compounds. It consists of five chapters in which different classes of sulfur compounds are treated by recognized experts.



In the first chapter the authors review the use of optically active β-ketosulfoxides and analogous compounds in asymmetric synthesis. A concise survey of methods for synthesizing chiral sulfoxides is followed by descriptions of stereoselective reactions using such chiral auxiliaries. The β-ketosulfoxides are easily prepared and can be used to achieve efficient diastereoselective reductions to give β-hydroxysulfoxides, which are useful precursors for synthesizing carbinols, secondary allyl alcohols, epoxides, and lactones. Their use in total syntheses of insect pheromones, macrolides, polyhydroxylated natural products, and other compounds follows logically from this, and is described with the help of some informative reaction schemes. The next section is concerned with Diels–Alder reactions using sulfinyl compounds, which can act both as dienophiles and as dienes. As well as syntheses of enantiomerically pure sulfinyl acrylates and maleimides, several important [4+2]-cycloaddition reactions are described, some of which are catalyzed by Lewis acids. These reactions, in which the stereoselectivity has been shown to be controlled by the S=O group, yield precursors for synthesizing nucleosides and cancerostatic agents. Some representative cycloaddition reactions in which the regiochemistry is of special importance lead to interesting products such as phenols with well-defined substitution patterns, naphthoquinones and anthraquinones, and homochiral sulfinylquinones. The chapter ends with some examples of reactions of dienes that are activated by sulfinyl groups.

Chapter 2 is concerned with homolytic processes at the sulfur center, and deals in detail with reactions initiated by free radicals, which have probably been known for longer than any others. As well as the trivial case of addition to carbon–carbon multiple bonds, the discussion includes an application of these species that is especially attractive from the standpoint of organic synthesis, namely inter- and intramolecular carbon–carbon bond formation resulting from the β-elimination of thiyl and sulfonyl radicals. The importance of this method is reflected in the great variety of syntheses that are described, including transannular bond formation in cyclic polyenes, rearrangements of cyclopentane derivatives, efficient preparations of the synthetically important alkylstannanes, and Barton's *O*-acylthiohydroxamate method for attachment of side-chains to steroids. Due attention is also given to an application of thiyl radicals which has been known for more than twenty years but has only recently begun to be thoroughly investigated, namely the initiation of the cyclopropylmethyl-3-butenyl rearrangement. Following nature's example of glutathione, it has been shown that thiols can also serve as an efficient source of hydrogen atoms for quenching alkyl radicals. Another application of this reaction is in the reductive substitution of halogen atoms or OH groups, a method which is justifiably treated at some length. The next section deals with extrusion methods, emphasizing the value of sulfur-containing functional groups for mediating such reactions. As well as the cyclophane syntheses that are now well established methods, the discussion also includes modern applications such as Nicolaou's method for oxapolycyclenes. The final part of the chapter makes the point that carbon free radicals too can undergo selective reactions with organosulfur compounds. These include interesting intramolecular thiolactonization reactions and further developments based on the Barton–McCombie reaction.

Chapter 3 contains a survey of synthetic transformations involving thiiranium ions as intermediates. These cationic heterocycles with a three-membered ring, which can also be regarded as carbenium ions stabilized by β-thio groups, can undergo S_N1 or S_N2 ring-opening reactions depending on their substituents. The author gives a very good account of synthetic applications, describing how thiiranium ions formed in situ can react with a variety of nucleophiles. The methods for introducing oxy-, aza-, or carboxysulfenyl groups based on this principle are de-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

scribed with instructive examples; in many cases there is the additional bonus of a high degree of regio- and stereoselectivity. Some useful guidelines for predicting reactivities and cyclization routes, for example in the intramolecular etherification of unsaturated alcohols, are also included here.

Chapter 4, the longest in the book, is concerned with developments in the chemistry of 1,3-dithioacetals. This class of compounds is closely associated with "Umpolung" processes, but these are deliberately avoided in this chapter, as they are already very adequately covered elsewhere. At the beginning of the chapter is a very useful table listing review articles on 1,3-dithioacetals. Applications of these compounds in pharmacology and plant protection are then described. These include various interesting examples that act as mimetics of cyclohexane rings or as "super-*t*-butyl groups", and have applications as calcium channel blockers, leucotriene antagonists, or highly efficient insecticides. The sections on the synthesis of these compounds and their properties as functional groups are especially important from the synthetic chemist's standpoint. Various methods of synthesis are presented in the form of tables, including such details as advice on differentiating between aldehydes and ketones; analogous procedures have been used for regenerating carbonyl functions. The chapter ends with a brief section on applications in asymmetric synthesis, transformations yielding dithiins or geminally-substituted difluoro compounds, and reductions giving methylene groups.

The final chapter is devoted to thioaldehydes, and provides evidence that these are by no means birds of paradise (although thioformaldehyde has been found to occur in interstellar space!), but are useful intermediates for syntheses. Some interesting physicochemical properties of these compounds are also described. Their synthesis, properties, and reactions are treated, classifying them into transient species and stable compounds. In accordance with the chemical nature of these species, the main emphasis is on cycloadditions and their retro-variants and on sigmatropic processes. Their crystal structures and spectroscopic properties are also discussed.

Despite a few errors, especially in the reaction schemes, and some poorly drawn structural formulas, the book contains a valuable review of selected topics in organosulfur chemistry. It can be especially recommended for reading by synthetic chemists and as a source of ideas.

Introduction to Biocatalysis Using Enzymes and Micro-Organisms. By *S. M. Roberts, N. J. Turner, A. J. Willetts*, and *M. K. Turner*. Cambridge University Press, Cambridge, 1995. 195 pp., hardcover £ 11.95.—ISBN 0-521-43070-4

Twenty or thirty years ago the study of biotransformations of organic substrates was still more a matter of academic interest than of practical significance, but in recent years this field has increased greatly in importance, with regard to applications and future potential. This growing recognition has been accompanied by the appearance of a huge wealth of review articles and books. The authors of this book, who are recognized experts in the field of biotransformations of organic molecules, define their aim as being "to give the non-specialist a comprehensive insight into the science of biotransformations".

The book begins with a historical introduction of about 30 pages, starting from the beginnings of modern biochemistry in the early 19th century, exemplified by the development of the technologies of brewing and fermentation processes. The scientific developments described range from the contributions of Kirchhoff and Pasteur to the work of Reichstein, and the chapter makes interesting and enjoyable reading. Chapter 2 (40 pp.) begins by describing the use of enzymes and discussing the advantages and drawbacks of this method compared with the use of whole cells. Problems of immobilizing enzymes are discussed, as well as optimization strategies. The chapter contains a wealth of useful practical advice, but stops short of being a laboratory handbook. Appendix A, which describes the breeding and cultivation of microorganisms, seems rather out of place here, and the information about sterile procedures seems somewhat trivial.

Chapter 3 (about 20 pp.) is concerned with hydrolysis, which the authors illustrate by describing examples from their own synthetic work. These examples (including syntheses of the nucleoside analogs neplanocin, carbovir, aristeromycin, and others) are certainly highly topical, but does that necessarily make them good examples for teaching purposes? The chapter ends with an explanation of the "*E*-value" introduced by C. Sih. Unfortunately, however, the bibliography does not include a reference to the original publication. Also it would have greatly helped the non-specialist readers, for whom the book is intended, if the authors had included diagrams showing the relationship between (enantiomeric excess)/(conversion rate) and enantiomer ratio.

The descriptions of the basic reactions are completed by Chapter 4 (20 pp.) on redox reactions, with many examples from the authors' own research, and Chapter 5 (also 20 pp.) on methods for forming carbon–carbon, carbon–nitrogen, carbon–oxygen, and carbon–sulfur bonds. Chapter 6 (40 pp.) describes processes for the manufacture of various important fine chemicals, including antibiotics, amino-acids, nucleic acids, peptides, and oligosaccharides, and summarizes the basic principles of genetic engineering. A separate section is devoted to "novel reaction conditions"; however, the curiosity awakened by this misleading title is soon dispelled, as one finds here only some further reactions in non-aqueous media. Hardly any applications in inorganic or organometallic chemistry are mentioned.

Much of the book is intended specifically for newcomers to the field, with the aim of encouraging them to incorporate biotransformations into the planning of their synthetic work. Nevertheless, even specialists will find here and there some useful bits of information, though unfortunately without references to the original publications. Each chapter has an appendix giving references, but only to review articles and books, and even these lists are incomplete. Both the bibliographies and the text contain annoying mistakes, which could easily have been avoided by a little more care on the part of the authors and final checking by the publishers. Already it has come to be regarded as something of an achievement to avoid incorrect spellings of names such as Liebig, which are hardly unfamiliar. The book is a useful addition to the many excellent publications covering the field of biocatalysis. It makes no claim to be comprehensive. Reading it will not make one an expert on the subject, but that was not the authors' intention. With a little more love and care it could have been a very good book; however, despite the fact that it has some shortcomings, I enjoyed reading it.

The Schenck Ene Reaction: Diastereoselective Oxyfunctionalization with Singlet Oxygen in Synthetic Applications**

Michael Prein and Waldemar Adam*

Dedicated to Professor Georg O. Schenck on the occasion of his 80th birthday

Oxyfunctionalized molecules are principal building blocks in organic synthesis. In cellular processes highly efficient enzymes serve as selective catalysts for the formation of such synthetic units, for example the oxygenases oxyfunctionalize substrates by activating molecular oxygen. To date no comparable effective chemical oxidation system has been found. A useful photochemical process is the oxyfunctionalization of allylic substrates by sensitized photooxygenation, for which molecular oxygen and light serve as natural sources. This allylic oxidation of olefins by the ene reaction with singlet oxygen (Schenck reaction) figures as a highly versatile synthetic method. While the regioselectivity of this transformation has been studied for decades, only during the last years has attention focused on stereocontrol. Through these recent efforts it has become possible to control high stereoselectivity in the photooxygenation of organic substrates. This breakthrough has enhanced substantially the utility of singlet oxygen in diastereoselective synthesis.

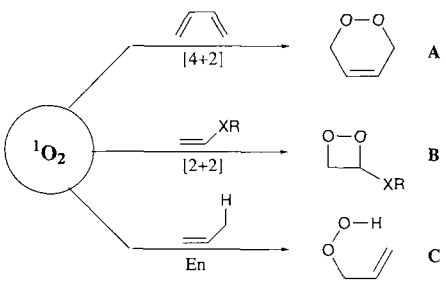
1. Sensitized Photooxygenation

1.1. General Aspects

The reaction of organic substrates with molecular oxygen, the most abundant and accessible oxidant, has always been an attractive method for the preparation of oxyfunctionalized target molecules. Since molecular oxygen exists in a triplet ground state ($^3O_2$), the spin conservation rule restricts its transformations to radical-type reactions, which are normally quite unselective.[1] In contrast, in its singlet excited state, O_2 ($^1\Delta_g$) circumvents the problem of spin-forbidden reactions and, consequently, selective novel cycloadditions become possible, which complement in a useful way the activation of dioxygen by metal complexes.[2] Besides the chemical generation of singlet oxygen,[3-5] photosensitization of triplet molecular oxygen by visible light is by far the most common and convenient method for in situ generation of this highly reactive, yet selective oxidant.

In the past there has been considerable dispute about the nature of the species involved in sensitized photooxygenation.[6] This, unfortunately, has at times distracted attention from the synthetic utility of reactions with singlet oxygen, although the experimental setup for photooxygenation is quite straightforward and the workup and product isolation often entails merely evaporation of the solvent. Selective oxidations combined with the practical simplicity render sensitized photooxygenation a most attractive method for the synthetic chemist.

During the last two decades three monographs[7-9] and several review articles[10-14] have appeared on reactions of singlet oxygen in synthesis. The majority of the $^1O_2$ reactions with olefins can be divided into three major groups according to their pathways (Scheme 1): 1) conjugated dienes react preferably



Scheme 1. Reactions of singlet oxygen.

by [4+2] cycloaddition to form endoperoxides (pathway A),[15-17] 2) electron-rich olefins give preferably 1,2-dioxetanes by the [2+2] cycloaddition (pathway B),[9,16,18] and 3) unactivated olefins with allylic hydrogen atoms undergo ene-type reaction to form allylic hydroperoxides (pathway C).[10,19] This review will focus on the stereoselectivity of the latter reaction type, for synthetic applications the most important reaction with singlet oxygen, and provide an updated mechanistic rationalization of the observed experimental results.

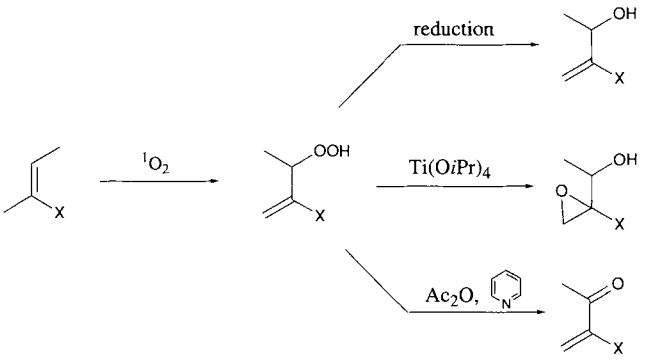
1.2. The Schenck Reaction

1.2.1. General Aspects

The ene reaction with singlet oxygen was discovered in 1943 by Schenck,[20] many years after the classical [4+2] cycloaddition,[21] but before the [2+2] cycloaddition, which affords 1,2-dioxetanes.[22] Schenck called this type of hydroperoxidation reaction the "indirect substitutive addition in the allylic position";[23] later it was termed the "Schenck reaction" by Schönberg,[24] although this recognition of its discoverer has not received widespread support.

The allylic hydroperoxides that result from the Schenck reaction have proven to be synthetically useful intermediates (Scheme 2).[9,12,13,25] While reduction leads to allylic alcohols,



Scheme 2. Synthetic applications of allylic hydroperoxides.

the reaction with Ti^{IV} complexes has been utilized to prepare epoxy alcohols from simple olefins in a one-pot operation.[26,27] Finally, dehydration[28] provides convenient access to synthetically useful enones with silicon ($X = SiR_3$)[29] or tin substituents ($X = SnR_3$)[30] at the α-C atom.

1.2.2. Mechanism

Over the years a diversity of mechanisms has been proposed to account for the complex structure–reactivity relationships of the Schenck reaction (Fig. 1). Depending on the rigor of the

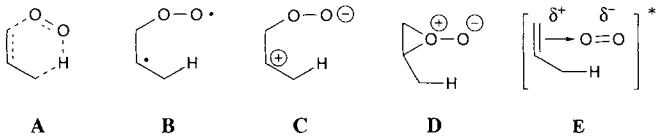


Fig. 1. Possible transition states and intermediates for the Schenck reaction.

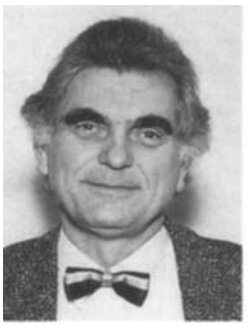
theoretical work, arguments in favor of the concerted pathway via the transition state **A**[31] and stepwise mechanisms via the biradical intermediate **B**[32] or the perepoxide-like intermediate **D**[33] have been proposed. This reflects a general problem in scrutinizing reactions of electronically excited molecules such as singlet oxygen by theoretical methods[34] and obliges the mechanistic chemist to rely mainly on experimental data. Although much research has been dedicated to this mechanistic enigma,[7–9,35–42] discussions in this review will be limited to points relevant to understanding the stereoselectivity of the Schenck reaction.

Kinetic data[36,37] clearly favor a stepwise mechanism, while the recognized suprafacial nature[36,39] and the lack of Markovnikov orientation[38] rule out the intermediacy of longer-lived diradical (Fig. 1, **B**) or zwitterionic (Fig. 1, **C**) intermediates. Most experimental data accumulated so far suggest that a bona fide perepoxide **D** or a exciplex **E** of similar geometry occur along the reaction coordinate.[35,36,40,41] The perepoxide intermediate was proposed as early as 1960 by Sharp.[43] The exciplex constitutes an excited state charge transfer complex between singlet oxygen and the substrate, for which on the basis of experimental kinetic data reversible formation has been argued.[41,42]

Waldemar Adam was born in the Ukraine in 1937. He studied chemistry at the University of Illinois in Chicago and the Massachusetts Institute of Technology. In 1961 he received his Ph. D. degree with the thesis "The Diacyl Peroxide–Olefin Reaction" under the direction of Prof. F. D. Greene. In 1962 he carried out postdoctoral research with Prof. R. Criegee at the University of Karlsruhe. In 1961 he was appointed Assistant Professor at the University of Puerto Rico, where he was promoted to Associate Professor in 1965 and Professor in 1970. Since 1980 he has held the Chair of Organic Chemistry at the University of Würzburg. His main research interest is physical organic chemistry with emphasis on high-energy molecules (dioxetanes and dioxiranes), chemi- and bioluminescence, the photobiological oxidation of DNA, laser chemistry, high-spin systems (di- and polyradicals), the application of peroxides and singlet oxygen in organic synthesis, and enzyme- and metal-catalyzed oxyfunctionalization.



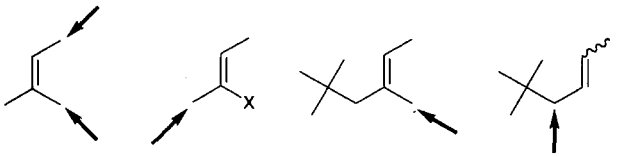
W. Adam

M. Prein

Michael Prein, born in Bad Kissingen (Germany) in 1967, studied chemistry at the University of Würzburg. He received his "Diplom" in 1992 and his doctor's degree in March 1995 with the dissertation "Diastereoselectivity of the [4+2] Cycloaddition of Singlet Oxygen" under the direction of Prof. Adam. At present he is with Prof. Padwa at Emory University, Atlanta, GA (USA), as a NATO postdoctoral fellow. His research interests are cycloadditions and stereochemistry.

1.2.3. Regioselectivity

Since singlet oxygen is a highly reactive oxidant that undergoes reactions with a wide variety of substrates, selectivity in its transformations is mandatory for synthetic utility. A central problem of the Schenck reaction is that of regioselectivity. When a given substrate has several allylic hydrogen atoms, abstraction can take place at all possible sites to lead to complex mixtures of isomeric products. This problem has been studied intensively over the years and several empirical rules have been proposed to allow the a priori determination of the regioselectivity of reactions with a variety of substrates. For example, the "*cis* effect" describes the finding that H abstraction takes place preferably at the more highly substituted side of the double bond (Fig. 2a).[44] The "*gem* effect" applies to *gem*-substituted



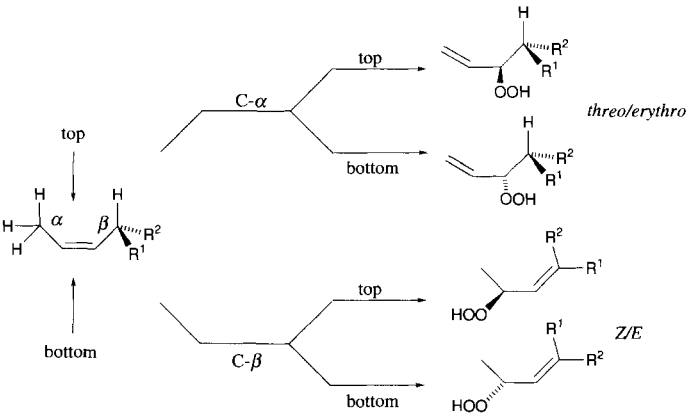
a) *cis* effect b) *gem* effect c) "large group nonbonding effect"

Fig. 2. Regioselectivity of the Schenck reaction.

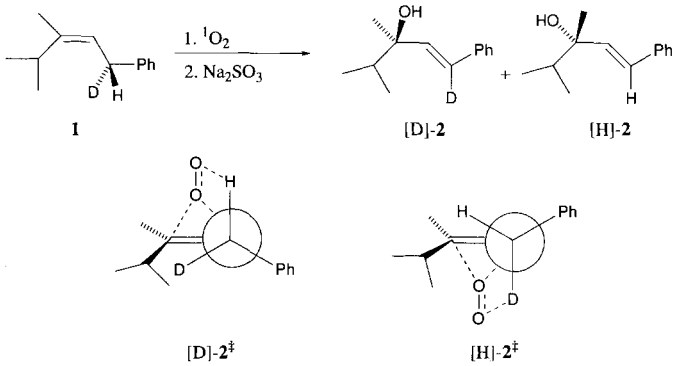
olefins (X = C(O)R, SO_xR, CN, SiR_3, SnR_3, Ph), for which abstraction at the geminal position predominates (Fig. 2b).[45–48] The "*large group nonbonding effect*",[49] the least general of the regioselectivity rules, describes the preferred site of abstraction for highly substituted olefins (Fig. 2c). Nevertheless, while some progress has been made recently in controlling the regioselectivity of the Schenck reaction, it is important to emphasize that the complexities of the regioselectivity also influence the stereoselectivity of this reaction.

1.2.4. Stereoselectivity

Owing to the inherent lack of stereochemical features in the linear diatomic singlet oxygen molecule, stereoselectivity in the Schenck reaction is directed by the substrate; reactions of this type have been reviewed recently in detail.[50] The presence of two diastereotopic faces in a given chiral substrate allows for two diastereomeric transition states of different energies in the attack of singlet oxygen. In the product-forming step, hydrogen abstraction takes place either at the neighboring alkyl group or directly at the stereogenic center. In the latter case the stereochemistry of the resulting double bond reflects the π-facial selectivity of the initial singlet oxygen attack, provided suprafacial attack applies (Scheme 3). The latter requirement has been examined by Stephenson et al. with the cleverly designed substrate **1**.[39] In the photooxygenation of the optically active olefin **1** the observed products [H]-**2** and [D]-**2** (Scheme 4) differ in the absolute configuration at the newly formed stereogenic center. These stereochemical results clearly demonstrate the suprafacial attack of singlet oxygen, as exhibited in the transition states [D]-$\mathbf{2}^+$ and [H]-$\mathbf{2}^+$. The present case also exhibits another stereochemical feature of the Schenck reaction, namely that for hydrogen abstraction at a prochiral center (Scheme 3, $R^1 = H$) the *E* isomer of the two possible products generally prevails for



Scheme 3. Stereochemical possibilities for chiral substrates in the Schenck reaction.



Scheme 4. Suprafacial attack of singlet oxygen in the Schenck reaction.

steric reasons. In the present review we will concentrate on ene reactions with singlet oxygen in which the original stereogenic center is maintained throughout the reaction; in other words, hydrogen abstraction takes place at a neighboring alkyl group with formation of an additional stereogenic center and shift of the double bond (Scheme 3). This pathway predominates in most Schenck reactions. Since the highly functionalized products of this transformation are very useful in synthesis, it is most desirable to find novel methods for their highly diastereoselective preparation.

The factors governing π-facial selectivity can be divided into four distinct types (Fig. 3), which we shall discuss and illustrate in detail. In the case of steric control (Fig. 3a), nonbonding repulsion between substrate and reagent makes one π face of the double bond more accessible to the attacking singlet oxygen than the other. This type of interaction is present in all types of substrates and should show little or no solvent dependence. This stereocontrol is expected to be most important for rigid systems

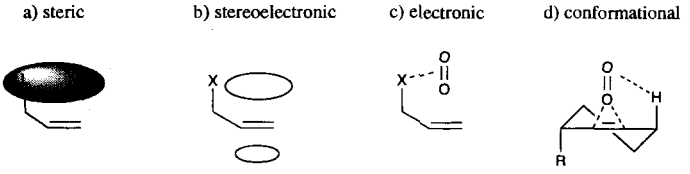


Fig. 3. Factors that determine diastereoselectivity in the Schenck reaction. a) Nonbonding interactions: repulsion, b) electron density: attraction or repulsion; c) direct interaction with substituents: attraction or repulsion; d) availability of abstractable hydrogen atoms.

(cyclic and polycyclic substrates), which cannot adjust their conformations to minimize steric interactions.

Such repulsive interactions between the reaction partners can be modulated by stereoelectronic and electronic factors. Although in this context the distinction between these two factors is not clearcut, we use the term "stereoelectronic control" (Fig. 3b) to describe those cases in which one face of the substrate displays a higher π electron density due to special features of the overall geometry of the substrate molecule, for instance orbital distortion. In contrast, the term "electronic control" (Fig. 3c) describes specific interactions between a substituent of the substrate and the incoming singlet oxygen enophile. This includes attractive hydrogen bonding interactions and electrostatic attractions and repulsions. Thus, ene reactions with singlet oxygen, which are controlled primarily by electronic factors, are expected to be highly sensitive to solvent polarity.[50]

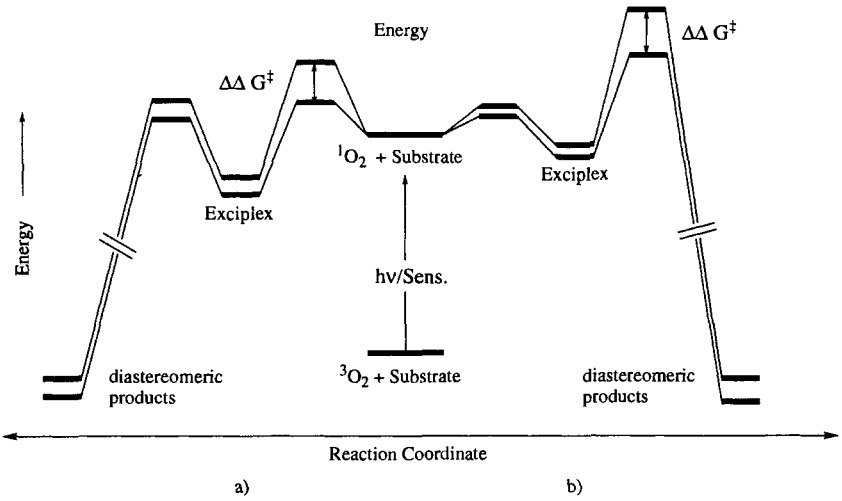

Fig. 4. Energy profiles for the Schenck reaction of chiral substrates. a) Formation of the exciplex determines the diastereoselectivity; b) formation of the exciplex is reversible; the subsequent step leading to the perepoxide or directly to the product determines the diastereoselectivity.

While the three stereocontrolling factors presented so far apply to a wide variety of substrate-directed reactions, the special features of the Schenck reaction make it necessary to include an additional mechanistic criterion, namely conformational features (Fig. 3d). Since the product-forming step involves abstraction of an allylic hydrogen atom, which must not only be present in the substrate molecule but also aligned correctly, conformational control may play a dominant role (Fig. 3d). This is expected to be important especially in cyclic systems, in which allylic hydrogen atoms may be accessible only on one π face of the substrate, and, therefore, express a pronounced influence on the observed stereoselectivity. Since the most suitable geometry for effective hydrogen atom abstraction requires a perpendicular arrangement of the C–H bond with respect to the plane passing through the four atoms attached to the double bond (the plane of the double bond), subtle conformational features may be decisive factors. These stereocontrolling factors alone make understanding the experimental stereoselectivities of the Schenck reaction quite complex. Further complexity, however, derives from the fact that along the reaction coordinate a reversible step has been postulated, which on the basis of kinetic data has been ascribed to exciplex formation between singlet oxygen (electronically excited) and the olefinic substrate.[42]

The postulated energy profile of the Schenck reaction incorporating reversible exciplex formation is featured in Figure 4. Exciplex formation proceeds with a nearly zero activation enthalpy and is thus controlled by the entropy of activation. Therefore, the stereoselectivity of the ene reaction appears to be determined by the difference in activation energies for the subsequent transformation of the reversible, diastereomeric exciplexes (Fig. 4, right). For some substrates this step may proceed directly to the products or proceed via perepoxide intermediates.[35] For the mechanistic rationalization of π-facial selectivity, this distinction is not particulary relevant since perepoxide formation is quite late along the reaction coordinate. Furthermore, even if formation of the perepoxide were reversible, similar geometrical and electronic features for the exciplexes and the corresponding perepoxide intermediates would be expected, which would lead to the same sense of stereoselectivity.

Since the formation of the exciplex is fast and reversible, the situation displayed on the left side of Figure 4 is much less likely, namely the π-facial selectivity in the initial encounter of singlet oxygen and the olefinic substrate to form diastereomeric exciplexes will in most cases not directly determine the final diastereomeric ratio. Nevertheless, one should bear in mind that also the subsequent step from the exciplex to the products, or even through possible perepoxide intermediates, may be quite fast. Consequently, when exciplex formation is not completely reversible, it may also influence π-facial selectivity.[51]

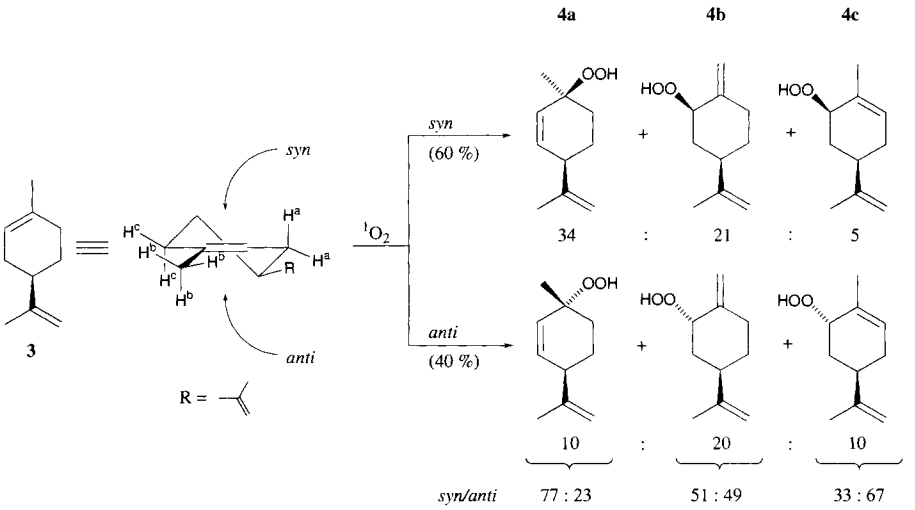
We will analyze the observed diastereoselectivities of the Schenck reaction in terms of the electronic and geometric characteristics (Fig. 3) of the exciplex. However, for ene reactions with high overall reaction rates, ground state properties of the substrate will also have to be taken into consideration, if subtle features are to be understood mechanistically. Since the exciplex and the corresponding perepoxide have apparent structural similarities, rationalizing the selectivity-determining factors may be facilitated by considering the characteristics of the perepoxide.

2. Diastereoselectivity in the Schenck Reaction: Case Studies

The consideration of the general factors that may influence the diastereoselectivity in the Schenck reaction (Section 1) showed that a rather complex situation can be expected when one tries to find a common rationalization of the experimental results for diverse substrates. Fortunately, at least in most cases, the experimental conditions (solvent, sensitizer, light source) have little or no effect on the diastereoselectivities. Moreover, the photooxygenations have been conducted under a variety of experimental conditions; in the older literature, in particular, exact reaction conditions (light source, reaction time) are rarely described. Therefore, in this review we will generally not give

exact reaction conditions for the particular photooxygenations but will refer to the reactant as $^1O_2$, whereby it is understood that the $^1\Delta_g$ electronic state is involved. However, for reactions in which the diastereoselectivity depends strongly on the reaction conditions (especially solvent effects), these will be given and discussed explicitly.

It should be also noted that some of the diastereomeric ratios reported in the literature were determined either after purification of the initial crude product mixture by column chromatography or after reduction of the labile hydroperoxides to the corresponding alcohols, a reaction that generally occurs in nearly quantitative yields and with complete retention of configuration. Therefore, the values reported here may not in all cases reflect the exact diastereoselectivity for the initial attack of singlet oxygen; however, the deviations are expected to be generally quite small.



Scheme 5. Schenck reaction of (+)-limonene (**3**).

As mentioned in Section 1.2.4, the ene reaction with singlet oxygen is a substrate-controlled reaction and, therefore, any attempted classification should concentrate on common features of the olefin substrates employed. Whereas the photooxygenation of chiral mono- and polycyclic olefins has been studied ever since the very discovery of the Schenck reaction in 1943, recent results from our group have shown convincingly that high stereocontrol can be achieved in open-chain systems as well. Stereocontrol in reactions of cyclic and polycyclic substrates and that in transformations of acyclic substrates appear to stem from quite different structural features. Whereas through the inherent rigidity of cyclic and polycyclic substrates steric and stereoelectronic effects will principally determine π-facial selectivity, for open-chain olefins electronic interactions take the dominant role in controlling diastereoselectivity. In view of this marked difference between cyclic and acyclic systems, the classification of the olefinic substrates according to this structural feature is convenient on mechanistic grounds.

2.1. Cyclic Olefins

2.1.1. Monocyclic Hydrocarbons

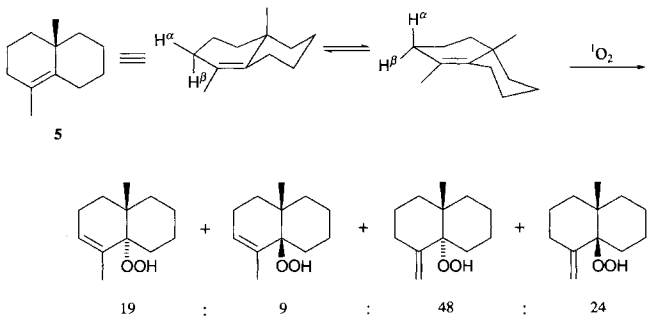
This class of substrates, for which the monoterpenes are good prototypes, was studied by Schenck et al. as far back as 1943. The lack of heteroatom substituents restricts the factors that may influence the diastereoselectivity to steric and conformational effects. One prominent representative is (+)-limonene (**3**), which gives on photooxygenation a mixture of regio- and diastereomeric hydroperoxides **4** in very characteristic ratios (Scheme 5).[52] Historically pertinent, this olefin was used to prove the involvement of singlet oxygen in oxygenation reactions and to rule out radical pathways.[53]

On inspection of the data in Scheme 5, it is evident that there is little overall *syn*/*anti* selectivity (60:40). This is expected since there seems to be no special steric preference for attack from either side of the double bond in the substrate. Nevertheless, if one looks at the regioisomeric hydroperoxides **4a–c** in detail, remarkable differences in the diastereoselectivity become apparent. The observed diastereoselectivity can be explained by the previously discussed preference for abstraction of hydrogen atoms perpendicular to the plane of the double bond (Fig. 3d). Therefore, with the assumption of the preferred ground state conformation displayed in Scheme 5, abstraction of atom H^a should occur preferentially from the *syn* face. Indeed, for the corresponding hydroperoxides **4a** a notable 77:23 *syn*/*anti* preference was found. For abstration of H^c, the opposite applies (67:33 *anti*/*syn* preference for **4c**), while for abstraction at the methyl group, which is conformationally not fixed, abstraction from either face is equally likely. Once the preferences for *syn* and *anti* attack are estimated, the regioselectivity of the abstraction can be examined. An alternative interpretation of the limonene results is to consider the reversible formation of an exciplex intermediate. Stereocontrolled attack of singlet oxygen would be expected to occur from that π face which bears the *better* set of abstractable allylic hydrogen atoms. That this may indeed have a remarkable influence on π-facial selectivity will become evident in Section 2.1.2.

There are numerous other examples for the photooxygenation of monoterpenes without heteroatom substituents,[8–11,54,55] but the general trend shows that low overall *syn*/*anti* selectivities are obtained for substrates in which the double bond is in a six-membered ring. Furthermore, the ground state conformation, specifically the availability of abstractable allylic hydrogen atoms, has a remarkable effect on the diastereoselectivity in many cases.

2.1.2. Bi- and Polycyclic Hydrocarbons

As we have seen, the Schenck reaction of monocyclic olefins shows complex stereoselectivity with little if any overall *syn*/*anti* preference. The photooxygenation of the bicyclic octalene **5** (Scheme 6) shows similar stereoselectivity.[56] Here, too, slight changes in the substitution pattern alter the distribution of both regio- and stereoisomeric products, but the deciding factors are interconnected so subtly that the selectivities are difficult to rationalize mechanistically. The 4a-methyl group seems to block



Scheme 6. Schenck reaction of 1,10-dimethyl-1(9)-octalene (**5**).

the β face to some extent, and a slight overall preference (67:33) for the less shielded α face is found. The diastereoselectivity in the photooxygenation of steroids is also governed mainly by steric shielding through angular methyl substituents.[57–59] Furthermore, the rigid conformation of these substrates plays an important role with regard to π-facial selectivity, since hydrogen atoms perpendicular to the plane of the double bond may be accessible from only one π face.

Similar selectivity control is expected for [2.2.1], [3.1.1], and [4.1.0] bicyclic substrates, a class of compounds for which the monoterpenes in the rosette of Scheme 7 are representative and instructive. As expected for these rigid, bicyclic substrates, steric bias induces high π-facial selectivities. The experimental results can in all cases be explained straightforwardly: the favored attack takes place on the sterically less congested π face. While 2-methylnorbornene (**6**)[60] reacts with high *exo* selectivity, as known for other types of electrophilic[65] and nucleophilic[66] additions to norbornene derivatives, two methyl groups at the methylene bridge alter the stereochemical outcome.[67] Thus, quite generally, a dimethylmethylene bridge, as in α-pinene (**8**), Δ^4-carene (**9**), Δ^3-carene (**10**), and *cis*-Δ^2-carene (**11**), is distinctly *anti*-directing, and thus, the hydroperoxides that result from *syn* attack are formed only in traces. In this context it is interesting that *trans*-Δ^2-carene (**12**) is inert to photooxygenation.[62] The reason is that the *syn* face is blocked sterically towards attack of singlet oxygen and the accessible *anti* face bears no abstractable hydrogen atoms. Therefore, physical quenching prevails, and the initially formed *anti* exciplex reverts to the starting material without net reaction. The reaction of α-thujene (**13**) illustrates that the methylene bridge results in complete *anti* selectivity in a [3.1.0] bicyclic substrate.

Paquette and co-workers[68] examined the photooxygenation of a series of cyclopropanated cyclohexenes **14** (Scheme 8). In contrast to the reaction of **13**, for these [4.1.0] bicyclic systems attack occurs diastereoselectively either *syn* or *anti* to the methylene bridge and depends on the overall substitution pattern. Conformational features are important for these particular substrates. Clearly, subtle changes in the substitution pattern of olefin **14** are enough to effect amazingly high levels of either *syn* or *anti* diastereoselectivity.

14d	$-(CH_2)_3-$	H	100	:	0

Scheme 8. Photooxygenation of cyclopropanated cyclohexenes **14**.

The numerous other examples of the Schenck reaction with bi- and polycyclic hydrocarbons,[7–10] mostly natural products, display diastereoselectivities similar to those presented above. Most of these can be explained by simple steric arguments. An increase in the rigidity of the olefinic substrate, for example on going from mono- to bi- and polycyclic systems, leads to a remarkable selectivity enhancement. Conformational adjustment either to minimize steric hindrance with the attacking singlet oxygen or to bring a hydrogen atom into the proper position for abstraction by singlet oxygen on either diastereotopic π face is not usually possible for rigid substrates.

2.1.3. Cyclic Olefins with Heteroatom Substituents

This section will feature cyclic substrates that bear an additional functional group. While for simple hydrocarbons (Sections 2.1.1 and 2.1.2) π-facial selectivity is determined mainly by steric and conformational effects, substitution of the carbon framework with one or more heteroatom-containing functional groups requires that stereoelectronic and electronic features also come into play. Therefore, the rationalization of experimental diastereoselectivities for this type of substrate is less straightforward than for those examined in the previous sections. Nevertheless, the rigidity of cyclic systems will circumvent the difficulties that may complicate simple explanations in the conformationally flexible open-chain derivatives.

One relatively simple, but highly interesting substrate is the substituted 7-isopropylidenenorbornene **15b** (Scheme 9).[69] In this compound the substituents are located too far from the

	R	Yield [%]	*syn*		*anti*

15b	COOMe	90	46	:	54

Scheme 9. Photooxygenation of 7-isopropylidenenorbornenes **15**.

reacting double bond to have any steering influence by direct attraction or repulsion of the incoming singlet oxygen enophile. Nevertheless, substitution by the electron-withdrawing ester groups reduces the diastereoselectivity from 83:17 for the parent system **15a** to 54:46 for derivative **15b**. A very similar situation is encountered in the photooxygenation of substituted 7-isopropylidenebenzonorbornenes **16** (Scheme 10).[69–71] Here, too, reaction of the parent system **16b** shows moderate *anti* selectivity (76:24). Substitution of the benzene ring with electron-donating substituents as in derivative **16a** leads to a slight increase of *anti* preference, whereas electron-withdrawing substituents such as F (**16c**) or Cl (**16d**) even invert the overall selectivity so that now *syn* attack is preferred. In these reactions singlet oxygen shows the same stereochemical behavior as other uncharged electrophiles, for example *m*-chloroperbenzoic acid (*m*CPBA), *N*-methyl-1,2,4-triazolinedione, and *N*-bromosuccinimide (NBS),[70] whereas strong and highly electron-deficient electrophiles such as CH_3CO^+, CCl_2, and *tert*-butyl hypochlorite/H^+ give preferably *syn* attack.

16d	Cl	Cl	59	:	41

Scheme 10. Photooxygenation of 7-isopropylidenebenzonorbornenes **16**.

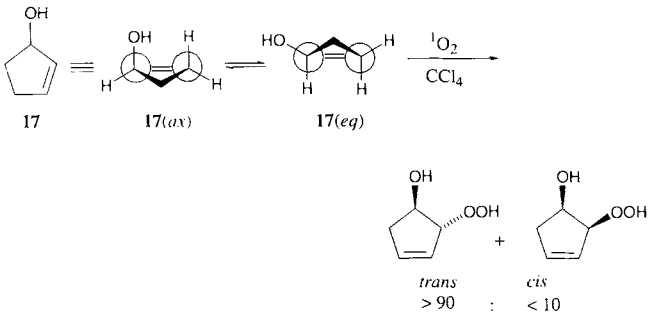
The attempts to rationalize these results evoked considerable dispute over the years. Okada and Mukai[69] favored orbital distortion at the reacting double bond through σ–π mixing due to the perturbation caused by the C2–C3 double bond. Paquette, Gleiter, et al.[71] stressed the importance of π bond assistance in the transition state through homoconjugative charge delocalization on the side opposite to the incoming electrophile. This is expected to be important for weak, uncharged electrophiles.

This matter was recently reexamined by Houk et al.,[72] who on the basis of RFG/6-31G* calculations concluded that the attack is determined mainly by electrostatic interactions. The overall electron density in substrates **15a** and **16b** is higher on the less reactive *syn* face of the reacting double bond; attack on this face is also slightly preferred for steric reasons. For uncharged electrophiles with lone pair electrons and high electron densities such as singlet oxygen, which are defined by Hehre et al.[73] as "transvestial enophiles", attack from the *syn* face is disfavored due to repulsion of these "negative" enophiles by the high electron density of the double bond. Another way to rationalize this effect is to propose that in the exciplex the attacking singlet oxygen enophile bears a partial negative charge which is unfavorable for attack at the more electron-rich *syn* face.

It is evident from the substrates **15** and **16** that for these rigid systems the lack of conformational flexibility leads to permanently disturbed electron densities on the diastereotopic faces of the reacting double bond and, consequently, to diastereoselec-

tive attack of singlet oxygen. Such stereoelectronic effects must be also considered in cyclic systems that bear a heteroatom substituent in a suitable position for interacting with the incoming singlet oxygen enophile.

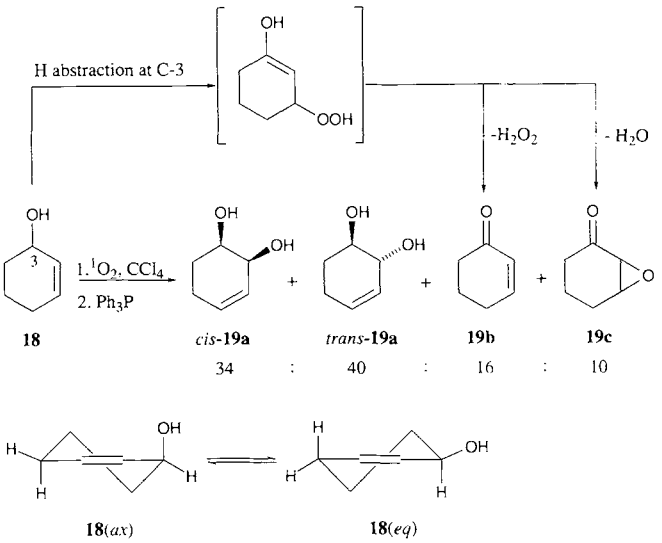
Unfortunately, the photooxygenation of only a few examples of this informative class of olefinic substrates has been reported. The simplest cases, namely 2-cyclopentenol (**17**) and 2-cyclohexenol (**18**), were recently examined in our group.[74] In the reaction of **17** high *trans* selectivity (>90:10) was observed (Scheme 11). This is in complete contrast to the epoxidation of



Scheme 11. Photooxygenation of 2-cyclopentenol (**17**).

this particular substrate with *m*CPBA, in which the reagent is directed to the *syn* face through hydrogen bond formation with the free hydroxyl group.[75] The low overall reaction rate in the photooxygenation of these cyclic, chiral allylic alcohols implies substantial reversibility in the exciplex formation. Consequently, it is unlikely that any preference for one of the two possible ground state conformations **17**(*ax*) and **17**(*eq*) dictates the final product ratio. An explanation of the observed π-facial *anti* selectivity is that attack on the *syn* face and abstraction of a hydrogen atom aligned perpendicular to the plane of the double bond from conformation **17**(*ax*) is disfavored due to steric interactions of the incoming singlet oxygen with the axial hydroxyl functionality. However, as we have seen in Section 2.1.1, such simple steric effects are usually not sufficient to induce high selectivities in monocyclic systems and electronic effects must also be invoked. Evidently, the hydroxyl functionality in **17** plays no beneficial role in directing the incoming singlet oxygen to the *syn* face, a result in sharp contrast to what will be encountered in the photooxygenation of acyclic, chiral allylic alcohols (cf. Section 2.2). For the present cyclic substrate only the conformations **17**(*ax*) and **17**(*eq*) are accessible, which bear the heteroatom substituent on the *syn* face. Therefore, stereoelectronic effects come into play in that due to the electron-accepting nature of the oxygen substituent, a high overall electron density accumulates on the *syn* face of the substrate. This would be expected[76] to cause electrostatic repulsion of the "transvestial enophile", as discussed previously for **15** and **16**. This repulsive effect is not counterbalanced by effective attractive interactions of the incoming enophile with the hydroxyl functionality through hydrogen bonding, as in the case of *m*CPBA epoxidation.

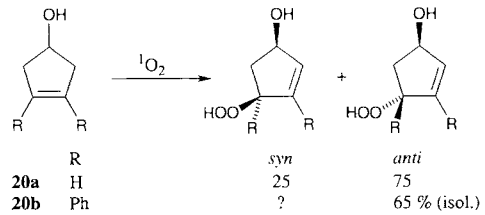
A similar outcome is observed for the photooxygenation of 2-cyclohexenol (**18**)[74] (Scheme 12). In this case the products **19b,c**, which arise from regioisomeric hydrogen abstraction,



Scheme 12. Schenck reaction of 2-cyclohexenol (**18**).

complicate matters a bit because the stereochemical information is lost. However, these products are formed by *anti* attack since only one allylic hydrogen atom is available at the chiral center. Thus, a moderate overall *anti* selectivity (66:34) is observed. The conformational situation for hydrogen abstraction at the C6 position in cyclohexene **18** is actually opposite to that in the cyclopentene **17**. Because of the perpendicular arrangement of the abstractable hydrogen atom with respect to the plane of the double bond on the *syn* face in conformer **18**(*eq*), the hydroxyl functionality is in a pseudo-equatorial position, where it should not present any steric obstacle towards singlet oxygen attack. This may explain the observed increased *syn* attack in this case.[77]

Preferred *anti* attack of singlet oxygen with respect to the hydroxyl functionality is also observed in reactions of homoallylic alcohols **20a**[78] and **20b**[79] (Scheme 13). Analogous to the



Scheme 13. Schenck reaction of 3-cyclopentenols **20**.

mechanistic rationalization for the allylic alcohols **17** and **18**, repulsion of the singlet oxygen by the enhanced electron density on the *syn* face may be responsible for the observed *anti* diastereoselectivity. The present results seem to indicate a moderate to high *anti*-directing propensity for the hydroxyl functionality in cyclic systems. Similar effects seem to apply for carboxylic acids and their anions, as was recently shown in the photooxygenation of the 1,4-cyclohexadienes **21**[80] (Scheme 14). The complete reversal of π-facial selectivity from preferred *anti* attack with respect to the carboxylate group for R = Me (*syn*:*anti* = 87:13) to strongly favored *syn* attack for R = *i*Pr

Scheme 14. π-Facial selectivity in the Schenck reaction of 2,5-cyclohexadiene-1-carboxylic acids **21**. Py = pyridine.

(*syn*:*anti* = 4:96) shows that this rigid, almost planar system is quite sensitive to steric effects. Nevertheless, the selectivity in the reaction of derivative **21a**, which opposes steric preference, clearly demonstrates the involvement of stereoelectronic and/or electronic effects in determining the π-facial selectivity. Accordingly, these experimental results have been rationalized[80] in terms of electrostatic repulsion between the carboxylate group and the partially negatively charged singlet oxygen in the exciplex or a perepoxide intermediate (Scheme 14). The trend for increased *anti* selectivity observed for the pyridinium and sodium salts **21b, c, e, f** implies that this electronic effect (electrostatic repulsion) is general.

From the few examples mentioned we can conclude that for cyclic olefins no functional group has yet been found that exercises a *syn*-directing effect on singlet oxygen in the Schenck reaction.[81,82] The reasons for this may be that electron-accepting substituents (inductive effects) that reside on one π face of the substrate molecule render attack of singlet oxygen unfavorable due to long-range electrostatic repulsion. This may occur either through direct interaction between the singlet oxygen enophile and the electron acceptor, as proposed for carboxylic acids, or by an increase in the overall electron density of a particular π face of the olefinic substrate. Although many cyclic olefins have been photooxygenated,[7-11] no systematic studies have been conducted to probe the directing propensity of a variety of common substituents and answer these mechanistic queries. Such studies would provide a better understanding of the diastereoselectivities in reactions of cyclic systems and would allow the synthetic chemist to use the Schenck reaction for applications with predicted stereocontrol.

2.2. Acyclic Systems

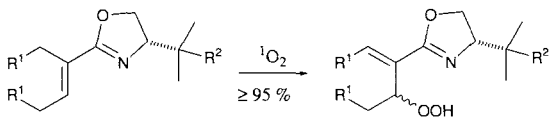
The diastereoselective Schenck reaction of acyclic, chiral substrates would be of great benefit to the synthetic chemist for the oxyfunctionalization of olefins. Compared to cyclic systems, which were discussed in the previous section, the enhanced conformational flexibility of open-chain substrates would be expected to reduce the influence of steric and stereoelectronic effects but increase the effect of electronic factors. The ability of a functional group to direct the attack of singlet oxygen preferentially to one π face of the substrate would be decisive for stereocontrol.

Two approaches to the diastereoselective photooxygenation of acyclic substrates have been employed. One option is to introduce a nonracemic, chiral auxiliary to an achiral substrate, which may, after the diastereoselective ene reaction with singlet oxygen, be removed for the preparation of enantiomerically enriched allylic hydroperoxides. Another method for the synthesis of highly oxyfunctionalized, chiral compounds is the diastereoselective photooxygenation of olefins bearing an adjacent stereogenic center. As will be seen, the latter approach has been used for the selective oxyfunctionalization of substrates that bear a variety of functional groups at the stereogenic center.

2.2.1. Chiral Auxiliaries

The use of auxiliaries from the chiral pool has proven successful for a variety of chemical transformations,[83] and consequently, its utility was tested also in ene reactions with singlet oxygen. All attempts reported so far have concentrated on the incorporation of an α,β-unsaturated carboxylic acid unit into a chiral environment; regioselective hydrogen abstraction at the *gem*-substituted position should produce a β-hydroperoxy carboxylic acid.[45] The keystone of this approach is that the conformation of the α,β-unsaturated carboxylic acid has to be fixed by secondary interactions so that singlet oxygen is forced to attack preferentially only on one of the π faces.

One early but unsuccessful attempt is featured in Scheme 15. Photooxygenation of a series of 2-alkenyldihydrooxazoles **22**,



22 **23**

which can be prepared easily from the corresponding carboxylic acids and optically active amino alcohols, yielded in each case only a 50:50 mixture of the diastereomeric hydroperoxides **23**.[84] Despite its lack of selectivity, this reaction is instructive with regard to the reaction mechanism. For example, to explain the observed geminal regioselectivity, Ensley et al.[85] proposed initial [4+2] cycloaddition of singlet oxygen to the α,β-unsaturated carbonyl moiety as heterodiene partner. The allyldihydrooxazoles **22** should adopt a cisoid conformation for effective [4+2] cycloaddition, attack of singlet oxygen on the *si* face would be severely hindered by the bulky alkyl substituents on

the oxazole ring, and appreciable diastereoselectivity would be expected. However, the enophile $^1O_2$ does not discriminate between the two π faces, indicating that the proposed[85] cisoid conformation is unlikely in the ene reaction.

A very recent and more successful case is documented in Scheme 16. Photooxygenation of the substituted cyclohexyl tiglates **24** gave the corresponding hydroperoxides.[86] While

	R^1	R^2	Solvent	T [°C]	d.r.

24d **24d'**

Scheme 16. Schenck reaction of chiral enoates **24**. Np = naphthyl.

esters **24a,b** with an aromatic ring attached directly to the cyclohexyl group showed no diastereoselectivity in the ene reaction, the menthol-derived esters **24c,d** displayed moderate π-facial selectivity at room temperature. The diastereoselectivities could be enhanced significantly when the reaction was carried out at −60 °C. These experimental results have been rationalized in terms of different populations of the conformers **24d** and **24d'** (Scheme 16); at lower temperatures the difference is enhanced. The conformer **24d'**, which can be attacked by singlet oxygen only from the *re* face, is lower in energy due to π stacking of the enoate with the aromatic system. The coplanar arrangement and, therefore, maximized π stacking can be optimally achieved for esters **24c,d**, while for the derivatives **24a,b** such a favorable arrangement is not possible due to considerable tilting of the substituents on the cyclohexane.[86]

The lack of an ideal coplanar arrangement of enoate and aromatic ring and, consequently, loss of conformational preference due to π stacking, is presumably also responsible for the lack of π-facial selectivity in the Schenck reaction of 3-naphthylborneol tiglates[86] and for the closely related ester **25a**[87] (Scheme 17). Steric bias alone, as in tiglate **25b**, is also not sufficient to induce good π-facial selectivity. The enoate may

	R	T [°C]	d.r.
25a	CH_2Ph	-50	60 : 40

Scheme 17. Photooxygenation of chiral enoates **25**.

adopt either a cisoid or a transoid conformation, which both react with singlet oxygen at comparable rates, explaining the observed low π-facial selectivity.

At the present time the use of chiral auxiliaries in the photooxygenation of tiglates has provided only limited success. Since the cisoid and transoid conformations of the enoate show similar reactivity towards singlet oxygen, control of conformer population is essential. The use of π-stacking concepts will require more carefully constructed substrates to guarantee progress along these lines. It should also be noted that in one attempt to induce asymmetry in the Schenck reaction the heterogeneous photooxygenation of 2-methoxy-2-butene was conducted within the dissymmetric cavities of a clathrate, namely *tri-o*-thymotide.[88] The resulting hydroperoxides indeed showed low optical activity; however, the absolute configuration and the enantiomeric excess were unfortunately not determined.

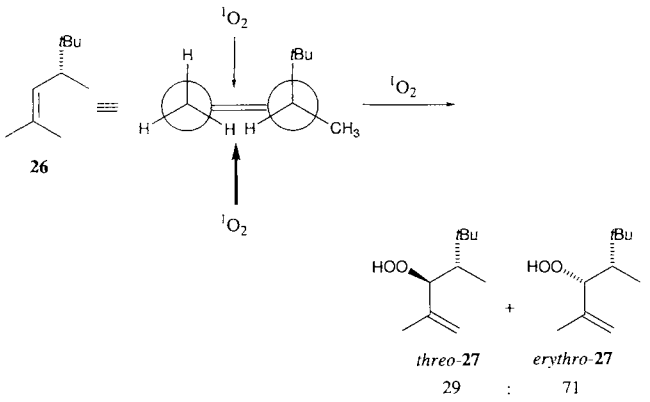
2.2.2. *Olefins Bearing Adjacent Stereogenic Centers*

The alternative approach to achieving high diastereocontrol in the formation of oxyfunctionalized products is by substrate control, in other words by starting with chiral olefins. Numerous such substrates are available for the Schenck reaction, but to apply successfully diastereoselective ene reactions with singlet oxygen in synthesis, the basic features of stereocontrol in such systems must be understood. Mechanistically relevant questions to be examined are: 1) How effective is steric bias in open-chain substrates? 2) Which functional groups at the stereogenic center direct the attack of singlet oxygen in the Schenck reaction? 3) What special structural features should the olefin have for high diastereoselectivities?

During the last five years considerable efforts have been expended on these questions and some general trends on the scope and limitations of this highly attractive synthetic route to stereochemically defined oxyfunctionalized products have become apparent. These make the Schenck reaction even more useful for preparative chemists, especially since the yields of the desired oxyfunctionalized products are generally ≥85%, and in addition excellent regiocontrol is also achieved.

2.2.2.1. Substrates without Heteroatom Functional Groups at the Stereogenic Center

In reactions of chiral olefins bearing only carbon substituents at the stereogenic center the electronic effects should be minimized, and these compounds should thus serve as probes for the effect of steric bias on the stereochemical course of the Schenck reaction in acyclic systems. Photooxygenation of alkene **26** gave a moderate preference for *erythro*-**27** (71:29)[89] (Scheme 18). This result can be rationalized with the Newman projection of alkene **26**. The presence of a methyl group *cis* to the stereogenic center induces considerable 1,3-allylic strain,[90] and in the preferred orientation the hydrogen atom at the stereogenic center is directed inward. Consequently, the singlet oxygen attacks main-



Scheme 18. Stereocontrol in the photooxygenation of chiral olefin **26**.

ly the bottom face, that is, opposite the *tert*-butyl group, to afford preferentially the *erythro* product.

A similar situation is encountered in the photooxygenation of the phenyl-substituted alkenes **28a,b**[91,92] (Scheme 19). Again, the *erythro* hydroperoxide is formed mainly, and the explanation in terms of steric effects is quite similar to that for the

	R	*threo*		*erythro*
28a	Me	19	:	81
28b	COOMe (*E*)	20	:	80
28c	COOMe (*Z*)	35	:	65

Scheme 19. Schenck reaction of chiral olefins **28**.

reaction of the *tert*-butyl-substituted alkene **26**. The slight drop in π-facial selectivity for the *Z*-configurated ester **28** (Scheme 19) arises because the ester group is less effective in inducing 1,3-allylic strain than the spherical methyl group in substrates **26** and **28a,b**. In conclusion, steric bias effects only low to moderate *erythro* selectivities in the Schenck reaction of chiral, open-chain substrates. Next the steering properties of polar heteroatom substituents at the stereogenic center will be scrutinized.

2.2.2.2. *Allylic Alcohols and Derivatives*

Chiral allylic alcohols are readily available substrates for testing the diastereoselectivity of the Schenck reaction and thereby assessing the electronic factors on the steering propensity of the hydroxyl group in open-chain substrates. As we have seen for cyclic allylic alcohols (Section 2.1.3), the hydroxyl group increases the electron density on one π face of the system and through electrostatic interaction repels the attacking singlet oxygen. For acyclic, allylic alcohols such stereoelectronic effects are expected to be much less important since the stereogenic center can adopt a variety of conformations which may place the hydroxyl functionality on either π face. Consequently, long-range, electrostatic repulsion towards the approaching singlet oxygen enophile is expected to be reduced and electronic interactions may come into play during exciplex formation.

In the definitive experiment featured in Scheme 20 a series of *Z*-configurated chiral allylic alcohols **29** were photooxygenated in chlorinated solvents to afford for every derivative in high preference (d.r. ≥93:7) the *threo*-configurated hydroxyhydroperoxides **30**.[93] The size of the aliphatic substituent at the stereogenic center does not influence the diastereoselectivity, which confirms that steric control is not important in the Schenck reaction of these substrates.

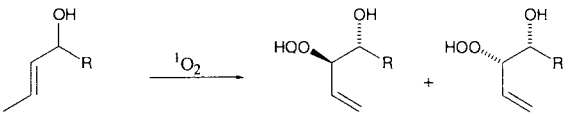
29c	*i*Pr	94	:	6
29d	*t*Bu	95	:	5

Scheme 20. The directing effect of the hydroxyl group in the photooxygenation of alcohols **29**.

For the mechanistic interpretation of these stereochemical results, it is important to compare them to those for the *E*-configurated allylic alcohol (*E*)-**29a** (Scheme 21).[93] In this second set of experiments essentially no π-facial selectivity was observed, which stresses again the requirement of a substituent in the *cis* position relative to the hydroxyalkyl group to induce 1,3-allylic strain, which is essential for high diastereoselectivity.



(*E*)-**29a** *threo*-**30a** : *erythro*-**30a** = 54 : 46

Scheme 21. Unselective Schenck reaction due to lack of 1,3-allylic strain in (*E*)-**29a**.

The experiments in Scheme 22 offer insights into the mechanism of the Schenck oxyfunctionalization. As expected, the photooxygenation of allylic alcohol **31a** displays *threo* selectivity in nonpolar solvents; however, in polar and protic solvents a significant drop in diastereoselectivity is observed.[93] This again

31e	Ac	CCl_4	82	39	:	61

Scheme 22. Solvent effects and product distribution in the Schenck reaction of chiral allylic alcohol derivatives **31**.

indicates that electronic effects may be responsible for the observed π-facial selectivity in the present system. Thus, protection of the free hydroxyl group by either electron donors (**31b–d**) or by an electron acceptor (**31e**) leads to a substantial drop in the π-facial selectivity compared to that with the parent allylic alcohol **31a**. For the acetate **31e** the *erythro*-configurated hydroperoxide was even the major product.

Based on the stereochemical data from Schemes 20–22, a conclusive mechanistic picture can be drawn for the ene reaction of singlet oxygen with chiral allylic alcohols. The steric factors without electronic interactions are represented in the Newman projections of conformers **31** and **31′** (Fig. 5). To minimize 1,3-allylic strain the smallest substituent at the stereogenic center,

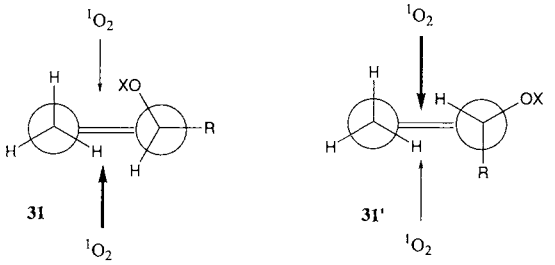

Fig. 5. Steric control in the photooxygenation of chiral allylic alcohol derivatives.

the hydrogen atom, is directed preferentially towards the inside position. When the OX and R substituents at the stereogenic center have roughly the same steric demand, the conformers **31** and **31′** are similar in energy. As a result both π faces of the olefin are exposed towards the attacking singlet oxygen enophile and low diastereoselectivity would be expected. Indeed, the low to moderate π-facial selectivities in the photooxygenation of the alcohol derivatives **31b–e** are all within the range that might be explained in terms of steric factors. Thus, to account for the high diastereoselectivity in the reaction of the free alcohol **31a**, hydrogen bonding is proposed in the exciplex between the hydroxyl group of the allylic alcohol and the partially negatively charged singlet oxygen (Fig. 6). This type of stabilizing electron-

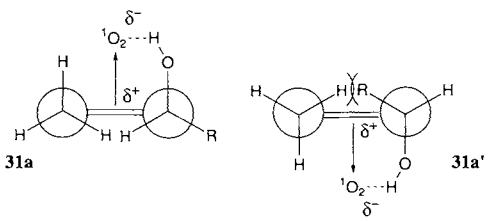

Fig. 6. Stabilization of the *threo* exciplex through hydrogen bonding.

ic interaction in the exciplex is effective only in conformer **31a**, which leads to the *threo*-configurated product; conformer **31a′** does not come into play owing to unfavorable 1,3-allylic strain. A similar rationale applies to the allylic alcohol (*Z*)-**29a** (Scheme 20), but not to its diastereomer (*E*)-**29a**. Since the latter lacks effective 1,3-allylic strain (no *cis* methyl group), the two conformers analogous to structures **31a** and **31a′** are similar in energy. Thus, hydroxyl assistance alone can no longer discriminate between the two π faces and consequently diastereoselectivity is lost. This mechanistic rationalization is further substantiated by the fact that the allylic alcohols show surprisingly high regioselectivity in the Schenck reaction: alcohol **31a** gives products arising from hydrogen abstraction at the stereogenic center in only 4% yield.[93] The Newman projections for the conformers **31a** and **31a′** in Figure 6 clearly reveal that coordination of singlet oxygen to the hydroxyl group precludes hydrogen abstraction at the stereogenic center. Also the observed solvent effect can be explained directly: with increasing polarity of the reaction medium, electronic interactions such as hydrogen bonding will be reduced and, consequently, the preference for the *threo* product diminished. Moreover, the lack of steric effects for the R group in the allylic alcohols **29** (Scheme 20) is evident; for the preferred conformer **31a** (Fig. 6) this substituent is located at the periphery and steric interactions are nominal, in other words, R = Me is large enough to generate sufficient allylic strain.

The high π-facial selectivity in photooxygenations of unprotected allylic alcohols through the directing effect of the hydroxyl group[93] is in accord with the "transvestial nature"[73] of the singlet oxygen enophile. On one hand, singlet oxygen is an electrophilic enophile and responds to high electron densities of the substrate; on the other hand, when it is complexed to the substrate in the form of an exciplex, stabilizing nucleophilic interactions through hydrogen bonding, for example, come into play. This recognition is of general importance[94] and when applied to nonracemic allylic alcohols, the preparation of optically active, highly oxyfunctionalized target molecules can be achieved with high stereocontrol. This was recently demonstrated by application of the novel hydroxyl group assisted Schenck reaction in natural product synthesis.[95]

As we have seen, 1,3-allylic strain plays a decisive role in the hydroxyl group directed ene reaction with singlet oxygen. But how important is 1,2-allylic strain caused by a geminal substituent near the stereogenic center in determining the stereoselectivity of the Schenck reation? To answer this question, the alcohols (*E*)-**32** and (*Z*)-**32** were photooxygenated in nonpolar solvents (Scheme 23).[96] The diastereomer (*E*)-**32**, which does

	Yield [%]	*threo*		*erythro*

(*E*)-**32**	55	66	:	34

Scheme 23. Schenck reaction of chiral allylic alcohols **32**.

not have a methyl group *cis* to the stereocenter, showed only moderate *threo* selectivity (66:34). In contrast, the *Z*-configurated alcohol led to the *threo*-hydroperoxide with high π-facial selectivity (93:7), which is in fact as high as that found in the photooxygenation of (*Z*)-**29a** (Scheme 20) and **31a** (Scheme 22), allylic alcohols without geminal substituents.[93] These results clearly establish that 1,2-allylic strain does not effectively compete with 1,3-allylic strain in differentiating the relative energy of the corresponding diastereomeric exciplexes (Fig. 7). Although significant 1,2-allylic strain is implicated in

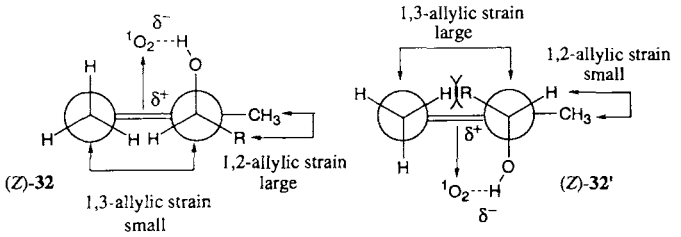

Fig. 7. Competition between 1,2- and 1,3-allylic strain in alcohol (*Z*)-**32**.

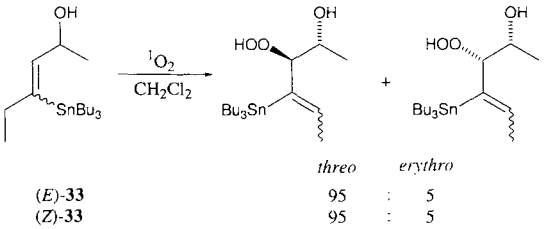

Scheme 24. Schenck reaction of stannyl alcohols **33**.

the conformer (*Z*)-**32**, the *threo* product is formed preferentially, while conformer (*Z*)-**32'** is unimportant. That 1,2-allylic strain by itself is indeed quite ineffective, is emphasized by the photooxygenation of the diastereomer (*E*)-**32**. Here only 1,2-allylic strain may operate and a low π-facial selectivity was found (diastereomer ratio d.r. = 66:34). These results imply that the C-C-C-O dihedral angle α in the exciplex is roughly 90–110° (Fig. 8a), analogous to that in the transition state postulated for the epoxidation by peracids (Fig. 8b).[97] A smaller angle would significantly enhance the importance of 1,2-allylic strain,[50,98] as observed in vanadium-catalyzed oxygen transfer reactions (Fig. 8c).

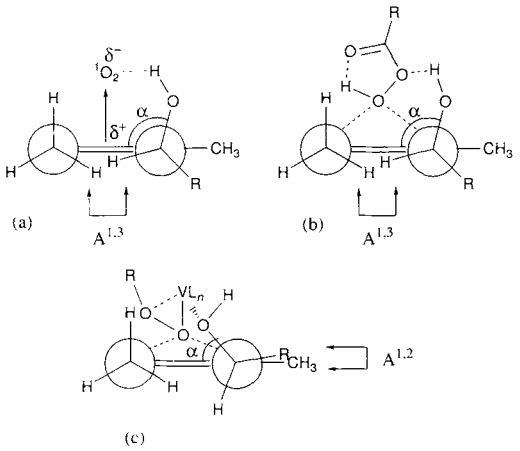

Fig. 8. Transition states in the Schenck reaction (a), the peracid epoxidation (b), and the vanadium(v)-catalyzed epoxidation (c) of chiral allylic alcohols. $A^{1,2}$, $A^{1,3}$: 1,2- and 1,3-allylic strain, respectively.

It may be argued that the π-facial selectivity in the Schenck reaction of (*E*)-**32** is minimal because in this particular substrate a hydrogen atom must be abstracted from a methyl group that is located *trans* to the stereogenic center. In other words, the directing effect of the hydroxyl group may hold only for hydrogen abstraction from an alkyl group located *cis* to the stereocontrolling chiral center. That this assumption does not apply, is shown in the photooxygenation of the stannyl alcohols (*E*)-**33** and (*Z*)-**33** (Scheme 24). In this case for both isomers high *threo* selectivities (95:5) were found.[99] Therefore, also chiral allylic alcohols such as (*Z*)-**33**, for which hydrogen abstraction has to take place from the "wrong" side of the double bond, react with high π-facial selectivity.

This brings up the important question as to the structure of the intermediate stabilized by the hydroxyl group. Two logical alternatives come to mind: the unsymmetrical perepoxide structure (Fig. 9a) and the symmetrical arrangement (Fig. 9b), in which the O–O and C–C bonds are oriented crosswise to each other. In the case of the perepoxide structure, for the hydroxyl group directing effect to be operative in the abstraction at R^1, inversion of the epoxide ring at O1 would be necessary. Such an inversion is unlikely, since the isoelectronic *N*-chloroaziridines,

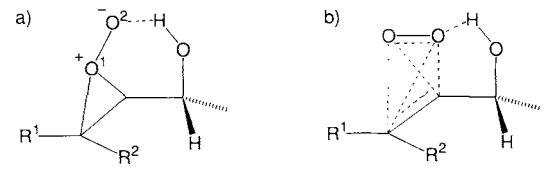

Fig. 9. Hydroxyl group stabilized perepoxide (a) and exciplex (b).

which may be taken as models, are configurationally stable and have been resolved into enantiomers even at room temperature.[100] Therefore, we propose the novel symmetrical structure (Fig. 9b) for the exciplex as a more likely stereocontrolling intermediate. Product formation by allylic hydrogen abstraction may take place either at R^1 or at R^2, depending on the substitution pattern. Whether the product is formed via a bona fide perepoxide intermediate is of no particular consequence for the product distribution because the π-facial selectivity is decided already at the exciplex stage.

For preparative purposes it would be most desirable to be able to use other functional groups to obtain preferentially the *erythro*-configurated product; this would complement the *threo*-selective photooxygenation of chiral allylic alcohols mediated by the hydroxyl group. The Schenck reaction of the allylic acetate **31e** (Scheme 22), which proceeded with modest *erythro* selectivity (61:39), is the only example known so far. The modest *erythro* control that is observed presumably arises from repulsion between the incipient negatively charged singlet oxygen and the negatively charged carbonyl oxygen of the acetate substituent in the exciplex.

To explore this further, a series of allylic esters was photooxygenated to determine which combination of steric and electronic features for the ester functionality would enhance formation of the *erythro* product (Scheme 25). Unfortunately, the results show that this goal is difficult to achieve for allylic esters because both steric and electronic repulsions are too weak to be effective in differentiating the π faces in these substrates.[99]

In summary, the hydroxyl group directed Schenck reaction of open-chain, allylic alcohols provides a mild and highly efficient method for the preparation of *threo*-configurated alkenediols in high yields. The concept can be applied to chiral di-, tri-, and tetrasubstituted olefins; the only prerequisite for high π-facial

selectivity is the presence of a *Z*-configurated double bond with a substituent vicinal to the stereogenic center in the allylic alcohol. Mechanistically significant is the fact that the hydrogen atom may also be abstracted from a *trans* alkyl group without loss of diastereoselectivity. This finding speaks for a symmetrical exciplex with crossed bonds as the stereocontrolling initial intermediate rather than the unsymmetrical, end-on perepoxide structure. The observed *threo* selectivity is based on the favored pathway, which features hydrogen bonding of the incoming enophile and for which 1,3-allylic strain is minimal. Unfortunately, no chiral substrates with an oxygen functionality in the allylic position are known to date that undergo the ene reaction with singlet oxygen to give exclusively *erythro* products.

2.2.2.3. *Allylic Amines and Acylated Derivatives*

While the hydroxyl group directed Schenck reaction can be used to prepare *threo*-configurated 1,2-diols after reduction of the hydroperoxy functionality, for preparative purposes, it would be also most desirable to have access to 1,2-amino alcohols of defined stereochemistry through photooxygenation of appropriate allylic amines. For these substrates chemoselectivity is an additional criterion for synthetic utility since a diastereoselective transformation will be useful only when side reactions, for example oxidation at the nitrogen atom[101] or oxidative cleavage of C–N bonds,[102] can be suppressed in favor of the ene reaction.

The results of the photooxygenation are shown in Scheme 26.[89,103] Like the reactions of the allylic alcohols previously discussed (Section 2.2.2.2), the Schenck reaction of the unprotected amine **35a** also shows high *threo* selectivity in nonpolar solvents, which decreases in the polar, protic methanol. Similarly, photooxygenation of the hydrochloride **35b** yielded also the *threo*-configurated β-hydroperoxy amine highly selectively (94:6). This again indicates that hydrogen bonding in the exciplex is the decisive stereochemical directing effect. For the monoacylated amines **35c,d**, which are comparable to the previously mentioned acetate **31e**, only moderate selectivity was achieved with the *erythro* product as the major one. In contrast photooxygenation of the diacylated derivatives **35e,f** produced again the *erythro*-configurated β-hydroperoxyamines diastereoselectively in high yields; this reaction is unquestionably most useful for synthesis. These stereochemical results can again be explained by the formation of the preferred *threo* product from the hydrogen-bonded exciplex **35** (Fig. 10). Thus, in the reaction of the allylic amines, like that of the structurally related allylic alcohols, the *erythro* product does not benefit by the hydrogen bonding stabilization since increased 1,3-allylic strain, as in exciplex **35'**, would be the consequence.

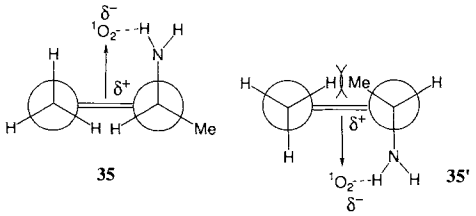

Fig. 10. The directing effect of the amino group in the photooxygenation of chiral allylic amines.

For monoacylated amines **35c,d** this effect no longer applies, possibly because of the increased steric bulk at the nitrogen atom. Synthetically more interesting, however, is the highly diastereoselective formation of the *erythro*-configurated product in the Schenck reaction of the diacylated amines **35e,f**. As mentioned previously (cf. Section 2.2.2.1), steric control alone leads to the *erythro* product, and additional electrostatic repulsion between the carbonyl oxygen atoms and the incoming singlet oxygen enophile further enhances *erythro* control; thus for these substrates steric and electronic effects operate synergistically. This stereochemical steering by electrostatic repulsion will be discussed in more detail in Section 2.2.2.4, but suffice it to say here, the observed solvent effect in the photooxygenation of phthalimide **35f** (Scheme 26) clearly substantiates this mechanistic rationalization.

Compared to the directing effect of the hydroxyl group in the Schenck reaction of allylic alcohols, that of the amino group appears to be of less synthetic applicability, since the readily oxidized amino functionality can interfere in the reactions of substrates with diminished ene reactivity. While allylic amines **35**, which have a trisubstituted double bond, do not suffer from such a drawback and give high yields of the corresponding hydroperoxides, the photooxygenation of allylic amines with a disubstituted double bond is problematic since for these less

reactive substrates the ene reaction cannot compete with other oxidations.[89] Of course, this is only a problem for the unprotected amines; diacylated derivatives are insensitive to such oxidative damage and are converted efficiently into *erythro*-configurated products. Secondary and tertiary amines can also not be employed due to predominant oxidative dealkylation under these reaction conditions.[102] The use of the less nucleophilic hydrochlorides, however, might in these cases be the solution.

Unquestionably, the Schenck reaction of chiral allylic amines and their acyl derivatives provides a highly stereoselective entry to either *threo*- or *erythro*-configurated hydroperoxyamines, which can be readily reduced to the corresponding amino alcohols. This spectacular switch in diastereoselectivity by simple acylation of the amino functionality promises interesting applications in the preparation of oxyfunctionalized allylic amines.[104] For this ene reaction to be of general utility, however, geminal substitution should be explored to assess the effects of 1,2-allylic strain.

2.2.2.4. *Other Functional Groups at the Stereogenic Center*

As we have seen, for allylic alcohols (Section 2.2.2.2) and amines (Section 2.2.2.3) numerous examples reveal the general scope and limitations of the stereochemical steering propensity of hydroxyl and amino functional groups in the Schenck reaction. For compounds with other functional groups at the stereogenic center, however, little if anything is presently known, besides the few recent examples conducted in our research group (Scheme 27).[105] With the exception of the homoallylic alcohol

	X	R	Yield [%]	*threo*		*erythro*

36f	COOH	H	88	20	:	80
36f	COOH/Py	H	90	15	:	85
36g	COOEt	H	77	22	:	78

Scheme 27. Directing propensities of various functional groups in the allylic position.

36e, the few substrates examined all display *erythro* diastereoselectivity, irrespective of whether the substituent bears a free OH group, which could serve as a hydrogen bond donor, as in derivatives **36d–f**. Apparently, the geometric requirements for efficient hydrogen bonding are no longer fulfilled for a homoallylic OH group (Fig. 11a). For the allylic halides **36a, b** and the sulfone **36c**, electrostatic repulsion between the substituent and the incoming singlet oxygen in the exciplex (Fig. 11b) appears to be responsible for the high preference of the *erythro*-configurated product. This argumentation has been applied previously to rationalize the stereoselectivities in the reactions of cyclic carboxylic acids (Section 2.1.3) and acyclic diacylated allylic amines (Section 2.2.2.3). Moreover, it seems most reasonable

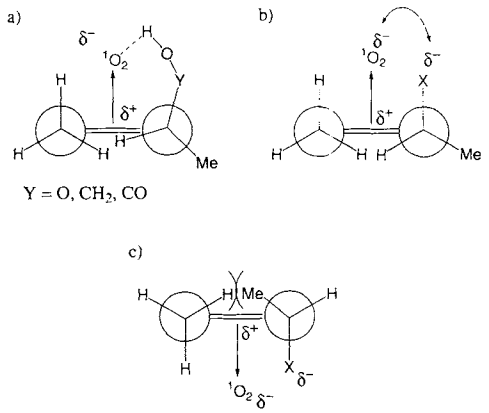

Fig. 11. Stereocontrolling factors in the Schenck reaction of chiral olefins **27**. a) Inefficient hydrogen bonding, b) electrostatic repulsion, c) 1,3-allylic strain.

for compounds with highly electronegative halogen substituents or with the negatively charged oxygen atoms of the electron-attracting sulfonyl group. Furthermore, the slightly enhanced *erythro* selectivity in the Schenck reaction for the pyridinium salt of the carboxylic acid **36f** (d.r. = 15:85) compared to that of the parent acid (d.r. = 20:80) also indicates that such electrostatic effects are operating. Thus, the carboxylate anion is expected to exert a larger repulsion on the incoming singlet oxygen than the carboxylic acid itself.

While for the allylic alcohols and amines hydrogen bonding in the exciplex provides extra stabilization and leads to *threo* control in the Schenck oxyfunctionalization, for the derivatives **36** electrostatic repulsion disfavors approach of singlet oxygen from the π face with the electron acceptor and, therefore, renders formation of the *erythro* product the major pathway. The *erythro* exciplex is not destabilized through such electrostatic repulsion since this would require a structure with significant 1,3-allylic strain (Fig. 11c).

For the sulfoxide **37** an additional stereochemical feature comes into play through the stereogenic sulfur center (Scheme 28).[105] Unfortunately, in the preparation of the sulf-

	threo		*erythro*

37b	15	:	85

Scheme 28. Schenck reaction of chiral allylic sulfoxides **37**.

oxide the two diastereomers **37a, b** were obtained whose relative configurations could not be assigned. While the Schenck reaction of the diastereomer **37a** gave essentially exclusively the *erythro* product (d.r. ≥ 95:5), the π-facial selectivity was significantly lower for sulfoxide **37b**. These results clearly demonstrate that the stereogenic center at the sulfur atom exercises some stereocontrol in this ene reaction.[106] Since the steric demand of the allylic substituents in the diastereomeric sulfoxides **37a** and **37b** must be very similar, electronic reasons are presumably

responsible for the observed difference in the stereocontrol. In agreement with the previous rationalization that the *erythro* exciplex is destabilized by electrostatic repulsion, diastereomer **37a** can easily adopt a conformation in which such a repulsion can operate efficiently, while for sulfoxide **37b** this appears to be more difficult. Since we do not have any information at the present time on the relative stereochemistry of the starting sulfoxides **37**, the stereochemically controlling conformations are not known.

In summary, halogen-, sulfinyl-, and sulfonyl-substituted stereogenic centers exhibit a pronounced propensity for *erythro* control in the Schenck reaction. Furthermore, homoallylic protic groups (e.g. CH_2OH, OOH, COOH) are much less effective than allylic ones (OH, NH_2, NH_3^+) in dictating *threo* stereocontrol through hydrogen bonding in the exciplex.

For the future, it should be of interest to test the directing propensities of other functional groups at the stereogenic center, for example chiral amine oxides, nitriles, azides, imines, aldehydes, ketones, phosphonates, and phosphine oxides. It should be instructive to design chiral substrates having both *threo*- and *erythro*-directing functionalities at the same stereogenic center to assess synergistic effects by electrostatic repulsion of singlet oxygen on one π face reinforced by attractions through hydrogen bonding on the other. This concept, which has already been applied successfully in the photooxygenation of chiral silyl cyanohydrins **38** (d.r. $\geq 99:1$ in Scheme 29),[107] should be tested for chiral β,γ-unsaturated amino and hydroxyl acids.

We have seen that the ene reaction with singlet oxygen can proceed with amazingly high levels of stereocontrol in open-chain systems. Electronic effects seem to determine the sense and extent of diastereoselectivity. While hydrogen bonding benefits the *threo* products in the photooxygenation of chiral allylic alcohols and amines, electrostatic repulsion in the *threo* exciplex seems to be responsible for the preferred formation of *erythro* products for other functional groups at the stereogenic center. All these directing effects critically depend on the presence of a substituent *cis* to the stereogenic center. Only the effective differentiation in the energies of the different conformers in the exciplex through 1,3-allylic strain can efficiently guide the attack of singlet oxygen preferentially on one of the diastereotopic faces and, thus, give the product with high π-facial selectivity.

3. Summary

The large number of stereoselective photooxygenations that were compiled in the present review clearly demonstrate that the Schenck reaction constitutes a versatile and efficient oxyfunctionalization in organic chemistry. As we have seen, over the years many different methods have been developed to control stereoselectivity efficiently. Several special factors are involved in the stereocontrol of ene reactions with singlet oxygen, and it is impossible to explains the results obtained from the diverse substrates in terms of a single mechanistic picture. This is expected in view of the fact that stereoselectivity in reactions with singlet oxygen is substrate-controlled since this symmetrical reagent lacks stereochemical information. Nevertheless, at this point we will try to evaluate some of the more important features in order to compile a guide for the preparative chemist in the application of the stereoselective Schenck reaction in synthesis. In Table 1 the more important substrate classes that were covered in Section 2 are summarized with respect to type, sense, extent, and scope of stereocontrol in the Schenck reaction. The selective formation of either diastereomer by simple modification of the electronic properties of the functional group at the chiral center would be most useful, as described for different allylic amines in Section 2.2.2.3.

Table 1. Substrate-dependent π-facial selectivity in the Schenck reaction.

Substrate class	Stereocontrol			Scope
	Type[a]	Extent	Sense[b]	
monocyclic olefins	steric conformational	low	*anti*	general
bi- and polycyclic olefins	steric conformational	moderate to high	*anti*	limited
functionalized cyclic olefins	steric stereoelectronic	low to high	*anti*	limited
acyclic allylic alcohols	electronic	high	*threo*	general[c]
acyclic allylic ethers and esters	steric	low	*threo*/*erythro*	general
acyclic allylic amines	electronic	high	*threo*	general[c, d]
diacylated acyclic allylic amines	steric electronic	high	*erythro*	?
acyclic allylic halides, sulfoxides, and sulfones	electronic	high	*erythro*	?

[a] Major selectivity-determining effects as defined in Section 1. [b] For cyclic substrates *syn*/*anti*, for acyclic ones *threo*/*erythro*. [c] A *cis* substituent adjacent to the stereogenic center must be present. [d] Limitations due to side reactions for unreactive amines.

Inspection of the compilation in Table 1 shows that effective stereocontrol has not yet been achieved for cyclic systems. Polycyclic systems in particular will in many cases give very high levels of diastereoselectivity, but only if the substrate itself already bears very special structural features. This applies to many natural products such monoterpenes and steroids, but for synthetic utility it would be much more important if simple monocyclic model substrates would react with high and predictable stereocontrol. However, especially for this class of substrates the stereoselectivity is poor. Thus, incorporating into a synthetic sequence a potentially stereoselective Schenck reaction for a cyclic substrate is problematic. For monocyclic systems, which are easily prepared, low levels of π-facial selectivity are to be expected, while the more difficult to prepare polycyclic substrates still bear the risk of an unselective ene reaction. Too many effects are involved in the Schenck reaction of cyclic substrates to reduce the experimental data to some simple rules.

Nonbonding repulsion, that is, steric control, will in all cases make its contribution, but due the small size of singlet oxygen molecule and its symmetrical structure high levels of stereocontrol cannot be expected. Conformational effects will in many cases also play a major role. Since singlet oxygen is an electronically excited compound, its reactions will always proceed exothermically. This means that early transition states are involved and that even conformational preferences in the substrate may be evident in the final product ratio. This may be effective in some cases, but an a priori evaluation is extremely difficult.

Furthermore, for the Schenck reaction of cyclic systems, no effective methods are known to date for taming singlet oxygen sufficiently by attractive interactions to overcome the steric bias of the substituent and favor *syn* attack. However, repulsion of singlet oxygen by functional groups may be a useful approach in the future for controlling *anti* attack in the preparation of ene products. For synthetic utility it will be important whether highly selective *anti* attack can be achieved for simple cyclic allylic alcohols or carboxylic acids.

Surprisingly, the situation looks much more promising for acyclic systems. The Schenck reaction of acyclic allylic alcohols and amines constitutes a very general and efficient method for the diastereoselective preparation of highly oxyfunctionalized, *threo*-configurated target molecules. The only prerequisite for the substrate structure is the presence of a substituent located *cis* with respect to the chiral center, which allows for efficient differentiation in the energies of the different conformers through 1,3-allylic strain. Furthermore, simple diacylation of the free allylic amine can be used to prepare efficiently the *erythro* product. Also other hetero substituents, for example sulfinyl, sulfonyl, and halogen groups, seem to have remarkable *erythro*-directing propensity, but for these substrates it is still necessary to define the scope and limitations.

What was unfavorable for cyclic substrates, namely the relatively low sensitivity of singlet oxygen to steric effects and the critical dependence on certain conformational arrangements, may be most beneficial in open-chain systems. In these highly flexible substrates, electronic effects such as hydrogen bonding and electrostatic repulsion come into play and override any possible steric effects. Furthermore, for abstraction at an acyclic alkyl site, the optimal arrangement of the hydrogen atom perpendicular to the plane of the double bond can usually be readily achieved, so that conformational effects will also not be decisive. The high sensitivity to solvent effects clearly demonstrates that the operating electronic effects in the photooxygenation are only very weak. Since the list of suitable, nonpolar solvents includes very common ones such as carbon tetrachloride, chloroform, and aromatic hydrocarbons, this should be no major drawback for synthetic applications. The substrate-directed Schenck reaction of olefins with an adjacent, heteroatom-substituted chiral center is a very versatile and mild method for the predicted stereoselective oxyfunctionalization of acyclic substrates. The effects encountered seem to be rather general and, therefore, application in a synthetic sequence should be profitable.

We have shown that singlet oxygen, although it is a highly reactive oxidant, can be utilized in a highly stereoselective manner in the Schenck reaction for the preparation of a variety of valuable oxyfunctionalized target molecules. The operative mechanistic features are highly diverse and complex, nevertheless, most interesting. While quite special mechanistic rationalizations apply for the individual substrates, consideration of all the case studies reported here leads also to a better understanding of the behavior of singlet oxygen in general. Since single oxygen is electronically excited, the oxyfunctionalization reaction starts out on a high-energy potential enery surface with expected shallow wells. The electronically excited system will tend to dissipate the excess energy by either physical quenching or chemical formation of a product. It is this feature of singlet oxygen that makes it difficult to predict and rationalize the chemo-, regio-, and stereoselectivity of photooxygenations. Nevertheless, we have shown that this highly reactive oxidant can be guided to perform selective oxyfunctionalizations for practical applications. Unquestionably, the electronically excited singlet oxygen enophile continues to present an intellectual challenge for both experimental and theoretical chemists!

Electron Domains and the VSEPR Model of Molecular Geometry

Ronald J. Gillespie* and Edward A. Robinson

The valence shell electron pair repulsion (VSEPR) model—also known as the Gillespie–Nyholm rules—has for many years provided a useful basis for understanding and rationalizing molecular geometry, and because of its simplicity it has gained widespread acceptance as a pedagogical tool. In its original formulation the model was based on the concept that the valence shell electron pairs behave as if they repel each other and thus keep as far apart as possible. But in recent years more emphasis has been placed on the space occupied by a valence shell electron pair, called the domain of the electron pair, and on the relative sizes and shapes of these domains. This reformulated version of the model is simpler to apply, and it shows more clearly that the Pauli principle provides the physical basis of the model. Moreover, Bader and his co-workers' analysis of the electron density distribution of many covalent molecules have shown that the local concentrations of electron density (charge concentrations) in the valence shells of the atoms in a molecule have the same relative locations and sizes as have been assumed for the electron pair domains in the VSEPR model, thus providing further support for the model. This increased understanding of the model has inspired efforts to examine the electron density distribution in molecules that have long been regarded as exceptions to the VSEPR model to try to understand these exceptions better. This work has shown that it is often important to consider not only the relative locations and sizes, but also the shapes, of both bonding and lone pair domains in accounting for the details of molecular geometry. It has also been shown that a basic assumption of the VSEPR model, namely that the core of an atom underlying its valence shell is spherical and has no influence on the geometry of a molecule, is normally valid for the nonmetals but often not valid for the metals, including the transition metals. The cores of polarizable metal atoms may be nonspherical because they include nonbonding electrons or because they are distorted by the ligands, and these nonspherical cores may have an important influence on the geometry of a molecule.

Keywords: electron density distribution · electron pair domains · molecular geometry · VSEPR model

1. Introduction

The valence shell electron pair repulsion (VSEPR) model has for many years provided a useful basis for understanding and rationalizing molecular geometry, and its simplicity has led to its widespread acceptance as a pedagogical tool.[1–3] Nevertheless it has often been regarded as a purely empirical theory having no real physical basis, or as a classical electrostatic theory. It is the purpose of this review to show that 1) the model continues to provide a simple explanation of the structures of many new molecules that have been prepared in recent years, including many detailed features of their structures that often cannot be easily accounted for in any other way; 2) the formulation of the model in terms of electron domains is simpler to understand and to apply than the original version of the model; 3) the Pauli principle is the physical basis of the electron pair domain concept and therefore of the VSEPR model; 4) the domain version of the VSEPR model provides a complement to the conventional orbital models that is useful in introductory chemistry for discussing not only the topic of molecular geometry but also the concept of the chemical bond itself; 5) the domain version of the model is supported by the analysis of the total electron density of a molecule in terms of both electron density deformation maps and the Laplacian of the electron density; 6) the analysis of the Laplacian of the electron density leads to a better understanding of the structures of metal–nonmetal type molecules, including those of the transition metals and shows how the VSEPR model can be modified so that it applies to such molecules.

2. The Pauli Principle and Electron Pair Domains

2.1. The Pauli Principle

The Pauli principle provides the physical basis for the VSEPR model. In its most general form it states the following: *The total wave function for a system must be antisymmetric to the exchange*

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3505-0495 $ 15.00+.25/0

of any two electrons.[4] A direct conclusion is that two electrons of the same spin have a zero probability of being at the same point in space and a maximum probability of being as far apart as possible, in other words, electrons with the same spin tend to keep apart in space.[5] The Pauli principle places no restrictions on electrons of opposite spin, however, which may indeed be close together or even at the same location.

The importance of the Pauli principle in determining molecular geometry can be clearly seen if we consider the valence shell of eight electrons (the octet) that is commonly found for many atoms in their molecules. In such a valence shell there are four electrons of α spin and four of β spin. As a consequence of the Pauli principle there is a high probability that the four electrons of α spin will have a mutually tetrahedral arrangement, as will the four β electrons (Fig. 1a, b, d, e).[5] From the point of view of the Pauli principle the two tetrahedral sets of electrons are not correlated. However, electrostatic repulsion not only reinforces the tendency of each set of electrons to adopt a tetrahedral arrangement but also tends to keep the two tetrahedra apart. In a free atom such as the neon atom no external force restrains the free movement of the two tetrahedral sets of electrons, which results in an overall spherical total electron density. In contrast, in a molecule the positive cores of one or more ligand atoms attract the valence shell electrons of the central atom. In accordance with the Pauli principle a ligand core may attract two electrons of opposite spin into the same region to form a bond. If A is the central atom with tetrahedral arrangements of both α electrons and β electrons in its valence shell, the formation of two A–H (or two A–X bonds where X is a singly bonded ligand) brings the α spin tetrahedron into approximate coincidence with the β spin tetrahedron, thus forming four electron pairs—two bonding pairs and two nonbonding (lone) pairs (Fig. 1c, f). Each pair of electrons is approximately localized in a part of the valence shell of A—one pair in each of two bonding regions and one pair in each of two nonbonding regions.

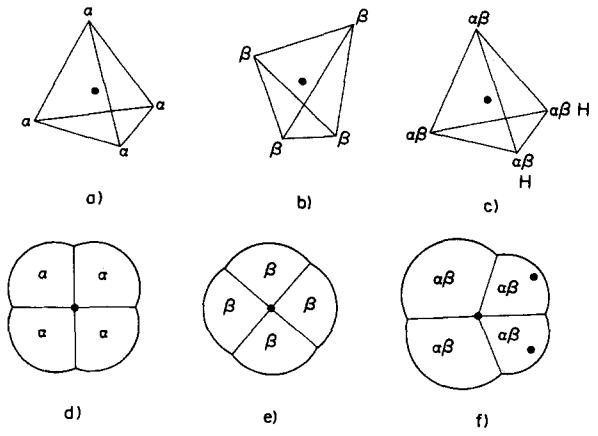

Fig. 1. Most probable arrangement of four valence shell electrons with spin α (a) and spin β (b), and of eight valence shell electrons in an AH_2 molecule (c). Two dimensional representations of the domains of four valence shell electrons with spin α (d) and spin β (e), and of eight valence shell electrons (f) in an AH_2 molecule.

2.2. Electron Pair Domains

We call the region of space in the valence shell in which an electron pair is most probably to be found an electron pair domain. Daudel[6] has previously called such a region of space a loge. Thus a valence shell containing four electron pairs may

R. J. Gillespie

E. A. Robinson

Prof. Ronald J. Gillespie graduated from University College London, obtaining his Ph.D. degree in 1949 and DSc. in 1957. He was a Lecturer at University College London from 1948 to 1958 when he moved to McMaster University as Associate Professor, becoming Professor in 1960 and Emeritus Professor in 1989. After his Ph.D. research on aromatic nitration in sulphuric acid with Sir Christopher Ingold, he did extensive work on the chemistry of superacid media such as H_2SO_4, HSO_3F, and HF including the preparation of noble gas fluorocations and a large number of novel polyatomic cations of the nonmetals. He has received many awards for his work, including election to the Fellowship of the Royal Society of London in 1977 and the American Chemical Society awards for Creative Work in Fluorine Chemistry and for Distinguished Service to Inorganic Chemistry. He has had a long standing interest in Chemical Education and in the use of simple models in the teaching of chemistry. He first proposed the widely used VSEPR model with Ronald S. Nyholm in 1957.

Born in London, England, in 1933, E. A. (Peter) Robinson obtained his Ph.D. under Ronald J. Gillespie in 1958 at the University College, London. Then he moved to McMaster University and worked as an original member of the Gillespie research group in Canada. From 1961 to 1994 he was at the University of Toronto, where he is now Professor Emeritus. In 1965 he became a founding member of the University of Toronto's Erindale Campus in Mississauga. As the first Associate Dean, the second Dean, and the third Principal, he played a major role in the organization and construction of the newest Toronto campus, which is now equally recognized for the quality of its teaching and research. Ongoing research interests include the understanding of both lengths in terms of the Lewis octet rule and expanded octets, and hydrogen bonding involving C–H bonds. He was awarded a D.Sc. by the University of London in 1969.

be thought of as being divided into four tetrahedrally arranged regions or domains in each of which the probability of finding an electron pair is high. We will see later that it is important to consider the shapes of domains but as a rough first approximation we may consider that a domain has a spherical shape, as first proposed by Bent in his tangent-sphere model.[7] Four spheres pack as closely as possible around a point (the core of the atom) by adopting a tetrahedral arrangement, which demonstrates in a simple way that four equivalent domains are expected to have a tetrahedral arrangement (Fig. 2). Similarly

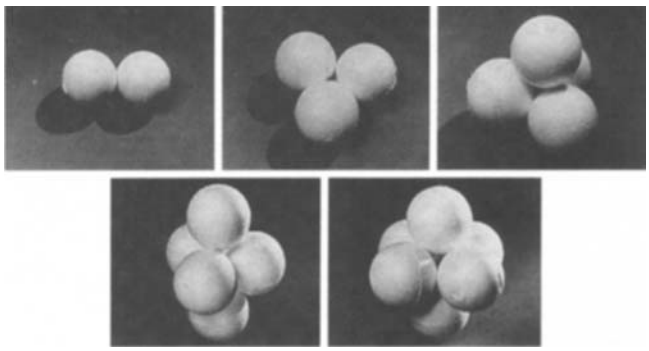

Fig. 2. Arrangements of two to six spherical domains surrounding the core.

two spheres representing two electron pair domains adopt a linear arrangement, three spheres a triangular arrangement, five spheres a trigonal-bipyramidal arrangement, and six spheres an octahedral arrangement (Fig. 2). In the arrangements of two, three, four, and six electron pairs all the domains are equivalent. However, it is not possible to have an arrangement of five equivalent domains, except by arranging them in a plane. But this arrangement does not keep the domains as far apart as possible. In the trigonal-bipyramidal arrangement there is a set of three equivalent (equatorial) domains and a set of two equivalent (axial) domains (Fig. 2). As a result AX_5, molecules with five identical ligands do not have five equal AX bonds, but have two longer axial bonds and three shorter equatorial bonds.

The basic assumption of the VSEPR model in its original form was that a given number of valence shell electron pairs, considered as points, adopt that arrangement that keeps them as far apart as possible (the points-on-a-sphere model). This formulation of the model has sometimes led to the misunderstanding that it is just electrostatic repulsion that keeps electron pairs apart. But the formulation of the model in terms of electron pair domains makes it clear that the formation of electron pairs that keep as far apart as possible is a consequence of the Pauli exclusion principle, electron–nucleus attraction, and electron–electron repulsion.

2.3. Single Bond and Lone Pair Domains

In the valence shell of an atom that obeys the octet rule there are four electron pair domains. When these domains are equivalent, as in an AX_4 molecule where X is a singly bonded ligand, the four equivalent single bond domains are arranged tetrahedrally, and the molecule has a tetrahedral geometry. In an AX_3E molecule, where E is a lone pair, there are three single bond domains giving a triangular-pyramidal molecule with an approximately tetrahedral bond angle. In an AX_2E_2 molecule two single bond domains and two lone pair domains give a molecule with an angular geometry and a bond angle of approximately 109° (Fig. 3).

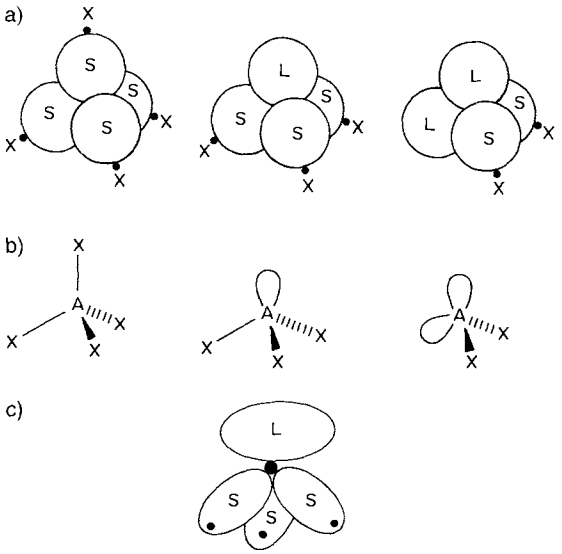

Fig. 3. AX_4, AX_3E, and AX_2E_2 molecules. a) Domain models; S is a single bond domain and L a lone pair domain. b) Conventional bond line structures. c) Approximate relative shapes and sizes of the domains in an AX_3E molecule.

Deviations in bond angles from the ideal angles corresponding to the various most probable electron pair arrangements can be accounted for by recognizing that bonding and nonbonding domains are not equivalent, and in particular, by assuming that they have different shapes and sizes. A nonbonding valence shell electron pair is attracted by just one positive core and so its domain tends to surround the core and thus take up as much space as possible in the valence shell. However, a single bond domain is restricted in size and has a different shape because the two electrons are attracted by two positive cores. Thus in any valence shell a nonbonding domain is larger and is closer to the core than a bonding domain (Fig. 3c). The larger size of a lone pair domain accounts for the observation that in very many molecules in which an atom has one or more lone pairs the angles between the bonds are smaller than the ideal values. For example, they are smaller than 109.5° for AX_3E and AX_2E_2 molecules (Tables 1 and 2) and smaller than 90° for an AX_5E molecule (Table 3). Although electron pair domains are not as localized as shown in Figures 2 and 3 it is very convenient, as we shall see, to think of them as nonoverlapping. So the representations of the domains in Figures 2 and 3 can be regarded as approximately denoting those regions where there is a relatively high probability of finding an electron pair.

In its original form[8] the VSEPR model postulated that the strength of the repulsions between electron pairs decreases in the order lone-pair–lone-pair > lone-pair–bond-pair > bond-pair–bond-pair. This assumption leads to the same conclusions about bond angles as the domain model, although the conclu-

sions are not always reached so simply. Because electrons of the same spin have a low probability of being close together, electron pair domains resist overlap. It is in this sense that domains may be said to repel each other, and so larger domains appear to repel other domains more strongly than smaller domains.

The importance of considering the relative sizes and shapes of electron pair domains was pointed out by Gillespie many years ago,[1] although the term electron domain was not introduced at that time. However, even though it has several advantages over the electron-pair repulsion formulation, the domain concept has not often been used in the discussion of molecular shapes in terms of the VSEPR model. These advantages are particularly evident for AX_4E, AX_3E_2 and AX_2E_3 molecules. It is simple to understand, for example, why a lone pair always occupies an equatorial position in these types of molecules. An equatorial position is less crowded than an axial position because it has two neighboring axial positions at 90° and two equatorial positions further away at 120°, whereas an axial position has three neighboring equatorial positions at 90°. Because they are larger than bond pair domains, lone pair domains always occupy the less crowded equatorial positions of these molecules, so that AX_4E molecules such as SF_4 always have a disphenoidal shape, AX_3E_2 molecules such as ClF_3 always have a T-shape, and AX_2E_3 molecules such as XeF_2 always have a linear shape (Fig. 4). Another advantage of the domain model is that it allows us to understand how a lone pair domain may exert direc-

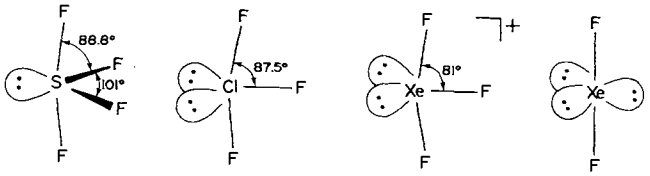

Fig. 4. Examples of AX_4E, AX_3E_2, and AX_2E_3 molecules in which lone pairs always occupy equatorial positions.

tional repulsive effects. The angles between the domains in the equatorial plane of AX_4E, AX_3E_2, and AX_2E_3 molecules are larger than the angles between the axial and equatorial domains. Accordingly a lone pair domain in an equatorial position spreads out more in the equatorial direction than in the axial direction giving it a noncylindrically symmetrical shape, and distorting a larger equatorial bond angle more than a smaller axial–equatorial bond angle. Thus in SF_4, for example, the more easily distorted $F_{eq}SF_{eq}$ angle is reduced by 19° from the ideal value of 120°, while the $F_{ax}SF_{eq}$ angles are reduced by only 1.2° from the ideal angle of 90°. Other similar data are given in Table 4. A recent analysis of the electron density of the SF_4 molecule through its Laplacian[9] (discussed in Section 3.2) has confirmed the unsymmetrical shape of its lone pair domain.

We can similarly understand the shape of the planar XeF_5^- ion, the unique example of an AX_5E_2 molecule (Fig. 5).[10] Although the best arrangement of seven equivalent domains cannot be predicted with certainty,[2] it is reasonable to suppose that the geometry of XeF_5^- would be based on that of the closely related IF_7 and TeF_7^- molecules, which have a pentagonal-bipyramidal geometry.[11, 12] In the pentagonal-bipyramidal arrangement of seven domains in a valence shell more space is available in the axial positions, which make angles of 90° with the neighboring equatorial positions, than in an equatorial position, which makes two angles of 72° and two of 90° with neighboring positions. Hence, large lone pair domains are always expected to occupy the axial positions in a pentagonal bipyramidal arrangement of seven domains leading to the observed pentagonal-planar shape of the XeF_5^- ion.

2.4. Single Electron Domains

In some free radicals the unpaired electron is located mainly on a single atom. A single electron can be considered to occupy a single electron domain that is expected to be smaller than an electron pair domain, so it affects the geometry of a molecule

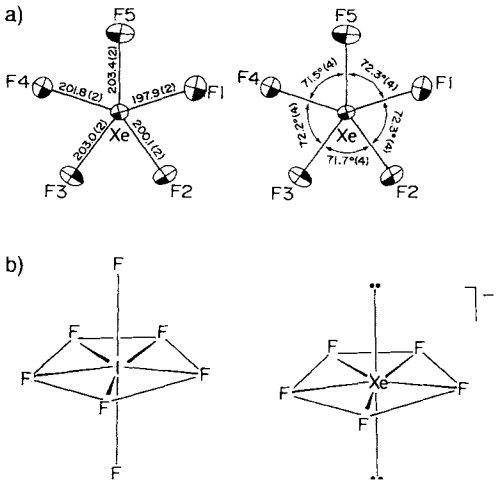

Fig. 5. a) Structure of the XeF_5^- ion (bond lengths in pm). b) Comparison of the structure of IF_7 (an AX_7 molecule) and XeF_5^- (an AX_5E_2 molecule).

less than a lone pair as exemplified by the three molecules NO_2^+, NO_2, and NO_2^-, which have bond angles of 180°, 134°, 115° respectively (Fig. 6a). The difference in size between an electron pair domain and a single electron domain is also seen clearly in the calculated structure of the SF_4^- radical, which has C_{4v} symmetry. This structure is consistent with a trans arrangement of the lone pair and the single electron and with the bending of the SF bonds, away from the lone pair towards the single electron (Fig. 6b).[113] SF_4^- may be said to have an AX_4Ee geometry, where e represents a single electron domain.

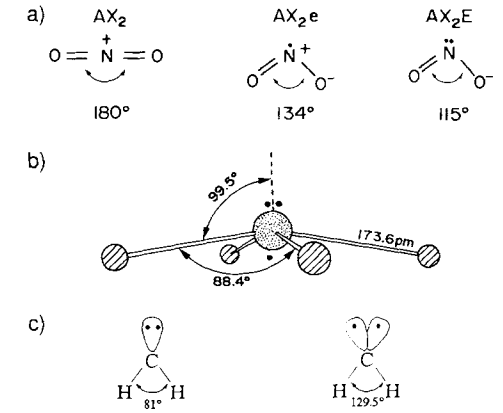

Fig. 6. Single electron domains. a) The bond angle decreases in the series NO_2^+, NO_2, NO_2^-. b) The SF_4^- radical has a C_{4v} structure consistent with the smaller domain for a single nonbonding electron and a larger domain for the nonbonding lone pair. c) Bond angles in the singlet (left) and triplet (right) states of CH_2.

The different stereochemical influence of single electron domains and those of lone pairs is further exemplified by the singlet and triplet states of carbene (Fig. 6c). In the singlet state CH_2 may be described as an AX_2E molecule and, as expected, has a bonding angle small than 120°. The triplet state, which may be described as an AX_2E_2 molecule, has a bond angle larger than the tetrahedral angle, showing the smaller stereochemical effect of the single electron domains.[113b]

2.5. Single Bond Domains and Electronegativity

The space occupied by a single bond domain in the valence shell of A depends on the relative electronegativities of the central atom A and the ligand X. The larger the electronegativity of X and the smaller the electronegativity of A, the less space the A–X bond domain occupies in the valence shell of the central atom A and the smaller the angle between the A–X bond and other neighboring bonds, as can be seen in many of the examples in Tables 1–4. If we consider a lone pair as a bond pair that is bonding a ligand of zero electronegativity we can again see why a lone pair has a domain that is larger than that of any bond pair.

The bond angles of the hydrides of the elements of groups V (that is, Group 15) and VI (that is, Group 16), however, appear to be exceptions to the rule that the X-A-X bond angle decreases with increasing electronegativity of X. The bond angles in PH_3 and H_2S, for example are smaller than in PF_3 and SF_2, although hydrogen is less electronegative than fluorine (Tables 1 and 2). However, hydrogen is a unique element in several ways. One important difference between hydrogen and any other ligand is that the electron pair of an A–H bond has to play the role of both a bonding pair and a nonbonding pair in that it also shields the proton on the opposite side to the bond, in other words the domain of this pair of electrons is not confined to the bonding region but extends into the nonbonding region of the hydrogen atom. Hence the electron density in an A–H bond is smaller than in other single bonds. It follows that A–H bonds can be squeezed together by lone pairs on A much more easily than any A–X bonds, thereby giving a smaller bond angle.

The existence of SF_6, SeF_6, and BrF_6^+, but not of ClF_7 and BrF_7, suggests that the elements of periods 3 and 4 can accommodate up to, but no more than, six electron pair domains with an octahedral arrangement in their valence shells.[14] A few molecules such as $SeCl_6^{2-}$ that appear to be exceptions to this rule are discussed later (Section 3). Hence it is reasonable to suppose that the repulsions between bonding domains in the valence shells of these elements only become significant as the angle between them approaches 90°---the bond angle in an octahedral arrangement of six domains. Hence the bond angles in PH_3, AsH_3, H_2S, and H_2Se approach this limiting value of 90°. However, for all other ligands, repulsions between the bond pair domains become significantly large before the bond angle is close to 90°.

It has long been recognized that more electronegative ligands have a preference for the axial sites and less electronegative ligands a preference for the equatorial sites of a trigonal-bipyramidal structure, as in the examples in Figure 7. The electron pair domains in the axial positions are more crowded than those in the equatorial positions, so the smaller domains bonding the more electronegative ligands favor the axial sites, while the larger domains bonding the less electronegative ligands favor the equatorial sites. In contrast in a pentagonal-bipyramidal AX_7 structure, the axial sites are less crowded and the equatorial sites are more crowded, and the less electronegative ligands favor the axial sites (Fig. 8).

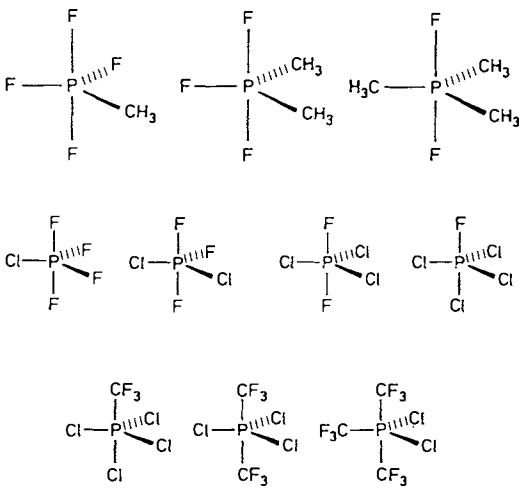

Fig. 7. Examples of PX_5 molecules in which the less electronegative ligands always occupy the equatorial positions.

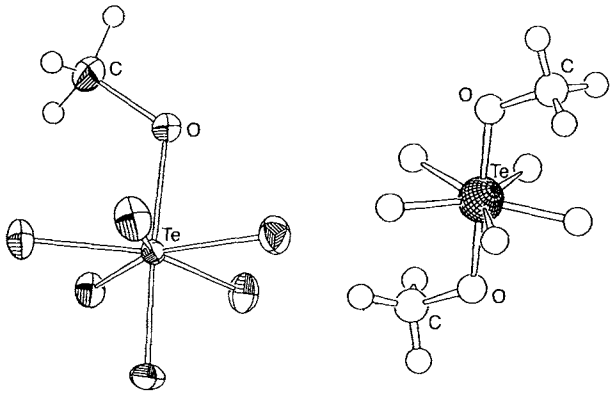

Fig. 8. Structures of the pentagonal-bipyramidal molecules $TeF_6(OMe)$ (left) and $TeF_5(OMe)_2$ (right) in which the less electronegative OMe group preferentially occupies an axial position.

2.6. Multiple Bond Domains

A double bond is formed by the sharing of two electron pair domains between two atoms and a triple bond by the sharing of three electron pair domains between two atoms (Fig. 9a, b). These representations of multiple bonds correspond to the classical bent bond descriptions (Fig. 9c, d), which account for the planar shape of the ethene molecule and the linear shape of the ethyne molecule, and for the decreased CC bond lengths in these molecules.[15] However, we would not expect the HCH bond angle in ethene to retain the ideal tetrahedral angle. The two bonding pairs are attracted toward the same two positive carbon cores and are therefore squeezed together, which allows the repulsion between the CH bond domains to open the HCH bond angle to 117.4° in ethene. In C_2F_4 the FCF bond angle of 112.4° is still smaller and is closer to the tetrahedral angle (Table 5).

Alternatively, and often more conveniently, the two single bond electron pair domains forming a double bond may be considered to be overlapped to such an extent that they form

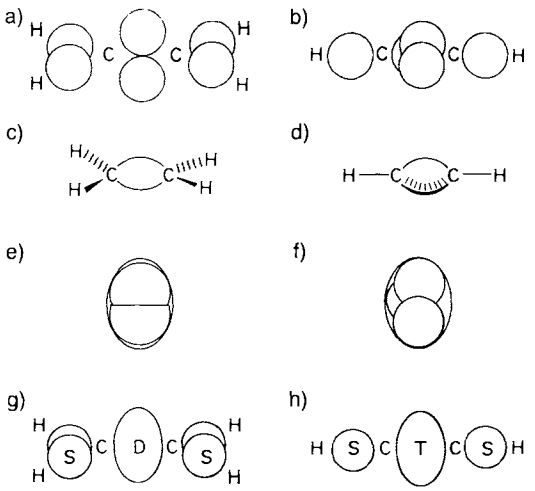

Fig. 9. Representations of the structures of ethene and ethyne. a), b) Electron pair domain models. c), d) Bent bond structural diagrams. e) Prolate ellipsoidal double bond domain formed from two electron pair domains. f) Oblate ellipsoidal triple bond domain formed from three electron pair domains. g) Domain model of ethene showing the AX_3 triangular arrangement of two single bond domains S and a prolate ellipsoidal double-bond domain D at both carbon atoms. h) Domain model of ethyne showing the linear AX_2 arrangement of a single-bond domain S and an oblate ellipsoidal triple-bond domain T at both carbon atoms.

one double bond domain containing four electrons in which the two separate pairs cannot be distinguished (Fig. 9e). The total electron density distribution has an elliptical cross section with a maximum on the CC axis. Figure 9g shows the arrangement of the single and double bond domains giving a planar ethene molecule. Similarly the three single electron pair domains forming a triple bond may be considered to be overlapped to form one six electron triple bond domain (Fig. 9f). Figure 9h shows the arrangement of single and triple bond domains giving a linear ethyne molecule.

The bent bond picture of a double or a triple bond is sometimes criticized, because it appears to suggest that there is an absence of electron density along the bond axis. However, this is an incorrect interpretation of the bent bond model, because bond lines give no indication of the size of the corresponding electron pair domain; in particular they do not show that there is considerable overlap of the bent bond domains to give a double or triple bond domain that has an electron density along the CC axis that is greater than along any other line between the two nuclei. The bent bond model is also sometimes criticized on the grounds that the photoelectron spectrum of ethene shows two ionization energies associated with the double bond, whereas the bent bond model implies that all four of the bond electrons are equivalent. The photoelectron spectrum does not, however, tell us anything about the ground state of ethene but only that, when one electron is removed from the double bond, two states of the ion may be obtained, which can be described as $\sigma^2\pi^1$ and as $\sigma^1\pi^2$. Clearly it is convenient when discussing such spectra to represent the ground state as $\sigma^2\pi^2$, but it is not essential to do so, because a bent bond description, for example one based on sp^3 hybrid orbitals, is essentially equivalent.[15] The bent bond description is, however, not convenient for the ionized state because the unpaired electron is more delocalized than this description permits.

Only the most electronegative atoms attract electrons strongly enough to pull two or three electron pairs into the bonding region against their mutual repulsion so that in the vast majority of multiple bonds at least one of the atoms is C, N, or O. Only a few examples of molecules containing double bonds between third and subsequent period elements exist, because their smaller electronegativity than that of period 2 elements allows the repulsion between the four electrons to produce a larger, more diffuse and hence more reactive domain that is very readily attacked by electrophilic reagents. The only stable examples of such molecules have large bulky groups protecting the double bond from attack, as for example in tetramesityldisilene $(Mes)_2Si=Si(Mes)_2$.

The general shapes of molecules containing multiple bonds can be readily predicted simply on the basis of the number of single, double, triple, and lone-pair domains in the valence shell of any given atom by using the basic rule that the domains share out the space in the valence shell of an atom so as to keep as far apart as possible. So three domains (single, double, triple, or lone-pair) always have a trigonal planar arrangement, four do-

mains a tetrahedral arrangement, five domains a trigonal-bipyramidal arrangement, and six domains an octahedral arrangement. Examples of shapes of molecules containing multiple bonds are given in Figure 10.

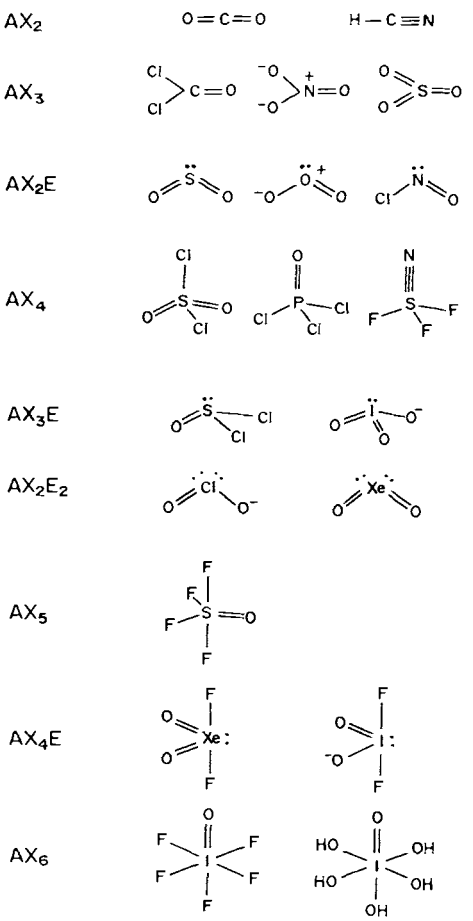

Fig. 10. Shapes of molecules containing multiple bonds.

Qualitative predictions about the relative magnitudes of bond angles in molecules containing multiple bonds can be made on the basis of the relative sizes of the single, double, and triple bond domains. It is clear that a double bond domain must be larger than a single bond domain, and a triple bond domain larger still. For example, in ethene the H-C-C angles that involve the double bond domain are larger (121.3°) than the H-C-H bond angle (117.4°); in SO_2Cl_2 the angle between the two S–O double bonds (123.5°) is much larger than that between the two S–Cl single bonds (100.3°). Other examples are given in Tables 5 and 6.

The larger size of a multiple bond domain compared to a single bond domain also explains the observation that a doubly bonded ligand Y, like a lone pair, always occupies an equatorial site in trigonal-bipyramidal and related molecules, as can be seen from the examples given in Figure 11. Similarly in the case of the pentagonal-bipyramidal seven-coordinated molecule IOF_6^- the doubly bonded oxygen atom occupies a less crowded axial site (Fig. 12).[112] Unlike the IF_7 molecule that is nonrigid and fluxional[111,112] IOF_6^- has a rigid structure, which can be attributed to the resistance of the I–O double bond domain against moving into a more crowded position.[112]

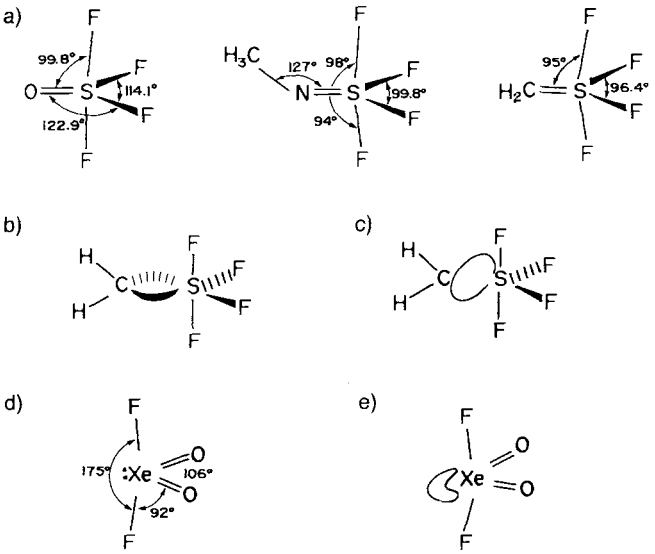

Fig. 11. a) Shapes of some $AX_4=Y$ molecules in which the doubly bonded ligand Y always occupies a less crowded equatorial position. b) Bent bond model of $H_2C=SF_4$ showing that the CH_2 group lies in the axial plane of the SF_4 group. c) Model showing the ellipsoidal double bond domain with its long axis in the equatorial plane of the SF_4 group. d) Structure of XeO_2F_2. e) Illustration of the XeO_2F_2 molecule showing the approximate shape of the xenon lone pair domain.

In interpreting details of molecular geometry it is often important to take into account not only the size of a multiple bond domain but also its shape, which depends on the directions of the other bonds formed by the two bonded atoms. In the common case of a carbon atom forming one double and two single bonds, the double bond domain has a prolate ellipsoidal shape; its long axis is constrained to lie perpendicular to the CX_2 plane to minimize its interaction with the single bond domains. In the ethene molecule the two CH_2 groups are thereby constrained to lie in the same plane, and so the molecule overall is planar (Fig. 9g).

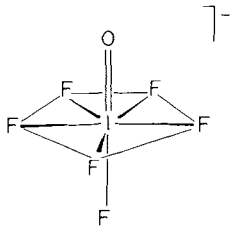

Fig. 12. The double bond domain occupies a less crowded axial position in an $AX_6=Y$ pentagonal bipyramidal molecule such as IOF_6^-.

Another example of the importance of taking into account the shape of a multiple bond domain is seen in the molecules OSF_4 and H_2CSF_4. Here the large size of the SO and SC double bond domains compared to the SF single bond domains causes all the F-S-F angles to be smaller than the ideal angles of 120° and 90° (Fig. 11a). The SC double bond domain is forced by the CH_2 group to have a prolate ellipsoidal shape with its long axis perpendicular to the CH_2 plane (Fig. 11c). To minimize its interaction with the axial SF bond domains, the double bond domain lies in the equatorial plane (with the CH_2 group perpendicular to this plane) so that it decreases the F_{eq}-S-F_{eq} angle from 120° to 96.4°, while it only decreases the F_{ax}-S-F_{ax} angle from 180° to 170°.[16a] Here the bent bond model of the double bond is particularly appropriate (Fig. 11b), as all the angles approach the ideal angle of 90° for an octahedral arrangement of six domains. In contrast the OS double bond domain is not constrained to have an ellipsoidal shape, by any bonds on the oxygen atom so it has an almost cylindrically symmetrical shape. Therefore the SO double bond domain in SOF_4 affects the F_{eq}-S-F_{eq} angle, which is decreased to 114.7°, much less than does the CS double bond in H_2CSF_4, while it has a larger effect on the F_{ax}-S-F_{ax} angle, which is reduced to 160.4°.[9] These conclusions about the shapes of the SO and SC double bonds domains have been confirmed in a study of the Laplacian of the electron density of these molecules (Section 3.2). The shape of the SC double bond domain is also shown to be elliptical in an electron density deformation map of the related molecule $(CF_3)(CH_3)(C{=}SF_4$.[16b]

It is interesting to note that the F-Xe-F angle in the AX_2Y_2E molecule XeO_2F_2 is less than 180° (174.7°) rather than greater than 180° as is normally the case for AX_4E molecules such as SF_4 (Fig. 9f). Because of the large size of the xenon core the lone pair domain is expected to be much more spread out in the equatorial plane than in the axial plane; indeed, while it exerts a strong repulsion on the Xe=O bonds it exerts a weaker repulsion on the Xe–F bond domains than do the Xe=O bond domains. Consequently, the Xe–F bonds bend towards the lone pair and away from the Xe=O bonds.

2.7. Linear Molecules

In linear (cylindrically symmetrical) molecules such as HF and CO_2 there is no requirement that the domains of electrons of opposite spin are brought into coincidence. This was recognized many years ago by Linnett when he formulated the double quartet model.[5] For example, in the HF molecule two electrons of opposite spin are attracted into the bonding region, but the two tetrahedra of electrons of opposite spin are still free to rotate around the bond axis so that the remaining electrons do not form pairs but keep apart due to electrostatic repulsion (see Fig. 13a, b). Similarly in the CO_2 molecule the tetrahedra of electrons of opposite spin are not brought into coincidence and so do not form close pairs (Fig. 13c, d). Rather there are four noncoincident single electron domains forming a cylindrically symmetric double bond (Fig. 13e). Thus the CO_2 molecule can be described as a linear AX_2 molecule in which there is a linear arrangement of two cylindrically symmetric double bond domains. As the electron–electron repulsion in this kind of double bond domain should be less than in an elliptical double bond domain in which the electrons are more closely paired, it is not surprising that the C=O bond in CO_2 (116 pm) is shorter than the standard C=O bond distance (118 pm).

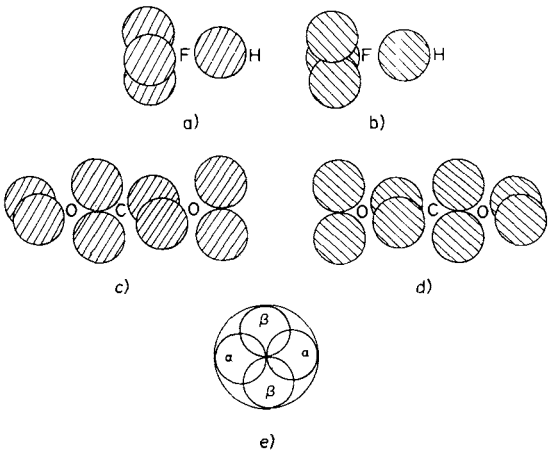

Fig. 13. Domain version of the Linnett double quartet model for the HF and CO_2 molecules: Domains of the α electrons (a) and the β electrons (b) of HF. Domains of the α electrons (c) and the β electrons (d) in CO_2. e) Cross-section of the C–O double bond showing the two α electron domains and the two β electron domains which lead to overall cylindrical symmetry.

3. The Analysis of Electron Density Distributions

The domain model is a very approximate description of the electron density distribution in a molecule and yet a useful tool for the understanding of molecular geometry. But an increasing amount of accurate information about the total electron density in molecules is now forthcoming from X-ray crystallographic studies and from ab initio calculations, and increasing attention is being paid to the analysis of these electron density distributions in an attempt to extract from them the concepts of bonding and nonbonding electron pairs or domains and to improve our understanding of molecular geometry. However, because the electron density changes accompanying bond formation are relatively very small, very accurate low-temperature X-ray crystallographic studies or high-level ab initio calculations are needed to obtain sufficiently accurate electron density distributions to justify a detailed analysis.

At first sight the total electron density distribution provides little information of interest to the chemist, because there is apparently no evidence of the localized pairs of electrons that chemists associate with bonds and lone pairs, as we see, for example, in the illustration of the total electron density of the water molecule in Figure 14. The electron density distribution of a molecule is dominated by the very large electron density close to each nucleus while the electron density in the interatomic regions in which changes in the electron density distribution due to bond formation occur are relatively very small and correspondingly difficult to detect. Bader et al.[17] has shown that the total electron density of a molecule can be partitioned into atomic densities by a rigorous quantum mechanical method and that between any two bonded atoms there is a line, called the bond path, along which the electron density is greater than

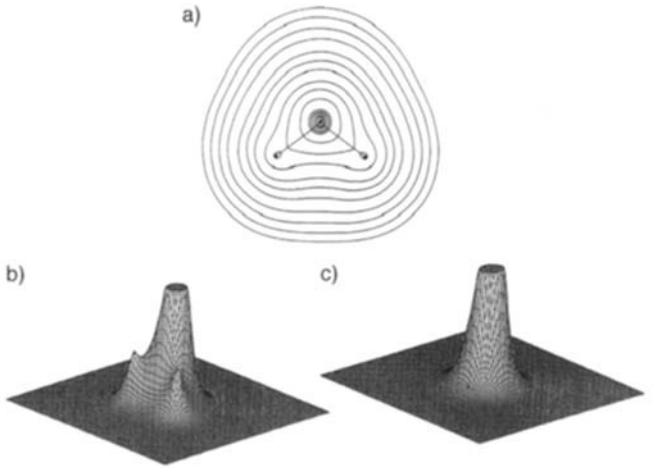

Fig. 14. Electron density distribution in the water molecule. a) Contour map in the plane in which all atoms lie. b) Relief map of the electron density in the plane depicted in (a). c) Relief map of the electron density in the plane through the oxygen atom, perpendicular to the plane depicted in (a) and bisecting the HOH angle.

along any other line between the two nuclei. The bond path appears as a ridge connecting two bonded nuclei in a relief map of the electron density in a plane containing all atoms of the molecule (Fig. 14b). However, there is no indication of bonding or nonbonding electron pairs in these plots of the electron density. There have been several approaches to the problem of analyzing the electron density distribution to provide support for the concept of localized bonding and nonbonding electron pairs. We next consider two of these: the calculation of electron density deformation maps and the analysis of the total electron density in terms of its Laplacian.

3.1. Electron Density Deformation Maps

Electron density deformation maps are obtained by subtracting from the experimental or calculated total electron density of a molecule the density of a promolecule constructed from spherical atoms with the same geometrical arrangement as the actual molecule. In principle such a deformation map should show the changes in electron density that occur on bond formation, and in many cases such maps do show concentrations of electron density in bonding regions and in lone pair regions that correspond to the bond pair and lone pair domains of the VSEPR model. Thus these studies provide some support for the model. An early electron density deformation map is that obtained for the AX_4E molecule $(CH_3)_2TeCl_2$ (Fig. 15a), which clearly shows electron density corresponding to the lone pair.[18] A recent example shows the noncylindrically symmetrical (ellipsoidal) shape of the C=S bond in the molecule $(CF_3)(CH_3)C{=}SF_4$ (Fig. 15b).[16b] However, such deformation maps do not always show the presence of the expected bonding or lone pair densities and there are serious difficulties associated with the construction of an appropriate promolecule.[19] Increasing attention is therefore being paid to other methods for the analysis of the electron density distribution, such as the topological analysis of its Laplacian.

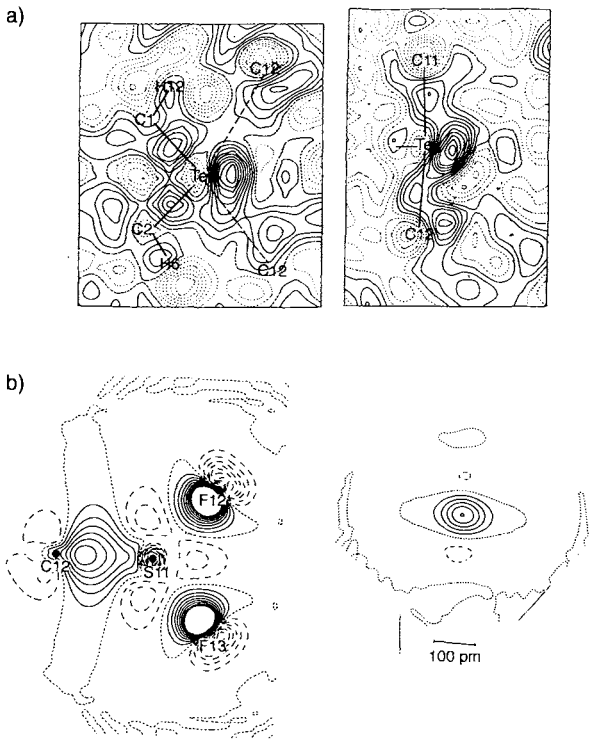

Fig. 15. a) Electron density deformation maps of $Te(CH_3)_2Cl_2$ in the equatorial plane (left) and the axial plane bisecting the angle between the CH_3 ligands (right) showing the deformation density associated with the lone pair. b) Deformation maps of the $(CF_3)(CH_3)C{=}SF_4$ molecule in the FSF equatorial plane (left) and in a plane bisecting the C=S bond showing the anisotropy of the bond corresponding to an ellipsoidal shaped double bond domain.

3.2. The Topological Analysis of the Electron Density and its Laplacian

Bader et al.[17] have shown that the total electron density of a molecule can be usefully analyzed by studying the Laplacian $\nabla^2\rho$ of the electron density ρ, which is given in Equation (a).

$$\nabla^2\rho = \partial^2\rho/\partial x^2 + \partial^2\rho/\partial y^2 + \partial^2\rho/\partial z^2 \quad \text{(a)}$$

This function has the property of magnifying very small variations in the electron density and revealing small local electron density concentrations (charge concentrations) that are not apparent in the total electron density distribution (see appendix). For example, in a free atom there is a continuous decrease in the total density with increasing distance from the nucleus, and there are no maxima and minima in the total electron density corresponding to the successive electron shells. But these shells are revealed clearly in the Laplacian as a local concentration of electron density in the form of a spherical shell surrounded by a spherical region of density depletion (Fig. 16). Although the electron shells in a free atom are also apparent in the radial distribution function, the radial distribution function has no meaning in a molecule. However, the Laplacian of a molecule still reveals the electron shells as regions of concentration and depletion of electron density but distorted by bond formation. In a large number of covalent molecules the valence shell charge concentration exhibits maxima corresponding to each of the bonds and each of the lone pairs expected from the conventional Lewis diagram for the molecule as shown in Figures 17–19 for

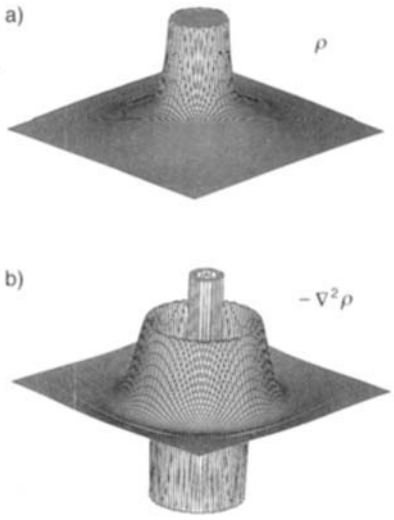

Fig. 16. a) Relief map of the electron density (ρ) in a plane through the nucleus of the argon atom. b) Relief map of the negative Laplacian ($-\nabla^2\rho$) of the electron density in the same plane.

the H_2O, ClF_3 and SF_4 molecules.[17a] Moreover, these local charge concentrations have the same locations and the same relative sizes as the electron pair domains of the VSEPR model.

In the valence shell of the oxygen atom in the water molecule there are charge concentrations in an approximately tetrahedral arrangement that correspond to two bonding and two nonbonding (lone pair) domains of the VSEPR model. Similarly the valence shell of the chlorine atom in ClF_3 contains three bond-

In the valence shell of the oxygen atom in the water molecule there are charge concentrations in an approximately tetrahedral arrangement that correspond to two bonding and two nonbonding (lone pair) domains of the VSEPR model. Similarly the valence shell of the chlorine atom in ClF_3 contains three bonding and two nonbonding charge concentrations in a trigonal-bipyramidal arrangement. And in the valence shell of sulfur in SF_4 the four bonding and one lone pair charge concentration

Two of the maxima in the valence shell charge concentration of O in a) are bonding charge concentrations. The third apparent maximum in a) is the saddle between the two maxima observed in b) that are nonbonding (lone pair) charge concentrations.

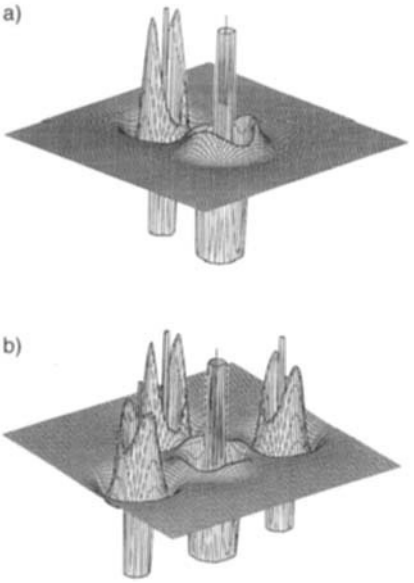

Fig. 18. Relief map of $-\nabla^2\rho$ for the mirror planes σ_v' (a) and σ_v (b) of the ClF_3 molecule. In a) the three maxima in the valence shell of Cl correspond to two nonbonding charge concentrations and a nonbonding (lone pair) charge concentration. In b) three bonding charge concentrations can be seen. The fourth apparent maximum represents the saddle between the two nonbonding maxima in a).

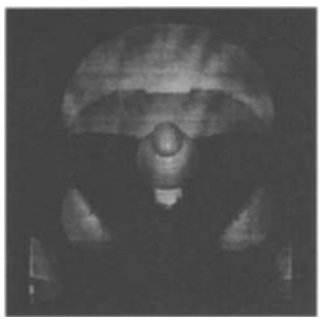

Fig. 19. Isosurface of the Laplacian distribution of the sulfur atom in SF_4, showing a large charge concentration for the lone pair two small charge concentrations for the bonding equatorial electrons, and two still smaller charge concentrations for the axial bonding electrons surrounding a spherical core. Parts of the valence shell charge concentrations of the equatorial fluorine atoms are seen in the lower corners.

are in a trigonal bipyramidal arrangement. Moreover, the Laplacian provides confirmation (Fig. 20) of the increasingly

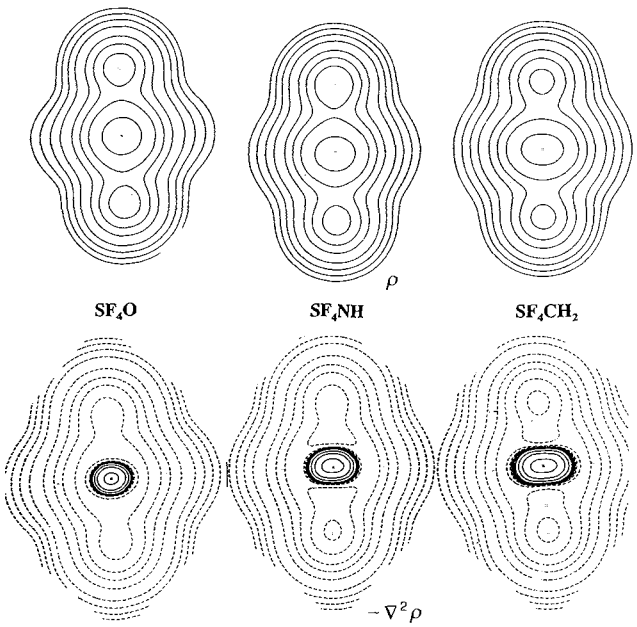

Fig. 20. Contour plot of the electron density ρ (top) and of $-\nabla^2\rho$ (bottom) in a plane through the maximum of $-\nabla^2\rho$ for the double bond in $O=SF_4$, $HN=SF_4$, and $H_2C=SF_4$ showing the increasing ellipticity of the double bond.

elliptical shape of the double bond domain in the series $O=SF_4$, $HN=SF_4$, and $H_2C=SF_4$ that we discussed in Sections 2.2 and 2.5.[9]

The Laplacian therefore provides evidence that the domain version of the VSEPR model has a real physical basis. Although electrons are not as localized into pairs as the domain model depicts them, local concentrations of electron density nevertheless correspond to and have the same properties of relative size and shape as, both bonding and nonbonding electron pair domains.

4. Exceptions to the VSEPR Model

As we have seen in the preceding sections the VSEPR model accounts very successfully for the general shapes of the molecules of the main group nonmetals and also in a qualitative way for deviations of the bond angles from the "ideal" values. However, certain exceptions to the predictions of the model have been recognized, particularly among metal–nonmetal molecules. The rest of this review is concerned with these exceptions, real or apparent. Because the model is so successful in many cases, it is worthwhile examining the exceptions in an attempt to discover why the model breaks down in some cases. In this way we can hope to improve our understanding of bonding and to see if the VSEPR model can be appropriately modified to cover the apparent exceptions. First we discuss exceptions among the main group elements.

4.1. AX_5 Molecules

Although the trigonal bipyramid with longer axial than equatorial bonds is the preferred structure, the energy of the square pyramid is only slightly higher, as is shown, for example, by the fact that it is the transition state in the Berry pseudorotation of a trigonal-bipyramidal molecule. PX_5 and AsX_5 molecules all have the expected trigonal-bipyramidal structures with longer axial than equatorial bonds, as do most SbX_5 molecules. Examples are $SbCl_5$, $Sb(CH_3)_5$,[20a] and also $Bi(CH_3)_5$.[20b] In contrast, $Sb(C_6H_5)_5$[21a] and $Bi(C_6H_5)_5$[21b] in the solid state have structures that can best be described as square pyramids, although they both are somewhat distorted towards trigonal-bipyramidal geometry. However, the closely related molecules $Sb(p\text{-}CH_3C_6H_4)_5$ and $Bi(o\text{-}FC_6H_4)_5$ are trigonal-bipyramidal in the solid state, although the latter exists as an equilibrium mixture of both trigonal-bipyramidal and square-pyramidal molecules in solution.[22] It is clear that the energy difference between the trigonal-bipyramidal and square-pyramidal structures is very small; moreover, it is to be expected that the difference in energy between the two structures will decrease with the decreasing interaction between the bonding domains as the size of the central atom increases, so it is not surprising that it is essentially zero for $Bi(o\text{-}FC_6H_4)_5$. It seems clear therefore that because of the very small energy difference between the trigonal-bipyramidal and square-pyramidal structures of AX_5 molecules, solid-state effects cause the square pyramid to be the preferred structure in a few molecules of antimony and bismuth.

4.2. Stereochemically Inactive Lone Pairs

As we have mentioned, $SeCl_6^{2-}$ and the other AX_6E molecules listed in Table 7 are exceptions to the duodecet rule: they appear to have seven electron pairs in the valence shell of the central atom whereas six is the maximum number normally observed.

Table 7. Bond lengths in some AX_6E ions with octahedral geometry.

Ion	Bond length [pm] obs.	calcd [a]	difference [%] [b]	Ref.
$SnCl_6^{4-}$	283	239	18.4	[164]

BrF_6^-	185	168 [c]	10.1	[25]

[a] Sum of covalent radii r_{cov}. [b] Observed/calculated ratio. [c] $r_{cov}^{Br} + r_{cov}^{F} = (114 + 54) = 168$ pm, where the covalent radius of fluorine has the value of 54 pm as we suggested recently [178].

They are also exceptional in another sense: they appear to have regular octahedral structures, so the lone pair is said to be stereochemically inactive or to be an "inert pair".[23] However, the experimental evidence on the structures of these molecules is not always clear: For solid state structures disorder in the crystal may lead to an average octahedral structure and in solution the spectroscopic evidence for an octahedral structure is not always unambiguous.[24] In solution some of the molecules may appear to be octahedral because they have fluxional non-octahedral structures. However, it seems certain that some of these molecules have octahedral structures. Apparently in these cases either the valence shell electron pairs and/or the ligands would be too crowded if the valence shell contained seven electron pair domains. So the lone pair is forced inside the six bond domains to occupy a spherical domain surrounding the core. This explanation is given some support by the observation that the bonds in these molecules are unusually long (Table 7).

That crowding of the electron pairs in the valence shell of the central atom is important in determining the octahedral structures of some AX_6E molecules is supported by the observations that, although the BrF_6^- ion has an octahedral structure,[25] both IF_6^-[26] and XeF_6[27] with larger cores and therefore less crowding of the electron pair domains have monocapped octahedral structures with the lone pair in the capping position. But if the crowding of the electron pairs in the valence shell of xenon is increased as in the XeF_8^{2-} ion,[28] which is an AX_8E molecule, the lone pair again becomes "inert", because this ion has the square antiprismatic structure expected for an AX_8 molecule, just like IF_8^-. That the Xe–F distances are longer than the I–F distances in IF_8^- again suggests that the lone pair occupies an inner spherical domain.

4.3. "Ionic" Molecules

Molecules of the type OX_2E_2 are expected to be angular with bond angles smaller than the tetrahedral angle. Although this is the case in H_2O and F_2O, for example (Table 2), in other molecules of this type such as $(SiH_3)_2O$ and $(GeH_3)_2O$ the bond angles are 144° and 126°, respectively, and in Li_2O and Na_2O the bond angles are 180°. The VSEPR model rests on the assumption that the ligands X in an AX_n molecule attract the electrons of the central atom A sufficiently strongly to form relatively well localized pairs. This is the case when X has an electronegativity that is comparable to, or greater than, the electronegativity of A, for example when the ligands are F, =O, or OH, and so such molecules always have the VSEPR-predicted geometry. However, when the ligands are less electronegative than the central atom, the electrons on A are not well localized into pairs. In an extreme case such as Na_2O, there is little localization of the electrons in the oxygen valence shell; consequently the molecule can be described as consisting of a slightly distorted oxide ion and two sodium ions. In such a case ligand–ligand repulsions dominate to give a linear molecule. Many ligands are less electronegative than oxygen, and in such cases we expect the bonds to have considerable ionic character and the oxygen electrons to be only poorly localized giving bond angles larger than the tetrahedral angle. For example, the charges on oxygen and silicon in $(SiH_3)_2O$ have been found from ab initio calculations[28a] to be −1.7 and +3.1, respectively, the molecule has considerable ionic character consistent with the large bond angle. The analogous $(CH_3)_2O$ molecule has a bond angle of 112°, which is slightly larger than 109°, consistent with the smaller electronegativity difference between oxygen and carbon than between oxygen and silicon and the smaller ionic character of the C–O bonds. In general, the VSEPR rules only apply when the ligands have an electronegativity that is comparable to that of the central atom with the result that the bonds are predominately covalent.

5. Metal–Nonmetal Molecules

The largest number of apparent exceptions to the VSEPR model are found among molecules of the metals, including the transition metals. For this reason and because the bonds in many metal–nonmetal molecules are predominantly ionic, it is widely believed that the model does not apply to these molecules, although it was shown over twenty years ago that, if distortion of the core of the metal atom to a nonspherical shape is taken into account, many of these exceptions can be accounted for.[1] Recent studies of the Laplacian of the core electron density in several metal–nonmetal molecules have given support to this view and provided important information on the nature of the core distortion. We review this recent work in this section.

5.1. The Alkaline Earth Dihalides and Related Molecules

It was suggested some time ago[29] that polarization of the metal atom core in the alkaline earth dihalide molecules by the halide ligands could account for the angular shape of some of the alkaline earth dihalides in the gas phase, although a simple electrostatic model for an ionic molecule and the VSEPR model for a covalent molecule would both predict a linear geometry. For CaF_2 it was later proposed[1,2] that, if the molecule is considered to be predominately ionic, the interaction of the negatively charged fluorine ligands with the polarizable Ca^{2+} core would cause the eight electrons of the outer shell of the core to become partially localized to form four tetrahedrally oriented pairs, hence giving the core a nonspherical shape. According to this model the negatively charged ligands tend to adopt the arrangement that places them opposite two of the faces of this tetrahedron, so as to minimize their interaction with these four partially localized electron pairs (Fig. 21c). Thus, if the core is sufficiently polarized an MX_2 molecule will have an angular rather than a linear geometry (Fig. 21a, b). According to this model the bond angle would be expected to decrease from 180° with increasing polarizability of the metal, that is from Be to Ba, and with increasing polarizing power of the ligand from I to F, as is observed (Table 8).

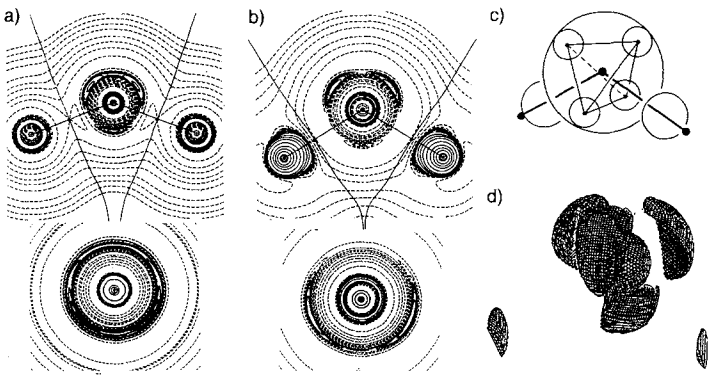

Fig. 21. Structures of the alkaline earth dihalides a) Contour maps of $-\nabla^2\rho$ for SrF_2 in the plane of the molecule (top) and perpendicular to this plane and bisecting the F-Sr-F angle (bottom). b) Contour maps of $\nabla^2\rho$ for BaH_2 in the plane of the molecule (top) and perpendicular to this plane and bisecting the H-Ba-H angle (bottom). c) Model originally proposed to explain the angular shape of the CaF_2 molecule showing four tetrahedrally arranged partially localized electron pairs. d) Three-dimensional plot of an isosurface of $-\nabla^2\rho$ for BaH_2 showing the four charge concentrations in the outer shell of the core surrounding the spherical inner core.

Table 8. Bond angles [°] of halides of Group II in the gaseous phase [2].

MX_2	X = F	Cl	Br	I
BeX_2	180	180	180	180
MgX_2	180	180	180	180
CaX_2	133–155	180	173–180	180
SrX_2	108–135	120–143	133–180	161 180
BaX_2	100–117	100–127	95–135	102–105

Ab initio calculations have likewise shown that the dihalides and the dihydrides of Ca, Sr, and Ba should have an angular shape,[30a,b] and the total electron densities obtained from these calculations have been analyzed in terms of their Laplacians. Although the Laplacian of the calculated electron density of each of the fluorides and hydrides of Ca, Sr, and Ba, and of $Ca(CH_3)_2$, does not display a valence shell charge concentration, presumably because of the ionic nature of the molecules, in

each case it does show that the outer shell of the core is nonspherical with four approximately tetrahedrally arranged charge concentrations (Fig. 21).[30b] Two of these core charge concentrations (CCs) are on the opposite side of the core from the ligands. These CCs arise from the repulsion of the core electrons by the ligands, while the other two charge concentrations arise from the operation of the Pauli principle. Thus the model proposed earlier is fully confirmed by the Laplacian of the electron density. The formation of four charge concentrations in the outer shell of the core of the metal in these molecules is analogous to the formation of four charge concentrations in the valence shell of the oxygen atom in the water molecule. In the water molecule it is the *attraction* of the hydrogen nuclei for electrons combined with the Pauli principle that determines the formation of two bonding charge concentrations and two nonbonding charge concentrations. In contrast in the BaF_2 molecule, for example, it is the *repulsion* of the core electrons by the fluoride ion ligands that causes the formation of four charge concentrations in the outer shell of the core; the fluoride ions adopt positions opposite the "holes" between the charge concentrations thus giving an angular molecule.

It is reasonable to suppose that the bent structure of bis(pentamethylcyclopentadienyl)calcium[31] is similarly due to distortion of the calcium core by the ligands.

5.2. Compounds of d^0 Transition Metals

It has usually been assumed that the VSEPR model does not apply to compounds with transition metals and most recent discussions of the shapes of such molecules have been based on the molecular orbital (MO) model. Nevertheless, the VSEPR model does apply to many molecules containing transition metals, although the number of exceptions is rather large. The application of the VSEPR model to transition metal atoms is, at first sight, straightforward as the lack of nonbonding electrons in the valence shell of the metal yields no other predicted shapes than the AX_2, AX_3, ... AX_n shapes. As a consequence, the predicted shapes are completely independent of the ionic character of the bonds; the packing of negative ions around a central positive ion and the packing of electron pair domains in the valence shell of the central atom give the same shapes. However, even some d^0 metal molecules have nonVSEPR shapes. We will now see that these shapes may be accounted for by the distortion of the core by the ligands (as we have seen for the group 2 halides and hydrides) and that this core distortion has been confirmed in some cases by studies of the Laplacian of electron density of the core of the metal atom.

5.2.1. MX_3 Molecules

The calculated structures of ScH_3, TiH_3^+ and $Ti(CH_3)_3^+$ are pyramidal[32, 33] rather than planar. This pyramidal structure is consistent with the formation of a tetrahedral arrangement of charge concentrations as in BaH_2. The pyramidal geometry of these molecules then results from the ligands' occupying positions opposite the "holes" between these CCs (Fig. 22). This conclusion awaits conformation by the study of the Laplacian of the electron density.

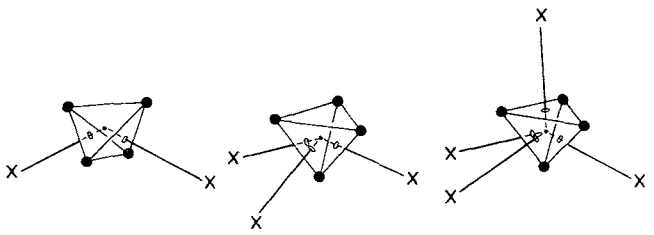

Fig. 22. Diagrammatic representation of the effect of four tetrahedral core charge concentrations on the structures of MX_2, MX_3, and MX_4 molecules (M is a polarizable metal atom) giving angular, pyramidal, and tetrahedral molecules respectively.

5.2.2. MX_4, MX_3Y, MX_2Y_2, and MX_3Z Molecules

Four ligands are expected to produce four core CCs. If the ligands have a tetrahedral arrangement they will be opposite the holes between these CCs, and so no distortion of the VSEPR-predicted tetrahedral geometry is expected (Fig. 22). All MX_4 molecules with a central d^0 transition metal atom have been found to have the regular tetrahedral structure, including the tetrahalides of Ti, Zr, and Hf, all the MO_4^n ions, and the tetraoxides RuO_4 and OsO_4. The tetrahedral structure of TiH_4 has been shown by calculation to be a local minimum, and it is also very probably a global minimum.[34] All MX_3Y, MX_2Y_2,

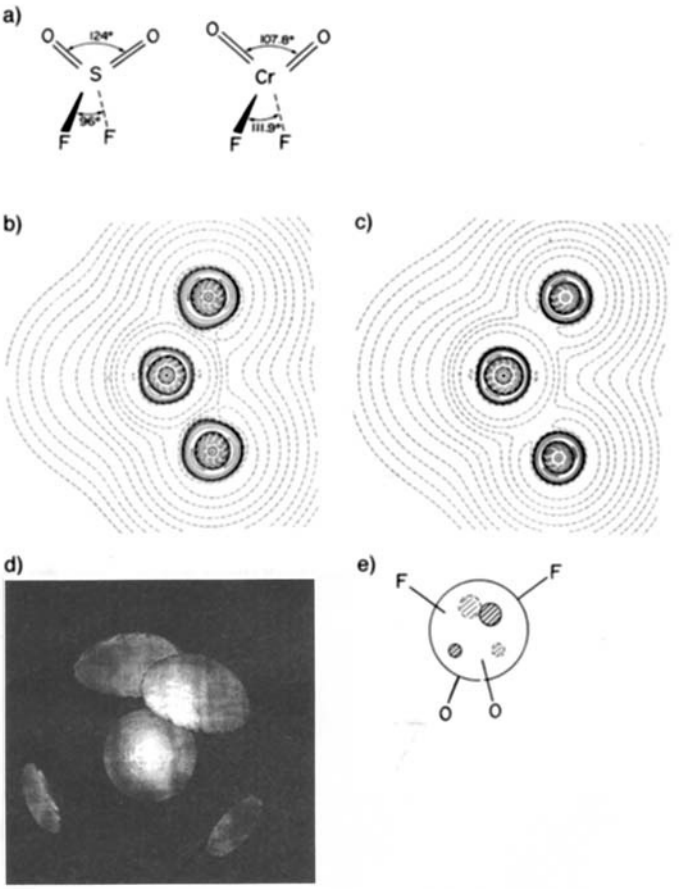

Fig. 23. a) Structural parameters of the SO_2F_2 and CrO_2F_2 molecules. b)–e) Details for CrO_2F_2: Contour map of $-\nabla^2\rho$ in the OCrO plane (b) and the FCrF plane (c). Three-dimensional plot of an isosurface of $-\nabla^2\rho$ for the core of the Cr atom (d) showing four charge concentrations, two larger concentrations opposite the O atoms and two smaller concentrations opposite the F atoms, surrounding a spherical inner core. Diagrammatic representation of CrO_2F_2 molecule (e) showing the ligands and the core charge concentrations.

and MX_3Z molecules such as VOF_3, $VOCl_3$, $MoNF_3$, CrO_2F_2, CrO_2Cl_2, and WNF_3 also have a tetrahedral geometry, although the bond angles are distorted in an unexpected way from the ideal tetrahedral angle.[2] For example, in CrO_2F_2 and CrO_2Cl_2 the O=Cr=O angles are smaller than the tetrahedral angle, whereas in an analogous molecule with a central main group element such as SO_2F_2 this angle is, as expected, larger than the tetrahedral angle (Fig. 23a). The Laplacian of the electron density[35] shows no valence shell charge concentration but charge concentrations in the outer shell of the core opposite each ligand; those opposite the oxygen ligands are larger than those opposite the halogen ligands (Fig. 23b–d). Interaction of the double bond domains with these larger charge concentrations reduces the O=Cr=O bond angle allowing the F-Cr-F angle to increase (Fig. 23e). Similarly in $VOCl_3$ the O-V-Cl bond angles are smaller than tetrahedral, whereas in $POCl_3$ the O-P-Cl angles are larger than tetrahedral as expected because of the large size of the P–O double bond domain. In this case also, a large charge concentration is found in the outer shell of the core opposite the oxygen atom, which tends to open up the Cl-V-Cl angles and thereby reduce the O-V-Cl angles (Fig. 24).[36] A similar situation is observed in the calculated structures of $MoNF_3$ and WNF_3, where the N-Mo-F (104.5°) and N-W-F (105.8°) angles are smaller than the tetrahedral angle, and large CCs are observed opposite the triply bonded nitrogen atom.[37]

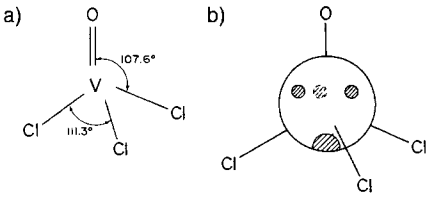

Fig. 24. a) Structural parameters and b) location of the core charge concentrations relative to the ligands in the $VOCl_3$ molecule.

5.2.3. MX_5 and MX_4Y Molecules

The known pentahalides of V, Nb, and Ta all have the geometry predicted by the VSEPR model: trigonal-bipyramidal with longer axial than equatorial bonds. However, $Ta(CH_3)_5$ has square-pyramidal geometry,[20a] and the calculated structures of $Ta(CH_3)_5$ and the hypothetical molecules VH_5, $V(CH_3)_5$, and TaH_5 are also square-pyramidal.[38]

The Laplacian of the electron density has been studied for VF_5, VH_5, and $V(CH_3)_5$. In each case there is no valence shell charge concentration but there are five ligand opposed charge concentrations in the outer shell of the core (Fig. 25).[35] In the trigonal-bipyramidal VF_5 model the equatorial fluorine ligands are opposite holes in the core but the axial fluorine ligands are opposite charge concentrations, whereas in the square-pyramidal VH_5 and $V(CH_3)_5$ molecules all the ligands are opposite holes in the core. The interaction of the ligands with the core charge concentrations would be expected to increase the energy of the trigonal-bipyramidal structure relative to that of the square pyramid. So if the interaction of the ligands with the core is sufficiently great, the square pyramidal structure will be stabilized with respect to the trigonal bipyramid. Thus the more

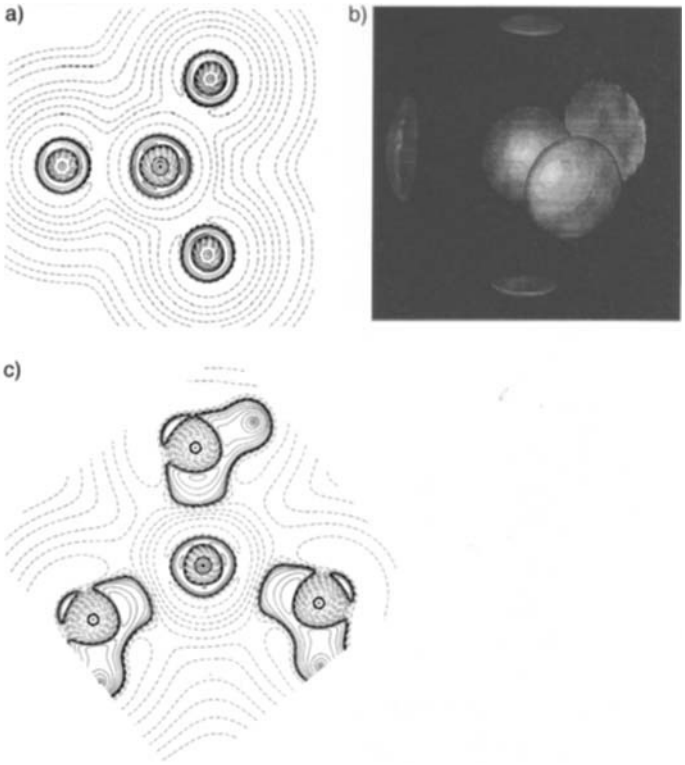

Fig. 25. a) Contour map of $-\nabla^2\rho$ in the equatorial plane of the trigonal-bipyramidal VF_5 molecule. b) Isosurface of $-\nabla^2\rho$ for the core of the vanadium atom in VF_5, showing five ligand opposed charge concentrations surrounding the inner spherical core. c) Contour map of $-\nabla^2\rho$ for the plane through the C_4 axis of the square planar $V(CH_3)_5$ molecule containing two basal and the axial CH_3 groups.

covalently bound ligands such as -H and $-CH_3$ stabilize the square pyramid structure as in VH_5, TaH_5, and $Ta(CH_3)_5$, whereas the less covalently bound halide ligands, such as the halogens, do not perturb the core sufficiently to make this the preferred structure, and the VSEPR-predicted trigonal-bipyramidal structure is retained in molecules such as VF_5.

All the known $(d^0\text{-}M)X_4Y$ molecules such as $CrOF_4$, $MoOF_4$, and $WSCl_4$ have square-pyramidal structures[2] rather than the expected trigonal-bipyramidal structure of the analogous SOF_4 molecule. The Laplacian of the electron density of $CrOF_4$ and $MoOF_4$[35] shows that, as in VF_5, there is no valence shell charge concentration but in each case the core has five CCs in a square-pyramidal arrangement. The CC produced by the doubly bonded oxygen is larger than those produced by the singly bonded F ligands (Fig. 26a–c). This large charge concentration produced by oxygen is responsible for stabilizing the square pyramidal structure with respect to the trigonal bipyramidal structure (Fig. 26). The structures of these square-pyramidal MX_4Y molecules of transition metals bear a noteworthy similarity to the square pyramidal AX_5E molecules of the main group elements, such as BrF_5, in which the nonbonding electron pair E occupies a position in the base of the square pyramid completing an octahedral arrangement of six valence shell domains. The large charge concentration opposite the oxygen in $MoOF_4$ and $CrOF_4$ behaves like a lone pair in that it distorts the trigonal bipyramid to a square pyramid. But as we might expect, the distortion is less than that caused by the lone pair in an AX_5E molecule; the X_b-A-X_a angles in the square-pyramidal

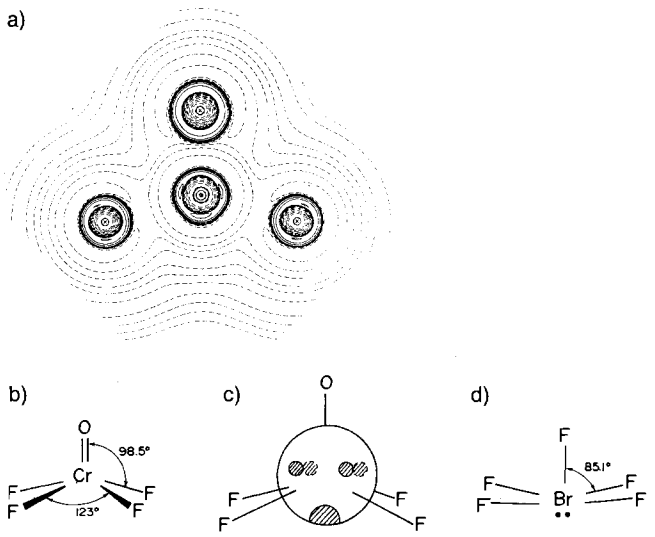

Fig. 26. a) Contour map of $-\nabla^2\rho$ in a vertical plane containing two basal atoms of the square-pyramidal $CrOF_4$ molecule. b) Structural parameters and c) arrangement of the Cr core charge concentrations relative to the ligands in $CrOF_4$. d) Shape of the BrF_5 molecule.

molecules of transition metals are greater than 90° whereas in the AX_5E molecules they are smaller than 90° (Fig. 26d).

In all cases that have been studied so far a doubly bonded ligand such as oxygen distorts the core more than a singly bonded ligand such as fluorine or chlorine. Moreover, it appears from the Laplacian of the calculated electron densities of nitrido complexes such as $MoNF_3$ and $MoNF_4^-$ that the triply bonded nitrogen atom perturbs the metal atom core even more strongly than a doubly bonded oxygen atom.[37] So $MoNF_4^-$ has a square pyramidal structure like $MoOF_4$.

5.2.4. MX_6 Molecules

Two structures have been found for MX_6 molecules of d^0 transition metals—the VSEPR-predicted octahedron for CrF_6, MoF_6, WF_6, WCl_6, WBr_6, TiF_6^{2-}, $ZrCl_6^{2-}$, $W(NMe_2)_6$, and $W(OMe)_6$[38] and the trigonal prism for WMe_6,[39] and $ZrMe_6^{2-}$.[40] The Laplacian of the electron density of the metal atom core in CrF_6 has six LOCCs in an octahedral arrangement, so each ligand is opposite a charge concentration (Fig. 27).[35] The Laplacian of the electron density has not been calculated for either WMe_6 or $ZrMe_6^{2-}$, but it has been calculated for an assumed trigonal prismatic structure for $CrMe_6$ (Fig. 27b, c).[35] Five LOCCs were found in a trigonal bipyramidal arrangement with each ligand opposite one of the six faces of the trigonal bipyramid—that is, opposite holes in the charge density of the core. Apparently, interaction between the fluorine ligands and the core is not strong enough to modify the VSEPR-predicted octahedral structure of CrF_6, but for $CrMe_6$ the stronger interaction of the methyl ligand distorts the Cr core more strongly and causes the change to the trigonal prism in which the interaction between the ligands and the LOCCs is minimized.[35]

On the basis of an accumulating number of examples it seems reasonable to conclude that the cores of metal atoms are distorted by the ligands acting in conjunction with the Pauli principle to form a number of charge concentrations. These charge concentrations have an arrangement that minimizes their mutual

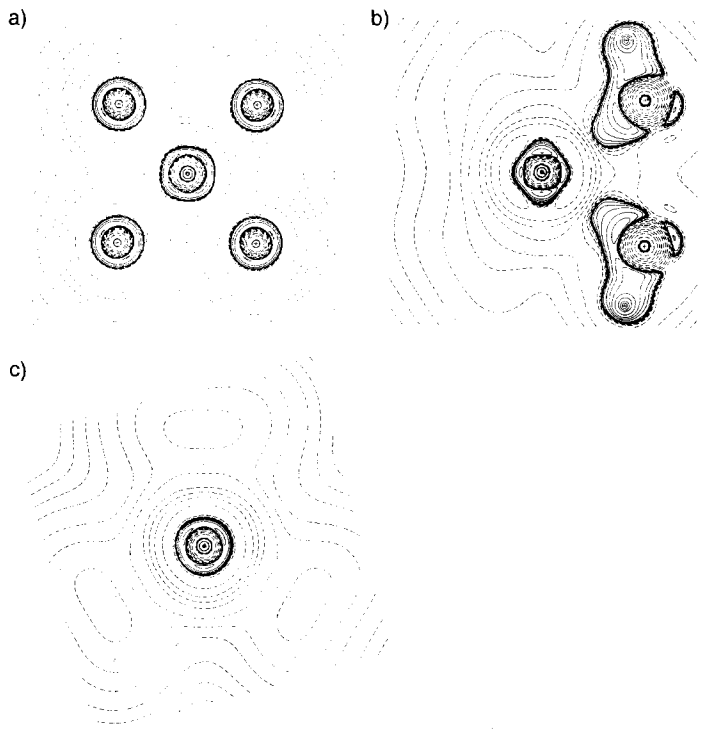

Fig. 27. Contour map of $-\nabla^2\rho$ in an equatorial plane of the octahedral CrF_6 molecule. b) Contour map of $-\nabla^2\rho$ in a vertical plane containing a C_2 axis of the trigonal-prismatic $Cr(CH_3)_6$ molecule. c) Contour map of $-\nabla^2\rho$ for the horizontal symmetry plane of $Cr(CH_3)_6$.

interaction: four CCs have a tetrahedral arrangement, five a trigonal-bipyramidal or square-pyramidal arrangement, and six an octahedral arrangement. Ligands that interact sufficiently strongly with the core of the metal atom (in particular $-H$, $-CH_3$, and $=O$ in the case of transition metals, and F, H, and CH_3 in the case of the more polarizable group 2 metals) adopt a geometry that in some cases differs from the VSEPR-predicted geometry, in which they occupy sites opposite the "holes" in the core between the CCs and which therefore minimizes their interaction with these CCs while it does not greatly increase the ligand–ligand interactions. The geometry of molecules containing ligands that interact only weakly with the core, for example F in the case of the transition metals, is dominated by the interactions between the bonding electron pairs or the ligands, so they have the expected VSEPR geometry. Moreover, it appears that the more strongly covalently bonded ligands induce a larger distortion of the core electrons. For example, in the series ScH_6^{3-}, TiH_6^{2-}, VH_6^-, CrH_6, MnH_6^+, ab initio calculations[33] have shown that for the more ionic molecules ScH_6^{3-} and TiH_6^{2-} the octahedral structure has a lower energy than the trigonal prismatic structure, whereas the trigonal prism has the lower energy for the more covalent VH_6^-, CrH_6, and MnH_6^+ molecules. Further studies are needed before these hypotheses can be fully confirmed.

5.3. Compounds with d^1–d^{10} Transition Metals

It seems clear that the shapes of molecules containing non-transition metal and d^0 transition metal centers are distorted from the VSEPR-predicted shapes by the interaction between

the ligands and a distorted (nonspherical) core of the metal's electrons. So it is reasonable to assume that the shapes of compounds with d^1-d^{10} transition metal centers will also be determined by the shape of the metal atom's core. Indeed, if it is assumed, as a rough first approximation, that an incompletely filled d shell (d^1-d^9) has either a prolate or oblate ellipsoidal shape, the geometry of many such molecules can be accounted for.[2] For example, a prolate ellipsoidal core can result in a square-planar AX_4 molecule, a square-pyramidal AX_5 molecule, and a square-bipyramidal molecule (D_{4h}).

A preliminary study of the Laplacian of the electron density of molecules with transition metal centers with incomplete d shells has been reported by MacDougall and Hall.[41] As yet there have been too few similar studies to enable any general conclusions to be drawn about the influence of the core on the shapes of these molecules. Laing[42] has drawn attention to the striking fact that molecules with transition metal centers that obey Sidgwick's effective atomic number rule[43] (in which, therefore, the metal atom has a total of 18 bonding and nonbonding electrons in its outer shell) always have the predicted VSEPR geometry. No simple and general explanation of Sidgwick's rule has yet been proposed, but it seems reasonable to suppose that further studies of the electron density distribution of the core of the metal atom will eventually lead to a much better understanding of how the shape of the core modifies the VSEPR-predicted geometry for all molecules containing transition metals. And it seems reasonable to hope that a modified VSEPR model can be developed that will prove as useful for transition metal molecules as the original model has been for nonmetal molecules.

6. Conclusions and Pedagogical Considerations

The VSEPR model, particularly when formulated in terms of electron pair domains, continues to be the most useful and most easily used model for the qualitative prediction of molecular shape. It enables us to understand in a qualitative way many features of the structures of molecules that are not readily accounted for in other ways, and it continues to form the basis for the discussion and understanding of the structures of many new molecules. Its physical basis rests on the Pauli principle, and it is independent of any orbital model. It thus provides a useful alternative to the familiar valence bond and molecular orbital methods that can also give us useful new insights into molecular geometry.

Elementary treatments of bonding and molecular geometry are almost always based on hydrogen-like atomic orbitals. It is commonly stated at this level that "an orbital may be thought of as a region of space where there is a high probability of finding an electron". An orbital is often pictured as a charge cloud of varying density. The shapes of s, p, and sometimes d orbitals are then described—usually in a very approximate manner—but are not derived, explained, or otherwise accounted for. A bond in this model is considered to be a "merging or overlapping of the orbitals of the bonded atoms to create a charge cloud that spreads over and between the nuclei and binds them together." Because atomic orbitals are not suitable as a basis for this type of description of many molecules including those of carbon, the concept of hybrid orbitals is introduced, and the hybrid orbitals are chosen to match the observed geometry. Again the mathematical operation of forming hybrid orbitals cannot be explained at the introductory level, and the conventional diagrams of these hybrid orbitals give the incorrect impression that hybridization of a set of atomic orbitals to give a set of hybrid orbitals is a physical phenomenon that results in a change in the total electron density of the atom. Not only does this conventional introductory treatment give no explanation of molecular geometry, it introduces incorrect, or at least very misleading, ideas. In contrast the domain version of the VSEPR model provides a straightforward and readily understandable picture of the chemical bond, while at the same time leading directly to an explanation of molecular geometry without giving incorrect or misleading descriptions of quantum mechanical concepts that cannot be adequately dealt with at the introductory level.

Good quantitative predictions of molecular shape can be made by ab initio molecular orbital calculations for many molecules, but because of the complexity of the large set of basis functions (modified atomic orbitals) used in these calculations they provide little understanding of the factors that determine molecular shape. However, from these calculations, as well as from very careful, low-temperature X-ray crystallographic studies we can obtain a rather accurate map of the electron density distribution in a molecule; from its analysis we may hope to obtain a better understanding of bonding. It is particularly important to derive more electron density distributions from low-temperature X-ray crystallographic studies to confirm the results of ab initio calculations. It is also important to note that the electron density distribution of a molecule is an observable property of the molecule that is independent of the particular experimental or theoretical method used to determine it, provided that it is determined with sufficient accuracy. It is therefore incorrect to claim, as has sometimes been done, that the analysis of an electron density distribution obtained by ab initio calculations using the molecular orbital method cannot yield any more information than is provided by a molecular orbital description of the molecule.

The analysis of the electron density distribution in terms of its Laplacian has been particularly fruitful. The Laplacian of the electron density of molecules containing the main group nonmetals shows that the local concentrations of electron density correspond rather closely in location, size, and shape to the electron pair domains of the VSEPR model, thus giving substantial support to the model, which can be regarded as giving a very crude but nevertheless useful picture of the valence shell electron density distribution in a molecule. Moreover, the study of the Laplacian of the electron density provides considerable insight into the reasons why certain molecules appear to be exceptions to the VSEPR model. In particular it has been shown that it is important to take into account not only the relative sizes of lone pairs and multiple bonds but also their shapes. A basic assumption of the VSEPR model, namely that the core of an atom is spherical and therefore has no effect on the arrangement of the surrounding ligands appears to be true for the compounds of nonmetals, but recent studies of the Laplacian of the cores of metal atoms in their molecules show that they often have nonspherical cores, which do affect the geometry of the

molecule. Even though we cannot yet predict the shapes of molecules with transition metal centers with certainty in all cases, it is clear that the nonspherical shape of the core is an important factor that must be taken into account. Further studies of the shapes of the cores of molecules containing transition metals are needed to give us a better understanding of their geometries and to enable us to extend the VSEPR model to such molecules.

R. J. G. thanks Trevellyan College, University of Durham (UK) for the award of a fellowship in 1994, which enabled him to write the first draft of this article, and Professor K. Wade for fruitful discussions and useful comments.

Appendix: The Laplacian of the Electron Density

The Laplacian of a function $[\nabla^2 f(x,y,z)]$ is the second derivative of this function of x, y, and z. To understand, in an approximate way, how the Laplacian of the electron density distribution of a molecule ($\nabla^2\rho$) reveals features that are not readily apparent in the total electron density, we consider the derivatives of a one-dimensional function such as that shown in Figure 28. This function might represent the radial behavior of the

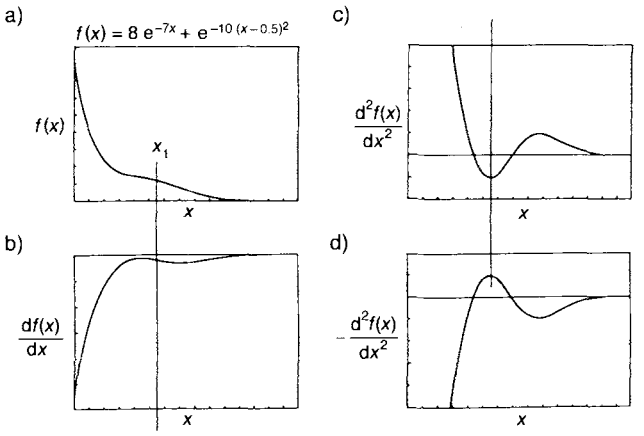

Fig. 28. a) The function $f(x) = 8e^{-7x} + e^{-10(x-0.5)^2}$, b) its first derivative $f'(x)$, c) its second derivative $f''(x)$, and d) the negative of the second derivative $-f''(x)$.

electron density of an atom although in real cases the shoulder at x_1, where $f(x)$ is greater than the average of $f(x + dx)$ and $f(x - dx)$, would not be so apparent. The first derivative $df(x)/dx$ (Fig. 28b) is negative for all values of x, showing the absence of any maximum in $f(x)$, but it has a point of inflection at x_1. At this point the second derivative (Fig. 28c) has a pronounced minimum and therefore $-d^2f(x)/dx^2$ (Fig. 28d) has a maximum. So the shoulder at x_1 at which $f(x) > [f(x + dx) + f(x - dx)]/2$ is made much more apparent in $-d^2f(x)$. If this function represents the radial behavior of the electron density, we could say that the electron density is locally concentrated in the radial direction. Similarly a maximum in $-\nabla^2\rho$ indicates a local concentration in the three-dimensional electron density distribution. Maxwell (*Treatise on Electricity and Magnetism, Vol. 1*, p. 31, Dover reprint, New York, **1954**) coined the phrase *locally concentrated* to signify that the value of a function of r (in this case $\rho(r)$) at a particular r is larger than the average value of ρ on the surface of an infinitesimal sphere centered at r. Thus in the regions in which $-\nabla^2\rho$ is positive (or $\nabla^2\rho$ negative) the electron density is locally concentrated. Analogously, regions where $-\nabla^2\rho$ has negative values correspond to regions of local depletion of electron density. A more detailed discussion of the Laplacian of the electron density is given in Ref. [17].

Voids in Variable Chemical Surroundings: Mesoporous Metal Oxides

Peter Behrens*

The design of the structure of materials is a current challenge in solid-state chemistry. However, binary metal oxides, for example, typically possess only one or a few thermodynamically stable modifications, providing only a limited range for design. If, however, the formation of solid oxides is carried out at low temperatures and thus under kinetic control, it is possible to prepare metastable modifications and to influence the reaction process. Following these guidelines, several groups have recently reported on the preparation of mesoporous metal oxides, that is metal oxide structures that are penetrated by regular arrangements of holes of the same size. Among these metal oxides are alumina,[1-3] titania,[4] niobia,[5] and zirconia.[6]

The preparative methods used are based on classical syntheses of zeolite-type solids and rely on the fact that small organic molecules (templates in the sense of structure directors) are occluded by crystallizing inorganic frameworks during hydrothermal synthesis and that these molecules thus influence the structure of these frameworks.[7] The tetrahedral network is composed typically of silicates, aluminosilicates, or aluminophosphates; correspondingly, the microporous solids are designated as porosils, porolites (zeolites belong to this class), or "AlPOs". The size and shape of the organic molecules that are added to the synthesis mixture influence the arrangement of the TO_4 building units (T = tetrahedrally surrounded atom; Si, Al, etc.) such that the resulting tetrahedral network forms voids for the occlusion of the molecules. The framework structure of these typical host–guest compounds[8] can be determined to a certain degree by the choice of the molecule ("structure-directed solid-state synthesis"). The maximum size of the pores is restricted to cage and channel diameters of about 15 Å, but due to the crystalline structure of these substances their pore-size distribution is very narrow. Thus, in addition to the important industrial applications of microporous materials, the idea of controlling the structure of inorganic solids by organic molecules is appealing to the preparative solid-state chemist. Classical synthetic methods for solid compounds, such as reaction of solids at high temperatures, offer hardly any possibilities to direct the reaction. There is a good chance that the structure-directing effect of organic molecules may some day make it possible to "design" solid-state syntheses.[9]

A substantial extension of this approach to the synthesis of porous materials was achieved by chemists from Mobil Oil at the beginning of the nineties.[10, 11] Instead of using single molecules as templates, they employed supramolecular long-range ordered aggregates of surfactant molecules which form in aqueous solutions. Use of these lyotropic phases led to mesostructured materials (silicates, aluminosilicates, alumophosphates) with different structure types (Fig. 1). After calcination these mesostructured materials leave ordered arrangements of pores; the diameter of these pores can be tuned between 20 and 100 Å by varying the length of the hydrophobic part of the surfactant. These materials, designated as M41S, are not crystalline, and so their pore-size distributions are not as narrow as those of the microporous substances. Nevertheless, these substances may legitimately be called the "big brothers" of zeolite-type materials. They are currently being tested in several applications which are analogous to those of zeolites and which appear appropriate to be extended to larger molecules.

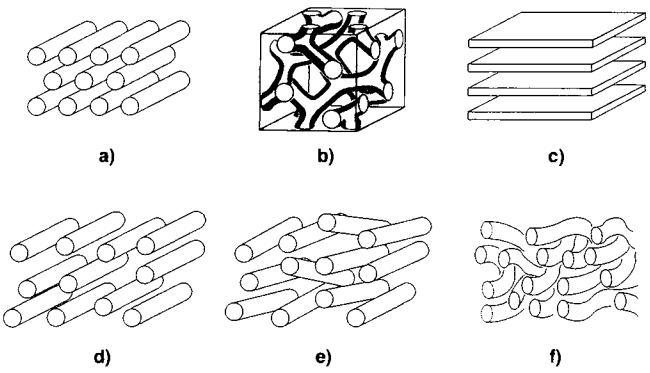

Fig. 1. Structures of mesostructured phases. The top row shows structures with long-range order: a) hexagonal phase, b) cubic $Ia\bar{3}d$ phase, c) lamellar phase. The bottom row shows possible disordered structures, as they may occur in some of the mesoporous metal oxides: d) disordered arrangement of parallel cylindrical pores, e) disordered packing of cylindrical pores (according to ref. [24]), f) worm-shaped pores.

One of these applications is shape-selective catalysis. In the realm of microporous solids, the research in this area during the last ten years has focused on the production of specific reactivities by framework substitutions. The most well-known example is possibly titanium silicalite-1 (TS-1).[12] Substitution of only one percent of the Si atoms in the SiO_2 framework of silicalite-1 creates a highly reactive and shape-selective catalyst for oxidations with hydrogen peroxide. Other substitutions (Ga, Fe, Co)

of Al or Si in the framework of silicates or aluminophosphates allow the controlled tuning of the acidic catalytic activity of these solid acids. In the last two years, it was shown that such framework substitutions are also possible in M41S materials.[13]

The chemical variability of structure direction with lyotropic phases, however, extends far beyond the incorporation of small amounts of metals in typical framework builders such as silicate, aluminosilicate, and aluminophosphate. Mesostructured phases can be prepared with oxides of a wide variety of metals (Fe, W, Pb, Sb, Mn, Ga) and with salts such as zinc phosphate, as was first shown by the groups of Stucky and Schüth.[14]

For the construction of such mesostructures it is important to adapt the headgroup chemistry of the surfactants to that of the inorganic component. In aqueous solution, the latter forms—in a certain pH range—oligomeric cations or anions that are able to undergo further condensation. Silicate mesopores were originally synthesized in basic solutions in which the silicate species occur as oligoanions. Thus, cationic surfactants S^+ were used for the structuring of negatively charged inorganic species I^-. Such organic–inorganic mesostructures are designated as S^+I^- mesostructures (Fig. 2a). Examples of S^-I^- mesostructures are cationic lead oxide species structured by anionic surfactants such as alkylsulfonates (Fig. 2b). Surprisingly, also

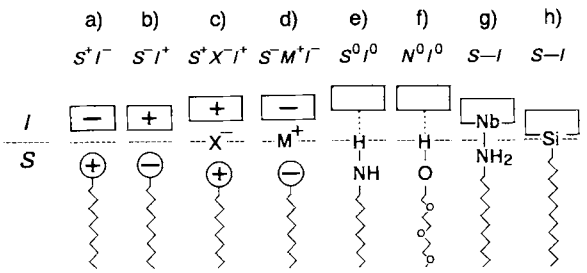

Fig. 2. Interactions at the interface between organic phase (S, N) and inorganic phase (I): a) to d) ionic interactions, e) and f) hydrogen bonding, g) and h) covalent bonds.

organic–inorganic combinations with identically charged partners are possible, but then the formation of the mesostructure is mediated by counter-charged ions which must be present in stoichiometric amounts: $S^+X^-I^+$ mesostructures (Fig. 2c, for example with S^+ = tetraalkylammonium ion, X^- = bromide, and I^+ = cationic silica species which form in strongly acidic solutions) or $S^-M^+I^-$ mesostructures (Fig. 2d, for example with S^- = alkylcarboxylate, $M^+ = Na^+$, and I^- = zincate ions).[14b]

However, most oxides only gave organic–inorganic composites possessing a lamellar structure (Fig. 1c) when the synthesis was based on the compensation of the ionic charges at the S/I interface. These mesostructures collapse upon removal of the organic component and yield dense (in most cases amorphous) metal oxides. They are thus not appropiate for the preparation of mesoporous phases. Iron, tungsten, lead, and antimony oxides also formed hexagonal mesostructured phases (Fig. 1a), and antimony oxide in addition gave cubic ones (Fig. 1b). However, these phases also did not exhibit porosity after calcination: The ordered mesostructure collapsed.[14] The reason for this is probably that the degree of condensation of the oligomeric ions, which form the walls, is lower than in silicates; the redox instability of the metal cations may also play a role. Milder routes for template removal were also tested: For silicate mesophases it was shown that surfactant cations can be extracted from S^+I^- combinations by solvents that contained cations for exchange; treatment of $S^+X^-I^+$ combinations based on silica with ethanol liberates the S^+X^- ion pairs. However, in the case of mesostructured metal oxides based on charge compensation at the S/I interface, this route does not seem to work.

Initial progress with regard to a milder route to template removal from mesostructured metal oxides was achieved by Pinnavaia and co-workers.[1, 2] Interestingly, mesostructures can also be formed without the participation of charges: S^0I^0 combinations were introduced by the formation of hexagonal silica materials that were prepared by using neutral amine surfactants S^0 (Fig. 2e).[11] Also nonionic polyethylene oxide surfactants N^0 can act as structure directors in a N^0I^0 combination (Fig. 2f).[2] In the case of these neutral templating routes the interaction at the S/I interface probably occurs through hydrogen bonds.[15] Thus, the forces at the interface are weak compared to electrostatic coupling. This allows extraction of the neutral template molecules by washing with ethanol.

It was also possible to prepare mesoporous aluminum oxides by S^0I^0 and N^0I^0 combinations.[1, 2] The use of neutral structure directors opens the possibility of forming hexagonal phases (ionic coupling at the interface produces only lamellar surfactant/alumina composites), and template removal can be performed under mild conditions by extraction with ethanol. Aluminum oxide mesostructures that were prepared by using surfactants based on polyethylene oxide/polypropylene oxide copolymers can even be calcined at 773 K to give mesoporous materials.[2, 3] The specific surface areas of these samples range from 420 to 535 $m^2 g^{-1}$ (Table 1).

Table 1. Specific surface areas of mesoporous metal oxides.

Material	Approximate composition [b]	Specific surface area [a] $[m^2 g^{-1}]$	$[10^3 m^2 mol^{-1}]$	Ref.
M41S	SiO_2	>1000	>60	[10]
MSU-1	$AlO_{1.5}$	535	27.3	[3]
Ti-TMS1	TiO_2	<200	<16	[4]
Nb-TMS1	$NbO_{2.5}$	434	100.8	[5]
zirconia	ZrO_2	280	34.5	[6]
zirconium oxo phosphate	ZrO_2	390	48	[6]

[a] In the original publications, the specific surface areas are always related to mass and are given in $m^2 g^{-1}$. To be able to make a better comparison of the surface areas of mesoporous materials of different composition, here also the areas related to one mol of metal atoms are provided, together with the typical value for mesoporous silicates. [b] This composition was used for the transformation of mass-related to molar-specific surface area.

In the syntheses by Pinnavaia et al., alkoxides such as tetraethylorthosilicate or aluminum tri-*sec*-butoxide were used for the construction of the inorganic walls. Metal alkoxides may generally be considered as the precursors of choice for the generation of metal oxide walls in aqueous solutions that are structured by surfactants. However, attempts to prepare mesostructured titania from titanium propoxide and surfactants with different headgroups (phosphate, carboxylate, sulfate) failed and only yielded the dense anatase modification.[4] Evidently, the condensation reaction was too fast so that the species formed by the hydrolysis of the titanium alkoxide could not be

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3505-0516 $ 15.00+.25/0

directed into mesostructural arrangements by the surfactant molecules. By clever use of the coordination chemistry at the metal center Antonelli and Ying[4] were able to correct this negative result: If titanium (acetylacetonate)triisopropoxide is used as the metal alkoxide, the hydrolysis rate is slowed down so that a common hexagonal mesostructure of the surfactant and the inorganic species can form, although only surfactants with phosphate headgroups can be used successfully. The composite produced by using this modified sol–gel process was the first transition metal oxide that could be calcined with a partial conservation of the mesostructure: The calcination yields Ti-TMS-1, a mesoporous material with a narrow pore-width distribution but with a specific surface area of only about 200 $m^2 g^{-1}$. This is quite a small value, even when the difference in relative molecular masses between TiO_2 and SiO_2 is taken into account (Table 1). The phosphate headgroups at least in part remain in the mesoporous material.[4]

By taking advantage of the possibilities of varying the coordination chemistry at the metal center of an alkoxide, Antonelli and Ying[5] recently succeeded in preparing a stable transition metal oxide mesostructure from which the template could easily be removed. The authors first allowed niobium(v) ethoxide to react with a long-chain alkylamine in the absence of water to form an amino(tetraethoxy)niobium complex. In this way they obtained a covalent connection between the organic and the inorganic component. This type of interface interaction may perhaps best be represented by a bonding dash as in "*S–I*" (Fig. 2g). After this composite surfactant had been given sufficient time to form ordered hexagonal structures, water was added to hydrolyze the Nb–O–C bonds. The condensation reaction started immediately and was reinforced by hydrothermal treatment. Template removal was most easily achieved by washing the sample with a HNO_3/EtOH solution at 40 °C. In this way Nb-TMS1, a mesoporous, hydrated niobium oxide, was obtained that exhibited a specific surface area of 434 $m^2 g^{-1}$ (see Table 1). This ligand-assisted template synthesis should also be applicable to the metal oxides of Ti, Zr, Ta, Ce, and Y.[5] We are currently investigating similar structuring processes in silicate systems, in which the headgroup of the surfactant is simultaneously a building unit of the inorganic material (Fig. 2h). For this purpose we use trialkoxyalkylsilanes. Their Si–O–C bonds are hydrolyzed during the synthesis, thus generating an anionic surfactant. In a reaction with tetraethoxysilane a self-organization process occurs that—until now—however, has mainly led to lamellar phases.[16]

In this issue of *Angewandte Chemie* the synthesis of mesoporous zirconium oxide derivatives is reported by Schüth and co-workers.[6] The hydrolysis of zirconium propoxide in a strongly acidic solution of the common S^+ surfactant alkyltrimethylammonium yields hexagonally structured zirconium oxide, when the solution also contains $(NH_4)_2SO_4$. Calcination at 773 K leaves a zirconium oxide that contains only a small amount of sulfur and that has a specific surface area of 280 $m^2 g^{-1}$ (see Table 1). When zirconium sulfate hydrate is used instead of the propoxide and ammonium sulfate, a hexagonal mesostructure is also formed, but this one collapses on calcination. Only treatment with a phosphoric acid solution provides sufficient stability. Possibly, the phosphate ions increase the degree of interlinking in the walls which probably possess only a small degree of condensation. The calcination gives mesoporous materials with a narrow pore-width distribution and specific surface areas of up to 390 $m^2 g^{-1}$ (see Table 1). These materials still contain a considerable amount of phosphorus and should be designated as zirconium oxo phosphate. In the products of their surfactant-based syntheses of zirconium oxides, M. J. Hudson et al. find similar values for the specific surface area, but no ordered pore system.[17]

For all mesoporous metal oxides described here, sorption measurements and a peak appearing at small angles in their X-ray diffraction diagram indicate that the pore size in one sample is rather uniform. In most cases, however, there are no additional X-ray diffraction reflections, whereas well-ordered hexagonal silica materials exhibit three or four of these. This finding indicates that the pores in the metal oxides do not possess a long-range order as perfect as that in the silica materials. Transmission electron microscopic images substantiate this idea (Fig. 4 in ref. [4], Fig. 2 in ref. [5]). The available data can best be explained by structural models containing disorder like those shown in Figure 1d and 1e. In the case of mesoporous aluminum oxide, electron microscopy (for example Fig. 2 in ref. [3]) indicates a drastically changed pore shape. Evidently, the pores are not straight cylinders, but appear with a curved wormlike shape, although of uniform diameter (Fig. 1f).

The application of mesoporous metal oxides in heterogeneous catalysis is evident. Alumina has been known as a catalyst support for a long time. The availability of this support with high surface area and regular pore distribution should in many cases lead to substantial advantages. Larger molecules may possibly be transformed with shape-selectivity like that zeolites demonstrate for small molecules. Transition metal oxides introduce their redox activity as an additional component and could possibly be used directly as redox catalysts. These materials could also be of interest as sorbents because sorption processes depend on the chemical composition of the walls.

Apart from these classical applications mesoporous metal oxides are interesting for other reasons. As the structuring of the mesoporous metal oxides occurs on a length scale where quantum confinement of the electronic states can be expected, these oxides should also possess altered electronic structures. For example, investigations on mesoporous rhenium(VI) oxide would be of interest. As a bulk solid this a metallic conductor; thus a size-induced metal–semiconductor transition should occur as a function of the pore diameter, because the quantum restrictions decrease the overlap of bands. The length of an organic alkyl group would thus ultimately determine the electronic properties of an inorganic solid. In mesoporous materials of semiconducting metal oxides ("expanded semiconductors"),[18] the band gap should widen with increasing pore diameter. Such mesoporous semiconductors with their large internal surface might find applications as highly sensitive sensors if their electronic surface states react to the substances to be detected.

The examples given above for the structure-directed synthesis of mesoporous metal oxides show how strongly the success of these labile kinetically controlled formation processes of inorganic solids depends on minor, delicately tuned manipulations of the synthesis systems. Use of the fine-tuned interplay of the coordination chemistry of metal alkoxide precursors and the additional interlinking of weakly condensed wall material by

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3505-0517 $ 15.00+.25 0

phosphate ions (which plays a role in the synthesis of Ti-TMS-1 and zirconium oxo phosphate) are particularly worthy of mention in this context. Finally, it should not be forgotten that also in the area of structuring inorganic solids, nature is the true master. In biomineralization processes of highly and lowly developed living creatures, supramolecular aggregates of organic substances also serve as structure directors for the construction of inorganic solids; products are created that are optimized for their respective tasks, but which often also are aesthetically pleasing.[19] Recent work in the area of "biomimetic solid-state synthesis" by the groups of Mann[20] and Ozin may point the way ahead.[21] Walsh and Mann prepared hollow spheres of $CaCO_3$-aragonite that possess a striking resemblance to the skeletons of marine algae (Fig. 3 in ref. [20]). In these solid-state syntheses, a microemulsion of didodecyl(dimethyl)ammonium bromide, tetradecane, and water (in which calcium hydrogencarbonate was dissolved) acted as structure director, again a supramolecular structure built from simple organic substances.[20] Oliver, Coombs, and Ozin prepared hollow aluminophosphate spheres by combining phosphoric acid, primary alkylamines, and pseudoboehmite in tetraethyleneglycol.[21b] However, this group also calls the attention to the fact, that these "skeletons from the beaker" have been standing in the archives cupboards of science for quite some time:[22] As far back as 1872 the Dutch scientist Pieter Harting published his investigations "*On the Artificial Production of Some of the Principal Organic Calcareous Formations*", which he had started in 1840, stressing the importance of the controlling action of organic substances.[23]

[15] Recently an interesting variation of the neutral templating route was described (G. S. Attard, J. C. Glyde, C. G. Göltner, *Nature* **1995**, *378*, 366–368). These authors used commercially available nonionic surfactants such as octaethyleneglycolhexadecyl ether in concentrations that were so high that the aqueous solution of the surfactant formed a uniform and continuous liquid crystalline phase. By adding silicate solution it was possible to obtain monolithic surfactant/silicon dioxide mesostructures, quite in contrast to the usual synthesis which yields only fine powders. However, the monoliths suffered from cracks upon heating. If their temperature stability can be raised and when mesoporous monoliths become available, this would significantly broaden the applicability of this class of materials.

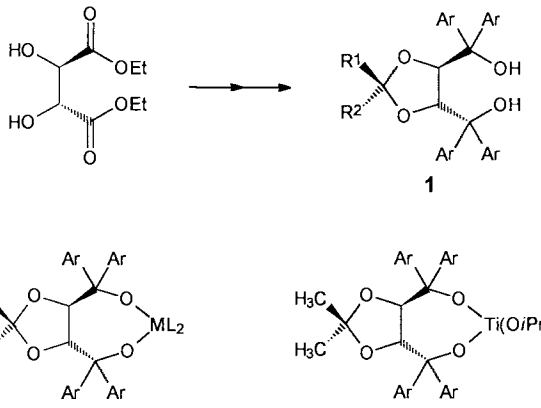
The "Magic" Diarylhydroxymethyl Group

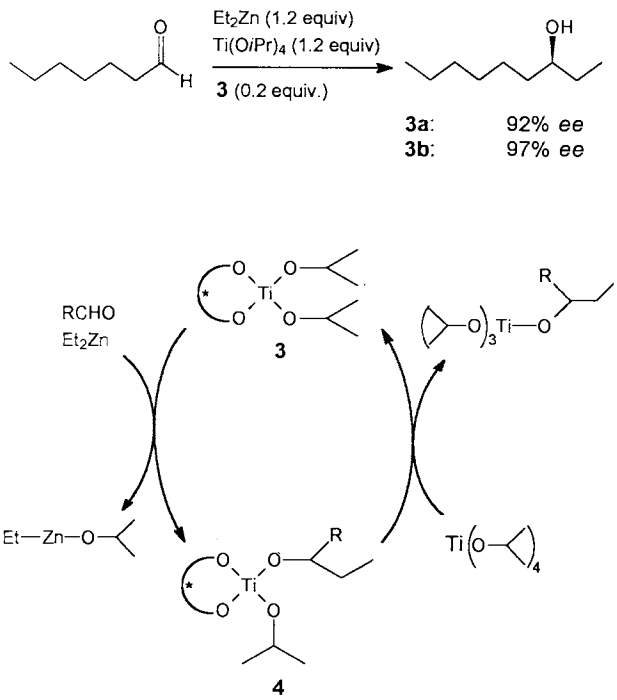
Manfred Braun*

Anyone following the rapid development of asymmetric synthesis during the last decade has certainly noticed the increasing use of the diarylhydroxymethyl group as a structural unit in covalently bound auxiliaries, in ligands, and in catalysts. Although it is not a stereogenic unit, it plays a crucial role in various stereoselective reactions or at least leads to an enhancement of selectivity. After numerous applications the function of the "magic" diarylhydroxymethyl group is now under intense examination.

When acetal-protected (*R*,*R*)-diethyl tartrate was treated with aryl Grignard reagents by Seebach's group in 1983, the first α,α,α′,α′-tetraaryl-1,3-dioxolane-4,5-dimethanols were obtained. The original "TADDOL" **1** ($R^1 = R^2 = CH_3$; Ar = Ph) was followed by a number of analogous compounds with different aryl groups (Ar) and acetal moieties (R^1, R^2).[1] Simultaneously, more and more applications were developed, leading to enantiomerically pure targets: metal complexes **2** with TADDOL ligands, used in stoichiometric or catalytic amounts, make possible enantioselective aldol additions, formation of cyanohydrins, inter- and intramolecular Diels–Alder reactions, [2 + 2]cycloadditions, ene reactions, hydrophosphonylations, iodolactonizations, and transesterifications.[2]



The large number of TADDOL-catalyzed enantioselective additions of polar alkyl-, aryl-, and allylmetal compounds to aldehydes and nitro olefins is exemplified by the reaction of diethylzinc with heptanal. The titanates **3** usually generated from TADDOLs and titanium tetraisopropoxide control the addition of diethylzinc by ligand-accelerated catalysis. An increase in selectivity is achieved not only by using the β-naphthyl derivative **3b** instead of the titanium complex **3a** but, surprisingly, also in the presence of excess achiral titanium tetraisopropoxide (relative to the amount of catalyst) and catalytic amounts of either of the chiral titanates **3a** and **3b** (Scheme 1). Evidently the titanium tetraisopropoxide takes over the alkoxide formed during the addition of diethylzinc, thus regenerating the active catalyst **3**. Titanates like **4** can also catalyze the addition of diethylzinc, albeit with poorer enantioselectivity. Therefore ligand exchange (**4** → **3**) has to take place in order to suppress this competitive reaction.[3a]



Scheme 1. Reaction of diethylzinc with heptanal in the presence of **3**, and mechanism of the TADDOL-catalyzed addition of diethylzine to aldehydes.

Extensive studies of the titanate-catalyzed addition of diethylzinc employing various TADDOL ligands and TADDOL analogues, for the most part characterized by X-ray crystal structure analysis, have shown a uniform topicity for the nucleophilic attack on aldehydes. All titanium–TADDOL complexes derived from (*R*,*R*)-tartaric acid effect preferential addition to the *Si* face of the aldehyde. This is apparently due to the pseudoaxial arrangement of one of the two geminal diaryl groups, which is clearly observed in crystal structure analyses of TADDOLs as well as their titanium complexes. According to a model suggested by Seebach, an isopropoxide ligand is displaced and the titanium atom coordinates, and thereby activates, the carbonyl oxygen of the aldehyde. In the transition state models represented in **5** and **6** the metal atom is in the foreground (the dioxolane ring in (*R*,*R*) configuration has been omitted for clarity). Consequently, the transfer of the nucleophile should take place from the side of the titanates **5** and **6** directed

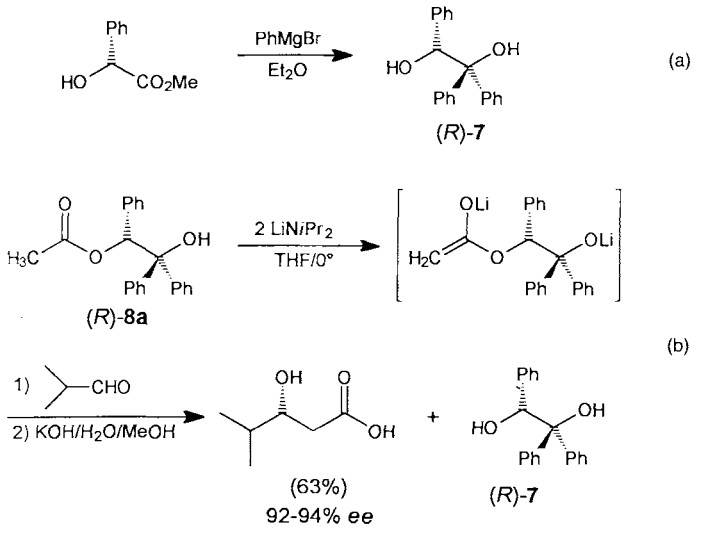
5 6

toward the observer. The diarylmethoxide moiety is responsible for the preference of transition state model **5** (attack from the *Si* face) over the diastereomorphous alternative **6** (*Re*-face attack); the steric interaction between the aldehyde hydrogen and the pseudo-axial aryl unit offers a plausible explanation. Accordingly, the titanate of tetrabenzyl TADDOL (**1**, $R^1 = R^2 = CH_3$; CH_2Ph instead of Ar), in which the aryl groups are no longer conformationally fixed, leads to only marginal enantioselectivity (8% *ee* for the addition of diethylzinc to benzaldehyde). The pseudo-equatorial aryl groups are essential to the ligand-accelerated catalysis of TADDOL titanates as well as those in pseudo-axial positions, as they permit fast exchange of an isopropoxide ligand for the aldehyde. In their absence the addition of diethylzinc is not only slower, but also less stereoselective.[3b]

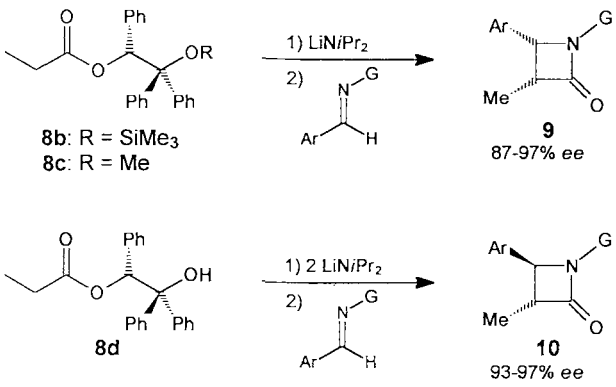
TADDOLs form clathrates with a wide variety of organic compounds such as tetrachloromethane, alcohols, carbonyl compounds, and amines. These clathrates can be used for resolutions of racemates as well as in enantioselective solid-state reactions.[4a] The TADDOL unit can also serve as a template in the anionic homopolymerization of methacrylates. The isotactic polymer obtained after liberation of the template is chiral and shows optical activity if the two chain ends are not identical and if the degree of polymerization is not too high.[4b]

(*R*)- and (*S*)-triphenylglycols **7** are available through addition of phenylmagnesium bromide to the corresponding enantiomer of methyl mandelate [Eq. (a)]. The monoacetates of triphenylglycol, (*R*)-and (*S*)-HYTRA **8a** (HYTRA = 2-hydroxy-1,2,2-triphenylethyl acetate), which were developed shortly after and independently of TADDOLs, can be utilized for the stereoselective addition of an acetate enolate to aldehydes.[5] As shown in the example of the reaction with isobutyraldehyde [Eq. (b)], this



offers a practical solution to the problem of the acetate aldol reaction.[6]

Although the X-ray structure analysis of the HYTRA enolate has not been carried out (yet), research on its derivatives and analogues has shown the (deprotonated) hydroxydiphenylmethyl group again to be responsible for the stereoselectivity of the aldol reaction. The propionate **8b** derived from triphenylglycol **7** permits *anti*- and diastereofacially selective aldol additions.[7a] Ester–imine condensations show a surprising stereodivergence, probably due to the different configurations of the enolate (*E* or *Z*). Whereas the lithium enolates of the O-protected esters **8b** and **8c** lead to *cis*-β-lactams **9**, the condensation of the doubly deprotonated propionate **8d** with imines yields the *trans* diastereomers **10** with high enantiomeric excess.[7b]



G = Ph, 4-MeOC$_6$H$_4$; Ar = Ph, 2-furyl

The diphenylmethyl unit is also found in the cyclic sulfites **12** used by Kagan and Rebiere to synthesize enantiomerically pure sulfoxides. In this case lactic acid is used as a chiral auxiliary. The diphenylpropanediol **11** derived from (*S*)-ethyl lactate reacts diastereoselectively (*90:10*) with thionyl chloride, resulting in the cyclic sulfite **12**, which can be recrystallized to give the diastereomerically pure substance (Scheme 2). Subsequent substitution at the heterocycle **12** through alkyllithium or Grignard reagents leads to complete inversion at the sulfur atom. However, in principle the formation of two regioisomers is possible, depending on whether the secondary or the tertiary alkoxide serves as the leaving group. Fortunately the regiochemistry of the ring opening reaction is controlled largely by the size of the nucleophile. If R^1 is small, the reaction should proceed via the trigonal-bipyramidal transition state **13** with the two geminal phenyl groups in equatorial position (assuming an S_N2-type reaction without pseudorotation). As a result the secondary alkoxide is the leaving group and the sulfinate **15** is the main product. Bulky nucleophiles with large R^1 groups push the geminal diphenyl group into the axial position to minimize steric interactions. This puts the sterically demanding groups in the trigonal-bipyramidal **14** in the *anti* position, and the tertiary alkoxide is now the leaving group; consequently sulfinate **16** is formed as the main product. In both cases the predominantly produced isomer **15** or **16** can be obtained in pure form by recrystallization. The subsequent second substitution yields the enantiomerically pure sulfoxides **17** and **18**, both with complete inversion at the sulfur atom. This method has the advantage of

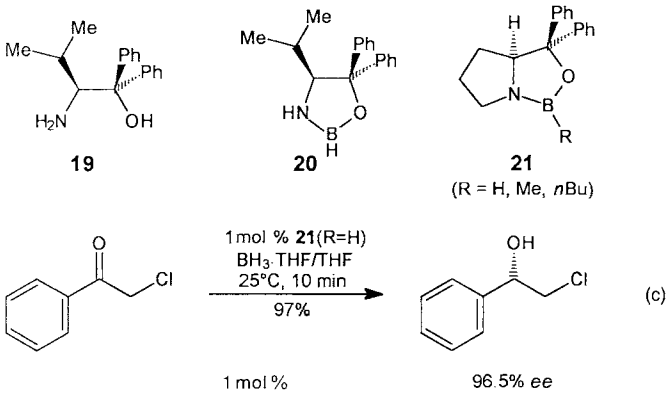
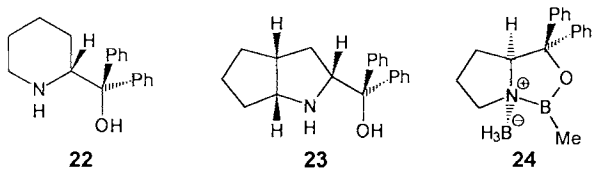
making sulfoxides with predictable absolute configuration accessible.[8]

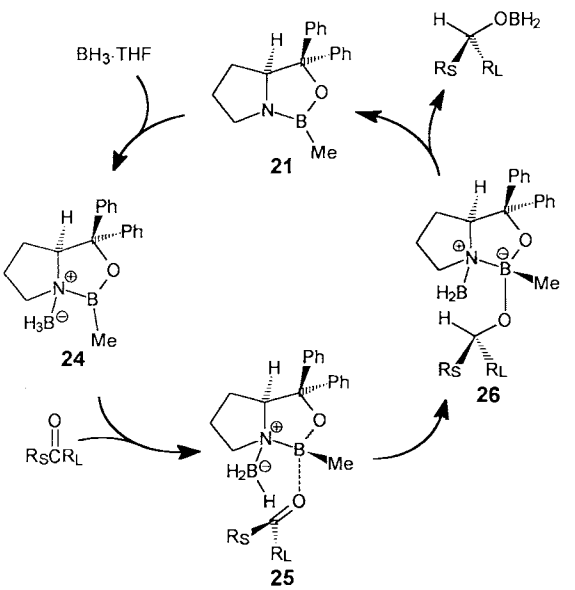
The enantioselective reduction of prochiral ketones has long been researched intensively in the context of asymmetric synthesis, leading to numerous publications on chirally modified aluminum and boron hydrides.[9] Itsuno and co-workers were the first to report on the use of the geminally diphenyl-substituted amino alcohol **19** for the enantioselective control of the reduction of ketones by boranes.[10] In one example of this, initially stoichiometric, procedure (*R*)-1-phenylethanol is obtained in 94% *ee* by reduction of acetophenone. In work starting in 1987 Corey's group not only identified the structure of Itsuno's reagent **20**, but also worked out a catalytic variant.[11] Eventually the derivatives of open-chain α-amino acids were replaced by the oxazaborolidine **21**, the (*S*) enantiomer of which is easily available from L-proline. The high cost of D-proline made an alternative approach to the (*R*) reagent **21** desirable. This was accomplished by starting from pyroglutamic acid and resolving an intermediate.[11b] In typical procedures, ketones such as chloroacetophenone react with $BH_3 \cdot SMe_2$, $BH_3 \cdot THF$ or catechol borane in the presence of 1–10 mol% of oxazaborolidine **21** [Eq. (c)].[11c] As a rule, selectivities of more than 90% *ee*



can be achieved. Various analogous ligands, for example **22** and **23**, were described, some of them capable of catalyzing other enantioselective reactions besides the borane reduction.[12] Oxazaborolidines **21** derived from diphenylprolinol[13] have so far found the widest range of applications. The B-methyl derivative (R = Me), a colorless solid, is stable at room temperature and can be handled in air. The borane adduct **24** is available in large quantities through reaction of the oxazaborolidine **21** (R = Me) with $BH_3 \cdot SMe_2$.[14]



The following mechanism seems plausible to explain the catalytic activity of the oxazaborolidines (Scheme 3). In the first step the reagents **21** and borane·THF form adduct **24** in an equilibrium reaction. The Lewis-acidic boron atom of the heterocycle coordinates the carbonyl oxygen of the ketone (structure **25**). In



Scheme 3. Proposed mechanism for the reduction of ketones with $BH_3 \cdot THF$ and a catalytic amount of oxazaborolidine **21**.

the subsequent six-membered transition state a hydride is transferred to the ketone (R_S = small, R_L = large substituent), leading predominantly to diastereomer **26**. Finally detachment of the alkoxide takes place, thus regenerating the catalyst.[11a]

The energies of the diastereomeric chair and boat transition states for the reduction of acetophenone with a variety of oxazaborolidine–BH_3 complexes were obtained through MNDO calculations. In the lowest energy chair conformation **27** shown for the parent compound **21** the ketone phenyl group assumes the favored *anti* position (in relation to R) and lies parallel to the axial phenyl group of the geminal diphenylmethoxide unit with a ring distance of at least 5.5 Å. In the diastereomeric transition state **28**, which is 3.5 kcal mol^{-1} higher in energy, the acetophenone methyl substituent is 1.5 Å closer to the axial phenyl group.[15] Again the pseudo-axially orientated aryl group of the diphenylmethoxide unit seems to be essential for high selectivity: the calculated *ee* value of 98% is matched by an experimental value of 97%. Exchange of the hydroxydiphenylmethane group in the ligand for a CH_2OH unit leads to a substantial loss in selectivity. Thus the hydroxydiphenylmethane group, although it is not a permanent stereogenic center, exerts a critical influence on the course of the asymmetric reaction due to its fixation in a chiral reactive conformation.[16] Changing from prolinol to diphenylprolinol auxiliaries also results in an increase in stereoselectivity[19] in the addition of dialkylzinc to aldehydes,[13b] Reformatsky reactions,[17] and pinacol-type coupling of 2-formylbenzamides.[18] Even the usually very efficient RAMP/SAMP hydrazone method (RAMP, SAMP = (*R*)- and (*S*)-*N*-amino-2-(methoxymethyl)pyrrolidine) can be improved in individual cases through replacement of the methoxymethyl group by the diphenylmethoxymethyl side chain.[13a]

28

With increasing frequency, chiral oxazaborolidines are proving to be the reagents of choice for the enantioselective reduction of prochiral carbonyl compounds. Their unusual efficiency is taken into account by the description "chemzymes",[11d] a term that is, however, not undisputed.[20]

Pyridinium Ions Adjacent to Oxirane Rings: Useful Intermediates for the Stereospecific Synthesis of β-Hydroxy Ketones**

Yousef Al-Abed, Noshena Naz, Khalid Mohammed Khan, and Wolfgang Voelter*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Chiral β-hydroxy carbonyl compounds are interesting building blocks for natural product synthesis.[1, 2] They are typically prepared by 1,2-rearrangement of epoxysilylethenes under Lewis acid conditions.[3] We have made use of the unlimited amounts of carbohydrates available from the "chiral pool" and report here on a simple procedure for the introduction of enantiomerically pure β-carbonyl hydroxy functions in the pyranose ring.

In studies directed toward the development of chiral building blocks for synthesis[4] our research group has frequently used the epoxypyranosides benzyl-2,3-anhydro-β-L-ribopyranoside (**1**) and benzyl-2,3-anhydro-α-D-ribopyranoside (**2**). We describe here a one-pot procedure for converting epoxyhydroxy functions in compounds such as these into β-carbonyl hydroxy functions. The strategy relies on the introduction of a pyridinium ion adjacent to the oxirane ring, which facilitates opening of the epoxy ring with formation of an *N*-vinylpyridinium derivative. Subsequent reduction with $NaBH_4$ yields an *N*-alkyl-1,2,5,6-tetrahydropyridine derivative,[5] which can be hydrolyzed under acidic conditions to yield a β-hydroxy ketone (Scheme 1).

[**] This work was supported by the Fonds der Chemischen Industrie and the German Academic Exchange (doctoral stipend for Y. A.-A.).

In a representative procedure **1** was treated with one equivalent of trifluoromethanesulfonic anhydride in pyridine at room temperature for 3 h to give the pyridinium salt **3** in quantitative yield. When a solution of **3** in pyridine was diluted with the same amount of water and heated at reflux for 3 h, **4** was obtained. The solvent was removed under reduced pressure and the residue taken up in water, treated with $NaBH_4$ at 0 °C for 2 h, acidified with 0.1 N HCl, and extracted with ethyl acetate. The extract was concentrated to dryness and the residue was purified by column chromatography to provide the desired β-hydroxy ketone **5** in 82% yield.

The structure of **4** was confirmed unequivocally by ^1H and ^{13}C NMR spectra (Table 1). The chemical shifts of the pyridinium protons are similar to those in **3**; the signal of the olefinic proton is at $\delta = 6.54$, and those of the sp^2 C atoms are at $\delta = 140.8$ and 127.0. Since no vicinal coupling is observed for the C-5 protons, the pyridinium residue must be linked to C-4. The lowfield shift of the anomeric C atom ($\delta = 99.7$; the C-1 signal of **3** is at $\delta = 94.7$) also indicates that the oxirane ring is cleaved.

Table 1. Selected ^1H and ^{13}C NMR data for compounds **3**–**5**.

3: ^1H NMR(400 MHz, [D$_6$]DMSO): $\delta = 9.07$ (d, 2 H, $J = 5.7$ Hz, H^{α}-Py), 8.67 (dd, 1 H, $J = 7.8$ Hz, H^{γ}-Py), 8.22 (dd, 2 H, $J = 7.3$, 7.0 Hz, H^{β}-Py), 7.44–7.30 (m, 5 H, aromat. H), 5.34 (dd, 1 H, $J = 6.2$, 5.9 Hz, H-4), 5.16 (s, 1 H, H-1), 4.80 (d, 1 H, $J = 11.8$ Hz, OC*H*HPh), 4.66 (d, 1 H, $J = 11.8$ Hz, OCH*H*Ph), 3.93 (dd, 1 H, $J = 12.3$, 5.4 Hz, H-5), 3.88 (dd, 1 H, $J = 11.9$, 7.5 Hz, H-5), 3.88 (d, 1 H, $J = 4.0$ Hz, H-3), 3.50 (d, 1 H, $J = 3.5$ Hz, H-2); ^{13}C NMR (100 MHz, [D$_6$]DMSO): $\delta = 146.5$ (C^{γ}-Py), 144.5 (C^{α}-Py), 137.1–127.7 (aromat. C), 128.4 (C^{β}-Py), 120.6 (CF_3SO_3, q, $J = 322.4$, 644.8 Hz), 94.7 (C-1), 70.1 (OCH_2Ph), 61.4 (C-4), 59.2 (C-5), 50.9 (C-3), 50.5 (C-2)

4: ^1H NMR (400 MHz, [D$_6$]DMSO): $\delta = 9.20$ (d, 2 H, $J = 5.7$ Hz, H^{α}-Py), 8.72 (dd, 1 H, $J = 7.8$ Hz, H^{γ}-Py), 8.22 (dd, 2 H, $J = 7.6$, 6.8 Hz, H^{β}-Py), 7.50–7.30 (m, 5 H, aromat. H), 6.54 (d, 1 H, $J = 4.3$ Hz, H-3), 5.87 (d, 1 H, $J = 6.2$ Hz, OH), 4.85 (d, 1 H, $J = 2.3$ Hz, H-1), 4.78 (d, 1 H, $J = 12.0$ Hz, OC*H*HPh), 4.67 (s, 2 H, C-5,5'H), 4.61 (d, 1 H, $J = 12.0$ Hz, OCH*H*Ph), 4.10 (br. s, 1 H, H-2); ^{13}C NMR (100 MHz, [D$_6$]DMSO): $\delta = 147.5$ (C^{γ}-Py), 143.7 (C^{α}-Py), 140.8 (C-4), 137.5–126.4 (aromat. C), 128.9 (C^{β}-Py), 127.0 (C-3), 120.8 (CF_3SO_3, q, $J = 322.0$, 644.0 Hz), 99.7 (C-1), 70.1 (OCH_2Ph), 64.2 (C-2), 59.4 (C-5)

5: ^1H NMR (400 MHz, $CDCl_3$): $\delta = 7.40–7.30$ (m, 5 H, aromat. H), 4.86 (d, 1 H, $J = 2.6$ Hz, H-1), 4.84 (d, 1 H, $J = 11.7$ Hz, OC*H*HPh), 4.64 (d, 1 H, $J = 11.7$ Hz, OCH*H*Ph), 4.16 (m, 1 H, H-2), 4.16 (d, 1 H, $J = 16.6$ Hz, H-5), 3.99 (d, 1 H, $J = 16.6$ Hz, H-5'), 2.90 (dd, 1 H, $J = 16.8$, 4.6 Hz, H-3), 2.58 (d, 1 H, $J = 16.8$, 4.4 Hz, H-3'), 2.0 (br. s, 1 H, OH); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 205.9$ (C-4), 136.8–128.1 (aromat. C), 98.1 (C-1), 70.1 (OCH_2Ph), 68.6 (C-2), 68.1 (C-5), 43.1 (C-3)

The formation of **4** can be explained by the abstraction of the acidic proton at C-4 in **3** by the pyridine base. The transition state is presumably an ylide structure stabilized by the pyridinium residue, which leads to opening of the epoxy ring and simultaneously to introduction of a double bond in the pyranose ring.

The reduced form of **4** could not be isolated despite numerous attempts. However, when the reduction was conducted in D_2O and the ^1H NMR spectrum recorded before workup in acidic medium, the occurence of the olefinic proton signal and simultaneous disappearence of the pyridinium proton signals was observed. Moreover, the NMR spectra indicate that the opening of

the epoxy ring occurs with retention of configuration at C-2. This is illustrated by the 3-deoxyketoses **5** and **6**. The geminal coupling constants $J_{2,3}$ for **5** are 4.4 and 4.6 Hz, and for **6**, 5.0 and 8.3 Hz. This indicates that in **5** the OH group at C-2 is axial, whereas in **6** it is equatorial. The carbonyl signals of compounds **5** and **6** are at $\delta = 205.9$.

The same procedure was used to convert **2** and **7**–**9** into **6**, **5**, **10**, and **11**, respectively, in yields of 71–84% (Table 2). The reaction is not limited to carbohydrates as the transformation of **12** into **13** indicates.

Table 2. Products and yields for the reaction of epoxyhydroxy compounds with 1) Tf_2O/pyridine/CH_2Cl_2, 2) water/pyridine (1/1), 100 °C, 3) $NaBH_4$/water.

New Cobalt Catalysts for Hydroformylations in Two-Phase Systems**

Uwe Ritter, Norbert Winkhofer, Hans-Georg Schmidt, and Herbert W. Roesky*

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

The Ruhrchemie/Rhône-Poulenc technique and the SHOP process (SHOP = Shell Higher Olefin Process) are examples of two-phase catalysis on an industrial scale.[1–3] Further evidence of the topical relevance of this theme is the recent publication of papers by Horváth et al.[4] and Cornils[5] describing new methods of two-phase catalysis. The main advantages of such systems are the ease with which the catalyst phase can be removed and the high product selectivity that results from the quasi-homogeneous reaction. Consequent benefits include low primary energy costs and reduced amounts of undesired by-products. The demand for two-phase catalysts will therefore undoubtedly grow during the years to come. Water-soluble transition metal compounds are synthesized by forming complexes of the metal with water-soluble phosphanes as donor ligands. Solubility in water is usually achieved by incorporating a sulfonic acid group in the phosphane ligand, although the use of carboxyl, ammonium, phosphonium, hydroxyl, and polyether groups has also been reported.[3] The aim of our investigations was to synthesize compounds with stable σ-bonding that are suitable for two-phase catalysis.

We now report the synthesis of a phosphane-free methylidyne-bridged cobalt carbonyl cluster and its use as a hydroformylation catalyst in a two-phase system. The parent compound is [tris(tricarbonylcobaltio)methylidyne]silanetriol (**2**), which was first described by Seyferth et al. on the basis of spectroscopic data.[6] We have been able to crystallize this compound.[7] The previously known silanetriols that have been characterized by X-ray structural analysis reveal three-dimensional frameworks linked through layers[8, 9] or through hydrogen bonds in a cagelike arrangement.[10, 11] Like $(SiMe_3)_3SiSi(OH)_3$ and $(SiMe_3)_3CSi(OH)_3$, **2** forms a cage. However, in contrast to the hexameric structures of the above-mentioned compounds, **2** forms an oval framework structure consisting of eight monomeric units (Figs. 1 and 2).

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the BMBF, the Volkswagenstiftung, and Hoechst AG.

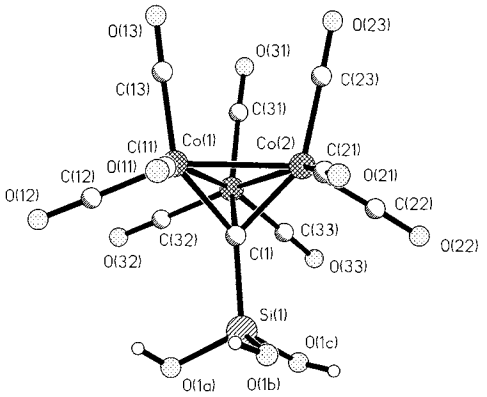

Fig. 1. The monomeric basic unit of **2** in the crystal. Bond lengths and bond angles are given in the text.

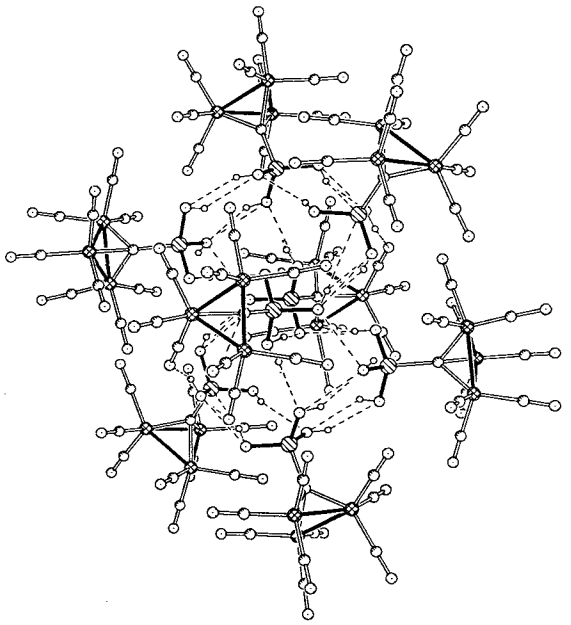

Fig. 2. In the crystal eight molecules of **2** are linked by hydrogen bonds to form a cagelike framework.

The Si–O bond lengths (161.0(5)–164.8(7) pm) and the O-Si-O angles (105.9(3)–111.7(3)°) are in agreement with corresponding values in other silanetriols.[8–10] The Co–Co bond lengths in the cluster fragments lie between 245.46(14) and 247.58(12) pm. The mean distance between the Co atoms and the apical C atoms is 190.9 pm. This value is similar to those in other tris(tricarbonylcobaltio)methylidyne compounds.[12]

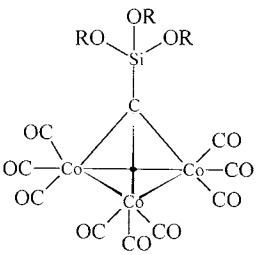
The eight cobalt carbonyl fragments form the surface of the cagelike structure and shield the condensation-labile silanetriol groups. This shielding and the electron donor properties of the hydrophobic cluster fragments explain the unusual stability of the silanetriol towards condensation and its almost complete insolubility in water. However, desired modifications of the silanetriol core can be brought about by reactions at the SiOH groups. It is not possible to introduce sulfonic acid groups directly into tricobaltnonacarbonylmethylidyne derivatives.[6, 13] Instead of the intended sulfonation of the apical C atom or of organic groups bonded to it, cluster fragmentation or formation of $[(\mu^3\text{-CH})Co_3(CO)_9]$ is observed. Our investigations confirm these results. Silanols can be derivatized very simply by condensation with alcohols. Another possibility is the direct alcoholysis of the trichlorosilane **1**. The compounds **3a–c** can be obtained by this route (Scheme 1).

$$[Co_3(CO)_9CSiCl_3] + 3\,H_2O \xrightarrow[-3\,HCl]{} [Co_3(CO)_9CSi(OH)_3]$$

1 **2**

$$[Co_3(CO)_9CSiCl_3] + 3\,ROH \xrightarrow[-3\,HCl]{} [Co_3(CO)_9CSi(OR)_3]$$

1 **3a–c, 4**



3a, $R = CH(CH_2OCH_2CH_3)_2$

3b, $R = CH_2CH_2OCH_2CH_2OCH_3$

3c, $R = CH_2CH_2(OCH_2CH_2)_2OCH_3$

4, $R = CH_2CH_2(OCH_2CH_2)_nOH$ ($n = 9$)

Scheme 1. Synthesis of **2**, **3a–c**, and **4**.

Compounds **3a–c**, like glycol-substituted phosphanes, are only slightly soluble in water. Only derivatives of the higher glycols (degree of polymerization > 16) show appreciable solubility in water.[14] Following a method comparable to the alcoholysis mentioned above, we reacted polyethylene glycol 400 with **1** to obtain **4** (Scheme 1). A solution of **4** in an excess of polyethylene glycol is completely miscible with water. However, this intensely violet-colored solution is not significantly miscible with lipophilic solvents such as hexane, hexene, and heptanal.

Hydroformylation experiments with the polymer-bound cluster units $[(\mu^3\text{-CCH}_3)Co_3(CO)_9]$ and $[(\mu^3\text{-CC}_6H_5)Co_3(CO)_9]$ and with phosphane derivatives of these compounds are described in the literature.[12, 15–17] The nature of the active species has not yet been completely elucidated and continues to be the subject of controversy. Seyferth et al.[17] and Richmond et al.,[18, 19] on the basis of IR investigations, suggest a fragmentation of the cluster, while Pittman, Jr. et al. and Balavoine et al. consider that the ease with which the compound used can be recovered indicates that the methylidyne bridge remains intact during the catalysis.[12, 15, 16]

We have investigated the catalytic activity of $[(\mu^3\text{-CSi(OH)}_3)Co_3(CO)_9]$ (**2**), two phosphane derivatives of **2**, and the polyethylene glycol compound **4** in the hydroformylation of 1-hexene. The results are given in Table 1.

Table 1. Hydroformylation of 1-hexene.

[a] Catalysis with **2** in toluene, and with **4** and $[Co_2(CO)_8]$ in polyethylene glycol. [b] Initial pressure. [c] Substrate: 2 mL 1-hexene. [d] Based on 1-hexene, ref. [21]. [e] *n/iso* ratio = 1-heptanal/(2-methylhexanal + 2-ethylpentanal). [f] With added triphenylphosphane (1:1 molar ratio to catalyst). [g] With added bis(diphenylphosphanyl)methane (1:1 molar ratio to catalyst). [h] Reused catalyst after separation of phases. [i] Chemoselectivity: 44% aldehydes/56% alcohols.

High conversions and high chemoselectivities similar to those obtained with **4** are obtained with **2** (Table 1, entries 1 and 7). However, while a decrease in the amount of **2** leads to a decrease in the regioselectivity of the products (entries 1 and 2), a change in the amount of **4** (entries 7–9) has hardly any effect on regioselectivity. As expected, the addition of phosphanes gives improved regioselectivity (entries 5 and 6). The catalyst phase can be recovered and reused many times, but shows a reduction in activity (entry 10). The formation of alcohols, which occurs as a side reaction with industrial catalytic processes, is almost completely prevented.[20] The experiments carried out with $[Co_2(CO)_8]$ in polyethylene glycol gave a product phase with a high content of alcohols, so another mechanism is occurring here (Table 1, entry 11). The conversions and selectivities obtained are comparable to results with $[(\mu^3\text{-}CH_3C)Co_3(CO)_9]$ and $[(\mu^3\text{-}C_6H_5C)Co_3(CO)_9]$ as catalysts.[12, 15] This shows that the activity induced by the metal fragment of the molecule is almost independent of the substituent on the methylidyne carbon atom. This is reflected in the fact that the frequencies of the IR vibrations of the CO groups on the cluster hardly change when substituents are introduced on the methylidyne carbon atom.[6]

A precise picture of the progress of a catalytic reaction is obtained by following the hydroformylation of 1-hexene by gas chromatography. The conversion is plotted against time in Figure 3.

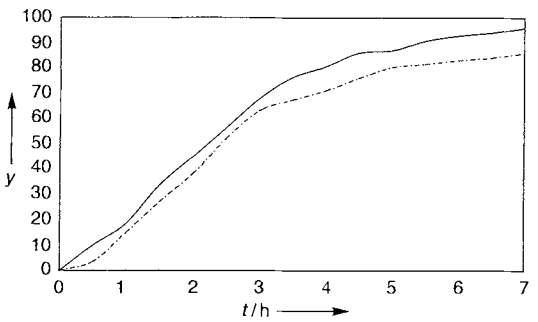

Fig. 3. Course of the hydroformylation reaction of 1-hexene catalyzed by **2** (—) and **4** (– · – · –); $T = 120\,^{\circ}C$; $p = 80$ bar; $CO:H_2 = 1:1$; 1-hexene 20 mL; catalysis with **2** in 20 mL of toluene, Co content: 110 mg; catalysis with **4** in 20 mL of polyethylene glycol 400, Co content: 130 mg. The conversion y [%] is based on all of the total C7 aldehydes formed.

The catalytic activity of the polyethylene glycol compound **4** is similar to that of **2**. With both catalysts, the reactions proceed without any significant induction phase. The similarity between the courses of the reactions indicates that their mechanisms are similar. The formation of cluster units under hydroformylation conditions cannot be excluded.

After the reaction the hydrophilic polyethylene glycol compound **4** can be recovered by simple phase separation and can then be reused. The active catalyst species cannot be determined. The dark violet color of **4** changes to a deep blue during the reaction, and this color is stable even after several catalytic cycles. Most likely polyether groups coordinate reversibly to the cobalt centers with partial displacement of CO molecules.

In contrast to the well-known water-soluble catalysts based on phosphane, the catalyst that we have been able to synthesize owes its properties as a two-phase catalyst to the presence of σ-bonded fragments. By modifying the silanol unit it should be possible to fine-tune the properties of the catalyst as desired, or combine a number of properties. The introduction of chiral substituents is currently under investigation.

Experimental Procedure

3a–c: A solution of **1** (0.574 g, 1 mmol) in 10 mL of the alcohol was stirred at 25 °C for 48 h under an atmosphere of CO. Excess alcohol was then removed by distillation under high vacuum. Compounds **3a–c** were isolated in the form of violet oils. They are not soluble in water and show IR bands typical for tris(tricarbonylcobaltio)methylidyne compounds (ν 2025(w), 2037(s), 2055(ss) cm^{-1}).

4: Chlorosilane **1** (0.574 g, 1 mmol) was taken up in polyethylene glycol 400 (10 mL) and maintained at 80 °C for 24 h under an atmosphere of CO. The sediment was filtered off; the Co content of the solution was 13.75 $g\,L^{-1}$ (determined by atomic absorption spectroscopy).

Hydroformylation of 1-hexene: The catalysis tests were carried out in a 100 mL laboratory autoclave. In a typical reaction, a solution of compound **4** in polyethylene glycol (2 mL) as prepared above (for Co content see Table 1) was added under nitrogen to 1-hexene (2 mL, 16 mmol). The autoclave was then filled with a mixture of CO and H_2 (1/1) at 70 bar, and the mixture was stirred at 120 °C for 8 h. After the reaction the phases separated within ca. 2 h. Phase separation can be accelerated by adding pentane. The product phase was separated and recovered, and the products were analyzed by gas chromatography by comparison with authentic samples and by GC-MS. The yields of aldehyde were determined by gas chromatography (DB-5, 30 m) using heptane as an internal standard. The polyethylene glycol phase containing the catalyst can be used for further catalytic cycles. Catalysis tests with **2** were carried out analogously under the conditions given in Table 1.

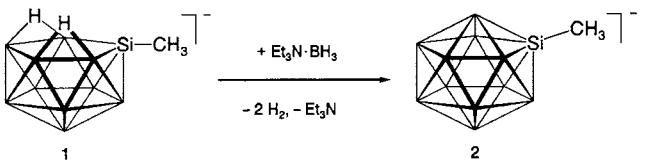
[21] The main products detected were 1-heptanal, 2-methylhexanal, and 2-ethylpentanal. Hydrogenation of 1-hexene to hexane and of the aldehydes to alcohols was not observed. After longer reaction times, small amounts of aldehyde condensation products and oxidation products could be detected (< 6%).

The First *closo*-Monosilaborane**

Lars Wesemann* and Ulli Englert

In comparison to the thoroughly investigated carboranes[1] the study of silaboranes is still very young; until now only two of these compounds have been structurally characterized.[2, 3] Recently we were able to establish that the nucleophilic fragmentation of 1,2-dimethyl-*o*-silaborane forms **1** and thereby achieved the synthesis of the first *nido*-silaborane.[3] Here we report on the first reaction of **1**, which can be described as the first cluster construction reaction with a silaborane. Compound **1** reacts with an excess of $Et_3N \cdot BH_3$[4] in boiling bis(2-methoxyethyl) ether to form 1-methyl-1-sila-*closo*-dodecaborate(1 −) **2** in 93% yield.



1 2

The constitution of 2 can be ascertained unequivocally from its NMR spectra. The appearance of only three signals in the ^{11}B NMR with an intensity ratio of 5:1:5 for eleven B atoms indicates that the cluster framework has fivefold symmetry. The assignment of the signals for the groups B2–B6 and B7–B11 as well as for B12 (for numbering scheme see Fig. 1) can be confirmed by the 2D ^{11}B-^{11}B NMR spectrum. Interestingly the influence of the heteroatom on the ^{11}B NMR shifts of $EB_{11}H_{11}$ in comparison to those of $[B_{12}H_{12}]^{2-}$ ($\delta = -15.3$) is especially significant for the B atom directly opposite to the heteroatom (B12).[5] This phenomenon has also been termed an "antipodal effect". In the above-mentioned example the value of the shift for B12 ($\delta = -14.6$) deviates only slightly from that for $[B_{12}H_{12}]^{2-}$. The signals for the B-bound H atoms can be assigned to the respective B groups by interpretation of the 2D ^1H-^{11}B NMR spectrum.

[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG-Schwerpunktprogramm "Polyeder").

The results of the crystal structure analysis[6] (Fig. 1) are in agreement with the structure in solution determined from spectroscopic data. The distances between the B atoms of the five-membered ring (B2–B6) capped by the Si atom are, as expected, larger [1.847(3)–1.860(3) Å] than the remaining B–B distances [1.762(3)–1.786(4) Å]. These are in turn only insignificantly longer than those in $[B_{12}H_{12}]^{2-}$ [1.755(7)–1.780(7) Å].[10] The Si–B distances are similar to those in the starting material **1**.[3]

Surprisingly many examples of the class of compounds $EB_{11}H_{11}$, to the which the title compound belongs, are already known: E = $MeAl^{2-}$,[11] RC^-,[12] $MeGe^-$,[13] $MeSn^-$,[13] Pb^{2-},[13] HN,[14] MeP,[15] As^-,[16] Sb^-,[17] S,[18] Se,[19] Te.[18] While the carbon compound homologous to **2** was synthesized as early as 1963, the higher homologues (Ge, Sn, Pb), which are formed by metathesis from $[B_{11}H_{11}]^{4-}$ and the metal dihalide, were first prepared in 1992.

Experimental Procedure

2: A solution of Et_4N-**1** (0.40 g, 1.36 mmol) and $BH_3 \cdot NEt_3$ (2.00 g, 17.4 mmol) in 5 mL of bis(2-methoxyethyl) ether was heated at reflux for 64 h. After all the volatile components were removed in vacuum, the residue was dissolved in 15 mL of THF and filtered. The product crystallized at room temperature when Et_2O was layered on top of the THF solution. Yield: 0.38 g (93%) Et_4N-**2**. Correct C, H analysis. NMR spectra at 25 °C in [D$_8$]THF: ^1H NMR (500 MHz, TMS): $\delta = 1.49$ (H7–H11, H12), 1.41 (H2–H6), 0.75 (s, SiMe), measurement and assignment of the B–H signals as crosspeaks in the 2D ^{11}B-^1H NMR spectrum; ^{11}B NMR (160 MHz, $Et_2O \cdot BF_3$): $\delta = -12.6$ (d, $J = 147$ Hz, B7–B11), −14.6 (d, $J = 134$ Hz, B12), −17.4 (d, $J = 134$ Hz, B2–B6); ^{13}C NMR (125 MHz, TMS): $\delta = -12.1$ (s, SiMe); ^{29}Si NMR (100 MHz, TMS): $\delta = -28$ (s).

Bis(lithiomethyl) Sulfide, An Unexpectedly Stable 1,3-Dilithiated Synthetic Building Block**

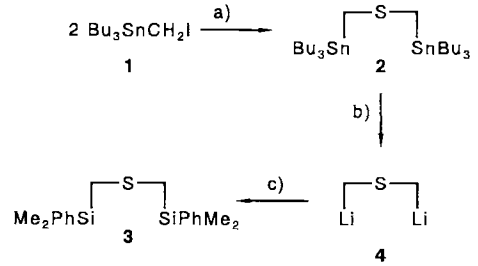
Carsten Strohmann*

Dilithio compounds can be classified as 1,1-, 1,2-, 1,3-, etc., dilithium compounds according to the distance between the metalated carbon atoms.[1] Despite their enormous synthetic potential only few 1,3-dilithio compounds are among the dilithio alkanes reported.[1] This deficit is due on one hand to facile lithium hydride β-elimination,[2, 3] and on the other to the absence of suitable synthetic methods.[1, 3] In the course of a systematic study aimed at the preparation of 1,3-dimetalated compounds of general formula $M-CH_2-E-CH_2-M$ (M = Li, MgBr, etc.; E = element of group 14–16, possibly with substituents), we prepared bis(lithiomethyl) sulfide **4**. This 1,3-dilithio compound serves as a bifunctional synthetic building block suitable for the preparation of inorganic and organic compounds containing a $-CH_2-S-CH_2-$ structural unit.

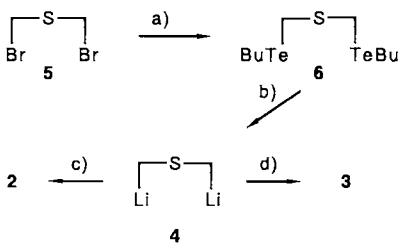
The most important strategies for the synthesis of organolithium compounds of general formula R_nE-CH_2-Li (E = element of group 14–16) are as follows: 1) hydrogen–lithium exchange, 2) halogen–lithium exchange, 3) metal–lithium exchange (each with either lithium bases or lithium metal).[1] Applying these strategies to the preparation of dilithio compounds of the general formula $Li-CH_2-E-CH_2-Li$ shows that direct metalation (first strategy) is often too slow (e.g., for $RP(CH_3)_2$)[4] or too unreactive (e.g., for $S(CH_3)_2$) for preparative purposes.[3] Halogen–lithium exchange in 1,3-dihalide compounds usually results in intramolecular lithium halide elimination after monometalation.[6] Double metal–lithium exchange therefore appeared the most suitable route, as this reaction proceeds very rapidly even at low temperatures and almost always quantitatively.[1, 7] The preparation of $MeN(CH_2Li)_2$ by tin–lithium exchange has been reported starting from $MeN(CH_2SnBu_3)_2$.[8] In case of the homologous $Me_2Si(CH_2SnPh_3)_2$ a stable cyclic stannate complex forms, and consequently only one organotin group exchanges.[1b] $Me_2C(CH_2Li)_2$ was prepared by mercury–lithium exchange.[2] The more recently reported tellurium–lithium exchange reaction[7, 9] has not yet been employed in the preparation of 1,3-dilithio compounds. To synthesize **4** we decided to attempt double tellurium–lithium or tin–lithium exchange.

The bis(tributylstannylmethyl) sulfide **2** was obtained in 92% yield by treating Bu_3SnCH_2I[10] with $Na_2S\cdot Al_2O_3$ in THF (Scheme 1) and purifying the product by Kugelrohr distillation. The analogous bis(butyltelluromethyl) sulfide **6** was synthesized analytically pure in 83% yield by treating $S(CH_2Br)_2$ (**5**)[11] with BuTeLi. Once again, purification was accomplished by Kugelrohr distillation (Scheme 2).

Treating the tellurium compound **6** with two equivalents *n*-BuLi in diethyl ether at −30 °C provided a colorless solid, which was identified by its chemical reactivity as **4**.[12] The by-product, di-*n*-butyl telluride, was removed by filtration, and, after washing with diethyl ether and drying under vacuum, **4** was obtained as a colorless powder that explosively ignites upon contact with traces of air. In the solid state **4** decomposed under argon at approximately 60 °C or explosively on impact. However, at



Scheme 1. Synthesis of bis(lithiomethyl)sulfide **4** by tin–lithium exchange: a) $+Na_2S\cdot Al_2O_3/-2\,NaI$; b) $+n$BuLi/ $-2\,SnBu_4$; c) $+2\,Me_2PhSiCl/-2\,LiCl$.



Scheme 2. Synthesis of bis(lithiomethyl) sulfide (**4**) by tellurium–lithium exchange: a) $+2$ BuTeLi/ -2 LiBr; b) $+2\,n$BuLi/ $-2\,TeBu_2$; c) $+2\,Bu_3SnCl/-2\,LiCl$; d) $+2\,Me_2PhSiCl/-2\,LiCl$.

−20 °C **4** could be stored for six months without decomposition. For preparative purposes a suspension of **4** in diethyl ether was used, as we found that after centrifugation the contaminant, di-*n*-butyl telluride, can be removed with the supernatant. An analogous transformation can be carried out in hexane as solvent. Interestingly, **4** also forms as a colorless solid by double tin–lithium exchange on **2** with *n*-BuLi in THF. No solvent has yet been found in which **4** dissolves without decomposition; determination of the structure of **4** in solution is thus not possible.[13]

The formation of **4** was confirmed by a series of control experiments: the reaction of **4**, which had been obtained from **6** by tellurium–lithium exchange, with Bu_3SnCl and $Me_2PhSiCl$ was studied, as was the reaction of **4**, which had been obtained from **2** by tin–lithium exchange, with $Me_2PhSiCl$ (cf. Schemes 1 and 2[14]). These studies were designed to answer two questions: 1. Is it indeed $LiCH_2SCH_2Li$ (**4**) that is afforded by complete metal–lithium exchange? 2. Is **4** the sole product of the metal–lithium exchange or do rearrangements also occur; rearrangements are, for example, well documented for lithiomethyl ether.[15] After separating $TeBu_2$ and $SnBu_4$, both of which are products of the metal–lithium exchange, we were able to answer the first question by showing that this exchange occurs quantitatively. Treatment of **4** with Bu_3SnCl yielded the anticipated **2** in greater than 95% yield (NMR spectroscopic studies, unseparated $TeBu_2$ as internal standard) confirming the product homogeneity of **4**, thus answering the second question.

In the solvents hexane, diethyl ether, and THF, bis(lithiomethyl) sulfide exhibits the chemical reactivity anticipated for a 1,3-dilithio compound. The observation of double tellurium–lithium exchange in both hexane and ethers is rather unusual; in contrast, 1,4-ditellura compounds react differently towards *n*-BuLi in hexane and THF.[16] The surprising stability of **4** is attributable to the fact that it forms a solid.

Additional reactions of **4** with inorganic and organic mono- and bifunctional reagents are currently being investigated. Preliminary results with analogous 1,3-dimetalated compounds consisting of main group elements other than sulfur show that the concept of double tellurium–lithium and tin–lithium ex-

change can be extended to encompass 1,3-dilithiated compounds of general formula $Li-CH_2-E-CH_2-Li$ (E = element of group 14–16, possibly with substituents).

Experimental Procedure

2 (from starting material **1**): Bu_3SnCH_2I (20 mmol) was added to a suspension of $Na_2S \cdot Al_2O_3$ (11 mmol) in THF (30 mL). The mixture was stirred at room temperature for 16 h, after which the solvent was removed under vacuum. The residue was extracted three times with 25 mL portions of hexane. The solvent was removed and, following purification by Kugelrohr distillation (oven temperature 165 °C/ *0.001 Torr*), compound **2** was obtained in 92% yield as a colorless oil. ^1H NMR (200.1 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.75-1.1$ (m, 12H; CH_3, $SnCH_2C$), 1.2–1.4, 1.4–1.7 (m, 42H; CCH_2C, CCH_3), 2.00 (s, 4H, $^2J(H,Sn) = 40.4$ Hz; $SnCH_2S$); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): $\delta = 9.6$ (6C, $^1J(C,^{119/117}Sn) = 329.6/315.0$ Hz; $SnCH_2C$), 13.7 (6C, CCH_3), 17.3 (2C, $^1J(C,^{119/117}Sn) = 233.7/223.2$ Hz, $^3J(C,Sn) = 30.3$ Hz; $SnCH_2S$), 27.3 (6C, $^3J(C,^{119/117}Sn) = 55.9/53.7$ Hz; $SnCH_2CH_2CH_2C$), 29.1 (6C, $^2J(C,Sn) = 20.8$ Hz; $SnCH_2CH_2C$); ^{119}Sn NMR (74.6 MHz, $CDCl_3$, 25 °C, $SnMe_4$): $\delta = -18.3$; MS (EI, 70 eV): *m/z* (%) = 640 (4) $[M^+]$, 583 (40) $[M^+ - C_4H_9]$, 527 (37) $[M^+ - C_4H_9 - C_4H_8]$, 291 (70) $[HSnBu_3^+]$, 235 (78) $[H_2SnBu_2^+]$, 179 (100) $[H_3SnBu^+]$; correct elemental analysis for $C_{26}H_{58}SSn_2$.

2 and **3** (from **6**): Under an inert atmosphere **6** (10 mmol) was dissolved in Et_2O (50 mL), and at −30 °C a solution of *n*-BuLi (20 mmol) in hexane was added. The mixture was stirred for 5 min at this temperature. Upon warming to room temperature **4** precipitated as a colorless solid. After centrifugation, the by-product $TeBu_2$ was removed with the supernatant, and the precipitate was washed with diethyl ether. This centrifugation–washing step was repeated four times. To the resulting suspension of **4** in Et_2O (approx. 30 mL) was added at −20 °C a solution of Bu_3SnCl (or $Me_2PhSiCl$ for **3**) (20 mmol), in 5 mL Et_2O. The mixture was warmed to room temperature, the solvent removed, and the mixture worked up as previously described (vide supra). Yield: 89% **2**/74% **3** (purification by Kugelrohr distillation at 155 °C oven temperature/0.001 Torr). Analogously, **3** was obtained from **2** employing THF as solvent. Yield: 84% [14].

6: Under an inert atmosphere a solution of BuTeLi was prepared by combining *tellurium* powder (12.8 g, 0.1 mol) in THF (150 mL) with a solution of *n*-BuLi (0.1 mol) in hexane (42 mL). Next, **5** (0.05 mol) dissolved in THF (5 mL) was added at −78 °C. The solution was allowed to warm to room temperature over 1 h, and volatile components were removed under vacuum. The residue was extracted with four 100 mL portions of hexane and volatile components were again removed under vacuum. Compound **6** was obtained as a colorless oil (traces of ditellurides can render the compound red) in 83% yield after Kugelrohr distillation at 135 °C oven temperature/0.001 Torr. ^1H NMR (200.1 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.87$ (t, 6H, $^3J(H,H) = 7.2$ Hz; CCH_3), 1.34 (sextet, 4H, $^3J(H,H) = 7.3$ Hz; CCH_2CH_3), 1.73 (quin, 4H, $^3J(H,H) = 7.4$ Hz; $CH_2CH_2CH_2$), 2.72 (t, 4H, $^3J(H,H) = 7.5$ Hz; $TeCH_2C$), 3.69 (s, 4H, $^1J(H,Te) = 32.3$ Hz; $TeCH_2S$); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): $\delta = 5.0$ (2C, $^1J(C,Te) = 201.2$ Hz; $TeCH_2S$), 5.4 (2C, $^1J(C,Te) = 151.4$ Hz; $TeCH_2C$), 13.3 (2C, CCH_3), 24.9 (2C, $^3J(C,Te) = 10.7$ Hz; CCH_2CH_3), 33.9 (2C, $^2J(C,Te) = 9.8$ Hz; $TeCH_2CH_2C$); ^{127}Te NMR (63.2 MHz, $CDCl_3$, 25 °C, $TeMe_2$): $\delta = 303.4$; MS (EI, 70 eV): *m/z* (%) = 430 (2) $[M^+]$, 373 (22) $[M^+ - C_4H_9]$, 58 (100) $[C_4H_{10}^+]$; correct elemental analysis for $C_{10}H_{22}STe_2$.

Trapping and Imaging Molecular Dynamics by Combining Scanning Force Microscopy with Topology**

Bruno Samorì,* Carmelo Nigro, Amalia Gordano, Innocenzo Muzzalupo, and Carla Quagliariello

Scanning force microscopy (SFM) makes it possible to image molecules tightly adsorbed on flat substrates such as mica, gold, or glass.[1, 2] The SFM images contain information on the height above the surface for the molecules examined. This made it possible directly to observe and identify the chiralities of native supercoiled DNA[3, 4] and F-actin,[5] and to reveal the three-dimensional structure of chromatin fibers.[6]

The main research emphasis with SFM is now shifting from the visualization of static structures to studies of chemical processes that attempt to use this technique as a tool for investigating the dynamics and reactions of molecules loosely attached to the substrate.[2, 7, 8] Linear fragments of DNA loosely adsorbed on mica have very recently been imaged in aqueous buffer solution and their dynamics observed within the SFM time resolution, which is of the order of one minute per image.[7, 8] However, as already pointed out,[8] in this kind of experiment the motion of the scanning probe-tip could contribute to the movement when very loosely attached molecules are examined. The "ghost" of the uncertainty principle could also haunt this kind of experiment. As in the classical Heisenberg uncertainty principle, the interaction between the measuring instrument and the object of observation might be not negligible relative to the magnitude of the measurement sought.

We tailored an experiment in which subtle vibrational motions following a transient and partial desorption of chain segments of DNA molecules attached to mica were trapped and detected by combining SFM and topological restriction.

Instead of imaging the molecules continuously to catch their movement during diffusion, we monitored those processes by trapping them topologically and imaging just before and just after they had taken place.

Supercoiled pBR322 DNA plasmids were deposited on mica from a buffer solution containing 10 mM Mg^{2+} ions that induce cross-bridges between mica and DNA phosphates.[9] The sample was blown dry with nitrogen, irradiated with UV light to induce nicks, and dipped in water for different periods before being dried again and imaged with the tapping mode in air. Figure 1 shows that the molecules gradually acquire a more

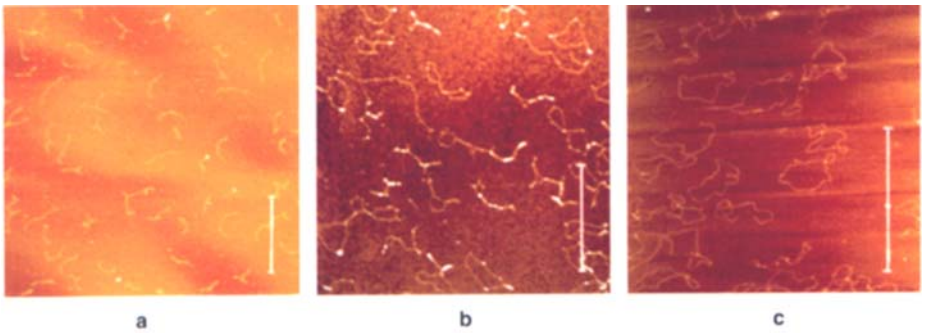

Fig. 1. SFM overview image of tightly supercoiled circular DNA molecules with either branched or unbranched shapes, deposited and dried on mica (a). When the sample is dipped in water the forces of adsorption are gradually released. Images (b) and (c) were obtained after 60 min and 12 h dipping, respectively. Bars represent 1 μm.

Fig. 2. Transient desorptions and detachments of chain segments in tightly supercoiled DNA molecules adsorbed on mica as in (a) are topologically trapped and revealed, whenever they take place, by the opening and the enlarging of loops as in (b). Detachments of increasingly larger chain segments cause the molecules to assume open circular shapes as in (c). Bars represent 100 nm.

open shape as the dipping time increases. In control experiments with nonirradiated samples the molecules maintain their tightly supercoiled shapes even after 12 h in water. As the images in Figures 1 and 2 show, the opening of the nicked molecules produces structures with open loops, which expand locally and gradually at the expense of other segments that are still very tightly supercoiled.

The chains of supercoiled circular DNA molecules are under permanent torsional strain because they have fewer duplex turns than linear DNA molecules of the same length, and because the unbroken looping of their two polynucleotide strands constricts their topology.[10] This constriction is released and the molecules are allowed to relax to open circular shapes (Fig. 1c and 2c) only when at least one of the covalent bonds in one strand is nicked so that one strand can rotate freely about the other at the nick site. In our experiment, after being nicked by the UV light[11] and ozone[12] in the irradiation box (see experimental), the DNA molecules cannot relax their supercoiling as long as they are left dried and fossilized on mica (Fig. 1a and 2a). When the samples are dipped in water, the Mg^{2+} ions anchoring the DNA chains to mica are gradually removed. Larger and larger chain segments detach from the mica and acquire the mobility required to relax their supercoiling torsional strain at the nicks induced in the strands by irradiation with UV light (Fig. 1b and 2b). The extent of the nicking thus affects the sensitivity of this approach.[13] If the frequency of the nicks along the chain is high, the supercoiling of a chain segment is relaxed whenever it moves away from the substrate. Even very minor and transient[14] motions of single adsorbed molecules, which would be very difficult to detect with any other physical technique or even with direct SFM imaging in solution, can be trapped and detected with this method without the risk that they might have been induced by the scanning tip.

Chemical topology provides permanent internal markers of any molecular event linked to bond-breakage and reunion events, no matter how evanescent the molecular structures are and how fast and transient the process is.[10] SFM imaging combined with topological restrictions can make it possible to catch those events and to study them without interfering with their dynamics.

Experimental Procedure

A 20 μL droplet of a 40 μM HEPES buffer solution containing 1 $\mu g mL^{-1}$ of supercoiled pBR322 DNA plasmid and 10 mM $MgCl_2$ was deposited on a disk of freshly cleaved ruby mica. The sample was quickly rinsed with few drops of water, blotted with filter paper, dried under a gentle flow of nitrogen, and then irradiated for 90 s in a small box with three 15 W Hg/Xe lamps. It was then immersed face-up and left for different periods in the dark in a dish with approximately 50 mL of deionized, doubly distilled water, degassed with a flow of argon. The samples were blotted and blown dry again, and then imaged under a dry nitrogen atmosphere with the tapping mode SFM (Nanoscope III, Digital Instruments, Santa Barbara, CA).

The original DNA sample was at least 95% supercoiled, as determined by agarose electrophoresis. Linear and open-circular nicked molecules were eliminated by treating the native *E. coli* pBR322 DNA samples with exonuclease III [15] in order to avoid deposition on mica of DNA molecules already relaxed.

[13] It is most likely that a better control of the extent of the nicking can be achieved in the future by using cleavage methods that have been employed as probes of DNA structure in solution (D. M. J. Lilley, *Methods Enzymol.* **1992**, *212*, 133–139). Ozone has been found to nick pBR322 plasmids at specific sites [12].
[14] These segments are transiently released from the surface, because the number of molecules in the field of vision remains pratically constant for hours after all of them have already assumed an open shape. With a lower initial Mg^{2+} concentration the number of molecules adsorbed on mica decreases and their complete desorption is reached after shorter dipping times.

Programmed Self-Assembly of Copper(II)-L- and -D-Arginine Complexes with Aromatic Dicarboxylates to Form Chiral Double-Helical Structures**

Nayumi Ohata, Hideki Masuda, and Osamu Yamauchi*

Self-assembly of molecules leading to unique properties and functions has attracted a great deal of attention in recent years.[1-4] It results from an interplay of various noncovalent interactions and is often assisted by coordination to metal ions. The stereospecific assembly of molecular aggregates can be achieved by introducing chiral building blocks. Typical examples include the right-handed spiral of α-helices in proteins[5] and the right-handed double-helical structure of DNA.[6] We report here on the formation of crystalline $[Cu(L\text{-}Arg)_2](L)$ (L = *m*-phthalate (pa), 2,6-dicarboxylate (2,6-dipic)) and $[Cu(D\text{-}Arg)_2](L)$ (L = pyridine-3,5-dicarboxylate (3,5-dipic)) from copper(II), L- or D-arginine (Arg), respectively, and an aromatic dicarboxylate (L). These crystals reveal a unique hydrogen bonding network, which forms a right-handed and a left-handed double helix, respectively, depending on which arginine enantiomer was used.

Double- and triple-helical metal complexes have been shown to form for metal ions favoring tetrahedral coordination geometry such as Cu^{I}, Ag^{I}, and Ni^{II}.[7-12] The formation of such complexes is also involved in the sequence-specific DNA binding by zinc finger proteins, as revealed by X-ray studies.[13-15] The guanidinium group of arginine in proteins plays an important role in binding with carboxylate[16,17] and phosphate[18] moieties; two types (types A and B) of hydrogen bonds[19] can occur which contribute to the hydrogen bonding network. The guanidinium–carboxylate pair is ideal for bridge formation, and by using double hydrogen bonds,[19] complexes may thus form in a "programmable" way by self-assembly of the components Cu^{II}, Arg, and a dicarboxylate L.

Single crystals of $[Cu(L\text{-}Arg)_2](pa)\cdot 6H_2O$ (**1**), $[Cu(L\text{-}Arg)_2](2,6\text{-dipic})\cdot 5H_2O$ (**2**), and $[Cu(D\text{-}Arg)_2](3,5\text{-dipic})\cdot 5H_2O$ (**3**) suitable for X-ray analysis were obtained in 30–40% yields by mixing an aqueous solution containing $CuCl_2\cdot 2H_2O$ (0.171 g, 1.0 mmol) and L- or D-Arg (0.348 g, 2.0 mmol), respectively, with an alkaline (2 equiv NaOH), aqueous solution of L (L = pa, 2,6-dipic, and 3,5-dipic, respectively) and subsequent slow vapor diffusion with ethanol. The complexes **1**–**3** crystallize in the same space group, and the corresponding crystallographic parameters are very similar, although the three carboxylates L are subtly different due to the presence of the ring nitrogen and the positions of the carboxylate substituents relative to the nitrogen.[20] The crystallographic parameters of the D-enantiomer analog of **1** are similar to those of **1**.[21] The crystals of **1**–**3** contain four $[Cu(Arg)_2]^{2+}$ ions, four L^{2-} ions, and twenty or twenty-four water molecules in the unit cell, all of which are connected by a hydrogen bonding network. Figure 1a shows a view of crystallographically independent molecules in the unit cell of **1**. The Cu^{II} ion has a square-planar geometry with the two amine nitrogen atoms and two carboxylate oxygen atoms from two L-Arg molecules coordinated in the *cis* configuration. The Arg side chains of the complex ion are extended outward from the Cu^{II} coordination sphere, forming type A hydrogen bonds with the carboxylate group of an L^{2-} ion situated between the complex ions. The L^{2-} ions thus connect the Arg side chains to form an infinite chain from L^{2-}-$[Cu(L\text{-}Arg)_2]^{2+}$ units with a helical structure extended along the crystallographic *a* axis. Two such chains or strands are bound together through the hydrogen bonds between the coordinated amino groups of one strand and the L^{2-} carboxylate groups of the other strand to form a double helix. In the crystal structure one double helix thus formed is connected to a neighboring double helix through type B hydrogen bonds between the guanidinium group of one double helix and the carbonyl oxygen atoms of two carboxylate groups coordinated to a Cu^{II} ion bound in the neighboring double helix (Fig. 1b). Considering

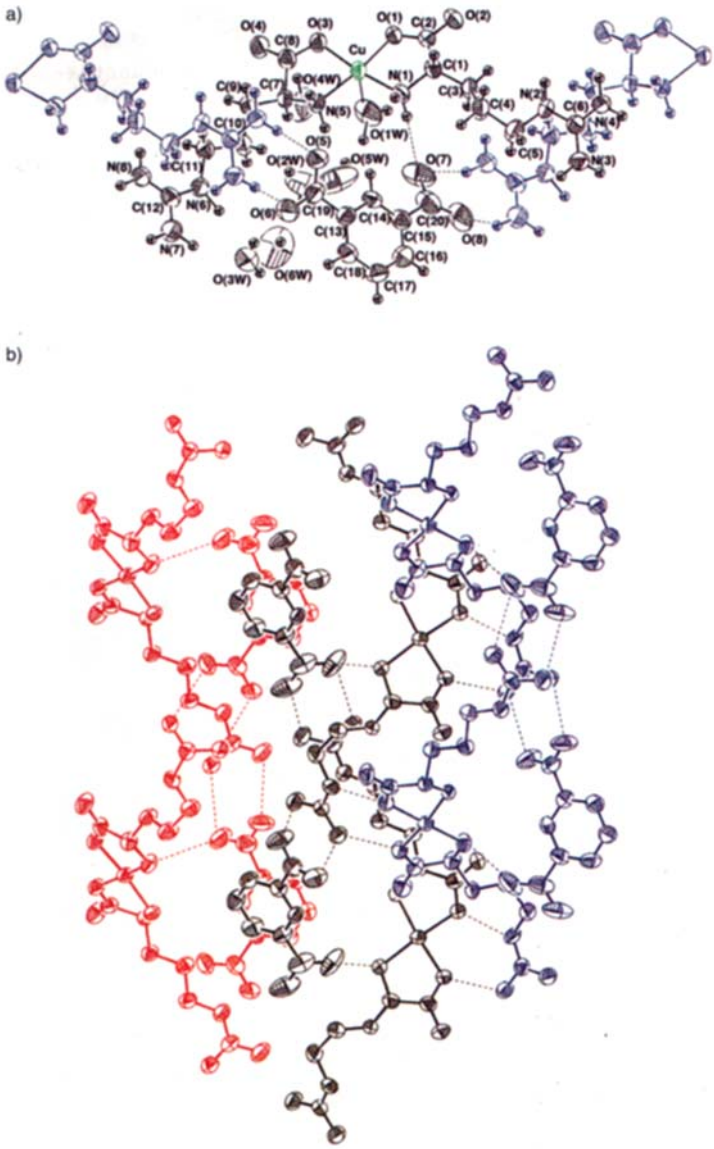

Fig. 1. a) Structure of crystallographically independent molecules in the unit cell of $[Cu(L\text{-}Arg)_2](pa)\cdot 6H_2O$ (**1**). b) Crystal structure of **1** showing the hydrogen bonds between a double helix (black) and two neighboring double helices (red and blue).

that Cu^{II}–Arg complexes can usually assume both *cis* and *trans* configurations in the Cu^{II} coordination plane,[22, 23] these hydrogen bonds probably contribute to the *cis* configuration of the Cu^{II} coordination structure. The stacking of the aromatic rings of the L^{2-} ions with a mean interfacial distance of 3.49 Å leads to a further stabilization of the association between the double helices. The crystal structures of **2** and **3**, which are similar to the structure of **1**, reveal that the nitrogen atoms of 2,6-dipic and 3,5-dipic are not involved in coordination and hydrogen bonding, indicating that all the dianions L used function as bridging groups in essentially the same manner. In all three structures water molecules are not involved in the intra- and interstrand hydrogen bonding, except one water molecule which is axially coordinated with a Cu–O distance of 2.522(6), 2.387(8), and 2.385(5) Å for **1**, **2**, and **3**, respectively.

Interestingly, complexes **1** and **2** involving L-Arg form a right-handed helix, whereas complex **3** with D-Arg forms a left-handed helix (Fig. 2). This indicates that the handedness of the

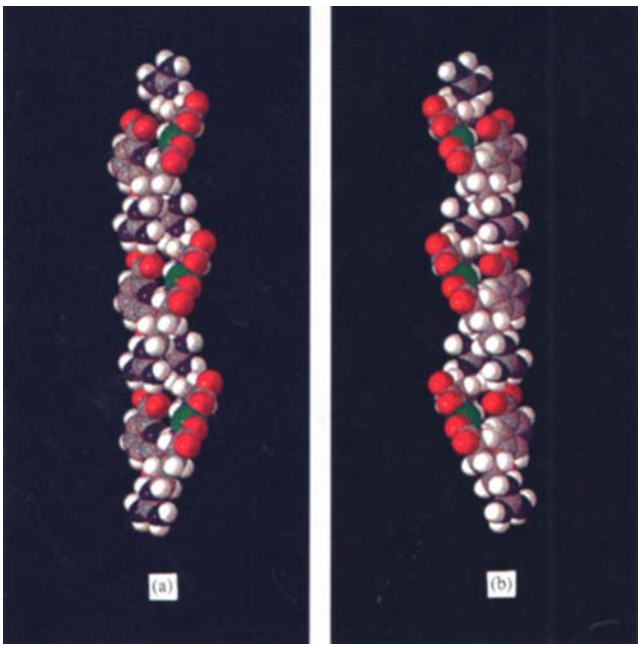

Fig. 2. Space-filling models of $[Cu(L\text{-}Arg)_2](2,6\text{-dipic})\cdot 5H_2O$ (**2**) (a) and $[Cu(D\text{-}Arg)_2](3,5\text{-dipic})\cdot 5H_2O$ (**3**) (b) showing a right-handed and a left-handed double helix, respectively, formed by intra- and interstrand hydrogen bonds. C: gray, H: white, O: red, N: blue, Cu: green.

double helices in the solid state is governed by the configuration of the α-carbon atom of the amino acids and is therefore coded in the $[Cu(L\text{-}Arg)_2]^{2+}$ and $[Cu(D\text{-}Arg)_2]^{2+}$ units, respectively. On the other hand, the *cis*-configurated complex $[Cu(L\text{-}Arg)_2](NO_3)_2\cdot 3H_2O$ does not form a double-helical structure but exhibits an infinite three-dimensional network of hydrogen bonding in which the guanidinium group, nitrate ions, and water molecules participate.[23] Weak hydrogen bonding in chiral diamine and diol motifs has recently been reported to give a triple-stranded helicate, whose helicity is dependent on the configurations of the two asymmetric carbon atoms of the diamine.[24]

The crucial difference between the structures of complexes **1**–**3** and that of $[Cu(L\text{-}Arg)_2](NO_3)_2$ lies in anionic bridging groups, L^{2-} and NO_3^-, respectively. Whereas the NO_3^- ion is small and located relatively independent of neighboring NO_3^- ions in the crystal, L^{2-} requires more space and can form two sets of spacially isolated hydrogen bonds. Therefore, the stereospecific helix formation may be regarded as "programmed" by the L^{2-} unit, which serves as a knot for the guanidinium–carboxylate bridge and reads the information of handedness coded in the $[Cu(L\text{-}Arg)_2]^{2+}$ or $[Cu(D\text{-}Arg)_2]^{2+}$ units.

These results point to the intrinsic factors for self-assembly of molecules by hydrogen bonding and for the handedness of the resulting helices, and may contribute to the understanding of organized systems in biology.

[20] Ali X-ray diffraction data were collected at 295 K with a Rigaku AFC-5R four-circle diffractometer with a rotating anode and using graphite-monochromated $Cu_{K\alpha}$ radiation ($\lambda = 1.54178$ Å) up to $2\theta_{max} = 120°$. The intensities were corrected for Lorentz and polarization effects. An empirical absorption correction, based on Ψ scans, was applied for all the crystals. The structures were solved by direct methods and refined anisotropically for non-hydrogen atoms by full-matrix least-squares methods by using reflections with $I > 3\sigma(I)$. The weighting scheme $w^{-1} = \sigma^2(F_o)$ was employed for each crystal. All calculations were performed by using the program system teXsan. All the hydrogen atoms, except for some of the water hydrogen atoms, were located from the difference Fourier maps, whose parameters were not refined. **1**: $C_{20}H_{44}N_8O_{14}Cu$, $M_r = 684.16$, orthorhombic, space group $P2_12_12_1$, $a = 13.293(4)$, $b = 30.100(7)$, $c = 7.57(1)$ Å, $V = 3027(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.501$ g cm^{-3}, $\mu = 17.11$ cm^{-1}, $F(000) = 1444.0$, $R = 0.043$, $R_w = 0.031$ for 1953 observed reflections. **2**: $C_{19}H_{41}N_9O_{13}Cu$, $M_r = 667.13$, orthorhombic, space group $P2_12_12_1$, $a = 13.158(3)$, $b = 29.608(2)$, $c = 7.457(3)$ Å, $V = 2905(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.525$ g cm^{-3}, $\mu = 17.53$ cm^{-1}, $F(000) = 1404.0$, $R = 0.047$, $R_w = 0.042$ for 1694 observed reflections. **3**: $C_{19}H_{41}N_9O_{13}Cu$, $M_r = 667.13$, orthorhombic, space group $P2_12_12_1$, $a = 13.158(4)$, $b = 29.596(5)$, $c = 7.464(3)$ Å, $V = 2906(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.524$ g cm^{-3}, $\mu = 17.52$ cm^{-1}, $F(000) = 1404.0$, $R = 0.044$, $R_w = 0.039$ for 2274 observed reflections. Methyltrioxorhenium(VII)-Catalyzed Epoxidation of Alkenes with the Urea/Hydrogen Peroxide Adduct

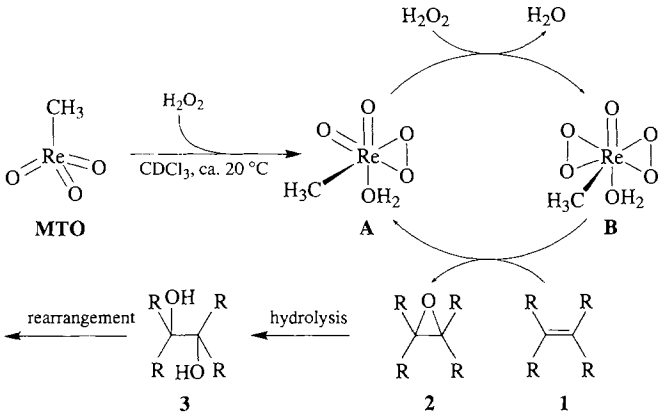
Waldemar Adam* and Catherine M. Mitchell

Selective catalytic oxidations are rapidly gaining importance in organic synthesis. The use of transition metal complexes as catalysts for such reactions is of particular interest,[1] on the one hand because of the high selectivity and the versatility of these complexes and on the other hand due to their ability to activate oxidants such as molecular oxygen and hydrogen peroxide. During the last five years, a broad spectrum of transformations of organic compounds catalyzed by the organometallic complex methyltrioxorhenium (MTO) has been reported.[2] The epoxidation of olefins with hydrogen peroxide was the first type of reaction to be described[2a-d] (Scheme 1). Although the oxidation of olefins in many cases



Scheme 1.

leads efficiently and selectively to the corresponding epoxides, a typical side reaction is the conversion of the hydrolytically sensitive epoxides to 1,2-diols,[2b] which sometimes undergo cleavage and rearrangement reactions (pinacol rearrangement, Hock cleavage, etc.). Such secondary reactions can now be suppressed by replacing hydrogen peroxide with the urea/hydrogen peroxide adduct (UHP) as primary oxidant. This enables epoxidations to be carried out in nonaqueous media, whereby the formation of diols and cleavage and rearrangement reactions are largely avoided. In the case of the epoxidation of chiral allylic alcohols, for the first time high diastereoselectivities (dr > 90:10) were achieved for an MTO-catalyzed reaction.

H_2O_2 adducts have already been widely employed as oxidants in organic synthesis[3] and are also particularly important in the detergent industry; one example is the peroxy salt $4Na_2SO_4 \cdot NaCl \cdot 2H_2O_2$ in neutral washing powders.[3i, 4] The only known metal-catalyzed oxidations are the epoxidation of 1,2-dihydronaphthalene with urea/hydrogen peroxide catalyzed by a Mn(salen) derivative (H_2salen = bis(salicyliden)ethylenediamine)[5] and the Mn(porphyrin)-catalyzed epoxidation of cyclooctene with various H_2O_2 adducts.[6] The adducts used in these cases include Na_2CO_3, $(CH_3)_3NO$, and $(C_6H_5)_3PO$, and also urea in one case. The urea presumably acts as a ligand; moreover, in the form of the adduct, which is present in solid and undissolved form, it also allows the H_2O_2 concentration in the reaction mixture to be exactly dosed. However, in most cases the addition of a coreactant (acetic anhydride, maleic anhydride, *para*-nitrobenzoyl chloride, *para*-nitrobenzoyl imidazolide, phthalic anhydride, tetrabutylammonium hydroxide, trifluoroacetic anhydride, etc.) is necessary for successful oxidation.

The use of additives such as amines, for instance 4,4'-dimethyl-2,2'-bipyridine, quinine, and quinchonine,[2b, 2d] has been reported for MTO-catalyzed epoxidations directly with hydrogen peroxide. Although formation of 1,2-diols is thereby suppressed, the activity of the catalyst is also diminished.[2d] When an equimolar amount of the adduct (with respect to the oxidant) is used, the conversion drops by 23% for 2,2'-bipyridine, by 60% for quinoline, and even by 96% in the case of isoquinoline. In contrast, when UHP is employed as oxidant, the respective epoxide is obtained selectively, often with high conversion.

We report here on our investigation of the MTO-catalyzed epoxidation of several selected olefins. Our results (Table 1) show that the hydrolytic ring-opening of the epoxide **2** to give the corresponding diol **3** with aqueous H_2O_2 (Table 1, entries 2 and 5) can be avoided with UHP (Table 1, entries 1 and 4). As the most striking example, the reaction of camphene (Table 1, entries 4 and 5) in the absence of urea adduct and after only 3 h

Table 1. MTO-catalyzed epoxidation of olefins with the urea/hydrogen peroxide adduct (UHP) [a].

Entry	Olefin **1**	Oxidant	*t* [h]	Conv. [%]	Epoxide [b] **2**	1,2-Diol [b, c] **3**

[a] Olefin:oxidant:MTO = 1:1:0.01 (mol ratio) in $CDCl_3$, ca. 20 °C, argon atmosphere, mass balance 100%, error ±5% of the stated values. [b] Normalized to 100% conversion. [c] Yield of the pinacol rearrangement product (aldehyde) in parentheses. [d] Traces of rearrangement products were also obtained. [e] Traces of *trans*-cinnamaldehyde were detected in the ^{1}H NMR spectrum of the crude reaction mixture.

results exclusively in cleavage and rearrangement products; however, with UHP only the desired camphene oxide is obtained, which is stable under the modified reaction conditions (conversion 92% after 30 h at room temperature (ca. 20 °C) with UHP in $CDCl_3$). In the absence of MTO no reaction takes place under otherwise identical reaction conditions. Further examples (Table 1, entries 3, 6, 8–11) illustrate the scope (<10% ring opening); considerable hydrolysis (ca. 32%) occurs only for the very hydrolytically sensitive α-methylstyrene oxide (Table 1, entry 7). Presumably the high Lewis acidity of the peroxo complexes **A** and **B** (Scheme 1) is not sufficiently buffered by the addition of urea to suppress completely such secondary reactions under the reaction conditions. [**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 347 "Selektive Reaktionen metallaktivierter Moleküle"), Schwerpunktprogramm "Peroxidchemie: Mechanistische und präparative Aspekte des Sauerstofftransfers", Bayerischer Forschungsverbund Katalyse (FORKAT), and the Fonds der Chemischen Industrie. We are grateful to Prof. Dr. W. A. Herrmann for a generous supply of methyltrioxorhenium.

ditives such as amides, peptides, and amino acids, which control the hydrolysis of cyclohexene oxide in analogy to urea (not shown in Table 1), have a much more limited influence on the reaction. So far the mechanism behind the buffering effect of these additives on the Lewis acidity of Re^{VII} has not been elucidated.

In the case of electron-poor olefins such as *trans*-cinnamaldehyde, *trans*-methyl cinnamate, and 2-cyclohexenone (not shown in Table 1), the reactivity of the substrate is reduced to such an extent that the epoxidation competes with the decomposition of the catalyst. Even after approximately 20 h at about 20 °C with UHP in $CDCl_3$ hardly any conversion ($\leq 5\%$) was observed for these substrates.

To date, the diastereoselectivity of the MTO-catalyzed epoxidation has not been investigated, presumably because of the various subsequent reactions (hydrolysis, cleavage, rearrangement), which can now be avoided with UHP as oxidant. To test the selectivity, the epoxidation of chiral allylic alcohols **1a–f** to give the respective *threo*- and *erythro*-epoxy alcohols **2a–f** was carried out, for which high yields ($\geq 95\%$) were achieved (Table 2). What is noticable in Table 2 are the high diastereoselectivities (*threo*/*erythro* > 80:20) for substrates **1c–f** (Table 2, entries 3–6) in comparison with those for **1a,b** (Table 2, entries 1 and 2). It is mechanistically relevant to compare the derivatives **1a** (1,2-allylic strain), **1c** (1,3-allylic strain), and **1d** (1,2- and 1,3-allylic strain), as the diastereoselectivities in Table 2 (entries 1, 3, and 4) show. The 1,3-allylic strain[7] is decisive for the high diastereoselectivities demonstrated by results obtained with substrates **1e,f** (Table 2, entries 5 and 6); it operates in combination with the established hydroxyl group control[8] to afford the preferred *threo* isomer. These high π-facial diastereoselectivities point to pronounced interaction between the oxygen acceptor (chiral allylic alcohol) and the activated oxygen donor (diperoxorhenium complex) by the formation of hydrogen bonds.

Table 2. MTO-catalyzed oxidation [a] of chiral allylic alcohols **1** to the corresponding *threo*- and *erythro*-epoxides **2** with the urea/hydrogen peroxide adduct and comparison with the diastereoselectivities of reported epoxidations.

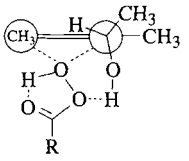
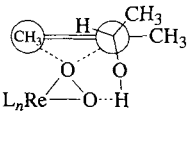
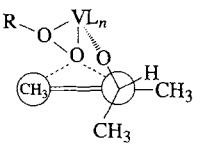
[a] Olefin:oxidant:MTO = 1:1:0.01 (mol ratio) in $CDCl_3$, ca. 20 °C, argon atmosphere, mass balance 100%, error ±5% of the stated values. [b] Ref. [9]. [c] Ref. [10]. [d] Ref. [11].

To ascertain the structural aspects of the interaction between the chiral allylic alcohol substrate and the metal-activated oxidant, a comparison with stereochemically established epoxidations such as those with peracid (*threo*-selective)[9–11] and $VO(acac)_2$/*t*BuOOH (*erythro*-selective)[9,10] is informative (Table 2). In the epoxidation of the allylic alcohol **1d** (Table 2, entry 4) as a stereochemical probe (1,2- and 1,3-allylic strain), it becomes clear that the MTO/UHP reaction proceeds through a transition state analogous to the peracid transition state *threo*-**1d**‡ and not one analogous to *erythro*-**1d**‡, the $VO(acac)_2$/*t*BuOOH transition state. Therefore it is certain that our system relies on hydrogen bond formation similar to that in epoxidations with peracids and not on direct bonding of the alcoholate to the metal complex as in the vanadium case. These are first hints on the transition state structure for the oxygen transfer in MTO-catalyzed epoxidation.



threo-**1d**‡





erythro-**1d**‡

One advantage of our simple MTO/H_2O_2 epoxidation of alkenes **1** with urea/hydrogen peroxide is the catalytic mode (which can be extended to the preparative scale (cf. Experimental Procedure; e.g. the epoxidation of 0.5 g of the allylic alcohol **1e** leads to the epoxide *threo*-**2e** in 67% yield [*dr* 88:12]). In addition, acid-catalyzed secondary reactions (hydrolysis, cleavage, rearrangement) are largely suppressed due to the buffering action of urea, without adversely effecting the reactivity, as is the case when amines are added.[2d] We have also established that the high *threo* diastereoselectivity for chiral allylic alcohols requires a peracid-like transition state with π-facial control of hydrogen bond formation between oxygen donor and acceptor.

Experimental Procedure

General procedure for the epoxidation of olefins: A solution of MTO (12.3 mg, 49.0 μmol, 0.01 equiv) in $CHCl_3$ (10 mL) was mixed with the urea/hydrogen peroxide adduct (940 mg, 10.0 mmol, 2.00 equiv) and stirred under an argon atmosphere at ca. 20 °C for 10 min. The olefin **1e** (500 mg, 4.99 mmol, 1.00 equiv) was added dropwise and the suspension stirred for 18 h at about 20 °C, after which 5 mL of water was added. The mixture was extracted with CH_2Cl_2 (3 × 15 mL). The combined organic phases were washed with water (2 × 5 mL) and brine (5 mL), dried over $MgSO_4$, and then concentrated at 0 °C/30 mbar. Conversion ≥95% (determined by ^1H NMR analysis). Column chromatography (silica gel, ether/hexane

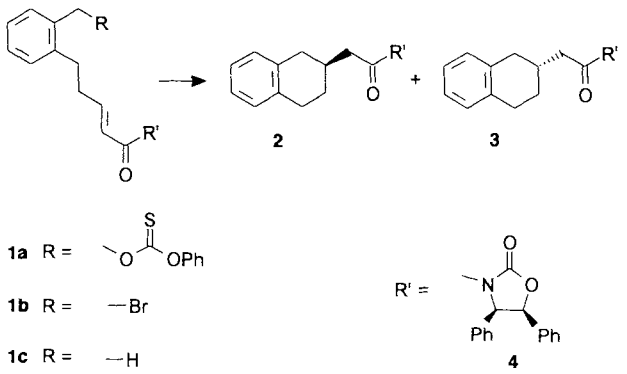
Diastereoselective Chelation-Controlled Radical Cyclization of Chiral Oxazolidinone-Derived 2-Alkenamides and Modeling of the Transition State**

Domenico Badone,* Jean-Marie Bernassau, Rosanna Cardamone, and Umberto Guzzi

The formation of carbon–carbon bonds by radical addition to alkenes is one of the most useful synthetic reactions in organic synthesis.[1] Though high α-stereoselection has been observed in radical additions to chiral acceptors, such as α,β-unsaturated amides and imides,[2] a high degree of β-stereoselection is difficult to achieve and remains a challenge. Recently Curran et al. introduced an auxiliary, derived from Kemp's triacid, that provides high β-diastereoselectivity in radical addition and annulation reactions.[3] However, several steps are required for the preparation of the auxiliary, and development of easier methodologies is still required.

We now report that the radical cyclization of **1a,b** bearing the oxazolidinone chiral auxiliary R′ gives **2** with good diastereoselectivity in the presence of a Lewis acid (Scheme 1). β-Tetralines like **2**, **3**, and their derivatives are valuable compounds in pharmaceutical research.[4]



Scheme 1. Radical cyclization of **1a,b**.

Asymmetric 1,4-additions of organometallic reagents to chiral α,β-unsaturated *N*-acyloxazolidinones has been studied, and they show excellent diastereoselectivity.[5] Scheme 2 outlines the synthesis of key intermediates **5** and **6**.[6] Coupling of **5** and **6** (DMAP, $CHCl_3$, 60 °C, 8 h) followed by acid hydrolysis of THP ether (AcOH, THF/H_2O, 50 °C, 8 h) gave the single diastereoisomer **7** ($E:Z$ >99:1) in 50% overall yield. Synthesis of **1a,b** was easily carried out (Scheme 3).

Radical generation and cyclization were obtained by three different reaction conditions: addition by syringe pump (3.4 mL h^{-1}) of TTMS and AIBN in C_6H_6 to a solution of **1a,b** (9×10^{-3} M) in C_6H_6 at 80 °C (A);[7] addition by syringe pump (3.4 mL h^{-1}) of SmI_2 in THF (0.1 M) to **1b** (9×10^{-3} M) in THF/HMPA 95/5 at 25 °C (B);[8] stirring of a solution of **1b** (10^{-2} M),

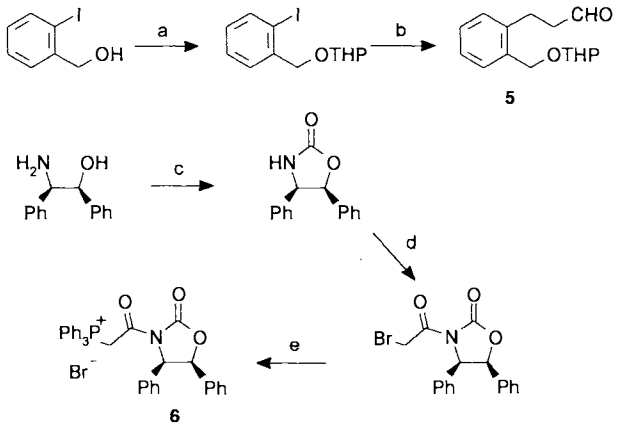
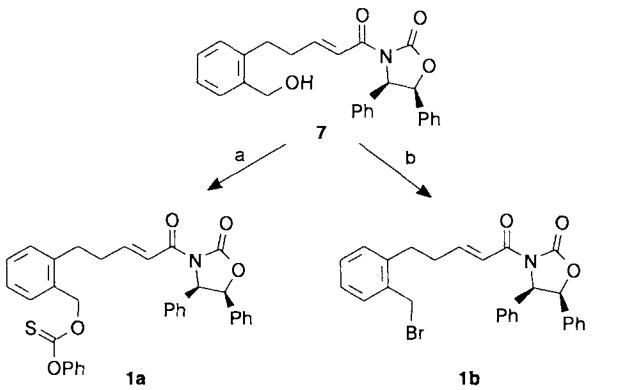


Scheme 2. Synthesis of **5** and **6**. a) 3,4-dihydro-2H-pyran, PTSA, CH_2Cl_2, 25 °C, 12 h (93%); b) allyl alcohol, $KHCO_3$, nBu_4NBr, $Pd(OAc)_2$ (2%), DMF, 90 °C, 2 h (87%); c) 1,1'-carbonyldiimidazole, THF, reflux, 3 h (70%); d) *n*BuLi, THF, −78 °C, 15 min, then $BrCH_2COBr$, -78 °C, 2 h (85%); e) Ph_3P, benzene, reflux, 3 h (90%).



Scheme 3. Synthesis of **1a,b**. a) ClCSOPh, pyridine, CH_2Cl_2, 0 °C, 2 h (65%); b) PBr_3, pyridine, benzene, 50 °C, 30 min, (95%).

nBu_3SnH, and Et_3B (10%) in toluene at 0 °C for 13 h (C).[9] The absolute configuration at the newly formed stereocenter of **2** was determined by comparison with the spectral data (^1H NMR, ^{13}C NMR) of a sample of **2** synthesized from known (*S*)-(−)-methyl 1,2,3,4-tetrahydronaphth-2-yl carboxylate.[10]

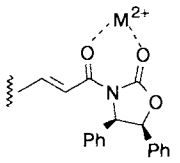


Fig. 1. Possible chelated *syn*-conformation of **1a,b**.

Good yields were obtained, but only modest diastereoselectivity (Table 1, entries 1–3).[11] The reversed diastereoselectivity observed when the cyclization was performed with SmI_2 (Table 1, compare entry 2 with entry 1) suggested that the Sm center was weakly or partially coordinated to the 1,3-dicarbonylic system (Fig. 1). Few stereoselective chelation-controlled radical reactions have been described, so we decided to test this idea with our substrate **1b**, using a Lewis acid with better coordinating properties than SmI_2.[12] Thus, cyclization of **1b** with method A in the presence of one equivalent of $MgBr_2 \cdot Et_2O$ gave an 82:18 mixture of **2** and **3** in fairly good yield (45%).[13] As shown in Table 1, no diastereoselectivity was obtained in the presence of $Ti(OiPr)_4$, in accord with reported results.[12b] When $ZnCl_2$ and $Sn(OTf)_2$ were employed, we obtained almost exclusively the product of Friedel–Crafts alkylation of the solvent (benzene) with **1b**.

Table 1. Radical cyclization of **1a,b**.

No.	Substrate	Method [a]	Lewis acid	**2**:**3** [b]	Yield [%] [c]
1	**1a**	A	none	45:55	75
2	**1b**	B	none	60:40	46
3	**1b**	C	none	50:50	60
4	**1b**	A	$Ti(OiPr)_4$	50:50	60
5	**1b**	A	$MgBr_2 \cdot Et_2O$	82:18	45

[a] For methods A–C see text. [b] The ratio was determined by ^{13}C NMR. [c] Yields of isolated products.

No simple stereochemical rationale for the observed diastereoselectivities (Table 1, compare entries 5 and 2 with entry 1) can be offered.[14] Compared to analogous Michael-like radical additions,[12b,e] which may be rationalized in an straightforward manner, the situation here is more complex. In order to gain insight into the key factors guiding the stereochemical course and possibly to improve the diastereomeric ratio, we decided to model the transition state by using a specifically developed "radical force-field".[15] The modeled transition state is shown schematically in Figure 2. Atom types of the

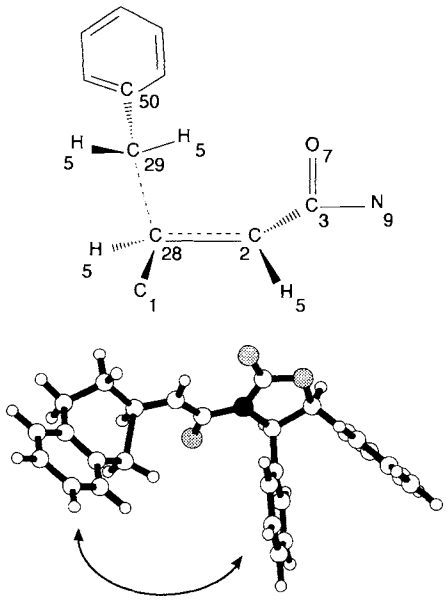

Fig. 2. Top: model of the transition state for the cyclization of **1a,b**. The numbers indicate the atom types used in the force field calculations. Bottom: van der Waals arene–arene attractive interaction in the structures of the transition states **A** and **B**.

MM2 force field were used in the calculations. The Spellmeyer–Houk parameter set for intramolecular alkenyl radical cyclizations proved to be a convenient starting point.[16] In this model the incoming radical center is defined as MM2 type 29 with type 1 (C_{sp^3}-hybridized C atom) atom equivalence.

However, radical cyclization of **1a,b** involved a benzylic radical, which is stiffer and reacts more slowly with alkenes than simple alkyl radicals, because "it resists pyramidalization more strongly than other species".[17] For this reason, we chose to change the atom type equivalence for the radical center from atom type 1 to atom type 2 (C_{sp^2}-hybridized C atom). This means that any undefined parameters corresponding to the radical carbon atom were assigned values equal to analogous parameters for type 2 atoms. The newly developed list of parameters is then as follows: For bond stretching, type 29-28 has bond length $L_0 = 2.14$ Å[18] and 50-29 has $L_0 = 1.39$ Å with the original force constants. For torsional parameters type 29-28-2-3 has the potentials $V_1 = 0$, $V_2 = -25.0$, $V_3 = 0$ by

analogy with Houk's parameters for type 29-28-2-5. Types 28-2-3-7 and 28-2-3-9 have $V_1 = 0$, $V_2 = 6.25$, $V_3 = 0$. This large V_2 term resulted in an overestimation of the rotational barrier around the X-C2-C3-Y bond, but it fits the experimental data better than smaller terms. These modifications generated a force field that modeled a Spellmeyer–Houk-like transition state in which the radical center is pyramidal.

The diastereoselectivity of the radical cyclization of **1a** (Table 1, entry 1) was computed by first calculating all possible minimum-energy transition conformations. We found eight structures. When included in a Boltzmann distribution calculation at a reaction temperature of 80 °C, four have energies within 3 kcal mol^{-1} of the transition state of lowest energy. Prediction of the diastereomeric ratio was in very good agreement with the experimental result (Fig. 3). Careful comparison of

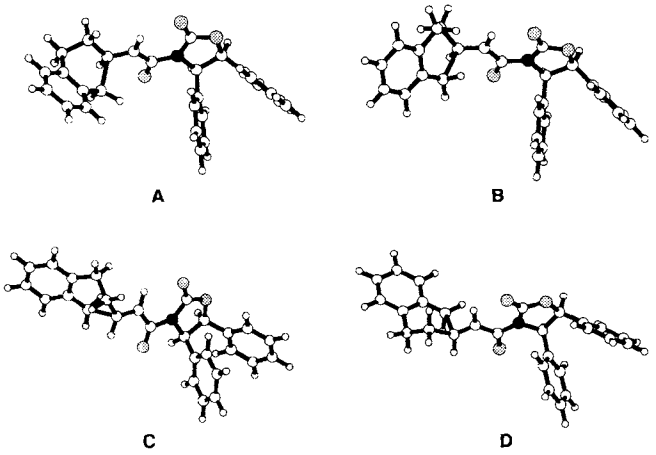

Fig. 3. Four models of the transition structures for the radical cyclization of **1a**. Experimentally determined ratio $R:S = 55:45$. Calculated ratio $R:S = 59:41$. The difference in energy between the structure **A** and **B**, **C**, and **D** are +0.02, +0.22, and +0.24 kcal mol^{-1}, respectively.

individual components of the total energies revealed that the van der Waals potential was the main difference in energy (-0.22 kcal mol^{-1} between **A** and **D**!). Detailed analysis of the van der Waals interactions between various atom groups of **A**–**D** showed an important attractive arene–arene interaction in conformations **A** and **B** (Fig. 2).[19] Therefore, the observed diastereoselectivity can be ascribed to attractive van der Waals interactions, and steric factors seem to play a secondary role.

Next, we computed the diastereoselectivity in radical cyclization of *syn*-1,3-dicarbonylic conformers to mimic the rigid system that is presumably formed in the presence of a Lewis acid (Fig. 1). The relative energies of the four structures obtained indicated that the diastereoisomer **2** was favored, and the diastereomeric ratio (81:19) calculated for **2**:**3** was in good agreement with the experimental data (Table 1, entry 5). Attractive van der Waals interactions between arenes, as for cyclization of **1a**, were again the major intraatomic forces responsible for the observed energy differences (Fig. 4).

In conclusion, according to the performed calculations, oxazolidinone group efficiently controls the *syn*- and *anti*-conformations of the amide linkage (Fig. 3), but the steric shielding of the 4-phenyl substituent plays only a minor role, and the diastereoselectivity is probably rather the result of attractive van der Waals interactions. We are currently conducting additional experiments to identify a suitable chiral auxiliary.

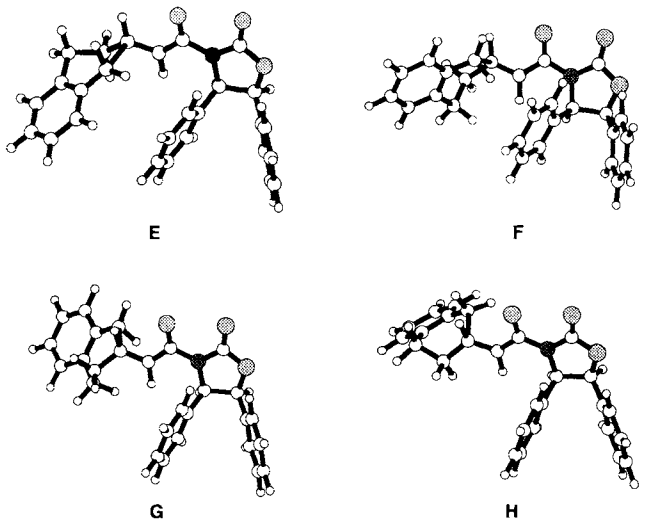

Fig. 4. Models of the transition states for the radical cyclization of *syn*-1,3-dicarbonylic conformer of **1b**. Experimentally determined ratio $R:S = 18:82$. Calculated ratio $R:S = 19:81$. The difference in energy between the structure **E** and **F**, **G**, and **H** are +0.08, +1.03, and +1.12 kcal mol^{-1}, respectively.

[14] Since after addition of a phenyl-stabilized radical another stabilized radical formed, it is possible that cyclization is thermodynamically controlled; then the observed diastereoselectivity is the result of the relative stabilities of the cyclized radicals. In order to gain some insight into this reaction mechanism, we conducted a control experiment in which the α-bromo derivative of pure **2** (easily obtained by Evans's procedure, ref. [20]) was treated by method A. The reaction yielded **2** quantitatively, and neither the reduced ring-opened product nor **3** could be detected. This result indicates that cyclization is under kinetic control.

Synthesis and NLO Properties of Polar Self-Assemblies of Molecular Pyramids Covalently Bound on Oxide Surfaces**

Xiaoguang Yang, Duncan McBranch, Basil Swanson, and DeQuan Li*

The construction of artificial supramolecular architectures on surfaces is currently of great interest and represents an important aspect of the chemistry of self-assembly processes,[1] because self-assembly offers rational design and construction of highly ordered mesoscale structures with defined chemical functionalities and physical properties. The preparation of polar molecular superstructures is particularly challenging and is an important endeavor since polar molecular compounds are essential for the development of materials with second-order nonlinear optical (NLO) properties. Several approaches such as the Langmuir–Blodgett technique, liquid crystals, and electric field poled polymers have been reported to generate molecular-based materials with organized polar architecture.[2, 3] However, the orientation in these materials is maintained by weak bonding or steric hindrance, which results in metastable structures with the loss of polar alignment over time. Recent developments in self-assembly and host–guest chemistry offer a novel route to ordered materials through the design and synthesis of new molecular building blocks, templates, and substructures that can be organized into supramolecular assemblies. The synthetic approach here is to fix dipole orientation by structural interlocking of NLO chromophores into cone-shaped "supermolecules", and then to utilize them to build polar self-assembled monolayers. In this communication, we report on the molecular design of calixarene-based NLO molecular "pyramids", their self-assembly on oxide surfaces, and their spectroscopic second-order NLO properties.

Organic NLO chromophores are typically π-conjugated molecules with a D-π-A structure, where D and A are electron donor and acceptor, respectively, and π is a π-conjugated segment or sensitizer. This structural feature has been widely used to attain large values of the molecular second-order nonlinear susceptibility β. By tethering these linear molecular units together through methylene bridges, a calixarene-based NLO chromophoric pyramid is derived.[4] Reinhoudt et al. have recently reported the study of poled neat calixarene films and calixarene-doped polymeric films for second-order nonlinear optics.[5] To achieve an optimum molecular value of β, the orientation of each D-π-A unit should be fixed in nearly the same direction. Therefore, we based our approach on the synthesis of a calix[4]arene with a frozen "cone" conformation by substitution at the lower rim with ethoxyethyl groups (Scheme 1). Similar procedures have been employed for the synthesis of bowl-shaped calixarene-based liquid crystals.[6, 7] The upper rim of the calixarene was then functionalized for the incorporation of pyridyl units (Scheme 1). Compounds **1a** and **1b** were synthesized according to literature procedures.[8, 9] Reduction of the nitrocalixarene **1b** gave the *p*-aminocalix[4]arene **1c** in 79% yield. The condensation of **1c** with 4-pyridylcarboxaldehyde gave the desired cone-shaped chromophoric precursor **2**. The total mass of compound **2** with a protonated pyridyl group (M + H) was determined by matrix-assisted laser desorption/ionization mass spectrometry (LDIMS). All of the compounds were characterized by ^{1}H NMR and IR spectroscopy. The ^{1}H NMR spectrum of **2** in $CDCl_3$ confirmed that it has a rigid cone conformation in which the D-π-A dipolar units are aligned in the same direction, since two doublets (J = 12 Hz) were observed for the equatorial and axial methylene protons.[4] The long ethoxyethyl groups prevent flip-over of the individual NLO units in **2**, and

the cone conformation is virtually frozen. Because of the rigid structure and fixed dipole orientation of the molecular building block, it is expected that the self-assembled monolayer (SAM) of **2** will have higher alignment and better thermal and structural stability than SAMs from single chromophoric units.

The construction of covalently bonded self-assembled monolayers of **2** is based on the methodologies reported by Li et al.[10] Silicon wafer and fused silica substrates were treated with the silane coupling agent *p*-chloromethylphenyltrichlorosilane in either toluene or chloroform for 24 h, followed by an incubation of silylated substrate in 1 mM of compound **2** in toluene at 110 °C for three days to quaternize the pyridyl groups on **2** (Scheme 1). Under these conditions, compound **2** is stable and no decomposition was observed. The monolayer was thoroughly cleaned by sonication in $CHCl_3$, followed by vigorous rinsing with $CHCl_3$ to remove any noncovalently bonded surface species. The self-assembled monolayers consisting of the pyramidlike imine derivative of calix[4]stilbazole were characterized by surface-polarized FTIR spectroscopy (Fig. 1a) by using internal attenuated total reflection (ATR) (Ge hemisphere crystal with *p*-polarization at 45° of incidence).[11] The formation of covalent C–N bonds between **2** and the silane anchoring layer was revealed by the presence of pyridinium species ($\tilde{\nu} = 1638\ cm^{-1}$ in Fig. 1b) on

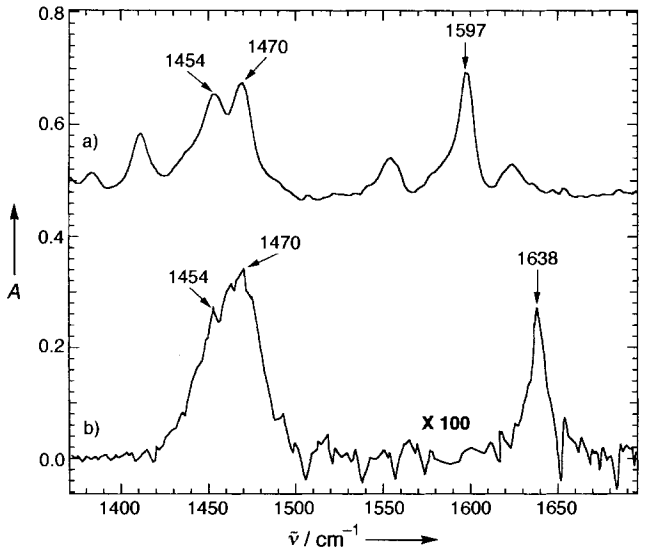

Fig. 1. a) FTIR spectrum of compound **2** (KBr disk). b) Surface FTIR spectrum of a monolayer of **2** on a Si (100) surface, with *p*-polarized light incident at 45°. The baseline was corrected to zero absorbance and offset for display purposes.

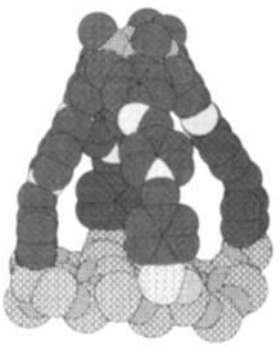

Fig. 2. A space-filling model of a self-assembled, calix[4]arene-based monolayer on an idealized silica surface.

the surface.[12] A space-filling model of **2** on the surface is shown in Figure 2 in which the ethoxyethyl groups are replaced by methyl groups for clarity. The fact that no pyridine mode at 1597 cm^{-1} was observed indicated that the surface quaternization was complete; thus no dangling stilbazole imine structures were left in the self-assembled monolayer (Fig. 1a). The advantages of four-point C–N attachment are that the molecular orientation angle is fixed by the cone configuration and does not depend on the surface coverage. However, the alignment in films of single-poled chromophores relies on steric interplay among chromophores, that is, lower coverage results in poorer alignment.[13b] The average molecular orientation angle ψ is defined as the angle of the dipole moment of the chromophore with respect to the surface normal. The electronic absorption spectrum of the monolayer exhibits a characteristic charge transfer transition at 380 nm, which is typical for pyridinium compounds and confirms that the Schiff base structure is intact; this indicates a successful quaternization reaction. The absorption peak of the monolayer at 380 nm is red-shifted in comparison with the absorption of **2** in solution (350 nm), which is also consistent with the presence of stronger electron-withdrawing groups (pyridinium vs. pyridyl group) in the film. The surface coverage[13] of **2** was found to be 0.92 molecules per nm^2, which corresponds to a densely packed monolayer consisting of calix[4]stilbazole pyramids with bases of about $10 \times 10\ Å^2$, as derived from a space-filling model (Fig. 2).

To study the molecular orientation and the NLO response on the surface, the spectroscopic second harmonic generation (SHG) was measured on the quaternized monolayers of **2**. These measurements were performed by using a mode-locked Ti-sapphire laser in either femtosecond (150 fs autocorrelation width) or picosecond (2 ps width) mode with 100 MHz repetition rate, for fundamental wavelengths between 890 nm and 750 nm. The angular dependence of the SHG for picosecond pulsed excitation has been discussed elsewhere;[11, 14] results obtained by using femtosecond pulses to generate *p*-polarized SHG from both *p*- and *s*-polarized fundamental are shown in Figure 3a for

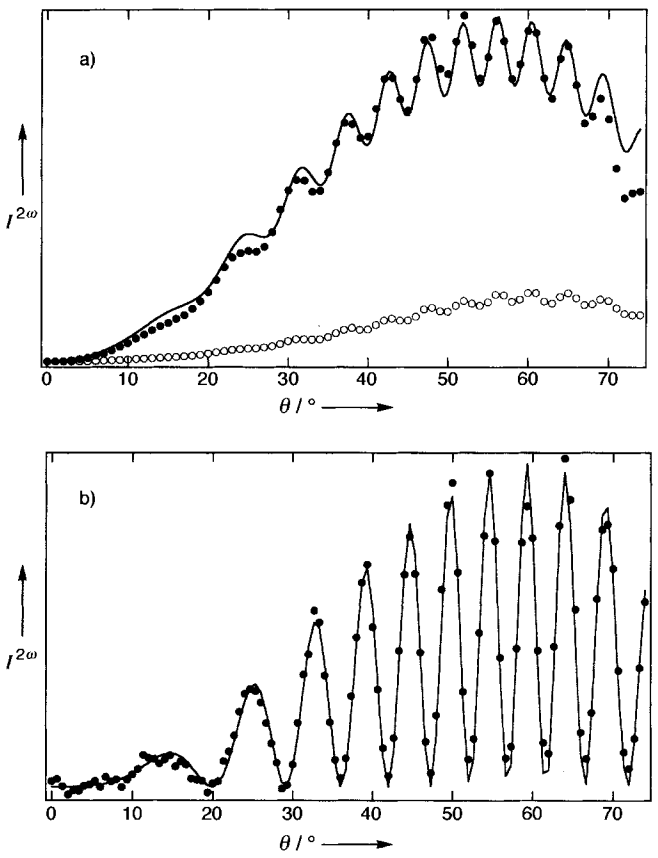

Fig. 3. a) SHG signal versus incident angle for *p*-polarized SHG from both *p*- (dots) and *s*-polarized (circles) fundamental at a wavelength of 862 nm and 150 fs pulsewidth. The solid line is the best theoretical fit to the measured values. b) The *p*-polarized SHG from *p*-polarized fundamental (dots) at a wavelength of 890 nm and 2 ps pulsewidth, and best fit (solid line).

a fundamental wavelength of 862 nm. An average molecular orientation of $\psi \approx 35 \pm 5°$ was deduced by modeling the angular-dependent SHG response ($n_{film} = 1.7$, n = refractive index); an absolute magnitude of $d_{33} \approx 80\ pm\ V^{-1}$ for monolayers of **2** was deduced by calibrating to reference Y-cut quartz. The solid lines in Figure 3 are best fits to an expression developed in reference [13], modulated by an interference term, which has the same physical origin and angular dependence as the well-known Maker fringes in bulk samples.[15] We performed an experiment at 890 nm in picosecond mode to verify that complete destructive interference is observed in these films (Fig. 3b). This proves that the two films on opposite sides are identical. In Figure 3a, however, the amplitude of the fringes is much smaller, due to the increased spectral width of the femtospecond pulses; complete destructive (or constructive) interference cannot be achieved across the entire pulse spectrum. For the fused silica samples (1 mm) considered here, effects of pulse walk-off due to mismatched group velocities of the fundamental and SH pulses can be neglected.

Figure 4 shows the measured values of d_{33} plotted against the fundamental wavelength for monolayer films of **2** together with

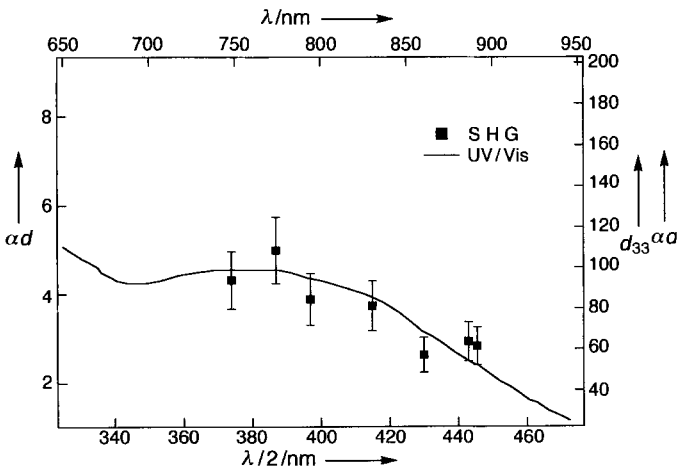

Fig. 4. Second-order nonlinear susceptibility d_{33} in $pm\ V^{-1}$ (solid squares) versus fundamental wavelength (top and right axes) or second harmonic wavelength (bottom and right axes) along with the linear absorption spectrum αd (solid line) vs. wavelength (bottom and left axes) for a self-assembled monolayer of **2**. The lowest two-photon resonance is at 390 nm corresponding to 780 nm in the d_{33} dispersion.

the linear absorption spectrum αd taken from the same sample; α is the linear absorption coefficient and d is the film thickness. The nonlinear optical spectrum closely resembles the linear optical absorption spectrum, which is fairly featureless. The wavelength dependence (fundamental $\lambda = 890-750$ nm; harmonic $\lambda = 445-375$ nm) indicates a gradual increase of d_{33} as the fundamental moves to shorter wavelength, consistent with normal refractive index dispersion in this spectral region approaching the charge transfer resonance at 390 nm. Figure 4 reveals that the charge transfer resonance is fairly broad; the measured value for d_{33} at the longest wavelength (60 $pm\ V^{-1}$ at 890 nm) is still somewhat resonance-enhanced. We find a value of $d_{33} \approx 110\ pm\ V^{-1}$ at $\lambda = 775$ nm, which indicates a nearly twofold two-photon resonant enhancement at the peak of the charge transfer band.

To summarize, we have made a significant step forward in the construction of supramolecular materials by demonstrating the formation of self-assembled monolayers with pyramidlike molecular building blocks. Structural interlocking through the bridging methylene groups among the D-π-A units yields films with extremely large second-order nonlinearities ($d_{33} \approx 60\ pm\ V^{-1}$; $\lambda = 890$ nm), and robust molecular dipole alignment. It is expected that the multilayer films synthesized from pyramidlike molecules would have similarly attractive properties. We are currently pursuing calixarene building blocks in which both rims are functionalized in an attempt to construct multilayer molecular films for nonlinear optical studies.

Experimental Procedure

1c: A suspension of 5,11,17,23-tetranitro-25,26,27,28-tetrakis(2-ethoxyethoxy)-calix[4]arene (**1b**) (0.88 g, 0.98 mmol), hydrazine monohydrate (4 mL), and a catalytic amount of Raney nickel in methanol (50 mL) was heated to reflux for 3 h. The reaction mixture was filtered and the solvent was removed. The residue was dissolved in CH_2Cl_2 and washed with 2 M NaOH (10 mL), H_2O (10 mL), and brine (10 mL) until the aqueous phase was neutral. The organic phase was then dried over $MgSO_4$. After filtration, the solvent was removed to give **1c** (600 mg; yield: 79%). IR (KBr): $\tilde{\nu}$ = 3421, 3345, 3212 (N-H), 2966, 2860 (C-H), 1598, 1464, 1445, 1215, 1114 (CC) cm^{-1}. ^1H NMR (300 MHz, $[D_1]CDCl_3$, 25°C, TMS): δ = 6.04 (s, 8H, Ar*H*), 4.32, 2.99 (d, $^2J(H,H) = 12$ Hz, 8H, $ArCH_2Ar$), 3.97 (t, 8H, OCH_2CH_2), 3.78 (t, 8H, OCH_2CH_2O), 3.49 (q, 8H, OCH_2CH_3), 3.18 (b, 8H, $ArNH_2$), 1.18 (t, 12H, OCH_2CH_3).

2: Compound **1c** (0.2 g, 0.26 mmol) was dissolved in EtOH (10 mL) and two drops of glacial acetic acid and 4-pyridinecarboxyaldehyde (0.11 g, 1.04 mmol) were added. The resulting yellow solution was heated to reflux at 78°C for 20 h. The solvent was then removed in vacuum and the residue was recrystallized from toluene and hexane. Yield: 0.16 g. IR (KBr): $\tilde{\nu}$ = 3027, 2968, 2923, 2860 (C-H), 1595, 1553, 1471, 1452, 1410, 1211, 1116 (CC and NC), 1054, 887, 807 cm^{-1}. ^1H NMR (300 MHz, $[D_1]CDCl_3$, 25°C, TMS): δ = 8.55, 7.49 (AB d, 16H, $^2J(H,H) = 6$ Hz, Py*H*), 8.12 (s, 8H, Ar*H*), 6.71 (s, 4H, C*H*N), 4.63, 3.23 (AB d, $^2J(H,H) = 12$ Hz, 8H, $ArCH_2Ar$), 4.20 (t, 8H, OCH_2CH_2), 3.85 (t, 8H, OCH_2CH_2O), 3.55 (q, 8H, OCH_2CH_3), 1.21 (t, 12H, OCH_2CH_3). Matrix-assisted LDIMS, *m/z* (%): 1129 (100) [$M^+ > H$], 1038 (54) [$M + H -$ pyCH], 947 (24) [$M^+H -$ 2pyCH].

Formation of a Porous Zirconium Oxo Phosphate with a High Surface Area by a Surfactant-Assisted Synthesis**

Ulrike Ciesla, Stefan Schacht, Galen D. Stucky, Klaus K. Unger, and Ferdi Schüth*

The synthesis of MCM-41, a silica with a hexagonal arrangement of cylindrical pores, the sizes of which are adjustable from 2 to 10 nm, and related materials[1] has stimulated a considerable amount of interest in this new class of mesoporous materials. Shortly after its synthesis, different mechanisms were developed to explain the formation of this porous material.[2] The mechanism suggested by Monnier et al.[2a] implies the possibility of substituting the silicate with other metal oxides to prepare a wide range of mesostructured oxidic materials. Subsequently, mesostructured surfactant composites of tungsten oxide, antimony oxide, and other metal oxides have been synthesized.[3, 4] However, a major problem of these non-siliceous materials is the removal of the template: It was neither possible to remove the surfactant by conventional methods like calcination or extraction nor by oxygen plasma calcination without destroying the pore structure. An exception is the recently described mesoporous TiO_2, in which the hexagonal pore structure remains stable even after calcination, but the BET surface area is only about 200 $m^2 g^{-1}$.[5] The thermal instability of the mesostructured metal oxide composites is probably due to the different oxo chemistry of the metals in comparison with silicon. For instance, the walls in the tungsten oxide surfactant composite are formed by Keggin ions, and a complete condensation seems improbable.[6] Another reason is probably the existence of several relatively stable oxidation states of the metal centers. Thus, during the calcination, reduction by the surfactant and/or oxidation by air oxygen could occur leading to structural collapse.

We have chosen zirconium as the metal species because it has only one stable oxidation state and exhibits a pronounced polyoxo ion chemistry in aqueous solutions.[7] Here we present two different syntheses leading to zirconia compounds with high surface areas and regular pore systems, in which either zirconium sulfate or zirconium propoxide is used as the Zr source.

The syntheses were carried out in aqueous solution at 373 K with a surfactant—unless otherwise stated hexadecyltrimethylammonium bromide—as template and a zirconium compound. We initially used $Zr(SO_4)_2 \cdot 4H_2O$ as Zr source. Zirconium sulfate forms polymeric $[Zr(OH)_2SO_4OH_2]$ units in water that are capable of crosslinking through sulfate bridges.[8] Charge interactions between the sulfate groups and the positively charged surfactant headgroups lead to the formation of the $ZrO_x(SO_4)_{2-x}$ surfactant composite.

The X-ray diffraction (XRD) pattern of the colorless solid product shows three reflections at very low angles (Fig. 1, trace A). These reflections correspond to d spacings of 4.06 nm, 2.37 nm, and 2.04 nm. Three reflections are usually not sufficient to index a pattern; however, in analogy to MCM-41 these reflections can be indexed as (100), (110), and (200), assuming a hexagonal unit cell. There are no more reflections in the X-ray diffraction pattern at higher angles. Only around 30° (2θ) a broad halo can be distinguished which is typical for amorphous material and which can also be detected in the siliceous MCM-41 material. Whether this halo is due to large amorphous regions or to disorder in the pore walls, as discussed for MCM-41, is at present uncertain. All available structural data suggest that the zirconia compound prepared as described above has a structure that is similar to MCM-41.[9] We believe that the structure possesses a hexagonal arrangement of cylindrical pores that are filled with surfactant. The pore walls consist of $ZrO_x(SO_4)_{2-x}$. The rodlike pores build up a two-dimensional system with no long-range order in the *c* direction—similar to the pure surfactant liquid crystal.

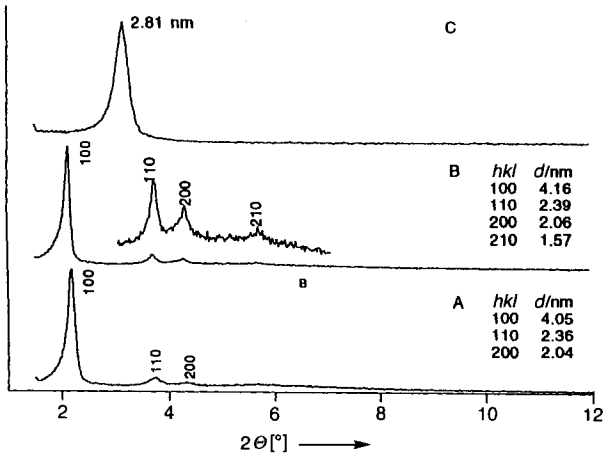

Fig. 1. X-ray diffraction pattern of the zirconium oxide compound synthesized with zirconium sulfate as Zr source. As-synthesized containing surfactant (A), after treatment with phosphoric acid (B), and sample after calcination at 773 K (C).

Thermal treatment of such samples in air at 773 K for five hours leads to a collapse of the ordered pore structure which is noticeable in the loss of intensity or disappearance of the low angle reflections. This may be due to incomplete condensation of the walls because of the very low pH value during the synthesis.

To stabilize the structure the as-synthesized surfactant composite was treated with phosphoric acid solution. During this treatment the uncondensed Zr–OH groups probably react with the phosphate ions, leading to complete crosslinking. The XRD pattern of this sample shows four sharp reflections, which, in comparison to the reflections of the untreated sample, are shifted to lower angles (Fig. 1, trace B and Table 1). This pattern can also be indexed assuming a hexagonal unit cell as (100), (110), (200), and (210) reflections. After calcination (6 h at 773 K) a

porous material is obtained that shows only one reflection, which has a d spacing of 2.81 nm (Fig. 1, trace C). The higher order reflections are no longer observed which is probably due to a decrease in the long-range order of the hexagonal pore arrangement. Nevertheless, nitrogen adsorption measurements (see below) show that the pores still exist in the calcined material.

Variation of the chain length of the surfactant changes the dimensions of the system: If trimethyl(octadecyl) or icosyltrimethyl ammonium bromide is used, the corresponding reflections are shifted to lower angles, both for the as-synthesized product and the calcined form (Table 1). Similar results have also been obtained for MCM-41. Moreover, nitrogen adsorption measurements at 77 K show that the surface areas increase with longer surfactant chain length. From nitrogen adsorption analysis, Brunauer–Emmett–Teller (BET) surface areas of 230 $m^2 g^{-1}$ for the sample synthesized with C_{16}-surfactant, 320 $m^2 g^{-1}$ for that with the C_{18}-surfactant, and 390 $m^2 g^{-1}$ for the sample prepared with the C_{20}-surfactant can be calculated. To the best of our knowledge these are the highest surface areas obtained for zirconia. In a recently described surfactant-assisted synthesis for zirconia by M. J. Hudson et al., BET surface areas up to 329 $m^2 g^{-1}$ were obtained.[10] However, these materials do not possess a regular pore system, neither in the as-synthesized nor in the calcined form.

Figure 2 shows the nitrogen isotherms for the samples synthesized with C_{16}-surfactant (Fig. 2A), C_{18}-surfactant (Fig. 2B), and C_{20}-surfactant (Fig. 2C). The difference in the position of

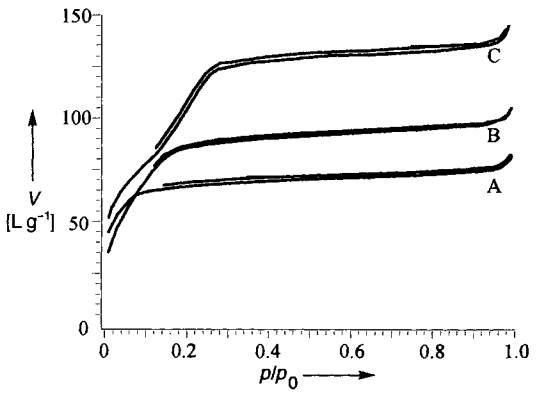

Fig. 2. Nitrogen adsorption isotherms at 77.4 K for calcined and post-treated samples synthesized with hexadecyltrimethylammonium bromide (A), trimethyl(octadecyl)ammonium bromide (B), and icosyltrimethylammonium bromide (C).

the steep increase in the volume adsorbed is apparent from the isotherms. The increase for the sample synthesized with C_{16}-surfactant is at low pressure and thus is an indication for the presence of micropores, whereas the step of the isotherm for the C_{20}-surfactant sample is around a relative pressure of 0.2. N_2 isotherms of this type are typical for pores with sizes between micro- and mesopores. Similar adsorption isotherms have been described for MCM-41 with pore sizes of 2.5 nm;[11] however, in this case the step in the isotherm was obtained at a slightly higher relative pressure of $p/p_0 = 0.3$. Therefore a pore diameter of 2 nm can be estimated for the zirconium compound. However, the pore size determination by nitrogen adsorption measurements is not very precise in this region because BJH analysis (BJH = Barrett–Joyner–Halenda) does not yield reliable data and other algorithms do differ in their results. The relatively small pore diameter seems to be inconsistent with the d spacings determined by X-ray diffraction which would be 3.5 nm for MCM-41. This is probably due to the existence of thicker walls in the zirconia material than in the silicate MCM-41. The structural parameters obtained by analysis of the nitrogen adsorption are in good agreement with the data from X-ray diffraction: An increase of the lattice parameter corresponds to an increase of the pore diameter, the pore volume, and the BET surface area.

The sulfur content of the calcined sample determined by X-ray fluorescence analysis is less than 1 wt%, the phosphorus content about 10 wt%. From this a nominal wall composition of 45 wt% zirconium oxide (based on ZrO_2), 54 wt% zirconium phosphate (based on $Zr_3(PO_4)_4$), and only 0.5–1 wt% zirconium sulfate (based on $Zr(SO_4)_2$) can be calculated.

Starting from zirconium propoxide, the synthesis is carried out analogous to the acidic synthesis of MCM-41 developed by Huo et al,[4] in which strong HCl acidic surfactant solutions are used. In contrast to the MCM-41 synthesis, the addition of $(NH_4)_2SO_4$ is necessary for the formation of the corresponding zirconia surfactant composite. After isolation and drying of the product at 363 K, three reflections were observed in the XRD pattern (4.51 nm, 2.60 nm, and 2.24 nm); however, the intensities of the latter two corresponding to the (110) and (200) reflections are very weak (Fig. 3 trace A). The reason for the broad signal at 6–8° (2θ) is not yet clear.

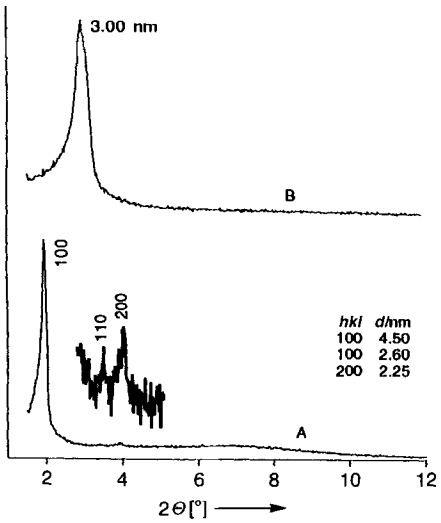

Fig. 3. X-ray diffraction pattern of the zirconium oxide compound synthesized with zirconium propoxide as Zr source; as-synthesized (A) and after calcination at 773 K (B).

In contrast to the material from zirconium sulfate, it is possible to calcine the material from zirconium propoxide at 773 K without the structure collapsing. However, also in this case the (100) reflection is shifted to higher angles (Fig. 3, trace B) and the intensity decreases. The (110) and (200) reflections disappear completely. The nitrogen adsorption isotherm is typical for a microporous material; the BET surface area can be calculated to 280 $m^2 g^{-1}$. The sulfur content of this zirconia after calcination at 500 °C is about 2 wt%; thus, this material essentially consists of zirconium oxide.

The fact that the samples contain sulfur even after calcination is interesting for potential applications. The sulfur remains in the calcined products in form of sulfate groups which could be detected by IR spectroscopy. Zirconias are important as catalysts and catalyst supports. Sulfated zirconias are used as super

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3505-0542 $ 15.00+.25/0

acidic catalysts in isomerization reactions. High surface areas are often the main requirement of such materials. The new zirconias prepared by surfactant-controlled syntheses show interesting structures and could become important for technical applications.

Experimental Procedure

Synthesis with $Zr(SO_4)_2 \cdot 4H_2O$: Hexadecyltrimethylammonium bromide (2.5 g, 6.87 mmol) was dissolved in H_2O (85 g), and $Zr(SO_4)_2 \cdot 4H_2O$ (4.55 g, 0.0128 mol) dissolved in H_2O (15 g) was added. This led to a colorless solid precipitate. The mixture was stirred for 2 h at room temperature and then heated to 100 °C for two days in a closed polypropylene beaker. The precipitate was filtered and dried at 100 °C. The dried precipitate was stirred in a phosphoric acid solution (0.87 M 0.87 M) for 2 h, then filtered and dried again at 100 °C. The colorless product was then calcined at 500 °C for 5 h. S-content after calcination: 1–2 wt%, P-content after H_3PO_4 treatment and calcination: 10 wt%.

Synthesis with $Zr(OC_3H_7)_4$: Hexadecyltrimethylammonium bromide (2.5 g, 6.87 mmol) was dissolved in a solution of water (115 g) and HCl (24.4 g) (37 wt%). After the hydrolysis products had dissolved, $(NH_4)SO_4$ (2.04 g, 0.0155 mol) in water (23 g) was added and the mixture was stirred at room temperature for 1 h. The initially clear solution was then heated at 100 °C for two days. The colorless precipitate was filtered, dried, and calcined at 500 °C for 5 h. S-content after calcination: 1–2 wt%. The as-synthesized samples contain 40–50 wt% surfactant, as detected by thermogravimetric analysis between 200 and 600 °C.

X-ray diffraction: Scintag PADX diffractometer with nitrogen-cooled Ge-detector. $Cu_{K\alpha}$ radiation ($\lambda = 1.54056$ nm), step 0.02°, scan 2.4 s.

Nitrogen adsorption measurements: Micromeritics ASAP 2000, 77.4 K, equilibration time: 60s.

[9] The mesoporous silicates could also only be characterized by X-ray diffraction, chemical analysis, and nitrogen adsorption measurements, sometimes assisted by transmission electron microscopy (TEM) and ^{29}Si and ^{27}Al MAS NMR. The reason for this is nature of the material itself: It has no order in the walls and therefore diffraction methods are limited, except for the information about the periodicity of the pore system. TEM analysis gives only selective information about the particle but not about the whole sample. By using TEM we detected hexagonal pore arrangements in the zirconium compounds. However, X-ray diffraction and nitrogen adsorption appear to us to be more important than TEM for the characterization of the structure.

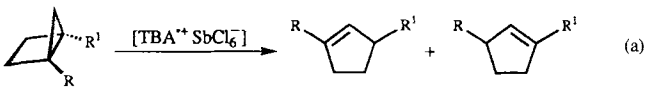
Generation of a Heterocyclic 1,3-Cyclopentanediyl Radical Cation by Chemically Induced Electron Transfer Oxidation and Pulse Radiolysis**

Waldemar Adam,* Thomas Kammel, and Steen Steenken*

Although the chemistry of 1,3-diradicals derived from cyclic azoalkanes and their corresponding strained hydrocarbons (housane ≡ bicyclo[2.1.0]pentane) has been extensively studied,[1] their electron transfer oxidation[2, 3] was investigated only recently. The reaction of 1,3-disubstituted bicyclo[2.1.0]pentanes with catalytic amounts of the oxidant tris(4-bromophenyl)aminium hexachloroantimonate ($TBA^{\cdot+}SbCl_6^-$) led to the corresponding cyclopentenes after 1,2-hydrogen or -alkyl migration in the intermediary 1,3-radical cations [Eq. (a)].[4]



(a)

Since no examples of heterocyclic analogues of these distonic 1,3-radical cations were known, it was of interest, particularly with regard to the reaction mechanism, to investigate the chemical behavior of these systems. Arnold et al.[5] had synthesized the urazole-substituted azoalkanes (urazole = 1,2,4-triazolidine-3,5-dione) by Diels–Alder reaction of 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) with substituted isopyrazoles. Direct photolysis of these azoalkanes led to the corresponding housanes. The latter are suitable precursors for the desired heterocyclic 1,3-radical cations. By replacing PTAD with 4-methyl-1,2,4-triazoline-3,5-dione (MTAD), the solubility of the radical cation was significantly improved, which allowed a thorough examination of these urazole-annelated azoalkanes and their corresponding housanes.[6] Moreover, it is known from the work of Nelsen et al.[7] that substituted hydrazine derivatives yield stable radical cations upon oxidation at the nitrogen atoms. Consequently, it was of interest to assess the effect of heteroatoms on the mechanism of the chemically induced electron transfer (CET) reaction of these housanes. Herein, we report on the generation and spectroscopic detection of the first urazole-bridged 1,3-radical cation and its unusual chemical transformations.

Direct photolysis of azoalkane **1** (Scheme 1, path a) led exclusively to the corresponding housane **2**.[8] The latter is heat and acid labile and rearranges subsequently to the olefin **3** (Scheme 1, pathways c and d). In contrast to carbocyclic bicyclo[2.1.0]pentane derivatives (heteroatom-free housanes) [Eq. (a)], stoichiometric amounts of tris(4-bromophenyl)-aminium hexachloroantimonate are necessary for the CET reaction of **2** (Scheme 1, path e). The CET product **4**[9] could only

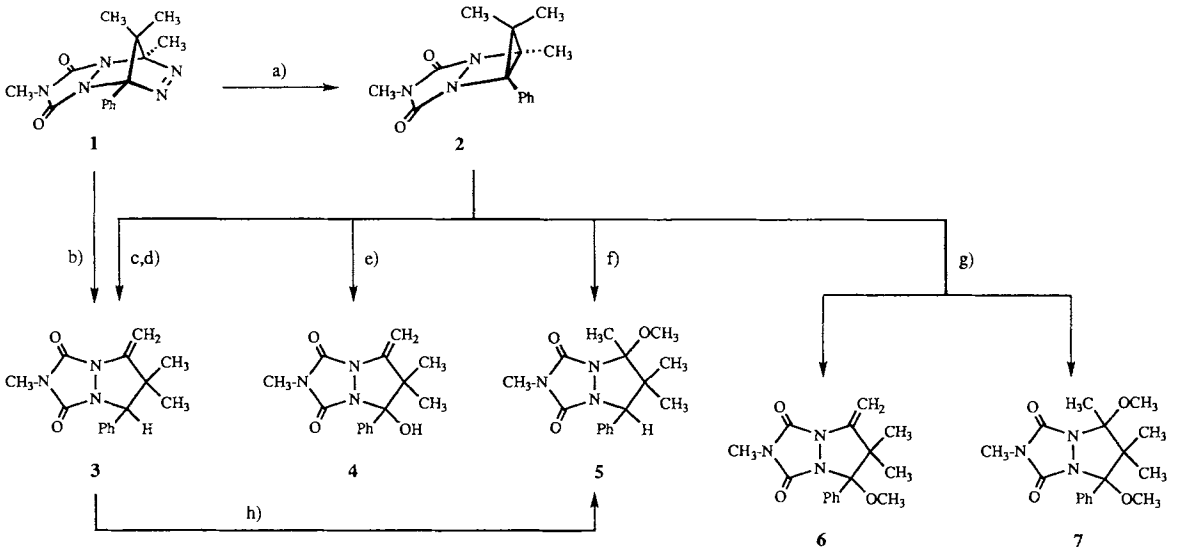
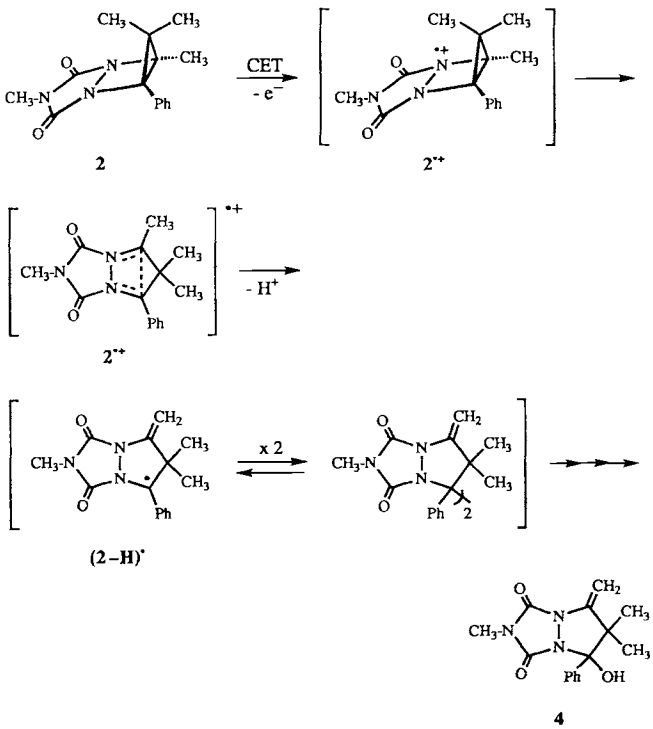
Harrer for performing the PM3 calculations and M. Toubartz for experimental assistance with the pulse radiolyses at the Max-Planck-Institut, Mülheim an der Ruhr.



Scheme 1. Synthesis and transformations of the housane **2**. a) Photolysis, 364-nm line of argon ion laser, $CDCl_3$ or CH_2Cl_2 as solvent, $-10\,^{\circ}C$, 100% conversion (^1H NMR); b) thermolysis, 110 °C, 52%; c) thermolysis, 70 °C, 98%; d) CF_3COOH (0.25 molar equiv), $CDCl_3$, 0 °C, 70%; e) $TBA^{\bullet+}SbCl_6^-$ (1 molar equiv), 2,6-di-*tert*-butylpyridine (2 molar equiv), 0 °C, 80%; f) $TBA^{\bullet+}SbCl_6^-$ (1 molar equiv), 2,6-di-*tert*-butylpyridine (2 molar equiv), methanol (200 molar equiv), 81%; g) $TBA^{\bullet+}SbCl_6^-$ (2 molar equiv), 2,6-di-*tert*-butylpyridine (4 molar equiv), methanol (200 molar equiv), **5** (16%) and **6** (19%); when about 10 molar equiv of base were used, **7** was isolated in less than 2% yield, along with **5** in 47% yield; h) CF_3COOH (ca. 0.1 molar equiv) and methanol (ca. 100 molar equiv) gave a 41:59 mixture of **3** and **5** (^1H NMR), while 2,6-di-*tert*-butylpyridinium salt (1.0 molar equiv) and methanol (ca. 20 molar equiv) led to a 13:87 mixture of **3** and **5** (^1H NMR).

be detected and isolated when the oxidation was performed in the presence of a base to avoid acid catalysis. The intermediary dimer of the corresponding monoradical **(2 − H)•** was identified under these conditions (Scheme 2) by NMR spectroscopy.[10] Upon workup and silica gel chromatography, the dimer reacts further to give the hydroxylated monoolefin **4** when oxygen or water are present. When the CET reaction was performed in the presence of methanol as nucleophilic scavenger, the products



Scheme 2. Mechanism of the oxidation of **2** initiated by chemical electron transfer (CET).

5–7 were observed. When stoichiometric amounts of $TBA^{\bullet+}SbCl_6^-$ were used, the only product was the monoether **5** (Scheme 1, path f). Addition of two equivalents of CET oxidant led to **5–7**, besides spectroscopically unidentified material (Scheme 1, path g). To avoid the acid-catalyzed rearrangement of housane **2** to the monoolefin **3** caused by the protons released during the CET reaction, the oxidations were performed in the presence of an excess of the base 2,6-di-*tert*-butylpyridine.[11] When a large excess of base was used, the double-trapping product **7** was observed, which establishes the double oxidation of the housane **2** unequivocally.

Comparison of the results for the urazole-bridged systems (Scheme 1) with those for the corresponding carbocylic bicyclo[2.1.0]pentenes [Eq. (a)][4] clearly indicates the significant influence of the heteroatom on the chemistry of distonic 1,3-radical cations. In the first place, the CET reaction does not proceed catalytically,[4] but stoichiometric amounts are necessary, as observed by Nelsen et al.[7] for substituted hydrazine derivatives. In addition, the 1,3-radical cation is not stabilized by rearrangement to the olefinic radical cation followed by electron back transfer. Instead, deprotonation leads to the formation of an exocyclic double bond, a process which Shono et al.[12] have observed upon anodic oxidation of substituted cyclopropane derivatives. Presumably, the carbonyl function in the urazole moiety facilitates deprotonation, because the proton is directly released to the carbonyl group, a favorable process for which a six-membered transition state applies. A control experiment established the conversion of **3** to the monoether **5** (Scheme 1, path h); thus, the latter trapping product is formed from the olefin **3**. In addition, **2** is so sensitive towards acids that even the 2,6-di-*tert*-butylpyridinium ion rearranges it to the monoolefin **3**. The ene-ether product **6** is formed by oxidation of the monoradical **(2 − H)•** to the corresponding cation, which subsequently is trapped by methanol. The ene-ether **6** oxidation product as well as the bis-ether **7** double-trapping product were only observed when two molar equivalents of $TBA^{\bullet+}SbCl_6^-$ were added.

In addition, semiempirical PM3 calculations were performed to assess whether the initial ionization occurs from the hy-

drazine moiety or the cyclopropane central bond. The results clearly establish that especially in the puckered conformation most of the positive charge is located at the two nitrogen atoms of the hydrazine bond in the urazole-bridged 1,3-radical cation $\mathbf{2}^{\bullet+}$. As a consequence, the initially formed radical cation is generated by abstraction of an electron from one of these nitrogen atoms (Scheme 2).[13] After relaxation to the planar conformation, most of the charge is relocated at the two carbon atoms C-1 and C-3. Compared with the carbocyclic derivatives,[4] the charge is delocalized to a larger extent in the radical cation $\mathbf{2}^{\bullet+}$ and thereby the urazole moiety suppresses the usually observed 1,2-methyl migration.

The formation of the radical cation $\mathbf{2}^{\bullet+}$ was spectroscopically established by time-resolved pulse radiolysis of azoalkane **1** in *n*-butyl chloride as solvent. First, a transient with maxima at ca. 280 and 330 nm was observed, which was relatively unreactive toward molecular oxygen. This species transformed with a rate constant $k = 4 \times 10^5\,s^{-1}$ into a second intermediate having a narrow absorption band with $\lambda_{max} = 325$ nm, which reacted efficiently with oxygen. The initially formed transient most probably corresponds to the radical cation $\mathbf{2}^{\bullet+}$, which upon deprotonation yields the radical $(\mathbf{2} - \mathrm{H})^{\bullet}$. This interpretation was confirmed by comparison with pulse radiolyses of analogous systems.[14]

In summary, the present novel results establish that the heterocyclic 1,3-radical cation $\mathbf{2}^{\bullet+}$ can conveniently be generated by chemical oxidation of the corresponding housane **2** by using stoichiometric amounts of tris(4-bromphenyl)aminium hexachloroantimonate. Instead of 1,2-alkyl migration, as is usually observed for carbocyclic 1,3-radical cations,[4] the analogous urazole-bridged derivative $\mathbf{2}^{\bullet+}$ reacts further through deprotonation by transferring the proton to the well-located carbonyl function. This unprecedented stabilization process of 1,3-radical cations enhances our knowledge about such short-lived, highly reactive intermediates.

[13] W. Adam, T. Kammel, unpublished results. Cyclic voltammetry of analogous substrates established, as expected, irreversible oxidation for the urazole-bridged systems. Comparison with the corresponding carbocyclic derivatives revealed that the oxidation occurs at one of the nitrogen atoms of the urazole moiety.

[14] In addition, laser flash photolyses of the azoalkane **1** (excitation wavelengths 248 und 408 nm) confirmed that the transients observed in the pulse radiolysis do not correspond to 1,3-diradical intermediates.

Sibyllimycine, 5,6,7,8-Tetrahydro-3-methyl-8-oxo-4-azaindolizidine, a Novel Metabolite from *Thermoactinomyces* sp.**

Doris Hafenbradl, Martin Keller,* Karl O. Stetter, Peter Hammann,* Frank Hoyer, and Herbert Kogler

For a few years it has been known that hot, volcanic springs contain thermophilic and hyperthermophilic organisms.[1] These organisms have been studied intensively owing to possible applications in biotechnology, for example as producers of heat-stable enzymes. However, it is not known whether thermophilic or hyperthermophilic organisms are able to produce novel natural products and active compounds. Therefore we tried to collect and selectively enrich potential secondary metabolite producing organisms such as organisms from the family *Bacillaceae* from hot springs. Several thermophilic actinomyces were isolated from hydrothermal sources for the first time, for example from a 60 °C hot spring at Lake Tanganyika in Cape Banza (Africa). Previously *Thermoactinomyces* were isolated only from self-heating biotopes like hay, compost, and soil.[2] *Thermoactinomyces* belong to the family of the *Bacil-*

laceae and are assigned to the *Actinomycetales* based on their morphological similarities.[3] So far within the genus *Thermoactinomyces* six different species have been described.[2] Only *Thermoactinomyces vulgaris* is known give rise to two natural products, namely 5-deoxyguanosine[4] and thermorubine.[5]

To test whether the new isolates are able to produce novel natural products we subjected them to chemical screening and compared the results.[6] The isolate CB21 from a hot spring at Lake Tanganyika attracted our attention because of its pattern of metabolites. For further characterization the new isolate CB21 was cultivated in a 50 L fermenter at 60 °C and was harvested in fractions over five days. After the mycel was removed, the culture filtrate was concentrated with Amberlite XAD-16. Among the diverse metabolites we were particularly interested in a compound that appeared at the third fermentation day and stained yellow with anisaldehyde (solvent system $CHCl_3$/MeOH 30/1, $R_f = 0.5$, HPTLC plates, Merck). This compound was obtained from the concentrated supernatant by flash chromatography (silica gel, $CHCl_3$). Final chromatography on Sephadex LH-20 with acetone as eluent yielded in 4 mg of a colorless powder.

The molecular formula $C_8H_{10}N_2O$ was determined unequivocally by quantitative elemental analysis (C 64.9, H 6.7, N 18.5%) and a mass spectrum (m/z [$(M+H)$]$^+$ = 151.08). The spectroscopic data (see Table 1) was interpreted systematically by stepwise exclusion of possible structures.[7–9] Structure **1** was supported by the assigned ^1H-^{13}C through-space coupling constants (Fig. 1); however, application of statistically reliable criteria for interpretation of spectroscopic data did not lead to an unequivocal structure assignment.[9] Therefore the proposed structure **1** was verified by synthesis.

4-Methylimidazole (**2**) was treated with acetanhydride for 1.5 h at 100 °C,[10–12] then alkylated with 4-bromobutyronitrile (Scheme 1, Table 2). The two *N*-alkyl compounds **3a** and **3b** were purified by chromatography on silica gel (solvent system $CHCl_3$/MeOH 25/1). Deprotonation of **3b** with two equivalents of BuLi led to ring closure. Sibyllimycine (**1**) was obtained by hydrolysis of the imine with 4 M HCl. The physical properties of the synthetic compound **1** are identical to those of the compound isolated from the culture ($\Delta\delta(^{13}C) < 0.5$ ppm). After confirmation of the cyclic structure by synthesis, the position of the methyl group was secured by NOE experiments (Table 1).

Phosphaalkyne Hydrometalation: Synthesis of $[RuCl(P{=}CH\,tBu)(CO)(PPh_3)_2]$**

Robin B. Bedford, Anthony F. Hill,* and Cameron Jones*

The notional similarity between alkynes (RC≡CR) and phosphaalkynes (P≡CR) raises the question of metal-mediated transformations of the reactive P≡C linkage.[1] To date, the majority of such studies have focused on oligomerizations, effected by organometallic substrates which bear essentially "innocent" co-ligands.[2, 3] We have previously described the interaction of P≡C*t*Bu (**1**) with a transition metal alkylidyne which proceeded by a metathesis of Mo≡C and P≡C triple bonds.[4] Subsequently it was shown that **1** could also be induced to couple with the metal–carbon multiple bonds in alkylidene[5] and vinylidene complexes.[6] Given that one of the most fundamental activation processes of alkynes by metal centers is the hydrometalation reaction to provide σ-vinyl complexes, it is noteworthy that the hydrometalation of **1** has remained prior to this report one of the "holy grails" of phosphaalkyne chemistry. Our studies on alkyne hydrometalation have centered on the complex $[RuHCl(CO)(PPh_3)_3]$ (**2**) and its derivatives,[7] and in this report we discuss the extension of this chemistry to **1**. This leads to the formation of stable coordinatively unsaturated σ-phosphaalkenyl complexes in a reaction completely and reassuringly analogous to those of alkynes. Furthermore such compounds are shown to be precursors to a range of complexes of otherwise unstable phosphaalkenes.

Treatment of a solution of **2** in dichloromethane with **1** leads to the clean formation of an orange-red complex, spectroscopic data (Table 1) for which are consistent with the formulation $[RuCl(P{=}CH\,tBu)(CO)(PPh_3)_2]$ (**3**) (Scheme 1). The ^{31}P NMR spectrum shows a doublet for the phosphane ligands (δ = 33.9, $^2J(P_2,P)$ 10.0 Hz) and a triplet (δ = 450.4, $^2J(P_2,P)$ 10.0 Hz) in an area considered typical of phosphaalkenyl ligands[6, 8] (although such a simple and non-kinetically stabilized derivative has not been previously reported). The alkenic proton appears as a doublet of triplets (δ = 7.12) with a large coupling ($^2J(P,H)$ = 16.9 Hz) to the adjacent phosphorus atom and a

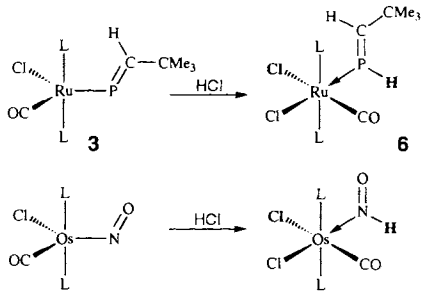
smaller coupling to the phosphorus atoms of the phosphane ligands ($^4J(P_2,H) = 2.8$ Hz). The gross molecular formulation is confirmed by FAB mass spectrometry; the mass spectrum shows in addition to a molecular ion, fragmentations for the loss of the phosphaalkenyl ligand as well as the formation of a nitrobenzyl alcohol adduct.

The recently reported transformation of a phosphaalkyne-(hydrido)iron complex to a fluoro(phosphaalkene) complex[9] is a process which could plausibly proceed by a hydroferration of the coordinated phospaalkyne, akin to the result reported here. Other than this report the remaining examples of phosphaalkenyl complexes are limited to those featuring kinetically stabilizing substituents[8a] or the metallacyclic complexes $[OsP{=}C(CF_3)O(CO)_2(PPh_3)_2]$[8b] and $[RhP{=}CtBuC(=CH_2)Cl(PiPr_3)_2]$.[6]

The implied coordinative unsaturation at ruthenium raises the questions of σ-π coordination of the phosphaalkenyl ligand and the possibility of ligand addition reactions. The former may be discounted as this would render the phosphane ligands diastereotopic, a possibility not supported by ^{31}P NMR data. The latter, however, provides a point of interest and this was subsequently investigated. The complex **3** rapidly reacts with CO under ambient conditions to provide the pale yellow complex **4a** (see Scheme 1), the stereochemistry of which follows unequivocally from spectroscopic data, whilst the gross molecular composition follows from FAB-MS data. Complex **4a** readily decarbonylates both in solution and in the solid state to reform **3**. This observation points to a substantial *trans* effect for the phosphalkenyl ligand, although this has not been previously appreciated since the majority of prior examples are of the "piano-stool" variety. A similar reaction occurs with 2,6-$Me_2C_6H_3NC$ to provide **4b**; however, in this case ligand addition is not as readily reversible. The phosphorus center in the free phosphalkyne **1** is typically electrophilic; however, hydroruthenation reverses this polarity making the phosphorus nucleophilic. This is reflected in the clean protonation of **4b** with $HBF_4 \cdot OEt_2$ to afford the cationic phosphaalkene complex **5**. The site of protonation is unambiguously established by the appearance of a doublet of triplets in the proton-coupled ^{31}P NMR spectrum at $\delta = 164.3$ ($J(P,P) = 45.0$, $J(P,H) = 376.4$ Hz), which collapses to a triplet in the proton-decoupled spectrum, and a doublet of doublet of triplets in the ^1H NMR spectrum at $\delta = 5.73$ ($^1J(P,H) = 375.8$; $^3J(H,H) = 20.5$ Hz; $^3J(P_2,H)$ discernable but not resolved) due to the phosphorus-bound proton. This protonation is readily reversed upon treatment with a non-nucleophilic base such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU). These transformations in effect represent the unprecedented metal-mediated hydrogenation of a phosphaalkyne to a phosphaalkene.

The reaction of **3** with HCl also proceeds to a give a neutral phosphaalkene complex **6** (see Scheme 1). This raises questions about the bonding in **3** in that coordinative unsaturation in phosphaalkenyl complexes is normally accommodated by linearization of the M-P-C linkage, a process which renders the phosphorus center electrophilic. Clearly the phosphorus center in **3** is nucleophilic. Thus, we suggest the possibility that in metal centers that combine high d-occupancies and coordinative unsaturation the linearization of phosphaalkenyl ligands is not necessarily favored. In this context we note the isoelectronic relationship between the ligands -P=CR_2, -NO, and -NNR. The complex $[OsCl(NO)(CO)(PPh_3)_2]$ requires a linear nitrosyl on effective atomic number (EAN) grounds but actually features a bent and nucleophilic nitrosyl ligand as illustrated by the facile and reversible hydrochlorination to provide $[OsCl_2(HNO)(CO)(PPh_3)_2]$ (Scheme 2).[10] We therefore suggest



Scheme 2. Nitrosyl and phosphaalkenyl hydrochlorination. L = PPh_3.

that the arguments used to rationalize the geometries of late transition metal nitrosyl complexes[11] may equally well find application in the developing chemistry of phosphaalkenyl ligands.

Experimental Procedure

3: A solution of $[RuHCl(CO)(PPh_3)_3]$ (1.00 g, 1.05 mmol) in dichloromethane (50 mL) was treated with P≡C*t*Bu (0.43 mL, about 2.4 equivalents) and stirred for 1 h and then freed of volatiles. The residue was recrystallized (CH_2Cl_2/Et_2O) to provide **3**. Yield 0.76 g (92%). Anal. found C 62.5, H 6.2%. $C_{42}H_{40}ClOP_3Ru$ requires C 63.8, H 5.1%.

Note: The hydrometalation of adamantylphosphaalkyne proceeds under analogous conditions to those described above; however, the product could not be isolated in greater than about 90% purity due to its high solubility.

4a: Carbon monoxide was passed through a solution of **3** (0.15 g, 0.19 mmol) in dichloromethane (4 mL) for 2 min. Addition of diethyl ether (20 mL) and cooling to −10 °C for 12 h provided **4a**. Yield 0.13 g (84%). Analytical data not obtained due to rapid decarbonylation in the solid state.

4b: A solution of **3** (0.15 g, 0.19 mmol) in dichloromethane (5 mL) was treated with 2,6-$Me_2C_6H_3NC$ (0.03 g, 0.23 mmol) and stirred for 5 min and then freed of volatiles. The residue was crystallized from a mixture of dichloromethane and diethyl ether to provide **4b**. Yield 0.12 g (69%). Anal. found C 65.0, H 5.7, N 1.5%. $C_{51}H_{49}ClONP_3Ru \cdot 0.5CH_2Cl_2$ requires C 65.3, H 5.3, N 1.5%.

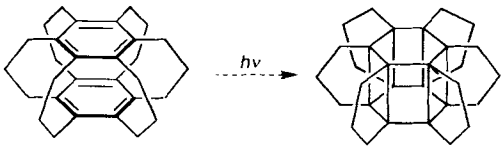
Synthesis of a "Molecular Pinwheel": [3.3.3.3.3.3]-(1,2,3,4,5,6)Cyclophane**

Youichi Sakamoto, Naomi Miyoshi, and Teruo Shinmyozu*

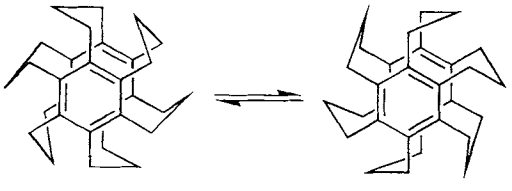
[3_6](1,2,3,4,5,6)Cyclophane **1**, a compound we have long sought[1, 2] and one of the final target molecules in the field of [3.3]cyclophane chemistry, has finally been synthesized and characterized. We expect **1** to have fascinating chemical and structural features. A photochemical isomerization of **1** to the propella[3_6]prismane **2** (Scheme 1) has been predicted based on



1 **2**

Scheme 1. Predicted photochemical isomerization of **1** to the propella[3_6]prismane **2**.

semiempirical MO calculations,[3] and a correlated inversion of the six trimethylene chains, which resemble six blades of a pinwheel, is expected in solution (Scheme 2).[4]



1a **1b**

Scheme 2. Predicted most stable conformations and correlated inversion of the six trimethylene bridges of **1**.

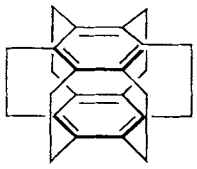
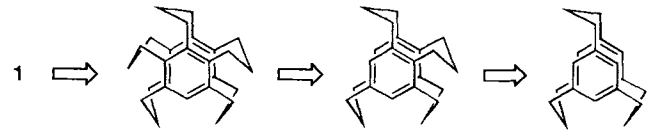
[**] Multibridged [3_6]cyclophanes, Part 3. We gratefully acknowledge financial support by the Grant-in-Aid for Scientific Research (no. 06453042) and the Grant-in-Aid for Scientific Research on Priority Area of New Development of Organic Electrochemistry (no. 06226264) from the Ministry of Education, Science and Culture, Japan. Part 2: ref. [2].

The synthesis of the highly strained [2_6](1,2,3,4,5,6)cyclophane **3**, named "superphane", was accomplished by Boekelheide et al. in 1979,[5] and the work opened the new field of superphane chemistry.[6] Since then syntheses, novel structures, and chemical properties of various superphanes such as **3** by Hopf et al.,[7] [4_5](1,2,3,4,5)ferrocenophane (superferrocenophane) by Hisatome et al.,[8] metal-capped [3_4](1,2,3,4)cyclobutadienophane by Gleiter et al.,[9] and [2_4](2,3,4,5)thiopenophane (superthiophenophane) by Tashiro et al.[10] have been reported.



3

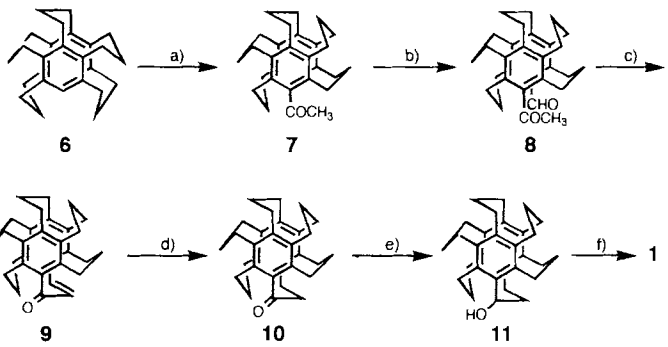
In our efforts toward the stepwise synthesis of **1** starting from the [3_3](1,3,5)cyclophane **4**[4c] (Scheme 3), we reported



1 **6** **5** **4**

Scheme 3. The stepwise synthetic approach.

the syntheses of the [3_4](1,2,3,5)cyclophane **5**[1] and the [3_5](1,2,3,4,5)cyclophane **6**,[2] in which the key reaction for the construction of a trimethylene bridge was the acid-catalyzed condensation between the acetyl group and the pseudogeminally substituted chloromethyl group. Recently we developed an alternative method using aldol condensation between the acetyl group and a pseudogeminally substituted formyl group, in place of chloromethyl group. This reaction proceeds in very high yields, and the resultant enones can be readily reduced to give trimethylene bridges. Since the precursors of **1** are now available in multigram quantities, we set about the synthesis of **1** from the [3_5]cyclophane **6** (Scheme 4).[2]



6 **7** **8** **9** **10** **11**

Scheme 4. Synthetic route to **1** from **6**. a) $(CH_3CO)_2O$, $AlCl_3$, CS_2, reflux, 3 d, **7**: 52% (based on recovered **6**); b) CH_3OCHCl_2, $AlCl_3$, CH_2Cl_2, room temperature (RT), 3 h, **8**: quantitative; c) 3N aqueous NaOH, THF, CH_3OH, reflux, 82 h, **9**: 92% (based on recovered **8**); d) H_2, PtO_2, $CHCl_3$-CH_3OH, RT, 41 h, **10**: quantitative; e) SmI_2, 1N aqueous KOH, THF, RT, 30 min; f) $AlCl_3$, $LiAlH_4$, THF, reflux, 12 h, **1**: 61% (based on **10**).

Formylation of the acetyl compound **7**, prepared by treatment of **6** with acetic anhydride in the presence of $AlCl_3$ (52%), quantitatively provided the pseudogeminally substituted compound **8**. Intramolecular aldol condensation of **8** under alkaline conditions afforded the enone **9** (92%), which was readily hydrogenated in the presence of catalytic amounts of PtO_2 to give the ketone **10** quantitatively. We initially attempted to reduce

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3505-0549 $ 15.00+.25/0

the carbonyl group of **10** to give us **1** directly; however, the reaction did not proceed at all by using either $LiAlH_4$-$AlCl_3$[11] or triethylsilane[12] as the reducing agents. Thus, we studied the reduction of the carbonyl group **10** via the hydroxyl compound **11**. Reduction of the carbonyl group of **10** by $LiAlH_4$ in refluxing THF or by *n*-Bu_4NBH_4 in dichloromethane[13] resulted in the complete recovery of the starting ketone **10**. Finally we chose SmI_2 in THF,[14, 15] since this reagent is a potentially powerful reducing agent toward a variety of functional groups, particularly in the presence of acids or bases.[16] In fact, the reduction of the extremely inert carbonyl group of **10** to alcohol **11** was accomplished with SmI_2 in THF in the presence of 1 N aqueous KOH. The resultant alcohol **11** was readily reduced by $LiAlH_4$-$AlCl_3$ to give the desired compound **1** as colorless crystals which decomposed above 358 °C (yield 61% from **10**).

In the ^{1}H NMR spectrum (270 MHz, $CDCl_3$, 22 °C, TMS: $\delta = 2.41-2.51$ (m, 12H; $CH_2CH_2CH_2$), 3.19 (t, $J = 7.3$ Hz, 24H; $CH_2CH_2CH_2$)), two groups of well-averaged proton signals are observed for the trimethylene bridges. The proton-decoupled ^{13}C NMR spectrum (90 MHz, $CDCl_3$, 22 °C, TMS) shows three singlets at $\delta = 20.5$ (t, $CH_2CH_2CH_2$), 28.2 (t, $CH_2CH_2CH_2$), and 135.4 (s, aromatic). The multiplicity of the signals (in parentheses) is determined by the off-resonance decoupled ^{13}C NMR spectrum. These NMR data are consistent with the proposed, highly symmetrical structure of **1** and its dynamic nature (Scheme 2). Elemental analysis and mass spectral data (MS (70 eV): M^+ $m/z = 396$) are also in good agreement with the calculated values for **1**. The spectroscopic data of the intermediates **7**–**11** are listed in Table 1.

Table 1. Spectroscopic data for the intermediates **7**–**11** [a].

7: ^{1}H NMR: $\delta = 2.12$ (s, 3H, $COCH_3$), 2.22–2.80 (m, 14H, $CH_2CH_2CH_2$), 3.05–3.22 (m, 16H, $CH_2CH_2CH_2$), 7.02 (s, 1H, ArH); IR (KBr): $\tilde{\nu} = 1692$ cm^{-1} (C=O); MS: m/z 398 [M^+]

8: ^{1}H NMR: $\delta = 2.08$ (s, 3H, $COCH_3$), 2.11–2.65 (m, 12H, $CH_2CH_2CH_2$), 3.08–3.29 (m, 16H, $CH_2CH_2CH_2$), 3.54–3.63 (m, 2H, $CH_2CH_2CH_2$), 10.59 (s, 1H, CHO); IR (KBr): $\tilde{\nu} = 1694$ cm^{-1} (C=O), 1671 cm^{-1} (C=O); MS: m/z 426 [M^+]

9: ^{1}H NMR: $\delta = 2.11-2.57$ (m, 10H, $CH_2CH_2CH_2$), 2.72–3.28 (m, 20H, $CH_2CH_2CH_2$), 6.78 (d, $J = 11.9$ Hz, 1H), 7.74 (d, $J = 11.9$ Hz, 1H); IR (KBr): $\tilde{\nu} = 1647$ cm^{-1} (C=O); MS: m/z 408 [M^+]

10: ^{1}H NMR: $\delta = 2.01-2.60$ (m, 10H, $CH_2CH_2CH_2$), 2.76–3.43 (m, 24H, $CH_2CH_2CH_2$ and CH_2CH_2CO); IR (KBr): $\tilde{\nu} = 1674$ cm^{-1} (C=O); MS: m/z 410 [M^+]

11: ^{1}H NMR: $\delta = 1.94-2.16$ (m, 6H, $CH_2CH_2CH_2$), 2.42–2.56 (m, 2H, $CH_2CH_2CH_2$), 2.69–3.09 (m, 16H, $CH_2CH_2CH_2$), 3.26–3.54 (m, 10H, $CH_2CH_2CH_2$), 4.19–4.31 (m, 1H, CH_2CH_2CHOH), 5.75–5.82 (m, 1H, CH_2CH_2CHOH); IR (KBr): $\tilde{\nu} = 3416$ cm^{-1} (OH); MS: m/z 412 [M^+]

[a] ^{1}H NMR: Jeol JNX-EX 270 spectrometer; standard: TMS; solvent: $CDCl_3$; IR: Hitachi Nicolet I-5040 FT-IR spectrometer; MS: Jeol JMS-SX/SX102A tandem mass spectrometer (EI, 70 eV).

In conclusion, we have synthesized **1** by using the newly developed aldol condensation of **8** as the key reaction for introducing the final trimethylene bridge. An X-ray crystal structure analysis of **1** is in progress, as are studies on the dynamic behavior of the compound and its photochemical properties.

Synthesis and Structure of a Digallane with Tris(trimethylsilyl)silyl and Chloro Substituents**

Gerald Linti* and Wolfgang Köstler

Organoelement compounds of divalent gallium containing a gallium–gallium bond have been structurally investigated predominantly as tetraorgano derivatives such as $\{[(Me_3Si)_2CH]_2Ga\}_2$[1] and $[Aren_2Ga]_2$[2, 3] (Aren = 2,4,6-triisopropylphenyl, 2,4,6-tris(trifluoromethyl)phenyl). Gallium(II) halides with a metal–metal bond, either in the form of donor adducts like $Ga_2Cl_4 \cdot 2$dioxane[4] or as hexahalogeno digallates $[Ga_2Cl_6]^{2-}$,[5] have been known for a longer period. However, no digallanes containing two different substituents, such as $R_2Ga_2Cl_2$, have been isolated to date. These would, however, as an inspection of the corresponding boron compounds reveals,[6] be ideal starting materials for the synthesis of novel gallium(II) derivatives. Compounds containing gallium–silicon bonds have been rarely studied;[7–9] the stabilization and isolation of some metal(I) and metal(II) derivatives of Group 13 elements was achieved by using sterically demanding silyl substituents:

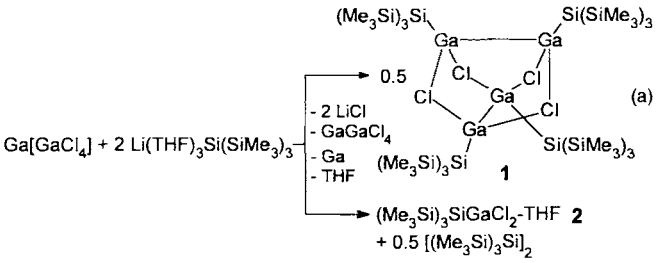
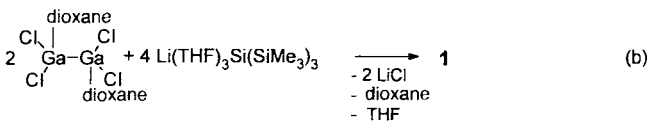
[**] The Chemistry of Gallium Compounds, Part VII. This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. H. Schnöckel for his support, and Prof. Dr. D. Fenske and Prof. Dr. P. Klüfers for collecting diffractometer data sets. Part VI: Ref. [11].

$[MSiR_3]_4$ (M = Al, R = *t*Bu;[10] M = Ga, R = $SiMe_3$[11]), $\{[(SiMe_3)Si]_2Tl\}_2$.[12] We report here on the use of the tris(trimethylsilyl)silyl group (hypersilyl) for the preparation of silyl-substituted digallanes.

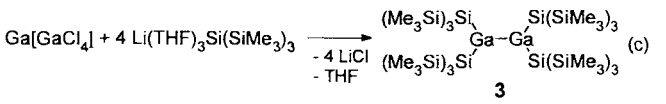
If mixed-valent gallium (I,III) chloride is allowed to react with lithium tris(trimethylsilyl)silanide·3THF[13] [Eq. (a)] in a molar



ratio of 1:1, among other products, colorless crystals of the dimeric dichlorobis(hypersilyl)digallane **1** are isolated. The formation of this compound of the type $R_2Ga_2Cl_2$ is surprising, because such compounds were considered to be unstable towards a disproportionation into gallium and gallium(III) derivatives.[1] $[(Me_3Si)_3SiGa]_4$ was neither isolated nor detected by NMR spectroscopy. Additional products in the nonuniform reaction [Eq. (a)] are **2**, which will not be discussed here further, gallium metal, and the disilane $[(Me_3Si)_3Si]_2$ (molar ratio of disilane to **2** = 1:2). According to ^{1}H NMR spectroscopic investigations of the reaction mixtures, the ratio in which the compounds **1** and **2** are formed is sensitive to the exact reaction conditions and varies between 1:1 and 1:3 (ratio of integrals in the ^{1}H NMR spectrum). This suggests that a redox reaction competes with the substitution. Compound **1** probably originates via intermediary formed Ga_2Cl_4·2THF, since **1** is formed in high yield in the reaction of two molar equivalents of lithium tris(trimethylsilyl)silanide·3THF with Ga_2Cl_4·2dioxane [Eq. (b)].



If two or more molar equivalents of lithium tris(trimethylsilyl)silanide·3THF are used in a reaction analogous to Equation (a), [Eq. (c)] compound **1** was not detected; in this



case **3** is isolated as the major gallium-containing product. Compound **3** is also formed as a by-product in the synthesis of $[(Me_3Si)_3SiGa]_4$ (**4**) from three equivalents of lithium tris(trimethylsilyl)silanide·3THF and Ga_2Cl_4·2dioxane.

The analysis of the crystal structure[14] of **1** (Fig. 1) shows a cage comprising four gallium and four chlorine atoms, in which the four gallium atoms are situated at the corners of a bisphenoid (Fig. 2). Pairs of gallium atoms are bonded to each other (d_{Ga-Ga} = 250.5 pm (average)). These bond lengths are typical for digallanes with four bulky organo substituents (d_{Ga-Ga} = 247–255 pm).[1–3] According to a preliminary crystal structure

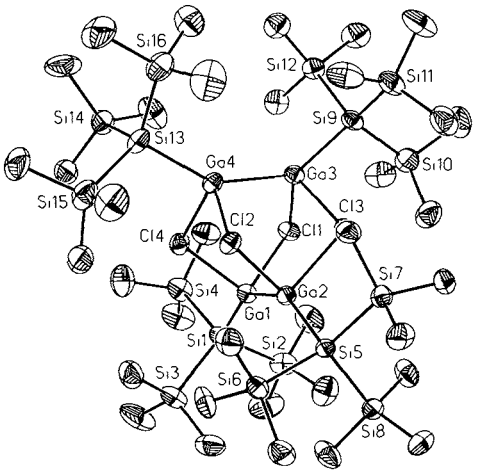


Fig. 1. Crystal structure of **1** (ORTEP, 30% probability ellipsoids). The hydrogen atoms are omitted for clarity. Selected bond lengths [pm] and angles [°]: Ga(1)–Ga(2) 250.14(10), Ga(3)–Ga(4) 250.93(12), Ga-Cl 238.9(2)–240.1(2), Ga-Si 239.0(2)–240.2(2); Si-Ga-Ga 145.02(7)–146.76(7), Ga-Cl-Ga 99.85(6)–100.54(7), Cl-Ga-Cl 91.02(7)–92.28(7), Cl-Ga-Ga 100.31(6)–102.33(6), Cl-Ga-Si 100.79(9)–103.71(7).

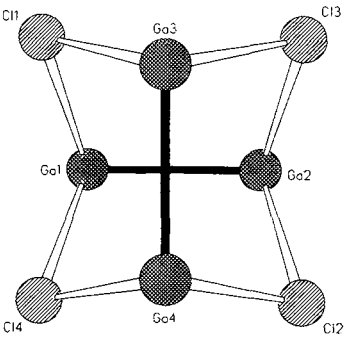

Fig. 2. Frame of the gallium and chlorine atoms in **1**.

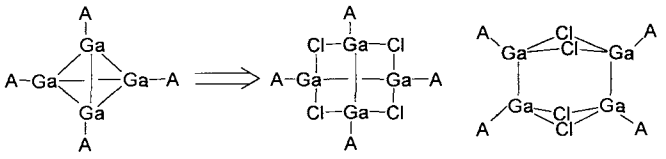
determination, compound **3** has a Ga–Ga bond that is 9 pm longer (d_{Ga-Ga} = 259.9(4) pm) than that in **1**, and a nearly orthogonal arrangement of the Si_2Ga planes (interplanar angle: 80°). Compound **4** also has longer Ga–Ga distances (d_{Ga-Ga} = 258.4(2) pm),[11] which can be attributed to the sterically demanding hypersilyl groups. The other four edges of the bisphenoid are too long (d_{Ga-Ga} = 365–369 pm) for Ga–Ga interactions, and are instead bridged by four chlorine atoms, forming a square (d_{Cl-Cl} = 345 pm). The Ga–Cl distances in the nearly symmetric Ga-Cl-Ga bridges (d_{Ga-Cl} = 240.1 pm (average)) are similar in length to those, for example, in dimeric Mes_2GaCl (d_{Ga-Cl} = 240.7(1), 238.4(1) pm),[15] but shorter than those in $[(\eta^1\text{-}C_5Me_5)_2GaCl]_2$ (d_{Ga-Cl} = 243.2(7), 249.9(8) pm).[16] Significantly shorter Ga–Cl bridging distances are observed ($d_{Ga-Cl(bridging)}$ = 229 pm) in Ga_2Cl_6.[17]

The Ga–Si distances in **1** (d_{Ga-Si} = 239.8 pm (average)) lie in the expected range and are nearly equal the sum of covalent radii of the participating elements. They are markedly shorter than the Ga–Si distance in the sterically strained $tmp_2GaSi(SiMe_3)_3$ (d_{Ga-Si} = 246.8(2) pm)[9] (tmp = 2,2,6,6-tetramethylpiperido) and comparable to those in $[(Me_3Si)_3SiGa]_4$[11] (d_{Ga-Si} = 240.6(2) pm). The bond angles centered at the silicon atoms bonded to gallium approach the tetrahedral angle. The very wide Ga-Ga-Si angles (145°) are striking, and for the planar arrangement of the Ga_2Si_2 units (torsional angle Si1-Ga1-Ga2-Si5: 1.3°) this allows the lowest steric strain between the hypersilyl groups. Compound **1** can be considered as a product of the partial oxidation of tetrahedrally built **4** (Scheme 1); the preformed structure of the gallium frame remains essentially intact. An isomeric structure (**5**) with double chlorine bridges, typical for dimeric diorganogallium chlorides, would have—according to simple MM+ force field calcula-



4 1 5

Scheme 1. A = $Si(SiMe_3)_3$.

tions—short Cl–Cl distances (less than 300 pm) between the parallel, nonplanar Ga_2Cl_2 rings and would evidently suffer from a high ring strain.

The dichlorobis(hypersilyl)digallane opens manifold possibilties for the synthesis of new gallium(II) compounds, in particular, heterocycles containing a Ga_2 unit.

Experimental Procedure

1: A suspension of $Ga[GaCl_4]$ (0.48 g, 1.68 mmol) in pentane (10 mL) was combined at −78 °C with a solution of $Li(THF)_3Si(SiMe_3)_3$ (0.79 g, 1.68 mmol) in pentane (15 mL). After slow warming to room temperature, the mixture was stirred overnight and all volatiles were removed from the red solution in vacuum. The residue was taken up in pentane (10 mL) and filtered. Colorless plates of **2** (0.20 g, 24%) crystallized from the solution at −30 °C; then after reducing the volume of the mother liquor, colorless prisms of **1** (0.21 g; 35% relative to $Li(THF)_3Si(SiMe_3)_3$) subsequently crystallized; m. p. >180 °C (decomp.). **1**: ^{1}H NMR (C_6D_6): $\delta = 0.44$; ^{13}C NMR (C_6D_6): $\delta = 3.5$. MS (70 eV, EI, ^{69}Ga): *m/z* (%): 1053 (4) $[Ga_3[Si(SiMe_3)_3]_3Cl_3]^+$, 667 (11) $[Ga_2[Si(SiMe_3)_3]_2Cl]^+$, 598 (1) $[Ga[Si(SiMe_3)_3]_2Cl]^+$, 583 (12) $[Ga[Si(SiMe_3)_3]_2Cl - Me]^+$, 563 (6) $[Ga[Si(SiMe_3)_3]_2]^+$, 351 (1) $[GaSi(SiMe_3)_3Cl]^+$, 316 (80) $[GaSi(SiMe_3)_3]^+$, 73 (100) $[SiMe_3]^+$. **2**: ^{1}H NMR (C_6D_6): $\delta = 3.72$ (m, 4H, OCH_2), 1.10 (m, 4H, CH_2), 0.38 (s, 27H, $SiMe_3$); ^{13}C NMR (C_6D_6): $\delta = 69.1$ (OCH_2), 25.8 (CH_2), 2.8 ($SiMe_3$). MS (70 eV, EI, ^{69}Ga): *m/z* (%): 386 (0.5) [M − THF]$^+$, 371 (0.5) [M − THF − Me]$^+$, 351 (15) [M − THF − Cl]$^+$, 247 (90) $[Si(SiMe_3)_3]^+$, 73 (100) $[SiMe_3]^+$.

3: Compound **3** was synthesized analogously to **1** from $Ga[GaCl_4]$ (0.25 g, 0.88 mmol) and $Li(THF)_3Si(SiMe_3)_3$ (0.83 g, 1.75 mmol). Yield: 0.22 g **3** (49%). ^{1}H NMR (C_6D_6): $\delta = 0.35$; ^{13}C NMR (C_6D_6): $\delta = 3.1$. MS (70 eV, EI, ^{69}Ga): *m/z* (%) 563: (10) $[Ga[Si(SiMe_3)_3]_2]^+$, 73 (100) $[SiMe_3]^+$.

[14] Details of the crystal structure determination of **1**: Crystal size: 0.30 × 0.15 × 0.15 mm, orthorhombic, space group $Pca2_1$, $a = 3606.3(6)$, $b = 1472.6(1)$, $c = 3253.7(3)$ pm, $V = 17.279(6)$ nm^3, $Z = 8$, $\rho_{calcd} = 1.085$ g cm^{-3}, $\mu = 1.60$ mm^{-1}, 64041 measured reflections in $2\theta = 4–52°$, STOE IPDS, $Mo_{K\alpha}$ radiation. Structure solution with direct methods, 28580 (23486 with $F > 4\sigma(F)$) unique reflections were used in the full-matrix refinement of 1172 parameters against F^2. $R_1 = 0.057$, $wR_2 = 0.186$ (all data), hydrogen atoms with riding model, max. residual electron density 0.725 e Å^{-3}. TWIN parameter for racemic twinning set. In one of the two independent molecules in the asymmetric unit, one of the hypersilyl groups is disordered in such a way that two silicon positions are observed for each of the three trimethylsilyl groups, but no split positions are seen for the carbon atoms. The two molecules do not markedly differ in terms of their bond lengths and angles. Both molecules (neglecting the disorder) are correlated by a pseudo center of inversion in (0, 0.25, −0.14). Refinement of the structure in space group *Pcab* (no. 61, *Pbca*) did result in a R_1 value of 0.20. The advice of Prof. Dr. H. Bärnighausen is gratefully acknowledged. Details of the crystal structure determination of **3**: The examined crystals were of very low diffracting intensity. Therefore the present X-ray structure determination only confirms the constitution of **3**, but allows no further discussion of the structure. Crystal size: 0.20 × 0.20 × 0.04 mm, monoclinic, space group $P2_1/c$, $a = 2324.6(10)$, $b = 1285.6(2)$, $c = 2304.9(5)$ pm, $\beta = 101.69(3)°$, $V = 6.745(3)$ nm^3, $Z = 4$, $\rho_{calcd} = 1.11$ g cm^{-3}, $\mu = 1.11$ mm^{-1}. Programs used are Siemens SHELXTL Plus (PC) and SHELXL93 (PC). Further details of the crystal structure investigation of **1** may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the number CSD-404582.

$Na_{14}Ba_{14}CaN_6$—A Nanodispersion of a Salt in a Metal**

Ulrich Steinbrenner and Arndt Simon*

Subnitrides of sodium and barium have recently been discovered. These compounds contain discrete Ba_6N octahedra in $Na_{16}Ba_6N$[1] as well as chains of face-sharing $Ba_{6/2}N$ octahedra in $NaBa_3N$[2] and Na_5Ba_3N.[3] The bond between barium and nitrogen is ionic, whereas that between barium and sodium is metallic.

The replacement of sodium by potassium as well as the introduction of additional potassium into a sodium-barium subnitride seemed a logical extension of this work. The reaction with NaK alloy (Na:K = 3:1) and barium (which had been pretreated with nitrogen in the ratio Ba:N = 3:1) led to a rather unexpected result: a few brittle crystals isolated from the liquid had the composition "$Na_{14}Ba_{14}KN_6$" according to X-ray structure analysis. The subnitride cluster unit of this structure is shown in Fig. 1a. The atom in the cluster can easily be refined as potassium. However, since potassium nitrides are unknown,[4] the coordination of nitrogen atoms to potassium is rather uncommon. All attempts to synthesize a compound of the composition above in high yield were unsuccessful.

A refinement of the X-ray data with calcium instead of potassium gave slightly better *R* values,[5] and subsequent attempts to synthesize $Na_{14}Ba_{14}CaN_6$ by specific addition of calcium were indeed successful.[6] The compound formed in approximately 65% yield together with $NaBa_3N$ and Ba_2N. A quantitative synthesis of the new compound $Na_{14}Ba_{14}CaN_6$ has not yet been achieved, probably because of the low solubility of Ca (added in small pieces) in NaK alloy and because of the generally low reaction rate.[7]

[**] We thank Dr. T. Braun, O. Buresch, Dr. J. Köhler, Dr. R. Pöttgen, and Dr. R. Ramlau for experimental assistance and discussions.

The spurious formation of $Na_{14}Ba_{14}CaN_6$ in the reaction performed without added Ca has an interesting interpretation. The barium used, which had been distilled in high vacuum, still contained 0.3(1) wt% Ca according to AAS analysis (AAS = atomic absorption spectrometry). Virtually all the calcium impurity was incorporated into the solid subnitride. An EDX analysis (EDX = energy dispersive X-ray spectroscopy) verifies that calcium is trapped in $Na_{14}Ba_{14}CaN_6$ crystals.[8]

From a structural point of view, the $Ba_{14}CaN_6$ cluster extends the series of previously known subnitride and suboxide clusters (Fig. 1). While the M_6A octahedra in $Na_{16}Ba_6N$ remain

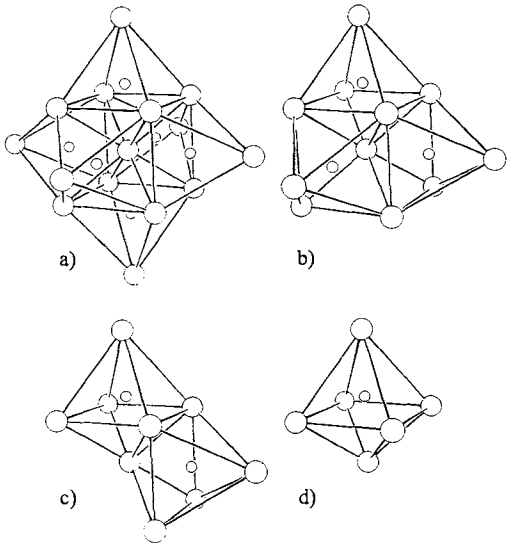

Fig. 1. The $Ba_{14}CaN_6$ cluster (a) in $Na_{14}Ba_{14}CaN_6$ and its schematic fragmentation into $M_{11}A_3$ (b), M_9A_2 (c), and MA_6 fragments (d) (see text). Drawn from the center outwards, the $Ba_{14}CaN_6$ cluster consists of a central Ca atom, an octahedron of N atoms, a cube of Ba^i atoms, and an octahedron of Ba^a atoms.

discrete, in Rb_9O_2[9] two of them share a face to form the M_9A_2 cluster;[10] in $Cs_{11}O_3$[11] three octahedra are connected through common faces to form the $M_{11}A_3$ cluster. The $M_{15}A_6$ cluster in $Na_{14}Ba_{14}CaN_6$ results from six analogously connected octahedra. Consequently, the central calcium atom is surrounded by an octahedron of N atoms and a cube of Ba atoms (Ba^i). Six additional Ba atoms (Ba^a) cap the faces of this cube. In the structure of $Na_{14}Ba_{14}CaN_6$ the clusters are arranged in the cubic close packing scheme. The tetrahedral voids of the packing are occupied by eight of the fourteen Na atoms in two Na tetrahedra whose edges are bridged by the six remaining Na atoms. Remarkably, the octahedral voids of the cluster packing remain empty.

The Ca–N distance of 257(1) pm in the cluster (Fig. 1a) is about 14 pm longer than corresponding distances in comparable structures (Ca_2N: 243 pm,[12] α-Ca_3N_2: 246 pm,[13] Ca_3NAu: 241 pm[14]). On the other hand the Ba^a–N distance of 250(1) pm is 25 pm shorter (Ba_2N: 276 pm,[15] $NaBa_3N$: 273 pm[2]), and the Ba^a–Na distances (440 pm and 451 pm) are somewhat longer than Ba–N or Ba–Na distances in comparable structures ($NaBa_3N$: 420 pm and 450 pm, Na_2Ba: 432 pm,[16] NaBa: 410 pm and 435 pm[17]). The distance between Ba^i and N is 276 pm. The striking differentiation in the Ba–Ba distances (Ba^i–Ba^i: 379 pm, Ba^i–Ba^a: 416 pm) is also found in the cluster chain Ba_3N in $NaBa_3N$ and Na_5Ba_3N (365 pm and 408 pm), in contrast to the intermetallic phases NaBa (449 pm and 459 pm) and Na_2Ba (452 pm) in which this differentiation does not occur. The Na–Na distances are 401(1) pm between atoms in the Na tetrahedra and 366 pm to the bridging Na atoms (Na_5Ba_3N: 370 pm to 410 pm, Na_2Ba: 370 pm, NaBa: 366 pm and 387 pm).

The band structure calculated with the Extended-Hückel approximation shows a distinct separation in energy between the sharp, localized levels of the N atoms and a broad band consisting of Na and Ba orbitals, which extends beyond the Fermi level. A Mulliken population analysis resulted in highly negatively charged nitrogen atoms, which can be interpreted as N^{3-} ions. Calcium and barium supply the electrons needed to form these ions. The Ca and Ba^i atoms have a higher positive charge than the Ba^a atoms, which indicates that especially the Ba^a atoms are responsible for the bonding between the cluster and the Na matrix. Both the cluster unit itself and the Na atoms may be considered neutral.

On the basis of a purely electrostatic model the shift of the nitride ions out of the centers of the Ba_5CaN octahedra, which is responsible for the long Ca–N distances, is a result of the mutual repulsion of the highly charged N^{3-} ions. A similar displacement is found for the O^{2-} ions in the suboxide structures $Cs_{11}O_3$[11] and Rb_9O_2.[9] In the latter the anions are situated 31 pm from the centers of the octahedra. This model also explains the trigonal distorsion of the Ba_6N octahedra in $NaBa_3N$[2] and Na_5Ba_3N,[3] which results in the two different Ba–Ba distances in the Ba_3N chains.

The plausible assumption that the bonds within the cluster are predominantly ionic and that it is embedded in a metallic matrix leads to a formal description of the bonding as $[Na_{14}Ba_6][Ba_8^{2+}Ca^{2+}N_6^{3-}]$. In this model one part of the structure forms a metallic $Na_{14}Ba_6$ matrix, which contains discrete, finely dispersed unit cells of the hypothetical perovskite type "$BaCaN_3$". $Na_{14}Ba_{14}CaN_6$ may be considered a nanodispersion of a salt in a metal.

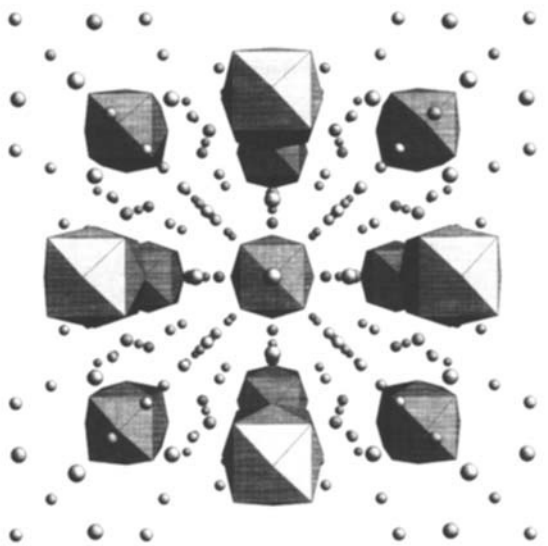

Fig. 2. A schematic view of the structure of $Na_{14}Ba_{14}CaN_6$: a dispersion of ionic Ba_8CaN_6 units in a metallic matrix of sodium and barium. The shaded polyhedra represent Ca-centered Ba_8 cubes whose faces are all capped by N atoms.

It is interesting to note that the amount of sodium is variable. So far we synthesized four different, strictly stoichiometric phases $Na_nBa_{14}CaN_6$ with $n = 14$, 17, 21 and 22. According to X-ray analysis all these phases contain the described $Ba_{14}CaN_6$ cluster in different Na environments.[20]

[6] Under an inert argon atmosphere distilled Ba (555.6 mg, 4.046 mmol), distilled Ca (11.6 mg, 0.289 mmol), NaN_3 dried under high vacuum (37.6 mg, 0.578 mmol), and Na–K alloy (1223.8 mg, 69 atom%) were sealed in a tantalum ampoule. To prevent oxidation of the tantalum, the ampoule was additionally sealed in a *Duran* glass ampoule. This ampoule was heated to 400 °C at $20\ K\,h^{-1}$. After 24 h at this temperature, the ampoule was cooled at $1\ K\,h^{-1}$ to 120 °C and annealed at this temperature for 3 months. Excess alloy was removed from the metal slurry in a press (about 5 kbar). The product was a brittle metallic substance, two-thirds of which consisted of $Na_{14}Ba_{14}CaN_6$. All manipulations were performed in a glovebox under argon.
[7] Experiments with Ca_2N or Ca–Ba alloy as calcium source are in progress.
[8] Standardless EDX point analysis on a $Na_{14}Ba_{14}CaN_6$ crystal gave a Ca:Ba ratio of 1:15.8.

[18] Band structure calculations [21,22] have been performed with the program package EHMACC/EHPC/EHPP [23] using relativistic *single-zeta* orbitals and orbital energies [24] (N 2s: $H_{ii} = -26.253$ eV, $\zeta = 1.886$; N 2p: $H_{ii} = -13.829$ eV, $\zeta = 1.728$; Na 3s: $H_{ii} = -4.962$ eV, $\zeta = 0.833$; Na 3p: $H_{ii} = -2.975$ eV, $\zeta = 0.611$; Ca 4s: $H_{ii} = -5.342$ eV, $\zeta = 1.071$; Ca 4p: $H_{ii} = -3.561$ eV, $\zeta = 0.891$; Ba 6s: $H_{ii} = -4.440$ eV, $\zeta = 1.279$; Ba 6p: $H_{ii} = -2.991$ eV, $\zeta = 1.059$). The results yield a sharp band of N 2s character (−27.0 to −26.0 eV), another sharp band of N 2p character (−14.4 to −13.4 eV), and a diffuse band (starting at −8.0 eV) with Na and Ba character, which extends beyond the Fermi level. Obviously, the bond energies found for the N 2s and N 2p bands are too high [25]. This is not surprising, since the nitride ions in the subnitrides can not be treated satisfactorily within the Extended-Hückel approximation. A similar band structure calculation for $NaBa_3N$ results in a bond energy of 9.7 eV for the N 2p levels. In contrast, the UP spectra of the N 2p levels in this substance show that the experimental bond energy is only 2.0 eV [25]. The result corresponds with UPS measurements of the alkali metal suboxides, which show photoemission from the O 2p levels at 2.7 eV.[26]
[19] Without charge iteration the band structure calculation results in the following Mulliken charges: N −2.77, Ba^i +1.58, Ba^a +1.14, Ca +1.43, Na1 −0.24, Na2 −0.38.

A Magnum Opus in Stereochemistry

Stereochemistry of Organic Compounds. By *E. L. Eliel* and *S. H. Wilen*. Wiley, Chichester, 1994. 1267 pp. $ 80.00/£ 29.95.—ISBN 0-471-01670-5/0-471-05446-1

In 1962 Eliel's book *Stereochemistry of Carbon Compounds* appeared. It summarized the status quo at that time in organic stereochemistry, and for a long time was the standard work on the subject. More than thirty years later the author has now brought out a second book, and since the information on the topic has burgeoned in the last three decades, he sought the help of two co-authors, Samuel H. Wilen and Lewis N. Mander. The structure of the thoroughly revised and updated book follows that of the previous work. Thus its strengths lie in the updated representation of the classical approaches to static stereochemistry. New directions in stereochemistry, for instance molecular dynamics or conformational analysis of peptides and oligonucleotides, are treated only lightly in the new book. In the foreword the authors point out that these days complete coverage of organic stereochemistry is no longer possible in one book. One has to make a selection, and where the focus lies depends on the point of view of the authors. For Eliel the emphasis is on the physical-organic aspects of stereochemistry.

The book is divided into 14 chapters. Chapter 1 (Introduction) serves to delineate the extent of the material, gives a historical outline of organic stereochemistry, and explains the concepts of polarimetry and optical rotation. Chapter 2 (Structure) defines structure from the view of organic chemistry with its subdivisions of constitution, configuration, and conformation, and touches upon experimental determination of structure and predictions of structure by calculations. A concluding subsection explains the most common molecular models, without, however, showing pictures of them. Chapter 3 (Stereoisomers) and Chapter 4 (Symmetry) present the distinction between enantiomers and diastereomers, as well as the classification of molecular structures according to symmetry arguments. In Chapter 5 (Configuration) absolute and relative configuration are defined. Chapter 6 (Properties of Stereoisomers. Stereoisomer Discrimination) and Chapter 7 (Separation of Stereoisomers. Resolution. Racemization) cover the physical properties of stereoisomers and stereoisomer mixtures. Both chapters are not only full of important information about chiroptic methods and NMR spectroscopic, kinetic, and calometric procedures, but also give the reader an outstanding overview of the present state of the art of stereoisomer separation. The ensuing Chapter 8 (Heterotopic Ligands and Faces) treats the distinction between homotopic, enantiotopic, and heterotopic ligands and surfaces as well as their spectroscopic and chemical consequences. The next three chapters, 9 (Stereochemistry of Alkanes), 10 (Conformation of Acyclic Molecules), and 11 (Configuration and Conformation of Cyclic Molecules), offer a contextually updated discussion of conformation analysis, which is, however related to the first edition of 1962 in its structure.

In Chapter 12 (Stereoselective Synthesis) the "guest author" Lewis M. Mander presents stereoselective synthesis in a compressed form. A caveat at the beginning of the chapter deals with the correct use of the terms stereoselective and stereospecific, and an introduction into the stereochemical classification of reactions. This is followed by a selection of the most important methods of stereoselective synthesis of alkenes. Finally Mander provides examples on the control of diastereoselective reactions, including a short overview on chiral auxiliaries. Then the well-written presentation of nucleophilic additions to carbonyl takes up a large portion of the chapter. The subsequent section deals with pericyclic transformations. The stereochemical course of radical reactions, methods for enantioselective synthesis, and examples of double stereocontrol conclude the chapter on stereoselective synthesis. The reader can certainly find many well-chosen examples in this chapter. Nevertheless, Mander himself correctly points out that for a more thorough review the reader should study the multivolume work *Asymmetric Synthesis*. One could also add *Comprehensive Organic Synthesis*, or the new volumes of Houben-Weyl's *Stereoselective Synthesis*, that, however, had not yet appeared when Eliel's work was published.

In Chapter 13 (Chiroptical Properties) the most important chiroptic methods and the applications are presented. Besides chiral allenes, alkylidenecycloalkanes, spiranes, and biphenylene, the concluding Chapter 14 (Chiralty in Molecules Devoid of Chiral Centers) also treats molecular propellers, helical structures, molecules with planar chirality, and cyclostereoisomers. Each chapter contains an extensive reference section, covering the literature to 1993. At the end of the book is a glossary with about 230 definitions and explanations of important concepts and common abbreviations. The detailed subject index is a useful reference.

To whom can I recommend this book? Every chemistry library should have the new "Eliel/Wilen/Mander" besides the old "Eliel" as reference work. Everyone interested in stereochemistry will find the desired information in the fields of characterization and separation of stereoisomers, and those who seek the historical roots and development in all aspects of organic stereochemistry, will have their research rewarded in the new "Eliel". Whether students on a tight budget will find the purchase worthwhile must be left to each individual case. In view of the extent of the material, students might have difficulty sifting out the important aspects for a beginner. The new book is not a typical textbook because it does not concentrate on principles in a skillful didactic manner. It is a useful compendium of stereochemical knowledge.

Friedrich Hund and Chemistry

Werner Kutzelnigg*

Friedrich Hund, one of the few physicists still alive of the generation that pioneered quantum mechanics, celebrates his 100th birthday this year. This is an occasion to recall how much chemistry owes to him. The important contributions of Hund to theoretical chemistry will not be presented in a primarily historical context—the cooperation of Hund and Mulliken during the development of MO theory will, however, be duly discussed—but the stress will be on the impact of the concepts introduced by Hund on theoretical chemistry today. Nearly all methods of quantum chemical calculations presently in use have a first step based on Hund's MO theory. Hund recognized that the use of delocalized molecular orbitals does not necessarily conflict with a description of a molecule in terms of localized bonds. Moreover, he formulated conditions for localizability that are still pertinent today. The classification of the spectra of diatomic molecules by Hund in 1925 was virtually definitive. Recently Hund's rules, which, among other things, make predictions about the energetic ordering of states with different spin multiplicities within the same electronic configuration, have aroused renewed interest. The concept of atomic states of natural and unnatural parity plays a key role in this context. Hund's first two rules for atomic states have been found to be special cases of more general rules. Molecules can violate Hund's first rule through spin polarization and through the preference of different equilibrium geometries of the singlet and triplet states.

Keywords: history of chemistry · Hund, Friedrich · Hund's rules · MO theory

1. Introduction

Few physicists of the generation that pioneered quantum mechanics have played as important a role for chemistry as Friedrich Hund, who celebrates his hundredth birthday this year. His name is omnipresent in "Hund's rules"[1–3] and "Hund's coupling cases".[4, 5] The fact that Hund,[6] together with Mulliken,[7] laid the foundations of MO theory is also widely known. Hund's localization criteria[8] are probably only familiar to the readers of my textbooks[9] (in particular Vol. 2) and students who have had assignments on this topic.

This article reviews the above-mentioned contributions not from the angle of science history, but in terms of the role played by Hund's concepts in current theoretical chemistry.

2. Biographical Details

Friedrich Hund was born on February 4, 1896, in Karlsruhe. He studied in Göttingen and Marburg to become a high school teacher of mathematics, physics, and geography. Fortunately he changed his mind and decided to pursue an academic career. He obtained his doctorate in 1922 in Göttingen and while working as Max Born's assistent completed his habilitation in 1925. Already two years later he became associate professor at Rostock and a further two years later full professor in Leipzig, where Heisenberg and Debye were among his colleagues. He spent the winter of 1926/27 with Niels Bohr in Copenhagen as a visiting scientist, and in 1929 was a visiting professor at Harvard University. Further stations of his career included Jena in 1946, and Frankfurt in 1951, before, in 1956 he returned to Göttingen to take the chair once held by his mentor, Max Born. In 1965 Friedrich Hund became Professor Emeritus. He lectured until beyond his 90th birthday, primarily on the history of physics from the viewpoint of a contemporary witness. At the age of 95 he gave his farewell lecture at Göttingen on "What I Have Not Found".

Those of Hund's publications that are relevant to chemistry stem from the years 1925 to 1933. The particularly important papers on MO theory were written around 1927. For the breakthrough of MO theory, the cooperation with Robert S. Mulliken was of crucial importance. This aspect will be outlined in the next chapter.

Hund fulfilled the criteria that would have enabled him to serve as the "seed crystal" in Germany for a theoretical chemistry based on quantum mechanics. When I asked him many years later why he did not take this opportunity, he answered with his well-known humility that his knowledge of chemistry had been insufficient to take on this task. On another occasion

he said—and here his humility is somewhat less apparent—that he dealt with a topic only until all fundamental questions had been answered. He has repeatedly commented on his role in the early days of quantum chemistry.[10, 11] Hund speaks of the early history of quantum mechanical theories of chemical bonding, when the primary goal was a qualitative understanding, as "the happy days when the cream had not yet been scooped off the top".[10] In answer to my question, Hund might have also correctly pointed out that the German chemistry community in the 30s, and even later, was hardly ready to accept a physics-based theory. Erich Hückel, another pioneer of theoretical chemistry in Germany, had painful experiences in this field. His theory of π-electron systems[13, 14], which is based on Hund's MO theory, was scarcely appreciated by chemists in Germany, even though his brother Walter—an established chemist—worked hard to bridge the gap between theory and the chemistry of the day. Only in the 1960s, after Hückel's MO theory had become popular in England,[15] France,[16] and the United States,[17] did it become accepted in Germany. Robert Mulliken, who saw the foundation of theoretical chemistry as one of his most important tasks,[18] found much more favorable conditions in the United States, as the chemistry community there was less bound by tradition and, hence, more flexible. From hindsight, Hund's departure from chemistry in the early 1930s might not have been a mistake in the long run, especially as there remained enough for him to do in physics. But this is not the topic of this article and is being appraised elsewhere.[12] Suffice it to say that Hund's experience with the quantum theory of molecules could be applied to solids, for an understanding of which chemical knowledge was not so important.

Now a few remarks on my personal contacts with Friedrich Hund: I first met him in Paris in 1962 where he was giving a lecture at the Cité universitaire. By chance, I met him again the following weekend in Chartres, where we had the opportunity for a longer conversation. When I came to Göttingen at the end of 1964, I listened with great enthusiasm to a lecture of Hund on the history of quantum theory. Hund was a member of my habilitation committee, and of course the most prominent one. In 1976 I was asked by Jürgen Hinze to give a lecture at a symposium honoring Hund and Mulliken's 80th birthdays (Fig. 1) in Bielefeld. I titled it "Hund's Localization Criteria and Their Relevance to Chemistry". I had apparently coined that term and Hund did not appear to be too pleased. The gist of his

Fig. 1. Professors Mulliken (left) and Hund (right) on July 8, 1976, in Göttingen, Germany. (Photograph by courtesy of the *Neuen Westfälischen* newspaper.)

complaint was that he minded less being mentioned in the name index of a scientific publication than in the subject index. His place in the subject indexes of physics, however, was already well established by then.

I remember one detail from a conversation with Friedrich Hund particularly well. He explained to me that in order to understand a physical problem, he first examined it in the framework of classical physics. Then he would apply the correspondence principle. I responded that I had grown up with quantum mechanics, that classical mechanics and the correspondence principle were rather foreign to me, and that I rather regarded classical theory as a limiting case of quantum theory. Hund replied that this was a good reason for the mandatory retirement age for professors and that he would reach his in two years.

Hund is a particularly friendly and also a tolerant man. Nevertheless, he is very critical and cannot be easily fooled. His "stupid questions" after lectures at the "Physikalisches Kolloquien" in Göttingen were much feared, because they could be quite penetrating.

3. Hund and Mulliken

The cooperation between Hund and Mulliken, who were of the same age, proved particularly fruitful for the theory of chemistry. Actually, this was no conventional cooperation, for

Werner Kutzelnigg, born on September 10, 1933 in Vienna, studied chemistry in Bonn (Vordiplom in 1954) and Freiburg (Diplom 1958). He obtained his doctorate with R. Mecke in 1960, working on IR spectroscopy. He was a postdoctoral fellow in Paris with B. Pullmann and G. Berthier (1960–1963), and in Uppsala with P. O. Löwdin (1963/64). He completed his habilitation in Göttingen in 1967. From 1970–1973 he was H2/H3 professor at the TU Karlsruhe. Since 1973 he has been H4/C4 professor at the Ruhr-Universität Bochum. His research interests are in theoretical chemistry, in particular the development of new methods, with the emphasis on electron correlation in molecules, relativistic quantum chemistry, magnetic properties of molecules, theory of chemical bonding, intermolecular forces, and formal and mathematical aspects of theories.

as far as I know there are no joint publications by Hund and Mulliken. As an aside, neither Hund nor Mulliken had coauthors for most of their fundamental papers. Their cooperation consisted mainly of a mutual stimulation, in sometimes similar and sometimes complementary ideas. The two scientists met several times and, in a way, always at the right time. Mulliken has written nicely about these encounters.[19] Reading Mulliken's memoirs one is surprised at the ease with which he, in European terms merely a young "Privatdozent", approached the leading figures in his field, and not just his peers in terms of age and experience like F. Hund. Perhaps this unconventional behavior was tolerated because he was an American, whereas it would not have been accepted from a European. Recently Hund also commented in some detail on his cooperation with Mulliken in an introduction to Mulliken's autobiography *Life of a Scientist*.[20] Mulliken had made several trips to Europe during each of which he visited a number of countries such as England, France, Denmark, Germany, Switzerland, the Netherlands, Austria, and Italy. The itinerary of his first European trip in 1925 included Göttingen, where he met Hund for the first time. Hund had just finished his paper "Zur Deutung einiger Erscheinungen in den Molekel-Spektren",[4] in which he introduced the coupling cases later named after him, and was working on his book on atomic spectra.[3] Two years later Mulliken was in Göttingen again, and the cooperation with Hund on molecular spectra continued, also during a hiking trip to the Black Forest. Mulliken's publication "Assignment of Quantum Numbers for Electrons in Molecules", Part I and II,[7] appeared in 1928. He stated that the main ideas and methods were those that had been previously successfully applied by Hund.[6] However, he went beyond Hund's approach. He sent Hund a copy of the manuscript, upon which Hund answered that it overlapped closely with a paper that he had just finished. He did not want to duplicate anything and therefore left out all those details from his own manuscript[21] that he considered Mulliken had dealt with in his work. In the summer of 1929 Hund, Heisenberg, and Dirac were guests in Chicago, where Mulliken had recently been appointed full professor. In 1930 Mulliken traveled to Europe again and spent a large part of his time in Leipzig as Hund's guest. Erich Hückel was also in Leipzig during this period. In 1930 Hückel's publication "Die Quantentheorie der Doppelbindungen" appeared[13] and in 1931 his habilitation paper "Elektronenkonfiguration des Benzols und verwandter Verbindungen".[14] Hückel expressly built upon Hund's work. Mulliken was again in Leipzig in 1932/33, after which he and Hund did not meet again until 1953, when Hund was Professor at Frankfurt University.

Attempts to disentangle Hund's and Mulliken's contributions to the development of molecular orbital (MO) theory might attribute to Hund a primary interest in the fundamental physical concepts, whereas Mulliken was concerned with the actual application to problems of molecular spectra and to the theory of chemical bonding. Hund much more than Mulliken was involved in comparing alternative approaches. One should also not forget the contributions of other scientists, in particular Herzberg[22] and Lennard-Jones,[23] to the development of MO theory. At about the same time as MO theory was developed, another approach to the theory of molecules was proposed primarily by F. London.[24] It came to be known as the theory of spin valence, and is based on the idea of constructing the wave function of a molecule from those of the separate atoms. This is a generalization of the successful Heitler–London approach for the H_2 molecule (which will be discussed briefly in Chapter 4).[25] A related approach came from Heitler and Rumer,[26] and an important paper by Wigner and Witmer should also be mentioned in this context.[27] Another method based on the Heitler–London approach for H_2 is the valence bond (or HLSP method) of Slater[28] and Pauling,[29] in which Heitler–London type pair functions are assigned to the individual bonds.

While the theory of spin valence never became very popular, the valence bond (VB) theory turned out to be a serious competitor of MO theory. It was so successful, because it could be viewed as the visualization of the concept of mesomerism, which was then very popular in chemistry. Moreover, Mulliken's comprehensive papers[18, 31] were relatively difficult to read, in contrast to those of his opponent Linus Pauling,[29, 30] who quickly swayed chemists toward his theory. This is not the place to review critically the role of Pauling in the development of theoretical chemistry. Pauling certainly had a profound knowledge of quantum mechanics, but he was not averse to easy success, and did not always mind dubious simplifications; in critical situations, he relied more on his chemical intuition than on rigorous theory. It is in part due to Pauling's influence that the breakthrough of the MO theory took such a long time.

While today we use the terms molecular orbital theory or MO theory, coined by Mulliken, Hund referred less spectacularly to a "Zuordnungsschema" (correlation scheme).[6, 21] A key concept in his theory is what is now generally called a correlation diagram. Hund was the first to realize that molecules can be constructed from molecular orbitals, even if he did not yet use that term. He correctly classified the molecular one-electron states according to symmetry and correctly gave occupation schemes for molecular configurations. Instead of looking for a way to calculate the molecular orbitals explicitly, Hund essentially proposed interpolating them from the states of the united atom and those of the isolated atoms by means of a correlation diagram. From these diagrams (Fig. 2) one can see which MOs are bonding[22] and which antibonding ("loosening"). Coulson[32] said of a similar correlation diagram[9, 31] that it deserved a place next to the periodic system of the elements in every chemical institute.

The proposal to represent molecular orbitals as linear combinations of atomic orbitals (LCAO) goes back to Lennard-Jones.[23] Such an approach had previously been used by Pauling[33] for the H_2^+ ion. At this point, it might be noteworthy that the first quantitative MO calculations for diatomic molecules were performed at the end of the 1950s at the Mulliken Institute in Chicago by Clemens Roothan and coworkers.[34]

In 1966 Mulliken received the Nobel Prize in Chemistry for his work on MO theory. He repeatedly stressed that he would have liked to share this honor with his friend Hund. Erich Hückel would have also been a worthy corecipient.

Mulliken[19] mentioned that he never could understand why Hund (like, by the way, Sommerfeld) used the term "die Molekel", while all other German-speaking colleagues referred

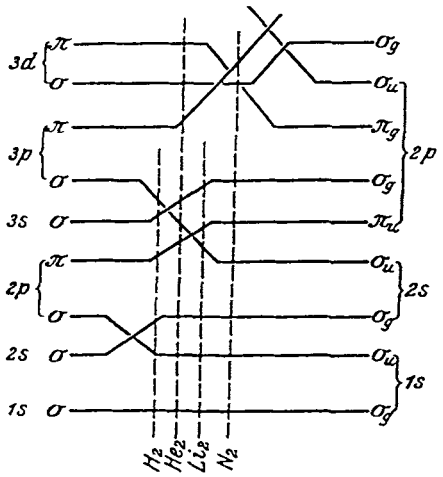

Fig. 2. Correlation diagram for the one-electron states in a homonuclear diatomic molecule (from Ref. [6d]).

to "das Molekül". A purist ought to argue that the correct German equivalent of the Latin "molecula" or French "la molecule" should be "die Molekel" in analogy to the Latin word "particula" (in French "la particule" and in German "die Partikel"), and in contrast to "calculus" ("le calcul" and "der Kalkül"). How "molecula" became "das Molekül" is hard to comprehend. Anyway, terminology has become established and "die Molekel" sounds artificial. An analogous situation arises in English: why is the word "molecule" and not "molecle"?

4. The Theory of Molecular Orbitals (MO Theory)

Even though Hund did not formulate MO theory—at least in his first papers—in terms of the LCAO approximation, this approach should be discussed here in this article, because it allows a clear comparison with the valence-bond method. Both the VB and the MO theory of molecules start with the theory of atoms. In the VB approximation, one attempts to construct the wave function of a molecule directly from those of the individual atoms. In MO theory, on the other hand, one regards the molecule as a unit and attempts to describe it like an atom, with the difference that several nuclei are present rather than one. In the older German literature the term "Methode der Molekülzustände" (method of molecular states) was popular for a while. The direct translation of Mulliken's term molecular orbital (Molekülorbital) is now standard, even in German. It is useful to recapitulate briefly the difference between the VB and MO descriptions using the H_2 molecule as example.

In view of the present special occasion I repeat something here that a reader of *Angewandte Chemie* is expected to be familiar with. More details can be found in my textbooks.[9] A look at overviews from the 1930s can also be recommended, in particular the book by Hellmann[35] and the article by VanVleck and Sherman.[36]

Let a and b be wave functions of the two isolated hydrogen atoms. In VB theory (which in this case is identical to the approach by Heitler and London),[25] one first formulates the product $a(\vec{r}_1)b(\vec{r}_2)$—which would be exact for noninteracting atoms. One then realizes that $a(\vec{r}_2)b(\vec{r}_1)$ is an equivalent description and that, for reasons of symmetry, the wave function must be either a (+) or a (−) linear combination of these two primitive product functions. The term $\vec{r}_1$ stands for the spatial coordinates of the first electron, $\vec{r}_2$ for those of the second electron. Hence there are, starting from the 1s functions of the isolated hydrogen atoms, two approximate wave functions for the molecule (Eq. (a)), where $N_\pm$ is a normalization factor, which is

$$\psi_\pm(1,2) = N_\pm\{a(\vec{r}_1)b(\vec{r}_2) \pm b(\vec{r}_1)a(\vec{r}_2)\} \quad \text{(a)}$$

different for the two functions. If these two wave functions are used to calculate the energy expectation value as a function of the internuclear distance R, as was first done by Heitler and London,[25] one obtains two potential curves. One of them is bonding and therefore describes the ground state of the H_2 molecule, while the other one is repulsive for all internuclear distances and does not represent a bonding state. Qualitatively, the bonding potential curve (E_{HL}) of the ground state of the H_2 molecule is rather similar to the exact potential curve (E_{ex}, Fig. 3).

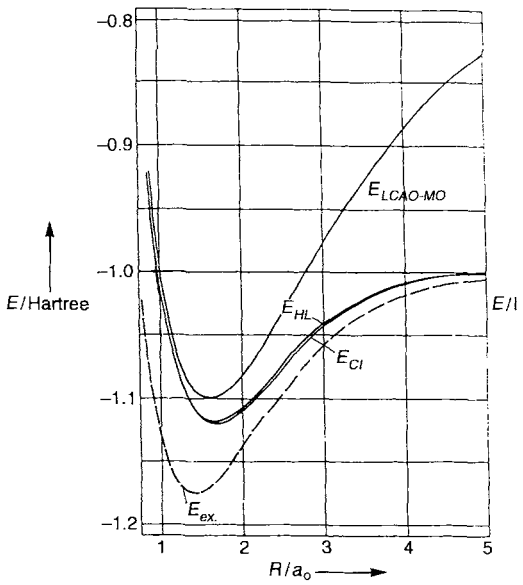

Fig. 3. Potential curves of the H_2 ground state according to the Heitler–London approximation, the LCAO-MO approximation, and the CI approximation, as well as the exact curve.

As mentioned above, in MO theory one regards the H_2 molecule as a unit. It is then described by a configuration of molecular orbitals, just like the He atom is approximated by a configuration of atomic orbitals. Corresponding to the ground state configuration of the He atom of $1s^2$, the ground state configuration of H_2 is $1\sigma_g^2$. Hence, the lowest-lying molecular orbital $1\sigma_g$ is doubly occupied. This molecular orbital is represented by a linear combination of the orbitals a and b of the isolated hydrogen atoms [Eq. (b)]. An antibonding MO $1\sigma_u$ can be constructed analogously [Eq. (c)]. The factors N_g and N_u serve to normal-

$$1\sigma_g(\vec{r}) = N_g\{a(\vec{r}) + b(\vec{r})\} \quad \text{(b)}$$

$$1\sigma_u(\vec{r}) = N_u\{a(\vec{r}) - b(\vec{r})\} \quad \text{(c)}$$

ize each MO to 1. Hence, the MO wave function of the H_2 ground state is given by equation (d).

$$\psi(\vec{r}_1,\vec{r}_2) = \sigma_g(\vec{r}_1)\sigma_g(\vec{r}_2) \quad \text{(d)}$$

A calculation of the energy expectation value as a function of the distance R between the two H atoms yields again a potential curve ($E_{LCAO\ MO}$) with a minimum in the vicinity of the actual equilibrium separation of the H_2 molecule. That is, the MO approach also describes the bonding (Fig. 3).

A comparison of the VB and MO functions for the H_2 ground state shows that the VB function is significantly better (Fig. 3). Both functions exhibit a minimum in the vicinity of the actual equilibrium separation in the H_2 molecule, but only the VB wave function behaves correctly for large distances, that is, the energy converges to the sum of the energies of two H atoms. The MO energy shows a physically unreasonable behavior at large internuclear separations; it is much too large. This defect of MO theory can be corrected, as the following discussion shows.

As is the case for atoms, molecular states may only be described by a single configuration (such as $1\sigma_g^2$) if this configuration is clearly separated in energy from other possible configurations. For large internuclear distances, however, the configurations $1\sigma_g^2$ and $1\sigma_u^2$ have nearly the same energy (and the same overall symmetry, $^1\Sigma_g^+$; the configuration $1\sigma_g 1\sigma_u$ has a different overall symmetry, $^1\Sigma_u^+$, and does not mix in). In this case, one must not use a single configuration to describe the molecule, but rather a linear combination of both configurations [Eq. (e)].

$$\psi(\vec{r}_1,\vec{r}_2) = c_1\sigma_g(\vec{r}_1)\sigma_g(\vec{r}_2) + c_2\sigma_u(\vec{r}_1)\sigma_u(\vec{r}_2) \quad \text{(e)}$$

This is called configuration interaction (CI). The potential curve that belongs to the MO-CI wave function (e) (E_{CI} in Fig. 3) gives the correct behavior for $R \rightarrow \infty$ and is overall a slightly better approximation for the exact potential curve than the VB approach. A proponent of the VB approximation would not give up at this stage, but would point out that a further improvement of the VB approach is also feasible. This consists of adding ionic structures, such as $a(\vec{r}_1)a(\vec{r}_2)$ and $b(\vec{r}_1)b(\vec{r}_2)$, where, in a sense, both electrons are located on the same atom. Indeed it can be shown that the MO approach with full configuration interaction and the VB approximation including all ionic structures are exactly equivalent.[37]

Once one proceeds beyond the H_2 molecule to more complex molecules, the MO approach does have some advantages over the VB description. Specifically, these are:

a) While the simple VB description fails for an ion-pair molecule, such as LiH, the ionic bond results naturally from MO theory. The valence MO of LiH is localized primarily on the H atom, that is, the MO description reflects the idea that a Li^+ and a H^- is present, between which there exists a Coulombic attraction. The VB theory, however, requires the inclusion of ionic structures even at the lowest level of approximation.

b) MO theory automatically yields the tetravalent nature of the carbon atom, for example in CH_4, while the VB approximation requires additional assumptions: in particular, a "valence state" is to be formed initially, and the atomic orbitals must hybridize before the chemical bond can be described.[28–30] Neither the concept of a valence state nor that of hybridization is required within the MO approximation.

c) Delocalized bonds, such as in benzene or even in H_3^+, follow automatically from the MO approach—the molecular orbitals are delocalized over the entire molecule—while in VB theory, one has to postulate the resonance of several valence structures. Hückel,[13, 14] in particular, recognized the potential of MO theory in this area and contributed greatly to its popularization (even if this occurred only relatively late in Germany).

d) The classification of the spectra of molecules, as well as the description of optical transitions, is much more straightforward with the MO theory than with the VB approach. The description of spectral transitions as excitations from an occupied to an unoccupied MO is often a good approximation. This is one of the reasons why Hund and Mulliken, who initially studied the analysis of molecular spectra, preferred MO theory.

e) The similarity in physical properties of isosteric compounds like N_2 and CO is readily understood on the basis of MO theory, whereas this is rather more difficult in the VB approach.[22]

f) MO theory can be much more easily and better handled than VB theory when it comes to practical calculations. Certainly, to Mulliken this argument was as important as statement d), because he was interested in real calculations of molecular structures.

g) Woodward and Hoffmann[38] intentionally based their theory of the orbital-symmetry control of electrocyclic reactions on MO theory. They employed correlation diagrams similar to those used by Hund, with the difference that the correlation was not between separated and united atoms, but between starting materials and products of a chemical reaction.

From Hund's point of view, a weak point of the Heitler–London approximation, which forms the basis of the method of spin valence[24] as well as of the VB method, was that it was originally formulated as a perturbation theory. The noninteracting atoms represented the unperturbed system. The interaction of the atoms is a rather unusual perturbation, as it also entails a change in symmetry. The extension of perturbation theory to the next higher order[39] caused unexpected difficulties, which were understood only later.[40–43] It is now known that such a perturbation approach does not converge except for H_2^+ and H_2,[40, 44, 45] even if the first order exists and is well defined.

One has to accept a certain hierarchy of approximation steps for both MO and VB theory. In the early days, it only appeared feasible to formulate theories with minimal basis sets.

The considerations about the H_2 molecule given above are based on such a minimal basis set, which is constructed from the *1s* orbitals of both the two H atoms. For the CH_4 molecule a minimal set for the C atom would include the orbitals 1s, 2s, $2p_x$, $2p_y$, and $2p_z$. Minimal basis sets never played an important role in ab initio MO calculations. The results obtained in this way are too inaccurate, and the extra effort with an enlarged basis set, for instance of the double-zeta kind (with about twice as many functions than the minimal set), is not all that much

bigger. In qualitative approaches or in a semiempirical version of the theory (where the integrals are not solved but used as adjustable parameters), one often employs minimal basis sets, for example in the CNDO (complete neglect of differential overlap) approximation[46] or in EHT (extended Hückel theory).[47]

While the semiempirical variant of MO theory is more or less consistent, there were fundamental difficulties with semiempirical VB theory, which were related to the nonorthogonality of VB structures. It was often incorrectly assumed that these structures were, in fact, orthogonal. One then attempted to compensate for this error by using physically unrealistic values for the exchange integrals (these exchange integrals in VB theory are not to be confused with the true two-electron exchange integrals that will play a role in the discussions in Chapter 6).[36] In an ab initio version of VB theory, it was necessary to explicitly account for the overlap integrals between valence structures, which lead to significant practical difficulties. This was one of the reasons why ab initio VB calculations have only played a marginal role. It was also unclear for a long time how a VB approximation using a non-minimal basis set should be formulated.

The MO calculations usually performed today employ basis sets that have very little in common with the atomic orbitals of the original LCAO-MO approximations. They can, however, be systematically enlarged to approach a complete basis set, and all occurring integrals can be readily evaluated.[48] This approach led to the SCF approximation or molecular Hartree–Fock theory, which began its conquest of this field in the 1960s. If one is interested not only in geometries close to the equilibrium structure, but also in the behavior at large distances from it—in which case MO theory becomes invalid in the single-configuration approximation—the SCF approximation has to be improved by including configuration interaction (CI).[49] In practical terms this is often difficult, but does not present any fundamental problems these days.

There have been repeated attempts to revive the VB approximation. Recently, the modern valence-bond theory has been propagated, in particular by Gerratt.[50] In this approach, one retains the formal structure of the VB functions; however, the atomic orbitals are not those of isolated atoms, but are strongly deformed. They are determined by the requirement that the total energy becomes minimized (similar to the MOs in ab initio SCF theory). For quite some time now, Goddard[51] has preferred the generalized valence bond (GVB) method. The term "generalized" is somewhat misleading, because the GVB structures are chosen to be orthonormal, which is a loss of generality relative to the original VB structures.

Nowadays, the choice between MO and VB has become obsolete. For precise calculations one uses the MO-CI method, which includes the VB approximation as a special case, or CI-like methods of the coupled-cluster (CC) type.[52] If very high accuracy is desired, neither MO-CI nor CC procedures are sufficient, and one has to employ wave functions that depend explicitly on the interelectronic coordinates.[53–56]

It should be realized that ab initio MO theory, including its improvements such as CI and CC, have a serious rival in density function theory.[57] This theory has been very popular in solid-state physics for some time, but is now also conquering chemistry. In essence, however, this alternative approach is also based on the MO concept. Only the electron interaction is evaluated differently from the usual ab initio methods. At least, one can interpret density function theory in this manner. Formally, the exchange interaction of MO theory (including self-exchange) is replaced by an exchange-correlation function. This has the effect of partially compensating for the errors of MO theory and of approximating correlation effects.

From today's vantage point, one can say that the MO approximation, proposed by Hund and Mulliken in 1927, has become fully accepted and the method of choice, although for a long time the VB approximation of Heitler, London, Slater, and Pauling was the more popular. Nowadays, MO theory is the basis for the qualitative understanding of the chemical bond and the properties of molecules, as well as the first step in sophisticated ab initio calculations.

5. Hund's Localization Criteria

The molecular orbitals of MO theory are generally delocalized over the entire molecule. The crystal orbitals in a solid behave similarly. In many cases, this delocalization is unavoidable and physically significant, for example in the case of metallic bonds. In other cases, however, delocalization conflicts with physical or chemical intuition. There are molecules and even crystals where the indications are that the bonds are localized. Hund was one of the first to recognize that there is no inherent contradiction between a localized and a delocalized description. The important issue is that some situations can be described with localized or delocalized functions, while others only correspond to the delocalized description. Diamond would be an example of the first case, sodium metal an example of the second.

In 1931 Hund[8] succeeded in formulating criteria that indicate when an equivalent localized formulation can be valid in addition to the always applicable delocalized description. The equivalence of the two approaches—if the localization criteria are satisfied—has a simple explanation, which was pointed out much later, in particular by Lennard-Jones et al.[58] A wave function in the form of a single Slater determinant is invariant with respect to a unitary transformation of the occupied orbitals. This is best explained with the example of the BeH_2 molecule.[9]

This linear, symmetrical molecule has in its ground state the MO configuration $1\sigma_g^2 2\sigma_g^2 1\sigma_u^2$, where the $1\sigma_g$ MO is essentially identical to the 1s AO (K shell AO) of Be, and $2\sigma_g$ and $1\sigma_u$ are symmetry adapted and delocalized over the entire molecule. In the LCAO approximation (that is, using a minimal basis set), $2\sigma_g$ and $1\sigma_u$ can be approximated by equations (f) and (g).

$$2\sigma_g = c_1 h_1 + c_2 s + c_1 h_2 \quad \text{(f)}$$

$$1\sigma_u = c_3 h_1 + c_4 p - c_3 h_2 \quad \text{(g)}$$

Here, h_1 and h_2 represent the 1s AOs of the two H atoms, while s stands for the 2s orbital and p for the $2p_z$ orbital of Be (z is the molecular axis). The symbols $c_1 - c_4$ are coefficients.

Contour diagrams of the $2\sigma_g$ and $1\sigma_u$ MOs resulting from a MO-SCF calculation are depicted in Figure 4a. If one assumes that s and p are equally capable of forming bonds to the H

atoms—which implies that $c_1 \approx c_3$ and $c_2 \approx c_4$—and takes into consideration that the total wave function does not change when $2\sigma_g$ and $1\sigma_u$ are replaced by linear combinations, for example φ_1 and φ_2 according to Equations (h) and (i), one can

$$\varphi_1 = \frac{1}{\sqrt{2}}(2\sigma_g + 1\sigma_u) \approx c_1\sqrt{2}\, h_1 + \frac{c_2}{\sqrt{2}}(s+p) \quad \text{(h)}$$

$$\varphi_2 = \frac{1}{\sqrt{2}}(2\sigma_g - 1\sigma_u) \approx c_1\sqrt{2}\, h_2 + \frac{c_2}{\sqrt{2}}(s-p) \quad \text{(i)}$$

now recognize that φ_1 and φ_2 are two approximately localized two-center molecular orbitals. Only the 1s AO of one H atom and one sp hybrid orbital of Be participates in each MO. This means that in this case a localized description is possible. Figure 4b shows the contour diagrams of the localized MOs φ_1 and

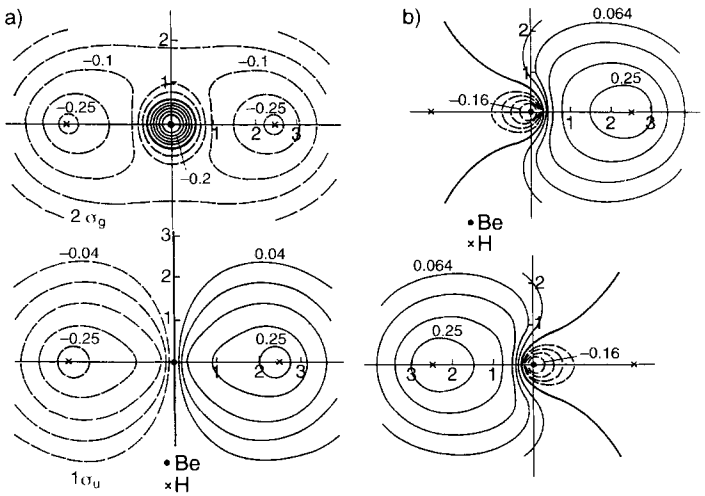

Fig. 4. Contour diagrams of the MOs of the BeH_2 molecule: a) canonical (delocalized), b) equivalent (localized) (from ref. [9]). The axes represent the distance from the Be core in units of a_0.

φ_2. The localization criteria that Hund formulated can be illustrated for this example. For each atom, three numbers have to be identical: 1) the number r of bound neighbors, 2) the number n of available valence electrons, and 3) the number t of valence atomic orbitals participating in the bonding. In BeH_2 these three numbers are 2 for the Be atom and 1 for each H atom.

The requirement that r, n, and t must be equal is a necessary condition for localization, which can be seen when one arbitrarily changes one of them. Let us assume, for example, that s and p do not participate equally in the bond, because, for example, p is too high in energy or overlaps poorly with h_1 and h_2. The conditions $c_1 \approx c_3$ and $c_2 \approx c_4$ would then no longer be valid, and the equivalent MOs φ_1 and φ_2, which could still be constructed according to Equations (h) and (i), would no longer represent two-center orbitals, but rather a four-electron, three-center bond. This is approximately the case in MgH_2, where the 3p orbital is much less involved in bonding than the 2p orbital in BeH_2. In this case, Mg only provides one valence AO. Of course, BeH_2 as well as MgH_2 fall between the limiting cases of systems with two-center bonds and those with a four-electron, three-center bond. BeH_2, however, is closer to the first case, whereas MgH_2 is closer to the second one.

Let us now remove an electron from BeH_2 and form the ion BeH_2^+! Now Be only provides one valence electron and Hund's localization criteria are no longer satisfied. Indeed, now the MO $2\sigma_g$ is doubly occupied, while $1\sigma_u$ is only singly occupied. One can still construct the localized MOs according to Equations (h) and (i), but there is no configuration of localized MOs that would be equivalent to $2\sigma_g^2 1\sigma_u$. Hence, BeH_2^+ can only be described as delocalized.

Further examples can be found in my textbook.[9] There one can also read how the localization criteria must be modified when semipolar or multiple bonds are present. The possibility that three critical numbers cannot be uniquely assigned is also discussed there.

Methane (CH_4) and diamond are examples of systems that can be described by localized two-center bonds: the three numbers r, n, t are equal to 4 for each C atom. The situation is different for benzene or graphite. If one looks at the σ-system, all three numbers are equal to 3. In the case of the π-system, however, two neighbors are present in benzene and three in graphite, while per carbon atom only one electron and one p-AO are available. Hence, a description using localized π-bonds is not possible. An extreme case in terms of non-fulfillment of the Hund's localization criteria is illustrated by a cubic-closest-packed lattice of atoms with one valence electron per atom. The number of neighbors is 12, the number of available valence orbitals is 4 (s, p_x, p_y, p_z), and the number of available valence electrons per atom is 1. Of course, it is a characteristic of the metallic bond that it cannot be described by localized two-center bonding.

6. Hund's Rules

Friedrich Hund's name appears in the literature probably most frequently in connection with Hund's rules. This is somewhat surprising as these rules originate from one of Hund's earliest scientific publications: "Zur Deutung verwickelter Spektren, insbesondere der Elemente Scandium bis Nickel"[1] ("On the interpretation of complex spectra, particularly of the elements scandium to nickel") from 1925. The quantum mechanical tools to interpret these spectra were then available in rudimentary form only. One was aware, for example, that the angular momentum in the central field is a constant of motion, and the Pauli principle was known. Quantum mechanics enabled the possible terms for a given electronic configuration to be stated, but it was necessary to resort to empirical analyses of spectra to order them in terms of energy. Hund made the remarkable observations that (as quoted from ref. [1]) (1) the energetically lowest lying term of an electron configuration always has the highest possible spin multiplicity (2) among the terms with the highest spin multiplicity, the one with the largest angular momentum quantum number L appears to be lowest in energy.

Hund later formulated these rules in somewhat more precise terms,[3] but did not give a quantum mechanical explanation. He did not state under which conditions these rules are valid, even though one can conclude from the context that they apply to energetically low-lying configurations with at most one open shell with $l > 0$, that is, for example to 1s2p or $1s^2 2s^2 2p^4$. For

such configurations, Hund's rules hold surprisingly well. Those who have criticized Hund's rules have often intentionally assumed that they are valid almost unconditionally in order to find many exceptions.

A few years after the publication of Hund's rules, Slater presented his theory of the spectra of complex atoms.[59] If one restricts this theory to two-electron configurations with only a single angular momentum L, one immediately notes that, in agreement with Hund's rules, the triplet state is lower in energy than the singlet state. Slater, however, also found configurations, albeit having more than one open shell with $l>0$, that apparently contradicted Hund's rules, while his theory was in accord with experimental results. Slater therefore declared Hund's rules obsolete. Hund himself no longer mentioned them in his 1933 review article for the Handbuch der Physik.[60] Despite their popularity, Hund's rules are mentioned almost by the way in textbooks on the electronic structures and spectra of atoms,[61-63] and caution is advised when applying them.

Hund also formulated a third rule,[2, 3] which is less commonly associated with his name. This rule concerns the spin–orbit interaction and predicts whether a normal or an inverted multiplet is present. Even though the explanation of this rule requires relativistic quantum mechanics, which did not yet exist in 1925, Hund quite correctly traced this third rule to a magnetic interaction between angular momentum and electron spin.

It is remarkable that Hund's first two rules have enjoyed continuous popularity until now, and that one usually turns to them first when the ordering of energy levels in a configuration needs to be predicted. Apparently the prevailing opinion is that Hund's rules are based on some fundamental physical principle, even if one does not fully understand it. Particularly for the theory of molecules Hund's first rule has become invaluable, though Hund did not initially consider this aspect (the second rule does not apply to molecules).

In order to understand Hund's rules, it is useful to look at the special case mentioned above where only the first rule is relevant, because a configuration then has, for example, only a single value of L (like in a 1s2s or 1s2p configuration) or because L is not defined (as in molecules). We shall limit the discussion to a two-electron system (or a system with two electrons outside a closed shell). For the configuration $\varphi_1\varphi_2$, a singlet and a triplet wave function can be constructed; the spin-independent parts are given by (j) and (k) and the corresponding energies by (l) and (m) where h_1 and h_2 are single-electron contributions,

$$^1\psi = \frac{1}{\sqrt{2}}[\varphi_1(1)\varphi_2(2) + \varphi_2(1)\varphi_1(2)] \quad \text{(j)}$$

$$^3\psi = \frac{1}{\sqrt{2}}[\varphi_1(1)\varphi_2(2) - \varphi_2(1)\varphi_1(2)] \quad \text{(k)}$$

$$^1\mathrm{E} = h_1 + h_2 + (11|22) + (12|21) \quad \text{(l)}$$

$$^3\mathrm{E} = h_1 + h_2 + (11|22) - (12|21) \quad \text{(m)}$$

(11|22) is a Coulomb integral, and (12|21) is an exchange integral. It can now be shown that such exchange integrals are always positive.[64, 65] This directly implies that ^3E is lower than ^1E.

In this proof, it was assumed that the two states can be described exactly by (j) and (k) and that the orbitals φ_1 and φ_2 are the same for both states. Both assumptions are only approximately justified.[66, 67] It can be shown[65, 67] that $^3E<{}^1E$ remains valid if one allows different orbitals for the two states. Even though in such an improved description the difference between (l) and (m) is no longer equal to twice the exchange integral (12|21), this integral remains the critical quantity that determines the energetic ordering. If one deviates from the single-configuration description, $^3E<{}^1E$ is no longer rigorously valid, that is, electron correlation effects (not accounted for in the single-configuration model) can lead to violations of Hund's first rule. These kinds of violations are rather rare, however. The violations of Hund's first rule due to the spin polarization[68] are more interesting. These arise for certain molecules, but rarely for atoms, and will be discussed in more detail at the end of this chapter.

At this point, it is tempting to see an analogy between the singlet and triplet functions (j, k) of an atom and the VB wave functions (a) of an H_2 molecule. A fundamental difference, however, lies in the fact that the two functions φ_1 and φ_2 in Equations (j) and (k) are orthogonal, so that the energy difference between ^1E and ^3E according to Equations (l) and (m) is given by a genuine two-electron exchange integral. Such integrals are positive, so ^3E must be lower in energy than ^1E. The atomic orbitals a and b of the VB function for H_2 are not orthogonal, but overlap strongly, and this overlap is at the very origin of the bonding. Furthermore, the exchange integrals of the VB approximation still contain single-particle contributions. All this leads to the a bonding singlet state lower in energy than the antibonding triplet state. This has nothing to do with Hund's rule. One of the conditions for its validity is the orthogonality of the involved atomic or molecular orbitals.

Things become more complicated when several values of L are possible for a configuration, that is, when both of Hund's rules must be considered.

The simplest example is the configuration p^2, for which the energetic ordering of the possible terms is $^3P<{}^1D<{}^1S$. The fact that ^3P is lowest in energy is apparently in agreement with Hund's first rule, but is not immediately obvious in light of the considerations discussed above. One could come to the conclusion that the relationship $^1D<{}^1S$ is a manifestation of Hund's second rule. The energetic ordering of terms for a d^2 configuration, $^3F<{}^1D<{}^3P<{}^1G<{}^1S$, indicates that this is indeed premature. As required by Hund's first rule, a triplet term, ^3F, is lowest in energy, and the second rule applies as well inasmuch as $^3F<{}^3P$. The ordering indicates, however, that the second rule does not apply to terms other than those with the highest multiplicity (in this case, not for the singlet terms, as ^1D lies lower than ^1G). It is rather strange that Hund's second rule should apply to the triplet, but not the singlet terms. Things get even more intriguing when we consider states with two open shells, like pp′ (for example 2p3p) or pd configurations. For pp′, there are singlet and triplet terms for P, D, and S. The lowest-lying term in this case is ^1P, a clear violation of both Hund's first and second rules.

This was known to some extent in the late 1920s. Russell and Meggers[68] formulated the alternating rule especially for two-electron states: Among the two-electron terms from two open

shells with minimum and maximum total angular momentum quantum numbers defined according to (n) and (o), something

$$L_{max} = l_1 + l_2 \quad (n)$$

$$L_{min} = |l_1 - l_2| \quad (o)$$

similar to Hund's first rule holds for L_{max} and L_{min}, as well as $L_{max} - 2$, $L_{max} - 4$, ... $L_{min} + 2$, that is, the triplet is lower in energy than the singlet, while for $L_{max} - 1$, $L_{max} - 3$ etc., the order is inverted, and the singlet lies below the triplet. Hence, for pp' configurations $^3D < {}^1D, {}^1P < {}^3P$, and $^3S < {}^1S$. This rule does not, however, predict why ^1P is the lowest of all states.

There have been attempts to make the alternating rule plausible, but a convincing explanation has only been given recently.[65] The key lies in the distinction between states of natural and unnatural parity.

The parity of an atomic state is defined as its behavior upon the coordinate transformation $\vec{r} \rightarrow -\vec{r}$. It is readily apparent that orbitals with $l = 0, 2, 4$ (that is, s,d,g...) have even parity, while those with $l = 1, 3, 5$ (that is, p,f,h...) have odd parity. For a multielectron atom, the parities of the orbitals must be multiplied. Hence the configuration p^2 has even parity, the configuration p^3 odd parity, d^2 and d^3 are both even, dp is odd, etc.

While for one-electron states, every angular momentum l has exactly one associated parity, both parities (even and odd) are possible for each L for multielectron states. It is useful to label states like S_g, P_u, D_g, etc. as having natural parity, while S_u, P_g, D_u, etc. are labeled as states of unnatural parity.[69] For one-electron states, only natural parity is possible, that is, s_g, p_u, d_g, etc. Among the states of configuration d^2 (which are all even), ^1S_g, ^1D_g, and ^1G_g have natural parity, whereas ^3P_g, ^3F_g have unnatural parity. In this case, all triplet states show unnatural parity. For the configuration dd', however, ^1S_g, ^3S_g, ^1D_g, ^3D_g, ^1G_g, and ^3G_g have natural parity, and ^1P_g, ^3P_g, ^1F_g, ^3F_g have unnatural parity. The alternating rule can now be formulated as follows: Among the terms of a two-electron configuration with the same L, the triplet state is lower in energy for states of natural parity, while the singlet state is lower in energy for states of unnatural parity.

This statement has been rigorously proven, under the assumption that the states could be described by a single configuration.[65] The proof contains several complicated and nontrivial steps and will not be given here. However, a fundamental physical concept that forms the basis for the alternating rule will be presented here.

A discussion of the analytical behavior of the solutions of a two-electron Schrödinger equation reveals that in the limit $r_{12} \rightarrow 0$ (r_{12} is the interelectronic distance), there are exactly three possibilities:[69]

1) $\psi(r_{12}) \sim r_{12}^0$ = const: relative s wave
2) $\psi(r_{12}) \sim r_{12}$: relative p wave
3) $\psi(r_{12}) \sim r_{12}^2$: relative d wave

Case 1 is realized for a singlet state of natural parity, case 2 for a triplet state (either natural or unnatural parity), and case 3 for a singlet state of unnatural parity. If one plots the probability density that the distance between the electrons is close to $r_{12} = 0$ (Fig. 5), one recognizes the typical correlation cusp for case 1, the well-known Fermi hole that keeps the electrons apart, for case 2, and--and this is the surprising feature--an even broader symmetry hole for case 3.

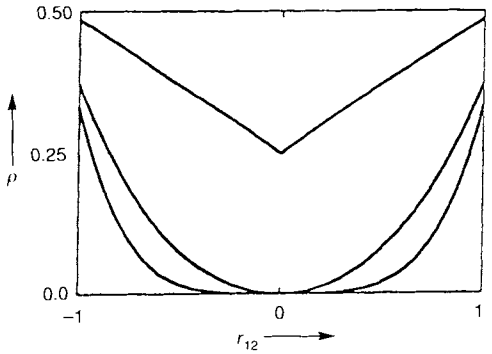

Fig. 5. Schematic representation of the probability density ρ for finding two electrons at a distance r_{12} for a singlet state of natural parity (top), a triplet state (center), and a singlet state of unnatural parity (bottom).

In a singlet state of unnatural parity, the electrons avoid each other even more strongly than in a triplet state, which results in a reduction of the electron–electron repulsion (assuming that both states have the same orbitals). This makes it at least plausible why the energy of such a state is lower than that of the corresponding triplet state.

Hund's 100th birthday stimulated me to continue earlier joint work with J. D. Morgan and think in more detail about Hund's rules,[65, 69] concentrating mainly on their physical foundation, range of validity, and extension to situations where they do not apply in their original form.[70]

This collaboration was the source of some surprising results, which confirmed that, up to now, no rigorous explanation of Hund's second rule has been attempted. Details can be found in a publication on this topic.[70] The pertinent results are the following:

1) The ordering of the mean values of the energy for the singlet and triplet terms of a two-electron configuration for the same angular momentum quantum number L (as functions of L) is governed by two effects:

a) the electrostatic interaction of the non-totally symmetric parts of the orbital density, which are dominated by quadrupole-like charge densities. This interaction is determined by the coefficient $a_2(L)$ of Slater's theory.[59] This $a_2(L)$ is a fourth-order polynomial in L. The minimum of $a_2(L)$, for sufficiently large l_1 and l_2, is found when (p) is valid.[70]

$$L + \tfrac{1}{2} \approx (l_1 + l_2 + 1)/\sqrt{2} \quad (p)$$

b) the short-range electrostatic interaction, which is markedly smaller for states of unnatural parity than for those of natural parity, as only for the former does the probability that $\vec{r}_1/r_1 = \vec{r}_2/r_2$ vanish.[70]

2) The alternating rule determines how the singlet–triplet mean values are split into a singlet and a triplet term.[65, 68]

The energetic ordering of $^3P < {}^1D < {}^1S$ for p^2 configurations and $^3F < {}^1D < {}^3P < {}^1G < {}^1S$ for d^2 configurations follows directly from these new rules. One finds, however, that, for example for an h^2 configuration, Hund's second rule no longer applies (the ground state is not ^3M with $L = 9$, but ^3K with $L = 7$). It also follows that the ground state for a 2p3d configura-

tion is ^1P. Our analysis suggests that it is somewhat accidental that Hund's second rule apparently applies well to triplet states of two-electron atoms, but not to the singlet states.

Interestingly, Hund's rules in their original form are valid for the ground states of nearly all atoms for which Z is small enough to allow the states to be described by L and S. A remarkable exception is Ce, which has a ground state configuration $\ldots 4f5s^2 5p^6 5d$, the ground state being ^1G_u, in agreement with the alternating rule.[65]

Before concluding this section, a few words are in order about Hund's rules for molecules. Its importance for chemistry can, for example, be illustrated by the observation that a review article by Berson on metaquinoid compounds[71] contains a separate chapter about Hund's rules. Apart from linear molecules, such as O_2 (for which the terms are $^3\Sigma_g^- < {}^1\Delta_g < {}^3\Sigma_g^+$), only Hund's first rule plays a role for molecules. It applies surprisingly well, but there is a remarkable class of exceptions, which was analyzed in particular by Kollmar and Staemmler.[72]

Cyclobutadiene is the classic example for a violation of Hund's first rule as a consequence of spin polarization. In this molecule with a planar, square structure, the bonding π-MO φ_1 is fully, that is, doubly, occupied, while the degenerate π-MOs φ_2 and φ_3 are half-occupied, with two of four possible electrons. These MOs are represented in Figure 6. In terms of Hund's rule,

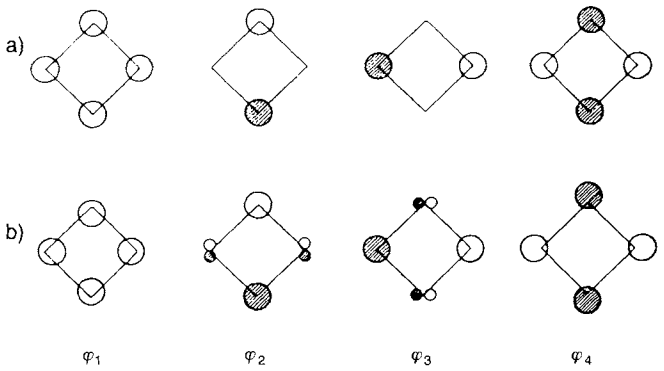

Fig. 6. Schematic representation of the π MOs of cyclobutadiene according to ref. [72] without (a) and with (b) d-function participation.

the exchange integral between the two degenerate π-MOs φ_2 and φ_3 is responsible for the singlet–triplet splitting. As these two MOs overlap only minimally (this is a special characteristic of the fourfold symmetry), the exchange interaction is also extraordinarily small. The spin polarization of the doubly occupied bonding MO by the singly occupied, degenerate MOs, on the other hand, is relatively big. This spin polarization can be understood on referring to Figure 7.

In a first approximation, the MO φ_1 is doubly occupied, that is, $\varphi_1\alpha$ and $\varphi_1\beta$ are each singly occupied. If the electron in MO φ_2 has, for example, α-spin, then $\varphi_1\alpha$ and $\varphi_1\beta$ experience a different field and become spin polarized. This is taken into account by replacing $(\varphi_1\alpha)(\varphi_1\beta)$ with $(\varphi_1'\alpha)(\varphi_1''\beta)$, that is, a single MO φ_1 is replaced by two different MOs φ_1' and φ_2''. The singly occupied φ_3-MO leads similarly to a spin polarization. The total spin polarization depends upon whether φ_2 and φ_3 are coupled to a singlet or a triplet. In the former case (Fig. 7a), a spin polarization is possible for which φ_1' and φ_1'' are linear

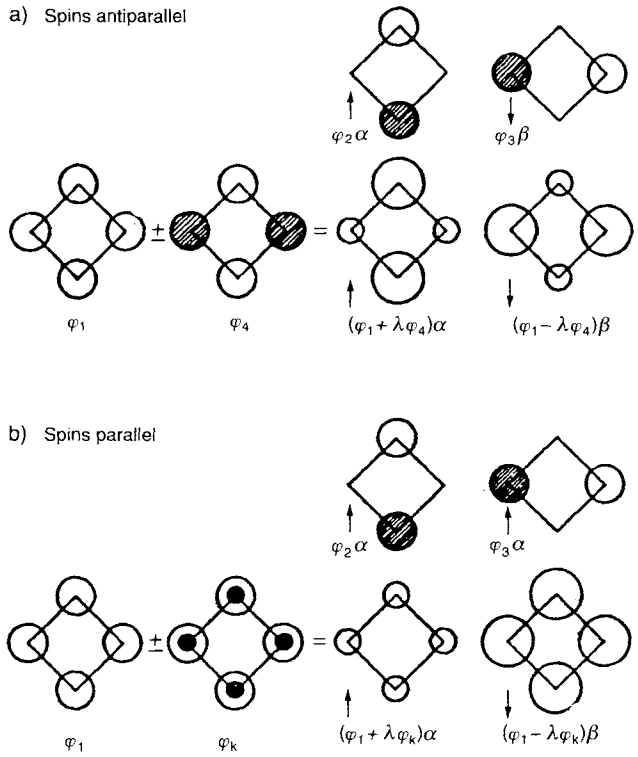

Fig. 7. Explanation of the spin polarization in cyclobutadiene according to ref. [72].

combinations of the π-MOs φ_1 and φ_4. This is particularly effective because φ_4 is low in energy. If φ_2 and φ_3 are coupled to a triplet, there is only a spin polarization by mixing in an MO of the same symmetry as φ_1 formed from the $3p_z$ AO. This leads only to a small energetic stabilization. Overall, this spin polarization, and the ensuing lowering of the energy, is larger for the singlet state than for the triplet state. This effect overcompensates for the exchange effect, so that the singlet state ends up lower in energy than the triplet state.

Actually, the situation for the cyclobutadiene molecule is even more complicated, because in addition to the above-mentioned effect, which counteracts Hund's rule, there is a second effect in the same direction. It is, namely, possible to lower the energy of the singlet state by distorting the C_4 frame from a square into a rectangular structure. This distortion, termed a pseudo-Jahn-Teller effect, does not effect the triplet state. If one compares the lowest-lying singlet and triplet states in their respective equilibrium geometries, one finds that the singlet state is distinctly lower in energy than the triplet state, and the pseudo-Jahn-Teller stabilization becomes more important than the spin polarization (which is the deciding factor if one compares identical geometries).

The fact that for two states of the same configuration sometimes the triplet and sometimes the singlet state is lower in energy is generally not only connected to Hund's rule, but also related to the mechanisms that dictate the equilibrium geometry of the two states.

The classic example for the singlet–triplet competition is the CH_2 species. The potential energy diagrams of the lowest triplet and singlet states as a function of the HCH angle are shown in Figure 8a. From the Walsh diagram in Figure 8b it can be seen that the highest doubly occupied MO, $1\pi_u$ is doubly degenerate

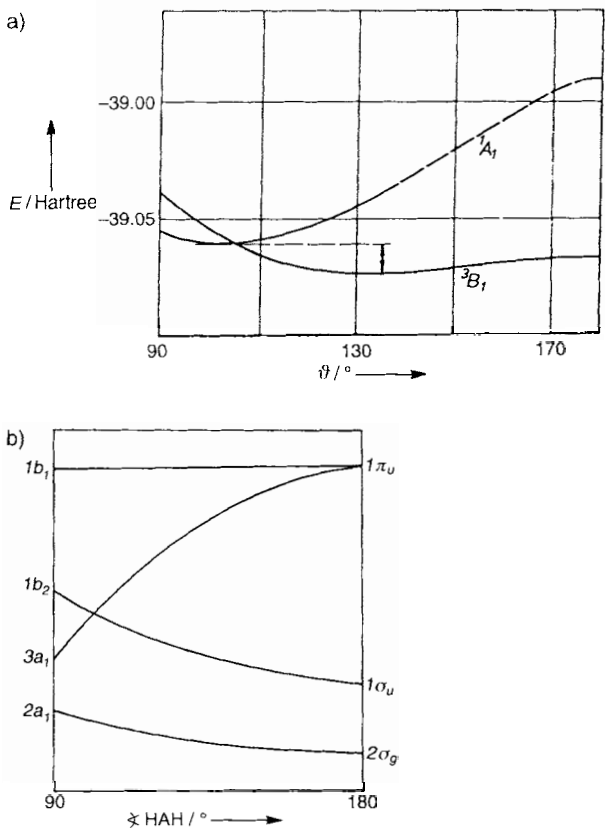

Fig. 8. a) Potential energy curves of the lowest singlet and triplet states of CH_2 as functions of the HCH angle ϑ (from ref. [9]). b) Walsh diagram for AH_2 molecules. For a bent geometry, $2a_1$, $1b_2$, and $3a_1$ are each doubly occupied in lowest singlet state of CH_2

in the limiting case of linear geometry. According to Hund's rule, for this geometry the triplet state lies lower, provided this degenerate MO is occupied. For HCH angles close to 90°, the difference in energy between the two components $1b_1$ and $3a_1$ of the original $1\pi_u$-MOs is so large, that, following the Aufbau principle, the lower-lying $3a_1$ MO prefers to be doubly occupied, and the ground state is a singlet. For angles between these extremes the Aufbau principle competes with Hund's rules. This leads to different equilibrium geometries for the singlet and the triplet state. The actual difference in energy between the two minima is rather small. There is no longer any doubt that the $^3CH_2$ is approximately 10 kcal mol^{-1} more stable than $^1CH_2$.[9, 73]

I hope that this presentation of Hund's rules has shown that they still are of great importance today, although they are only rules and not theorems. In each instance where they do not apply, a physically remarkable effect is involved. The study of actual or apparent violations of Hund's rules allows a better understanding of the physics of atoms and molecules.

7. Hund's Coupling Cases

For Hund's coupling cases we can be brief. These cases deal with the classification of band spectra of diatomic molecules, which Hund, in his fundamental papers,[4, 5] essentially accomplished. His formulation is still the basis for the analysis of these spectra today, as Herzberg's book makes plain.[74] These coupling cases are less interesting for a regular chemist than for a molecular spectroscopist. They are only relevant for those diatomic molecules that have a nonzero angular momentum about the molecular axis or a nonzero spin, like, for example, O_2 and NO.

One can characterize the state of a molecule in which the nuclei and electrons move by a few angular-momentum-like quantities,[74] such as

J = total angular momentum
N (or R) = angular momentum of the nuclear motion (perpendicular to the nuclear axis)
L = electronic angular momentum
Λ = projection of L onto the molecular axis
S = electron spin
Σ = projection of the spin onto the molecular axis
J_a = $L + S$ = total electronic angular momentum
Ω = $\Lambda + \Sigma$ = projection of J_a onto the molecular axis

In a strict sense only the total angular momentum J is a constant of motion—and, hence, suitable for the classification of states.

If in the Hamiltonian the interaction terms between different partial angular momenta are small, other quantities can also be regarded as almost good quantum numbers and can be used to characterize states. For light atoms, for example, the spin–orbit interaction is small and one can characterize atomic states to a good approximation by J, L, and S, where L and S primarily determine the energy level, while J only leads to a small splitting. This is referred to a Russell-Saunders (or LS) coupling. For molecules there are correspondingly more possibilities.

Hund's coupling case a) assumes that the interaction between nuclear and electronic motion is weak, but also that the motion of the electrons is referred to the nuclear axis, even in a rotating molecule. Here the projection Ω of the electronic angular momentum (including spin) onto the nuclear axis is well-defined. Ω and the nuclear rotation N couple to give the total angular momentum J. Figure 9 shows that a rotational progression is built up on each fine structure level.

In case b) the coupling of the spin to the molecular axis is negligibly small. This case occurs frequently when L = 0. Here

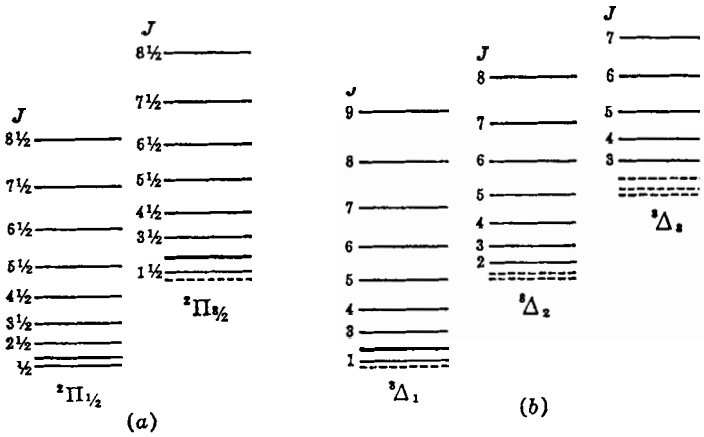

Fig. 9 Term scheme for the Hund coupling case a) for a diatomic molecule (according to ref. [74]) for a ^2P (a) and a ^3D state (b).

L and N couple to give a total angular momentum K without spin contribution. Interaction with spin then leads to a fine structure splitting of the rotational levels. Hence, one finds rotational progressions with fine structure splitting of each rotational level (Fig. 10).

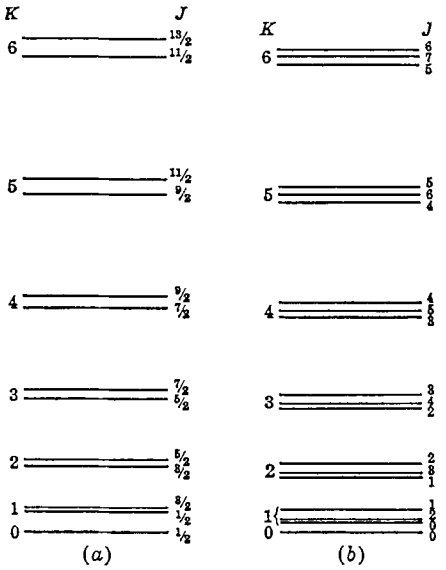

Fig. 10. Term scheme for the Hund coupling case b) (according to ref. [74]) for a ^2S (a) and a ^3S state (b).

The coupling cases c), d), and e) are less important. In case c) the interaction between L and S is stronger than the interaction with the molecular axis. This occurs particularly for molecules with at least one very heavy atom. In case d) the interaction between L and the molecular axis is weak, but the interaction with the rotational axis is strong. Case e) resembles d), but the interaction between L and S is strong and must be considered first.

In practice, transitions between the different coupling cases become important. These have been extensively discussed by Herzberg.[74]

8. Qualitative or Quantitative Theory?

Upon reading Hund's original papers,[1-6, 8, 21] one always realizes that he strives for simplicity and clarity. This is equally true for his textbooks[75] and other papers.[76] Instead of long mathematical derivations, one finds readily visualizable arguments. In the early days a nomenclature different from the present was used, but this does not make the reading difficult (for example, atomic quantum numbers were half-integral). For Hund, apparently "understanding" enables one to present a simple image of reality that is also convincing to a nonexpert. In view of this attitude of Hund it is questionable whether modern numerical ab initio quantum chemistry, which is based on the MO theory founded by Hund, can claim him as one of its fathers. Mulliken's position in this respect leaves no doubt. He not only encouraged numerical calculations, but also performed them himself after his retirement, at IBM in San José. He is certainly a pioneer of ab initio theory.

Did Hund then prefer qualitative to quantitative theory? In this context, a critical assessment of the progress of modern numeric quantum chemistry is in order. The solution of the Schrödinger equation for an atom or molecule with many electrons to any desired degree of accuracy seemed hopeless in the pioneering era of quantum mechanics; today it is feasible. Dirac[77] once stated that all of chemistry is in the Schrödinger equation, but that its solution was so difficult that it would never be achieved. With hindsight one can say that Dirac could not anticipate the advances in computer technology. Nevertheless, he did suggest that techniques should be developed to approximate solutions of the Schrödinger equation "without too much computation", which one can interpret as the suggestion to adjust the level of approximation to the available computer power.

As an alternative to the previous definition of understanding, one could also argue that understanding means that one can make predictions. While the simple qualitative theories available in the early days of quantum chemistry succeeded in explaining experimental observations, predictions based on them were uncertain at best, and even risky. Nowadays, however, in many areas reliable predictions are possible. Present-day computer chemistry is popularly caricaturized as a black box theory. Basically the black box predicts the same results that would be obtained from an experiment, if this could be performed, but gives no information about what happens between input and output. A long time ago, E. P. Wigner[78] argued that such a black box – if it were available, which it was not at the time – would hardly contribute to our understanding. This opinion, together with a manifest, and often irrational, disdain for numerical theory was very popular in researchers of Wigner's generation (there are no indications of this in F. Hund's work). I believe this is based on a misunderstanding.

On one hand, such a black box can give useful information that is not accessible by experiment. Theory, on which, after all, the black box is founded, can look at situations that are inaccessible to experiment. Theory can focus on a single molecule, while experiment usually has to deal with an ensemble of molecules under certain external conditions of pressure, temperature, etc. Theory can easily prepare a single quantum state of a molecule. It can study extremely short-lived molecules, even transition states of chemical reactions. It can artificially suppress certain mechanisms (such as hyperconjugation or d-orbital participation), and much more. All this means that the black box furnishes a lot of information that allows a better interpretation or classification of experimentally observed phenomena.

There is also a further aspect. The approaches used in modern quantum chemical calculations are rarely of a brute force type lacking transparency between input and output. To some extent Monte Carlo-type methods belong to this group. Most methods, however, are based on initial assumptions, which are successively improved. For instance, one usually starts with MO theory and then improves it by means of configuration interaction. It is often meaningful to notice that a certain observation can already be explained in the framework of MO theory, and that nothing crucial changes upon inclusion of configuration interaction. On the other hand, there are phenomena that can only be accounted for beyond the MO approximation, namely, those that depend strongly on the electron correlation. Likewise,

some experimental results can be understood in terms of a nonrelativistic theory, while others require a relativistic approach. Similarly, one can distinguish between effects that can be rationalized within the framework of the Born–Oppenheimer approximation while others cannot be explained within this approximation. It is thus generally possible to define models, that is, simplified theoretical approaches, and to specify phenomena that are understandable on the basis of a particular model. Without doubt some phenomena have simple explanations, while other empirical observations are the result of the interplay of several different, often opposing contributions. For those, it may be extremely difficult to give qualitative explanations. Many physical effects can finally be fully explained in different, and at first glance contradictory, ways that are nevertheless equivalent. W. H. E. Schwarz has given some convincing examples.[79] One has, of course, to face the argument that this approach for explaining chemical observations requires a certain hierarchy of approximations, which makes it somewhat arbitrary. But one can also consider other types of hierarchies or look for explanations that are independent of the chosen hierarchy, for example, in terms of observables only. Whether one should dispense with nonobservables altogether is a matter of discussion.

Even though the mere laconic statement that the explanation of a chemical finding lies in the Schrödinger equation certainly does not impart any understanding, modern quantum chemistry does contribute to the explanation by providing not only the black box, but also models, illustrations, and concepts, whose importance should not be underestimated.

At this point a few comments on reductionism are in order. In the present context, reductionism means, in simplified form, that chemistry can be derived from physics. This concept is plausible according to modern knowledge, but it is not entirely undisputed. The question of reductionism was not relevant for Hund, because for him molecules were objects of physics and therefore subject to physical explanations. If one wants to enter a realm of chemistry that is not just the theory of the physical properties of molecules, it makes sense to ask whether there are intrinsically chemical qualities that do not arise from quantum mechanics. Primas, among others, has dealt with this question.[80] He has pointed out, that reductionism is already relevant within physics in the context of the derivation of thermodynamics from statistical mechanics. Even though this derivation is correct and useful, thermodynamics can also be defined axiomatically without any reference to the statistical derivation. Thermodynamics contains qualities that are not a direct consequence of its atomistic, statistical mechanics derivation. The thermodynamic functions are, for example, classical, that is, commuting variables, that have no place in the framework of quantum theory. Whether there can be an axiomatic basis for chemistry, as for thermodynamics, and what the classical variables corresponding to the thermodynamic functions would look like, is yet unknown.

A famous example of a classical concept that has no place in quantum theory –at least in that of stationary states—is the chirality of molecules. There is an apparent paradox, namely that stationary states must be adapted to the symmetry of the Hamiltonian operator, so chiral molecules should not exist at all. Hund[81] has resolved this apparent paradox by pointing out that stationary states are only realized if the time scale of the measurement is large relative to the time for the tunneling between the nonstationary states of two optical isomers, which may even be larger than the age of the universe. Then stationary states are not realized.

It is questionable whether it is possible to specify more precisely some of the simplified concepts that are rather popular in qualitative theoretical chemistry, such as resonance or electronegativity, in order to use them, like the thermodynamic functions, without having to rely on their derivation from quantum mechanics. I regard it unlikely that drastically simplified theories, which often contain semiempirical corrections, can contribute more to the understanding of chemistry than exact quantum chemical calculations, since the predictive power of such simplified theories is small. However, the last word may not yet have been said in this context.

From Friedrich Hund we can learn to separate the essential from the marginal aspects and to search for simple explanations even for very complex phenomena, without, of course, forcing theory beyond its limits.

My thanks are due to D. Herschbach for suggesting that I write this article, to W. Lüttke for many valuable suggestions, to V. Staemmler as well as C. van Wüllen for reviewing the manuscript, and to E. Heilbronner for constructive comments. I am grateful to D. D. Morgan for helping with the English version.

Crystals of brevetoxin B

The Total Synthesis of Brevetoxin B: A Twelve-Year Odyssey in Organic Synthesis

Kyriacos Costa Nicolaou*

Dedicated to Professor Elias J. Corey on the occasion of his 65th birthday

The total synthesis of brevetoxin B has been achieved recently after a long search for a suitable pathway. This twelve-year odyssey[1] in synthetic organic chemistry was marked by several strategic and tactical routes, and resulted in numerous new synthetic methods. This article is a behind-the-scenes account of the total synthesis of brevetoxin B, from its origins at the University of Pennsylvania to its completion at the University of California, San Diego, and The Scripps Research Institute, La Jolla, California.

Keywords: brevetoxin B · natural products · total syntheses

1. Introduction

One day in November 1981, while scanning through the latest issue of the chemistry journal with the gray cover, I came to an abrupt halt on page 6773. There it was: the imposing and beautifully complex structure of brevetoxin B (**1**) (Fig. 1).[2] Only rarely before or since, has the structure of a molecule, natural or designed, evoked in me the same feeling of awe and admiration. My instincts as a synthetic chemist were, no doubt, responsible for the pause, after which I immediately proceeded to read the entire paper, something I rarely do nowadays I have to admit. The paper by Lin, Clardy, Nakanishi, et al.[2] began with the gloomy lines: "A dense growth, or bloom, of dinoflagellates can occur under certain favorable conditions, causing a phenomenon descriptively known as 'red tide'. Blooms of the dinoflagellate *Ptychodiscus brevis* Davis (*Gymnodinium breve* Davis) have caused massive fish kills, mollusk poisoning, and human food poisoning along the Florida coast and in the Gulf of Mexico..." and ended with an appropriately striking statement: "Brevetoxin B is made up of a single carbon chain locked into a rigid ladder-like structure consisting of 11 contiguous trans-fused ether rings. There is no precedent for this extraordinary structure, and in addition, a plausible biogenetic scheme is not obvious..." (see Fig. 1 for structure and computer-generated models).

It was love at first sight! I was intrigued, challenged, and excited by brevetoxin's exquisite and fascinating regularity. I was attracted by the opportunity I recognized in the molecule for the discovery and development of new reactions and novel synthetic strategies, and by its important and deadly biological activity (vide infra), and simply by the sheer thought that I had

no idea how to even begin to synthesize it! I considered the wealth of new insights and findings my students and I would encounter in our journey to this formidable target. But worries also crept into my mind, leaving me in a difficult dilemma: What if we never finish the synthesis? What if we end up chasing an elusive goal while our competitors make progress in other, more attainable projects? It would clearly be a treacherous and risky project, I concluded, but surely, just like the Odyssey,[1] an adventurous and, it was hoped, rewarding journey.

Still vacillating whether to commit ourselves to the total synthesis of such a formidable target, I opted to postpone the final decision until I heard from the National Institutes of Health (NIH), where a proposal would be dispatched as soon as we had formulated a synthetic plan. This way, I would not only buy more time to think about taking such a gamble, but also I would benefit from the comments of other, more senior colleagues evaluating my plans. This maneuver, of course, carried the risk that the project could end abruptly as a major embarrassment if the study section members found my plans totally ridiculous.

Before proceeding with the "synthetic odyssey," it is interesting at this point to review briefly the history of the "red tides," the catastrophic phenomena with which brevetoxin B (**1**) is associated.

2. History of the Red Tides

"...and the waters that were in the river were turned to blood. And the fish that was in the river died; and the river stank and the Egyptians could not drink of the water of the river..."

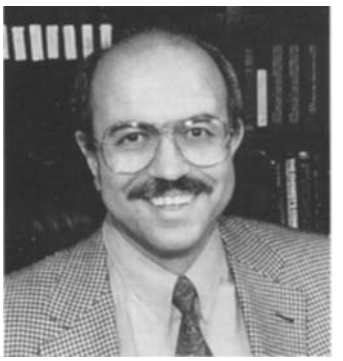
Exodus 7:20–21

This passage in the Bible describes an occurrence in roughly 1000 BC which could be the first recorded incident of a "red tide" phenomenon. Red tide is the common name given to vast blooms of single-celled algae[3–6] called phytoplankton, which constitute the base of the marine food chain. Although only a few dozen of the approximately 5000 species of algae known today are implicated in toxin production, the red tide phenomenon can be catastrophic to marine life, including fish, shellfish, and mammals such as dolphins and whales. Humans can also be endangered by the red tides through eating poisonous seafood and general environmental pollution. The name red tide is derived from the color of some of these blooms, which is due to the dense growth of algae containing the carotenoid pigment peridinin.[7] In the broader sense, however, the term red tide is used to describe all such phenomena in which brown or green colorations are observed or even cases without visible discoloration. These catastrophes are quite common today and occur periodically in most parts of the world, causing major environmental, economic, and health problems. Figure 2 shows dramatic pictures from four red tides near the Japanese coast, and Figure 3 shows fish killed during an outbreak of a red tide off the coast of Florida.

The first modern-day incident of human poisoning with shellfish contaminated by a red tide was recorded in 1793 when Captain George Vancouver and his crew landed in British Columbia in the area known today as Poison Cove. Captain Vancouver noted that the native Indians considered it dangerous to eat shellfish when the seawater was colored by algae blooms.

A famous red tide incident, which has been repeated every year ever since, was the October 1972 outbreak in which a massive bloom stretched from Maine to Massachussets on the east coast of the United States. The outbreak followed a September hurricane that originated in the Gulf of Mexico and presumably carried the poisonous algae with it to the New England coast. 1972 was also a disastrous year for Japanese fisheries. In a severe red tide occurrence an estimated $ 500 million worth of caged yellowtail fish were killed in the Seto Inland Sea.

The story of the fourteen humpback whales that suddenly died off the coast of Cape Cod, Massachussetts in 1987 is, perhaps, one of the most striking events due to a red tide.[3,4] Investigators later traced the cause of death of the whales to the saxitoxins, a group of powerful biotoxins produced by the algae *Alexandrium tamarense*, which had been eaten by mackerel, the main food of the humpback whales. At about the same time that year, and in two different incidents along the coast of North Carolina, several hundred people were poisoned from bathing in the ocean and consuming local seafood. The victims complained of diarrhea, dizziness, respiratory problems, eye irritation, and other symptoms, which all pointed to neurotoxic poi-



K. C. Nicolaou was born in Cyprus and received his Ph.D. degree from the University of London under the direction of F. Sondheimer and P. Garratt. After postdoctoral work at Columbia University with T. Katz and at Harvard University with E. J. Cory, in 1976 he joined the faculty at the University of Pennsylvania, where he was promoted to Rhodes-Thompson Professor of Chemistry. In 1989 he accepted joint appointments as Professor of Chemistry at the University of California, San Diego and as Darlene Shiley Professor of Chemistry and Chairman of the Department of Chemistry at The Scripps Research Institute. His awards include a Guggenheim Fellowship, a Humboldt Senior American Scientist Award, the American Chemical Society Award for Creative Work in Synthetic Organic Chemistry, the American Chemical Society's Gunther Award, the Dr. Paul Janssen Prize for Creativity in Organic Synthesis, and the Nichols medal. He has received honorary degrees from the Universities of Pennsylvania, London, and Athens. Nicolaou's research interests focus on chemical synthesis, molecular design and recognition, and the biological function of molecules. He is the author of 350 publications, 45 patents, and two books. A new textbook by Nicolaou, "Classics in Total Synthesis: Targets, Strategies, Methods" (Coauthor: E. J. Sorensen) was published by VCH in January 1996.

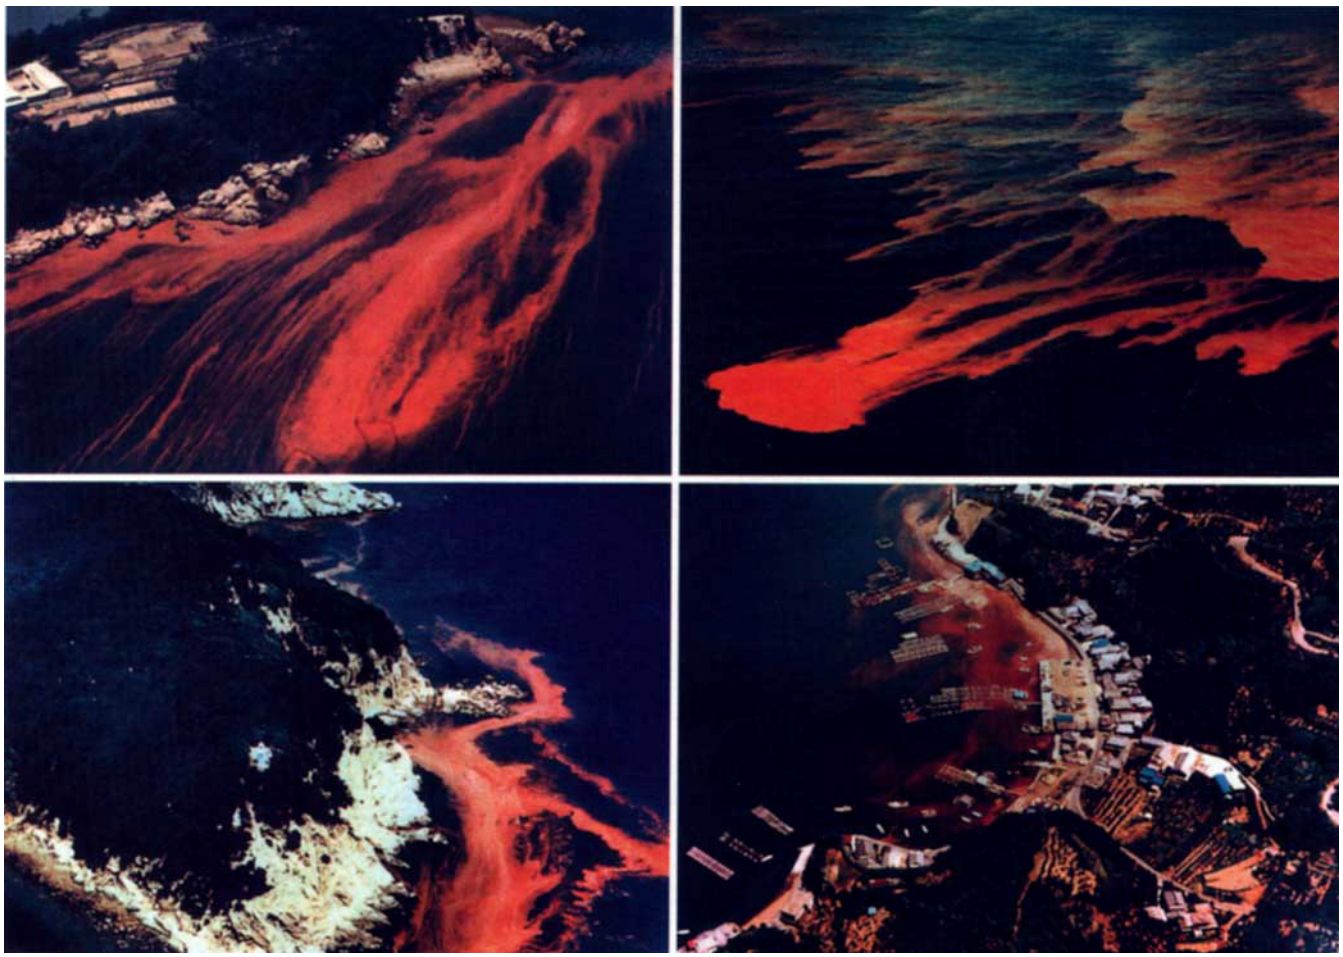


Fig. 2. Top left: A red tide on June 16, 1974, near Otafu Island, Okayama Prefecture, Japan. Top right: A red tide on May 6, 1976, approaching the coast of Oshima Island, Tokushima Prefecture, Japan. Bottom left: A red tide on May 8, 1976, off the coast of Matsushima Island, one of the Ieshima Islands, Hyogo Prefecture, Japan. Bottom right: A red tide on August 18, 1983, in Araihanatsu Bay, Japan, which resulted in a massive kill of caged fish.

soning. Yet another mass poisoning in 1987 erupted in Canada with patients complaining of vomiting, diarrhea, disorientation, and abdominal cramps. In some cases, permanent short-term memory loss was also observed. This outbreak was traced to mussels from Prince Edward Island that apparently were contaminated with marine toxins from red tide blooms of a *Pseudonitzschia* species. The same type of algae were responsible for a 1991 incident near Monterey, California, in which hundreds of sick and dying pelicans were found on the beaches. In both of these last cases domoic acid, a potent paralytic toxin secreted by the phytoplankton, was implicated as the causative agent.

Fig. 3. Fish killed by a ride tide that occurred off the coast of Florida.

Another devastating red tide incident hit the east coast of the United States between 1987 and 1988, right after the humpback whales had been poisoned. On that occasion, 740 bottlenose dolphins were found washed up along the Atlantic coast from New Jersey to Florida. Scientists later determined that the dolphins were probably the victims of yet another species of algae, *Gymnodinium brevis*, the producers of the lethal brevetoxins. Such incidents clearly demonstrate the great danger to the environment through poisoning in the food chain.

The frequency of these oceanic catastrophes has increased alarmingly in recent years because of environmental pollution and shipping practices that tend to spread and facilitate algal growth. Recent scientific evidence links the production of powerful biotoxins by the algae to a defense-related mechanism against their natural predators. However, alternative sources of these biotoxins, for example, bacteria residing in or on such

algae cannot, as yet, be ruled out. Regardless of the origins and reasons behind the biogenesis of these toxins, scientists agree that coastal pollution provides the necessary nutrients and creates the favorable conditions required for rapid and frequent proliferation of these algae and is, perhaps, responsible for the increase of these incidents during the last few decades. It is noteworthy, for example, that in Tolo Harbor in Hong Kong between 1976 and 1986, the frequency of appearance of the red tides increased eightfold as the human population and activities along the coastal area increased sixfold. Similar dramatic effects have been observed in Japan. Uncontrolled transfer of contaminated seawater and microorganisms from one area to another by oil tankers and other naval vessels may also be equally responsible for the appearance of new algal colonies in previously unaffected areas. Studies revealed that certain conditions of temperature (10–33 °C), salinity (levels of 27–37%), and sunlight (duration and intensity) are important factors favoring algal proliferation. Furthermore, analysis of satellite photographs of the coastal areas of Florida and hydrographic measurements implicated currents in red tide blooms.[8] Even more intriguing are the findings involving nutritional factors. For example, high concentrations of chelated iron discharged from the Peace River in Florida proved very crucial to the initiation of algal blooms and can be used as an index to predict the occurrence of red tides near Tampa, Florida. Heavy rains carrying soil rich in organic chelates to the ocean is also thought to stimulate growth of algae. Gibberellic acid, a plant hormone, has also been implicated as a promoter of red tides.[8]

Of particular danger is the way these microorganisms suddenly spread and colonize certain areas. A number of these species encapsulate themselves inside hard shells, called cysts, and move around in the oceans in a dormant state until they encounter favorable conditions, when they germinate and proliferate rapidly, causing massive blooms. The worldwide losses due to red tides and related phenomena such as *ciguatera* are devastating to marine life and human health; the ecological damage and economic loss may exceed hundreds of millions of dollars annually. Clearly these unicellular marine organisms, like viruses and bacteria, can endanger some of the largest and most sophisticated creatures of our planet, including humans, through the food chain.

Realizing the danger from and the significance of red tides, scientists have devoted increasing attention in recent years to understanding and controlling this phenomenon. Working together, chemists and biologists have isolated and identified a number of marine biotoxins and their phytoplankton sources. Among them are tetrodotoxin[9] (from the puffer fish), palytoxin[10] (from the coral *Palythoa toxica*), the saxitoxins[11] (from *Alexandrium*), domoic acid[12] (from *Pseudonitzschia*), ciguatoxin[13] and maitotoxin,[14] cause of the *ciguatera* phenomenon (both from *Gambierdiscus toxicus*), and the brevetoxins[15] (from *Gymnodinium breve*).

Brevetoxin B (**1**) was the first of these marine toxins to be reported, and is perhaps the most prominent member of the brevetoxin family of biotoxins[15] because of its complex structure and biological activity. Isolated and characterized in 1981,[2] brevetoxin B is lethal to fish and highly harmful to humans. This compound exerts its damaging effects by acting on the voltage-sensitive domains of sodium channels, which are situated in the membranes of the cells.[5, 6] The brevetoxins are thought to be responsible for massive fish kills in the Gulf of Mexico, along the Atlantic coast, and in many other regions of the world, and for many mass poisonings of humans caused by consumption of seafood. The symptoms in human victims include a tingling sensation in the mouth and digits, disruption of coordination (ataxia), hot–cold reversal of temperature sensation, dilated pupils (mydriasis), brachycardia, diarrhea and, occasionally, respiratory problems. Poisoning with these symptons is commonly known as neurotoxic shellfish poisoning (NSP), paralytic shellfish poisoning (PSP), amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP), and ciguatera seafood poisoning (CSP).[3–6]

3. Total Synthesis

3.1. Planning the Initial Strategy

We now return to brevetoxin B (**1**) and the dilemma it posed as a target for total synthesis. As decided, a proposal on the total synthesis of brevetoxin B was developed and dispatched to the NIH on January 24, 1982, and the long and anxious wait for a response began. In the meantime, the challenging structure of the molecule attracted two young and ambitious first-year graduate students at the University of Pennsylvania, where the project was initiated. Chan-Kou (Jack) Hwang and Mark Duggan in their innocence and naïvete expected to complete the total synthesis together in their Ph.D. theses within three years. I did not discourage them, even though, of course, I suspected differently, and in the summer of 1982, after completion of their course work, they embarked on the project with great enthusiasm and no shortage of ideas.

Soon thereafter, the "pink sheet" (summary statement) from the NIH arrived with the verdict from the study section ("the jury"). An incredible and very pleasing score of 1.45 (on a scale of 5, in which 1 is the best) worked magic on our morale. This score was much better than I had expected even in my wildest dreams, particularly in view of the miserable performances I had become accustomed to in my previous experiences with the NIH. I was wondering what had happened until I carefully examined the list of study section members. Among them were Yoshito Kishi from Harvard University, Stephen Hanessian from the University of Montreal, and Larry Overman from the University of California, Irvine, masterful chemists, whose opinions I valued highly. Twelve years later, when we finally reached the island of "Ithaca",[1] we remembered these pioneers and saluted their contributions to the field of total synthesis, an area of research that they had championed and whose future they continue to shape. Despite its highly encouraging score, however, the summary statement ended with a gloomy estimation: "This is a clever approach to a novel, biologically interesting molecule, whose stereochemical complexities have been reduced to the synthesis of appropriate allylic alcohols, their epoxidation, and the regioselective opening of these epoxides. The overall plan is remarkably convergent but it is high risk." Work began in earnest and funding started on January 1, 1983.

At this juncture, it will be constructive to briefly review the initial plan, as flawed as it was, to help us reconstruct and follow the story chronologically. Inspection of the structure of brevetoxin B (**1**) led immediately to the first exciting recognition that this formidable structure could be reduced, by virtue of its regularity, to single polyepoxide precursors (Scheme 1). Equipped with an initiator at one side of the structure and a terminator at the other side of the structure, these polyepoxides could, in principle, be considered as potential precursors to brevetoxin B (**1**). The following verbatim abstract from the original proposal of 1982 conveys accurately our thoughts and reservations on this possibility at the time:

"In theory a 'zip reaction' as indicated by the arrows (Scheme 1) and accompanied by the expected inversions could lead to brevetoxin B (**1**) in a single step under 'favorable conditions'. Synthetically, however, there are two serious problems with such an approach, at least with the present state of the art. The first problem is the lack of regioselectivity (or 'ringselectivity') in the consecutive opening of these epoxides. Indeed, either under basic or acidic conditions, some of these epoxides can safely be predicted to open in the undesired fashion giving rise to the wrong size rings. The second problem with this one-step approach is the difficulty in synthesizing stereoselectively such a polyepoxide precursor due to the absence of any 'handles' adjacent to the epoxide functionalities that may be used to direct epoxide formation and also the reactivity of the epoxide unit that may preclude long sequences involving polyepoxides. Thus, it is unlikely that such a 'zip', one-step generation of brevetoxin B will succeed in the laboratory under presently known chemical means."

Fearing that no graduate student would ever undertake such a risky, one-step approach (not to mention the reaction of the NIH study section!), I had included a more realistic strategy to brevetoxin B in the proposal. This second plan depended on a convergent strategy involving intermediates **3**–**5** (Scheme 1). The synthesis and utilization of these intermediates as originally conceived are outlined in Schemes 2 and 3. Key to the success of these proposals were the postulates that base-induced openings of hydroxyepoxides would prefer pathways involving nucleophilic attacks on secondary rather than tertiary centers and on epoxide positions being activated by adjacent double bonds. The latter epoxide openings, in which the carbon centers are

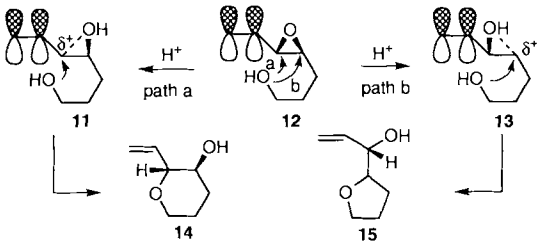
activated by adjacent electron density, would also proceed under acid catalysis. These concepts needed development and verification with model studies, but one could take comfort in the success of prior related work.

3.2. The Tetrahydropyran Problem

According to the original plan, the first objective of the brevetoxin project was to develop the necessary methodology for the regioselective and stereospecific construction of the tetrahydropyran systems of the target. The results of the model studies in this direction were remarkably successful and involved simple chemical principles and manipulations (Scheme 4). The basic



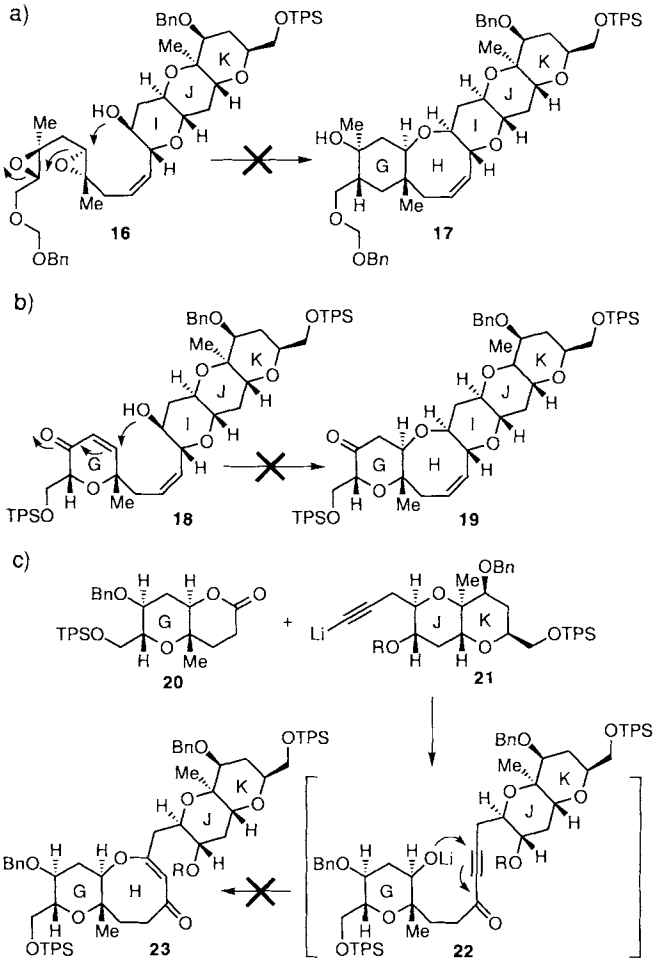
Scheme 4. The basic concept behind the regio- and stereospecific ring closure leading to tetrahydropyrans. The orbital with developing electron deficiency is stabilized by conjugation with a π orbital in the same plane; path a: 6-*endo* ring closure; path B: 5-*exo* ring closure.

concept here was to utilize the p orbitals of an adjacent double bond to bias the location of the incipient positive charge and, thereby favor formation of the desired six-membered ring. Combination of this new chemistry[16] with the then recently discovered Sharpless asymmetric epoxidation reaction[17] allowed the quick assembly of the polycyclic building blocks required for the synthesis of brevetoxin B. Thus, the project moved forward, and in a relatively short time we were in a position to proceed to the next stage.

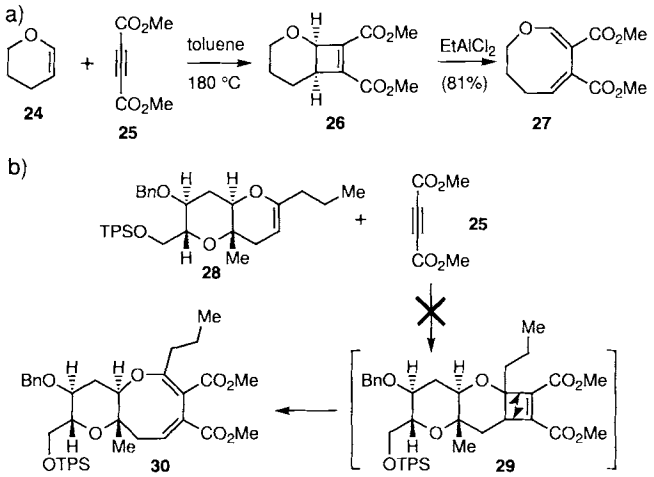
3.3. The Oxocene Problem

While the coupling reactions of the tetrahydropyran segments proceeded smoothly, the oxocene ring proved more than equal to its reputation as a notoriously difficult system to construct and, thus, became a major obstacle. Although we had no illusions regarding the construction of medium-sized rings, the initial failures we encountered were frustrating. First to fail was the projected hydroxy-diepoxide opening cascade shown in Scheme 5a. Then came the disappointment of the failure of the intramolecular Michael reaction depicted in Scheme 5b. Finally, a timely report by Schreiber et al.[18] prompted us to try the ring expansion shown in Scheme 5c, but again to no avail.

After several other conventional approaches also failed, we decided that it was time to go back to the drawing board, for we then realized that the strain in the oxocene region of the molecule would not allow us easy passage. A new method for the construction of eight-membered ring ethers, based on consecutive [2 + 2]cycloaddition and cyclobutene opening reactions, was tested successfully with a model system (Scheme 6a).[19]



Scheme 5. Unsuccessful attempts to synthesize the oxocene ring of brevetoxin B (1) by: a) polyepoxide opening, b) conjugate addition c) ring expansion following a report by Schreiber et al. [18].

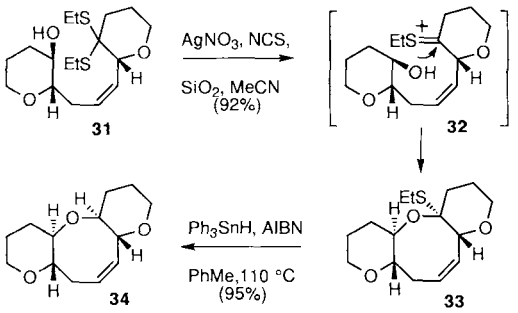


Scheme 6. Synthesis of oxocenes by [2 + 2]cycloaddition and cyclobutene ring opening. a) Successful model study; b) unsuccessful attempt with substrates resembling brevetoxin B (1).

However, a more realistic system did not undergo this newly developed reaction (Scheme 6b), presumably for steric reasons. Our initial excitement faded quickly, but in rethinking the problem we found a radically different solution.

The new concept focused on the attack of a highly reactive, perhaps polar species to overcome the strain and entropic barri-

ers encountered during the formation of the oxocene ring system of brevetoxin B. It was clear that, despite the favorable effect of the (*Z*) double bond of the ring-forming chain, considerable driving force was still needed before ring closure could be realized. A hydroxydithioketal was chosen as a potential progenitor of a hydroxysulfonium species (e.g. **32**, Scheme 7),



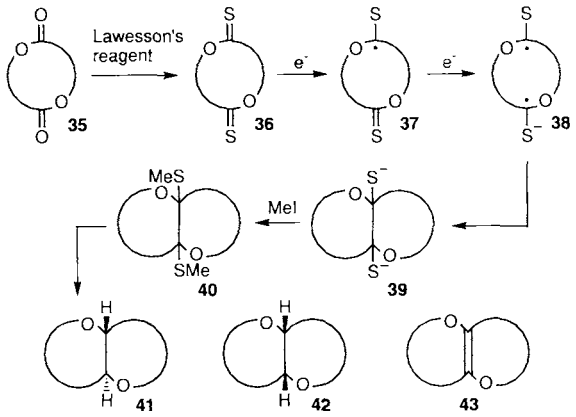
Scheme 7. Hydroxydithioketal strategy for the synthesis of oxocene systems.

which was expected to undergo rapid intramolecular reaction leading to the oxocene ring system. The remaining ethylthio group was expected to be easily excised from the product (**33**, Scheme 7) and replaced with a hydrogen atom docking in from the desired face. These predictions proved delightfully correct, and graduate students Mark Duggan and Jack Hwang proceeded to execute successfully the designed experiments with characteristic speed and precision (Scheme 7). This method proved to be remarkably efficient and quite general in scope.[20] It is certainly a prime candidate for the honor of "best reaction in the brevetoxin odyssey", for so crucial and effective was its role in the final outcome of the venture.

3.4. The Bis(oxepane) Problem

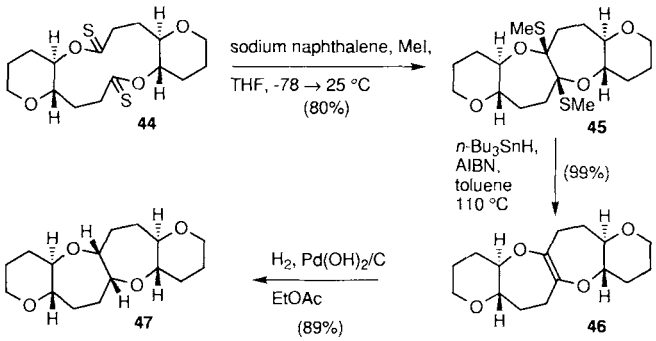
With powerful methods of constructing six- and eight-membered ether rings at our disposal, we turned our attention to the third and final problem, the annelated bis(oxepane) ring system of brevetoxin B. The hydroxyepoxide and the hydroxydithioketal methods appeared, based on model system studies, to be reasonably promising for this task, but the opportunity to develop yet another method for synthesizing medium-sized heterocycles was too tempting to pass. It was in this spirit and context that we postponed a final drive towards the target molecule in order to explore yet another important idea for the synthesis of bicyclic compounds. The concept of bridging macrocycles to form bicycles was thus born (Scheme 8).

Particularly appealing was the idea of utilizing the easily accessible macrodilactones as potential precursors, which would give bridged bicyclic systems through radical coupling reactions. Unfortunately, however, such couplings proved unsuccessful in forming the desired bicyclic systems under electron transfer conditions due to facile and rapid ring openings induced by the negative charge on the generated alkoxide species. In retrospect, this was not so surprising, considering the ring strain of the cyclic frameworks formed and the relatively low nucleophilicity of oxygen towards added trapping agents that



Scheme 8. The concept behind bridging macrocycles to give bicycles.

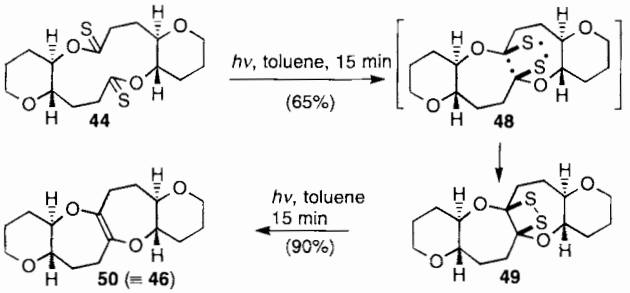
could have prevented such ruptures. In pondering over these difficulties, we immediately thought of replacing oxygen with sulfur as a more appropriate element. The relatively low reduction potential of the C=S group, the ability of sulfur to stabilize a negative charge, and its high nucleophilicity, coupled with the multitude of possibilities in sulfur chemistry for further chemical manipulations indicated that macrodi(thiolactones) like **36** should be ideal candidates for the conceptualized bridging reaction (Scheme 8). Convinced of the soundness of the new idea, Jack and Mark rushed to the laboratory to execute the designed sequences. It was not long before the first successful experimental results on the bridging of macrocycles to give bicycles were at hand (Scheme 9).[21] Realizing what a gold mine we had struck, we immediately took time to test the generality of the new reaction and explore the chemistry of the products (Scheme 9). Furthermore, a photo-induced version of this



Scheme 9. Bridging macrocycles to give bicycles: first successful experiments with macrodi(thiolactones).

bridging process was developed, which led to the first, exquisitely beautiful and crystalline 1,2-dithietane (Scheme 10).[22] So aesthetically pleasing were the crystals (Fig. 4) of this compound that I took them home to show my wife, Georgette, and my daughter, Colette, whose immediate reaction upon seeing them was: "They look like gemstones, like topaz. Can we make rings with them?" "No, they are too fragile," I explained, "But thanks for the idea." The first stable 1,2-dithietane became known as dithiatopazine.

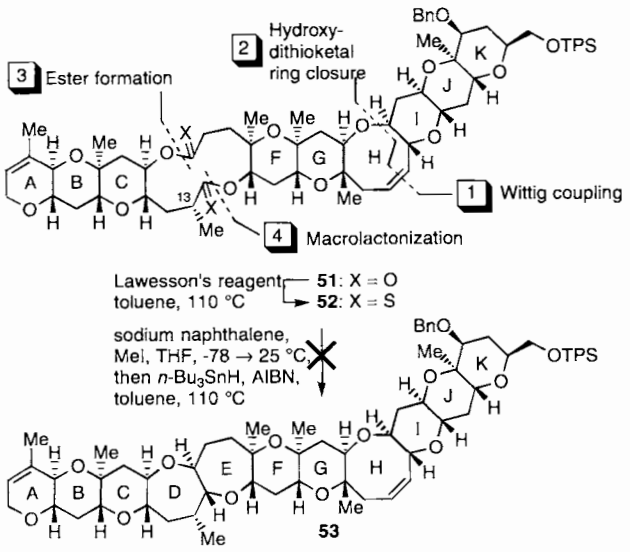
We shall return to further explorations of the di(thiolactone) bridging chemistry later, but first we will proceed to the applica-



Scheme 10. Photo-induced bridging of macrodi(thiolactones) via dithiatopazine **49**, the first stable 1,2-dithietane.

Fig. 4. Crystals of dithiatopazine **49**.

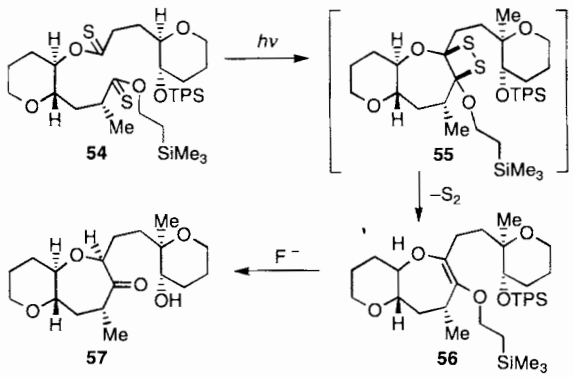
tion of this powerful reaction to the problem at hand, the construction of the entire skeleton of brevetoxin B (**1**). The newly discovered bridging reaction would be reserved for the final C–C bond formation to give the bis(oxepane) system (**52** → **53**, Scheme 11). The synthesis of the requisite precursor **51** proceeded smoothly and swiftly as summarized in Scheme 11. The tetrahydropyran-containing fragments were constructed through hydroxyepoxide ring closures and related chemistry and elaborated according to the sequence of steps [1] → [2] → [3] → [4] as indicated in structure **51** (Scheme 12). The euphoria generated by the speed and efficiency of the sequences leading to **51** was, however, soon to dwindle, as we shall see.



Scheme 11. When applied to the synthesis of brevetoxin, the bridging of macrodi(thiolactones) fails.

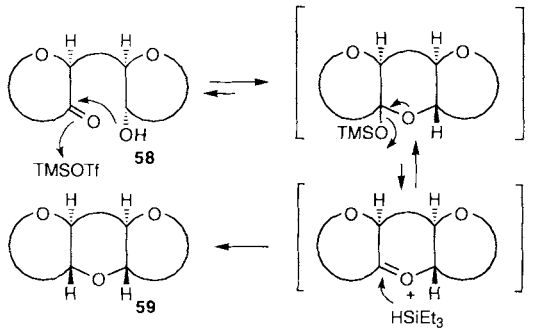
First, it was the miserably low-yielding conversion of the dilactone functionality into the corresponding di(thiolactone) system using Lawessons's reagent (**51** → **52**, Scheme 11) that brought the operations to a virtual halt.[23] Several other known Lawesson-type reagents also gave disappointing results, and no conditions could be found to increase the yield of this difficult step. Then the bridging reaction, attempted on the meager amounts of di(thiolactone) **52** obtained, proved equally problematic, leading to mixtures of products in low yields. In both instances, the steric hindrance of the C-13 methyl group adjacent to one of the reaction sites was to blame. That seemingly innocent methyl group, perfectly positioned to thwart our advance, was almost certainly responsible for this failure. Furthermore, we became convinced that, had that methyl group not been there, brevetoxin B (**1**) could have been reached in short order. But the methyl group was there, and we decided to face the challenge rather than opt for the easy way out, the synthesis of 13-norbrevetoxin B, that some suggested. We believed in the promise of new chemistry that such a challenge would bring. We were not disappointed for, as we shall see, much more adventure was ahead before we reached the real "Ithaca". For a start, a number of new Lawesson-type reagents were designed, synthesized, and tested in order to overcome the steric hindrance around the resisting carbonyl group.[24] Despite the novelty and effectiveness of these reagents in model systems, however, progress could not be made along this bridging pathway.

Having failed to construct the final C–C bond of the brevetoxin B framework by bridging the 12-membered macrocycle, we then opted for a stepwise construction of the two oxepane rings, a decision that we suspected would detract from the elegance of the synthesis. Again, instead of attempting to apply known reactions for this task, we proceeded to design new synthetic technology for the synthesis of oxepane systems. Scheme 12 summarizes a new route to oxepanes from

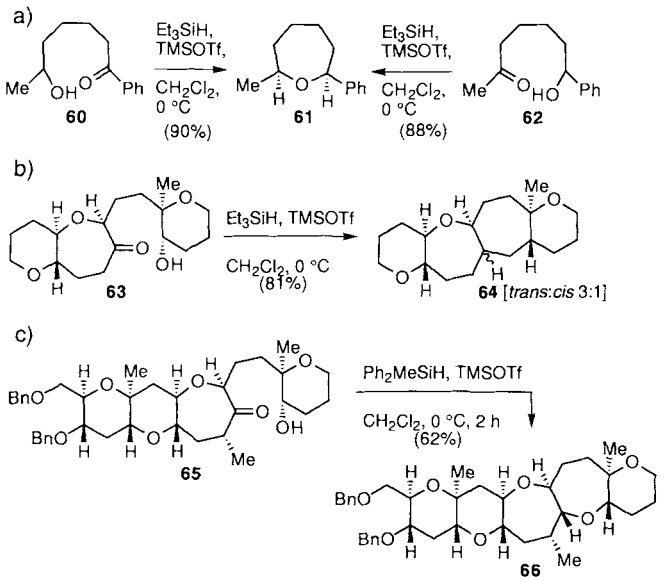


Scheme 12. Bridging of di(thioesters) for construction of oxepane systems.

di(thioesters) by photo-induced radical coupling followed by sulfur extrusion and selective enol hydrolysis.[23, 25] For our purpose, however, a second method for oxepane synthesis was needed, which would immediately follow the construction of the first oxepane ring. Such a strategy was tailor-made for the brevetoxin structure (Scheme 13) and quickly demonstrated in the laboratory with simple model systems (Scheme 14a).[23, 26] Although, the initially demonstrated method was successfully

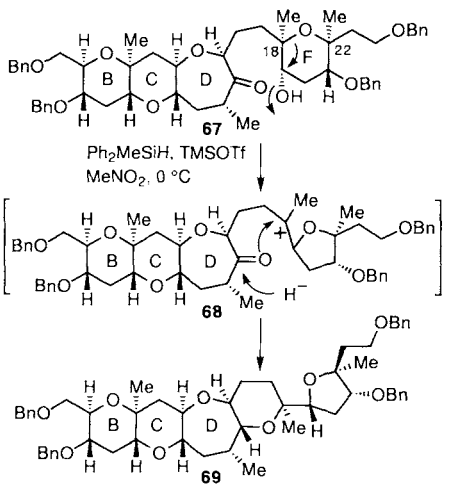


Scheme 13. General strategy for bis(oxepane) formation through TMSOTf-induced cyclization of hydroxyketones.



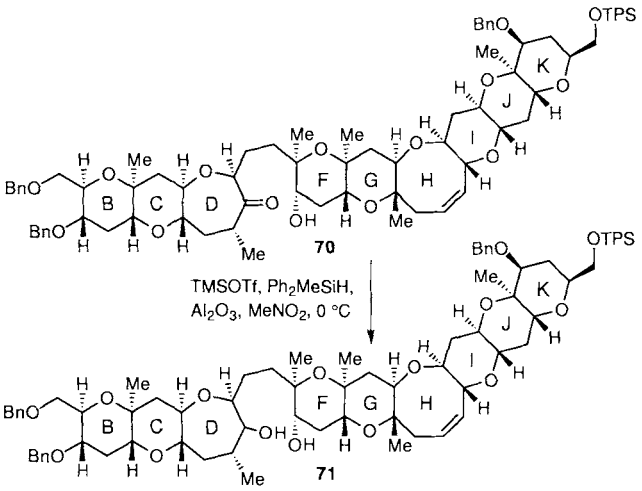
Scheme 14. TMSOTf-induced cyclizations of hydroxyketones for the construction of oxepanes and bis(oxepanes).

applied to a number of more complex systems (Schemes 14b and 14c), these efforts were again destined to fail as we approached the real system.[23, 26] The first bitter surprise came when we subjected the advanced hydroxyketone **67** (Scheme 15)



Scheme 15. Hydroxyketone cyclizations: applications to more advanced brevetoxin intermediates fail.

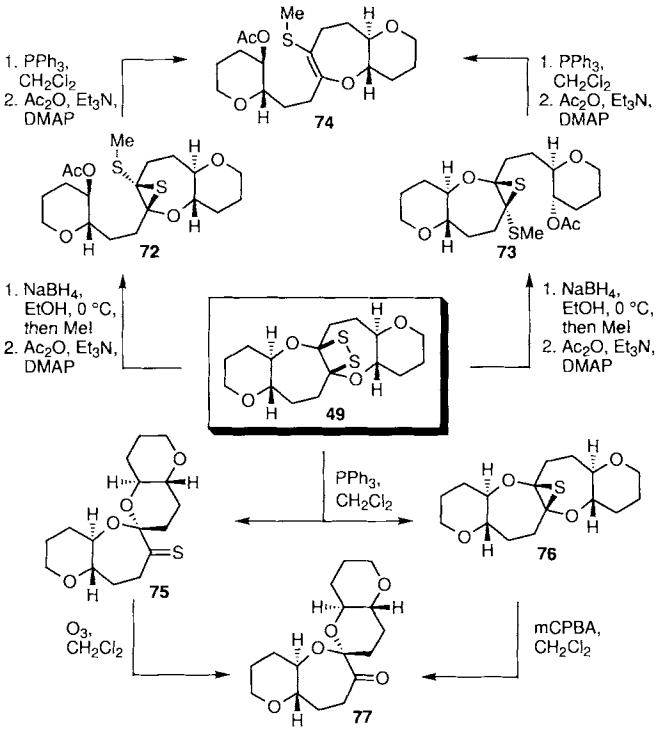
to the ring closure conditions. We did not obtain the expected bis(oxepane) system; we soon realized (and confirmed by X-ray crystallography) that a drastic rearrangement had accompanied the reductive ring closure of the carbonyl oxygen onto an incipient carbenium ion (Scheme 15).[23] Once again our problems could be traced to methyl groups, those at C-18 and C-22 (brevetoxin B (**1**) numbering) which, owing to steric repulsion (1,3-diaxial interactions), facilitate collapse of the six-membered ring to which they are attached, leading to a conveniently stabilized tertiary carbocation and, thence, to the observed reductive cyclization product **69** (Scheme 15). This was a novel



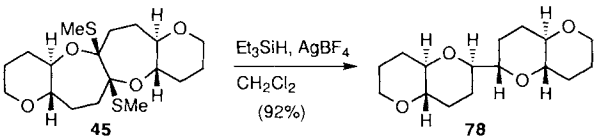
Scheme 16. Attempts to close the E-ring by reductive hydroxyketone cyclization fail.

ring contraction, but we had no use for it in our quest for brevetoxin B (**1**). A second, and more ambitious approach relying on the reductive hydroxyketone cyclization was designed and tested (Scheme 16).[23] Again, the skeleton of brevetoxin B, only one C–O bond away, eluded us; we were left with a dihydroxy by-product and pondered our misfortunes. Further explorations along these lines led to more frustrations, and the plan of constructing the bis(oxepane) system by this strategy was abandoned. The new chemistry was the only gleanings from the failed first and second approaches to the bis(oxepane) unit. In the long run, this was not a bad deal, of course, considering the wealth of chemistry that was discovered.

In the meantime, members of the group were devoting considerable time to exploring the novel chemistry of dithiatopazine **49** (Scheme 10) and devising new synthetic transformations that made use of the properties of the thiolactone functionality. It is instructive to briefly survey this chemistry here, for the exercise serves to focus attention on an important aspect of total synthesis: the exploitation of the opportunities encountered in such endeavors to discover, invent, and develop new chemistry. The reactions shown in Schemes 17–19 are representative of the wealth of designed and serendipitously discovered chemistry during this phase of the program. Thus, several novel and unexpected rearrangements and ring systems were encountered (Schemes 17 and 18),[22] and numerous new methods for the construction of cyclic ethers were developed (Scheme 19).[27, 28] Having collected this "merchandise and gems in foreign lands,"



Scheme 17. Novel chemistry of dithiatopazine **49**.

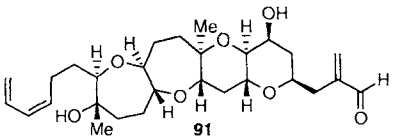


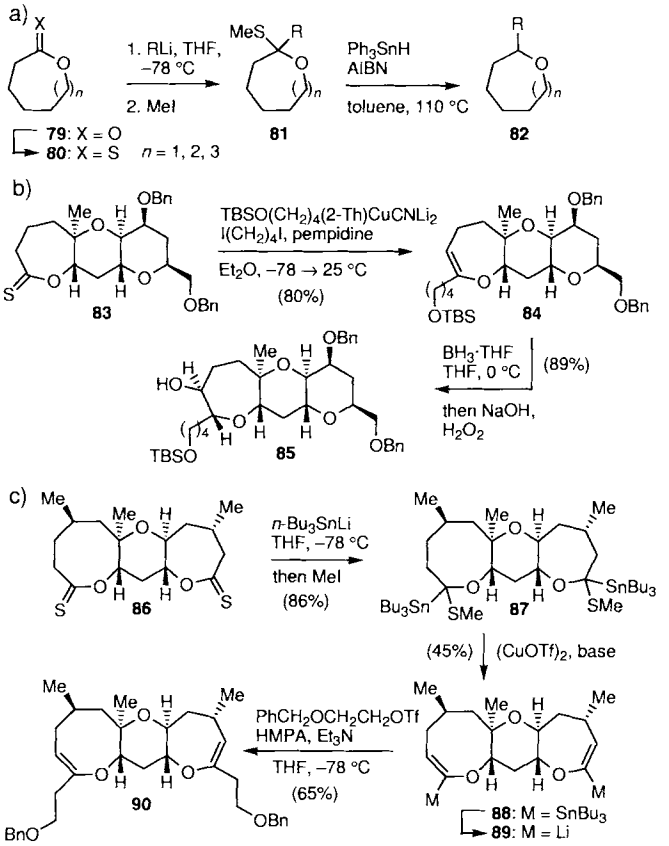
Scheme 18. Novel rearrangement of polycyclic ether frameworks, which could be useful for the synthesis of maitotoxin.

we were still not completely content, for back in our minds was still "Ithaca" and how to get there.

3.5. Moving to the West Coast and Planning a New Strategy

Our repeatedly thwarted attempts to construct the final bonds around the bis(oxepane) region of brevetoxin B left us scrambling for new ideas and led us to consider a less convergent approach towards the ABCDE framework. By now it was the middle of 1989 and the group was preparing to move from Philadelphia to La Jolla, where new laboratories were awaiting for us at The Scripps Research Institute and the University of California, San Diego. Our recent setbacks on the project, coupled with the move to California and the new exciting projects that were taking shape in the group, resulted in a brief lull in activity, and for a while no major assaults were launched on brevetoxin B (**1**). It was at about the same time that Shimizu et al. reported the structure of hemibrevetoxin B (**91**), a tetracyclic

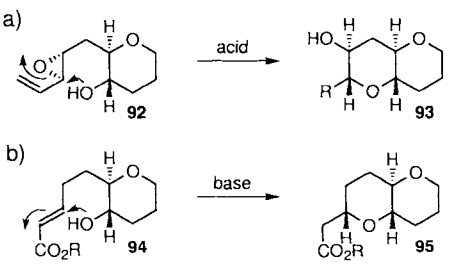




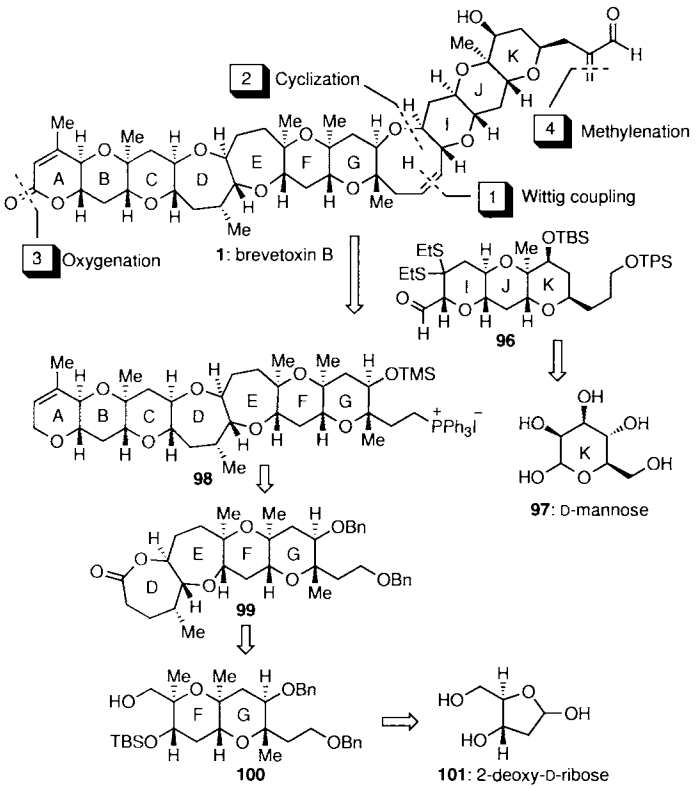
Scheme 19. Nucleophilic additions to thiolactones: a) synthesis of cyclic ethers; b) synthesis of medium-sized cyclic ethers (for application to the synthesis of hemibrevetoxin B (**91**) see ref. [30]); c) bidirectional synthesis of medium-sized cyclic ethers (for application to the synthesis of brevetoxin A see ref. [28]).

"little sister" of brevetoxin B (**1**).[29] With this considerably less complex target a new brevetoxin team was recuited and trained. By 1992 we had completed the first total synthesis of hemibrevetoxin B (**91**).[30] Most importantly, we had tested some new strategies, morale was high, and we were now poised for the final campaign towards the real prize, brevetoxin B (**1**).

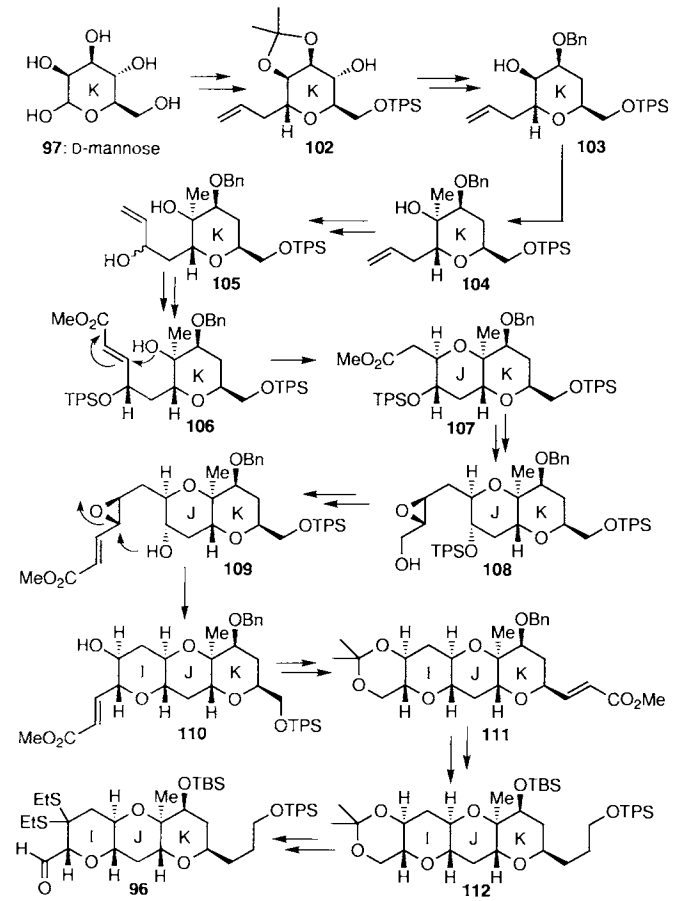
The new strategy for the total synthesis of brevetoxin B (**1**) was designed to take advantage of the regioselective and stereospecific reactions shown in Scheme 20[31, 32] to form the tetrahydropyran ring systems of the molecule and was based on the retrosynthetic analysis shown in Scheme 21. This convergent approach relied on the hydroxydithioketal cyclization as the "anchor" reaction to complete the brevetoxin B skeleton by forming the oxocene ring at the final stages of the sequence. The



Scheme 20. Crucial synthetic transformations for the regio- and stereospecific ring closure of the tetrahydropyran systems of brevetoxin B (**1**).



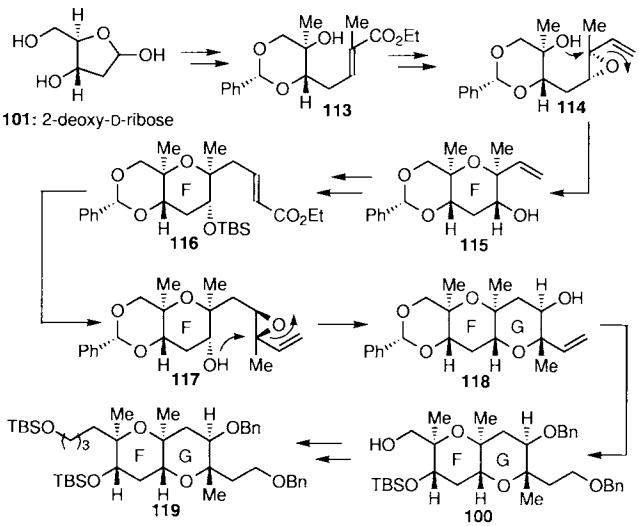
Scheme 21. A new approach: strategic bond disconnections and retrosynthetic analysis of brevetoxin B (**1**).



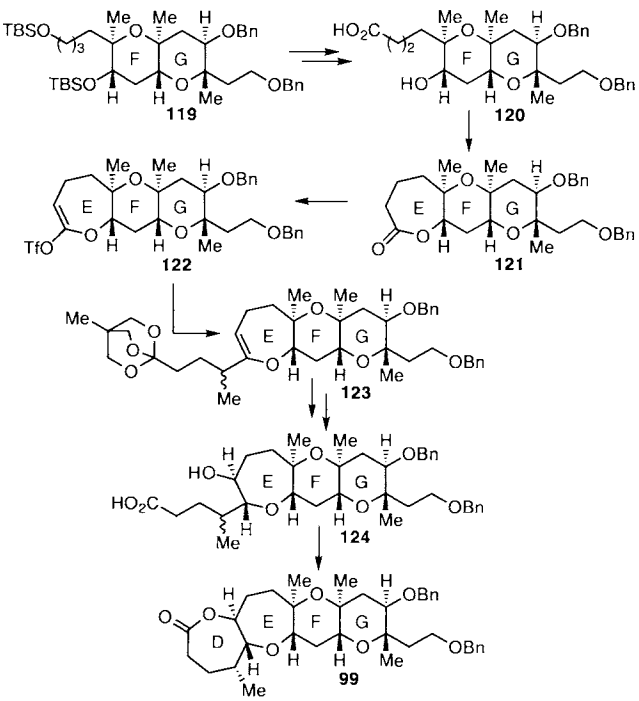
Scheme 22. Synthesis of the IJK framework from D-mannose.

aldehyde **96** (IJK segment) and the phosphonium salt **98** (ABCDEFG segment) were chosen as advanced intermediates. While the IJK framework **96** was to be derived from D-mannose (**97**), the more complex ABCDEFG ring system **98** was traced back to 2-deoxy-D-ribose (**101**) via key intermediates **99** (DEFG system) and **100** (FG system).

The construction of the IJK aldehyde **96** proceeded smoothly following the sequence K → JK → IJK as summarized in Scheme 22.[33] The synthesis of the DEFG lactone **99** also proceeded along a linear route according to which each ring was fused onto the previous one in the direction F → FG → EFG → DEFG (Schemes 23[34] and 24[35, 36]). Since our dreams of optimum convergency had been ruined, we deliberately chose these linear approaches; mundane as they may seem at first, they later proved their worth.

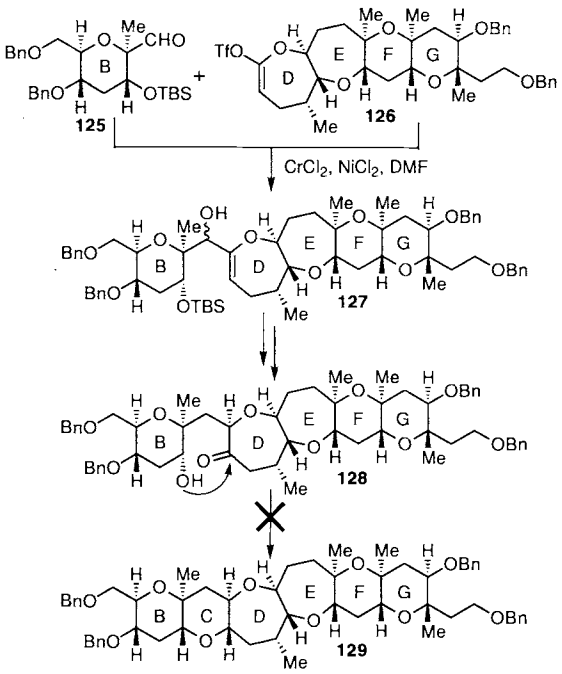


Scheme 23. Synthesis of the FG ring framework from 2-deoxy-D-ribose.



Scheme 24. Synthesis of the DEFG ring framework.

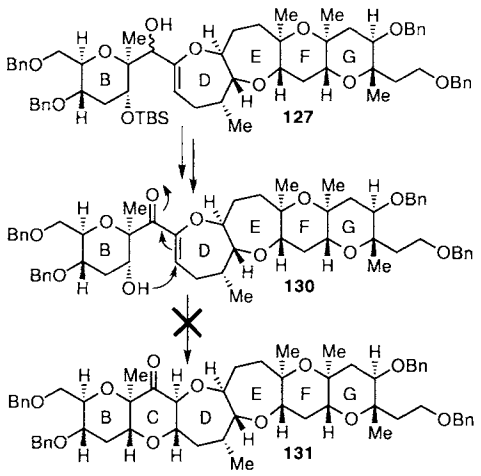
Despite the dividends of our stepwise approach, we were still intrigued by possible convergency in the synthesis, and once again we took a risk, namely, a shortcut for the installment of the next two rings resulting in the BCDEFG system. Thus, in our first approach towards this goal, ring B, as aldehyde **125**, was to be coupled to a suitable derivative of the DEFG ring system (Scheme 25) and the coupling product elaborated in



Scheme 25. Convergent approach to the BCDEFG fragment based on reductive hydroxyketone cyclization fails.

preparation for ring closure and construction of ring C. The first order of business was to find ways to effect the coupling of aldehyde **125** to lactone **99** (Scheme 24). A literature search revealed that enol triflates derived from ketones participate in Cr/Ni-induced couplings with aldehydes,[37] an encouraging finding for our intentions. Extending this coupling reaction to include trifluoromethylsulfonyl ketene acetals derived from lactones was a reasonable proposition. Postdoctoral fellow Emmanuel Theodorakis was the first to demonstrate this reaction using the aldehyde and triflate partners shown in Scheme 25.[35, 36] Later this reaction proved to be crucial for the success of the project, and it is sure to find widespread applications in other areas of synthesis.

Having secured the requisite coupling product **127** (Scheme 25), we then proceeded to implement the rest of the plan towards closing ring C. The first option called for deoxygenation of the newly generated hydroxyl group followed by reductive cyclization of the hydroxyketone **128**, which was arrived at by hydroboration, oxidation, and desilylation. For reasons still unknown, this ring closure could not be effected under a variety of conditions, leading us to abandon it as part of the sequence. The second strategy (Scheme 26) began with oxidation of the newly generated hydroxyl group in **127**, followed by intramolecular attack of the liberated secondary alcohol onto the formed enone (**130**) through a Michael-type reaction (see also Scheme 5b). Again this approach met with stubborn resistance at the closure of ring C. The molecule would not give in

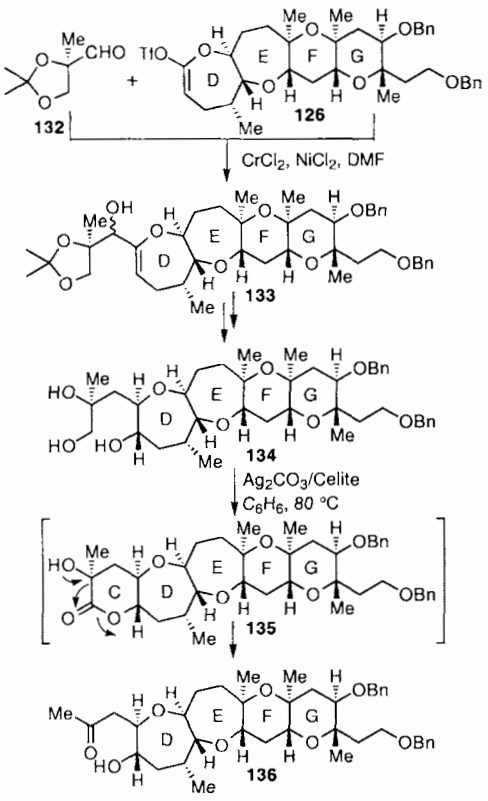


Scheme 26. Convergent approach to the BCDEFG fragment based on intramolecular conjugate addition fails.

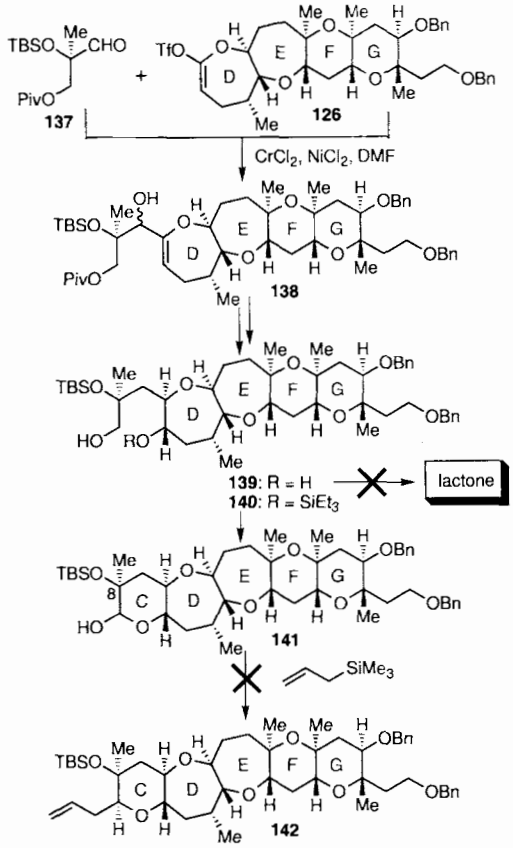
to convergency! This was the last stroke, and we decided once and for all to abandon our dreams of convergence for the construction of this region of brevetoxin B. Nature had sent us enough messages and we learned the hard way that linearity has its place in total synthesis after all! From this point on there would be no more risky shortcuts, and we proceeded with the idea of one ring fusion at a time. The distinction of convergency would be reserved for the construction of the oxocene ring.

In the meantime, a courageous member of the team, postdoctoral fellow Jörg Tiebes, supported by his teammates (and behind my back!) started work on a shorter version of brevetoxin B, which we later called "truncated brevetoxin B" (AFGHIJK) **148** (Scheme 30). Lacking the trouble-causing BCDE ring system, this molecule was an easier target. The rationale behind this excursion was twofold. First we would have the opportunity to explore the final stages of the projected total synthesis, particularly the construction of the oxocene ring, and the completion of the two ends. Second, a paper just published by the groups of Baden and Gawley[38] proposed an interesting hypothesis regarding an essential length for the "cigar-shaped" brevetoxins in order for them to bind to their receptors. The designed truncated brevetoxin B **148** seemed just the right molecule to test this hypothesis. I also suspected an attempt for a "quick strike" by Jörg, whose time on the project was running out. Pressed by impending job interviews in Germany, he may have wished for a nice publication and at least partial success before leaving California. Be that as it may, I did not object to the operation and work intensified on the truncated compound in parallel to the latest, totally linear strategy towards the ABCDEFG segment of the real target, brevetoxin B (**1**). We shall first follow the path leading to the original target.

The plans now called for fusing ring C onto ring D of the DEFG lactone fragment. In the first step the newly developed Cr/Ni-coupling process mentioned previously was proposed to attach the required side chain, and then appropriate manipulations would effect ring closure. Scheme 27 outlines one of our early attempts to build the polycyclic framework CDEFG following this general approach. Thus, coupling of acetonide aldehyde **132** with lactone-derived enol triflate **126**, followed by a standard deoxygenation and deprotection protocol led to the triol **134**, which was projected as a substrate for a Fetizon oxida-



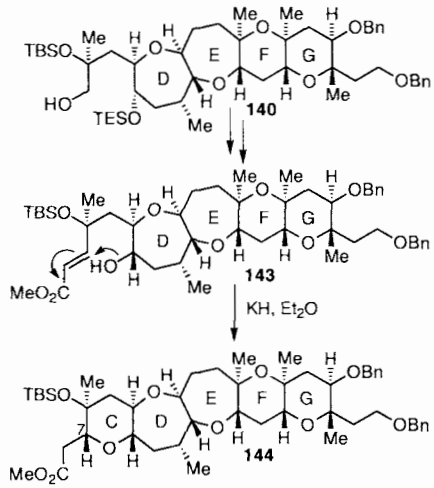
Scheme 27. Attempts to fuse a functionalized C-ring onto the DEFG ring system leads to unexpected decarbonylation.



Scheme 28. Attempts to functionalize C-ring of **141** fail.

tion to afford the corresponding α-hydroxy-δ-lactone **135** (Scheme 27). However, despite much precedent from other laboratories,[39] the Fetizon reaction did not furnish the desired product. Rather, it surprised us with the unexpected formation of methyl ketone **136** (Scheme 27) as the sole product. This rather bizarre outcome could be explained by the mechanism proposed in Scheme 27, which involves spontaneous loss of carbon monoxide from the postulated hydroxylactone intermediate **135**. The logical solution to this problem was to protect the tertiary alcohol in order to prevent the collapse of the intermediate hydroxylactone **135**. This scheme required the utilization of the differentially protected aldehyde **137** in the coupling reaction with enol triflate **126** (Scheme 28). The new sequence proceeded according to plan until we encountered a different obstacle: the Fetizon oxidation of diol **139** did not lead to lactone formation, presumably due to steric hindrance of the bulky neighboring groups. We then tried a stepwise approach to the lactol via the silyl ether **140**. But again, attempts to attach an allyl chain at the anomeric center of lactol **141** did not prove fruitful (Scheme 28). We were pretty convinced that this latest series of defeats could once more be ascribed to a simple methyl group, this time the one situated at C-8 (brevetoxin B numbering). We now know that these methyl groups are the fiercest defenders of fortress brevetoxin B (**1**)!

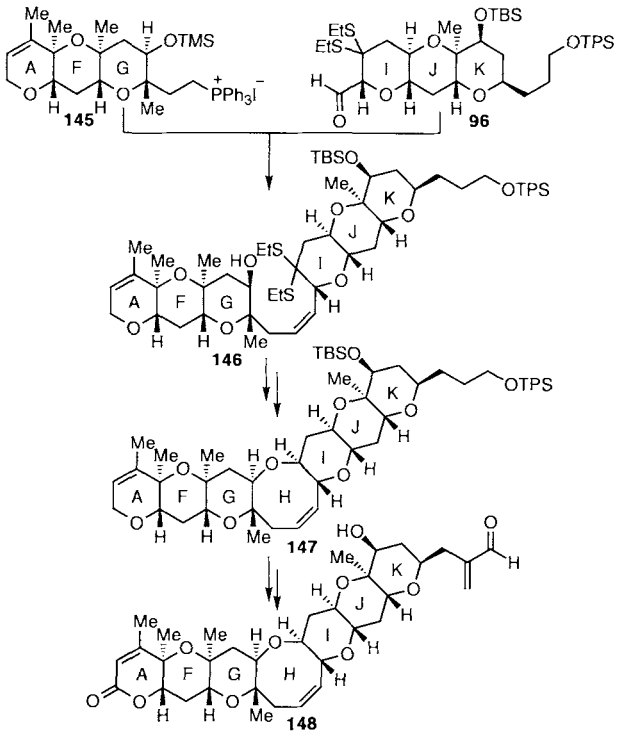
Armed with another idea (Scheme 29), postdoctoral fellow Floris Rutjes was back in the front line attempting to overcome what seemed to be one of the last barriers to the total synthesis. According to this latest strategy towards the ABCDEFG ring system, an α,β-unsaturated ester at the end of the side chain on ring D of the DEFG compound was to serve as a Michael acceptor for the hydroxyl group attached to the adjacent oxepane system (Scheme 29). On June 2, 1994, this objective was achieved with complete stereoselectivity and in high yield! At that point we knew that the most stubbornly resistant region of brevetoxin B, the CDEFG framework, was captured. Yet we were still uncertain about the configuration of the newly formed stereogenic center at C-7 in **144**. Our fears were soon dispelled, however, when X-ray crystallographic analysis of a later intermediate revealed the proper configuration of all stereocenters, including the C-7. In the meantime, further good news was coming in from Jörg Tiebe's campaign directed at the truncated



Scheme 29. June 2, 1994. Ring closure of the completely functionalized C-ring by intramolecular conjugate additions yields the long-sought CDEFG ring framework.

brevetoxin B **148**. Let us then now return to that campaign and see how the goal was reached and what we learned.

Scheme 30 summarizes the synthesis of truncated brevetoxin B **148** (AFGHIJK), which proceeded amazingly well and beyond our wildest expectations.[33] Considering the many torturous setbacks we experienced on our main front, this smooth



Scheme 30. May 10, 1994. Total synthesis of truncated brevetoxin B **148**. This model study furnished essential information about the final stages of the total synthesis of brevetoxin B (**1**).

sequence was certainly refreshing and helped us to establish an important beachhead for the conquest. This was perhaps the greatest testament to the effectiveness by which the "bis(oxepane) phalanx" and its adjacent rings and methyl groups defended the fortress for so long. The synthesis of truncated brevetoxin B **148**, completed on May 10, 1994, was highly valuable, because we then knew how the final triumphant march to brevetoxin B would proceed. We now could almost see brevetoxin B (**1**) far away on the horizon. To quote from Homer's Odyssey (Book I, v. 281):[1] "*... it looked like a shield lying on the misty face of the water.*"

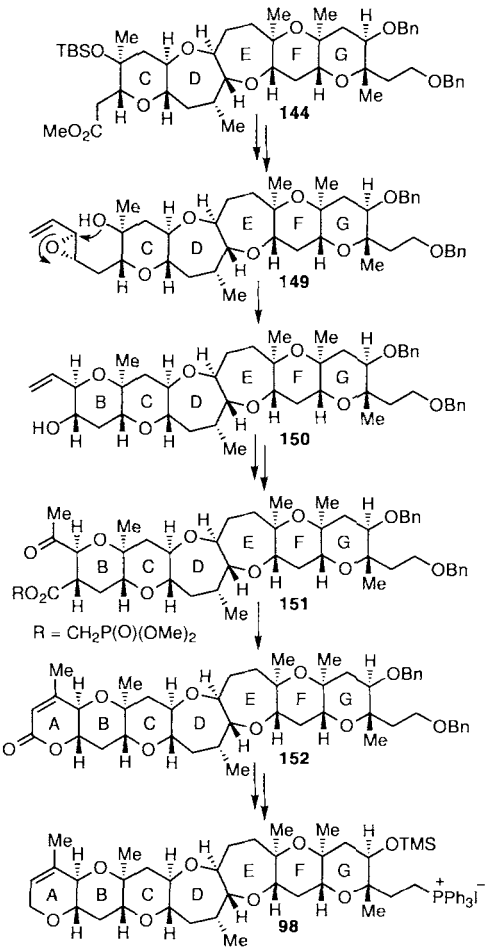
3.6. The Final Stage

At the beginning of the summer of 1994 the final brevetoxin B team, consisting of Emmanuel A. Theodorakis (Greece), Floris P. J. T. Rutjes (Netherlands), Jörg Tiebes (Germany), Edouard Untersteller (France), and Mitsunobu Sato (Japan), was poised for the final assault on brevetoxin B (**1**) and the "homecoming to Ithaca". Projections were made that by the end of August 1994 we would reach our destination and submit the papers for publication early in September. I was convinced that these five men would carry out their mission as planned, for by then I was well aware of their talents and commitment. As it happened, however, one more August would come and go before we would arrive at "Ithaca". In my calculations, I had neglected a small detail, a detail that became an important factor, and one that "Poseidon" would exploit at our expense and inflict one more delay before the final success...

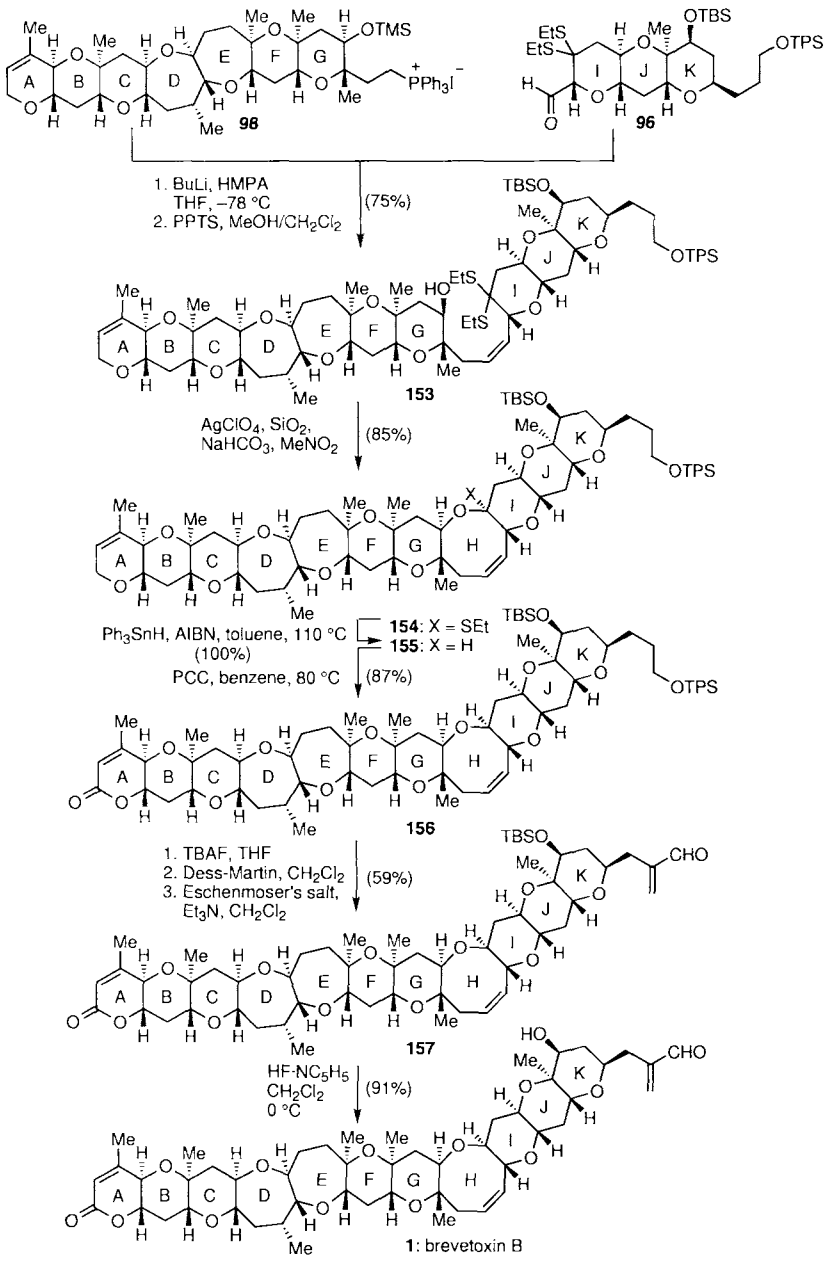
> "*It is the earth encircler Poseidon who, ever relentless, nurses a grudge because of the Cyclops, whose eye he blinded; ... For his sake Poseidon, shaker of the earth, although he does not kill Odysseus, yet drives him back from the land of his fathers.*"
> Book V, v. 68, 69, and 74, 75[1]

During the summer of 1994, when the final campaign towards brevetoxin B was taking place, the World Cup in Soccer was hosted in the U. S., and all the members of the brevetoxin B team were either European or Japanese! Placing such soccer fanatics on the team for this highly demanding operation was rather unfortunate. Well, you can never think of everything in total synthesis! Brevetoxin B (**1**) could not, however, escape for much longer, and before the end of the fall in that year it was destined to yield to the enthusiasm and pressure of these relentless professionals. Needless to say, this victory was to serve well as a consolation to each one of them for their countries' not winning the World Cup!

The completion of the synthesis of the ABCDEFG ring framework as the phosphonium salt **98**, proceeded smoothly and swiftly (Scheme 31). An X-ray crystallographic analysis on



Scheme 31. Linearity and fusion of the ABCDEFG ring system.



Scheme 32. Convergency and final stages of the total synthesis.

the iodide precursor of **98** confirmed its structure. Scheme 32 details the final stages of the total synthesis of brevetoxin B (**1**). As anticipated, both the coupling of the two segments and the oxocene formation proceeded extremely well, leading to compound **155**. We celebrated the long-sought victory of completing the skeleton of brevetoxin B! Before euphoria overwhelmed the group, on October 1, 1994, a day-by-day schedule was drawn on the wall between the fumehoods of Floris and Emmanuel, where the front work was being carried out. This timetable was to end on October 20, 1994, the day I was scheduled to fly from Copenhagen, Denmark, to Athens, Greece.

My trip to Europe took me to Lünd on the southern tip of Sweden, where Professors Salo Gronowitz and Torbjörn Frejd met me at the airport with the bad news that on their way they had hit a "kronjort" (red deer), which caused considerable harm to both the animal and the car. The deer was "sacrificed" later that evening by the authorities, and, for the next two days I was driven by Torbjörn in a hardly functioning car, a fortuitous experience I must admit, and one that I enjoyed very much, since it gave me the chance to spend more time inside the car than outside, where it was bitterly cold! After an exceedingly pleasant visit, which included two exquisite meals on venison, I crossed the Öresund channel to Copenhagen on the morning of October 20th and boarded a flight to Athens. There, I was met at the airport by Elias Couladouros and Demetris Papahatjis, two of my former students, who now teach and do research in Athens. They immediately took me to "Dionysos," a cafe below the Akropolis, for an afternoon drink. From there I could see the Parthenon, the temple of Athene, standing majestically and radiating serene contentment and wisdom through its beautiful architecture. Perhaps she, Athene, had a secret victorious message for me—at least so I wished!

Comfortable, but anxious, back at the Hilton Hotel later on that evening, I received, a fax from my students just before midnight with the news of the completed total synthesis of brevetoxin B (**1**), accompanied by the first ^{1}H NMR spectrum of the synthetic brevetoxin B. (A sample of the authentic, natural material from Dan Baden and Bob Gawley would arrive the following week.) It was a great moment for me and certainly for my students, and my first reaction was to thank God in a heartfelt silent prayer for helping us reach our target. Since my departure from California on October 15, I had intentionally not communicated with the brevetoxin team. The tension was simply too high, and besides, I suspected that they would do better without my interference—and they did!

Poseidon, however, would have the last word! As if to take vengeance one last time, the ruler of the sea unleashed a major storm the next day, and Athens suffered the worst floods in forty years!

Figure 5 shows the ^{1}H and ^{13}C NMR spectra of synthetic and natural samples of brevetoxin B (**1**), Figure 6 presents some of the beautiful crystals of synthetic brevetoxin B, and Figure 7 depicts results of the X-ray crystallographic analysis (ORTEP representation). There is little need to attempt to describe the thrill, contentment, and happiness we had at the moment of final success. Figure 8 tells it all! Particularly pleasing for me was the fact that I was able to provide these students and postdoctoral fellows, and those before them, the opportunity to be independent, to learn, create, imagine, and succeed; and all those things they accomplished and more! My pride in them cannot be described in words, but will always remain a precious part of my reward as a teacher.

4. Epilogue

It is hoped that with its light style this article has made abundantly clear, and in an enjoyable way, the many findings along the way to brevetoxin B (**1**) and their potential value to future basic and applied research.[40] Lest there are skeptics remaining, here is an appropriate and beautiful poem to help us understand what it was and should be all about. The modern Greek poet C. P. Cavafy points out in his poem "Ithaca" that it is not the destination that finally matters the most, but rather what one observes, discovers, and accumulates on the way.[41]

Ithaca

When you start on your journey to Ithaca,
Then pray that the road is long,
Full of adventure, full of knowledge,
Do not fear the Lestrygonians
And the Cyclopes and the angry Poseidon.
You will never meet such as these on your path,
If your thoughts remain lofty, if a fine
Emotion touches your body and your spirit.
You will never meet the Lestrygonians,
The Cyclopes and the fierce Poseidon,
If you do not carry them within your soul,
If your soul does not raise them up before you.

Then pray the road is long.
That the summer mornings are many,
That you will enter ports seen for the first time
With such pleasure, with such joy!
Stop at Phoenician markets,
And purchase fine merchandise,
Mother-of-pearl and corals, amber and ebony,
And pleasurable perfumes of all kinds,
Buy as many pleasurable perfumes as you can;
Visit host of Egyptian cities,
To learn and learn from those who have knowledge.
Always keep Ithaca fixed in your mind.
To arrive there is your ultimate goal.
But do not hurry the voyage at all.
It is better to let it last for long years;
And even to anchor at the isle when you are old,
Rich withal that you have gained on the way,
Not expecting that Ithaca will offer you riches.

Ithaca has given you the beautiful voyage.

Without her you would never have taken the road.
But she has nothing more to give you.

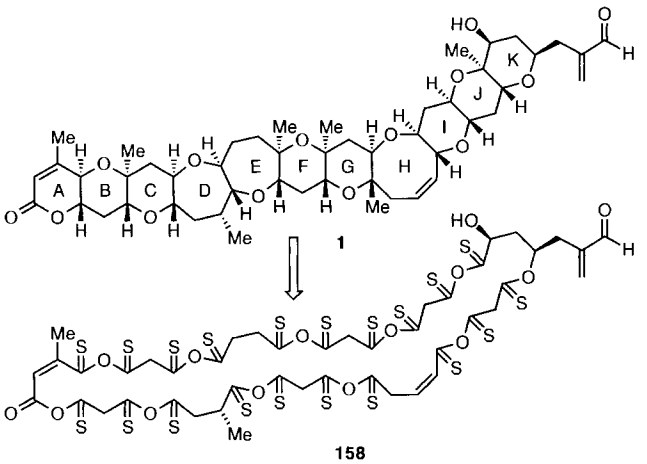
And if you find her poor, Ithaca has not defrauded you.
With the Great Wisdom you have gained,
with so much experience,
You must surely have understood by then what Ithacas mean.

C. P. Cavafy

The great British novelist Robert Lewis Stephenson said it much more succinctly: "It is better to travel in hope than to arrive." There is no denying that exercises such as the one described, as torturous as they are, provide invaluable opportunities for strengthening the mind, skills, and character. This story, like the personal accounts written earlier on the total syntheses of calicheamicin[42] and taxol,[43] describes the strategies, exhilarations, frustrations, and behind-the-scenes maneuvers often encountered in the total synthesis of complex molecules, and are meant to be light, entertaining, and educational to both practitioners and students of the art.

It is perhaps appropriate to conclude this article with some thoughts regarding the state of the art of total synthesis today. The polycyclization of polyepoxides following a zip-type mech-

anism (Scheme 1) proposed in 1982, intriguing as it might be, is still a far-off dream for synthetic chemists. Another, distant dream is the "magical zipping" approach to brevetoxin B involving a poly(thioxooxamacrocycle) such as **158** shown in Scheme 33, an idea that arose from the bridging reactions dis-



Scheme 33. A "magical zipping" approach to brevetoxin B (**1**).

covered during this campaign. Developing new synthetic methods for such transformations is the challenge of tomorrow, while elucidating the mechanism by which nature makes this compound remains another exciting odyssey. Finally, the merging of the chemistry and biology of natural products such as the brevetoxins through chemical synthesis is also destined to provide further fuel for the field of total synthesis.

I am deeply indebted to my talented collaborators, all of whom worked on the brevetoxin B project with the outmost enthusiasm, dedication, and persistence (listed alphabetically): Y. Abe, R. A. Awartani, K. Bal Reddy, T. Bleckman, E. A. Couladouros, S. A. DeFrees, M. E. Duggan, H.-M. He, C.-K. Hwang, D. A. Nugiel, D. R. Reddy, F. P. J. T. Rutjes, F. Sato, M. Sato, J. Shin, E. A. Theodorakis, J. Tiebes, E. Untersteller, X.-Y. Xiao, and Z. Yang. I am also grateful to Dee H. Huang, Gary Siuzdak, and Raj Chadha from The Scripps Research Institute, and George Furst, John Dykins, and Pat Carroll from the University of Pennsylvania for their superb and invaluable assistance with NMR (D. H. H. and G. F.), mass spectroscopy (G. S. and J. D.), and X-ray crystallography (R. C. and P. C.). I am particularly grateful to Emmanuel Theodorakis and Floris Rutjes for their assistance in the preparation of this article. This research was carried out at the University of Pennsylvania, The Scripps Research Institute, and the University of California, San Diego, and was supported financially by The National Institutes of Health, the University of Pennsylvania, The Scripps Research Institute, the University of California, San Diego, the ALSAM Foundation (USA), Dainippon Pharmaceutical Co., Ltd. (Japan), Glaxo (USA), Hoffmann La Roche (USA), Merck Sharp & Dohme (USA), Pfizer (USA), Rhone-Poulenc Rorer (USA), Schering Plough (USA), and Smith Kline Beecham (USA), and through fellowships by Rhone-Poulenc Rorer (C.-K. H.), the Netherlands Organization for Scientific Research (NWO) (F. P. J. T. R.), the Deutsche Forschungsgemeinschaft (J. T.), the Agricultural University of Athens (E. A. C.), Unitika, Ltd. (M. S.), and Rhone-Poulenc Rorer, S. A. (E. U.).

[1] *The Odyssey of Homer*, translated by R. Lattimore, Harper Perenial, New York, **1975**. Homer's *Odyssey*, one of the western world's first two poems (the *Iliad* is the other), is the tale of the adventures, wanderings, and exploits of Odysseus, a Greek hero of the Trojan war, as he attempts to reach Ithaca, his home island where his wife Penelope awaits him. During his journey Odysseus has an incredible series of adventures and setbacks caused by the anger of the god Poseidon, whose son Odysseus had blinded. Finally, assisted by his patroness, the goddess Athene, Odysseus returns home to Ithaca to find and punish the suitors, evil men who tried to win his wife's hand and who squandered his wealth and corrupted his servants while he was away. Telemachus, Odysseus' son, who had his own share of adventures while growing up, facing the suitors and, looking for his father, joins him in glory and wisdom as they reestablish their throne on Ithaca. Besides Odysseus, other main characters of *Odyssey* are as follows:
Telemachus: The son of Odysseus, who is just entering manhood, is highly conscious of his duties as a prince successor to the throne and protector of his mother as well as the need to live up to his father's reputation as a hero. His actions waver between the immature and the well-thought over as he searches for the truth about his father and desperately appeals to others for help. It is not until towards the end of the story that he exhibits great courage, skills, and confidence and one feels that he is, indeed, the son of Odysseus.
Athene: She is the daughter of Zeus, goddess of wisdom, and patroness of arts and crafts. Odysseus is her favorite and protegé and she is his heroine, even though she is a goddess. She plays a leading role in all important events in the narrative, and her spirit and power always influence and assist Odysseus and Telemachus in their difficult moments. A friend and a confidant to Odysseus, she enjoys winning him over and her relationship with him, while the hero adores her and finds special comfort, companionship, and understanding in her.
Poseidon: Younger brother to Zeus, god of the sea and of earthquakes, father of Polyphenus the one-eyed Cyclops whom Odysseus blinds. As a ruler of the sea and natural phenomena, Poseidon is able to place many obstacles in front of Odysseus, whom he despises. Poseidon, however, is unable to hold out against the combined pressure of the other gods, particularly Athene, of whom Odysseus is a favorite, and so eventually relents, but not before he repeatedly unleashes his anger.
The Cyclops, Scylla, and The Sirens: Some of the superhuman and monstrous characters of the tale who inflicted tremendous tortures and blows at Odysseus and his men, before he finally overcame them.
The Suitors: The evil noblemen of Ithaca who attempt to undermine Odysseus, win the hand of his queen, Penelope, and corrupt his palace servants. They succeed partly, wasting away a great deal of Odysseus fortune, but he eventually prevails and punishes them.
Ithaca: The island kingdom of Odysseus, most likely located somewhere off the western coast of Greece and the destination of the hero in this adventure. It is interesting to compare places, events, and characters from the Odyssey to those of modern-day total synthesis, an excercise left to the imagination of the reader!

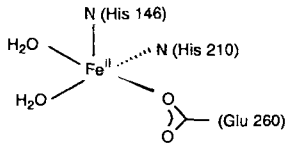
Oxygen Activation by Mononuclear Non-Heme Iron Proteins**

Alexandre L. Nivorozhkin and Jean-Jacques Girerd*

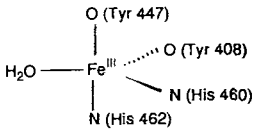
Mono- and dinuclear non-heme iron centers are frequently present in the active centers of enzymes that catalyze oxidations.[1] However, in the past more effort has been focused on enzymes with dinuclear than those with mononuclear iron centers—at the last International Conference on Bioinorganic Chemistry (ICBIC-7) last year in Lübeck, 26 contributions were devoted to dinuclear iron proteins and only 13 to the mononuclear ones. Nevertheless, interest in mononuclear iron enzymes is rapidly growing in biology and chemistry.[2] The amazingly diverse functional properties of the mononuclear iron enzymes from lipid oxidation (lipid dioxygenases, LO) through oxidations of arenes (arene dioxygenases, catechol dioxygenases, pteridine-dependent enzymes) to the synthesis of isopenicillin (isopenicillin N synthase, IPNS) and oxidation of nonactivated C–H bonds (α-keto acid dependent enzymes) undoubtedly make this a worthwhile field of research from which both industry and medicine can apparently benefit. An important topic of research in this field is bleomycin (BLM), a naturally occurring iron-containing glycopeptide, which like cisplatin is successful as an anti-cancer drug.

Studies on the sequence-specific oxidative cleavage of DNA by BLM[3] and the investigation of synthetic model complexes were particulary instructive for understanding the key features of the oxygen activation steps and of the mechanism of the catalytic oxidation by activated mononuclear iron complexes. The latest results[4] leave no doubts that the formation of the spectroscopically detected BLM transient mononuclear peroxo species, "activated BLM", is one of the primary steps of the oxygen activation. The debates on the reactivity mechanism are still continuing. The involvement of the radical species OH· can probably be excluded, but ferryl species are frequently discussed even though they have never been detected spectroscopically. One of the most impressive results obtained by using BLM mimics[4a] is that the DNA cleavage pathway is essentially determined by the metal-binding domain; metal complexes without a polypeptide tail with specific dithiazole terminus, which is believed to be decisive for binding to DNA, display a very similar cleavage pattern to that of BLM. This fact may have important consequences for finding other distinct simple synthetic iron complexes with an activity which could rival that of BLM.[5a] Iron complexes with aminopyridine ligands[5b,c] have been reported to display a DNA cleavage activity only ten times lower than that of BLM.[5b] Studies on these and other aminopyridine iron complexes as well as on bipyridine iron complexes[5d–g] provide reliable spectroscopic evidence for the occurrence of the Fe^{III}-peroxo transient species with characteristics similar to those of "activated BLM".

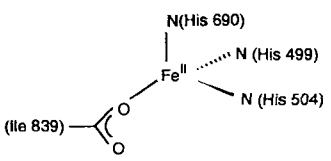
Knowledge of the atomic structure of the active site is one of the key requirements for elucidating an enzymatic reaction mechanism. Recently achieved milestones are the crystal structure analyses of several important mononuclear non-heme iron proteins: extradiol dioxygenase, IPNS, and lipid dioxygenase.



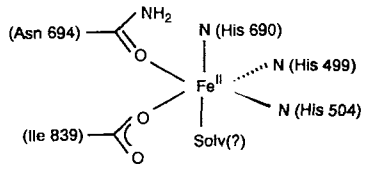
2,3-dihydroxybiphenyl 1,2-dioxygenase



intradiol dioxygenase

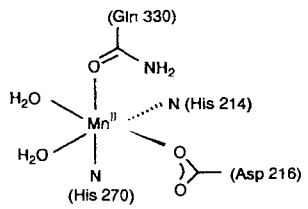


(Amzel et al.)



(Axelrod et al.)

soybean lipoxygenase L-1



isopenicillin N synthase

The lipid oxidation catalyzed by lipoxygenase (oxygenation of a *cis,cis*-1,4-diene to a conjugated 1-hydroperoxodiene) appears chemically to be one of the most simple transformations. The structure of the enzyme active site reported by Amzel et al.[6a] at the 2.5 Å resolution contains a Fe^{II} center (bound to three histidine nitrogens and a monodentate terminal carboxylate) in a distorted tetrahedral geometry similar to that found for the iron superoxide dismutase. This finding is contrary to all previous spectroscopic results, which indicated an octahedral geometry. The authors confidently excluded other ligating groups such as water or hydroxide ions, and envisaged an essential role for an Asn residue close to the iron center in stabilizing a probable iron–peroxo intermediate. Nevertheless, an X-ray structure analysis of an isomeric form of the same enzyme published by Axelrod et al.[6b] reveals the presence of a five-coordinate iron center with a monodentate-bound asparagine residue. This has been confirmed by a recent spectroscopic study.[6c] The first step of the lipid oxidation is the generation of a carbon-centered radical, which is subsequently attacked by oxygen to form a 1-OOH species. Regio- and stereoselectivity of this process indicates an absence of hydroxy radicals in the course of the oxidation. Experiments with substrates in anaerobic conditions revealed that the ferric form of the enzyme is responsible for the primary hydrogen abstraction step. Characteristic changes in the UV/Vis spectrum indicate the formation of the iron–peroxo intermediates in presence of oxygen and substrate. Based on this observation, Nelson et al. recently proposed a novel reaction mechanism for LO.[7a] Mascharak et al.[7b] have described model iron complexes that show activity similar to that of BLM and form unambiguously detected iron–peroxo species; these complexes react with linoleic and arachidonic acid in the presence of O_2 or H_2O_2 to afford very efficiently 1-OOH products with good stereoselectivity.

IPNS catalyzes a fairly sophisticated reaction in penicillin biosynthesis—transformation of the linear tripeptide (δ-(L-α-aminoadipoyl)-L-cysteinyl-D-valine) (ACV) into isopenicillin N. Unlike other non-heme oxidases, IPNS does not require electron donors or oxidized cofactors. The X-ray structure analysis of a Mn^{II}-substituted IPNS reveals[8] a metal center in an octahedral environment with two histidine nitrogens, one monodentate carboxylate, one O-bound amido group, and two water molecules. This structure is in good agreement with spectroscopic data; thus, almost no revision of the proposed multistep reaction mechanism, which was based mainly on experiments with substrate analogs and isotopic labeling, is required. The development of biomimetic model complexes to clarify the enzyme–substrate interaction modes and to verify the occurrence of a transient ferryl species should now be the aims of bioinorganic chemists.

The features of the active site of 2,3-dihydroxybiphenyl 1,2-dioxygenase,[9a] an extradiol dioxygenase, which along with intradiol dioxygenase controls two metabolic pathways of catechol degradation, were also successfully predicted by spectroscopy, as a subsequent X-ray analysis has shown. Consistent with spectral data by Solomon, Lipscomb et al.,[9b,c] the enzyme contains a square-pyramidal Fe^{II} center bound to two histidine nitrogen atoms, a terminal monodentate carboxylate, and two water molecules that are probably exchanged for a chelated substrate in the catalytic cycle. A distinct feature of extradiol dioxygenase is that the oxidation state of the iron center is conserved for all the reaction steps. Very few mechanistic studies have been carried out,[9d] and up to date no biomimetic complexes possessing extradiol cleavage activity are known. The results of the X-ray structure analysis[9a] now provide a good starting point to investigate the reaction mechanism and to compare it with the well-studied intradiol cleavage oxidation. Knowledge of the rich chemistry of the iron–phenolato complexes facilitated the elucidation of the reaction mechanism[10a] of intradiol–dioxygenase, in the active site of which the iron center is bound to two tyrosine and two histidine residues and a water molecule or a hydroxide anion, as a refined X-ray structure has recently shown[10b,c]. Several synthetic complexes that can catalyze the intradiol cleavage have also been reported.[11] The most efficient systems surprisingly contain only nitrogen ligands, whereas the phenolato complexes are inhibited after the catechol–semiquinone oxidation step, which thus provides evidence for direct attack of the oxygen on the aromatic ring.

Three classes of nonheme iron enzymes for which the structure of the active site as well as the catalytic mechanism are poorly understood are arene dioxygenases and pterin-dependent and α-keto acid dependent enzymes. They are strongly dependent on the cofactors that deliver the electrons for oxygen reduction. Far less is known with respect to pertubations at the metal center in the mechanism of arene dioxygenases.[12a,b] Putative peroxo intermediates similar to "activated BLM" may be involved in the catalytic cycle of these dioxygenases and putidamonooxin[12c] (oxygen activation component of 4-methoxybenzoate monooxygenase). Arene dioxygenases and putidamonooxin contain a mononuclear iron center and a Rieske iron–sulfur cluster as cofactors. The mechanism of pterin-dependent metalloenzymes (tyrosine, phenylalanine, and tryptophan hydroxylase) is still unresolved: Is the iron–peroxo species the primary transient species or is it a secondary product generated by initially produced hydroperoxy-pterin?[13a] Hydroxylation of a metal-bound phenol in a simple synthetic iron complex, which had been treated with *m*-chloroperbenzoic, was observed by Kitajima et al.[13b] The first model complexes of α-keto acid dependent, Fe^{II}-containing dioxygenases were reported by L. Que et al.[14a,b] The hitherto best model complex was synthesized by J. Valentine et al.[14c] and was capable of reproducing the complete reactivity of the enzyme: oxygenation of the substrate (epoxidation of cyclohexene and stilbene) with concomitant oxygenation and decarboxylation of the iron-bound benzoylformate to benzoic acid. These results open favorable perspectives for modeling complicated catalytic reactions involving cofactor transformations. The simple biomimetic modeling of the oxygen activation has, however, a general problem, namely the formation of μ-peroxo dimers.[15]

Taking into account the diverse and complex interactions between the active site and substrate, which are often modulated further by participation of cofactors, one can hardly expect a unified view of the reaction mechanism and the active oxygenating species for mononuclear non-heme iron proteins. Nevertheless the intensive research over the last few years has revealed that the non-heme iron enzyme probably reacts via a peroxo intermediate, thus different from iron porphyrins for which high-valent iron–oxo species are the predominant intermediate.

The Dimeric Steroid–Pyrazine Marine Alkaloids: Challenges for Isolation, Synthesis, and Biological Studies**

Arasu Ganesan

Dedicated to Professor Clayton Heathcock on the occasion of his 60th birthday

Isolation of Cephalostatins and Ritterazines

Since 1955 the American National Cancer Institute (NCI) has conducted a massive search for compounds with antitumor activity. Between 1955 and 1980 alone, some 130000 plant and animal extracts were screened, with the major success story being the discovery of taxol from the Pacific yew tree. This highlight covers a family of steroids also discovered by the NCI efforts.

In 1974 extracts of the tiny (ca. 5 mm) marine tube worm *Cephalodiscus gilchristi* collected off the coast of South Africa were found to be active in the NCI's primary assay, the murine lymphocytic leukemia P388. Fifteen years of relentless research by Pettit's group culminated in the isolation of 139 mg of the major bioactive component, cephalostatin 1, from 166 kg wet weight of the tube worm, and its structural elucidation.[1] This stage was summarized[2] as follows: "Interest in such a powerfully antileukemic agent as cephalostatin 1 ... has prompted Americans to dive extensively at a depth of 20 meters to collect *C. gilchristi* in open seawaters controlled by the white shark."

Cephalostatin 1 is extremely potent against P388, with an ED_{50} value of 10^{-7} to 10^{-9} $\mu g\,mL^{-1}$. Over the years, the Pettit group has characterized[3] sixteen other cephalostatins, all containing the novel structural framework of two steroid units linked at the A ring by a pyrazine (Scheme 1). The "right half" is identical in fifteen of the alkaloids, while cephalostatin 12 is a C_2-symmetric homodimer.

In 1994 a steroid–pyrazine dimer was reported[4] from an unexpected source. Fusetani's group isolated ritterazine A, which has an ED_{50} of 10^{-3} $\mu g\,mL^{-1}$ against P388, from the tunicate *Ritterella tokioka* collected off the coast of Japan. Twelve other ritterazines have since been described[5] (Scheme 2), including one homodimer, ritterazine K. A possible mechanism accounting for the rearranged "right half" in some of the ritterazines may involve protonation of the double bond in the D ring followed by either a 1,2 Wagner - Meerwein shift or retro-Prins ring opening and alternative Prins ring closure (Scheme 3).

The compounds from *C. gilchristi* and *R. tokioka* are clearly related (ritterazine K, for example, contains the "left half" of cephalostatin 7), although the same alkaloid has yet to be identified from both species. The presence of these compounds in two phyla suggests they may be produced by a symbiotic microorganism.

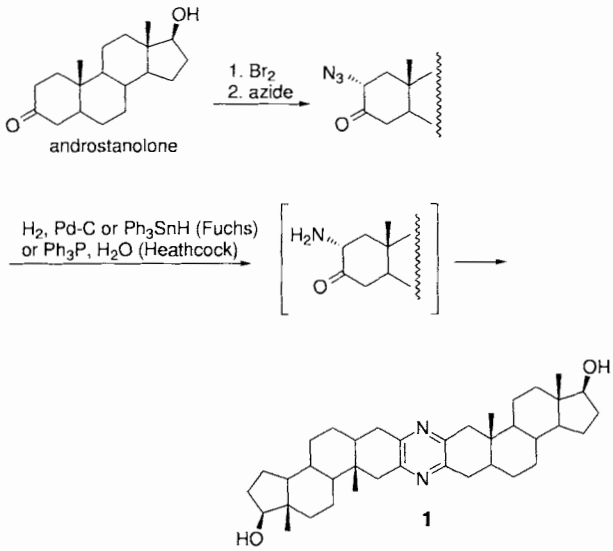
Synthetic Studies

Initial synthetic attention focused on preparation[6] of symmetrical steroid–pyrazine dimers by the classical condensation of α-amino ketones (Scheme 4). Interestingly, dimer **1** is itself weakly cytotoxic, with an ED_{50} around 10 μg mL^{-1} against tumor cell lines.



Scheme 4. Synthesis of symmetrical steroid–pyrazine dimers.

Smith and Heathcock[6b] achieved the synthesis of unsymmetrical dimers (most of these natural products fit this category) (Scheme 5). At 90 °C, α-amino oxime ether **2** and α-acetoxy ketone **3** preferentially react with each other to give intermediates that aromatize to give pyrazine **4** at higher temperature. The two-stage protocol is necessary as the α-amino oxime ether condenses with itself at 140 °C.

Introduction of asymmetry into a homodimer was demonstrated by Winterfeldt and co-workers (Scheme 6).[7] Commercially available hecogenin acetate was transformed into ketone **5** following literature precedents, and dimerized to give **6**. Eno-

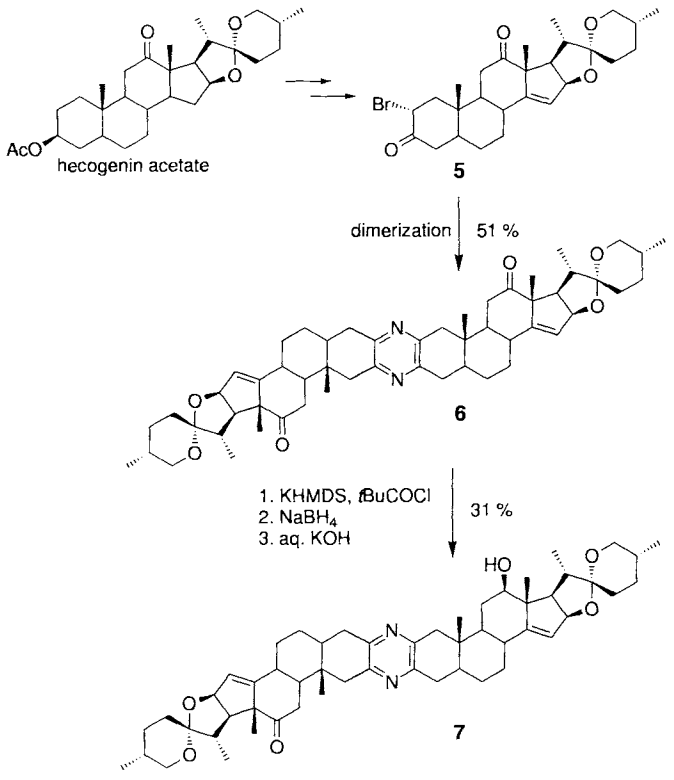
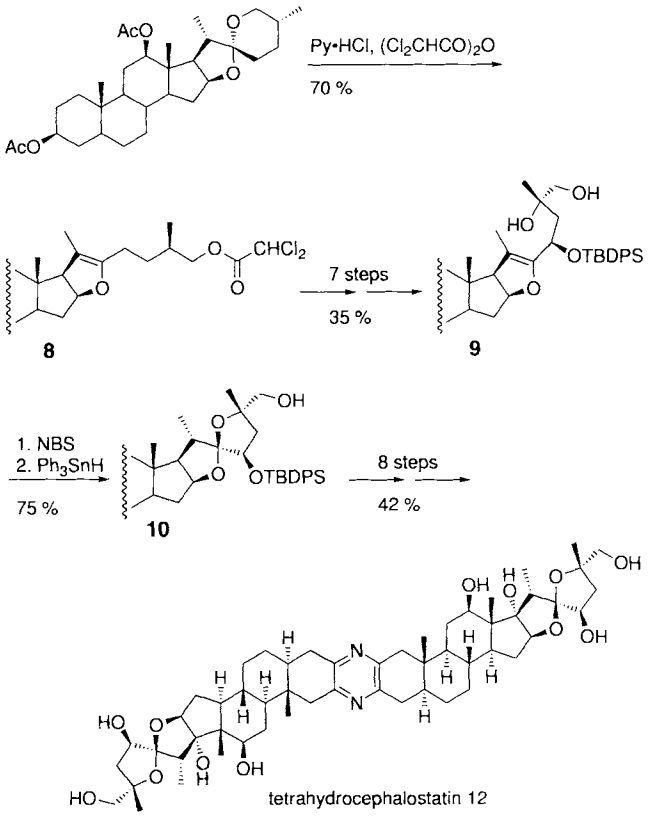


Scheme 6. Selective manipulation of a symmetrical dimer into an unsymmetrical dimer by Winterfeldt et al.

lization and trapping yielded a statistical mixture of separable asymmetric mono- and symmetric bis-enol esters. The former was reduced and hydrolyzed to afford dimer **7**, which has the C-ring oxygenation pattern and D-ring double bond of cephalostatin 1.

So far, all the publications related to total synthesis have been from Fuchs's group, who first reported[8] a symmetrical dimer corresponding to the "right half" of cephalostatin 1 but lacking the D-ring double bond. In fact, this dimer is the tetrahydro derivative of cephalostatin 12, whose existence had yet to be disclosed at that time.

The synthesis began with a derivative of hecogenin acetate, which already contains all the carbons needed. Classical Marker ring opening of the sapogenin spiroketal gave **8** (Scheme 7), which was carried forward to **9**. Acid-catalyzed cyclization of **9**



Scheme 7. Synthesis of tetrahydrocephalostatin 12 by Fuchs et al.

yielded a mixture of 5/5 and 6/5 spiroketals epimeric to the natural product. In general, for cephalostatin intermediates the ratio of spiroketal products is highly sensitive to the specific substitution pattern. The natural products also reflect this fine balance: there are three pairs of ritterazines differing only in spiroketal configuration. In this case, the desired product **10** was obtained from **9** by electrophilic bromination and halogen removal. Dimerization afforded tetrahydrocephalostatin 12, whose biological activity was not described.

Recent communications from the Fuchs group have climaxed[9] in the total synthesis of three alkaloids in this family. The presence of the D-ring double bond and C-17 hydroxyl group necessitated a different route from that for tetrahydrocephalostatin 12. First, Marker side chain degradation of hecogenin acetate gave enone **11** (Scheme 8). The D-ring functionality was introduced, and ring E constructed by intramolecular Wadsworth–Emmons reaction of **12**. The rest of the side chain was reintroduced by methallyl stannane addition to **13** yielding **14**.

The two diastereomers of **14** were separated, and individually processed to eventually yield monomers **15** and **16**. In the grand finale, a 1:1 mixture of the α-azido ketones was reduced to give roughly the expected 1:2:1 mixture of three dimers, with the heterodimer predominating. Separation and deprotection afforded the natural products. Fuchs et al. suggest that similar

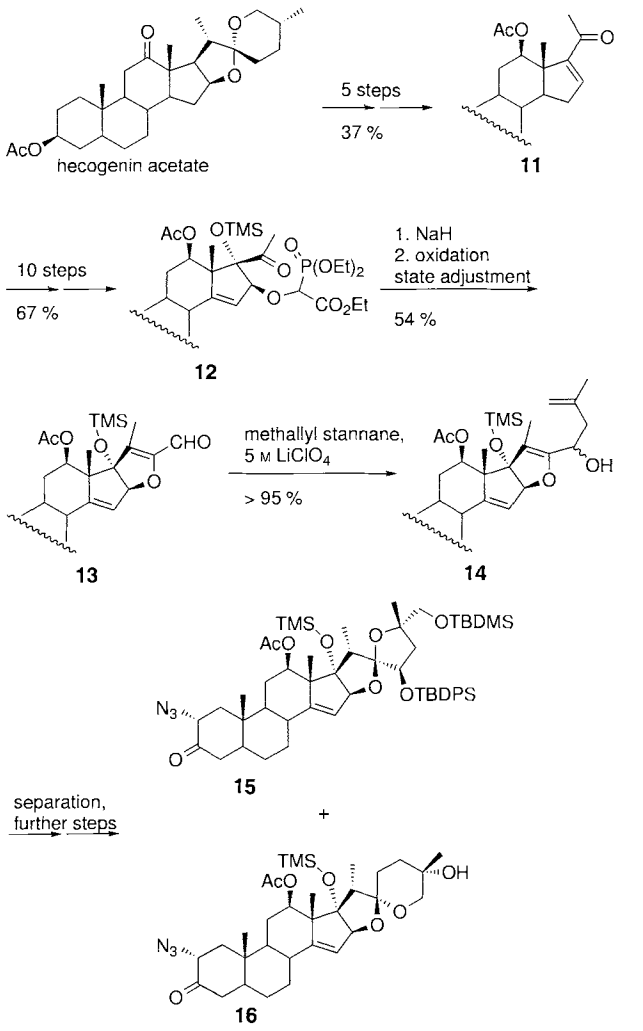
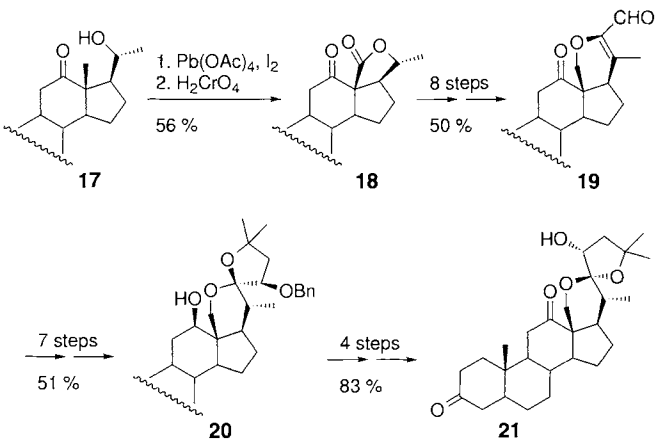


Scheme 8. Synthesis of cephalostatin 7, cephalostatin 12, and ritterazine K by Fuchs et al.

statistical coupling occurs in nature, which implies that ritterazine K is also produced by *C. gilchristi*. Indeed, examination of residual material in the Pettit group identified a compound in microgram quantities with the same chromatographic profile.

This work represents a milestone in the synthesis of complex marine natural products. At the same time, it reflects on the state of organic synthesis, which some consider to be a fully mature science. While total synthesis is *effective*, in the sense that any stable compound can probably be made, it is seldom *efficient*. This is particularly true for targets containing a multiplicity of oxygenated functional groups. The preparation of the two halves required over 20 steps from hecogenin acetate, the majority of which involve functional group interchange and protecting group manipulations. Clearly, there is much left for organic chemists to do in the next century!

The Fuchs group has also prepared[10] the "left half" of cephalostatin 1 without the D-ring double bond, hoping to determine the importance of the latter functional group. In this synthesis (Scheme 9), the angular methyl group of keto alcohol **17** (obtained from hecogenin acetate) was functionalized by Meystre's hypoiodite method and oxidized to yield **18**. Further reactions via intermediates **19** and **20** afforded **21**, which will presumably be carried forward to an α-azido ketone suitable for coupling with **15**.



Scheme 9. Synthesis of a precursor to the "left half" of dihydrocephalostatin 1 by Bhandaru and Fuchs.

Biological Studies

These alkaloids do not contain functional groups commonly associated with cytotoxicity such as alkylation sites, Michael acceptors, intercalators, or redox-active quinones, and their scarcity has hindered investigation of the mechanism of action. An early proposal,[11] taking into account the steroidal and dimeric nature of the alkaloids, was that these compounds span the lipid bilayer (cephalostatin 1 is 30 Å long) and perturb the eukaryotic cell membrane. Later, Fuchs considered[6a] that they may be enzyme inhibitors that form hydrogen bonds with a specific target. More recently, he has suggested[10a] that a process similar to that in Scheme 3 (vide infra) may occur in vivo, in which protonation or epoxidation of the D-ring double bond generates reactive electrophilic intermediates. The advantage for the alkaloids to be dimeric is also unclear. An analogy may be drawn with the potent immunosuppressive agent FK 506, where a synthetic dimer has unique properties.[12]

Steroids have important roles in providing membrane rigidity, as components of lipoproteins, and as ligands that dimerize a superfamily of nuclear hormones, resulting in gene transcription or repression. The effects of steroids can also be indirect, for example, in triggering apoptosis (programmed cell death), while the antiinflammatory glucocorticoids have recently been shown to interfere with signal transduction in addition to binding their hormone response element.[13] The determination of the precise target of the cephalostatins and ritterazines may require large-scale preparation of simpler analogs of the natural products.

Random screening continues to be an important source of leads for drug discovery. The cephalostatins and ritterazines highlight the power of screening natural product extracts in the

search for novel, complex lead structures over the screening of synthetic combinatorial libraries currently in fashion. At the present time, libraries are constructed by short sequences of synthetic transformations, whereas natural products are the result of much longer and more creative pathways.

Crystal Structure Analysis of a Synthetic Non-Heme Diiron–O_2 Adduct: Insight into the Mechanism of Oxygen Activation**

Yanhong Dong, Shiping Yan, Victor G. Young, Jr., and Lawrence Que, Jr.*

Dedicated to the memory of Nobumasa Kitajima

Dioxygen binding and activation are key processes carried out by a number of metalloproteins, including those of an emerging subclass with non-heme diiron active sites.[1] For example, the diiron active site of hemerythrin (Hr)[2] functions to bind O_2 reversibly in invertebrates, while those of methane monooxygenase (MMO)[3] and ribonucleotide reductase (RNR)[4] activate dioxygen to carry out their respective functions. Interestingly, Hr has a histidine-rich active site (five His and two Asp/Glu residues), while MMO and RNR have carboxylate-rich diiron sites (two His and four Asp/Glu residues). One goal of our research efforts has been to understand the principles underlying nature's choice of ligands for such proteins. Coordination chemists have obtained important insights into the nature and reactivity of the bound O_2 from studies of synthetic metal–dioxygen complexes;[5] in particular, the crystal structure analyses of O_2 adducts of biomimetic heme and dicopper complexes have yielded crucial structural information.[6–8] However, no crystal structure analysis of a synthetic nonheme diiron–O_2 adduct has thus far been reported, though several such complexes have been characterized in solution.[9, 10] We report here on the first crystal structure analysis of a nonheme diiron–O_2 adduct which provides the first structural details on a (μ-1,2-peroxo)diiron unit. Furthermore some novel features of this structure prompted us to carry out kinetic experiments that have shed light on the stability of the O_2 adduct and show how the ligand environment can modulate the reactivity of the O_2 adduct in nonheme diiron enzymes.

We previously reported that the diiron(II) complex **1** binds O_2 irreversibly at $-60\,^{\circ}C$ in CH_2Cl_2 to afford a metastable blue adduct **1**-O_2[10a, b, 11] that has a proposed structure similar to

$[Fe_2(N\text{-Et-hptb})(O_2CC_6H_5)]^{2+}$ **1**

$[Fe_2(\mu\text{-}1,2\text{-}O_2)(N\text{-Et-hptb})(\mu\text{-}O,O'\text{-}O_2CC_6H_5)]^{2+}$ **1**-O_2

that recently reported for $[Co_2(O_2)(tpdb)(O_2CC_6H_5)]^{2+}$.[12] We surmised that the benzoate bridge present in the precursor was retained upon binding of O_2, since the peroxo-to-iron(III) charge transfer (CT) band was blue shifted when the benzoate was substituted with the more basic propionate.[10b] Furthermore the lifetime of this adduct could be extended by the addition of Ph_3PO. This enhanced stability has allowed us to grow crystals of the O_2 adduct at $-40\,^{\circ}C$ over a period of several weeks.[13]

The crystal structure analysis (Fig. 1) revealed that the O_2 adduct has a (μ-alkoxo)diiron core supported by a μ-1,2-dioxygen bridge; the Fe–Fe separation is 3.462(2) Å. The Fe–μ-O_{alkoxo} bond length is 1.991(3) Å, typical of those found in related (μ-alkoxo)diiron(III) complexes.[14] The dioxygen moiety coordinates in a *cis* μ-1,2 fashion, and the O–O bond is 1.416(7) Å long. This distance is consistent with the reduction

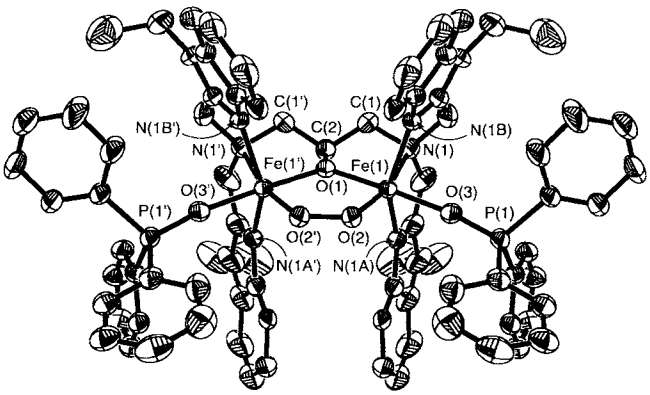

Fig. 1. Crystal structure of $[Fe_2(\mu\text{-}1,2\text{-}O_2)(N\text{-Et-hptb})(Ph_3PO)_2]^{3+}$ (ORTEP plot showing 30% probability thermal ellipsoids). Selected bond lengths [Å] and angles [°]: Fe1–O1 1.991(3), Fe1–O2 1.880(4), Fe1–O3 2.035(4), Fe1–N1 2.364(5), Fe1–N1A 2.082(4), Fe1–N1B 2.094(4), O2–O2' 1.416(7), Fe1···Fe1' 3.462(3); Fe1-O1-Fe1' 120.8(3), Fe1-O2-O2' 122.97(10), O1-Fe1-O2 86.5(2), O1-Fe1-N1 78.0(2), O2-Fe1-O3 90.4(2), N1-Fe1-O3 105.2(2), O1-Fe1-N1A 93.7(2), O1-Fe1-N1B 97.7(2).

of O_2 to peroxide upon coordination, as was first indicated by resonance Raman data.[10a] For comparison, $[Fe_6(\mu\text{-}O)_2(\mu_4\text{-}O_2)(O_2CC_6H_5)_{12}(OH_2)_2]$, the only previously structurally characterized synthetic iron peroxide complex, has an O–O bond length of 1.480(12) Å,[15] while dicopper–O_2 adducts such as $[Cu_2(Tp^{iPr2})_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]$ and $[Cu_2(tpa)_2(\mu\text{-}trans\text{-}1,2\text{-}O_2)]^{2+}$ have O–O bond lengths of 1.412(12) and 1.432(6) Å, respectively.[7, 8] The Fe–O_{peroxo} bonds are 1.880(4) Å long, a value consistent with the basicity of the peroxide ligand. Comparably short Fe–O bonds (1.88–1.91 Å) are found for complexes with terminal Fe^{III}–OH and Fe^{III}–OCH_3 groups.[16] Thus, in agreement with the spectroscopic studies, the structure analysis shows that O_2 binding to **1** converts it into an adduct with a (μ-alkoxo)(μ-1,2-peroxo)diiron(III) core.

The iron coordination spheres are completed by the nitrogen atoms of the N-Et-hptb ligand and the oxygen atoms of two phosphane oxides. As are typical of tripodal ligands of this type, the tertiary amine nitrogens have the longest metal–ligand bond lengths and coordinate *trans* to the most basic ligand in the complex, the peroxide in this case. The pendant benzimidazole rings on each iron are coordinated *trans* to each other, perpendicular to the plane defined by the two iron centers, the alkoxide, and the peroxo bridge. To our surprise, the benzoate bridge is absent in the crystalline O_2 adduct; instead two triphenylphosphane oxide ligands are coordinated *trans* to the alkoxo bridge. The Fe–O bonds to the two Ph_3PO ligands are 2.035(4) Å long, a distance which is typical of such bonds.[17] The presence of these Ph_3PO ligands is the key to the enhanced stability of this O_2 adduct.

$[Fe_2(\mu\text{-}1,2\text{-}O_2)(N\text{-Et-hptb})(Ph_3PO)_2]^{3+}$ is stable for months at $-40\,^{\circ}C$, but decomposes at $30\,^{\circ}C$ within an hour to form a diiron(III) product. The decay of the characteristic peroxide-to-iron(III) CT band of the O_2 adduct follows first-order kinetics over at least five half-lives ($k_1 = 1.1 \times 10^{-3}\,s^{-1}$). The decomposition of the O_2 adduct presumably occurs by cleavage of the O–O bond which would result in the oxidation of the iron(III) centers to a higher oxidation state. In view of the symmetry of the diiron complex, we favor homolysis of the O–O bond, leading to the generation of a diiron(IV) unit as shown in Figure 2.

According to the proposed mechanism, the O–O bond cleavage should be enhanced by the substitution of the neutral phosphane oxide ligands by the more electron-donating anionic benzoate. The increased electron density provided to the metal

centers would promote the cleavage of the O–O bond and stabilize the resulting high valent oxidation state. Indeed **1**-O_2 decomposes within seconds at 30 °C. The decay rate can be modulated by the introduction of substituents on the bridging benzoate and shows an excellent correlation with Hammett σ values (Fig. 3). The ρ value of -1.1 indicates a process that is

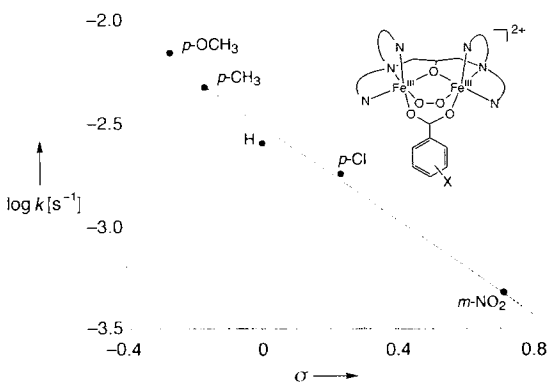

Fig. 3. Hammett plot for the decomposition rates of a series of O_2 adducts of the type $[Fe_2(\mu\text{-}1,2\text{-}O_2)(N\text{-Et-hptb})(O_2CC_6H_4\text{-}X)]^{2+}$ in CH_3CN at -10 °C ($\rho = -1.1$).

accelerated by electron-donating groups. While earlier studies on diiron–O_2 complexes have concentrated on the Fe–O_2 bond formation reaction and its reversibility,[10c, 18] this investigation has focused on the factors that affect the integrity of the O–O bond and its activation, and provides a quantitative basis for the mechanism proposed in Figure 2. A similar "push" effect is observed for the cleavage of the O–O bond in heme–peroxy acid complexes, leading to the formation of higher valent iron–oxo species, when electron-donating ligands are introduced.[19] We have also examined the temperature dependence of the decomposition of **1**-O_2 and obtained activation parameters, $\Delta H^{\ddagger} = 15.5 \pm 0.8$ kcal mol^{-1} and $\Delta S^{\ddagger} = -11 \pm 5$ cal mol^{-1} K^{-1}, which are consistent with values associated with the cleavage of the O–O bond in other O_2 adducts.[20]

The studies described here contribute insights into nature's design of non-heme diiron active sites for controlling dioxygen chemistry. They clearly demonstrate that the amount of electron density contributed by the ligands can modulate the reactivity of the O_2 adduct. The histidine-rich active site of the dioxygen carrier hemerythrin helps maintain the integrity of the O–O bond, thereby contributing to reversibility of O_2 binding. The presence of a larger number of anionic carboxylate ligands in the diiron sites of MMO and RNR activates the O–O bond and provides access to the higher valent iron states that are needed to carry out the hydrogen abstraction reactions associated with their respective functions. Indeed rapid kinetic studies of these enzymes have provided evidence for the participation of transient intermediates with high-valent iron centers that derive from peroxodiiron(III) species in their reaction cycles.[21, 22] Although other factors undoubtedly come into play, the functional differences between hemerythrin, on the one hand, and MMO and RNR, on the other, can now be rationalized in light of the ligand–reactivity relationships we have uncovered through the determination of the crystal structure of this non-heme diiron–O_2 adduct.[23]

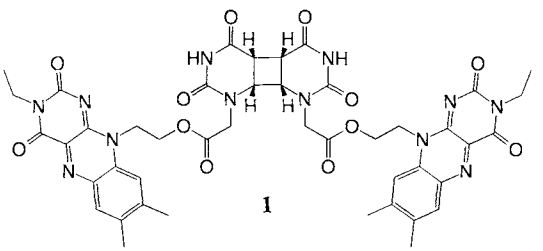
[23] **Note added in proof** (February 21, 1996): After this paper was accepted, Ookubo et al. reported the crystal structure of a reversible diiron–O_2 adduct with a structure similar to that of **1**-O_2 proposed in Figure 3 (T. Ookubo, H. Sugimoto, T. Nagayama, H. Masuda, T. Sato, K. Tanaka, Y. Maeda, H. Okawa, Y. Hayashi, A. Uehara, M. Suzuki, *J. Am. Chem. Soc.* **1996**, *118*, 701–702). The structure of one other O_2 adduct $[Fe_2(Tp^{iPr2})_2(O_2CCH_2Ph)_2(O_2)]$ has also been solved by K. Kim, and S. J. Lippard (S. J. Lippard, personal communication).

Synthesis of Flavin-Containing Model Compounds for DNA Photolyase Mediated DNA Repair**

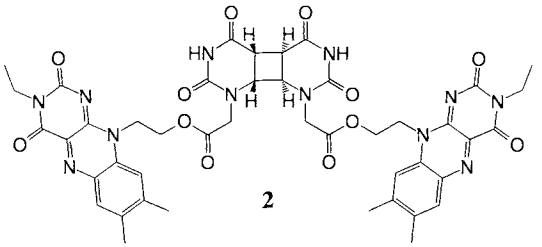
Thomas Carell,* Robert Epple, and Volker Gramlich

Irradiation of cells with UV light causes severe genome damage.[1] In double-stranded DNA, the major alteration is the formation of *cis-syn* cyclobutane pyrimidine dimers by [2+2]cycloaddition.[2] In single-stranded DNA, a second isomer, the *trans-syn* configured species is also formed, but to a lesser extent. These photoproducts are known to induce various forms of skin cancer, such as basal and squamous cell carcinomas, and to cause cell death.[2] Since it was established that the ozone layer, which shields the earth from harmful solar UV radiation, is becoming depleted, rising skin cancer incidents are predicted.[3] This situation has stimulated renewed interest in the mechanisms used by organisms to remove sunlight-induced DNA lesions from the genome. One widespread DNA repair system employs a single enzyme, the flavin-containing DNA photolyase, to revert *cis-syn* cyclobutane pyrimidine dimers to their pyrimidine precursors in a process initiated by sunlight (300–500 nm).[4] It is widely accepted that the essential event in the repair reaction is a light-induced electron transfer from a reduced flavin cofactor, tightly bound by the enzyme, to the cyclobutane pyrimidine dimer moiety within the DNA double strand.

Through the synthesis and investigation of model compounds that are able to mimic crucial steps of a complex biological process, important aspects of the underlying reaction sequence can be investigated.[5] The few model compounds prepared to study photolyase-mediated DNA repair consist predominantly of pyrimidine photodimers covalently linked to electron-rich aromatic systems such as indole or dimethoxybenzene derivatives.[6, 7] Although, reduced and deprotonated flavins have been shown to reverse the cyclobutane formation if they are added to a solution containing photodimers and subsequently irradiated,[8] no functionally active model compounds containing both, biologically relevant reduced flavins and pyrimidine photodimers have been prepared.[9, 10] To investigate the requirements for an efficient cleavage of pyrimidine photodimers mediated by reduced flavins, we prepared the series of model compounds **1**–**3**. The parent compound **1** contains



1



2

two riboflavin derivatives covalently attached to a cyclobutane uracil photodimer with *cis-syn* configuration. Since photolyases were shown to also split thymine photodimers with *trans-syn* configuration (but only at high enzyme concentration) two other derivatives, **2** and **3**, containing uracil dimers with *trans-syn* and *trans-anti* geometry, respectively, were prepared to investigate if these structural alterations effect the splitting efficiency.[11]

The uracil photodimers were prepared without a methyl group or an additional linking chain at the imide nitrogens, since such substitution was found to dramatically reduce splitting efficiencies.[9] To counter potentially poor solubility, the flavins were ethylated at the N-3 positions. Rather flexible ethyl chains were chosen as the connecting elements between the flavin subunits and the pyrimidine photodimer to allow the flavins to adopt conformations with van der Waals contacts to the cyclobutane moiety.

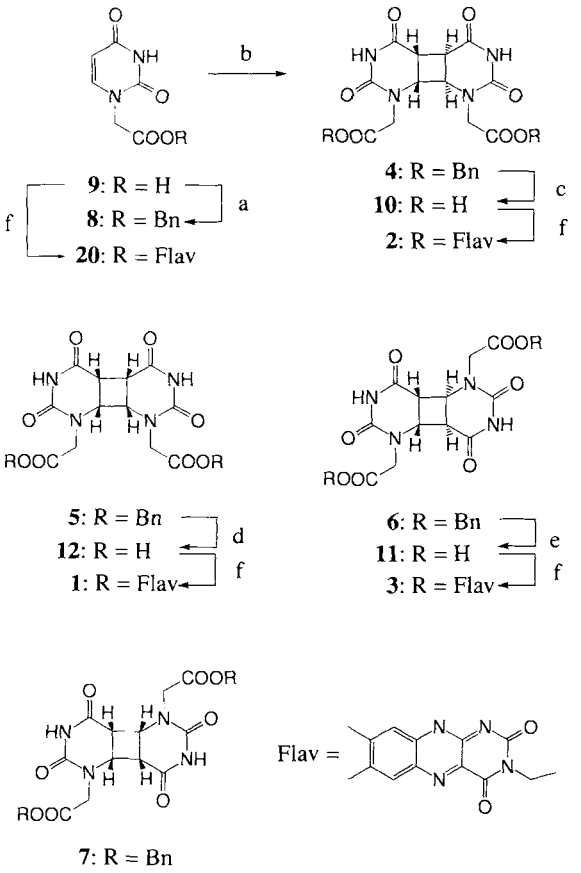
[**] This work was supported by Hoffmann-La Roche, Basel. We thank the German Stiftung Stipendien-Fonds des Verbandes der Chemischen Industrie for a Liebig-Stipendium to T. C., Prof. F. Diederich for his generous support of this research, and Dr. R. Thomas for carefully reading the manuscript.

While the dicarboxylic acid **10** with *trans-syn* geometry had been described,[7] all other pyrimidine dimers depicted in Scheme 1, including **5** and **12** with the biologically relevant *cis-syn* structure, were unknown. We found that all four possible



Scheme 1. Synthesis of the four cyclobutane uracil photodimer isomers **4**–**7** and the debenzylated compounds **10**–**12**. a) $C_6H_5CH_2OH$, carbonyldiimidazole, DMF, 20 °C, 95%; b) $h\nu > 290$ nm, acetone, 2 h, 20 °C, **4**: 18%, **6**: 30%, **5**: 5%, **7**: 2.5%; c) 1 N NaOH, 3.5 h, 20 °C then conc. HCl to pH 1, 86%; d) Pd/C (10%), H_2, EtOH, 20 °C; quant.; e) conc. HCl, 3 h reflux, 70%; f) **13**, DMF, BOP, Et_3N, 12 h, 20 °C.

cyclobutane uracil dimers can be prepared as their benzyl esters **4**–**7**. Irradiation of the benzyl ester **8**, which is readily available through esterification of **9**[12] with benzyl alcohol, in 2 g portions in acetone for 2 h in a pyrex reaction vessel with a medium-pressure mercury lamp yielded predominantly the four dimers **4**–**7**. They can be separated by a combination of chromatography and selective precipitation. The *trans-anti* isomer **6** is insoluble in acetone and can be separated in excellent purity from the reaction suspension by filtration (600 mg). Concentration of the filtrate and trituration with ice-cold chloroform caused precipitation of approximately half of the *trans-syn* isomer **4** (350 mg) present. After filtration, the residual solution was concentrated and the remaining oil treated sequentially with ether and boiling toluene to remove nonpolar impurities. The remaining two isomers, the *cis-syn* compound **5** (100 mg) and the *cis-anti* compound **7** (50 mg), were isolated from the residual powdery material by flash-chromatography (SiO_2-H, $CHCl_3$/MeOH).

The structures of **4**–**7** were assigned based on their ^{1}H NMR spectra (Table 1) and by X-ray crystal structure analyses of the two dibenzyl esters **4** and **5** (Fig. 1).[13] The crystal structures confirmed the *trans-syn* configuration of the cyclobutane ring in **4** and the *cis-syn* configuration of the cyclobutane ring in **5**.[13]

[a] All new compounds described were fully characterized by ^{1}H and ^{13}C NMR spectroscopy, FT-IR spectroscopy, and FAB$^+$ mass spectrometry.

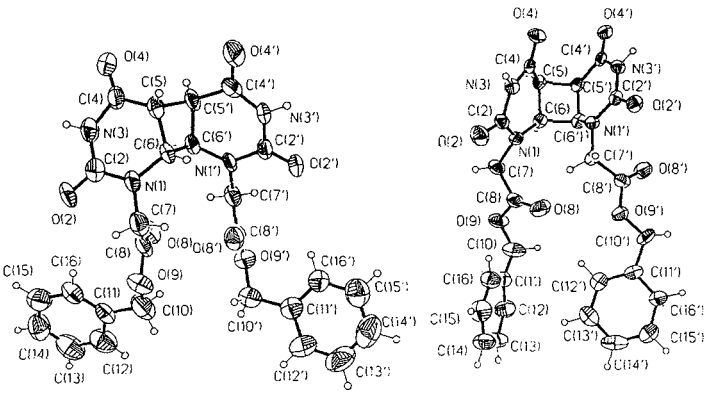

Fig. 1. Crystal structures of the dibenzyl esters **4** (*trans-syn*) and **5** (*cis-syn*) [13].

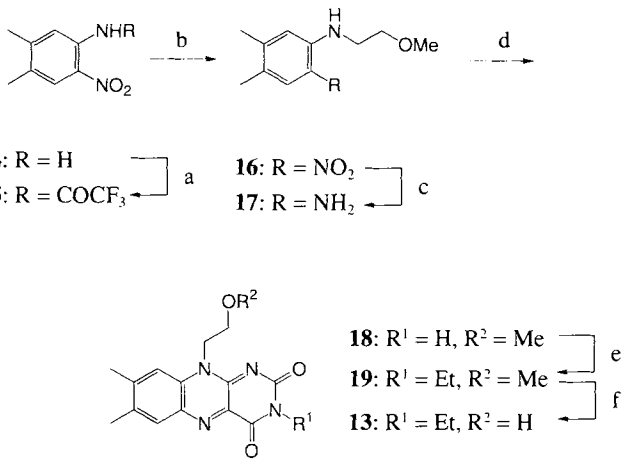
The structures of the remaining isomers **6** and **7** were assigned on the basis of their differing coupling patterns for the four cyclobutane protons in their ^{1}H NMR spectra.[14] Since only **7** featured two overlapping doublets of doublets for the four cyclobutane protons, each caused by two *cis* couplings of similar magnitude (in one case between C(5)-H and C(6)-H, C(6′)-H and in the second between C(6)-H and C(5)-H, C(5′)-H), **7** was assigned the *cis-anti* structure. Compound **6** exhibited two doublets of doublets for the four protons, caused by *trans* coupling between C(5)-H and C(6′)-H and between C(5′)-H and C(6)-H) and *cis* coupling between C(5)-H and C(6)-H and between C(5′)-H and C(6′)-H, and thus **6** was assigned the *trans-anti* structure.

The isomer **4** was deprotected to give **10** with 1 N sodium hydroxide. Cleavage of the benzyl ester in **6** to give **11** was achieved with concentrated hydrochloric acid and debenzylation of the *cis-syn* isomer **5** to afford **12** was found to be optimal through catalytic hydrogenation in ethanol. The hydroxyethyl-substituted flavin **13**, required for the preparation of the model compounds **1**–**3**, was synthesized in six steps from commercially available 4,5-dimethyl-2-nitroaniline (**14**) as depicted in Scheme 2.



Scheme 2. Synthesis of the flavin building block **13**. a) $(CF_3CO)_2O$, 2 h, 20 °C, 90%; b) $BrCH_2CH_2OCH_3$ [15], K_2CO_3, DMF, 100 °C then 90 min reflux, 89%; c) Pd/C (10%), H_2, CH_3COOH, 20 °C (yield not determined); d) alloxane monohydrate, boric acid, 3 h, 20 °C, 70%; e) CH_3CH_2I, K_2CO_3, DMF, 11 h, 20 °C, 83%; f) BBr_3, CH_2Cl_2, 4.5 h, 0 °C, 81%.

The esterification of **13** with the cyclobutane uracil dimers **10**–**12** was achieved by using the strong carboxyl-activating Castro's reagent (benzotriazol-1-yloxytris(dimethylamino)-phosphonium hexafluorophosphate, BOP).[16] All three model compounds **1**–**3** were obtained as orange powders after chromatography (SiO_2-H, $CHCl_3$/MeOH). As a reference compound, the product of the cyclobutane splitting reaction, **20**, was prepared by esterification of **13** with **9** (Scheme 1). All spectroscopic data of the model compounds **1**–**3** (Table 1) are consistent with the proposed structures. The positive ion FAB mass spectra gave a strong molecular ion peak for $[M\mathrm{H}]^+$ at $m/z = 933$; a high-resolution scan of this molecular ion peak confirmed the elemental composition of these compounds ($C_{44}H_{44}N_{12}O_{12}$). Apart from the splitting pattern of the signals for protons of the cyclobutane ring, the ^{1}H NMR spectra of the **1**–**3** are very similar. All three feature the same coupling characteristics of their four cyclobutane protons as determined for their corresponding dibenzyl esters. This indicates that the harsh debenzylation conditions caused no isomerization of the cyclobutane moieties. The ^{13}C NMR spectra of the model compounds showed the requisite peaks. All three model compounds are sufficiently soluble in a variety of different solvents, enabling the planned splitting experiments and further spectroscopic studies.

In the initial splitting experiments solutions of **1**–**3** in chloroform were irradiated with light at 254 nm to study the cleavage reaction under conditions in which the flavin units do not participate. The irradiation at 254 nm caused the awaited partial conversion of **1**–**3** into **20** and established a photosteady monomer–dimer state. Compound **20** is the only product formed as shown by TLC. We found that at this wavelength, the *trans-syn* isomer **2** cleaved approximately 1.5 times faster than the *cis-syn* compound **1**. Negligible opening of the cyclobutane ring was observed for the *trans-anti* species **3**.[17] To discover if the compounds are able to mimic the biological repair reaction, they were dissolved in ethyleneglycol, acetonitrile, or dioxane and the flavins were reduced by additon of an 0.05 M aqueous sodium dithionite solution (inert gas atmosphere). Upon addition the strong flavin fluorescence immediately disappeared, indicating complete reduction of the flavin unit. Alternatively, the flavins were reduced by addition of an aqueous solution of sodium ethylenediamine tetraacetate and subsequent irradiation with white light.[18] Our preliminary experiments show that the *cis-syn* compound **1** and the *trans-syn* compound **2**, when reduced, cleanly yield the reference compound **20** upon irradiation with either white light or light at 366 nm. Under all conditions employed, the cyclobutane substructure of the *cis-syn* model compound **1** cleaved significantly faster than in the *trans-syn* species **2**. In the case of compound **3**, as with irradiation at 254 nm, only a very slow cleavage could be detected. Without prior reduction of the flavins, no cleavage reaction in any of the three model compounds was observed. In other control experiments in which the dibenzyl ester compounds **4** and **5** were irradiated in the presence of the reduced model compound **1**, only cleavage of the model compound and not of the benzyl esters was observed, indicating that the cleavage reaction of the cyclobutane moiety is an intramolecular process.

The reluctance of the *trans-anti* isomer **3** to cleave can be explained by the lack of mesomeric stabilization of the intermediate radicals by an adjacent carbonyl group.[2c, 19] We propose that the difference in cleavage rate between the two isomers **2** and **1** is related to the greater accessibility of the cyclobutane ring for the flavin units in **1**.

Both **1** and **2** mimic the photoreactivation process, and to our knowledge they are the first functionally active model compounds for the DNA photolyase mediated repair reaction. We are currently in the process of investigating the structural requirements of this repair process through detailed studies of splitting efficiencies of these and further analogues.

Polymerization of Ethylene Oxide with Alkyllithium Compounds and the Phosphazene Base "*t*Bu-P_4"**

Beate Esswein and Martin Möller*

The ring opening anionic polymerization of ethylene oxide occurs via alkoxide ions as a "living polymerization".[1] The rate of polymerization depends on the association and formation of ion pairs, which is still important even at the low concentrations of growing ends and in highly polar solvents such as hexamethylphosphortriamide (HMPT).[2]

The rates of monomer addition can differ by several orders of magnitude for the different states of the reaction solution.[1] Strong dipole interactions of the ion pairs compete successfully with the solvation of the cation,[2] and the alkoxides of the smaller alkali metal cations like Li^+ and Na^+ form unreactive associates. Li^+ ions show the strongest association behavior because of their tendency to form covalent bonds.[3] No propagation reaction occurs, even though poly(ethylene oxide) itself is known to interact strongly with Li^+ ions.[4]

Complexation of the alkali metal cation by cryptands[5] has been shown to shift the equilibrium towards the reactive free anions and leads to simple polymerization kinetics for ethylene oxide.[6–8] The dissociation constant K_{Diss} has been determined to be 3×10^{-7} for a mixture of RO^-K^+ and [2.2.2]cryptand[3] compared to 1.8×10^{-10} for RO^-K^+[9] alone in THF at 20 °C. Although the ions are complexed, they are slightly less or just as reactive in the polymerization of oxirane as the corresponding noncomplexed ion pairs[3, 10] (Table 1). In the RO^-K^+ complex

Table 1. Propagation constants k_p for ion pairs and free anions for the polymerization of ethylene oxide in THF [10].

Monomer	k_p for counterion [$M^{-1}\,s^{-1}$]				k_p [$M^{-1}\,s^{-1}$]
	Li^+	Na^+	K^+	Cs^+	free anion
ethylene oxide	–	–	0.05	0.12	1.7
ethylene oxide + [2.2.2]cryptand	–	–	0.025	0.09	

with [2.2.2]cryptand an interionic distance of only 4.6 Å has been deduced according to the Fuoss equation.[10] This value is significantly smaller than that for cryptated living poly(propylene sulfide)[11] and for cryptated tetraphenylborides in THF,[12] indicating that the K^+ is not placed in the cavity, or that the oxy anion can penetrate into the cavity of the cryptand.

In the case of Li^+ alkoxides, neither we nor others observed efficient polymerization.[13] This was also the case when we employed an even more efficient complexing agent for Li^+ ions, the spherand first synthesized by Cram.[14] We know of only one report on the successful polymerization of oxirane with BuLi in the presence of *N,N,N',N'*-tetramethylethylenediamine (tmeda), which, however, does not give data on the degree of polymerization, polydispersity, or yield.[15]

We addressed the question of whether the recently developed, extremely strong phosphorazene bases[16, 17] can efficiently complex lithium ions and facilitate polymerization of ethylene oxide through formation of lithium alkoxides. The base "*t*Bu-P_4" fulfills an important criterium of a cryptand: the polar amino groups are located inside the globular molecule, and the outer shell is formed by the alkyl substituents. The free volume inside the molecule might be sufficient to host the rather compact Li^+ ion. We recently reported on the application of the protonated polyiminophosphazene base [H-*t*Bu-P_4]$^+$ for the initiation of the anionic polymerization of ethylene oxide.[18]

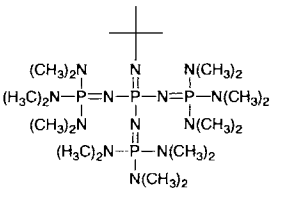

Table 2 summarizes the results of the homopolymerization of ethylene oxide in THF with BuLi/*t*Bu-P_4 as the initiator system. Good yields of poly(ethylene oxide) (> 80% after precipitation) with low polydispersity were obtained. The molecular weights determined by GPC correspond well with the theoretical molecular weights (M_n(th.) = 2200, 6600, and 22000).

Yield [a]	81%	89%	84%
M_n (th.) [g mol^{-1}]	2200	6600	22000
M_n [g mol^{-1}] [b]	1900	5900	18100
M_w [g mol^{-1}] [b]	2800	6900	23300
D	1.08	1.16	1.28

[a] After precipitation. [b] Relative to polyethylene glycol standards.

Furthermore, a diblock copolymer of poly(styrene-β-ethylene oxide) (theoretically 100 styrene and 300 ethylene oxide monomer units) was synthesized in toluene at room temperature (Table 3). First, styrene was polymerized with sBuLi as the initiator. After three hours a small sample was taken, and the molecular weight was determined by gel permeation chromatography (GPC) before ethylene oxide and tBu-P_4 were added to the living polystyrene solution. The diblock copolymer was characterized by GPC and ^{1}H NMR measurements. The theoretically expected molecular weight and composition agreed rather well with the experimental results (Table 3). The block copolymer could be dissolved in water as well as in toluene, indicating micelle formation. Transmission electron microscopy demonstrated microphase separation of the two incompatible blocks.

Table 3. Molecular weights and polydispersities D of the polystyrene (PSt) block and the poly(styrene-β-ethylene oxide) (PSt-β-EO) block copolymer prepared with tBu-P_4/sBuLi as initiator system; GPC data of the block copolymer are determined in chloroform, the data for the styrene block in toluene.

	PSt Block	P(St-β-EO)

[a] After precipitation. [b] Relative to polystyrene standards. [c] Determined in $CDCl_3$, relative to TMS.

The results demonstrate that the phosphorazene bases can efficiently complex lithium ions. This interpretation was confirmed by the results of ^{7}Li NMR studies with lithium octanolate in [D_8]toluene (Fig. 1). While pure lithium octanolate in toluene gives rise to a ^{7}Li NMR peak at $\delta = 0.68$, addition of tBu-P_4 resulted in a split signal with a maximum at $\delta = 0.81$. This change in the chemical shift indicates an altered structure of the Li–alkoxide ion pair. Yet it is not clear why the spectrum of a solution with tBu-P_4 shows different ^{7}Li NMR signals. Preliminary polymerization experiments with varying Li^+/tBu-P_4 ratios demonstrate that all lithium alkoxides are equally reactive, thus indicating that the splitting of the Li NMR signal cannot be attributed to a slow exchange between the complexed and the uncomplexed state.

We conclude that the phosphazene base can form a [Li–tBu-P_4]$^+$ complex that suppresses ion pair association. The activation of lithium alkoxides by tBu-P_4 for the polymerization of ethylene oxide is rather remarkable in view of the negative results with the [2.1.1]cryptand and the spherand. Detailed NMR and kinetic investigations on the exact nature of the interaction are currently in progress.

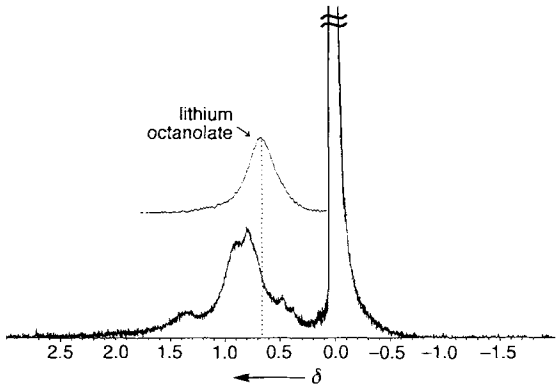

Fig. 1. ^{7}Li NMR spectrum of lithium octanolate and tBu-P_4 in [D_8]toluene.

Experimental Procedure

Materials: Ethylene oxide (Linde 2.7) was dried over CaH_2 and distilled into an ampoule. tBu-P_4 (1.0 M solution in hexane from Fluka), BuLi (Aldrich, 1.6 M in hexane), sBuLi (Aldrich, 1.4 M in cyclohexane), acetic acid (Merck), and dibutylmagnesium (Aldrich, 1.0 M in heptane) were used without further purification. THF and toluene (Merck p.a.) were freshly distilled from sodium–benzophenone ketyl under argon. Styrene (Aldrich, 99%, GC) was distilled twice, first from CaH_2 and then from dibutylmagnesium directly into an ampoule with a PTFE stopcock. Petroleum ether (Merck, technical grade) and diethyl ether (Merck, technical grade) were distilled. Reactions were performed on a high-vacuum line. The apparatus was dried by several heating and evacuation cycles, and flushed with argon.

Homopolymerization: Freshly distilled THF (100 mL) was cooled to −78 °C and 10 mL (200 mmol) of ethylene oxide was introduced from an ampoule. After addition of 250 μL (0.4 mmol) of BuLi, the reaction mixture was stirred for 30 min at −78 °C. To this solution was added 0.4 mL (0.4 mmol) of tBu-P_4, and the mixture was stirred for 48 h at room temperature. The reaction was quenched with 0.1 mL of acetic acid, and the solvent was removed under vacuum. The residue was dissolved in some THF and precipitated by addition of diethyl ether. The polymer was obtained as a white powder and was dried under vacuum. Yield: 7.4 g (84%). ^{1}H NMR: $\delta = 3.61-3.65$ (CH_2-O).

Block copolymerization: Styrene (8 mL, 70 mmol) was introduced from an ampoule into a flask containing 80 mL of freshly distilled toluene. After addition of 600 μL (0.70 mmol) of sBuLi, the reaction mixture was stirred for 3 h at room temperature. Then the solution was cooled to −78 °C and 11 mL (220 mmol) of ethylene oxide was introduced from an ampoule. The reddish color disappeared immediately. The reaction mixture was stirred for another 2 h, then 720 μL (0.72 mmol) of tBu-P_4 was added. The reaction mixture was stirred for further 48 h at room temperature. Subsequently the reaction was quenched with 0.1 mL of acetic acid, the solvent evaporated, and the residue dissolved in THF. The polymer was precipitated in petroleum ether and collected as a white powder, which was dried under vacuum. Yield: 12.8 g (75%). ^{1}H NMR: $\delta = 3.61-3.65$ (CH_2O) 7.16–6.20 (aromat. C-H), 2.06–1.14 (aliphat. C-H).

Characterization: GPC measurements were carried out with chloroform as solvent, using Waters microstyragel columns (pore size 10^5, 10^4, and 10^3 Å). Molecular weights were determined by universal calibration and are relative to narrow polystyrene and polyethylene glycol standards. A dual detection system consisting of a differential refractometer (Waters model 410) and a differential viscometer (Viscotek model H502, GPC-Win software) was employed. ^{1}H NMR spectra were performed in $CDCl_3$ on a Bruker AC 200 spectrometer at 200 MHz. Chemical shifts are relative to TMS. ^{7}Li NMR spectroscopy was performed in [D_8]toluene on a Bruker AMX 500 spectrometer at 194.4 MHz. A 4 M solution of $LiClO_4$ in D_2O was used as external standard.

Synthesis and Structure Determination of $BaHg_2O_2Cl_2$ by Powder X-ray Diffraction: Isolated Hg_4O_4 Squares**

William T. A. Harrison,* Lumei Liu, and Allan J. Jacobson

A great deal of work has been recently been reported on layered, high-T_c, mercury-based superconductors,[1-4] all of which contain isolated, linear O-Hg^{II}-O "dumbbell" units. During our own synthetic investigations of barium- and mercury-based phases, we observed the formation of $BaHg_2O_2Cl_2$ **1**, the new phase described below. Single crystals of $BaHg_2O_2Cl_2$ could not be synthesized under the reaction conditions employed, but the structure[5] was determined by ab initio methods from medium-resolution laboratory powder X-ray diffraction data.[6] This phase, which contains isolated squares of Hg_4O_4 units, is the first well-characterized barium mercury oxide chloride.

The structure of **1** (Table 1, Fig. 1) is built up from distorted squares of alternating mercury and oxygen atoms. The Hg atoms occupy the sides of the squares, and the O atoms the corners: d(Hg–O) = 2.03(3) Å and 2.09(4) Å; θ(O-Hg-O) = 169.0(2)°; θ(Hg-O-Hg) = 101.1(2)°. These perfectly flat Hg_4O_4 units are aligned in the *ab* plane. Four long Hg–Cl bonds (d > 3.03 Å) to two Cl(2) and two Cl(3) atoms complete a grossly squashed HgO_2Cl_4 octahedron. Four of these distorted octahedra share edges [through two Cl(3) atoms] and faces [through one O(1) and two Cl(3) atoms]. They are bonded into infinite columns in the *c*-direction through the Cl(3) atoms (Fig. 2), which are bonded to eight Hg atoms in elongated cubic coordination. The columns are crosslinked in the *ab* plane by Cl(2) atoms, which bond to four Hg atoms and one Ba atom in square-pyramidal geometry (apical atom Ba). The minimum Hg–Hg separation is 3.182(4) Å, across the corner of the Hg_4O_4 square.

Table 1. Atomic position parameters for **1**.

Atom	W [a]	x	y	z	U_{iso} [Å^2]
Hg(1)	8*j*	0.5789(3)	0.3272(3)	1/2	0.0078 [b]
Ba(1)	4*g*	0.3648(4)	0.1352	0	0.0084 [b]
Cl(1)	2*c*	1/2	0	1/2	0.02(1)
Cl(2)	4*g*	0.673(2)	0.172	0	0.014(6)
Cl(3)	2*a*	0	0	0	0.002(80)
O(1)	8*j*	0.228(3)	0.089(3)	1/2	0.001(100)

[a] Wyckoff letter from International tables. [b] U_{eq} [Å^2] = $\frac{1}{3}\sum_i\sum_j U_{ij} a_i^* a_j^* \mathbf{a}_i \mathbf{a}_j$.

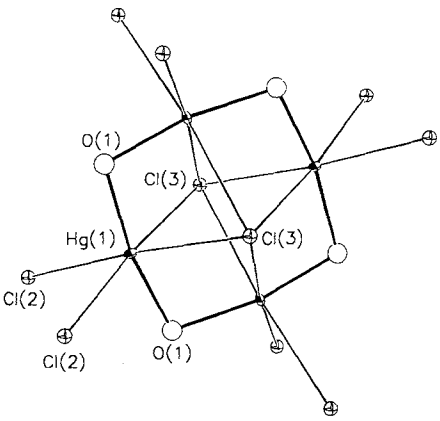

Fig. 2. Detail of the structure of **1** showing an Hg_4O_4 square.

The Ba(1) and Cl(1) atoms complete the $BaHg_2O_2Cl_2$ structure; Ba(1) coordinates to three Cl atoms and four O atoms (Fig. 3, Table 2) in capped trigonal-prismatic geometry [d(Ba–Cl) = 3.119(4)–3.22(2) Å; d(Ba–O) = 2.74(2) Å]. As a result the bond angles at O(1), which is surrounded by two Ba and two Hg atoms, are fairly close to those of a regular tetrahedron, despite the gross disparity in Ba–O and Hg–O bond lengths. Finally, the Cl(1) atom (square-planar coordination) bonds to four adjacent Ba atoms. If these Ba, O, and Cl atoms were considered in isolation, then a pattern of isolated double "fishbones" propagating along the *c*-direction would result.

Assuming the usual oxidation states of barium, chlorine, and oxygen, charge balancing requires that all the mercury atoms in **1** are present as Hg^{II}. Thus, we may assume that all the Hg^{I} centers in the Hg_2Cl_2 starting material have been oxidized to Hg^{II} by the barium peroxide. This electroneutrality requirement for Hg^{II} is consistent with the presence of the pseudo-linear O-Hg-O units in $BaHg_2O_2Cl_2$ and the minimum Hg–Hg separation (3.182 Å). Phases containing Hg^{I} have a typical minimum Hg–Hg separation of roughly 2.5 Å,[7] which is much less than the distance of 3.18 Å observed in **1**. Assuming that **1** contains solely Hg^{II}, the isolated Hg_4O_4 units are formally electronically neutral.

The isolated Hg_4O_4 squares in **1** are unique in mercury(II)-containing systems. Many mercury/oxygen-containing phases such as $BaHgO_2$,[3] $CdHgO_2$,[8] and the superconductor phases noted above contain isolated dumbbell-shaped $O\text{-}Hg^{II}\text{-}O$ groups, in which the oxygen atoms are associated with only one nearby mercury cation. Other Hg^{II}/O-containing phases such as $Hg(OHg)_4Br_2$[9] contain infinite chains of alternating mercury and oxygen atoms as $[\text{-O-Hg-}]_\infty$ units, in which each oxygen atom is associated with two nearby Hg^{II} neighbors. $Hg_6O_4Cl_4$[10] contains also contains $[\text{-O-Hg-}]_\infty$ units, but they are linked into double chains, which involves some three-coordinate (to Hg) oxygen atoms. The recently reported phase $Hg_3O_2CrO_4$[11] contains novel, infinite sheets of edge-sharing six-rings of mercury(II) and oxygen (two-coordinate Hg, three-coordinate O), which surround isolated $[Cr^{VI}O_4]^{2-}$ tetrahedra.

In summary, the new phase $BaHg_2O_2Cl_2$ **1** has been prepared and structurally characterized from powder X-ray diffraction data. The precision of the refined atomic parameters is quite satisfactory, based on the X-ray powder refinement. The thermal factors for Cl(3) and O(1) are small, but their uncertainties are large. The crystal chemistry of **1** is consistent with the presence of solely Hg^{2+} centers in this phase. Novel Hg_4O_4 squares are present in $BaHg_2O_2Cl_2$.

Experimental Procedure

$BaHg_2O_2Cl_2$ was synthesized by the reaction of BaO_2 and Hg_2Cl_2 in the mole ratio 2:3. The reactants were intimately mixed and then sealed in a Pyrex tube under vacuum (10^{-3} Torr), which was then heated to 360 °C for three days. After reaction, one end of the tube was cooled to ambient temperature and the excess Hg_2Cl_2 removed by sublimation. The pure $BaHg_2O_2Cl_2$ product was recovered as an ivory-colored, microcrystalline powder, which yielded a powder X-ray diffraction pattern unlike those of the starting materials or known Hg/Ba phases. X-ray microanalysis (EDAX) indicated an approximate Ba:Hg:Cl ratio of 1:2:2.

The crystal structure of $BaHg_2O_2Cl_2$ was determined ab initio from laboratory X-ray powder diffraction data (Scintag automated diffractometer, $Cu_{K\alpha}$ radiation; $\lambda = 1.5418$ Å). The primitive tetragonal powder pattern of $BaHg_2O_2Cl_2$ was indexed using TREOR90, and possible space groups were determined by inspection. Starting positions for Ba, Hg, and two Cl atoms in space group *P4/mbm* (No. 127) were determined by using the direct methods program SIRPOW90. These initial atomic positions were optimized by Rietveld refinement (program GSAS) against powder X-ray data. The other atoms (one Cl, one O) were easily found from difference Fourier syntheses and added to the model. Refinement of 30 profile and atomic parameters converged to final residuals of $R_p = 0.097$, $R_{wp} = 0.138$, $R_{F^2} = 0.0621$, and $\chi^2 = 1.77$. The final Rietveld profiles are shown in Figure 4.

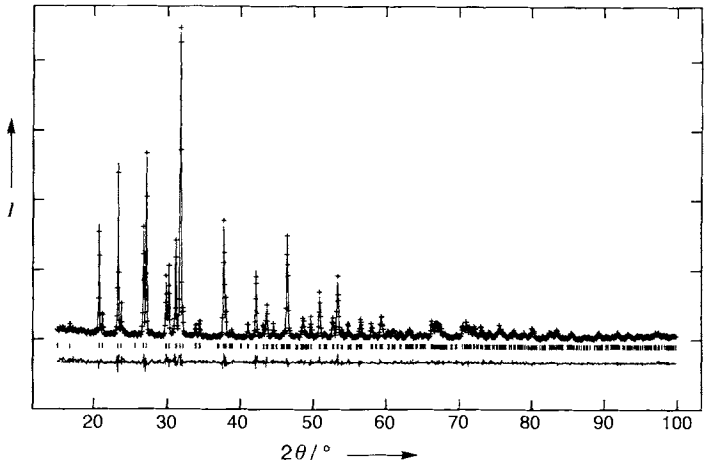

Fig. 4. Final observed (crosses), calculated (line), and difference profiles for the Rietveld refinement of **1**. Allowed reflection positions are indicated by tick marks.

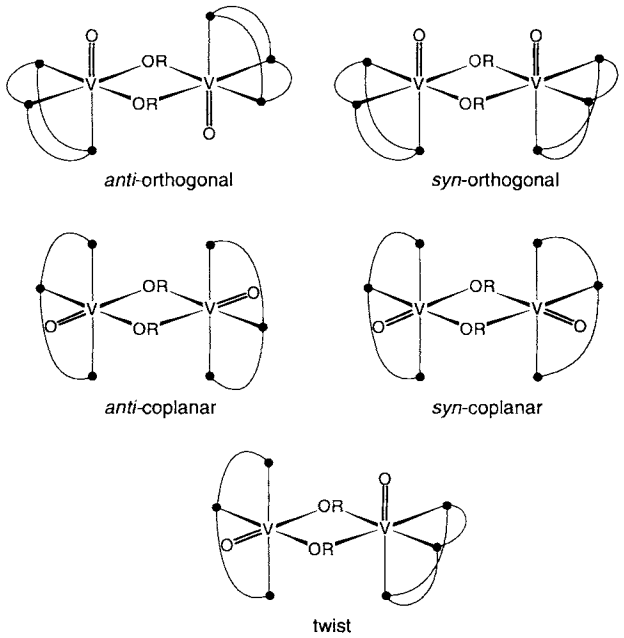
Magneto-Structural Correlations in Dinuclear d^1-d^1 Complexes: Structure and Magnetochemistry of Two Ferromagnetically Coupled Vanadium(IV) Dimers**

Winfried Plass*

The magnetic properties of molecular compounds have attracted considerable interest in recent years because of their relevance for the understanding of magnetically coupled active sites in metalloproteins as well as their potential applications as magnetic materials.[1] An important aspect of this research area is devoted to magneto-structural correlations. For some dinuclear systems it was possible to establish quantitative magneto-structural relationships,[2] among which the dihydroxo-bridged dicopper(II) complexes (d^9–d^9) are the most thoroughly investigated examples. However, little is known about other systems containing transition metal centers with an $S = 1/2$ ground state, in particular, well-characterized dinuclear oxovanadium(IV) complexes for which a structural-magnetic correlation has been established are rather rare.[3, 4]

For dimeric oxovanadium(IV) complexes only two arrangements are reported to yield a ferromagnetic interaction, namely a series of tartrate complexes[3a–d] composed of two square pyramidal coordinated oxovanadium(IV) centers bridged through the carbon backbone of the ligands and a fluoride-bridged complex containing two octahedrally coordinated oxovanadium(IV) centers.[3e] A common feature of both structure types is the almost linear arrangement of the two oxovanadium(IV) groups in an antiparallel orientation. As a consequence the two magnetic orbitals (d_{xy}) are more or less perpendicular to the dimer axis. In contrast, all other reported dimeric oxovanadium(IV) complexes exhibit an antiferromagnetic exchange interaction.[4, 5]

In this context the question arises whether it is possible to design ligand environments to introduce specific magnetic properties to dinuclear d^1–d^1 systems containing two oxovanadium(IV) centers. This can be achieved most easily for a dinuclear system composed of two octahedrally coordinated oxovanadium(IV) centers bridged by one shared edge leading to the formation of a $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core, since the three remaining coordination sites—with either facial or meridional arrangement—can be blocked at each center by chelating ligands which force the two oxo groups into specific configurations as shown in Scheme 1. The resulting classification is not limited to octahedrally coordinated oxovanadium(IV) centers but is also applicable to dimers containing centers with a square pyramidal coordination environment, although the missing donor atom in the *trans* position to the oxo group at the vanadium(IV) center restricts the possible arrangements to the *syn*- and *anti*-orthogonal as well as the twist configuration (cf. Scheme 1). Hitherto, structurally and magnetically characterized examples of dimeric vanadium(IV) complexes containing a $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core have only been reported for the two orthogonal configurations depicted in Scheme 1.[4a–e]



Scheme 1. Possible configurations of a $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core in complexes consisting of two edge-sharing octahedrally coordinated oxovanadium(IV) centers. The configurations are classified according the orientation of the V=O groups with respect to the plane defined by the two vanadium centers and the two bridging oxygen atoms (orthogonal, coplanar, twist) and the orientation of the two V=O groups (*syn*, *anti*).

By utilizing the trivalent, pentadentate Schiff base ligand *N*-salicyclidene-2-(bis(2-hydroxyethyl)amino)ethylamine (H_3sabhea) it has now been possible to synthesize the first examples of dimeric vanadium(IV) complexes with an *anti*-coplanar and a twist configuration, **1** and **2**, respectively. The reaction

$[\{VO(Hsabhea)\}_2]$ **1**

$[\{VO(Hsabhea)\}\{VO(acac)(HOMe)\}(\mu_2\text{-}OMe)]$ **2**

of $[VO(acac)_2]$ (Hacac = 2,4-pentanedione) with H_3sabhea in chloroform yields the neutral complex **1** as a green microcrystalline solid which is insoluble in most organic solvents.[6] Complex **1** is only sparingly soluble in hot *N*,*N*-dimethylformamide (DMF) and completely reprecipitates at temperatures below 90 °C. These solubility properties, which are also observed for other N,O chelating ligands,[5a, 8] are probably why only one X-ray crystallographically characterized neutral oxovanadium(IV) complex with an amino alcohol ligand has been reported.[4c] When the reaction was performed in methanol, however,

The two halves of the molecule are related by a crystallographic inversion center (indicated by the letter a in the atomic numbering scheme). Thermal ellipsoids of the non-hydrogen atoms are drawn at the 50% probability level. Pertinent bond lengths [pm] and angles [°]: V–O1 162.6(2), V–O2 193.8(2), V–O3 207.9(2), V–O3a 203.6(2), V–N1 212.1(2), V–N2 227.1(2); O1-V-O2 104.98(9), O1-V-O3 159.29(8), O1-V-O3a 96.03(8), O1-V-N1 94.91(9), O1-V-N2 89.51(9), O3-V-O3a 73.03(7). Bottom: Representation of the chains parallel to the [010] axis formed by the association of **1** (only the chain formed by one enantiomer is shown) through hydrogen bonding to methanol molecules (O5) in crystals of **1** · 2 MeOH. Relevant distances: O4–O5 277.7, O5–O1 275.0 pm.

meridional orientation for three donor sets of the H_3sabhea ligand (N1, N2, and O2; see Fig. 1 top and Fig. 2 top) provides the necessary condition for the formation of either a coplanar or twist configuration. In addition the deprotonated oxygen atom of one of the hydroxyethyl groups (O3) is coordinated to the oxovanadium(IV) center thereby generating a {VO(Hsabhea)} fragment with a five-coordinate vanadium center, which in the case of **1** is dimerized to give centrosymmetric molecular structure with O3 and O3a in the μ_2-bridging positions. In **2** the {VO(Hsabhea)} fragment (V1) is linked to a $\{VO(acac)(HOMe)\}^+$ fragment (V2) through the oxygen atom O3 of the former and an additional coordinating methoxide (O5). The observed *anti* configuration for the V=O group of the latter fragment (V2) and the phenolate oxygen (O2) at the $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core is favored by the formation of an intramolecular hydrogen bond between O2 and O7 (see Fig. 2). The different configuration of the $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core found for **1**

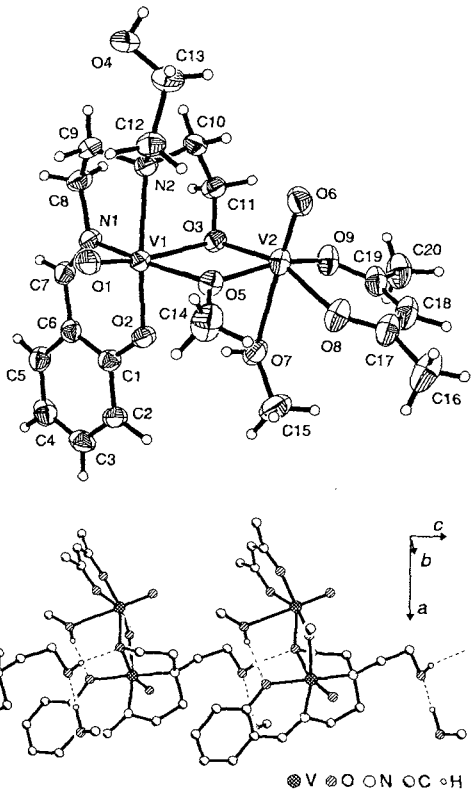

Fig. 2. Top: Molecular structure of the neutral complex **2** in crystals of **2** · MeOH. Thermal ellipsoids of the non-hydrogen atoms are drawn at the 50% probability level. Pertinent bond lengths [pm] and angles [°]: V1–O1 160.6(2), V1–O2 196.0(2), V1–O3 216.3(2), V1–O5 201.2(2), V1–N1 207.5(3), V1–N2 222.9(3), V2–O6 159.9(3), V2-O3 201.4(2), V2-O5 197.2(2), V2-O7 245.7(3), V2-O8 199.5(3), V2-O9 198.9(3); O1-V1-O2 106.12(11), O1-V1-O3 163.91(10), O1-V1-O5 99.07(11), O1-V1-N1 97.66(12), O1-V1-N2 91.69(11), O3-V1-O5 73.35(9), O3-V2-O6 104.00(12), O5-V2-O6 101.13(12), O6-V2-O7 177.46(12), O6-V2-O8 99.41(13), O6-V2-O9 99.40(13), O3-V2-O5 77.55(9), V1-O3-V2 101.01(9), V1-O5-V2 108.02(10). Bottom: Representation of the chains parallel to the [001] axis formed by the association of **2** through hydrogen bonding in crystals of **2** · MeOH (the methanol molecule (O10) forms a terminal hydrogen bond). Relevant distances: O3–O4 276.1 (intermolecular, chain), O2–O7 267.5 (intramolecular), O4–O10 276.7 pm.

and **2** and the asymmetric structure of the latter are consistent with the vibrational spectra observed for **1** · 2 MeOH and **2** · MeOH.[11] The neutral complexes **1** and **2** form hydrogen-bridged chains in crystals of **1** · 2 MeOH (see Fig. 1 bottom; for **1** · MeOH cf. ref. [10]) and **2** · MeOH (see Fig. 2 bottom) due to the pendant hydroxyethyl group of the constituent {VO(Hsabhea)} fragment. The presence of both intra- and intermolecular hydrogen bonds in **2** · MeOH is consistent with the observation of two bands at distinctively different energies for the ν(OH) stretching vibrations in the IR spectrum.[11]

The X-band ESR powder spectra of **1** · 2 MeOH and **2** · MeOH recorded at room temperature show broad structured bands with no detectable hyperfine structure at $g = 1.984$ (peak to peak separation: 20 mT, total width: 200 mT, shoulders at 294 and 395 mT) and $g = 1.989$ (peak to peak separation: 50 mT, total width: 250 mT, shoulders at 269 and 423 mT, and two small additional signals at 210 and 500 mT), respectively, and a band at half-field from the forbidden $\Delta m_s = 2$ transition at approximately 160 mT. The spectral data are consistent with an $S = 1$ spin system that exhibits a small zero-field splitting, as typically observed for other dimeric vanadium(IV) compounds with intramolecular interactions.[12] In addition no marked temperature dependence of the ESR spectra was detected, and even at 5 K the signals did not lose intensity; only the width of the band observed for **1** · 2 MeOH decreased by about 20 mT.

These observations are indicative of intramolecular ferromagnetic interactions in the exchange-coupled d^1-d^1 systems of **1** and **2** and thus of a triplet ground state.

The magnetic susceptibility χ of polycrystalline samples of **1** · 2MeOH and **2** · MeOH was measured in a temperature range of 4–250 K with a SQUID magnetometer with an applied field of $H = 10$ kOe. The temperature dependence of the product $\chi_M T$ is shown in Figure 3. At temperatures above 150 K

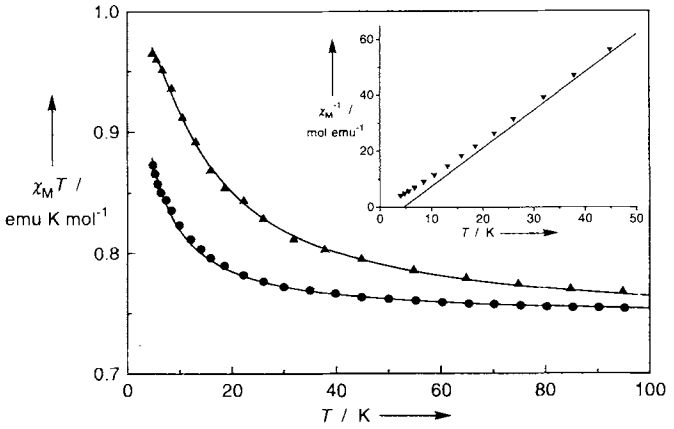

Fig. 3. Temperature dependence of the product of the molar magnetic susceptibility with temperature for **1** · 2MeOH (exp., ●) and **2** · MeOH (exp., ▲). The solid lines represent the calculated values (see text). The inset shows χ_M^{-1} vs temperature for **2** · MeOH, yielding a Curie–Weiss temperature of 4.6 K (for **1** · 2MeOH a Curie–Weiss temperature of 1.3 K is obtained).

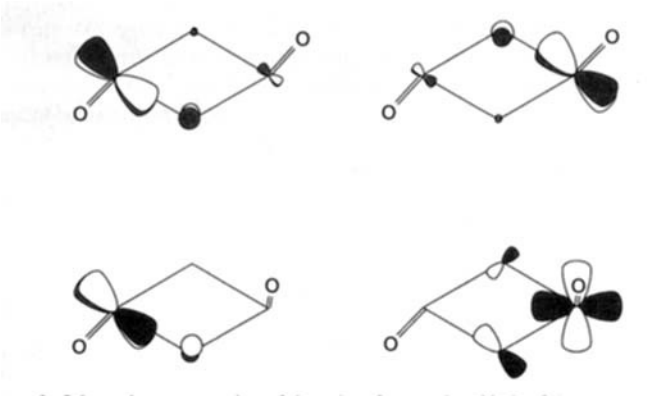
the susceptibility data obeys the Curie–Weiss law (see inset in Fig. 3), and $\chi_M T$ is close to the expected spin-only value for two independent vanadium(IV) centers per molecule. The observed increase of $\chi_M T$ upon cooling is in accord with intramolecular ferromagnetic interactions in the oxovanadium(IV) dimers **1** and **2**. A quantitative analysis of the susceptibility data (corrected for diamagnetic contributions by using Pascal constants) under the assumption of an isotropic interaction by using the Heisenberg–Dirac–Van Vleck Hamiltonian $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$[1d] was used to describe the temperature dependence of the product $\chi_M T$. As shown in Figure 3, good fits to the experimental data were attained for the magnetic parameters $g = 1.99$ and $J = +3.1$ cm^{-1} for **1** · 2MeOH and $g = 1.98$ and $J = +10.6$ cm^{-1} for **2** · MeOH.[13]

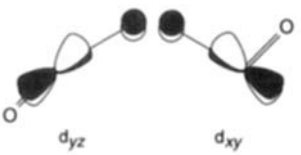
Density functional calculations using the broken-symmetry formalism were performed for the neutral complexes **1** and **2**.[14] The comparison of the results obtained by restricted and unrestricted Hartree–Fock–Slater (RHFS and UHFS, respectively) calculations as well as the fact that the magnetic orbitals based on broken-symmetry UHFS calculations are largely localized (see Scheme 2) indicate the presence of weak interactions between the two vanadium(IV) centers. For such weakly interacting dimers (i.e. $S_{ab}^2 \ll 1$; S_{ab} is the overlap integral between the magnetic orbitals) spin-projection techniques within the broken-symmetry formalism allow the isotropic interaction parameter to be determined according to $J = 2[E_B - E(S=1)]$,[15] where E_B is the energy of the broken-symmetry state. The calculated singlet–triplet splittings of +46 and +65 cm^{-1} for **1** and **2**, respectively, although somewhat too large when compared to the experimental values, are in line with their observed ferromagnetic behavior.

A qualitative interpretation of the magnetic interactions in transition metal dimers is usually given by the well-known



Scheme 2. Schematic representation of the pairs of magnetic orbitals of the complexes **1** (top) and **2** (bottom) derived from broken-symmetry density functional calculations. (Only contributions from atoms of the $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core are depicted.)

Goodenough–Kanamori rules,[16] which are based on the interaction between pairs of natural magnetic orbitals. Since the unpaired electron in oxovanadium(IV) complexes generally resides in a metal-centered orbital with d_{xy} character (with the oxo group oriented along the z axis), the five configurations outlined in Scheme 1 impose specific interactions between the corresponding magnetic orbitals. For the two orthogonal configurations either a direct interaction or a superexchange mechanism between the magnetic orbitals can be expected to be operative, yielding rather strong antiferromagnetic coupling. In fact this is in agreement with the observed magnetic behavior of all compounds reported to possess such a core configuration.[4a–e] Although a dinuclear complex with a *syn*-coplanar configuration has not yet been synthesized, similar orbital interactions are possible and suggest that such dimers should also exhibit antiferromagnetic coupling. The situation is different for the *anti*-coplanar and twist configuration where neither a direct interaction nor a superexchange mechanism can be effective. In general, ferromagnetic interactions are expected if the magnetic orbitals are orthogonal. Such orthogonality may be strict—in the sense that it is imposed by symmetry—as observed for some copper-containing heterodinuclear complexes,[17] or accidental as found for several dimeric copper(II) and nickel(II) complexes.[18] For the twist configuration a case of accidental orthogonality can be expected, which is in accord with the observed ferromagnetic coupling for **2** and the magnetic orbitals obtained from broken-symmetry UHFS calculations (see Scheme 2). Whereas for complexes with *anti*-coplanar configuration such as **1**, the accidental orthogonality (cf. Scheme 2) is certainly dependent on the structural parameters of the $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core and, moreover, the overlap between the two magnetic orbitals is expected to be rather small. Therefore an alternative mechanism might be invoked to explain the ferromagnetic coupling. Such a mechanism might be the "crossed interaction" between singly occupied and empty orbitals at either transition metal center, a mechanism that has already been used to justify the ferromagnetic interaction observed for some manganese(III)-containing dimeric complexes.[19] A possible crossed pathway for an *anti*-coplanar configuration of the $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core is depicted in Scheme 3.



Scheme 3. Sketch of the interaction between a singly occupied d_{xy} atomic orbital and an empty d_{yz} atomic orbital located at the vanadium centers in an *anti*-coplanar arrangement as found in **1**. The interaction is mediated by the p_y atomic orbital of the bridging oxygen towards which both d atomic orbitals are delocalized.

The neutral complexes **1** and **2** are the first edge-sharing octahedral oxovanadium(IV) dimers that exhibit ferromagnetic interactions between the metal centers. These examples show that it is possible to enforce specific magnetic properties on such systems through the choice of ligand employed. Furthermore, the correlation between the structure of a $\{VO(\mu_2\text{-}OR)_2VO\}^{2+}$ core and the related magnetic properties has been demonstrated. Consequently this magneto-structural correlation facilitates the differentiation between configurational arrangements in corresponding dimeric complexes and, moreover, allows the interpretation of magnetic interactions in larger vanadium(IV) clusters with similar structural features.

Experimental Procedure

The syntheses were carried out under an argon atmosphere using Schlenk line techniques, and the solvents were purified prior to use. The ligand H_3sabhea was synthesized as described previously [7].

1: H_3sabhea (1.00 g, 4.0 mmol) dissolved in $CHCl_3$ (15 mL) was added to a solution of $[VO(acac)_2]$ (1.02 g, 4.0 mmol) in $CHCl_3$ (50 mL) at room temperature. After the addition a green precipitate was observed and the resulting suspension was stirred for 12 h (or alternatively heated to reflux for 1 h) to complete the reaction. The green microcrystalline solid **1** was isolated by filtration, washed twice with $CHCl_3$, and dried in vacuo (2.05 g, 85%). Analysis for $C_{26}H_{36}N_4O_8V_2$: calcd: C, 49.22; H, 5.72; N, 8.83; found: C, 49.38; H, 5.81; N, 8.69.

1 · MeOH and **1** · 2MeOH: A solution of H_3sabhea (1.80 g, 7.2 mmol) in methanol (5 mL) was added to $[VO(acac)_2]$ (0.37 g, 1.4 mmol) dissolved in methanol (10 mL). The resulting deep green solution was allowed to stand at room temperature. After 2–3 d green crystals of **1** · MeOH (plates) and **1** · 2MeOH (prisms) began to grow and could be harvested after two weeks to yield a total amount of 0.25 g (80%). The crystals of **1** · MeOH and **1** · 2MeOH could be separated by hand according their shape and were obtained approximately in a 1:1 ratio. Analysis for $C_{28}H_{44}N_4O_{10}V_2$ (**1** · 2MeOH): calcd: C, 48.14; H 6.35; N, 8.02; found: C, 47.98; H, 6.39; N, 8.15. Analysis for $C_{27}H_{40}N_4O_9V_2$ (**1** · MeOH): calcd: C, 48.66; H, 6.05; N, 8.41; found: C, 48.72; H, 6.13; N, 8.45.

2 · MeOH: To a solution of $[VO(acac)_2]$ (1.24 g, 4.7 mmol) in methanol (20 mL) was added H_3sabhea (0.60 g, 2.3 mmol) dissolved in methanol (5 mL). After the mixture had been allowed to stand at room temperature for 3–4 d dark brownish green (almost black) crystals of **2** · MeOH formed. After a period of two weeks the crystals of **2** · MeOH were collected by filtration to yield 0.43 g (32%). Analysis for $C_{21}H_{36}N_2O_{10}V_2$: calcd: C, 43.61 H, 6.27; N, 4.84; found: C, 43.90; H, 6.31, N, 4.84.

[9] Data for crystal structure analyses: a) **1** · 2MeOH: $C_{28}H_{44}N_4O_{10}V_2$, M = 698.6, crystal dimensions 0.2 × 0.3 × 0.4 mm, monoclinic, $P2_1/c$, a = 1102.5(3), b = 1009.6(3), c = 1407.9(3) pm, β = 95.22(2)°, V = 1.5606(7) nm^3, Z = 2, ρ_{calcd} = 1.487 g cm^{-3}, $F(000)$ = 732, T = 188 K, λ = 71.073 pm, $\mu(Mo_{K\alpha})$ = 0.660 mm^{-1}, ω-scan, range $4 < 2\theta < 54°$, 3721 measured, 3389 independent (R_{int} = 0.028), 3381 used reflections, 276 parameters, $R1(F > 4\sigma(F))$ = 0.045, $wR2$ = 0.121 (all data). b) **1** · MeOH: $C_{27}H_{40}N_4O_9V_2$, M = 666.5, crystal dimensions 0.1 × 0.3 × 0.4 mm, monoclinic, $P2_1/c$, a = 2049.9(3), b = 978.5(2), c = 1423.0(3) pm, β = 92.14(1)°, V = 2.8523(9) nm^3, Z = 4, ρ_{calcd} = 1.552 g cm^{-3}, $F(000)$ = 1392, T = 188 K, λ = 71.073 pm, $\mu(Mo_{K\alpha})$ = 0.716 mm^{-1}, ω-scan, range $4 < 2\theta < 50°$, 4402 measured, 4025 independent (R_{int} = 0.021), 4010 used reflections, 383 parameters, $R1(F > 4\sigma(F))$ = 0.086, $wR2$ = 0.240 (all data). c) **2** · MeOH: $C_{21}H_{36}N_2O_{10}V_2$, M = 578.4, crystal dimensions 0.3 × 0.4 × 0.6 mm, monoclinic, $C2/c$, a = 4056.7(6), b = 854.2(2), c = 1514.8(3) pm, β = 90.30(2)°, V = 5.249(2) nm^3, Z = 8, ρ_{calcd} = 1.464 g cm^{-3}, $F(000)$ = 2416, T = 188 K, λ = 71.073 pm, $\mu(Mo_{K\alpha})$ = 0.766 mm^{-1}, ω-scan, range $4 < 2\theta < 54°$, 6039 measured, 5700 independent (R_{int} = 0.040), 5677 used reflections, 404 parameters, $R1(F > 4\sigma(F))$ = 0.057, $wR2$ = 0.157 (all data). Instrumentation and conditions: The data were collected on a Siemens R3m/V diffractometer by using graphite-monochromated $Mo_{K\alpha}$ radiation. Lorentz and polarization corrections were applied to the data. An absorption correction based on azimuthal Ψ scans was made for **1** · 2MeOH and **2** · MeOH. The structures were solved by direct methods (SHELXTL PLUS); full-matrix least-squares refinement of the function $\Sigma w(F_o^2 - F_c^2)^2$ (G. M. Sheldrick, SHELXL-93, Universität Göttingen, **1993**). For **1** · 2MeOH and **2** · MeOH the hydrogen atoms of the CH_3 groups were refined by using a rotating group model, whereas all other hydrogen atoms were located from the difference fourier map and refined isotropically. For **1** · MeOH all hydrogen atoms were refined by using the appropriate riding model. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository numbers CSD-404246 (**1** · 2MeOH), CSD-404247 (**1** · MeOH), and CSD-404248 (**2** · MeOH).

[10] The neutral complex **1** is isolated in two different crystalline compounds **1** · 2MeOH and **1** · MeOH [9]. The structural parameters of the two symmetry-independent molecules of **1** in **1** · MeOH are, within the uncertainty limits, the same as those observed in crystals of **1** · 2MeOH (see legend to Fig. 1). Differences are observed for the packing of **1** in both crystal structures. In **1** · 2MeOH all molecules of **1** are involved in the formation of chains along the [010] direction through hydrogen bonding through methanol molecules (see Fig. 1 bottom), whereas in **1** · MeOH only one of the two independent molecules forms such hydrogen-bonded chains along the [010] direction.

[11] Additional characteristic physical data: for **1** · 2MeOH: IR (Nujol mull): $\tilde{\nu}$ = 3430 (m, br, ν(OH)), 1629 (vs, ν(C=N)), 921 cm^{-1} (vs, ν(V=O)); Raman (λ_e = 514.5 nm): 1630 (vs, ν(C=N)), 922 cm^{-1} (s, ν(V=O)); Vis (solid-state reflection) and NIR (KBr pellet, transmission): 20800 (sh), 16400, 11900 cm^{-1}; for **2** · MeOH: IR (Nujol mull): 3410 (m, br, ν(OH)), 3240 (m, br, ν(OH)), 1632 (vs, ν(C=N)), 972 (vs, ν(V=O), V2 see Fig. 2 top), 955 cm^{-1} (vs, ν(V=O), V1 see Fig. 2 top); Raman (λ_e = 514.5 nm): 1631 (vs, ν(C=N)), 971 (w, ν(V=O), V2), 952 cm^{-1} (w, ν(V=O), V1); Vis (solid-state reflection) and NIR (KBr pellet, transmission): ν = 21300 (sh), 17500, 13500 (sh), 11100 cm^{-1}.

Mabbs, D. Collison, *Electron Paramagnetic Resonance of d Transition Metal Compounds*, Elsevier, Amsterdam, **1992**.

[13] If in addition intermolecular interactions are taken into account in the numerical analysis of the susceptibility data of **1** · 2MeOH and **1** · MeOH according to the equation

$$\chi_M = 2Ng^2\beta^2\left[kT - \frac{2zJ'}{3 + \exp(-J/kT)}\right]^{-1}\,[3 + \exp(-J/kT)]^{-1}$$

(A. P. Ginsberg, M. E. Lines, *Inorg. Chem.* **1972**, *11*, 2289), the following parameters are obtained: g = 1.99, J = +3.8 cm^{-1}, and zJ' = −0.15 cm^{-1} for **1** · 2MeOH and g = 1.99, J = +11.1 cm^{-1}, and zJ' = −0.06 cm^{-1} for **2** · MeOH. According to the rather small intermolecular exchange parameters zJ', magnetic interactions between dimers in **1** · 2MeOH and **1** · MeOH seem not to play an important role.

$[\{Na^+(thf)_2\}_4(rubrene^{4-})]$: Crystallization and Structure Determination of a Contact-Ion Quintuple for the First π-Hydrocarbon Tetraanion**

Hans Bock,* Katayoun Gharagozloo-Hubmann, Christian Näther, Norbert Nagel, and Zdenek Havlas

Dedicated to Professor Herbert W. Roesky on the occasion of his 60th birthday

The insertion of electrons into π-hydrocarbons C_xH_y releases less energy than is needed for electron expulsion, and within the total energy scale for the molecular states, the resulting molecular anions $[C_xH_y]^{n-}$ are located below the ground state of the uncharged molecule,[1] in contrast to the molecular cations $[C_xH_y]^{n+}$. Single-electron reductions generate radical anion salts, which can be either solvent-separated $[Met^+_{solv}][C_xH_y]^{\bullet -}$ or solvent-shared contact ion pairs $[Met^+(C_xH_y)^{\bullet -}]_{solv}$, and the structural changes upon transition from the neutral molecule to the radical anion are only small.[1, 2] In contrast, two electron reductions to either solvent-separated or solvent-shared contact ion triples $[Met^+_{solv}]_2[C_xH_y]^{2-}$ or $[Met_2^+(C_xH_y)^{2-}]_{solv}$ usually cause severe structural distortions.[1] For instance, in ethylene derivatives $R_2C{=}CR_2$, on reduction of the neutral molecule to the dianion the double bond is stretched to a single one, around which the two molecular halves twist;[1] allenes $R_2C{=}C{=}CR_2$ are folded at their central C center and protonated;[1] and six-membered benzene rings can be deformed into a "boat" conformation.[4] Although up to four consecutive reversible one-electron oxidations are observed in cyclic voltammetric studies,[1] a single-electron reduction of benzene can be achieved only under extremely aprotic conditions at the potential range limit. Extensive Chemical Abstracts Service (CAS) and Cambridge Structural Database searches gave no hint of known structures of π-hydrocarbon trianions or tetraanions.[6]

Much to our surprise, therefore, the structure determination of the product of rubrene reduction at a sodium metal mirror[7] proved the existence of the first π-hydrocarbon tetraanion (Fig. 1).

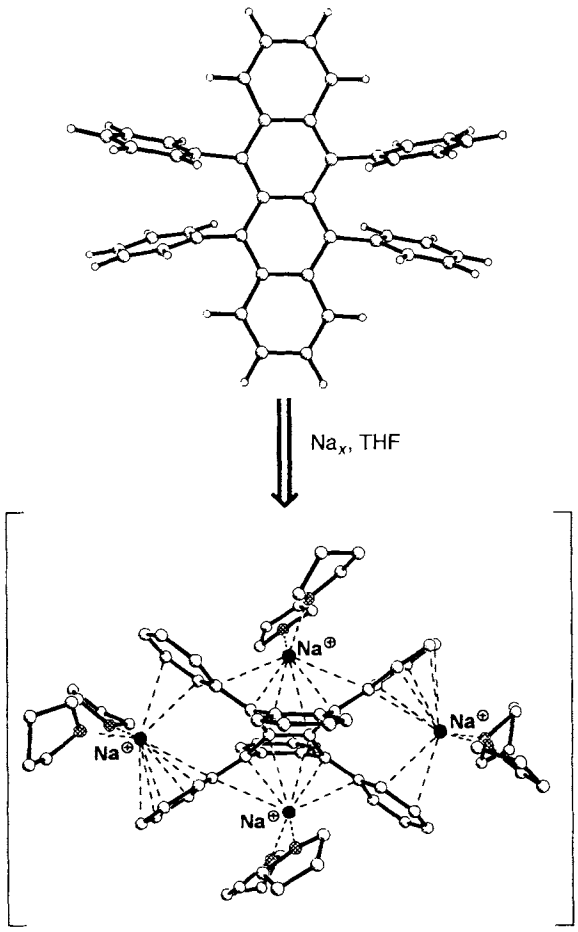

Fig. 1. Structural changes on the fourfold reduction of rubrene at a sodium metal mirror to form the contact-ion quintuple of its tetraanion.

In the tetrakis[bis(tetrahydrofuran)sodium]-5,6,11,12-tetraphenyltetracene (triclinic, $P\bar{1}$, $Z = 1$), the four Na^+ countercations, each doubly solvated by THF, are located in two different positions: either above and below the central tetracene skeleton or between the peripheral bis(phenyl) pincers. The central Na^+ ions are eightfold coordinated with shortest $Na^+ \cdots C^{\delta -}$ contacts of between 260 and 263 to the two phenyl-substituted carbon centers and longer ones of 272 pm to the tetracene carbon centers. Other contacts, namely to the *ipso* centers of the two phenyl rings that face each other, exceed 290 pm. The $Na^+ \cdots O_{THF}$ contacts of 227 pm are short.[8] The peripheral Na^+ centers exhibit a higher coordination number of 10: one of the C_6 rings is η^6-coordinated and the other one only η^2, because the spatial arrangement of the phenyl substituents of the tetracene does not allow a symmetrical dibenzene sodium sandwich.[1] The contact distances $Na^+ \cdots C^{\delta -}$ range from 277 to 293 pm for the η^6-coordinated ring and from 275 to 284 pm for the η^2 one.

The incorporation of four electrons into rubrene, the tetracene skeleton of which is planar,[9] causes drastic structural

[**] Interactions in Crystals, Part 100. This project has been supported by the Adolf-Messer-Stiftung, the Deutschen Forschungsgemeinschaft, the State of Hesse (Germany), and the Fonds der Chemischen Industrie. Part 99: H. Bock, C. Näther, N. Nagel, *Angew. Chem.* and *Angew. Chem. Int. Ed. Engl.*, submitted.

distortions: The tetraanion is bent at the phenyl substitution centers 5/12 and 6/11, in each case by 43°(!) (Fig. 2, top). Numerous short bonds are elongated and long ones shortened (Fig. 2, bottom). In detail, the central CC bond length in the

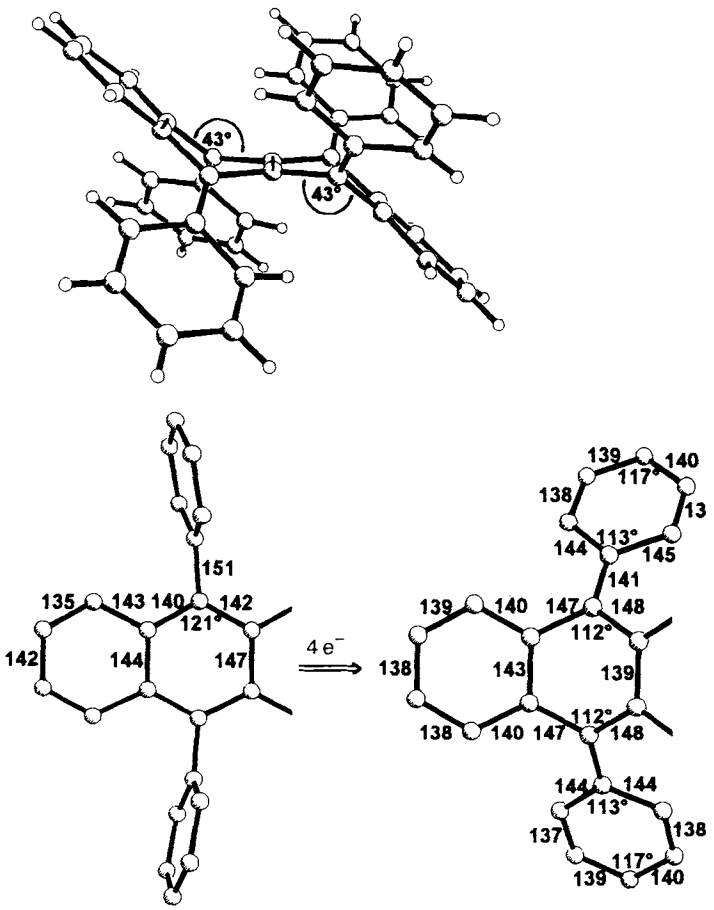

Fig. 2. Molecular structure of the rubrene tetraanion. Top: side view. Bottom: comparison with rubrene.

tetraanion is cut by 8 pm(!) from 147 to 139 pm, and the four adjacent CC bonds are increased by 6 pm(!) from 142 to 148 pm. Both bent six-membered rings exhibit record angle compressions from 121 to 112°(!), which together with the quinoid ring distortions—the CC bond connecting the rings is shortened from 151 pm by 10 pm(!) to 141 pm, and the *ipso* angle reduced to 113°[1]—indicate where most of the fourfold negative surplus charge is localized.

Tetraanions such as the one reported above are supposed to be an excellent testing ground for calculations that employ highly correlated wavefunctions. Meanwhile we estimated from the experimental structural parameters within the MNDO approximation both the charge distribution as well as the heats of formation. This method revealed the following: 1) The four negative charges are unexpectedly distributed rather uniformly over the entire molecule: on average -0.62 for the phenyl rings and -0.60 each for the six-membered tetracene rings (counting the central CC bonds twice). Expectedly, rather high single charges of -0.22 are predicted for each of the four C centers at which the framework bends. 2) The heat of formation for the eightfold THF-solvated tetrasodium salt is calculated to be $\Delta H_f^{MNDO} = -2520$ kJ mol^{-1} versus $\Delta H_f^{MNDO} = +1076$ kJ mol^{-1} for neutral rubrene. Subtracting the total contribution of -521 kJ mol^{-1} from the four $[Na^+(thf)_2]$ countercations yields for the rubrene tetraanion $\Delta H_f^{MNDO} = -1992$ kJ mol^{-1} and still $\Delta\Delta H_f^{MNDO} = +916$ kJ mol^{-1} for the electron affinity (rubrene + 4 e$^-$ → rubrene^{4-}); that is, about 2.4 eV per electron.

Despite all rationalization attempts, the fourfold rubrene reduction at a sodium metal mirror remains strange: Presumably only two electrons are initially incorporated, which generate a contact-ion triple with two Na^+ countercations above and below the tetracene skeleton and simultaneously bend the dianion to such an extent that two more electron transfer steps to the peripheral bis(phenyl) Na-subunits become feasible.

Whatever the microscopic reduction pathway to the contact-ion quintuple of the rubrene tetraanion might be, our report should stimulate the search for further three- or four-electron incorporation into unsaturated hydrocarbons! Under comparable conditions the reduction of anthracene in THF at a potassium metal mirror generates the first contact ion septuple of $[\{K^+(thf)\}_4(anthracene)_3^{4-}]_\infty$, which despite its extreme air-sensitivity, could be structurally characterized down to an *R*1 value of only 0.043 [11].

[7] Preparation and single crystal growth of $[\{Na(thf)_2\}_4(C_{42}H_{28})]$: freshly cut sodium (40 mg, 1.74 mmol) was weighed into a Schlenk trap, dried at 10^{-3} mbar, and distilled to form a metal mirror on the trap walls. Under argon dried 5,6,11,12-tetraphenyltetracene (rubrene) (50 mg, 0.094 mmol) was added, as well as 10 mL thoroughly dried tetrahydrofuran. The Schlenck trap was fixed in a diagonal position so that the rubrene solution covered the metal mirror. After 2 d almost black crystals with a green luster grew from the dark-green colored solution. Crystal structure determination: Black blocks, $C_{42}H_{28}Na_4 \cdot 4\,C_4H_8O$ ($M_r = 1201.44$), $a = 1139.4(1)$, $b = 1295.8(1)$, $c = 1301.9(1)$ pm, $\alpha = 99.02(1)$, $\beta = 108.07(1)$, $\gamma = 109.31(1)°$, $V = 1650.9 \times 10^6$ pm^3 ($T = 150$ K), $\rho_{calcd} = 1.208$ g cm^{-3}, triclinic, $P\bar{1}$ (No. 2), $Z = 1$, Siemens P4 four-circle diffractometer, $Mo_{K\alpha}$ radiation, $\mu = 0.10$ mm^{-1}, 7233 registered reflections within $3° \le 2\theta \le 54°$, of which 6885 are independent and used for refinement ($R_{int} = 0.0241$). Structure solution by direct methods and difference Fourier technique (SHELXS-86), refinement versus F^2 (SHELXL-93), 436 parameters, $w = 1/[\sigma^2(F_o^2) + (0.0717\,P)^2 + 1.02\,P]$, R for 5066 $F_o > 4\,\sigma(F_o) = 0.0588$, wR_2 (for all 6885 data) = 0.1627, GOOF = 1.023, residual electron density 0.29/−0.26 e Å^{-3}. All positions C, O, and Na were refined anisotropically; all H were positioned in geometrically ideal sites and refined with individual isotropic displacement parameters ($[U_{iso} = 1.2 \times U_{eq}(CH/CH_2)]$; $[U_{iso} = 1.5 \times U_{eq}(CH_3)]$ within a riding model. Further details of the crystal structure determinations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-404813.

Novel Neutral and Anionic Rhodium Complexes Containing Imido Ligands**

Cristina Tejel, You-Mao Shi, Miguel A. Ciriano*, Andrew J. Edwards, Fernando J. Lahoz, and Luis A. Oro*

The interest in the chemistry of transition metal imido complexes has grown substantially in recent years.[1] These compounds are believed to be intermediates in many important catalytic processes such as propene ammoxidation,[2] nitrile reduction,[3] imide group transfer,[4] and reduction and carbonylation of nitroarenes,[5] and they are models for the Haber ammonia synthesis. Whereas the majority of complexes with imido ligands contain early transition metals in high oxidation states, few imido complexes are known for the late transition metals in low oxidation states.[6] Dinuclear amido–imido tautomers, which are stabilized by dppm bridging ligands (dppm = methylenebis(diphenylphosphane)), are the only examples of such complexes with rhodium in a low oxidation state.[6a] We report here on the first neutral and anionic clusters of rhodium bridged by imido ligands. These novel compounds, which contain diene and carbonyl groups as ancillary ligands, possess new, interesting bonding and structural features.

Reactions of equimolar amounts of the complexes $[\{Rh(\mu\text{-}Cl)(diene)\}_2]$ with a solution of *para*-toluidine and butyllithium (in a 1:2 molar ratio) in diethyl ether at room temperature afforded complexes of the type $[Rh_4(\mu\text{-}N\text{-tolyl})_2(diene)_4]$ (diene = 1,5-cyclooctadiene (cod) (**1**), tetrafluorobenzobarrelene (tfb) (**2**)) as dark red crystalline solids in high yields. Characterization of the new complexes as imido clusters was based on spectroscopic data and an X-ray crystal structure analysis.[7] In the neutral tetranuclear complex **1** (Fig. 1) two *para*-tolylimido ligands cap either side of a trirhodium triangle through their nitrogen atoms, while the ring of the phenyl group of one of these ligands coordinates an isolated [Rh(cod)] fragment. Three remaining cyclooctadiene ligands are each bound to a rhodium atom of the trinuclear triangular core, which consists of two clearly bonded edges and one slightly longer, apparently nonbonded edge. Discounting the metal–metal interactions, each rhodium atom in the trimetallic core, is essentially square-planar coordinated. The molecular structure of **1** found in the crystal is also maintained in solution. The ^1H NMR spectra of **1** and **2** reveal the presence of two types of phenyl rings, each showing a well-defined A_2B_2 pattern, one of which, as a result of the π coordination to the fourth Rh atom, is shifted to higher field by approximately 1 ppm. Furthermore, signals for two types of diene ligands appear in the ratio 3:1, which are attributed to the ligands at the trimetallic core and to that bonded to the isolated rhodium atom, respectively. Complex **1** is the first example of an μ_3-imido rhodium system. Within **1**, the average Rh–N bond lengths differ significantly (0.04 Å) between the two face-capping ligands, unlike in comparable examples such as $[Os_3(NC_6H_5)_2(CO)_9]$,[8] where they are essentially equivalent. The η^5-cyclohexadienyl-like coordination of the imido ligand to the fourth rhodium atom follows from the deviation of the *ipso* carbon from the ring plane by 17.4(4)° and from the Rh–C_{ipso} distance which is 0.294 Å longer than the average Rh–C distance for this ligand. Associated with this peculiar η^5 coordination is a dramatic shortening of the C_{ipso}–N bond, indicative of clear partial C–N double bond character.[9] These data suggest a charge delocalization from the nitrogen atom into the ring. Furthermore, attempts to isolate pentanuclear complexes by coordination of mononuclear cationic species such as $[Rh(cod)S_x]BF_4$ (S = solvent) at the free phenyl group have proved unsuccessful, since **1** lacks coordination sites with sufficient electron density. However, the imido nitrogen atom still possesses nucleophilic character, since complexes **1** and **2** react slowly with methanol to give the known methoxo complexes $[\{Rh(\mu\text{-}OMe)(diene)\}_2]$ and *para*-toluidine.

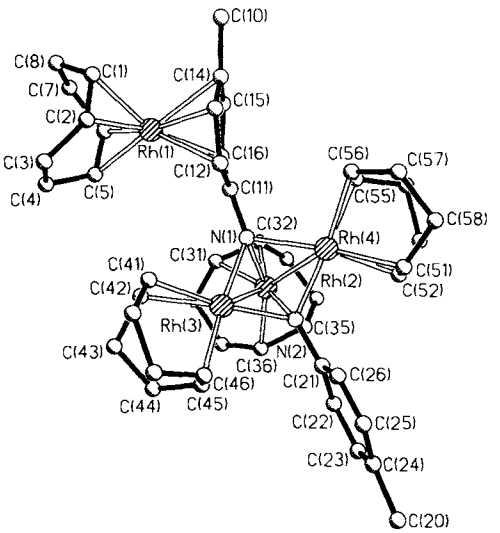

Fig. 1. Molecular structure of **1**. Selected interatomic distances [Å] and angles [°]: Rh(2)-Rh(3) 2.765(1), Rh(2)-Rh(4) 2.774(1), Rh(3)···Rh(4) 3.108(1), Rh(2)-N(1) 2.107(3), Rh(2)-N(2) 2.112(3), Rh(3)-N(1) 2.088(3), Rh(3)-N(2) 2.058(3), Rh(4)-N(1) 2.139(3), Rh(4)-N(2) 2.043(3), N(1)-C(11) 1.355(5), N(2)-C(21) 1.422(6), Rh(1)-C(12)/C(16) 2.224–2.375(5). Rh(1)···C(11) 2.576(11), Rh(3)-Rh(2)-Rh(4) 68.27(3), Rh(2)-Rh(3)-Rh(4) 56.00(2), Rh(2)-N(1)-Rh(3) 82.5(1), Rh(2)-N(1)-Rh(4) 81.6(1), Rh(3)-N(1)-Rh(4) 94.7(1), C(11)-N(1)-Rh(2) 138.2(3), C(11)-N(1)-Rh(3) 130.8(3), C(11)-N(1)-Rh(4) 114.1(3), Rh(2)-N(2)-Rh(3) 83.0(1), Rh(2)-N(2)-Rh(4) 83.8(1), Rh(3)-N(2)-Rh(4) 98.6(1), C(21)-N(2)-Rh(2) 138.1(3), C(21)-N(2)-Rh(3) 119.7(3), C(21)-N(2)-Rh(4) 122.2(3).

Complexes **1** and **2** can be considered, in a simplified way, to be related to the known species $[Rh(cod)BPh_4]$, where the trimetallic core takes the role of the BPh_4^- ion. However, in our case the η^5 coordination of the imido ligand seems to be nonlabile when compared with π-coordinated arene ligands in corresponding complexes of rhodium.[10] With this in mind, the preparation of μ_3-imido anionic complexes, for example $[Rh_3(\mu\text{-}N\text{-tolyl})_2(tfb)_3]^-$, requires the formation of very stable cations such as $[Rh(CN\mathit{t}Bu)_4]^+$. Thus, reaction of **2** with excess $CN\mathit{t}Bu$ leads to the rupture of the Rh-π-cyclohexadienyl interaction, yielding the anionic imidorhodium cluster $[Rh_3(\mu\text{-}N\text{-tolyl})_2(tfb)_3][Rh(CN\mathit{t}Bu)_4]$ **3** (Scheme 1). Complex **3** is isolated as a yellow crystalline solid in 75% yield and shows the expected spectroscopic features. Thus, the anion is detected in the negative ion FAB mass spectrum, and the *para*-tolylimido groups are equivalent in the ^1H and $^{13}C\{^1H\}$ NMR spectra (Table 1). Furthermore, the *ortho* carbon atoms give rise to quartets in the $^{13}C\{^1H\}$ NMR spectrum because of coupling with three equivalent Rh nuclei, while the *ipso* carbon atoms give a broad singlet. Complex **3** is the first characterized anionic imido complex of rhodium which, despite the low oxidation state of the

[a] The new compounds give satisfactory C,H,N, elemental analyses; the superscript a denotes the η^5-(μ-N-*p*-tolyl)Th(diene) fragment; H,H-COSY experiments, and high-resolution processing of the ^{13}C{^{1}H} NMR spectra were used for accurate assignments.

metals and the high electronic density (hard-base character) of the imido ligand, is surprisingly stable. Substitution of the ancillary ligands in the periphery of the trinuclear core of **1** by carbon monoxide reveals the inequivalence of the metals within this triad. Thus, reaction of **1** with carbon monoxide at room temperature leads to [Rh_4(μ-N-tolyl)$_2$(CO)$_4$(cod)$_2$] (**4**) (Scheme 1), which is isolated in 90% yield as a yellow microcrystalline solid. Further studies on the reactivity of the electron-rich complexes **3** and **4** are in progress.

In conclusion, neutral and anionic imidorhodium(I) clusters are feasible and stable and could possibly be intermediates in the catalytic reduction and carbonylation of nitroarenes by Rh complexes.

Experimental Procedure

General synthesis of **1** and **2**: Solid [{Rh(μ-Cl)(diene)}$_2$] (0.5 mmol) was added to a solution of *para*-toluidine (0.5 mmol) and butyllithium (1.0 mmol) in diethyl ether at room temperature to give a dark red solid. Further extraction with dichloromethane and work up yielded the complexes **1** and **2** as crystalline solids.

[7] Crystal data for **1**: $C_{46}H_{62}N_2Rh_4 \cdot C_4H_8O$, M_r = 1126.74, monoclinic, space group $P2_1/n$ (No. 14), a = 17.912(4), b = 12.419(2), c = 20.649(4) Å, β = 105.41(3)°, V = 4428(2) Å^3, Z = 4, ρ_{calcd} = 1.690 g cm^{-3}, F(000) = 2288, λ = 0.71073 Å, T = 173.0(2) K, μ($Mo_{K\alpha}$) = 1.504 mm^{-1}. Data were collected on a Stoe AED diffractometer by using an oil-coated rapidly cooled crystal of dimensions 0.29 × 0.23 × 0.18 mm mounted directly from solution (T. Kottke, D. Stalke, *J. Appl. Crystallogr.* **1993**, *26*, 615). A total of 5665 unique reflections were collected by the $2\theta/\omega$ method ($3.5 \le 2\theta \le 45.0$). The structure was solved by direct methods (SHELXTL PLUS, G. M. Sheldrick, Siemens Analytical X-ray Instruments, Inc., Madison, WI **1990**) and refined by full-matrix least-squares on F^2 (SHELXL-93; G. M. Sheldrick, Göttingen, 1993) to R_1 = 0.0264 [$F > 4\sigma(F)$, for 4830 reflections] and R_2 = 0.0716 (all data) [$R_1 = \sum||F_o| - |F_c||/\sum|F_o|$, $R_2 = \{\sum w(F_o^2 - F_c^2)^2/\sum wF_o^4\}^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (xP)^2 + yP]$($x$ = 0.0358, y = 8.1612), $P = (F_o^2 + 2F_c^2)/3$]. A THF molecule was located and found to be disordered over two sites, these were modelled at 50% occupancy. All non-hydrogen atoms were refined anisotropically, with the exception of disordered oxygen and carbon atoms in the THF solvate molecule. All hydrogen atoms riding on sp^2 carbon atoms were located and allowed to freely refine isotropically, the remaining hydrogen atoms were fixed in idealized positions with thermal parameters (1.2 times that of the corresponding parent carbon atom). Largest peak and hole in the final difference map 0.528 and −0.362 e Å^{-3}. Further details of the crystal structure investigation are available on request from the Director of the Cambridge Crystallographic Data Centre, 12 Union Road, GB-Cambridge, CB21EZ (UK), on quoting the full journal citation.

Double Oxygen Atom Centered Rhodium–Gold Clusters**

Hui Shan and Paul R. Sharp*

Main group atom centered gold clusters such as $[(Ph_3PAu)_nC]^{(n-4)+}$ ($n = 5$, 6), $[(Ph_3PAu)_5N]^{2+}$, and $[(Ph_3PAu)_4S]^{2+}$ are remarkable because of their unexpected stability and the "hypercoordinate" nature of the central atom.[1] A major contributory factor to the stability of these clusters is the bonding interaction between the gold(I) atoms of the clusters ("aurophilicity"[2]). Here we describe the synthesis and characterization of related clusters which are stabilized by Au–Rh interactions as well Au–Au interactions. In addition, these new clusters contain not one main group atom center but two and show oxygen in an unusual trigonal pyramidal geometry.

In previous work we observed that oxo/halide exchange occurred between the gold oxo complexes $[(LAu)_3(\mu\text{-O})]BF_4$ and the gold halide complexes L'AuCl [Eq. (a), L and L' = phosphane].[3] We have discovered that this type of exchange

$$[(LAu)_3(\mu\text{-O})]BF_4 + L'AuCl \rightleftharpoons [(L'Au)(LAu)_2(\mu\text{-O})]BF_4 + LAuCl \quad (a)$$

reaction also occurs for other metal halide systems. Thus, the reactions of $[\{Rh(diene)(\mu\text{-Cl})\}_2]$ (diene = 1,5-cyclooctadiene (cod), norbornadiene (nbd)) with two equivalents of $[(Ph_3PAu)_3(\mu\text{-O})]BF_4$ give the orange-yellow to yellow products **1** [Eq. (b), diene = cod, nbd].

$$[\{Rh(dien)(\mu\text{-Cl})\}_2] + 2[(Ph_3PAu)_3(\mu\text{-O})]BF_4 \longrightarrow [\{(dien)Rh[(\mu\text{-O}(AuPPh_3)_2]\}_2][BF_4]_2 + 2\,Ph_3PAuCl \quad (b)$$

^{1}H NMR spectra for **1** show resonances for a single type of diene and PPh_3 ligand. ^{31}P NMR spectra show a single sharp resonance at $\delta = 25$ very near the position found for the parent complex $[(Ph_3PAu)_3(\mu\text{-O})]BF_4$ ($\delta = 27$).[4] This data and the formula for **1** suggested a highly symmetric structure with four-coordinate oxygen atoms in an approximately tetrahedral geometry. The X-ray structure analysis of **1**, diene = nbd, revealed a surprising result:[5] the dication (Fig. 1) consists of a planar $[(nbd)Rh(\mu\text{-O})_2Rh(nbd)]^{2-}$ array in which two Ph_3PAu^+ groups are coordinated to each oxygen atom. One of the Ph_3PAu^+ groups (Au1) is in the $[(nbd)Rh(\mu\text{-O})_2Rh(nbd)]^{2-}$ plane, while the other (Au2) is orthogonal to the plane. This results in a trigonal pyramidal coordination geometry for the oxygen atoms.[6] An examination of the metal–metal distances suggests the reason for this unusual geometry. The out-of-plane, axial, gold atom (Au2) bonds with the in-plane gold atom (Au1) and with the two rhodium atoms (Fig. 1). The Au–Au distance of 3.008 Å is typical of Au–Au distances observed in all-gold main group atom centered clusters and in other gold compounds where "aurophilic" interactions occur.[1, 2] The Rh–Au distances (3.020 and 2.984 Å) are similar to those observed in

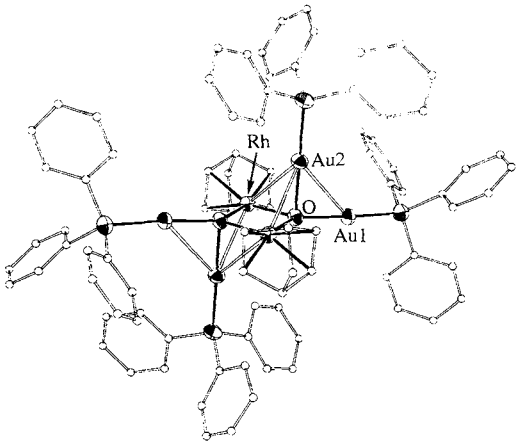

Fig. 1. Crystal structure of the dication of **1**, diene = nbd; ORTEP drawing (50% ellipsoids for non-carbon atoms, hydrogen atoms excluded). The dication is located on a center of symmetry.

compounds where long Au–M (M = Rh, Ir, Pt) bonds are found.[7] The metal–metal interactions in **1** appear to be responsible for the unusual oxygen coordination geometry and indicate a close relationship to the main group atom centered clusters of gold. Complex **1** is the first heteronuclear cluster of this type containing a central oxygen atom[8] and the first to involve two main group atom centers. Finally, **1** should be compared to the recently reported cluster $[(LAu)_4O]^{2+}$ (L = $(2\text{-}CH_3C_6H_4)_3P$).[9] In this all-gold oxygen-centered cluster, the oxygen atom is in a more common tetrahedral environment and although Au···Au interactions are present they are longer (3.359 Å) than those in **1** as required for the more symmetric distribution of the metal atoms.

In conclusion, **1** is a novel double oxygen atom centered cluster in which the unusual trigonal pyramidal oxygen coordination geometry is maintained by Au–Au and Au–Rh bonds. Other examples of unusual main group atom centered clusters containing gold and other transition metals may be expected by exchange reactions similar to that in Equation (b).

Experimental Procedure

1, (diene = 1,5-cod): A solution of $[\{Rh(cod)(\mu\text{-Cl})\}_2]$ (40.2 mg, 0.0815 mmol) in THF (10 mL) was vigorously stirred with solid $[(Ph_3PAu)_3(\mu\text{-O})]BF_4$ (241 mg, 0.0163 mmol). The mixture became an almost clear red-orange solution within 5 minutes and meanwhile an orange-yellow solid gradually precipitated. After the mixture had been stirred for 15 minutes, the orange-yellow product was isolated by filtration, washed with THF and then ether, and dried in vacuo. Yield: 190 mg (94.9%). Elemental analysis: calcd (found): C 42.88 (42.72), H 3.43 (3.36); ^{1}H NMR (300 MHz, $CDCl_3$, 22 °C): δ = 7.34–7.59 (m, 30H, Ph), 3.93 (br, 4H, CH), 2.08 (br, 4H, CH_2), 1.65 (d, t, 4H, CH_2, J(H,H) = 8.4 Hz, J'(H,H) = 5.5 Hz); ^{31}P NMR (121.2 MHz, CH_2Cl_2, 22 °C, ext H_3PO_4 ref): δ = 25; IR (thin film on NaCl plate): ν = 3075–2829 (m, CH), 1482, 1437 (m, C=C), 1104 (s), 1060 cm^{-1} (br, s, B-F).

1, (diene = nbd): A solution of $[\{Rh(nbd)(\mu\text{-Cl})\}_2]$ (46.1 mg, 0.100 mmol) in THF (10 mL) was vigorously stirred with solid $[(Ph_3PAu)_3(\mu\text{-O})]BF_4$ (296 mg, 0.200 mmol). The mixture became an almost clear orange solution within 5 minutes and meanwhile a yellow solid gradually precipitated. After the mixture had been stirred for 15 minutes, the yellow product was isolated by filtration, washed with THF and then ether, and dried in vacuo. Yield: 230 mg (94.5%). Elemental analysis: calcd (found): C 42.46 (41.50), H 3.15 (2.98); ^{1}H NMR (250 MHz, $CDCl_3$, 22 °C): δ = 7.36–7.59 (m, 30H, Ph), 3.75 (m, 4H, CH), 3.66 (br, 2H, CH), 1.12 (br, 2H, CH_2); ^{31}P NMR (101.3 MHz, CH_2Cl_2, 22 °C, ext H_3PO_4 ref): δ = 25. IR (thin film on NaCl plate): ν = 3060–2860 (m, CH), 1480, 1438 (m, C=C), 1104 (m), 1063 cm^{-1} (br, s, B-F).

Hexalithiated Hexakis(cyclohexylamino)-cyclotriphosphazene; a $(Li^+)_{12}$ Cage Containing Puckered $[NP(NCy)_2]_3^{6-}$ Ions**

Alexander Steiner* and Dominic S. Wright

Highly charged anionic systems are well known in inorganic solid-state chemistry. The extensive class of silicates contains a variety of anionic host lattices from mononuclear $[SiO_4]^{4-}$ units to polymeric networks.[1] Recently a number of isoelectric lithium phosphorus nitrides have been described.[2] Further examples are anionic main group element clusters in Zintl phases.[3] In contrast, highly charged anions have rarely been investigated in molecular species. Compared with dimetalated organic compounds far less is known about coordination compounds containing triply or more highly charged anions.[4, 5] A structurally characterized example of the latter is the tetralithiated dibenzyl(methyl)phosphane, which exists as a TMEDA-solvated (TMEDA = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) dimer in the solid state.[4] Metalated organonitrogen species up to trianions are widely used as shielding ligands towards metal centers.[6] However, metal complexes containing more highly charged organonitrogen anions, to our knowledge, have not been structurally characterized to date.

A large number of organometallic phosphazene compounds[7] and metallophosphazenes[8] have been described, owing to the high stability of their partially delocalized P–N skeletons.[9] As a precursor for producing a highly charged organonitrogen ligand system, we chose hexakis(cyclohexylamino)triphosphazene $[NP(NHCy)_2]_3$ (Cy = cyclohexyl), which contains six potentially acidic N–H functions. The deprotonation of $[NP(NHCy)_2]_3$ with *n*BuLi (molar ratio 1:6) in the presence of TMEDA in toluene yields **1**. Crystals of **1** proved unsuitable for X-ray structure analysis; however, crystallization of **1** from THF/hexane afforded X-ray quality crystals of **2** (see also Experimental Procedure).

$[\{NP(NLiCy)_2\}_3(tmeda)_3]$ **1**

$[\{[NP(NLiCy)_2]_3(thf)_2\}_2] \cdot 2.5\,THF$ **2**

A low-temperature X-ray study[10] of **2** shows it to have a centrosymmetric dimeric cage structure, in which twelve Li cations are complexed by two chair-shaped $[NP(NCy)_2]_3^{6-}$ ions and by four thf donor molecules (Fig. 1). The central core of the molecule is that of an approximately D_{3d}-symmetric polyhedron, formed by the interaction of the ring-N and equatorially substituted NCy groups of the two $[NP(NCy)_2]_3^{6-}$ ions with six Li centers. Each metal center is coordinated by a bidentate

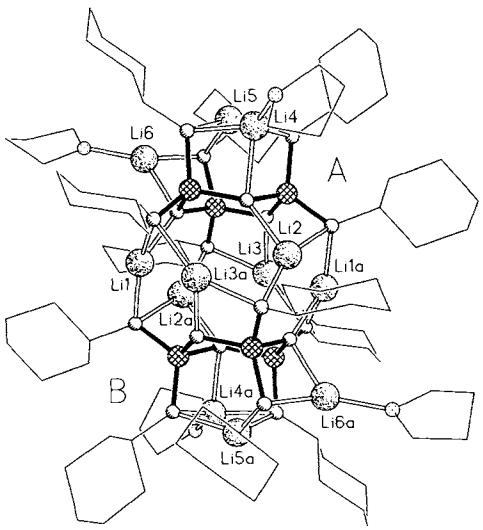

Fig. 1. Crystal structure of **2**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°] (average): P–N(Ring) 1.66, P–N(eq) 1.63, P–N(ax) 1.64, Li(1,2,3)–N(ringA) 2.01, Li(1,2,3)–N(eqA) 2.02, Li(1,2,3)–N(eqB) 2.01, Li(4)–N(ax) 2.04, Li(4)–N(ring) 2.12, Li(4)–O(thf) 1.94, Li(5)–N(ax) 2.05, Li(6)–N(ring) 2.04, Li(6)–N(ax) 1.96, Li(6)–O(thf) 1.90; N(ring)–P–N(ring) 110, N(eq)–P–N(ax) 118, N(ring)–P–N(eq) 106, N(ring)–P–N(ax) 108, P–N(ring)–P 120.

N(ring)–P–N(eq)-chelate system [N(ring)–Li 1.971(8)–2.054(8), N(eq)–Li 1.979(8)–2.067(8) Å] from one anion and by a further N(eq) interaction [N(eq)–Li 1.973(8)–2.070(9) Å] from the other anion. The remaining lithium cations are accommodated at the other P_3N_3 faces of each of the hexaanions. While Li5 is coordinated in a tridentate manner by all three axial NCy groups [N(ax)–Li5 2.028(8)–2.076(8) Å], Li6 is tricoordinated by a N(ax)–P–N(ring) chelate system [N(ax)–Li6 1.957(8), N(ring)–Li6 2.038(8) Å] and by a thf donor molecule [O2–Li6 1.904(8) Å]. Li4 is the only tetracoordinate metal center in **2**; it is coordinated by two axial nitrogen atoms [N(ax)–Li4 2.027(8)–2.044(9) Å], one ring nitrogen atom [N(ring)–Li4 2.124(8) Å], and by a further thf molecule [O1–Li4 1.936(8) Å]. All N–Li distances in **2** are similar to those found in other lithiated phosphazenes.[11]

In addition to the electrostatic stabilization of each hexaanion in **2** by tight ion-pairing with nine Li counterions, delocalization of the negative charge from the substituent nitrogen on to the ring nitrogen centers can be assumed. The central phosphazene ring shows marked distortion from planarity into a chair conformation and all P–N distances throughout the whole anion are in the same range [P–N(ring) 1.651(3)–1.674(3), P–N(eq) 1.624(4)–1.637(4), P–N(ax) 1.638(3)–1.652(3) Å]. In contrast, cyclotriphosphazene skeletons of neutral hexaamino-substituted derivatives are planar or only slightly chair-shaped and their P–N(ring) distances are about 0.06 Å shorter than their terminal P–N distances.[12] While the terminal N–P–N angles in the neutral species are far more acute than their ring N–P–N angles, the N(eq)–P–N(ax) angles [116.9(2)–119.7(2)°] in **2** are significantly wider than the N–P–N ring angles [108.2(2)–111.1(2)°].

In the IR spectrum of **1** the phosphazene P=N–P stretching band (1016 cm^{-1}) shows a strong red shift in the hexaanion compared to neutral hexaaminocyclotriphosphazenes (typical stretching frequencies 1170–1195 cm^{-1}).[8] This shift is greater than that in lithium complexes with uncharged N-phosphazene ligands[13] and indicates weakening of the P–N(ring) bonds in **1**, while the terminal P–N bonds are strengthened as a result of the electron excess. The change in charge distribution upon lithiation is also indicated by the high-field shift of the ^{31}P NMR resonance of **1** ($\delta = -55.0$ in **1**; cf. $-50 < \delta < +50$ in cyclic phosphazenes and metallophosphazenes relative to 85% H_3PO_4[8, 9]).

The hexalithiated hexaaminophosphazene **2** is a molecular analogue of lithium phosphorus nitrides, which exist as polymeric ionic lattice compounds.[2] However, in contrast to the latter the high solubility of **2** in aprotic solvents promises an extensive chemistry of this highly charged anionic system in solution. Transmetalation reactions of **2** with main group metal and transition metal halides looks promising and may lead to a large number of interesting multinuclear metal complexes.

Experimental Procedure

All experiments were carried out under a dry argon atmosphere by using Schlenk techniques and a glove box. Solvents were dried over Na/benzophenone and distilled prior to use. $[NP(NCy)_2]_3$ was prepared as described in the literature [14].

1: *n*BuLi (9 mL, 13.5 mmol, 1.5 M solution in hexane) was added at 0 °C over 15 min to a solution of $[NP(NCy)_2]_3$ (1.4 g, 1.93 mmol) in TMEDA (1.5 mL) and toluene (15 mL). The resulting orange solution was stirred for 2 h at room temperature. During this time a yellow precipitate was formed. This was separated by filtration, and the solid washed twice with hexane (10 mL). Yield: 1.6 g (75%). Decomp. >250 °C; IR (Nujol): ν [cm^{-1}] = 1586, 1290, 1253, 1154, 1136, 1016, 908, 841, 791, 729; ^1H NMR (25 °C, [D$_8$]THF): δ = 3.01 (m, CH, 6 H), 2.25 (s, N–CH_2, 12 H), 2.11 (s, N CH_3, 36 H), 1.0–1.7 (m, CH_2, 60 H); ^{31}P NMR (25 °C, [D$_8$]THF, relative to 85% H_3PO_4): $\delta = -55.0$.

2: When **1** was stored for three weeks at 3 °C in THF/hexane single crystals of **2** suitable for X-ray structure analysis were obtained in low yield.

π-Dimers of End-Capped Oligopyrrole Cation Radicals**

J. A. E. H. van Haare, L. Groenendaal, E. E. Havinga, R. A. J. Janssen,* and E. W. Meijer

The conductivity of doped polymers with conjugated π-electron systems is directly related to their redox states and part of it has been rationalized in terms of polarons (cation radicals) and bipolarons (dications) migrating along the conjugated chain.[1] The general understanding of the electronic structure and redox states of semiconducting polymers has benefited from studies on well-defined conjugated oligomers that allow functional properties to be investigated as a function of (effective) conjugation length.[2-7] In recent years, numerous studies have addressed the redox states of oligothiophenes,[2-5] and it was found that in addition to cation radicals and dications, spinless π-dimers of cation radicals can be formed.[3-5] These interchain cation radical π-dimers have been proposed as an alternative to diamagnetic bipolarons as an explanation for the weak ESR signal for highly oxidized polythiophenes.[3-5] Although several organic ion radicals form π-complexes in solution, dimerization has never been reported for conjugated oligomers other than oligothiophenes. The availability of well-defined oligopyrroles[8] makes such a study possible for one of the most interesting conducting polymers: polypyrrole.

α-Oligopyrroles with phenyl end caps (PhPy$_n$Ph, n = 2, 3, 4) exhibit two chemically reversible one-electron oxidation waves (Table 1).[9] The chemical stability of the first two oxidation states of PhPy$_n$Ph is a result of the phenyl end caps, which prevent polymerization over the α-positions. The successive electrochemical oxidation of the oligomers to cation radicals (PhPy$_n$Ph$^{\bullet+}$) and dications (PhPy$_n$Ph^{2+}) at controlled potentials was monitored by in-situ UV/Vis/NIR absorption spectroscopy (Fig. 1). Several optical transitions, listed in Table 1, are observed. The number and relative ordering of the absorption bands closely resembles the spectral characteristics of oxidized oligothiophenes.[2-5] For the oligopyrrole cation radicals two bands (M1 and M2) appear at low and high energy, respectively. Each of the M1 and M2 bands has an associated second transition (D1 and D2), shifted to higher energy by about 0.3 eV. These second transitions are attributed to π-dimers of oligopyrrole cation radicals. In contrast, for the oligopyrrole dications, only a single electronic transition (DC) is observed, with one or two associated vibronics at higher energy. Each of the optical transitions (N, M1, M2, D1, D2, and DC; Table 1) shifts to lower energy for longer oligomers, in accord with an approximately linear dependence with the inverse length of the oligomer (taken as $1/m$; where $m = n + 2$ is the total number of aromatic rings).[9]

Table 1. Electrochemical data [a] and optical transition energies [b] of redox states of PhPy$_n$Ph oligopyrroles.

	$n = 2$ E [eV]	$n = 3$ E [eV]	$n = 4$ E [eV]
E_1^0	0.37	0.13	0.01

M1 [c]	1.60, 1.79	1.32	1.13
M2	2.55	2.26	2.10
D1	1.91	1.65	1.39
D2	2.86	2.63	2.42
DC [c]	2.21, 2.34	1.88, 2.05, (2.23)	1.58, 1.70, (1.88)

[a] Potentials in CH_2Cl_2/NBu_4PF_6 (0.1 M) solution at 100 mVs^{-1} and oligomer concentration c = 0.1–1.0 mM vs SCE, internally calibrated vs Fc/Fc$^+$. [b] Transitions of redox states labeled as follows: N: neutral oligomer; M1, M2: monomer cation radical; D1, D2: dimer of cation radicals; DC: dication. [c] Second and third entries are attributed to different vibronics of the same electronic transition.

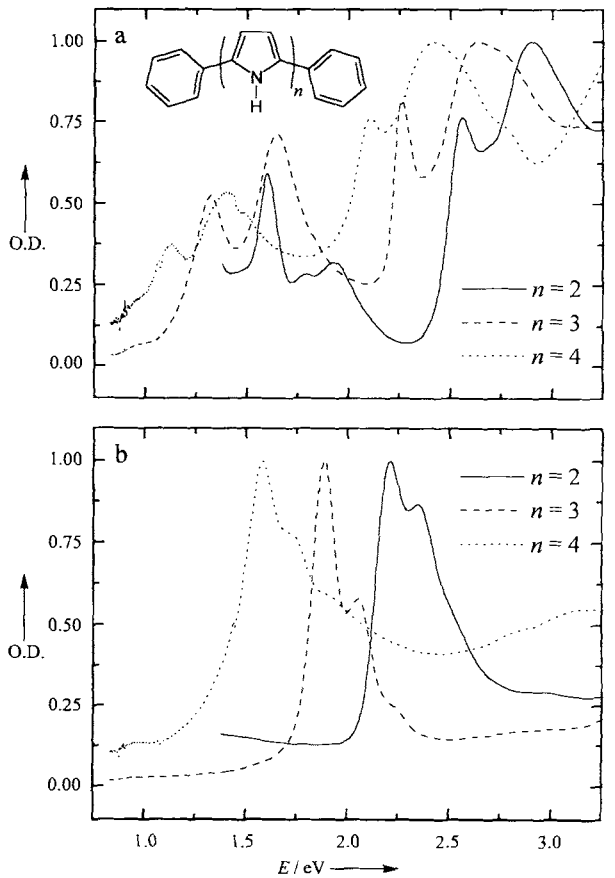

Fig. 1. Normalized electronic spectra obtained after electrochemical oxidation of PhPy$_n$Ph to the corresponding cation radicals (a) and dications (b). Spectra were recorded in a CH_2Cl_2/NBu_4PF_6 (0.1 M) solution at room temperature with 0.1 mm path length and an oligomer concentration c = 0.1–1.0 mM.

The various bands can be assigned to specific transitions using the molecular symmetry of PhPy$_n$Ph. Assuming an all-*transoid* conformation of the bonds between pyrrole rings, the molecular symmetry is either C_{2h} (n = 2, 4) or C_{2v} (n = 3). The symmetry of the frontier π orbitals is given in Figure 2a; the dipole-allowed transitions among these orbitals are indicated. Since these excitations are all polarized along the oligomer chain axis they are expected to be intense.[10] The π-interaction between two cation radicals to give a π-dimer will cause a splitting of frontier orbitals into bonding (+) and antibonding (−) levels (Fig. 2b). In this dimer the D1 (− ← −) and D2 (+ ← +) transitions (originating from the states M1 and M2, respectively, in the cation radical) are dipole-allowed and polarized along the

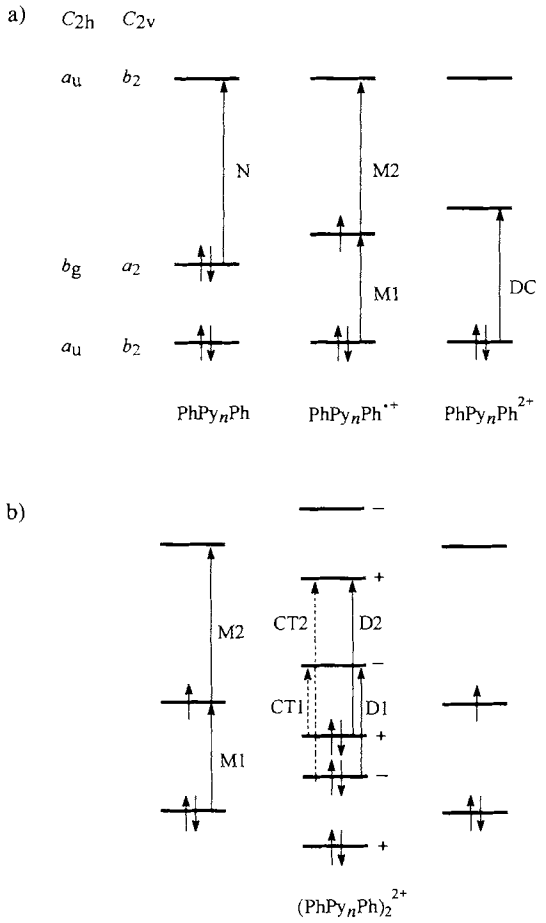

Fig. 2. Schematic energy diagram and symmetry of the frontier orbitals for the neutral, cation radical, and dication states of $PhPy_nPh$ (a), and cation radical π-dimers (b). Dipole-allowed transitions are indicated. Experimentally D1 and D2 exhibit an additional blue shift as a result of a Davydov interaction.

long axis of the oligomer. Experimentally the D1 and D2 transitions are shifted to higher energy than M1 and M2 by about 0.3 eV, comparable with shifts found for oligothiophene cation radical dimers[4] and other π-radical ion dimers.[11] Such a blue shift is a well-known phenomenon for ionic π-dimers and has been attributed to the interaction between transition dipole moments on the adjacent cation radicals (Davydov shift),[11] although other phenomena may contribute such as different splittings of frontier orbitals upon dimerization. In addition to D1 and D2, two charge transfer transitions CT1 and CT2 are possible in the π-dimer, polarized along the short axis connecting the two cation radicals. As a consequence, the CT1 and CT2 bands are expected to be less intense than D1 and D2.

The temperature dependence of the electronic spectrum of $PhPy_2Ph^{\bullet+}$ (Fig. 3), obtained by chemical oxidation with iron(III) chloride ($FeCl_3$), reveals that the intensities of the M1 and M2 bands decrease at lower temperatures in favor of the intensities of the D1 and D2 bands. These changes with temperature are reversible and consistent with the proposed equilibrium between two oligopyrrole cation radicals and their π-dimer.

The in situ electrochemical or chemical ($FeCl_3$) oxidation of $PhPy_nPh$ to the cation radical produces a strong ESR signal at $g = 2.0025$. A subsequent decrease of ESR signal intensity is observed upon further oxidation, leading to the loss of the signal after complete conversion of the cation radical to the (diamagnetic) dication. Highly resolved ESR spectra of the oligopyrrole cation radicals can be obtained by oxidizing the $PhPy_nPh$

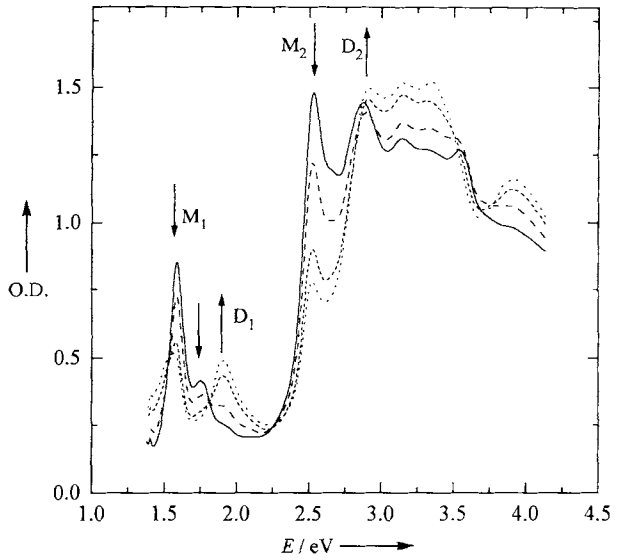

Fig. 3. Electronic spectrum of $PhPy_2Ph^{\bullet+}$ cation radicals, obtained by oxidation with $FeCl_3$ in CH_2Cl_2 solution between 295 and 245 K ($c = 0.2$ mM, path length 10 mm). The arrows mark the decay of the M1 and M2 transitions and the increase of D1 and D2 transitions with decreasing temperature.

oligomers in a 1:1 mixture of CH_2Cl_2 and trifluoroacetic acid (TFA).[12] Figure 4 shows the ESR spectrum of $PhPy_2Ph^{\bullet+}$ in CH_2Cl_2/TFA. The ESR spectrum is fully symmetric, indicating the formation of a single doublet species and arguing against the presence of different conformations of the $PhPy_2Ph^{\bullet+}$ cation radical (e.g. *s-transoid* and *s-cisoid*), as has been found for oligothiophene cation radicals.[13] The intensity of the ESR signal decreases by one order of magnitude upon lowering the temperature from 295 K to 200 K (Fig. 4). This temperature dependence is reversible and in agreement with the expected behavior for an equilibrium between two oligopyrrole cation radicals and a diamagnetic π-dimer.[14]

In conclusion we have shown that phenyl end-capped oligopyrroles can be oxidized reversibly to the corresponding

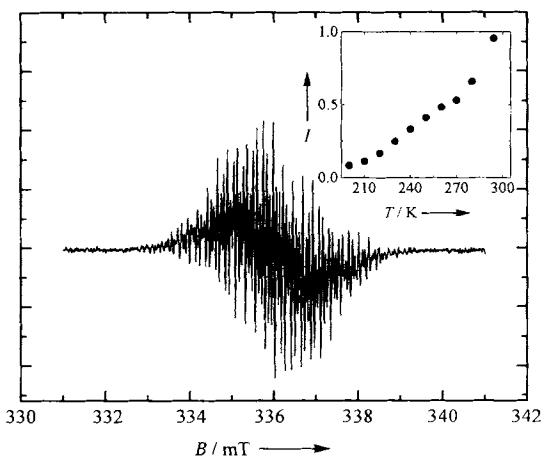

Fig. 4. ESR spectrum of the $PhP_2Ph^{\bullet+}$ cation radical generated by dissolving $PhPy_2Ph$ (0.4 mM) in CH_2Cl_2/TFA (1:1) at 295 K. The inset shows the temperature dependence of the ESR intensity. The ESR spectrum can be simulated by using the following parameters $a_H(4H) = 0.614$, $a_H(2H) = 0.853$, $a_H(4H) = 0.328$, $a_H(2H) = 0.703$, $a_H(2H) = 0.395$, $a_H(2H) = 0.470$, and $DH_{pp} = 0.03$ mT. These couplings are tentatively assigned to *o*-PhH, *p*-PhH, *m*-PhH, C3H, C4H, and NH based on a semiempirical quantum chemical calculation using the PM3 Hamiltonian.

cation radicals and dications. Variable temperature UV/Vis/NIR and ESR spectra give direct evidence for the π-dimerization of oligopyrrole cation radicals. The results on oligopyrroles are in full analogy to π-dimerization of oligothiophene cation radicals.[3–5] Therefore, the present results together with those on oligothiophenes, give credence to the proposition that π-dimers have an important role as interchain conducting entities for conducting polymers in general.

Experimental Procedure

The preparation of $PhPy_nPh$ oligomers and conditions for cyclic voltammetry have been described elsewhere [9]. All experiments were conducted under rigorously inert conditions. UV/Vis/NIR spectroelectrochemical data were obtained with a Perkin Elmer Lambda 9 spectrophotometer in CH_2Cl_2/NBu_4PF_6 (0.1 M) solution with a thin-layer cell consisting of two ITO glasses separated by a spacer of 0.1 mm as the optical transparent working electrode, a platinum disk as a counter electrode, and an Ag/AgCl wire as reference electrode [4]. ESR spectra were recorded on a Bruker ER200D SRC X-band spectrometer with a ER4111 variable temperature unit.

[14] From the one order of magnitude decrease of the ESR intensity it is possible to estimate the enthalpy of dimerization to be on the order of $\Delta H^0 = -25$ to $-35\ kJ\ mol^{-1}$. Further studies on the equilibrium and thermodynamic parameters are currently in progress.

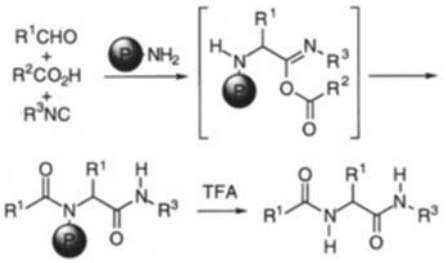
Solid-Phase, Parallel Syntheses by Ugi Multicomponent Condensation**

Paul A. Tempest, S. David Brown, and Robert W. Armstrong*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

The combinatorial synthesis of chemical libraries of small organic molecules represents a new tool for investigating the effects of structure on biological activity.[1] Recent efforts have focused on the solid-phase syntheses of a core set of atoms (or a pharmacophore), in which diversity is introduced sequentially at each step of a linear synthesis.[2] The theoretical number of compounds that can be generated in these libraries is related to the number of steps required for their synthesis and the availability of chemical starting compounds (inputs) for each step. An alternative strategy for the generation of chemical libraries involves the use of multicomponent condensation reactions (MCCs).[3] MCC-derived compounds require a single synthetic transformation. The potential size of these libraries is dependent on the number of components in the MCC and their availability—not on the number of synthetic steps. Described herein is the solid-phase synthesis of a library of α-acylamino amides by a four-component condensation (4CC) and a strategy for increasing the structure diversity of one of its inputs by a pre-MCC condensation of two substrates in solution.

The Ugi 4CC is ideally suited for the construction of chemical libraries based on the α-acylamino amide core structure (Scheme 1).[4] When the synthesis is conducted on a solid support, libraries of structurally diverse mono- and disubstituted α-amino acids may be obtained. While any of the four inputs (aldehyde, carboxylic acid, isonitrile, and amine) can be tethered covalently to a solid support, we chose to use an immobilized amino group since a variety of amino-functionalized matrices are readily available. A secondary amide results upon cleavage from the solid support.



Scheme 1. A 4CC reaction on solid support (P) to generate compounds with an α-acylamino core.

A 96-member library was generated (12 acids, 8 aldehydes, 1 amine, and 1 isocyanide were the starting compounds) in a 96-well microtiter plate with a distribution of one product per well. The inputs of this library were chosen so that a substituent effect analysis of the 4CC reaction on solid support could

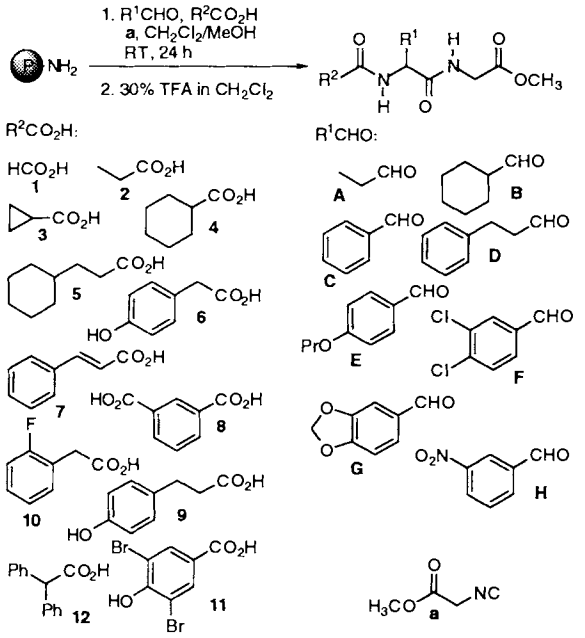
be obtained with a single plate (96 individual reactions). For the reaction, 0.014 mmole of Rink-amine[5] resin per well in $MeOH/CH_2Cl_2$ (1/2) served as the amine input, and methylisocyanoacetate (10 equiv) as the single isocyanide input. The carboxylic acids **1**–**12** (10 equiv) and aldehydes **A**–**H** (10 equiv) used for construction of the library are shown in Scheme 2.



Scheme 2. Carboxylic acid and aldehyde inputs for the synthesis of a compound library.

After stirring for 24 h, the products were cleaved from the resin; 1–3 mg of predicted product was obtained as the single component in 88 wells. In parallel with solution reactions, the product yields were most sensitive to the structure of the aldehyde inputs (Table 1). Reactions with aliphatic aldehydes and those containing electron-donating groups exhibit good overall yields, compared to the reactions of aldehydes with electron-withdrawing groups (**F** and **H**) even in the presence of large excess of reagents or repeated addition of fresh reagents. For the carboxylic acid inputs, the reactions involving phenolic derivatives **6**, **9**, and **11** gave generally low yields, owing in part to their precipitation from solution over the 24 h reaction period. Four reactions were carried out on larger scale (0.12 mmol) and afforded products in the following yields[6]: **7Ba**, 30 mg, 69%; **8Ea**, 40 mg, 80%; **10Aa**, 26 mg, 68%; and **12Da**, 41 mg, 77%. Similar yields are observed for the solution reactions. Analysis by ^{13}C and ^1H NMR revealed >90% purity.

Table 1. Yields [%] based on the support-bound amine for the three steps a) deprotection of the amine, b) four-component condensation with the carboxylic acids **1**–**12**, aldehydes **A**–**H**, and the isonitrile **a**, and c) cleavage from the resin with TFA.

We next addressed the issue of the limited commercial availability of isocyanides as starting materials for the Ugi reaction. For the purpose of library generation, this greatly reduces the structural diversity of this input (and size of the library). The generation of diverse structures would require substantial synthetic effort. The approach described herein represents a general strategy for the generation of input diversity by the solution condensation of two or more subunits prior to the solid-phase synthesis of the library. α-Lithiated benzylisocyanide (1 equiv) was treated with a small excess (1.1 equiv) of methyl iodide, benzyl bromide, and cyclohexyl bromide to afford respective isocyanides **c**–**e**.[7] Each crude reaction mixture was concentrated and, along with isocyanide **b**, used without purification to generate a library on solid support by the Ugi 4CC reaction (3 carboxylic acids, 3 aldehydes, 4 isocyanides, 1 amine). This array afforded all 36 products distributed as one compound per well in a microtiter plate (Scheme 3, Table 2). Four reactions

were performed on larger scale, affording the condensation products in the following yields: **7Jb**, 51 mg, 61%; **7Jc**, 37 mg, 43%; **7Jd**, 38 mg, 37%; **7Je**, 31 mg, 31%. Even though unpurified isocyanides were used in the 4CC reaction, the observed purity of the products was still >90%.

We have described the parallel syntheses of a combinatorial library on solid support based on the Ugi 4CC. We generated

isocyanides otherwise not commercially available by quenching α-lithiated isocyanides with alkyl halides, thus improving the diversity of the isocyanide input. In addition, condensation of the isocyanide input in solution prior to library generation effectively produces a "5CC" library on the solid support. This strategy has been extended to the synthesis of ethanolamine libraries effectively containing six components.[8]

Experimental Procedure

Synthesis of a library in 96-well microtiter plate: Rink FMOC-amide resin (2.88 g, 0.46 mmol g^{-1}) was deblocked with piperidine and partitioned equally into a 96-well polyethylene microtiter plate. Each of the eight aldehydes (1 M in CH_2Cl_2, 138 μL, 10 equiv) and twelve carboxylic acids (1 M in CH_3OH, 138 μL, 10 equiv) was added to the appropriate wells such that each column contained a different aldehyde and each row contained a different carboxylic acid. After 30 min methyl isocyanoacetate (1 M in CH_2Cl_2, 138 μL, 10 equiv) was added to all the wells. The plate was capped for 24 h then allowed to evaporate to dryness. The resin was transferred to a 96-well filtration apparatus and washed liberally with methanol and CH_2Cl_2. The products were removed from the resin and washed into a second 96-well plate with TFA in CH_2Cl_2 (2 × 600 μL), then rinsed with CH_2Cl_2 (200 μL) and CH_3OH (200 μL). The solvents were then removed in a reduced-pressure oven.

[8] Condensation of α-lithiated benzyl isocyanide with benzaldehyde followed by addition of acetic anhydride affords a three-input isocyanide, which can be used without purification in the solid-phase 4CC reaction.

Continuous Asymmetric Synthesis in a Membrane Reactor

Udo Kragl* and Claus Dreisbach

Decoupling the residence time of catalyst and reactants in a reactor can be achieved by immobilization of the catalyst. The aim is to achieve a high total turnover number or an easy recovery of the catalyst for repeated use, or to enable the use of continuously operated reactors.[1] The latter offers the advantage of better controlled reaction conditions; for instance, if the steady state is reached, concentrations of reactants are constant with time. To address these problems homogeneous catalysts are most often anchored to insoluble supports. The main problems related to this approach are the nonuniform and partly unknown structures of the resulting heterogeneous catalysts, mass transport limitation due to hindered diffusion, and a low catalytic activity. In addition, there have been attempts to recover catalysts by using membrane processes such as ultrafiltration or reverse osmosis.[2, 3] Examples in hydroformylation,[4, 5] hydrogenation,[6] or reduction of NAD(P)$^+$[7] have been reported. But no data for industrial processes that use this approach have yet been published. In contrast, in biotechnology, enzyme membrane reactors, where the soluble enzyme is retained behind an ultrafiltration membrane, are used on a scale of 100 tons per year for the synthesis of fine chemicals.[8] The advantage of this method is that fresh catalyst can be supplemented even in the continuous process, which is difficult for a fixed bed reactor.

For the example of the enantioselective addition of diethylzinc **2** to benzaldehyde **1**, we here describe the continuous asymmetric synthesis in a membrane reactor using the homogeneously soluble catalyst **4**. The α,α-diphenyl-L-prolinol used as chiral ligand was coupled to a copolymer made from 2-hydroxyethyl methacrylate and octadecyl methacrylate (molecular weight 96000 g mol^{-1})[9] in order that it can be retained by an ultrafiltration membrane within the reaction vessel. The reac-

[+] New address: Bayer AG, Leverkusen (Germany)

[**] This work was supported by the Deutsche Forschungsgemeinschaft. We thank Bayer AG, Leverkusen, for a sample of the copolymer and Hoechst AG, Frankfurt, for the ultrafiltration membranes.

tion chosen is very suitable for process development, as it occurs only in the presence of the catalyst. Leakage of the catalyst from the reactor would cause a decrease in conversion due to a lowered volumetric activity but not a change in the enantiomeric excess of the product.

For a stable continuous process high retention of the catalyst is required. The solvent-stable polyaramide ultrafiltration membrane Hoechst Nadir UF PA20[10] retains more than 99.8% of **4**. The enantiomeric excess of **3** that can be achieved with the soluble polymer-bound α,α-diphenyl-L-prolinol is somewhat lower than that achieved with the noncoupled ligand (80% compared to 97%[11]). For polymer-supported ligands *ee* values between 10 and 92% are reported; the majority of values are below 80%.[12a] An enantiomeric excess of 94% has been reported for the addition of diethylzinc to 4-chlorobenzaldehyde with this type of catalyst in a flow-through reactor.[12b]

For the addition of **2** to **1** catalyzed by **4** in a batch reactor, the enantiomeric excess of **3** is strongly influenced by the ratio of the starting materials.[13] A surplus of **2** yields the (*S*)-alcohol, whereas a surplus of **1** surprisingly yields the (*R*)-alcohol. The reason for this behavior of **4** may be the coupling of the polymer to the nitrogen atom of the prolinol. Attempts to verify this by replacing the polymer with less bulky analogues were not successful. The resulting catalysts were either insoluble or inactive. Experiments with a constant amount of catalyst but varying amounts of reactants reveal that the ratio between catalyst and reactants has only a minor influence.

The enantiomeric excesses achieved are similar in the batch reactor and the continuously operated membrane reactor. Figure 1 shows the change in the enantiomeric excess as function of

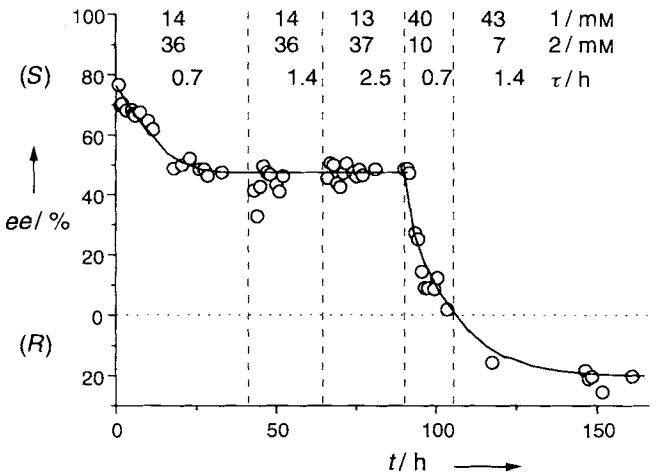

Fig. 1. Change in the enantiomeric excess of **3** with time for the addition of **2** to **1** in a continuously operated membrane reactor. Conditions: c(**4**) 10 g L^{-1}; concentrations of reactants and the residence time τ are given in the figure; solvent: *n*-hexane; 0 °C.

time. Different residence times τ and starting material ratios were used. For the given concentrations of 14 mM of **1** and 36 mM of **2**, an enantiomeric excess of about 50% was reached for **3** in the continuous process. The higher values at the beginning of up to 80% are caused by the start-up conditions of a high excess of **2**. With the same concentrations similar values for the enantiomeric excess can be reached in a batch reactor as well.[13] Because of the limited reaction rate of the addition of **2** to aldehydes, the maximum conversion that could be reached at a residence time of 2.5 hours was 30%. Higher concentrations of **4** are not possible due to its limited solubility at 0 °C. In contrast to ligands coupled to insoluble polymers, where the reaction rate is reduced to 20% by the immobilization,[12a] the ligand bound to the soluble polymer is as active as before. The residence time in the continuous reactor has no influence on the enantiomeric excess in the conversion range from 7 to 30%. However, the enantiomeric excess reached in the batch reactor depends on the time elapsed and therefore on the conversion.[13] An excess of **1** yields the (*R*)-alcohol with up to 20% *ee*. But the conversion based on the limiting compound **2** of 12% is quite low. For all operating conditions used, the undesirable reduction of the aldehyde to the corresponding alcohol is negligible. Although almost stoichiometric amounts of catalyst and aldehyde are present (10 g L^{-1} catalyst, corresponding to 5 mmol L^{-1} of ligand), high chemoselectivities of between 89 and 96% were obtained.

The values for conversion and the enantiomeric excesses reached here are not yet sufficient for preparative use. The big advantage of this approach is the increase of the total turnover number for the chiral ligand. By varying the ratio of concentrations and the duration of continuous operation, the total turnover number for **4** has been raised by a factor of 10 from 50 to 500.[14] No deactivation of the catalyst was observed within seven days, which indicates that, in principle, longer operating times are possible for the reactor. To reach a total turnover number of 500 in batch experiments without any recovery of the catalyst its concentration has to be reduced from 2 to 0.2 mol%. Such low concentrations of chiral ligands are still seldom used in asymmetric synthesis. It should be possible, in principle, to convert a reaction with stoichiometric amounts of catalyst into a catalytic reaction by decoupling the residence time of catalyst and reactants in a continuously operated reactor. Besides an increase of the total turnover number, poor selectivity may be improved by high catalyst concentrations.

Recently dendrimers have been described that act as homogeneous catalysts.[15] These catalysts may be used in the reactor configuration described above. Since a steadily increasing number of solvent-stable membranes are now available for ultrafiltration and nanofiltration, the recovery of homogeneous catalysts becomes possible with methods already established in biocatalytic reactions such as 'repetitive batch'[16] or continuously operated reactors.

Experimental Procedure

The synthesis of **4** has been described elsewhere [13]. As reactor a flat membrane cell (volume 10 mL, membrane diameter 62 mm) made from polypropylene was used with stirring, as described for enzymatic reactions [17]. Connections were made with PEEK capillaries used for high performance liquid chromatography (HPLC). To ensure inert conditions substrate and product flasks were kept under argon. Additionally, the whole set-up was kept under argon in a box made from Plexiglas. The ultrafiltration membrane (Nadir UF PA 20, Hoechst AG, Frankfurt, Germany) was conditioned with dry *n*-hexane as described by the supplier. Catalyst **4** (100 mg) was dissolved in *n*-hexane (10 mL) and pumped into the reactor, which was subsequently rinsed with dry *n*-hexane for 12 h. The temperature was set to 0 °C. Solutions of **1** and **2** (50 mM each) in *n*-hexane were pumped separately into the reactor by means of two piston pumps P500 from Pharmacia (Freiburg, Germany). Different residence times and concentration ratios were obtained by varying the flow rate of the pumps. To determine the enantiomeric excess and conversion, aliquots (0.5 mL) of solution were collected at the reactor outlet and hydrolyzed with NH_4Cl solution. The samples were analyzed by GC (carrier gas H_2, 105 °C isothermal, injector 240 °C) on a permethylated β-cyclodextrin column (CS-Chromatographieservice, Langerwehe, Germany).

[14] For all calculations a conversion of 30% was used, as found for the continuously operated reactor for a residence time of 2.5 h. The total turnover number for the continuous reactor was calculated only under these conditions. Based on the amount of product formed during the whole operating time of the reactor, the total turnover number is higher than 2 000.

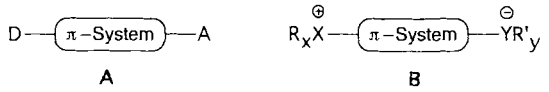
Polarized π-Electron Systems in a Chemically Generated Electric Field: Second-Order Nonlinear Optical Properties of Ammonium/Borate Zwitterions**

Christoph Lambert,* Stefan Stadler, Grant Bourhill, and Christoph Bräuchle

Second- and third-order nonlinear optical materials play an important role in future optoelectronic technology.[1] Among the second-order effects studied are second harmonic generation (SHG) and the electrooptic or Pockels' effect. Efforts are therefore directed at increasing the first-order hyperpolarizability β, which is the molecular property responsible for these effects. The compounds commonly employed are donor–acceptor substituted π-electron systems **A** with polarized electron distribution that exhibit internal charge transfer (CT) bands in the UV/Vis spectrum, such as *p*-aminonitrobenzene (*p*NA), 4-amino-4'-nitrotolane (ANT), and 4-*N*,*N*-dimethylamino-4'-nitrostilbene (DANS).



A **B**

The two-level model [Eq. (a)],[2] derived from a sum over states (SOS) approximation of the hyperpolarizability,

$$\beta_0 \propto \mu_{eg}^2 (\mu_e - \mu_g)/\tilde{\nu}_{eg}^2 \qquad \text{(a)}$$

shows that the CT transition energy ($\tilde{\nu}_{eg}$), the difference between exited- and ground-state dipole moment (μ_e and μ_g), and the transition dipole moment (μ_{eg}) govern the magnitude of the static first-order hyperpolarizability (β_0). The trivial approach to increasing β_0 is to lower the transition energy $\tilde{\nu}_{eg}$, for example, by increasing the conjugation length (*p*NA → DANS) (which will also alter μ_{eg} and $\mu_e - \mu_g$).[3] However, because this leads to less transparent molecules, the use of these systems for SHG applications is hampered by self-absorption of the second harmonic.[4] For this reason, we tried to maximize the $\mu_e - \mu_g$ difference by designing transparent zwitterionic systems **B** that show a very high ground-state dipole moment and are expected to have a small dipole moment in the first excited singlet state.

The general synthetic procedure for compounds **1**–**4** is similar for all derivatives and is outlined for **1** in Scheme 1.[5] All zwitterions are air stable but hygroscopic crystalline compounds that dissolve readily in polar nonhydrogen-bonding solvents such as THF (least polar) and MeCN (most polar). In these zwitterions the π-electron systems benzene, tolane, stilbene, and diphenylbutadiene have onium and at substituent groups along

the molecular z axis. These onium and at groups generate an electric field and consequently polarize the π-electron systems[6] much in the same way as a combination of push- and pull-substituents do, but by an inductive and/or field effect rather than by a mesomeric effect.[7] Since the onium and at groups are not conjugated with the π-electron systems, the internal CT transition of the zwitterions are expected to be at shorter wavelengths than those of analogous push–pull-substituted compounds. Indeed, for all zwitterions we observed CT bands in the UV spectra (see Table 1); the wavelengths of the CT bands and the extinction coefficients increase with the size of the π-system, but even in THF the former are substantially smaller than those of analogous NMe_2/NO_2-substituted species (for example in $CHCl_3$: *p*NA 348, ANT 380, DANS 430 nm[8, 9]).

Table 1. Comparison of calculated (AM1) and experimental optical data: absorption maximum (λ_{max}), extinction coefficient (ε), AM1-computed static hyperpolarizability ($\beta_{\mu 0}$), and hyperpolarizability at 1064 nm (β_μ), as well as the total isotropic averaged hyperpolarizabilities (β_0 and β) from HRS measurements.

[a] Error ± 15%. [b] In Et_2O.

All zwitterions investigated show strong negative solvatochromism, that is, the CT wavelengths decrease with increasing solvent polarity (Table 1): the shift of λ_{max} for solutions of **1**–**4** in MeCN and in THF is 1740–2670 cm^{-1}. The negative solvatochromism is indicative of a high ground-state dipole moment and a small excited-state dipole moment.[10] Indeed, AM1 calculations[11] of the zwitterions in the gas phase predict huge μ_g (**1** 20.0, **2** 44.5, **3** 41.9, **4** 47.1 D) and small μ_e (**1** 4.2, **2** 6.3, **3** 9.4, **4** 13.0 D). Although the dipole moment difference $\mu_e - \mu_g$ of the zwitterions might be overestimated by AM1 calculations,[16] it is substantially higher than those of comparable push–pull-substituted compounds [$(\mu_e - \mu_g)_{exp.}$ of *p*NA is 8.6, ANT 9.5, and DANS 18.2 D[17]].

How can charge transfer excitation in the zwitterionic systems be rationalized? AM1 calculation of the difference of Coulson charges of the ground and singlet excited state (calculated with the pairs and singles excitation CI (PECI) method) of, for example, **4** in the gas phase demonstrates the z-polarized charge transfer very well (Fig. 1). From the difference electron populations one can see that the negative charge located in the ground state at the BR_3Ph^- group is partially transferred to the phenyl ring adjacent to the ammonium group upon excitation. The charge transfer *within* the diphenylbutadiene moiety occurs solely in the π system; the σ electrons are not influenced.

Using the self consistent reaction field (SCRF) method implemented in the VAMP program, we calculated the CT bands of the zwitterions in MeCN and in Et_2O (the calculations for THF cannot be performed, but Et_2O has a similar permittivity). The agreement between observed and calculated CT bands is quite good (see Table 1), and the negative solvatochromic shift is also reproduced very well. This encouraged us to calculate the first-order hyperpolarizability β_μ at zero frequency (static hyperpolarizability) and 1064 nm excitation wavelength with an SOS method and using the SCRF approximation to model the solvent influence on β_μ. We found consistently higher β_μ values in Et_2O than in MeCN, which is predominantly due to the lower CT energy of the zwitterions in Et_2O (see Eq. a). The total isotropic averaged hyperpolarizability β[18] has been measured in MeCN by Hyper-Rayleigh scattering (HRS)[19] at 1064 nm with *p*NA as an external reference (β_μ(1064nm) = 29.2×10^{-30} esu in MeCN[8]); β_0 values have been calculated from these values by the two-level model approximation.[2] The agreement with the theoretical data is amazingly good, especially because neither the AM1 nor the SCRF method are parametrized to reproduce UV data (as are, for example, CNDO/S and INDO/S).[1f]

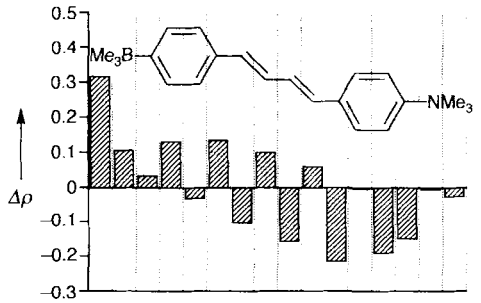

Fig. 1. Coulson charge differences $\Delta\rho$, calculated with the AM1 approximation, between the ground state and the first excited singlet state of an analogue of **4** (*n*-butyl groups are replaced by methyl groups). The charge differences refer to the sum of charges of all heavy atoms and hydrogen atoms drawn in each column. A positive charge difference indicates loss of negative charge upon excitation.

The β_0 values observed are similar to $\beta_{\mu 0}$ of analogous NMe_2/NO_2- or NH_2/NO_2-substituted systems (*p*NA 7.6, ANT 19, DANS 55×10^{-30} esu[9]). Although direct comparison with these literature data is hampered by different measurement techniques and different reference compounds the trends of β_0 in the zwitterion series is the same as for the push–pull-substituted analogues.

In conclusion, we have shown in this study that onium and at groups can polarize π-electron systems; the resulting main group organometallic zwitterions exhibit z-polarized CT bands as do comparable push–pull-substituted compounds. However, these zwitterions are more transparent than their push–pull analogues, which should promote application in SHG devices. Nonetheless, the first-order hyperpolarizability of the zwitterions is about the same as that of analogous donor–acceptor-substituted species. In addition, the high ground-state dipole moment of the zwitterions should favor the alignment of these derivatives in polymer films in order to obtain enhanced macroscopic SHG and electrooptic effects (note the very high $\mu\beta_0$ value of, for example **4**: about 3250×10^{-48} esu). Furthermore, it might be possible to introduce chiral ligands to boron or to nitrogen to induce a noncentrosymmetric space group in the crystalline state. These topics are currently under investigation.

[11] The AM1 calculations were performed with the VAMP 5.01. program [12]. An analogue of compound **4** was calculated: the *n*-butyl groups were replaced by methyl groups. The excited states were calculated at the geometry of the ground states with the PECI = 10 [13]. The UV transitions and hyperpolarizabilities were computed with the SCRF method in order to model the influence of the solvent [14]. The hyperpolarizability β_μ was calculated with the SOS method at zero and at 1.16 eV excitation energy (1064 nm) [13]. β_μ is the projection of the β tensor on the dipole moment vector. To compare the calculated β_μ values with the experimental values, they must be divided by 3, since the SOS approximation refers to β based on a perturbation theory, whereas β of the experimental reference compound is differently defined [8,15].

[18] Although β measured in the HRS experiment is the averaged isotropic value it corresponds to β_μ in dipolar molecules where the largest β component lies parallel to the CT direction; see G. J. T. Heesink, A. G. T. Ruiter, N. F. van Hulst, B. Bölger, *Phys. Rev. Lett.* **1993**, *71*, 999; E. Hendrickx, C. Clays, A. Persoons, C. Dehu, J. L. Bredas, *J. Am. Chem. Soc.* **1995**, *117*, 3547.
[19] A description of the specific experimental set-up used in this study and the data analysis can be found in S. Stadler, F. Feiner, C. Bräuchle, S. Brandl, R. Gompper, *Chem. Phys. Lett.* **1995**, *245*, 292. For general introductions into HRS measurements, see K. Clays, A. Persoons, *Phys. Rev. Lett.* **1991**, *66*, 2980; *Rev. Sci. Instrum.* **1992**, *63*, 3285; K. Clays, A. Persoons, L. De Maeyer, *Adv. Chem. Phys.* **1994**, *85*, 455. The chromophores were checked for fluorescence prior to HRS measurements. In addition, the spectral purity of the HRS signal was investigated with a set of narrow bandpass filters of varying transmission peak wavelength (500, 532, and 570 nm). Only at the wavelength of the second harmonic (532 nm) could a signal be detected. Thus, we can exclude the possibility of broadband contributions such as hot-two-photon- or three-photon-induced fluorescence. For **3** we found an unusually strong bathochromic shift of $\lambda_{cut-off}$ at higher number densities (15.71×10^{18} cm^{-3}). For **4** we found a positive deviation from a linear correlation between the SHG signal and the number density above about 2.5×10^{18} cm^{-3} (these data have been omitted in the data evaluation of β). Both effects might indicate aggregation at these very high concentrations. It is currently not known to which extent these aggregation effects influence the HRS signal, for example, by correlated scattering.

Automated Solid Phase Synthesis of Platinated Oligonucleotides via Nucleoside Phosphonates**

Jürgen Schliepe, Ulrich Berghoff, Bernd Lippert, and Dieter Cech*

Platinum compounds, in particular, *cis*-diamminedichloroplatinum(II) (cisplatin, CDDP) and several of its derivatives, are widely used nowadays in the treatment of a number of tumour diseases.[1] The cancerostatic activity of these compounds is directly related to their reaction with cell DNA, and the formation of covalent adducts.[2] On the basis of numerous studies with model nucleobases, nucleosides, nucleotides, and short DNA fragments, we now believe that we understand the fundamental aspects of these interactions.[3] Till now, studies of the platination of oligonucleotides have been carried out exclusively with presynthesized samples.[4] To our knowledge, there has been no report to date of any platinated oligonucleotide that was obtained by direct inclusion of a platinated nucleotide building block in an automated DNA synthesis, though this route offers clear advantages with respect to possible synthetic variations.

We describe herein the automated synthesis of *trans*-$(NH_3)_2$-Pt^{II}-modified oligonucleotides via a 3′-phosphitylated platinum nucleoside synthon. Initial studies showed that it is necessary to carry out the phosphitylation before the platination. For reasons of greater stability, we chose to use phosphonates[5] in this procedure, rather than the more usual phosphoramidites.[6] Till now, we have concentrated on the reaction of the 5′-dimethoxytritylated thymidine-3′-phosphonate **1** with *trans*-$[(NH_3)_2PtCl_2]$ (TDDP) (Scheme 1). Compound **1** was synthe-

[**] This work was supported by the Deutsche Forschungsgemeinschaft

sized as previously reported,[7] deprotonated with KOH[8] to give **2**, and subsequently treated with *trans*-$[(NH_3)_2PtCl_2)]$ to afford the Pt complex **3**.[9] Complex **3** was characterized by elemental analysis, as well as by ^1H NMR, ^{195}Pt NMR, and IR spectroscopy.[10] The ^{195}Pt NMR signal of **3** ($\delta = -2265$, $[D_7DMF]$) lies in the expected region for a PtN_3Cl coordination sphere,[11] and its chemical shift is also clearly distinct from that of free *trans*-$[(NH_3)_2PtCl_2)]$ and its DMF solvolysis products. The thymine H6 resonance signal of **3** is shifted upfield compared to that of **1**, as expected, and is obscured by the resonance signals of the dimethoxytrityl group.[12] However, its existence can be unambiguously proven by $^1H,^1H$-COSY experiments (coupling to the $C(5)CH_3$ of the thymine). The formulation of **3** as a KCl adduct is based on the analytical data[10] and is possibly due to the tendency of N3-platinated thymine or uracil to take up further cations at O4 or O5, respectively, as described several times in the past.[13]

The modified oligodeoxyribonucleotides 5′-d(CXCA) and 5′-d(ATAGTAXACAGA), with X = *trans*-$[(NH_3)_2Pt^{II}]$-T were synthesized by using **3** and an automated synthesizer (Gene Assembler, Pharmacia).[14] The coupling of **3** to the unmodified nucleotides was carried out following usual synthesis protocols. To improve the yield, **3** and the following phosphonate in the elongation cycle were added in two- to threefold excess. The yields were estimated to be 98.3% per coupling step and 85.2% in overall yield (by measurement of DMTr release). Following the final cycle, the oligonucleotides were cleaved from the carrier and purified by reversed-phase high-performance liquid chromatography (RP-HPLC).[15] The yields of platinated product were about 30% (estimated from the HPLC signal intensities, Fig. 1) based on the yields obtained from similar syntheses with

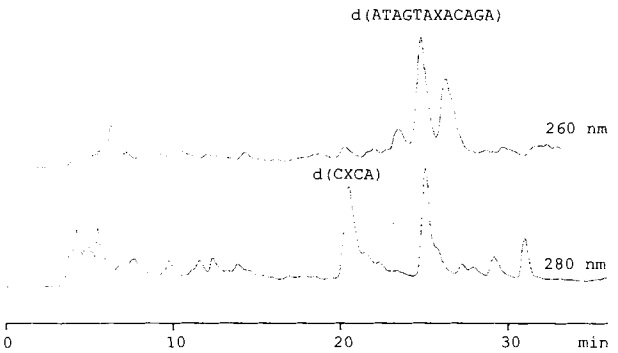

Fig. 1. HPL chromatograms of the oligonucleotides d(CXCA) and d(ATAGTAXACAGA) (X = Pt-T), before purification [15].

unmodified oligonucleotides. Although the yields for the individual coupling steps and the estimated overall yield was in the region expected for standard oligonucleotide syntheses, the low yields of isolated product point to numerous side reactions during cleavage and workup, which still need to be optimized. Deplatination of the sensitive oligonucleotides presumably plays a large role here. The *trans*-$(NH_3)_2TPt^{II}(py)$ unit which is produced during the synthetic cycle remains unchanged during deprotection with NH_3; substitution by NH_3, as for Cl-containing compounds, does not occur.[16] Matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) revealed the molecular ion at 3985.0, as calculated for the platinated 12-mer; 3984.7 for *trans*-$[(NH_3)_2Py\{d(ATAGTATACAGA)$-N3-T(7)$\}Pt]^+$. The non-occurrence of the triammine complex was confirmed by a comparison of the retention times (HPLC) of the platinum-modified nucleoside obtained after enzymatic hydrolysis with synthetically produced $[(NH_3)_3(N3\text{-}T)Pt]^+$.[17] The *trans*-$(NH_3)_2Pt^{II}$ structure is also retained after deprotection with NaOH. The platinated 4-mer gave monoisotope peaks of m/z 1439.8 ($z = 1$) and m/z 720.9 ($z = 2$) in the ion spray mass spectra. This also corresponds to the pyridine-coordinated platinum complex (m/z 1440).

The synthesized platinated oligonucleotides were investigated by gel electrophoresis before and after deplatination.[18] As expected, the platinated oligonucleotides showed a shift in comparison with the unmodified oligonucleotides,[19] which was no longer observed after treatment with cyanide (Fig. 2). Enzy-

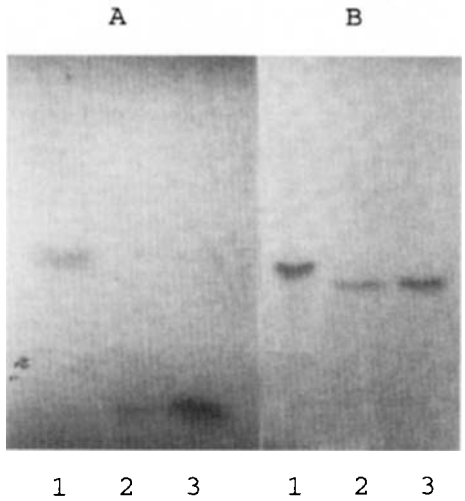

Fig. 2. A) Gel electrophoresis of d(CXCA) before (lane 1) and after deplatination (lane 2), and of d(CTCA) (lane 3); B) gel electrophoresis of d(ATAGTAXACAGA) before (lane 1) and after deplatination (lane 2), and of d(ATAGTATACAGA) (lane 3) [18].

matic hydrolysis under the usual conditions[20] showed the expected total composition in the HPL chromatogram of the oligonucleotides (Fig. 3).[21] The peaks at 27.1 and 2.6 min. are

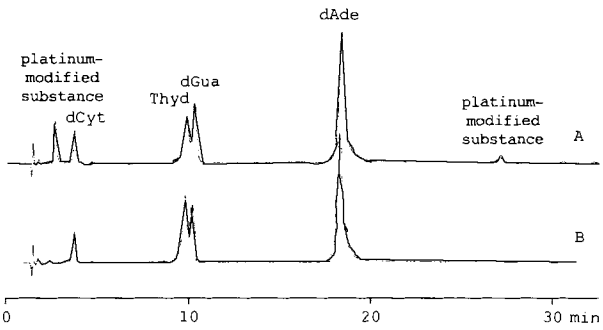

Fig. 3. Enzymatic hydrolysis of the modified 12-mer (A) and of the unmodified 12-mer (B) with 0.2 u snake venom phosphodiesterase and 2 u alkaline phosphatase, as described in ref [20].

an indication of the successful incorporation of the platinated thymidine. The latter peak can be assigned to the platinated thymidine on the basis of its polarity. However, the platinum-modified material appears initially as a peak at 27.1 min., which is degraded with time and reappears as a peak at 2.6 min. Presumably the first peak can be assigned to a platinated dinucleotide containing the incorporated platinated thymidine, that is, the modification evidently leads to a reduction in the enzymatic

hydrolysis rate. Such products are known for the enzymatic hydrolysis of modified oligonucleotides.[22] The presence of Pt in the synthetic oligonucleotides was shown qualitatively with $SnCl_2$ (thin layer chromatography) and electrochemically.[23] Quantitative Pt analysis by atomic absorption spectroscopy (AAS) yielded a value of 1.05 Pt per tetramer or dodecamer.

The medium-term aim of our studies is to synthesize platinated oligonucleotides that are able to react with target sequences in DNA or RNA via the metal ion. Such reactions cannot be expected with the coordinately saturated platinum oligonucleotides described here. They could then lead to the development of useful chemical nucleic acid probes and/or antisense and antigen reagents.[24]

[8] Synthesis in analogy to that of thymine: C. J. L. Lock, P. Pilon, B. Lippert, *Acta Crystallogr. Sect. B* **1979**, *35*, 2533–2537; the Na salt analogous to **2** has in the meantime also been synthesized and converted to **3**.

[9] Method: Compound **2** (206 mg, 0.3 mmol) was made anhydrous by repeated distillation in vacuo with anhydrous pyridine, and was then treated with *trans*-$[(NH_3)_2PtCl_2]$ (90 mg, 0.3 mmol) in DMF (1.5 mL) (5 h 50 °C, 3 d 22 °C). After removal of the DMF in vacuo, MeOH (6 mL) was added, filtered after 24 h, and the filtrate reduced to dryness. After reprecipitation in acetone, the product **3** (255 mg, 86 %) was used without further purification.

[10] Satisfactory elemental analysis for C, H, N, Cl; Proof of Na and K by scanning electron microscopy (SEM); IR (KBr): ν(Pt-Cl) 330 cm^{-1}; ^1H NMR ([D$_7$]DMF): δ (**3**) = 1.47 (s, 3H, 5-CH_3), 2.28–2.41 (m, 2H, H-2′,H-2″), 3.26–3.44 (m, 2H, H-5′,H-5″), 3.80 (s, 6H, CH_3O), 3.89 (b, 6H, $(NH_3)_2$Pt), 4.15 (m, 1H, H-4′), 4.95 (m, 1H, H-3′), 6.41 (m, 1H, H-1′), 6.79 (d, $J(^{31}P,^1H)$ = 577 Hz, 1H, H-P), 6.93–7.53 (m, 13H, DMTr), 7.50 according to ^1H-^1H-COSY (s, 1H, H-6); ^{195}Pt NMR ([D$_7$]DMF): δ = −2265 relative to $[PtCl_6]^{2-}$. The NMR measurements were carried out on Bruker-AC 200; -AM 300- as well as -DRX-400-approaches.

The First "Charm Bracelet" Conjugated Polymer: An Electroconducting Polythiophene with Covalently Bound Fullerene Moieties**

Tiziana Benincori, Elisabetta Brenna, Franco Sannicolò,* Licia Trimarco, Gianni Zotti, and Piero Sozzani

A great deal of effort is currently being directed towards the design and realization of functionalized "intelligent" materials:[1] the synthesis of polymers containing fullerene moieties in either the main or side chains[2, 3] and which show peculiar electrical[4] and electrochemical[5] properties is a challenging topic in this field of research. We report here the first conjugated conducting "charm bracelet" polymer,[6] consisting of fullerene moieties linked to a highly ordered polythiophene backbone. One of the potential interests in associating a p-type conjugated polythiophene and an n-type fullerene lies in the possibility of charge transfer between these two moieties, as recently shown by Heeger and Wudl et al., who, however, prepared and studied heterogeneous blends of C_{60} and poly(3-alkylthiophenes) only.[7]

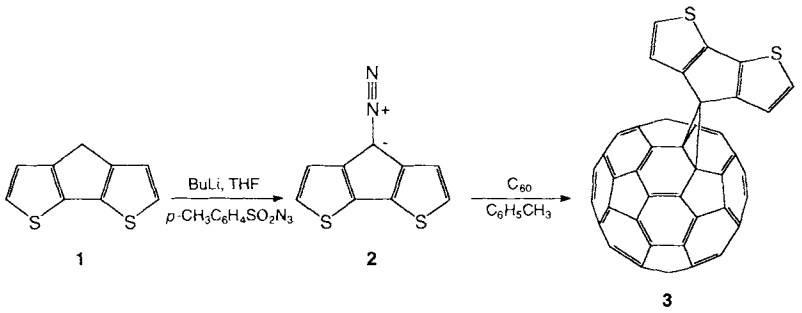
[**] This work was supported by CNR - Progetto Strategico Materiali Innovativi.

Our aim was to connect a C_{60} unit to a suitable thiophene monomer, through stable and possibly rigid bonds capable of exchanging electronic information between the two moieties, and then to anodically oxidize the resulting system to give a conducting polymer. The plan was designed on the basis of the well-documented[8] reactivity of C_{60} towards diazoalkanes and on the possibility of obtaining the 4-diazocyclopenta[2,1-*b*:3,4-*b'*]dithiophene **2** from 4*H*-cyclopenta[2,1-*b*:3,4-*b'*]dithiophene (**1**), a 2,2'-bithiophene monomer recently made accessible



Scheme 1. Synthesis of the cyclopentadithiophene fullerene adduct **3**

through a simple and reproducible route.[9] The cyclopentadithiophene structure satisfactorily answered all the synthetic, geometric, and electronic requirements:

1. The cyclopentadithiophene **1** could give, at least in theory, a diazo derivative capable of reacting with C_{60}, just as fluorene does.[6]
2. The planar cyclopentadithiophene can be electrochemically polymerized to give a material endowed with good electrical conductivity ($\sigma = 40\ S\,cm^{-1}$) and extended conjugation (λ_{max} of the neutral polymer: 545 nm).[9]
3. The C_{2v} symmetry of **1** and the homotopism of the positions involved in the polymerization process would be preserved in the adduct: this is a prerequisite for regioselective polymerization.
4. The diameter of C_{60}[5] and the distance between the two α-carbon atoms[10] of cyclopentadithiophene involved in the polymerization process are of similar length: thus polymerization would not be prevented by steric factors.
5. The cyclopropane bonds, connecting the C_{60} and the cyclopentadithiophene units, are known to exhibit a high π character.[11] This would allow conjugative interaction between the polythiophene chain and the fullerene pendants.

We converted **1** into the stable diazo derivative **2** by using the "diazo transfer reaction"[12] (Scheme 1), and then allowed **2** to react with one equivalent of C_{60} in toluene at room temperature for 12 hours. This led to the thermodynamically favored adduct **3**, which has the structure of a closed 6,6-bridged methanofullerene (elemental analysis, MS, ^1H and ^{13}C CP-MAS NMR, and UV spectroscopy).[13] The ^1H NMR spectrum of **3** showed only two doublets, which were assigned to the α and β thiophene hydrogen atoms. This provided evidence for the addition of the cyclopentadithiophene moiety across a 6,6 ring junction. The ^{13}C CP-MAS spectrum of **3** contained a signal at $\delta = 45.9$, which corresponds to the sp^3 carbon atom in position 4 of the cyclopentadithiophene system ($\delta = 31$ in **1**). A signal at $\delta = 76.1$ was assigned to the two homotopic carbon atoms of C_{60} involved in the cyclopropane ring formation. The signals of the α and β carbon atoms of the cyclopentadithiophene system at $\delta = 123.3$ and 127.7 were not markedly affected by substitution ($\delta = 122.7$ and 124.2 in **1**). The signals at $\delta = 139.5$ and 147.5 result from the superimposition of thiophene ($\delta = 138.4$ and 147.4 in **1**) and fullerene carbon atoms. A complex pattern of signals, in which two main peaks emerge at $\delta = 143.1$ and 144.6, was assigned to the C_{60} moiety. Furthermore, the UV spectrum resembled those of other fullerene cyclopropane derivatives,[14] showing a characteristic absorption band at 434 nm.

The electrochemical behavior of **3** was first examined in a 5×10^{-5} M toluene/acetonitrile (5/1) solution. The cathodic cyclic voltammogram (Fig. 1) showed three one-electron reversible processes, typical of C_{60} derivatives, at -0.82, -1.21, and -1.73 V, close to the potential values reported for C_{60}.[15] In the anodic scan, **3** was irreversibly oxidized with no polymerization.

The electrochemical oxidation of **3** was then investigated in a 2×10^{-4} M chlorobenzene solution. In the first anodic scan ($0.1\ Vs^{-1}$), **3** displayed a two-electron irreversible oxidation peak at 1.05 V related to the cyclopentadithiophene moiety. This peak is 0.55 V more positive than the oxidation potential of the parent compound **1**;[9] this is attributed to the electron-withdrawing properties of the fullerene substituent. The oxidation of C_{60} and its derivatives is described[16] at potential values 2.3–2.4 V more positive than the first reduction step. The continuous cycling of

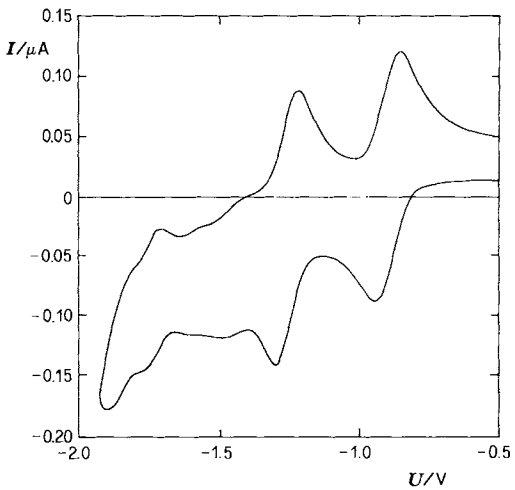


Fig. 1. Cathodic cyclic voltammogram of **3** in toluene/acetonitrile 5/1. Scan rate: $0.1\ Vs^{-1}$.

the potential at the oxidation peak developed the redox response of the polymer growing on the anode (Fig. 2, left).

The anodic and cathodic cyclic voltammograms of poly-**3** were investigated in acetonitrile. The polythiophene backbone was reversibly oxidized at 0.1 and 0.5 V (Fig. 2, right), whereas the corresponding poly-**1** showed a redox system centered at 0.0 V.[9] The charge involved is about 50% of that needed for a one-electron exchange, measured in reduction. Thus, oxidation corresponds to about 0.25 electrons per thiophene ring, a value which is usually found for polythiophenes. The side chain C_{60} substituents were reversibly reduced in three steps at -0.88, -1.38, and -1.85 V (Fig. 3).

The neutral film appeared as a violet deposit, showing an absorption maximum at 440 nm and a shoulder at 600 nm

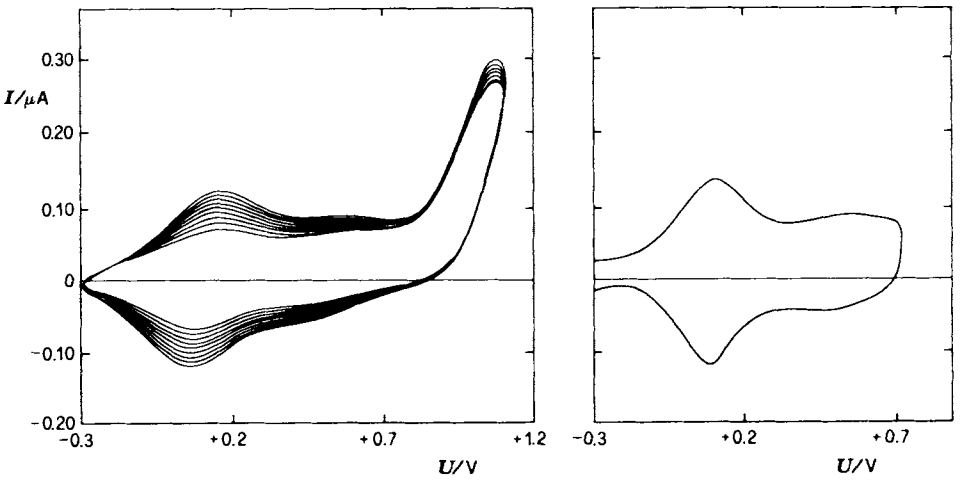

Fig. 2. Left: Repetitive cyclic voltammogram of **3** in chlorobenzene. Scan rate: 0.1 Vs^{-1}. Right: Anodic cyclic voltammogram of poly-**3** in acetonitrile. Scan rate: 0.1 Vs^{-1}.

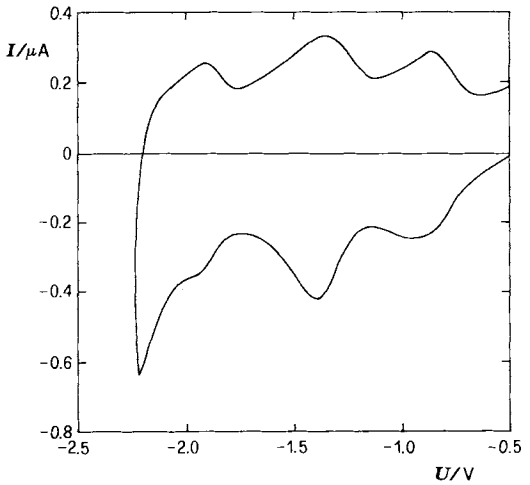

Fig. 3. Cathodic cyclic voltammogram of poly-**3** in acetonitrile. Scan rate: 0.1 Vs^{-1}.

(Fig. 4). This shoulder was assigned to the low-energy transitions of fullerene,[17] vibronically enhanced in the solid state.[18] The band at 440 nm, interpreted as the UV conjugation band of the polythiophene chain, is blue shifted in comparison with the corresponding band of poly-**1** (λ_{max} of the neutral polymer: 545 nm). This blue shift is better interpreted on the basis of a low polymerization degree, due to the very low solubility of **3**, than as the effect of the twisting of the polythiophene backbone.

Poly-**3** is the first conjugated polymer that contains covalently bound fullerene moieties as functional groups. Cyclic voltammetry has shown that both the polythiophene backbone and the C_{60} substituents retain, unaltered, their peculiar electrochemical behavior, though new properties are expected from their interaction. Work is in progress on the following aspects: 1. Characterization of the conductivity of the p-dopable polythiophene that is associated to the n-dopable fullerene pendants. 2. Study of the intermolecular photoinduced electron transfer between the C_{60} units and the conjugated polythiophene chain, as already described for C_{60}-doped polythiophenes.[19, 7]. 3. Copolymerization of **3** with a thiophene derivative carrying solubilizing groups, in order to obtain a more easily characterizable material with a lower loading of C_{60}.

Experimental Procedure

2: A solution of BuLi (1.6 M) in *n*-hexane (2.0 mL) was added dropwise to a solution of **1** (0.500 g, 2.8 mmol) in THF (10 mL) at −10 °C under nitrogen. After 15 min the reaction mixture was added to a solution of *p*-toluenesulfonylazide (0.600 g, 3.0 mmol) in THF (10 mL) at −30 °C. After evaporation of THF at reduced pressure, the residue was treated with petroleum ether and filtered. The diazo compound **2** precipitated as a red solid (0.497 g, 87% yield; m.p. 65–67 °C (decomp)) upon concentration of the clear filtrate under reduced pressure. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.2 (d, J = 5 Hz, 2H), 7.1 (d, J = 5 Hz, 2H); IR (Nujol): $\tilde{\nu}$ = 2099 (N_2) cm^{-1}. Anal. for $C_9H_4N_2S_2$: calc. C 52.92, H 1.97, N 13.71, S 31.39; found C 52.77, H 1.67, N 13.52, S 31.12.

3: **2** (0.051 g, 0.25 mmol) was added to a solution of C_{60} (0.178 g, 0.25 mmol) in toluene (200 mL) at room temperature. After 12 h, removal of the solvent under reduced pressure left a solid residue which was washed with diethyl ether to give the adduct **3** (0.112 g, 50% yield). ^{1}H NMR (300 MHz, $CS_2/CDCl_3$): δ = 7.60 (d, J = 5 Hz, 2H), 7.13 (d, J = 5 Hz, 2H); ^{13}C CP-MAS NMR (75.5 MHz, spinning speed: 4.5 kHz, contact time: 1.5 ms, TMS): main resonances at δ = 45.9, 76.1, 123.3, 127.4, 139.5, 143.1, 144.6, 147.5; FAB-MS (4-nitrobenzylalcohol): m/z 720 [$M^+ - C_9H_4S_2$], 176 [$C_9H_4S_2^+$]; UV/Vis (cyclohexane): λ_{max} = 209, 258, 328, 404, 434 nm; thermally stable up to 500 °C (DSC, in nitrogen atmosphere). Anal. for $C_{69}H_4S_2$: calc. C 92.40, H 0.45, S 7.15; found C 92.32, H 0.51, S 7.07.

Electrochemical experiments were performed at 25 °C, under nitrogen, in a three electrode cell, with a platinum working electrode (0.003 cm^2) and counterelectrode. The reference electrode was silver/0.1 M silver perchlorate in acetonitrile (0.34 V vs saturated calomel electrode). The supporting electrolyte was 0.1 M tetrabutylammonium perchlorate. Polymeric films for electronic spectroscopy were grown on indium tin oxide (ITO) sheets (0.8 × 2.5 cm; sheet resistance: 20 Ω/square).

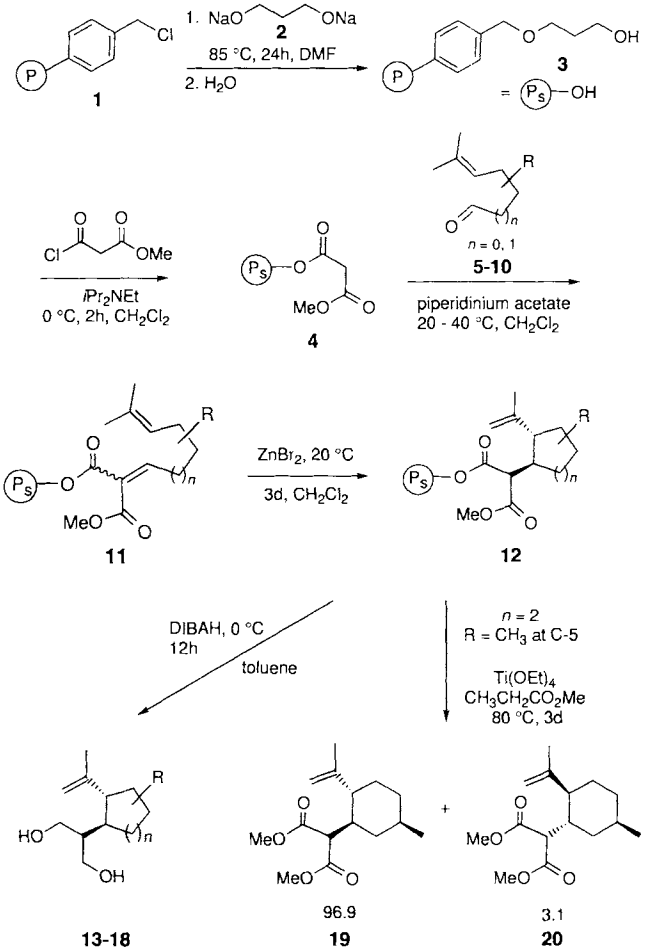
Stereoselective Solid-Phase Synthesis of Cyclopentane and Cyclohexane Derivatives by Two-Component Domino Reactions: Generation of Combinatorial Libraries**

Lutz F. Tietze* and Adrian Steinmetz

Dedicated to Professor Burchard Franck on the occasion of his 70th birthday

Despite some remarkable successes in rational drug design for the development of novel substances with interesting biological activity, one cannot neglect the importance of random screening for the identification of new lead structures. For this reason the generation of libraries of chemical compounds is of great significance. Due to the availibility of screening assays for testing the biological activity of compounds, in which only minimal amounts are needed, the area of combinatorial chemistry has developed. With this approach a huge number of products are accessible by manifold combination of different substrates, mostly by the use of solid-phase reactions.[1] Although many examples for the synthesis of biopolymers exist,[2-4] there are only a few reports on the generation of small-molecule libraries.[5-12] Herein, we describe a two-component domino reaction[13] on a solid support for the generation of diversomer libraries.

Commercially available Merrifield resin **1** (2.58 mmole of Cl per gram of resin, 2% DVB, Acros) was treated with disodium 1,3-propanediolate **2** (2 equiv, 85 °C, 24 h, DMF) and then quenched with with water to give **3**. By this procedure a spacer with a free hydroxyl group was introduced to guarantee enhanced reactivity of the substrates bound to the polymer (Scheme 1). To estimate the number of free hydroxyl groups, the



Scheme 1. Synthesis of the malonate-functionalized polymer **4** and reactions with aldehydes **5**–**10** to give the cycloalkanes **13**–**20**. Ⓟ = polymer, Ⓡ = spacer-modified polymer.

spacer-functionalized resin **3** was treated with 3,5-dinitrobenzoyl chloride in pyridine to afford the corresponding immobilized ester. Measurement of the nitrogen content by elemental analysis indicated 0.75 mmole of hydroxyl groups per gram of resin. Compound **3** was then transformed into the malonate-functionalized polymer **4**, which was needed for the subsequent domino Knoevenagel–ene reaction, by treatment with malonic acid methyl ester chloride (2 equiv iPr_2NEt, 0 °C, 2 h, CH_2Cl_2). The two-component domino reaction was performed by condensation of **4** with the Δ^5 and Δ^6 unsaturated aldehydes **5**–**10** (3 equiv) in the presence of catalytic amounts of piperidinium acetate (0.1–0.2 equiv, 20 °C, 1–3 h, CH_2Cl_2) and subsequent addition of $ZnBr_2$ (1.1 equiv, 20 °C, 3 d, CH_2Cl_2). Generally, the primary Knoevenagel reaction yielding **11** proceeded without the addition of any drying agents; however, condensation of α-substituted aldehydes required added sodium sulfate and elevated temperatures (40 °C). The subsequent intramolecular ene reaction led to the cyclopentane and cyclohexane derivatives **12**, which can be cleaved from the support providing the products **13**–**18**,[14] and **19** and **20**, respectively. Thus, the reduction of **12** with diisobutylaluminum hydride (4 equiv, 0 °C, 12 h, toluene)

[**] This work was supported by BASF and the Fonds der chemischen Industrie.

resulted in the generation of the corresponding diols **13**–**18**, whereas transesterification in dry methyl propionate in the presence of titanium(IV) ethoxide (1 equiv, 80 °C, 3 d)[15] afforded the substituted methyl malonates **19** and **20**. In both transformations the products were obtained in good yield and high purity as well as with excellent simple and induced diastereoselectivity (Table 1). The yields based on the number of free hydroxyl groups on the polymer range from 41 to 61% and the cleaved products had purities of about 90%. The linkage to the polymeric support seems not to influence the simple and induced diastereoselectivity of the ene reaction.[13, 16] This is surprising when one assumes that the alkylidene intermediates exist as *E*/*Z* mixtures. In each case the *trans*-1,2-disubstituted cyclohexanes were formed with a simple diastereoselectivity of *ds* > 99:1 and the corresponding *trans*-1,2-disubstituted cyclopentanes with *ds* = 98.5:1.5. For the reaction with the α-substituted aldehydes **5** and **8**, the induced diastereoselectivity was *ds* > 99:1, whereas for the reaction of the β-substituted aldehyde **7** an induced diastereoselectivity of *ds* = 96.9:3.1 was found. As expected, employing the geminally disubstituted aldehydes **9** and **10** resulted in only a low induced diastereoselectivity.

Table 1. Yields and diastereoselectivities of the reactions of polymer-bound malonate **4** with aldehydes **5**–**10** giving products **13**–**18**.

Substrate	Major product	Yield [%] [a]	*trans*:*cis* [b]
 **5**	 **13**	61	98.5:1.5
 **6**	 **14**	63	>99:1
 **7**	 **15** + diastereomer 97.2 : 2.8	61	>99:1
 **8**	 **16**	59	>99:1
 **9**	 **17** + diastereomer 78 : 22 [c]	51	>99:1
 **10**	 **18** + diastereomer 58 : 42	48	>99:1

[a] The overall yield is based on the concentration of free hydroxyl groups in **3**. [b] Determined by GC analysis of the silylated crude products. [c] The major product was assigned based on the assumption of a chair-like transition structure [16, 17] and the preferred orientation of the geminal substituents [18].

The transformations on solid support have significant advantages over those in solution. Since products are obtained with higher purity, chromatographic separation is unnecessary. Furthermore, isomerization of the double bond in the initially formed alkylidene 1,3-dicarbonyl compounds, which is frequently observed for reactions in solution, does not occur. Also the possible intramolecular carbonyl ene reaction of the aldehydes is of little importance since the free alcohols formed are removed when the polymer-bound products are washed.

The good yields, the high purity of the products, and the simple procedure for the reaction sequence described here make its application for the synthesis of combinatorial libraries very attractive. Therefore we synthesized a sample library by simultaneous Knoevenagel condensation of an equimolar mixture containing the aldehydes **5**–**10** and polymer-bound malonate **4** (0.15 equiv of each aldehyde for 1 equiv of malonate) followed by $ZnBr_2$-initiated ene reaction and reductive cleavage of the products from the resin. To analyze the mixture of the resulting diols **13**–**18**, they were transformed into the corresponding bis(trimethylsilyl) ethers and examined by gas chromatography. It was found that the purity was greater than 90% and all compounds occurred in similar ratio (with the exception of **16** which showed a concentration of only 7%) in an overall yield of about 45%.

A major advantage of this procedure is the possibility of conducting the synthesis without the "split and combine" technique. Moreover, it can be carried out on readily available and inexpensive Merrifield resin. We are currently investigating the increase of diversity by studying the cleavage of the products using different alcohols and amines and the implementation of a three-component reaction on a solid support.

Addition of Organic 1,3-Dipolar Compounds across a Heterobinuclear Bond between Early and Late Transition Metals: Mechanism of Nitrogen Loss from an Organoazido Complex To Form a Bridging Imido Complex**

Tracy A. Hanna, Anne M. Baranger, and Robert G. Bergman*

Organic azides are commonly used in transition metal chemistry as sources of :NR moieties to form metal imido complexes.[1-3] When a metal–metal bond is exposed to an organic azide, for example, the product is usually a complex with a bridging imido group.[4, 5] However, in spite of the frequent use of this methodology, little mechanistic information is available on either the mono-[6, 7] or binuclear versions of this reaction. In this paper we report: a) that both azides and diazo compounds add smoothly, and without N_2 loss, to the polarized metal–metal bond in an early–late heterobinuclear (ELHB) complex, to yield new heterobinuclear adducts that have very similar solid-state structures; b) the diazo compound adduct is inert to both heat and light, but thermolysis of the azide complexes leads smoothly to N_2 and the corresponding ELHB bridging imido complexes; c) studies involving isotope labeling, kinetics, and substituent effects reveal a mechanism in which electron-withdrawing substituents stabilize the transition state for imido complex formation.

Addition of phenyl azide to $[Cp_2Zr(\mu\text{-}NtBu)IrCp^*]$ (**1**)[8, 9] resulted in immediate formation of dark green **2** in 75% yield (Fig. 1). Similarly, addition of ethyl diazoacetate to **1** produced the dark green diazo adduct **3** in 59% yield. Both reactions proceed without loss of N_2. X-ray diffraction studies of **2** and **3** have been carried out, and their solid-state structures are remarkably similar.[10, 11] As shown in Figure 1, both are end-on (terminal) adducts, and the terminal nitrogen atom and phenyl or carboxylate groups are oriented *anti* to one another. The phenyl azido ligand of **2**, the diazo ligand of **3**, and the heteronuclear cores in both complexes are planar, and in both molecules the $IrZrN_2$ core and RXN_2 fragments lie in the same plane. The nitrogen–nitrogen distances in **2** are intermediate between single- and double-bond distances, showing some electron delocalization across the ligand. Likewise, the N2-N3-N4 angle is 111° rather than the 120° that would be expected for an sp^2 nitrogen center. In **3** the N–N distance (1.30 Å) is shorter than that of a typical single bond, consistent with electron delocalization, but the N2-N3-C25 angle of 119° is closer to the sp^2 standard. The C25–N3 bond length of 1.33 Å is also indicative of some delocalization (for example, C–N of pyridine is 1.338 Å). There is no sign of the formation of the more sterically hindered isomers in either compound.[12-17]

Irradiation of azide adduct **2** and diazo adduct **3** in a quartz vessel for 12 hours at room temperature led to only a trace of the product formed by nitrogen loss. Complex **3** also did not undergo clean thermal decomposition. However, thermolysis of **2** at 75 °C readily caused nitrogen loss and quantitative formation (NMR determination) of the diimido complex **4** (43% yield of isolated product). The structure of this material has also been determined by X-ray diffraction (Fig. 2). In contrast to **2** and **3**, in **4** the $ZrIrN_2$ core is slightly buckled. The metal–nitrogen distances are very similar to one another and typical for complexes with bridging imido ligands.[2, 18-20]

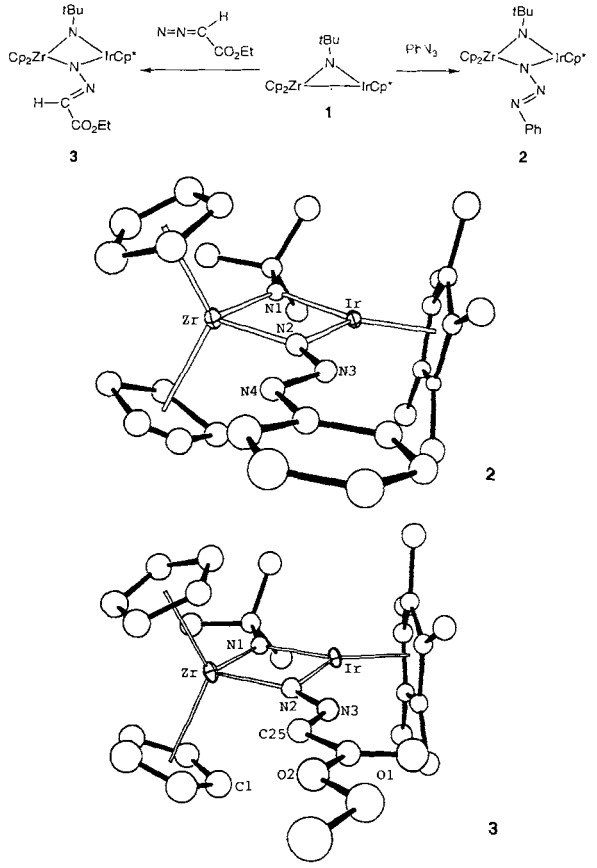

Fig. 1. Formation of **2** and **3** from **1** (top) and ORTEP diagrams showing the structures of complexes **2** and **3** (bottom) (Cp = C_5H_5; Cp* = C_5Me_5). Disorder in one of the Cp rings of complex **2** is not shown. Selected intramolecular distances [Å] and angles [°] for **2**: Ir–Zr 2.938(1), Ir–N1 1.983(9), Ir–N2 2.072(10), Zr–N1 2.076(10); Zr–N2 2.027(10), N1-Ir-N2 88.4(4), N1-Zr-N2 87.2(4), Ir-N1-Zr 92.7(4), Ir-N2-Zr 91.6(4), N2–N3 1.320(13), N3–N4 1.331(13), N4–C25 1.417(15), N2-N3-N4 111.1(9), N3-N4-C25 111.6(10). For **3** Ir–Zr: 2.922(1), Ir–N1 1.948(9), Ir–N2 2.096(7), Zr–N1 2.071(7), Zr–N2 2.020(7), N1-Ir-N2 88.8(3), N1-Zr-N2 87.6(3), Ir-N1-Zr 93.2(3), Ir-N2-Zr 90.4(3), N2–N3 1.304(10), N3–C25 1.331(12), N2-N3-C25 119.2(7), N3-C25-C26 115.2(8).

The smooth thermal conversion of **2** to **4** provided us with an opportunity to investigate the mechanism of this N_2-loss reaction. The kinetics of N_2 loss from **2** were followed by ^1H NMR spectroscopy from 75 to 105 °C. The rate law was rigorously first order at all temperatures. A plot of $\ln k/T$ vs. $1/T$ (Fig. 3) provided the following activation parameters for the thermolysis: $\Delta H^{\ddagger} = 29 \pm 1$ kcal mol^{-} and $\Delta S^{\ddagger} = 0 \pm 2$ e.u. The activation entropy indicates little gain or loss of geometrical restriction in the transition state and is consistent with the exchange studies in suggesting that dissociation of PhN_3 is unlikely. Complex **2** labeled with ^{15}N at the phenyl-substituted nitrogen was prepared by treating the starting Zr–Ir complex **1** with $Ph-{}^{15}N{=}N{=}N$. Upon thermolysis the corresponding isotopically labeled arylimido complex **4**-^{15}N was obtained, with no evidence of the presence of unlabeled **4**.

[**] We acknowledge Dr. F. J. Hollander, Director of the X-ray Diffraction Facility (CHEXRAY) at the University of California, Berkeley, for solving the crystal structures of compounds **2**, **3**, and **4**, and Professors T. Don Tilley and K. N. Raymond for helpful discussions. Support for this work was provided by the National Science Foundation (Grant no. CHE-9113261). We are also grateful to the Johnson Matthey Aesar/Alpha Corporation for a generous loan of iridium trichloride.

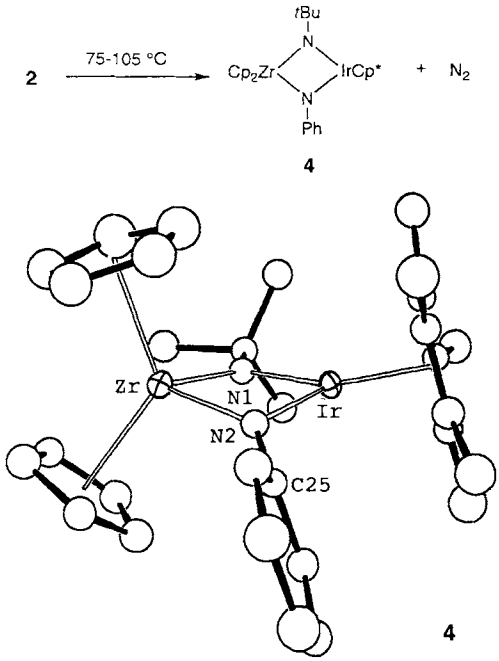

Fig. 2. Formation of complex **4** from complex **2** (top) and ORTEP diagram showing the structure of complex **4**. Selected intramolecular distances [Å] and angles [°]: Ir–Zr 2.900(1), Ir–N1 1.977(7), Ir–N2 2.066(7), Zr–N1 2.055(7), Zr–N2 1.985(7); N1-Ir-N2 87.1(3), N1-Zr-N2 87.2(3), Ir-N1-Zr 92.0(3), Ir-N2-Zr 91.4(3).

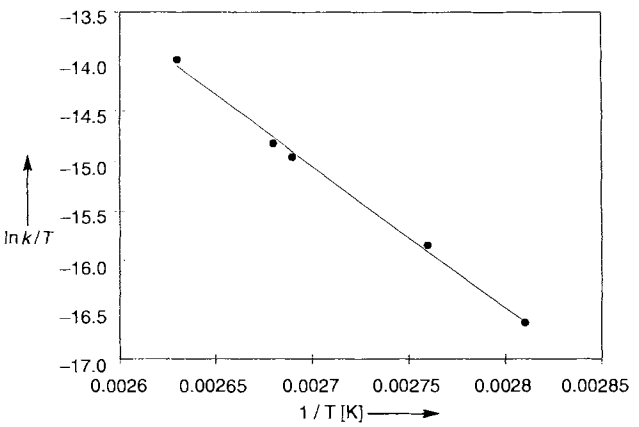

Fig. 3. Eyring plot for the loss of nitrogen from **2** to form **4**.

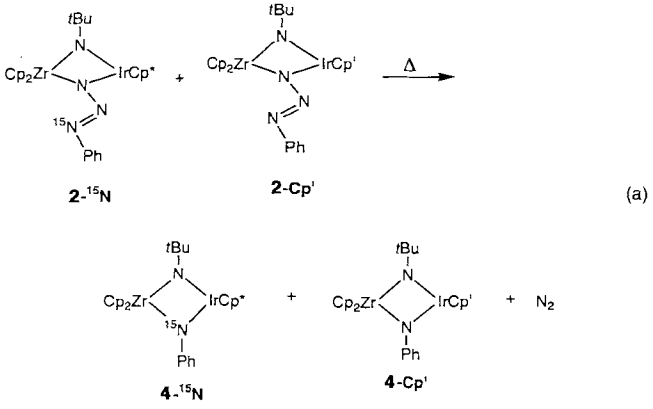
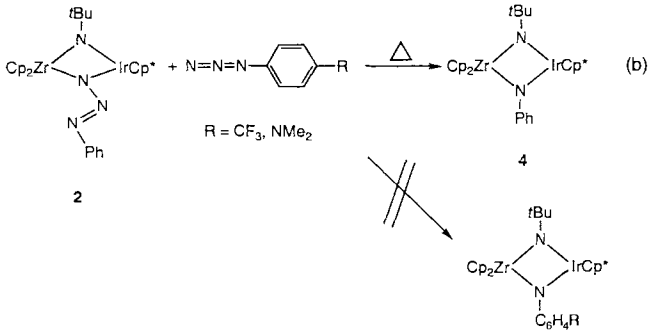
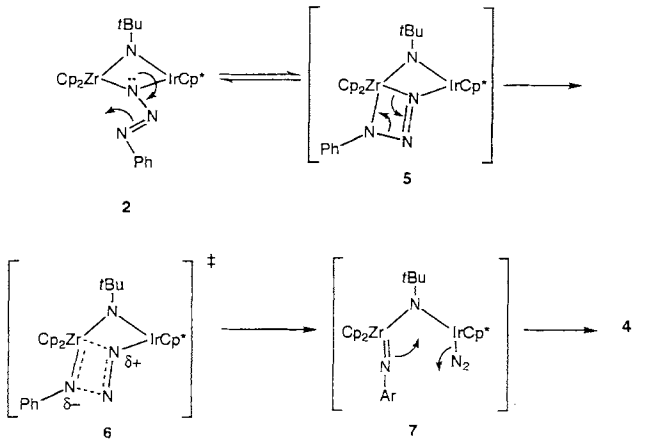
A crossover experiment [Eq. (a), Cp′ = $EtMe_4Cp$] established that the nitrogen loss proceeds without fragmentation of the heterobimetallic core. Thermolysis of a mixture of **2**-^{15}N and **2**-Cp′ led to **4**-^{15}N and **4**-Cp′ but no crossover products (**4**-Cp′,^{15}N or **4**).[21] The possibility of reversible loss of RN_3 from adduct **2** was investigated by addition of excess *p*-$CF_3C_6H_4N_3$ and *p*-NMe_2-C_6H_4-N_3 to solutions containing **2** [Eq. (b)]. Only **4** was formed; neither exchange product was observed at temperatures up to 75 °C.





To examine the effect of electron density changes on the N_2 loss, we measured the rate of decomposition of several ArN_3 complexes in which the *para* substituent on the aryl group was varied. A linear Hammett plot was constructed from these data; this yielded an ρ value of +0.4, which indicates that electron-withdrawing substituents exert a modest activating effect upon the reaction rate. This is somewhat surprising, because we expected that the rate-determining step of the reaction would involve nucleophilic attack of the phenyl-substituted azide nitrogen atom at the zirconium center.

The overall mechanism illustrated in Scheme 1 is most consistent with our observations. Because the N–Ph group is located



Scheme 1. Proposed mechanism for the loss of nitrogen from **2** to form **4**.

close to the Zr center in the starting material, we suggest (as initially assumed) that Zr–N bond formation involving nucleophilic attack of the N atom at the Zr center is the first step in the reaction. However, to account for the aryl substituent effects we suggest that this step is rapid and reversible, probably taking place over a relatively low barrier and leading to intermediate **5**. The second step of the reaction, which proceeds via the rate-determining transition state **6**, involves cleavage of the Zr–N and N–N bonds to give intermediate **7**. This species then undergoes fast N_2 dissociation and recyclization to give the final product **4**. The electronic effect supports a partial negative charge on the aryl nitrogen in the transition state **6**, as shown.

Experimental Procedure

General laboratory procedures were as described previously [9]. Commercial reagents were used, except for phenyl azide [22] and **1** [8,9], which were prepared by published procedures.

2: PhN_3 (34.8 mg, 0.293 mol) in toluene (3 mL) was added to a solution of **1** (201 mg, 0.325 mol) in toluene (5 mL). The color changed immediately to dark green. Dark green **2** (162 mg, 120 mmol, 75%) was crystallized directly from the reaction mixture at −30 °C. ^1H NMR ([D$_8$]THF) δ = 1.69 (s, 9H), 1.80 (s, 15H), 5.76 (s, 10H), 6.92 (t, J = 7.33 Hz, 1H), 7.26 (t, J = 7.25 Hz, 2H), 7.60 (m, 2H); $^{13}C\{^1H\}$ NMR ([D$_8$]THF) δ = 10.7, 35.9, 71.1, 90.8, 108.7, 120.9, 122.4, 129.2, 156.0; IR ([D$_8$]THF) $\tilde{\nu}$ = 3419 (br), 2917, 1590, 1477, 1376, 1343, 1229, 1182, 787, 673 cm^{-1}. Elemental analysis: Calcd. for $C_{30}H_{34}IrN_4Zr$: C 48.75, H 5.32, N 7.58. Found: C 48.43, H 5.35, N 7.20.

3: Ethyl diazoacetate (21.9 μL, 0.208 mol) in toluene (5 mL) was added to a solution of **1** (110 mg, 0.177 mol) in toluene (15 mL); the color changed immediately to dark green. The reaction mixture was concentrated in vacuo to approximately 2 mL and cooled to −30 °C to obtain dark green **3** (77 mg, 0.105 mol, 59%). ^1H NMR ([D$_8$]THF) δ = 1.30 (t, J = 7.12 Hz, 3H), 1.47 (s, 15H), 1.50 (s, 9H), 4.49 (q, J = 7.12 Hz, 2H), 5.61 (s, 10H), 7.29 (s, 1H); $^{13}C\{^1H\}$ NMR ([D$_8$]THF) δ = 9.9, 15.1, 35.3, 59.0, 69.9, 91.0, 107.5, 121.0, 166.2; IR (Nujol) $\tilde{\nu}$ = 3103, 2996, 1674, 1425, 1479, 1338, 1116, 1022, 788, 694, 553 cm^{-1}. Elemental analysis: Calcd. for $C_{28}H_{40}N_3O_2IrZr$: C 45.81, H 5.49, N 5.72. Found: C 45.67, H 5.43; N 5.68.

4: Complex **2** (159 mg, 0.215 mol) was dissolved in toluene (15 mL) and loaded into an airtight reaction bomb. The solution was heated to 75 °C for one week, and then the volatile materials were removed in vacuo. The solid was recrystallized from a mixture of hexanes to obtain dark green **4** (66 mg, 0.093 mmol, 43%). ^1H NMR ([D$_8$]THF) δ = 1.53 (s, 15H), 1.70 (s, 9H), 5.62 (s, 10H), 6.75 (m, 1H), 6.81 (m, 2H), 7.18 (m, 2H); $^{13}C\{^1H\}$ NMR ([D$_8$]THF) δ = 11.0, 36.1, 68.9, 88.6, 109.5, 120.0, 125.3, 128.3, 167.9; IR ([D$_8$]THF) $\tilde{\nu}$ = 3103, 3062, 2967, 2912, 1584, 1482, 1379, 1352, 1284, 800, 691 cm^{-1}. HRMS (EI) m/z: calcd. for $C_{30}H_{39}IrN_2Zr$: 710.1790 (M^+); found: 710.1782 (M^+).

[11] A referee expressed concern about several of the difficulties we encountered in solving the structure of complex **2**. We therefore re-analyzed the structure after receiving the reviews of the paper. One cyclopentadienyl ring is disordered; as an alternative to the modeling method used in the first report (fixed B_{iso} constant, refined occupancies), this part of the structure was modeled with nine atomic carbon positions to give a total occupancy of 5.0 carbons. In the new analysis the metal atoms and all four nitrogen atoms have been refined anisotropically, but we were not able to refine the carbon atoms of the complex with anisotropic thermal parameters, because these always yielded solutions in which one or more carbon atoms had nonpositive, definite thermal tensors. Inspection of the data revealed that there were many reflections in the data set with F_o significantly greater than F_{calc}, both for low and high intensity reflections, indicating some minor problem of unknown nature with the data set. The 29 reflections with worst agreement between F_o and F_{calc} were removed from the least squares refinement. With these adjustments, the structure refined with R = 0.037, wR = 0.039 and GOF = 1.29. We have consulted with Prof. K. N. Raymond about the overall reliability of the structure. Both he and Dr. Hollander agree that there may be some minor error in the final metrical parameters but there is very little chance that the atom connectivity is incorrect.
[12] Some representative examples of structurally characterized metal–metal bridging organodiazo complexes are given in Refs. [13–20].

Pr[MOE-DO3A], a Praseodymium Complex of a Tetraazacyclododecane: An In Vivo NMR Thermometer

K. Roth,* G. Bartholomae, H. Bauer, T. Frenzel, S. Kossler, J. Platzek, B. Radüchel, and H.-J. Weinmann

As most biochemical reaction cascades are exothermic, the spatial temperature distribution within a living organism directly reflects local metabolic activity. NMR spectroscopy is an ideal technique for measuring in vivo tissue temperature because it is noninvasive. Potential applications of an in vivo NMR thermometer could be the detection and localization of tumors, inflammations, and infarctions. Furthermore, an in vivo NMR thermometer would be of invaluable help in hyperthermia treatment of malignant tumours,[1,2] where the amount of heat applied depends on the actual temperature in the region of interest and its surroundings. Unfortunately, none of the various existing thermometers developed for high-resolution NMR studies is suitable for in vivo studies because the majority of the reference compounds are not soluble in water and/or are toxic.[3–8] To the best of our knowledge, only perfluorotributylamine has been used as a temperature probe in an in vivo system.[9] However, the application of this compound is very limited, because as perfluorotributylamine is not miscible with water, small bubbles of the pure substance have to be injected into the region of interest.

We have developed a new type of highly water-soluble in vivo NMR temperature probes based on paramagnetic lanthanide chelate complexes. This class of compounds is closely related to the gadolinium-based contrast agents used routinely in clinical magnetic resonance imaging. These complexes are suitable temperature probes based on the following considerations. The chemical shift δ_{obs} of a nucleus in a paramagnetic compound is given by Equation (a).[10,11] The diamagnetic term, δ_{dia}, is small

$$\delta_{obs} = \delta_{dia} + \delta_{con} + \delta_{dip} \quad (a)$$

and virtually temperature-independent, whereas the other terms, δ_{con} and δ_{dip}, vary strongly with temperature.[12,13] The contact term, δ_{con}, describes the through-bond transfer of electron spin density from the lanthanide ion to the observed nucle-

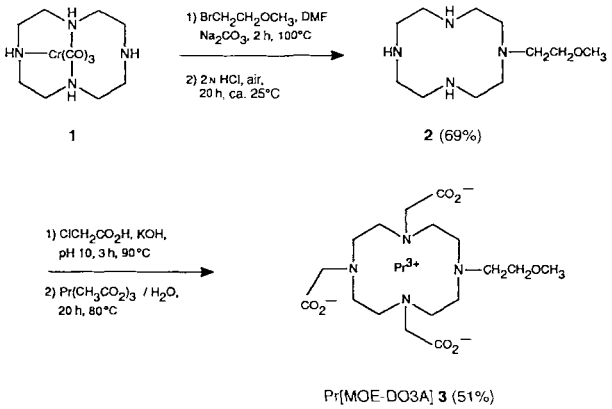
us; the dipolar term, δ_{dip}, describes the through-space interaction between the dipolar magnetic field centered at the lanthanide ion and the observed nucleus.

In the course of our studies of paramagnetic lanthanide chelate complexes[14] we have examined the applicability of many chelates as NMR thermometers. Pr[MOE-DO3A] **3**, the praseodymium complex of 10-(2-methoxyethyl)-1,4,7,10-tetraazacyclododecane-1,4,7-triacetate,[15] proved to be the most promising compound.

Complex **3** was synthesized by alkylating the chromium tricarbonyl complex (**1**) of cyclene[16] with 2-methoxyethyl bromide, resulting in the monoalkylated product **2**. Reaction of **2**



with monochloroacetic acid[17] and complex formation with praseodymium triacetate yielded **3**. Thermodynamically, complex **3** is very stable ($\lg K = 19.2 \pm 0.1$[18]); its high tolerance in mice (LD_{50} (mouse) $= 12.5$ mmol kg^{-1}) is comparable to that of the gadolinium chelates used routinely as contrast media in diagnostic imaging.

The great number of signals in the ^{1}H NMR spectrum (Fig. 1) of a solution of **3** in D_2O is the result of the chirality of the complex. In the solid state the praseodymium ion in **3** is ninefold coordinated, as in other related lanthanide complexes.[19–21]

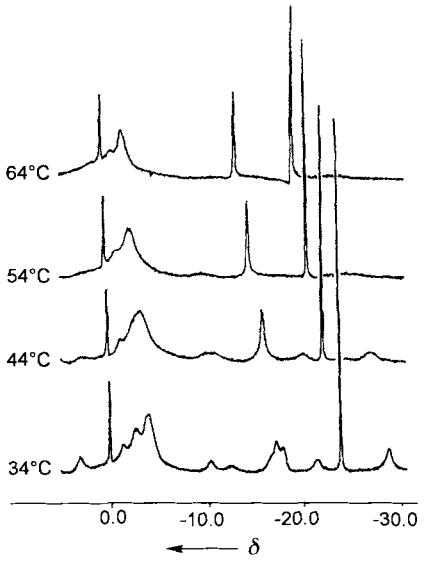


Fig. 1. High-resolution 250 MHz ^{1}H NMR spectrum of a 5 mM solution of **3** in D_2O at several temperatures. The chemical shift scale is referenced to the residual proton signal of D_2O ($\delta = 0$). For each spectrum 64 FIDs were accumulated with a repetition time of 0.5 s. No time-domain filter functions were applied.

Due to intramolecular racemization in solution, the ^{1}H NMR spectrum shows line-broadening effects with varying temperature. Unlike all other signals, however, the line width of the methoxy group signal at approximately $\delta = -24$ (relative to water) remains virtually unchanged in the temperature range studied. It is this temperature-sensitive signal ($\Delta\delta = 0.131$ ppm K^{-1}) that forms the basis for the temperature determination.

The detection of weak ^{1}H NMR signals from compounds in the millimolar concentration range in an in vivo system is much more difficult, due to the presence of the strong signal arising from water in tissue. The large dynamic range of $1:10^5$ leads to an additional noise contribution because of the limited resolution of the analog-to-digital converter.[22] Since the frequency difference between the protons of the methoxy group of Pr[MOE-DO3A] and the protons of the water tissue is relatively large (24 ppm), the strong water signal can be suppressed very effectively through various techniques such as selective excitation of the signal of interest, selective saturation of the water signal, and use of low-pass audiofilters, which are standard in every NMR spectrometer or imager.

The chemical shift of the methoxy protons of **3** varies linearly with temperature within the range relevant to clinical situations. The temperature calibration curve was determined with a solution of the complex in bovine plasma, which approximates the extracellular matrix where **3** is distributed in vivo. Other physiological parameters such as pH (± 1.0 pH unit) and the concentration of the complex (between 0.2 and 10 mmol L^{-1}) do not change the calibration curve within experimental error. The calibration curve can be obtained from a least-square fit (correlation coefficient = 0.998) and is given by Equation (b).

$$T[°C] = 210.2 - 7.634\,\delta_{obs} \qquad (b)$$

In a first in vivo application of the new NMR thermometer we monitored the body temperature of a rat during anesthesia. Thirty minutes after anesthetization, one mmole of **3** per kilogram body weight was administered intravenously. The NMR spectrum was measured by using a surface coil positioned over the liver. In this arrangement, the NMR signal originated only from liver tissue (lower spectrum in Fig. 2). To demonstrate the response of the NMR thermometer, the animal's body temperature was raised a few degrees with a heated waterbed (upper spectrum in Fig. 2).

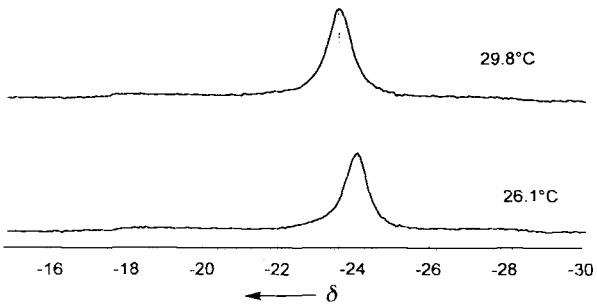

Fig. 2. In vivo ^{1}H NMR spectra of the liver of an anaesthetized rat after intravenous administration of 1 mmol of **3** per kg of body weight. The ^{1}H NMR signal of the methoxy group was excited with a frequency-selective 4 ms Gauss pulse and detected by using a surface coil (2 cm diameter) placed above the liver of the animal. 1500 FIDs with a repetition time of 0.16 s were accumulated, resulting in a total measurement time of about 4 min. The temperature was determined from the chemical shift (with respect to tissue water) according to Equation (b). These calculated values agreed closely with those measured directly with a rectal thermocouple. Upper spectrum: anesthesized rat with additional heating (waterbed at 44 °C). Lower spectrum: anesthesized rat without additional heating.

Although the volume selection in this first in vivo demonstration was achieved with a simple surface coil, **3** can be used as a thermometer in other, more sophisticated localization schemes.[23] Since the a transversal relaxation time (T_2) of the methoxy protons is approximately 10 ms, short spin-echo pulse sequences may be used for volume selection. The longitudinal relaxation time (T_1) of the methoxy protons is 47 ms in bovine plasma, which allows short repetition times. The high sensitivity and precision of the Pr[MOE-DO3A] thermometer could be used to generate images representing temperature distribution[24] in order to identify and localize regions of abnormal metabolic activity or to monitor temperature during thermal energy therapy (for instance, laser-induced interstitial thermotherapy, hyperthermia).

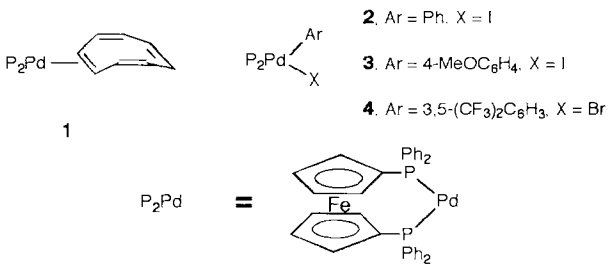
Characterization of Reactive Intermediates in Palladium-Catalyzed Arylation of Methyl Acrylate (Heck Reaction)**

John M. Brown* and King Kuok (Mimi) Hii

Among palladium-catalyzed reactions available to the synthetic organic chemist, the Heck reaction has enjoyed widespread use. This stems in part from the variety of circumstances in which coupling occurs with high yield and regioselectivity,[1] and in part from successful application to asymmetric synthesis.[2] The coupling reaction often requires forcing conditions, and optimization has proceeded by empirical methods, with a bewildering variation of base, solvent, and catalysts. Since mechanistic information is rather lacking, we have begun a project with an emphasis on the characterization of true catalytic intermediates in solution for the case of a bis(phosphane)palladium catalyst.

Much recent work employed organotriflate electrophiles[3] or organohalides in the presence of silver salts, which has led to the presumption that cationic palladium intermediates are involved. In the first instance we studied the addition of aryl triflates to the organopalladium complex **1**, which had been



previously used in mechanistic work on catalytic cross-coupling.[4] The reaction is fairly slow at −25 °C and did not give rise to the desired product (vide infra). For this reason the fully characterized aryl halide complexes **2**–**4** were treated with silver triflate in THF at −78 °C, and the products examined by ^{31}P NMR after removal of silver salts by low-temperature centrifugation. In each case an AB quartet was observed in the range −60° to −35 °C, although only the product from **4** was stable at higher temperatures. In that case rapid isolation at 0 °C gave a yellow ionic solid (specific molar conductivity, Λ_m = 4.91 $S cm^{-1} mol^{-1}$ (THF, −20 °C))[5] with an electrospray MS (*m*/*z* 873) that corresponds to the $Ar\{P_2Pd\}^+$ ion with the predicted isotope pattern. In all three cases the low-temperature ^{31}P NMR spectrum in THF exhibited characteristic broadening of both signals, more evident in the high-field partner. The reaction with complex **2** was investigated in most detail. On cooling from −40 °C, the ^{31}P NMR spectrum at 101.3 MHz in THF broadened and then separated below the coalescence region of about −70 °C into two distinct AB systems: At −98 °C the chemical shifts for spin system (A) were δ_P = 35.4 and 13.5

[**] We thank EPSRC for postdoctoral support (to K. K. H.) and Johnson-Matthey for the loan of palladium salts. We are grateful to Professor P. J. Stang for his insights into Pd triflate chemistry and Professor A. Jutand for an exchange of information. Dr. R. T. Aplin was very helpful in the obtention of electrospray MS.

(J = 30 Hz), and those for spin system (B) δ_P = 34.8 and 16.0 (J = 30 Hz); the ratio of signal intensities was about 1:2. Assuming a dissociative exchange mechanism we calculated a rate constant k_{ex} of 800 s^{-1} at −70 °C (Fig. 1). The identity of the second complex was defined by addition of H_2O to the sample,

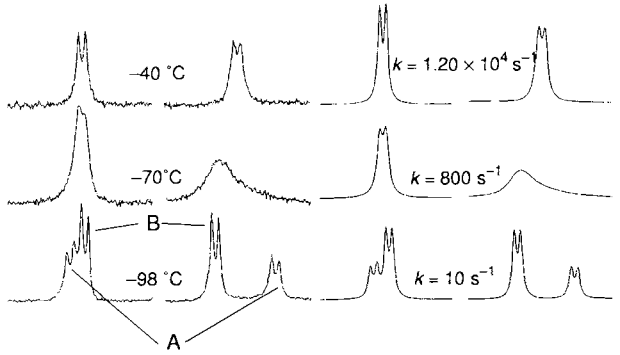

Fig. 1. The observed (left) and simulated (right) $^{31}P\{^1H\}$ NMR spectra for the equilibrium between solvate complexes **5** and **6**; simulation was carried out with the program gNMR.

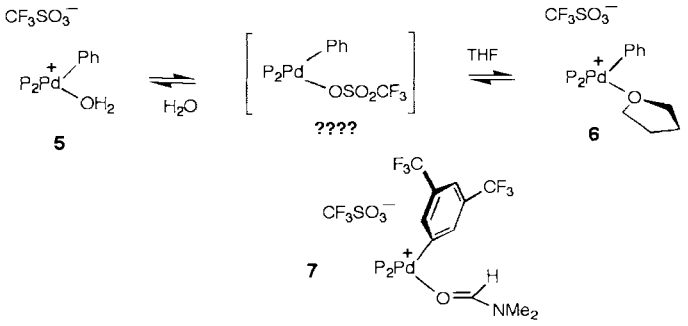
which shifts the equilibrium towards spin system (A). These observations are consistent with a fast exchange between solvates **5** and **6** (giving rise to signals (A) and (B) respectively, Scheme 1). Since the concentration of H_2O is low, its binding

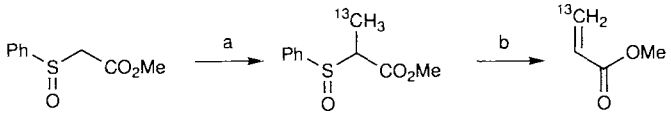


Scheme 1. Solvation equilibria for arylpalladium cations.

constant to Pd is concomitantly high:[6] $K_{aq} \approx 500$ M^{-1} has been estimated from the titration of the THF solution of the triflate derived from **2** with 1% H_2O in THF. When dimethylformamide (DMF) (1–3 μL) was added to a sample of the triflate salt derived from **4** (0.02 M in THF) at −78 °C, a single nondynamic species, (δ_P = 15.3 and 37.1, J = 27 Hz) was observed, which can be attributed to structure **7**. An important recent study of the addition of aryl triflates to $[(PPh_3)_nPd^0]$ complexes concluded that the main species produced was an ionic *trans*-$[Ar(PPh_3)_2Pd^+]$ complex; the existence of strongly bound DMF complexes was noted.[7]

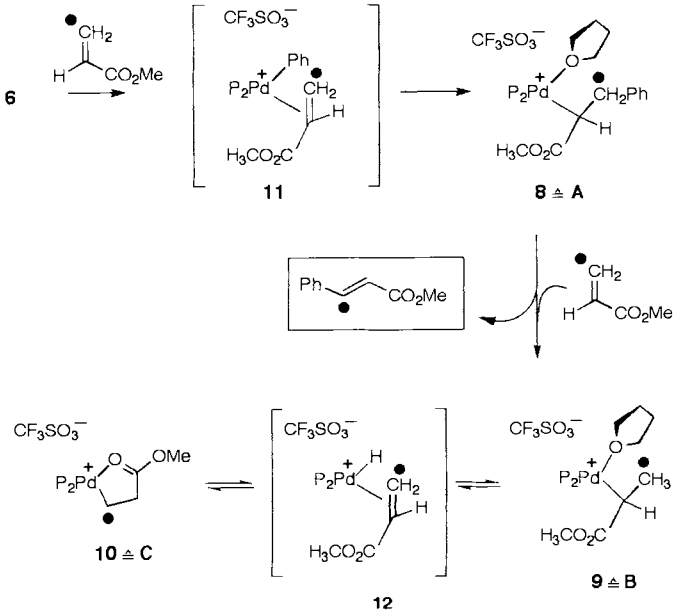
Alkenes, including norbornene, methyl acrylate, 2,3-dihydrofuran, and 2,5-dihydrofuran, reacted with the triflate complexes at low temperatures. For the most part, this was manifested by changes in the ^{31}P NMR first to form a new AB quartet, and then by decomposition around −30 °C. The most clear-cut results were obtained with an excess of methyl acrylate. At −60 °C, there is a slow pseudo-first-order conversion of complex **6** ($k_{obs} = 2.35 \times 10^{-4}$ s^{-1} with 20-fold excess of methyl acrylate; **5**:**6** = 1:3) into a new species A (δ_P = 42.5, 20.8, J = 33 Hz). The rate is slower at lower concentrations of methyl acrylate, and also when H_2O (1.5 equiv) is added, indicating a pre-equilibrium competition between alkene and solvent for the labile coordination site.[8] If the sample is then warmed to −40 °C, a further transformation takes place, which results in the formation of **B** (δ_P = 41.4 and 20.6, J = 37 Hz). This intermediate is in turn converted into C (δ_P = 40.4 and 17.5, J = 35 Hz), and that product is stable to 0 °C. Electrospray MS of **C** isolated as the bromide (m/z 746) indicated the basic structural elements ($H_2C{=}CHCO_2Me$ and $\{P_2Pd\}H^+$). Direct electrospray MS whilst **A** was still present indicated the structural elements $H_2C{=}CHCO_2Me$ and $\{P_2Pd\}Ph^+$. The ^1H NMR spectrum indicated concomitant formation of *E*-methyl cinnamate as the only organic product at −40 °C, which was confirmed by its isolation.

In order to identify the various transient species, a new synthesis of [3-^{13}C] methyl acrylate was developed (Scheme 2).[9]



Scheme 2. Synthesis of ^{13}C-labeled methyl acrylate. a) NaH, 1,3-dimethylhexahydro-2-pyrimidinone (DMPU), THF, 0 °C then $^{13}CH_3I$, 51% yield; b) 125 °C, 2 h, 74% yield.

Reaction of an excess of this labeled compound with complex **6** (Scheme 3) clearly showed that **A** was the Pd alkyl **8** ($\delta(^{13}C)$ = 35.3, $J_{C,P}$ = 4 Hz for the ^{13}C nucleus *trans* to the P atom). In similar manner complex **B** was shown to have structure **9** (δ = 13.6; $J_{C,P}$ = 5 Hz), and **C** to be the regioisomeric complex **10** (δ = 30.8; $J_{C,P}$ = 85 Hz). Complexes **8** and **9** both disappear rapidly when 2,4,6-trimethylpyridine is added to the solution at the appropriate stage, but complex **10** is robust to this treatment. The rearrangement is intermolecular and occurs via the unobserved hydride complex **12**, since addition of unlabeled methyl acrylate to the reaction after **8** had disappeared led to the equilibrium distribution of ^{13}C-label in the ultimate product **10**. No other species except *E*-methyl cinnamate (δ = 145.5) were detectable by ^{13}C NMR spectroscopy. Two ^{31}P NMR spectra



Scheme 3. Heck intermediates observed by heteronuclear NMR spectroscopy. The complex **12** exchanges acrylate ligands with the acrylate pool. The labeled C atom is indicated as ·C.

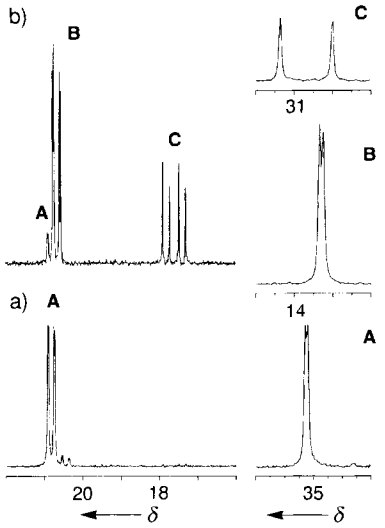


Fig. 2. Left : the high-field region of the $^{31}P\{^1H\}$ NMR spectrum of the reaction between the solvate species **5**/**6** and 3-$\{^{13}C\}$ methyl acrylate a) after about 2 h at −60 °C and b) after warming to −40 °C and holding for a further hour. The $^{13}C\{^1H\}$ NMR spectra of the three intermediates **A**–**C** recorded in the same experiment are reproduced on the right.

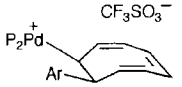
recorded in the course of a single experiment are shown in Figure 2; at −40 °C the separation of the stages **A** through **B** to **C** is less clear than at −60 °C.

With this information in hand, the structure of the initial species formed from complex **1** and 3,5-$(CF_3)_2C_6H_3OTf$ was investigated. At −30 °C, the now familiar AB type ^{31}P NMR spectrum ($\delta_P = 12.6$ and 32.8, $J = 29$ Hz) developed cleanly over an hour, and the electrospray MS in MeOH indicated that the probable structure of the new complex was **13** (*m/z* 873; $\{P_2Pd\}^+ + Ar + C_8H_8 + MeOH$). In this case the initially formed migration product is stabilized by the absence of a feasible β-elimination pathway.



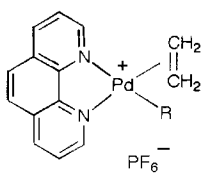
13

These observations clarify several features of the Heck reaction catalyzed by bis(phosphane)palladium complexes:

a) The Pd aryl triflate complex, already shown to be cationic in the PPh_3 series, is also ionized in chelate complexes, and solvent molecules rapidly exchange at the labile coordination site.

b) Traces of water can alter the composition of the initial ionic Pd complex, since its binding constant is high. Influences of water on the Heck reaction have been noted.[10]

c) The putative η^2-alkene complex **11** cannot be observed at −60 °C, thus putting a conservative upper limit of $\Delta G^{\neq} \approx 14$ kcal mol^{-1} on the barrier for the C–C bond-forming step under these conditions. In a search for intermediates in the Pd-catalyzed copolymerization of propene and CO, complexes **14** and **15** were characterized by low-temperature NMR spectroscopy, and $\Delta G^{\neq}$ values of 18.5 and 19.4 kcal mol^{-1} were measured for respective migration of Me and Et groups.[11]



14, R = CH_3

15, R = C_2H_5

d) The aryl migration is completely regiospecific; the only product is *E*-methyl cinnamate, the expected outcome of a Heck reaction. The elimination step generates an unseen Pd–H intermediate, which adds regiospecifically to methyl acrylate to give a new alkyl complex **9**.

e) The initially formed complex **9** then rearranges cleanly to the more stable, primary alkyl regioisomer, for which a chelate form with coordinated ester carbonyl group is likely (**10**).[12] A precedent for such a rearrangement by reversible β-hydride transfer to Pd has already been established, although the precursor of the stable alkyl complex was not observed in the previous case.[13] In addition, a Pt analogue of complex **10** formed by Pt–H insertion into methyl acrylate has been demonstrated.[14]

In summary, a key intermediate of the Heck reaction was characterized in a catalytically viable system, and the alkene elimination step then observed directly. A stoichiometric amount of base is widely employed in catalysis, and its likely function is seen to be the deprotonation of a hydridopalladium complex to regenerate the oxidative addition precursor; otherwise this may intercept the alkene as observed here. Future work will endeavour to clarify the role of base, to define the enantioselective variant, and to pursue the elusive η^2-alkene complex, which could not be observed here.

Experimental Procedure

The ^{13}C-labeled methyl 2-phenylsulfinylpropanoate was prepared as an (*R*R**)/(*R*S**) mixture from $^{13}CH_3I$ according to the general procedure in Ref. [9] and purified by chromatography on silica (1:1 ethyl acetate:petroleum). Yield 51%, ^{13}C NMR (125.7 MHz, $CDCl_3$, 25 °C) $\delta = 8.6, 9.3$, ($^1J(C,H) = 131$, $^2J(C,H) = 3.5$ Hz from ^1H NMR). Thermolysis was carried out in a Kugelrohr apparatus at 125 °C for 2 h under A. Yield 74%, $\delta_C = 130.8$, $^1J(C,H) = 160$, 160.6, $^2J(C,H) \approx 0$ Hz.

[8] When an excess of methyl 2-butenoate was added to a solution of **6** in THF at −60 °C, no changes were observed in the ^{31}P NMR spectrum, which shows that complexation of the ester carbonyl group was not important.

The First Rotational Isomers of Stable Selenoaldehydes and Their η^1-Tungsten Complexes**

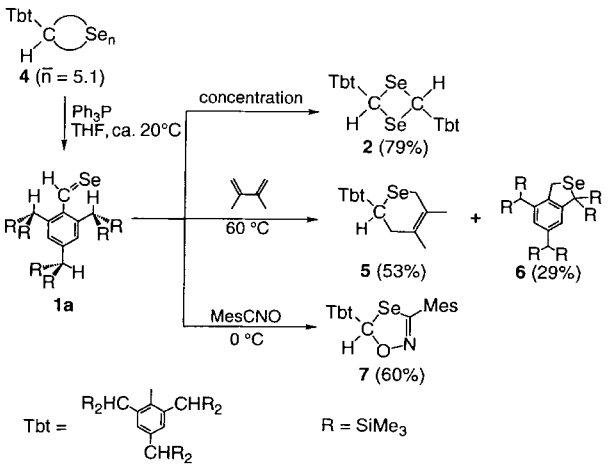
Nobuhiro Takeda, Norihiro Tokitoh, and Renji Okazaki*

In recent decades much attention has been paid to the chemistry of thiocarbonyl[1] and selenocarbonyl[2] compounds. Selenoaldehydes, however, have been very little explored because they are highly reactive and difficult to prepare. Some selenoaldehydes stabilized by mesomeric effects due to heteroatoms such as nitrogen and sulfur[3] or by coordination to transition metals[2, 4, 5] have been isolated. The only known stable, electronically unperturbed selenoaldehyde, 2,4,6-tri-*tert*-butylselenobenzaldehyde, is stabilized kinetically by a bulky substituent.[6] In addition, some transient selenoaldehydes have been reported.[7]

Recently, we succeeded in synthesizing rotational isomers of 2,4,6-tris[bis(trimethylsilyl)methyl]thiobenzaldehydes as stable compounds[8] by the desulfurization of the corresponding cyclic polysulfides TbtCHS$_n$ (n = 5, 8).[9] This synthesis takes advantage of an efficient steric protecting group, 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl, which we will refer to Tbt. We now report here on 1) the synthesis of stable selenoaldehydes **1a** and **1b** (the rotational isomer of **1a**), 2) an equilibrium among 1,3-diselenetane **2** and the seleoaldehydes **1a** and **1b**, and 3) the synthesis of η^1-selenoaldehyde complexes **3a** and **3b** and the structure of **3a**, the first η^1-selenoaldehyde complex characterized by X-ray crystallography.

Deselenation of cyclic polyselenide TbtCHSe$_n$ **4**[10] with excess triphenylphosphane at room temperature resulted in the formation of the corresponding selenoaldehyde **1a** (greenish yellow solution), which was identified based on its spectroscopic data (δ_H(CHSe) = 16.06, δ_C(CHSe) = 237.6, $^1J_{CH}$(CHSe) = 161.2 Hz, δ_{Se} = 2075, λ_{max} = 792 nm; Scheme 1, Table 1). This deselenation of cyclic polyselenides with a trivalent phosphorous reagent is a novel synthetic approach to selenocarbonyl compounds. The isolation of **1a** was unsuccessful; concentration of the reaction solution resulted in the complete conversion of **1a** into the head-to-tail dimer **2** (79%). Like reactive selenoaldehydes generated in situ,[7] **1a** reacted with 2,3-dimethyl-1,3-butadiene and mesitonitrile oxide to afford the corresponding cycloadducts **5** (53%) and **7**[12] (60%), respectively (Scheme 1). The formation of **5** and **7** indicates that **1a** still has a high reactivity toward these reagents in spite of its severe steric congestion, which prohibits its dimerization in a dilute solution for several hours. This is in sharp contrast to the fact that 2,4,6-tri-*tert*-butylselenobenzaldehyde is too crowded to produce the corresponding cycloadducts.[13]

When a solution of **2** was heated at 45 °C, the formation of **1a** and its isomer **1b** (rotation of the bis(trimethylsilyl)methyl (disyl) group at the 2-position[14]) was evident in the ^{1}H NMR and UV/Vis spectra (**2**:**1a**:**1b** = 1:8:3). In another experiment **1a** was trapped when **2** was treated with 2,3-dimethyl-1,3-butadiene at 60 °C giving the [4 + 2] cycloadduct **5** (81%) (Scheme 2). A few years ago Erker et al. reported a similar formation of monomeric selenobenzophenone from the corresponding 1,3-diselenetane, although the monomer was not isolated.[15] It is interesting that only **5**, which was formed from **1a**, was obtained in spite of the equilibrium among **1a**, **1b**, and **2**; this indicates that the two rotamers have different reactivities. Heating the solution at 100 °C in the absence of the trapping agent resulted in the quantitative formation of benzoselenolane **6**. The formation of **1b**, which was not observed in the deselenation at room temperature, suggests the occurrence of the thermal isomerization **1a** → **1b** in solution at 45 °C. Selenoaldehyde **1b** was isolated from the equilibrium mixture by flash column chromatography on silica gel at −20 °C under nitrogen atmosphere (Table 1). It is noteworthy that in **1b** the signal of the methine proton in one *o*-disyl group is at much lower field (δ = 5.87)



Scheme 1. Synthesis and reactions of selenoaldehyde **1a**.

Table 1. Selected spectroscopic data for compounds **1** and **3**. ^{1}H NMR: 500 MHz, $CDCl_3$, 27 °C, TMS; ^{13}C NMR: 125 MHz, $CDCl_3$, 27 °C, TMS; ^{77}Se NMR: 95 MHz, $CDCl_3$, 27 °C, Me_2Se; UV/Vis: hexane; IR: KBr.

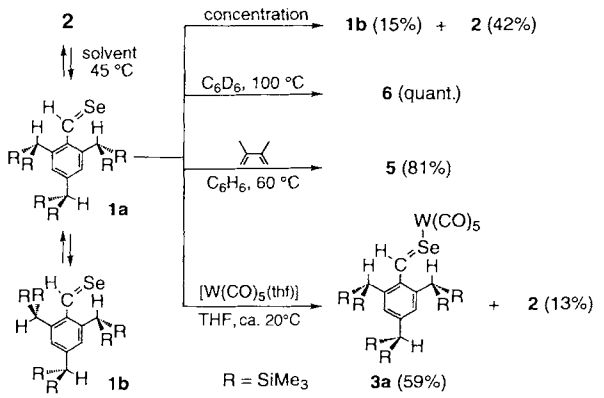

Scheme 2. Synthesis of selenoaldehydes **1a** and **1b** from 1,3-diselenetane **2**.

than that of the other ($\delta = 1.75$). This can be explained by the strong anisotropic effect of the C=Se bond, which is directed toward the methine hydrogen in the former *o*-disyl group in order to avoid steric interactions with the trimethylsilyl groups of the latter *o*-disyl group. In the solid state **1b** is stable even in air, whereas in solution it slowly isomerizes at room temperature to give **1a**, which then dimerizes to afford **2** as a precipitate. The higher stability of **1b** as a monomer indicates that the *o*-disyl groups of **1b** prevent the dimerization of the selenoformyl group more efficiently than those of **1a**; in **1b** one of the *o*-disyl groups is rotated in such a way that the bulky trimethylsilyl groups face the selenoformyl group.

The reaction of **1a**, generated from **2**, with $[W(CO)_5(thf)]$ gave the corresponding η^1-selenoaldehyde tungsten complex **3a** as stable, deep blue crystals (Scheme 2, Table 1). The structure of **3a** was established by X-ray crystallographic analysis (Fig. 1).[16] Although some η^1-selenoaldehyde complexes have

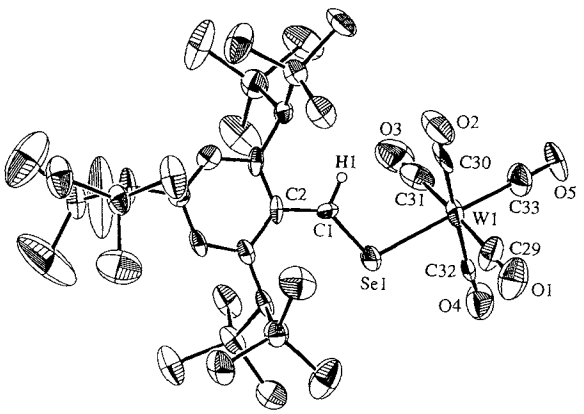

Fig. 1. X-ray crystal structure of **3a** (ORTEP drawing with thermal ellipsoids at 30% probability for non-hydrogen atoms). Selected bond lengths [Å] and angles [°]: C1–Se1 1.783(15), C1–C2 1.44(2), W1–Se1 2.638(2), W1–C29 1.95(2), W1–C30 1.97(2), W1–C31 1.93(2), W1–C32 2.02(2), W1–C33 2.01(2), O1–C29 1.19(2), O2–C30 1.14(2), O3–C31 1.17(2), O4–C32 1.17(2), O5–C33 1.13(2); Se1-C1-C2 136(1), W1-Se1-C1 107.8(4), Se1-W1-C29 87.8(6), Se1-W1-C30 91.4(5), Se1-W1-C31 89.2(6), Se1-W1-C32 89.8(5), Se1-W1-C33 178.9(6).

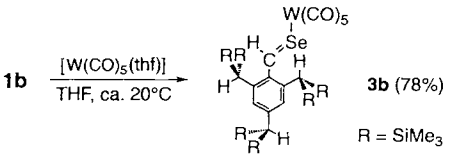
been synthesized,[4] this is the first to be characterized by X-ray structure analysis. The C–Se bond in **3a** (1.783(15) Å) is significantly shorter than a C–Se single bond (1.970 Å)[17] and the C–Se bond in pentacarbonyl(η^2-selenobenzaldehyde)tungsten (1.864 Å),[4a] and rather close to the length of the C–Se double bond in selenoketones (1,5-dimethyl-3,7-dithiabicyclo[3.3.1]-nonaneselone: 1.774 Å,[18] 4,4′-dimethoxyselenobenzophenone: 1.790 Å[19]). This result indicates weak coordination of the selenoformyl group to the metal in **3a**.

The rotational isomer **1b** was also treated with $[W(CO)_5(thf)]$ to afford the corresponding η^1-selenoaldehyde tungsten complex **3b** [Eq. (a)], which showed satisfactory spectral data



(a)

(Table 1). Complex **3b** is stable in the solid state even in air; however, in solution, it isomerized almost completely to **3a** over several days. This is probably because repulsion between the $[W(CO)_5]$ moiety and the trimethylsilyl groups makes **3b** less stable than **3a**, which does not have such repulsion. It is interesting that as free selenoaldehydes **1b** is isolable but **1a** is not, whereas both complexes **3a** and **3b** are isolable, but **3a** is much more stable than **3b**.

Experimental Procedure

1a, 2: A solution of **4** (26.2 mg, 0.0273 mmol) in THF (10 mL) was added dropwise over 5 min to a solution of Ph_3P (36.7 mg, 0.140 mmol) in THF (5 mL) at room temperature. After stirring for 45 min, the resulting greenish yellow solution containing **1a** was concentrated to dryness under reduced pressure. Distilled hexane (5 mL) was added to the residue and evaporated to remove remaining THF. After hexane (5 mL) was added and evaporated again, a small amount of benzene was added to the pale yellow residue, and insoluble **2** (13.8 mg, 0.0107 mmol, 79%) was removed by filtration. The filtrate was concentrated to dryness, hexane was added to the residue, and insoluble $Ph_3P=Se$ (35.7 mg, 0.105 mmol, 94%) was removed by filtration. The NMR and UV/Vis spectra of **1a** were recorded after the reaction had been performed in $CDCl_3$ and hexane, respectively.

1b: When a suspension of **2** (31.2 mg, 0.0242 mmol) in THF (25 mL) was heated at 45 °C for 17 h under an argon atmosphere, the reaction mixture turned greenish yellow. After evaporation of the solvent, degassed pentane was added to the residue and evaporated to remove the remaining THF. The residue was again dissolved in pentane and insoluble material was filtered off under argon. The filtrate was purified by flash column chromatography (SiO_2, pentane, at −20 °C under nitrogen) to afford **1b** (4.7 mg, 0.0073 mmol, 15%) as a greenish yellow powder. All other fractions were combined and dissolved in hexane, and then insoluble **2** (17.0 mg, 0.0132 mmol, 54%) was recovered by filtration.

Enantioselective Cycloisomerization of 1,6-Enynes Catalyzed by Chiral Diphosphane–Palladium Complexes

Andreas Goeke, Masaya Sawamura, Ryoichi Kuwano, and Yoshihiko Ito*

The cycloisomerization of 1,6-enynes in the presence of Pd^0, acetic acid, and phosphane ligands reported by Trost opened elegant pathways to 1,3- and 1,4-dienes, which are difficult to produce using other methods. 1,3-Dienes with exocyclic double bonds are suitable for Diels–Alder reactions.[1, 2] Of particular interest is the formation of the Alder–ene type 1,4-diene, since the construction of a stereogenic center offers an economical access to optically active five-membered carbo- and heterocycles, which occur abundantly in natural products. To date, only two examples of asymmetric induction have been reported utilizing 1) optically active carboxylic acids in conjunction with Pd^0[3] and 2) chiral phosphanes for the double stereodifferentiation of optically active substrates.[4] We now demonstrate that chiral diphosphane–Pd complexes effectively catalyze this interesting cycloisomerization, furnishing 1,4-dienes in medium to high enantioselectivities.

Although phosphane ligands reduce the rate of the cyclization, they are crucial for smooth conversion and for minimizing side reactions. Pd complexes with (*S,S*)-(*R,R*)-TRAP ligands **4**[5] were found to be particularly effective for the cyclization of **1a** (R = SiMe$_3$) at room temperature [Eq. (a), Table 1]. In-

results. In addition, optically active *cis*-chelating phosphanes such as CHIRAPHOS,[6] DIOP,[7] BPPFA,[8] and PPFA[8] only led to selectivities of 6–15% *ee* with conversions of 56–85%. Moreover, with BINAP[9] and the electron-donating EtTRAP[10] no conversion occurred even at 80 °C. Neither isomerization to the constitutional isomer **3** nor racemization, which may be responsible for low enantiomeric excesses of the cyclization products, was observed on treatment of **2** with $[Pd(PPh_3)_4]$ under the reaction conditions.

The regioselective formation of 1,4-dienes **2** can be explained by the relative ease of the β-elimination of H_a over H_b in the proposed palladium(II) intermediate **B**. The β-elimination of H_a, however, is affected by steric and electronic factors and leads to mixtures of 1,4- (**2**) and 1,3-dienes (**3**) in most cases.[2, 3] When a silylallyl unit[11] serves as the alkene component, the 1,4-dienes are formed selectively due to the kinetically enhanced acidity of the CH group α to silicon. The configuration of the double bond in **2** was always *E* (*E*:*Z* > 50:1), indicating that the cis-β-elimination took place out of the sterically less congested conformation. Although the reaction mechanism remains highly speculative, we believe the *trans*-chelation of the TRAP ligands to the palladium atom to be essential for the enantioselectivity-determining step. This premise is supported by the observation of only two doublets at $\delta = 21.4$ and 38.3 ($J = 455$ Hz) in the ^{31}P NMR spectrum (81 MHz, C_6D_6, **4a** as ligand, 30 °C) of the catalyst system under conditions similar to the reaction conditions described in Table 1.

Results of the cycloisomerization of various 1,6-enynes (**1a–i**) with (*S*,*S*)-(*R*,*R*)-*p*-$CF_3C_6H_4$-TRAP (**4e**) are summarized in Table 2. The replacement of one of methyl substituents of the

silicon atom with a phenyl group had only a limited influence on both the reactivity and enantioselectivity (entries 1, 2). The preferential formation of 1,4-dienes in substrates bearing a silylallyl group was extinguished in substrates having a homoallyl (**1c**, entry 3) or an even more remote silyl group (**1d**, entry 4), leading to some 1,3-diene formation. Interestingly, when steric congestion was relieved by placing the silyl group on a remote position, the enantioselectivity increased considerably, peaking at 95% *ee*. However, steric reasons alone cannot account for this observation, since *ee* values obtained with substrates having alkyl or phenyl substituents at the homoallylic position (**1g–i**) were lower (entries 8–10). It is important to note that the product of (*Z*)-**1f** has opposite configuration to that of substrate (*E*)-**1f** (entries 6, 7). Therefore, the use of diasteriomerically pure enynes is a prerequisite for obtaining high enantioselectivities.

The enantioselectivity was also sensitive towards the sulfonamide groups. The idea of stabilizing the conformation of intermediate **A** by the introducing bulkier sulfonamide groups was not tenable, since the selectivities continuously decreased (data not shown). Moreover, the reaction of an enyne carrying a methanesulfonamide group (R = $SiMe_3$) proceeded with very low enantioselectivity (0 °C 11% *ee*). This low selectivity may indicate that the substituent on the sulfonamide group may be primarily electronic.

Experimental Procedure

A solution of $[Pd_2(dba)_3]\cdot CHCl_3$ (2.2 mg, 2.25 mol%) (dba = dibenzylideneacetone) and *p*-$CF_3C_6H_4$-TRAP **4e** (8.6 mg, 8.1 mol%) in toluene (0.5 mL) was stirred under N_2 at 25 °C for 30 min. Acetic acid was added (15 mg), and after 5 min **1c** (31.0 mg, 0.093 mmol, entry 3 in Table 2) was added, and the mixture was stirred for 20 h. The solvent was evaporated in vacuo and the residue purified by preparative thin-layer chromatography (silica gel, hexane/EtOAc 5/1) affording **2c** and **3c** as a mixture (**2c**:**3c** = 3.5:1, 21.1 mg, 68%). For the determination of the enantioselectivity **3c** was removed by stirring the above mixture in CH_2Cl_2 (1 mL) with phenyl maleimide (ca. 10 equiv). Purification by preparative thin-layer chromatography (silica gel, hexane/EtOAc 5/1) afforded pure **2c** (95% *ee* (*R*), Chiralcel OJ, $[\alpha]_D^{23} = +31.9$ (*c* = 0.31 in $CHCl_3$)).

Structure Made Crystal Clear

Structure Correlation. Vols. 1 and 2. Edited by *H.-B. Bürgi* and *J. D. Dunitz*. VCH Verlagsgesellschaft, Weinheim, 1994; 888 pp., hardcover, DM 398.00.—ISBN 3-527-29042-7

In less than 100 years, our concept of a chemical substance has reversed from the thermodynamicist view of a statistical ensemble of independent entities with internal energies unrelated to the peculiarities of molecular structure, to the stereochemical/quantum chemical picture of a structurally definable chemical (molecular) entity with a specific relationship between molecular geometry and internal energy. Indeed, as strongly the chemist of today would cling as strongly to a CPK model or ORTEP diagram for reassurance that his chemical intuition was still valid, as Mach in 1880 rejected the consideration that modeling molecular structure could give rise to any chemical insight. This peculiar change in philosophy was made technologically possible by Bragg at the turn of the century; it was conceptually founded by Pauling's (the grandfather of structure-correlation) exposé on "The Nature of the Chemical Bond"; and, it was finally embossed on the chemist's "tabula rasa" by high gloss and sumptuously seductive images provided by modern computer generated molecular graphics. The structural molecular hypothesis has been so successful that it is now taken for granted by virtually every branch of natural science.

Since Pauling's revolutionary work, the silos for structural data have been filled relentlessly. The fiduciary structural correlations shown by Pauling with 0.1% of the present available data still hold fast. In the last 20 years, however, the concepts of structural correlation have evolved beyond structure-structure correlations, primarily due to the work of Hans-Beat Bürgi and Jack D. Dunitz, to permit extremely detailed and enlightening studies on chemical dynamics (Structure-Energy and Structure-Activity Correlations). The combined expansion of data-base size and application of statistical methods has driven structure correlation theory to have a major impact on small molecular chemical physics, solid-state chemistry, and biochemical mechanism and action. Much of this work has been dispersed so widely in the chemical literature as to dilute the fundamental message. The task of bringing to order the many tiles of this mosaic is nothing less than gargantuan. Nonetheless, Bürgi and Dunitz have succeeded in creating a magnificent mural of molecular structure correlation in their recent two volume set from VCH.

"Structure Correlation" by Bürgi and Dunitz covers the entire field in a didactic, yet research-motivated style. The four parts of this two volume set break down the subject into digestible sections: 1) *Basics*—the "handyman's" guide to getting started in structure correlation; 2) *Molecular Structure and Reactivity*—demonstration of the principles and the kinds of chemical intuition that can be derived; 3) *Crystal Packing*—a view separating the forest from the trees in solid-state chemistry; 4) *Proteins and Nucleic Acids*—biochemical insight from an ordered look at biomolecular structure. As a (self) teaching tool, this collection will empower the structural chemist to tackle the most important problems at the heart of materials and biomolecular technology. As a reference it will provide researchers from all facets of molecular science with a compass to facilitate their structural investigations.

1) *Basics*: The first part of the series contains five well written chapters which, with some mathematical background (or fundamental references) will give the reader the necessary foundations in structure correlation theory. Chapters 1 and 2 cover fundamental quantitative specification of structures and structural distortions. The discussion of coordinate systems and symmetry arguments starts at an entry level that will be useful in course work. Chapter 3 provides an excellent overview of the hows and whys of the various available crystallographic data bases. Statistical packages accompany several databases, and Chapter 4 covers many of the common types of analysis that can be done with these packages and the significance of these analyses to structural correlation studies. Chapter 5 introduces the reader to chemical questions that can be addressed by the structure correlation method. The concept of the potential energy surface and the physical parameters that can be derived from knowing this surface are discussed with select chemical examples. As this first part of five chapters is strongly oriented toward newcomers to the field, I list here some small typographical errors to alert the reader that it is not a glitch in their own algebraic manipulations. For example, page 5, the block matrix formula entry for column 3, row 2 should be A_{23} not A_{33}; page 47, Figure 2.9, the line numbering would be more consistent if the ends were swapped on the last four linear projections; page 53, Table 2.6, the operation $R_{AB}s(xz)$ in the left column should be R_{AB}; page 168, lines 14–15, the sentence should read "The eigenvector, associated with the smallest eigenvalue of f, points in the direction..."; page 196, line 5, the equation should read $q_0 = (Dr_{10}^2 + Dr_{20}^2)^{1/2}$. These are trivial matters and in no way detract from the desirability of the book.

2) *Molecular Structure and Reactivity*: The second part begins to expand the concepts and applications of structural correlation. The chapter on organic addition and elimination reactions, by Cieplak, is an exhaustive and scholarly treatise, but does not have the same teaching value as some others. It is a wonderfully detailed collection of the subtleties of reactions at trigonal carbon, but one wonders if the depth and detail are warrented in the present context. Chapter 7 by Bürgi and Shklover depicts the classical art of structure-correlation theory. Working from data on the structural distortions of primarily inorganic compounds, they show the similarity of reactions based on coordination number rather than atom type. These early examples established the generality of the methods. The chapter by

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Auf der Heyde on transition metal complexes is very well written and gives the reader a good perspective how to use statistical methods to extract order from (greatly simplified) clusters of data. Cluster analysis and principle coordinate analysis are techniques to which the average chemist is exposed; however, Auf der Heyde does an excellent job showing the usefulness of such methods in studies of ligand field exchanges and rearrangements. The final chapter of Volume 1 by Schweizer on conformational analysis is also a classic in the field. The conformational analysis of polyaryl X compounds and medium ring systems is one of the proving grounds for structure correlation analysis. Schweizer clearly presents these classic studies.

3) *Crystal Packing*: Part 3 comprises three chapters which really display the power of structural correlation theory to elucidate molecular interactions when linked to a database like that of CCDB. The chapter by Brown builds directly on Pauling's fundamental work; this chapter demonstrates how elegantly the Pauling's bond-length/bond-order relationship applies to a wide variety of systems. Indeed, this is really the basis of the original structural correlation ideas. The following chapter, by Bernstein, Etter, and Leiserowitz, on hydrogen bonding is one of the best in the collection. Although I found their original definition for the existence of a hydrogen bond to be cyclic (a hydrogen bond exists when there is evidence for the existence of a bond involving a hydrogen atom) they present a practical scheme for describing and organizing hydrogen bonding patterns as well as a number of useful energetic thumb rules for predicting the hierarchy of hydrogen-bonded aggregates. This chapter would be improved if standard chemical structural formula accompanied the many packing diagrams which contain no atomic or bonding labels, and it would be nice if they consistently used their network notation to annotate all of the exemplary figures. Figure 11.15 on page 459 has the labels for part a and part b reversed. The chapter by Gavzzoti describes the substantial advances that have been made toward the derivation of a consistent force field for crystal environments. This chapter is perhaps one of the most important for future developments in computational crystal engineering. The formulae in the chapter often used the same capital letters to mean different things which makes the reading a little bit cumbersome, but the ideas are well worth the effort. Table 12.2 must have some numbers for F switched or wrong, particularly those for tetraphenylmethane, adamantane, and DABCO.

4) *Proteins and Nucleic Acids*: Part 4 contains a series of chapters on biological structure, which except for Chapter 13 by Klebe do not fully blend into the style of the book. The chapter on steroids is more an expose than a lesson. The chapter of protein structural motifs is not easily accessible to the nonspecialist; this chapter could have been a jewel with a few more pages of background, and a conscientious attempt to define terms and jargon rather than just citing literature and expecting the readers to fend themselves. Blundell's contribution was for me interesting but of such small scope that I felt it might well have been included with a broader discussion. Indeed, a combined chapter containing the principles of Chapters 15, 16, and 17 from a generalist's perspective would have been more fitting for the book. Ultimately, although this final section of four chapters is competent, it reads like an afterthought rather than an integral part of the structural correlation field.

In summary, I feel all of the contributing authors did a splendid job; however, the diversity of topics is such that few readers will remain "riveted" throughout the whole 18 chapters. Indeed, in this day of interdisciplinary hype, it is a pleasure finally to read a book that truly captures the spirit of boundary-free research. Thus, I would call "Structure Correlation" by Bürgi and Dunitz a "must have" for anyone interested in molecular structure. My copy stands on my shelf of most accessed books.

High Resolution NMR in the Solid State. Fundamentals of CP/MAS. By *E. O. Stejskal* and *J. D. Memory*. Oxford University Press, Oxford, 1994. 189 pp., hardcover £ 30.00.—ISBN 0-19-507380-0

The subject of high-resolution solid-state NMR, including all fundamental aspects of NMR of solids, has been thoroughly treated in several excellent monographs. However, these books have been written by physicists in language which is often not at all familiar to chemists. At the other extreme, a number of fairly oversimplified, purely qualitative introductions to solid-state NMR have appeared, aiming at the chemists' approach by trying to more or less completely avoid "unloved" topics such as mathematics and quantum mechanics. In between these two extremes there exists a large gap: the attempt to provide a bridge between these two worlds is, by its very nature, an extremely difficult task, like trying to square the circle. The task is so difficult because there simply is no purely qualitative approach to high-resolution solid-state NMR which would do justice to the subject. This difficulty of translating and communicating between the worlds of physics and chemistry is almost certainly the reason why no such "intermediate" textbooks on CP/MAS NMR have appeared on the otherwise well supplied NMR book market. On the other hand, a textbook on CP/MAS NMR at that level would certainly represent a much needed commodity, especially since many fascinating and challenging applications of high-resolution solid-state NMR methodology in the field of chemistry remain to be explored. Any serious effort to make the principles of CP/MAS NMR more accessible to the chemistry community is therefore to be welcomed.

The book by Steijskal and Memory represents a quite successful attempt at squaring the circle. From every page in this book it is obvious that it has resulted from long experience of teaching the subject to undergraduate and graduate students. The strategy follows a step-by-step method, starting with the introduction of the basic principles of NMR in Chapter 1. This introduction also includes a brief explanation of the density matrix formalism which is absolutely necessary. This explanation should certainly provide a golden bridge for readers more familiar with solution-state NMR; the example chosen is the polarization transfer experiment in solution using the DEPT sequence. Naturally, an introduction compressed into approximately ten printed pages can only outline the general idea, but all important references for further reading are given.

Chapter 2 is devoted to cross-polarization (CP) in the solid state and follows "traditional" descriptions within the framework of a thermodynamic approach, introducing the concept of spin temperature. For this chapter too all important key references are given in the bibliography. Although it is implicitly clear that this approach to explaining CP under Hartmann–Hahn matching conditions is only valid for a rigid lattice with an abundant spin reservoir as the source of magnetization, a more explicit statement about the limitations of the thermodynamic approach would seem necessary. Also, given the strategy of starting out

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3506-0666 $ 15.00+.25/0

from a familiar solution-state polarization transfer experiment in Chapter 1, a mention of Hartmann–Hahn CP in solution via *J*-coupling would probably have helped the reader to appreciate the unified picture of gradual changes of NMR behavior all the way from non-viscous liquids to rigid solids.

Chapters 3 and 4 deal with spin–spin interactions and with magic angle spinning (MAS), including a very brief encounter with average Hamiltonian theory. Again, this is a topic of fundamental importance for the understanding of MAS spectra, and for a more thorough understanding the reader will need to refer to the original literature. Finally, Chapter 5 is concerned with spectrometer and probe design. It is probably a matter of taste whether one considers such technicalities as an important aspect of the fundamentals of CP/MAS. Personally I would tend to agree with the authors that such a chapter should be included: tuned rf circuits and the principles of construction of double resonance probes are of vital practical importance. A short description of the basic features may, therefore, help to bridge yet another gap. I feel that this chapter will help to improve communication between "users" and engineers and technicians. The collected appendices at the end of the book are too short to be useful.

In summary, I can recommend this book as a useful, solid guide to the "secrets" of CP/MAS for all readers who would tend to be frightened by physics monographs, but nevertheless want a deeper understanding than merely being able to extract an isotropic chemical shift from a CP/MAS spectrum. Armed with this book, with the desire to *understand*, and with access to the library (for the literature cited in the bibliographies), every chemist should be able to master the basics of high-resolution solid-state NMR.

The Chemistry of Organophosphorus Compounds. Volume 3. Phosphonium Salts, Ylides and Phosphoranes. (Series: The Chemistry of Functional Groups. Series editor: *S. Patai.*) Edited by *F. R. Hartley*. Wiley, Chichester, 1994. 442 pp., hardcover £ 120.00.—ISBN 0-471-93057-1

Volumes 1 and 2 of this four-volume series on the chemistry of organophosphorus compounds appeared in 1990 and 1992; the third volume has now been published. A survey of this nature covering the still rapidly advancing field of organophosphorus chemistry is very welcome, especially since other works in this area, such as the handbook edited by G. M. Kosolapoff and L. Maier, are now over twenty years old.

It was noted earlier in reviews of the two previous volumes (*Angew. Chem. Int. Ed. Engl.* **1991**, *30*, 1046; *ibid.* **1993**, *32*, 1215) that a clear plan for the work as a whole did not seem to emerge. This third volume does little to alter that view, but it is at least internally consistent. It covers the phosphonium ylides and phosphonium salts, together with the closely related phosphoranes containing a five-coordinated pentacovalent phosphorus atom. The final chapter ("Chemical Analysis of Organophosphorus Compounds", by H. Feilchenfeld) does not really fit into the context of the rest of the volume, and is not directly related to the preceding chapters. It is in itself a very welcome contribution, but would perhaps have been better placed at the beginning of the series, or alternatively it could have been delayed until the last volume.

The book contains six contributions altogether on the ylides and phosphoranes, all written by recognized experts in their fields. Chapter 1 (D. G. Gilheaney) and Chapter 4 (S. M. Bachrach and C. I. Nitsche) are concerned with bonding and structure in phosphonium ylides, phosphonium salts, and phosphoranes. These two fundamental chapters deal with similar subjects, but differ in their lengths and in the depth of the treatment. A certain degree of overlapping is evident.

The longest chapters are those concerned with the preparation, properties, and reactions of phosphonium salts (Ch. 2, H. J. Cristau and F. Plenat) and with phosphoranes (Ch. 3, R. Burgada and R. Setton). Chapter 5 (K. S. V. Santhanam) deals with the electrochemistry of ylides, phosphonium salts, and phosphoranes, and Chapter 6 (M. Dankowski) with the photochemistry of these classes of compounds.

Concluding the book, Chapter 7 describes the chemical analysis of organophosphorus compounds, giving an overview of the available methods, from the classical wet-chemical methods to the various instrumental methods (gas chromatography, mass spectrometry, etc.). The very important method of NMR spectroscopy, especially the application of ^{31}P NMR methodology to phosphorus compounds, is not included (although it is true that this has recently been covered by other authors). Chapter 7 alone contains over 400 literature references.

The book provides a detailed coverage of the field of phosphonium ylides, phosphonium salts, and phosphoranes in about 350 pages of closely printed text. For each of these classes of compounds several hundred well-chosen references are listed (original papers, review articles, and monographs), giving the reader easy access to the literature. However, only a few of these refer to publications from 1990 onwards. Also there are many instances where insufficient care has been taken with the references. It is disconcerting when the same author's name appears with two, or even three, different spellings, and these garbled names then reappear in the author index, sometimes immediately adjacent to each other and sometimes widely separated.

Despite some shortcomings of the kind mentioned above, this third volume in the series edited by Hartley is an indispensable addition to the literature for all organophosphorus chemists, and the final volume is awaited with interest. Finally, this review would be incomplete without a comment which unfortunately nowadays applies all too often, namely that although the book should be in the departmental library of every organophosphorus chemist, its high price is likely to discourage any wider circulation.

Understanding and Manipulating Inorganic Materials with Scanning Probe Microscopes

Charles M. Lieber,* Jie Liu, and Paul E. Sheehan

Scanning probe microscopies, such as scanning tunneling microscopy and atomic force microscopy, are uniquely powerful tools for probing the microscopic properties of surfaces. If these microscopies are used to study low-dimensional materials, from two-dimensional solids such as graphite to zero-dimensional nanostructures, it is possible to elucidate atomic-scale structural and electronic properties characteristic of the bulk of a material and not simply the surface. By combining such measurements with chemical synthesis or direct manipulation it is further possible to elucidate relationships between composition, structure, and physical properties, thus promoting an understanding of the chemical basis of material properties. This article illustrates that the combination of scanning probe microscopies and chemical synthesis has advanced our understanding of charge density waves, high-temperature superconductivity, and nanofabrication in low-dimensional materials. This new approach to studying materials has directly contributed to our knowledge of how metal dopants interact with charge density waves and elucidated the local crystal chemistry of complex copper oxides, microscopic details of the superconducting states in materials with a high superconducting transition T_c, and new approaches to the fabrication of multicomponent nanostructures. Coupling scanning probe microscopy measurement and manipulation with chemical synthesis should provide an approach to understanding material properties and creating complex nanostructures in general.

Keywords: atomic force microscopy · low-dimensional materials · nanosyntheses · scanning tunneling microscopy · superconductivity

1. Introduction

An important goal of condensed matter research is to understand how microscopic or atomic level structural and electronic characteristics of a solid determine observable properties like superconductivity and magnetism. This goal is motivated by the recognition that such an understanding will enable scientists to design bulk solids and nanostructures having predictable properties rationally. For chemists, instrumental methodologies that provide a real-space picture of the connectivity of atoms in a solid or of the local electronic structure are perhaps most appealing, since our training in chemistry typically focuses on the direct analysis of the properties of isolated molecules and macromolecules and not the inverse (that is, reciprocal space) analysis of periodic ensembles of atoms and molecules. Furthermore, real-space probes are required to assess the intrinsic structural and electronic properties of very small material structures that are a focus of the burgeoning area of nanotechnology.

Scanning tunneling microscopy (STM), atomic force microscopy (AFM), and other scanning probe microscopies (SPMs) are uniquely powerful tools for probing the microscopic properties of materials.[1-12] STM can be used to probe the surface structure and electronic states of conducting and semiconducting materials directly on the atomic scale,[1-3,9] while AFM can be used to assess the structure and elastic properties of insulators, semiconductors, and conductors at the nanometer scale.[2,4-6,10-12] SPMs are also effective tools for manipulating matter on the atomic to nanometer scales and for constructing individual nanostructures.[9-11,13,14] Additionally, these techniques represent one of the best approaches for relating nanoscale structures to the world we can visualize.

SPMs are, by their very nature, highly surface-sensitive techniques. The ability to probe the uppermost layers of a material is an important advantage in studies of very small supported structures, such as nanocrystals on surfaces, and in fundamental investigations of growth and catalysis on metal and semiconductor surfaces.[15-17] Surface sensitivity can, however, be a severe limitation in studies designed to probe the bulk properties of a material. For example, the coordinatively unsaturated surface atoms of three-dimensional (3D) solids typically adopt a different geometrical arrangement from those in the bulk (that is, they reconstruct). However, highly anisotropic materials—for example, layered solids possessing strong covalent bonding

in two-dimensional (2D) sheets with weak noncovalent bonds holding these layers together—cleave preferentially along planes defined by the weak noncovalent bonds. The coordination of atoms at the surface cleavage plane in such low-dimensional solids is similar to that in the bulk, since the covalent bonding is unchanged, and thus these surfaces do not reconstruct. SPM studies of such low-dimensional materials offer the opportunity of probing atomic level structural and electronic properties that are representative of the bulk of a material.

Low-dimensional solids offer a great richness and complexity of physical phenomena that make them generally an important focal point of condensed matter research. For example, many two-dimensional and one-dimensional metal chalcogenide materials exhibit complex charge density wave and spin density wave phases, and furthermore, the layered structure of the copper oxide superconductors is central to the high-temperature superconductivity that these materials exhibit. This review highlights first the application of SPM techniques to understanding fundamental properties of low-dimensional inorganic materials that exhibit charge density wave and superconducting states. By utilizing these microscopies often combined with systematic chemical modifications, new and unique insight into the properties of these materials has been gained that goes far beyond that obtained with more conventional approaches. Secondly, this review will also focus on the use of SPMs to manipulate inorganic systems. Direct manipulation of atoms and clusters enables the construction of new low-dimensional materials—nanostructures—that can then be investigated by SPM techniques in a nonperturbative mode.

2. Background: Scanning Probe Microscopies

2.1. Scanning Tunneling Microscopy

The scanning tunneling microscope was invented by Binnig and Rohrer in the early 1980s[1] and is now a widely used tool in many fields of research.[1-16] Here we briefly review key features of STM and the theoretical underpinning necessary to understand the investigations discussed below. The basic design of a scanning tunneling microscope is illustrated in Figure 1.

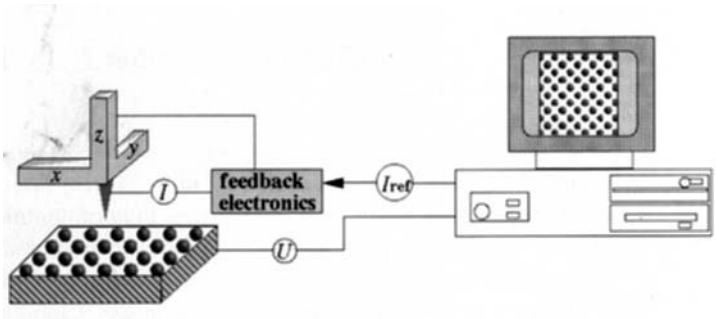

Fig. 1. Schematic diagram of a scanning tunneling microscope.

The essential components include a sharp metal tip, which acts as the local probe, a sample with a conducting surface, a system for positioning the probe in the x, y, and z directions that uses piezoceramic drivers, a feedback loop for controlling the separation between tip and sample with subangstrom precision, and an overall controller that drives the scanner while recording the surface image.

C. M. Lieber

J. Liu

P. E. Sheehan

Charles M. Lieber obtained his early education in New Jersey. He completed a B. A. with honors in chemistry in 1981 at Franklin and Marshall College, earned his Ph.D. at Stanford University under the direction of N. S. Lewis, and carried out postdoctoral research at the California Institute of Technology under H. B. Gray. He is currently a Professor at Harvard University, where he is a member of the Chemistry Department and Division of Applied Sciences. His research integrates several disciplines, including inorganic, physical and materials chemistry, condensed matter physics, and materials science. His research group has been using scanning probe microscopies and other new techniques combined with materials synthesis to understand and control the fundamental properties of materials.

Jie Liu was born in Shandong, China, in 1968. He received his B. Sc. and M. S. degrees from Shandong University in 1987 and 1990. He is currently a graduate student in Professor Lieber's research group at Harvard, investigating the structural and electronic properties of low-dimensional materials, including high-T_c superconductors and transition metal dichalcogenides.

Paul E. Sheehan was raised and educated in North Carolina. He received his B. S. in Materials Science in 1993 from the University of North Carolina-Chapel Hill. He is currently a graduate student in Professor Lieber's research group at Harvard, pursuing the mechanics and tribology of nanoscale structures.

The underlying basis for the operation of the microscope is electron tunneling between a sharp metal tip and a conducting sample.[1-3] When the tip and sample are brought sufficiently close (5–10 Å), their wave functions can overlap. If a bias voltage U is then applied to the sample, a tunneling current I will flow between the sample and tip. Electrons will tunnel from filled electronic states in the tip to empty states in the sample when U is positive, and from filled sample states to empty tip states when U is negative. The tunneling current that flows when U is applied varies exponentially with the tip–sample separation, and for typical work functions decreases tenfold for an increase of one angstrom in separation. The strong exponential dependence of the tunneling current on distance enables STM to achieve high vertical resolution. An atomic resolution map of the surface can then be generated by rastering the tip over the sample with control in the angstrom range provided by the piezoceramic positioners. Under favorable conditions, a vertical resolution of hundredths of an angstrom and a lateral resolution of about one angstrom can be achieved.

There are two principal modes of surface imaging with the STM: constant current and constant height. In the constant current mode, the feedback loop controls the vertical position of the tip above the sample so that I is equal to a reference current at all coordinates on the surface. Features in constant current mode images thus correspond to vertical displacements of the positioner needed to maintain a constant tunneling current. In constant height mode imaging the tip height above the surface is constant, and images correspond to the variation of I with position. Since the feedback loop does not respond to rapid height variations in this mode, it is possible to scan at a higher rate than in the constant current mode. The constant height mode is, however, limited to flat samples.

To interpret STM data requires an understanding of the response of the tunneling current to a number of factors, including applied voltage, tunneling barrier height, and the sample's electronic structure.[2e, 3] As first discussed by Tersoff and Hamann, an expression for I can be readily derived by using perturbation theory to treat the interaction between sample and tip wave functions.[18] In the limit of small bias voltage and low temperature this treatment yields Equation (a), where M_{st} is the tunneling matrix element between wave functions on the tip (Ψ_t) and sample (Ψ_s). As shown by Bardeen,[19] the tunneling matrix element can be written as Equation (b), where the integral corresponds to a surface within the barrier region between the sample and tip. To evaluate M_{st} in a way that the resulting expression for I can be compared quantitatively to STM images in general (that is, not for one specific choice of sample and tip) requires several approximations. Tersoff and Hamann showed that by assuming that the tip forms a locally spherical potential well with only s-wavefunctions, I could be expressed as (c).

$$I = (2\pi/\hbar)e^2 U \sum |M_{st}|^2 \delta(E_s - E_f)\delta(E_t - E_f) \quad (a)$$

$$M_{st} = (\hbar^2/2m) \int (\Psi_t^* \nabla \Psi_s - \Psi_s \nabla \Psi_t^*) dS \quad (b)$$

$$I \sim \sum_s |\Psi_s(r_0)|^2 \delta(E_s - E_f) \quad (c)$$

By definition the summation is the local density of sample electronic states, $\rho(r_0,E)$, at the center of curvature of the tip (d).

Thus, constant current images correspond simply to contours of constant density of sample electronic states.

$$\rho(r_0,E) \equiv \sum_s |\Psi_s(r_0)|^2 \delta(E_s - E_f) \quad (d)$$

It is useful to consider the effect of the approximations made in deriving (d). Treatment of the tip's potential as spherical is reasonable, because although the experimental tip shape is generally unknown, it probably terminates in a cluster of atoms; that is, the tip is approximately spherical. The s-wavefunction approximation for the tip is even more significant, because it leads to a cancellation in Equation (b) which makes I dependent only on the square of the sample wavefunction with no contribution from the tip. Tersoff has examined more general descriptions of the tip and found that constant current images still correspond to contours of constant density of sample electronic states for metals.[20, 21] STM images of semiconductor surfaces at low U could, however, deviate significantly from this simple picture, since only a small pocket of the surface Brillouin zone contributes to the tunneling. This deviation is limited, however, to the lowest Fourier component of the image, and thus the model of the tip approximated by an s-wavefunction may still be used in many cases to interpret images at higher bias voltages. While these results indicate that the assumptions used to derive (d) are reasonable, it is important to develop further theoretical models so that data can be quantitatively interpreted.[6, 22]

The dependence of the tunneling current on applied bias voltage, which corresponds to tunneling spectroscopy, can probe the local density of electronic states versus energy, since I is proportional to the local density of states. For finite voltages (c) can be rewritten as (e), where $T(E,eU)$ is the transmission probability that takes into account the energy-dependent wavefunction decay. This expression incorporates the assumption that the density of tip states does not vary significantly with energy. In the limit of small bias, dI/dU is proportional to the density of states; however, for finite bias the exponential dependence of $T(E,eU)$ on U becomes important. This exponential dependence can be effectively removed by normalizing dI/dU by U/I[23] [expression (f)].

$$I \sim \int \rho(r,E) T(E,eU) dE \quad (e)$$

$$(U/I)dI/dU \sim \text{LDOS} \quad (f)$$

Comparisons of the local density of states data obtained by STS with photoemission and inverse photoemission results show that the approximations made in arriving at (f) are reasonable.

2.2. Atomic Force Microscopy

The atomic force microscope, which was invented several years after STM,[10] is now perhaps the most widely used probe microscopy technique.[4-6, 11, 12, 24] The underlying basis for

force microscopy is similar to a simple profilometer;[25] that is, the forces on a probe tip attached to a cantilever are detected and plotted as a sample is scanned beneath the tip. The magnitude of the load in force microscopy is, however, many orders of magnitude smaller than those applied with a conventional profilometer: 10^{-13} to 10^{-6} versus 10^{-4} N. The combination of small loads with sharp tips enables AFM to image at close to atomic resolution. Importantly, force microscopy can, in principle, be used to probe the structure of any solid material, be it a conductor, an insulator, or a living cell, since this technique relies solely on the mechanical interaction between the tip and sample.

The basic design of a modern force microscope is illustrated schematically in Figure 2. The essential components that differ

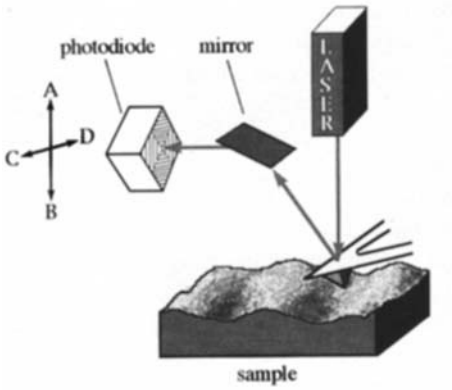

Fig. 2. Illustration of a force microscope that utillizes optical detection.

from those shown for the tunneling microscope (Fig. 1) include an integral tip-cantilever assembly and optical detection system that measures the cantilever deflection. Since the cantilever (spring) deflection is linearly related to the force, the experimental signal is a measure of the force. In operation, variations in the cantilever position, which result from sample topography and/or differing sample–tip interaction, lead to a deflection of the laser beam on a quadrant photodiode detector. By measuring the vertical (A–B) and horizontal (C–D) displacements on the photodiode it is possible to extract both normal and lateral forces. Furthermore, if the normal and lateral spring constants of the cantilever are known, it is possible to quantify these forces from the measured cantilever displacements.[24]

There are several common modes of imaging in contact-mode force microscopy, including constant normal force and lateral force. In the constant-force mode, which is analogous to constant-current mode of STM, the feedback loop controls the vertical position of the sample so that the cantilever displacement and hence normal force is constant at all points on the surface. Features in images recorded in constant-force mode thus correspond to vertical displacements of the positioner needed to maintain a set force between the cantilever–tip assembly and sample surface. In the lateral-force mode, the frictional or lateral force between the tip and sample is mapped as a function of x, y coordinates for a constant applied load. Thus, the constant-force mode of imaging provides a good measure of surface structure, while the lateral-force mode provides indirect information about variations in surface composition (reflected by variations in friction).

3. Quasi-Two-Dimensional Transition Metal Dichalcogenides

3.1. Basic Structure

The dichalcogenides of transition metals of Groups IV, V, and VI have layered structures in which the transition metal (M) occupies either octahedral or trigonal prismatic sites between two layers of hexagonal close packed chalcogenide atoms (X). The X-M-X sandwiches are then stacked in a direction perpendicular to the chalcogenide layer to complete the structure.[26] The octahedral coordination of Ta atoms in 1T-TaS_2[*] is schematically shown in Figure 3. In general, the X-M-X layers are held together by strong covalent or ionic bonding, whereas the interactions holding the layers together are much weaker dispersion forces. These materials cleave readily between the weakly bonded layers to yield free surfaces that are structurally and electronically similar to the bulk material.[7, 8, 26–29]

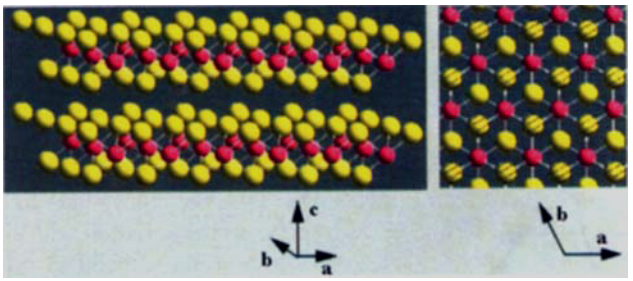

Fig. 3. Schematic side view (left) and top view (right) of 1T-TaS_2. White bonds between yellow sulfur and magenta tantalum atoms highlight the octahedral coordination of tantalum. In the top view, the upper sulfur layer (solid yellow), tantalum, and lower sulfur layer (yellow with black lines) are superimposed.

3.2. Charge Density Waves

The d^1 transition metal dichalcogenide materials exhibit rich temperature-dependent structural and electronic properties. Electronically, the partially filled t_{2g} conduction band in a d^1 system should give rise to metallic conductivity. Indeed, at high temperatures the compound 1T-TaS_2 is metallic; however, on cooling below 543 K 1T-TaS_2 exhibits four distinct temperature-dependent charge density wave (CDW) states.[8, 27, 28] A schematic diagram of the CDW and atomic lattice in 1T-TaS_2 is shown in Figure 4. In general, CDWs are found in low-dimensional systems that exhibit significant Fermi surface nesting (nesting refers to the condition that a piece of the solid's Fermi surface may be translated and superimposed on another piece by a wave vector $\boldsymbol{q}$). Fermi surface nesting leads to a divergence

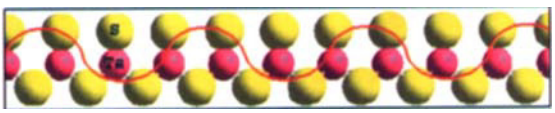

Fig. 4. Cross sectional view of a CDW (sinusoidal red line) in a single layer of TaS_2.

[*] The notation 1T indicates the polytype in which all tantalum atoms are octahedrally coordinated.

in the electronic susceptibility at the q, and through electron–phonon coupling can yield a stable periodic modulation of the atomic lattice and of the electron density in the conduction bond; that is, a CDW. The wavelength (λ) of the CDW is governed by q. Since λ is determined by the Fermi surface size through q, it might not correspond to an integral number of lattice constants (na). In the case where $\lambda \neq na$ the CDW is called incommensurate; however, when $\lambda = na$ it is commensurate.

Prior to the advent of STM the structure of the CDW phases in TaS_2 and other materials had been investigated by X-ray and electron diffraction methods. These techniques showed in 1T-TaS_2 that the high temperature CDW was incommensurate, and that for $T < 183$ K the CDW rotated 13.9° relative to the atomic lattice to become commensurate.[27–29] The real-space structures of these phases are illustrated schematically in Figure 5.

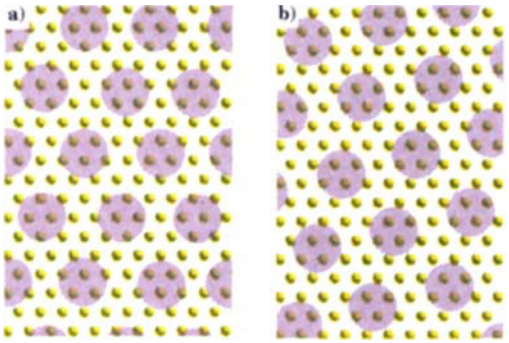

Fig. 5. Schematic top views of the incommensurate (a) and commensurate (b) CDW phases in 1T-TaS_2. The CDW maxima are indicated by pink-shaded circles and the atomic lattice by yellow spheres.

The CDW superlattice of both phases has a regular hexagonal symmetry. In the incommensurate phase the peaks of CDW are located randomly relative to the atomic lattice. In the commensurate phase, the CDW superlattice rotates 13.9° relative to the atomic lattice and expand by 2% with the result that each CDW maximum is oriented over a similar atomic lattice site. Unfortunately it was not possible to resolve the structures of the intermediate-temperature nearly-commensurate and triclinic nearly-commensurate CDW phases by means of diffraction techniques. These two phases had been suggested to exhibit either uniformly incommensurate structures or domainlike structures.[30, 31]

The first application of STM to CDWs was carried out by Coleman and co-workers in 1985.[32] Significantly, this work showed that the charge modulation of a CDW and atomic lattice could be viewed simultaneously in real space. In addition, comparison of early STM data with previous diffraction results demonstrated that the surface-sensitive STM experiment truly reflected the bulk properties of 1T-TaS_2.[32, 33] The ability of STM to determine simultaneously both CDW and atomic lattice positions has subsequently been exploited to resolve the complicated structural details of the intermediate-temperature CDW phases in TaS_2 that previously could not be determined by diffraction techniques.[6, 7, 34–38]

STM studies of the real-space structure of TaS_2 at room temperature showed that the nearly-commensurate CDW phase adopts a novel, hexagonal, domainlike structure, in which there is a periodic variation in the CDW amplitude that occurs on a wavelength much larger than the CDW wavelength λ (Fig. 6).[34] In images of large areas the CDW maxima (Fig. 6a, filled white circles) define a regular hexagonal superlattice with an average wavelength that is consistent in diffraction and STM measurements. The amplitude of the CDW maxima further exhibits a larger periodic modulation that defines domains consisting of relatively high-amplitude CDW maxima separated by lower amplitude domain boundaries. The roughly circular, high-amplitude domains are arranged in a hexagonal superstructure with a period of approximately 70 Å at room temperature. Hence, the nearly-commensurate CDW exhibits a fascinating hierarchy of structures: the hexagonal atomic lattice with period 3.35 Å, the fundamental hexagonal CDW lattice with period of about 12 Å, and the hexagonal domain superlattice with period 70 Å.

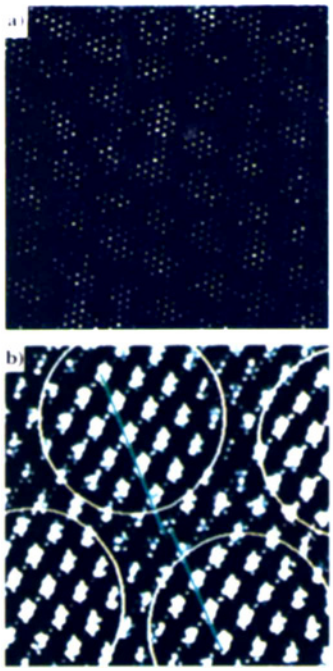

Fig. 6. STM images of 1T-TaS_2 at room temperature: a) 50×50 nm^2 surface showing CDW maxima and domains; b) atomic-resolution imge of four domains.

Images with atomic resolution of the nearly-commensurate phase have provided further insight into the complex structure of the domain phase; four domains are highlighted by white circular lines in Figure 6b. This image shows well-defined phase shifts of one atomic lattice period between the CDWs in adjacent domains:[34, 35, 38] the green lines indicating the CDW directions in adjacent domains have a one-atom mismatch. The abrupt changes in CDW phase are clear in real-space images, but are quite difficult to detect in diffraction measurements. Furthermore, the high-resolution images show a similar arrangement of atoms at each CDW maximum within a domain, thus indicating that the CDW is approximately commensurate (see for example, schematic representation in Fig. 5) in the domains. Because the actual angle between the atomic lattice and CDW superlattice can be measured, such images also enable the issue of commensurability to be addressed quantitatively. Significantly, these measurements showed the angle within single domains was that expected for a commensurate CDW (approximately 13.9°). Taken together, these STM studies unambiguously resolved the long standing controversy about the structure of the nearly-commensurate CDW phase in 1T-TaS_2.

Temperature-dependent SPM measurements are also important for probing CDW phases in the transition metal dichalcogenides further, since temperature variations can be used to assess melting and other phase transitions.[33, 35, 36] STM studies of the nearly-commensurate phase in 1T-TaS_2 first demonstrated the power of such measurements.[35] Images recorded

between 200 and 350 K exhibit the hexagonal CDW domain structure described above. The period of the domain structure was found to undergo a remarkable and unexpected change with temperature decreasing from 100 Å at 200 K to approximately 60 Å at 350 K (Figs. 7a–c). At still higher temperatures, there is an abrupt loss of the domain structure as the true incommensurate phase is formed (Fig. 7d). Significantly, the decrease in domain size appears similar to a second-order melting transition as the sample temperature is raised; however, it is important to point out that this corresponds to melting of an electronic (CDW) lattice and not the atomic lattice.

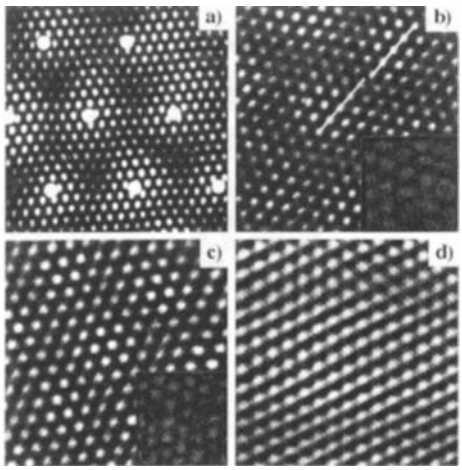

Fig. 7. STM images of 1T-TaS_2 recorded at sample temperatures of 242 (a), 298 (b), 349 (c), and 357 K (d). The imaged surfaces are 30×30 (a), 17.5×17.5 (b), and 15.5×15.5 nm^2 (c and d). The insets in b) and c) are 30×30 nm^2. The domain center positions for an ideal hexagonal structure are marked with white dots in a).

3.3. Role of Metal Substitution

From a chemist's perspective one of the most exciting areas of SPM-related materials research is that focusing on understanding how chemical substitutions or doping affect the structural and electronic properties of a solid at the atomic level. In the specific case of materials with CDWs, the crucial issue is to understand how a CDW interacts with the metal impurities doped into the atomic lattice, since the nature of the interaction between impurities and a CDW controls both the static and dynamic properties of the CDW state.[39–45] CDW pinning can, in general, be classified as either strong or weak depending on the competing energetics of the CDW–impurity interaction and the CDW deformation energy (Fig. 8).[39, 41, 42] In strong pinning, the impurity's potential dominates the CDW elastic energy and pins the phase of the CDW at each impurity site. In weak pinning, the CDW breaks up into constant phase regions that are pinned collectively by impurities. Despite the fundamentally different structural manifestations of strong and weak pinning, there has been considerable controversy concerning the nature of pinning in CDW systems.[39–49] This controversy has been due in large part to the lack of data characterizing the evolution of CDW structure with impurity doping. Real-space imaging of the CDW structure in doped materials by STM has, however, addressed and resolved directly the important issue of strong versus weak pinning.[8, 50–57]

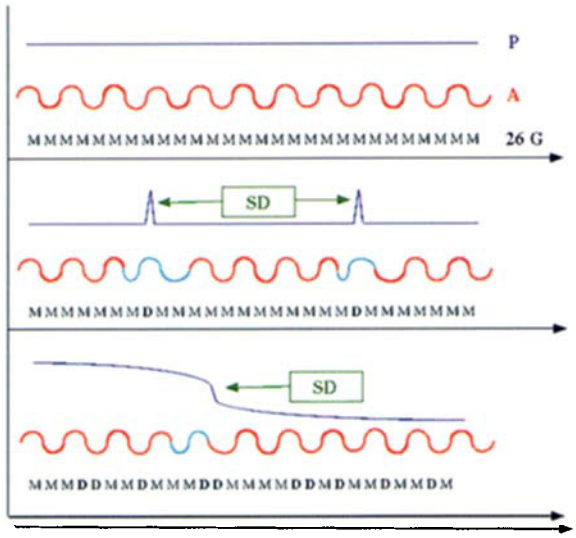

Fig. 8. Plots of the CDW phase and amplitude as a function of lattice position for a perfect one-dimensional lattice (top), a lattice containing strong pinning impurities (middle), and a lattice containing weak pinning impurities (bottom). A = CDW amplitude, L = lattice, P = CDW phase, SD = structural defect. D in the lattice represents dopant molecules.

We have investigated the effect of impurities through systematic studies of metal-substituted tantalum disulfide, $M_xTa_{1-x}S_2$, where M atoms randomly replace Ta sites in the lattice.[50–57] In principle, substitution of isoelectronic Nb^{IV} for Ta^{IV} centers represents the weakest perturbation on the potential that is possible with metal substitution, and thus serves as the best test of the weak pinning regime. The effect of Nb-substitution on the macroscopic transport properties of these $Nb_xTa_{1-x}S_2$ materials has been assessed by variable-temperature resistivity measurements.[27, 28] Nb-substitution (and other metal substitutions) decreases the transition temperature from the high-temperature incommensurate CDW state to the lower temperature nearly-commensurate state. Qualitatively, the suppression in the transition temperature can be rationalized by assuming that the incommensurate state is stabilized by impurity pinning. Structural studies of these same materials with electron diffraction confirmed that the Nb-impurities pin the incommensurate CDW, but could not provide information about the nature of pinning.[27] STM images do, however, provide direct insight into the structural effects and mechanism of pinning.

STM images of $Nb_xTa_{1-x}S_2$ single crystals with values of x ranging from 0 to 0.07 are shown in Figure 9. The images were recorded at the elevated temperatures of 380 K ($x = 0$), 340 K ($x = 0.04$), and 315 K ($x = 0.07$) to ensure that the samples were in the incommensurate state, where the CDW interacts only weakly with the underlying lattice.[53, 57] Pure TaS_2 exhibits a nearly perfect hexagonal CDW lattice that is characteristic of the known incommensurate state in this material. In contrast, substitution with niobium causes disorder in the CDW lattice. The images of the Nb-doped materials exhibit areas in which the CDW lattice has hexagonal order and regions containing defects. These defects introduce disorder into the CDW lattice. The predominant defects observed in the samples in which $x(Nb) < 0.07$ are dislocations. Dislocations are formed by the insertion of extra half rows of CDW sites in the lattice. Importantly, there is a significant strain field associated with the dislo-

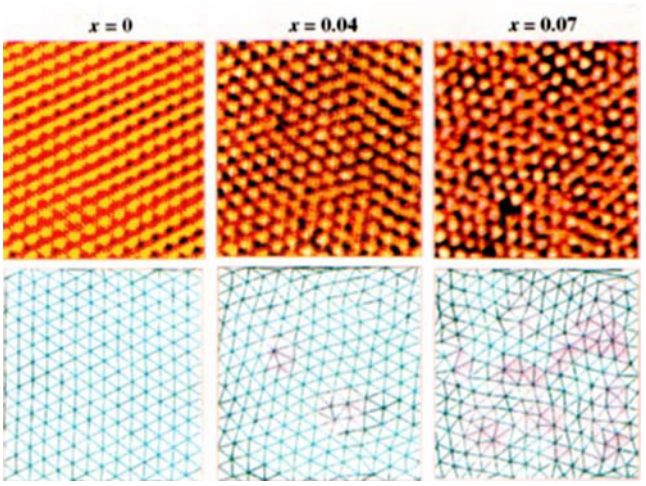

Fig. 9. STM images of the $Nb_xTa_{1-x}S_2$ crystals recorded at 380 ($x = 0$, 340 ($x = 0.04$) and 315 K ($x = 0.07$). Delaunay triangulations are shown below the corresponding STM images.

cations.[58] The CDW can relax the strain field by locally deforming through positional shifts and rotations, although these deformations introduce disorder into the lattice. In the samples containing higher impurity concentrations (x(Nb) ≥ 0.07) STM images exhibit extended defects. The CDW lattice in these latter samples exhibits significant disorder, and regions of hexagonal order and positional order extend only several lattice constants. Nevertheless, it is important to note that the disorder does not appear to destroy the orientational order of the CDW lattice. The presence of relatively long-range orientational order can be seen qualitatively by sighting down the rows of the CDW lattice: this shows that the average direction is defined regardless of the Nb impurity concentration.

To examine in more detail the order of a lattice it has been instructive to analyze the images quantitatively. The quantitative analysis involves defining the location (x, y coordinates) of each CDW maxima and the nearest neighbors in the lattice. Once the lattice points are determined, the Voronoi diagram, which uniquely defines the nearest neighbors of all lattice points, is computed for the lattice.[59] To highlight defects in the lattice we triangulate the Voronoi diagram by drawing "bonds" from all CDW lattice points to their nearest neighbors.[55, 57, 59] This resulting plot is termed the Delaunay triangulation. For the CDW lattice, fully coordinated sites are indicated by six bonds, while topological defects containing a smaller or greater number of bonds are highlighted by shading. The triangulated images are shown below their corresponding STM images in Figure 9; the topological defects are shaded pink. These data demonstrate clearly that the pure 1T-TaS_2 CDW lattice is defect free and that the number of topological defects increases with increasing Nb impurity concentration. Significantly, analysis of the average spacing between topological defects shows that it is much greater than the average spacing between Nb impurities, and thus this analysis unambiguously shows that the pinning by Nb atoms is a weak or collective effect.[8]

It is also possible to obtain further insight into the changing order in this system by calculating the translational [$G_T(r)$] and orientational [$G_6(r)$] correlation functions for a two-dimensional lattice.[8, 55, 59, 60] Significantly, analyses of $G_T(r)$ and $G_6(r)$ as a function of the Nb impurity concentration show that 1) for $x = 0$, both $G_T(r)$ and $G_6(r)$ exhibit long-range order; 2) for $0 < x \leq 0.04$, $G_T(r)$ decays exponentially (which indicates short-range order), and $G_6(r)$ exhibits long-range order; and 3) for $x \geq 0.07$, $G_T(r)$ and $G_6(r)$ decay exponentially. The existence of long-range orientational order but short-range translational order was an important observation, because it showed the existence of a hexatic glass state in these doped materials.[55, 59, 60] Hence, these microscopic STM studies led to the unexpected discovery that the CDW lattice evolves from a crystalline state in the pure solid through a hexatic glass state to a liquid-like amorphous state as the impurity concentration increases.

A very different impurity pinning effect has been observed in our STM studies of titanium-doped $TaSe_2$.[54] The CDW state in 1T-$TaSe_2$ is commensurate at all experimentally accessible temperatures, and each CDW maximum is located on a similar symmetric Ta atom site (Fig. 5b) effectively pinning the CDW to the underlying atomic lattice. The driving force for the commensurate state is an electrostatic interaction between the Ta ions and the CDW. In the incommensurate state, this electrostatic pinning term would be zero. The strong interaction between the CDW and atomic lattice that exists in the commensurate state suggests that the added pinning effect of metal impurities should be quite different than observed in the above studies of $Nb_xTa_{1-x}S_2$. STM images recorded on a series of $Ti_xTa_{1-x}Se_2$ single crystals with $x = 0$, 0.02, and 0.04 support this idea (Fig. 10). The CDW lattices observed in samples containing

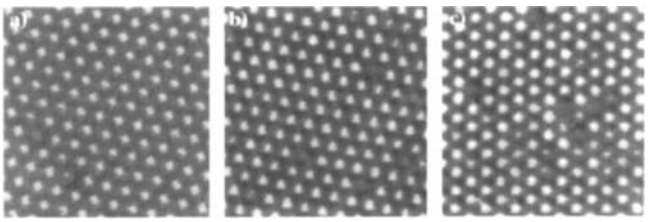

Fig. 10. STM images ($13.5 \times 13.5\,nm^2$) of $TaSe_2$ (a), $Ti_{0.02}Ta_{0.98}Se_2$ (b), and $Ti_{0.04}Ta_{0.96}Se_2$ samples (c) recorded at room temperature.

titanium impurities exhibit a regular hexagonal structure that is similar to the pure sample. The overall order in the CDW lattice of the Ti-doped materials thus differs significantly from that observed in the $Nb_xTa_{1-x}S_2$ materials where the niobium impurities create substantial disorder in the CDW superlattice. The images of the Ti-doped materials do, however, exhibit localized regions where the CDW amplitude is suppressed relative to the surrounding CDW maxima. In addition, we have shown that the density of these localized defects increases linearly with the titanium impurity concentration. These data and the highly localized nature of the CDW defects represent solid evidence for strong pinning.

The studies of $Nb_xTa_{1-x}S_2$ and $Ti_xTa_{1-x}Se_2$ demonstrate the power of STM in elucidating complex structural problems in these CDW materials. It is also possible that detailed spectroscopic studies of single CDW defects at strong pinning sites will provide unique information relating to the microscopic details of CDW formation. In particular, it should be possible to probe the symmetry properties of the CDW gap by probing electron

scattering at CDW defect sites. Careful analysis of the symmetry and decay of the charge density around the defects, which is measured in voltage-dependent STM images, should provide unique information about the Fermi surface topography and scattering in these materials.

4. Copper Oxide Superconductors

4.1. $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ Materials: The Incommensurate Superstructure

The copper oxide superconductors are highly anisotropic materials containing two-dimensional copper oxide planes as a key structural element.[61-63] The other components of these materials determine the overall structural anisotropy, chemical complexity, and ultimately the superconducting transition temperatures T_c of these materials. Among the high-temperature superconductors now known, the $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$ family of materials ($n = 1-3$) are the most anisotropic and probably best suited to surface-sensitive experiments. The $n = 2$ compound, $Bi_2Sr_2CaCu_2O_8$ (BSCCO-2212), is structurally representative of this family and consists of two-dimensional repeat units containing 2-BiO, 2-SrO, Ca, and 2-CuO_2 layers (Fig. 11).[61a, 63, 64]

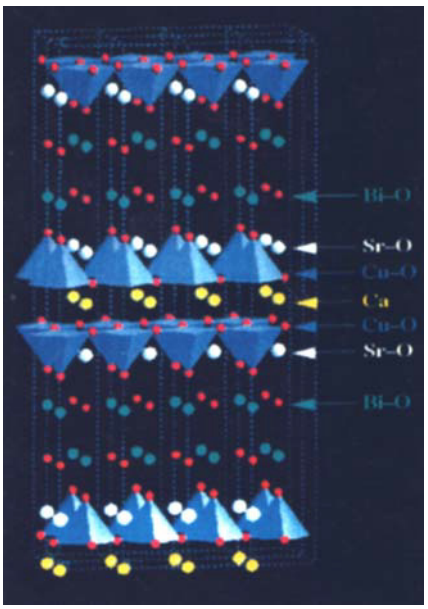

Fig. 11. Structural model of $Bi_2Sr_2CaCu_2O_8$.

The average structure of BSCCO-2212 obtained from diffraction studies is quite straightforward, although in reality these materials exhibit a wide range of structural complexities.[64, 65] For example, BSCCO-2212 shows considerable disorder in the atomic structure of the BiO layer, oxygen nonstoichiometry, and exchange of metals between the idealized layers shown in Figure 11. The detailed nature of such local disorder is intrinsically difficult to address by conventional diffraction techniques, as are the electronic consequences of these structural variations. A complete picture of the microscopic properties of these materials is, however, almost certainly necessary to understand high-temperature superconductivity, since the structural disorder has a dimensionality similar to the coherence length of the superconducting electron pairs. Moreover, the complex high-T_c materials can also serve as models to understand the role of intricate compositional and structural variations that are present in multicomponent materials in general.

The crystallographic separation between adjacent BiO layers in BSCCO is quite large (greater than 3 Å) and as such provides a natural cleavage plane in crystals of these materials.[63, 64] Because covalent bonds are not broken when cleaving crystals between the weakly interacting BiO layers, the BiO surface layer does not reconstruct; hence, STM experiments probe properties similar to that found in the bulk.[66-68] STM images of cleaved BSCCO-2212 crystal surfaces exhibit structure on several length scales (Fig. 12). Of particular interest has been the one-dimen-

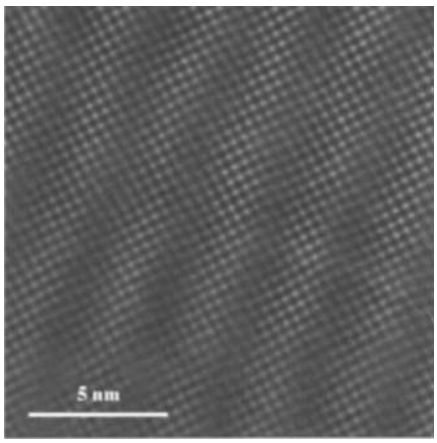

Fig. 12. STM image of $Bi_2Sr_2CaCu_2O_8$ exhibiting the one-dimensional superstructure and BiO layer atomic lattice.

sional superstructure modulation of period 27 Å that occurs along the a axis. A number of models have been proposed to explain the origin of this unique structural modulation in BSCCO, including 1) lattice mismatch between the BiO and CuO layers; 2) extra oxygen atoms substituted into the BiO layer, which causes it to buckle periodically; and 3) periodic Cu or Sr substitution for Bi in the BiO layer.[64, 66, 67, 69, 70] At least three problems intrinsic to these materials have hampered efforts based on diffraction to elucidate the origin of this superstructure. Firstly, the superstructure period is incommensurate with respect to the lattice. Secondly, the BiO layer has considerable disorder, and thirdly, the X-ray and electron scattering cross sections for oxygen are significantly smaller than for Bi.[65, 70]

STM is not limited by these problems and has provided unique insight into the origin and effects of this modulation.[66-68] Real space STM images such as Figure 12 show that the superstructure period is not a sinusoidal modulation; the period varies randomly from 22 to 27 Å.[67] These results demonstrated that the superstructure could not be due simply to BiO/CuO lattice mismatch (which would yield a sinusoidal modulation), but must have a random substitutional component that caused local fluctuations in the superstructure period. Further evidence for the importance of substitution in determin-

ing the properties of the superstructure will be discussed below with relation to metal substitution and oxygen doping.

The atomic structure in images of the BiO layer (for example, Fig. 12) has tetragonal symmetry with a period of 3.8 Å. This distance is consistent with both the average Bi–Bi and O–O distances determined by crystallography; that is, alternate atomic sites, either Bi or O, are imaged by STM. Because only one site is imaged by STM, such data cannot be used to define unambiguously the complete atomic structure associated with the superstructure modulation. The images at atomic resolution do show, however, that there can be significant positional disorder in the BiO layer. We have suggested that this disorder reflects inhomogeneity at the atomic level in the material. Hence, one possible application of STM is the improvement crystal quality achieved by monitoring order in the real-space atomic structure as a function of crystal growth conditions.

4.2. Chemical Inhomogeneity in $Tl_2Ba_2Ca_2Cu_3O_{10}$

The ability of SPM techniques to monitor growth-dependent local atomic order in these complex systems and thereby provide insight into observable properties at a microscopic level is general. Studies of the $Tl_2Ba_2C_{n-1}Cu_nO_{2n+4}$ family of materials ($n = 2, 3$) have clearly illustrated this point.[71, 72] These materials are derived from the Bi family simply by replacing Bi with Tl and Sr with Ba.[61, 63] In general, the average atomic structures of the Tl-based materials are similar to those of the Bi family, although there are several important differences: 1) the Tl materials do not exhibit a regular one-dimensional superstructure and 2) the bonding between adjacent TlO layers is significantly stronger.[61, 63, 73] Despite the stronger bonding between the TlO double layers, crystals of $Tl_2Ba_2CaCu_2O_8$ and $Tl_2Ba_2Ca_2Cu_3O_{10}$ cleave predominantly between the TlO double layers to expose a TlO surface in a manner analogous to that for BSCCO.[71, 72]

The correlation of the microscopic studies by means of STM with macroscopic conductivity measurements have been particularly interesting. Temperature-dependent resistivity measurements made on $Tl_2Ba_2Ca_2Cu_3O_{10}$ crystals grown under various conditions showed strikingly different T_c values (Fig. 13).[72] Crystals grown from a flux containing a Tl:Ba:Ca:Cu ratio of 4:1:3:6 exhibited a broad superconducting transition and a low

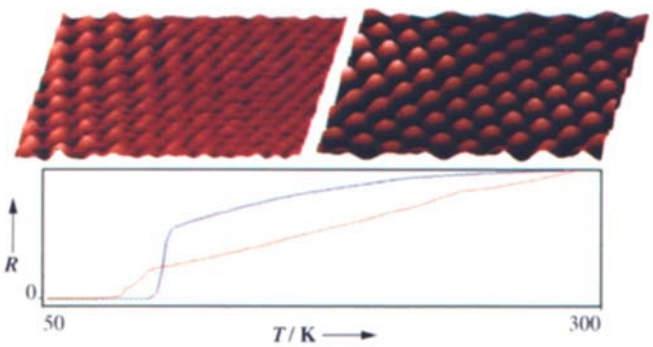

Fig. 13. Top: STM images $Tl_2Ba_2Ca_2Cu_3O_{10}$ crystals grown from 4:3:1:6 (left) and 4:3:1:10 Tl:Ba:Ca:Cu mixtures (right). Bottom: Temperature-dependent resistivity measurements made on $Tl_2Ba_2Ca_2Cu_3O_{10}$ crystals grown under these conditions. R = resistivity.

T_c of 72 K. In contrast, crystals grown from a flux containing a Tl:Ba:Ca:Cu ratio of 4:1:3:10 had a sharp T_c of 110 K. Despite the large differences in T_c, X-ray diffraction and the analysis of the composition showed that these two types of crystals had the same average structure and composition.[61a, 73, 74] The origin of these differences in T_c were, however, readily traced from atomic resolution STM measurements (Fig. 13). The STM images showed clearly that the lower T_c $Tl_2Ba_2Ca_2Cu_3O_{10}$ crystals had pronounced atomic structural disorder, while images of the higher T_c materials exhibited a very regular atomic lattice.[72] These results thus indicate that difference in the macroscopic parameter T_c are due to localized, microscopic variations in the structure of the $Tl_2Ba_2Ca_2Cu_3O_{10}$ samples.

4.3. Metal Substitution: Probing Local Crystal Chemistry

SPM techniques have also been used to probe the effects on the microscopic level of metal substitution in high-T_c copper oxide materials.[7a, 67, 75, 76] In the case of Pb-substituted BSCCO crystals ($Pb_xBi_{2-x}Sr_2CaCu_2O_8$), STM is an especially good probe, since lead primarily replaces bismuth in the BiO layers. The Pb-doped crystals can be cleaved to expose a Bi(Pb)O layer directly at the surface (Fig. 14).[67] STM images

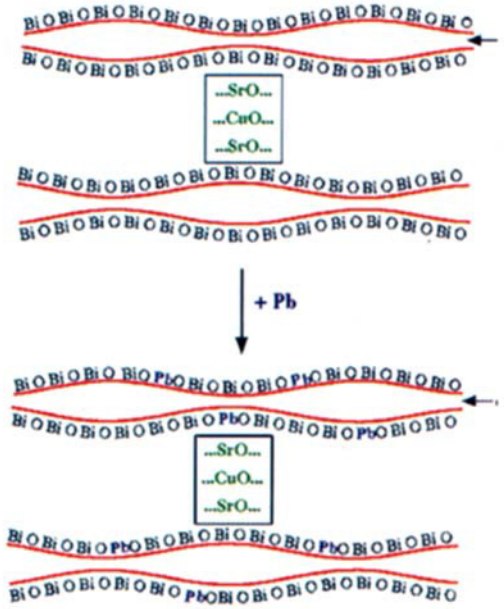

Fig. 14. Schematic illustration of Pb-substitution into the BiO layer of BSCCO-2212. The arrows indicate cleavage planes.

of the Bi(Pb)O layer of Pb-doped BSCCO-2212 single crystals are shown in Figure 15. Images of pure ($x = 0$) BSCCO-2212 crystals exhibit the one-dimensional, incommensurate superstructure that is characteristic of the BSCCO materials.[67, 75] As Pb atoms are substituted for Bi atoms in these crystals, however, the superstructure exhibits increasing disorder. STM images of materials with $x \leq 0.2$ show that the one-dimensional superstructure is less regular than in Pb-doped BSCCO as evidenced by the random displacements along the a axis.[67] The distortions of the superlattice have been attributed to the random substitution of lead for bismuth in the Bi(Pb)O planes and

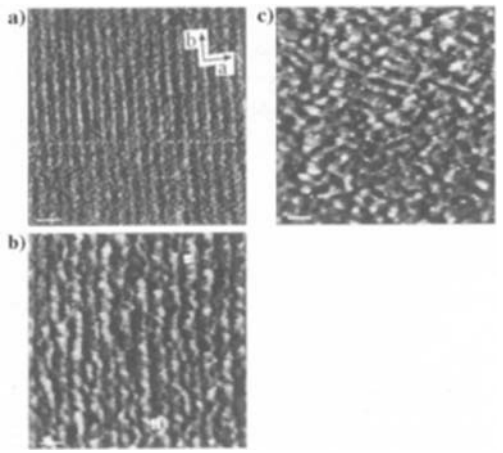

Fig. 15. STM images of $Bi_2Sr_2CaCu_2O_8$ (a), $Pb_{0.3}Bi_{1.7}Sr_2CaCu_2O_8$ (b), and $Pb_{0.5}Bi_{1.5}Sr_2CaCu_2O_8$ (c). The underlying a and b cell axes are indicated in a). The white bar corresponds to 5 nm in these images. The tiny arrows in b) indicate two locations where the superstructure fluctuates significantly from its average position.

the differences between PbO and BiO bonding. Significantly, distortions in the superstructure imaged directly by STM explain the decrease in correlation length reported in diffraction studies of these materials;[77] that is, random fluctuations along the a axis (due to Pb-substitution) reduces the scattering coherence. The suggestion that Pb-substitution distorts the superlattice has been further supported by STM images of samples containing high concentrations of lead (Fig. 15c), since these images exhibit a highly disordered superstructure modulation.

The STM structural data have also provided an understanding of observed variations in the critical current density (J_c) that occur with Pb-substitution. Studies of J_c in Pb-doped BSCCO-2212 have shown that the substitution of lead causes reproducible and significant enhancements in J_c.[78] While it is well known that crystal "defects" can enhance pinning of the fluxlines in superconductors, thereby increasing J_c, the nature of these defects are often not well understood. In the case of Pb-doped BSCCO, the STM images suggest that it is the Pb-induced disorder that enhances flux pinning.

STM studies of crystals of Pb-doped BSCCO-2201, $Pb_xBi_{2-x}Sr_2CuO_6$ single crystals have shown similar results and have been used to develop a new approach for understanding the local disorder probed by SPM measurements.[76] Images of Pb-doped BSCCO-2201 crystals exhibit increasing disorder as the concentration of Pb atoms is increased (Fig. 16). To quantify the order in these crystals and to compare the results to those obtained by electron diffraction we have used the two-dimensional structure factor $S_{2D}(k)$ ($S_{2D}(k) = |\rho(k)|^2$, where $\rho(k)$ is the Fourier transform of the atom density calculated from STM images as function of Pb concentration (Fig. 17). Consideration of this analysis has shown several significant points. Firstly, for samples with intermediate Pb concentrations the comparison of $S_{2D}(k)$ and real-space images with in-plane electron diffraction patterns show that the multiple superlattices inferred from electron diffraction[77] are due to harmonics of the principle superlattice period (Figs. 16b, 17b, e). Secondly, at higher Pb concentrations this same comparison demonstrates that the absence of the one-dimensional superstructure inferred from electron diffraction[79] is due to extreme disorder in this

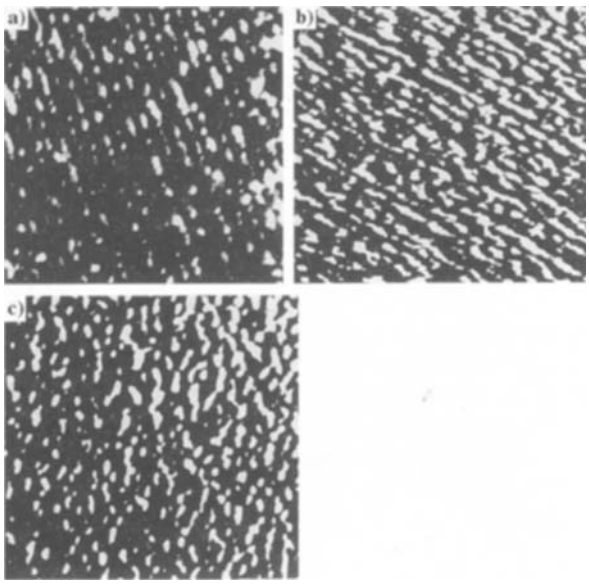

Fig. 16. Images ($60 \times 60\ nm^2$) of $Bi_2Sr_2CuO_6$ (a), $Pb_{0.15}Bi_{1.85}Sr_2CuO_6$ (b), and $Pb_{0.3}Bi_{1.7}Sr_2CuO_6$ (c).

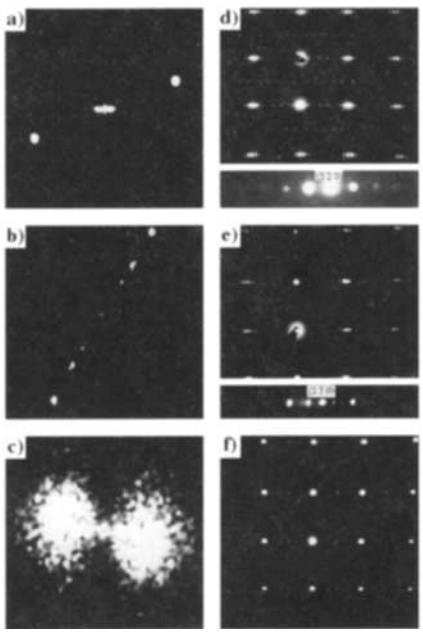

Fig. 17. a)–c): Two-dimensional Fourier transform power spectra of the STM images in Figure 16. d)–f): Electron diffraction patterns recorded on same Pb-doped samples.

structural modulation. Thirdly, it is possible to use the calculated $S_{2D}(k)$ to define a correlation length for the superlattice. More generally, the approach of calculating $S_{2D}(k)$ from real-space images enables the quantitative determination of local crystalline order and should thus be of great utility in materials science (for example, in comparing local microstructures and optimizing growth conditions).

4.4. Oxygen Doping: Probing Local Electronic Structure

It is widely recognized that oxygen doping plays a key role in determining the properties of oxide superconductors.[61, 62] The results from a number of studies have shown that variations in

oxygen concentration change the average carrier concentration and thereby the superconducting transition temperature. X-ray photoemission spectroscopy (PES) studies of BSCCO-2212 crystals doped at high oxygen pressure showed that the density of states near the Fermi level increases with increasing oxygen concentration.[80] To explain this increase in the density of states it has been suggested that oxygen doping transforms the BiO structural element into a metallic layer. The PES interpretation is complicated, however, by the fact that this technique probes several unit cells in depth. STM is uniquely suited to elucidating the origin of high-pressure doping, since it can probe directly the surface BiO layer's electronic states with little contribution form the underlying CuO_2 planes.

STM spectroscopy data obtained on as-grown and oxygen-annealed BSCCO crystals exhibit distinctly different $I-U$ behavior for the different oxygen treatments (Fig. 18),[81-83] attributable to distinctly different electronic structures near the

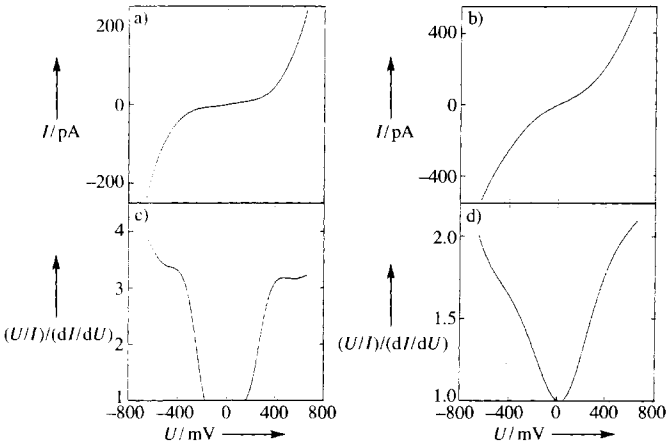

Fig. 18. Current versus voltage data (a, b) and normalized conductivity curves (c, d) obtained on as-grown (a, c) and oxygen-annealed (b, d) BSCCO-2212 single crystal samples.

Fermi level. The as-grown crystals exhibit a low current within ± 200 mV of E_f and relatively sharp increases in I beyond these points, while the oxygen-annealed samples show a smooth increase in I for all U. Indeed, the normalized conductivity $(U/I)\mathrm{d}I/\mathrm{d}U$ shows that there is a 330 mV gap in BiO layer density of states for the as-grown sample, but no obvious gap for the oxygen-annealed sample. The absence of a gap in the oxygen-annealed samples suggests that oxygen doping introduces impurity states into the gap or causes the BiO layer to become metallic.

STM imaging of the BiO layer atomic structure has provided additional information helping to resolve these two possibilities.[82] Atomic resolution images of the as-grown and oxygen-annealed samples exhibit the same surface atomic structure (Fig. 19). The lattices for the samples have periods of 3.8 ± 0.2 Å that corresponds to either the Bi–Bi or O–O distances. The observation of alternate lattice sites for a range of bias conditions indicates that the BiO layer is semiconducting in both as-grown and oxygen-annealed crystals. These structural results combined with the spectroscopic measurements thus suggest that the BiO layer's density of states increases with oxygen annealing, although this layer does not become metallic.

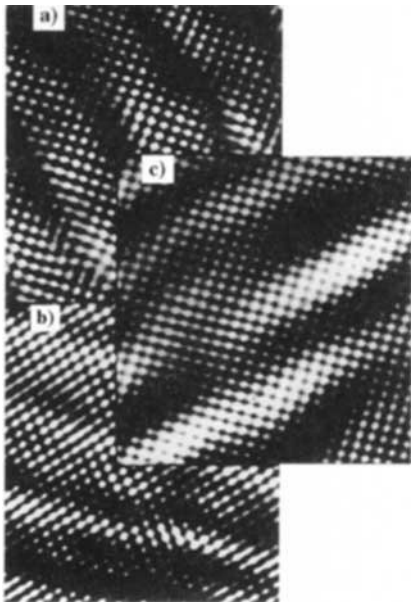

Fig. 19. STM images (10×10 nm^2) recorded on BSCCO crystals. Sample preparation: a) as-grown, b) annealed under 12 atm oxygen, and c) annealed under 150 atm oxygen.

4.5. The Superconducting Energy Gap

The spectroscopic capabilities of STM have also been exploited by many research groups to study the superconducting state of the high-T_c copper oxide materials.[84] The emphasis in this work has been to probe the superconducting energy gap (2Δ) and low-energy excitations in these materials, since this information is essential to understanding the mechanism of superconductivity. In the conventional Bardeen, Cooper, and Schrieffer (BCS) model of superconductivity, there is a complete gap in the density of electronic states as the temperature approaches 0, and the magnitude of 2Δ has the universal value of $3.53\,kT_c$.[85] For conventional superconductors these predictions have agreed well with measurements of the density of states by tunneling spectroscopy.[84, 86] In the case of the copper oxide materials, however, tunneling spectroscopy measurements have led to suggested values of 2Δ between 0 and $12\,kT_c$, although recent studies have converged towards an energy scale of $5-8\,kT_c$.[84, 87-90] It is likely that material inhomogeneity, such as oxygen nonstoichiometry, have been responsible for many of the apparently conflicting measurements of 2Δ by tunneling spectroscopy,[88-91] since the short coherence lengths of the copper oxide materials make these measurements especially susceptible to local variations in the superconducting properties. Indeed, spatially resolved spectroscopy measurements have shown clear evidence for variations in 2Δ associated with structural inhomogeneity.[88, 89]

To delineate the intrinsic versus extrinsic features of the superconducting energy gap in the high-T_c materials we have reported systematic measurements on carefully annealed BSCCO-2212 samples with T_c values ranging from 79 to 92 K. The STM spectroscopy measurements exhibited values of 2Δ that were uniform over the sample surfaces (Fig. 20). The $I-U$ curves recorded on crystals with T_c values of 79, 86, and 92 K all exhibit similar features including a relatively flat low-current

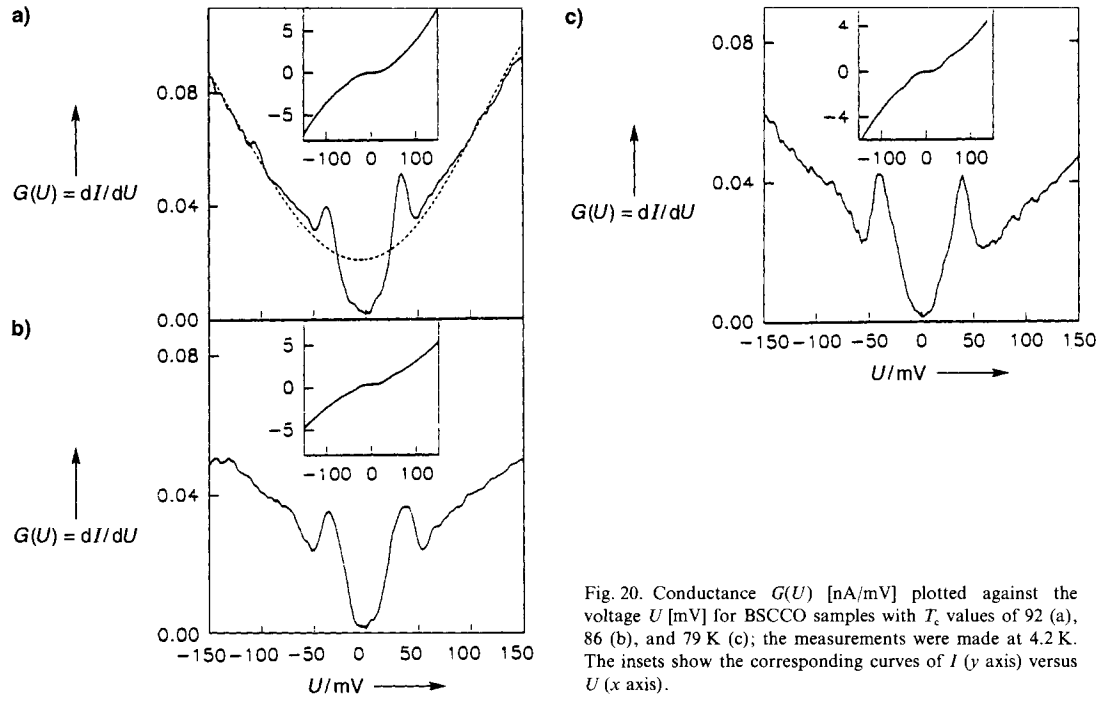

Fig. 20. Conductance $G(U)$ [nA/mV] plotted against the voltage U [mV] for BSCCO samples with T_c values of 92 (a), 86 (b), and 79 K (c); the measurements were made at 4.2 K. The insets show the corresponding curves of I (y axis) versus U (x axis).

region about $U = 0$ and pronounced conductance onsets at $\pm(20-25)$ mV. These features agree qualitatively with those expected for a superconducting gap. Clear insight into the electronic spectrum of the BSCCO samples in the superconducting state was obtained from the conductance $G(U)$, since it is proportional to the density of states N_S. The $G(U)$ vs. U curves obtained on the samples with T_c values varying from 79 to 92 K all showed similar features (Fig. 20). Reproducible features reported in these tunneling spectra include excitations within the gap region for $|U| > 0$ and well-defined conductance peaks. Significantly, the magnitudes of 2Δ determined from this data are similar, irrespective of the sample T_c.[90] These results demonstrate that 2Δ does not scale with T_c as found previously with conventional superconductors and thus have important implications regarding the mechanism of superconductivity.[90]

These data have also afforded the opportunity to examine in detail the quasi-particle excitations within the gap region (Fig. 21). Such an analysis is important, since it can provide insight into the symmetry of the energy gap function. Several models have been used to fit the tunneling spectroscopy data including the broadened BCS s-wave, the gapless, and the d-wave models. The broadened BCS function (g) does not provide

$$\frac{N_S}{N_N} = \mathrm{Re}\left\{\frac{\varepsilon}{\sqrt{\varepsilon^2 - \Delta^2}}\right\} \qquad (g)$$

($\varepsilon = eV - i\Gamma$, where V is the applied voltage and Γ a broadening parameter that reflects the finite lifetimes of quasi-particles)

a good fit of the experimental data, since it cannot simultaneously have sharp conductance peaks and excitations within the gap (Fig. 21 a). Hence, it is not expected to provide new insight into the physics of pairing. Alternatively, strong pair-breaking can lead to quasi-particle excitations within the gap. The long-dashed line in Figure 21 b was fit using a small amount of pair breaking ($\alpha = \Gamma/\Delta = 0.05$, where α is the pair-breaking parameter), while the short-dashed line corresponds to the behavior expected for a gapless superconductor ($\alpha = 1$). For s-wave symmetry pairing, previous theoretical studies have shown that as inelastic scattering is increased, the conductance peaks broaden and the observed gap ω_g gets smaller, but until the "gapless" regime is reached, no quasi-particle excitations should be observed within the gap.[92] In the context of s-wave pairing, this description is inconsistent with the observation of sharp conductance peaks.

The fact that $G(U)$ is strongly peaked around $\pm\Delta$ and decreases gradually to a minimum at $U = 0$ strongly suggests that there are nodes in the gap function. A function with d-wave symmetry (for example, $d_{x^2-y^2}$: $\Delta(k) \sim \cos k_x a - \cos k_y a$) is one that will have nodes and also has the symmetry that in several theoretical models is a prerequisite for pairing. Significantly, good agreement was obtained by fitting the energy-dependent density of states predicted for gap functions with d-wave symmetry to the tunneling spectroscopy data (Fig. 21 c, d).[90] The fit in Figure 21 c corresponds to the function of N_S/N_N expected for a pure d-wave symmetry gap, while that in Figure 21 d corresponds to the specific d-wave pairing model of

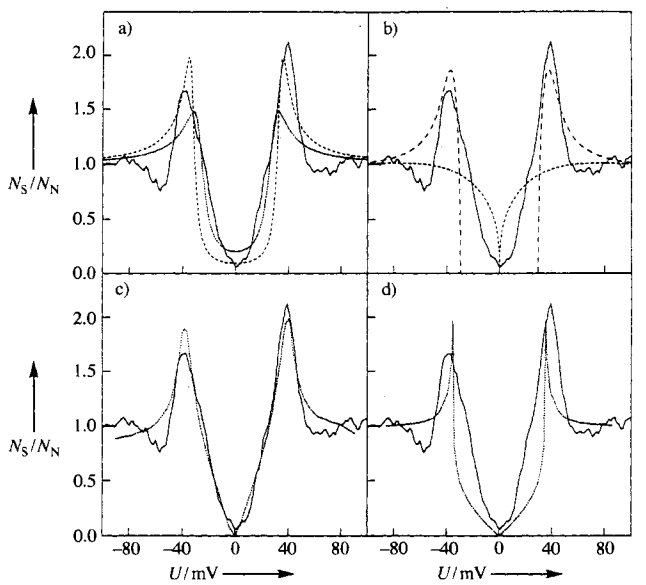

Fig. 21. Curve fitting to typical normalized conductance N_S/N_N versus voltage U data. In all cases the solid curve corresponds to the experimental data and the dashed lines to the fits. The fits were made with Equation (a), varying Δ and Γ in a) and α in b). The curve in c) represents a pure d-wave superconductors, and that in d) the d-wave model of Monthoux, Balatsky, and Pines.

Monthoux, Balatsky, and Pines.[93] Hence, the tunneling data strongly support the idea of an anisotropic gap function, but does not distinguish conclusively between d-wave and anisotropic s-wave models.

4.6. Magnetic Flux-Lines

When a type-II superconductor, such as a material of the copper oxide family, is placed in a sufficiently large field, magnetic flux penetrates through the sample in the form of quantized magnetic flux-lines called vortices.[95, 96] In the absence of crystal defects and pinning the vortices are expected to be arranged in a hexagonal lattice that minimizes the repulsive interaction between lines. This hexagonal structure was recorded beautifully in STM images of flux-line arrays in $NbSe_2$ (Fig. 22).[97] In contrast, when pinning is present, the flux-line lattice structure will change to maximize the pinning interaction, and defects are balanced against the elastic deformation energy expended to distort the lattice.[95, 96]

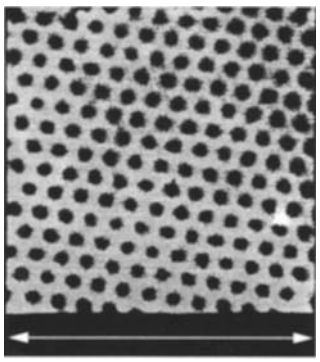

Fig. 22. STM image of the magnetic flux-line lattice in $NbSe_2$ at a field of 1 Tesla. The data were recorded at 1.8 K [97]. The arrow represents 6000 Å.

Surface and bulk defects can play an important role in pinning magnetic flux-lines in high-T_c materials.[95, 96, 98, 99] Because flux-line pinning determines to large extent the magnitude of J_c in superconductors (and therefore possible applications), an understanding of pinning is central to much work in the high-T_c field. Several techniques, including Bitter decoration and neutron diffraction, have been used to study the structure of flux-line lattices in the copper oxide materials.[95, 98] While both of these techniques have provided significant insight into the structure of flux-line lattices, they have not been able to provide direct information about the defects that pin the flux-lines. A new approach that we have developed combining conventional Bitter decoration and AFM has yielded significant insight into this critical area.[100] Bitter decoration is a well-established technique for highlighting reproducibly large numbers of flux-lines, and when combined with AFM, enables us to image the decorated flux-line positions and map out surface defects with a resolution of nanometers. Typical AFM images obtained on BSCCO single crystals that had been decorated in a magnetic field of 33 G are shown in Figure 23. Two distinct types of structures are seen in these images: the magnetic flux-line positions, which appear as small circular spots, and surface steps that appear as lines running through each image. Analysis of the surface topography demonstrates that these steps have heights of 30, 100, and 300 nm. Importantly, we have shown that the flux-line lattice structure can differ significantly depending on the surface step height.[100]

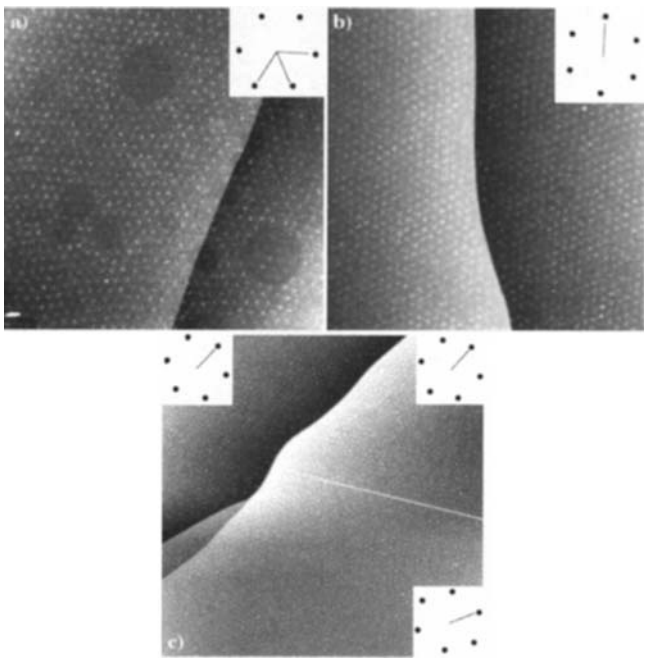

Fig. 23. AFM images recorded on a BSCCO crystal that was decorated at 4.2 K in a magnetic field of 33 Gauss. See text for further details.

The flux-line lattice orientation is seen most clearly in two-dimensional Fourier transform power spectra (2DFT) of selected regions of these images. The 2DFT, which are plotted as insets in each of the figures, each exhibit six diffraction spots characteristic of the hexagonal symmetry of the flux-line lattice and orientation defined by the reciprocal lattice vectors. In Figure 23a, the flux-line lattice orientation is independent of the surface step as is clearly evident when comparing the flux-line lattice reciprocal lattice vectors with the step direction. In Figure 23b, which contains a larger step, the 2DFT shows that a principle axis of the flux-line lattice is aligned preferentially along the straight section of the step. The overall orientation of the flux-line lattice is not perturbed, however, by the curvature in the step at the bottom of the image. The structure of the flux-line lattice in Figure 23c, which contains the largest step, is more complex and interesting. On the lower surface terrace in the upper left of the image, the 2DFT shows that the flux-line lattice orientation is pinned to the step direction. The flux-line lattice in the upper right portion of the image is also pinned in this same orientation. However, the 2DFT demonstrates that the flux-line lattice orientation in the lower part of the image is rotated relative to the upper part. This rotation follows the change in step direction that occurs at the bottom of the image. Significantly, the two distinct flux-line lattice orientations lead to the formation of a grain boundary in the lattice that is indicated by the white line running across the right side of this image. We have developed a model to understand the propagation of these grain boundaries through a sample by considering the pinning energy associated with the surface step and the energy required to elastically deform the flux-lattice.[98] Importantly, using the AFM data it has been possible to demonstrate that the grain boundaries propagate completely through the superconductor samples and thus influence significantly the bulk structure of the flux-line lattice.

5. Manipulation of Matter

5.1. New Nanomaterials Using SPMs

SPM techniques can, in addition to probing the microscopic properties of low-dimensional materials, be used to create new low-dimensional materials—nanostructures. SPM techniques are particularly powerful in nanoscale research, since they can be exploited for both the synthesis and the characterization of a material.[13, 14, 101-113] For example, STM has been used to assemble individual iron atoms into circular structures on a copper metal surface, and to show that the resulting structure exhibited properties of quantum confinement.[111]

The simplicity and flexibility of SPM techniques are a significant advantage for the synthesis and characterization of nanostructures. STM and AFM tips may be coated with thin films of almost any material thereby enabling researchers to control interactions and reactions at substrate surfaces.[114, 115] Experiments may also be carried out in vacuum or in ambient or fluid environments. Such flexibility is not possible in other top down lithography techniques.

5.2. General Approaches to Manipulation

SPM techniques have been used extensively to modify surfaces at the atomic to nanometer scale.[13, 14, 101-113] While modification of a surface in and of itself does not constitute the preparation of a nanostructure, an understanding of the processes involved in modification and manipulation are needed to prepare new structures rationally. Below we describe several processes that have been employed in STM and AFM studies.

Two general types of processes that have been used for STM-based manipulation involve the parallel or perpendicular motion of atoms and clusters (Fig. 24).[14a] In parallel processes, manipulated material is not removed from a surface but rather slid to a particular surface location. In perpendicular processes, however, the probe tip is used to pick up material from the surface and then redeposit it at another location. Parallel processes rely on either electric fields or chemical forces to slide atoms. An electric field emanating from a STM tip induces a dipole in adsorbates that attract them to the tip.[14a, 107] When this attraction is greater than the potential barrier associated with the dipole's moving across a surface, the adsorbate will move towards the tip. An advantage of this technique is that it enables both sample manipulation and the measurement of the dipole moment of an adsorbate. A second parallel process exploits short range attractive interactions between the probe tip and adsorbate to overcome the barrier to surface motion.

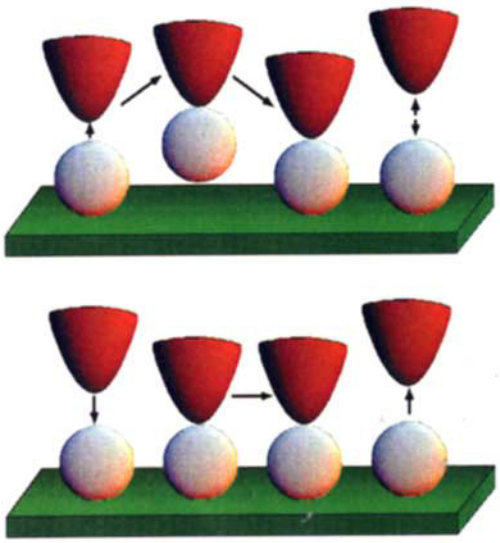

Fig. 24. Schematic diagram illustrating perpendicular (top) and parallel (bottom) manipulation processes.

The principal perpendicular processes are field evaporation and transfer-on-contact. The simpler of the two is transfer-on-contact whereby the tip is lowered onto an atom or cluster so that tip interacts strongly with the surface adsorbate.[14] As the tip is lifted from the surface, it carries the atom or cluster with it. At a desired location the tip is again lowered until the atom or cluster transfers back to the surface. The second type of perpendicular process involves field evaporation or chemically assisted field evaporation.[14, 106, 109] Field evaporation occurs when a large positive bias is applied to the sample (or tip) causing positive cluster ions to evaporate and ideally redeposit on the tip (or sample). An important example of this approach has been the selective removal and deposition small silicon clusters on the surface of crystalline silicon.[106]

AFM modification and manipulation processes are generally more direct than those for the STM. Manipulation based on force microscopy typically involves direct mechanical interactions between the probe tip and substrate. Force microscopy has been used to manipulate materials both by nanomachining[104, 110, 116] and sliding.[112, 113] In nanomachining, the AFM removes atoms from the surface through fatigue wear.[110, 117] For example, the pattern of letters "MoO_3" shown in Figure 25 was machined in a MoO_3 nanocrystal with an AFM probe tip.

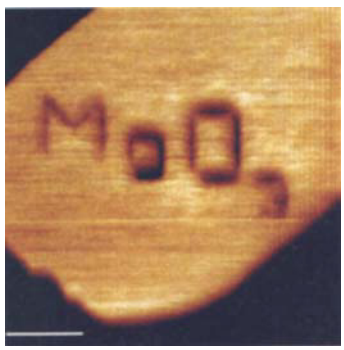

Fig. 25. AFM image engraved with "MoO_3". The pattern of letters was machined in a MoO_3 nanocrystal using the AFM probe tip.

The mechanics of the interaction between tip and sample that is relevant to nanomachining are illustrated in Figure 26. The tip elastically deforms due to the applied load, where the dashed line in the figure shows the shape of the nondeformed tip. A detailed view of the stresses felt by the sample are shown in the zoom of the tip–sample contact region (Fig. 26, right). The upper half of the zoom shows that the pressure distribution felt by the surface, while the lower half shows the stresses in the sample. The maximum stress occurs at a depth of $0.48/a$ below the surface, where a is proportional the radius of curvature of the tip. Under sufficient stress the sample will plastically deform, bonds will break, and material will be lost. All the material in the region may be removed by scanning the tip over it several times. Practical considerations limit the materials that may be machined in this way. The material should be softer than the tip and should not

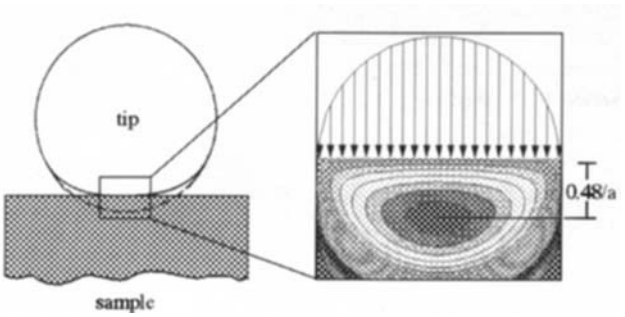

Fig. 26. Illustration of an AFM tip in contact with a surface. Left: The tip elastically deforms on the surface. Right: The arrows represent the pressure experienced by the surface and the gray hatched regions the stresses in the surface. See text for further details.

have of low friction coefficient. A soft material is needed, so that the tip may reproducibly modify the sample and not be modified itself, while a high friction coefficient ensures high interfacial shear and hence large transfer of energy.

The second means of AFM manipulation involves sliding small islands of material on a surface with the AFM's tip.[112, 113] A particularly interesting example of sliding is the phenomenon of lattice-directed sliding that we have recently discovered while manipulating nanocrystals of MoO_3 on MoS_2.[113] MoO_3 nanocrystals can be grown on the surface of MoS_2 by controlled thermal oxidation.[110] When these nanocrystals are pushed with an AFM tip, they move along only one of the lattice directions of the underlying MoS_2 substrate. The motion of two distinct MoO_3 nanocrystals are illustrated in the sequence of images shown in Figure 27a–c.[113] A composite view of these three images and the underlying MoS_2 atomic lattice (Fig. 27d) shows that these two nanocrystals move at a 60° angle with respect to each other and that this motion is along two distinct directions of the MoS_2 lattice. Under most conditions the MoO_3 nanocrystal will slide on this predetermined path indefinitely. The nanocrystals path can be changed, however, by applying a large torque using the tip. Hence, by combining lattice directed sliding with nanomachining it should be possible to construct complex multicomponent nanostructures.

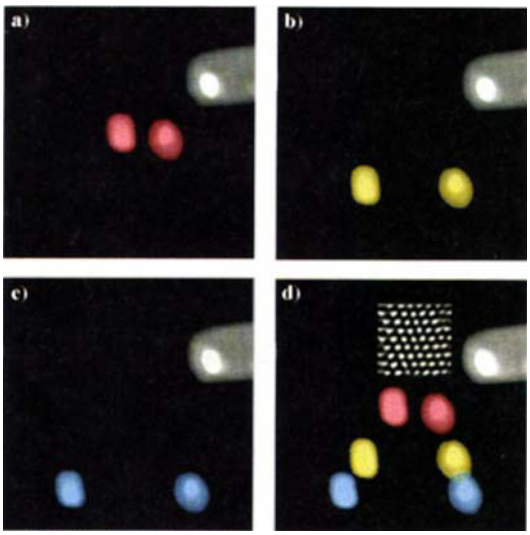

Fig. 27. AFM images showing the lattice-directed sliding of two MoO_3 nanocrystals on a MoS_2 surface. The red (a), white (b), and blue (c) colors correspond to the initial, intermediate, and final positions of the nanocrystals, respectively. d) Depicts a superposition of a), b), and c). The inset shows the atomic lattice of MoS_2.

5.3. Nanostructures

We now turn to two exciting examples of complex nanostructures that have been *synthesized* with the STM and AFM. One of the most elegant structures created with STM is the "quantum corral" built by Eigler and co-workers (Fig. 28).[111] Using a low-temperature (4 K) STM operating in ultrahigh vacuum, they slid 48 Fe atoms into a 14.3 nm ring on a Cu(111) surface. This ring of atoms acted as a hard wall, reflecting electrons trapped in a two-dimensional state at the surface of the copper substrate. The quantum-mechanical interference between these electrons created circular regions of high and low electron density (Fig. 28d).[111] Structures like the quantum corral, though currently limited to low temperature and high vacuum, are solid steps forward in quantum electronics research.

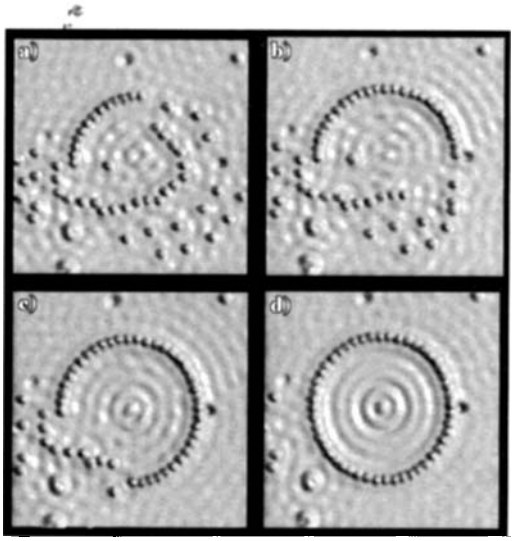

Fig. 28. Steps a)–d) in the formation of a quantum corral [111]. The corral has a radius of 14.3 nm and was created with parallel processes in STM manipulation. In d) the surface electron waves scatter from the Fe atoms leaving fringes.

We have used AFM to create an interlocking nanostructure that is stable at room temperature by combining nanomachining and lattice-directed sliding to manipulate MoO_3 nanocrystals on MoS_2 (Fig. 29).[113] Initially, nanomachining is used to define a notch in crystal 2 (Fig. 29b) and a rectangular latch in crystal 1 (Fig. 29c). Lattice-directed sliding is used to move crystal 2 to crystal 1 (Fig. 29c) and then move the latch into the notch of crystal 2 (Fig. 29d). The smaller crystallite is thereby locked into place by the latch. The preferred lattice-directed sliding directions of the small crystallite and the latch are different, which prevents the small crystallite from moving. The latch itself is prevented from rotating by the large crystallite. An interesting feature of this system is the reversibility of the connection. The smaller nanocrystal may be locked into place, unlocked, manipulated, and then relocked. This is exactly what has oc-

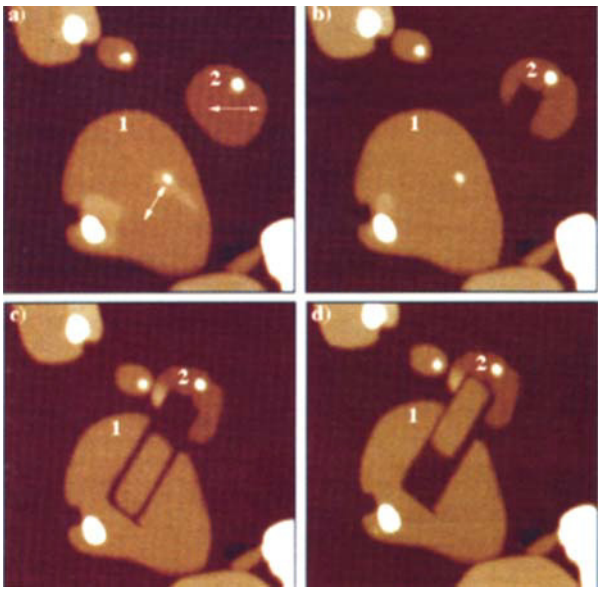

Fig. 29. AFM images illustrating the fabrication and final structure of three interlocking MoO_3 nanocrystals. See text for further details.

curred in Figures 29 c and d. This locking mechanism can, however, readily resist motion, relative to the larger crystal, of the small nanocrystal along its preferred sliding direction. Hence, the lock can be used as a structure to facilitate the fabrication of larger, more complicated systems that include, for example, electronically distinct oxide pieces. In addition, such a mechanical latch corresponds to the basic components needed to construct a nano logic gate.

6. Summary and Outlook

The combination of scanning probe microscopies and chemical synthesis has significantly advanced the understanding of charge density waves, high-temperature superconductivity, and nanofabrication in low-dimensional materials. This new approach to studying materials has directly elucidated the structure of complex charge density wave phases and how metal dopants interact with charge density waves in two-dimensional metal dichalcogenide solids. The real-space picture of atomic and charge density wave lattices provided by STM transforms the diffuse structural view based on diffraction into one that has demonstrated clearly the theoretical concept of weak pinning and has led to discovery of new phases not yet understood theoretically. The coupling of STM with synthesis has also illuminated complex structural disorder in two distinct classes of copper oxide superconductors, thus providing an understanding of observed variations in the bulk transition temperature and critical current density. The methods developed to quantify structural disorder in these studies—termed local crystallography—provide an approach for preparing pure and doped crystals that are homogeneous on a nanometer scale and should be of general utility in the future. Application of this approach to the superconducting state has elucidated details of the electronic excitations important in defining the mechanism of superconductivity and also the structure of magnetic flux-line arrays that are crucial to most technological applications. Such studies are, however, still in their infancy and will require additional work to broaden their impact. Lastly, the combination of scanning probe microscopy measurement and manipulation with chemical synthesis has provided a novel route to the fabrication of nanostructures (which represent the ultimate dimensional reduction in materials). Selective synthesis yields nanocrystals that have, through fundamental studies of friction and wear, been selectively modified and manipulated using force microscopy into interlocking, multicomponent structures. By using this strategy it should be possible to extend nanostructure complexity, and importantly, to readily investigate the physical properties of any new structure created with the probe microscope. More generally, the studies outlined in this review provide a clear pathway to unify work on bulk low-dimensional materials and nanostructures and our understanding of these solids, and in so doing they promise to expand our knowledge and our ability to conceive of new materials for the future.

EVENTS

IRaP 96

2nd International Symposium on Ionizing Radiation and Polymers

Nov. 3-8, 1996, Saint-François, Guadeloupe, FWI

IRaP96 is the second symposium of an international series devoted to ionizing radiation effects in polymers. IRaP conferences bring together scientists from research, universities and industries involved in radiation polymer science. Their aim is to facilitate the exchange of knowledge and information in this cross-disciplinary field and to promote innovative industrial applications. The topics will cover fundamental process, surface and bulk modifications, advanced materials and technological applications. Furthermore, IRaP96 will highlight the influence of ionizing radiation on the modification of chemical and physical properties (e.g. electrical, mechanical, optical, tribological, diffusion...). In addition to electron, photon and ion beam effects, studies with lasers and cluster beams in polymers will be included.

The program consists of keynote lectures, invited and contributed talks, and posters.

A particular attention is given to new materials which can find applications in medecine, biology, biotechnology, defense, environmental protection, and energy saving.

For more information and registration (before September the 15th), please contact:

A prerequisite for the catalytic efficiency of a synthetic enzyme is that it stabilize the transition state.

Enzyme Mechanisms, Models, and Mimics

Anthony J. Kirby*

"One of the great intellectual challenges presented to Science by Nature is a proper understanding of how enzymes work. At one level we can 'explain' enzyme catalysis— what an enzyme does is bind, and thus stabilize, selectively the transition state for a particular reaction.[1] But our current level of understanding fails the more severe, practical test that of designing and making artificial enzyme systems with catalytic efficiencies which rival those of natural enzymes." This was the introduction to a recent Highlight in *Angewandte Chemie*,[2] prompted by the appearance of a paper[2] that appeared to defy established ideas, by claiming artificial enzyme systems that did indeed attain catalytic efficiency rivaling that of natural enzymes. The "pepzymes" of Atassi and Manshouri[3] were relatively small (29-residue) peptides modeled on the active site structures of trypsin and chymotrypsin by "surface simulation." One was claimed to hydrolyze the simple trypsin "substrate" *N*-tosyl-L-arginine methyl ester with k_{cat} and K_m values comparable to those of the native enzyme, and also to hydrolyze the peptide bonds of test proteins to give comparable peptide profiles. This extraordinary result provoked as much skepticism as excitement, and several groups tried to reproduce the results. They failed, comprehensively.[3, 4] Some specific reasons why this failure came as no surprise have been summarized by Matthews et al.[5] This review examines the problems involved in the design of enzyme mimics in more general terms, with the emphasis specifically on the efficiency of catalysis.

Keywords: catalytic antibodies · enzymatic catalysis · enzyme mimics · molecular recognition

1. Introduction: Approaches to Artificial Enzymes

Quite apart from the intellectual challenge, a proper understanding of how enzymes work holds out the promise of artificial catalysts more robust than proteins and available for practically any organic reaction of interest. How far this is a practical proposition at the present time is an important question. To begin to answer the question, and to read the literature critically, we need to understand first of all what the term "artificial enzyme" currently means.

Real enzymes are more than just highly evolved catalysts: they also recognize and respond to molecules other than their specific substrate and product, as part of the control mechanisms of the cell. The evolution of artificial enzymes is at a much more primitive stage, with efficient catalysis the primary objective. Systems are known that model various other functions, including potential control mechanisms. But to be useful as an industrial catalyst, for example, an artificial enzyme does not need sophisticated built-in feedback control or high substrate specificity. A stable molecule that is an efficient catalyst for a key target reaction in a chemical reactor will not be required to select its substrate from many hundreds in the same solution, as enzymes routinely must in the cell. So the sensible design strategy is minimalist: just those features of enzymes that are essential for catalytic efficiency are considered. This review adopts the same strategy.

We first discuss enzyme mechanism in rather general terms, to identify and define their key features. We then go on to enzyme models, systems designed to reproduce specific features of enzyme reactions, and so test basic ideas on enzyme mechanism. Finally we discuss enzyme mimics, the most successful of which combine more than one of the key features identified previously and catalyze reactions by mechanisms that are demonstrably enzyme-like. An enzyme mimic that can do all this, *and* achieve turnover, deserves to be called an artificial enzyme. (If it also proves to be of practical utility it certainly will be.)

2. Enzyme mechanisms

2.1. Molecular Recognition of Transition States

What an enzyme does is bind, and thus stabilize, selectively, the transition state for a particular reaction.[7–9] So the problem can be defined in terms of the molecular recognition of transition states.[10] First we need to recall a few familiar terms.

[*] Prof. A. J. Kirby
University Chemical Laboratory

Fax: Int. code +(1223)-336362
e-mail: AJK1 *a* cus.cam.ac.uk

Experimentally the characteristic feature of an enzyme-catalyzed reaction is that it follows saturation or Michaelis–Menten kinetics[1] characteristic of a mechanism involving formation of an enzyme–substrate complex (**E·S**) as the first step [Eq. (a)].

$$\mathbf{E} + \mathbf{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathbf{E \cdot S} \xrightarrow{k_2\,(k_{cat})} \mathbf{E \cdot P} \overset{\text{fast}}{\rightleftharpoons} \mathbf{E} + \text{products} \qquad \text{(a)}$$

Note that almost any enzyme reaction is a great deal more complicated than this, but the equation describes reactions catalyzed by enzyme models and mimics very well.

If the substrate concentration is high enough, the catalyst becomes saturated. Under these conditions the rate is determined solely by k_2 (usually called k_{cat}), and the reaction is first order (in enzyme concentration). The substrate concentration that gives half this maximum rate is called K_m. At sufficiently low substrate concentrations the first step becomes rate determining and the reaction is second order (rate $= k_1[\mathbf{E}][\mathbf{S}]$; for further details see ref. [1]).

It is important to have a feel for what these parameters mean:

- k_{cat} is the first-order rate constant for the reaction of the bound substrate. It can be compared directly with those of other first-order reactions, for example intramolecular reactions, and allows estimates of the effective molarity (see Section 3.1) within the complex if the mechanism is known. It is easy to interpret: bigger is better.
- K_m is a measure of binding, generally of all enzyme-bound species, but of the substrate in the simplest case, when the binding step is a rapid preequilibrium (i.e. $k_{-1} \gg k_2$). K_m then becomes equal to the dissociation constant of the catalytic complex [**E·S**] and is easy to interpret: smaller values correspond to tighter binding.
- k_{cat}/K_m is the apparent second-order rate constant at very low substrate concentrations; under these conditions it is a useful measure of the overall efficiency of the catalyst, *including the binding step*. It can be compared with other second-order rate constants. (Competitive catalytic chemists like it because it gives big numbers.)

So far we have not considered the transition state explicitly. This is done most simply with an energy profile diagram for enzyme-catalyzed and uncatalyzed reactions of a substrate **S** (Fig. 1). The two transition states of interest are $\mathbf{TS}_{cat}$ for the catalyzed reaction and $\mathbf{TS}_{uncat}$ for the reaction in the absence of the catalyst. Molecular recognition of the transition state is

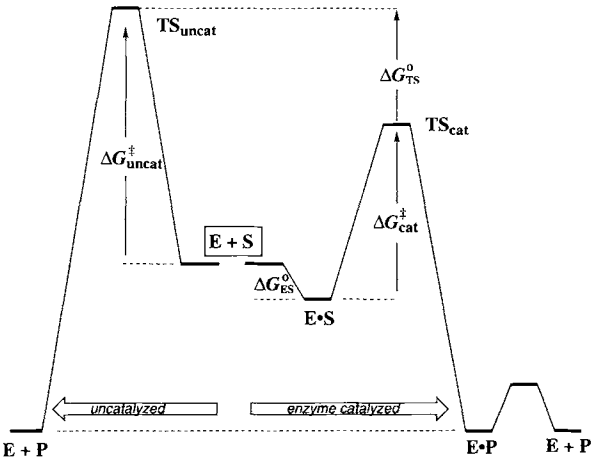

Fig. 1. Energy profiles for both enzyme-catalyzed (left to right) and uncatalyzed (right to left) reactions of a substrate **S**. The ordinate represents (qualitatively) the Gibbs free energy, the abscissa the progress along a theoretical reaction coordinate. (Note that the route via **E·S** is the unique low-energy pathway from starting materials to transition state.)

measured by its free energy of binding $-\Delta G^0_{TS}$, which is derived simply from Figure 1 by applying Equations (b) and (c). We

$$\Delta G^{\ddagger}_{uncat} + \Delta G^0_{ES} = \Delta G^{\ddagger}_{cat} + \Delta G^0_{TS} \qquad \text{(b)}$$

$$-\Delta G^0_{TS} = \Delta G^{\ddagger}_{cat} - (\Delta G^{\ddagger}_{uncat} + \Delta G^0_{ES}) \qquad \text{(c)}$$

will use this parameter in the later stages of this review to compare the efficiencies of different sorts of enzyme mimics (see Tables 4 and 5). Note, also in the simplest case, that in terms of rate and equilibrium constants $k_{cat}/k_{uncat} = K_M/K_{TS}$; in other words, the rate acceleration due to transition state binding is given by the stronger binding of the transition state compared with the ground state.

2.2. Passive Versus Dynamic Binding

It is helpful for the analysis to distinguish two sorts of binding relevant to transition states: *passive binding*, referring to ordinary molecular recognition through hydrogen bonding, hydrophobic interactions, and the like, and *dynamic binding*. Dynamic binding refers to interactions between catalyst and substrate *at the reaction center*. These interactions are of crucial importance

Anthony John Kirby was born in Welwyn Garden City (UK), on the railway line between Cambridge and London (which he has been able to use ever since). He graduated and received his Ph.D. from the University of Cambridge in 1962, then spent a decisive postdoctoral year (1963–1964) with William P. Jencks at Brandeis University, Waltham, MA (USA), where he learned the value of a systematic approach to the problems of bioorganic mechanism. Since 1964 he has been at the University Chemical Laboratory in Cambridge, where he is currently Professor of Bioorganic Chemistry. His research interests focus on enzymes and chemical descriptions of their catalytic activity.

for catalysis, because they are the most obvious difference between the binding of the substrate and that of the transition state. They differ from the interactions involved in passive binding, because they change substantially as bonds are made and broken, and because they are generally stronger than the interactions involved in ordinary molecular recognition.

Before we discuss dynamic binding any further it should be stressed that there is no clear-cut distinction between the two sorts of binding. A real example will illustrate the point (Fig. 2). Fersht and his co-workers used site-directed mutagenesis in a series of elegant experiments to identify the amino acid side

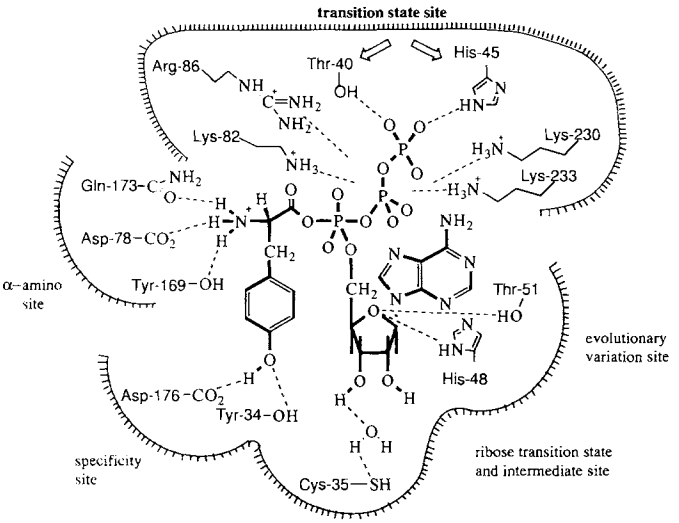

Fig. 2. Binding interactions of the transition state in the tyrosyl tRNA synthetase reaction [11]. The substrate is in bold. I am grateful to Alan Fersht for this updated version.

chains involved in binding and catalysis in the tyrosyl *t*RNA synthetase reaction.[11] Several amino acids identified as involved in binding in the transition state but not in the enzyme–substrate complex (e.g. Thr40 and His45) are clearly not interacting directly with the reaction center. They act primarily to position the terminal phosphate of ATP, helping to set up the favorable geometry for the reaction at the α-phosphate center, but they are not involved directly in bond making or breaking. The actual binding at these sites is thus more passive than dynamic. For purposes of the analysis we use the simple definition of dynamic binding given above, as referring specifically to interactions at the reaction center between catalyst and transition state.

To illustrate dynamic binding we take the familiar reaction catalyzed by a serine protease such as chymotrypsin (Fig. 3a),[1] in which a general base **B** (the imidazole of His57 in the case of α-chymotrypsin) assists the attack of a nucleophilic OH group (of Ser195) at the carbonyl carbon center of the amide substrate. A backbone amide NH group provides further assistance, acting in effect as a general acid (**HA**). (Because it is familiar the process looks easy, but amide cleavage is one of the most daunting challenges for man-made catalysts, and so far we are not even close.) In the transition state for this step (Fig. 3b) at least six bonds are being made and broken, probably simultaneously, and it is not obvious where transition state binding starts and

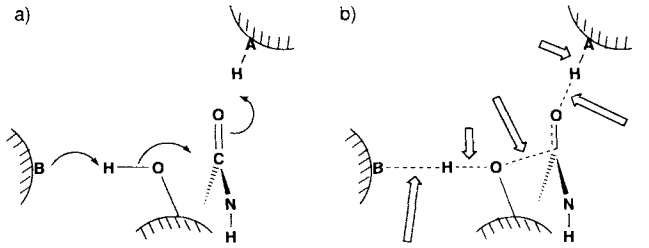

Fig. 3. a) Schematic representation of the mechanism of the first step, an acylation, in a serine protease reaction. For clarity only the amide group of the substrate is shown. b) The transition state for the reaction in (a). The arrows indicate bonds being formed and broken, corresponding to dynamic binding interactions between the enzyme and the transition state.

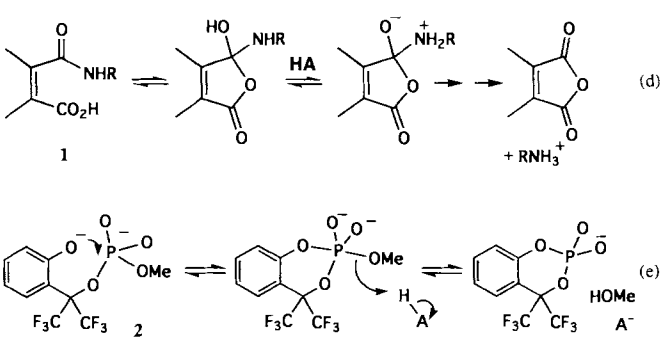
finishes, since in this case the nucleophile is part of the enzyme. But the details are unimportant: the important point is that the "binding" of the transition state by the enzyme involves more than ordinary molecular recognition. These *dynamic* interactions at the reaction center involve partially formed or broken covalent bonds (marked by arrows in Fig. 3b). These interactions, this "dynamic binding," can be substantially stronger than the individual interactions involved in ordinary molecular recognition, and so can make a major contribution to catalytic efficiency. We need to know how strong these interactions can be and understand the factors that can make them so strong in the enzyme situation. This information is most easily obtained from model systems.

3. Enzyme Models

3.1. Intramolecular Reactions

The only simple reactions that can rival their enzyme-catalyzed counterparts in rate are intramolecular reactions such as cyclizations, and specifically intramolecular nucleophilic reactions. Making the reaction of interest part of a thermodynamically favorable cyclization can produce systems in which the extraordinarily stable groups of structural biology (amides, glycosides, and phosphate esters typically have half-lives of many tens of years under physiological conditions near pH 7) can be cleaved in seconds or less. An early example is the cyclization of **1**, in which an ordinary aliphatic amide is forced into close proximity with a COOH group[12] [Eq. (d)]. A more recent case, which models enzyme reactions in which the OH group of a tyrosine side chain acts as a nucleophile, is the cyclization of phosphate diester **2**, which reacts in this case as the anion[13] [Eq. (e)].

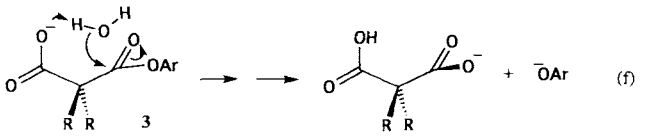


The efficiency of intramolecular catalysis[14] is conveniently measured in terms of the effective molarity (EM) of the catalytic group.[15] The EM is the ratio of the first-order rate constant for the intramolecular reaction and the second-order rate constant for the intermolecular reaction that proceeds by the same mechanism under the same conditions. The EM has the dimensions of molarity and is easy to understand as the nominal concentration of the catalytic group that would be required in the equivalent intermolecular process to match the rate of the intramolecular reaction. (In the examples cited, which have EMs greater than 10^{10} M, this is *purely* nominal.) EMs can tell us how catalytic efficiency relates to structure in systems designed to bring functional groups together in close proximity, just as the same functional groups are brought together in an enzyme–substrate complex.

Two generalizations are of major importance:

1. Catalysis can be highly efficient in cyclization reactions, which involve the formation of bonds between heavy (non-hydrogen) atoms. EMs of 10^8–10^9 M can be attained even in flexible systems,[16] and higher figures are possible in systems in which ground state strain is relieved as part of the reaction. The EM of the carboxyl group in the cyclization of **1**, for example, is over 10^{13} M.[12] (Enzymes cannot exert the sorts of very strong nonbonding interactions that can be built into synthesized structures like **1**, because proteins are fairly flexible. But studies of such rigid systems give us access to mechanistic information about the reactions of relevant functional groups proceeding at rates comparable to those of the corresponding enzyme-catalyzed processes.) There has been much discussion of the origins of the rate enhancements in these systems; at least a dozen theories have been proposed,[15] ranging from orbital steering to the spatiotemporal hypothesis.[17] Some of these provide useful guidance for system design, but the fundamental requirement for a high (kinetic) EM is a thermodynamically favorable cyclization with no stereoelectronic impediment to the reaction.[18]

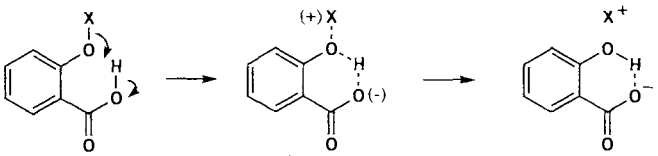
2. Intramolecular reactions involving rate-determining proton transfer, for example general acid and general base catalyzed reactions, are far less efficient, with EMs generally less than about 10 M.[15] For instance, the EM of the carboxylate group in half-esters **3** of dialkylmalonic acids, which are hydrolyzed by general base catalysis because cyclization is strongly disfavored, ranges from less than 1 M up to 60 M[19] [Eq. (f)].



(f)

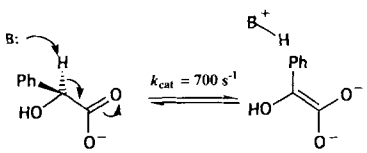
Though the highest EM measured for intramolecular general base catalysis, 60 M is tiny compared with figures easily attained in nucleophilic reactions. For several years this dichotomy presented a serious problem, since proton transfer is the most common enzyme-catalyzed reaction. It is scarcely possible to carry out an ionic reaction in water without involving a proton transfer at some point. The model reactions with **1** and **2** make the point. They are fast because the nucleophilic reaction is very favorable, but in both cases the rate is now limited by a proton transfer step; a general acid is required to take the reaction forward from the high-energy intermediate. Note that though the rate constant for proton transfer is very high, the *rate* of a particular step depends also on the concentration of the reactant, and the concentration of a high-energy intermediate is by definition very low. Even intrinsically very fast reactions can thus be rate determining under these circumstances.

There is no doubt that enzymes catalyze proton transfers efficiently. Thus the reasonable conclusion is that the models, not the enzymes, are deficient. Recent work suggests a solution. Efficient intramolecular proton transfer reactions (EMs up to at least 10^6 M) are found to be possible in systems specially designed to form strong intramolecular hydrogen bonds. In the best known case, which provided the initial clue, derivatives **4** of salicylic acid—acetals, phosphates, even ethers—lose a stable "electrofuge" X^+ in a reaction involving protonation of the X-substituted oxygen atom and formation of the salicylate monoanion. Anion **5** is stabilized by over 20 kJ mol^{-1} in water



by the intramolecular hydrogen bond, and so too is transition state **4**‡. Since hydrogen bonding is much weaker in the starting material, this amounts to selective stabilization of the transition state. The result is an exceptionally rapid reaction, corresponding to an effective molarity of up to 10^4 M for the COOH group.

This provides a general basis for efficient proton transfer catalysis, and several new efficient systems have been devised recently.[20] Perhaps most interesting is the extension to reactions involving proton transfer to and from carbon atoms. Enolizations, for example, are key steps in enzyme-catalyzed aldol condensations. Proton transfer to and from carbon centers is known to be intrinsically slow, and in enzyme reactions efficient catalysis is needed here more than for proton transfers to O and N centers, which are already reasonably fast (usually diffusion-controlled in the thermodynamically favorable direction). Efficient catalysis is clearly available, as shown by the example of mandelate racemase,[21] which removes a proton from the α-carbon of the mandelate anion [Eq. (g)]. Gerlt and Gassman[22]

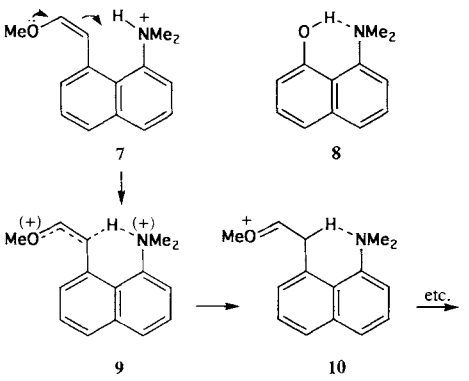


(g)

have proposed that the enolate intermediate, and the transition state leading to it, are stabilized by "short strong hydrogen bonds" to the negatively charged oxygen. These have the effect of increasing the effective acidity of the proton to be removed, which otherwise would be very weakly acidic, with $pK_a > 25$.

This idea is consistent with the effects of the strong (and so by definition short) intramolecular hydrogen bonds identified

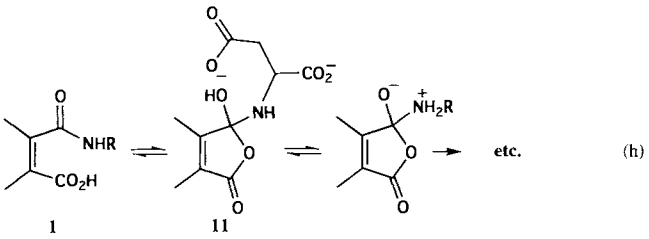
above as the source of high effective molarities in general acid or base catalysis. Furthermore, recent work on enol ethers suggests that even C–H protons can become acidic enough to become involved in strong hydrogen bonding in enolization reactions. Thus enol ether **7** is based on compound **8**, which is known to



be stabilized by a strong intramolecular hydrogen bond ($pK_a(OH) = 14.9$). The effective molarity of the dimethylammonium group in the reaction of **7** (half-life 10 s at 39 °C) is of the order of 10^6 M (the figure is approximate since the corresponding intermolecular reaction is too slow to measure) and is consistent with very effective selective stabilization of the transition state.[23] This is ascribed to the strong intramolecular hydrogen bonding indicated in transition state **9**. C–H protons are normally too weakly acidic to be involved in hydrogen bonds in aqueous solution, but a simple calculation shows that the C–H proton in the intermediate **10** is in fact strongly acidic (at least as strong as H_3O^+!) and expected to be stabilized by hydrogen bonding to an available basic center.

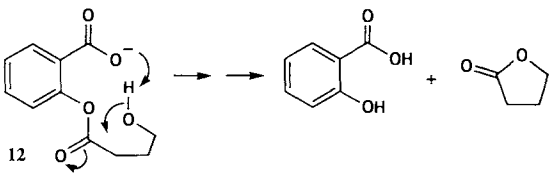
The structural requirements for hydrogen bonding of this sort strong enough to be significant in water—are very precise, which is why relevant systems are only now being identified. Such precision is, however, no problem in enzyme–substrate interactions, where precise group–group interactions in three dimensions may be presumed to be the norm. We conclude that the key requirement for efficient proton transfer catalysis is dynamic binding of the proton during transfer in a strong transition state hydrogen bond. Note that this may very well be stronger than the corresponding hydrogen bond in either starting material or product: hydrogen bonds are primarily electrostatic and the charge distribution around the central proton changes continuously as bond making or breaking proceeds. It is not easy to estimate just how strong such dynamic binding might be at this stage in the work, but the evidence from the systems so far available suggests figures of at least 30–40 kJ mol^{-1} in water.

To maintain high catalytic efficiency enzymes must provide catalysis for each individual step of a reaction, and not just the rate-determining step. The majority of enzyme models, on the other hand, are designed simply to catalyze the slowest chemical step; however, models are known in which two different intramolecular groups catalyze separate steps of the same reaction. The proton transfer involved in the hydrolysis of the amide group of **1**, for example, is catalyzed by a second carboxyl group, as in the β-amino acid derivative **11**, efficiently enough that the proton transfer step is no longer rate determining[24] [Eq. (h)].



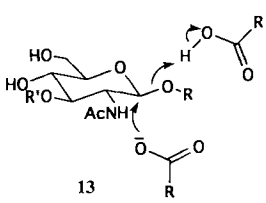
(h)

Reactions involving the concerted action of two catalytic groups on the same step of a reaction are more elusive—and more interesting. A simple example is the lactonization of the aspirin analogue **12**, for which the EM of the carboxylate and hydroxyl groups are the same as for the hydrolysis of aspirin and the lactonization of 4-hydroxybutyric acid (13 and 500 M, respectively).[25] Here a two-step mechanism with separate proton transfer and bond-forming steps is possible, but the concerted process is preferred [Eq. (i)].



(i)

This, like most known examples, involves an activated system with a good (phenolic) leaving group. Enzymes, on the other hand, and thus also the most interesting potential artificial enzymes, must deal with unactivated systems and often have to displace poor leaving groups (e.g. the OH groups of aliphatic alcohols and sugars). Of special current interest is the possibility of synergy, or cooperativity in concerted reactions of such systems. The idea arises naturally when one considers reactions like glycoside cleavage. Glycosidases like lysozyme catalyze this chemically very difficult reaction (at pH 7) by way of a mechanism involving two carboxyl groups, one in the COOH and one in the COO^- form. Since a glycosyl carbenium ion is probably too unstable to exist in the presence of a nucleophile, a simple S_N1 process looks unlikely. A double displacement mechanism (with the initial displacement by carboxylate, acting as a nucleophilic catalyst) would explain the observed retention of configuration at C1 of the glycosyl residue,[26] and is known to be involved in some cases. The problem is explaining the high rate of this normally very difficult process. A possible solution is that nucleophilic attack and general acid catalysis of the departure of the leaving group act efficiently in concert, as in structure **13**. We know that both general acid and nucleophilic catalysis can be efficient if the leaving group is good enough. The question is: can efficient nucleophilic catalysis make a poor leaving group good



enough *in the transition state* to support efficient general acid catalysis? And, can efficient general acid catalysis make the leaving group good enough to trigger even more efficient nucleophilic catalysis? If the answer to both questions is yes, the result will be a group transfer reaction more efficient than the sum of the parts.[27]

3.2. Passive Binding and Molecular Recognition

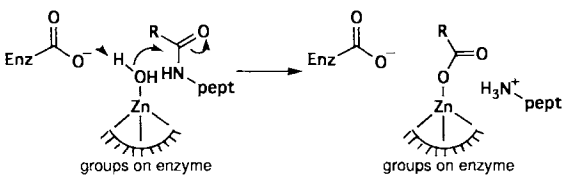
It is, at least in principle, simple enough to design a system with two groups on the same molecule in a desired geometrical relationship. But enzymes must first recognize and bind their substrate(s) to set up the correct geometry. The binding process is a major problem in the development of artificial enzymes.

The principles involved in binding are well understood from work on small-molecule systems. To understand the interplay between binding and reactivity it is convenient to recognize three important classes of association. In order of decreasing strength these are covalent, weak covalent (primarily hydrogen bonding), and noncovalent (hydrophobic and electrostatic).

3.2.1. Covalent Binding

The strongest single interaction possible between two molecules is of course the formation of a covalent bond, and acyl, glycosyl, and phosphoryl intermediates, for example, are often involved in enzyme-catalyzed group transfer reactions. Reactions with other active site functional groups then become intramolecular, with close control of geometry, and we have seen that intramolecular catalysis can be highly efficient. However, true catalysis is only possible if the formation of the covalent bond is readily reversible; otherwise the catalytic cycle is not complete.

Reversible formation of covalent bonds is particularly important in enzyme reactions involving active site metal cations. The suggested mechanism for the reaction of metalloproteinase carboxypeptidase A (Scheme 1) is an example. At the end of the

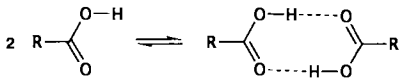


Scheme 1. Proposed mechanism for the reaction of the metalloprotease carboxypeptidase A. Enz = enzyme, Pept = peptide chain.

process the $RCOO^-$ group cleaved from the N-terminus of the peptide diffuses away from the metal and is replaced by an new water molecule from the solvent; the catalytic cycle can then start anew. The metal in this mechanism helps to solve two problems. Hydrolytic enzymes must use water as a nucleophile at some stage, but binding and positioning such a small molecule presents a problem. This is neatly resolved by attaching water as a ligand to the active site metal, which in turn increases the chemical reactivity of the water molecule, because the pK_a of bound H_2O is reduced. The reactivity of the water molecule can also be fine-tuned because it now depends not only on the metal concerned but also on the number, type, and arrangement of the other ligands. We will not discuss metal ion catalysis explicitly in this review; interested readers are referred to a book on the subject.[28] But the study of metal ion catalysis clearly has a great deal to offer in the design of enzyme mimics.

3.2.2. Hydrogen Bonding

A hydrogen bond is much weaker than a covalent bond, although it retains definite directional preferences.[29] The strength of a single hydrogen bond is very sensitive to its environment and is typically of the order of 5–20 kJ mol^{-1}—too weak to support significant association at room temperature. Multiple H-bonding can lead to observable, but strongly medium-dependent association, as shown by the equilibrium constants K_{ass} for the formation of the familiar carboxylic acid dimer **14** [Eq. (j)]. Carboxylic acids almost always crystallize in

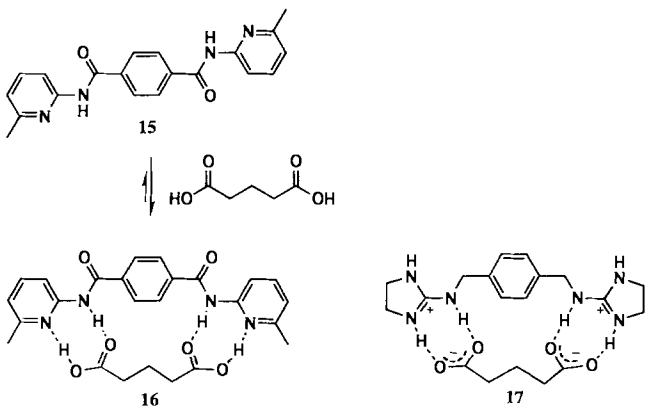


(j)

14

the dimeric form, and dimers also form in solution in chloroform (K_{ass} = 4000 M^{-1}). But in water K_{ass} is only 0.1 M^{-1}: each proton and lone pair of the monomer is strongly solvated by hydrogen bonding to water molecules and dimerization is suppressed. Of course any sort of association in solution is in direct competition with solvation, and water is very good at solvating ions and H-bond donors and acceptors. Thus multiple H-bonding is the basis of protein secondary structures like the α-helix, but isolated α-helices are only marginally stable in water,[30] and the stability of protein structures depends on additional, noncovalent interactions. A simple illustration comes from the work of Hamilton et al. on H-bonding receptors for dicarboxylic acids.[31]

The diamide **15** binds glutaric acid strongly in chloroform (K_{ass} = 60 000 M^{-1}) but not in dimethyl sulfoxide (DMSO).[31] However, the bisguanidinium system **17**, which has the same number of hydrogen bonds, is almost as good a receptor (K_{ass} = 50 000 M^{-1}) in DMSO containing 5% tetrahydrofuran, and binding is still measurable in the presence of 25% D_2O.[32] The main difference is that the strongly basic guanidine group is protonated by COOH, so hydrogen bonding is reinforced by electrostatic attraction.

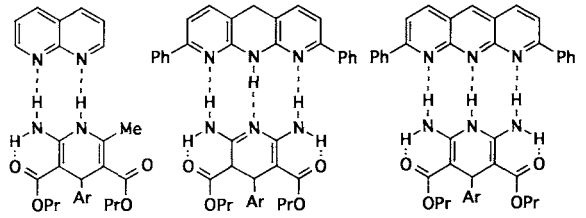


15

16

17

The strength of multiple H-bonding interactions is also subject to more subtle influences, as shown by the big difference between the two apparently similar triply H-bonded systems shown in Scheme 2.[33] These differ in the sequence of H-bond



Scheme 2. Systems held together by multiple hydrogen bonds with different sequences of the H-bond acceptors (**A**) and donors (**D**).

acceptor (**A**) and donor (**D**) groups. Remarkably the binding of all-acceptor to all-donor systems is so strongly preferred that the third hydrogen bond does not increase K_{ass} at all if it is introduced in the wrong place. Clearly multiple hydrogen bonding includes an element of specificity and provides the possibility of strong, geometrically defined association.

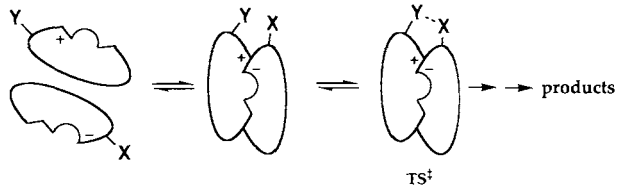
3.2.3. *Noncovalent Interactions*

Electrostatic[34] and hydrophobic interactions[35] play essential, complementary[36] roles in determining the three-dimensional structures of proteins,[30] and of protein–ligand complexes in general. Their roles in host–guest interactions have been extensively documented. However, the forces involved are not intrinsically strongly directional, and they can be used to set up specific geometries only in combination. This problem may have been underestimated, partly because it is avoided in the cyclodextrins, which are perhaps the most studied models for hydrophobic binding.[37] In some cases cyclodextrins are rather effective as enzyme mimics (see Section 4.1), partly because they carry large numbers of hydroxyl groups in all directions around the cavity. Consequently, a bound substrate does not have to assume a specific orientation for proximity to a OH group.

It should be clear, even from this brief summary, why enzymes use an array of complementary noncovalent binding interactions to bring their substrate into productive association with the catalytic apparatus of the active site. However, defining the structure of the enzyme–substrate complex—as can be done with some confidence when good three-dimensional structures of complexes with substrate analogues are available—does not necessarily tell us more about the reaction than the structure of the starting materials.

3.3. The Strength of Dynamic Binding

The key transformation of the enzyme–substrate complex into the enzyme–transition state complex (see Fig. 1) is conveniently described by Scheme 3. The binding process first brings



Scheme 3. Formation of an enzyme–substrate complex and its conversion into the enzyme–transition state complex. **TS*** = transition state.

the functional groups X and Y into close enough proximity for reaction to be favored. This process may include some activation of the ground state, for example by binding in a reactive conformation.[16] It will certainly include desolvation of reacting polar groups. Any polar functional group is strongly solvated, and thus stabilized, in water. (One way of looking at the selective stabilization of the transition state is in terms of specific "solvation" of the reactants by the enzyme active site, which replaces the random solvation by the solvent.) The subsequent formation of the transition state **TS*** involves partial bond formation between X and Y. The driving force for bond formation comes partly from the intrinsic chemical reactivity of the groups concerned and partly from the way the groups are brought together; it is this second factor that controls efficiency.

The clear message from the work on intramolecular reactions is that a prerequisite for efficient catalysis is a stable platform. Table 1 shows how tighter binding of the reacting groups in a

Table 1. Strength of dynamic binding based on effective molarities for intramolecular cyclizations.

	EM [M]	$\Delta\Delta G^*$ [kJ mol^{-1}]
	1	0
	220	13
	5×10^4	27
	3×10^9	54
	4×10^{12}	(73)

simple cyclization reaction leads to higher effective molarities. This treatment allows for the intrinsic chemical reactivity of the reacting groups. When expressed as free energy differences, the EMs give a measure of the strength of dynamic binding in each system. (The comparison is with the corresponding intermolecular process in the presence of 1 M acetate; thus $\Delta\Delta G^*$ is a conservative estimate for a reaction under physiological conditions, where concentrations are much lower.) Simply bringing the reacting groups together on the same molecule makes productive encounters more probable, but the most efficient systems are those in which multivalent bonding eliminates conformational flexibility and a transition state-like geometry is prescribed. This

sort of information has been available for many years for cyclization reactions, but recent work on the efficiency of intramolecular proton transfer reactions reveals a similar pattern. Table 2 shows data for a series of acetal hydrolysis reactions for which intramolecular general acid catalysis is particularly efficient. (Note that for the great majority of general acid or base catalyzed reactions the EMs are of the order of 1 M or less ($\Delta\Delta G^{\neq} \leq 10\,kJ\,mol^{-1}$) and show no strong dependence on structure.)

Table 2. Strength of dynamic binding for intramolecular proton transfer.

	$\Delta\Delta G^{\neq}$ [kJ mol^{-1}]
	0
	10
	28
	ca. 36

In Table 2 the comparison with the spontaneous hydrolysis reaction gives a quantitative idea of the effectiveness of an external general acid and is a common way of measuring k_{cat}/k_{uncat}. The intrinsic chemical reactivity of the catalytic group depends most strongly on the bond being formed, so varies most for nucleophilic reactions, which are generally the most efficient intramolecular reactions. For example, the $\Delta\Delta G^{\neq}$ parameter for nucleophilic catalysis (Table 1) can be compared with that for the hydrolysis of *p*-nitrophenyl acetate at 25 °C.[38] The strength of dynamic binding is only about 5 kJ mol^{-1} for acetate, which has to displace a more basic leaving group, but rises to 36 kJ mol^{-1} for imidazole and to 47 kJ mol^{-1} for the reaction with the thiolate group of mercapto acetate. So the most efficient intramolecular general acid group of Table 2 is still less efficient than the best intermolecular nucleophiles. The efficient systems in Table 2 all depend on the formation of a strong intramolecular hydrogen bond in the initial product, and, as discussed in Section 3.1, this gives an indication of the potential strength of the binding of the transferred proton in the transition state. The most efficient system in Table 2 (last entry) is hydrolyzed 16 times faster than the corresponding acetal of salicylic acid. The naphthylamine system **7** discussed in Section 3.1 is probably more efficient still in terms of EM.

3.4. Cooperativity in Binding and Catalysis

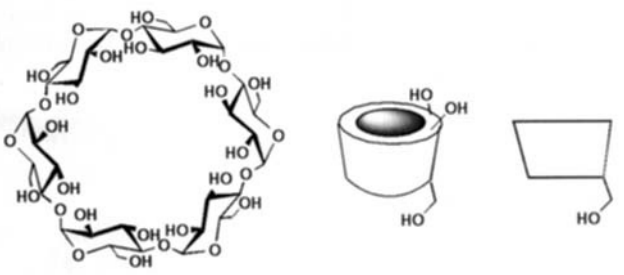
The simple general conclusions that emerge from work on models are that efficient catalysis depends on tight binding, and that the geometrical requirements are particularly stringent for proton transfer catalysis. The effect can be regarded as an extension to transition states of a familiar phenomenon, which appears as high equilibrium constants (thermodynamic EMs) for certain cyclization reactions,[15] as the chelate effect on the stability of metal complexes,[39] and as cooperativity in binding processes.[30] The stronger the binding interaction between two systems, the stronger a given additional interaction can be, for example between the groups X and Y in Scheme 3; this applies to dynamic as well as to passive binding. Furthermore the effect can be reciprocated—the development of bonding between X and Y can strengthen the original binding interaction. We will go on to discuss some of the most interesting enzyme mimics in the light of these ideas.

4. Enzyme Mimics

Enzyme mimics catalyze reactions by mechanisms that are demonstrably enzyme-like. The minimum requirement is that the reactions concerned should involve an initial binding interaction between the substrate and the catalyst. This gives rise to Michaelis–Menten kinetics, and reactivity is measured in terms of the familiar parameters k_{cat} and K_m. Since these systems are relatively simple, we can discuss the binding of the transition state in terms of Figure 1 (Section 2) and **E** can denote either enzyme or enzyme mimic. The key parameter for discussion is ΔG^0_{TS} [Eqs. (b), (c)]. Further details of the treatment can be found in the excellent review by Tee.[40] ΔG^0_{TS} is the difference in energy between the transition state for the catalyzed reaction and that for the reaction in water (or other aqueous mixed solvent). Since this takes no account of the intrinsic reactivity of the catalytic group,[41] the effective molarity of the catalytic group, which makes this allowance and is a more specific measure of the efficiency of the system at bringing groups together, is also quoted where the data are available and the mechanism is known.

4.1. Catalysis by Cyclodextrins

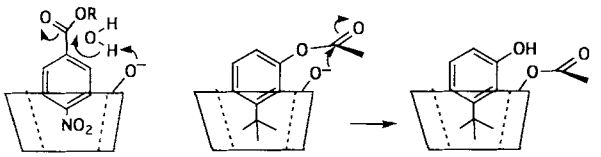
Cyclodextrins—familiar, readily available, stable, water-soluble cyclic oligomers of α-D-glucose—have proved the most enduringly popular enzyme mimics (Section 3.2.3). Their central hydrophobic cavity is lined with CH groups and glycosidic oxygen atoms, and carries arrays of functional hydroxyl groups on both rims. The full structural formula (e.g. **18** for α-cyclodextrin) is usually represented in simplified form (e.g. **19**), often showing only the single functional group of interest, as in **20**



18 **19** **20**

(which like **19** does not specify the oligomer). The torus is slightly more open on the side of the secondary OH groups. This, plus some steric hindrance by the primary 6'-CH_2OH groups on the other face, makes this face more accessible to hydrophobic guests, which can bind in the cavity if they are of the right size.[37]

The unmodified cyclodextrins are themselves good functional enzyme mimics, catalyzing various relatively rapid reactions, like the hydrolysis of nitrophenyl esters, in reactions that show Michaelis–Menten kinetics. The mechanism typically involves nucleophilic attack by the secondary OH groups, which have pK_a values of 12–12.5 and so are present in the reactive anionic form in higher concentration than hydroxide ion. This nucleophilic reaction is inefficient for *p*-substituted benzene derivatives because the ester group is bound near the central axis of the cavity, so that the reacting groups cannot come easily come into close proximity if binding is reasonably tight. In this situation general base catalysis can compete, and is the main route for the reactions of some 4-nitrobenzoate (pNB) esters (**21**, α-cyclodextrin).[42] Though relatively inefficient (EM per OH group < 0.1 M), this general base catalyzed reaction is true



21 **22** **23**

catalysis, at least by one criterion: the catalytic group is unchanged and immediately available for further reaction. The nucleophilic mechanism on the other hand, which is favored for aryl acetates with substituents in the *meta* position of the aromatic ring, gives the acylated cyclodextrin **23** as the initial product. The EM per OH group is less than 1 M even for the most efficient reaction of this sort (**22** → **23**) with *m-tert*-butylphenyl acetate.[37] The subsequent hydrolysis of this intermediate ester, which is usually less reactive than the original substrate, then becomes rate determining. The hydrophobic part of the product is also bound, so product inhibition is a problem. The problem is typically circumvented by using an excess of the cyclodextrin: thus the observed "catalysis" does not involve turnover.

The binding of the substrate is not very strong in these systems (K_{ass} is 295 and 500 M^{-1} for **21** and **23**, respectively, and typically less than 10^3 M^{-1}), so the most obvious way to improve efficiency is to improve binding. This can be done by modification of the cyclodextrin, but the synthesis required can be a major undertaking, and this approach has not produced large rate accelerations.[40] However, cyclodextrins of three sizes are available—α-, β-, and γ-cyclodextrins, with cavity diameters of about 5, 7, and 9 Å, respectively—and these show clear binding specificities. Thus *m-tert*-butylphenyl acetate binds more strongly to β-cyclodextrin, and transition state binding is also improved (Table 3). In fact Tee[40] has shown that a simple linear free relationship exists between substrate and transition state binding for the hydrolysis of series of similar esters, and that transition state binding is more sensitive (slope greater than unity) to structural change for these reactions. This is specific, quantitative evidence justifying the simple approach to improved design, which aims at improved substrate binding. The experimental results described below provide more, convincing evidence.

The easier way to improve binding (not available to enzymes!) is to modify the substrate. This approach is based on the principle that in these simple systems tighter binding should increase the EM of the catalytic hydroxyl groups as well as the passive binding of the substrate, and thus make possible the desired net increase in transition state binding. Most successful are systems based on adamantane and ferrocene, designed by Breslow to optimize fit in the hydrophobic cavity of β-cyclodextrin.[43–45] These systems are based on models of the transition state (tetrahedral carbonyl C atom) in nucleophilic attack by the OH groups of the cyclodextrin on the *p*-nitrophenyl ester group of the substrate; after the reaction the acyl group remains bound, rather than the leaving group. The adamantyl derivative **24** binds strongly but probably mostly unproductively, with the *p*-nitrophenyl ester group inside the cavity,[43] that is, the wrong way around. This is a common problem not unknown in reac-

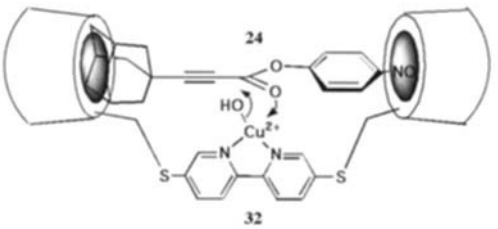
[a] At pH 8.6, 16 °C [42]. [b] The authors' figure, after several extrapolations, is about 5 M. [c] At pH 10.6, 25 °C [37]. [d] Measured at 30 °C in DMSO/water (60/40), because of low substrate solubility; pH ≈ 10 (pH ≈ 7 in water). [e] Approximate values, estimated from the original data; considered accurate within an order of magnitude. The figures are more accurate relative to each other. [f] **29** is a phosphodiester. Data measured at 25 °C at the pH-optimum of 6.3. [g] Compared with catalysis by *N*-methylimidazole under the same conditions.

tions of enzymes with synthetic substrates. With ferrocenyl derivatives this problem does not arise; the ferrocene nucleus fits snugly in the cavity of β-cyclodextrin (though this is not reflected in particularly strong "enzyme"–substrate binding). Varying the geometry of a rigidly attached side chain produced the series of esters **25**–**27**, which showed accelerations of 10^5 to 10^6 (Table 3).[43,44] The acceleration comes specifically from improved transition state binding. The relatively weak binding of the ground states of **25**–**27** indicates that dynamic binding—partial formation of a C–O bond—in the transition state reinforces the passive binding of the ferrocenyl unit within the cavity, as discussed in Section 3.4.

The effective molarities attained in the most efficient of these reactions are moderate compared with those available in efficient intramolecular reactions, and not high enough to support catalysis of the hydrolysis of unactivated (ethyl or methyl) esters, or amides near pH 7. To improve reactivity—though not necessarily efficiency—still further, cyclodextrins can be functionalized with groups more reactive at pH 7 than hydroxyl. Most interesting are the more specific enzyme mimics this strategy makes available. The functional groups may be those of coenzymes[45] or match those in the active site of a particular enzyme.[46] Breslow et al. has described β-cyclodextrins **28** carrying two imidazole groups, which may be arranged in three different ways on the rim of a β-cyclodextrin: on glucose units that are adjacent (**AB**), one apart (**AC**), or two apart (**AD**). The imidazole groups on the three isomers have different geometries of interaction with a bound substrate or transition state; if both groups in one isomer are involved in catalysis its efficiency will reflect the strength of dynamic binding. Both imidazoles appear to be involved in the hydrolysis of the (doubly activated) cyclic phosphodiester **29**; one is in the conjugate acid form, as indicated by pH optima near pH 7. The **AB** isomer is clearly the most efficient, by factors of about 4 and 6 and over **AC** and **AD**, respectively (which are themselves not much better than the monoimidazole derivative). A proton inventory study[47] suggests that the mechanism involves concerted general acid and general base catalysis, as sketched in structure **29**/**30**. This mechanism is likely to be involved in the reactions of ribonucleases, but has not been achieved previously in models.

Although catalysis is not particularly efficient (Table 3), the degree of organization implicit in the mechanism shown in **29**/**30** begins to approach that involved in enzyme reactions, and can in principle provide suggestive evidence about geometric preferences, which can be related to fundamental stereoelectronic effects. Thus the higher efficiency of the **AB** isomer of **28** in the hydrolysis of **29** is relevant to the stereoelectronic preferences for displacement at the phosphorus center of phosphodiesters.[48] In the same vein the bisimidazole derivatives **28** also catalyze the enolization of the ketone **31** (R = H), but in this case the **AD** isomer is most effective; this could imply stereoelectronic preferences for the proton transfer (though the reactivity is only about twice that of the monoimidazole-substituted cyclodextrin).[49] This work has recently been extended to the intramolecular aldolization of the related substrate **31** with R = $(CH_2)_4CHO$.[50]

An alternative approach to improved binding, which is normal in interactions between enzyme and substrate, and enzyme and transition state, is to introduce a second binding site. This has the further advantage of making available an improved degree of organization that allows specific provision for stereoelectronic preferences, and provides one of the most promising ways towards more efficient enzyme mimics. Breslow et al.,[51] amongst others,[52] have joined two β-cyclodextrins with various linkers and find that the binding of molecules with two hydrophobic groups is improved, as expected. When the linker includes a catalytic group this improved binding can be converted into catalysis.[53,54] Thus the Cu^{2+} complex **32** (M = Cu^{2+}) is an efficient catalyst for the hydrolysis of the



32

adamantanyl ester **24**. This reaction was a problem for the cyclodextrin monomer because the ester was bound the wrong way round (see above).[52] Complex **32** binds both ends of **24**, the ester group is presented to the reactive Cu–OH unit, and the reaction is effectively intramolecular. In contrast to the reaction with free hydroxide, catalysis is most efficient near pH 7, because the pK_a of the bound water is 7.15. The overall process represents true catalysis: not only can the metal exchange the bound carboxylate for water (see Scheme 1), the bifunctional binding of the substrate is sufficiently stronger than that of the two halves produced on ester cleavage that they are released into solution fast enough for turnover to be observed.[52]

4.2. Synthetic Hosts

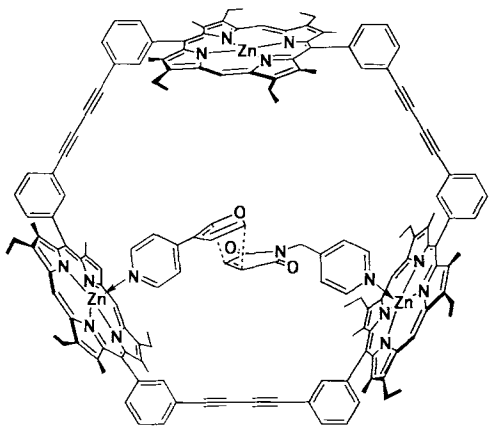
The challenge of understanding enzyme catalysis and the quest for artificial enzymes have been powerful driving forces for the rapid developments in host–guest chemistry, and in molecular recognition in general. These fields have been thoroughly reviewed. The discussion here is limited to a handful of particularly instructive, and occasionally successful, cases designed specifically as catalysts. These fall naturally into two classes: systems that bind mostly single substrates *and* react with them, and those, which we will discuss first, that bind two (or more) substrates which can *then* react with each other. (More sophisticated still as an enzyme mimic would be a system that binds two separate reactants and actively catalyzes the reaction between them; the reverse of a reaction like the hydrolysis of **24** catalyzed by **32** above would make a good target.)

4.2.1. Synthetic Hosts as Matchmakers

One function of enzymes that can be achieved rather successfully in models is the binding, and thus bringing together of two reactants in the active site. To get them to react together is more difficult, but model builders have reported some notable successes. Nevertheless, to achieve catalysis with turnover remains a major problem. Its origin is the same effect that *permits* turnover in the cleavage of **24** catalyzed by **32**. A simple system that binds the transition state better than the ground state is likely to bind the product at least as well, and the formation of a bond—or a partial bond—between two bound reactants, other things being equal, inevitably strengthens the binding interaction with the host.

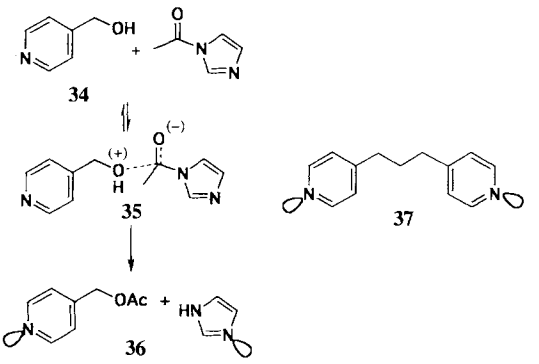
β-Cyclodextrin can accommodate small diene–dienophile combinations, and thus transition states for Diels–Alder reactions.[55] Catalysis is not very efficient compared with the already accelerated reaction in water, reflecting relatively weak substrate binding. A synthetic model with much improved binding is the (substrate-free) porphyrin trimer **33** described by Sanders et al.[56] This host binds symmetrical di- and tripyridyl systems very strongly, and substituted monomeric pyridines well enough to accelerate the Diels–Alder reaction between suitable guests when they are bound inside the cavity. The binding controls the stereochemistry of the reaction (shown in **33**) well enough to reverse the normal kinetic selectivity, so that the *exo* adduct is produced up to 1000 times faster than the corresponding *endo* isomer (which is the kinetic product in the absence of the macrocycle). This acceleration corresponds to a reasonable EM of about 20 M, but the system is not catalytic because of product inhibition.

The porphyrin trimer host in **33** similarly catalyzes the acetylation of 4-hydroxymethylpyridine (**34**) by acetylimidazole.[57]



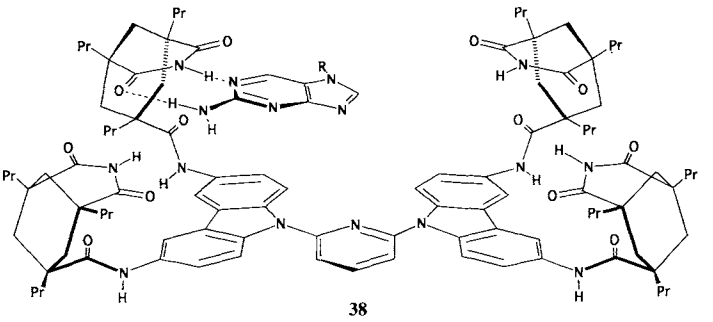
33

Here the two reactants are bound as before, but now the extra bond is present only in the transition state **35** (and the related tetrahedral intermediate). The two products (**36**) are thus not strongly bound, and turnover is possible. Catalysis is not highly efficient; the EM is estimated at 2 M, and the turnover per trimer is about 25 per week (in toluene at 70 °C[58]). But the potential for selective binding of the transition state is illustrated by the strong binding of the dipyridyl **37**, which acts as a competitive inhibitor of the acyl transfer reaction. (K_{ass}(**37**) = 2.3×10^7 M^{-1}; for comparison: K_{ass}(pyridine) = 1.8×10^3 M^{-1}, K_{ass}(*N*-acetylimidazole) = 360 M^{-1}. These values are similar to those in Table 3 obtained for binding to cyclodextrins.) Presumably neither the geometry nor the charge distribution in transition state **35** matches the preferences of the cavity as well as **37**.



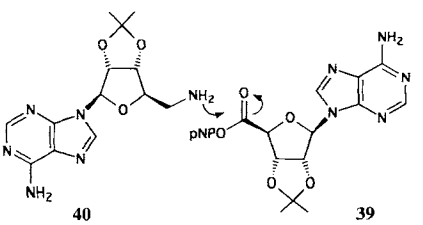
34 **35** **36** **37**

Similar problems arise with Rebek's host **38**, designed to catalyze the aminolysis of the (highly reactive) *p*-nitrophenyl ester



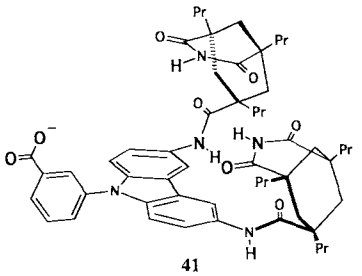
38

39 by 5-aminoadenosine (**40**).[59] **38** and systems like it bind adenine derivatives[60] as shown, with K_{ass} up to 10^6 M^{-1} in chloroform, by a combination of hydrogen bonding to the Kemp triacid imide and dispersion interactions between the aromatic systems (stacking interactions), which would be strengthened in a water-soluble version. The dimeric system **38** (with various central spacers providing a range of convergent binding sites) is designed to bring together two adenine derivatives. **38** is the most effective catalyst of the series in promoting the reaction of **39** with **40**, achieving a 160-fold acceleration (k_{cat}/k_{uncat} at 25 °C in chloroform containing an excess of triethylamine). However, the observed acceleration applies only to the initial stages of the reaction. The amide product, with two adenine groups now covalently attached to each other, binds more strongly than the reactants, thus inhibiting the later stages of the



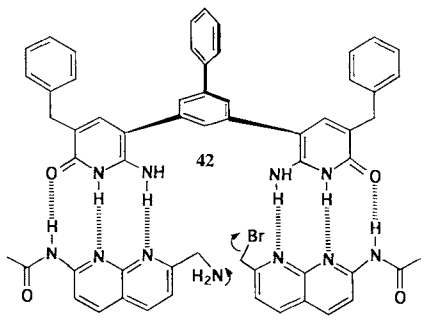
40 **39**

reaction and precluding turnover.[61] Even this fastest reaction is relatively inefficient, with an estimated effective molarity of 35 mM, and it seems evident that the reactants are not bound predominantly in the optimal geometry for reaction.[62] In more recent work on the simple *n*-butylaminolysis of **39** in the presence of a series of functionalized monomeric hosts, an acceleration of up to 100-fold is obtained for the benzoate derivative **41**.[61] The carboxylate group of **41** is evidently better than triethylamine alone in replacing the second molecule of amine involved in intermolecular aminolysis reactions in non-hydroxylic solvents.



41

One of the biggest challenges in this area is to devise catalysts for the S_N2 reaction, which is known to have strict stereoelectronic requirements for a linear transition state. Since, by definition, a new bond is formed between two reactants, problems with product inhibition are virtually certain. Host **42** was designed by Kelly et al. as a template for reactants that can form three hydrogen bonds to each aminopyridone system.[63] The reactants were the aminomethyl- and bromomethylnaphthyridine derivatives **43** and **44**, respectively,



43 **44**

which bind strongly ($K_{ass} > 10^4\ M^{-1}$) to the aminopyridone structure (and turned out to have the advantage that the product ammonium ion precipitated from solution). However, the rate acceleration observed was only sixfold, and turnover could not be demonstrated. This disappointing result points up a number of problems. A minor one is that the two binding sites are identical, allowing nonproductive binding of two identical reactant molecules. Reactivity was indeed improved by the expected factor of 2 by changing one binding site. More fundamental is the conclusion that the host does not bind the transition state effectively, and that what is in effect a cyclization reaction is evidently not favored thermodynamically.

In one system enhanced transition state binding has been shown to provide a significant rate acceleration for an S_N2 reaction. Dougherty and his co-workers[64] have shown that the water-soluble host **45** binds positively charged hydrophobic guests particularly well. For example, K_{ass} for the *N*-methylquinolinium cation **46** is $1.4 \times 10^6\ M^{-1}$, but for the neutral but isosteric 4-methylquinoline it is some 100 times weaker. Macrocycle **45** also catalyzes the formation of **46** from bound quinoline [Eq. (k)]. The reaction with methyl iodide (which is not itself bound) is 80 times faster than in the absence of **45** (Table 4), and in water at pH 9 the transition state is bound almost as tightly as product **46**. Of particular interest is the observation that the transition state is in some cases bound more strongly than product, and this led to the discovery that dealkylation of a cationic aromatic guest can also be catalyzed. For the demethylation of the sulfonium compound **47** [Eq. (l)] in the presence of a modified host k_{cat}/k_{uncat} is 9.[64] Clearly binding does not depend simply on charge: possibly the higher polarizability of the transition state allows a better electronic match to the cavity of the host.

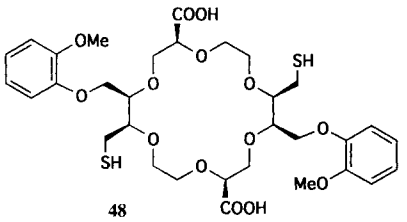
[a] Substrate-free host compound.

4.2.2. Synthetic Hosts with Built-In Functionality

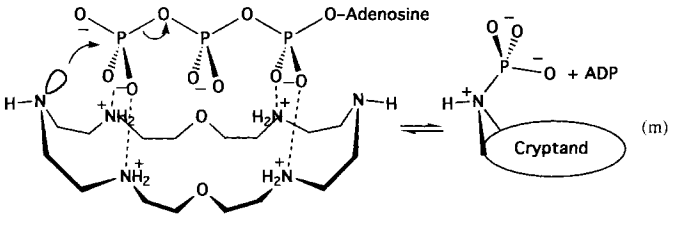
A rational approach to catalyst design is to optimize the binding arrangements for the substrate of interest, then add the catalytic functionality in the right place. In practice this is not so easy, because in the dynamic situation in solution guests often do not bind exclusively where the designer plans (or even suspects). But the approach has had some notable successes, based—as would be expected—on multiple host–guest binding interactions. Early attempts based on crown ethers and cryptands[65] often achieved significant rate accelerations, though not high efficiency or true catalysis, when a reactive nucleophile like thiolate was built in. Recent trends are typified by dithiol **48** devised by Koga et al.,[66] which is based on a simpler dithiol that can be used to synthesize peptide bonds.[67]



48

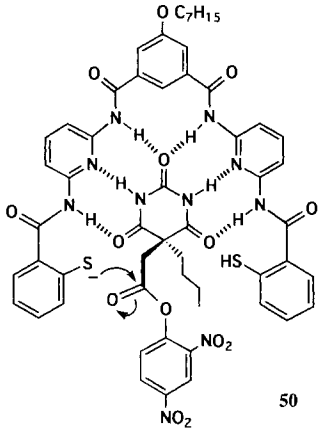
Early work, by Cram and Lehn in particular, had shown that crown ethers bind the ammonium group of amino acid derivatives, and that bound activated esters will acylate groups like SH attached to the crown. Loading **48** with first one then a second α-amino acid (as thioesters) allows (not very efficient) intramolecular aminolysis and the formation of the dipeptide, as the thioester. The COOH groups in **48** were added in the hope that they would catalyze the slow intramolecular aminolysis step. In fact they quenched it.

Perhaps the most elegant system of this sort is Lehn's cryptand **49**, which binds polyphosphate anions by a combination of electrostatic interactions and multiple hydrogen bonds. The cryptand is nucleophilic by virtue of the ring nitrogens, only four of which are protonated at pH 7, and can catalyze in vitro the key biological phosphate transfer reaction from ATP by way of an intermediate phosphoramidate [Eq. (m)].[68] The hydrolysis of ATP is catalyzed by this mechanism and accelerated by a factor of 500 at pH 7. This system remains one of the most efficient enzyme mimics (Table 4).



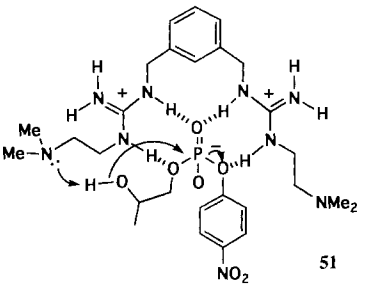
49 (m)

Alone, even multiple hydrogen bonding is not enough to bind a substrate in water, but H-bonding hosts with built-in functionality can work well in organic solvents. Hamilton et al. has added SH groups to his hydrogen-bonding receptors, which bind barbiturates in a well-defined orientation. The dithiol **50** binds and rapidly cleaves the 2,4-dinitrophenyl ester as shown ($k_{cat}/k_{uncat} > 10^4$, in CH_2Cl_2 at 25 °C) in the presence of 2,6-lutidine as a nonnucleophilic base.[69] This is not catalysis—the receptor is used in considerable excess and the product is its thioester—but the reaction is efficient, with an EM of 6760 M for the SH groups as nucleophiles. This is consistent with both the basic requirement for tight, properly orientated binding, and with the observation that SH groups attached by more flexible linkers are much less efficient.[69]



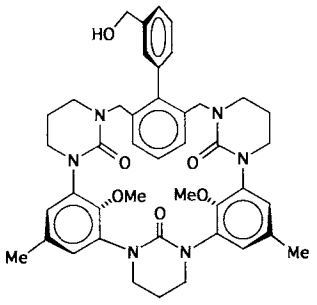
50

Similar principles were considered in the design of new enzyme mimics that facilitate phosphodiester cleavage. The most highly developed is the host compound in **51**, which binds phosphodiester anions with its two alkylguanidinium groups by hydrogen bonding reinforced by electrostatic attraction. This interaction mimics the well-established role of the alkylguanidinium group of arginine at the active sites of various nucleases. The model reaction is the intramolecular cyclization of *p*-nitrophenyl 2-hydroxypropyl phosphate. The phosphate group is doubly activated by virtue of the good leaving group and the intramolecular nucleophile (itself a model for the nucleophilic 2′-hydroxyl group of ribose in the ribonuclease reaction). The reaction requires a general base. The most effective of several tried[70] was the dimethylaminoethyl group shown in **51**, which improves the acceleration observed from 14- to 290-fold (in acetonitrile at 25 °C, in the absence of the built-in tertiary amino group but with added 2,6-lutidine). The EM for the dimethylamino group (correcting for the difference in pK_a between the catalytic group and lutidine using pK_a values in water and a β-value of 0.67[71]) is over 20 M, which would be unusually good for simple intramolecular general base catalysis by the dimethylaminoethyl group. But the monocations of ethylene diamines are known to be particularly effective catalysts for the cleavage of phosphodiesters, probably by a mechanism involving an electrostatic contribution to dynamic binding.[72]

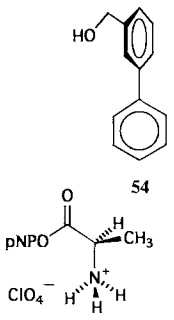


51

Perhaps the most highly developed synthetic hosts are Cram's spherands, based on three urea subunits linked by electron-rich anisyl rings. These hosts bind ammonium ions such as $Me_3CNH_3^+$ in a tripodal orientation to the three urea C=O groups, as shown by crystal structures of complexes. Binding can be very strong, with K_{ass} values up to 10^9 M^{-1},[73] and attaching a carefully placed hydroxyl group gave system **52**, which was a far better nucleophile towards the bound *p*-nitrophenyl ester of L-alanine **53** than the model compound **54** under the same conditions. (Adding an imidazole group in an attempt to generate a more faithful chymotrypsin mimic gave a more reactive system, but now the imidazole acted as a nucleophile rather



52



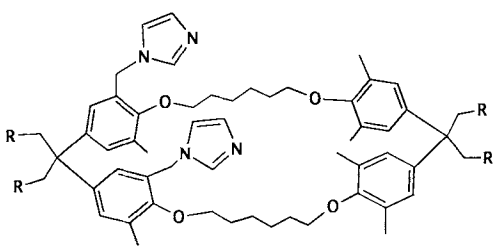
54

53

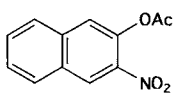
than a general base catalyst for the hydroxide reaction. This will always happen unless the reaction with the better nucleophile is prevented by the geometry of the system.) The rate accelerations observed in this work are impressive: under the given conditions $(k_{cat}/k_{uncat})K_{ass}$ is of the order of 10^{11} for the second-order reaction. (Here, too, **52** is not a true catalyst: it is used in excess and turnover is not possible because the reactive OH group is esterified in the reaction.) An effective molarity cannot be estimated, because the reaction within the complex involves the anion of the benzylic alcohol (pK_a unknown), whereas the comparison reaction with **54** was not detectable under the conditions ($CDCl_3$ containing 0.15% DMF, buffered with a tertiary amine and its salt). So the figure of 10^{11} comes from the low estimate of the upper limit for this reaction and the high value of K_{ass}. However—as Cram et al. make clear[74]—the very high rate acceleration does not mean that the system shows high absolute reactivity, for reasons already discussed.[58] To put the figures in perspective, the absolute rate of the reaction of the bound substrate **53** (k_{cat}) is reached for the alkaline hydrolysis in water of this reactive ester between pH 7 and 8.[75]

Diederich et al.[76] have reported work with phenol-capped cationic cyclophanes similar to macrocycle **55** with R,R = $-CH_2NEtCH_2-$, which are acylated by bound naphthyl acetates in predominantly aqueous solutions. At pH 8 the most effective system gives a ratio $(k_{cat}/k_{uncat})K_{ass}$ of about 6×10^5. This value is smaller than the figures attained by Cram et al. discussed above but reflects the somewhat higher k_{cat} values. (K_{ass}, at about 1500 M^{-1}, is much less favorable than that for the binding of amino acid esters by **52** in $CDCl_3$.) The phenolate anion serves as the nucleophile, and deacylation is fast enough at pH 8 and low host concentration for some turnover to be observed. The reaction in the presence of 10^{-5} M host is 20–30% faster than the background reaction.

As found by Cram et al., the nucleophilic hydroxyl group is not a great asset in these model systems, and the most effective catalyst of this sort, the anionic macrocycle **55** (R = COO^-), has two imidazoles in place of the phenol. Both binding and solubility are reduced, so that saturation kinetics are no longer observed. But the hydrolysis of **56** (in phosphate buffer, pH 8, with 25% DMSO) is now some ten times faster than the background rate for the hydrolysis of this ester,[77] corresponding to an EM of 1.3 M per imidazole.



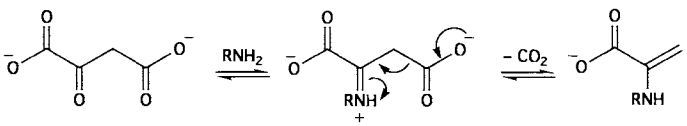
55



56

Diederich et al. have also attached the functional groups of coenzymes to their cationic cyclophanes to produce representative members of a major class of enzyme mimics of this sort.[78] For example, the thiazolium heterocycle of thiamine has been attached to cyclodextrins,[79] crown ethers,[80] and cyclophanes; flavin has been built in to a crown ether;[81] and pyridoxal, which was attached with long alkyl chains in a supramolecular assembly with a synthetic peptide–lipid bilayer containing histidine, has been shown to catalyze transamination.[82] These systems show accelerations ranging from a few percent to several hundred-fold, but the reactions are multistep and catalytic efficiency is not readily analyzed in detail.

A more specific use of synthetic peptides as catalysts has been reported by Benner and his group,[83] who based the design of a synthetic decarboxylase on the known properties of proteins and the mechanism of amine-catalyzed decarboxylation of β-keto acids. Their enzyme mimics are 14-residue peptides (oxaldie 1 and 2, Scheme 4) based on leucine and lysine. The amino acid



Oxaldie 1: H_2NLeuAlaLysLeuLeuLysAlaLeuAlaLysLeuLeuLysLysCONH$_2$

Scheme 4. Decarboxylation of oxaloacetate catalyzed by an enzyme mimic. R = lysine side chain.

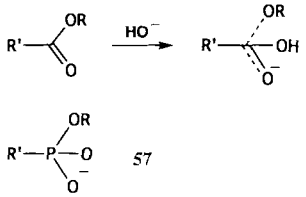
sequence is intended to favor α-helix formation, and thus the mimics are expected to exist in water in protein-like conformations, with a hydrophobic core and a hydrophilic exterior. They catalyze the decarboxylation of oxaloacetate by the expected mechanism shown; the cationic lysine side chains are presumably involved in binding the carboxylates of both the substrate and transition state (acetoacetate, with a single COO^- group, is not a substrate). Michaelis–Menten kinetics are observed and imine formation is 10^3 to 10^4 times faster than with simple amine catalysts. Activity does indeed seem to depend on the degree of α-helix formation. Given the relative ease of peptide synthesis, and current progress in our understanding of protein folding, we may expect to see renewed activity in the area of designed peptide catalysts.

4.3. Catalytic Antibodies

Catalytic antibodies (or abzymes)[84] are currently the most successful enzyme mimics, though they too fall far short of enzymes in terms of catalytic efficiency. They are proteins raised in a biological system specifically against transition state analogues (haptens) for the reaction of interest. Consequently, the problems of design and synthesis involve in principle only small molecules on a scale familiar to the organic chemist. Under the right conditions the immune system responds to the transition

state analogue by producing vast numbers of antibodies that recognize and bind to it—literally an exercise in the molecular recognition of transition states. The primary limitations are the accuracy of the hapten as a model for the transition state and the effectiveness of screening the large numbers of antibodies produced for catalysis. (Standard immunological methods screen very efficiently for *binding*.)

Though their specificity and potentially regio- and enantioselectivity are good, current catalytic antibodies are not much more efficient than other enzyme mimics. They are quite good at catalyzing easy reactions, like the hydrolysis of *p*-nitrophenyl esters, and have been reported to catalyze the hydrolysis of benzyl[85] and other alkyl esters,[86] but not that of ordinary amides at a useful rate.[87] Catalysis of the hydrolysis of activated esters is rather reliably obtained with suitable, usually phosphonate haptens (e.g. **57**), which model the structure of the tetrahedral transition states [Eq. (n)] involved. In this rather



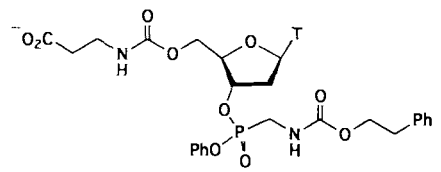
(n)

57

basic strategy the nucleophile comes from the solvent and the hapten is a rather approximate analogue as far as charge is concerned. For this reason more efficient catalysis should be possible when both reactants are recognized and bound, or when a nucleophilic group is located in the abzyme binding site.

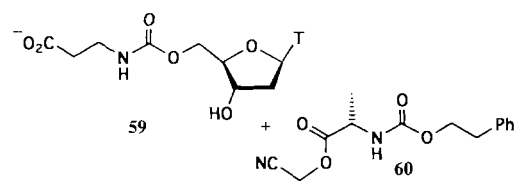
Antibodies designed to catalyze the formation of a bond between two bound substrates suffer from the same problems of product inhibition as other enzyme mimics. Thus Schultz's antibodies raised against hapten **58** catalyzed transesterification of the activated ester **60** with **59** (when T = thymidyl the reaction

Hapten:



58

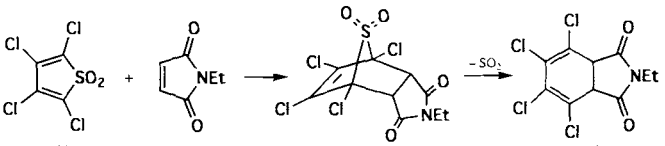
Substrates:



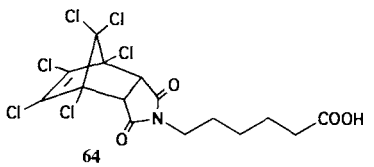
59 60

is a model for the aminoacylation of tRNA)[88] with high efficiency (EM $\approx 10^5$ M). But the product ester binds strongly to the antibody ($K_{diss} = 18$ nM) and thus inhibits turnover. The comparison with Rebek's synthetic enzyme mimic **38**, which catalyzes an ester aminolysis reaction between two very similar reactants, shows that the EM is some 10^6 times higher for the abzyme-catalyzed reaction (Tables 4 and 5). The product amide—and no doubt the transition state also—is bound much more weakly by the synthetic host.

This problem can be avoided by careful hapten design in favorable cases. Thus Hilvert's antibody catalyzing the Diels–Alder reaction of tetrachlorothiophene dioxide **61** and *N*-ethylmaleimide achieves turnover because the initial adduct **62** rapidly loses SO_2 to give the bicyclic product **63**.[89] Catalysis results simply from productive binding (an EM > 110 M is estimated). The hapten **64** is a reasonable transition state analogue but geometrically very different from the final product.

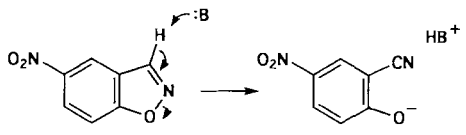


61 62 63



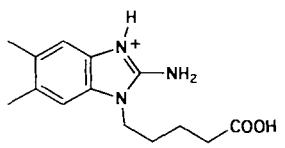
64

More ambitious systems with catalytic groups built in can in principle be obtained by careful hapten design. Building a charged group into the hapten could—and occasionally does—elicit a charged group of opposite sign in the antibody, which might act as a general acid or base, or as a nucleophile. The cleavage of compound **65**[90] is of particular interest because it involves general base catalysis, typically an inefficient intramolecular process, as already discussed. Like the heterocyclic substrate, the hapten is [5.6]-fused, and as a 2-aminobenzimidazole it is protonated at physiological pH and thus elicits a complementary anionic group as part of the binding site of antibodies generated against it. Two antibodies out of >1000 that bound the hapten catalyzed the E2 reaction of substrate **65** [Eq. (o)] with notably high efficiency (EM = 5000–6000 M, with



(o)

65



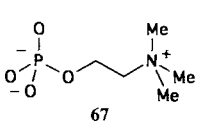
66

proton transfer rate-determining) and good turnover, since the product is geometrically and electrostatically very different from the hapten.

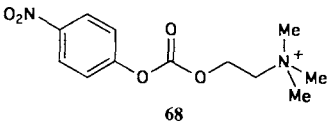
An alternative strategy is to introduce a functional group into an existing catalytic antibody by protein engineering. As might be expected, site-directed mutagenesis of enzymes does not nor-

mally improve the efficiency of reactions with natural substrates. But catalytic antibodies, which have no significant evolutionary history and rarely even a functional group in the active site, are expected to be more promising candidates. The evidence available is insufficient to confirm this judgement. Benkovic and his group used site-directed mutagenesis to probe the mechanism of action of their antibody 43C9, which accelerates the hydrolysis of a *p*-nitroanilide by a factor of 10^6.[91] The mechanism is thought to involve nucleophilic catalysis by a histidine imidazole, and indeed replacing the relevant histidine by glutamine eliminates catalysis. Of seven mutations, made for various reasons, none improved catalytic efficiency.

In a similar study Schultz and his co-workers[92] used a mechanistically simpler antibody, which was known to bind phosphorylcholine (**67**) and to catalyze the hydrolysis of the carbonate **68**. Of seven mutants, one, in which a tyrosine residue shown not to be catalytically active was replaced by imidazole, led to an eightfold increase in k_{cat}. The new functionality is thought not to be ideally placed for catalysis, but it is a good nucleophile close enough to attack the C=O group of the substrate (EM ≈ 11 M).



67



68

Finally, just as with a synthetic host, it is possible to introduce a functional group chemically into an abzyme. To do this with precision requires a good understanding of the three-dimensional arrangements at the binding site. But targeting this site is not difficult in principle by using affinity labeling. Pollack and Schultz used this technique to introduce a nucleophilic thiol group into the binding site of an antibody that binds 2,4-dinitrophenyl compounds, and they were able to attach an imidazole to the SH group by disulfide exchange.[93] The semisynthetic catalytic antibody produced was a rather good catalyst for the hydrolysis of activated esters with a suitably positioned 2,4-dinitrophenyl group (Table 5). The data in Tables 4 and 5 show that catalytic antibodies are generally more efficient than synthetic enzyme mimics, when some of the best catalysts of each type acting on similar substrates are compared (absolute values of k_{cat} and k_{cat}/k_{uncat}). Both sorts of catalysts suffer from similar problems of product inhibition, so that turnover is currently a major limitation to their utility. This limitation is magnified by both the absolute rates and the rate accelerations that can be achieved. Thus transition state binding for the hydrolysis of the unactivated amide in Table 5 is almost as good as that achieved by Schultz's mutant enzyme for the hydrolysis of the carbonate ester **68**. But the amide is so intrinsically unreactive that the actual rates obtained are hardly detectable.

5. Summary and Outlook

The comparison of enzyme mimics with real enzymes is sobering. Table 6 presents a small set of data taken from a recent paper of Radzicka and Wolfenden.[94] The k_{cat} values are larger by at least two orders of magnitude than those in Table 5 for catalysis by abzymes. The rates of the enzyme-catalyzed reactions are in the practically useful range and may not seem too great a challenge for improved design of enzyme mimics. But the big difference lies in the values of k_{cat}/k_{uncat} and transition state stabilization ($-\Delta G^0_{TS}$): for slow reactions—like those of the extraordinarily stable groups of structural biology (see Section 1)—the enzyme reactions are more efficient by up to ten orders of magnitude in k_{cat}/k_{uncat} and 60 kJ mol^{-1} in transition state binding.[95]

This is a measure of the intellectual challenge of this field of research. For some practical applications, particularly in synthesis, the prospect of useful catalysts is by no means so remote. We have concentrated in this review on systems where reliable kinetic information is available, rather than on reactions of

Table 6. Selected data on the reactivity and transition state binding in enzyme-catalyzed reactions [94].

Enzyme	k_{cat} [s^{-1}]	k_{cat}/k_{uncat}	$-\Delta G^0_{ES}$ [a] [kJ mol^{-1}]	$-\Delta G^0_{TS}$ [kJ mol^{-1}]

immediate interest to the organic chemist. But most useful synthetic reactions are by definition not very slow, and catalysts that lead to excellent chemo- and regioselectivity, and even good diastereo- and enantioselectivity must be of potential interest.[100] Synthetically useful differences between pathways rely on only rather small differences in activation energy (about 7 kJ mol^{-1} for a 95% preference). So enzyme mimics, and especially antibody catalysis, remains an area of definite promise and of much current activity.

[18] The entropy term is always more favorable for an intramolecular process (the basis of the description of enzymes as "entropy traps"). But this factor is common to all intramolecular processes and does not vary a great deal for many favorable reactions. In contrast, the entbalpy term can depend strongly on the way the reacting groups are brought together. See L. Mandolini, *Adv. Phys. Org. Chem.* **1986**, *22*, 1.

[27] This sort of concerted process was often described and sometimes tested in the early research on the subject, but in practice the two catalytic groups generally turned out to act on separate steps of model reactions. With the availability of systems showing more efficient general acid or base catalysis it becomes possible to design a new generation of test systems containing unactivated groups.

[58] Note the slow absolute rate: most synthetic hosts are only soluble in organic solvents, and ionic reactions—especially those involving proton transfers—are generally much slower than in water. Efficiency can be measured in the usual way, but a very low k_{uncat} can mean that even highly efficient catalysis may not bring the absolute rate up to the level of k_{uncat} in water.

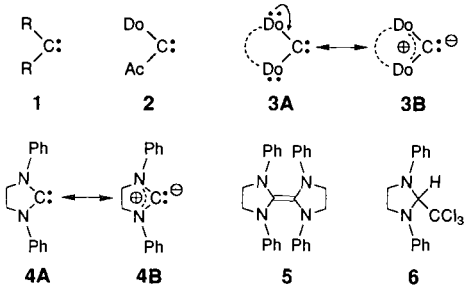
Nucleophilic Carbenes: An Incredible Renaissance

Manfred Regitz*

Carbenes **1** can be considered typical representatives of reactive intermediates and have found a broad range of applications in synthetic chemistry. Their impressive reactivity is comprehensively documented in two thick volumes of a standard reference series on organic synthesis.[1] As a result of the deficit of electrons they have electrophilic character, provided that the two substituents R are not electron donors. If this is not the case as, for example in the system **3A** ↔ **3B**, the donor groups enforce



nucleophilic character at the carbene center. The ambiphilic carbenes **2** having both a donor and an acceptor substituent occupy a position between carbenes **1** and **3**. Only carbenes of type **3** can be isolated as stable compounds ("carbenes in a bottle"), and these were realized for the first time just a few years ago.[2]

The beginnings of the chemistry of nucleophilic carbenes **3** date back to the early 1960s and are associated with the name H.-W. Wanzlick.[3] At that time species of the type **4A** ↔ **4B** were examined; precursors of **4** include the dimeric and electron-rich olefin **5** and imidazolidine **6** (thermal α-elimination of chloroform). By means of cross-coupling experiments, however, it was shown that **5** is not in equilibrium with the two carbene units **4**.[4] On the other hand, it is certain that the C–C double bond of **5** is cleaved in reactions with electrophiles with liberation of **4**.[5] The carbene-stabilizing influence of the donor groups of **4** was clearly recognized and an even larger effect was correctly predicted for structurally related carbenes of type **7** owing to the participation of the "aromatic resonance structures" (**7A** ↔ **7B** ↔ **7C** ↔ **7D**);[3a] however, serious attempts to isolate carbenes of types **4** and **7** were not undertaken until 1991.

Even so, H.-W. Wanzlick and co-workers did demonstrate in 1970 that imidazolium salts such as **8** and **11** are deprotonated by potassium *tert*-butoxide to furnish carbenes **9** and **12**, respectively, which were then trapped (but not isolated). With phenyl isothiocyanate as trapping agent, the zwitterion **10**[6] was isolated, and treatment with mercury acetate gave the carbene complex **13**.[7] Thus, the first opportunity to isolate stable carbenes of the type **7**, to which **9** and **12** also belong, was missed. Just this principle was used almost two decades later by A. J. Arduengo et al.[8] to isolate electronically stabilized, nucleophilic carbenes for the first time.

When bis(1-adamantyl)imidazolium chloride (**14a**) was deprotonated with sodium hydride in tetrahydrofuran in the presence of a catalytic amount of dimethyl sulfoxide anion, **15a** precipitated as a colorless, crystalline, and thermally stable compound.[8] The crystal structure analysis unequivocally confirmed this result; in the ^{13}C NMR spectrum the lowfield position of the signal for the carbene carbon atom (δ = 211.4) is characteristic. A singlet ground state for imidazolylidene (**15**, $R^1 = R^2 = H$) was determined from ab initio MO calculations;[9] the dominating carbene character was deduced from neutron diffraction studies and crystal structure analysis of perdeuterated **15b**.[10]

In addition to the obvious steric effects, electronic factors are considered responsible for the stability of **15a**. These include π-electron transfer from the electron-rich π system of the heterocyclic ring (see resonance structures **7A**–**7D**) into the p orbital of the carbene carbon atom that is perpendicular to the ring plane.[2, 8]

18 (100%)

The importance of steric effects was without doubt overestimated initially. This is apparent when one considers that stable carbenes of the same type can also be obtained by deprotonation of imidazolium salts bearing less bulky substituents in the 1- and 3-positions (**14b–e** → **15b–e**).[11] These species also exhibit characteristic ^{13}C NMR signals (δ = 213.7–219.7) for the carbene carbon atom.

Polyfunctional derivatives also open interesting perspectives for the chemistry of stable carbenes. The developments were initiated by the synthesis of the triscarbene **16** (^{13}C NMR: δ = 215.2), in which the imidazolylidene units are attached to a benzene ring. This compound was prepared by deprotonating the corresponding trisimidazolium salt with sodium hydride/*tert*-butoxide.[12] The biscarbene **17** is also stable and accessible by the same method except that sodium hydride in liquid ammonia/tetrahydrofuran is used as the deprotonating agent.[13] Advantages of this alternative method, which also provides access to **15c**, are low reaction temperatures (– 50 °C) and short reaction times. The series of stable, nucleophilic carbenes was extended by incorporating an additional nitrogen atom in the five-membered ring. 1,2,4-Triazol-5-ylidene **18** (^{13}C NMR: δ = 214.6 (C-5)) is obtained in quantitative yield by the thermal α-elimination of methanol from 5-methoxy-1,3,4-triphenyl-4,5-dihydro-1*H*-1,2,4-triazole.[14]

N. Kuhn and co-workers reported on a similarly successful synthesis of imidazolylidenes in 1993 which was completely independent of the above-mentioned examples. They condensed aldol **19** with thioureas **20a–c** to furnish imidazole-2(3*H*)-thiones **21a–c**, which were subsequently reduced with metallic potassium in tetrahydrofuran to give carbenes **22a–c** (**22a** ≡ **15b**).[15] The scope of this elegant method has not yet been fully explored.

The climax of the current developments is the isolation by A. J. Arduengo and co-workers of the first of the imidazolidin-2-ylidenes originally postulated by H.-W. Wanzlick. The stable, nucleophilic carbene **24** was obtained by deprotonation of the bis(mesityl)imidazolium chloride **23** with potassium hydride.[16]

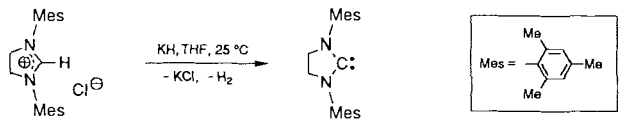
b R = Et (96%)
c R = *i*Pr (93%)

A ^{13}C NMR signal at δ = 244.5 (relatively low field in comparison to the analogous signal of compounds of type **7**) and a crystal structure analysis conclusively confirmed the monomeric nature of the molecule.[16]



23 24 (72%)

In spite of their thermodynamic stability, nucleophilic carbenes exhibit an undeniable tendency to increase their coordination number and covalency state. For example, **22a–c** undergo smooth addition of elemental selenium at 20 °C to furnish **25a–c**[17] and of tellurium at 0 °C to give **26a–c**[18] in yields of ≥84%; the latter species can be considered to be imidazolium chalcogenides. Reactions with the carbon electrophile CS_2 lead to the stable, red zwitterions **27a–c** (69–82%).[19, 20]

1,2,4-Triazolylidene **18** undergoes insertion into the H–X bond of protic nucleophiles with quantitative formation of triazolines **28** and **29**.[14, 21] Compound **18** reacts with dimethyl fumarate or maleate to furnish the methylenetriazoline **30**.[22] It is assumed that the initial step is a [2 + 1]cycloaddition to give a cyclopropane, and that subsequent ring opening and [1,2]-hydrogen shift lead to **30**.[14]

The coordinative unsaturation of stable carbenes is also reflected in the reaction of **15d** with imidazolium salts: the bis(carbene) - hydrogen complex **33** is formed with the salt **31**. A significant structural feature of **33** is the C-H-C moiety.[23] Analogously, reaction of **15d** with the iodoimidazolium salt **32** gives rise to the bis(carbene) - iodine complex **34**.[24, 25] In both cases the bond angle at the bridging atom X deviates only slightly from 180°.[23, 24]

In contrast to the organic chemistry of the stable, nucleophilic carbenes, which is still rather modest, the perspectives for the coordination chemistry of the same compounds have developed much more rapidly; this will be illustrated by a selection of carbene complexes of differing stoichiometries.

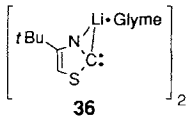
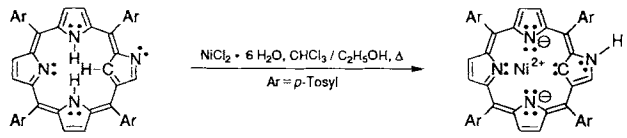
The formation of these complexes is based on the pronounced Lewis base character of the carbenes **15** and **22**. Lewis acids with main group elements as the central atom such as diethylmagnesium, borane, boron trifluoride, aluminum hydride, silicon tetrachloride (→ formation of hypervalent silicon), and germanium diiodide undergo addition as such or in the form of "stabilized adducts" to furnish the carbene complexes **35a–f** in high yields.[26–30] In principle, Lewis acids of the transition metals behave analogously: titanium tetrachloride (→ formation of hypervalent titanium) is incorporated as readily as the pentacarbonylchromium, tetracarbonyliron, tricarbonylnickel, and diethylzinc fragments to furnish the carbene complexes **35g–k**.[26, 31–33] Finally, carbene complexes with chloro(1,5-cyclooctadiene)-rhodium and -iridium (**35l**)[13] as well as bis(pentamethylcyclopentadienyl)samarium (**35m**)[34, 35] can be prepared easily.

The structures of the nickel and platinum[36] as well as the copper and silver complexes,[37] in which two nucleophilic carbene ligands are coordinated to the central atom, are similar to the structures of compounds **33** and **34** described previously, which have hydrogen or iodine as bridging elements. Two or three carbene ligands can also be incorporated in complexes containing chromium, molybdenum, or tungsten as the central atom.[38] Nucleophilic carbenes such as **15c** are coordinated by transition metal halides and oxides as well. Titanium(IV), hafnium(IV), vanadium(II), niobium(IV), and tantalum(IV) complexes of the general formula $[MX_nL_m]$ as well as rhenium complexes of the type $[MeReO_3L_2]$ (L = carbene ligand) have been isolated and their structures elucidated.[39] Beryllium–carbene complexes (1:3) are also known.[40]

The chemistry of stable (nucleophilic) carbenes has also had an impact on other, totally different fields, as will be shown in the following examples. The formyl anion character of a lithium derivative of 4-*tert*-butylthiazole, which exists in crystalline form as a complex with glyme (**36**), has been reported;[41] the synthetic potential of this species has been mentioned but not yet fully exploited.



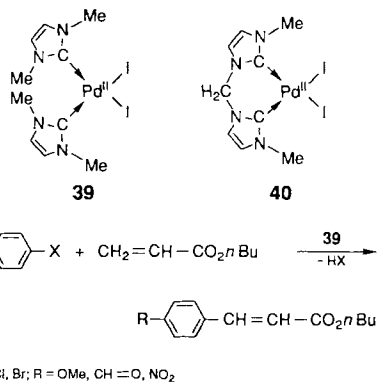
36



37 **38**

Nucleophilic carbenes also play a significant role as complex ligands in the chemistry of the "N-confused" porphyrins **37**. Complex **38**, accessible from **37** and nickel(II) chloride, can be viewed as an Ni-stabilized carbene.[42] Ab initio and LDF (low density functional) calculations are in accord with this description.[42]

The applications of the carbene–palladium complexes **39** and **40** in homogeneous catalysis are completely new and their full



perspectives cannot yet be predicted. In a model study, this new structural principle for catalysts was investigated for the Heck reaction of aryl halides with *n*-butyl acrylate.[43] Both palladium complexes can be obtained from the corresponding imidazolium salts and palladium(II) acetate. Complex **39** is exceptionally stable towards heat, oxygen, and moisture; these are favorable characteristics for its use as a catalyst under extreme conditions. The palladium complex **40** is less suitable for the Heck reaction since it begins to decompose in solution at 70 °C.

The advantage of this novel structural principle for catalysts is the formation of active species stable for long periods even at the higher temperatures still necessary for the activation of chlorine atoms.[43] The addition of a reducing agent to **39** and the

independent generation of the active species, presumably the palladium(0) compound [Pd(carbene)$_2$], allow the Heck reaction to proceed without an induction period; deposition of palladium has not been observed.[43]

We wait with interest to see how the chemistry of the nucleophilic, stable carbenes will develop: surprises may be just around the corner. In addition, the exploration of the chemistry of the higher homologues (silylenes, germylenes with similar environments) will be a journey into uncharted territory.[44, 45]

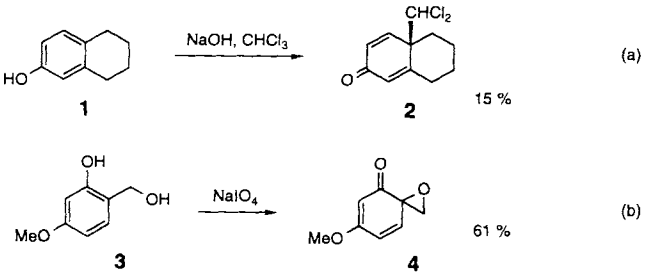
Additions to Functionalized Arenes with Concurrent Dearomatization

Thorsten Bach*

The six-membered aromatic ring of benzene and its derivatives is a C_6 unit that may be used as an alicyclic synthetic building block if the conjugated π system can be successfully broken up. The fascination of such a reaction rests on its high economy and its simple elegance, as demonstrated by two examples from the annals of organic synthesis. Woodward conceived the introduction of the angular methyl group to tetralin **1** by a Reimer–Tiemann reaction and subsequent dehalogenation of intermediate **2** [Eq. (a)].[1] This work was related to earlier observations by Auwers et al. that cyclohexadienones form as side products in the reaction of *ortho*- and *para*-alkylated phenols with $CHCl_3$/NaOH.[2] The Adler reaction,[3] which was discovered in the beginning of the 1970s, was chosen by Corey et al. as a key step in the synthesis of ovalicin to construct the spirocyclic product **4** from the salicylic alcohol **3** in a single step [Eq. (b)].[4]



Modern dearomatization reactions,[5] which will be presented in this account, often utilize transition metal complexation to activate the arene. For example, the tendency for C-alkylations in phenols can be enhanced by η^2-complexation with Os^{II} fragments, which bind selectively to C-2 and C-3.[6] An intermolecular addition to Michael acceptors becomes possible due to the partial localization of the π-electron density in racemic complexes such as **5**. 2,5-Cyclohexadienones are formed in a process that is thermodynamically favored by the enhanced π-acidity of these ligands [Eq. (c), only one enantiomer is shown].[7] The addition proceeds stereoselectively from the face of the six-membered ring opposite to the metal. In general, *para*-substituted products such as **6** are formed predominantly; however, the regioselectivity can be shifted to preferential *ortho*-addition at C-6 upon Lewis acid catalysis. Anilines were shown to react in an analogous fashion.[8]

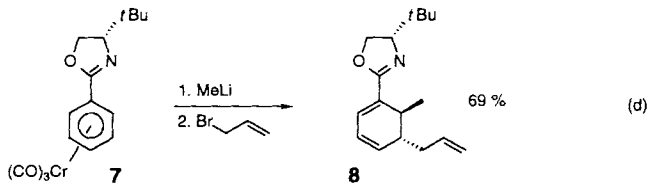
In contrast to this method, in which the nucleophilicity of an arene is increased by η^2-complexation, several dearomatization reactions can be conducted on η^6-arene complexes.[9] The most prominent examples are found in the area of the corresponding $Cr(CO)_3$ complexes. Nucleophilic attack on the electrophilic arene occurs readily, and under carefully controlled conditions the reaction may be completed by subsequent quenching with an electrophile to yield a cyclohexadiene. During the conversion of a monosubstituted benzene a stereogenic center is generated on the six-membered ring whose absolute configuration is determined by the enantiotopic position of the nucleophilic attack.[10] If the substituent attached to the arene is chiral, both the *ortho* and the *meta* carbon atoms are diastereotopic and a differentiation by achiral reagents is feasible. Based on these considerations Kündig et al. developed a chelation-induced, diastereoselective *ortho*-alkylation of complex **7** as exemplified in Equation (d).[11] The product **8** is formed with excellent diastereomeric excess (>98% *de*).[12]

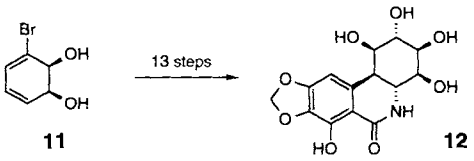


The oxazoline auxiliary employed by Kündig et al. is reminiscent of the pioneering work by Meyers in the field of asymmetric addition to 1- or 2-(dihydrooxazolyl)naphthalenes.[13] In the case of a 1-substituted naphthalene selective addition of nucleophiles at the 2-position proceeds with excellent diastereofacial selectivities, provided the oxazoline is chiral. Similar addition reactions were conducted on naphthalenes bearing a carbonyl or a carboxyl substituent in 1-position.[14] A recent result reported by the group of H. Yamamoto shows that even acceptor-substituted benzene derivatives can be dearomatized under suitable conditions.[15] For a successful reaction the complexation of the carbonyl group in aromatic aldehydes or ketones such as acetophenone (**9**) by the sterically demanding Lewis acid aluminum tris(2,6-diphenylphenoxide) (ATPH) is mandatory. A deoxygenated mixture of toluene and THF (1/1) serves as the solvent. Since the *ortho* positions and the carbonyl group are shielded by the Lewis acid, an enolate is formed by 1,6-addition of the alkyl lithium species. Under carefully chosen workup conditions (conc. HCl) the cyclohexadiene **10** can be isolated [Eq. (e)]. Slight modification of the reaction conditions

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3507-0729 $ 15.00+.25/0

(workup with acetic acid or reaction in CH_2Cl_2) leads to the formation of the aromatic substitution product.[16]

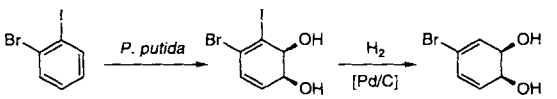
All of the methods previously mentioned rely on conventional electrophilic or nucleophilic reagents. To close, a reaction will be addressed that proceeds by an enzymatic transformation. The oxidation of monosubstituted arenes by mutant strains of *Pseudomonas putida* leads to enantiomerically pure diols[17] such as **11**, which are widely used starting materials for the synthesis of alkaloids and carbohydrates.[18] In a recent example diol **11** is transformed into the central six-membered ring of (+)-pancratistatin (**12**) [Eq. (f)]; the diol's stereochemical information



11 **12** (f)

and its C–C connectivity are essential.[19] The aromatic residue in **12** was attached in the form of an *ortho*-metalated arene to an aziridine by nucleophilic substitution. The aziridine, in turn, was generated regio- and diastereoselectively from diol **11**. In the synthesis of (+)-deoxypancratistatin a structurally related mixed higher-order cuprate was employed for this purpose.[20]

The enzyme-catalyzed dihydroxylation of disubstituted iodobenzenes proceeds with high regioselectivity at their unsubstituted *ortho* and *meta* carbon atoms [**13** → **14**, Eq. (g)]. After



13 **14** **15** 65 % (g)

the directing power of the iodine substituent has been used, it can be removed by catalytic hydrogenolysis on palladium. This sequence was applied to the synthesis of *cis*-3,4-dihydrodiols such as **15** and also to the preparation of the (2*R*,3*R*) enantiomers[21] of *cis*-2,3-dihydrodiols, which cannot be obtained by conventional oxidation with *Pseudomonas putida*.[22]

The methods presented here were selected to show some recent developments in the field of dearomatization reactions. Besides regio- and diastereoselectivity as criteria for synthetic efficiency, the preparation of enantiomerically pure compounds and the formation of C–C bonds are further goals. The ubiquitous occurrence of six-membered rings in natural products and biologically relevant molecules should be a sufficient reason to search for improvements on the existing methods and to develop novel dearomatization reactions.

Directed Self-Assembly of Chiral, Optically Active Macrocyclic Tetranuclear Molecular Squares**

Peter J. Stang* and Bogdan Olenyuk

Dedicated to Professor Cheves T. Walling on the occasion of his 80th birthday

Chiral macromolecules play an essential role in biology and chemistry and are key constituents of all living organisms. The structural elegance and complexity of proteins and nucleic acids evolved by nature have been intriguing subjects for numerous investigations for over a century. The design and study of various artificial models of complex biological systems have largely been developed in the last three decades and now represent one of the major frontiers of modern supramolecular chemistry. Among the many systems investigated, the most intriguing are the chiral macrocycles: crown ethers,[1] cyclophanes,[2] cyclodextrins,[3] and calixarenes.[4] Molecular recognition studies in these model systems provide insights into not only fundamental concepts of noncovalent interactions, occlusion phenomena, and chiral recognition, but also into enzymatic processes. The exact molecular architecture of these compounds, as manifested in their precise shape, size, conformation, and configuration, is critical to their function.[5]

Recently, conformationally more rigid macrocycles, with unique geometric features, commonly referred to as molecular squares, have emerged. To date, three distinct types of these assemblies are known: those with a main-group element (polyvalent iodine) at the corners,[6] transition metal based systems,[7] and hybrid species, incorporating both polyvalent iodine and transition metals.[8]

Their high-yielding, facile, and rapid preparation as well as air and thermal stability make molecular squares interesting targets for investigations of inclusion phenomena, host–guest interactions, and potentially even biomimetic studies.[9] Therefore, the application of the self-assembly phenomenon in an attempt to create hitherto unknown symmetrical yet chiral metallamacrocycles was particularly interesting and challenging.

The de novo design of chiral macromoleculecular assemblies, due to their conformational rigidity, required an alternative approach to that used for the preparation of the achiral square-shaped species. Whereas the spatial orientation of the donor atoms (e.g. nitrogens) of the bidentate ligand may remain 180° relative to each other, the ligand should possess C_{2h} symmetry, as opposed to the D_{2d}- or D_{2h}-symmetrical diaza ligands used in all molecular squares assembled to date.[7, 8] Although several such bidentate ligands are feasible, 2,6-diazaanthracene (daa) and 2,6-diazaanthracene-9,10-dione (daad) seemed to be among the most suitable. Moreover, upon formation of the conformationally rigid tetranuclear assembly, these ligands must be restricted in rotation around the metal–nitrogen bonds and remain orthogonal to the transition metal coordination plane.

Because six diastereomers may be formed in complexes with such ligands (Fig. 1), the separation of the diastereomers of these tetranuclear species was expected to be very difficult. The solution to this problem was unexpectedly simple: the components of the assembly are defined, which under appropriate conditions would generate exclusively one enantiomer; in other words, the internal properties of the components are used to achieve stereoselective self-assembly.

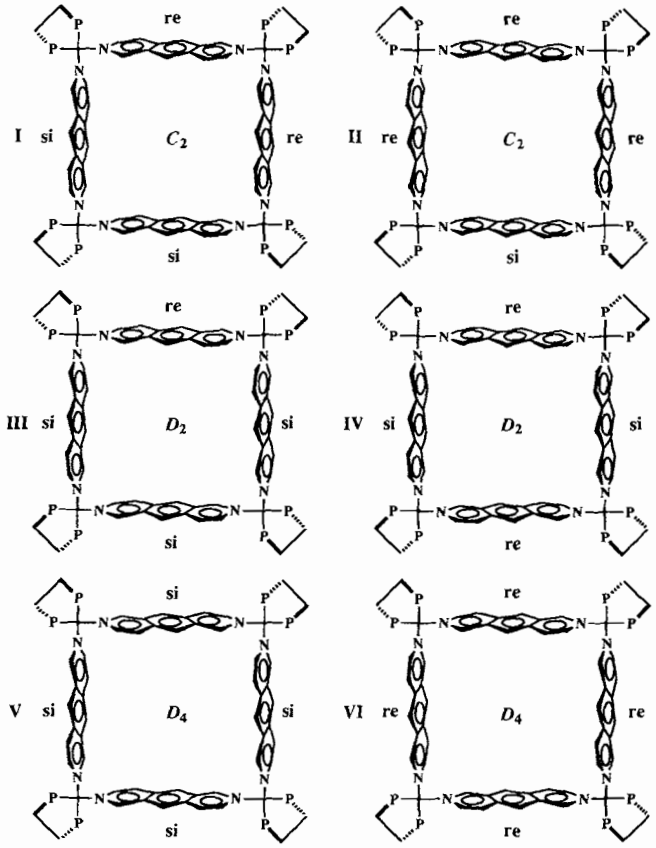

Fig. 1. Schematic representation of the symmetries of all possible diastereomeric cyclic tetranuclear complexes incorporating chiral transition metal bisphosphane *R*-(+)-binap units and the C_{2h}-symmetric ligand daa. Each face of the diaza ligands is labeled according to the π stacking rules [13a].

The reaction of the chiral, square-planar (around the metal) *R*-(+)-binap palladium(II) and platinum(II) bis(triflate) complexes **1** and **2** (binap = *P*, *o'*-(1,1'-binaphthyl-2,2'-diyl)bis-(diphenylphosphane)) with 2,6-diazaanthracene (daa) **3** in acetone at room temperature gives excellent yields of the self-assembled, single, diastereomeric, stable products **4** and **5**, respectively (Scheme 1), as assessed by NMR techniques. Chiral molecular squares **4** and **5** are air-stable (albeit hygroscopic), microcrystalline solids with high decomposition points. In spite of both the large charge (+8) and relatively high molecular mass (ca. 5000), these molecules are remarkably soluble in polar organic solvents such as acetone, nitromethane, and methanol.

The spectroscopic data and, especially the fact that the ^{31}P NMR spectra of **4** and **5** each show only a single signal, indicate that all the phosphorus atoms are equivalent, and hence these molecules must be highly symmetrical. In particular, the singlet in the ^{31}P NMR spectra of **4** and **5** indicates that the orientation of the two coordinated diaza ligands is *anti* (structures **V** and **VI**, Fig. 1) with respect to *each* square-planar metal center, because the molecules with *syn*-oriented ligands (structures **I**–**IV**) have different, lower symmetry. Also the *syn* orientation of the ligands would reveal itself in the ^{31}P NMR spectrum as a set of AB-type doublets due to the desymmetrization of the two neighboring binap P atoms. Therefore, the ^{31}P NMR spectra of the C_2-symmterical isomers **I**–**III** (Fig. 1) would contain a singlet and

Scheme 1.

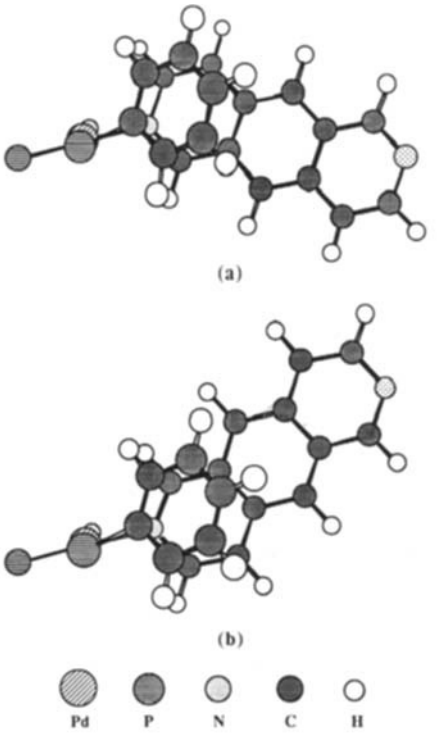

Fig. 2. Model of a fragment of molecular square **4** obtained from MM2 calculations, indicating the geometry of the arene–heteroarene stacking. Favored (a) and disfavored (b) rotamers are shown from the same viewing angle.

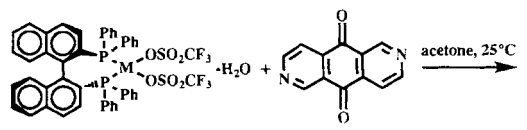
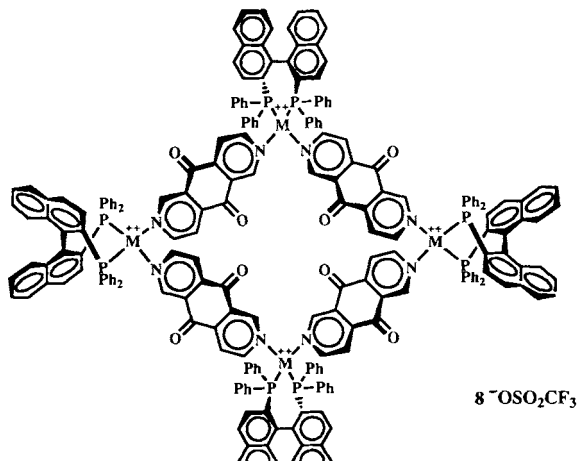
an AB-type doublet, whereas the D_2-symmetrical square **IV** would give rise to only an AB-type doublet. Moreover, had the other *anti* diastereomer (structure **V**, Fig. 1) been formed as well, its ^{31}P NMR signal would have been a separate singlet. This assertion is based on our previous studies of the mononuclear palladium(II) and platinum(II) complexes of *R*-(+)-binap, **1** and **2**, respectively, and isoquinoline.[10] Three different isomers formed due to restricted rotation about the metal–nitrogen bond: two C_2-symmetrical *anti* isomers (one of them as the major product) and one unsymmetrical *syn* isomer, with readily detectable chemical shift differences of $\Delta\delta = 0.2-0.8$ in the ^{31}P NMR spectra.[10] In the ^{31}P NMR spectra of the $[Pd(R\text{-}(+)\text{-binap})(C_{12}H_8N_2)]_4[OTf]_8$ **4** recorded between -80 and $+80$ °C no line broadening or signal splitting was evident, which ruled out isomerization, and therefore confirmed that at least within this temperature range, all diaza ligands are indeed restricted in rotation. Hence, **4** and **5** are each formed, within the limits of NMR detection, in diastereomerically pure form (structure **VI**, Fig. 1) with complete asymmetric induction in a conformationally rigid manner. MM2 force field calculations[11] indicate that the preferred formation of the chiral tetranuclear molecular square with the symmetrical all-*anti* orientation, *R,S,S* configuration[12] of each metal center, and D_4 symmetry (structure **VI**, Fig. 1) is likely a consequence of electronic factors. Although in the absence of strong charge transfer the preferred alignment of aryl rings is normally edge-to-face,[13] the face-to-face arene–heteroarene stacking in these squares is the result of the enforced proximity of the daa units and the binap phenyls. The spatial disposition of the P-phenyl rings of the chelate ligands and the metal-daa groups is sustained by the rigid binaphthyl backbone, and in the preferred diastereomer **VI** the dipole of the neighboring daa is forced away from the centroid of the nearest P-phenyl ring. This interaction (Fig. 2a) is favored over the alternative (Fig. 2b), where the dipole is in proximity to the P-phenyl centroid, and likely accounts for the preferred formation of only one diastereoisomer.

Use of 2,6-diazaanthracene-9,10-dione **6** (daad) as a ligand for the assembly of optically active molecular squares **7** and **8** (Scheme 2) results in highly symmetrical, chiral major products by asymmetric induction. However, small but detectable amounts of additional diastereomers are formed in each case, as evident in the ^{31}P NMR spectrum of **8** (Fig. 3). In other words,



1, M = Pd
2, M = Pt

6



7, M = Pd, 94%, $[\alpha]_D = +395$ (CH_3COCH_3)
8, M = Pt, 89%, $[\alpha]_D = +154$ (CH_3NO_2)

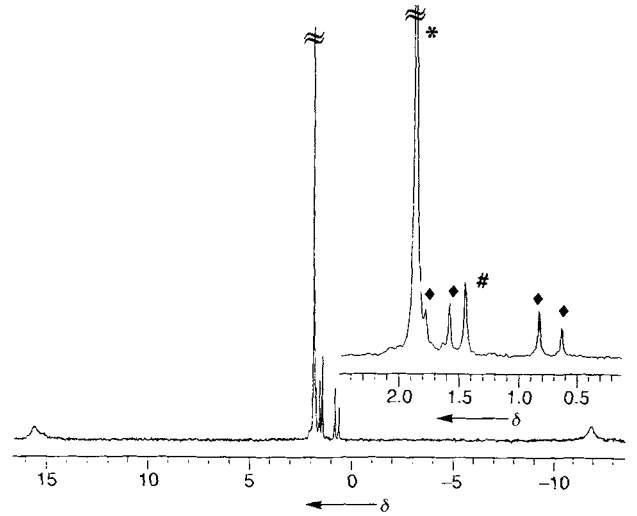

Fig. 3. Proton-decoupled ^{31}P NMR spectrum of molecular square **8** (*, #: *anti* isomers, ♦: *syn* isomer).

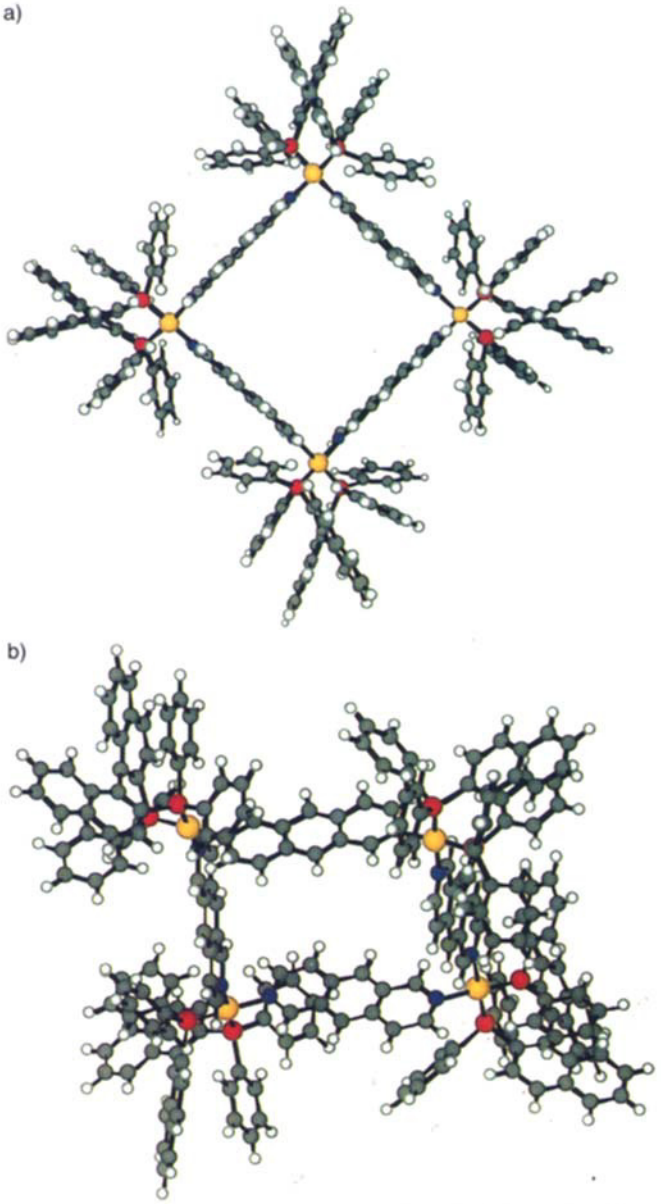

Fig. 4. Ball-and-stick model of molecular square **4**. Note the the large cavity evident in the top view (a) and the elements of helicity in the side view (b).

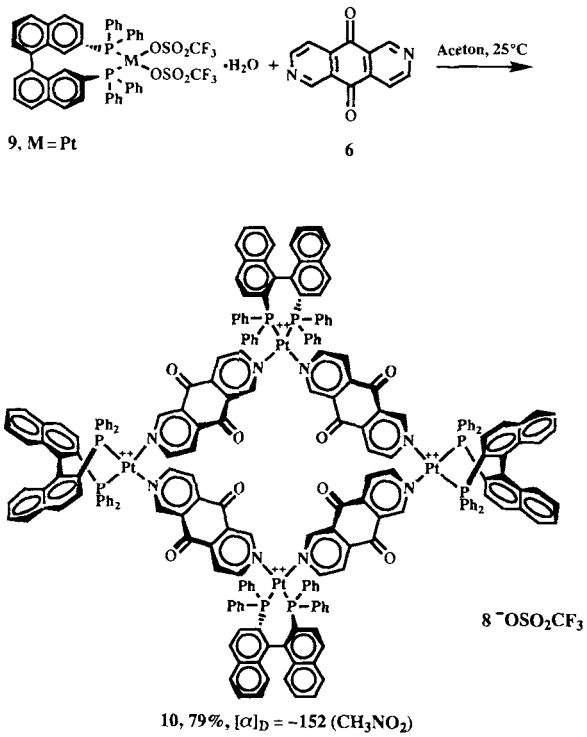
asymmetric induction is incomplete; only 81% of the major diastereomer of **7** and 72% of that of **8** are formed. These observations support our hypothesis concerning the conformations of **4** and **5**.

Electrospray (ES) mass spectrometric data for **8** show the presence of the doubly charged $[M-2\,^{-}OTf]^{2+}$ and quadruply charged $[M-4\,^{-}OTf]^{4+}$ ions with m/z ratios of 2503 and 1177, respectively. These signals correspond to the loss of two and four triflate anions, but the cationic part of the molecule remains intact, as assessed by the analysis of the isotopic distributions. These novel chiral species possess a large molecular-sized cavity in a unique combination with the elements of molecular helicity (Fig. 4).

The synthesis was also carried out with the other enantiomer of the chiral platinum bisphosphane complex (ligand: *S*-(−)-binap). Use of the opposite enantiomer in asymmetric induction predicts formation of the mirror image product. Indeed, interaction of [Pt(*S*-(−)-binap)(H_2O)($OTf)_2$] **9** with **6** results in the formation of the opposite enantiomeric product, molecular square **10** (Scheme 3). The physical and NMR spectroscopic



Scheme 3.

data of **10** are identical with those of **8**, but its optical rotation (within experimental error) is opposite. The mirror image relationship of **8** and **10** is confirmed by the circular dichroism (CD) spectra displayed in Figure 5 along with the CD spectrum of the palladium analogue **7**.

In summary, a new class of supramolecular assemblies, molecular squares that are chiral due to molecular helicity, can be readily constructed by self-assembly and coordination between the chiral square-planar Pd^{II} and Pt^{II} bisphosphane triflate complexes and appropriate achiral bidentate diaza ligands as building blocks. Asymmetric induction through a chiral bisphosphane (binap) auxiliary chelated to the metal center, and restricted rotation about the metal–nitrogen bond of the heteroarene ligand bond play a vital role in the stereoselective for-

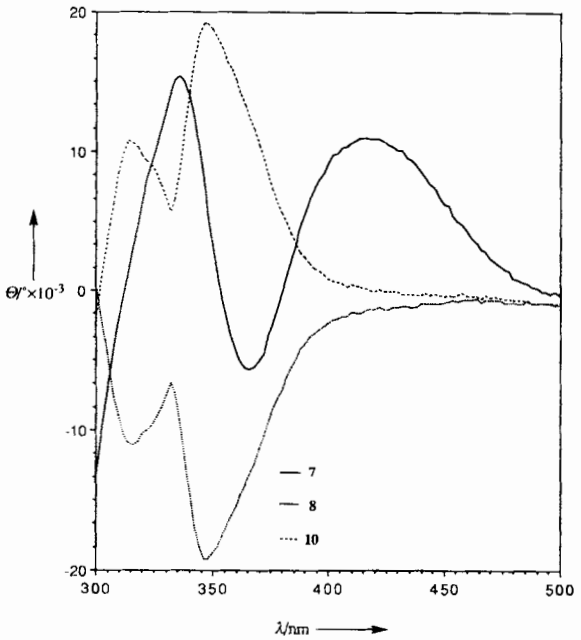


Fig. 5. CD spectra of the molecular squares **7**, **8**, and **10**.

mation of these cyclic, symmetrical, yet chiral species. The possible use of these chiral molecular squares as model systems in biomimetic studies, for asymmetric catalysis, and in other potential applications are currently under investigation.

Experimental Procedure

Preparation of **4**, **5**, **7**, **8**, and **10**: Schlenk techniques and dry N_2 were employed. A solution of 0.051 mmol of daa or daad in 8 mL of dry acetone was charged with 0.050 mmol of the appropriate chiral palladium(II) or platinum(II) triflates **1**, **2** [10], or **9** [14], and the solution was stirred under nitrogen for 30 min. Diethyl ether was then added and the precipitate was collected, washed with diethyl ether, and dried in vacuo.

4: Yield: 86%; m.p. 268–270 °C (decomp); $[\alpha]_D = +441$ ($c = 0.015$, acetone, 20 °C); ^{1}H NMR (300 MHz, [D$_6$]acetone, 25 °C, TMS): $\delta = 9.71$ (s, 8H, daa H-1 and H-5), 8.66 (d, $J = 6.8$ Hz, daa H-3 and H-7), 8.34 (s, 8H, daa H-9 and H-10), 8.16 (t, $J = 9.0$ Hz, 8H, binap), 8.06 (t, $J = 7.6$ Hz, 8H, binap), 7.87 (m, 16H, binap +daa H-4 and H-8), 7.55 (t, $J = 8.0$ Hz, 8H, binap), 7.44 (d, $J = 6.6$ Hz, 8H, binap), 7.14 (m, 24H, binap), 6.87 (t, $J = 7.3$ Hz, 8H, binap), 6.46 (d, $J = 8.5$ Hz, 8H, binap); ^{13}C{^{1}H} NMR (75 MHz, [D$_6$]acetone, 25 °C, TMS): $\delta = 160.2$ (s), 141.3 (t), 140.2 (s), 135.7 (overlapping m), 134.2 (t), 132.7 (s), 132.5 (s), 131.6 (s), 131.1 (t), 130.2 (m), 130.0 (s), 129.8 (s), 129.5 (s), 129.4 (s), 128.2 (s), 127.8 (s), 127.7 (s), 125.0 (t), 124.9 (s), 121.3 (q), 120.2 (t); ^{31}P{^{1}H} NMR (121 MHz, [D$_6$]acetone, 25 °C, H_3PO_4): $\delta = 27.42$ (s); ^{19}F NMR (282 MHz, [D$_6$]acetone, 25 °C, $CFCl_3$): $\delta = -75.7$ (s, CF_3SO_3); IR (neat): $\tilde{\nu}$ [cm^{-1}]: 1259, 1159, 1097, 1029 (all OTf); Anal. calcd for $C_{232}H_{160}N_8S_8P_8O_{24}F_{24}Pd_4 \cdot 3H_2O$: C 57.06, H 3.43, N 2.29, S 5.25; found: C 56.94, H 3.44, N 2.31, S 5.28.

Cuprates as Selective Metalating Reagents for Aromatic Halides

Yoshinori Kondo, Tetsuji Matsudaira, Junko Sato, Naoko Murata, and Takao Sakamoto*

Ate complexes such as cuprates have been used as versatile reagents for selective carbon-carbon bond forming reactions; however, little attention has been paid to halogen-metal exchange reactions using ate complexes.[1] With the aim of developing a new facile method for the preparation of arylcuprates, we investigated the halogen-copper exchange reaction of aromatic halides using cuprates. [$Li_2Cu(CN)Me_2$] was found to be an excellent metalating reagent. We describe here the application of this metalating method for the asymmetric synthesis of precursors of the CC-1065/duocarmycin pharmacophore with high enantiomeric purity.

Organocopper complexes are the organotransition metal reagents most widely used as soft nucleophiles in organic synthesis.[2] Organocopper and organocuprate reagents are employed for carbon-carbon bond formation owing to their characteristic reactivities in conjugate additions to α,β-unsaturated carbonyl compounds, in substitution reactions, and in carbometalations of carbon-carbon triple bonds. Although these reagents tolerate a wide range of electrophilic functional groups, the formation of functionalized organocopper reagents is not promising, because transmetalation of organolithium or Grignard reagents is typically required. Functionalized organocopper reagents have been prepared by transmetalation of functionalized organozinc compounds[3] and by direct oxidative addition of active copper to organic halides.[4]

Since the first preparation of [$LiCuMe_2$][5] a number of Gilman-type reagents of the general formula [$LiCuR_2$] have been used in organic syntheses, and recently higher order, mixed cuprates [$Li_2Cu(CN)R_2$] have been reported to show high reactivity toward a variety of organic substrates.[6] During our recent studies on arene and heteroarene chemistry,[7] we became interested in developing methods for preparing mixed arylcuprates with functional groups from haloarenes by halogen-copper exchange. The halogen-metal exchange reaction is one of the most useful processes for the preparation of metalated arenes such as the lithium[8] and magnesium[9] compounds. However, use of other organometallic compounds other than organolithiums and organomagnesiums for the halogen-metal exchange reaction seems to be rather limited. Although the possibility of halogen-copper exchange has been suggested in the coupling reaction of aryl halides with cuprates,[10] the reactions of organocopper intermediates with electrophiles are still unexplored from the viewpoint of synthetic chemistry.

Cuprate **2a** was prepared by reaction of iodobenzene (**1a**) with [$Li_2Cu(CN)Me_2$] in THF at $-40\,^{\circ}C$ for 2.5 h (Table 1).

Table 1. Formation of cuprates **2a-c** by halogen-metal exchange and addition to benzaldehyde. RT = room temperature.

	R	Solvent	T [°C]	t [h]	Yield [%]
a	H	THF	−40	2.5	89
a	H	Et_2O	−40	2.5	56
b	OMe	THF	−20	2	59
c	CO_2Me	THF	−78	4	56

Subsequent reaction with benzaldehyde at $-78\,^{\circ}C$ gave benzhydrol **3a** in 89% yield. Yields were moderate when Et_2O was employed as solvent. Other mixed cuprates such as [$LiCuMe_2$], [$Li_2CuMe_2(SCN)$], [$Li_2Cu(C{\equiv}CPh)(CN)Me$], and [$Li_2Cu(C_4H_3S)(CN)Me$] ($C_4H_3S$ = thienyl) were found to be less reactive than [$Li_2Cu(CN)Me_2$], and benzhydrol **3a** was obtained in 12-32% yield under otherwise identical reaction conditions. The halogen-copper exchange reaction of *p*-iodoanisole (**1b**) with [$Li_2Cu(CN)Me_2$] seemed to be slower than the reaction of iodobenzene. Satisfactory results were obtained when the metalation was conducted at $-20\,^{\circ}C$. A *p*-methoxycarbonyl group (**1c**) was tolerated in the halogen-copper exchange reaction, and the intermediary copper reagent **2c** reacted with benzaldehyde to give the alcohol **3c**. For better yields the metalation was conducted at $-78\,^{\circ}C$.

The high reactivity of the cuprates formed in this halogen-copper exchange reaction in 1,2-addition reactions encouraged us to investigate other classical reactions for carbon-carbon bond formation. The conjugate addition of the phenylcuprate **2a** to 2-cyclohexenone afforded 3-phenylcyclohexanone (**4**) in 61% yield without additional reagents (Scheme 1). The reaction of **2a** with 1,2-epoxycyclohexane gave *trans*-2-phenylcyclohexanol (**5**) in 53% yield in the absence of additives.

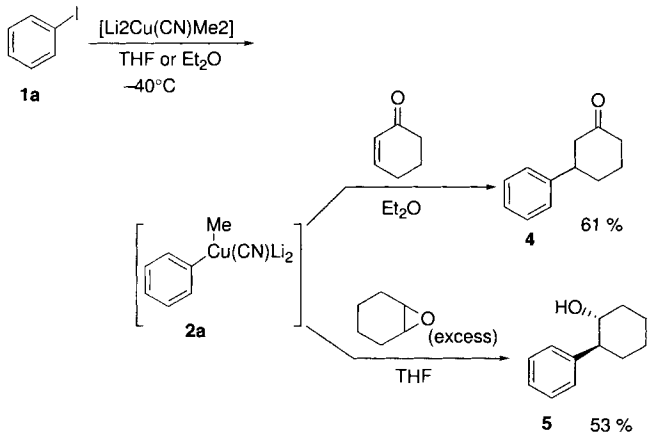
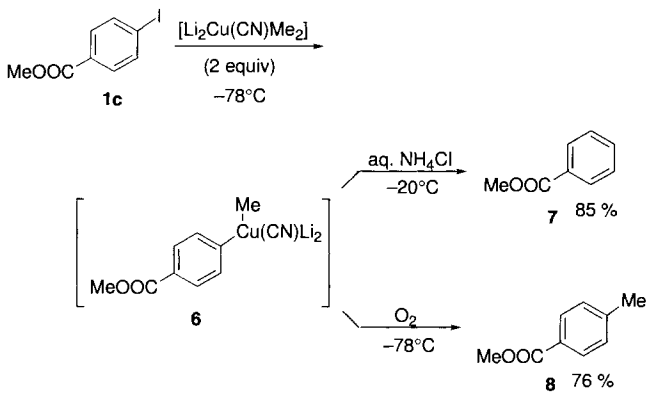


Scheme 1. 1,4-Addition and epoxide opening with cuprate **2a**, which is formed from **1a**.

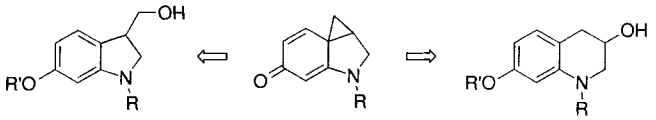
The halogen–copper exchange reaction of aryl halides with $[Li_2Cu(CN)Me_2]$ is a new method for the preparation of functionalized arylcuprates. To determine the structure of the arylcopper intermediate, arylcuprate **6**, which was obtained by halogen–copper exchange reaction of methyl *p*-iodobenzoate (**1c**), was hydrolyzed and oxidized with oxygen (Scheme 2). The hydrolysis of **6** in aqueous NH_4Cl at −40 °C gave methyl benzoate (**7**) in 85% yield; formation of methyl *p*-methylbenzoate (**8**) was not observed. In the halogen–copper exchange process MeI is probably produced and may be scavenged by another equivalent of $[Li_2Cu(CN)Me_2]$. The resulting [LiCu(CN)Me] is less reactive to electrophiles than $[Li_2CuAr(CN)Me]$ is. Oxidation of **6** by bubbling oxygen through the reaction mixture at −78 °C gave coupling product **8** in 76% yield. These results suggest the arylcopper intermediate is a mixed higher order species.[11]



Scheme 2. Hydrolysis and oxidation of cuprate **6**, which is formed from **1c**.

Our interest next focused on the application of the method to the synthesis of biologically active molecules. CC-1065[12a] and duocarmycins A[12b] and SA[12c] are potent antitumour antibiotics, and they have been synthetic targets for many synthetic chemists in connection with the mechanism of their biological activity.[13, 14] They contain a common spirocyclic subunit, and 3-hydroxymethyl-2,3-dihydroindoles and 3-hydroxy-1,2,3,4-tetrahydroquinolines are considered to be key precursors for the synthesis of the spirocyclic pharmacophore (Scheme 3).

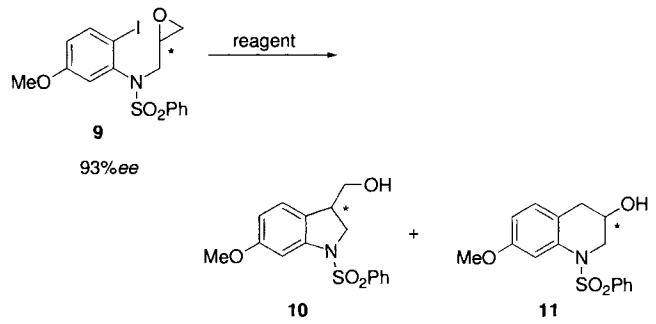
In connection with our recent studies on the synthesis of CC-1065/duocarmycin pharmacophores[15] we became interested in the asymmetric synthesis of 3-hydroxymethyl-2,3-dihydroindoles and 3-hydroxy-1,2,3,4-tetrahydroquinolines. If these precursors are available in enantiomerically pure form, asymmetric synthesis of the pharmacophore should be straightforward.



Scheme 3. Retrosynthetic analysis of the spirocyclic pharmacophore of CC-1065 and the duocarmycins leading back to 3-hydroxymethyl-2,3-dihydroindole and 3-hydroxy-1,2,3,4-tetrahydroquinoline precursors.

The intramolecular ring opening of epoxyorganometallic compounds is of interest in particular with regard to the regioselectivity of subsequent cyclizations.[16] We investigated the synthesis of a precursor of the CC-1065/duocarmycin pharmacophore by intramolecular ring opening of epoxyarylmetal ate complexes. The chiral epoxide **9** was chosen as a substrate and the regioselectivity of the cyclization was investigated. When **9** was treated with *n*BuLi at −90 °C, the 5-*exo* cyclization product[17] **10** was formed in 43% yield without loss of enantiomeric purity (Table 2, Entry 1). At higher temperature the yield of the product decreased dramatically (Entry 2). The reaction of **9** with lithium trimethylzincate at −50 °C gave the 5-*exo* product **10** in 40% yield and the 6-*endo* product **11** in 57% yield. Reaction with the zincate obtained from three equivalents of MeLi and $[Zn(SCN)_2]$[18] furnished the 5-*exo* product **10** as the main product together with the 6-*endo* product **11** (Entry 3).[16] The reactions of **9** with cuprates (Entries 4,5) showed reverse regioselectivity, and the 6-*endo* product **11** was obtained exclusively when $[Li_3Cu(CN)Me_3]$[19] was used as the metalating reagent. In general, enantiomeric purity was unchanged after the ring opening; the only exception was the 5-*exo* product **10** in the reaction of **9** with $[Li_2Cu(CN)Me_2]$.

Table 2. Synthesis of the precursors **10** and **11** of the CC-1065/duocarmycin pharmacophore.



Entry	Reagent	T [°C]	Yield [%] (*ee* [%] [a]) **10**	**11**
1	*n*BuLi	−90	43 (93)	0
2	$[LiZnMe_3]$	−50	40 (91)	57 (91)
3	$[Li_3ZnMe_3(SCN)_2]$	−78	72 (90)	15 (91)
4	$[Li_2Cu(CN)Me_2]$	−78	6 (78)	62 (90)
5	$[Li_3Cu(CN)Me_3]$	−78	0	73 (92)

[a] The enantiomeric excesses were determined with a Chiralcel OD-H column.

We do not yet have enough experimental data for discussing the origin of this diverse selectivity in the cyclization which

depends on the metalating reagent. However, the coordination of the oxygen atoms of the epoxide and sulfonyl groups to the metals of the ate complex is considered to be important in determining the direction of cyclization.

We have described a new method for the synthesis of enantiomerically pure 3-hydroxmethyl-2,3-dihydroindole and 3-hydroxyl-1,2,3,4-tetrahydroquinoline. The reagents of choice for the regioselective ring closure are $[Li_3ZnMe_3(SCN)_2]$ for the 5-*exo* cyclization and $[Li_3Cu(CN)Me_3]$ for the 6-*endo* cyclization.

Experimental Procedure

General procedure for halogen–copper exchange reaction followed by reaction with an electrophile: MeLi (1.04 M solution in Et_2O; 3.84 mL, 4 mmol) was added to a suspension of dry CuCN (179 mg, 2 mmol) in THF or Et_2O (5 mL) at −78 °C, and the mixture was stirred at −40 °C for 30 min. Then an aryl iodide (1 mmol) in THF or Et_2O (1 mL) was added and the reaction mixture stirred at −40 °C for 1 h. The mixture was cooled to −78 °C before an electrophile (2 mmol or excess) was added. The mixture was gradually warmed to room temperature over 12 h. The reaction mixture was quenched with aqueous NH_4Cl (2 mL) and the solvent removed in vacuo. The residue was diluted with H_2O (30 mL), and the mixture was extracted with $CHCl_3$ (3 × 30 mL). The combined organic layers were dried over anhydrous $MgSO_4$. After purification by silica gel column chromatography, the crude material was recrystallized or distilled under reduced pressure.

Reaction of **8** with $[Li_2Cu(CN)Me_2]$: Under Ar atomosphere, MeLi (1.03 M solution in Et_2O, 1.46 mL, 1.5 mmol) was added to the mixture of 90% CuCN (74.6 mg, 0.75 mmol) and dry THF (3 mL) at −78 °C. The mixture was warmed to −40 °C and stirred for 30 min. The mixture was cooled to −78 °C and a solution of **9** (223 mg, 0.50 mmol) in dry THF (5 mL) was added dropwise. The mixture was allowed to warm to room temperature and was stirred for 12 h. After evaporation of the solvent, the residue was diluted with H_2O (30 mL) and was extracted with CH_2Cl_2 (3 × 50 mL). The combined extracts were dried over $MgSO_4$ and the solvent was removed under reduced pressure. The residue was purified by silica gel column chromatography (EtOAc/hexane (1/1)) to give a viscous oil (**10**: 9.5 mg, 6%, 78% *ee*) and a colorless solid (**11**: 98.1 mg, 62%, 90% *ee*). **10**: viscous oil; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 1.87–2.06 (br. s, 1H), 3.20–3.32 (m, 2H), 3.47–3.56 (m, 1H), 3.81 (s, 3H), 3.88 (dd, 1H, J = 4.6, 11.0 Hz), 3.97 (dd, 1H, J = 8.8, 11.0 Hz), 6.53 (dd, 1H, J = 2.2, 8.1 Hz), 7.00 (d, 1H, J = 8.1 Hz), 7.26 (d, 1H, J = 2.2 Hz), 7.44 (dd, 2H, J = 7.3, 7.3 Hz), 7.55 (t, 1H, J = 7.3 Hz), 7.82 (d, 2H, J = 7.3 Hz); MS: *m/z*: 319 [M^+]. **11**: m.p. 113 °C; ^{1}H NMR (300 MHz, $CDCl_3$, TMS): δ = 1.79 (d, 1H, J = 5.1 Hz), 2.45 (dd, 1H, J = 6.4, 15.9 Hz), 2.70 (dd, 1H, J = 4.6, 15.9 Hz), 3.57–3.68 (m, 1H), 3.78 (s, 3H), 3.98–4.07 (m, 2H), 6.67 (d, 1H, J = 8.4 Hz), 6.93 (d, 1H, J = 8.4 Hz), 7.30 (s, 1H), 7.41–7.47 (m, 2H), 7.55 (t, 1H, J = 7.3 Hz), 7.73 (d, 2H, J = 7.7 Hz); MS: *m/z*: 319 [M^+]; $[\alpha]_D^{23}$ = −50.0 (c = 3.09, $CHCl_3$).

[18] We are currently studying the nature of organozinc compounds derived from $[Zn(SCN)_2]$ and organolithiums; the difference in the reactivity of $[LiZnMe_3]$ and $[Li_3ZnMe_3(SCN)_2]$ was observed. Details of these new organozinc derivatives will be reported elsewhere soon.

[19] The formula $[Li_3Cu(CN)Me_3]$ indicates a mixture of CuCN (1 equiv) and MeLi (3 equiv); however, the reactivity described in the present study suggests that $[Li_3Cu(CN)Me_3]$ is not a mixture of $[Li_2Cu(CN)Me_2]$ and and MeLi.

An Unprecedented Example of Pt_4Ag_3 Cluster Formation: Synthesis and Crystal Structure of $[Pt_2(dppy)_4(\mu_3\text{-}S)_2Ag_3(\mu_3\text{-}S)_2Pt_2(dppy)_4]^{3+}$**

Vivian Wing-Wah Yam,* Phyllis Kok-Yan Yeung, and Kung-Kai Cheung

The chemistry of soluble metal–sulfur complexes has been of considerable interest for a number years.[1] Recently, we showed that a tetranuclear d^{10} copper(I) cluster containing a μ_4-sulfido moiety exhibits rich photophysical and photochemical properties.[2] This together with our enormous efforts on the design of luminescent polynuclear d^8 and d^{10} metal complexes[2, 3] prompted us to extend our studies to polynuclear d^8 metal–sulfur clusters.[3a, b] We report herein on the novel reaction of a dimeric $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ complex (dppy = 2-diphenylphosphanopyridine) with silver(I) that gives a heptanuclear heterometallic complex, which contains a triangular Ag_3 unit and direct Pt–Ag bonding interactions. Although there have been reports on clusters containing triangular d^{10}-M_3 fragments,[4] those of the coinage metals are mostly held together by polyhydrido complexes of late transition metals.[4, 5] Herein we report the X-ray crystal structure and luminescent behavior of the heptanuclear complex **1**, which contains a non-hydrido bridged Ag_3 unit. Furthermore, the synthesis and photophysical behavior of the related tetranuclear complex **2** dppm = bis(diphenylphosphano)methane) is also described.

$[Pt_2(dppy)_4(\mu_3\text{-}S)_2Ag_3(\mu_3\text{-}S)_2Pt_2(dppy)_4](PF_6)_3$ **1**

$[Pt_2(dppy)_4(\mu_3\text{-}S)_2Ag_2(dppm)](BF_4)_2$ **2**

Reaction of $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ with $[Ag(MeCN)_4]PF_6$ in the molar ratio of 2:3 in THF/MeCN (v/v 1:1) in an inert atmosphere of nitrogen, followed by recrystallization from MeCN/Et_2O gave the heptanuclear complex **1** as yellow crystals in about 50% yield;[6] the identity of **1** has been confirmed by single-crystal X-ray diffraction.[7] Attempted synthesis of the pentanuclear complex cation $[Pt_2(dppy)_4(\mu_3\text{-}S)_2Ag(\mu_3\text{-}S)_2Pt_2(dppy)_4]^+$ by reacting $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ with $[Ag(MeCN)_4](PF_6)$ in a molar ratio of 2:1 was, however, unsuccessful: the reaction afforded **1**; however, in slightly lower yield. This was surprising since an analogous reaction of $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ with silver(I) afforded the complex cation $[Ag_2\{Pt_2(\mu_3\text{-}S)_2(PPh_3)_4\}_2]^{2+}$.[8] On the other hand, reaction of $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ with $[Ag_2(dppm)_2(MeCN)_2](BF_4)_2$ in the molar ratio of 1:1 in THF/MeCN (v/v 1:1) in an inert atmosphere of nitrogen, followed by recrystallization from MeCN/Et_2O gave the desired tetranuclear complex **2**. The structure of **1** (Fig. 1) consists of an isosceles triangle of Ag atoms sandwiched between two $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ units, leading to an overall barrel-shaped structure. The Ag(1)–Ag(2) and Ag(2)–Ag(2*) distances of 2.854(3) and 3.042(4) Å, respectively, may indicate weak Ag–Ag interactions, since the Ag–Ag distance in metallic silver is 2.889(6) Å[9] and other reported Ag–Ag distances where bonding is considered to occur range from 2.740 to 3.085 Å;[5a, 10] however, examples of structures with metal atoms at fairly close proximity but without any appreciable bonding interaction between them are also known. The Pt(1)–Ag(2) distance of 2.824(2) Å is also indicative of Pt–Ag bonding.[11] No Pt–Ag bonding is observed in the related complex cation $[Ag_2\{Pt_2(\mu_3\text{-}S)_2(PPh_3)_4\}_2]^{2+}$ (Pt···Ag 3.450(3)–3.905(3) Å).[8] Upon coordination to the Ag_3 unit, the $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ ligand changes the conformation of the Pt_2S_2 four-membered ring from a flat square-planar geometry,[3a] unusual for this class of compounds, to a hinged square-planar geometry, in which the dihedral angle opens from 0 to 132.6°. The Pt(1)–Pt(2) distance of 3.23 Å in **1** is shorter than that in the parent complex $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ (3.555(1) Å).[3a] The S···S separation of 3.11 Å is slightly longer than that in $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ (3.005(2) Å). The Ag(1)-Ag(2)-Ag(2*) and Ag(2)-Ag(1)-Ag(2*) angles of 57.79(5) and 64.41(10)° are close to the value of 60° expected for an equilateral triangle, as observed in a related Ag_3 cluster.[5a] Although as yet we have not determined the X-ray structure of complex **2**, it is likely that the nitrogen atom on the dppy ligand coordinates to the Ag atom to give three-coordinate Ag atoms (Scheme 1).

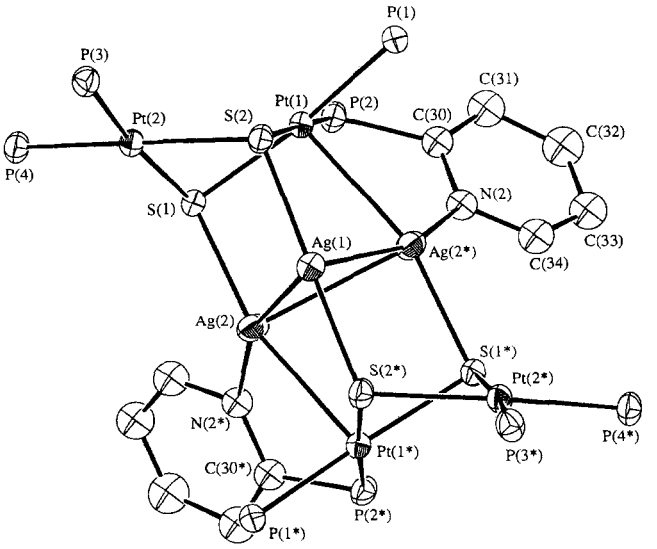

Fig. 1. Perspective drawing of the cation of complex **1** with the atomic numbering scheme. Phenyl and non-coordinating pyridyl rings on the phosphorus atoms have been omitted for clarity. Thermal ellipsoids are shown at the 30% probability levels. Symmetry related atoms (*) have coordinates at $(-x, y, (1/2)-z)$. Selected bond lengths [Å] and angles [°]: Pt(1)–Ag(2*) 2.824(2), Ag(1)–Ag(2) 2.854(3), Ag(2)–Ag(2*) 3.042(4), Pt(1)–S(1) 2.339(6), Pt(1)–S(2) 2.353(6), Pt(2)–S(1) 2.359(6), Pt(2)–S(2) 2.350(6), Ag(1)–S(2) 2.430(6), Ag(2)–S(1) 2.489(6), Ag(2)–N(2*) 2.38(2), Pt···Pt* 3.23, S···S* 3.11; Ag(2)-Ag(1)-Ag(2*) 64.41(10), Ag(1)-Ag(2)-Ag(2*) 57.79(5), S(2)-Ag(1)-S(2*) 178.9(3), S(1)-Ag(2)-Pt(1*) 164.5(2), S(1)-Ag(2)-N(2*) 102.9(5), Pt(1)-Ag(2*)-N(2) 83.9(5), Pt(1)-S(1)-Pt(2) 86.8(2), Pt(1)-S(1)-Ag(2) 98.4(2), Pt(1)-S(2)-Pt(2) 86.7(2), Pt(1)-S(2)-Ag(1) 99.3(2).

The UV/Vis spectra of complexes **1** and **2** show a low-energy absorption band at about 400 nm. Excitation of solid samples of **1** and **2** at $\lambda > 350$ nm at 77 K shows long-lived luminescence at about 560–660 nm (Table 1). An emission lifetime of about 1.5 μs was measured for a solid sample of **2** at room temperature. The long lifetime of the excited state suggests that the

[a] EtOH:MeOH (4:1, v/v).

emission is most likely associated with a spin-forbidden transition. Similar findings have been observed in the parent complex $[Pt_2(\mu\text{-}S)_2(dppy)_4]$.[3a] Presumably the origin of these transitions is derived from the $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ core. Since the low-energy absorption bands at about 370–400 nm and the emission at about 630 nm are only observable in the parent complex $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ and complexes **1** and **2**, and not in $[Pt(dppy)_2Cl_2]$, we suggest that the origin of these low-energy transitions does not lie in dppy intraligand (IL) nor in metal-to-ligand charge transfer (d(Pt) → π*(dppy), MLCT) transitions. As the sulfido moiety is a good σ-donor, it is likely that the low-energy emitting state arises from states bearing a large amount of ligand-to-metal charge transfer (LMCT) character characteristic of the platinum–sulfur core.[3a] However, for complexes **1** and **2** we cannot exclude the possibility that the emission originates from silver-centered d-s/S → Ag LMCT. In contrast to $[Pt_2(\mu\text{-}S)_2(dppy)_4]$ and complex **2**, complex **1** also emits at about 560 nm in the solid state and in EtOH/MeOH glass. The band at 560 nm may arise from the Ag_3/Ag–S or the Pt–Ag metal-centered cluster core. Silver thiocarbamate clusters have been shown to exhibit low-temperature emissive behavior at similar energies, thought to originate from metal-centered cluster d-s/LMCT.[12] Interestingly, $[Pt_2(dppy)_4(\mu_3\text{-}S)_2Cu_2(dppm)](PF_6)_2$, a complex related to **2**, emits at about 695 nm at 77 K in the solid state.[13] The red shift in emission energy relative to that of **2** may be suggestive of an emitting state bearing a large sulfur-to-metal LMCT character. Assuming that the first quasireversible oxidation couple of **2** at +0.53 V and the first irreversible oxidation wave of **1** at +0.66 V (vs the ferrocenium–ferrocene couple) are metal-centered in nature, excited state reduction potentials $E^\circ(\{Pt_2Ag_2\}^{3+/2+*})$ and $E^\circ(\{Pt_4Ag_3\}^{4+/3+*})$ of about −1.09 and −0.96 V, respectively, versus the saturated calomel electrode (zero spectroscopic energy $E_{o-o} \approx 2.00$ eV) are estimated.

Preliminary work shows that **2** reacts photochemically with alkyl halides.[14] Comparison of the relative quantum yields using a series of structurally related alkyl halides such as CBr_4, $CHBr_3$, and their chloro analogues shows that the reactivity appears to follow the trend of the reduction potentials of the halides. This suggests a photoredox mechanism for the reactions.

[14] The photoreactivity studies were performed by irradiating degassed samples of **2** (4×10^{-4} mol L^{-1}) with various alkyl halides (in the concentration range of 0.05–0.85 mol L^{-1}) in acetone with an Oriel 200 W mercury (xenon) lamp equipped with a water lens to remove IR radiation and a UV cutoff filter to allow only light of $\lambda > 350$ nm to pass through. The UV/Vis spectral changes during the course of the reaction were monitored by using a Hewlett-Packard HP8452A diode array spectrophotometer. Comparison of the relative quantum yields using a series of structurally related alkyl halides revealed the following trend in reactivity: $CBr_4 \gg CHBr_3 \geq CCl_4 \gg CHCl_3 \approx CH_2Br_2 \approx CH_2Cl_2$.

Synthesis and Characterization of the Novel Iron Carbonyl Tellurium Chloride Cluster $[Fe_2(CO)_6(\mu\text{-}Cl)(\mu\text{-}TeCl)_2]_2[\eta^2,\mu_2,\mu_2\text{-}Te_2Cl_{10}]$, and Its Decomposition to the Zintl Ion Complex $[Fe_2(CO)_6(\eta^2, \mu_2,\mu_2\text{-}Te_4)(\mu\text{-}TeCl_2)]$**

Jeffrey R. Eveland and Kenton H. Whitmire*

Dedicated to Professor Dr. Herbert W. Roesky on the occasion of his 60th birthday

Clusters comprising transition metal carbonyls and phosphanes with heavy chalcogenide main group elements have been studied in several groups, particularly in the last decade. This work has shown these types of compounds to have a very rich and varied chemistry, and compounds of new structural types continue to be produced.[1] The types of compounds observed have ranged from simple complexes and small clusters[2-5] through polynuclear clusters with large cage structures.[6] In addition, some very novel complexes of polychalcogenide (Zintl) ions with transition metals have been produced in recent years.[1d, e] However, such compounds containing intact chalcogenide–halogen bonds have been conspicuously absent, with the exception of one recent report.[7] In an attempt to oxidize the square-pyramidal cluster $[Te_2Fe_3(CO)_9]$ to a cationic species which would be isoelectronic to the known Group 15 compound $[Bi_2Fe_3(CO)_9]$.[8] we studied its reactivity toward SO_2Cl_2 and $SOCl_2$, which are known to oxidize main group centers.[9] Rather than oxidation to $[Te_2Fe_3(CO)_9]^{2+}$, we observed a complex halogenation reaction that gave some very interesting new compounds. Here we report the synthesis and structural characterization of the iron carbonyl tellurium chloride cluster **1**, and its decomposition to the complex **2**, which contains both a novel dibridging Te_4 unit and a linear $TeCl_2$ moiety.

$[Fe_2(CO)_6(\mu\text{-}Cl)(\mu\text{-}TeCl)_2]_2[\eta^2,\mu_2,\mu_2\text{-}Te_2Cl_{10}]$ **1**

$[Fe_2(CO)_6(\eta^2,\mu_2,\mu_2\text{-}Te_4)(\mu\text{-}TeCl_2)]$ **2**

The reaction of $[Te_2Fe_3(CO)_9]$ (**3**) with SO_2Cl_2 (or $SOCl_2$) in CH_2Cl_2 gives **1** cleanly. It may be isolated as an orange solid in 89% yield based on Te and 40% based on Fe, indicating that tellurium is the limiting agent in the reaction. Compound **1** is reasonably stable in solution, and may be recrystallized from CH_2Cl_2 by cooling a concentrated solution to $-20\,^{\circ}C$, or by solvent diffusion with hexanes. Allowing a solution of **1** to stand for a week to ten days gives complex **2** as a crystalline orange solid in 73% yield based on Te and 44% based on Fe. Complex **2** dissolves in CH_3CN, but is extremely unstable in solution; the half-life is approximately three minutes. It is, however, stable over long periods of time in the solid state. Carbon monoxide analyses of compounds **1** and **2** gave results consistent with the formulas derived from the crystal structure determinations.[10] The ^{13}C NMR spectrum of **1** at room temperature shows two resonances for the carbonyl ligands ($\delta = 204.1$ and 194.8) with relative peak areas of approximately 1:2, respectively. These resonances are within the expected regions for carbonyl ligands in cluster molecules, but the resonance at about $\delta = 195$ is at very high field for CO ligands bound to iron. These signals are quite sharp, indicating that little or no exchange of the carbonyl ligands in the two environments takes place at room temperature. Attempts to obtain ^{125}Te spectra were unsuccessful, probably due to the presence of the quadrupolar Cl nuclei, but fluxional processes cannot be ruled out.

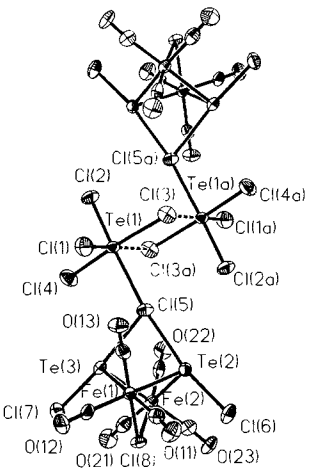

Fig. 1. Crystal structure of **1** showing 50% probability thermal ellipsoids and the atom labeling scheme. Important bond lengths [Å] and angles [°]: Te(1)–Cl(1) 2.343(2), Te(1)–Cl(2) 2.341(2), Te(1)–Cl(3) 2.716(2), Te(1)–Cl(3A) 2.858(2), Te(1)–Cl(4) 2.376(2), Te(1)–Cl(5) 2.829(2), Te(2)–Cl(5) 2.857(2), Te(2)–Cl(6) 2.401(2), Te(3)–Cl(5) 2.860(2), Te(3)–Cl(7) 2.409(2), Te–Fe av 2.604(2), Fe–Cl(8) av 2.334(2); *cis* Cl-Te(1)-Cl av 89.98(8), *trans* Cl-Te(1)-Cl av 176.11(7), Te(1)-Cl(5)-Te(2) 171.35(9), Te(1)-Cl(5)-Te(3) 114.10(7), Te(2)-Cl(5)-Te(3) 73.63(5), Te-Fe-Te av 82.26(4), Te-Fe-Cl(8) av 84.17(6), Cl(5)-Te(2,3)-Cl av 171.92(7), Fe-Te-Fe av 75.70(4), Fe(1)-Cl(8)-Fe(2) 86.41(6).

The solid-state structure of **1** (Fig. 1)[10a] consists of two $[\{Fe_2(CO)_6(\mu\text{-}Cl)(\mu\text{-}TeCl)_2\}]^+$ units, linked by coordination of the two μ-Te atoms to a chloro ligand of the $[Te_2Cl_{10}]^{2-}$ complex ion, producing an unusual triply bridging chloride ion (Cl(5)). The iron centers have approximate octahedral coordination, while the tellurium atoms have a coordination environment which may best be described as trigonal bipyramidal; a stereochemically active lone pair of electrons occupies an equatorial site. The terminal chloro ligands are tilted slightly away from the cluster core and toward Cl(5), giving a smaller Cl-Te-Cl(5) angle (av 171.92(7)°). The most likely cause of this effect is steric repulsions between the terminal chloro ligands and the carbonyl ligands on the iron centers. The coordination around Te(1) is very nearly octahedral; only very slight distortions are observed. Octahedral coordination by halogeno ligands is observed for tellurium in many of its complexes,[11] but this type of arrangement has not been observed in molecular organo-transition metal compounds, although some very interesting main group tellurium chloride compounds in which the Te has square-pyramidal geometry have been reported.[12] Te(1) retains a lone pair of electrons which does not appear to be stereochemically active but may exert an influence on the Te–Cl bond lengths. The Te–Fe (av 2.604(2) Å)[2-5] and Fe–Cl (av 2.334(2) Å)[13] distances are within the expected range.

The angles around Cl(5) are unusual in that the angles are severely distorted from the anticipated pyramidal configuration. The Cl atom resides in a planar environment (sum of angles at Cl(5) = 359.1°), but the angles are very asymmetric, as can be seen in Figure 1. The most remarkable feature is the nearly linear Te(1)-Cl(5)-Te(2) angle, which may result from repulsions between the cluster unit and the other chloro ligands on the $[Te_2Cl_{10}]^{2-}$ group.

The Te–Cl bond lengths to the terminal chloro ligands in the cluster unit (Te(2)–Cl(6) and Te(3)–Cl(7)) are within the normal bonding range (av 2.405 Å),[11, 14] as are those for the chloro ligands terminally bound to the tellurium atoms of the central $[Te_2Cl_{10}]^{2-}$ unit (av 2.353(2) Å). The Te(1)–Cl(3) and Te(1)–Cl(3a) distances are much longer (2.716(2) and 2.858(2) Å, respectively). The observed asymmetry in these bonds is not surprising, since bridging ligands are quite often

[**] The authors wish to thank the National Science Foundation and the Robert A. Welch foundation for financial support of this research.

unequally shared between the two centers; however, one of the contacts under such circumstances is usually a normal bonding length. The greater length of the two bonds here may be caused by the presence of a lone pair of electrons on Te(1). Nearly equal sharing of the chloro ligands between the two tellurium centers is an effect also observed in other inorganic halides of tellurium. The distances between the Te atoms and the μ_3-chloro ligand Cl(5) are also long and nearly equal; only the Te(1)–Cl(5) distance is slightly shorter (2.829(2) Å) than the others (av 2.859(2) Å).

Compound **1** contains many more chloro ligands than may be accounted for by the reaction stoichiometry relative to SO_2Cl_2, so it is clear that the halogenated solvent, CH_2Cl_2, plays a key role in the production of this cluster. The fate of the methylene unit of the solvent molecule was not traced in the reaction. The structural relationship between the starting cluster $[Te_2Fe_3(CO)_9]$ and **1** gives no obvious indication of the mechanism of this reaction, but in spite of the loss of a considerable amount of iron (detected spectrophotometrically as $FeCl_2$), most of the tellurium in the starting material is retained in the isolated product. Similarly, the mechanistic route in the transformation from **1** to **2** by necessity involves the loss of chloro ligands and some iron species, perhaps through the initial dissociation of the central $[Te_2Cl_{10}]^{2-}$ ion from the cluster.

Compound **2** exists in the solid state[10b] as discrete molecules; two crystallographically unique molecules are present per asymmetric unit (Fig. 2). These molecules are very similar in

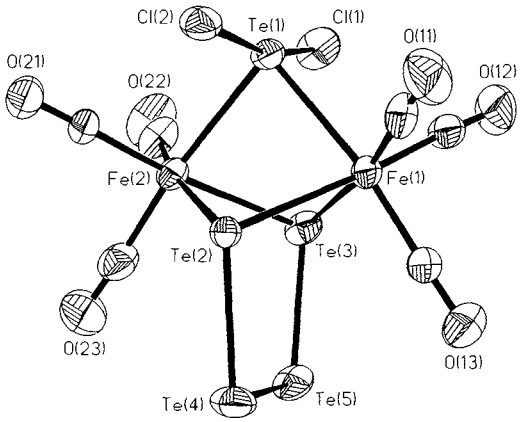

Fig. 2. Crystal structure of **2** showing 50% probability thermal ellipsoids and the atom labeling scheme. Important bond distances [Å] and angles [°]: Te–Fe av 2.624(2), Te(2)–Te(4) 2.744(2), Te(3)–Te(5) 2.730(2), Te(4)–Te(5) 3.738(2), Te(1)–Cl(1) 2.549(4), Te(1)–Cl(2) 2.705(3), Fe-Te-Fe av 81.94(7), Fe-Te(1)-Cl(1) av 96.2(1), Fe-Te(1)-Cl(2) av 92.94(9), Cl(1)-Te(1)-Cl(2) 167.9(1), Te(2)-Te(4)-Te(5) 99.12(5), Te(3)-Te(5)-Te(4) 96.26(5), Te(1)-Fe-Te av 81.08(7), Te(2)-Fe-Te(3) av 82.83(6). For the other unique molecule in the asymmetric unit, the values are: Te–Fe av 2.618(2), Te(7)–Te(9) 2.734(1), Te(8)–Te(10) 2.739(1), Te(9)–Te(10) 2.740(2), Te(6)–Cl(3) 2.579(3), Te(6)–Cl(4) 2.662(3), Fe-Te-Fe av 81.46(6), Fe-Te(6)-Cl(3) av 94.86(9), Fe-Te(6)-Cl(4) av 92.65(9), Cl(3)-Te(6)-Cl(4) 170.0(1), Te(7)-Te(9)-Te(10) 98.85(4), Te(8)-Te(10)-Te(9) 96.79(5), Te(6)-Fe-Te av 81.38(6), Te(7)-Fe-Te(8) av 83.33(5)

structure, but some bond lengths and angles differ by slightly more than 3σ. There are two $[Fe(CO)_3]^+$ fragments doubly bridged by a $[Te_4]^{2-}$ unit and also bridged by an unusual $TeCl_2$ moiety. An unusual feature of this complex is the presence of both oxidized ($TeCl_2$) and reduced (Te_4^{2-}) tellurium. The bridging $TeCl_2$ unit has a trigonal-bipyramidal arrangement of electron pairs with the lone pair occupying an equatorial site, as observed for the iron-bound tellurium atoms in **1**. Since the Te center of the $TeCl_2$ unit apparently retains lone pairs of electrons, it is best considered as Te^{4+} and serves as a one-electron donor to each iron atom. Each iron atom attains an 18-electron configuration without formation of an Fe–Fe bond.

The square Te_4 unit bridges symmetrically between the two iron centers through two terminal atoms of the ring. The Te-Te-Te angles in the Te_4^{2-} chain (av 97.69(5)°) are slightly larger than 90°, which is normal for a metal-bound E_4 unit as has been established in a number of mononuclear complexes. The Te–Te distances within the Te_4 unit are within the normal range for a metal-bound tellurium ring[15] and are all approximately equal within experimental error. To our knowledge, the only other compounds reported to have an E_4 unit bridging two metals are $[Cp^*_2M_2(\mu\text{-Se})(\eta^2,\mu_2,\mu_2\text{-Se}_4)]$ (M = Co, Rh; Cp* = C_5Me_5).[16]

The Cl-Te-Cl angle is nearly linear (167.9(1)°) and the Te-Cl distances are quite asymmetric. For the first molecule in the asymmetric unit, one Te–Cl distance is similar to that observed in inorganic tellurium chlorides,[11,13] but the other (Te(1)–Cl(2)) is considerably longer. The lengths of the Te–Cl distances in the second molecule (2.579(3) and 2.662(3) Å) show less asymmetry. There are no short intermolecular contacts under about 3.8 Å which could account for this effect.

The coordination spheres around the iron atoms are quite regular; the angles are very near to 90° (av 93.1(7)°). Te–Fe bond parameters (av 2.624(2) Å) are within the range normally observed for bridging tellurium–iron bonding interactions.

Experimental Procedure

1: $[Te_2Fe_3(CO)_9]$ (1.50 g, 2.22 mmol) was weighed into a Schlenk flask and dissolved in CH_2Cl_2 (80 mL). SO_2Cl_2 (0.36 mL, 4.5 mmol, 0.60 g) was added by syringe, and the solution stirred for one hour. The deep orange solution was then filtered through diatomaceous earth and the solvent removed in vacuo. The solid was washed with Et_2O (3 × 20 mL) and dried under vacuum to give analytically pure **1** (yield 1.25g, 89% based on Te). The solid was recrystallized by dissolution in CH_2Cl_2 (30 mL) and cooling at −20 °C for two days, giving bright orange platelike crystals of **1**. Compound **1** is soluble in THF, CH_2Cl_2, and CH_3CN, partially soluble in acetone, and insoluble in hexanes, diethyl ether, and toluene. The compound is unstable in strongly coordinating solvents such as CH_3CN. IR (ν(CO) [cm^{-1}], CH_2Cl_2): 2115 (w), 2101 (vs), 2085 (w), 2072 (m), 2049 (ms). ^{13}C NMR (62.90 MHz, CD_2Cl_2, 295 K): δ = 204.1, 194.8 (s, CO). Analysis of CO content by digestion of compounds with $[C_6H_5NH]Br_3$ in CH_2Cl_2 and subsequent quantitation of liberated CO with a Toepler pump. Anal. calcd. for **1**: 1.08 mmol CO; found: 1.07 mmol CO.

2: **1** (0.500 g, 0.528 mmol) was weighed into a Schlenk flask and dissolved in CH_2Cl_2 (30 mL). The solution was allowed to stand for one week at room temperature, yielding a mixture of deep orange block-shaped crystals of **2** and a black powder. The powder was partially removed by swirling the solution followed by decanting the fine powder suspension. This was repeated several times with fresh CH_2Cl_2 to give nearly pure **2**. The crystals were separated manually from the remainder of the dark powder to give analytically pure **2** (yield 0.227 g, 73% based on Te). Compound **2** is insoluble in all common organic solvents except CH_3CN, but is extremely unstable in solution. IR (ν(CO) [cm^{-1}], CH_3CN): 2075 (vs), 2036 (m). Analysis of CO content by digestion of compounds with $[C_6H_5NH]Br_3$ in CH_2Cl_2 and subsequent quantitation of liberated CO with a Toepler pump. Anal. calc. for **2**. 0.82 mmol CO; found. 0.80 mmol CO.

Formation of Stable DNA Loops by Incorporation of Nonpolar, Non-Hydrogen-Bonding Nucleoside Isosteres**

Xiao-Feng Ren, Barbara A. Schweitzer, Charles J. Sheils, and Eric T. Kool*

Hairpin loops are ubiquitous structures found in folded RNA and DNA sequences in nature. Recent reports have noted special stability for certain loop sequences. For example, RNA tetranucleotide loops (tetraloops) having the sequence GNRA and UUCG are more stable than other tetraloops and are highly conserved in nature.[1, 2] DNA tetraloops having the sequence GAAA, in certain contexts, are unusually stable in duplex DNA;[3] in triplex structures the loop sequence CTTTG has been reported to be especially stable as well.[4] In most or all of these cases, structural study has either implicated or identified intraloop hydrogen bonds between bases and/or phosphates as important structural features. It has long been recognized, however, that hydrogen bonds in aqueous solution are weak. In this regard a detailed study of hydrogen bonding in the GAAA tetraloop in RNA concluded that single hydrogen bonds contribute relatively little to the overall stability.[5] While less well understood, base stacking is also known to be at least as important a contribution to nucleic acid stability as hydrogen bonding.[6–8] Studies of loop structures in RNA and DNA have not generally addressed the relative importance of base stacking and hydrogen bonding in stabilizing such loops.

We have undertaken a program to design and synthesize non-hydrogen-bonding nucleoside analogues to be used as probes of the biological noncovalent interactions of oligonucleotides and nucleic acids in general.[9] We now describe the incorporation of three such isosteres into DNA loops, and we have found that such substitutions can lead to significant stabilization of double- and triple-helical folded structures in DNA.

Nucleosides **1** (F), **2** (B), and **3** (D) were designed to act as nearly perfect isosteres for the natural nucleosides thymidine (T) and deoxyadenosine (A) (Fig. 1). However, in contrast to the natural nucleosides, analogues **1**–**3** have little or no hydrogen bonding capability.[9] Compounds **1**–**3** are considerably more hydrophobic and less polar than the natural structures, and evidence from dangling-base studies in our laboratory indicate that they are more efficient at base stacking as well.[9b, 10] To test the effects of their properties on folded DNA structures, we incorporated **1**–**3** at loop positions into DNA hairpin-forming sequences and evaluated the thermal and thermodynamic stabilities of the folded structures.

Nucleosides **1**–**3** were synthesized by using previously described methods.[9] The primary products of coupling of the bases of **1** and **2** with the α-chlorodeoxyribose toluoyl ester synthon are α-anomers,[11] which were converted to β-anomers by acid-catalyzed epimerization.[11b] Compounds **1**–**3** were unknown previous to our reports, although two other substituted indole nucleoside derivatives have recently been described.[12] The coupling of **1**–**3** in oligodeoxynucleotides using standard phosphoramidite chemistry was efficient, with stepwise yields of >95% (trityl cation monitoring). For comparison we also syn-

[a] Conditions: 100 mM NaCl, 10 mM phosphate (pH 7.0); DNA concentration: 5.0 μM. The sequences with the natural nucleotides are the same as those described in ref. [13]. Data shown are averages; error limits are given in parentheses.

thesized analogous sequences containing the corresponding natural nucleosides at the same positions (see Tables 1 and 2).

We first studied the effects of **1** (F), **2** (B), and **3** (D) in a duplex DNA hairpin loop, by using two self-complementary sequences of eight base pairs bridged by a tetranucleotide loop consisting of four identical residues. Previous studies of this sequence by Breslauer et al.[13] showed that, of sequences containing A_4, C_4, G_4, and T_4 loops, the most stable was the T_4 case, and the least stable, the A_4 case. We studied the properties of sequences containing F_4, B_4, and D_4 loops, and we synthesized the natural T_4 and A_4 analogues for comparison.

Table 1 shows data obtained for the duplex hairpin sequences. Buffer conditions were pH 7.0 (10 mM phosphate) with 100 mM NaCl. All five sequences gave melting transitions that were independent of concentration, confirming the expected hairpin structure as opposed to intermolecular complexes. The data show that the modified hairpin sequences containing **1** (F) and **2** (B) are significantly more stable than the T_4 analogue. The melting temperature (T_m) for the modified F_4 sequence, which contains difluorotoluene nucleosides, is 78.5 °C, or 10.8 °C higher than that of the T_4 loop structure, which is the most stable tetraloop containing four identical natural nucleosides.[13] The four hairpin structures with natural nucleosides (A_4, T_4, C_4, G_4) have T_m values lying in a narrow range between 62 and 68 °C.[13] Free energy values obtained by curve fitting show that the modified loop containing **1** is thermodynamically more stable than the most stable natural loop (the T_4 loop) (Table 1). Similarly, the B_4 hairpin sequence, with trimethylphenyl nucleosides, is almost as stable as the sequence with the F_4 loop.

Interestingly, just as the pyrimidine isosteres give more stable loops than a natural pyrimidine, we find that the purine analogue **3** is more stabilizing than its deoxyadenosine counterpart ($\Delta T_m = 4.5$ K). As was reported by Breslauer et al.,[13] we find that the T_4 loop is more stabilizing than the A_4 loop. Moreover, we find that the nonnatural pyrimidine isosteres **1** and **2** are more stabilizing than the purine isostere **3**. This difference in the natural hairpin structures has been attributed to cross-loop hydrogen bonding. Since in the nonnatural cases this difference cannot be due to hydrogen bonding, it seems likely that steric differences in the pyrimidine and purine analogues may play an important role both in the natural and nonnatural cases.

Because the nonpolar thymidine isostere **1** was found to be the better stabilizing of the two analogues and because it is the best isosteric substitution, we tested it in a triple helix bridging loop. Such folded triplex-forming oligonucleotides are finding increasing use as ligands for single-stranded nucleic acids.[14] The stability of the loops in such a complex depends largely on the nature of the first and last bases in the loop.[4] The nucleoside **1** was therefore placed at these positions in a pentanucleotide loop bridging the pyrimidine strands in an eight-base triplex. For comparison we synthesized the natural T_5-bridged triplex (see Table 2). We examined both 5'- and 3'-type loop orientations[4] at pH 7.0 with 100 mM NaCl and 10 mM $MgCl_2$.

The nonpolar nucleoside **1** gives complexes that are both thermally and thermodynamically more stable than structures containing the natural nucleosides (Table 2). For example, the hydrophobic nucleoside F gives complexes that are 4.8–5.4 K more thermostable than the T,T-substituted oligonucleotides, and

[a] Conditions: 100 mM NaCl, 10 mM $MgCl_2$, 10 mM Na-PIPES (pH 7.0); DNA concentration: 2.0 μM per strand. Errors: ±5 °C in T_m and ± 10% in free energy.

free energies are 1.8–2.2 kcal mol^{-1} more favorable. Previous studies carried out with natural bases in this loop[4] have shown that the T,T case is intermediate in stability; the C,C loop is the least stable and the G,G loop the most stable. The G,G loop was found to be more stable than the T,T analogue by 1.5 kcal mol^{-1}.[4] Thus our F,F loop is more stable than all four cases doubly substituted with the natural bases.

Previous studies have described the use of simple nonnucleotide linkers as loop replacements in nucleic acids.[15] Such loops are often less stabilizing than natural nucleotide loops; this may be due both to the greater rigidity of nucleotide loops relative to the highly flexible nonnucleotide linkers and to favorable base stacking interactions in natural loops, which are missing in simple linkers. The nucleoside analogues in this study are designed to stabilize nucleic acid helices as a result of both rigidity and base stacking. In contrast to natural DNAs, loops containing nucleosides **1**–**3** have the added advantage of being resistant to degradation by nucleases (data not shown). In addition, such nonpolar nucleosides have been shown to pair with low affinity and low specificity with natural sequences[9b] and thus would not interfere with the expected pairing in biological systems.

The present results on the incorporation of hydrophobic nucleoside analogues in oligonucleotide loops show that in general these compounds are significantly stabilizing. Because they do not undergo measurable hydrogen bonding interactions,[9b] it would seem that the best explanation for this behavior is superior base stacking propensity. This suggests a general strategy for stabilizing nucleic acid complexes containing loops: the use of arenes instead of natural bases, especially at positions adjacent to the helix, where stacking interactions are expected to make the greatest contributions. Although the present compounds cannot form stabilizing cross-loop hydrogen bonds, they may have favorable hydrophobic or van der Waals interactions. Detailed structural and physical studies will be necessary to investigate the specific origins of this stability.

Experimental Procedure

Epimerization of α-anomers of **1a** and **2a** (bis-*p*-toluoyl esters) to β-anomers.

1a: To a solution of the α-anomer of the bis-*p*-toluoyl ester of compound **1a** (synthesis described in ref. [9a]) (780 mg, 1.62 mmol) in toluene (50 mL) was added a catalytic amount of benzenesulfonic acid (ca. 10%), one drop of concentrated H_2SO_4, and two to four drops of H_2O. The reaction mixture was stirred vigorously at reflux for 4–6 h, and the mixture was then poured into 5% aqueous $NaHCO_3$ (50 mL) and extracted with EtOAc (3 × 50 mL). The combined organic layers were dried over anhydrous $MgSO_4$ and concentrated to dryness. Silica column chromatography (eluent 8/1 → 2/1 hexanes/EtOAc) of the crude mixture gave 430 mg of **1a** (β-epimer, 46% yield). ^{1}H NMR ($CDCl_3$): δ = 8.02 (2H, d, J = 8.0 Hz), 7.97 (2H, d, J = 8.0 Hz), 7.30–7.37 (1H, m, obscured), 7.31 (2H, d, J = 8.0 Hz), 7.25 (2H, d, J = 8.0 Hz), 6.75 (1H, dd, J = 8.0, 8.0 Hz), 5.64 (1H, br d, J = 5.8 Hz), 5.47 (1H, dd, J = 5.1, 10.8 Hz), 4.78 (1H, dd, J = 3.8, 11.8 Hz), 4.66 (1H, dd, J = 3.7, 11.8 Hz), 4.54 (1H, m), 2.64 (1H, m), 2.46 (3H, s), 2.43 (3H, s), 2.23 (1H, m), 2.17 (3H, s); ^{13}C NMR ($CDCl_3$): δ = 13.8 (d), 22.0 (d), 40.1, 64.9, 74.9, 83.0, 103.0 (t), 120.1 (d), 124.5 (d), 127.3 (d), 128.6, 128.8 (d), 128.9 (d), 144.0 (d), 156.5 (d), 158.0 (d), 155.9 (d), 162.3 (d), 166.1 (d); HRMS (FAB, 3-nitrobenzyl alcohol matrix, M + H$^+$): calcd for $C_{28}H_{26}F_2O_5$ 481.1827, found 481.1853.

2a (β-epimer, 54% yield). ^{1}H NMR ($CDCl_3$): δ = 8.02 (2H, d, J = 8.0 Hz), 7.97 (2H, d, J = 8.0 Hz), 7.30–7.37 (1H, m, obscured) 7.32 (2H, br d, J = 10.7 Hz), 7.31 (2H, br d, J = 11.2 Hz), 7.24 (1H, s), 6.95 (1H, s), 5.65 (1H, br d, J = 5.6 Hz), 5.42 (1H, dd, J = 5.0, 10.8 Hz), 4.76 (1H, dd, J = 3.9, 11.8 Hz), 4.70 (1H, dd, J = 3.6, 11.8 Hz), 4.55 (1H, m), 2.56 (1H, m), 2.46 (3H, s), 2.43 (3H, s), 2.31 (3H, s), 2.23 (3H, s), 2.18 (1H, m), 2.13 (3H, s); ^{13}C NMR ($CDCl_3$): δ = 18.2, 19.5, 22.1 (d), 41.0, 65.0, 82.5, 126.2, 127.0 (d), 128.6 (d), 128.8 (d), 132.1 (d), 135.5, 136.2, 141.4, 144.5, 165.5, 166.0; HRMS (FAB, 3-nitrobenzyl alcohol matrix, M^+): calcd for $C_{30}H_{32}O_5$ 472.2250, found 472.2234.

Conversion of nucleoside bis-*p*-toluoyl esters of **1a**, **2a** to phosphoramidite derivatives **1c**, **2c**: The hydrolysis of the bis-*p*-toluoyl esters, subsequent conversion to 5′-O-dimethoxytrityl derivatives, and 3′-O-phosphitylation in preparation for automated DNA synthesis were carried out by using the same methods previously described for the α-isomers [9b]. Analytical data for these compounds were in complete accord with their assigned structures [11b].

Oligonucleotide synthesis: DNA oligonucleotides were synthesized on an Applied Biosystems 392 instrument by using standard β-cyanoethylphosphoramidite chemistry [16]. Methods for deprotection, tritylation, and phosphitylation of nucleosides **3a**–**c** were as described previously [9b]. Oligomers were purified by preparative gel electrophoresis with 20% denaturing polyacrylamide (detection at 260 nm). Molar extinction coefficients for sequences containing the natural nucleosides were calculated by the nearest neighbor method [17]. The molar extinction coefficients measured for nucleosides **1**, **2**, and **3** were 1200, 851, and 6362, respectively; molar absorptivities for oligonucleotides containing these residues were derived as previously described [9b]. Oligodeoxynucleotides were obtained after purification as the sodium salts. Intact incorporation of residues **1**–**3** was confirmed by synthesis of short oligomers of sequence 5′-T-X-T (where X = **1**, **2**, or **3**). The ^{1}H NMR spectra (500 MHz) indicated the presence of the intact aromatic ring structures with the expected integration relative to thymine C-5 protons and methyl groups. Enzymatic degradation analysis could not be performed because the nonnatural residues were found to inhibit enzymatic cleavage.

Thermal denaturation studies: Buffers used for optical melting experiments were 100 mM NaCl, 10 mM Na-phosphate (for duplex hairpins) or 100 mM NaCl, 10 mM $MgCl_2$, 10 mM Na-PIPES (1,4-piperazine(bisethanesulfonate)) (for triplexes). The buffer pH is that of a 1.4x stock solution at 25 °C containing the buffer and salts. After the solutions were prepared they were heated to 90 °C and allowed to cool slowly to room temperature prior to the melting experiments.

The melting studies were carried out in Teflon-stoppered quartz cells (1 cm pathlength) under nitrogen atmosphere on a Varian Cary 1 UV/Vis spectophotometer equipped with a thermoprogrammer. Absorbance was monitored at 260 nm while temperature was increased at a rate of 0.5 °C min^{-1}; a slower heating rate with this instrument does not affect the results. In all cases the complexes displayed sharp, apparently two-state melting transitions. Melting temperatures (T_m) were determined by computer fit of the first derivative of absorbance with respect to $1/T$. Uncertainty in individual T_m values is estimated at ±0.5 K. Free energy values were derived by computer-fitting the denaturation data with an algorithm employing linear sloping baselines by using the two-state approximation for melting [7]. Uncertainty in individual free energy measurements is estimated at ±5 to 10%.

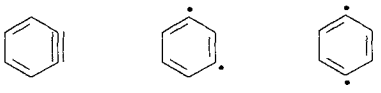
1,3-Didehydrobenzene (*m*-Benzyne)**

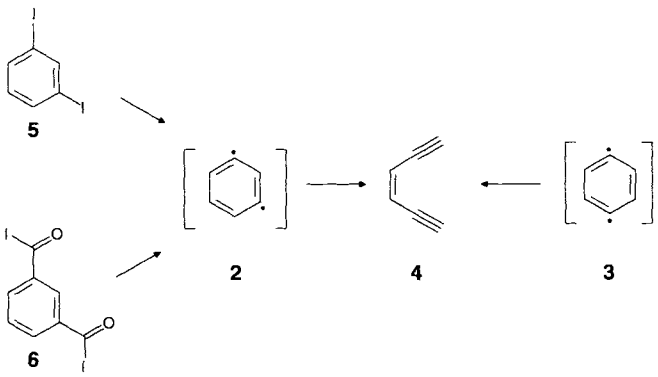
Ralph Marquardt, Wolfram Sander,* and Elfi Kraka*

Of the three isomeric didehydrobenzenes, only 1,2-didehydrobenzene (**1**) has been characterized unequivocally by direct spectroscopic methods.[1] The only derivative of **2** that has been characterized by matrix IR spectroscopy is 2,4-didehydrophenol.[2] Early reports on the UV/Vis spectroscopic characterization of **2** and **3** are questionable, since the reaction conditions and reported properties suggest that a more stable isomer, such as enediyne **4**, was observed.



1 **2** **3**

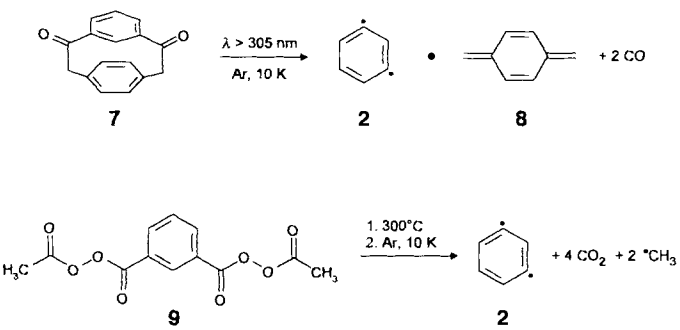
A barrier of only 19.8 kcal mol^{-1} was determined for the ring opening of **3** by Roth et al.,[3] which compares well with barriers of 19.4 and 20.5 kcal mol^{-1} for this reaction calculated at the CCSD(T) level of theory by Kraka and Cremer.[4, 5] Flash vacuum pyrolysis of both 1,3-diiodobenzene (**5**)[6] and isophthaloyl diiodide (**6**)[7] produced **4** as the principal product, which suggests that **2** also undergoes thermal ring opening to give **4** (Scheme 1).



Scheme 1. Thermochemistry of 1,3-diiodobenzene (**5**) and isophthaloyl diiodide (**6**).

Squires et al. determined the heats of formation of the arynes **1**–**3** from collision-induced dissociation measurements to be 106.6 ± 3.0, 122.0 ± 3.1, and 137.3 ± 3.3 kcal mol^{-1}, respectively.[8, 9] These thermodynamic data have been confirmed by Kraka and Cremer [4, 5] and Lindh et al.[10] using high-level ab initio methods. Here we describe the matrix isolation and IR spectroscopic characterization of 1,3-didehydrobenzene (**2**), generated from two independent precursors.

UV photolysis ($\lambda > 305$ nm) of matrix-isolated[11] [2.2]metaparacyclophane-2,9-dione (**7**)[12] results in the formation of carbon monoxide, *p*-xylylene (**8**),[13] and a new compound with an intense IR absorption at 547 cm^{-1} and several weak absorptions (Scheme 2, Table 1). The new compound was stable toward prolonged irradiation at 248 nm, and based on the comparison of the IR spectrum obtained experimentally with the ab initio calculated IR spectrum (vide infra) it was assigned the structure of **2** (Fig. 1).



Scheme 2. Photochemistry of [2.2]metaparacyclophane-2,9-dione (**7**) and thermochemistry of isophthaloyl diacetyl peroxide (**9**).

Flash vacuum pyrolysis (300 °C) of isophthaloyl diacetyl peroxide (**9**)[14] with subsequent trapping of the products in argon at 10 K produced carbon dioxide and methyl radicals (Scheme 2).[15] In addition, the same intense IR absorption at 547 cm^{-1} assigned to **2** was observed. Annealing of the matrix at 30–35 K resulted in the loss of the methyl radicals and a simultaneous decrease in intensity of the absorptions assigned to **2**. In solid argon at temperatures above 30 K the diffusion of

[a] Number of calculated vibrations (ab initio); only vibrational frequencies with relative intensities (I) greater than 1 are listed. [b] Calculated frequencies are unscaled. [c] Relative intensities based on the most intense band (100). [d] Symmetry of vibrations obtained from the calculated spectrum. [e] The assignment of experimental and calculated vibrations is based on band positions and relative intensities. [f] Because of overlapping bands, only one CH stretching absorption could be identified. Note that $\tilde{\nu}_{24}$ scaled with 0.92 yields a value of 3026 cm^{-1}.

small molecules (such as CH_3) is rapid, and thus radical recombinations become possible. We were not able to identify the products formed during annealing the matrix; however, this method allowed for the identification of several weak absorptions of **2**.

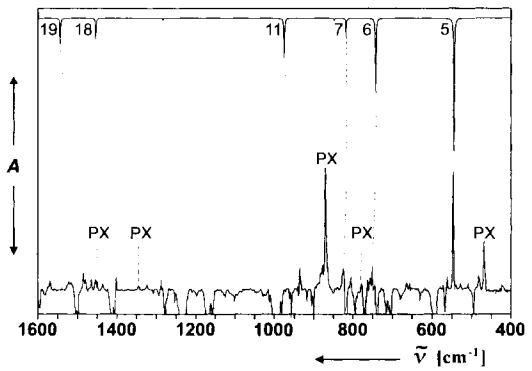

Fig. 1. Bottom: IR difference spectrum showing the photolysis ($\lambda > 305$ nm, argon, 10 K) of matrix-isolated [2.2]metaparacyclophane-2,9-dione (**7**). Bands of **7** which disappear upon irradiation point downwards; bands of **2** and **8** which appear upon irradiation point upwards; PX: bands assigned to *p*-xylylene (**8**). Top: IR spectrum of **2** calculated at the CCSD(T)/6-31G(d,p) level.

Energy and geometry of **2** (Fig. 2) were determined at the CCSD(T)/6-31G(d,p) level of theory using analytical energy gradients.[4, 5] According to these calculations **2** is a planar distorted hexagon. The CCSD(T) method is known to provide a reliable description of the energetics of dehydrobenzenes[4, 5] as well as of the vibrational spectrum of 1,2-didehydrobenzene (**1**).[1 6] It should be noted that despite previous claims, neither HF, GVB(1), and MP2, nor CCSD lead to a reasonable description of the vibrational spectrum of dehydrobenzenes, which is due to the necessity of both large dynamic correlation corrections and a significant coverage of multireference effects in these cases.

In the presence of other didehydrobenzenes, **2** can be identified by the strong ring deformation motion at 547 cm^{-1}, which in the cases of the *o*- and *p*-isomer appears in the IR spectrum at 470 (exp. 472) and 727 cm^{-1}, respectively.[1 6] Comparison of the IR spectrum calculated at the CCSD(T) level of theory with the IR spectra of the decomposition products of **7** and **9** allows for the identification of several weak absorptions due to **2**

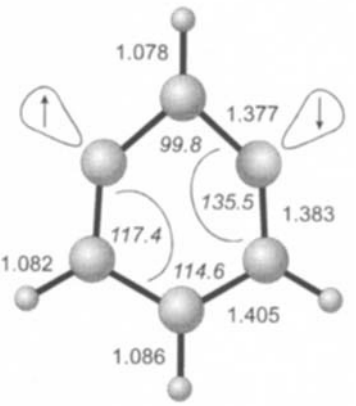

Fig. 2. CCSD(T)/6-31G(d,p) geometry, heat of formation ΔH_f, and dipole moment μ of **2**. Bond lengths in Å, bond angles (in italics) in degrees.

(Table 1, Fig. 1), which result from CH wagging (824 and 751 cm^{-1}, Table 1) as well as ring stretch and CH deformation motions (936, 1402, 1486 cm^{-1}, Table 1). Depending on the overlap with bands from other molecules (**8**, etc.), these absorptions can be also used to identify **2**.

In conclusion, we have synthesized *m*-benzyne from two precursors and characterized this species spectroscopically for the first time. The experimental and theoretical IR spectra are in excellent agreement and demonstrate that IR spectra of diradicals with limited multireference character can be calculated with experimental accuracy at the CCSD(T) level of theory.

Synthesis and Structure of Gallium Siloxane Cages: Model Substances for Gallium-Containing Silicates**

Andreas Voigt, Ramaswamy Murugavel, Emilio Parisini, and Herbert W. Roesky*

Dedicated to Professor Kurt Dehnicke on the occasion of his 65th birthday

Silicates are used as catalysts in a number of industrial processes.[1–3] The breakthrough of zeolites, in particular, into technical applications is due to their easily variable characteristics such as form-selectivity, acidity, and temperature stability. The acidity, and the catalytic properties associated with it, can be altered by isomorphic substitution of Si or Al atoms of the zeolite lattice with other elements. In general, these solids have only been characterized by X-ray powder diffraction. As a result, the local structure at the catalytic center is not known. It is therefore appropriate to use model compounds in order to describe this structure more clearly.[4–9]

Titanium-containing zeolites (TS1 and TS2) are employed in oxidation reactions such as the epoxidation of olefins and the oxidation of nonactive hydrocarbons.[10–13] The synthesis of model compounds for titanium-containing zeolites would make it possible to throw light on the catalytically active species.[7, 9]

Gallium-containing zeolites are used as dehydrogenation catalysts.[1] Successful dehydrogenation of C2 to C5 alkanes occurs with Ga-theta-1-zeolite.[14] Other catalysts (Ga-ZSM-5, 30 Ga MFI) afford aromatic products in high yields upon the dehydrocyclization reaction of propene.[15, 16]

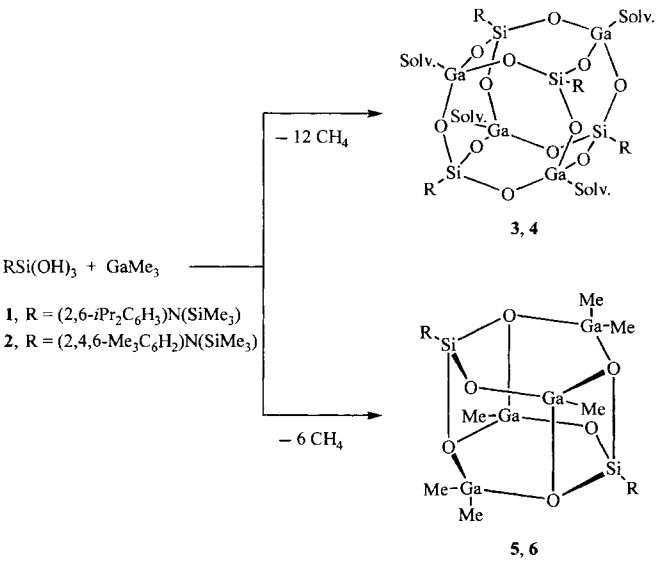
[**] This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Bundesministerium für Bildung und Forschung, and the Hoechst AG. R. M. thanks the Alexander von Humboldt Foundation and E. P. the European Union for postdoctoral stipends (ERB CHBG 940731).

Our work concentrates on the synthesis of heterosiloxanes as model compounds for metal-containing zeolites.[6–9, 17] We report here on the synthesis of soluble gallium siloxane cages and the first single crystal X-ray structure determination of such a species.

Several methods have been described for the synthesis of gallium siloxanes.[18, 19] The most favorable are the addition of silanolates or silanols to gallium trichloride or the reaction of silanols with alkylgallium compounds. As has been shown by the synthesis of aluminum siloxanes, the reaction of alkylaluminum compounds with silanetriols, accompanied by elimination of alkane, is a simple and elegant method to obtain aluminum siloxanes.[8, 20, 21] Therefore, **1** and **2** were allowed to react with trimethylgallium. Depending on the stoichiometry used, the gallium siloxanes **3**, **4**, **5**, and **6** could be obtained (Scheme 1). They are soluble in common organic solvents (diethyl ether, THF, *n*-hexane, toluene).

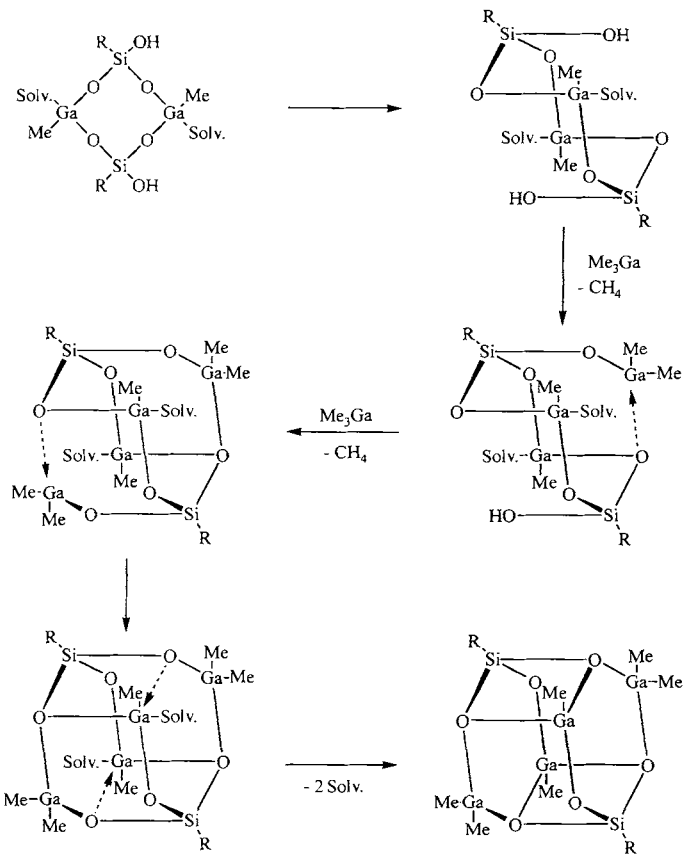


Scheme 1. Synthesis of **3**–**6** from **1** and **2**. Solv. = 1,4-dioxane.

The compounds **3** and **4** were formed on addition of one equivalent of trimethylgallium to a suspension of **1** or **2**, respectively, in *n*-hexane/1,4-dioxane (10/1). A donor solvent is necessary for this reaction, and methane is spontaneously released during the addition. In order to carry the reaction to completion, the mixture is heated at reflux until gas evolution ceases. Single crystals for an X-ray structure analysis have not yet been obtained for either compound **3** or **4**. They are both very soluble in common organic solvents (diethyl ether, THF, toluene, pentane) and have been fully characterized by IR and NMR spectroscopy, mass spectrometry, and elemental analysis. The IR spectra show no free OH bands, and the signals in the mass spectrum can be unambiguously assigned. Furthermore, the ^{1}H NMR spectra show one signal each[22] for the protons of the 1,4-dioxane molecule coordinated to the Ga atom. The relative intensity (1/1) of the signals for the silanetriol ligand and the dioxane enables the unequivocal determination of the number of Ga atoms. For **3** and **4** we assume a cubic ground structure, which has also been found in compounds formed by the reaction of silanetriols with alkylaluminum compounds.[8, 21]

When **1** and **2** are allowed to react with trimethylgallium in a 1:2 molar ratio in *n*-hexane/1,4-dioxane (10/1), the compounds **5** and **6**, respectively, are obtained. The framework of these polyhedra shows a Si–Ga ratio of 1:2. During the synthesis of the two

different structures (**3**,**4** and **5**,**6**), a white solid is observed which could not be isolated. We suppose that an eight-membered Ga-O-Si ring with free OH groups on the Si atoms is first formed. This is insoluble in the reaction mixture and therefore precipitates out.[23] In the formation of **5** and **6** the ring presumably folds and reacts with a further equivalent of trimethylgallium, finally forming **5** and **6** (Scheme 2).



Scheme 2. Postulated reaction pathway for the synthesis of **5** and **6**. Solv. = 1,4-dioxane.

Suitable single crystals of **5** and **6** were obtained at room temperature within several hours from a mixture of *n*-hexane/THF (5/1). The X-ray structure analyses of **5** and **6** show $Ga_4O_6Si_2$ polyhedra, which can be described as six-sided prisms. The basic surfaces consist of six-membered Ga_2SiO_3 rings, which are connected to each other by four oxygen atoms—two from each ring. All the six-membered rings are in a boat configuration. In contrast, the four-membered rings are completely planar. As the bond lengths and angles in **5** and **6** are very similar, only the structure of **5** will be described here (Fig. 1).

Compound **5** shows two Si–O bonds of different lengths; the longer of the two (1.670 Å) is part of the four-membered ring. Likewise, two Ga–O bond lengths can be detected. The η^3-Ga–O bonds (1.96 Å) are considerably longer than the η^2-Ga–O bonds (1.82 Å). This difference affects the angle in the polyhedron: the expected tetrahedral angle at the Si atom is reduced to 94.2°. The angles at the μ^3 oxygen atom are also smaller (94°), whereas the tetrahedral angles at the Ga atoms vary over a wide range (77.2–129.1°). Especially noticeable is the positioning of the two Si atoms, the two N atoms the Ga atoms (Ga1, Ga1A) and the O atoms (O1, O1A). They all lie in a plane, which is perpendicular to the plane formed by the atoms Ga2, Ga2A, O1, O1A, O2, and O2A.

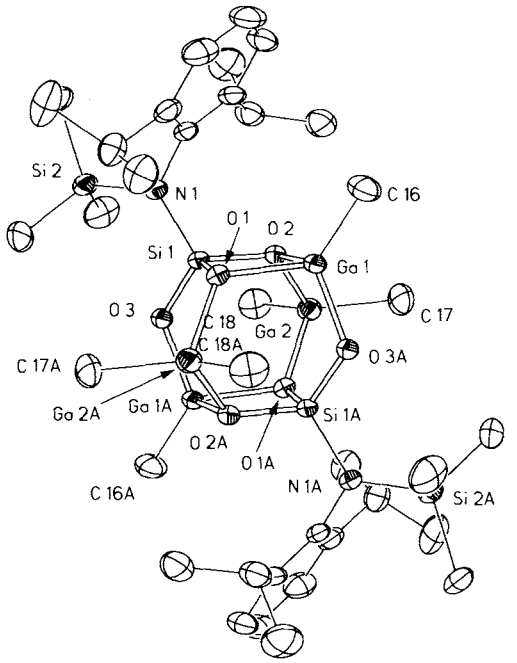


Fig. 1. Structure of **5** in the crystal. Selected bond lengths [Å] and angles [°]: Si1-O1 1.668(2), Si1-O2 1.671(2), Si1-O3 1.599(2), Ga1-O1 1.957(2), Ga1-O2 1.960(2), Ga1-O3A 1.824(2), Ga2-O1A 1.966, Ga2-O2 1.973(2); O1-Ga1-O2 77.24(8), O1-Ga1-O3A 103.38(9), O2-Ga1-O3A 103.15(9), O2-Ga2-O1A 92.37(9), C17-Ga2-C18 129.1.

The synthesis and structural characterization of the gallium siloxane compounds presented here provide an important contribution towards explaining the bonding in these systems. The Si–N and the Ga–C bonds are easy to cleave hydrolytically, which makes these molecules promising precursors for the synthesis of gallium-containing silicates under the mild conditions used for sol–gel techniques.

Experimental Procedure

3 and **4**: A solution of $GaMe_3$ (3.00 mmol) in *n*-hexane (5 mL) was slowly added at room temperature to a suspension of **1** [24] or **2** [24] (3.00 mmol) in *n*-hexane (30 mL) and 1,4-dioxane (3 mL). Afterwards the reaction mixture was stirred for 10 min at room temperature and then heated at reflux for 1 h. Compounds **3** and **4** were obtained in quantitative yields upon removal of the volatiles in vacuum. **3**: M.p. 205–211 °C; ^{1}H NMR (200 MHz, C_6D_6): δ = 0.08 (s, 36H, Si(CH_3)$_3$), 1.18 (m, 48H, CH(CH_3)$_2$), 3.45 (m, 8H, CH(CH$_3$)$_2$), 3.70 (s, 32H, OCH_2), 7.05 (m, 12H, aromat.); ^{29}Si NMR (50 MHz, C_6D_6): δ = −77.9 (s, SiO_3), 3.5 (s, $SiMe_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 1497, 1318, 1250, 1182, 1052, 971, 905, 840, 802, 754, 688, 597 cm^{-1}; MS(EI): *m*/*z*: 1928 [M^+]; elemental analysis: $C_{76}H_{136}Ga_4N_4O_{20}Si_8$; calcd. C 47.34, H 7.05, N 2.90; found C 47.0, H 6.8, N 3.1. **4**: M.p. 198–202 °C; ^{1}H NMR (200 MHz, C_6D_6): δ = 0.26 (s, 36H, Si(CH_3)$_3$), 2.01 (s, 12H, CH_3), 2.11 (s, 24H, CH_3), 3.30 (s, 32H, OCH_2), 6.65 (s, 8H, aromat.); ^{29}Si NMR (50 MHz, C_6D_6): δ = −76.8 (s, SiO_3), 5.0 (s, $SiMe_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 1606, 1303, 1258, 1214, 1153, 1049, 971, 889, 840, 800, 754, 589, 470 cm^{-1}; MS(EI): *m*/*z*: 1730 [M^+ − 2CH$_3$]; elemental analysis: $C_{60}H_{104}Ga_4N_4O_{20}Si_8$; calcd. C 42.26, H 6.15, N 3.29; found C 41.9, H 6.4, N 3.3.

5 and **6**: A solution of $GaMe_3$ (6.00 mmol) in *n*-hexane (5 mL) was quickly added at room temperature to a suspension of **1** or **2** (3.00 mmol) in *n*-hexane (30 mL)/1,4-dioxane (3 mL). The solution was then heated at reflux. During the reaction a white solid precipitates out. The reaction mixture was heated for an additional hour until a clear solution was obtained. Within 12 h crystals were formed that were suitable for single-crystal X-ray structure analysis. Further concentration of the solutions provided **5** and **6** in nearly quantitative yields. **5**: M.p. 223–227 °C; ^{1}H NMR (400 MHz, C_6D_6): δ = − 0.62 (s, 6H, Ga(CH_3)), 0.15 (s, 12H, Ga(CH_3)$_2$), 0.30 (s, 18H, Si(CH_3)$_3$), 1.21, 1.26 (d, ^3J(H,H) = 6.9 Hz, 24H, CH(CH_3)$_2$), 3.65 (sept, ^3J(H,H) = 6.9 Hz, 4H, CH(CH$_3$)$_2$), 7.05 (m, 6H, aromat.); ^{29}Si NMR (50 MHz, THF, C_6D_6): δ = − 65.4 (s, SiO_3), 6.7 (s, $SiMe_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 1321, 1253, 1515, 1186, 1076, 1025, 959, 933, 843, 810, 743, 689, 544 cm^{-1}; MS(EI): *m*/*z*: 1018 [M^+]; elemental analysis: $C_{36}H_{70}Ga_4N_2O_6Si_4$; calcd. C 42.49, H 6.88, N 2.75;

found C 42.1, H 7.0, N 3.1. **6**: M.p. 255–258 C; ^{1}H NMR (200 MHz, C_6D_6): $\delta = -0.52$ (s, 6H, Ga(CH_3)), 0.14 (s, 12H, Ga(CH_3)$_2$), 0.27 (s, 18H, Si(CH_3)$_3$), 2.08 (s, 6H, CH_3), 2.34 (s, 12H, CH_3), 6.78 (s, 4H, aromat.); ^{29}Si NMR (50 MHz, C_6D_6): $\delta = -66.9$ (s, SiO_3), 8.7 (s, $SiMe_3$); IR (KBr, Nujol): $\tilde{\nu}$ = 1302, 1208, 1150, 1015, 989, 956, 892, 822, 723, 629, 546, 465 cm^{-1}; *MS(EI)*: *m/z*: 919 [$M^+ - CH_3$]; elemental analysis: $C_{30}H_{58}Ga_4N_2O_6Si_4$; calcd. C 38.58, H 6.26, N 3.00; found C 38.4, H 6.3, N 3.0.

Crystal structure data for **5**: $C_{36}H_{70}Ga_4N_2O_6Si_4$, M_r = 1018.18, triclinic, space group $P\bar{1}$, a = 10.233(2), b = 10.298(2), c = 13.975(3) Å, α = 94.20(3), β = 104.58(3), γ = 117.68(3), V = 1230.7(4) Å^3, Z = 1, ρ_{calcd} = 1.374 g cm^{-3}, $F(000)$ = 528, λ = 0.71073 Å, T = 193(2) K, $\mu(Mo_{K\alpha})$ = 2.30 mm^{-1}. The intensities were measured by a Stoe-Siemens-AED four-circle diffractometer on a crystal with the dimensions 0.50 × 0.30 × 0.25 mm^3 in the range of $5 \leq 2\theta \leq 50$ using the Learnt Profile Method [25]. From the 4342 collected reflections 4339 were independent, and 4329 were used in the structure refinement. $R1 = \sum|F_o - F_c|/\sum F_o$ = 0.0395($F > 4\sigma F$), $wR2 = [w(F_o^2 - F_c^2)^2/\sum wF_o^4]^{1/2}$ = 0.1295 (total data) for $w^{-1} = \sigma^2(F_o^2) + (g_1 \times P)^2 + (g_2 \times P)$ with $P = (F_o^2 + 2F_c^2)/3$ and g_1 = 0.0754 and g_2 = 0.9659; minimum/maximum residual electron density: 1.072/−1.294 eÅ^{-3}. Crystal structure data for **6**: $C_{30}H_{58}Ga_4N_2O_6Si_4$, M_r = 934.02, monoclinic, space group $P2_1/n$, a = 11.484(2), b = 12.707(3), c = 15.674(3) Å, β = 107.71(3)°, V = 2178.9(7) Å^3, Z = 2, ρ_{calcd} = 1.424 g cm^{-3}, $F(000)$ = 960, λ = 0.71073 Å, T = 193(2) K, $\mu(Mo_{K\alpha})$ = 2.59 mm^{-1}. The intensities were measured by a Stoe-Siemens-AED four-circle diffractometer on a crystal with the dimensions 0.60 × 0.30 × 0.20 mm^3 in the range $5 \leq 2\theta \leq 50$ using the Learnt Profile Method.[25] From the 4627 collected reflections 3820 were independent and 3819 were used in the structure refinement. $R1 = \sum|F_o - F_c|/\sum F_o$ = 0.0384($F > 4\sigma F$), $wR2 = [w(F_o^2 - F_c^2)^2/\sum wF_o^4]^{1/2}$ = 0.1260 (total data) for $w^{-1} = \sigma^2(F_o^2) + (g_1 \times P)^2 + (g_2 \times P)$ with $P = (F_o^2 + 2F_c^2)/3$ and g_1 = 0.0495 and g_2 = 2.1870; minimum/maximum residual electron density: 0.706/−0.642 eÅ^{-3}. Both structures were solved by direct methods (SHELXS-90) [26] and refined with all data by the least squares fit method on F^2 (SHELXL-93) [27]. All non-hydrogen atoms were anisotropically refined. The hydrogen atoms were added in idealized positions and included in the refinement. Crystallographic data (excluding structural factors) for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-1 and CCDC-179-2. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, GB-Cambridge CB2 1EZ, UK (Fax: Int. code +1223/336-033; e-mail: teched@chemcrys.cam.ac.uk).

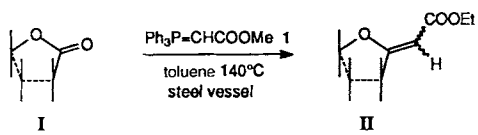
Wittig Olefination of Lactones

Mohammed Lakhrissi and Yves Chapleur*

The formation of carbon–carbon double bonds from carbonyl compounds by the Wittig reaction and its variants,[1] or Peterson olefination,[2] has become an invaluable method in organic synthesis. However, enol ether formation from an ester by olefination has hardly been reported. Carbonyl groups of esters are much less reactive in the Wittig reaction than those of aldehydes or ketones, and only a few cases dealing with intramolecular reactions of this type have appeared.[3] More recently the Tebbe methylenation of lactones and esters has been described.[4] Several applications to the synthesis of C-methylene glycosides have been reported.[5]

Direct olefination at the anomeric center of sugars is an interesting way to introduce a carbon chain, which can be in turn chemically manipulated. We have been interested in such a transformation for several years now and have developed the dichloroolefination of lactones and esters using phosphorus-based chemistry.[6] This new reaction on ester carbonyl groups led to interesting developments in carbohydrate chemistry such as stereocontrolled methylation and methylenation of the anomeric center.[7, 8] However, a direct route from lactones **I** to C-glycosylidene compounds **II** (Scheme 1) remains to be found.



I **II**

Scheme 1.

In an effort to open such a new route, we investigated the direct Wittig olefination of esters by stabilized phosphoranes and now report our preliminary results. Some C-glycosylidene sugars such as **II**, a precursor of chiral cyclopentanones, have been prepared by a stepwise procedure.[9]

We reasoned that by analogy with the dichloromethylenation reaction of lactones, which proceeds at room temperature for aldehydes and ketones but needs to be performed at higher

temperature on lactones, the reaction of a lactone with a stabilized phosphorane should require more drastic conditions than those routinely used for aldehydes and ketones.

Attempts to treat methoxycarbonylmethylene(triphenyl)-phosphorane **1** with lactone **2** at reflux in tetrahydrofuran or toluene failed completely. However heating a toluene solution of these compounds at 140 °C in a sealed vessel for 24 hours gave an excellent yield of the expected olefins (*E*)-**3** and (*Z*)-**3** as a 1.6:1 mixture (Entry 1 in Table 1). The structure of these olefins was clearly established by mass spectrometry and ^1H and ^{13}C NMR spectroscopy. The configuration at the double bond was tentatively assigned on the basis of the chemical shifts of the vinylic (H-2) and H-4 protons (octitol numbering; *E* isomer: $\delta = 5.5$ and 5.75, respectively; *Z* isomer: both protons appear between $\delta = 5.0$ and 5.1). The difference in chemical shifts observed for the vinylic protons in the *E* and *Z* isomers ($\Delta\delta \approx 0.5$) fits well with the values observed for the vinylic protons in 1-C-methylene glycosides.[8]

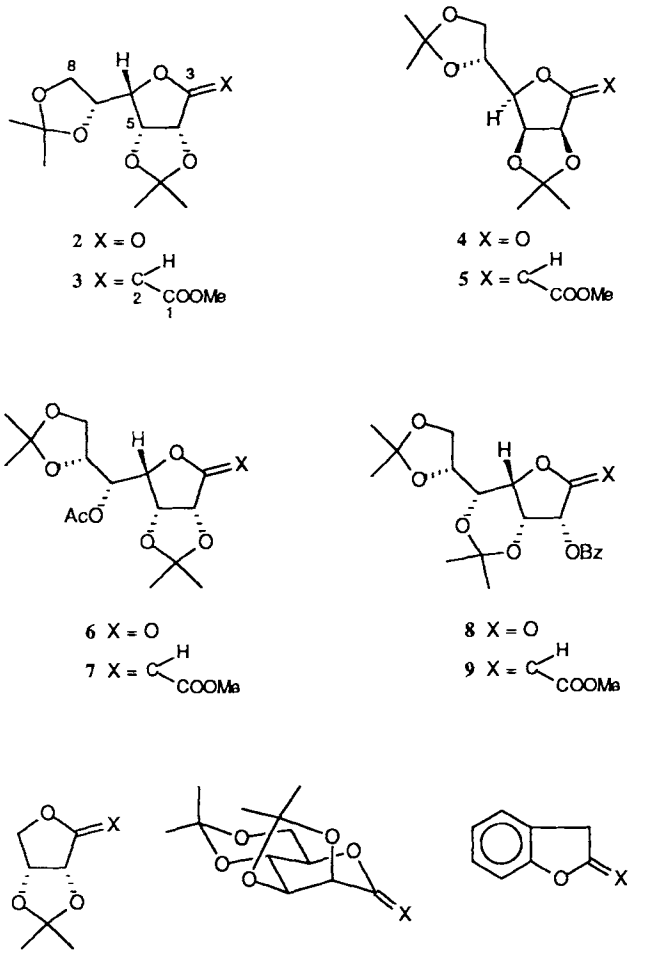

Table 1. Wittig olefinations of lactones.

Entry	Starting material	Product	*E*/*Z* ratio	*t* [h]	Yield [%]
1	**2**	(*E*)-**3**, (*Z*)-**3**	1.6:1	24	90
2	**4**	(*E*)-**5**, (*Z*)-**5**	1.1:1	24	80
3	**6**	(*E*)-**7**, (*Z*)-**7**	1.4:1	16	69
4	**8**	(*E*)-**9**		48	27
5	**10**	(*E*)-**11**, (*Z*)-**11**	1:1	17	56
6	**12**	(*E*)-**13**, (*Z*)-**13**	3:1	15	71
7	**14**	(*E*)-**15**		4	58

The reaction proceeded equally well for the mannono-1,4-lactone **4**, which gave a mixture of (*E*)-**5** and (*Z*)-**5** in a 1.1:1 ratio (Entry 2). It is noteworthy that this Wittig reaction tolerates the presence of an acetate group remote to the lactone carbonyl of compound **6** (Entry 3). The reaction was also possible with a lactone having a benzoate group at C-2 such as in compound **8**. A single olefinic compound (*E*)-**9** was isolated albeit in low yield (Entry 4). However, the acetate analogue of **8** could not be efficiently transformed into olefins and led to numerous products. We had previously demonstrated that the presence of esters at position 2 of a lactone was also troublesome in the dichloromethylenation reaction. Finally the six-membered ring lactone **12** derived from D-mannose was treated under the same conditions and gave a 3:1 mixture of olefins (*E*)-**13** and (*Z*)-**13** as seen from NMR data (Entry 6). Another interesting reaction was the alkylidenation of lactone **14** which gave olefin (*E*)-**15** as a single isomer in 58% yield together with another yet unidentified side-product.

The reaction of D-ribono-1,4-lactone derivatives protected at the primary position either with an acetate or a methoxy methyl ether failed. Tetra-*O*-benzyl-D-gluconolactone also failed to react under these conditions and was recovered unchanged. These failures should be explained by the steric hindrance induced on both faces of the lactone ring by the protective groups at C-2 and C-5/C-6 of the starting lactone.

In conclusion, this new application of the Wittig reaction proceeds with poor stereochemical control of the double bond configuration with 1,4-lactones, whereas a better stereocontrol was observed with a 1,5-lactone. Although it is still limited to bicyclic sugar lactones, interesting results have been obtained with an aromatic lactone. Further studies are currently underway to determine the scope and limitations of this reaction with other substrates and using other Wittig reagents. Obviously the olefins obtained in this way might be extremely useful starting compounds to access a variety of highly functionalized C-glycosides by subsequent 1,4-addition, reduction etc.

Experimental Procedure

Typical synthesis: (*E*)-**3**/(*Z*)-**3**: A solution of the lactone **2** (258 mg, 1 mmol) and the triphenylphosphorane **1** (670 mg, 2 mmol) in toluene (10 mL) was placed in a standard stainless steel vessel under an argon atmosphere and heated for 24h at 140 °C. After cooling, the solvent was removed under vacuum, and the residue was taken up in dichloromethane and placed on a silica gel column. Elution with a 3:2 mixture of hexane/ethyl acetate gave analytically pure olefins (*E*)-**3** and (*Z*)-**3**. (*E*)-**3**: 170 mg, 56%; $[\alpha]_D^{20} = -108$ ($c = 0.3$, $CHCl^3$); $\nu_{max} = 1716$, 1666 cm^{-1}; ^1H NMR ($CDCl_3$, 250 MHz, octitol numbering, see formula): $\delta = 1.40$ (s, 6H, $2CH_3$), 1.47 (s, 6H, $2CH_3$), 3.70 (s, 3H, OCH_3), 3.75 (dd, $J(8,8') = 9$, $J(7,8) = 6.5$ Hz, 1H, H-8), 4.18 (dd, $J(5,6) = 4.5$, $J(6,7) = 8$ Hz, 1H, H-6), 4.25 (dd, $J(7,8') = 7.5$ Hz, 1H, H-8'), 4.42 (m, 1H, H-7), 4.74 (dd, $J(4,5) = 6.5$ Hz, 1H, H-5), 5.54 (d, $J(2,4) = 1.5$ Hz, 1H, H-2), 5.78 (dd, 1H, H-4); ^{13}C NMR: $\delta = 25.24$ (CH_3), 26.01 (CH_3), 26.61 (CH_3), 26.93 (CH_3), 51.03 (OCH_3), 65.66 (C-8); 75.21, 76.49, 81.72, 87.43 (C-4 to C-7), 92.13 (C-2), 110.26, 114.46 ($2 \times C(CH_3)_2$), 165.57 (C-3), 168.54 (C=O); EI-MS: $m/z = 314$ ($M^{+\cdot}$), 299, 283, 243, 185, 167, 101, and 43.

(*Z*)-**3**: 106 mg, 34%; $[\alpha]_D^{20} = -139$ ($c = 0.2$, $CHCl_3$); $\nu_{max} = 1709$, 1659 cm^{-1}; ^1H NMR ($CDCl_3$, 250 MHz): $\delta = 1.35$ (s, 3H, CH_3), 1.38 (s, 3H, CH_3), 1.42 (s, 3H, CH_3), 1.45 (s, 3H, CH_3), 3.70 (s, 3H, OCH_3), 3.75 (dd, $J(7,8) = 6$, $J(8,8') = 9$ Hz, 1H, H-8), 4.12 (dd, $J(7,8') = 8$ Hz, 1H', H-8'), 4.44 (m, 2H, H-6,7), 5.12 (d, $J(2,4) = 1.5$ Hz, 1H, H-4), 4.65 (dd, $J(4,5) = 6$, $J(5,6) = 3$ Hz, 1H, H-5), 5.15 (dd, 1H, H-4); ^{13}C NMR: $\delta = 25.22$ (CH_3), 25.98 (CH_3), 26.58 (CH_3), 26.90 (CH_3), 50.98 (OCH_3), 65.64 (C-8), 75.18, 76.48, 81.69, 87.42 (C-4 to C-7), 92.08 (C-2), 110.26, 114.25 ($2 \times C(CH_3)_2$) 165.57 (C-3), 168.58 (C=O). EI-MS: m/z: 314 ($M^{+\cdot}$), 299, 243, 181, 167, 101, 43.

Superconductivity in Intercalated and Substituted $Y_2Br_2C_2$

Michael Bäcker, Arndt Simon,* Reinhard K. Kremer, Hans-Jürgen Mattausch, Richard Dronskowski, and Jean Rouxel

The superconductors $(RE)_2X_2C_2$ (RE = nonmagnetic rare earth element; X = Cl, Br, I) are model systems for an understanding of superconductivity in terms of chemistry.[1, 2] So far the yttrium compounds were investigated in detail.[3, 4]

The structures are characterized by planar slabs X-Y-Y-X with closest packing of the atoms in the slab and van der Waals forces between the X atoms of adjacent slabs. All octahedral voids within the Y–Y double layer are occupied by C_2 units.[5] $Y_2Cl_2C_2$ and $Y_2I_2C_2$ crystallize in a different structure type to $Y_2Br_2C_2$; the difference lies in the stacking sequence of the slabs. The monoclinic cells of the two types exhibit angles of $\beta \approx 93°$ (1s phase)[6] and $\beta \approx 100°$ (3s phase).

Within the Zintl–Klemm concept the chemical bonding is approximated by the formula $(Y^{3+})_2(X^-)_2C_2^{4-}$. However, due to C_2-π^* and Y-d mixing electron delocalization and conductivity in two-dimensions results. In contrast, the compound Y_2Br_2C $(Y_2^{3+})(Br^-)_2C^{4-}$ with a single C atom is a semiconductor as expected. According to our view, superconductivity of $Y_2X_2C_2$ is due to the tendency of pairwise occupation of quasimolecular C_2-π^* states at the Fermi level E_F, that is, a situation near to electronic localization. This assumption is corroborated by band structure calculations.[3]

Fundamentally, the electronic and, hence, the superconducting properties can be varied chemically in the following ways: I A change of the lattice dimensions by isoelectronic substitution leads to a variation in the degree of covalency in the C–Y bonds. The change can be performed a) in the center of the slab by substitution of Y by other (nonmagnetic) RE elements or b) in the periphery by exchange with the differently sized X atoms. II The Fermi level can be shifted relative to the C_2-π^* level by a) substitution of Y by Ca (lowering E_F) and Y by Th (raising E_F) within the slabs, or by b) intercalation of acceptors or donors into the gap between the slabs.

As detailed investigations with method Ib on $Y_2(Cl,Br)_2C_2$, $Y_2(Cl,I)_2C_2$ and $Y_2(Br,I)_2C_2$ show,[3, 7] the transition temperature T_c increases from 2.30 K for $Y_2Cl_2C_2$ to 5.05 K for $Y_2Br_2C_2$, has a maximum at 11.20 K for $Y_2Br_{0.4}I_{1.6}C_2$, and again decreases towards $Y_2I_2C_2$ (T_c = 9.85 K). It is interesting to note that the changes of the structure (1s → 3s → 1s form) are not reflected in the T_c values. This result indicates that the origin of superconductivity is to be sought in the central Y-C_2-Y part of the slab. Chemical changes introduced with methods Ib and IIb do not influence this central region significantly, whereas changes with Ia and IIa cause lattice defects in this part.

In particular, the intercalation of alkali metals (that is, route IIb) allows a well-defined variation of the carrier concentration in the $Y_2X_2C_2$ slab. As a complication the halides, in contrast to chalcogenides, intercalate only with difficulty.[8, 9, 10] A topochemical reaction is possible with a solution of sodium and potassium in THF in the presence of benzophenone and naphthalene, respectively.[11, 12] First results of intercalation reactions with $Y_2Br_2C_2$, which was chosen because of its well-defined superconducting transition, are summarized in Table 1.[13]

As expected, the incorporation of sodium in $Y_2Br_2C_2$ leads to an expansion along [001]. Moreover, a transition[15] from the 3s to the 1s phase is found. After the reaction with benzophenone sodium is complete at room temperature[16] the X-ray powder diagram shows only diffuse lines except for the narrow 00l reflections. Annealing of a pressed pellet at 400 °C for one week yields X-ray diagrams with reflections sufficiently sharp for a Rietveld refinement.[17] A projection of the structure of $Na_{0.23}Y_2Br_2C_2$[19] is shown in Figure 1. The sodium content

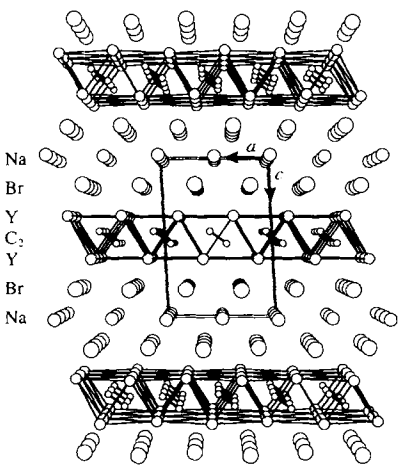

Fig. 1. Structure of $Na_{0.23}Y_2Br_2C_2$ as central projection along [010].

was determined by the refinement. The other phases $Na_xY_2Br_2C_2$ characterized in Table 1 were prepared by annealing of appropriate mixtures of $Na_{0.23}Y_2Br_2C_2$ and $Y_2Br_2C_2$. On the basis of lattice constants the product of the reaction of $Y_2Br_2C_2$ with naphthalenesodium contains more than 0.23 Na atoms per formula unit. However, an unambiguous refinement of the site occupancy factor for Na is not possible for this phase. The experiments give evidence for the increase of T_c by an injection of electrons into the $Y_2Br_2C_2$ slab. The degree of order is important, as an increased T_c after annealing of the samples clearly indicates.

When increasing E_F by partial substitution of Y^{3+} by Th^{4+} ions, disorder is introduced into the central part of the slab. As shown in Table 2,[13] T_c decreases with increasing Th content.

$Na_{0.12(1)}Y_2Br_2C_2$	Na/Bzph		5.90	7.020(1)	3.745(1)	10.349(1)	93.02(2)
$Na_{0.23(1)}Y_2Br_2C_2$	Na/Bzph	5.6	6.2	7.061(1)	3.724(1)	10.464(1)	92.96(1)
$Na_xY_2Br_2C_2$	Na/Naph	6.0		7.081(2)	3.727(1)	10.509(1)	92.83(2)

[a] Bzph = benzophenone, Naph = naphthalene. [b] As prepared. [c] Annealed.

Table 2. Lattice constants [Å] and transition temperatures T_c [K] of thorium yttrium carbide bromide and $Y_2Br_2C_2$.

Composition	T_c	a	b	c	β [°]
$Y_2Br_2C_2$	5.05	6.958(1)	3.767(1)	9.932(1)	99.97(1)
$Th_{0.1}Y_{1.9}Br_2C_2$	4.70	6.984(1)	3.772(1)	9.949(1)	100.05(1)
$Th_{0.2}Y_{1.8}Br_2C_2$	4.15	7.014(2)	3.774(1)	9.964(3)	100.09(2)
$Th_{0.3}Y_{1.7}Br_2C_2$	3.65	7.038(1)	3.776(1)	9.979(1)	100.29(1)
$Th_{0.4}Y_{1.6}Br_2C_2$	3.60	7.061(3)	3.776(1)	9.983(2)	100.36(1)

This result appears to contradict the intercalation experiment and must be interpreted in terms of an overcompensation effect. The T_c increase due to increased carrier concentration is outweighed by the T_c decrease due to the introduced disorder.

The corresponding substitution of Y by Ca has not yet been achieved.

[16] For intercalation reactions in the presence of benzophenone or naphthalene, benzophenone (130 mg, 0.71 mmol) and freshly cut sodium (50 mg, 2.2 mmol) or naphthalene (90 mg, 0.71) and sodium (30 mg, 1.3 mmol) were added to $Y_2C_2Br_2$ (200 mg, 0.55 mmol) in a 100 mL Schlenk flask. After introducing 40 mL freshly distilled THF, the mixture was stirred for 5 days at room temperature. The reaction mixture was filtered and washed several times with THF before the excess of agglomerated Na was removed. All operations were carried out under an inert atmosphere (argon). The color of the intercalated crystals intensifies from bronze ($Y_2C_2Br_2$) to deep copper red.
[17] X-ray powder diagrams were measured at room temperature with an INEL powder diffractometer (0.2 mm capillary; $Cu_{K\alpha1}$ radiation; $6.72° \geq 2\theta \geq 113.70°$; step rate 0.03°). Rietveld refinement was carried out with the program DBW 9006 [18] for two phases with YOBr as minority phase. The profile matching of the 3567 data points was performed with a pseudo-Voigt function and 19 parameters, of which 7 global (1 instrumental parameter, 5 profile parameter, 1 asymmetry parameter) and 11 + 1 local parameters (1 overall scale parameter, 1 parameter for preferred orientation, 4 for the lattice constants, 4 positional parameters, 1 site occupation parameter for $Na_{0.23}Y_2C_2Br_2$; 1 overall scale parameter for YOBr). Thermal vibrations were neglected. The C positions were calculated for $d(C-C) = 1.3$ Å and fixed. The residual values are $R_p = 0.076$, $R_{wp} = 0.105$ and $R_{Bragg}(I) = 0.057$ for $Na_{0.23}Y_2C_2Br_2$ and $R_{Bragg}(I) = 0.076$ for YOBr, the goodness of fit $GOF = 2.97$.
[18] D. W. Wiles, R. A. Young, *J. Appl. Crystallogr.* **1981**, *14*, 148.
[19] The obtained positions (lattice constants in Table 2) for $Na_{0.23}Y_2C_2Br_2$ in the space group $C2/m$ (No. 12) are Na in *2a* with site occupancy factor *SOF* of 0.116(6); Y in *4i* with $x = 0.3540(6)$, $z = 0.3680(3)$; Br in *4i* with $x = 0.6861(6)$, $z = 0.1780(3)$, and C in *4i* (not refined) with $x = 0.081$, $z = 0.470$. The sample contained 92.8(9)% $Na_{0.23}Y_2C_2Br_2$. The lattice and positional parameters for YOBr were taken from Ref. [20] and were not refined.

Stoichiometric Dependence of the Long-Established Reaction of Butyllithium with Pyridine: A Hidden Secondary Reaction That Produces a Pyridine Adduct of a Lithiodihydropyridine**

William Clegg, Lorraine Dunbar, Lynne Horsburgh, and Robert E. Mulvey*

Over 60 years ago Ziegler first recognized the value of alkyllithium compounds in converting pyridine to 2-alkyl-substituted derivatives.[1] However, only recently has the reactive intermediate in such processes, a solvated nitrogen–lithium adduct **1**, been isolated and studied directly.[2]. Examination of the adduct **1**[2] revealed that addition is accompanied by bis(pyridine) solvation of the nitrogen-attached metal center, which requires a *n*-butyllithium: pyridine ratio of 1:3. As reported here, by using more than a threefold molar excess of the heterocycle, we have uncovered a remarkable secondary reaction which, despite the age of and considerable attention given to this chemistry, had previously gone unnoticed. Formally the new reaction involves reduction of pyridine by lithium hydride, though it is certain that the conventional ionic solid does not form during the process. The isolated product **2**, characterized both in the crystal and in solution, is a novel bis(pyridine)-dihydropyridyllithium dimer.

Earlier work[2] established that the solid adduct **1** was susceptible to LiH elimination even at ambient temperature. Here, by preparing it in situ in hexane solution warmed to near boiling

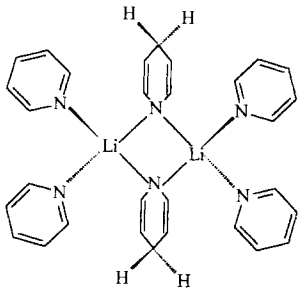
1



2

for three minutes, this process would presumably accelerate. Critically, however, the dark wine red solution still maintained its homogeneity (i.e., with no visible signs of LiH precipitation). The introduction of further pyridine at this stage (making seven equivalents overall per equivalent of *n*-BuLi) followed by allowing the solution to slowly cool from this elevated temperature, produced yellow-orange crystals of **2**.[3] This adduct is noticeably more robust than **1**, which begins to degrade immediately following isolation; **2** is stable indefinitely in the absence of air and moisture. The byproduct of this reaction is 2-*n*-butylpyridine. Significantly, no reaction was observed when a suspension of lithium hydride in pyridine (more than 15 molar equivalents in a small amount of hexane) was heated vigorously for five hours, reflecting the formidable barrier presented by the high lattice energy of the ionic solid.

The molecular constitution of **2** gives it the distinct advantage of being soluble in arenes, a property denied conventional lithium hydride because of its extended face-centred cubic lattice structure. ^{1}H NMR spectroscopic studies of **2** in [D_6]benzene[4] revealed a 1:1 mixture of 1,2-dihydro- and 1,4-dihydropyridyl anions as well as four normal pyridine molecules. Lithium tetrakis(*N*-dihydropyridyl)aluminate,[5] a reducing agent which exhibits novel selectivity towards certain ketones, is known to contain a similar mixture of dihydropyridyl anions, though they are reported to be bound to aluminum and not to lithium. Each distinct type of proton in **2** gives rise to an individual resonance signal in the ^{1}H NMR spectrum, generally well-separated from each other, thus making assignments straightforward.[4]

Consistent with this solution data, a dinuclear arrangement is found for crystalline **2** by an X-ray diffraction study.[6] This structure (Fig. 1) shows that the anions occupy the bridging positions, while the neutral ligands bind terminally, as is the norm in complexed lithium dimers. While other neutral ligands such as THF have occasionally been reported in bridging roles to lithium,[7] it is significant that to date no such cases have been found for pyridine. Two of the terminal pyridine ligands exhibit twofold disorder, but this could be resolved and refined with the assistance of restraints. The geometries of the terminal pyridine ligands compare favorably with those of the forty-four neutral pyridine ligands bonded to lithium (covering seventeen crystal structures) presently contained in the Cambridge Structural Database: the mean geometry in the database is shown in Figure 2.

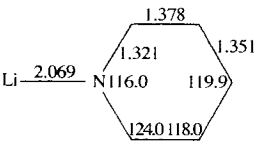


Fig. 2. Mean bond lengths [Å] and angles [°] in Li-bound pyridine ligands. The data were taken from the Cambridge Structural Database.

Though the two central N atoms (N(1), N(2)) bridge the Li centers they form slightly shorter bonds to lithium (mean length, 2.069 Å) than their terminal counterparts (mean length, 2.098 Å), reflecting the anionic nature of the central pyridine ligands. These bridging ligands have geometries consistent with 1,4-dihydropyridyl anions, as evidenced by a comparison with the structure of bis(1,4-dihydro-1-pyridyl)-bis(pyridine)zinc(II),[8] which also contains neutral, terminally bound pyridine ligands: in particular, the positions of the C=C double bonds [C24–C25, C21–C22 and C11–C12, C14–C15] are clearly indicated by the pattern in bond lengths (see legend to Fig. 1). Presumably, in view of the mixture of 1,2-dihydro- and 1,4-dihydropyridyl anions found in solution, the latter must crystallize preferentially in **2**.

One possible explanation for the formation of **2** is the intramolecular mechanism depicted in Scheme 1. The incoming "excess" pyridine molecule in solvating (or attempting to solvate) the Li^+ center sets up a six-membered cyclic intermediate. Hydride transfer then occurs driven by the electron-poor, $\delta+$ nature of the pyridine C atoms and aided by the electron-donating character of the 2-butyl substituent in **1**. Thus LiH never actually forms in this formal LiH reduction process. Complex **2** could undergo a similar elimination process but the absence of an electron-donating group in the 2-position—where two H atoms reside—makes it less favorable, hence the reason why **2** is more stable than **1**.

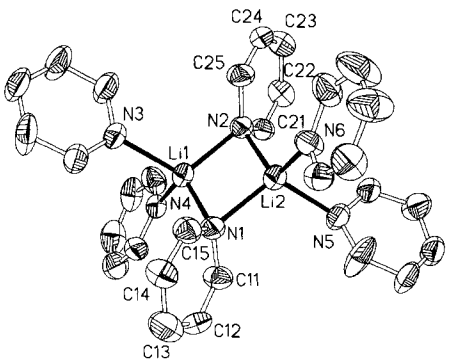

Fig. 1. Molecular structure of **2** with important atoms labeled (thermal ellipsoid plot (30% probability)). Hydrogen atoms and minor disorder components are omitted for clarity. Seleeted bond lengths [Å] and angles [°]: Li1-N1 2.070(10), Li1-N2 2.047(9), Li2-N1 2.088(10), Li2-N2 2.069(10), Li1-N3 2.104(9), Li1-N4 2.081(8), Li2-N5 2.106(10), Li2-N6 2.102(9); Li1-N1-Li2 74.8(3), Li1-N2-Li2 75.7(4), N1-Li1-N2 105.4(4), N1-Li2-N2 104.1(4), N3-Li1-N4 100.7(4), N5-Li2-N6 102.2(4); within bridging ligands: N-C 1.373(7)–1.412(7), C=C 1.288(8)–1.338(8), C-C 1.387(9)–1.453(10).

Experimental Procedure

2: The preparation was performed in a Schlenk tube under a dry argon blanket. *n*-Butyllithium (10 mmol in hexane) was added to a chilled volume of pyridine (30 mmol). The mixture was allowed to warm to ambient temperature, leading to an orange precipitate. Dissolution occurred on gently rewarming the mixture and additional pyridine (40 mmol) was then added. Immersing the solution in a water bath maintained at 50 °C led to the growth of transparent orange crystals of **2** [3]. Decomp. from 90 °C. Satisfactory C, H, Li, N analyses. Single crystals suitable for X-ray crystallography were examined and mounted under an inert oil.

[6] Crystal data for **2**: $C_{30}H_{32}Li_2N_6$, M = 490.5, orthorhombic, $Pna2_1$, a = 17.808(4), b = 10.849(2), c = 14.579(3) Å, V = 2816.6(10) Å^3, Z = 4, ρ_{calcd} = 1.157 g cm^{-3}, $\lambda(Cu_{K\alpha})$ = 1.54184 Å, μ = 0.535 mm^{-1}, $F(000)$ = 1040. Measurements were made at 160 K on a Stoe-Siemens diffractometer with an Oxford Cryostream cooler from a crystal of size 0.8 × 0.6 × 0.5 mm^3. Structure solution was by direct methods and refinement by full-matrix least squares on F^2. 2693 reflections measured, 2611 unique (R_{int} = 0.0147), 435 refined parameters, $wR2 = \{\sum[w(F_o^2 - F_c^2)^2] / \sum[w(F_o^2)^2]\}^{1/2}$ = 0.1958, conventional R = 0.0598 for F values of 2030 reflections having $F_o^2 > 2\sigma(F_o^2)$, goodness of fit S = 1.052 on F^2, largest peak hole 0.229 −0.168 e Å^{-3}. Twofold disorder of orientation was resolved and refined for two terminal pyridine ligands, with occupancy factors 0.771:0.229(8) and 0.52:0.48(2); relatively high displacement parameters for many of the carbon atoms indicates possible further unresolved disorder in the ligands. Restraints for similarity of geometry and on displacement parameters were applied to the terminal ligands to aid the disorder refinement, but the bridging ligands were refined freely. Hydrogen atoms were geometrically positioned and constrained with a riding model; other atoms were refined anisotropically. The absolute structure (polar axis direction) could not be reliably determined. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-4. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemerys.cam.ac.uk).

Diazodi(4-pyridyl)methane and Diazophenyl-(4-pyridyl)methane as Photoresponsive Ligands for Metal–Carbene Hetero-Spin Systems

Noboru Koga,* Yoichiro Ishimaru, and Hiizu Iwamura*

Diphenylcarbene with a triplet ground state has served as an important building block in the construction of molecules and molecular assemblies with high spin multiplicities.[1, 2] Thus the connection of n carbene units through *meta*-phenylene, 1,3,5-benzenetriyl, and other ferromagnetic coupling units gives rise to various polycarbenes with $S = n$ ground states; in the series the highest spin state reported so far is $S = 9$.[3] Efforts to increase the number of aligned spins have, however, been hampered by the development of antiferromagnetic intra- and/or interchain interactions between the carbene centers assembled in high local concentration; chemical bonds appear to be formed in the extreme case.[4] Our last recourse is a strategy of assembling carbene centers in a rigid polymeric metal complex. We report here on the ligation of the pyridyl nitrogens of diazodi-(4-pyridyl)methane (**1**) with coordinatively doubly unsaturated paramagnetic metal ions and on the photolysis of the resulting complex.

The 1:1 complex [Mn(hfac)$_2$(**1**)] was obtained as orange rectangular prisms from a solution of anhydrous manganese(II) bis(hexafluoroacetylacetonate) [Mn(hfac)$_2$] and **1** in *n*-heptane/CH_2Cl_2 containing a small amount of methanol. The 1:2 complex [Mn(hfac)$_2$(**2**)$_2$] was also prepared analogously as a reference complex by using two mole equivalents of diazophenyl(4-pyridyl)-methane (**2**). X-ray crystal structure analysis of [Mn(hfac)$_2$(**2**)$_2$] shows that the two pyridyl nitrogens are ligated in *trans* form to a manganese ion (Fig. 1). The Mn–N and Mn–O bond lengths are 2.28 and 2.15 Å, respectively; the coordination geometry is an elongated octahedron. Considering that **1** is a bismonodentate ligand and forms a 1:1 complex with [Mn(hfac)$_2$] in contrast with the monodentate ligand **2**, we may assume that the two pyridyl nitrogens of **1** are coordinated to two different manganese ions to produce a one-dimensional chain.[5]

[**] This work was supported by a Grant-in-Aid on Priority-Area-Research "Photoreaction Dynamics" from the Ministry of Education, Science and Culture, Japan (No. 07228104).

Before irradiation, the $\chi_{mol}T$ values of finely crystalline samples of [Mn(hfac)$_2$(**2**)$_2$] and [Mn(hfac)$_2$(**1**)] were nearly constant in the range 2–300 K, and the values of 4.44 and 4.14 emu K mol^{-1} at 300 K, respectively, were close to the theoretical spin-only value of 4.37 emu K mol^{-1} expected for paramagnetic samples with $S = 5/2$. When the samples were irradiated with a xenon lamp ($\lambda > 400$ nm),[6] the $\chi_{mol}T$ values for both changed with irradiation time and remained constant after 18 h (Fig. 2). When the temperature was increased from 2 to

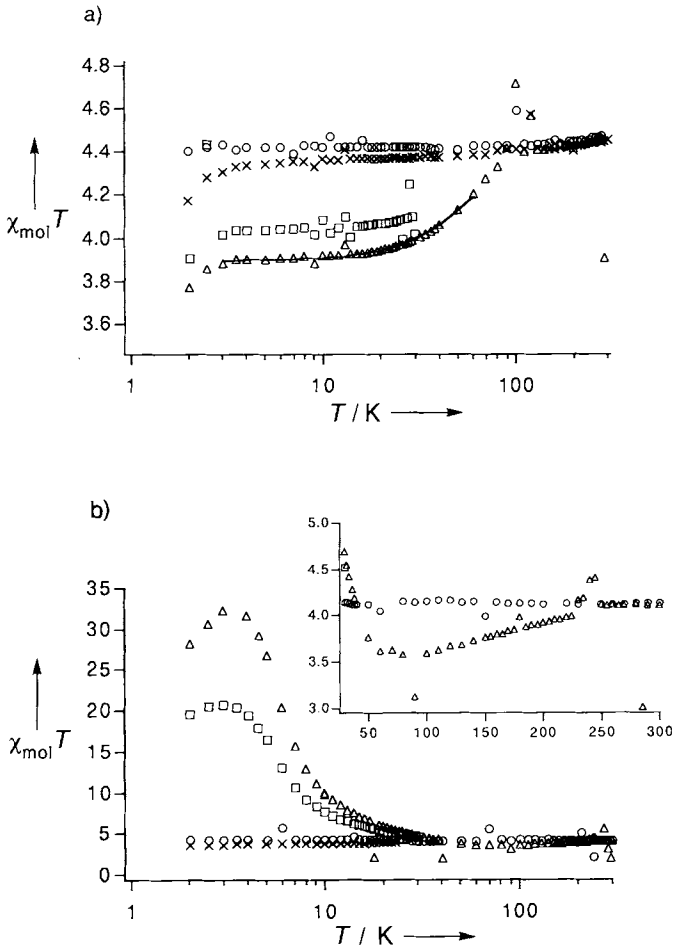

Fig. 2. The temperature dependence of $\chi_{mol}T$ [emu K mol^{-1}], the product of the "molar" magnetic susceptibility and temperature per formula unit of crystalline samples of a) [Mn(hfac)$_2$(**2**)$_2$] and b) [Mn(hfac)$_2$(**1**)] before (○) and after irradiation for 2 h (□) and 18 h (△), and then after maintaining the samples at 300 K for one hour (×). The changes for [Mn(hfac)$_2$(**1**)] are also given in inset in (b). The solid curve in (a) is the curve calculated based on the linear three-spin system with optimized parameters (see Experimental Procedure).

300 K in the dark after the photolysis, the $\chi_{mol}T$ values of [Mn(hfac)$_2$(**2**)$_2$] remained nearly constant at 3–20 K, gradually increased until approximately 90 K, and then corresponded exactly to those before irradiation. The 1:1 complex [Mn(hfac)$_2$(**1**)], showed strongly contrasting behavior under similar conditions. As the temperature was increased from 2 K, $\chi_{mol}T$ values increased, reached a maximum of 32.2 emu K mol^{-1} at 3 K, rapidly decreased to a shallow minimum of 3.58 emu K mol^{-1} at approximately 80 K, and then gradually increased up to 230 K. An abrupt change in the $\chi_{mol}T$ value was observed at 230 K, above which it retraced the horizontal line recorded before irradiation. For both complexes, subsequent measurements of the $\chi_{mol}T$ values at 2–300 K of samples that had been left at 300 K for an hour showed temperature-independent horizontal lines overlapping with those before irradiation.

The temperature-independent $\chi_{mol}T$ values before irradiation and after irradiation followed by annealing at >90 and >230 K for [Mn(hfac)$_2$(**2**)$_2$] and [Mn(hfac)$_2$(**1**)], respectively, are characteristic of magnetically dilute d^5 manganese(II) centers; both the diazo ligands **2** and **1**, and the annealed carbene ligands are insulating magnetic couplers. The $\chi_{mol}T/T$ plot after photolysis of [Mn(hfac)$_2$(**2**)$_2$] revealed that the two generated carbene centers interact with the manganese ion antiferromagnetically.[7] The temperature dependence ($T < 230$ K) of the $\chi_{mol}T$ values after photolysis of [Mn(hfac)$_2$(**1**)] is best interpreted in terms of the formation of a ferrimagnetic chain[5] composed of alternating units of triplet di(4-pyridyl)carbenes and d^5 manganese(II) ions. As the temperature is lowered, the antiferromagnetic coupling of the unpaired electrons of the manganese ion ($S = 5/2$) and the carbene center ($S = 2/2$) becomes stronger than kT and leads to a minimum in the $\chi_{mol}T/T$ plot, similar to behavior in a number of hetero-spin systems.[8, 9] The correlation over increasing length along the ferrimagnetic chain leads to the increases in $\chi_{mol}T$;[9] the correlation length at 3 K is estimated to be the ordering over about 40 units. The decrease in $\chi_{mol}T$ below 3 K is mostly due to the antiferromagnetic interchain interaction and partly to the saturation of magnetization under the field of 500 Oe used for the measurement. The discontinuous change of the $\chi_{mol}T$ value at 230 K and its temperature independence after annealing at 300 K indicate that the triplet carbene units undergo chemical reaction back to diamagnetic products at temperatures higher than 230 K and clearly imply the role of the di(4-pyridyl)carbene as a spin source and magnetic coupler.

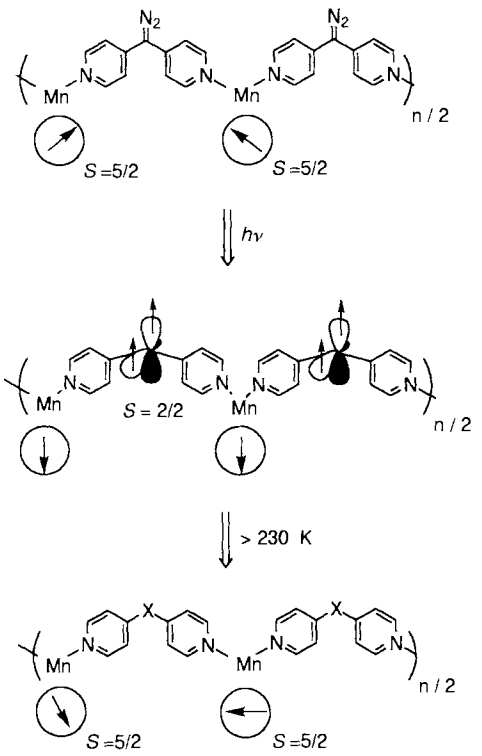
It is worth noting that while the carbene species generated in the crystal of [Mn(hfac)$_2$(**2**)$_2$] disappeared at approximately 90 K, those in the crystal of [Mn(hfac)$_2$(**1**)] survived temperatures as high as roughly 200 K. The free carbenes from **1** and **2** in a 2-methyltetrahydrofuran matrix ($|D/hc| = 0.434$, $|E/hc| = 0.020$ cm^{-1} from **1**)[10] started to disappear at 60–80 K as observed by EPR spectroscopy.

It is concluded that the photochemical generation of the triplet carbene centers induces polarization of the π electrons on the pyridine rings, which in turn effects the coupling of magnetically isolated, unpaired 3d electrons of the Mn ions[11] along the one-dimensional chain (Scheme 1). In the present communication we have described the first example of the photochemical generation of a ferrimagnetic chain. This system is a prototype of a molecular optomagnetic recording device, in which only the irradiated domain of the nonmagnetic or weakly magnetic material becomes strongly magnetic, just as the irradiated portions of photoresists become functional for printing circuit elements.[12]

Experimental Procedure

1 [10]: A solution of di(4-pyridyl) ketone [13] (0.11 g, 0.60 mmol) and 1 mL of 85% hydrazine hydrate in 2 mL of ethanol was heated at reflux for ca. 12 h. The cooled reaction mixture was treated with ice water and the colorless precipitate was collected and dried over $CaCl_2$ under vacuum to give 0.11 g (0.56 mmol) of the corresponding hydrazone in 93% yield. To a solution of 0.11 g (0.56 mmol) of the hydrazone in 1 mL of *n*-hexane and 0.2 mL of dichloromethane was added 0.15 g of yellow HgO and a drop of saturated sodium hydroxide solution in ethanol. The mixture was stirred vigorously for 12 h with careful exclusion of light. The filtrate was concentrated under vacuum to give an orange solid, which was recrystallized from *n*-pentane/dichloromethane to give 0.02 g (17%) of **1** as red crystals. IR (KBr): $\tilde{\nu} = 2060$ cm^{-1}; UV/Vis (CH_2Cl_2): $\lambda = 304$, 484 nm; ^{1}H NMR ($CDCl_3$, 270 MHz): $\delta = 8.60$ (dd, 4H, $J = 4.6$, 1.6 Hz), 7.21 (dd, 4H, $J = 4.6$, 1.6 Hz); Anal. calcd for $C_{11}H_8N_4$: C 67.33, H 4.11, N 28.56; found: C 67.24, H 4.44, N 28.94.

2: This compound was obtained in 51% yield from 4-benzoylpyridine as described in the literature [14].



Scheme 1. Exchange coupling in [Mn(hfac)$_2$(**1**)] and the resulting complexes generated by irradiation (loss of N_2) and annealing at higher temperature. X = nonmagnetic carbon center. The hfac ligands are omitted for clarity.

[Mn(hfac)$_2$(**1**)] and [Mn(hfac)$_2$(**2**)$_2$]: A solution of **1** in CH_2Cl_2 was mixed with an equimolar solution of [Mn(hfac)$_2$] in *n*-heptane containing a small amount of methanol. For the preparation of the latter complex, two mole equivalents of **2** was used. The mixtures were kept in a refrigerator to give orange rectangular prisms.

[Mn(hfac)$_2$(**1**)]: Anal. calcd for $C_{21}H_{12}N_4O_4F_{12}Mn$: C 37.80, H 1.81, N 8.40; found: C 38.08, H 1.74, N 8.11. Owing to the limited quality of the single crystal (orthorhombic, space group *Pbca* for [Mn(hfac)$_2$(**1**)]) and its sensitivity to X-ray irradiation, we could not improve the residuals beyond $R = 0.244$ and $R_w = 0.121$.

[Mn(hfac)$_2$(**2**)$_2$]: Anal. calcd for $C_{34}H_{22}N_6O_4F_{12}Mn$: C 47.40, H 2.57, N 9.76; found: C 47.45, H 2.51, N 9.89. The following crystal parameters were obtained: monoclinic, space group $P2_1/c$ (No. 14), $a = 12.432(3)$, $b = 6.739(4)$, $c = 22.192(3)$ Å, $\beta = 104.87(1)°$, $V = 1797(1)$ Å^3, $Z = 3$, $\rho_{calcd} = 1.267$ g cm^{-1}, $R = 0.039$, $R_w = 0.026$.

Magnetic measurement: Finely crystalline samples of [Mn(hfac)$_2$(**1**)] and [Mn(hfac)$_2$(**2**)$_2$] (each ca. 0.5 mg) were measured on a SQUID susceptometer/magnetometer before and after irradiation with a 300 W xenon lamp through an optical fiber [8] at or below 5 K. Light in the range $770 > \lambda > 400$ nm obtained by a combination of a Kenko L-42 sharp-cut filter and an OCLI B cold mirror was used. The light intensity at the inside edge of the optical fiber was ca. 35 mW. The degree of the photolysis was estimated to be 68 and 25% for [Mn(hfac)$_2$(**1**)] and [Mn(hfac)$_2$(**2**)$_2$], respectively, by comparing the absorptivity of the diazo groups at 2072 cm^{-1} for [Mn(hfac)$_2$(**1**)] and 2060 cm^{-1} for [Mn(hfac)$_2$(**2**)$_2$] before and after the photolysis. The progress of the photolysis was found not to be even; visual inspection proved that the irradiated side of the crystalline samples suffered higher decomposition on photolysis than the unirradiated side. Therefore the production of the carbene species on the irradiated side of the crystals is judged to be higher than these figures. The temperature dependence of the magnetic susceptibility per formula unit of [Mn(hfac)$_2$(**1**)] and [Mn(hfac)$_2$(**2**)$_2$] was investigated under constant fields of 500 and 5000 Oe below and above 70 K, respectively. For a more quantitative analysis of the observed $\chi_{mol}T$ values for [Mn(hfac)$_2$(**2**)$_2$], the Hamiltonian $\boldsymbol{H} = -2J(\boldsymbol{S}_1\boldsymbol{S}_M + \boldsymbol{S}_M\boldsymbol{S}_2)$, which describes the linear three-spin system revealed by the X-ray crystal structure analysis, was employed. The resulting equation derived for χ_{mol} containing photolysis factor F, Weiss temperature θ, and Landé factor g, was fitted to the experimental data (after 18 h irradiation, between 3–60 K) by a least squares method. The best fitting parameters were $J/k_B = -17.8 \pm 0.4$ K, $\theta = -0.011 \pm 0.007$ K, $g = 2.06 \pm 0.01$, and $F = 18.0 \pm 0.1$%. The corresponding curve is included in Figure 2.

Selective Cation Movement across Lipid Bilayers Containing Brevetoxin B**

Stefan Matile* and Koji Nakanishi

The structures of a large number of polyether marine toxins with ladderlike skeletons are rapidly being elucidated.[1] One of the earliest identified toxins of this type is brevetoxin B (BTX-B), the "red tide" toxin produced by dinoflagellates.[2] However, despite the great interest in and importance of polyether marine toxins, the nature of their activity still remains largely unknown. In the case of BTX-B, specific binding to voltage-sensitive sodium channels (VSSC) implied that activation of VSSC

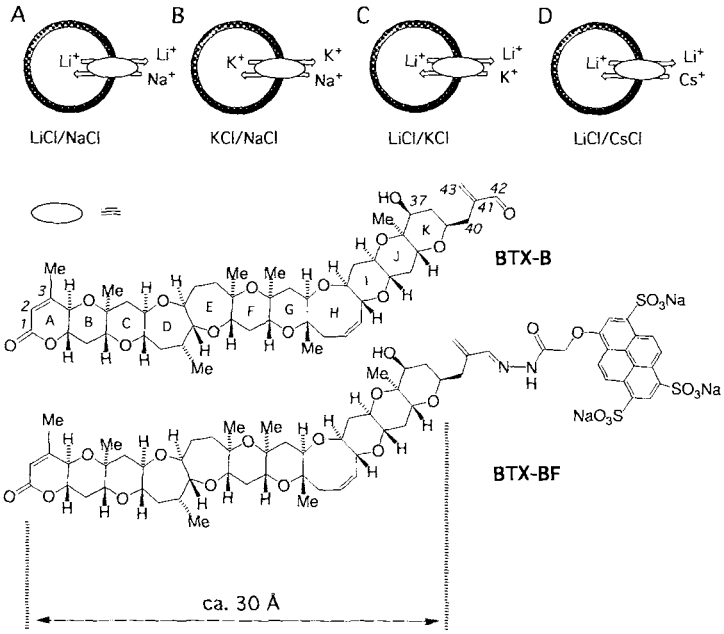
[**] We thank Dr. J. Decatur for assistance in NMR measurements and Prof. N. Berova, Dr. N. Sakai, and Prof. P. N. R. Usherwood for discussions. This work was supported by the U. S. National Institutes of Health (AI 10187) and the Schweizerischer Nationalfonds zur Förderung der wissenschaftlichen Forschung (S. M.).

is the mode of action of brevetoxins.[3] The results described in the following have disclosed a second, entirely new view regarding its mode of action: brevetoxin B presumably increases ion movement through cell membranes by transmembrane self-assembly.

Incorporation of macromolecular polyoxyethylene derivatives[4] into lipids has been shown to result in cation transport rates comparable to those of ion channels formed by natural and synthetic oligopeptides or antifungal macrolides.[5] Because of the polyether structure as well as the rigid skeleton of BTX-B with a length of approximately 30 Å, which corresponds to the thickness of lipid bilayers,[5a] the possibility of transmembrane BTX-B channel formation was suspected. Thus, ion movement across large unilamellar egg phosphatidylcholine (PC) vesicles containing 0.3 mol% BTX-B was investigated (Scheme 1).



Scheme 1. Structures of BTX-B and fluorescent ("cascade blue")-labeled brevetoxin B (BTX-BF). Schematic representation of the gradient systems used for ion transport kinetics: egg PC vesicles containing 0.3 mol% BTX-B or BTX-BF in aqueous LiCl (A, C, D) or KCl (B) diluted with isoosmolar NaCl (A, B), KCl (C), or CsCl (D). Thus, in (A) a sodium gradient from outside to inside the vesicle and a lithium gradient of opposite direction are established.

Transport rates were estimated by $^{23}Na/^{7}Li$ NMR spectroscopy[6] according to the system designed by Lehn and coworkers,[4a] which has the advantage that the intravesicular sodium concentration can be monitored in a noninvasive manner (Fig. 1).

Fig. 1. ^{23}Na NMR spectra of egg PC vesicles containing 0.3 mol% BTX-B measured a) immediately after establishment of the Na^+/Li^+ gradient and b) 1 h later. The added shift reagent leads to an upfield shift of the signal of the cations outside the vesicle: in the ^{23}Na NMR spectrum anisochronous Na^+_{in} and Na^+_{out} each give rise to one signal.

The observed transport rates of the ions were found to be sensitive to temperature of vesicle formation, cholesterol concentration, and ion size (Fig. 2, Table 1). The most dramatic

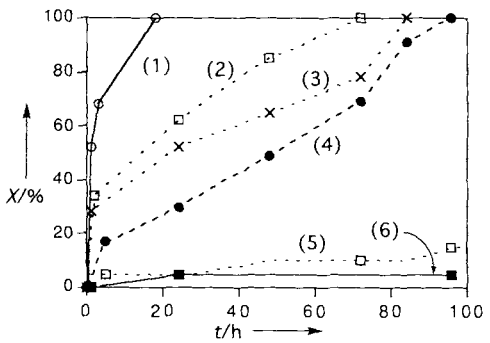


Fig. 2. Sodium ion influx into egg PC vesicles containing 0.3 mol% BTX-B (BTX-BF) (X is the proportion of exchanged cations; for conditions see Table 1). In control experiments in the absence of BTX-B (BTX-BF) no Na^+ entry was detected over the same time period.

Table 1. Conditions for the ion transport studies (1)–(6) represented in Figure 2 [a].

	(1)	(2)	(3)	(4)	(5)	(6)
Toxin	BTX-B	BTX-BF	BTX-B	BTX-B	BTX-BF	BTX-B
Dialysis temperature	RT	RT	RT	4 °C	4 °C	RT
Cholesterol [%]	50	50	0	0	50	50
Gradient	LiCl/NaCl	LiCl/NaCl	LiCl/NaCl	LiCl/NaCl	LiCl/NaCl	KCl/NaCl

[a] RT = room temperature.

rate increase was achieved with vesicles containing 50% cholesterol (curve 1). Since the addition of cholesterol reduces lipid/BTX-B dynamics, the observed rate increase implies ion transport through membrane-spanning channels (a "channel-like" mechanism) and not by a carrier mechanism.[7] Moreover, apparent first-order rate constants for Na^+ entry comparable to $k = 0.69 \pm 0.2\ h^{-1}$ have so far been observed only for amphotericin B measured in the same[4d] and gramicidin ion channels in a similar system.[5b] Cation selectivity was investigated by exchanging the lithium gradient for a potassium gradient (Scheme 1 B); the latter yielded very moderate transmembrane ion exchange (Fig. 2, curve 6). The decrease in the intensity and the broadening of the Li^+_{in} peak in the ^{7}Li NMR spectrum[4b] in the presence of sodium, potassium, and cesium gradients (Scheme 1 A, C, D, respectively) gave the selectivity order of $Na^+, Li^+ > K^+ > Cs^+$; even after two weeks, no Cs^+_{in} was detectable in the ^{133}Cs NMR spectrum.

Fluorescence labeling (BTX-BF) resulted in reduced rate constants (Fig. 2, curve 2) accompanied by a blue-shifted emission maximum in lipid-bound BTX-BF compared to the emission of BTX-BF in the absence of lipids (Fig. 3). A similar blue-shifted emission maximum (406 nm) in the micelle-forming, amphiphilic steroidal C-3 "cascade blue"[8] derivative strongly indicates that this effect is caused by self-assembly of BTX-BF in lipid bilayers and not by environmental influences on a single fluorophore at the lipid/water interface.[9] The blue-shifted emission of aggregated "cascade blue" can be explained, for example, by relaxation from the Franck–Condon excited state, which is "frozen in" by restricted molecular motion.[10] Upon treatment of the 100 mM LiCl stock solution with isoosmolar HCl (100 mM HCl, pH 1), the emission maxima of lipid-bound

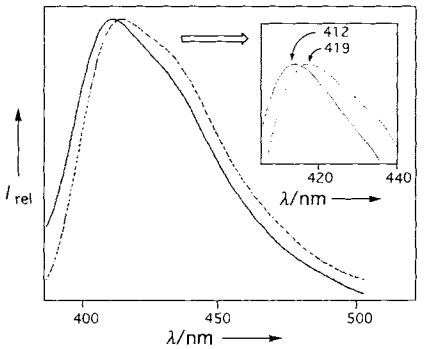

Fig. 3. Emission spectra of BTX-BF in 100 mM LiCl, 10 mM Tris, pH 7.4, incorporated into egg PC vesicles (solid line) and without egg PC vesicles (dashed line); excitation 360 nm.

and free BTX-BF both shift to 416 nm. Protonation of the nitrogen moieties of the extra- as well as the intravesicular fluorescence labels shows them to be at the lipid surface, and thus the BTX-B skeleton to be oriented perpendicular to the lipid surface[9] (Fig. 4).

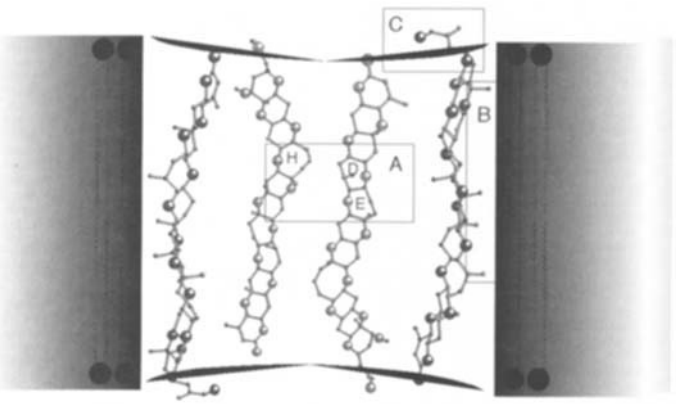

Fig. 4. Presentation of six cylindrically arranged BTX-B molecules (MacroModel V4.5 [12]; the specification of six molecules is hypothetical). The two BTX-B molecules in the front are not shown, and the carbon atoms are reduced and the oxygen atoms enlarged for clarity. The crown ether like arrangement of oxygen atoms, the stiff *trans*-fused rings with intermittent flexible D-, E-, and H-rings (A), the axial methyl groups (B), and the terminal K-ring substituents (C), all which are conserved motifs in brevetoxins and ciguatera toxins, probably play a crucial role for activity. Cholesterol is not shown here because we interpret that its role is to reduce the lipid/BTX-B dynamics rather than to interact in a specific manner with BTX-B.

Transmembrane self-assembly of BTX-B and selective cation transport via a "channel-like" mechanism[7] are consistent with the model structure shown in Figure 4. Consequently, a second mode of action of BTX has to be considered: cation movement across cell membranes mediated by transmembrane self-assembly of BTX-B itself. In view of the similar structures of polyether marine toxins,[1] it is possible that transmembrane cation transport is a general mode of action. In particular, maitotoxin[1a] may be considered as a covalently linked brevetoxin assembly; its enhanced toxicity could then be rationalized by reduced critical micelle concentration. The observed sensitivity of brevetoxin B channel formation to temperature, presence or absence of cholesterol, etc., suggests that in vivo, penetration into specific cell membranes and self-assembly stabilization may also be governed by the presence or absence of membrane proteins. Further investigations, in particular structural studies of transmembrane BTX self-assemblies[9] and single-channel measurements, will be reported in due course.

Experimental Procedure

BTX-BF was prepared according to ref. [8]. Following the method of Reynolds et al. [11], fresh egg yolk PC (15 mg), octyl β-D-glucopyranoside (90 mg), BTX-B or BTX-BF (60 nmol), and in some experiments (see Fig. 2) cholesterol (3.9 mg) were dissolved in 5 mL of chloroform/methanol (2/1) and the solution evaporated to a thin film. After complete removal of organic solvents, the residue was dissolved in 1 mL of 100 mM LiCl (Scheme 1 A, C, D) or KCl (Scheme 1 B), 10 mM tri(hydroxymethyl)aminomethane (Tris), pH 7.4. The resulting clear solution was dialyzed against 100 mM LiCl (Scheme 1 A, C, D) or KCl (Scheme 1 B), and 10 mM Tris, pH 7.4 (3 × 800 mL, 4 °C or room temperature (see Fig. 2)). The lipid concentration of the resulting vesicle solution was estimated by measuring the phosphate content after digestion, and the BTX-B/BTX-BF concentration by quantitative reversed-phase HPLC (detection at 210 nm/400 nm). The concentration of lipid-bound BTX-BF was further monitored by fluorescence spectroscopy by comparing the emission with known concentrations of free BTX-BF. Chromatography of the resulting vesicle solution on Sephadex G-25 or Sepharose CL 4B did not change the vesicle composition. To 300 μL of the vesicle solution were added 240 μL of 100 mM NaCl (Scheme 1 A), KCl (Scheme 1 C), or CsCl (Scheme 1 D), 10 mM Tris (pH 7.4), and 100 μL of shift reagent (10 mM $DyCl_3$, 30 mM $(Me_4N)_5P_3O_{10}$, 10 mM Tris, pH 7.4).

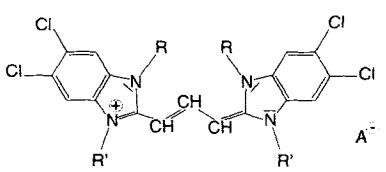
Spontaneous Formation of Chirality in J-Aggregates Showing Davydov Splitting

Umberto De Rossi,* Siegfried Dähne, Stefan C. J. Meskers, and Harry P. J. M. Dekkers

Dedicated to Professor Heinz A. Staab on the occasion of his 70th birthday

The origin of optical activity on earth continues to be a main topic of interest in science. In the absence of chiral auxiliaries or applied external forces, all known synthetic procedures yield racemates, 1:1 mixtures of the enantiomers, in accordance with the principle of parity. Thus, the existence of a multitude of optically active compounds in the biosphere is hard to understand. Processes leading to spontaneous formation of chirality, besides mechanisms such as surface-controlled catalysis with enantiomorphic crystals, are thought to be responsible. Famous examples are the crystallization of 1,1'-binaphthyl[1] and sodium chlorate.[2]

We report on two new model systems, benzimidocyanines **1** and **2**[3] with long alkyl chains, which spontaneously show optical activity due to aggregation of the achiral monomers to form chiral J-aggregates. J-aggregates are of great importance for the study of biologically relevant processes because they serve as model systems for energy migration in antennae systems.[4] Additionally, aggregation phenomena in general play an important role in nature.[5]



1 : R', R' = $(CH_2)_3CO_2H$; R, R = C_8H_{17}, A = Br

2 : R', R' = $(CH_2)_3CO_2H$; R, R = $C_{12}H_{25}$, A = Br

Cyanine dyes show a great tendency to self-associate. The aggregates formed can be distinguished by UV/Vis spectroscopy because either one sharp absorption band is red-shifted relative to that in the absorption spectrum of the monomer (J-aggregates) or one broad absorption band is blue-shifted (H-aggregates). Their spectroscopic properties can be understood qualitatively on the basis of the exciton model formulated by McRae and Kasha.[6] While the parallel arrangement of monomers with only *one* molecule per unit cell leads to the formation of *one* aggregate band, interaction of two, not translationally equivalent molecules produces a splitting of the absorption band (Davydov splitting), which depends on the angle of the transition dipole moments and the distance between the molecules.[7] In accordance with the principle of parity, circular dichroism (CD) of J-aggregates has to date been observed only under the influence of external chiral disturbances.[8, 9]

[**] Energy Migration Phenomena in J-Aggregates, Part 7. These results were first presented on March 8, 1996 at the University of Eindhoven, Institute of Organic Chemistry. This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 337) and the Fonds der Chemischen Industrie. The model dyes **1** and **2** were synthesized by M. Lisk, Max-Planck-Institut für Kolloid- und Grenzflächenforschung [3]. To check the presented results model system **1** was prepared by a second, independent route. We thank Prof. Saenger (Freie Universität Berlin) for access to a CD spectrometer. Part 6: U. De Rossi, S. Dähne, M. Lindrum, *Langmuir*, in press.

A solution of monomeric **1** in methanol has an absorption maximum at 523 nm and is, as expected, optically inactive. Strong aggregation of the dye is observed in 0.01 N NaOH, and the two absorption maxima at 604 nm and 575 nm are attributed to Davydov splitting (Fig. 1a, thin line). In contrast to the solution of the monomer, that of the aggregate is optically active; its CD spectrum shows a well-resolved couplet with a Davydov splitting energy of 835 cm^{-1} (Fig. 1a, thick line). The lack of orientation dependence of the ΔA values of **1** prove that the optical activity is not due to experimental errors such as linear dichroism[10] or light scattering. The origin of the CD band at 565 nm is unknown and will not be discussed further here. The measured CD amplitudes depend on the preparation of the sample and reach a maximum value of 3×10^{-4} for a concentration of 1×10^{-4} mol L^{-1} of the monomer in NaOH and a cuvette of 0.1 cm thickness (Fig. 1b, broken line). When the dye is dissolved in monomeric form in ethanol, and this solution is treated with a threefold excess of 0.01 N aqueous NaOH, ΔA increases a further, five- to tenfold, although the aggregation is strongly suppressed by the large proportion of ethanol in the solvent mixture (Fig. 1b, solid line). This is confirmed by the occurrence of large ΔA values for a series of dye solutions in NaOH when the concentration of J-aggregates is low.

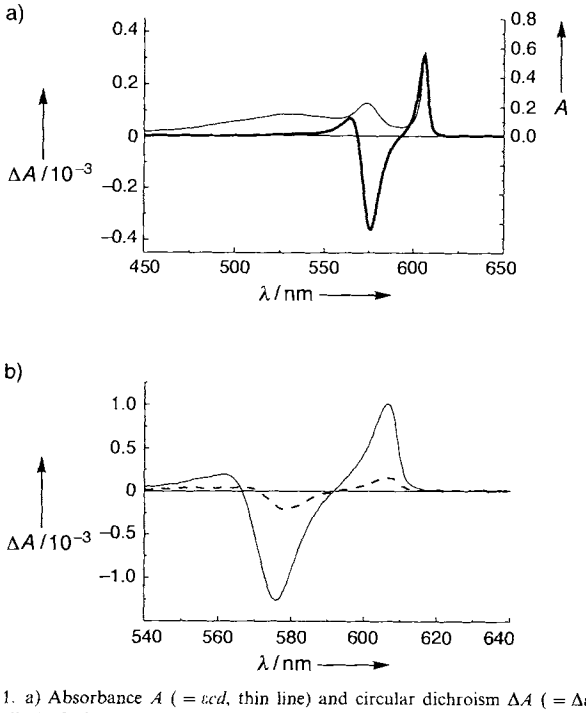

Fig. 1. a) Absorbance A ($= \varepsilon cd$, thin line) and circular dichroism ΔA ($= \Delta\varepsilon cd$, thick line) of **1** in 0.01 N NaOH. b) Dependence of the ΔA values on sample preparation. Dissolving **1** directly in 0.01 N NaOH (– – –) leads to lower amplitudes than the addition of NaOH to a solution of the dye in ethanol (——).

Optically active anions such as tartrate significantly influence the aggregation behavior. Addition of 50 vol% of a saturated solution of sodium (+)-tartrate in 0.01 N NaOH changes the sign of the originally positive couplet of the aggregate solution (Fig. 2b, thin line) and simultaneously increases the ΔA value (Fig. 2b, thick line). The blue shift that appears in the absorption spectrum is evident in the CD spectrum as well and is attributed to a change of the effective dielectric constant. Addition of a (+)-tartrate solution always induces a negative couplet, while addition of a (–)-tartrate solution results in a positive couplet, regardless of the sign of the couplet of the starting solution.

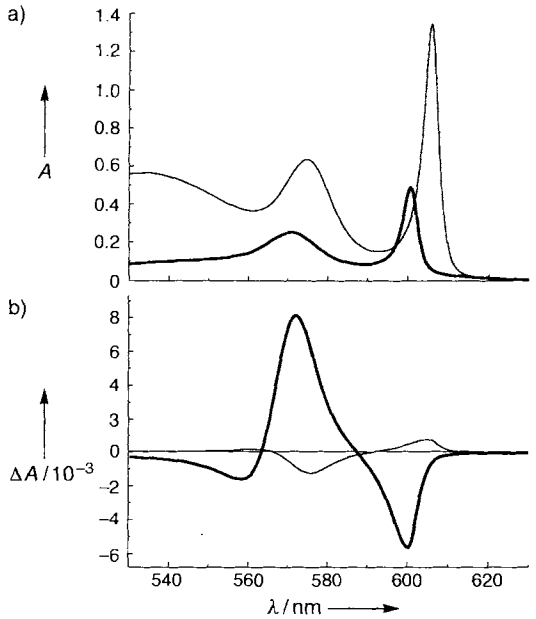

Fig. 2. Effect of added (+)-tartrate solution in NaOH on the a) absorption and b) CD spectrum of 1. Addition of 50 vol% (+)-tartrate solution (thick line) shifts the absorption of the starting solution (thin line) and changes the sign of the CD couplet.

The spontaneous formation of chirality in an achiral system seems to contradict the principle of parity, but the evaluation of 27 experiments, in which aggregation of the dye in an ethanolic solution was induced by addition of NaOH, gave a statistical distribution of 15 positive and 12 negative couplets (Fig. 3).

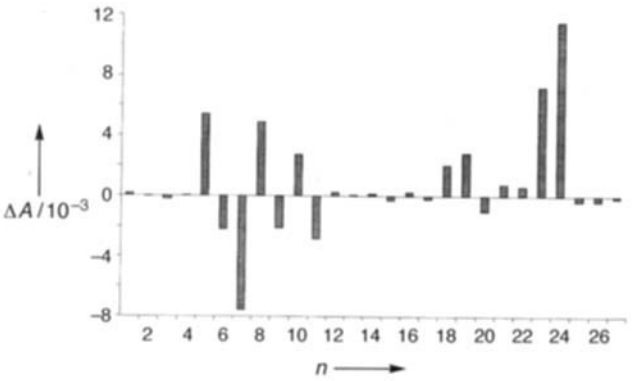

Fig. 3. Distribution of the signs and the CD amplitudes of J-aggregates of model system **1** determined for 27 experiments. The concentration of the monomer in all the experiments described is 1.7×10^{-6} mol L^{-1}. n = experiment number.

Chiral interferences of remaining preagglomerates or adsorbed species on the cuvette surface were excluded by using very low dye concentrations (1.7×10^{-6} mol L^{-1}) and new cuvettes for each experiment.

A clue to the mechanism favoring the formation of an excess of one enantiomer could be derived from the temperature dependence of the CD and absorption spectra. According to the absorption spectra, an increase in temperature shifts the equilibrium between the aggregate and the monomer in the direction of the monomer (steady decrease of the absorption of the J-band, Fig. 4). In constrast, the CD spectra display a two-step temperature dependence. ΔA remains constant below approxi-

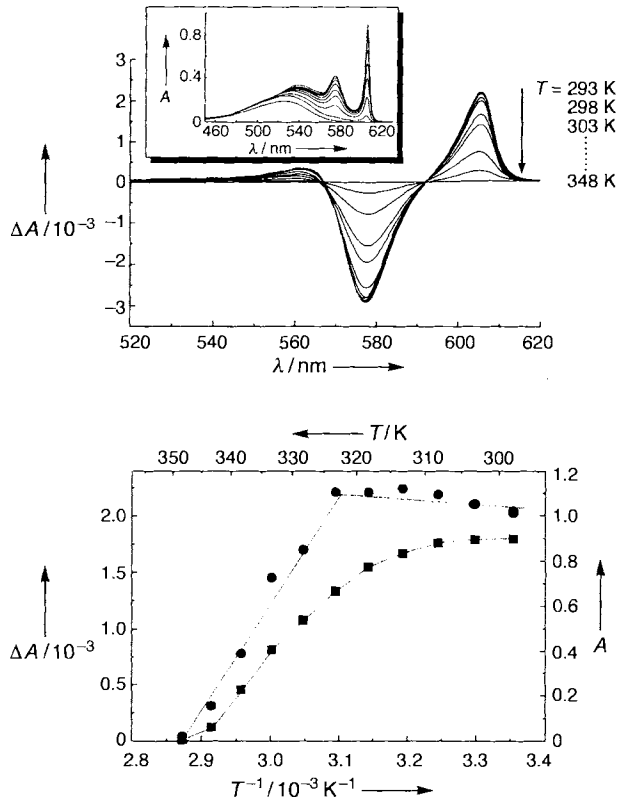

Fig. 4. Top: Absorption spectrum (insert) and CD spectrum of **1** in the temperature region of 293 to 348 K. Bottom: Temperature dependence of the absorption intensity at 604 nm (■) and the CD amplitude (●) of **1**.

mately 320 K and decreases drastically above this temperature. This behavior is reversible and leads to the conclusion that the solution consists of both racemic and enantiomeric aggregates. Racemic aggregates, in other words aggregates consisting of both dextro- and levorotatory subunits, do not contribute to the CD signal and are thus only detectable in the absorption spectrum. In comparison, enantiomerically pure aggregates give both a CD signal and an absorption band and can be detected by both spectroscopic methods. If one assumes that the enantiomerically pure aggregates are more stable than the racemic, as is observed for 1,1'-binaphthyl,[11] the racemic aggregates should be the first to dissociate when the temperature is increased. This behavior should only diminish the absorption of the J-band and should not affect the amplitude of the CD signal. The diminution of both the absorption and the CD signal above 320 K is ascribed to the dissolution of the enantiomerically pure aggregates.

At room temperature model systems **1** and **2** have the same properties. The absorption spectrum of a solution of the monomer **2** in methanol has a maximum at 523 nm. The dye forms aggregates in 0.01 N NaOH as evidenced by absorption maxima at 578 nm and 606 nm and a couplet at the same wavelengths in the CD spectrum. Samples prepared under different conditions yield ΔA values comparable to those of **1**.

However, between 270 and 300 K model system **2** exists in two different types of aggregates showing two distinct J-absorption bands. These two aggregate structures can be reversibly transformed into each other. The aggregate formed on cooling a solution of **2** has an absorption maximum at 595 nm (Fig. 5a). The CD spectrum of a solution containing both aggregate types displays only the already observed couplet of aggregate J_2 (Fig. 5b). Even at higher absorption of the aggregate J_1, no

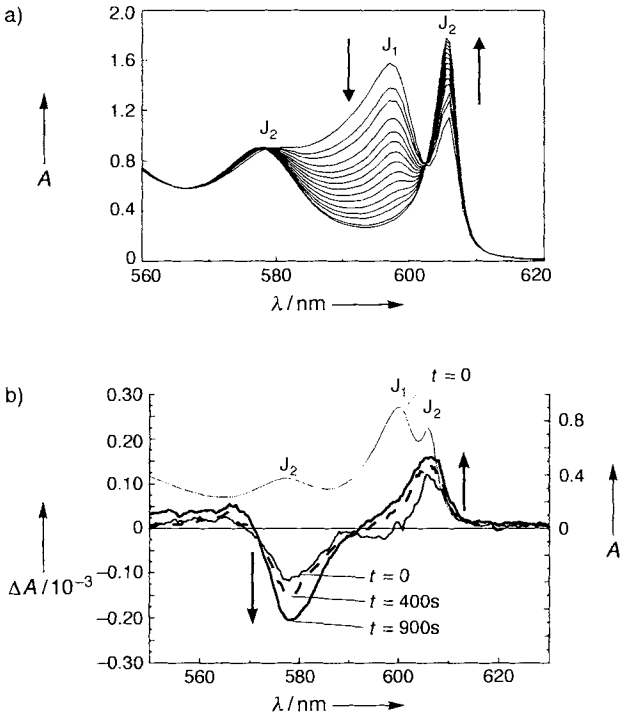

Fig. 5. a) UV/Vis spectra recorded during the transformation of aggregate J_1 into J_2 at room temperature. A spectrum was recorded every 300 s; the sample had been cooled to 270 K for 30 min prior to measurement. b) Absorption spectrum (thin line) and CD spectrum (thick lines) of a solution containing both aggregate species at $t = 0$. The increase of the absorption of J_2 with time (not shown) is accompanied by an increase in the ΔA values (CD spectra at $t = 400$ and 900 s).

circular dichroism is detectable for the band at 595 nm, which suggests that this aggregate form is achiral. At room temperature aggregate J_2 is formed again and the CD signal increases (Fig. 5b).

To the best of our knowledge, this is the first example for spontaneous formation of chirality through aggregation. If one regards J-aggregation as a first step towards crystallization, then the observed phenomena are comparable to the formation of chirality from racemic mixtures (e.g. 1,1'-binaphthyl) or achiral substances (e.g. sodium chlorate). From a theoretical point of view, the formation of an enantiomeric excess cannot be excluded;[12] the probability of this formation is a consequence of a Gaussian distribution. The effect has been proved experimentally for the crystallization of sodium chlorate,[2b] where the observed equimolecular formation of both enantiomers simply has the highest probability.

So far, only speculations can be made on the complicated dynamics of the coupled reactions of formation, growth, and possible decomposition of crystal nuclei. The occurrence of statistical fluctuations during the first phase of the crystal nucleation could lead to an accidental excess of one enantiomeric species. This excess depends on the number of crystal nuclei formed and explains the decrease in ΔA with increasing J-aggregate absorption and the strong variation of ΔA for samples prepared by different procedures. If the size of the aggregate exceeds a critical value, fracture into smaller fragments could be the consequence. These fragments would then serve as crystal nuclei for new aggregates of the same chirality, which would result in an autocatalytic increase in the selection of *one* enantiomeric species.

The absorption and CD spectra give some important evidence for the structure of the aggregates, too. The appearance of two absorption bands suggests the coupling of two nontranslationally equivalent molecules arranged in a herringbone-type structure. Following exciton theory,[7] the ratio of the oscillator strengths of the absorptions of **1** at 575 and 604 nm allows an estimation of the angle α between the two transition dipole moments; this angle is roughly 50°. Calculations based on the model of extended dipoles confirm that an aggregate with $\alpha = 50°$ should give rise to two J-bands red-shifted relative to the monomer spectrum.[13]

The CD spectra also support a herringbone-type structure. Because coplanar arrangement of the molecules would lead to an achiral aggregate structure giving no CD signal, the observed CD spectra allows the conclusion that the planes of the two facing molecules are tilted against each other by the dihedral angle δ along the axis of the herringbone structure. A possible model for the structure taking into account interactions both between the single dye molecules and between the long alkyl substituents is shown in Figure 6. Similar structures have been proposed for a chiral dye dimer incorporated into cyclodextrins[14] as well as for a chiral dye whose cyclohexane ring is substituted with two pentamethinecyanine chromophores in *ortho* position.[15]

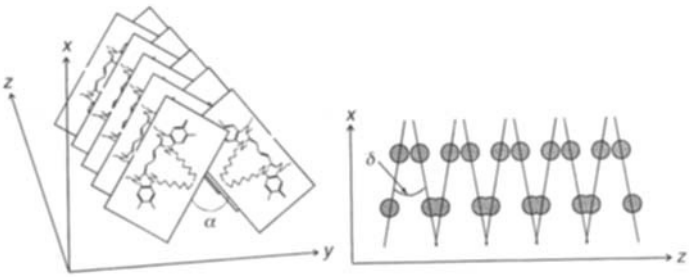

Fig. 6. Front (left) and side view (right) of the proposed structure of aggregates of **1**. α designates the angle between the transition dipole moments of the aggregated molecules of **1**. The dihedral angle δ indicates the tilting of two facing molecules within the herringbone structure. – : chromophore, ○: octyl chain.

On assumption that the presented model resembles the real structure, the *g*-factor can be estimated by applying exciton theory ($g = 4R/D$, R = rotational strength, D = dipole strength).[16] Comparison of the calculated value of 10^{-3} to 10^{-2} with the measured *g*-factors ($= \Delta A/A$) shows that the optical purity of the aggregates lies within the range of 10–100%. Such high values support the assumption of an autocatalytic process during the spontaneous formation of optical active J-aggregates.

The results described here indicate a new and promising way of designing chiral supramolecular structures from achiral substances by combination of two principles, the self-association of organic dyes and the hydrophobic interaction between long alkyl chains.

Organic Reactions Classified by Neural Networks: Michael Additions, Friedel–Crafts Alkylations by Alkenes, and Related Reactions**

Lingran Chen and Johann Gasteiger*

Organic reactions are influenced by many factors: the structures of the starting materials, reagents, and catalysts as well as reaction conditions such as temperature, solvent, pressure, and light. Each of these factors can be considered as a separate coordinate spanning a multidimensional space, and in this sense a chemical reaction is an event in this type of multidimensional space. Chemists have largely gained their knowledge on organic reactions from observations on a series of reactions; common and differentiating features were sought in order to assign reactions to classes, which were frequently named after the principal discovers, for example Wittig reaction, Michael addition, and Beckmann rearrangement. Clearly, such a one-dimensional classification scheme can only insufficiently account for the variety of observations on chemical reactions.

We will show here that a set of chemical reactions can be projected by a self-organizing neural network into a two-dimensional map. A reaction consists of a point in such a map, and the distance between two points reflects how similar two reactions are. Different types of similarities between reactions can be represented by projection into different directions of the two-dimensional map.

The human brain generates two-dimensional maps in the visual, auditory, and somatosensory cortex from corresponding sensory information obtained from the environment. The self-organizing neural network method developed by Kohonen[1] models this feature of the human brain.[2] In this network the basic processing units, the artificial neurons, are arranged in two dimensions and thus "maps" are obtained of the analyzed information.

Clearly, an enormous range of variations exists for organic reactions, and a map reflecting this broad spectrum of possibilities would be large indeed. To illustrate the potential of our method we will therefore limit the discussion to a set of reactions having an important feature in common: the reaction center, the set of atoms and bonds directly involved in the bond rearrangement during reaction. The reaction scheme chosen is the addition of a C–H bond to a C=C bond (Table 1) and includes such important reaction types as Michael additions, Friedel–Crafts alkylations by alkenes, and free radical additions to alkenes.

Table 1. Electronic variables for characterizing the reaction centers of the reactions discussed [a].

Electronic variables	C=C		+ H–C → H–C–C–C				
	1	2	4	3	4	1	2	3
α_i				×			
q_{tot}		×		×			
χ_σ	×			×			
χ_π	×			×			

[a] For definitions of the symbols refer to the text.

A set of 120 reactions was obtained by a search with the reaction retrieval system ISIS Host[3] in the 1991 version of the ChemInform-RX data base.[4] As the changes in the structures of the starting materials are the most decisive influences on a chemical reaction, we concentrated in this investigation only on these structural influences. The question is then, how should the structures be coded? Clearly, lists of functional groups around the reaction center cannot be the best method, because this list would be quite extensive. Actually, chemists have already tackled the problem of having to compare diverse functional groups and have generalized the influence of functional groups with concepts such as partial charges and inductive/field, resonance, and polarizability effects. Methods for the empirical calculations of these effects developed in our group[5–8] were used to calculate the influence of functional groups on the atoms of the reaction center. Specifically, σ- and π-electronegativities, χ_σ and χ_π, were considered at atoms C-1 and C-3, the total charges, q_{tot}, on atoms C-2 and C-3, and the effective polarizability, α_i, on C-3 (see Table 1).

These seven variables were used to describe each individual reaction of the data set and used as input to the Kohonen neural network. This network projects a seven-dimensional space into a map consisting of 12 × 12 neurons. Each neuron has as many weights as there are input variables for each object; in our case there are seven. A reaction s will be mapped into that neuron c that has weights w_{ji} most similar to the input variables x_{si} of the reaction considered [Eq. (a)]. After each input of a reaction the

$$c \leftarrow \min\left\{\sum_{i=1}^{7}(w_{ji}-x_{si})^2\right\} \quad j = 1-144 \qquad \text{(a)}$$

weights of all neurons are adjusted such as to make them more similar to the input variables. However, this adjustment is largest for the winning neuron c and decreases with increasing distance of a neuron from this central neuron. Reactions that have similar electronic variables will thus be mapped into the

same or adjacent neurons. In our case quite a few neurons obtained several reactions (up to five), indicating a high degree of similarity for those reactions. A number of neurons (78) did not obtain any reaction at all.

To visualize the results of the self-organization of the 120 reactions in the Kohonen network, the reactions were inspected by chemists and assigned to appropriate reaction types, which were identified by symbols (Table 2). The neurons were labeled with these symbols to indicate which reaction was projected into which neuron. The results are shown in Figure 1.

Table 2. Assigned reaction types, associated symbols (see Fig. 1), and the number of reaction instances.

	Reaction type	No. of reactions	Reaction index
A	Michael addition	75	1–14, 24–84
B	misassigned reaction center	1	85
C	Friedel–Crafts alkylation by alkenes	18	15–23, 86–92, 115, 116
D	electron transfer reaction	1	93
E	photochemical addition of an acyl radical to an electron-poor olefin	1	94
F	photoinduced alkylation	4	95–97, 101
G	$H^{\bullet}$ transfer reaction	3	98–100
H	reaction with special mechanism	1	102
I	hydride abstraction reaction	3	103–105
J	Nazarov reaction	5	106–110
K	allylation of an oxo ester and subsequent anti-Markovnikov addition of HBr[a]	1	111
L	palladium-catalyzed hexatrienolate cyclization[a]	3	112–114

N	photoinitiated radical addition to crown ethers	3	118–120

[a] Two-step reaction.

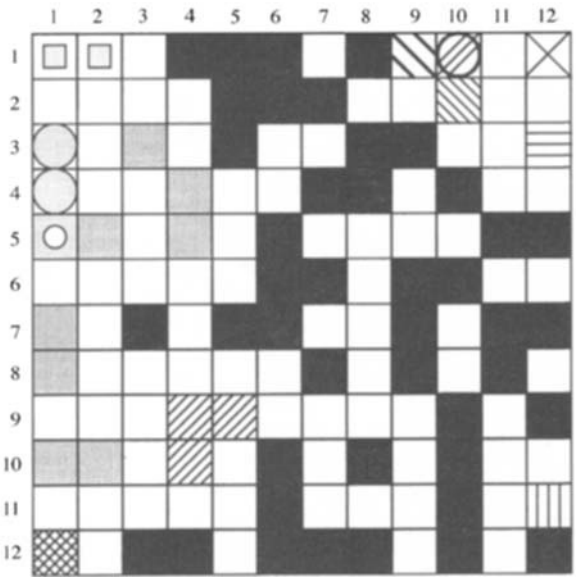

Fig. 1. Kohonen feature map obtained for the classification of 120 reactions. White boxes represent empty neurons; boxes with an × denote conflict neurons. The symbols are defined in Table 2.

Quite a few neurons obtained several reactions, which were always of the same type, indicating the power of the Kohonen network in perceiving similarities of different reactions. Only one neuron, neuron (12,1) stored conflicting information: it contained both a condensation reaction and a reaction that had been coded in the data base with a wrong reaction center.

Michael additions comprised the bulk of the reactions, and consequently the Kohonen network reserved the largest area for this reaction type. The more specialized reaction types and those with only a few members were pushed to the edges of the map. It is quite remarkable that the reaction types assigned by a chemist were also perceived by a Kohonen network, which used the specified physicochemical variables of the reaction center as criteria for assigning reactions; in the Kohonen network the individual reactions of one type were collected in the same region of the map.

Even within the area of one reaction type the site in which a reaction is located contains a lot of chemical information. Figure 2 shows the part of the map of Figure 1 containing Michael

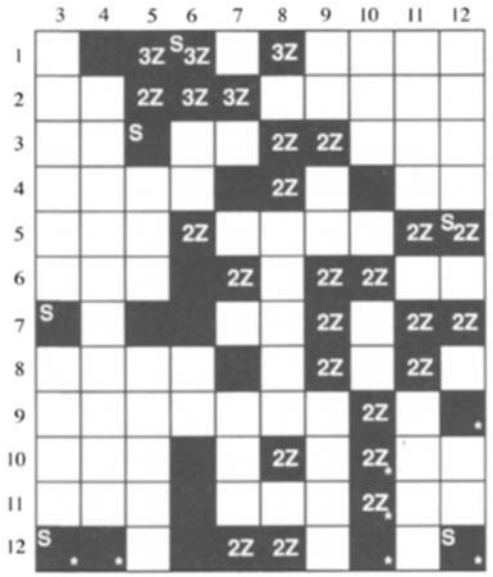

Fig. 2. Detailed analysis of the cluster of Michael additions in the Kohonen feature map in Fig. 1. The neurons marked with 2Z and 3Z were mapped by Michael additions in which the reacting H–C bonds are activated by two or three strongly electron-withdrawing groups, respectively. The neurons marked with * indicate Michael additions in which the reacting C=C bonds are activated by two strongly electron-withdrawing groups. The neurons marked with S were mapped by special Michael additions.

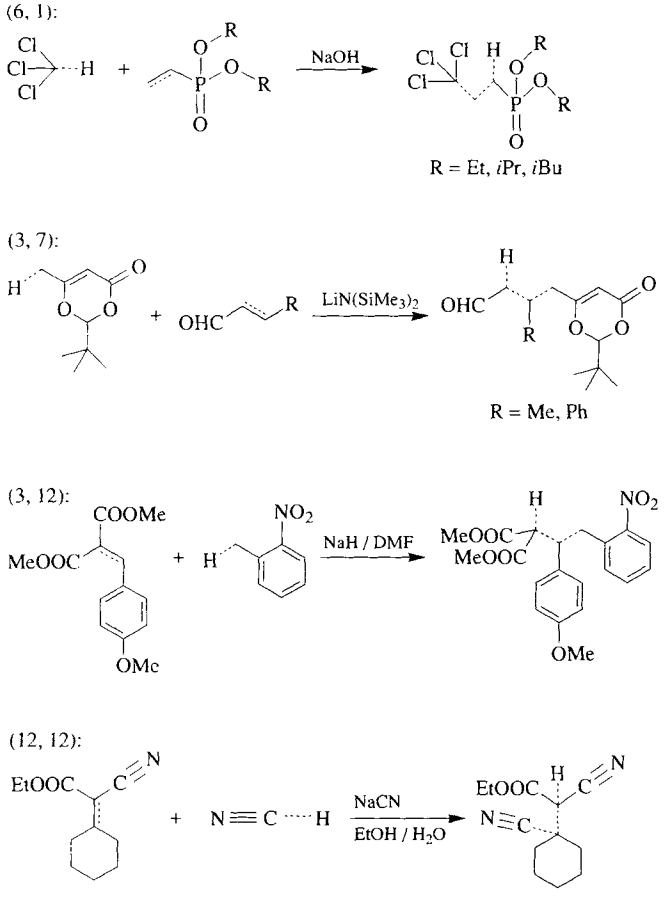
additions. Additional labels give further information on the individual reactions. Reactions that have only one (no label), two (2Z), or three (3Z) electron-withdrawing groups at the reacting H–C bond are quite well separated. By the same token, reactions that have two strongly electron-withdrawing groups (*) at the C=C bond are separated from those that have only one (no label). An important advantage of a two-dimensional map is that structural variations at both reacting bonds, the C–H and the C=C bonds, can be indicated simultaneously. Furthermore, also within a reaction type such as Michael additions the more special examples (S) are found at the edges of the map.

We will now discuss some of the special Michael additions in more detail. Scheme 1 shows the reactions mapped into neurons (6,1), (3,7), (3,12), and (12,12). Whereas in most Michael additions a H–C bond is activated by groups that exert a –M effect, the three reactions mapped into neuron (6,1) show that the



Scheme 1. Michael additions mapped into neurons (6,1), (3,7), (3,12) and (12,12). The bonds denoted by dashed lines are those broken or made in the reaction.

carbanion initiating a Michael addition can also be stabilized by three groups exerting a $-I$ effect.[9] The two reactions in neuron (3,7) are quite unique: the CH_3 group reacting is activated by an ester group that exerts its influence through conjugation across a double bond.[10] A CH_3 group also reacts in the reaction stored in neuron (3,12), but it is activated by an *ortho*-nitro substituent on the phenyl group.[11] Clearly, a common feature in the last two reactions is that a CH_3 group is activated by an electron-withdrawing group in conjugation; however, this effect is transmitted across different π systems. Thus, it is gratifying that these two special Michael additions end up in similar regions of the map (neuron (3,7) and (3,12)).

The reaction in neuron (12,12) is the only Michael addition[12] in this set of reactions in which a $H-C_{sp}$ bond reacts; all other cases involve a $H-C_{sp^3}$ bond. This reaction thus extends the scope of Michael additions and is stored at the borderline of the area of this reaction type.

One of the exciting features of the Kohonen network is that in classifying the reactions, the network automatically gains chemical knowledge from those reaction instances. This "trained" network can then be used to predict reaction types of the unknown reactions. To illustrate this point, the 120 reactions of the previous data set were divided into two groups. The 60 reactions with odd indices (see Table 2) were used as the training set, the other 60 reactions as test set. The result is quite impressive: The reaction types of 95 % (57 instances) of the reactions in the test set were correctly predicted. The reason for two undecided cases and one wrong case is very simple: these three special reactions are not represented in the training set. In fact, all three of these reactions were mapped into empty neurons at the edges of the map.

The two-dimensional Kohonen feature maps can show the relationships of the chemical reactions under investigation, point out the major reaction types, present their scopes, and indicate also unusual reactions. Thus, they allow the chemist to order observations on chemical reactions in an intuitively more appealing and chemically more significant manner.

Schellman Motif in Dehydrooligopeptides: Crystal and Molecular Structure of Boc-Val-ΔPhe-Leu-Phe-Ala-ΔPhe-Leu-OMe**

Kanagalaghatta Ramabhatta Rajashankar, Suryanarayanarao Ramakumar, Tapas Kumar Mal, Ratan Mani Jain, and Virander Singh Chauhan*

In the last few years it has become increasingly apparent that peptides containing α,β-didehydrophenylalanine residues (ΔPhe) exhibit preferential secondary structural features both in the solid state and in solution.[1–13] Introduction of ΔPhe residues in peptide sequences results in β-turns[14] and helical structures.[1–13] Recently we observed a novel β-bend ribbon structure in a pentapeptide containing two ΔPhe residues.[12] In longer peptides containing several ΔPhe residues 3_{10}-helical structures dominate.[5–8, 10] In a recent example an α-helical

conformation was observed in a pentapeptide containing a single ΔPhe residue.[13] Apparently the final conformation of any ΔPhe peptide depends upon the number and position of ΔPhe residues as well as the nature of the amino acids flanking them.

Amino acids such as ΔPhe and Aib,[15-17] which do not occur in natural proteins, have proved to be useful in generating secondary structural motifs and may be useful in the de novo synthesis of protein mimics.[18] In proteins most of the helices terminate with a reversal of helix sense at the C-terminus; the helix-breaking residue adopts an α_L conformation ($\phi = +50°$, $\psi = +30°$) conformation.[19-25] This conformation generally results in the formation of a 6 → 1 hydrogen bond accompanied by a 5 → 2 hydrogen bond. The 6 → 1 and 5 → 2 hydrogen bonded turn motif in which the fifth residue adopts an α_L conformation has been referred to as a Schellman motif.[25] This conformation, which may be useful in designing helix-terminating motifs, has been identified recently in the crystal structures of oligopeptides containing multiple aminoisobutyric acid (Aib) residues.[26-28] We report here on the crystal and molecular structure of the dehydroheptapeptide **1**, which also exhibits a

Boc-Val-ΔPhe-Leu-Phe-Ala-ΔPhe-Leu-OMe **1**

helical structure terminated by a Schellman motif at the C-terminus. A comparison of the structure of **1** with the crystal structure of Boc-Leu-Phe-Ala-ΔPhe-Leu-OMe,[11] a fragment thereof, highlights the versatility of ΔPhe residues in designing structural motifs.

Heptapeptide **1** was synthesized by conventional solution-phase procedures using a fragment condensation approach.[7] In the characterization of **1** by X-ray structure analysis[29] three standard reflections, which were monitored at regular intervals during data collection, did not vary significantly in their intensities, implying crystal and electronic stability.

In the molecular structure shown in Figure 1 a number of features are evident. The Boc group assumes a double-transoid conformation (relative to O1–C5 and C5–N1) as indicated by the torsion angles θ^1 and ω^0 (Table 1). This particular conformation enables the O2(Boc) atom to participate in the first 4 → 1 intramolecular hydrogen bond.[31] The urethane moiety adopts the generally preferred planar conformation.[31] The value of the dihedral angle $\theta^{1\prime}$ indicates that the C5–O2 bond is *syn*-planar with C4–O1 bond. The three methyl carbon atoms of the Boc group are staggered with respect to O1–C5 bond [$\theta^{2,1} = -60.6(6)°$, $\theta^{2,2} = 63.7(6)°$, and $\theta^{2,3} = -179.4(6)°$]. As expected, the side chains of both ΔPhe residues are planar, as indicated by the dihedral angle χ^1. The side chain conformation of residues Val [g^-t], Phe [$g^-(g^-g^+)$] and Leu [$g^-(g^-t)$] and

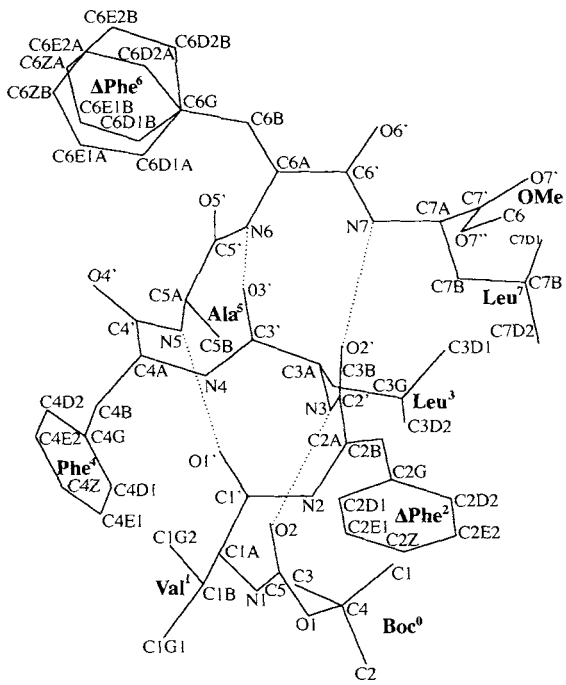

Fig. 1. Molecular structure of **1** in the crystal. The dotted lines indicate the intramolecular N–H···O hydrogen bonds. The two positions of the disordered benzene ring in ΔPhe[6] are also shown.

[$t(g^+t)$] is consistent with the observed conformation in peptide crystal structures[32] (Table 1). The two Leu side chains adopt two different conformations.

The molecule is characterized by a mixed $3_{10}/\alpha$-helix at the N-terminus comprising the first five residues, Boc-Val-ΔPhe-Leu-Phe-Ala. This helix is stabilized by three intramolecular N–H···O hydrogen bonds. Two of these are 4 → 1 type [N3···O2 and N6···O3′] and leads to type III β-bends,[14] and one is 5 → 1 type [N5···O1′] and results in an α-turn[33] (Table 2). α-Turns are quite rare in dehydropeptides. We

						151.1(7)	

[a] For the Boc group: $\omega_0 = -175.7(3)$, $\theta^1 = -176.2(4)$, $\theta^{1\prime} = 4.6(6)$, $\theta^{2,1} = -60.7(6)$, $\theta^{2,2} = 63.7(6)$, and $\theta^{2,3} = -179.3(5)°$. [b] ψ_7 = N7-C7A-C7′-O3, ω_7 = C7A-C7′-O3-C6. [c] The two values correspond to the disordered positions of the benzene ring in ΔPhe[6].

recently found an α-helical conformation in the crystal structure of the dehydropentapeptide Boc-Val-ΔPhe-Ala-Leu-Gly-OMe.[13] In **1** the NH group of the fourth residue, Phe^4, does not participate in any hydrogen bonds. [The strongest interaction of N4 is characterized by N4···O1′ = 3.053(3) Å, H···O1′ = 2.668(3) Å, and N4–H···O = 108.7(2)°]. The average main chain torsion angles for the first five residues are $\phi = -65.7°$ and $\psi = -28.8°$, which corresponds to a helical conformation and is in agreement with the values observed for the helical modules in peptides and proteins.[34–36] The sixth residue, ΔPhe^6, adopts an unusual left-handed α-helical conformation (α_L) as evident from its backbone dihedral angles (Table 1). The α_L conformation of ΔPhe^6 encourages the formation of a 6→1 hydrogen bond between NH of Leu^7 and CO of ΔPhe^2. This 6→1 hydrogen bond along with the 5→2 hydrogen bond between NH of ΔPhe^6 and CO of Leu^3 leads to a Schellman motif.[25]

The packing mode of the peptide molecules in the crystal is illustrated in Figure 2. The helical part of the peptide molecule

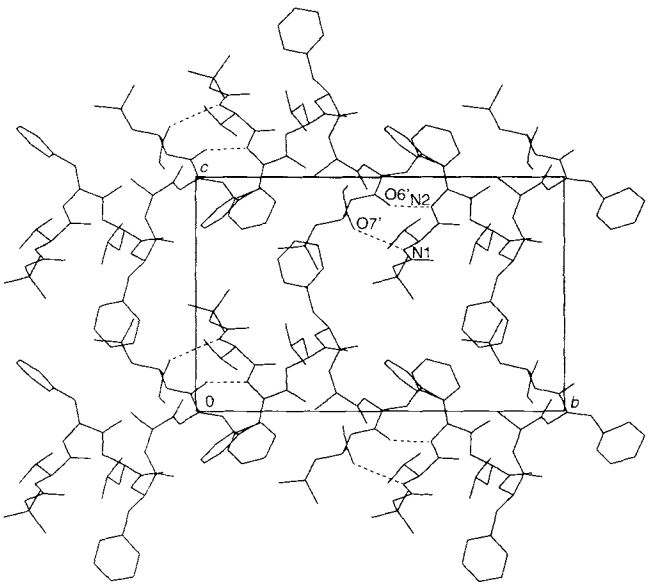

Fig. 2. Crystal packing of **1**; view down the crystallographic *a* axis. The dashed lines indicate the intermolecular N–H···O hydrogen bonds.

is approximately parallel to the crystallographic *b* axis. As the helix axis is along this axis, the neighboring helices are parallel. The helices related by the 2_1 screw axis interact through head-to-tail N–H···O hydrogen bonds (Table 2). The geometries of the hydrogen bond donor and acceptor do not match very well. Hence helical rods, a frequent feature observed in helical peptides,[10, 15] do not form. Instead a slightly zigzagged pattern of peptide molecules is evident along crystallographic *b* axis.

The Schellman motif at the C-terminus of the helix is not surprising in light of the fact that helices in proteins generally terminate with a Schellman motif.[19–25] Also, ΔPhe^6 at position 5 of the Schellman motif[25] is well suited to adopt the left-handed helical conformation since as an achiral residue it can exhibit helical conformations of either sense. The residue adopting the α_L conformation is frequently Gly, and less often Asn, in Schellman motifs of proteins.[19–25] Heptapeptide **1** provides an example wherein a residue with a rigid and bulky side chain is accommodated in the α_L position of the Schellman motif.[25] This might suggest that the achiral nature of the residue occupying the α_L position is more important than the size of the side chain. However, more studies with model peptides are needed to confirm this hypothesis. It has also been observed in proteins that positions 1 and 6 in the Schellman motif[25] are frequently occupied by hydrophobic residues.[19, 21, 25] In **1** these positions are occupied by ΔPhe and Leu, respectively, which are highly hydrophobic.

In oligopeptides containing ΔPhe residues helical structures are generally stabilized. For example, the structure of Boc-Leu-Phe-Ala-ΔPhe-Leu-OMe (**2**), which we recently solved,[11] shows a 3_{10}-helical conformation. Though **2** occurs as a fragment in the present peptide, its conformations in these two cases are different. The reason for this discrepency is not clear. The maximization of intramolecular hydrogen bond interactions is not likely to be a decisive factor, since a perfect $3_{10}/\alpha$-helical conformation would provide a greater number of well-matched helical hydrogen bonds than observed in **1**. Even the crystal packing considerations also do not explain this unusual conformation at the C-terminus of **1**. It is likely that the intramolecular nonbonding interactions play a main role in determining the final conformation. In fact the distances C7D2–C2D2 (4.08 Å), C7B–C2B(4.07 Å), and C7D2–C2B (4.11 Å) indicate significant nonbonding interactions between residues ΔPhe^2 and Leu^7. The residues at these positions are known to show nonbonding interactions in proteins as well.[25]

Experimental Procedure

Synthesis of **1**: The Boc group of the pentapeptide **2** [11] (1.5 g, 2.075 mmol) was removed by treatment with trifluoroacetic acid in dichloromethane (1:1, 20 mL) at room temperature for 30 min. The excess acid was removed in vacuo and the residue triturated with anhydrous ether and filtered. To a solution of Boc-Val-ΔPhe-azlactone (1.12 g, 3.11 mmol) in CH_2Cl_2 (20 mL) was added deprotected **2** and triethylamine (0.3 mL). The reaction mixture was stirred for 72 h at room temperature. After removal of solvent in vacuo, the residue was dissolved in ethyl acetate and washed with saturated $NaHCO_3$ solution, water, and saturated NaCl solution, and dried over Na_2SO_4. Evaporation of solvent in vacuo gave the desired heptapeptide. Yield: 1.5 g (76 %): m.p. 162–164 °C; R_f ($CHCl_3$:CH_3OH 9:1) = 0.93, R_f (*n*-butanol:acetic acid:water 4:1:1) = 0.97. ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.35 (1H, s, NH(ΔPhe^6)), 7.90 (1H, s, NH(ΔPhe^2)), 7.66 (1H, d, NH(Phe^4)), 7.64 (1H, d, NH(Ala^5)), 7.38 (1H, d, Leu^7), 7.32 (1H, d, Leu^3), 7.31–7.22 (17H, m, aromatic protons of ΔPhe^6, ΔPhe^2, Phe^4, C$^\beta$H (ΔPhe^6 and ΔPhe^2)), 5.03 (1H, s, NH(Val^1)), 4.73 (1H, br, C$^\alpha$H(Leu^7)), 4.47 (1H, br, C$^\alpha$H(Ala^5)), 4.45 (1H, br, C$^\alpha$H(Phe^4)), 4.13 (1H, br, C$^\alpha$H(Leu^3)), 3.84 (1H, br, C$^\alpha$H(Val^1)), 3.68 (3H, s, OCH_3), 3.45 (1H, d, C$^\alpha H_A$(Phe^4)), 3.07 (1H, t, C$^\beta H_B$(Phe^4)), 2.24 (1H, br, C$^\beta$H(Val^1)), 1.79 (2H, br, C$^\beta$H(Leu^7)), 1.77 (1H, br, C$^\gamma$H(Leu^7)), 1.59 (2H, br, C$^\beta$H(Leu^3)), 1.58 (1H, br, C$^\gamma$H(Leu^3)), 1.45 (9H, s, 3×CH_3 (Boc)), 1.12 (6H, dd, C$^\delta H_3$(Val^1)), 0.96 (6H, dd, C$^\delta H_3$(Leu^3)), 0.79 (6H, dd, C$^\delta H_3$(Leu^7)). Crystals suitable for X-ray structure analysis were grown by slow evaporation of a solution of **1** in methanol and water at 4 °C.

[29] Structure analysis of **1** ($T = 295$ K): Data were collected from a dry crystal mounted on a glass fiber by using a Enraf–Nonius CAD4 diffractometer. $M_r = 966.2$ ($C_{53}H_{71}N_7O_{10}$), monoclinic, space group $P2_1$, $a = 10.953(2)$, $b = 20.065(2)$, $c = 12.862(2)$ Å, $\beta = 95.1(1)°$, $V = 2815.3(7)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.14$ g cm^{-3}; $Cu_{K\alpha}$ radiation, $\lambda = 1.5418$ Å, $\mu = 6.109$ cm^{-1}; $F(000) = 1036.0$, $2\theta = 130°$, ($\omega - 2\theta$) scans; 4926 independent reflections, of which 4674 with $|F_o| > 4\sigma(|F_o|)$ were considered as independent. Lorentz and polarization corrections were applied to the data, but no absorption correction was made. The structure was determined using the direct methods employing the SHELXS86 [29] computer program and full-matrix least-squares refinement was carried out using the software SHELXL93 [30]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms fixed on the basis of stereochemistry were used only for structure factor calculations. The atoms of the benzene ring in residue ΔPhe^6 (except C6G) were found to be disordered between two positions (see Fig. 1). These five atoms were refined isotropically with the effective occupancy adding up to 1. Final *R*-values (based on $|F_o|$) for the observed reflections 0.046, for all reflections 0.048, (based on *I*) for all reflections 0.136, GoF = 1.049. Crystallographic data (excluding structure factors) for the structure described in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-5". Chlorine Tetraoxide**

Hinrich Grothe and Helge Willner*

The existence of the ClO_4 radical, one of the simplest chlorine oxides ClO_x ($x = 1-4$), has not yet been unequivocally established. Yet it has been postulated as a reactive intermediate in several reactions and should be a binary compound of fundamental significance. ClO_4 is probably an intermediate in the photochemical formation of Cl_2O_7 from Cl_2 and O_3,[1] as well as in the thermal decomposition of Cl_2O_6[2] and Cl_2O_7,[3] and in the anodic oxidation of ClO_4^- ions.[4] An indication of the existence of ClO_4 was obtained from ESR measurements on $KClO_4$ crystals that had been irradiated with X-rays.[5] However, the assignment and analysis of the ESR signals is still controversial.[6,7] The formation enthalpy of the endothermic ClO_4, derived from mass spectrometric and kinetic measurements on Cl_2O_7, amounts to 200–270 kJ mol^{-1}.[8,9]

The successful synthesis and spectroscopic identification of ClO_3 in the vacuum thermolysis of $ClOClO_3$ and matrix isolation of the products[10] encouraged us to generate a ClO_4 radical in the same way. For this purpose a sample of Cl_2O_6 (or Cl_2O_7) in a U-tube was cooled to -35 (or -105 °C) such that the partial pressure was roughly 10^{-3} mbar. Neon or argon was passed over the cold sample to give a 1:500 mixture of starting material and noble gas. This gas stream was thermolyzed at 230 °C (410 °C) at the orifice of the nozzle. Under these conditions 95 % of the molecules decay within a few milliseconds. The construction of the vacuum thermolysis and the matrix isolation apparatus is described elsewhere.[11] IR and UV/Vis spectra of the matrix-isolated thermolysis products were recorded. The proportion of decayed starting material was calculated by comparison with reference spectra of pure matrix-isolated starting material. In a total of 25 experiments we found five new bands in the IR spectra of the thermolysis products of Cl_2O_6 and Cl_2O_7 (Fig. 1, Table 1). These reproducible bands belonging to an

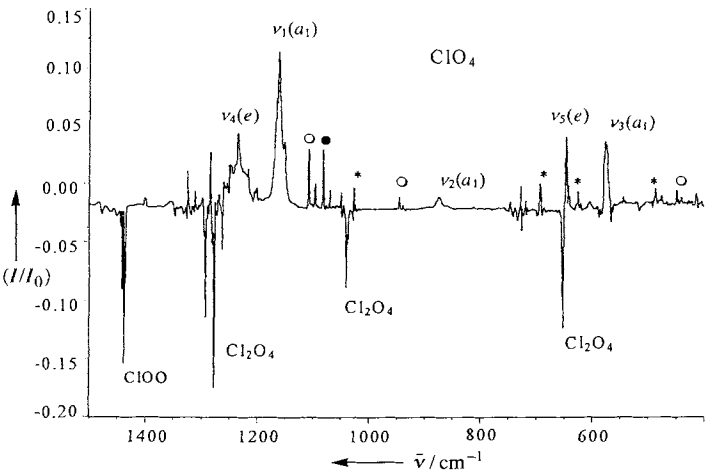

Fig. 1. Difference spectrum before and after the photolysis ($\lambda > 495$ nm) from the IR spectra of the thermolysis products of Cl_2O_6 isolated in a neon matrix. The bands of ClO_4 point upwards and those of the photolysis products downwards. Some noncompensated bands disrupt the spectrum. Bands arising from the by-products OClO (o), ClO_3 (•), and the starting material Cl_2O_6 (*) are labeled. Cl_2O_4 is formed in the photolysis of Cl_2O_6 [2].

unknown chlorine oxide are remarkable because their full width at half maximum is up to 10 cm^{-1}. This partly obscures the $^{35/37}Cl$ isotopic pattern, which is typical of species with one Cl atom. Since the relative intensities of the bands were the same in all experiments and since the bands decreased uniformly after photolysis of the matrix (tungsten–halogen lamp, cutoff filter, $\lambda > 495$ nm), all bands must belong to one single species. By IR spectroscopy we identified only ClOO as a product of the photolysis; it is probably formed by the primary decomposition of ClO_4 to give OClO and O_2 and subsequent photoisomerization of OClO.[12] In the UV/Vis spectra ClO_4 shows a wide absorption band ranging from 380 to 510 nm (maximum at 425 nm) with vibrational fine structure. The intensity of this band on photolysis decreases in the same fashion as the infrared bands of ClO_4. Below 380 nm the UV spectrum is obscured by the bands of ClO_3, ClO_2, and the starting material.

ClO_2 and ClO_3 are the most important by-products formed in the thermolysis of Cl_2O_6 and Cl_2O_7, respectively. Thus the primary decomposition can be described according to Equations (a) and (b), and the new bands can be assigned to the

$$Cl_2O_6 \longrightarrow ClO_4 + ClO_2 \quad (a)$$

$$Cl_2O_7 \longrightarrow ClO_4 + ClO_3 \quad (b)$$

ClO_4 radical. Experiments with $Cl_2{}^{18}O_6$ and the calculation of the vibrational frequencies with the program NORCOR[13] verify the existence of ClO_4. There are numerous possibilities for the arrangement of atoms in a ClO_4 molecule and for its symmetry. Based on the mode of formation, it can be assumed that ClO_4 has a tetrahedral or distorted tetrahedral structure with T_d, C_{3v}, C_{2v}, or C_s symmetry. Therefore two, six, eight, or nine corresponding bands can be expected in the range of fundamental vibrations in the IR spectrum. Comparison of the five new vibrations with the fundamentals of the similarly built $FClO_3$ and the isosteric FSO_3 radical clearly indicates a ClO_4 molecule with C_{3v} symmetry (Table 1). We have not yet been able to detect the missing $\nu_6(e)$ vibration, which is expected as a weak band around 400 cm^{-1}.

Our assignment of the bands to the vibrational modes is supported by the product rule for the mode a_1. The wavenumbers of the three a_1 vibrations of $^{35}Cl^{16}O_4$ and $^{35}Cl^{18}O_4$ were used to calculate the quotient of the wavenumber products (observed: 1.311; calculated: 1.308). In addition, a normal coordinate analysis of the vibrational data was performed with the bond lengths listed and a bond angle of 116° between the short ClO bonds of OClO. The results are three strong (8.7×10^2 $N m^{-1}$) and one weak ClO bond (5.3×10^2 $N m^{-1}$). The correlation of the force constant with the bond length (Fig. 2) leads to the structure of the ClO_4 radical shown in Figure 3.

The distortion of the ClO_4 radical to C_{3v} symmetry is dynamic (Jahn–Teller effect). One electron switches from an antibonding σ* orbital of one ClO bond to that of another, resulting in the broadening of the IR bands.

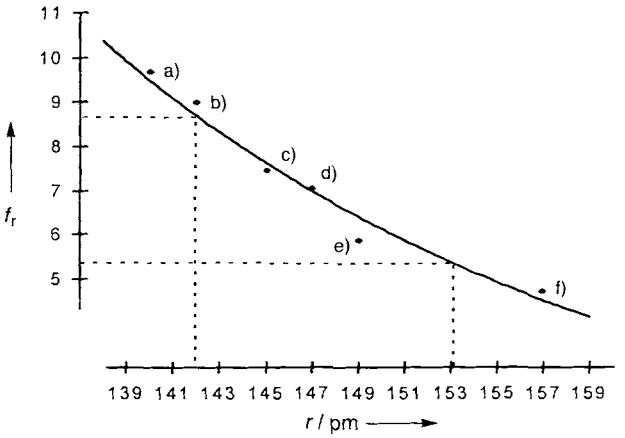

Fig. 2. Plot of the length of the Cl–O versus the force constant in 10^2 $N m^{-1}$ for the Cl–O bond for a) $FClO_3$, b) $FClO_2$, c) ClO_4^-, d) OClO, e) ClO_3^-, and f) ClO. An exponential function was fitted to the data. The broken lines relate the force constants of the ClO_4 radical with the corresponding bond lengths.

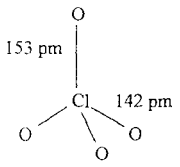

Fig. 3. Structure of ClO_4.

The ClO_4 radical completes the series of mononuclear binary chlorine oxides known, which can combined formally to give the binuclear species Cl_2O_2, Cl_2O_3, Cl_2O_4, Cl_2O_6, and Cl_2O_7. We have demonstrated that the primary thermal decay of two binuclear chlorine oxides yields the corresponding mononuclear radicals, with a preference for the formation of OClO. The chemistry of NO_x is analogous: the radicals NO, NO_2, and NO_3 participate in the formation and the decomposition of N_2O_3, N_2O_4, and N_2O_5, respectively.

Electronic Structure of Non-Heme High-Valent Oxoiron Complexes with the Unprecedented $[Fe_2(\mu\text{-}O)_2]^{3+}$ Core**

Abhik Ghosh, Jan Almlöf, and Lawrence Que, Jr.*

The chemistry of dioxygen activation at non-heme diiron centers in enzymes such as ribonucleotide reductase and methane monooxygenase has recently attracted significant attention.[1, 2] For the latter enzyme, a transient intermediate, "compound Q", which is kinetically competent to hydroxylate methane, has been characterized by Mössbauer spectroscopy as a coupled diiron(IV) species.[2] Our synthetic efforts to model such high-valent intermediates have resulted in two complexes with the general formula $[LFe(\mu\text{-}O)_2FeL](ClO_4)_3$ [**1**: L = tris(2-pyridylmethyl)amine (tpa); **2**: L = tris(5-methyl-2-pyridylmethyl)amine (tpa′)], which contain the unprecedented high-valent $[Fe_2(\mu\text{-}O)_2]^{3+}$ core.[3, 4] The EPR spectra of intermediates **1** and **2** are indicative of a quartet spin state ($S = 3/2$), and the Mössbauer spectral parameters are very similar to those of compound Q.[4] Though the iron centers in the $[Fe_2(\mu\text{-}O)_2]^{3+}$ core can naively be assigned the formal oxidation states III and IV, Mössbauer spectra of **1** and **2** show that the two iron centers are identical. To gain insight into the electronic structure of these novel species, we have carried out first-principles quantum chemical calculations on **1** (C_{2h}) and report our results herein.

The large size of the molecules of interest severely limits the choice of an appropriate theoretical method. Transition metal complexes are generally poorly described at the Hartree–Fock level, while standard ab initio correlated methods require prohibitive amounts of computer time and memory. In contrast, density functional theory (DFT)[5, 6] is attractive, owing to its computational expediency and because it implicitly includes the effects of electron correlation. Local density functional (LDF) calculations, including a geometry optimization, were performed on **1**[7] (excluding the perchlorate ions) with a C_{2h} symmetry constraint, to take advantage of the experimentally established indistinguishability of the iron centers. Of the various electronic configurations examined, the configuration with the lowest energy had three unpaired electrons with parallel spins, consistent with the experimentally observed quartet spin states of **1** and **2**.[4]

The optimized structure of **1** (Fig. 1) provides valuable structural information on the novel high-valent $Fe_2(\mu\text{-}O)_2$ core of **1** and **2**. The two symmetry-distinct Fe–O vectors are 1.77 and 1.83 Å in length; the shorter one is *trans* to the nitrogen atom of the aliphatic amino group of tpa. The exceptionally short Fe–Fe separation (2.83 Å) and the compressed Fe-O-Fe angle (105.1°) are a consequence of the Fe_2O_2 core structure and reminiscent of analogous features in the ions $[(tpa)Mn^{III}(\mu\text{-}O)_2Mn^{IV}(tpa)]^{3+}$,[10] $[(tpa'')Fe^{III}(\mu\text{-}O)(\mu\text{-}OH)Fe^{III}(tpa'')]^{3+}$ [tpa″ = tris(6-methyl-2-pyridylmethyl)amine],[11] and $[(tpa'')Fe^{III}(\mu\text{-}O)_2Fe^{III}(tpa'')]^{2+}$.[12] The Fe–N distances in the Fe_2O_2 plane of **1** are 1.95 and 2.03 Å; the longer bond is associated with the more weakly bound nitrogen atom of the aliphatic amino group, while the Fe–N distances outside the Fe_2O_2 plane are 1.91 Å. These Fe–N distances are significantly shorter than those in high-spin Fe^{III} tpa complexes,[1] but are in excellent agreement with those in low-spin $[Fe^{III}(tpa')(acac)](ClO_4)_3$ (acac = 2,4-pentanedionate).[14]

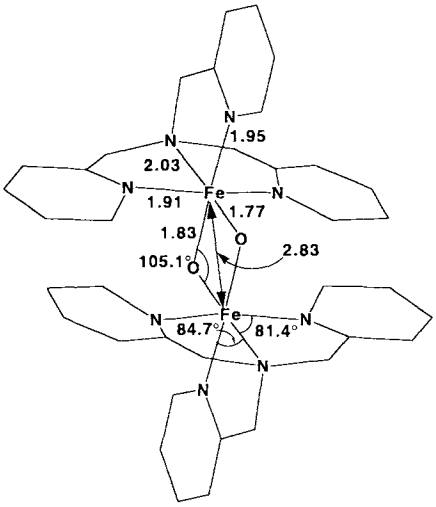

Fig. 1. Optimized geometry in the core of **1**; distances in [Å], angles in [°].

The optimized geometry of **1** can be compared with experimental EXAFS data (Fe K-edge) on the related complex **2**.[4] The best EXAFS fit for **2** consists of one Fe–N/O vector at 1.76 Å, three Fe–N/O vectors at 1.94 Å, two Fe–N/O vectors at 2.17 Å, and one Fe–Fe vector at 2.89 Å. Our optimized geometry is in good agreement with the presence of shells at 1.76, 1.94, and 2.89 Å in the EXAFS fit, but does not reproduce the shell at 2.17 Å. At present, it is not clear whether this discrepancy reflects a limitation of our calculation or of the EXAFS analysis. Overall, despite minor discrepancies, the optimized structure of **1** and experimental data agree quite well.

Figure 2 depicts the energy level diagram of the frontier molecular orbitals (MOs) of **1** that have predominant Fe 3d character.[15] While the symmetries of the frontier orbitals may be predicted from qualitative arguments alone, we obtained

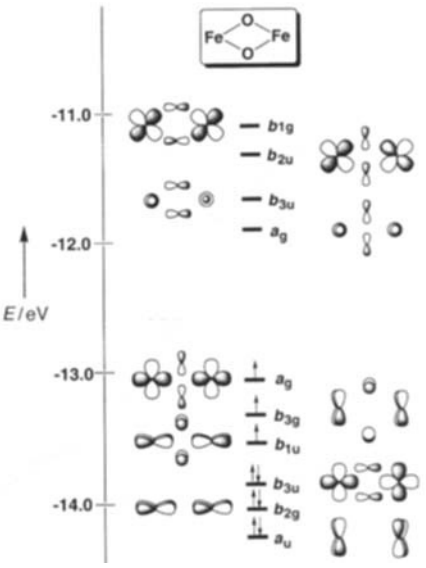

Fig. 2. Shapes and energy level diagram of the canonical MOs constituting the 3d band of **1**. The irreducible representations refer to the D_{2h} point group, which is the maximum possible symmetry of the $[Fe_2O_2]$ unit. E = orbital energy.

their orbital energies and occupancies directly from our calculations. Occupation of these MOs with the nine 3d electrons of the formally $[Fe^{III}Fe^{IV}]$ dinuclear center according to Hund's rule results in the configuration shown, which is as expected on the basis of the large HOMO–LUMO gap (> 1 eV). This configuration has three unpaired electrons, in agreement with the EPR measurements. The six singly or doubly occupied MOs depicted in Figure 2 are exactly those derived from symmetric and antisymmetric combinations of the three $3d_\pi$ ("t_{2g}-type") AOs of the two irons. Similarly, the unoccupied MOs shown in Figure 2 can be recognized as based on Fe $3d_\sigma$ ("e_g") AOs. Thus, the quartet spin state of **1** appears to be a direct result of a substantial t_{2g}–e_g band gap.[16]

Some further insight into the electronic structure of the $[Fe_2(\mu\text{-}O)_2]^{3+}$ group can be obtained from the Mulliken population analysis results, including gross AO populations and gross AO spin populations (Table 1). As might be expected from Figure 2, the Fe $3d_\pi$ or "t_{2g}-type" AOs (d_{xz}, d_{yz}, and $d_{x^2-y^2}$) have larger Mulliken populations than the $3d_\sigma$ or "e_g-type" AOs (d_{xy} and d_{z^2}). Thus, the very small population of the Fe $3d_{z^2}$ AO is consistent with this notion. The Fe d_{xy} $3d_\sigma$ AO, on the other hand, has a significant population of 0.68, but this results solely from partial iron character of subfrontier, predominantly oxygen-based MOs with Fe–O bonding character, which reflects the essentially covalent nature of the interaction between the high-valent iron centers and the oxide ions. Relatively large Fe $3d_\sigma$ AO populations have also been found in other calculations on low-spin high-valent oxoiron species such as Fe^{IV}=O porphyrin complexes which have Fe $3d_{z^2}$ (the Fe=O vector defines the z axis) AO populations of 0.73–0.76.[17] However, the Fe $3d_\sigma$ AOs contribute only to doubly occupied MOs and thus do not carry any spin population. Overall, to the extent that spin states can be assigned to individual atoms in a polynuclear complex, the calculations predict that the iron centers in **1** may be described as low-spin. This is an important insight since the majority of known iron tpa or methyl-substituted tpa complexes have high-spin configurations.[13, 14]

Table 1. Gross electron and spin populations of AOs of **1** [a].

	Fe "t_{2g}" MOs			Fe "e_g" MOs		O		
AO	d_{xz}	d_{yz}	$d_{x^2-y^2}$	d_{xy}	d_{z^2}	p_x	p_y	p_z
AO population	1.63	1.59	1.48	0.68	0.04	1.93	1.36	1.77
AO spin population	0.36	0.39	0.41	0.00	0.00	0.00	0.11	0.23

[a] AO = atomic orbital, MO = molecular orbital.

The three unpaired electrons of **1** are nearly fully localized on the Fe_2O_2 core, and distributed in a 4:1 ratio between the Fe and O atoms, which have spin populations of 1.16 and 0.34, respectively. Clearly, the iron or oxygen atoms do not have integral spin populations, which shows that the bonding in the $[Fe_2O_2]^{3+}$ core has substantial covalent character. Thus, purely ionic formulations[4] of the electronic structure of **1**, such as $Fe^{III}(O^{2-})_2Fe^{IV} \leftrightarrow Fe^{IV}(O^{2-})_2Fe^{III}$ or $Fe^{III}(O^{\bullet})(O^{2-})Fe^{III} \leftrightarrow Fe^{III}(O^{2-})(O^{\bullet})Fe^{III}$ are simplistic. An interesting point of similarity between the LDF spin density distributions of the present $[Fe_2O_2]^{3+}$ complexes and Fe^{IV}=O porphyrins is that in both classes of compounds, the spin density is confined to the Fe and O atoms with essentially none delocalized over to the organic ligand(s) constituting the rest of the molecule. Moreover, the spin populations of the iron centers are nearly identical (ca. 1.2) in the $[Fe_2O_2]^{3+}$ complexes and Fe^{IV}=O porphyrins.[6] The spin population of the oxygen atom in an Fe^{IV}=O unit is about 0.8;[6] that is about half an electron spin higher than the spin population of each oxygen atom in the $[Fe_2O_2]^{3+}$ group. Thus, the $[Fe_2O_2]^{3+}$ unit is electronically equivalent to a one-electron reduced dimerized pair of $[Fe^{IV}$=O$]^{2+}$ groups; the decrease in spin population takes place exclusively on the two oxygen atoms (Fig. 3).

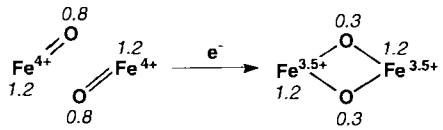

Fig. 3. Populations of unpaired spins (in italics) in the $[Fe{=}O]^{2+}$ and $[Fe_2O_2]^{3+}$ units.

This bonding scheme is qualitatively consistent with the unusual Mössbauer spectral parameters of these species. The low-spin configurations of the iron centers in **1** are consistent with the low Mössbauer isomer shifts of these species (ca. 0.13 mm s^{-1}). In addition, the populations of the three $3d_\pi$ AOs of each iron are quite similar, suggesting a highly isotropic electron spin distribution around each iron center, which may explain the perplexingly low Mössbauer quadrupole splittings of **1** and **2** (ca. 0.5 mm s^{-1}).

These calculations also provide some insight into the Raman-active vibrations of the $[Fe_2O_2]^{3+}$ core. For simplicity, we have used a D_{2h}-symmetric model of **1**, $[(py)_4Fe(\mu\text{-}O)_2Fe(py)_4]^{3+}$ **3** (py = pyridine) to construct the following three-coordinate potential energy surface. The potential energy V is calculated by Equation (a), where where r_1 is the Fe–Fe distance, r_2 is the

$$V = A(\Delta r_1)^2 + B(\Delta r_2)^2 + C(\Delta r_1)(\Delta r_2) + D(\Delta\theta)^2 \quad \text{(a)}$$

O–O distance, θ is the angle between the Fe–Fe and O–O vectors, and Δ indicates deviations from equilibrium values.[18, 19] This potential energy was used to perform a standard vibrational analysis using an $[Fe_2O_2]$ four-atom model. The normal modes are schematized (with some exaggeration) in Figure 4,

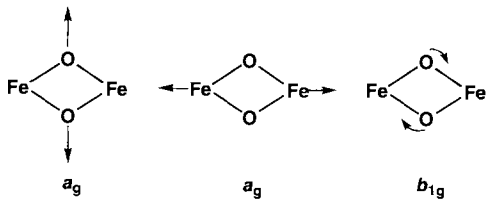

Fig. 4. Schematic representation of the calculated normal modes of the $[Fe_2O_2]$ unit of **3**.

and calculated frequencies and isotope shifts are given in Table 2. One of the a_g normal modes (712.6 cm^{-1}) exhibits significant oxygen isotope sensitivity (^{18}O shift of −39 cm^{-1}), which corresponds to the experimentally observed feature at 666 cm^{-1} in the resonance Raman spectra of **1** and **2**.[4] The experimentally observed ^{18}O shifts of −29 to −32 cm^{-1} are in good qualitative agreement with theory, especially in view of the point group symmetries of **1** and **2** (C_{2h}) versus that of **3** (D_{2h}).[19] Table 2 also predicts that this mode should be insensitive to iron isotope substitution, as qualitatively suggested by Figure 4; experiments are underway to verify this prediction.

In summary, DFT calculations have provided full structural and some vibrational data on $[Fe_2O_2]^{3+}$ complexes. A conceptual framework has also emerged for understanding key electronic and structural (EPR and Mössbauer) properties of these

Table 2. Calculated frequencies [cm^{-1}] and isotope shifts (in parentheses [Δcm^{-1}]) of the Raman-active normal modes of the $[Fe_2O_2]$ unit of **3**.

Symmetry	$^{56}Fe_2{}^{16}O_2$	$^{56}Fe_2{}^{18}O_2$	$^{54}Fe_2{}^{16}O_2$	$^{58}Fe_2{}^{16}O_2$
a_g	712.6 (0.0)	673.4 (−39.2)	713.1 (0.5)	712.1 (−0.5)

[15] The Kohn–Sham orbitals in DFT are often similar to their counterparts in Hartree–Fock theory, and their treatment in the computational schemes is nearly indistinguishable. Thus, in spite of the formal lack of a many-electron wavefunction, an analysis of the LDF MOs permits us to construct a qualitative framework for understanding the electronic structure and spin state of **1**.
[16] The terms "e_g-type" and "t_{2g}-type" are used to loosely describe MOs whose amplitudes or shapes, near the approximately octahedral metal centers, resemble rigorous e_g and t_{2g} d AOs of centers with perfect O_h local symmetry. The terms d_σ and d_π are used synonymously with "e_g-type" and "t_{2g}-type", respectively, and do not refer to the molecular mirror plane of **1**.

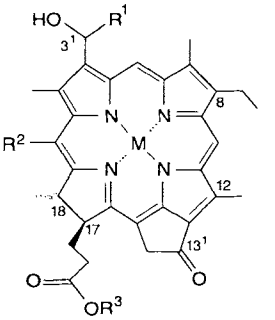
[18] A series of single-point calculations on **3** were performed with various values of r_1, r_2, and θ; all other internal coordinates were fixed at their optimized values. The potential energy surface was obtained by multi-variable least-squares fitting of the data sets $V(r_1, r_2, \theta)$ (where V is the molecular total energy) with a polynomial including up to quadratic terms. The calculated values of $\partial^2 V/\partial r_1^2$ ($= 2A$), $\partial^2 V/\partial r_2^2$ ($= 2B$), and $\partial^2 V/\partial r_1 \partial r_2$ ($= C$) are 0.22226, 0.15013, and 0.03338 Hartree $Bohr^{-2}$, respectively, and $\partial^2 V/\partial \theta^2$ ($= 2D$) is 1.48105 Hartree $radian^{-2}$; all force constants were evaluated at the equilibrium geometry.
[19] The force constants $\partial^2 V/\partial r_1 \partial \theta$ and $\partial^2 V/\partial r_2 \partial \theta$ are required by symmetry to be zero in **3** but not in **1** or **2**.

Self-Assembly of an Artificial Light-Harvesting Antenna: Energy Transfer from a Zinc Chlorin to a Bacteriochlorin in a Supramolecular Aggregate**

Hitoshi Tamiaki,* Tomohiro Miyatake, Rikukei Tanikaga, Alfred R. Holzwarth,* and Kurt Schaffner

In recent years many supramolecular assemblies with novel chemical and material properties have been shown to form by self-organization of identical or complementary building blocks.[1] We have studied extensively the self-assembly of metallochlorins ((17,18-dihydroporphyrinato)metal complexes) in nonpolar organic solvents[2–4] and have demonstrated that these in vitro homoaggregates have the same structure as aggregates of bacteriochlorophyll *c* and *d* (Scheme 1) present in



BChlc, M = Mg, $R^{1,2} = CH_3$, R^3 = stearyl

BChld, M = Mg, $R^1 = CH_3$, R^2 = H, R^3 = farnesyl

1, M = Zn, $R^{1,2}$ = H, $R^3 = CH_3$

Scheme 1. Bacteriochlorophylls(BChl) *c* and *d* and zinc chlorin model **1**; numerous other structural variants are encountered in vivo, which differ in the alkyl substituents at C-8 and C-12, and in R^3 [15].

natural chlorosomes. These aggregates, the light-harvesting system of green bacteria,[5] are notably the first photosynthetic antenna system known not to require a protein for the pigment organization.[6–8] The understanding of the principles of the interactions (for example hydrogen bonding, van der Waals, $\pi-\pi$, and electrostatic interactions) responsible for the self-assembly of both in vitro and in vivo supramolecular aggregates of metallochlorins can now be exploited in various ways. One of the possibilities is to construct artificial photoactive devices capable of performing a useful task.

We describe in the following a supramolecular system, in which efficient transfer of singlet excitation energy occurs from about 50–100 aggregated zinc chlorins to a single metal-free bacteriochlorin. It is the first example of a functional self-

assembled unit that mimics the function of a natural photosynthetic antenna and represents the first step en route to a potential photoactive device.

Zinc chlorins possessing 3^1-hydroxyl and 13^1-ketone functions readily aggregate in nonpolar organic solvents such as hexane. These aggregates have been judged to be good structural models for bacteriochlorophyll *c* and *d* aggregates formed in both nonpolar solvents and in native chlorosomes.[2-4, 9]

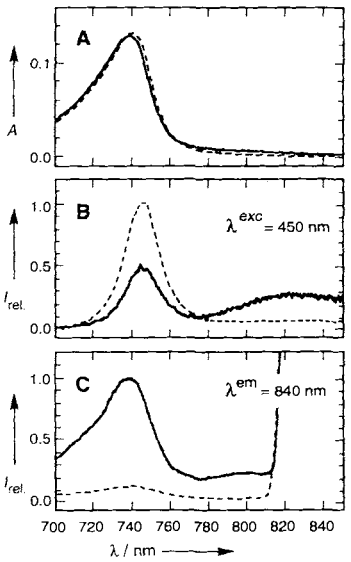

Fig. 1. Visible absorption (A), corrected fluorescence (B), and corrected fluorescence excitation spectra (C) of **1** (- - -) and a 50:1 mixture of **1** and **3** (—) in THF/hexane (1/99 v/v).

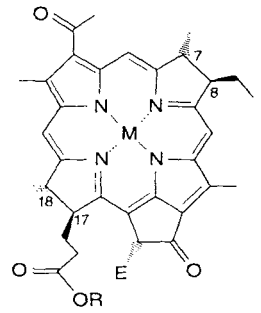


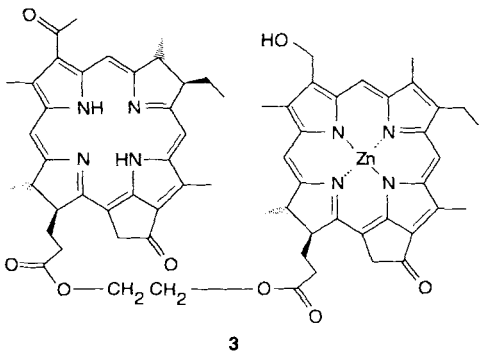
BChla, M = Mg, E = CO_2CH_3, R = phytyl

2, M = 2 H, E = H, R = CH_3

Scheme 2. Bacteriochlorophyll(BChl) *a* and the metal-free bacteriochlorin model compound **2**.

The absorption of zinc chlorin **1**[3] is red-shifted on conversion from the monomeric form (λ_{max} = 647 nm, in THF) to the aggregate (λ_{max} = 740 nm, in THF/hexane (1/99)),[4] and the fluorescence of the aggregate peaks at approximately 750 nm (Figs. 1A and B). Addition of a small amount of metal-free bacteriochlorin **2**[10] (a 7,8,17,18-tetrahydroporphyrin; Scheme 2) effects neither a change in the 740-nm absorption of aggregate **1** nor in its 750-nm emission, although monomeric **2** (λ^{abs}_{max} = 755 nm) should be a suitable acceptor in terms of exothermic energy transfer conditions—similar to bacteriochlorophyll *a*, which in chlorosomes traps the light energy absorbed by the core bacteriochlorophyll *c* and *d* aggregates.[11] The failure of **2** to quench excited aggregate **1** can be explained by a large mean donor–acceptor distance; **2** is not capable of coaggregating with **1** because it lacks both a central metal and a 3^1-hydroxyl group. (The concentration of **1** is only 2.5×10^{-6} M. Taking into account that several thousand zinc chlorin molecules (**1**) may form an aggregate, the average distance to an acceptor (**2**) will be far too large for the efficient operation of any kind of energy transfer mechanism.)

In contrast, quite a different result is obtained when the chromophoric systems of **1** and **2** are linked covalently, as in compound **3**. When a solution of a 50:1 mixture of **1** and **3** in THF is diluted with hexane, the 740-nm absorption of aggregate **1** is accompanied by a proportionate weak absorption of **3** growing in at around 800 nm (Fig. 1A). In the fluorescence spectrum, the 750-nm emission of aggregate **1** (*hν'* in Fig. 2) is decreased to about 50% of the intensity of that in the absence of **3**, and a new broad emission appears instead at around 820 nm (Fig. 1B; *hν''* in Fig. 2). The fluorescence excitation spectrum (Fig. 1C) of the



3

mixture shows that an appreciable part of this new fluorescence, which is attributable to the bacteriochlorin chromophore of **3**, arises by way of excitation of the aggregate **1** (cf. the 740-nm excitation band). This then clearly documents intrasupramolecular energy transfer from singlet-excited aggregate **1** to the bacteriochlorin moiety of **3** (Fig. 2). The de-

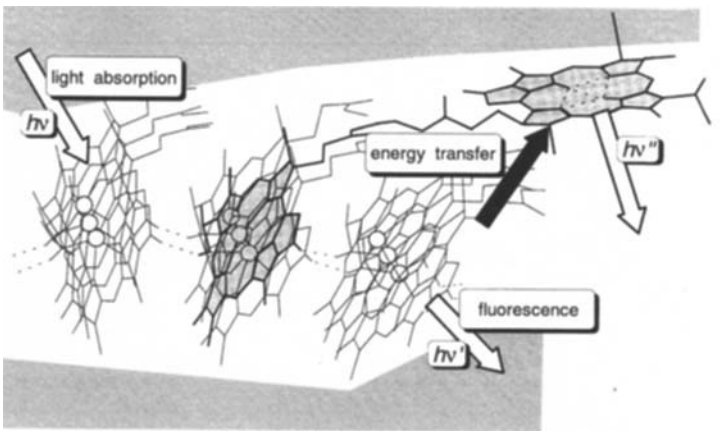


Fig. 2. Representation of the intrasupramolecular energy transfer from a singlet-excited aggregate of **1** (nonshaded stack) to the metal-free bacteriochlorin moiety of **3** (shaded molecule): ○, zinc atom; - - -, C=O···H–O hydrogen bond; the solvation sphere (nonpolar solvent, lipid, detergent) is indicated by the shaded area enveloping the stacked aggregate. This picture represents a section of the three-dimensional arrangement of an aggregate adopted from molecular modeling results [8a].

crease in the donor fluorescence by a factor of about two is close to that expected theoretically for a rapidly established energy transfer equilibrium between the donor and (long-lived) acceptor states.[12] This indicates that the energy transfer is fast as well as highly efficient.

The seemingly low quenching effect of 50% would not limit the maximal yield of energy usage in a potential electron transfer device, since the electron transfer yield would primarily depend on the ratio of the rate constants of, for example, a useful electron transfer reaction and of nonradiative relaxation of the system. We note, furthermore, that the rates of radiationless deactivation in the natural chlorosomes and in artifical bacteriochlorophyll aggregates are similarly high, leading to excited-state lifetimes in the order of 10 to 100 ps in systems without an acceptor.[13] Nevertheless, this does not harm in any way the efficient light-harvesting function of natural chlorosomes.

An even more efficient energy transfer than that in nonpolar organic solvent is achieved by providing the heteroaggregate **1**·**3** with a higher order solvation sphere: while aqueous solutions of

1·**3** with either α-lecithin (a lipid) or Triton X-100 (a nonionic detergent) give absorption and emission spectra qualitatively similar to those shown in Figure 1, the quenching of the donor fluorescence by energy transfer is substantially increased, up to 80–90%. This suggests that embedding the heteroaggregate in a nonpolar lipid or detergent sphere either increases the size of the aggregates or—perhaps even more likely—invokes efficient interaggregate energy transfer like that in natural chlorosomes.[11] Both possibilities increase the probability that an energy acceptor (**3**) is available to the excited donor aggregate (**1**).

In conclusion, in vitro zinc chlorin aggregates are not only adequate model systems for in vivo bacteriochlorophyll *c* and *d* aggregates in the chlorosomal core in terms of their supramolecular structure,[2–4] but also enable the self-assembly of efficient functional units for heterogeneous energy transfer.

Experimental Procedure

Following literature procedures [3,14] compound **3** was synthesized by condensation of pyropheophorbide *d* with 2-hydroxyethyl bacteriopyropheophorbide *a*, followed by selective reduction of the 3-formyl group and equally selective zinc metalation of the pyropheophorbide half of the molecule. HPLC chromatography gave pure **3** as a dark purple solid. M.p. > 300 °C. ^{1}H NMR ($CDCl_3$/CD_3OD 7/3): δ = 9.13, 8.95, 8.61, 8.14, 8.04, 8.02 (6 s, 1H each; meso-CH), 5.40 (s, 2H; CH_2-3), 4.88, 4.72, 4.64, 4.42 (4 d, ^2J(HH) = 20 Hz, 1H each; CH_2-13^2), 4.05–4.15 (m, 1H), 3.65–3.97 (m, 8H), 3.29–3.49 (m, 3H), 3.81, 3.25, 2.96, 2.93, 2.81 (5 s, 3H each; CH_3), 1.77–2.28 (m, 10H), 1.53, 1.43, 1.34 (3 d, ^3J(HH) = 7 Hz, 3H each; CH_3), 1.39, 0.83 (2 t, ^3J(HH) = 7 Hz, 3H each; CH_3); UV/Vis (THF): λ_{max} (I_{rel}): 751 (0.49; Q_y band of metal-free bacteriochlorin moiety *a*), 678 (0.08), 647 (0.68; Q_y of zinc chlorin moiety), 605 (0.11), 566 (0.06), 530 (0.22), 424 (0.90), 387 (0.69), 359 nm (1.00); MS (FAB): *m/z*: 1178 (M^+ for ^{64}Zn).

[12] If we make the reasonable assumption that the rates of energy transfer between donor and acceptor are fast relative to the rates of nonradiative relaxation in either system, and that the nonradiative donor relaxation is essentially unaffected by the binding of the acceptor, then an energy transfer equilibrium will be established between donor and acceptor. Taking into account the energy differences as judged by the absorption spectra, and the donor/acceptor ratio, one can estimate that the donor fluorescence should be quenched by about 60%, in good agreement with the experiment.

Hexaterphenylyl- and Hexaquaterphenylylbenzene: The Behavior of Chromophores and Electrophores in a Restricted Space**

Menno A. Keegstra, Steven De Feyter, Frans C. De Schryver, and Klaus Müllen*

Oligo-*para*-phenylenes and poly-*para*-phenylenes are classical chromophores and redox systems.[1] Because of their electroluminescent properties, they have been used often recently as active components in light-emitting diodes,[2] but they can also be employed to investigate the influence of chain length and geometry on charging processes.[1a, 3] For both applications, it would be desirable to have model compounds that contain several identical oligomer building blocks in a restricted space. We therefore directed our attention to the aesthetically appealing benzene derivatives hexa-*p*-terphenylylbenzene (**1**) and hexa-*p*-quaterphenylylbenzene (**2**). Formally, the star-shaped compound **1** can be regarded as being constructed of three septiphenyl chains with one benzene unit in common. However, the interplanar angle makes an arrangement of six electronically coupled terphenylyl chains a more plausible structure.[4] We describe the synthesis and the electrophoric and chromophoric properties of **1** and **2**.

As a synthesis of **1** by formation of aryl–aryl bonds to a central benzene unit did not seem to be a promising approach, the method of choice was a cyclotrimerization of suitable derivatives of diphenylacetylene. It is well known that hexaphenylbenzene can be formed from diphenylacetylene in the presence of a transition metal catalyst.[5] However, the rigid diterphenylylacetylene **3** to be used as the starting material must contain alkyl groups to increase its solubility. These must be *tert*-alkyl groups to shield the *ortho* positions in the alkylbenzene **7**, as shown in Scheme 1.

Bromination of **7** is followed by a Suzuki coupling[6] with 4-biphenylboric acid.[7] The terphenyl **9** formed can be brominated regioselectively in the 4″ position, and this bromide (**10**) is

3

then subjected to a three-step synthesis sequence to give the disubstituted acetylene **3**.[8, 9] All the reactions can be carried out on a 0.5 mol scale, and compounds **5**–**8** are obtained in an analytically pure state without further purification, while the other compounds can be purified by recrystallization from acetone.

Acetylene **3** is converted into **1** by a palladium(II)-catalyzed trimerization.[5] The solubility of **1** in common solvents is excellent, unlike that of the starting compound **3**. The expected twisting of the terphenyl units at an angle of about 65° to the central benzene ring in **1**[4] probably hinders close packing of the molecules in the solid state, and this explains the good solubility of **1** compared with that of **3**. Selected physical and spectroscopic data for **1**, **2**, and **3** are given in Table 1.

The low solubility of the acetylene precursor means that one cannot assume that cyclotrimerization would give successful results with larger systems. Hexaquaterphenylylbenzene **2**, a homologue of **1**, was therefore synthesized by a Suzuki reaction of hexa(4-iodophenyl)benzene[10] with terphenylboric acid **13**[11] (Scheme 2). As 4-(1,1-dimethylpentadecyl)-*p*-quaterphenyl is formed as a by-product of the reaction, it can be deduced that, under the reaction conditions used, cleavage of the bond to the central benzene ring occurs.

The behavior of **1** and **2** as multielectrophore and multichromophore π systems was investigated by cyclovoltammetric, ESR/ENDOR-spectroscopic, and optical methods. The electro-

Table 1. Selected physical and spectroscopic data for **1**–**3**.

1: MS (FD, 8 kV): *m/z*: 2884.3 $[M^+]$; ^{1}H NMR (300 MHz, $CDCl_3$, 30 °C): δ = 0.85 (t, ^3J = 6.7 Hz, 3H), 0.99–1.27 (m, 24H), 1.28 (s, 6H), 1.57–1.64 (m, 2H), 6.99 (d, ^3J = 8.3 Hz, 2H), 7.22 (d, ^3J = 8.3 Hz, 2H), 7.34 (d, ^3J = 8.5 Hz, 2H), 7.48–7.55 (m, 6H).

2: MS (FD, 8 kV): *m/z*: 3336.3 $[M^+]$; ^{1}H NMR (300 MHz, $CDCl_3$, 30 °C): δ = 0.86 (t, ^3J = 6.5 Hz, 3H), 0.99–1.28 (m, 24H), 1.31 (s, 6H), 1.54–1.66 (m, 2H), 7.05 (d, ^3J = 7.9 Hz, 2H), 7.22 (d, ^3J = 8.2 Hz, 2H), 7.38 (d, ^3J = 8.0 Hz, 2H), 7.52–7.62 (m, 10H).

3: MS (FD, 8 kV): *m/z*: 959.9 $[M^+]$; ^{1}H NMR (300 MHz, $CDCl_3$, 30 °C): δ = 0.86 (t, ^{3}J = 6.8 Hz, 3H), 1.02–1.31 (m, 24H), 1.32 (s, 6H), 1.52–1.64 (m, 2H), 7.40 (d, ^{3}J = 8.2 Hz, 2H), 7.57 (d, ^3J = 8.3 Hz, 2H), 7.63 (m, 4H), 7.68 (m, 4H); UV/Vis (CH_2Cl_2): λ_{max} = 332 nm.

chemical reduction of **1** (THF, 0.05 M Bu_4NPF_6, Au electrode, v = 100 mV s^{-1}, 258 K) under cyclovoltammetric control indicates a fivefold charge on the system ($E^{1-3}_{1/2}$ = −2.56 V, E^4_{pc} = −3.12 V, E^5_{pc} = −3.24 V, where pc = peak in the cathodic cycle).[12] The ready formation of the trianion indicates minimal coulombic repulsion, that is, a localization of the individual charges on the terphenyl units. Comparison of the first reduction potential with that of *p*-terphenyl ($E^1_{1/2}$ = −2.60 V, E^2_{pc} = −2.92 V) confirms the conclusion that considerably decoupled terphenyl redox units are present in **1**. It is worth noting that the ENDOR spectrum of the radical monoanion of **1** (K^+, THF, 260 K) shows a maximum hyperfine coupling constant a_h of 0.023 mT. Thus, there is effective delocalization over the entire π system brought about by an electron transfer between the terphenyl redox units that is rapid relative to the measurement time scale. UV/Vis spectroscopic observation of the reduction of **1** with potassium (K^+, THF, 260 K) reveals a monoanion (λ_{max} = 990, 780, 487 nm) and a dianion (λ_{max} = 1060, 720 nm). However, further charging under these conditions leads to the decomposition of **1**. The appearance of terphenyl radical anions shows that the aryl–aryl bond is cleaved to some extent.

Table 2. Optical properties of **1**, **2**, **9**, and **14** [a].

Compd	λ_{max} (abs) [nm] [b]	ε [L mol^{-1}cm^{-1}]	λ_{max} (em) [nm] [c]	Quantum yield [g]
1	305	2.5×10^5	360–380 [d]	0.66
2	316	3.2×10^5	425 [e], 385, 374 [f]	0.93
9	285	3.6×10^4	364, 346, 332	0.99
14	299	4.7×10^4	390 [e], 367, 354	0.96

[a] Solvent CH_2Cl_2, 298 K. [b] No fine structure. [c] Excitation wavelengths corresponding to absorption maxima. [d] Broad, fine structure at 77 K. [e] Shoulder. [f] Further splitting on temperature reduction. [g] Relative error 10%.

To describe the optical properties of **1** and **2**, model substances (alkyl-substituted terphenyl **9** and *p*-quaterphenyl **14**) were used as for comparison (Table 2). The bathochromic shift in the absorption and emission spectra of **1** and **2** relative to **9** and **14**, respectively, is not consistent with the picture of completely independent oligophenyl chromophores in **1** and **2**. However, in view of the high local concentration of these chromophores, the molecular extinction coefficients of **1** and **2** are remarkably higher than those of **9** and **14**, respectively (six to seven times). It is also interesting that the fluorescence quantum yields of the star-shaped compounds **1** and **2** are only slightly smaller than those of the model substances. Furthermore, the similarity between the fluorescence spectra of the film and those of the solution excludes the formation of aggregates in the solid state.

The absence of excimer formation, the high fluorescence quantum yields, the good solubility, and the low crystallization tendency make **1** and **2** extremely good potential materials for light-emitting diodes.[13] Their electroluminescence properties will be reported elsewhere.

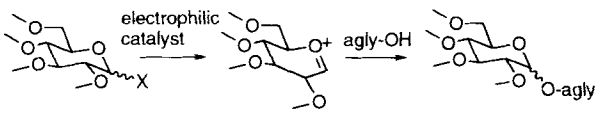
The Cycloaddition Way to Glycosyl Transfer**

Giuseppe Capozzi, Angelos Dios, Richard W. Franck,* Aloma Geer, Cecilia Marzabadi, Stefano Menichetti, Christina Nativi, and Maria Tamarez

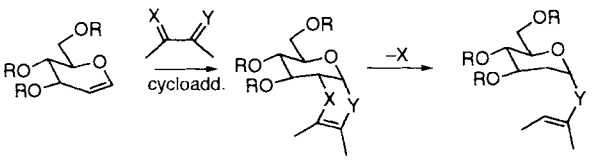
Dedicated to the memory of William S. Johnson

A century of glycosyl transfer chemistry can be summarized, with a few exceptions, by Equation (a), in which the anomeric



(a)

carbon of a sugar is activated to become electrophilic whereupon it bonds to a nucleophilic aglycone.[1] The extent and subtlety of glycosidation methodology rests on the development of diverse activation methods and the control of stereochemistry in the formation of the glycoside bond. This communication outlines our successful application of a different concept for glycosyl transfer, a cycloaddition method depicted in general form in Equation (b). Thus, a diene with heteroatoms at its



(b)

termini undergoes cycloaddition to a glycal followed by ring-opening of the adduct at the heteroatom not at the glycosidic position.

This sequence would yield a glycoside without reverting to traditional glycoside chemistry. Our approach has its antecedents in two earlier reports of cycloadditions to glycals. Inverse electron demand Bradsher cycloadditions of isoquinolinium salts to glycals demonstrated both the ease and high stereoselectivity of these cycloadditions [Eq. (c) DNP = 2,4-dinitrophenyl].[2] Of course, the products formed are not glycosides since the new bonds are C–C linkages.

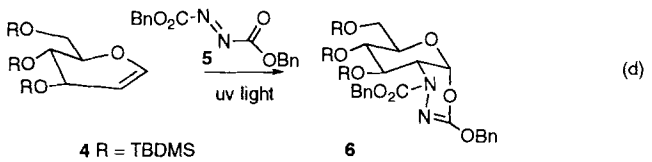
[**] The research conducted at Hunter College was supported in part by the National Institutes of Health (grants GM51216, RR03037 (RCMI support for the NMR and X-ray facilities), and GM08176) (MBRS for M. T.) and by the PSC-CUNY. The Firenze group was supported by MURST.

At about the same time, the light-catalyzed [4 + 2]cycloaddition of azodicarboxylates to glycals to form oxadiazenes was reported.[3] The reaction was usually highly stereoselective and when followed by catalyzed ring-opening at the anomeric carbon and reduction of the hydrazo group, the reaction sequence led to an elegant synthesis of glycosides of 2-aminosugars [Eq. (d); TBDMS = *tert*-butyldimethylsilyl].



(d)

4 R = TBDMS 6

The heterodiene system that led to the development of our new method is the diacylthione **9**, which is generated in situ with a weak base from the phthalimidosulfenyl precursor **8**. In turn, **8** is easily formed from pentanedione and phthalimidosulfenyl chloride [Eq. (e)].[4]
