Fig. 2. Contour diagrams of the S_0 and T_1 PES for the ring-closure reaction of 1,2-dimethyltrimethylene, as calculated by the CI approach and estimated by SCF and force-field (MMX) methods. Triplet–singlet intersection $E_{ST} = 0$ is indicated by heavy lines.

From these results, it can be concluded that, as in the unsubstituted TM, the reactive structure of optimal ISC is characterized by a face-to-face orientation of the radical centers and a C-C-C angle γ slightly smaller than for the triplet minima. As the singlet PES drops steeply toward the cyclopropane minimum for small values of γ, the triplet reaction yields preferably cyclic products. The conditions for optimal ISC are similar for both minima M_{cis} and M_{trans}; therefore, the stereochemical differentiation between *cis*- and *trans*-substituted products is due, in this special case, to the energy difference of the two minima M_{cis} and M_{trans}. This explains the experimental observation that the triplet-sensitized photoreaction of *cis*- as well as *trans*-3,4-dimethyl-1-pyrazoline yields preferably *trans*-1,2-dimethylcyclopropane, and negligible amounts of acyclic products, in contrast to the singlet photoreaction, which occurs preferably with retention of the configuration and yields appreciable amounts of acyclic products.[10]

Thus, the reactive structure of the triplet photoreaction of trimethylene that corresponds to optimal ISC is hardly affected by methyl substitution, and the product ratio reflects the energy difference between M_{cis} and M_{trans} on the T_1 surface. Since this energy difference is due mainly to steric effects, it should be possible to estimate it on the basis of simple models. For this purpose we calculated the difference PES E(DMTM) − E(TM) for DMTM and the unsubstituted TM by SCF-MO as well as by force-field methods[11] and added this difference to the PES of the unsubstituted TM.[6] The resulting contour diagrams together with the singlet–triplet intersection line ($E_{ST} = 0$) are shown in Figure 2 for the T_1 as well as the S_0 state. For comparison, results of the complete CI calculations are also given. The rotational angle is varied from $\alpha = -90°$ to $\alpha = 90°$, thus including the *syn* and *anti* motions that are shown separately in Figure 1 (cf. the contour diagrams of the triplet PES given at the bottom of Figure 1). It is quite apparent that both methods describe the main features of steric effects on the PES quite correctly; the SCF results slightly overestimate and the force-field results slightly underestimate the nuclear repulsions at small values of the C-C-C angle .

In summary, the combined analysis of PES and SOC surfaces is very well suited for determining the reactive geometries that are most favorable for ISC. The knowledge of these geometries together with the T_1 excited-state PES then allows for a detailed elucidation of the mechanism of a triplet photoreaction and a rationalization of the stereoselectivity. Since purely steric substituents like methyl groups do not affect the SOC values, it is possible to evaluate the structural dependence of SOC for the unsubstituted system only, and to use simple models to estimate steric effects on the PES. In the case of DMTM different reactive geometries leading to *cis*- and *trans*-1,2-dimethylcyclopropane may be reached from the minima M_{cis} and M_{trans}, and the necessary energies are less than 1 kcal mol^{-1}. Thus, stereodifferentiation is due to energetic behavior of the T_1 PES. Since this is, to our knowledge, the first triplet photoreaction for which the mechanism has been elucidated in detail, future investigations have to show whether this is a general feature of stereodifferentiation in triplet reactions.

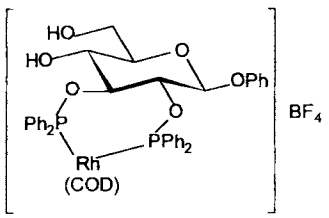
Proof of a Reversible, Pairwise Hydrogen Transfer during the Homogeneously Rhodium(I)-Catalyzed Hydrogenation of α,β-Unsaturated Carbonic Acid Derivatives with In Situ NMR Spectroscopy and Parahydrogen**

Andreas Harthun, Rüdiger Selke,* and Joachim Bargon*

In recent years hydrogenations with para-enriched hydrogen (p-H_2) in combination with in situ NMR spectroscopy have been successfully applied to elucidate mechanistic aspects of homogeneously catalyzed hydrogenations.[1] Contrary to the usual Boltzmann distribution, hydrogenation with p-H_2 leads to a selective population of nuclear spin levels, which generates enhanced (up to 10^5) ("polarization") signals in emission and absorption in the ^{1}H NMR spectra of the hydrogenated products. This leads to a high sensitivity for registering these products in low concentration. A prerequisite for detecting polarization signals is a pairwise transfer of both p-H_2 atoms to the product.[2] This polarization phenomenon is known by the acronyms PASADENA (*P*arahydrogen *A*nd *S*ynthesis *A*llows *D*ramatically *E*nhanced *N*uclear *A*lignment)/ALTADENA (*A*diabatic *L*ongitudinal *T*ransport *A*fter *D*issociation *E*ngenders *N*et *A*lignment)[3] and PHIP (*P*arahydrogen *I*nduced *P*olarization).[4]

For the first time, we have used the PHIP method to detect polarization not only in the products but also in the reactant employed, which indicates a *reversible* hydrogenation reaction. For this purpose we investigated the hydrogenation of substituted alkenes with an α- and/or β-carbonyl function by using the cationic rhodium(I) precatalyst **1**.[5] The question of whether the hydrogenation proceeds reversibly or not usually cannot be decided when normal hydrogen is used for the hydrogenation, because the regenerated reactant cannot be distinguished from the original substrate. Deuteration experiments can give indications whether the reaction is reversible or not, but they are not conclusive for a *concerted* reaction, that is, a *pairwise* exchange mechanism. Therefore, it remains uncertain in which step the exchange of the olefinic protons occurs.



1

The hydrogenation of methyl acrylate **2a** with p-H_2 was investigated as an example for a pairwise exchange of the geminal protons in the olefinic starting material. From the beginning of the hydrogenation, polarization signals are detected in the reactant, which are superimposed by usual reactant NMR signals, however. Nevertheless, the observed polarization pattern reveals the formation of regenerated reactant, which must result from a pairwise p-H_2 transfer into the *geminal* positions of the double bond (Fig. 1).

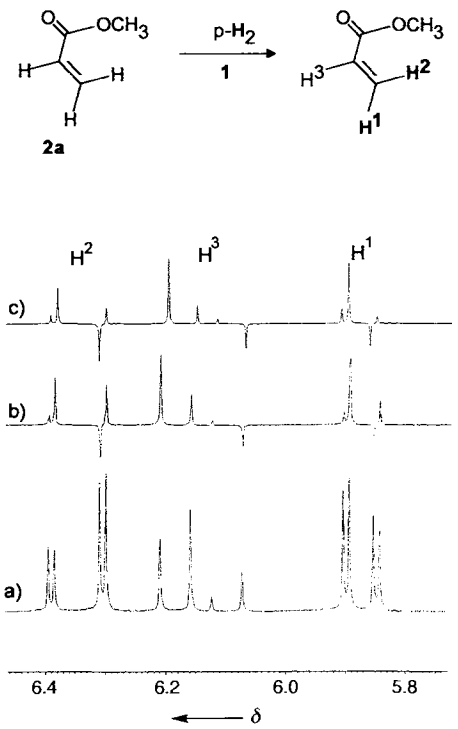


Fig. 1. The olefinic region of the ^{1}H NMR spectra (δ = 5.7–6.5) of the hydrogenation of methyl acrylate **2a** with **1**: a) spectrum of the starting material; b) spectrum after starting the hydrogenation with p-H_2. The polarization of the regenerated reactant ($R_{pol.}$) is identified by characteristic emission signals; c) simulation of spectrum b), considering normal reactant signals R ($R_{pol.}$: R = 3:1).

In contrast to the reaction of **2a**, at the beginning of the hydrogenation of itaconic acid **2b** only rather weak polarization signals in the resonances of the geminal protons of **2b**—resembling somewhat a "phase shift"—are observed besides huge polarization signals of the saturated hydrogenation product methyl succinic acid. The intensity of this signal changes during the reaction until it becomes a significant polarization signal. Figure 2 illustrates a comparison of simulated spectra[6] with the experimental spectrum. The observed time-dependent change of the signal phase is a result of a superimposition of normal reactant signals and reactant signals that are generated by polarization transfer due to a reversible pairwise proton exchange.

The superimposition of normal reactant signals with freshly generated polarization signals can be suppressed if deuterated [D_3]methyl acrylate (98%) **2c** is used as the substrate. As an example, Figure 3 shows the experimental spectrum of the olefinic protons of [D_8]methyl methacrylate (96%) **2d** after hydrogenation with p-H_2 compared with appropriate simulations.

When using itaconic acid anhydride **2e** as the substrate, this reactant is not hydrogenated itself. Nevertheless, polarization signals are observed that can be attributed to itaconic acid **2b**. Apparently, some part of the anhydride gets converted to the acid during the reaction. Therefore, polarization signals of the acid are readily detected, and are not superimposed by normal signals of **2b**, because of the low acid concentration at the beginning of the hydrogenation reaction.

To confirm the pairwise proton exchange, deuteration experiments were conducted. The substrate **2a** also becomes deuterat-

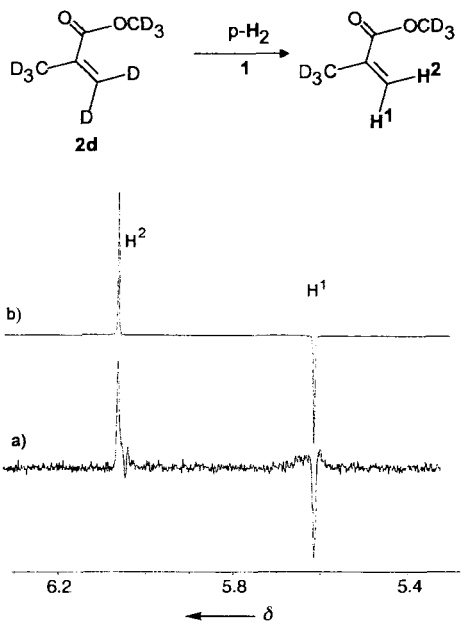

Fig. 3. The olefinic region of the ^{1}H NMR spectra (δ = 5.3–6.3) of the hydrogenation (p-H_2) of [D_6]methyl methacrylate (96%) **2d** with **1**: a) spectrum of the hydrogenation of **2d**; b) simulation. The simulation considers the coupling of the exchanged geminal protons to the nonexchanged deuterium atoms.

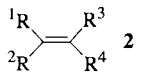
ed in the geminal positions by H/D exchange, as is evident from the ^{2}H NMR spectrum, which confirms the result of the former hydrogenation experiment that used p-H_2. The ^{2}H NMR spectrum of **2b** also demonstrates that both olefinic protons in starting material are exchanged by H/D exchange. Moreover, the ^{1}H NMR spectrum recorded after the deuteration of **2b** reveals that the monodeuterated H/D exchange product is formed likewise. The proton signals of the monodeuterated substrate **2b** are slightly shifted to higher field, because of an isotope effect,[7] and are, therefore, easily identified. The results of these and of analogous hydrogenation and deuteration experiments are summarized in Table 1.

Table 1. Hydrogenation of alkenes **2** with an α- and/or β-carbonyl function with **1** (+ = detected, − = not detected, o = experiment not performed).



Compd.	R^1	R^2	R^3	R^4	p-H_2 Polarization (pairwise) ^{1}H NMR	D_2 H/D-exchange (mono) ^{1}H NMR	D_2 ^{2}H{^{1}H} NMR
2a	H	H	CO_2CH_3	H	+	−	+

2c	D	D	CO_2CH_3	D	+	o	o
2d	D	D	CO_2CD_3	CD_3	+	o	o
2f[b]	H	H	CO_2CH_3	CH_3	−	−	+
2g	H	H	$CH_2CO_2CH_3$	CO_2CH_3	+	+	+
2h	H	H	$NHCOCH_3$	CO_2CH_3	−	−	−

[a] The detected polarization signals are proof for a pairwise proton exchange mechanism. In favorable cases, mono H/D exchange is detected in ^{1}H NMR spectra due to a shift of the nonexchanged protons (isotope shift); in the ^{2}H NMR spectra the broad resonances of the partially exchanged olefinic deuterium atoms do not reveal whether a mono- or bisdeuterated substrate is generated. [b] Itaconic acid anhydride **2e** is not listed in Table 1 since this substrate is not hydrogenated itself.

A generalized hydrogenation mechanism depicted in Figure 4, considers an individual mono H/D exchange as well as a pairwise H/D exchange of the geminal substrate protons. Formation of the catalyst–substrate complex **A** and of the alkylhydrido complex **B** is assumed to be reversible. Reversibility of the hydrogenation reaction as suggested here has so far not been proposed[11,12] for either dimethyl itaconate **2g** or for the N-acetamidoacrylic acid derivatives, which are structurally related[8] (compare Table 1 **2h**). ^{1}H NMR measurements conducted at low temperature have been used previously to demonstrate that the substrate **2g** changes the coordination side of the olefin from *Re* to *Si* and vice versa in a catalyst–substrate complex **A**. The process is favorable due to an intramolecular equilibrium reaction that leads to the formation of diastereomeric catalyst–substrate complexes.[9] The result confirms that during a "major–minor isomerization"[9,10] a reversible intramolecular coordination of the olefin to the catalyst is favored over an intermolecular isomerization, without leaving the catalyst's sphere of coordination. At present we cannot yet decide whether the pairwise proton exchange in the geminal position of olefinic reactants really follows the intramolecular mechanism depicted in Figure 4. Conclusive proof of our theses has to await a detailed analysis and characterization of the intermediates of the exchange reaction.

Experimental Procedure

All substrates were purchased and used without further purification: **2a,b,e–h** (Aldrich), **2c,d** (Promochem).

Deuteration experiments: The NMR tube (Wilmad WPS500) was filled with acetone (1 mL) (Aldrich) (degassed with argon for 5 min), substrate **2a,g** (ca. 40 μL) (and 20 mg **2b**, respectively), **1** (5 mg), and about 3 bar D_2, and was shaken for 1 min. The reacting solution was then investigated immediately by ^{2}H NMR and ^{2}H{^{1}H} NMR spectroscopy.

Hydrogenation experiments (p-H_2): Parahydrogen was enriched to about 50% at 77 K and taken successively out of a U-shaped flow-through cell filled with activated charcoal [11]. The NMR tube was filled with [D_6]acetone (1 mL) (Promochem),

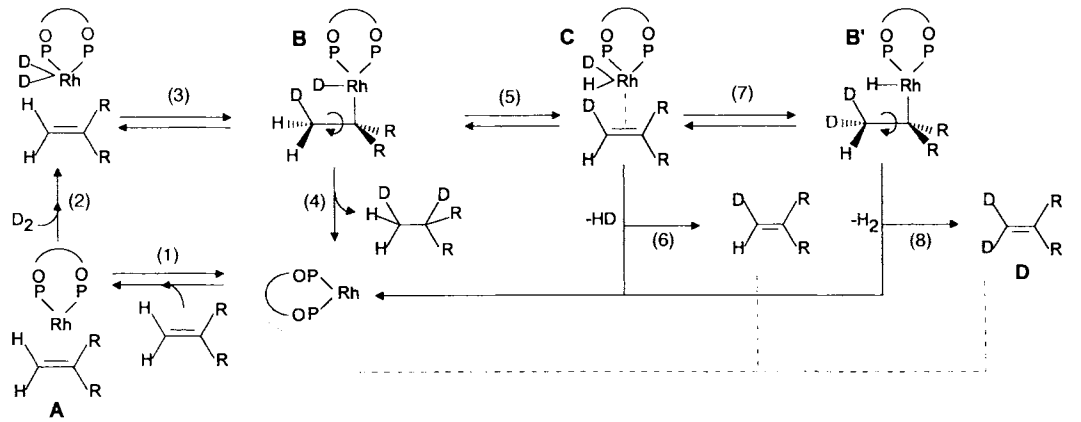

Fig. 4. Proposed mechanism for the deuteration of terminal alkenes by the rhodium(I) bis(phosphinite) complex **1** as a precatalyst. The mechanism explains both the partial deuteration of the saturated product and a mono- and pairwise H/D exchange in the geminal olefinic protons. The coordination of the solvent molecules and substrate is generally not depicted. The formation (1) of the catalyst–substrate complex **A** is considered to be reversible [8]. The intermediately generated complex **B** (2,3) reacts either to give the 1,2-deuterated product (4) or reversibly (5) to give **C**. The *side-on*-bound monodeuterated alkene is either set free from **C** (6), or it generates the complex **B'** in a reversible reaction (7). The statistically generated bisdeuterated alkene can be eliminated from **B'** by a reversible reaction step (8). If D_2 is substituted by p-H_2, the bisdeuterated substrate **D** is generated, which contains two parahydrogen atoms. These display nuclear spin polarization, which indicates that a pair correlation is maintained in spite of the two-step exchange process.

different amounts of substrate, namely **2f,g** (20 μL), **2a,c,d** (40 μL), **2b,e,h** (5 mg), **1** (5 mg), and about 3 bar p-H_2, and was shaken for about 10 s and transferred into the NMR spectrometer. After this procedure a ^{1}H NMR spectrum was recorded directly by using a 45° pulse [2]. ^{1}H NMR (200 MHz, [D$_6$]acetone, 25 °C): **2a**: δ = 3.71 (s, 3H; CH_3), 5.87 (dd, ^3J(H,H) = 10.27, ^2J(H,H) = 2.06 Hz, 1H; =C*H*H), 6.14 (dd, ^3J(H,H) = 17.15, ^3J(H,H) = 10.27 Hz, 1H; =CH-), 6.35 (dd, ^3J(H,H) = 17.15, ^2J(H,H) = 2.06 Hz, 1H; =CH*H*).

2b: δ = 3.33 (d, ^4J(H,H) = 1.16 Hz, 2H; CH_2), 5.75 (dt, ^2J(H,H) = 1.6, ^4J(H,H) = 1.16 Hz, 1H; =C*H*H), 6.23 (d, ^2J(H,H) = 1.6 Hz, 1H; =CH*H*).

Simulation parameters of the geminally hydrogenated (p-H_2) reactants of **2d**: **2d'**: δ = 5.61 (dd, ^2J(H,H) = 1.62, ^4J(H,D) = 0.25 Hz, 1H; =C*H*H), 6.04 (dd, ^2J(H,H) = 1.62, ^4J(H,D) = 0.16 Hz, 1H, =CH*H*), **D** (dd, ^4J(D,H) = 0.25 Hz, ^4J(D,H) = 0.16 Hz, 3D; CD_3).

Lithium Arsanylalanates as Arsenide Sources: A Simple Route to the Zintl Anion As_7^{3-} and the Synthesis of a Tetraarsatetrasilacubane**

Matthias Driess,* Klaus Merz, Hans Pritzkow, and Rudolf Janoschek

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

Multiple phosphanyl-substituted and arsanyl-substituted element hydrides of groups 13 and 14, $E_n(XH_2)_m$ (E = B, Al, Ga, In, Si, Ge, Sn; X = P, As), are of importance as potential starting materials for the preparation of optoelectronic layers (doping, organometallic chemical vapor epitaxy (OMCVE) methods).[1] We have therefore been concerned with the synthesis of multiple arsanyl-substituted silanes, germanes, and stannanes such as $RE(AsH_2)_3$ and $E_2(AsH_2)_6$ (E = Si, Ge, Sn; R = alkyl, aryl), which can be prepared by mild arsanylation of the corresponding element halides. In order to be in a position to carry out multiple arsanylations, in analogy to the successful oligophosphanylation of chlorosilanes, chlorogermanes, and chlorostannanes that works with the nucleophilic and at the same time only slightly basic $[LiAl(PH_2)_4]$,[2] we first focused our attention on the existence of lithium arsanylalanates **1**.

We report here on the thermolabile lithium tetraarsanylalanate **1a**, which is only stable in solution, and on the related compounds **1b** and **1c**, which in comparison to $[LiAsH_2(dme)]$ (dme = 1,2-dimethoxyethane) surprisingly lead to the Zintl an-

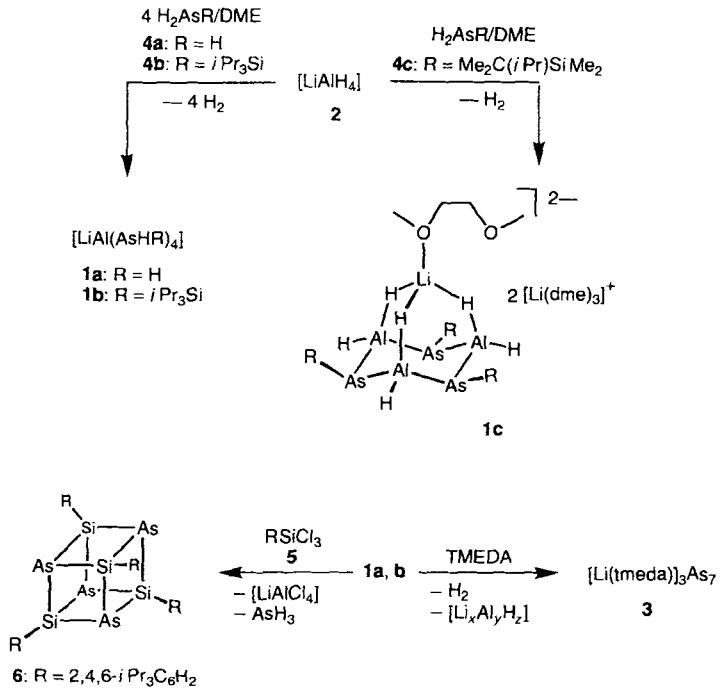
ion As_7^{3-} on thermal decomposition. In addition, we describe the first tetraarsatetrasilacubane, which was obtained by the reaction of **1a** with (2,4,6-triisopropylphenyl)trichlorosilane.

The alanate **1a**[3] was best prepared by introduction of AsH_3 into a solution of $[LiAlH_4]$ **2** in DME; the course of the reaction was monitored by ^{27}Al NMR spectroscopy. Once the reaction had gone to completion and **1a** had been formed in quantitative



yield, a singlet was observed in the ^{27}Al NMR spectrum of the solution at $\delta = 150.4$. The protolysis produced the expected amount of AsH_3 as the sole gaseous product. Compound **1a** is admittedly only moderately stable even in solution and decomposed immediately on removal of the solvent to form AsH_3, H_2, and a brown insoluble solid that could not be identified. We have now found that the decomposition of **1a** in solution at 25 °C over a period of 3–4 days leads to the formation of the Zintl ion As_7^{3-} in high yield, H_2, and as yet hitherto unknown (polymeric?) lithium alanates. The formation of As_7^{3-} was confirmed by the isolation and characterization[4] of the structure of its TMEDA-solvated trilithium salt **3** (TMEDA = *N,N'*-tetramethylethylenediamine), which was formed on addition of TMEDA to the reaction solution and was isolated by fractional crystallization in 85 % yield in the form of orange needles. This was the first time that a solvate of Li_3As_7 had been characterized crystallographically (Fig. 1), whereas related silylated, germylated, and stannylated molecular As_7 derivatives were already known.[5] The salt **3** is isotypic with the phosphorus analogue.[6] The four-coordinate Li centers bridge each of the otherwise two-coordinate As atoms. The three different As-As distances *a*–*c* reflect the same electronic relationships as in the phosphorus analogue.[6]

The formation of As_7^{3-} does not only occur on decomposition of **1a**, however, but somewhat surprisingly also takes place on reaction of solutions of lithium tetrakis(silylarsanyl)alanate **1b** with TMEDA; in this case, **3** is also formed in 73 % yield. The alanate **1b** is formed quantitatively (^{27}Al NMR spectroscopy) on reaction of **2** with four molar equivalents of the primary arsane **4b** and is, like **1a**, in spite of, or perhaps even because of, its bulky silyl groups, only stable in solution and

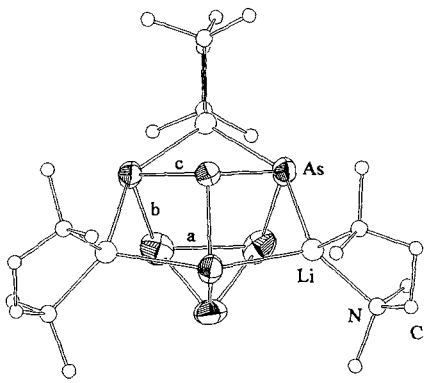


Fig. 1. Molecular structure of **3** in the crystal. Selected average distances [Å]: Li–As 2.63(2), a = 2.487(2), b = 2.372(2), c = 2.427(2).

decomposes slowly at room temperature. The mechanism of the Si–As bond cleavage and the fate of the silyl groups at the As atoms have not yet been clarified. The chelation of the Li cation by TMEDA apparently increases the reactivity of the alanate ion to such an extent that a "self-destruction" of the $AlAs_4$ framework sets in. The intrinsically weak Al–As bond is probably also responsible for the formation of the thermodynamically more favorable As_7 framework, because other decomposition reactions occur with analogous lithium phosphanylalanates in which the phosphorus analogue of **3** is not formed.[7]

In addition to this we also obtained the first lithium arsanylalanate stable in the solid state; the unusual aggregate **1c** is formed in 81 % yield by the reaction of **2** with one molar equivalent of the primary arsane **4c** in DME at 25 °C. The crystal structure analysis [4] of the colorless crystals showed that a ion-triple is present, consisting of two $[Li(dme)_3]^+$ ions and one cyclotriarsatrialanate with alternating Al and As atoms coordinating to a DME-solvated lithium cation (Li1) through three Al–H bonds in a tripodal fashion; consequently, a dianionic heteroadamantane-like framework is present (Fig. 2). Whereas donor stabilization of Li^+ by hydridic H atoms has also been observed in other molecular lithium alanates,[8] the coordinative surroundings of the Li1 center shows additional characteristics: The hydridic H atoms are evidently better (harder) donors than the As atoms, and the DME molecule functions rather surpris-

ingly as a monodentate ligand. In contrast, the Li2 and Li3 centers are octahedrally coordinated. The Li1–H distances lie between 1.65–1.90(7) Å, that is they are the same as the values that were determined for related complexes.[8] The As–Si distances of 2.327–2.341(3) Å are not unusual. The bulky silyl groups are arranged equatorially. The Al–As distances in the chair-shaped Al_3As_3 framework lie between 2.457–2.485(3) Å and are thus only slightly longer than in a trialuminatriarsacyclohexane with λ^3,σ^3-coordinate Al and As atoms (2.43 Å).[9] The alanate **1c** does not exhibit the same thermal behavior as **1a** and **1b** because of its different Al, As framework; the As_7^{3-} ion is neither formed by heating nor by reaction with TMEDA. The $Li1(HAl)_3$ arrangement in the complex dianion of **1c** is apparently not retained in organic solvents at 20 °C. Instead, a rapid exchange of the [Li(dme)] units takes place, since only one sharp singlet can be found in the ^{7}Li NMR spectrum at $\delta = -3.0$. Low-temperature NMR investigations in solution and CP/MAS solid-state NMR studies are not yet complete and will be reported in due course.

In spite of its lability, initial results show that **1a** is a valuable synthetic building block for the construction of novel polyarsenic compounds with elements of group 14. The reaction of **1a** with the bulky trichlorosilane **5**, for example, led to the first tetraarsatetrasilacubane $(AsSiIs)_4$ **6** (Is = 2,4,6-iPr$_3$C$_6$H$_2$), which was obtained in 36 % yield in the form of bright yellow crystals. The mechanism of formation is not yet known. It is highly probable, however, that **6**—analogous to the $(PSitBu)_4$ cubane—is formed in a number of steps from polycyclic precursors.[10] Its structure was determined by single-crystal X-ray analysis (Fig. 3).[4] The As_4Si_4 framework is strongly distorted

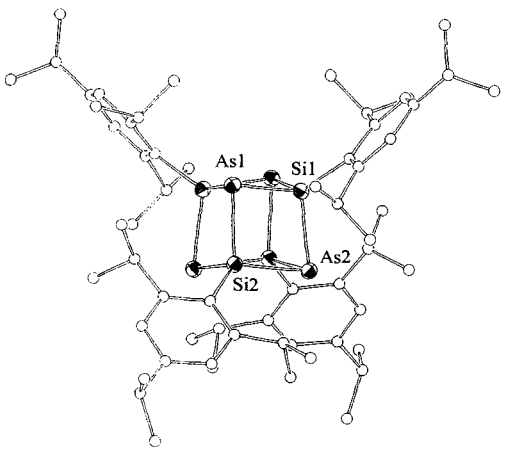

Fig. 3. Molecular structure of **6** in the crystal. Selected distances [Å] and angles [°]: As1–Si1 2.400(3), As1–Si1a 2.408(3), As1–Si2 2.411(3), As2–Si2a 2.398(3), As2–Si1 2.409(3), As2–Si2 2.409(3), Si–C(ipso) 1.896(8), 1.890(8); Si1-As1-Si1a 80.20(1), Si1-As1-Si2 79.01(8), Si1a-As1-Si2 78.60(8), Si2a-As2-Si1 78.83(8), Si2a-As2-Si2 80.1(1), Si1-As2-Si2 78.87(8), As1-Si1-As1a 98.43(10), As1-Si1-As2 100.42(9), As1a-Si1-As2 100.46(8), As2a-Si2-As2 98.54(9), As2a-Si2-As1 100.69(9), As2-Si2-As1 100.11(9).

in comparison to the recently synthesized As_4C_4 cubane $(AsCtBu)_4$,[11] so that its topography can be most simply described as an overlap of a Si_4 and an As_4 tetrahedron (C_2 point symmetry). The As–Si distances of 2.398–2.409(3) Å are almost identical with those in less strained As_2Si_2 cyclobutanes.[12] The endocyclic angles at the Si (98.4–100.5(1)°) and at the As atom (78.8–80.2°) reflect very similar bonding relationships to those in the $(PSitBu)_4$ cubane with a partial negative charge on the pnictogen, whereas in the carbon analogues positively polarized pnictogen atoms with strong n/σ interactions are present.[13] The geometry optimization of $(AsSiMe)_4$ (**6***), carried out by using the density functional method according to Becke (B3LYP/6-31G*),[14] resulted in T_d point symmetry with slightly longer As–Si distances (2.429 Å) than in **6**, and almost identical endocyclic angles at the Si (100.6°) and at the As atom (78.3°). Moreover, the ^{29}Si NMR chemical shift of **6*** ($\delta = -35.8$) was calculated at the GIAO/6-311 + + G(2d,2p) level;[14] in spite of the aryl group at the Si atom it is very similar to the experimental value of **6** ($\delta = -30.4$).

Experimental Procedure

1a: A moderate gas stream of **4a** (approx. 1–3 gas bubbles per second) was fed into a solution of **2** (7.4 g, 195 mmol) in DME (150 mL) at 25 °C for about 6 h. A clear yellow solution was formed, from which DME-solvated Li_3As_7 precipitated as a yellow solid after about 12 h. The end point of the reaction was determined by ^{27}Al NMR spectroscopy ($\delta = 150.4$); the ^{7}Li NMR spectrum then showed one singlet at $\delta = -2.7$.

1b: **2** (1 mmol, 0.7 mL of a 1.4 M solution in DME) was added to a solution of **4b** (0.96 g, 4.1 mmol) in DME (10 mL) at 25 °C. The reaction mixture was stirred for 24 h whereupon a clear orange-yellow solution was formed. The end point of the reaction was determined by ^{27}Al NMR spectroscopy ($\delta = 145$); the ^{7}Li NMR spectrum then showed a singlet at $\delta = -3.4$.

1c: **2** (3.6 mmol, 2.6 mL of a 1.4 M solution in DME) was added to a solution of **4c** (0.8 g, 3.6 mmol) in DME (10 mL) at 25 °C. The reaction mixture was heated under reflux for 2 h and the solvent removed under reduced pressure to leave approximately 5 mL of the solution. The product crystallized at 25 °C in the form of colorless columns. ^{27}Al NMR ([D$_8$]THF): $\delta = 132.3$ (s); ^{7}Li NMR ([D$_8$]THF): $\delta = -3.0$ (s); ^{29}Si NMR ([D$_8$]THF): $\delta = 13.6$ (s); ^{1}H NMR ([D$_8$]THF): $\delta = 1.0$ (br. m, 36H, $Me_2C(CHMe_2)$), 2.3 (m, 3H, J(H,H) ≈ 6.8 Hz, $Me_2C(CHMe_2)$), 3.17 (s, 42H, DME), 3.25 (s, 28H, DME), 4.2 (br., $h_{1/2}$ = 60 Hz, 6H, Al-H).

3: a) TMEDA (1 g, 8.6 mmol) was added to **1a** (10 mL of a 1.3 M solution in DME) at 25 °C. After 12 h **3** crystallized in the form of orange needles. Yield: 2.1 g (2.3 mmol, 81 % with respect to TMEDA); ^{7}Li NMR (THF): $\delta = -2.0$ (s). b) TMEDA (1 g, 8.6 mmol) was added to a solution of **1b** (7.2 g, 7.5 mmol) in DME ((25 mL). Compound **3** crystallized after 48 h. Yield: 1.9 g (2.1 mmol, 73 % with respect to TMEDA).

6: A solution of **5** (0.6 g, 1.8 mmol) in DME (10 mL) was treated with freshly prepared **1a** (1.4 mmol, 0.93 mL of a 1.3 M solution in DME) under continuous stirring at 25 °C. The dark red reaction solution was stirred for a further 3 h. Solvent was removed under reduced pressure to leave approximately 5 mL of the solution. The salts were then precipitated by addition of n-pentane (5 mL) and filtered off. TMEDA (0.5 mL) was added to the clear, dark green filtrate. The product crystallized in the form of light yellow cubes after a period of 96 h. Yield: 0.2 g (0.16 mmol, 36 %). ^{1}H NMR (C_6D_6): $\delta = 1.24$ (br. m, 72H, $CHMe_2$), 3.0 (m, 4H, p-$CHMe_2$), 4.2 (br., 8H, o-$CHMe_2$), 7.29 (s, 8H, arom. H); ^{29}Si-NMR (C_6D_6): $\delta = -30.4$ (s); MS (EI, 70 eV): m/z (%): 1224 (M^+, 100), 993 ($(M - SiIs)^+$, 6), 687 ($(M - (IsSi)_2As)^+$, 21), 231 ($(SiIs)^+$, 56).

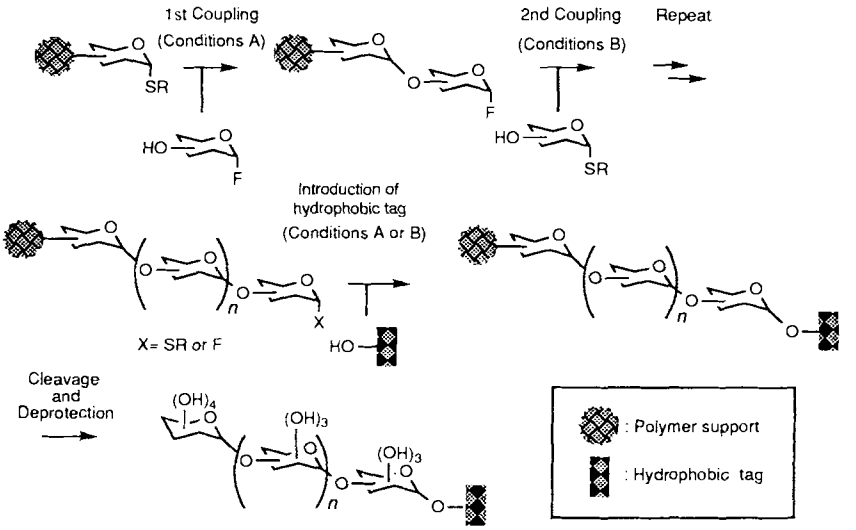
Orthogonal Glycosylation Strategy for Rapid Assembly of Oligosaccharides on a Polymer Support**

Yukishige Ito,* Osamu Kanie, and Tomoya Ogawa

Solid-phase synthesis has been demonstrated to be extremely valuable for routine preparations of oligopeptides and oligonucleotides, and is attracting renewed attention in connection with combinatorial chemistry.[1] Recently, the synthesis of oligosaccharides on polymer supports has also attracted interest and several intriguing approaches have been reported.[2–5] We report here on a novel strategy for the synthesis of oligosaccharides on polymer supports based on the concept of orthogonal glycosylation,[6] which enables the ready preparation of oligosaccharides.

For the synthesis of oligosaccharides on polymer supports two approaches can be considered with respect to the direction of chain elongation: from the reducing end to the non-reducing end (Approach A), and from the non-reducing end to the reducing end (Approach B). Approach A is generally considered to be more advantageous because when both the polymer-supported aglycon and the glycosyl donor are reactive enough to ensure that all glycosylations go to completion, a nearly homogeneous product can be obtained. Approach B is less straightforward in principle because all by-products accumulate on the polymer phase together with desired O-glycoside, which complicates the isolation of the correctly assembled oligosaccharide, and after each glycosylation the the anomeric position at the reducing end must be transformed into a leaving group.

In addressing the problems inherent to Approach B, our attention has turned to the application of the orthogonal glycosylation strategy to chemistry on polymer supports (Scheme 1).



Scheme 1. Oligosaccharide synthesis on solid supports based on an orthogonal glycosylation strategy.

Thioglycoside and glycosyl fluoride were used in combination, because these were demonstrated to be a competent set of orthogonal glycosyl donors.[6] To avoid potential difficulties in isolating the final product, a hydrophobic aglycon was to be incorporated as a tag at the anomeric position of the reducing end after the oligosaccharide had been assembled. The target oligosaccharide can thus be distinguished from all other polymer-supported products, since it should be the only tag-carrying molecule. Therefore, the product should be isolable in a single step, irrespective of the number of glycosylation steps, by using reversed-phase silica gel chromatography.[7]

To test this hypothesis, the first attempt was made with polyethylene glycol (PEG) as a "soluble" polymer,[3] and the trimannoside portion (i.e. **13**) of high mannose type glycoprotein oligosaccharides[8] was chosen as a target (Scheme 2). In this instance, the 2-(trimethylsilyl)ethyl (SE) group was used as a hydrophobic tag.[9]

The synthesis started with the ester **1**, which was prepared from the chloride **2**[10] via **3**, **5**, and **6**. Saponification yielded

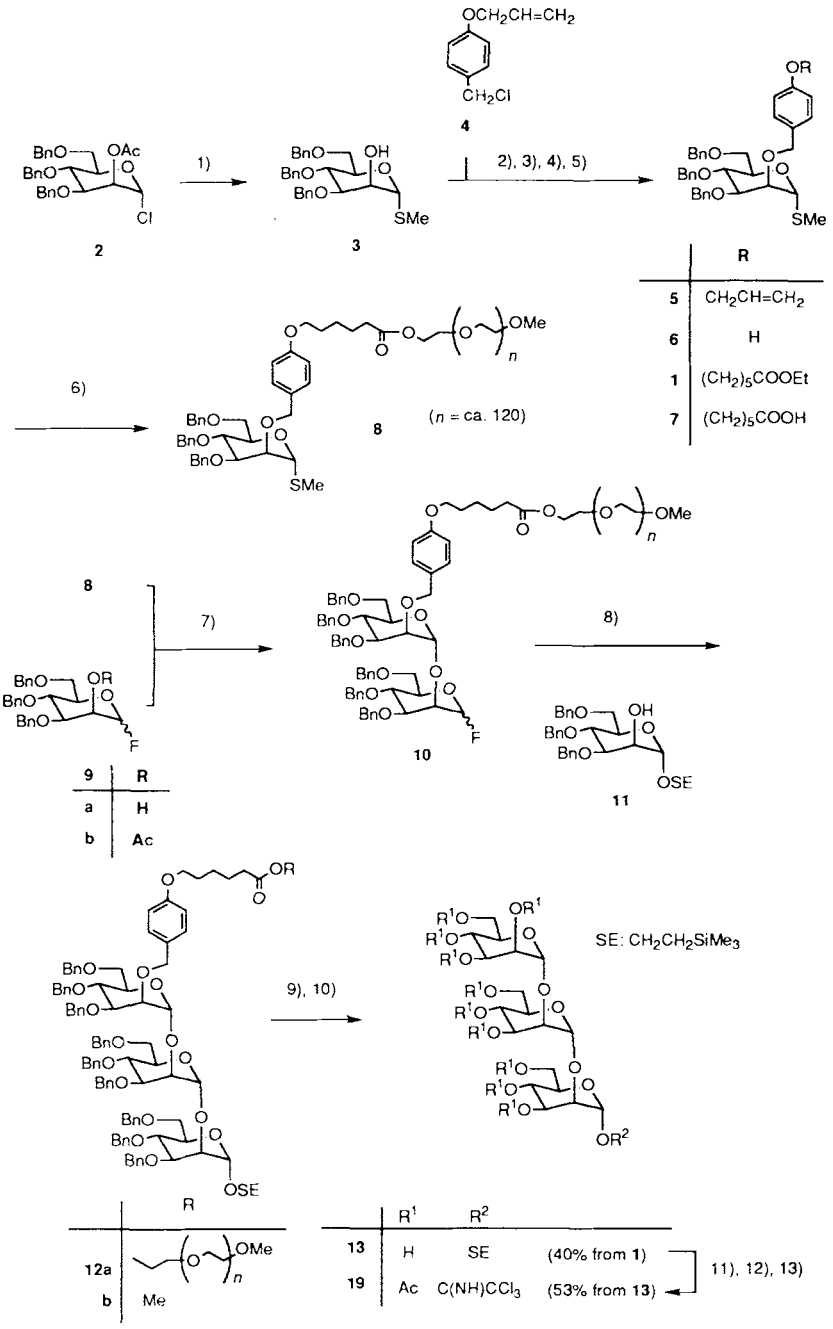
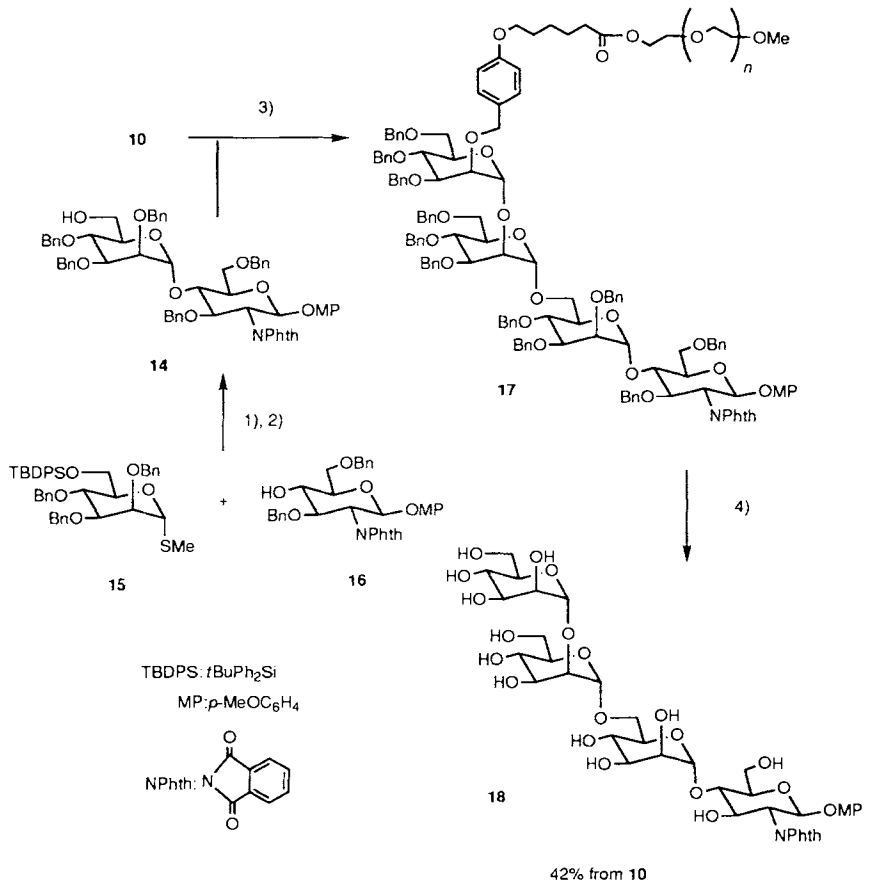


Scheme 2. Synthesis of trimannoside **13**. 1) MeSSMe, *n*BuLi/THF, 87%; 2) **4**, NaH/DMF, 100%; 3) $[(Ph_3P)_4Pd]$, $NaBH_4$/THF, 96%; 4) $Br(CH_2)_5CO_2Et$, Cs_2CO_3/DMF, 91%; 5) aq. NaOH/THF–EtOH, quantitative; 6) $EtO_2C-N=N-CO_2Et$, Ph_3P, PEG monomethyl ether/THF–CH_2Cl_2, 95%; 7) $MeOSO_2CF_3$, MeSSMe, molecular sieves 4Å/CH_2Cl_2, room temperature, 89%; 8) **11**, $[Cp_2HfCl_2]$, $AgOSO_2CF_3$, molecular sieves 4Å/CH_2Cl_2, 0 °C to room temperature, 99%; 9) NaOMe/MeOH; 10) H_2, $Pd(OH)_2$/MeOH–ethyl acetate; 11) Ac_2O, 4-dimethylaminopyridine (4-DMAP)/pyridine; 12) CF_3COOH/CH_2Cl_2; 13) CCl_3CN, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU)/CH_2Cl_2, then chromatographic purification.

carboxylic acid **7**, which was coupled with PEG monomethyl ether (Aldrich, average molecular mass 5000) to afford the thiomannoside–polymer conjugate **8**.[11] The first coupling with the fluoride **9a**[12] was performed in the presence of $MeOSO_2CF_3$[13] and MeSSMe in CH_2Cl_2 to furnish the disaccharide–PEG conjugate **10** in 89% yield.[11,14] In the second coupling the reducing end of the diasaccharide was linked to the 2-(trimethylsilyl)ethyl (SE) glycoside **11**,[15] in which the SE group served as a hydrophobic aglycon. The reaction was performed under Suzuki conditions ($[Cp_2HfCl_2]$/$AgOSO_2CF_3$/CH_2Cl_2)[16] to afford the trisaccharide–PEG **12a**.[11] After the trisaccharide sequence had been completed, PEG was cleaved off under basic conditions, and the crude trisaccharide **12b** was hydrogenated over $Pd(OH)_2$. The resulting mixture was then passed through a short column of C_{18} reversed-phase silica gel (Senshu Kagaku, Tokyo), which was first eluted with water to remove all by-products. Subsequent elution with 50% MeOH gave the desired trisaccharide **13**[17,18] in 40% overall yield from **1**.

Disaccharide–PEG **10** was also converted into the tetrasaccharide **18**, which corresponds to the partially protected form of the common carbohydrate structure of the glycosyl phosphatidyl inositol (GPI) anchor (Scheme 3).[19] Thus, disaccharide **14** was synthesized from the monosaccharide derivatives **15** and **16**, and then coupled with **10** in the presence of $[Cp_2HfCl_2]$/$AgOSO_2CF_3$ in benzene.[20] The resultant tetrasaccharide–PEG conjugate **17**[11] was subjected to catalytic hydrogenation. In this case, due to its *p*-methoxyphenyl and phthalimide groups, the product is hydrophobic enough to be retained on a C_{18} column. Thus, reversed-phase chromatographic separation, in a similar manner as that described for **13**, gave tetrasaccharide **18**[17,21] in 42% yield based on **10**.



Scheme 3. Synthesis of tetrasaccharide **18**. 1) $MeOSO_2CF_3$, MeSSMe, molecular sieves 4Å/$ClCH_2CH_2Cl$, room temperature, 80%; 2) $(nBu)_4NF$, acetic acid/THF, 93%; 3) $[Cp_2HfCl_2]$, $AgOSO_2CF_3$, molecular sieves 4Å/benzene, room temperature, 86%; 4) H_2, $Pd(OH)_2$/MeOH.

The strategy reported here, featuring a novel combination of chemistry on polymer supports and orthogonal glycosylation, results in the construction of oligosaccharides by a minimum number of operations. It should also be noted that the anomeric positions of **13** and **18** are masked by protecting groups that are selectively cleavable.[22] For example, the trisaccharide **13** was easily transformed into the trichloroacetimidate **19**,[17, 23] which should be a valuable synthetic building block for mannose-rich glycans (Scheme 2).

Silaethene $H_2C{=}SiH_2$: Millimeter Wave Spectrum and Ab Initio Calculations**

Stephane Bailleux, Marcel Bogey,* Jürgen Breidung, Hans Bürger,* Radek Fajgar, Yuyan Liu, Josef Pola, Michael Senzlober, and Walter Thiel*

While silaethenes $CR^1R^2{=}SiR^3R^4$ that are kinetically stabilized by bulky ligands R^1-R^4 are well documented, the parent molecule $CH_2{=}SiH_2$ (silene, silaethene, **1**) still awaits unambiguous characterization in the gas phase, although convincing evidence for its formation as a transient has been deduced from trapping experiments.[1] Moreover, IR and UV spectra of products isolated in an Ar matrix at 10 K and generated by vacuum flash pyrolysis of 5,6-bis(trifluoromethyl)-2-silabicyclo[2.2.2]-octa-5,7-diene (SBO) at 650 °C and 1.4×10^{-5} mbar were attributed to **1**, and this conclusion was supported by ab initio calculations of the vibrational wavenumbers and by deuteration experiments.[2] Furthermore, the first band observed and predicted at 8.95 eV in the He(I) photoelectron (PE) spectrum of **1** produced from SBO under similar conditions showed vibrational fine structure that was consistent with the expected vibrational energy pattern.[3]

Photochemical generation of **1** both from silacyclobutane (SCB) and 1,3-disilacyclobutane (DSB) has been achieved by using pulsed ArF (193 nm) and TEA CO_2 lasers (10P(20) line) at low flux.[4] Since the CO_2-laser-induced decomposition of SCB and DSB is a promising technique for low-temperature chemical vapor deposition of amorphous SiC,[5] there is great interest in the nature of the transients involved. Spectroscopic techniques are most suited to provide answers to this question. Microwave and millimeter wave (mmw) spectroscopy combine sensitivity and specificity, and their potential to detect short-lived silicon-containing transients has been recently demonstrated for H_2Si_2[6] and H_2SiO.[7] More importantly these techniques provide accurate information on molecular parameters for which predictions may be obtained from ab initio calculations. Furthermore, decay processes can be monitored, and decomposition products identified.

We have guided our mmw spectroscopic search for **1** by predictions derived from ab initio calculations. Although ab initio calculations at different levels have been previously performed,[8] we needed optimized ground state rotational constants to predict transitions as reliably as possible.

The molecular geometry of **1** was optimized within the constraints of C_{2v} point group symmetry at the Hartree–Fock self-consistent field (SCF) level of theory[9] and at the correlated levels of second-order Møller–Plesset perturbation theory (MP2),[10] coupled cluster theory with single and double excitations (CCSD),[11] and CCSD augmented by a perturbational estimate of the contributions from triple excitations (CCSD(T)).[12] The geometry optimizations were performed with analytical gradients as implemented in the GRADSCF,[13] GAUSSIAN 92,[14] and ACES II[15] program systems. All quantum-chemical calculations were performed by employing a valence triple-zeta plus double polarization plus f functions basis set (TZ2Pf): Si: (12s9p)/[6s5p] basis[16] with two sets of d and one set of f polarization functions;[17] C: (10s6p)/[5s3p] basis[18] with two sets of d and one set of f polarization functions;[19] H: (5s)/[3s] basis (scale factor 1.2)[18] with two sets of p and one set of d polarization functions.[19] Spherical harmonics were used in the correlated calculations, whereas SCF wavefunctions were represented by cartesian Gaussian-type orbitals. All electrons were correlated in the MP2, CCSD, and CCSD(T) treatments. At the theoretical equilibrium geometries the harmonic force fields were evaluated either analytically (SCF, MP2)[13, 14] or numerically from analytical energy gradients (CCSD, CCSD(T)).[15] Anharmonic normal coordinate force fields were determined (SCF, MP2) by using a finite difference procedure.[20] Spectroscopic constants that are listed in Table 1 were then derived by established methods.[21]

The mmw spectrometer used has been described in detail.[6, 7] The mmw irradiation was obtained by harmonic generation from phase-locked Varian klystrons using Schottky barrier diodes mounted in a commercial multiplier. In the highest frequency range (340–473 GHz), two phase-locked carcinotrons (backward wave oscillators) were used. The detection of the signal was achieved with a helium-cooled InSb detector. Source modulation at 40 kHz and lock-in detection at twice this frequency were used, inducing a second derivative line shape.

Frequency scanning, data acquisition, signal processing, and frequency measurement were controlled by uisng a microcomputer; the estimated errors were less than 50 kHz.

The measurement cell consisted of a 1 m long pyrex tube connected at one end to the pump and at the other end to a cross-shaped glass vessel (50 cm long and 10 cm internal diameter), into the side-arm of which a small oven was introduced. This comprised a quartz tube (2 cm long, 0.8 cm internal diameter) heated by a tungsten coil. The cross-shaped part of the cell was cooled by flowing liquid nitrogen through a rubber tube around it. This system allowed production of the reactive species directly in the cell. Argon served as a buffer and carrier gas and was flowed together with SBO through the oven heated to 600 °C. The best experimental conditions were $p(\mathrm{SBO}) = 7\times10^{-3}$ mbar and $p(\mathrm{Ar}) = 1.5\times10^{-2}$ mbar.

We have also generated a spectrum of **1**, which is half as intense, by pyrolysis of SCB at about 1000 °C, but at higher partial pressure. Very weak signals could also be obtained from DSB, but this required even higher temperatures and pressure. In both cases, lines of CH_3SiH_3 were observed with significant intensity.

Photolytic generation of **1** from SBO was studied by using an ArF excimer laser. Although the efficiency of the photolysis was poor, the pulsed emission of the laser allowed the measurement of the lifetime of **1** in the gas phase at room temperature by recording the decay of the $7_{1,6}\leftarrow6_{1,5}$ rotational line.[22] A least squares adjustment of this experimental signal to an exponential decay led to a $1/e$ lifetime of 30 ± 2 ms.

Since the dipole moment of **1** lies along the C_2 symmetry axis, which is the axis of the least moment of inertia, the rotational spectrum should display the characteristic *a*-type pattern of a slightly asymmetric prolate top, $\kappa = -0.9597$. Owing to the two pairs of identical hydrogen nuclei, the relative intensities of the rotational lines were determined by employing nuclear spin statistical weights; that is, 10 for the K_aK_c = oo and oe and 6 for the ee and eo rotational levels.

According to the rotational and centrifugal distortion constants calculated by ab initio methods (Table 1), for the three levels of theory MP2, CCSD, and CCSD(T), the $K_a = 0$, $J = 7\leftarrow6$ line was predicted to lie at 191575, 191508, and 190012 MHz, respectively. Starting a frequency scan at 190 GHz, lines corresponding to an *a*-type pattern with the right relative intensities were observed; the $K_a = 0$ component lies at 192484 MHz. A first least squares fit of the K_a components of the $J = 7\leftarrow6$ series allowed a more precise prediction of the other transitions. Repeating this procedure eventually led to the measurement of 139 rotational lines corresponding to $6\geq J\geq16$ and $K_a\geq11$ in the 180–473 GHz frequency range. These frequencies were fitted to Watson's A-reduced Hamiltonian in I^r representation[23] with a standard deviation of 16.9 kHz. The residuals were well below 50 kHz, the estimated accuracy of the measurements. Two experimentally unresolved K_a doublets, $J = 7\leftarrow6$, $K_a = 4$, and $J = 13\leftarrow12$, $K_a = 5$, were not taken into consideration in the fit. The adjusted rotational and centrifugal distortion constants are given in Table 1 and can be compared with the values calculated by ab initio methods. The two sextic parameters Φ_{KJ} and Φ_K can only be considered as fitting terms.

The CCSD(T)/TZ2Pf results should generally be the most reliable because they represent the highest theoretical level applied. By comparing analogous theoretical and experimental results for $H_2C{=}S$, it is found that the CCSD(T) calculations overestimate the C=S bond length by 0.009 Å, while the MP2 and CCSD values are virtually identical with the experimental results. The same applies to **1**, for which the theoretical B_o/C_o values are only 0.46/0.36 and 0.59/0.47% higher than the experimental ones at the MP2 and CCSD levels, respectively.[24] The quartic centrifugal distortion parameters are in close agreement with the theoretical predictions.

The excellent agreement between experiment and theory enables us to ascertain that we have observed the rotational spectrum of $H_2C{=}SiH_2$. This is the first high-resolution spectroscopic identification of this compound, and additional confirmation was provided by the observation of lines belonging to the ^{29}Si isotopomer in natural abundance and other isotopomers from isotopically labeled precursors. Work directed towards the determination of an experimental structure is in progress. The observed nuclear spin statistics confirm the assumed C_{2v} symmetry of **1**, and the small size of the inertial defect, $\Delta = 0.0627$ u Å^2, proves the planarity of the molecule.

By comparing the present experiment with previous fruitless attempts, started in 1981 by M. Bogey in collaboration with H. P. Reisenauer, G. Maier, and M. Winnewisser, it seems that three experimental modifications have led to its success: the shortening of the oven, the use of Ar as a carrier gas, and the cooling of the cell. We are convinced that each of the two latter modifications are indispensable since only when these conditions were applied was the observed spectrum very clean and the strongest observed lines belonged only to **1** and CH_3SiH_3. Thus present results explain the failure of the previous attempts in mmw spectroscopy and confirm observations made by Rosmus et al.[3] when studying the photoelectron spectrum.

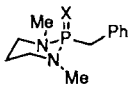
Solution and Solid-State Structure of a Lithiated Phosphane Oxide**

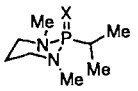
Scott E. Denmark,* Kevin A. Swiss, and Scott R. Wilson

The report by L. Horner et al. in 1959 on the use of lithiated phosphane oxides to carry out carbonyl olefination further ensured a lasting legacy for organophosphorus reagents in organic synthesis.[1] Beyond the already established Wittig[2] and Wadsworth–Emmons[3] reactions, the Horner–Wittig process allowed interception of the critical intermediate in the olefination, and therefrom, mechanistic insight and practical value. Given the importance of these reagents in modern synthesis,[4] it is remarkable that the solution and solid-state structures of lithiated phosphane oxides have not been established.[5, 6]

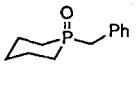
Our interest in lithiated phosphane oxides derives from our general program on the design, development, and application of chiral, phosphorus-based anionic reagents.[7] We have extensively investigated these features in phosphonamide and thiophosphonamide anions,[8] and have recently disclosed the solution and X-ray structures of lithio phosphonamides $Li^+\mathbf{1}^-$ (Li(**1** – H), that is the lithium salt of **1** generated by the reaction with, for example, *n*BuLi)[8a] and $Li^+\mathbf{3}^-$[8b] and lithio thiophosphonamides $Li^+\mathbf{2}^-$[8c] and $Li^+\mathbf{4}^-$.[8e] The benzylic anions have



X = O: **1**
X = S: **2**



X = O: **3**
X = S: **4**



5

strikingly similar characteristics: 1) no C–Li contact, 2) antiparallel alignment of the benzylic moiety to the P=X bond ($\theta = 180°$, see Fig. 1), and 3) a planar anionic carbon atom. An important difference between phosphonamide and thiophosphonamide anions is that the rotational barrier about the C–P bond is approximately 3.1 kcal mol^{-1} larger in $Li^+\mathbf{4}^-$[8c] than in $Li^+\mathbf{3}^-$.[8c, e, 9]

[**] We are grateful to the National Institutes of Health (GM 45532) for generous support of this research. We thank Dr. Vera Mainz for NMR technical assistance.

To provide support for our understanding of the electronic contributions to anion conformation and energetics, we chose to examine a phosphane oxide anion. We proposed that the origin of the conformational ground state preference is the splitting of the $2e_x$ and $2e_y$ acceptor orbitals on phosphorus (Fig. 1).[8d, 9] In phosphonamides the $2e_x$ orbital is the better acceptor orbital (constructed from P–N σ^* orbitals) thus leading to a parallel anion. If this were true, replacement of the nitrogen atoms in $Li^+\mathbf{1}^-$ or $Li^+\mathbf{2}^-$ with less electronegative carbon atoms would attenuate the acceptor properties of the $2e_x$ orbital, leading to a preference for an orthogonal-like anion ($\theta = 90°$, Fig. 1) on the basis of a more effective $2e_y$ acceptor orbital.

For this study, the *P*-benzylphosphorinane-1-oxide **5** was selected due to its structural similarity to **1** and **2**. Moreover, the benzyl group would vouchsafe the selective generation of a single anionic species. Since lithiated phosphane oxide anions have not previously been spectroscopically characterized, $Li^+\mathbf{5}^-$ was compared with $Li^+\mathbf{1}^-$ and $Li^+\mathbf{2}^-$ (Table 1).[10] Several features immediately distinguished $Li^+\mathbf{5}^-$ from the phosphonamides. First, the ^{31}P NMR shifts for **5** and $Li^+\mathbf{5}^-$ were found to be very similar. This contrasts remarkably to $Li^+\mathbf{1}^-$ and $Li^+\mathbf{2}^-$, which are shifted strongly downfield and upfield, respectively, in their ^{31}P NMR spectra. Presumably the polarization of the P=O bond and the increase of anionic charge on C6 cancel each other out. The position of the ^{13}C NMR resonance of the benzylic carbon atom C6 was found to be more strongly shifted downfield in $Li^+\mathbf{5}^-$ than in **5**. These attributes clearly suggest a carbanion devoid of a lithium contact. The large change in chemical shift is indicative of a stronger delocalization of the phenyl ring in $Li^+\mathbf{5}^-$ than in the other anions[11]. The differences in the coupling constants $\Delta\ ^1J_{CP}$ and $\Delta\ ^1J_{CH}$, which are indicators of hybridization, also increased in magnitude upon lithiation of **5**, indicating an increase in s-character of the carbanionic carbon atom. All of these features signal the presence of an sp^2-hybridized carbanion. Finally, a

triplet was found in the ^{6}Li NMR spectrum, which indicates a static, dimeric anion similar to the phosphonamide $Li^+\mathbf{1}^-$ but with a slightly smaller ^{6}Li–P coupling constant.

Determination of the P–C6 rotational barrier and the conformation of the benzyl group in solution for $Li^+\mathbf{5}^-$ was very difficult. The ground state conformations are expected to be degenerate and have C_1 symmetry ($\theta = 90°/270°$, Fig. 1). ^{1}H and ^{13}C NMR spectroscopic examination of the resonances of the backbone (H_2C1, H_2C5) of $Li^+\mathbf{5}^-$ showed no broadening at temperatures as low as $-100\,°C$.

Insight into the preferred ground state conformation is available from analysis of the $^2J_{HP}$ coupling constant (P-C6-H). This parameter has been shown experimentally[12] and by theory[13] to be sensitive to conformations around the P–C bond. We and others have found that a $^2J_{HP}$ coupling of more than 20 Hz is indicative of a conformation with an O-P-C-H dihedral angle of 0–60°, while a small $^2J_{HP}$ coupling (<9 Hz) indicates a dihedral angle of approximately 120–180° (Fig. 1).[14] Remarkably, the $^2J_{HP}$ coupling constants for $Li^+\mathbf{5}^-$ and $Li^+\mathbf{2}^-$ are similar (Table 1). This data is indicative of a solution conformation biased in the ±-synclinal range.

Crystallization of $Li^+\mathbf{5}^-$ in THF afforded twinned crystals, but fortunately a suitable crystal was found.[15] Like the phosphonamides, $Li^+\mathbf{5}^-$ crystallizes as a C_2-symmetric dimer with each lithium bound to both P=O groups and solvated by two THF molecules; the anionic carbon atom C6 resides in a nearly planar environment (Fig. 2). The planarity of the carbon environment is judged by the following criteria: 1) the sum of the angles around C6 is 358.9°, 2) the distance of C6 above the P1-H6-C7 plane (δ) is 0.08 Å, and 3) the angle (γ) between the C6–P1 vector and the C6-H6-C7 plane is 10.4°.[16]

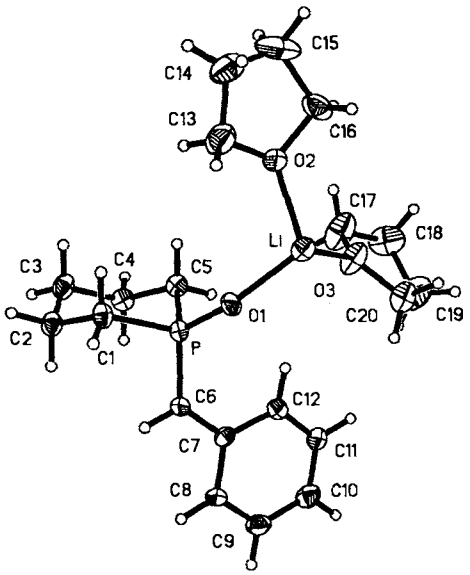

Fig. 2. ORTEP plot of the structure of $[Li^+\mathbf{5}^-\cdot 2THF]_2$; monomeric unit shown for clarity (35% thermal ellipsoids). Selected bond lengths [Å] and angles [°]: P–O1, 1.522(4), P–C1, 1.806(5), P–C5 1.806(5), P–C6 1.690(5), Li–O1 1.918(10); O1-P-C1 111.2(2), O1-P-C5 106.9(1), O1-P-C6 118.2(2), P-O1-Li 142.7(3), P-C6-C7 127.5(4).

The most significant differences between $Li^+\mathbf{5}^-$ and the other compounds are concerned with the conformations of the ring and the benzyl group. In all of the anions studied to date, the chalcogen attached to the phosphorus atom occupies an axial position, thus placing the carbanionic moiety equatorially. In $Li^+\mathbf{5}^-$ the benzyl group is disposed axially in the phosphorinane ring. Moreover, in all of the anions studied previously, the benzyl (or isopropyl) group is oriented in an antiparallel fashion with respect to the P=X group. In $Li^+\mathbf{5}^-$ the benzyl group adopts a *gauche* conformation. The O1-P-C6-C7 and P-C6-C7-C12 dihedral angles were determined to be $-65.1(6)°$ and 6.4(8)°, respectively, from the X-ray structure analysis.

In $Li^+\mathbf{1}^-$ the idealized anomeric stabilization of nitrogen- and carbon-bearing pairs of electrons leads to the familiar "pinwheel" conformation of methyl and benzyl groups.[8e, 9] This can best be accommodated in a chair conformation with the P=O group axially oriented. Replacement of the nitrogen atoms in $Li^+\mathbf{1}^-$ with carbon atoms, as in $Li^+\mathbf{5}^-$, has a dramatic effect on the electronic structure of the phosphanyl carbanion. Now, there is no electronic advantage to orient the P=O group in an axial position. The primary hyperconjugative-type stabilization arises from $n \rightarrow \sigma^*_{PO}$ donation which is best accommodated in a perfectly orthogonal conformation ($\theta = 90°$, Fig. 1). However, it appears that avoidance of nonbonding interactions between the *ortho* hydrogen atoms of the benzene ring and the equatorial hydrogen atoms on C1 and C5 adjusts the torsional angle. The lack of electronic significance to this nonideal conformation is supported by the identical P–C1 and P–C5 bond lengths.[17]

Of the four benzylic P-stabilized anions that we have crystallographically characterized, $Li^+\mathbf{5}^-$ is the most pyramidalized and in this regard approximates $Li^+\mathbf{3}^-$. This behavior most certainly arises from the less effective stabilization afforded by the phosphanyl moiety and the lower symmetry environment around the phosphorus atom. Future studies will address the rotational barrier and the ground state conformation of related anions in solution.

Experimental Procedure

5 [17]: A solution of sodium bis(2-methoxyethoxy)aluminum hydride (Red-Al, 70%, 3.4 M in toluene, 30 mL, 102 mmol, 2.08 equiv) in THF (30 mL) was added dropwise to a refluxing solution of diethyl benzylphosphonate (11.12 g, 49 mmol, 1.0 equiv) in THF (250 mL) over 1 h. The mixture was heated to reflux for 1 h further and then 1,5-dibromopentane (7.2 mL, 53 mmol, 1.04 equiv) was added at once and the mixture was heated to reflux for 16 h. The suspension was cooled in an ice bath and water (7 mL) was added dropwise. The mixture was filtered through a Celite pad and the filtrate was concentrated in vacuo to give a viscous oil that was purified by column chromatography (SiO_2) with EtOAc (1 L) 10% *i*PrOH/EtOAc (500 mL), 20% *i*PrOH/EtOAc (500 mL), and finally 50% *i*PrOH/EtOAc (1 L) to give 4.395 g (46%) of **5** as a white solid. Two recrystallizations from hot toluene (5 mL g^{-1}) gave 2.16 g (22%) of analytically pure **5**. M.p. 143–145 °C (toluene); $R_f = 0.28$ (3/7, *i*PrOH/EtOAc); ^{1}H NMR (500 MHz, $CDCl_3$, 25 °C): $\delta = 7.28$ (m, 5H, HC8–12), 3.16 (d, $^2J_{HP} = 13.9$, 2H, H_2C6), 2.04 (m, 2H, $H_{ax}2,4$), 1.72 (m, 6H, $H_{eq}2,4$, $H_2C1,5$), 1.52 (m 2H, H_2C3); ^{13}C NMR (125.8 MHz, $CDCl_3$, 25 °C): $\delta = 131.61$ (d, $^2J_{CP} = 7.7$, C7), 129.24 (d, $J_{CP} = 4.6$, C8,12 or C9,11), 128.50 (d, $J_{CP} = 2.3$, C9,11 or C8,12), 126.54 (d, $^5J_{CP} = 2.3$, C10), 35.46 (d, $^1J_{CP} = 60.3$, C6), 26.39 (d, $^1J_{CP} = 62.5$, C1,5), 26.07 (d, $^3J_{CP} = 6.9$, C3), 22.41 (d, $^2J_{CP} = 5.4$, C2,4); ^{31}P NMR (121.7 MHz, $CDCl_3$, 25 °C): $\delta = 39.32$; IR (KBr) $\tilde{\nu}$: [cm^{-1}] = 3080, 2946, 2934, 2926, 1600, 1493, 1161 (P=O); MS (EI, 70 eV) *m/z* (%): 209 (14) [$M^+ + 1$], 208 (94) [M^+], 207 (27) [$M^+ - H$], 91 (100); elemental analysis $C_{12}H_{17}OP$ (208.24) calcd. C, 69.21; H, 8.23; P, 14.87; found: C, 69.23; H, 8.26; P, 14.82.

In situ preparation of $Li^+\mathbf{5}^-$: A 10-mm NMR tube was charged with **5** (56.6 mg, 0.291 mmol) and [D_8]THF (2.5 mL). The sample was cooled to −60 °C and *n*-butyllithium (10 M, 29 µL, 0.29 mmol, 1.0 equiv) was added (monitored by ^{31}P NMR spectroscopy) to give a 0.11 M solution.

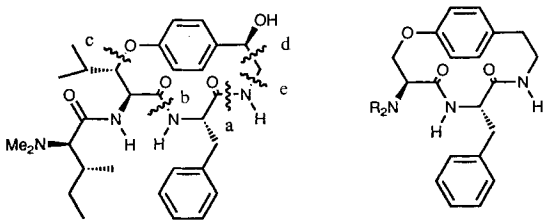
A Novel Strategy towards the Total Synthesis of Cyclopeptide Alkaloids

Jieping Zhu,* Taoues Laïb, Jacqueline Chastanet, and René Beugelmans

Since the first structural determination of pandamine (**1**) by Goutarel and Païs in 1963,[1] the family of cyclopeptide alkaloids has grown rapidly and now encompasses over 200 compounds. These 13-, 14-, and 15-membered macrocycles typically contain a para- or metacyclophane unit with a characteristic aryl–alkyl ether linkage.[2] The widespread occurence of these compounds in nature makes them an important class of natural products. However, little is known about their biological and pharmacological properties due to their limited availability.[3] The development of a practical synthetic method is therefore of utmost importance.

The total synthesis of cyclopeptide alkaloids has been investigated by a number of research groups, notably those of Schmidt,[4a] Rapoport,[4b] Joullié,[4c] and Lipshutz.[4d] The main difficulty is the construction of the obviously strained macrocycles. As shown in Scheme 1, various strategies based upon



Pandamine **1**

2a R = allyl
2b R = Bn

Scheme 1.

macrolactamization (disconnections a and b), intramolecular Michael addition (disconnection c), intramolecular aldol condensation (disconnection d), and very recently, intramolecular amide alkylation (disconnection e)[4d] have been studied.[2] Until now, only macrolactamization has been fruitful; this strategy culminated in the total syntheses of three natural products[5] by means of an efficient activating method developed by Schmidt et al.[6]

Because of the synthetic challenges posed by this family of natural products, we were interested in an approach based upon the hitherto unknown ring-forming process in which formation of aryl–alkyl ether bond is the crucial step (disconnection f, Scheme 2). The realization of this intramolecular S_NAr-based[7] strategy illustrated by the synthesis of 14-membered macrocycle **2** is the subject of the present communication.

Synthesis of the linear peptide **11** is shown in Scheme 3. Coupling of 2-(3′-nitro-4′-fluoro)phenylethylamine (**8**), prepared in five steps from 4-fluorobenzaldehyde,[7b] with *N*-Boc-Phe afforded dipeptide **9**. Deprotection under mild acidic conditions (HCl/MeCN) followed by reaction with *N*-Boc-Ser(TBS)OH (TBS = *tert*-butyldimethylsilyl) gave the tripeptide **10** in 68% overall yield. Selective removal of the silyl ether (CsF, DMF) furnished compound **11**, which was ready for cyclization studies.

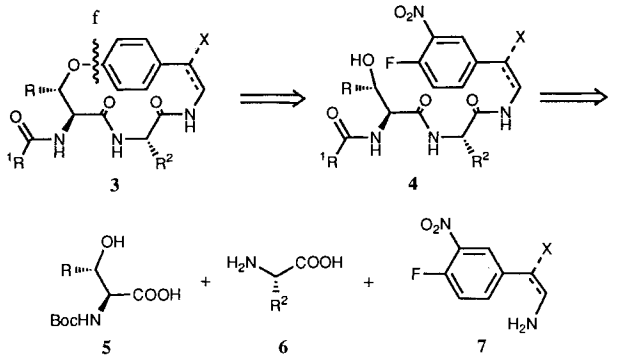
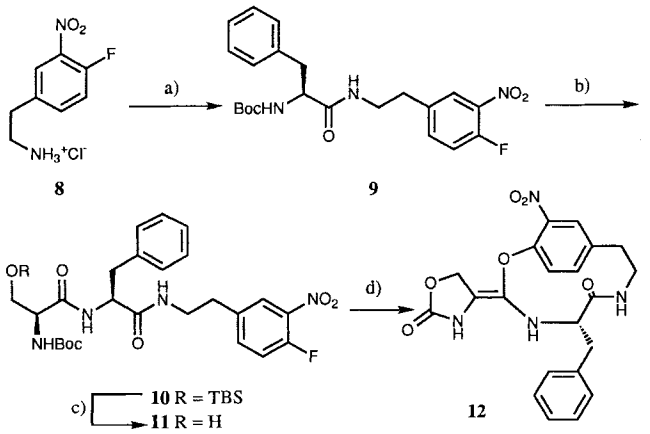
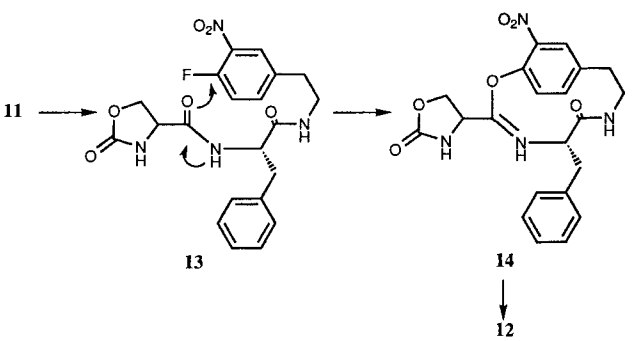


Scheme 2.



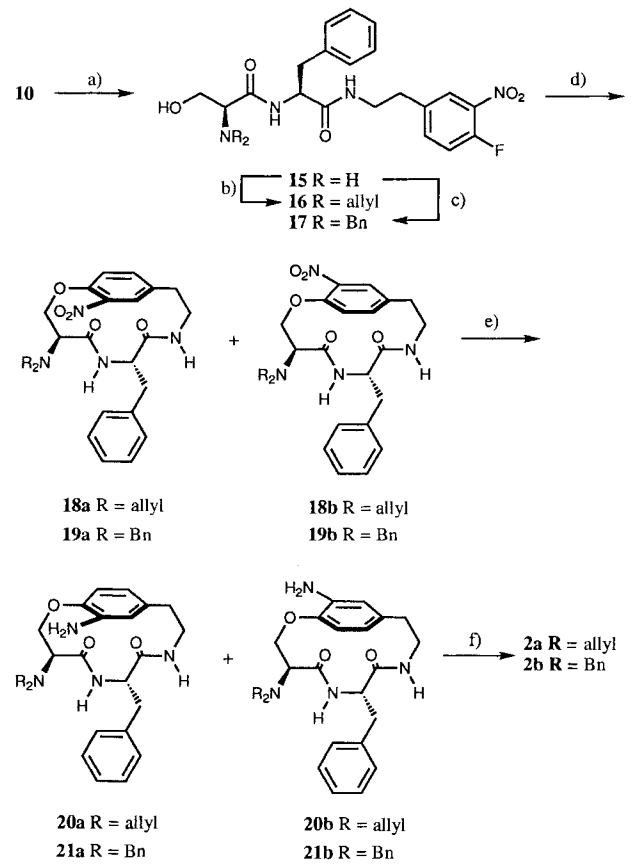
Scheme 3. a) Et_3N, *N*-Boc-Phe (Boc = *tert*-butoxycarbonyl), 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), 1-hydroxy-1*H*-benzotriazole (HOBt), 85%; b) 1) HCl/MeCN; 2) Et_3N, *N*-Boc-Ser(TBS)OH (TBS = *tert*-butyldimethylsilyl), EDC, HOBt, 68%; c) CsF, DMF, 86%; d) TBAF, THF, 48%.

Extensive efforts to effect ring closure of **11**, including variations in solvent (THF, DMF, DMSO), base (NaH, potassium hexamethyldisilazanide (KHDMS), K_2CO_3, and CsF), temperature, and concentration, were unsuccessful. Surprisingly, when a THF solution of **10** or **11** was treated with tetrabutylammonium fluoride (TBAF) in the presence of molecular sieves, the unstable compound **12** was obtained as the only isolable product in 48% yield. The structure of **12** was tentatively assigned as that shown in Scheme 3 from detailed spectroscopic studies, and a possible reaction path is proposed in Scheme 4 to explain its formation. Owing to the proximity between the hydroxyl group and the N-carbamate function in **11**, oxazolidinone **13** formed readily at the expense of the desired macrocyclization. Participation of the amide oxygen in an S_NAr reaction gave then the 12-membered macrocycle **14**, which tautomerized into the observed product **12**. Supporting this mechanism, compound **13**, obtained after brief treatment of **11** with TBAF, cyclized under identical conditions to afford **12** in similar yield.



Scheme 4.

To avoid oxazolidinone formation, the protecting group of amine needs to be carefully reconsidered. We reasoned that the N-bisalkylated derivative meet our requirements. As shown in Scheme 5, simultaneous deprotection of the N-carbamate and O-silyl ether with HCl/MeCN gave amino alcohol **15** without event. Selective N-bisallylation or N-bisbenzylation in the presence of the primary hydroxyl function was best realized with $NaHCO_3$[8] in a mixed solvent system (DMSO/THF = 1/4) to afford **16** and **17** in 78% yield. Under these conditions, neither O- nor amide alkylation were observed.



Scheme 5. a) HCl/MeCN, 93%; b) THF/DMSO (4/1), allyl bromide, $NaHCO_3$, 80 °C, 82%; c) THF/DMSO (4/1), BnBr, $NaHCO_3$, 80 °C, 78%; d) TBAF, DMF, molecular sieves, room temperature, 4 h, 60–75%; e) $NaBH_4$, elemental sulfur, THF, reflux, 81%; f) 1) *t*BuONO, $BF_3 \cdot Et_2O$, CH_2Cl_2, −15 °C; 2) $FeSO_4$, DMF, room temperature, 45–55%.

When a DMF solution of **16** (0.01 M) was treated with TBAF in the presence of molecular sieves at room temperature, a mixture of the two cyclized monomers **18a** and **18b** was isolated in 70% overall yield. Interestingly, similar treatment of compound **17** afforded the two separable products **19a** (32%) and **19b** (48%), which were identified as atropisomers based on spectroscopic studies; the assignment was confirmed by subsequent chemical transformation. The presence of a single nitro substituent on the aromatic ring *ortho* to the aryl–alkyl linkage is sufficient to hinder free rotation of that bond creating thus a plane of chirality.[9] A control experiment showed that

compounds **19a** and **19b** do not equilibrate under the cyclization conditions, indicating therefore that the product distribution is kinetically controlled. The lack of atropdiastereoselectivity is of no consequence as the plane of chirality will be destroyed on removal of nitro group at the final stage of the synthesis. This ring-forming process is noteworthy in that high-dilution techniques[10] were not needed and possible side reactions such as β-elimination, transacylation, and dimerization were not observed. THF could also be used as solvent though the reaction time was significantly prolonged. The easy formation of the 14-membered macrocycles **18a,b** and **19a,b** is rather spectacular considering the obvious strain in this ring system and the fact that only very few methods are available. Intramolecular recognition leading to the preorganized, reactive conformation of the linear precursor may be responsible for such facile cyclization.[11]

The nitro group was removed in a two-step sequence. Reduction of mixture of **18a** and **18b** with sulfurated $NaBH_4$[12] in THF gave the corresponding amino compounds, and two atropisomers were separable at this stage by flash chromatography. Diazotization of **20a** and **20b** under Doyle's conditions[13] followed by $FeSO_4$-mediated reduction of the crude diazonium salts[14] gave the desired cyclophane **2a**[15] (R = allyl) in 53% nonoptimized yield. The same sequence applied to **19a** and **19b** gave the amino compounds **21a** and **21b,** and then the target compound **2b** (R = Bn) in 47% yield.

In conclusion, we have developed a new synthetic strategy for the synthesis of 14-membered cyclopeptide alkaloids. This report, to the best of our knowledge, gives the first examples of S_NAr-based macrocyclization with formation of an aryl–alkyl ether bond.[16] Application of this methodology to the synthesis of natural cyclopeptide alkaloids will be reported in due course.

A Unique Ni^{II} Complex with Three Different Azido Bridges: Magneto-Structural Correlations in the First Triply Alternating $S = 1$ Chain**

Joan Ribas,* Montserrat Monfort, Immaculada Resino, Xavier Solans, Pierre Rabu, Fabrice Maingot, and Marc Drillon

The μ-azido bridging ligand is undoubtedly one of the most versatile for the creation of new materials with different magnetic properties. This ligand also allows the study of magneto-structural correlations in discrete complexes as well as in polymeric one- (1D), two- (2D), and three-dimensional (3D) complexes. There are two main coordination modes for azido bridging ligands: end-to-end (or μ-1,3) (EE) and end-on (or μ-1,1) (EO) (Fig. 1). The EO mode leads to ferromagnetic coupling and the EE mode to antiferromagnetic. This variation in magnetic behavior appears to be generally valid for metal ions like Ni^{II},[1-7] Cu^{II},[8] Mn^{II},[9] Mn^{III},[10] Co^{II},[11] and Fe^{II}.[12]

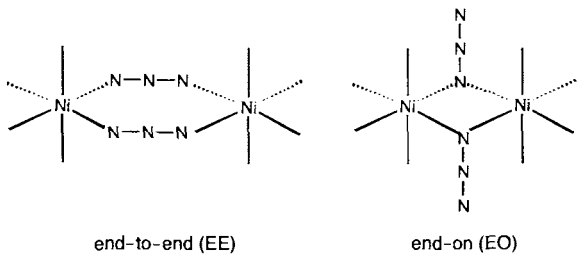

Fig. 1. Schematic representation of the two coordination modes of the μ-azido bridging ligand (see text for effects on the magnetic properties).

Recently we synthesized and fully characterized new Ni^{II} compounds that exhibited the two kinds of coordination mode: 1) a new two-dimensional molecular magnet[5] of empirical formula $[Ni\{H_2NCH_2CH(CH_3)_2CH_2NH_2\}(\mu\text{-}N_3)_2]$, 2) a unique triply EO- and singly EE-bridged alternating chain of empirical formula $[Ni(tmen)(\mu\text{-}N_3)_2]$ (tmen = *N,N,N',N'*-tetramethylethylenediamine),[6] and 3) two alternating EO and EE chains: $[Ni(N,N\text{-dmen})(\mu\text{-}N_3)_2]$ and $[Ni(aep)(\mu\text{-}N_3)_2]$ (dmen = *N,N*-dimethylethylenediamine; aep = 2-aminoethylpyridine).[7]

Here we report on the synthesis and characterization of $[Ni(N,N'\text{-dmen})(\mu\text{-}N_3)_2]$ (*N,N'*-dmen = *N,N'*-dimethylethylenediamine), an unprecedented and unexpected complex. According to the X-ray structure analysis[13] the molecular structure consists of Ni^{II} centers alternatively linked by three double EO entities (two of them crystallographically equivalent) and one double EE entity (Fig. 2). Each Ni^{II} ion completes its distorted octahedral coordination by binding to one bidentate *N,N'*-dmen ligand. The Ni–Ni distances are 3.27 Å and 3.35 Å for the EO part and 5.25 Å for the EE part. These values lie in the range for all known $[Ni(\mu\text{-}N_3)_2Ni]$ units with two μ-azido bridging ligands.[2,4] The Ni–N distances of between 2.11 and

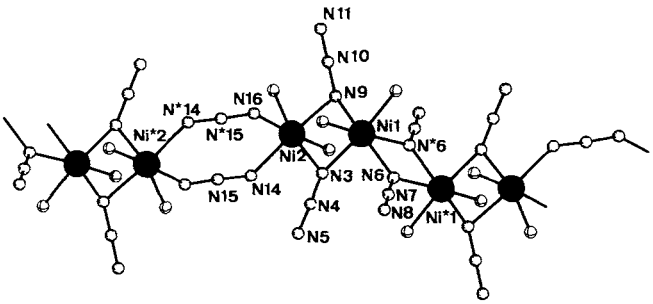

Fig. 2. Molecular structure of $[Ni(N,N'\text{-dmen})(\mu\text{-}N_3)_2]$. The C atoms of the *N,N'*-dmen rings have been omitted for clarity. In the Ni1-N6-Ni1*-N6* part there is an inversion center as in the Ni2-N15-Ni2*-N15* part. Selected bond lengths [Å] and angles [°] (standard deviation in parentheses): Ni1–N3 2.111(3), Ni1–N6* 2.123(3), Ni1–N9 2.121(3), Ni1–N6 2.161(3), Ni2–N3 2.145(3), Ni2–N9 2.114(3), Ni2–N14 2.118(4), Ni2–N16 2.099(4), Ni1–Ni1* 3.350(2), Ni1–Ni2 3.272(4), Ni2–Ni2* 5.247(3); N3-Ni1-N9 79.18(13), N9-Ni2-N3 78.56(12), Ni1-N3-Ni2 100.50(14), Ni2-N9-Ni1 101.19(14), Ni1*-N6-Ni1 102.88(14), N6*-Ni1-N6 77.12(14), N16-Ni2-N14 91.58(14), N15-N14-Ni2 132.9(3), N15-N16-Ni2 130.9(3).

2.14 Å also lie in the expected range. The most important structural features are the $Ni(\mu\text{-}N_3)_2Ni$ angles, which are directly related to the magnetic coupling. The angles in the two crystallographically independent EO modes are 100.5, 101.2, and 102.9°, and thus also lie in the range of all known $Ni(\mu_{1,1}\text{-}N_3)_2Ni$ (between 100.6 and 104.9°).[4] In the EE fragment the N-N-Ni angles are 130.9 and 132.9°, and thus lie in the middle of the range of known values (between 120.0 and 139.0°).[2] The $Ni(\mu_{1,3}\text{-}N_3)_2Ni$ dihedral angle δ is 8.4° (Fig. 3).

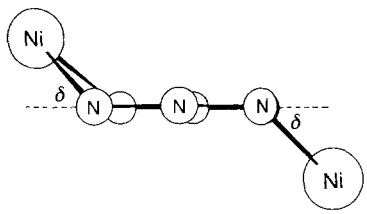

Fig. 3. Schematic representation for the $Ni(\mu_{1,3}\text{-}N_3)_2Ni$ dihedral angle δ (see text for its importance in magnetic coupling).

The temperature dependence of the molar magnetic susceptibility is illustrated in Figure 4. The χ_M value increases with de-

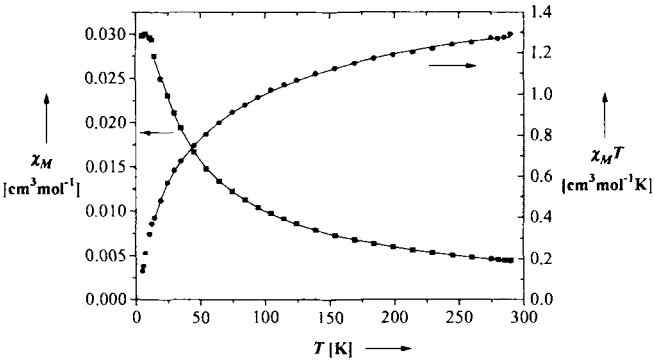

Fig. 4. Plots of χ_M and $\chi_M T$ versus T for $[Ni(N,N'\text{-dmen})(\mu\text{-}N_3)_2]$. Solid lines correspond to the best theoretical fitting.

creasing temperature, reaching a maximum near 15 K, and then slightly decreases down to 4 K. The variation of the product $\chi_M T$, from 1.3 $cm^3 mol^{-1}$ K at 290 K down to zero at very low temperature, clearly indicates the predominance of antiferromagnetic interactions. To explain these data we considered a stacking of quasi-isolated Ni^{II} chains with nearest-neighbor interactions. From the structural features, three exchange interac-

tions may be assumed, namely J_1 and J_2 for the EO mode and J_3 for the EE mode. Based on previous findings with azido-bridged dimeric units, J_1 and J_2 are expected to be ferromagnetic couplings and J_3 an antiferromagnetic coupling.[1-5] The Heisenberg spin Hamiltonian may be formulated as Equation (a). The S_i values stand for the spin operator ($S = 1$), D is the

$$\boldsymbol{H} = -\sum_{i=0}^{N-1}[J_1(S_{4i}S_{4i+1} + S_{4i+2}S_{4i+3}) + J_2S_{4i+1}S_{4i+2} + J_3S_{4i+3}S_{4i+4}] - D\sum_{i=0}^{4N-1}S_i^{z2} - g\mu_B H\sum_{i=0}^{4N-1}S_i^z \quad \text{(a)}$$

zero-field splitting for Ni^{II}, H the applied field, and g the Landé factor. For simplification, it is assumed that D and g are identical for all the sites. There is no mathematical expression to evaluate the susceptibility of such a complicated alternating $S = 1$ system. Thus, the usual numerical procedure was used,[14] based on the extrapolation of results computed for rings of $4N$ spins. The resolution of the Hamiltonian operator requires the diagonalization of matrices of the dimensions $3^{4N} \times 3^{4N}$, which rapidly becomes intractable when N increases. However, a significant reduction of the computational work is achieved by introducing the spin space symmetries of the $4N$-site closed chain.[15] In the present case the calculations were performed up to $N = 2$ (eight spins), which gave a satisfactory description of the magnetic behavior in an acceptable amount of computer time.[16] The experimental data have been analyzed in the range 20 K – 300 K by using the above model of eight spins, and by adjusting the J_i and D parameters and the g factor. A first attempt, in which no distortion ($D = 0$) and $g = 2.2$ (as mean value for octahedral Ni^{II}[17]) were assumed, was not entirely satisfactory. In particular, the shape of the $\chi_M T = f(T)$ curve is not well reproduced. Thus, by varying all the parameters, the best agreement between theory and experiment (Fig. 4) is obtained with $J_1 = 20\ cm^{-1}$, $J_2 = 37\ cm^{-1}$, $J_3 = -120\ cm^{-1}$, $D = 6\ cm^{-1}$, and $g = 2.39$. The estimated errors are 10% for J_i and D, and 1% for g. These values for the interaction are similar to those obtained previously with fixed D and g, except for J_3 which is somewhat higher but of the same order of magnitude. The number of parameters (five) could mitigate their significance. Note, however, that the examination of the correlation matrix does not reveal very strong correlations between the refined J_i. In fact, the most important source of error is the limited number of spins considered in the model. It remains that these values agree very well with those predicted according to the structural features. Indeed, our previous study[2] on dinuclear Ni^{II} complexes with EE coordination shows that the antiferromagnetic coupling is highest for a $Ni(\mu_{1,3}\text{-}N_3)_2Ni$ dihedral angle of 0° (Fig. 3). The lower the angle, the higher the coupling. In the present case, this angle is low and the Ni–N distance is short (2.11 Å); thus J_3 (antiferromagnetic interaction) must be high. In fact, assuming that the refined value is correct ($J = -120\ cm^{-1}$), it would be the highest one reported so far for this kind of structure. The behavior of the $Ni(\mu_{1,1}\text{-}N_3)_2Ni$ core is more difficult to predict. Very recently Christou et al.[1g] attempted to correlate the $Ni(\mu_{1,1}\text{-}N_3)Ni$ angles with J values, but the correlation appeared not to be very pronounced. We can only note that all experimental J values for $Ni(\mu_{1,1}\text{-}N_3)Ni$ angles between 86.2 and 104.9° lie in the range of $15-40\ cm^{-1}$. For similar Cu^{II} complexes Kahn et al. explained the ferromagnetic behavior by way of the accidental orthogonality[18] concept and with ab initio calculations on model systems,[19] which led to the development of the theory of spin polarization. Accidental orthogonality occurs for angles close to 100°;[18] the Ni-N-Ni angles in all the Ni^{II} systems reported lie close to this value. Consequently, it is not surprising that all the Ni centers in these complexes are ferromagnetically coupled.

In conclusion the present complex is a further example in which changing the nonbridging ligand (*N,N'*-dmen instead of *N,N*-dmen[6]) has a dramatic effect on the μ-azido bonding mode. In terms of the magnetic behavior, it is the first time that an alternating ferro–antiferromagnetic $S = 1$ chain has been studied and its magnetic behavior analyzed. The J values obtained here agree well with the reported data for simpler polynuclear Ni^{II} complexes.

Experimental Procedure

A solution of *N,N'*-dmen (0.176 g, 2 mmol) in MeCN (10 mL) was added dropwise to a stirred aqueous solution (20 mL) of $Ni(NO_3)_2 \cdot 6H_2O$ (0.58 g; 2 mmol). This solution was filtered and NaN_3 (0.26 g, 4 mmol) dissolved in water (10 mL) was added slowly. The clear dark green solution was filtered to remove impurities and left to stand undisturbed at room temperature. One week later, X-ray quality green single crystals were obtained, which were filtered, washed with cold water, and air dried. Yield: 65%. The analysis for the bulk material was consistent with the formula proposed.

Activation of Carbon Dioxide by Coordination with Cations in the Gas Phase: SiF_3^+-Mediated Coupling of CO_2 and Aromatic C–H Bonds**

Patrizio Cecchi, Maria Elisa Crestoni, Felice Grandinetti,* and Vittorio Vinciguerra

Activation of carbon dioxide and its conversion into useful products still remains a fascinating challenge facing chemists.[1] Considerable progress has been made recently, but additional, intense effort is required "to put together the pieces of the mosaic".[2] Gas-phase ion chemistry can substantially contribute to investigations on fundamental aspects of CO_2 activation[3] and, in addition, may provide suggestions for novel synthetic procedures. Thus, the recently reported[4] Ta^+-mediated coupling of CH_4 and CO_2 in the gas phase has to be regarded with respect to the catalytic formation of acetic acid.

Fixation of CO_2 at active centers of biomolecules, solid catalysts, or transition metal complexes is considered a key elementary step of most natural and synthetic sequences that use carbon dioxide as a C_1 building block.[1] This concept could be convincingly demonstrated if carbonylation or carboxylation products were unambiguously observed arising from an intact CO_2 ligated to a cation in the gas phase; this model reaction would be even more interesting if it amounted to functionalization by CO_2 of unreactive hydrogen or hydrocarbons. In studies with this perspective, Schwarz and Schwarz recently isolated an Fe^+-(CO_2) complex and probed its reactivity toward H_2 and CH_4.[5a] A slow ligand exchange of carbon dioxide for methane was observed, but no evidence was found for the generation of CH_3CO_2H by activation of CO_2/CH_4. They rationalized this in terms of the low bond dissociation energy (BDE) of Fe^+ and CO_2 (experimental BDE: 9 ± 2 kcal mol^{-1}).[5b]

As a continuation of our interest in the gas-phase chemistry of fluorinated inorganic cations,[6] we report here on the coupled activation of CO_2 and aromatic C–H bonds mediated by SiF_3^+ in the gas phase and occurring under the conditions of Fourier transform ion cyclotron resonance (FT-ICR) spectrometry.[7]

Only few complexes of CO_2 with cations in the gas phase have yet been reported.[3f-g, 8] Figure 1 shows a typical mass spectrum from the ionization of a mixture of CO_2 and SiF_4 introduced into the external source of the FT-ICR. Besides the signals arising from the ionization of CO_2 and SiF_4, including SiF_3^+-(SiF_4) at $m/z=189$, we draw attention to the abundant ions detected at $m/z=129$, which are unambiguously assigned as $SiF_3CO_2^+$ by exact mass measurements. The observation of SiF_3^+ exclusively in the corresponding CID spectrum (CID = collision-induced dissociation) is consistent with an SiF_3^+-(CO_2) adduct, but does not help in assigning its detailed connectivity. However, in line with the high oxophilicity of silicon, we found that the oxygen-coordinated isomer shown in Figure 2 is by far the most stable among several conceivable SiF_3^+-(CO_2) adducts investigated at the MP2/6-311G**//HF/6-311G** level of theory. The computed Si–O2 distance of 1.770 Å suggests a significant interaction between SiF_3^+ and CO_2. Consistently, we arrived at an experimental BDE of SiF_3^+ and CO_2 as large as 58 ± 12 kcal mol^{-1}

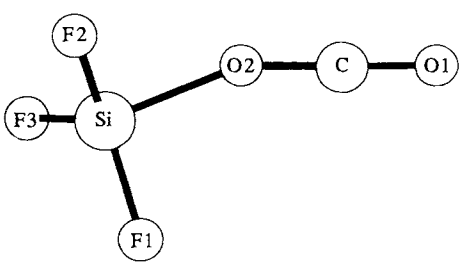

Fig. 2. HF/6-311G** optimized parameters (symmetry is C_s): C–O1 1.100, C–O2 1.179, Si–O2 1.770, Si–F1 1.531, Si–F2 1.527 Å, O1-C-O2 178.5, C-O2-Si 156.3, F1-Si-O2 101.8, F2-Si-O2 102.1, F2-Si-O2-F1 119.7°.

from the observation of the ligand-displacement reactions (1) and (2) and the BDEs of SiF_3^+ and HF and H_2O (46 and

$$F_3Si{-}FH^+ + CO_2 \longrightarrow SiF_3^+{-}(CO_2) + HF \quad (1)$$

$$SiF_3^+{-}(CO_2) + H_2O \longrightarrow F_3Si{-}OH_2^+ + CO_2 \quad (2)$$

70 kcal mol^{-1}, respectively).[9, 10] As an aside, we determined the enthalpy of formation of $SiF_3^+{-}(CO_2)$ to be -181 ± 12 kcal mol^{-1}. Detailed investigation of the conceivable ion–molecule reactions leading to $SiF_3^+{-}(CO_2)$ threw light on the ligand displacement reaction (3), which was unambiguously

$$SiF_3^+{-}(SiF_4) + CO_2 \longrightarrow SiF_3^+{-}(CO_2) + SiF_4 \quad (3)$$

detected by reacting thermalized $SiF_3^+{-}(SiF_4)$ from the external source of the FT-ICR with CO_2 in the resonance cell. The efficiency of reaction (3) is evaluated as 0.44 from the ratio of the experimental rate constant $k_3 = 2.8 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1} and the collision rate constant $k_3(\mathrm{ADO}) = 6.38 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}, calculated from the average dipole orientation (ADO) theory.[11]

The $SiF_3^+{-}(CO_2)$ ions isolated from the external source and allowed to react with nucleophiles introduced in the resonance cell of the FT-ICR are unreactive toward H_2, CH_4, and other saturated hydrocarbons, and are only able to undergo ligand displacement with C_2H_2, C_2H_4, and C_3H_6. However, treatment of $SiF_3^+{-}(CO_2)$ with benzene gave reactions (4a) and (4b) in the indicated proportions.

$$SiF_3^+{-}(CO_2) + C_6H_6 \xrightarrow{0.75} C_6H_5{-}CO^+ + SiF_3OH \quad (4a)$$

$$SiF_3^+{-}(CO_2) + C_6H_6 \xrightarrow{0.25} SiF_3^+{-}(C_6H_6) + CO_2 \quad (4b)$$

Typical intensity–time curves of the observed ions are shown in Figure 3. From the overall rate constant k_4 (8.8×10^{-10} cm^3 molecule^{-1} s^{-1}) we determine k_{4a} and k_{4b} to be 6.6×10^{-10} and 2.2×10^{-10} cm^3 molecule^{-1} s^{-1}, respectively. In addition, using the collision rate constant of $SiF_3^+{-}(CO_2)$ with C_6H_6 ($k_4(\mathrm{ADO}) = 1.1 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}) we evaluate the efficiency of reaction (4a) as $k_{4a}/k_4(\mathrm{ADO}) = 0.6$. The CID spectrum of the $C_7H_5O^+$ ions from (4a) ($C_7H_5O^+$ 34%, $C_6H_5^+$ 100%, $C_4H_3^+$ 27%) was indistinguishable from the CID spectrum of the $C_6H_5{-}CO^+$ ions of the model obtained from the ionization of $C_6H_5{-}CO{-}OCH_3$; however, the FT-ICR experiments do not provide direct structural information on the

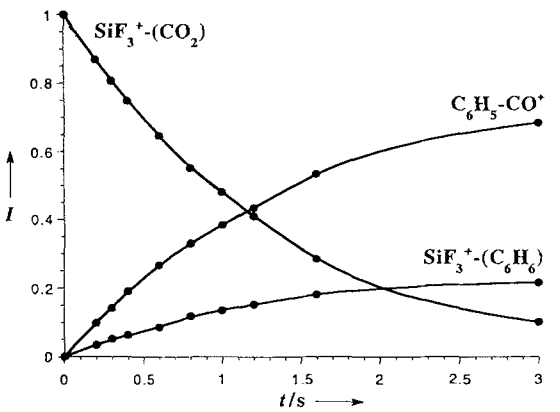

Fig. 3. Dependence of the relative intensities (I) on time of the ions observed when thermalized $SiF_3^+{-}(CO_2)$ is allowed to react with C_6H_6 ($P = 3.4 \times 10^{-8}$ mbar).

obtained neutral(s). Thus, we can only infer the formation of SiF_3OH and calculate $\Delta H°(4a)$ (-31 ± 12 kcal mol^{-1}).[12]

The carbonylation reaction (4a) provides unambiguous evidence for the activation of carbon dioxide by coordination to a gaseous cation. In addition, combining (3) with (4a) yields the net reaction equation (5), which describes the *coupled* activation

$$SiF_3^+{-}(SiF_4) + CO_2 + C_6H_6 \longrightarrow C_6H_5{-}CO^+ + SiF_3OH + SiF_4 \quad (5)$$

of CO_2 and aromatic C–H bonds. Indeed, a high intensity of $C_6H_5{-}CO^+$ is detected when thermalized $SiF_3^+{-}(SiF_4)$ from the external source of the FT-ICR is subjected to reaction with CO_2/C_6H_6 mixtures in the resonance cell (typical ratio 3/1, P approximately 5×10^{-8} mbar). Reaction (5) commences with the ligand-exchange (3), which converts the unreactive carbon dioxide into an electrophile that undergoes efficient carbonylation (4a). Since the $SiF_3^+{-}(C_6H_5{-}CO_2H)$ intermediate conceivably involved in this reaction is excited by the exothermicity of its formation process and lacks thermal stabilization in the low-pressure domain of the FT-ICR cell (P about 10^{-8} mbar), it undergoes fast elimination of SiF_3OH to give $C_6H_5{-}CO^+$ as the only product ion. The actual observation of an $SiF_3^+{-}(C_6H_5{-}CO_2H)$ adduct in the higher pressure domain of the FT-ICR external source (P about 10^{-4} mbar) supports this proposal (Fig. 4). The observation of $C_6H_5{-}CO^+$ exclusively in the CID

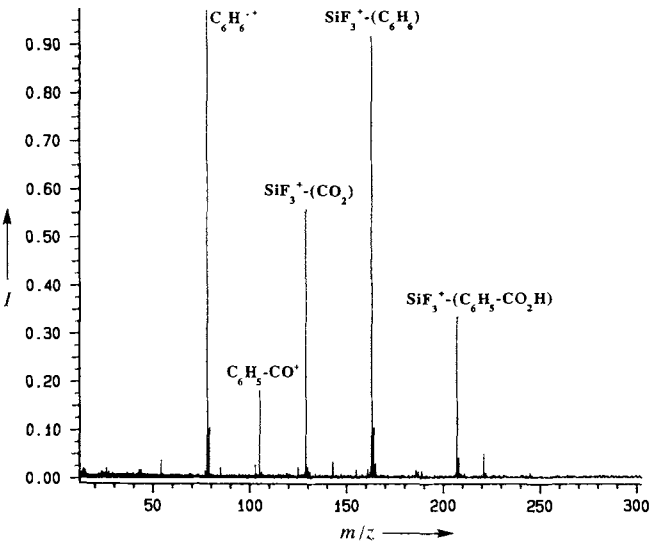

Fig. 4. Mass spectrum (70 eV) of a $CO_2/SiF_4/C_6H_6$ gaseous mixture (P about 1.7×10^{-4} mbar; approximate ratio 7/3/1).

spectrum of the $SiF_3C_7H_6O_2^+$ ions suggests the formation of an adduct between $C_6H_5{-}CO_2H$ and SiF_3^+ rather than a terbody complex ($SiF_3^+/CO_2/C_6H_6$), which we would expect to lose intact C_6H_6 and/or CO_2. In addition, we obtained a CID spectrum indistinguishable from that of the $SiF_3C_7H_6O_2^+$ ions generated in the external source of the FT-ICR from the ionization of a mixture of $C_6H_5{-}CO_2H$ and SiF_4 and reasonably regarded as a model for $SiF_3^+{-}(C_6H_5{-}CO_2H)$.

Mass spectra of ionized $CO_2/SiF_4/C_6H_5X$ mixtures (X = CH_3, F, Cl) were quite similar to that reported in Figure 4; we invariably detected the formation of $XC_6H_4{-}CO^+$ from the reaction of $SiF_3^+{-}(CO_2)$ from the external source of the FT-ICR with C_6H_5X introduced in the resonance cell. Thus, coordination of CO_2 to SiF_3^+ makes accessible the reactions (6), which

$$CO_2 + C_6H_5{-}X \longrightarrow X{-}C_6H_4{-}CO_2H \quad (6)$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3521-2523 $ 15.00+.25/0

are endothermic in the gas phase by several kcal mol^{-1} ($\Delta H°(6) = 3.9$ kcal mol^{-1}, X = H; 3.0 kcal mol^{-1}, X = CH_3; 4.9 kcal mol^{-1}, X = F). Besides providing unambiguous evidence for CO_2 activation by a coordination mechanism, this finding demonstrates the possibility of promoting endothermic reactions involving carbon dioxide by taking advantage of the larger interaction energy with the reaction products of a cation ligated to CO_2 in the gas phase.

Experimental Procedure

All experiments were performed on a Bruker Spectrospin Apex 47e FT-ICR spectrometer equipped with an external ion source [13]. To investigate the reactivity of selected ions produced in the external source, the ions were transferred to the resonance cell, trapped in the field of a superconducting magnet (4.7 T), isolated with single-shot and broad-band-ejection techniques [14], thermalized by unreactive collisions with argon pulsed into the cell with peak values of ca. 10^{-6} mbar, and reisolated. The pseudo-first-order rate constants were derived from the logarithmic decay of the precursor-ion intensity with time, corrected for reactions with background impurities, and converted into absolute rate constants by dividing by the number density of the neutral molecules in the ICR cell. To this end, the pressure readings from the ion gauge were first calibrated against the rate constants of suitable ion–molecule reactions and subsequently corrected for the different sensitivities toward the neutral molecules [15]. The estimated error in the absolute rates is about ±30%. All the neutral species were introduced into the cell at corrected pressures ranging from 2×10^{-8} to 8×10^{-8} mbar. The reported ligand-exchange reactions were confirmed by treating thermalized ions from the external source with the neutral species in the cell. The CID [16] experiments were performed by colliding isolated ions with argon, pulsed into the cell with peak values of about 1×10^{-6} mbar. Exact mass measurements were performed by operating the instrument in the high-resolution mode.

Standard ab initio calculations were performed with a RISC/6000 version of the Gaussian 94 set of programs [17].

Fast Atom Bombardment Mass Spectrometry for Characterizing Cationic Chelated Species**

Jeffery A. Whiteford, Elliot M. Rachlin,* and Peter J. Stang*

Dedicated to Professor Michael Hanack on the occasion of his 65th birthday

Supramolecular chemistry encompasses several areas of interest including organic macrocycles with covalent bonds, hydrogen-bonded species, and aggregates derived through metal coordination.[1–4] Moreover, self-assembly resulting in macrocycles has become a driving force in all of these areas.[4–11] Determining the structures and relative molecular masses of the self-assembled aggregates and macrocycles are major challenges in this field. Commonly employed techniques such as X-ray crystallography, vapor-phase osmometry (VPO), and gel permeation chromatography (GPC) all have limitations and shortcomings,[12, 13] which are particularly acute in the analysis of aggregates and macrocycles arising from metal coordination.[4–10] 1) X-ray quality single crystals are often difficult to obtain because of the considerable void space in these systems. Furthermore, removal of the crystals from the mother liquor generally results in rapid solvent loss and collapse to amorphous material.[8] Even when the single crystal survives, extensive solvent occlusion can cause disorder and consequent poor structure resolution (large *R*-value). 2) Molecular masses determined by VPO generally deviate substantially from those calculated, and error values tend to increase with increasing molecular mass.[13]

3) GPC works well for large biomolecules such as proteins and nucleic acids, as well as neutral linear polymers. For the latter, acceptable molecular weight distributions are obtainable by this technique.[14] Unfortunately, few coordination complexes, metal-based aggregates, or macrocycles survive GPC conditions, and GPC is usually best at molecular weights exceeding 10000.

Recently, electrospray (ES), fast atom bombardment (FAB), and matrix assisted laser desorption time of flight (MALDI-TOF) mass spectrometry have proven useful for the characterization of organic and inorganic supramolecular species formed in solution.[12, 15, 16] To date, several types of macrocycles have been distinguished by MS such as palladium catenanes with dative bonds,[17] covalently bound rapamycin,[18] and self-assembled hydrogen-bonded organic species.[12, 13] ES mass spectrometry has been used to characterize unique chains of interlocking oligoalkyne macrocycles and porphyrins linked through the coordination of copper(I) ions by 1,10-phenanthroline subunits.[19] The stability of the complex in the matrix and within the mass spectrometer typically determine the feasibility of mass spectral characterization.

Tetranuclear, transition metal based complexes termed "molecular squares" are some of the newest members of the family of supramolecular macrocycles.[4, 7, 8] Although MS data is reported for a rhenium–palladium-based square [10] and an all-silicon-based square,[15] mass spectral data for platinum–palladium, platinum–iodine, and palladium–iodine squares have not been reported. ESMS has been particularly useful in the characterization of organometallic species[20] and found advantageous for the observation of proteins and copper coordination compounds with higher molecular masses and charge states.[21] However, molecular squares have exhibited limited stability under commonly employed MS methods such as ESMS in both protic and aprotic solvents. This is probably due to the lability of the metal–ligand coordination bonds in the macrocycle. Although charge state resolution was possible by ESMS, isotopic resolution was not feasible on the triple quadrupole mass spectrometer used which had a limited m/z range. However, isotopic resolution was achieved with an ESIFTICR system (electrospray ionization Fourier transform ion cyclotron resonance), which verified the charges of the fragments observed.

Typically, molecular squares such as **4** and **5** containing only coordination bonds (Scheme 1) fragment by successive loss of each chelated metal corner and loss of the bipyridine units. Molecular squares containing σ-bonded ligands (Schemes 2–4) tend to fragment into the σ-bonded monomeric organometallic component and the previously dative-bonded metal chelate corners. Although use of ESMS has been unsuccessful to date for the characterization of molecular squares in solution, ongoing development will likely render this technique fruitful for the observation of self-assembled molecular squares.

We now report a Fast Atom Bombardment Mass Spectrometry (FABMS) method for the characterization of chelated cationic tetranuclear species formed by self-assembly in solution. Important data obtained by this method are the isotopic abundance patterns for species **4**, **5**, **9**, **10**, **14**, **15**, **17**, and **18**. The charge of each fragment or assembly is typically identified by the separation of the major peak of the fragment from the smaller peaks in the observed isotopic distribution. For example, for a doubly charged ion this separation is 0.5 m/z units, while for a singly charged ion it is 1.0 m/z units. Therefore optimal resolution is needed for the identification of each fragment. Sufficient resolution was obtained using the method we describe herein (see Experimental Procedure).

The M − OTf peak (m/z = 4097.0) and the peak corresponding to the corner fragment (m/z = 607.0) were observed for the coordination-bonded square **4**, which was formed from **1** and **2**, (Scheme 1, Table 1). Similarly, the M − OTf peak (m/z = 3743.2) and the peak for the corner fragment (m/z = 518.0) were

[a] OTf = trifluoromethanesulfonate.

observed for the coordination-bonded square **5**, accessible analogously from **1** and **3**. The isotopic distribution patterns for squares **4** and **5** both indicate a charge of 1+ (peak separation of 1.0 m/z units).

The fragmentation pattern for square **9**, which arises from **6** and **7** (Scheme 2), includes a M − OTf peak (m/z = 2937.8), which is in agreement with the calculated value (Table 1). Importantly, comparison of the calculated and experimental isotopic distribution for the M − OTf fragment of **9** are in excellent agreement and in accord with the expected m/z separation of 1 m/z units. The M − 2OTf peak was also observed for **9** (m/z = 1393.8). Further fragmentation of **9** resulted in the iodonium monomer **6** − OTf fragment (m/z = 435.1) as well as the ferrocenediyl corner fragment (m/z = 660.2), which are also in agreement with the calculated isotopic distribution patterns and

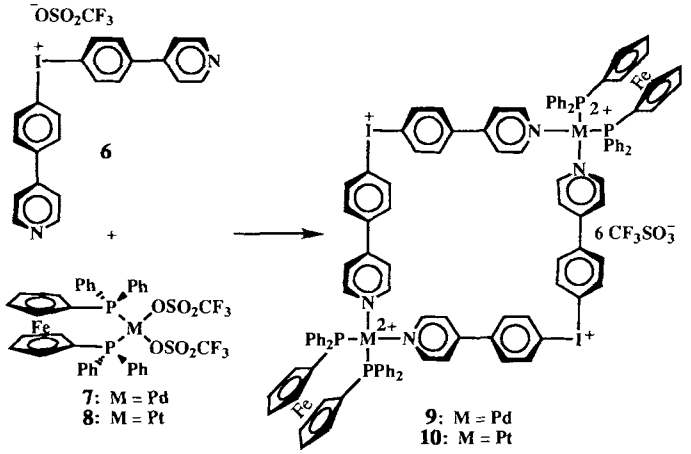
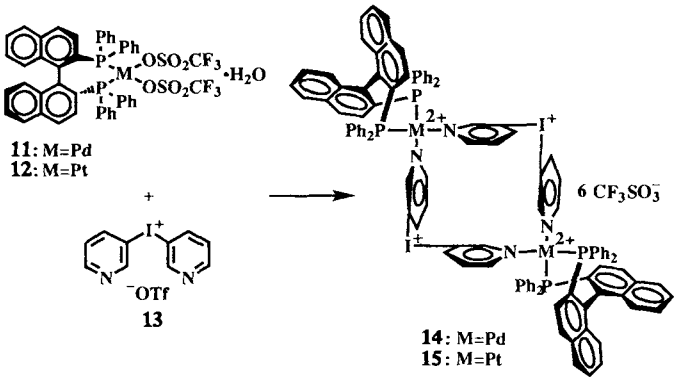


Scheme 2. Synthesis of Pt_2I_2 and Pd_2I_2 squares, in which two corners result from covalent bonds.



Scheme 3. Synthesis of **14** and **15**.

m/z values (Table 1). The M − OTf peak at m/z = 3115.4 was observed as well when square **10**, prepared from **6** and **8**, was subjected to FABMS conditions, and each of the isotope peaks were separated by 1 m/z units, as expected, indicating that this macrocyclic fragment has a charge of 1+ . Further evidence for this specific species was established by close correlation of the calculated isotopic distribution pattern with the experimental pattern (Fig. 1). The charge distribution, isotopic abundance pattern, and the m/z value for the base peak provide direct evidence for the existence of this specific species (**10** − OTf) in solution. Each macrocycle displayed different stability characteristics under FABMS conditions. Although peaks corresponding to M − 2OTf peak and the monomeric corner fragment **7** − 2OTf were observed for **9**, analogous signals were not observed for **10**; however, the iodonium monomer **6** − OTf peak was observed for both **9** and **10** (m/z = 435.1).

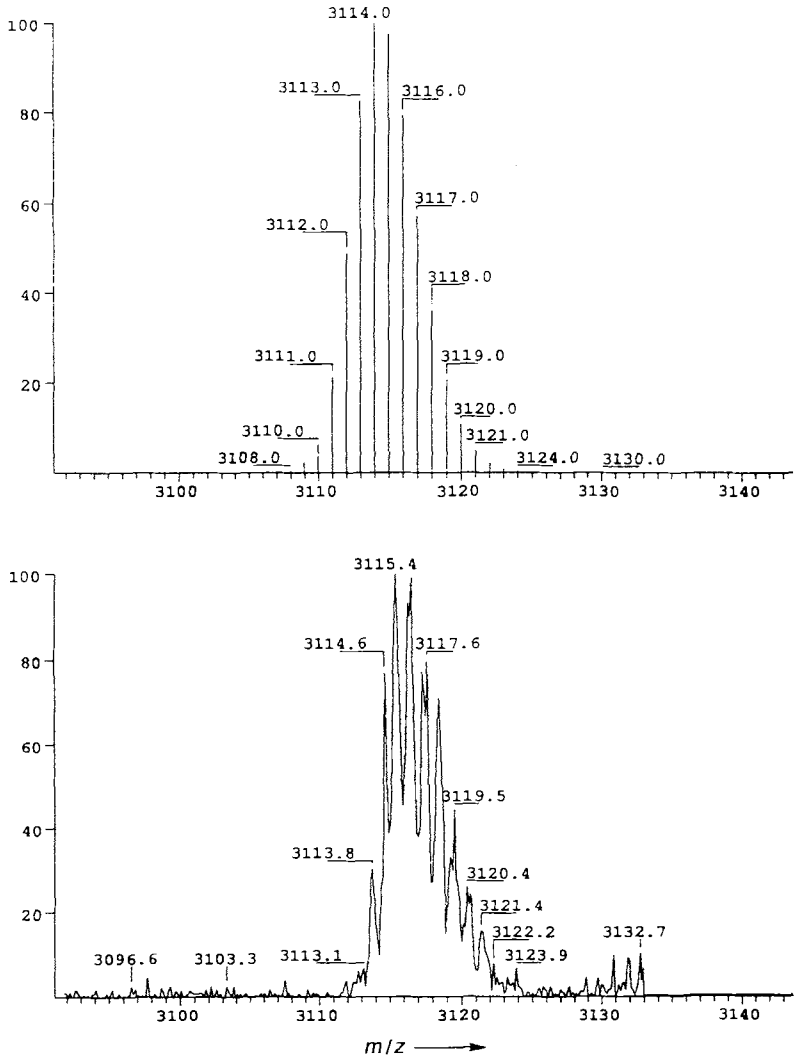


Fig. 1. Calculated (top) and observed (bottom) isotopic distribution patterns of the M − OTf peak for **10**.

Square **14**, the product of **11** and **13** (Scheme 3), exhibited the M − OTf peak at m/z = 2770 with an isotopic distribution pattern that is in close agreement with that calculated (Fig. 2). Although a peak was observed with the correct molecular weight for the M − 2OTf species, close inspection of the isotopic distribution revealed that it corresponded to a charge of 1+ and not 2+ , indicating that square **14** simply fragmented into two equal halves. In contrast, subjection of square **15**, which was prepared from **12** and **13**, to the same FABMS conditions resulted in the M − 2OTf peak (1397.8), but not the M−OTf peak, with a separation of 0.5 m/z units between the peaks of the isotopic pattern although **15** has about the same stability as **14** in the matrix. Further fragmentation of squares **14** and **15** resulted in the the respective palladium and platinum binapthalene phosphane chelated corners (728.7 and 817.7) and iodonium monomer fragments (255.0 and 255.2; Table 1).

The M − 2OTf peak (m/z = 1569.3) was observed for the all transition metal based square **17**, formed from the bisalkynyl complex **16** and **2** (Scheme 4), but the M − OTf peak was not evident. This may be attributed to the difference in stability of **4**, **5**, **9**, **10**, and **14** in solution compared to that of **17**. Although the hybrid iodonium/transition metal squares **9** and **10** are stable for several days in solution, square **17** decomposes within 12 h in the matrix. The 2+ charge was indicated for **17** by the peak separation of 0.5 m/z

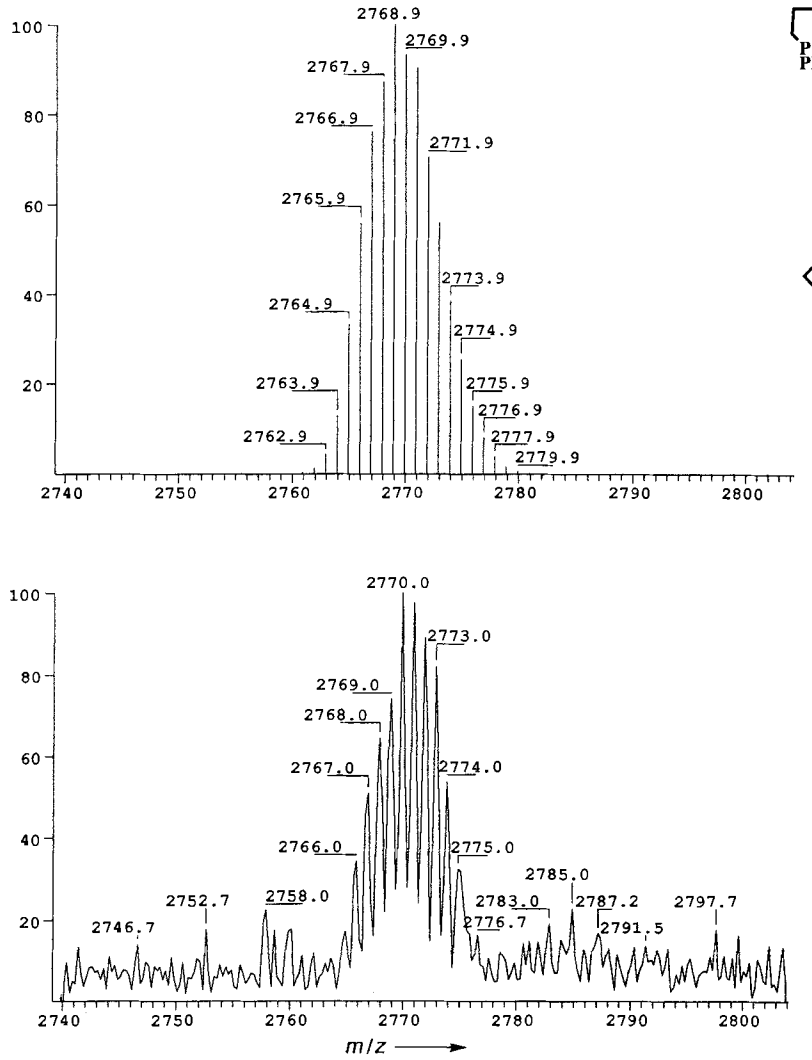

Fig. 2. Calculated (top) and observed (bottom) isotopic distribution patterns of the $M - OTf$ peak for **14**.

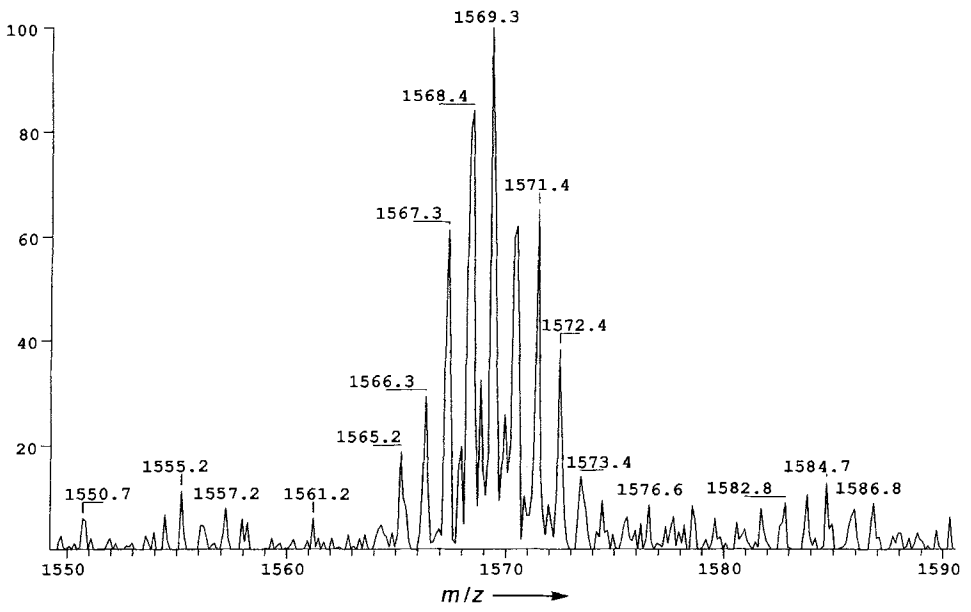

Fig. 3. Observed isotopic distribution pattern of the $M - 2OTf$ peak for **17** (charge 2+).

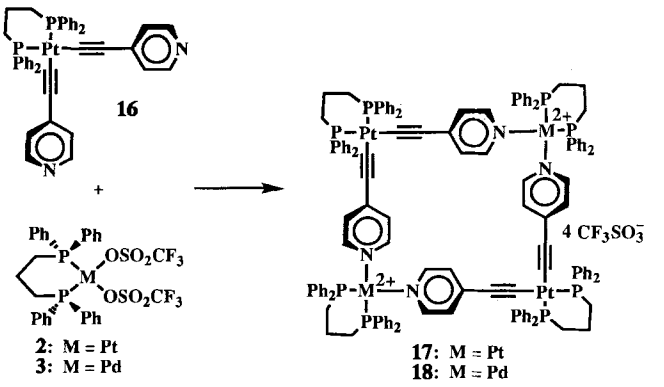

Scheme 4. Synthesis of the squares **17** and **18**, in which the corners result from metal–carbon σ bonds.

units in the isotopic distribution pattern (Fig. 3). As expected, when the least stable square **18** was subjected to the same FABMS parameters as squares **4**, **5**, **9**, **10**, **14**, **15**, and **17**, a peak corresponding to the protonated form of the platinum monomer fragment **16** ($m/z = 812.2$) was observed as the major species.

Monomers **6** and **16** were also studied in matrices similar to those used with the corresponding squares and observed by FABMS. In analogy with the square, the derived isotopic pattern and m/z value for monomer **6** were calculated and are in agreement with the observed spectrum. The $M - OTf$ peak was observed for **6** ($m/z = 435.1$) as well as a peak corresponding to loss of a 4-(4-pyridyl)phenyl substituent ($m/z = 282.1$) and a peak for this fragment alone ($m/z = 154.2$). Monomer **16** gave similar results, yielding the expected $M + H$ peak ($m/z = 812.2$) typically seen with this technique for a neutral chelated species that can be protonated (on the pyridine moiety). Also observed for **16** were the loss of each of the (4-pyridyl)ethynyl ligands ($m/z = 709.2$ and 607.3, respectively, Fig. 4). Finally, the calculated and the experimental isotopic distribution patterns for **16** are in full agreement (Fig. 5, Table 1).

In conclusion, self-assembled macrocyclic cationic chelated species in solution were characterized by FABMS along with monomeric charged and neutral chelated species. The observed fragmentation data and isotopic abundance patterns are in excellent agreement with calculated values and confirm the existence of these tetrameric macrocyclic species. As these examples illustrate, FABMS is a powerful technique for determining reliable molecular masses and for obtaining structural information on coordinated metal species. Particularly impressive is the applicability of this technique to self-assembled macrocycles based upon metal–ligand coordination. Hence, we think that the FABMS technique may be widely employed to characterize a broad range of coordinated

transition metal species including discrete supramolecular assemblies particularly in the molecular mass range of 300–5000. A particularly valuable aspect of this method is that it provides molecular mass and structural information in solution where most aggregates self-assemble under equilibrium conditions.

Experimental Procedure

Mass spectra were obtained with a Finnigan MAT 95 mass spectrometer under positive-ion fast atom bombardment (FAB) conditions using a CsI gun at 20 keV. 3-Nitrobenzyl alcohol was used as a matrix in dichloromethane, acetone, or dimethylsulfoxide as solvent; polypropylene glycol and CsI were used as calibration references. Each sample was dissolved in the appropriate solvent and mixed with the matrix on a standard Finnigan FAB probe. For optimal performance a thin film of matrix and sample on the target surface should form. Bombardment of the sample on the target surface by the CsI gun must result in an even introduction of all components of the mixture into the mass analyzer. To accomplish this, the solvent, substrate, and matrix used must form a homogeneous solution. Matrix systems that are not compatible with each other and form heterogeneous mixtures are easily recognized by erratic peak generation [22]. A reference spectrum of a standard aqueous solution of CsI was obtained by scanning from $m/z = 50$ to $m/z = 4500$. The mass spectrometer was then calibrated with the CsI spectrum. After slit adjustment to obtain a resolution of $m/z > 4500$ using the calibration mixture (entrance slit approximately 165–200, exit slit approximately 165–190) followed by standard tuning, a mass range of $m/z = 1000$ to $m/z = 4500$ was scanned to locate calibration peaks near the expected mass-to-charge range of each respective square. (The range was varied according to the molecular mass of the compound analyzed to scan for species larger than the target molecule to rule out pentamers, hexamers, etc.). Next, the mass range was increased to scan from $m/z = 50$ to $m/z = 4500$. Molecular squares **4**, **5**, **17**, and **18** were dissolved in dichloromethane (0.01 M), while **9**, **10**, **14**, and **15** were dissolved in acetone (0.01 M). Next, 3-nitrobenzylalcohol (0.5 μL) was used as a matrix and mixed with 1 μL of each of the standard solutions of the squares. The mass range of $m/z = 1000$ to $m/z = 4500$ was then scanned to obtain the $M - OTf$ peak and isotopic distribution. The range was then expanded again from $m/z = 50$ to $m/z = 4500$ to obtain the complete fragmentation pattern of each respective square. Then the scan range was changed to focus on the $M - 2OTf$ and/or the $M - OTf$ region from $m/z = 1000$ to $m/z = 4500$. Next, the scan range was changed to include only the $M - OTf$ peak from $m/z = 2700$ to $m/z = 4500$. Upon observation of the $M - OTf$ peak, 10–15 scans were compiled and averaged. The isotopic abundance pattern for each respective fragment peak obtained was calculated and compared to the experimental isotopic distribution. Next, the calibration standard was subjected to the same FABMS ionization conditions as the sample and the instrument calibration was verified. The mass spectral data of the squares was then compared to that of the standard and corrected according to software protocol. Extrapolation from the spectrum of the standard resulted in m/z values consistent with the predicted masses within error limits.

Monomer **6** was dissolved in dimethylsulfoxide (0.01 M); **16** was dissolved in dichloromethane (0.01 M). Next, 3-nitrobenzylalcohol (0.5 μL) was used as a matrix and mixed with 1 μL of each of the respective standard monomer solutions. The mass range of $m/z = 20$ to $m/z = 1000$ was used for obtaining spectra for monomers **6** and **16**.

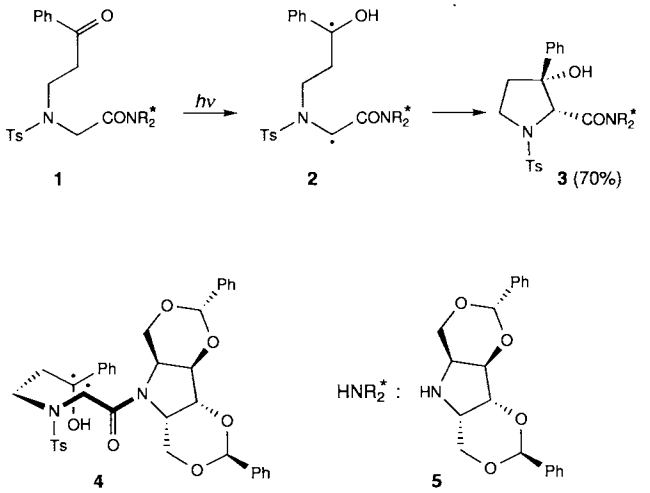
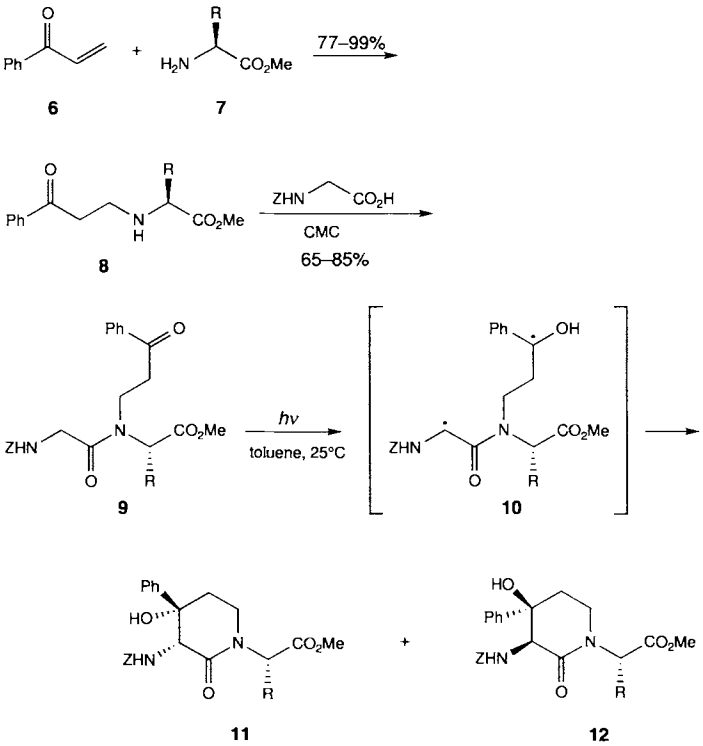
Selective Photocyclization of Glycine in Dipeptides**

Caroline Wyss, Rohit Batra, Christian Lehmann, Stefan Sauer, and Bernd Giese*

Recently we showed that the substituted glycine **1** undergoes a stereoselective photocyclization and yields proline derivative **3**.[1] Biradical **2** is the intermediate that cyclizes via conformer **4**. In this conformation the steric repulsion between the phenyl group and the attached chiral auxiliary **5** is minimized (Ts = *p*-toluenesulfonyl).



We have now observed that stereoselective photocyclization can also be carried out with dipeptides in which the asymmetric induction is caused by a constituent α-amino acid (substrate control). The dipeptides were synthesized in a Michael addition (**6** + **7** → **8**) and subsequent peptide coupling (**8** → **9**) (Z = benzyloxycarbonyl; CMC = *N*-cyclohexyl-*N'*-(2-morpholinoethyl)carbodiimide-methyl-*p*-toluenesulfonate). Photolysis of dipeptides **9a–d** produces δ-lactams **11a–d** and **12a–d** in about 70% yield.[2] Crystal structure analysis and NMR spectroscopy proved the structures of the δ-lactams.[3]



a, R = H	35%	35%
b, R = CH_3	48%	22%
c, R = $CH(CH_3)_2$	59%	8%

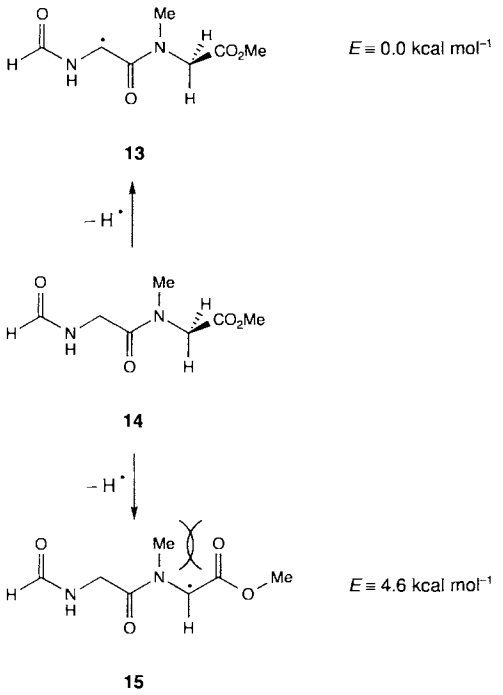
[**] This work was supported by grants from the Schweizerische Nationalfonds zur Förderung der wissenschaftlichen Forschung and by the Bundesamt für Bildung und Wissenschaft. We thank Prof. M. Zehnder and M. Neuburger for crystal structure analyses. C. W. thanks the Stipendienfonds der Basler Chemischen Industrie for a grant. We would like to thank Hoffmann-La Roche for providing us with the force field program MOLOC.

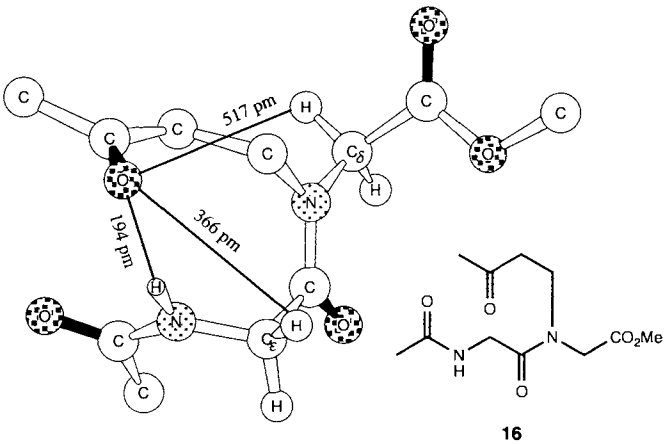
The high regioselectivity[4] of the formation of the six-membered ring, which proceeds via the 1,6-diradical **10**, is surprising. Ab initio calculations[5] of the isomeric radicals **13** and **15** offer a possible explanation. These radicals are generated by hydrogen abstraction from the tertiary amide **14**, which is a model of dipeptide **9**. The steric repulsion between the methyl group of the tertiary amide and the ester oxygen causes the ester group to twist out of the plane of the amide group. But hydrogen abstraction adjacent to the ester group (**14** → **15**) fixes the ester group in the plane of the amid function. The resulting steric interaction between the N-methyl group and the ester oxygen makes radical **15** 4.6 kcal mol^{-1} higher in energy than the isomeric radical **13**. The more stable radical **13** corresponds to biradical **10**, which yields the δ-lactams **11** and **12**.



Presumably, the regioselectivity is not only governed by the stability of the radicals but also by the conformations of the substrates. Force field calculations[6] with the substituted dipeptide **16** suggest that in the preferred conformation the distance between the carbonyl function of the phenyl ketone in **9** and the ε-methylene group is considerably shorter (366 pm) than that to the δ-methylene group (517 pm; Fig. 1).

In toluene only *cis* isomers of the δ-lactams are formed. In this configuration hydrogen bonds can exist between the OH and NHZ substituents, and the phenyl group remains in an equatorial position. In contrast, hydrogen bonds between the heterosubstituents in *trans* isomers is only possible when the phenyl group is in an axial position.[7, 8] According to this interpretation,[9] reduced stereoselectivity should be expected for reactions conducted in solvents that break intramolecular hydrogen bonding. Indeed, the *cis*:*trans* stereoselectivity decreased from >20:1 in toluene to 2.7:1 in acetone, 2.4:1 in diethyl ether, and 1.7:1 in methanol (25 °C).

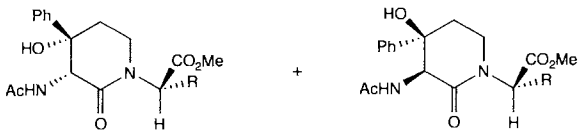
The asymmetric induction caused by the stereogenic centers in valine and phenylalanine is also very surprising. Crystal structures and MOLOC calculations[8] indicate that the amino acids in **11** and **12** adopt the preferred conformations **A** and **B** in which 1,3-allylic strain is minimized. In the main products **11c,d**



16

Fig. 1. Structure of the dipeptide **16** according to force field calculations.

and **A**, respectively, the amide and ester groups are on opposite sides of the lactam ring and the dipole moments (AM1 calculations) are 1.0 and 1.4 Debye smaller than that of **B**. The negligible asymmetric induction of the cyclization with alanine (**9b** → **11b** + **12b**) is reflected in the dipole moments of **A** and **B**, which are comparable.[9]



A **B**

R = CH_3	5.4 D	5.5 D
R = $CH(CH_3)_2$	4.0 D	5.4 D
R = $CH_2C_6H_5$	3.8 D	4.8 D

Reaction products **11** and **12** are important peptidomimetics, which are conformationally restricted because of the δ-lactam structure.[10] Until now dipeptides of this type had been synthesized by functionalization and subsequent cyclization of the side chains of amino acids.[11] Our photochemical method opens a short, flexible route. In preliminary experiments γ-lactams such as **18** have been synthesized by photolysis of benzoylmethyl peptide **17**.[12]

[2] A degassed solution (100–200 mL toluene) was cooled to 20–25 °C, and 100–500 mg of **9**, **16**, or **18** was added. The solution was irradiated with a 150 W Hg high-pressure lamp (Heraeus TQ 150) for 1.5–2.5 h. The products were separated by chromatography. All new compounds were characterized by spectroscopy and elemental analysis.

[3] The configurations of **11d** (*p*-nitrobenzenesulfonyl instead of the Z protecting group) and the *trans* isomers of the glycine-substituted δ-lactams **11a** and **12a** (Boc instead of the Z protecting group) were determined by X-ray structure analysis. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-103. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk). The ^{13}C NMR signals of C-4 and C-5 in the δ-lactam rings in **11b–d** are $\Delta\delta = 0.3-1.3$ ppm upfield of those of **12b–d**.

[4] The regioselectivity of the dipeptide cyclization is 8:1 for **9a** and greater than 20:1 for **9b–d** (25 °C).

[5] The calculations were carried out at the PMP2/6-31G*//UHF/3-21G* level of theory: Gaussian 94, Revision B.2: M. J. Frisch, G. W. Trucks, H. B. Schlegel, P. M. W. Gill, B. G. Johnson, M. A. Robb, J. R. Cheeseman, T. Keith, G. A. Petersson, J. A. Montgomery, K. Raghavachari, M. A. Al-Laham, V. G. Zakrzewski, J. V. Ortiz, J. B. Foresman, J. Cioslowski, B. B. Stefanov, A. Nanayakkara, M. Challacombe, C. Y. Peng, P. Y. Ayala, W. Chen, M. W. Wong, J. L. Andres, E. S. Replogle, R. Gomperts, R. L. Martin, D. J. Fox, J. S. Binkley, D. J. Defrees, J. Baker, J. P. Stewart, M. Head-Gordon, C. Gonzalez, J. A. Pople, Gaussian Inc., Pittsburgh, PA, **1995**. A similar explanation was used to discuss the preferred hydrogen abstraction from glycine in intermolecular reactions with peptides: C. J. Easton, in *Advances in Detailed Reaction Mechanism, Vol. 1*, (Ed.: J. M. Coxon), Jai, Greenwich **1991**, p. 83.

[6] The calculations were performed with MacroModel 4.5 and with the Amber* force field: D. Q. McDonald, W. C. Still, *Tetrahedron Lett.* **1992**, *33*, 7743.

[7] Calculations with the force field program MOLOC [8] show that the *cis* isomer is favored by at least 1 kcal mol^{-1} over both a) a hydrogen-bonded *trans* isomer with an axial phenyl group at the δ-lactam ring and b) a *trans* isomer with an equatorial phenyl group without hydrogen bonding.

Müller, *Acta Crystallogr. Sect. A* **1987**, *43*, 426.

[9] This interpretation is based on the steric arrangement of the substituents in the product and therefore its importance should not be overestimated. For the triplet–singlet transition the radical centers of the biradical have to come close to each other. Possibly the singlet biradical cyclizes directly to give the product. Therefore the steric and polar effects of the products may already play an important part in the transition state. For further discussion see a) A. G. Griesbeck, H. Mauder, S. Stadtmüller, *Acc. Chem. Res.* **1994**, *27*, 70; b) I. V. Khudyakov, Y. A. Serebrennikov, N. J. Turro, *Chem. Rev.* **1993**, *93*, 537; c) P. J. Wagner, *Acc. Chem. Res.* **1983**, *16*, 461.

D. Aster, J. P. Snyder, J. P. Springer, J. Hirshfeld, E. W. Tristram, A. A. Patchett, E. H. Ulm, T. C. Vassil, *ibid.* **1986**, *29*, 251; c) R. M. Freidinger, D. Schwenk Perlow, D. F. Veber, *J. Org. Chem.* **1982**, *47*, 104.

[12] Compound **17** was synthesized from valine benzyl ester and benzoyl methyl bromide and coupled with a Z-protected glycine. The structures of **18a** and **18b** were assigned by NMR spectroscopy. NOE experiments proved the *cis* configuration, and the quaternary C-4 signal of the γ-lactams shows the same relative shifts as that of the δ-lactams.

Models of Oxovanadium(IV)–Protein Interactions: The First Oxovanadium(IV) Complexes with Dipeptides**

Anastasios J. Tasiopoulos, Antonis T. Vlahos, Anastasios D. Keramidas, Themistoklis A. Kabanos,* Yiannis G. Deligiannakis, Catherine P. Raptopoulou, and Aris Terzis

Vanadium is a trace element that produces significant physiological effects; for example, vanadate inhibits ion transport ATP-ases,[1] phosphotyrosine phosphatase[2] etc. Arguably, the most important physiological effect is the stimulation of glucose uptake and glucose metabolism, that is, the insulin-like properties of both vanadate[3] and oxovanadium(IV) species.[4] The efficacy and relative lack of toxicity of oxovanadium(IV) derivatives in animal models of diabetes makes them a potential oral therapy in human diabetes in general, and in those forms of the disease that are resistant to insulin in particular. The mode of action of oxovanadium(IV) species is still not understood. Cornman[5] and co-workers have suggested that a possible mechanism of $V^{IV}O^{2+}$ action is the inhibition of protein tyrosine phosphatases (PTPases) by binding thiolate sulfur to $V^{IV}O^{2+}$. In addition, Saper[6] and co-workers have recently reported an X-ray crystal structure of *Yersinia* PTPase with $V^{V}O_4^{3-}$, where there is a covalent bond between vanadium and the sulfur of the 403-cysteine residue. The elucidation of the mode and the site of $V^{IV}O^{2+}$ action could provide valuable insight into the mechanism of insulin action as well as in the design of more potent oral insulin substitutes.

In order to understand the function of VO^{2+} species in diabetes and in various biological processes in general, it is first necessary to develop its coordination chemistry[7] with biologically relevant ligands such as peptides and in particular sulfhydryl-containing peptides in light of Cornman's[5] observation and Saper's crystallographic characterization of $V^{V}O_4^{3-}$ with *Yersinia* PTPase mentioned above. To date, several complexes of oxovanadium(IV)[8–10] have been prepared and structurally characterized, but only with aromatic amides. Herein we report the synthesis and structural and physicochemical characterization of the first oxovanadium(IV)–dipeptide complex with the sulfhydryl-containing dipeptide *N*-(2-mercaptopropionyl)glycine (H_3mpg), as well as the first synthesis of VO^{2+} with the dipeptides glycylglycine (glygly) and glycylalanine (glyala).

Sequential addition of one equivalent of 1,10-phenanthroline (phen) and of an acetonitrile solution containing one equivalent of H_3mpg and five equivalents of triethylamine to a solution of $[VOCl_2(CH_3CN)_2]$ in acetonitrile yields the complex **1**. The reaction was carried out at −15 °C. At this point two features are worth noting: 1) the ease with which $V^{IV}O^{2+}$ promotes amide

$Et_3NH[VO(mpg)(phen)]$ **1**

hydrogen ionization, in marked contrast to almost all other cases with aromatic amides[8-10] where the ionization of hydrogen in the presence of $V^{IV}O^{2+}$ takes place under reflux with the use of strong bases, and 2) the deprotonation of amide nitrogen at room temperature as revealed by solution studies (water) of vanadium(v) with dipeptides.[11, 12] Figure 1 shows a perspective view[13] of the anion of **1**. The vanadium atom in the anion

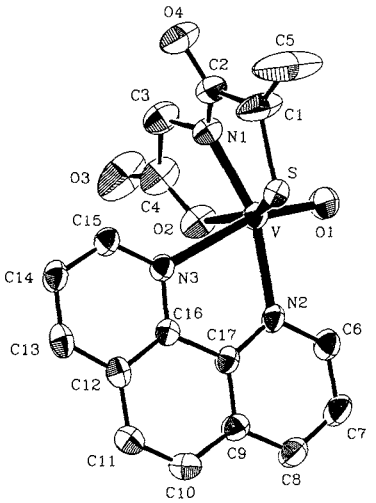

Fig. 1. Structure of the anion of **1** (ORTEP drawing with 30% probability ellipsoids) giving atomic numbering. For clarity, hydrogen atoms are omitted. Selected interatomic distances [Å] and angles [°]: V–O1 1.602(3), V–O2 2.014(4), V–N1 1.997(4), V–N2 2.173(4), V–N3 2.343(4), V–S 2.3820(14); O1-V-N1 108.9(2), O1-V-O2 100.4(2), N1-V-O2 79.9(2), O1-V-N2 90.3(2), N1-V-N2 160.2(2), O2-V-N2 92.15(14), O1-V-N3 162.0(2), N1-V-N3 88.8(2), O2-V-N3 78.73(14), N2-V-N3 71.81(12), O1-V-S 101.8(2), N1-V-S 81.74(12), O2-V-S 154.81(11), N2-V-S 99.46(10), N3-V-S 83.75(9).

of **1** has a severely distorted octahedral geometry. It is bonded to a tridentate mpg^{3-} ligand at the sulfur atom, the deprotonated N_{amide} atom N1, and one of the $O_{carboxylato}$ atoms O2, as well as an oxo group O1 and two phenanthroline nitrogens N2 and N3. The $V-N_{amide}$ bond length [1.997(4) A] is very close (almost indentical) to the reported mean $V-N_{amide}$ value[10] [1.999(12) Å] for various vanadium–aromatic amide structures and is slightly shorter (approximately 0.03 Å) than the $V-N_{amide}$ bond distance of the only other vanadium(v)–peptide[14] complex studied structurally, $Et_4N[VO(O_2)(glygly)]\cdot 1.58\,H_2O$ [$V-N_{amide}$ = 2.032(5) Å]. The V–S distance [2.3820(14) Å] is consistent with values found in other oxovanadium(IV) complexes,[10, 15] but is substantially longer (about 0.14 Å) than the V–S bond length [mean ($V-S_{thiolato}$ = 2.246(3) Å] of the recently reported first oxovanadium(v)–thiolate complex, $[VO(SCH_2CH_2)_3N]$;[16] this is unexpected[17] as the V^VO^{3+} is considered a "hard acid", the sulfur a "soft" base, and the $V^{IV}O^{2+}$ a "softer" acid than V^VO^{3+}.

Complexes **2** and **3** were prepared in a fashion similar to that used for complex **1**, but at room temperature and with methanol

$[V^{IV}O(glygly)(phen)]\cdot 2CH_3OH$ **2**

$[V^{IV}O(glyala)(phen)]\cdot CH_3OH$ **3**

as solvent. The elemental analyses[18] for complexes **2** and **3** are in accord with the formulas given above. The $A_{x,y}$ and $g_{x,y}$ values of continuous wave (cw) EPR data for the complexes **2** and **3** (Table 1) can be compared with those previously reported for various oxovanadium(IV) complexes.[19, 20] According to this correlation the $A_{x,y}$ and $g_{x,y}$ values estimated for **2** and **3** (Table 1) are intermediate between those for oxovanadium(IV)

Table 1. EPR parameters [a] for the complexes **1**–**3**.

Complex	g_z	$g_{x,y}$	A [$cm^{-1} \times 10^{-4}$] $A_{x,y}$	A_z	$A_{z,amide}$
1	1.956	1.987	52.1	151.1	35
2	1.951	1.984	54.8	158.9	36
3	1.951	1.984	54.9	159.0	36

[a] Errors: g values ±0.003; hyperfine coupling constants $\pm 0.7 \times 10^{-4}\,cm^{-1}$.

complexes with equatorial ligands of the types $V^{IV}O(N_2O_2)$ and $VO(N_4)$. This, in combination with the additivity for A_z, is conistent with the binding of $V^{IV}O^{2+}$ to three nitrogens and one oxygen. Strong support for this comes from ^{14}N Electron Spin Echo Envelope Modulation (ESEEM) experiments, which indicate that $V^{IV}O^{2+}$ binds to amine, amide, as well as one phenanthroline nitrogen atoms. From the cw EPR, ESEEM, and IR data it is concluded that the dipeptides glycylglycine and glycylalanine are bonded to $V^{IV}O^{2+}$ center through the amine nitrogen, the deprotonated amide nitrogen, and one of the carboxylato oxygens.

The redox properties of **1** in acetonitrile have been studied by cyclic voltammetric and polarographic techniques. The complex displays a reversible one-electron redox process [Eq. (a); $E_{1/2}$

$$[V^{IV}O(mpg)(phen)]^- + e^- \longrightarrow [V^{III}O(mpg)(phen)]^{2-}\ E_{1/2} = -1.42\,V \quad (a)$$

versus normal hydrogen electrode]. The electronic absorption spectrum of **1** in acetonitrile (λ[nm], $\varepsilon[M^{-1}cm^{-1}]$) consists of five bands and a shoulder: 532 (970), 356 (1550), 288 sh (9000), 269 (22900), 225 (31500), 200 (35000). The intense absorptions in the visible region of the spectrum are assigned as $S \rightarrow V^{IV}$ charge transfer transitions. Continuous wave EPR spectra for the complexes **1**, **2**, and **3** were recorded at 40 K in C_2H_5OH. The calculated values[20] for $A_{z,amide}$ (35×10^{-4}, 36×10^{-4}, and $36 \times 10^{-4}\,cm^{-1}$ for the complexes **1**, **2**, and **3**, respectively) are slightly higher than the average $A_{z,amide}$ value [$34 \times 10^{-4}\,cm^{-1}$] reported by Corman[9] and co-workers for oxovanadium(IV) center with various aromatic amides.

Experimental Procedure

All syntheses were carried out under an inert atmosphere (argon) and with dry and deoxygenated solvents distilled just prior to use.

1: To a stirred acetonitrile (10 mL) solution of $VOCl_2\cdot 2CH_3CN$ (0.300 g, 1.36 mmol) at −15 °C was added in one portion solid 1,10-phenanthroline (0.246 g, 1.36 mmol). The color immediately changed from blue to green and a green solid precipitated. The mixture was stirred for 15 min before a solution (5 mL in acetonitrile) containing H_3mpg (0.222 g, 1.36 mmol) and triethylamine (0.690 g, 6.82 mmol) was added to it. A series of color changes ensued, followed by the formation of a deep purple solution and of a purple precipitate. The solution was stirred for 6 h, and the solid was collected by filtration, washed with diethyl ether, and dried to yield 0.523 g of **1** (75%). Elemental analysis: $C_{23}H_{30}N_4O_4SV$ (509.52), calcd C 54.22, H 5.93, N 11.00, S 6.29, V 10.00; found C 54.15, H 5.90, N 10.85, S 6.15, V 10.01; IR (KBr disk) $\tilde{\nu}$(V=O) = 938 cm^{-1}.

[20] The calculated $A_{z,amide}$ values were derived from the relation $A_{z,total} = \sum n_i A_{z,i}/4$, where i denotes the different types of equatorial ligand donor groups ($i = 1-4$), n_i is the number of equatorial ligands of type i and $A_{z,i}$ is the measured coupling constant (from model studies) when all four equatorial ligand donor groups are of type i. See N. D. Chasteen in *Biological Magnetic Resonance, Vol. 3* (Eds.: L. J. Berliner, J. Reuben), Plenum, New York, **1981**, p. 53.

Spontaneous Magnetization in a Sulfur–Nitrogen Radical at 36 K

Arthur J. Banister, Neil Bricklebank, Ian Lavender, Jeremy M. Rawson,* Christopher I. Gregory, Brian K. Tanner, William Clegg, Mark R. J. Elsegood, and Fernando Palacio

There has been considerable interest in the magnetic behavior of organic free radicals,[1, 2] and particularly in the development of materials that exhibit spontaneous magnetic order or ferromagnetism. The number of radicals of this type are few and have been based exclusively on NO radicals[3–5], with magnetic ordering temperatures of a few Kelvin. We now report a new phase of the sulfur–nitrogen dithiadiazolyl radical *p*-NC·C_6F_4·CNSSN$^\bullet$ (**1**), which exhibits weak ferromagnetism at the unprecedentedly high temperature of 36 K. It is the first main-group radical to exhibit spontaneous magnetization above liquid helium temperature.

Radical **1** is a member of a large class of dithiadiazolyl radicals,[6] which are particularly suitable for study as potential "organic metals".[7] Most dithiadiazolyl radicals are diamagnetic, associating to form dimers in the solid state[6] through an out-of-plane, spin-paired interaction between sulfur atoms. This dimerization energy is small and has been estimated at about 35 kJ mol^{-1}.[8] In order to prepare dithiadiazolyl radicals with unusual magnetic properties we must first overcome this dimerization process. This has been achieved in **1** by carefully chosen substituents, in which 1) in-plane cyano–sulfur interactions compete with the out-of-plane dimerization process and 2) fluorine–fluorine repulsions between molecules assist the break-up of the dimeric structure. The synthesis of **1** has been described previously.[9] It can be prepared as either of two polymorphs, the formation of which is dependent upon sublimation conditions. We recently reported[9] the structure and magnetic properties of the α-phase (**1**α) obtained by very rapid sublimation (120 °C, 10^{-2} Torr) of crude **1**. Phase **1**α is paramagnetic at room temperature, and has an effective magnetic moment of 1.60 μ_B, slightly less than that expected for unpaired $S = \frac{1}{2}$ spins. It exhibits Curie–Weiss behavior ($\theta = -25$ K) down to low temperature, at which point long-range magnetic order sets in with a Néel temperature of 8 K.[9] The X-ray crystal structure of this phase consists of chains of monomeric radical units packed in a head-to-tail manner.[9]

The β-phase of **1** (**1**β) forms as long, plastically deformable needles by slow sublimation of **1** (100 °C, 10^{-2} Torr). The structure[10] consists of discrete monomeric dithiadiazolyl radicals. In **1**β the twist-angle between heterocyclic and aryl rings is more prominent than in **1**α: the twist angles about the C–C bond are 58° and 32° in **1**β and **1**α, respectively. The structures

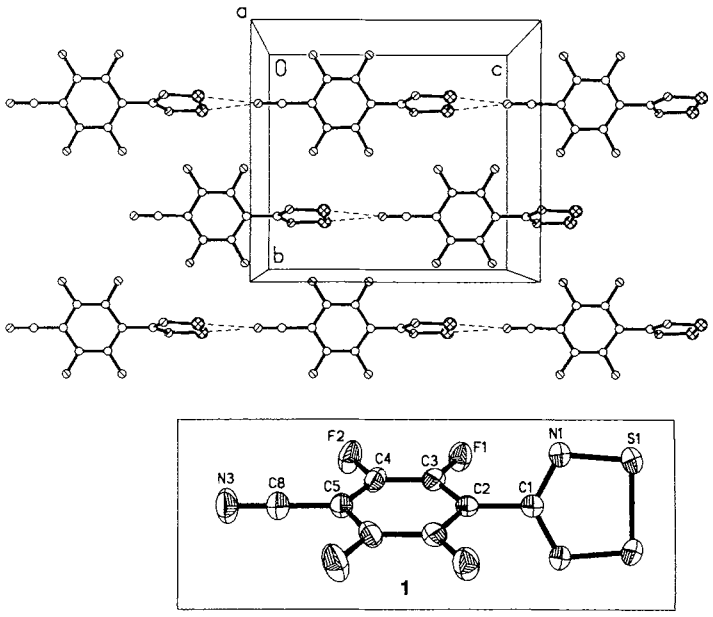

Fig. 1. Molecular packing of **1β**, illustrating the parallel alignment of radical chains. Inset: atom labeling and 50% probability ellipsoids.

of both **1α** and **1β** consist of infinite chains of monomeric radicals (Fig. 1) held together in a head-to-tail arrangement through strong CN···S interactions between neighboring radical units. The intermolecular CN···S distances in **1β** are slightly shorter and more symmetrical than those in **1α**, ($d_{N\cdots S}$: **1β** 2.986 Å, **1α** 3.068 Å and 3.105 Å). The key structural difference between the two phases is that the chains of **1β** are all aligned in the same direction, whereas chains of **1α** are arranged antiparallel to one another, and molecules in neighboring chains are related through an inversion center. This has important magnetic implications, which will be discussed later. There are no short range S···S or S···N interactions between the radical chains of **1β**, although a number of close S···F and CN···F contacts are observed.

Reports of "organic" materials exhibiting ferromagnet-like behavior have often been controversial[11] (especially with weakly ferromagnetic samples) and have been linked to contamination of the sample with small quantities of ferromagnetic impurity.[11] Our own magnetic measurements have been recorded on three different instruments[12] at different institutions, each examining separate samples of material. Crystalline samples (typically 40–150 mg) were prepared by vacuum sublimation, and reproducible sets of data were recorded on multiple samples from the same batch of material and from different batches. A total of 12 independent samples have been examined on these machines. This reliability, coupled with results from atomic absorption spectroscopy, which indicate that Fe, Co, and Ni concentrations are below the level of detection, and the absence of frequency dependence of the alternating current susceptibility vs. T curves in the range from 1 to 1000 Hz makes the likelihood of persistently small quantities of ferromagnetic impurity extremely unlikely.

At room temperature, the effective magnetic moment of 1.55 μ_B is somewhat less than the spin-only value of 1.73 μ_B expected for noninteracting spins and is comparable to that observed for the α-phase (1.60 μ_B). Extrapolation of the inverse susceptibility plot above 120 K produces a Weiss constant ($\theta = -102$ K) indicative of a strongly antiferromagnetically coupled regime and noticeably larger than that observed for the α-phase. As the temperature decreases, the susceptibility rises to a broad maximum centered at 60 K, below which it decreases, indicative of the existence of short-range antiferromagnetic interactions. This behavior can be modeled with a modified Bonner–Fischer equation[13] for a one-dimensional chain, with an intra-chain exchange term, $J = -83$ K (Fig. 2). However, interchain interactions are not negligible.

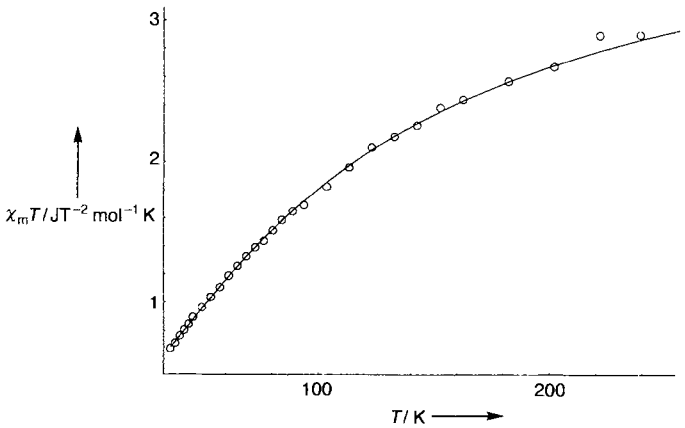

Fig. 2. Plot of $\chi_m T$ against T for **1β** in the region between 40 and 240 K. Solid line: best-fit curve according to Fischer for a classical linear chain.

The variation of magnetic susceptibility as a function of both temperature and applied magnetic field is shown in Figure 3, which highlights the discontinuity in the gradient of magnet-

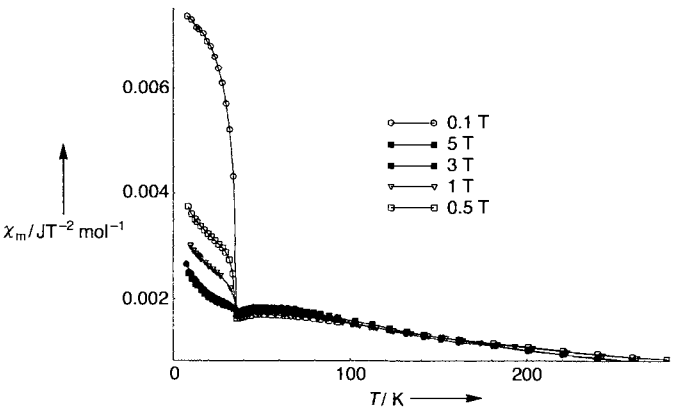

Fig. 3. Variation of molar magnetic susceptibility χ_m of **1β** as a function of temperature and applied magnetic field.

ization with temperature at 36 K. Below this temperature the susceptibility is field-dependent, indicative of the onset of long-range magnetic order. Although the measured differential susceptibility is constant, a residual field-independent magnetization is observed. This residual magnetization is strongly temperature-dependent, falling to zero at 36 K and saturating as T approaches zero (Fig. 4). At 1.8 K, low-field magnetization measurements show clear evidence of hysteresis (Fig. 5). The value of the spontaneous magnetization extrapolated to $T = 0$ K, $M_s(0)$, is $(1.5 \pm 0.1) \times 10^{-3}$ μ_B, significantly lower than that anticipated for a purely ferromagnetic material.

The phase-change from a low-dimensional antiferromagnetically coupled material to a weakly ferromagnetic state can be explained in terms of a spin-canting mechanism in which canting of the antiferromagnetically aligned spins on each sublattice

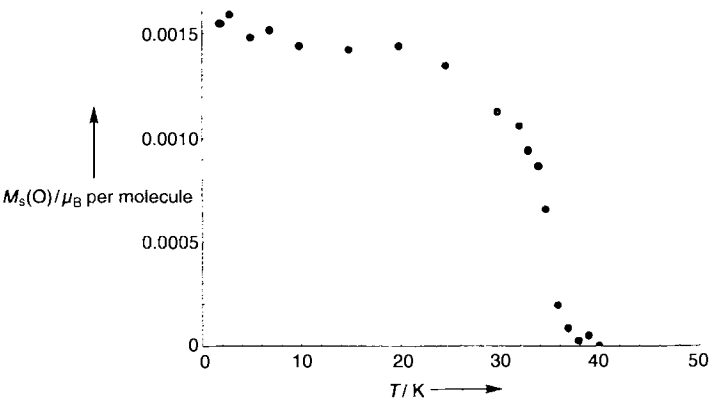

Fig. 4 Spontaneous magnetization M_s of **1β** extrapolated to zero field as a function of temperature.

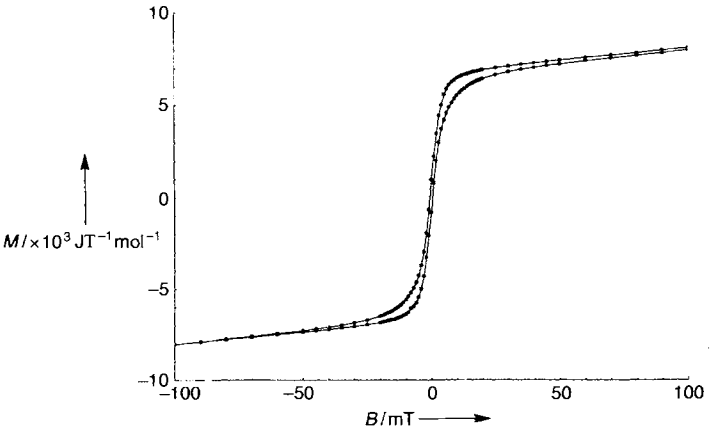

Fig. 5. Hysteresis loop exhibited by **1β** at 1.8 K.

leads to a small spontaneous magnetization, which saturates in a small field. Using the value of the spontaneous magnetization M_s we can estimate a canting angle of about $(0.085 \pm 0.005)°$. Spin-canting is known to be favored in low-dimensional systems[13] and results from antiferromagnetic alignment of spins on two sublattices that are equivalent in number but not exactly antiparallel. The sublattices are canted in the absence of a magnetic field provided that the total symmetry is unchanged, and this leads to a net magnetization. Spin-canting cannot be observed in compounds whose spins are related through an inversion center (for example **1α**, space group $P\bar{1}$) but can be achieved in **1β**. Canting may arise through a Dzyaloshinsky–Moriya interaction,[13] which minimizes the coupling energy when the two spins are perpendicular to one another. This is proportional to $\Delta g/g$, which is found to be 0.005 ± 0.001 from e.p.r. measurements. The isotropic g-tensor for S/N radicals of this type is typically about 2.01, whilst for organic radicals the g-value is normally very close to the free-electron value, and the term $\Delta g/g$ tends to zero.

We have shown that **1β** would appear to constitute the first example of an open-shell molecule that exhibits a spontaneous magnetization above liquid helium temperature and may also possibly be the first example of an "organic" radical to exhibit spin-canting. We are now investigating the nature of the exchange interactions leading to both the strong antiferromagnetic coupling above the ordering temperature and those giving rise to canting of the sublattices.

[12] Static magnetization measurements were performed on an Oxford Instruments Maglab Faraday Balance (University of Durham): A typical sample of material (50–150 mg) was cooled to 4.2 K in zero magnetic field, and data were recorded at increasing temperature in applied fields of 0.1, 0.5, 1.0, 3.0, and 5.0 T. Further measurements were made on Quantum Design SQUID magnetometers (University of Zaragoza and University of Edinburgh) between 1.8 and 300 K. Alternating current susceptibility measurements were made on a SQUID magnetometer equiped with an a.c. susceptibility attachment (Zaragoza). In another set of experiments isothermal magnetization curves were measured as a function of the magnetic field.
[13] R. L. Carlin, *Magnetochemistry*, Springer, Berlin, **1989**. Note: Although the Bonner–Fischer equation reproduced the experimental data reported here, the magnitude of zJ_{inter}/J_{intra} [of the order of 0.1] indicates that **1β** is not a good one-dimensional system. We have used two independent approaches to calculate this ratio, and a full analysis will be included in a future paper.

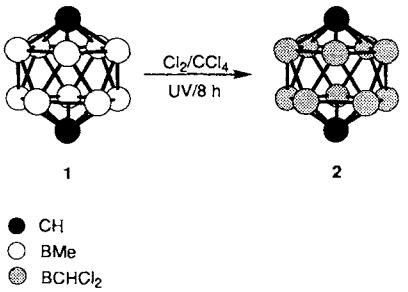
Decakis(dichloromethyl)-1,12-dicarba-*closo*-dodecaborane(12): Camouflage of an Icosahedral Carborane by Using Bulky Functional Substituents**

Wei Jiang, Carolyn B. Knobler, and M. Frederick Hawthorne*

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

The icosahedral carboranes constitute a class of structurally unique molecules with properties common to both organic and polyhedral borane chemistry. Their exceptional thermal and chemical stabilities and their ability to hold substituents in rigid three-dimensional spatial orientations has made their derivatives desirable synthetic targets for modular chemistry.[1] In contrast to the well-developed chemistry of the CH vertices of the carboranes,[2] substitution reactions that occur at BH vertices tend to be less straightforward and of limited utility due to a lack of regiospecific control. Thus, electrophilic substitution reactions at BH vertices typically lead to mixtures of products.[3] Under robust conditions, however, substitution of all available BH vertices may occur to give a single final product.[4] Thus, we have developed a synthetic procedure that leads to a class of 1,12-dicarba-*closo*-dodecaborane derivatives (*para*-carborane derivatives), which are methylated at all boron vertices and which also may have none, one, or both of the two CH vertices similarly substituted.[5] Molecules of this class are structural hybrids composed of an icosahedral carborane substructure covered by an external sheath of hydrocarbon. Consequently, the general reactivity of these molecules should resemble that of aliphatic hydrocarbons, although the steric constraints placed upon the alkyl groups present in these species would be expected to control reactivity in a manner not exhibited by simple alkanes. Functionalization of the full array of alkyl groups on the icosahedral framework will generate an outer sphere of molecular camouflage composed of reactive organic groups of great importance to the further elaboration of carborane chemistry. Depending upon the specific substituent groups introduced, such compounds should be accessible for modular syntheses and serve as precursors for other derivatives, as well. We here report an entry into this chemistry. Beginning with decamethyl-1,12-dicarba-*closo*-dodecaborane(12) (**1**), we have synthesized a derivative in which all the methyl groups at the boron centers are halogenated under radical-inducing conditions to afford decakis(dichloromethyl)-1,12-dicarba-*closo*-dodecaborane(12) (**2**), which has been structurally characterized by X-ray diffraction studies (see Fig. 1).

Chlorination of compound **1** (Scheme 1) in solution in carbon tetrachloride by reacting **1** with chlorine under UV light for eight hours at room temperature afforded **2** in 88% yield. In the ^{1}H NMR spectrum of **2**, only two peaks were observed in a 1:5 integrated ratio. The signal at $\delta = 2.95$ was assigned to the H atoms attached to the C atoms of the icosahedral framework, while the dichloromethyl groups attached to the B atoms gave rise to a resonance at $\delta = 1.55$, which may be compared to the resonances of the methyl groups at the boron atoms in **1** ($\delta = 0.05$[5]). Similarly, in the ^{13}C{^{1}H} NMR spectrum of **2**, only resonances arising from a single type of CH vertex and a single type of dichloromethyl group were observed. A single, relatively broad signal in the ^{11}B NMR spectrum with no BH coupling further confirmed the structure of **2**. Mass spectral analysis was consistent with a decamethyl *para*-carborane in which twenty hydrogen atoms had been replaced with chlorine.



Scheme 1. Chlorination of **1**.

Reaction of **1** with chlorine under these conditions is relatively rapid. Control experiments based upon EI mass spectra indicated that within thirty minutes the chlorination of **1** had reached 80% completion. Species **2** exhibited reduced solubility in typical organic solvents compared to **1**; it was only moderately soluble in carbon tetrachloride.

The radical-induced halogenation of methyl groups attached to aromatic rings is a well-known organic procedure. Chlorination of methylated aromatic compounds can be carried out in the presence of halogenation reagents such as *N*-chlorosuccinimide in a controlled way. However, this synthetic methodology has not previously been explored with B-methyl groups attached to a carborane cage, since halogenation of the BH vertices normally present is a facile competing reaction.[7] In this study of the halogenation reactions of **1**, such reactions are not a problem since all of the hydrogen atoms originally attached to boron atoms in *para*-carborane have been replaced by methyl groups. Interestingly, even in the presence of a large excess of halogenation reagent and under rather robust photochemical conditions, great selectivity is exhibited in the degree of halogenation of the methyl groups. Chlorination of **1** affords only dichlorination at each methyl carbon atom, whereas bromination under a variety of conditions has, as yet, been unsuccessful. Substitution of a chlorine atom, however, activates the methyl carbon atom towards attack by a second chlorine atom and, under normal circumstances, a third reaction of this sort will occur. Clearly, steric constraints which arise on the crowded surface of the carborane restrict this process to the formation of dichloromethyl groups.

The synthesis of a mono(chloromethyl) derivative of **1** was attempted by using a photochemical reaction which employed only 1.3 equivalents of *N*-chlorosuccinimide. Analysis of the product mixture by GC-MS revealed that both a monochlorinated and a single dichlorinated product were formed, together with unconverted starting material. This result suggests that the chloromethyl group first formed is more susceptible to radical attack than are any of the nine remaining methyl groups, since otherwise, several isomeric bis(chloromethyl) derivatives of **1** would have been observed. We speculate that the perfluoro derivative of **1** may be an accessible compound exhibiting enhanced acidity of the carborane CH vertices coupled with steric protection at these sites by surrounding CF_3 groups.

A structural study was carried out on compound **2**, and an ORTEP representation of the structure is shown in Figure 1.[8] In the solid state the dichloromethyl groups attached to the

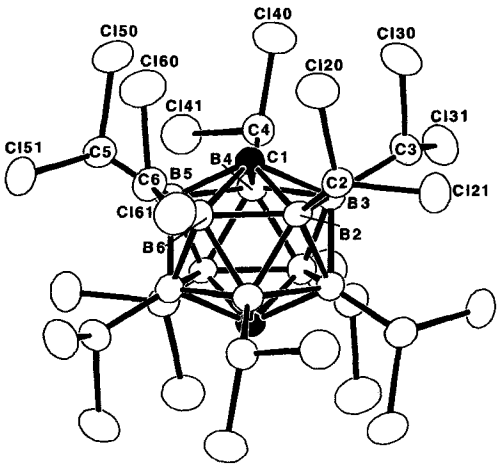

Fig. 1. The structure of **2** (ORTEP representation). Hydrogen atoms are omitted for clarity. The molecule has a crystallographically imposed center of symmetry. Selected bond lengths [Å]: C1–B2 1.735(7), C2–B2 1.613(7), B2–B3 1.824(7), C2–Cl20 1.779(5), C2–Cl21 1.797(5).

boron centers adopt a highly symmetrical arrangement with each group having an "equatorial" chlorine atom and an "axial" chlorine atom. Thus, each of the carborane CH vertices is surrounded by a ring of five axial chlorine atoms, providing very effective steric shielding; the remaining ten chlorine atoms form two coplanar belts around the icosahedron. This arrangement minimizes steric repulsions between the large chlorine atoms.

The C1–C1 distance in **2** is fairly short [3.080(7) Å] compared to most *para*-carborane derivatives,[9] but longer than the corresponding distances found in other decakis-substituted derivatives. We have posited a sterically induced "roll-over" effect on the orbitals responsible for cluster bonding in decakis-substituted *para*-carborane derivatives,[5, 9] leading to a displacement of the substituents on the boron vertices towards the relatively unhindered CH vertices, accompanied by a shortening of the C–C crosscage distance. This effect is not particularly pronounced in **2**, possibly due to the crowding around the CH vertices by the axial chlorine atoms, but there is a significant, if small, displacement of the boron substituents towards the C1–C1 axis. The average angle defined by a carbon vertex, the midpoint of the C1–C1 axis, and the carbon atom of a dichloromethyl group is 61.9(2)°, whereas the value of the average carbon vertex-midpoint-boron vertex angle is 63.7(2)° in **2**.

The successful radical chlorination of **1** leading to **2** represents an important elaboration of this unique icosahedral cluster. The new species reported here should undergo transformations to form an unprecedented class of carborane-supported multifunctionalized compounds. The juxtaposition of organic-type reactivity onto cluster rigidity and the sheer density of functional groups is expected to lead to novel properties including an increase in molecular dimensions. Exploratory reactivity studies with these molecules is currently under active investigation.

Experimental Procedure

Standard Schlenk line techniques were employed for all manipulations. Carbon tetrachloride was freshly distilled from calcium hydride under nitrogen prior to use and degassed by three freeze-pump-thaw cycles. All reactions were carried out under a N_2 atmosphere. Photolysis reactions were carried out using a Hanovia high-pressure mercury vapor lamp.

2: Compound **1** (0.10 g, 0.35 mmol) was dissolved in carbon tetrachloride (25 mL) in a tube-type quartz photoreactor equipped with a gas bubbler connected to a chlorine gas cylinder. The solution was photolyzed at room temperature for 8 h. Solvent was removed in vacuo, and the crude product was extracted with hexane. After filtration, the solid was recrystallized from a solvent mixture of carbon tetrachloride and hexane to afford **2** as a white solid (0.30 g, 88%). 290 °C (decomp) (sealed capillary); ^{1}H NMR ($CDCl_3$): δ = 2.95 (s, 2H, CH), 1.55 (br s, 10H, BCH-Cl_2); $^{13}C\{^1H\}$ NMR ($CDCl_3$ in CCl_4): δ = 73.2 (CH), d = 4.6 (vbr, $BCHCl_2$); ^{11}B NMR (Et_2O): δ = −7.2 (10B, $BCHCl_2$); MS (EI) for $C_{12}B_{10}H_{12}Cl_{20}$ (*m/z*): calcd. 973.3, found 973.2 (M^+).

[8] Crystallographic data for **2**·2(C_7H_8): $C_{26}B_{10}H_{28}Cl_{20}$, M_r = 1157.8, monoclinic, space group $P2_1/c$, a = 10.589(7), b = 10.626(7), c = 19.662(13) Å, β = 92.68(2)°, V = 2210 Å^3, Z = 2, ρ_{calcd} = 1.74 g cm^{-3}, T = 25 °C, μ = 12.7 cm^{-1}. Data were collected on a Huber diffractometer constructed by Prof. C. E. Strouse of this department, by using $Mo_{K\alpha}$ radiation (λ = 0.7107 Å) to a maximum 2θ = 60°, giving 6444 unique reflections, of which 3098 reflections with $I > 3\sigma(I)$ were retained for structure analysis. The data were corrected for Lorentz and polarization effects and for secondary extinction and absorption. The Cl atoms were located by using direct methods (SHELX86). The crystal contains two molecules of toluene per carborane molecule. All non-hydrogen atoms were refined anisotropically. All solvent hydrogen atoms were placed in calculated positions, C–H = 1.0 Å. The benzene ring of the toluene molecule has been treated as a rigid group, angle = 120°, C–C = 1.395 Å. All other H atoms were located and were included but parameters were not refined. The final discrepancy index was R = 0.049, R_w = 0.062. The largest peak on a final difference electron density map was 0.57 e Å^{-3}. Large Sulfur–Nitrogen Heterocycles: Preparation of the Sulfur Imides S_nNH (n = 8, 9, 11) and Structures of S_8NH and S_9NH**

Ralf Steudel,* Klaus Bergemann, Jürgen Buschmann, and Peter Luger

A considerable number of sulfur homocycles S_n has been prepared as pure materials (n = 6–13, 15, 18, 20) and most of these have been characterized by X-ray crystal structure analyses.[2]

[**] Sulfur Compounds, Part 196. This work has been supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. Part 195: see ref. [1].

In addition, the structures of several compounds with S_nC frameworks are known (with $n = 2, 5-8, 11$).[3] In contrast, of the conceivable compounds with an S_nN framework, only that with $n = 7$ is known to date. Heptasulfur imide S_7NH like S_8 forms a crown-shaped ring,[4] of which quite a number of organic derivatives S_7NR have been prepared.[5] The fact that neither S_5NH, S_6NH, nor $S_{11}NH$ have been prepared or identified in reaction mixtures was probably attributable to the lack of a suitable synthetic route and to the assumption that S_nN rings with more or less than eight members could not exist in the presence of basic nitrogen atoms, since ammonia and amines catalyze the conversion of S_6, S_7, and S_{12} to S_8. Here we report on the preparation of the novel sulfur imides S_8NH, S_9NH, and $S_{11}NH$ utilizing the recently discovered titanocene complex $[Cp_2Ti(\mu\text{-}S_2)(\mu\text{-}S_5)NH]$ **1** ($Cp = \eta^5\text{-}C_5H_5$), which is accessible from $[Cp_2Ti(CO)_2]$ and S_7NH,[6] and which may gain a similar importance in sulfur–nitrogen chemistry as $[Cp_2TiS_5]$ has for the chemistry of elemental sulfur. The two chlorosulfanes SCl_2 and S_2Cl_2 react with **1** at 20 °C in dichloromethane to give octa- and nonasulfur imide [Eq. (a)].

$$[Cp_2TiS_7NH] + S_nCl_2 \longrightarrow S_{7+n}NH + [Cp_2TiCl_2] \quad (a)$$
$$n = 1, 2$$

For the synthesis of undecasulfur imide $S_{11}NH$, complex **1** was treated with $S_6(CN)_2$, which reacts as $S_4(SCN)_2$ [Eq. (b)].[7]

$$[Cp_2TiS_7NH] + S_4(SCN)_2 \longrightarrow S_{11}NH + [Cp_2Ti(NCS)_2] \quad (b)$$

In the by-product $[Cp_2Ti(NCS)_2]$, the pseudo-halide ligands coordinate the metal through the nitrogen atom, as was shown by comparison of the color of the compound and the IR spectrum with those of an authentic sample.[8] The three new sulfur imides form pale yellow crystalline solids that are well soluble in carbon disulfide but less so in *n*-hexane. At −22 °C in the dark they can be stored for weeks without decomposition; at 25 °C in diffuse daylight, S_8NH decomposes after about one week, S_9NH after about four days, but $S_{11}NH$ only after several weeks. Decomposition products are S_7NH and S_8. Rapid decomposition occurs at the melting points of each of the compounds (S_8NH: 85 °C, S_9NH: 84–90 °C, $S_{11}NH$: 117 °C). The three imides have been characterized by correct elemental analyses, HPLC analyses, as well as IR, Raman, and mass spectra. The vibrational spectra are highly characteristic and quite different from those of S_7NH,[9] allowing the identification of these S_nNH species (Table 1). The range 400–525 cm^{-1} is particularly informative since it contains the SS stretching and the SNH out-of-plane bending (γ) vibration. The different number of S–S bonds and the geometry-dependent coupling between γ(SNH) and the symmetric SS stretching modes results in marked differences in the spectra of the cyclic sulfur imides. The EI mass spectra of all species exhibit a signal for the molecular ion, either with high (S_8NH) or low relative intensity (S_9NH, $S_{11}NH$). In addition, only fragments of types $S_n^{\cdot+}$, $S_nNH^{\cdot+}$, and S_nN^+ were observed.

On chromatography by reversed-phase HPLC[10] the three new compounds behave like members of a homologous series: the logarithms of the capacity factors k' ($k' = t_R - t_o/t_o$) linearly depend on the number n of sulfur atoms in the molecule.[11] This relationship allows the retention time of the still unknown molecule $S_{10}NH$ to be calculated by interpolation. In fact, the reaction solutions obtained according to Equations (a) and (b) showed a peak at the retention time of $S_{10}NH$. This observation indicates that the imides S_nNH form a similar homologous series as the homocycles S_n. Only one HPLC signal was observed for the pure substances S_nNH.

Octasulfur imide S_8NH was obtained as needlelike, pale yellow single crystals from a solution in $CS_2/CHCl_3$. An X-ray structural analysis[12] carried out at −85 °C revealed asymmetric molecules (C_1 symmetry), the conformation of which is similar to that of homocyclic nonasulfur (Fig. 1). The motif of S_8NH (the signs of torsional angles within the ring) is $++--++-+-$, which is identical to the motif of S_9.[7] The values of the torsional angles range from 70.0 to 114.6°. Since complex **1** shows the same conformation of the TiS_7N ring it can be concluded that the structures of these nine-membered

rings are not dominated by intermolecular interactions. The S–S and S–N internuclear distances in S_8NH lie in the expected range, the position of the hydrogen atom has been calculated.

Nonasulfur imide S_9NH crystallized from a $CS_2/CHCl_3$ mixture as transparent, pale yellow prismatic single crystals, which were subjected to an X-ray structural analysis at $-150\,^{\circ}C$.[12] The structure consists of ten-membered heterocycles, between which there are only van der Waals intermolecular interactions and no hydrogen bonds. The molecules occupy sites of C_S symmetry. Surprisingly, the conformation of the ten-membered ring is different from that of S_{10} (symmetry D_2)[15] and characterized by the following motif: $+-+-+-+--+$. In this respect S_9NH resembles the S_8 molecule (motif $+-+-+-+-$); it can be derived from the latter by insertion of the SN(H) unit.

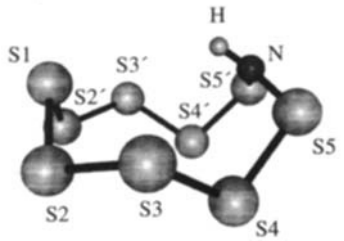

Fig. 2. Structure of S_9NH in the crystal. Selected bond lengths [pm], valence and torsion angles [°]: S1–S2 207.4(3), S2–S3 204.2(3), S3–S4 206.6(3), S4–S5 205.2(3), S5–N 167.1(5), N–H 85(13); S2′-S1-S2 103.2(2), S1-S2-S3 109.8(1), S2-S3-S4 107.3(1), S3-S4-S5 103.2(1), S4-S5-N 109.3(3), S5-N-S5′ 124.0(6), S5-N-H 116(2), S2′-S1-S2-S3 120.9(1), S1-S2-S3-S4 −86.1(1), S2-S3-S4-S5 119.1(1), S3-S4-S5-N −81.1(3), S4-S5-N-S5′ −85.0(6).

As a result the torsion angles τ at the bonds S1–S2, S1′–S2′, S3–S4, and S3′–S4′ increase from 99° in S_8 to $120\pm1°$ in S_9NH, while the remaining torsion angles decrease to values of 81–86°. Nevertheless, the S–S and S–N bond lengths are normal and comparable to those of S_7NH.[4] As in other sulfur imides[4, 5] and their derivatives[5, 6] the coordination of the nitrogen atom in S_9NH is almost planar: the sum of the angles S-N-S, S-N-H, and S′-N-H is 356.8°. Consequently the nitrogen atom is not very basic.[16]

The similarity of the spectra shows that $S_{11}NH$ must also be a cyclic molecule (Table 1). As is the case with S_{12}, $S_{11}NH$ is thermally more stable than S_8NH and S_9NH. This allows the conclusion that it should be possible to prepare even more sulfur-rich imides in analogy to S_{13}, S_{15}, S_{18}, and S_{20}. The chemistry of cyclic sulfur–nitrogen compounds has so far been dominated by small rings. The syntheses according to Equations (a) and (b)—with a variety of reagents—open the access to a new area of SN chemistry.

Experimental Procedure

S_8NH: SCl_2 (0.44 mmol, 2.8 mL of a 0.157 M solution in CH_2Cl_2) was added dropwise to a solution of **1** (198 mg, 0.47 mmol) in dichloromethane (200 mL) and stirred at 20 °C. After 30 min the solvent was removed in a vacuum, the residue was dissolved in a little carbon disulfide, and the solution stored for 2 h at −22 °C. The precipitate of $[Cp_2TiCl_2]$ was filtered off. The filtrate was stirred with a little silica gel for a short time to remove residual $[Cp_2TiCl_2]$ and after filtration the volume was reduced by 50%. *n*-Hexane was added until a permanent turbidity appeared and the mixture was cooled to −22 °C to afford S_8NH, which after recrystallization from a $CS_2/CHCl_3$ (1:1) mixture was collected in 33% yield (41 mg) based on SCl_2.

S_9NH: In analogy to the preparation of S_8NH by using **1** (350 mg, 0.84 mmol), S_2Cl_2 (0.06 mL, 0.75 mmol), and CH_2Cl_2 (370 mL). Yield: 123 mg (54% based on S_2Cl_2).

$S_{11}NH$: In analogy to the preparation of S_8NH by using **1** (372 mg, 0.9 mmol), $S_6(CN)_2$ (197 mg, 0.8 mmol), and CH_2Cl_2 (390 mL). Yield: 90.5 mg (31% based on $S_6(CN)_2$). For further details see ref. [17].

No Longer a Laboratory Curiosity

Metallomesogens. Synthesis, Properties, and Applications. Edited by *J. L. Serrano*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1996. 498 pp., hardcover DM 298.00.—ISBN 3-527-29296-9

Over a hundred years have passed since the discovery of the first liquid crystals by F. Reinitzer in 1888, yet the chemistry of mesogens has lost none of its attraction and fascination. In particular it was the close collaboration between synthetic chemists and materials scientists that led to a renaissance in liquid crystals, with the result that much of modern everyday life is scarcely imaginable without these materials. Metallomesogens are a relatively new offshoot of conventional liquid crystals. The chemistry of metal-containing liquid crystals, at first just a laboratory curiosity attracting little attention, has developed almost explosively within the last ten years. There now exists an enormous wealth of research results in this field, and its collection together in book form was long overdue. Although there have been several important review articles in the last few years, in many cases these have only treated selected aspects. It can already be said at the outset that the book edited by J. L. Serrano fills this gap admirably. His name is a guarantee of the soundness of the work, since he and the other authors have for many years been actively engaged in the synthesis of paramagnetic and ferroelectric metallomesogens as one of their main interests.

The book contains four sections giving clear and thorough treatments of the following aspects: the various characteristic structural features of metallomesogens (Part A, Chapters 2-5), synthetic aspects (Part B, Chapters 6 and 7), physical methods of characterization (Part C, Chapters 8 and 9), and physical properties and applications (Part D, Chapters 10 and 11). It all adds up to an excellent collection of articles covering all modern aspects of this field.

In Chapter 1 the editor, J. L. Serrano, gives a short introduction to thermotropic and lyotropic mesophases, with special reference to metallomesogens, thus easing the way for the novice approaching the subject for the first time. The brief account of the history describes the contribution of F. Reinitzer, but should also have mentioned O. Lehmann and G. Friedel. Chapter 2 (T. Sierra), on lyotropic metallomesogens, is the first comprehensive overview of this topic, which has hitherto been rather neglected in the literature. Chapters 3 and 4 (J. L. Serrano, T. Sierra, J. Barberá) are concerned with the well-known classes of the calamitic and discotic low molecular mass metallomesogens, which are treated very thoroughly and comprehensively, with over 300 literature references. These chapters include clear tables which list details for each example discussed, including the general formula types and the melting behavior of the complexes for different metal ions and chain lengths. Each subsection is followed by a short summary recapitulating the characteristic features of that class of substances. Chapter 5 (L. Oriol) contains a detailed account of the new and fascinating topic of metallomesogenic polymers, emphasizing the great potential of such macromolecules for materials science.

In Chapters 6 and 7 (Part B) M. Marcos and L. Oriol deal with the synthetic aspects of the chemistry of metallomesogens. Their separate treatment of this topic is thorough and competent, but it would perhaps have been better to combine this part with Chapters 3-5, thereby avoiding some repetition of textual content and literature citations. Also, the inclusion of a few carefully chosen laboratory procedures for synthesizing some typical ligands and metallomesogens of different classes would have better justified the title "Design and Synthesis ".

Part C is devoted to physical methods for determining the structures of mesogenic phases, with treatments of X-ray diffraction in Chapter 8 (J. Barberá) and EPR spectroscopy in Chapter 9 (P. J. Alonso). However, there is not a word here about the "classical" methods such as optical polarization microscopy and thermal analysis (DSC). Although these are of a routine nature, they should at least have been mentioned, especially bearing in mind the needs of readers entering this field for the first time.

The last two chapters (Chs. 10 and 11, Part D) are concerned with the materials science properties of metallomesogens and with applications. The lucid survey by M. B. Ros covers a wide variety of properties and conveys a good impression of the many-faceted nature of this class of substances. On the other hand, P. J. Alonso adopts a rather too specialized approach in Chapter 11, concentrating only on the magnetic properties.

As stated at the beginning of this review, J. L. Serrano and his team of authors have produced a very important contribution to the literature on liquid crystals. The book provides an up-to-date treatment of the subject, very clearly presented (apart from a few minor cosmetic shortcomings, such as inconsistencies in the style of the figures, and some structural formulas that are upside-down), and with comprehensive coverage of the primary literature. However, the potential readership is relatively small, not least because of the high price. The book can be recommended unreservedly for chemists already active in this field and for those seeking a good introduction into it.

Fundamentals of Chemical Kinetics. By *S. R. Logan*. Longman, Harlow, 1996. 264 pp., paperback £ 19.99.—ISBN 0-582-25185-0

S. R. Logan has set out to provide students of chemistry and related disciplines with a textbook which, at an affordable

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

price, covers all the essential aspects of the study of chemical reactions as they progress towards an equilibrium state. The author's aim is is to teach the fundamental concepts rather than to treat the subject in minute detail. This has resulted in a book that will be useful not only for physical chemists but also for organic and inorganic chemists, whose work nowadays includes an increasing amount of kinetic studies. Logan's book covers reactions in the gas phase, in solutions, and at solid catalyst surfaces. Solid state kinetics has rightly been excluded, as it is outside the scope of a book of this kind. Each of the twelve chapters, except for the last one, ends with a set of exercise problems that are intended to give deeper insights into what has been learned. The data for the examples are mostly taken from the chemical literature, thereby linking the discussion to real situations.

In Chapter 1 the author explains the empirical framework of chemical kinetics. After introducing the concept of the reaction rate he formulates a general rate equation and uses this to explain the idea of the order of a reaction. The rate equations for different reaction orders are integrated, and methods for determining the reaction order are described. Lastly, the temperature dependence of rate constants is discussed on the basis of the Arrhenius equation. Regrettably, this chapter contains several annoying errors. Thus, a minus sign is missing from Equation (1.11), the definition of the reaction rate. The treatment of signs is again rather haphazard in the integration of the rate equation for a first-order reaction [Equations (1.14) and (1.15)]. In the integration of the rate equation for a second-order reaction (first-order in each of the two educts) the author merely refers the student to "simple algebra" instead of explicitly setting out the breakdown into partial fractions. Here he fails to completely live up to his assurance on the back cover of the book, which states that the mathematics involved will be carefully explained for students with limited capabilities in that direction. The omission of units in the calculation of the activation energy from the gradient of an Arrhenius plot (p. 19) is also questionable from a teaching standpoint.

Chapter 2 is concerned with practical aspects of planning and carrying out kinetic experiments. After discussing certain minimal requirements (such as temperature control, rapid mixing of the reactants, and a clearly defined reaction path) the author describes different methods for monitoring the progress of reactions in solutions: the "clock method", polarimetry, spectrophotometry, electrical conductivity measurements, and dilatometry. For gas phase reactions the conventional method of measuring the total pressure is described, and also the possibility of using mass spectrometry is discussed. A description of modern stopped-flow techniques is followed by warnings about the risks of errors being introduced when determining rate constants, arising for example from incorrect weighting in a linear regression analysis.

Chapter 3 deals with a number of simple types of reaction mechanisms, such as sequential reactions, the formation of intermediate complexes, parallel reactions, and opposing reactions, and discusses the kinetic behavior resulting from these. The important distinction between the molecularity and the order of a reaction is clearly explained. The author also introduces the stationarity principle that is often used in analyzing the subsequent stages. Chapter 4 discusses theoretical treatments of bimolecular reactions (collision theory, transition state theory, the theory of diffusion-controlled reactions in solutions).

Chapter 5 is concerned with the interpretation of measurements on bimolecular reactions in solutions, including the Marcus theory for electron transfer reactions. After treating unimolecular gas phase reactions in Chapter 6, the author devotes Chapter 7 to chain reactions. Chapters 9 and 10 then deal with the important subject of catalysis, including such interesting aspects as oscillatory reactions and enzyme kinetics. The last three chapters are devoted respectively to studies of fast reactions using modern relaxation techniques, the reaction kinetics of photochemically excited molecules, and studies of elementary reactions in crossed molecular beams.

The book is completed by two short appendices, brief answers to the exercise problems, a keyword index, and an index of reactions mentioned in the text. Despite the minor shortcomings in Chapter 1 as already mentioned, this is a valuable book in which the author has succeeded in conveying an impression of a very broad range of aspects of chemical kinetics in the gas and solution phases and on solid catalysts. It provides the reader with a comprehensive overview encompassing both the history of chemical kinetics and the latest developments in the field.

In view of the reasonable price, *Fundamentals of Chemical Kinetics* can be recommended unreservedly for readers seeking a broad introductory insight into the subject.

Dirk Wilmer
Institut für Physikalische Chemie
der Universität Münster (Germany)

Stereochemistry of Radical Reactions. By *D. P. Curran, N. A. Porter and B. Giese*. VCH Verlagsgesellschaft, Weinheim, 1995. 280 pp., hardcover DM 148.00.—ISBN 3-527-29372-8

Until a decade ago, a researcher contemplating how to construct a carbon-carbon bond stereoselectively would not have considered radical reactions as a method of choice. This is partly because radical reactions with high stereoselectivity were an anomaly rather than the norm. In the past ten years, however, one can scarcely open a new issue of a journal without seeing some work on stereoselective radical reactions. It is timely that three leading experts in organic free radical chemistry, Professors Curran, Porter, and Giese, have now written an outstanding monograph on stereoselective radical reactions.

The monograph is divided into six chapters. In Chapter 1 the reader is introduced to the basic concepts required for successful execution of a radical reaction and to the general principles of stereoselectivity in ionic as well as radical reactions. A brief discussion of the different methods for generating radicals is followed by a liberal citation of key reviews and leading articles at the end of the chapter. The next four chapters discuss different aspects of stereoselective radical reactions. The reactions are classified according to substrate or chiral auxiliary control of stereoselectivity. Chapter 2, a major portion of the monograph, focuses on stereocontrol in radical cyclizations. The reactions in this chapter are further classified on the basis of ring size. Although this is not intended to be an exhaustive treatment, the important factors responsible for stereoselectivity in cyclizations are described in a very authoritative and concise manner. A short section on stereoselectivity of cyclizations under group transfer conditions is also included. The third chapter deals with aspects of substrate controlled diastereoselectivity in cyclic systems. The focus of this chapter is again on control of stereochemistry in radical reactions of five- and six-membered rings, systems which are generally more selective. Chapter 4 discusses issues of stereocontrol in radical reactions of acyclic systems. The models used for explaining stereoselectivity in acyclic systems undergoing ionic reactions are extended to radical processes and are nicely illustrated. Chapter 5 takes the reader through chiral auxiliary mediated diastereoselective reactions. This portion of the monograph, reflecting the strengths of the three authors, is well written and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3521-2542 $ 15.00+.25/0

gives a detailed account of the present state of knowledge of diastereoselective radical reactions. The monograph ends with a short chapter on stereoselectivity occurring during radical combinations, radical rearrangements, and formation of alkenes from radical intermediates. The information in this monograph gives guidelines which should ensure that a scientist embarking on a stereoselective radical reaction has enough control over its design and will be able to predict its outcome with reasonable confidence.

Overall, this is a very well written, easy to read, and timely work on the stereochemistry of radical reactions. It is well referenced and the citations are current up to the beginning of 1995. The index at the end is more than adequate. This is a "must buy" book for libraries and practitioners of organic free radical chemistry, or for scientists who wish to venture into the fascinating field of stereoselective organic free radical reactions. The monograph will be an excellent "recommended text" for a graduate course on stereochemistry or free radical chemistry.

Free Radicals in Organic Chemistry. By *J. Fossy, D. Lefort* and *J. Sorba*. Wiley, New York, 1995. 307 pp., paperback $ 39.80.—ISBN 0-471-95496-9

Development of new synthetic organic methodology using free radical intermediates continues to advance at a rapid rate. Although there are excellent monographs and review articles on organic free radical chemistry, there are no good textbooks. With such an active and important branch of organic chemistry, if one is required to teach an upper level undergraduate or beginning graduate level class on organic free radical chemistry, one is at a loss to find an appropriate textbook. The book by Fossy, Lefort, and Sorba fills this void to a certain extent. They have written a good book on organic free radical chemistry.

The book is divided into four parts. Part 1 contains eight chapters. This part of the book introduces the reader to the fundamental aspects of free radical chemistry. A brief chapter on the detection and characterization of free radicals by electron paramagnetic resonance (EPR) and chemically induced dynamic nuclear polarization (CIDNP) starts the text. The next six chapters discuss the issues of radical structure, stability, reactivity, mechanisms, and kinetics. Carbon as well as heteroatom radicals are covered as part of the discussion. Although each chapter is quite short, enough details including tables are included. Aspects of radical reactions are the main thrust of the second part of the book. Chapter 9 describes different methods for generating radicals. The important low-temperature radical initiation method using triethylborane-oxygen is absent from this discussion. Different aspects of radical-radical and radical-molecule reactions are detailed in the next three chapters. Radical substitution, addition, and fragmentation reactions are analyzed, including aspects of their regio- and stereochemical outcome. Radical cyclizations and rearrangements are discussed in some detail in Chapter 13. Aromatic homolytic substitutions and reactivity of radical cations and anions are discussed in Chapters 14 and 15 respectively. A short chapter on free radicals in biochemistry is included as Chapter 16. This section of the text ends with a discussion of different methods used to determine whether or not a particular reaction proceeds through a radical intermediate. Part 3 of the book treats synthetic aspects of organic free radical chemistry. These include: functionalization of non-activated carbon-hydrogen bonds leading to halogenation and hydroxylation, functional group interconversion, addition to multiple bonds, cyclization, aromatic substitution, and coupling reactions. This section ends with a brief discussion on the industrial application of free radical methods. Part 4 of the book provides references and a set of tables containing important thermochemical and kinetic data for a variety of reactions.

This book is an ambitious project. The authors attempt to cover all aspects of organic free radical chemistry, but sometimes these are treated only in a cursory manner. The tables at the end are very useful and the index is adequate. The book could have been strengthened by a better and more up-to-date reference section. Overall, this is a valuable addition to any library and to the bookshelves of practitioners of free radical chemistry. With supplementary information from the teacher, the book could serve as a text for upper level undergraduate or beginning graduate level courses on organic free radical chemistry.

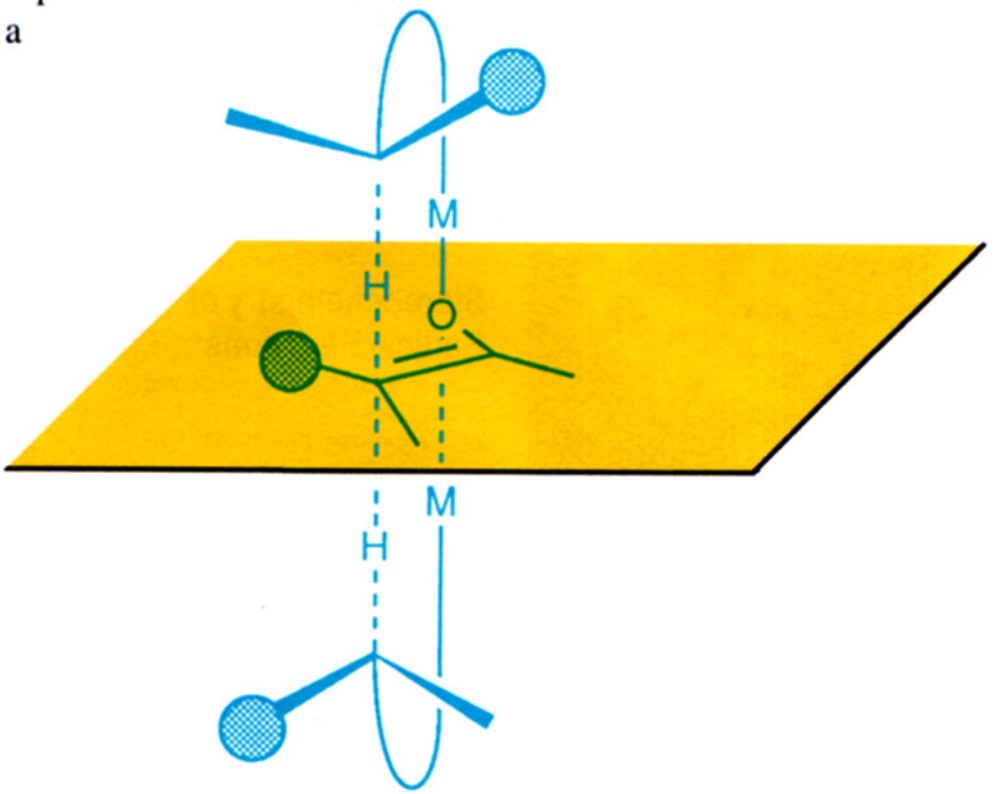
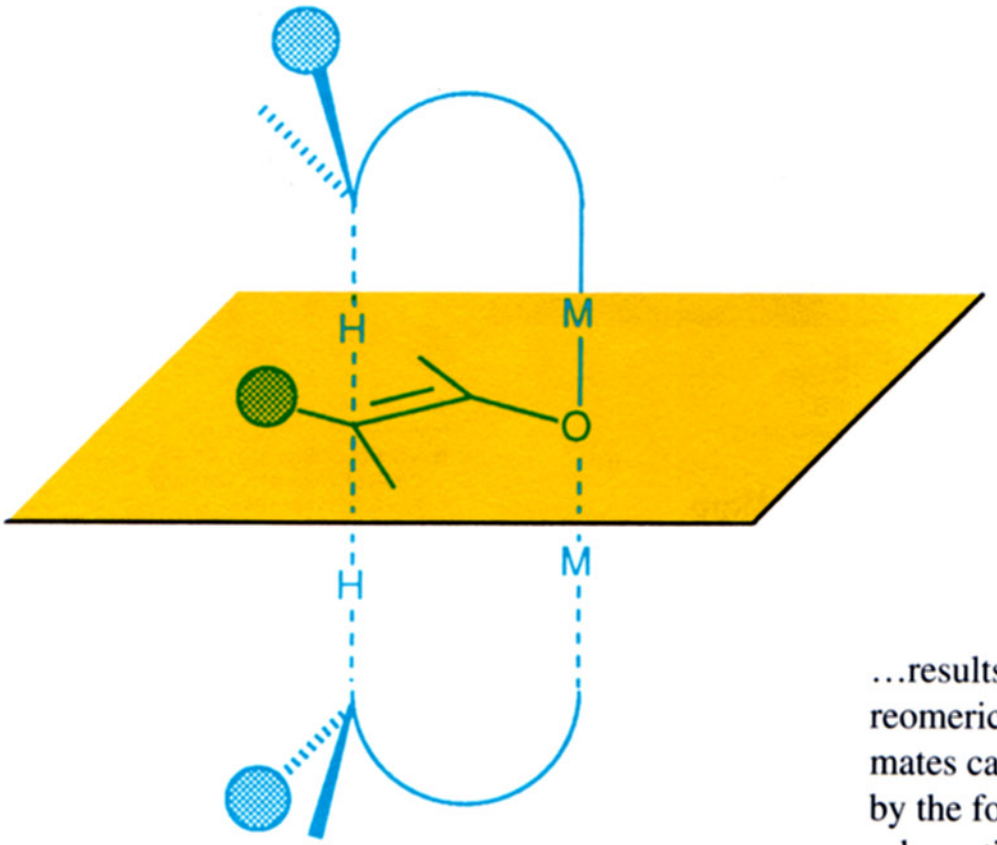
The enantioselective protonation of prochiral *Z*- and *E*-enolates (top right and bottom left, respectively) by protonation with a chiral proton donor…





…results in a total of four diastereomeric transition states. Racemates can thus be "deracemized" by the formation of enolates. This schematic representation indicates that *Z*- and *E*-enolates react with different enantiofacial selectivities.

Enantioselective Protonation of Enolates and Enols

Charles Fehr*

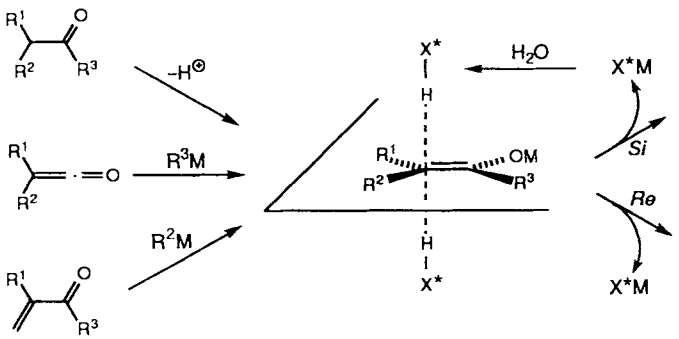
In memory of Wolfgang Oppolzer

Enantioselective protonation, until recently a largely overlooked reaction, has, in the last five years, developed into a field of intense research activity. The progress achieved parallels or complements that obtained in the understanding of enolate structures and reactivities. The conceptual simplicity and attractiveness of enantioselective protonation results from the fact that after reaction, the chiral proton donor is regenerated in its original protonated form by an extractive workup. Enantioselective protonation has been applied to the synthesis of amino acids, antiinflammatory agents (2-arylpropanoic acids), and fragrance compounds such as (*S*)-α-damascone, for which its industrial feasibility has been demonstrated.

Keywords: asymmetric syntheses · enols · lithium compounds · protonations

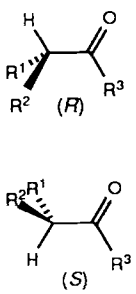
1. Introduction

Conceptually, enantioselective protonation is extremely simple. Because a prochiral enolate has two enantiotopic faces, the transfer of a proton from a chiral, nonracemic proton source to the enolate will be kinetically favored either from the top or bottom face, thus affording the carbonyl compound enriched with either the (*R*) or (*S*) enantiomer (Scheme 1).[1] The importance of enolates as intermediates in synthesis, the recent advances achieved in the regio- and stereoselective generation of enolates with the desired counterion, and the increased knowledge of their structure and reactivity[2] make their protonation a very attractive method for obtaining enantiomerically pure carbonyl compounds. Indeed, the enolate, obtained either by deprotonation of the parent carbonyl compound or directly from a synthetic operation such as nucleophilic addition to a ketene[3] or an enone,[4] is "quenched" with the chiral proton donor to afford the enantiomerically enriched carbonyl compound. On addition of water, the chiral reagent is reprotonated and recovered by simple extraction!



Scheme 1. Enolate generation and enantioselective protonation.

Enantioselective protonation can also be performed on enols. In this case (M = H; Scheme 1) the chiral reagent (X*H or $X^{*\ominus}$) is not consumed. Therefore, in principle, these tautomerizations require only catalytic amounts of the chiral reagent. Still another possible variant is the protonation of a complex formed between the enolate and the chiral ligand with an achiral proton source.[5] These three reaction types are closely interrelated, and because of possible reversible proton exchange reactions between the various reaction partners, it is often difficult to unambiguously differentiate between them.



2. What Has Refrained Chemists from Exploring Enantioselective Protonations?

In spite of the potential synthetic power of enantioselective protonation, this subject has not attracted great interest until recently.[6] This is probably due to the following reasons:

- Proton exchange reactions between electronegative atoms are considered to be among the most rapid, often diffusion-controlled reactions,[7] and thus it is difficult to discriminate efficiently between two diastereomeric transition states. There-

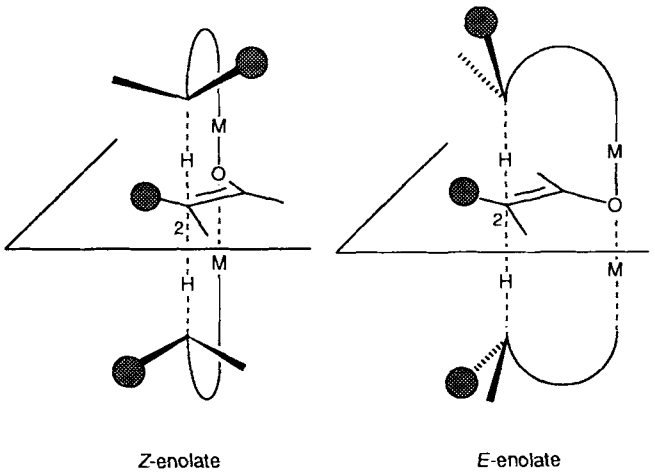
e-mail: charles.fehr@firmenich.ch

fore, the chiral reagent should be only weakly acidic. In addition, O-protonation of enolates leads reversibly to enols, which may be transformed into ketones without enantiofacial discrimination, or may act as an undesired proton source for C-protonation. The risk can be minimized by using an excess of a chiral proton source and by applying reaction conditions that allow complete C-protonation (for example appropriate temperature range).

- Enantioselective protonations are kinetically controlled reactions. Under thermodynamic control racemic products are obtained. To prevent concomitant or subsequent racemization in the polar protic medium the choice of a chiral proton donor of appropriate acidity is essential and short reaction times enhance the chances of success. Evidently, this does not apply to bulky systems, where racemization is difficult. Quenching the reaction mixture with Me_3SiCl prior to hydrolysis is often recommended for following the progress of the reaction (see Sections 3 and 4).
- *E*- and *Z*-enolates exhibit different enantiofacial selectivities, because the two diastereomeric transition states for the protonation of the *E*-enolate are different from those for the *Z*-enolate. This is schematically represented with a chelate model (Scheme 2), in which both the enolate O and C(2) atoms are involved in the transition state. Accordingly, the four possible transition state structures are diastereomeric, as evidenced by the relative positioning of the substitutents. It is thus important to minimize the amount of that enolate isomer which leads to lower, possibly reversed asymmetric induction.
- The preferred trajectory for the C-protonation of enolates is a vertical approach of the "proton" to the plane defined by the enolate π-system, with a preferential colinear arrangement between donor atom, proton, and acceptor atom (Scheme 1). More precise information concerning transition state structures is, however, still lacking. As will be discussed in Section 3, solvation, aggregation, and complexation phenomena also often dramatically influence the outcome of the reaction. Efficient chiral proton donors or chiral ligands generally have electron-rich groups capable of undergoing chelation (see Section 3.2).
- The first synthetically useful example of enolate protonation that afforded a maximum enantiomeric excess of 70 % was reported in 1978 by L. Duhamel and J.-C. Plaquevent.[8] Prior to this study only scattered publications had appeared, describing for the most part only very weak inductions.[9] This early period was reviewed in detail by Duhamel et al. in 1984.[6a]



Scheme 2. Two diastereomeric enolates: four diastereomeric transition states. The gray circles represent the largest substituents.

In recent years, intense research activity has concentrated on the general scope of enantioselective protonation. Due to the vast structural diversity of chiral reagents investigated, it seems judicious to subdivide the following section, after a presentation of Duhamel's work, into substrate structural classes.

3. Enantioselective Protonation of Enolates

3.1. The Pioneering Work of the Duhamel Group

The first in-depth study on the "deracemization" of amino acid derivatives by enantioselective protonation of the corresponding anions was carried out by L. Duhamel and J.-C. Plaquevent,[8] who proposed the commercially available (*R*,*R*)-di-*O*,*O*′-pivaloyltartaric acid ((−)-**2a**) to be the chiral reagent of choice. Thus, deprotonation of racemic methyl *N*-benzylidenephenylglycinate ((±)-**1a**) with lithium diisopropylamide (LDA) and protonation of the resulting enolate with excess (−)-**2a** gives (*S*)-**1a** with 50 % *ee* (Scheme 3; Table 1, entry 1).

The size of the acyl group of the chiral acid is very critical, as replacement of the *tert*-butyl groups by methyl or triethylmethyl groups almost completely destroys the enantiofacial selectivity of the chiral reagent (Table 1, entries 2 and 3). A wide range of

Charles Fehr, born in Zürich, Switzerland, in 1946, studied chemistry at the ETH in Zürich. He completed his doctoral thesis in 1974 under the direction of Dr. Theodor Petrzilka for work conducted in the group of Prof. Albert Eschenmoser. From 1974 to 1977 he conducted postdoctoral research at the University of Geneva with Prof. Wolfgang Oppolzer and at the Johns Hopkins University, Baltimore, with Prof. Gary H. Posner. In 1978 he joined the Corporate Research Division of Firmenich SA and in 1990 he received the Ruzicka Prize.

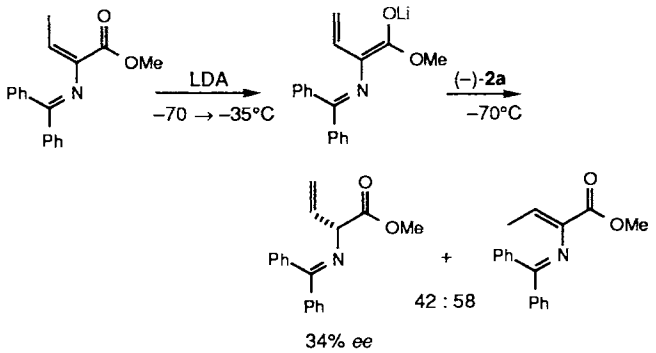
10	(±)-**1a**	[b]	−70	(±)-**2a**	(*S*)-**1a**	39	
11	(±)-**1a**	[b]	−70	*meso*-**2a**	(*S*)-**1a**	24	

[a] LTMP = Lithium 2,2,6,6-tetramethylpiperidide. [b] (*R*)-LiN(Et)CH(Me)Ph.

aldimino esters was investigated and shown to afford selectivities of 24–70% *ee*.[8, 10, 11] Aldimino groups possessing electron-donating groups have a beneficial effect, whilst lowering the temperature increases both the yield and the enantioselectivity (entries 4 and 5).

The French group has also demonstrated the crucial role that the secondary amine, which is liberated after metalation, plays in the proton transfer. Whereas the combination LDA/(−)-**2a** affords (*S*)-**1** with 50% *ee* (entry 1), a much weaker induction results when the deprotonation is performed with $LiNEt_2$ or with lithium 2,2,6,6-tetramethylpiperidide (LTMP) (entries 6 and 7). It is therefore not surprising that the combination of (−)-**2a** with a chiral amine leads to a substantially improved selectivity of 70% *ee* (entry 8). In line with this example of double stereodifferentiation, the mismatched pair (entry 9) produces almost racemic product, and protonation with either racemic (±)-**2a** (entry 10) or achiral *meso*-**2a** (entry 11) also gives significant induction.[10, 12] The same results are obtained by deprotonation of the ester with lithium bis(trimethylsilyl)-amide (LHMDS) and subsequent addition of the appropriate amine.[13] Apparently, the disilazane does not form a strong complex with the enolate and therefore does not actively participate in the protonation.[14, 15] It is not yet established whether the importance of amine ligands rests exclusively on the formation of an enolate–amine complex[16] or whether an ammonium tartrate formed in situ acts as a proton transfer agent.

The deracemization of a variety of α-amino acid derivatives with (−)-**2a** as the chiral proton donor predictably afforded the (*S*)-esters as the major enantiomers (34–70% *ee*).[11] A model based on minimal steric interactions between (−)-**2a** and the enolate–amine complex was proposed.[10] However, the deconjugation–protonation sequence shown in Scheme 4 led to the



Scheme 4. Formation of a vinylglycine ester by deconjugation and enantioselective protonation.

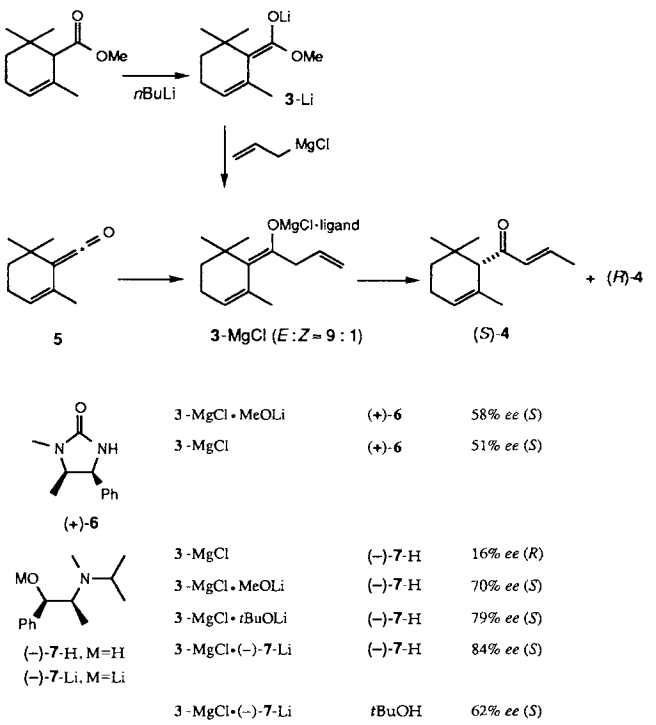
(*R*)-vinylglycine ester (34% *ee*).[11, 17] This reversal of the sense of induction can be rationalized by the altered configuration of the ester enolate.

Finally, (*R*,*R*)-di-*O*,*O*'-pivaloyltartaric acid ((−)-**2a**) was also successfully used for the preparation of (*S*)-benzoin with 80% *ee* (see Section 5).[18]

3.2. Protonation of Open-Chain Ketone Enolates

In our laboratory, enantioselective protonation of open-chain enolates is under development and has been applied to the synthesis of fragrance compounds of high enantiomeric purity[19] (for example **3**-MgCl → (*S*)-α-damascone ((*S*)-**4**), Scheme 5).[20, 21] In contrast to the amino- and hydroxyl-substituted enolates discussed above, ketone enolate **3**-MgCl has no internal chelation sites. Thus, both its formation and protonation were anticipated to be more difficult to achieve in a stereocontrolled manner.

In the search for an efficient chiral protonating agent we were guided by the following criteria.[6b, 20] Ideally, the chiral reagent should be only weakly acidic to allow better discrimination between transition states. It should also contain electron-rich groups capable of coordinating or chelating, which may enhance conformational rigidity in the transition state. Optimally, the transferred proton should be located near the stereogenic center (within the "chiral environment"). Finally, to be synthetically useful, the protonating agent should be readily accessible in both enantiomeric forms and be easily recuperable. These criteria are satisfied with the ephedrine derivatives (+)-**6** and (−)-**6**, and (+)-**7**-H and (−)-**7**-H (Scheme 5). In imidazolidinone **6** an NH bond is confined in a rigid cyclic system, and **7**-H (and the corresponding alkoxide) can attain conformational rigidity through chelation. It should be added that (+)-**6** and (−)-**6** are commercially available (Merck), and that both enantiomers of **7**-H are readily accessible by treatment of enantiomerically pure ephedrine with acetone under conditions of catalytic hydrogenation.[22]

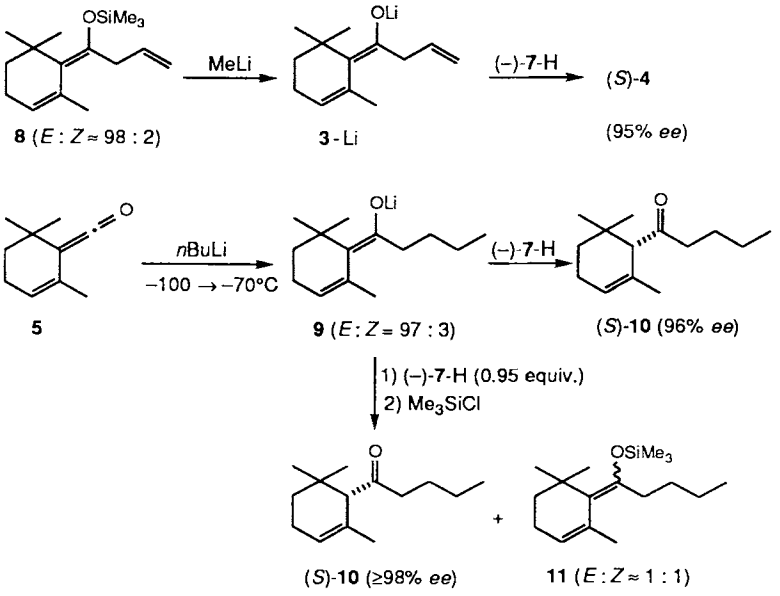


Scheme 5. Generation of a ketone enolate by C–C bond formation and enantioselective protonation of a Mg-enolate with or without a Li-alkoxide ligand. Proton sources: (+)-**6**, (−)-7-H, and *t*BuOH.

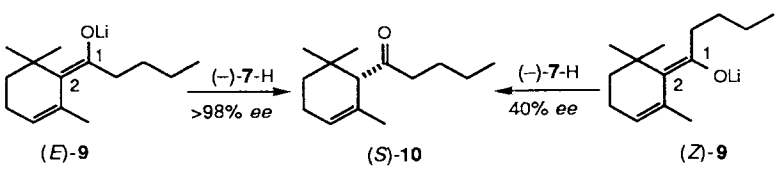
For the synthesis of (*S*)-α-damascone ((*S*)-**4**),[20, 21] the required enolate cannot be generated by deprotonation of the parent ketone because of preferential deprotonation in the side chain. However, the enolate **3**-MgCl is directly produced as a 9:1 mixture of *E*- and *Z*-isomers by C–C bond formation through a Grignard reaction with either the ester enolate[23, 24] or the ketene **5** (Scheme 5).[25] It should be emphasized that this reaction of the ester enolate also produces one equivalent of lithium alkoxide, which can profoundly alter the subsequent protonation step. Addition to ketenes generally takes place from the least hindered side, affording with good selectivity the enolate in which the oxygen atom is oriented towards the larger group.[3] When the required ketenes are stable and readily accessible, they are the best precursors to alkoxide-free enolates, which can be complexed subsequently.

The protonations performed on enolates **3**-MgCl and **3**-MgCl·MeOLi revealed that modification of the ligand sphere of the enolate only slightly influenced proton delivery from urea (+)-**6**, affording consistent enantiofacial discriminations ranging between 50 and 60% *ee*. A transition state model in which the enolate complexes the carbonyl group of (+)-**6** was proposed to rationalize the observed absolute configuration.[6b] In sharp contrast, protonation with (−)-*N*-isopropylephedrine ((−)-7-H) proved to be highly sensitive to the exact nature of the enolate: whereas alkoxide-free enolate afforded (*R*)-α-damascone as the major enantiomer (16% *ee*), the LiOMe-complexed Mg-enolate (prepared from either the methyl ester or the ketene) gave (*S*)-**4** with 70% *ee*.[26] LiO*t*Bu proved to be a superior ligand (79% *ee*), and the best results were obtained with the chiral Li-alkoxide (−)-**7**-Li (84% *ee*).[27] If the formation of a chiral complex between Mg-enolate and Li-alkoxide is a prerequisite for high enantioselectivity,[28] then protonation of a chiral complex with an achiral proton source should also lead to asymmetric induction. Indeed, protonation of the same chiral enolate complex with *t*BuOH affords (*S*)-**4** with 62% *ee*. In view of the complexity of the described reaction (see Section 8) and the lack of structural information about the complexes involved we consider it premature to propose a transition state model.

During further investigations it was found that protonation of the ligand-free, *E*-enriched enolate **3**-Li ($E:Z \gg 98:2$)[29] with (−)-7-H afforded (*S*)-**4** with excellent enantioselectivity (95% *ee*; Scheme 6).[30] Likewise, protonation of *E*-rich enolate **9** ($E:Z = 97:3$), obtained from the reaction of *n*BuLi with ketene **5**, produced ketone (*S*)-**10** with 96% *ee*. For the first time, a marked difference in the the protonation rates of *E*- and *Z*-enolates was noticed and exploited to further improve the enantioselectivity. Thus, when enolate **9** ($E:Z = 97:3$) was treated with 0.95 equivalents of (−)-7-H and the unreacted enolate was quenched as an enol silyl ether ($E:Z \approx 1:1$), ketone (*S*)-**10** was generated with an enantiomeric ratio of >99:1.[31] We have recently succeeded in generating the *Z*-enolate (*Z*)-**9**, which displays the same enantiofacial preference on protonation with (−)-7-H but with a dramatically decreased enantiofacial discrimination of 40% *ee* (Scheme 7).[32] This result convincingly illustrates the statement made in Section 2 (Scheme 2): For transition state considerations, the *global* enolate structure



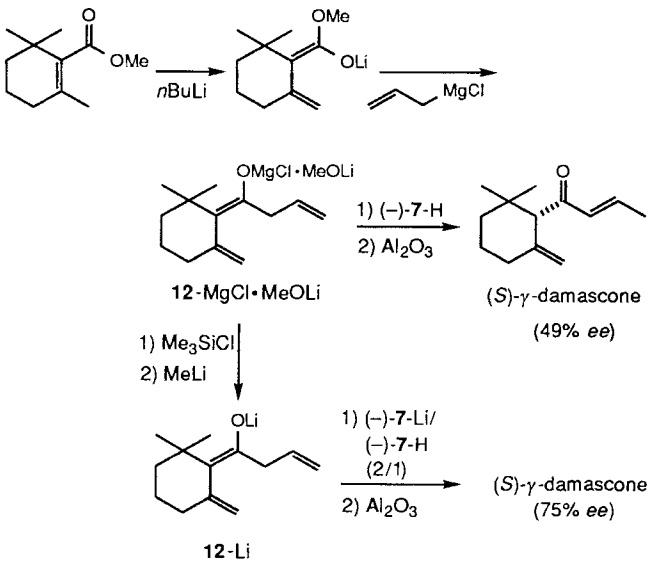
Scheme 6. Enantioselective protonation of Li-enolates.



Scheme 7. Dependence of enantiofacial discrimination on enolate configuration.

has to be taken into account, and thus the relative positioning of all four substituents of the enolate double bond.[33]

Enantioselective protonation was also used as the key step in the synthesis of (*S*)-γ-damascone (Scheme 8). The synthetic

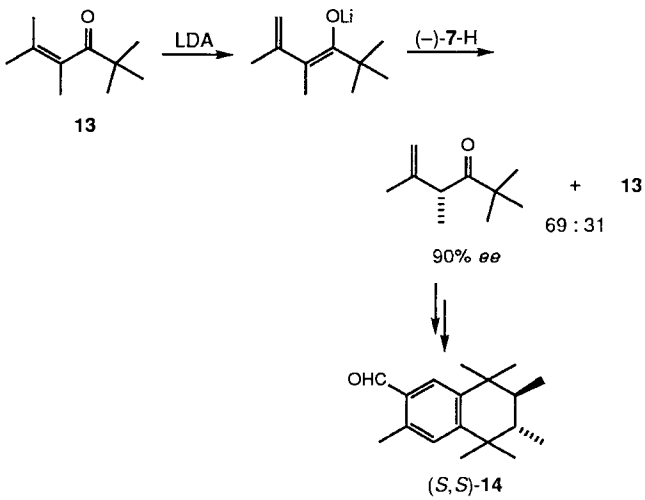


Scheme 8. Synthesis of (*S*)-γ-damascone by enantioselective protonation.

route for racemic γ-damascone proceeds via the prochiral *E*-enolate **12**-MgCl·MeOLi.[34] Its protonation with (−)-**7**-H, followed by alumina-catalyzed isomerization of one double bond, produces (*S*)-γ-damascone with a 3:1 ratio of enantiomers. Interestingly, protonation of the Li-enolate **12**-Li by addition to (−)-**7**-H proceeds with low enantioselectivity in the early stages of the reaction (roughly 35% *ee* after addition of 50%) and with increased selectivity towards the end of addition (final value 49% *ee*). Thus, the production of chiral Li-alkoxide during the process increases the selectivity of the proton transfer. An optimum *ee* value of 75% is obtained by addition of the Li-enolate to a 2:1 mixture of Li-alkoxide (−)-**7**-Li and amino alcohol (−)-**7**-H.[35] The complexity of this reaction is further demonstrated by the nonlinear relationship between enantiomeric purity of chiral reagent and reaction product (100% *ee* (reagent) → 75% *ee* (product); 50% *ee* (reagent) → 50% *ee* (product)).

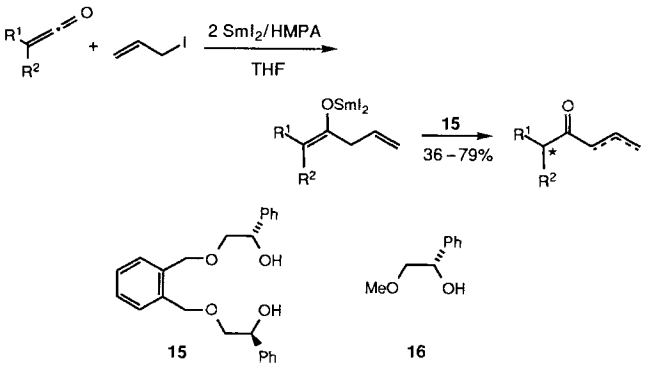
Enantioselective protonation using (−)-**7**-H or its enantiomer is not restricted to damascone-like enolates. In a recent enantioselective synthesis of the more relevant enantiomer of the important tetralin musk odorant (±)-**14**[36] the required chiral building block was prepared in 90% *ee* by chelation-controlled deprotonation of enone **13** and enantioselective protonation of the *Z*-enolate (Scheme 9).[37]

The SmI_2-mediated allylation of ketenes with allyl iodide and hexamethylphorphoric triamide (HMPA) in THF,[38] believed to proceed via an allylsamarium species, has been demonstrated by Takeuchi and co-workers to afford diastereoselectively Sm-enolates, which can be then protonated enantioselectively.[39] The most efficient chiral proton donor proved to be the C_2-symmetric diol **15**; methoxy alcohol **16** gave slightly inferior results (Table 2). Both reagents are prepared from (*S*)-mandelic acid.



Scheme 9. Synthesis of a musk odorant by enantioselective protonation.

Table 2. Enantioselective protonation of Sm-enolates.



Entry	R^1	R^2	*de* [%]	*ee* [%]

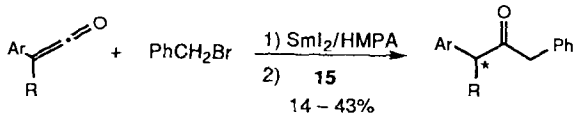
9			>98 (*Z*)	48 (*R*)

[a] With **16** as proton source. [b] The assignment reported in ref. [39b] ((*E*) and (*S*)) is probably incorrect (according to IUPAC priority rules).

The enolate configurations reflect, with one exception (entry 8), preferential nucleophilic attack of the allylsamarium species from the least hindered side. The striking similarity between enolate *de* values and ketone *ee* values led the authors to speculate that with pure *Z*-enolates selectivities approaching 100% *ee* would result, and analogously, the corresponding pure *E*-enolates would undergo protonation with high, but opposite enantiofacial selectivity. If this were the case, the chiral recognition would be solely accomplished by the $OSmI_2$ and allyl substituents, regardless of R^1 and R^2.[33] Until the authors confirm their hypothesis by separate protonation of *E*- and *Z*-isomeric enolates, an alternative explanation seems more likely. High selectivity in the enolate-forming step could be due to the

strong steric (and electronic) control exercised by the structurally different R^1 and R^2 groups, and these substituents would also allow better enantiofacial discrimination in the protonation step.[40] The same methodology was also applied to benzylation/protonation, affording benzyl ketones in lower yield but with satisfactory enantioselectivity (Scheme 10).[39a]



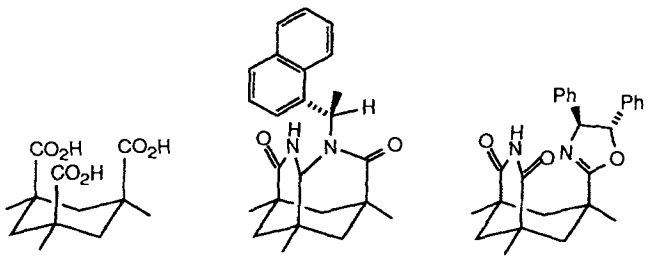
Ar, R: Ph, Me	88% *ee* (*R*)
Ar, R: Ph, Et	90% *ee* (*R*)
Ar, R: *p*-Cl-Ph, *i*Pr	61% *ee* (*S*)

Scheme 10. Benzyl ketones prepared by enantioselective protonation of Sm-enolates.

Takeuchi's tetradentate reagent is very promising, as it proved efficient with structurally diverse enolates. However, this ketone synthesis appears to be limited to allylic and benzylic systems, the reaction requires two equivalents of SmI_2, and its success critically depends on the correct relative proportions of the chiral reagent, SmI_2, and HMPA. Finally, the same group reported the generation of (*R*)-benzoin (91% *ee*) by protonation of the corresponding Sm-enediolate with quinidine.[41] Presumably, these protonations are governed by complexation of the tetradentate diol **15** with the highly oxophilic and coordinatively unsaturated Sm-enolates.

3.3. Protonation of Cyclic Ketone Enolates

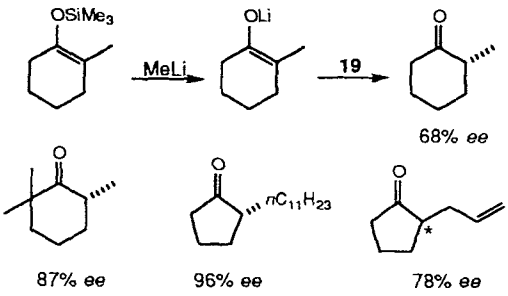
Based on the criteria that had led to the design of urea **6** and amino alcohol **7** as chiral proton donors,[20] Rebek et al. prepared the chiral lactam **18**, starting from Kemp's triacid (**17**) (Section 3.4).[42] Similarily, Yamamoto et al. have elaborated the chiral imide-2-oxazoline system **19** to serve as a proton



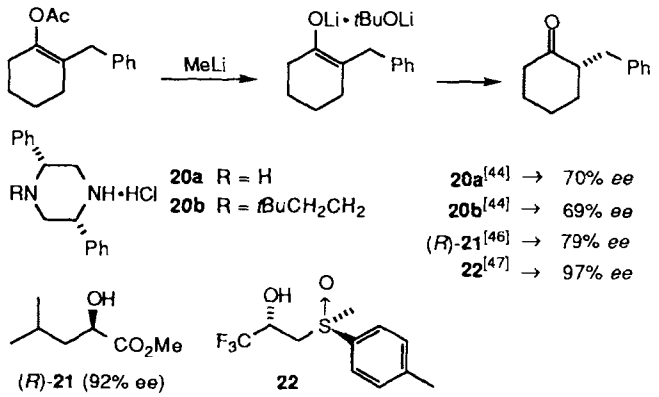
17 **18** **19**

source.[43] Imide **19** and its enantiomer can be prepared from **17** and (1*R*,2*S*)-2-amino-1,2-diphenylethanol and its enantiomer, respectively, in four efficient steps. Imide **19** has been used to protonate structurally simple cyclic enolates (Scheme 11) with high enantioselectivity.

The low-temperature protonation ($\leqq -78\,^\circ C$) of a structurally related cyclic enolate, generated (together with LiO*t*Bu!) from the reaction of the corresponding enol acetate with MeLi, has been studied by three Japanese groups (Scheme 12).



Scheme 11. Cycloalkanones prepared by enantioselective protonation with imide **19**.

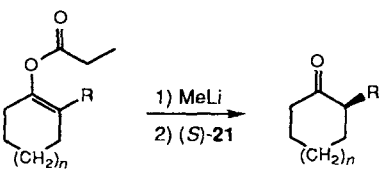


Scheme 12. (*S*)-2-Benzylcyclohexanone prepared by enantioselective protonation with **20a**, **20b**, (*R*)-**21**, and **22** as proton donors.

Fuji et al.[44] used various salts of chiral piperazine derivatives as proton donors. A maximum selectivity of 70% *ee* was obtained for the reaction of (*S*)-2-benzylcyclohexanone with **20a** in Et_2O/CH_2Cl_2 at $-90\,^\circ C$. Replacement of one amine proton by an alkyl group (as in **20b**) still led to significant inductions (32–69% *ee*), but dialkylated piperazines were totally ineffective. The enantiofacial differentiation showed a strong dependence on the nature of the ammonium salt, the solvent, and the temperature. For unspecified reasons, protonations could be effected with only 0.6 equivalents of the ammonium salt.[45]

Matsumoto and Ohta[46] found that quite high enantioselectivities were achieved for the same substrate when the enolate was protonated at $-100\,^\circ C$ with an excess of an α-hydroxy ester, ideally (*R*)-**21**. The enantiomeric hydroxy ester (*S*)-**21** of higher enantiomeric purity (96% *ee*) was used in related systems (Scheme 13).

Most recently, Kosugi et al.[47] reported that 2-sulfinyl alcohol **22** (Scheme 12) is a powerful chiral protonating agent. The



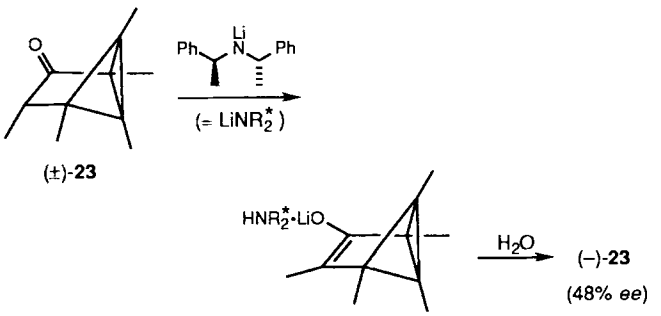
n = 0,	R = CH_2Ph	34% *ee*
n = 1,	R = CH_2Ph	82% *ee*
n = 1,	R = Me	57% *ee*
n = 1,	R = Allyl	72% *ee*

Scheme 13. Cycloalkanones prepared by enantioselective protonation with (*S*)-**21** as the proton donor.

excellent enantiofacial discrimination is most likely due to the ability of the hydroxy sulfoxide to coordinate to the lithium enolate. Presumably, electronic effects also influence the enantiofacial selection.

3.4. Protonation of Enolate/Chiral Amine Complexes

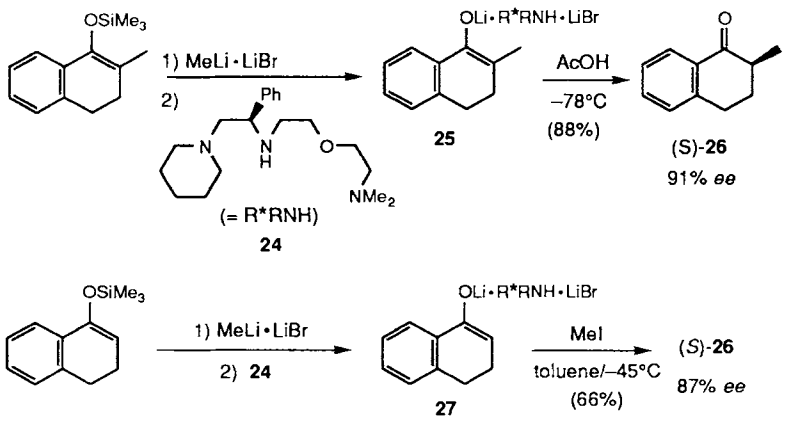
The pioneering work on the protonation of an enolate/chiral amine complex by Duhamel et al.[10, 12, 13] using an achiral proton donor (→ 24% *ee*) was discussed in Section 3.1. Inspired by these results, Hogeveen and Zwart[48] deprotonated the racemic ketone (±)-**23** (Scheme 14) with four equivalents



Scheme 14. Protonation (with H_2O) of a complex composed of a lithium enolate and a chiral amine.

of lithium (*S*,*S*)-bis(1-phenylethyl)amide between −90 and −75 °C and quenched the enolate/chiral amine complex with water. Ketone (−)-**23** of unknown absolute configuration was obtained with 48% *ee*. Unfortunately, it was not verified whether the deprotonation had been complete (for example by silylation), and therefore the observed induction could also be the result of enantioselective deprotonation by kinetic resolution.[49]

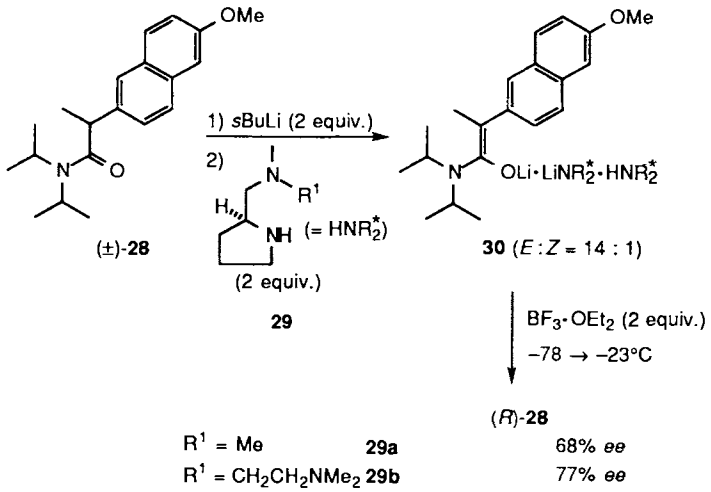
Yasukata and Koga[50] reported on the very efficient protonation of a complex formed between an achiral lithium enolate, a chiral secondary amine, and LiBr with AcOH (Scheme 15). Tetralone (*S*)-**26** was thus obtained with 91% *ee*. Interestingly, enantioselective methylation of the analogous *nor*-methyl complex, using excess MeI under almost identical conditions, also furnished (*S*)-**26** with 87% *ee*.[51] Thus, protonation occurs from the *Re* face and alkylation from the *Si* face of the lithium enolate. Perhaps the amine shields one enolate face, and alkylation occurs from the opposite side,[52] whereas the protonation takes place within the framework of the complex. Such an explanation would be compatible with Vedejs's discovery that an enantioselective "internal proton return" from a complexed chiral amine to the enolate can be achieved by addition of a Lewis acid.[53]



Scheme 15. Comparison of enantioselective protonation and enantioselective alkylation of an enolate/chiral amine complex.

3.5. Protonation of Amide, Ester, and Thioester Enolates

The enantioselective protonation of amide enolates has been investigated by the Vedejs group.[53, 54] Deprotonation of the racemic naproxen amide (±)-**28** with two equivalents of *s*BuLi afforded a yellow enolate, which was shown by silylation to consist of a 14:1 mixture of *E*- and *Z*-isomers. Treatment of this solution with two equivalents of triamine **29b** generated the wine-red complex **30** (a 1:1:1 complex of enolate, amine, and lithium amide; Scheme 16). Protonation of this complex with

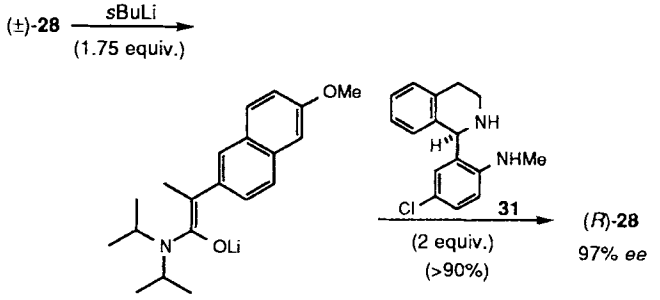


Scheme 16. Enantioselective protonation of a complex composed of an amide enolate and a chiral amine by BF_3-induced internal proton return.

protic acids gave (*R*)-**28** with at best 6% *ee* (CF_3CO_2H). However, in the presence of $BF_3 \cdot OEt_2$, the NH acidity of the amine ligand is increased, and the proton is transferred within "a specific, highly chirotopic environment" to produce amide (*R*)-**28** with 77% *ee* (internal proton return).[53] Treatment of the *ligand-free* enolate with a 1:1 mixture of **29b** and $BF_3 \cdot OEt_2$ leads to only weak induction (25% *ee*), thus further demonstrating the importance of proper complexation. Nevertheless, the exact nature of the actual proton donor remains to be determined. Moderate success was achieved in applications to other 2-arylpropionamides (50–60% *ee*).

More recently, Vedejs et al.[54] have achieved very high enantioselectivities by external protonation of lithium enolates of β,γ-unsaturated amides with commercially available *N*-methylaniline **31**. Using the same amide (±)-**28** as before, and an excess of *s*BuLi (1.75 equiv) to ensure complete

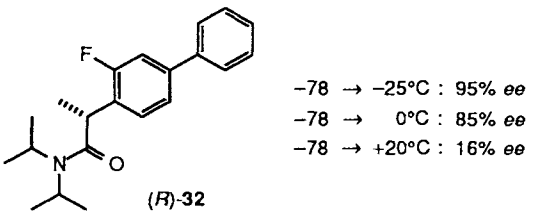
deprotonation, the resulting enolate was protonated by addition of diamine **31** (2 equiv), which delivered its proton while the reaction mixture warmed from −78 to 0 °C, to yield (*R*)-**28** (Scheme 17). Although there is no prior complexation step, a



Scheme 17. External, enantioselective protonation of an amide enolate.

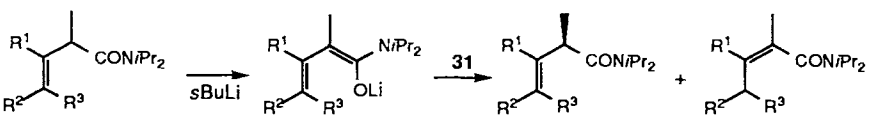
precomplexation of the enolate with lithiated aniline may be envisaged, due to the excess *s*BuLi.

Since the pK_a of the aniline is lower than that of amide **28** by only two to three orders of magnitude, the effective acidities of proton donor and acceptor are well-matched. However, if the pK_a values are too similar, incomplete proton transfer would result and the risk of product racemization would be augmented. Reversible deprotonation was indeed observed with the slightly more acidic amide **32**. Whereas the usual protonation of



the corresponding enolate between −78 and −25 °C and subsequent addition of aqueous NH_4Cl solution afforded (*R*)-**32** with 95% *ee*, quenching of the reaction mixture at 0 or 20 °C led to diminished *ee* values of 85 and 16%, respectively.

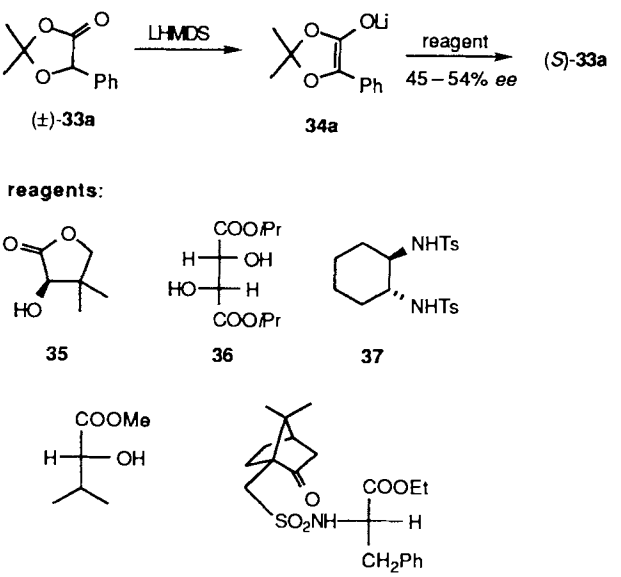
The enantioselective protonation with aniline **31** was successfully extended to various amide dienolates (Scheme 18). With the exception of the β-unbranched enolate ($R^1 = H$), all examples gave consistently high *ee* values (95–97%). In two cases, competing γ-protonation also gave rise to significant amounts of the α,β-unsaturated isomers.



$R^1, R^2 = (CH_2)_4$; $R^3 = H$	97% *ee*	(>90%)	
$R^1, R^2 = (CH_2)_3$; $R^3 = H$	95% *ee*	(18%)	(66%)
$R^1, R^2 = CH_3$; $R^3 = H$	97% *ee*	(>90%)	
$R^1, R^3 = CH_3$, $R^2 = H$	95% *ee*	(60%)	(30%)
$R^1 = H$; $R^2, R^3 = CH_3$	53% *ee*	(>90%)	

Scheme 18. Enantioselective protonation of amide dienolates.

Hünig et al.[14, 55] have extensively studied the enantioselective protonation of cyclic ester enolates of type **34** derived from mandelic acid (Scheme 19). Of the multitude of proton donors tested, the most efficient bifunctional reagents (45–54% *ee*) are listed.[14a, b]



Scheme 19. Enantioselective protonation of a dioxolanone enolate.

Protonation of the oxathiolanone enolate **38** revealed a strong dependence on the precise reaction conditions; oxathiolanone (*S*)-**39** was obtained with a maximum *ee* value of 77%. Interestingly, a very pronounced solvent effect was observed when enolate **38** was protonated with (*R*)-pantolactone (**35**): the highest selectivity (72% *ee*) was achieved in Et_2O/THF (9/1) (Scheme 20)![14c]

With tartrate **36** as the chiral proton source, a dramatic salt effect was noticed: the *ee* of (*S*)-**39** increases from 39% (no LiCl) to 77% in the presence of excess LiCl, but only when the LiCl is already present during the deprotonation of (±)-**39** with LHMDS.[14c] The generation of an ate complex with two equivalents of $Ti(OiPr)_4$ is also beneficial, as shown by the protonation of **38** with diamine **37**. However, other Lewis acids led to decreased enantioselectivities and sodium or potassium enol-

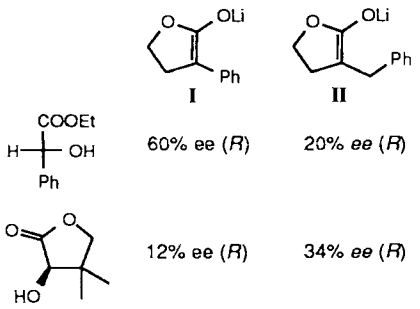
Scheme 20. Enantioselective protonation of an oxathiolanone enolate.

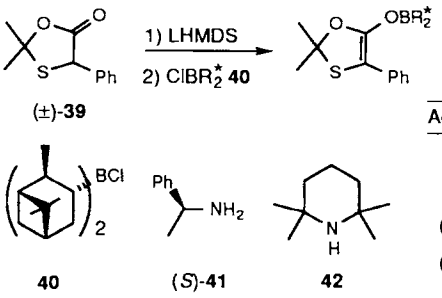
ates of **33a** proved unsuitable for enantioselective protonation ($\leq 3\%$ *ee* with **35**).[14c]

Hünig's study shows that an understanding of the underlying chemistry is extremely difficult and that it is still premature to establish any guidelines for the protonation of enolates **34a** and **38**.[56] Indeed, all described effects are only strongly pronounced in conjunction with specific chiral reagents. Likewise, structually related lactone enolates such as **I** and **II** show totally unpredictable enantiofacial selectivities.[14d]



Surprisingly, the protonation of the lithium endates is insensitive to the presence or absence of secondary amines, although deuterium incorporation strongly depends on the nature of the amine present (see Section 8).[14a, c]

The noncovalent interactions between substrate and reagents can lead, via highly varied aggregates, to a multitude of diastereomeric transition states, which account for the generally modest protonation selectivities. For this reason Hünig's group has extended its study to the stereoselective protonation of a monomeric, chiral boron enolate, in which the chiral ligands are covalently bound to boron.[55] This enolate was prepared by treatment of the lithium enolate **38** with (−)-*B*-chlorodiisopinocampheylborane (**40**) (Scheme 21).



Additive	HX	*ee*	Config.

–	TFA	32	(*S*)
(*S*)-**41**	AcOH	43	(*R*)
(*R*)-**41**	AcOH	2	(*R*)
42	AcOH	76	(*R*)
42	TFA	39	(*S*)

Scheme 21. Protonation of a chiral boron enolate.

Whereas protonation of the boron enolate with AcOH at −70 °C leads to an enrichment of (*R*)-**39** (54% *ee*), protonation with the less nucleophilic trifluoroacetic acid (TFA) favors the formation of the (*S*) enantiomer (32% *ee*). It is assumed that the binding of the AcOH carbonyl group by the boron atom allows the proton to be transferred internally in an eight-membered, cyclic transition state. In contrast, TFA predominantly delivers its proton without prior complexation from the opposite face of the enolate. The outcome of the protonation is strongly influenced by the presence of excess primary or secondary amines. For instance, in conjunction with AcOH, the enantiomeric 1-phenylethylamines (**41**) produce a complete selectivity change (43% *ee* (*R*) with (*S*)-**41**, 2% *ee* with (*R*)-**41**). The best result (76% *ee* (*R*)) was obtained with piperidine **42**, and the combination **42**/TFA furnished (*S*)-**39** with 39% *ee*. These results demonstrate that the amines are incorporated into the transition state. Whether a rapidly formed ammonium species is the effective proton donor was not discussed, and protonation with a preformed ammonium carboxylate was not tested.

Rebek and co-workers[42] reasoned that higher selectivities should be achieved in the protonation **34a** → **33a** (Scheme 22)

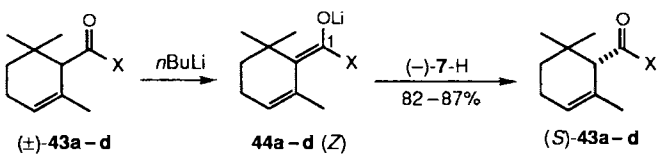
18

Scheme 22. Enantioselective protonation of dioxolanone enolates with **18**.

with a chiral reagent, in which the proton is "buried within an asymmetric environment". For this purpose, they prepared chiral lactam **18**, in which the NH group is shielded by a naphthyl group, as evident in the ^{1}H NMR spectrum. Protonation of **34a**, initially reported to be highly enantioselective,[57] led to irreproducible results which were subsequently withdrawn. Apparently, **18** is not acidic enough to protonate the weakly basic enolate **34a**. However, the alkyl-substituted enolates **34b–e** were successfully protonated with selectivities ranging between 9 and 91% *ee* (Scheme 22), depending on the size of the R substituent. A chelated eight-membered ring transition structure in which the larger R group preferentially remains outside the cavity was proposed to rationalize the observed absolute configurations.

In our laboratory, the enantioselective protonation of ketone enolates (Section 3.2.) was extended to ester and thioester enolates derived from α-cyclogeranates, whose enantiomers are pivotal, versatile building blocks for the synthesis of fragrances and pharmaceuticals (Scheme 23).[58] When the racemic methyl es-



a	X = OMe	36% *ee*
b	X = OPh	77% *ee*
c	X = SPh	99% *ee*

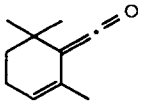
Scheme 23. Enantioselective protonation of α-cyclogeranates and α-thiocyclogeranates. 2-Naphth = 2-naphthyl.

ter **43a** was deprotonated with *n*BuLi at −78 °C and the resulting enolate **44a** (*Z*:*E* = 19:1) protonated with (−)-*N*-isopropylephedrine ((−)-7-H) at low temperature (−100 → −10 °C), ester (*S*)-**43a** was produced with a selectivity of only 36% *ee*. This marked difference to the protonation of related ketone enolates (>90% *ee*) led us to assume that the low enantiofacial differentiation was due to insufficient structural differentiation of the substituents at C(1) of the enolate (OLi vs. OMe) and an overly rapid protonation of **44a** due to the high pK_a of **43a**. In line with our expectations, protonation of the phenyl ester enolate is more selective (77% *ee*), and the thioester enolates **44c** and **44d** afford the respective (*S*)-thioesters with an unprecedented enantioselectivity of >200:1. Likewise, protonation with the enantiomeric amino alcohol (+)-7-H affords (*R*)-**43c** with 99% *ee*.[58]

It should be added that esters **43b–d** were deprotonated at −100 °C because the corresponding enolates (≥98% *Z*) are unstable, decomposing above −80 °C to give ketene **5** and LiSPh. The reverse reaction, the enantioselective thiol addition to **5** in the presence of stoichiometric or catalytic amounts of (−)-7-H,[59] is discussed in Section 4.



5

In view of the importance of γ-cyclogeranates **47** in the perfume industry and as synthetic intermediates, we also applied enantioselective protonation to the enolates **46a** and **46b** (Scheme 24).[35] Here, deprotonation of the β-cyclogeranates **45a** and **45b** with *n*BuLi or LDA generates, in a highly selective manner, the *E*-enolates, and the use of the dextrorotatory amino alcohol (+)-7-H provides (*S*)-**47a** and (*S*)-**47b**. As observed with the α-cyclogeranate series (Scheme 23), methyl ester enolate **46a** is a much poorer substrate for protonation (50% *ee*) than the thioester enolate **46b** (94–97% *ee*). Although neither the amine nor excess LDA affect the enantioselectivity, they influence the regioselectivity of protonation (**47a,b**:**45a,b**). The same protocol was also applied to enolate **49** of undetermined configuration to afford thioester (*R*)-**50** with 55% *ee* (Scheme 25).[60]

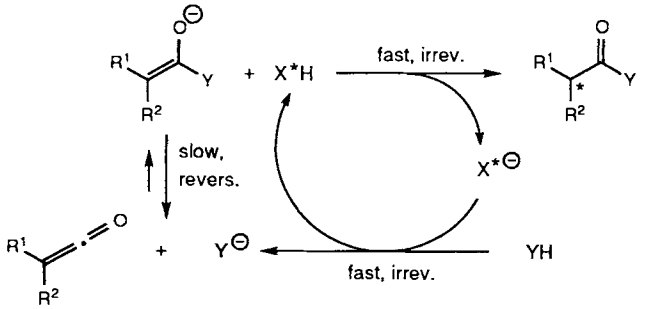
Scheme 25. Enantioselective protonation of a thioester enolate.



Scheme 26. Principle of catalytic enantioselective protonation involving transient enolates.

One attractive strategy for rendering a stoichiometric process catalytic without altering the reagent/enolate molar ratio consists of slowly generating the enolate (for example by addition of $Y^{\ominus}$ to a ketene, Scheme 26) under conditions that allow rapid, irreversible protonation of the transient species. The rate of regeneration of the catalyst, and thus of the enolate, can be adjusted by the delivery of the external protonating agent YH. Obviously, for such a scheme to be feasible, the proton exchange between YH and $X^{*\ominus}$ must be fast and complete, and $Y^{\ominus}$ must be more nucleophilic than the chiral reagent. Because the added species YH may also act as an undesired proton source for the enolate, its concentration in the reaction medium should be kept as low as possible.[61]

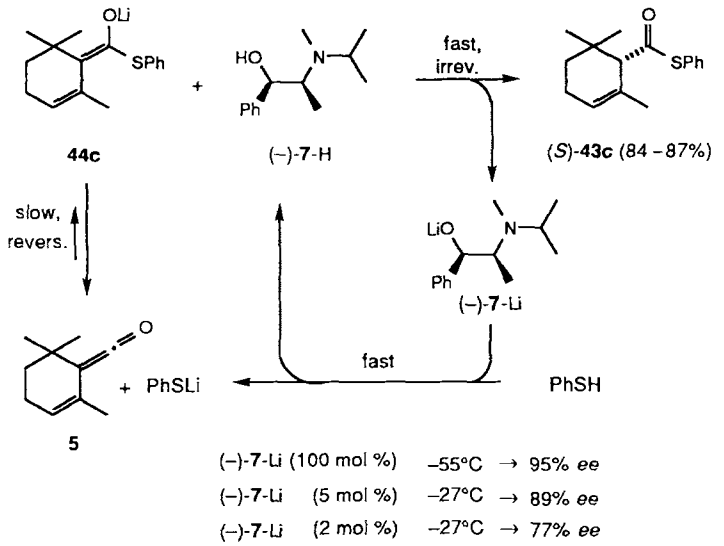
This concept has been realized in our laboratory for the synthesis of thioester (*S*)-**43c** by addition of thiophenol to ketene **5** in the presence of (−)-7- Li (Scheme 27).[59] As discussed in Section 3.5, thioester (*S*)-**43** is obtained with 99% *ee* by protonation of enolate **44c** at −100 °C, using (−)-7-H as the chiral proton donor (Scheme 27, top line). At temperatures above −80 °C the enolate eliminates PhSLi to give ketene **5**. In order to favor the addition reaction, the presence of a protic species is necessary. Thus, slow addition of equimolar amounts of (−)-7-H to a solution of ketene **5** and PhSLi in THF at −55 °C afforded (*S*)-**43c** with 95% *ee*.

For the extension of this reaction to a catalytic process, the continually added thiol serves as both nucleophile and proton source in the presence of catalytic amounts of (−)-7-Li. The rate of introduction of PhSH has to be kept low (addition over 3–4 h at −27 °C) to prevent accumulation ([PhSH] ≤ [(−)-7-Li]) and to minimize the risk of enolate protonation by PhSH. As shown in Scheme 27, very high enantioselectivities have been achieved with as little as 2–5 mol% (−)-7-Li. Of the other thiols tested, 4-chlorothiophenol, which is more acidic than PhSH, proved the most efficient (97% *ee* with 1 equiv (−)-7-Li;

4. Catalytic Enantioselective Protonation of Enolates

4.1. Processes Involving Transient Enolates

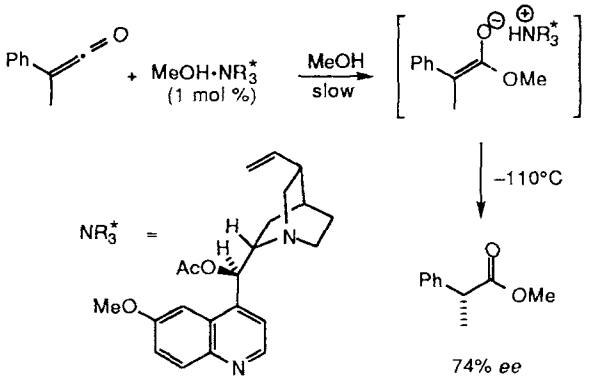
Up to this point we have considered preformed enolates, which have been submitted to at least equimolar amounts of a chiral proton donor X*H according to Scheme 26 (top line).



Scheme 27. Catalytic enantioselective addition–protonation of a thiophenol to a ketene.

90% *ee* with 0.05 equiv (−)-7-Li), whereas aliphatic thiols and alcohols were inefficient (10–40% *ee*).

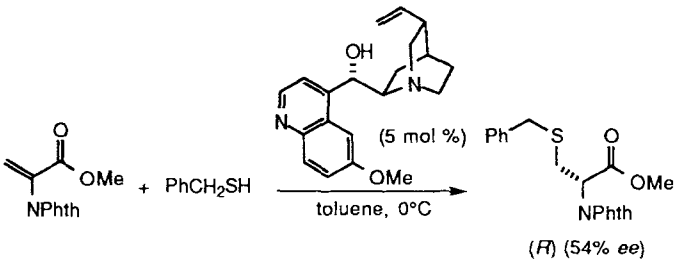
It should be added that the presence of free thiol in the reaction medium has a deleterious effect. A reaction solution containing ketene **5**, thiophenol, and 20 mol% (−)-7-Li afforded racemic thioester **43c**! However, this restriction does not apply to the related enantioselective additions of alcohols to ketenes, which were studied by Pracejus et al.[62] as early as the 1960s, in which the alcohol (MeOH, EtOH) serves as solvent (Scheme 28).



Scheme 28. Catalytic enantioselective addition–protonation of methanol to a ketene.

They found that the nucleophilic species in the low-temperature reaction (< −50 °C) consists of a 1:1 aggregate of the alcohol and the chiral tertiary amine; the uncatalyzed addition was negligible. A slow, rate-determining addition step is followed by a fast, selectivity-determining proton transfer from the postulated ammonium ion to the enolate. Among the hundreds of experiments performed with the most diverse amine catalysts under different reaction conditions, the most successful case in terms of asymmetric induction (74% *ee*) is shown in Scheme 28. In his work, Pracejus put special emphasis on the temperature dependence of the stereoselectivity. Thus, in the above example, a reaction temperature of −70 °C (instead of −110 °C) leads to almost racemic ester (< 5% *ee*). The complexity of the reaction is due to the existence of rapidly interconverting conformers leading to competing transition states, which undergo proton transfers at different rates. This and related work have been extensively reviewed by Scharf and co-workers[63] in their article on the isoinversion principle[64] and will not be discussed further here.

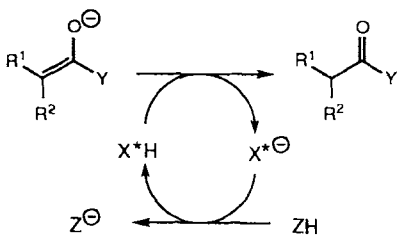
Pracejus et al.[65] have also extended their work on reaction sequences consisting of a thiol Michael addition and enantioselective protonation in the presence of a catalytic amount of a chiral amine. A prerequisite for achieving significant inductions (20–54% *ee*) is the use of a *β*-*N*,*N*-dialkylamino alcohol. The addition of phenylmethanethiol to methyl 2-phthalimidoacrylate with 5 mol% quinidine as catalyst furnishes the (*R*)-cysteine ester with 54% *ee* (Scheme 29). Recently, the closely related quinidine-catalyzed addition of thiophenol to 2-phenylacrylates has also been reported (45–51% *ee*).[66]



Scheme 29. Catalytic enantioselective sequence: Michael addition followed by protonation. Nphth = phthalimido.

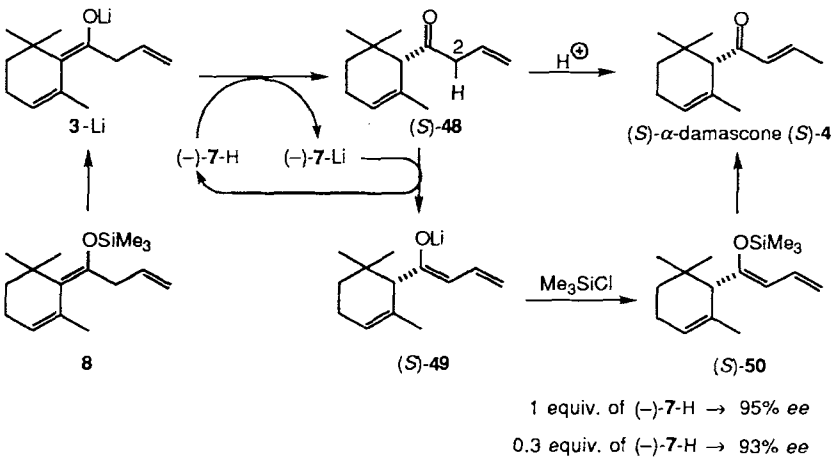
4.2. Preformed Enolates

In catalytic, enantioselective protonations of preformed enolates, the concentration of the enolate exceeds that of the chiral catalyst. Formally, an external, achiral proton donor ZH selectively reprotonates $X^{*\ominus}$ (Scheme 30), whilst the enolate is unaffected.[67]



Scheme 30. Formal reaction scheme for the catalytic enantioselective protonation of preformed enolates.

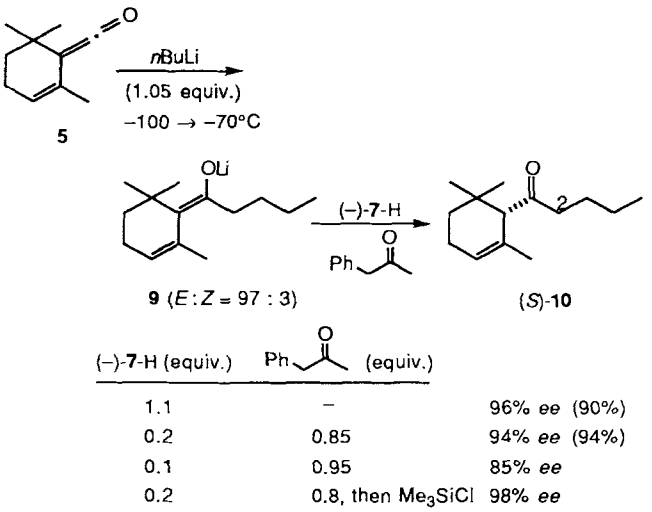
The first reported enolate protonation using catalytic amounts of a chiral reagent is a special case, because the most acidic proton of the product ketone (*S*)-**48** (at C(2)) serves to protonate (−)-7-Li or, more likely, the mixed aggregate **3**-Li,(−)-7-Li (Scheme 31).[30] Whereas protonation of enolate **3**-Li with an equimolar quantity of amino alcohol (−)-7-H affords ketone (*S*)-**48** with 95% *ee*, as little as 0.3 equivalents of (−)-7-H also suffice for highly enantioselective protonation. The α-damascone isomer (*S*)-**48** and subsequently (*S*)-**4** are produced efficiently with 93% *ee* and 86% yield.[68] This autocatalytic cycle is based on subtle kinetic differences in the proton transfer reactions between chiral reagents, enolate, and non-inducing proton donor.[69] When the quantity of (−)-7-H



Scheme 31. "Autocatalytic" enantioselective protonation of 3-Li.

is reduced to less than about 0.2 equivalents, the reaction rate and selectivity are significantly decreased.

This case is, of course, very particular, because the product ketone (*S*)-**48** is rapidly and exclusively deprotonated at C(2). An analogous autocatalytic reaction is not possible with enolate **9**, as the acidity of the C(2) protons of (*S*)-**10** is substantially weaker. To circumvent this problem, phenyl-2-propanone has been successfully used as an external, achiral proton donor (Scheme 32).[70] Thus, protonation of **9** (*E*:*Z* = 97:3), readily



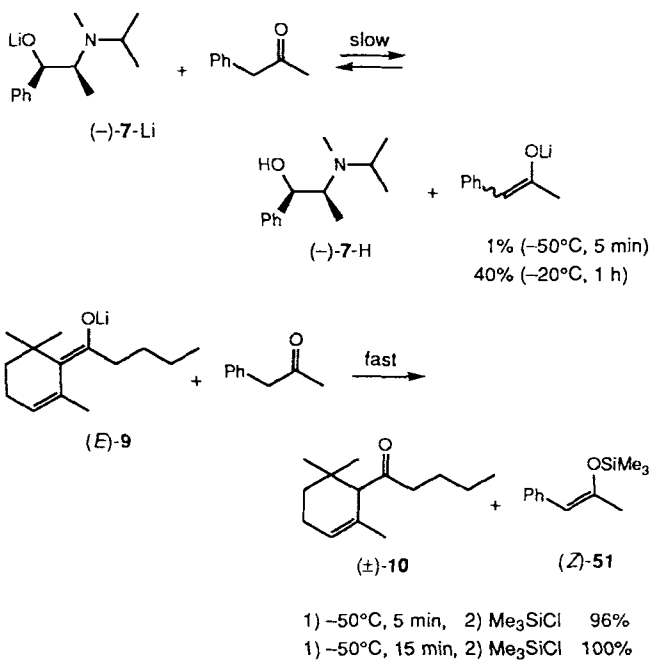
(−)-7-H (equiv.)	Ph (equiv.)	
1.1	–	96% *ee* (90%)
0.2	0.85	94% *ee* (94%)
0.1	0.95	85% *ee*
0.2	0.8, then Me_3SiCl	98% *ee*

Scheme 32. Catalytic enantioselective protonation of **9**.

obtained from ketene **5** and *n*BuLi, with equimolar amounts of (−)-7-H affords the butyl ketone (*S*)-**10** with 96% *ee*, and the catalytic enantioselective protonation with 0.2 equivalents of (−)-7-H, followed by the addition of 0.85 equivalents of phenyl-2-propanone furnishes (*S*)-**10** also with high enantioselectivity (94% *ee*). With 0.1 equivalents of (−)-7-H the selectivity decreases to 85% *ee*.

We have succeeded in further improving the attained selectivity by exploiting the observed rate difference between protonation of (*E*)-**9** and (*Z*)-**9** (Section 3.2.). When slightly less than one equivalent of the proton donor (0.2 equiv (−)-7-H, 0.8 equiv phenyl-2-propanone) for a total amount of 1.05 equiv *n*BuLi are used, and the reaction mixture is quenched with Me_3SiCl, (*S*)-**10** is obtained with 98% *ee*![31] Under these conditions, only (*E*)-**9**, which allows a better enantiofacial discrimination, is protonated (see also Section 3.2.). Interestingly, this experiment also revealed that deprotonation of phenyl-2-propanone is kinetically controlled, as the (*Z*)-silyl enol ether was formed exclusively.

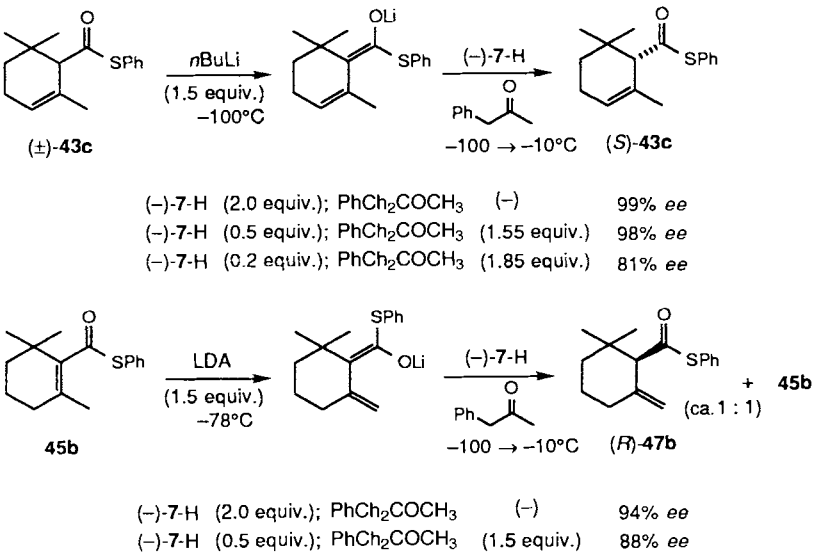
In contrast to the simplified reaction in Scheme 30, which implies a rapid proton transfer between ZH and $X^{*\ominus}$, the proton exchanges between (−)-7-Li and phenyl-2-propanone are slow, incomplete (in other words reversible), and unselective (mixture of *E*- and *Z*-enolates). However, protonation of enolate (*E*)-**9** by phenyl-2-propanone is rapid, irreversible, and selective, affording the (*Z*)-silyl ether (*Z*)-**51** after silylation (Scheme 33). Therefore, phenyl-2-propanone certainly furnishes



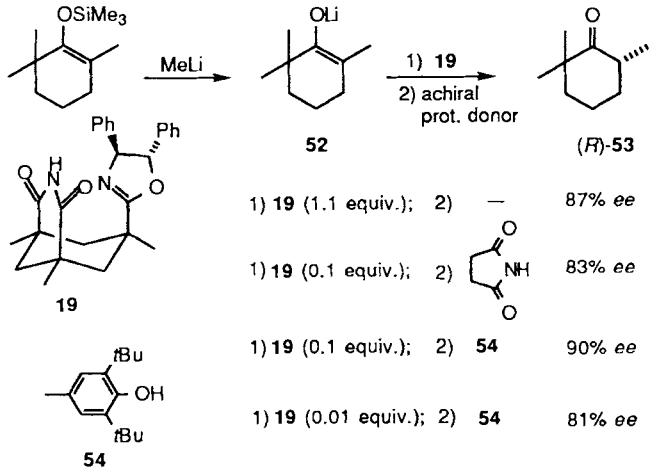
Scheme 33. Proton exchange reactions between phenyl-2-propanone and (−)-7-Li and (*E*)-**9**.

its proton directly to enolate (*E*)-**9** or to a chiral enolate complex formed from (*E*)-**9** and (−)-7-Li.[71] The catalytic conditions were also extended to the preparation of thioesters of high enantiomeric purity (Scheme 34).[35]

Very recently, Yamamoto et al.[72] have reported that enolate **52** can be enantioselectively protonated at −78 °C by sequential addition of (*S*,*S*)-imide **19** (0.1 equiv) and succinimide (1 equiv) (Scheme 35). The selectivity (83% *ee*) approaches that obtained with stoichiometric quantities of **19** (87% *ee*, see Section 3.3.). With phenol **54**, as little as 0.01 equivalents of chiral imide **19** were required to achieve 81% *ee*. The reaction is believed to follow the general mechanism shown in Scheme 30.[73]



Scheme 34. Enantioselective protonation of thioester enolates with substoichiometric amounts of (−)-7-H.

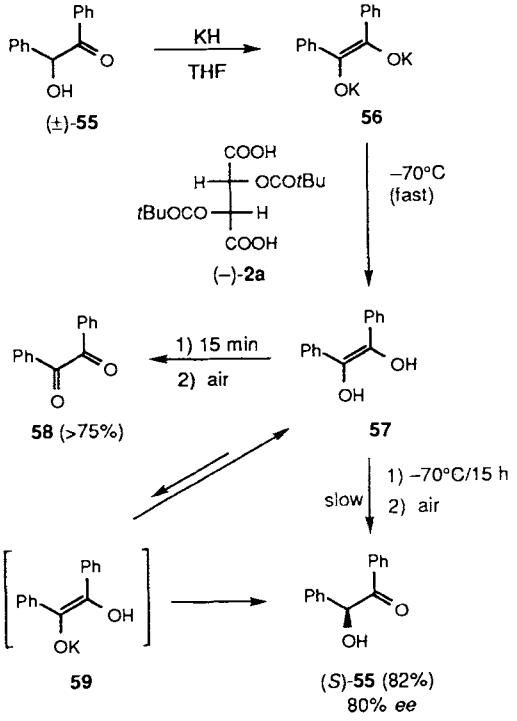


Scheme 35. Enantioselective protonation with catalytic amounts of **19**.

5. Enantioselective Tautomerization of Enols

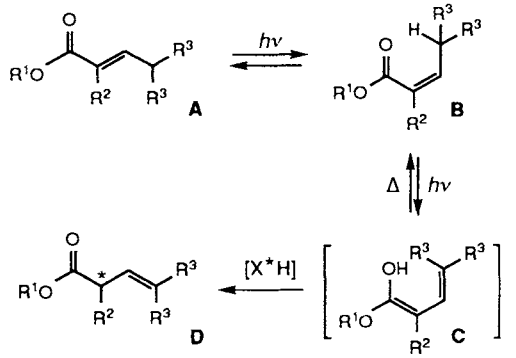
In this section the reactions proceeding via enol intermediates are reviewed. Since enols and enolates are often rapidly interconverting, enol tautomerizations are closely related to the previously discussed enolate protonations.

As a borderline case, Duhamel's protonation of enediolate **56** has to be cited (Scheme 36).[18] In the presence of (*R*,*R*)-di-*O*,*O'*-pivaloyltartaric acid ((−)-**2a**) at −70 °C, enediol **57** is rapidly formed. Its tautomerization, however, is much slower, and quenching of the reaction mixture after less than 1 h affords essentially benzil (**58**), which is formed by autoxidation of enediol **57** during workup. In contrast, when the reaction is allowed to continue for 15 h, (*S*)-benzoin ((*S*)-**55**) is obtained in high yield (80%) with 80% *ee*. As **57** is certainly in equilibrium with its monoanion **59**, we suggest **59** as the reactive intermediate. The fact that large excesses of chiral diacid (−)-**2a** are deleterious to the process may also be rationalized by an unfavorable shift of the equilibrium between **57** and **59**.



Scheme 36. Enantioselective tautomerization of an enediol.

The most important contribution to the enantioselective protonation of dienols is attributed to Pete and co-workers. In a series of publications[74] they have demonstrated that α,β-unsaturated esters and lactones can be enantioselectively deconjugated by irradiation at 254 nm in the presence of a chiral catalyst (Scheme 37). This reaction involves an intramolecular γ-hydrogen abstraction of the allylic hydrogen from the singlet excited state (**B** → **C**; Norrish type II).[75] The transient dienol species **C**, which is in equilibrium with ester **B** (thermal 1,5 H-shift), then undergoes a base-catalyzed tautomerization. With catalytic amounts (0.1–0.15 equiv) of chiral β-amino alcohols, this rate-determining, irreversible C-protonation affords enantiomerically enriched esters with fair to excellent *ee* values (Scheme 38). Essential to this photodeconjugation is that the dienol is maintained at a low steady-state concentration ([**C**] < [X*H]) and that the reaction product **D** is more inert than **A** to the photochemical conditions. For good results,



Scheme 37. Enantioselective photodeconjugation of an α,β-unsaturated ester.

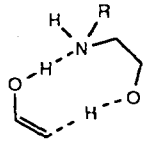
Scheme 38. Structural requirements of the chiral catalyst in the enantioselective photodeconjugation of ester **60**. A: 0.1 equiv catalyst, −78 °C; B: 0.15 equiv catalyst, −55 °C; C: 0.1 equiv catalyst, −40 °C (or −50 °C).

rigorously moisture-free, apolar solvents such as *n*-heptane and CH_2Cl_2 had to be used, and the optimal temperature was determined to be approximately −55 °C.[74a, 76]

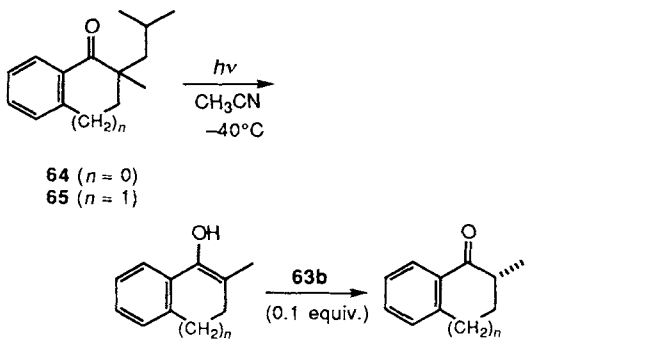
Amino alcohols that have a secondary NH group were found to be more efficient inductors. The size of the N-alkyl substituents is extremely critical; **62d**, **63b**, and **63c** (R^2 = *i*Pr, $PhCH_2$) gave the best results (70–91 % *ee*). Either decreasing or increasing the size of the amine substituent led to diminished enantioselectivities. (+)-Cinchonine and (−)-cinchonidine gave modest, opposite inductions. With bornane **63b**, various other esters of type **A** have been deconjugated with 43–77 % *ee*. In general, better results were obtained with γ-disubstituted esters.[74c]



E

Pète et al. propose that the enantioselective protonation of the dienol proceeds by the formation of a complex of type **E**.[74] The hydrogen bonding between the enolic proton and the nitrogen atom increases the electron density on C(2) and allows a more or less concerted proton transfer via a nine-membered cyclic transition state. An alternative reaction course involving the intermediacy of an enolate/ammonium ion pair was considered unlikely in view of the analogous phenol/tertiary amine complexes in apolar solvents, in which the OH bond is not cleaved.

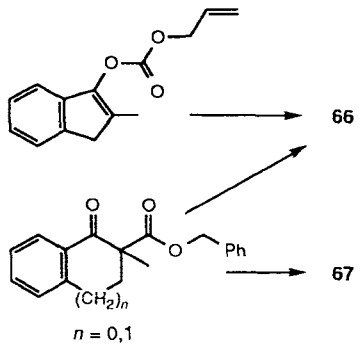
These enantioselective tautomerizations are not restricted to dienols. Aryl enols **66** and **67** have been generated by Norrish type *II* photoeliminations from **64** and **65** in acetonitrile ($\lambda > 290$ nm) and tautomerized in the presence of β-amino alcohols (Scheme 39).[77] Enol **66** was shown to be stable under the irradiation conditions ($\lambda = 337$ nm) in the absence of amino alcohol catalysts, but it tautomerized in the dark with as little as 1 mol % (−)-ephedrine (**62a**) (**68**: 45 % *ee*). One disadvantage of this interesting method is that prolonged irradiation times lead,



Scheme 39. Enantioselective tautomerization of aryl enols.

through Norrish type I fission, to competing cleavage reactions and product racemization.

Alternatively, enols **66** and **67** have also been generated by Pd-catalyzed cleavage reactions of appropriate precursors (Scheme 40) and ketonized in the presence of chiral β-amino alcohols (max. 64 % *ee*).[78] The intermediacy of enol species remains, however, speculative, and the possibility of the C-protonation of a Pd-enolate cannot be excluded. Also worthy of mention are a related enol tautomerization catalyzed by [Rh-(*S*)-BINAP]$^{\oplus}$ (BINAP = 2,2′-bis(diphenylphosphanyl)-1,1′-binaphthyl) affording 2-phenylpropanol with 18 % *ee*,[79] and a Cu^{I}-alkoxide-catalyzed decarboxylation of methylphenylmalonates (max. 36 % *ee*).[80]

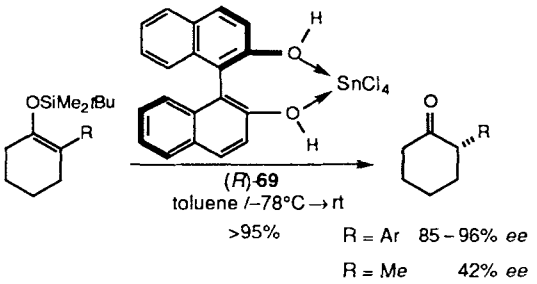


Scheme 40. Pd-catalyzed generation of enols.

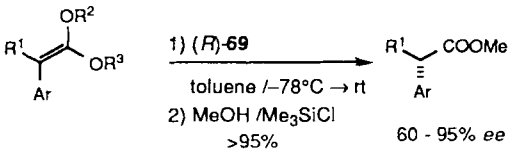
6. Enantioselective Protonation of Enol Ethers, Ketene Acetals, and Enol Esters

6.1. $SnCl_4$-Complexed Binaphthol as a New Chiral Proton Donor

Yamamoto et al.[81] have found that the complex between (*R*)-binaphthol and $SnCl_4$, (*R*)-**69**, generated in situ is highly effective for the enantioselective protonation of 2-aryl enol ethers but less suitable for the protonation of 2-alkyl enol ethers (Scheme 41). This reaction was also successfully applied to ketene bis(trialkylsilyl) acetals, affording 2-aryl esters with 60–95 % *ee* (Scheme 42). Ketene acetals with different substituents R^2 and R^3 usually exist as mixtures of (*E*) and (*Z*) isomers and undergo protonation with lower induction. The authors propose a transition state model based on minimum steric interactions, which accounts for the fact that the highest enantiofacial discriminations are observed with small R^1 groups (methyl). In one case it was ascertained that the protonation did not occur via a tin enolate, but the question of a concerted or



Scheme 41. Enantioselective protonation of enol ethers. rt = room temperature.

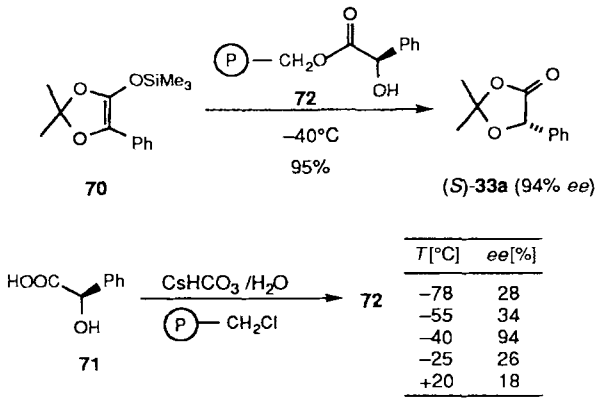


Scheme 42. Enantioselective protonation of ketene acetals. rt = room temperature.

stepwise[82] mechanism was not clarified.[83] It should also be noted that in this process the chiral reagent is transformed into the monosilylated binaphthol derivative.

6.2. A Polymer-Supported Chiral Proton Donor

The enantioselective protonation of ketene acetal **70** (see also Section 3.5) has been achieved with excellent enantioselectivity (94% *ee*) when the proton donor (*R*)-mandelic acid (**71**) was bound to a polymeric resin (→**72**, Scheme 43).[84] Most intrigu-



T[°C]	ee[%]
–78	28

–25	26
+20	18

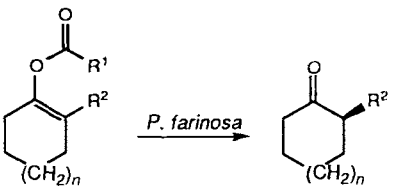
Scheme 43. Enantioselective protonation of a ketene acetal using a polymer-supported chiral proton donor. (P) $-CH_2Cl$ = Merrifield resin.

ingly, this protonation is highly temperature dependent: when the temperature deviates only slightly from −40 °C, a surprisingly large decrease in enantioselectivity results. In application of the isoinversion principle[63, 64] Verducci et al. attribute these changes to a two-step mechanism involving the preliminary formation of rapidly interconverting diastereomeric complexes. However, it can be verified readily that the selectivity of 94% *ee* obtained at −40 °C does not fit the Eyring plot.[76] Therefore, these results cannot be explained solely by a change in dominance of enthalpy and entropy in the partial steps.

In a previous investigation the same group found that protonation of **70** with (*R*)-pantolactone (**35**) and with (*R*)-methyl mandelate with or without $ZnCl_2$ or LiCl additives at −78 °C led to (*S*)-**33a** with generally low selectivities (13–50% *ee*).[85] In conclusion, the polymer-supported chiral reagent leads to a substantially improved asymmetric induction and offers the advantage of simple recovery of the reagent by filtration without loss of activity.

6.3. Enzyme-Mediated Hydrolysis of Enol Esters

Enzymatic ester hydrolyses are known to generally proceed by acylation of the enzyme, followed by hydrolysis of the acylated species. When this hydrolysis method is applied to prochiral enol esters, concomitant acyl group cleavage and C-protonation of the liberated enols by the enzyme is expected to give enantiomerically enriched products. With this reasoning, Ohta et al.[86] have thoroughly investigated the hydrolysis of a series of α-substituted cycloalkanone enol esters. After extensive screening, the yeast *Pichia farinosa* IAM 4682 was found to be the most efficient in terms of reactivity and selectivity. Generally, when the reaction was performed with a large excess of *Pichia farinosa*, high *ee* values were obtained with a variety of substrates (Scheme 44). For example, 78 mg of enol acetate



n	R^1	R^2	ee[%]	Yield[%]
1	Me	Me	90	79
1	Et	Me	92	78

7	Me	Me	95 (*R*)	67
7	Ph	Me	96 (*R*)	59
10	Me	Me	<2	38
10	Ph	Me	11	25

Scheme 44. Enzyme-mediated enantioselective hydrolysis of enol esters. The yeast strain *P. farinosa* is used in large excess. For enol esters with $n = 7$ the induction is opposite to that with other ring sizes although the configuration is the same.

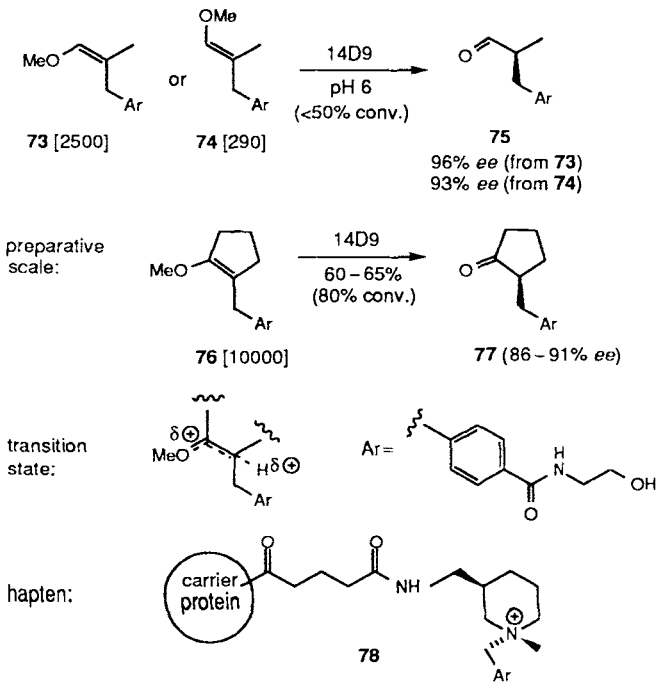
(Scheme 44; $n = 1$, $R^1 = R^2 = Me$) and 14 g of grown, centrifuged cells in phosphate buffer (pH 6.5) at 30 °C furnished (*S*)-2-methylcyclohexanone with 90% *ee*. Reducing the weight of the cells to 2.7 g slowed down the reaction rate and favored nonspecific reactions catalyzed by other enzymes of the cell (41% *ee*). The possibility of racemization due to prolonged reaction times at 30 °C (24 h instead of 3 h) should also be taken into consideration.

The large amount of yeast cells necessary for this process and the severe emulsion problems encountered during the extraction prompted the Japanese group to develop a procedure that would be more amenable to large-scale preparations.[87] As hydrolysis with immobilized cells resulted in only very poor conversions, a new system ("interface bioreactor") was tested, in

which the microorganism was grown on a hydrophilic polysaccharide layer (agar plate). For the desired hydrolysis a solution of the substrate enol ester in an apolar solvent was added, and the reaction proceeded at the interface between the entrapped cells and solvent. In this way, the microorganisms are protected against toxic compounds, the freshly grown cells can be used directly in organic solvents, and the recovery of the product is greatly facilitated. Thus, with 50 mL of isooctane as the solvent, 500 mg of enol ester ($n = 1$, $R^1 = Et$, $R^2 = CH_2Ph$) was hydrolyzed with 21 g of wet cells (on a surface of 638 cm^2) to afford, after 24 h at 25 °C, (*R*)-2-benzylcyclohexanone in 66% yield with 84–87% *ee*.

6.4. Antibody-Catalyzed Protonation of Enol Ethers

Whereas active enzymes are found by screening, catalytic antibodies (or abzymes) are raised against rationally designed antigens (haptens) that mimic the transition state of the planned reaction.[88] The first encouraging result—the enantioselective protonation of an enol ester affording (*R*)-2-methylcyclohexanone with 42% *ee*—was achieved by an antibody elicited against a hapten possessing a phosphonate moiety.[89] For the acid-catalyzed protonation of enol ethers **73**, **74**, and **76**, the scientists at the Scripps Research Institute selected cationic haptens such as **78** and structurally related ammonium species,[90] with the assumption that the antibodies generated would contain a carboxylate group in the combining site for reasons of electrostatic complementarity. This functional group may either stabilize the transition state or assist the desired C-protonation. In view of the similarity between the hapten and the pyramidalized transition state for the proton transfer, a good binding affinity of the activated substrate to the antibody was expected (Scheme 45).

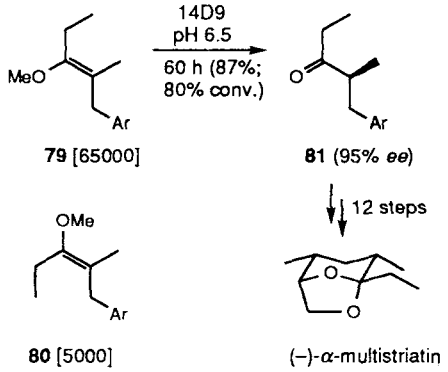


Scheme 45. Antibody-catalyzed enantioselective protonation of enol ethers. The rate enhancements k_{cat}/k_{uncat} are given in square brackets.

Indeed, monoclonal antibody 14D9 (from 23 antibodies raised against **78**) showed excellent activity for both rate enhancement and enantioselectivity in the hydrolysis of **73** ($k_{cat}/k_{uncat} = 2500$; 96% *ee*) and to a lesser degree **74** ($k_{cat}/k_{uncat} = 290$; 93% *ee*).[90a] Interestingly, the *E*- and *Z*-enol ethers afford the same enantiomer. The reaction was performed in a cyanide buffer (pH 6) at 25 °C for several days (< 50% conversion). Under these conditions the formed aldehyde **75** is protected from racemization by conversion into the corresponding cyanohydrin diastereomers. However, an estimated loss in enantiomeric purity of approximately 1.5% *ee* (hydrolysis of **73**) and about 5% *ee* (hydrolysis of **74**) is attributed to the noncatalyzed background reaction.

The same abzyme hydrolyzes **76** with a rate enhancement (k_{cat}/k_{uncat}) of 10^4.[90b] When a catalytic amount of antibody 14D9 (400 mg, ca. 2.7 μmol; ca. 0.15 mol%) is used, hydrolysis of **76** (500 mg, 1.83 mmol) proceeds to 80% conversion in 5 h giving ketone **77** with 89–91% *ee*. After separation of the low molecular weight compounds **76** and **77** by dialysis, **77** is obtained after recrystallization in 60–65% yield (86% *ee*), and the antibody is recycled with roughly 5% loss of activity. The background reaction is considered to have eroded the *ee* by about 10%. If larger amounts of abzyme had been used, it could have been proved that the antibody-catalyzed hydrolysis is indeed 100% enantioselective.

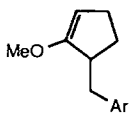
Very recently,[91] a rate acceleration of 65 000 and an enantiofacial discrimination greater than 200:1 was measured for the 14D9-catalyzed hydrolysis of *Z*-enol ether **79** (Scheme 46). In



Scheme 46. Antibody-catalyzed enantioselective protonation of an enol ether. The rate enhancements k_{cat}/k_{uncat} are given in square brackets.

analogy to the reaction of *Z*- and *E*-enol ethers **73** and **74**, catalysis is much more effective with **79** than with **80** ($k_{cat}/k_{uncat} = 5000$). On a preparative scale, with 180 mg of **79** and 0.23 mol% partially purified 14D9, **81** was isolated after 80% conversion in 87% yield and with 95% *ee*. Ketone **81** was used as a chiral building block for the synthesis of the insect aggregation pheromone (–)-α-multistriatin.

Based on recent mechanistic investigations, Reymond, Lerner, et al.[92] arrived at the conclusion that the assumed carboxylate function in the antibody active site is not within binding distance of the transient tetragonal carbon undergoing protonation, but it more likely interacts with the electron-deficient carbon bearing the methoxy group. Indeed, hydrolysis of both **76** and the regioisomeric enol ether **82** is significantly catalyzed by

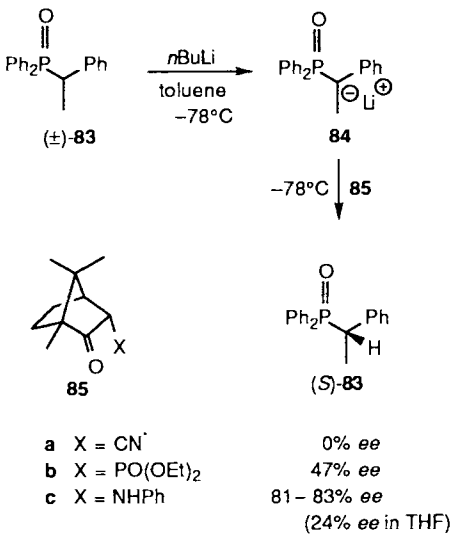


82

14D9. Therefore, the initially proposed structural similarity between the hapten and the transition state does not fully account for the observed effect.[92a] From inhibition experiments of the hydrolysis of **73** in the presence of hapten analogs, the orientation of the enol ether at the transition state relative to the hapten was deduced, and the importance of hydrophobic binding interactions between enol ether substituents and the antibody for pyramidalization of the proton-accepting carbon atom was recognized.[92b]

7. Enantioselective Protonation of a Phosphane Oxide Carbanion

Recently, Vedejs and Garcia-Rivas[93] were able to deracemize phosphane oxide **83** by enantioselective protonation of the corresponding carbanion **84** (Scheme 47), thus confirming that benzylic carbanions stabilized by a P=O substituent are either planar or invert rapidly.



Scheme 47. Enantioselective protonation of a phosphane oxide carbanion.

For the protonation of carbanion **84**, the camphor-derived chiral proton donors **85b** and **85c** gave satisfactory enantiofacial discriminations of 47 and 81–83% *ee*, respectively. Interestingly, the chiral di- and triamines **29a** and **29b**, which efficiently promote enolate protonation (see Section 3.5), were ineffective for anion **84** (0–29% *ee*). In this reaction, where the least acidic camphor derivative **85c** gives the highest induction, the formation of transient mixed-aggregate species of defined but unknown structure appears to be crucial.[94] With the strongly coordinating solvent THF, the reaction course is markedly changed and a selectivity of only 24% *ee* results.

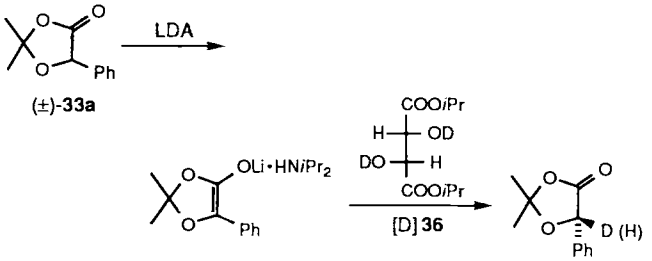
8. Summary and Outlook

In recent years enantioselective protonation has become a field of intense research, and numerous procedures have been developed allowing direct and efficient access to carbonyl compounds of high enantiomeric purity. The importance of this "young" reaction is now being confirmed by a growing number of applications in the syntheses of antiinflammatory agents,[53,54,66] pheromones[87,92] and fragrances.[19] However, currently, no generally applicable reagent is known and each chiral proton donor is only specific for a particular type of substrate under well-defined reaction conditions.

The complexity of enolate protonation stems from the fact that the reaction partners are not simple monomolecular entities, but a multitude of interconvertible aggregates of differing reactivity. During protonation the changing composition of the reaction mixture further complicates the process. The effects of amines and lithium salts,[5] the crucial role of solvent,[14c] and the nonlinearity between chiral induction and the enantiomeric composition of the reagent[35] are typical phenomena of changes in the supramolecular structure of the reaction species.

The participation of amines and lithium amides was first demonstrated by Duhamel's group[10,12,13] (see Section 3.1), who showed that the enantiofacial selectivity of protonation is strongly dependent on the chiral or achiral lithium amide employed. Protonation of an enolate/chiral amine complex[5] with an achiral proton source also afforded enantiomerically enriched product.[10,12,48]

Hünig et al.[14a,c] demonstrated that amines interact or interfere during protonation, as incomplete deuteration was observed when (±)-**33a** was deprotonated with LDA and the enolate/$HN(iPr)_2$ complex was submitted to deuteration with [D]**36** (Scheme 48). However, the amine has no effect on the

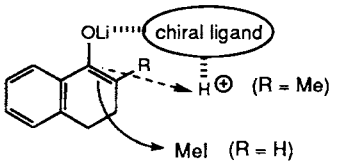


[D]**36**: 55% *ee*
([D] : [H] = 41 : 59)
36: 45% *ee*

Scheme 48. D/H-scrambling in the enantioselective deuteration of an enolate/secondary amine complex.

enantioselectivity and does not necessarily participate in the transition state. Complete deuteration and a selectivity of 57% *ee* could be attained by substituting LDA for LHMDS in the deprotonation step. The absence of an amine effect during deuteration in the presence of the less basic HMDS was already noticed by Duhamel et al.[13] Likewise, we have observed that the site selectivity for protonation of dienolates is improved in the presence of LDA and $HN(iPr)_2$, although the amine has little effect on the enantioselectivity (see Schemes 10,[37] 25,[35] and 26[60]).[95]

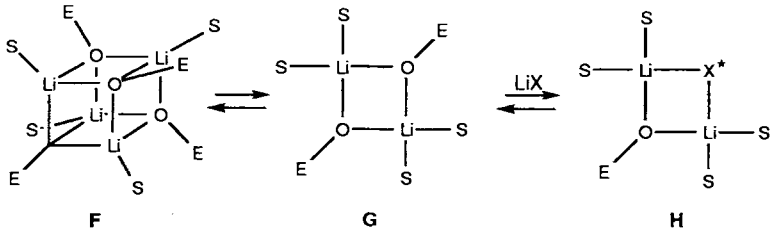
In contrast, the groups of Vedejs[53] and Koga[50] demonstrated that chiral amine ligands can efficiently control the enantiofacial proton delivery to the enolate. The "internal proton return"[53] from the 1:1:1 complex **30**, which consists of an



25 R = Me
27 R = H

enolate, a chiral amine, and a chiral lithium amide, back to the enolate has been achieved by increasing the acidity of the NH group with $BF_3 \cdot OEt_2$ (see Section 3.5). A very impressive example of "external" protonation of a complex composed of an enolate, a tetradentate chiral amine, and LiBr with AcOH was recently reported by Yasukata and Koga.[50] Interestingly, protonation of the chiral enolate complex **25** and methylation of the chiral enolate complex **27** take place with opposite enantiotopicity, thus giving the *same* product (see Section 3.3). In view of Vedejs's results, it may be assumed that the proton is transferred internally from the chiral ligand to one enolate face, whereas the methylation of a structurally and conformationally related complex proceeds from the opposite face.[52, 96]

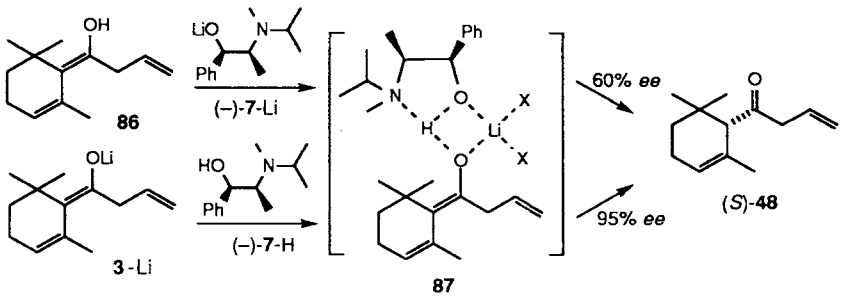
The presence of LiBr in toluene is essential for the success of the aforementioned reaction. Added lithium halides, lithium alkoxides, and lithium amides are known to profoundly affect enolate aggregation and to favor deaggregation of enolate tetramers **F** and dimers **G**, leading to monomeric, mixed aggregates **H** (Scheme 49).[2a, 97, 98] In addition, oligomeric cyclic enolate structures are disfavored for sterically hindered systems.[97a]



F **G** **H**

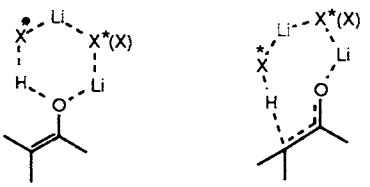
Scheme 49. Structures of enolate aggregates. E = enolate, S = solvent, X = ligand (halide, $RO^{\ominus}$, $R_2N^{\ominus}$).

It therefore seems reasonable to assume that efficient enantioselective protonation reactions proceed by the formation of monomeric enolate complexes of type **I**, **J**, or **K** (X* = bi- (or poly-) dentate chiral ligand, X = achiral ligand), which are followed immediately by irreversible C-protonation.[6b, 99] In these complexes the chiral information necessary for the subsequent irreversible proton transfer is still intact. Some support in favor of the intermediacy of hybride enol/enolate structures (for example **87** in Scheme 50) was obtained from the enantioselective ketonization of isolated enol **86** in the presence of chiral lithium alkoxide (−)-7-Li, which afforded the same (*S*)-ketone **48** as that obtained by enolate protonation. The lower *ee* value (60%) is presumably due to concurrent nonenantioface-discriminating protonation.[100] Complex **87**, which is probably further aggregated with chiral or achiral ligands, may ultimately transfer the proton with the participation of the N atom, via a nine-membered ring transition state, in which a more or less colinear arrangement is attained for N–H–C.



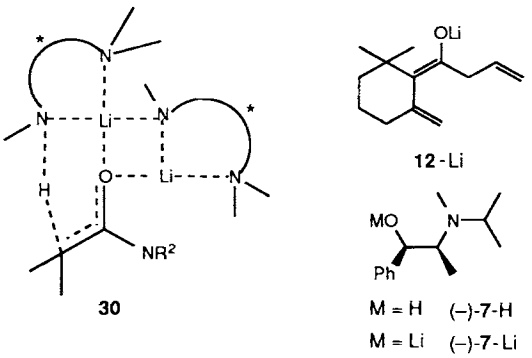
Scheme 50. Comparison of enol and enolate protonation.

In view of the related deprotonations of ketones, often involving two lithium amide molecules in an optimal eight-membered cyclic transition structure,[97a, c] an analogous general model for enolate protonations can be formulated by inspection of the more highly aggregated structures **J** and **K**: Formal disconnection of the inner bond in the ladder structures **J** and **K** would lead to complex **L**,[101] which then would undergo C-protonation via the eight-membered ring transition state **M**.



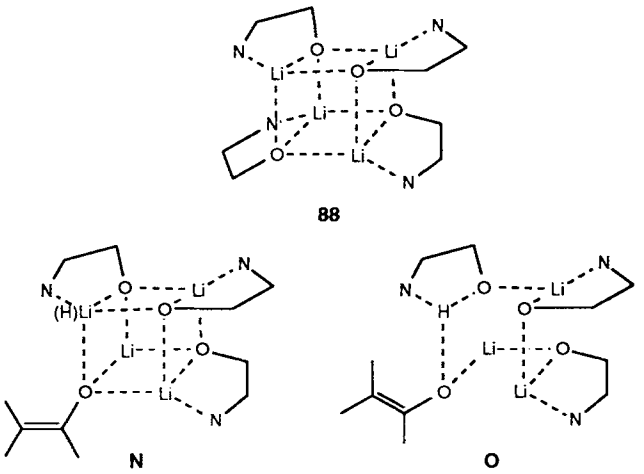
L **M**

At least two examples can be cited in which protonation indicates the participation of two or more chiral reagent molecules, namely Vedejs's internal protonations of 1:1:1 complexes **30** consisting of an enolate, a chiral amine, and a chiral lithium amide[53] (Scheme 51, see Section 3.5), and the protonation of enolate **12**-Li with a 1:2 mixture of the amino alcohol (−)-7-H and the corresponding lithium alkoxide (−)-7-Li[35] (see Section 3.2). The outcome of this reaction is not significantly changed when the enolate is first complexed with the lithium alkoxide and then protonated by the amino alcohol. Nevertheless, it is essential that (−)-7-Li is present at the beginning of the protonation. Consistent with these facts, a nonlinear relationship between the enantiomeric purity of the chiral reagent and the enantiomeric excess of the reaction product was found. Possibly (−)-7-Li not only affects the structure of the interacting species but also lowers its acidity.[102]



Scheme 51. Representation of complex **30** and structural formulas of the chiral compounds **12**-Li, (–)-7-H, and (–)-7-Li.

In analogy to the tetrameric structure **88** (simplified representation) of crystalline lithium ephedrate,[103] it is tempting to speculate on analogous 3:1 mixed aggregates **N** for enolate protonations promoted by amino alcohols. In solution and in the presence of a proton donor, a multitude of partially disconnected species such as **O** would be expected to be in equilibrium with each other.



88

N **O**

Recent stability evaluations of eight-membered ring aggregates[97] as well as fascinating X-ray structures of "partially deprotonated" mixed aggregates (with Li- and H-binding),[104] give some credibility to the above mechanistic considerations and also highlight the complexity of proton transfer reactions. Certainly the application of new spectroscopic and computational methods will lead to a better understanding of the dynamic behavior of interacting aggregates and open the door to the development of tailor-made reagents and catalysts in the area of enolate protonation.

After this review had been written two relevant articles appeared: the efficient enantioselective protonation of Mg-enolates of 2-alkyltetralones with 1,1′-binaphthalene-8,8′-diol-derived carbamates has been reported[105] and a review article on enantio- and diastereoselective protonation has been published.[106]

I would like to thank my colleagues, in particular Dr. R. L. Snowden, Dr. B. Winter, Dr. V. Rautenstrauch, and Dr. B. Maurer, for valuable suggestions and critical proofreading of the manuscript.

[24] The electrophilic nature of ester enolates may be due to charge delocalization. It is also possible that loss of LiOMe allows the Grignard reaction to proceed via a ketene[23b] or ketenoid species.

[25] F. Naef, R. Decorzant, *Tetrahedron* **1986**, *42*, 3245.

[26] Protonation with (*R,R*)-di-*O,O'*-pivaloyltartaric acid[8] or with (*R*)-pantolactone[14] provides (*S*)-**4** with 8 and 25% *ee*, respectively.

[27] Likewise, use of the enantiomeric reagent (+)-7-H affords (*R*)-**4** with 84% *ee*. The enantiofacial discrimination with pure *E*-enolate is expected to be even higher. This synthetic scheme can be used to prepare (*S*)-α-damascone ((*S*)-**4**) with excellent enantiomeric purity (99% *ee* after recrystallization) and in an improved yield of 55% starting from ketene **5**: C. Fehr, O. Guntern, *Helv. Chim. Acta* **1992**, *75*, 1023.

[28] The analogous Li-enolate/Li-alkoxide complex shows lower enantiofacial discrimination (65% *ee*), and the MgCl-enolate/MgCl-alkoxide complex is ineffective (10% *ee*).

[29] Addition of allyl-Li to ketene **5** gives a mixture of *E*-and *Z*-enolates (**3**-Li, $E:Z = 2:1$).

[30] C. Fehr, J. Galindo, *Angew. Chem.* **1994**, *106*, 1967; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 1888.

[67] This reaction type may also proceed by O-protonation either by X*H or ZH, followed by enantioselective tautomerization of the enol or by protonation of an enolate/chiral ligand complex (see Section 8).
[68] The formation of enolate **49** was proved by isolation of the corresponding silyl enol ether **50**. Under acidic conditions both **48** and **50** are converted into (*S*)-α-damascone ((*S*)-**4**).
[69] (*S*)-**48** does not protonate **3**-Li enantioselectively in the absence of (−)-**7**-H.
[70] Various CH-, OH-, and SH-acidic compounds (β-ketoesters, phenols, thiophenol, carboxylic acids, and *rac*-**48**), all of which are more acidic than (*S*)-**10** by several orders of magnitude, were tested and shown to be effective.
[71] See ref. [67]. As the catalytic enantioselective reaction (Scheme 32) is even more rapid (2 min at −50 °C), protonation of an enolate/chiral ligand complex seems more probable.
[72] A. Yanagisawa, T. Kikuchi, T. Watanabe, T. Kuribayashi, H. Yamamoto, *Synlett* **1995**, 372.
[73] The small but significant gain in enantioselectivity under catalytic conditions (0.1 equiv **19** in the presence of **54** rather than 1 equiv **19**) reflects a more complex scenario, in which **54** (or its anion) is involved in the transition state. It would be interesting to verify that this difference is not due to a modified workup procedure (which includes treatment with Me_3SiCl).

What Can We Learn from Molecular Recognition in Protein–Ligand Complexes for the Design of New Drugs?

Hans-Joachim Böhm* and Gerhard Klebe*

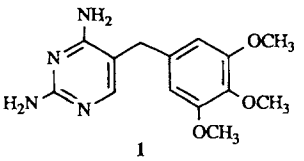
The understanding of noncovalent interactions in protein–ligand complexes is essential in modern biochemistry and should contribute toward the discovery of new drugs. In the present review, we summarize recent work aimed at a better understanding of the physical nature of molecular recognition in protein–ligand complexes and also at the development and application of new computational tools that exploit our current knowledge on structural and energetic aspects of protein–ligand interactions in the design of novel ligands. These approaches are based on the exponentially growing amount of information about the geometry of protein structures and the properties of small organic molecules exposed to a structured molecular environment. The various contributions that determine the binding affinity of ligands toward a particular receptor are discussed. Their putative binding site conformations are analyzed, and some predictions are attempted. The similarity of ligands is examined with respect to their recognition properties. This information is used to understand and propose binding modes. In addition, an overview of the existing methods for the design and selection of novel protein ligands is given.

Keywords: computer chemistry · drug design · molecular recognition · protein–ligand complexes

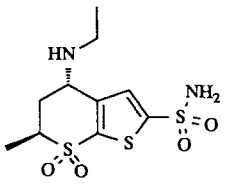
1. Introduction

Molecular recognition in protein–ligand complexes is responsible for the selective binding of a low molecular weight ligand to a specific protein.[1] In biological systems, the protein–ligand interactions serve a particular purpose, for example an enzymatic transformation, substance transportation, or signal transduction. They are usually noncovalent in nature. The experimentally determined binding constants K_i are typically in the range of 10^{-2} to 10^{-12} M, which corresponds to a negative free energy of binding of 10–80 kJ mol^{-1} in aqueous solution.[2]

Compounds that interact specifically with a particular protein of pharmacological interest can be useful in the treatment of various diseases. In particular, enzymes that regulate biochemical reactions are important targets in contemporary medicinal chemistry. Two representative examples should be mentioned: 1) The enzyme inhibitor trimethoprim (**1**), which inhibits the bacterial dihydrofolate reductase, has proven its potency in the treatment of bacterial infections for quite some time.[3] 2) Recently dorzolamide (**2**) has been approved as a drug against glaucoma.[4] This inhibitor of carbonic anhydrase is the first compound introduced into the market for which the methods of structure-based drug design contributed significantly to its discovery. Besides enzymes, another important class of protein targets are receptors such as G-protein-coupled receptors.[5]



1



2

Our current knowledge about the structures of protein–ligand complexes is derived mostly from globular proteins. Although a few membrane proteins have been studied by X-ray crystallography,[6–13] no high-resolution structure of a pharmacologically relevant, membrane-bound receptor is yet available. Therefore we restrict our discussion to data from small-molecule ligands bound to globular proteins, especially enzymes. However, we are confident that data from these systems are also applicable to membrane-bound receptor proteins.

An understanding of the principles of molecular recognition in protein–ligand complexes is important for structure-based ligand design. If the three-dimensional (3D) structure of a given protein is known, this information can be directly exploited in

the design process. Progress in the isolation and crystallization of pure proteins and the subsequent structure determination either by multidimensional NMR spectroscopy[14–17] or by X-ray crystallography[18,19] has led to an exponential increase in the number of solved protein structures. The August 1995 release from the Brookhaven Protein Database contains more than 4000 entries.[20] Furthermore, our knowledge on the structures of small organic molecules and their interactions with a structured molecular environment is based on the steadily increasing supply of crystal structures stored in the Cambridge Crystallographic Database (>140000 entries),[21–23] and the results obtained from high-level ab initio calculations.[24]

As a consequence, structure-based design and discovery of protein ligands has emerged as a new tool in medicinal chemistry.[25] In particular, the knowledge of the three-dimensional structure of a protein can be used to derive new protein ligands with improved binding properties (Table 1).[26–42] In most examples, a tailored optimization of a known lead structure has been achieved but in some cases the 3D structures have been used to design novel ligands "de novo". This new approach in drug discovery calls for the development of new software tools. Algorithms and methods along these lines have emerged in the literature. They are concerned with the following questions:

- What is the binding affinity of a novel ligand toward a particular receptor?
- What are the likely conformations of a ligand at the binding site?
- What are the similarities of different ligands in terms of their recognition capabilities?
- Where and in which orientation will a ligand bind to the active site?
- What strategies are available to select and rank new protein ligands?

Structure-based ligand design is an iterative approach. First of all, the crystal structure or a model derived from the crystal structure of a closely related homologue of the target protein, preferably complexed with a ligand, is required. This complex acts as the starting point for identifying the binding mode and conformation of a ligand under investigation as well as the essential aspects that determine its binding affinity. This knowledge is then used to create new ideas about how to improve an existing ligand or how to develop new alternative bonding skeletons. Computational methods supplemented by molecular graphics are applied to assist this step of hypotheses generation. At this stage, discussions with synthetic organic chemists take place to eliminate unfeasible proposals for synthesis. Then, the newly proposed compounds have to be synthesized or purchased and tested. Subsequently, their binding properties are determined by biochemical, crystallographic, and spectroscopic methods. By carefully analyzing the obtained results, the next cycle of ligand design is started. The important advantage of this approach is clearly the information provided by every new 3D structure of a protein–ligand complex. They reveal the binding

trypanosomal GAPDH	antiparasitic agent	[26,41]
glycogen phosphorylase	treatment of diabetis	[58]
carbonic anhydrase	treatment of glaucoma	[4,27,31]

Hans-Joachim Böhm, born in 1956 in Frankfurt am Main, studied chemistry in Karlsruhe, where he received his doctorate in theoretical chemistry under the supervision of Reinhart Ahlrichs in 1984. During work on his thesis, he spent one year as a DAAD fellow at the Department of Physical Chemistry at the University of Cambridge, where he worked with Ian McDonald and Paul Madden. In 1993 he habilitated in theoretical chemistry at the Universität Karlsruhe. From 1985 to 1987 he worked in the central research laboratory of Siemens AG in München, and subsequently from 1988 to 1996 at the Hauptlaboratorium of BASF AG in Ludwigshafen, where he was responsible for the development and application of new methods for structure-based drug design. In April 1996, he joined Hoffmann-La Roche in Basel.

H.-J. Böhm

G. Klebe

Gerhard Klebe, born in 1954 in Frankfurt am Main, studied chemistry at the university there, and received his doctorate in physical chemistry in 1982. As a fellow of the Studienstiftung he spent a year in Grenoble at the CNRS and ILL at the Crystallographic Institute of Erwin F. Bertaut. After post-doctorate periods in crystallography with Hartmut Fuess (Frankfurt) and Hans-Beat Bürgi (Bern, Switzerland), he joined the Hauptlaboratorium of BASF AG in 1984. In 1992 he habilitated in pharmaceutical and structural chemistry at the Universität Heidelberg. In the summer of 1995 he received a call to a chair in pharmaceutical chemistry at the Universität Marburg, and he took up the position in the winter semester 1996/97. His main field of interest is the determination and correlation of crystal structures, and the development and application of methods for structure-based drug design.

modes of the ligands. If a proposed ligand does not show the expected affinity, the analysis often gives an explanation for this finding. This can then provide new insights on how to improve the ligand.

Besides lead optimization this approach also offers a new route to create completely novel lead structures. Based on the structural features of a particular binding site, de novo design strategies propose novel molecular frameworks as putative ligands. The suggestions are based on extensive database searches or on the docking and assembly of smaller molecular portions into larger drug-size molecules.

Despite the above-mentioned advances in experimental methods, we still face a situation that for many of the pharmacologically relevant proteins no 3D structures to atomic resolution are available. What can structure-based ligand design contribute in the absence of an experimental structure? A comparative analysis of known ligands can provide some ideas about the essential prerequisites for receptor binding. Such similarity analyses of existing ligands with respect to their recognition properties can stimulate the discovery of novel molecules with deviating bonding skeletons. However, most crucial are reliable estimates about possible binding geometries within a set of ligands. This information can be derived from either pharmacophore hypotheses or systematic ligand rigidizations. Methods applied to handle these problems have to be developed and subsequently validated by using the growing knowledge base of structurally characterized protein–ligand complexes.

In the present review, we summarize some of the recent experimental results that shed some light on the physical nature of protein–ligand interactions. We do not attempt to review all recent work on the nature of these interactions but instead focus on structural aspects that provide a better understanding and description of the relationship between 3D structures and binding properties. Our own recent studies have focussed on the question of how the vast and rapidly growing knowledge base on the 3D structures of protein–ligand complexes and small organic molecules can be exploited in the development of computational procedures to predict binding affinities, molecular conformation, and binding modes. These different approaches are used for the design of novel protein ligands. Nevertheless, we will show in this contribution that ligand design still requires a substantial amount of basic research and thus is far from being a pure engineering technique.

2. Experimental Data Used To Correlate Structure with Binding Properties

Herein, we evaluate structural and binding data from different sources. Before we start to draw conclusions from these data, we would like to summarize some aspects concerning their accuracy. Binding site geometries are obtained from protein–ligand complexes, mainly determined by protein crystallography. Structures from these experiments are not resolved to atomic resolution; however, they are the only reliable source to learn about the protein–ligand interface. The average errors in atomic positions depend on the diffraction powers of the protein crystals. For a resolution of about 2.4 Å it has been estimated to about 0.4 Å in space[43–46] (as a general rule of thumb, the positional error amounts to approximately 1/6 of the resolution). Owing to improvements in the crystal growth techniques and the equipment used for diffraction experiments, the resolution of structure determinations has steadily increased over recent years. If a resolution of 1.5–1.8 Å is achieved and full occupancy of the binding pocket by the ligand is detected, the electron density is well defined and the molecules can be docked without ambiguities. However, in the range beyond 2.0–3.0 Å, or in the case of partial occupancy, the assignment becomes more difficult. Usually, small molecules are modeled into the trace of the electron density during structure determination.[47] The setting of the initial ligand conformation is the most crucial step in this procedure. Starting with some arbitrary conformation using standard bond lengths and angles of the ligand, subsequent rotations are manually performed about the various rotatable bonds of the ligand in order to optimize its fit to the electron density. Finally, the entire protein–ligand complex is refined to minimize the difference between observed and calculated structure factors. Due to an unsatisfactory observation-to-parameter ratio in protein structure determination, the manually adjusted conformation of the ligand is often kept rigid during refinement. At best, some degrees of torsional freedom are allowed to vary according to the applied force field and the structure–factor constraints.[48] However, these force fields are usually tailored toward protein structures, and their accuracy for normal organic molecules is difficult to assess. These limitations are of minor importance if data from crystals that diffract to high resolution are used, but become more serious with decreasing resolution, disorder, or partial occupancy.

For the statistical analyses of conformational preferences and interaction geometries, data from crystal structures of small molecules are used. Generally, these data are resolved to atomic resolution with low positional errors. The positions of hydrogen atoms are less precisely defined than those of heavier atoms by X-ray diffraction. However, the accuracy of structural data of small molecules can be influenced, for example, by crystal defects, inappropriate data collection and reduction, space group uncertainties, or disorder phenomena. Data are retrieved from the Cambridge Crystallographic Database[21–23] by using a predefined query structure. In some cases the matching of a chemical connectivity onto crystal coordinates is not unambigious. Thus, a small number of inadequate examples might still be contained in the data sets collected for the statistical evaluation as undetected noise.

The experimental binding data can be used to derive models for predictions of the affinities. Difficulties arise if binding data from different laboratories obtained on different proteins are compared. Variations in the experimental conditions (e.g., temperature, salt concentration) can have an impact on the data. For instance, several measurements have been published on the same protein–ligand complex, however, a variation of up to a factor of five[49] has been reported. This finding stands as a caveat and poses a limit to any theoretical description.

3. Noncovalent Interactions in Protein–Ligand Complexes

Low molecular weight ligands can interact with macromolecular receptors through both covalent and noncovalent interactions. Examples of ligands that form covalent bonds with the

target protein are trifluoromethyl ketone inhibitors of elastase,[50, 51] β-lactam antibiotics, aspirin, and other nonsteroidal antiinflammatory drugs.[52] However, in the present discussion, we shall exclude such examples and consider only noncovalently interacting ligands. The major contributions to noncovalent protein–ligand interactions are shown in Figure 1, in which the

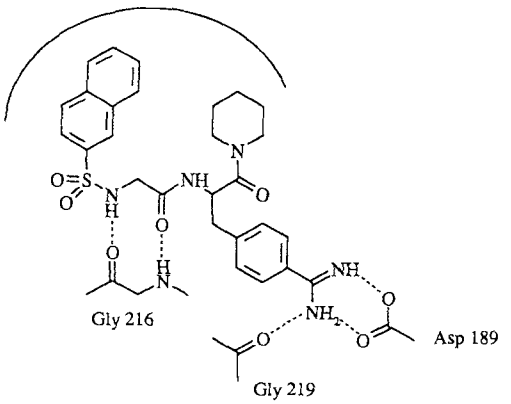

Fig. 1. Interactions between the serine protease thrombin and the thrombin inhibitor NAPAP, as observed in the X-ray crystal structure of the complex solved by Brandstedter et al. [53]. The arc denotes the lipophilic binding site.

thrombin–NAPAP complex[53] is used as an example. Usually, several hydrogen bonds are formed between the protein and the ligand.[54] In addition, oppositely charged functional groups of the protein and the ligand are paired. Furthermore, lipophilic groups of the ligand are found in hydrophobic pockets formed by side chains of the hydrophobic amino acids. The binding constant K_i and the related free binding enthalpy ΔG ($\Delta G = -RT\ln K_i$) have been determined for a large number of protein–ligand complexes. The binding constant K_i is routinely measured in numerous laboratories.

The knowledge-base from these data immediately leads to the following questions: 1) How does the binding constant relate to structural properties of a complex? 2) What are the important properties that allow a protein to bind a ligand tightly and selectively? 3) What makes a cleft in a protein structure a ligand binding site? Our current understanding of protein–ligand interactions is still far from being sufficient to fully answer these questions. The most important prerequisite appears to be good steric and electronic complementarity between protein and ligand. However, due to desolvation effects this criterion alone is not sufficient to fully describe tight binding of ligands.

3.1. Hydrogen Bonds

We have analyzed a set of 80 diverse protein–ligand complexes for which both the 3D structure and the binding constant are known. In Figure 2 the binding constants K_i are plotted against the number of hydrogen bonds formed between proteins and their ligands. Although the binding affinities roughly increase by one order of magnitude per hydrogen bond, it is evident that there is a very broad scatter of the data. Several protein–ligand complexes exhibit strong binding in the nanomolar range with no hydrogen bonds (e.g., the complex between the retinol binding protein and retinol[55]) or very few hydrogen bonds (e.g. that

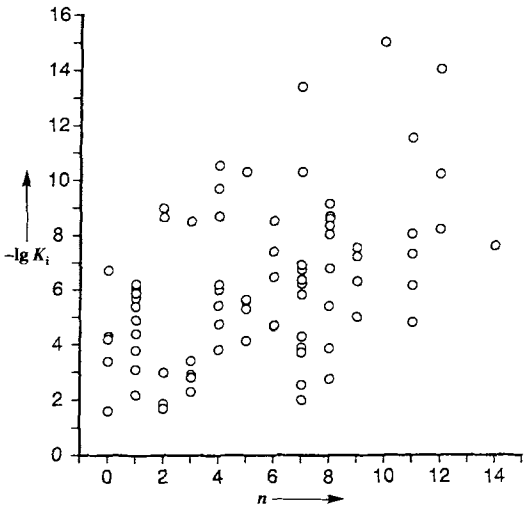

Fig. 2. The contribution from hydrogen bonds to the binding affinity of protein ligands. The logarithm of the binding constant K_i is plotted as a function of the number n of hydrogen bonds between the protein and the ligand (data were extracted from 80 structures of protein–ligand complexes determined by crystallography).

between an antibody and a steroid,[56] as well as that between an antibody and fluorescein [57]). The binding of these ligands arises from nonpolar interactions. Furthermore, some ligands form many hydrogen bonds with the protein but exhibit only very weak binding (e.g. glycogen phophorylase–glucose,[58] hemagglutinin–sialic acid,[59] gluthathion S transferase–gluthathion complexes[60]). Interestingly, these ligands are all characterized by the absence of significant lipophilic groups.

On the other hand, our current knowledge indicates that unpaired buried polar groups at the protein–ligand interface are strongly adverse to binding. A recent statistical analysis of high-resolution protein structures showed that in proteins less than 2% of the polar atoms are buried without forming a hydrogen bond.[61] There is a strong tendency to saturate polar groups in hydrogen bonds. Therefore, in the ligand design process one has to ensure that the polar functional groups either of the protein or the ligand will find suitable counterparts if they become buried upon ligand binding.

In addition to hydrogen bonding, there are other important polar interactions in protein–ligand complexes such as coordinative bonds with metal ions. For example, hydroxamic acids and thiols bind strongly to the zinc ion in the active site of metalloproteases.[62] This interaction is the most important contribution to binding in many metalloprotease-inhibitor complexes.

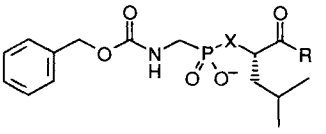
3.2. The Role of Solvent in Polar Protein–Ligand Interactions

The contribution of a hydrogen bond depends on its microscopic environment in the protein–ligand complex and can vary drastically. Desolvation effects can completely compensate for the intermolecular hydrogen bond so that the net contribution to binding is close to zero. On the other hand, large contributions to the binding affinity seem to arise from those hydroxy groups that constitute an essential structural element of a tran-

sition state analog in enzyme inhibitors.[63] As demonstrated by Matthews et al. for lysozyme mutants, the effect of buried and solvent-accessible salt bridges on protein stability differs considerably.[64]

An instructive example underlining the importance of desolvation effects was reported by Bartlett et al. for the binding of inhibitors containing phosphonamides, phosphonates, and phosphinates to thermolysin.[65] The measured binding constants are summarized in Table 2. The interactions between

Table 2. Binding constants K_i [μM] for inhibitors of thermolysin containing a phosphonamide (X = NH), phosphonate (X = O) or phosphinate (X = CH_2).



R	X = NH	O	CH_2
OH	0.76	660	1.4

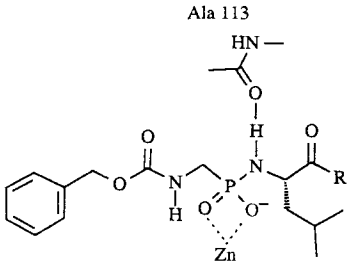
Phe-OH	0.08	53	0.07
Ala-OH	0.02	13	0.02
Leu-OH	0.01	9	0.01



Scheme 1. Interactions between the phosphonamide group of the thermolysin inhibitor ZG^{P}LR and thermolysin.

the phosphonamide moiety and thermolysin are shown in Scheme 1. The PO_2 group interacts with the zinc atom, and the NH group forms a hydrogen bond with the backbone carbonyl group of Ala113. The replacement of this NH group by a CH_2 group does not affect the binding affinity. These results can be understood by comparing the number of hydrogen bonds formed between the inhibitor and the protein or the solvent. The NH group of the phosphonamide forms a hydrogen bond with the protein. It also forms a hydrogen bond with a water molecule in solution. Therefore, ligand binding maintains the total number of hydrogen bonds. On the other hand, the CH_2 group is unable to form a hydrogen bond with thermolysin or with a water molecule in solution. Therefore, the hydrogen bond inventory is also balanced for the CH_2 group. In contrast, the analogous phosphonates exhibit a 1000-fold reduced binding affinity to thermolysin (see Table 2). This poor binding is a result of the repulsive electrostatic interaction between the oxygen atom of the ligand and the C=O group of Ala113, which both bear a negative partial charge. The oxygen derivative lacks a hydrogen bond, which is presumably present in solution. The X-ray structure analysis of the phosphonate revealed that this inhibitor does indeed bind to thermolysin in the same way as the phosphonamide.[66] Interestingly, the relative binding affinities of these three classes of inhibitors were correctly computed by Bash et al.[67] and Merz and Kollman[68] by using a thermodynamic perturbation method implemented with molecular dynamics simulation (see also Section 3.7).

Tight binding can be achieved if the total number of hydrogen bonds increases upon ligand binding. We believe that the complex avidin–biotin[69] achieves tight binding partly through a large number of hydrogen bonds that water molecules cannot form to the same extent at the binding site. The X-ray structures of both the complexed and uncomplexed protein have been determined. The binding site of the uncomplexed protein contains four water molecules, according to the X-ray structure. If we assume that this figure underestimates the actual number of water molecules in the binding site because mobile water molecules cannot be detected in the crystal structure, and employ a molecular mechanics calculation to fill the binding site with water molecules, we end up with nine to ten water molecules [Böhm, unpublished results]. These water molecules still form fewer hydrogen bonds with avidin than biotin.

One of the keys to a better understanding of protein–ligand interactions is the role of water. All direct protein–ligand interactions compete with interactions to water molecules. Both the ligand and the protein are solvated before complex formation. They lose part of their solvation shell upon binding, a process that involves various enthalpic and entropic contributions.[70–73] Hydrogen bonds are broken and new ones are formed. Furthermore, the solvent structure is reorganized at the protein–ligand interface. Water has the unique ability to form an extensive network of hydrogen bonds.[54] The hydrogen bond between two water molecules in the gas phase is strong: the dimerization enthalpy is roughly $-20\ kJ\,mol^{-1}$.[74, 75] Therefore, if the binding of a ligand simply replaces tightly bound water molecules and does not yield additional interactions, its binding affinity will be small. On the other hand, the replacement of loosely bound water molecules contributes to binding because both entropic (release of water molecules into bulk solvent) and enthalpic factors (favorable interactions with other water molecules) favor the replacement by the ligand. Unfortunately, detailed investigations of the role of water molecules in protein–ligand interactions have underlined a fairly complex picture.[76] For example, results from recent calorimetric studies suggest that in certain cases solvent reorganization provides more than 25% of the observed enthalpy of binding.[77] An upper limit of $28\ J\,mol^{-1}\,K^{-1}$ for the entropy gain from the release of a water molecule into bulk solvent was given by Dunitz[78] based on thermodynamic arguments.

Interestingly, several small molecules containing functional groups, which are frequently involved in protein–ligand interactions, do not associate in water. For example, acetic acid does not form a stable complex with guanidine in water.[79] Similarly, simple amides do not associate in water.[80] Apparently, the direct interaction between the small molecules is not strong enough to override the factors favoring the dissociation such as interactions with solvent molecules. As further discussed by Williams and others,[70–73] there is also an entropic penalty for complex formation, which may overcompensate favorable interactions.

3.3. Lipophilic Interactions

A plot of the binding constants K_i against the lipophilic contact surfaces using the same 80 protein–ligand complexes as for the hydrogen-bond statistics (see Fig. 2) is given in Figure 3.

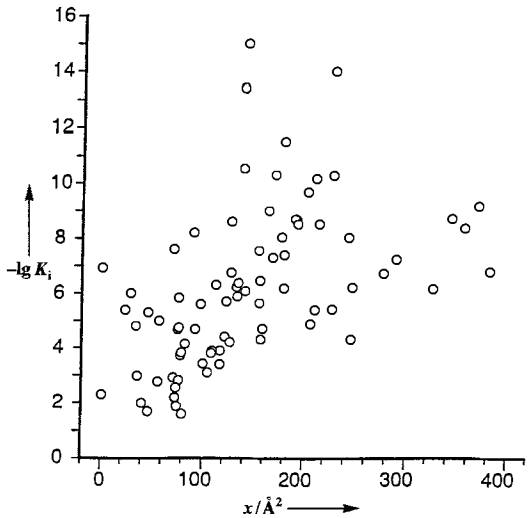


Fig. 3. The contribution from lipophilic contacts to the binding affinity of protein ligands. The logarithm of the binding constant K_i is plotted as a function of the lipophilic contact surface x between the protein and the ligand (data were extracted from 80 structures of protein–ligand complexes determined by crystallography).

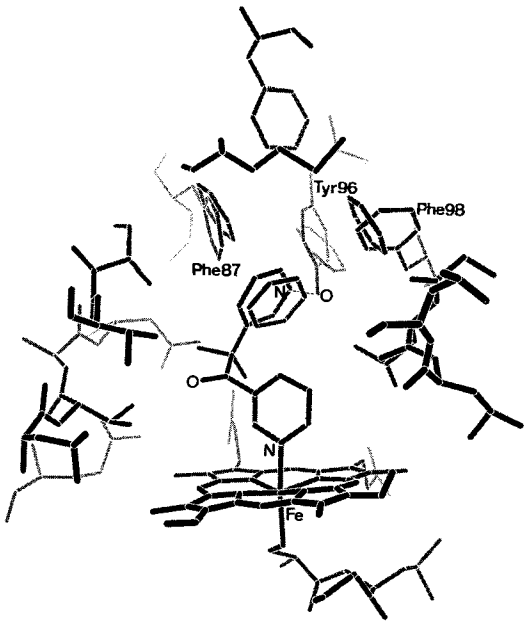

Fig. 4. Structure of the metyrapone–cytochrome $P450_{CAM}$ complex determined by crystallography, superimposed with a section from the crystal packing of benzene. Four phenyl moieties fall close to the aromatic groups of the ligand, Phe87, Tyr96, and Phe98.

There is a correlation between the binding affinity and the lipophilic contact surface, but the spread of data is again large. Retinol is an example of a ligand that binds to the protein (retinol-binding protein) solely by lipophilic interactions.[54] The X-ray structure analysis of this complex shows no hydrogen bonds between the protein and the ligand. The binding constant K_i is 190 nM, corresponding to a free energy of binding of $-38\ kJ\,mol^{-1}$. The total molecular surface of retinol, as determined by a grid-based program,[81] amounts to 326 $Å^2$ of which 295 $Å^2$ (90%) become buried upon binding. On the other hand, ligands such as SO_4^{2-} have no lipophilic contact surface, but are tighly bound to an appropriate receptor (e.g. SO_4^{2-} binds to the sulfate binding protein with $K_i = 100$ nM[82]). The generally accepted view is that lipophilic interactions are mainly due to the replacement and release of ordered water molecules and are therefore entropy-driven.[83, 84] The entropic gain arises because the water molecules are no longer positionally confined. There are also enthalpic contributions to lipophilic interactions. Water molecules occupying lipophilic binding sites are unable to form hydrogen bonds with the protein. If they are released they can form hydrogen bonds with other water molecules. In addition, there is a favorable interaction between the lipophilic groups in contact (mainly dispersion interactions).

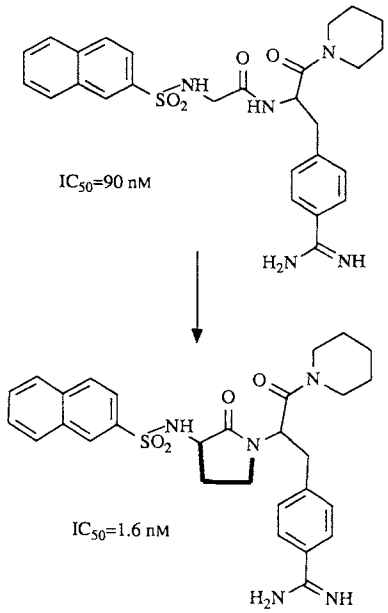
Recently the role of specific interactions between aromatic rings has attracted increasing attention.[85] A statistical analysis of the interaction between phenyl rings in proteins reveals a preference for contact geometries that lead to electrostatically favorable quadrupole–quadrupole interactions.[86] In addition, data from the binding of aromatic guest molecules to cyclophanes in water suggest that the binding is enthalpy-driven.[87] We observed a striking similarity between the noncovalent contact patterns of aromatic rings found in the crystal packing of benzene and in several protein–ligand or aromatic host–guest complexes.[88] An example is shown in Figure 4. Furthermore, due to their large polarizability, aromatic side chains can also interact with the positive charge of a quarternary ammonium group. This type of interaction is found for example in the complex of acetylcholinesterase with acetylcholine.[89] It also contributes significantly to the binding in host–guest complexes.[90] On the other hand, results obtained from many different protein–ligand complexes indicate that a phenyl group occupying a lipophilic binding site can be replaced by a cyclohexyl group without loss of binding affinity.[91] In addition, recent results on the effect of aromatic interactions on conformational preferences appear to contradict the notion of a dominant role of this type of interaction.[92]

3.4. Additivity of Protein–Ligand Interactions

An important aspect of protein–ligand interactions is the additivity of group contributions. Data from protein mutants yield estimates of $-5 \pm 2.5\ kJ\,mol^{-1}$ for the contribution from individual hydrogen bonds to the binding affinity.[93, 94] Similar values have been obtained for the contribution of an intramolecular hydrogen bond to protein stability.[95–97] The consistency of values derived from different proteins suggests some degree of additivity in the hydrogen-bonding interactions. In a recent analysis of thermolysin-inhibitor complexes, Bohacek and McMartin[98] observed a linear relationship between the binding constant and the number of hydrogen bonds and lipophilic contacts. Similar observations have been reported by Schneider and coworkers for the binding of host–guest complexes.[99] The concept of pairwise additivity of noncovalent interactions in protein–ligand complexes is also supported by the success of simple empirical approaches,[2, 81, 100–102] which assume this additivity.

Similar to polar interactions, the additivity of apolar interactions has been the subject of several investigations. For lipophilic interactions, the free enthalpy of binding is proportional to the lipophilic surface buried from solvent.[103–105] Contributions to ΔG for lipophilic surfaces that are removed

from the aqueous solution and get buried upon binding, range from 80[106-108] to 200 J mol^{-1} Å^{-2}).[109] On the other hand, the binding of some inhibitors to carboxypeptidase-A offers a striking example for nonadditive effects. The replacement of the C-terminal alanine by phenylalanine in the inhibitor ZFA^{P}(O)A increases its lipophilic surface. As a consequence, the binding affinity is enhanced by more than a factor of 50000.[110] The replacement of the second alanine residue by valine also increases the lipophilic surface and increases binding affinity by an additional factor of 100. ZFV^{P}(O)F binds to carboxypeptidase-A with $K_i = 10-27$ fM. The first strong affinity enhancing replacement (Ala → Phe) results in a perfect filling of a lipophilic pocket, which was unoccupied in the complex with the Ala derivative. The second less enhancing replacement (Ala → Val) has two effects. First, the larger side chain of Val results in an increased intermolecular lipophilic contact with the protein. Second, there is also a larger intramolecular lipophilic contact in the protein-bound conformation of the Val derivative than in that of the Ala peptide. The second effect stabilizes the bound conformation in solution, resulting in a preorganization of the ligand. This phenomenon of minimization of the lipophilic surface in aqueous solution was termed "hydrophobic collapse" by Wiley and Rich.[111] Similar behavior is observed for the thrombin inhibitor D-Phe-Pro-boro-Arg (where "boro" of boro-Arg indicates that the carbonyl group of the amino acid residue is replaced by $B(OH)_2$).[112] The intramolecular contact between the side chains of the amino acids D-Phe and Pro stabilizes the receptor-bound conformation. NMR studies reveal a conformation for this molecule in water that is very similar to the receptor-bound one. The authors estimate that the preorganization of the ligand increases the binding affinity by a factor of 10. Other examples of preorganized protein ligands have been reported.[113] Improved binding due to preorganization is clearly a nonadditive phenomenon.



Scheme 2. The introduction of a lactam (highlighted as thick bonds) into the known thrombin inhibitor NAPAP (top) reduces the flexibility and improves the binding affinity by a factor of 60.

3.5. The Role of Ligand Flexibility and Mobility

The flexibility of the ligand is another important factor in determining the strength of protein–ligand interactions. In this section we discuss energetic aspects (structural aspects are described in Section 4). If a flexible and a rigid ligand form the same pattern of hydrogen bonds and lipophilic interactions with the protein, the rigid ligand will exhibit much stronger binding. A central tenet in structure-based ligand design is that the binding affinity of a flexible ligand will be improved if its conformational motion can be restricted to that of the bound state.[114] Several studies have been reported on the design of constrained inhibitors that are found to bind much more tightly than the unconstrained structure.[36, 37, 115] The consequence of conformational rigidization is illustrated in a study by Mack et al. on inhibitors of thrombin.[36] The X-ray structure of thrombin complexed with the inhibitor NAPAP was used to design novel inhibitors with improved binding properties. The 3D structure suggested the introduction of a lactam ring as shown in Scheme 2. The conformational immobilization by the additional ring reduces the number of rotatable bonds in the inhibitor. The binding affinity of the new inhibitor to thrombin is 60 times higher than NAPAP.

Experimental data indicate that in several cases the ligand still has considerable mobility when bound to the protein. An interesting example is the binding of camphane, adamantane, and thiocamphor to cytochrome $P450_{CAM}$.[116] These ligands do not form hydrogen bonds to the enzyme and can freely rotate in the binding site. As a result of the residual mobility they are hydroxylated without clear stereoselectivity. In a recent molecular dynamics simulation of this system, a good correlation between the calculated statistical probability of the various ligand orientations in the active site with the experimentally observed hydroxylation rates was observed.[117]

Crystallographic and thermodynamic studies, performed in parallel by Weber et al.,[118] demonstrate that the water displacement from the ligand binding site, and the retention of considerable ligand flexibility in the bound state contribute favorably to entropy changes upon ligand binding. In a series of streptavidin ligands, the ligand exhibiting the highest binding affinity appears to have a larger residual mobility than the other compounds.[118] Similar results have also been obtained for the binding of small guest molecules to α-, β-, and γ-cyclodextrins in water.[119]

3.6. Enthalpic and Entropic Contributions to Protein–Ligand Interactions

In summary it appears that the physical nature of ligand binding is more complicated than has been assumed by many workers in the field. Figure 5 summarizes various effects that determine the binding affinity. The ligand and the protein binding site are fully solvated before binding; the polar groups form hydrogen bonds with the solvent. The ligand is usually flexible with several rotatable bonds and can, in principle, adopt a potentially large number of low energy conformations (see Section 4). The protein is also flexible and its conformation in the unbound state can be significantly different from that in the protein–ligand complex. Upon binding to the protein, the lig-

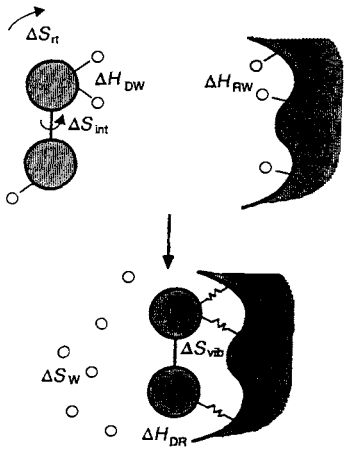


Fig. 5. Factors that influence the strength of protein–ligand interactions. In the uncomplexed state (top), the protein receptor (R) and drug ligand (D) both interact with water molecules (small circles, ΔH_{DW}, ΔH_{RW}). On complexation, an enthalpic contribution ΔH_{DR} arises from direct protein–ligand interactions. In the unbound state the ligand has an overall rotational and translational entropy ΔS_{rt} and an internal entropy ΔS_{int} owing to conformational degrees of freedom. Upon binding, both terms change; they are (partially) compensated by an increase in entropy due the liberation of bound water from the surface and from the binding site of the protein and the ligand (ΔS_W). In addition, new low-frequency vibrational modes associated with the noncovalent protein–ligand interactions contribute to this value (sketch adapted from Andrews et. al [2]).

and loses part of its solvation shell and replaces the water molecules that occupy the binding site. This process involves the breaking of several hydrogen bonds with water molecules. The ligand is then able to form favorable direct interactions with the protein. As a consequence of binding, the ligand and also the protein may change their conformation and also lose some internal flexibility. Due to steric restrictions of the binding site, certain parts of the conformational space of the ligand are no longer accessible.

ΔG has an enthalpic and an entropic component ($\Delta G = \Delta H - T\Delta S$). Both individual contributions to binding can be obtained, for example, from microcalorimetric measurements.[120] Unfortunately, these important experimental studies on the enthalpic and entropic contributions to ligand binding are still sparse. Nevertheless, the available data[121–124] suggest a number of conclusions. First, and most important, all studies show that there is no correlation between the binding enthalpy ΔH and the free binding enthalpy ΔG. For a given protein, different ligands can bind by enthalpy- or entropy-driven mechanisms. For example, the binding of biotin to streptavidin is enthalpy-driven, whereas the binding of azobenzene ligands to the same protein is entropy-driven.[125] If ΔH is plotted against ΔS for a set of related protein ligands, frequently a straight line is obtained. This enthalpy–entropy compensation has been explained by a solvent reorganization effect.[126]

The experimental determination of ΔH and ΔS sometimes yields surprising results. For example, Connelly et al.[94] studied the thermodynamics of hydrogen bond formation in the complex of FK506 or rapamycin with FK506-binding protein. Binding to the wild type and to the mutant Tyr82 → Phe was studied. From X-ray studies, it is known that the side chain of Tyr82 forms a hydrogen bond with the ligand. If Tyr82 is replaced by Phe, one hydrogen bond between the protein and the ligand is lost. As expected, the ligand binding affinity is slightly reduced by the replacement of Tyr with Phe. The free enthalpy difference is $4 \pm 1.5\ kJ\,mol^{-1}$. Somewhat unexpectedly, however, this destabilization is attributed to an entropy loss. In other words, the formation of this particular hydrogen bond is enthalpically unfavorable but entropically favorable. The entropy gain appears to be mainly due to the replacement of two water molecules.

In order to understand and be able to make predictions about ligand binding, a partition of the free energy of binding into individual, physically interpretable terms is desirable; however, these attempts are not without problems. In an early quantitative analysis of drug–receptor interactions by Andrews et al.,[2] it was assumed that a bound ligand loses its translational and rotational degrees of freedom (both rigid body rotation and internal rotations) completely. Rather high contributions adverse to binding ($\Delta G_{trans.,rot} = +48\ kJ\,mol^{-1}$, $\Delta G_{rot.,bond} = +5.6\ kJ\,mol^{-1}$) have been reported. As a consequence of this assumption, the analysis of binding data yielded large contributions for the individual functional groups to binding. Several studies by Williams and coworkers[127] have highlighted the difficulty in separating these contributions. One important conclusion from their work is that ligand binding leads to a loss in entropy that is significantly smaller than estimated earlier by Page.[70] Apparently, a significant residual vibrational motion remains for the bound ligands. Recently Murphy et al.[128] showed that the calculation of the translational entropy loss using the Sackur–Tetrode equation produces largely overestimated values. They argue that the volume available for the movement of a ligand in solution and in a complex are similar. They conclude that the cratic entropy (contribution arising from the mixing of solute and solvent molecules) provides the best estimate for the loss of translational entropy.

3.7. The Role of Computational Methods in Predicting Ligand Binding Affinities

The observation that both ΔH and ΔS contribute significantly to ligand binding has important consequences for the theoretical description of protein–ligand interactions. A popular approach for investigating the energetics of protein–ligand interactions is to perform a molecular mechanics force field optimization and then to analyze the interaction energies of the optimized structure. Several groups have tried to correlate experimentally determined binding affinities with protein–ligand interaction energies obtained from a force field calculation. For one set of HIV-protease inhibitors,[129] and for an ensemble of thrombin inhibitors,[130] a good correlation was observed. However, this approach will only be successful if the entropic contributions to the binding are similar for different ligands; although, this is not generally the case. Therefore, interaction energies obtained from molecular mechanics calculations should in general not be expected to correlate with measured free energies of binding.

In principle, relative free enthalpies of binding can be calculated, for example, from free energy perturbation (FEP) or thermodynamic integration (TI) methods.[131] Some impressive results have been obtained by using these techniques.[132, 133] The FEP and TI calculations have provided valuable insights into

the physical nature of specific protein–ligand interactions. For example, the relative binding affinities in a series of thermolysin inhibitors[67, 68] and HIV-protease inhibitors[132] were correctly predicted. The advantage of these methods is the rigorous treatment of basically all effects in protein–ligand interactions, including solvent effects and conformational changes. In practice, however, the methods suffer from convergence problems and therefore require very long simulation times. Furthermore, the calculations are still based on several approximations such as the use of a force field. In addition, at present the approaches are only capable of predicting differences in binding affinities between closely related ligands. Therefore, it appears quite difficult to accurately predict binding energies of protein–ligand complexes, even if the 3D structure of the complex is known. The rigorous modeling of such interactions is still a considerable challenge.[134] In view of the current limitations with the FEP and the TI approach, a number of different approaches have been evaluated for predicting binding affinities. Recently Warshel et al.[135] have shown that the semimacroscopic version of the Protein Dipoles Langevin Dipoles method (PDLD/S) can provide a good estimate for ΔG in a reasonable amount of computer time on current workstations.

In view of the importance of interactions with the solvent, a substantial amount of work has been invested into the development of methods for calculating solvation energies, in particular free energies of solvation.[136] Empirical[137, 138] and quantum mechanical methods[139, 140] have been used to calculate solvation energies of small organic molecules.

3.7.1. Scoring Functions for Protein–Ligand Complexes

The prediction of the binding affinity of a ligand is currently the most challenging problem in computer-aided ligand design. We have tested a simple empirical scoring function for predicting binding affinities for a protein–ligand complex with a known 3D structure.[81] The purpose of the scoring function is to prioritize the hits obtained from a computer program for de novo design or from a search of 3D structures in a database (see also Section 5). The noncovalent protein–ligand interactions are assumed to be additive. The function takes into account hydrogen bonds, ionic interactions, the lipophilic protein–ligand contact surface, and the number of rotatable bonds in the ligand, and is formulated according to Equation (a).

$$\Delta G_{\text{binding}} = \Delta G_0 + \Delta G_{\text{hb}} \sum_{\text{H-bonds}} f(\Delta R,\Delta\alpha) + \delta G_{\text{ionic}} \sum_{\text{ionic int.}} f(\Delta R,\Delta\alpha) + \Delta G_{\text{lipo}} |A_{\text{lipo}}| + \Delta G_{\text{rot}} \text{NROT} \quad \text{(a)}$$

$f(\Delta R,\Delta\alpha)$ is a penalty function that accounts for large deviations of the hydrogen bonds from ideal geometries.[81] It tolerates small deviations of up to 0.2 Å and 30° from the ideal geometry that are often due to positional uncertainties in the X-ray structures. ΔG_0 is a contribution to the binding energy that does not directly depend on any specific interactions with the protein, but is associated with the overall loss of translational and rotational entropy of the ligand on binding. ΔG_{hb} describes the contribution from an ideal hydrogen bond. ΔG_{ionic} is the contribution from an unperturbed ionic interaction. ΔG_{lipo} is the contribution from lipophilic interactions, and is assumed to be proportional to the lipophilic contact surface A_{lipo} between the protein and the ligand. The final parameter ΔG_{rot} describes the loss of binding energy due to the immobilization of internal degrees of freedom in the ligand. NROT is the number of rotatable bonds.

The data set used for the calibration of the function consisted of 45 protein–ligand complexes. For this set, the energy function reproduced the binding constants (ranging from 2.5×10^{-2} M to 4×10^{-14} M, corresponding to binding energies between -9 and -76 kJ mol^{-1}) with a standard deviation of 7.9 kJ mol^{-1} corresponding to 1.4 orders of magnitude in binding affinity. The individual contributions to protein–ligand binding obtained from the scoring function are: for an unperturbed uncharged hydrogen bond (ΔG_{hb}): -4.7 kJ mol^{-1}, an ideal ionic interaction (ΔG_{ionic}): -8.3 kJ mol^{-1}, lipophilic contact (ΔG_{lipo}): -0.17 kJ mol^{-1} Å^2, one rotatable bond in the ligand (ΔG_{rot}): $+1.4$ kJ mol^{-1}. The constant contribution (ΔG_0) obtained from the calibration is $+5.4$ kJ mol^{-1} (adverse to binding). The present approach is fast: For a given protein it allows the scoring of 10 small ligands per second on a current single-processor UNIX workstation.

We are currently investigating an improved scoring function. This function contains three additional new terms. The first new term (ΔG_{aro}) accounts for specific interactions between aromatic rings. The replacement of water molecules that form hydrogen bonds with the protein ($\Delta G_{\text{H-bonded water}}$) and the replacement of those water molecules that do not form a hydrogen bond ($\Delta G_{\text{not H-bonded water}}$) are considered as different contributions. In addition, the terms ΔG_{hb} and ΔG_{ionic} are now modulated by a new factor to discriminate between buried interactions and solvent-accessible interactions. The new scoring function is currently based on 80 protein–ligand complexes. It is applicable to a broader range of protein–ligand complexes [Böhm, unpublished results].

4. Molecular Conformation at the Binding Site

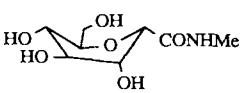
The binding of a small-molecule ligand to a protein requires shape and property complementarity. In the course of binding they have to adapt to each other in order to achieve a successful recognition process. The small-molecule ligand, which is usually the more flexible partner with several rotatable bonds, can adopt a large variety of different low-energy conformations. Hopefully one of these corresponds to the receptor-bound situation. An appropriate handling of conformational flexibility is essential for the prediction of ligand binding and binding affinities.

4.1. Methods for Generating Multiple Conformers

A variety of computational search techniques have been developed to generate a large number of multiple conformers for a given drug-size molecule (< 500 D).[141–143] These methods generate low-energy conformers that correspond to local minima on a particular energy surface. The efficiency and reliability of these methods is usually assessed by the following criteria: 1) Is the global minimum found? 2) How many

local minima are detected within a particular energy range above the global minimum. Mostly, in this context the ligand is considered alone, not just for the sake of simplification to keep the problem computationally tractable, but often because no information about the protein binding site is available. Therefore, the important question arises whether ligands adopt conformations at the protein binding site that correspond to local energy minima also exhibited in the isolated state. One can imagine that a local environment is capable of modifying conformational properties, and therefore an appropriate definition of system boundaries becomes essential. In the consideration of ligand–receptor interactions, the system should include, at least, the ligand, the protein, and the neighboring solvent molecules or a membrane environment. With respect to these considerations, is a limitation to local minima of the ligand itself justified and can we expect any relevant conclusions?

The best approach to address this latter question is to start with experimental data on protein–ligand complexes, determined, for example, by protein crystallography.[20] We have to remember that protein structures are resolved to a limited resolution. Ligand conformations are fitted into the trace of the electron density. Recently the need for caution in setting initial ligand conformations for protein structure determination has been indicated by a series of structure determinations of glucose-type ligands with glycogen phosphorylase.[144] As found in related complexes of this enzyme, the glucose derivative **3** (a rather weakly binding inhibitor, K_i = 37 mM) was fitted to the difference Fourier electron density with the usual, energetically most favored chair conformation of a pyranose ring. Since only an unsatisfactory fit was obtained (data to 2.3 Å), the molecular structure of the ligand was investigated in parallel by X-ray crystallography.[145] Surprisingly, a skew-boat conformation was observed. The unexpected ring conformation in this derivative also gave a much better fit to the electron density in the protein structure. In the development of nonpeptidic seven-membered cyclic ureas as HIV-protease inhibitors, crystallography of small molecules has been used to confirm unusual conformational preferences observed at the protein binding site.[29]



3

4.1.1. Conformational Libraries Derived from Crystal Structures

The above-mentioned examples might suggest that the crystal structure of a ligand is a good starting point to collect information about the receptor-bound conformation. In several cases, such as the nonpolar ligand retinol, the adopted conformation at the binding site is indeed very similar to that found in the corresponding crystal structure of the ligand.[146] However, the inspection of a larger data set of ligands shows that the reliance on just the crystal structures of the ligand itself is not, in most cases, an infallible and reliable indicator of a biologically active conformation.[147, 148] Perhaps, this correspondence is to some extent given for rather nonpolar and rigid ligands in which the environment is composed of many isotropically distributed atom/atom potential contributions. In such cases, the adopted conformation is mainly determined by intramolecular forces, and no significant perturbations arise from strong directional interactions with the crystal or active-site environment. Presumably, this assumption is also valid for hydrophobic portions of a ligand skeleton.

Which conclusions can be drawn for polar ligands? Let us consider citric acid as an example. In small-molecule crystal structures it has been found to adopt a number of distinct conformations.[146] Therefore, it appears difficult to predict a correct receptor-bound conformation for this molecule, for example at the binding site of the enzyme citrate synthase. Fortunately, its geometry has been determined in the complex with this enzyme. The torsion angles in this structure are similar to those found in several small-molecule crystal structures. But, instead of using individual structures to suggest a single possible conformation, we rather analyze them in terms of conformational preferences adopted in various molecular and crystal environments. This approach provides important information also relevant for conformations adopted in the structured environment of a protein binding site. Through exhausive searches of the Cambridge Crystallographic Data Base[21–23] we have retrieved conformational libraries for torsional fragments. These libraries can be used in a conformational analysis to generate biologically relevant conformations.[146, 149]

To illustrate the key aspects of this approach, some results are given. A data set of 80 ligands observed in crystallographically determined protein structures has been analyzed for frequently occurring torsion angle fragments. The considered examples show rotatable bonds between two sp^3 or an sp^2 and an sp^3 center. The angular distribution in these torsional fragments is shown in Figure 6. For comparison, univariate statistics on equivalent fragments observed in small-molecule crystal structures were also compiled.[141] Apparently, comparable distributions are obtained. The angular ranges outlined by the higher populated small-molecule data coincide convincingly with those obtained from protein complexes. These findings underline the relevance of torsional libraries as guidelines for the prediction of putative binding-site geometries.

4.1.2. Comparison of Conformational Preferences in Crystal Packing and in the Environment of a Binding Site

The inhibitor trimethoprim (**1**) has been cocrystallized with dihydrofolate reductase (DHFR) from two different species (*Escherichia coli* and chicken liver).[150] Surprisingly, it adopts distinctly different conformations at the binding sites of both proteins. In the chicken liver enzyme, a butterfly-like conformation is observed (torsion angles between the bridging atom and the two phenyl rings: $\tau_1/\tau_2 = -85°/102°$), whereas in the bacterial enzyme, the aromatic rings are oriented nearly perpendicular to each other ("twisted" conformation, $\tau_1/\tau_2 = 177°/76°$). The skeleton of trimethoprim resembles that of a diphenylmethane fragment. A statistical analysis of the torsion angles in crystalline diphenylmethane derivatives[151, 152] reveals both receptor-bound conformations to be also populated in low-molecular weight structures. In these, the twisted conformation is more frequently adopted than the butterfly-like one, suggesting that the latter is higher in energy. Interestingly, the inhibitor shows higher affinity for the bacterial enzyme, and the lower

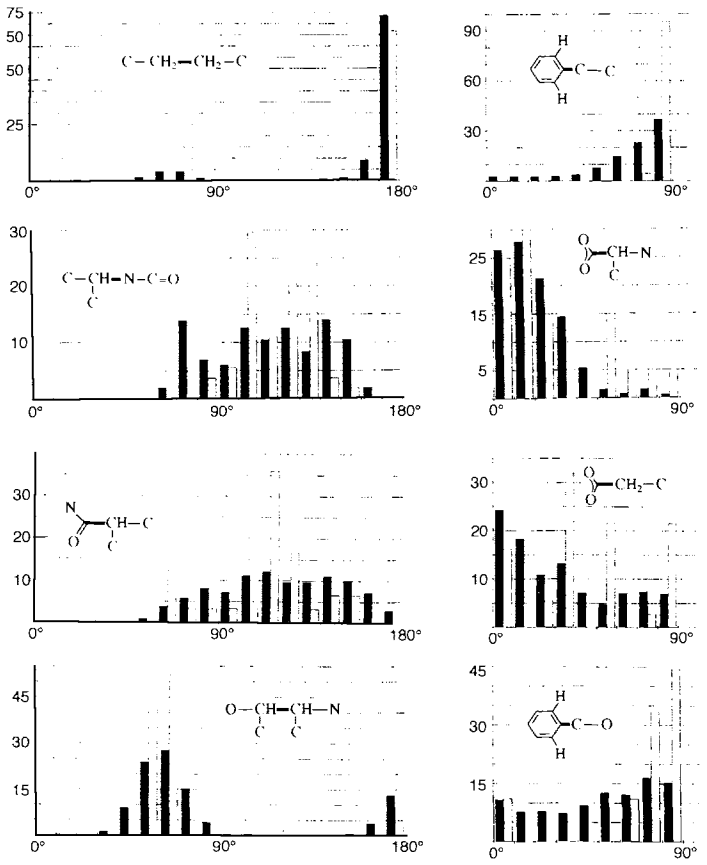


Fig. 6. Histographical distribution of torsion angles found in frequently occurring fragments (see formulae) in small organic molecules (solid columns) and ligands bound to proteins (open columns). Data are taken from crystal structures either of small molecules or protein–ligand complexes. Each distribution (y axis) is given as a percentage of the total number of structures considered in each case.

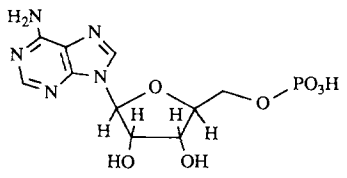
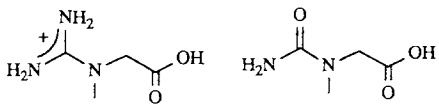
energy of the twisted conformation may be partially responsible for the greater binding affinity.

In order to analyze the correspondences in conformational properties in more detail, we have considered a ligand for which enough data are available to perform statistics both on protein and small-molecule crystal data. Adenosine and guanosine monophosphate fragments **4** are frequently found in proteins as part of cofactors. In parallel, they have often been studied in small-molecule crystal structures.[141, 146] Two distinct conformations of the ribose ring (C(2′)- and C(3′)-*endo*[153, 154]) cover the major part of structural variances either in protein or small-molecule structures. The remaining variance can be ascribed to the torsion angles in the phosphate side-chain and to the purine moiety. A reasonable agreement is found between small-molecule and protein data for the two angles next to the phosphate group (C-C-O-P about 180°, C-O-P-O about ±60°, 180°) and to the purine base (broad distribution between 0 and 90°). Data from protein structures are less sharply clustered, a result that may be due to their limited accuracy. The side-chain angle adjacent to the ribose ring shows remarkable differences between protein and small-molecule structures. In the low-molecular weight compounds, the O-C-C-O fragment mostly occurs in a *g*-conformation, whereas for the protein environment frequently g^+ and g^-, and a considerable number of examples with *trans* geometry are observed. In agreement with this observation, the distance between phosphorus and the purine moiety is found to be about 6.5 Å in most small-molecule structures. In the protein cases, this distance covers the entire range between 6 and 9 Å with a pronounced cluster of values at 8.8 Å. In their crystal structures, the molecules preferentially adopt a compact folded conformation, whereas in the protein environment both geometries, a compact and an extended one, are observed. The preference for the folded conformation of the nucleotides in the small-molecule structures is also observed in solution. In most crystalline examples, it results from a stabilization through a cation or a bridging water molecule that mediates an interaction between the phosphate group and a basic nitrogen atom of the purine moiety. The extended conformation, more frequently found in proteins, is supposedly observed because a long and polar molecule can expose its polar groups better and thus binds more efficiently to the surface of a globular protein. This fact indicates that special conditions in the different environments can bias the statistics.

For polar molecules, which are embedded into a network of strongly directional interactions, such as hydrogen bonds, the environment has a strong impact on the adopted conformation. As a consequence, in some protein structures ligands are observed in arrangements that appear to correspond to "high-energy" conformations, "high" with respect to the conformation adopted in the isolated state. For example, in the enzyme creatinase, the natural substrate creatine **5** or a related inhibitor carbamoyl sarcosine **6** occur with a twisted guanidinium or carbamoyl moiety.[155, 156] This moiety forms strong charge-assisted hydrogen bonds. For the isolated molecule one would expect a planar geometry of the unsaturated π-system. Nevertheless, by using small-molecule crystal data as a reference, possible perturbations in a structured environment toward twisted geometries are indicated. In these latter structures the guanidinium group forms strong charge-assisted hydrogen bonds similar to those in creatine in the enzyme. Quantum chemical studies show that the energy difference between twisted and planar geometry is dramatically reduced in a polar environment with hydrogen bonds.[157, 158] These polarizing interactions result in a redistribution of the electron density in the molecule. Accordingly, the barrier to rotation is substantially reduced. Experimental evidence for the pronounced redistribution of the molecular electron density on going from the isolated state to a structured molecular environment originates from precise diffraction data, which determines the charge density distribution in crystals.[159]

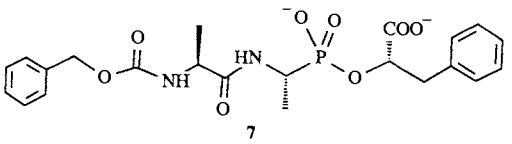


4



5 **6**

Peptidic inhibitors of carboxypeptidase A such as **7** bind a *cis*-oriented peptide bond in a terminal carbamate moiety.[160]

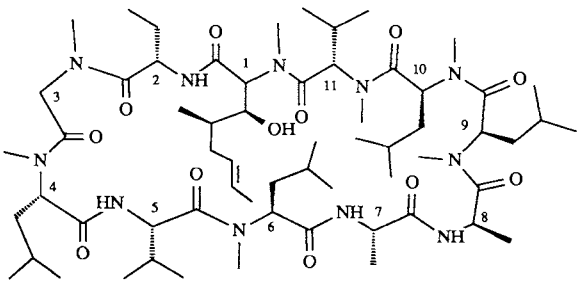


7

Apart from proline residues, *cis* conformation is rarely observed in noncyclic peptides.[161] A statistical evaluation of small-molecule crystal data shows a clear preference for *trans* peptide bonds in carbamates; however, a remarkable number of *cis*-oriented structures occur. Closer inspection of their molecular structures does not provide a simple "intramolecular rationale" for the observed preference. In contrast, the ester bond in the carbamates occurs nearly exclusively in a *trans* conformation.

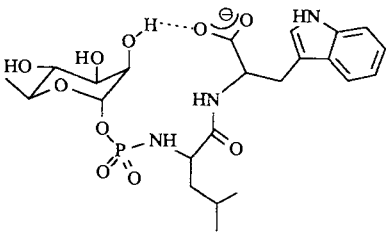
4.1.3. Intramolecular Hydrogen Bonds in Receptor-Bound Conformations

The importance of environmental effects on molecular conformations is particularly apparent if the formation of possible intramolecular hydrogen bonds is considered. Geometry optimizations performed on isolated molecules capable of forming hydrogen bonds will result in local minima showing intramolecular hydrogen bonds. For example, a conformational analysis on citric acid, performed in vacuum, only generates low-energy conformers with intramolecular hydrogen bonds.[146] However, at the binding site of citrate synthase, solely intermolecular hydrogen bonds with the protein are observed. The presence of intramolecular hydrogen bonds at the binding site appears to be very rare. Usually all groups capable of forming hydrogen bonds are involved in intermolecular interactions with the protein. For example, in the crystal structure and in nonpolar solvents the undecapeptide cyclosporin A (**8**) forms four intramolecular hydrogen bonds that organize the molecule in a β-sheet geometry.[162, 163] At the binding site of cyclophillin, this intramolecularly organized fold is completely disrupted:[164] Virtually all groups intramolecularly satisfied by hydrogen bonds are turned inside-out. The ligand now forms solely intermolecular hydrogen bonds with the protein. NMR studies performed on polar derivatives of cyclosporin in water show a conformation related to the one adopted at the binding site.[165]

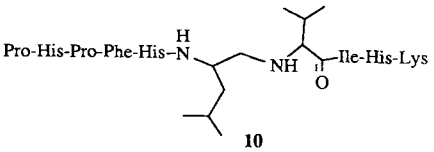


Cyclosporin A **8**

Nevertheless, a few examples with intramolecular hydrogen bonds at the binding site are known. For instance, phosphoramidon (**9**), a potent inhibitor of the endopeptidase thermolysin,[166] binds to the enzyme with one intramolecular hydrogen bond. This bond is formed between the carboxy terminus of the inhibitor and the C2-hydroxyl group of the rhamnose moiety. It may serve two purposes: on the one hand, it helps to immobilize the inhibitor in a conformation optimal for binding, and, on the other, it binds its free carboxy terminus, which is not appropriately satisfied through contacts to the enzyme, in a hydrogen bond. A free negatively charged carboxylate function is not assumed to occur at this position in the natural thermolysin substrate (polypeptide chain). Thus, not surprisingly, the enzyme does not provide, for example, a specific bidentate recognition site for this carboxylate. Another example is the receptor-bound conformation of the peptidic inhibitor H-142 (**10**) of endothiapepsin.[167] This ligand contains a reduced H_2C-NH_2 isoster for the scissile peptide bond. Overall, it adopts an extended conformation, forming an antiparallel pleated sheet with the active-site residues of the enzyme. The putative transition-state isoster at P1–P1′ is in close juxtaposition with the two catalytic carboxy groups of Asp32 and Asp215. The observed binding geometry can be interpreted to mean that the amino acid group, which is protonated under physiological conditions, interacts through one of its NH protons with the two carboxylate groups, similar to the OH group in the transition state-like statine residues. The remaining NH hydrogen bond donor is involved in an intramolecular γ-turn-type hydrogen bond with the neighboring carbonyl group. Such a second hydrogen-bond donor group does not occur during the peptide cleavage reaction. Accordingly, no specific recognition site is provided by the enzyme for this additional acceptor group. Supposedly, intramolecular hydrogen bonds are only observed at the binding site if an unbalanced ratio of hydrogen-bond donors and acceptors is present between ligand and receptor, and if this bond assists in immobilizing the ligand precisely in the required receptor-bound conformation.



9



10

4.2. Toward a Fast Method for Generating Biologically Relevant Conformations

In the previous section, we analyzed the conformational properties of low-molecular weight ligands in their receptor-bound states. We concluded that the structured environment

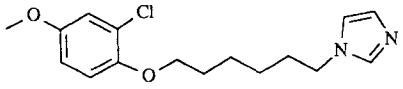
present at the protein binding site imposes substantial influences on the geometry of a ligand. Accordingly, a crystal structure of a ligand itself or any local minima identified for the isolated state are of little or no relevance for the situation in a protein. However, we also noticed that conformational preferences observed for torsional fragments in the structured environment of a small-molecule crystal are in accordance with those observed in protein binding pockets. Any computational method that deals with the prediction of binding site geometries without explicitly taking the protein environment into account has to consider implicitly the presence or possible influences of a structured molecular environment in terms of appropriate "selection rules".

To demonstrate that the described libraries of torsion angles possess some potential for predicting putative binding site geometries of ligands, we have incorporated this information into a computer algorithm.[149] In the program MIMUMBA, a ligand is analyzed by assigning rotatable bonds. The ligand is split into rigid fragments or flexible ring portions. For the latter, low-energy conformations are taken from a library of predefined ring templates that have been obtained from crystal data. A relative energy scaling has been assigned to the various templates. Any conformational multiplicity due to pseudorotation or inversion of each elementary ring is considered.[168]

Dihedral angles for rotatable bonds in the open-chain portions are selected according to the conformational preferences of torsional fragments as retrieved from small-molecule crystal structures.[149] The various angles stored for the different fragments are ranked in terms of their relative energy. Similar to the study of cyclic ring portions, the program builds the entire molecule from the individual fragments by using preferably those open-chain torsion angles that are more frequently found in crystal structures. While merging all fragments in their various conformations, the individual energy contributions are added, and again an energy "penalty" is assigned if fragments overlap. In a subsequent geometry optimization, performed in torsion angle space, the program removes steric overlaps. In this step, only van der Waals and torsion angle potentials are considered. The latter potentials are derived from the statistically observed torsion angle distributions. They guarantee that during the minimization step the individual torsion angles are maintained as close as possible to the most frequently occurring values in experimental structures.[149] The method is fast: for each generated conformer 1–2 s are required on a single-processor UNIX workstation.

To check how well minimum structures obtained by this approach correspond to conformations of ligands bound to proteins, the crystallographically observed geometries of 63 ligands (containing 3–45 rotatable bonds) have been minimized into the next local minimum by using the force-field in MIMUMBA.[141] Visual inspection of these structures shows that the experimental and minimized structures closely resemble each other. On average, a root mean square deviation for all atoms of 0.07 Å per rotatable bond (that is 0.7 Å for 10 rotatable bonds) has been obtained between crystallographically observed and minimized structures.

A closer inspection of the examples with the largest deviations shows that in the experimental structures nonbonded interatomic contacts below 1.5 Å are present. These obviously unreasonable geometries built into the electron density must drift away during a minimization procedure that considers van der Waals interactions. One example (PDB code: 1HRI) is an antiviral compound (**11**) that binds to human rhinovirus (HRV14). In the



11

refined protein structure it is given with an eclipsed conformation along an aliphatic carbon chain and a rather unlikely torsion angle at an *ortho*-substituted phenoxy fragment (the methylene group at the oxygen atom bends toward a chlorine atom located at the *ortho* position).[169] The minimized structure drifts away from its experimental reference. Nevertheless, another local minimum can be found that avoids unreasonably short contacts and unlikely torsion angles that should fit equally well into the trace of the electron density (Fig. 7). For a subset

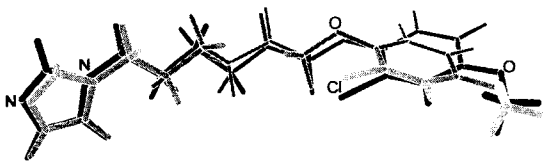


Fig. 7. Conformation of an antiviral compound (**11**) as modeled into the electron density in protein structure determination (gray), and an alternative conformation that avoids an unfavorable torsion angle in the *ortho*-substituted phenoxy fragment (black). The latter structure should fit equally well into the trace of the electron density.

of 23 ligands showing up to 15 rotatable bonds, multiple conformers (between 6 and 150) have been generated to assess the relevance of the conformers generated by MIMUMBA. On average, a deviation of 0.1 Å per rotatable bond has been obtained for those of the computed conformers that approximate experimentally observed geometries most closely. A random superposition of the generated conformers, in which only the centers of mass are placed in equal positions, reveals a mean root mean square deviation of about 0.3 Å per rotatable bond.[141]

4.3. Molecular Recognition Properties of Molecules and Their Mutual Similarity

In drug discovery, lead compounds are modified in a well-planned manner to enhance their affinities and to improve their selectivities. Receptor binding is a molecular recognition process dependent on the properties of both partners. They determine the mutual interactions of the different functional groups in the ligands with the amino acid residues of the protein. They define the relative orientations of the ligands in the binding pocket ("binding mode"). Assuming unchanged properties of a given receptor, can we correlate the binding modes observed for a set of ligands with the differences in their recognition capabilities? If such a relationship can be established it can be used to compare molecules and to predict their binding modes.

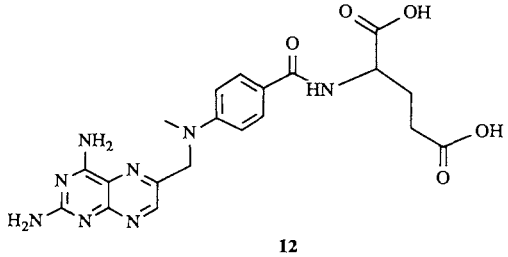
Appropriate steric and electronic complementarities of the ligand and the binding pocket are prerequisites for successful recognition between a ligand and its receptor. Shape and electronic properties are determined by the electron density distri-

bution, which also defines the hydrogen-bond donor and acceptor properties, the hydrophobicity, and the polarizability. All these features define the recognition capabilities of ligands. They can be used to compare molecules and to measure their similarity. However, since such similarities are always measured with respect to the binding properties toward a particular receptor (therefore relative to some reference) they will never be defined in absolute terms. However, the basic assumption is that similar molecules will bind to a receptor in a similar way. Is this assumption justified?

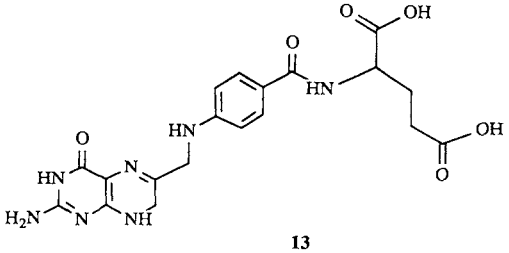
4.3.1. Binding Modes Observed for Different Ligands in the Same Protein

Again, structures of experimentally determined protein–ligand complexes can be used to address this question. In the last few years, several structure determinations have become available, in which a particular protein has been crystallized together with a series of different ligands. For many of these complexes the structure determinations revealed that ligands with related bonding skeletons also occupy similar regions in the binding pocket (e.g. α-lytic protease,[170] endothiapepsin,[171] renin,[172] HIV-protease[173–175]). For example, the structures of thrombin with four different inhibitors have been reported to deviate by not more than 1 Å for any of the residues. Several rearrangements on the order of 0.5–1.0 Å are observed, which can be clearly explained in terms of the protein adapting to a particular inhibitor.[176] HIV protease-inhibitor complexes have been determined in five different crystal forms. Independent of the crystal form and nature of a particular inhibitor, the enzyme structure is well conserved; the root mean square deviations lie in the range of 0.7 Å. This structural conservation also extends to the active site.[177] These series suggest that molecules with common or related skeletons show similar binding modes. However, a substantial number of examples is available that indicate a more complex and less clear-cut relationship. In the following we shall describe some of these examples to highlight the problems involved.

The inhibitor methotrexate (MTX, **12**) and the natural substrate dihydrofolate (DHF, ionic form of folic acid **13**) are both recognized by dihydrofolate reductase (DHFR).[150, 178] Considering the heterocyclic portion only, one might be tempted to directly compare the molecules in terms of an atom-by-atom correspondence (Fig. 8). If we match the hydrogen-bonding capabilities of the two molecules (pK_a considerations suggest MTX to be protonated at N1[178]) and neglect the underlying molecular skeleton, we find that the protein environment experiences quite different hydrogen-bonding patterns in this orientation (Fig. 8 top). Flipping the heterocycle in **13** about the bond to the side chain reveals an orientation, in which both moieties are no longer in optimal space-filling correspondence. However, in this conformation the hydrogen-bonding pattern now shows much better correspondence (Fig. 8, bottom). Crystallographic data on the binding modes are available for both ligands.[178, 179] They show that considerations based on simi-



12



13

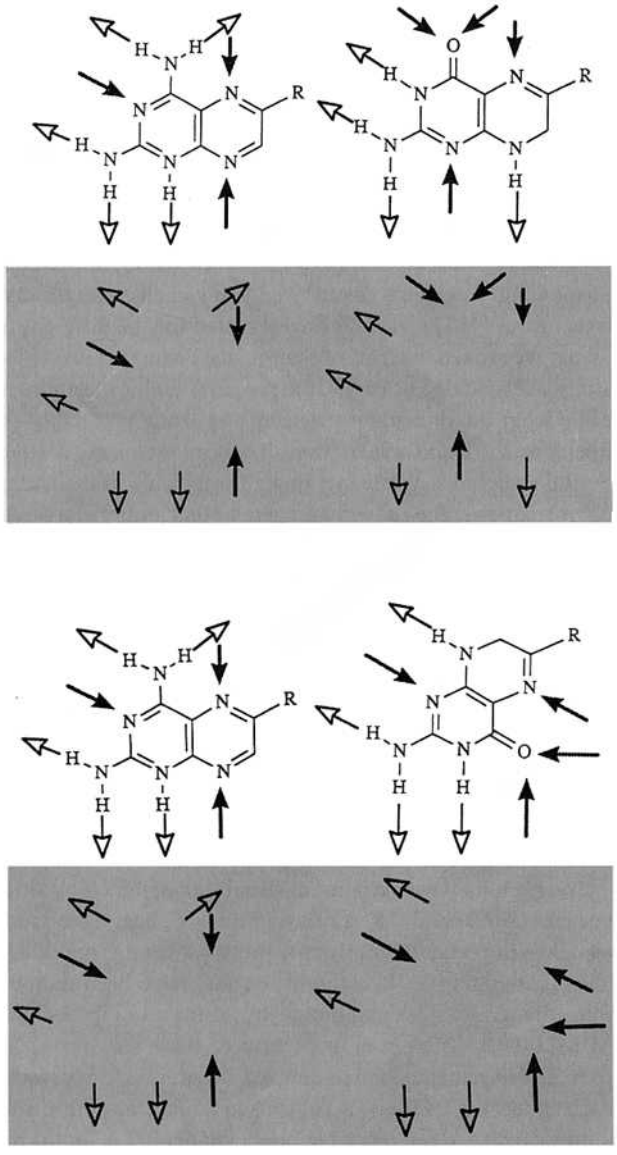


Fig. 8. Comparison of the heterocyclic building blocks in the two ligands methotrexate (**12**) and dihydrofolate (ionized form of **13**). In a direct atom-by-atom superimposition of the two ligands (top), very little similarity in the hydrogen-bonding patterns is achieved (the arrows pointing toward the ligand correspond to hydrogen-bond acceptor properties, those pointing away to donor properties). Changing the conformation of **13** by flipping the heterocycle about 180° (bottom) results in a mutual orientation that shows convincing similarity in the hydrogen-bonding patterns.

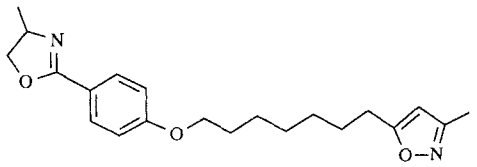
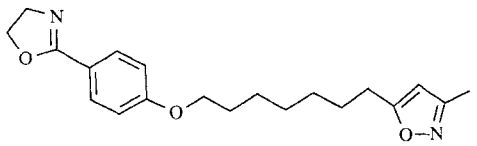
larities in the hydrogen-bonding properties lead to the correct binding modes.[178] A comparison of the electrostatic properties leads to similar conclusions.

Rather surprising binding modes are observed for two antiviral compounds (**14**, **15**), which possess very similar bonding



14



15

skeletons. They bind with reverse orientation into a canyon on the surface of human rhinovirus.[180] Approximate mirror symmetry is apparent when their volume requirements and electrostatic fields are taken into consideration.[181] Figure 9 shows the similar shape of the electrostatic potential (isocontour planes at different levels) for both ligands in the ("regular" vs. "reverse") orientation observed at the protein binding site.

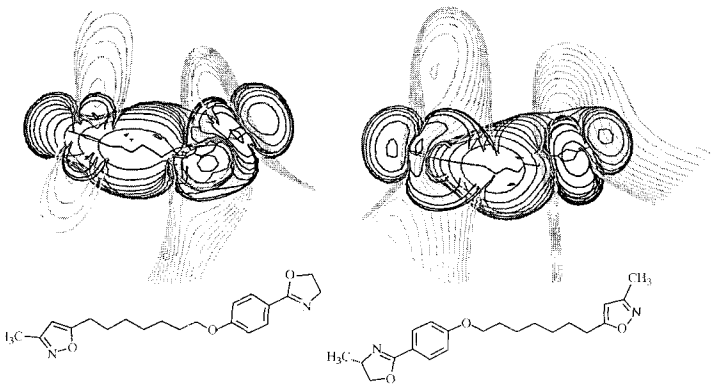


Fig. 9. Two structurally related antiviral compounds (**14**,**15**) in their binding orientations, as determined by X-ray crystallography. The electrostatic potentials calculated from AM1 charges (gray/light gray/black: $4.14/0/-4.14\,kJ\,mol^{-1}$) are displayed by isocontour surfaces. At first glance, the potentials for both molecules possess an approximately mirror symmetrical pattern with respect to the long molecule axis. This observation is a possible explanation why the two molecules in the binding site are observed with "reverse" orientation.

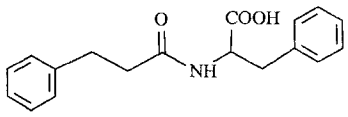
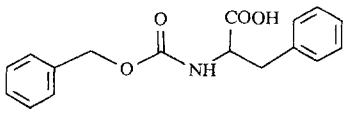
Another example of two ligands with very similar bonding skeletons but exhibiting binding geometries that deviate from a simple atom-by-atom matching are *N*-(3-phenylpropionyl)-phenylalanine (**16**) and *N*-benzyloxycarbonyl)phenylalanine (**17**). Both inhibit the zinc protease thermolysin.[182] They are composed of two hydrophobic terminal groups and a central polar part capable of forming hydrogen bonds or coordinating the zinc center. According to the geometry determined by crystallography, the terminal phenyl groups of both compounds occupy two hydrophobic pockets in a comparable manner. Compound **17** coordinates to zinc through its carboxy group, whereas **16** orients its carbonyl group toward the metal ion (Fig. 10). The opposing residues Ala113 and Arg203 provide two additional binding sites. In **17** the central amide function forms hydrogen bonds to both residues; however, that to Arg203 is mediated through a water molecule. In **16** the carboxy groups interact directly with Arg203, and a hydrogen bond is formed to Ala113.



16



17

4.3.2. Similar, Alternative, and Multiple Binding Modes

To describe the orientation of different ligands in the binding pocket of a protein, expressions like "similar", "alternative", and "multiple" binding mode are used in literature. In our opinion, the application of these expressions is somewhat confusing and requires a proper definition. Related molecules with similar recognition properties (see above) that interact with the same functional groups of the protein thereby covering a largely analogous contact surface exhibit "similar" binding modes (e.g. MTX **12** and DHF **13**). If different amino acid residues are involved in the binding, or distinct functional groups of the ligands are engaged in the ligand/protein interface, "alternative" binding modes are detected (e.g. in thrombin,[42, 183] in thyroid binding protein,[184] in elastase,[185, 186] and in P450 camphor[187]). Even minor modifications with respect to the topology of the underlying bonding skeleton can substantially modify the conformational and accordingly the recognition

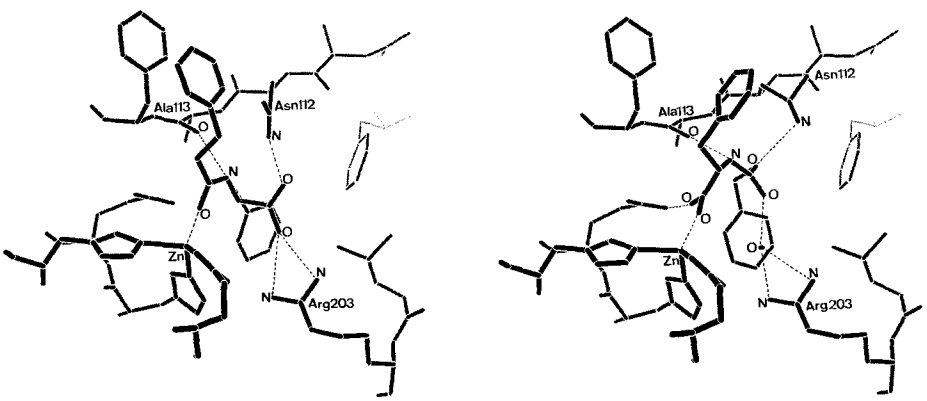


Fig. 10. Alternative binding modes as observed crystallographically for the two thermolysin inhibitors **16** (left) and **17** (right), which differ in their bonding skeleton by only one atom. In **17** the central amide bond forms hydrogen bonds to Ala113 and, mediated through a water molecule, to Arg203, and its carboxy group coordinates to the zinc ion. However, **16** coordinates the metal ion through its amide carbonyl group, and the carboxy group is directly hydrogen bonded to Arg203. In addition, a hydrogen bond is formed with Asn112 and through the amide nitrogen atom to Ala113.

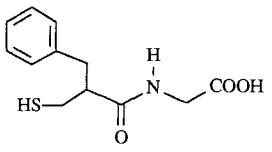
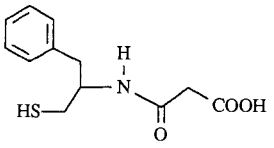
properties. At present, our understanding of the similarity of flexible molecules is not thorough enough to uniquely relate changes in these properties with changes in the bonding topology.

In our opinion, the expression "multiple" binding mode should only be used in cases where more than one orientation of the same ligand in the binding pocket has been detected experimentally. An association with small-molecule crystal structures should be given where positional disorder is a well-known phenomenon. However, only in very rare cases the actual nature of the disorder in crystal packing has been elucidated. It can result either from a random disorder (from unit cell to unit cell) or from a domain-wise disorder of regularly packed mosaic blocks. The first and presumably rather rare case indicates that a particular molecular portion can be recognized by its environment in two or more ("multiple") orientations. It is likely that also in proteins "multiple" binding modes with respect to the features determining recognition are more the exception than the rule. Soaking experiments with trypsin crystals in an almost saturated solution of *p*-guanidiniobenzoate have revealed multiple binding modes.[188] Two disordered orientations have been fitted to the electron density (1.8 Å resolution) in the specificity pocket, one with the usual bidentate hydrogen bonding interaction between the guanidinium group and Asp 189. A third position is found near His 57 with the guanidinium group pointing toward Cys 58 and Lys 60. In all cases, the carboxylate of the inhibitor is close to the γ-O atom of Ser 195. Multiple binding modes have also been observed for chymotrypsin,[189] HIV protease [190] or *para*-hydroxybenzoate hydroxylase.[191] Some care is, however, required in the assignment of multiple binding modes. Such situations can result in ligand disorder or partial occupancy. Accordingly, a less clearly defined electron density has to be interpreted.

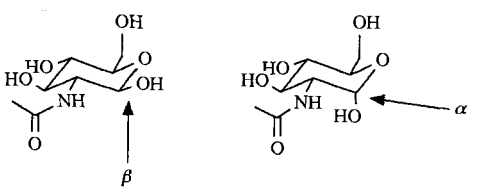


18



19

Molecules with structurally different bonding topologies can interact similarly with a protein (similar binding mode). The inhibitors thiorphan (**18**) and retrothiorphan (**19**) both inhibit the metalloprotease thermolysin,[192] and both molecules bind with the same functional groups to the same residues of the protein. A similar "reverse" recognition of a peptide group has been observed in lysozyme for α- and β-*N*-acetylglucosamide (**20**).[193] The *N*-acetyl side chain of both compounds that exhibits enantiomeric configuration at atom C2 is equivalently recognized by Ala 107 and Asn 59 (Fig. 11). The recognition properties of both forms are so strongly modified that different regions of the binding pocket are occupied (alternative binding mode): The



20

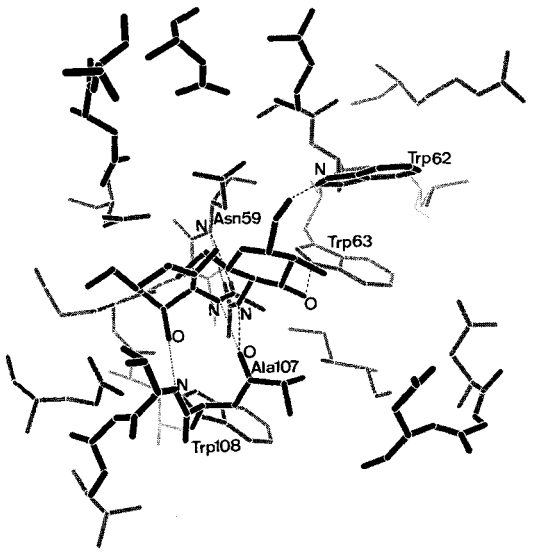


Fig. 11. Binding geometry of α- and β-**20** to lysozyme as determined by X-ray crystallography. Both ligands are shown superimposed in the same figure. The β-form orients to the right and is hydrogen-bonded (dashed lines) to Trp 62 and Trp 63. The amide group of the ligand interacts with the carbonyl oxygen atom of Ala 107 and the backbone NH group of Asn 59. The α-form orients to the left and forms the same interactions through its amide group to lysozyme (dotted lines). In addition, it forms a hydrogen bond to the backbone NH group of Trp 108.

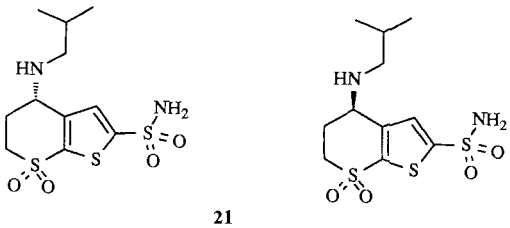
α-form is engaged in a hydrogen bond to Trp 108, whereas the β-isomer interacts with Trp 62 and Trp 63. Lysozyme provides a rather extended binding pocket that can accommodate molecules much larger than **20**. In the lysozyme complex with tri-*N*-acetylchitotriose $(GlcNAC)_3$, the first sugar moiety binds similarly to the pyranose moiety in the β-form,[194] and the region occupied by the α-isomer is filled by five water molecules. Owing to the chirality of protein structures, different binding modes for enantiomers appear not very surprising. However, also the opposite has been observed. For instance, the affinities of the two enantiomeric sulfonamides (**21**) for human carbonic anhydrase[195] differ by a factor of 100. Protein crystallography revealed that both ligands occupy similar regions in the binding pocket (similar binding modes).



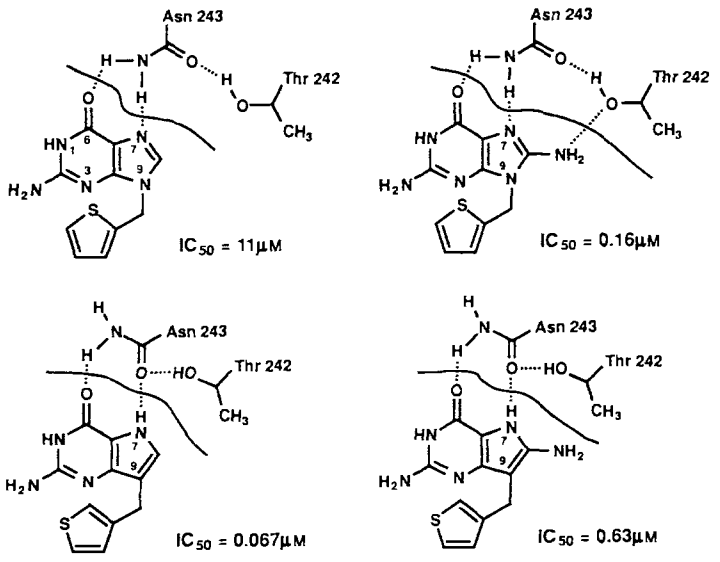
21

4.3.3. *Ligand-Induced Fit at the Binding Site*

So far we have considered only the properties of the ligand, and have assumed the protein to be rigid. However, ligand binding is a recognition process between two flexible molecules. Accordingly, the binding of a ligand can also induce spatial rearrangements in the protein. In a number of cases the protein structures have been determined with and without bound ligand. These studies give some indication about possible conformational changes upon ligand binding. Proteins such as trypsin[196] have fairly rigid binding sites. In other cases, parts

of the protein (e.g. a loop) move as a consequence of the ligand binding.[171, 172, 197] Fortunately, these changes appear to be quite similar for a set of different ligands (e.g. conserved orientation of the amino acid residue in thrombin,[176] HIV-protease,[177] thermolysin,[198] renin,[172] and endothiapepsin[170]). The structure of uninhibited renin shows two independent molecules in the asymmetric unit of a cubic crystal form.[172] Both adopt different conformations due to different crystal contacts. They can be characterized as an "open" and "closed" form and differ by a rigid-body rotation of the C- toward the N-terminal domain around an axis near the active site. Interestingly, the "closed" form is conformationally much more similar to the structure of an inhibited renin complex determined from tetragonal crystals. The conformational changes induced by crystal contacts are very similar to those resulting from ligand binding. For the structurally related endothiapepsin, inspection of 15 protein–ligand complexes reveals two forms of the enzyme.[171] However, no clear correlation with the type of inhibitor or the crystal contacts is evident. Presumably many of the conformational changes observed upon ligand binding can be related to functional rigid-body transitions of the protein. Pronounced changes in the active site have been reported between apo- and complexed form, for example, for HRV-14.[180]

An instructive example highlighting the importance of such induced-fit effects is provided by the binding of guanine to the active site of purine nucleoside phosphorylase.[199] This ligand forms hydrogen bonds through N7 and the oxygen atom at C6 to the side chain amide group of Asn 243 (Scheme 3). A simple and formally isosteric replacement of N by C at the 9-position implies an exchange of a hydrogen-bond acceptor by a donor at the 7-position. Surprisingly, 9-deazaguanine shows an even higher affinity, adopting a binding geometry very similar to that of guanine. The reason for this is that the adjacent Asn residue swings over and presents, instead of its NH_2 group, one of its NH protons and the C=O group to the ligand. This induced fit can hardly be predicted without determining protein–ligand structures.



Scheme 3. Binding modes of four different ligands in purine nucleoside phosphorylase. The replacement of N by C at the 9-position of the guanine moiety results in an unexpected induced fit: In the 7-position a hydrogen-bond acceptor changes to a donor, and the Asn 243 side chain swings by and presents instead of its NH_2 group its NH and C=O groups to the ligands. This induced fit explains why only in the aza-analogue (top) an additional NH_2 group at the 8-position improves affinity. In the deaza derivative (bottom) an unfavorable steric repulsion occurs between the NH_2 group and the methyl group of the adjacent threonine.

4.3.4. Binding Modes in Different Species and at Different pH Conditions

Binding geometries can also differ between enzymes from different species. As already mentioned, trimethoprim (**1**) binds to chicken liver dihydrofolate reductase (DHFR) with a butterfly-type conformation, whereas in the bacterial enzyme from *E. coli* a twisted conformation is found.[150] This example may serve as a caveat for using data observed in one protein to describe the conditions in binding modes to others (e.g. modeled homologues).

The binding modes of molecules in the active site of a protein depend on the protonation state of the amino acid residues involved. A simple case that illustrates this influence is the pH-dependent binding of carbonate to creatinase.[156] Two crystal forms of the enzyme, each of which have a carbonate ion and a water molecule in the active site, have been grown under different pH conditions (5.4, 7.4) and structurally characterized. The guest molecules occupy different positions in the two structures, thus indicating pH-dependent binding modes. At low pH values, the recognition site for the anion, presumably present as bicarbonate, is formed by two protonated Glu residues. The water molecule mediates a hydrogen-bond network to the opposing Arg residues. At high pH values, the anion (again assumed to be a bicarbonate) binds in a reverse orientation. It now faces two Arg residues, while the water molecule bridges to the two Glu residues.

This observation also has consequences for the design of enzyme ligands possessing tailored recognition properties. Phosphastatine analogs have been reported to be potent inhibitors of the aspartyl protease pepsin, but they are relatively weak inhibitors of renin, another aspartyl protease. The difference may be attributed, at least in part, to the different pH optima at which the two enzymes function. Pepsin is a digestive protease that operates in a strongly acidic medium, whereas renin operates under neutral conditions. For the latter, it has to be assumed that the hydroxy group at phosphorus is largely deprotonated and therefore not suited to bind to the aspartates in the active site of renin.[200]

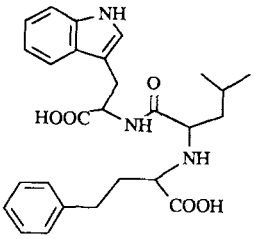
4.4. Automatic Alignment of Molecules in the Binding Pocket by Comparing Their Recognition Capabilities

The experimentally observed examples, discussed in the last section, indicate a rather complex relationship between the bonding skeletons of ligands, their binding modes, and their recognition properties. Nevertheless, let us return to our initial question and examine to what extent we can describe and predict binding modes by comparing recognition properties. When attempting to define a spatial difference or similarity measure among ligands, we have to remember that binding properties are defined with respect to a particular receptor. Measures of similarity are therefore defined relative to some reference.

Computational approaches that are applied to handle this problem can suggest alternatives for docking novel ligands into the binding site of a protein.[181] In the absence of a detailed structure of a receptor such methods can be used to superimpose ligands. The resulting alignment is a prerequisite for a comparative molecular field analysis (CoMFA).[201] This method can be used to quantify differences between ligands that are responsible for the variations of their binding affinities. Several approaches have been described for the computation of such alignments.[202-209] We have extended the procedure SEAL, originally described by Kearsley and Smith,[209] to allow a simultaneous consideration of steric, electrostatic, hydrophobic, and hydrogen-bonding properties.[141, 210] To quantify the similarity of two molecules, their shape is approximated by a set of spatial Gaussian-type functions centered at the atomic positions. For each molecule these functions are then associated with a vector of physicochemical properties derived from atom-based descriptors. To compute the similarity of two molecules in space, the scalar product of the vectors corresponding to the two molecules and weighted by the overlap of the associated Gaussian functions is evaluated. The obtained quantity is used to maximize spatial similarity. Starting from random orientations, it is subsequently optimized by minimizing the mutual distances between molecular portions having similar physicochemical properties. This method does not require predefined pairs of matching centers in the molecular framework. Accordingly, also strongly deviating bonding skeletons can be compared and aligned.

This alignment function has been applied to a data set of 184 ligand pairs binding to the same protein.[141] Their actual binding modes and accordingly their relative structural alignments are known from protein crystallography. Across this reference set, the observed alignments could be reproduced in one third of the cases with a root mean square deviation below 0.7 Å; 51% below 1 Å, and nearly 90% below 2 Å. Considering the inherent accuracy limits of about 0.7 Å for such a superposition of two experimentally determined protein–ligand complexes, the observed agreements are rather convincing.[210] The alignment function exhibits several minima. Thus, the approach generates several alignments, each with a particular similarity scoring. In two thirds of the test cases, the solution with the highest similarity scoring also approximates the experimentally observed alignment. In 91% of the investigated cases, the experimental observations are covered by the best and second best solutions. The different solutions suggest alternative binding modes. For example, the "reverse" binding mode of the two antiviral compounds **14** and **15** with very similar bonding skeletons (see Fig. 9) are proposed since the best solution corresponds to the "regular" superposition. However, the second best solution, ranked only 4% less in similarity, approximates correctly the experimentally observed binding mode.

The alignment function incorporated into the described approach considers steric, electrostatic, hydrophobic, and hydrogen-bond donor and acceptor properties. Strictly speaking, these properties are not independent, they highlight different aspects responsible for molecular recognition. A closer inspection of their contributions to the similarity scorings calculated from 184 test examples provides the opportunity to estimate their relative importance. Interestingly, in all cases, steric similarity achieves the greatest importance, contributing between 30 and 85% to the total similarity scoring. This finding underlines the importance of a similar spatial occupancy in a binding pocket as a prerequisite for successful binding.



22

One example should be given, however, where the approach fails to perform satisfactorily. The two thermolysin inhibitors **16**[182] and **22**[211] are superimposed with a residual root mean square deviation of 0.54 Å. Similarly, the reaction product Val-Trp of the proteinase cleavage reaction can be superimposed onto **22** with a root mean square deviation of 1.03 Å (Fig. 12). Val-Trp and **16** are both smaller in size than **22** and their superpositions with **22** involve different parts of the molecule. However, if a comparative alignment of **16** and Val-Trp is calculated, steric overlap is optimized among both inhibitors. Thus, no correspondence with the observed situation is achieved. This example clearly indicates the limitation of approaches that consider the 3D structures of ligands only. It also serves as a warning not to use the superimposition of molecules as a prerequisite for 3D QSAR analyses without additional considerations.

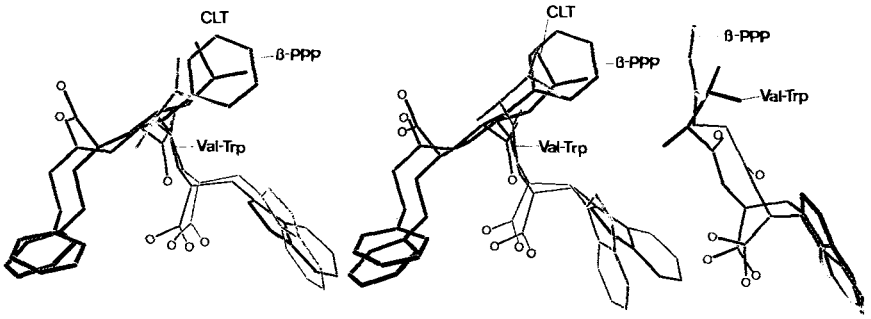


Fig. 12. Observed and computed structural alignment of thermolysin inhibitors. In the center the mutual alignment of CLT **22** (black), β-PPP **16** (dark gray), and Val-Trp (light gray) are shown, as determined by X-ray crystallography. On the left, the computed alignment is given using CLT (black) as a reference. The residual root mean square deviation to the experimental arrangement is 0.54 Å, and for Val-Trp 1.03 Å. On the right, the alignment of β-PPP (gray) with Val-Trp (black) as a reference is shown. An arrangement, like that found in thermolysin, which cannot be achieved since the steric overlap at the protein binding site is rather small (cf. center).

In the computational approach described so far, molecular flexibility has not yet been incorporated. To account for flexibility during the superposition process, the above-mentioned similarity condition has been introduced as additional term into the potential function used in MIMUMBA.[210] Since the approach performs only a local optimization, an initial orientation and start conformation are required. To circumvent this important limitation, multiple conformations, generated by a conformational search with MIMUMBA, are subjected to mutual alignments. Subsequently, those of the pairwise aligned conformers that receive the highest similarity scores are subjected to local

conformational relaxations with simultaneous similarity maximizations. This combined approach has been applied to thrombin and thermolysin inhibitors. Conformers are generated and selected that approximate experimentally observed geometries and orientation.[210]

5. Current Computational Methods for Lead Discovery

The 3D structures of proteins and protein–ligand complexes can be used to identify the essential interactions in these structures and to search for additional binding sites not used by previously known ligands. Possible binding sites may be positions where hydrogen bonds can be formed with the enzyme, or hydrophobic pockets in the enzyme structure which can be occupied by lipophilic groups. A number of computational tools have recently been described to select putative ligands and to predict their interactions with the protein. In general, these novel tools for ligand design can be divided into the following major categories:[212]

1) Analysis of the protein structure
2) Ligand docking and 3D database searching
3) De novo ligand design
4) Assessment of the ligand binding affinity
5) Analysis of the electronic and conformational properties of the ligand

We briefly summarize the current status of these methods. Basically, to find new ligands one can either search 3D databases of known small molecules, or one can attempt a de novo design. The latter approach tries to construct a new molecule completely or in part from scratch. The possible approaches are sketched in Figure 13.

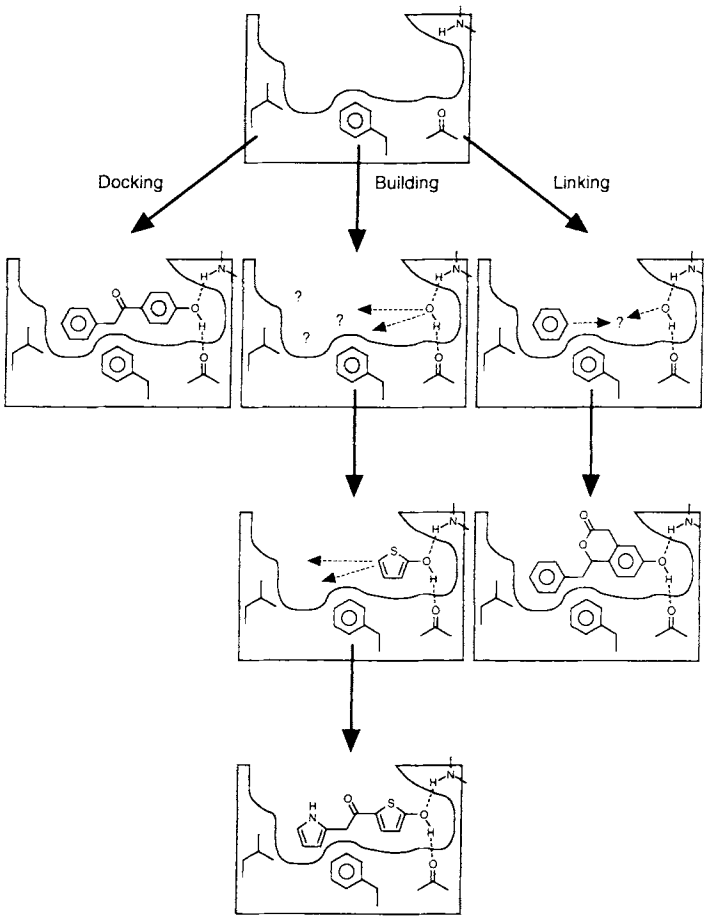

Fig. 13. Strategies for discovering new lead structures by ligand docking (see also Section 5.3.1). A complete ligand, for example taken from a database, can be docked into the binding site (left). The de novo design of new ligands can be performed either by positioning a seed which is further extended by additional building blocks (center) or by the simultaneous placement of several fragments that are connected by suitable linking groups (right). The sketch was adapted from Verlinde and Hol [26].

5.1. Analysis of the Protein Structure

The first step in the search for a new ligand is the analysis of the 3D structure of the target protein. The surface of the protein can be displayed together with certain properties such as the lipophilicity[213, 214] or the electrostatic potential.[215] Computational methods have been described that can detect clefts or cavities in the protein.[216–218] Other approaches are available for predicting favorable binding sites for probes or small molecules such as a water molecule or a carbonyl group.[219–221] One of the most frequently used approaches is to calculate interaction energies with different probes on a grid spanning the binding site. Such grids can be displayed and then subsequently be used as a valuable guide in the design of new ligands.

Probably the most widely used technique for the computational analysis of protein–ligand interactions is molecular mechanics. Recently new force fields have been developed[222–225] that provide an improved description of noncovalent and covalent interactions in these complexes. Simple molecular mechanics geometry optimizations can be useful in addressing the problem of steric and electronic complementarity between the protein and the ligand.

The program MCSS developed by Miranker and Karplus[226] combines the analysis of the protein binding site with a placement of small functional groups in an energetically favorable orientation. MCSS uses a molecular mechanics force field for the placement of small ligands.

We have adopted a different approach to the analysis of the protein binding site focussing on the geometric aspects of protein–ligand interactions.[227] Information on typical interaction patterns between functional groups of a ligand and amino acids of a protein can be obtained from a statistical analysis of intermolecular contact geometries found between various functional groups in the crystal packings of organic molecules. Composite pictures of these interaction geometries can be used to elucidate orientational preferences. As an example, the composite picture of hydrogen-bonding partners that interact as donors or acceptors with a phenolic oxygen are shown in Figure 14. The observed clusters in space are representative of preferred interactions with the tyrosine side chain. To justify that these composite crystal-field environments indeed serve as reliable guides in the prediction of binding site geometries, we have mapped them onto the amino acids pointing into the binding site of a protein. In Figure 15, the crystallographically determined binding geometry of methotrexate (**12**) in dihydrofolate reductase is shown together with the distribution around the functional groups that interact with the in-

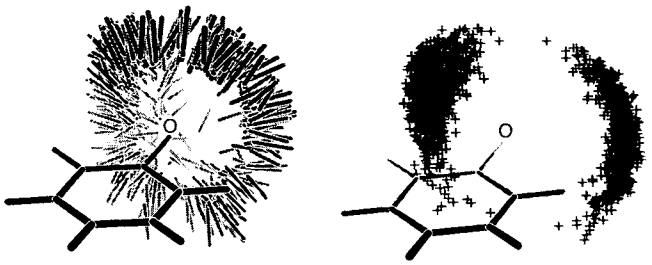

Fig. 14. Composite picture of the contact geometries used to map out possible spatial orientations of interactions between a phenolic oxygen atom and hydrogen-bond donors (left) or acceptors (right). Data were retrieved from crystal structure analyses of small molecules. The coordinates of the probe functional group together with those of the contacting atoms (NH, OH or N, O) were extracted. A common orientation of all considered examples was achieved by a least-squares superposition of the atoms of the phenyl rings. The hydrogen atoms directly bound to the phenol oxygen have been omitted for clarity.

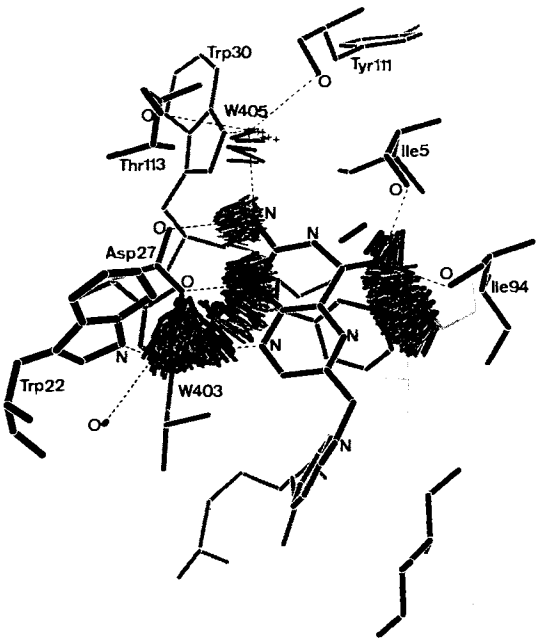

Fig. 15. Section through the binding pocket of the dihydrofolate reductase from *E. coli* with the ligand **12**. View perpendicular to the pteridine moiety, hydrogen bonds as dashed lines. The water molecules 403 and 405 mediate hydrogen bonds from the protein to the ligand. Matched onto the amino residues oriented towards the binding site are the appropriate distributions from the crystal structures. After contact atoms that penetrate into atoms of the protein have been rejected, the indicated positions remain as putative binding sites about the carboxylate group of Asp27, the backbone carbonyl group of Ile5, Ile94, and Tyr111, the side-chain oxygen atom of Thr113 (NH, OH bond vectors), and the indole NH group of Trp30 (N, O atom positions).

hibitor. The positions of the ligand atoms coincide with regions that are frequently occupied by similar partners in organic crystal structures. A similar picture was found for several other protein–ligand complexes.[227] The information contained in these composite crystal-field environments has been translated into rules that serve as guidelines for the automatic docking of small molecules into the active site of proteins (see Section 5.3).

A very important property of proteins is their flexibility. The most widely used computational technique to obtain information about protein flexibility is molecular dynamics (MD) simulation. Several reviews have summarized the potential of this method.[228, 229] Significant progress has recently been obtained in the methodology of molecular dynamics simulations.[230–232] Together with the developments in computer hardware, these advances now enable us to perform longer and more accurate MD simulations. Indeed, several impressive calculations have been reported that provide new insights into the nature of protein flexibility.[233, 234]

5.2. Database Searching

The most direct way to find a new ligand with a computer is to search a database containing 3D structures.[235–237] The pioneering program in this field is DOCK developed by Kuntz and coworkers (see Fig. 13, left).[238] DOCK is used to search a 3D database for possible ligands based on shape complementarity between protein and ligand. Recently the ability to account for electronic complementarity by means of a molecular mechanics force field was also incorporated into the program.[239, 240] A number of successful applications of DOCK have been reported.[241–243] Other computer programs for searching 3D databases have been described:[244, 245] CLIX[244] uses the GRID force field[219, 220] in the docking of putative ligands; the program FLOG developed by Miller et al.[245] accounts for ligand flexibility by including up to 25 conformers of each structure in the database; the program LUDI described in the following section can also be used for searching 3D databases.[246]

5.3. De Novo Ligand Design

A number of computer programs have recently been described that attempt to design new ligands for a given protein structure automatically.[247–270] Several reviews have been published on this topic.[247, 248] Most programs try to assemble novel molecules from pieces. These pieces are either atoms[249–252] or larger, chemically reasonable fragments.[253–255, 269, 270] Both approaches have advantages and disadvantages. The use of single atoms as building blocks can generate the largest possible diversity of chemical structures. However, a large structural diversity can also be obtained with a fragment-based approach by using a large variety of different fragments. A potential advantage of the fragment-based approach is the synthetic accessibility of the generated structures. The use of fragments offers the advantage that chemical knowledge can be built into the fragment connection step. For example, amino acids can be used as building blocks to construct peptides.[253] The extension to other simple chemical reactions such as the formation of an ether is straightforward. In contrast, this control of synthetic accessibility is difficult to achieve for atom-by-atom build-up programs. Therefore, the latter approach requires that the synthetic accessibility is checked at the very end of the design cycle. This is a much more complex task than to check whether the formation of a particular bond is synthetically feasible.

Two major strategies exist for fragment-based de novo ligand design. The first possibility is to place several fragments independently (or take them from a known ligand structure) and then to search for suitable templates that connect these fragments into one molecule (see Fig. 13, right). The advantage of

this approach is that the individual fragments are placed without any bond constraints and are likely to be at their optimal positions. Furthermore, this strategy has the desired tendency to generate rigid structures. A possible disadvantage is that it may be difficult to find appropriate templates that connect the fragments in a stereochemically and synthetically reasonable way. The alternative is to start with a seed fragment in a certain region of the binding site, and then to append additional fragments in a stepwise build-up procedure (Fig. 13, center). An advantage of this approach is that chemical knowledge can be easily incorporated into the linking step. Therefore, synthetically accessible structures are more likely to be obtained by this approach. However, it tends to generate more flexible structures. Furthermore Rotstein and Murcko[255] have pointed out that the build-up procedure can run into difficulties if a large gap between two separated regions of the binding pocket has to be bridged without the possibility of forming extensive specific interactions with the protein in the gap region.

The most important challenge both in de novo design and 3D database searching is currently the development of new methods to prioritize the large number of diverse putative protein ligands resulting from such calculations. Available computational procedures based on a molecular dynamics simulation are too time-consuming to score more than 10–100 ligand structures. Therefore, a fast and reliable ranking of the candidate structures is required. A possible approach is to use a two-step procedure. First, a fast and simple empirical scoring function is used to prioritize the hits. Then the top scoring structures are analyzed more rigorously by using more accurate and computationally demanding approaches. Several simple scoring functions have been proposed,[2, 81, 100–102, 253] among them the one we described in Section 3.7.

5.3.1. The Computer Program LUDI

LUDI is a fragment-based de novo design program that can be used both for searching 3D databases and for the automatic construction of novel ligands either through building (step-by-step build-up) or linking (placement of individual fragments and subsequent connection, see Fig. 13).[269, 270] The program positions molecules or adds new substituents to a given lead in clefts of a protein such that hydrogen bonds can be formed and hydrophobic pockets are filled with lipophilic groups. Like other programs for ligand design, LUDI basically requires the following information: 1) the 3D structure of the target protein, 2) 3D structures of putative ligands or fragments for docking or constructing novel molecules, and 3) information about possible favorable interactions between the protein and the ligand.

The program first calculates "interaction sites", which are discrete positions and vectors in space suitable for forming hydrogen bonds or for filling a hydrophobic pocket. These interaction sites are derived from composite crystal-field environments as described in Section 5.1.[227] In the next step molecular fragments are fitted onto these sites. The fragments are taken from a library containing 1100 diverse small molecules. Larger fragment libraries can also be searched, as compiled from the "Available Chemicals Directory" (ACD)[271] or the Cambridge Structural Database (CSD).[21–23] Then LUDI can be used in the "link-mode", in which the placed fragments are connected by bridge fragments to form a single molecule. Alternatively, LUDI can append new fragments onto an already positioned fragment or lead compound. Finally, the obtained structures are scored by using the function described in Section 3.7. The concept of LUDI is summarized in Figure 16.

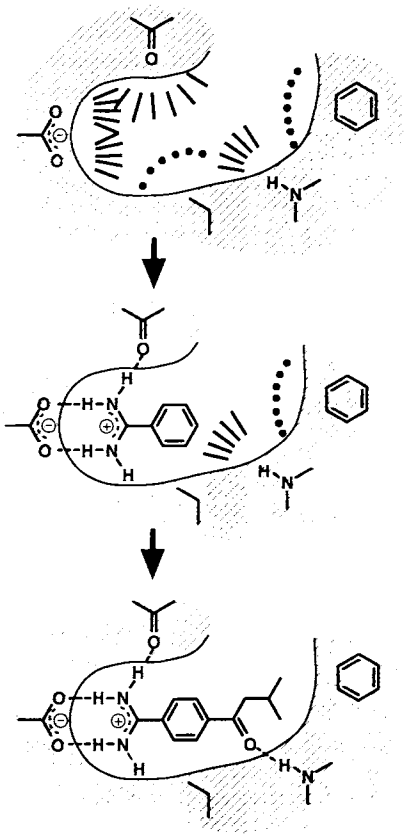

Fig. 16. Basic steps in de novo ligand design using the program LUDI. First the interaction sites are generated according to a rule-based approach (top). Then small fragments are fitted onto the interaction sites (center). Finally, positioned fragments are linked together or extended by additional substituents (bottom).

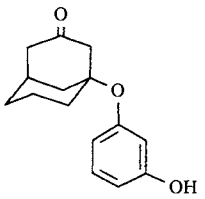
An important aspect of LUDI is its ability to tolerate small uncertainties in the experimentally determined protein structures. Any positioning of fragments is completely based on geometric operations. We have decided to refrain from using force-field calculations either in the positioning or the ligand scoring step. The latter methods would be computationally rather demanding. Futhermore, the uncertainties in protein geometry can give rise to unreasonably large contributions to the protein–ligand interaction energy if calculated by a force field. The resulting values can only be interpreted if a full geometry optimization including all degrees of freedom is performed. Instead, we decided to use the fast and error-tolerant empirical scoring function in LUDI described in Section 3.7.[81]

In a validation study, we successfully applied LUDI to the design of inhibitors of dihydrofolate reductase and HIV-protease.[270] Pisabarro et al.[38] used the program in the successful design of a novel inhibitor of human synovial fluid phospholipase A_2 with enhanced binding affinity. Recently Babine et al.[39] used LUDI to design **23** as a novel ligand for FKBP-12.



23

Subsequently, compound **23** was synthesized and found to be a strongly binding ligand of FKBP-12 (K_i = 12 μM). In another application,[246] a subset of about 30000 small molecules (< 40 atoms, 0–2 rotatable bonds) from the fine chemicals directory (FCD[271]) was used to suggest possible novel ligands for trypsin, HIV-protease, purine nucleoside phosphorylase, and streptavidin. The 3D ligand structures were generated with the program CONCORD[272] (more recently, we also employed the program CORINA[273] for the generation of the 3D structures). For the specificity pocket of the enzyme trypsin, the calculation took two hours on a Silicon Graphics Indigo R4000 workstation and retrieved 153 compounds. The hits obtained with the highest score are *para*-methylbenzamidine and benzamidine. Both compounds are indeed found experimentally to bind trypsin with micromolar binding affinities.[274, 275]

One of the strengths of LUDI is its ability to find small polar ligands for tight polar binding sites as present, for example, in trypsin. Our current experience indicates that for such proteins the program can retrieve interesting small molecules that form multiple hydrogen bonds with the protein. LUDI is now widely used in the pharmaceutical industry.[276]

6. Outlook and Future Developments

During the last five years we have witnessed dramatic improvements in computational tools for structure-based ligand design. New computer programs for conformational analysis, ligand docking, structural alignment, and de novo ligand design have been described. The first examples for a successful design of protein ligands are emerging.[29–42] The motivation for further developments of these methods is the intellectual challenge of understanding the nature of protein–ligand interactions, but also the need to speed-up the drug discovery process. As this driving force gets even stronger, the development of advanced methods for structure-based ligand design becomes more and more important.

Despite the remarkable recent progress, the current computational methods for lead discovery still face a number of limitations. Most important is the availability of the 3D structure of the target protein. Substantial efforts are still necessary to develop techniques to make these systems accessible to structure determination. In the optimal case, their 3D structures are determined together with a series of different ligands. In the absence of such data, it may be possible to construct a model of the target protein from the known structure of a closely related homologue. Otherwise design methods have to rely on comparisons of ligands only. It should be noted that in such cases the comparison has to refer to the spatial distribution of the physicochemical properties. However, as the level of information on the structural aspects of the protein–ligand system decreases, the results from design methods get less and less conclusive and reliable.

Design methods consider ligands and their putative interactions with the target. Other important factors are not taken into account, such as transport properties, metabolic stability, good oral availability, low toxicity, sufficient half life, and minor addictive potential. These factors also determine whether a ligand can be applied as a drug. Furthermore, the current de novo design programs hardly address the problem of the synthetic accessibility of the suggested structures. Finally, current methods for the prediction of binding affinities need to be improved.

In cases where the protein structure is available, most current docking and de novo design methods treat the protein as rigid. In reality, however, ligand-induced fit is observed and has to be considered. Nevertheless, since similar changes of the protein have been observed with several related ligands, the 3D structure of a complex appears to be a good starting point for de novo design. The consideration of molecular flexibility of the ligand, especially for species with more than five rotatable bonds, still represents a considerable challenge. This property has to be efficiently incorporated into methods for comparing molecules and ligand docking.

Computational methods are only one aspect in the strategy for drug research and development. In the last few years experimental high throughput screening methods have been established based on molecular test systems. In favorable cases, several thousand compounds can be tested in an assay per day. This has stimulated the development of new methods to synthesize large libraries of diverse molecules. Combinatorial chemistry[277–279] offers great promise in the discovery of new lead structures. In our opinion, the computer-based methods nicely complement such screening approaches. Hits from these searches often display rather diverse structures. Molecular comparison methods have to elucidate common features that are likely to be responsible for receptor binding. Once lead structures have been discovered, either through experimental or computer screening methods, molecular modeling and X-ray crystallography come into play to assist efficient optimization of lead structures.

At present, we are starting to understand some important phenomena and underlying principles that determine molecular recognition in protein–ligand complexes. Computational approaches based on empirical knowledge provide powerful tools to support the finding and optimization of new lead structures. It can be expected that with the growing experimental data on structures and thermodynamics of protein–ligand complexes the range of applicability of these approaches will be further extended.

We are very grateful to our colleagues Wolfgang Höffken, Hugo Kubinyi, Thomas Mietzner, and Nigel Walker for numerous stimulating discussions. Some of our own work described in the article was funded by the BMBF projects RELIWE and ÄBAV. The offered financial support is gratefully acknowledged.

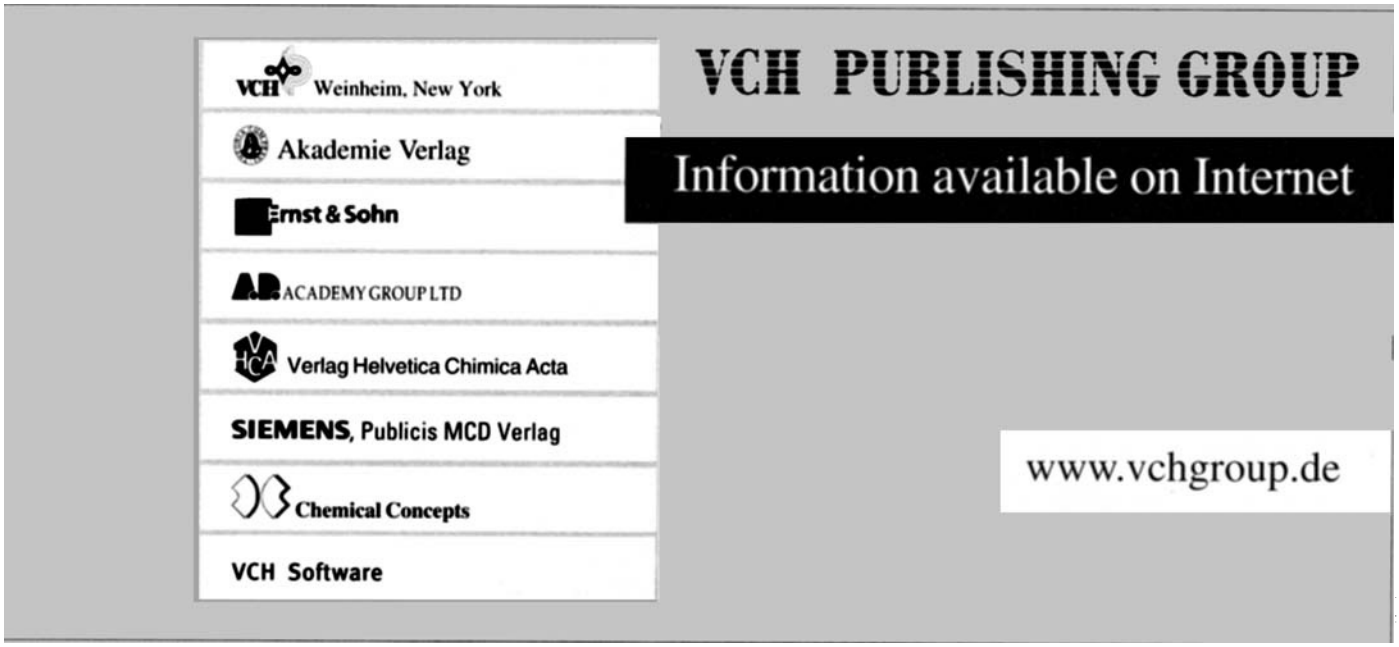
EVENTS



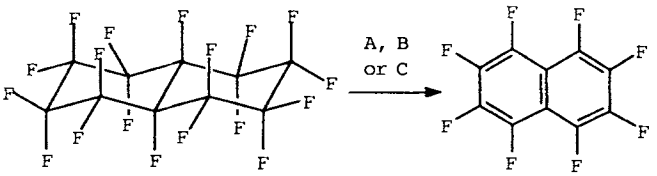
Defluorination of Perfluoroalkanes and Chlorofluorocarbons**

Graham C. Saunders*

The great strength of the carbon–fluorine bond has been the basis for much technological progress. Inert polyfluoro- and perfluorocarbons have found many industrial and domestic applications because of their low toxicity and noninflammability coupled with their high thermal stability and good thermodynamic properties. Chlorofluorocarbons (CFCs), however, pose a severe environmental problem because of their large contribution to ozone depletion, due to the release of chlorine radicals under UV photolysis in the stratosphere, and their contribution to global warming. Effective disposal of existing stockpiles of CFCs is thus extremely desirable but, because of the chemical inertness of the C–F bond, represents a significant challenge.

The chemical activaion of C–F bonds has attracted much attention, and recent research, driven partly by academic interest in the properties of these strong bonds and partly by the development of new, biologically active organofluorine compounds, has yielded exciting results. The cleavage of strong and apparently inert C–F bonds, which has always been a considerable challenge to the synthetic chemist, is being achieved in an increasing number of systems. Although aryl C–F bonds are stronger than alkyl C–F bonds, greater success has been achieved in activating the former. It has been known for some time that aryl C–F bonds are susceptible to nucleophilic attack, especially as the degree of fluorination increases,[1] and can be activated by transition metal and lanthanide complexes.[2] Indeed, recently Aizenberg and Milstein[3] and Kiplinger and Richmond[4] have described catalytic processes for the hydrogenolysis of perfluoroarenes using $[RhH(PMe_3)_4]$ and $[(\eta^5\text{-}C_5H_5)_2ZrCl_2]$ respectively. In contrast, the activation of the C–F bonds of perfluoroalkanes had only been achieved under extreme conditions. For example, in the elemental analysis of organofluorine compounds the substrate is treated with either alkali metal cations, peroxides, or oxygen at elevated temperatures, typically above 600 °C,[5] and formerly hexafluorobenzene was manufactured industrially by the defluorination of perfluorocyclohexane with iron at 450–500 °C.[6] A small number of highly reactive organometallic complexes have also been reported to activate alkyl C–F bonds. For example, $[(\eta^5\text{-}C_5H_4Me)_3(UCMe_3)]$ reacts with dodecafluorocyclohexane to give undecafluorocyclohexane.[7]

As tertiary C–F bonds possess low-lying σ^* orbitals that may readily accept electrons under certain conditions,[8] one possible approach to activating C–F bonds involves electron transfer from a reducing agent to the fluorocarbon moiety. This occurs in the reactions between fluorocarbons and strong reducing agents such as alkali metals and organic radical anions.[5, 9] These reactions are usually unselective and lead to complete defluorination of the fluorocarbon. The sodium benzophenone radical anion, however, has been reported by Pez et al. to selectively defluorinate perfluorocycloalkanes to give perfluoroarenes at ambient temperature (Scheme 1).[10] Single-electron



Scheme 1. A) $10\,Na^+[Ph_2CO]^-$, THF, room temperature, 1.5 h, $-10\,NaF$, $-10\,Ph_2CO$, 61%; B) $10[(C_5H_5)_2Co]$, $10\,LiO_3SCF_3$, Et_2O, room temperature, 12 h, $-10[(C_5H_5)_2Co]^+$, $[O_3SCF_3]^-$, $-10\,LiF$, 53%; C) $[(C_5H_5)_2TiF_2]$ (cat.), Al/$HgCl_2$, THF, room temperature, 130 h, 40%.

transfer processes have also been postulated in a number of reactions involving transition metal and lanthanide complexes,[3, 11] and ESR evidence supports this mechanism in the reaction between *trans*-$[Pt(H)_2\{P(cyclo\text{-}C_6H_{11})_3\}_2]$ and pentafluorobenzonitrile.[12]

Richmond et al. reported that cobaltocene and perfluorodecalin react readily at ambient temperature to yield cobaltocenium fluoride, which is a potent source of "naked" fluoride ions.[13] Presumably the reaction proceeds by single-electron transfer from the cobaltocene to the fluorocarbon. The fate of the perfluorodecalin was not determined, but when the reaction was carried out with cobaltocene and perfluorodecalin in a 10:1 ratio and in the presence of LiO_3SCF_3, the lithium cation of which acts as a fluoride-abstracting agent, perfluoronaphthalene was obtained in 53% yield (Scheme 1). Subsequently, Kiplinger and Richmond have developed a catalytic system for the synthesis of perfluoroarenes from perfluorocycloalkanes. The process uses $[(\eta^5\text{-}C_5H_5)_2TiF_2]$ or $[(\eta^5\text{-}C_5H_5)_2ZrCl_2]$ as catalyst and aluminum as terminal reducing agent;[14] 6.2 mmol of perfluorodecalin in the presence of an

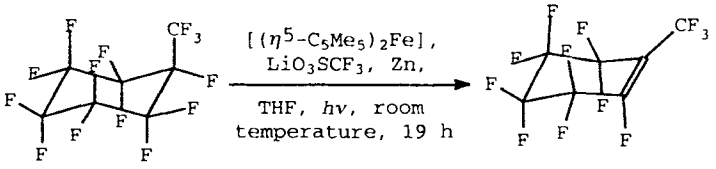
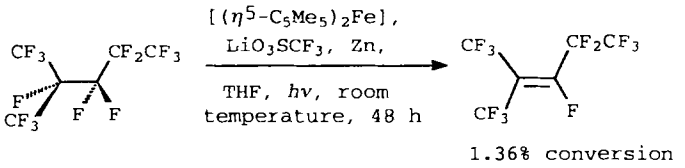
excess of aluminum (87 mmol), $HgCl_2$ (0.19 mmol), and 0.026 mmol of $[(\eta^5\text{-}C_5H_5)_2TiF_2]$ in THF at ambient temperature produced 3.2 mmol of octafluoronaphthalene after 130 h; this conversion corresponds to 12 turnovers (Scheme 1). Other perfluorocycloalkanes were also defluorinated to afford perfluoroarenes under similar conditions. Richmond suggests that the organometallic complex in these systems acts as an "electron shuttle", transferring electrons from aluminum to the fluorinated substrate. Richmond's system leads exclusively to aromatic products.

Crabtree et al. have used similar methods to defluorinate perfluoroalkanes to yield perfluoroalkenes. They reported that the mercury-photosensitized reduction of perfluoroalkanes by ammonia yields perfluoroimines and perfluoronitriles, and proposed that the reactions proceed via perfluoroalkene intermediates.[15] Further development of this reaction led to a catalytic process for the defluorination of perfluoroalkanes to give perfluoroalkenes (Scheme 2).[16] Decamethylferrocene was used as



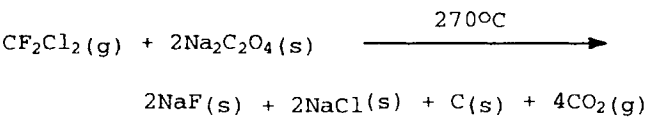


Scheme 2.

a one-electron reducing agent which, under irradiation from a medium-pressure Hg lamp, activated alkyl C–F bonds by photoinduced charge transfer. THF was found to favor this process and was therefore the preferred solvent. The resulting decamethylferrocenium ion was reduced by zinc to complete the cycle. As in Richmond's cobaltocene system the fluoride ions were abstracted by the lithium cations of LiO_3SCF_3. Conversions, however, were low even after lengthy periods. Perfluoromethylcyclohex-1-ene was obtained from perfluoromethylcyclohexane (11.43 mmol) in 11.9% conversion after 19 h of irradiation in the presence of $[(\eta^5\text{-}C_5Me_5)_2Fe]$ (0.30 mmol) and LiO_3SCF_3 (8.33 mmol), and perfluoro-2-methylpent-2-ene was produced from perfluoro-2-methylpentane in 1.36% conversion (40 turnovers) after 40 h under similar conditions. Attempts to increase the conversion resulted in byproducts. Unlike Richmond's system, however, defluorination of perfluorocycloalkanes to yield perfluoroarenes was not observed.

The catalytic selective defluorination of compounds that have usually been considered as inert has thus been realized. The selectivity and convenience of these methods, which require easily handled reagents and mild conditions, represent a major advance in the chemistry of the C–F bond. If further elaboration can increase the conversions, these methods may become powerful weapons in the armory of the synthetic organofluorine chemist.

Crabtree has further utilized reducing agents in the activation of C–F bonds to develop a convenient thermal process for the destruction of chlorofluorocarbons.[17] Passage of chlorofluorocarbon vapor through a bed of powdered sodium oxalate at 270 °C and at a rate of 4 mL min^{-1} resulted in the mineralization of the substrate with the formation of NaF, NaCl, and C, and evolution of CO_2, as shown for CF_2Cl_2 in Scheme 3. The

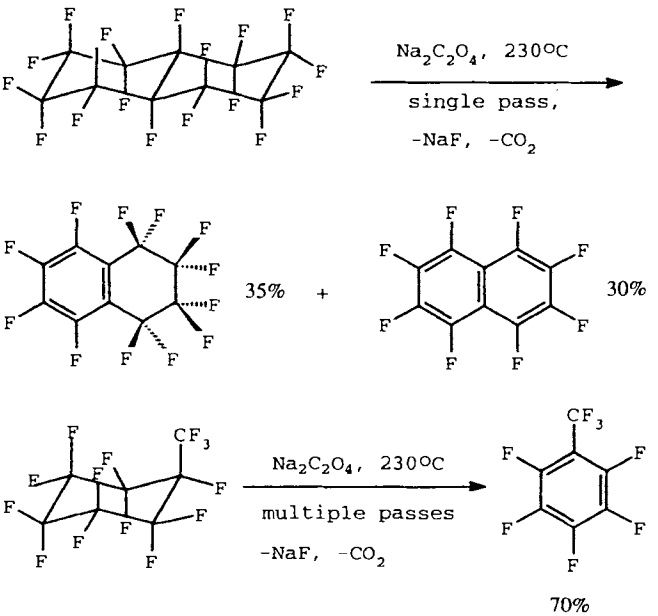


Scheme 3.

oxalate dianion acts as a two-electron reducing agent, which obviates the problems associated with radicals formed in single-electron transfer reactions. The sodium ions act as halide-abstracting agents. Evidence for an electron transfer process is provided by the observation that perhalocarbons react, but partially hydrogenated species such as $ClCH_2CH_2Cl$, which are poorer electron acceptors, do not.

For certain CFCs such as ClF_2CCF_2Cl only a single pass through the sodium oxalate bed was required, and no more than three passes were ever required. Complete mineralization was achieved, and the reactions showed no tendency to give uncontrollable exotherms. As sodium oxalate is an inexpensive, noncorrosive reagent, and the solid products are easily handled, this reaction is an efficient, convenient, and relatively cheap method for the destruction of CFCs.

The oxalate dianion can also be used to defluorinate perfluorocycloalkanes to produce perfluoroarenes. Passage of the perfluoroalkane vapor in nitrogen through sodium oxalate at 230 °C at rate of 200 mL min^{-1} gave the perfluoroarene in yields exceeding 40% after a single pass. Perfluoromethylcyclohexane was defluorinated to produce perfluorotoluene in 70% yield after several passes (Scheme 4). For perfluorodecalin a mixture



Scheme 4.

of perfluoronaphthalene and perfluorotetralene was obtained. The cation has a significant effect on these reactions. At 200 °C potassium oxalate defluorinates perfluoromethylcyclohexane to give perfluorotoluene in 72% yield, whereas sodium oxalate and lithium oxalate gave no reaction. At 230 °C, however, the yields of perfluorotoluene were 70 and 50%, respectively.

In summary, Richmond et al. and Crabtree et al. have developed convenient, catalytic processes for the cleavage of alkyl C–F bonds under mild conditions. Furthermore, Crabtree et al. have detailed a convenient and inexpensive method for the destruction of CFCs that has significant environmental benefits. This work highlights the special properties of C–F bonds and, together with the research cited here, begins to provide a rationale for the activation of these bonds. The prospect of further developments promises an exciting future for the synthetic organofluorine chemist.

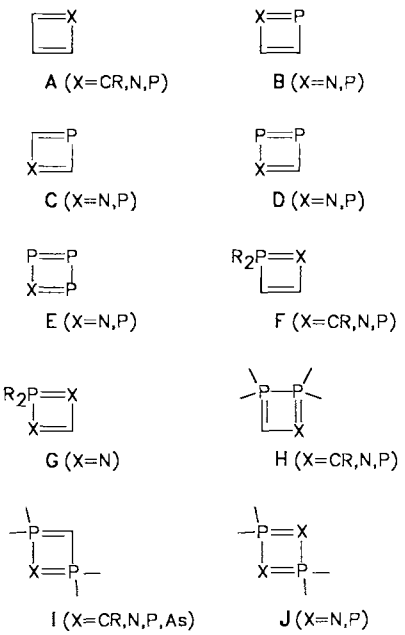
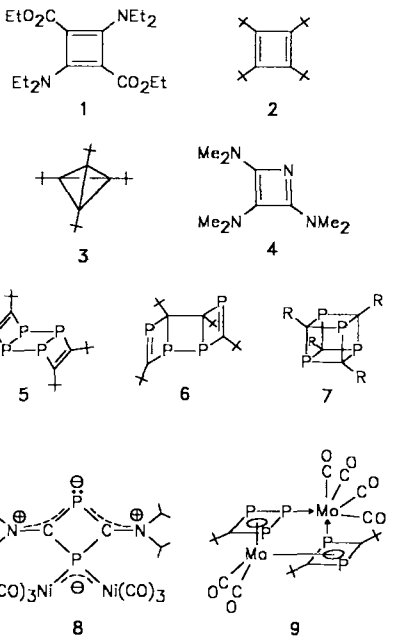
Ylidic Four-Membered Rings with Four π-Electrons—Another Exciting Chapter in Phosphorus Chemistry

Lothar Weber*

The synthesis of stable four-membered ring compounds containing four π-electrons (**A**–**E**) remains a challenge for chemists even though the quest for stable cyclobutadienes ended successfully.[1] In 1968 the first unsupported cyclobutadiene **1** was reported, and its existence was ascribed to the push–pull effect of the two ethyl ester and the two diethylamino substituents.[2] Tetra-*tert*-butylcyclobutadiene (**2**) has to be regarded as a highlight in the field of cyclobutadiene chemistry. It was obtained quantitatively from the thermolysis of tetra-*tert*-butyltetrahedrane (**3**) at 130 °C, and, in contrast to mono-, di-, and tri-*tert*-butylcyclobutadiene, does not dimerize. The thermally induced ring-opening of **3** to yield **2** is reversed upon irradiating the cyclobutadiene derivative. The surprising stability of the tetrahedrane was attributed to the "corset effect" displayed by four bulky substituents, which resulted in a reduction of the steric hindrance.[1]



The interest in heterocyclobutadienes was stimulated by the preparation of tris(dimethylamino)azete (**4**)[3a] and its kinetically stabilized analogue $(t\mathrm{BuC})_3\mathrm{N}$.[3b] Calculations previously indicated that a nitrogen atom has a stabilizing effect on the cyclodiene system (decrease of the negative resonance energy).[3c] In contrast, λ^3-phosphetes (type **A**, X = P) have only been identified as η^4 ligands in transition metal complexes such as $[\mathrm{Co}(\eta^5\text{-}\mathrm{C_5H_5})\{\eta^4\text{-}t\mathrm{Bu(Me_3Si)_2C_3P}\}]$[4] and $[\mathrm{Rh}(\eta^5\text{-}\mathrm{C_5H_5})\{\eta^4\text{-}\mathrm{RPh_2C_3P}\}]$ (R = *t*Bu, N*i*Pr(SiMe$_3$)).[5] Unsupported diphosphetes of types **B** and **C** (X = P) are extremely reactive species, which spontaneously oligomerize to give tricyclic compounds such as **5**[6, 7] and **6**,[6] or the tetraphosphacubanes **7** (R = *t*Bu, $\mathrm{CMe_2Et}$, 1-adamantyl),[8] respectively.



η^4-Diphosphete ligands are usually generated by metal-assisted dimerization of phosphaalkynes in the coordination sphere of transition metal complexes.[9] The 1,3-diphosphabutadiene ligand $(i\mathrm{Pr_2NCP})_2$ in complex **8** is stabilized by σ-coordination to two $[\mathrm{Ni(CO)_3}]$ fragments.[10] Compound **9** is the only $\eta^4{:}\eta^1$-triphosphete complex known to date.[11] *cyclo*-$\mathrm{P_4}$, which is isomeric to white phosphorus, only exists as a ligand in coordination compounds such as $[\mathrm{Ta}\{(1,3\text{-}t\mathrm{Bu})_2\mathrm{C_5H_3}\}(\mathrm{CO})_2\{\eta^4\text{-}\mathrm{P_4}\}]$[12] and $[\mathrm{W(CO)_4}\{(\mathrm{CO})_5\mathrm{WP}\}_4]$.[13, 14]

In addition to ring strain, negative resonance energy ("antiaromaticity") accounts for the instability of cyclobutadienes, azetes, and phosphetes. As we now know, the exchange of a single CH group by a $\mathrm{R_2P}$ function efficiently suppresses the conjugation of the four π-electrons, allowing the preparation of significantly more stable systems of the type **F**. Two nitrogen atoms in the α positions of the λ^5-phosphorus are also tolerated in the four-membered ring (type **G**).

Whereas, monocyclic λ^5-phosphetes are still elusive compounds and are postulated as intermediates in the reaction of $(i\mathrm{Pr_2N})_2\mathrm{P(Cl)}{=}\mathrm{C(H)SiMe_3}$ with dimethyl acetylenedicarboxylate, the benzo- and naphtho-λ^5-phosphetes **10a,b** are synthesized from suitable P-chlorophosphorus ylides and $\mathrm{AlCl_3}$.[15] 1,2λ^5-Azaphosphetes **F** (X = N) are accessible by two different routes. The [2 + 4]cycloaddition of azidobis(diisopropylamino)phosphane with dimethyl acetylenedicarboxylate yields a 1,2,3,4λ^5-triazaphosphinine derivative, which is smoothly converted into **11** in boiling toluene by elimination of dinitro-

gen.[16] A catalytic amount of $PdCl_2$ induces the ring contraction even at room temperature.[16c]

The ring expansion of 2H-azirine **12** to **13** is achieved by catalysis with [(p-cymene)RuCl$_2$].[17] The array of four-membered heterocycles with four π-electrons is enriched by the 1λ^5,2λ^3-diphosphete **15**, which is obtained as a yellow oil during the codimerization of tBuC≡P with the in situ photochemically generated λ^5-phosphaalkyne (phosphinocarbene) **14**. The reaction of bromophenyldiazirine with (iPr$_2$N)$_2$PSnMe$_3$ gives the crystalline, colorless 1,3,2λ^5-diazaphosphete **17** by ring expansion of the transient N-phosphinodiazirine **16**.[19]

Diphosphetes with two λ^5-phosphorus centers can be expected as 1λ^5,2λ^5 or 1λ^5,3λ^5 isomers (**H** and **I**), but only examples of type **I** are known. 1λ^5,3λ^5-diphosphetes (type **I**, X = CR) are among the longest known four-membered rings with four π-electrons. Treatment of $CH_3PF_2(NMe_2)_2$ with two equivalents of n-butyllithium affords compound **18**,[20a] and this procedure is also useful for the preparation of C-substituted diphosphetes.[20b] Reactive λ^5-phosphaalkynes are assumed as intermediates in this process. More recently λ^5-phosphaalkynes were generated by thermolysis or photolysis of phosphinodiazoalkanes, and by using sufficient kinetic stabilization through bulky substituents at the P≡C unit they could be isolated. However, without such protection λ^5-phosphaalkynes dimerize to give 1λ^5,3λ^5-diphosphetes such as **19**.[21]

The photochemical synthesis of 1,2λ^5,4λ^5,6λ^5-azatriphosphinines from phosphinodiazomethanes $R_2PC(N_2)SiMe_3$ involve transient 1,2λ^5,4λ^5-azadiphosphetes (type **I**, X = N), which presumably result from the [2 + 2]cycloaddition between transient λ^5-phosphaalkynes $R_2P{\equiv}CSiMe_3$ and nitrilo-λ^5-phosphanes $R_2P{\equiv}N$.[21c]

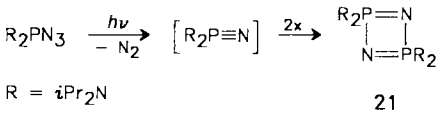
(PPh$_2$)(SiMe$_3$)C=P(Cl)Ph$_2$

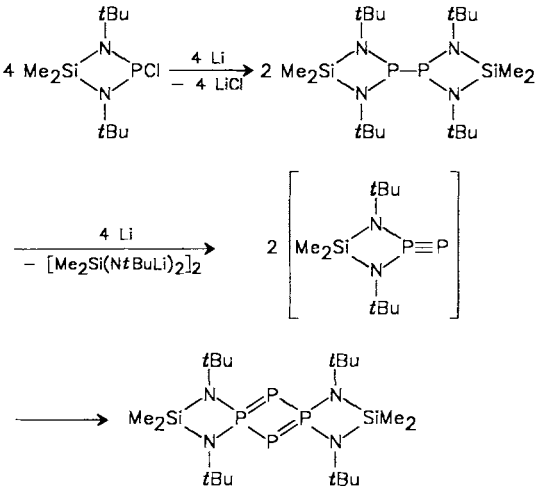


21

The reaction of PCl_3 with Li[C(PPh$_2$)$_2$(SiMe$_3$)] gave the first triphosphete **20** (type **I**, X = P), which was isolated in the form of colorless crystals. The ylide Ph$_2$P(Cl) = C(PPh$_2$)(SiMe$_3$) is obtained in this reaction as a by-product.[22] The analogous 1,2λ^5,4λ^5-arsadiphosphete was obtained when $AsCl_3$ was used instead of PCl_3.[22] An alternative synthetic approach to compound **20** is based on the treatment of the lithium diphosphinomethanide with white phosphorus.[22] The course of the reaction with PCl_3 is sensitive to the nature of the substituents and the solvent. For example, diphosphetes have not been obtained from reactions of Li[C(PMe$_2$)$_2$(SiMe$_3$)] with PCl_3[23] or $AsCl_3$.[24]

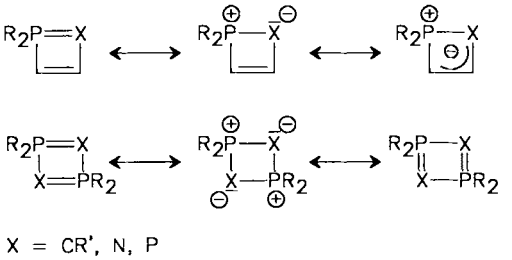
A few 1,3,2λ^5,4λ^5-diazadiphosphetes **21** (cyclodiphosphazenes) of type **J** (X = N) are dimerization products of transient nitrilo-

λ^5-phosphanes, which result from the photolysis or thermolysis of suitably functionalized azidophosphanes.[25] The first $1\lambda^5,3\lambda^5,2\lambda^3,4\lambda^3$-tetraphosphete (**22**; type **J**, X = P), which occurs as the central building block in a dispiro compound, may formally be related to a series of $1\lambda^5,3\lambda^5$-diphosphetes and 1,3,2-$\lambda^5,4\lambda^5$-diazadiphosphetes. Compound **22** is produced by the reduction of the respective bis(amino)chlorophosphane with lithium metal.[26]



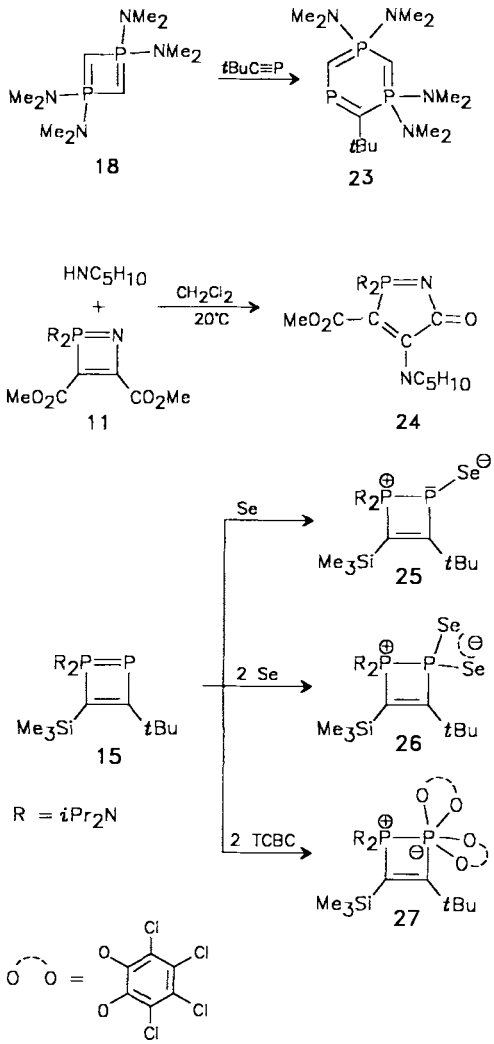
22

According to calculations and the X-ray crystal structure analysis the bonding in the planar four-membered rings **F-J** is best described as zwitterionic (ylidic); the P–X bond lengths range between those of single and double bonds. Therefore, the comparison with phosphorus ylides, phosphazenes,[27] phosphinidene phosphoranes,[28] and triphosphenium systems is particularly pertinent (Scheme 1).



Scheme 1. Bonding in the planar four-membered rings of the type **F**–**J**.

The rich chemistry of these new four-membered ring compounds is particularly interesting and innovative. The ring expansion processes, oxidative additions with retention of the ring skeleton, substitution reactions, and complex formation all merit attention, and the synthetic potential is illustrated here with a few examples. The sole product observed in the reaction of diphosphete **18** with *t*BuC≡P is the $1\lambda^5,3\lambda^5,5\lambda^3$-triphosphabenzene **23**.[30] Treatment of **11** with piperidine at ambient temperature gives rise to the rapid formation of the five-membered heterocycle **24**.[16c] The two-coordinate phosphorus atom of the $1\lambda^5,2\lambda^3$-diphosphete **15** reacts with elemental selenium (one or two equivalents) or with tetrachloro-*o*-benzoquinone (TCBQ; two equivalents) to afford the heterocycles **25**–**27**,[31] respectively. Remarkably, the P–P bond remains intact during these oxidations.



Particularly noteworthy is the reaction of the triphosphete **20** with $Ph_2(Cl)P{=}C(PPh_2)(SiMe_3)$, in which chloride abstraction of the ylidic precursor leads to the formation of the spirocyclic 10e cation **28** with an unprecedented pseudo trigonal bipyramidal PP_4 skeleton.[22] The cation of **28** is an additional member in the family of isoelectronic element(II) compounds of the general composition $E[C(PR_2)_2(SiMe_3)]_2$ (E = Si, Ge, Sn, Pb).[32]

The coordination chemistry of these new ring compounds is also unusual. A representative example is the conversion of diphosphete **18** into the phosphonium acetylide complex **29** and the acylylide complex **30** by exposure to $[Fe(CO)_5]$.[33]

The chemistry of small unsaturated phosphorus heterocycles has been developed in parallel to the chemistry of low-coordinate phosphorus compounds. While the "antiaromatic" four-membered rings with λ^3,σ^2-phosphorus centers remain elusive and undergo spontaneous oligomerization, or in special cases may be intercepted as ligands in transition metal complexes, doubly unsaturated four-membered rings with λ^5,σ^4-phosphorus centers are "non-antiaromatic" zwitterionic isolable com-

pounds. They are employed as key compounds in the synthesis of a number of novel heterocycles and polycycles that exhibit unusual bonding situations. Besides the four-membered rings discussed, the chemistry of five-membered phosphorus heterocycles still has a number of surprises in store, as emphasized by the synthesis of an unprecedented "aromatic" 1,2,3,4-diazadiphosphole from $Li[CH(SiMe_3)N_2]$ and white phosphorus.[34]

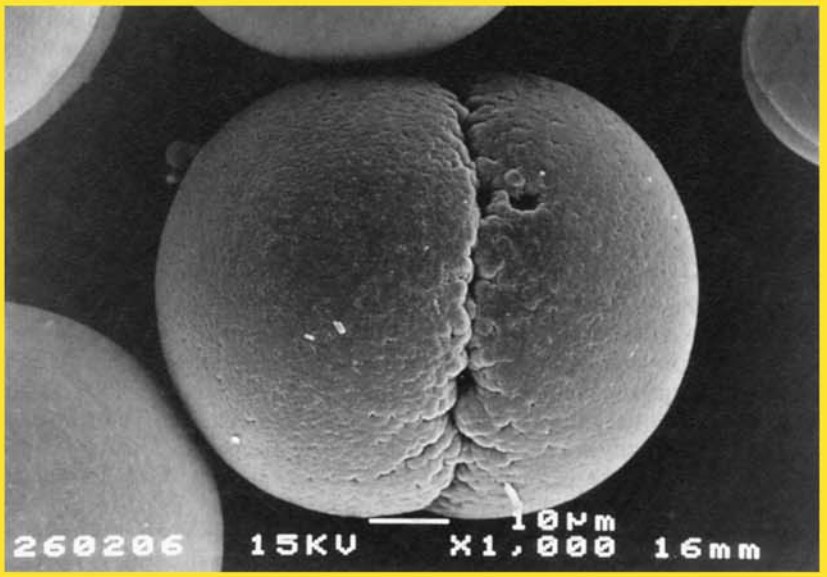
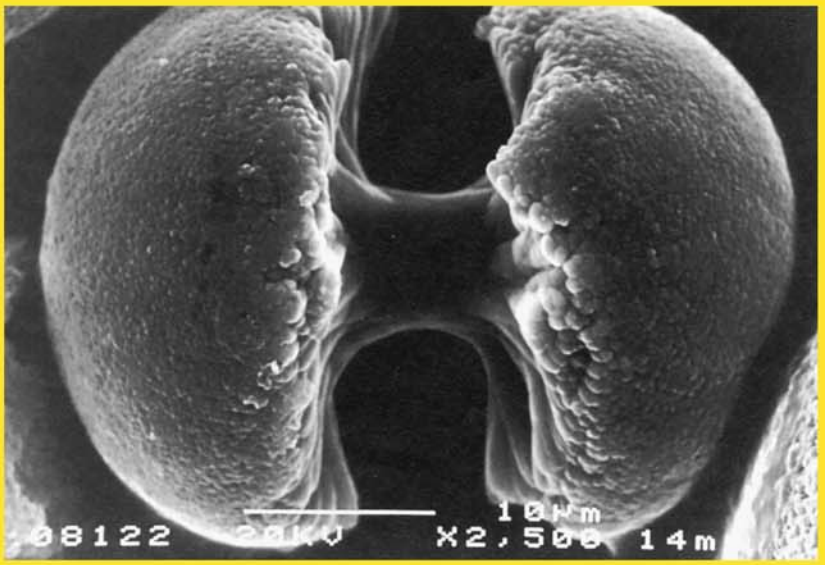
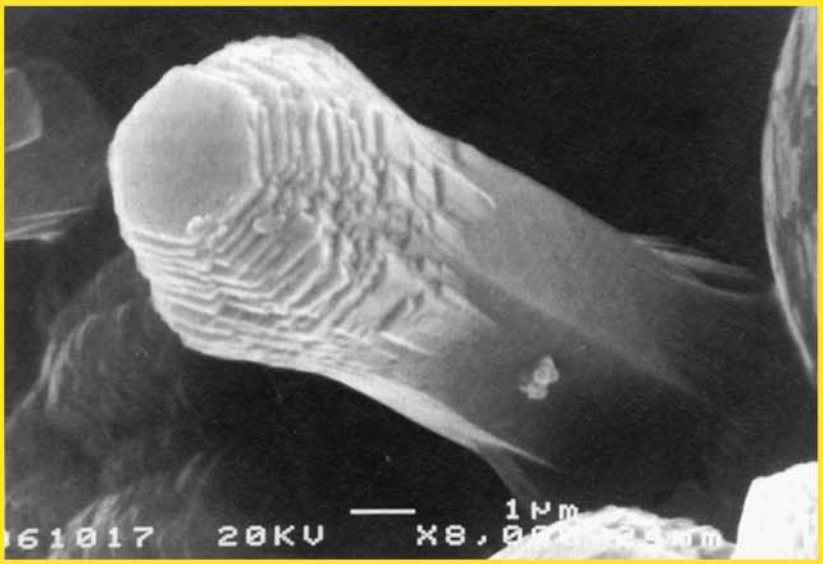
Within a week, hexagonal-prismatic seed crystals (below left) grow into dumbbell-shaped aggregates, which close to form fluorapatite spheres.







More about the biomimetic crystallization is reported by R. Kniep and S. Busch on the following pages.

Biomimetic Growth and Self-Assembly of Fluorapatite Aggregates by Diffusion into Denatured Collagen Matrices**

Rüdiger Kniep* and Susanne Busch

Nature produces inorganic solids with fascinating outer shapes well suited to their function. The mechanisms of formation of these biogenic solids involve the combination of organic and inorganic components. Organic matrices control the mass transfer, define the location and number of nucleation centers, determine the orientation of the (crystal) growth, and/or act as templates for the final morphology of the inorganic solids.

In our studies on mimicking the processes involved in bone or tooth formation,[1] we have investigated the biomimetic growth of fluorapatite in gelatin matrices. A simple (static) diffusion cell was employed, like that known, in principle, for solid-state reactions[2] and that already used in more complex form in dynamic collagen systems.[3] The experimental conditions[4] were chosen such that at constant temperature (25 °C) solutions of calcium and of phosphate/fluoride diffuse into a gelatin plug from opposite ends (the so-called double diffusion technique[5]). In the course of the diffusion, discrete crystallization zones form, which are denoted as Liesegang bands in analogy to the classical work of Liesegang (Liesegang rings).[6] The time-dependent growth of the fluorapatite aggregates can be particularly well monitored in the middle band on the phosphate side; the largest aggregates were also obtained in this band. The crystallization products in all stages of development correspond to the fluorine-rich boundary region of the solid solution series hydroxyapatite/fluorapatite (Fig. 1).[7, 8]

Although the gelatin[4] used here as the organic matrix is of rather poorly defined structure,[9, 10] it is responsible for a specific function in the control of the growth of the fluorapatite aggregates. The use of other organic matrices (e.g., polysaccharides, agar, and carragenan) under otherwise identical experimental conditions[4] leads to fundamentally different morphologies of the fluorapatite (irregular intergrowth of short hexagonal prisms or xenomorphic precipitates). When gelatin is used as the organic matrix, "anisotropic" spheres are formed as the end product, the centers of which contain an elongated hexagonal-prismatic seed crystal.

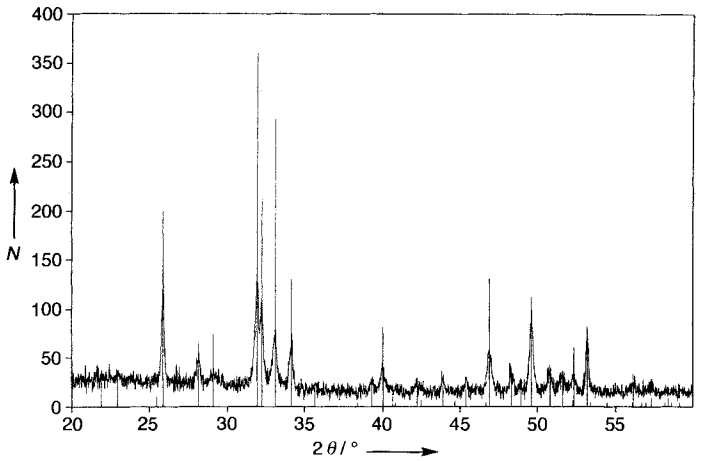

Fig. 1. X-ray powder diagram ($Cu_{K\alpha 1}$ radiation) of a sphere fraction and calculated diagram of fluorapatite ($P6_3/m$; $a = 936.6(3)$, $c = 688.3(3)$ pm) [8]. Refined lattice constants of the sphere fraction: $a = 937.6(3)$, $c = 688.6(2)$ pm (hydroxyapatite [7]: $a = 942.4(4)$, $c = 687.9(4)$ pm). Remarkably, the diffraction peaks of the sphere fraction are comparatively sharp for biomimetic apatite, the X-ray diagram indicates a single phase, and the background is relatively low (small amounts of X-ray amorphous components). N = count rate.

For unchanged morphology of the aggregates, the rates of diffusion of the solutions and of formation of the Liesegang bands, and hence the rate of growth of the fluorapatite are determined by the initial pH of the gelatin. Thus, in a gelatin plug that has not been acidified (pH 5.5, length 3 cm), apatite spheres with diameters of 100 μm are first observed after six weeks in the middle Liesegang band on the phosphate side. If the pH of the gelatin is adjusted to 2.5–3.5, apatite spheres with a diameter of 100 μm are formed after only two weeks. The growth of the fluorapatite spheres begins with elongated hexagonal-prismatic seed crystals, which reach a critical length of 5–10 μm. The progressive stages of the self-assembled growth of the needlelike seed crystals to give spherical aggregates are shown in Figure 2, and require approximately one week. First, oriented upgrowths occur on the prism faces at both ends of the seed crystal simultaneously and roughly symmetrically (mirror symmetry perpendicular to the prism axis), leading to the formation of dumbbell-shaped aggregates. The orientation of these upgrowths does not necessarily indicate the existence of strict crystallographic relations; nevertheless, the maximum angle of divergence (between the prism axes of the growing crystals and the prism axis of the seed crystal) appears to be fixed at approximately 45°. The dumbbell region is extended through further growing generations according to the principles of self-similarity;[11] however, the "bar" of the dumbbell (seed crystal) initially remains visible. This situation can be simulated in a two-dimensional form which mirrors reality very well in a simplified way, as shown in Figure 3.[12] Starting from a needlelike seed crystal, in the first generation similar needlelike crystals are formed at both ends, which have a maximum angle of 45° to the long axis of the seed crystal. The length of the crystals of each successive generation is shorter than the length of the crystals of the preceding generation by a factor of about 0.68 (estimated mean value from scanning electron microscope (SEM) images, error = ca. ±10%). Each "new" end of a crystal generation leads to self-similar multiplication. The result is illustrated in Figure 3, which shows the simulation of five successive self-similar crystal generations at each end of the seed crystal. The fact that the crystals interpenetrate in the simulation is certainly not realistic, but this has no great effect on the morphology of the aggregate. It is more important that the bar of the dumbbell (the seed crystal) remains visible in this growth state and correspondingly in the simulation, that the surface curvature of the dumbbell in the direction of the seed crystal is already indicative of the "closing" of the aggregate, and that the extent of the aggregate, growing from the two ends of the seed crystal, increases by a factor of approximately 2 relative to the length of the seed crystal. The further development of the aggregate—going from the dumbbell to a sphere—can again be seen in Figure 2. Figure 4 shows the SEM image of the surface of a just completed (notched) surface of a sphere. This reveals that also in this last generation needlelike crystals are formed. Their prism cross section is only about 0.05 μm, which means that the closed aggregate has a very large surface area.

The (notched) spheres formed in the gelatin matrix continue their growth by adding radial shells of material and forming almost perfect spheres. This is a second (probably more conven-

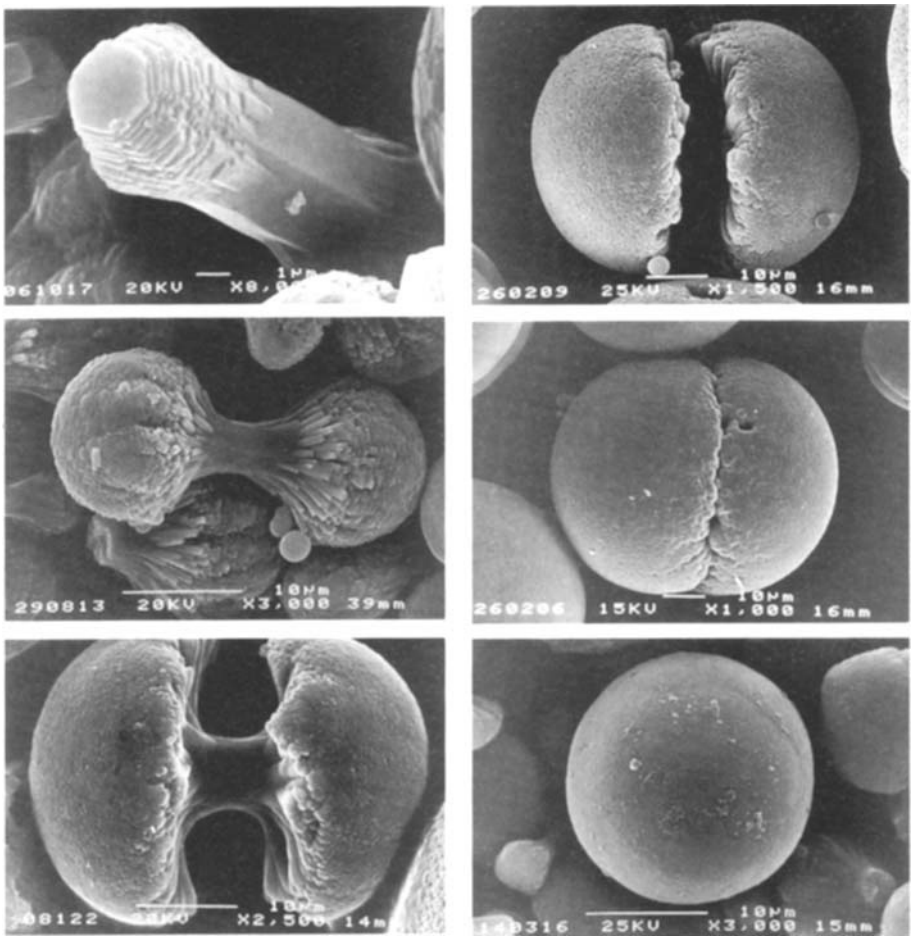

Fig. 2. SEM images of progressive stages of the self-assembled (hierarchical) growth of the fluorapatite aggregates: from the elongated hexagonal-prismatic seed (top left) through dumbbell shapes to the sphere (bottom right).

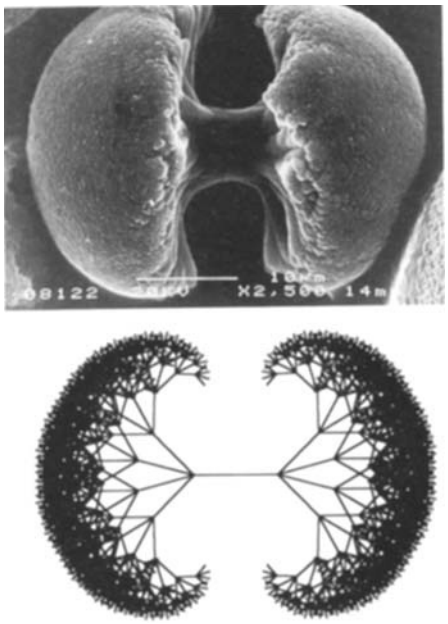

Fig. 3. SEM image of a dumbbell-shaped fluorapatite aggregate (top). Two-dimensional simulation [12] of self-similar branching in five successive generations (bottom). The simulation shows branching (splitting) into only four crystals (with divergence angles of 30°) of the new generation, which is a simplified representation. In fact, orders of branching are higher (see also Fig. 2), and are, in principle, only limited by the maximum angle of divergence (ca. $\pm 45°$) formed by the long axis of the new crystals and the long axis of the preceding seed crystal. The factor of shortening of preceding generations is discussed in the text.

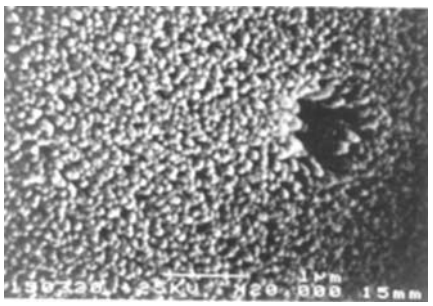

Fig. 4. SEM image of the surface of a just closed sphere aggregate. In accordance with the self-similar branching patterns [12] described in the text and shown in Figure 3, the dumbbell-shaped aggregates close to give notched spheres after the tenth generation.

tionally spherolitic) growth mechanism, which will not be described further here. After about four weeks, sphere diameters of up to 400 μm are found. Our observations indicate that the important limiting factor in the growth of the spheres is the gelatin matrix, which, under the given experimental conditions, is stable for only about six weeks.

The self-assembled hierarchical growth of the fluorapatite aggregates shows immediate parallels to the topological branching criteria of the macromolecular starburst dendrimers.[13] However, the dimensionality—and thus the information transfer—in the aggregates described here extends to the macroscopic range.

In accordance with their microcrystalline structure, the spherical aggregates are opalescent. A fraction of spheres with diameters of up to 300 μm is shown in Figure 5. On a flat support, the

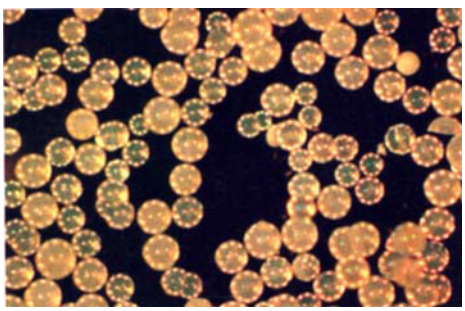

Fig. 5. Optical micrograph of a fluorapatite sphere fraction. The long edge of the figure corresponds to about 4 mm.

spheres orient themselves preferentially to form chains (electrostatic effects), and can be lifted out in the form of "strings of beads" by using the point of a needle. Thermoanalytical investigations (thermogravimetry (TG) and differential thermal analysis (DTA)) on spherical aggregates dried at room temperature were carried out at temperatures up to a maximum of 1000 °C (heating rate 4 °C min^{-1}; atmosphere: air).[14] The X-ray powder diagram of the sample after thermal treatment is identical to

the diagram shown in Figure 1 except that the profiles of the diffraction peaks are sharper (refined lattice constants: $a = 937.4(1)$ pm, $c = 688.7(1)$ pm). The mass loss (total ca. 6.5%) takes place in two stages: stage 1 (80–200 °C) 1.5 wt%, and stage 2 (200–860 °C) 5 wt%. In accord with DTA experiments on human dentine,[15] the second stage is associated with an exothermic reaction (pyrolysis of the protein fibers).

Figure 6 shows the interference image of a just closed fluorapatite aggregate with a diameter of 125 μm, which was obtained with an optical microscope with cross polarizers, as viewed along the optical axis of the hexagonal central seed. The

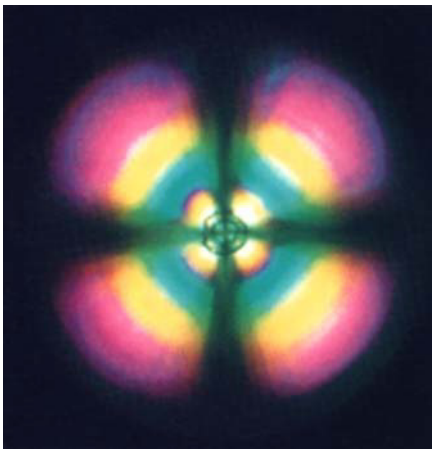

Fig. 6. Image from a polarization microscope (cross polarizers) of a just closed fluorapatite aggregate of diameter 125 μm. Viewed along the hexagonal-prismatic seed.

hexagonal cross section of the seed crystal can be seen in the center, its diameter increases approximately twofold during the course of the growth of the spherical aggregate. The interference pattern of the total aggregate is characterized by the "Brewster polarization cross" and the polarization colors within the cross segments (increasing thickness of the spheres from the surface to their centers, and variable inclination between the optical axes of the individual crystallites and the incident polarized light).

We conclude by mentioning some possible interpretations of the growth phenomenon described, although detailed investigations have either not been started or are not yet complete.[12, 16, 17] There are two basic possibilities, which, individually or taken together, could be responsible for the self-assembled control of the aggregate growth:

1) The aggregates correspond to organized composite systems in which the growth of generations is controlled by an epitaxially linked composite of fluorapatite and the organic component.
2) The individual crystallites or composite units contain a permanent dipole, so that intrinsic electrical lines of force take over control of the growth of the aggregates. The polarity of collagen, the piezoelectric properties of calcified bone tissue,[18] and the structural peculiarity of the apatite family, fluctuating between centrosymmetric and acentric distribution of the X species (X = F, Cl, OH),[19] support these ideas, also bearing in mind the extremely mild biomimetic growth conditions, which should favor a high degree of order of the atomic arrangements, and the fact that partial exchange of F^- by OH^- causes an asymmetric displacement of the two species from their normal positions.[20]

In summary, a wide interdisciplinary area is emerging, which encompasses chemistry, physics, materials science, and medicine.

[4] *Experimental Procedure*: Pig skin gelatin (5.5 g, 300 Bloom, Aldrich) was placed in water (50 mL), acidified with glutamic acid or 2 N HCl to pH 2.5–3.5, and then heated with stirring for a few minutes in a water bath. The central tube of the diffusion cell (length 3 cm, diameter 2.5 cm, closed at one end) was filled with the hot gelatin and left at room temperature for 24 h in a vertical position until gelation occurred. The L-shaped tubes (vertical section: 18 cm, horizontal section: 6 cm, standard ground joints) were then attached to the central gelatin tube, filled with the aqueous solutions (0.133 M $CaCl_2$ or 0.08 M Na_2HPO_4/0.027 M KF), and closed with ground glass stoppers. Both solutions were previously adjusted to the physiological pH of 7.4 with α,α,α-tris(hydroxymethyl)methylamine/HCl. The diffusion experiments were carried out at 25 °C (thermostat). At the end of the experiment, the gelatin plug was pressed out of the central tube and cut into sections corresponding to the Liesegang bands. To isolate the solids, these sections were washed several times with hot water and centrifuged.

Prototypical Reagent for the Synthesis of Substituted Hydrazines**

Uno Mäeorg, Leif Grehn, and Ulf Ragnarsson*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Substituted hydrazines are valuable precursors of heterocycles and components of many pharmaceuticals, agrochemicals, and dyestuffs. Direct alkylation of hydrazine normally gives rise to mixtures of mono-, di-, and trisubstituted products in which all the groups are located at the same nitrogen atoms.[1] This often makes purification troublesome. Although many

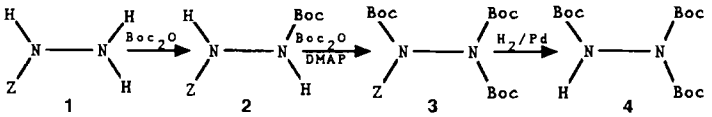
[**] We thank the Swedish Natural Science Research Council, the National Agency for Higher Education, the National Board for Industrial and Technical Development, and Astra Draco AB for their generous support of our programs.

other methods to prepare mono- and dialkylated hydrazines have been developed,[1] a simple, general procedure is still lacking. This is the background to the present work in which the triprotected hydrazine **4** has been developed and investigated.

The idea of alkylating acylated hydrazines is not new,[1] but only little work has been done using modern techniques.[2] Młotkowska and Zwierzak, however, made simple alkylhydrazines in two steps by alkylating diphenylphosphinic hydrazide with bromides under phase-transfer catalysis (PTC) in boiling benzene, followed by deprotection with boiling HCl.[3a] A similar approach was later used with the triprotected derivative acetone *N*-(diethoxyphosphoryl)hydrazone.[3b] When an additional acetylation step was included, selective alkylation of the second nitrogen was possible with the first reagent, resulting, after removal of both protecting groups, in *N,N'*-dialkyl derivatives.[3c] We realized that triacylated derivatives like **4** might possibly undergo alkylations similar to those of the two hydrazine reagents mentioned. Besides, in **4** and its derivatives, one of the Boc groups of the imidodicarbonate function should be particularly labile to acid[4] and thus, after deprotection, allow selective alkylation on the other nitrogen.

We have earlier expanded the scope of Boc protection of amino functions.[5] In this context we designed an efficient synthesis of $HNBoc_2$,[5c,e] which was used to prepare amines including ^{15}N-labeled derivatives. Now we have produced reagent **4** from Z-hydrazine **1**, liberated from the hydrochloride,[6] and treated it with Boc_2O in the presence of 4-(dimethylamino)pyridine (DMAP).[7] The best results are obtained when this reaction is allowed to take place in two consecutive steps, in other words, with formation of **2** before DMAP is added (Scheme 1).

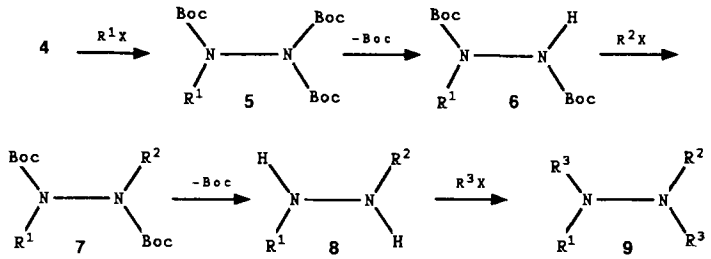


Scheme 1. Synthesis of **4**. Boc = *tert*-butoxycarbonyl, Z = benzyloxycarbonyl.

Crude **3** was obtained as an oil which, after catalytic hydrogenolysis, directly furnished crystalline **4** in an overall yield of 82%. Compound **4** is stable on storage. Moreover, it undergoes rapid alkylation with several reagents under various PTC conditions in benzene at room temperature to give **5**. Although the reaction conditions have not yet been optimized, the six examples in Table 1 indicate that compound **4** reacts satisfactorily.

Compound **5** was treated with small quantities of trifluoroacetic acid[4] to cleave the imidodicarbonate function, giving rise to **6** (Table 1). Thus, also in hydrazines of type **5** one of the Boc groups on the bisprotected nitrogen is indeed selectively cleavable as postulated.

A second alkylation has so far been undertaken only in two cases under experimental conditions similar to those used in the case of **4** (Table 1). In products **7c** and **7d**, however, the Boc groups cannot be cleaved selectively, so both compounds were treated with 4 M HCl/dioxane to give **8c** (96%) and **8d** (87%), respectively, as hydrochlorides. The former was diacetylated as previously described[9] to give **9c** (R^3 = Ac). Upon treatment with a suitable reducing agent, compounds of this type should give rise to tetraalkylhydrazines.



Our experiments with the prototypical reagent **4** led us to conclude that an analogous reagent having two Boc functions and one additional protecting group orthogonal to Boc, should provide hydrazine derivatives with four nonidentical substituents in a similar fashion. Furthermore, a similar strategy might be useful also for the derivatization of diamines.

Table 1. Synthesis of hydrazines **5**–**7** [8].

	R^1	**5**		**6**		R^2	**7**	
		Yield [%]	M.p. [°C]	Yield [%]	M.p. [°C]		Yield [%]	M.p. [°C]

f	dansyl [b]	61	144.5–145.5	–	–			

[a] Exists as an oil. [b] dansyl = 5-(dimethylamino)naphthalene-1-sulfonyl.

Experimental Procedure

4: To molten Boc_2O (43.3 g, 200 mmol) hydrazine **1** (10.0 g, 60.2 mmol) was added in one portion under vigorous stirring. After 15 min of violent gas evolution when the reaction was deemed complete by TLC, a solution of DMAP (183 mg, 1.5 mmol) in CH_3CN (6 mL) was added over 10 min with rapid stirring. After another 15 min, when gas evolution had subsided, the reaction was complete (TLC). The reaction mixture was concentrated, the residue dissolved in diethyl ether, and the solution extracted with citric acid, $NaHCO_3$, and brine, and then dried ($MgSO_4$). Removal of volatiles afforded **3** as a colorless oil in nearly quantitative yield. ^1H NMR (270 MHz, $CDCl_3$): δ = 1.42 (s, 18H, $NBoc_2$), 1.49 (s, 9H, NHBoc), 5.26 (s, 2H, CH_2Ph), 7.30–7.41 (br.m, 5H, Ph). Compound **3**, dissolved in CH_3OH (500 mL), was hydrogenolyzed over Pd/C (5%/carbon, 1.2 g) for 3 h. When TLC indicated complete reaction, the catalyst was filtered off (Celite). The solvent was removed to give a solid, which was recrystallized from light petroleum ether to afford pure **4** as white crystals; yield: 16.3 g (82% from **1**); m.p. 104.5–105.5 °C; pure by TLC. ^1H NMR (270 MHz, $CDCl_3$, 20 °C, TMS): δ = 1.48/1.51 (2 signals, together 27H, Boc), 6.47/6.18 (2 br. signals, together 1H, NH); correct C,H,N analysis.

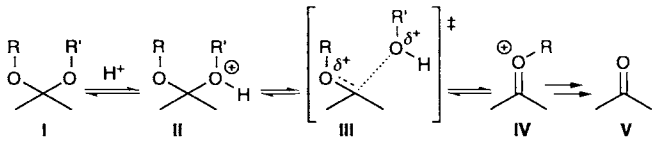
Catalytic Antibodies as Probes of Evolution: Modeling of a Primordial Glycosidase**

Doron Shabat, Subhash C. Sinha,* Jean-Louis Reymond,* and Ehud Keinan*

Enzymes achieve remarkable catalytic efficiency by several effects operating in concert. This is the result of evolution and natural selection over eons. One might wonder how primordial enzymes became catalytically active in the first place. To answer such a question it is important to know which of the effects operating in a modern enzyme is capable of triggering catalysis independently of the others. Catalytic antibodies,[1] which are designed by the experimenter, offer a unique opportunity to study such issues and to examine experimentally various hypotheses about primordial enzymes. It is much easier to dissect the individual parameters of catalysis in catalytic antibodies than in highly evolved enzymes in which all these parameters operate together. Indeed, Schultz et al.'s fundamental structural studies provide much insight into the evolution of catalytic capabilities in proteins.[2]

Along these lines and owing to the importance of carbohydrates in the early stages of evolution, the emergence of glycosidase activity is of particular interest. Herein we report on an antibody-catalyzed hydrolysis of unactivated cyclic ketals, a reaction that is closely related to the cleavage of the glycosidic bond.[3] These catalytic antibodies may therefore be considered as mechanistic analogs of the glycosidase enzymes. We show here that general acid catalysis and/or strain effects, which are of central importance in the activity of modern glycosidases,[4] have only minor significance in these catalytic antibodies. Conversely, simple charge complementarity proves to be the major factor in determining their catalytic activity.

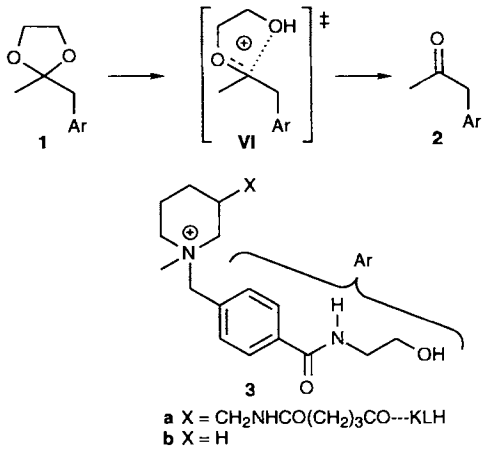
Hydrolysis of ketal **I** involves protonation at one of the oxygen atoms, followed by heterolysis of a C–O bond to generate the intermediate ion **IV** and ultimately the carbonyl compound **V** (Scheme 1). In the case of ketals and acetals with an activated



Scheme 1. General mechanism of ketal hydrolysis under acidic conditions.

leaving group (e.g. R′ = aryl), the first step is the rate-limiting one, and their hydrolysis can be catalyzed by weak acids (general acid catalysis).[5, 6] In contrast, with unactivated ketals (e.g. R′ = alkyl)[7] the O-protonated species **II** is a relatively stable intermediate formed in a preequilibrium. In such cases cleavage of the C–O bond (via transition state **III**) is the rate-limiting step. Therefore, the hydrolysis of unactivated ketals or acetals is not catalyzed by weak acids and depends only on the pH (specific acid catalysis). This reactivity pattern, which also applies for the hydrolysis of glycosidic bonds, poses a particular challenge for the design of a biocatalyst since the presence of a weak acid alone is not sufficient to promote the reaction.

Dioxolane **1**[8] is hydrolyzed in aqueous acidic medium to give ketone **2** and ethylene glycol. Although the hydrolysis rate is pH-dependent, it is totally indifferent to the buffer type and concentration. The observed inverse solvent isotope effect ($k_H/k_D = 0.4$) confirms that the reaction is specific acid catalyzed; the rate-limiting cleavage of the C–O bond of the protonated intermediate **II** leads to the intermediate **IV**. This step involves expansion of the protonated dioxolane ring, during which the positive charge moves from the leaving oxygen atom to the remaining one. We reasoned that the piperidinium ion **3** would be an accurate analog of transition state **VI** (Scheme 2). The positively charged nitrogen center in **3** mimics the emerging ion **IV**, and the six-membered piperidinium ring mimics the expanded five-membered ring of **VI**.



Scheme 2. Transition state **VI** and transition state analog **3** for the hydrolysis of ketal **1** to ketone **2**. KLH = Keyhole Limpet H aemocyanin (carrier protein).

A series of 46 monoclonal antibodies directed against **3a**[6a] were assayed for catalysis of the hydrolysis of **1**. Two of them, antibody 14D9 and antibody 20B11,[9] catalyzed the reaction. In both cases catalysis followed Michaelis–Menten kinetics (Fig. 1) and was totally inhibited by the hapten (**3b**), indicating that the catalytic reactions take place in the combining sites of these antibodies.[10]

In most of the glycosidase enzymes, shape complementarity to the transition state plays a key role in catalysis by inducing productive strain in the substrate.[11] We attempted to obtain similar, shape-selective recognition of the inflated dioxolane ring in the transition state **VI** by using a six-membered ring transition state analog in eliciting the antibodies. To appreciate the effect of this shape complementarity on catalysis by our antibodies we studied the six- and seven-membered ring ketal analogs of substrate **1**: dioxane **4** and dioxepane **5**.

Both antibody 14D9 and antibody 20B11 catalyzed hydrolysis of dioxane **4**. However, in comparison to the hydrolysis of **1**, catalytic efficiency was reduced, in terms of both rate enhancement (k_{cat}/k_{uncat} is decreased 2.6-fold with 14D9 and 8.2-fold

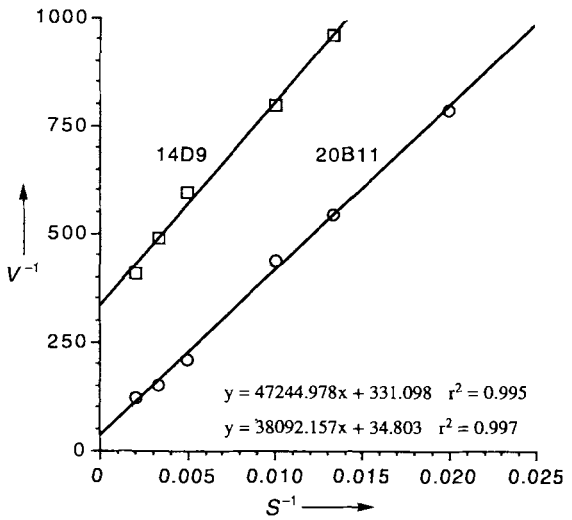

Fig. 1. Lineweaver–Burk plot of antibody-catalyzed hydrolysis of ketal **1** with antibodies 14D9 (squares) and 20B11 (circles). For the reaction conditions see ref. [10]. V = hydrolysis velocity ($\mu M\,h^{-1}$), S = substrate concentration (μM).

with 20B11) and transition state binding (K_{TS} is increased 4.5-fold with 14D9 and 2.9-fold with 20B11) (Table 1). This trend continued further with the seven-membered substrate **5** with a further decrease in k_{cat}/k_{uncat} and increase in K_{TS} relative to the hydrolysis of **1** (k_{cat}/k_{uncat} is decreased 28-fold with 14D9 and 12-fold with 20B11 and K_{TS} is increased 6- and 3.8-fold, respectively).

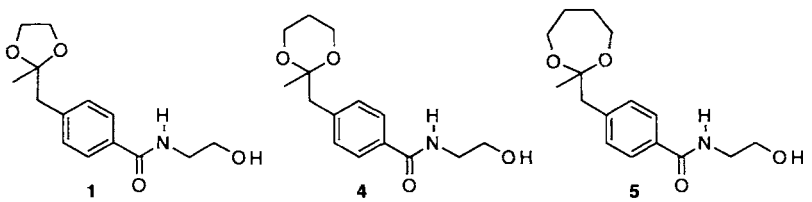

Table 1. Kinetic data for antibody-catalyzed hydrolysis of ketals **1**, **4**, and **5** (K_m and K_{TS} in μM).

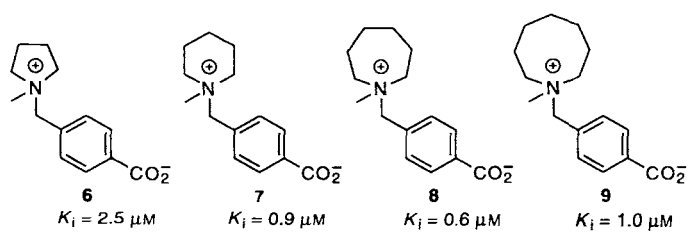
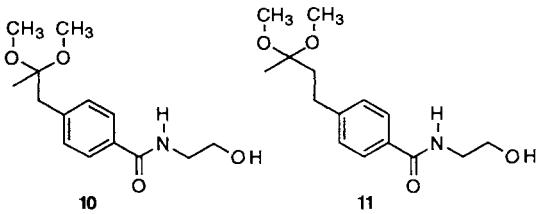
Antibody	1 K_m	1 k_{cat}/k_{uncat}	1 K_{TS}	4 K_m	4 k_{cat}/k_{uncat}	4 K_{TS}	5 K_m	5 k_{cat}/k_{uncat}	5 K_{TS}
14D9	143	113	1.3	250	43	5.8	30	4	7.8
20B11	1095	870	1.3	403	106	3.8	376	76	5.0

Antibody 14D9 was chosen for further studies because it showed a more distinct shape discrimination in catalysis. The shape complementarity between this antibody and the piperidinium ring was estimated by measuring competitive inhibitions with hapten homologs having larger rings. For convenient kinetic analysis with this series of inhibitors their binding efficiency was uniformly reduced by changing the 2-hydroxyethylamide side chain to a carboxylate functionality.[12] Antibody 14D9 bound pyrrolidinium **6** (K_i = 2.5 μM)[12] less tightly than piperidinium **7** (K_i = 0.9 μM)[12] and showed almost no discrimination between **7** and its two higher homologs, azepinium **8** (K_i = 0.6 μM) and the ion **9** (K_i = 1.0 μM).[13]



The active site of antibody 14D9 has been shown previously to possess an ionizable functionality, presumably an aspartate or glutamate side chain, capable of general acid–base catalysis.[14] The solvent kinetic isotope effect in the 14D9-catalyzed hydrolysis of **1** showed that the reaction is specific acid catalyzed (k_{catH}/k_{catD} = 0.4), with no direct participation of this protein side chain as a general acid. In this case the antibody side chain might act as an electrostatic point charge that stabilizes the transition state.[15] Substrate **4** (K_m = 250 μM), which can be considered as a neutral analog of the hapten, was bound by antibody 14D9 approximately 10^4-fold less tightly than the hapten **3b** ($K_i \approx 10^{-8}$ M). In fact the actual transition states for hydrolysis of **1**, **4**, and **5**, whose affinities are given by K_{TS}, are bound approximately 10^2 times tighter than the substrates themselves. These effects on transition state and hapten binding are much stronger than those seen by modulating molecular shapes and indicate that catalysis of ketal hydrolysis with antibody 14D9 depends primarily on electrostatic complementarity. This is also consistent with the observation that dimethyl ketal **10** (k_{cat}/k_{uncat} = 70, K_m = 70 μM) and its homolog **11** (k_{cat}/k_{uncat} = 430, K_m = 230 μM)[16] are also substrates of antibody 14D9.[17] The substrate's shape probably plays only a limited role in enabling the formation of a catalytically productive complex with the antibody.



We have shown here that antibodies catalyzing the hydrolysis of unactivated ketals can be achieved by a very simple design. We have presented evidence that the observed catalysis is triggered by electrostatic complementarity of the antibody binding site to the transition state, and that the effect of shape complementarity on catalysis is relatively limited. Since the hydrolysis of unactivated ketals is mechanistically closely related to the cleavage of glycosidic bonds, this study provides experimental support for the hypothesis that glycosidases would have first appeared as "electrostatic" catalysts. Shape complementarity and general acid catalysis, which dominate the catalytic effect in modern glycosidase,[3] would only have emerged in the later course of evolution.

[8] All ketals were prepared from methyl (4-bromomethyl)benzoate in a four-step sequence: Cross-coupling with divinyl cuprate [prepared from vinylmagnesium bromide (2 equiv) and cuprous iodide (1 equiv) in THF at $-30\,^{\circ}C$] afforded methyl (4-allyl)benzoate. Wacker oxidation at room temperature with $PdCl_2$ (0.1 equiv) and $CuCl_2$ (1.5 equiv) in DMF/H_2O (2/1) afforded (4-methoxycarbonyl)phenylacetone, which was ketalized in benzene at reflux in the presence of the appropriate diol (ethylene glycol, 1,3-dihydroxypropane, 1,4-dihydroxybutane) and catalytic amounts of *p*-toluenesulfonic acid. Dimethyl ketal **10** was obtained by treating the corresponding ketone with trimethylorthoformate and methanol in the presence of *p*-toluenesulfonic acid. Finally, the methyl ester was converted to the 2-hydroxyethylamide by heating it in 2-aminoethanol (100 °C, 2 h).

[17] Hydrolysis of **10** was carried out at 24 °C, pH 7.4, and that of **11** at 0 °C, pH 7.55; both were conducted in 50 mM phosphate/100 mM NaCl).

Synthesis and Structure of $CoB_2P_3O_{12}(OH)\cdot C_2H_{10}N_2$: The First Metal Borophosphate with an Open Framework Structure**

Slavi C. Sevov*

The most notable trend in the field of molecular sieve synthesis in the past few years is the profound expansion of the variety of studied systems and the rapidly growing number of acronyms associated with them. In addition to the conventional zeolites there are AlPOs (Al-P-O systems), SAPOs (Si-Al-P-O systems), GaPOs (Ga-P-O systems), MeAPOs (metal-Al-P-O systems), Ga-As-O systems, Al-As-O systems, etc. Virtually all combinations of the mixed oxides of the heavier analogs of the boron and nitrogen groups have been explored. With this in mind it is quite surprising that molecular sieves in the B-P-O or Me-B-P-O systems have not yet been synthesized. This is even more surprising considering that BPO_4 itself is a catalyst used industrially for many reactions including hydration, dehydration, alkylation, and oligomerization,[1] and extensive research efforts have been devoted to finding ways to increase its surface-to-volume ratio.[2] Furthermore, incorporation of boron in zeolites and molecular sieves has been a goal pursued for quite some time, since even small amounts of boron have been shown to improve enormously the properties of the host.[3] With a few exceptions, however,[4] such boron incorporation has been possible only on a very small scale, usually less than one percent.[3a, 5] Reported here is the first member of a new class of molecular sieves, namely metal borophosphates (BPOs) with open framework structures in which boron is an integral part of the framework.

The title compound (designated BPO-1) was made hydrothermally from H_3BO_3, H_3PO_4, $[Co(en)_3Cl_3]$ (en = ethylenediamine), and $BF_3\cdot CH_3CH_2NH_2$. Although fluorine is not incorporated in the compound (see Experimental Procedure), boron trifluoride apparently plays an important role in the synthesis since attempts to make the compound without it or with other fluoride sources were unsuccessful. The role of fluorides in the formation of novel framework structures has been well documented, although it is not quite clear what exactly that role might be.[6]

The structure of BPO-1 was determined by single-crystal X-ray diffraction (see Experimental Procedure). The atomic coordinates and some selected bond lengths are listed in Tables 1 and 2, respectively. The structure of the deep purple BPO-1 can be best described as an open framework with one-dimensional channels along the *b* direction of the orthorhombic unit cell (Fig. 1). The framework is built of corner-sharing CoO_6 octahedra and BO_4 and PO_4 tetrahedra. All but two oxygen atoms are shared by two polyhedra. The two exceptions are O13, which is shared by three polyhedra (one CoO_6 octahedron and two BO_4 tetrahedra), and O12, which belongs to only one polyhedron (PO_4 tetrahedron) and is a part of an OH group. No two

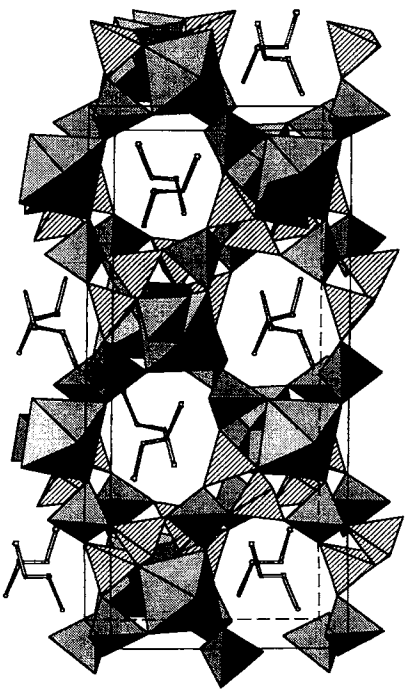

Fig. 1. View of BPO-1 nearly along the *b* axis; the *c*-axis is vertical and the unit cell is outlined. The striped tetrahedra are BO_4 units and the rest are PO_4 units. The octahedra correspond to CoO_6. The ethylenediamine molecules are shown without the hydrogen atoms.

PO_4 tetrahedra are bonded to each other but the two BO_4 tetrahedra share a corner, O13, the same three-coordinate oxygen atom that is also part of the CoO_6 octahedron. The P–O, Co–O, and B–O distances are within the expected ranges.

The channels in the structure are formed from eight polyhedra sharing corners in the following sequence: -PO_4-CoO_6-PO_4-BO_4-PO_4-BO_4-PO_4-CoO_4-. The channels are not exactly straight and round but rather wavelike and oblong (Fig. 1). The short axis of the opening is about 5.2 Å, and the long one is about 7.6 Å (O–O distances). The channels are occupied by the ethylenediamine molecules, which are positioned nearly perpendicular to the direction of the channel and with their N–N axis along the long axis of the ellipse. The two C–N distances and the C–C distance (1.465(5), 1.478(5), and 1.517(6) Å, respectively) are in the normal range. The molecules are well locked in their positions by hydrogen bonds to oxygen atoms lining the channel (Fig. 2), and no disorder was observed at the C, N, and

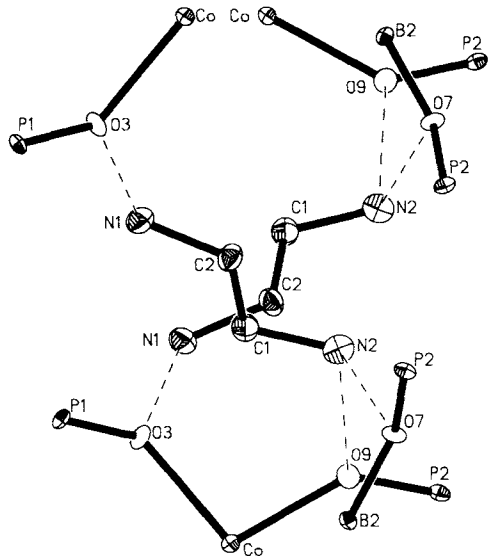

Fig. 2. An ORTEP drawing (thermal ellipsoids at 50% probability) of one ethylenediamine molecule (without the hydrogen atoms) and its hydrogen bonds (broken lines) to oxygen atoms lining the channel.

H positions. One of the hydrogen atoms at N1 is involved in hydrogen bonding ($d_{N1-O3} = 2.878(5)$ Å, $d_{H-O3} = 2.05$ Å, $\alpha_{N1-H-O3} = 168.4°$), while two of the hydrogens at N2 form hydrogen bonds ($d_{N2-O7} = 2.892(4)$ Å, $d_{H-O7} = 2.06$ Å, $\alpha_{N2-H-O7} = 171.1°$; $d_{N2-O9} = 2.802(5)$ Å, $d_{H-O9} = 1.91$ Å, $\alpha_{N2-H-O9} = 167.5°$).

The oxygen atom of the OH group, O12, is also hydrogen bonded. It is only 2.525(4) Å from O4 ($d_{H-O4} = 1.83$ Å, $\alpha_{O12-H-O4} = 170.3°$). The OH group is also positioned in the channel but is between the ethylenediamine molecules and not hydrogen bonded to them.

Upon heating under vacuum the compound is stable up to roughly 500 °C, above which it becomes amorphous. This structural change is most likely due to decomposition of the ethylenediamine dication followed by a collapse of the framework. The amorphous mass was further heated at 950 °C for a few hours. After cooling to room temperature it was put back in an autoclave, water was added, and the autoclave was heated for four days at 180 °C. The product of this reaction (without an organic template) is the known cobalt (hydrogen)phosphate $Co_7P_6O_{20}(OH)_4$,[7] which is composed of well-packed CoO_6 octahedra and PO_4 tetrahedra.

In conclusion, it is possible to synthesize molecular sieve type compounds with networks constructed from BO_4 and PO_4 tetrahedra (and CoO_6 octahedra) similarly to the way the AlPOs are built. It is very likely that the organic template can be removed from similar compounds and that the channels can then be used for appropriate catalytic reactions. The presence of boron at relatively high concentrations should improve the catalytic properties of such catalysts.

Experimental Procedure

Synthesis: BPO-1 was synthesized hydrothermally (heated at 180 °C for five days followed by oven cooling) in Teflon-lined stainless steel autoclaves from a mixture of $[Co(en)_3Cl_3]\cdot 2H_2O$, H_3BO_3, H_3PO_4 (85%), $BF_3\cdot CH_3CH_2NH_2$ (all from Aldrich), and water in the molar ratio of 0.25:1:1:1:45. Bar-shaped as well as large spheres (3–5 mm diameter) of wedge-shaped, deep purple crystals were recovered and washed with water. Both types of crystals were of the same compound (nearly 100% yield with respect to Co). Chemical analysis confirmed the amounts of ethylenediamine (M-H-W Laboratories: C 5.07, H 2.52, N 6.30%; theoretical: C 5.40, H 2.49, N 6.30%) and the absence of fluorine (Galbraith Laboratories: F 0.27%; theoretical if one atom of oxygen is replaced by fluorine: F 4.2%) in the compound.

Structure Determination: A few bar-shaped crystals of BPO-1 were cut into smaller pieces and then checked for singularity by oscillation film technique. One of the crystals ($0.4 \times 0.3 \times 0.2$ mm) was additionally studied by taking Weissenberg photographs of the zeroth and first layers. These revealed an *mmm* Laue class, the possible space groups, and the approximate unit cell dimensions. Two octants of data up to $2\theta = 50°$ were collected at 21 °C with monochromated $Mo_{K\alpha}$ radiation on a CAD4 single-crystal diffractometer with ω-2θ scans. (Some additional details of the data collection and refinement are listed in Table 3.) Corrections for Lorentz and polarization effects and for absorption (SDP package, Enraf-Nonius, 1985) with the aid of the average of five ψ-scans collected at different θ angles gave a data set that was consistent with only one space group, *Pbca*. Subsequent structure solution and refinement were performed with the aid of the SHELXTL program package. Application of direct methods revealed the Co and P positions and most of the oxygen sites. Successive least-square cycles and difference Fourier syntheses provided the positions of the remaining non-hydrogen atoms. One oxygen atom, O12, was one-coordinate, which suggested that it was part of an OH group. Additionally, ten more hydrogen atoms were needed for the ethylenediamine dication. Eleven peaks from the subsequent difference Fourier synthesis were at distances around O, C, and N appropriate for hydrogen atoms. These were assigned as such. Refinement of the hydrogen atoms (without constraints) with isotropic thermal parameters, refinement of the non-hydrogen atoms with anisotropic thermal parameters, and application of a secondary extinction coefficient gave final residuals of R and wR of 0.044 and 0.113, respectively (as defined in Table 1). Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-405370.

Synthesis and Properties of PNA/DNA Chimeras**

Eugen Uhlmann,* David W. Will, Gerhard Breipohl, Dietrich Langner, and Antonina Ryte

Synthetic oligonucleotides play a central role in a multitude of molecular biology techniques.[1–3] They are, for example, routinely used as linkers, primers, and gene probes. More recently their potential use as antisense or antigene oligonucleotides has attracted increasing interest.[4–7] To develop the desired biological activity in vivo, oligonucleotides must be stable against the nucleases found in serum and in cells. They must also be capable of entering the cell in order to bind sequence-specifically to their intracellular target sequence. From the huge variety of modifications carried out on oligonucleotides,[4, 8] the nonionic oligonucleotide analogues[9] are of particular interest. Besides their increased stability toward nucleases they can also be expected to have a higher binding affinity to their target nucleic acid because of the lack of charge–repulsion effects. One of the most remarkable of the nonionic oligonucleotide analogues are the polyamide nucleic acids (PNAs), since these bind to complementary DNA and RNA with a higher affinity than natural oligonucleotides.[10–13]

PNAs are nucleic acid mimetics in which the entire sugar–phosphate backbone is replaced by *N*-(2-aminoethyl)glycine units. Although the recognition of complementary nucleic acid sequences by PNAs obeys the Watson–Crick base-pairing rules, the orientation of the strands is ambiguous. This means that PNAs can form both parallel and antiparallel duplexes,[13] in contrast to the purely antiparallel strand orientation in natural nucleic acids. As well as their tendency to self-aggregate, a further hurdle to their application as antisense oligomers is their extremely low, or nonexistent cellular uptake.[12] Here we report on a method for the fully automated synthesis of PNA/DNA chimeras (Fig. 1) that contain all four natural nucleobases. We have found that these PNA/DNA chimeras bind to their complementary DNA and RNA exclusively in the antiparallel orientation. The negative charge on the DNA part of the chimeras reduces their tendency to self-aggregation and thus improves their solubility.

Ideally the synthesis of PNA/DNA chimeras of any desired sequence (5′-DNA-PNA-pseudo-3′; pseudo-5′-PNA-DNA-3′) should be carried out "online" on an automated synthesizer with commercially available DNA monomers. The synthesis of PNA/DNA chimeras has been reported previously; however, in those reports the DNA part of the chimeras was composed entirely of acid-stable pyrimidine nucleotides.[14–16] In one case the use of specially protected DNA monomers was necessary.[14] The binding affinities of the PNA–DNA chimeras[14] and the DNA–(HomoPNA) chimeras[15] were reported to be lower than the corresponding DNA sequences. Recently we reported on the synthesis of pure PNAs with a new type of PNA monomer,[17] in which the acid-labile monomethoxytrityl (Mmt) group is employed for temporary protection of the amino function of the aminoethylglycine and the exocyclic amino functions of the nucleobases are protected with base-

labile acyl protecting groups. This orthogonal protecting-group strategy was designed to be fully compatible with the phosphoramidite DNA synthesis method of Caruthers.[18]

For the synthesis of DNA–PNA chimera **1a**, which is composed of a DNA 5′-terminus and a PNA (pseudo) 3′-terminus, the PNA part is synthesized first on CPG (controlled pore glass) solid support from PNA monomers **2a–d** (Fig. 2), as described previously.[17] One of the linker monomers **3a–d**, which are derivatives of *N*-(2-hydroxyethyl)glycine, is then coupled to the amino terminus. This allows the synthesis of the DNA part by reaction with the nucleoside phosphoramidites **4a–d**. The use of an expanded DNA synthesizer (Eppendorf–Biotronik GmbH, Maintal, Germany) with ten positions for monomer solutions allowed the fully automatic synthesis of DNA–PNA chimeras **6–9** (Fig. 3). These chimeras contain all four nucleobases in both the PNA part and the DNA part. The 5′-terminal dimethoxytrityl protecting group is cleaved on the synthesizer, and the chimera is treated with aqueous ammonia solution to cleave it from the solid support and to remove the base-labile phosphate- and amino-protecting groups. Since a base-labile 6-aminohexylsuccinate linker is employed[17] the resulting DNA–PNA chimeras are obtained as C-terminal hydroxyhexylamides. DNA–PNA chimeras **6–9** are highly water-soluble and can be analyzed and purified by polyacrylamide gel electrophoresis or by ion-exchange HPLC. For the synthesis of PNA–DNA–PNA chimera **10** the DNA–PNA part is synthesized as described for **6–9**. A 5′-*N*-monomethoxytrityl-5′-amino-2′,5′-dideoxynucleoside-3′-*O*-phosphoramidite (**5a–d**) is then coupled to the free 5′-hydroxyl function and serves as a linker to the 5′-terminal PNA part of the chimera (Fig. 1, structure **1b**). After detritylation with trichloroacetic acid the 5′-terminal PNA part is synthesized as described above. All of the new PNA/DNA chimeras **6–11** were characterized by electrospray mass spectrometry.

The binding affinity of the DNA–PNA chimeras to their complementary nucleic acid sequences was investigated by measuring the melting temperatures T_m of the duplexes. Figure 4 compares the UV-melting curves of the chimeric (DNA–PNA)·DNA duplex **6·15** (Fig. 4A) with those of the

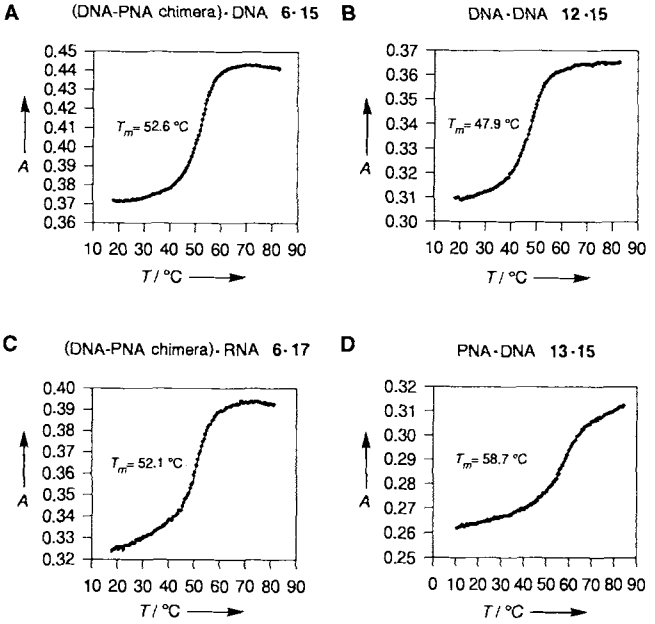

Fig. 4. Comparison of the UV-melting curves of the duplex formed by DNA–PNA chimera **6** and the complementary DNA **15** (A) and RNA **17** (C) sequences with those of the duplexes formed by DNA **12** (B) and pure PNA **13** (D) with the complementary DNA **15**.

DNA·DNA duplex **12·15** (Fig. 4B) and the PNA·DNA duplex **13·15** (Fig. 4D). The PNA·DNA duplex is the most stable (T_m = 59 °C). However, the (DNA–PNA)·DNA duplex (T_m = 53 °C) also has a considerably higher stability than the natural DNA·DNA duplex (T_m = 48 °C). The pure PNA **13** binds with **15** in the antiparallel orientation (T_m = 59 °C) and with **16** in the parallel orientation (T_m = 48 °C), whereas the analogous DNA–PNA chimera **6** binds only to the antiparallel oligonucleotide **15**, but no binding to the parallel oligonucleotide **16** is detected at room temperature (Table 1). The T_m values of the various oligomers against their complementary RNA sequences were also measured (Table 1, Fig. 4C). This is the most relevant model for the use of DNA–PNA chimeras as mRNA-targeting antisense oligomers. Again oligomer **6**, which is composed of 50% PNA, has a significantly higher antiparallel duplex stability than the pure DNA analogue (ΔT_m = 8 K). Although the pure PNA has a higher binding affinity than either the chimera or the oligonucleotide, it also binds to the parallel complementary sequence.

Oligonucleotide phosphorothioates are the most thoroughly investigated and widely used oligonucleotide analogues in biological systems. We compared the binding affinities of the DNA–PNA chimera **6** with the analogous phosphodiester–phosphorothioate chimera **14** in which the PNA is replaced by phosphorothioate-linked DNA (S-DNA). Interestingly, the DNA–PNA chimera **6** forms a duplex with complementary RNA **17** that melts 10 K higher than the DNA–(S-DNA) chimera **14**. The binding affinity is largely dependent upon the ratio of PNA to DNA in the chimera. Thus undecamer **7**, in which 72% of the sequence is composed of PNA, melts 14 K higher than the corresponding DNA analogue **28** (Table 2). In chimera **8** the DNA part contains phosphorothioate linkages but still binds better to the complementary DNA sequence than the corresponding oligonucleotide **27**.

Table 1. Comparison of the T_m values [a] of the oligomers **6** and **12–14** when hybridized to their complementary parallel and antiparallel DNA or RNA sequences.

5'-CGCGAA**t**tcgcg-3'
3'-gcgct**t**AAGCGC-5'
[b] Measured at pH 5, forms a triple helix:
5'-ctcttc-**TT**
3'-GAGAAG T
(3')-ctcttc-**t**T

The self-complementary DNA–PNA chimera **9**, which forms a duplex **9·9** in which all PNA bases are opposite DNA bases, has a T_m value 13 K higher than the analogous DNA duplex **29·29**. The PNA–DNA–PNA chimera **10** is designed so that the C-terminal PNA part (pseudo 3' end) forms a Watson–Crick duplex with complementary hexamer **25**. The DNA part acts as a loop to allow the N-terminal PNA part (pseudo 5' end) to fold back and form Hoogsteen base-pairs under acidic conditions. The resulting triplex has a remarkably high T_m (65 °C) for a hexamer complex. The corresponding DNA analogue melts at 27 °C.

To investigate the specificity of the base-pairing in the PNA and DNA parts of the PNA/DNA chimeras, the melting temperatures of duplexes formed by DNA–PNA chimera **6**, DNA oligonucleotide **12**, and PNA oligomer **13** with complementary DNA sequences each containing one base mismatch in three different positions were determined. One of the mismatches was positioned in the DNA part, one in the PNA part, and one directly at the DNA → PNA crossover.

As can be seen in Figure 5, the destabilising effect of a PNA–DNA mismatch is approximately the same as that of a DNA–DNA mismatch at the same position. It should be emphasized that a base mismatch at the DNA → PNA crossover also results in a clear reduction of the T_m. This strongly suggests that the nucleobase at the crossover is also involved in cooperative binding to the complementary nucleic acid. However, since the ΔT_m

Fig. 5. Comparison of the difference in the T_m value (ΔT_m [K]) between the duplex formed by DNA-PNA chimera **6**, DNA **12**, or PNA **13** with the complementary DNA **15** and the corresponding duplexes formed with the complementary DNA strands that contain base mismatches (A → T) in three different positions (**19**-**21**).

is smaller than that for the pure PNA or DNA oligomers there might be a minor disturbance in the duplex structure at the site of the crossover. It is also possible to use simple linkers that are not involved in base-pairing, such as the γ-hydroxybutyric acid linker in sequence **11**.

The use of PNA/DNA chimeras as antisense or antigene oligomers requires that they are capable of entering cells. The uptake of DNA-PNA chimera **11** by Vero cells was determined by labeling the oligomer at the 5′ end with ^{35}S-γ-ATP and incubating the cells with the radiolabeled oligomer. Figure 6 shows that cellular uptake of the DNA-PNA chimera, measured as cell-associated oligomer,[19] is almost identical to that of the analogous oligonucleotide **24** at both 1 μM and 10 μM extracellular concentration.

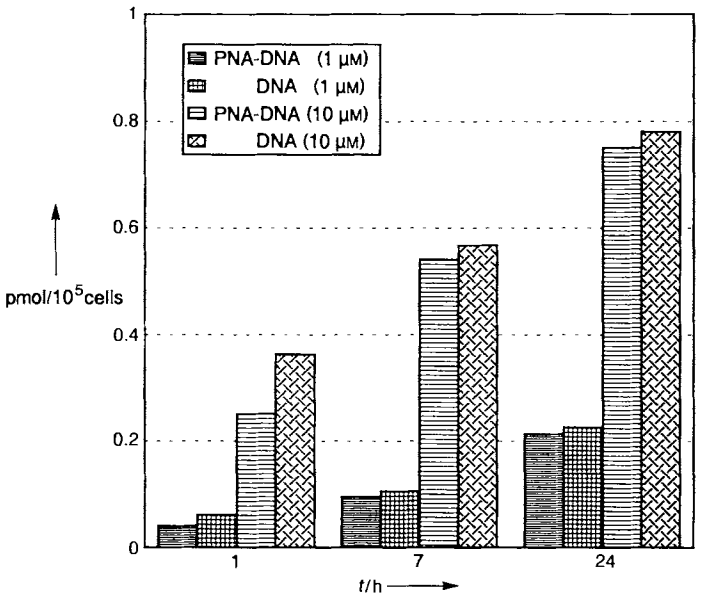

Fig. 6. Comparison of the cellular uptake of the DNA-PNA chimera **11** labeled at the 5′ end with ^{35}S-γ-ATP with that of the analogously labeled DNA oligomer **24** at 37 °C in Vero cells.

Preliminary experiments in cell culture have shown that DNA-PNA chimeras used as antisense oligomers are capable of inhibiting the expression of specific target genes, even when only 30% of the oligomer is composed of DNA. The fact that PNA/DNA chimeras activate cellular RNase H, which cleaves the RNA strand of a DNA·RNA duplex, may well be of importance in this respect. Pure PNAs do not activate RNase H. The biological activity of RNase H inducing oligonucleotide analogues is generally superior to that of those which do not activate this enzyme.[4, 5]

We have developed a generally applicable method for the automated synthesis of DNA/PNA chimeras. This method is fully compatible with standard DNA synthesis methods and requires no additional deprotection steps at the end of oligomer synthesis. The binding affinity of DNA-PNA chimeras is higher than that of the comparable DNA-phosphorothioate chimeras or natural oligonucleotides. Unlike pure PNAs, the DNA-PNA chimeras investigated bind only in the antiparallel orientation to their complementary nucleic acids under physiological conditions. The DNA-PNA chimeras in which the PNA part was attached to the 3′ end of the DNA part are especially stable against degradation by 3′-exonucleases, which are the major type of oligonucleotide-degrading enzymes found in serum. DNA-PNA chimeras are taken up by cells to a similar extent as oligonucleotides, are largely nuclease-resistant, and have an excellent binding affinity to complementary RNA. They thus fulfill the basic requirements for antisense oligomers to be biologically active.

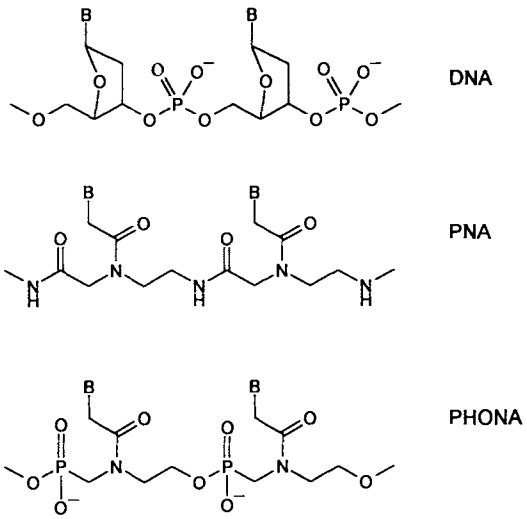
Phosphonic Ester Nucleic Acids (PHONAs): Oligonucleotide Analogues with an Achiral Phosphonic Acid Ester Backbone

Anusch Peyman,* Eugen Uhlmann, Konrad Wagner, Sascha Augustin, Gerhard Breipohl, David W. Will, Andrea Schäfer, and Holger Wallmeier

Oligonucleotides have become increasingly important as potential therapeutics and diagnostic tools.[1, 2] When used as antisense oligonucleotides they are not only required to recognize their specific mRNA target, but also to be taken up by cells and to be nuclease-resistant.[1, 2] A plethora of modified oligonucleotide analogues with improved properties has been synthesized.[1] These modifications range from simple modifications of the phosphodiester bridge, such as phosphorothioates, to total replacement of the phosphate group,[1, 3] or even to replacement of the complete sugar–phosphate backbone, such as the "morpholino-nucleoside oligomers"[4] or the polyamide nucleic acids (PNAs).[5]

Due to their excellent binding properties the PNAs (Scheme 1) are the most interesting of the oligonucleotide analogues. Structurally PNAs consist of oligomers of *N*-(2-aminoethyl)glycine to which the nucleobases are attached by carboxymethylene units. PNAs are synthesized by condensation

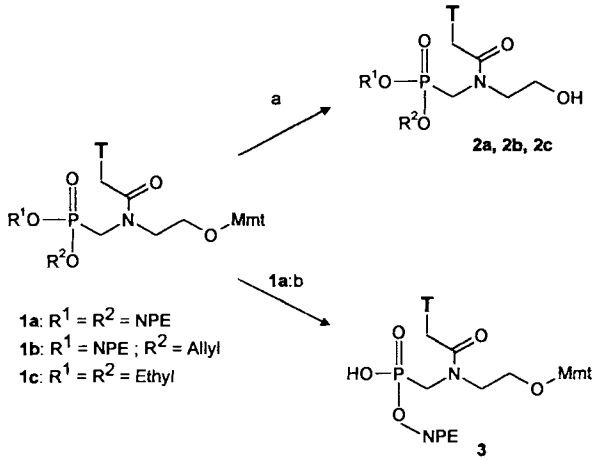


Scheme 1. Structural elements of DNA, PNA, and PHONA.

of appropriately protected monomers using peptide synthesis methodology.[5–7] As well as forming duplexes with complementary DNA, PNAs can also form extraordinarily stable $(PNA)_2$–DNA triple helices. The biggest obstacles to the use of PNAs as therapeutics are their poor water-solubility, their tendency to self-aggregate, and their insufficient cellular uptake.[5, 8]

The aim of the work described here was to synthesize a new PNA analogue with an achiral and negatively charged backbone to which the nucleobases are attached through carboxymethylene linkers. In order to maintain the strong binding to complementary nucleic acids the new structure was designed to be isosteric with PNAs, and the introduction of negative charges in the backbone should lead to improved solubility characteristics. A scaffold that fulfills the described requirements is the carboxymethylene nucleobase derivatized, *N*-(2-hydroxyethyl)aminomethylphosphonic acid ester (Scheme 1, *phos*phonic ester *n*ucleic *a*cid = PHONA). Here we describe the synthesis of a PHONA nonamer and its DNA-binding properties. Thymine was chosen as the nucleobase, as it requires no additional protecting groups.

The synthesis of the nonamer was carried out by block condensation in solution by the phosphotriester method that has been used successfully for DNA synthesis.[9] The choice of protecting groups is critical for successful oligomer synthesis. For the monomers **1a–c** the orthogonal protecting group combination of 4-methoxyphenyldiphenylmethyl (Mmt) for the hydroxyl function and 2-(4-nitrophenyl)ethyl group (NPE)[10] for the phosphonic acid was chosen (Scheme 2). Removal of the Mmt



Scheme 2. Synthesis of monomers **2** and **3** from **1**. T: thymine; Mmt: 4-methoxyphenyldiphenylmethyl; NPE: 2-(4-nitrophenyl)ethyl; a) 80% AcOH, RT, 4 h, 80%; b) 0.1 M DBU, pyridine (py), 4 h, 90%.

group of compounds **1a–c** with acetic acid gave compounds **2a–c** with free hydroxyl functions. Selective cleavage of one of the two NPE phosphonic acid protecting groups of **1a** by β-elimination with 0.1 M DBU gave monomer **3**. The synthetic route to monomers **1** is shown in Scheme 3. The backbone scaffold **6** is synthesized by addition of a phosphite to the trimeric Schiff base **5**. The coupling of the carboxymethylene nucleobase is carried out analogously to PNA monomer synthesis.[6] To activate the PHONA trimer selectively during block condensation it was necessary to synthesize monomer **1b**, which contains additional orthogonal protection[11] of the phosphonic ester. The allyl phosphonic ester protection was introduced by condensation of **3** with allyl alcohol and 3-nitro-1-(*p*-toluenesulfonyl)-1*H*-1,2,4-triazole (TSNT) in pyridine.[1, 9]

The trimers **8** were synthesized by stepwise condensation of **2** with **3** (Scheme 4), again with TSNT in pyridine. The yield of isolated product was 70–90%. The allyl group of **8b** could be removed under neutral conditions with Pd^0, without loss of the Mmt or NPE groups,[11] to give the phosphonic acid monoester **9**.

The synthesis of PHONA nonamer **12** is carried out by consecutive condensation of trimer **8c** with two trimers **9** (Scheme 5). The Mmt group is removed by treatment with 80% acetic acid, and finally the NPE protecting groups are removed

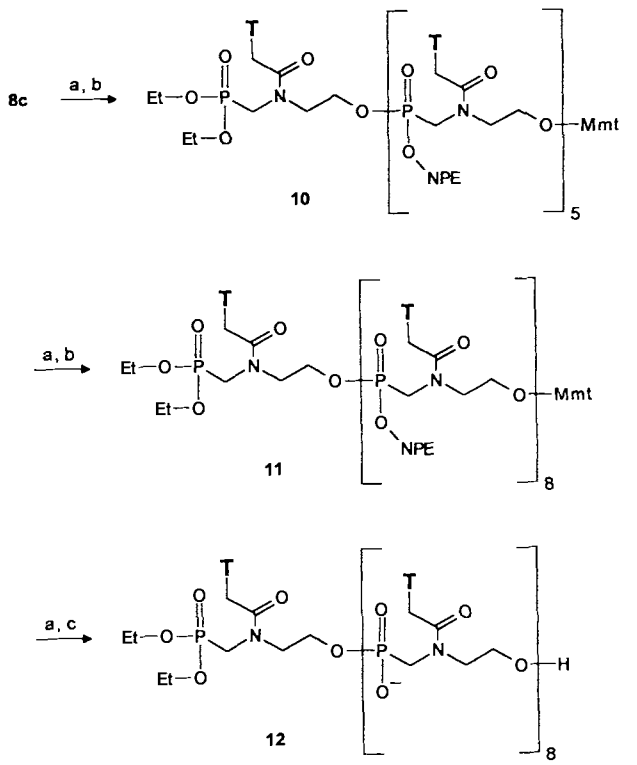

Scheme 5. Block synthesis of a PHONA nonamer (**12**) from three trimers. a) 80% AcOH, RT, 4 h, 80%; b) **9**, TSNT, py, 70%; c) 0.5 M DBU, py, 24 h, RT, 80%.

by treatment with 0.5 M DBU in pyridine. As expected the PHONA **12** is highly water-soluble and shows no tendency to self-aggregate. The purity and identity of **12** were confirmed by HPLC and mass spectrometry [ES^- (*m/z*): calcd 2803; found 2802 $(M-H)^-$].

The ability of the new oligomer to form stable hybrids with complementary DNA was investigated by UV-melting and gel-shift experiments and by mass spectrometry. Figure 1 shows the

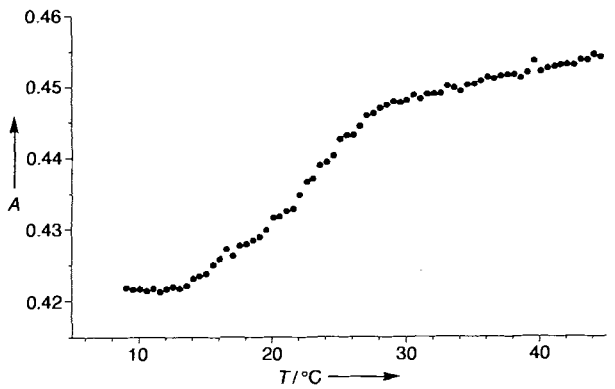

Fig. 1. UV-melting curve (λ = 260 nm) of the hybrid between **12** and $d(A_9)$: 0.15 OD **12** and 0.15 OD $d(A_9)$ in 0.7 mL buffer (1 M NaCl, 20 mM $MgCl_2$, 10 mM HEPES [= 2-(4-(hydroxyethyl)piperazin-1-yl)ethanesulfonic acid], pH 7.5); heating rate: 1 K min^{-1}; T_m of the duplex: 21 °C.

UV-melting curve of **12** with $d(A_9)$ (1:1) in 1 M NaCl at pH 7.5. A clear transition can be seen with a melting temperature T_m of approximately 21 °C. For comparison, the T_m of the corresponding DNA–DNA hybrid from $d(T_9)$ and $d(A_9)$ is 22 °C. No transition was observed on heating **12** alone. A 2:1 mixture

of **12** and $d(A_9)$ gave an identical UV-melting curve, which suggests that the stoichiometry of the hybrid is 1:1. On cooling, a clear transition was not observed, probably due to the hysteresis commonly observed for some PNA sequences.

The hybridization of **12** with $d(A_9)$ was also demonstrated in a gel-shift experiment. PHONA **12** and $d(A_9)$ were loaded on a nondenaturing polyacrylamide gel (20%, 50 mM tris(hydroxymethyl)aminomethaneborate, pH 8.0, 2 mM EDTA, 10 mM $MgCl_2$) either alone or mixed in the ratios 1:1, 1:2, 1:5, or 1:10. The gel mobility of the components was then determined at 10 °C, which is below the hybrid melting temperature. The results are shown in Figure 2: $d(A_9)$ runs faster than **12**; in the

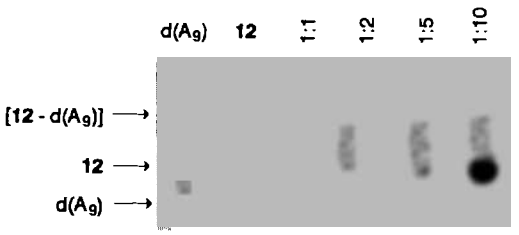

Fig. 2. Gel-shift experiment showing formation of a hybrid between $d(A_9)$ and **12**. The gel mobilities of $d(A_9)$ and **12** alone, and mixed in the ratios 1:1, 1:2, 1:5, and 1:10 (0.1 OD $d(A_9)$ and 0.1, 0.2, 0.5, and 1.0 OD **12**), were determined on a 20% nondenaturing polyacrylamide gel. (Buffer: 50 mM tris(hydroxymethyl)aminomethaneborate, pH 8.0, 2 mM EDTA, 10 mM $MgCl_2$, 10 °C).

1:1 mixture both components are difficult to see, but a slower-running band corresponding to a complex between the two components appears. In the 1:2 mixture the $d(A_9)$ band can no longer be seen, but the complex band is much stronger. The same is also true for the 1:5 and 1:10 mixtures, where the excess of **12** can clearly be seen. The results of the gel-shift experiment strongly suggest that a 1:1 PHONA–DNA hybrid is formed, since in similar experiments[12] duplex formation results in the formation of one new band, whereas triple helix formation gives two new bands, corresponding to the duplex and the triplex. It should be noted, however, that in the case of homopyrimidine PNAs, the initial PNA–DNA duplex is almost undetectable, as it immediately binds to a second PNA strand to form a $(PNA)_2$–DNA triple helix. This process, although unlikely, may also occur for PHONAs.

The **12**–$d(A_9)$ hybrid as well as the $d(T_9)$–$d(A_9)$ hybrid are also detectable by negative-ion electrospray mass spectrometry.[13] A mass of 5559.8 (calcd: 5559.9) was found for the nonameric PHONA–DNA duplex. The corresponding DNA–DNA duplex $d(T_9)$–$d(A_9)$ had a mass of 5431.4 (calcd: 5432.7). Evidence for triple helix formation was not found in this experiment.

We have described the synthesis of a new class of DNA analogues based on an achiral (2-hydroxyethyl)aminomethylphosphonic acid ester backbone. These compounds have promising binding properties to complementary DNA, and excellent water-solubility. Other important properties such as nuclease stability require further investigation. We are now extending our work to the synthesis of PHONAs with mixed base sequences.

Are the Most Stable Fused Heterobicycles the Most Aromatic?**

Govindan Subramanian, Paul von Ragué Schleyer,* and Haijun Jiao

The quantitative relationships among the magnetic, energetic, and geometric criteria of aromaticity have been demonstrated recently for a wide ranging set of five-membered heterocycles.[1] However, we emphasize here that these three criteria also can deviate strongly[2] when other influences are important. This is shown by our theoretical investigations on the positional isomers of furanofuran (**1a–d**), thienothiophene (**2a–d**), benzofuran (**3a,b**), and benzothiophene (**4a,b**). According to the topological charge stabilization rule,[3] the best placement of electronegative heteroatoms is at the positions with the greatest charge in the isovalence-electronic and isostructural hydrocarbons, for example, the pentalene dianion (**I**) and indenyl anion (**II**, Scheme 1). Such placements can give lower energies, but lead to less symmetrical geometries and decreased aromaticity.

Thus, the stability orders of the furanofuran (**1a** > **1b** > **1c** > **1d**) and thienothiophene positional isomers (**2a** > **2b** > **2c** > **2d**) based on the topological rule[3] are verified by our Becke3LYP/6-311+G** relative energies (Table 1 and Fig. 1).[5] Similarly, the relative energies of benzofuran (**3a,b**)

and benzothiophene (**4a,b**) isomers follow the charge density pattern of the indenyl anion (**II**).

While no experimental or theoretical study is available for **1a–d**, various early π-electron treatments have been used to assess the aromaticity in **2–4**. Dewar and Trinajstic's[6] resonance energy (DRE) evaluation of the thienothiophene (**2a–d**) and the benzothiophene isomers (**4a,b**) (Table 1), suggested that **2d** is a very unstable antiaromatic compound. Further, they predicted that the thiophene ring in **4b** should destroy the aromaticity of the benzene moiety, whereas both the rings in **4a** should retain their aromaticity.[6] Earlier, Gimarc[3] showed that the qualitative stability ordering of the isomers of **2–4** follows the same trend as the Hess–Schaad resonance energies (HSRE),[7] the topological resonance energies (TRE) of Gutman et al.,[8] and DRE.[6] Hess et al.[7] concluded that the furan

[k] At GIAO-HF/6-31+G*//Becke3LYP/6-311+G**. NICS is the negative of the magnetic shieldings that can be computed easily, for example at the ring centers.

ring in **3a** is not aromatic, because the total resonance energy of **3a** (0.356 β) was close to that of benzene (0.39 β). Similarly, **2d** and **3b** were claimed to be nonaromatic, since their resonance energies were very low (Table 1).[7, 8] Recently, Zhou and Parr[9] justified the use of absolute hardness (η) as an indicator of aromaticity by correlations with TRE and HSRE (Table 1). However, the reliability of the semiempirical DREs, HSREs, and TREs have never been verified. For example, in contradiction to the conclusion deduced from the HSRE,[7] Warrener[10] concluded from the experimental ^{1}H NMR chemical shifts that **3b** possesses a strong diamagnetic ring current, typical for 10π-electron, planar Hückel arenes. Similarly, Bird's Aromaticity Index (BAI),[11] evaluated from the bond lengths, indicates that **2d** is more aromatic than **2a**,[12] in disagreement with DRE,[6] TRE,[8] and η.[9]

We have reevaluated the BAIs[13] (Table 1) using Becke3LYP/6-311+G** geometries throughout (Fig. 1). In agreement with Bird's earlier findings concerning **2d**,[12] **1d** and **2d** have the largest BAIs, followed by **1a** > **1b** > **1c** and **2a** > **2b** > **2c**. Similarly, the aromaticity of **3b** is greater than that of **3a**[2b, 11] and **4b** is more aromatic than **4a**. Thus, according to the geometric criterion the least stable positional isomers, **1d**, **2d**, **3b**, and **4b**, should be the most aromatic.

Anisotropies and exaltations of the magnetic susceptibility, as well as abnormal ^{1}H NMR chemical shifts, are effective aromaticity criteria in a wide range of molecules.[14–17] The computed ^{1}H NMR chemical shifts (GIAO-HF/6-31+G*//Becke3LYP/6-311+G**)[18] of the various positional isomers (**1**–**4**, Fig. 1) correspond closely to the ^{1}H NMR data for furan, thiophene, and benzene. This strongly suggests that all these bicyclic systems retain significant aromaticity.

The relative aromaticities of **1**–**4**, characterized by comparing their magnetic susceptibilities ($\Delta\chi$) and anisotropies (χ_{anis}), computed at CSGT-HF/6-31+G*,[19] show the least stable forms, **1d** and **2d**, to be the most strongly aromatic (Table 1), in striking contrast to the earlier conclusions on **2d** based on DRE,[6] TRE,[8] and η.[9] However, the relative energies (ΔE) and $\Delta\chi$ of **2a**–**c**, **3a** vs. **3b**, and **4a** vs. **4b** agree roughly with DRE, HSRE, and TRE, but not with BAI for the benzo-fused molecules (Table 1).

The most stable positional isomers (e.g., **1a**, **2a**) need not have the largest aromatic or resonance stabilization. Thermodynamic stability is influenced by strain and many other effects besides aromaticity. Aromaticity is best associated with cyclic electron delocalization and can be revealed most directly by the magnetic criteria.[1, 15–17] The aromaticity ratio (χ_r) of **1**–**4**, based on $\sum\chi$(monocycles) is given in Table 1. The substantial χ_r values of **1**–**4**, varying between 0.74 (**1c**) to 0.88 (**2d**), demonstrate that both rings in **1**–**4** contribute to the aromaticity. This contradicts many of the earlier conclusions on the aromaticity of **2d**, **3a**, **3b**, and **4a**, **4b** (Table 1).[6–9]

Resonance energies and magnetic susceptibilities are measures of the overall aromaticity of a polycycle, but do not provide information about the individual rings. However, the two annelated rings in **1**–**4**, unless related by symmetry, do not contribute to the overall aromaticity to the same extent. Further, the resonance energies of polycyclic aromatics are not the sum of the component rings.[20] Our new magnetic criterion, NICS (Nucleus Independent Chemical Shift),[1c, 17] provides an effective and simple way to assess the aromaticity of individual rings in the polycyclic systems (Fig. 1).

The five-membered rings of **1d**, **2d**, **3b**, and **4b**, and the six-membered rings of **3a** and **4a** have larger NICS values (greater aromaticity) than the corresponding monocycles. As indicated by the schematic representation in Figure 1, one of the rings of **1c**, **2c**, **3b**, and **4b** is weakly aromatic (NICS is less than half that of the corresponding monocycles), whereas the second ring in each case has a somewhat enhanced NICS value. Furthermore, the sum of the NICS values of the two rings along the **1a**–**c** and the **2a**–**c** series (Table 1) are less than twice the NICS values of furan and of thiophene, respectively. The NICS trends of the positional isomers agree qualitatively with the magnetic susceptibility data ($\Delta\chi$ and χ_r, as well as χ_{anis}) and with BAI (except for the benzo-fused isomers), and contradict many of the earlier conclusions based on, for instance, π-electron treatments.[6–9]

In conclusion, we have demonstrated that there need not be any direct relationship between the thermodynamic stability of heterobicyclic isomers and their aromaticity. The aromatic character in **1**–**4** is delineated by the ^{1}H NMR chemical shifts, the relative magnetic susceptibilities ($\Delta\chi$ and χ_r) and anisotropies (χ_{anis}), the NICS values and, less uniformly, by the geometric parameters (BAI). Our results quantify the rule of topological charge stabilization,[3] but refute many other earlier conclusions, for example, that **2d** is "antiaromatic" and the furan ring in **3a** is "not aromatic".[6–9] Hence, the reliability of DRE, TRE, HSRE, and the hardness concept as aromaticity indices in such fused bicyclics is questioned strongly. In contrast, the NICS criterion appears to function well as a general and quantitative measure for delineating the aromaticity of individual rings in polycyclic frameworks.

Liquid-Crystalline, Substituted Octakis-(dimethylsiloxy)octasilsesquioxanes: Oligomeric Supermolecular Materials with Defined Topology**

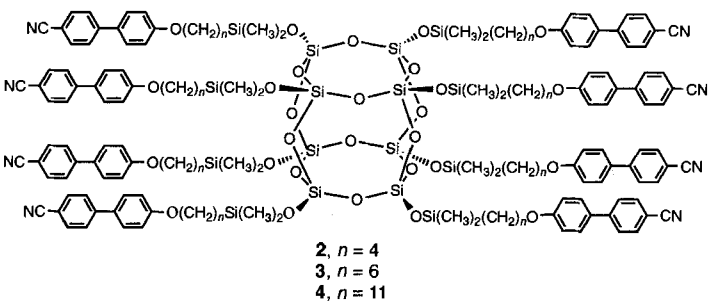
Georg H. Mehl* and John W. Goodby

Oligomeric liquid-crystalline materials, which form a distinct class of supramolecular mesogens, have become interesting subjects of research in recent years, because they combine properties of low molar mass liquid crystals, for example low viscosity and fast response to external stimuli, with those of polymers, for example mechanical stability and robustness. However, the physical properties of oligomeric liquid crystals have been found to depend strongly on the degree of polymerization and dispersity. Consequently, greater interest is now being paid to well-defined, discrete molecular systems comprising simple dimers, trimers, tetramers...to dendrimers.

The possibility of synthesizing oligomeric liquid crystals with defined topological, configurational, and conformational features has, until now, centered mainly on the use of small cyclic or tetrahedral systems as the central core units.[1, 2, 3–5] Thus, the concept of utilizing a cuboid silsesquioxane as the core unit in a mesogenic material (Fig. 1) provides a novel approach to oligomeric liquid crystals of defined structure. This core unit can be used as a basic building block for the creation of interesting classes of monodispersed materials with defined topologies, which are essentially supermolecules that reside structurally between simple dimers or trimers and complex dendrimers.[6]

Conveniently, families of cuboid liquid crystals can be prepared by a convergent synthetic route that combines an octa-substituted variant of the core with an appropriately substituted olefinic mesogenic unit. The octa-substituted core was obtained by the reaction of tetramethylammonium silicate with dimethylchlorosilane,[7a–c] which yielded compound **1** (Fig. 1). 4′-ω-Alkenyl-4-cyanobiphenyls were prepared according to published methods and employed as the mesogenic substrates in preparation of the cubic oligomers (Fig. 2).[5]

Initial coupling experiments between the core unit and the mesogenic substrates, with dicyclopentadienylplatinum and Speier's catalyst (H_2PtCl_6) as the catalysts, led to incomplete



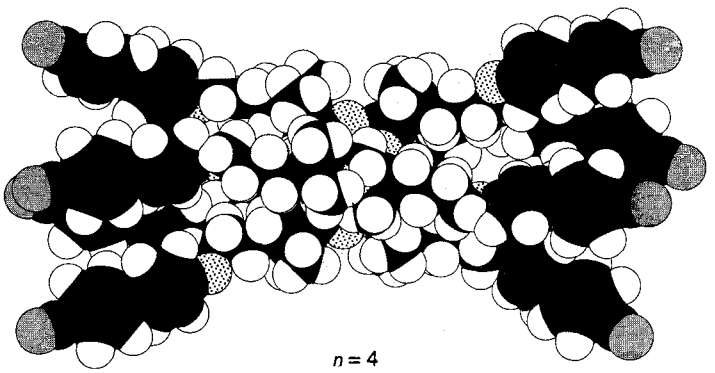


Fig. 2. Structure of the liquid-crystalline materials **2** to **4**, the space-filling model of compound **2** demonstrating the alignment of the mesogenic side chains.

substitution of the hydrogen atoms at the peripheral Si–H groups of the core. The targeted products were obtained, however, by hydrosylations in toluene at room temperature with Karstedt's catalyst.[8] These reactions gave complete substitution of the eight Si–H groups. The replacement of these groups was monitored by the disappearance of the Si–H bands in the IR spectra at 2142 cm^{-1} and by the disappearance of the peak at $\delta = 4.7$ in the ^1H NMR spectrum. The absence of peaks in the vicinity of $\delta = 2.0$ in the ^1H NMR spectra was indicative (within experimental error) of complete α-addition of the hydridosilicones to the vinyl groups. The addition of a small amount of triphenylphosphane was used in these reactions to convert the catalyst into a less reactive platinum–triphenylphosphane complex. This technique allowed for a controlled termination of the reaction. Furthermore, upon precipitation into methanol the platinum–triphenylphosphine complex remained in solution, which allowed for the easy isolation of products. Consequently,

[**] We thank the EPSRC and the DRA (Malvern) for their financial support and Dr. I. M. Saez for helpful discussions on the chemistry of organometallic materials. We acknowledge Dr. D. Ewing and Mrs. B. Worthington for spectroscopic analyses.

the final products were not colored by platinum residues. The monodispersities of the products were confirmed by GPC analysis with polystyrene standards. The single peaks were calculated to have M_w/M_n values of 1.00 to 1.01 for each material. The occurrence of a signal at $\delta = -108.8$ in the ^{29}Si NMR spectra indicated that the silicon atoms bound to four oxygen atoms were totally substituted and in a symmetrical environment. The singlet with a chemical shift at $\delta = 12.34$ is typical for the dimethylalkylsiloxy group. These results were matched by high resolution ^1H NMR spectra, which is not usually the case for oligomeric materials.

Calorimetric studies reveal that the final products **2**–**4** exhibit liquid crystal phases. The values for the transition temperatures, and the associated enthalpies and entropies for the second heating cycles of each compound are listed in Table 1. Thermal polarized light transmission microscopy reveals the formation of a

Table 1. The transition temperatures [°C] and enthalpic data (ΔH [$J g^{-1}$], ΔC_p [$J g^{-1} K^{-1}$]) obtained for compounds **2** to **4**. S_1, S_2, S_3 are smectic or soft crystalline phases.

focal-conic defect texture, with hyperbolic and elliptical lines of optical discontinuity, as each material is cooled from the amorphous liquid into the liquid-crystalline state. These observations classify the high-temperature, liquid-crystalline phase of each material as smectic A. Mechanical shearing of the specimens in the microscope shows that the high-temperature mesophase flows easily and has a relatively low viscosity. In addition, the short time required to form focal-conic defect textures on cooling from the isotropic liquid indicates that the compounds have properties more in keeping with low molar mass materials than polymers.

Increasing the number of methylene units in the spacer chain between the biphenyl moiety and the core units from four to eleven carbon atoms results in an increase of the isotropization temperature from 93.9 to 128.5 °C. In addition, the size of the enthalpy peak also increases with increasing spacer length, which suggests that the molecules are more ordered within the liquid-crystalline phase. This conjecture is supported by the increase in the calculated reduced molar entropy ($\Delta S_{mol}/R$), from 4.35 to 9.68, as the series is ascended. Moreover, the injection of a higher ordered smectic phase close to the glass transition in compound **3**, and the occurrence of two soft crystalline phases and a crystalline phase in **4** indicates a strong increase in ordering of the molecules with increasing spacer length. On a molecular level this can be explained by the increasing separation of the mesogenic cyanobiphenyl groups from the core. Stronger intramolecular interactions between the mesogenic groups are favored as the spacer length is increased (Fig. 2), thereby enhancing the mesomorphic properties as the series is ascended.

Materials **2** and **3** exhibit glass transition transitions in the region of 11.0 and 3.0 °C, for which the values of the specific heats (0.22 and 0.32 $J g^{-1} K^{-1}$, respectively) were found to be similar. The decrease of the value of the glass transition temperature with increasing spacer length is attributed to the plastifying effect of the aliphatic spacers. This is supported by the fact that the glass transition temperature for compound **4** is the lowest of all at −7.5 °C.

The high-temperature liquid-crystalline phase of each material showed an X-ray diffraction pattern that was obtained from fiber samples recorded in Lindemann tubes and found to be typical of the smectic A phase.[5] The X-ray spacings found are listed in Table 2. Compound **4**, as well as the other final products, showed a diffuse, wide angle halo at 4.5 Å typical for the

Table 2. The *d* spacings [Å] determined by X-ray diffraction for compounds **2** to **4**.

[a] Reflections are very weak.

lateral distance between mesogenic units and a diffuse reflection at 13.2 Å, which was attributed to the periodicity of the arrangement of the silicone cores.[1, 2, 5] At 125.0 °C pointlike small-angle reflections at 42.1 and 21.0 Å corresponding to the values for the first- and second-order reflections of the smectic layers were observed. The small increase in the lattice dimensions at lower temperatures was attributed to a decrease in the disordering of the structures of the molecules as the molecules themselves become more ordered within the layers as the temperature falls. Materials **2** and **3** exhibit similar behavior; however, a decrease in the lattice dimensions was found to occur with shortening of the spacer unit. Additionally the layer reflections become very weak for **3**, and for **2** the second order reflection is lost altogether. The structures of the crystal or soft crystalline phases S_1, S_2, and S_3 occurring for compounds **3** and **4** will be the subject of a seperate report.

These results are consistent with a structure in which the silicone cores are located in the central regions of the layers and the terminal cyanobiphenyl groups overlap somewhat.[5, 9] This classifies the high-temperature smectic phase as an S_{Ad} phase.

The isotropization temperatures of the materials were lower than those of comparable linear siloxanes bearing mesogenic side-chains of similar structure.[10] Materials with analogous tetrahedral or cyclic siloxane cores are found to have similar isotropization temperatures and higher glass transition temperatures, but to exhibit less rich polymorphism.[5, 1, 9, 11] Thus the results obtained for the octasilsesquioxanes are intermediate between those of linear polymers and the smaller tetramers and cyclic systems. This outcome is not too surprising, since, in principle, octasilsesquioxanes can be viewed as twinned tetrahedrons or doubled four-membered cyclic rings.

Experimental Procedure

The equipment and techniques used to evaluate material structures and purities, and to determine mesophase behavior have been described elsewhere [5].

1: Tetramethylammonium silicate (4.7 g, 0.05 mol) was added as a 10% aqueous solution to a solution of heptane (100 mL), dimethylformamide (200 mL), and chlorodimethylsilane (100 mL) that had been previously stirred for 20 min. The weakly exothermic reaction was then cooled slowly to 4 °C, and 1 L of water at 4 °C was added slowly. The organic phase was separated from the aqueous phase and

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3522-2642 $ 15.00+.25/0

washed with water until acid free. The organic solution was concentrated by evaporation under reduced pressure, and the resulting mixture was cooled to 4 °C to facilitate the precipitation of **1** as a white solid, which was isolated after purification by recrystallization from acetone. Yield 1.48 g (73.8%). Spectroscopic data: IR (KBr): $\tilde{\nu}$ = 2960 (C–H), 2142 (Si–H); ^{1}H NMR (270 MHz, $CDCl_3$, TMS): δ = 4.7 (s, 1H, SiH), 0.2 (s, 6H, $SiCH_3$), ^{29}Si NMR (53.5 MHz, $CDCl_3$, TMS): δ = 0.5 ($HSiCH_3$), –108.8 ($Si(O)_4$).

2: A solution of toluene (20 mL), 4-cyano-4′-(5-hexenyloxy)biphenyl) (0.55 g, 1.58 mmol), and 10 μL of a 3.0–3.5% solution of Karstedt's catalyst dissolved in xylene was prepared. The solution was gently aerated for 20 s, and then a solution of **1** (0.1 g, 0.098 mmol) in dry toluene (10 mL) was added dropwise at room temperature over a period of 1 h. A few minutes after the addition was complete, no Si–H band (2142 cm^{-1}) could be detected in the IR spectrum. A spatula tip of triphenylphosphane was added to convert the catalyst into the less reactive triphenylphosphane complex, and the solution was concentrated under reduced pressure. The oligomeric material was isolated by precipitation in methanol. The product was separated by filtration and purified by repetitive precipitation from methanol until no monomer could be detected by chromatographic methods. Recrystallization from pentane/dichloromethane yielded 0.31 g of **2** (85% yield). Spectroscopic data: IR (KBr): $\tilde{\nu}$ = 3020 (Ar–H), 2940 (C–H), 2220 (C≡N), 1600 (Ar), 860 (C–H) cm^{-1}; ^{1}H NMR (270 MHz, $CDCl_3$, TMS): δ = 7.65 (m, 4H, ArH), 7.52 (m, 2H, ArH), 6.95 (m, 2H, ArH), 3.93 (t, 2H, $ArOCH_2$), 1.75 (m, 2H, OCH_2CH_2), 1.45 (m, 6H, $CH_2CH_2CH_2$), 0.62 (t, 2H, t, CH_2Si), 0.14 (s, 6H, CH_3Si); ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 0.01 (CH_3Si), 18.14 (CH_2Si), 23.49, 26.31, 24.78, 33.75, ($CH_2CH_2CH_2$), 110.82 (aryl C4′, CCN), 115.19 (aryl C3, C5), 126.89, 128.48 (aryl C2, C6, C2′, C6′), 131.56 (aryl C1), 132.49 (aryl C3′, C5′), 144.71 (aryl C1′), 160.11 (aryl C4, OC), 118.87 (CN); ^{29}Si NMR (53.5 MHz, $CDCl_3$, TMS): δ = 12.34 ($SiCH_3$), –108.8 ($Si(O)_4$).

Oligo-THF Peptides: Synthesis, Membrane Insertion, and Studies of Ion Channel Activity**

Holger Wagner, Klaus Harms, Ulrich Koert,* Sabine Meder, and Günther Boheim*

The physiological importance and pharmacological relevance of membrane-bound ion channels have led to intensive studies on this class of compounds.[1, 2] Although the function of biological ion channels has been thoroughly examined, their structure is not well understood.[3] Artificial ion channels[4–6] with a predictable active conformation may be important for understanding their biological counterparts. We have reported on 2,5-*trans*-linked oligo(tetrahydrofurans) as potential building blocks for a polyether helix with ion channel activity.[7a, 7b] However, the THF-pentamer **1** was too short to span a membrane bilayer. To achieve longer oligo(tetrahydrofurans)[7c] at a reasonable synthetic expense we turned to oligo-THF peptides of the type **3**–**6**.

2c n = 0, R^1 = H, R^2 = Bn
3 n = 1, R^1 = BOC, R^2 = Bn
4 n = 3, R^1 = BOC, R^2 = Bn
5 n = 5, R^1 = BOC, R^2 = Bn
6a n = 9, R^1 = BOC, R^2 = Bn
6b n = 9, R^1 = H • CF_3COOH, R^2 = Bn
6c n = 9, R^1 = H • CF_3COOH, R^2 = H

The starting point for the synthesis of ter(tetrahydrofuranyl) amino acid **2a** was *N*-tosyl-L-alanine (**7**) (Scheme 1). Addition of the lithium salt of **7** to 3-butenylmagnesium bromide gave ketone **8**. Subsequent reduction with L-selectride (stereoselectivity 85:15) and separation of the major epimer by recrystallization led to the desired alcohol **9** in 80% yield.[8] After epoxidation of the terminal double bond in **9** and intramolecular 5-*exo* opening

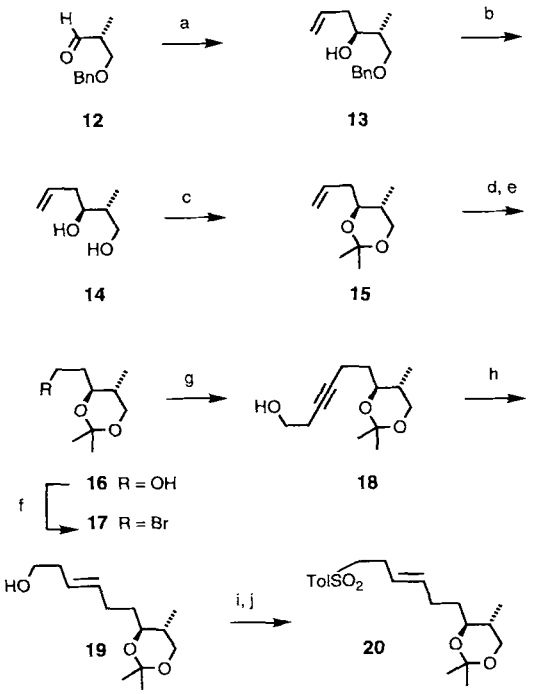
of the epoxide, the *trans*-THF alcohol **10** was obtained in 45% yield.[9] A Swern oxidation converted alcohol **10** into the mono-THF aldehyde **11**.

For the synthesis of sulfone **20**, aldehyde **12**[10] was transformed into alcohol **13** by the chelate-controlled addition of allyltrimethylsilane (Scheme 2).[11] A few standard steps converted alcohol **13** into the bromide **17**. The reaction of **17** with the dilithium salt of 3-butyn-1-ol gave alkyne **18**. After an *E*-selective reduction of alkyne **18** to afford alkene **19** and conversion of the primary hydroxyl group into an arylsulfone, the desired building block **20** was obtained.

In the coupling step the lithiated sulfone prepared from **20** was allowed to react with aldehyde **11** at −78 °C (Scheme 3).



Scheme 2. Synthesis of sulfone **20**; Tol = *p*-tolyl. a) 1 equiv $SnCl_4$, 1.1 equiv allyltrimethylsilane, CH_2Cl_2, −78 °C, 0.5 h, (87%); b) 2.4 equiv Na, NH_3/THF 2.5:1, −40 °C, 1 h (98%); c) 2 equiv 2,2-dimethoxypropane, cat. DMSO, THF, 40 °C, 3 h (86%, 2 steps); j) 1. 4.7 equiv Na, NH_3/THF 1/1, −40 °C, 15 min, 2. 2 equiv. $(BOC)_2O$, NaOH, THF/H_2O 10/1, 3 h, rt, (75%, 2 steps); k) 1. $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, 2. 6.5 equiv $KMnO_4$, *t*BuOH/5% NaH_2PO_4 3/1, 30 min, 86%, 2 steps); l) 1.5 equiv *O*-benzyl-*N*,*N*'-diisopropylisourea, CH_2Cl_2, 3 d, rt (61%).

The resulting alcohol could be oxidized to oxosulfone **21** by the Dess–Martin[12] procedure. After reductive desulfonation the stereochemically pure ketone **22** was obtained. Stereoselective reduction of the carbonyl group in **22** and subsequent protection of the resulting hydroxyl group as a TMS ether yielded alkene **23**. The two THF units still missing were installed simultaneously by a Sharpless dihydroxylation (**23** → **24**) followed by a multiple Williamson reaction[13] (**25** → **26**). In preparation for the peptide synthesis the tosyl protecting group in **26** was exchanged for the BOC group. In the last step of the synthesis of the BOC-protected ter-THF amino acid **2a** the primary hydroxyl group was oxidized to provide the corresponding carboxylic acid.

With the ter-THF amino acid **2a** in hand, oligo-THF peptides of type **3**–**6** were readily accessible. By employing standard peptide protecting group techniques[14] and pentafluorophenyldiphenyl phosphinate[15] as coupling reagent the two ter-THF building blocks **2a** and **2c** were linked to the dipeptide **3** in 78% yield (Table 1). Two dipeptide building blocks were coupled to provide tetrapeptide **4** in 71% yield. Reaction of a dipeptide with a tetrapeptide afforded the hexapeptide **5** in 70% yield. Finally the coupling of a hexapeptide with a tetrapeptide gave decapeptide **6a** in 42% yield.[16]

To span the lipophilic part of a lipid bilayer a functional ion channel must be at least 3 nm long. For instance, gramicidin A, a naturally occurring peptide with a *β*-helical secondary structure, forms an ion channel active structure 3 nm in length in membranes.[17] Inspection of molecular models of oligo-THF peptides indicate that a decapeptide of the type **6a** with a helical arrangement and five turns may have the required minimum length (Fig. 1).

Table 1. Selected analytical and spectroscopic data for compounds **2b** and **3**.

2b: colorless oil; $[\alpha]_D^{20} = -10$ ($c = 3.12$ in $CHCl_3$); ^1H NMR [a]: $\delta = 1.05$ (d, $J = 6.3$ Hz, 6H), 1.36 (s, 9H), 1.45–1.96 (m, 12H), 2.51–2.63 (m, 1H), 3.51–3.64 (m, 1H), 3.69–3.91 (m, 5H), 4.09 (dt, $J = 5.7$, 8.2 Hz, 1H), 4.74 (br. s, 1H), 5.03–5.11 (m, 2H), 7.22–7.32 (m, 5H); ^{13}C NMR [b]: $\delta = 13.0$, 19.3, 28.0, 28.2, 28.4, 28.9, 29.4, 45.1, 48.8, 66.0, 78.9, 80.7, 81.6, 81.7, 82.1, 128.0, 128.1, 128.5, 136.3, 156.0, 174.7.

3: colorless oil; $[\alpha]_D^{20} = -20$ ($c = 1.06$ in $CHCl_3$); ^1H NMR [a]: $\delta = 1.10$ (d, $J = 7.0$ Hz, 3H), 1.11 (d, $J = 7.0$ Hz, 3H), 1.16 (d, $J = 6.8$ Hz, 3H), 1.17 (d, $J = 6.8$ Hz, 3H), 1.42 (s, 9H), 1.50–2.06 (m, 24H), 2.20–2.35 (m, 1H), 2.55–2.70 (m, 1H), 3.64 (br. s, 1H), 3.82–3.95 (m, 10H), 3.95–4.02 (m, 1H), 4.04–4.09 (m, 1H), 4.12–4.20 (m, 1H); 4.79 (bs, 1H), 5.10 (d, $J = 12.3$ Hz, 1H), 5.14 (d, $J = 12.3$ Hz, 1H), 6.24 (d, $J = 9.1$ Hz, 1H), 7.30–7.35 (m, 5H); ^{13}C NMR [b]: $\delta = 12.9$, 14.4, 19.1, 19.2, 28.4, 27.9, 28.0, 28.1, 28.2, 28.6, 28.8, 29.3, 30.2, 45.0, 46.4, 46.5, 48.6, 66.0, 78.9, 80.7, 81.6, 81.9, 82.0, 82.1, 127.9, 128.0, 128.4, 136.2, 156.0, 174.2, 174.7; correct HRMS.

[a] 300 MHz ($CDCl_3$), 20 °C; [b] 75 MHz ($CDCl_3$), 20C.

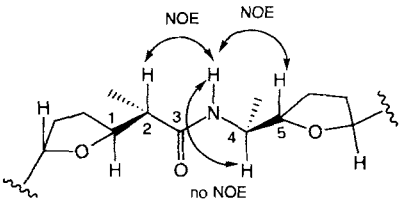

Fig. 2. Prefered conformation of the oligo-THF dipeptide **2b** in the area of the amide bond, as deduced from NOESY spectra.

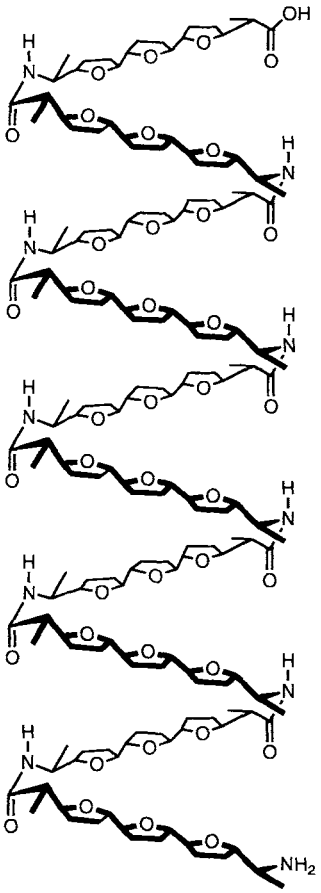

Fig. 1. Schematic illustration of an oligo-THF peptide helix.

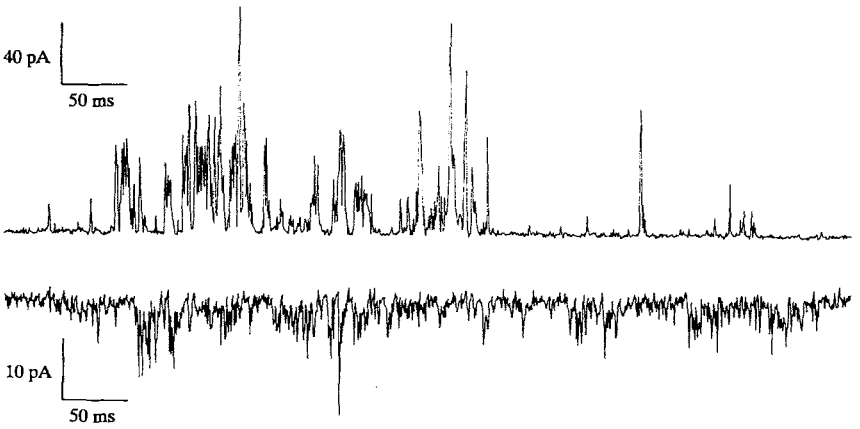

Fig. 3. Changes in the conductance of planar lipid bilayers after addition of the oligo-THF peptide **6b** (top: +50 mV; bottom: −50 mV). The experimental conditions are described in ref. [18].

The stereogenic centers bearing methyl groups and adjacent to the carbonyl and amino groups serve to stabilize the helical structure in the area of the peptide bond. To examine the influence of these stereogenic centers on the conformation of the oligo-THF peptide chain NMR studies in $CDCl_3$ were carried out. Owing to its polarity, $CDCl_3$ is a good model for the lipophilic part of the membrane. Figure 2 summarizes the results of NOE studies on dipeptide **2b**. A NOESY crosspeak between the NH signal of the peptide bond and the H-2 signal is in accord with the expected *anti* conformation of the peptide bond and the torsions angle C1-C2-C3-N. No NOE interaction was evident between NH and H-4, but there was one between NH and H-5. This indicates the conformation indicated at C3-N-C4-C5.

We examined the following three oligo-THF peptide derivatives in terms of their propensity to modify membranes and increase conductance: the N- und C-protected decapeptide **6a**, the N-deprotected compound **6b**, and the completely deprotected compound **6c**. The conductance measurements were carried out with planar lipid bilayers.[18] The increase in conductance of the membrane caused by additional transport of potassium ions was examined. The oligo-THF peptide **6b** was inserted into the membrane with an applied a membrane voltage (+ 50 mV). This led to rapid changes in conductance on the order of milliseconds, which could not be resolved as a series of discrete single events (frequency limit 3 kHz, Fig. 3, top). The observed current peaks of varying intensity (up to 100 pA) are indicative of a membrane-spanning, porelike structure rather than a carrier mechanism.[19] However, the possibility of short-lived permeation structures, which could arise as a result of disturbances in the lipid structure due to the insertion of oligo-THF peptides into the membrane, may not be excluded.

When the polarity of the membrane voltage was changed to −50 mV, smaller current peaks were detected (Fig. 3, bottom). The asymmetric insertion and transport characteristics displayed by compound **6b** are similar to the properties of defensines,[20] naturally occuring peptidic pore formers.

In contrast to **6b**, the N-protected oligo-THF peptide **6a** showed voltage-symmetric increases in conductance. However, at the same membrane voltage, current peaks could already been observed at lower peptide concentrations. Even at lower concentrations of the completely deprotected oligo-THF peptide **6c** ($> 10^{-6}$ g mL^{-1}) no changes in membrane conductance could be detected. Probably the high solubility of **6c** in water prevents insertion into the membrane. This shows that variation of an end group that is small in relation to the whole molecule may have remarkable effects on the properties of such compounds.

This work opens an efficient approach towards enantiomerically pure oligo-THF amino acids and oligo-THF peptides. The decapeptides **6a** and **6b** show conductance-increasing properties and are possible lead structures for future artificial ion channels. Variations in the length of the molecule and the end groups are conceivable for optimization of this lead structure.

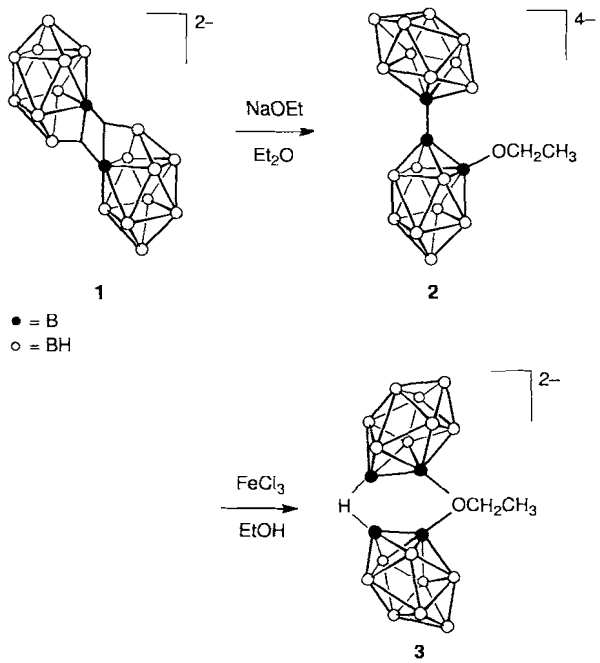
The Novel, $[n\text{-}B_{20}H_{18}]^{2-}$-Induced Nucleophilic Ring Opening of Tetrahydrofuran by Alkoxide Anions**

Fangbiao Li, Kenneth Shelly, Robert R. Kane, Carolyn B. Knobler, and M. Frederick Hawthorne*

Boron neutron capture therapy (BNCT) is a binary cancer treatment that requires the selective deposition of a significant amount of the ^{10}B isotope within cancer cells.[1] Various derivatives of the polyhedral borate anion $[n\text{-}B_{20}H_{18}]^{2-}$ (**1**)[***] have been synthesized in order to investigate the effects of charge, substituent, and structure upon the tumor retention of these anionic borate species.[2, 3] We have recently described the reaction of ethoxide ion with **1** in diethyl ether solution to produce the $[ae\text{-}B_{20}H_{17}OCH_2CH_3]^{4-}$ ion (**2**, Scheme 1).[3] This species was subsequently oxidized to produce an unusual oxygen and hydrogen doubly-bridged polyhedral borate, the $[\mu\text{-}B_{20}H_{17}OCH_2CH_3]^{2-}$ ion (**3**, Scheme 1).[3]



Scheme 1. Synthesis of **2** and **3**

Recent studies of the reaction of alkoxide ions (RO^-) with **1** in tetrahydrofuran (THF) did not result in the expected $[ae\text{-}B_{20}H_{17}OR]^{4-}$ ions. Instead, the products obtained were the ions **4** ($[ae\text{-}B_{20}H_{17}O(CH_2)_4OR]^{4-}$: **4a**, R = methyl; **4b**, R = isopentyl) shown in Scheme 2. These species contain a substituent comprising a terminal alkoxyl group attached to a bu-

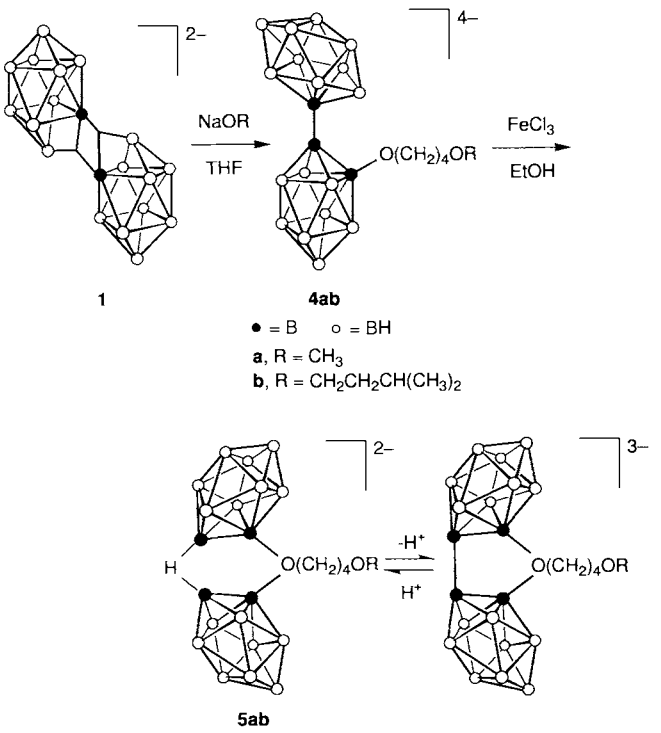
[***] The following prefixes are used as isomer designations: *n* normal isomer of $[B_{20}H_{18}]^{2-}$, *ae* and *a*^{2} apical-equatorial and apical-apical isomers of $[B_{20}H_{18}]^{4-}$ derivatives.



Scheme 2. Synthesis of **4a,b** and **5a,b**.

toxide group that is bonded to the polyhedral borate substrate. This substituent originates from the $[n\text{-}B_{20}H_{18}]^{2-}$ promoted nucleophilic ring opening of a THF solvent molecule by the alkoxide nucleophile.

The subsequent oxidation of **4** produced the oxygen- and hydrogen-bridged polyhedral borates **5** (Scheme 2). We report here the synthesis, crystal stucture, and reactions of **5**.

The addition of $(Et_3NH)_2$**[1]**[4] to a stirred suspension of NaOR (prepared in situ from NaH and ROH) in dry THF resulted in the formation of Na_4**[4]** (**4a** R = methyl, **4b** R = isopentyl) in high yield (Scheme 2). The anion was isolated as its tetramethylammonium salt. Aqueous solutions of **4** are stable only under basic conditions. In neutral aqueous media, $[ae\text{-}B_{20}H_{17}O(CH_2)_4OR]^{4-}$ slowly isomerizes to $[a^2\text{-}B_{20}H_{17}O\text{-}(CH_2)_4OR]^{4-}$; in strongly acidic solutions (1 N HCl), **4** decomposes to form $[B_{10}H_{10}]^{2-}$ and other unidentified products.

The oxidation of **4** at room temperature by Fe^{3+} in anhydrous ethanol produced the ions **5**, isolated in approximately 70% yields as the corresponding tetramethylammonium salts (Scheme 2). The products were characterized by electrospray ionization mass spectroscopy (ESI-MS) and multinuclear (^1H, ^{13}C, and ^{11}B) NMR spectroscopy. The structure of $(Me_4N)_2$-**[5b]** was determined by single crystal X-ray diffraction studies (Fig. 1).[5] The polyhedral borane anion consists of two intact decaborate cages joined together by one oxygen atom and one hydrogen atom. The bonding distances within the two decaborate cages are normal and similar to those found in other structures derived from $[B_{10}H_{10}]^{2-}$. As a consequence of the bridging atoms between the two borane cages a six-membered BHBBOB ring is formed, which is essentially planar. This configuration has been observed previously in the structure of the polyhedral borate anion $[\mu\text{-}B_{20}H_{17}OH]^{2-}$ (**6**).[3] The carbon atom (C2) also lies in the plane of the six-membered ring, and the three-coordinate oxygen atom of **5b** exhibits trigonal-planar geometry. The sum of the three bond angles about the oxonium center of **5b** is 359.4° (which may be compared to the value of

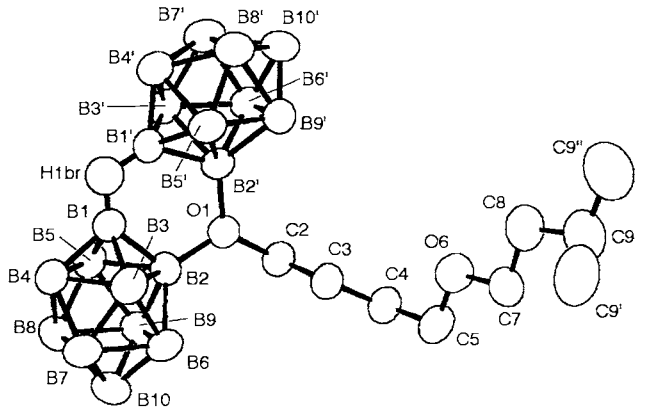


Fig. 1. ORTEP representation of **5b** depicting the atom numbering scheme. For clarity, the terminal B–H hydrogen atoms have been omitted. Selected bond lengths [Å] and angles [°] (estimated standard deviations in parentheses): O1–B2 = 1.500(6), O1–B2′ = 1.499(6), B1–B2 = 1.651(7), B1′–B2′ = 1.652(7), B1–B1′ = 1.895(7), B1–H1br = 1.23(5), B1′–H1br = 1.16(5), O1 C2 = 1.469(5); B2-O1-B2′ = 113.5(3), O1-B2-B1 = 112.5(4), B1′-B2′-O1 = 112.6(4), B1-H1br-B1′ = 112(4), B2′-O1-C2 = 122.9(3), B2-O1-C2 = 123.0(3).

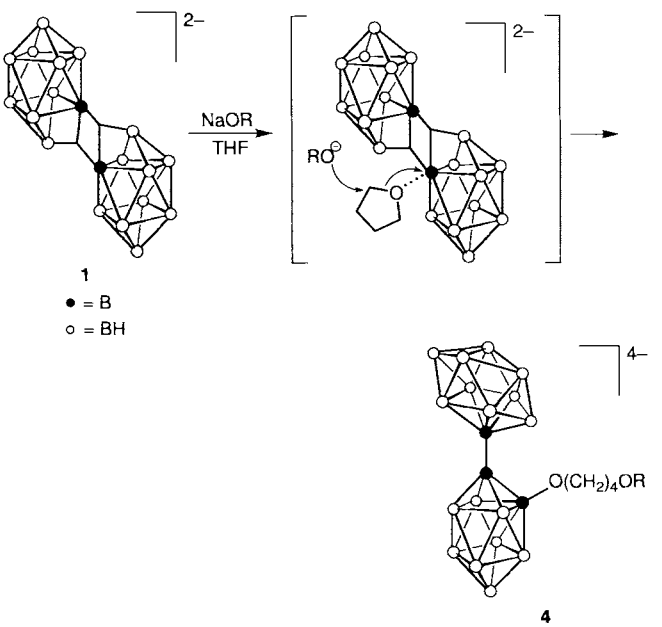
353.7° observed in **6**).[3] This planar geometry of tricoordinate oxygen atom has been observed previously in several other structurally characterized species containing oxygen atoms bound to polyhedral boranes and carboranes.[6]

A significant feature of the structure of **5b** is the presence of an $-O(CH_2)_4-$ group inserted between the polyhedral borate and the isopentoxide nucleophile. The resulting $-O(CH_2)_4OR$ substituent arises from the nucleophilic attack of an alkoxide ion on, and the subsequent ring opening of, a THF solvent molecule (Scheme 3). The product of this reaction (**4**) may then be oxidized to produce **5**.

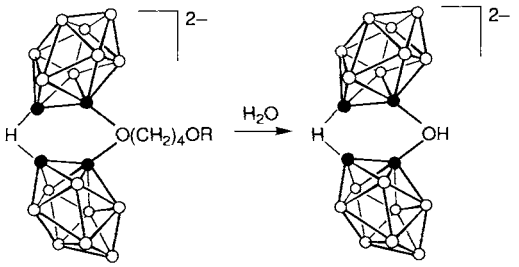


Scheme 3. Postulated mechanism for the synthesis of **4**.

The nucleophilc ring opening of THF induced by metal cations or neutral Lewis acids has been reported previously,[7] but similar reactions promoted by anions are unknown. To our knowledge, the electrophilic $[n\text{-}B_{20}H_{18}]^{2-}$ ion is the only anion capable of providing the requisite Lewis acidity to produce this

type of reactivity. No evidence for the formation of a discrete thf·**1** complex was discerned; the ^{11}B NMR of **1** remained essentially unchanged when dissolved in THF, H_2O, CH_3CN, or CH_2Cl_2. However, it may be reasonably assumed that the solvation of $[n\text{-}B_{20}H_{18}]^{2-}$ by THF places a solvent molecule close to the electrophilic boron atoms of **1** as shown in Scheme 3. When the alkoxide nucleophile approaches the borate ion, it is apparently unable to penetrate this solvation shell to reach the reactive boron site before it attacks an α-carbon atom of THF. The resulting nucleophilic ring opening is promoted by incipient bond formation between the THF oxygen atom and an electrophilic boron atom of **1**. No evidence was found for the formation of the simple alkoxide derivative $[ae\text{-}B_{20}H_{17}OR]^{4-}$ in THF; this product may be obtained by performing the reaction in diethyl ether.[3]

The hydrolysis of **5** in H_2O at 100 °C produced **6** (Scheme 4) in approximately 75% yield. The anion **6** was previously reported to arise from the hydrolysis of **3**[3] and is a useful precursor for the production of derivatives with a variety of other oxygen-bound substituents through O-alkylation.[3]



5ab **6**

• = B ○ = BH

a, R = CH_3

b, R = $CH_2CH_2CH(CH_3)_2$

Scheme 4. Hydrolysis of **5a,b**.

The bridging hydrogen atom of **5** is weakly acidic and can be titrated by aqueous base (Scheme 2). This deprotonation results in the formation of the corresponding $[\mu\text{-}B_{20}H_{16}O(CH_2)_4OR]^{3-}$ ion, which can be easily distinguished from **5** in the ^{11}B NMR spectrum. The pK_a of this bridging hydrogen was estimated to be 6.3,[8] which is comparable to the acidity of $[a^2\text{-}B_{20}H_{19}]^{3-}$ ($pK_a = 7.3$),[9] a hydrogen-bridged species that does not contain the bridging oxygen atom of **5**.

The unusual THF ring opening and insertion reaction induced by the $[n\text{-}B_{20}H_{18}]^{2-}$ ion provides an efficient means for the synthesis for oxygen-substituted derivatives of this polyhedral borane anion containing a variety of ether functionalities. We are currently extending these investigations to other cyclic ethers and nucleophiles.

Experimental Procedure

$(Me_4N)_4$**[4a]**: Dry $(Et_3NH)_2$**[1]** (2.00 g, 4.57 mmol) was added to a stirred suspension prepared from NaH (500 mg, 20.8 mmol) and methanol (500 μL, 12.4 mmol) in 125 mL THF. Hydrogen gas was evolved, and the mixture was stirred at room temperature for 3 h. Crude Na_4**[4a]** was obtained by removal of the solvent in vacuo. The crude product was dissolved in 100 mL of absolute ethanol. The addition of excess tetramethylammonium hydroxide in ethanol resulted in a white precipitate of $(Me_4N)_4$**[4a]**. The precipitate was separated by filtration, washed with absolute ethanol (3 × 30 mL) and dried in vacuo to yield 2.54 g of $(Me_4N)_4$**[4a]** (4.01 mmol, 88%). $^{11}B\{^1H\}$ NMR (160 MHz, H_2O): $\delta = 7.9$ (2B, B–B), 2.9 (1B, apical B–H), 2.6 (2B, B–O and apical B–H), −9.4 (1B, apical B–H), −24.3, −25.6, −29.2, −33.6 (total 14B, equatorial B–H); ^1H NMR (400 MHz, D_2O): $\delta = 3.35$ (t, $J = 7.0$ Hz, 2H), 3.27 (t, $J = 7.1$ Hz, 2H), 3.22 (s, 3H), 1.36 (m, 2H), 1.28 (m, 2H); ^{13}C NMR (100 MHz, D_2O): $\delta = 72.79$, 70.11, 57.62, 27.46, 25.27; ESI-MS (*m/z*): 169.2 $\{(H)_2(B_{20}H_{17}O(CH_2)_4OCH_3)\}^{2-}$, 339.2 $\{(H)_3(B_{20}H_{17}O(CH_2)_4OCH_3)\}^-$, 412.5 $\{(Me_4N)(H)_2(B_{20}H_{17}OC_4H_8OCH_3)\}^-$.

4b: $(Me_4N)_4$**[4b]** was prepared as described above for $(Me_4N)_4$**[4a]** except for the use of isopentyl alcohol (1.00 mL, 9.18 mmol) instead of methanol. Yield: 2.84 g (4.11 mmol, 90%). $^{11}B\{^1H\}$ NMR (160 MHz, H_2O): $\delta = 7.5$ (2B, B–B), 3.5 (1B, apical B–H), −2.1 (2B, B–O and apical B–H), −8.0 (1B, apical B–H), 24.35, 25.45, 28.72, 30.68, 32.61 (total 14B, equatorial B–H); ^1H NMR (400 MHz, D_2O): $\delta = 3.29$ (t, $J = 7.0$ Hz, 2H), 3.26 (t, $J = 7.0$ Hz, 2H), 3.14 (t, $J = 7.0$ Hz, 2H), 1.93 (m, 2H), 1.53 (m, 1H), 1.33 (m, 2H), 1.15 (m, 2H), 0.83 (d, $J = 7.0$ Hz, 6H); ^{13}C NMR (100 MHz, D_2O): $\delta = 69.39$, 65.46, 55.42, 38.33, 24.92, 24.90, 21.99, 17.83. ESI-MS(*m/z*): 196.8 $\{(H)_2(B_{20}H_{17}O(CH_2)_4OCH_2CH_2CH(CH_3)_2)\}^{2-}$, 395.8 $\{(H)_3(B_{20}H_{17}O(CH_2)_4OCH_2CH_2CH(CH_3)_2)\}^-$, 468.8 $\{(Me_4N)(H)_2(B_{20}H_{17}O(CH_2)_4OCH_2CH_2CH(CH_3)_2)\}^-$.

5a: A suspension of Na_4**[4a]** in THF was prepared from $(Et_3NH)_2$**[1]** (2.00 g, 4.57 mmol) as described above. After removal of the THF solvent in vacuo, the residue was dissolved in 50 mL of absolute ethanol. A solution of anhydrous $FeCl_3$ (2.30 g, 14.2 mmol) dissolved in absolute ethanol (100 mL) was added, and the mixture was stirred at room temperature for 4 h. The solution was filtered, and the ethanol was removed from the filtrate in vacuo. The residue was dissolved in 50 mL of H_2O, cooled to 0 °C, and $(Me_4N)_2$**[5a]** was precipitated by the addition of aqueous Me_4NCl. The precipitate was removed by filtration, and the resulting solid was dissolved in 50 mL of CH_3CN/H_2O (1/1) and passed through a column of cation exchange resin (Bio-Rad AG 50W-X2, sodium form) to produce a solution of Na_2**[5a]**. The product was again precipitated by the addition of Me_4NCl and removed by filtration to afford a white powder. Recrystallization from CH_3CN/C_2H_5OH yielded $(Me_4N)_2$**[5a]** (1.52 g, 3.13 mmol, 69%). $^{11}B\{^1H\}$NMR (160 MHz, H_2O): $\delta = 14.0$ (2B, B–B), 6.2 (2B, apical B–H), −8.8 (2B, B–O–B), −20.7, −26.8, −29.5 (total 14B, equatorial B–H); ESI-MS (*m/z*): 165.7 $\{B_{20}H_{17}O(CH_2)_4OCH_3\}^{2-}$, 336.1 $\{(H)(B_{20}H_{17}O(CH_2)_4OCH_3)\}^-$, 410.5 $\{(Me_4N)(B_{20}H_{17}O(CH_2)_4OCH_3)\}^-$. The compound was dissolved in CH_3CN/H_2O (1/1) and ion-exchanged to produce a solution of Na_2**[5a]**. ^1H NMR (400 MHz, D_2O): $\delta = 2.76$ (t, $J = 7.0$ Hz, 2H); 2.70 (m, 3H), 0.70 (m, 2H), 0.62 (m, 2H); ^{13}C NMR (100 MHz, D_2O): $\delta = 82.81$, 71.32, 57.51, 23.54, 23.38.

5b: $(Me_4N)_2$**[5b]** was prepared from Na_4**[4b]** as described above for the transformation of **4a** to **5a**. Yield: 1.75 g, 3.23 mmol, 71%. $^{11}B\{^1H\}$ NMR (160 MHz, H_2O): $\delta = 14.7$ (2B, B–B), 7.0 (2B, apical B–H), −8.4 (2B, B–O–B), −19.85, −20.50, −26.22, −28.89 (total 14B, equatorial B–H); ESI-MS (*m/z*): 195.8 $\{B_{20}H_{17}O(CH_2)_4OCH_2CH_2CH(CH_3)_2\}^{2-}$, 466.2 $\{(Me_4N)(B_{20}H_{17}O(CH_2)_4OCH_2CH_2CH(CH_3)\}^-$. The compound was dissolved in CH_3CN/H_2O (1/1) and ion-exchanged to produce a solution of Na_2**[5a]**. ^1H NMR (400 MHz, CD_3CN): $\delta = 2.90$ (t, $J = 7.0$ Hz, 2H), 2.81 (t, $J = 7.0$ Hz, 2H), 2.73 (t, $J = 7.0$ Hz, 2H), 1.07 (m, 1H), 0.87(m, 2H), 0.78 (m, 2H), 0.67 (m, 2H), 0.33 (d, $J = 6.6$ Hz, 6H); ^{13}C NMR (100 MHz, D_2O): $\delta = 82.76$, 69.33, 68.90, 37.21, 24.29, 23.81, 23.62, 22.00.

6: Solid $(Me_4N)_2$**[5a]** (1.00 g, 2.06 mmol) was placed in 50 mL H_2O. The solid dissolved upon heating, and the mixture was heated at reflux for 24 h. The solution was cooled to 0 °C to produce a white precipitate. The precipitate was separated by filtration and dried in vacuo. Recrystallization from CH_3CN/C_2H_5OH yielded $(Me_4N)_2$**[6]** (610 mg, 77%). The product was identified by its $^{11}B\{^1H\}$ NMR and ESI-MS.[3] The hydrolysis of $(Me_4N)_2$**[5b]** also produced $(Me_4N)_2$**[6]** in 74% yield.

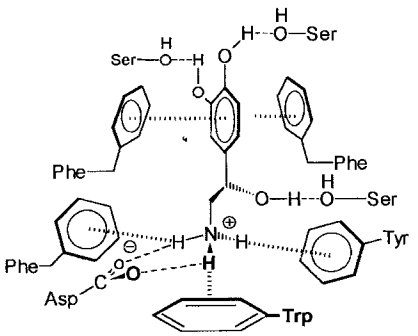
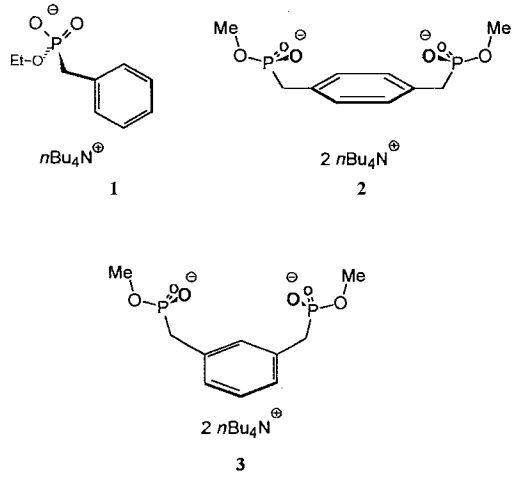
Towards Synthetic Adrenaline Receptors—Strong Binding of Amino Alcohols by Bisphosphonates**

Thomas Schrader*

Research on the mechanism of action of the adrenergic receptor family has received much attention during the past decade,[1] notably because many pharmaceuticals act as agonists or antagonists for the β-adrenergic receptor, for example the well-known β-blockers.[2] Scheme 1 summarizes the present understanding of neurotransmitter binding.[3] The ammonium functionality is recognized through electrostatic and hydrogen bond interactions with an aspartate carboxylate group; simultaneously the NH_3^+ protons are in close contact with three electron-rich aromatic residues, resulting in π–cation stabilization. The aliphatic and catechol hydroxyls are each hydrogen-bonded to a serine OH group, while the aromatic ring is buried in a deep cleft flanked by two phenylalanine aromatic rings that are involved in double π-stacking. We recently embarked on a program for the development of synthetic receptors for adrenaline derivatives that focuses on imitation of the natural receptor–ligand interactions. This led to the design of simple benzylic bisphosphonates that should be able to act as strong chelating agents for the alkylammonium group (Scheme 2). The great advantage of the phosphonate over a carboxylate group stems from the fact that at pH 7 phosphonates are fully dissociated due to their much lower pK_a values (1.8 vs. 4.8).[4] The phosphonic acid methyl ester can be easily replaced by more sophisticated alcohol moieties for lateral and possibly chiral recognition of the substrate. Force-field calculations show that when an alkylammonium ion approaches the *p*-xylylene bisphosphonate, not only strong electrostatic attractions result, but also an almost ideal array of short linear hydrogen bonds can be formed (Fig. 1).[5] In addition, the ammonium protons lie exactly 3.5 Å above the aromatic ring, a distance that is ideal for π–cation interactions.[6]



Scheme 1. Noncovalent interactions between noradrenaline and the β-adrenergic receptor.



Scheme 2. Phosphonate receptors.

In both the ^1H and ^{31}P NMR spectra of equimolar mixtures of aliphatic primary ammonium chlorides with phosphonate receptors **2** and **3** large complexation-induced shifts (CIS) of host and guest signals can be observed.[7]

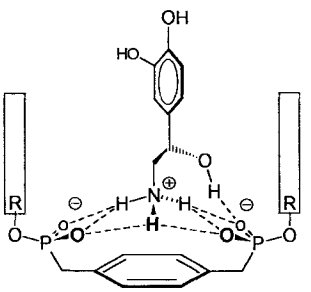


Fig. 1. Complex of *p*-xylylene bisphosphonates with noradrenaline according to force-field calculations [5].

We performed NMR titrations of benzylammonium chloride with phosphonate receptors **1**–**3** in [D_6]DMSO. We measured the CIS of the α-methylene protons and analyzed the binding curves by nonlinear regression methods.[8] The calculated association constants are summarized in Table 1. The 14-fold differ-

[**] I thank Prof. H.-J. Schneider, Saarbrücken, for his program to evaluate 1:1 complexes.

Table 1. Association constants $K_{1:1}$ [a] from NMR titrations in DMSO at 20 °C.

Receptor	Benzylamine 10^3 [M^{-1}]	(±)-**4** 10^3 [M^{-1}]
1	0.2	-
2	2.8	15.5
3	7.4	55.0

[a] Because of the strongly hygroscopic character of both titration partners the [D_6]DMSO solution contained about 0.1% of water. Errors in K_a are estimated at ±10–40%.

ence in K_a values between the mono- and *p*-diphosphonates **1** and **2** indicates strongly that the chelate effect results in double electrostatic attraction for the alkylammonium ion. Unfortunately the signal for the *p*-xylylene aromatic protons remains unchanged, so that a π–cation interaction seems doubtful. Force-field calculations suggest that in going from *para* to *meta* substitution (i.e. from **2** to **3**), the PO $\cdots HN^+$ distance decreases slightly in favor of both electrostatic interactions and hydrogen bonding.[5]

Job's method of continuous variations confirms the postulated 1:1 stoichiometry of the complex.[9] Maxima in the range of $x = 0.5-0.55$ are observed for signals of both the guest and the host.

When 2-hydroxy-2-phenylethylamine hydrochloride (**4**, a model for the amino alcohol moiety in adrenaline derivatives, Scheme 3) is employed, its K_a value is significantly greater than that of benzylamine, reaching 55000 M^{-1} for **3** (Table 1). We examined other biologically important 1,2-amino alcohols (Scheme 3) and compared them to the respective amines (Table 2). We obtained the following results:

a) Binding to the bisphosphonate receptor **3** is three to nine times stronger for all amino alcohols except for the serine

Table 2. Association constants $K_{1:1}$ [a] from NMR titrations with **3** in DMSO at 20 °C.

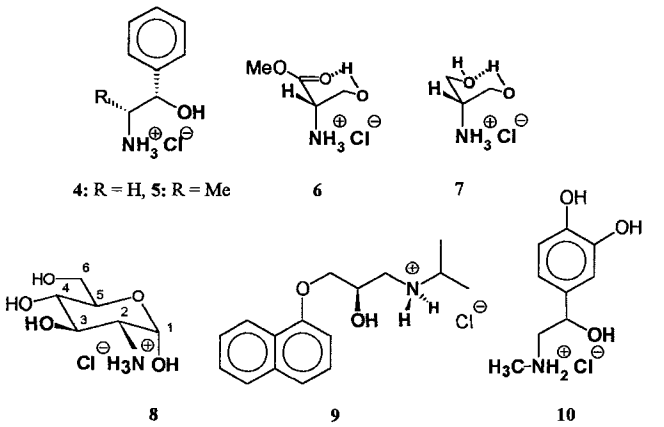
Amine	$K_{1:1} \times 10^3$ [M^{-1}]	Amino alcohol	$K_{1:1} \times 10^3$ [M^{-1}]
benzylamine	7	(*L*)-serine methyl ester **6**	7
(L)-alanine methyl ester	10	serinol **7**	16
2-phenylethylamine	12	(±)- **4**	55
N-benzyl-*N*-methylamine	19	α-D-glucosamine **8**	59
		(1*S*,2*R*)-norephedrine **5**	62
		(*R*)-propranolol **9**	66
		(±)-adrenaline **10**	16

[a] Because of the strongly hygroscopic character of both titration partners the [D_6]DMSO solution contained about 0.1% of water. Errors in K_a are estimated at ±20–40%.

derivatives **6** and **7**. Only the latter, however, are able to form an intramolecular hydrogen bond, giving a six-membered ring that has to be broken before hydrogen bonding to the phosphonate can occur (Scheme 3).

b) Further structural information based on the NMR experiments confirms the strong hydroxyl binding: In the free glucosamine **8** only the signals of OH-1 and OH-3, which are adjacent to the ammonium functionality, shift during the titration. In propranolol **9** the diastereotopic ammonium and methylene protons immediately become magnetically nonequivalent on addition of phosphonate because the OH group is conformationally locked.

c) The binding constant for adrenaline **10** seems to contradict the general trend; however, the ^1H NMR spectrum shows large shifts of the signals of the catechol OH groups on addition of



Scheme 3. Amino alcohols for the NMR titrations.

phosphonate, so that its evaluation has to take into account a second superimposed equilibrium. We therefore assume that adrenaline also binds to the bisphosphonate **3** as strongly as the other amino alcohols.

These results suggest that we have indeed found a basic structural motif for a receptor of 1,2-amino alcohols. Very few synthetic receptors are known that selectively bind to this biologically and pharmaceutically important structure. Reetz created a host for amines *and* alcohols, but only in nonpolar dichloromethane;[10a] Gellman's P=O/S=O "bowls" are also restricted to organic solvents.[10b] For complexations that strongly rely on hydrogen bonds our binding constants of around 60000 in a competitive solvent such as DMSO are remarkably high. The binding constant for **3** with **4** in methanol is still 620 M^{-1} (glucosamine 490 M^{-1}) and even in water weak binding can be observed (Fig. 2).

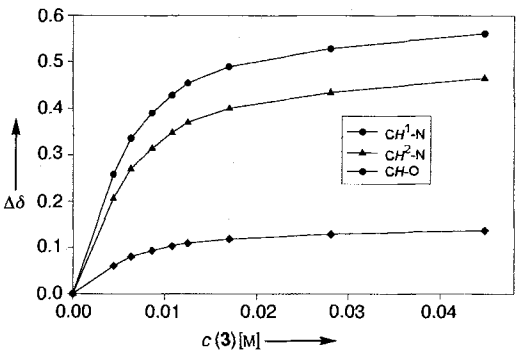


Fig. 2. Dependance of the change in chemical shift of three CH signals of 2-hydroxy-2-phenylethylamine **4** (c = 8 mM) on the concentration of bisphosphonate **3** in [D_4]methanol at 20 °C.

To realize biomimetic recognition of the aromatic ring by π-stacking interactions we are at present examining bisaryl esters of **2**. Macrocycles should provide preorientation and possibly embed the guest in an aromatic groove similar to the natural receptor.

$K_7HW_5O_{19}\cdot 10H_2O$—A Novel Isopolyoxotungstate(VI)**

Joachim Fuchs, Rosemarie Palm, and Hans Hartl*

On acidification of an aqueous tungstate solution, addition (expansion of the tetrahedral to the octahedral coordination of W) and condensation reactions occur, leading to the formation of polymolecular isopolytungstate ions,[1] of which nine types are known. Which structure type is formed depends primarily on the degree of acidification of the tungstate solution, that is on the molar ratio of protons to monotungstate ions.[2] In addition the age of the solution and the total concentration (no aggregation occurs in highly dilute solutions) plays a role.[3] Investigations on how the pH value influences aqueous tungstate solutions are difficult to perform due in part to the very slow establishment of equilibrium and are often hard to interpret. Therefore, one is still dependent on being able to carry out crystal structure investigations on isolable compounds to be in a position, for example, through ^1H, ^{183}W, and ^{17}O NMR spectroscopic studies,[4, 5] to draw conclusions on the state of the solution. Unlike for polymolybdates[6] the influence of the inorganic counterion present in the tungstate solutions has hitherto been studied very little. We have ascertained that the influence of the cation can be very large, at least in solids, which crystallize from the solutions.[7] There are also clear indications that the nature of the cation has a strong influence on the reaction pathways in solution. Thus, ^{183}W NMR spectroscopic investigations in the presence of Li^+ indicate that cations influence the protonation of polyoxometalates (by blocking the positions of oxygen atoms) and thereby also the condensation processes in different ways.[5]

Recently we reported the synthesis and structure of the sodium hexatungstate $Na_5H_3W_6O_{22}\cdot 18H_2O$ **1**.[8] Our attempts to prepare the corresponding potassium salt by an analogous method in which potassium monotungstate K_2WO_4 was used instead of sodium monotungstate $Na_2WO_4\cdot 2H_2O$, however, resulted in no potassium hexatungstate(VI). Crystals were obtained from the solution after about a year whose vibrational spectra resembled those of the sodium hexatungstate, but showed several distinct differences. (Fig. 1). IR spectra are particularly suitable for identifying polyoxoanions. Whereas the different types of anion show a characteristic IR spectrum in the fingerprint region (roughly between 1000 and 300 cm^{-1}) that is almost unaffected by the participating cations, Raman spectra were strongly influenced by the different cations and amounts of water present.

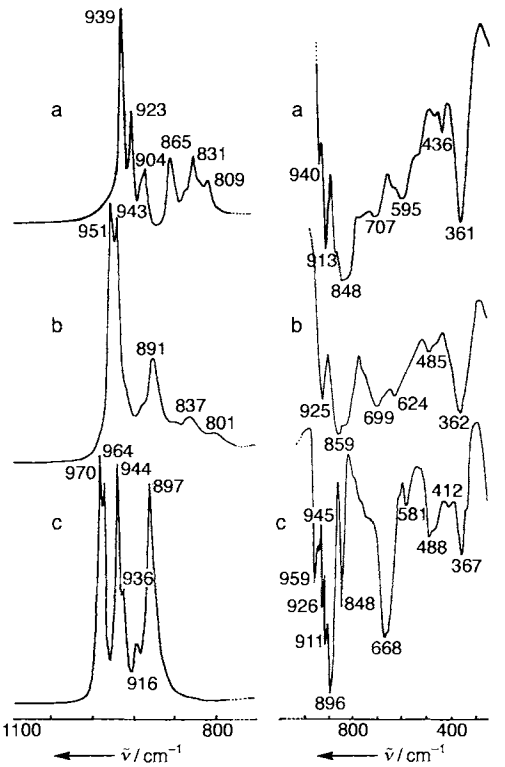

Fig. 1. IR and Raman spectra of a) $Na_5H_3W_6O_{22}\cdot 18H_2O$ **1**, b) $K_7HW_5O_{19}\cdot 10H_2O$ **2**, and c) $Na_6W_7O_{24}\cdot 18H_2O$ (in the region for the W–O vibrational bands). Left: Raman, right: IR spectrum.

According to X-ray structure analysis[9] the potassium pentatungstate $K_7HW_5O_{19}\cdot 10H_2O$ **2** surprisingly existed with a hitherto unknown polytungstate ion. This anion has one of the three structures[10] possible for blocklike W_5O_{19} frameworks, and is a fragment of the hexatungstate ion $[H_3W_6O_{22}]^{5-}$ and thus also of the heptatungstate ion $[W_7O_{24}]^{6-}$[11] (Fig. 2). It consists of five WO_6 octahedra, two of which have free faces, thus each face contains three neighboring terminal oxygen

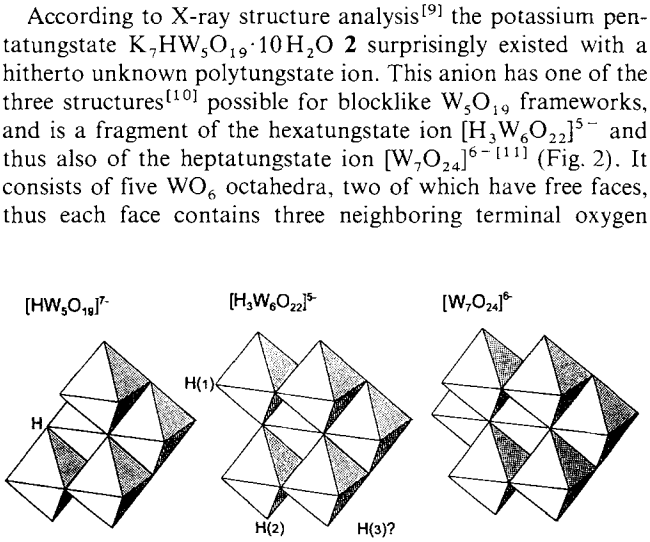

Fig. 2. Polyhedral representation of the structures of $[HW_5O_{19}]^{7-}$, $[H_3W_6O_{22}]^{5-}$, and $[W_7O_{24}]^{6-}$.

[**] This work was supported by the Fonds der Chemischen Industrie.

atoms. Two octahedra have a free edge with two terminal oxygen atoms, one octahedron has only one free corner. Of the seven potassium ions, five are coordinated to both oxygen atoms of the polyanion and to water molecules. They all have a bridging function and form a link from one polyanion to five neighboring polyanions. The coordination numbers range between 6 and 8. The two remaining potassium ions are only coordinated by water molecules. Thus, tetranuclear K^+/H_2O clusters consisting of square antiprisms $[K(H_2O)_8]^+$ and monocapped octahedra $[K(H_2O)_7]^+$ are formed; these are bridged alternately through common square faces and edges (Fig. 3, right).

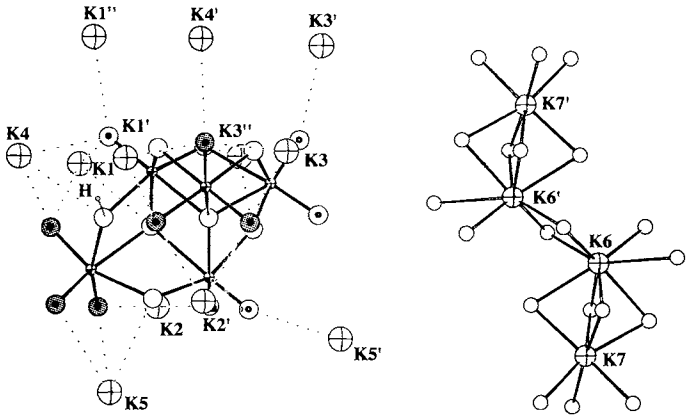

Fig. 3. Ball-and-stick representation of the anion $[HW_5O_{19}]^{7-}$ (with the K^+ coordination by K1 to K5; left) and the K^+/H_2O polyhedra of K6 and K7 (right), small spheres: W; medium: O; large: K, gray: terminal O of the *fac*-$[WO_3]$ grouping, spheres with cross: terminal O. W–O and K–O bond lengths [Å]: $W-O_{terminal}$ 1.71–1.79 (av 1.75), $W-\mu_2$-O 1.78–2.34 (av 2.02), $W-\mu_3$-O 1.93–2.31 (av 2.14), $W-\mu_4$-O 2.14–2.26 (av 2.20), K–O 2.63–3.12 (av 2.89), $K-OH_2$ 2.66–3.30 (av 2.92), average standard deviation ±0.02 Å.

Through a comparison of the systems with Na^+ and K^+ ions, it was clear that the influence of the cation is of greater significance than the degree of acidification of the tungstate solution. The hexatungstate **1** and the pentatungstate **2** were not obtained from acidic, but from alkaline solution (pH about 9).

The hexatungstate ion requires a H^+/WO_4^{2-} ratio of 7/6 = 1.167 [Eq. (a)]; thus, like the heptatungstate ion it formally

$$6WO_4^{2-} + 7H^+ \longrightarrow [W_6O_{19}(OH)_3]^{5-} + 2H_2O \quad (a)$$

belongs to the group of paratungstates. For the pentatungstate ion a lower H^+/WO_4^{2-} ratio of 3/5 = 0.60 [Eq. (b)] can be calculated; and in fact the solution was much less acidified than would be necessary according to the reaction equation (degree of acidification of the 2 M tungstate solution: 0.29; in the preparation of **1** with a H^+/WO_4^{2-} ratio of 1.167, the real degree of acidification of the tungstate solution was only 0.15).

$$5WO_4^{2-} + 3H^+ \longrightarrow [W_5O_{18}(OH)]^{7-} + H_2O \quad (b)$$

In light of the structure of **2**, a general assumption, which was previously also shared by us, needs to be corrected: WO_6 octahedra with three or more terminal oxygen atoms should generally not occur (Lipscomb rule[12]) in polyoxotungstates(VI). They should only be stable when at least one of the three terminal oxygen atoms of the face is protonated. Compound **2** contains two free faces (Fig. 2) and only one OH group, and according to calculations of the valence sums, the proton is not located at one terminal oxygen atom but at the bridging oxygen atom marked in Figure 2. Without the proton, this oxygen atom has a bonding valence sum[13] of only 1.0, whereas all other oxygen atoms of the anion have valence sums greater than 1.65.

The occurrence of free octahedra faces has been explained previously[1, 14] by the fact that at higher pH values no diprotonated monometalate ions participate in the condensation reactions (no possibility for the formation of closed structures). The two WO_6 octahedra present in the anion of **2**, each having three terminal oxo groups, in the crystal are coordinated and thereby stabilized partly by K^+ (Fig. 3, left) and by hydrogen bonding of water of crystallization. In solution such terminal *fac*-$[MO_3]$ groups (M = Mo, W) are very unstable and reactive;[15, 16] the number of neighboring terminal oxo groups is reduced by addition and condensation reactions. Although with the methods currently available it cannot be proved experimentally that the penta- and hexatungstate ions are precursors of the anion $[W_7O_{24}]^{6-}$ (Fig. 2), this appears plausible (cf. ref. [1,14]). The reason why the anions of the polytungstates **1** and **2** could not be proven analogously to $[W_7O_{24}]^{6-}$ by Raman or ^{17}O and ^{183}W NMR spectroscopic measurements[4, 5] in solution, seems to be that the anions of **1** and **2** immediately react further to give the more stable, more highly condensed heptatungstate ion, and thus exist in such low concentrations that they cannot be detected experimentally. The $[W_7O_{24}]^{6-}$ ion found in solution and in the solid state has no free octahedra faces with *fac*-$[WO_3]$ groups.

Experimental Procedure

K_2WO_4 (11.2 g, 0.0343 mol) was stirred with $WO_3 \cdot H_2O$ (1.25 g, 0.005 mol; degree of acidification (formal ratio H^+/WO_4^{2-} = 0.2) in water (12.5 mL) (tungstate concentration of the solution: about 2 mol L^{-1}) in a closed Cautex vessel at 20 °C with exclusion of CO_2. The initially yellow suspension lost color and turned almost white and was filtered. From the mother liquor, which had completely dried up after about a year, air-stable single crystals of **2** were obtained together with two other compounds (main product $K_{10}H_2W_{12}O_{42} \cdot 10H_20$ **3**).

Compound **2** could be obtained in slightly larger quantities in (almost) pure form if, at intervals of about one month, the crystals of **3** were centrifuged off from the mother liquor three times. After seeding the solution with single crystals of **2** followed by careful addition of acetone, **2** was formed in a finely crystalline form, as has been confirmed by IR spectroscopy. The yield in both cases was very low.

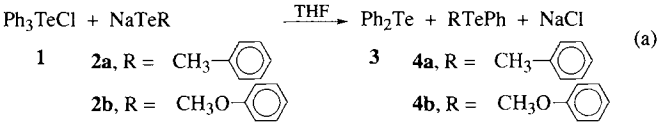
Dimeric Triaryltelluronium Arenetellurolates: New Metastable Tetramers of Diaryltellurium**

Jörg Jeske, Wolf-Walther du Mont,* and Peter G. Jones

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

Water and its homologous dihydrogen chalcogenides H_2E (E = S, Se, Te) dissociate to only a very limited extent. Neither their ionic dimers $H_3E^+EH^-$ nor organic derivatives $R_3E^+ER^-$ have been isolated in a pure state. Water dimers are typically formed by O–H···O hydrogen bonds. However, in the case of sulfur, selenium, and tellurium, metastable "dimers" R_3EER might exist as ion pairs or as molecular compounds with covalent chalcogen–chalcogen bonds. The "dimer" of SF_2 (S_2F_4) is indeed the mixed-valent molecule $F_3S–SF$ with a covalent $S^{III}–S^{I}$ bond.[1] Thus the existence and structures of the hypothetical nonclassical dimeric or oligomeric relatives of diorganotellurides R_2Te are of considerable interest, especially since it was recognized that contributions from packing of cations and anions are most important for the structures of nonclassical polytellurides implying expanded valence shells.[2–4] Possible features of "nonclassical diaryltellurium" compounds could be ionic telluronium tellurolate interactions ($R_3Te^+TeR^-$) and covalent tellurium(IV)–tellurium(II) bonds ($R_3Te–TeR$, perhaps similar to Böttcher's $CsTe_4$).[2] Cooperative charge-transfer-like interactions between tellurium atoms would also be possible. Such interactions are typical for intermolecular contacts in elemental iodine,[5] diorganic ditellurides,[6] and tetraalkyl distibanes,[6–8] and for homonuclear cation–anion contacts in iodophosphonium iodides.[9] These homonuclear interactions (n → σ* overlap) imply hypervalency of the acceptor atoms.

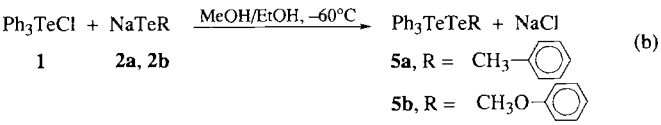
Oxonium salts $R_3O^+BF_4^-$ are known to alkylate alcoholates very efficiently. Accordingly triphenyltelluronium salts in THF solution transfer quantitatively one of their phenyl groups to tellurolates under mild conditions [Eq. (a)]. This phenyl transfer



(a)

Scheme 1.

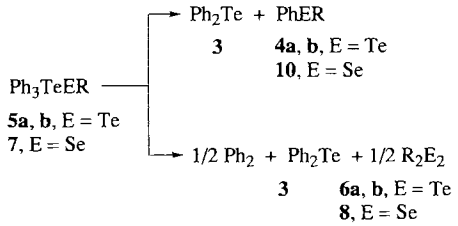
can be inhibited by adding triphenyltelluronium chloride (**1**) dissolved in methanol to an ethanolic solution of the sodium tellurolates **2a,b** at low temperatures. At temperatures below −30 °C orange powders of Ph_3TeTeR (**5**: **5a**, R = *p*-$CH_3C_6H_4N$; **5b**, R = *p*-$CH_3OC_6H_4N$) precipitated immediately from the alcoholic solutions. These reactions can be controlled to yield single crystals of the metastable **5** suitable for X-ray structure determinations. The by-product, sodium chloride, remains in solution [Eq. (b)].



(b)

Scheme 2.

The orange crystals of **5a** and **5b** are stable below −18 °C. At room temperature they decompose gradually, furnishing oily mixtures of diaryltellurides (Ph_2Te **3**, PhTeR **4a**: R = *p*-$CH_3C_6H_4N$; **4b**: R = *p*-$CH_3OC_6H_4N$), which accelerate this decomposition. Among the products are minor amounts of diorganic ditellurides (**6a,b**) and biphenyl (detected by EI mass spectra). Telluronium tellurolates **5** are insoluble in ethanol, THF, toluene, and hexane, but slightly soluble in cold methanol. However, in solution decomposition takes place even at low temperature (−18 °C). Therefore all attempts failed to dissolve **5** for the purpose of recrystallization or for recording NMR spectra. Mass spectra always show peaks and fragments of decomposition products [Eq. (c)].



Scheme 3.

From the class of chalcogenotelluranes or telluronium chalcogenolates (R_3TeER', E = O, S, Se, Te; R = alkyl or aryl) only the (monomeric) phenoxide compound **9a** (that is, E = O) and two derivatives have been structurally characterized.[10] A nitro function *para* to the phenoxide leads to longer Te–O bonds (**9a**: 2.294, **9b**: 2.461 Å). The 2,4,6-trichlorophenoxide derivative **9c** is a dimer with inversion symmetry. Te–O distances within the dimer lie between 2.762 and 2.787 Å.[10] The first arylthio derivatives (E = S) have been postulated as inter-

9a, $R^1 = R^2 = R^3 = H$
9b, $R^1 = R^2 = H$, $R^3 = NO_2$
9c, $R^1 = R^2 = R^3 = Cl$ (as Te_2O_2 dimer)

mediates in the thermal decomposition of telluronium carboxylates;[11] they decompose above 0 °C, especially in solution.[12]

X-ray single-crystal structure analyses of the solids **5a** and **5b**[13] show cyclic units of the composition R_8Te_4 containing tellurium–tellurium interactions. These units can be (formally) regarded as tetramers of diaryltellurium compounds. The nearly planar Te_4 rings contain alternate triphenyltelluronium and aryltellurolate units (Fig. 1). The tellurium–tellurium contacts

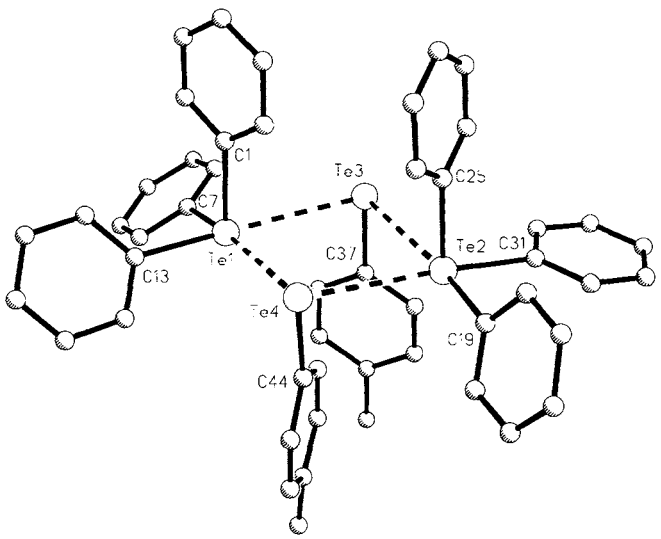

Fig. 1. Crystal structure of **5a**. Selected bond lengths [Å] and angles [°]: Te1 ··· Te3 3.5259(13), Te1 ··· Te4 3.3796(13), Te2 ··· Te3 3.3233(13), Te2 ··· Te4 3.5958(13); Te3-Te1-Te4 87.52(3), Te3-Te2-Te4 87.24(3), Te1-Te3-Te2 93.51(3), Te1-Te4-Te2 91.32(3).

(Te ··· Te: **5a** 3.3233(13), 3.5958(13), 3.3796(13), 3.5259(13); **5b** 3.481(2), 3.441(2), 3.396(2), 3.447(2) Å) within the four-membered ring system are substantially longer than covalent Te–Te single bonds[5] and than the distances between hypervalent and divalent tellurium atoms within solid $CsTe_4$.[2] However, Te–Te contacts in **5a,b** are significantly shorter than the sum of the van der Waals radii (4.40 Å). On average they are slightly shorter than the shortest intermolecular Te–Te distances between diorganic ditellurides or the distances between tellurium chains in elemental tellurium (3.50 Å).[4, 5] Corresponding *intermolecular* Se–Se interactions in elemental gray selenium are only slightly shorter (3.44 Å);[5] but covalent Se–Se bonds are about 0.40 Å shorter than Te–Te bonds. Therefore the question arises whether a mixed tellurium–selenium compound Ph_3TeSeR would exhibit nearly the same chalcogen–chalcogen distances as its analogues **5a,b** or whether the Se–Te distances would be significantly shorter.

Triphenyltelluronium 4-methylphenylselenolate (**7**) was isolated analogously to **5a** after treating triphenyltelluronium chloride with sodium 4-methylphenylselenolate. The structure of the metastable yellow–orange crystals was also determined by X-ray diffraction at −130 °C. The selenolate **7** appears to be slightly more stable than tellurolate **5a**; after thermal decomposition more diaryldiselenide and biphenyl is formed than with **5a** [Eq. (c), detected by EI-mass spectra and ^{77}Se-NMR, ratio of diarylselenide to diaryldiselenide approximately 2:1]. Solid **7** reveals the same essentially planar, four-membered ring of chalcogen atoms as in **5a,b** (Fig. 2); the average Te–Se distance (3.151–3.339 Å) is about 0.20 Å shorter than the average Te–Te distance of compounds **5a,b**.

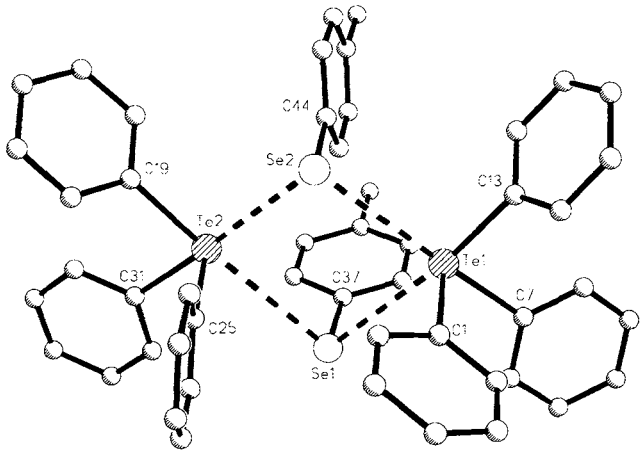

Fig. 2. Crystal structure of **7**. Selected bond lengths [Å] and angles [°]: Te1 ··· Se1 3.3081(8), Te1 ··· Se2 3.2768(9), Te2 ··· Se1 3.1507(8), Te2 ··· Se2 3.3388(8); Se1-Te1-Se2 86.382(14), Se1-Te2-Se2 87.924(14), Te1-Se1-Te2 94.129(14), Te1-Se2-Te2 91.272(14).

Including the bridging chalcogen anions, the acceptor tellurium atoms of the triphenyltelluronium cations of **5a,b** and **7** achieve the coordination number 5 (12-Te-5).[14] The coordination geometry is (3+2)-distorted, pseudo-tetragonal-monopyramidal. The coordination geometry of the donating chalcogen atoms is trigonal-pyramidal (8-Te-3, 8-Se-3). Thus the solid state structures of **5a,b** and **7** are in accordance with the valence shell electron pair repulsion (VSEPR) theory. The Te–C bonds and angles of the triphenyltelluronium fragments are scarcely distorted by cation–anion interactions.[15] Stable monomeric 2,2′-biphenylylene-2-biphenyltellurium phenoxide (10-Te-4) **9a** has a pseudo-trigonal-bipyramidal-coordinated tellurium center. The apical Te–C bond of the chelating biphenyl moiety opposite the phenoxide group is considerably longer than the equatorial Te–C bonds (2.103, 2.122 Å).[10] Dimeric **9c** contains two Te–C bonds *trans* to bridging oxygen atoms. Only one of these—the Te–C bond involving the 2-biphenyl substituent—is significantly elongated (2.159 Å). The gradual elongation of Te–O bonds in the sequence of tellurium phenoxides **9a–c** reflects the gradual change from predominantly hypervalent covalent bonds (**9a**) to a more onium-salt-like structure (**9c**).[10]

Our finding that the Te–Te and Te–Se contacts in **5a,b** and **7** are about 0.65–0.70 Å longer than the corresponding covalent bonds of Te^{II} or Se^{II} indicates that the contribution from covalence of the Te–Te and Te–Se interactions is only slight relative to that of the Te–O bond of **9a**.

Calculations (EHT, PM3) based on models of **5a,b** and **7** with appropriate symmetry give no indication of explicit bonding contributions from orbital overlap within Te_4 or Te_2Se_2 ring systems.[16] The compounds can be best described as pairs of ion pairs. The existence of the solid compounds **5a,b**, which are metastable with respect to the diaryltellurides **3** and **4**, as well as of color (**1** and **2** are colorless) and of a geometry in accordance with VSEPR indicates the importance of cooperative tellurium–tellurium interactions in the solids.

Experimental Procedure

5a,b; 7: To a solution of 1.0 mmol sodium aryltellurolate or -selenolate (freshly prepared from diaryditellurium and -diselenium, respectively, and sodium borohydride in 20 mL of ethanol) was added triphenyltelluronium chloride (0.39 g, 1.0 mmol) in methanol (20 mL) at -60 °C. Immediately a microcrystalline product precipitated. After filtration at -60 °C and washing with ethanol it was dried in vacuo. Crystals suitable for X-ray diffraction were obtained by diffusion of the dissolved starting materials at -30 °C. **5a** (triphenyltelluronium 4-methylphenyltellurolate): Yield 0.51 g (89%). Elemental analysis of $C_{25}H_{22}Te_2$: calcd C 51.98, H 3.84; found C 52.75, H 4.00. **5b** (triphenyltelluronium 4-methoxyphenyltellurolate): Yield 0.47 g (80%). Elemental analysis of $C_{25}H_{22}OTe_2$: calcd C 50.58, H 3.74; found C 50.48, H 3.75. **7** (triphenyltelluronium 4-methylphenyl selenolate): Yield 0.35 g (67%). Elemental analysis of $C_{25}H_{22}SeTe$: calcd C 56.76, H 4.19; found C 56.03, H 3.96.

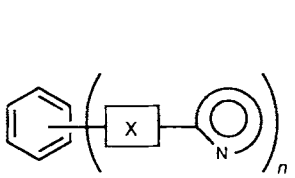
Coelenterands: A New Class of Metal-Encapsulating Ligands

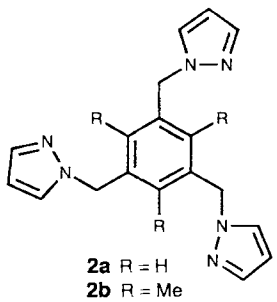
Chris M. Hartshorn and Peter J. Steel*

Heterocyclic tripodal ligands have long been used in coordination and organometallic chemistry,[1] most notably the anionic tripyrazolylborates (scorpionates),[2, 3] and their neutral carbon analogues, the tripyrazolylmethanes.[4] A separate area of chemistry that has received much attention is the study of π-arene complexes of transition metals. Benzene forms stable organometallic complexes with many metals, for example, $[Ru(\eta^6\text{-}C_6H_6)_2]^{2+}$,[5] but half-sandwich complexes of ruthenium (e.g., $[Ru(\eta^6\text{-}C_6H_6)L_3]^{2+}$; L = monodentate ligand) are less well studied.[5, 6] In this paper we bring together for the first time these two important areas of chemistry and introduce a new class of ligands, the coelenterands.[7] The structures of these molecules is such that a coordinated metal is simultaneously involved in η^6-bonding to the benzene ring and tripodal coordination to suitably placed heterocycles.

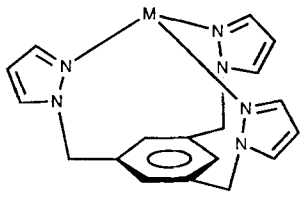
We are currently engaged in the synthesis and study of an extensive range of compounds (represented by the generalized structure **1**) that comprise a benzene (or other arene) ring to



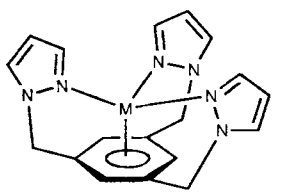
1



2a R = H
2b R = Me



3



4

which are appended multiple heterocyclic rings connected through a variety of spacer groups. These polyheteroaryl-substituted arenes exhibit a variety of modes of coordination to different transition metals.[8] We recently reported[9] the syntheses of a number of poly(pyrazol-1-ylmethyl)benzenes including the 1,3,5-tri(pyrazol-1-ylmethyl)benzenes (**2a,b**), and speculated that such compounds might act as tripodal chelating ligands, as in **3**, or even encapsulate a metal with additional coordination to the benzene ring, as in **4**. We now report the successful realization of this second mode of coordination.

Reaction of **2b**, readily available in two steps from mesitylene,[9] with $[Ru(dmso)_4Cl_2]$ in ethanol/water at reflux

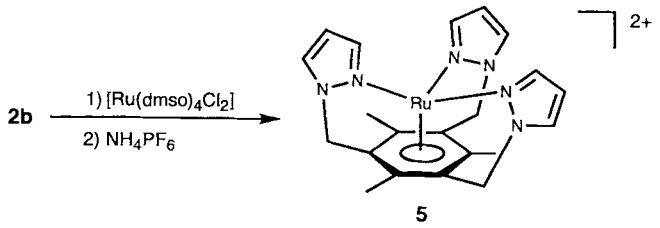
gave a product that was isolated in 42% yield as the hexafluorophosphate salt (Scheme 1). X-ray quality crystals of **5** proved very elusive; of the several counterions tried, only the tetrachlorozincate anion furnished single crystals.[10]



5

Scheme 1. Preparation of **5**.

Figure 1 shows a perspective view of the structure of cation **5**.[11,12] This clearly shows that the ligand encapsulates the ruthenium atom, with joint chelation by the three pyrazole nitrogens and π-coordination by the benzene ring, in this 18-electron species. The cation has approximate C_{3v} symmetry; the coordination about the ruthenium atom is distorted octahedral. The benzene ring is measurably distorted towards a chair conformation: the pyrazolylmethyl-substituted carbons are displaced towards the ruthenium atom (mean deviation from the plane 0.029 Å). Whereas the three methyl substituents lie in the plane of the benzene ring (maximum deviation from the plane 0.069 Å), the three attached methylene carbons are severely displaced from this plane (mean deviation 0.470 Å), an indication of significant pyramidalization of the aromatic carbons. By necessity, the the structure has an eclipsed, rather than staggered, piano-stool-type arrangement.

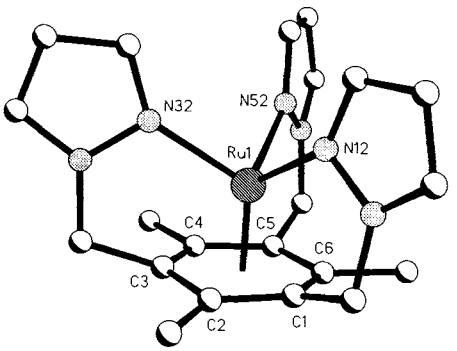


Fig. 1. Perspective view and atom labeling of the X-ray crystal structure of the cation **5**. Selected bond lengths [Å] and angles [°]: Ru1–N12 2.107(8), Ru1–N32 2.091(8), Ru1–N52 2.094(8), Ru1–C1 2.103(9), Ru1–C2 2.186(9), Ru1–C3 2.096(9), Ru1–C4 2.156(9), Ru1–C5 2.083(9), Ru1–C6 2.149(9); N12-Ru1-N32 96.7(3), N12-Ru1-N52 94.5(3), N32-Ru1-N52 92.6(3).

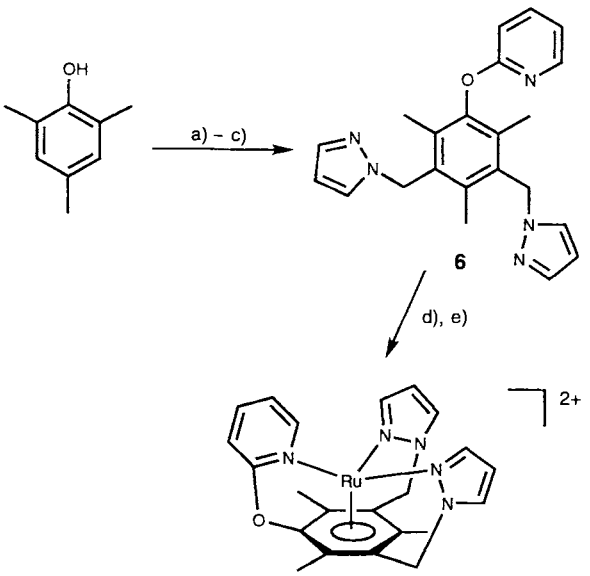
A search of the Cambridge Crystallographic Data Base for [Ru(η^6-arene)] structures with three additional nitrogens coordinated to the ruthenium disclosed five related structures, with $B(pz)_4^-$,[13] $(pzH)_2pz$,[14] $(PhNH^-)_3$,[15] $(MeCN)_3$,[16] and $pyCH_2N(Me)CH_2CH_2py$[6] (where pz = pyrazole and py = pyridine) as additional ligands. The structures of two *p*-cymeneruthenium complexes of a tripyrazolylborate and a tripyrazolylmethane have also recently been reported.[17] In none of these literature structures is any of the nitrogen atoms linked to the benzene ring. The most significant difference between these structures and that of **5** is in the distance of the ruthenium atom from the arene ring; in **5** the ruthenium lies 1.579 Å from the centroid of the benzene ring, whereas in the previously reported structures the corresponding distances are significantly longer, lying in the range 1.67–1.70 Å. This indicates a strong metal–arene interaction in **5**, which is undoubtedly reinforced by multiple chelate effects. In the published structures[6,13–17] the N-Ru-N angles are generally acute, whereas in the case of **5** the internal attachments to the benzene rings result in these angles being obtuse (92.6–96.7°).

According to the similarity of the spectroscopic and electrochemical[18] properties of **5** to those of Ru(η^6-arene) complexes with additional nitrogen donors, this structure is maintained in solution.[6,14,17,19] In particular, the large upfield shifts (about 30 ppm) of the arene carbons in the ^{13}C NMR spectrum clearly establish their coordination to the ruthenium atom.

Having demonstrated the ability of these ligands to encapsulate a ruthenium atom, we are currently studying their complexation of other metal ions. We are also synthesizing other coelenterands with different heterocyclic rings and different spacer groups. For example, we have prepared the new, less symmetrical ligand **6**, with a 2-pyridoxy group, from 2,4,6-trimethylphenol by a reaction sequence involving heteroarylation,[8] double bromomethylation,[20] and phase-transfer-catalyzed alkylation[21] with pyrazole (Scheme 2). This new coelenterand also reacts with $[Ru(dmso)_4Cl_2]$ to form a complex analogous to that of **5**.



Scheme 2. Preparation and complexation of **6**. a) 2-Bromopyridine/K_2CO_3/Δ; b) CH_2O/HBr; c) pyrazole/NaOH/NBu_4OH; d) $[Ru(dmso)_4Cl_2]$; e) NH_4PF_6

In conclusion, we here describe the formation of novel organometallic compounds derived from a new class of ligands, the coelenterands, which encapsulate metal ions with simultaneous η^6-arene coordination and tripodal chelation from within the same ligand.

Experimental Procedure

5: An equimolar mixture of **2b** and $[Ru(dmso)_4Cl_2]$ was heated at reflux in ethanol/water (3/1) for 12 h. The ethanol was removed under reduced pressure to give the chloride salt of **5**. High-resolution MS: calcd for $[C_{21}H_{24}N_6{}^{35}Cl^{102}Ru]^+$ 497.0795, found 497.0801. This was dissolved in water and filtered. Ammonium hexafluorophosphate was added to the filtrate to give a pale yellow/green precipitate of **5** as the PF_6 salt in 42% overall yield. M.p. >250 °C (decomp). UV/Vis (CH_3CN):

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3522-2656 $ 15.00+.25/0

λ [nm] (ε [$M^{-1}cm^{-1}$]) = 222 (11200), 344 (625). ^{1}H NMR (300 MHz, CD_3CN): δ = 2.19 (s, 9H), 5.48 (s, 6H), 6.70 (t, 3H), 7.69 (d, 3H), 8.12 (d, 3H). ^{13}C NMR (75 MHz, CD_3CN): δ = 13.0 (CH_3), 51.6 (CH_2), 100.6 (C2,4,6), 109.2 (C1,3,5), 109.6 (C4'), 135.1 (C5'), 140.7 (C3'). Alternatively, zinc chloride (2 equiv) and hydrochloric acid were added to the above filtrate, which, over a period of weeks, furnished yellow crystals of the $ZnCl_4^{2-}$ salt of **5**, which were suitable for single crystal X-ray structure analysis. C,H,N anal. calcd. for $C_{21}H_{24}N_6RuZnCl_4 \cdot 2H_2O$: C 35.79, H 4.00, N 11.92; found: C 35.60, H 3.91, N 11.83.

6: a) 2,4,6-Trimethylphenol (2 equiv), 2-bromopyridine (1 equiv) and potassium carbonate (1 equiv) were heated, with stirring, at 220–230 °C for 8 hours. The resulting mixture was extracted repeatedly with diethyl ether, and the extracts combined and washed with aqueous sodium hydroxide. Removal of the solvent under reduced pressure yielded 2,4,6-trimethyl(2-pyridoxy)benzene in 62% yield. b) A mixture of 2,4,6-trimethyl(2-pyridoxy)benzene (1 equiv), paraformaldehyde (4 equiv), and 40% hydrobromic acid was heated at reflux in acetic acid for 14 days; additional hydrobromic acid was added to the reaction mixture every second day. The resulting solution was poured into water, and the solid filtered and recrystallized from petroleum ether to give 3,5-bis(bromomethyl)-2,4,6-trimethyl(2-pyridoxy)benzene in 29% yield. M.p. = 160–161 °C. C,H,N anal. calcd. for $C_{16}H_{17}Br_2NO$: C 48.15, H 4.29, N 3.51; found: C 48.57, H 4.28, N 3.44. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.18 (s, 6H), 2.47 (s, 3H), 4.59 (s, 4H), 6.90 (d, 1H), 6.95 (t, 1H), 7.69 (t, 1H), 8.11 (d, 1H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 12.79, 14.92, 29.71, 109.96, 117.84, 131.73, 133.52, 134.26, 139.56, 147.75, 148.53, 162.95. c) A mixture of 3,5-bis(bromomethyl)-2,4,6-trimethyl(2-pyridoxy)benzene (1 equiv) pyrazole (2 equiv) and tetrabutylammonium hydroxide was heated at reflux in benzene/aqueous sodium hydroxide for 18 hours. The benzene layer was then separated, dried (sodium sulfate), and concentrated under reduced pressure to give a crude product, which was recrystallized from petroleum ether to give the pyridoxybenzene **6** as a colorless solid in 58% yield. M.p. = 127 °C. C,H,N anal. calcd. for $C_{22}H_{23}N_5O$: C 70.76, H 6.21, N 18.75; found: C 70.51, H 6.05, N 18.66. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.15 (s, 6H), 2.27 (s, 3H), 5.43 (s, 4H), 6.20 (t, 2H), 6.94 (d, 1H), 6.95 (t, 1H), 7.09 (d, 2H), 7.53 (d, 2H), 7.70 (t, 1H), 8.10 (d, 1H). ^{13}C NMR (75 MHz, $CDCl_3$): δ = 13.24, 15.58, 50.42, 105.33, 110.07, 117.86, 127.85, 131.36, 132.52, 135.55, 139.22, 139.53, 147.67, 148.88, 162.88.

Molecular Redox-Switches by Ligand Exchange**

Christophe Canevet, Jacqueline Libman, and Abraham Shanzer*

The increasing interest in molecule-based technologies[1] is stimulating extensive research on the synthesis of task-oriented molecules such as molecular wires,[2, 3] diodes,[4, 5] light converters,[6] and switches.[7–14] Recently, several molecular switches have been introduced that respond to external triggers such as photons, protons, and electrons. Examples include photochromic materials that undergo reversible, light-induced cyclizations,[11] rotaxanes in which macrocyclic structures shuttle between two stations on a rodlike molecule,[12] catenates in which redox processes of a guest ion promote swinging motions of two rings relative to each other,[13] and triple-stranded helices that undergo electron-induced translocation of an iron atom between neighboring cavities.[14] Here we introduce a novel redox-switch that interconverts between two distinct states by ligand exchange. At the heart of this switch is a molecule that possesses two sets of ion-binding groups: one set of "hard" and one set of "soft" ligating groups. The two sets are anchored on a calix[4]arene ring[15] in an alternating fashion, such that they can form either a "hard" or a "soft" ion-binding cavity; one cavity is formed at the exclusion of the other. Calix[4]arene was selected as the anchor since it directs both sets of ion-binding groups to the same face of the ring and allows either set to converge by means of a rocking motion. When loaded with Fe^{III}, the "hard" binding groups, hydroxamates, converge to embrace the "hard" metal ion, while the soft groups diverge. Upon reduction, the ligand rearranges to engulf Fe^{II} with its "soft"

[**] This work was financially supported by the Israel Academy of Sciences and Humanities and by the Minerva Foundation. We thank Dr. S. J. Harris, Dublin University, Ireland, for sharing his knowledge of calix[4]arene chemistry. The French–Israeli l'Arc-en-ciel Program is acknowledged.

bipyridyl groups (Fig. 1), while the "hard" groups diverge. Subsequent oxidation reverses this process. The distinctly different spectroscopic characteristics of this switch in its two states enables ready monitoring of the switching process in real time, as it turns from orange into pink upon reduction.

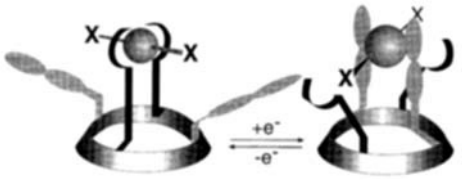

Fig. 1. Schematic representation of the redox-switch.

The mixed-ligand binders **3** and **5** and the reference binders **1**, **2**, and **4** were prepared from calix[4]arene by a series of steps shown in Figure 2. The structures of the compounds were established by ^{1}H NMR, FT IR and, FAB MS, and their cone conformations were confirmed by the large chemical shift difference of the anchors' methylene bridges[15] ($\Delta\delta$(Ar-CH_AH_B-Ar) = 0.88, 0.96, 0.72, 1.02, and 1.10, for ligands **1**, **2**, **3**, **4**, and **5**, respectively).

Addition of $FeCl_3$ to a buffered solution of the mixed-ligand binder **3** resulted in the formation of the bishydroxamate complex Fe^{III}-**3**, as indicated by its UV/Vis spectrum (λ_{max} (ε) = 464 nm (1900)).[16] Subsequent addition of ascorbic acid caused the appearance of new, bathochromically displaced maxima (λ_{max} (ε) = 494 (3000), 526 nm (3000)), characteristic for the Fe^{II}–bipyridyl complex Fe^{II}-**3**.[17] Addition of ammonium persulfate reversed this process (Fig. 3). The identity of the reduced form of the switch, Fe^{II}-**3**, was confirmed by comparison with the same complex prepared directly by reaction of **3** with $FeCl_2$ under argon. Independent characterization of each state of the switch was achieved by FAB MS, which confirmed the presence of 1:1 calixarene:iron complexes without contamination of higher oligomers (see *Experimental Procedure*). Moreover, the stability of binder **3** to the reduction and oxidation procedures applied was demonstrated by thin layer chromatography.

These redox processes are most likely to occur intramolecularly, as the half life of the reduction processes was found to be shorter ($t_{1/2}$ = 30 min) than that for the complexation of solvated Fe^{II} ions to the mixed-ligand binder **3** under the same conditions ($t_{1/2}$ > 2 h).[18] Considering the coordinative requirements of iron, it is plausible that each set of ligating groups on the calixarene binds the guest ion in a cisoid, square-planar arrangement, which is completed by two buffer molecules to form an octahedral coordination environment (Fig. 1). The redox processes of the guest ions are consequently accompanied by a rearrangement in which the two sets of ligating chains exchange positions.

The closely related calix[4]arene binder **5**, in which the bipyridyl residues had been attached to the 6-positions rather than 5-positions, failed to form uniquely defined Fe^{III}–hydroxamate and Fe^{II}–bipyridyl complexes. Binder **5** yielded mixed-ligand complexes as indicated by the UV/Vis spectra of Fe^{III}-**5** and Fe^{II}-**5**, and therefore failed to function as switch. The different behaviors of **5** and **3** can readily be rationalized by molecular models. In **5** the two sets of ligands lie in the same imaginary plane above the calixarene ring and may therefore bind the guest ions simultaneously. In switch **3** the two sets of ligands lie in different planes, prohibiting simultaneous coordination.

Because this switch is amphiphilic it is eminently suited for incorporation into air/water or lipid/water interfaces.[19]

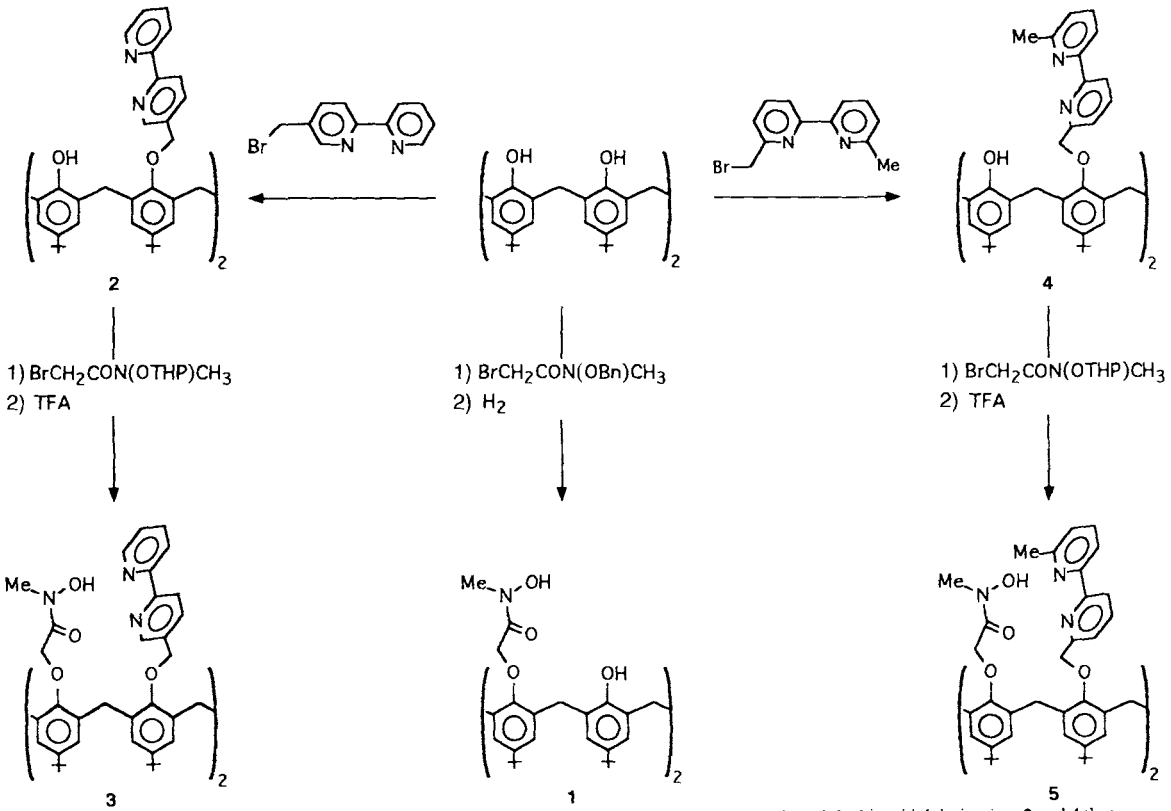

Fig. 2. Synthetic scheme for the preparation of the mixed-ligand binders **3** and **5**, the hydroxamate **1**, and the bipyridyl derivatives **2** and **4** that serve as reference compounds. THP = tetrahydropyran, TFA = trifluoroacetic acid.

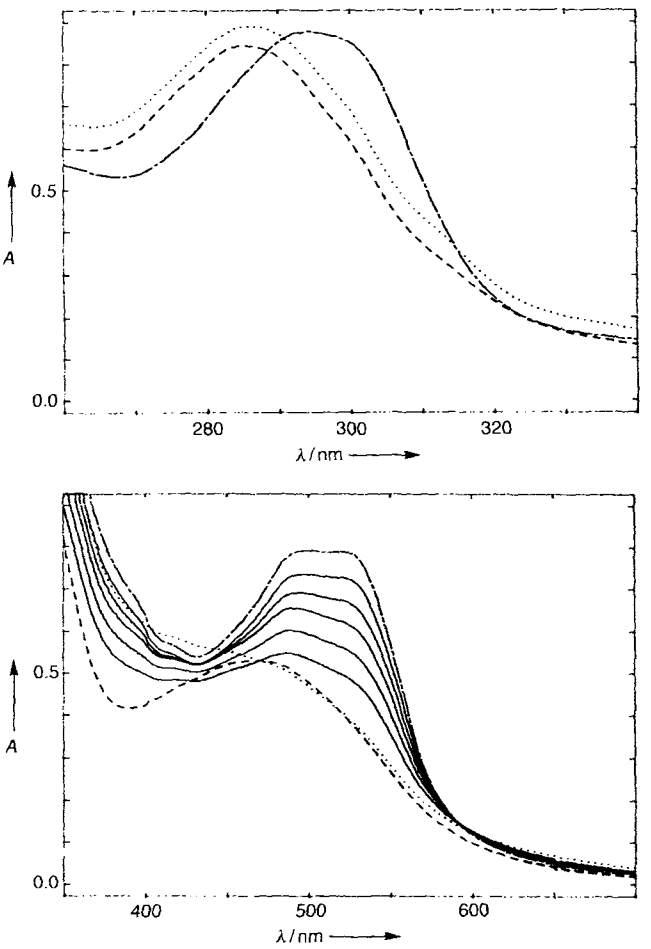

Fig. 3. UV (top) and Vis (bottom) absorption spectra of Fe^{III}-**3** (– – – –) and Fe^{II}-**3** (- · · · -) (0.27 mM); Changes in the Vis spectrum (bottom) of Fe^{III}-**3** after treatment with ascorbic acid at several time intervals (——), and final Vis (bottom) and UV (top) spectra after subsequent treatment with ammonium persulfate (....).

These options are under current consideration as is the possibility of disrupting the orientation of organized assemblies by the pronounced conformational changes of these switches.

Experimental Procedure

1: To a solution of tetra-*tert*-butylcalix[4]arene [15] (0.25 g, 0.38 mmol) in anhydrous DMSO (10 mL) was added $BrCH_2CON(OBn)Me$ (0.40 g, 1.5 mmol) and anhydrous potassium carbonate (0.25 g, 1.8 mmol). The reaction mixture was stirred for 2 d at ambient temperature and poured into 10% aq. HCl (40 mL). The precipitate was removed by filtration and washed twice with water. Chromatographic purification provided protected **1**, which was hydrogenated at atmospheric pressure in the presence of Pd/C to yield **1** (0.15 g, 40%). M.p. 208–213 °C; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 7.03$ and 6.93 (each s, each 4H, ArH), 4.82 (s, 4H, CH_2), 4.26 and 3.38 (each d, each 4H, Ar-CH_AH_B-Ar, $\Delta\delta = 0.88$, $J_{A,B} = 13$ Hz), 3.40 (s, 6H, CH_3), 1.25 and 1.06 (each s, each 18H, *t*Bu); IR ($CDCl_3$): $\tilde{\nu} = 1657\ cm^{-1}$ (C=O); FAB MS: *m/z*: 845.4 $[(M + Na)^+]$.

2: To a solution of tetra-*tert*-butylcalix[4]arene [15] (0.50 g, 0.77 mmol) in anhydrous DMF (20 mL) was added *5-bromomethyl-2,2'-bipyridine* [20] (1.0 g, 4.0 mmol) and anhydrous potassium carbonate (0.50 g, 3.6 mmol). The reaction mixture was stirred for 20 h at 70 °C, cooled, and poured into water (100 mL). The precipitate was collected by filtration. Chromatography provided pure **2** (0.24 g, 30%). M.p. 161–163 °C; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.88$, 8.60, 8.47, 8.39, 8.18, 7.71, 7.27–7.13 (d, md, dd, td, dd, dt, and m, respectively, each 2H, pyH), 7.13 (s, 2H, OH), 7.05 and 6.81 (each s, each 4H, ArH), 5.18 (s, 4H, CH_2), 4.24 and 3.28 (each d, each 4H, Ar-CH_AH_B-Ar, $\Delta\delta = 0.96$, $J_{A,B} = 13$ Hz), 1.29 and 0.96 (each s, each 18H, *t*Bu); FAB-MS: *m/z*: 985.7 $[(M + H)^+]$.

3: Bisbipyridine **2** (0.21 g, 0.21 mmol) in anhydrous THF (20 mL) was treated with $BrCH_2CON(OTHP)Me$ (0.84 g, 3.3 mmol), potassium iodide (0.31 g, 1.9 mmol), and sodium hydride (37 mg, 1.2 mmol), and heated at reflux overnight. The product was filtered and chromatographed to provide 70 mg (25% yield) of protected tetra-substituted calix[4]arene. Deprotection by treatment with trifluoroacetic acid, neutralization with diethylaminomethyl polystyrene, and chromatographic purification yielded switch **3** in 20% yield. M.p. 213–215 °C; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.68$, 8.65, 8.26, 8.12, 7.91, 7.79, 7.41 (d, s, d, d, t, d, and m, respectively, each 2H, pyH), 7.05 and 6.97 (each s, each 4H, ArH), 5.22 and 4.49 (each s, each 4H, CH_2), 3.83 and 3.11 (each d, each 4H, Ar-CH_AH_B-Ar, $\Delta\delta = 0.72$, $J_{A,B} = 12$ Hz), 3.73 (s, 6H, CH_2), 1.14 and 1.07 (each s, each 18H, *t*Bu); IR ($CDCl_3$): $\tilde{\nu} = 1653\ cm^{-1}$ (C=O); FAB-MS: *m/z*: 1181.7 $[(M + Na)^+]$.

4: In a procedure analogous to that used for **2**, tetra-*tert*-butylcalix[4]arene [15] (0.20 g, 0.31 mmol) was treated with 6-bromomethyl-6'-methyl-2,2'-bipyridine [21] (0.43 g, 1.6 mmol) and anhydrous potassium carbonate (0.20 g, 1.4 mmol) in anhydrous DMF (10 mL) to yield **4** (0.17 g, 55% yield). M.p. 108–110 °C; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.34$, 8.20, 7.73–7.62, 7.15 (d, t, m, d, 2H, 4H, 4H, 2H, respectively, pyH), 7.34 (s, 2H, OH), 7.08 and 6.82 (each s, each 4H, ArH), 5.26 (s, 4H, CH_2), 4.37 and 3.35 (each d, each 4H, Ar-CH_AH_B-Ar, $\Delta\delta = 1.02$, $J_{A,B} = 13$ Hz), 2.65 (s, 6H, CH_3), 1.30 and 0.95 (each s, each 18H, *t*Bu); FAB-MS: *m/z*: 1013.5 $[(M + H)^+]$.

5: In a procedure analogous to that used for **3**, calixarene **4** (0.35 g, 0.35 mmol) was treated with $BrCH_2CON(OTHP)Me$ (1.25 g, 5.0 mmol), potassium iodide (0.50 g, 3.0 mmol), and sodium hydride (60 mg, 2.0 mmol), in anhydrous THF (25 mL) to provide 200 mg (45% yield) of the protected product. Deprotection by treatment with TFA yielded binder **5** in 40% yield. M.p. > 300 °C; ^{1}H NMR (400 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 8.19$, 7.90, 7.74, 7.67, 7.56, and 7.17 (d, t, d, t, d, and d, respectively, each 2H, pyH), 7.03 and 6.94 (each s, each 4H, ArH), 5.15 and 4.45 (each s, each 4H, CH_2), 4.17 and 3.07 (each d, each 4H, Ar-CH_AH_B-Ar, $\Delta\delta = 1.10$, $J_{A,B} = 12$ Hz), 3.57 and 2.59 (each s, each 6H, CH_3), 1.15 and 1.04 (each s, each 18H, *t*Bu); IR ($CDCl_3$): $\tilde{\nu} = 1654\ cm^{-1}$ (C=O); FAB-MS: *m/z*: 1209.6 $[(M + Na)^+]$.

Fe^{III}-**3**: 1.0 mL of a solution of **3** (1.2 mM in CF_3CH_2OH) was diluted with 1.0 mL of CH_3OH, and 1.2 mL of a solution of $FeCl_3$ (0.90 mM in CH_3OH) and 0.80 mL of 2-(*N*-morpholino)ethanesulfonic acid (MES) (0.10 M in H_2O) were added. The pH was adjusted to 6.2 with NaOH (1.0 N in H_2O). FAB-MS: *m/z*: 1213.4 $[(M + Fe^{III} - 2H^+)]$.

Fe^{II}-**3**: A procedure analogous to that used for Fe^{III}-**3** was applied, except a solution of $FeCl_2$ was used and the experiments were conducted under argon.

Redox reactions: 3.0 mL of a solution of Fe^{III}-**3** (as prepared above) was treated with 30 μL of a solution of ascorbic acid (0.20 M in H_2O) and the reduction process was monitored at regular time intervals by recording the Vis spectra. The reduced solution was subjected to FAB-MS: *m/z*: 1215.2 $[(M + Fe^{II})]$; *m/z*: 1237.1 $[(M + Fe^{II} + Na^+)]$. 2.0 mL of the resulting mixture was then oxidized by treatment with 26 μL of a solution of ammonium persulfate (0.40 M in H_2O) at 70 °C for 5 min. Oxidation was indicated by the conversion of the pink color of the mixture to the original orange color, and by its UV/Vis spectra.

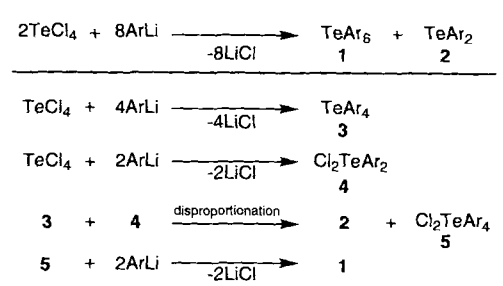
Hexaaryltellurium, the First Neutral Compounds Comprising Hexaarylated Elements**

Mao Minoura, Takao Sagami, Kin-ya Akiba,* Claudia Modrakowski, Allexander Sudau, Konrad Seppelt,* and Stephan Wallenhauer

The rich diversity and practical utility of organotellurium chemistry[1] continues to attract widespread interest, for instance in organic synthesis[2] and in the chemistry of low-[3] and hypervalent[4] compounds. Although considerable attention has been paid to the hypervalency of some tetraaryltellurium derivatives ($TeAr_4$) over the past forty years,[5, 6] a hexaaryltellurium ($TeAr_6$), with tellurium in its highest oxidation state, has not been reported.[7] Only three examples of neutral peralkylated hexavalent compounds[8] ($W(CH_3)_6$,[9, 10] $Re(CH_3)_6$,[10, 11] and $Te(CH_3)_6$[12, 13]) have been published. Here we report the synthesis and structure of the first neutral hexaarylated compounds, namely, $TeAr_6$ (Ar = C_6H_4-4-CF_3: **1a**; Ar = C_6H_5: **1b**), which are thermally extraordinarily stable (up to 300 °C).

First we succeeded in preparing **1a** (13.5% yield based on tellurium) by a one-pot reaction of LiC_6H_4-4-CF_3 (ArLi) and $TeCl_4$ in the molar ratio 4:1, $TeAr_2$ (**2a**, 28.1%) was also formed. The reaction of a stoichiometric quantity (6:1) or excess of ArLi with $TeCl_4$ did not produce **1a**.

The reaction sequence is obviously multistep (Scheme 1) and has not been studied in detail. However, the key step seems to involve a disproportionation reaction between $TeAr_4$ (**3**) and Cl_2TeAr_2 (**4**), which are formed in situ, to afford Cl_2TeAr_4 (**5**) and $TeAr_2$ (**2**). $TeAr_6$ (**1a**) is most likely formed by the succeeding reaction of **5** with ArLi during warming of the reaction mixture to room temperature. Unfortunately, $Te(C_6H_5)_6$ (**1b**) was obtained only in low yield (ca. 0.5%) in the above-mentioned one-pot process. We could, however, prepare **1b** by reaction of $F_2Te(C_6H_5)_4$ (**6**) with phenyllithium (PhLi). Following our experience with **1a**, we successfully treated **6** with PhLi at room temperature[14] for several hours (**1b**, 7.1%). Difluoride



Scheme 1. Probable course of the synthesis of **1**.

6 was prepared as described in Ref. [7a] from XeF_2 and $Te(C_6H_5)_4$,[5a] and the *cis*-configuration was established by a single crystal structure determination.[15]

Compounds **1a** and **1b** are both thermally extremely stable, colorless solids and are not light sensitive, unlike tetraorganotellurium compounds.[5, 6] Crystals of **1a** and **1b** were obtained from chloroform. Molecular structures of both $TeAr_6$ were determined by X-ray crystallographic analysis (Figs. 1 and 2).[16]

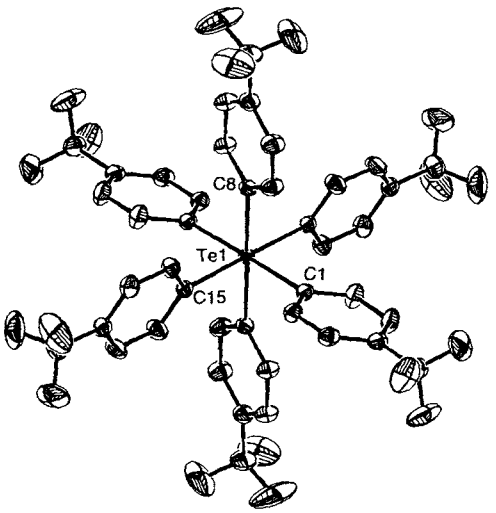


Fig. 1. ORTEP drawing of the structure of **1a** (thermal ellipsoids represent 50% probability). Selected bond lengths [Å] and bond angles [°]: Te1–C1 2.229(4), Te1–C8 2.240(2), Te1–C15 2.226(4); C1–Te1–C8 88.9(1), C1–Te1–C15 91.4(2), C8–Te1–C15 88.8(1).

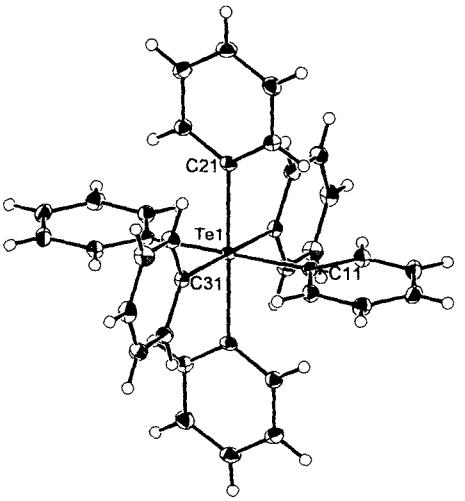

Fig. 2. ORTEP drawing of the structure of **1b** (thermal ellipsoids represent 50% probability). Selected bond lengths [Å] and bond angles [°]: Te1–C11 2.228(1), Te1–C21 2.228(1), Te1–C31 2.227(1); C11–Te1–C21 90.63(5), C11–Te1–C31 90.33(5), C21–Te1–C31 90.34(5).

[**] Financial support from the Ministry of Education, Science, Culture, and Sports, Japan, the Deutsche Forschungsgemeinschaft, and the Fonds der Chemischen Industrie is gratefully acknowledged.

The octahedral tellurium environment is very regular. The six Te–C bond lengths in each molecule are very similar [**1a** 2.226(4)–2.240(2), **1b** 2.227(1)–2.228(1) Å] and a little longer than average Te^{II}–Caryl bonds (2.116 Å),[17] but comparable to the average (2.21 Å) of axial (2.29 Å) and equatorial (2.13 Å) bond lengths of tetraphenyltellurium.[5g] The planes of adjacent phenyl groups are nearly perpendicular, and *trans*-phenyl groups are coplanar. These molecules have approximate T_h symmetry, which is not common in chemistry.[18] This peculiar symmetry seems to be favorable with regard to interligand repulsion.

The ^{125}Te NMR spectra of **1a** ($\delta = 467$) and **1b** ($\delta = 493$) exhibit upfield resonances relative to $Te(C_6H_5)_4$ ($\delta = 509$) and the corresponding diaryltellurides ($\delta = 727$ and 685). This upfield shift upon increasing the valency state of the Te center in $Te(C_6H_5)_n$ ($n = 2$, 4, 6) contrasts with the irregular trend for $Te(CH_3)_n$.[12a] In the ^{13}C NMR of **1a** the *ipso* carbons resonate at $\delta = 152.1$, and the coupling constant $^1J_{C,Te}$ is 42 Hz. The resonance signal is shifted significantly downfield, and the coupling constant is very much smaller than those of $TeAr_2$ (**2**, $\delta = 119.9$, 288 Hz) and other organotellurium compounds.[19] Further investigation of physical and chemical properties of **1** and the applicability of the one-pot synthesis for other hexaorganotellurium are currently in progress.

Experimental Procedure

1a. A solution of LiC_6H_4-4-CF_3 was prepared from BrC_6H_4-4-CF_3 (4.95 g, 22.0 mmol) in ether (30 mL) and *n*BuLi (1.63 M solution in hexane, 13.5 mL, 22.0 mmol) at −78 °C. The mixture was warmed to room temperature and stirred for 1 h. At −78 °C a suspension of $TeCl_4$ (1.35 g 5.00 mmol) in ether (30 mL) cooled to −78 °C was added through a Teflon tube within 30 min. After stirring for 1.5 h, warming to room temperature, and further stirring for another 3 h, the solvent was removed under reduced pressure. The residue was washed with hexane and water, and dried to afford **1a** (685 mg, 0.686 mmol; 13.7% based on tellurium) after recrystallization from dichloromethane. Chromatographic separation and distillation of hexane-soluble products gave **2a**, Ar = C_6H_4-4-CF_3 (586 mg, 28.1%). **1a**: colorless crystals, m.p. 328–330 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.12 (d, J = 8.3 Hz), 7.55 (d, J = 8.3 Hz); ^{19}F NMR (376 MHz, $CDCl_3$) $\delta = -63.1$; ^{13}C NMR (100 MHz, $CDCl_3$): δ = 123.7 (q, ^1J(C,F) = 272 Hz), 125.8 (d), 131.9 (q, ^2J(C,F) = 33 Hz), 133.5 (d), 152.1 (s); ^{13}C NMR (100 MHz, [D$_8$] THF): δ = 126.1 (q, ^1J(C,F) = 273 Hz), 125.8 (d), 133.4 (q, ^2J(C,F) = 33 Hz), 136.0 (s), 154.7 (s, ^1J(C,Te) = 42 Hz); ^{125}Te NMR (126 MHz, [D$_8$]THF, Me_2Te): δ = 467.3; IR (KBr) 3075 (w), 2356 (w), 1926 (w), 1598 (m), 1390 (m), 1326 (s), 1274 (m), 1032 (s), 1008 (m), 957 (m), 846 (w), 825 (s), 773 (s), 631 (w), 595 (m), 498 (m), 408 (m) cm^{-1}; Raman (solid, Ar ion laser) 1600 (m), 1560 (w), 1490 (w), 1395 (w), 1330 (m), 1205 (w), 1080 (m), 1040 (m), 1025 (w), 998 (w), 835 (m), 780 (s), 730 (w), 650 (s), 595 (w), 500 (w), 395 (m), 345 (m), 240 (m), 140 (vs) cm^{-1}. C, H analysis: ($C_{42}H_{24}F_{18}Te$, 998.22): calcd. C 50.54, H 2.42; found C 50.83, H 2.32.

1b: To a suspension of **6** (2.50 g, 5.27 mmol) in ether (30 mL) was added a 1.8 M solution of PhLi in cyclohexane/ether (6.45 mL, 11.6 mmol) at −78 °C. Stirring at room temperature for 1 day, filtration of the colorless residue, washing with hexane and water, and drying afforded **1b** (220 mg, 7.1%). **1b**: colorless crystals, m.p. 312 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$) δ = 7.04 (d), 7.15 (t), 7.29 (d). ^{13}C NMR (100 MHz, $CDCl_3$) δ = 128.1 (d), 128.3 (d), 133.6 (d), 150.1 (s). ^{125}Te NMR (126 MHz, CD_2Cl_2, Me_2Te): δ = 493.0; IR (KBr) 3049 (m), 1569 (m), 1476 (m), 1428 (s), 1187 (m), 1058 (s), 997 (m), 743 (s), 693 (s), 641 (w), 473 (s), 279 (s) cm^{-1}; Raman (solid, Ar ion laser) 1572 (m), 1478 (w), 1434 (w), 1335 (w), 1189 (w), 1125 (m), 1051 (w), 1016 (m), 1003 (s), 914 (w), 646 (w), 638 (m), 616 (w), 211 (w), 183 (m), 78 (vs) cm^{-1}. MS (70 eV, EI): *m/z* (%) 591 (0.41) [M^+], 515 (16) [$Te(C_6H_5)_5^+$], 361 (94) [$Te(C_6H_5)_3^+$], 154 (100) [$(C_6H_5)_2^+$].

6: $Te(C_6H_5)_4$ (12.3 g, 28.3 mmol) in CH_3CN (85 mL) was treated with XeF_2 (4.78 g, 28.3 mmol) at −45 °C. The colorless solid was filtered off at room temperature. Recrystallization from $CHCl_3$ afforded *cis*-$F_2Te(C_6H_5)_4$ (**6**, 11.6 g, 86.7%); m.p. 187 °C (decomp.). ^{1}H NMR (400 MHz, $CDCl_3$) δ = 7.18 (t), 7.24 (t), 7.32 (t), 7.40 (d), 7.49 (d). ^{13}C NMR (100 MHz, $CDCl_3$) δ = 128.0 (d), 128.5 (d), 129.4 (d), 130.3 (d), 131.4 (d), 132.4 (d), 139.0 (s), 148.1 (s). ^{19}F NMR (376 MHz, $CDCl_3$) $\delta = -30.98$ (^1J(^{19}F,^{125}Te) = 2049 Hz, ^1J(^{19}F,^{123}Te) = 1698 Hz.). ^{125}Te NMR (126 MHz, $CDCl_3$, Me_2Te): δ = 650.8 (^1J(^{19}F,^{125}Te) = 2049 Hz).

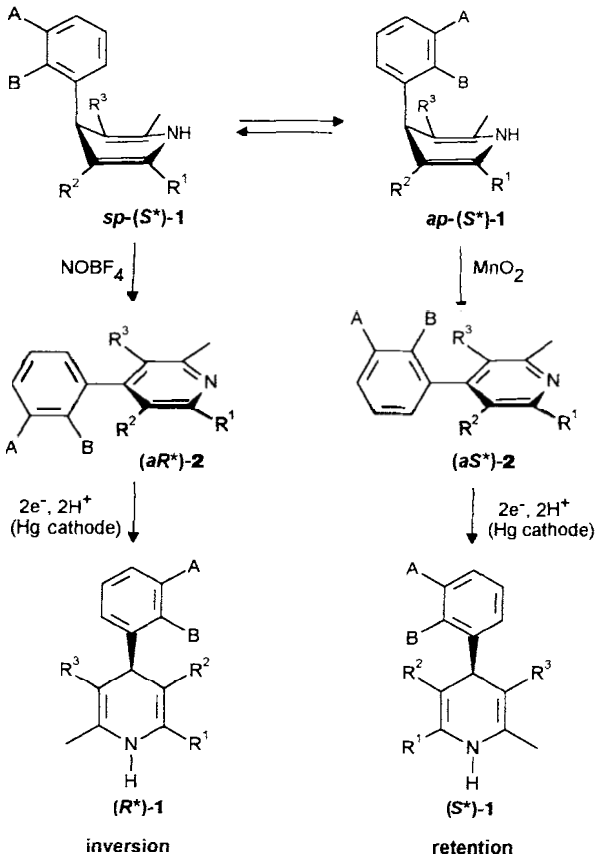
Inversion of Optically Active Dihydropyridines by Oxidation and Electroreduction**

Alexander Straub* and Axel Goehrt

Dihydropyridines (DHPs) **1** play an important role as calcium channel ligands in cardiovascular therapy.[1] The pharmacological activity of asymmetrically substituted DHPs depends on the configuration of the stereogenic C4 carbon atom, which determines whether the compound acts as a calcium antagonist or as an calcium agonist.[1c] A stereoselective route to this class of compounds is therefore extremely important. As most of the enantioselective synthetic methods known to date are not generally applicable,[1c] optically active compounds are usually obtained by resolution of racemates via diastereomeric derivatives. This methodology, however, provides 50% of the undesired enantiomer, which cannot be used further. For this reason, we sought to develop a strategy for the conversion of the wrong enantiomer into the desired one.

Although DHPs can be oxidized to pyridines by numerous methods,[2, 3] the stereochemical course of these oxidations has not been investigated to date. However, appropriately substituted 4-arylpyridines obtained by such methods are suitable intermediates for an optical inversion process, since they store the chiral information of the DHPs in the form of atropisomers. The subsequent reduction of the 4-arylpyridine to the DHP should then proceed with stereochemical induction. From the various methods known for the reduction of pyridines[2–6] we selected the electrochemical cathodic reduction.[5, 6] Since it is a heterogenous reaction, this method appears to be most suitable for a stereocontrolled process[7, 8] and it displays the highest efficiency in terms of atom economy. We herein describe the stereochemical course of the oxidation and reduction reactions of 4-aryl-DHPs and -pyridines.

DHPs **1** exist as two rotamers (Scheme 1), which are referred to as the synperiplanar (*sp*) and antiperiplanar (*ap*) rotamers.



Scheme 1

The *sp* rotamer is the predominant conformer in the solid and solution state,[9] and has been confirmed by X-ray analysis to be present in several of the examples we will discuss here. We assumed, therefore, that when the *sp* form of DHP (−)-(*S*)-**1e**, the absolute configuration of which has been determined for the well-crystallizing derivative (−)-(*S*)-**1g** (*sp* rotamer),[24] is oxidized with manganese dioxide, the atropisomer (*aR*)-**2e** should result (Table 1). In **2e** the *ortho* aryl substituent blocks

Table 1. Compounds investigated

1, 2	A	B	R^1	R^2	R^3
a [10]	CN	Cl	Me	$CO_2(CH_2)_2OMe$	CO_2iPr
b [11]	H	Me	$-CH_2OCO-$		CO_2iPr
c	H	CH_2CH_2Ph	$-CH_2OCO-$		CO_2Et
d [11]	H	SCH_2Ph	$-CH_2OCO-$		CO_2Et
e [11]	H	SCH_2CH_2Ph	$-CH_2OCO-$		CO_2Et
f [12]	$-COCH=C(Ph)-S-$		$-CH_2OCO-$		CO_2Et
g	H	SCH_2CH_2Ph	$-CH_2OCO-$		COOH

one side of the molecule such that an electrochemical reduction should proceed preferentially from the opposite side, thus providing the inverted (*R*)-DHP enantiomer. Interestingly, the oxidation with manganese dioxide afforded with high enantioselectivity the unexpected atropisomer (+)-(*aS*)-**2e**, the absolute configuration of which was determined by X-ray crystallography.[24] This indicates that the oxidation with manganese dioxide occurs with the thermodynamically less stable *ap* form. Thus the accessibility of the H4 atom seems to be crucial for the kinetics of the oxidation. Prompted by this observation, we used

(−)-(*S*)-**1d** to investigate the influence of various oxidizing agents (including those functioning by single-electron transfer and hydride-type mechanisms) on the atropisomer ratio of **2d** (Table 2). We observed that the atropisomer ratio resulting from the oxidation with concentrated nitric acid was opposite to that resulting from the oxidation with manganese dioxide. Since this advantageous ratio was not obtained in reactions using either dilute nitric acid or nitrogen oxide formed in situ, the nitronium ion present in the strongly acidic solution is presumably responsible for the selectivity of the oxidation. This assumption was supported by the use of nitronium and nitrosonium tetrafluoroborate (Table 2). When $NOBF_4$ was employed, the *sp*-DHP rotamer of (*S*)-**1e** was selectively oxidized to form the desired atropisomer (*aR*)-**2e** (Table 3). This high selectivity, which is opposite to that of the manganese dioxide oxidation, can be explained by the electrophilic character of the nitrosonium ion, which leads to a different oxidation mechanism than that of the manganese dioxide oxidation.[19, 22] It is conceivable that the atropisomer ratios obtained with $NOBF_4$ might reflect the *sp* fraction present in the equilibrium of DHP rotamers.[9a, h]

Table 2. Oxidation of (−)-(*S*)-**1d** to **2d** with various oxidizing agents and the resulting atropisomer and enantiomeric ratios (in %).

[a] After electroreduction of **2**. [b] The first number in the ratio refers to the proportion of the enantiomer eluting first from the chiral HPLC column (all numbers in %); the absolute configurations determined by crystallography are given in parentheses.

In order to obtain the inverted DHP from the atropisomeric pyridine derivative, **2** was reduced at a mercury cathode in a divided electrolytic cell. The voltammetric measurement showed a half-wave potential between −1.6 and −1.7 V. The transfer of the hydrogen atom to the pyridine ring proceeds from the sterically less hindered side (Table 3). The expected pronounced dependency of the selectivity on the steric demand of the aryl *ortho* substituent can be readily seen: with the benzylthio substituent (**1d**) good selectivities for both oxidation and reduction were obtained, whereas the methyl substituent (**1b**) resulted in only average selectivity for the oxidation and very low selectivity for the electrochemical reduction.

This is the first report on both inversion and racemization of optically active dihydropyridines. Due to the importance of DHPs as biologically active compounds, future investigations will focus on alternative oxidation methods as well as various substituent effects.

Experimental Procedure

Enantiomeric ratios were determined by HPLC primarily with the chiral phase Chiralcel OD-H (5 μm particle size; mobile phase: 85% *n*-heptane and 15% of a mixture of 1% water and 2% trifluoroacetic acid in ethanol). The free racemic DHP-carboxylic acids such as **1g**, which were resolved into both enantiomers by preparative chiral chromatography[23], were converted into the chiral esters **1** by reaction with ethyl iodide in DMF in the presence of cesium fluoride.

Oxidation of (−)-**1d** with manganese dioxide to yield (+)-**2d** : (−)-**1d** (3.3 mmol, $[\alpha]_D^{20} = -45.1$, $c = 0.93$ in DMSO) was dissolved in chloroform (150 mL), manganese dioxide (5.73 g, Merck-Schuchardt, precipitated, activated, reagent grade) was added, and the resulting mixture was sonicated. Vacuum filtration and removal of the solvent afforded (+)-**2d** (89% yield, $[\alpha]_D^{20} = +51.35$, $c = 0.56$ in $CHCl_3$).

Oxidation of (−)-**1d** with nitrosonium tetrafluoroborate to yield (−)-**2d** : To a solution of (−)-**1d** (9.5 mmol) in acetonitrile (200 mL) was added a solution of nitrosonium tetrafluoroborate (10.3 mmol) in acetonitrile (200 mL). After 4 h the solution was concentrated in vacuum, and the residue was dissolved in toluene/ethyl acetate and stirred overnight with an aqueous solution of sodium hydrogen carbonate. The organic layer was concentrated to dryness and the residue subjected to chromatography on silica gel. The yield of (−)-**2d** was 80%, ($[\alpha]_D^{20} = -48.72$, $c = 0.77$ in $CHCl_3$).

Cathodic reduction of (−)-**2d** to yield (+)-**1d**: A divided electrolytic cell equipped with a glass frit diaphragm, a mercury pool cathode, Pt anode, and Ag/AgCl reference electrode was employed. The cathode compartment contained a solution of (−)-**2d** (0.72 mmol) and tetraethylammonium tetrafluoroborate (1.1 g) in methanol (50 mL), and the anode compartment contained the same solution without the starting material. The solution was electrolyzed under argon between 10 and 20 mA (−1.6 to −2 V) until the starting material could no longer be detected by thin layer chromatography. The cathodic solution was removed and concentrated to a small volume, water was added, and the precipitate of **1** was removed by filtration. Chromatography on silica gel afforded (+)-**1d** in 83% yield ($[\alpha]_D^{20} = +46.8$, $c = 1.0$ in DMSO). The mercury used in the electrolysis was washed with methanol and reused.

Cyclic [6]- and [8]Paraphenylacetylenes**

Takeshi Kawase, Hossein R. Darabi, and Masaji Oda*

The π-orbitals of carbocyclic conjugated systems (annulenes) are oriented usually vertical to the plane of the ring. Besides this type of cyclic conjugation, another type is topologically possible in which the π-orbitals are aligned horizontally on a rigid surface and form a belt-shaped conjugated system. Since the recent discovery of fullerenes[1] and carbon nanotubes,[2] fully conjugated systems with a curved surface have received much attention.[3] In this context, the attempted syntheses of belt-shaped compounds having a conjugated π-system, for example [*n*]cyclocarbons,[4] cyclacene,[5] cyclic oligoparaphenylene,[6] and others,[7] have been reported. These molecules are of interest not only from the synthetic and theoretical points of view but also as host molecules having a rigid cavity lined with a conjugated π-system. Another class of belt-shaped molecules with a conjugated π-system are the cyclic oligomers of phenylacetylene linked at the *para* position, namely [2$_n$]paracyclophane-*n*-yne (**1**, cyclic [*n*]paraphenylacetylene, [*n*]CPPA)[8]. One of these compounds, [6]CPPA **1b**, is a structural isomer of kekulene **2**[9] and both have D_{6h} symmetry. We report here on the syntheses of **1b** and [8]CPPA **1c**, which are the first isolable, belt-shaped compounds with a conjugated π-system.

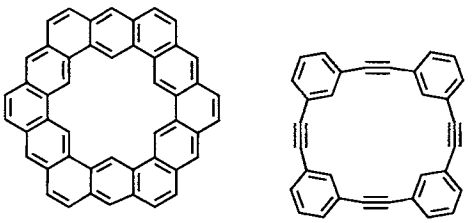
1b (*n* = 6) (*n* = *m* + 5)
1c (*n* = 8)



2 **3**

We have recently described the synthesis of [2$_4$]metacyclophanetetrayne **3**, a structural isomer of [4]CPPA **1a**, through bromination–dehydrobromination of the precursor tetraenes.[10] In view of the successful formation and fair stability of **3** under basic conditions despite sizable strain, we expected that **1**, which has a more favorable ring size, could be synthesized similarly. In analogy to kekulene, the high symmetry of the CPPA should disperse the strain energy over the molecule and reduce its kinetic instability.

The reaction of a mixture of [2$_6$]paracyclophanehexaene **4b** and [2$_8$]paracyclophaneoctaene **4c** (ca. 4:1), which was obtained from the McMurry coupling of 4,4′-diformyl-(*Z*)-stilbene in about 20% yield (together with [2$_4$]paracyclophanetetraenes in 30–40% yield),[11] with bromine (10 equiv, $CHCl_3$, room temperature) and subsequent treatment of the crude bromide mixture with *t*BuOK (16 equiv, room temperature) in diethyl ether afforded a mixture of **1b** and **1c** (4:1) in 85% yield (Scheme 1). The CPPA mixture (45% yield) also resulted when

[**] This work was supported by Grants-in-Aid for Scientific Research (08454201 and 08640683) from the Ministry of Education, Science and Culture (Japan).

furan was used as the solvent, but reactions in THF and DME gave complex mixtures.

The CPPAs were separated by gel permeation chromatography[12] to afford **1b** and **1c** as fine yellow needles. Both compounds, in particular **1b**, are sensitive to oxygen both in solution and in the solid state but are fairly stable under inert gas. Upon heating under air, **1b** explosively decomposed at about 80 °C producing a brown polymeric material, but in a degassed sealed glass capillary tube it did not decompose until about 240 °C. The less strained **1c** decomposed at about 120 °C under air. Notably, **1b** and **1c** are fairly soluble in organic solvents, whereas acyclic oligomers **5**[13] having *tert*-butyl groups were poorly soluble at the stage of hexamer **5b**.

The structures of **1b** and **1c** were deduced from their spectral data (Table 1).[14] Both compounds show only one singlet in the

Table 1. Physical and spectral data of **1b**, **1c**, **5a**, **5b**, **6**, and 7.

1b: MS (FAB): $m/z = 600$ (M^+); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 7.35$ (s); ^{13}C NMR (67.8 MHz, $CDCl_3$): $\delta = 97.65, 123.93, 130.87$; UV/Vis (cyclohexane): λ_{max} [nm] ($\log \varepsilon$) = 252 (4.55), 330 sh (4.85), 350 (5.09), 400 sh (3.95); Raman (KBr): $\tilde{\nu} = 2203.4\ cm^{-1}$ (C≡C).

1c: MS (FAB): $m/z = 800$ (M^+); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 7.40$ (s); ^{13}C NMR (67.8 MHz, $CDCl_3$): $\delta = 94.95, 123.67, 131.21$; UV/Vis (cyclohexane): λ_{max} [nm] ($\lg \varepsilon$) = 245 (4.55), 335 sh (4.85), 356 (4.91), 390 sh (4.40); Raman (KBr): $\tilde{\nu} = 2204.5\ cm^{-1}$ (C≡C).

5a: M.p. 290–291 °C; MS (FAB): $m/z = 803$ ($M^+ + H$); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 1.34$ (s, 36H), 7.39 (t, $J = 1.5$ Hz, 2H), 7.42 (d, $J = 1.5$ Hz, 4H), 7.52 (br. s, 16H); ^{13}C NMR (67.8 MHz, $CDCl_3$): d = 31.34, 34.83, 87.85, 90.80, 91.07, 91.23, 92.69, 121.96, 122.55, 123.00, 123.70, 125.89, 126.56, 128.32, 129.15, 131.54, 131.57, 131.99, 150.94); UV/Vis (cyclohexane): λ_{max} [nm] ($\log \varepsilon$) = 351 (4.91), 360 (4.87), 384 sh (4.70).

5b: M.p. 309–310 °C; MS (FAB): $m/z = 903$ ($M^+ + H$); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 1.34$ (s, 36H), 7.39 (t, $J = 1.5$ Hz, 2H), 7.42 (d, $J = 1.5$ Hz, 4H), 7.52 (br. s, 20H); UV/Vis (cyclohexane): λ_{max} [nm] ($\log \varepsilon$) = 345 sh (5.00), 358 (5.05), 388 sh (4.75) [a].

6 (ca. 1:1 mixture of regioisomers): MS (FAB): $m/z = 548$ (M^+); ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 1.40$ (s, 18H), 6.34 (br. s, 2H), 6.73 (br. d, $J = 8.6$ Hz, 2H), 6.94 (d, $J = 8.6$ Hz, 1H), 6.95 (d, $J = 8.6$ Hz, 1H), 7.08 (d, $J = 8.6$ Hz, 1H), 7.09 (d, $J = 8.6$ Hz, 1H), 7.13 (d, $J = 8.6$ Hz, 1H), 7.14 (d, $J = 8.6$ Hz, 1H); ^{13}C NMR (67.8 MHz, $CDCl_3$): sp carbon atoms: $\delta = 93.32, 93.82, 93.86, 94.39$.

7 (ca. 1:1 mixture of stereoisomers): ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 4.11$ (br. s, 4H), 6.34 (br. s, 4H), 6.73 (d, $J = 7.9$ Hz, 4H), 6.94 (d, $J = 8.6$ Hz, 4H), 7.1–7.2 (m, 8H).

[a] Owing to the poor solubility of this compound, proof of the sp carbon atoms could not be obtained.

^{1}H NMR spectrum and a set of three signals in the ^{13}C NMR spectrum in accord with their D_{6h} and D_{8h} symmetry, respectively. While the chemical shifts of the ^{1}H and ^{13}C signals arising from the benzene rings of **1b** and **1c** are comparable to those of the acyclic oligomers **5a** and **5b**, the signals of the acetylenic carbons are observed at considerably lower field than those of **5a** and **5b**; this reflects the appreciable strain in the triple bonds due to bending. In particular, the chemical shift of the sp carbon in **1b** ($\delta = 97.65$) is considerably lower than that of **3** ($\delta = 92.20$) and even lower than that of 1,5-cyclooctadiyne ($\delta = 95.8$[15]). The Raman frequencies of the triple bonds ($\tilde{\nu} = 2203.4\ cm^{-1}$ for **1b** and $2204.5\ cm^{-1}$ for **1c**) are comparable to that of **3** ($\tilde{\nu} = 2202.0\ cm^{-1}$).

The UV/Vis spectra of **1b**, **1c**, **5a**, and **5b** show similar absorption maxima, except for the relative decrease in the intensity of the shoulder absorptions at the longest wavelength band at about 390 nm (the smaller the cycle the weaker the intensity). In contrast, the fluorescence spectra differ appreciably in the emission wavelengths and quantum yields (Fig. 1 and Table 2). The fluorescence quantum yields of the CPPAs are considerably

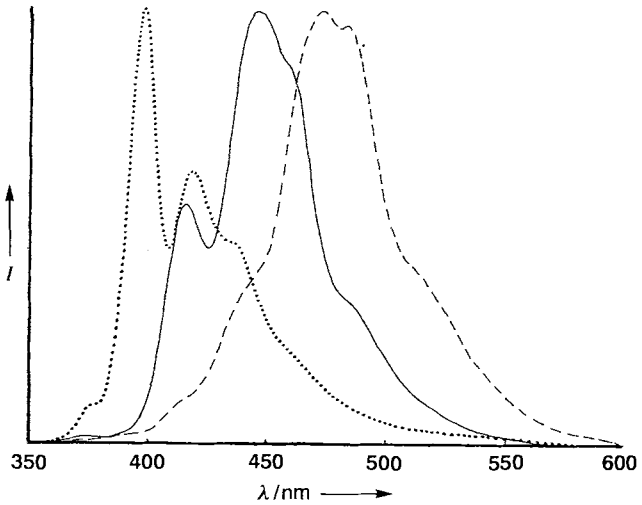

Fig. 1. Fluorescence spectra of **1b** (broken line), **1c** (solid line), and **5b** (dotted line) in cyclohexane.

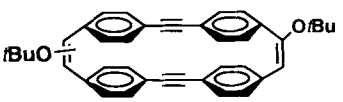
Table 2. Data from the emission spectra of **1b**, **1c**, **5a**, and **5b** [a].

Cmpd.	Emission maxima [nm]	Stokes shift [nm]	Quantum yield [b]
1b	471, 483	121	0.27
1c	416, 447	91	0.15
5a	394, 416	65 [c]	0.84
5b	398, 418	60 [c]	0.74

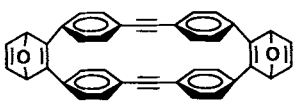
[a] In cyclohexane, $\lambda_{excitation} = 375$ nm. [b] Ref. [16]. [c] Difference between the middle of the absorption and emission because of appreciable change of the spectral shape.

smaller than those of the acyclic oligomers, and the Stokes shift becomes larger as the ring decreases in size.[16] This observation suggests greater geometrical changes between the ground state and excited state in CPPAs of smaller ring size.

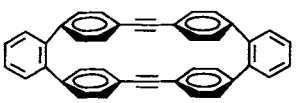
The analogous synthesis of [4]CPPA **1a** from **4a** was unsuccessful, affording a mixture of *tert*-butanol adducts **6**[17] in 30–40% yield. Dehydrobromination in furan, on the other hand, yielded a stereoisomeric mixture of furan adducts **7** (36%),[18] which were aromatized and deoxygenated with $TiCl_4$/Zn to yield the known dibenzodiyne **8**.[17] For the formation of **7** we



6



7



8

currently prefer the stepwise elimination–addition sequence rather than the intermediacy of **1a** from an energetic point of view. Thus, [4]CPPA **1a** seems too strained to be formed by the present approach.

Designed Synthesis of $[TiSe_2]_m[NbSe_2]_n$ Superlattices from Modulated Reactants**

Myungkeun Noh and David C. Johnson*

Artificially structured materials—new materials with planned spatial variations in composition on length scales as short as 5–10 Å—have received considerable attention because of their unique properties. The ability to produce nanostructured materials has already led to many advances in technology associated with semiconductors (for example, higher device speeds,[1] solid-state lasers, and "band-gap engineering" of materials[2]) and also to fundamentally new physical phenomena such as the quantized Hall effect[3] and the fractional quantized Hall effect.[4] The ability to control the length scale of the artificial structure of materials containing metals has also lead to interesting physical phenomena of technological importance such as giant magnetoresistance.

The methods used to produce these artificially structured materials are dominated by the need to prepare the samples at low temperatures, where interdiffusion of the constituents is low. At thermal equilibrium these materials would either be uniform solid solutions or phase-separated with much larger domain sizes. The compositional modulation in these new materials is kinetically stable, because the bulk diffusion process in solids near room temperature is so slow.

Common synthesis techniques include sequential evaporation or sputtering on to a heated substrate, molecular beam epitaxy (MBE), chemical vapor deposition (CVD), and liquid phase epitaxy. In these techniques the deposition and substrate conditions are carefully controlled such that epitaxial growth of the sample occurs layer by layer. In MBE growth of a binary compound, the deposition rate of the less volatile element is used to control the growth rate, while the deposition rate of the more volatile element is typically much higher to prevent vacancy formation. The substrate temperature controls desorption rates and lateral mobility of the constituent atoms. In situ probes are used to optimize the layer by layer growth of the growing crystal. The reward for determining the optimal growth conditions is the ability to prepare high-purity epitaxial materials with atomically smooth interfaces and designed compositional profiles.[5]

The above approaches to artificially structured materials become more difficult as systems become more complicated. In ternary systems, for example, finding suitable growth conditions can be a difficult process. If the ternary system contains more than one volatile element, it is often difficult to find substrate temperatures where all three elements are mobile but the volatile elements still have sufficient concentrations on the growing surface. If two elements are involatile, the difficulty then becomes controlling the relative deposition rates accurately enough in addition to finding temperatures where all elements have compatible surface mobilities. The development of alternative synthetic approaches to artificially structured materials containing interleaved binary and ternary compounds continues to be a significant challenge.

In this regard, an interesting series of experiments regarding the high quality epitaxial growth of metal silicides were reported in the early 1980s. In these studies, silicides were formed by the room-temperature deposition of metals on silicon followed by high-temperature anneals. The best results were obtained with nickel depositions, in part due to the small lattice mismatch between $NiSi_2$ and silicon. A sequence of nonepitaxial nickel silicides were initially formed before the final growth of $NiSi_2$, which was found to be epitaxial with respect to the silicon substrate. The growth rate for the formation of the silicides is determined by the rate of diffusion of silicon through the silicide. Consequently, growth temperatures near 800 °C are required in this system to achieve reasonable growth rates.[6] Subsequent research showed that much lower growth temperatures and higher quality epitaxial structures could be obtained if the nickel deposition thickness was less than 20 Å.[7]

In an extension of these results, we recently demonstrated that we could use the kinetics of solid-state reactions to prepare materials with controlled nanoscale structure.[8] In this approach to artificially structured materials, we prepare interwoven layers of the elements within a superlattice reactant. Subsequent annealing at low temperatures results in interfacial nucleation and growth of the constituent heterostructure com-

pounds, which kinetically traps the desired superlattice structure. Low- and high-angle diffraction studies permitted us to follow the evolution of the initial superlattice reactant into the final, crystalline superlattice product. The information from these studies enabled us to propose a model or mechanism for this transformation. Our hope was that this model would permit us to extend our initial results easily and allow us to prepare structurally related products. Conceptually, this approach parallels that of molecular chemists in the development of a working model for a reaction mechanism, which is subsequently used to aid design of reactants that will react to form structurally related products in kinetically controlled reactions.

We chose for this investigation artificially structured superlattices containing the compounds $NbSe_2$ and $TiSe_2$ for several reasons. First, the binary constituents independently have interesting physical properties, and we wanted to study the interplay of these properties as a function of the length scale of the artificial nanostructure. $NbSe_2$ is metallic with a charge density wave transition that varies with polytype, as well as being a 7 K superconductor, and $TiSe_2$ is either a metal with a low density of states or a semimetal, depending upon stoichiometry. Second, previous studies in our laboratory revealed that modulated reactants of either metal with selenium-rich overall composition result in the initial formation of the diselenide at the interfaces. Finally, the van der Waals epitaxy studies by Koma et al. on similar dichalcogenides[9, 10] and the work described above on silicides provided additional reasons to expect the formation of high-quality artificially structured superlattices containing the compounds $NbSe_2$ and $TiSe_2$.

This paper uses our previously proposed mechanism to design superlattice reactants and guide the kinetic trapping of desired heterostructured products.[8] A series of superlattice reactants with the overall structure shown in Figure 1 were prepared with niobium and titanium layers of varying thicknesses and number to yield several series of compounds with superlattice periods corresponding to $[TiSe_2]_m[NbSe_2]_6$ ($m = 1$, 2, 3, 6, and 9), $[TiSe_2]_m[NbSe_2]_9$ ($m = 1$, 3, 6, 9, and 12), $[TiSe_2]_m[NbSe_2]_{12}$ ($m = 3$, 6, 9, and 12), and $[TiSe_2]_m[NbSe_2]_{15}$ ($m = 6$, 9, 12, and 15). These samples were made in a custom-built ultra-high vacuum chamber with element sources independently controlled and monitored with quartz crystal microbalances. Above each of the sources are computer-controlled shutters to allow precise control of elemental layer thicknesses.[11] The elements were sequentially deposited in layers as shown schematically in Figure 1. Through calibration samples, the composition of each niobium–selenium and titanium–selenium block was adjusted to be that of the desired dichalcogenide compounds. The total amount of each component was also calibrated and adjusted to be the desired integral multiple of the known crystallographic unit cells, so that there would be no elemental reactants left in the superlattice after extended annealing. Table 1 summarizes the layer thicknesses used to prepare the initial reactants, the expected and measured repeat layer thickness of the initial reactant as well as the measured and calculated lattice parameters of the crystalline superlattice products.

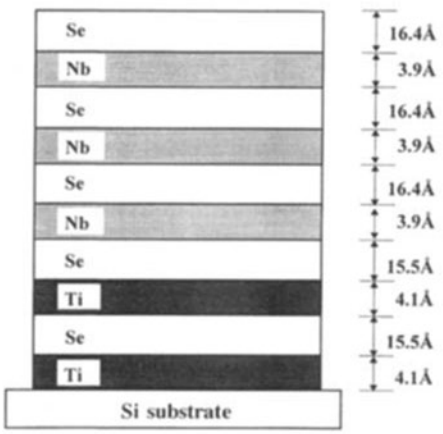
[a] The factor in front of the layer thickness indicates the number of times a layer was deposited. [b] Intended thickness of the titanium layer. [c] Intended thickness of the selenium layer. [d] Intended thickness of the niobium layer. [e] Intended thickness of the selenium layer. [f] Thickness of the total layer. [g] Measured thickness of the repeat unit after deposition. [h] Calculated lattice parameter c of the superlattice of the product, based on the lattice parameters of the binary constituents. [i] Calculated lattice parameter c of the superlattice of the reactant.



The structure and compositional modulation of the as deposited reactants was determined by low-angle X-ray diffraction. The low-angle diffraction of the as-deposited reactants (Fig. 2) contained Bragg diffraction maxima from the compositional modulation as well as subsidiary maxima resulting from interference from the front and back of the film and incomplete destructive interference from the modulated structure of the initial reactants. The modulation period of the reactants varied as expected given the thicknesses of the deposited elements in the repeating unit.

Following deposition, the superlattice reactants were removed from the deposition system and annealed in a nitrogen atmosphere. The annealing conditions were based on previous results, which showed that low-temperature annealing resulted in the nucleation and growth of the dichalcogenide components along the reacting metal–selenium interfaces.[8] We observed a decrease in the repeat layer thickness during the annealing, presumably due to the elimination of vacancies formed during deposition (see Fig. 2). The reactants evolved into crystalline su-

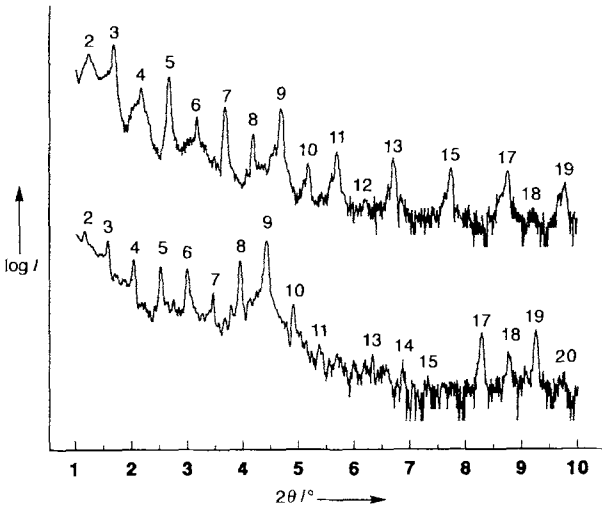

Fig. 2. Low-angle diffraction data collected for a superlattice reactant in which elemental layers of appropriate thickness were deposited to yield twelve $TiSe_2$ layers and fifteen $NbSe_2$ layers in the unit cell. The bottom diffraction scan was collected for the as-deposited reactant, whereas the upper diffraction scan was collected after annealing to form the crystalline superlattice. Note the shift in positions as a result of the contraction of the unit cell on annealing. The numbers above the diffraction maxima refer to the index of the Bragg diffraction maxima.

perlattices containing many well resolved diffraction maxima as shown in Figures 3 and 4. The diffraction patterns qualitatively resemble those expected for the intended structures; they consist

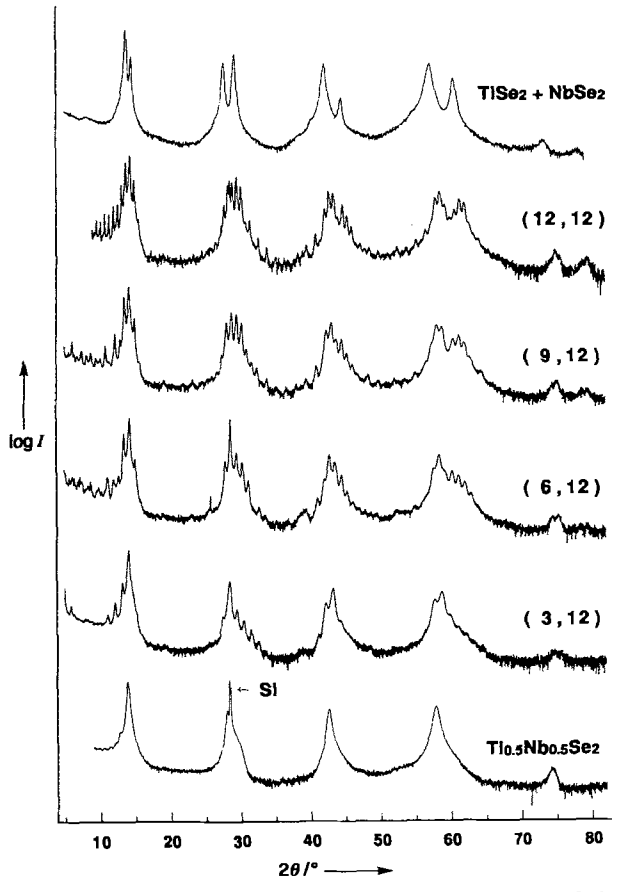

Fig. 3. Diffraction data collected for members of the series $[TiSe_2]_m[NbSe_2]_{12}$. The diffraction patterns of the homogenous alloy $NbTiSe_4$ (bottom diffraction pattern) and 3/12, 6/12, 9/12, and 12/12 $TiSe_2/NbSe_2$ units as the unit cell of the superlattice, and a mixture of the binary compounds (top diffraction pattern) are shown offset for clarity.

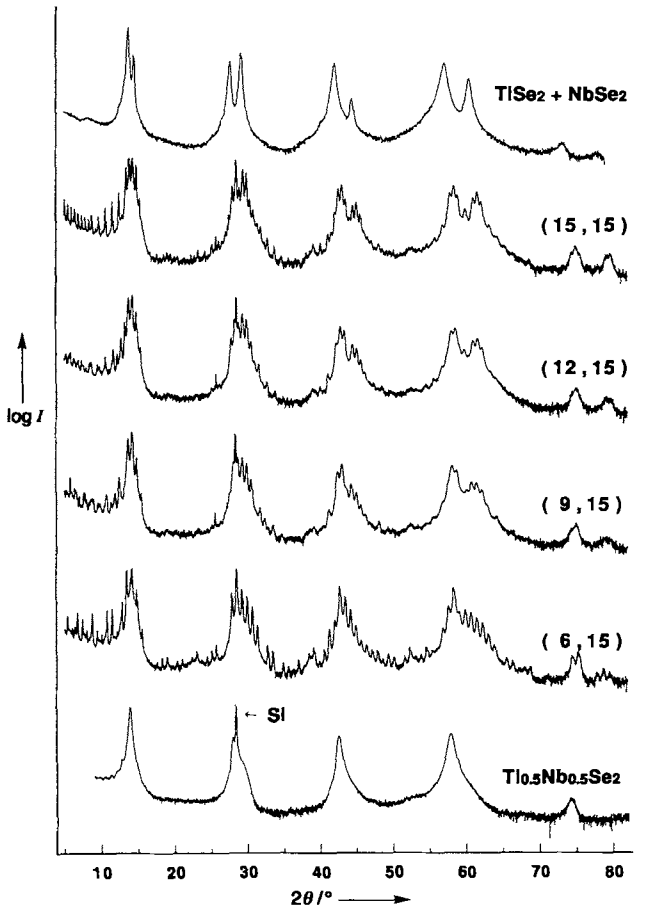

Fig. 4. Diffraction data collected for members of the series $[TiSe_2]_m[NbSe_2]_{15}$. The diffraction patterns of the homogenous alloy $NbTiSe_4$ (bottom diffraction pattern), and 6/15, 9/15, 12/15, and 15/15 $TiSe_2/NbSe_2$ units as the unit cell of the superlattice, and a mixture of the binary compounds (top diffraction pattern) are shown offset for clarity.

of the convolution of the supercell diffraction and the bulk dichalcogenide diffraction. The maxima in the diffraction patterns can be indexed as 00*l* reflections resulting in *c*-axis lattice parameters consistent with the desired number of $NbSe_2$ and $TiSe_2$ layers in the repeating unit of the superlattice sample as summarized in Figure 5. The lines fitted through each set of samples shown in Figure 5 contain information on the average *c*-axis lattice parameter of the $TiSe_2$ layers in the superlattices (the slopes) as well as the average *c*-axis lattice parameter of the $NbSe_2$ layers (the intercepts). From the calculated slopes of these four linear fits, the average $TiSe_2$ *c*-axis lattice parameter is 6.005 ± 0.028 Å, which is very close to the value observed in the binary compound $TiSe_2$ (6.008 Å).[12] The average $NbSe_2$ lattice parameter calculated from the intercepts of these lines is 6.349 ± 0.016 Å, which is close to the range of values reported for the different polytypes of the binary compound $NbSe_2$ (6.27–6.31 Å).[13] For a more quantitative evaluation of the structures, the observed diffraction intensities were compared with simulated diffraction patterns based on the interfacial structure determined previously for a $[TiSe_2]_6[NbSe_2]_6$ superlattice.[8] The similarity of the diffraction intensities between the data and the simulations suggests that the composition gradient at the $TiSe_2$–$NbSe_2$ interface is confined to a single mixed dichalcogenide layer. The agreement between the lattice parameters of the binary compounds and the layer thicknesses observed in the superlattice, as well as the high quality of the 00*l* diffraction patterns, highlights the well-formed structure that

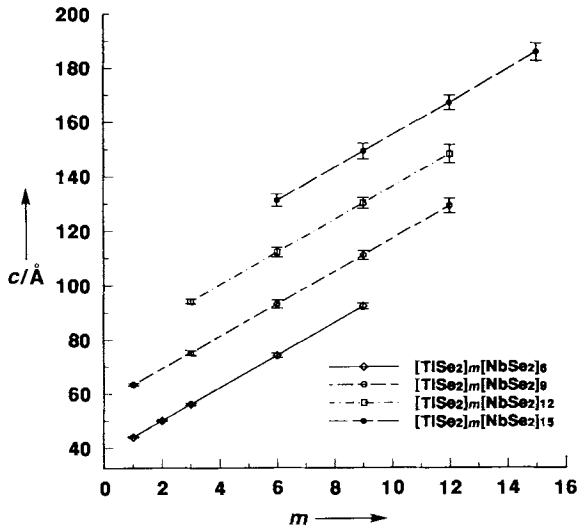

Fig. 5. A plot of the refined c-axis lattice parameters for the superlattices versus the desired number of $TiSe_2$ units m, the unit cell of the superlattice. The linear relationship between these parameters highlights the ability of this approach to design the structure of the desired final product through control of the initial reactant.

develops along the c axis as the superlattice structures are kinetically trapped.

This synthetic advance sets the stage for the synthesis of materials with unexpected bonding and mechanical and electrical properties that can be systematically examined as a function of heterostructure length scales. Other phenomena, such as phase transformations and interface-related processes in thin-film and layered alloys, may also be profoundly different in these heterostructured materials from those which are now well-known in the bulk alloy or composite systems. In addition, a transition from composite behavior to that of a new compound should occur as the length scale of the compositional modulation decreases; the length scale of the transition would depend upon the property being monitored. This new synthesis approach provides new opportunities to probe for these effects by enabling the preparation of superlattice materials for which epitaxial growth conditions have yet to be determined. This ability to synthesize new "designed" layer structures from superlattice reactants also implies the potential design of physical and chemical properties.

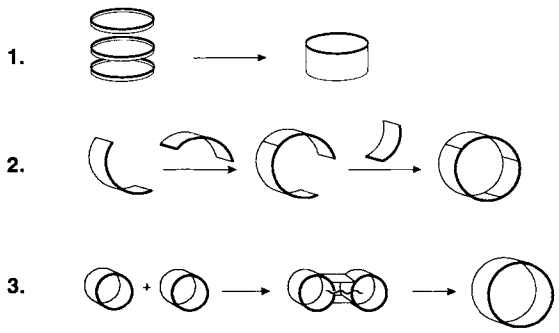
Ring-Expanding Metathesis of Tetradehydroanthracene—Synthesis and Structure of a Tubelike, Fully Conjugated Hydrocarbon**

Stefan Kammermeier, Peter G. Jones, and Rainer Herges*

In principle, tubelike molecules[1] can be synthesized in three ways (Scheme 1). Firstly, rings can be stacked, as was successful with cyclodextrins,[2] cyclopeptides,[3] and cyclic hydrocarbons,[4] and which is probably how "nanotubes" are formed in



Scheme 1. Three approaches for the construction of tube-shaped molecules.

a direct-current electric arc[5] and during chemical vapor deposition of carbon-containing gases.[6] Secondly, prefabricated convex parts can be assembled (see for example the synthesis of 12[collarene] by Stoddart et al.[7] and of the ribbon-shaped cyclophanes by Vögtle and co-workers[8])[9]. We pursued a third approach based on a ring-expanding metathesis reaction,[10] which is analogous to the formation of a large bubble by the combination of two small ones.

Tetradehydrodianthracene (TDDA)[11] **1** was used as the starting material because its structure is well-suited for the synthesis of a tubelike molecule and because its extremely high strain energy provides the driving force for a metathesis reaction; the metathesis is therefore directed towards ring expansion. In earlier studies we investigated the general reactivity of TDDA towards electrophiles,[12] nucleophiles,[13] and Diels–Alder partners.[14] Photochemically induced metathesis reactions with ethene, propene, cyclic alkenes, and even with benzene have already been performed.[15] The attempted dimerizing metathesis, however, was achieved only after numerous variations of the reaction conditions finally by photolysis of a suspension of TDDA in benzene with a high-pressure mercury lamp in a quartz apparatus (Scheme 2).

In homogeneous solution in benzene only very small amounts of the dimerization product were obtained. The main product is the known metathesis product with the solvent.[15] In other solvents like toluene and hexane transfer of hydrogen and ring opening to bianthryl is predominant. Apparently a suspension of the reactant in benzene is essential for dimerization of **1**.

An X-ray analysis of TDDA **1**[16] was performed to test the hypothesis of a solid-phase mechanism (Fig. 1). In the crystal

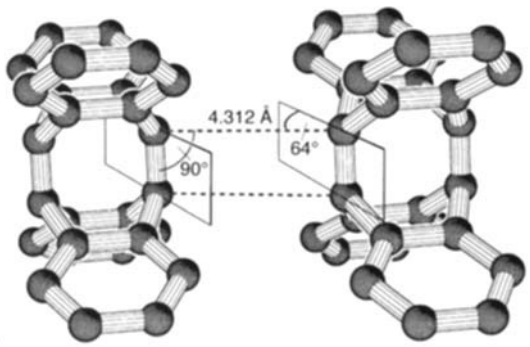

Fig. 1. X-ray crystal structure of TDDA **1**.

the double bonds are oriented in a favorable arrangement for a [2 + 2]cycloaddition. Both π-planes[17] are parallel and form an angle of 64° with the two cyclobutane C–C bonds made during the cycloaddition. The distance between bridgehead atoms in neighboring molecules of **1** is 4.31 Å and in the upper range of distances suitable for cycloaddition[18] (Fig. 1).

One observation does not support the solid-phase reaction of **1**: irradiation of solid TDDA in an argon atmosphere does not lead to an observable reaction. This, however, could be due to the very strong UV absorption of the product in the range of the π–π* transition of TDDA (282 nm), and thus the crystal surface could be "passivated" towards further reaction in the interior. In suspension in benzene the surface of the dimer would be continuously dissolved and removed. Additionally benzene probably acts as a singlet sensitizer. The π–π* transition of TDDA is symmetry forbidden ($\varepsilon_{max} = 1270$). Since the photolysis is performed in a quartz apparatus, excitation of benzene followed by energy transfer to TDDA is likely. A triplet reaction can be excluded because the addition of triplet sensitizers such as acetone and benzophenone leads almost exclusively to the formation of anthracene.

The ^{1}H NMR spectrum with two signals and the ^{13}C NMR spectrum with only four signals indicates that the metathesis product **2**, at least on time average, should have a very high (D_{4h}) symmetry. Besides the M^+ peak at m/z 704 there is only one additional peak in the mass spectrum at half the molecular weight at m/z 352. Most probably this does not arise from a fragment but from the aromatic dication of **1**. The final proof of structure was provided by a crystal structure analysis. Unfortunately the crystals of **2** contain large amounts of disordered THF, which prevented sufficient refinement of the structure ($R(F) = 0.14$). The connectivity of the atoms and the high symmetry of D_{4h}, however, can be determined unequivocally (Fig. 2).[19]

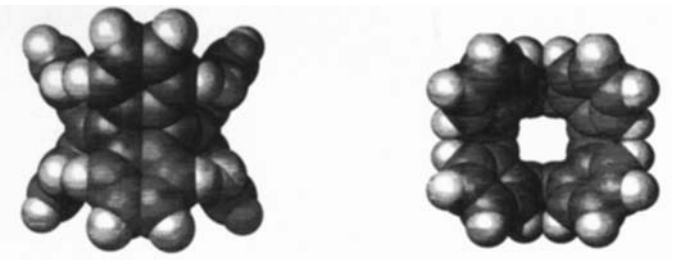

Fig. 2. Van der Waals surface of **2** (D_{4h}) based on the data from an X-ray structure analysis.

The "picotube"[20] **2** consisting of four anthracene units has an approximate tubular structure with a diameter of 5.4 Å and a length of 8.2 Å (Fig. 2). All C=C bonds are conjugated and the 16 e perimeter is antiaromatic. To our knowledge **2** is the first conventionally synthesized and completely conjugated belt- or tubelike hydrocarbon besides the nano- and buckytubes, which are formed by vaporization of carbon. Unlike typical aromatic compounds, which have a perfect or a at most slightly curved π-plane, the π-plane of **2** is tubular.

In contrast to the crystal structure, semiempirical calculations of **2** indicate that it has only time-averaged D_{4h} symmetry. The lowest energy conformation is a D_{2d} structure, which is formed by a 20° twist of the quinoid double bonds (Fig. 3). Lowering the symmetry, however, provides a gain in energy of only 6.5 kcal mol^{-1} (AM1 calculations). The two possible D_{2d} structures should interconvert very rapidly at room temperature. Freezing of the conformational motion could not be observed at temperatures down to −70 °C.

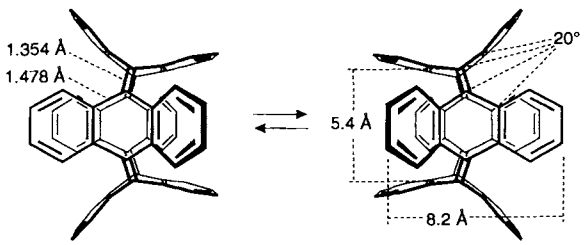

Fig. 3. AM1-calculated conformational movement of **2**.

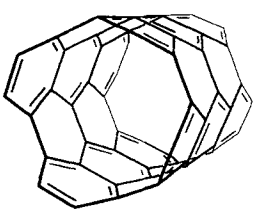
Picotube **2** is extraordinarily stable and unreactive. Neither melting nor decomposition were observed at temperatures up to 450 °C. **2** also is completely inert towards *m*-chloroperbenzoic acid and bromine at room temperature. The cylindrical cavity and the π-orbitals pointing towards the interior suggest that **2** could be used as a π-spherand.[21] Experiments with silver(I) salts provide preliminary evidence.[19] Poorly soluble **2** suspended in THF can be dissolved by addition of silver(I) triflate. The FAB mass spectrum of the residue after removal of the solvent shows peaks at m/z 811 and 813, which correspond to the mass of 1:1 complexes of **2** with $^{107}Ag^+$ and $^{109}Ag^+$, respectively. The ^{13}C NMR spectrum, however, does not exhibit a low-field shift or a carbon–silver coupling. Apparently there is a fast equilibrium at room temperature in which the solvent-separated reaction partners are predominant.



3

Intramolecular cyclization–dehydrogenation of **2** would lead to the buckytube **3** with a length of three and a perimeter of eight benzene rings. Experiments aimed at this target are underway.

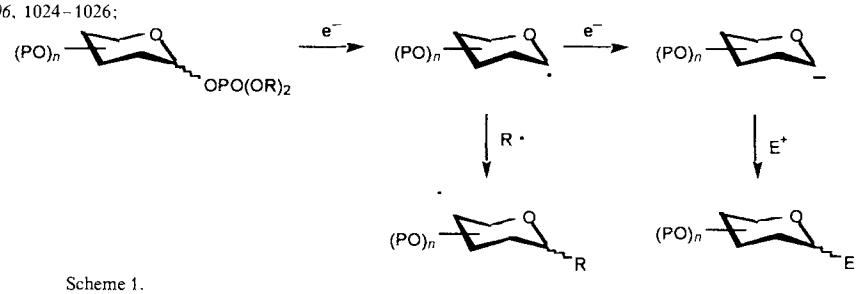
Samarium Diiodide Mediated Coupling of Glycosyl Phosphates with Carbon Radical or Anion Acceptors—Synthesis of C-Glycosides**

Shang-Cheng Hung and Chi-Huey Wong*

C-Glycosides, which have conformations similar to those of the parent O-linked structures,[1] have been used as stable carbohydrate mimetics for the study of carbohydrate recognition in biological systems.[2–7] C-Glycosides are often prepared through the coupling of anomeric carbocations, radicals, carbanions, and carbenes.[8] Recently, Sinaÿ et al.[9] and Beau et al.[10] reported that glycosylsamarium(III) derivatives, generated from glycosyl chlorides or sulfones, undergo a Barbier-type reaction with carbonyl compounds to form C-glycosides. The reactions were considered to proceed through two consecutive one-electron reductions to form a glycosyl anion intermediate. Dilithiated D-glucopyranosyl derivatives have been developed by Kessler and his co-workers.[11] The use of a phosphate group as an acceptor in the initial electron transfer mediated by SmI_2/THF has already been described for α-cyanophosphates[12] and allylic phosphates.[13] Here, we report a relatively simple method for the synthesis of C-glycosides under very mild conditions by the umpolung coupling of pyranosyl or furanosyl phosphates with a carbon radical or anion acceptor in the presence of samarium diiodide (Scheme 1).



Scheme 1.

[**] We thank Dr. Kap-Sun Yeung and Chun-Chen Lin for supplying some starting materials.

In a representative study, a solution of glycosyl dibenzylphosphate **1a**[14] or a glycosyl diphenylphosphate (**1b**, **7**, **9**, or **12**[15,16]) in tetrahydrofuran was mixed with an electrophilic acceptor in the presence of samarium diiodide[17] (Table 1). In the absence of electrophiles, the reaction of D-mannopyranosyl dibenzylphosphate **1a** with SmI_2 gave the 1-deoxymannose derivative **2** and 3,4,6-tri-*O*-benzyl-D-glucal (*β*-elimination product) in 72 and 11% yields, respectively. The yield of the coupling was improved to 85% (6% elimination) on addition of *tert*-amyl alcohol as a proton source. When cyclopentanone, acetone, and isobutyraldehyde were used as electrophiles, only the α-anomeric products **3**, **4**, and **5** were isolated, respectively, in yields of 81, 74, and 68% after purification by silica gel column chromatography. Compound **5** was found to consist of a 12/1 mixture of epimers at the newly generated stereogenic center as determined by ^1H NMR analysis. When diphenylphosphate **1b** was used as a substrate, similar results were obtained. Reaction with dry carbon dioxide gas at room temperature afforded the carboxylic acid **6** in 56% yield. The configuration of **3**–**6** was deduced from the $J_{H1,H2}$ coupling constant and further confirmed by the observation of a nuclear Overhauser effect in the 2D ROESY spectra between H1 and H6.[10a] When the glucosyl phosphate **7** was allowed to react with acetone, only the *β*-isomer **8** was isolated (52%), as indicated by the coupling constant ($J_{H1,H2}$ = 9.2 Hz); the other main by-product was 3,4,6-tri-*O*-benzyl glucal (28%). In the furanoside system, when diphenylphosphate **9** (*β*/α = 1.9/1) and *tert*-amyl alcohol were treated with a solution of samarium diiodide in tetrahydrofuran, the 1-deoxy sugar **10** and the *β*-elimination product were isolated in 76 and 18% yield, respectively. When cyclopentanone was used as an electrophile, a 1/3.6 α/*β* mixture of the C-glycoside **11** was isolated in 77% yield. When 2,3:5,6-di-*O*-isopropylidene-D-mannofuranosyl phosphate **12** was used as a substrate, however, only the α-isomers **14**–**16** were isolated in good yields and no *β*-elimination was observed. The configuration of **14**–**16** at the anomeric center was verified by the NOE effect between H2 and the protons of the cyclopentyl group, the dimethyl group, and the new stereogenic center, respectively. It appears that the high 1,2-*trans*-diastereoselectivity observed in both the furanoside and the pyranoside systems is mainly controlled by steric effects.

Application of this method to the preparation of a 1,6-C-linked disaccharide via anionic intermediates is shown in Scheme 2. Aldehyde **19**[18], which was obtained from **17** via **18**, was used as the acceptor for formation of the 1,6-C-linked disaccharide **20**[19] (Table 2; 22/1 mixture of epimers at the newly formed stereogenic center) in 73% yield after purification by silica gel column chromatography.

With regard to the mechanism of the C-glycosylation, the reduction of glycosyl phosphates with samarium diiodide is believed to proceed through two consecutive one-electron processes. A similar mechanism was proposed for the reaction of glycosyl sulfones[9b,10a] and chlorides.[9a] After the generation of the glycosyl anion, addition to a carbonyl compound and *syn*-elimination compete with each other. As suggested by Beau et al.,[10a] unproductive

Table 1. SmI_2-mediated umpolung coupling of glycosyl phosphates with various electrophiles [a].

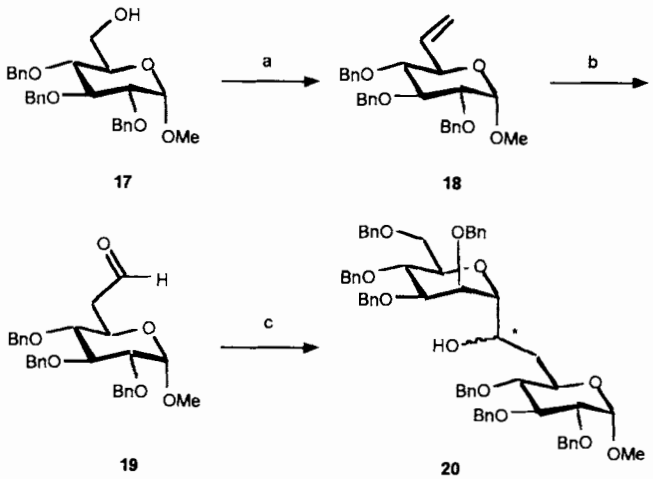
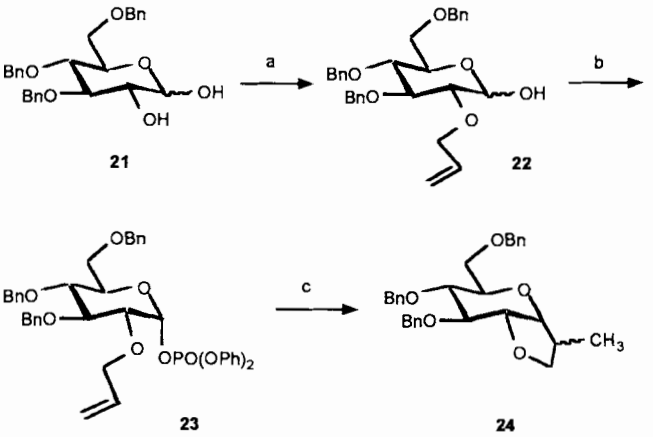
[a] All reactions perhaps proceed through a glycosyl anion intermediate. [b] Ratio of epimers at the newly formed stereogenic center.



Scheme 2. a) 1. DMSO, $(COCl)_2$, Et_3N, CH_2Cl_2, $-78\,^{\circ}C$, 93%; 2. Ph_3PCH_3Cl, *n*BuLi, THF, $-78 \rightarrow 25\,^{\circ}C$, 55%; b) 1. BH_3/DMS, THF, 25 °C; 30% H_2O_2, 2 N NaOH, 0 °C, 79%; 2. DMSO, $(COCl)_2$, Et_3N, CH_2Cl_2, $-78\,^{\circ}C$, 90%; c) **1b**, SmI_2, THF, 25 °C, 73%, 91% *de*.

syn-elimination might occur when the C1–Sm and C2–O bonds are *syn-coplanar* (with possible coordination). In the reaction with 2,3:5,6-di-*O*-isopropylidene-D-mannofuranosyl phosphate, high diastereoselectivity was observed and no elimination was detected, perhaps due to the lack of coordination between samarium(III) and the oxygen atom at C2.

In another reaction (Scheme 3), compound **23** (obtained from **21** via **22**), when treated with SmI_2 at 25 °C, underwent a *5-exo-trig* cyclization to give adduct **24**[9b] (ca. 1/1 mixture of epimers) in 63% yield. This reaction is believed to proceed through a glycosyl radical intermediate because the reaction occurs under very mild conditions.



Scheme 3. a) 1. NaH, $H_2C{=}CHCH_2Br$, DMF, 60 °C, 88%; 2. 2 N H_2SO_4, HOAc, 90 °C, 74%; b) *n*BuLi, $(PhO)_2POCl$, THF, $-78\,^{\circ}C$, 82%; c) 0.1 N SmI_2, THF, 25 °C, 63%.

We have described a new effective method for the synthesis of C-linked glycosides. Work is in progress to apply this method to the synthesis of bioactive C-glycosides.

Experimental Procedure

General procedure for the preparation of C-glycosides: Glycosyl dibenzylphosphate **1a** [14] or a glycosyl diphenylphosphate (**1b**, 7, **9**, or **12**) [15, 16] (0.1 mmol) in degassed tetrahydrofuran (0.4 mL) was mixed with an electrophilic acceptor (0.15 mmol of a carbonyl compound or *tert*-amyl alcohol) and a solution of 0.1 N samarium diiodide [17] in tetrahydrofuran (3 mL, 0.3 mmol) at 25 °C under argon. After the deep blue reaction solution turned yellow (approximately 15–30 min), it was quenched by addition of a saturated aqueous ammonium chloride solution (3 mL) and extracted with ethyl acetate (3 × 5 mL). The combined organic layers were washed with brine, dried with anhydrous magnesium sulfate, filtered, and concentrated to dryness. The residue was purified by column chromatography on silica gel to obtain the product (Table 1).

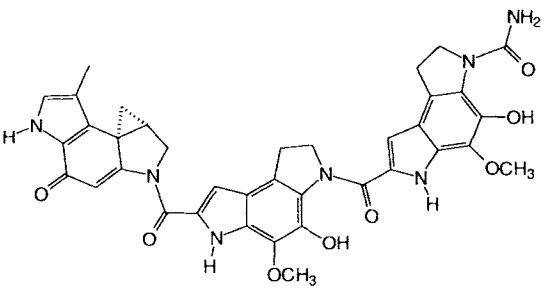
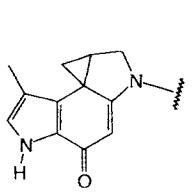
Prodrugs of the Cytostatic CC-1065 That Can Be Activated in a Tumor-Selective Manner**

Lutz F. Tietze,* Robert Hannemann, Wilm Buhr, Michael Lögers, Pia Menningen, Monika Lieb, Dorothea Starck, Thomas Grote, Angela Döring, and Ingrid Schuberth

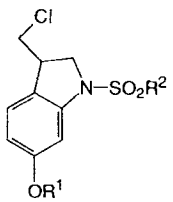
The limited therapeutic spectrum of available cytostatics is a problem in modern cancer therapy. Serious side effects can arise, which are dose-limiting and often lead to a discontinuation of the treatment.[1] One promising approach to selective cancer therapy makes use of the genetic and phenotypic differences between malignant and normal cells.[2] In studies in vitro and in vivo we have discovered that the increased glycolysis rate observed in hyperglycemic cancer cells and the drop in pH associated with it[3] can be used to selectively release a cytostatic drug within a malignant tumor from an acid-labile, nontoxic prodrug.[4] Here we describe the synthesis of novel glycosidic prodrugs of the highly cytotoxic antibiotic CC-1065 (**1**), which can be cleaved by enzymatic hydrolysis with glycohydrolases. The cytostatic can be selectively released in the tumor by conjugates of glycohydrolases and monoclonal antibodies which bind to tumour-associated antigens on the surface of malignant cells.



1



2



3: $R^1 = H$, $R^2 = CH_3$
4: $R^1 = CH_2Ph$, $R^2 = Ph$

The cytostatic used, seco-CI[6] **3**, is the simplified *seco* form of the pharmacophoric group **2** of the antibiotic CC-1065 (**1**). This compound was first isolated from *Streptomyces zelensis* in 1978

and is one of the most effective cytostatics known.[7] Our studies have demonstrated that the cytotoxicity of compounds such as **4**, which are etherified at the phenol hydroxyl group, is significantly less than that of **3**. We therefore prepared the seco-CI-galactoside **11** and the seco-CI-glucoside **12a**, and tested their cytotoxicity with and without added glycohydrolases.

Iodobenzene **5**, which can be prepared in a few steps from the commercially available 4-methoxy-3-nitroaniline, was converted into the indoline derivative **7** by a Heck reaction and subsequent hydroboration (Scheme 1). After protecting group

Ac_2O, NaOAc; 2. BBr_3, CH_2Cl_2, 24 h, −15 °C; 3. $PhCH_2Br$, K_2CO_3, acetone, DMF, 20 h, 25 °C; c) 1. K_2CO_3, MeOH, 30 min, 25 °C; 2. $tBuPh_2SiCl$, NEt_3, DMAP, 24 h, 25 °C; 3. Pd/C, H_2 (3 bar), ethyl acetate, 16 h, 25 °C; d) $BF_3 \cdot Et_2O$, 4 Å molecular sieves, CH_2Cl_2, 2 h, −10 °C; e) 1. TBAF/SiO_2, 20 h, 0 °C; 2. PPh_3, CCl_4, 5 h, 50 °C; 3. K_2CO_3, MeOH, 10 min, 25 °C.

manipulations, the phenol derivative **9** was obtained in 70% yield, which was then used for glycosidations. The series of protecting group exchanges on the hydroxyl groups was necessary because substrate **5** is available simply and in very good yields, whereas the benzyloxy derivative **6** gave only moderate yields in the Heck reaction.

For the glycosidation we tested the Koenigs–Knorr reaction,[8] the reaction with tetraacetyltrimethylsilylglycosides in the presence of trimethylsilyltriflate, and the reaction with tetraacetylglycosyltrichloroacetimidates according to Schmidt;[10] the latter gave the best results. Reaction of **9** with tetraacetyl-α-D-galactosyltrichloroacetimidate in the presence of boron trifluoride etherate gave a 73% yield of the β-D-galactoside, with high selectivity (α-galactoside < 3%). Cleavage of the silyl protecting group with tetrabutylammonium fluoride (TBAF) on silica gel, conversion of the hydroxymethyl group into a chloromethyl group according to Appel,[11] and cleavage of the acetyl groups by solvolysis with methanol and potassium carbonate afforded the desired prodrug **11**.[12] The β-D-glucoside **12a** was synthesized from **9** in a similar manner, in 52% overall yield.

Since racemic **9** was used in the synthesis of **11** and **12a**, the glycosidation reaction led to a 1:1 mixture of two diastereomers in each case. For the glucoside, these could be separated by column chromatography over silica at the stage of **12b**. By solvolysis of the acetyl groups and enzymatic cleavage of the diastereomers of **12b**, both enantiomers of **9** can be isolated and subsequently used for the synthesis of the seco-CI-glycosides. However, here the biological studies were carried out with the diastereomeric mixtures of **11** and **12a**.

In toxicity tests[13] with **3**, **4**, **11**, and **12a** on human bronchial carcinoma cells of line A 549[14] we found that **4** displays almost no cytotoxicity, whereas **3** is considerably cytotoxic, with an ED_{50} value of 1.8 μM (Fig. 1). Analysis of the glycosides **11** and

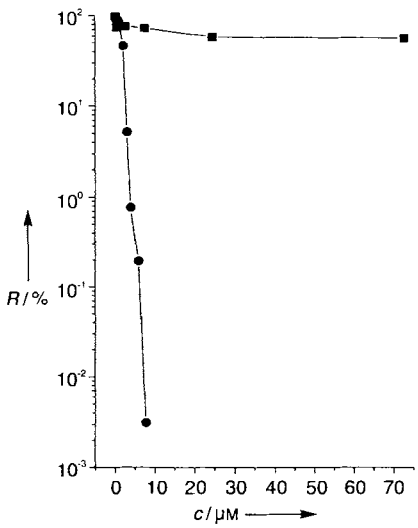

Fig. 1. In vitro cytotoxicity of compounds **3** (●) and **4** (■) on human bronchial carcinoma cells of line A 549 after 24 hours of incubation. The relative clone formation rates R of the cell population were determined by comparing the ability to form colonies in the absence or presence of **3** and **4**, respectively; R = relative clone forming rate, c = concentration.

12a gave unexpected results. Although the phenolic hydroxyl group is blocked, these compounds significantly inhibited cell proliferation in the usual incubation medium. The media were checked for possible glycohydrolase activities[15] caused by the addition of fetal calf serum (FCS) or of serum substitute (Basal Medium Supplement, BMS). Indeed, the FCS medium showed a β-D-galactosidase activity of 0.73 mU mL^{-1} and a β-D-glucosidase activity of 1.00 mU mL^{-1}, whereas the BMS medium gave values of 0.03 mU mL^{-1} and 0.05 mU mL^{-1} respectively. However, with DMEM (Dulbecco's modified Eagle's Medium) without addition of FCS or BMS, neither galactosidase nor glucosidase activities were detected (Fig. 2). Control experi-

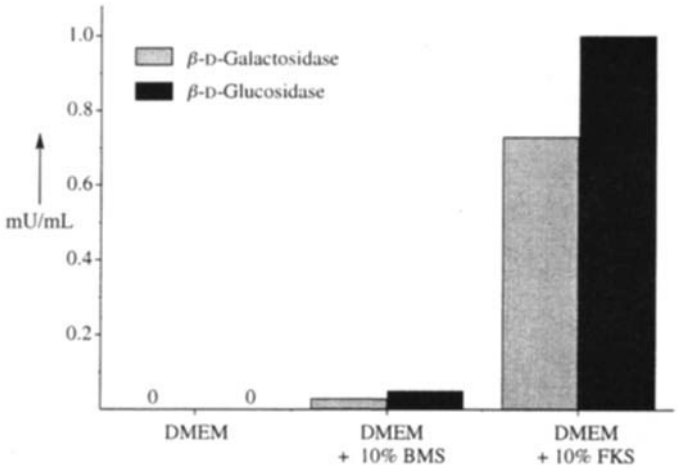

Fig. 2. β-D-galactosidase and β-D-glucosidase activities in various media.

ments showed that cell growth was not impaired if FCS or BMS was removed from the medium during the 24 h exposure to **11** or **12a**, and resupplemented afterwards.

As expected, proliferation was not significantly inhibited by **11** or **12a** in nonsupplemented DMEM, whereas the toxic effect of the prodrug in other media could be correlated with the respective enzyme activities (Fig. 3). In DMEM enriched with BMS, an ED_{50} value of 62 μM was observed for the seco-CI-galactoside **11**, and an ED_{50} value of 14 μM for the seco-CI-glucoside **12a**. This indicates that either the concentration or the activity of the β-D-glucosidase is higher than that of the β-D-galactosidase in the medium. With DMEM (10% FCS added), an ED_{50} value of 3.6 μM was measured for **11**. A similar toxic effect on the tumor cells (ED_{50} = 3.3 μM) is also apparent if 0.2 U mL^{-1} β-D-galactosidase is added with the seco-CI-galactoside **11** in the DMEM incubation medium, since in both cases **11** is rapidly cleaved to release **3**.

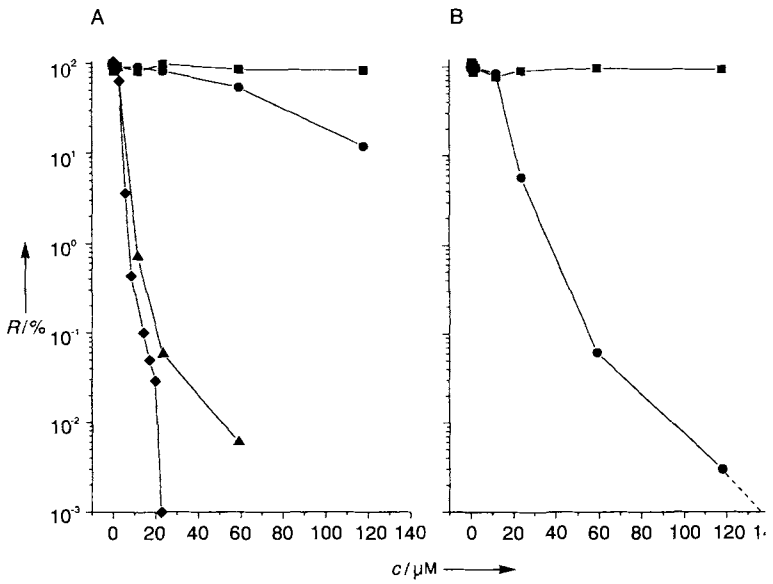

Fig. 3. In vitro cytotoxicity of **11** (A) and **12a** (B) on the cell line A 549 in various media during 24 hours of incubation with the toxin: DMEM (■), DMEM +10% BMS (●), DMEM +10% FCS (▲), DMEM +0.2 U mL^{-1} β-galactosidase (◆); R = relative clone forming rate, c = concentration.

The investigations have shown that the highly cytotoxic seco-CI derivative **3** of the antibiotic CC-1065 (**1**) can be converted into a nontoxic prodrug by O-glycosidation, which after enzymatic cleavage of the glycosidic bond regains its cytotoxicity. In vivo experiments with the prodrugs using conjugates of glycohydrolases and monoclonal antibodies are the subject of our ongoing studies.

Experimental Procedure

Adherent cells of a human tumor cell line were sown in triplicate in 6 multiwell plates at concentrations of 10^2, 10^3, 10^4, and 10^5 cells per cavity, and were incubated with freshly prepared solutions of the compound to be tested at various concentrations. DMSO was used as solubilizing agent (final concentration 0.2%). After 24 h of exposure, the test substance was removed and the cells were treated with fresh medium. After 12 d of cultivation at 37 °C and 7.5% CO_2 in air, the medium was removed; the clones were dried, stained with Löffler's methylene blue, and counted macroscopically. The relative clone forming rate was determined according to the following formula: relative clone forming rate [%] = (number of clones counted after exposure)/(number of clones counted in the control) × 100.

Cells for the toxicity tests were cultivated at 37 °C and 7.5% CO_2 in air in DMEM (Biochrom) supplemented with 4 mM L-glutamine (Gibco), 44 mM $NaHCO_3$ (Biochrom), and 10% fetal calf serum (FCS; heat-inactivated for 30 min at 56 °C, Gibco). During exposure of the cells to the test substances various incubation media were used. The base medium DMEM contained either (a) 4 mM L-glutamine and 44 mM $NaHCO_3$, (b) additional 10% BMS (Biochrom), (c) additional 10% FCS, or (d) additional 0.2 U mL^{-1} β-D-galactosidase (G 5635 Sigma).

$[(enH_2)_{0.5}][Zr_2(PO_4)_2(HPO_4)F]\cdot H_2O$: A Unique Zirconium Fluoride Phosphate with a Cavity Structure**

Erhard Kemnitz,* Martin Wloka, Sergej Trojanov, and Anja Stiewe

The discovery of microporous aluminophosphates ($AlPO_4$-*n*) by Wilson et al.[1] has spurred great interest in this class of compounds. The substitution of aluminum in the lattice by gallium has led to a series of new phases[2] including several aluminophosphate analogs.[3–5] A key achievement in this field reported by Guth et al.[6] is the development of a new synthetic procedure conducted in the presence of fluoride ions, in which the fluoride is incorporated into the open framework of the structure. The best example of one of the new compounds obtained by this route is cloverit,[7] which contains three-dimensional, 20-membered ring channels, in which the fluoride ion is located at the center of a double, four-membered cage. Likewise, a series of gallium phosphates has been synthesized hydrothermally by Férey et al.[8–12] by using fluoride as a mineralizer and several amines of varying chain lengths as templates. The compounds were structurally characterized and dubbed ULM phases after the authors' location (Université Le Mans). Some isotypic 3D structures analogous to the $AlPO_4$-*n* phases were also found with similar cavities and channels.[13]

The synthesis of transition metal coordinated microporous materials with defined pore structures is of particular interest, owing to their potential as catalysts. Compounds such as vanadium phosphate containing elliptic cavities,[14] microporous cobalt phosphates,[15] and microporous heteropolyoxometalates with Dawson anions[16] have already been synthesized. Clearfield[17] has synthesized and characterized multilayered zirconium phosphates. Xu et al.[18] have recently reported the synthesis of a new zirconium phosphate of composition **1**, the structure of which has now been reported.[19] However, since **1** has a double-stranded chain structure without cavities, and considering its hydrogen bonding system, it can also in fact be described as layered.

$(enH_2)_{1.5}[Zr(HPO_4)(PO_4)F_2]$ **1**

[**] This work was supported by the Deutsche Forschungsgemeinschaft, by the Volkswagenstiftung, and by the Fonds der Chemischen Industrie. en = ethylenediamine.

We report here on the synthesis and characterization of the new zirconium fluoride phosphate **2** containing a microporous

$[(enH_2)_{0.5}][Zr_2(PO_4)_2(HPO_4)F]\cdot H_2O$ **2**

3D structure, which we refer to as $ZrPO_4$-1 because of its similarity to the $AlPO_4$-*n* phases.

Well-formed crystals of compound **2** were prepared by hydrothermal synthesis starting from zirconyl chloride, ethylenediamine, hydrogen fluoride, and phosphoric acid.[20] The composition of **2** was deduced by single-crystal X-ray structure determination[21] and confirmed by chemical analysis. The crystal structure determination reveals that the incorporated fluorine does not participate in fluorophosphate bonding, but rather is directly bonded to zirconium, leading to the formation of what might be the first example of a zirconium phosphate with channels in the structure.

Both of the crystallographically independent Zr atoms are octahedrally coordinated, either as ZrO_6 or as ZrO_5F (Fig. 1). Each of the coordinating oxygen atoms belong to different PO_4

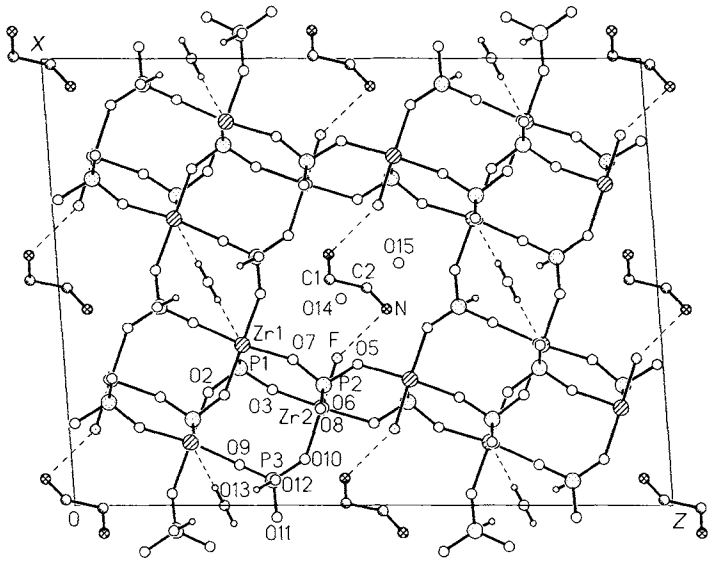

Fig. 1. Projection of the crystal structure of **2** along the crystallographic *b* axis with atom labels (O1 and O4 are not shown below Zr1). The ZrO_6 and ZrO_5F octahedra shown are linked by PO_4 and $PO_3(OH)$ tetrahedra, respectively. Half of the water molecules are situated in the smaller cavities and half are in the larger channels together with protonated ethylenediamine (O14 and O15 are shown only once).

tetrahedra. In contrast to these bridging oxygen atoms, the fluorine atom is terminally bound. Both types of octahedra are slightly distorted with Zr–O distances ranging from 2.022 to 2.101 Å. The terminal Zr–F bond with a bond length of 1.988 Å is only 0.01 to 0.03 Å shorter than that in compound **1** (1.998–2.016 Å).[17] The octahedra are linked by three crystallographically distinct PO_4 and $PO_3(OH)$ tetrahedra. The P–O distances in the PO_4 tetrahedra range from 1.513 to 1.542 Å, similar to the values given for compound **1**. As was expected, the P–OH bond (P3–O12 1.568 Å) is about 0.04 Å longer than the average P–O bond. As is already known from many other examples of SO_4 and $SO_3(OH)$ tetrahedra[22], the P–O bonds of the PO_4 tetrahedra are longer (1.527–1.542 Å) than that of the $PO_3(OH)$ tetrahedra (1.513–1.523 Å). The reduced fluorine content in **2** (0.5 F atoms per Zr atom) results in a lower charge distribution in the anionic region of the structure and therefore the degree of aggregation is higher than that of **1** (2 F atoms per Zr atom). This

finding should encourage further investigation and synthesis of additional examples of this class of compound.

The polyhedra representation in Figure 2 clearly shows the three-dimensional linkage of the structure. The bridging O atoms in the [010] direction are O1 and O4 from the P1 tetrahedra and O6 and O8 from the P2 tetrahedra. The protonated

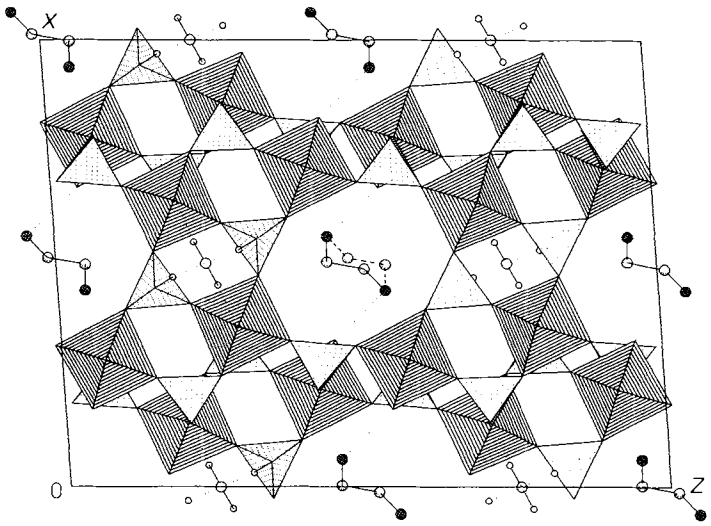

Fig. 2. Projection of the crystal structure of compound **2** in a polyhedra presentation. The enH_2 ions are disordered around the inversion center (the second position is shown only at one site). Half of the water molecules (those at the position of the disordered enH_2 ions) are not shown.

ethylenediamine molecules and half of the water molecules are situated in the channels of the framework. The size of the channels in the [010] direction is limited by eight-membered rings (two ZrO_6 and two ZrO_5F octahedra, alternating with two PO_4 and two $PO_3(OH)$ tetrahedra). The width of the channels varies slightly with the height and depends on the interatomic distances F···F′ (6.11 Å) and O12···O12′ (7.91 Å) at the level of the enH_2 ions and by the distances O5···O(10) (5.63 Å) and O7···O11′ (7.14 Å) at the level of the eight-membered rings.

The situation is slightly complicated because the enH_2 ions are statistically disordered. Consequently, the water molecules at this position appear disordered as well (occupancy for two O atoms 0.25). This disordering phenomena made it impossible to determine the positions of the hydrogen atoms on the amine nitrogen. The same situation arises with the water molecules incorporated on alternating free amine sites; their hydrogen atoms could not be directly determined. However, the measureable N···F and O···O distances and angles are indicative of hydrogen bonds.

The other half of the water molecules are located in the small cavities of the framework and have four hydrogen bonds, two O13–H13···O4 and two O12–H12···O13. Thus water is bound in two different cavities in the structure. Surprisingly, simultaneous DTA/TG measurements[23] exhibit a nonstructured continuous TG curve, with a mass decrease of 3.6%, which corresponds to the loss of one mole of water. This dehydration occurs completely at temperatures above 140 °C. The inorganic framework is unaffected; the powder diffraction pattern recorded for the dehydrated sample showed no changes. At room temperature the sample rehydrates completely after a few hours of contact with air ($\Delta m = +3.6\%$). First attempts at removing all of the ethylenediamine template from the channels failed when acids or bases were utilized. As would be expected, thermal degradation of the amine proceeds by a more complex mechanism and is the focus of current investigation. Preliminary sorption experiments[24] with pure, dehydrated, and partially amine-free samples of compound **2** using nitrogen as a sorbant do not give any evidence for channel accessibility. Further investigations should focus not only on the microporosity and catalytic potential of compound **2**, but also on the influence of other amines on the framework structure. Nevertheless, the first successful preparation of a zirconium phosphate fluoride having a cavity structure may provide a preparative route to novel compounds, which may be of interest, for example, as heterogeneous catalysts.

NMR—A Tool for all Disciplines

Encyclopedia of Nuclear Magnetic Resonance. Editors-in-chief: *D. M. Grant* and *R. K. Harris*. Wiley, Chichester, 1996. 5323 pp., hardcover £ 2250.00.—ISBN 0-471-93871-8

The publication of this hefty work, consisting of eight volumes in large-page format, weighing about 23 kg and occupying 0.4 m of shelf space, coincides with the golden jubilee of the discovery of nuclear magnetic resonance in 1945/1946. Volume 1 ("Historical Perspectives", 728 pages of text, ISBN 0-471-95839-5) is also available separately at the price of £ 125.00 (an offer well worth considering – see below); apart from this exception, the eight volumes can only be bought as a set. The publishers, Wiley, have been active for some time in the area of encyclopedias covering aspects of chemistry, produced in a similar style and organized along the same lines as this one, such as the *Encyclopedia of Inorganic Chemistry* previously reviewed in this journal (*Angew. Chem.* **1996**, *108*, 1333; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 1738). Editors-in-chief of the *Encyclopedia of Nuclear Magnetic Resonance* ("ENMR") are two well recognized experts, David M. Grant (University of Utah, USA) and Robin K. Harris (University of Durham, UK), who have been active in the NMR field since the late 1950s. They have classified the contents into six topic groups and appointed a specialist as section editor for each group: E. D. Becker (National Institutes of Health, USA) for the volume "Historical Perspectives", J. W. Emsley (University of Southampton, UK) for the topics "Inorganic Applications", "Polymer and Liquid Crystalline Solutions", "Quadrupolar Nuclei", and "One- and Multidimensional Spectroscopy of Solutions", B. C. Gerstein (Iowa State University, USA) for "Physics Applications", "Solid Methods", and "Solid-State Applications", S. I. Chan (California Institute of Technology, USA) for "Biological Applications", T. C. Farrar (University of Wisconsin, USA) for "Instrumentation", "Organic Applications", "Relaxation Topics", and "Theory", and I. R. Young (Hammersmith Hospital, UK) for "Biomedical Applications" and "Imaging Principles and Applications". From these section titles it can be seen that in this encyclopedia "nuclear magnetic resonance" means much more than NMR spectroscopy and its use in chemistry. It includes aspects such as imaging, NMR microscopy, in-vivo spectroscopy, data processing, and alongside chemistry such diverse fields of application as biology (e.g., plant physiology), medicine (e.g., clinical applications), physics, materials science, geology (oil exploration), and agriculture. The topics named above have been covered in about 520 separate articles contributed by nearly 630 specialists. The articles vary greatly in length, from two to thirty pages. The level of treatment also varies, which is not necessarily a disadvantage since the users of the work will also differ widely in their expectations. Moreover, the level of treatment must also be partly determined by the nature of the topic. It would not be appropriate to discuss individual contributions in this review, as there are so many that only a small selection could be mentioned, which would be unfair to the rest of the authors.

Because of the alphabetical arrangement the articles belonging to a given section do not appear together, but are distributed through the different volumes. However, the preface is repeated in each of the volumes 2 to 8, and includes a seven-page list of the titles of all the articles in the complete work. This list is set out under sections and subsections, so that one can see at a glance the connections between articles on related subjects. Each volume also contains a complete alphabetical list of all the articles. Furthermore, the individual articles consistently provide cross-references to related articles. Volume 8 contains a comprehensive 205-page keyword index, a list of authors (33 pp.), and a glossary of medical terms and those relating to imaging (11 pp.), which is very useful for users unfamiliar with these fields. Where else would such a user learn, for example, that MRV stands for magnetic resonance venography, or that US means not the United States but ultrasonography? The list of authors and the topics that they cover is also repeated, in a corrected version, as a separate supplement. Thus it can be seen that much effort has been devoted to making it as easy as possible for the reader to find the required information.

Volume 1 is a delightful treat which I read with much pleasure. It describes the development of NMR, from its beginnings in the hands of a small number of physicists to its emergence as a fully-fledged area of research, subsequently maturing to become a practical method with applications in a remarkably wide variety of scientific disciplines. The volume begins with a very interesting and detailed contribution entitled "The Development of NMR", by E. D. Becker, C. L. Fisk, and C. L. Khetrapal (158 pp., 1099 literature references). The article includes reprints of the two short communications (*Phys. Rev.*, **1946**) by the groups led by Purcell and Bloch, which eventually led to the shared award of the Nobel Prize for physics in 1952. This is followed by a collection of short articles in which more than 200 authors describe the development of NMR and their roles in it, often from very personal viewpoints. These contributions contain much anecdotal material which, because it would be unsuitable for separate publication, might otherwise have been lost forever. The list of authors includes many pioneers from the early days of NMR, as well as other scientists whose names have only come to prominence in recent times. These personal recollections make fascinating reading. Short biographical notes about the authors are attached to all these essays, and also to the more specialized articles in Volumes 2–8.

Thanks to the combined efforts of the editors and of the many authors, ENMR is a very impressive work. It will be of special value to users who are in the pro-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

cess of getting to grips with a new area in the broad field of nuclear magnetic resonance, and to those wishing to look beyond the boundaries of their own, usually fairly narrow, specialist area. The price of this highly desirable work is likely to put it beyond the means of most private individuals, other than true fanatics. However, libraries whose budgets are not yet exhausted, despite present-day cuts in funding, are strongly recommended to buy it. All readers interested in nuclear magnetic resonance would certainly appreciate having access to this reference source. Finally, a suggestion for the publishers: might not a CD-ROM version tempt private individuals to buy the work, if the saving in production cost were passed on to the potential buyer? Admittedly though, for this reviewer at least, the prospect of browsing via the monitor screen seems less attractive. By contrast, the idea of retiring to the sofa with Volume 1 of ENMR is most inviting.

Industrial Organic Chemicals. By *H. A. Wittcoff* and *B. G. Reuben*. Wiley, New York, 1996. 531 pp., hardcover £ 60.00.—ISBN 0-471-54036-6

This book is a completely revised and enlarged version of *Industrial Organic Chemicals in Perspective*, by the same authors, originally published in 1980. It aims to provide a wide range of users, from students to industrial chemists, with a survey of the technologies and products of industrial organic chemistry.

The contents are arranged in a clear and systematic structure. The preface gives an overview of the chapters that follow, and a summary of available monographs, encyclopedias, and the most important industrially-orientated journals and on-line data banks that contain relevant information. Each chapter also has a useful and often quite extensive section headed "Notes and References", which lists publications for further reading, recent review articles, key patents, and sources of information on related topics, and even includes occasional anecdotes relating to the history of the petrochemical industry. Often, however, only the cryptic comment "see note" in the main text tells the reader that there is a reference to a source of further information, and one is left to search for the relevant item.

Chapter 1 (33 pp.) discusses the importance of the chemical industry in the context of the overall economic environment, and describes modern developments such as economies of scale, problems of overcapacity, market saturation, research and development costs, and effects of legislation. Here one becomes aware of one of the book's limitations, which also applies to the later chapters, in that the main emphasis is on the USA chemical industry. Developments in Western Europe and Japan only appear occasionally and, for example, the discussion of political influences makes no mention of European legislation on chemicals.

Chapter 2 contains a very clear description of the production of basic petrochemicals by the distillation of crude oil and the subsequent refining processes.

Chapters 3–11 then deal in turn with these basic chemicals and their associated downstream chemistry, from ethylene through aromatics to alkanes. The various derivatization processes and routes to end-products are described systematically, with special attention to polymer production. Thus the reader is provided with a good insight into the entire materials flow of the industry. For example, one can follow the series of processes leading from ethylene via ethylene oxide and ethanolamine to quaternary ammonium compounds. As one is taken along the route to the end-product the amount of industrial background information diminishes, so that often the later stages are described only by reaction schemes with a few general comments about the process. However, one should not be surprised at this, because otherwise the book would have expanded well beyond its planned size. The authors also give examples of the uses of the end-products, so as to give an impression of the range of potential applications. However, the reader will sometimes find it difficult to gain a true picture of the importance of the markets, as the information given is usually only of a general nature.

As a consequence of the decision to include a very wide range of undoubtedly interesting topics, the main industrial processes are not treated in such depth as one finds in other standard works. The reader from an industrial background may have hoped to find more detailed factual information, going beyond an introductory treatment. Also, data such as annual tonnages are not always presented in a convenient form for easy reference, and one has to search laboriously through the text.

Chapters 12–14 deal with the chemistry of coal, natural oils, fats, and carbohydrates. The chapter on oils and fats gives only an incomplete picture of the industrial processes based on these increasingly important feedstocks. Some important processes, such as physical refining, are not mentioned at all, whereas much space is devoted to less important raw materials and reactions, and some outdated areas of application are described. In the section on fatty alcohols the authors seem to be unaware that a process for manufacturing unsaturated fatty alcohols based on a "new catalyst" has already been in commercial use for several decades. Even if the authors consider that the annual tonnages are trivial in the context of petrochemicals, the reader has the right to expect that a little more care is taken after the decision to devote a whole chapter to these products Chapters 15 and 16, which complete the book, deal with polymer production and catalysis.

On the whole the book provides a good overview of the industrially important aspects of organic chemistry and polymer chemistry, giving concise and informative descriptions of the most important chemicals and polymers, and relegating reactions of little industrial importance to the background. However, it should be regarded more as a textbook of applied organic synthesis than a detailed description of industrial practice.

Asymmetric Synthesis. By *G. Procter*. Oxford University Press, Oxford, 1996. 237 pp., paperback £ 19.50.—ISBN 0-19-855725-6

Enantioselective Reactions in Organic Chemistry. By *O. Červinka*. Ellis Horwood, London, 1995. 194 pp., hardcover $ 119.95.—ISBN 0-13-276239-0

We have here two further additions to the considerable family of books on the subject of stereoselective synthesis. As will be seen below, these are widely different in all respects apart from their similarity in length. Procter's book originated from a lecture course and is intended for students. As the title indicates, the emphasis is on synthesis. The book is concerned with various methods for preparing chiral non-racemic compounds, and describes important applications to the synthesis of natural products and active agents. The author has deliberately kept "stereochemical jargon" to a minimum. Thus, instead of the usual lengthy introduction explaining all the terms employed in stereochemistry, the explanations are limited to the expressions actually used in the book, and are given

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3522-2680 $ 15.00+.25/0

where they first appear. All the topics are treated clearly and systematically.

The subject matter is arranged according to reaction types. Each chapter is self-contained and includes a bibliography. Chapter 1 is devoted to diastereoselective and enantioselective addition reactions of carbonyl compounds, and Chapter 2 describes reactions of chiral enolates with electrophiles. The following chapters deal in turn with asymmetric aldol reactions, additions to carbon–carbon double bonds, reductions and oxidations, rearrangement reactions, and enzymatic hydrolyses and esterifications.

All the important concepts of stereochemistry are covered, beginning with the Cram and Felkin–Ahn models, then ranging from the Zimmermann–Traxler transition state through "chiral amplification", enolate geometry, CBS reduction, DIOP, BINAP, BINAL-H, alpineborane, RAMP, SAMP, the Claisen and Wittig rearrangements, etc., to the Sharpless epoxidation and dihydroxylation reactions. The author discusses the preparation and the various applications of chiral auxiliaries based on the oxazoline, oxazolidinone, sultam, and η^5-CpFe(PPh$_3$)(CO) structures. Organometallic reagents discussed include allylboranes, allylstannanes, allylsilanes, organozinc compounds, and boron, tin, and titanium enolates.

This first edition contains many mistakes such as incorrect structural formulas or printing errors, but most are harmless and of a kind that will be immediately obvious to the reader who is able to follow the discussion. As examples, on page 32 the formulas shown for (+)- and (−)-α-pinene are identical, on page 35 the relative configuration is given as *trans* instead of *anti*, on page 116 compounds 6.40 and 6.39 have become interchanged in the text, and on page 212 the double bond has been omitted from a molecule that is undergoing hydrogenation. I found no errors more serious than these.

There are a few instances where important reactions relevant to the topic under discussion have been omitted. For example, the treatment of asymmetric cyclopropanation reactions fails to mention the well-established chiral rhodium catalysts described by Doyle, Davies, and Pfaltz. As many of the chiral auxiliaries appear in more than one chapter, I suggest that the second edition of the book should include an appendix summarizing the different applications of each of the auxiliaries. Also it would be desirable to break down some of the chapters into sections so that changes of topic would be more clearly evident. This applies especially to Chapters 5, 6, and 7, each of which is a giant block of nearly fifty pages without subdivisions, the three together occupying over half the book. The subject index, containing about 500 entries, is satisfactory, and there are about 400 literature references extending up to 1993.

The book covers the core aspects of modern asymmetric synthesis and can therefore be emphatically recommended for students and other newcomers to the subject, especially in view of its affordable price.

The book by Červinka is orientated more towards the fundamental principles of chirality and enantioselective reactions, with synthetic applications relegated to a secondary role.

There are 18 chapters on topics such as racemate cleavage, enantioselective reactions, strategies for asymmetric synthesis, synthesis of enantiomeric compounds, asymmetric reactions using transition metal catalysts, asymmetric reactions using chiral auxiliaries, enantiomerically pure building blocks, and enzyme-catalyzed reactions. This range of topics looks excellent at first glance, but on closer examination it turns out that almost half the chapters (Chs. 1, 2, 6, 9, 11, 13, and 14) consist of only one or two pages each. Often these merely refer the reader to review articles. If this were an appropriate way of treating the subject, the author might as well have replaced the whole book by similar references! Chapters 8 and 18 contain only literature references (see below).

The work as a whole has the appearance of a classification of the field of stereochemistry into subject areas, amplified here and there by motley collections of information. For example, enantioselective cyclopropanation reactions appear in the section on double bond isomerizations using transition metal complexes (p. 95), and the reaction of an allylborane with an aldehyde is described in the chapter on hydroboranation reactions (p. 104). Where topics are treated more thoroughly the main thread of the discussion tends to get lost. Often one finds that relatively unimportant matters are covered in great detail, whereas more important ones are only mentioned briefly or even neglected entirely. Thus, in the discussion of chiral ligands for transition metal catalyzed reactions, DIPAMP and DIOP are buried within a mass of information about numerous exotic ligands (pp. 69–83), and in describing the use of Diels–Alder reactions (pp. 108 ff) there is no mention of the possible formation of regioisomers.

Reading the book is made more difficult by the circumlocutory style and a tendency towards abstract and woolly language. For example, it would be difficult to make sense of the description of kinetic racemate cleavage on page 55 if one did not already know what this was all about. The translation from Czech into English may be responsible for these problems, but whether that is the case is immaterial to the reader.

The difficulties also extend into the formula diagrams. Almost all the equations lack important information such as yields and reaction conditions, and equilibrium arrows are sometimes omitted (e.g., on p. 88). The problems are further aggravated by the Roman numerals used to identify compounds. For example, it is not particularly easy to distinguish at a glance between compounds CXXXVII and CXXXVIII. In general the quality of the figures and formulas is not very good. The more disturbing examples include Figure 12 (p. 34), which at first glance looks as though a dozen graphics have been accidentally superimposed, Scheme 3 (p. 14), which could hardly be described as self-explanatory, and Figure 1 (p. 167), which shows a "diamond lattice" that could have been the work of Escher. Also many molecular structures are shown wrongly: examples are the Darvon alcohol on page 55, the nonsensical stereochemical structure of compound II shown on page 70, the chiral compounds with C_s symmetry shown in Scheme 2 on page 72, the geminal dimethyl groups that are claimed on page 87 to appear with 96% *ee*, the peracid with only two oxygen atoms on page 98, and a pentavalent carbon atom on page 94. There are occasional examples of incorrect terminology, as on page 18 where "homochiral" and "enantiomerically pure" are treated as synonymous. On page 71 there is a mention of "diphosphines with a chiral group connecting two chiral phosphorus atoms"; in fact there are no such compounds in the book, but in any case a phosphorus atom, although it may be a chiral center, is not itself chiral.

The subject index is rather scanty, containing only about 260 entries. Chapter 8 consists solely of 205 references (up to the year 1990) for Chapters 1–7, and Chapter 18 similarly consists of 416 references (up to 1994) for Chapters 9–17.

This book is only suitable for the reader who already has a good grasp of stereochemistry, and who might discover in it a few facts that he or she has not previously known. The contents of the book does not justify its cost relative to other works on this subject.

Organometallics in Synthesis – A Manual. Edited by *M. Schlosser*. Wiley, Chichester, 1994. 603 pp., hardcover £ 60.00.—ISBN 0-471-93637-5

Two of the most interesting publications of recent years in the field of organometallic chemistry are the second edition of *Comprehensive Organometallic Chemistry* and the book under review here, *Organometallics in Synthesis,* edited by Manfred Schlosser. The difference between the two books could hardly be greater: on the one hand a 14-volume "encyclopedia" of organometallic chemistry with many thousands of pages, on the other hand a manual covering the most important recent developments in the field in just over 600 pages. Schlosser's book is intended mainly for the newcomer to the area, who has scarcely any knowledge of the basic principles and working techniques. The approach is rather similar to that of *Best Synthetic Methods,* first providing the reader with an understanding of the fundamental reaction mechanisms, then following this up with practical advice, rules of thumb, and, most importantly, carefully chosen laboratory recipes, so as to enable the novice to successfully synthesize organic compounds using organometallic reagents. The choice of examples has necessarily been restricted to what are described in the preface as the "most popular metals and methods".

To achieve this goal the editor has assembled a team of well qualified authors, whose names are inseparably associated with this field of study. In Chapter 1 (166 pp.) M. Schlosser describes the use of organometallic compounds of the alkali metals in synthetic applications. This is followed by a short chapter (28 pp.) in which the industrial chemists F. Totter and P. Rittmeyer discuss the handling and industrial applications of organolithium compounds. Chapters 3 and 4 (88 and 100 pp. respectively) provide detailed treatments of the synthetic applications of titanium compounds (by M. T. Reetz) and organocopper reagents (B. H. Lipshutz). Chapter 5, by L. S. Hegedus (77 pp.), is devoted to palladium-catalyzed reactions, and this is followed by three shorter chapters, dealing with organoboron chemistry (Ch. 6, 48 pp., by K. Smith), organoaluminum compounds (Ch. 7, 25 pp., H. Yamamoto), and organotin chemistry (Ch. 8, 44 pp., H. Nozaki). The book is completed by a detailed subject index and a very useful formula index, which enables one to compare different organometallic species. All the chapters have comprehensive bibliographies, which in some cases cover publications up to very recent dates. The visual quality of the book is excellent: a consistent typeface has been used throughout, and the structural formulas have been very carefully drawn.

Does "Schlosser" achieve its declared aim of helping the novice to overcome the psychological and practical barriers to getting started in organometallic chemistry? Well, to begin with, it comes as no surprise that in a multiauthor work of this kind the contributions vary considerably in both length and quality. I liked especially the chapters on titanium, copper, and boron compounds and their reactions, not least because they contain a wealth of practical advice and laboratory recipes (in the chapters by Lipshutz and Smith the procedures have been blended into the text in a very successful way). All three chapters cover not only "classical" applications in chemo-, regio-, and stereoselective reactions but also many important recent developments. Examples of these include the use of chiral organotitanium catalysts for enantioselective additions and cycloadditions, and the preparation of organocopper reagents with complex structures by transmetallation from organozinc, organoaluminum, and organozirconium compounds. However, in the copper chapter on page 199 an error with possibly serious consequences has crept in: only one half of the quantity of methyllithium needed for the preparation of the cuprate is shown, so that instead of Me_2CuLi one would obtain methylcopper, which is unstable in its pure form and could decompose explosively during the subsequent removal of the solvent!

The chapter on the industrial applications of organolithium compounds does not, of course, contain laboratory recipes, but there is much useful advice concerning the stability and handling of these reagents. On the other hand, the rest of the chapters are, in my view, not quite so good as those just mentioned. In particular, Schlosser seems to have given way to the temptation to devote a disproportionate amount of space to his own field of research, as the chapter on organic compounds of alkali metals contains many details and anecdotes of a marginal kind that are unlikely to be very useful to the intended readers. In contrast, the chapters on palladium-catalyzed reactions and organoaluminum and organozinc compounds contain little in the way of practical advice; these are more like abbreviated monographs, and the few laboratory recipes that have been grafted on sit uneasily in these chapters. It is also doubtful whether the claim to cover the "most popular metals and methods" is fully justified. With a better organization of the contents it would certainly have been possible to include some more metals, for example by covering organozinc reagents, which are important in stereoselective synthesis (e.g., the work of Noyori et al.), and are also compatible with a wide variety of functional groups (as shown by Rieke and Knochel). However, the preface promises that there will eventually be a second, enlarged edition covering these topics.

Notwithstanding these criticisms, I was left with a very good impression of "Schlosser", and one hopes that the weaknesses will be remedied in a new edition in due course. No chemist seriously interested in synthetic applications of organometallic reagents can afford to be without this book.

Crystallographic Methods and Protocols. (Series: Methods in Molecular Biology. Vol. 56). Edited by *C. Jones, B. Mulloy* and *M. R. Sanderson*. Humana Press, Clifton, NJ, 1996. 394 pp., loose-leaf edition $ 69.50.—ISBN 0-896-03259-0

This publication is intended as a "recipe book" for protein crystallographers. It gives information about practical laboratory procedures that cannot be found in ordinary textbooks. Cryocrystallographic methods, which are becoming ever more important, are described in practical detail, as also is the installation and operation of different types of commonly used area detectors. The book gives details of computer programs for processing X-ray diffraction data and determining and refining protein crystal structures. The use of such programs is explained clearly and in sufficient detail to enable even the novice to succeed in getting results. The information provided here is normally only available in the dedicated handbooks supplied with the relevant hardware and software, and it should also be helpful in choosing and buying equipment. The book describes strategies for determining the positions of heavy atoms, which are needed for phase determination, and gives protocols for refining a structure once it has been solved. All these working procedures ("recipes") are described clearly and in detail, so that the reader with a back-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3522-2682 $ 15.00+.25/0

ground in molecular biology or biochemistry and an interest in structural biology can quickly master the methods. The final part of the book describes methods for crystallizing oligonucleotides, protein–DNA complexes, viruses, and membrane proteins.

The contents are clearly arranged, and all the chapters have been written by internationally recognized experts. In the first chapter ("Introduction"), the fundamentals of protein crystallography are briefly explained. Next, in "Overexpression, Isolation and Crystallization of Proteins", the production of proteins in prokaryontic and eukaryontic overexpression systems and their isolation and purification are described, followed by strategies for obtaining suitable crystals by "screening" and improving the process by seeding. Under the heading "Preliminary Characterization of Crystals", the subject of crystal symmetries is introduced, followed by the "mounting" of crystals in capillaries and the shock-freezing process used in cryocrystallography. The recording and evaluation of precession patterns to yield information on space groups and cell constants is then described. The chapter "Modern Methods for Rapid X-Ray Diffraction Data Collection from Crystals of Macromolecules" introduces the area detectors that are now generally used, and gives a clear and detailed description of their manner of operation and the processing and reduction of the data. Here the subject of cryocrystallography is again addressed. The next chapter has the title "Use of Multiple Wavelength Anomalous Diffraction (MAD) Measurements in ab initio Phase Determination for Macromolecular Structures". An introduction to the theory of anomalous dispersion leads into an account of how data recorded at different wavelengths using a synchrotron source are analyzed to determine phase angles. The chapter on "Structure Determination Using Isomorphous Replacement" describes the preparation of heavy-atom derivatives, the use of Patterson methods to determine the positions of the introduced atoms, and the final refinement of these positional data. Various criteria used in the calculations are discussed, such as the "figure of merit", the Cullis *R*-factor, and the "lack of closure error", as also is the use of Patterson difference and Fourier difference methods. In "Molecular Replacement Using Known Structural Data" the reader is introduced to these methods, which are becoming increasingly important as a result of the continuing growth of protein data banks. The various programs of importance for rotation and translation methods are clearly described and their use is illustrated by examples of practical applications. Next is a chapter on "Density Modification in X-Ray Crystallography", describing the very effective methods based on this principle which can improve the initial electron density distribution, thus facilitating comparison with model predictions. The chapter "Refinement of Protein and Nucleic Acids Structures" discusses the most recently developed programs whereby the refinement can be carried out more effectively, describes their applications, and sets out protocols. Methods are also described whereby models are first constructed manually and subsequently improved; these can be used alternately in conjunction with refinement procedures. The chapter ends by discussing quality criteria that can be applied to a structure model, such as the *R*-factor and the free *R*-factor. The latter topics are treated in greater depth in "Recent Developments for Crystallographic Refinement of Macromolecules", where the methods are described in detail, as also is the use of "simulated annealing".

The next four chapters are devoted to methods for preparing crystals and determining the structures of oligonucleotides, protein–DNA complexes, viruses, and membrane proteins. These chapters form a very useful extension to the crystallization protocols for proteins that were described at the beginning of the book. I regard the tables listing the oligonucleotides, protein–DNA complexes, and viruses that have so far been crystallized, together with the protocols used to achieve the crystallization, as a valuable and important resource. The particular problems that arise in the crystallization, data collection, data processing, and structure determination for molecules of this type are discussed. Special attention is given to the difficulties caused by noncrystallographic symmetry and phase broadening in analyzing the structures of viruses. The final chapter is mainly concerned with the two-dimensional crystallization of membrane proteins; in addition there is a discussion of methods for growing three-dimensional crystals, with references to the relevant literature so that the interested reader can pursue this aspect in more detail. However, a list of the commonly used detergents would have been a useful addition.

This book fills a gap in the literature on protein crystallography, as the main emphasis here is on the practical matter of protocols for analyzing protein crystal structures rather than on the theoretical fundamentals. It can be recommended not only for biochemists and molecular biologists who wish to learn and apply the methods of protein crystallography, but also for experienced protein crystallographers, who will find in it a very good overview of the subject and many useful ideas and tips in relation to their work. Accordingly, I have just ordered three copies of the book for my research group.

In the same manner that the Nasobem, Stümpke's mythical creature, teaches his child the peculiar way of life of the species *Nasobema lyricum*, the work of Seebach et al. on the self-regeneration of stereocenters has been governed by a fanciful idea. On the way, many tricks have been learned and much knowledge gained. Finally, they have come back down to earth and find themselves once again in the unimaginative world of enantiomer separation for the synthesis of enantiomerically pure compounds.

Self-Regeneration of Stereocenters (SRS)—Applications, Limitations, and Abandonment of a Synthetic Principle

Dieter Seebach,* Andrea R. Sting, and Matthias Hoffmann

Dedicated to our much-admired teacher and mentor, Professor Dr. Vladimir Prelog, on the occasion of his 90th birthday

In order to replace a substituent at a single stereogenic center of a chiral molecule without racemization, a temporary center of chirality is first generated diastereoselectively, the original tetragonal center is then trigonalized by removal of a substituent, a new ligand is introduced, again diastereoselectively, and finally, the temporary center is removed. By means of these four steps (the "Self-Regeneration of Stereocenters", SRS), 2- and 3-amino-, hydroxy-, and sulfanylcarboxylic acids have been successfully alkylated with formation of tertiary carbon centers and without the use of a chiral auxiliary. Use of this methodology has allowed the potential of these inexpensive chiral building blocks to be expanded considerably. This article aims to demonstrate (using, in part, examples from natural product syntheses) that chiral heterocyclic acetals with enamine, enol ether, enolate, dienolate, enoate, radical, and acyliminium functionalities and also those that are potential reactants for Michael additions and pericyclic processes (for example, electron-rich and electron-poor dienophiles and dienes) are now easily accessible, more often than not, in both enantiomeric forms. Stereogenic nitrogen atoms of aziridines, boron atoms of cyclic or linear systems, and stereogenic planes of π-complexes can also be used as the temporary chirality element in other approaches to the realization of the SRS principle. Enantiomerically pure derivatives of, for example, glycine, hydroxy- and sulfanylacetic acid, 3-aminopropanoic acid, and 3-oxocarboxylic acids can be prepared by resolution of racemic mixtures via diastereoisomeric salts or by chromatography on a chiral column. Hence, the extensive reactivity of compounds developed to test the SRS principle and, above all, the outstanding stereoselectivities of the reactions can be put to good use even when no suitable chiral precursor is available—even though this amounts to an abandonment of the principle! The readily available 2-*tert*-butyl-1,3-imidazolidin-3-one, -oxazolidin-5-one, -dioxin-3-one, and -hydropyrimidinone (all of which contain a single stereogenic center at the acetal C atom) can thus be used in the preparation of a vast range of 2-amino- and 3-hydroxycarboxylic acids, and no chiral auxiliary has to be removed or regenerated during these procedures. (One example is the synthesis of 4-fluoro-MeBmt, a derivative of the C_9 amino acid found in cyclosporin.) In the final chapter we will discuss the most useful findings gained from investigations into both the self-regeneration of stereocenters and the use of chiral acetals in the synthesis of enantiomerically pure compounds (EPC synthesis): the formation and characteristics of complexes obtained from Li-enolates and other Li compounds with secondary amines; the application of α-alkoxy and α-amino-Li-alkoxides as in situ bases and sources of aldehydes in C–C bond forming reactions with unstable enolates or nitronates; the significance of $A^{1,3}$ effects on the stereochemical course of nucleophilic, radical, and electrophilic reactions of *N*-acylated heterocycles and homo- or heterocyclic carboxylic ester enolates; and the effects of the amide protecting group on the reactivity of neighboring centers and on the stereoselectivity of the reactions at those centers. At the end of this article we have included an appendix containing tables, which are intended to summarize all the examples known in as complete a fashion as possible.

1. Introduction and Definition of the Problem

Was nicht sein kann,
das nicht sein darf![**]

It is a fundamental part of every basic lecture course in organic chemistry that a reaction at a trigonal center bearing three different substituents in an achiral molecule results, if neither

[**] "Surely the impossible is just not possible."

the other reactants nor the surroundings are chiral, in the formation of a racemic product containing one center of chirality. The consequence of this is that a substitution that proceeds in either a homolytic or heterolytic manner at a solitary stereogenic center of a molecule yields enantiomeric products in a 1:1 ratio and hence, a racemic mixture is formed (Scheme 1a). If the trigonal center in the intermediate is cationic or part of a π-system, it will have a trigonal-planar geometry and if it is radical or anionic in nature, it may have a trigonal-pyramidal geometry but will be capable of rapid inversion, particularly in noncyclic systems.

There are, of course, exceptions that can be of practical significance. These include the S_Ni substitution of OH by Cl using thionyl chloride (Scheme 1b),[1] which proceeds with retention of configuration, and the cationic cyclization of linalol *p*-nitrobenzoate to terpineol (Scheme 1c).[2] Stereoselective reactions proceeding via carbanionic intermediates are also known. For example, the D/H exchange with retention of configuration shown in Scheme 1d,[3] which is really of rather academic interest, and the decarboxylation, with retention, of an intermediate used in the preparation of the anaesthetic Desfluran[4] (Scheme 1e). Once it had been appreciated that within so-called carbanion chemistry, there is also a cation, more often than not a metal ion, which can be sufficiently strongly bound[5] to allow the formation of configurationally stable organometallic derivatives[6–8] such as those shown in Scheme 1f, a whole new branch of stereoselective synthesis developed.[9–14]

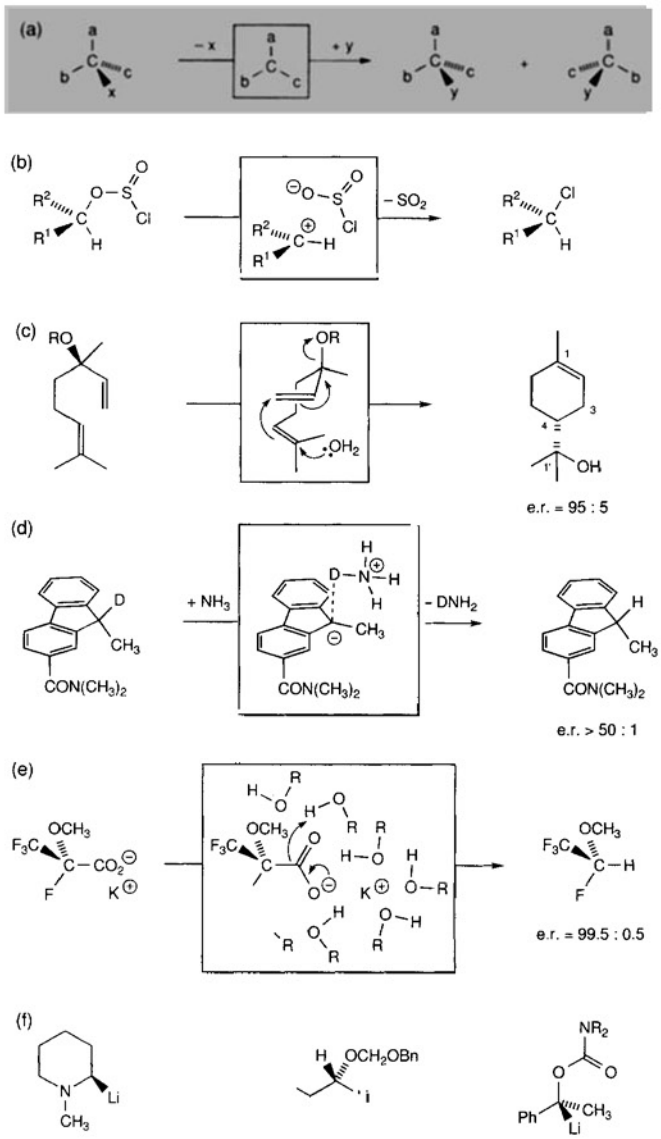
Even in enolate chemistry there are exceptions to the rules formulated above (see the examples in Scheme 2). Although the sole center of chirality in the starting material is removed, enantiomerically pure or enantiomerically enriched products may result. This can be attributed to the formation of aggregates of achiral enolates with chiral components in the reaction mixture (Scheme 2a)[15] or also to sufficiently conformationally stable enolate intermediates which possess axes of chirality (Scheme 2b–e).[16–20] The cation also plays a decisive role in the reactions of enolates. Owing to the successful creation of a variety of alternatives, today practically any type of imaginable reactivity or selectivity of these nucleophiles, which are of central importance in organic synthesis, can be achieved. Possibilities include the participation of aggregates ("supramolecular" structures) of Li-, Na-, K- and Mg-enolates[21–25] and their complexes with salts,[26, 27] amides,[28] and amines,[21–24, 29, 30] the reduction of the coordination sphere of the participating metal

A. R. Sting D. Seebach M. Hoffmann

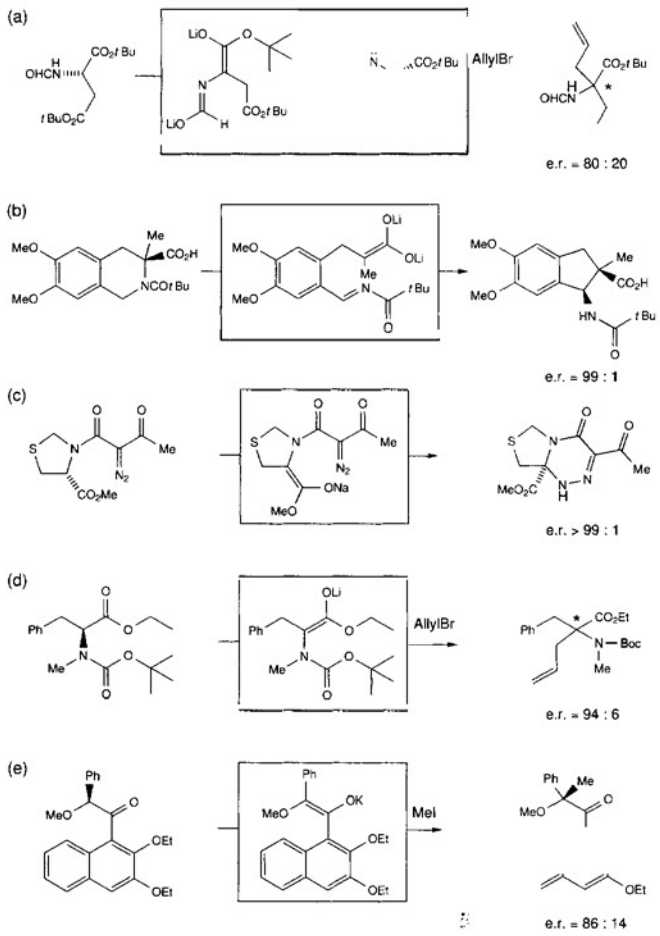
Andrea Rolf Sting was born in Samedan, Canton Graubünden (Switzerland) in 1963. After an apprenticeship and then a further three years working in the chemistry laboratories of Ciba-Geigy in Basel (Dyes and Chemicals Division), he studied from 1986 to 1989 at the "Ingenieurschule Beider Basel" (IBB) in Muttenz (Canton Basel-Land), where he earned the title Dipl.-Chem. HTL. Subsequently, he moved to the ETH in Zürich to continue his chemistry studies (Diploma 1992). In the spring of 1993 he began working in the group of Prof. D. Seebach and completed his Ph.D. thesis on the synthesis of 4-fluoro-MeBmt in the spring of 1996. He is now working in the Division of Crop Protection of Ciba-Geigy in Basel.

Dieter Seebach was born in Karlsruhe (Germany) in 1937. He studied chemistry at the University of Karlsruhe and completed his Ph.D. thesis on small rings and peroxides under the supervision of Prof. R. Criegee in 1964. After a two-year stay at Harvard University as postdoctoral co-worker (with Prof. E. J. Corey) and lecturer, he returned to Karlsruhe and, in 1969, completed his "habilitation" on the topic of S- and Se-stabilized carbanion and carbene derivatives. In 1971 he moved to the University of Giessen as a full professor and then in 1977 to the Eidgenössische Technische Hochschule (Swiss Federal Institute of Technology) in Zürich. He has been a visiting professor at the Universities of Wisconsin–Madison, Strasbourg, Munich (TU), and Kaiserslautern and also at Caltech (Pasadena) and the Max Planck Institute in Mülheim. A main emphasis of his research is the development of new synthetic methods; in the last decade the subject discussed here and the Ti-TADDOLates have been major interests. His work also involves mechanistic studies and determination of structures. More recent research topics include chiral dendrimers, the short-chain oligomers of 3-hydroxybutanoic acid, the bioploymer PHB, and backbone-modified peptides.

Matthias Hoffmann was born in Zürich (Switzerland) in 1969. He completed his Diploma studies in chemistry at the ETH in Zürich in 1993 with research conducted in the group of Prof. D. Seebach. Later that year, he began working on his Ph.D. thesis in the same area. His research focuses on the development of methods for the preparation of enantiomerically pure, non-proteinogenic amino acids.



Scheme 1. Dissociative reactions at stereogenic centers (a–e) and chiral organolithium compounds (f). In this article, the enantiomeric purity of compounds will be given exclusively in the form of enantiomer ratios (e.r.), which are typically determined by NMR, GC, or HPLC analysis. a) Racemization during dissociative substitution at a stereogenic center proceeding via a trigonal intermediate. b) OH/Cl substitution using thionyl chloride with retention of configuration [1]. c) The highly stereoselective cyclization of linalol to terpineol. The use of appropriately labeled derivatives has shown that the carbon atoms C4, C3 (H/D), and C1′ (CH_3/CD_3) are present in only one configuration in the product [2]. d) D/H exchange, with retention, in a fluorene derivative using ammonia as the base; the ratio of the rate of isotope exchange (k_e) to the rate of racemization (k_r) is greater than 50:1 [3]. e) Decarboxylation, with retention of configuration, of (*R*)-2,3,3,3-tetrafluoro-2-methoxypropanoate to give (*R*)-1,1,1,2-tetrafluoro-2-methoxyethane [4]. f) Configurationally stable organolithium compounds described by Gawley et al. [6], Still et al. [7], and Hoppe et al. [8].



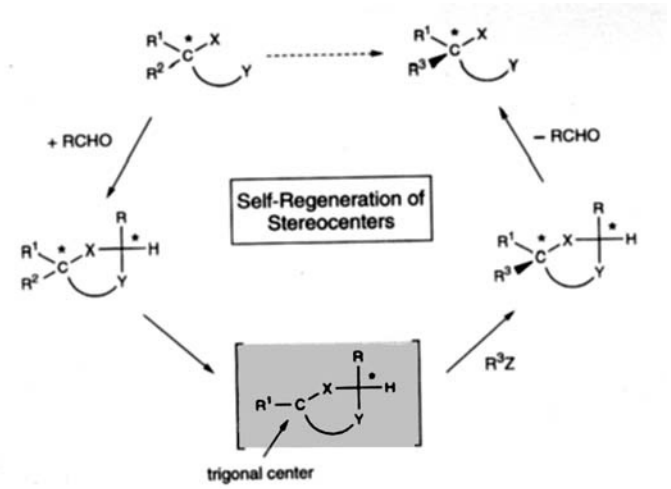
Scheme 2. Some reactions of enantiomerically pure esters and a ketone, which have only one center of chirality in the α-carbonyl position, giving enantiomerically pure or enriched products via the appropriate enolate. a) Enantioselective reaction of an achiral enolate in the presence of a chiral enolate [15]. b) Tetrahydroisoquinoline/aminoindane ring contraction without loss of enantiomeric purity, presumably via an imino-enediolate [16]. Strictly speaking, this is the nitrogen analog of the Wittig rearrangement, with retention of configuration at the migrating C atom (cf. the Stevens, Sommelet, and Hauser rearrangements [17]). c) Stereoselective intramolecular trapping of an enolate by a diazooxoketo group with retention [18]. d) Preparation of an α,α-disubstituted *N*-methylamino acid derivative without the aid of a chiral auxiliary and without a temporary stereogenic center [19]. e) H/Me exchange with inversion of configuration of a 1-naphthylketone (via an axially chiral intermediate?) [20].

center in boron enolates[31] and its enlargement in titanium enolates,[32–34] the activation of the reaction partners with a variety of Lewis acids,[34] and the generation of enolates by the use of metal-free bases such as F^- in Bu_4NF[35] and phosphazenes,[36–38] from silyl enol ethers,[39] or by direct deprotonation.

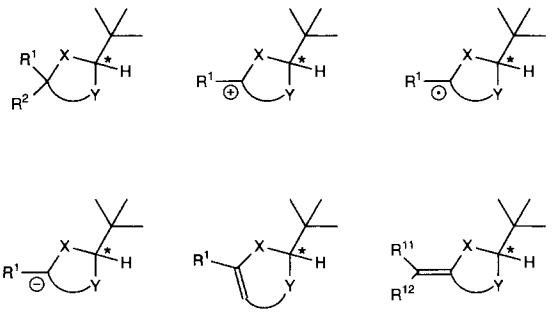
Within the framework of our work over many years devoted to the incorporation of inexpensive, simple, chiral, naturally occurring compounds (the "pool of chiral building blocks"[40]) into complex target molecules, we wondered whether it would be possible to develop some sort of "trick" for producing enolates of α-amino or α-hydroxy acids such that subsequent reactions with electrophiles yield nonracemic products. This led us to a simple yet broadly applicable synthetic principle[41–43] that we call the "Self-Regeneration of Stereocenters" (SRS).[44–48]

Wenn zwei das Gleiche tun,
ist es noch lange nicht Dasselbe.[*]

The principle is extremely simple (Scheme 3): The chiral starting material possessing two functional groups but one (and only



Scheme 3. The principle of the self-regeneration of a stereogenic entity illustrated with the example of a chirality center. In fact, the replacement of one of the four substituents at a single stereogenic center of the starting material requires four steps and is achieved without formation of a racemic product. The auxiliary is an achiral aldehyde.

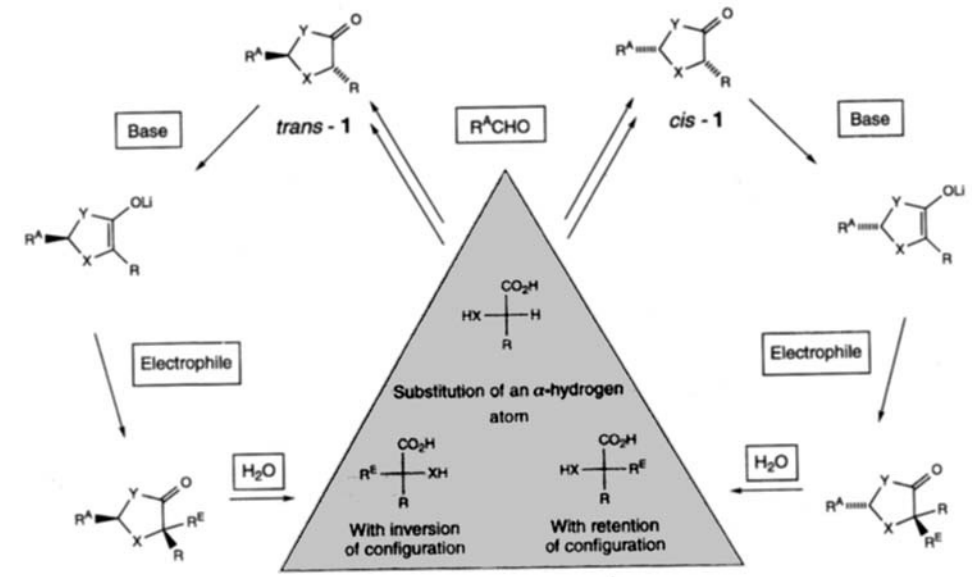


Scheme 4. Chiral species with cationic, radical, and anionic trigonal centers and also those with a π-system, all of which can act as the intermediate in the self-regeneration of a stereocenter (see Scheme 3).

one) stereogenic center is allowed to react with an aldehyde to form an acetal, with preference for one isomer. Annihilation of the original stereogenic center and concomitant formation of a trigonal center yields an intermediate, which, due to the stereogenic center of the acetal, is chiral. Subsequent reaction at the trigonal center proceeds diastereoselectively under the influence of this temporary stereogenic center, and finally, cleavage of the acetal unit leads to a product in which one of the substituents at the stereogenic center of the starting material has been replaced by a new one. The reaction sequence proceeds by dissociative, enantioselective substitution at a center of chirality and without the need for a chiral auxiliary—hence, the name "Self-Regeneration". Of course, an auxiliary is necessary—the aldehyde, which is introduced at the acetalization step and is then regenerated by hydrolysis.

Naturally, an unsymmetrical ketone[49–52] or some other achiral compound can be used in place of the aldehyde such that reaction with the precursor occurs diastereoselectively, and hence, the stereogenic center of the precursor can be destroyed with no cause for concern. The temporary center of chirality can also be replaced by an alternative, but again temporary, element of chirality (axis or plane[53–56], see Section 6).

An illustration of the breadth of possible applications of the SRS principle is given in Scheme 4. It shows suitable reactive intermediates or derivatives, in which the original stereocenter is destroyed by removal of one of the ligands (R^2). Cationic (electrophilic), radical, or anionic (nucleophilic) reactivity can be generated, and endocyclic or exocyclic π-systems can be formed in which one or more trigonal centers with diastereotopic faces are present. In Scheme 4, a *tert*-butyl group is shown as the substituent at the acetal temporary stereogenic center. In our own work in this area, we prefer to use pivalaldehyde as the acetalization reagent for a number of reasons: a) the bulky *t*Bu group results in particularly high diastereoselectivity in the acetalization step (Scheme 3); b) the yields of acetalization are generally good (indeed, they are practically quantitative when the new transition metal catalysts[52] developed by Venanzi et al.[57] are employed); c) the *t*Bu group also leads to high diastereoselectivities in subsequent reactions at the trigonal center; d) the *t*Bu group is completely unreactive (in contrast to the Ph group introduced by the use of benzaldehyde) and enol derivatives cannot be formed; e) since the NMR signal of the



Scheme 5. α-Alkylation of an α-amino, α-hydroxy-, or α-sulfanylcarboxylic acid without racemization. Depending on whether a *cis*-substituted heterocycle **1** (when Y = NH, NCH_3, O) or the other isomer *trans*-**1** (when X = NH, Y = NCH_3) is formed, heterochiral enolates are formed in the deprotonation step, and subsequent diastereoselective alkylation leads to the enantiomerically pure products resulting from electrophilic substitution of the α-carbonyl proton. The letter A in R^A on the aldehyde reagent and at the acetal temporary stereogenic center stands for auxiliary. R^E represents the group in the product introduced by way of the electrophile. Specific examples can be found in Table A in the appendix. Short review articles on imidazolidinones [75] and oxazolidinones [66] derived from amino acids and dioxolanones [67] derived from α-hydroxycarboxylic acids have been published in the *Encyclopedia of Reagents for Organic Synthesis* (see also the reviews in refs. [48, 68]).

*t*Bu group is one sharp singlet, it does not overlap with signals in large areas of the spectrum, and it can also serve as a useful reference in NMR analysis of the crude product; f) pivalaldehyde is available on a large scale (it is obtained as a side-product during the hydroformylation of isobutylene[58] and is also used in the synthesis of fragrances[59]); g) as pivalaldehyde has a low boiling point (74 °C), it can be readily removed after the last step of the reaction sequence shown in Scheme 3, the hydrolysis.[60]

3. Chiral Heterocyclic Enolates of 2-Amino-, 2-Hydroxy-, and 2-Sulfanylcarboxylic Acids

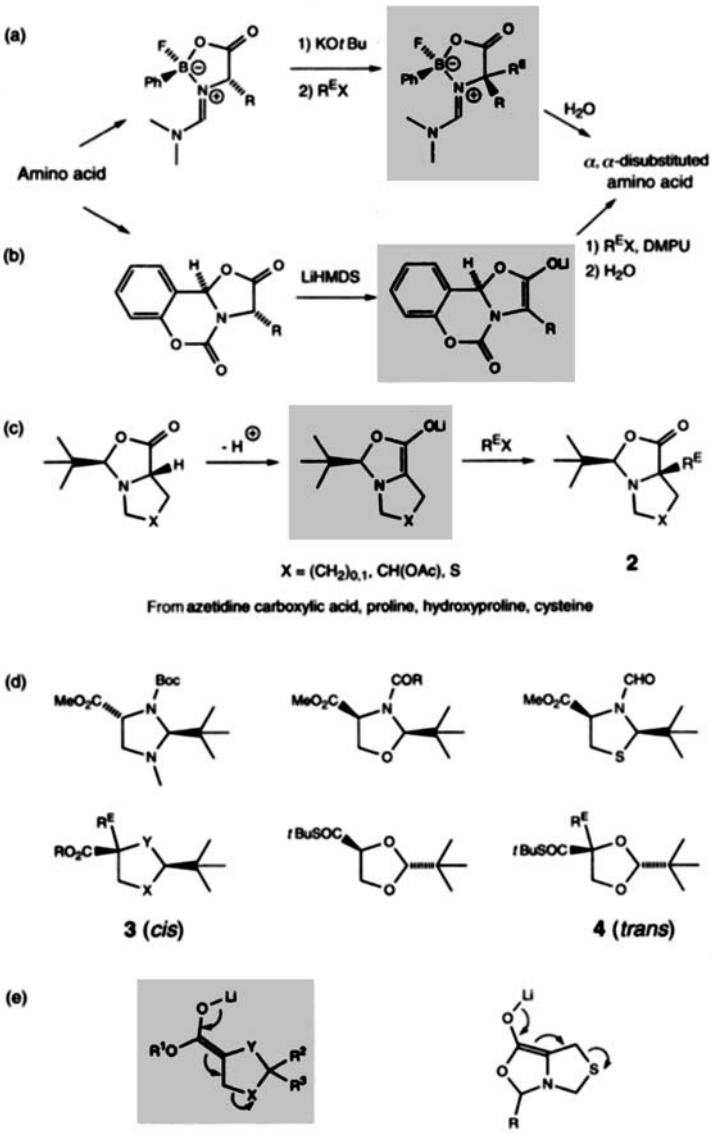
It's the exception that proves the rule!

The twenty proteinogenic amino acids and the related α-hydroxy acids (which are formed by diazotization of the amino acids in aqueous media with retention of configuration), as well as other naturally occurring members of this class of compounds—for example lactic acid, glyceric acid, malic acid, and mandelic acid—provide us with vast reserves of chiral building blocks. By applying the SRS principle these compounds can be alkylated at the stereogenic center to yield products containing a tertiary C atom.[61]

In the acetalization (the first step of the reaction sequence), the *cis*-substituted oxazolidinone, dioxolanone, or thioxolanone usually results from the thermodynamically controlled reaction of the carboxylic acid derivatives listed above.[62] The *cis*-substituted product is also formed in the case of the imidazolidinone derivative,[63, 64] which is obtained from an amino acid amide, and this is the precursor of a particularly reactive Li-enolate. Under kinetic control the reaction leads to the *trans*-imidazolidinone. Hence, acetals derived from (*S*)-amino-, -hydroxy-, and -sulfanylcarboxylic acids can be produced with (*R*) and/or (*S*) configuration at the acetal center. Subsequent formation of the Li-enolate, reaction with an electrophile, and finally cleavage of the acetal results in a wide variety of α-branched, α-heterosubstituted carboxylic acids (see Scheme 5[65-68] and Table A in the appendix, which contains numerous references.[47, 48])

The *cis*-heterocycle **1** is formed with a selectivity that is usually over 90%, and clearly the enantiomeric purity of the intended substitution product cannot exceed the diastereoisomeric purity of the cyclic acetal. It is, therefore, usually necessary to purify these acetals by recrystallization or chromatography.[69] Detailed procedures are available for the preparation of the imidazolidinones (**1**, X = NCOPh, Y = NMe)[63] and oxazolidinones (**1**, X = NCOPh, Y = O)[70, 71] from alanine, phenylalanine, valine, and methionine.[71, 72] The synthesis of the dioxolanone (**1**, X = Y = O, R^A = *t*Bu, R = Me) from lactic acid and pivalaldehyde has also been described.[46, 47] (This compound is obtained with a *cis*/*trans* ratio of 96:4 after crystallization.) Finally, the acid-catalyzed acetalization of malic acid, which yields a dioxolanylacetic acid and not a dioxanone carboxylic acid, has been published.[47, 73, 74]

The Li-enolates of the imidazolidinones have the greatest stability and tolerate reactions with electrophiles at temperatures above 0 °C, whereas enolates of the dioxolanones[46, 47, 75-79] can only be handled at low temperatures. The most successful method for formation of the enolates relies on the use of lithium diisopropylamide (LDA) or hexamethyldisilazanide (LHMDS). All the common electrophiles such as H^+, D^+, alkyl, allyl, and benzyl halides, α-haloesters and amides, aldehydes, ketones, α,β-unsaturated carbonyl compounds, and nitroolefins together with the more unusual ones such as tricarbonyl(benzene)-

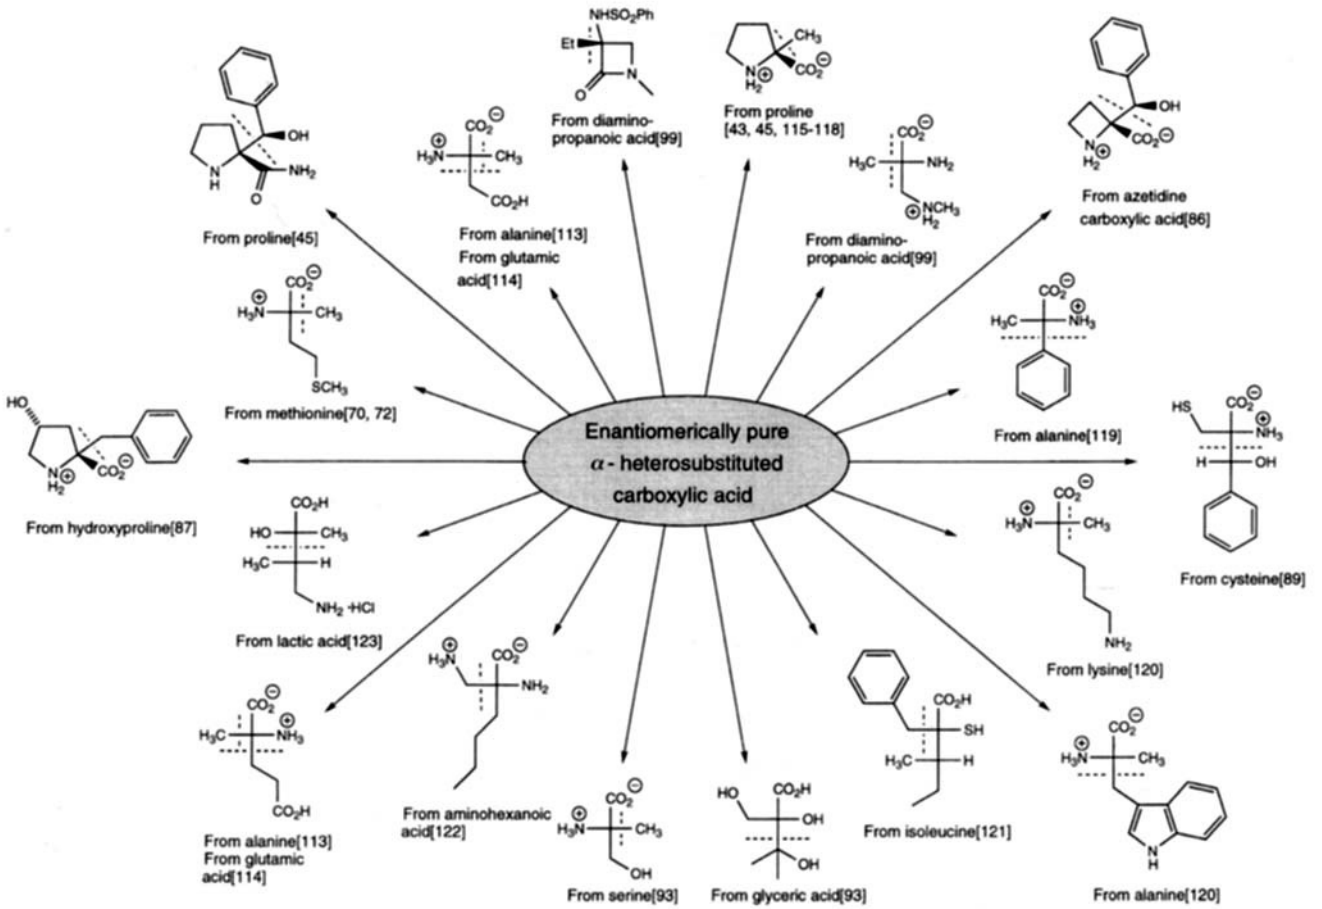


Scheme 6. Further α-alkylations of amino acids following the SRS principle. a) A boraoxazolidinone [84] is alkylated via its K-enolate, and the boron atom serves as the stereogenic center. (This has been applied to phenylalanine, phenylglycine, and valine, which were allowed to react with methyl and propyl iodide, and allyl and benzyl bromide.) b) The amino acids alanine, phenylalanine, and leucine have been methylated and allylated via a tricyclic compound (derived from salicylaldehyde) [85]. c) Alkylation of a cyclic amino acid via a bicyclic enolate [43, 45, 86-89]; enolization of the cysteine derivative (X = S) without β-elimination (see e)) is successful only when a special trick is used (see Section 9) [89, 90]; with *O*-acetyl-hydroxyproline (X = CHOAc), the acetate group is also enolized [87, 88]. d) Branching of 2,3-diaminopropanoic acid [99], serine [93, 100, 101], cysteine [103-109], and glyceric acid [93, 102] via the geminal-disubstituted intermediates **3** and **4**; the Li-enolate intermediate (see e)) with an exocyclic double bond is fairly stable despite the (endocyclic) β-leaving group [93, 102-109]; as can be seen in the case of the cysteine derivative, the stability is very sensitive to the nature of the *N*-acyl group. Only the enolate formed from the formyl derivative is stable enough to undergo alkylation [93, 105-109] (see also Scheme 33 in Section 9). Further examples are given in Scheme 7 and in Tables B and C in the appendix. LiHMDS = lithium hexamethyldisilazanide, DMPU = *N*,*N*′-dimethyl-*N*,*N*′-propyleneurea, Boc = *tert*-butoxycarbonyl.

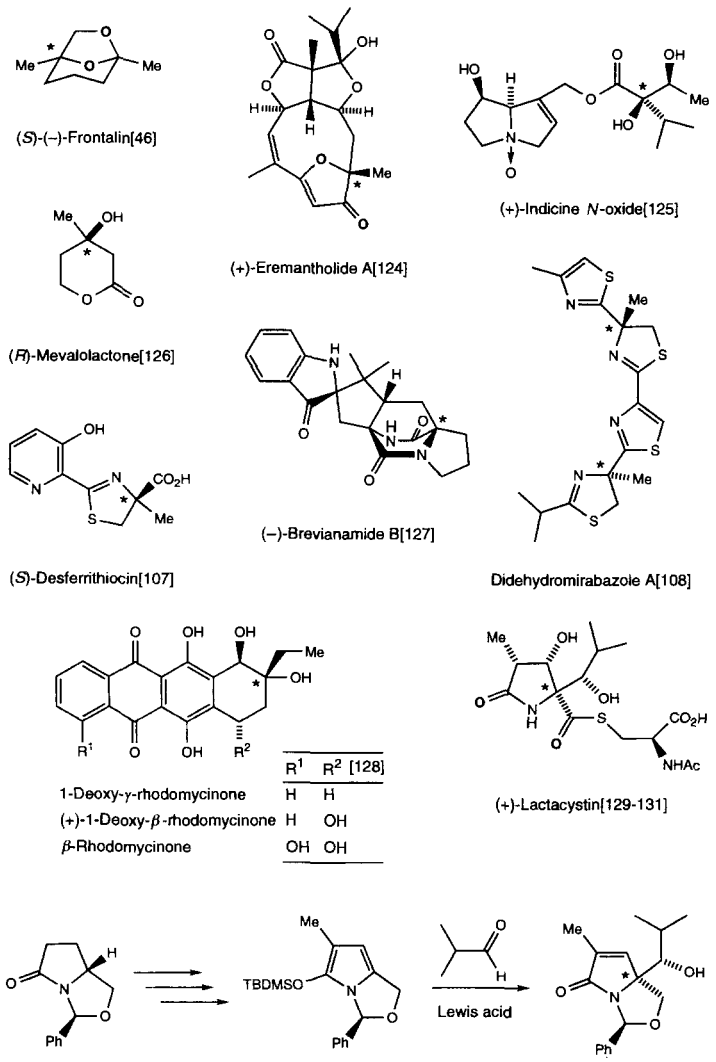
chromium have been employed (see the R^E groups in Table A of the appendix and the accompanying references). The reactions proceed with high selectivity at the face of the enolate double bond[80] opposite to that shielded by the *tert*-butyl substituent on the acetal center. Furthermore, the products are usually highly crystalline or are easily purified by chromatography, such that a single diastereoisomer may be subjected to the final hydrolysis step. As the stereogenic center in the final product (the α-heterosubstituted α,α-disubstituted carboxylic acid) is stable, rather drastic conditions may be used for the hydrolysis of the heterocycles in the last step of the SRS sequence of Scheme 5.[64, 81–83]

α-Substituents have also been introduced to simple amino acids via other heterocyclic derivatives and their enolates. In the particularly clever "trick" outlined in Scheme 6a the temporary stereogenic center is a boron atom, and, of course, hydrolysis after the alkylation can be achieved under very mild conditions in this case.[84] Salicylaldehyde has also been employed as an achiral auxiliary for the SRS alkylation of amino acids (see Scheme 6b).[85] Cyclic amino acids such as azetidine carboxylic acid,[86] proline,[43, 45] hydroxyproline,[87, 88] and the cysteine derivative 4-thiaproline[89, 90] may be alkylated via bicyclic enolates, which react with a wide variety of electrophiles at the *exo* face exclusively (see **2** in Scheme 6c and Table B in the appendix).[91–98]

The heterocycles derived from 2,3-diamino-,[99] 2-amino-3-hydroxy-,[93, 100, 101] and 2,3-dihydroxycarboxylic acids[93, 102] (Scheme 6d) are of particular interest. *cis*/*trans* Mixtures are formed during acetalization and the diastereoisomeric purity is highly dependent upon reaction conditions (thermodynamic control for acid catalysis,[62, 93, 101–109] kinetic control for Rh^{3+} catalysis[52, 57]), upon the substitution of the ring, and upon the nature of the heteroatoms in the ring. Both the oxazolidine[93, 100, 101] and the thiazolidinecarboxylic esters[103–109] are normally formed as 1:1 *cis*/*trans* mixtures. However, the subsequent *N*-acylation results in the formation of only the *cis* derivative.[62, 93, 100, 101, 103–110] The enolates of the N,N-, N,O- and N,S-heterocycles are alkylated from the side opposite to that shielded by the *tert*-butyl group to give the products *cis*-**3** (Scheme 6d[100, 104–109]). The reactivity of the glyceric acid derivative is somewhat different: the *tert*-butylthiol ester cyclizes preferentially (5:1) to give the *trans* product, and subsequent alkylation occurs *cis* to the *t*Bu group (→ **4**).[93, 102] The enolates of the heterocyclic carboxylic esters have a range of stabilities with regard to β-elimination (Scheme 6e left), which should, in fact, be stereoelectronically unfavorable.[111] In spite of this problem, very high yields of the required product can be obtained under suitable reaction conditions. Examples with references can be found in Table C of the appendix and in Schemes 7 and 8, in which structures of some amino acids and natural products are shown that have been prepared using the intermediates shown in Schemes 5 and 6c,d,e or by different applications of the SRS principle.[112–131]



Scheme 7. Selected examples of α,α-disubstituted α-heterocarboxylic acids prepared following the SRS principle described in Schemes 5 and 6. TBDMS = *tert*-butyldimethylsilyl.



Scheme 8. At least one step in the syntheses of the natural products shown here follows the principle of self-regeneration of stereocenters; the tertiary carbon atoms formed in this way are marked by an asterisk. (*S*)-(−)-Frontalin was obtained by alkylation of the enolate of *cis*-**1** (X = Y = O, R^A = *t*Bu, R = Me, Scheme 5, derived from lactic acid) with 1-iodo-4,4-dimethoxypentane, reduction with lithium aluminium hydride, and interchange of acetals. The key step in the synthesis of (+)-eremantholide A was the reaction of the same lactic acid enolate with 2,3-dibromopropene; the final product was obtained after many more steps. In the alkaloid (+)-indicine *N*-oxide the carboxylic acid unit in the ester side chain was prepared by hydroxyalkylation of *cis*-**1** (X = Y = O, R^A = *t*Bu, R = *i*Pr) with acetaldehyde in 43% yield. (*R*)-Mevalolactone was prepared from both lactic acid (via *cis*-**1** (X = Y = O, R^A = *t*Bu, R = Me)) and malic acid (**1**, X = Y = O, R^A = *t*Bu, R = CH_2CO_2*t*Bu) following the SRS principle. The important point about this synthesis is that labels (^{13}C, ^2H, ^3H) can be introduced at numerous positions to produce derivatives suitable for biosynthetic investigations. Proline was the starting point for an elegant total synthesis of brevianamide B. The synthesis proceeded via compound **2** (R^E = allyl), which was prepared by the reaction of the bicyclic compound shown in Scheme 6c (X = CH_2) with allyl bromide. The mirabazoles are a group of alkaloids that all contain an α-methylcysteine functionality. Dehydromirabazole A was synthesized from the methyl ester of α-methylcysteine, which was obtained from the appropriate heterocycle of type *cis*-**3** (Y = NCHO, X = S, R = Me, R^E = Me, Scheme 6). α-Methylcysteine was employed in the same way in the synthesis of (*S*)-desferrithiocin. The synthesis of rhodomycinone began with enantiomerically pure (*S*)-aminobutanoic acid, which was converted into the hydroxy acid by diazotization. Subsequent reaction of the enolate of **1** (X = Y = O, R^A = *t*Bu, R = Et, Scheme 5) with allyl bromide proceeded in the normal manner. Reduction of the carbonyl functionality with DIBAH, acetal interchange, and ozonolysis led to the 1,4-dialdehyde, which was suitably protected such that a Marschalk reaction with the appropriately substituted anthrahydroquinones could then be carried out. This resulted in the formation of the rhodomycinones. The total synthesis of (+)-lactacystin was achieved by three different routes; two [129, 130] followed the SRS principle and the third used the strategy described in ref. [92]. The synthesis carried out by E. J. Corey and co-workers [129] began with the oxazolidine derived from serine, which was hydroxyalkylated with isobutyraldehyde to yield a product of type *cis*-**3** (X = O, Y = BnN, R = Me, R^E = $Me_2CHCH(OH)$, Scheme 6); J. E. Baldwin and co-workers described an extremely sophisticated application of the SRS principle. Pyroglutamic acid was allowed to react with benzaldehyde and then reduced to the bicyclic compound, shown in the last line. A series of subsequent steps led to the silyloxypyrrole shown, which reacted stereoselectively with isobutyraldehyde in the following key step.

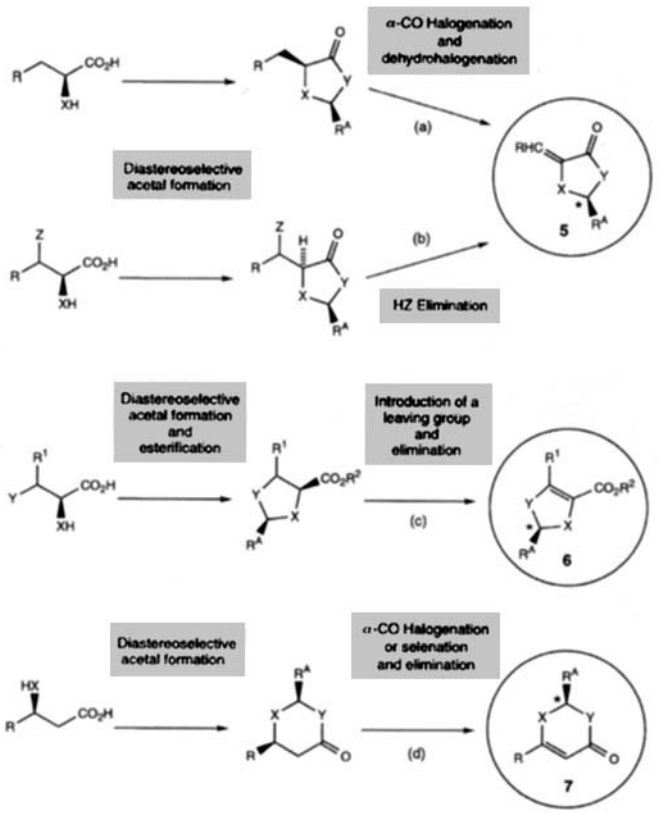
4. Using the SRS Principle in the Preparation and Reactions of α,β-Unsaturated, α- and/or β-Heterosubstituted Carboxylic Acid Derivatives (Dienolates, Radicals, Michael Acceptors, and Components for Cycloadditions)

Ich habe nicht mehr Glück als Sie, aber ich probiere mehr als Sie![*]

Adolf von Baeyer

Cyclic acetals with endo- or exocyclic C–C double bonds must be prepared in order to introduce new substituents at the position β or γ to a carbonyl group of a chiral, heterosubstituted carboxylic acid, as was described in the previous scheme for the α-position. This can be achieved in a number of ways (Scheme 9). Firstly, the familiar five-membered cyclic acetal is prepared diastereoselectively from an aldehyde R^ACHO and the α- or α,β-amino-, -hydroxy-, or -sulfanylcarboxylic acids. Subsequently, the resulting dioxolanones, oxazolidinones, and imidazolidinones can be, for example, brominated by means of a radical process. Such brominations display a surprisingly high preference for the CH-position adjacent to the carbonyl group (captodative radical stabilization[132]) over the acetal center (this has a bulky R^A substituent, *t*Bu, and is therefore sterically hindered).[133–136] Diastereoselectivity was observed early on in brominations that proceed via an α-carbonyl radical intermediate[133] (see Section 9.3) rather than via an enolate (Schemes 5 and 6). Elimination of HBr then leads to acetals **5**, which have an exocyclic double bond (Path a in Scheme 9). In the simplest case (R=H), these are chiral non-racemic derivatives of α-hydroxy- or α-aminoacrylic acid, in other words, of pyruvic acid! An alternative method (Path b in Scheme 9) begins with a carboxylic acid bearing functional groups in the α- and β-positions. After the necessary functional group manipulations, a five-membered cyclic acetal with a leaving group in the exocyclic position β to the carbonyl group is obtained and hence, the alkylidene derivative **5** can now be readily prepared.[137–139] Furthermore, the oxazoline and thiazoline carboxylic esters **6**, heterocycles with conjugated endocyclic C–C double bonds, can be prepared from the appropriate acetals of serine, threonine,[140] and cysteine[103, 104] (Schemes 6d and 9c). Finally, perhydropyrimidinones[62, 141–149] and dioxanones[150–162] can be prepared diastereoselectively from β-amino- and β-hydroxycarboxylic acids, respectively, by a variety of

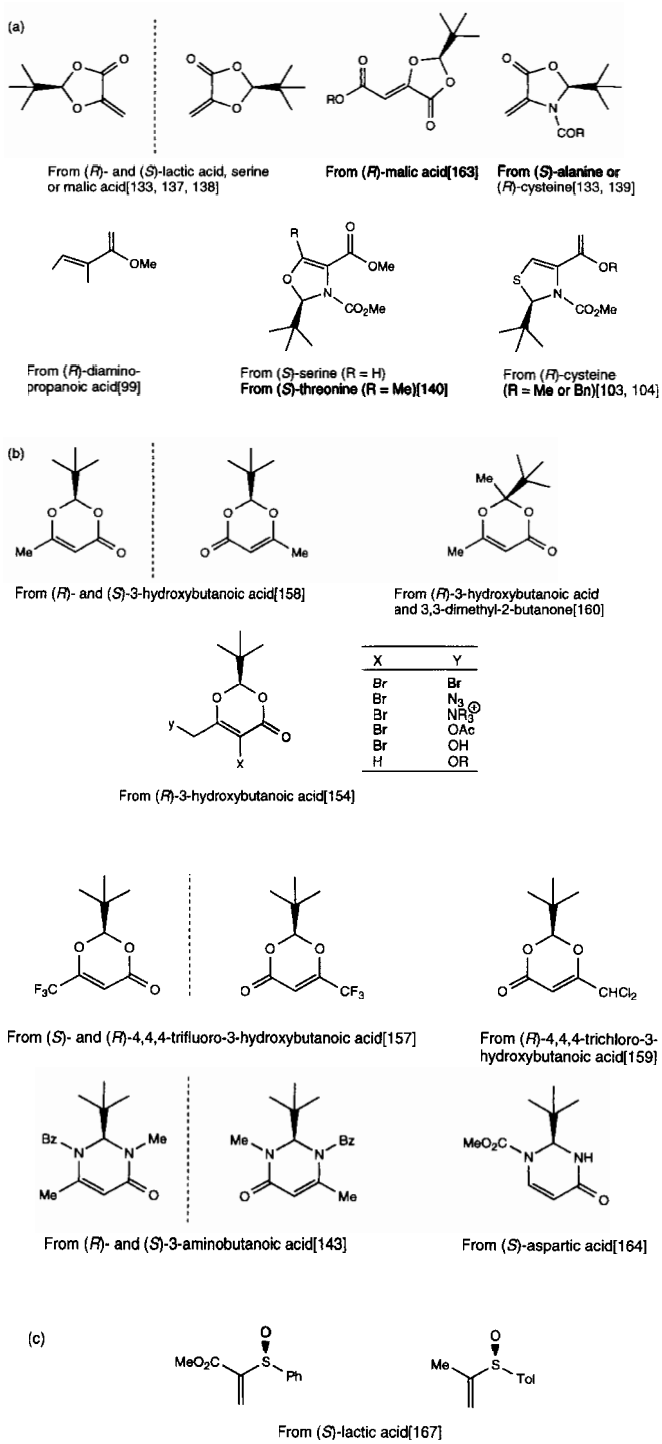
[*] "I am not luckier than you, I simply try harder!"



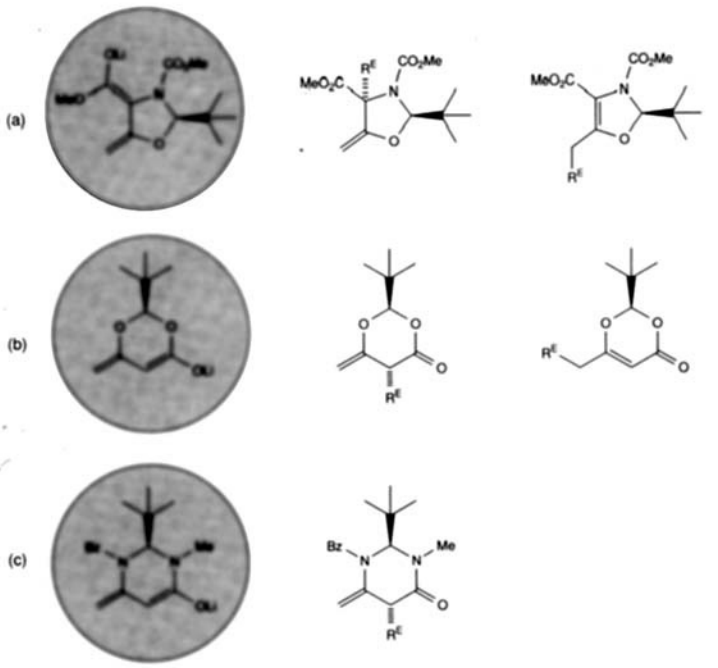
Scheme 9. Preparation of chiral α,β-unsaturated carbonyl compounds from amino-, hydroxy-, and sulfanylcarboxylic acids with destruction of the original stereogenic center in the position α or β to the carbonyl group. (For specific examples, see Scheme 10; for further reactions, see Schemes 11–14. See the text for a discussion of pathways (a)–(d). Tables D1–D4 in the appendix give examples of the applications of these heterocycles.)

methods. Subsequent formal dehydrogenation leads to the heterocyclic α,β-unsaturated carbonyl compounds **7** (Scheme 9d), which are, in fact, chiral, nonracemic acetals of, for example, acetoacetic acid and other β-ketocarboxylic acids.

The formulas of several five- and six-membered cyclic heterocycles with α,β-unsaturated carbonyl functionality, together with the appropriate precursors and literature references are given in Schemes 10a and b.[163–166] An α-sulfinylacrylate and a 2-propenylsulfoxide are depicted in Scheme 10c; here, the stereogenic center of a sulfoxide, rather than that of an acetal, is utilized to preserve the chirality of the Michael acceptor.[167, 168] These readily prepared α,β-unsaturated carbonyl compounds can be used as chiral building blocks in a variety of processes: the Michael addition of nucleophiles (such as cuprates or Cu^I-doped Grignard reagents), the addition of radicals, in cycloadditions (photochemical [2+2] cycloadditions, Diels–Alder reactions), and catalytic *cis*-hydrogenations or deuterations. Reactions with electrophiles are also possible (via the dienolates shown in Scheme 11), and in this way new substituents can be introduced at the position α or γ to the carbonyl group (see the examples in Schemes 11a–c). An assortment of products, which may be prepared by various types of additions at the C–C double bond of the heterocyclic acceptors discussed above, is shown in Scheme 12.[169–176] Structures derived from

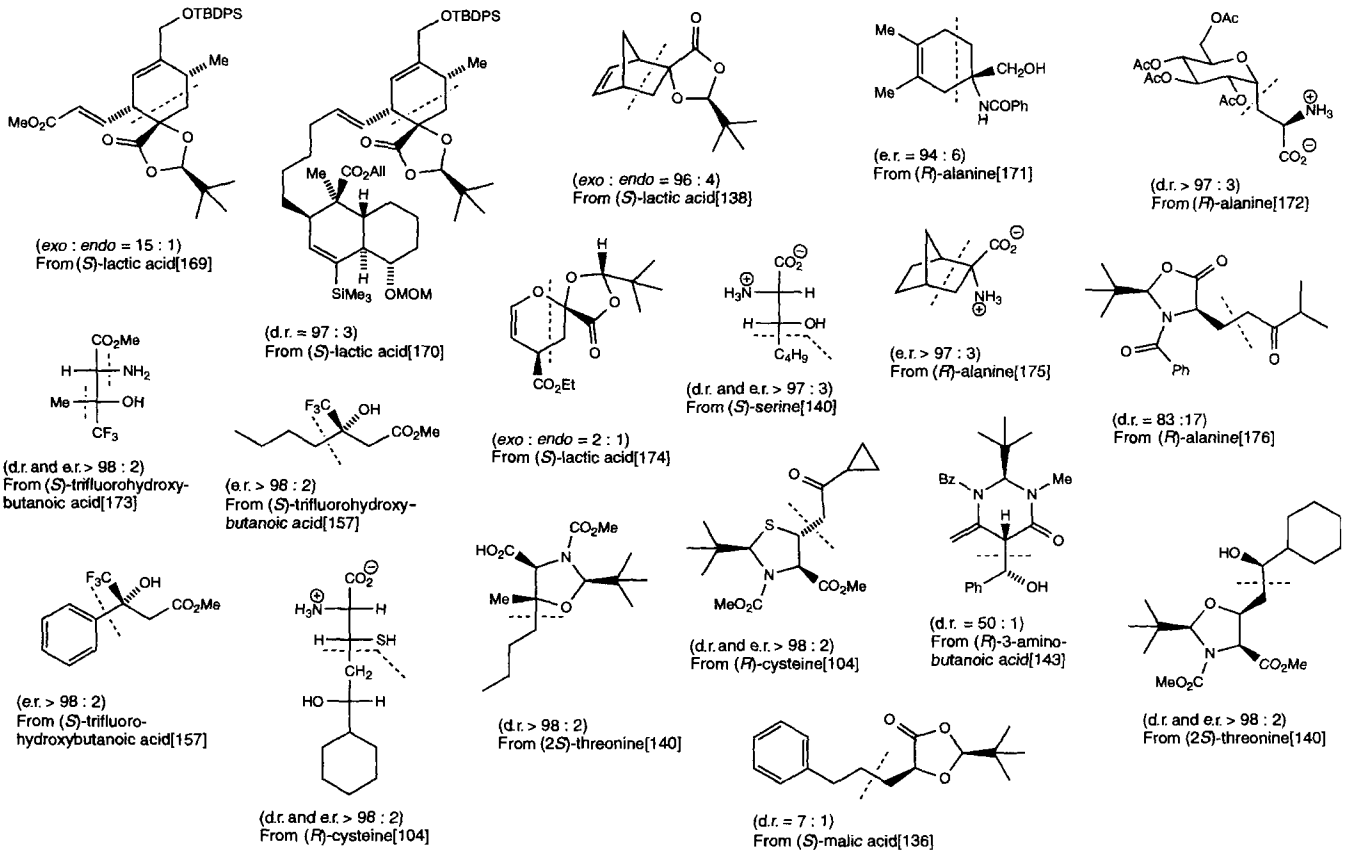


Scheme 10. Chiral products of formal dehydrogenation derived from lactic acid, malic acid, 3-hydroxybutanoic acid, and the amino acids alanine, serine, threonine, cysteine, aspartic acid, and 3-aminobutanoic acid. a) Five-membered ring heterocycles from α- and α,β-disubstituted carboxylic acids. b) Six-membered ring heterocycles from β-hydroxy and β-amino acids. c) Chiral, noncyclic sulfoxides from lactic acid. Subsequent products are depicted in Schemes 11–14 and in Tables D1–D4 in the appendix. For short review articles with information on methylene derivatives of dioxolanones [67], oxazolidinones [66], oxazolidine dicarboxylates [165], and dioxinones [166] see the *Encyclopedia of Reagents for Organic Synthesis*. Bz = COC_6H_5, Tol = $C_6H_4CH_3$.

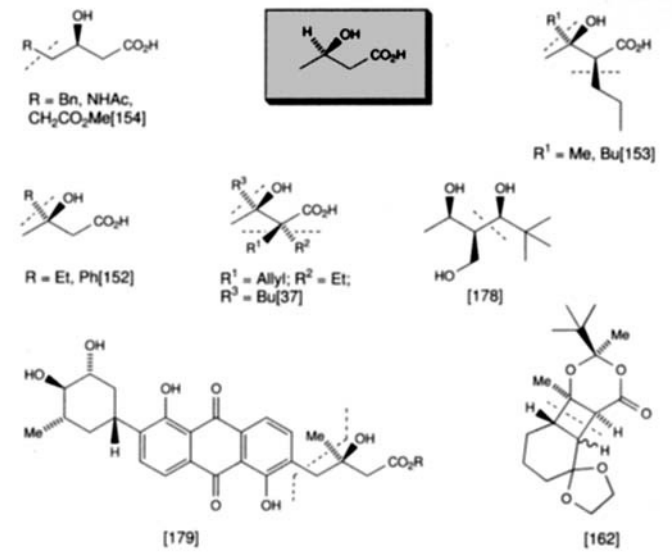


Scheme 11. Chiral Li-dienolates derived from threonine (a), 3-hydroxybutanoic acid (b), and 3-aminobutanoic acid (c) together with products resulting from their reactions with electrophiles. Specific examples are given in Schemes 12 and 13.

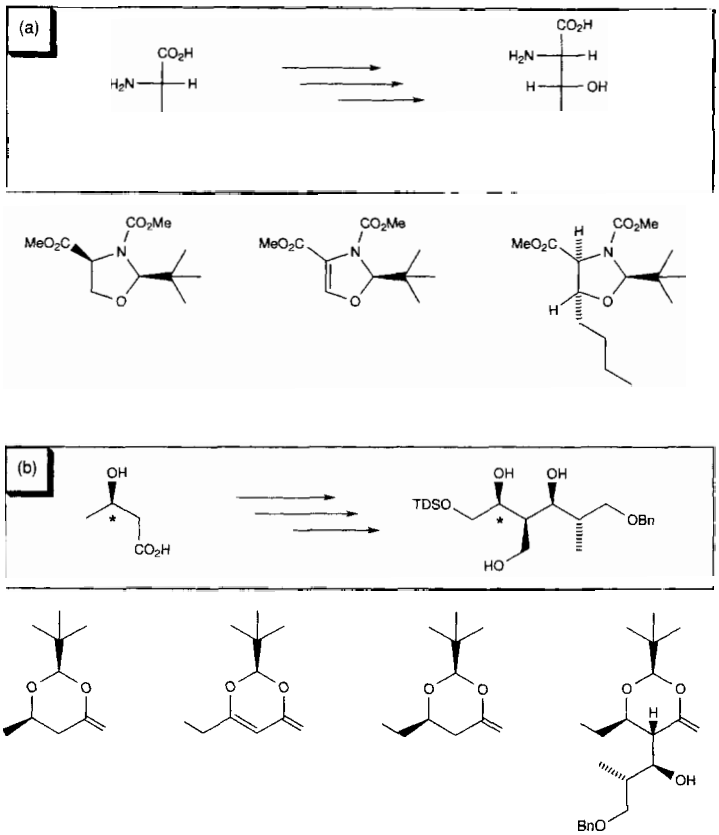
3-hydroxybutanoic acid[151, 177] and constructed via the previously mentioned dioxinones **7** (Schemes 9d, 10b, and 11b) are depicted in Scheme 13.[178–180] Finally, Tables D1–D4 in the appendix document, in as complete a fashion as possible, previous applications of the SRS principle to reactions of α,β-unsaturated carbonyl compounds. It is not always immediately clear that self-regeneration is involved in these processes; the two examples shown in Scheme 14 should demonstrate this point. In the first case, a hydrogen atom at the C3 position of serine is replaced by a butyl group in a diastereoselective fashion,[140] and apparently nothing has happened at the original stereogenic center of serine. However, upon closer examination of the reaction sequence, it becomes clear that substitution at the C2 position has also occurred: The H atom is initially replaced with bromine by reaction with *N*-bromosuccinimide (NBS); the trigonal center of the enolate, which is generated by cuprate addition, is then diastereoselectively protonated such that a "new" hydrogen atom occupies the 2-position of the chain-extended serine derivative! Similarly in the second reaction sequence shown in Scheme 14 (part of a synthesis of soraphen[181]), the stereogenic center (indicated by an asterisk) of the hydroxy acid starting material appears to be present in an unchanged form in the product. In reality, however, this reaction sequence relies on the use of a temporary trigonal center at every C atom: Func-



Scheme 12. Selected examples of products prepared via the unsaturated heterocycles shown in Schemes 9–11. Dashed lines are used to mark the newly formed bonds, which result from Michael additions, radical additions, Diels–Alder reactions, and reactions of enolates and dienolates with electrophiles; further examples are given in Schemes 13 and 14 and also in Tables D1–D4 in the appendix. Complete details can be found in the literature references. TBDPS = *tert*-butyldiphenylsilyl, All = allyl, MOM = methoxymethyl.



Scheme 13. Products prepared from (*R*)-3-hydroxybutanoic acid in which the preparation involves the temporary destruction of the original stereogenic center; see the dioxinone derivatives in Schemes 9d, 10b, 11b, 14b and in Tables D3 and D4 of the appendix. Of course, the methods used here are not only applicable to both enantiomers of hydroxybutanoic acid but are also generally applicable to 3-hydroxycarboxylic acids (for example, see ref. [180]).



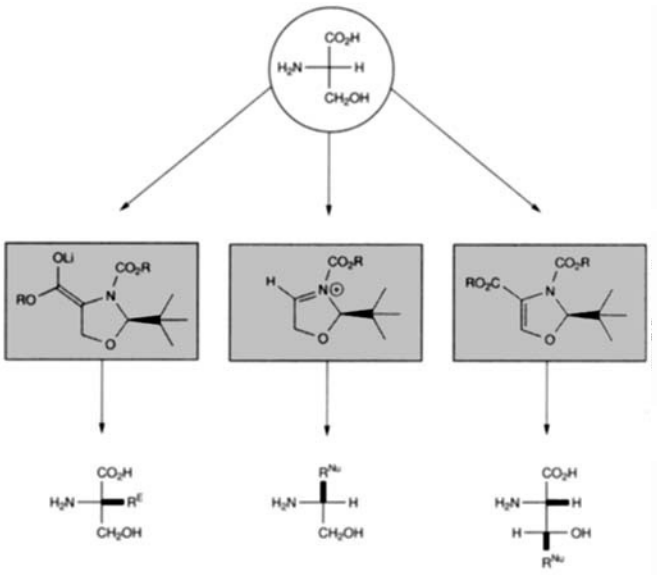
Scheme 14. Reactions of serine (a) [140] and (*R*)-3-hydroxybutanoic acid (b) [181] with substitution of the hydrogen atom in the position β or γ to the carbonyl functionality by C_4H_9 or RO groups. The formulas of the most important intermediates are shown. The original stereogenic center is temporarily destroyed in order to achieve the necessary reactivity at the 3- or 4-position of the carbon skeleton. In both products, an H atom (at C2 of serine and at C3 of hydroxybutanoic acid) is stereoselectively replaced (with retention!) by a new one; this could have been proved by deuterolysis in case (a) and by the use of D_2 in case (b).

tionalization of the terminal CH_3 group of the hydroxybutanoic acid is only possible via the dioxinone derivative, and the hydrogen atom at the C atom marked by the asterisk is derived from the H_2 used in a catalytic hydrogenation step!

5. SRS via Acyliminium Ions and the Resulting Products

Umpolung doubles the possibilities.

In the previous two sections we have shown that new substituents can be introduced, without racemization, at the 2- or 3-position of carboxylic acids by means of enolate and enoate chemistry with the aid of electrophilic and nucleophilic reagents. The crucial intermediates derived from serine for the preparation of modified 2-amino-3-hydroxycarboxylic acids are depicted in Scheme 15. In all of the previous examples, it has been a hydrogen atom that has been replaced by a new substituent.

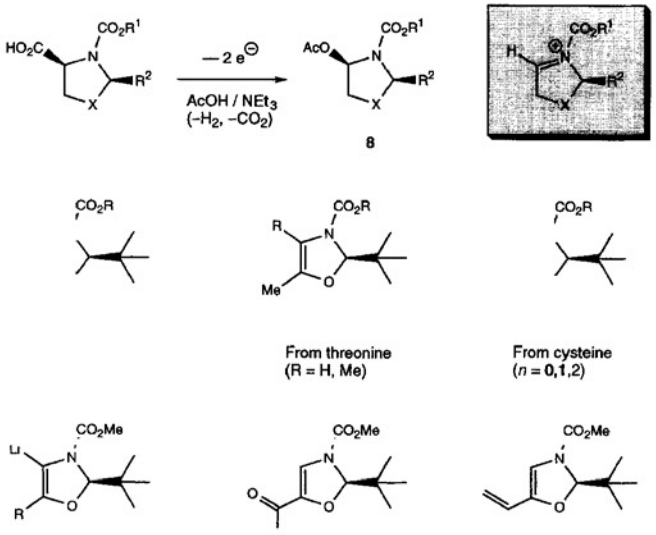


Scheme 15. Stereoselective replacement of H atoms and of the CO_2H group of serine by new substituents following the SRS principle. Bonds marked in bold are those resulting from this transformation and do not break the convention used for the depiction of Fischer projections (see center and right). The alkylation yielding the α,α-disubstituted amino acid (left) and the modification resulting in chain extension at the C atom in β-position (right) are also possible with simple amino acids such as alanine (Schemes 5, 9a, 10a), whereas the decarboxylation (center) [182] is not.

However, in the case of the trifunctional amino acids such as serine, threonine, cysteine, and aspartic acid the SRS principle can be applied to replace the carboxyl functionality with other groups. For example, in the case of aspartic acid, the reaction sequence proceeds via the dihydropyrimidinone[145–149] (shown in Scheme 10b), and for serine, the acyliminium ion[182] (shown in the center of Scheme 15) is involved. As can be seen, the carboxyl group is replaced by a new substituent R^{Nu}, which is introduced by the use of a nucleophilic reagent (umpolung of the nucleophilic reactivity of the Li-enolate to produce electrophilic reactivity at the former C2 of the acid). Interestingly, these reactions often proceed in a far superior fashion when an *i*Pr rather than the usual *t*Bu substituent is present at the tempo-

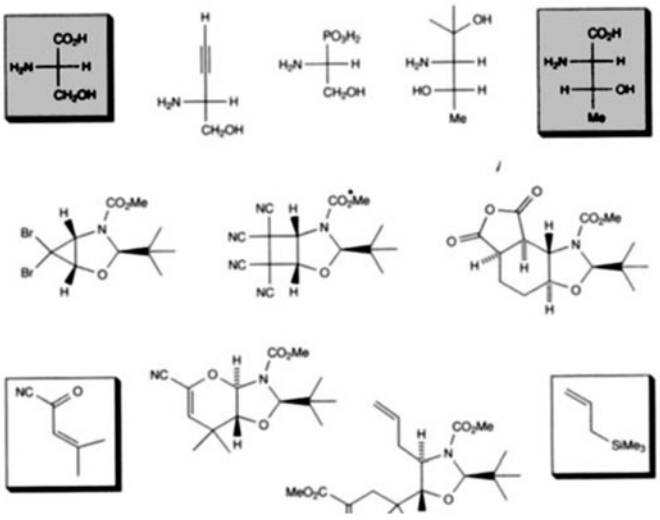
rary stereogenic center, and generally the new substituent enters *cis* to the substituent at the acetal C atom![183]

The key step in the removal of the carboxyl group from the derivatives of serine, threonine, and cysteine is the electrolytic anodic oxidation of the carboxylic acid. Faraday[184] and Kolbe[185] demonstrated that simple carboxylic acids are coupled under these conditions ($2\,RCO_2H \rightarrow R-R + 2CO_2 + H_2$), and Hofer and Moest[186] showed that oxidative decarboxylation occurs with carboxylic acids when R is a cation-stabilizing substituent ($RCO_2H + R'OH \rightarrow ROR' + CO_2 + H_2$). The reaction of the amino acids mentioned occurs as shown at the top of Scheme 16. In contrast to most other electrolysis procedures,



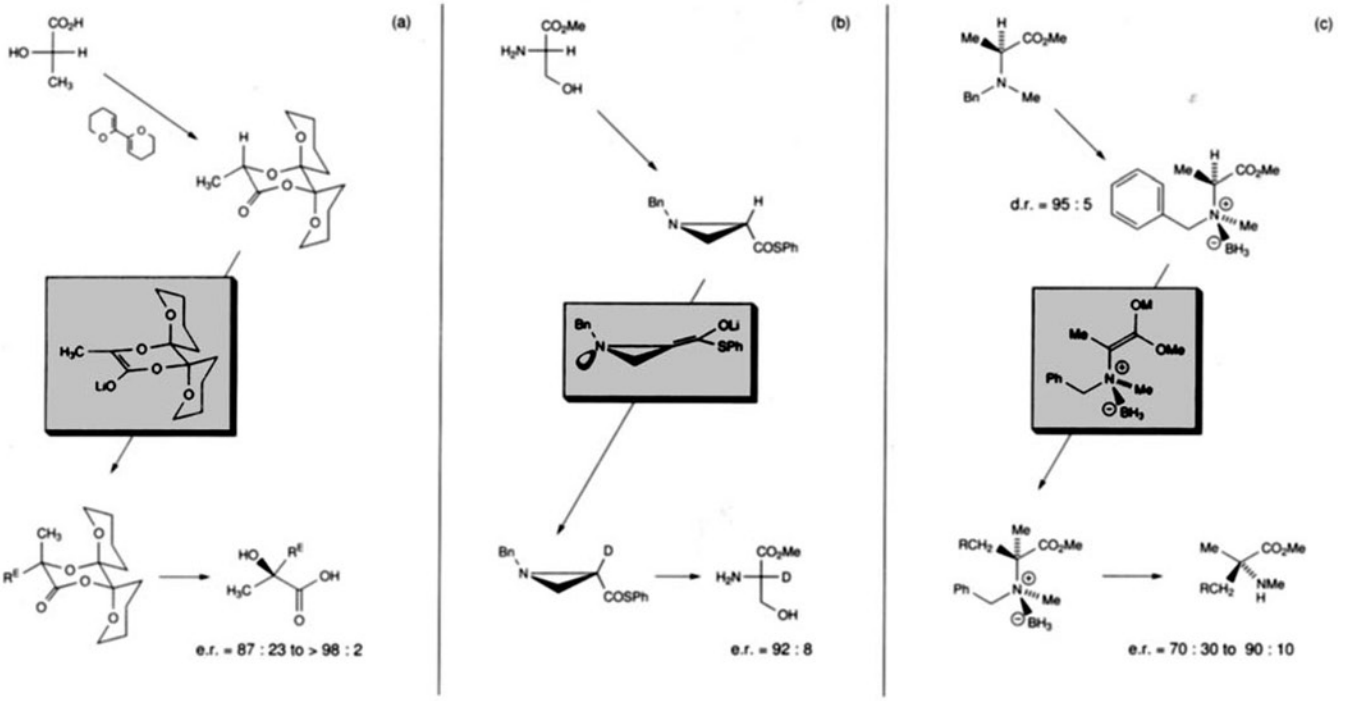
Scheme 16. Electrolysis of the oxazolidine and thiazolidine carboxylic acids (e.g. **8**) derived from L-amino acids, elimination of HOAc to yield the oxazoline and thiazoline derivatives (e.g. **9**), and electrophilic substitution at the C–C double bond by means of lithiation or by direct Vilsmeier formylation (subsequent Wittig olefination produces the electron-rich diene **10**) [101, 103, 140, 182, 190]. A short review article about **9** has been published in the *Encyclopedia of Reagents for Organic Synthesis* [165].

this decarboxylation is a simple, easily conducted reaction. The electrodes need not be separated by diaphragms and the addition of a supporting electrolyte is also not required. A solution of the oxazolidine[101] or oxidothiazolidine carboxylic acid[103] in a protic solvent such as acetic acid (this is much less susceptible to decarboxylation!) or methanol is mixed with triethylamine (formation of the supporting electrolyte, $RCO_2^- Et_3NH^+$) and then electrolyzed in an undivided cell until the gas evolution ceases and the conductivity falls due to complete consumption of the carboxylate. This reaction can be carried out at high concentrations of the carboxylic acid on a multigram scale and results in excellent yields of the decarboxylated product (**8**, X = O, R^1 = Me, R^2 = *t*Bu, ca. 90% yield for the decarboxylation step, ca. 55% yield from serine over four steps;[101] the 2-isopropyl derivative can be prepared analogously). Here again, the *cis*-acetoxyoxazolidine is produced, which results from attack of the acyliminium salt (shown in the box in Scheme 16) at the apparently more sterically hindered face.[183] Lewis acid assisted nucleophilic substitution of the AcO group of the useful, readily available, enantiomerically pure derivatives **8**[140, 187–194] can be performed, and once again, this proceeds via the acyliminium ion. Products obtained from the reaction with bis(trimethylsilyl)acetylene or from the Michaelis–Arbuzov reaction (triphenylphosphite/$TiCl_4$) (yields of 80 and 95%, respectively; diastereoselectivities of 90 and 80%, respectively) are shown at the top of Scheme 17.[182, 195]



Scheme 17. Top: An acetylenic amino alcohol and a phosphoserine derived from heterocycle **8** [182, 195], which is shown in Scheme 16 and derived from serine; an amino diol prepared by addition of the Li threonine derivative from Scheme 16 to acetone, hydrogenation of the double bond, and hydrolysis [140]. Middle: Compounds resulting from addition of dibromocarbene, tetracyanoethylene, and an acyl cyanide to heterocycle **9**; a product with four neighboring stereogenic centers (two of which are derived from serine) results from hydrogenation of the Diels–Alder adduct of maleic anhydride and diene **10** [192]. Bottom: The addition of the α,β-unsaturated acyl cyanide to **9** apparently proceeds via a zwitterion (enolate/acyl iminium ion) and results in the formation of a *trans*-fused bicyclic compound. The allylation of this compound (allylsilane/$TiCl_4$, Sakurai method) proceeds *cis* to the *tert*-butyl group with formation of a 6-amino-5-hydroxy-4,4-dimethyl-2-oxonon-8-ene carboxylic acid derivative (the two C atoms derived from serine in the C_9 chain are both stereogenic centers).

Nucleophilic substitution of the electrolysis products **8**, derived from serine, threonine, and cysteine, gives these intermediates a wide-ranging potential in synthesis. Elimination of acetic acid yields the heterocycles shown in the center of Scheme 16, which have highly reactive C–C double bonds. The oxazoline **9** contains the structural features of both an enol ether and an *N*-acyl-enamine.[101, 140, 182, 190, 192] The hydrogen atoms at the double bond of **9** can be substituted by means of an *N*-acyl-directed metalation (next to the N atom) and by the use of a Friedel–Crafts type reaction (next to the O atom). Here, once again, the stability of the acyliminium ion is responsible for the regioselectivity of the kinetically controlled reaction with electrophiles[140, 192, 196] (see the formyl- and vinyloxazoline carboxylic acid ester **10** in Scheme 16 and the bicyclic and tricyclic species in Scheme 17, resulting from cycloaddition reactions). The relative configuration of the products, which are frequently formed with complete diastereoselectivity, was assigned by chemical correlation or NMR spectroscopy. All products are enantiomerically pure and all are also available in the enantiomeric form by the use of D- instead of L-serine, -threonine, or -cysteine.



Scheme 18. Three applications of the SRS principle in which the temporary stereogenic center is a) a spiroacetal C atom [205], b) an aziridine nitrogen atom [208], and c) a nitrogen atom of a boron–amine adduct $R^1R^2R^3N^+BH_3^-$ [211].

6. Other "Tricks" for the Self-Regeneration of Stereocenters

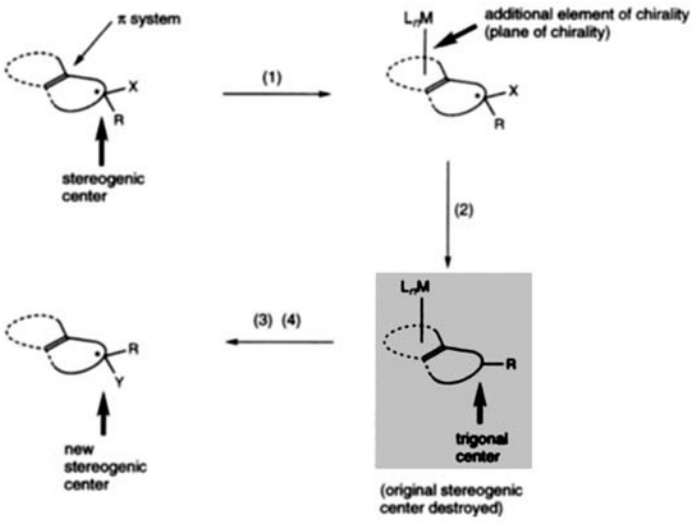
Phantasie ist wichtiger als Wissen.[*]

Albert Einstein

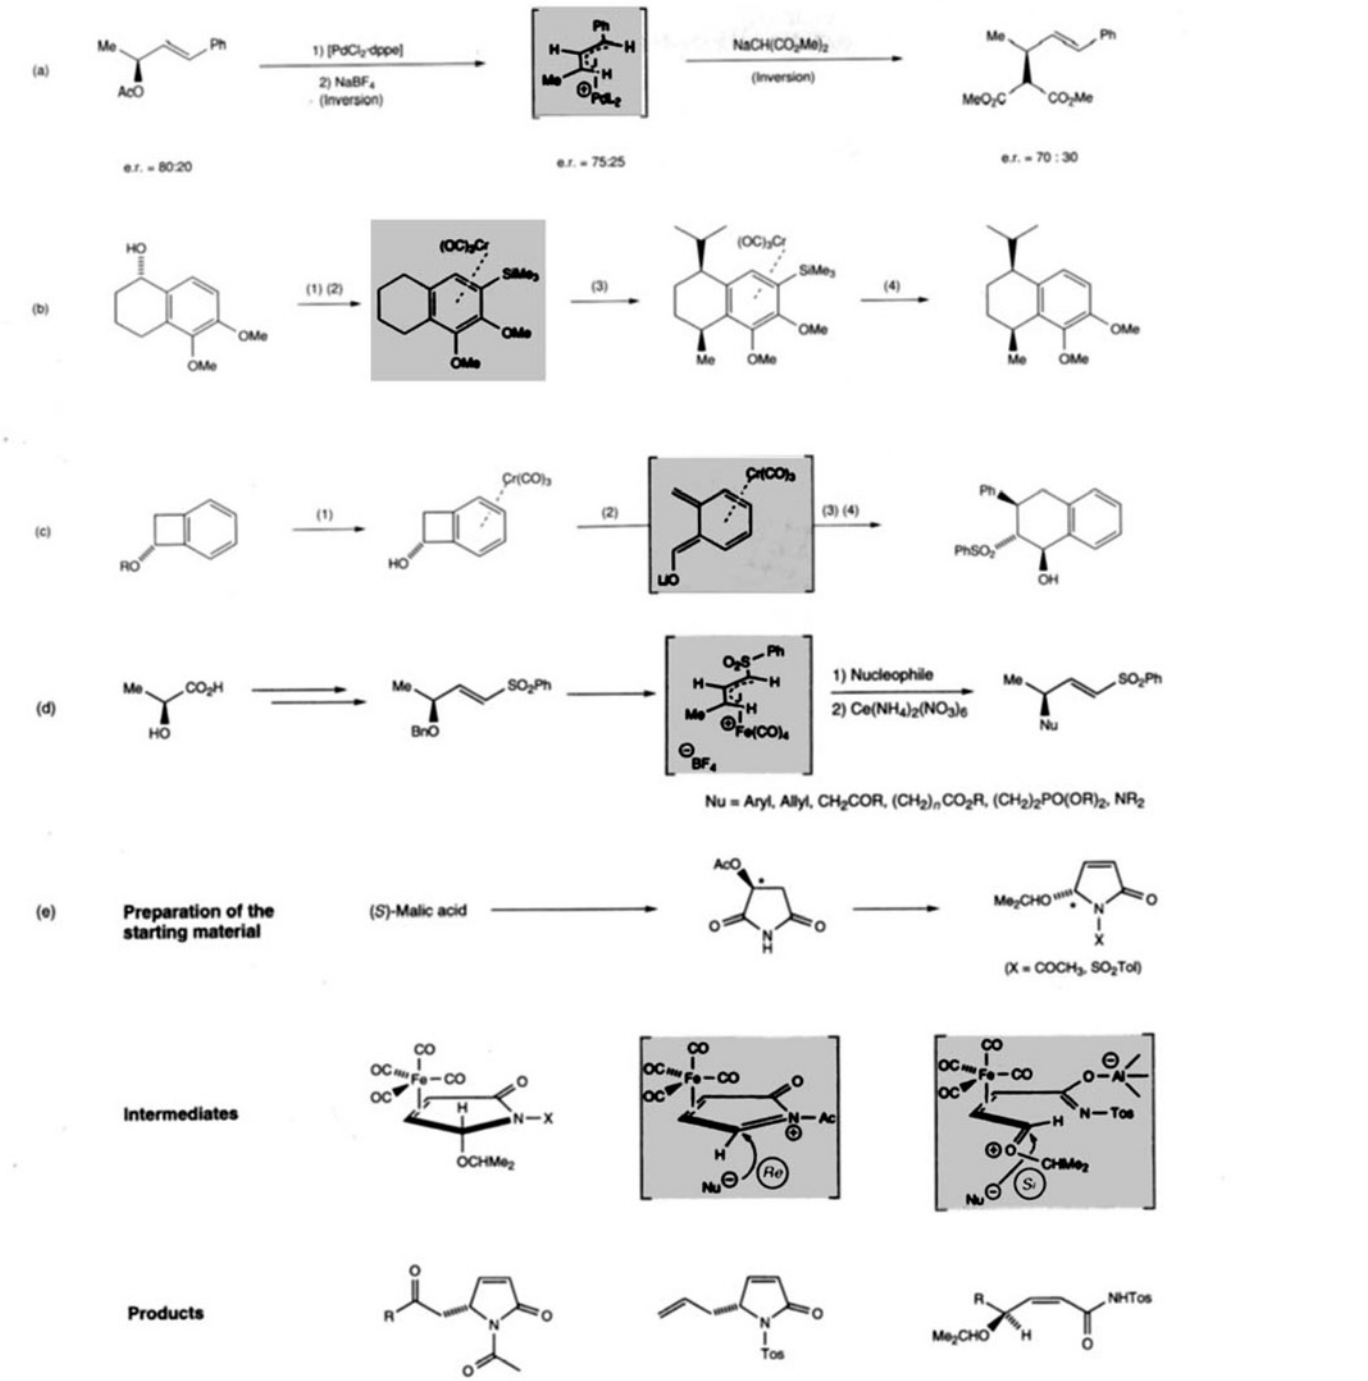
Once a synthetic principle has been understood, only the chemist's imagination sets the limits! In recent years numerous reactions have been described that intentionally or unintentionally make use of the self-regeneration of stereocenters.[197, 198] We describe only a few here.

In Scheme 18a the key step[205] is the diastereoselective formation of a dispirodiacetal from 1,1′-bis(dihydropyran) and lactic acid, a procedure that is useful in a variety of other transformations.[199–204] In Scheme 18b the configurationally stable stereogenic center at the nitrogen atom of an aziridine facilitates the introduction of new substituents at the 2-position of serine[206] via enolates of the aziridine carboxylic ester.[207–209] Scheme 18c depicts a highly refined, and yet conceptually simple α-allylation of an amino acid derivative: After diastereoselective formation of a Lewis acid/Lewis base complex from BH_3 and *N*-benzyl-*N*-methylalanine methyl ester, an enolate is formed, which is chiral owing to the stereogenic center at the nitrogen atom. This intermediate reacts diastereoselectively with alkyl halides such that removal of BH_3 and debenzylation leads to α,α-disubstituted *N*-methylamino acids with enantiomer ratios of up to 9:1.[210, 211]

Obviously, not only stereogenic centers but also stereogenic axes and planes are able to self-regenerate. Hence, it is also clear that not only temporary stereogenic centers but also every other chirality element (axis, plane, helix) can be employed in self-regeneration. The application of chirality planes within transition metal complexes is well-documented. The principle is described in Scheme 19 (cf. Scheme 3) and some specific examples are given in Scheme 20.[212–217] As can be seen, the single stereogenic center of the starting material is destroyed in the process. Simultaneously, a plane of chirality is formed[218] or preserved. The metal center, together with its



Scheme 19. Self-regeneration of stereocenters with the assistance of transition metal π-complexes. An enantiomerically pure compound with only one stereogenic center is complexed diastereoselectively (1). The configurationally stable plane of chirality ensures that the subsequent destruction of the stereogenic center results in the formation of a nonracemic intermediate (2). Hence the next reaction (3) proceeds diastereoselectively and the destruction of the π-complex (4) results in the formation of an enantiomerically pure or enriched compound [212–217] (cf. Scheme 3).



Scheme 20. SRS processes via π-complexes with planes of chirality. Steps (1)–(4) in (b) and (c) correspond to steps (1)–(4) in Scheme 19. a) Nucleophilic substitution, with two inversions of configuration, at the allylic position via a stoichiometrically or catalytically generated Pd–π-allyl complex [213] (dppe = ethane-1,2-diylbis(diphenylphosphane)). b) Substitution of an OH by an *i*Pr group with inversion. The intermediate is a benzene–chromium(tricarbonyl) complex, which is Me_3Si-protected in the position on the benzene ring *ortho* to the methoxy group. This complex is first lithiated and methylated next to the methoxy group, and then an isopropyl group is introduced at the second benzylic position in an analogous fashion. The sequence shown is part of the total synthesis of the sesquiterpene *cis*-7,8-dihydroxy-11,12-dehydrocalamenene [214]. c) Diels–Alder reaction of an *ortho*-quinodimethane with ω-phenylsulfonylstyrene. The starting alcohol is produced by enzymatic kinetic resolution. The lithium alkoxide of the benzene–chromium(tricarbonyl) complex ring opens to the planar-chiral quinodimethane at approximately −30 °C [215]. d) Reaction of one of the π-allyl(carbonyl)iron complexes, available by transformation of lactic acid, with nucleophiles. This reaction was used in the synthesis of simple natural products such as pheremones and terpenes [216a]; analogous reactions are also possible with the complex derived from benzyloxy-2-pentenoic acid [216b]. e) Substitutions via cationic tetracarbonyliron complexes, in which the organic ligand is formally a derivative of maleic aldehyde but actually derived from malic acid [216c] (cf. the substitution reactions of **8**, Schemes 16 and 17). Similar reactions have been carried out with the tricarbonyliron complexes of 2-alkoxy-4-vinyl-2,5-dihydrofurans [217].

ligands, acts as a temporary substituent and hence, influences the stereochemical course of subsequent reaction(s) and the formation of new centers of chirality. Once the metal complex has been destroyed, the organic ligand is released in an enantiomerically pure or enriched form. The result of this reaction sequence is that a new substituent is introduced stereoselectively at the original stereogenic center. Since this is achieved without the aid of a chiral auxiliary, this sequence can also be considered to follow the general concept of the self-regeneration of stereocenters.

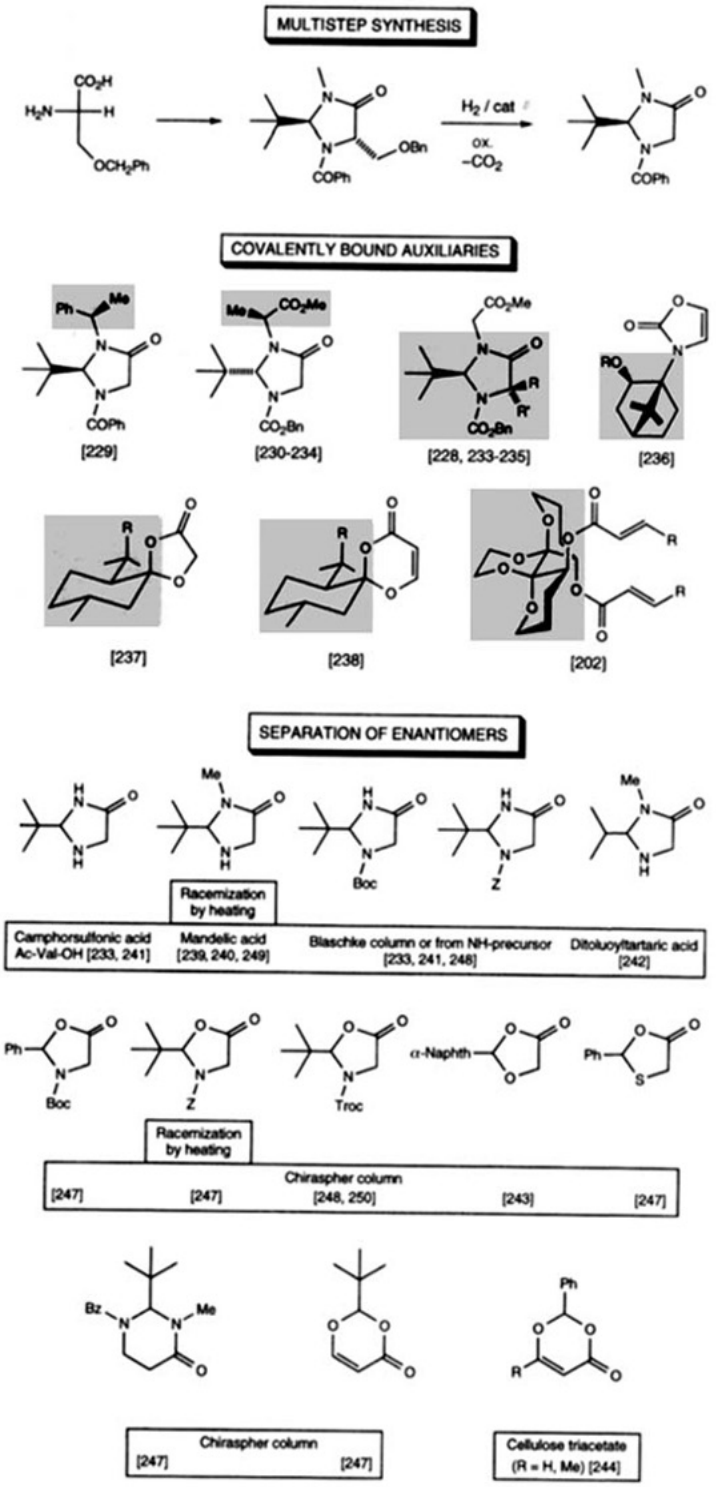
7. What Can Be Done When No Suitable Precursor for the Self-Regeneration of a Stereocenter Is Available?

Nothing is worse than harping on principles!

The heterocyclic products described in Sections 3–5 (Li-enolates, Michael acceptors, radical intermediates, acyliminium salts) display high reactivity, and their reactions usually proceed with outstanding diastereoselectivity. Availability, reactivity, and stereoselectivity are the marks of quality of synthetically useful compounds. For this reason we aimed to make such enantiomerically pure dioxolanones, oxazolidinones, imidazolidinones, perhydropyrimidinones, and dioxinones readily available, even when no suitable, inexpensive chiral precursors were available. The solution to this problem is illustrated with examples from the synthesis of α-amino acids.[219, 220] As was shown in Section 3, amino acids can be substituted at the α-position by applying the principles of SRS. This approach provides relatively easy access only to compounds in which one of the substituents at the stereogenic center is derived from one of the 20 proteinogenic amino acids. It is, however, impossible to produce an amino acid with a single, "unnatural" side chain in the α-position by this method. Clearly what is needed is a chiral glycine derivative with an oxazolidine or imidazolidine structure. Reaction of this compound either once or twice with appropriate electrophiles and subsequent hydrolysis would lead to the desired amino acid. There are three ways to prepare a glycine derivative of this type, and we wish to denote them as the *laborious*, the *fashionable*, and the *classical* approach.

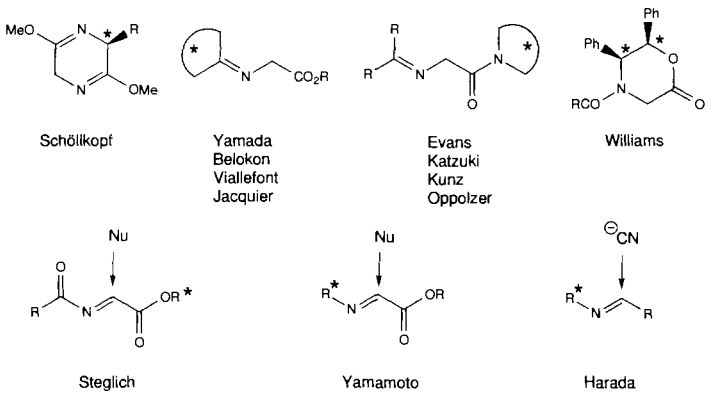
If you want to strictly follow the SRS principle then you have to use the laborious approach[221] (see Scheme 21 top). Serine is O-benzyl-protected and the imidazolidinone is formed by the usual methods (Scheme 5). This is then debenzylated, oxidized to an aminomalonic acid derivative,[222, 223] and then decarboxylated. A chiral, nonracemic glycine derivative results owing to the acetal center, and it can be alkylated via the Li-enolate in the usual manner.[71, 224]

Today, the most commonly used method (the fashionable approach) for the synthesis of enantiomerically pure compounds (EPC synthesis)[225] on a laboratory scale relies on covalently bound chiral auxiliaries which force the reaction to proceed in a diastereoselective fashion. In the extremely successful approach based on chiral auxiliaries, a readily available, enantiomerically pure compound is attached to the achiral compound that is to be modified enantioselectively in the overall process. The reaction is then carried out with as high a diastereoselectivity as possible and finally, the chiral auxiliary is cleaved. On a laboratory scale, the chiral auxiliary is commonly sacrificed, but in industrial applications, the auxiliary, which is used in a stoichiometric amount, must be recovered for further reactions.[226] Evans's method employing an oxazolidin-2-one, which is usually derived from an amino acid, with an appropriate substituent in the 4-position is perhaps the archetype of this form of EPC synthesis.[31, 227] There are numerous examples of compounds derived from glycine and a chiral auxiliary; Scheme 22 shows the different types together



Scheme 21. Three possible routes to chiral acetals of achiral amino- and hydroxycarboxylic acids (glycine, glycolic acid, thioglycolic acid, formyl- and acetoacetic acid, 3-aminopropanoic acid). *Multistep syntheses* that "uphold" the SRS principle [71, 221–224]; the *auxiliary approach* via covalently bound auxiliaries (see text for further references; the auxiliary component is highlighted in each case). The *separation of enantiomers* via diastereoisomeric salts or by preparative chromatography on a chiral solid support. Short review articles on imidazolidinones [65], oxazolidinones [66], dioxolanones [67], and dioxinones [166] can be found in the *Encyclopedia of Reagents for Organic Synthesis*. α-Naphth = α-naphthyl, Bn = $CH_2C_6H_5$, Bz = COC_6H_5, Boc = CO_2tBu, Z = CO_2Bn, Troc = $CO_2CH_2CCl_3$.

with the names of their creators and references.[228] Some of the chiral imidazolidinone-containing derivatives of glycine are shown in Scheme 21, which also contains references to the use of the chiral auxiliary approach in the reactions of oxazolines (cf.



Scheme 22. Some glycine, dehydroglycine, and imine derivatives that have been used (or proposed for application) in the auxiliary approach to *C–C bond formation* in amino acid synthesis. Due to the wide variety of different systems and the large number of research groups working in this field, the names of only a few of the authors are listed here. For further information, see Williams's book [219] and the recent review articles [220, 228]. The method developed by Williams is in some respects very similar to the "Separation of Enantiomers" method outlined in Scheme 21 as the 2-amino-1,2-diphenylethanol used is obtained by resolution of a racemic mixture. However, in the latter case the stereogenic center is actually eliminated at the end (→aldehyde), whereas here the auxiliary, which initially also had to be prepared, is destroyed by hydrogenolysis (→1,2-diphenylethane!).

9 in Scheme 16), dioxolanones (glycolic acid, cf. Scheme 5), dioxinones (cf. **7** in Scheme 9 and Schemes 10b, 11b, 13, 14) and the dispiro-THP derivative (cf. Scheme 18a).[229–238]

The third, so-called *classical* approach is the route we have chosen to adopt: either the resolution of a racemic mixture through diastereoisomeric salts or, the more recently developed approach, the separation of enantiomers by preparative HPLC on a chiral column. The structures of the heterocyclic acetals separated in this way are shown at the bottom of Scheme 21.[239–250] The following advantages rapidly became clear:

1) Large quantities of both enantiomers are readily available. Hundreds of grams, even several kilograms, of 2-*tert*-butyl-3-methyl-1,3-imidazolidin-4-one (BMI) can, for example, be prepared by crystallization of the mandelate salt.[240, 249, 251] The chromatographic separation of enantiomers (for example, benzyloxycarbonyl (Z) protected 2-*tert*-butyl-oxazolidin-5-one on a 100 × 400 mm Chiraspher column) is possible on a multigram scale.[246, 247]
2) The enantiomer that is not required for a particular synthetic target can be easily recycled by thermally induced racemization (BMI,[240] oxazolidinone[246]).
3) Since the enantiomerically pure cyclic acetals are obtained by resolution (Scheme 21 bottom), an auxilary does not have to be recovered. The aldehyde (ArCHO, *i*PrCHO, *t*BuCHO) formed during the hydrolysis step is cheap and can be discarded. In this case, the chiral auxiliary is the carboxylic acid or chromatography column used for the separation of the enantiomers. This is done at a very early stage of the overall process and of course, further use of this type of auxiliary ("recycling") is not a problem.
4) The reactivity of the heterocyclic glycine enolates and other intermediates is outstanding; the *t*Bu group is the source of the high diastereoselectivity.
5) The majority of the products are not only solid but also have a high tendency to crystallize. If necessary, the major product can be further purified by recrystallization in most cases.
6) Those heterocycles that are not derived from glycine (the dioxolanones, thioxolanones, perhydropyrimidinones, and dioxinones, see Scheme 21 bottom) can also be separated on chiral columns.[243, 244, 247]

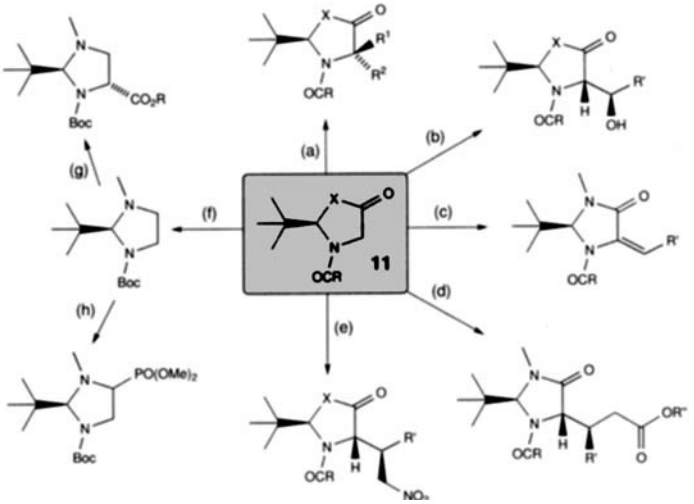
8. The Synthesis of Amino Acids via Chiral, Glycine-Derived Imidazolidinones and Oxazolidinones—Even Better than the SRS Principle

Le mieux est l'ennemi du bien.[*]

Voltaire

In this section, we aim to demonstrate the wide variety of possibilities now open to us by using the glycine derivatives produced by the resolution of a racemic mixture as an example. Only the 2-*tert*-butyl-*N*-acyl-1,3-imidazolidinones and -oxazolidinones will be considered because they have proved to be particularly useful and their chemistry has been investigated in the most depth.[252]

The heterocycles described by the general formula **11** in Scheme 23 can be either mono- or dialkylated (a). The yield of



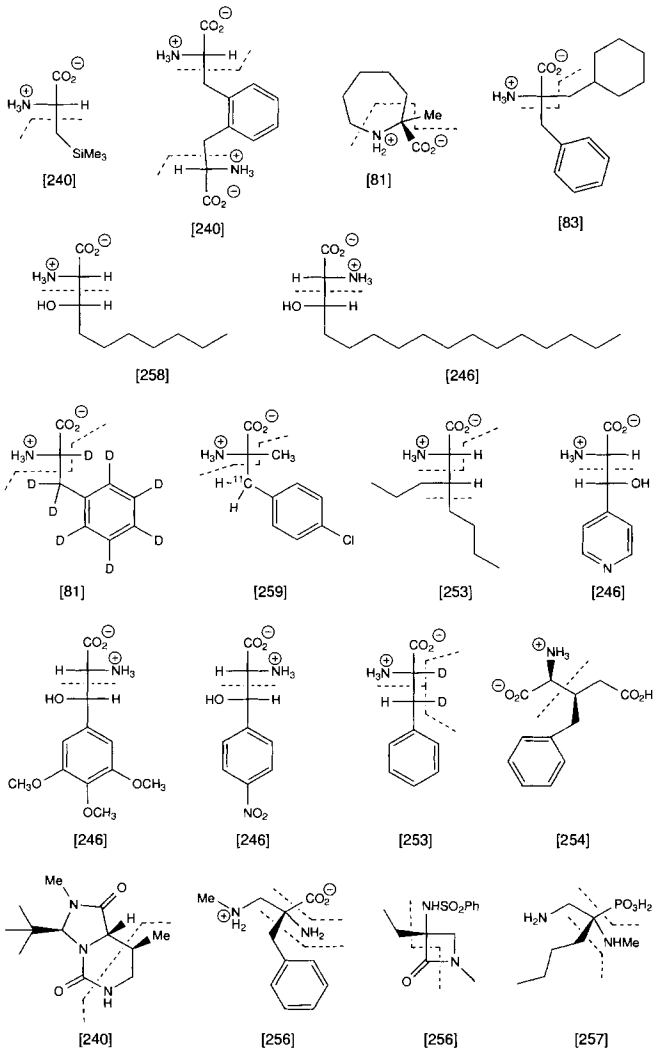
Scheme 23. Reactions (a)–(h) of acyl-*tert*-butyloxazolidinones **11** (X = O) and acyl-*tert*-butylmethylimidazolidinones **11** (X = NMe) to give a variety of amino acid derivatives. See text for references; short review articles can be found in refs. [65, 66]; specific examples are shown in Schemes 24 and 25 and also in Table E (appendix). Compound **11** (X = NMe, RCO = Boc) is also known as Boc-BMI and oxazolidinone **11** (X = O, RCO = Z) is also known as Z-BOX.

the first alkylation[81, 240] is usually so high with a wide variety of alkyl halides that the second alkylation can be carried out immediately in situ.[82, 83] The order of addition of the two different electrophiles determines the absolute configuration of the α-branched amino acid isolated at the end of the procedure. Good procedures[83] now exist for the hydrolysis of imidazolidinones with even the bulkiest substituents (derived from Boc-BMI, **11**, X = NMe, R = *t*BuO). This method has also been applied frequently for the synthesis of radiolabeled amino acids (examples in Table E in the appendix). The aldol addition (b) of

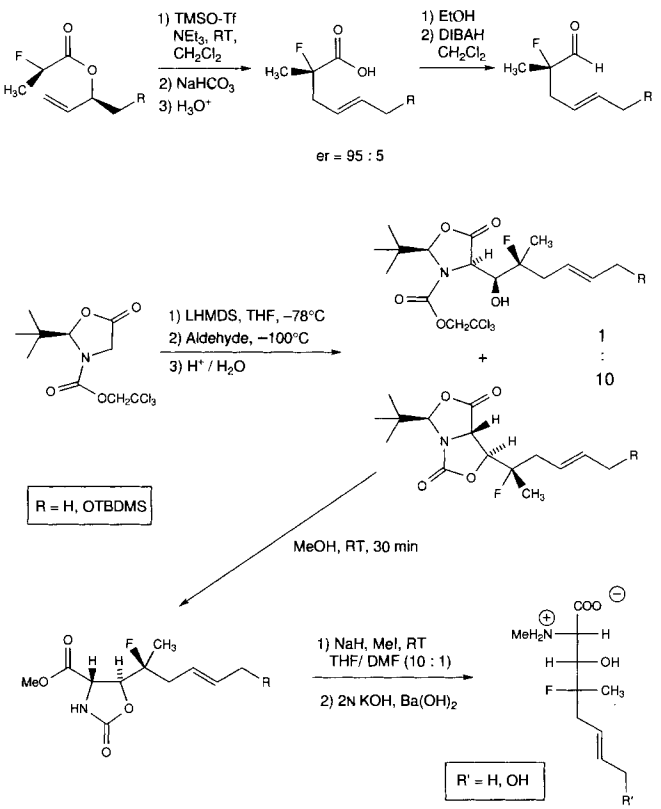
[*] "The best is the enemy of the good."

oxazolidinone **11**, X = O, R = BnO (Z-BOX),[245, 246] to aldehydes proceeds with high diastereoselectivity. If the aldehyde is chiral, the relative topicity is almost always determined by the enolate component.[71, 245, 250] (See the notes on the mechanism in Section 9.3, Scheme 29 and Table F.) Aldol condensations (c) are best brought about by a Wittig–Horner olefination using Boc-BMI. The imidazolidinone is brominated with NBS, the bromide is then converted by the Michaelis–Arbuzow procedure into a phosphonic ester ($PO(OMe)_2$ *cis* to *t*Bu), and this is condensed with an aldehyde to yield the (*E*)-alkylidene derivative.[134] These compounds are superb Michael acceptors and the addition of cuprates followed by aqueous workup yields pure derivatives of β-branched α-amino acids with almost complete diastereoselectivity (R″ and H add to the exocyclic double bond in a *cis* fashion from the face opposite to that occupied by the *t*Bu group).[253] Michael additions of enolates derived from **11** to enoates[254] and enones (d)[255] and to nitroolefins (e)[240] proceed selectively with respect to both of the newly formed stereogenic centers. Finally, the oxygen atom on the ring of Boc-BMI can be smoothly removed with $LiBH_4$ (Scheme 23 (f)) and the resulting chiral 1,2-diaminoethane derivative can be alkoxycarbonylated (g) or phosphonylated (h). This methodology provides α-branched α,β-diaminopropanoic[99, 256] and -ethanephosphonic acids,[257] respectively, in enantiomerically pure form. Selected examples of such amino acids are shown in Scheme 24,[258, 259] and Table E in the appendix contains a complete list. The synthesis of (*S*,*S*,*S*)-2-amino-4-fluoro-3-hydroxy-*N*,4-dimethyl-(*E*)-6-octenoic acid (MeBmt) is outlined in Scheme 25.[250] This synthesis follows a route very similar to that used for the preparation of the parent compound MeBmt,[245] the unique amino acid found in the immunosuppressant cyclosporin. The preparation of MeBmt once again underlines the peculiar effects of a fluorine substituent on the properties and reactivities of organic compounds.[260, 261]

All of the advantages of the glycine derivative **11** have been emphasized, but the conditions necessary for the hydrolysis of

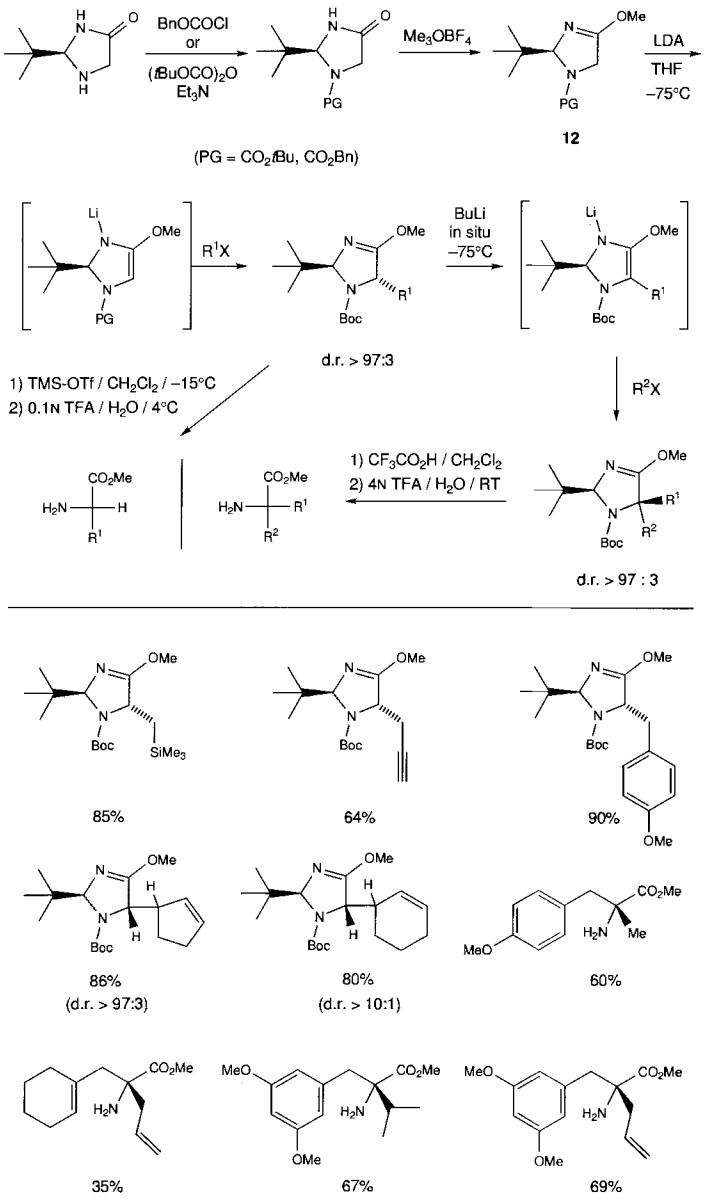


Scheme 24. Amino, diamino, and aminohydroxy acids derived from Boc-BMI and Z-BOX (**11**, X = NMe, RCO = Boc and X = O, RCO = Z, respectively, Scheme 23). The C–H, C–D, C–N, C–C, and C–P bonds resulting from connections to the skeleton of building block **11** are marked with dashed lines. These components were introduced by enolate protonation, deuterolysis, and alkylation, by aldol additions (to give (*S*)- or (*R*)-threonines or allothreonines), by aldol condensations and Michael additions, by catalytic hydrogenation of C–C double bonds, and by carboxylation and phosphonylation. See also Table E in the appendix, where many further examples can be found.



Scheme 25. Synthesis of fluorinated analogs of MeBmt (formula bottom right, R′ = H and H in place of F), the unique amino acid in cyclosporin. A modified Ireland–Claisen rearrangement of the 2-fluoropropanoic acid allyl esters shown led to the appropriate (2*S*,4*E*)-2-fluoro-2-methylhex-4-enoic acid (R = H, OTBDMS) with enantiomer ratios of 95:5 (yields 45–52%). Esterification and subsequent reduction yielded the aldehydes (formula top right), which were allowed to react with the enantiomerically pure (*R*)-oxazolidinone Troc-BOX to give the products shown (65%). Methanolysis of the bicyclic major product, followed by methylation at nitrogen, yielded the *trans*-substituted cyclic carbamates. Finally, these carbamates were converted to the free, 4-fluoro-substituted amino acids under the mildest possible conditions (danger of epoxide formation via the intermediate alkoxide with loss of F^-) [250].

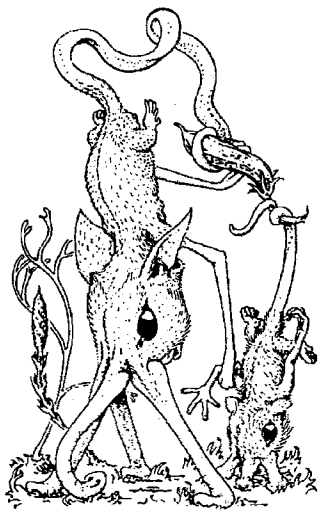
the amino acid precursors prepared from Boc-BMI still leave a lot to be desired. As the last step is the cleavage of an *N*-alkylcarboxylic acid amide, the highly acidic conditions required are not surprising. These conditions range (according to the substituent in the α-position) from 0.75 N HCl/acidic ion-exchange resin/reflux,[240] to 4 N HCl/dioxane/H_2O/80 °C, to 6 N HCl/10% MeOH/reflux,[83] to conc. HCl/100 °C[83] and finally up to 6 N HCl/180 °C/sealed tube.[64, 81, 262] A solution to this problem has now been found with the imidazolines **12** shown in Scheme 26. 2-*tert*-Butylimidazolidin-4-one, which is unsubstituted at both nitrogen atoms and available by the resolution of a racemic mixture with camphor sulfonic acid and *N*-acetylvaline, can be converted into the methoxyimidazoline **12** by protection of the amine nitrogen with either a Boc or Z group and then O-methylation with Meerwein's salt. The enolate—or to be more precise, enaminate—is an extremely reactive nucleophile particularly when the nitrogen is Boc-protected. Here too, the yields of alkylation are so high that a second alkylation can be carried out immediately in situ. The stereoselectivity of both steps is outstanding, and the 5-monosubstituted products can be hydrolyzed with 0.1 N aqueous trifluoroacetic acid at 4 °C; hydrolysis of the 5,5-disubstituted products requires 4 N trifluoroacetic acid in water at room temperature.[233, 241] It is, therefore, now possible to produce amino acids with highly acid-sensitive side chains (see the lower section of Scheme 26) by this procedure.



Scheme 26. 1-Boc- and 1-Z-2-*tert*-butyl-3-methoxy-Δ^3-imidazoline **12** (PG = Boc and Z, respectively) as chiral, nonracemic, glycine-derived, synthetic building blocks [233, 241]. Reactions with alkyl halides proceed with high selectivity; the use of an excess of the racemic allylation reagents bromocyclopentene and -hexene results in an efficient kinetic resolution (as in the reaction of Boc-BMI-enolate with 1-bromo-1-phenylethane [240, 254]); the absolute configuration at the cycloalkenyl C atom is not yet known. The quoted diastereoisomer ratio, d.r. > 97:3, means that the second isomer is not detectable in the high-field NMR spectrum of the crude product. The yields listed below the imidazolines refer to the alkylation step and those below the amino acids refer to the hydrolysis step. Addition of the deprotonated iminoester Li-**12** to the aldehyde does not result, after hydrolysis, in threonine (as observed with the enolate of heterocycle **11**) but gives allothreonine derivatives instead. LDA = lithium diisopropylamide, TFA = trifluoroacetic acid.

The reactions of the glycine derivatives, which are prepared by resolution of racemic mixtures, proceed so well that these synthetic building blocks are now preferred even for the synthesis of α,α-disubstituted amino acids derived from natural amino acids, in other words when the side chain is "proteinogenic" and the principles of SRS could also be applied.

9. What Have We Learned?



"Nasobem with Child" (from H. Stümpke, *Bau und Leben der Rhinogradentia*, Copyright© Gustav Fischer, Stuttgart, **1961**).

There is no disgrace in not knowing, but there is in not wanting to learn.

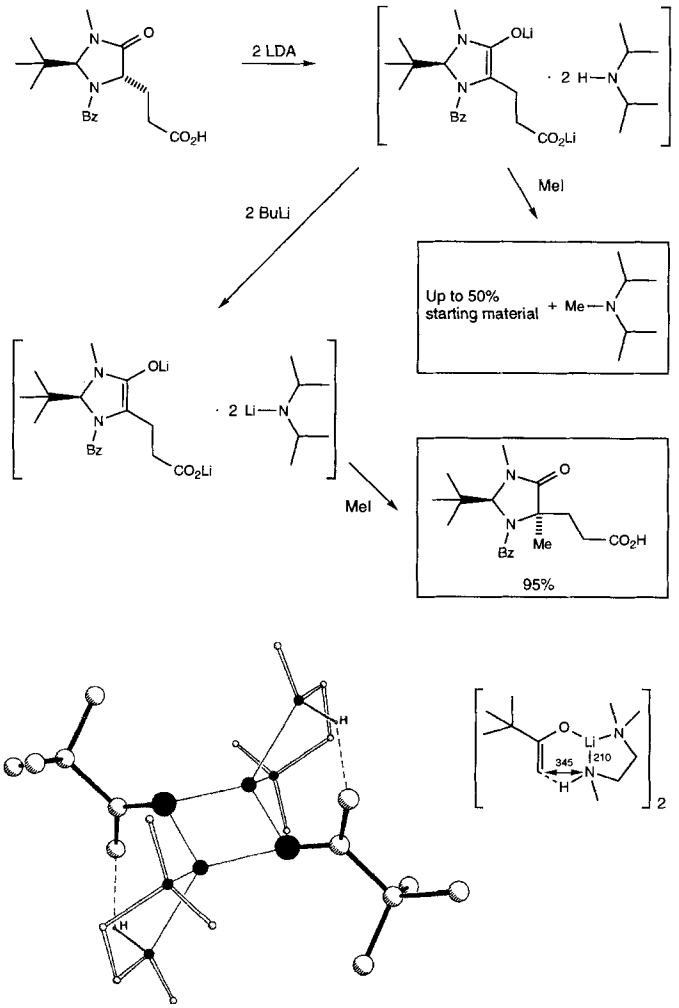
Socrates

There have been a few record-breaking cases of stereoselectivity resulting from long-range effects (with up to six atoms between the "inducing" and the newly formed stereogenic center!)[263–266] and spectacular effects of fluorine substitution (reversal of the regio- and stereochemical course of the reaction on replacement of a CH_3 group by CF_3 in a reactant).[267] In the past we have somewhat cautiously speculated (sometimes only in footnotes) about the causes of these observations. They have, however, led us to become interested in the nucleophilic, radical, and electrophilic reactivity of the heterocycles prepared in stud-

ies of the SRS principle, and this in turn has led to some insights into the reactivity that are of general importance and not simply confined to this area. These topics will be discussed in the following sections.

9.1. The Effect of Secondary Amines

We first stumbled upon this effect while studying the reactions of the lithium enolates of oxazolidinones and imidazolidinones, and it is now clear that this effect is particularly marked for polylithiated derivatives.[29, 45, 114, 268] One example is the reaction of the enolate derived from glutamic acid[269] (Scheme 27). The enolate-carboxylate forms a complex with the diisopropylamine that results from the enolate formation. (The structure of such a complex has been determined by X-ray crystallography.[29]) Subsequent reaction of the complex with electrophiles results in the recovery of up to 50% of the starting material. It

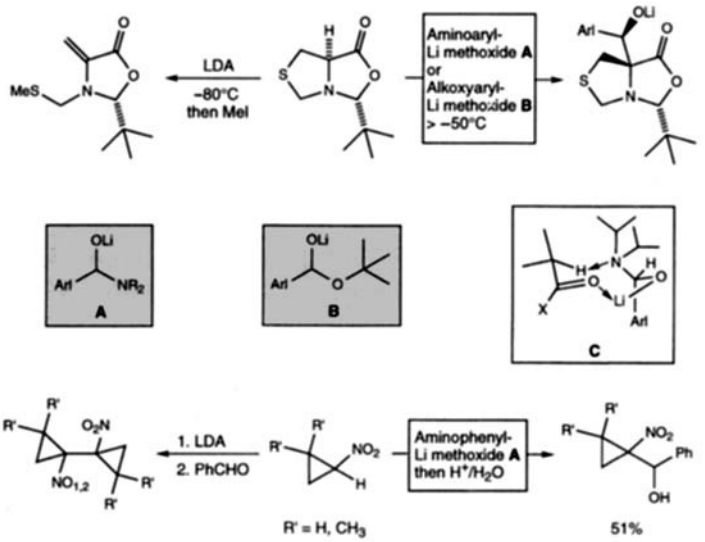


Scheme 27. The effect of secondary amines on the reactivity of Li-enolates and other Li derivatives. In a complex formed between an enolate and an amine, the nucleophilicity of the amine is enhanced, and hence, in the ensuing reaction with electrophiles, it acts as a proton source! Similarly, the reactivity of the Li-enolate·Li-amide complex is very different from that of the enolate alone [269]. The structure shown is that of a complex between the Li-enolate of pinacolone and *N,N,N*-trimethylethylenediamine, which contains a hydrogen bond between the NH hydrogen atom and the enolate C atom [29]. (The numbers on the formula in the bottom right-hand corner are the interatomic distances in pm.)

was proved that the proton of the amine was actually donated back to the enolate (apparently contrary to the relative pK_a values of a lactam and an amine!) and that the amine was N-methylated under these conditions, although, in the absence of the Li-enolate, it would not normally react. Irreversible removal of the NH proton with BuLi leads to the formation of a new complex between the Li-enolate and the Li-amide, and subsequent alkylation now proceeds in excellent yield.[269] Today it is now commonplace to attempt to improve poor results of reactions between lithiated compounds, generated with LDA and an electrophile, by adding BuLi prior to the electrophile; it often, but not always, helps.[270]

9.2. LiX Adducts with Aromatic Aldehydes—In Situ Sources of Bases and Electrophiles

During attempts to α-alkylate cysteine via a bicyclic acetal in an analogous fashion to the proline derivative, it became clear to us that the (expected?)[271] β-elimination interferes in any reaction with LDA under all the conditions tested.[45] However, when a complex of an aromatic aldehyde and LDA[272] or lithium *tert*-butoxide is employed, the aldol products shown in Scheme 28 are formed in good yield.[48, 89] Transformations of



Scheme 28. In situ generation and trapping of unstable enolates [48, 89] and nitronates [273, 274] with aromatic aldehydes with the assistance of the aldehyde adducts **A** [272] and **B** (lithiated hemi-aminal and lithiated hemi-acetal [89], respectively); the Li derivative **A** is usually used for the orthometalation of aromatic aldehydes [272]. In light of the instability of the enolates formed from the bicyclic compound shown, we conclude that this does not result from reaction of the free $LiNR_2$, which exists in equilibrium with **A**, but that deprotonation, generation of the aldehyde, and aldol or nitroaldol addition result in a "collision complex" (see for example **C** and the accompanying caveat in the text). Arl = aryl.

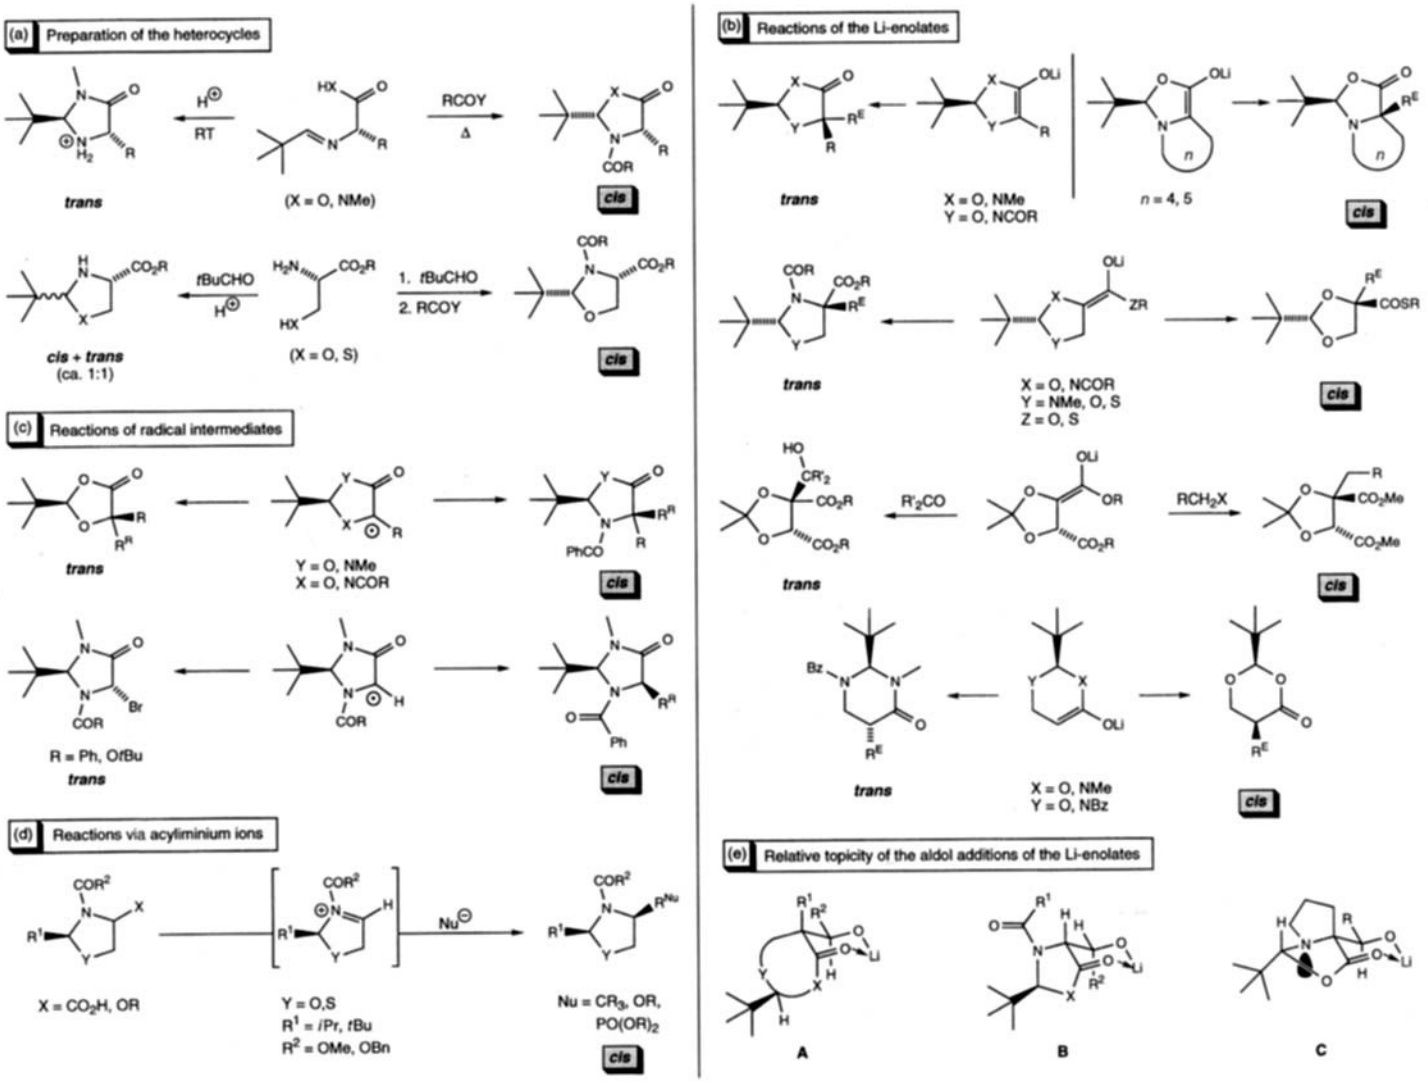
other unstable anionic derivatives such as those derived from nitrocyclopropane[273] are possible when functionalized, lithiated hemi-aminals or hemi-acetals are used as both base and electrophile.[274] Fully realizing the complexity of the reactions of lithiated compounds[5, 21–29] and hence with all due caution, we have proposed a mechanistic model for this process.[275]

9.3. *cis* Selectivity Here, There, and Everywhere—The Power of the $A^{1,3}$ Effect

An observant reader of Sections 3 through 8 and the accompanying schemes can hardly have failed to notice that numerous, at first sight surprising, stereochemical outcomes of reactions have been presented; these could all be collected together loosely under the heading "the *cis* effect" and they are summarized in Scheme 29. Except for a few examples from the early publications, we have interpreted[276] and summarized these results in more recent articles.[62, 196, 254]

First of all, it must be stressed that the level of stereoselectivity found in the alkylations and hydroxyalkylations of our heteromonocyclic enolates has still not been achieved with the carbocyclic analogs.[277] For example, the reactions of the Li-enolates of 4- and 3-*tert*-butylcyclohexanone with CH_3I proceed with diastereoselectivities of 55:45 and 80:20, respectively.[278] The addition of the Li-enolate of cyclohexanone to PhCHO proceeds with a maximum diastereoselectivity of 92:8,[279] whereas the equivalent reactions of the five- and six-membered ring enolates of dioxolanones, dioxanones, oxazolidinones, imidazolidinones, thioxolanones, and perhydropyrimidinones with alkyl halides, aldehydes, and Michael acceptors are so highly selective that the second diastereoisomer cannot normally be seen in the high-field NMR spectrum of the crude product. The same is true for Michael additions to alkylidene derivatives (for example, that from Boc-BMI[253] or from dioxanones[153, 280]).

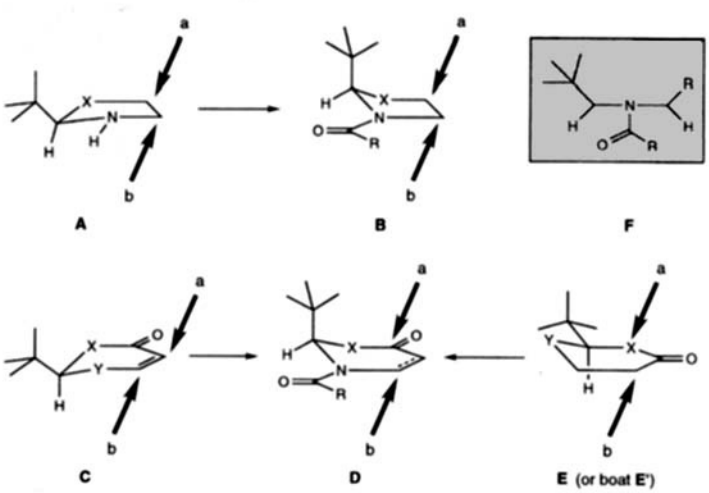
Together with these questions of the degree of stereoselectivity, the direction of selectivity has also always surprised us, in other words, both the type and manner of the influence on the relative topicity of the reaction process of certain substituents on the heterocycle. Scheme 29 summarizes reactions in which an



Scheme 29. Examples of reactions which, during the SRS process, result in substitution *cis* to the original substituent on the heterocycles (see Sections 3–5 for references). a) *cis*-Disubstituted five-membered ring heterocycles that are more stable than the *trans* isomers. b) Reactions of Li-enolates of the five- and six-membered ring N,N-, N,O-, N,S-, and O,O-acetals that often lead preferentially to the *cis* products; the geometry of the exocyclic enolate double bond is unknown and is drawn arbitrarily here. c) Dichotomy of reactions of captodative-substituted radical centers in *cis*- and *trans*-selective processes. The assignment of the configuration of the bromo derivative is somewhat uncertain [135]. d) Known reactions of 1,3-oxazolidines and -thiazolidines via acyliminium ions that proceed with a strong preference for the *cis* product. e) Three Zimmerman–Traxler diagrams [291] **A**, **B**, and **C** for the interpretation of aldol additions of heterocyclic enolates to aldehydes. For a compilation of the topicities observed in additions of the five- and six-membered ring heterocyclic enolates discussed here to aldehydes, enones, enoates, and nitroolefins, see Table F in the appendix. For the definition of the "*cis* effect", see the text and Schemes 30–32.

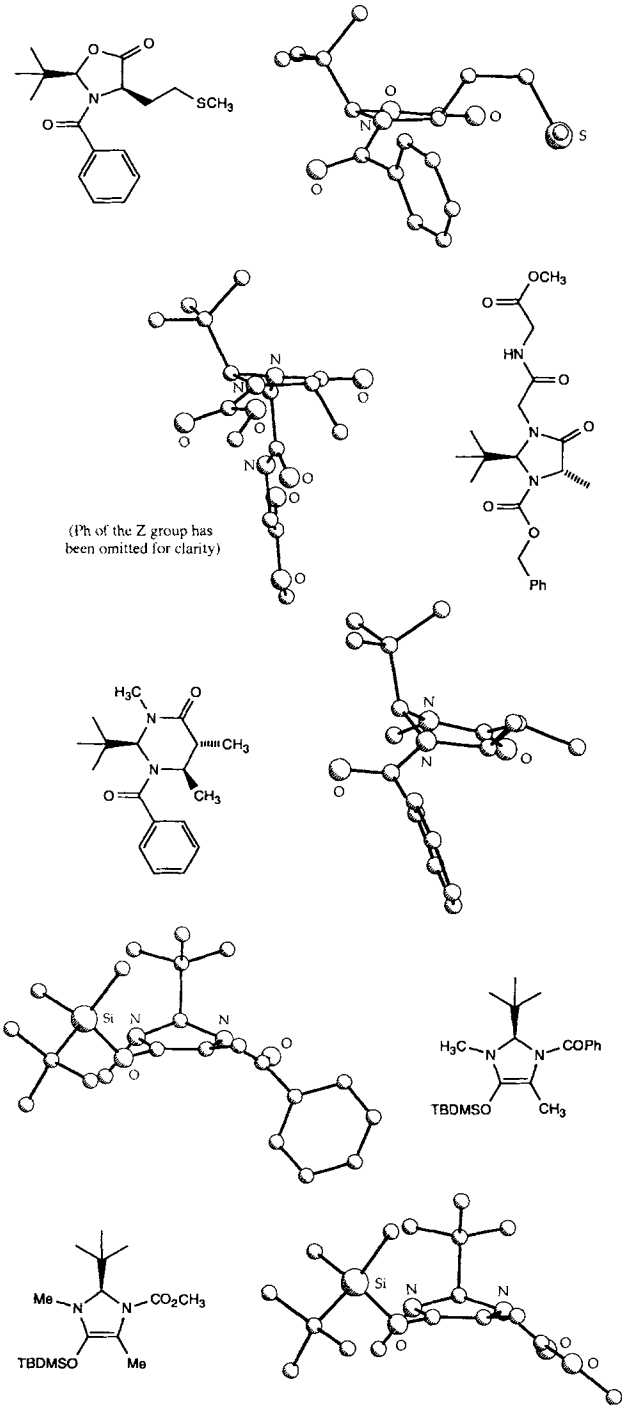
apparently small change in the structure of the reactant results in the reversal of the stereochemical course of the reaction. As has already been mentioned, the point most worthy of note is perhaps that these reactions so often occur with *cis* selectivity. In these cases, either the *cis* product is thermodynamically more stable than the *trans* isomer or, when the reaction proceeds under kinetic control, the trigonal enolate, radical, or acyliminium center of the reactant reacts preferentially from the side that features the substituent (usually a *t*Bu group) at the acetal center. In this fashion, the cyclization with concomitant acylation of a Schiff base derived from an amino acid or amide yields the *cis*-oxazolidines, -oxazolidinones, or -imidazolidinones either predominantly or exclusively (Scheme 29a).[281,282] The example shown in Scheme 29b (top right) is the *cis* attack on a bicyclic enolate[283] leading to the thermodynamically more stable product (*cis* fusion of four and five-membered rings, with substituents in the *exo* position!). The *cis*-selective reaction of dioxolanone enolates with exocyclic double bonds[284] and the reversal of this preference on moving from alkylation to hydroxyalkylation of a tartrate derivative are particularly interesting.[92–94,285] When a dioxanone enolate is replaced with a perhydropyrimidinone enolate, the poor *cis* selectivity is transformed into an excellent *trans* preference (66% vs. 97% *ds*,[141,286] Scheme 29b bottom). This increase in selectivity is typical of the differences observed in reactions of all O-substituted heterocycles relative to those of an N-heterocycle with an N-acyl exocyclic group (cf. the ester enolate of dioxolane and the *N*-acyloxazolidine and thiazolidine carboxylic acids[287]). The stereochemical course of radical reactions is also very dependent upon the heteroatoms in the ring. Such reactions occur with preferential *cis* attack at an *N*-acyl derivative and *trans* attack at a dioxolanone, and the result also appears to be dependent upon the reaction partner (R_3SnH vs. NBS, see Scheme 29c[288–290]). Nucleophilic substitution next to the nitrogen atom of the *N*-acyloxazolidine and -thiazolidine (Scheme 29d) occurring via acyliminium ions (with the assistance of a Lewis acid) virtually always provides the *cis*-substituted compound as the major product (see Section 5 and the references cited therein). Finally, examination of the six-membered ring chair model[291] for the Li-enolate aldol addition of *N*-acylimidazolidinones and -oxazolidinones shows a preference for the R group of RCHO to adopt an axial position, that is, *cis* to the heterocyclic ring (Scheme 23b and **B** in Scheme 29e; Table F[254]).

Closer examination of X-ray crystal structures (either those carried out by us to determine the configuration of our products[62,143,157,229,255,292,293] or by others, which were retrieved from the Cambridge Database) proved to be crucial in the interpretation of the observed *cis* effects. It is well known that five-membered rings ("natural" angle 108°) with trigonal, sp^2 centers ("natural" angle 120°) are strained and that pyramidalization leads to a reduction in this strain.[294] However, the crystal structures made us realize the enormous effect of the 1,3-allyl ($A^{1,3}$) strain[295–297] of amide and carbamate groups. The substituent at the acetal C atom of 1,3-dioxolanones, 1,3-dioxanones, 1,3-dioxinones, and even of 1,3-oxazolidinones and 1,3-imidazolidinones not having *N*-acyl substituents adopts an equatorial or quasi-equatorial position (**A**, **C**, **E** in Scheme 30). In contrast, in the *N*-acyl derivatives, these substituents are usually found in a quasi-axial position on five-membered rings and in fully axial positions on the hydropyrimidones (see **B** and **D** in Scheme 30). The amide nitrogen in the five-membered ring is indeed considerably pyramidalized ($\Delta \leq 0.43$ Å,[298] indicative of a nearly sp^3 amine nitrogen). However, in the majority of cases, the amide group is hardly twisted at all. Obviously much less resonance energy is lost if the nitrogen of the amide group is pyramidalized rather than the R_2N-CO bond rotated.[299] The resulting substructures of the *N*-acyl heterocycles then appear, if viewed from the carbonyl C atom, like structure **F** in Scheme 30. If possible, the O=C–R unit adopts a position to a greater (five-membered ring) or lesser (six-membered ring) extent[300] below the plane formed by the C,N,C ring atoms; the substituents at the neighboring C atoms are above the plane. Some particularly impressive examples are shown in Scheme 31.[301]

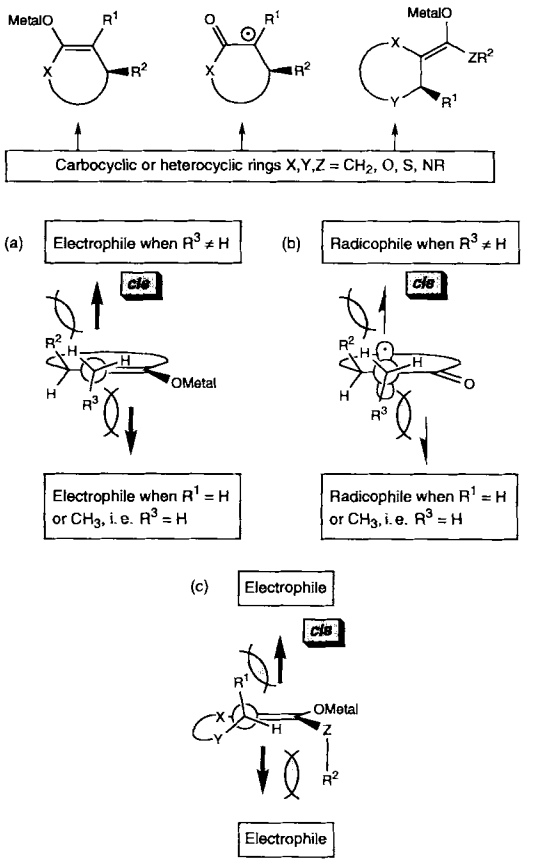


Scheme 30. A compilation of schematic diagrams of the typical structures of acylated (**B**, **D**) and nonacylated heterocycles (**A**, also when NH = O, **C** and **E**) such as dioxolanones, imidazolidinones, oxazolidinones, dioxanones, dioxinones, and hydropyrimidinones, which have been used in reactions employing the SRS principle (see also Scheme 29). Between 1991 and 1995 the Cambridge Structural Database listed 55 structures of such molecules (CSD codes given below), an additional 8 structures have been published in ref. [143], and a further 14 older structures are shown and discussed in ref. [62]. **F** is the most commonly found arrangement with a pyramidalized amide nitrogen (to minimize the angle strain) and with the neighboring centers pointing in the opposite direction so as to minimize the $A^{1,3}$ strain. Six of the structures referred to belong to Type **A** (HEBSEM, KOYXIF, LERLEZ, VURBEP, VURBIT, YADSEB), 18 to Type **B** (HEVTIL, JILROL, JILRUR, JODMEU10, JOPWUG, JOPXER, LAFWEU, LAFWIY, LAXWEM, LAXXIR, PATCAO, PEFLOB, PEVWUI, PEXFED, PIWFIK, SOSDEJ, TAPSOS, VOBYUG), 2 to Type **C** (HEJNAL, KOHKEX), 8 to Type **D** (JOPYUI, JOPZAP, JOPZET, JOPZIX, JOPZOD, SUCJEF, SUCJIJ, SUMNIX), 8 further Type **D** structures are described in [143], 16 belong to Type **E** (*sofa* conformers) (JOPYAO, JOPYES, JOPYIW, JOPYOC, LEDXAT, LEDXEX, LESJEY, LESJIC, LESJOI, LESJUO, PEKTII, SOSFIP, WEBXAC, WEBXEG, WEBXIK, WEBXUW) and 5 to Type **E'** (*boat* conformers) (PALFEN, PIPJAZ, PIPJED, PIPJIH, PIPJON). The majority of the structures were determined by the groups of A. L. J. Beckwith, S. G. Pyne, D. Seebach, and F. J. Urban; the literature citations not given here can be retrieved from the CSD files.

This structural information explains the higher thermodynamic stability of the *cis*-substituted *N*-acyl five-membered ring heterocycles (Scheme 29a) and also the many differences in the reactivity of heterocycles with or without exocyclic *N*-acyl groups (Scheme 29b,c,e[302]). However, another type of $A^{1,3}$ strain (Scheme 32) is responsible for the *cis* selectivity of several enolate and radical reactions (cf. Scheme 29b,c). It is known that an exocyclic CH_2R group at an enolate double



Scheme 31. Typical crystal structures of derivatives of *N*-acylimidazoline [301], -imidazolidine [234], -oxazolidine [62], and -perhydropyrimidine [62,143]. The plane of the benzene ring of the *N*-benzoyl group in the structures shown here, and in almost all those of this type known, is practically perpendicular to the carbonyl plane. The degree of pyramidalization Δ [298] at the methyl-substituted ring C atom of the methyl carbamate and of the benzamide silyl enol ether is 0.07 and 0.11 Å, respectively. In most of the structures the carbonyl oxygen of the *N*-acyl group is in a *cisoid* arrangement with the acetal center; exceptions are found in structures of compounds in which there is a bulky substituent on the α-carbonyl carbon. For details of further structures of this type and the corresponding referenees, see Scheme 30.



Scheme 32. Reactions of enolates and α-carbonyl radicals. When R^1 is H or CH_3 in those systems with an endocyclic double bond, reaction occurs from below (*trans* to R^2). When $R^1 = CH_2R^3$, the R^3 group is positioned beneath the plane due to $A^{1,3}$ strain and hence, the lower face is shielded to a greater extent than the top face is by R^2 (see a) and b)). An analogous effect is likely to be responsible for the *cis* selectivity observed with certain ester enolates containing exocyclic double bonds (c). References are given in the text.

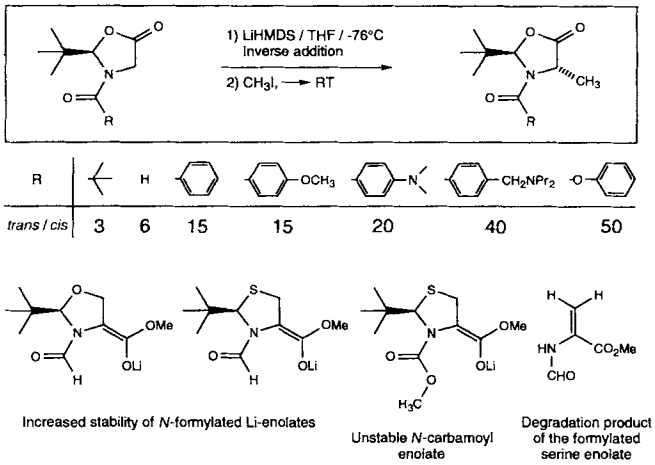
bond can lead to a reversal of the topicity of attack at the double bond due to the "allylic" endocyclic substituent (Scheme 32a). This has been observed for both carbocyclic (cyclopentanones[303]) and heterocyclic enolates (lactones,[304] dioxanones[37,153,280]) with endocyclic double bonds. Equally, in a whole range of examples of reactions of carboxylic ester and thioester Li-enolates with carbocycles[98] and heterocycles[93–95,102,285] electrophilic attack at the exocyclic enolate double bond occurs *cis* to a substituent in the ring (Scheme 29b, 32[305,306]). This can also be explained by some form of the $A^{1,3}$ effect: the RO or RS group of the ester enolate shields the "lower face" of the enolate plane and the allylic substituent on the neighboring stereogenic center shields the "upper face". (Furthermore, in the case of the heterocyclic carboxylic ester enolates, a chelate effect might be involved.[306]) Whether or not attack occurs from the side *cis* to R^1 at the trigonal center is dependent upon whether the transition state of the electrophilic attack at the enolate double bond is early or late and also upon the relative sizes of the R^1 and R^2 groups (Scheme 32c). The movement of the RZ group out of the plane of the ester enolate has been confirmed by X-ray crystal structure analysis,[209,307–312] and the relationship between *cis* selectivity and size of the RO group has been noticed previously.[95]

Incidentally, $A^{1,3}$ effects of this type in reactions of α-carbonyl radicals, in which the radical center in the ring bears a RCH_2 substituent and is adjacent to a stereogenic center in the ring (Scheme 32b[290]), were first noticed in 1977.[313]

The *cis* selectivity of reactions that proceed via acyliminium ions (Scheme 29d) can be traced back to, amongst other things, the barrier to rotation of the RCO–N bond, which is much lower for cations than for amides (by roughly one-third), and hence the $A^{1,3}$ effect no longer dominates the course of the reaction.[62, 183, 196]

9.4. Protecting Groups Are Not Just Passive Spectators!

Numerous examples have confirmed one observation: a protecting group can have differing influences on the course of a reaction at a neighboring functional group—it is certainly not simply a spectator. For example, the diastereoselectivity of reactions of the Li-enolate of *N*-acyl-2-*tert*-butyl-1,3-oxazolidine-5-ones is extremely dependent upon the nature of the acyl group (Scheme 33[314]). It can be seen from the structures of enol



Scheme 33. The influence of "protecting" groups on the course of the reaction. Top: The diastereoselectivity of methylation of a range of N-protected 2-*tert*-butyl-1,3-oxazolidin-5-ones varies from 3:1 to 50:1. Bottom: The stability of enolates of 2-*tert*-butyl-1,3-oxazolidine and -thiazolidine carboxylic esters is highly dependent on the nature of the *N*-acyl group. The reaction of the aldehyde $CH_3CH{=}CHCH_2CF(CH_3)CHO$, shown in Scheme 25, with a variety of Li-enolates of *N*-acylated 2-*tert*-butyl-1,3-oxazolidin-5-ones is a further example of the influence of *N*-acyl groups on enolate reactions of these types of heterocycles: Use of allyloxy-, benzyloxy-, and phenyloxycarbonyl-substituted oxazolidinones did not lead to the required products; the use of the trichloroethoxycarbonyl protecting group led to the first success. As in all the examples shown in this article, the geometry of the enolate double bond is not known and is drawn arbitrarily. For details about the *cisoid* arrangement of the carbonyl oxygen atom of the *N*-acyl group and the acetal center, see also the legend of Scheme 31; to date, the conformation of the *N*-formyl group has not been determined.

derivatives of such heterocycles (Scheme 31 bottom[315]) that the substituent at the carbonyl C atom of the acyl group could formally be in contact with the atoms and groups involved in the transition sate of an S_N2 reaction. This also applies to the acyl groups of the oxazolidine and thiazolidine carboxylic esters (Scheme 33 bottom): The *N*-formyl derivative is more stable than the carbamoyl analog possibly because the formyl-substituted enolate has less $A^{1,3}$ strain than the carbamoyl derivative[316] and not only because the formyl group is more electron-withdrawing.

10. Concluding Remarks

The principle of the self-regeneration of stereocenters has led not only to the increase in the synthetic potential of readily available, chiral synthetic building blocks such as naturally occurring amino acids, but also to the development of simple, synthetic, heterocyclic starting materials which are available by resolution of racemic mixtures. There is very little risk involved in predicting that the SRS principle will find many more applications and that the chiral acetals, which are now also commercially available in large quantities, will be employed more and more frequently in EPC synthesis.

The enthusiastic work of many graduate students and postdoctoral co-workers over the last 15 years has led to the results of our group described in this article. D. S. expresses his deepest thanks to them all; their names are given in the list of references. The following people are due special thanks: Reto Naef[317] *for his crucial contributions during the conception of the SRS principle and also Robert Fitzi,*[318] *Stefan Müller, Urs Gysel,*[319] *and Joachim Kinkel*[320] *for solving the problems related to the resolution of racemic mixtures of glycine acetals. We thank the following companies for their generous donations of chemicals: BASF AG (Ludwigshafen, Germany; pivalaldehyde), Degussa AG (Hanau, Germany; amino acids and Boc-BMI), Zeneca Bio Products (Billingham, UK; PHB and BIOPOL). We are very grateful to Sandoz Pharma AG (Basel, Switzerland) for their generous financial support of our research group over so many years. S. Sigrist and M. Graedel are thanked for their considerable help during the preparation of this manuscript. Finally, we also acknowledge Privatdozent Dr. Volker Gramlich, the organizer of the crystallography laboratory courses at ETH-Zürich, where so many of the crystal structures were solved; his work has had so much significance, in so many different ways, on the work from our laboratories described here.*

Appendix

The following abbreviations are used in the tables: All = $H_2C{=}CHCH_2$; Alloc = $H_2C{=}CHCH_2OCO$; Bn = $PhCH_2$; Boc = *t*BuOCO; Bz = PhCO; MOM = CH_3OCH_2; TBS = TBDMS = *tert*-butyldimethylsilyl; TBDPS = *tert*-butyldiphenylsilyl; Z = $PhCH_2OCO$.

Table A. Examples of the α-alkylation of a variety of amino-, hydroxy-, and sulfanylcarboxylic acids according to Scheme 5. In many cases the heterocyclic alkylation products were not hydrolyzed to give the corresponding α-,α-disubstituted, α-heterosubstituted carboxylic acids. Some examples of carboxylic acid derivatives prepared in this manner and some applications in natural product synthesis are shown in Scheme 7 and 8.

Table F. Stereochemical course of the aldol addition of cyclic enolates **a**–**o** to aldehydes **u**, and the Michael addition to α,β-unsaturated carbonyl compounds **v** and nitroolefins **w** [364]. The primary adducts are presented as Newman projections and as Zimmerman–Traxler diagrams on the right side of the table. The substituent R^4 is always equatorial in case **A** and axial in case **B** for the adducts shown in the chair conformation (see the discussion in the text and Scheme 29e).

[3] D. J. Cram, *Fundamentals of Carbanion Chemistry*, Academic Press, New York, London, **1965**, pp. 85–135; Inversion of configuration (i.e. racemization without loss of deuterium in a protic medium) has been observed in similar systems when other bases are used. Cram has suggested that the term "conducted tour mechanism" be used to describe such reactions.

[4] Initially, Ramig et al. suggested that the decarboxylation described proceeds with inversion of configuration: L. A. Rozov, K. Ramig, *Tetrahedron Lett.* **1994**, *35*, 4501–4504; K. Ramig, L. Brockunier, P. W. Rafalko, L. A. Rozov, *Angew. Chem.* **1995**, *107*, 254–255; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 222–223. However, Schurig et al. have recently shown that this occurs with retention and not with inversion of configuration: V. Schurig, M. Juza, B. S. Green, J. Horakh, A. Simon, *Angew. Chem.* **1996**, *108*, 1814–1816; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 1660–1682. A mechanistic discussion on stereoselective decarboxylation, C–C bond cleavage, and proton transfers of this type can be found in Cram's classic textbook [3].

[41] One of the first applications of this principle was independently published by G. Fráter [42] and by us [43].

[42] G. Fráter, U. Müller, W. Günther, *Tetrahedron Lett.* **1981**, *22*, 4221–4224.

[43] D. Seebach, R. Naef, *Helv. Chim. Acta* **1981**, *64*, 2704–2708.

[44] Initially, we used the term "self-reproduction of chirality" or "of stereogenic centers" [45–48]. Our colleague Vladimir Prelog has, however, convinced us that the term "self-reproduction" should be reserved only for living organisms.

[45] D. Seebach, M. Boes, R. Naef, W. B. Schweizer, *J. Am. Chem. Soc.* **1983**, *105*, 5390–5398.

[48] "EPC Syntheses with C,C Bond Formation via Acetals and Enamines": D. Seebach, R. Imwinkelried, T. Weber in *Modern Synthetic Methods, Vol. 4* (Ed.: R. Scheffold), Springer, Berlin, **1986**, pp. 125–259.

[49] Many people call such a ketone prochiral. Vladimir Prelog, who could be described as our "stereochemical conscience", always points out that this definition is absurd, because it gives no clear structural definition (see also Scheme 5 in ref. [48]). Hence, for example, the imine **V** is prochiral as far as the addition of a nucleophilic alkylation reagent such as a Grignard reagent is concerned, but it is not prochiral with respect to reduction or hydrogenation. For the correct use and definition of the term "prochirality center" and other stereochemical terms, see the glossaries in: E. L. Eliel, S. H. Wilen, L. N. Mander, *Stereochemistry of Organic Compounds*, Wiley, New York, **1994**; "Nomenclature and Vocabulary of Organic Stereochemistry": G. Helmchen in *Methods of Organic Chemistry, Vol. E21a* (Eds.: G. Aubé in *Tetrahedron Organic Chemistry Series, Vol. 12* (Eds.: J. E. Baldwin, P. D. Magnus), Pergamon, Oxford, **1996**.

V

[50] 2,2-Disubstituted 1,3-dioxolanones have been prepared from lactic acid, mandelic acid, and alkyl aryl and other unsymmetrical ketones by using acid catalysis [51] or Ru catalysis [52]. However, reactions of the resulting enolates tend to occur, albeit not unexpectedly, in a not particularly stereoselective fashion [51]. On the other hand, the diastereoselectivity of Michael additions to dioxinones remains high even when the acetal center is substituted by both a *t*Bu and a Me group or when the six-membered ring derived from menthone is the substituent on the acetal center. See the work of Lange et al. [160–162] and of Kaneko et al. [238] and ref. [302].

[58] BASF kindly donated large quantities of pivalaldehyde to us over many years. We thank them for their generosity.

[59] Shell Chemicals is a source of large quantities of pivalaldehyde.

[60] It is highly likely that transformations previously described in the literature have followed the principles of self-regeneration of stereocenters; however, we know of no example where this synthetic principle was recognized, explicitly formulated, and systematically used before our own work.

[61] For more recent work on the stereoselective formation of tertiary centers, see also: S. V. Frye, E. L. Eliel, *J. Am. Chem. Soc.* **1988**, *110*, 484–489; T. Harder, T. Löhl, M. Bolte, K. Wagner, D. Hoppe, *Tetrahedron Lett.* **1994**, *35*, 7365–7368; B. Weber, D. Seebach, *Angew. Chem.* **1992**, *104*, 96–97; *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 84–86; B. Weber, D. Seebach, *Tetrahedron* **1994**, *50*, 6117–6128, and references cited therein. An article written by S. F. Martin deals with the particularly difficult problem of the stereoselective formation of quaternary centers: "Methodology for the Construction of Quaternary Carbon Centers": S. F. Martin, *Tetrahedron* **1980**, *36*, 419–460.

[80] The selectivity with regard to the configuration of the newly formed stereogenic center at the 1′-position (addition to aldehydes and Michael acceptors) is generally low. For highly diastereoselective reactions of chiral, glycine-derived enolates with concomitant formation of two new stereogenic centers, see Section 9.3 and Scheme 29e.

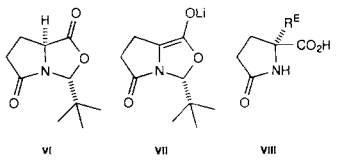
[87] T. Weber, D. Seebach, *Helv. Chim. Acta* **1985**, *68*, 155–161.

[88] The use of the SRS principle is not necessary in the case of hydroxyproline as this amino acid contains a second stereogenic center.

[89] D. Seebach, T. Weber, *Tetrahedron Lett.* **1983**, *24*, 3315–3318; D. Seebach, T. Weber, *Helv. Chim. Acta* **1984**, *67*, 1650–1661.

[90] See also the discussion in Sections 9.2 and 9.4, and Schemes 28 and 33, which relate to this particularly problematic case.

[91] It has recently been reported that when the bicyclic compound **VI**, which is prepared from pyroglutamic acid and pivalaldehyde, is deprotonated with LHMDS, it is not the amide enolate (deprotonation at the CH_2 group α to the carbonyl) but the ester enolate **VII** (new sp^2 center at the bridgehead position between two five rings!) that is formed. This results in a route to the α,α-disubstituted α-amino acid derivatives **VIII**. D. K. Dikshit, A. Maheshwari, S. K. Panday, *Tetrahedron Letters* **1995**, *36*, 6131–6134.



[92] Amino-, hydroxy-, and dihydroxycarboxylic acids with a temporary stereogenic center (for example, threonine, dihydroxybutanoic acid, and tartaric acid) may also be α-alkylated via the appropriate heterocycles. In these cases, the generation of a temporary stereogenic center is not necessary and the reaction sequence cannot be described as an example of the SRS principle. For the formation of products of type **XII** from reactions of threonine-derived enolates of type **IX**, see ref. [93] and D. Seebach, J. D. Aebi, *Tetrahedron Lett.* **1983**, *24*, 3311–3314; G. Fronza, C. Fuganti, G. Pedrocchi-Fantoni, *J. Carbohydr. Chem.* **1989**, *8*, 85–101; G. Fronza, A. Mele, G. Pedrocchi-Fantoni, D. Pizzi, S. Servi, *J. Org. Chem.* **1990**, *55*, 6216–6219; see also ref. [131]. For the formation of products of type **XIII** and **XIV** from reactions of dioxolanone carboxylic ester enolates such as **X** and **XI** and for related reactions of cyclopentane carboxylic ester enolates, which interestingly may proceed *cis* to the neighboring substituent at the stereogenic center, see refs. [62, 93–98]. The enolate **XI** has a relatively high tendency to decompose by β-elimination (see the discussion in the text and the legends of Scheme 6 and Schemes 29b and 32c, and also the review in ref. [36]).

[112] In the base-initiated cyclization of derivatives of type **XV** ($R^1 = CO_2Et$; R^2 = H, Me, Ph) attack occurs *trans* to the *t*Bu group (→ **XVI**) as expected. Altering the substituents in **XV** (R^1 = H, R^2 = CN; R^1 = Ph, R^2 = H) results in the formation of products of type **XVII** ($R^3 = NH_2$ or OH); this must be due to formation of the *trans* isomer of **XV** by epimerization at C4 before the cyclization step. [197] Together with "memory of chirality", which was referred to in ref. [20], other newfangled expressions such as "asymmetric memory technology", "asymmetric memory concept", "chiral memory", "chiral relay system", and "disposable chirality center" have appeared in the literature in recent years in relation to the SRS principle (A. S. Anslow, L. M. Harwood, H. Phillips, D. Watkin, *Tetrahedron: Asymmetry* **1991**, *2*, 169–172, and refs. [84, 217]).
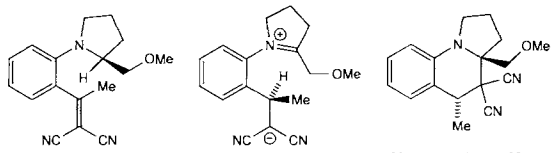
[198] In a true case of self-regeneration with concomitant generation of another stereogenic center, which clearly cannot have been conceived as a synthetic procedure, a stereoselective 1,5-hydride shift (**XX** → **XXI**) is followed by a diastereoselective ring closure (**XXI** → **XXII**), whereby substitution at the original stereogenic center occurs with retention (W. H. N. Nijhuis, W. Verboom, D. N. Reinhoudt, *J. Am. Chem. Soc.* **1987**, *109*, 3136–3138).



XX **XXI** **XXII**

[218] The decision as to whether we should include the usually catalytic process of the allylation of nucleophiles via Pd-π-allyl complexes such as that shown in Scheme 20a in this discussion was not an easy one. On no account would we wish to cram an S_N2 reaction that proceeds with inversion of configuration at a single stereogenic center of an enantiomerically pure substrate into the corset of the SRS principle!
[219] R. M. Williams, *Synthesis of Optically Active α-Amino Acids*, Pergamon, Oxford, **1989**.
[220] "Recent Developments in the Stereoselective Synthesis of α-Amino Acids": R. O. Duthaler, *Tetrahedron* **1994**, *50*, 1539–1650.
[221] If one considers the necessary steps, the chiral cyclic acetals shown in Schemes 10 and 16, which are derivatives of achiral carboxylic acids and are prepared by decarboxylation (aspartic acid → dihydropyrimidinone; serine, threonine, cysteine → imidazoline, oxazoline, thiazoline), are perhaps already results of overextending the SRS principle (laborious), despite their unique reactivity!
[222] The glycine derivative shown in Scheme 21 (top right) may also be prepared from methionine by formation of the imidazolidinone, elimination via a vinylglycine derivative, oxidative cleavage, and finally decarboxylation [223].

[223] T. Weber, R. Aeschimann, T. Maetzke, D. Seebach, *Helv. Chim. Acta* **1986**, *69*, 1365–1377.

[224] D. Seebach, D. D. Miller, S. Müller, T. Weber, *Helv. Chim. Acta* **1985**, *68*, 949–952. In the overall process, amino acids prepared by alkylation of the imidazolidinone shown in Scheme 21 (top) are the result of the replacement of the serine CH_2OH group by another substituent following the SRS principle.

[226] The separation of the product may also cause difficulties: for example, in Schöllkopf's synthesis of amino acids via bislactim ethers derived from diketopiperazines, the final step requires the separation of two amino acid esters (for a reference, see Scheme 22).

[251] Boc-BMI, Bz-BMI, and Z-BMI are commercially available in both enantiomeric forms from the following companies: Aldrich Chemical Company, Fluka Chemie AG, Interchim s. a. (France), E. Merck (Germany), Senn Chemicals AG (Switzerland), Wako Chemicals (USA).

[252] There are many examples in the literature of other applications of the chiral acetals shown at the bottom of Scheme 21. Two examples are briefly described here: 1) Formation of ylide **XXIII** by reaction of BMI with formaldehyde and subsequent treatment with, for example, *N*-phenylmalonic acid imide results in the tricyclic compound **XXIV**, which contains three new stereocenters (J.-F. Peyronel, S. Grisoni, B. Carboni, T. Courgeon, R. Carrié, *Tetrahedron* **1994**, *50*, 189–198). 2) Michael addition to a methyl phenyl dioxinone (→ **XXV**) with subsequent hydrogenolysis of one of the benzylic C–O bonds results in the formation of *O*-benzyl-protected 3-hydroxy-3-methylheptanoic acid **XXVI** [244].

[260] For example, see the discussion about "flustrates" in Section 2.2 of ref. [261].

[261] D. Seebach, *Angew. Chem.* **1990**, *102*, 1363–1409; *Angew. Chem. Int. Ed. Engl.* **1990**, *29*, 1320–1367.

[262] Only the use of a special trick allows the formation of the free α-branched amino acids that bear two bulky substituents [83]. Interestingly, drastic conditions are required for the hydrolysis of the 5,5-disubstituted *N*-benzoyl oxazolidinones with bulky substituents; the final step in which the benzoyl amide is cleaved requires: HOAc/conc. HCl (2/1), reflux [82], cf. ref. [83] and D. Obrecht, C. Spiegler, P. Schönholzer, K. Müller, H. Heimgartner, F. Stierli, *Helv. Chim. Acta* **1992**, *75*, 1666–1696; D. Obrecht, U. Bohdal, R. Ruffieux, K. Müller, *ibid.* **1994**, *77*, 1423–1429.

[263] For example, the addition of a cuprate to an alkylidene-Boc-BMI derivative is completely selective (rel. topicity 1,4-*lk*) by NMR analysis, even though three bonds and three trigonal centers separate the inducing and newly formed stereogenic centers (**XXVII** → **XXVIII**) [134, 253]. It is even more surprising that the reaction of the dienylidene **XXIX** with dibutylcuprate leads to a single product **XXX** (to date of unknown configuration), although five bonds separate the stereogenic acetal center and the site of substitution in the substrate (see ref. [253] and footnote [27] therein). Stereogenic centers positioned in a 1,5-fashion result from the 1,2- or 1,4-addition of the dienolate **XXXI** of 2-*tert*-butyl-6-methyl-1,3-dioxin-4-one, at the 5- and 1′-position, to an aliphatic aldehyde (→ **XXXII**) or enal (→ **XXXIII**), respectively [264, 265].

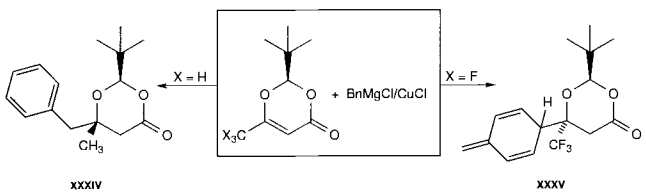
[265] D. Seebach, U. Misslitz, P. Uhlmann, *Chem. Ber.* **1991**, *124*, 1845–1852.
[266] For examples of 1,5-, 1,6-, and 1,7-induction see M. Nógrádi, *Stereoselective Synthesis—A Practical Approach*, 2nd ed., VCH, Weinheim, **1995**.
[267] Reactions of 4-methyl and 4-trifluoromethyldioxinones with Cu-doped benzyl Grignard reagents (to give **XXXIV** and **XXXV**, respectively) under identical conditions. In the first case, the standard *trans* addition (of the benzylic C atom) occurs, but the second example shows a *cis* addition (of the *para* C atom) with concomitant formation of the quinoid system [156, 157]! We have previously called F-containing reactants "flustrates" [261].



[268] As is evident from the discussion in ref. [29], it has been accepted for many years (work of Creger and Pfeffer) that deuterolysis of an enolate produced by the use of LDA is not a reliable method for determining the degree of enolate formation.
[269] For a review article dealing with the themes [Li-enolate·HNR_2] and [Li-enolate·$LiNR_2$], see refs. [21–23, 26–28, 48] and K. Rück, *Angew. Chem.* **1995**, *107*, 475–477; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 433–435.
[270] One further equivalent of Li-amide is produced, such that the desired product of the reaction with electrophiles is now at the mercy of this strong base!
[271] The stereoelectronic barrier, already discussed in Section 3, which protects the corresponding enolate from facile β-elimination, is nowhere near as high when the leaving group is RS^- in place of RO^-. When the rules for cyclization (the reverse of this elimination) were initially proposed, Baldwin explicitly stated that these are only valid for cases in which no elements of the second or a higher period are involved (see also Scheme 6 and ref. [111a]).

[275] Such adducts of RXLi and carbonyl groups appear to be involved in other reactions of Li-enolates and possibly play a much larger role than previously thought [272]. They could, for example, be responsible for the 2:1 reactions of aldehydes with Li-enolates and also possibly for the known stabilization of Li-aldolates against elimination to give α,β-unsaturated carbonyl compounds (see **XXXVI** → **XXXVII** and **XXXVIII** → **XXXIX** → **XL** [293]).

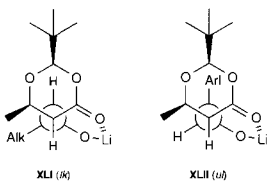
[292] See ref. [178a].
[293] J.-M. Lapierre, M. Gautschi, G. Greiveldinger, D. Seebach, *Chem. Ber.* **1993**, *126*, 2739–2746.
[294] It was not to be expected that the larger stability of the 1,3-*cis*-substituted five-membered ring heterocycle would be due to the diequatorial arrangement of the substituents in an envelope conformation (the *cis*/*trans* energy difference of 1,3-dimethylcyclopentane is 0.2 kcal mol^{-1}!). See: J. Dale, *Stereochemie und Konformationsanalyse*, 1st ed., VCH, Weinheim, **1978**.
[295] F. Johnson, *Chem. Rev.* **1968**, *68*, 375–413.
[296] R. W. Hoffmann, *Chem. Rev.* **1989**, *89*, 1841–1860.
[297] J. L. Broeker, R. W. Hoffmann, K. N. Houk, *J. Am. Chem. Soc.* **1991**, *113*, 5006–5017.
[298] Here, we use Dunitz's definition for pyramidalization (Δ) of trigonal centers: K. L. Brown, L. Damm, J. D. Dunitz, A. Eschenmoser, R. Hobi, C. Kratky, *Helv. Chim. Acta* **1978**, *61*, 3108–3135.
[299] The value of almost 20 kcal mol^{-1} of the partial amide C=N bond corresponds to practically a third of that of the C=C bond.
[300] For example, see the data in Table 1 of both refs. [62] and [178a] and also Table 4 of ref. [143].
[301] D. Seebach, T. Maetzke, W. Petter, B. Klötzer, D. A. Plattner, *J. Am. Chem. Soc.* **1991**, *113*, 1781–1786.
[302] Hence, the reversal of topicity from a weakly *unlike* to a strongly *like* preference during the aldol addition reaction of a trigonal center of a dioxolanone, *N*-acyloxazolidinone, or *N*-acylimidazolidinone Li-enolate to an aldehyde might be attributed to the close proximity of R^1 and H (in comparison with R^1 and R^2) (see structure **B** in Scheme 29e). See the general discussion in ref. [254] and the collection of data in Table F. Aldol additions of dioxolanones: ref. [47] and C. H. Heathcock, M. C. Pirrung, S. D. Young, J. P. Hagen, E. T. Jarvi, U. Badertscher, H.-P. Märki, S. H. Montgomery, *J. Am. Chem. Soc.* **1984**, *106*, 8161–8174; of oxazolidinones: [71, 246, 250]; of imidazolidinones: [71, 134, 258]. The higher proportion of *ul*-combination seen in the transition from aliphatic to aromatic aldehydes in the aldol addition of dioxanone-enolates [153, 178, 265, 293] may be due to a π–π interaction (see **XLI** und **XLII**).



[303] A. J. Birch, G. S. R. Subba Rao, *Aust. J. Chem.* **1970**, *23*, 547–552.

[305] Following a suggestion of B. Trost during a discussion with R. W. Hoffmann, the rather unfortunate expression "contrasteric" has been used in the literature for this effect [95, 98].

[306] In previous publications [93, 102], we have suggested that the *cis* selectivity could be due to the bicyclic nature of the dioxolane carboxylic ester enolate, which is attacked by the electrophile at the *exo* face, that is, *cis* to the existing substituent (see **XLIII** and compare the reactions of the bicyclic enolates derived from proline, hydroxyproline, thiaproline, azetidine carboxylic acid, and pyroglutamic acid, Section 3 and Table B). The chelate structure of the Li-enolate of α-RO-substituted carbonyl compounds has been established by NMR analysis of the corresponding silyl enol ether [31, 227].

Erich Hückel

A scientist caught between two stools: physicists found his work too nonphysical, and chemists didn't listen to him because he was a physicist.

Erich Hückel, Pioneer of Organic Quantum Chemistry: Reflections on Theory and Experiment

Jerome A. Berson*

In the period between 1930 and 1937, Erich Hückel, a theoretical physicist, made profound contributions to organic chemistry in his quantum mechanical descriptions of unsaturated and conjugated compounds. A brief account of his academic career is followed by simplified expositions, from the point of view of an organic chemist, of the highly approximate theoretical methods he used. Of special significance in the case of cyclic molecules of the class C_nH_n is the concept of filled shells when the number of π electrons is $(4N+2)$ $(N = 0, 1, 2, \ldots)$. Examinations of key applications of Hückel's ideas reveal how they eventually motivated the exploration of new fields in organic synthesis and organic reaction mechanism. Another significant (but until recently, virtually ignored) contribution by Hückel was the recognition that atomic connectivity is a strong determinant of spin multiplicity in non-Kekulé molecules. This idea provides, in principle, a basis for predicting violations of Hund's rule, as recent computational and experimental developments confirm. The interaction of experiment with different styles of quantum theory, and the impact of this relationship on the development of chemistry, are briefly considered. Speculations are given on why Hückel's work exerted so little influence on organic chemistry for decades before its importance finally began to be recognized.

Keywords: aromaticity · history of chemistry · Hückel, Erich · pericyclic reactions

1. Introduction

Erich Hückel's position as one of the early leaders in the development of quantum chemistry now is secure. Every modern chemist uses ideas that sprang from his work. Yet certain causes, undoubtedly connected but still not entirely clear, marked his career with bitter frustration, delayed the recognition that he deserved, and not incidentally, retarded the development of organic chemistry by muffling the impact of his contributions.

To trace the intellectual origins of his work is a challenge to the historian of science. How did a man trained as a theoretical physicist have the insight to choose problems of such significance to organic chemistry? Where did he find the daring self-confidence to make the gross (but ultimately successful) approximations of Hückel molecular orbital theory? What circumstances delayed the incorporation of his ideas into the everyday working knowledge of organic chemists?

2. Biographical Sketch[1–3]

This is the centennial year of Erich Hückel, who was born on August 9, 1896, the second of three sons of Marie and Armand Hückel. The intellectual development of the three boys was strongly influenced by their father, a physician with an interest in pure science. In the family line were several scientific notables, including the distinguished botanist Josef Gärtner (1732–1791). Erich Hückel enriched this heritage in 1921, when he married Anne Zsigmondy, the daughter of Professor Richard Zsigmondy of Göttingen, a renowned colloid chemist (Nobel Prize in Chemistry, 1925). The marriage endured until Hückel's death in 1980. Erich Hückel's brothers, Rudi (1899–1949) and Walter (1895–1973), followed in the family tradition. Rudi became a physician, but died prematurely. Walter achieved prominence as a professor of organic chemistry and a prolific author of significant research contributions and influential textbooks.[4]

Erich Hückel was trained as a physicist. His thesis for the D. Phil. at Göttingen (1921) under the supervision of Peter Debye was an experimental study of the scattering of X-rays. Afterward, he served briefly as an assistant to the mathematician David Hilbert at Göttingen but then rejoined Debye, who had moved to the Eidgenössische Technische Hochschule in Zürich. Hückel stayed in Zürich until 1927. Two years on a Rockefeller

Foundation scholarship, which he spent with Donnan in London and with Bohr in Copenhagen, were followed by two more years on a Deutsche Notgemeinschaft scholarship in Leipzig with Heisenberg and Hund. It was in Leipzig in 1930 that Hückel finished the first of his landmark papers on organic quantum chemistry.

Note that nine years after the D. Phil, Hückel still had no permanent job. In effect, his situation was like that of all too many of today's postdoctoral researchers, who float in semi-employed limbo. Through Debye's intervention, a *dozentur* of sorts was arranged for him at the Technische Hochschule in Stuttgart during the period 1930–1937. However, this was not a regularly budgeted position, and even Hückel's salary was insecure. In his book published in 1975,[1] Hückel relates that his wife often referred to this time as "seven years of disgrace".

Finally, in 1937 came a call to Marburg as Extraordinary Professor (Associate Professor) of Theoretical Physics. Except for a brief period immediately following the war, Hückel held this position until it was upgraded to that of Ordinary (Full) Professor in 1961, a year before his formal retirement. It was a mean career, blighted by marginalization and outright humiliation, and in some ways incommensurate with the magnitude of his contributions to science. As we shall see, some of his difficulties in gaining recognition arguably were self-inflicted, but others were not. More research would be needed to unravel all the causes, but there is little doubt that that the personal frustrations of Hückel's career mirrored the decades-long delay in general acceptance of the significance of his work.

3. Hückel's Early Contributions to Fundamental Physical Chemistry: The Debye–Hückel Theory of Electrolytic Solutions

As an assistant in Zürich, Hückel collaborated on the famous Debye–Hückel theory of strong electrolytes (1923),[5] which is described authoritatively elsewhere.[2, 6, 7] The details of the theory need not detain us here, but even an amateur comes away after reading these accounts with an appreciation of two major characteristics of Hückel's later independent work, particularly in the field of organic quantum chemistry: first the identification of the significant questions for which no satisfactory answers were yet available, and second the design of a theory based upon bold simplifying assumptions, which although perhaps not rigorously justifiable at the time, nevertheless showed the way to plausible explanations of known facts and to testable predictions. What is really operating here in this early phase of Hückel's career is a particular style of theory in which the goal is not a perfect, unshakable construct that will last for eternity, but rather a more pragmatic procedure, which might be described with the motto: *let's see if this works, and if it does, let's keep using it until it shows deficiencies.* Of course, this is the way many theoreticians often operate, whether or not they admit as much.

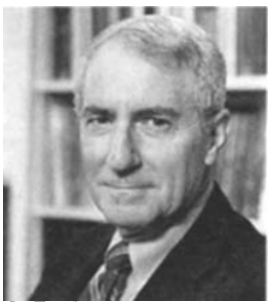
It is true, as has been said,[2] that we don't know for sure whether Debye or Hückel was the dominant partner in designing the approach to their joint problem, but this issue is almost beside the point here. One way or another, Hückel learned (or invented, or re-invented) this style in the work on the theory of electrolytes. It was to be a hallmark of his later independent research.

4. The Nature of the Double Bond

4.1. Origins of Hückel's Interest in Organic Chemistry

In searching for a pattern of influence on Hückel's famous 1930 papers[8] "Zur Quantentheorie der Doppelbindung," we note that he acknowledges the stimulus given by Bohr, in whose institute in Copenhagen he began the work in the summer of 1929. The first paper was finished in Leipzig at the end of the year. Hückel's autobiography[1] implies that Bohr's role consisted largely of identifying chemistry as a field to which the new quantum ideas might be fruitfully applied. There is no indication that Bohr made specific suggestions as to the areas of chemistry that might be interesting to examine.

Where then did Hückel get the idea to work on unsaturated and aromatic compounds? One might imagine that this much insight into the details of so foreign a discipline would have been unusual for a theoretical physicist of the time. It is conceivable that as a student or subsequently in preparation for his theoretical work, he may have acquired enough knowledge of chemistry, especially of organic chemistry, to generate the required motivation, but he makes no mention of special study. One can hardly avoid the conjecture that Walter Hückel's encyclopedic knowledge of the subject offered a far more accessible source. According to Erich Hückel's acknowledgment in the 1930 paper, Edward Teller was especially helpful on quantum mechanical questions and Walter Hückel on chemical matters. Our understanding of the human factors that condition the interaction of theory and experiment would be greatly enhanced if we knew



Jerome A. Berson was born in Sanford, Florida in 1924. He received the degree of B. S. in chemistry from the City College of New York in 1944. After service in the Army of the United States (1944–1946, China-Burma-India Theater), he returned to the study of chemistry at Columbia University, where he received MA (1947) and PhD (1949) degrees, working with W. von E. Doering. Following a postdoctoral year (1949–1950) at Harvard University with R. B. Woodward, Berson held faculty positions successively at the University of Southern California (1950–1963) and the University of Wisconsin (1963–1969). Since 1969, he has been on the faculty of Yale University, where he is now Sterling Professor Emeritus of Chemistry.

more about Walter's role. Although Erich's autobiography and other writings so far available to me are quite nonspecific about just what Walter provided, it is my (as yet undocumented) working hypothesis that Walter served as more than a mere source of factual information. It seems likely that his professional immersion in the culture of organic chemistry made it natural for him to point out to Erich several profound unsolved problems of the structure and reactions of organic compounds which one could hope to illuminate with the new quantum theory. In other words, Walter was in a position to perform a crucial service to Erich: he could ask the right questions. Whether he did so remains to be established.

4.2. Restricted Rotation of Double Bonds

In his first paper on organic quantum chemistry, Erich Hückel undertook to solve an intimidatingly deep problem, which is concisely stated in his own words:[8]

> "The chemist, especially the organic chemist, tends to link more to the concept of valence than merely the valence of the atoms. He would like to ascribe to the valence lines between bonded atoms a definite real existence, in which, especially in the chemistry of carbon, not only the number of valence bonds, but also their direction in space should have significance... In this work the generality of this question will not be treated; rather only a special case will be examined, which makes a contribution to this question. This case concerns what chemists call the 'restricted rotation of double bonds'".

The persistence of stereochemical configuration about C=C and C=N bonds had long been known and had been rationalized by the postulate of restricted rotation in such compounds. J. H. van't Hoff[9] had provided a classical (that is a prequantum theoretical) "explanation." The carbon–carbon double bond was imagined to be made up by contact of two tetrahedrally disposed valences of each atom (Fig. 1). This would result in the

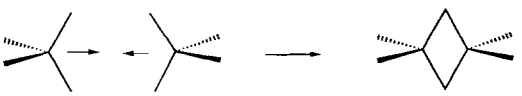


Fig. 1. Junction of two sets of tetrahedral carbon valences to produce a double bond, in the manner of van't Hoff [9]. The bonds lie outside the C–C direction; the remaining four valences lie pairwise above and below the plane of the paper.

stereochemistry shown, with the four remaining valences lying in the same plane as the carbon atoms. The structure would be resistant to rotation of the carbon atoms with respect to each other about the line joining them, because such twisting would diminish the contact of the valences. Of course, this proposal begged the question that Hückel was concerned with: what is the physical nature of these valences?

Soon after the first[8] of Hückel's papers on the double bond appeared, Pauling[10a] and Slater[11] independently were to develop a quantum mechanical description of ethylene which was very close in spirit to van't Hoff's representation. They visualized the two carbon–carbon bonds as *equivalent entities* made up by overlap of sp^3 hybrid orbitals whose axes lay on either side of the actual C–C internuclear line. As part of a general theory of directed valence, these same sp^3 hybrid orbitals had been postulated to account for the tetrahedral orientation of the bonds of tetravalent carbon atom.

Several textbook authors have wrongly ascribed to Pauling the concept of trigonal (sp^2) hybridization of the doubly bonded carbon atoms in ethylene (see below). Pauling's example of this hybridization was graphite, not ethylene. In fact, he remained strongly opposed to the concept that the two ethylene C–C bonds were different, an unavoidable consequence of trigonal hybridization. The H–C=C angle in a trigonally hybridized alkene is predicted to be 120°, but Pauling's *The Nature of the Chemical Bond* (1961 edition[10a]), which cites a number of experimental determinations near 125°17′, stoutly defends the tetrahedral model, which predicts the latter value (half the difference between 360° and the tetrahedral angle H-C-H angle 109°26′). It is probably fair to say that in the current era of ab initio theory, a decision between these two approaches, which are after all only models, has become moot.[10b]

Curiously, one often sees, in implied or direct form, similar misattributions of the trigonal hybridization concept to Hückel. It is true that the essence of Hückel's model is that the two C–C bonds are *nonequivalent*, one σ and one π bond, a basic distinction from the tetrahedral model favored by Pauling. However, Hückel's ethylene model in the first instance did not arise from hybridization considerations and did not require trigonal hybridization. In fact, the $\sigma-\pi$ ethylene model originated in the quantum theoretical treatment of a seemingly very different molecule, molecular oxygen, O_2. How Hückel's new plant sprang from such unlikely soil makes a long story, but the lessons to be learned about the genesis of ideas justify an abbreviated version. The hybridization question is discussed in more detail in Section 4.4.

4.3. From Dioxygen to Formaldehyde to Ethylene

In 1929 the year just preceding the appearance of Hückel's paper, Lennard-Jones[12] had made a molecular orbital analysis of the electronic structure of dioxygen in its ground state, which he represented as having the following occupation pattern: $(1s)^2(1s)^2(2s)^2(2s)^2(2p_+)^2(2p_-)^2(2p\sigma)^2\{2p\pi_+, 2p\pi_-\}$ As Hückel points out,[8] this notation differs from the "united atom" MO formalism of Hund and Mulliken, which is more familiar now, and which had been developed for diatomic molecules. Lennard-Jones's notation is more suitable for showing the electronic states that are being generated during dissociation of the "united atom."

The results are shown in Figure 2.[13] Note that the interaction of the two filled 2s atomic orbitals gives rise to no net bonding in this approximation, which (with apologies) limits the discussion to the molecular orbitals (MOs) derived from the atomic 2p orbitals and alters Lennard-Jones's presentation to a "united atom" form. An oxygen atom in its ground state has four electrons in the three mutually perpendicular p atomic orbitals (AOs). When two such atoms are brought into bonding distance, the six AOs give rise to six MOs. Two of the MOs, a strongly bonding ($\sigma 2p$) and a strongly antibonding ($\sigma^* 2p$) pair,

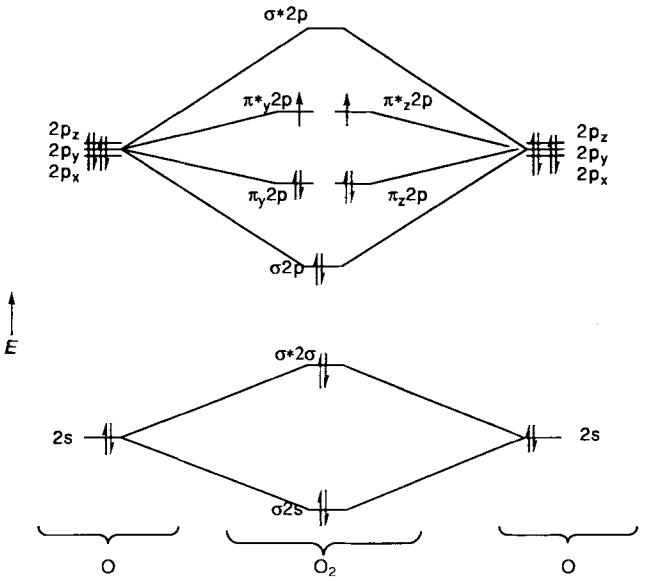

Fig. 2. Formation of O_2 molecular orbitals from oxygen atomic orbitals. The occupation pattern and spin state are derived by application of Hund's highest multiplicity rule. The energies are shown schematically (adapted ref. [13] with permission of Oxford University Press).

result from mixing of the two original p orbitals that lie along the internuclear line. The remaining four atomic p orbitals mix to form two degenerate π MOs and two degenerate π* MOs. The nodal planes of the π MOs are a mutually perpendicular (arbitrarily chosen) pair containing the two atomic nuclei, and the π* MOs each have the same pair of nodal planes in addition to a perpendicular nodal plane bisecting the internuclear O–O line. The total of eight electrons (originally from p orbitals) now must be fed into this set of MOs. Two each, with opposed spins, go into the bonding σ and the two bonding π MOs. Although formally the remaining two electrons can go into the pair of π* orbitals in any of several occupancy and spin configurations, Lennard-Jones assumed that, in energy, "that state is held to be lowest which has the greatest multiplicity, as is the case in atoms". Here, this would be a triplet state, in which the last two electrons each occupy one of the degenerate π_y^* and π_z^* orbitals and their spin vectors are parallel. The nominal overall bond order is two, since although there are three bonds, one of them can be considered to be formally cancelled by an antibond.

By this explanation of the experimentally known fact that dioxygen is paramagnetic in its ground state, Lennard-Jones's analysis provided a brilliant early triumph for the quantum theory. Apparently, Hund's first rule,[14, 15] which originally had been promulgated for atoms, also applies to certain molecules. Dioxygen is a case in which the rule might be expected to apply strictly, because of the symmetry-enforced degeneracy of the π* orbitals (see below).

Nevertheless, this insight was not the major focus of Hückel's interest in Lennard-Jones's paper. In fact, the triplet nature of dioxygen might well have bemused a lesser intellect, and a connection between the intriguing special case of dioxygen and the less spectacular but far more general problem of ethylene might never have become clear. What attracted Hückel was the idea that there can be *two kinds* of oxygen–oxygen bonds, σ and π.

The next step toward the description of doubly bonded carbon was an ingenious *gedanken* experiment. Hückel imagined the conversion of one of the oxygen nuclei of dioxygen to carbon by the extraction of two protons, which then were bound to the resulting carbon nucleus to give formaldehyde. If we today were following this protocol, we probably would make formaldehyde analogously to the construction of dioxygen shown in Figure 2, with the exception that one of the oxygen atoms would be replaced by an sp^2-hybridized fragment CH_2, and the units would be brought together so that all four atoms were in a common plane. Again, one of the carbon 2p orbitals could form a σ bond by overlapping a 2p orbital of the oxygen, and the other carbon 2p orbital would form a π bond with the oxygen p orbital. However, Hückel declined to make the assumption of coplanarity at the start, and argued his way through alternative geometries before rejecting them in favor of the planar one. Also, in 1930, it was not obvious what should be the ordering of the energies of the MOs resulting from the procedure. Hückel again presented arguments that favored the ordering we accept today.

The details, though interesting, are too lengthy to give here, but one major point is worth emphasizing. In both arguments, Hückel resorted to experimental data to make his decisions. With regard to the multiplicity question, it was clear that because of the need to bind the substituent hydrogens to the carbon atom in formaldehyde, the π* MOs would not be each singly occupied, and the degeneracy that causes a triplet ground state in dioxygen would not exist in formaldehyde. Nevertheless, it was (then) a difficult computational problem to decide whether the multiplicity of the ground state of formaldehyde should be a singlet π or a triplet π–π*. Hückel's basis for rejecting the triplet was analogical: although no experimental information on the magnetic properties of formaldehyde was available, it was known that acetaldehyde was diamagnetic and hence a singlet.

Similarly, with regard to the molecular geometry, Hückel pointed out that a nonplanar monosubstituted formaldehyde, for example, acetaldehyde, would be pyramidal, with three nonequivalent substituents, and hence one would predict the existence of optical isomers. No such isomers were known. It is heartening to realize that Hückel, a pioneer of theory, was in the latter case not too proud to use the organic chemist's traditional (but nonrigorous) argument of isomer numbers! We have no evidence that Walter Hückel provided this insight to his brother, but it is easy to imagine his doing so.

Formaldehyde-to-ethylene then required only a repetition of the oxygen-to-CH_2 *gedanken* step. Again, the presence of the substituent hydrogens is the key structural feature that favors a singlet ground state. Hückel had now achieved his first objective, a quantum mechanical description of the double bond that would explain restricted rotation. In his model, the C=C double bond is made up of a σ and a π bond. The σ bond is axially symmetric about the internuclear C–C line, but the π bond is not. Rotation of one of the CH_2 groups out of the plane of the other is resisted because to continue this process to 90° would require breaking a π bond. Hückel did not provide a quantitative estimate of the strength of this bond, but it must be substantial to account for the thermal stability of olefinic *cis–trans* isomers. He emphasized the deep structural difference between this model and that of van't Hoff, in which both of the C–C bonds are equivalent.

4.4. Hybridization in Double Bonds

It will be clear that a bit of mystery still lingers over Hückel's picture of ethylene at this point: What is the nature of the C–H bonds? Hückel never clarified this but left it to others. In 1931 and 1932, the years immediately following Hückel's first paper on ethylene, the concept of quantum mechanical hybridization was introduced as the basis of a theory of directed bonding. As we have seen, this idea played an important role in the development of the Pauling–Slater equivalent-bond model of ethylene. In 1933 Mulliken[16] suggested trigonal hybridization of the carbon valences in ethylene, and in 1934 Penney[17] made a more extensive comparison of this model with two alternatives, the so-called "right angle" model and the van't Hoff-like Pauling–Slater tetrahedral model.

In the right angle model (Fig. 3), Penney imagined the C–H bonds to be pure 2pσ bonds, and the double bond joining the two carbons to be made up of one (s,s) and one (σ,σ) bond.

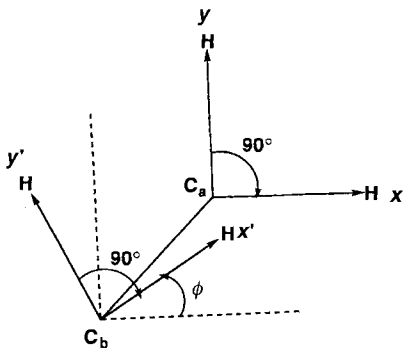

Fig. 3. Penney's right angle model (ultimately rejected in favor of the σ–π model) for ethylene.

The vicinal hydrogen interactions are neglected, and the C–C bonds, although not equivalent, are both axially symmetrical about the C–C direction, so that the energy of the configuration does not depend on the the angle ϕ through which one carbon is rotated with respect to the other. As Penney recognized, this model predicts free rotation about the C=C bond, and therefore cannot account for one of the characteristic properties of alkenes.

Penney compared the tetrahedral model and the trigonal model by means of a valence bond calculation and concluded that the trigonal model was energetically preferred. Although the sp^3 hybrid orbitals of the tetrahedral model have more extension along the orbital axis than the sp^2 orbitals of the trigonal model, the sp^3 orbitals are necessarily canted outward from the internuclear C–C line and hence overlap poorly. He subsequently proposed trigonally hybridized carbon as the building block of the σ framework of the benzene ring.

Eventually these suggestions became widely adopted for discussions of doubly bonded carbon. In part, this acceptance must have been furthered by later group theoretical arguments by Kimball,[18] but one may speculate that it also was based on the simple conceptual continuity of the hybridization picture (sp^3 for methane, sp^2 for ethylene, sp for acetylene), which made the idea pedagogically attractive. Actually a more hard-eyed evaluation of the quantitative merits of Penney's calculations might have been appropriate. One certainly should have been concerned about Penney's conclusion that the energy needed to rotate one CH_2 plane in sp^2 hybridized ethylene by 90° with respect to the other was "quite small, probably about 1/2 volt," (about 11.5 kcal mol^{-1}). If a similar value were required in substituted ethylenes, stable *cis–trans* isomerism could not have been observed at room temperature. In other words, were one to take the calculation at face value, the same argument used to reject the right angle model logically would have required rejection of the trigonal model.

5. The Benzene Problem

It might be surmised that Hückel proceeded from ethylene to conjugated chain compounds such as allyl, butadiene, pentadienyl, hexatriene, etc., and then to benzene, and other cyclopolyenes, in the systematic manner that we teach Hückel molecular orbital (HMO) theory to students today. Actually, this is not the sequence that occurred. Hückel eventually considered unsaturated chains as a class,[19] but in the breakthrough paper in 1931,[20] his target was benzene itself.

The paper was Hückel's *Habilitationsschrift* for attaining the *venia legendi* (right to teach) in theoretical physics at the Technische Hochschule Stuttgart. A massive document of 84 printed pages, it gave two descriptions of benzene and other conjugated cyclopolyenes: the "first method," which eventually came to be the valence bond (VB) theory, and the "second method," now called the molecular orbital (MO) theory. Hückel gave reasons for preferring the MO procedure, and although some of these might not be very convincing today, he persisted in this choice thereafter. Both the first method and the second method assumed that the unique properties of cyclic conjugated systems could be attributed approximately to the π electrons without explicit consideration of their interaction with the σ electrons.

5.1. Hückel's First Method and Classical Valence Bond Theory

The valence bond method, which Hückel had rejected, was taken up soon after by Pauling and others,[10, 21–25] who simplified the mathematical procedures and gave reasons for preferring the VB to the MO method. Again, with regard to the problem of cyclic conjugated molecules, their reasons seem insufficient today, but these workers held unwaveringly to their choice in later years. This "classical" VB method, and Pauling's pedagogical packaging of its major results in the form of the "theory of resonance," dominated theoretical chemistry for 25 years after 1930. The reasons for this, further examined below, were not necessarily that the theory was "correct" in any absolute sense, but rather that Pauling, with consummate knowledge of the whole field of chemistry, convincingly showed how a broad range of chemical phenomena, especially in small molecules, could be explained by some kind of quantum ideas[10a] and thereby established a faithful and largely uncritical following. As it happened, however, the classical VB method, in the truncated form of it he used, was to prove theoretically inadequate when applied to the problem of aromaticity.

It is true that with the emergence of high-speed digital computers, as is described elsewhere,[14, 26, 27] the MO method, in increasingly sophisticated manifestations, gradually became the major basis for the explosive computational development of electronic structure theory. However, one should not conclude that VB theory is without adherents today. On the contrary, many investigators have contributed developments of advanced VB methods and successful applications to significant problems, including as we shall see, the reconciliation of the VB and MO theories of aromaticity.[28, 29]

The most characteristic feature of the valence bond method is that it considers the combining atoms as a whole.[30] The formation of a molecule is thought of as arising from the bringing together of complete atoms, which are then allowed to interact. In this it differs from the MO method, in which only the nuclei (or nuclei + electron inner shells) are first brought into position, and afterwards the valence electrons are allotted to polycentric molecular orbitals. Clearly the VB method corresponds more closely with the conventional chemical picture, which probably accounts for its widespread acceptance in the form presented by Pauling.

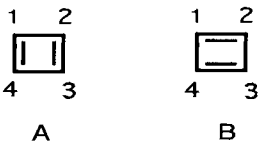
Hückel's first method, the early form of VB theory, was derived from Heitler–London[31] theory for the formation of molecular hydrogen from two hydrogen atoms. It starts with each atom in a specified quantum state and then introduces exchange. The exchange procedure, which takes into account the indistinguishability of the two electrons 1 and 2 in the form of the exchange integral $\langle \Psi_A(1)\Psi_B(2)|\mathscr{H}|\Psi_B(1)\Psi_A(2)\rangle$, has major significance in the VB method. For example, the binding energy of hydrogen calculated without exchange is only 5.5 kcal mol^{-1} but when exchange is included in the wave function, the binding energy rises to 69 kcal mol^{-1}, a substantial fraction of the experimental value of 104 kcal mol^{-1}.[30]

By application of group theoretical procedures, Heisenberg[32] used this exchange method to explain ferromagnetism. Slater[32] then developed a useful determinantal method which made possible the treatment of interaction among a large number of atoms without group theory and applied it to electrons in metallic lattices. This method was further applied by Bloch[33] in place of the Heisenberg group theoretical method for the theory of ferromagnetism. Hückel used the Bloch formalism directly in his first method.

As described by Hückel,[34] the treatment of a conjugated molecule (such as benzene) by the classical VB method begins by assigning to each carbon atom a π electron which is in a given state with the positional eigenfunction $\phi_a(r_{ia})$, where the suffixes indicate the ith electron in the atom a. The total positional eigenfunction, taking coupling of the π electrons into account, is written as a linear combination of the products $\phi_1(r_{i1}) \ldots \phi_6(r_{i6})$. Starting from this, the Heitler–London perturbation method is worked out to the first approximation. Spin is taken into account, and only the linear combinations that conform to the Pauli principle are considered.

In the Pauling modification of VB theory,[21] one selects from these linear combinations those which correspond to the smallest value of the total spin (in this case $S = 0$), and chooses from these the ones that are linearly independent. These functions which belong to the value $S = 0$ can be associated with models of the valency pattern of the π electrons in which the atoms are joined in pairs by single bonds, one and only one bond radiating from each atom in such a way that the bonds do not cross one another. Pauling called the schemes of valencies corresponding to the functions "canonical structures." One then formulates and solves the secular perturbations corresponding to these functions, restricting the coupling to that between adjacent atoms.

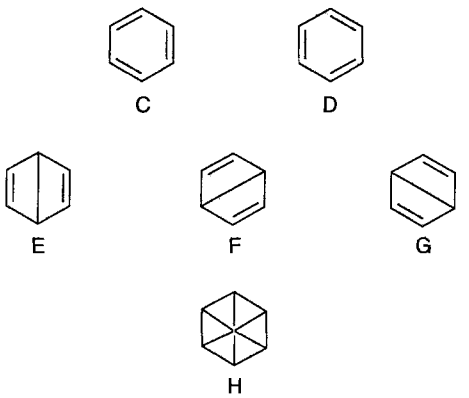
Wheland[22] gives a simple example of the application of this method to the case of cyclobutadiene. The canonical structures are **A** and **B**. One designates the eigenvalue of the energy as W, the 2p function on the ith carbon atom as Ψ_i, the coulomb integral $\langle \Psi_1\Psi_2\Psi_3\Psi_4|\mathscr{H}|\Psi_1\Psi_2\Psi_3\Psi_4\rangle$ as Q, and the single exchange integral between adjacent carbons, for example, $\langle \Psi_1\Psi_2\Psi_3\Psi_4|\mathscr{H}|\Psi_2\Psi_1\Psi_3\Psi_4\rangle$ as α'. All single interchange integrals of the energy between nonadjacent atoms, all multiple interchange integrals, and all interchange integrals of unity are neglected. The Slater valence-bond eigenfunction may be expressed as secular equation (a).



$$\begin{vmatrix} Q+\alpha'-W & (1/2)Q+2\alpha'-(1/2)W \\ (1/2)Q+2\alpha'-(1/2)W & Q+\alpha'-W \end{vmatrix} = 0 \qquad \text{(a)}$$

This has the solutions $W = Q + 2\alpha'$ and $W = Q - 2\alpha'$, of which the former represents the ground state since the exchange integral α' is presumably negative. The resonance energy is obtained by subtracting from this a quantity $Q + \alpha'$, the energy of one of the two canonical structures: $Q + 2\alpha' - (Q + \alpha') = \alpha'$.

In the case of benzene, there are five canonical structures with corresponding canonical functions: **C** and **D** correspond to the Kekulé forms, **E**, **F**, and **G** to the Dewar forms. Other structures,



such as for example **H**, that of Claus, can be expressed as linear combinations of the canonical functions [Eq. (b)].

$$\phi_H = \phi_C + \phi_D - [\phi_E + \phi_F + \phi_G] \qquad \text{(b)}$$

Following a procedure similar to that used for cyclobutadiene, the coupling energy for benzene is $6Q + 2.6055\alpha'$, and the molecular eigenfunction is given by Equation (c).

$$\phi_{benzene} = 0.62435\,(\phi_C + \phi_D) + 0.27101\,(\phi_E + \phi_F + \phi_G) \qquad \text{(c)}$$

In the sense of the approximation, the ground state thus may be considered to result from the superposition of the two Kekulé and the three Dewar forms.

One might be concerned about the approximation which limits the exchanges to pairwise nearest neighbors. Clearly there are many more permutations that could be included. Wheland[22] himself states:

"This assumption is an extremely drastic one and no rigorous justification for it can be given. The integrals we ignore are probably, to be sure, rather smaller in magnitude than the other ones which we retain. There are, however, an enormous number of the former integrals, and, even though some of them are positive and some are negative, we can have no assurance that their net effect is negligible. We shall, nevertheless, make the assumption because, without it, our calculation would become impracticably complicated, and because, with it, surprisingly satisfactory results can be obtained."

As we shall see, the neglect of some of these other permutations has serious consequences for the description of cyclic conjugated systems.

Although the classical VB procedure came to be called[22] the Heitler–London–Slater–Pauling (HLSP) method, Slater in fact preferred to put some distance between himself and Pauling in applications of the method. Thus, in a discussion[35] at the International Conference of Physics in 1934, Slater remarked that he was in "entire agreement" with Hückel and Hund that the MO method is superior to the Heitler–London method for computing interatomic forces, and that "the calculations of Pauling, for instance, seem to make quite unwarranted use of the theory." Slater gave no further details, but it seems a reasonable conjecture that he was expressing misgivings over the truncation.

5.2. Hückel's Second Method and Molecular Orbital Theory

This procedure, subsequently called[22] the Hund–Mulliken–Hückel (HMH) method, had as an immediate intellectual precursor another study[36] by Bloch on the quantum mechanics of electrons in crystal lattices. Bloch, at that time in Leipzig, was actively developing the theory of metals in order to understand such phenomena as conduction and magnetism. Subsequently, of course, he became famous for providing some of the theoretical foundations for the field of nuclear magnetic resonance.

Bloch approached the problem of the electronic interactions in a many-electron system by considering the properties of a single electron in a spatial force field perturbed by the atomic nuclei and the statistical charge distribution of the remaining electrons. The idea is very similar to the Hartree–Fock method for treating many-electron atoms. In Bloch's sinewy words, "the force field has the same periodicity as the crystal lattice itself," and "we are thus dealing with plain de Broglie waves which are modulated in rhythm with the lattice."

The procedure Hückel used[20] was to set up such a lattice for benzene, calculate the MOs (wave functions) and energy levels in terms of the parameters α and β (defined below) by solving the Schrödinger equation, and construct the electronic configuration by *aufbau*, in accord with the Pauli principle and in analogy to the practice of Hund, Mulliken, and Lennard-Jones for diatomic molecules. Hückel's benzene lattice was a regular hexagonal array of carbon $2p_z$ orbitals. As every chemistry student now knows, the results can be expressed as shown in Figure 4,

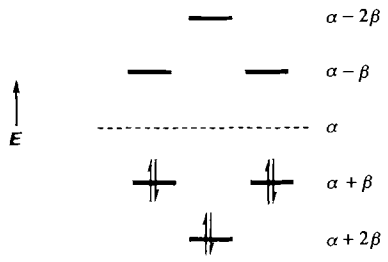


Fig. 4. Energy levels of benzene and occupation pattern in the ground state as calculated by Hückel's second method. The parameters α and β are defined in the text.

where α is the energy of an electron in an unperturbed carbon 2p orbital, and β is the stabilization energy (relative to α) experienced by an electron when two such units interact at a defined distance.

Hückel generalized this result to other conjugated systems with n centers, both to rings of other sizes and to chains.[19, 20, 34, 37] The energy levels can be expressed in the famous Hückel Equations (d), $j = 1, 2, 3, \ldots n$, and (e), $k = 0, \pm 1, \pm 2, \ldots m$, where $m = (n-1)/2$ for n odd and $m = n/2$ for n even.

$$\text{Chains } C_nH_{n+2}\text{: } E = \alpha + 2\beta\cos[j\pi/(n+1)] \quad \text{(d)}$$

$$\text{Rings } C_nH_n\text{: } E = \alpha + 2\beta\cos[2k\pi/n] \quad \text{(e)}$$

Among the messages that these equations convey are that the energy levels for the chains are unique, whereas some of those for the rings are doubly degenerate, that is, the eigenvalues sometimes occur in pairs of equivalent energy. As Hückel pointed out,[37] these degeneracies are a direct consequence of the cyclic nature of the electron circulation in the ring compounds. The physical reason is that in the energy states that have a finite angular momentum associated with the electronic motion, the circulation is *directional* in either a clockwise or a counterclockwise sense. The eigenfunctions corresponding to these states are not identical, even though the energies are, so *two* MOs must exist at that energy. An equally important point is that for n even or odd the lowest eigenvalues of the ring compounds are unique, and for n even, the highest also are unique. These are nonintuitive results that come out of the solution of the Schrödinger equation and that mark this approach as fundamentally different from the old (Bohr) quantum theory. Whereas in the old theory, for example, the lowest atomic s states still had angular momentum $h/2\pi$, in the new theory the s states now have zero angular momentum. Similarly, in the unique states of benzene, the angular momentum is zero, and consequently, the "sense" of the electronic circulation becomes meaningless.

This difference between rings and chains will be familiar to students of elementary quantum mechanics,[38–41] where a favorite pedagogical exercise is the calculation of the eigenvalues of the "one-dimensional" Schrödinger equation. An electron is

imagined to be constrained to move along a line or in a circle under zero potential. The solutions for the linear case are unique; those for the circular case have the lowest energy level unique but all the rest pairwise degenerate.

Hückel[19, 20, 34, 37] emphasized that the MO method, in producing such energy level patterns, led to the idea of closed electron shells analogous to those of the noble gas closed shells in atoms. Particularly significant for the n even conjugated rings was the case of six electrons in benzene, which had been recognized for some time as a feature leading to aromatic properties. Since the Pauli principle allows each orbital to accommodate two electrons of opposite spin, filling the first three orbitals (first two energy levels) of the benzene set 1, 2, 2, 1 in this way would give a stable configuration. On the other hand, four electrons in cyclobutadiene would not give a closed shell, since only the lowest level of the 1, 2, 1 set could be filled. The next higher level could accommodate four electrons but only would have two available. Moreover, in the case of ions derived from odd-membered rings, where all levels above the lowest are degenerate, a closed shell configuration again is reached with six electrons, as in the cyclopentadienide ion, but not with eight, as in the cycloheptatrienide ion or with four as in the cyclopentadienylium ion.

This rule, subsequently stated by others in the abbreviated form $(4N+2)$ $(N = 0,1,2...)$, namely that aromaticity should be associated with monocyclic π electron systems containing $2, 6, 10...$ electrons, was in accord with the known facts of organic chemistry at the time. In addition, predictions now could be made about the existence and properties of unknown but easily imaginable new structures. Although the rule does not apply strictly to polycyclic compounds such as naphthalene or biphenyl, Hückel showed by explicit MO calculations[37] that these systems too should be considered aromatic, as might have been expected. There are limitations to the rule, but much computational research in recent years confirms the essential fact that Hückel's broad classification of aromatic and antiaromatic character survives at higher levels of MO theory and is not just an artifact of the approximations used in the early treatment.[42]

Significantly, the classical VB method did not produce these results. For example, it predicted that cyclobutadiene should have the highest resonance energy per electron of any of the even cyclic polyenes, and it gave no reason to expect that cyclopentadiene should be a much stronger acid than cycloheptatriene. These failures of classical VB theory were among the reasons that Hückel in 1931 turned away from it as a basis for understanding aromaticity. More than half a century later, the opinion persists[43] that classical VB theory is "decisively unsuccessful"[44] for this purpose.

Nevertheless, one feels intuitively that a higher level of VB theory should be capable of reproducing the Hückel rule. After all, both the MO and the VB approaches are approximations of the complete solution of the Schrödinger equation. At successively higher degrees of approximation, the two methods should converge to give equivalent results. In fact, such convergence can be shown analytically for a simple molecule such as H_2 and is expected generally, however complicated the molecule may be.[45] It comes as no real surprise, therefore, that eventually methods for deriving the Hückel rule by VB theory should emerge.[44, 46, 47] The key insight in solving this problem is the crucial necessity to include *cyclic* permutations of the π electrons in the exchange procedure. Just such exchange integrals were among those omitted in the classical VB method. An experimentalist senses a gratifying propriety in this result.

6. A Chilly Reception from the Experimentalists

Hückel's pioneering papers on the molecular orbital theory of unsaturated and aromatic compounds appeared in the period 1930–1931, but they seemed to make little impact on the community of chemists for many years after. In their biographical memoir on Hückel, Hartmann and Longuet-Higgins[3] ascribe the general neglect of his results to the national culture of German science:

> "... physicists in that country in any case were not ready to accept investigations about more complicated chemical bond phenomena as a typical contribution of a physicist. Still more difficult was his (Hückel's) relationship to the chemists. Before World War II, especially in the Anglo-Saxon countries, chemical physics and within that field quantum chemistry also was accepted by both physicists and chemists as an interesting new field of science. Chemists in Germany, on the other hand maintained that chemistry is what chemists do. They did not do quantum chemistry and therefore this kind of science did not belong to chemistry."

It may well be true that German chemists of that period or even later resisted quantum ideas. Although Rolf Huisgen reports[48] that he was teaching Hückel's results (but not the details of how the calculations were done) as early as 1949, this undoubtedly was exceptional. Even Walter Hückel makes only cursory reference in his textbook[49] to the contribution his brother had made to the problem of the aromatic sextet.

However, I regret to say that crediting a more receptive attitude to "Anglo-Saxon" chemists, especially the experimental organic chemists, pays them a higher compliment than most of them deserve. Again, there were scattered exceptions. For example, Ingold[50] in Britain and Hammett[51] in the United States clearly were aware of the importance of Hückel's work. Elsewhere in these countries, however, even though the problem of aromaticity was prominent in the minds of chemists, and much experimental effort was devoted to it, whatever theoretical reasoning experimentalists brought to bear on such issues in their research or teaching depended almost entirely on resonance theory.[52] Noller's review of 1950,[53] ostensibly an exposition of molecular orbital theory prepared for the edification of organic chemistry teachers, does not cite a single reference to Hückel. Most elementary and even advanced textbooks of those years make no mention whatever of Hückel's ideas. One of the most influential books in the field, the second edition (1943) of the multi-authored *Organic Chemistry – An Advanced Treatise*, edited by Gilman, contains a substantial chapter by Fieser on aromatic compounds.[54] The question of aromaticity is presented only from a historical perspective, and for a theoretical rationale, Fieser defers entirely to Pauling, who contributes a chapter on theory in the same work,[23] using the already well-known resonance method. Although Pauling mentions the Hückel theory there, he declines to discuss it further on the grounds that the

resonance approach "is the more closely related to the usual concepts of chemistry". Not surprisingly, Pauling's omissions of scholarly exposition and comparison here and elsewhere infuriated Hückel.[1]

It is true that there was a flurry of theoretical activity, especially in Britain, following up further implications of some of Hückel's ideas. This included work[55] by, among others, Coulson on mobile bond orders, Coulson and Rushbrooke on alternant π-conjugated systems, Longuet-Higgins on non-Kekulé-molecules, and Dewar on a range of chemical properties deducible from perturbational MO considerations. These papers, written in the elegant lapidary style familiar to mathematicians, and often published outside the conventional chemical journals, were important, but they were either unknown or largely unintelligible to many organic chemists.

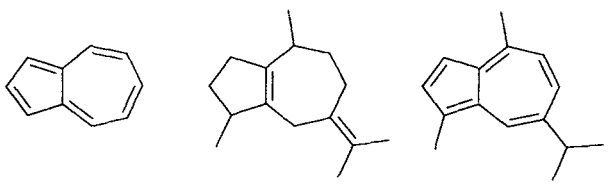
Similarly, a key two-part paper[56a] by Mulliken and an important early textbook by the Pullmans,[56b] both in French, influenced a few young theoretically able workers such as Simonetta, and through him, Heilbronner,[57] but their immediate impact on the thinking of most organic chemists was not great.

Having lived through that period, I can attest that the attitude of many American organic chemists toward MO theory was uninformed and indifferent, if not hostile. Few of them would have taken the trouble to slog through Hückel's highly technical papers, which bristled with equations and matrices, and which, with one obscurely placed exception,[34] were not available in English. The charismatic Pauling had provided them with a theory which at some level required no mathematics and could be applied by using familiar bond structures. Most of them were content with that.

7. Experimental Tests of the MO Description of Conjugated Cyclic Compounds

If organic chemists were to a large extent unaware of the Hückel rule, how could there have been deliberate tests to explore its scope? In fact, a number of molecules synthesized or discovered in nature after Hückel's papers in the early 1930s eventually turned out to be relevant test species, even though the authors originally had some other motivation for studying them. In this inadvertent process, we see again the familiar paradoxical sequence encountered so frequently in science: "Here's the answer, what's the question?"

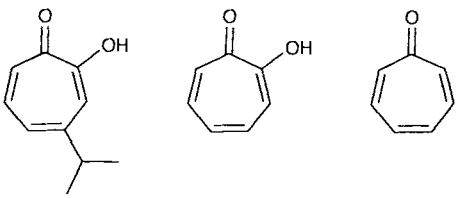
Early examples of this come from the chemistry of the azulenes (Scheme 1), a fascinating group of blue or violet substances, several of which, including the parent compound, are found in nature as such or are formed by chemical transformation of hydroazulenic sesquiterpenoid precursors.[58-60]



Scheme 1. Structural formulae of azulene (left) and its derivatives guaiene (center) and guaiazulene (right).

The substantial variety of natural and synthetic azulenes available from the work of Plattner[58] and others[59] was augmented by the powerful new Ziegler-Hafner synthesis,[61] which made azulenes accessible in a small number of steps without the difficult final dehydrogenation previously employed. A rich store of facts embodying the chemical and physical properties of these substances now called for theoretical rationalization, which, as has been instructively summarized by Heilbronner,[60] Hückel MO theory ultimately provided.

This theme of answers anticipating questions lies at the heart of one of the inspiring stories of organic chemistry, the discovery of the troponoids.[62] Space does not permit a full recounting here, but a brief outline may suffice to make the relevant point. In 1926 the Japanese chemist Tetsuo Nozoe settled in Formosa (now Taiwan), where he was to live and work for the next 22 years. During the period between 1944 and 1947, he and his co-workers had deduced the structure of hinokitiol (Scheme 2),



Scheme 2. Structural formulae of hinokitiol (β-thujaplicin, left), tropolone (center), tropone (right).

an isopropyltropolone, but because of disruptions caused by the war and the remoteness of his location, he was not aware of related activity elsewhere,[62] nor did others know of his work on this subject, most of which was not published in readily accessible journals until 1950.

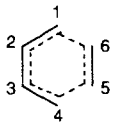
Nozoe[62] recounts his attempts to explain by the theory of resonance the peculiar aromatic properties of hinokitiol and of tropolone itself, which he subsequently synthesized. His first exposure to this form of quantum theory came in 1942/43, when copies of the 1940 edition of Pauling's *Nature of the Chemical Bond* became available in Formosa. However, although one could write resonance structures, this gave no real enlightenment on the aromaticity of tropolone, and the matter remained somewhat mysterious to him until 1951. In that year, simultaneously published papers by Dauben and Ringold[63a] and by Doering and Detert[63b] described the first syntheses of tropone. Both papers called attention to the electronic structure of this ketone and emphasized the presence of a potential aromatic sextet. The Doering paper, giving an explicit reference to Hückel's 1937 summary[37] of π electron theory, pointed out that the sextet was but one of a general class of stable configurations characterized by having $(4N + 2)$ π electrons. (To my knowledge, this was the first time that Hückel's rule was stated in this succinct form). Nozoe reports[62] that at that time, he had not heard of such a rule, but it was immediately obvious to him that tropolone's aromaticity must be derived from the same source.

Forerunners of numerous contributions by many authors that followed,[64] the two tropone papers[63] clearly were examples of directed rather than serendipitous tests of π electron

theory. Nevertheless, the most persuasive pieces of evidence leading to the acceptance of Hückel's ideas seem to have been the subsequent syntheses of tropylium[65] and cyclopropenylium[66] ions, which were specifically mentioned in the citation to Hückel's Otto Hahn Prize in 1965 (see below).

8. Orbital Symmetry—The Extension of Cyclic π-Electron MO Theory to Transition States of Pericyclic Reactions[67–69]

Pericyclic reactions, as the name implies, are those "in which all first-order changes in bonding relationships take place in concert on a closed curve".[69] It would be natural to conjecture that Hückel MO methods, which had been successful in rationalizing the behavior of *ground state* conjugated cyclic molecules, also might give a fruitful account of the *transition states* of pericyclic reactions. The idea of applying π-electron theory to reactions with cyclic transition states probably was first put forth by M. G. Evans in 1939.[70] He treated the six-electron transition state of the Diels–Alder reaction as an analog of benzene (Scheme 3) and actually wrote down a secular determi-



Scheme 3. The transition state of the Diels–Alder reaction between butadiene (centers 1–4) and ethylene (centers 5 and 6) as benzene analogs.

nant for it differing from that of benzene only in the 1,6 and 4,5 bond integrals. In his words:

> "very qualitatively we may say that whereas in the initial state the mobile electrons are those characteristic of an ethylene and a butadiene structure in the transition state they simulate the behaviour in a benzene structure."

This is a definite insight, quite remarkable for its time. However, it is questionable to maintain, as some have, that Evans was thus formulating a "rule" of aromatic transition states. Such a rule requires not only that one assert that aromatic transition states are more favorable, but also that one have a procedure for recognizing which transition states are aromatic. Without such a procedure, a "rule" of aromatic transition states verges on a tautology. Evans undoubtedly recognized this, and in fact, he attempted to provide a procedure. Unfortunately, his suggestions did not solve the problem. Apparently as a result of an improper conflation of MO and classical VB resonance ideas, Evans had only an uncertain grasp of the concept of aromaticity and especially of antiaromaticity. In this way, he was led to a formulation that stressed the *total number* of reactive electrons:

> "... there are qualitative rules which follow. The energy levels of the mobile electrons lie lower in cyclical structures than in straight chain compounds with the same number of centres available. The energy levels of the mobile electrons are lower the greater the number of available centres. These rules imply that the lowering of the activation energy due to the resonance effect will be greater in cyclisation reactions than in chain formation and that the resonance energy in the transition state will increase with the increasing degree of conjugation of the reacting molecules."

These rules must be carefully distinguished from the orbital symmetry rules. The overarching lesson taught by orbital symmetry and related theories is that favorable ("allowed") pericyclic transition states *in a given geometry* can be recognized according to whether the number of reactive electrons is $4N$ or $4N + 2$. In disrotatory electrocyclic reactions and *supra–supra* cycloadditions, for example, this number is $4N + 2$, whereas in conrotatory electrocyclic reactions and *supra–antara* cycloadditions it is $4N$. The predictions thus alternate accordingly. Violation of these requirements results in a "forbidden" reaction.

A literal application of the Evans rule favoring more highly conjugated reactants would predict, for example, that resonance stabilization in the cyclooctatetraene-like transition state of the hypothetical *supra–supra* [4+4] dimerization of butadiene should be greater than that in the benzene-like transition state of the *supra–supra* [4+2] association of butadiene and ethylene. But we now recognize the *supra–supra* [4+4] transition state as *antiaromatic* and therefore orbital symmetry forbidden.

Moreover, stereochemistry and electron count are inseparably entwined in orbital symmetry theory. Because Evans had no experimental examples of reactions whose stereochemistry would be favorable with $4N$ electrons, he could not have incorporated them into his thinking except by imagining them, which he did not do. Nothing in his paper gives any indication that he anticipated the idea that is central to orbital symmetry, that of allowed versus forbidden (aromatic vs. antiaromatic) transition states dependent on orbital phasing. To the contrary, continuation along the direction he started would have ended in a theoretical cul-de-sac. Therefore, Evans's contribution was at most a collateral, rather than a lineal, antecedent in the development of orbital symmetry theory.

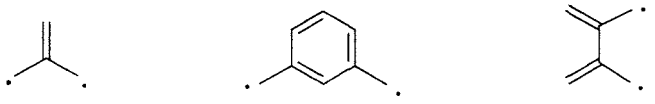
On the other hand, the intimate relationship of orbital symmetry and the Hückel "magic numbers" is obvious. Quite analogously to our previous discussion of ground state molecules, it is precisely because of the *cyclic* nature of pericyclic reactions that one expects them to be more properly described by Hückel MO methods than by classical VB theory. The major extension needed for the application of Hückel theory to transition states was the expansion of the original Hückel $(4N + 2)$ magic numbers, derived for conventional cyclic conjugated π-electron systems with no forced orbital phase inversions, to another arrangement with a forced phase inversion, for which the magic number is $4N$.

9. Violations of Hund's Rule in Biradicals

As we have seen, Lennard-Jones[12] applied to molecules (for example, O_2, B_2) the generalization that later came to be known as Hund's first rule. This governs the prediction of the spin multiplicity in cases where two electrons occupy degenerate orbitals: "that state is held to be lowest which has the greatest

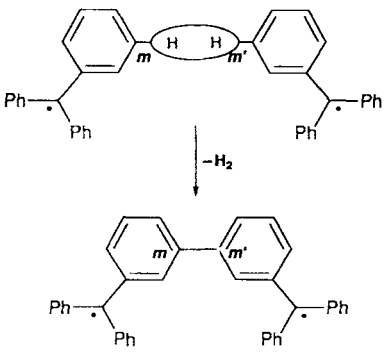
multiplicity."[12-15] Some theoreticians choose to interpret Hund's rule as applicable only when the orbitals in question are exactly degenerate, which except for rare accidental cases, would limit the rule to molecules like O_2, in which the degeneracy is symmetry-enforced. Other theoreticians apply the rule even when the degeneracy is only approximate.

Longuet-Higgins[55] invoked the approximate form (without so identifying it) in a seminal 1950 paper, which is perhaps the most influential theoretical writing on π-conjugated biradicals in the period between 1930 and 1970. He showed that, at the Hückel MO theoretical level, non-Kekulé molecules such as trimethylenemethane (TMM), *meta*-quinodimethane (MQDM), and tetramethyleneethane (TME), each have a de-



generate pair of nonbonding (NB) MOs occupied by only two electrons, and predicted for each of these molecules a triplet ground state. The symmetry point group of TMM (D_{3h}) contains E representations, but those of MQDM (C_{2v}) and TME (D_{2h}) do not. Thus, in the latter two cases, the NBMO degeneracies are not symmetry-enforced, and the energies are expected to split apart at higher levels of theory.

Longuet-Higgins cited no precedent for his predictions of spin multiplicities in organic biradicals, and apparently there had been only one prior such case in the literature: In 1936, Hund himself[71] had predicted a triplet ground state for one of the Schlenk-Brauns hydrocarbons studied by Müller et al. (Scheme 4).[72] This molecule too has degenerate NBMOs at the Hückel level of theory and would have fit easily into the Longuet-Higgins scheme.



Scheme 4. Formal synthesis of the *m,m'*-Schlenk-Brauns hydrocarbon.

However, Hund's prediction was immediately challenged by Hückel,[73] who pointed out reasons why the rule of highest multiplicity was of dubious validity in the case of the Schlenk-Brauns compound. Hückel's argument developed from his recognition that the Schlenk-Brauns structure could be derived (conceptually) by a union of two triphenylmethyl radicals at the *m* and *m'* positions. In the NBMO of triphenylmethyl, the *m* positions of the phenyl rings are *nodes*, that is, they have π-electron coefficients of zero at this level of approximation. In these circumstances, the exchange energy between the two halves of the Schlenk-Brauns molecule is close to zero. Since it is essentially just the exchange energy that accounts for the separation between the triplet and the lowest singlet,[14, 15] these two states will be almost degenerate. Note that the argument has nothing directly to do with the fact that the NBMO degeneracy in the Schlenk-Brauns hydrocarbon is accidental and will be lifted at higher levels of theory. Instead, in MO terminology, it really is a recognition of the spatial separability of the NBMOs, a property later to be called "disjoint" by Borden and Davidson[74a] (see below). Hückel's main conclusion was that the ground state is not predictable at this level of theory, contrary to the previous assumption of Hund's rule.

The Schlenk-Brauns hydrocarbon, one of the few biradicals known in 1936, after all was an esoteric species. One might then think of Hückel's argument as pertaining to a highly specialized compound of little interest to those outside the small field of biradicals. Indeed the paper stimulated little or no interest. In my view, however, it had significance far beyond the specific compound, because it showed that the magnetic properties of molecules cannot be treated by imagining that the exchange interaction of two electrons in the field of the nuclei and the remaining electrons will always favor the triplet. On the contrary, such a problem must take into account the *connectivity* of the atoms. This is a profoundly *chemical* point of view, which emphasizes something familiar to every chemist: molecular structure determines molecular properties.

A simple extension of Hückel's argument reveals that of the three biradicals TMM, MQDM, and TME, the latter has the same connectivity feature as the Schlenk-Brauns compound: it can be made by a union of two radicals (allyl in this case) at NBMO nodal positions. Applying Hückel's argument, we can see that TME should not have been classified by Hund's rule.

Because of Longuet-Higgins' (deservedly) high reputation in the field of theory, his unqualified use of Hund's rule in this case had the effect of steering experimentalists along the same oversimplified line of thinking. Also, the absence of a citation to Hückel's 1936 work contributed to decades of obscurity for that paper. One does not disparage the seminal significance of the work of Borden and Davidson[74a] and of Ovchinnikov[74b] by noting that they rediscovered the essence of Hückel's connectivity argument after a lapse of forty years. As might be expected after such a passage of time, these papers went far beyond Hückel's original rather qualitative discussion.[73] They brought to bear the full power of modern electronic structure theory to derive, by both MO (Borden and Davidson) and VB (Ovchinnikov) methods, the idea that when the π-electron system of a biradical has the Hückel type of NBMO node-to-node connectivity, only a small energy gap separates the multiplet states.[75] Ironically, at the time of their publications, these workers also were unaware of Hückel's paper!

Recent experimental and computational confirmations that Hund's rule is violated in properly constituted disjoint π-conjugated biradicals are reviewed elsewhere.[76]

10. Honors

Formal recognitions of Hückel's work were sparse until late in his career. Three notable distinctions were: in 1965, the Otto Hahn Prize, jointly awarded by the German Chemical Society and the German Physical Society; in 1966, nearly 30 years after his departure, an honorary degree from the Technische Hochschule in Stuttgart; and in 1977, election as a Foreign Member of the Royal Society.

11. Reflections on Hückel's Career

Hückel's entire contribution to organic quantum chemistry amounted to 17 papers, a list that includes several summaries and reviews. After 1937, when he was only 41 years old, his original contributions to this field virtually stopped. (If Hückel were working now, subject to our dubious emphasis on "productivity", that publication record would put his grant applications in grave jeopardy). As a member of the Marburg physics department, he unsuccessfully tried to initiate work on the theory of the nucleus, but apparently did not bestir himself to seek professional contact with chemists such as, for example, the talented and creative Hans Meerwein, then professor of organic chemistry at Marburg. One cannot put all the blame for the missed collaborative opportunities on Hückel, however. For example, in the period around 1950, Meerwein tried to persuade one of his graduate students to undertake the preparation of the cycloheptatrienide ion,[77] apparently unaware that a few yards away in the physics department lived a man who twenty years before had predicted the properties of this very species.

The history of the field of organic quantum chemistry after 1937 shows that there was much more to be done. What can explain Hückel's withdrawal? Some have the opinion that he became discouraged when he failed to develop any further ideas in the field comparable in significance to his early work. This may be true, but, of course, it merely pushes the problem one step deeper: Why did he run out of ideas?

Although there are shadowed aspects of Hückel's life that may hide some clues, I think we already know enough to make a few plausible speculations. Hückel[1] blamed the experiences of the war, the political atmosphere of the Third Reich, and a succession of illnesses for the exhaustion of his energies. The recollection of several colleagues who knew him tend to confirm this diagnosis, but there is also agreement that his was a difficult and even paradoxical personality—shy yet sardonically witty, hypochondriacal, petulant, pessimistic, depressed, ultimately lethargic and withdrawn from academic contact with colleagues and students. Reasons why these characteristics came to dominate Hückel's psyche remain to be elucidated.

A glimpse of Hückel's quirky character comes through in the story of his absence from the Hahn Prize ceremony, which was held in Bonn in September 1965, simultaneously with a symposium celebrating the 100th anniversary of Kekulé's benzene formula. In his letter[78] to Richard Kuhn, president of the German Chemical Society, Hückel pleads that, "the state of my health does not permit me to receive this honor in person", but from his autobiography[1] we get a significantly different excuse: "I was on vacation and dreaded first the trip and then the pompous style in which the Kekulé symposium was planned. In November the medal was presented to me in a small ceremony, which went very harmoniously and was more to my taste than a big display."

Hückel's personality traits surely contributed to his inability to persuade others of the significance of his scientific work.[1, 77, 79] This would have required a level of showmanship above his capacities. The dull, pedagogically ineffective lectures for which Hückel was known,[79] for example, did little to enhance his impact.

Particularly damaging was his confrontation with Pauling. As we have seen, Pauling's classical VB theory, although successful in other applications, really did not provide a good account of conjugation and aromaticity, yet his ideas dominated the field for decades. Here was a clear case of the power of persuasion. Pauling's personal magnetism, expository skill, and intellectual breadth were dazzling. Few organic chemists really knew the theoretical basis of Pauling's ideas on aromatic molecules, but he made it easy for them to apply his theory, such as it was. One can only guess what the history of this field might have been had Hückel just made an effort to reach his potential constituency in chemistry, for example by casting his equations in the form of the simple mnemonic diagram put forward twenty years later by Frost and Musulin,[80] or even by making use of the catchy $(4N+2)$ slogan. These steps would have gone far to popularize his results and make them more intelligible.

12. Summary and Outlook

In the introduction to his landmark paper on partial valence, Johannes Thiele[81] gives his view of the role of theory in nurturing a fruitful relationship with experiment:

> "The opinions about unsaturated compounds that I shall develop in the following may appear quite rash to many. However, if one holds fast to the idea that a theory actually is nothing other than a point of view which permits known facts to be surveyed in a unified way and new facts to be predicted, a point of view whose value and significance naturally can change with the progress of scientific knowledge, then it seems to me that my opinions satisfy both of these requirements."

Certainly, the development of modern electronic structure theory, from the early approaches by Hückel and his followers to the powerful methods of today, illustrates this view. Because the original Hückel MO method was a very approximate form of a theory that others later took to a much higher level, one senses now a certain amused condescension from some adepts, who view it as a quaint relic. One must ask, however, whether any other theoretical advance ultimately has done more to enlighten the thinking of organic chemists than Hückel's brief, bright flare of cognition, regrettably quenched too soon. Words suitable to his legacy are found in Eliot's terse homage to pioneers:[82]

> "Someone said: 'The dead writers are remote from us because we *know* so much more than they did.' Precisely, and they are that which we know."

Many colleagues have provided relevant advice and documentation. Several have submitted to recorded personal interviews. I am greatly indebted to P. D. Bartlett, A. D. Buckingham, J. Fruton, K. Hafner, M. Hanack, E. Heilbronner, P. C. Hiberty, E. F. Hilinski, R. Hoffmann, H. Hopf, R. Huisgen, F. Hund, T. Komm, W. Lüttke, T. Nozoe, A. Streitwieser, H. Tietz, H. A. Turner, E. Vogel, W. Walcher, E. Wasserman, and K. B. Wiberg. B. Z. Berson and staff members of the Yale University Library Department of Manuscripts and Archives provided bibliographic help.

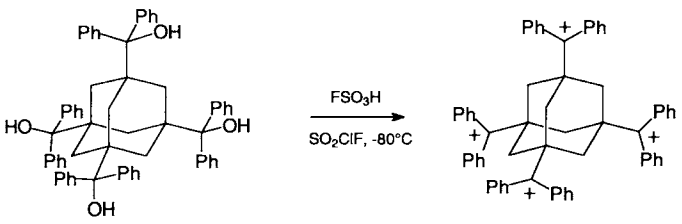
New Carbocations—From Physical Organic Chemistry to Biochemistry**

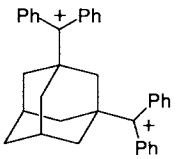
Thomas Laube*

Carbocations are an important class of reactive intermediates in organic chemistry along with radicals, carbanions, and carbenes. The 1994 Nobel Prize in Chemistry was awarded to George A. Olah, the pioneer in the area of physical chemical investigations of carbocations, for the development of methods for the preparation of stable solutions of carbocations and their NMR spectroscopic investigation. In this highlight, four interesting new publications are discussed, which illustrate intriguing aspects of modern carbocation chemistry. Carbocations are not only important in physical organic chemistry, but also in crystal engineering, organometallic chemistry, and biochemistry.

Head et al.[1] have prepared the first carbotetracation **2** from the tetraalcohol **1**. The tetracation **2**, in which the positive charges have a tetrahedral arrangement, shows four and seven signals in temperature-independent ^1H and ^{13}C NMR spectra, respectively, between -80 and $-40\,^\circ C$. The positive charge in **2** is more delocalized into the phenyl rings and less into the adamantane cage than in the dication **3**.[2] This is explained by the stronger repulsion of the four positive charges in **2**. Polycations like **2** are very interesting because of possible applications in the design and synthesis of stable salts. The tetrahedral arrangement of the charged groups in **2** could be used in "crystal engineering"[3] for the formation of three-dimensional networks with suitable bidentate donor ligands. The tetracation could also be used as an initiator in cationic polymerizations that should lead to dendrimeric and hyperbranched polymers.

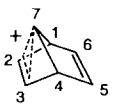


1 **2**

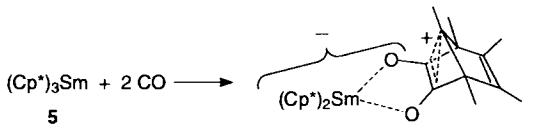


3

Winstein et al.,[4] Saunders et al.,[5] Olah et al.,[6] and other groups demonstrated the bishomoaromatic character of the norbornadienyl cation (**4**) by solvolytic methods and by NMR spectroscopy. Bremer et al.[7] confirmed these results by high-level ab initio calculations, and the structure of a substituted 7-norbornenyl cation[8] was determined by X-ray diffraction. Recently Evans et al.[9] found that the reaction of tris(pentamethylcyclopentadienyl)samarium (**5**) with carbon monoxide gives the unexpected product **6**, which they characterized by



4



5 **6**

NMR spectroscopy and a crystal structure analysis. The two incorporated CO molecules form a new ligand with one (formally anionic) Cp* ligand—a 2,3-dioxygen-substituted norbornadienyl cation. In this fragment of **6** (atom numbering analogous to that in cation **4**), the short C2–C7 and C3–C7 distances (1.876(4) Å) and the elongated C2–C3 double bond (1.426(4) Å) can be rationalized by invoking bishomoaromatic stabilization involving C2, C3, and C7 centers. The cationic center C7 interacts only with the C2–C3 bond but not with the C5–C6 bond (1.328(5) Å). The structure of the cation fragment in **6** agrees relatively well with that of the substituted 7-norbornenyl cation;[8] the synthesis of **6** provides additional evidence for the facile formation of substituted bishomoaromatic carbocations.

Bicyclobutonium ions, rapidly equilibrating nonclassical cations generated from cyclopropylmethyl or cyclobutyl compounds, are among the conceptually most difficult nonclassical carbocations.[10] Only one static cyclopropylmethyl cation, **7**, had been observed previously.[11] Olah et al. now describe the preparation of a new, substituted bicyclobutonium ion, the triaxane-2-methyl cation (**9**), starting from the alcohol **8**.[12] Between -100 and $-40\,^\circ C$, seven signals with unchanged chemi-

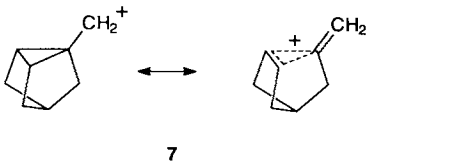
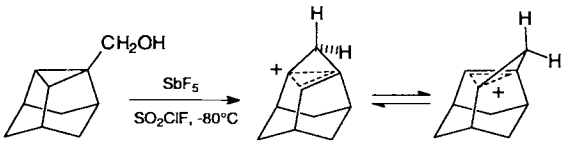
Fax: Int. code +(1)272-4924
e-mail: cplus@wawona.vmsmail.ethz.ch

[**] This article was written during a ten and a half month stay at the Loker Hydrocarbon Research Institute, University of Southern California. I thank Prof. G. A. Olah and Prof. R. Bau, Los Angeles, for their support.

cal shifts are observed in the ^{13}C NMR spectrum of **9**. This result is in accord with a static cation (point group C_s) as well as with a rapidly equilibrating mixture of less symmetric cations. The authors have computed the structures and the NMR chemical shifts of all possible cations by ab initio methods. For the ions with the lowest energy, the bicyclobutonium ion **9a** and its enantiomer **9b** (both point group C_1), the experimental and the computed chemical shifts are in good agreement if one assumes a rapid equilibrium between **9a** and **9b**. The involvement of



7



8 **9a** **9b**

higher energy cations need not to be considered despite the flat potential energy surface of such systems. An analogous result was obtained for a related dication, the ditriaxane-2,10-dimethyl dication, which contains two bicyclobutonium moieties. Comparison of these results with the properties of **7** seem to indicate that subtle changes in cyclopropylmethyl cations can lead to different structures.

The occurrence of a carbocation intermediate having a pentacoordinate carbon atom is also the subject of a recent paper of Berkessel and Thauer,[13] in which the possible mechanism of the reversible, stereospecific hydrogen transfer by a metal-free enzyme to a substituted amidinium ion **13** is discussed (see Scheme 1, the italicized H atom is not involved). A new mechanism is proposed for the enzymatic reaction, since the hydrogenase that catalyzes the reaction **10** $\rightleftharpoons$ **13** does not contain a metal atom that could activate H_2. It is suggested that in the enzyme the amidinium ion is activated by N-protonation such that it binds a H_2 molecule with a three-center, two-electron bond at C14a (**12**). Nearly 30 years ago, Olah et al.[14,15] and Hogeveen et al.[16,17] showed that analogous reactions of saturated hydrocarbons (or of aliphatic carbocations in the reverse direction) occur in superacidic media, and they discussed pentacoordinate carbocations as intermediates. Very recently Olah proposed this type of activation in enzymatic systems.[18] Thus it seems reasonable and justified to dub the hydrogenase involved in the reaction mentioned above an "Olah enzyme".[19]

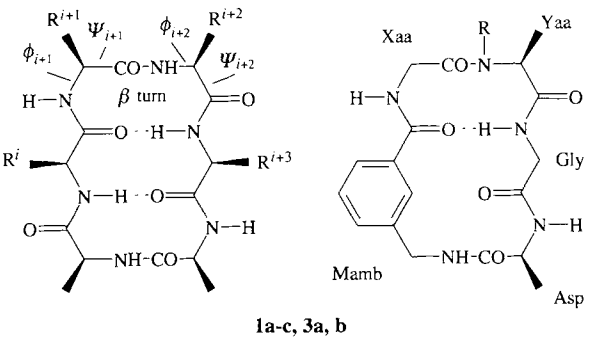
The β Turn as a Selectivity Switch: βI or βII′? That Is the Question**

Gerhard Müller*

The discovery of low molecular weight compounds capable of selectively modulating the functions of enzymes or receptors is a central topic in medicinal chemistry. Once a lead compound is identified it is developed further into a potential drug candidate by a repetitive procedure comprising the synthesis and biological characterization of successive generations of analogs. In this context medicinal chemists constantly seek new molecular templates patentable for a particular pharmaceutical indication, which facilitate the controlled spatial orientation of interacting groups and thus enable the chemist to exercise steric control over the construction of a potential pharmacophore.

Nature apparently utilizes a generic set of presentation scaffolds, since the demand of biochemical processes on molecular recognition is extremely high. The biological activity of endogenous peptide hormones is often encoded in exposed loop regions, in which two to four amino acid residues, essential for the activity, adopt β turn conformations.[1] These β turns have been employed as structural scaffolds in the design of biologically active oligopeptides, for which the research area of antiadhesive Arg-Gly-Asp (RGD in the one-letter notation; a universal cell recognition sequence[2]) mimetics turned out to be an excellent example.[3] Using modified RGD peptide analogs and non-peptide RGD mimics it has been attempted to selectively address the endogenous targets, which are members of the integrin receptor family.[4] Interaction with the platelet-associated $\alpha_{IIb}\beta_3$ integrin inhibits thrombus formation, whilst the tumor cell associated $\alpha_v\beta_3$ integrin appears to influence the adhesion properties of metastatic cells. RGD mimics are therefore promising candidates not only for the development of antithrombotics, but also as inhibitors of formation of new blood vessels (angiogenesis), necessary for tumor growth, which qualifies them as potential antimetastatic drugs.[3, 4] In addition, the implications of integrins in the pathogenic mechanisms of osteoporosis is about to emerge, which may have a significant biomedical potential.[5]

These therapeutically promising perspectives motivated several research groups at the beginning of the 1990s to study cyclic RGD peptides[3] with the aim of deducing the biologically active, in other words receptor-complementary, conformation by determining their three-dimensional structures.[6] Not only highly active, but also receptor-selective adhesion antagonists emerged from the systematic study of β turns as presentation modules.[3, 7] In this context, researchers from the American pharmaceutical company DuPont Merck recently reported on the structure determination of some RGD peptides (**1a–c**, Fig. 1), which show pronounced $\alpha_v\beta_3$-integrin selectivity.[8]



1a-c, 3a, b

Fig. 1. Comparison of a cyclic hexapeptide comprising two β turns (left) with the basic structure of the cyclic peptides **1a–c** and **3a,b** (right). Yaa: L-Arg.

These compounds resulted from a systematic investigation of structure–activity relationships on cyclic RGD peptide analogs at DuPont Merck,[9] all of which were rationally designed based on the experimentally determined three-dimensional structure of the disulfide-bridged pentapeptide *cyclo*-(1,5)-[Ac-Cys-(NMe)Arg-Gly-Asp-Pen-NH_2] (Pen: penicillamine, β,β'-dimethylcysteine) **2** (SK & F 106760) from the company Smith Kline Beecham.[10] The primary aim of these studies at that time was to develop active antithrombotics, selective $\alpha_{IIb}\beta_3$-integrin binding RGD mimetics, which, at DuPont Merck, resulted in the compound DMP 728 (**3a**) as a candidate for clinical development.[11]

The main conclusion of the work presented by the DuPont Merck group[8] refers to the exchange of the dipeptide units D-Abu-(NMe)Arg (in **3a**, D-Abu: D-2-aminobutanoic acid) and D-Ala-(NMe)Arg (in **3b**) for L-Xxx-Arg (Xxx = Ala, Pro in **1a** and **1c**, respectively), which transforms a $\alpha_{IIb}\beta_3$-selective peptide into a $\alpha_v\beta_3$-selective compound (Table 1). This in itself did not

Table 1. Comparison of the biological activity of the DuPont Merck peptide discussed here against tumor cell associated ($\alpha_v\beta_3$) and platelet-associated ($\alpha_{IIb}\beta_3$) integrins. Yaa = L-Arg.

Cmpd.	Xaa	R	$IC_{50}(\alpha_v\beta_3)$ [nM]	$IC_{50}(\alpha_{IIb}\beta_3)$ [nM]	β Turn type
1a	L-Ala	H	20	18000	I
1b	Aib	H	36	9000	I
1c	L-Pro	H	13	45000	I

[**] The author would like to thank William F. DeGrado and Alvin C. Bach for supplying the structural coordinates of some of the peptides described in this contribution.

al.[8] are correlated with the experimentally determined three-dimensional structures of the peptides mentioned above, the conformation–activity data are extremely interesting and deserve a detailed discussion.

The structure of peptides **1a–c**, **3a**, and **3b** closely resembles the main structural features of the generic template of a cyclic hexapeptide composed of two β turn modules[7] (Fig. 1). Since the *meta*-aminomethylbenzoic acid (Mamb) moiety in **1a–c**, **3a**, and **3b** lacks a hydrogen bond donor functionality at the C2 atom of the benzene ring, only a single hydrogen bond is formed between Gly-NH and Mamb-CO, while the cyclic hexapeptide displays two hydrogen bonds. This single hydrogen bond stabilizes a β turn with residues L-Ala (**1a**), L-Pro (**1c**), D-Abu (**3a**), and D-Ala (**3b**) at the $i+1$ position and L-Arg (**1a**, **1c**) and L-(NMe)Arg (**3a**, **3b**) at the $i+2$ position. The most striking structural difference between the $\alpha_{IIb}\beta_3$-selective DMP 728 (**3**) and the $\alpha_v\beta_3$-selective peptides **1a–c** refers to the type of the β turn. Whilst all L-Xaa^{i+1}-L-Arg^{i+2} peptides form type I β turns, the sequences D-Abu^{i+1}-L-(NMe)Arg^{i+2} in **3a** and D-Ala^{i+1}-L-(NMe)Arg^{i+2} in **3b** adopt β turns of type II′. Apart from the opposite orientation of the hydrogen bonds relative to the peptide ring plane, the turns of types βI and βII′ differ in the relative spatial orientation of the ingoing and outgoing peptide strands (Fig. 2).

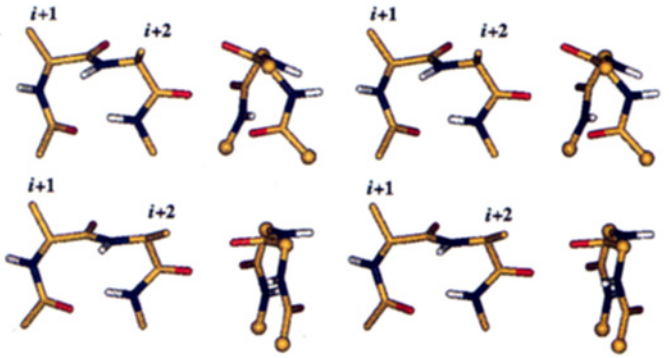

Fig. 2. Stereoview of a βI (top) and a βII′ turn (bottom). For clarity only heavy atoms and the amide hydrogen atoms of the model compounds Ac-L-Ala- L-Ala-$NHCH_3$ (top) and Ac-D-Ala-L-Ala-$NHCH_3$ (bottom) are shown. A front view of the turns is shown on the left; a Newman-type projection is depicted on the right. The four consecutive C^α atoms of the β turn forming a pseudo-dihedral angle are shown as small spheres.

In the βI turn the pseudo-dihedral angle spanned by the four consecutive C^α atoms of the amino acids in turn positions i to $i+3$ is 49° (assuming ideal values for the backbone torsions[11]) and results in an approximate synclinal (+ sc, *gauche*) orientation. In contrast, the βII′ turn displays a synperiplanar (− sp, *eclipsed*) conformation (− 3° assuming ideal values for the backbone torsions[11]) (Fig. 2). This difference in the type of the β turn has profound influence on the relative vectoral orientation of the Arg and Asp side chains and thus on the discriminating selectivity profile of the peptides. These amino acid side chains, constituting the potential pharmacophore, are found in a pseudo-diaxial arrangement in peptides **1a–c**, whereas the βII′ turn enables a diequatorial alignment in peptides **3a** and **3b** (Fig. 3).

The authors succeeded in correlating receptor selectivity with vectoral orientation of the Arg and Asp side chains[8]. The

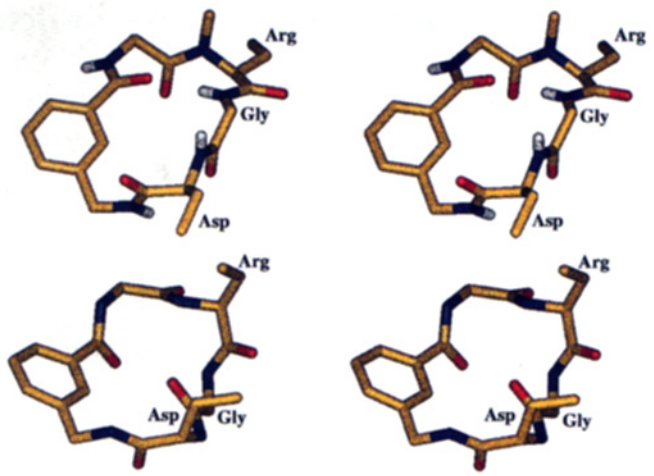

Fig. 3. Comparison of the three-dimensional structure of **3a** (top) with **1c** (bottom), which are shown as stereoviews. For clarity only the backbone atoms and the C^β and C^γ atoms of the Arg and Asp side chains are shown. The structure of **3a** is available from the Cambridge Crystal Structure Data Base (code: HAJRAP).

change in β turn type from βII′ to βI leads to an inverted selectivity profile of the described peptides. This discovery is in accord with the structural characteristics of the $\alpha_v\beta_3$-selective prototype peptide **4** mentioned above.[3a, 8, 12, 13] The superimposed structures of the RGD sequences of **4** and **1c** depicted in Figure 4 display an unexpected correspondence, although the crucial recognition sequence in **1c** "extends" along the longitudinal edge of the generic hexapeptide template structure (see Fig. 1), whilst in **4**, it adopts an extremely tight γ turn conformation.[12]

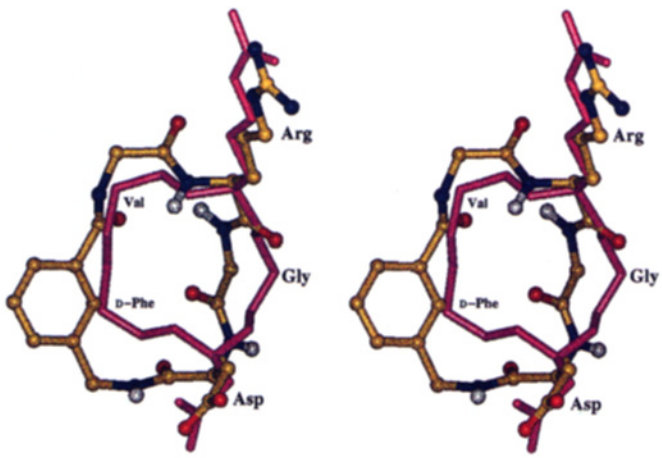

Fig. 4. Stereoview of the superimposed structures of **1c** and **4** (magenta). The C^α and C^β atoms of the Arg and Asp side chains served as reference atoms for superposition. Apart from the backbone atoms of **4** only the side chains of Arg and Asp are depicted.

The βI turn of, for example, **1c** enables an approximate synperiplanar orientation of two side chains at the $i+2$ and $i+4$ positions, which is apparently essential for $\alpha_v\beta_3$-complementarity. This particular arrangement can additionally only be achieved by incorporation of the RGD tripeptide into a regular γ turn, thereby occupying the turn positions i, $i+1$, and $i+2$, as shown by **4**. This stuctural analogy worked out by Bach et al. has led to a new peptide design principle, namely the Mamb-Pro element of **1c** can be utilized as a "structural clamp" in cyclic

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2768 $ 15.00+.25/0

pentapeptides of the type *cyclo*-[-Mamb-Pro-Xaa-Yaa-Zaa-], thereby inducing a γ turn compatible conformation for the Xaa-Yaa-Zaa tripeptide.

These results have not only further refined the existing pharmacophore models for $\alpha_v\beta_3$-integrin binding, which can be employed as search profiles for mining structure databases in attempt to discover lead structures of $\alpha_v\beta_3$-selective RGD mimics, but have also increased awareness of the importance of controlled variation of the β turn type for spatial fine-tuning of potential pharmacophore groups. For the "peptide designers" among medicinal chemists the work described here and other findings have evolved into guidelines for the sterically controlled orientation of functional groups. It has been shown several times that β turns can be induced in cyclic peptides at specific positions by incorporation of turn-favoring elements such as proline, glycine, D-amino acids, and α,α'-dialkylated amino acids into the sequence.[6, 7] The DuPont Merck work[8, 9, 11] further underlines the importance of the steric control over the β turn architecture and the effect on receptor selectivity, exemplified with a biomedical application of significant importance.

The entire potential of β turns as structural templates is just becoming apparent, owing to numerous projects in current pharmaceutical research aimed at developing peptide receptor agonists and antagonists,[14] for which the members of the G-protein coupled receptor family are mentioned as representative examples.[16] In this context, the structural aspects discussed here almost take on the characteristics of a model applicable to related research projects dealing with structure-based drug design. For further development of therapeutics it would be desirable to turn to non-peptide β turn mimetics,[16] which would not only enable control of the turn type formed, but would also allow for optional functionalization of the turn mimetic, so that any underlying di-, tri-, or tetrapeptide sequence could be mimicked. This is, without doubt, a tremendous challenge for synthetic organic chemists motivated by structural chemistry, but it would also address an aspect of pharmaceutical research neglected so far.

In conclusion, the research area of antiadhesive RGD mimetics provides an excellent example of the complementarity of rational structure-based drug design and screening efforts for the discovery of new leads. In the near future, both approaches will certainly lead to non-peptidic $\alpha_v\beta_3$-selective RGD mimetics.

Unprecedented Conversion of a Compound with Metal–Metal Bonding into a Solvated Molecular Wire**

Gary M. Finniss, Enric Canadell, Charles Campana, and Kim R. Dunbar*

One-dimensional (1D) compounds have intrigued chemists and physicists for decades.[1, 2] A primary reason for this fascination is the theoretical prediction advanced by Little over thirty years ago that 1D conductors may exhibit high-temperature superconductivity.[3] The largest class of 1D inorganic compounds are square-planar d^8 complexes that form columnar stacks in the solid-state.[4] The closed-shell systems are poor conductors, but oxidative doping to give a mixed-valence state leads to the onset of metallic behavior as exemplified by the partially oxidized tetracyanoplatinates (POTCPs) often referred to as Krogmann salts.[4a, c, d] Mononuclear Rh^I compounds also form oligomers at high concentrations in solution and in the solid state, but oxidation of these compounds yields "dimerized" compounds with metal–metal bonding or mononuclear Rh^{II} radicals if bulky ligands are employed.[5a, b, 6] Although less common, mixed-valence Rh^I/Rh^{II} species have been documented,[7] but these are also dinuclear with the exception of several well-characterized examples.[8a–c]

It is evident from the tremendous body of available data that the formation of discrete "dimers" with metal–metal (M–M) bonding (the extreme case of Peierls distortion) is a dominant theme in transition metal chemistry.[5] This situation aroused our curiosity as to the role of the ligands on the tendency for unbridged dinuclear compounds to crystallize without intermolecular metal–metal interactions. One reason for the scarcity of infinite M–M bonded chains may be the fact that the typical ligands used in coordination compounds, such as carboxylates, halides, and phosphanes, do not facilitate the direct approach of metal atoms along the axial direction. In support of this theory are the reports by Peng et al., that planar diimine ligands stabilize short oligomers that exhibit both metal–metal and ligand–ligand interactions.[8a] We reasoned that, given the proper ligand set, it may be possible to induce a dinuclear complex to actually "polymerize" into an infinite metal–metal bonded array. The unbridged compounds $[M_2(MeCN)_8]^{4+}$ and $[M_2(MeCN)_{10}]^{4+}$ with quadruple (M = Mo, Tc), triple (M = Re), and single (M = Rh) bonds were chosen for this investigation because these molecules possess only small, linear MeCN ligands whose steric effects are minimal. Our objective was to oxidize or reduce these diamagnetic molecules by one electron and to elucidate the solid-state structures of the resulting radical species. Herein we report the synthesis, X-ray crystal structure analysis, and band structure calculations of a novel solvated molecular wire prepared from a discrete metal-metal bonded precursor.

$[Rh_2(MeCN)_{10}](BF_4)_4$ exhibits an irreversible redox process at −0.05 V versus Ag/AgCl that corresponds to a one-electron reduction.[9, 10] Bulk electrolysis performed at −0.20 V versus Ag/AgCl in $(Bu_4N)BF_4$/MeCN immediately yields a gray-green microcrystalline solid that exhibits a solid-state EPR spectrum with axial symmetry.[11] Dissolution of this material in pure MeCN without supporting electrolyte yields an orange solution whose electronic properties resemble those of a mixture of the original $(Rh^{II})_2$ species (λ_{max} = 468 nm) and a Rh^I compound (λ_{max} = 414 nm).[10, 12] Slow galvanostatic reduction of $[Rh_2(MeCN)_{10}](BF_4)_4$ at low currents produces single crystals of **1** at the Pt cathode in about 30% yield over a period of three weeks.[13]

The novel material $\{[Rh(MeCN)_4](BF_4)_{1.5}\}_\infty$ (**1**) crystallizes in the acentric space group $P6_222$ which does not impose symmetry on adjacent Rh–Rh distances. As a consequence, there are two different Rh–Rh interactions in the chain: 2.8442(8) and 2.9277(8) Å. An ORTEP representation of the portion of the chain contained in each unit cell, namely "$[Rh_6(MeCN)_{24}]^{9+}$", is depicted in Figure 1. The charge of 9 + for the Rh_6 segment was

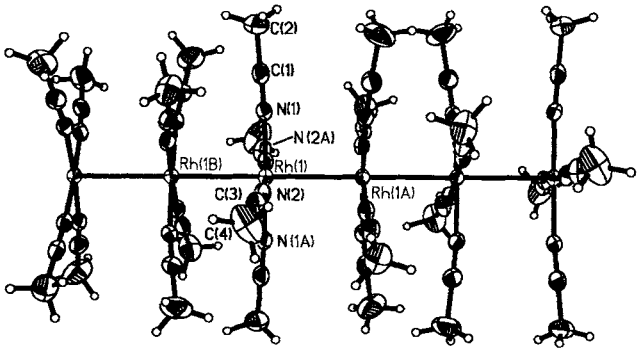

Fig. 1. ORTEP representation of a $[Rh_6(MeCN)_{24}]^{9+}$ segment of **1** with selected distances [Å] and angles [°]: Rh(1)–Rh(1A) 2.9277(8), Rh(1)–Rh(1B) 2.8442(8), Rh(1)–N(1) 1.991(4), Rh(1)–N(2) 1.985(4); N(1)-Rh(1)-N(2) 91.2(2), N(1)-Rh(1)-N(2A) 88.7(2), N(1)-Rh(1)-N(1A) 176.9(2), N(2)-Rh(1)-N(2A) 177.8(2), N(1)-Rh(1)-Rh(1A) 88.91(11), N(1)-Rh(1)-Rh(1B) 91.09(11), N(2)-Rh(1)-Rh(1A) 88.44(11), N(2)-Rh(1)-Rh(1B) 91.56(11).

deduced from the number of independent BF_4^- ions, which is precisely nine from refinement of the occupancies. These results are convincing evidence for the description of the material as being composed of Rh atoms in an average oxidation state of + 1.5.

A salient feature of the chain geometry is the orientation of the $Rh(MeCN)_4$ planes with respect to each other. Dinuclear complexes with a single M–M bond, including the parent molecule $[Rh_2(MeCN)_{10}]^{4+}$ ($\bar{\chi}$ = 44.8[2]°), typically adopt torsion angles of 45°. In **1** the MeCN ligands on Rh(1) and Rh(1B) that define the shorter Rh–Rh distance are twisted by 44.8°, whereas the ligands on Rh(1) and Rh(1A) adopt a torsion angle of 15.3°. These angles add up to 60° which allows for the presence of a 6_2 screw axis along the direction of the chain. As a result of subtle, but evidently real, steric effects brought about by the small differences in torsion angles, the MeCN ligands actually bend slightly away (ca. 1°) from the longer Rh–Rh interactions (2.9277(8) Å) and towards the shorter Rh–Rh contact (2.8442(8) Å) as can be seen in the space-filling representation of a portion of the chain (Fig. 2). A packing diagram of **1** in the crystal along the *c* axis is provided in Figure 3.

The calculated band structure of **1** (Fig. 4) reveals that the bands appear as six folded sub-bands, which is attributed to the

fact that the unit cell contents are $[\{Rh(MeCN)_4\}_6]^{9+}$.[14] Essentially, there is a dispersive d_{z^2} band, which in the lower part of the diagram overlaps with a series of flatter bands that originate mainly from xy,xz, and yz orbitals of the square-planar Rh units. As a consequence of the "dimerization" there is a gap between the third and fourth sub-bands (i.e. the middle of the z^2 band), but there are no gaps between the other sub-bands. Assuming that a double occupancy of the levels occurs, the stoichiometry dictates that the second sub-band from the top should be half-filled. Consequently, if the metallic state of this material can be stabilized, for example by applying pressure, the material is expected to undergo a metal-to-insulator Peierls type distortion like every 1D metal, which would double the size of the unit cell. It should be noted that the total width of the entire z^2 band is quite large. In fact the dispersion of the upper group of three sub-bands, which are partially filled, is as large as the z^2 band of potassium tetracyanoplatinate (KCP).[15] The preliminary charge transport data obtained by D. Jerome et al.[16] suggest that the appropriate electronic description of the chain is that of a series of $[\{Rh(MeCN)_4\}_2]^{3+}$ dimers with two electrons in the bonding combination (Ψ^+) of the two z^2 orbitals of the dimer and one electron in the antibonding combination (Ψ^-). The results of the calculation, however, indicate that these Y^- levels interact quite strongly along the chain so that it is not unreasonable to predict that a metallic state for the chain could be stabilized. If so, it would be interesting to observe the influence of the methyl groups in the possible Peierls distortion. Because of the interlocking of the groups on adjacent monomers, the methyl groups could provide an important elastic energy cost for the distortion. Thus, a systematic replacement of these methyl groups would be very interesting. Such tailoring would also be worthwhile in terms of the possibility for obtaining materials with different numbers of anions.

$\{[Rh(MeCN)_4](BF_4)_{1.5}\}_\infty$ (**1**) is novel in several respects. It is the first mixed-valence 1D compound of rhodium and is the only example of an infinite metal–metal bonded chain synthesized from a dinuclear precursor. Furthermore, the ligands are neutral donors which leads to a cationic charge on the chains, as opposed to the tetracyanoplatinates which are anionic. Most importantly, the new material provides a rare opportunity to apply the theories of one-dimensionality to a metal chain that differs considerably from the partially oxidized cyanoplatinate systems. Owing to the potential for tailoring the ligands, which is not possible for cyanide-based systems, one can envision the use of nitriles with much longer or bulkier aliphatic substituents. Such alterations will serve to increase the insulating organic "sheath" around the central core of metal atoms in the chain and may allow for the onset of liquid crystallinity if, for example, *n*-octyl groups were employed. The effects of these chemical modifications on the structures and transport properties will be extremely valuable for the understanding of this novel class of mixed-valence materials.

Experimental Procedure

Solutions of $[Rh_2(CH_3CN)_{10}](BF_4)_4$ (0.030 g, 0.031 mmol) and $[(nC_4H_9)_4N]BF_4$ (0.103 g, 0.311 mmol) in MeCN were loaded into a fritted two-compartment cell. Pt electrodes were inserted and a current of 2.0 μA was applied. After three weeks, bronze needles were harvested from the cathode (ca. 0.007 g, 28.3%). A large-scale preparation with 200 mg of precursor leads to bulk quantities of the material.

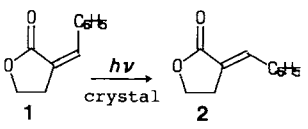
E/*Z* Isomerization in Crystals—Phase Rebuilding on Photolysis with Long-Wavelength Radiation**

Gerd Kaupp* and Michael Haak

In the crystal lattice of organic compounds the molecules have only very small freedom of movement, because they are as closely packed as possible. Therefore, the few known *E*/*Z* isomerizations that involve internal rotations of about 180° for unsaturated compounds containing large substituents are difficult to understand according to topochemical concepts.[1] The principle of phase rebuilding[2] should be more suitable, as it considers the far-reaching, anisotropic, molecular migrations with lattice-controlled formation of characteristic features on the surface, as was shown for cycloadditions and other reaction types.[2] Irradiation with wavelengths that correspond to the absorption tail of the crystals ("tail irradiation")[3] leads to a deeper penetration of the light into the crystal and to concomitant formation of features on the surfaces that are anchored deeper in the crystal, and therefore stable. This was demonstrated for the [4+4] photodimerization of 9-chloroanthracene (which according to earlier views conformed to the topochemical principle),[4] and implies that on tail irradiation the mechanism does not change.[5]

We now report on the space-intensive *E*/*Z* photoisomerization of **1** to form **2** on excitation with radiation of very long wavelength, on atomic force microscopy (AFM) imaged surface features, and on the X-ray crystallographic characterization[6] of **1**. The phase rebuilding on *E*/*Z* isomerization in the crystal is crystallographically explicable without resorting to "electronically excited phantom dimers".[7, 8] The few known *E*/*Z* isomerizations in organic crystals are collated in ref. [2]. Only with unselective irradiation ($\lambda > 300$ nm) does the photodimerization follow after the reaction of **1** to form **2**.[2, 4, 9] Figure 1 contrasts the diffuse reflectance spectra of crystals of **1** and **2** with the much shorter wavelength absorptions in solution. The $\lg(k/s)$ curves of the Kubelka–Munk function (k = absorption coefficient, s = scattering coefficient) formally correspond to absorption spectra.[10] They show that the forming crystal **2**, unlike **1**, no longer absorbs at 365 nm (bandpass 6.4 nm).



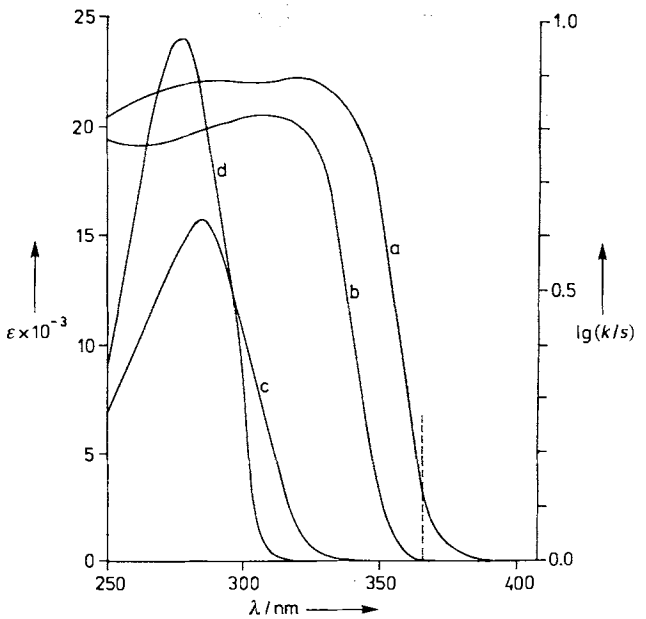


Fig. 1. Comparison of the diffuse reflectance spectra of **1** and **2** (a and b, respectively; $\lg(k/s)$) and the absorption spectra in acetonitrile (c and d, respectively; ε).

Figure 2 shows the effect of long-wavelength radiation (365 nm) on the initially only slightly rough ($R_{ms} = 0.42$ nm) (010) face of **1** (Fig. 2a). After five minutes the form of the irregularities on the surface changes, though without significant increase in roughness. Only after 10 min irradiation are craters observed (1.5–2 μm wide and 10–20 nm deep, angle of slope 1–3°; Fig. 2b) with upcast edges that are better formed than is shown in ref. [2,4] because they are anchored deeper in the

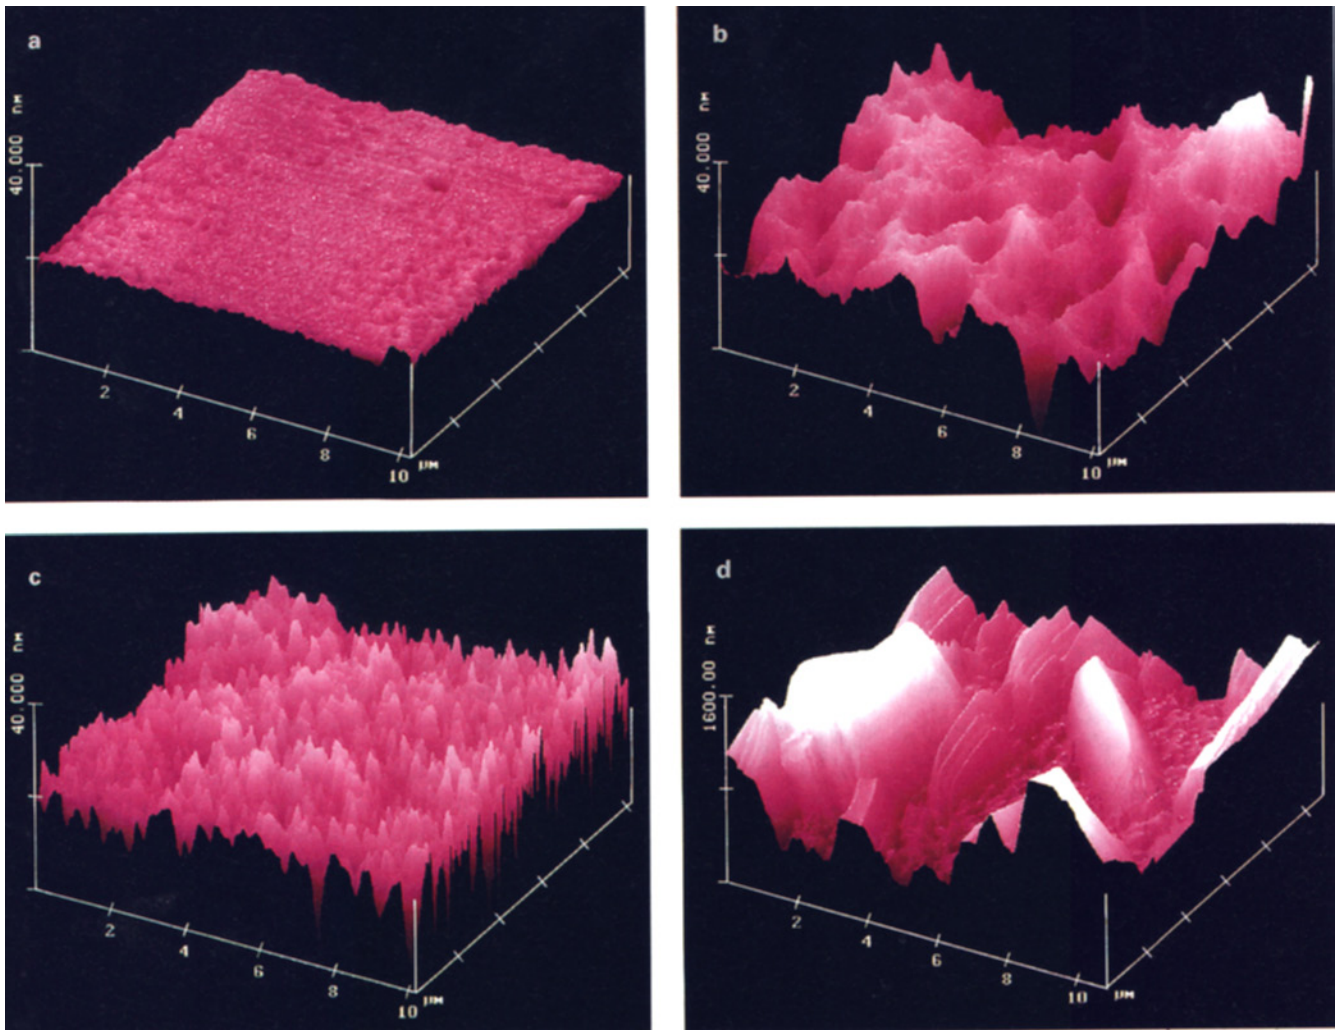

Fig. 2. Contact-AFM surfaces of **1** (crystallized from ether/*n*-hexane) on (010): a) starting surface; b) after 10 min irradiation (365 nm, 6.0 mWcm^{-2}, bandpass 6.4 nm); c) after 15 min irradiation; d) after 60 min irradiation, *z* axis magnified 40 times relative to Figs. a–c. The direction of imaging is always from left to right in the *x* direction. The crystallographic *c* axis of **1** is parallel to the *y* axis.

crystal and because here the complications of a reverse reaction are absent.[11] On further irradiation (15 min) the craters grow together, and many more are formed (typical diameter now 300–500 nm but with the same depth, Fig. 2c). Continued stepwise irradiation (20 min, 25 min) leads to further decrease in the size of the craters (approximately halving the diameter); some, nevertheless, double in depth. Only after 30 min irradiation (and suddenly) large, angular crystalline protrusions form, predominantly oriented along the *c* axis (parallel to (100)) of the original crystal, just as was found under preparative conditions.[2, 4] Figure 2d shows the result (with 40-fold magnification of the *z* axis) after 60 min irradiation. The steep, angular crystallites are as high as 1.5 µm, and the orientation of only very few deviate from the direction of the *c* axis.

Whereas crater formation is attributed to the phase rebuilding stage (little product in the lattice of the starting material), the deep-seated changes in the second stage are seen as phase transformation (little starting material in the product lattice).[12] The two-stage process of the lattice changes can also be observed on the (001) face of **1**. Short broad-band irradiation creates volcanoes and craters ("egg trays") with preferred direction along the *b* axis. The cleavage plane (100) coincides with this direction.[4] Long-wavelength radiation (365 nm, 6 mWcm^{-2}; not depicted) provides no striking improvement in the features of the phase rebuilding. Just as here, the µm-high, final crystallites of the phase transformation are aligned parallel to the *b* axis but are narrower on (001) than on (010): Interestingly, they are no longer deeply anchored in the base, but can break off and turn out of the preferred alignment. It is repeatedly observed that a µm-high crystallite changes its orientation relative to all other crystallites between two successive AFM measurements. In general these large crystallites parallel to the front face (100) grow epitactically around the whole crystal, despite the preceding phase rebuilding.

We wish to emphasize that the phase transformation to form the 1.5 µm-high crystallites also proceeds without any (nano)-liquid phase; characteristic instabilities in the contact-AFM images would otherwise result.[2, 4, 13] The lowest eutectic temperature of 67 °C lies distinctly above the photolysis temperature.[14]

For successful *E*/*Z* photoisomerization, each crystal layer must have a phase rebuilding mechanism available. This can be derived from or founded in the packing diagrams from the X-ray structure data.[6] Molecule **1** has the normal screw geometry: its double bond is twisted by 4.6° and the phenyl group

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2775 $ 15.00+.25/0

turned by 35.6°. The other bond lengths and angles lie within the normal range. Molecules of **1** arrange in a monoclinic crystal lattice ($P2_1/c$) with complicated packing: bands of molecules with the same alignment lie at angles of 77° to one another; the bands have alternating alignments. The formation of the (less convincing) "phantom dimers"[7, 8] is not possible. Figure 3 depicts a model of a stereoview onto the (001) face. The central molecule with the highlighted double bond (violet) shows how after irradiation the $Z \rightarrow E$ isomerization proceeds by internal rotation. If the remaining lattice is held rigid, the phenyl group (in Fig. 3a) can rotate by up to 45° (counterclockwise) and the lactone moiety by −45° (clockwise), without excessive van der Waals hindrance (modeling in 5° steps with the program SCHAKAL indicates that the approach is never below 76% of the standard radii). Figure 3b shows this rotational state as a model of the transition state. The central molecule in the fixed lattice can make way to the left to allow the rotation to continue to planar **2** (a total of 184.6°). In the process, the phenyl group is also turned in by −35.6° (Fig. 3c).

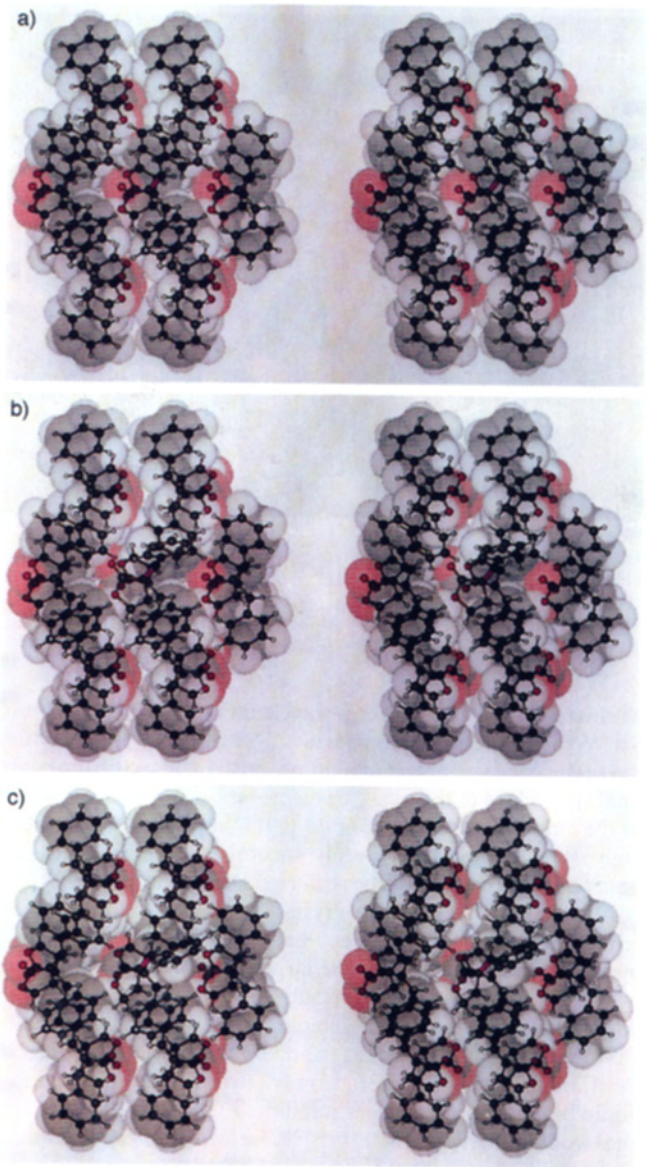

Fig. 3. Stereoscopic representation of the packing of **1** on (001) ((010) face on top) and modeling of the partial rotations for isomerization of the central molecule with highlighted double bond for fixed lattice and without relaxation by molecular migration. a) Prior to isomerization, b) model of the transition state with rotation of the CHPh moiety by 45° and the lactone moiety by −45°, c) after completed isomerization.

After their formation, the molecules of **2** must arrange themselves in a supramolecular way as foreign molecules within the fundamental lattice. They can find access into the corrugated planes perpendicular to the illustrated plane between the lattice molecules and initiate the long-range molecular transport for up to 50 nm. On (010) this leads to shallow craters with ridges, whereas on (001) the features align along the cleavage plane direction (aligned volcanoes and craters;[4] not depicted). Thus, the availability of the required phase rebuilding mechanism for **1** becomes evident. The crystal lattice of **1** does not simply change continuously into that of **2** ($P2_1/n$).[15] Rather the lattice of **2** (phase transformation) forms on both surfaces discontinuously after the phase rebuilding with molecular migration, but only when the product concentration is so high that the old lattice is no longer energetically viable. Interestingly, it is equally discontinuous when the reaction zone is generated with more pronounced absorption gradients ($\lambda > 300$ nm)[2] or with 365 nm light[16] that penetrates deeper into the crystal. In both cases the influence of the original lattice is still present, as is verified by the edges that are predominantly parallel to the original (100) cleavage plane.

The molecular mechanism deduced for **1** from AFM and X-ray diffraction measurements exploits supramolecular cooperative effects. This is not an isolated case. A supramolecular phase rebuilding mechanism was also deduced from X-ray diffraction data[8] for the isomerization of 1,2-bis(1-naphthyl)-ethene,[2] and the same can be expected for the other examples.[2] Complications through transitions from nontopotactic to topotactic courses of reaction need not be anticipated in any of these cases. A reviewer suggested attempting a single-crystal to single-crystal transformation for **1** through irradiation with a very low intensity (over months) very close to the equilibrium conditions for the crystal transformations. Such experiments with daylight filtered through Pyrex filters (see Fig. 1) in an inert atmosphere have been initiated.

E/*Z* isomerizations in the crystal have unusually large spatial requirements and therefore are particularly impressive examples of the new understanding of organic solid-state reactions, which imparts fundamental significance to the model systems for all kinds of crystal reactions that have larger or smaller space demands and in the face of previous reservations stimulates their execution and practical evaluation.

[11] As long as product molecules of **2** are not yet aligned in their own crystal lattice, but in the rebuilt lattice of **1**, short-wavelength excitation can cause a photochemical reverse reaction. Only crystalline **2** photodimerizes exclusively to form the cyclobutane derivative [9].
[12] The lack of absorption of light at $\lambda = 365$ nm by the crystalline product **2** prevents the formation of its [2+2]-dimer. Irradiation of **1** (4 h) with light from a 150 W Hanau Hg high-pressure lamp passed through a Wertheimer UVW-55 bandpass filter (isolation of the 365 nm light with 2.8% contribution from 334 nm light (% transmission <1 at 315 nm and at 410 nm)) in a powder cuvette leads to a considerable shift of the diffuse reflectance spectrum to curve b in Figure 1, whereas the broad-band irradiation ($\lambda > 300$ nm) of crystalline **2** produces a decrease in the long-wavelength absorption and an increase in a band of the photodimer [9] at 266 nm.

[16] The 90% light penetration depth derived with the Lambert–Beer law for $\varepsilon_{max} \approx 15000$ L mol^{-1} cm^{-1}, $d = 1.239$ g cm^{-3} from Figure 1 at approximately diagonal position of the chromophore is less than 100 double layers at 302, 313, and 334 nm, and 370 double layers at 365 nm.

Designed Restructuring of Iodine with Microporous SiO_2**

Gernot Wirnsberger, Harald P. Fritzer, Alois Popitsch, Gianpietro van de Goor, and Peter Behrens*

Tailor-made host systems with designed topologies and adapted surface properties are an important prerequisite for supramolecular inorganic host–guest chemistry.[1] Herein, we show how the interactions between iodine molecules can be controlled by the topotactical insertion into selected, crystalline porous materials which assume a structure-directing role for the arrangement of the guest species.

[**] Part of this work was supported by the Deutsche Forschungemeinschaft (Be 1664/1-2) and the Fonds der Chemischen Industrie. We thank Andreas M. Schneider for assistance with the preparation of the figures.

The pore systems of zeolites, which are accessible to many ions and molecules, can not only be used in technical applications as catalysis and sorption, but also offer the opportunity for a rich host–guest chemistry. Inorganic clusters with special electronic[2] or magnetic[3] properties can be stabilized inside the well-defined and uniform cavities of aluminosilicate zeolites. However, the use of zeolites as host matrices bears an inherent problem: As the framework is composed of $[AlO_{4/2}]^-$ and $[SiO_{4/2}]$ tetrahedra, it carries a negative charge that must be balanced by the inserted species themselves or by guest cations that are present in addition. Therefore, the properties of the guest components will always be influenced by ionic interactions with the host matrix or with the charge-compensating guest cations.

In our attempts[4] at the restructuring of guest components by porous solids, we have used porosils[5] rather than zeolites as host components. The structures of porosils resemble those of zeolites; however, their frameworks are composed of $[SiO_{4/2}]$ tetrahedra only, which are interlinked through their vertices; thus, the composition of a porosil framework is neutral SiO_2. Porosils are prepared under mild solvothermal conditions; organic molecules, which are necessary to form a desired porosil structure, become occluded in the cavities of the crystallizing SiO_2 framework.[6] The organic molecules can be removed oxidatively by calcination (treatment at high temperature), leaving behind a (thermodynamically metastable)[7] microporous SiO_2 modification, whose empty void system can now be filled. In the case of host–guest compounds with a porosil as the host component and with neutral guest species, the interactions are restricted to weak van der Waals type forces. The void structure of the host framework thus determines the geometrical arrangement of the guest species and consequently also limits the electronic interactions between them. Insertion compounds of iodine serve as an especially impressive example of this concept, as changes in the electronic properties of the guest arrangement can be monitored directly by changes in color.

We have used porosils with zero-, one-, two-, and three-dimensional pore systems as host compounds: decadodecasil 3R (DDR[8]), silica-ZSM-22 (TON), silica-ferrierite (FER), and silicalite-1 (MFI). Their cavities or channel systems are shown in Figure 1. Since the diameters of the pores of these host

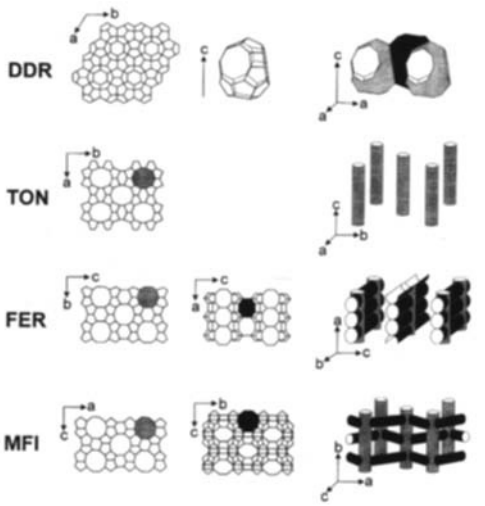

Fig. 1. Structures of the host systems (oxygen atoms are omitted): For DDR, a view of the layers consisting of pentagon dodecahedra is given on the left. In an ABCABC stacking of these layers, cages (center) are formed which are typical for this structure. Each cage is surrounded by three other cages arranged at angles of 120° to each other (right). For the other porosils, views along the channels (left and center) and schematic views of the channel systems (right) are given.

Fig. 2. Colors of the iodine–porosil composites compared to that of solid iodine. From top to bottom: iodine in DDR, iodine in TON, iodine in FER, iodine in MFI, and solid iodine.

systems are similar, they are suitable for investigating the influence of the different dimensionalities on the interactions between the iodine molecules. Figure 2 shows the colors of the iodine–porosil composites that were prepared by the insertion of iodine into these hosts. Iodine in DDR is violet, similar to the color of gaseous iodine, indicating that the iodine molecules are in a vapor-phase-like state. In contrast, the iodine in the TON host, in which the unidimensional channel system permits interactions between the iodine molecules in one dimension, is violet to dark blue, similar to the color observed for iodine–starch compounds. Iodine inserted into the two-dimensional channel system of FER exhibits a color between that of iodine in DDR and TON. Interactions between iodine molecules in three dimensions, which are, however, regularly interrupted by the MFI silica framework, result in a red–brown color resembling that of liquid iodine.

These visual impressions can be quantified by UV/Vis spectroscopy. The absorptions in the visible region, which are responsible for the colors, vary in a characteristic fashion (Fig. 3).

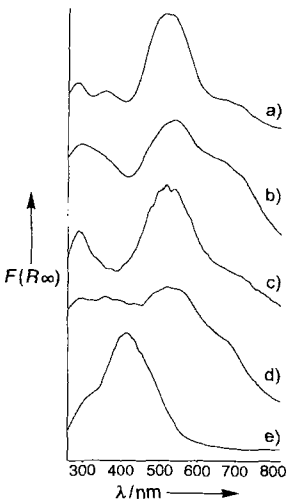

Fig. 3. UV/Vis spectra (converted to Kubelka–Munk functions $F(R_\infty)$) of the iodine–porosil composites and of solid iodine: a) iodine in DDR, b) iodine in TON, c) iodine in FER, d) iodine in MFI, and e) solid iodine.

The spectrum of iodine in DDR exhibits a relatively strong band at 518 nm and one of weaker intensity at 688 nm. The positions of these bands coincide with those observed for gaseous iodine, and are atrributed to the B←X transition (518 nm) and the A←X transition (688 nm).[10] The notion that iodine in DDR is in fact in a vapor-phase-like state is also supported by the composition of the compound,[11a] which fits for a structure in which each cage of the DDR host structure is occupied by one iodine molecule and thus the iodine molecules can be regarded as isolated from each other.[11b]

In contrast to the cage structure of DDR, the one-dimensional channels of TON permit interactions between the iodine molecules along the channel axis. The transition from isolated molecules to molecules that are part of an infinite chain (in the limiting case) should manifest itself by a shift of the absorption bands to higher wavelengths.[12] In fact, a 22 nm shift of the B←X transition to 540 nm was observed for the iodine in TON. In addition, the spectrum contains a broad shoulder in the region of the A←X transition, which is responsible for the dark blue hue of this compound. Thus, the changes in the electronic structure caused by the chainlike aggregation of the iodine molecules (which in turn is caused by the templating action of the TON framework) are not only evident from a shift of the absorption band maxima, but also from changes in the intensities and thus the transition probabilities.

A further enhancement of the interaction between the iodine molecules might be expected for the insertion compound of FER, which possesses a two-dimensional channel structure. However, the electronic spectrum shows that in this case the geometric restrictions by the host are too strong to allow the formation of a two-dimensional layered structure (which would be regularly pierced by SiO_2). The double maximum in the strongest absorption band indicates the presence of two different iodine species, one of which is in a vapor-phase-like state (maximum at 519 nm). For the second maximum at 537 nm, we observe a shift to higher wavelengths, similar to that observed for iodine in TON.

The MFI-based insertion compound reveals most clearly the tendency of the iodine molecules to use the available volume for maximizing their interactions. It possesses the highest concentration of iodine[13] and its UV/Vis spectrum shows enhanced intensity in the region between 400 and 260 nm in which liquid iodine also has its strongest absorptions.[14]

The Raman spectra in Figure 4 confirm and supplement the picture gained from the UV/Vis spectra. The band for iodine encaged in the DDR host structure occurs at 208 cm^{-1}, similar to that of gaseous iodine (213 cm^{-1}), which again supports the idea of a vapor-phase-like state of the inserted iodine. For the iodine molecules restructured to a chainlike arrangement by the TON framework, the iodine–iodine vibration shifts to 199 cm^{-1}. We attribute this shift to the presence of intermolecular iodine–iodine interactions, which cause a weakening of the intramolecular iodine–iodine bond, resulting in a decrease of its force constant. However, a comparison with the spectrum of solid iodine[15] (Fig. 4e) shows that the extent of these interactions is much weaker than in bulk iodine. The splitting of the B←X transition in the UV/Vis spectra indicated the presence of two different iodine species for the iodine in FER; the Raman spectrum confirms this presumption. We ascribe the weak band at 210 cm^{-1} to isolated iodine molecules, and the stronger band at 196 cm^{-1} to a chainlike arrangement of iodine molecules. Evidently, the apertures of the ten-ring channels are just large enough to allow for interactions between the iodine molecules (band at 196 cm^{-1}), whereas the iodine molecules in the eight-ring channels remain isolated like those in iodine–DDR. For the insertion compound of MFI we observe a band at 202 cm^{-1}, which we attribute again to a chainlike arrangement of iodine molecules. In addition, this signal exhibits a shoulder at 188 cm^{-1}; this has to be ascribed to iodine molecules that are allowed to exert even stronger interactions. The only regions that permit such interactions are the spherical voids at the intersections of the channel systems. On the one hand, each of these voids (9 Å diameter) can accommodate several iodine molecules, on the other, the molecules inside them are able to interact with those molecules that reside in the channels through the ten-ring channels. It is

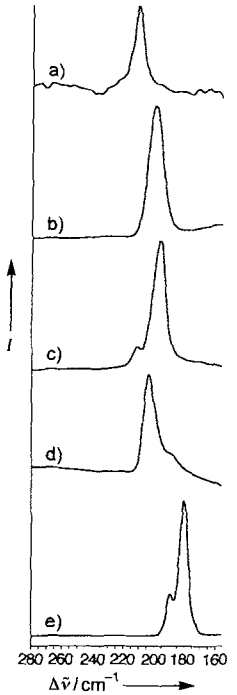

Fig. 4. Raman spectra of the iodine–porosil composites and of solid iodine: a) iodine in DDR, b) iodine in TON, c) iodine in FER, d) iodine in MFI, and e) solid iodine; I in arbitrary units.

noteworthy that broad bands in the range from 175 to 185 cm^{-1} in Raman experiments on liquid iodine have been attributed to the presence of $(I_2)_n$ molecular clusters.[16]

Our investigations on iodine insertion compounds prepared by topotactical reactions show that by restricting the geometrical arrangement of the iodine molecules, the electronic properties of the guest species can be engineered.

Experimental Procedure

Syntheses of the porosils TON, FER, and MFI were performed according to the literature [17]. A new procedure was developed for DDR: A mixture of hydrofluoric acid, water, ammonium fluoride, 1-aminoadamantane, and SiO_2 (Cab-osil M-5, Fluka) in the molar ratio 0.15:20:1:0.15:1 was maintained at 433 K for 21 days in a Teflon-lined autoclave. After the mixture had been cooled to room temperature, the crystalline product was filtered off, freed from amorphous gel residues by treatment with 2M NaOH, and washed neutral with H_2O. The organic molecules occluded inside the porosils were removed by calcination in air. For that purpose, the porosils are heated to the final calcination temperature (DDR, TON, FER: 1123 K, MFI: 923 K) over two days, kept at this temperature for another two days and then cooled to room temperature within one day. Insertion of iodine was performed in the vapor phase at 433 K in Teflon-lined autoclaves. After a reaction time of four days, iodine–porosil compounds were obtained, from which iodine desorbed above 313 K. At room temperature, they are stable for several weeks.

UV/Vis spectra in diffuse reflection were obtained on a Beckmann spectrometer model DK-2A. Quartz powder was used as a reference and for dilution of the samples. Raman spectra were recorded with an FT-Raman apparatus (Nicolet FT-Raman 910); the 1064 nm line of a Nd:YAG laser was used for excitation. For each measurement 200 scans were accumulated; the laser power was 200 mW for the insertion compounds, and 20 mW for bulk iodine.

A Noninterpenetrated Molecular Ladder with Hydrophobic Cavities**

Pierre Losier and Michael J. Zaworotko*

Crystal engineering of supramolecular architectures sustained by coordinate covalent bonds[1, 2] or hydrogen bonds[3] represents a rapidly expanding field that offers potential for rational development of new classes of functional solids. It is now established that the architectures of coordination polymers can be reliably predicted, since previously known metal coordination environments are propagated into one- (1D), two- (2D), and three-dimensional (3D) motifs with rigid multitopic organic "spacer" ligands. Recent examples include diamondoid,[4] honeycomb,[5] grid,[1, 2, 6] ladder,[7] brick wall,[7] and octahedral[8] frameworks from tetrahedral, trigonal, and octahedral metal templates (e.g. Zn^{II}, Cd^{II}, Ag^{I}, Cu^{I}, Scheme 1). Unfortunately, if the void created in this way is more than 50% of the crystal by volume, it is almost always reduced by interpenetration or self-inclusion.[1, 4–7] We report herein what is to our knowledge the first example of a noninterpenetrated molecular ladder:[7] $[Co(NO_3)_2(4,4'\text{-bpy})_{1.5}]_\infty$ (1) (4,4'-bpy = 4,4'-bipyridine), an open framework infinite ladder that clathrates small organic guests despite possessing a cavity that is large enough to self-include.[6]

In principle, the formation of molecular square grids[1, 2, 4] or molecular ladders/brick walls[7] depends on the metal-to-ligand ratio (1:2 or 1:1.5, respectively). We therefore anticipated that reaction of $[Co(NO_3)_2]\cdot 6H_2O$ with three molar equivalents of 4,4'-bpy would afford a square grid polymeric motif.[9] However, when the reaction was conducted with 1.5 or 3 molar

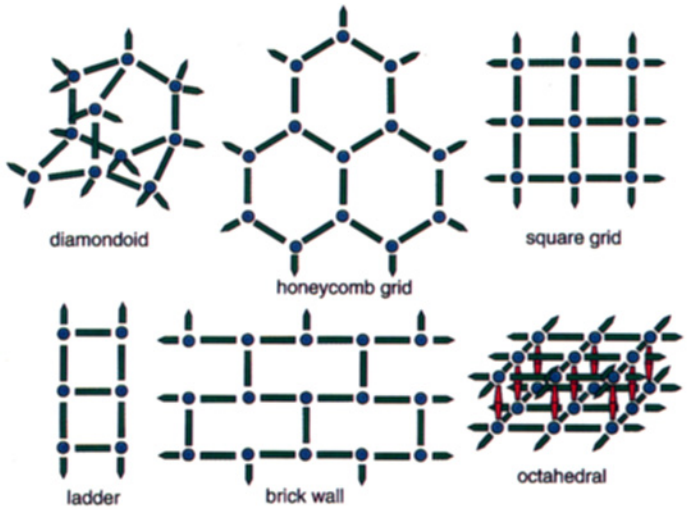
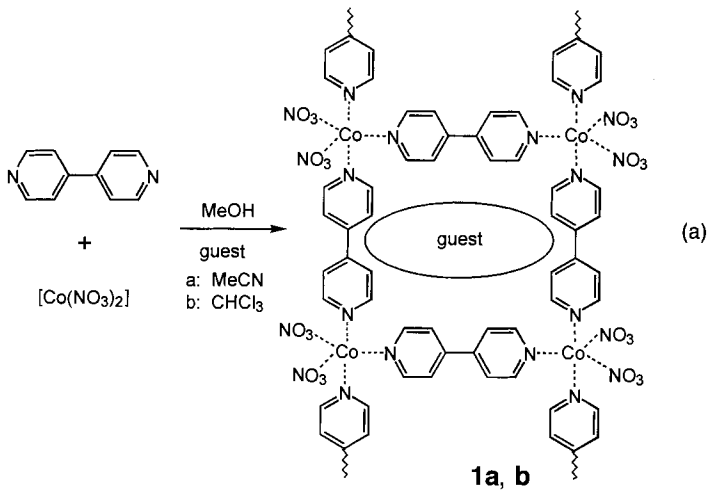


Scheme 1. Examples of coordination polymer frameworks formed from metal ions and linear ditopic ligands.

equivalents of 4,4′-bpy in MeOH/MeCN or MeOH/$CHCl_3$ mixtures, the MeCN and $CHCl_3$ solvates of **1**, **1a** and **1b**, respectively, were isolated.[10] The X-ray crystal structures of **1a** and **1b** reveal that **1** adopts an infinite molecular ladder motif that



(a)

can be regarded as a manifestation of self-assembly of "T-shaped" units (Fig. 1).[11] The 4,4′-bpy ligands coordinate to Co^{II} ions and form the "side rails" and "rungs" of a ladder that extends along the *a* and *b* axes for **1a** and **1b**, respectively. The remaining coordination sites at the metal are occupied by two bidentate nitrate ions.[12]

Compound **1** possesses large square hydrophobic cavities with dimensions of 11.4 × 11.4 Å enclosed by the 4,4′-bpy ligands. In **1a** a disordered MeCN solvent molecule sits at the center of the square void,[13] whereas in **1b** there are two crystallographically independent molecules of $CHCl_3$ per metal atom. Each square cavity is effectively sandwiched by four chloroform molecules, two above and two below (Fig. 2). One chlorine atom from each chloroform molecule is directed towards the inside of the cavity through weak Cl···H-C interactions (3.68 and 3.77 Å).[14] Hydrogen bonding is also apparent between the chloroform molecules and the terminal oxygen atom of nitrates on neighboring ladders (O···H-C 3.50 and 3.23 Å). Schemes 2

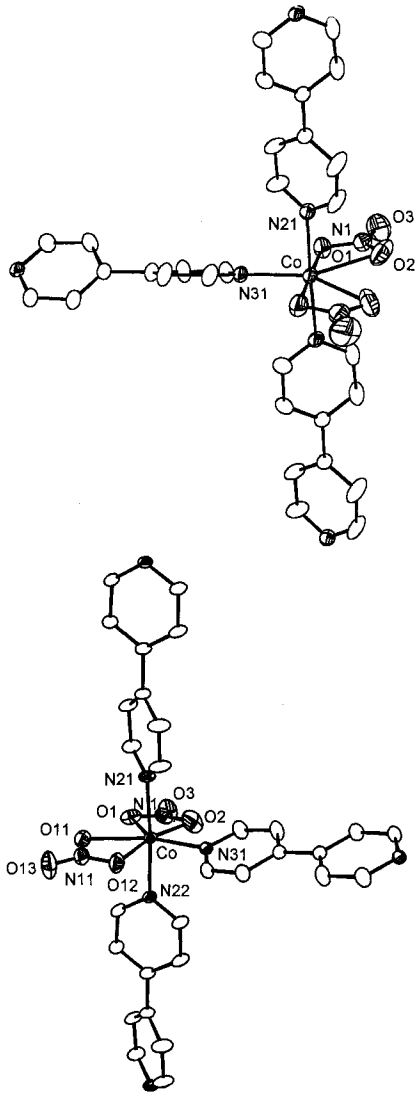


Fig. 1. ORTEP views of the structures of **1a** (top) and **1b** (bottom), showing the metal coordination environment. The Co–N bonds are comparable in both structures (av 2.15 and 2.14 Å, respectively) [12] and the "rungs" are orthogonal to the "rails" in **1a** but slightly distorted ($\measuredangle$ = 82.6°) in **1b**. The nitrate ions in **1b** are almost symmetrically bound to the metal (Co–O 2.207(4), 2.228(3), 2.226(4), and 2.322(5) Å); however, in **1a** they approach a unidentate coordination (Co–O 2.127(4) and 2.436(5) Å).

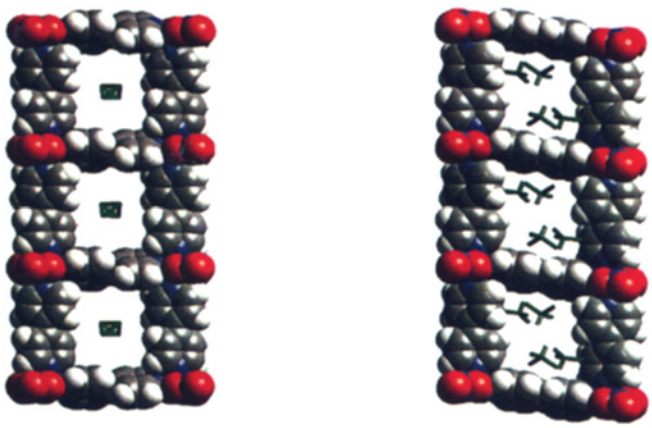

Fig. 2. Space-filling views of molecular ladders **1a** (left) and **1b** (right). Enclathrated solvent molecules are shown in green in stick form. In **1a** the enclathrated MeCN molecules are disordered, therefore only the region of occupancy is shown.

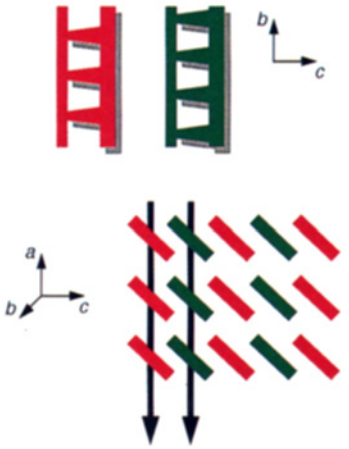
Scheme 2. A schematic representation of the crystal packing in **1a**. The arrow denotes the direction of the channels.



Scheme 3. A schematic representation of the crystal packing in **1b**. The arrow denotes the direction of the channels.

and 3 illustrate the crystal packing of the ladders. In **1a** two infinite ladders are juxtaposed in the *ac* plane and are offset by half a "step" along *a*. These sheets subsequently stack along *b* in a close-packed stairlike manner (interplanar separation: 5.2 Å) and are offset by a quarter of a "step" along *a*. Such packing yields oblique solvent-filled microchannels that criss-cross. In **1b** the ladders stack sideways along *c* in a "bookshelf" fashion with a spacing of 10.6 Å and, as in **1a**, adjacent ladders are offset by half a "step" along *b*. The superposition of these layers along *a* results in a much larger interplanar separation of 11.3 Å due to the presence of the solvent molecules. Microchannels extending along the *a* axis are also formed and have columns of chloroform molecules running through their cavities.

The design of square- or box-shaped macrocycles self-assembled from square-planar metal centers and 4,4′-bpy has attracted much attention in the context of molecular recognition of guests by tailored hosts.[1 5] Compound **1** is effectively a one-dimensional polymer of macrocyclic squares that exhibit a clear preference for hydrophobic guests (i.e. arenes,[9] $CHCl_3$, and MeCN over MeOH and H_2O). This study illustrates the importance of solvent medium upon anion coordination, interpenetration, and which polymeric motif is generated.[9, 11] However, it remains to be seen if this new class of polymeric structure can reversibly adsorb guest molecules, an issue we are currently addressing.

Experimental Procedure

1a: A solution of $[Co(NO_3)_2]\cdot 6H_2O$ (0.29 g, 1.0 mmol) in MeOH (20 mL) was added to a solution of 4,4′-bpy (0.23 g, 1.5 mmol) in MeCN (20 mL). After the solution was left to stand at room temperature for 3 h, red crystals of **1a** were obtained (yield: 0.17 g, 0.39 mmol, 39%). IR (KBr diffuse reflectance): $\tilde{\nu}$ [cm^{-1}] = 3053, 2510, 2447, 2252 (C≡N), 1609, 1535, 1490, 1415, 1325, 1297, 1221, 1074, 1025, 1010, 858, 812, 736. Crystals exposed to the atmosphere appear stable for hours but eventually become opaque. TGA analysis reveals the following: gradual 5% weight loss from 60–200 °C and stability to 240 °C; 17% weight loss from 240–280 °C; 58% weight loss from 280–320 °C. This data suggests loss of 0.75 moles of MeCN, conversion of $[Co(NO_3)_2]$ to Co_3O_4, NO_2, and O_2, and loss of 4,4′-bipyridine, respectively. The remaining 18% would correspond to Co_3O_4.

1b: A solution of $[Co(NO_3)_2]\cdot 6H_2O$ (0.29 g, 1.0 mmol) in MeOH (20 mL) was added to a solution of 4,4′-bpy (0.29 g, 1.5 mmol) in $CHCl_3$. Deep red crystals of **1b** were collected (yield: 0.33 g, 0.50 mmol, 50%) after the mixture was left to stand at room temperature for 12 h. IR (KBr diffuse reflectance): $\tilde{\nu}$ [cm^{-1}] = 3050, 2509, 2446, 1608, 1535, 1492, 1414, 1326, 1295, 1221, 1074, 1025, 1010, 859, 812, 754 (C–Cl). Crystals exposed to the atmosphere become opaque within hours. TGA analysis reveals the following: gradual 36% weight loss from 60–180 °C and stability to 240 °C; 12% weight loss from 240–280 °C; 40% weight loss from 280–320 °C. This data suggests loss of 2 moles of $CHCl_3$, conversion of $Co(NO_3)_2$ to Co_3O_4, NO_2, and O_2, and loss of 4,4′-bipyridine, respectively. The remaining 12% would correspond to Co_3O_4.

[9] Square grid polymers based upon $[Co(NO_3)_2(4,4'\text{-bpy})_2]$ are afforded if this reaction is effected in the presence of aromatic solvents such as benzene, xylenes, and chlorobenzenes. Up to five moles of arene per mole of metal are present and the reaction appears to be independent of the stoichiometry of the system: C. Hogg, P. Losier, K. N. Power, M. J. Zaworotko, R. D. Rogers, unpublished results.
[10] Structure analysis of **1a**: 0.2 × 0.3 × 0.4 mm, red rectangular crystal, orthorhombic, *Fddd*, $a = 11.3681(12)$, $b = 20.767(3)$, $c = 34.585(4)$ Å, $Z = 16$, $V = 8164.8(17)$ Å^3, $\rho_{calcd} = 1.534$ M gm^{-3}, $\mu = 0.88$ mm^{-1}, min./max. transmission = 0.873/0.980, $2.0 < 2\theta < 49.8$. Structure analysis of **1b**: 0.2 × 0.5 × 0.4 mm, red rectangular crystal, triclinic, $P\bar{1}$, $a = 11.2902(9)$, $b = 11.3776(10)$, $c = 11.8358(13)$ Å, $Z = 2$, $V = 1302.52(21)$ Å^3, $\rho_{calcd} = 1.673$ M gm^{-3}, $\mu = 1.32$ mm^{-1}, min./max. transmission = 0.790/0.999, $2.0 > 2\theta > 49.9$. Data were collected on an Enraf-Nonius CAD-4 diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.70930$ Å) using the ω scan mode at 290 K. Structures were solved by direct methods using the NRCVAX system. Non-hydrogen atoms of the coordination polymer were refined with anisotropic thermal parameters. The solvent molecules in **1a** were observed to be disordered in a manner that could not be readily resolved. These solvent atoms were therefore treated as carbon atoms and refined with fixed isotropic thermal parameters and variable site occupancy. Values of $R = 0.047$ and $R_w = 0.053$ were obtained for 1027 out of 1795 reflections with $I > 3.0\sigma(I)$ and 135 parameters. For **1b**, values of $R = 0.055$ and $R_w = 0.055$ were obtained for 3535 out of 4585 reflections with $I > 3.0\sigma(I)$ and 343 parameters. Hydrogen atoms of the 4,4′-bpy moieties were placed in calculated positions with d(C–H) = 1.00 Å. Residual electron density (min./max., e Å^{-3}): −0.980/0.420 and −0.590/0.750 for **1a** and **1b**, respectively. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-126. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

Anion Binding: Self-Assembly of Polypyrrolic Macrocycles**

Jonathan L. Sessler,* Andrei Andrievsky, Philip A. Gale, and Vincent Lynch

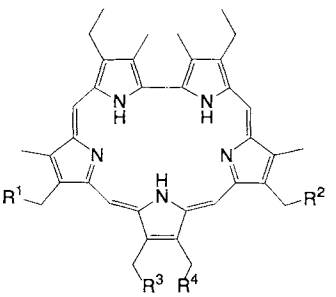
In memory of Professor Emanuel Gil-Av

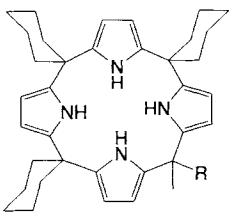
The self-assembly of complementary fragments occurs throughout Nature and plays an essential role in the construction of such biological "superstructures" as nucleic acids (for example their duplexes and complexes with peptides), multicomponent enzymes, cell membranes, and viral capsids.[1] The structural information required for facile self-assembly is preprogrammed in the topography and functionality of the building block surfaces. These small subunits bind together reversibly through multiple weak noncovalent interactions. This minimalistic yet effective approach to molecular architecture has challenged supramolecular chemists to design systems capable of recognition, self-assembly, replication, and transport.[2, 3] However, it has not been until recently, that the first abiotic self-assembling supramolecular aggregates were reported.[2–15]

Most notably, many of the structural motifs discovered were employed for production of the "functioning structures" such as interlocked molecules[4] (capable of switching, information storage, and electron transfer), noncovalent dimers (capable of encapsulation[5] and binding[6] of small molecules), molecules capable of self-replication,[7] noncovalent dendrimers,[8] helices, racks, ladders, and grids,[3a] nanotube-forming cyclic peptides,[9] molecular zippers,[10] oligonucleotide-based supramolecular assemblies,[11] monolayers, multilayers, and vesicles,[12] ordered solid-state structures,[3a–e, 13] and self-assembled photoactive aggregates.[14] Noncovalent forces used to generate these arrays include hydrogen bonding, metal–ligand coordination, π-π stacking, and hydrophobic interactions. On the other hand, there are but few self-assembled supramolecular systems that are predicated on anion chelation.[15] These include chiral bicyclic guanidinium dimers and tetramers that assemble into a double helix around sulfate templates,[15a] copper(II)–arginine complexes that form chiral double-helical structures with aromatic dicarboxylates,[15b] self-assembling diamidopyridinium phosphates,[15c] and dianionic and dicationic moieties that form self-assembled infinite rods.[15d] In all cases, the resulting complexes contain a minimum of two different components, one of which is an anion.

It occurred to us that the anion binding properties of expanded porphyrins such as sapphyrins (e.g. **1**)[16] could be effectively employed for the self-assembly of novel supramolecular species. In particular, we speculated that the previously synthesized zwitterionic sapphyrins **1a** and **1c**,[16d] which contain anionic carboxylate groups attached to a protonated sapphyrin core,[17] but which are precluded from "biting their own tails," due to the length of the carboxylate-sapphyrin spacer, should self-assemble readily. This assumption was made on the basis of our previous finding that sapphyrins, when protonated, effectively chelate carboxylate ions through a combination of hydrogen bonding and electrostatic attractions involving the pyrrolic hydrogens and the ligated oxyanion.[16b, c] Herein we report that this is indeed the case in the gas phase, in solution, and in the solid state. Taking this methodology a step further, and exploiting our recent discovery that calix[4]pyrroles (a class of molecules known for over a century[18]) are capable of anion chelation through multiple hydrogen bonds,[19] we have synthesized a new calix[4]pyrrole with a carboxylate pendant arm, and found that these purely anionic species also self-assemble. In contrast to the previously reported anionic systems capable of self-assembly,[15] the sapphyrin- and calix[4]pyrrole-based carboxylate building blocks of this report are self-complementary, and thus, no other extra components are required for self-assembly.

Calix[4]pyrrole monoacid **2a** was synthesized by the acid-catalyzed condensation of methyl 4-acetylbutyrate and cyclohexanone with pyrrole. This produced the monomethyl ester **2b** in 12% yield (after chromatographic purification). Subsequent hydrolysis of **2b** (sodium hydroxide ethanol/water solution at reflux; see Experimental Procedure) afforded the monoacid **2a**, which was immediately converted to its tetrabutylammonium or trimethylammonium salts (see Experimental Procedure).





1a: $R^1 = R^2 = CH_3$; $R^3 = H$; $R^4 = CH_2CO_2H$
1b: $R^1 = R^2 = CH_3$; $R^3 = H$; $R^4 = CH_2CO_2CH_3$
1c: $R^1 = R^2 = CH_2CO_2H$; $R^3 = R^4 = CH_3$
1d: $R^1 = R^2 = CH_2CO_2CH_3$; $R^3 = R^4 = CH_3$

2a: $R = (CH_2)_3CO_2H$
2b: $R = (CH_2)_3CO_2CH_3$

Initial evidence for self-assembly in the gas phase came from low- and high-resolution fast atom bombardment (FAB) mass spectrometry. Intense peaks for the dimer (but not trimer or tetramer) at double the molecular weight were observed for the carboxylates **1a**, **1c**, and **2a** (Fig. 1). Such peaks, however, were not seen with "control" methyl esters **1b**, **1d**, and **2b**. This indicates that the presence of unprotected carboxylate groups in the molecule is essential for self-assembly, and rules out formation of dimers due to simple van der Waals or hydrophobic attractions between the macrocycles. In addition, and in support of the

[a] Positive ion FAB mass spectrometry. [b] Negative ion FAB mass spectrometry.

As a further test of the proposed self-assembly process, experiments were carried out in the presence of fluoride ion. Since protonated sapphyrins have a significantly higher affinity for fluoride ion than other anions,[16e] it was expected that the addition of fluoride ion would inhibit sapphyrin dimer formation in the gas phase. This proved to be the case. When tetrabutylammonium fluoride was added to the samples of sapphyrin mono- and/or dicarboxylates, the peaks in the mass spectra ascribed to the dimer species disappeared completely. In the case of **2a**, addition of tetrabutylammonium fluoride decreased the intensity of the dimer ion peak but did not eliminate it completely.

X-ray quality crystals of sapphyrin carboxylate **1c** were obtained by slow diffusion of ether into a solution of **1c** in dichloromethane/methanol (3/1).[20] The structure analysis revealed that the appended macrocycle forms a supramolecular dimer in the solid state (Fig. 2a). A carboxylate "hook" from one molecule of **1c** is chelated to the pyrrole core of the second macrocycle. Simultaneously, this second macrocycle shares its carboxylate "tail" with the first sapphyrin subunit. A trifluoroacetate ion is coordinated to each of unchelated faces in the dimer and prevents these sites from being involved in further binding. Perhaps as a result of this, the second carboxylic acid is not bound to a sapphyrin core, but is coordinated to a methanol molecule. The macrocycles of the dimer are related by a crystallographic inversion center at 1/2, 1/2, 0. The separation between the root mean square (RMS) planes of the nitrogen atoms in this structure is 3.39(1) Å.

X-ray quality crystals of the tetrabutylammonium salt of calix[4]pyrrole carboxylate **2a** were obtained by slow evaporation of a solution of **2a** in dichloromethane in the presence of excess tetrabutylammonium fluoride trihydrate.[21] The resulting crystal structure confirmed that this anionic calix[4]pyrrole also self-assembles into dimers in the solid state. In this instance, in analogy to the sapphyrin case, the carboxylate moiety is hydrogen-bonded to the pyrrole array of an adjacent calix[4]pyrrole (Fig. 2b). Now, however, the separation between the RMS planes of the nitrogen atoms in each macrocycle is 7.41(1) Å. The calix[4]pyrrole **2a** adopts a cone conformation in the dimer, as is observed in the anion complexes of related systems.[19]

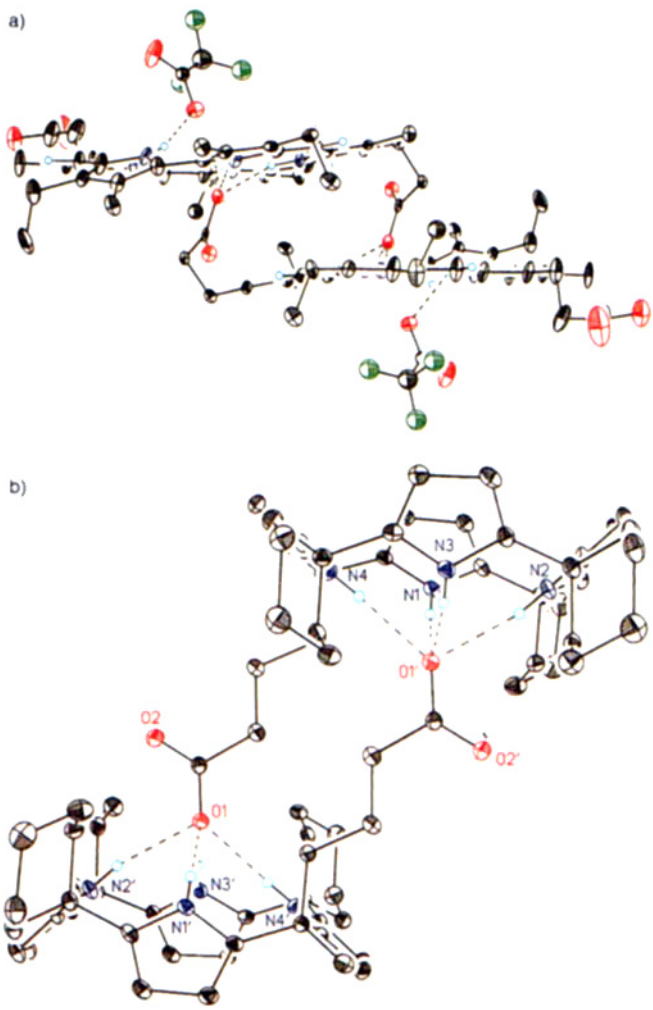

Fig. 2. Side view of the supramolecular sapphyrin dimer **1c**·**1c** (a) and of the noncovalent calix[4]pyrrole dimer **2a**·**2a** (b) in the solid state (thermal ellipsoids are scaled to the 30% probability level). C: black, H: light blue, N: blue, O: red, F: green.

The ^{1}H NMR spectra of sapphyrin monocarboxylate **1a** in [D_4]methanol or $CDCl_3$, and dicarboxylate **1c** in a [D_4]-methanol/$CDCl_3$ (2/1) mixture[22] showed strong line broadening, which is consistent with self-aggregation of these species.[23] Dilution experiments performed over a concentration range of 50 to 5 mM in these solvents showed little change in the spectra, which is taken as an indication that the putative aggregates prevail over the monomers at these concentrations even in these highly polar solvent mixtures.

In order to determine the stoichiometry of aggregation, vapor pressure osmometry (VPO) measurements were carried out in 1,2-dichloroethane using compound **1a**. The average molecular weight of the species in solution determined by this method ($M = 1281\ g\,mol^{-1}$; calculated 1261 $g\,mol^{-1}$) corresponds to that of the dimer. In contrast, these same VPO measurements carried out under identical conditions with the control sapphyrin methyl ester **1b** confirmed its monomeric state in solution ($M = 690\ g\,mol^{-1}$ calculated 643 $g\,mol^{-1}$).

Fluoride inhibition of sapphyrin dimerization was also studied by ^{1}H NMR spectroscopy. This was done by adding aliquots of tetrabutylammonium fluoride trihydrate solution (up to 3 equiv) to stock solutions of the sapphyrin carboxylates **1a** and **1c**, and recording the resulting changes in the proton NMR spectra. Generally, upon addition of fluoride ion, the spectra became well-resolved and all sapphyrin proton signals were seen to shift. The signals of the ethylene protons of the linker between the sapphyrin macrocycle and its carboxylate pendant arm were found to be particularly diagnostic. These, undergo downfield shifts on addition of fluoride ion (**1a**: $\delta = 1.67$ and 1.07 for $CH_2CH_2CO_2^-$ and $CH_2CH_2CO_2^-$, respectively).[24, 25] These signals are the ones most affected by the ring current of the "partner" aromatic sapphyrin macrocycle, and are thus the most indicative of dimer break-up. This is because in solution, as in the solid state, the dimers are probably held together in an offset manner. Such a binding arrangement would force the protons of the ethylene "arm" to resonate at higher field. When fluoride ion is added in sufficient quantities (generally less than 2 equiv), it binds to the sapphyrin cavity and displaces the carboxylates. This breaks the dimers and reestablishes the "normal" lower field chemical shift for the ethylene proton signals (Fig. 3).

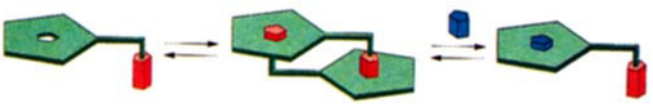

Fig. 3. Schematic representation of the sapphyrin **1a**, dimerization, and fluoride ion inhibition thereof. Green blocks: sapphyrin **1a**; red blocks: carboxylate appendages of **1a**; blue block: fluoride ion.

Unfortunately, the low solubility of the trimethylammonium salt of **2a** in organic solvents precluded a quantitative ^{1}H NMR analysis of this system. However, a ROESY NMR spectrum of of a suspension of this salt in CD_2Cl_2 provides evidence for association of the calix[4]pyrrole anions in solution. For instance, two resonances are observed between $\delta = 7.0$ and 7.5. These are typical shifts for NH protons in other noncomplexed calix[4]pyrroles[19] and are thus assigned to the signals of NH protons in the calix[4]pyrrole monomer. In addition, a broad resonance is observed at about $\delta = 11$, which is ascribed to an exchange peak involving the NH protons bound to the carboxylate portion of complementary, paired calix[4]pyrrole. Upon addition of [D_4]methanol, the resonance at $\delta = 11$ vanishes as would be expected upon break-up of the calix[4]pyrrole aggregates. From these experiments it is thus inferred that, as was true for sapphyrins **1a** and **1c**, conditions can be found under which dimerization is precluded.

In conclusion, anion-binding interactions may be used as a means of effecting the spontaneous self-assembly of appropriately designed supramolecular ensembles. This is important because it shows yet one more way in which a simple to control recognition motif (in this case sapphyrin- or calix[4]pyrrole-based anion binding) may be used to "program in" information that encodes for the self-controlled construction of higher order structures that, in turn, display considerable molecular complexity.

Experimental Procedure

2b: Methyl 4-acetylbutyrate (0.80 g, 5.6 mmol), cyclohexanone (0.55 g, 5.6 mmol), and pyrrole (0.75 g, 11.2 mmol) were dissolved in methanol (50 mL), and the mixture cooled to 0 °C. Methanesulfonic acid (0.5 mL) was added dropwise over the course of five minutes, and the mixture stirred at 0 °C for 1 h and then at room temperature overnight. The solvent was removed in vacuo. FAB mass spectra showed the presence of mono-, di-, tri-, and tetrafunctionalized material in the crude reaction mixture. Chromatographic purification (silica gel, dichloromethane) yielded **2b** as a white foamy solid (211 mg, 0.33 mmol, 12%). ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 7.07$ (br. m, 4H, NH), 5.88 (m, 8H, pyrrole CH), 3.63 (s, 3H, OCH_3), 2.22 (t, $J = 7.2$ Hz, 2H, CH_2), 1.93 (br., 14H, $6CH_2$(cyclohexyl), + CH_2(hook)), 1.56–1.35 (br., 23H, CH_2(hook) + $9CH_2$(cyclohexyl) + CCH_3). The term hook refers to the propionic acid side chain. ^{13}C NMR (62.9 MHz, $CDCl_3$): $\delta = 173.8$, 137.2, 136.5, 136.3, 130.7, 103.6, 103.5, 103.2, 53.4, 51.4, 39.7, 39.5, 39.4, 38.5, 37.5, 37.2, 36.9, 36.8, 34.0, 26.1, 25.9, 22.8, 22.7, 19.9. CI MS: *m/z*: 635 (MH^+); HRMS: calculated for $C_{41}H_{54}N_4O_2$: *m/z*: 634.4247; found: 634.4236; elemental analysis: calculated for $C_{41}H_{54}N_4O_2$: C 77.56, H 8.57, N 8.82; found: C 77.41, H 8.50, N 8.84.

2a: Methyl ester **2b** (211 mg, 0.33 mmol) in ethanol (20 mL) was heated to reflux. Aqueous sodium hydroxide (20 mL, 2.0 M) was then added and the mixture stirred at reflux for 4 h. The solution was allowed to cool and ethanol removed in vacuo. After acidification with perchloric acid (70%), the product was extracted with dichloromethane (50 mL). The organic layer was then washed with water (100 mL) and dried over $MgSO_4$. Removal of the solvent afforded **2a** as a white foamy solid (187 mg, 0.30 mmol, 91%). ^{1}H NMR (250 MHz, $CDCl_3$): $\delta = 7.02$ (br. m, 4H, NH), 5.89 (m, 8H, pyrrole CH), 2.26 (t, 2H, CH_2), 1.91 (br. m, 14H, $6CH_2$(cyclohexyl) + CH_2(hook)), 1.44 (br. m, 24H, $9CH_2$(cyclohexyl) + CH_2-(hook) + CCH_3 + $0.5H_2O$). The term hook refers to the propionic acid side chain. ^{13}C NMR (62.9 MHz, $CDCl_3$): $\delta = 179.4$, 137.3, 136.6, 136.2, 103.7, 103.6, 103.5, 103.2, 53.4, 39.7, 39.4, 39.3, 38.5, 37.4, 37.2, 36.9, 36.8, 33.8, 26.0, 25.9, 22.7, 22.6, 19.5. FAB MS: *m/z*: 620 (MH^+). HRMS: calculated for $C_{40}H_{52}N_4O_2$: *m/z*: 620.4090; found 620.4073; elemental analysis: calculated for $C_{40}H_{52}N_4O_2$: C 77.38, H 8.44, N 9.02; found: C 76.78, H 8.42, N 8.92.

The tetrabutylammonium salt of **2a** was precipitated in quantitative yield from a solution of **2a** in diethyl ether by the addition of tetrabutylammonium hydroxide (2.0 equiv). It was then washed with ether and water followed by drying in vacuo. Elemental analysis: calculated for $C_{56}H_{87}N_5O_2 \cdot H_2O$: C 76.40, H 10.19, N 7.96; found: C 76.58, H 10.04, N 7.95.

The trimethylammonium salt of **2a** was obtained by passing trimethylamine gas through a methanolic solution of **2a** at −10 °C. The salt precipitated in quantitative yield and was then dried in vacuo. Elemental analysis: calculated for $C_{43}H_{62}N_5O_2 \cdot 1/3(H_2O)$: C 75.18, H 9.18, N 10.19; found: C 75.00, H 8.97, N 10.10.

[22] The sapphyrin bisacid **1c** is insoluble in either pure chloroform (or dichloromethane) or methanol, but is soluble in mixtures of these solvents.

[23] The signals of the ^{1}H NMR spectra of sapphyrin methyl esters **1b** and **1d** are, on the other hand, well resolved in these solvents.

[24] These same linker ethylene signals in sapphyrin bisacid **1c** were broadened to such an extent that their initial shifts could not be determined accurately.

[25] The proton chemical shifts of the linker ethylene group in the control methyl ester **1b**, recorded under conditions analogous to those of the fluoride titration, were found to remain almost unchanged.

In Situ Observation of Transient Reaction Phenomena Occurring on Zeolite Catalysts with the Aid of Positron Emission Profiling

Rutger A. van Santen,* B. G. Anderson, R. H. Cunningham, A. V. G. Mangnus, Dr. L. J. van IJzendoorn, and M. J. A. de Voigt

Zeolites are widely used in the petroleum refining industry as solid acid catalysts to convert hydrocarbons into gasoline products of high octane number by isomerization or by cracking reactions.[1] Stable operation at mild reaction conditions is made possible by the addition of noble metals to acidic zeolites. For example, after addition of platinum to the zeolite H-mordenite *n*-hexane isomerizes to its structural isomers at 240 °C rather than at 400 °C.[2] The state of the platinum in the working catalyst and the distribution profiles of the reactive surface intermediates are strongly dependent on pretreatment and reaction conditions. Thus in situ measurement is necessary.

Positron emission tomography (PET) is a noninvasive, in situ, radiochemical imaging technique used in nuclear medicine to monitor biomedical functions.[3, 4] This technique has recently been applied to systems in engineering research by Bridgwater et al.[5, 6] to study mechanical mixing within a powder mixer. In addition we have shown that this technique can be used to provide information on the concentration distributions of reactants and products as a function of time and position along the reactor bed during the CO oxidation under steady-state conditions.[7, 8] This information is essential for the development of kinetic models describing the rates of elementary reaction steps.

We have since developed a new detection system for positron emission profiling (PEP), which is a one-dimensional analogue to PET. This study is the first to measure in situ reaction profiles under transient conditions.

Due to the short half-life of ^{11}C (20.3 min) the positron-emitting molecules must be produced on-site with a cyclotron in combination with chemical processing. We have developed a unique route for on-line synthesis of $^{11}CH_3C_nH_{2n+1}$ $(3 \geq n \leq 6)$[10, 11] based on our method for the homologation of olefins by ^{11}CO.[12] An optimized vanadium-promoted Ru/SiO_2 system is used to adsorb ^{11}CO and 1-pentene. Secondly, the mixture of hydrocarbons formed by hydrogenative desorption at 110 °C is separated by a technique of freezing, flash heating, and gas chromatography. Finally, a pulse that contains approximately 2×10^{-6} moles of nonlabeled *n*-hexane and 1 MBq of *n*-$^{11}CH_3C_5H_{11}$ (about 10^{-15} mol) can be injected into the feed stream of the zeolite-containing, solid-bed reactor positioned in a newly developed PEP detection system.

The PEP system is based on two banks of nine detection elements. Each element consists of a specially shaped and polished $Bi_4Ge_3O_{12}$ scintillation crystal and a slit-shaped photomultiplier. The system is optimized for imaging in one dimension; the detector thus has a faster sampling time (0.5 s) and a higher sensitivity than state-of-the-art research PET cameras whilst maintaining a resolution of 2.7 mm.[9] Reactor bed lengths varying between 4 and 50 cm can be handled.

Figure 1a shows the PEP image obtained after a pulse of labeled *n*-hexane was injected into a feed stream of *n*-hexane/hydrogen flowing through a bed of Pt/H-mordenite. The catalytic reactor was operating under steady-state conditions at 230 °C,

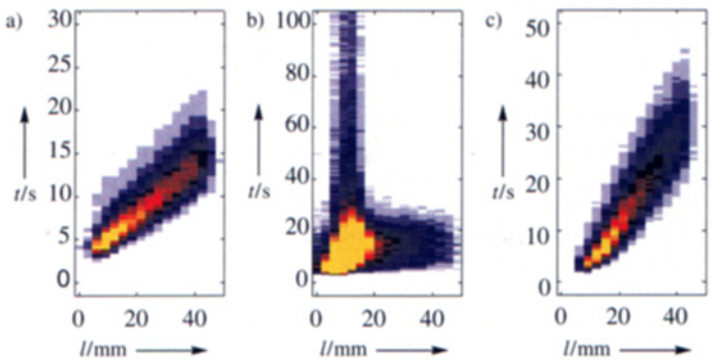

Fig. 1. Positron emission profiling (PEP) images of *n*-$^{11}CH_3C_5H_{11}$ pulse experiments on a Pt/H-mordenite catalyst bed (l = position along the catalyst bed, t = residence time). The color scale indicates the concentration of the ^{11}C label: the brighter the color, the higher the concentration. Labeled samples were injected into the feed streams (1 atm; 150 NmL min^{-1} total flow rate). a) The reactor was operating under steady-state conditions at 230 °C with a feed mixture of *n*-hexane/H_2 (1/28 mol). b) [^{11}C]-*n*-hexane pulse in hydrogen over the catalyst with freshly reduced Pt at 230 °C. c) [^{11}C]-*n*-hexane pulse in hydrogen over the catalyst, which was previously used in the hydroisomerization reaction at 230 °C.

which converts 19% of hexane into structural isomers. Since these isomers have similar adsorption/desorption and diffusion properties on H-mordenite to *n*-hexane, the pulse continues through the reactor in a manner similar to that of *n*-hexane on the zeolite alone.[13]

A very different behavior is observed if the platinum metal is freshly reduced. After reduction by H_2 at 400 °C, the temperature was lowered to 230 °C, and a pulse of labeled *n*-hexane was then injected into a hydrogen stream. The pulse adsorbs strongly near the beginning of the reactor bed and reacts rapidly (Fig. 1b). Some of the radio-labeled species exit the reactor very quickly (the near horizontal band), and some remain on the catalyst surface. Analysis of the radio-labeled reaction products by trapping and subsequent GC separation with NaI scintillation detection revealed light alkanes between C_1 and C_4.

When one uses a Pt/H-mordenite catalyst that was first used in the steady-state hydroisomerization of *n*-hexane at 230 °C, very different results were obtained. The reaction was interrupted by stopping the hexane feed, and after 5 minutes the labeled *n*-hexane was again injected into the hydrogen stream (see Fig. 1c). In contrast to the profile shown in Figure 1b, an image similar to that shown in Figure 1a was obtained. (The difference in the observed retention times between (a) and (c) is due to differences in the number of adsorption sites available[13]). Analysis of the trapped products revealed only C_6 hydrocarbons.

Apparently, the undesirable metal cracking reactions that occur on freshly reduced platinum are suppressed by "preconditioning" the surface of the platinum metal by the hydroisomerization reaction. As concluded from Figure 1b this "preconditioning" involves the deposition of a carbonaceous overlayer that prevents cracking of the hexane. As we will see from the experiments reported in Figure 2, the only function of the "preconditioned" platinum surface is to dehydrogenate hexane to hexene or to hydrogenate olefins. This result is consistent with the conclusions of others who work on model transition metal catalysts: hydrogenation and dehydrogenation reactions occur on a surface covered by a carbonaceous overlayer.[14–16] The effect of the carbonaceous overlayer may be to restrict the surface ensemble size available to the cracking reaction; the hydrogenation and dehydrogenation reactions are less structure-sensitive.[17]

The hydroisomerization reaction must be carried out in the presence of hydrogen in order to avoid loss of activity through "deactivation". The following type of experiments illustrate the details of deactivation of the acid sites. Steady-state hydroisomerization of *n*-hexane over Pt/H-mordenite at 240 °C is interrupted by replacing the feed with flowing helium. After 5 minutes labeled *n*-hexane is injected into the helium stream (Fig. 2a). A rapid reaction near the beginning of the reactor bed forms products that remain strongly adsorbed. Only a small portion of the pulse passes through the bed. Radio-GC analysis of this fraction revealed mainly unchanged C_6 hydrocarbons with small amounts of C_1 and C_2 hydrocarbons. All of the labeled products remaining on the surface could be removed if

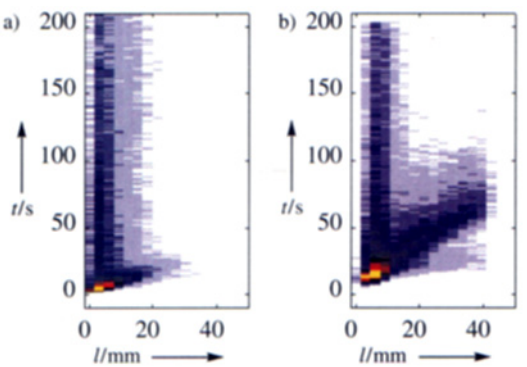

Fig. 2. PEP images of separate *n*-$^{11}CH_3C_5H_{11}$ pulse experiments on a Pt/H-mordenite catalyst. The hydroisomerization reaction under steady-state conditions was interrupted 5 min prior to injection by switching to a flow of hydrogen. Injection was then made into a stream of helium (75 NmL min^{-1}) at 240 °C. a) The majority of *n*-hexane is dehydrogenated to hexene on the Pt surface, and the hexene isomers remain strongly adsorbed to acidic sites in the absence of hydrogen. b) Conditions similar to those for (a) but at injection made at 230 °C.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2786 $ 15.00+.25/0

the temperature was increased to 400 °C in a stream of hydrogen. Analysis of this fraction revealed mainly C_6 hydrocarbons with small amounts of C_7, C_8, C_1, and C_2 species. This shows that *n*-hexane is rapidly dehydrogenated by platinum, and the resulting hexene molecules are adsorbed on the acid sites of the zeolite. In the absence of hydrogen they can not be rehydrogenated and therefore remain adsorbed, poisoning the sites for subsequent reaction. Dimerization or further oligomerization reactions do not occur to a great extent, since no large fraction of higher and lower hydrocarbons was found. The PEP image shown in Figure 2b was obtained when the above reaction was repeated at 230 °C. Comparison with Figure 2a reveals that a greater portion of the hexane pulse passes unchanged through the bed; the lower reaction rate is due to the lower reaction temperature.

These experiments under transient conditions provide the first direct demonstration of the so-called bifunctional reaction mechanism[18, 19] proposed for alkane hydroisomerization. The platinum promoter acts as an alkane dehydrogenation and an alkene hydrogenation catalyst. The zeolitic protons protonate the alkanes, which then, as predicted by theory,[20, 21] remain strongly adsorbed (enthalpy of protonation $\approx 180 \pm 20\ kJ\,mol^{-1}$).

The protonated alkenes isomerize. From steady-state experiments we deduced an activation energy of isomerization to isohexane of approximately $135 \pm 20\ kJ\,mol^{-1}$.[22] The protonated, isomerized intermediate remains strongly adsorbed. Further reaction only proceeds in the presence of gaseous hydrogen. Desorbing alkenes then will be hydrogenated by platinum to form the product alkanes. This is consistent with previous studies, which showed that the reaction has a positive order in hydrogen partial pressure in the absence of platinum.[23]

In summary a technique has been developed that enables the analysis of reactant concentration profiles as a function of time. Radiochemical PEP measurements with a great variety of alkanes extensively used in practice are now possible under a wide range of practical reaction conditions. Here we have demonstrated the use of the technique to probe the elementary reaction steps in the hydroisomerization of hexane.

The Titanium(IV)-Catalyzed Epoxidation of Alkenes by *tert*-Alkyl Hydroperoxides**

Richard D. Oldroyd, John Meurig Thomas,* Thomas Maschmeyer, Philip A. MacFaul, Darren W. Snelgrove, Keith U. Ingold,* and Danial D. M. Wayner

Ever since it was reported that titanosilicalites, such as TS-1 synthesized by the company Enichem,[1] could catalytically and selectively oxidize certain organic compounds in the presence of H_2O_2 (for example, phenol to hydroquinone[2] and propene to propene oxide[3]), there has been considerable interest in other low-temperature selective oxidations with various kinds of Ti^{IV}-containing siliceous microporous catalysts.[4] Corma et al. have demonstrated the catalytic merit of using larger pore microporous materials,[5] such as Ti^{IV}-containing β-zeolite, and the commercially available *tert*-butyl hydroperoxide (TBHP) as a sacrificial oxidant.

Interest in Ti^{IV}-catalyzed epoxidations of alkenes has recently intensified, because Ti^{IV}-containing mesoporous MCM41 silicas with their larger pore apertures (typically 30 Å) are capable of oxidizing relatively bulky reactants.[6, 7] Two distinct kinds of Ti^{IV}-modified MCM41 epoxidation catalysts have been described. The first (Ti→MCM41) accommodates the titanium ions (identified along with distances between Ti and the O atoms attached to silicon by X-ray absorption spectroscopy)[6] within the walls of the mesoporous silica. The second (Ti↑MCM41) has the tetracoordinated Ti^{IV} ions grafted onto the inner surfaces of the mesoporous host and is formed from a titanocene dichloride precursor as recently described by Maschmeyer et al.[8, 9] The Ti→MCM41 reported here (Si:Ti ratio of 1:0.058) was synthesized from $Ti(OiPr)_4$, which was incorporated into the MCM41 synthesis gel, according to the procedure of Rey et al.[10] The Ti↑MCM41 used in this study had a Si:Ti ratio of 1:0.041.

Sheldon and co-workers have concluded that alkyl hydroperoxide catalyzed epoxidation of olefins occurs by a heterolytic mechanism in the presence of TiO_2–SiO_2 mixed-oxide cata-

lysts.[11] In this communication we show that this is also the case for our two catalyst systems, and, in addition, we answer the following questions:

1. Is 2-methyl-1-phenyl-2-propyl hydroperoxide (MPPH) an effective epoxidizing agent with our two catalysts?
2. Can MPPH be used as a reliable probe for free-radical mechanisms in other metal-catalyzed hydrocarbon oxidations utilizing *tert*-alkyl hydroperoxides as oxidizing agents ?
3. By how much does the reported[8] improved efficiency of epoxidation using a Ti^{IV} ion protruding from the silica surface (Fig. 1a) surpass that of buried Ti^{IV} ions (Fig. 1b)?

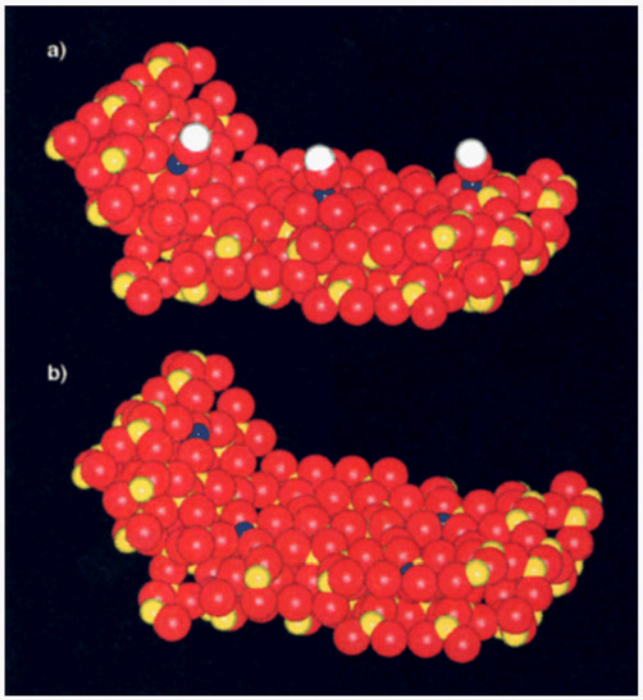

Fig. 1. Environment of the titanium ions in the two modified MCM41 catalysts. Blue = Ti, yellow = Si, red = O, white = H. a) Surface-grafted Ti↑MCM41 and b) framework-embedded Ti→MCM41. (Surface silanol groups have been omitted for clarity).

The importance of MPPH is that homolytic cleavage of its peroxidic O–O bond yields an alkoxyl radical (MPPO), which undergoes an extremely rapid β-scission ($k_1 \approx 2 \times 10^8\ s^{-1}$) [Eq. (a)].[12] The very short lifetime of the MPPO radical

$$\underset{\text{MPPH}}{PhH_2CMe_2OOH} \longrightarrow \underset{\text{MPPO}}{PhCH_2CMe_2O^{\bullet}} \xrightarrow{k_1} PhCH_2^{\bullet} + Me_2CO \qquad \text{(a)}$$

precludes reaction with any substrate at concentrations smaller than or equal to 1 M, even when the alkoxyl radical and substrate reaction is diffusion-controlled.

Some of us have recently used MPPH as a mechanistic probe in some iron(III)-catalyzed cycloalkane oxidations.[12–14] Previously[15, 16] *tert*-butyl hydroperoxide (TBHP) was employed as the oxidant, and cycloalkane oxidation products were formed. However, when TBHP was replaced by MPPH, no cycloalkane oxidation products were evident, the main products were instead benzyl alcohol, benzaldehyde, and bibenzyl, all of which clearly arise from the benzyl radical formed by β-scission of MPPO. The difference between TBHP and MPPH is most simply explained by the very much slower β-scission of the *tert*-butoxyl radical,[14] which has a sufficiently long lifetime for it to abstract a hydrogen atom from the cycloalkane. Despite the simplicity of this explanation, both explicit[17] and implicit[18] arguments have been made that MPPH is not a competent substitute for TBHP in iron(III)-catalyzed oxidations of cycloalkanes[17] and epoxidations of cycloalkenes.[18] Instead, nonradical mechanisms that involve TBHP coordination to the Fe^{III} centers are favored with subsequent heterolytic cleavage of the O–O bond to yield a high-valent iron–oxo intermediate (formally Fe^{V}=O) which inserts its oxygen atom into C–H and C=C bonds. Therefore, we decided to extend our studies of cyclohexene epoxidation by using our heterogeneous Ti^{IV} catalysts with both TBHP and MPPH in order to see whether MPPH is a competent replacement for TBHP in what is probably[11] a nonradical oxidation.

The first six entries in Table 1 show that epoxide is the major product with both TBHP and MPPH at room temperature; no products are formed in the absence of hydroperoxide. This convincingly proves that *tert*-alkyl hydroperoxides convert cyclohexene into cyclohexene oxide by a nonradical mechanism in the presence of both Ti↑MCM41 and Ti→MCM41. Moreover, MPPH is revealed to be an extremely effective oxidant, surpassing TBHP in this regard.[19] This is the first time, to our knowledge, that MPPH has been shown to be capable of oxidizing a hydrocarbon substrate. A third conclusion is that, as an epoxidation catalyst, Ti↑MCM41 is over ten times as active per Ti^{IV} ion as Ti→MCM41.[20]

If radicals had been involved in these Ti^{IV}-catalyzed oxidations, we would expect to obtain very little cyclohexene oxide relative to the yields of cyclohexenol, cyclohexenone, and *tert*-alkyl cyclohexenyl peroxide (see Scheme 1) and, with MPPH, products derived from benzyl radicals would be formed. These products were indeed produced when reactions were initiated by UV irradiation of the reactants in the absence of catalyst (see entries 10–12 in Table 1).

Table 1. Cyclohexene epoxidation at 25 °C in acetonitrile. Two numbers indicate the results from duplicate experiments.

No.	Catalyst	Oxidant	Cyclohexene oxide [%] [a]	Other products [%] [b]	Selectivity w.r.t. the epoxide [%] [c]	Turnover frequency [h^{-1}] [d]

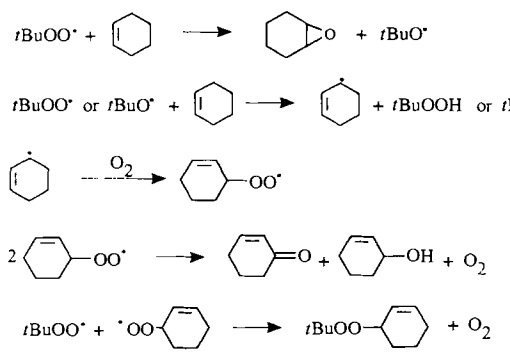

Scheme 1. Potential reactions between cyclohexene and TBHP under free-radical conditions.

The oxidation of *cis*-stilbene with *tert*-butyl peroxyl radicals, generated by the thermal decomposition of di-*tert*-butyl hyponitrite in the presence of TBHP [Eq. (b)], yields benzaldehyde and

$$t\mathrm{BuO{-}N{=}N{-}O}t\mathrm{Bu} \xrightarrow{\Delta} \mathrm{N_2} + 2\ t\mathrm{BuO}^{\bullet} \xrightarrow{2\ t\mathrm{BuOOH}} 2\ t\mathrm{BuOH} + 2\ t\mathrm{BuOO}^{\bullet} \quad \text{(b)}$$

trans-stilbene oxide in approximately equal amounts, together with a small quantity of *trans*-stilbene. However, reaction of *cis*-stilbene with TBHP or MPPH, in the presence of our two Ti^{IV} catalysts, gave *cis*-stilbene oxide as the only oxidation product (Table 2). (Low levels of *trans*-stilbene were also identified, which probably arose from photo- or acid-catalyzed isomerization on the mildly acidic surface of the support.) The formation of *cis*-stilbene oxide as the sole oxidation product provides further evidence in favor of a nonradical epoxidation mechanism.[21]

Table 2. *cis*-Stilbene epoxidation at 25 °C in acetonitrile. Two numbers indicate the results from duplicate experiments.

No.	Catalyst	Oxidant	*cis*-Stilbene oxide [%] [a]	*trans*-Stilbene [%] [a]	Selectivity w.r.t. the epoxide [%] [b]	Turnover frequency [h^{-1}] [c]
1	Ti↑MCM41	TBHP	5.4, 4.1	1.6, 1.2	77.3, 77.6	3.7, 2.4
2	Ti↑MCM41	MPPH	16.0, 17.9	0.7, 1.0	95.7, 94.9	9.7, 11.7
3	Ti↑MCM41	air	0.0	0.0	0.0	0.0
4	Ti→MCM41	TBHP	0.3, 0.4	1.8, 2.1	14.2, 17.1	0.1, 0.1
5	Ti→MCM41	MPPH	3.5, 1.9	0.9, 0.4	80.6, 84.5	1.0, 0.5
6	Ti→MCM41	air	<0.02	0.0	–	–
7	MCM41	TBHP	0.0	3.2	0.0	–
8	MCM41	MPPH	0.0	0.0	0.0	–

[a] Percentages given are based on the amount of *cis*-stilbene converted into the listed products. [b] Based on stilbene-derived products. [c] Moles of epoxide produced per mole Ti^{IV} per hour.

Pretreatment of Ti↑MCM41 with either neat TBHP or an acetonitrile solution of MPPH caused the initially white catalyst to turn yellow. This color was retained even after filtration and thorough washing with acetonitrile. Mixing the yellow, washed catalyst with cyclohexene gave little or no cyclohexene oxide (entries 13 and 14 in Table 1). If all the Ti centers managed to coordinate peroxide and if each of these reacted with one molecule of cyclohexene, approximately 2% conversion into epoxide should have been observed. Similar results have been previously obtained for a homogeneous titanium–porphyrin catalyst pretreated with TBHP in a similar fashion.[22] The obvious conclusion is that the yellow titanium–peroxo complex (presumably containing η^2-coordinated peroxide, based on a recent crystal structure of a model complex)[23] is not the oxygen atom transfer agent. This implicates a coordination of cyclohexene to the titanium center (as opposed to its merely reacting with coordinated peroxide from outside the coordination sphere). Further studies are in progress in order to gain greater insight into the nature of the active intermediate.

Since there are literature precedents for alkane oxidations catalyzed by titanium silicalites,[4b, 24] we assumed that cyclooctane would be oxidized by *tert*-alkyl hydroperoxides in the presence of Ti↑MCM41. However, with TBHP, no reaction took place at room temperature. Significant oxidation was only achieved when the temperature was increased to 70 °C with the formation of radical-derived products, namely, cyclooctanol, cyclooctanone, *tert*-butyl cyclooctyl peroxide, and cyclooctene oxide (the last presumably formed by catalytic oxidation of cyclooctene created during the reaction by cyclooctyl radical–radical disproportionation. The reaction with MPPH at the same temperature gave mainly benzyl alcohol.

In summary, we conclude that "surface-grafted" Ti↑MCM41 catalysts are substantially more active than "framework-embedded" Ti→MCM41 materials in terms of activity per titanium center. We have also demonstrated that MPPH is a better alkene epoxidizing agent than TBHP in the presence of these Ti^{IV}-modified MCM41 catalysts. It is clear that epoxidation proceeds by nonradical chemistry, and results indicate that the alkene and the peroxide must both be coordinated to the titanium centers for reaction to occur. MPPH is inactive as a cycloalkane oxidizing agent, which demonstrates that a radical mechanism is in operation. It is now abundantly evident that, whenever MPPH and TBHP give different hydrocarbon oxidation products in the presence of metal catalysts, there are compelling reasons to presume that both hydroperoxides are involved in free-radical and not in radical-free chemistry.

Experimental Procedure

Catalysts were prepared by published methods [8,10]. MPPH was synthesized by a slightly modified literature procedure [25]. TBHP and acetonitrile were distilled prior to use to remove water. Cyclohexene and *cis*-stilbene were purified to remove 2,6-di-*tert*-butyl-4-methylphenol (BHT) in the former and *trans*-stilbene in the latter. All experiments were performed under argon in degassed solutions, unless no hydroperoxide was used (these were carried out in air). At the end of all catalytic reactions, PPh_3 (1.5 g) was added to destroy any unchanged hydroperoxide. Products were analyzed by GC and GC-MS with either dibromobenzene or hexadecane as internal standards.

Cyclohexene oxidation: catalyst (75 mg) was added to cyclohexene (0.5 mL, 4.9 mmol), hydroperoxide (5 mmol), and acetonitrile (8 mL). The reaction was stopped after one hour.

cis-Stilbene oxidation: Ti↑MCM41 (40 mg) or Ti→MCM41 (65 mg) was added to *cis*-stilbene (0.5 mL, 2.7 mmol), hydroperoxide (3.1 mmol), and acetonitrile (5.2 mL). These reactions were carried out in a foil-covered reaction flask (to keep out light) for two hours.

Cyclooctane oxidation: Experiments were performed over 5 h at 70 °C, cyclooctane (0.67 mL, 5.0 mmol), peroxide (5.0 mmol), and acetonitrile (15 mL) in the presence of Ti↑MCM41 catalyst (75 mg).

Reactions with UV light: The solutions were made as above in quartz tubes, but no catalyst was added. They were then subjected to UV light for the specified time.

Hydroperoxide pretreatment of Ti↑MCM41: Ti↑MCM41 (150 mg) was stirred in either neat TBHP or an acetonitrile solution of MPPH for 3 h. The yellow material formed was filtered off, washed with acetonitrile (200 mL), and subsequently stirred in cyclohexene (0.5 mL) and acetonitrile (8 mL) overnight before analysis.

Di-*tert*-butyl hyponitrite and *cis*-stilbene: A mixture of hyponitrite (5.2 mg), TBHP (0.11 mL), glacial acetic acid (0.3 mL), pyridine (3 mL), and *cis*-stilbene (0.096 mL) were sealed in a vessel and kept at 37 °C in the dark for 72 h.

[19] The fate of MPPH after oxidation was determined by treating it with a 30-fold molar excess of cyclohexene in the presence of Ti↑MCM41 for 16 h. Analysis by GC (without quenching the reaction with PPh_3) revealed that the only major MPPH-derived product was the alcohol MPPOH, which was present in roughly similar amounts to the cyclohexene oxide produced (MPPOH:epoxide ≈1.2:1). This effectively demonstrates that MPPH does not form MPPO radicals, and hence epoxidation does not occur by peroxyl addition to the olefinic double bond followed by loss of the alkoxyl radical (see Scheme 1).

[20] Some very recent work by A. Corma et al, yet to be published, demonstrates that the maximum catalytic activity as a function of titanium loading for Ti→MCM41 is different from that for Ti↑MCM41. Therefore, in a "worst case scenario", we could possibly be comparing the most catalytically efficient loading for Ti↑MCM41 with a poorly efficient loading for Ti→MCM41.

[21] Under the same conditions *trans*-stilbene was not oxidized to *trans*-stilbene oxide. Since the pore dimensions of the catalyst are large enough to allow free passage of both *cis*- and *trans*-stilbene molecules throughout its structure, the lack of oxidation implies that steric effects may be important around the Ti^{IV} centers.

Amide Backbones with Conformationally Restricted Furanose Rings: Highly Improved Affinity of the Modified Oligonucleotides for Their RNA Complements**

Alain De Mesmaeker,* Catherine Lesueur, Marc-Olivier Bévière, Adrian Waldner, Valérie Fritsch, and Romain M. Wolf

The replacement of phosphodiester bonds in natural 2′-deoxyoligonucleotides by amide bonds was recently described[1] for their application to the antisense strategy.[2] Among the five structural amide isomers we incorporated into oligonucleotides, compounds with modification 2 (Fig. 1) contributed to a slight increase in the thermodynamic stability of the duplexes formed with complementary RNA strands. Moreover, oligonucleotides with alternating phosphodiester and amide linkages showed a largely increased resistance towards endo- and exonucleases.

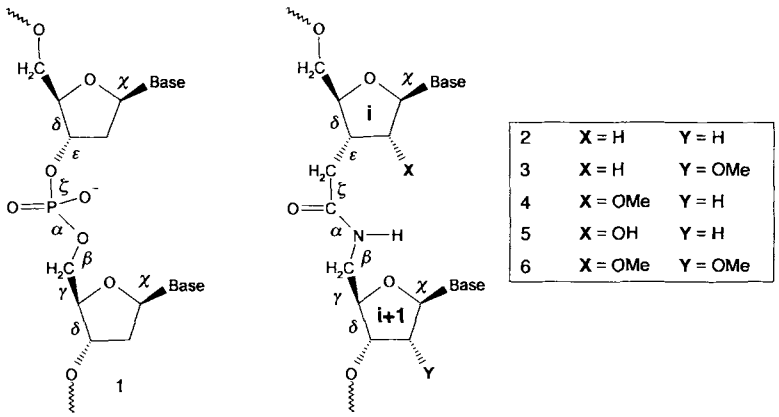

Fig. 1. Structure of a dimer in a natural DNA strand (left) and of modified dimers 2–6 (right). Torsion angles in the modified structure are defined as in natural nucleic acids (IUPAC-IUB, Joint Commission on Biochemical Nomenclature, *Eur. J. Biochem.* **1983**, *131*, 9). In modified strands where the modified residues alternate with wild-type monomers, there are two distinct types of residues: residue i, in which the modified backbone portion is attached to C3′, and residue i + 1, in which the modified linkage is attached at C5′.

The charge reduction might have a positive effect on their penetration into cells.[3] In light of the very promising properties of compounds with modification 2, we investigated further structural changes of this prototype in an effort to improve the affinity of the corresponding oligonucleotides for their RNA complements. Although many parameters may influence the potential activity of an oligonucleotide as antisense agent under physiological conditions,[2, 4] it is essential that the structural modifications introduced in this strand contribute substantially to an increase in affinity for an RNA target. We describe here the syntheses of dimers with the amide modifications 3–6, which carry additional 2′-substituents in their furanosyl residues, and the incorporation of these dimers into oligonucleotides (Fig. 1). The highly increased thermodynamic stability (a measure of which is the melting temperature T_m) of the du-

[**] We thank Dr. U. Pieles and Dr. D. Hüsken for the synthesis and the purification of the oligonucleotides.

plexes formed between the oligonucleotides containing the modifications 3 and 6 and an RNA complement are presented together with a molecular modeling study.

Our NMR[5] and molecular mechanics studies[6] on RNA·DNA duplexes with DNA strands modified with 2 have shown that the furanose bearing the modified backbone portion at the C3′ end (i residue in Fig. 1) tends to adopt a conformation closer to C3′-*endo* than the sugar with the amide-modified portion attached at C5′ (i + 1 residue in Fig. 1). The latter was found to behave like the deoxyribose in an unmodified RNA·DNA duplex; that is, it oscillates between the C2′-*endo* and C3′-*endo* conformations.[7]

We postulated that an increase in the thermodynamic stability of the duplex might be achieved if both sugar moieties could be forced into the C3′-*endo* puckering conformation.[8] A 2′-O-alkyl substituent in a ribonucleoside having a phosphodiester or a phoshorothioate backbone favors the C3′-*endo* conformation of the five-membered ring[9] and increases the melting temperature T_m of the duplexes with an RNA complement.[10] However, the effect of a 2′-O-alkyl substituent on the sugar residues of a modified backbone is very difficult to predict. Depending on the preferred conformation adopted by a modified backbone, the effects of the puckering of the upper and lower sugar moieties will be different. Our molecular modeling and NMR data suggested that oligonucleotides containing modification 3 would display a better affinity than those containing the prototype 2 for a complementary RNA strand. In contrast, a 2′-O-alkyl substituent on the upper sugar moiety (as in modification 4) should not substantially influence the stability of the duplex because this residue already tends more to a C3′-*endo* conformation in the parent backbone 2. The combination of 2′-O-alkyl substituents on both sugar residues (as in modification 6) would thus lead to a thermal stability of the duplex that is similar or slightly better than that for modification 3. As described below, our hypotheses were fully validated by our experiments.

Modifications 3–6 were introduced into oligonucleotides as dimers containing a 5′-DMT group (DMT = dimethoxytrityl) and a phosphoramidite at the 3′-end. The required amines **3** and **4** were synthesized starting from 2′-OMe thymidine **1** (Scheme 1). The primary iodide was obtained in high yield by treatment of **1** with iodine and triphenylphosphane in pyridine.[11] After substitution with sodium azide and protection of the 3′-hydroxylic function with tBuPh$_2$SiCl, the intermediate **2** was obtained. The transformation of thymidine to the *N*-methylpyrrolidino-protected 5-methyl cytidine was realized in a high overall yield.[12] As in the case of the preparation of the dimer with the modification 2, the amine **4** was used without purification for the formation of the amide dimer.[13]

Initially we attempted the synthesis of the carboxylic acid derivative **10** (Scheme 2) by addition of the 3′-centered radical to allyltributyltin, followed by oxidative cleavage of the C–C double bond. This process is

very efficient in the case of the 2′-deoxy derivatives.[1] In contrast, the radical addition reaction between allyltributyltin and the 3′-thionocarbonate derived from **1** (having a 2′-OMe substituent) furnished the β-3′-allyl derivative as the major product rather than the desired α-3′-allyl derivative. These difficulties could be circumvented by using the anhydro derivative **5**[14] (Scheme 2).

The radical addition of **6** to allyltributyltin was highly stereoselective because all the substituents were on the β face. Only the 3′-allyl derivative **7** was detected by ^{1}H NMR spectroscopy (500 MHz) of the crude reaction mixture. The anhydro ring was hydrolyzed, and the resulting thymine base was protected by treatment with BOMCl and DBU. The 2′-hydroxylic function was inverted by a Mitsunobu reaction with chloroacetic acid.[15] After removal of the chloroacetate residue with NaOMe, the resulting alcohol was methylated. Cleavage of the BOM-protective group was realized after dihydroxylation of the C–C double

For the synthesis of compounds with the modification 5, which carry a 2′-OH group on the upper sugar moiety, we developed a new strategy that relies on the stereoselective glycosylation of a primarily formed dimer that already contains a thymine residue on the lower sugar moiety (Scheme 4). The carboxylic acid **25**[17] was coupled in very good yield to the amine **12**.[1b] The selective removal of the 1,2-isopropylidene group in **26** with thiophenol in the presence of CF_3COOH afforded the β-thioglycoside in 51% yield. The stereoselective introduction of the second thymine base on the 2′-acetoxy derivative, obtained by acetylation (Ac_2O, Py, RT), was performed by glycosylation of the anomeric phenylsulfoxide **27**.[18] The selective oxidation of the thiophenyl derivative to the sulfoxide **27** was achieved at low temperature with purified *m*CPBA; this avoids the formation of the sulfone, which does not undergo the desired glycosylation reaction. The introduction of the upper thymine residue of **28** was performed in good yield (65%) without epimerization of the lower one and without interference (cyclization) of the amide bond of the backbone (Scheme 4). The corresponding phosphoramidite **29** was obtained after exchange of protective groups.

The melting temperature T_m of the duplexes formed between the modified oligonucleotides and their RNA and DNA complements are summarized in Table 2.[19] The T_m values obtained for the duplexes that contain the oligonucleotides with the modifications 3–6 are compared to the those for oligonucleotides of the parent modification 2 and the wild type 1.[1b, 13] A 2′-OMe substituent on the lower sugar unit of the amides (modifications 3 and 6) has a dramatic effect on the T_m value of the duplexes with RNA (sequence A): the additional 2′-OMe substituent in modification 3 increases the melting temperature by +1.7 °C compared to the value for modification 2. When the modification 3 was introduced in an alternating mode with phosphodiester linkages in sequence C, the T_m value increased by +2.5 °C per modification 3 with respect to the value for the wild type (sequence C). It is noteworthy that the increase of the melting

[a] A–D with RNA complement, E–F with DNA complement. [b] $\Delta T_m = [T_m$(modified oligonucleotide) $- T_m$ (wild-type)$]/$(number of modified dinucleosides)

temperature gained with the additional 2′-OMe substituent in the case of the amide backbone 3 is greater than that observed for the natural phosphodiester backbone. Indeed, the T_m value that is reached with the 2′-OMe substituent on thymidine and 5-methylcytosine residues in sequence C is only +1.0 °C per modification higher than that of the corresponding natural 2′-deoxyribofuranosides.[20]

A 2′-OMe group on the upper sugar unit had a much less pronounced effect than the one on the lower sugar unit (modifications 4 and 3, respectively). The upper sugar adopted a conformation closer to the C3′-*endo* conformation in the parent amide modification 2. Therefore, the additional 2′-OMe group in modification 4 does not significantly change the puckering scheme of the ribofuranose ring. However, when a 2′-OH group is present, this can form an intramolecular hydrogen bond with the amide backbone. This would result in a conformational change of the backbone. The negative impact of the 2′-OH substituent in the upper sugar in modification 5 was confirmed experimentally ($\Delta T_m = -1.2$ °C). The substitution of both sugar residues with 2′-OMe groups (modification 6; sequences A and D) increased the T_m value by +2.6 and +3.0 °C, respectively, with respect to the value for the wild type.

Interestingly, the amide modifications 2, 3, 4, and 6 have a much less favorable effect on the thermodynamic stability of the duplexes formed with a DNA complement (sequences E, F) than with the RNA complement.

Molecular mechanics and dynamics studies have been carried out with the AMBER[21] force field as incorporated in the DISCOVER 2.9.5. software from BIOSYM Technologies, San Diego, USA. The conformational analysis was performed on octamer duplexes r[GA_6G]·d[CTTT*TTTC] with one modified dimer T*T in the middle of the DNA strand; molecular dynamics studies were carried out on alternatingly modified 14mer RNA·DNA duplex structures r[$G(A)_{12}G$]·d[$CT(T*T)_5TC$], by using the settings for amide modifications.[1, 6]

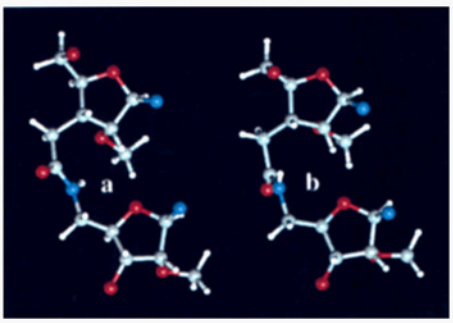

Fig. 2. Lowest energy conformations of modification 6 (modified dimer cut out of the DNA strand of the RNA·DNA octamer duplex). Conformation **b** is 0.5 kcal mol^{-1} higher in energy than conformation **a** (when the energies of the entire octamer hybrid duplex are compared) and differs mainly in torsion angles β(i) and ζ(i + 1) (see Fig. 1 for definitions).

Irrespective of the various modifications at C2′, the conformational analysis generally confirms the results found for the corresponding amide-modified backbone without further substituents at C2′. The two lowest energy conformations of the modifications 3–6 resemble **a** (lowest energy level) and **b** (second lowest energy level), as shown for modification 6 in Figure 2. Like for the parent structure 2, the conformation **b** is generally 0.5 to 1.5 kcal mol^{-1} higher in energy than conformation **a** (energy based on entire octamer duplex). The conformation **a** corresponds to $(\alpha, \beta, \gamma) \approx (t, t, t)$, a geometry sometimes observed in A-form DNA duplexes as a variant of the standard (g^-, t, g^+) backbone conformation of DNA.[22]

Molecular dynamics (MD) trajectories have been recorded for all modifications; the low-energy conformations were used as starting structures. Generally, standard Watson–Crick base pairing is conserved over the entire MD trajectories. However, some notable differences with respect to the unsubstituted amide modification 2 are observed. The introduction of an oxygen atom at C2′ of the furanose limits the sugar puckering to the C3′-*endo* puckering range; the phase angle of pseudorotation P[23] is around 18° (Fig. 3). Thus, the i + 1 residues in modifications 3 and 6 clearly behave differently from those in the unsubstituted modification 2. The effect of introducing an oxygen at the C2′ of the i residue is less pronounced, since even in modification 2, this sugar tends more to A-type puckering (average value for P is 86° for conformation **a** and 48° for conformation **b**).[6]

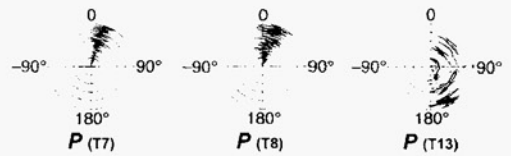

Fig. 3. Phase angle of pseudorotation P [23] of the bases T7, T8, and T13 in the DNA strand (modification 6) of a RNA·DNA 14mer duplex. The values are given in the form of polar coordinates with P as phase, and time as radial coordinate; circles represent intervals of 20 picoseconds. The sugars in T7 (i residue) and T8 (i + 1 residue) remain in the C3′-*endo* conformation, whereas the unmodified deoxyribose of T13 oscillates between the C3′-*endo* and C2′-*endo* conformations.

The average MD structure of the RNA·DNA duplex r[$G(A)_{12}G$]·d[$CT(T*T)_5TC$] (T*T: dimer with modification 6) is depicted in Figure 4. The ribbons symbolize the backbone, whose position was determined by instantaneous MD pictures recorded at intervals of 10 picoseconds. Qualitatively, this modified hybrid duplex behaves definitely more conservative during the molecular dynamics simulations than the corresponding wild-type duplex; this is mainly ascribed to the constrained C3′-*endo* puckering of the furanoses in the modified DNA strand. The modifications introduced in the DNA strand do not affect the RNA strand.[7]

In conclusion, we have designed and incorporated amide modifications into oligonucleotides that substantially increase their affinity for an RNA target compared to the wild type and

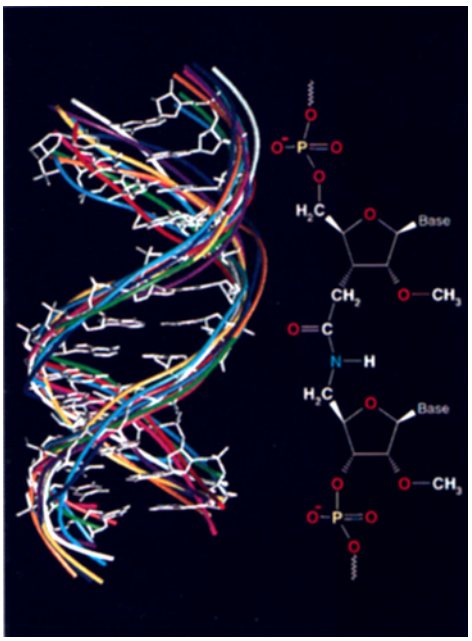

Fig. 4. Hybrid duplex RNA·DNA with an alternatingly modified DNA strand d[CT(T*T)$_5$TC]; T*T: dimer with the modification 6, X = Y = OMe (see Fig. 1). The structure corresponds to the molecular dynamics average structure (hydrogens are not shown). The ribbons pass through the backbones of momentary molecular dynamics structures spaced by 10 picoseconds.

to the parent modification 2. The introduction of a 2′-OMe group on the lower sugar moiety in the amide modifications 3 and 6 increased the T_m value of the duplexes with RNA by 2.0–3.0 °C. The second 2′-OMe substituent on the upper sugar moiety in modification 6 has also a positive effect on the thermodynamic stability of the duplex with an RNA complement, although less pronounced. The very large increase in T_m observed for modifications 3 and 6 results from the compatibility of the preferred conformations adopted by the amide backbone with the C3′-*endo* puckering of both furanose rings. These modifications are very promising for their application in the antisense strategy, in particular because of the increased stability of the corresponding oligonucleotides towards nucleases.

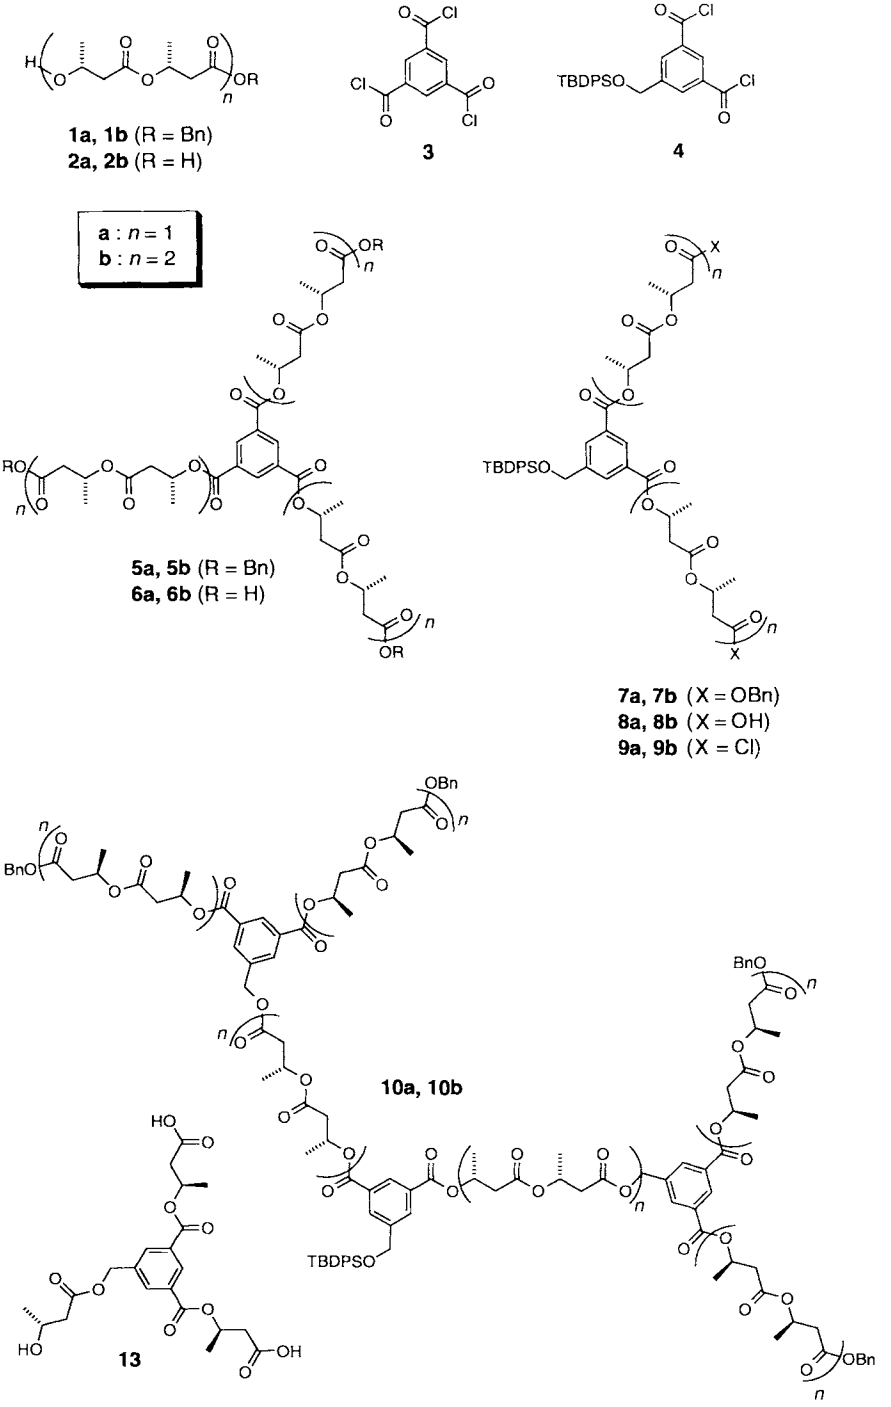
Synthesis and Enzymatic Degradation of Dendrimers from (*R*)-3-Hydroxybutanoic Acid and Trimesic Acid**

Dieter Seebach,* Guido F. Herrmann, Urs D. Lengweiler, Beat M. Bachmann, and Walter Amrein

Dendrimers are attracting growing interest for use in stereoselective synthesis,[1] as a new type of material,[2] and in biological studies, for example as DNA carriers.[3] We now report on the first synthesis of monodisperse, enzymatically degradable, polyanionic dendrimers from (*R*)-3-hydroxybutanoic acid (HB)[4] and trimesic acid.

The convergent synthesis starts with the previously described[4] benzyl esters **1a** and **1b** of the dimer and the tetramer of HB, respectively, which were used as elongation units. For the assembly of the dendritic core and the branching units we employed the commercially available trimesic acid trichloride **3** and the TBDPS-protected 5-hydroxymethyl-1,3-benzenedicarboxylic acid dichloride **4**,[5] which can be easily obtained from the corresponding trimethyl trimesate. Acylation of the HB-oligomers **1** with **3** gave the core structures **5**, and debenzylation yielded the tricarboxylic acids **6**. Branching unit **7** was obtained by acylation of **1** with **4**. The branches **10** for the dendrimers of the second generation were synthesized starting from the silylated ester **7**, followed by debenzylation (→ **8**), then activation (→ **9**),[5] and subsequent acylation of the desilylated derivative of **7** with the acid chloride **9**. The coupling of **6** with the desilylated branches **7** and **10** finally gave the dendrimers of the first (green circle in formula **11**/**12**) and of the second generation (**11**), respectively. The selective hydrogenolysis of the terminal benzyl groups of the dendrimers was achieved by catalytic transfer hydrogenation[6] and gave the polyanionic dendrimers of the first and second generation (**12a**). The dendritic compounds were obtained in 150 mg (**11b**) to 450 mg (**11a**) quantities as viscous oils that were soluble in CH_2Cl_2. All compounds were fully characterized (optical rotation, IR, ^1H and ^{13}C NMR spectroscopy, MS, elemental analysis; see experimental part a); Figure 1 shows five MALDI-MS molecular peaks and proves the identity and the monodispersity of the corresponding compounds.



To study the biodegradability[7] of the dendrimers, we tested their stability in the presence of various hydrolases. Figure 2 depicts the degradation of three dendritic compounds **6a**, **6b**, and **11b** with a PHB-depolymerase.[8] The linear tetrameric HB **2b** was used as the standard substrate for the depolymerase. The protected dendrimers with dimeric HB-elongation units were not degraded by the depolymerase, whereas the free acids were moderately good substrates for this enzyme.[9] This observation is surprising as the simple dimeric HB **2a** is not a substrate for the depolymerase. ^1H NMR spectroscopic investigations of the degradation products of the deprotected, first-generation dendrimer with dimeric HB-elongation units (green circle in formula **11**/**12**) revealed free HB, the triester of 1,3,5-benzenetricarboxylic acid with HB, and also compound **13**.[10] The enzymatic hydrolysis of the deprotected, first-generation dendrimer, which has dimeric HB-elongation units, was followed by ti-

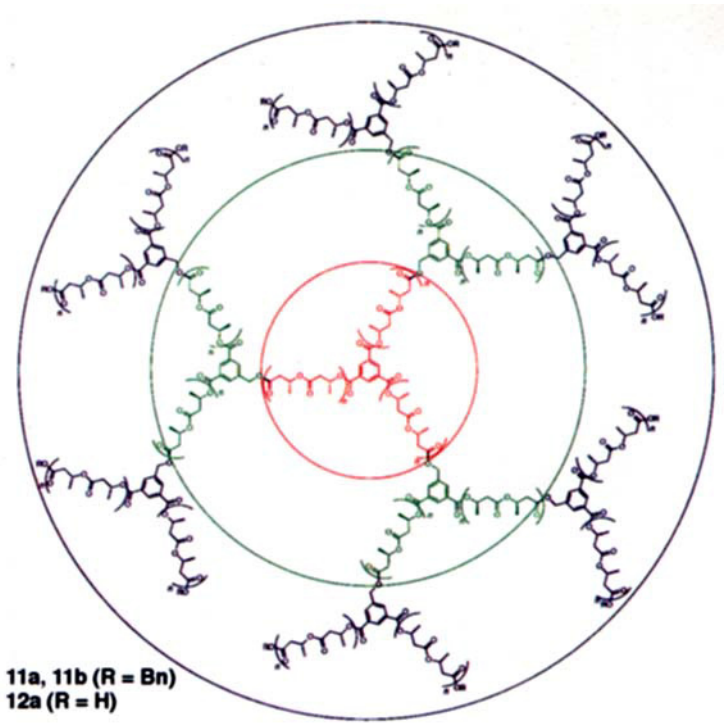

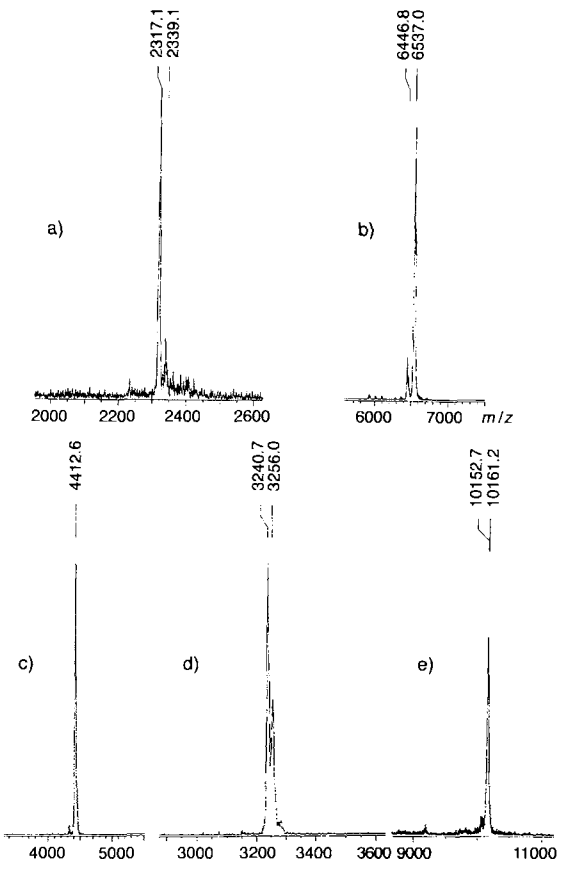

Fig. 1. Characterization of the dendrimers and the building blocks by mass spectrometry (MALDI-MS): a) first generation with dimeric HB-elongation units and free acid groups ($C_{108}H_{132}O_{54}$, 2294.2 g mol^{-1}, 2317 $[M+Na]^+$); b) second generation with dimeric HB-elongation units and R = Bn (**11a**: $C_{342}H_{384}O_{126}$, 6510.7 g mol^{-1}, 6537 $[M+Na]^+$); c) first generation with tetrameric HB-elongation units and protected acid groups ($C_{222}H_{282}O_{90}$, 4390.6 g mol^{-1}, 4412 $[M+Na]^+$); d) protected branch of the second generation with tetrameric HB-elongation units (**10b**: $C_{167}H_{206}O_{61}$, 3217.5 g mol^{-1}, 3240 $[M+Na]^+$, 3256 $[M+K]^+$); e) second generation with tetrameric HB-elongation units and R = Bn (**11b**: $C_{510}H_{640}O_{210}$, 10130.5 g mol^{-1}, 10153 $[M+Na]^+$).

tristatic experiments over 24 hours. More than five equivalents of base were consumed, which corresponds to a conversion of more than 55%. Like **2b**, all dendrimers with tetrameric HB-elongation units are good substrates for the depolymerase (Fig. 2). Zero-order kinetics is observed for the first de-

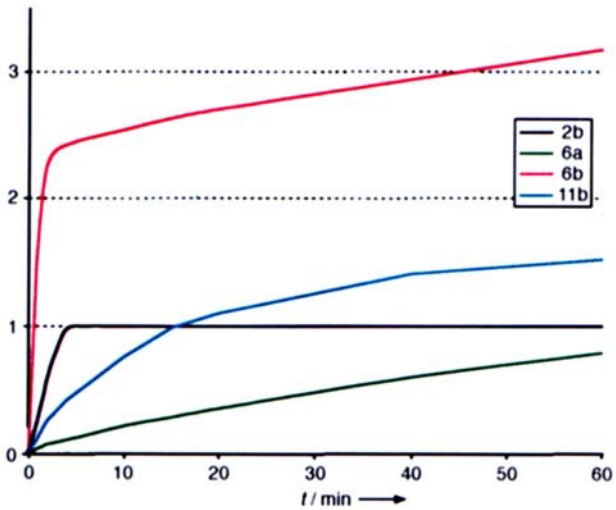

Fig. 2. Enzymatic degradation of the tetrameric HB **2b**, the core unit **6**, and the second-generation dendrimer **11b** with the PHB-depolymerase (0.25 mg mL^{-1} substrate in H_2O, 4.25 U mL^{-1} depolymerase from *Alcaligenes faecalis* [8], pH = 7.5, 30 °C). x = "acid equivalents" formed, in arbitrary units.

gradation step. The reaction is about one hundred times faster than the degradation of dendrimers with dimeric HB-elongation units. In the second degradation step (also zero order), the kinetics is comparable with that of dendrimers with dimeric HB-elongation units. Furthermore, the dendritic compounds were degraded by an esterase, a lipase, and a protease.[11]

In conclusion, we have described the first examples of biodegradable[7] dendrimers, which may have applications in materials science (for example, for the construction of defined nanocavities[2h]) that are similar to those for chemically degradable dendritic and hyperbranched organosilicon compounds.[12] Furthermore, they could possibly be used as drug carriers.[3]

Experimental Procedure

a) Analytical data of two selected compounds [13]:

11a (6510.7 g mol^{-1}): 48% yield (450 mg of material purified on 75 g silica gel, eluent CH_2Cl_2/Et_2O 4/1) for the coupling of **6a** and 3 equiv. desilylated **10a**). $[\alpha]_D = -32.9$ ($c = 1.275$, CH_2Cl_2); IR ($CHCl_3$, cm^{-1}): $\tilde{\nu}$ = 3035 w, 2986 w, 1735 vs, 1607 w, 1498 w, 1455 m, 1383 m, 1303 s, 1248 s, 1135 s, 1101 m, 1057 s, 973 w; ^{1}H NMR (500 MHz, $CDCl_3$): δ = 8.75 (s, 3H, arene H), 8.53 (t, J = 1.57 Hz, 9H, arene H), 8.15 (d, J = 1.58 Hz, 6H, arene H), 8.14 (d, J = 1.60 Hz, 12H, arene H), 7.34–7.27 (m, 60H, arene H), 5.55–5.44 (m, 21H, HC), 5.34–5.26 (m, 21H, HC), 5.18–5.10 (m, 18H, H_2C), 5.09–5.05 (m, 24H, H_2C), 2.88–2.50 (m, 84H, H_2C), 1.44–1.38 (m, 63H, H_3C), 1.25–1.21 (m, 63H, H_3C); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 169.83, 169.69, 169.09, 169.00, 164.44, 136.75, 135.67, 133.21, 131.21, 130.35, 128.54, 128.30, 128.28, 68.89, 68.63, 68.57, 67.69, 67.56, 67.52, 66.41, 65.22, 40.98, 40.91, 40.62, 40.36, 19.83, 19.78; MALDI-MS (see Fig. 1b): 6537.0 $[M+3H+Na]^+$; Analysis calcd for $C_{342}H_{384}O_{126}$: C 63.06, H 5.99; found: C 62.99, H 6.20.

10b (3217.48 g mol^{-1}): 69% yield (900 mg of material purified on 80 g silica gel, eluent CH_2Cl_2/Et_2O 8/1) for the coupling of **9b** and 2 equiv. desilylated **7b**). $[\alpha]_D = -16.03$ ($c = 1.135$, CH_2Cl_2); IR ($CHCl_3$, cm^{-1}): $\tilde{\nu}$ = 3032 m, 2986 m, 2936 m, 2878 w, 1736 vs, 1607 w, 1497 w, 1456 s, 1383 s, 1302 s, 1177 m, 1134 s, 1101 m, 1056 s, 976 m; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.54 (t, J = 1.63 Hz, 2H, arene H), 8.48 (s, 1H, arene H), 8.17 (s, 2H, arene H), 8.15 (d, J = 1.59 Hz, 4H,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2796 $ 15.00+.25/0

arene H), 7.67–7.65 (d, J = 7.02 Hz, 4H, arene H), 7.42–7.30 (m, 26H, arene H), 5.54–5.49 (m, 6H, HC), 5.30–5.18 (m, 18H, HC), 5.17 (d, J = 3.13 Hz, 4H, H_2C), 5.10 (s, 8H, H_2C), 4.82 (s, 2H, H_2C), 2.81–2.35 (m, 48H, H_2C), 1.42 (d, J = 6.31 Hz, 9H, H_3C), 1.41 (d, J = 6.26 Hz, 9H, H_3C), 1.28–1.20 (m, 54H, H_3C), 1.11 (s, 9H, $(H_3C)_3C$); ^{13}C NMR (100 MHz, $CDCl_3$): 169.88, 169.71, 169.14, 169.11, 169.07, 164.46, 136.76, 135.69, 135.51, 133.24, 131.22, 130.39, 129.86, 128.57, 128.31, 127.80, 68.61, 68.29, 67.66, 67.63, 67.56, 67.49, 66.44, 65.23, 40.96, 40.75, 40.64, 40.39, 26.81, 19.89, 19.78, 19.75, 19.69; MALDI-MS (see Fig. 1d): 3256.0 $[M + K]^+$; 3240.7 $[M + Na]^+$; Analysis calcd for $C_{167}H_{206}O_{61}Si$: C 61.73, H 6.39; found: C 61.80, H 6.39.

b) Determination of the biodegradability: The substrate (1.0 mg) was dissolved or suspended in 4 mL H_2O. The pH was adjusted to 7.5 after which the hydrolase was added. The pH was kept constant throughout the addition of 5 mM NaOH at 30 °C, and the consumption of base was recorded (1 U = 1 μmol acid formed per min^{-1}). Enzymes used for the experiments: 35 mg of a PHB-depolymerase [8] (from *Alcaligenes faecalis*, 486 U mg^{-1} [14]), 1 mg of an esterase (from pig liver, 220 U mg^{-1} [14]), 1 mg of a lipase (from *Pseudomonas fluorescens*, 42 U mg^{-1} [14]) and 1.25 mg of a protease (trypsin, from bovine pancreas).

Synthesis and a Preliminary DNA Binding Study of Hybrids of the Carbohydrate Domain of Calicheamicin γ_1^I and the Aglycone of Daunorubicin: Calichearubicins A and B**

Kristopher M. Depew, Steven M. Zeman, Serge H. Boyer, Derek J. Denhart, Norihiro Ikemoto, Samuel J. Danishefsky,* and Donald M. Crothers

Many important medicinal agents of natural origin contain a sugar or sugarlike moiety. From a chemical standpoint, such agents can be dissected into aglycone and carbohydrate domains. In most instances, both components in themselves are totally lacking in useful biological activity.[1] Traditionally, considerations about the mechanism of action of the drug have been directed to the aglycone, with the carbohydrate viewed as a necessary appendage for biotransport or for other factors related to drug availability.

While the nature of interplay of the aglycone and carbohydrate components in various drugs presumably varies from case to case, it is now apparent that in some important instances the carbohydrate domain may play a critical role in drug receptor recognition. One example of such a critical role for the carbohydrate sector in receptor contact is that of the enediyne antibiotics[2] such as calicheamicin γ_1^I (**1**)[3] (Fig. 1). Work from our laboratories,[4] as well as from Nicolaou et al.[5] and others[6–8] has established that contacts between the pentacyclic carbohydrate region and the minor groove of DNA provide much of the remarkable sequence selectivity of calicheamicin γ_1^I. Similarly, such interactions also foster the molecular contacts between esperimicin A_1 and its target DNA.[9] Though the aglycones such as calicheamicinone (**2**) retain cytotoxicity and some double-strand cleaving ability, sequence selectivity requires the existence of the carbohydrate domain.[4c] Indeed, moderate sequence selectivity can be realized through co-incubation of non-

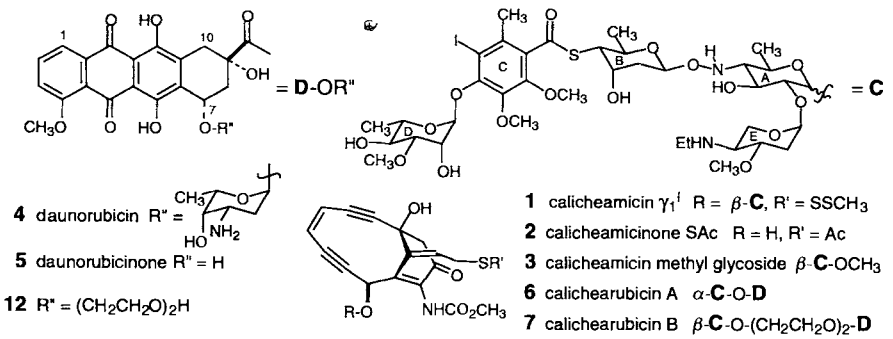

Fig. 1. Anthracycline and calicheamicin antibiotics and the calichearubicins.

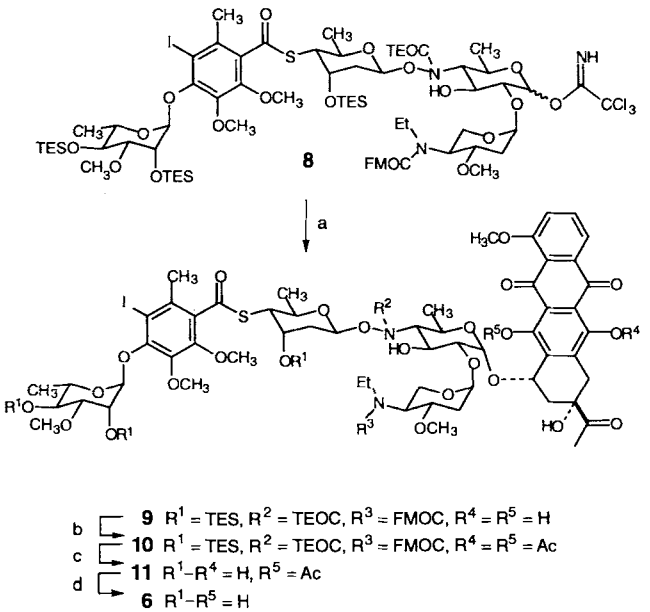
linked carbohydrate (**3**) and aglycone moieties, further underscoring the role of the complex carbohydrate network at the level of molecular recognition.[4a]

Another family of drugs bearing a carbohydrate unit is the anthracyclines, exemplified by daunorubicin (**4**).[10] One function of these compounds involves intercalation of the aglycone, a tetracyclic anthraquinone moiety, between DNA base pairs. The aglycones alone (for example daunorubicinone (**5**)) are inactive both as drugs and as intercalating agents.[10a] The role of the carbohydrate domain in facilitating molecular reaction to the DNA "receptor" appears to be confined to a relatively nonspecific salt bridge type of contact to the phosphate backbone.[11] Unlike the enediyne drugs, daunorubicin does not exhibit appreciable sequence selectivity in its intercalation.[10d, 10g]

From this perspective, we wondered about the possibility of a hybrid entity containing both the daunorubicinone aglycone **5** and calicheamicin sugar domains. We term these constructs "calichearubicins".[12] Here we describe the synthesis and preliminary evaluation of calichearubicins A and B (**6** and **7**, respectively). The former is the product of the direct glycosylation of **5** with the carbohydrate domain of calicheamicin γ_1^I; in **7** a bis(ethylene)glycol spacer is inserted between these domains.

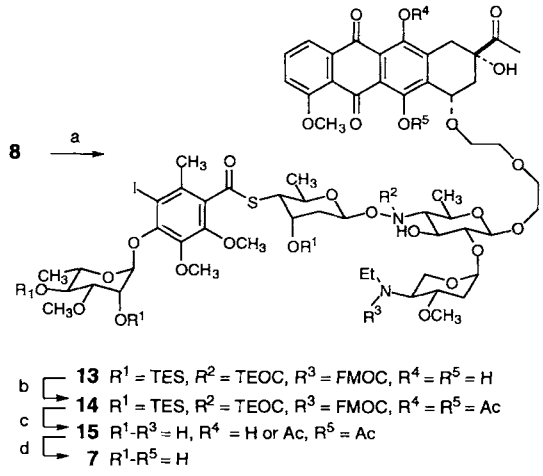


Scheme 1. Synthesis of calichearubicin A (**6**). a) **5**, AgOTf, 4Å molecular sieves, CH_2Cl_2 (α:β = 5:1, 45%); b) Ac_2O/py (2/5), 0°C, 10 min (89%); c) TBAF, THF, −5°C (92%); d) 3 equiv 0.1 N LiOH, THF (0.0015 M dilution), 12 h (44%). FMOC = 9-fluorenylmethoxycarbonyl, py = pyridine, TBAF = tetrabutylammonium fluoride, TEOC = trimethylsilylethoxycarbonyl, TES = triethylsilyl, Tf = trifluoromethanesulfonate.

The synthesis of such compounds posed no small challenge. In the end, it was accomplished by relying heavily on chemistry we had previously developed for both families of drugs. We exploited our synthesis[13] of the Schmidt[14] type of glycosyl donor, trichloroacetimidate **8** (Scheme 1). Here the glycosyl donor version of the calicheamicin γ_1^I carbohydrate is delivered at the correct oxidation level and appropriately substituted, and ideally all blocking groups would be cleaved upon brief exposure to fluoride ions. In practice, coupling[13] of **5** with **8** by employing AgOTF afforded a 5:1 ratio of **9** and its β anomer (not shown). However, the anthracycline proved to be unstable to the fluoridolysis conditions[15] needed to discharge the protecting groups from the construct. Interestingly, the anthracyclinone sector is apparently more vulnerable than the enediyne core of **1** toward tetrabutylammonium fluoride, which had served us so well in our total synthesis of calicheamicin γ_1^I.

Fortunately, our work in the anthracycline area helped to chart a response to this serious and unexpected problem. Earlier, we had demonstrated[16] that acetylation of the phenolic hydroxyl groups of daunorubicin (**4**) facilitates a major stabilizing effect toward reductively induced quinone methide formation. With this analogy in mind, compound **9** was acetylated to afford **10**. Treatment of **10** with fluoride ion led to the discharge of all of the blocking groups in the carbohydrate sector as well as the C11 acetyl group, resulting in the formation of **11**. Apparently, when even one acetyl protecting group is maintained at C6, the hybrid is stable to fluoridolysis. In the last step, calichearubicin A (**6**) was obtained by treatment of **11** with 0.1 N lithium hydroxide.

In a similar way, compound **12**[17] was coupled with **8** to give rise to a mixture of **13** and its α anomer (α:β ratio = 5:1; only the β isomer is shown in Scheme 2) in 30% yield. Preliminary molecular modeling and minimization based on structural information available from NMR solution spectra[8] of **1** bound to a d(TCCT)·d(AGGA) sequence, in conjunction with the crystal structure[11] of **4** intercalated between a pyrimidine/purine step within a DNA oligomer, had suggested that a five-



Scheme 2. Synthesis of calichearubicin B (**7**). a) **12**, $BF_3 \cdot OEt_2$, 4Å molecular sieves, CH_2Cl_2, −78C (β:α = 5:1, 35%); b) Ac_2O/py (2/5), 0°C, 10 min (79%); c) TBAF, THF, −5°C (90%); d) 5 equiv 0.1 N LiOH, THF (0.0015 M dilution), 6 h (35%).

atom spacer with a β-glycosidic linkage would be required for concurrent intercalation and contact with the minor groove. Fortunately, through the use of $BF_3 \cdot OEt_2$,[18] anomers **13** were obtained in a 4:1 β:α ratio in 35% yield. After acetylation, the anomers were separated to give **14**, which was processed as before to afford calichearubicin B (**7**).

The interactions of **6** and **7** with double-stranded DNA (dsDNA) were studied spectrophotometrically. The dsDNA·**4** complex served as a valuable spectroscopic standard.[10] Upon intercalating dsDNA, **4** exhibits a bathochromic shift of 29 nm[19] from the maximum wavelength of its nonintercalated form at 479 nm (Table 1).[19, 20] Because **6** and **7** bear the same chromophoric element as **4**, it was presumed that comparison of absorbance profiles upon addition of DNA to these hybrids might suggest whether **6** and **7**, like **4**, intercalate dsDNA.

In contrast to the natural drug **4**, the synthetic construct **6** is not appreciably red-shifted beyond experimental error on addition of DNA (see Table 1). At least by this measure, hybrid **6** would seem to be incapable of intercalating dsDNA under these conditions.[21] By sharp contrast, hybrid **7** is red-shifted to virtually the same extent as the natural drug **4**. Thus, the ethoxyethyl tether in the linked structure **7** disposes its anthracycline domain to strong intercalation.

Table 1. Absorption maxima und shifts of free and DNA-associated anthracyclines (pbp = pairs of base pairs) [21].

Drug	λ_{max}(drug)	λ_{max}(DNA(pbp)/drug) [a]	$\Delta\lambda_{max}$
4	479	508	+29
6	483	484.5	+1.5
7	482	508	+26

[a] [DNA(pbp)]:[drug] = 1:5.

Of particular interest was the question whether the carbohydrate domain confers any sequence preference to the anthracycline. To answer this question, $Fe^{II} \cdot MPE$[22] footprinting analyses (MPE = methidium propyl EDTA) were performed on the 155 base pair [^{32}P-3′-end-labeled] *Sph*I/*Sgr*AI fragment of pBR322. This fragment contains several sites for which calicheamicin γ_1^I has shown specificity,[6a, 7] as well as ample random DNA sequences to evaluate new affinities. The results for **4**, **6**, and **7** are shown in Figure 2. At a concentration of 100 μM, **7** demonstrated specificity in binding, but this specificity manifested itself as areas of enhanced $Fe^{II} \cdot MPE$ cleavage rather than as sites protected against cleavage, which are characteristic of standard footprinting analyses. This phenomenon had been previously observed in $Fe^{II} \cdot MPE$ studies with carbohydrate **3** alone, and was postulated to be the result of widening of the minor groove[4a] or local helical unwinding. While the cleavage enhancements caused by **7** do not occur at areas known to display calicheamicin γ_1^I preference, Figure 2 shows that this hypersensitivity correlates with the 3′ side of other homopyrimidine/homopurine tracts, namely d(CTTC)·d(GAAG) and d(TTTC)·d(GAAA). A model encompassing concurrent intercalation contacts and carbohydrate–DNA contacts in the minor groove is proposed in Figure 3. Each of these hypersensitive sites contains a pyrimidine/purine motif, for which **4** had demonstrated moderate selectivity.[10f, 10h] High concentrations of **4** (Fig. 2, lane 12) led to a general washing out of all bands, suggesting surface blockage of the $Fe^{II} \cdot MPE$ cleavage by nonspecific binding to DNA phosphates.

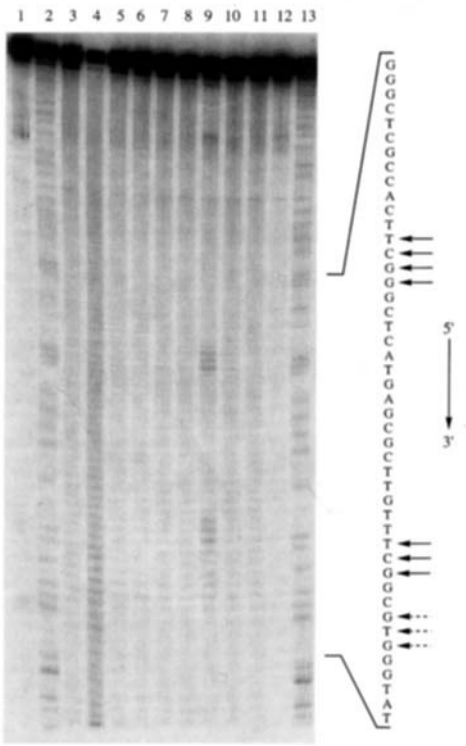

Fig. 2. $Fe^{II} \cdot MPE$ enhancement of DNA cleavage elicited by **7**: Autoradiogram scan of 12% denaturing polyacrylamide gel (8 M urea, 90 mM Tris-HCl, 90 mM boric acid, 3 mM EDTA) showing the binding of the drug to a region of the 155 bp *Sph*I/*Sgr*AI restriction fragment of pBR322. (Plasmid DNA was linearized with *Sph*I, ^{32}P-labeled on the 3′ end, and further restricted with *Sgr*AI.) The gel- and electroelution-purified fragment was preincubated in a (10 μL) solution containing Tris-HCl (10 mM, pH 7.6), NaCl (25 mM) and sonicated calf thymus DNA (1 mM in nucleotides) at 25 °C. After 25 min dithiothreitol (30 mM) and freshly prepared $Fe^{II} \cdot MPE$ (5 μM) were added to the solutions (concentrations of 2.5 mM and 0.4 μM, respectively), and the reaction mixture (now 12 μL total volume) was incubated an additional 15 min at 10 °C. The DNA in each reaction was precipitated by addition of ethanol and resolved by gel electrophoresis. The gel was dried at 80 °C; an autoradiogram was prepared (exposure time: 5 d, Fuji X-ray film) and then photographed. Lane 1: untreated labeled DNA fragment; lanes 2 and 13: Maxam-Gilbert A + G sequencing ladder; lane 3: $Fe^{II} \cdot MPE$-treated fragment containing no drug (control); lanes 4–6: labeled DNA fragment and 1, 10, and 100 μM **6**, respectively; lanes 7–9: labeled DNA fragment and 1, 10, and 100 μM **7**, respectively; lanes 10–12: labeled DNA fragment and 1, 10, and 100 μM **4**, respectively. The region of the sequence containing the enhancement sites discussed in the text is shown at the right with solid and dashed arrows respectively, indicating the stronger and weaker sites of cleavage enhancement elicited by **7**.

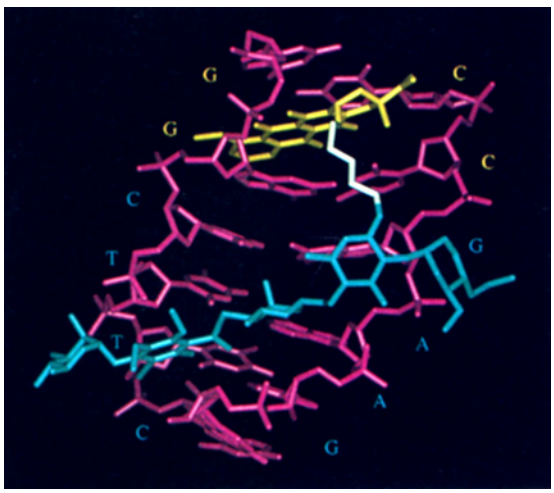

Fig. 3. A model of a possible drug–DNA complex containing calichearubicin B (**7**) and d(CCGAAG)·d(CTTCGG) (*magenta*). The minor groove binding carbohydrate domain [8] (cyan) and the intercalation domain [11d] (yellow) are tethered by an ethoxyethyl linker (white).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2799 $ 15.00+.25/0

It seems, then, that our synthetically derived hybrid **7** combines elements of the unique specificities exhibited by each of its parent component domains.

Having accomplished this demonstration, we will work on melding components of other drug–carbohydrate domains. Clearly, molecular modeling can be a valuable asset in identifying promising constructs.

Experimental Procedure

Calichearubicin A (**6**): Argon was bubbled through a THF solution (2.7 mL, 0.0015 M) of **11** (5.6 mg, 0.0040 mmol) for 20 min. Three equivalents of 0.1 N LiOH solution (argon saturated, 0.12 mL) was added and the solution was stirred for 12 h at ambient temperature; the color of the solution changed from bright yellow to deep blue. When an aliquot of the solution spotted red on TLC, the reaction was poured into saturated NH_4Cl solution and extracted with EtOAc. The organic layer was separated, washed with brine, dried over Na_2SO_4, filtered, concentrated, and chromatographed on a preparative TLC plate ($10 \times 20\ cm^2 \times 0.25$ mm, $CHCl_3$/MeOH (9/1)) to yield 2.4 mg (44%) of **6** as an orange-red amorphous solid; $R_f = 0.32$ (9/1 $CHCl_3$/MeOH); $[\alpha]_D^{25} = +16$ ($c = 0.275$ in $CHCl_3$); ^1H NMR (500 MHz, $CDCl_3$): Dau = daunorubicinone portion; A, B, C, D, and E (in parentheses) refer to the individual rings of the carbohydrate (see Fig. 1). The numbering of the protons refers to the hydrogens of the aglycone (see Fig. 1): $\delta = 14.18$ (s, 1H, C6-OH (Dau)), 13.41 (br. s, 1H, C11-OH (Dau)), 8.07 (d, $J = 7.7$ Hz, 1H, H1 (Dau)), 7.82 (t, $J = 8.1$ Hz, 1H, H2 (Dau)), 7.40 (d, $J = 8.5$ Hz, 1H, H3 (Dau)), 6.68 (br. s, 1H, NH-O), 5.72 (s, 1H, H1 (D)), 5.61 (br. s, 1H, H7 (Dau)), 5.25 (d, $J = 4$ Hz, 1H, H1 (A)), 5.19 (br. s, 1H, H1 (E)), 5.08 (d, $J = 7$ Hz, 1H, H1 (B)), 4.64 (m, 1H, H5 (A)), 4.50 (br. s, 1H, H2 (D)), 4.30 (t, $J = 10$ Hz, 1H, H3 (A)), 4.21 (m, 1H, H5 (D)), 4.10 (m, 1H, H5 (B)), 4.08 (s, 3H, OCH_3 (Dau)), 3.95 (br. s, 1H, H3 (B)), 3.84 (s, 6H, $2 \times OCH_3$ (C)), 3.83 (m, 1H, H3 (D)), 3.73 (dd, $J = 9.4$, 7.7 Hz, 1H, H2 (A)), 3.65 (pseudo-t, $J = 9.8$ Hz, 2H, H4 (B), H4, D)), 3.58 (s, 3H, OCH_3 (D)), 3.38 (s, 3H, OCH_3 (Dau)) (E)), 3.38 (d, $J = 18$ Hz, 1H, H10b (Dau)), 3.13 (d, $J = 18$ Hz, 1H, H10a (Dau)), 3.00–2.80 (br. s, 3H, NH, $NHCH_2CH_3$), 2.64 (d, $J = 18.5$ Hz, 1H, 8b (Dau)), 2.45 (s, 3H, $C(O)CH_3$ (Dau)), 2.31 (s, 3H, CH_3 (C)), 2.31 (m, 1H, H4 (A)), 2.17 (m, 1H, $H2_{eq}$ (E)), 1.98 (dd, $J = 14.0$, 4.0 Hz, 1H, H8a (Dau)), 1.71 (m, 1H, $H2_{ax}$ (E)), 1.59 (br. d, $J = 9$ Hz, 1H, $H2_{eq}$ (B)), 1.46 (m, 1H, $H2_{ax}$ (B)), 1.46 (d, $J = 6.2$ Hz, 3H, H6 (A)), 1.39 (d, $J = 6.2$ Hz, 3H, H6 (B)), 1.31 (d, $J = 6.2$ Hz, 3H, H6 (D)), 1.25 (br. s, 3H, $NHCH_2CH_3$); four protons H3, H4, $H5_{ax}$, and $H5_{eq}$ (of ring E) were unassignable; selective ROESY on H1 (A) enhanced H2 (A), H4 (A), H7 (Dau)); IR ($CHCl_3$): $\tilde{\nu} = 3686$, 3608, 3500, 3029, 2960, 2931, 1715, 1671, 1602, 1587, 1455, 1416, 1381, 1283, 1234, 1072, 1038, 989, 910 cm^{-1}; HRMS (FAB): *m/z*: 1343.3511; $[M+H]^+$; calcd for $C_{58}H_{76}IN_2O_{24}S$: 1343.3550.

Calichearubicin B (**7**): The same procedure was used as that for **6** except that five equivalents of 0.1 N LiOH solution were used and the reaction mixture was stirred for 6 h to give, after workup and chromatography, **7** as an orange-red amorphous solid in 35% yield: $R_f = 0.20$ ($CHCl_3$/MeOH (9/1)); $[\alpha]_D^{22} = +23$ ($c = 0.2$ in $CHCl_3$); ^1H NMR (500 MHz, $CDCl_3$): $\delta = 13.93$ (s, 1H, C6-OH (Dau)), 13.29 (s, 1H, C11-OH (Dau)), 7.94 (dd, $J = 7.7$, 1.0 Hz, 1H, H1 (Dau)), 7.71 (pseudo-t, $J = 8.1$ Hz, 1H, H2 (Dau)), 7.35 (d, $J = 7.8$ Hz, 1H, H3 (Dau)), 6.36–6.30 (br. s, 1H, NH-O), 5.73 (d, $J = 1.4$ Hz, 1H, H1 (D)), 5.30 (br. s, 1H, H1 (E)), 5.04 (m, 2H, H7, H1 (B)), 4.77 (d, $J = 1.4$ Hz, 1H, H2 (D)), 4.34 (d, $J = 7.8$ Hz, 1H, H1 (A)), 4.31 (br. s, 1H, H3 (B)), 4.19 (m, 1H, H5 (D)), 4.07 (m, 1H, H5 (B)), 4.01 (s, 3H, OCH_3 (Dau)), 3.97 (m, 3H, H3 (A), C7 (Dau))-CH_2CH_2), 3.89 (s, 3H, OCH_3 (C)), 3.84 (s, 4H, H3 (D), OCH_3 (C)), 3.76–3.73 (m, 5H, H4 (B), $H5_{ax}$ (B), $H5_{eq}$ (E), O7-CH_2CH_2), 3.70 (m, 1H, H5 (A)), 3.73–3.60 (m, 4H, OCH_2CH_2O-C1 (A)), 3.65 (t, $J = 9.5$ Hz, 1H, H4 (D)), 3.57 (s, 3H, OCH_3 (D)), 3.47 (t, $J = 8.7$ Hz, 2H, H2 (A), H3 (E)), 3.38 (br. s, 3H, OCH_3 (E)), 3.24 (d, $J = 18$ Hz, 1H, H10b (Dau)), 2.96 (d, $J = 18$ Hz, 1H, H10a (Dau)), 2.90–2.70 (br. m, 4H, $NHCH_2CH_3$, H4 (E)), 2.50 (m, 1H, H8b (Dau)), 2.43 (s, 3H, $C(O)CH_3$ (Dau)), 2.36 (s, 3H, CH_3 (C)), 2.36 (m, 1H, $H2_{eq}$ (E)), 2.32 (m, 1H, H4 (A)), 2.04 (m, 1H, $H2_{eq}$ (B)), 1.96 (m, 1H, H8a (Dau)), 1.78 (m, 1H, $H2_{ax}$ (B)), 1.62 (m, 1H, $H2_{ax}$ (E)), 1.41 (d, $J = 6.2$ Hz, 3H, H6 (B)), 1.31 (d, $J = 6.1$ Hz, 3H, H6 (A)), 1.30 (d, $J = 6.2$ Hz, 3H, H6 (D)), 1.11 (m, 3H, $NHCH_2CH_3$); IR ($CHCl_3$): $\tilde{\nu} = 3594$, 3469, 2930, 2856, 1718, 1677, 1619, 1580, 1460, 1416, 1402, 1354, 1321, 1287, 1239, 1071, 993, 965, 907, 825 cm^{-1}; HRMS (FAB): *m/z*: 1431.4094; $[M+H]^+$; calcd for $C_{62}H_{83}IN_2O_{26}S$: 1343.3550.

[21] Solutions of **6** and **7** (each 100 μM at start) were titrated with a solution of sonicated calf thymus DNA, and the resulting spectral profiles were measured. For each run, volume changes due to DNA additions were taken into account in the calculation of the [DNA]:[drug] ratio. DNA concentration is given in pairs of base pairs (pbp), as this unit represents the minimum structural motif required for intercalation (Table 1).

Total Synthesis of (−)-Epothilone A**

Aaron Balog, Dongfang Meng, Ted Kamenecka, Peter Bertinato, Dai-Shi Su, Erik J. Sorensen, and Samuel J. Danishefsky*

Epothilones A and B were isolated from the myxobacteria of the genus *Sorangium*. The full structures of these compounds, determined from an X-ray crystallographic analysis, were recently communicated by Höfle.[1] Interest in the total synthesis of the epothilones arises from several considerations. First, they contain substructural motifs that pose intrinsic problems for a total synthesis. Not uncommonly, solutions to novel structural challenges carry with them important lessons for organic chemistry, which transcend the particular goal under investigation. Moreover, the biological profiles of the epothilones warrant multidisciplinary scientific attention. As is well known by now, taxol is already a useful resource in chemotherapy against ovarian and breast cancers.[2] Furthermore, its range of applicability seems to be expanding under continuing clinical scrutiny. The mechanism of the cytotoxic action of taxol, at least at the in vitro level, involves stabilization of microtubule assemblies.[3] A series of complementary in vitro investigations with the epothilones indicated that they function by the same mechanism as the taxoids, apparently down to the binding sites to their protein target.[4] Moreover, the epothilones surpass taxol in terms of cytotoxicity and far surpass it as regards in vitro efficacy against drug-resistant cells. Since multiple drug resistance (MDR) is one of the serious limitations of taxol,[5] any agent that promises relief from this problem merits serious attention. Furthermore, formulatability of the epothilones is claimed to be more straightforward than is the case with taxol. Accordingly, we have undertaken the total synthesis of epothilones, focusing first on epothilone A (**1**). Herein we report for the first time the total synthesis of this target.

Carbons 9 through 11 insulate the chiral domains embracing carbons 3 through 8 on the acyl side of the macrolactone, and carbons 12 through 15 on the alkyl side. We reasoned from the outset that the prospects of transmitting stereochemical information from one of the segments to the other were bleak. Accordingly, it seemed more prudent to deal with the stereochemistry of each segment individually. In the acyl segment this required solution to both the relative and absolute configurations of the "polypropionate-like" network. In the alkyl segment, two possibilities presented themselves. In one instance, the C12–C13 epoxide would be included in the unit to be merged with the acyl-related substructure. In that case it would be necessary to secure the relative as well as absolute stereochemical relationships of carbons 15, 13, and 12. As matters transpired, we came to consider omitting the epoxide from the alkyl-side moiety undergoing coupling. This strategy would be feasible only if the epoxide could be introduced with acceptable stereocontrol after closure of the macrocycle.

In an earlier disclosure[6] we described the synthesis of compound **4**, which contains most of the requisite stereochemical information required for the acyl fragment. This intermediate was reached by a novel, oxidatively induced, solvolytic cleavage of the cyclopropanopyran **3**. We also described a construct containing the alkyl-side coupling partner embodying the absolute and relative stereochemistry at carbons 15, 13, and 12, which was not used in the studies described herein.[7]

Several potential connection sites attracted attention for the union of the alkyl and acyl domains. At some point an acylation would be required to establish an ester (or lactone) bond (see bold arrow *2*, Scheme 1). Furthermore, an aldol condensation seemed to be called for in fashioning a C2–C3 connection. Less obvious was the timing of this aldol step. It could be considered for the elongation of the C3–C9 construct to prepare it for acylation of the C-15 hydroxyl group. As matters developed, however, we employed a bolder possibility: the closure of the macrolide by a virtually unprecedented macroaldolization.[8] This risky but otherwise attractive option is implied by bold arrow *3*.

Considerable debate and experimentation attended the decision on the first union between the acyl and alkyl fragments (see bold arrow *1*). As alluded to in earlier publications,[6, 7] and as will be expanded upon in subsequent disclosures, significant resistance was encountered against proposed bond formation between carbons 9 and 10 or between carbons 10 and 11, for which the epoxide would be included in the alkyl coupling partner. Complications had arisen from unanticipated difficulties in fashioning acyl and alkyl reactants with the appropriate complementarity for merger across either of these bonds. We thus turned to the possibility of establishing the initial merger between carbons 11 and 12. This approach dictated deletion of the oxirane linkage from the O-alkyl coupling partner. After examination of several permutations, we settled upon generalized systems **5** and **6** to enter the first-stage coupling reaction. A de novo synthesis of a usable substrate corresponding to generalized system **5**, starting from **4**, would be necessary.

The steps leading from **4** to **11** are shown in Scheme 2. Protection of the future C-7 alcohol (see compound **7**) was followed by cleavage of the benzyl ether and oxidation to form aldehyde **8**. Elongation of the aldehyde to the terminal allyl-containing fragment **10** proceeded through enol ether **9** (mixture of *E* and *Z* geometrical isomers). Finally, the dithiane linkage was oxidatively cleaved under solvolytic trapping conditions[9] to give rise to specific coupling component **11**.

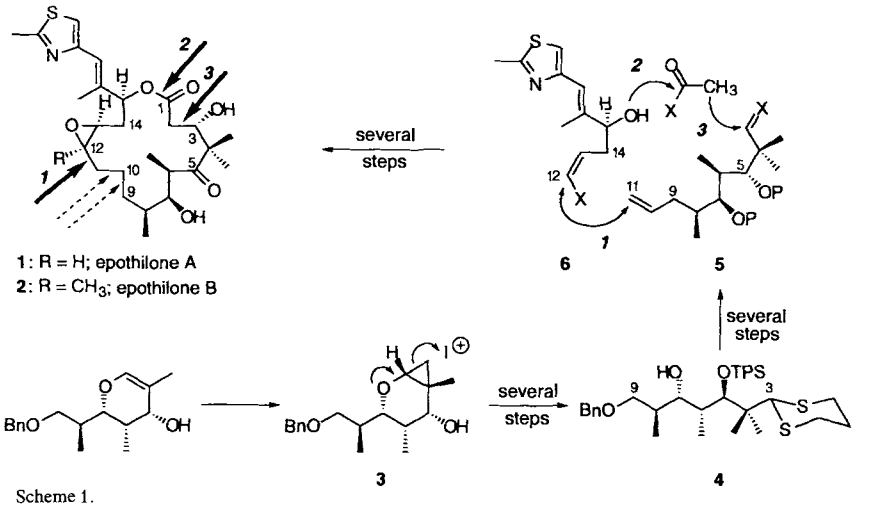
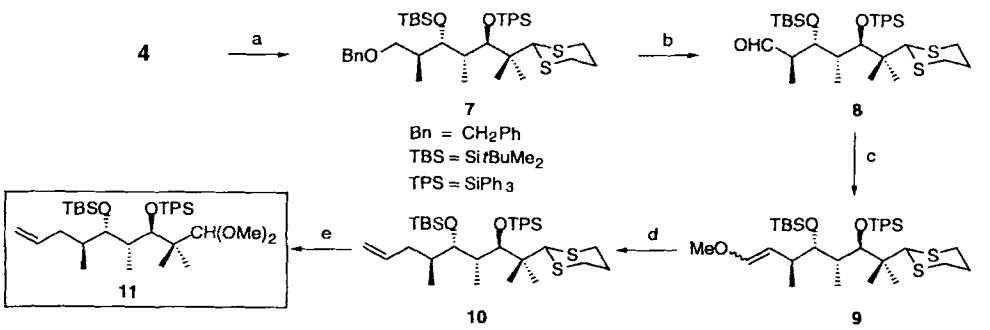
(N. I. H., CA-GM 72231), P. B. (N. I. H., CA 62948), T. K. (N. I. H., AI0-9355). We gratefully acknowledge Dr. George Sukenick (NMR Core Facility, Sloan-Kettering Institute) for NMR and mass spectral analyses. Professor Dr. G. Höfle of the Gesellschaft für Biotechnologische Forschung is gratefully acknowledged for providing natural epothilone A for comparative analysis. We also thank Professor Gunda Georg of the University of Kansas for bringing this problem to our attention.

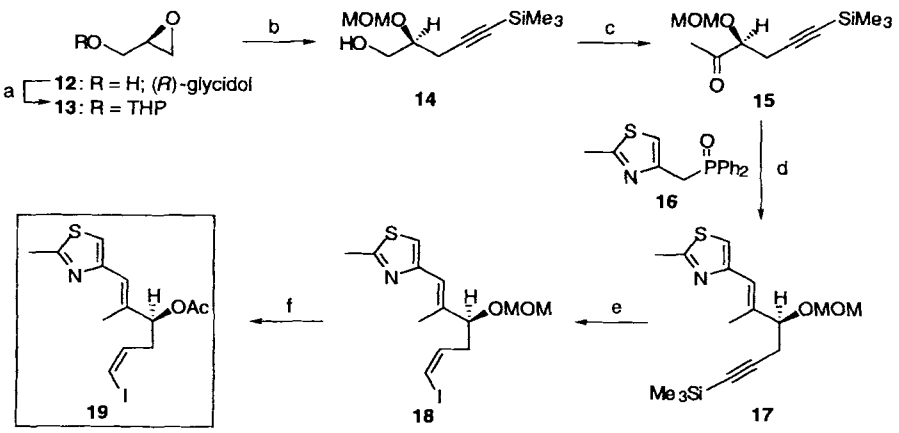


Scheme 1.



Scheme 2. a) *t*-BuMe$_2$OTf (Tf = trifluoromethanesulfonate), 2,6-lutidine, CH_2Cl_2, 98%; b) 1. 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), CH_2Cl_2/H_2O, 89%; 2. $(COCl)_2$, DMSO, CH_2Cl_2, $-78\,^{\circ}C$; then Et_3N, $-78\,^{\circ}C \rightarrow RT$, 90%; c) $MeOCH_2PPh_3Cl$, *t*-BuOK, THF, $0\,^{\circ}C \rightarrow RT$, 86%; d) 1. *p*-TsOH, dioxane/H_2O, $50\,^{\circ}C$, 99%; 2. CH_3PPh_3Br, sodium hexamethyldisilazide (NaHMDS), $PhCH_3$, $0\,^{\circ}C \rightarrow RT$, 76%; e) $PhI(OCOCF_3)_2$, MeOH/THF, RT, 0.25 h, 92%.

The synthesis of the alkyl fragment started with commercially available (*R*)-glycidol **12**, which was converted, via its THP derivative **13**, into alcohol **14**. After cleavage of the tetrahydropyran blocking group, the resultant alcohol was smoothly converted into the methyl ketone **15**, as shown. The latter underwent an Emmons-type homologation with phosphane oxide **16**.[7, 10] The resultant alkyne **17** was then converted, via compound **18**, into *Z*-iodoalkene **19**[11] (Scheme 3).



Scheme 3. a) Dihydropyran (DHP), pyridinium *p*-toluenesulfonate (PPTS), CH_2Cl_2, RT; b) 1. $Me_3SiCCLi$, $BF_3 \cdot OEt_2$, THF, $-78\,^{\circ}C$; 2. methoxymethyl chloride (MOMCl), iPr_2NEt, $Cl(CH_2)_2Cl$, $55\,^{\circ}C$; 3. PPTS, MeOH, RT; c) 1. $(COCl)_2$, DMSO, CH_2Cl_2, $-78\,^{\circ}C$, then Et_3N, $-78\,^{\circ}C \rightarrow RT$; 2. MeMgBr, Et_2O, $0\,^{\circ}C \rightarrow RT$; 3. tetra-*n*-propylammonium perruthenate (TPAP), *N*-methylmorpholine *N*-oxide (NMO), 4 Å mol. sieves, CH_2Cl_2, $0\,^{\circ}C \rightarrow RT$; d) **16**, *n*BuLi, THF, $-78\,^{\circ}C$, then **15**, THF, $-78\,^{\circ}C \rightarrow RT$; e) 1. *N*-iodosuccinimide, $AgNO_3$, $(CH_3)_2CO$; 2. Cy_2BH, Et_2O, AcOH; f) PhSH, $BF_3 \cdot OEt_2$, CH_2Cl_2, RT; 2. Ac_2O, Py, 4-dimethylaminopyridine (4-DMAP), CH_2Cl_2, RT.

The coupling of the two fragments, the all-critical first coupling, was achieved by a *B*-alkyl Suzuki carbon–carbon bond construction.[12] Hydroboration of the pre-acyl fragment **11** with 9-BBN furnished the mixed borane, which under the conditions indicated cross-coupled to iodoolefin **19** to give **20** in 71% yield. Upon cleavage of the acetal, aldehyde **21** was in hand.

With **21** we could explore the aggressive strategy of employing the methyl group of the C-1 bound acetoxy function as the nucleophilic component in a macroaldolization.[8] In the event, deprotonation was accomplished with potassium hexamethyldisilazide in THF at $-78\,^{\circ}C$. Remarkably, these conditions gave rise to a highly stereoselective macroaldolization, resulting in the formation of the C-3 (*S*)-alcohol **22** (Scheme 4). The heavy preponderance of **22** was favored when its precursor potassium aldolate was quenched at about $0\,^{\circ}C$. When the aldolate was protonated at lower temperature, higher amounts of the C-3 (*R*) compound were detected. In fact, under some treatments, the C-3 (*R*) epimer predominates. This matter remains to be fully sorted out. At present, we are able to generate highly favorable C-3 (*R*):C-3 (*S*) ratios if the quenching is performed on an analytical scale. In preparative-scale experiments, we can reliably obtain **22** and its C-3 epimer in a 6:1 ratio.

Having fashioned compound **22**, we could converge on our subgoal, desoxyepothilone (**23**). This objective was accomplished by selective removal of the triphenylsilyl (TPS) group in **22**, followed, sequentially, by selective silylation of the C-3 alcohol, oxidation of the C-5 alcohol, and, finally, fluoride-induced cleavage of the two silyl ethers.

Examination of a model based on the crystal structure of epothilone[1] suggested that the oxirane is disposed on the exterior face of the macrolide. In the event, oxidation of **23** was carried out with dimethyl dioxirane under the conditions shown. The major product of this reaction was (−)-epothilone A (**1**), whose identity was established by NMR and infrared spectroscopy, mass spectrometry, optical rotation, and chromatographic comparisons with authentic material kindly provided by Professor Höfle.[13]

While subject to further improvements, the synthesis in its present form, already provides us with workable amounts of epothilone A. More importantly, it provides routes to congeners not available from the natural product itself. The biological properties of some of these now accessible probe structures, as well as several of the chemical issues raised during the course of this synthesis, are receiving continuing attention.[14]

A Molecularly Defined, Grafted Olefin Metathesis Catalyst from Tris(neopentyl)-nitridomolybdenum(VI)**

Wolfgang A. Herrmann,* Andreas W. Stumpf, Thomas Priermeier, Sandra Bogdanović, Veronique Dufaud, and Jean-Marie Basset

The development of immobilized of homogeneous catalysts by grafting to reactive surface structures is still far behind scientific and industrial demands.[1] While the mechanistic features of olefin metathesis have been elucidated in much detail,[2] only little is known on immobilized heterogeneous catalysts having well-defined surface structures.[3] We now report on the potential of alkylnitrido complexes as suitable precursors for surface-grafted imidoalkylidene species.

Tris(neopentyl)nitridomolybdenum(VI) (**1**) represents a linear coordination polymer in the solid state but reacts like a tetracoordinated monomer in solution.[4] This complex exhibits catalytic activity in the ring-opening metathesis polymerization of cyclic olefins such as norbornene at 60 °C ([mon.]/[Mo] = 200, 5 h, 20%). The instability of the nitridoneopentylidene complex [N≡Mo(CH*t*Bu)(CH$_2$*t*Bu)] presumably formed in situ is demonstrated by the immediate degradation by elimination of the neopentylidene coupling product 2,2,5,5-tetramethyl-3-hex-

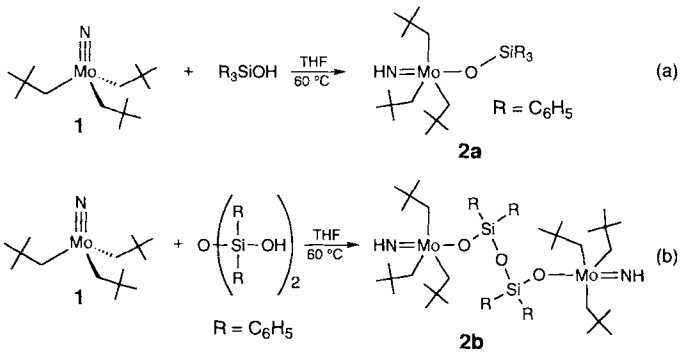
ene.[5] Cross-over experiments revealed an intermolecular mechanism for this decomposition reaction.[5] This fact and the reactivity profile of **1** toward organosilanols yielding imidotris(neopentyl)complexes[6] of type **2a** and **2b**, [Eqs. (a) and (b)] prompted the attempt to immobilize **1** on inorganic oxides.



The oxyfunctionalization of **1** demonstrates that this molecule exhibits ideal prerequisites for surface grafting, both from the molecular structure (low-coordinate molybdenum) and the electronic structure (electron-deficient metal center). The formation of the siloxy-bridged, dinuclear imidomolybdenum complex **2b** reflects the stability of the metal–alkyl bonds toward a possible protolytic scission. This complex exhibits two nearly linear HN=MoO arrangements [average N-Mo-O angle 178.3(1)°] and trigonal-bipyramidal core geometries around the two metal centers (Fig. 1).[7]

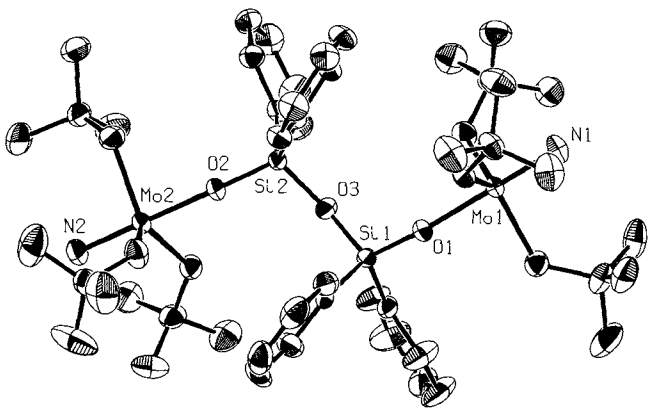


Fig. 1. Structure of the siloxy-bridged imidomolybdenum(VI) complex **2b** (PLATON representation). Hydrogen atoms are omitted for simplicity. Selected distances [Å] und angles [°]: Mo–N (av.): 1.727(3); Mo–O (av.): 1.988(2); Mo–C (av.): 2.124(5); Mo-N-H (av.): 179.2(1); Si1-O1-Mo1: 161.9(1); Si2-O2-Mo2: 156.8(1); Si2-O3-Si1: 143.7(1). Further details of the crystal structure investigation can be obtained from the Fachinformationszentrum Karlsruhe, Gesellschaft für Wissenschaftlich-Technische Information mbH, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-405836.

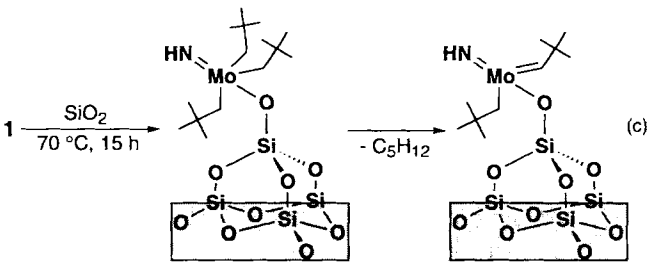
When a sample of **1** is sublimed at 70 °C onto a silica disc in a vacuum,[8] the intensity of the $\tilde{\nu}$(SiOH) bands at 3745 cm^{-1} decreases strongly, while simultaneously bands at 3370 cm^{-1} for $\tilde{\nu}$(NH), in the range 3000–2850 cm^{-1} for $\tilde{\nu}$(CH), and in the range 1500–1300 cm^{-1} for δ(CH) grow gradually within about 15 h. When deuterated silica was used (>90% SiOD according to IR), a band at 2465 cm^{-1} appeared during treatment with **1** in place of the former absorption at 3370 cm^{-1}, proving the assignment of an imido moiety (=ND vs. =NH) formed by 1,2-addition of surface silanols across the nitridomolybdenum fragment in **1**. The evolution of neopentane during the surface reaction is indicative of a further reaction step. Labeling experiments with $N{\equiv}Mo(CD_2tBu)_3$ ([D]-**1**) yielded [D_3]neopentane but *no* [D_2]neopentane (GC/MS). This result gives strong evidence that the detachment of *one* hydrocarbon equivalent from the metal is a α-hydrogen abstraction step subsequent to the initial grafting process of Equation (c). The proposed molecular structure of the final grafting complex **4** is in agreement with the elemental analyses, which yield a Mo/N/C ratio of 1/1/10.



The ^{2}H NMR spectrum of **4** exhibits a single resonance at $\delta = 2.45$ attributable to the CD_2 group in the remaining neopentyl ligand. Similar chemical shifts in the structurally related molybdenum alkylidene complex [tBuNMo(CHtBu)(CH_2tBu)(OSiPh$_3$)] were reported by Osborn.[9] The ^{13}C NMR spectrum of **4** exhibits one resonance at $\delta = 32.9$, readily assignable to the CH_3 carbon atoms of the *tert*-butyl groups. The alkylidene carbon atom was not detectable; similar problems were reported by Weiss and Basset.[3] The proposed neopentylidene structure of **4** is, however, in full accord with the observed reactivity. For example, treatment with dry acetone at ambient temperature for 30 min gave the Wittig-type coupling product 2,4,4-trimethylpent-2-ene in *quantitative* yield.

The catalytic activity of the immobilized species **4** in olefin metathesis and ring-opening metathesis polymerization was compared with the homogeneous precursor compound **1**. The surface grafting of **1** on the partially dehydroxylated silica surface results in a strong enhancement of the catalytic activity as shown in Table 1.

For example, norbornene yields at ambient temperature the ROMP polymer at an olefin/molybdenum ratio of 300 with turnover frequencies beyond 3000 h^{-1}. In contrast, the molecular nitrido complex is completely inactive under these and related reaction conditions. The concept of organometallic surface catalysis experienced its breakthrough when metal alkyls based

on tantalum or zirconium were used as molecular precursors. In these cases, however, alkyl groups are detached during the grafting process as a consequence of protolysis.[9] In our case, all alkyl groups first remain at the metal since the acidic surface silanols attack the nitridomolybdenum moiety, whereas only in the second step an α-elimination occurs, yielding the corresponding alkylidene species. Further work in this area is in progress.

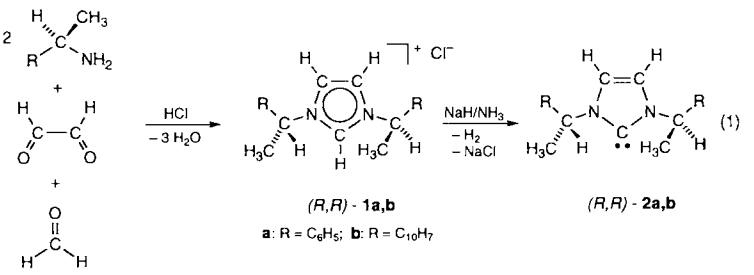
Chiral Heterocyclic Carbenes in Asymmetric Homogeneous Catalysis**

Wolfgang A. Herrmann,* Lukas J. Goossen, Christian Köcher, and Georg R. J. Artus

According to preliminary investigations, N-heterocyclic carbenes of the imidazole, pyrazole, and triazole type act as controlling ligands in organometallic homogeneous catalysis.[1, 2] The key advantage of these ligands appears to be that they do not dissociate from the metal centers, particularly in the case of electron-rich catalytically active metals like rhodium or palladium.[1] In contrast to the well-established phosphanes, an excess of ligand is not needed—an important criterion for future industrial applications. In this publication it is shown that *chiral* N-heterocyclic carbenes can be prepared conveniently; moreover, they form organometallic complexes for asymmetric homogeneous catalysis.

For the chiral imidazolium salts **1a,b** a ring closure synthesis starting from inexpensive materials was needed,[3] which can be applied broadly and which proceeds without racemization. The C_2-symmetric derivatives **1a,b** with chiral centers directly connected to the ligand core were obtained *in one step* and without racemization from chiral amines, glyoxal, and formaldehyde according to Equation (1). The identity of **1a** was confirmed by a crystal structure.[4] Deprotonation of the chiral imidazolium salts was accomplished quantitatively by a novel procedure[5] with sodium hydride in liquid ammonia at −33 °C.[6] No side reactions were observed.



(1)

If the ring closure is performed with racemic amines the *meso*-isomers of **1a,b** and **2a,b** are formed as well (NMR). This confirms that the synthesis is free from racemization up to the step of the free carbenes **2a,b**. A possible configurational lability of **2a,b** because of the high acidity of the α-protons could not be excluded.

The large tendency of the N-heterocyclic carbenes toward complexation[7] was confirmed with these new chiral derivatives. For example, hexacarbonyltungsten reacts at 25 °C with the (*R,R*)-configurated carbenes **2a,b** (generated in situ) to form the chiral carbene complexes (*R,R*)-**4a,b** as shown in Equation (2). According to an X-ray structure analysis the naphthyl

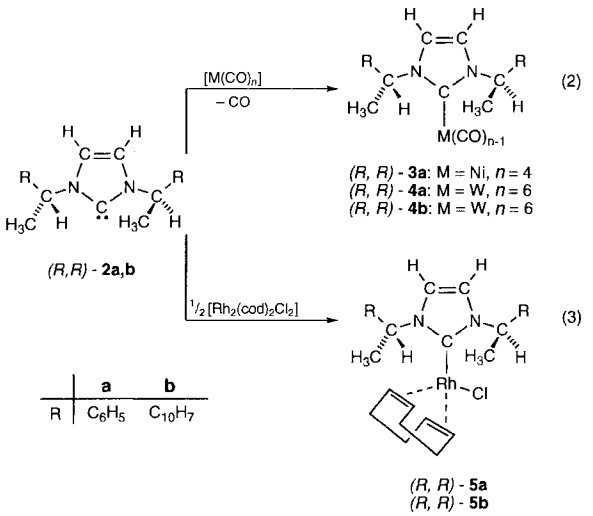
[**] Heterocyclic Carbenes, Part 9. This work received generous support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie (PhD scholarship to L.J.G.), the Bayerische Forschungsstiftung (Bayerischer Forschungsverbund Katalyse, FORKAT), and the Volkswagenstiftung. Part 8: W. A. Herrmann, M. Elison, O. Runte, G. R. J. Artus, *J. Organomet. Chem.* **1995**, *501*, C1–C4.



derivative **2b** contains two independent molecules in the asymmetric unit of the unit cell, which are distinguished by different conformations of the carbene ligand in relation to the $M(CO)_5$ fragment (Fig. 1).[8] The average carbene–tungsten distance C1–W1 is as long as expected (2.303 Å), and both the bond lengths and IR spectrum indicate that π backbonding is not significant with the N-heterocyclic ligand.[9] Starting from (*S*,*S*)-**1a** the nickel complex (*S*,*S*)-**3a** was synthesized in two steps.[10] The absolute configuration was confirmed by a crystal structure.[4]

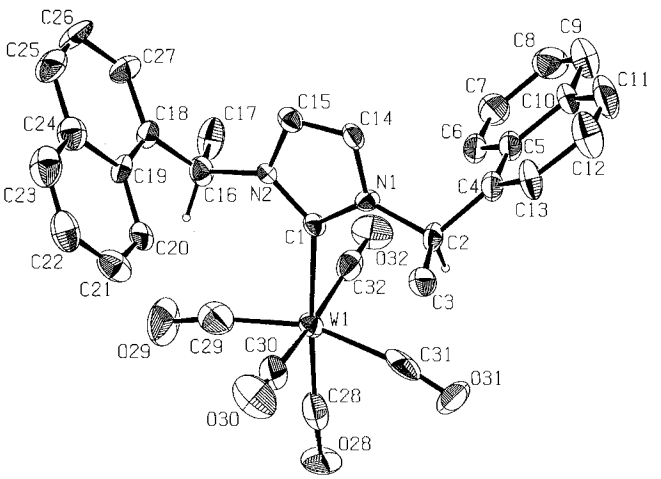


Fig. 1. Crystal structure (PLATON drawing) of one of the two independent molecules of the chiral tungsten complex (*R*,*R*)-**4b**. The thermal ellipsoides are drawn at the 50% probability level, and unimportant H atoms are omitted for clarity. Selected bond lengths [Å] and angles [°] (values in square brackets correspond to the second independent molecule in the unit cell): W1–C1 2.308(7), [2.298(7)] N1–C1 1.359(9), [1.36(1)] N1–C14 1.373(9), [1.349(9)] N2–C1 1.356(9) [1.37(1)], N2–C15 1.37(1) [1.36(1)], C14–C15 1.34(1) [1.33(1)]; C1-N1-C14 111.8(6) [112.9(6)], C1-N2-C15 111.0(6) [111.6(6)], N1-C1-N2 103.5(6) [101.9(6)], N1-C14-C15 106.0(6) [106.3(6)], N2-C15-C14 107(7) [107.3(6)].

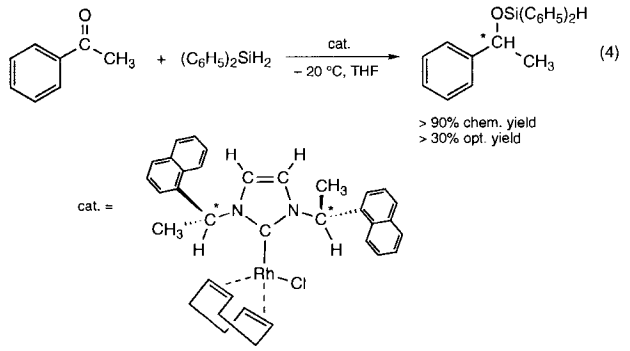
The rhodium complexes **5a**,**b** were obtained according to Equation (3) in 88% yield.[11] They are stable in air both as solids and in solution, and their thermal stability is also remarkable (decomposition at 202 °C (**5a**) and 210 °C (**5b**)). When heated in solution they do not lose the heterocyclic carbene ligand even at temperatures higher than 100 °C (NMR study). Thus, the new complex type has excellent properties for an application in asymmetric synthesis. This was confirmed in the first tested application, the hydrosilylation of acetophenone according to Equation (4): With complex **5b** as a catalyst, almost quantitative conversions and optical inductions higher than 30% were achieved.



The complexes **5a**,**b** are active in hydrosilylation *without* an induction period and even at low temperatures (Fig. 2). The enantiomeric excesses are independent of the catalyst concentration as well as of the degree of conversion. All observations lead to the conclusion that the chiral N-heterocyclic carbenes remain bound to the metal center, in particular because a dissociated carbene ligand would not be stable under the conditions of the catalysis. The lifetime of the catalysts is remarkably high; even after reaction times of more than two weeks the catalysts showed no signs of decomposition.

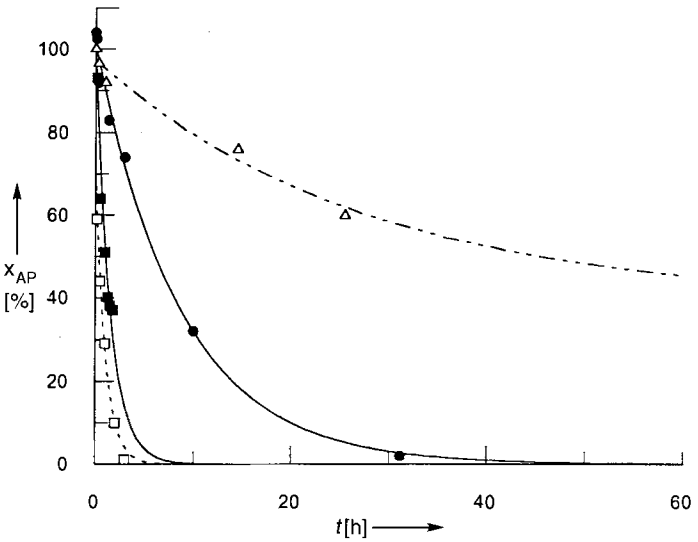


Fig. 2. Catalytic hydrosilylation of acetophenone: conversion vs. time. x_{AP} = acetophenone concentration. Conditions: ● −20 °C, 1% **5b**; □ 20 °C, 1% **5b**; ■ 0 °C, 1% **5b**; △ −20 °C, 0.1% **5b**.

These particular ligands were selected, because they do not contain any functional groups; decomposition products of the chiral ligands, for example the imiazolium salts **1a**,**b**, can therefore not coordinate to the catalytic center. All optical induction is lost if the catalyst is purposely degraded by addition of acid during the catalysis. A mixture of $[Rh_2(cod)_2Cl_2]$ and **1b** shows high activity in hydrosilylation; however, no enantiomeric enrichment results. Addition of **1b** alone also does not influence the optical induction of the catalysts **5a**,**b**. The optical induction is distinctly temperature-dependent and decreases at higher temperatures (Table 1). However, no significant solvent dependence could be observed.

1	20	1 h	90	< 5	90
1 [a]	−20	24 h	90	26	90
0.1 [b]	−20	6 d	90	24	900
1	−20	7 h	60	26	60
1 [c]	−20	24 h	60	27	60

[a] Addition of 3 equiv **1b**. [b] Containing 5% $[Rh_2(cod)_2Cl_2]$. [c] Methyl naphthyl ketone instead of acetophenone.

Only chiral chelate complexes of rhodium lead to higher enantiomeric excesses in the catalytic hydrosilylation. For example, Rh/glucophinite yields 65% *ee*,[12] Rh/MPFA 49% *ee*,[13] and Rh/Pybox (without excess ligand) 83% *ee*.[14]

In spite of as yet unsatisfactory *ee* values, N-heterocyclic carbenes indeed appear to be controlling ligands well suitable for asymmetric homogeneous catalysis. Because the metal–carbon bond is very stable, no ligand excess is needed. The inexpensive synthesis and the structural variety of these types of ligands is another advantage. A significant improvement in the optical yields can be anticipated from further modified, donor-functionalized ligands.

Experimental Procedure

1a,b: A 500 mL round-bottomed flask was charged with (*R*)- or (*S*)-1-phenylethylamine (11.9 g, 0.10 mol) in toluene (100 mL). Under vigorous stirring and slight cooling paraformaldehyde (3.00 g, 0.10 mol) was added. After 30 min another equivalent of the amine was added at 0 °C. Under constant cooling 3.3 N HCl (30 mL, 0.10 mol) was slowly added. After removal of the cold bath 40% aqueous glyoxal solution was slowly added (14.5 mL, 0.10 mol). The mixture was stirred for 12 h at 35–40 °C. For workup diethyl ether (100 mL) and saturated Na_2CO_3 solution (50 mL) were added, the phases separated, and the aqueous layer washed with diethyl ether. After removal of the volatiles in vacuo the residue was taken up in CH_2Cl_2 (150 mL), dried over $MgSO_4$, and filtered. The solvent was then evaporated off, and the yellow residue was washed with diethyl ether, which transformed it into a light yellow extremely hygroscopic powder. Yield: 24.5 g (79%). The naphthyl derivative **1b** was prepared similarly from (*R*)-naphthylethylamine in 77% yield.

2a,b: The imidazolium salts **1a,b** (10.0 mmol) were deprotonated in a mixture of THF (20 mL) and ammonia (100 mL) at −33 °C with NaH (10.8 mmol). The starting materials were not completely soluble, but during the deprotonation a clear yellow solution was formed. After evaporation of the ammonia the volume was adjusted to 40 mL with THF. The 0.25 M solution obtained this way was used without further workup. NMR spectroscopic characterization (100 MHz, (THF/CD_3NO_2): δ[C(carbene)] = 211.2 (**2a**), 210.5 (**2b**).

3a,b: Hexacarbonyltungsten (880 mg, 2.5 mmol) or tetracarbonylnickel (426 mg, 2.5 mmol) were treated with solutions of the free carbenes **2a** or **2b** (2.5 mmol). After chromatography the residues were crystallized from methylene chloride. Compounds **3a** (629 g, 63%, colorless crystals) and **4a** (945 mg, 63%, yellow crystals) were obtained in good yield, and **4b** in moderate yield (525 mg, 29%, yellow crystals).

5a,b: $[Rh_2(cod)_2Cl_2]$ (200 mg, 0.40 mmol) in THF (5 mL) was treated with a freshly produced carbene solution (see **2**, 3.3 mL, 0.8 mmol). After 1 h the solvent was removed in vacuo, the residue taken up in CH_2Cl_2, and the resulting mixture filtered. Compounds **5a,b** were purified by precipitation from *n*-pentane/CH_2Cl_2 mixtures. Yield: 327 mg **5a** (79%) and 441 mg **5b** (71%) as yellow powders.

Typical catalytic hydrosilylation: A vial equipped with magnetic stirrer and septum was charged with (*R,R*)-**5b** (25 mg, 1 mol%), acetophenone (0.5 mL, 4.2 mmol), THF (1 mL), and di-*n*-butyl ether (100 mg as internal standard). The solution was cooled to −20 °C, and diphenylsilane (0.8 mL, 4.2 mmol) was added by syringe. Thereafter, methanol (1 mL) and a catalytic amount of *p*-tolylsulfonic acid were added to hydrolyze the silyl ether (20 min). The 1-phenylethanol was separated from the silyl ethers by kugelrohr distillation, and its purity was determined by NMR spectroscopy. The enantiomeric excesses were determined by gas chromatography (Lipodex A column, 80 °C isothermal).

Supramolecular Host–Guest Compounds with Tripod–Metal Templates as Building Blocks at the Corners**

Susanne Mann, Gottfried Huttner,* Laszlo Zsolnai, and Katja Heinze

Dedicated to Professor Walter Siebert on the occasion of his 60th birthday

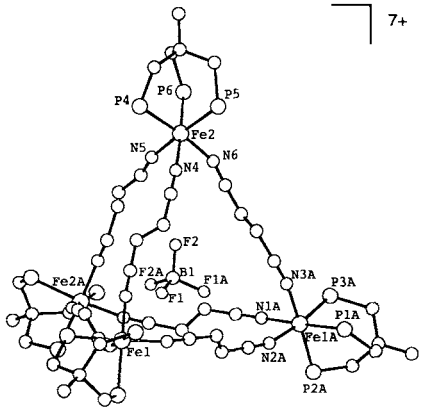
Tripod–metal templates tripodM^{n+} (tripod = $CH_3C(CH_2PPh_2)_3$) are stable units, which, depending on the metal center M and the charge n, can form strong bonds with a multitude of donors.[1–7] The coordination chemistry of these tripod–metal templates is established by the respective metal and its charge: tripod–cobalt(II) templates form, almost without exception,[4] five-coordinate complexes,[2] tripod–iron(II) templates form, likewise almost without exception,[3, 5] six-coordinate complexes, which adopt an idealized octahedral geometry.[4, 6, 7] These structure-determining properties have been detected and confirmed for many mononuclear complexes;[1–7] however, these templates have not been used for the specific construction of supramolecular units.[8] The fact that the tripod–iron(II) template binds relatively strongly to three additional ligands, and that the resulting bonds are at right angles to one another, suggests that these templates could be used for the construction of three-dimensional cage compounds. For cages of an appropriate size, counterions of matching symmetry could be incorporated into the framework of the host molecule. We report here on the synthesis of tetrahedral host–guest complexes, which are formed by molecular self-assembly according to this principle. According to Equation (a) six fumaronitrile ligands, four iron(II) ions, four tripod ligands, and one tetrafluoroborate ion react to give the tetrahedral host–guest complex **1a**.

$$4\,CH_3C(CH_2PPh_2)_3 + 4\,Fe(BF_4)_2 \cdot 6\,H_2O + 6\,NCC_2H_2CN \xrightarrow[20\,^\circ C]{[CH_2Cl_2/EtOH]} [\{(CH_3C(CH_2PPh_2)_3Fe)\}_4(NCC_2H_2CN)_6(BF_4)](BF_4)_7 \quad (a)$$

$$\mathbf{1a}(BF_4)_7$$

The BF_4^- salt of **1a** was characterized by a complete elemental analysis as well as by NMR spectroscopy and X-ray structure analysis.[9] The cationic unit of $\mathbf{1a}(BF_4)_7$, the host–guest complex **1a**, is shown in Figure 1.

This unit exhibits C_2 symmetry (twofold axis through the middle of the edges Fe1, Fe1A and Fe2, Fe2A, and the central BF_4^- ion); the symmetry of the core composed of the four iron centers that are located at the corners and the encapsulated BF_4^- ion is higher (Fig. 2). The B–F bonds of the encapsulated anion point towards the four iron centers located at the corners of the tetrahedron. The agreement between the symmetry of the guest molecule and that of the basic framework of the host molecule (Figs. 1 and 2) could be one of the reasons why 15 components, which exist isolated in solution, organize to give the molecular host–guest complex **1a**. Due to the width of the signals, the ^{19}F NMR spectra of the salt $\mathbf{1a}(BF_4)_7$ do not permit any clear differentiation between the encapsulated BF_4^- ion and the seven free BF_4^- ions at 25 °C; however, at −30 °C a clear splitting into two



1a

Fig. 1. Crystal structure of the tetrahedral host–guest complex **1a** (the phenyl rings at the phosphorus atoms of the four tripod ligands are omitted for clarity, those atoms labeled with an A were generated by symmetry operation). Bond lengths [Å] and angles [°]: Fe–N 1.93–1.98, Fe–P 2.29–2.31, Fe1–F1 (Fe1A–F1A) 4.38, Fe2–F2 (Fe2A–F2A) 4.60, B1–F1 (B1–F1A) 1.47, B1–F2 (B1–F2A) 1.40; N-Fe-N 81.8–84.6, P-Fe-P 87.8–91.1.

sharp signals occurs ($\delta = -202.5$ and -197.0), the integrals of which are as expected in the ratio of 1:7.

The specific and rigid form of the fumaronitrile ligand is not responsible for the formation of the tetranuclear host molecule: succinonitrile, the saturated derivative of fumaronitrile, leads, under reaction conditions analogous to those used for the preparation of **1a**, to the host–guest complex **1b** [Eq. (b)].

Fig. 2. Schematic representation of the iron tetrahedron with encapsulated BF_4^- tetrahedron of compound **1a**.

$$4\,CH_3C(CH_2PPh_2)_3 + 4\,Fe(BF_4)_2 \cdot 6\,H_2O + 6\,NCC_2H_4CN \xrightarrow[20\,^\circ C]{[CH_2Cl_2/EtOH]} [\{(CH_3C(CH_2PPh_2)_3Fe)\}_4(NCC_2H_4CN)_4(BF_4)](BF_4)_7 \quad (b)$$

$$\mathbf{1b}(BF_4)_7$$

Despite the considerably higher flexibility of the saturated derivative in comparison to that of fumaronitrile, a rigid tetrahedral arrangement of the four iron centers with an encapsulated BF_4^- ion, whose position is fit to the symmetry, is likewise formed (Fig. 2). Spectroscopic and analytical data confirm the composition of **1b**. The BF_4^- salt of **1b** crystallizes isotypic to the salt of **1a**, the structure is therefore shown only for **1a**[10] (Fig. 1).

The high positive charge of **1a** (**1b**) is the reason why in each case four BF_4^- anions occur in associated form in the outer coordination sphere of the tetrahedra ($\mathbf{1a}(BF_4)_4^{3+}$, Fig. 3). These anions occupy positions above the centers of the four triangular faces of each tetrahedron. They are oriented in such a way that in each case three B–F bonds are directed towards the iron centers, which form the triangular faces.

The shortest Fe–F distances in each case lie between 4.76 and 5.55 Å

Fig. 3. Schematic representation of the iron tetrahedron with encapsulated BF_4^- ion and the four tetrahedron-face-capping BF_4^- ions of the compound **1a** (**1b**) (light: iron tetrahedron; dark: central BF_4^- ion as well as the four capping BF_4^- ions).

[**] We thank Prof. D. Sellmann and Dr. M. Moll for the ^{19}F NMR spectroscopic measurements.

for the capping BF_4^- ions for **1a**, and between 4.68 and 5.57 Å for **1b**. They are significantly larger than the Fe–F distances of the BF_4^- ion encapsulated in the tetrahedron[10] (Fig. 1). The weaker coordination of the outer BF_4^- ions is apparent since, unlike the BF_4^- ion encapsulated in the tetrahedron, they can be rapidly exchanged for counterions in solution. In accordance with the comparatively isometric form of the associates $\mathbf{1a}(BF_4)_4^{3+}$ and $\mathbf{1b}(BF_4)_4^{3+}$, their crystal packing can be described to a good approximation as face-centered cubic[11] (Fig. 4).

Fig. 4. Space-filling representation of the associate $\mathbf{1b}(BF_4)_4^{3+}$ (light: host–guest complex **1b**, dark: tetrahedron-face-capping BF_4^- ions).

The remaining three BF_4^- ions per associate occupy the tetrahedral and octahedral holes of this idealized densest packing. In the larger octahedral holes they are distributed between two positions with 50% in each. According to NMR data, the packing present in the crystal is a result of the supramolecular organization of the building blocks.

The fact that the tetrahedral host–guest complexes **1** despite the different structure of the bifunctional bridging ligands are formed selectively in each case indicates the great variations possibile with the presented synthetic concept.

Experimental Procedure

A solution of 1,1,1-tris(diphenylphosphinomethyl)ethane [7] (624 mg, 1 mmol) in CH_2Cl_2 (20 mL) was added dropwise to a solution of $Fe(BF_4)_2 \cdot 6H_2O$ [12] (338 mg, 1 mmol) in EtOH (10 mL) and stirred. After the mixture had been stirred for 20 min at 20 °C, fumaronitrile (117 mg, 1.5 mmol) (in the case of **1a**) or succinonitrile (120 mg, 1.5 mmol) (in the case of **1b**) as a solid was added in one portion; the color did not change initially. After the mixture had been stirred for 15 h at 20 °C a slightly cloudy solution was formed (in the case of **1a** deep orange, in the case of **1b** red), which was concentrated to dryness. The residue was washed with Et_2O (3 × 20 mL) and subsequently dried under vacuum at 10^{-2} mbar. Crystals suitable for X-ray structure analysis were obtained by dissolving the microcrystalline powder in $CH_3NO_2 \cdot CH_2Cl_2$ (4:1) followed by gas-phase diffusion of Et_2O at room temperature.

1a: Yield: 92%; ^1H NMR: $\delta = 7.5-7.3$ (br., 120 H, H_{Ar}), 7.1 (br., 12 H, CN-CH), 2.9 (br., 24 H, CH_2-PPh_2), 1.95 (br., 12 H, CH_3-C); ^{31}P NMR: $\delta = 28.5$ (s); ^{13}C NMR: $\delta = 133.6$ (d, $^2J(CP_{trans}) = 10$ Hz, P-C_{ipso}), 133.2 (m, C_{ortho}), 131.9 (br., C_{para}), 130.1 (m, C_{meta}), 129.2 (m, C≡N), 122.8 (s, CH-C≡N), 37.3 (CH_3-C), 36.5 (CH_3-C), 31.0 (m, CH_2-P); ^{11}B NMR: $\delta = 0.25$ (s); ^{19}F NMR ($T = -30$ C): $\delta = -202.5$ (s, 28 F, BF_4 outer), −197.0 (s, 4 F, BF_4 inner); MS (FAB): m/z (%) = 699 (100, TripodFeF), 547 (66,Tripod-Ph), 1416 (6, $Tripod_2Fe_2F_3$-2); IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 2254 (w, C≡N), 1437 (m), 1062 (s, br., B-F), 833 (w, P-C-alkyl), 742 (m), 696 (m), 520 (m); elemental analysis calculated for $C_{188}H_{168}P_{12}N_{12}Fe_4B_8F_{32}$: C 58.12, H 4.36, P 9.57, N 4.33, B 2.23, F 15.65, Fe 5.75; found: C 56.38, H 4.34, P 6.37, N 4.04, B 4.05, F 16.4, Fe 6.25.

1b: Yield: 85%; ^1H NMR: $\delta = 7.5-7.4$ (m, 120 H, H_{Ar}), 3.5 (br., 24 H, CN-CH_2), 2.8 (br., 24 H, CH_2-PPh_2), 1.9 (br., 12 H, CH_3-C); ^{31}P NMR: $\delta = 30.9$ (s); ^{13}C NMR: $\delta = 134.1$ (dd, $^1J(CP) \approx 13.1$, $^3J(CP_{trans}) = 25.5$ Hz, P-C_{ipso}), 133.4 (m, C_{ortho}), 131.7 (br., C_{para}), 129.9 (m, C_{meta}), 36.9 (m, CH_3-C), 36.5 (m, CH_3-C), 31.6 (m, CH_2-P), 17.1(s, CH_2-C≡N); ^{11}B NMR: $\delta = 0.21$ (s); ^{19}F NMR ($T = 23$ C): $\delta = -198.3$ (br.); ^{19}F NMR ($T = -30$ °C): $\delta = -201.4$ (s, BF_4 outer), −199.6 (s, BF_4 inner); MS (FAB): m/z (%) = 699 (100, TripodFeF), 547 (54, Tripod-Ph), 1417 (15, $Tripod_2Fe_2F_3$-1); IR (CsI): $\tilde{\nu}$ [cm^{-1}] = 1484 (m), 1436 (m), 1060 (s, br., B-F), 837 (m, P-C-Alkyl), 742 (m), 700 (m), 521(m); elemental analysis calculated for $C_{188}H_{180}P_{12}N_{12}Fe_4B_8F_{32}$: C 57.94, H 4.66, P 9.54, N 4.31, B 2.22, F 15.6, Fe 5.73; found: C 56.67, H 4.75, P 7.27, N 5.04, B 2.12, F 16.7, Fe 4.91.

Smaller Substituents on Nitrogen Facilitate the Osmium-Catalyzed Asymmetric Aminohydroxylation**

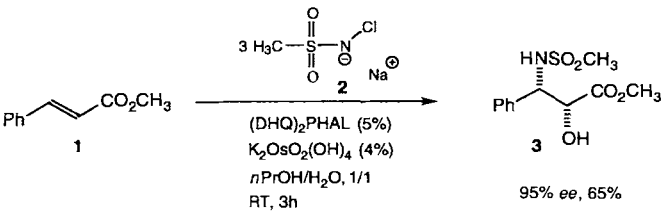
Joachim Rudolph, Peter C. Sennhenn, Cornelis P. Vlaar, and K. Barry Sharpless*

Dedicated to Professor Henri B. Kagan

The β-hydroxyamino structural unit is a key motif in many biologically important molecules. It is difficult to imagine a more efficient means of creating this functionality than by direct addition of the two heteroatom substituents to an olefin, especially if this transformation could also be regio- and/or enantioselective when required. We recently reported the discovery of such a catalytic asymmetric aminohydroxylation (AA) reaction. On treatment with a chiral alkaloid ligand, catalytic osmium, Chloramine-T as the nitrogen source, and water as the oxygen source, olefins undergo enantioselective vicinal addition of a sulfonamido and a hydroxyl group.[1] A limited range of substrates was investigated and enantioselectivities of up to 82% were achieved.[2] These initial results clearly leave much room for improvement. Above all, higher enantioselectivities are needed and, when applicable, higher regioselectivities. Another goal is better chemoselectivity, which principally means suppressing formation of the vicinal diol, sometimes a significant by-product.

We report here on progress in all three selectivity categories by use of sulfonamide-derived chloramine salts with smaller organic substituents on the sulfur.[3] The best results to date (Scheme 1, Table 1) were obtained with the methanesulfonamide-derived chloramine salt **2** (Chloramine-M[4]). This reagent can be prepared separately and added as the stable anhydrous salt or it can be generated in situ.[5, 6] The in situ method is preferred for large-scale applications.

As shown in Scheme 1 for methyl *trans*-cinnamate (**1**), the procedure is identical to the original AA procedure with the exception that Chloramine-M replaces Chloramine-T. This substitution results in the across-the-board improvements seen in Table 1 (cf. Table 1 in ref. [1]), where, for the sake of comparison, the olefins examined are the same ones used in the original Chloramine-T-based work.[7] In addition, it was possible to obtain all the products in enantiomerically pure form by recrystallization, an approach that did not always succeed with the related Chloramine-T derived products.[1] A further advantage is that residual methanesulfonamide, a major by-product (due to the use of three equivalents of Chloramine-M) can be removed quantitatively from the desired product by simply washing the



Scheme 1. AA process based on Chloramine-M. DHQ-H = dihydroquinine, PHAL = 1,3-phthalazinediyl, RT = room temperature.

Table 1. Catalytic asymmetric aminohydroxylation reaction with Chloramine-M as the nitrogen source.

Entry	Substrate	Product [a] $(DHQ)_2PHAL$	*ee* [%] [b] $(DHQD)_2PHAL$	Yield [%]	*t* [h]	M.p. [°C] [c]	$[\alpha]_D^{25}$ [c]
1 [d]		 **3**	95 (99)*	95	65	3	150–152	+28.3
2 [e]		 **4**	94 (99)*	95	65	3.5	97– 98	+26.2
3 [f]		 **5**	95 (99)*	94	76	2	91– 92	+16.8
4		 **6**	75 (99)	82	71	16	134–135	−6.9
5		 **7**	80 (99)	82	63	16	117–118	+8.1
6		 **8**	66 (99)	63	49	18	114–115	+18.8

[a] All reactions, except entry 3, were conducted in *n*PrOH/H_2O (1:1) in a room-temperature water bath. In all cases 4% $K_2OsO_2(OH)_4$ and 5% ligand were used. [b] Numbers in parentheses are *ee* values after recrystallization of the product from ethyl acetate/diethyl ether or ethyl acetate/hexane. (Asterisks mark cases in which the mother liquor is enantiomerically enriched, since the racemate crystallized preferentially.) [c] The melting points and optical rotations ($c = 1.0$ in 95% EtOH) refer to samples obtained by using $(DHQ)_2PHAL$ and which were subsequently recrystallized to enantiomeric purity. [d] Regioselectivity: 91:9. [e] Regioselectivity: 95:5. [f] CH_3CN/H_2O (1:1) was the solvent, and an additional 0.5 equiv of *tert*-butylhypochlorite was necessary to achieve these results. DHQ-H = dihydroquinine, DHQD-H = dihydroquinidine, PHAL = 1,3-phthalazinediyl.

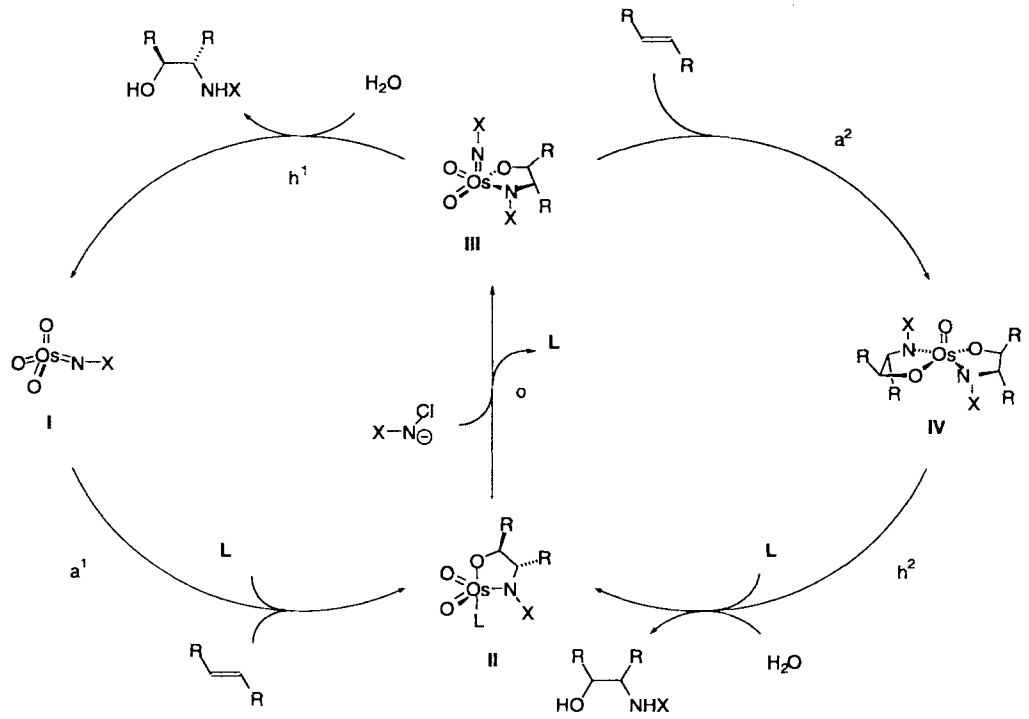
combined organic extracts with water. By contrast, removal of excess toluenesulfonamide often requires a tedious chromatographic separation. Methanesulfonamide was also easily removed by sublimation in vacuo.

A number of differences between the new and old systems are noteworthy: 1) Catalyst activity (i.e. turnover rate) is better in this new system. For example, in acetonitrile/water the AA process for isopropyl *trans*-cinnamate and Chloramine-T takes 3.5 hours to reach completion, while with Chloramine-M the reaction is complete in 40 minutes (side-by-side reactions in a water bath at room temperature). This rate increase is accompanied by significant increases in both enantioselectivity (from 60 to 89% *ee*) and regioselectivity (from 76:24 to 90:10). 2) The choice of solvent is a critical variable, and it can also be substrate dependent. In reactions with Chloramine-M, we found that *n*-propanol/water (1:1) generally gave better results than the acetonitrile/water system,[8] even though reactions in the former were slower (with isopropyl *trans*-cinnamate the reaction required 40 minutes in acetonitrile/water and 3.5 hours in *n*-propanol/water). Hence, the advantages of the *n*-propanol/water system are improved enantio-, regio-, and chemoselectivities but not rate. 3) A sensitive variable is temperature. Temperatures above 25 °C lead to a considerable increase in diol formation as well as a decline in selectivity. Therefore, use of a room-temperature water bath is usually adequate.[9] 4) Another significant difference between Chloramine-T and Chloramine-M in the AA process is the effect of the ligand on the rate. In the presence of the ligand, Chloramine-M generally reacts faster than Chloramine-T; in the absence of the ligand, Chloramine-T reacts faster. In fact, the ligand is required for the reaction of Chloramine-M to occur on a reasonable time scale. Thus this represents a clearcut example of the desirable phenomenon of ligand-accelerated catalysis.[10] By contrast, in the Chloramine-T system,[11] for most substrates, the ligand retards turnover (i.e. ligand-decelerated catalysis).

Scheme 2 shows our proposal for the key intermediate complexes involved in these catalytic systems. Like the AD process,[11] there is substantial evidence[12] that at least two catalytic cycles are operative in the AA system. The following discussion offers preliminary speculation on how the two cycles in Scheme 2 may explain some of the more important observations to date.

These initial investigations offer no decisive evidence as to why Chloramine-M is the superior reagent. However, experiments with other aliphatic and aromatic sulfonamide derivatives suggest that both electronic and steric factors play a role.[13] The steric demand of the organic substituent on the sulfonamide seems especially important. The smaller substituent (for example, methyl compared to *p*-tolyl) is thought to allow a better fit of the ensemble into the "binding pocket" of the catalyst in the transition state of the irreversible step (step a^1 in Scheme 2). However, effects on this irreversible step in the first cycle provide only part of the story, since the "direct"[14] effects of the ligand on selectivity are only possible when turnover occurs in the first cycle (Scheme 2). To whatever extent the ligand-independent second cycle intrudes, the ligand-mediated selectivity features are lost. Just like the *N*-morpholine-*N*-oxide (NMO) variants of the AD process,[15] these catalytic AA processes are conducted in homogeneous solution and therefore prone to the problems in the second cycle, where products are formed in a catalytic cycle not involving the ligand. Involvement of this cycle (a^2, h^2, o, repeat; Scheme 2) affords almost no enantio- or regioselectivity. In general, catalysis in the second cycle proceeds with much slower turnover rates, since the osmium(VI) bisazaglycolates (**IV**, Scheme 2) are often slow to hydrolyze (h^2), which is necessary before reoxidation (o) can occur.[12] There is considerable evidence that entry into the deleterious second cycle is suppressed by any factors that favor hydrolytic release of the glycolate or azaglycolate product from osmium. Since the methyl group is both smaller and less hydrophobic than the *p*-tolyl group, hydrolysis is expected to be easier in both cycles (steps h^1 and h^2), accounting for the faster catalysis rates. Of course, it is the suppression of the second cycle that is thought to account for most of the rate and selectivity advantages of the methyl over the *p*-tolyl substituent. This is not only because the second cycle is known to have devastating effects on both selectivity and turnover rate,[11] but also because once the second cycle is engaged, any enantio- and regioselectivity benefits that might accrue from better attractions in the catalyst binding pocket in the first cycle are irrelevant. Interestingly, the use of Chloramine-M seems to lead to faster hydrolysis of the azaglycolate complex (**III**, Scheme 2) *only* in the



Scheme 2. Proposed mechanism for the AA reaction. Sequence of steps in the first catalytic cycle (left): 1) addition (a^1), 2) reoxidation (o), 3) hydrolysis (h^1); in the second catalytic cycle: 1) addition (a^2), hydrolysis (h^2), reoxidation (o). The first cycle proceeds with high enantioselectivity, the second with low enantioselectivity. L = ligand, X = CH_3SO_2.

presence of the ligand, since in the absence of ligand only very slow turnover is observed, underscoring again the stronger ligand dependence of the Chloramine-M system.

This work constitutes a major improvement in all the desirable selectivity features of the catalytic AA process, and taken together with a known procedure for the deprotection of methanesulfonamides,[16] can be used to prepare unprotected amino alcohols. However, this deprotection method (Red-Al, refluxing toluene) does not tolerate many functional groups, so that discovery of other effective nitrenoid sources with groups more easily removed from nitrogen remains an important goal. In this connection, we have found that the chloramine salt $Me_3SiCH_2CH_2SO_2NClNa$, derived from the easily deprotected "Weinreb sulfonamide",[3] gives results very similar to those obtained with Chloramine-M,[13] presumably because the organic substituent near the reaction zone is also "small".

In conclusion, this and a related study[13] provided the key insight that (at least for sulfonamide-derived chloramine salts) the AA process is better with the least sterically demanding substituents on sulfur. Appreciation of this trend was in part responsible for our decision to have another look at the old carbamate-based version of the catalytic aminohydroxylation process.[17] This was a fortuitous decision, since it led to the discovery of the highly effective carbamate-based AA process described in the following paper.[18]

Experimental Procedure

Chloramine-M (**2**): To a stirred solution of methanesulfonamide (4.81 g, 50 mmol) and sodium hydroxide (2.0 g, 50 mmol) in 40 mL of water was added slowly *tert*-butylhypochlorite (5.63 mL, 5.4 g, 50 mmol). The solution was stirred for 1 h and concentrated to dryness in vacuo. After one trituration with diethyl ether the pure salt sodium *N*-chloro,*N*-methanesulfonamide was obtained in almost quantitative yield (7.5 g). CH_3NSO_2NaCl (M_r = 151.54); elemental analysis: calcd. C 7.93, H 2.00, N 9.24, Na 15.17, Cl 23.39; found: C 8.03, H 2.08, N 9.24, Na 15.36, Cl 23.12. Recrystallization of the product from *tert*-butyl alcohol did not lead to any change in its reaction behavior. The in situ generation of Chloramine-M was accomplished with this same procedure except that the amount of water used was adjusted to equal the required water content for the AA process for which it is intended and, of course, the resulting solution was used directly in the reaction.

General procedure: All AA reactions included in Table 1 were carried out as in the following example, the preparation of **4** on the 1 mmol scale: A 20 mL scintillation vial equipped with a magnetic stirrer was charged with a solution of $MeSO_2NClNa$ (455 mg, 3.0 mmol, 3.0 equiv) in 7.5 mL of water, 7.5 mL of *n*PrOH, and $(DHQD)_2PHAL$ (40 mg, 0.05 mmol, 0.05 equiv). To the resulting stirred clear colorless solution was then added isopropyl *trans*-cinnamate (190 mg, 1.0 mmol), followed by $K_2OsO_2(OH)_4$ (14.8 mg, 0.04 mmol, 0.04 equiv). The reaction mixture turned green after several minutes and was stirred for 3.5 h, by which time the reaction mixture had turned a clear, light yellow. The presumed significance of the color change as an indication of the end point of the reaction was confirmed by a TLC analysis, which revealed that no olefin remained. (With dimethyl fumarate the green color was only observed when an additional 0.5 equiv *tert*-butyl hypochlorite was added. For the fumarate case, the extra *tert*-butyl hypochlorite also resulted in much better *ee* and yield.) The reaction was then quenched by addition of 10 mL of saturated aqueous Na_2SO_3 (this reductive quench is exothermic and cooling is needed for large-scale reactions). The added salt caused phase separation. The aqueous phase was separated and extracted with ethyl acetate (3 × 30 mL). The combined organic phases were dried over $MgSO_4$ and concentrated to afford the crude product (impurities were mainly methanesulfonamide and diol). For an accurate yield the crude product was purified by flash chromatography (SiO_2, 30% ethyl acetate/hexane) and afforded 195 mg (65%) crystalline aminohydroxylation product. In cases in which regioisomeric products can result, the yields are given for the mixture of the two regioisomers. In the particular case described, crystallization from ethyl acetate/hexane furnished the regio- and enantiomerically pure (>99% *ee*) *β*-hydroxyaminomethanesulfonamide **4** (isopropyl (2*R*,3*S*)-*N*-(methanesulfonyl)-3-amino-2-hydroxy-2-phenyl-propanoate).

In preparative-scale applications the workup and purification steps can be simplified. Since methanesulfonamide is insoluble in CH_2Cl_2 and diethyl ether but quite soluble in aqueous solution (even saturated brine solutions), it can be removed from the crude product by two aqueous extractions. Alternatively it can be sublimed in vacuo (0.1 mbar) from the crude material at 80 °C. Finally, it also precipitates from solutions in CH_2Cl_2 and CH_2Cl_2/hexane.

In the case of **5** (the AA product from dimethyl fumarate) extractive and chromatographic purification both failed (**5** is too water soluble). On the other hand, sublimation at 80 °C removed both the diol by-product and the excess methanesulfonamide, leaving pure **5** behind.

Methyl (2*R*,3*S*)-*N*-(methanesulfonyl)-3-amino-2-hydroxy-2-phenylpropanoate (**3**): $C_{11}H_{15}NO_5S$, M_w = 273.30; m.p. 150–152 °C; $[\alpha]_D^{25}$ = + 28.3 (*c* = 1.0 in EtOH/H_2O 95:5); ^1H NMR (400 MHz, CD_3CN): δ = 2.63 (s, 3H, SO_2CH_3), 3.75 (s, 3H, CO_2CH_3), 3.78 (s, 1H, OH), 4.36 (s, 1H, *CH*OH), 4.86 (dd, *J* = 3.2, 9.9 Hz, 1H, CHN), 6.08 (d, *J* = 9.9 Hz, 1H, NH), 7.30–7.43 (m, 5H, arom. H); ^{13}C NMR (100 MHz, CD_3CN): δ = 41.8 (SO_2CH_3), 53.0 (CN), 60.4 (COH), 75.3 (CO_2CH_3), 128.1, 128.7, 129.3, 139.6 (arom. [1] a) G. Li, H.-T. Chang, K. B. Sharpless, *Angew. Chem.* **1996**, *108*, 449–452; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 451–454; b) G. Li, K. B. Sharpless, *Acta Chem. Scand.* **1996**, *50*, 649–651.

[2] Stopping the reaction after partial conversion usually leads to higher regio- and enantioselectivities. In addition, we have come across new substrates giving higher enantioselectivities in reactions with the Chloramine-T system since the original report appeared.

[3] Certain functionalized alkylsulfonamides have recently been found to be interesting candidates for deprotection: a) S. M. Weinreb, D. M. Demko, T. A. Lessen, J. P. Demers, *Tetrahedron Lett.* **1986**, *27*, 2099–2102; b) T. Fukuyama, personal communication.

[4] In analogy to the common names "Chloramine-T" for sodium *N*-chloro-*N*-toluenesulfonamide and "Chloramine-B" for sodium *N*-chloro-*N*-benzenesulfonamide, the trivial name "Chloramine-M" for the sodium *N*-chloro-*N*-methanesulfonamide seems appropiate.

[5] a) Chloramine-M is readily prepared from methanesulfonamide in water by addition of the stoichiometric amount of sodium hydroxide and *tert*-butylhypochlorite [5b]. This method is adapted from a procedure developed by Campbell et al. for the preparation of sodium *N*-chloro-*N*-carbamates [5c–e] and proved general for synthesis of both sodium *N*-chloro-*N*-aryl- and -alkylsulfonamides. Substitution of the recommended [5c–e] solvent methanol by water proved to be highly advantageous. b) *tert*-Butylhypochlorite is commercially available; for a simple preparative procedure see: M. J. Mintz, C. Walling, *Org. Synth. Coll. Vol. V*, **1983**, 183–187; c) M. M. Campbell, G. Johnson, *Chem. Rev.* **1978**, *78*, 65–79; d) E. Herranz, S. A. Biller, K. B. Sharpless, *J. Am. Chem. Soc.* **1978**, *100*, 3596–3598; e) E. Herranz, K. B. Sharpless, *J. Org. Chem.* **1978**, *43*, 2544–2548.

[6] Alkyl sulfonamide derived chloramine salts appear to have been little studied. In fact, we found only one earlier report on this class of compounds: F. E. Hardy, *J. Chem. Soc.* **1970**, 2087–2089.

[7] Only *tert*-butyl *trans*-crotonate and isopropyl *trans*-cinnamate did not appear in the first paper. The isopropyl *trans*-cinnamate is included here in addition to the methyl *trans*-cinnamate because it gave a considerably worse result when Chloramine-T in CH_3CN/H_2O was employed: regioselectivity: 76:24, *ee*: 60%).

[8] The *n*-propanol water solvent system was also shown to give better selectivities with Chloramine-T, although in some cases the reaction became too slow to be useful: A. Houri, K. B. Sharpless, unpublished results.

[9] Temperatures lower than 10 °C led to longer reaction times and problems with ligand solubility.

N-Halocarbamate Salts Lead to More Efficient Catalytic Asymmetric Aminohydroxylation**

Guigen Li, Hubert H. Angert, and K. Barry Sharpless*

Dedicated to Professor Koji Nakanishi

The recently discovered catalytic asymmetric aminohydroxylation (AA) process[1] has been easier to improve than anticipated. In the preceding paper, we described how substantial increases in enantio- and regioselectivity were achieved by replacing Chloramine-T (TsNClNa) with analogs bearing substituents smaller than the *p*-tolyl group (e.g. CH_3SO_2NClNa).[2] We report here that the process becomes even more effective when the chloramine salts of sulfonamides are replaced by those of alkyl carbamates. Application of the new procedure to 2-vinylnaphthalene (**1**) with BnOCONClNa as the oxidant and nitrogen source (Scheme 1) proceeds with exceptional enantioselectivity and regioselectivity (>10:1). In addition, in virtually all the entries in Tables 1 and 2 better selectivities were achieved than those realized in the sulfonamide-based procedures for the AA.[1–3] Also noteworthy is the increased scope, hinted at here by the very good results obtained with methyl acrylate and vinylnaphthalene **1** (Table 1, entries 4 and 7), which will be further documented soon.[4]

Styrene-type olefins such as **1** are conspicuously absent from the first sulfonamide-based AA reports[1, 2] for the simple reason that they were poor substrates. The reaction of styrene itself produced an approximately 2:1 mixture of regioisomers, 50–70% *ee* each, in low yield.[5] This was quite unexpected, since in terms of both turnover and enantioselectivity styrenes are by far the best substrates in the catalytic asymmetric dihydroxylation (AD) process.[6] However, even more surprising than the low selectivities were the abysmal rates. Styrenes, the fastest reacting AD substrates, were among the slowest reacting substrates in the sulfonamide-based AA reactions,[1, 2] and since the reactions were even slower when the ligand was added than when it was omitted, this is an example of ligand-decelerated catalysis.[6] By contrast, in this new carbamate-based process the reactions of all olefins studied to date are ligand-accelerated, as has been the universal experience in the AD process.[7]

In comparing Tables 1 and 2, it becomes clear that the ethyl carbamate series is superior to the benzyl carbamate series in terms of rate, enantioselectivity, regioselectivity, and yield. The effect of the smaller ethyl substituent may be analogous to that assumed on replacement of a methyl substituent for the *p*-tolyl substituent on the sulfonamide—suppression of the second cycle and better fit in the ligand binding pocket of the catalyst.[8] Despite the greater effectiveness of the ethyl reagent, the benzyl reagent will often be preferred because it can be cleaved easily by hydrogenolysis.

Since the other results in the tables need no comment, we now consider what general insight this new system offers for catalysis research. Such lessons are often more valuable than any particular catalytic process can ever be.

The original report on carbamate-based, osmium-catalyzed aminohydroxylation of olefins appeared in 1978,[9] two years after publication of the analogous sulfonamide-based process.[10] The latter process[10] was used many times over the past twenty years, especially in syntheses of amino sugars. The old carbamate version[9, 11] was used much less frequently, but it has the distinction of being a key step in the first synthesis of the *tert*-butoxycarbonyl (BOC) protected side chain analog of taxol, now known as Taxotere.[12]

Those familiar with the original, nonasymmetric, carbamate-based procedures will realize that the sodium *N*-chlorocarbamate salts were never used directly in the process, either by us or by others.[13] They were always first converted in situ to the corresponding silver or mercury salts. So why did we fail to discover earlier that the original sodium salts are superior to their silver and mercury analogs?[14] The answer is that far too little water was present, so we observed no turnover in the first few attempts to extend the effective process based on TsNClNa to one based on ROCONClNa. Scott Biller (then an undergraduate at MIT) came up with the idea of using the silver salt, which

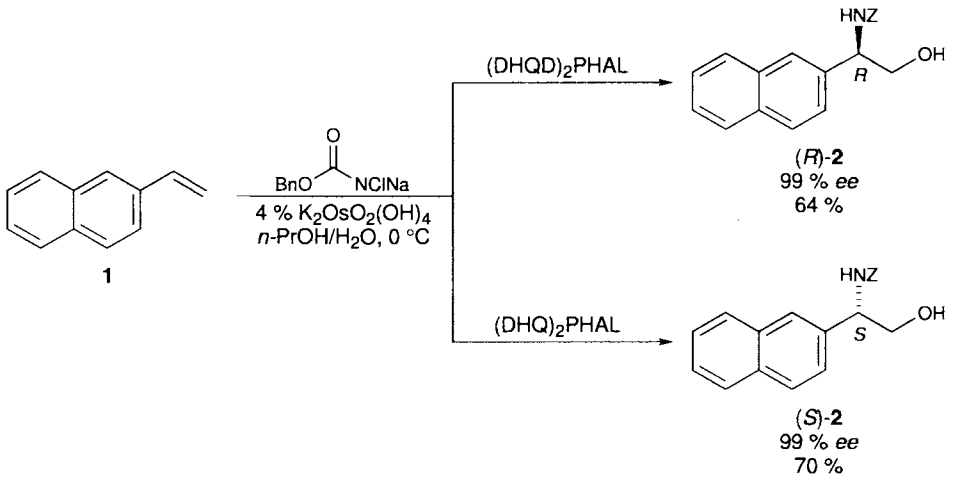

Scheme 1. AA reactions of 2-vinylnaphthalene (1) with benzyl carbamate. DHQD-H = dihydroquinidine, DHQ-H = dihydroquinine, PHAL = 1,3-phthalazinediyl, Z = benzyloxycarbonyl.

proved highly successful even under our water-starved conditions. No one ever tried the sodium salt again. Even if it had been tried, "no reaction" would have been the verdict unless a lot more water were present than described in any of the published procedures.

Following the encouraging results of the catalytic AA reaction with sulfonamides,[1, 2] we reexamined the carbamate-based catalytic aminohydroxylation process, primarily because carbamate protecting groups are easier to remove from nitrogen. Optimization of the AA procedure using $ArSO_2NClNa$ salts had led to the choice of cosolvent systems containing 50% water. The high water content is thought to speed the slow hydrolytic steps and thereby suppress involvement of the rate- and selectivity-damaging second cycle.[8] At this point, good fortune struck.

One of us (G. L.)—unaware that the standard carbamate process called for acetonitrile solvent with only a few equivalents of water and for the silver, not the sodium salt of the chloramine—ran the first experiment using 50% aqueous *n*-propyl alcohol as solvent, EtOCONClNa as the chloramine salt, $(DHQ)_2PHAL$ as the chiral ligand, and methyl cinnamate as the substrate. The result was spectacular (Table 2, entry 1). For even though the system was homogeneous, the reaction was almost free of the deleterious effects on selectivity that arise whenever second-cycle catalysis participates.[8] Recall that in all homogeneous versions of the AD, the second cycle always intrudes to some extent and can only be completely suppressed by using inconvenient two-phase systems.[6]

Further controls revealed which variables are crucial for maintaining the exceptional catalyst activity and selectivity of this new AA system.[16] The two most important factors are water concentration and the nature of the metal salt of the *N*-chlorocarbamate, and the two factors are linked. The interdependence is dramatic for the alkali metal salts of *N*-chlorocarbamates: from essentially no turnover with a few equivalents of water, to better and better reactivity as the percentage of solvent water increases. The effect of water concentration on reactivity in the silver *N*-chlorocarbamate system is, as expected, less dramatic. In any case, whatever the water concentration, in the system examined (stilbene, sodium or silver benzyl *N*-chlorocarbamate, $(DHQ)_2PHAL$, $K_2OsO_2(OH)_4$, CH_3CN, and H_2O),[16] reactions with the silver carbamate always gave lower yields, lower enantioselectivities, and more by-products than reactions with the sodium carbamate.

With this better catalytic asymmetric aminohydroxylation process now in hand, we and others are busy trying to map out its scope.[4] There may also be a message here of broader significance for catalyst-discovery research. As noted in the brief historical account, this trivially different, but successful, system was passed by long ago simply because we failed to examine the effect of water concentration with every change of chloramine salt. This joins the list of many important lessons in catalysis we have learned the hard way over the last 20 years. The common theme of these lessons is that catalytic cycles are sensitive to far too many reaction variables for even the best catalyst discovery endeavors to have a high success rate. Whether one is just trying to improve existing, but feeble catalysis, or prospecting for the first hint of a new catalytic transformation, unknown obstructions, usually interconnected in sinister ways, lie everywhere. Fast (automated) screening techniques, along with the chance discoveries they engender, would seem to offer the best chance of getting through such minefields quicker and more often. At present, it could be argued that attempts to discover new catalysts fail, because of the limited endurance of human researchers.

Finally, the significance of entry 7 in Table 1 will not be lost on chemists interested in the synthesis of unusual amino acids. This result opens a simple two-step route from vinyl arenes to enantiomerically pure aryl glycines of either *R* or *S* configuration.[17]

Experimental Procedure

General Procedure: Unless otherwise noted, all the carbamate AA reactions shown in Tables 1 and 2 were carried out on a 1 mmol scale as described here for methyl *trans*-cinnamate and the benzyl carbamate derived chloramine salt (Table 1, entry 1). Ethyl carbamate or *tert*-butyl carbamate can also be used in place of benzyl carbamate.

Benzyl carbamate (0.469 g, 3.10 mmol) was dissolved in 4 mL of *n*-propyl alcohol in a 20-mL scintillation vial equipped for magnetic stirring. To this stirred solution was added a freshly prepared solution of NaOH (NaOH (0.122 g, 3.05 mmol) in 7.5 mL of water), followed by a freshly prepared solution of *tert*-butyl hypochlorite (0.331 g, 3.05 mmol, ca. 0.35 mL) [18]. Then a solution of the ligand $(DHQ)_2PHAL$ (40 mg, 0.05 mmol, 5 mol%) in 3.5 mL of *n*-propyl alcohol was added. (It is important that the ligand be completely dissolved in the *n*-propyl alcohol before it is added; the DHQ analog is more readily soluble than the DHQD analog.) The reaction mixture should be homogeneous at this point. The vial was then immersed in a room-temperature water bath, and stirred for a few minutes. Then the olefin (*trans*-methyl cinnamate, 0.162 g, 1 mmol, 0.067 M) was added, followed by the osmium catalyst ($K_2OsO_2(OH)_4$, 14.7 mg, 0.04 mmol, 4 mol%). The reaction mixture was stirred for 40 min (the approximate reaction time is given for each entry in the tables), and the light green color of the solution gave way to light yellow at the end. After TLC analysis confirmed the absence of starting material, 7 mL of ethyl acetate was added and the phases were separated. The lower, aqueous phase was extracted with ethyl acetate (3 × 5 mL). The combined organic extracts were washed with water and brine, dried over $MgSO_4$, and concentrated to dryness to afford the crude product contaminated by some excess benzyl carbamate. Purification by flash chromatography (hexane/chloroform/methanol 6/4/1, v/v/v) provided (2*R*,3*S*)-**3** (0.204 g, 65% yield, 94% *ee*) as a colorless solid; m.p. 101–103 °C; $[\alpha]_D^{20} = +4.4$ ($c = 0.32$ in 95% EtOH).

Simplified procedures for cases in which the product crystallizes directly from the reaction mixture:

1) (*S*)-**2** (Table 1, entry 7): This is one of only three cases in which the reaction was conducted at 0 °C, but the procedure is otherwise identical (up to the generation of the chloramine salt) to the one used for methyl cinnamate. It then diverges as follows: The vial was immersed in a 0 °C icebath and 2-vinylnaphthalene (1) (0.154 g, 1 mmol) was added, followed by $K_2OsO_2(OH)_4$ (14.7 mg, 0.04 mmol,

[a] Major product from the reaction using (DHQ)$_2$PHAL. [b] Yields of the reactions using (DHQ)$_2$PHAL. [c] CH_3CN/H_2O was used as the solvent. [d] Reactions were performed at 0 °C.

4 mol%). The green homogeneous mixture was stirred at 0 °C for 3 h by which time it had transformed into an almost colorless slurry. A crystalline precipitate, which was nearly pure by HPLC and NMR, was removed by filtration. One wash with cold (ca. 5 °C) *n*PrOH/H_2O (1/1, 3 mL) yielded pure (*S*)-**2** (0.460 g, 70% yield, >99% *ee*). A small sample of this solid was dissolved in ethyl acetate and filtered through a small plug of silica gel; m.p. 133–134 °C; $[\alpha]_D^{20} = +50.9$ ($c = 0.32$ in 95% EtOH). (A practical note: Very similar results were realized in an otherwise identical experiment in which the solvent volume and the amounts of ligand and osmium were the same, but 2 mmol of olefin and 4 mmol of chloramine were used. One-half of the total amount of olefin was added at the beginning of the reaction. After that portion was consumed, the remainder was added and the reaction completed as usual.)

2) (1*S*,2*S*)-**8** (Table 1, entry 6): This procedure for stilbene is reminiscent of earlier AD [19] and AA [1] processes, which take advantage of the fact that both the stilbene and its oxidation product are insoluble in the medium. As in the preparation of **2**, workup consists of merely filtering the crude reaction mixture. The following procedure differs from that for **2** in that it is a straight sixfold scale-up and requires a 120-mL bottle. (Another small difference is that in addition to finishing as a slurry, the reaction mixture starts as a slurry.) However, since the reaction sequence is otherwise identical to that just described for **2** (even down to the reaction time of 3 h at 0 °C), the only new details describe the treatment of the product after its isolation from the reaction mixture. Filtration of the cold slurry provided the crude solid product which was washed once with cold (ca. 5 °C) *n*PrOH/H_2O (1/1, 12 mL) to give (1*S*,2*S*)-**8** (1.85 g, 92% yield, 91% *ee*, nearly pure by NMR and HPLC); m.p. 135–137 °C; $[\alpha]_D^{20} = -7.8$ ($c = 0.70$ in 95% EtOH). A single recrystallization from methanol raised the *ee* to >99%; m.p. 149–151 °C; $[\alpha]_D^{20} = -10.0$ ($c = 0.57$ in 95% EtOH).

Determination of enantiomeric excesses and optical rotations: Rotations were determined for the products in Tables 1 and 2 at the stated enantiomeric excesses obtained with the (DHQ)$_2$PHAL ligand unless otherwise indicated, and were measured in 95% EtOH.

3: Chiralcel OD-H, *i*PrOH/hexane (15/85), 0.60 mL min^{-1}; 16.9 min (2*S*,3*R*), 19.7 min (2*R*,3*S*); $[\alpha]_D^{20} = +4.4$ ($c = 0.32$).

4: Chiralcel AD, *i*PrOH/hexane (3/7), 0.60 mL min^{-1}, 10.4 min (2*S*,3*R*), 8.6 min (2*R*,3*S*); $[\alpha]_D^{20} = +8.75$ ($c = 0.13$).

5: Chiralcel AD, *i*PrOH/hexane (1/9), 0.80 mL min^{-1}, 40.7 min (2*S*,3*S*), 27.0 min (2*R*,3*R*); $[\alpha]_D^{20} = -5.4$ ($c = 1.2$; mother liquor after two recrystallizations from toluene).

6: Chiralcel OB, *i*PrOH/hexane (1/9), 0.70 mL min^{-1}, 54.7 min (2*R*), 68.9 min (2*S*); $[\alpha]_D^{20} = -17.6$ ($c = 0.80$).

7: Chiralcel AD, *i*PrOH/hexane (5/95), 0.60 mL min^{-1}, 44.2 min (1*S*,2*R*), 25.6 min (1*R*,2*S*); $[\alpha]_D^{20} = +19.8$ ($c = 1.5$).

8: Chiralcel OD-H, *i*PrOH/hexane (3/7), 0.70 mL min^{-1}, 10.7 min (1*S*,2*S*), 12.6 min (1*R*,2*R*); $[\alpha]_D^{20} = -7.8$ ($c = 0.57$).

Table 2. Results of AA reactions with EtOCONClNa.

[a] Major product from the reaction using $(DHQ)_2PHAL$. [b] Yields of the reactions using $(DHQ)_2PHAL$. [c] CH_3CN/H_2O was used as the solvent.

2: Chiralcel AD, *i*PrOH/hexane (3/7), 0.70 mL min^{-1}, 9.7 min (2*S*), 13.8 min (2*R*); $[\alpha]_D^{20} = +50.9$ ($c = 0.32$).
9: Chiralcel AD, *i*PrOH/hexane (1/9), 0.70 mL min^{-1}, 18.8 min (2*S*), 27.0 min (2*R*); $[\alpha]_D^{20} = +30.0$ ($c = 0.55$).
10: Chiralcel OD-H, *i*PrOH/hexane (15/85), 0.60 mL min^{-1}; 11.6 min (2*S*,3*R*), 12.6 min (2*R*,3*S*); $[\alpha]_D^{20} = +2.78$ ($c = 0.90$).
11: Chiralcel AD, *i*PrOH/hexane (1/9), 0.70 mL min^{-1}, 30.3 min (2*S*,3*R*), 19.5 min (2*R*,3*S*); $[\alpha]_D^{20} = +17.9$ ($c = 0.43$).
12: Chiralcel AD, *i*PrOH/hexane (1/9), 1.0 mL min^{-1}, 40.1 min (2*S*,3*R*), 23.9 min (2*R*,3*S*); $[\alpha]_D^{20} = +16.5$ ($c = 0.67$).
13: Chiralcel AD, *i*PrOH/hexane (1/9), 1.0 mL min^{-1}, 26.2 min (2*R*,3*R*), 18.0 min (2*S*,3*S*); $[\alpha]_D^{20} = -38.2$ ($c = 0.10$).

Assignment of the absolute configurations: The methyl cinnamate derivative **3** was converted into an authentic sample of the methyl ester of the taxol side chain by hydrogenolysis (Pd/C) and subsequent Schotten–Baumann acylation [3] [HPLC: Chiralcel AD, 10% *i*PrOH/hexane (1/9), 1 mL min^{-1}, 19.1 min (2*R*,3*S*), 22.1 min (2*S*,3*R*)] [1]. The methyl 2′,6′-dimethylcinnamate derivative **4** was assumed to have the same configuration as the methyl cinnamate derivative **3**. The signs of the rotations for the Z-protected derivatives of the dimethyl fumarate derivative **5** and the methyl acrylate derivative **6** were compared to the literature values; (2*R*,3*R*)-**5**: $[\alpha]_D^{25} = -22.6$ ($c = 2.0$ in $CHCl_3$); (2*S*,3*S*)-**5**: $[\alpha]_D^{25} = +24.2$ ($c = 1.0$ in $CHCl_3$) [21]; (2*R*)-**6**: $[\alpha]_D^{20} = -17.7$ ($c = 1.3$ in CH_3OH); (2*S*)-**6**: $[\alpha]_D^{20} = +18.8$ ($c = 1.42$ in CH_3OH) [22]. Cyclohexene derivative **7** and *trans*-stilbene derivative **8** were correlated with authentic samples of their *p*-toluenesulfonamide analogs by hydrogenolysis (Pd/C), followed by *N*-tosylsulfonylation [HPLC for sulfonamide from **7**: Chiralcel OG, 15% *i*PrOH/hexane, 1 mL min^{-1}, 14.3 min (1*S*,2*R*), 17.6 min (1*R*,2*S*). HPLC for sulfonamide from **8**: Chiralcel OD-H, 15% *i*PrOH/hexane, 1 mL min^{-1}, 14.3 min (1*S*,2*R*), 17.6 min (1*R*,2*S*)]. Styrene derivative **9** was converted into (*S*)-(+)-2-phenylglycinol, $[\alpha]_D^{25} = +29.8$ ($c = 0.5$ in 1 N HCl), $[\alpha]_D^{25} = +33$ ($c = 0.75$ in 1 N HCl) (Aldrich). The $RuCl_3/H_5IO_6$ oxidation of **9** also provided the known N^{α}-(benzyloxycarbonyl)-L-phenylglycine. Vinylnaphthalene derivative **2** was assumed to have the same configuration as styrene derivative **9**. Methyl cinnamate derivative **10** was compared with a sample that was prepared from the known toluenesulfonamide analog [1,3]. Compounds **11**–**13** were assumed to have the same configuration as **10**.

[14] In reexamining the results of the old experiments [9, 11] one sees that only trace amounts of water were used (2–4.5 equiv based on olefin (1% of total solvent)), probably due to concern that the $O_3Os{=}NCOOR$ species might hydrolyze to OsO_4 faster than it reacted with the olefin. In any case, it is frustrating to realize how very close, and on how many different occasions, one can come to the "right" conditions over years of experimenting, and still miss the target zone or zones within which the reaction conditions support useful, or at least detectable, catalytic turnover. – Metal-catalyzed redox processes are inherently multistep reactions, and the principal challenge in developing them is to find reaction conditions under which each of the steps can function at an acceptable rate. The search is guided above all by the knowledge that compromises are inevitable. A given set of reaction conditions can never be optimal for all the component reactions of the cycle. The slowest step constitutes the turnover-limiting step and defines the throughput (turnover rate) of the entire system [15]. In terms of the utility of a catalyst, the turnover rate (activity) is "not everything, it is the only thing" (paraphrased from a quote about the importance of winning, attributed to Vince Lombardi). – The complexity and interdependence of catalytic cycles means that "apparently" minor variations in the reaction conditions sometimes have major effects on the catalytic activity. This has certainly been the case for osmium-catalyzed oxidations of olefins, for which the maximum turnover rates (v_{max}) are virtually always identical with the rates for hydrolytic release of the chelated diol or amino alcohol product from the osmium coordination sphere. This is probably the least "interesting"

step in the entire sequence, but in catalysis every step in the cycle is by definition of equal importance.

[17] The oxidation of the Z-protected amino alcohol from styrene (see Experimental Procedure) gave the Z-protected aryl glycine in roughly 80% yield and with no loss of enantiomeric purity. The scope of this two-step amino acid synthesis will be reported soon: K. L. Reddy, G. Li, K. B. Sharpless, unpublished results.
[18] We strongly recommend using *tert*-butyl hypochlorite that has been freshly prepared following the procedure described in M. J. Mintz, C. Walling, *Org. Synth. Coll. Vol. V* **1983**, 183–187. This material has proven reliable for up to two months if it is kept and dispensed under cold (at roughly 4 °C) and dry conditions. Some commercially obtained samples of *tert*-butyl hypochlorite have given substandard enantioselectivities and yields, probably because they were stored for longer periods at or above room temperature and/or not under dry conditions.

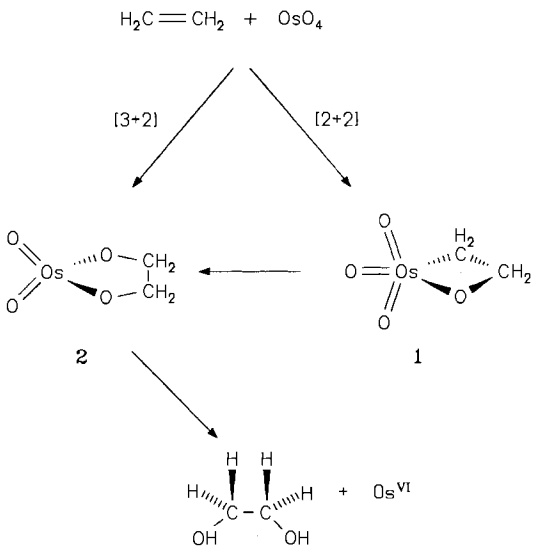

Scheme 1. Reaction course for the *cis*-dihydroxylation of olefins with OsO_4 as suggested by Sharpless.

Theory Rules Out a [2+2] Addition of Osmium Tetroxide to Olefins as Initial Step of the Dihydroxylation Reaction**

Ulrich Pidun, Christian Boehme, and Gernot Frenking*

The addition of OsO_4 to olefins yielding *cis*-diols has become an intensively investigated reaction in stereoselective synthesis since Sharpless developed the catalytic version of the reaction into a powerful method for highly enantioselective functionalization of olefins using cinchona alkaloids as ligands.[1] The transfer of the stereochemical information of the chiral ligand to the substrate was explained by Sharpless with a two-step mechanism for the addition reaction (Scheme 1), which should occur rather than a concerted [3 + 2] addition as originally proposed by Criegee.[2] It was suggested that the initial step of the reaction course is a [2 + 2] addition yielding the metallaoxetane **1**, which then rearranges to the cyclic ester **2**.[3] The barrier for the bond migration **1** → **2** must be very low, because intermediates of structure **1** have never been observed, whereas base adducts of **2** are well known.[4]

Strong support for a two-step mechanism of the osmylation reaction came from kinetic studies, which revealed a nonlinear correlation between the temperature and the enantioselectivity of the reaction.[5a] More recently kinetic studies of the addition of OsO_4 to various olefins both in the presence and the absence of a base (pyridine) have been carried out.[5b] In all cases the Eyring plots showed *two* linear regions. It follows that even the base-free osmylation appears to proceed by a two-step mechanism.

In a previous theoretical study at the QCISD(T)//HF level of theory we could show that the postulated intermediate **1** and the elusive base adduct **1**·NH_3 are indeed minima on the potential energy surfaces.[6] The metallaoxetane **1** was calculated to be 30.5 kcal mol^{-1} higher in energy than the osmate ester **2**. The reaction of ethylene with osmium tetroxide yielding **1** was predicted to be endothermic by +18.3 kcal mol^{-1}, while the [3+2] addition yielding **2** was calculated to be exothermic by −12.2 kcal mol^{-1}.[6] The activation barriers for the two reactions and for the rearrangement **1** → **2** were not given, however. In this paper we present the calculated transition states for the [2+2] and [3+2] additions of OsO_4 to C_2H_4 and for the rearrangement **1** → **2** using density functional theory (DFT)[7] in conjunction with a relativistic effective core potential (ECP) for osmium.[8] We also calculated the transition states for the base-catalyzed reaction using $OsO_4(NH_3)$ as model compound. The reaction energies and activation barriers for the base-free reaction are predicted at the CCSD(T) level of theory[9] with DFT optimized geometries. The nature of the transition states was analyzed by IRC (intrinsic reaction coordinate) calculations. The NH_3 complexed structures were studied only at the DFT level.[10]

Figure 1 shows the calculated geometries of the molecules and the transition states, optimized at B3LYP with basis set II.[10] The theoretically predicted Os–O distance for OsO_4 (1.716 Å) is in excellent agreement with the experimental value (1.711 Å).[11] The calculated geometry of the complex **2**·NH_3 is also in accord with the X-ray structure analyses of related cinchona alkaloid complexes of Os^{VI}.[12] The observed Os–N distances are 2.243(5) and 2.27(2) Å; the calculated value is 2.264 Å.

Figure 2 shows the calculated reaction profile for the base-free reaction. The theoretical reaction energy at CCSD(T)/II//B3LYP/II for the reaction $C_2H_4 + OsO_4 \rightarrow$ **1** is +11.1 kcal mol^{-1}, while the formation of **2** is exothermic (−21.2 kcal mol^{-1}). The [2+2] and [3+2] reactions are calculated to be thermodynamically slightly more favorable than determined in our previous work,[6] which is due to the different methods used in the two studies. The energy difference between **1** and **2** calculated here (32.3 kcal mol^{-1}) is very similar to our previous result (30.5 kcal mol^{-1}).[6]

The most important results of the present study are the activation barriers for the reactions. Figure 2 shows that the activation barrier at CCSD(T)/II[10] for the [2 + 2] addition yielding **1** is very high (44.7 kcal mol^{-1}). In contrast, the activation barrier for the [3 + 2] addition is much lower (9.6 kcal mol^{-1}). The

[**] Theoretical Studies of Organometallic Compounds, Part 24. This work has been supported by the Deutsche Forschungsgemeinschaft (SFB 260, Graduiertenkolleg Metallorganische Chemie) and the Fonds der Chemischen Industrie. We thank Dr. P.-O. Norrby for helpful comments. Part 23: S. Dapprich, G. Frenking, *Organometallics* **1996**, *15*, 4547.

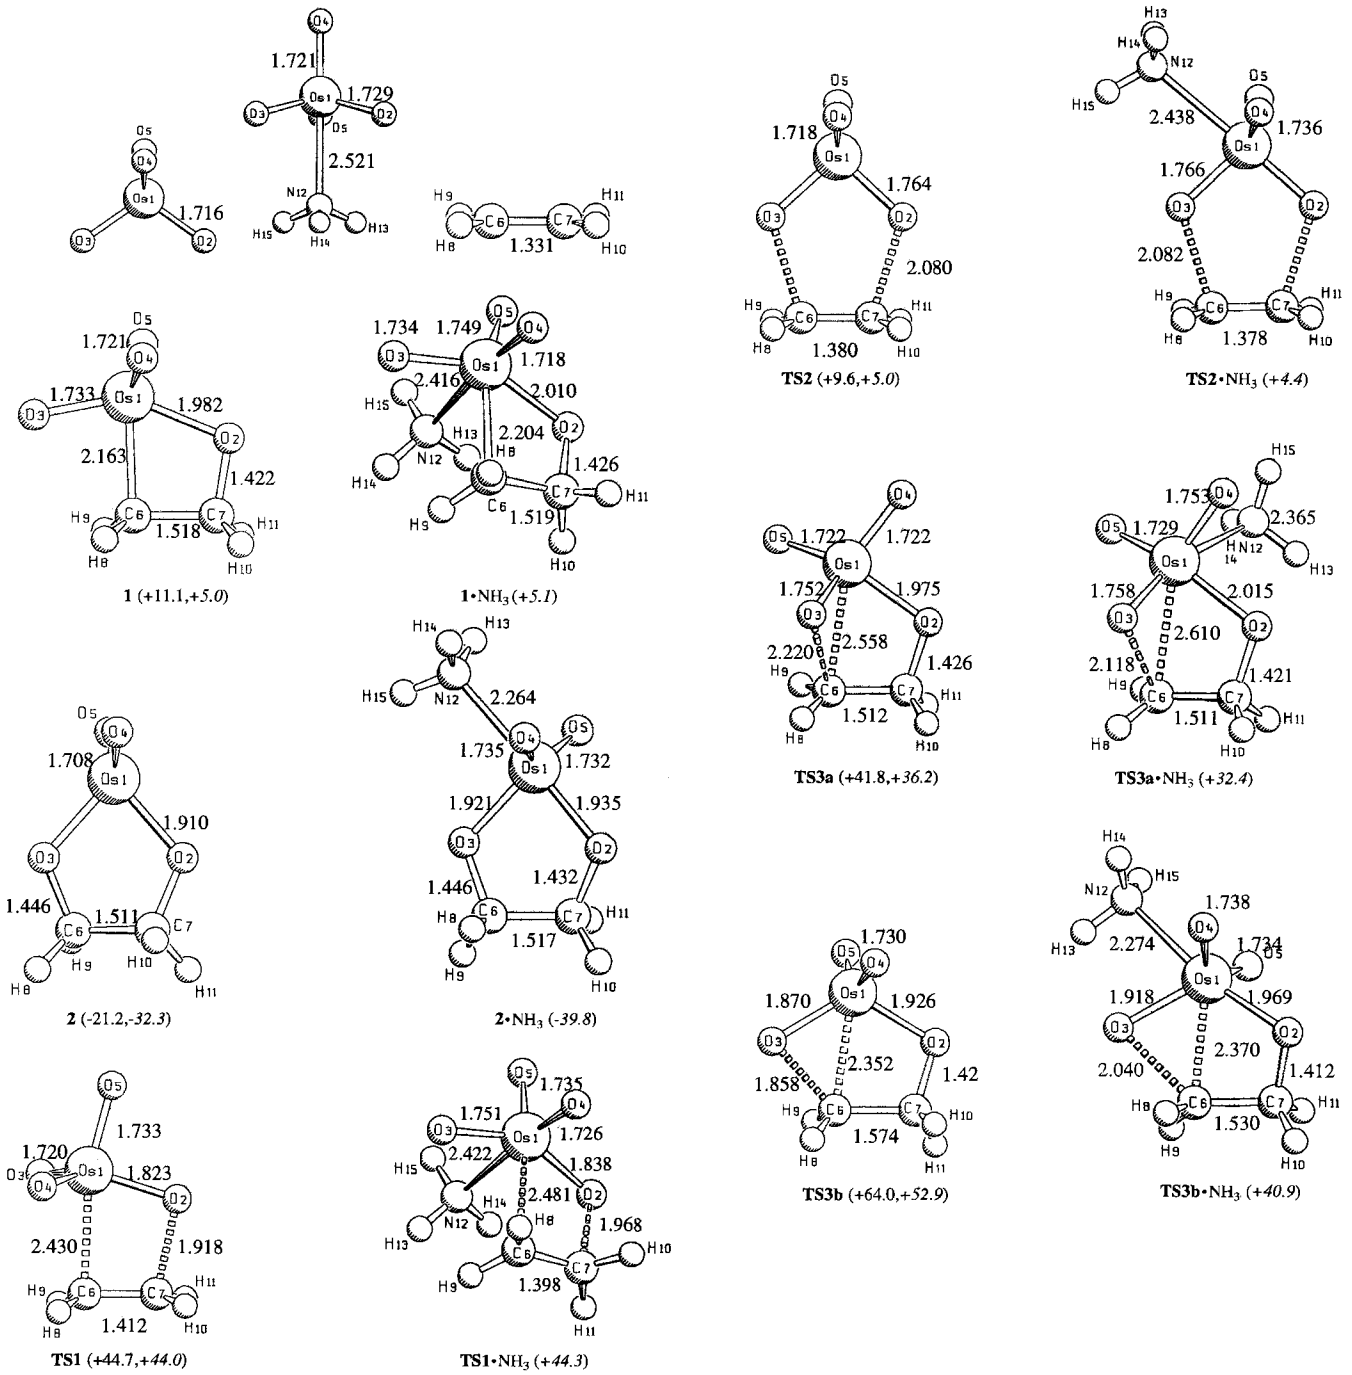

Fig. 1. Optimized geometries of energy minimum structures and transition states at B3LYP/II (distances in Å, energies in kcal mol^{-1} relative to that of the reactants ($OsO_4 + C_2H_4$ or $OsO_4(NH_3) + C_2H_4$) at CCSD(T)/II; values in italics refer to B3LYP/II energies).

energy differences change only slightly when zero-point energy contributions are considered. The energies at B3LYP give essentially the same reaction profile as the CCSD(T) values (Fig. 2). The large difference in the barrier heights for the two reactions does not agree with the suggestion that both mechanisms play a role in the course of the reaction, and that the dominance of one mechanism over the other depends on temperature.[5b] Such a scenario would require that the activation energies are much closer.

The calculations gave two transition states **TS3a** and **TS3b** for the rearrangement **1** → **2**. **TS3a** is the transition state along the reaction coordinate for the bond formation between C6 and the out-of-plane oxygen atom, whereas **TS3b** belongs to the bond formation between C6 and the in-plane oxygen atom (Fig. 1). **TS3a** is clearly lower in energy than **TS3b**. The barrier for the rearrangement **1** → **2** given by **TS3a** (41.8 kcal mol^{-1}) is still high, however, when compared with the activation barrier for the [3+2] addition given by **TS2** (9.6 kcal mol^{-1}). The theoretically predicted activation barriers for the base-free addition of OsO_4 to olefins (Fig. 2) rule out the competition between the stepwise [2+2] addition reaction and the [3+2] cycloaddition.

Does the reaction profile for the osmylation reaction in the presence of a base differ significantly from that of the base-free reaction? The answer is no! Figure 1 shows the optimized transition state structures **TS1**·NH_3 for the [2+2] addition and

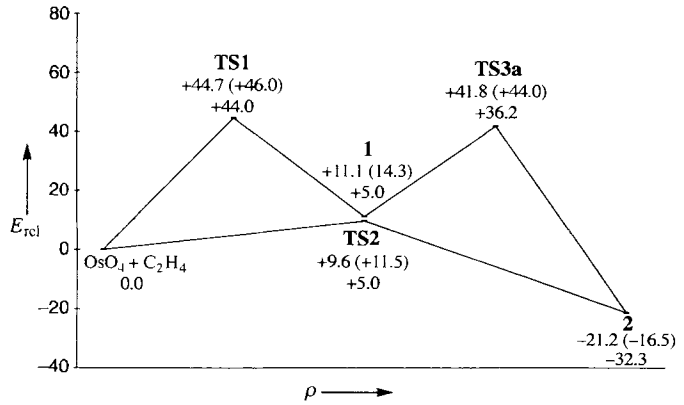

Fig. 2. Calculated reaction profile of the addition of OsO_4 to ethylene at CCSD(T)//B3LYP using basis sets as described in reference [10] (relative energies in kcal mol^{-1}; values in parentheses include ZPE contributions; values in italics refer to B3LYP energies).

TS2·NH_3 for the [3+2] addition of the $OsO_4(NH_3)$ adduct to C_2H_4. The activation barrier for the [3+2] addition in the presence of NH_3 is lower in energy (4.4 kcal mol^{-1} at B3LYP/II) than that of the base-free [3+2] reaction (5.0 kcal mol^{-1}). This is in agreement with the observed acceleration of the osmylation reaction by a base. The activation barrier for the [2+2] addition in the presence of NH_3 remains much higher than for the [3+2] reaction. Transition state **TS1**·NH_3 is energetically 44.3 kcal mol^{-1} (B3LYP/II) above the reactants and 39.9 kcal mol^{-1} higher in energy than **TS2**·NH_3. The calculated geometries of the transition states **TS1**·NH_3 and **TS2**·NH_3 are very similar to the geometries of **TS1** and **TS2**, respectively. The same holds true for the transition states of the rearrangement **TS3a**·NH_3 and **TS3b**·NH_3 relative to **TS3a** and **TS3b** (Fig. 1). The barrier height for the rearrangement **1** → **2** in the presence of NH_3 is slightly lower than without the base, but it still remains very high. The presence of a base therefore does not change the reaction profile of the osmylation reaction significantly. While the absolute values of the calculated activation barriers may change at different levels of theory, it is highly unlikely that the *relative* barrier heights for the concerted and stepwise reactions will change a lot.[13]

To make sure that the optimized transition states belong to the desired reaction courses, we calculated the intrinsic reaction coordinates (IRC)[14] starting from the transition state structures **TS1**, **TS2**, **TS3a**, and **TS3b** (Fig. 1). The results of the IRC calculations confirmed that **TS1** and **TS2** are the transition states for the [2+2] and [3+2] addition, respectively, and that **TS3a** and **TS3b** are transition states for the bond migration **1** → **2**. The high barriers for the [2+2] addition and for the bond migration **1** → **2** suggest that these reactions are symmetry forbidden, while the [3+2] addition is symmetry allowed. A previous frontier orbital study of the possible reaction mechanism by Jørgensen and Hoffmann did not conclusively discriminate between reaction paths via **1** and **2**, but arguments were given in favor of the [3+2] over the [2+2] addition.[15] The more quantitative results presented here indicate that the difference in the activation barriers is much higher than that deduced from the qualitative orbital diagrams. It is noteworthy that the geometry changes from **TS1** to **1** involve a rotation of the OsO_3 moiety about the Os–O2 axis (Fig. 1). In **TS1** an oxygen atom is *trans* to the incipient Os–C6 bond, whereas in **1** an oxygen is *trans* to the Os-O2 bond. The reaction path is clearly different from a least-motion path. This is a further hint that the reaction proceeds by an orbital-symmetry forbidden pathway.

While the results of the calculations show clearly that the [2+2] addition of OsO_4 to olefins can not compete energetically with the [3+2] addition, the calculations cannot explain the results of the kinetic studies of Sharpless et al.,[5] which indicate that two different mechanisms are operating in the ligand-free osmylation reaction. We want to point out, however, that an alternative mechanistic model for the enantioselective asymmetric dihydroxlation suggested by Corey assumes that the reaction proceeds by a [3+2] cycloaddition.[16] This model would be in better agreement with our calculations. Very recent experimental tests of the [3+2] and [2+2] pathways by means of $^{12}C/^{13}C$ kinetic isotope effects have shown that the [3+2] model is in accord with the experimental results, while the [2+2] model is not.[16d] The remaining puzzle concerns the interpretation and understanding of the kinetic measurements of Sharpless, which unequivocally show an inversion point in the Eyring diagram of the dihydroxylation.[5] A very recent kinetic study of Heller et al.[21] showed that a nonlinear temperature behavior of product ratios in selection processes may possibly be due to a distortion of the reactant equilibrium. Another explanation might be an intramolecular exchange between the diastereomeric substrate complexes, which has been determined for 7-membered chelates.[22] Further experimental studies appear necessary to clarify this point.

Although our previous theoretical study showed that the stepwise mechanism of the osmylation reaction by [2+2] addition might be possible, because the postulated metallaoxetane is indeed an intermediate that is not too high in energy,[6] the calculated activation barriers presented here and the experimentally observed kinetic isotope effects[16d] suggest that the reaction proceeds by a concerted [3 + 2] pathway as originally suggested by Criegee.[2]

[10] The program packages Gaussian 94 [17a] and ACESII [17b] have been used for the calculations. The geometries were optimized at the DFT level with the nonlocal hybrid functionals B3LYP of Becke [18]. A quasi-relativistic effective core potential (ECP) [8] for osmium (small core) with a (441/2111/21) basis set for the 16 valence and outer-core electrons in conjunction with a 6-31G(d) basis set for the other atoms was used. This is our standard basis set II [19]. The vibrational frequencies and the intrinsic reaction coordinates [14] were calculated at the same level of theory (B3LYP/II). Improved total energies of the base-free species were calculated at the CCSD(T) level [9] with the same basis

set II, except that for computational reasons an STO-3G basis set was employed for hydrogen. The accuracy of the CCSD(T) level of theory for calculating energies of transition metal compounds has been documented [19]. CCSD(T) calculations of the NH_3-complexed species could not be carried out for technical reasons (<2 GByte size limit for a single file). The accuracy of B3LYP calculations is also well known [20].

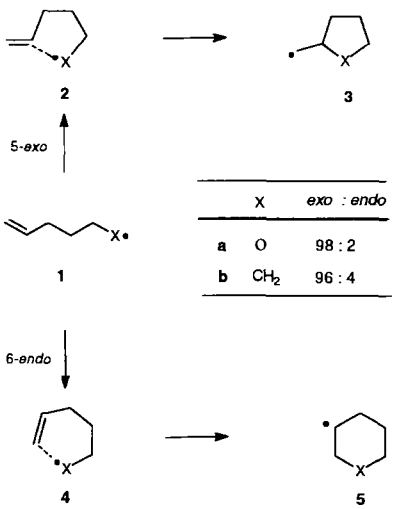
5-*exo* or 6-*endo*? Exploring Transition State Structures in Cyclizations of 4-Penten-1-oxyl Radicals**

Jens Hartung,* Ralf Stowasser, Daniel Vitt, and Gerhard Bringmann*

Dedicated to Professor Siegfried Hünig on the occasion of his 75th birthday

A recent study on stereoselective ring closures of substituted 4-penten-1-oxyl radicals indicates that transformations involving alkoxyl radicals may indeed be free radical reactions with notable synthetic utility.[1] Despite the high reactivity ($k^{exo} = (5 \pm 2) \times 10^8\ s^{-1}$) the 4-penten-1-oxyl radical **1a** cyclizes regioselectively; derivatives of **1a** even react stereoselectively. To uncover the origin of the high *exo* selectivity of the cyclization, the isoelectronic, all-carbon derivative **1b** of the 4-penten-1-oxyl radical **1a** has been the subject of several semiempirical and low-level ab initio calculations.[2] However, the prediction of radical selectivities in cyclization reactions remained a difficult task, because treatment of open-shell molecules with unrestricted Hartree–Fock (UHF) methods led in most of the cases to "spin contamination" in the transition states. To account for these problems and to obtain more reliable energy values in general, the computed heats of formation were often corrected by additional time-consuming configuration interaction calculations (CI calculations).[3]

Several new developments in the theoretical treatment of radical additions to olefins[3] sparked our interest in a more detailed description of the 5-*exo* (**1a** → **3a**) and the competitive 6-*endo* (**1a** → **5a**) cyclizations of the 4-penten-1-oxyl radical. We now



report on our results of semiempirical (AM1, PM3) and selected ab initio calculations (UHF/6-31G*, UQCISD/6-31G*//UHF/6-31G*, UHF/6-31+G*, UHF/6-311+G*) UBP/DZVP i.e. DFT[4]). We have included the 5-hexen-1-l radical (**1b**) in our studies, because according to our knowledge it had not been investigated by these methods previously.

All the methods used predict that the lowest energy transition structures **2** and **4** resemble cyclohexane chairs (Fig. 1).[5, 6] However, structures **2a** and **2b** are significantly flattened and more reminiscent of envelope conformations of the corresponding saturated five-membered ring compounds. The most important geometrical parameters, the distances between the radical center and the carbon atom C5 (r_1) and the second carbon C6 of the π-bond (r_2), the angle of attack (φ), and the torsion angles δ_1 and δ_2, which indicate the degree of rehybridization at C5 and C6 in the transition state, vary markedly depending on the computational method (Fig. 2, Table 1). The calculated relative heats of formation (ΔH_f) and corresponding expectation values of the respective spin operators $\hat{S}^2$ ($<\hat{S}^2>$ values) of the intermediates **1**–**5** are listed in Tables 2 and 3.

The data in Table 2 indicate that the semiempirical methods are not suitable for the description of the alkoxyl radical ring closures. Even considering the uncertainties of semiempirical methods, AM1 still predicts the formation of the thermodynamically favored 6-*endo* product **5a**, as judged by the differences in the enthalpies of activation $\Delta H^{\neq}_{exo} - \Delta H^{\neq}_{endo} = \Delta\Delta H^{\neq}$. PM3 does not lead to a clear-cut result.[7] However, the results of ab initio calculations are generally more satisfactory, and in some cases they are in excellent agreement with the experimental values.

H. and R. S. as well as equipment). We thank Dipl.-Chem. Martin Stahl for helpful discussions.

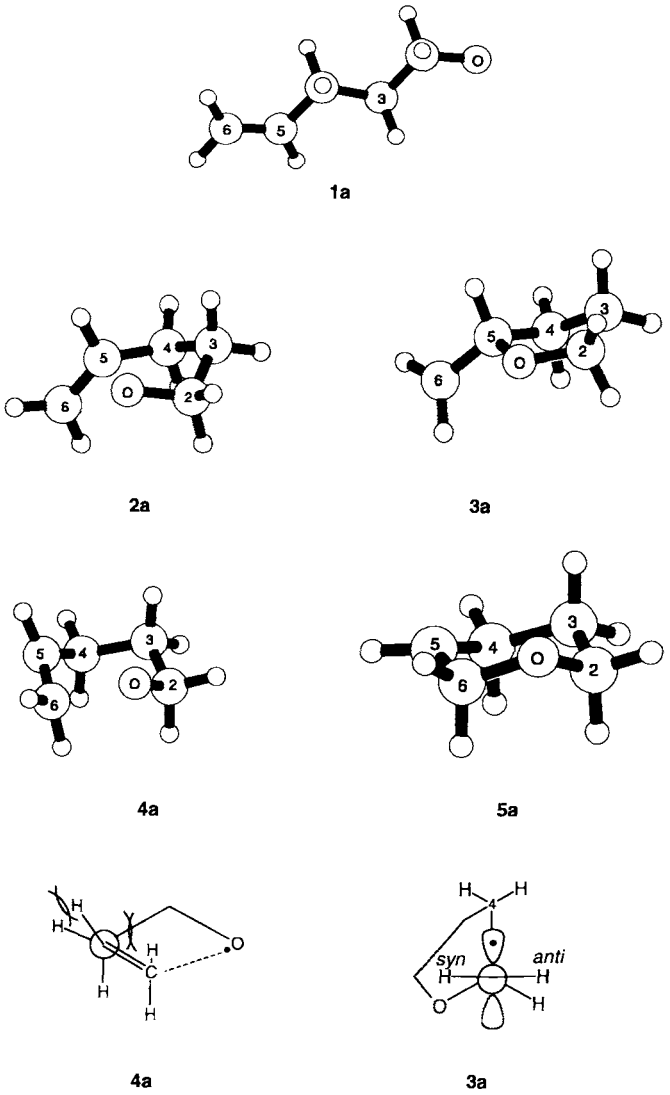

Fig. 1. Top: Computed structures (UHF/6-31G*) of radicals **1a**–**5a**. The structures **2a** and **4a** show the transition state structures of the 5-*exo* and 6-*endo* reactions, respectively. Bottom: The representation of the 5-*exo* product **3a** shows the coplanar arrangement of the unpaired electron and the C5–C4 bond of the heterocyclic ring (C4-C5-C6-H6*syn* = 83.08°, C4-C5-C6-H6*anti* = −83.14°) [5]. The Newman projection along the C5–C4 bond of the 6-*endo-trig* transition state structure **4a** indicates the torsional strain between the hydrogen atoms at C5 and the *syn* hydrogens bound at C4 and C6 [6].

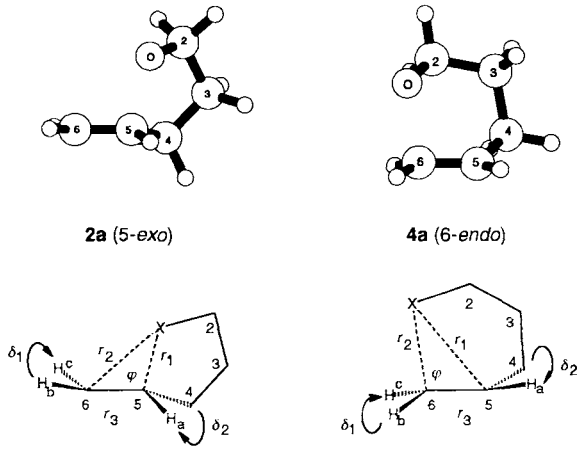

Fig. 2. Top: The calculated transition state structures for the 5-*exo* (**2a**) and 6-*endo* (**4a**) (UHF/6-31G*) cyclizations of the 4-penten-1-oxyl radical (**1a**). Bottom: Schematic representation of the geometric parameters used to describe the 5-*exo* and of the 6-*endo* transition state structures **2** and **4**. δ_1 corresponds to angle C5-C6-Hb-Hc, δ_2 angle C6-C5-C4-Ha, φ angle X-C5-C6 for the *exo* attack and X-C6-C5 for the *endo* approach of the radical.

Table 1. Parameters for describing the transition state structures for the 5-*exo* and 6-*endo* cyclizations of the 4-penten-1-oxyl (**1a**) and of the 5-hexenyl radical (**1b**) at different levels of theory.

The UHF/3-21G*-computed $\Delta\Delta H^{\neq}$ value is $-3.90\ kJ\,mol^{-1}$. When a larger basis set is used for the calculations (UHF/6-31G*), the difference in the activation enthalpies is even more pronounced ($\Delta\Delta H^{\neq} = -9.70\ kJ\,mol^{-1}$), which is in good agreement with the experimentally determined $\Delta\Delta G^{\neq}$ value of this reaction at 298 K ($-9.50\ kJ\,mol^{-1}$ [1, 8]). When the heats of formation of the UHF/6-31G*-optimized structures are corrected with UQCISD calculations, the $\Delta\Delta H^{\neq}$ value increases to $-4.75\ kJ\,mol^{-1}$. For the description of the 5-*exo* and the competitive 6-*endo* reaction, UQCISD/6-31//UHF/6-31G* corrections are inferior to calculations with a more flexible basis set (UHF/6-31+G*, $\Delta\Delta H^{\neq} = -7.30\ kJ\,mol^{-1}$). It is likely that the latter method better accounts for the diffuse electron distribution at the reacting centers and the double bond being attacked. However, computational studies on our structures using a triple-zeta basis set (UHF/6-311+G*) do not improve the $\Delta\Delta H^{\neq}$ values significantly in spite of prolonged computation time.[9] Density functional calculations (UBP/DZVP) are often faster to perform, and although the resulting calculated *exo*:*endo* ratio ($\Delta\Delta H^{\neq} = -5.59\ kJ\,mol^{-1}$) is lower than the experimental value, this method seems to be a useful alternative to the other ab initio methods (Table 2). Future studies will show whether this result is of general significance.

The results obtained for the cyclizations of the 5-hexenyl radical (Table 3) are qualitatively similar to the data for the reactions of the alkoxyl radical **1a**. The AM1 approximation predicts the formation of the 6-*endo* intermediate **5a** as the major product. However, the results from UHF/6-31G* calculations without corrections ($\Delta\Delta H^{\neq} = -8.75\ kJ\,mol^{-1}$) and with UQCISD/6-31G*//UHF/6-31G* corrections ($\Delta\Delta H^{\neq} =$

[a] The ΔH_f values from the AM1 calculations are ZPVE corrected. All ΔH_f values from ab initio calculations are ZPVE corrected, but not temperature corrected (1 Hartree = 2627.26 kJ mol^{-1}). [b] ΔH_{exo} = 38.5 kJ mol^{-1} (AM1), 47.01 kJ mol^{-1} (UHF/6-31G*//UHF/6-31G*), 36.29 kJ mol^{-1} (UQCISD/UHF/6-31G*//UHF/6-31G*), 20.41 kJ mol^{-1} (UBP/DZVP). [c] ΔH_{endo} = 33.50 kJ mol^{-1} (AM1), 55.76 kJ mol^{-1} (UHF/6-31G*//UHF/6-31G*), 45.56 kJ mol^{-1} (UQCISD/6-31G*//UHF/6-31G*), 26.69 kJ mol^{-1} (UBP/DZVP).

The ab initio procedures locate the transition state structures at different points on the potential energy surface. UHF/6-31G* calculations give a rather tight 5-*exo* transition state structure (r_1 = 1.907 Å), while UBP/DZVP computations set the reacting centers in the transition state 0.261 Å further apart. In general, the differences in r_1 (X–C5) for the 5-*exo* reaction and r_2 (X–C6) for the 6-*endo* reaction of alkoxyl radical **1a** are negligible, but the angle φ of attack is smaller in the *endo* approach of the incoming O-radical by 4.91° (UHF/6-31G*) and 8.70° (UBP/DZVP) than in the *exo* attack. The same angle φ is larger for the computed C-radical additions than for the alkoxyl radical cyclizations.

The intramolecular addition of the radical center (e.g. X = O in **2a**) to the C–C double bond causes a slight change in hybridization at C5 and at C6; in transition states **2** and **4** the torsion angles δ_1 = C5-C6-Hb-Hc and δ_2 = C6-C5-C4-Ha deviate significantly from 180°.[2c] The hydrogen atoms at the attacked carbon move slightly away from the oxygen atom, while the adjacent H atoms of the C–C double bond point towards the radical center (Fig. 2). These changes in geometry are of minor significance for the 5-*exo-trig* reaction (e.g. **1a** → **3a**). In the course of C–O bond formation the torsional strain between the *syn* hydrogens at C5 and at C6 is continuously minimized due to the transformation of the C–C double bond into a single bond and the resulting gain in rotational freedom of the *exo* methylene group. The product of the 5-*exo-trig* cyclization of the alkoxyl radical **1a** is the tetrahydrofurylmethyl radical **3a**, which shows a coplanar arrangement of the β-C–C bond and the radical center in the lowest energy conformer.[5a] In the course of the 6-*endo* reaction **1a** → **5a** the changes in δ_1 and in δ_2 described above lead to more severe torsional strain. The formation of the C–O bond is accompanied by a significant change in geometry at C5 and repulsive interactions due to the movement of H5 past the *syn* hydrogens at C4 and at C6 for the formation of the 6-*endo* product **5a**, which has an almost planar radical center C5[6a, 11] (Fig. 1, bottom). This torsional strain is possibly one of the reasons for the kinetic preference of the 5-*exo-trig* reaction of the 4-pentenoxyl radical **1a** and the isoelectronic 5-hexenyl radical **1b**.

The results of the theoretical treatment of the reactions of **1b** are slightly different from those of previous studies. The reacting centers are further apart in the 6-*endo* transition state structure than in the 5-*exo* transition state structure (UHF/6-31G*: Δr_1 = 0.074 Å; UBP/DZVP: Δr_1 = 0.117 Å), which could be caused by torsional strain in the reaction **1b** → **5b** as mentioned above. The large separation between the reacting centers in all transition states in UBP/DZVP calcula-

−9.27 kJ mol^{-1}) are in accord with the experimental value of $\Delta G^{\neq}$ (298 K) = −7.87 kJ mol^{-1}.[8, 10] The difference of the UBP/DZVP-computed relative heats of formation ($\Delta\Delta H^{\neq}$ = −6.80 kJ mol^{-1}) is even closer to the experimental value than in case of the 4-pentenoxyl radical reaction.

tions is significant, and future studies will show whether these findings are limited to the systems here or a general feature for density functional treatments of 5-hexenyl and related radical rearrangements.

In conclusion we have been able to draw a clear picture of the lowest energy transition state structures of the cyclizations of 4-penten-1-oxyl radical by ab initio methods. Semiempirical calculations are not suited for our calculations on open-shell molecules; however, computational studies on radicals **1**–**5** using UHF/6-31G* and UBP/DZVP methods provide results that are qualitatively and quantitatively in good agreement with the experimental findings.

Computational Methods

Semiempirical calculations were performed on an SGI IRIS INDIGO R4000/R4400 workstation with the program package VAMP 5.0/5.5 [12]. All other ab initio calculations were performed on a CRAY Y-MP/8-128 computer using the Gaussian 92 program [13] (Hartree–Fock approach) and DGauss 3.0 [14] (density functional approach). The UHF/6-31G*-minimized structures of radicals **1**, **3** and **5** were determined by using the default optimization algorithm as implemented in Gaussian 92. The DFT geometries of radicals **1**, **3** and **5**, were minimized by means of a Newton–Raphson/DFGS optimization technique using a unrestricted nonlocal SCF spin-density approach with the Becke–Perdew functional. A DZVP basis set was used and the electron density was fitted by means of a triple-zeta A1 set. The transition state geometries were optimized with the optimization algorithm by Baker (UHF) and the standard algorithm (DF) after full calculation of the hessian matrix. Force calculations were applied to characterize minima and transition structures by calculation of their normal vibrations.

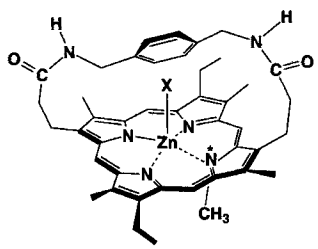
Recognition of the Helical Sense of Polypeptides by a Chiral Metalloporphyrin Receptor**

Katsuaki Konishi, Shu-ichi Kimata, Kiyoko Yoshida, Masanobu Tanaka, and Takuzo Aida*

Recognition of the secondary structures of biologically important macromolecules by synthetic receptors is a fascinating and challenging goal in biomimetic and supramolecular chemistry. Although the recognition of DNA helices has been successful,[1] examples are very limited for the recognition of the secondary structures of polypeptides in solution.[2] Herein we report the first example of the recognition of the helical sense of poly(glutamic acid) (PGA)[3] by using a chiral metalloporphyrin receptor (**1a**) having an α,α′-xylylenediamide strap. We have found that **1a** is capable of enantioselectively binding amino acid derivatives by means of axial ligand exchange.[4]



1a X = OAc
1b X = Cl

Poly(L-glutamic acid) (L-PGA) assumes a right-handed α-helical structure in aqueous CH_3OH or CH_3CN over a pH range of 3–8.[5] Addition of racemic

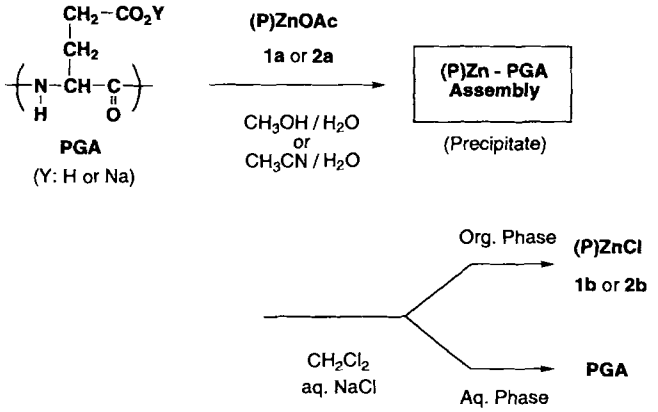
[**] This work was partly supported by Ministry of Education, Science, Sports, and Culture, Japan (Grant-in-Aid for Scientific Research No. 05234207). Compounds **1a,b** and **2a,b** were derived from mesoporphyrin II and etioporphyrin I with enantiotopic faces, respectively, and a stereogenic center at the alkylated nitrogen atom.

Table 1. Asymmetric binding of PGA with **1a** and **2a** [a].

Entry	Receptor	Medium	PGA		Product [d]	**1b** or **2b**
			P [b]	Conf. [c]	Yield [%] [e]	(*R*)/(*S*) (*ee*)[%] [f] [g]
1	**1a**	CH_3OH/H_2O (3/1, acidic)	186 L	α-helix	41	18.5/81.5(63)
2	**1a**	CH_3OH/H_2O (3/1, acidic)	84 L	α-helix	nd	32.5/67.5(35)
3	**1a**	CH_3CN/H_2O (3/1, acidic)	84 L	α-helix	nd	16.5/83.5(67)
4	**1a**	CH_3CN/H_2O (0.6/1, acidic)	84 L	α-helix	34	33.5/66.5(33)
5	**1a**	CH_3OH/H_2O (3/1, basic)	84 L	random coil	22	53.5/46.5(7)
6	**1a**	CH_3CN/H_2O (0.6/1, basic)	84 L	random coil	25	53.5/46.5(7)
7	**1a**	CH_3OH/H_2O (3/1, acidic)	68 D	α-helix	nd	71.0/29.0(42)
8	**2a**	CH_3CN/H_2O (0.6/1, acidic)	84 L	α-helix	21	54.5/45.5(9) [h]

[a] c_0(Receptor)/c_0(Glu) = 625/625 μM (40 mL solvent) at room temperature for 50 h. The apparent pH of the reaction mixture (indicated by a pH meter) was adjusted to either 4.1–5.2 (entries 1–4, 7, 8) or 11.0–11.7 (entries 5, 6) by addition of a few drops of CH_3CO_2H or 1 N aqueous NaOH. [b] *P* = degree of polymerization. [c] By CD spectroscopy (ref. [5]). [d] Precipitate was collected by centrifugation, washed with water, dried under vacuum, and weighed. nd = not determined. [e] From the weight of precipitate relative to sum of the weights of PGA and receptor. [f] *ee* [%] = $100 \times (|c(R) - c(S)|)/(c(R) + c(S))$. [g] From the CD intensity at 426 nm relative to that of the enantiomerically pure **1b** (ref. [4]). [h] By chiral HPLC (Chiralcel OD).



Scheme 1. Reaction of **1a** and **2a** with PGA.

1a (*rac*-**1a**) to an acidic solution of L-PGA gave an assembly, in which (*S*)-**1a** was enantioselectively incorporated (Scheme 1). For example, when *rac*-**1a** was mixed with L-PGA (degree of polymerization $P = 186$) in CH_3OH/water (3/1, v/v) (concentration of glutamic acid unit = 625 μM) at pH 4.6 and the resulting solution stirred for 50 h at room temperature,[6] a precipitate formed. Upon treatment of the precipitate with CH_2Cl_2/aqueous NaCl, the receptor was quantitatively extracted into the organic phase in the form of **1b**. The receptor thus recovered was highly enriched in the (*S*) enantiomer with an (*R*):(*S*) ratio of 18.5:81.5 (63% *ee*; entry 1, Table 1). As expected, mixing of a left-handed helical D-PGA ($P = 68$) with *rac*-**1a** under similar conditions resulted in preferential binding of the opposite receptor, (*R*)-**1a** [(*R*):(*S*) = 71:29) (entry 7). In sharp contrast, under basic conditions (pH 11.0)[6] where PGA assumes a randomly coiled conformation,[5] the binding was not enantioselective (entry 5). It should be mentioned that the complexation of (*R*)-**1a** with racemic *N*-*tert*-butoxycarbonylglutamic acid α-methyl ester or its sodium salt was not enantioselective.[7] Furthermore, a short-chain oligomer of L-glutamic acid ($P = 4$), whose secondary structure is labile,[8] did not undergo enantioselective complexation with *rac*-**1a** under acidic conditions. Thus, the enantioselectivity of the reaction of **1a** with α-helical PGA is induced by the helicity of the polypeptide chain rather than the chirality of the amino acid unit.

When L-PGA with a shorter helical chain ($P = 84$) was subjected to conditions similar to those in entry 1, a lower enantioselectivity resulted (entry 2). The polarity of the medium also affects the enantioselectivity: When the CH_3OH/H_2O solvent system in entry 2 was replaced by CH_3CN/H_2O, the enantioselectivity was much enhanced (entry 3). In contrast, it decreased when the proportion of water in the medium was increased (entry 4). However, even in CH_3CN/water (0.6/1, v/v), the binding was not enantioselective under basic conditions (randomly coiled L-PGA; entry 6).

When the concentration of **1a** was less than 50 μM in CH_3OH/water (3/1, v/v) at 20 °C, the reaction system was homogeneous and no precipitate formed. The reaction between **1a** and PGA was monitored quantitatively. Upon titration of (*R*)- or (*S*)-**1a** (10 μM) with L-PGA ($P = 84$) at pH 7.5, the Soret band of **1a** was observed to shift from 416.4 to 421.8 nm with a clear isosbestic point at 418.4 nm. According the circular dichroism (CD) profile, the L-PGA chain retains the right-handed α-helical structure. The changes in absorption for solutions of different starting concentrations c_0(Glu)/c_0(**1a**) were obviously different for (*R*)- and (*S*)-**1a** (Fig. 1). For example, at c_0(Glu)/c_0(**1a**) =

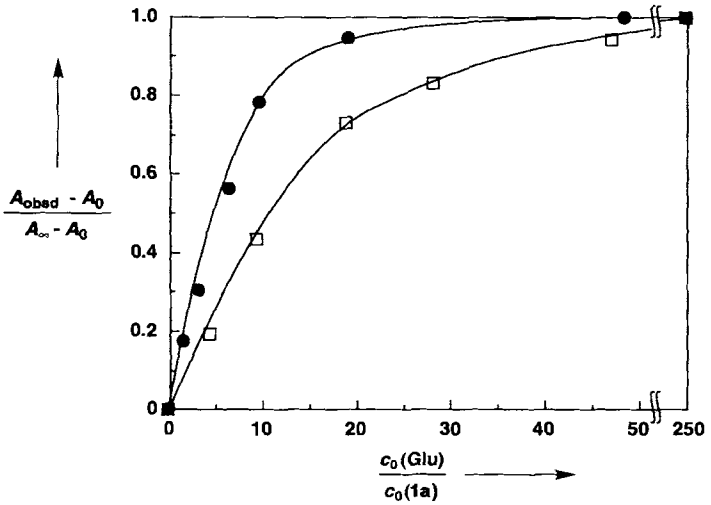


Fig. 1. Spectroscopic titration of (*R*)- (□) and (*S*)-**1a** (●) (c_0(**1a**) = 10 μM) at 20 °C with L-PGA in CH_3OH/water (3/1, v/v) at pH 7.5. Changes in absorption at 413 nm are plotted versus mole ratio of the glutamic acid unit to **1a** (c_0(Glu)/c_0(**1a**)). A_{obs} = observed absorption, A_0 = absorption of uncomplexed **1a**, A_∞ = absorption of complexed **1a**.

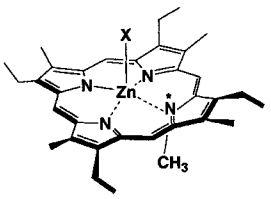
10, 74% of (*S*)-**1a** was complexed with L-PGA, whereas the extent of complexation was only 42% for (*R*)-**1a**. Fitting of the observed spectral changes for (*R*)- and (*S*)-**1a** to Equation (a)[9]

$$\text{(P)ZnOAc} + n\,\text{Glu} \underset{}{\overset{K_{ass}}{\rightleftharpoons}} \text{(P)ZnO}_2\text{C-(Glu)}_n + \text{AcOH} \qquad \text{(a)}$$

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2824 $ 15.00+.25/0

showed that, in both cases, approximately two amino acid units participate in binding one receptor molecule. On the other hand, in agreement with the preferred helical sense (Table 1), the association constant (K_{ass}) evaluated for (*S*)-**1a** (3.0×10^3 M^{-1}) is much higher than that for (*R*)-**1a** (5.1×10^2 M^{-1}). These K_{ass} values were used to estimate the selectivity (*ee*) and $\Delta\Delta G$ of the reaction to be 71% and -1.0 kcal mol^{-1} K^{-1}, respectively.

In previous work on the enantioselective binding of *N*-benzyloxycarbonylamino acids with **1a**,[4] we have clearly shown the presence of electrostatic ($Zn^+ \cdots {}^-O_2C$) and hydrogen-bonding ($NH \cdots O{=}C$) interactions between the receptor and the substrates. In relation to this, the free base of **1** did not interact with PGA in CH_3OH/water (3/1, v/v), irrespective of the acidity of the medium. Furthermore, although chiral **2a**,[10] bearing no hydrogen-bonding "strap amide" functionalities, formed a precipitate when it was mixed with L-PGA ($P = 84$) under acidic conditions, the observed enantioselectivity was negligibly low (entry 8).



2a X = OAc
2b X = Cl

Finally, it is also worth noting that the enantiomers of **1a** could be used to separate right- and left-handed PGA chains. For example, addition of (*S*)-**1a**, under acidic conditions in CH_3CN/water (3/1, v/v), to an equimolar mixture of helical L-PGA ($P = 84$) and D-PGA ($P = 87$) at a ratio c(Glu):c(**1a**) of 2:1 gave a precipitate, which showed, after the removal of the receptor, a CD profile in water at pH 4.2 typical of the right-handed helix. Hydrolysis of this PGA[11] gave glutamic acid that was rich in the L enantiomer (L:D = 82:18). In sharp contrast, under basic conditions, randomly coiled L-PGA and D-PGA were not separable with (*S*)-**1a**.

In conclusion, we have demonstrated that **1** is the first chiral receptor capable of recognizing the helical sense of poly(glutamic acid) in solution. Stereo- and sequence-selective recognition of natural proteins with a tuned metalloporphyrin receptor is a subject worthy of further investigation.

(Alkylidyne)tungsten Complexes Anchored to a Planar Tetraoxo Surface: Exhaustive Alkylation of a (Calixarene)tungsten Complex**

Luca Giannini, Euro Solari, Antonio Zanotti-Gerosa, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

The metal–alkylidyne group has had an extraordinary impact in organic synthesis and mainly in catalysis.[1] A variety of metal fragments have been used, and a significant preference has emerged for the Group VI metals bearing alkoxo groups as ancillary ligands, because of their reactivity and their use as catalysts.[2] In this context much attention has been devoted to coordination environments that can mimic an oxo surface.[3] In order to synthesize model compounds containing the metal–alkylidyne group anchored to an oxo-complex,[4, 5] we functionalized a metal–calix[4]arene complex, starting with the [*cis*-Cl_2W(cal)] (**1**, cal = calix[4]arene).[5c] During these investigations we observed the isomerization of **1** to the [*trans*-Cl_2W(cal)] (**2**), for which a selective synthesis is now available. This kind of isomerization is assisted by Lewis acids (WCl_6 excess, $AlCl_3$). Compound **2** has been identified both in solution (by NMR spectroscopy) and in the solid state (by X-ray analysis).

Alkylation of **1** (Scheme 1) with a metal alkylating agent in a 1:3 molar ratio cleanly forms the corresponding alkylidyne derivative. When lower metal/alkylating agent ratios were employed, a mixture of reduced and alkylated products (which are currently under investigation) were obtained. The reaction does not depend on the alkyl substituent and the nature of the alkylating agent. The solvent plays an important role both in the selection of the reaction path (elimination vs. reduction) and in the separation of Mg and Li halides. The reaction proceeds by a double α-elimination process, which seems impossible to stop at any earlier stage, that is, at the stage of alkyl or alkylidene derivatives.[6]

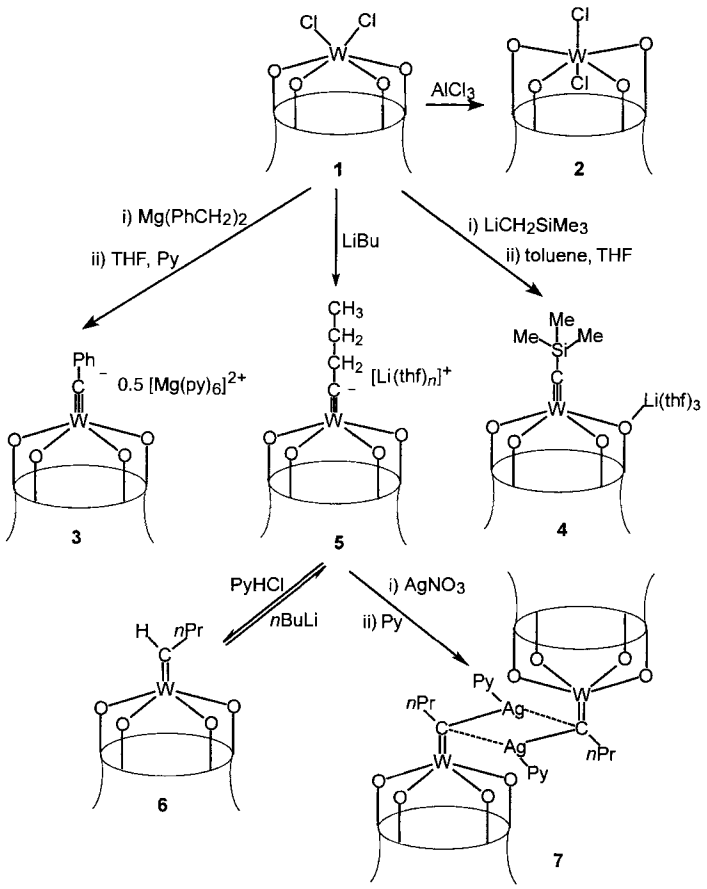

Scheme 1. Exhaustive alkylation of **1** leading to tungsten–alkylidyne derivatives.

Complexes **3**–**5** have been fully characterized; an X-ray analysis was performed on **3**[7] and **4**. The structure of **3** consists of a [PhC≡W(cal)] anion (Fig. 1) and the centrosymmetric cation

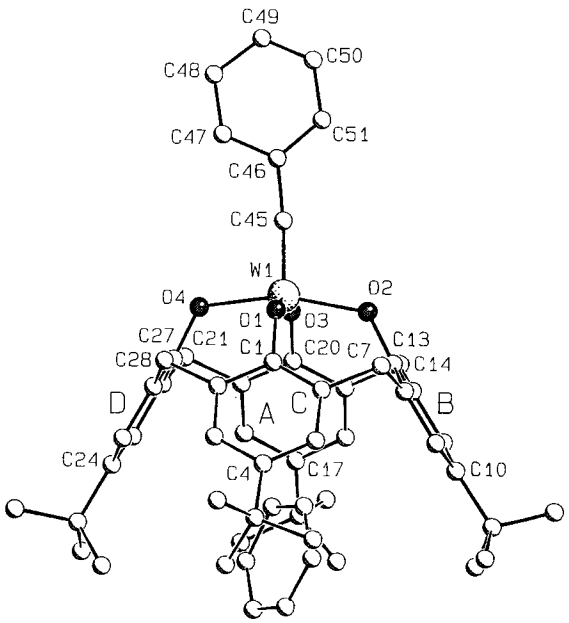

Fig. 1. Structure of the anion (SCHAKAL view) in complex **3**. Selected interatomic distances [Å]: W1–C45 1.722(7), W1–O1 2.000(5), W1–O2 1.995(5), W1–O3 1.957(5), W1–O4 1.987(5), C45–C46 1.449(11). Selected bond angles [°]: O3-W1-O4 88.5(2), O2-W1-O4 161.7(2), O2-W1-O3 88.3(2), O1-W1-O4 88.9(2), O1-W1-O3 160.1(2), O1-W1-O2 88.0(2), W1-C45-C46 173.8(7). For clarity only the E position is given for the disordered pyridine molecule.

$[MgPy_6]^{2+}$. Two additional molecules of pyridine are present, one as guest in the calix[4]arene cavity. The aromatic rings bonded to the O1, O2, O3, O4 oxygen atoms are labeled A, B, C, and D respectively. The tungsten atom exhibits square-pyramidal coordination with the four oxygen atoms of calixarene at the base and the C45 carbon atom of the phenylalkylidyne ligand at the apex. The W–C45 bond length [1.722(7) Å][8] has triple-bond character. The W–C45 bond forms an angle of 1.9(3)° with the normal to the planar O_4 core. Tungsten is displaced by 0.328(1) Å from this plane towards the C45 carbon. The W–O bond lengths, which fall in a rather narrow range, are longer than those in neutral [W(cal)] derivatives containing WCl_2,[5c] W=O,[5c] and $W(OAr)_2$[9] groups. The calix[4]arene unit is in a *cone* conformation as is usually found in square-pyramidal pentacoordinated metals.[5] The almost symmetrical conformation is indicated by the narrow range of the dihedral angles formed by the plane through the bridging methylene carbons C7, C14, C21, C28 (reference plane) and the aromatic rings [119.5(2)–125.1(2)°]. The reference plane is parallel to the O4 core [dihedral angle 1.3(1)°]. The guest pyridine molecule is disordered in two positions (E and F), which are rotated by about 30° and tilted by 13.1(11)° relative to each other. The molecular axis of the complex runs approximately through the midpoint of the C61–C66 bond for the E position (Fig. 1) and through the C66···C63 axis for the F position.[10]

Let us summarize some of the features of this novel class of tungsten–alkylidynes: 1) their synthesis is straightforward as alkylation is achieved under very mild conditions; 2) they occur in a rather rare and stable anionic form; 3) the bonding mode of the W≡CR fragment to a tetraalkoxo fragment renders the metal electronically saturated according to P. Hofmann's considerations;[11] 4) the O4 matrix binds so strongly to the metal that the reactivity of the W≡C group can be studied without disturbing from the ancillary ligand. This fourth feature suggests that this electron-rich alkylidyne fragment will be a particularly good candidate for electrophilic and oxidation reactions. We, for instance, observed the rather unique reversible protonation of the alkylidyne and deprotonation of the resulting alkylidene. Both occur without any rearrangement or protolysis of the ancillary ligand, as is usually the case.[12] Although the reaction is general for **3**–**5**, we report details for **5** only.

A synthetically useful derivatization of the anionic alkylidynes **3**–**5** is their metalation, which we performed with the carbophilic Ag^+. The reaction carried out on **5** with $AgNO_3$, followed by crystallization in pyridine, led to the silver–alkylidene complex **7** (Scheme 1). Such a formulation has been supported by an X-ray analysis on **7**. The W–C bond length supports the transformation of the alkylidyne into a metalated alkylidene [W=C, 1.835(7) vs. 1.722 in **3**]. Reaction of M≡C bonds with Cu^+ or Ag^+ normally lead to π interactions.[13] The reactions mentioned above show how the alkylidyne group anchored to a calixarene matrix undergoes some unprecedented and novel transformations.

Experimental Procedure

3: $Mg(PhCH_2)_2$ (23 mL, 0.67 N, 15.40 mmol) was added dropwise to suspension of $1 \cdot 3C_6H_6$ (5.81 g, 5.12 mmol) in THF (200 mL) at −30 °C. The resulting red solution was allowed to warm to room temperature and gave a yellow solid in a green solution. The solid was collected and then extracted with hot THF over 9 h (most of the solid was not soluble in THF). Bright yellow $[\{(cal)W{\equiv}CPh\}_2(thf)\{Mg(thf)_6\}_{0.5}]$ was left on the septum and then dried in vacuo (2.7 g, 42%). Elemental analysis calcd (found): C 66.05 (65.45), H 7.36 (7.70). ^{1}H NMR (400 MHz, $[D_5]$Py, 300 K): δ = 7.27 (s, 8H; ArH), 7.10 (m, 2H; ArH), 7.03 (m, 2H; ArH), 6.65 (m, 1H; ArH), 5.26 (d, J = 11.6 Hz, 4H; *endo*-CH_2), 3.62 (m, 16H; THF), 3.33 (d, J = 11.6 Hz, 4H; *exo*-CH_2), 1.59 (m, 16H; THF), 1.22 (s, 36H; *t*Bu). ^{13}C NMR ($[D_5]$Py, 300 K): δ = 267.9. The X-ray analysis of **3** was carried out on $[\{(cal)W{\equiv}CPh\}_2\{[MgPy_6]\}_{0.5}]$ recrystallized from pyridine.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2826 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1996, 35, No. 23/24

4: $LiCH_2SiMe_3$ (1.57 g, 16.70 mmol) was dissolved in toluene (150 mL), cooled (−30 °C), and then **1**·3 C_6H_6 (6.28 g, 5.54 mmol) was added. The resulting red solution was allowed to warm to room temperature overnight. Yellow [{(cal)W≡$CSiMe_3$}Li]·C_7H_8·LiCl formed and was collected and dried in vacuo (2.76 g, 47%). Elemental analysis calcd (found): C 62.53 (62.26), H 6.68 (6.67). ^{1}H NMR (400 MHz, [D_5]Py, 300 K): δ = 7.20 (m, tol), 7.16 (s, 8H; ArH), 5.28 (d, J = 11.6 Hz, 4H; *endo*-CH_2), 3.26 (d, J = 11.6 Hz, 4H; *exo*-CH_2), 2.20 (s, 3H; tol), 1.16 (s, 36H; *t*Bu), 0.26 (s, 9H; $SiMe_3$). ^{13}C NMR ([D_5]Py, 300 K): δ = 308.1 (W≡$CSi(CH_3)_3$), 2.57 (-Si(CH_3)$_3$). Crystals suitable for an X-ray analysis were obtained from crystallization in THF/toluene; the solvated form [{(Cal)W≡C-$SiMe_3$}{Li(thf)$_3$}] (**4**), which does not contain LiCl, has been isolated.

5: BuLi (6.6 mL, 1.65 N, 10.89 mmol) was added dropwise to a suspension of **1**·3 C_6H_6 (4.08 g, 3.60 mmol) in toluene (80 mL) at −30 °C. The resulting red solution was allowed to warm to room temperature, and THF (50 mL) was added to the reaction mixture. Volatiles were removed in vacuo, and Et_2O (100 mL) was added to the residue. A white powder was removed by filtration, and THF (10 mL) was added to the resulting brown solution. Volatiles were removed in vacuo, *n*-hexane (30 mL) was added to the residue, and the greenish Li[(cal)$WCCH_2CH_2CH_3$]·LiCl·2THF·C_6H_{12} then collected and dried in vacuo (2.2 g, 53%). Elemental analysis calcd (found): C 64.00 (64.30), H 7.71 (8.13). ^{1}H NMR (400 MHz, [D_5]Py, 300 K): δ = 7.15 (s, 8H; ArH), 5.22 (d, J = 11.6 Hz, 4H; *endo*-CH_2), 4.08 (t, J = 6.6 Hz, 2H; $WCCH_2CH_2CH_3$), 3.62 (m, 8H; THF), 3.23 (d, J = 11.6 Hz, 4H; *exo*-CH_2), 1.80 (m, 2H; $WCCH_2CH_2CH_3$), 1.59 (m, 8H; THF), 1.46 (t, J = 7.2 Hz, 3H; $WCCH_2CH_2CH_3$), 1.16 (s, 36H; *t*Bu). ^{13}C NMR ([D_5]Py, 300 K): δ = 276.6 (WC(Pr), J_{CW} = 278 Hz), 48.3 ($WCCH_2CH_2CH_3$), 27.0 ($WCCH_2CH_2CH_3$), 14.5 ($WCCH_2CH_2CH_3$).

Protonation and deprotonation of **5**: PyHCl (0.22 g, 1.9 mmol) was added to a solution of **5** (2.2 g, 1.9 mmol) in Et_2O (100 mL), and the mixture stirred for 2 h. A white solid was filtered off, volatiles were removed in vacuo, and pentane was added to the residue. Compound **6** was then collected as a brown solid and dried in vacuo (0.97 g, 57%). ^{1}H NMR (400 MHz, C_6D_6, 300 K): δ = 10.0 (t, J = 7.5 Hz, 1H; WC(Pr)H), 7.07 (s, 8H; ArH), 5.47 (m, 2H; $WCCH_2CH_2CH_3$), 4.95 (d, J = 12.2 Hz, 4H; *endo*-CH_2), 3.24 (d, J = 12.2 Hz, 4H; *exo*-CH_2), 1.69 (m, 2H; $WCCH_2CH_2CH_3$), 1.15 (t, J = 7.2 Hz, 3H; $WCCH_2CH_2CH_3$), 1.08 (s, 36H; *t*Bu). ^{13}C NMR (C_6D_6, 300 K): δ = 272 (WC(Pr)H, J_{CW} = 180 Hz, J_{CH} = 142 Hz), 41.6 ($WCCH_2CH_2CH_3$), 29.5 ($WCCH_2CH_2CH_3$), 14.5 ($WCCH_2CH_2CH_3$). The reaction of **6** with a stoichiometric amount of BuLi (in toluene at −30 °C) leads to pure **5**, as determined by ^{1}H NMR spectroscopy.

7: $AgNO_3$ (0.3 g, 1.76 mmol) was added to a solution of **5** (1.97 g, 1.69 mmol) in THF (100 mL), and the mixture stirred overnight. Volatiles were removed in vacuo, and the residue was extracted with Et_2O (100 mL). The resulting deep red solution was kept at −25 °C over 24 h to yield [(cal)W=C(Ag)(*n*Pr)] as red needles (0.5 g, 30%). Elemental analysis calcd (found): C 58.13 (57.95), H 6.00 (6.03). ^{1}H NMR (400 MHz, [D_5]Py, 300 K): δ = 7.25 (s, 8H; ArH), 5.31 (d, J = 11.6 Hz, 4H; *endo*-CH_2), 4.74 (t, J = 6.8 Hz, 2H; $WCCH_2CH_2CH_3$), 3.35 (d, J = 11.6 Hz, 4H; *exo*-CH_2), 2.0 (m, 2H; $WCCH_2CH_2CH_3$), 1.41 (t, J = 7.4 Hz, 3H; $WCCH_2CH_2CH_3$), 1.19 (s, 36H; *t*Bu). ^{13}C NMR ([D_5]Py, 300 K): δ = 272 (WC(Pr)Ag), 50.0 ($WCCH_2CH_2CH_3$), 27.9 ($WCCH_2CH_2CH_3$), 14.6 ($WCCH_2CH_2CH_3$). The X-ray analysis was performed on the solid [(cal)W=C(Ag)(*n*Pr)] recrystallized from pyridine to give [7·2Py].

[7] Crystal structure analysis of **3**: $C_{51}H_{57}W·0.5C_{30}H_{30}MgN_6·2C_5H_5N$, M_r = 1325.5, monoclinic, space group $P2_1/c$, a = 22.038(3), b = 12.415(2), c = 25.171(3) Å, β = 98.74(1)°, V = 6806.9(17) Å^3, Z = 4, ρ_{calcd} = 1.293 g cm^{-3}, $F(000)$ = 2740, $Mo_{K\alpha}$ radiation (λ = 0.71069 Å, $\mu(Mo_{K\alpha})$ = 17.86 cm^{-1}. Crystal dimensions 0.20 × 0.25 × 0.38 mm. The structure was solved by the heavy atom method, and all non-H atoms except those affected by disorder were anisotropically refined. The guest pyridine molecule (C61–C66) and the pyridine solvent molecule of crystallization (N4, C91–C95) were affected by high thermal parameters indicating the presence of disorder. The best fit was found by splitting the atoms over two positions (A and B), which were isotropically refined with site occupation factors of 0.65 and 0.35, respectively, for both molecules. The nitrogen atom in the guest pyridine molecule could not be unambiguosly distinguished. During the refinement the disordered pyridine solvent molecule of crystallization was constrained to be a regular hexagon. All the hydrogen atoms except those related to the disordered pyridine molecules, which were ignored, were located from a difference Fourier map and introduced as fixed contributors in the last stage of refinement (U_{iso} = 0.08 Å^2). For 7981 unique observed reflections [$I > 2\sigma(I)$], collected at T = 295 K on a Rigaku AFC6S diffractometer ($6° < 2\theta < 50°$) and corrected for absorption, the final R is 0.053 ($wR2$ = 0.133). All calculations were carried out on a Quansan Personal Computer equipped with an Intel Pentium processor. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-127. The First Stable Copper(III) Complex Containing Aliphatic Thiolates as Ligands: Structural and Spectroscopic Evidence for Cu^{II} and Cu^{III} Ions in Complexes with Square-Planar CuN_2S_2 Coordination Environments**

Jan Hanss and Hans-Jörg Krüger*

Dedicated to Professor Erwin Weiss on the occasion of his 70th birthday

The tremendous interest in copper(II) complexes containing thiolates as ligands has been inspired for the most part by the occurrence of such types of complexes in the mononuclear copper(II) sites of the electron transfer proteins plastocyanin and azurin, as well as in the dinuclear Cu_A-site of cytochrome-c oxidase.[1] The synthesis of suitable low molecular weight model complexes, however, has been thwarted by the intrinsic tendency of copper(II) thiolate complexes to suffer autoreduction of Cu^{II} by the coordinated thiolates with the concomitant formation of disulfides.[1a, 1e] Thus, the preparation of such complexes

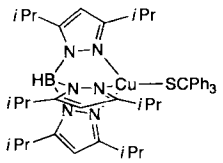
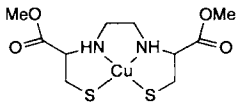
[**] This work was supported by the Deutsche Forschungsgemeinschaft.

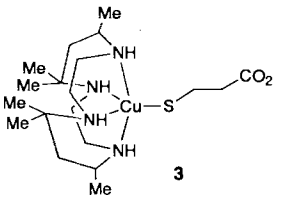
is still quite a challenging task for synthetic chemists. Of the few sufficiently stable copper thiolate compounds that can be characterized structurally, most of them contain anionic sulfur centers that are bound to sp^2-hybridized carbon atoms.[2, 3]. The preparation of mononuclear complexes containing aliphatic thiolates has been unsuccessful in most cases, and those complexes prepared in situ have such short lifetimes in solution that any detailed investigation is impeded. In only three cases have the structures of such aliphatic thiolate complexes been determined.[1e, 3-5] The copper(II) ions in these complexes have tetrahedral (**1**),[1e, 3] square-planar (**2**),[4] or trigonal-bipyramidal coordination geometries (**3**).[5] Here we report on the synthesis,



1



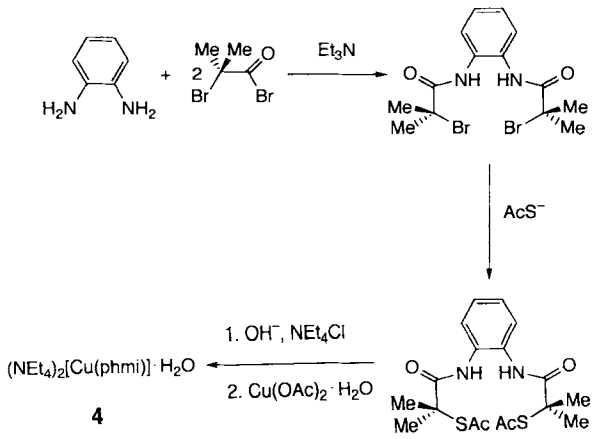
2



3

spectroscopic characterization, and structures of stable mononuclear complexes of aliphatic thiolates with square-planar Cu^{II} and Cu^{III} ions.

In analogy to the chemistry of copper(II) thiolates, nickel(II) thiolates are prone to form disulfides from coordinated thiolates upon oxidation.[6] Here, complexes containing both a nickel(III) ion and coordinated thiolates have been successfully prepared by utilizing ligands that provide nitrogen donor atoms from deprotonated amide functions in addition to the anionic sulfur donors of the thiolates.[7] This strategy was also employed in earlier works by Sugiura et al.,[8] who used peptides with SH groups that coordinate to copper(II) ions. In these complexes the coordination of thiolate was mainly inferred from ESR and electronic absorption spectroscopy on the copper(II) complexes and from NMR spectra of the copper(I) complexes; no X-ray structural evidence was given. We have synthesized the red copper(II) complex **4** from the bis-*S*-acetyl-derivative of the ligand *N*,*N*′-1,2-phenylenebis(2-mercapto-2-methylpropionamide) (H_4phmi) (Scheme 1).



Scheme 1.

A structure determination of **4**[9] reveals that the copper ion is coordinated by two thiolates and two deprotonated amides. Some selected bond lengths and angles are listed in the legend of Figure 2. All non-hydrogen atoms, except those of the four methyl groups, are coplanar (maximum deviation: ± 0.129 Å). The average Cu–N bond length of 1.963 ± 0.001 Å is at the high end of the range commonly observed for square-planar copper(II) ions coordinated to deprotonated amides of acyclic ligands.[10] The average Cu–S bond length of 2.241 ± 0.003 Å is quite similar to that observed for square-planar **2**.[4]

The visible region of the electronic absorption spectrum of **4** comprises a band at 489 nm ($\varepsilon_M = 538\ M^{-1}\ cm^{-1}$) with a shoulder at 580 nm ($\varepsilon_M = 110\ M^{-1}\ cm^{-1}$). Both features are tentatively assigned to d–d transitions. The position and the intensities of these absorptions reveal that the square-planar geometry around the copper(II) ion is preserved in solution. The ESR spectrum (Fig. 1) of **4** in acetonitrile/toluene (1:4) solution displays a signal at $g_{iso} = 2.060$. The hyperfine and superhyperfine

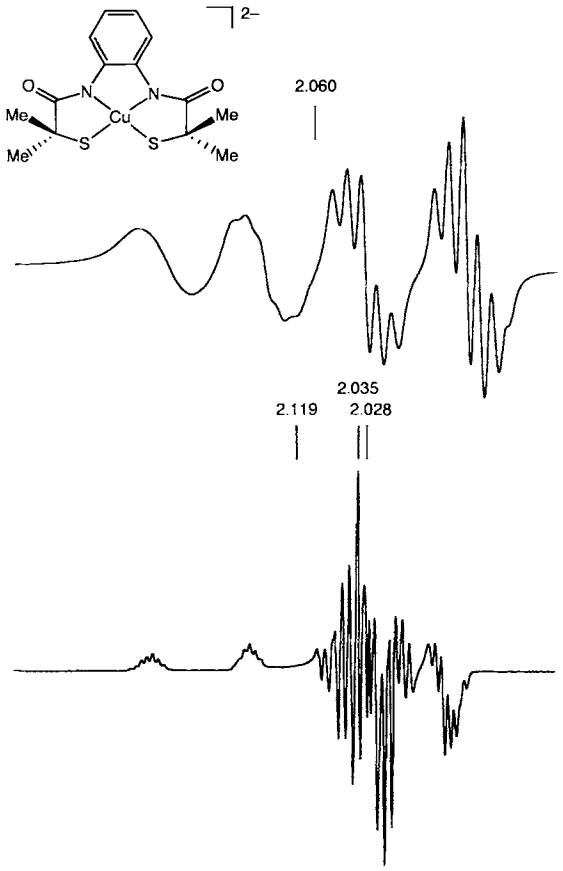


Fig. 1. X-Band EPR spectra of $(NEt_4)_2$[Cu(phmi)] · H_2O **4** in acetonitrile/toluene (v/v = 1:4) at room temperature (top) and as frozen glass in ethanol at 140 K (bottom).

coupling constants to the copper ion ($I = 1.5$) A^{Cu}_{iso} and to the two nitrogen atoms ($I = 1$) A^{N}_{iso} were determined to be 88.5×10^{-4} and $12.6 \times 10^{-4}\ cm^{-1}$, respectively. The powder spectrum of **4** in frozen ethanol solution consists of a nearly axial signal with a very distinct coupling pattern. Simulation[11] of the rather complex spectrum yielded $g_z = 2.119$, $g_y = 2.035$, and $g_x = 2.028$ as the best fit for the g-values, and $A^{Cu}_z = 195 \times 10^{-4}\ cm^{-1}$, $A^{Cu}_y = 35.2 \times 10^{-4}\ cm^{-1}$, $A^{Cu}_x = 36.8 \times 10^{-4}\ cm^{-1}$, $A^{N}_z = 12.3 \times 10^{-4}\ cm^{-1}$, $A^{N}_y = 15.1 \times 10^{-4}\ cm^{-1}$, and $A^{N}_x = 12.6 \times 10^{-4}\ cm^{-1}$ for the coupling constants. ESR spectra of **4** demonstrate unambiguously that the metal center is a copper(II) ion rather than a copper(I) ion coordinated to a ligand radical, and that the unpaired electron resides in the d_{xy} orbital[12] of the metal ion.

In the cyclic voltammogram of the extremely oxygen-sensitive complex **4**, an oxidation takes place at -1.16 V vs. the ferrocene/ferrocenium (Fc/Fc^+) redox couple. The oxidative response displays all the characteristics for an electron transfer reaction that approaches electrochemical reversibility. Coulometric oxidation at -0.96 V vs. Fc/Fc^+ shows that one electron is transferred; upon re-reduction, 99% of the original copper(II) species is recovered. No reversible reduction is observed for **4**.

The oxidized species was prepared by bulk electrolysis of the copper(II) complex at -0.96 V vs. Fc/Fc^+ and isolated as greenish-yellow (PPh_4)[Cu(phmi)] (**5**). The crystal structure of **5** (Fig. 2)[9] ascribes a square-planar coordination geometry to

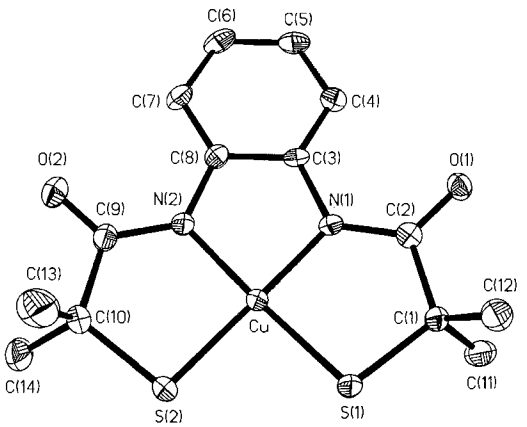

Fig. 2. Crystal structure of the $[Cu(phmi)]^-$ ion showing thermal ellipsoids at 50% probability and the atom numbering scheme. The complex anion $[Cu(phmi)]^{2-}$ has the same connectivity and coordination geometry. Selected distances [Å] and angles [°] in the $[Cu(phmi)]^-$ ion [in the $[Cu(phmi)]^{2-}$ ion]: Cu-S(1) 2.145(1) [2.2381(8)], Cu-S(2) 2.150(1) [2.243(1)], Cu-N(1) 1.863(3) [1.963(2)], Cu-N(2) 1.864(3) [1.962(2)], N(1)-C(2) 1.357(4) [1.329(3)], N(1)-C(3) 1.430(4) [1.425(3)], N(2)-C(9) 1.359(4) [1.332(3)], N(2)-C(8) 1.427(4) [1.419(3)], O(1)-C(2) 1.238(4) [1.252(4)], O(2)-C(9) 1.232(4) [1.247(3)], C(3)-C(4) 1.397(4) [1.400(4)], C(3)-C(8) 1.419(4) [1.424(4)], C(4)-C(5) 1.393(4) [1.396(4)], C(5)-C(6) 1.391(5) [1.381(4)], C(6)-C(7) 1.398(5) [1.399(4)], C(7)-C(8) 1.396(4) [1.400(4)]; S(1)-Cu-S(2) 92.11(4) [100.27(3)], S(1)-Cu-N(1) 90.36(8) [87.68(7)], S(1)-Cu-N(2) 176.24(8) [171.40(7)], S(2)-Cu-N(1) 174.93(8) [172.05(6)], S(2)-Cu-N(2) 90.24(8) [88.09(7)], N(1)-Cu-N(2) 87.52(11) [83.97(9)].

the copper ion. The most distinctive feature of the complex is the decrease of the Cu–N and Cu–S bond lengths from 1.963 and 2.241 Å in **4** to 1.864 ± 0.001 and 2.148 ± 0.003 Å in **5**, respectively. The C–C and C–N bond lengths of the phenylenediamide moiety in **5** are, within the 3σ criterion, the same as those in **4**. These findings clearly indicate that the oxidation is metal-centered and that the electron is removed from the strongly antibonding d_{xy} orbital,[12] thereby strengthening the Cu–N and Cu–S bonds in **5**. The Cu–N bond lengths are slightly longer than those observed in the other copper(III) complexes containing deprotonated amides as ligands.[13] Further, the average C–N and C–O bond lengths of the amide functions change from 1.331 ± 0.002 and 1.250 ± 0.003 Å in **4** to 1.358 ± 0.001 and 1.235 ± 0.003 Å in **5**, respectively.[14] This is interpreted to mean that, as a response to the higher positive charge on the metal ion in **5**, the partial double bond character of the C–N bond in the amide function is reduced in order to increase the negative charge on the nitrogen atom. As a consequence of the shorter distances between the metal and the donor atoms, the acyclic ligand can surround the metal ion more completely, as shown by the smaller S–Cu–S angle and S–S distance; despite the substantial decrease in the distance between the two sulfur atoms from 3.439 Å in **4** to 3.092 Å in **5**, no bonding interaction between the sulfur atoms exists.

As expected for a square-planar metal ion with a d^8 electron configuration, **5** is diamagnetic. A comparison of the NMR spectrum of **5** in deuterated acetonitrile [$\delta = 8.44$ (dd, 2H), 6.75 (dd, 2H), 1.46 (s, 12H)] with that of the nickel(II) complex $[Ni(phmi)]^{2-}$ [$\delta = 8.64$ (dd, 2H), 6.46 (dd, 2H), 1.23 (s, 12H)][15] and that of the copper(III) complex of the alcoholate analogue of $phmi^{4-}$ [$\delta = 7.85$ (dd, 2H), 6.75 (dd, 2H), 1.23 (s, 12H)][13b] is further indication that the ligand is not involved in the redox reaction.

All structural and spectroscopic results support the description of the metal ions as Cu^{II} in **4** and as Cu^{III} in **5**. The ligand itself is redox-inert. The oxidation potential of **4** is, to our knowledge, the lowest ever recorded for a true Cu^{III}/Cu^{II} redox couple. As in some Ni^{III}/Ni^{II} redox couples,[7a] the replacement of the thiolate donor functions in **4** by alcoholates raises the redox potential by 290 mV.[13b] Since the type of ligand donor sets in $phmi^{4-}$ are potentially available in nature in the form of cysteine-containing peptides, these results demonstrate that, in contrast to the previously stated opinion[1f] that "the Cu^{III} state is not a biologically relevant oxidation state" since "the redox potentials for the transition Cu^{III}/Cu^{II} are generally very high," the occurrence of Cu^{III} centers in natural systems cannot be dismissed as irrelevant.

Our investigation presents strong evidence that copper ions in high oxidation states are viable in the presence of aliphatic thiolates. For the first time, a copper(III) ion has been structurally characterized in a coordination environment consisting partly of thiolates. While the oxidation state of the metal ion in the complex $[Cu(tdt)_2]^-$[16] is ambiguous and thus the complex is better described as a copper(II) ion stabilized ligand radical,[16] the oxidation state of the copper ion in complexes **4** and **5** has been proven beyond doubt. However, one has to keep in mind that the stabilization of Cu^{II} and especially of Cu^{III} ions can only be accomplished here due to the presence of highly polarizable, anionic nitrogen donors. Deprotonated amides have been known to stabilize high oxidation states of copper,[13, 17] and it is only because these nitrogen donors are able to provide the electropositive copper ions in complexes **4** and **5** with sufficient electron density that autoreduction of the metal ion by the coordinated thiolates does not occur.

Experimental Procedure

4: Under strictly anaerobic conditions, a solution of *N,N'*-1,2-phenylenebis-(*S*-acetyl-2-mercapto-2-methylpropionamide) (200 mg, 0.5 mmol), KOH (140 mg, 2.5 mmol), and NEt_4Cl (166 mg, 1.0 mmol) in absolute ethanol (40 mL) was stirred for 0.5 h before a suspension of $Cu(OAc)_2 \cdot H_2O$ (99.8 mg, 0.5 mmol) in absolute ethanol (50 mL) was added. After the reaction mixture was heated at reflux for a short time, the solvent was completely removed in vacuo. The residue was treated with acetonitrile (30 mL) and the resulting red solution was filtered. Slow diffusion of ether into the acetonitrile solution afforded a red crystalline material which was collected, washed with ether, and dried in vacuo to yield analytically pure product (209 mg, 66% yield). Under vacuum the compound lost its crystal water molecule. Anal. calcd. for $C_{30}H_{56}CuN_4O_2S_2$: C 56.97, H 8.92, N 8.86; found: C 57.10, H 8.98, N 8.76. Absorption spectrum (acetonitrile): λ_{max} (ε_M) = 580 (sh, 110), 489 (538), 340 (sh, 3800), 310 (sh, 11000), 294 (23800), 285 (sh, 20900), 255 (sh, 23500), 247 (24100), 230 (25800) nm. The synthesis of $(PPh_4)_2$[Cu(phmi)] was achieved using PPh_4Cl following procedures similar to those described above.

5: A solution of $(PPh_4)_2$[Cu(phmi)] (286.8 mg, 273 mmol) in acetonitrile (10 mL) containing 0.05 M PPh_4Cl as supporting electrolyte was oxidized at -0.96 V vs. Fc/Fc^+ in an electrochemical cell placed in a glove box. The electrolysis was carried out at a platinum net electrode with a PAR Model 273A Potentiostat/Galvanostat controlled by the PAR Model 270 Research Electrochemistry Software. After the oxidation was complete, the electrolyte PPh_4Cl was precipitated by diffusion of

ether to the resulting solution. Removal of the solvent from the filtered solution yielded a greenish yellow solid, which was redissolved in acetone (10 mL) under air. Diffusion of ether to this solution afforded analytically pure product as greenish yellow crystals (164.9 mg, 85% yield). Anal. calcd. for $C_{38}H_{36}CuN_2O_2PS_2$: C 64.16, H 5.10, N 3.94; found: C 64.13, H 5.04, N 3.90. Absorption spectrum (acetonitrile): λ_{max} (ε_M) = 711 (218), 417 (6130), 295 (sh, 18900), 277 (32900), 245 (23000), 220 (22300) nm.

[14] Similar observations were also made with other divalent and trivalent metal ion complexes [15]; however, no water molecule was present in the crystal lattice. Therefore, the hydrogen bonding interaction between the water oxygen atom and the oxygen atom of the amide function can be discounted as the primary reason behind the elongation of the C–O bond length.

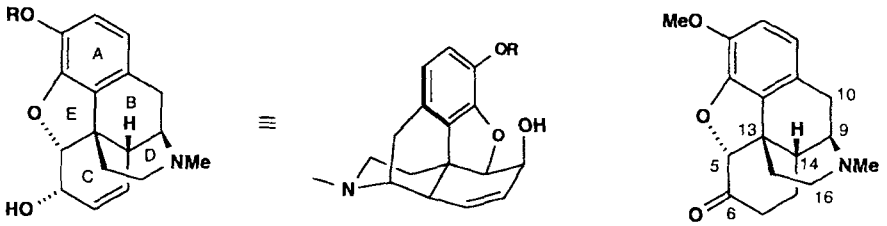
Formal Total Synthesis of (–)-Morphine by Cuprate Conjugate Addition

Johann Mulzer,* Gerd Dürner, and Dirk Trauner

Dedicated to Professor Wilhelm Fleischhacker on the occasion of his 65th birthday

The opium alkaloids (–)-morphine (**1**) and (–)-codeine (**2**) have long been challenges for natural product synthesis.[1] Remarkably, activity in this field has increased in recent years, as it has done with other "classical" alkaloids. The attraction of **1** and **2** results from their complex molecular architecture, which



R = H (–)-morphine **1**
R = Me (–)-codeine **2**

(–)-dihydrocodeinone **3**

is due to a dense network of three carbocycles and two heterocycles containing five vicinal stereogenic carbons. One of these stereocenters (C13) is a quaternary benzylic carbon atom and therefore difficult to create.

In fact, the total syntheses of morphine published recently focus on the construction of this quaternary benzylic stereocenter, by employing either an intramolecular Heck reaction,[2a] a tandem radical cyclization,[2b] a Diels–Alder reaction,[2c] an intramolecular conjugate addition to a vinylsulfone,[2d] or an Eschenmoser–Claisen rearrangement[2e] as key reactions. However, one of the most efficient methods for the synthesis of quaternary centers, the 1,4-addition of cuprates,[3] has not yet been attempted in this context.

Our synthetic strategy was first to provide a functionalized phenanthrene derivative of type **5** with a correctly substituted aromatic ring A and then to employ the conjugate addition of a C_2-unit for the construction of the quaternary benzylic stereocenter.[4] Formal insertion of an NCH_3 group between C16 and C9 would then complete the morphinan ring system.

The readily available tetralone **4**[5] was converted by Robinson annulation into phenanthrenone **5**, which contains 14 of the 17 carbons and all three carbocycles of the morphinan skeleton. Phenanthrenone **5** was resolved on a preparative scale by chromatography on cellulose triacetate.[6] The undesired enantiomer could be racemized by treatment with base.

We next turned our attention to the key conjugate addition of a vinyl cuprate to **5**. Because of the high steric hindrance at the reaction center, activation by chlorotrimethylsilane (TMSCl) seemed to be necessary.[3, 7] However, the conditions described in the literature led to complex reaction mixtures, which contained only modest amounts of the desired silyl enol ether. As by-

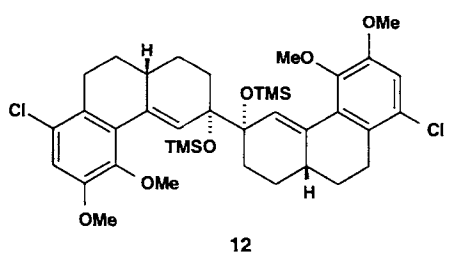
product we isolated the C_2-symmetric, silylated pinacol **12**. We regard this as evidence that the cuprate conjugate addition follows a single electron transfer (SET) mechanism (Fig. 2).[8]

In contrast, the simple vinyl cuprate $(CH_2{=}CH)_2CuMgCl$[9] reacts with **5** in absence of chlorosilanes to afford ketone **6a** in



12

91% yield. The enolate existing after conjugate addition could be trapped quantitatively by subsequent addition of TMSCl. Treatment of the crude silyl enol ether with *N*-bromosuccinimide (NBS)[10] then furnished α-bromoketones **6b** and **6c** in a 3:1 ratio. Compounds **6a–c** display the correct relative configuration at C13 and C14 and contain all carbons of morphine apart from the N-methyl group.

The main isomer **6b** cyclized quantitatively to **7** on brief heating at 140 °C in DMF.[11] Ketone **6c** remained unchanged under these conditions. Ketalization of the carbonyl function of **7**,[12] hydroboration/oxidation of the vinyl residue, and subsequent dechlorination of the aromatic ring with Raney-nickel proceeded uneventfully. The resulting primary alcohol **8** was converted into secomorphinan **9** by a novel variant of the Mitsunobu reaction[13] involving *N*-methylbenzenesulfonamide, 1,1′-(azodicarbonyl)dipiperidine (ADDP), and tributylphosphane.

For the final bond formation between C9 and the nitrogen we used the piperidine ring closure described by Parker and Focas.[2b] Benzylic bromination of **9** with NBS, followed by spontanous thermal elimination of HBr[14] furnished styrene **10**, which underwent radical (or anionic) cyclization to yield morphinan **11** on reductive desulfonation with lithium in liquid ammonia. The benzenesulfonyl group performs a threefold task in the sequence leading from **8** to **11** (acidification of the NH bond for Mitsunobu reaction, protection against NBS, generation of a nitrogen radical) and is therefore more than a mere protective group. Acidic cleavage of ethylene ketal **11** finally yielded (−)-dihydrocodeinone (**3**), which can be efficiently converted into (−)-codeine und (−)-morphine.[15] Synthetic **3** was identical with an authentic sample according to conventional standards (^1H and ^{13}C NMR, IR, MS, TLC, $[\alpha]_D^{20}$, m.p.). Table 1 contains selected physical data of compounds **5**, **6b**, **7**, **9**, **10**, **11**, and **12**.

Our chirally economic[16] asymmetric total synthesis is linear, yet very short with 11 isolated steps (total yield: 11.5%) from tetralone **4** to dihydrocodeinone **3**.[17] Its stereochemical course is determined by the first stereogenic center at C14. Due to the curvature of phenanthrenone **5**, the vinyl group and the bromine atom preferentially add to the convex side of the molecule. The subsequent ring closures of both heterocycles by an S_N2 reaction in one case and a radical cyclization in the other are

[4] Alternatively, the Eschenmoser–Claisen and [2,3]–Wittig rearrangements were successfully applied. The two strategies could be pursued in parallel, since the conjugate addition is performed with an enone, which on reduction delivers the allylic alcohol necessary for a sigmatropic rearrangement.

Pyrazolate "Golden" Rings: Trinuclear Complexes That Form Columnar Mesophases at Room Temperature**

Joaquín Barberá, Anabel Elduque, Raquel Giménez, Luis A. Oro,* and José Luis Serrano*

The interest in supramolecular columnar organizations has continued to increase since these systems possess many of the properties required for photonics, electronics, and ionic transport.[1] The incorporation of metal atoms into mesogenic molecules has brought about a considerable expansion in the field of columnar liquid crystals[2] and has at the same time introduced new properties attributed to the metal atoms, such as color, ease of polarization, and paramagnetism. One of our research interests involves the preparation of mesogenic pyrazole derivatives. Our original aim was to prepare columnar phases, which show hydrogen-bonding interactions (Scheme 1, **A** and **B**). However,

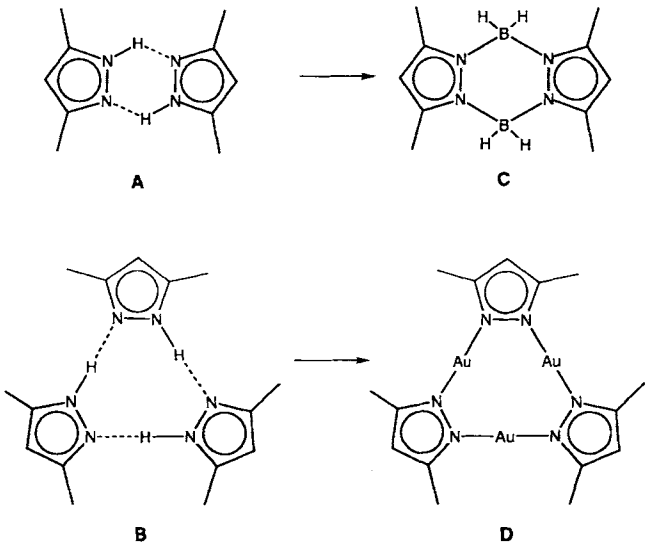


Scheme 1.

in the case of pyrazole derivatives, this objective failed,[3] and it was necessary to force the dimerization through the formation of covalent bonds like in **C**.[4]

As part of our ongoing investigations toward trimeric derivatives such as **B**, we decided to prepare new mesogenic gold compounds of type **D**, since the coinage metals are known to form trimers such as $[M(pz)]_3$ (pz = pyrazolate type ligands).[5] These complexes could present novel supramolecular structures and interesting reactivity.[5a, 6]

Several mesogenic complexes containing different ligands and metals have been described; however, no columnar structures with trinuclear complexes or gold atoms. Herein we report the first complex containing a trinuclear gold ring that exhibits a hexagonal columnar mesophase at room temperature.

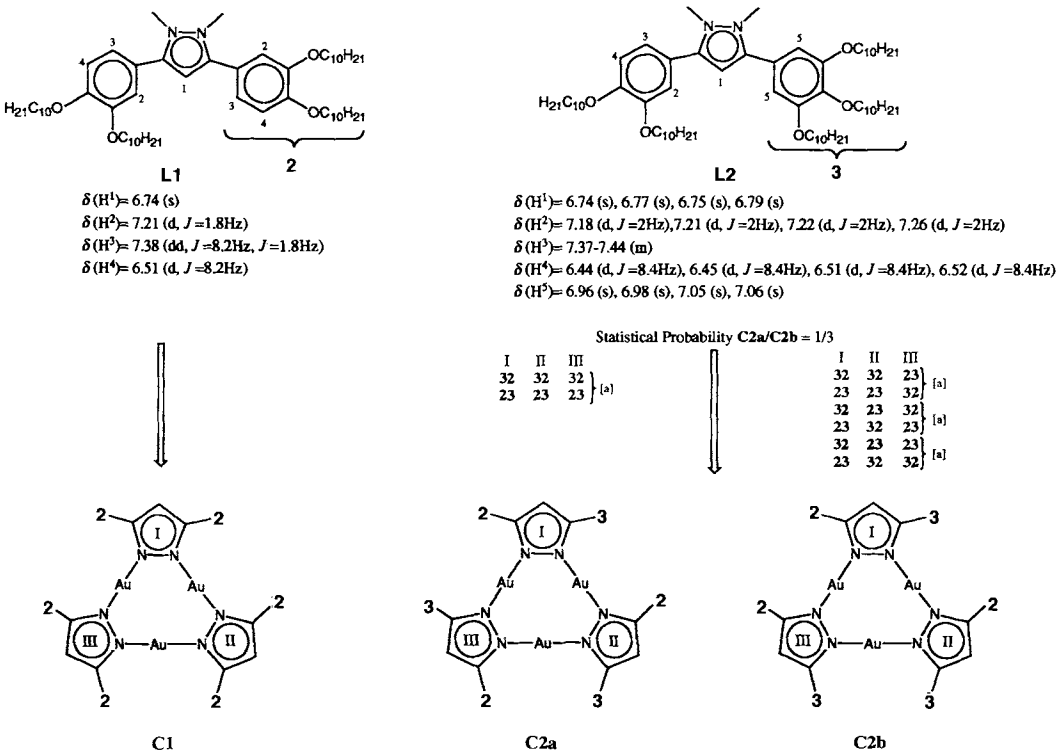
The potassium salts of the non-mesogenic pyrazolate ligands derived from 3,5-*bis*-(3′,4′-*di*-*n*-decyloxyphenyl)pyrazole (**L1**) and 3-(3′,4′,5′-*tri*-*n*-decyloxyphenyl)-5-(3″,4″-*di*-*n*-decyloxyphenyl)pyrazole (**L2**) react with [AuCl(tht)], (tht = tetrahydrothiophene) to yield the trinuclear complexes **C1** and **C2**, respectively. The nuclearity of the complexes were confirmed by molecular weight determinations and mass spectrometric measurements. Related trinuclear gold pyrazolate compounds have been reported previously.[5]

Interestingly, complexes **C1** and **C2** form hexagonal columnar mesophases (Scheme 2), which were studied by optical microscopy, differential scanning calorimetry (DSC), and X-ray diffraction. The most important data obtained by these three techniques is summarized in Table 1. Compound **C1** melts at 59 °C to give the columnar phase, and clears at 64 °C. The freshly prepared compound **C2** shows the same mesophase at room temperature and becomes isotropic at 59 °C. During the transition of the isotropic liquid to the mesophase, a slight hysteresis was observed in the cooling process (ca. 9 and 4 K, respectively). In both cases the mesophase remains up to temperatures of

Table 1. Optical and thermal properties of the complexes **C1** and **C2** and X-ray parameters of the mesophases.

Compound	Mesomorphic properties [a]					**a** [b]
C1	C	59 (112.1) [c]	D_{hd}	64 (2.8)	I	32.4
		– [d]	D_{hd}	55 (2.2)	I	
C2	C	36 [e]	D_{hd}	59 (5.8)	I	31.7
		– [d]	D_{hd}	55 (4.8)	I	

[a] C, crystal phase; D_{hd}, disordered hexagonal columnar phase (disordered means that there is no periodicity along the columnar axis); I, isotropic phase; T [°C] (ΔH [kJ mol^{-1}]). Temperatures given for onset of transition. Heating and cooling scans at 10 K min^{-1}. [b] Intercolumnar parameter [Å]. [c] This transition only appears in the first heating. [d] Cooling scan, the D_{hd} phase remains unchangeable at −30 °C. [e] This transition only appears when the compound is heated for the first time, several weeks after it was obtained. The enthalpy could not be measured because the sample was not fully crystalline.



Scheme 2. Assignment of the ^{1}H NMR signals of the aromatic protons in the complexes **C1**, **C2a**, and **C2b**, and the statistical probability of isomers for compound **C2**. [a] Those products with these statistical probabilities are structurally equivalent.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2833 $ 15.00+.25/0

−30 °C. However, compound **C1** crystallizes after five or six hours at room temperature. On the other hand, compound **C2** remains in the hexagonal mesophase for several weeks before starting to crystallize very slowly.

The textures observed by optical microscopy under polarized light are fan-shaped (Fig. 1), which is typical for hexagonal columnar mesophases.

Fig. 1. Fan-shaped texture of the D_{hd} phase of compound **C1** at 20 °C between two crossed polarizers.

In order to obtain more information on the structures of the different phases exhibited by compounds **C1** and **C2**, the mesophase of both compounds and the solid crystalline phase of compound **C1** were analyzed at room temperature by X-ray diffraction. The solid phase of **C2** could not be studied because it was not fully crystallized. The X-ray diffraction patterns of the mesophase of both compounds display a set of sharp peaks in the small-angle region with reciprocal spacings in the ratio $1:\sqrt{3}:\sqrt{4}:\sqrt{7}$. These peaks are the (1 0), (1 1), (2 0), and (2 1) reflections of a two-dimensional hexagonal network with a lattice constant $a = 32.4$ Å for compound **C1** and $a = 31.7$ Å for compound **C2** (see Table 1). This agrees with a hexagonal columnar mesophase, in which the column axes are located at the nodes of the two-dimensional network and are oriented along the c axis. The absence of any other peaks in the diffraction pattern rules out the existence of periodicity along the columns. For this reason, no reflection is observed with the Miller index $l \neq 0$, and only a broad diffuse halo centered at 4.4 Å is found in the large-angle region; this is attributed to the averaged short-range correlations between stacked macrocycles and aliphatic chains.

The solid phase of compound **C1** yields a more complex X-ray pattern containing numerous peaks, which can be conveniently assigned to a three-dimensional C-centered orthorhombic network with cell parameters $a = 28.5$, $b = 66$, $c = 9.4$ Å. If the unit cell contains four molecules ($Z = 4$), a density of 1.17 g cm^{-3} is calculated for this structure. The area per molecule in this structure is $28.5 \times 66/2 = 940$ Å^2, and thus comparable with the area per molecule in the mesophase ($32.4 \times 32.4 \times \sqrt{3}/2 = 909$ Å^2. This, together with the fact that parameter c is much shorter than a and b suggests that the molecules also stack along the c axis in the solid state. As the unit cell is C-centered, two molecules are located at 0,0,0 and 1/2,1/2,0. If the other two molecules are located at $z = 1/2$, the stacking distance is $9.4/2 = 4.7$ Å, a typical intermolecular distance in disklike molecules.[7] A plausible explanation for the duplicity of parameter c is based on the single-crystal structure of the analogous gold complex without aliphatic chains, which was determined by Fackler et al.:[5c] There is a correlated organization in which close-stacked neighboring macrocycles are mutually rotated in such a way that the gold atoms of a molecule lie on top of the pyrazole rings of the lower neighbor, whereas the next nearest neighbor, situated at 9.4 Å along the c axis, has the same orientation. Unfortunately, all attempts to grow single crystals of compound **C1** have been unsuccesful.

If we compare the cell parameters, the transition from the crystalline to the liquid crystal phase in compound **C1** could be viewed as a distorsion of the *ab* plane (cf. Fig. 2), together with the loss of long-range periodical order along the direction of the c axis.

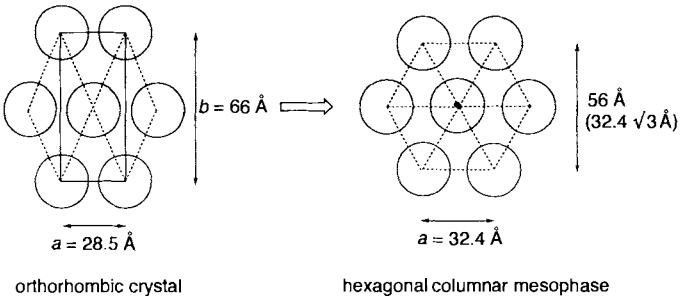


Fig. 2. Schematic diagram of the transition from the solid to the mesophase in the *ab* plane in compound **C1**; view along the c axis. The transition results in a lengthening of the orthorhombic lattice along the a axis and a shortening along the b axis; the ratio b/a becomes $\sqrt{3}$ (characteristic of a hexagonal structure).

The different mesogenic behavior of **C1** and **C2** could be explained based on their structural characteristics. The ^{1}H NMR spectrum of compound **C1** indicates the formation of only one isomer; a consequence of the free rotation of the aromatic rings around the C(pyrazole)–C(benzene) bond in solution. Only one type aromatic ring was detected. On the other hand, compound **C2**, which bears two different substituted aromatic rings on the pyrazolate groups, exhibits a more complicated ^{1}H NMR spectrum. Four signals were detected for each of the different hydrogen atoms of the pyrazolate core and the phenyl rings (Scheme 2). Curiously, the four signals have similar intensities. The spectra are consistent with the existence of two different geometrical isomers, **C2a** and **C2b**, in the ratio 1:3. Isomer **C2a** exhibits D_{3h} symmetry; this implies that the substituents **2** and **3** on the pyrazolate rings are magnetically equivalent. However, the pyrazolate substituents in isomer **C2b** are disposed asymmetrically, leading to three different possible geometrical arrangements (Scheme 2).

The existence of the two isomers in different proportions, hinders the interaction between the molecules. This interaction is necessary to obtain the crystal state, and thus compound **C2** remains as a mesophase at room temperature for a long time. On the other hand, compound **C1**, which is present in the form of one isomer and contains less aliphatic terminal chains, crystallizes more easily, melting at 59 °C and exists as a mesophase only in a narrow temperature range in the heating process.

Reactivity studies on these trinuclear compounds, aimed toward the formation of charge transfer complexes and the synthesis of new derivatives exhibiting D_{3h} symmetry (which are of interest for nonlinear optical applications) are currently in progress.

Experimental Procedure

All reactions were carried out under a N_2 atmosphere by using Schlenk techniques. The solvents were dried and freshly distilled. [AuCl(tht)] [8], **L1**, and **L2** were prepared by literature methods [3].

C1: A solution of K-**L1** (prepared in situ by reaction of a solution of **L1** (263 mg, 0.312 mmol) in acetone (20 mL) and KOH in methanol (1 mL, 0.309 M)) was added

dropwise to a suspension of [AuCl(tht)] (100 mg, 0.312 mmol) in acetone (10 mL). The reaction mixture was stirred for 5 h and the solvents were evaporated to dryness. Addition of hexane (10 mL) and filtration through Kieselguhr led to a colorless solution. Concentration of the solution to about 1 mL and addition of a mixture of ether (1 mL) and methanol (10 mL) gave a white solid which was separated by filtration, washed with methanol, and dried under vacuum. Compound **C1** was purified by column chromatography (hexane/dichloromethane 4/1) to give a white microcrystalline product. Yield: 40%. Elemental analysis for $C_{165}H_{273}N_6Au_3O_{12}$: calcd. (found) (%): C 63.44 (63.13), H 8.81 (8.69), N 2.69 (2.64); ^{1}H NMR (300 Hz, $CDCl_3$, 55 C): δ = 0.83–0.87 (m, 36H), 1.24–1.47 (m, 168H), 1.70–1.80 (m, 24H), 3.74 (t, J = 6.4 Hz, 12H), 3.92 (t, J = 6.4 Hz, 12H), 6.51 (d, J = 8.2 Hz, 6H, H4), 6.74 (s, 3H, H1), 7.21 (d, J = 1.8 Hz, 6H, H2), 7.38 (dd, J = 8.2 Hz, J = 1.8 Hz, 6H, H3); IR (nujol, NaCl pellet): ν (C=N and arC=C): 1607, 1589, 1528 and 1501 cm^{-1}; ν (C–O) = 1261 cm^{-1}; MS (FAB$^+$): m/z : 3123 ([M – 1]$^+$). M_r (calcd.) = 3124.0, M_r (found) = 3020.0.

C2: Compound **C2** was prepared analogously to **C1** starting from **L2** (312 mg, 0.312 mmol), KOH/MeOH (1 mL, 0.309 M), and [AuCl(tht)] (100 mg, 0.312 mmol), to give a colorless waxy product. Yield: 35%. Elemental analysis for $C_{195}H_{333}N_6Au_3O_{15}$: calc (found) (%): C 65.19 (65.42), H 9.34 (8.96), N 2.34 (2.37); ^{1}H NMR (300 MHz, $CDCl_3$, 55 °C): δ = 0.84–0.89 (m, 45H), 1.26–1.49 (m, 210H), 1.65–1.79 (m, 30H), 3.59-3.92 (4t, 30H), 6.44, 6.45, 6.51, 6.52 (4d, J = 8.4 Hz, 3H, H4), 6.74, 6.75, 6.77, 6.79 (4s, 3H, H1), 6.96, 6.98, 7.05, 7.06 (4s, 6H, H5), 7.18, 7.21, 7.22, and 7.26 (d, J = 2 Hz, 3H, H2), 7.37–7.44 (m, 3H, H3). IR (nujol, NaCl pellet): ν (C=N and arC=C): 1586, 1524, 1494 cm^{-1}; ν (C–O) = 1259, 1239 cm^{-1}; MS (FAB$^+$) m/z: 3593 (M^+); M_r (calcd.) = 3592.8, M_r (found) = 3432.8.

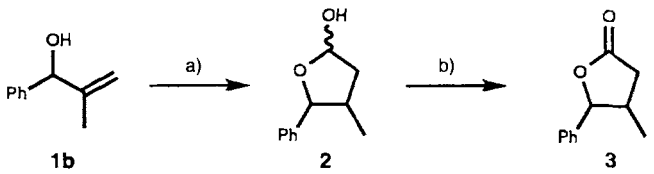
Substrate-Directed Diastereoselective Hydroformylation of Methallylic Alcohols**

Bernhard Breit*

Structural units with two adjacent stereocenters are important targets in stereoselective synthesis. In the construction of such units it is often advantageous to start with a compound already containing a stereocenter and to generate the second stereocenter by substrate-directed asymmetric induction.[1] For synthetic efficiency the second step should lead to an extension of the carbon framework. The hydroformylation of methallylic alcohols meets these requirements.[2, 3] However, preliminary studies with free methallylic alcohols showed, that in contrast to the rhodium-catalyzed hydrogenation of 2-substituted allylic alcohols,[4] the hydroxyl functionality alone is not able to direct the reaction efficiently. Thus hydroformylation of the methallylic alcohol **1b** gave a 1:1 *syn/anti* mixture of the lactols **2**. The diastereomer ratio was determined after oxidation to the lactones **3** (Scheme 1).



Scheme 1. a) 0.357 mol% $[Rh(CO)_2(acac)]$, 20 equiv PPh_3, 20 bar H_2/CO (1:1), toluene, 90 °C, 24 h, 83%; b) pyridinium chlorochromate, CH_2Cl_2, 20 °C, 16 h, 95%. For lactone **3**, *syn/anti* = 1:1. Hacac = acetyl acetone.

This experiment indicated that an effective directing metal-coordinating group is required and should meet several requirements. First, this functionality must be able to compete as a ligand with carbon monoxide, which is present in large excess. Simultaneously it must not coordinate irreversibly to the catalytically active transition metal center, because this would consume stoichiometric amounts of rhodium and catalysis would not be possible. One suitable ligand would be a triarylphosphane, because the rapid exchange of monodentate triarylphosphanes on rhodium complexes under hydroformylation conditions is documented.[5] Second, this coordinating group has to be introduced and removed readily, and should also be sufficiently stable against oxidation and hydrolysis. A ligand fulfilling all these requirements is the *ortho*-diphenylphosphinobenzoic acid (*o*-DPPBA), which is readily available from triphenylphosphane, sodium, and *ortho*-chlorobenzoic acid.[6] The corresponding methallylic *ortho*-diphenylphosphino benzoic esters **4a–i** can be obtained by esterification with dicyclohexylcarbodiimide in the presence of catalytic amounts of *N*,*N*-dimethylaminopyridine.[7]

In the catalytically active species in the hydroformylation the rhodium center is supposed to coordinate two P-donor ligands besides the olefin.[5] For that reason a second P-donor besides the coordinating *o*-DPPB unit becomes necessary. Such an ideal coligand should simultaneously stabilize the catalyst and enhance stereoselectivity of the reaction by increased steric interactions. Both might be achieved by using a sterically demanding π-acceptor ligand like triphenylphosphite.[8]

Hydroformylation of the methallylic *ortho*-diphenylphosphinobenzoates **4a–i** employing $[Rh(CO)_2(acac)]/P(OPh)_3$ as the catalyst system gave the *syn*-aldehydes **5a–i** as the major diastereomers usually in high yields and with mostly excellent diastereoselectivities (Scheme 2, Tables 1, 2). In particular, the reactions of methallylic alcohols with a branched substituent in the α-position, which is attached either by an sp^2- or sp^3-hybridized carbon atom, gave products with preparatively valuable diastereomeric ratios between 90:10 and 96:4 (entries 1–6, and 10). Only in the case of methallylic alcohols with primary alkyl substituents at the stereogenic center (entries 7 and 8) were the diastereoselectivities moderate. Evidently this α-substituent must exert a certain steric demand for differentiation of the two

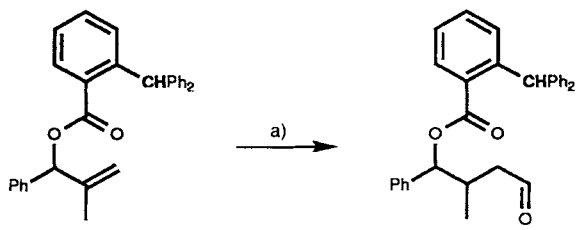
the lactols **2** and the phosphinocarboxylic acid. Oxidation of the lactols **2** provided the known lactones *syn*-**3** und *anti*-**3**.[10]

Even though the *ortho*-diphenylphosphinobenzoate unit is an intrinsically coordinating functionality, this role was not yet proven as the basis for the observed diastereoselectivity. An experiment that could give further mechanistic insight is the hydroformylation of the methallylic benzoate **6**, which differs from **4b** only by the replacement of the phosphorus atom by a CH unit. Although benzoate function in **6** should have almost the same structural features as the *o*-DPPB unit in **4b**, **6** cannot be temporarily coordinated by the catalytically active transition metal center (Scheme 3).



6 **7**

Scheme 3. a) 0.7 mol% [$Rh(CO)_2(acac)$], 4 equiv $P(OPh)_3$, 20 bar H_2/CO (1:1), toluene, 90 °C, 24 h, 60% conversion. For **7**, *syn*/*anti* = 1:1.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3523-2836 $ 15.00+.25/0

The reaction conditions in hydroformylation experiment with **6** were identical to those employed in the experiment with **4b**. At 60% conversion the crude reaction mixture contained a 1:1 mixture of *syn*- and *anti*-**7**, in other words, no diastereoselectivity. In contrast, **4b** reacted quantitatively to give **5b** (*syn*/*anti*, 92:8). This experiment demonstrates that the presence of a sterically demanding substituent alone is not sufficient for diastereoselective hydroformylation of methallylic alcohols; however, a structurally and electronically well-suited functionality like the *o*-DPPB unit can serve as a coordinating and directing group and lead to synthetically useful diastereoselectivities in hydroformylation. The extension of this concept to other substrates and transition metal catalyzed reactions is currently under way.

Experimental Procedure

5a (entry 1 in Table 1): A solution of $[Rh(CO)_2(acac)]$ (0.9 mg, 3.5×10^{-3} mmol) in 3 mL of toluene at 20 °C (exclusion of air and moisture) was charged with $P(OPh)_3$ (4.5 mg, 1.4×10^{-2} mmol) and stirred for 15 min at 20 °C. Subsequently **4a** (201 mg, 0.5 mmol) was added and the resulting solution was cannulated into a stainless-steel autoclave, which had been evacuated and refilled with argon several times. The cannula was rinsed with additional toluene (2 mL). The autoclave was heated to 90 °C and then pressurized successively with carbon monoxide (10 bar) and hydrogen (10 bar). The reaction mixture was stirred at 90 °C for 24 h, then the autoclave was cooled rapidly to 20 °C. The reaction mixture was filtered through a small plug of silica gel with *tert*-butyl methyl ether (30 mL). After evaporation of the solvent in vacuo, the crude product was analyzed by NMR to determine the conversion (99%) and the diastereomer ratio (96:4). Subsequent column chromatography on silica (solvent: 1/9 *tert*-butyl methyl ether/petroleum ether) provided **5a** (210 mg, 97%) as a highly viscous oil.

The Ca^{2+} Ion as a Cofactor for a Novel RNA-Cleaving Deoxyribozyme**

Dirk Faulhammer, and Michael Famulok*

The structure and reactivity of ribozymes and proteins depend on specific interactions of their monomers with each other, and in the end it is their primary sequence that determines their secondary and tertiary structure. However, the ionic strength of the buffer solution and the presence of certain divalent metal ions are often crucial for the formation of stable and active structures. This is particularly true for ribozymes,[1] for which Mg^{2+} or Mn^{2+} ions are commonly used as cofactors for catalysis. These ions are directly involved in the reaction by activating functional groups or water and cannot be substituted by other polycations. Therefore, ribozymes are a special class of metalloenzymes; no known ribozyme is active in the absence of divalent metal ions, which are thus essential for their chemistry. In principle, one can think of RNA as a scaffold for a site-specific reaction of the metal ion.

We wondered whether it might be possible to apply in vitro selection of combinatorial nucleic acid libraries to isolate a deoxyribozyme that cleaves an RNA substrate using a non-metal cofactor rather than divalent metal ions. As a promising candidate we chose the amino acid histidine, which plays a central role in the hydrolysis of RNA by ribonuclease A.[2] In the catalytic center of the enzyme the imidazole side chains of His12 and His119 form an acid–base pair and promote the hydrolysis of the phosphodiester bond. Free imidazole in solution is known to hydrolyze RNA by forming an acid–base pair.[3] Moreover, the catalytic center of ribonuclease A has been mimicked by model compounds.[4] Our experimental approach was based on the assumption that a histidine molecule would be complexed in the immediate proximity of the cleavage site and would form an acid–base pair with a free histidine molecule in solution. The nucleic acid would thus serve to position the imidazole residues in a suitable fashion and catalyze RNA cleavage.

The selection protocol was designed following a recent experiment by Breaker and Joyce which described the selection of Pb^{2+}- and Mg^{2+}-dependent DNA enzymes.[5] We constructed a library of single-stranded DNA with a complexity of roughly 5×10^{14} molecules. The 5′-end of the DNA was biotinylated and consisted of a constant region with a single ribonucleotide (rA) at position 28, which served as a defined cleavage site. This domain was followed by a randomized region of 74 nucleotides which carried a second constant primer-binding site at its 3′-end. The library prepared from synthetic DNA was amplified by the polymerase chain reaction (PCR); a second round of PCR was used to introduce the 5′-biotinylated region including the ribonucleotide cleavage site. The resulting double-stranded DNA pool was then immobilized on a streptavidin matrix. The non-biotinylated strand was removed by increasing the pH of the buffer, and the remaining immobilized library of single-stranded DNA was equilibrated and incubated with 20 mM histidine in buffered solution at pH 7.0 and 37 °C. The Mg^{2+} concentration of 0.5 mM was 40 times less than that of histidine,

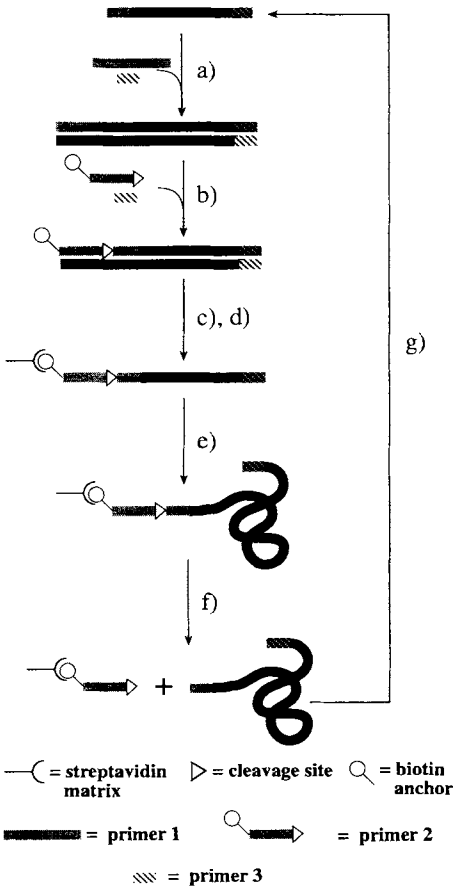
which was thought to result in a preference for the amino acid rather than the metal ion in cofactor selection (Scheme 1). To largely exclude the effect of heavy metals, the buffer also contained 20 μM EDTA. The eluted hydrolysis products were amplified as described above, and the enriched pool was subjected to subsequent selection cycles (Scheme 1). After seven cycles of selection and amplification, a marked increase in the rate of hydrolysis at the ribonucleotide position was observed. No activity was detected in a control experiment in which the ribonucleotide rA in the library was replaced by a deoxynucleotide. However, despite the large excess of histidine, the metal ion was selected as a cofactor, as shown in a control without histidine.[6]

After three additional cycles of selection/amplification, 44 clones were sequenced and could be divided into eight related classes, each of which contained individual sequences that differed only by point mutations or deletions (Table 1). Four classes showed homology within a 23 nucleotide region, which varied in location and sequence context from class to class. It could not be determined whether this homologous region is presented within a unique structural context (for example Watson–Crick helices or other structural elements). Thus, a common secondary structure was not found for these classes. Moreover, no homologies to a recently selected Mg^{2+}-dependent DNA enzyme were found.[5b]

Single clones from the different classes were chosen and tested for catalytic self-cleavage in solution under selection conditions, but in the absence of histidine. In addition, we tested the cleavage in the presence of other divalent metal ions (Mg^{2+}, Ca^{2+}, Ba^{2+}, Sr^{2+}, Pb^{2+}, Mn^{2+}, Zn^{2+}, Cd^{2+}). For clone Mg5 (Fig. 1), the extent of hydrolysis with 500 μM Ca^{2+} (63%) was significantly higher than with Mg^{2+} (25%). This result is remarkable not only because the selection had been performed in absence of Ca^{2+} ions but also because the pK_a von Mg^{2+} is considerably lower than that of Ca^{2+} (Table 2). On first glance this might argue against the direct participation of metal hydroxides, in contrast to the situation found, for example, for the hammerhead ribozyme.[7] However, Table 2 shows that for the other divalent metal ions the rates of hydrolysis follow the trend given by their pK_a values, as would be expected for the direct involvement of metal hydroxides. Furthermore, chemical modification analyses revealed no Mg^{2+}- or Ca^{2+}-dependent differences in the secondary structure of the DNA enzyme.

The catalytic efficiency of clone Mg5 strongly depends on the concentration of Mg^{2+} and Ca^{2+} ions. In both cases, the rate constants approach a saturation value with increasing metal ion concentration. Indeed, Figure 2a not only shows that the selection was performed at far below optimal concentration of the metal ion, but also that Ca^{2+} ions might promote the structure formation of this catalyst better than Mg^{2+} ions, because the saturation value is reached at a much lower concentration.

Based on the secondary structure of clone Mg5 (see Fig. 1), the unimolecular system was transferred into a bimolecular sys-



Scheme 1. Selection scheme; black strands: randomized region; gray and striped strands: constant regions (primer binding sites); ▽ in primer 2: rA position. a) In the first PCR the DNA library pool is amplified using primers **1** and **3**, whereas in the selection the eluted cleavage products are amplified (see Experimentel Procedure). b) In the second PCR with primers **2** and **3** the library is labeled with [α-^{32}P]-dCTP. c) Double-stranded DNA is dissolved in buffer containing 1 M NaCl and 50 mM 2-[4-(hydroxyethyl)piperazin-1-yl]ethanesulfonic acid (HEPES) (pH 7.4), loaded on 50–100 μL streptavidine agarose, and washed with the same buffer (5 × 500 μL). d) Single-stranded DNA is obtained by denaturing with 200 mM NaOH (5 × 500 μL). e) Single-stranded DNA is equilibrated by addition of 125 mM NaCl (5 × 500 μL), 125 mM KCl, 0.5 mM $MgCl_2$, 20 μM EDTA, and 50 mM NaH_2PO_4/Na_2HPO_4 (pH 7.0 at 37 °C). f) Single-stranded DNA is then incubated at 37 °C with the same buffer containing 50 mM histidine. Incubation time in rounds 1–8: 12 h, in rounds 9 and 10: 1 h. g) Eluted cleavage products were subjected to further cycles of selection and amplification.

Table 1. Sequence classes of the selected clones. Onla the randomized region with the constant primer binding sites is shown. The homologous regions found in four classes are highlighted in gray. Clone Mg5 belongs to class 2.

–	1.7 ± 0.2	–			

[a] The single-stranded clone Mg5 labeled at the 5'-end was incubated in the presence of the respective metal ion at 37 °C for 4 h with 125 mM NaCl, 125 mM KCl, 20 μM EDTA, and 50 mM MOPS/KOH (pH 7.0 at 37 °C). Cleavage products were separated on 10% PAGE and quantified with a phosphorimager. The tests were carried out twice. Absolute errors are given. [b] K_a is based on the equilibrium: $[M(H_2O)_n]^{2+} \rightleftharpoons [M(H_2O)_{n-1}(OH)]^{+} + H^{+}$. pK_a is thus a measure of the acidity of a water molecule coordinated to a metal ion (or the basity of a metal-coordinated hydroxide ion, which decreases with increasing pK_a). Therefore, $M(H_2O)_n^{2+}$ is cited instead of M^{2+}.

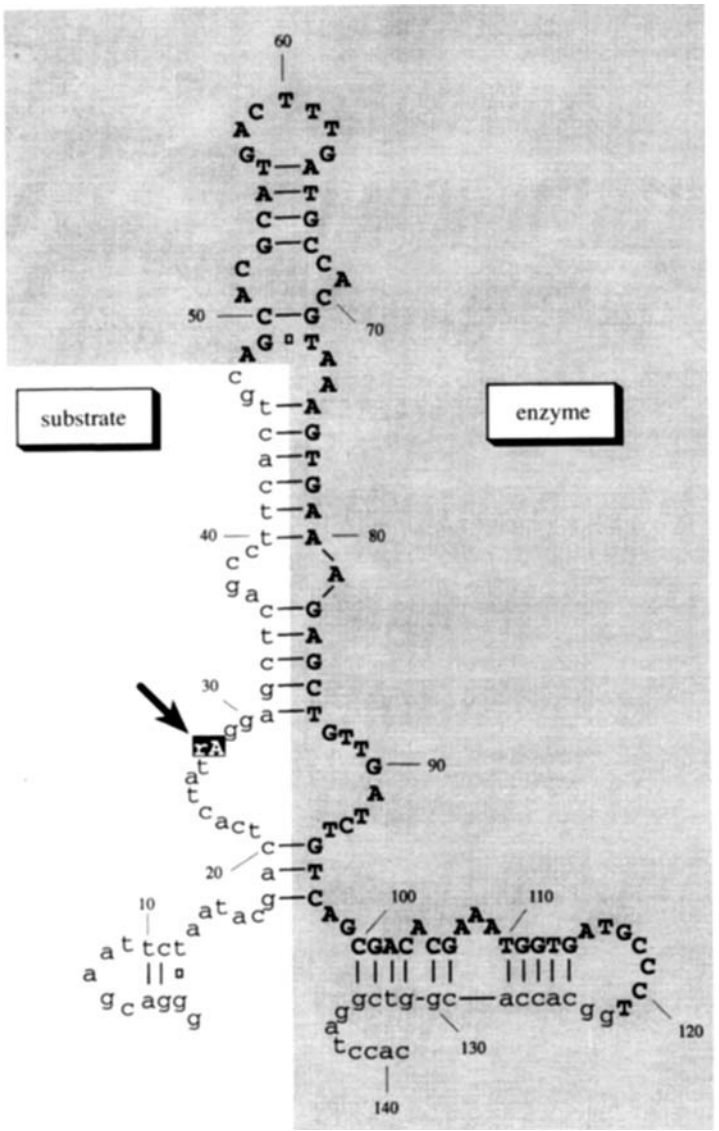

Fig. 1. a) Secondary structure of clone Mg5. The structure was proven by chemical modification analysis (data not shown). The 5'-primer binding site (in lowercase letters) is identical with the substrate. The defined rA cleavage site in this region is marked by an arrow. The enzyme consists of the randomized region (capital letters in boldface) and the primer binding site at the 3'-end (lowercase letters), both of which are printed on a gray background.

tem; the 47 nucleotide long, defined 5'-region with the rA cleavage site served as the substrate. The remaining 94 nucleotide enzyme contained the randomized region and the 3'-primer binding site. Like the intramolecular system, the cleavage efficiency of the intermolecular system was dependent on the concentrations of Mg^{2+} and Ca^{2+} ions (Fig. 2b). In analogy to similar catalyst systems,[9] the optimal metal ion concentration is much higher than in the intramolecular reaction. It is important to note, however, that in our system the values of the observed rate constants of the cleavage reaction are always lower with Mg^{2+} ions than with Ca^{2+} ions within the range of concentrations evaluated. When the pH of the buffer was increased while the other reaction conditions were left unchanged (10 mM Mg^{2+} or Ca^{2+}), the rate constants for the catalyzed hydrolysis increased (Fig. 3). This result clearly indicates the participitation of metal hydroxides in the reaction, particularly as an increase of the uncatalyzed hydrolysis under the same conditions could not be detected. Therefore, it seems reasonable to propose that catalysis in the presence of Ca^{2+} ions is more efficient owing to the more suitable positioning of this ion at the cleavage site, similar to special situations in the group I intron of *Tetrahymena*.[10] Alternatively, these results might indicate that the selection criterion is merely a favorable arrangement of the leaving group and the attacking nucleophile near the phosphodiester cleavage site[11] and that the divalent metal ion does not play any role initially. The metal ion could then serve as a Lewis acid or its hydroxide form could accelerate cleavage. It is known that Ca^{2+} ions can directly coordinate to ribose hydroxyl groups,[12] thereby contributing to the activation of the 2'-hydroxyl group of the sugar.

With substrate saturation, the intermolecular system shows the properties of a true enzyme–substrate complex (Table 3). At 10 mM concentration of the metal ion, the Michaelis–Menten constants K_M of the Mg^{2+}-dependent (5.7 μM) and the Ca^{2+}-dependent cleavage (6.4 μM) are on the same order of magnitude. The rate constants for Mg^{2+}- and Ca^{2+}-dependent cleavage ($k_{cat} = 0.01\ min^{-1}$ and $0.1\ min^{-1}$, respectively) differ significantly, by a factor of ten. However, in the Michaelis–Menten equation k_{cat} not only describes the rate of the chemical step but also that of the decomposition of the enzyme–product complex and other reaction parameters. So it still remains open to what extent the values of k_{cat} are influenced by the chemical step of the reaction—the hydrolysis of the phosphodiester bond. The mag-

Table 3. Michaelis–Menten parameters of the enzyme–substrate complex based on clone Mg5 (the same experimental conditions for both [a] and [b]).

M^{2+}	k_{cat} [min^{-1}]	K_M [μM]	k_{cat}/K_M [$M^{-1}\,min^{-1}$] [a]	$k_{cat}\,K_M$ [$M^{-1}\,min^{-1}$] [b]
Mg^{2+}	0.01	5.7	1.8×10^3	4.4×10^3
Ca^{2+}	0.1	6.4	1.6×10^4	3.4×10^4

[a] At substrate saturation; substrate concentrations: 0.1, 0.2, 0.5, 1, 2.5, 10, 20, and 50 μM; enzyme concentration: 0.1 μM. Both k_{cat} and K_M were determined by linearization in a Lineweaver–Burke plot. [b] Enzyme in excess over substrate. k_{cat}/K_M were determined at different enzyme concentrations (10, 20, 50, 100, 200, 500, and 1000 nM) and obtained by dividing pseudo-first order rate constants by the enzyme concentration. The calculated values were averaged for each metal ion. Substrate concentration: 1 nM.

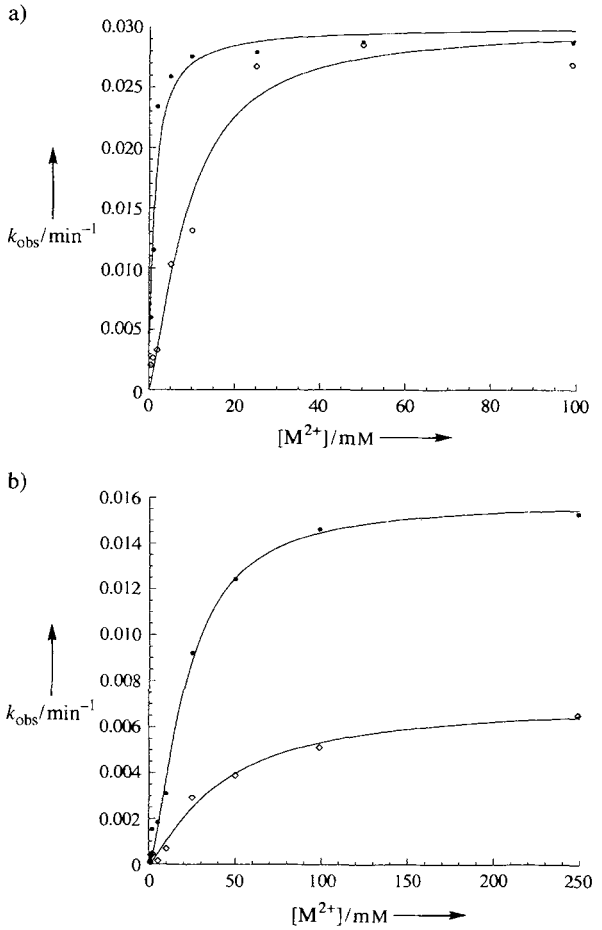

Fig. 2. Dependence of the cleavage activity on Mg^{2+} and Ca^{2+} concentrations: a) intramolecular reaction: clone Mg5 was amplified by PCR using primers **2a** and **3a** (see Experimental Procedure). 10 pmol of the purified PCR product was labeled at the 5'-end with [γ-^{32}P]-ATP (30 μCi) in 70 mM Tris-HCl (pH 7.6), 10 mM $MgCl_2$, and 5 mM dithiothretiol (DTT) using T4 polynucleotide kinase (NEB), and immobilized on streptavidin agarose. The labeled DNA strand was eluted by washing with 200 mM NaOH (300 μL) and precipitated with ethanol from 0.3 M NaOAc. After centrifugation and washing the DNA was resuspended in H_2O. Labeled single-stranded DNA with an activity of 150–200 cps was incubated at 37 °C with 250 mM NaCl, 250 mM KCl, 1 mM EDTA, 50 $\mu g mL^{-1}$ bovine serum albumin (BSA), 50 mM 2-(*N*-morpholino)propanesulfonic acid (MOPS)/KOH (pH 7.0 at 37 °C), and with 0.5, 1, 2, 5, 10, 25, 50, and 100 mM $MgCl_2$ ($\diamond$) or $CaCl_2$ ($\bullet$). Aliquots were taken after 0, 30, 60, 120, and 240 min, and the reaction was stopped by precipitation with ethanol. Hydrolysis products were separated on 10% polyacrylamide gel (PAGE) and quantified on a STORM 860 phosphorimager (Molecular Dynamics). Observed rate constants k_{obs} were determined by linear plots of the logarithm of substrate decay versus time. In the graph k_{obs} is plotted versus metal ion concentration. b) Intermolecular reaction: 1 nM substrate labeled at the 5'-end (prepared in analogy to a)) was incubated with 100 nM enzyme under the same conditions as described in a) with 0.5, 1, 2, 5, 10, 25, 50, 100, and 250 mM $MgCl_2$ ($\diamond$) and $CaCl_2$ ($\bullet$). Aliquots were taken after 0, 30, 60, 120, and 240 min, and the reaction was stopped by precipitation with ethanol. Analysis and quantification was as described in a). Observed rate constants k_{obs} were determined from the slope of the initial rates of substrate decay at the actual metal ion concentration. In the graph k_{obs} is plotted versus metal ion concentration.

nitudes of k_{cat}/K_M were confirmed by experiments under single-turnover conditions. Values were 4400 $M^{-1}min^{-1}$ (Mg^{2+}-dependent cleavage) and 34000 $M^{-1}min^{-1}$ (Ca^{2+}-dependent cleavage) (Table 3). Cleavage of a pure RNA substrate under the same reaction conditions was not observed.

The result of the selection described here is unexpected. Although the sequences of the selected library were not in contact with Ca^{2+} ions during the selection, cleavage with this cofactor is more efficient than with Mg^{2+} ions even though Mg^{2+} ions were present during selection, albeit in suboptimal concentrations, and even though the pK_a of Mg^{2+} is lower than that of Ca^{2+}. Despite the vast excess of histidine, the selected clones are histidine-independent. A possible explanation for this result might be that in a nucleic acid many more binding sites exist for metal ions than for non-metal cofactors. To select for cleavage induced by a non-metal cofactor it might therefore be more promising to use pools that contain a preformed binding pocket for the cofactor. In this way, the non-metal cofactor might be able to compete successfully against the high number of metal binding sites. Secondly, an amino acid might not be an optimal cofactor in such a system because of the electrostatic forces between the phosphate backbone of the nucleic acid and the negative charge of the α-carboxyl group. However, numerous in vitro selections for the binding of RNA or single-stranded DNA to various amino acids (for example arginine, citrulline, tryptophane, and even the hydrophobe valine) have demonstrated the ability of nucleic acids to recognize amino acids with high affinity and specificity.[13] It would be interesting to compare the results of the selection described here with those of a selection in which the cofactor is the uncharged imidazole or the positively charged histamine instead of the zwitterionic histidine.

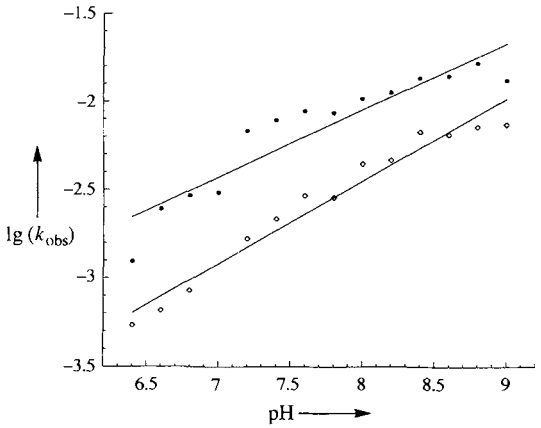

Fig. 3. Dependence of catalytic activity on pH: 1 nM substrate labeled at the 5'-end (see Fig. 2a) was incubated at 37 °C with 100 nM enzyme and 250 mM NaCl, 250 mM KCl, 1 mM EDTA, 50 $\mu g mL^{-1}$ BSA, and 50 mM buffer of the actual pH: 2-[*N*-morpholino]ethanesulfonic acid (MES)/KOH (pH 6.4, 6.6 at 37 °C), MOPS/KOH (pH 6.8, 7.0, 7.2, 7.4, 7.6, 7.8 at 37 °C), 3-[tris(hydroxymethyl)methylamino]-2-hydroxypropanesulfonic acid (TAPS)/KOH (pH 8.0, 8.2, 8.4, 8.6, 8.8, 9.0 at 37 °C). The incubation mixture contained 10 mM $MgCl_2$ ($\diamond$) or $CaCl_2$ ($\bullet$). Aliquots were taken after 0, 30, 60, 120, and 240 min, and the reaction was stopped by precipitation with ethanol (analysis and quantification as in Fig. 2a). Observed rate constants k_{obs} were determined from the slope of the initial rates of substrate decay at the actual metal ion concentration. In the graph $lg(k_{obs})$ is plotted versus pH.

Experimental Procedure

DNA library and oligonucleotides: The DNA library GGAGCTCAGC-CTTCACTGC—$(N)_{74}$—GGCACCACGGTCGGATCC (N = nucleotide), the oligonucleotides GGGACGAATTCTAATACGACTCACTATAGGAGCTCAGC-CTTCACTGC (**1**), biotin-GGGACGAATTCTAATACGACTCACTATrA (**2**), GTGGATCCGACCGTGGTGCC (**3**), and biotin-**3** (**3a**), and the DNA enzyme AGCACGCATGACTTTGATGCCACGTAAGTGAAAGAGCTGTTGATCTG-TCA GCGACACGAATGGTGATCCCTGGCACCACGGTCGGATCCAC were synthesized by solid-phase synthesis on a Millipore Expedite oligonucleotide synthesizer. The substrate 47 nucleotides long, GGGACGAATTCTAATACGACT-CACTATrAGGAGCTCAGCCTTCACTGC, was purchased from Eurogentec (Seraing, Belgium); oligonucleotide **2a** (same sequence as **2**, but lacking the biotin) was purchased from MWG Biotech (Ebersberg, Germany). The RNA substrate GGGACGAAUUCUAAUACGACUCACUAUAGGAGCUCAGCCUUCAC-UGC was transcribed in vitro from GCAGTGAAGGCTGAGCTCCTATAGT-GAGTCGTATTAGAATTCGTCCCTATAGTGAGTCGTATTAGAGCGC and GCGCTCTAATACGACTCACTATAGGGACGAATTC using T7 RNA polymerase.

Polymerase chain reaction (PCR): The library of random-sequence DNA was amplified by PCR (2 mL) with 800 pmol single-stranded DNA and 2 μM oligonucle-

otides **1** and **3** as primers, as well as 10 mM Tris-HCl (pH 8.3), 50 mM KCl, 1.5 mM $MgCl_2$, 0.03% polyoxyethylenesorbitan monolaurate (Tween 20), 0.001% gelatin, 200 μM of each dNTP, and 0.02 U μL^{-1} Taq DNA Polymerase, in five cycles at 94 °C for 1 min, 55 °C for 1 min, and 72 °C for 2 min. This PCR was followed by three cycles of PCR (20 mL) conducted under the same reaction conditions using 0.4 μM **2** and **3** as primers. Cycles of PCR were performed at 94 °C for 4 min, 55 °C for 7 min, and 72 °C for 7 min. During selection, eluted DNA was amplified first in 7–12 cycles of PCR (100 μL) using 0.2 μM **1** and **3**. Cycles of PCR were performed at 94 °C for 1 min, 55 °C for 1 min, and 72 °C for 2 min. A 10 μL sample of the reaction mixture was then subjected to 7–10 cycles of PCR (200 μL) with 1 μM **2** and **3**, and 10 μCi [α-^{32}P]-dCTP.

A Planar [15]Metallacrown-5 That Selectively Binds the Uranyl Cation**

Ann J. Stemmler, Jeff W. Kampf, and Vincent L. Pecoraro*

One of the enduring legacies of the Cold War is the vast quantity of radioactive isotopes generated as a result of nuclear weapons development. Predictably, considerable current interest is focused on the sequestration of actinides as a means of safe waste disposal.[1] One criterion that must be satisfied in order for a molecule to be an effective agent for these purposes is that it selectively recognizes actinides. The specific recognition of ions often relies on the match between the architecture of the host molecule and the size and shape of the guest molecule.[2] Many organic ligands can bind actinides with high affinity.[3] However, while many examples exist of the preorganization of a macrocyclic compound to bind ions specifically,[4] few are selective for actinides in the presence of other hard ions such as Ca^{II}.[5, 6] We report here the rationale for the design of the first planar [15]metallacrown-5. This agent incorporates copper atoms in a macrocyclic ring and binds the uranyl ion in preference to Cu^{2+} and Ca^{2+}.

Metallacrowns are one class of molecular recognition agents that selectively bind cations or anions.[7–11] Their names are based on their similarity in structure and function to organic crown ethers. The first metallacrowns were synthesized with the ligand, salicylohydroxamic acid. This ligand binds a metal in a five-membered chelate ring with the hydroximate moiety and in a six-membered chelate ring with the iminophenolate moiety. These two chelate rings allow for a $[M-N-O]_n$ repeat unit that forms a cyclic structure orienting oxime oxygen donors toward the center of a cavity that is capable of binding cations. This synthetic strategy with salicylhydroximate (shi^{3-}) has been used to generate metallacryptate,[7b] [9]metallacrown-3,[9] [12]metallacrown-4,[7a, 7c, 7d, 7f, 10] and *nonplanar* [15]metallacrown-5[11] structural types. The metallacrowns are generally prepared in a one-step synthesis by stoichiometric addition of metal salt to the ligand in either DMF or methanol. The yield of crystalline product is usually between 60–90%.[7f]

The strategy we used to prepare an actinide-specific chelating agent required the synthesis of a ligand that forces five donor atoms into a plane while generating a cavity of sufficient size to accommodate a large, high-valent cation. Salicylohydroximate is poorly suited for this application, since the [15]metallacrown-5 isolated with this ligand contained a ring that wrapped around a central Mn^{2+} ion forming a three-dimensional cavity.[11] Salicylohydroxamic acid (H_3shi) is the perfect vehicle to achieve the 12-metallacrown-4 structural type, since the ligands are oriented at 90° angles to one another; however, it is not possible for higher denticity, planar rings to form with the shi^{3-} ligand. As shown in Figure 1, a ligand that enforces an angle of 108° is necessary in order to realize a planar, pentagonal ring. Picolinyl hydroximate, which forms two five-membered chelate rings, sat-

[**] Note from the editor: According to IUPAC recommendations hydroxamic acid is retained as the name of a class, but the compounds are preferably named as *N*-hydroxy amides. The systematic name of the triply deprotonated ion salicylhydroximate (used throughout this communication) is thus *N*,2-dioxidobenzoyl amide.

isfies this requirement. A planar ring is realized with copper(II) as a ring metal, since it prefers square-planar coordination. Transition metal complexation by the central cavity of a [15]metallacrown-5 would be disfavored by the pentagonal coordination mode; however, there are several examples of the pentagonal-bipyramidal geometry for actinides.[4c]

The predicted, planar [15]metallacrown-5 structure was demonstrated with the facile synthesis[12] and subsequent crystal structure analysis of the uranyl complex **1** (Fig. 2).[13]

$[UO_2(15\text{-}MC_{Cu^{II}/N(pic)}\text{-}5)](NO_3)_2$ **1**

At the top of Figure 2 a top view of the molecule is illustrated; the metallacrown ring is outlined in bold. At the bottom is a side view of the molecule that shows the mostly planar structure of the [15]metallacrown-5. The slight deviations from planarity are due to solvent molecules, which are bound as fifth ligands to the copper ions and lead to a square-pyramidal geometry, thus buckling the ring slightly. Two nitrate ions are bound to two of the copper ions, and a DMF oxygen atom is bound to each of the other three copper ions. The uranyl ion resides in the plane of the five oxime oxygen donors.

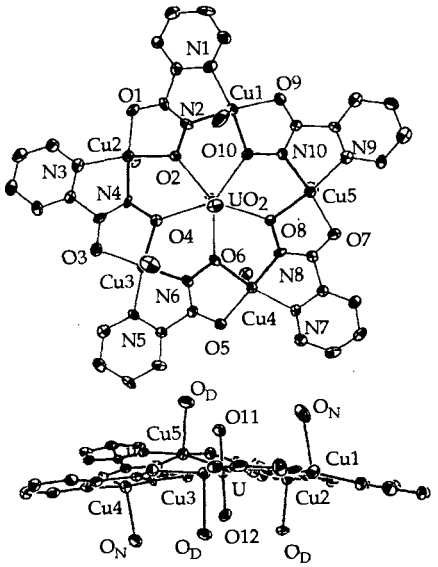

Fig. 2. Crystal structure of **1**. Top: full view. Bottom: side view. O_D = bound solvent (DMF), O_N = bound nitrate. Selected averaged bond lengths [Å] and angles [°]: U–O(11,12) 1.755(5), U–O(even) 2.402(5), Cu–O(even) 1.953(5), Cu–O(odd) 1.952(5), Cu–N(even) 1.924(6), Cu–N(odd) 2.002(6); O11-U-O12 179.2(3), O(11,12)-U-O(even) 90.0(2), O(even)-U-O(even, *cis*) 72.6(2).

Complex **1** retains its integrity in water. This conclusion is based upon mass spectral and NMR analyses. A clean electrospray ionization (ESI) mass spectrum is obtained in water with a base peak of the intact ion at *m/z* 634 ($[UO_2(15\text{-}MC_{Cu^{II}N(pic)}\text{-}5)]^{2+}$) and *m/z* 1329 ($[UO_2(NO_3)(15\text{-}MC_{Cu^{II}N(pic)}\text{-}5)]^{+}$). The four peaks from picoline protons are evident in the ^1H NMR spectrum at $\delta = +13.22, +40.97, +41.89$, and $+112$(br) in D_2O. The strong paramagnetic shift of the proton peaks can be attributed to the paramagnetism of the copper atoms. The UV/Vis spectrum of **1** in water has an absorption band at 614 nm ($\varepsilon = 397\,M^{-1}cm^{-1}$ per complex). The absorption varies linearly with the concentration of metallacrown, which demonstrates that the cluster does not decompose between 0.5 and 5 mM.

A similar metallacrown (**2**) was synthesized with calcium nitrate instead of uranyl nitrate. Complex **2** has an IR spectrum that closely resembles that of **1** except for the band at 920 cm^{-1}, which is assigned to the characteristic O=U=O stretch.[4b] It has two ESI-MS peaks, one at *m/z* 519 and one at *m/z* 1098 corresponding to $[Ca(15\text{-}MC_{Cu^{II}N(pic)}\text{-}5)]^{2+}$ and $[Ca(NO_3)(15\text{-}MC_{Cu^{II}N(pic)}\text{-}5)]^{+}\}$, respectively. The NMR spectrum showed peaks at $\delta = 10.92, 32.78, 31.79$, and 83(br) in D_2O. The UV/Vis spectrum also has a concentration-independent extinction coefficient ($\varepsilon = 420\,M^{-1}cm^{-1}$ per complex) at 569 nm. These data indicate that the basic [15]metallacrown-5 structure is retained with a different central cation.

Competition studies were undertaken to determine the selectivity of the planar [15]metallacrown-5 for these cations. NMR spectroscopy was used to monitor the addition of uranyl nitrate to **2** and calcium nitrate to **1**. After five days and a stoichiometric amount of uranyl nitrate, **2** is quantitatively converted into **1** in D_2O (Fig. 3). The reverse experiment showed no change in the NMR spectrum under the same conditions, or with a tenfold excess of Ca^{2+}, suggesting that the [15]metallacrown-5 thermodynamically prefers the uranyl ion over the calcium ion. Similarly, we have not found evidence for binding of Cu^{2+} ions in the central cavity, even when $U^{VI}O_2^{2+}$ or Ca^{II} are absent from the reaction mixture. In contrast, lanthanides can be sequestered by this metallacrown;[8] however, even these trivalent ions are displaced by UO_2^{2+} to form **1**.

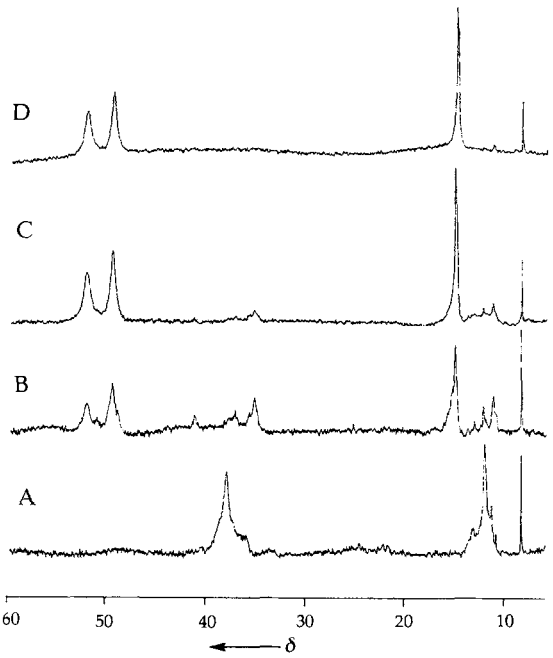

Fig. 3. ^1H NMR spectra of the conversion of **2** to **1** in D_2O. A: pure product **2**. B: **2** plus 1 equiv uranyl nitrate after 18 hours. C: same solution after 5 days. D: authentic sample of **1** dissolved in D_2O.

In summary, we have reported the preparation of a new class of molecules that can sequester UO_2^{2+} ion in aqueous solution. The [15]metallacrown-5 can be prepared in a one step synthesis with a 70% yield of crystalline product and is both stable and soluble in water. Furthermore, one can displace Ca^{2+} from the cavity of **2** with UO_2 to form **1** quantitatively. This synthetically simple and chemically stable molecule invites a new approach to sequestering actinides selectively.

[12] This [15]metallacrown-5 was synthesized with $Cu(OAc)_2$ (0.40 g, 2 mmol) and picolinyl hydroxamic acid (0.27 g, 2 mmol) dissolved in dimethylformamide (DMF) followed by the addition of $UO_2(NO_3)_2$ (0.20 g, 0.4 mmol). A 69% yield of crystals of **1** was realized after vapor diffusion with ether. Compound **2** was synthesized by adding calcium nitrate (2.5 mmol) to a solution of $Cu(OAc)_2$ (2 mmol) and picolinyl hydroxamic acid (2 mmol) dissolved in DMF. A brown solid precipitated from solution after one week (47.5% yield). The brown precipitate turned green when dissolved in methanol or water.

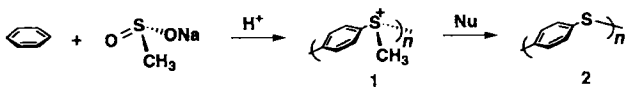
First Phenylene Polymers Linked by Sulfonium Groups

Eishun Tsuchida,* Kimihisa Yamamoto, Kenji Miyatake, and Yukio Nishimura

Arylsulfonium salts have been extensively used as photoactive cationic initiators[1–3] and for the photogeneration of protic acids in the area of lithographic resists (chemically amplified resists).[4] Polymeric sulfonium salts should also receive much attention as possible new materials. We were interested in whether the poly(phenylenesulfonium salt)s **1** could be synthesized even though the structure of the alternating phenylene rings and methylsulfonium groups is very simple and is estimated to be unstable due to the strong electron-withdrawing property of the sulfonium group. Until now, most known poly(arylenesulfonium salt)s, which were prepared by polymerization of methyl phenyl sulfoxide[5, 6] or by methylation or phenylation of poly(thiophenylene) (PPS) using methyl triflate or diphenyliodonium salts,[7] have a sulfonium substitution level below 50%.

We have already found and reported on the preparation of arylsulfonium salts with the sulfinate/acid system. For example, the reaction of sodium methanesulfinate with benzene (2:1 mol ratio) in trifluoromethanesulfonic acid gives methyldiphenylsulfonium trifluoromethanesulfonate in 92% yield.[8] This reaction should be applicable to the preparation of sulfonium-containing polymers. We report here on our successful preparation of a poly(methylsulfonio-1,4-phenylene salt) by the simple polymerization of benzene with sodium methanesulfinate in trifluoromethanesulfonic acid; the active electrophilic species in the polymerization is the dihydroxy(methyl)sulfonium cation.

Benzene was stirred with an equimolar amount of sodium methanesulfinate in trifluoromethanesulfonic acid under ambient conditions for 12 h (Scheme 1). A standard workup yielded



Scheme 1. Polymerization of benzene with sodium methanesulfinate in trifluoromethanesulfonic acid to yield **1** and **2**.

a white powder having the empirical formula $C_8H_7F_3O_3S_2$ in 42% yield.[9] A combination of NMR and IR spectra reveals the formation of poly(methylsulfonio-1,4-phenylene trifluoromethanesulfonate) (**1**). A singlet peak in range of aromatic phenyl protons is observed at $\delta = 8.30$ in the ^{1}H NMR spectrum (in CF_3COOD), which suggests that the phenylene units are symmetrically substituted at the 1- and 4-positions with electron-withdrawing groups. The peak is shifted to lower field due to the two sulfonium groups bound to the phenylene ring, and contrasts with the phenylene signals of the phenylene polymer with alternating sulfide and sulfonium groups, poly(methylsul-

fonio-1,4-phenylenethio-1,4-phenylene trifluoromethanesulfonate), which appear as an AB quartet ($\delta = 7.34$, 7.32, 7.30, 7.28, in D_2SO_4).[5] The peak assigned to the methyl protons of **1** ($\delta = 3.85$) is also observed at lower field than that of poly(methylsulfonio-1,4-phenylenethio-1,4-phenylene trifluoromethanesulfonate) ($\delta = 3.12$). The two peaks at $\delta = 133.5$ and 134.6 in the ^{13}C NMR spectrum of **1**, which are assigned to aromatic carbons, further support the structure. The experimental and calculated chemical shifts were in very good agreement. Polymer **1** was also characterized by a COSY ^1H-^{13}C NMR spectrum (Fig. 1). The minor peaks at $\delta = 3.72$ and 7.62–7.88 in the ^1H NMR spectrum and at $\delta = 131.5$, 135.2, and 137.6 in the ^{13}C NMR spectrum are assigned to the end group of the polymer chain.[10] The degree of polymerization is estimated to be 15 based on the integration ratio in the ^1H NMR spectrum.

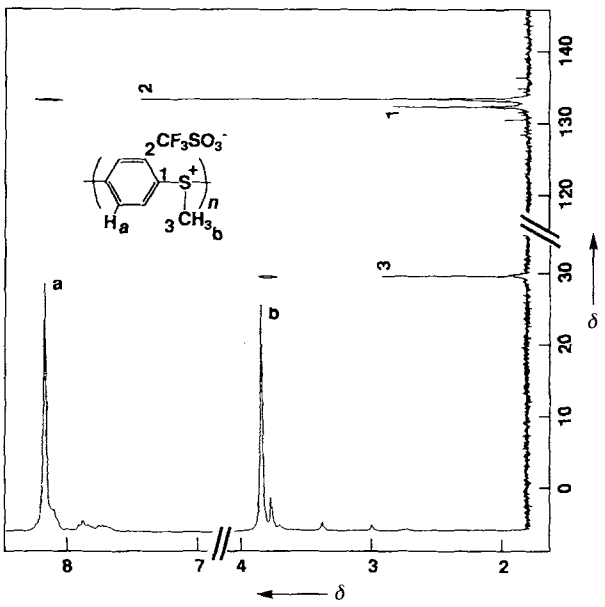

Fig. 1. COSY ^1H-^{13}C NMR spectrum of **1**.

The formation of the sulfonium bond was also confirmed by XPS investigations. The sulfur 2p core-level signals at 165.7 (S2p3/2) and 167.0 eV (S2p1/2) due to sulfonium are observed in the spectrum of **1**. The signals obviously differ from those of poly(thio-1,4-phenylene) (162.5 and 164.1 eV), which are assigned to the sulfide. The signals due to both sulfonium and sulfide groups are observed in the spectrum of poly(methylsulfonio-1,4-phenylenethio-1,4-phenylene trifluoromethanesulfonate). These results suggest that the polymer **1** consists of alternating methylsulfonium groups and 1,4-phenylene rings.

Polymer **1** is isolated as a white powder and is soluble in water, dimethyl sulfoxide (DMSO), trifluoroacetic acid, and sulfuric acid, however, it slowly demethylates in water and DMSO owing to the nucleophilic attack of the solvents. Compound **1** does not show any decomposition up to 135 °C in the solid state, and is stable in solution at up to 110 °C for over 12 h in trifluoromethanesulfonic acid, which was confirmed by thermogravimetric and ^1H NMR analyses. Polymer **1** can be quantitatively converted to poly(thio-1,4-phenylene) (PPS) (**2**) by demethylation using pyridine as a nucleophile. The IR spectrum of the resulting PPS is completely consistent with that of the previously reported PPS prepared by the polycondensation of *p*-dichlorobenzene with sodium sulfide. A single strong IR band at 820 cm^{-1} in the region of aromatic C–H out-of-plane bending supports the 1,4-linkage of the phenylene units in **2**. No absorption bands attributed to the methyl, sulfone, and sulfoxide groups are detected. High-temperature gel permeation chromatography analysis (210 °C, 1-chloronaphthalene) reveals the formation of PPS with a weight average molecular weight (M_w) of 2.7×10^3 (P_n (average degree of polymerization) = 25) and a number average molecular weight (M_n) of 1.9×10^3 ($P_n = 17$), which roughly agrees with the degree of polymerization determined from the ^1H NMR spectrum ($P_n = 15$). The melting temperature (T_m) of the PPS determined by differential scanning calorimetry (278 °C) is comparable to that of conventional PPS ($T_m = 282$ °C, $M_w = 18000$).

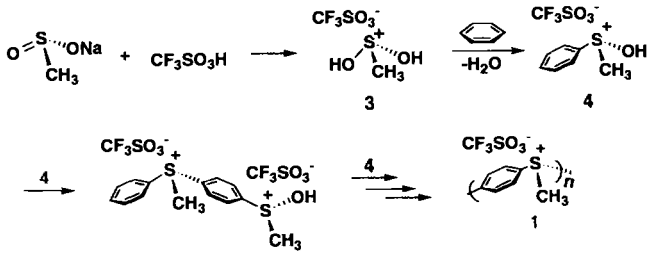
The sulfinate/acid polymerization system can be applied to other simple aromatic monomers. For example, the polymerization of *p*-xylene with sodium methanesulfinate produces poly(methylsulfonio-dimethylphenylene trifluoromethanesulfonate) (**5**) ($P_n = 10$) in 43% yield (Table 1). Polymer **5** is less hydrophilic than **1** because each phenyl ring has two methyl substituents. Consequently, **5** is soluble in acetone and acetonitrile but not in water. The electronic effect of two methyl substituents of **5** could also be confirmed by UV spectra; the λ_{max} of **5** (291 nm) is shifted bathochromically to compared to that of **1** (251 nm). Polymer **5** is consists mainly of 2,5-dimethyl-1,4-phenylene units; however, the splitting of the methyl and phenyl signals in the ^1H NMR spectrum indicates a small amount of the methylsulfonio-2,5-dimethyl-1,3-phenylene structure. Steric interactions between the methyl group and methylsulfonium group might explain why the molecular weight and the regularity of the 1,4-phenylene structure of **5** are lower than that of **1**. The polymerization of durene, which is more crowded than xylene or benzene, did not afford the corresponding sulfonium polymer. Arenes with a higher HOMO energy[11] than that of benzene (HOMO: −9.55 eV) are more effective for the polymerization. When diphenyl ether (HOMO: −9.27 eV) was polymerized with our system, the corresponding poly(sulfonium salt) **7** with a higher molecular weight ($P_n = 389$) was obtained. Diphenyl sulfide (HOMO = −9.31 eV), however, reacted to give the low molecular weight polymer **6** ($P_n = 16$) presumably due to side reactions such as the exchange[12] of the sulfide and the sulfonium species derived from sulfinic acid.

Table 1. Synthesis of poly(arylenesulfonium salt)s; the anions are trifluromethansulfonate ions in all cases.

Polymer		Yield [%]	P_n [a]	λ_{max} [nm]
	**1**	42	25	251
	**5**	43	11	291
	**6**	88	16	322
	**7**	95	389	270

[a] Average degree of polymerization based on the M_w value determined by GPC.

We postulate that the polymerization proceeds by electrophilic aromatic substitution; the dihydroxy(methyl)sulfonium cation (**3**) formed by protonation of the oxygen atom of the sulfinyl group serves as the active species (Scheme 2).



Scheme 2. Possible polymerization mechanism for the formation of **1**.

The formation of **3** requires a strong protic acid such as trifluoromethanesulfonic acid ($pK_a = -14.5$).[13] The sulfonium cation **3** reacts with a benzene unit to form a hydroxy(methyl)-phenylsulfonium cation (**4**), and successive electrophilic substitution results in the formation of poly(methylsulfonio-1,4-phenylene salt). It has not been clarified why electrophilic substitution of **4** occurs at the *para* position.[14] The electron-donating property of the lone pair of the sulfonium group through 3d–2p resonance might predominate over the electron-withdrawing effect in a strongly acidic media in analogy to electrophilic substitutions with aromatic sulfoxide.[15]

Experimental Procedure

1: (Typical polymerization procedure): To a solution of benzene (0.47 g, 6 mmol) in trifluoromethanesulfonic acid (5 mL) at 0 °C, was added anhydrous sodium methanesulfinate (0.41g, 4 mmol) slowly over 10 min. The mixture was stirred for 12 h at room temperature. The color of the reaction mixture gradually changed from pale yellow to orange. After the reaction, the mixture was poured into diethyl ether (200 mL) and a white powder precipitated. The precipitate was filtered and washed several times with diethyl ether and acetone, and then dried under high vacuum for 12 h to obtain **1** in 42% yield. Correct elemental analysis. ^{1}H NMR (400 MHz, CF_3COOD, 25 °C): $\delta = 3.85$ (s, 3H, CH_3), 8.30 (s, 4H, phenyl); ^{13}C NMR (100 MHz, CF_3COOD, 25 °C): $\delta = 28.9$ (s, CH_3, C1), 133.5 (s, phenyl, C2), 134.6 (s, phenyl, C3); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3094 m, 3027 m, 2938 m, 1638 w, 1572 w, 1400 m, 1258 vs, 1159 s, 1032 s, 820 m, 639 s.

2: A solution of **1** (0.15 g) in pyridine (3 mL) was stirred at room temperature for several minutes until a white powder precipitated. The reaction mixture was stirred a further 30 min and then heated to 120 °C for 10 h. The reaction mixture was poured into 15% hydrochloric acid (200 mL), and the precipitate was washed several times with water, methanol, and chloroform. After drying under high vacuum for 12 h, a **2** was obtained as a white powder in 100% yield. Correct elemental analysis. IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 2922 m, 2840 w, 1638 m, 1576 w, 1474 s, 1389 m, 1094 m, 1011 m, 820 s, 741 w, 691 vw.

5: As described for **1**, *p*-xylene and sodium methanesulfinate were polymerized. The usual workup gave **5** as a white powder in 43% yield. Correct elemental analysis. ^{1}H NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta = 2.24$–3.08 (m, 6H, CH_3), 3.87–4.00 (m, 3H, CH_3), 7.38–8.35 (m, 2H, phenyl); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3023 w, 2932 w, 1709 w, 1636 m, 1451 m, 1260 vs, 1165 s, 1032 s, 880 w, 820 w, 640 s.

6: As described for **1**, diphenylsulfide and sodium methanesulfinate were polymerized. The usual workup gave a **6** as a white powder in 88% yield. Correct elemental analysis. ^{1}H NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta = 3.95$ (s, 3H, CH_3), 7.68–8.15 (m, 8H, phenyl); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3086 w, 2930 w, 1570 m, 1478 m, 1260 vs, 1164 s, 1029 s, 818 w, 754 w, 639 s.

7: As described for **1**, diphenylether and sodium methanesulfinate were polymerized. The usual workup gave **7** as a white powder in 95% yield. Correct elemental analysis. ^{1}H NMR (400 MHz, CD_3CN, 25 °C): $\delta = 3.67$ (s, 3H, CH_3), 7.39, 7.42, 8.21, 8.23 (AB quartet, 8H, phenyl); ^{13}C NMR (400 MHz, CD_3CN, 25 °C): $\delta = 29.7$ (CH_3), 122.2, 122.5, 133.8, 161.6 (phenyl); IR (KBr): $\tilde{\nu}$ [cm^{-1}] = 3100 w, 2937 w, 1704 w, 1489 m, 1413 m, 1254 vs, 1168 s, 1035 s, 876 w, 856 w, 835 w, 640 s.

Vinyl Glycosides in Oligosaccharide Synthesis: A Strategy for the Preparation of Trisaccharide Libraries Based on Latent-Active Glycosylation**

Geert-Jan Boons,* Barbra Heskamp, and Floris Hout

Glycoconjugates are involved in many different biological processes, and (oligo)saccharides may provide lead compounds for drug development.[1] Recently, the generation of "chemical libraries" by combinatorial chemistry methods has received considerable interest, since these libraries are potential sources of new leads for drug discovery.[2] Combinatorial chemistry has been developed mainly for the preparation of peptide, nucleic acid, and small-molecule libraries,[2] and only a very few reports deal with combinatorial carbohydrate chemistry.[3, 4] The development of combinatorial carbohydrate chemistry is complicated by several factors,[5] the most important being the number of functionalities and the polyvalent nature of carbohydrates and the lack of a general method for forming glycosidic linkages.[6]

Recently, a random glycosylation strategy was reported for the preparation of saccharide libraries.[4] Although this strategy avoids extensive protecting group manipulations, the resulting library is not well-defined and identification of an active com-

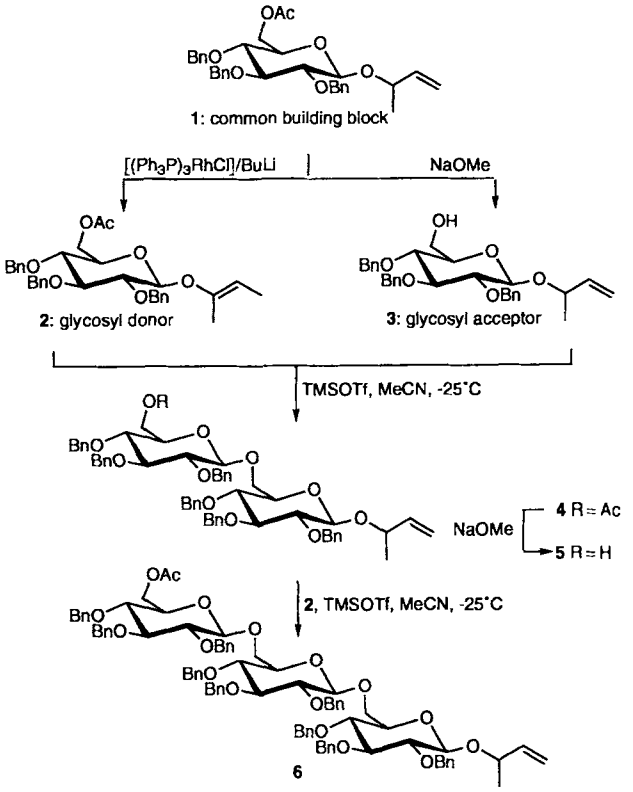
pound from such a library may be troublesome. A key element for the successful construction of a well-defined carbohydrate-based library is a technique that enables the rapid generation of building blocks that can be assembled in a controlled and combinatorial fashion.[5] We report here an efficient method for the synthesis of trisaccharide libraries, which relies on a known latent-active glycosylation strategy[7] and meets the requirements discussed above.

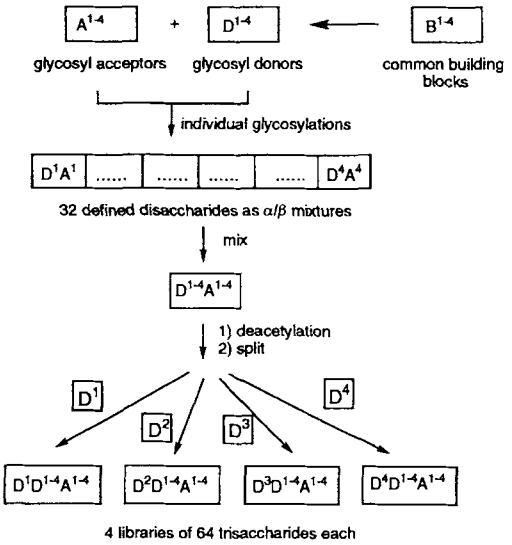
As illustrated in Scheme 1, the efficiency of latent-active glycosylation is based on the possibility of preparing a glycosyl donor and acceptor from a common building block. For example, removal of the acetyl protecting group of compound **1**



Scheme 1. TMSOTf = $Me_3SiOSO_2CF_3$.

gave glycosyl acceptor **3** and isomerization of the anomeric allyl ether function of **1** yielded the substituted vinyl glycosyl donor **2**. Glycosyl donor **2** was coupled with acceptor **3** in the presence of trimethylsilyl trifluoromethanesulfonate (TMSOTf) to give the β-linked dimer **4** in excellent yield (89%, $\alpha/\beta = 1/20$). Disaccharide **4** can be converted into a glycosyl acceptor by removing the acetyl protecting group and into a glycosyl donor by isomerizing the allyl moiety. These compounds can be used in oligosaccharide synthesis; for example, coupling of compound **5** with **2** gave trisaccharide **6**.

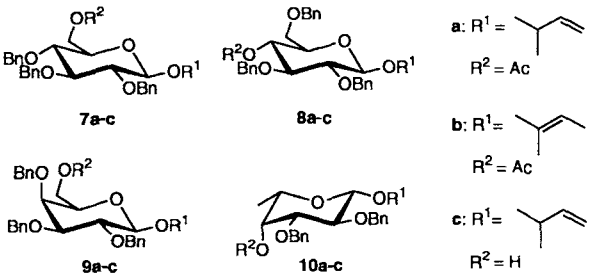
We envisaged that the allyl–vinyl glycosylation protocol would provide a powerful tool for the preparation of oligosaccharide libraries. For example, four allyl glycosyl building blocks ($B^{1\rightarrow4}$, e.g. **1**, see Schemes 1 and 2) can be converted into four vinyl glycosyl donors ($D^{1\rightarrow4}$, e.g. **2**) and four allyl glycosyl acceptors ($A^{1\rightarrow4}$, e.g. **3**). In individual glycosylations, each donor can be coupled with each acceptor to give 32 disaccharides as 16 mixtures of anomers ($D^{1\rightarrow4}A^{1\rightarrow4}$, e.g. **4**),[8] which can be purified and identified by conventional methods. Next, the disaccharides can be mixed; removal of the acetyl group of the saccharides will give a mixture of glycosyl acceptors. The



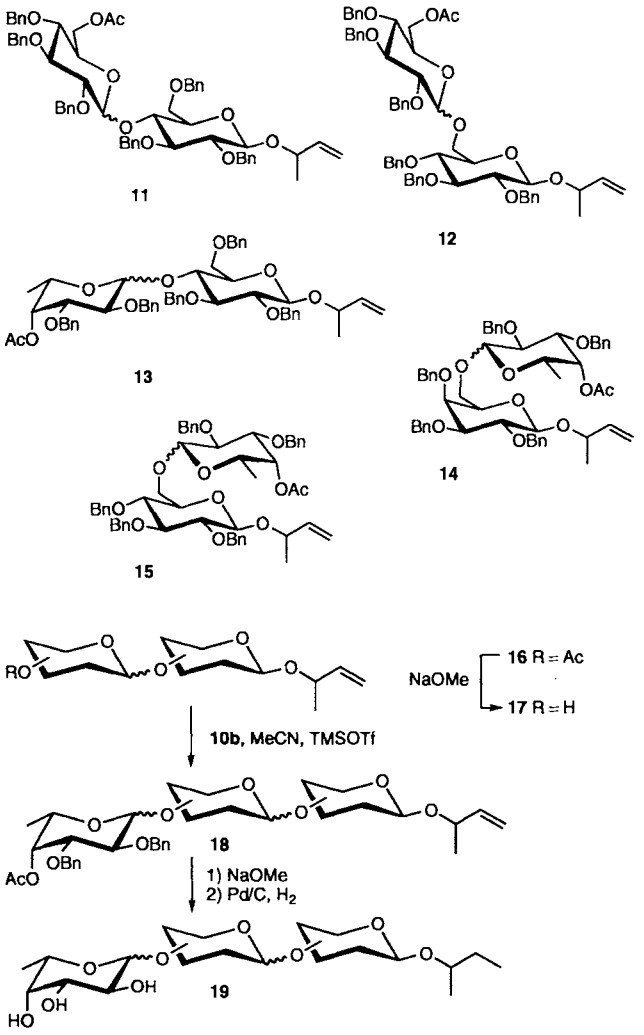
Scheme 2.

pool of compounds can be split, and in combinatorial steps each pool of glycosyl acceptors can be coupled with a particular glycosyl donor ($D^{1\rightarrow4}$), resulting in four libraries of 64 trisaccharides each ($D^1D^{1\rightarrow4}A^{1\rightarrow4}$, $D^2D^{1\rightarrow4}A^{1\rightarrow4}$, $D^3D^{1\rightarrow4}A^{1\rightarrow4}$, and $D^4D^{1\rightarrow4}A^{1\rightarrow4}$). Thus, in a minimum number of synthetic steps, four building blocks can in principle be converted into 256 trisaccharides. It should be noted that the reactions are performed in solution and since an excess of reagents is required, the libraries need to be purified. Size-exclusion chromatography is envisaged as the best means, since this purification method relies on the fact that all the saccharides in the library have very similar molecular weights. The purified libraries can be characterized by a combination of mass spectrometry[9] and monosaccharide composition analysis.[10] To verify the proposed strategy, a relatively small library of 20 trisaccharides[11] has been prepared.

In the first stage of the synthetic strategy, the allyl glycosyl building blocks **7a** and **10a** were converted into the vinyl glycosyl donors **7b** and **10b** by isomerization with [$(Ph_3P)_3$-RhCl]/BuLi[12] and the allyl glycosyl acceptors **7c**–**10c** were



obtained by removal of the acetyl protecting group from compounds **7a**–**10a**. Subsequently, the disaccharides **11**–**15** were prepared by coupling the appropriate donors and acceptors. The glycosylation reactions were performed at room temperature in acetonitrile and promoted by a catalytic amount of TMSOTf. Under these conditions,[8] each disaccharide was obtained as a mixture of anomers ($\alpha/\beta \approx 1/1$, yields in excess of 70%). Next, samples from the five disaccharides (α/β mixtures) were combined (library **16**); removal of the acetyl protecting group gave a pool of disaccharide acceptors (library **17**) (Scheme 3). In a combinatorial fashion, the vinyl glycosyl donor



Scheme 3.

10b was coupled with the acceptor pool **17** to give a fully protected trisaccharide library of 20 different compounds (**18**). The reaction was performed under standard conditions using an excess of glycosyl donor (2 equiv). The fast atom bombardment (FAB) mass spectrum of the crude reaction mixture indicated that no disaccharides were present and that trisaccharides had formed.[13] Also a substantial amount of unreacted donor was detected. Library **18** was purified by LH-20 gel filtration column chromatography, and the FAB mass spectra of appropriate fractions showed the presence of only trisaccharides. Finally, the protecting groups were removed by treatment with base followed by hydrogenation over Pd/C to give library **19**.[14] Under these conditions, the allyl moieties at the reducing end of the saccharides were converted into isobutyl groups. Alternatively, the allyl moieties can be removed easily by isomerization and acid-mediated cleavage.

Since formation of the glycosidic bond is not equally successful in every case, additional quality control is required and therefore a monosaccharide compositional analysis was performed. Thus, a portion of the trisaccharide library was treated with aqueous trifluoracetic acid (2 M solution) at 100 °C for 4 h. Analysis of the resulting mixture of monosaccharides on a Dionex HPLC system with a PA1 column and pulsed amperometric detection (PAD)[15] showed that glucose, galactose, and fucose were present in approximately the required ratio.[16]

The strategy described here for the preparation of saccharide libraries is very efficient, and a small number of building blocks is employed to generate a relatively large number of trisaccharides. Furthermore, the difficult stereoselective formation of glycosides is avoided, and relatively "pure" mixtures of compounds have been obtained. These aspects are of particular importance when an active compound is present in the library. The structure of such a compound can be determined by a deconvolution approach, which has to proceed through iterative resyntheses.[2] The required sublibraries can be prepared efficiently from the previously synthesized mono- and disaccharides. In this respect, it is important to note that no general protocols for the sequencing of oligosaccharides are available. At present, the libraries described here are being screened, and the results obtained will be published in due course.

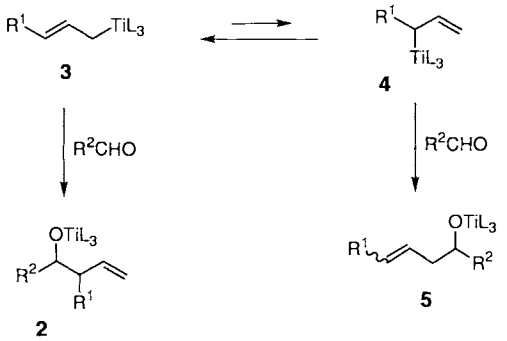
Unusual Regioselectivity in the Reaction of Allyl- or Allenylpropargyltitanium Compounds with Carbonyl Compounds: An Efficient Synthesis of Alkylidenecyclopropane Derivatives

Aleksandr Kasatkin and Fumie Sato*

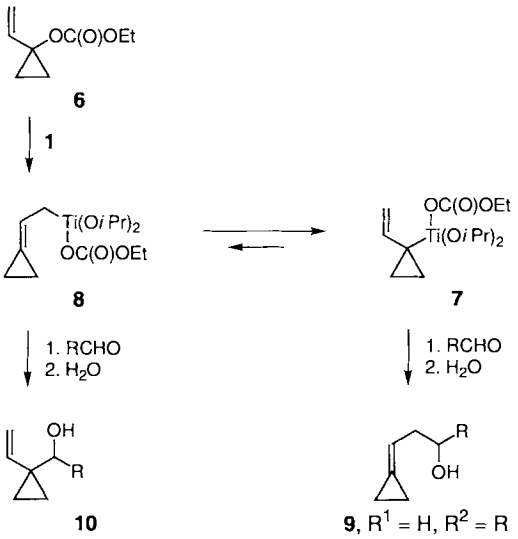
Recently, we have developed a highly efficient and practical procedure for preparation of allyltitanium compounds by the reaction of allylic substrates, including carbonates, with [(η^2-propene)Ti(O*i*Pr)$_2$] (**1**), which is readily generated from [Ti(O*i*Pr)$_4$] and two equivalents of *i*PrMgBr.[1] Allyltitanium compounds, prepared in this way or by transmetalation using organolithium or -magnesium compounds,[2] react with aldehydes exclusively at the most substituted allylic carbon to afford the "branched" addition product **2** (Scheme 1). This regiochemistry can be explained by the preference of the primary titanium derivative **3** over the more congested intermediate **4** and its reaction with aldehydes through a six-membered transition state.[3] However, the substituent R^1 is a functional group containing a heteroatom that can strongly coordinate to titanium, the equilibrium may be shifted in favor of the more hindered regioisomer **4**, thus providing the "terminal" addition product **5** by the reaction with aldehydes.[4, 5]



Scheme 1. Synthesis of **2** and **5**.

We postulated that ring strain might be another factor for controlling the equilibrium between **3** and **4**. Thus, we anticipated that the allyltitanium compound generated from **1** and the ethyl carbonate derivative (**6**) of 1-vinylcyclopropanol[6] would exist mostly as the tertiary titanium derivative **7** but not as the primary regioisomer **8** having the strained alkylidenecyclopropane fragment[8] (Scheme 2). The subsequent reaction with aldehydes, therefore, would result in alkylidenecyclopropanes **9** ("terminal" adducts), which are widely employed starting materials or intermediates in organic synthesis.[9]

Our assumption proved to be correct. The reaction of **1** with the carbonate **6** followed by treatment with EtCHO led to the alkylidenecyclopropane **9a** in high yield and the regioisomeric vinylcyclopropane **10a** in only 6% yield (Table 1, entry 1). Similar results were obtained when PhCHO and Me$_2$CO were used instead of EtCHO (**9** was the main product in both cases), although the regioselectivity was somewhat dependent on the nature of the carbonyl electrophile (entries 2 and 3).[10]

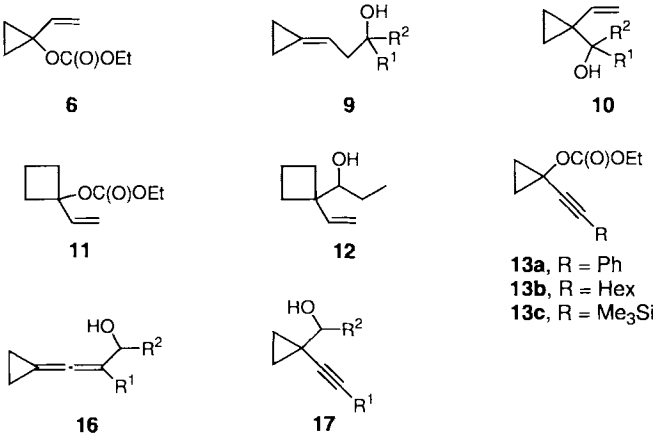


Scheme 2. Synthesis of **9** and **10**.

Table 1. Synthesis of **9**, **10**, **16**, and **17** [a].

Entry	Carbonate	Carbonyl cmpd.	Products, regioselectivity [%] [b]	Yield [%] [c]
1	**6**	EtCHO	**9a** (R^1 = H, R^2 = Et), 94; **10a**, 6	76
2	**6**	PhCHO	**9b** (R^1 = H, R^2 = Ph), 80; **10b**, 20	84
3	**6**	Me_2CO	**9c** (R^1 = R^2 = Me), >97	40
4	**11**	EtCHO	**12**, >97	65
5	**13a**	PhCHO	**16a** (R^1 = R^2 = Ph), 93; **17a**, 7	62
6	**13a**	EtCHO	**16b** (R^1 = Ph, R^2 = Et), >97	65
7	**13b**	EtCHO	**16c** (R^1 = Hex, R^2 = Et), >97	74
8	**13b**	CH_2O [d]	**16d** (R^1 = Hex, R^2 = H), >97	80
9	**13c**	EtCHO	**16e** (R^1 = Me_3Si, R^2 = Et), 74; **17e**, 26	45

[a] Titanium reagents were generated from 2.0 equiv [Ti(O*i*Pr)$_4$] and 4.0 equiv *i*PrMgCl in Et$_2$O at -40 to -45 °C (1 h); then 2.0 equiv carbonyl compound was added and the reaction mixture was stirred at -40 to -45 °C for 1 h. [b] According to ^{1}H NMR data of isolated regioisomeric mixtures. [c] Yields of isolated products based on starting carbonates. [d] Et$_2$O solution of monomeric CH_2O prepared by thermolysis of paraformaldehyde was used.



The fact that the reaction of **1** with ethyl 1-vinylcyclobutyl carbonate (**11**) (the carbonate derivative of vinylcyclobutanol), followed by treatment with EtCHO afforded exclusively the vinylcyclobutane **12** (the usual "branched" adduct) strongly demonstrates the principal role of the alkylidenecyclopropane

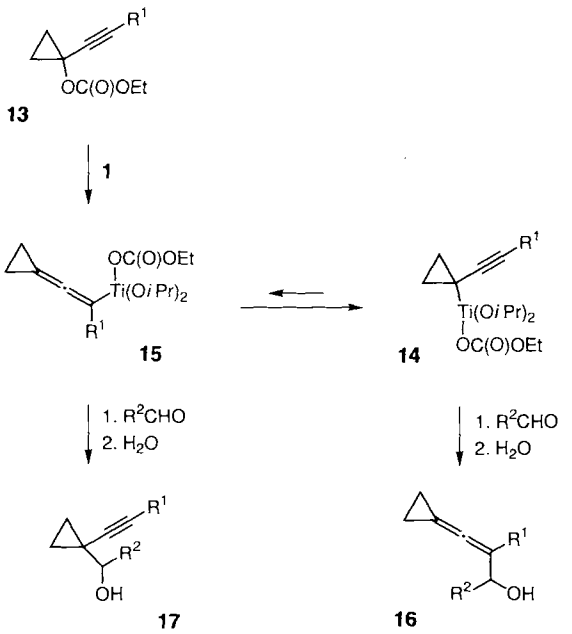
strain in controlling the regiochemistry observed here (Table 1, entry 4).

The reaction of **1** with secondary or tertiary propargylic carbonates has been shown to provide allenyltitanium compounds which, in turn, react with aldehydes to give homopropargyl alcohols.[11] However, the results obtained by the reaction of **1** with **6** strongly suggested that the reaction with carbonate derivatives **13** of 1-alkynylcyclopropanols[6] would afford the propargyltitanium compounds **14** rather than the more strained allenyltitaniums **15** as shown in Scheme 3.[12] Thus, the subsequent treatment with aldehydes would give the allenic cyclopropanes **16**, which are of synthetic interest but are not readily available by other methods.[13] As expected, the reaction of **1** with the ethyl carbonate derivative **13a** of 1-(phenylethynyl)cyclopropanol followed by addition of PhCHO led primarily to the allenic cyclopropane **16a** with only 7% yield of the corresponding regioisomeric alkynylcyclopropane **17a** (Table 1, entry 5). Similarly, the treatment of the titanium reagents generated from the carbonates **13a–c** with EtCHO and/or CH_2O afforded **16** exclusively (entries 6–8) or predominantly (entry 9).[14]



Scheme 3. Synthesis of **16** and **17**.

Experimental Procedure

The following procedure for preparation of **9a** and **10a** (entry 1 in Table 1) is representative: To a solution of $[Ti(OiPr)_4]$ (284 mg, 1.00 mmol) and **6** (156 mg, 0.50 mmol) in Et_2O (7.5 mL) was added dropwise *i*PrMgCl (1.35 mL, 1.48 M in Et_2O, 2.00 mmol) at −50 °C. The reaction mixture was stirred at −45 to −40 °C for 1 h, then EtCHO (58 mg, 1.00 mmol) was added. The reaction mixture was stirred for 1 h at −45 to −40 °C then hydrolyzed with a solution of water (1.2 mL) in THF (3.0 mL), warmed up to 20 °C, and stirred for 30 min. The organic layer was decanted and the white solid was washed thoroughly with ether. The combined organic layers were dried over $MgSO_4$ and concentrated under reduced pressure. After separation by column chromatography (silica gel, hexane: EtOAc = 5:1), a mixture of **9a** and **10a** (48 mg, 76% total yield) was isolated as a colorless oil. ^{1}H NMR (300 MHz, $CDCl_3$): **9a**: δ = 0.97 (t, J = 6.3 Hz, 3H), 1.09 (m, 2H), 1.43–1.70 (m, 4H), 2.22–2.48 (m, 2H), 3.67 (m, 1H), 5.80 (m, 1H); **10a**: δ = 0.62 (m, 2H), 2.95 (m, 1H), 4.96–5.03 (m, 2H), 6.13 (dd, J = 16.8, 10.2 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$): **9a**: δ = 1.93, 2.67, 9.91, 29.55, 39.31, 72.65, 114.25, 124.89; **10a**: δ = 11.02, 12.29, 27.90, 79.40, 113.57.

Diastereoselective Addition of *n*-Butyllithium to 2-Phenylpropanal: A Reassessment of the Solvent and Temperature Effects**

Gianfranco Cainelli,* Daria Giacomini,* P. Galletti, and A. Marini

The mechanism of asymmetric induction in reactions of α-chiral aldehydes and ketones has been a subject of continued speculation since Cram and Kopecky's seminal work.[1] Among several factors that have been recognized to influence the π-facial diastereoselectivity, the role of the solvent has hitherto been underestimated.

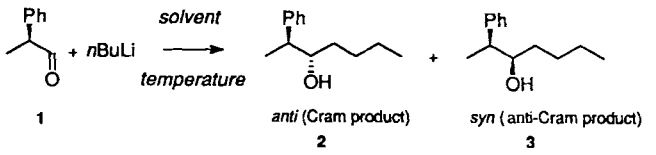
[**] This work was supported by Ministero dell' Università e della Ricerca Scientifica e Tecnologica (MURST) (fondi 60%) and the University of Bologna (fund for selected topics). We thank Micaela Fabbri for performing the HPLC analysis.

Recently we demonstrated that in nucleophilic addition reactions to O-protected (2*S*)-lactal[2] and to its corresponding *N*-(trimethylsilyl)imine,[3] the diastereoselection was highly dependent on the nature of the solvent and on the temperature. In these α-oxy substrates, chelation was often invoked to account for the stereochemical outcome of the reactions with organometallic reagents; thus, the diastereoselection was often discussed in terms of a chelation versus a nonchelation mechanism.[4]

In the present investigation, in which we use racemic 2-phenylpropanal **1**[5] as the model aldehyde, we focus on the influence of the solvent and temperature on the π-facial diastereoselectivity. Compound **1** has been studied previously by Reetz et al.,[6] who highlighted the high Cram-selectivity of this substrate (90–94%) in reaction with *n*BuLi under standard conditions (THF, −78 °C), while a lower selectivity was observed when the reaction was carried out using *n*-pentane as solvent. We report here on a systematic study of the diastereofacial selectivity of **1** in reactions with *n*BuLi using hydrocarbons and ethers as solvents.

The addition reaction was performed by adding a stoichiometric amount of *n*BuLi (1.6 M solution in hexane) to **1** in different dry solvents. The reaction temperature was varied over a range between the melting and boiling point of the respective solvents (Scheme 1). The diastereomeric excess (*de*) of products



Scheme 1. Syntheses of **2** and **3**. Solvents: THF, *t*BuOMe, 1,4-dioxane, propane, *n*-pentane, *n*-hexane, *n*-octane, *n*-decane, *n*-dodecane, cyclohexane, cyclopentane.

2 and **3** in the crude reaction mixture was determined by HPLC analysis.[7] Results obtained with THF, *t*BuOMe, *p*-dioxane, and *n*-hexane are given in Table 1.

The temperature dependence of the *de* values was analyzed according to the modified Eyring equation [Eq. (a)],[8] where

$$\ln P = -(\Delta\Delta H^{*}/RT) + (\Delta\Delta S^{*}/R) \qquad (1)$$

$P = k(anti)/k'(syn) = I/I'$, k and k' are the overall rate constants, and I and I' are the chromatographic area [%] of **2** and **3**, respectively. The results are summarized in Figure 1.

At low temperature, THF exhibited the best diastereoselectivity, while reactions in *t*BuOMe and 1,4-dioxane gave lower *de* values. A continuous linear correlation between the ln (*anti*/*syn*) value and $1/T$ was observed in all ethers; in contrast, in reactions carried out in *n*-hexane we established an inversion temperature (T_{inv}).[9] A small amount (5%) of THF in *n*-hexane was sufficient to obtain results similar to those obtained in pure THF. This could be attributed to a direct (primary shell) THF–lithium interaction, where the donor solvent acts as ligand to the lithium coordination sphere.[10] The evidence of an inversion temperature for *n*-hexane prompted further investigation. The Eyring plots for a series of linear and cyclic hydrocarbons is shown in Figure 2. Each aldehyde–solvent combination showed two linear regions, and a characteristic inversion temperature was observed in each case.[11]

Interestingly, for linear hydrocarbons and their cyclic counterparts, the inversion point T_{inv} represents a cusp with an opposite orientation. The pattern is consistent with the chain length

Table 1. Influence of temperature and solvent on the diastereoselectivity of the nucleophilic addition of *n*-butyllithium to 2-phenylpropanal. The *de* values were determined by HPLC analysis.

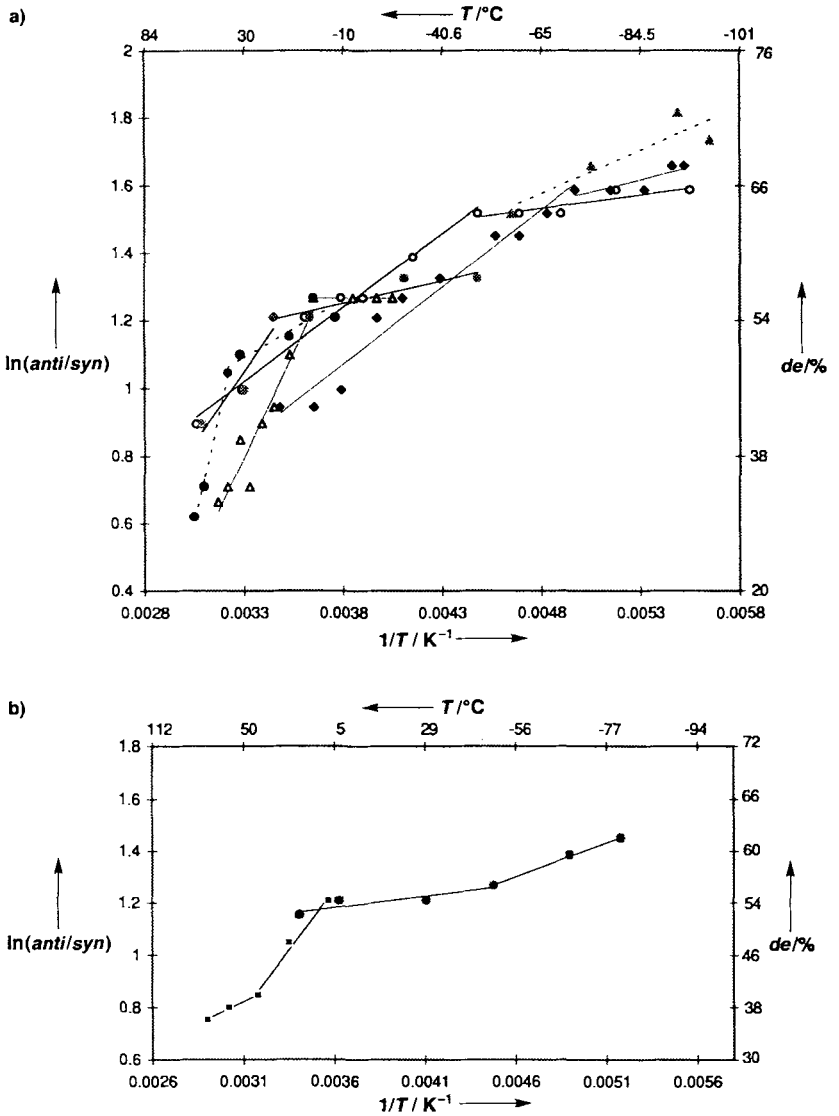

Fig. 2. Eyring plots for the diastereomeric excess obtained in the nucleophilic addition of *n*-butyllithium to **1** at various temperature a) in propane (△), *n*-pentane (◆), *n*-hexane (○), *n*-octane (○), *n*-decane (▲), *n*-dodecane (◆), and b) in cyclohexane (■), cyclopentane (○).

of the solvent: the longer the chain, the lower the diastereofacial selectivity; for example, the diastereofacial selectivity obtained with propane is better than that with *n*-dodecane. It appears that even though apolar aprotic solvents interact only slightly with the solute (since only the nonspecific directional, induction, and dispersion forces can operate) the diastereoselectivity could be doubled by using a solvent with a short chain length. To the best of our knowledge, this possibility has never been raised in the discussion of diastereofacial selectivity. In both temperature regions, the slopes of regression lines, which reflect the enthalpic contribution, are not very different. On the other hand, the differences in the intercepts ($\Delta\Delta S^{\ddagger}$) are significant. Thus, the chain length effect might be ascribed to entropic control over the selectivity of this type of organometallic addition.

Considerable attention has been paid to the significance of the difference $\delta\Delta\Delta H^{\ddagger} = \Delta\Delta H_1^{\ddagger} - \Delta\Delta H_2^{\ddagger}$ ($\Delta\Delta H_1^{\ddagger}$, $T > T_{inv}$ and $\Delta\Delta H_2^{\ddagger}$, $T < T_{inv}$). A plot of $\delta\Delta\Delta H^{\ddagger}$ against the corresponding entropy term $\delta\Delta\Delta H^{\ddagger}$ is linear for all the hydrocarbons measured. From the slope of this plot (Fig. 3) we can determine the isoinversion temperature $T_i = 299$ K (21 °C).

In contrast with our results with the *N*-(trimethylsilyl)imine of lactal,[3] we did not obtain an optimal value of the selectivity for the aldehyde **1** at a reaction temperature near to T_i, and moreover solvents with a T_{inv} value close to the T_i value, such as *n*-decane and *n*-dodecane, produced a lower diastereoselectivity.

The inversion temperatures for all the linear and cyclic hydrocarbon solvents examined ranged between 205 and 317 K, noteworthy is that the T_{inv} value for linear hydrocarbons increases as the chain length increases on going from *n*-pentane to *n*-dodecane (Table 2).[12]

Table 2. Melting points [K] of several solvents and inversion temperatures T_{inv} [K] for the reaction of **1** to give **2** and **3** in these solvents.

Solvent	M.p.	T_{inv}
n-pentane	143	205.3
n-hexane	178	227.8
cyclopentane	179	225.1
n-octane	216	287
n-decane	243	271.7
n-dodecane	261	309.6
cyclohexane	279.5	317

Assuming that the inversion temperature is a property of every substrate–solvent pair, all efforts to correlate T_{inv} with some classical solvent parameters, such as dielectric constant and viscosity, failed. Interestingly, we found an extrathermodynamic correlation between T_{inv} and the melting points of the linear and cyclic hydrocarbons; the resulting straight line has a correlation coefficient (r) of 0.96 (Fig. 4). This suggests a relationship between the inversion temperature and the phase modification that happens on melting. This could be consistent with the hypothesis that inversion points represent a transition between two "phases", which in the case of solutions could be represented by two different solvation states (a more ordered one in the low-temperature region) that have different k and k' values, and therefore different diastereoselectivity.

These results indicate the unexpected role the reaction solvent plays in determining the inversion temperature and confirms its peculiar influence on the diastereofacial selectivity.

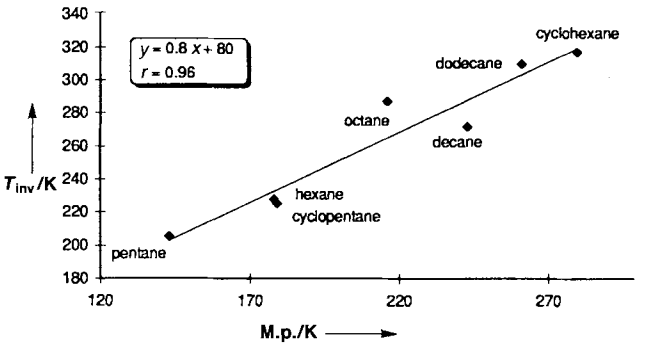

Fig. 4. Correlation between melting points and inversion temperature for hydrocarbons.

Experimental Procedure

In a typical experiment, **1** (0.268 g, 2 mmol) was dissolved in anhydrous solvent (20 mL) under inert atmosphere, and the solution cooled to the desired temperature; then *n*-butyllithium (2.2 mmol, 1.37 mL of a 1.6 M solution in *n*-hexane) was added. After the starting aldehyde had disappeared (GC-monitoring), the reaction was quenched at 0 °C with a saturated aqueous solution of NH_4Cl, extracted with CH_2Cl_2 (3 × 50 mL), and dried with $MgSO_4$. From HPLC analysis of the crude product the *anti*/*syn* ratio and the *de* value were obtained. Chromatography of the residue on a silica gel column gave the mixture of the two alcohols **2** and **3** so that the chemical yield could be calculated.

[11] In our opinion, this behavior is quite general for diastereoselective reactions in solution. The absence of the inversion temperature was attributed either to a limited temperature range (the T_{inv} results lie outside the observable range) or to the fact that the two slopes of the linear correlations differ too little to appreciate the cusp.
[12] The plot of ln (*anti*/*syn*) against $1/T$ in propane did not reveal an inversion temperature because in this reaction the inversion temperature could have a lower value than the lowest reaction temperature we reached. In fact, in this solvent, at $T \leq -100$ °C, the starting aldehyde was quite insoluble and the conversion yield was very low.

Synthesis and Structure of the Metalated Zintl Ion $[Ge_9(\mu_{10}\text{-}Ge)Ni(PPh_3)]^{2-}$

Donna R. Gardner, James C. Fettinger, and Bryan W. Eichhorn*

Since the discovery[1, 2] and subsequent investigation[3–6] of the Group 14 Zintl ions, only a few transition metal derivatives of these unusual clusters have been detected. The only structurally characterized examples, the tin and lead [*closo*-$E_9Cr(CO)_3]^{4-}$ ions[7, 8] and the $[Sn_6\{Cr(CO)_5\}_6]^{2-}$ ion,[9] were made by two vastly different synthetic methods. Teixidor et al. characterized two Pt–E_9 species (E = Sn, Pb) by NMR spectroscopy;[10] however, little is known about their structures. Even though there are several structurally characterized naked germanide ions (Ge_9^{n-}, where $n = 2$, 3, or 4; Ge_{10}^{2n-}),[11–14] complexes of the germanide Zintl anion with transition metals have not previously been described. Herein we report the synthesis and characterization of [K([2.2.2]-cryptand)]$_2$[$Ge_9(\mu_{10}$-Ge)Ni(PPh_3)]·en (for [2.2.2]cryptand see [17], en = ethylenediamine), the first metalated germanide anion and only the second example of the rare *nido*-10 (iv + iv)[15] structure type.

The reaction of $[Ni(CO)_2(PPh_3)_2]$, K_4Ge_9,[16] and [2.2.2]cryptand[17] in ethylenediamine gives $[Ge_9(\mu_{10}$-Ge)-$Ni(PPh_3)]^{2-}$ (**1**) as the [K([2.2.2]cryptand)]$^+$ salt in low yields. The compound [K([2.2.2]cryptand)]$_2$(**1**)·en decomposes upon exposure to air and moisture. The dark brown crystals have been characterized by single-crystal X-ray diffraction, energy dispersive X-ray analysis (EDX), microanalysis, and ^{31}P NMR.

A single crystal X-ray diffraction study[18, 19] revealed two [K([2.2.2]cryptand)]$^+$ cations, an en solvent molecule, and the $[Ge_9(\mu_{10}$-Ge)Ni$(PPh_3)]^{2-}$ (**1**) anion. This anion displays no crystallographic symmetry, consists of nine surface Ge atoms, one interstitial Ge atom Ge(i), and an [Ni(PPh_3)] fragment (Fig. 1). The [Ni(PPh_3)] fragment has been incorporated into the anion framework as a vertex of the cluster. The two [K([2.2.2]-cryptand)]$^+$ cations are well separated from the anion and are not disordered. The en solvent molecule is not fully resolved due to local disorder. Two independent crystal studies were performed on crystals of independent syntheses and both studies gave the same results within experimental error.

The Ge–Ge bond distances for the surface Ge atoms range from 2.595(4) Å to 3.291(4) Å. These distances are similar to those of Ge–Ge contacts in other polygermanide clusters such as [K([2.2.2]cryptand)]$_3$[$P(C_6H_5)_3Ge_9$], where bonding Ge contacts vary from 2.53 Å to 3.27 Å.[11–14] The distances between the nearest neighbor surface Ge atoms and the Ni atom range from 2.364(3) Å to 2.381(3) Å; a longer contact exists between Ni(1) and Ge(2) of 3.307(3) Å. Excluding the longer contact, the Ni–Ge bond lengths are similar to other reported distances, for example, 2.36 Å (av) in $[Ni_9(\mu_4\text{-}GeEt)_6(CO)_8]$.[20–25] The contacts between the surface Ge atoms and the interstitial atom Ge(i) range from 2.355(3) Å to 2.446(3) Å (average 2.40 Å) and are slightly shorter than those in metallic germanium (2.44 Å).[26] The Ni–Ge(i) distance in **1** of 2.361 Å is significantly shorter than the Ni–Ge(i) contacts in the interstitial Ge clusters $[Ni_{12}Ge(CO)_{22}]^{2-}$ (average 2.49 and 2.69 Å) and $[Ni_{10}Ge(CO)_{20}]^{2-}$ (average 2.47 Å).[27] The shorter distance in **1**

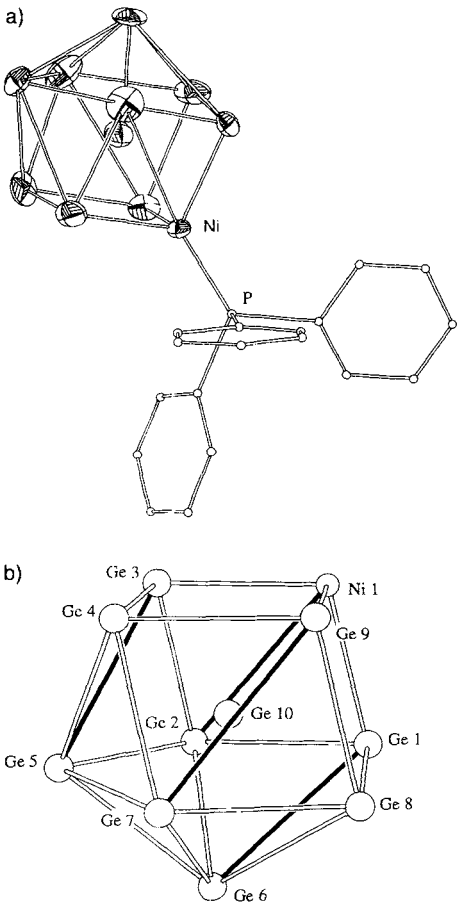

Fig. 1. a) ORTEP drawing of $[Ge_9(\mu_{10}\text{-}Ge)Ni(PPh_3)]^{2-}$ (**1**) (thermal ellipsoids are drawn at the 50% probability level). b) Ball-and-stick representation of cluster **1** emphasizing the cluster distortions and giving the atom numbering scheme. Darkened bonds represent long intracluster contacts. Pertinent bond lengths [Å] and angles [°] are: Ge1–Ge10 2.349(3), Ge2–Ge10 2.426(3), Ge3–Ge10 2.366(3), Ge4–Ge10 2.424(3), Ge5–Ge10 2.442(3), Ge6–Ge10 2.446(3), Ge7–Ge10 2.421(3), Ge8–Ge10 2.422(3), Ge9–Ge10 2.335(3), Ni1–Ge10 2.361(3), Ge1–Ni1 2.381(3), Ge2–Ni1 3.307(3), Ge3–Ni1 2.370(3), Ge4–Ni1 3.581(4), Ge8–Ni1 3.601(4), Ge9–Ni1 2.364(3), $Ge_{surface}$–$Ge_{surface}$ 2.74 (average) [included in the average are the longer contacts Ge1–Ge6 3.013(4), Ge3–Ge5 3.005(3), Ge7–Ge9 3.291(4)]; Ge1–Ge3 3.708(3), Ge1–Ge9 3.443(3), Ge2–Ge8 4.240(4), Ge3–Ge9 3.454(3), Ge4–Ge8 4.096(4); Ge3-Ge4-Ge9 82.68(10), Ge3-Ni1-Ge9 93.72(12), Ge4-Ge3-Ni1 92.22(12), Ge4-Ge9-Ni1 91.38(11), Ni1-Ge9-Ge8 92.21(12), Ni1-Ge1-Ge8 92.40(12), Ge9-Ni1-Ge1 93.04(12), Ge9-Ge8-Ge1 82.33(10).

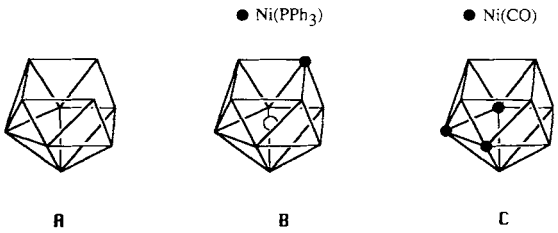

disparity in the interatomic distances between Ge atoms (average 2.74 Å) and those between Ge and Ni atoms (average 2.37 Å). It appears that the cluster compensates for the disparity by lengthening the contacts to the five coordinate Ge atoms (see Fig. 1b) while optimizing the Ge–Ni interactions.

In both the known *nido*-10 (iv+iv) structural types the [Ni–L] (L = CO or PPh_3) fragment occupies vertices on the surface of the cage but not in the same location. The three [Ni(CO)] fragments of the $[Sb_7Ni_3(CO)_3]^{3-}$ ion[33] (see **C**) occupy vertices on the pentagonal waist, whereas in the germanium complex, the $[Ni(PPh_3)]$ fragment occupies a vertex of one of the open square faces. Further investigations may elucidate new families of cluster structural types, which may only be accessible when derived from naked anions of heavier main group elements.

The solution dynamics of reaction mixtures containing polygermanide anions is clearly quite complicated. For example, the Ge_{10}^{2-} anion was isolated from ethylenediamine solutions of $KGe_{1.8}$ and [2.2.2]cryptand with tetrakis(triphenylphosphanyl)nickel(0).[13]

Experimental Procedure

K_4Ge_9 was prepared by fusing a stoichiometric ratio of the elements in a sealed, evacuated silica ampoule. Ethylenediamine was dried over CaH_2 and then distilled from K_4Sn_9. All manipulations were carried out under a dinitrogen atmosphere. In a dry box, K_4Ge_9 [16] (54 mg, 0.07 mmol), [2.2.2]cryptand (100 mg, 0.27 mmol), and $[Ni(CO)_2(PPh_3)_2]$ (84 mg, 0.14 mmol) were dissolved in 6 mL of ethylenediamine. The red-brown mixture was heated (35 °C < T < 45 °C) and stirred for about 15 min. The mixture was filtered and after 15 days well-formed brown crystals of $[K([2.2.2]cryptand)]_2$(**1**)·en could be isolated (22 mg; the exact yield could not be determined due to inconsistent microanalysis. Repeated microanalysis gave inconsistent and unsatisfactory results, presumably due to elemental Ge contaminants. The elemental analysis for Ni ranged from 0.95–4.45%; expected 3.03%.). EDX analysis on crystals showed presence of K, P, Ge, and Ni. In a $[D_7]$DMF solution, only free triphenylphosphane is observed in the ^{31}P NMR spectrum at room temperature.

than in the carbonyl clusters is consistent with the smaller cage size of **1**. The Ni–P contact of 2.121(6) Å is slightly shorter than most Ni–P distances for other zero-valent triphenyphosphanylnickel complexes (2.15–2.28 Å).[28–30]

If the interstitial Ge atom is considered a four-electron donor, the anion has 24 skeletal electrons which is indicative of a *nido* cluster in accordance with Wade's rules.[31] However, unlike the typical *nido*-10 (vi) cluster (for example, $B_{10}H_{14}$, $C_4B_6H_{10}$),[32] which has an open six-membered ring (**A**), anion **1** has two four-membered rings fused along a common bond between Ni(1) and Ge(9) (**B**, Fig. 1b). This structural type has been reported once before as the Zintl ion derivative $[Sb_7Ni_3(CO)_3]^{3-}$[33] (**C**) and was found to be a local minimum for geometries for carborane clusters.[34]

The cluster is significantly distorted from a *nido*-10 (iv+iv) idealized geometry. The $[Ni(PPh_3)]$ vertex of the cluster is pulled in towards the interstitial Ge atom and the Ge(3)–Ge(5), Ni(1)–Ge(2), Ge(9)–Ge(7), and Ge(1)–Ge(6) edges are elongated. The dominant factor for the distortion seems to be the

nent of such chemistry, the chemistry of halotellurato clusters of the early transition metals, especially Re, is undeveloped compared with that of halosulfato and haloselenato clusters. Yet the incipient chemistry of halotellurato clusters shows striking differences from that of the S and Se derivatives. For instance, there are unusual halotellurato ligands with no analogs in the S and Se systems. In these Te ligands, tellurium is predominantly in the oxidation state +II.[6, 7] Neutral $TeCl_2$ and $TeBr_2$ ligands are featured in the Re_6 cluster compounds $Re_6(\mu_3\text{-}Te)_6(\mu_3\text{-}Cl)_2(TeCl_2)_2Cl_4$ and $[Re_6(\mu_3\text{-}Te)_8(TeBr_2)_6]Br_2$.[8] However, halotellurium(IV) ligands, such as the $[TeCl_2]^{2+}$ ligand in $[Fe_2(CO)_6(Te_4)(TeCl_2)]$, are also known.[9] Here we present the synthesis and structures of two new solid-state compounds, $Re_6Te_{16}Cl_{18}$ and $Re_6Te_{16}Cl_6$, which contain $[Re_6Te_8]^{2+}$ octahedral clusters linked together by new tellurium and chlorotellurato ligands to form multidimensional structures.

$Re_6Te_{16}Cl_{18}$ may be thought of as $[(Re_6Te_8)(Te_8Cl_{18})]$ since it contains $[Re_6Te_8]^{2+}$ clusters and $[Te_8Cl_{18}]^{2-}$ ligands. The $[Re_6Te_8]^{2+}$ cluster consists of a Re^{III}–Re^{III}-bonded Re_6 octahedron inscribed in a cube by eight μ_3-Te^{2-} ligands. Re–Re bond lengths range from 2.674(2) to 2.691(2) Å and Re–μ_3-Te bond lengths from 2.669(2) to 2.699(2) Å. $[Re_6Te_8]^{2+}$ clusters have been previously observed in Re_6Te_{15} ($[(Re_6Te_8)(Te_7)]$),[10, 11] $[Re_6Te_8(TeBr_2)_6]Br_2$,[8] and the $[Re_6Te_8(CN)_6]^{4-}$ ion.[12] In addition to four μ_3-Te^{2-} ligands, each Re atom of the Re_6Te_8 core is coordinated by the previously unknown $[Te_8Cl_{18}]^{2-}$ chlorotellurato ligand through a Re–Te bond (2.638(2) Å). In turn, each $[Te_8Cl_{18}]^{2-}$ ligand chelates six $[Re_6Te_8]^{2+}$ clusters (Fig. 1);

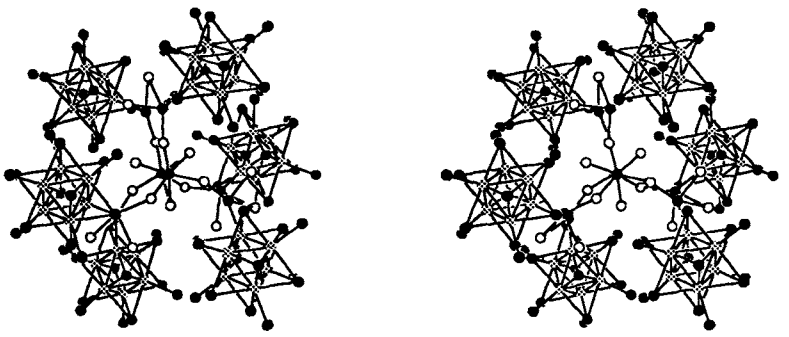

Fig. 1. Stereoview of the $[Te_8Cl_{18}]^{2-}$ ligand environment in $Re_6Te_{16}Cl_{18}$. Each ligand chelates six $[Re_6Te_8]^{2+}$ clusters, and each cluster is bound by an additional five ligands (not shown) through Te atoms (shown dangling). Re atoms are drawn as checkered spheres, Te atoms as solid spheres, and Cl atoms as hollow spheres.

Te_6, $[Te_8Cl_{18}]^{2-}$, and $[TeCl_3]^-$: New Tellurium and Chlorotellurato Ligands in the Re_6 Solid-State Cluster Compounds $Re_6Te_{16}Cl_{18}$ and $Re_6Te_{16}Cl_6$**

Dedicated to Professor Richard H. Holm

Re_6 octahedral clusters are important building blocks in the solid-state chemistry of Re-containing compounds.[1–5] Whereas halides and chalcogenides are an important component of such chemistry, the chemistry of halotellurato clusters of the early transition metals, especially Re, is undeveloped compared with that of halosulfato and haloselenato clusters. Yet the incipient chemistry of halotellurato clusters shows striking differences from that of the S and Se derivatives. For instance, there are unusual halotellurato ligands with no analogs in the S and Se systems. In these Te ligands, tellurium is predominantly in the oxidation state +II.[6, 7] Neutral $TeCl_2$ and $TeBr_2$ ligands are featured in the Re_6 cluster compounds $Re_6(\mu_3\text{-}Te)_6(\mu_3\text{-}Cl)_2(TeCl_2)_2Cl_4$ and $[Re_6(\mu_3\text{-}Te)_8(TeBr_2)_6]Br_2$.[8] However, halotellurium(IV) ligands, such as the $[TeCl_2]^{2+}$ ligand in $[Fe_2(CO)_6(Te_4)(TeCl_2)]$, are also known.[9] Here we present the synthesis and structures of two new solid-state compounds, $Re_6Te_{16}Cl_{18}$ and $Re_6Te_{16}Cl_6$, which contain $[Re_6Te_8]^{2+}$ octahedral clusters linked together by new tellurium and chlorotellurato ligands to form multidimensional structures.

$Re_6Te_{16}Cl_{18}$ may be thought of as $[(Re_6Te_8)(Te_8Cl_{18})]$ since it contains $[Re_6Te_8]^{2+}$ clusters and $[Te_8Cl_{18}]^{2-}$ ligands. The $[Re_6Te_8]^{2+}$ cluster consists of a Re^{III}–Re^{III}-bonded Re_6 octahedron inscribed in a cube by eight μ_3-Te^{2-} ligands. Re–Re bond lengths range from 2.674(2) to 2.691(2) Å and Re–μ_3-Te bond lengths from 2.669(2) to 2.699(2) Å. $[Re_6Te_8]^{2+}$ clusters have been previously observed in Re_6Te_{15} ($[(Re_6Te_8)(Te_7)]$),[10, 11] $[Re_6Te_8(TeBr_2)_6]Br_2$,[8] and the $[Re_6Te_8(CN)_6]^{4-}$ ion.[12] In addition to four μ_3-Te^{2-} ligands, each Re atom of the Re_6Te_8 core is coordinated by the previously unknown $[Te_8Cl_{18}]^{2-}$ chlorotellurato ligand through a Re–Te bond (2.638(2) Å). In turn, each $[Te_8Cl_{18}]^{2-}$ ligand chelates six $[Re_6Te_8]^{2+}$ clusters (Fig. 1); the ratio of $[Re_6Te_8]^{2+}$ clusters to $[Te_8Cl_{18}]^{2-}$ ligands is 1:1. The clusters and ligands are arranged in a nearly perfect rock-salt (NaCl) formation, similar to the arrangement of $[Re_6Te_8]^{2+}$ clusters and Te_7^{2-} ligands in Re_6Te_{15}. The structure of $Re_6Te_{16}Cl_{18}$ is thus three-dimensional. The $[Te_8Cl_{18}]^{2-}$ ligand can be described as consisting of two components. Component A is a central Te_2Cl_9 unit composed of a pair of face-sharing $TeCl_6$ octahedra, and component B comprises Te_2Cl_3 units that bridge A to two $[Re_6Te_8]^{2+}$ clusters (Fig. 2). There are three B units per A unit, and therefore six $[Re_6Te_8]^{2+}$ clusters are bridged to each A component (Fig. 3). In component A the Te–Te interatomic distance is 3.11(1) Å suggestive of a bonding interaction. The Te–μ_2-Cl bond length is 2.555(8) Å. Thus, component A may be formulated as $[Cl'_3TeCl_3TeCl'_3]$, where the two sets of Cl'_3 atoms join component A to component B; each B component bischelates an A component through one Cl atom per octahedron. Component B is a corner-sharing pair of $TeCl_2$

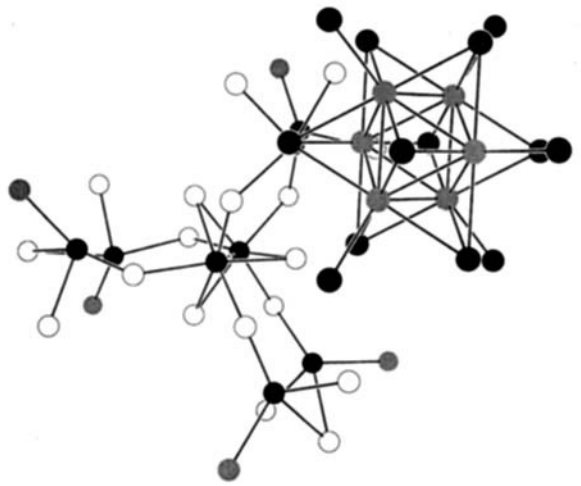

Fig. 2. View of a $[Te_8Cl_{18}]^{2-}$ ligand bound to a single $[Re_6Te_8]^{2+}$ cluster. Dangling Re atoms belong to other $[Re_6Te_8]^{2+}$ clusters, dangling Te atoms belong to other $[Te_8Cl_{18}]^{2-}$ ligands. Re atoms are drawn as checkered spheres, Te atoms as solid spheres, and Cl atoms as hollow spheres.

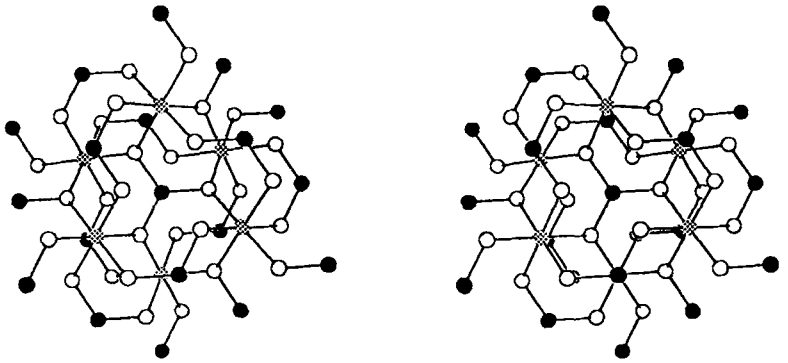

Fig. 3. Stereoview of the connectivity in $Re_6Te_{16}Cl_{18}$. Each $[Te_8Cl_{18}]^{2-}$ ligand is formed of a central A component (Te_2Cl_9) linked to three B components (Te_2Cl_3) through μ_2-Cl atoms. Each B component chelates two $[Re_6Te_8]^{2+}$ clusters. Thus $[Te_8Cl_{18}]^{2-}$ chelates a total of six clusters. A components are drawn as solid spheres, B components as hollow spheres, and Re_6Te_8 clusters as checkered spheres.

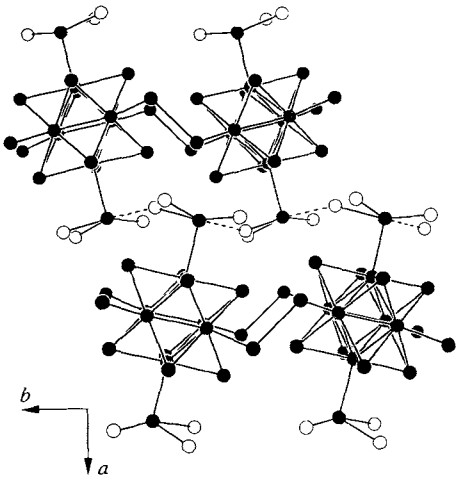

Fig. 4. Structure of $Re_6Te_{16}Cl_6$ viewed along [001].

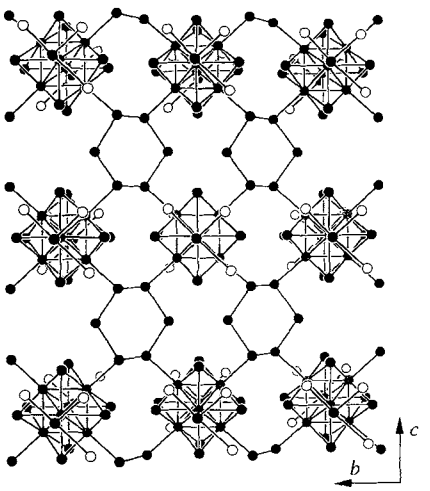

Fig. 5. Structure of $Re_6Te_{16}Cl_6$ viewed along [100].

units, Te_2Cl_3 or $(TeClCl_{1/2})_2$. The Te–Cl bond lengths in component B are 2.323(7) and 2.860(7) Å. Accordingly, we can write the $[Te_8Cl_{18}]^{2-}$ ligand as $[(Cl_3TeCl_3TeCl_3)((TeClCl_{1/2})_2)_3]^{2-}$, in which the Te centers are Te^{2+}.

$Re_6Te_{16}Cl_6$ may be thought of as $[(Re_6Te_8)(Te_6)(TeCl_3)_2]$, since it consists of $[Re_6Te_8]^{2+}$ clusters joined together by Te_6 and $[TeCl_3]^-$ ligands. The $[Re_6Te_8]^{2+}$ cluster core, which has a crystallographically imposed twofold axis, has bond lengths and angles similar to those observed in $Re_6Te_{16}Cl_{18}$. In $Re_6Te_{16}Cl_6$ two Re atoms at opposite vertices of the Re_6 octahedron are capped by $[TeCl_3]^-$ ligands (Fig. 4). The four remaining Re atoms are capped with neutral Te_6 ligands. The Te_6 ligands have a chair conformation with Te–Te bond lengths ranging from 2.762(4) to 2.899(5) Å. The neutral Te_6 species has not been previously observed, either as an isolated species or as a ligand. The neutral molecule S_6 has a chair conformation.[13] Known Te_6 species include $[Te_6I_2]^{2+}$, Te_6^{2+} (boat conformation),[14] and Te_6^{4+}.[15, 16] In the present structure each Te_6 chair chelates four $Re_6Te_8(TeCl_3)_2$ clusters (Re–Te = 2.697(3) and 2.707(3) Å) to create a two-dimensional network (Fig. 5). The four Re-bound Te atoms of the Te_6 chair are coplanar. The Te–Cl bond lengths in the $[TeCl_3]^-$ ligands are 2.387(8), 2.433(8), and 2.817(9) Å. The Cl atom that forms the longer Te–Cl bond interacts further with the Te^{2+} center of a $[TeCl_3]^-$ ligand from an adjacent layer, creating a square-planar geometry about the Te^{2+} center ($Cl_3Te\cdots Cl$ 3.028(9) Å, Cl-Te-Cl = 84.5(3)–101.0(2)°). A square-planar arrangement of Te^{2+} centers has also been observed in $Nb_2Te_8I_{12}$,[6] in which each Te atom of the $[Te_2I_6]^{2-}$ ligand resides in a square-planar environment. Whereas the $[TeI_3]^-$ ligand has been observed in $Mo_3Te_{10}I_{10}$,[7] no $[TeCl_3]^-$ ligands have been characterized previously.

The discovery of these remarkable new ligands is astonishing. Previous investigations in the $ReCl_5$/Te system yielded the isolated clusters $Re_6(\mu_3\text{-}Te)_6(\mu_3\text{-}Cl)_2(TeCl_2)_2Cl_4$[8] at similar reaction temperatures, and $Re_4Te_4(TeCl_2)_4Cl_8$[17] at lower reaction temperatures. The tremendous dependence of stoichiometry, ligand type, and structure dimensionality on reaction conditions in this system suggests that exciting new frontiers still exist in seemingly classical cluster halochalcogenide chemistry.

Experimental Procedure

$Re_6Te_{18}Cl_{16}$ and $Re_6Te_{16}Cl_6$ were obtained from the reaction of $ReCl_5$ and elemental Te in the ratio 1:3. The synthesis was carried out in an evacuated fused-silica tube heated at 450 °C for 1 d and then cooled at 4 K h^{-1} to promote crystal growth. The reaction mixture was washed with CH_3CN, and single crystals were collected and separated by their habits. The initial atomic composition of each compound was obtained from energy dispersive X-ray analysis (EDX).

X-ray structural analyses: $Re_6Te_{16}Cl_{18}$: black hexagonal plates, crystal dimensions $0.32 \times 0.30 \times 0.21 \times 0.046$ mm, trigonal, D_{3d}^6-$R\bar{3}c$, $Z = 6$, $a = 11.814(2)$, $c =$

First Experimental Determination of the Ionization Potentials of Berkelium and Californium

Stefan Köhler, Nicole Erdmann, Martin Nunnemann, Günter Herrmann, Gerhard Huber, Jens Volker Kratz, Gerd Passler, and Norbert Trautmann*

The first ionization potential is a fundamental property of an element and is of great importance for many physical and chemical processes. Its accurate determination enables one to identify systematic trends in binding energies from element to element, and to draw conclusions on the electronic structure of atoms, since the first ionization potential is directly connected to the atomic spectrum: The energy levels can either be given as (negative) binding energies, where the ionization potential represents the energetic zero point, or as (positive) excitation energies. In this case the level energy E_n for $n \rightarrow \infty$ converges to the ionization potential.

Reliable information about the electronic structure of the heaviest elements is needed to be able to state whether the regularities of the Periodic Table of Elements are maintained up through these elements or whether they are disturbed.[1] The first ionization potential is a property that sensitively depends on relativistic effects, which are expected in the heaviest elements as a result of the relativistic mass increase of the inner electrons.[2] The precise determination of the first ionization potential of these elements can serve as a test of the predictions of relativistic multiconfiguration Dirac–Fock calculations.[3] Furthermore, the first ionization potential is an important quantity in the Born–Haber cycle.[4]

The most accurate ionization potentials have been obtained by laser spectroscopic methods. The first ionization potentials of the lanthanide elements as well as those of uranium and the lighter transuranium elements neptunium and plutonium have been determined very accurately from the convergence of long series of highly excited Rydberg states.[5–8] A large amount of data is required for a correct interpretation of the spectra, due to configuration-interactions. The determination of the first ionization potential of plutonium by Worden et al.[8] shows the limitations of the method: up to 2 g of radioactive ^{239}Pu had to be used.

We present here a method that allows the accurate determination of the first ionization potential with samples in the nanogram range (ca. 10^{12} atoms). This opens the possibility for determining ionization potentials of the heavier actinide elements which can be conveniently handled only in very small quantities because of their strong radioactivity, or are available only in limited amounts. With such small amounts we were able to confirm the first ionization potential of ^{239}Pu, and to measure for the first time those of americium and curium.[9]

The method is based on the determination of photoionization thresholds in the presence of an external static electric field. The required detection efficiency is obtained by using resonance ion-

ization mass spectrometry developed by our group for ultratrace analysis of actinide elements.[10] According to the classical saddle point model[11] the Coulomb potential of an atom changes in the presence of an external electric field; the potential is shifted to lower values with increasing field strength. The energetic position of the saddle point depends linearly on the square root of the electric field strength.[12] All levels of higher energy than the saddle point are field ionized. Therefore, the saddle point denotes the ionization threshold as a function of the electric field. Experimentally, a high-lying state is populated by two-step resonant laser excitation. Located in a known static electric field, the atom is then ionized by scanning across the threshold the wavelength of the laser for the ionizing step. This is shown in Figure 1 for berkelium; two different excitation schemes were used as an internal control of the method.

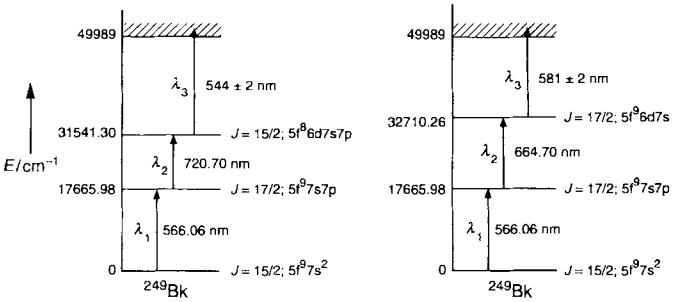

Fig. 1. Excitation schemes for berkelium as used in the determination of the first ionization potential by resonance ionization mass spectrometry. After a resonant two-step excitation (λ_1, λ_2) the wavelength λ_3 of the laser for the ionizing step is scanned across the ionization threshold W_{th}.

The ions produced are mass-selectively detected in a time-of-flight mass spectrometer. The ionization threshold is marked by the sudden increase of the intensity of the ion signal. Figure 2 illustrates for berkelium how the ionization threshold is shifted to lower values with increasing field strength. Only a very low

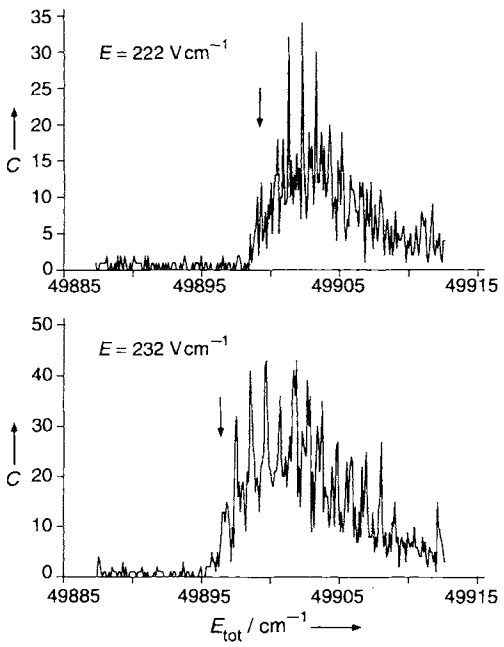

Fig. 2. Ionization thresholds (arrows) of berkelium for two different electric field strengths E in the interaction region of the atomic beam and the laser beams. Recorded is the number C of the ions as a function of the total photon energy E_{tot} of the three laser beams (λ_1, λ_2, λ_3, see Fig. 1).

background is present below the threshold which may be due to nonresonant multiphoton ionization. Hence, the increase of the ion signal at the threshold can be determined accurately. Beyond the threshold autoionizing Rydberg–Stark manifolds are observed. By measuring the ionization thresholds for various electric field strengths, the first ionization potential can be determined by extrapolation to zero field strength according to the saddle point model.[12] The precision of this method can be seen from Figure 3, which shows the data obtained for berkelium with two alternative excitation schemes. For berkelium as well as for californium the values fit perfectly the linear extrapolation to zero field strength by a least-squares fit.

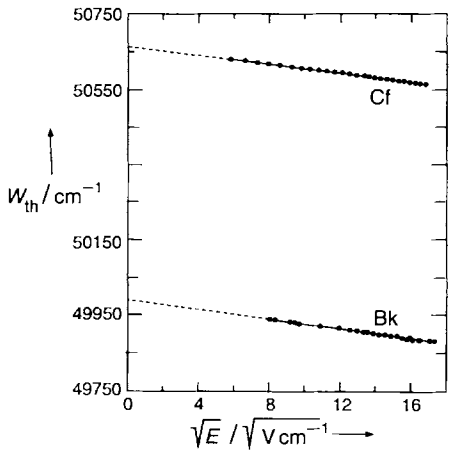

Fig. 3. Determination of the first ionization potentials of berkelium and californium. The measured ionization thresholds W_{th} of ^{249}Bk and ^{249}Cf are plotted versus the square root of the electric field strength E. Extrapolation to $E = 0$ gives the first ionization potential. Samples of 1×10^{12} atoms (0.4 ng) were used.

For the investigation of berkelium and californium three-step excitations were used starting from the atomic ground state. The excitation schemes were chosen taking into account the values for the first ionization potential predicted in the literature[13] from extrapolations of spectroscopic data (Table 1). Table 1 also gives the first ionization potentials I_{exp} obtained for ^{249}Bk ($T_{\frac{1}{2}}$ = 320 days) and ^{249}Cf ($T_{\frac{1}{2}}$ = 351 years); the corresponding values in cm^{-1} are 49989(2) and 50665(2), respectively.

Table. 1. First ionization potentials I of berkelium and californium determined by photoionization in an electric field. All wavelengths are given for vacuum. The values from the literature $I_{extr.}$ were extrapolated from spectral data [13].

Element	I[eV][a] (exp.)	$I_{extr.}$[eV] (extrapol.)	Excitation scheme λ_1[nm]	λ_2[nm]	λ_3[nm]
berkelium	6.1979(2)	6.229(25)	566.06	720.70	ca. 544
	6.1979(2)	6.229(25)	566.06	664.70	ca. 581
californium	6.2817(2)	6.298(25)	572.77	625.23	ca. 581

[a] The given 2σ errors of the first ionization potential result from the uncertainty of the ordinate of the least-squares fit.

The experimental values for the first ionization potentials of the actinide elements are between the extrapolated data[13] and those from Hartree–Fock calculations.[14] They follow the trend for binding energies of the s electrons determined by ab initio Hartree–Fock calculations for the ionization process 5f^{N}7s^2 → 5f^{N}7s. These binding energies are called the normalized ionization potentials I_n of the actinides. If the ground state dif-

fers from the configuration $5f^N7s^2$ due to population of the 6d shell, the values of the ionization potentials are corrected by the difference of the term energies. For berkelium and californium no correction is required. Hartree–Fock calculations predict that the normalized ionization potentials, when plotted against N, form two straight lines, changing the slope at americium (half-filled 5f shell) (Fig. 4). While the experimental data for the

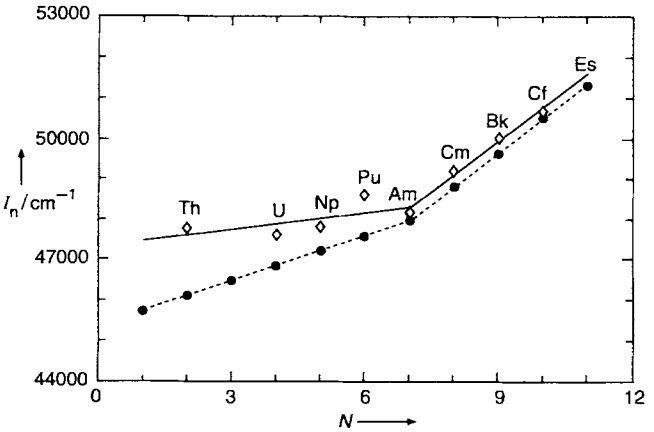

Fig. 4. Normalized first ionization potentials of the actinide elements for the ionization process $5f^N7s^2 \rightarrow 5f^N7s$ as a function of N. Plotted are the normalized experimental data (◇), this work and reference [9], and the theoretical values (●) obtained by Hartree–Fock calculations [14].

elements beyond americium agree very well with the assumption of a linear dependence, the lighter actinides show stronger deviations from the straight line. This may be due to the participation of 5f electrons in the ionization process. The determination of the still unknown first ionization potentials of protactinium and actinium is therefore of interest.

Experimental Procedure

Resonance ionization of the actinide elements required an atomic beam. This was achieved by resistive heating of a filament consisting of a thin tantalum foil, on which the element under investigation was electrochemically deposited as hydroxide, and covered with a titanium layer produced by sputtering. By heating such a filament the hydroxide was converted into the oxide, which was reduced to the metallic state during diffusion through the covering layer.

Three tunable dye lasers, which were pumped by two copper vapor lasers of high pulse repetition rate (6.5 kHz, 30 W, and 50 W average output power, 30 ns pulse duration), are used for optical excitation of the atoms. With the dye lasers a wavelength range from 520 nm to 850 nm can be covered; a conversion efficiency of up to 25% of the pump laser power can be achieved. The wavelengths were determined with a pulsed wavemeter. The dye laser beams were introduced with quartz fibers or prisms into the setup where they cross the atomic beam. The ions produced were accelerated by electric fields and detected with a multichannel plate detector after they had passed a field-free drift tube.

From Pagodanes to Nonpentagonal (Homo)Dodecahedranes—The Undecacyclo-[10.10.0.0^{2,20}.0^{3,10}.0^{4,19}.0^{5,9}.0^{6,18}.0^{7,15}.0^{8,13}.0^{19,22}.0^{16,21}]docosane Cage**

Veeraraghava Sharma, Manfred Keller, Andreas Weiler, Dieter Hunkler, and Horst Prinzbach*

Dedicated to Professor Rolf Gleiter on the occasion of his 60th birthday

Pagodane and (seco)dodecahedrane cage structures[1] allowed the study of unusual electronic phenomena[2] and of unusual molecular species (for example, valence isomeric 4c/3e radical cations[3] and σ-bishomoaromatic 4c/2e dications[4]). For the quantification of the factors determining the transannular electronic interactions, additional model structures with well-defined molecular dimensions are sought. In the synthetic route presented here, pagodanes **A** are transformed into unsubstituted and into pairwise symmetrically functionalized bis(homo)dodecahedranes **C**. This strategy, which in principle is also applicable to hetero analogs, is characterized by twofold cyclization of bissecododecahedranes **B**, with transcaveally opposed C=X bonds and *anti*-positioned leaving groups L, and corresponds to, without any mechanistic implication, substitution by the relatively distant X groups.[5, 6]

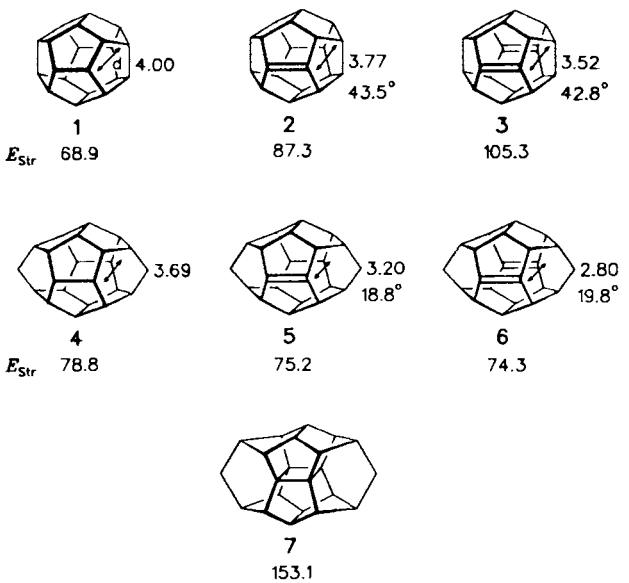
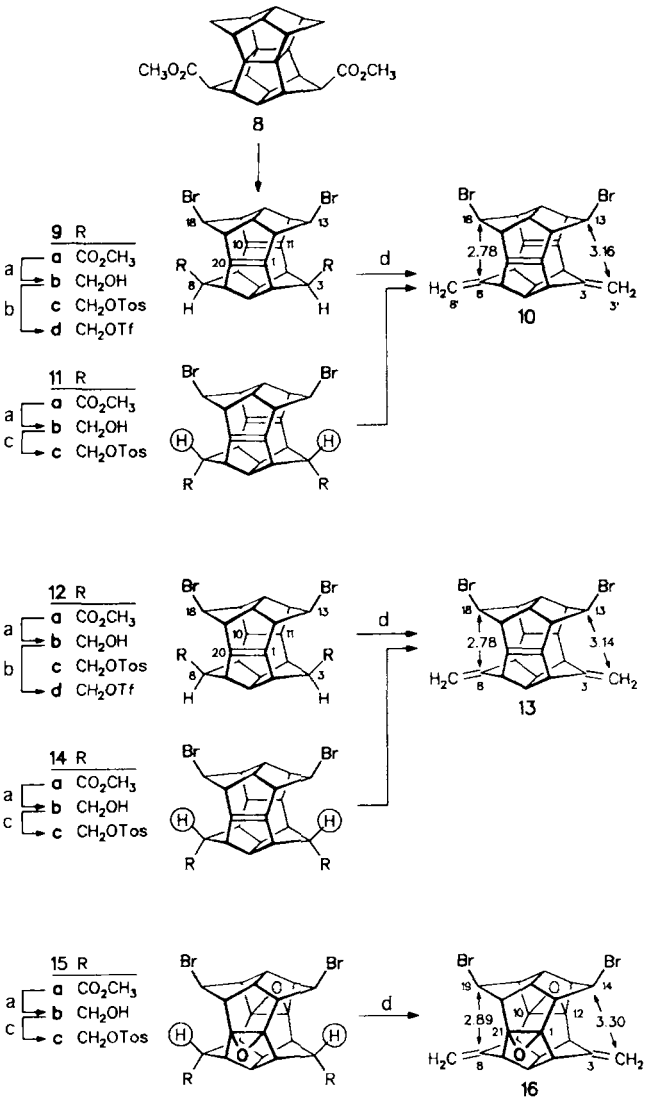
Based on the calculated energy and structure data (MM2)[7, 8] given in Scheme 1, the insertion of two methylene bridges into the pentagonal structures **1**–**3** has the following consequences:[8, 9] The molecular strain energy increases significantly for **1** → **4** (ΔE_{str} = 9.9 kcal mol^{-1}) and decreases significantly for **2** → **5** and even more for **3** → **6** (ΔE_{str} = −12.1 and −31.0 kcal mol^{-1}, respectively); the homologous cages are less "bulged" (e.g. Δd = −0.72 Å for **3** → **6**), the C=C bonds less "hyperstable", and the olefinic carbons much less but still significantly pyramidalized. From the comparison with the bismethano-bridged [1.1.1.1]pagodane **7** (**D**, X = CH_2) it is apparent that the alternative route **A** → **D** → **C** has no chance here.



Scheme 1. Calculated (MM2) strain energies E_{Str} [kcal mol^{-1}]), distances d[Å], and angles Φ [°].

In the first examples of the route **A** → **B** → **C** presented in Schemes 2 and 3, 3,8-bis(methylene)bissecododecahedranes with *anti*-positioned Br nucleofugs (**10**, **13**, **16**) serve as the central intermediates **B**. The cyclizations at the exocyclic methylene C atoms (C-3′(8′)) must potentially compete with the formation of five-membered rings (through C-3(8)) to give pentagonal dodecahedranes. Chances were seen a priori to steer this competition by appropriate "timing" of the bond-breaking and -forming events. A comparable competition in electrophilic and radical additions to 3,7-bis(methylene)bicyclo[3.3.1]nonanes (formation of noradamantanes vs. adamantanes) has been extensively studied.[10]

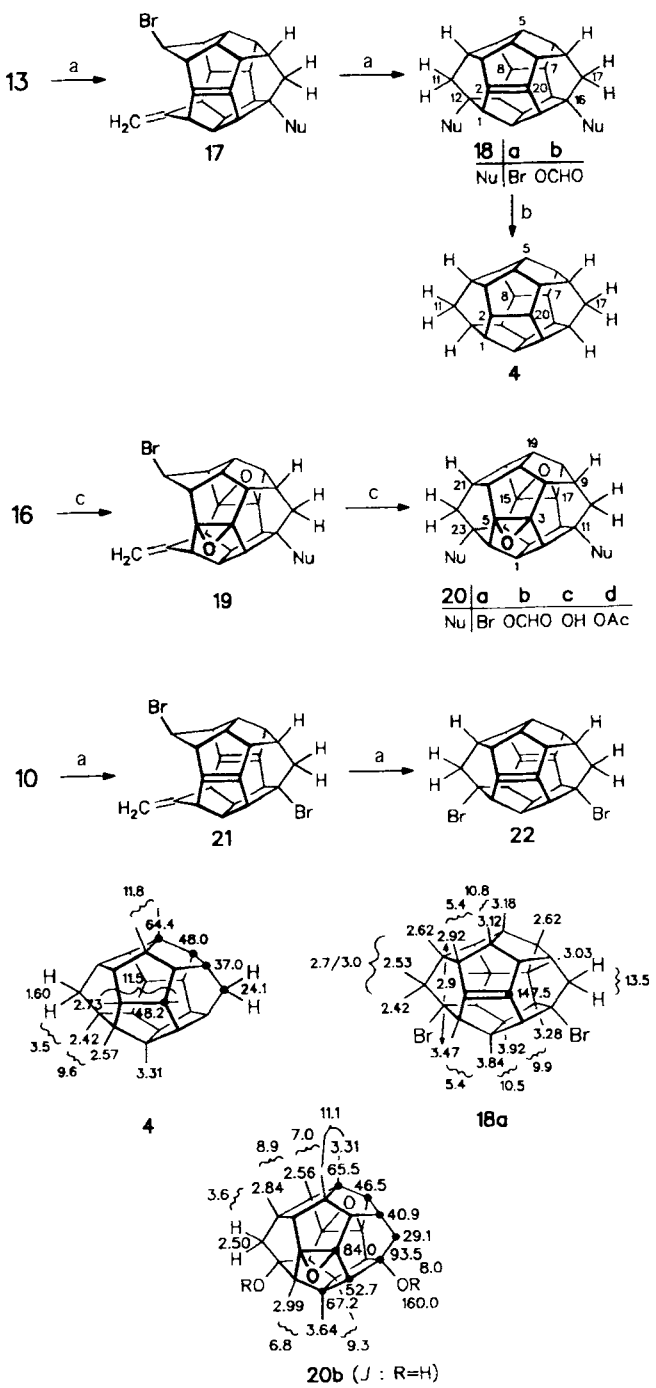


Scheme 2. a) DIBAH, CH_2Cl_2 (abs.), −78 °C, 3 h, 85%; b) Tf_2O, CH_2Cl_2 (abs.), pyridine (abs.), 0 °C → RT, 12 h, 60%; c) TosCl, pyridine (abs.), 50 °C, 24 h, 90%; d) "P2F" (6 equiv), benzene, RT, 1 h, 75–80%. DIBAH = diisobutylaluminum hydride, Tf = trifluoromethanesulfonyl, Tos = *p*-toluenesulfonyl.

Efficient protocols for the preparation of the precursors, the *syn,syn,anti,anti*- (**9a** and **12a**) and all-*anti*-dibromobissecodiesters (**11a**, **14a**, and **15a**), starting from the 4-*syn*,9-*syn*-diester **8** as a direct offshoot of the standard pagodane synthesis, have been described.[10, 11] We pursued two synthetic variants because of complications caused by the special structural situation in the lateral pockets of the bissecododecahedranes: *syn,syn*-Bistosylates **9c** and **12c**[13] are not accessible from the *syn,syn*-diols **9b** and **12b**; the accessible, sterically less encumbered bistriflates **9d** and **12d** reduce the strain through spontaneous β-eliminations to give **10** and **13**, respectively, in 60% yield. In the *anti,anti*-diols **11b**, **14b**, and **15b** twofold tosylation was unproblematic. Yet deprotonation in the effectively protected β-positions of the diesters **11c**, **14c** and **15c** was not possible with a variety of bases even under conditions leading to decomposition. The breakthrough came once again[12] by use of the small, very strong, and only weakly nucleophilic Schwesinger bases "P_2F" ("P_5F");[14] the colorless, crystalline dienes **10**, **13**, and **16** were obtained in 75–80% yield. The longer routes via **11a**, **14a**, and **15a** became the first choice also because of their better

accessibility (ca. 60% total yield based on **8**). Transcaveal 1,5-HBr eliminations as intrinsic alternatives to the β-eliminations (cf. the efficient base-catalyzed S_N2 cyclization of the diesters (**a**) to the corresponding pentagonal dodecahedranes[11]) do not play a significant role; there are indications that this competition only becomes detractive with better leaving groups as, for example, in the 13,18-diiodide corresponding to **11c**.

For the cyclizations of **10**, **13**, and **16** (**B** → **C**) to occur, steric as well as energetic aspects seem to require an effective interplay of C–Br bond breaking and transannular C–C bond forming events. For this problem a simple, though not yet optimal, and mechanistically still obscure solution was found (Scheme 3):



Scheme 3. a) KBr (10 equiv), DMF (abs.), 180 °C, 12 min; b) H_2, 10% Pd/C, methanol, RT, 1 h, >95%; c) analogous to a), 30 min.

When the degassed suspension of **13** and a large excess of KBr in DMF was heated at reflux until total conversion (TLC, ca. 12 min), the crude product isolated chromatographically in approximately 75% yield was practically uniform dibromo-bis(homo)dodecahedrene **18a** (and roughly 1% diformiate **18b**). Monitoring the reaction by TLC and ^{1}H NMR spectroscopy confirmed that the monocyclized **17a** was the only other monomeric component present in a low stationary concentration besides polymers; dodecahedranes resulting from bond formation between the less distant C3–C13 (C8–C18) positions would have been detected in small quantities (>2%). Obviously, within the analytical limits both cyclization steps were regiospecific.

The bis(homo)dodecahedrenes **18** ($\Phi \approx 19°$) are, as expected, much less reactive than their pentagonal analogs (e.g. **2**, $\Phi = 43.5°$[9]) and are relatively stable to air. Hydrogenation and twofold hydrogenolysis (Pd/C) of dibromide **18a** to give the $C_{22}H_{24}$ parent hydrocarbon **4** proceeded nearly quantitatively. The stability of the latter (m.p. >300 °C)—as in **1** the molecular strain (Scheme 1) is largely caused by H/H interactions—is mirrored in the mass spectrum: the molecular ion signal (*m/z*: 288) is by far the most intensive. The smaller molecular curvature of the "olefinic side" in the cages **18**—also compared with that in **2**—is manifested inter alia by the ^{13}C NMR shift of the olefinic C atoms (δ = 147.5 (**18**), 157.0 (**10**), 166.6 (**2**)) and by the vicinal H,H coupling constants, as determined by decoupling and simulation experiments (**18a**: e.g. $J_{1,22} = J_{3,4} = 5.4$, $J_{14,15} = 9.9$ Hz; **4**: $J_{1,12} = 9.6$, $J_{2,20} = 11.5$ Hz).

The diepoxide **16**, a "protected" form of diene **10**, reacts more slowly than **13** in the boiling DMF/KBr suspension—as was expected since the strain caused by the cyclization becomes larger with the increasing sp^3 character of the central C atoms (Scheme 1). After approximately 90% conversion (30 min) bromide **19a** (<5%), formiate **19b** (15%), and diformiate **20b** (42%) were isolated chromatographically (after longer reaction times the proportion of **20b** had decreased). The crystalline diformiate **20b** was transformed into diol **20c** by ammonolysis and additionally characterized as diacetate **20d**. According to the vicinal H,H coupling constants (e.g. $J_{1,24} = 6.8$, $J_{19,20} = 7.0$, $J_{20,21} = 8.9$ Hz), the curvature on the "epoxide sides" is larger than on the olefinic and smaller than on the saturated side of **18a**.

Cyclization of the tetraene **10** to give the "*syn*-periplanar" diene **22** of primary interest—the increase in strain is comparable to that for **13** → **18**—does not significantly affect the transannular π,π distance (2.75 → 2.80 Å, the calculated values are probably somewhat too small[6]). The consequently pronounced tendency in the starting compound and the product to undergo transannular additions[15] is considered to be (one) reason for the finding that the reaction of **10** under the conditions successfully used for **18** and **20** generated only traces of **21** and **22**, if any,[16] in complex product mixtures. If this complication cannot be overcome by changing the cyclization conditions, an approach to **22** via **20** is possible.

Crystallization of **4** from ethyl acetate provided small cubes suitable for an X-ray structural analysis.[17] In the crystal the molecule is situated on an inversion center. The structural details (Fig. 1), particularly the dimensions of the cavity, are in good agreement with the calculations. The C–C bond lengths range from 1.524 Å (C8–C9) to 1.556 Å (C3–C11), the C-C-C valence angles from 105.8° (C9-C7-C10) to 118.9° (C7-C6-C1); the cyclohexane rings of the bicyclo[3.3.1]nonane units are fixed as typical half-chairs. The symmetry-averaged H-C-C-H interplanar angles ($\alpha - \delta$) nicely correspond with the vicinal H,H coupling constants.

Aggregation of Modified Zinc Chlorins in Nonpolar Solvents–Bacteriochlorophyll *c* Mimics with Interchanged Hydroxy and Carbonyl Functions**

Aldo Jesorka, Teodor Silviu Balaban, Alfred R. Holzwarth,* and Kurt Schaffner

In the self-assembly of the zinc chlorin **1** in nonpolar solvents (hexane solutions containing up to 1% v/v CH_2Cl_2), the central metal and the 3^1-hydroxy and 13^1-keto groups play an essential role in the formation of large aggregates.[1] We now provide evidence that the conditions for this aggregation tolerate an interchange of the hydroxy and carbonyl functions. Such an interchange does not sacrifice the capacity to self-assemble and form aggregates of the same type. This finding is not trivial, as it might seem at first sight, since experimental experience and molecular modeling have shown that the extent of self-assembly as well as the type and stability of the aggregates formed are subject to seemingly slight structural factors such as diastereoselective control by the configuration at C3^1 (e.g. in **2**[2]), steric crowding by substituents,[3] and the size of the ester side chain.[4] The functionally "inverse" zinc chlorins (**6a**-Zn and **6b**-Zn) thus access novel types of self-assembled aggregates.

The large aggregates of **1** possess a broad Q_y absorption band at 740 nm, which amounts to a large red shift of about 1820 cm^{-1} from the absorption of monomeric **1** (in solutions containing up to 5% v/v CH_3OH). The absorption is reminis-

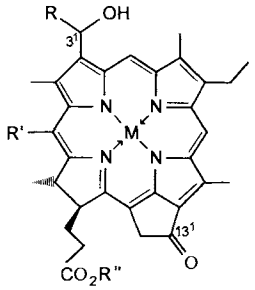

Scheme 1. Zinc chlorin model compounds:
1 R = R′ = H, R″ = CH_3, M = Zn
2 R = R″ = CH_3, R′ = H, M = Zn [1, 2]
3 R = R′ = CH_3, R″ = $C_{18}H_{37}$, M = Mg (BChl c_s, stearyl ester)

cent[5] of that of bacteriochlorophyll (BChl) *c* (e.g. **3**), *d*, and *e* aggregates, which function as antenna pigments in the light-harvesting chlorosomes of green photosynthetic bacteria.[6–8] The aggregates of **1**–**3** and related compounds, when formed in nonpolar solvents, possess comparable supramolecular structures based on cooperative interaction within a bonding network, which has been proposed on compelling molecular modeling[3b] and spectroscopic[6b, 7b, 9] data, and which is exemplified by the building block shown in Figure 1. The in vitro

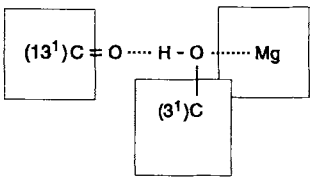

Fig. 1. Schematic representation of the central building block formed by a bonding network interconnecting three BChl *c* molecules (rectangles): the 3¹-hydroxy group of one BChl is bound to the magnesium of a second through oxygen ligation and simultaneously to the 13¹-keto group of a third BChl by hydrogen bonding [13].

aggregates possess tubular inverted micelle structures, the diameters of which Katz and co-workers[10, 11] found by neutron small-angle scattering to be very close to those determined by electron microscopy for the BChl *c*, *d*, and *e* rods in the interior of chlorosomes.[12]

Compounds **6a**-Zn and **6b**-Zn were prepared from methyl pyropheophorbide *a* (**4**-2H)[16] by $NaBH_4$ reduction to a 1:1 mixture of the (13¹*R*)- and (13¹*S*)-configurated diastereoisomeric alcohols (**5a**-2H and **5b**-ZH, respectively), vinyl cleavage with $OsO_4/NaIO_4$[17] to **6a**-2H and **6b**-2H, and metalation to **6a**-Zn and **6b**-Zn. The resulting diastereoisomers were separated by HPLC, and the configurations at C13¹ were assigned by ^{1}H NMR NOE difference spectra based on correlation with the fixed (*S*) configuration at C17.[18, 19]

When the solution of an equimolar mixture of **6a**-Zn and **6b**-Zn in dry CH_2Cl_2 was diluted with 99 parts of hexane, a broad Q_y maximum appeared at 738 nm (Fig. 2), red-shifted by 1760 cm^{-1} from the sharp 653 nm Q_y band of the monomers.[20]

	C13¹ config.	R	R′	R″
4-X	-	CH_2		-O-
5a-X	(*R*)	CH_2	H	OH
5b-X	(*S*)	CH_2	OH	H
6a-X	(*R*)	O	H	OH
6b-X	(*S*)	O	OH	H
7a-X	(*R*)	O	H	$OCOCH_3$
7b-X	(*S*)	O	$OCOCH_3$	H

X = 2H, Zn

Scheme 2. "Inverse" chlorin compounds **4**–**7**.

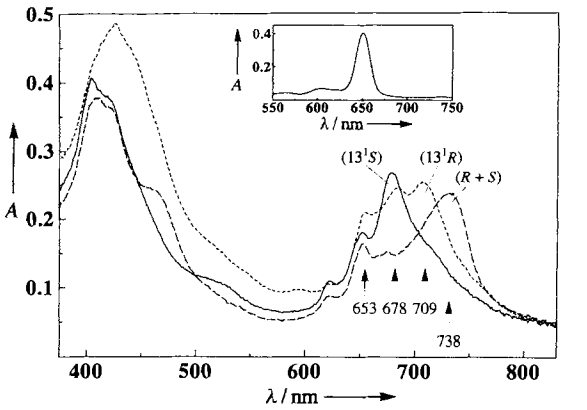

Fig. 2. UV/Vis absorption spectra of **6a**-Zn [(13¹*R*) ----], **6b**-Zn [(13¹*S*) ——], and a 1:1 epimer mixture of **6a**-Zn and **6b**-Zn [(13¹*R* + 13¹*S*) – – –]. All sample solutions (CH_2Cl_2/hexane, 1/99, v/v) were prepared by diluting concentrated CH_2Cl_2 solutions with *n*-hexane. Inset: Spectrum of the epimer mixture in CH_2Cl_2/hexane/methanol 1/99/5, v/v/v showing deaggregation after methanol addition. Spectra not corrected for scattering.

In conjunction with FT-IR data[21] recorded for the same solutions (for example, a 1640 cm^{-1} band for the hydrogen-bonded aldehyde), this aggregation can be assigned to the bonding network depicted in Figure 3, which is analogous to that elucidated

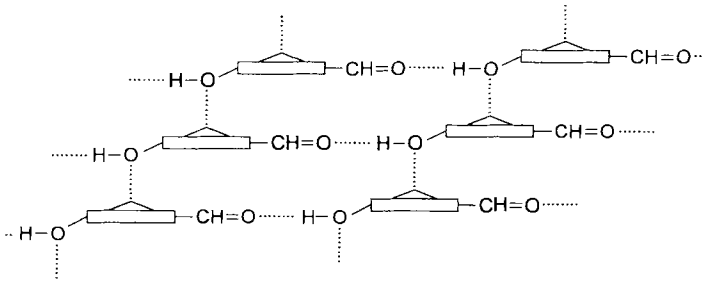

Fig. 3. Proposed bonding network for the large aggregate formed by **6a**-Zn and **6b**-Zn in *n*-hexane (absorption at λ_{max} = 738 nm), based on the building block as defined in Fig. 1; △: central zinc atom.

for BChl *c* and model compounds.[3b, 9] Thus both "normal" and "inverted" compounds lead to basically the same relative orientation of the chlorin rings. Aggregation of **6a**-Zn is subject to diastereoselective control, and clearly more so than the aggregation of **2** and **3**.[2, 9b] The absorption spectra of the separate (*R*) and (*S*) epimers under identical conditions show that monomers (λ_{max} 653 nm) and dimers (λ_{max} 678 nm) are the major components, but contribute a distinctly minor part of the composite absorption of the epimer mixture. Small oligomers absorbing around 708 nm are present in all three samples, which has been ascertained by Gaussian deconvolution. In the spectra of the separate epimers a minor longer wavelength absorption, attributable to large aggregates as in the (*R* + *S*) mixture, is observed for the (13¹*R*) epimer and for the (13¹*S*) epimer at higher concentrations.[22]

The epimer mixture affords more of the strongly red-shifted aggregate than the epimers separately. A rationalization of this observation cannot be offered at present. We should note, however, that in **1**–**3** configurational and conformational isomerism is restricted to the C3 substituent, whereas the constitution of **6a** and **6b** includes conformational isomerism of the C3 substituent and two configurations at C13¹. Cooperative self-

assembly[15] to large aggregates (Fig. 3) may involve selective stereocombinations that suffice to exert diastereoselective controls.

Addition of methanol, (which competes for ligation with zinc), to solutions of **6a**-Zn, **6b**-Zn, and (**6a**-Zn + **6b**-Zn) disintegrated all aggregates and formed homogeneous solutions of monomer (λ_{max} = 653 nm, see inset in Figure 2).

Neither **5a**-Zn/**5b**-Zn nor **7a**-Zn/**7b**-Zn in which one of the functional groups at either C3[1] or C13[1] is derivatized, exhibited any red shift in absorption in the wavelength region above 653 nm upon dilution of their CH_2Cl_2 solutions with hexane. This is in accordance with an earlier observation by Smith et al.[8] and confirms the binding roles of the 3[1]-aldehyde and the 13[1]-hydroxy groups (Fig. 1), as postulated previously for the original arrangement of the functions in **1**–**3**.[23] Furthermore, it provides independent evidence (in addition to FT-IR[21]) against the postulates that the C13[1] ketone[14c] and the C17[3] ester[14i] carbonyl groups coordinate directly with magnesium in BChl *c* aggregation.

Based on the structural conditions for the formation of chlorosomal type aggregates, as now defined by the two classes of metallochlorins (**1**–**3** and **6a**-Zn/**6b**-Zn) it should be possible to synthesize different macrocycles capable of similar self-assembly, and using them to design photoactive functional units by coupling to appropriate energy traps.[24]

[19] Satisfactory analytical data have been obtained for all new compounds.

[20] After elution with aqueous methanol from the HPLC column and evaporation of the solvents, a sharp blue-shifted peak at 622 nm is visible in the dichloromethane solutions of **6a**-Zn diluted with hexane. This peak is removed after washing with brine a dichloromethane extract of **6a**-Zn. We tentatively assign this peak to a methanol-bridged dimeric species.

[21] For **6a**-Zn and **6b**-Zn in dichloromethane solution the ester C=O band is at 1733 cm^{-1}, that of the aldehyde at 1664 cm^{-1}, and a chlorin mode at 1606 cm^{-1}. Upon addition of methanol the ester C=O band remains unshifted, whereas the aldehyde C=O appears at 1657 ± 2 cm^{-1}, probably due to hydrogen bonding to methanol. When dichloromethane solutions are diluted with hexane, the ester C=O band is slightly shifted to larger wavenumbers (1738 cm^{-1}), whereas the aldehyde carbonyl band is strongly shifted to lower frequencies [broad band at 1640 cm^{-1} for the more soluble (13[1]*S*) epimer]. This is reminiscent of the strongly down-shifted 13[1]-carbonyl vibration in BChl *c* aggregates and chlorosomes [9b]. We correspondingly assign this latter band to the aldehyde carbonyl group strongly hydrogen-bonded to a hydroxy group, which simultaneously coordinates with a zinc atom.

[22] The proportion of red-shifted oligomers is slightly greater on aggregation in pentane than for that in hexane and heptane. Furthermore, the amount is also determined by the concentration of the CH_2Cl_2 stock solution: the higher this concentration, the more aggregated species are formed, as is expected from a cooperative process for the self-assembly. This has been shown for BChl *c* oligomers (predominantly tetramers; cooperativity of 3.6) [15].

[23] Solutions of **5a**-Zn and **5b**-Zn in hexane tend to form deposits upon standing, albeit without a red shift in absorption of the supernatant.

[24] For a first example of a functional unit based on the self-organized assembly of zinc chlorins coupled to a metal-free bacteriochlorin as energy acceptor: H. Tamiaki, T. Miyatake, R. Tanikaga, A. R. Holzwarth, K. Schaffner, *Angew. Chem.* **1996**, *108*, 810–812; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 772–774.

New Imido-Bridged Transition Metal Clusters: $[(C_5H_5)_4Ti_4(NSnMe_3)_4]$, $[Co_{11}(PPh_3)_3(NPh)_{12}]$, $[Ni_{11}Br_6(NtBu)_8]$, and $[Li(thf)_4]_4[Cu_{24}(NPh)_{14}]$**

Andrea Decker, Dieter Fenske,* and Klaus Maczek

Dedicated to Professor Rudolf Taube on the occasion of his 65th birthday

Transition metal compounds with nitrogen-containing ligands usually form, with few exceptions, mononuclear compounds.[1–3] Recently Dehnicke et al, for example, described the synthesis of N-containing cluster compounds such as $[Cu_4(NPMe_3)_3(O_2CCH_3)_5]$, $[Cu_6Cl_6(NPMe_3)_4]^+$, and $[Cu_6Br_6(NPMe_3)_4]^+$,[4–6] in which the phosphane imine groups act as bridging ligands. These compounds were the first N-bridged clusters of electron-rich transition metals to be synthesized.

[**] This work was supported by the Deutsche Forschungsgemeinschaft.

Herein we report that imido-bridged transition metal clusters can also be synthesized. The synthetic strategy is based on the reaction of chlorotransition metal phosphane complexes with stannylamines; the elimination of trimethylchlorostannane leads to the formation of nitrogen-bridged clusters.

The Ti_4 cluster **1** can be isolated as brown crystals in a low yield (20%) from the reaction of $[CpTiCl_2(PEt_3)_2]$ ($Cp = C_5H_5$) with tris(trimethylstannyl)amine [Eq. (a)].

$$[CpTiCl_2(PEt_3)_2] \xrightarrow{N(SnMe_3)_3} [Cp_4Ti_4(\mu_3\text{-}NSnMe_3)_4] \quad (a)$$

1

The results of the single-crystal X-ray structure analysis of **1** are shown in Figure 1.[9] Compound **1** consists of a Ti_4N_4 cluster with a heterocubane structure, in which the titanium atoms

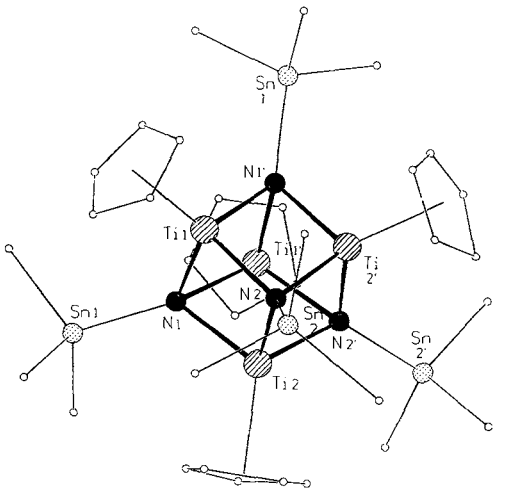

Fig. 1. Molecular structure of **1**. Hydrogen atoms have been omitted for clarity. Selected bond lengths [pm] and angles [°]: Ti1–Ti1′ 277.9(4), Ti1–Ti2′ 268.6(3), Ti2–Ti2′ 277.3(3), Ti1–Ti2 278.5(3), Ti1–N1 197.0(9), Ti1–N1′ 205.8(9), Ti1–N2 206.4(8), Ti2–N2 195.0(8), Ti2–N2′ 203.2(8); N1-Ti1-N2 91.2(3), N1′-Ti1-N2 97.4(3), Ti2-Ti1-Ti1′ 57.72(8), Ti2-Ti1-Ti2′ 60.86(8).

are each coordinated to an η_5-Cp ligand, and the N atoms are bound to $SnMe_3$ groups. Within the four-membered rings of the cubane framework, the Ti-N-Ti and the N-Ti-N angles lie between 87.2–88.2° and 91.1–92.3°, respectively. The Ti atoms in **1** are all formally in the oxidation state +III. Surprisingly this complex shows diamagnetic behavior. This must be a result of coupling between the d^1 spin centers.[8] Compound **1** has 52 valence electrons (VE) and therefore 8 VE less than expected for a M_4 cluster with a tetrahedral structure.[7a] However, **1** is isoelectronic with $[MXNPEt_3]_4$ (X = Cl, I), in which M_4N_4 heterocubane structures are also found.[7b]

On the other hand there are many heterocubane clusters for which the noble gas rule (60 VE) is exceeded or not met. Extended Hückel calculations show that a M_4 tetrahedral cluster with 52 VE should possess D_{2d} symmetry with four longer and two shorter M–M bonds.[8a] This is indeed found to be true for **1**, which has two short Ti–Ti bonds (268.3(3) pm) and four longer Ti–Ti bonds (277.2–278.5(3) pm). Other titanium clusters with the same number of valence electrons have already been reported. Examples include $[Cp_4Ti_4Te_4]$ and $[Cp'_4Ti_4S_4]$ ($Cp' = i\text{PrC}_5H_4$),[8a] in which the Ti–Ti distances are significantly longer (292.7–300.8 and 314.5–321.4 pm, respectively). $[Cp^*_4Ti_4N_4]$ ($Cp^* = C_5Me_5$) is another compound with a Ti_4N_4 structural unit that has recently been reported;[8b] however, in contrast to **1**, this compound contains an undistorted Ti_4 tetrahedron (Ti–Ti 278.8 pm).

Since **1** contains four $SnMe_3$ ligands, there are four reactive N–Sn bonds, which are potential centers for further reaction to form links between Ti_4N_4 heterocubane units. However, reactions with transition metal and main group element halide compounds have so far proved unsuccessful.

The reaction of $PhN(SnMe_3)_2$ with $[CoCl_2(PPh_3)_2]$ led to dark green crystals of **2** [Eq. (b)], which tend to decompose very quickly. The central metal framework in **2** consists of a planar

$$[CoCl_2(PPh_3)_2] \xrightarrow{PhN(SnMe_3)_2} [Co_{11}(PPh_3)_3(\mu_2\text{-}NPh)_6(\mu_3\text{-}NPh)_6] \quad (b)$$

2

Co_6 ring that is formed from the atoms Co1, Co3, Co4, Co6, Co7, and Co9 (Fig. 2). Single Co atoms lie above and below the Co_6 plane lie at distances of 118.6 pm (Co10) and 121 pm

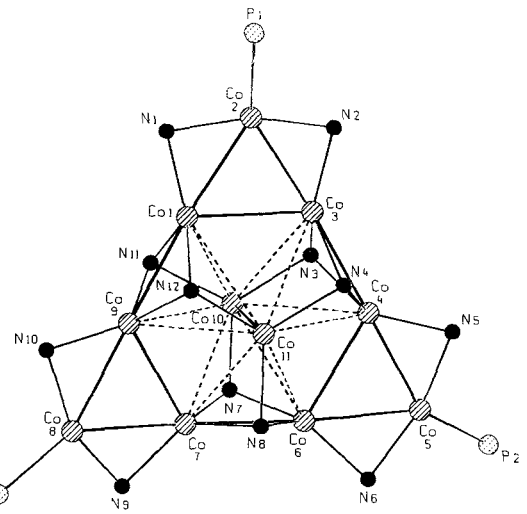

Fig. 2. Molecular structure of **2** (C and H atoms omitted). Selected bond lengths [pm]: Co1–Co2 242.9(3), Co1–Co3 258.4(3), Co1–Co9 248.2(3), Co1–Co10 272.4(3), Co1–Co11 287.2(3), Co2–Co3 243.7(3), Co3–Co4 247.3(3), Co3–Co10 279.0(4), Co3–Co11 282.5(3), Co4–Co5 242.0(3), Co4–Co6 255.9(3), Co4–Co10 279.5(3), Co4–Co11 271.5(3), Co5–Co6 243.7(3), Co6–Co7 246.0(3), Co6–Co10 280.9(2), Co6–Co11 275.3(2), Co7–Co8 243.6(3), Co7–Co9 249.6(3), Co7–Co10 275.9(3), Co7–Co11 277.4(3), Co8–Co9 245.4(3), Co9–Co10 276.9(2), Co9–Co11 276.8(3), Co10–Co11 239.8(3), Co–P 220.7–221.3(5), μ_2-N–Co 175.4–178.3(10) μ_3-N–Co 186.1–191.8(10)

(Co11), respectively. In addition, three alternate edges of the Co_6 ring are μ_2-bridged by Co atoms (Co2, Co5, and Co8). The distances between the Co ring atoms and the μ_2-bridging Co atoms, which lie in the plane of the ring, range between 242.9 and 245.4(3) pm. Within the Co_6 ring, the Co3–Co4, Co6–Co7, and Co1–Co9 bonds are significantly shorter (246.0–248.2(3) pm) than the Co4–Co6, Co7–Co9, and Co1–Co3 bonds (249.6–258.4(3) pm). In contrast, the bond lengths to the apical Co atoms in the Co_6 ring range from 271.5(3) to 287.2(3) pm. The Co10–Co11 bond length (239.8(3) pm) is conspicuously short. N3, N7, and N11 and N4, N7, and N12 form the triangular faces of an almost undistorted trigonal prism. Co10 and Co11 lie only 20 pm below the mean planes defined by these nitrogen atoms, which is a consequence of the short bond length between these two Co atoms. This unusual, distorted trigonal-planar coordination of Co10 and Co11 ($\sum$ N-Co-N: Co10: 358.5°; Co11: 357.0°) is a result of the steric shielding of the nitrogen-bound phenyl groups. The cluster framework of **2** is also sterically shielded by the terminally bound triphenylphosphane ligands at Co2, Co5, and Co8, as

well as by twelve phenylimido groups. These phenylimido groups bind in two ways: there are six μ_2-imido bridges (N1, N2, N3, N6, N9, and N10) between the Co atoms in the periphery of the cluster (Co-μ_2-N 175.4–178.3(10) pm) and six μ_3-imido groups (N3, N4, N7, N8, N11, and N12) that form bridges between the two apical Co atoms (Co10 and Co11) and the Co atoms in the Co_6 ring (Co-μ_3-N 186.1–191.8(10) pm).

Compound **2** contains a Co_{11} cluster, which possesses an overall charge of +24. Evidently, we are dealing with a mixed-valent cluster. A possible charge distribution would be nine Co^{2+} and two Co^{3+} ions. In agreement with this proposal, **2** is paramagnetic. Taking the coordination of the Co atoms into consideration, it is conceivable that the Co^{3+} ions can be assigned to Co10 and Co11.

The low reactivity of the amine derivative in the reaction of the stannylamine with transition metal halide complexes proved to be problematic. Therefore, we investigated whether the use of the significantly more reactive lithium amide would provide a pathway to the formation of imido-bridged clusters of the d^9 and d^{10} transition metals.

In the previously known nitrogen-bridged compounds of nickel, the Ni_3 cluster is the dominant structure motif.[8a, 10, 11] The reaction of $[NiBr_2(dme)]$ with *t*BuNHLi afforded the Ni_{11} cluster **3** [Eq. (c)].

$$[NiBr_2(dme)] \xrightarrow{t\text{BuNHLi}} \underset{\mathbf{3}}{[Ni_{11}Br_6(\mu_3\text{-N}t\text{Bu})_8]} \quad (c)$$

The main building blocks of **3** consist of two square pyramids of Ni atoms (Ni1–Ni5, Ni6–Ni10) (Fig. 3). The apical Ni atoms (Ni1 and Ni10) are coordinated to terminal bromo ligands (Br1, Br2; Ni–Br 236.5–238.0 pm). The Ni–Ni distances within the Ni_5 unit lie in the range 245.8(2)–259.2(13) pm, and can be described as bonding interactions.[8a] The two Ni pyramids are linked in several ways. Ni11 acts as a bridge bridge between Ni3 and Ni8, and the Ni–Ni distances are 240.2(2) pm. This distance is typical for a Ni–Ni bond.[8, 10, 11] There is a further metal–metal contact between the two Ni_5 pyramids from Ni5 to Ni6 (230.5(2) pm).

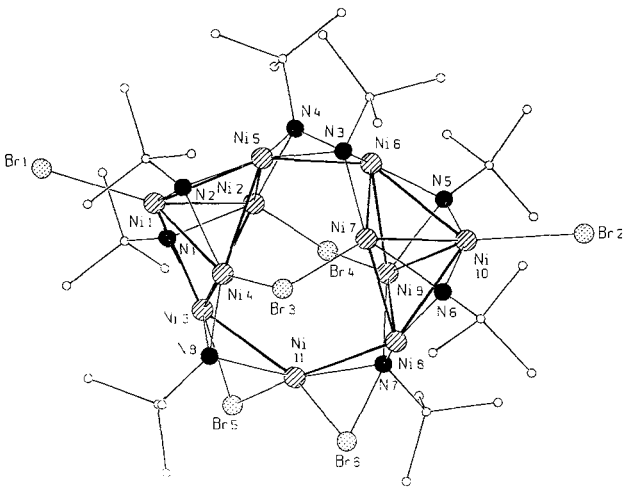

Fig. 3. Molecular structure of **3** (H atoms omitted). Selected bond lengths [pm]: Ni1–Ni 245.7–253.3(2), Ni2–Ni3 247.9(2), Ni3–Ni4 249.4(1), Ni2–Ni5 257.2(2), Ni4–Ni5 255.4(1), Ni5–Ni6 230.5(2), Ni3–Ni11 240.0(2), Ni8–Ni11 240.2(2), Ni10–Ni 245.8–253.2(2), Ni6–Ni7 259.2(1), Ni7–Ni8 247.4(1), Ni8–Ni9 249.2(2), Ni6–Ni9 254.3(1), N1–Ni 185.3–188.5(6), N2–Ni 184.9–185.2(5), N3–Ni 187.1–190.8(6), N4–Ni 186.6–190.5(7), N5–Ni 185.5–191.4(6), N6–Ni 183.7–188.5(6), N7–Ni 184.5–192.7(6), N8–Ni 184.9–193.7(6), Ni1–Br1 238.0(2), Ni10–Br2 236.5(2), Ni–Br3 236.3–238.3(2), Ni–Br4 235.9–238.5(2), Ni–Br5 240.0–251.1(1), Ni–Br6 239.8–252.2(1).

Apart from the metal–metal interactions, the two Ni_5 pyramids are also connected by four μ_2-bromo bridges (Br3–Br6) between Ni3–Ni11, Ni8–Ni11, Ni2–Ni9, and Ni4–Ni7 (Ni–Br 236.3(1)–240.9(1) pm). Irrespective of this there are eight μ_3-*tert*-butylimido groups in **3**; the Ni–N bond lengths range from 184.9(7) pm to 194.2(7) pm. The six Br^- and eight $Nt Bu^{2-}$ ligands lead to a formal oxidation state of +II for all nickel atoms.

The reaction of CuBr with $PhNLi_2$ affords the copper cluster **4** with NPh bridging ligands [Eq. (d)].[12] It is an orange colored

$$CuBr \xrightarrow{PhNLi_2} \underset{\mathbf{4}}{[Li(thf)_4]_4[Cu_{24}(\mu_3\text{-NPh})_8(\mu_4\text{-NPh})_6]} \quad (d)$$

ionic compound, which consists of four $[Li(thf)_4]^+$ ions and one $[Cu_{24}(NPh)_{14}]^{4-}$ ion. Correspondingly, all Cu atoms are in the oxidation state +I. The structure of the cluster anion (without C atoms) with $\bar{1}$ symmetry is shown in Figure 4. The metal

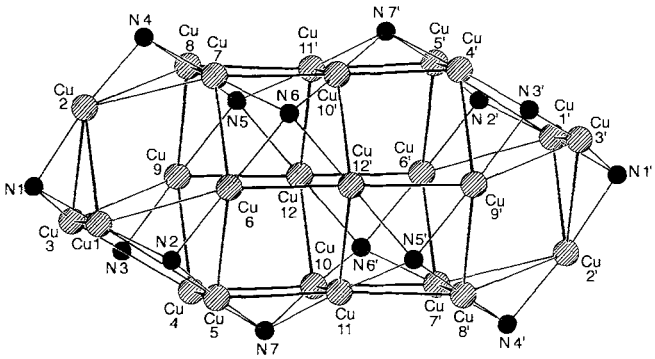

Fig. 4. Structure of the $Cu_{24}N_{14}$ cluster of **4**. Selected bond lengths [pm]: Cu1–Cu2 265.2, Cu1–Cu3 270.9, Cu2–Cu3 272.1, Cu4–Cu5 258.5, Cu5–Cu6 258.4 Cu6–Cu7 255.1, Cu7–Cu8 257.1, Cu8–Cu9 258.9, Cu4–Cu9 261.5, Cu10–Cu11 250.4, Cu10–Cu12 252.8, Cu11–Cu12 252.0, Cu1–Cu6 281.3, Cu2–Cu7 278.8, Cu2–Cu8 285.3, Cu3–Cu9 281.9, Cu3–Cu7 281.4, Cu4–Cu10 249.5, Cu5–Cu11 251.6, Cu6–Cu12′ 250.6, Cu7–Cu10′ 251.0, Cu8–Cu11′ 251.7, Cu9–Cu12 248.9, N1–Cu 186.3–189.2, N2–Cu 185.7–188.6, N3–Cu 184.2–189.2, N4–Cu 185.9–189.3, N5–Cu 193.3–196.7, N6–Cu 193.3–194.9, N7–Cu 193.0–195.5.

framework of **4** is formed from three planar Cu_6 rings (Cu4–Cu9, Cu10–Cu12, and Cu10′–Cu12′, Cu4′–Cu9′) and two Cu_3 rings (Cu1–Cu3, Cu1′–Cu3′). These rings lie parallel to one another with the two three-membered rings at either end. Thus, a Cu_{24} polyhedron is formed comprising Cu_3 and Cu_4 faces. The Cu_3 faces are bridged by μ_3-phenylimido groups (N1–N4, N1′–N4′) and half of the Cu_4 faces by μ_4-phenylimido groups (N5–N7, N5′–N7′). All the Cu atoms, as is usual for Cu^I ions, are approximately linearly coordinated by the N atoms of the NPh ligands (N-Cu-N 171.3–178.0°). The difference in the degree of bridging is also evident from the bond lengths. Thus, the Cu–μ_3-N bond lengths are 184.2(5) and 189.3(6) pm, while, as expected, the Cu–μ_4-N bond lengths are longer (193.0(6) and 196.7(6) pm). The Cu–Cu distances lie between 248.9(1) and 285.3(1) pm. Notably, the bond lengths of the Cu_3 rings, 265.2–272.2 pm are significantly longer than those found in the Cu_6 rings. The ring formed from Cu4–Cu9 contains Cu–Cu distances of between 257.1 and 261.5 pm. In comparison, the six-membered ring containing the atoms Cu10–Cu12 and Cu10′–Cu12′ has much shorter Cu–Cu contacts (250.3–252.8 pm). The interactions between the Cu atoms of the Cu_3 ring and between the Cu_3 ring (Cu1–Cu3) and the Cu_6 ring (Cu4–Cu9) are weak (Cu–Cu 278.9–285.3 pm). In

contrast the distances between the Cu_6 rings are significantly shorter (Cu–Cu 248.9–252.9 pm). In this respect, it is more meaningful to describe the structure of the cluster as a hexagonal prism derived from 18 Cu atoms that is linked to two Cu_3 clusters through μ_3-bridging NPh ligands. The construction principle of parallel hexagonal and triangular layers is observed in other Cu clusters such as $[Cu_{12}(PPh)_6(PPh_3)_6]$ and $[Cu_{12}S_6(PEt_3)_8]$.[12] Therefore one could describe the skeleton of **4** as a $[Cu_{12}E_6]$ structure fragment that has been extended by the insertion of two Cu_6 layers.

In contrast to other main group element bridged Cu clusters, the Cu framework in **4** is not shielded by terminal ligands coordinated to copper, but by the phenyl groups of the imido bridging ligands (Fig. 5). No definite statement can be made about

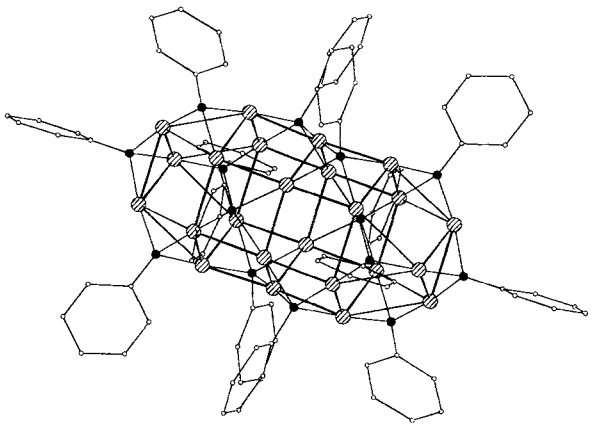

Fig. 5. Molecular structure of **4** (H atoms omitted). Cu atoms are shown striped and N atoms in black.

the results that have been obtained from preliminary reactions of AgCl with $PhNLi_2$. Interestingly, however, dark red solutions are formed, from which it has not yet been possible to isolate a crystalline product. If the solvent is evaporated, a red powder is afforded, the IR spectrum of which is very similar to that of **4**.

Experimental Procedure

1: PEt_3 (0.45 mL, 6 mmol) was added to a suspension of $[CpTiCl_2)_x]$ in toluene (30 mL). The solution became clear. To this tris(trimethylstannyl)amine (1 mL, 3 mmol) was added, and the mixture was stirred at room temperature to give a dark brown solution. The solvent was removed by evaporation and the residue redissolved in hexane and filtered, and the filtrate kept at −25 °C. Crystals of **1** (yield 20%) were isolated after a few days.

2: To a solution of $[CoCl_2(PPh_3)_2]$ (4.1 g, 6.26 mmol) in DME (100 mL), bis(trimethylstannyl)phenylamine (1.75 mL, 6.28 mmol) was added. The reaction mixture was heated to reflux for several days, which led to a black-brown solution. Dark green crystals of **2** (yield 40%) were obtained after several days at −25 °C.

3: To a suspension of $[NiBr_2(dme)]$ (2.75 g, 6.9 mmol) in THF (100 mL) at −78 °C, *t*BuNLiH (0.65 g, 8.3 mmol) was added. The reaction solution darkened at about −40 °C. The reaction mixture was allowed to warm to room temperature, and the solvent was removed by evaporation. The black residue was then stirred in a mixture of hexane/toluene (2:1). Some of the residue dissolved, and black rodlike crystals of **3** (yield 60%) were obtained from this fraction after reduction of the solvent.

4: To a suspension of CuBr (2.67 g, 18.6 mmol) in THF (100 mL), Bu_2NH (3.12 mL, 18.6 mmol) was added. The resulting clear solution was cooled in an ice bath, and $PhNLi_2$ (1.95 g, 18.6 mmol) was added slowly. Orange crystals of **4** (yield 80%) were formed from the red brown solution after several days at room temperature.

Monitoring the Reaction Progress in Combinatorial Chemistry: ^{1}H MAS NMR Investigations on Single Macro Beads in the Suspended State

Matthias Pursch, Götz Schlotterbeck, Li-Hong Tseng, Klaus Albert,* and Wolfgang Rapp

Dedicated to Professor E. Bayer on the occasion of his 70th birthday

Since R. B. Merrifield[1] introduced the synthesis of peptides on an insoluble polymeric support, solid-phase synthesis has become a major tool in many areas of organic chemistry and is continuously being improved. In recent years, organic chemistry on the solid support is facing a rapid growth and is being applied widely in many fields.[2] By the use of combinatorial methods, hundreds to thousands of compounds are prepared in parallel and mostly with automated work-stations. These combinatorial methods are poised to gain importance in discovering new lead structures in drug research and development.[3, 4] Already high throughput assays allow testing hundreds of compounds per day. As testing methods improve further, a higher throughput of compounds will be possible, which makes a higher throughput in synthesis mandatory. This is only possible by further optimization and miniaturization of organic synthesis incorporating combinatorial aspects.

We have developed a system that allows both the search for new drugs and the optimization of chemical reactions on a solid support in a miniaturized fashion on a nanomolar scale.[5–7] In solid-phase synthesis the polymeric support represents the reaction unit. This reaction unit (represented by the amount of resin employed) is divided into discrete small segments. Each single resin particle thus is a micro reaction unit.

The common resins used today for synthesis have particle sizes of 40–130 μm. The loading of each individual particle with reactive functional groups is in the order of 10–300 pmol per bead. Often, this loading is too low for sequential cleavage and subsequent characterization of the compound synthesized on the bead. We have therefore developed macro beads with particle sizes of 400–750 μm based on resins with long, flexible tentacles as tethers.[8] These are characterized as grafted polystyrene–polyoxyethylene copolymers. The capacity of the individual beads, depending on the particle size, is in the order of 10–65 nmol per bead. This thousandfold scaleup of the amount of substance per bead enables reactions to be performed and monitored on single beads and products to be investigated on the supports. The macro beads thus become micro reactors. A further big advantage in the reduction of the reaction space is that only small amounts of solvents are required. With a millimole of organic building blocks it is possible to perform 200–500 reactions. In the combinatorial approach where hundreds of reactions are carried out in parallel, the available resources can now be used more efficiently.

The fast and exact characterization of building blocks on a polymeric support presents a challenge for analytical methods. FT-IR/Raman spectroscopy, MALDI-TOF mass spectrometry, as well as ^{1}H and ^{13}C NMR spectroscopy in suspended state (gel-phase NMR) are some important tools for structural elucidation. In ^{1}H NMR spectra the broadness of the lines (in the order of at least 50–100 Hz) prevents an exact structural elucidation; ^{13}C NMR spectra in suspension exhibit small line widths due to reduced dipolar couplings and an increased dispersion of the chemical shift,[9–11] but the low sensitivity of the ^{13}C nucleus causes long measuring times.

The recently introduced ^{1}H MAS NMR spectroscopy (MAS = Magic Angle Spinning) of resins in suspension revealed that a very good resolution of the NMR signals is achievable.[12–17] Under fast sample spinning at the magic angle, differences in susceptibility within the sample as well as dipolar couplings are eliminated, while *J*-couplings are maintained. This leads to a resolution close to that obtained in liquid NMR spectroscopy.

On such a miniaturized system—a single macro bead—hydantoins were prepared in parallel by combinatorial methods. Each step in synthesis was followed by high-resolution ^{1}H MAS NMR spectroscopy. We took a single bead that was swollen in a solvent (for example, [D_6]DMSO or $CDCl_3$), fixed it into an insert, and placed it in a standard 4 mm solid-state NMR rotor (Fig. 1). The detection volume, depending on the size of the bead, is in the nanoliter region (200–400 nL). A commercially available CP/MAS (solid-state) NMR probe was used to perform the high-resolution MAS NMR measurements.

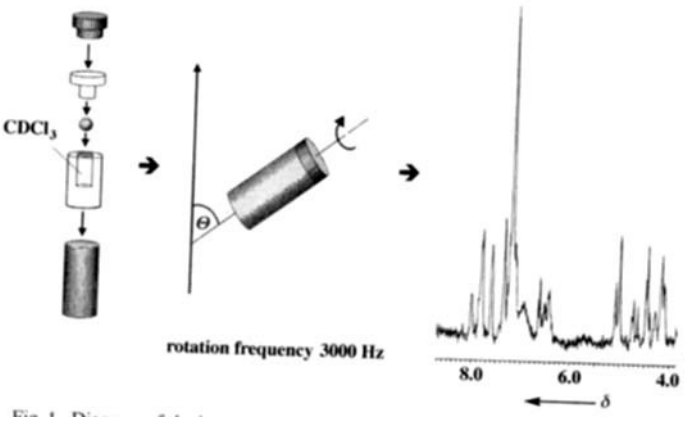

Fig. 1. Diagram of the instrumentation to record high-resolution ^{1}H MAS NMR spectra of individual resin particles in suspension. The ^{1}H NMR spectrum (on the right) is a except from Figure 2c.

The high-resolution ^{1}H MAS NMR spectra of the reaction sequence are shown in Figure 2. It takes only 6–8 minutes to record such a spectrum with 128–160 scans. Since the long polyoxyethylene spacer of the resin makes the organic building blocks attached to the bead very mobile, the line widths of the ^{1}H NMR signals are in the order of 5–8 Hz. Consequently, each reaction step can be monitored on a single macro bead. The main ^{1}H NMR signal of the OCH_2CH_2 units appears at $\delta = 3.5$. With every subsequent synthesis step, new characteristic peaks are observable, which allow an exact structural assignment (Fig. 2). The binding of an acid-sensitive linker (AC linker) to the polymeric support (Fig. 2a) is indicated in the ^{1}H MAS NMR spectrum by additional peaks in the aromatic region ($\delta = 6–7.5$) and signals from the CH_2O and the methoxy group (at $\delta = 4.8$ and 3.75, respectively; Fig. 2b). In the next step, phenylalanin–Fmoc is bound to the supported linker. The proton signals of the Fmoc unit are clearly visible in the aromatic region (Fig. 2c). Then Fmoc is cleaved, and the activated resin treated with *n*-propylisocyanate. Again, the intensity of the peaks in the aromatic region decreases, and additional signals in

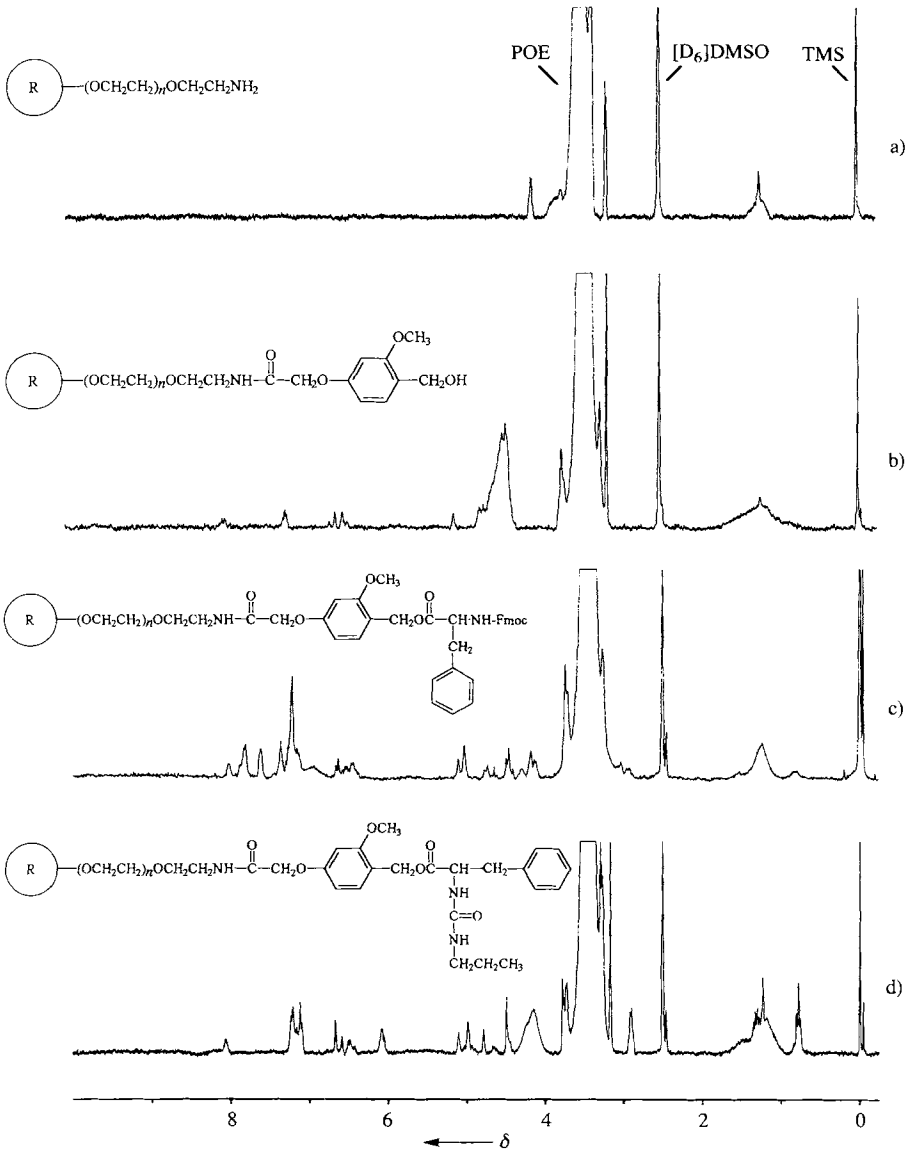

Fig. 2. ^{1}H MAS NMR spectra of a suspension of individual resin particles in the hydantoin reaction sequence: spectra of the support-bound polyoxyethylene spacer (POE, see a) (a), with acid-labile linker (b), after treatment with phenylalanine–Fmoc (c), and after scission of the Fmoc group and treatment with isocyanate (d).

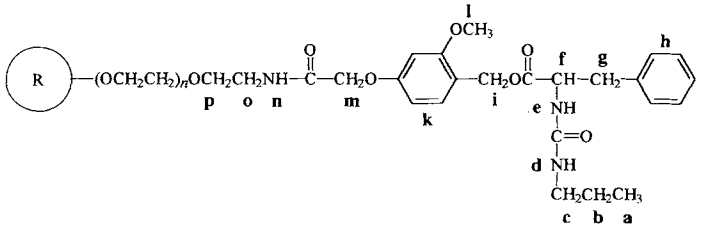
Table 1. Assignment of the signals with the aid of the ^{1}H MAS NMR spectrum of a hydantoin precursor (Fig. 2d).



Position	Functional group	δ	Position	Functional group	δ
a	CH_3	0.75	i	CH_2O	5.1
b	CH_2	1.2	k	H_{ar}	6.5, 6.6, 7.2
c	CH_2	2.9	l	OCH_3	3.75
d	CONH	6.0	m	CH_2O	4.8
e	NHCO	6.1	n	CONH	8.05
f	OCOCH	4.5	o	CH_2NH	3.15
g	CHz	3.5	p	OCH_2CH_2	3.3
h	H_{ar}	7.1			

the aliphatic region appear (Fig. 2d). The high resolution of the ^{1}H NMR signals is particularly remarkable; in the last spectum of a hydantoin precursor even the scalar couplings of the terminal *n*-propyl group are visible. The exact signal assignment is shown in Table 1. As can be seen from the NMR spectra of the reaction sequence, monitoring of syntheses on a single macro bead is possible within a short time (approximately 6 min per spectrum). Thus, time-consuming cleavage and isolation processes are no longer needed.

The polystyrene backbone of the grafted copolymer in [D_6]DMSO has (in contrast to $CDCl_3$) only a limited swelling capability. Extremely broad NMR signals result from very short T_2^* relaxation times, and in the ^{1}H MAS NMR spectra (Fig. 2) no polystyrene signals appear. The influence of various solvents on the line widths of the ^{1}H MAS NMR spectra of dissimilar resins has been thoroughly discussed recently.[15, 16]

In addition to the direct monitoring of syntheses on the resin, two-dimensional NMR techniques are crucial for structural investigations. Figure 3 shows an example of a 2D suspension MAS NMR spectrum (H,H-COSY), which was recorded in an acceptable measuring time of 40 minutes. The cross-peaks indicate that the *n*-propyl group is bound to the resin. It may be a general advantage to make use of an *n*-propyl group as a label for synthesis, for it is easily characterized by NMR spectroscopy and gives information about the success of the synthesis.

The ^{1}H MAS NMR spectroscopy in the nanoliter scale proves to be a fast and efficient tool in monitoring chemical reactions in combinatorial chemisty, even if only a single micro reactor is the analyte.

Experimental Procedure

The micro reactors were loaded with different amino acids (Fmoc-protected), which were bound to the resin on the acid-labile anchor 3-methoxy-4-hydroxymethylphenoxyacetic acid. Further reactions were performed in glass capillaries, 100 mm in length and 2.6 mm in diameter. The top end of the capillaries was open, and the bottom end contained a glass frit. One to four single beads loaded with amino acids were put into the glass capillaries. The loading was quantified by UV spectroscopy after the Fmoc protective unit had been cleaved with piperidine. After thorough washing out of the protective group, the micro reactors each were treated in the capillaries with 25 μL of a 1 M isocyanate solution. This corresponds to between a hundredfold and a thousandfold excess of reagent. After three hours the beads were washed in the capillaries to remove the excessive isocyanate.

NMR parameters: Bruker ASX-300 spectrometer, 4 mm CP/MAS probe, sample spinning (MAS) at 3000 Hz, 128–160 transients per FID, 60° pulse angle, delay time 1.5 s, time domain 16 K data points (TD) with a spectral width of (SW) 3800 Hz, acquisition time 1.1 s.

COSY 45: 16 transients per FID, time domain 2 K data points (TD2) with spectral width (SW2) of 4300 Hz, 128 increments (TD1), acquisition time 127 ms. Zerofilling in t_1 to 1 K data points, multiplication with a sine function along the F1 and F2 directions.

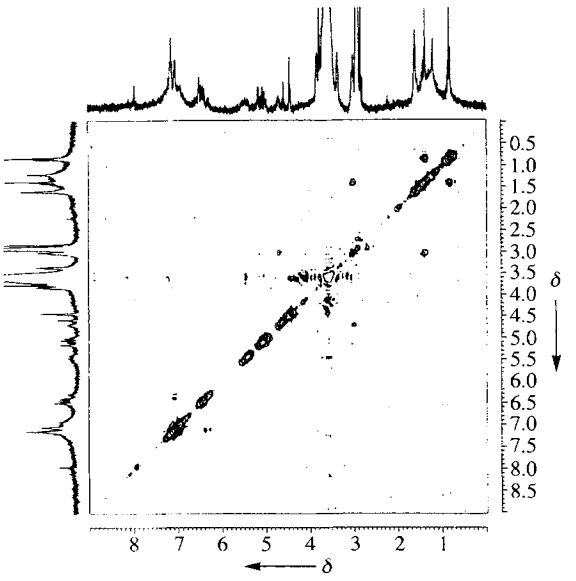


Fig. 3. 2D MAS NMR spectrum (COSY 45) of a hydantoin precursor on a bead in suspension.

For the acquisition of the 1D NMR spectra (in [D$_6$]DMSO), the deuterium lock of the available lock channel was used. The lock signal was detected by the heteronuclear transmitter coil. The COSY45 spectrum was acquired in $CDCl_3$, but due to the limited solvent volume the lock signal was too low.

A Layer Silicate: Synthesis and Structure of the Zeolite Precursor RUB-15—$[N(CH_3)_4]_8[Si_{24}O_{52}(OH)_4]\cdot 20H_2O$**

Uwe Oberhagemann, Parwis Bayat, Bernd Marler, Hermann Gies,* and Jordi Rius

The investigation of the synthesis mechanisms and the tailored synthesis of zeolites are areas of current interest in preparative inorganic chemistry. In the 1970s and 1980s many attempts were made to identify precursors in silicate solutions that would condense in the crystallization process to give the different zeolite structure types.[1, 2] In the 1990s the structure-directing potential of template molecules[3–5] and self-organizing template/silicate systems were seen as the key for the crystallization of micro- and mesoporous tectosilicate structures.[6–8] We present herein a crystalline zeolite precursor, RUB-15, which was obtained in mild hydrothermal syntheses by using tetramethylammonium cations as templates.

The crystalline layer silicate with the codename RUB-15 was synthesized from aqueous tetramethylammonium silicate solutions in the temperature range from 120 to 140 °C. Thermogravimetric analysis of the compound revealed the proportion of volatile components in the structure to be about 39%. ^{29}Si and ^{13}C solid-state MAS NMR investigations showed that the silicate layer is composed of Q^3- ($\delta = -101$) and Q^4-connected silicon ($\delta = -108$) in the ratio of 2:1 and that tetramethylammonium (TMA) ions ($\delta = 56.4$) are present as counterions. The X-ray powder diagram was indexed in the orthorhombic system with lattice constants $a = 27.92$, $b = 8.41$, and $c = 11.52$ Å. The evaluation of the systematic absences restricted the space group symmetry to *Ibam* and *Iba*2. The Rietveld analysis of the structure (see below) revealed that RUB-15 has the symmetry *Iba2*.

Crystalline silicate structures of low density such as RUB-15 are often microcrystalline powders of poor crystallinity. In addition, the scattering power of the material is low. Depending on the complexity of the structure, X-ray reflections can only be indexed unambiguously to *d*-spacings of about 2 Å ($2\theta = 45°$ for $\lambda = 1.5406$ Å). In the case of RUB-15, scattering information up to a resolution of about 2.0 Å could be used for the structure determination. This resolution is sufficient to clearly distinguish between neighboring [SiO_4] units in the electron density maps.

The crystal structure of RUB-15 was solved from integral intensities of unambiguously indexed reflections by direct methods by using a modified tangent formula.[9] The structure of the silicate layer was obtained directly from the direct method solution and geometrically optimized for the remaining structural analysis by distance least squares procedure (DLS). In the subsequent Rietveld analysis[10] this model of the partial structure was initially kept invariant and used to determine the phases for difference-Fourier calculations. All the X-ray powder data up to an angle of 65° 2θ was then included for the refine-

ment. These calculations gave the locations of the TMA ions, and their subsequent refinement in the structure revealed the hydrate water which was then successfully included into the Rietveld analysis. The results of the structure refinement are summarized in Table 1. A comparison of the experimental and calculated powder pattern after the final refinement is given in Figure 1.

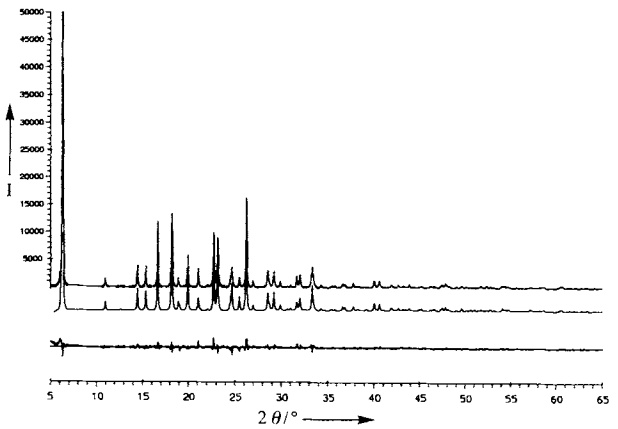

Fig. 1. The observed and calculated X-ray powder diagram of RUB-15 as well as its difference after the completion of the Rietveld analysis. I = intensity in arbitrary units.

In agreement with the results of the ^{29}Si solid-state MAS NMR spectroscopic investigation, the silicate layer is built from three-connected [SiO_3OH] ([SiO_3O^-]) and four-connected [SiO_4] tetrahedral units in the ratio of 2:1 (Fig. 2). The layer shows hemihedral cavities, which are formed from two six-rings and two four-rings, and which are similar to one half of the sodalite cage. Each cavity contains a TMA ion—with one methyl group pointing inwards—leading to an ideal space-filling arrangement. This arrangement is supported by the chemical shift of the ^{13}C NMR signal of the methyl carbon atoms ($\delta = 56.4$), which lies between the values for the TMA ions in the β-cages of the zeolite faujasite ($\delta = 56.7$) and that for the free TMA ion ($\delta = 56.0$).[11] Hydrate water molecules and hydroxide ions terminate the silicate layer by building a hydrogen bonding network together with the terminal oxygen atoms of the silicate layer. In this way the TMA ion is completely embedded in the silicate–hydrate layer (Fig. 3).

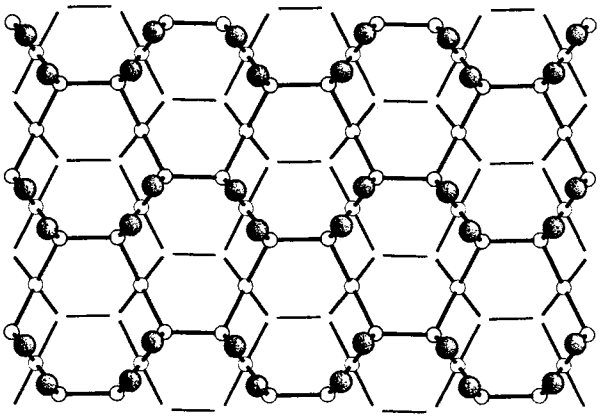

Fig. 2. Schematic view of a section of the silicate layer of RUB-15 including the terminal OH groups (projection along [100]). The Si atoms are located at the nodes of the network; the O atoms are located close to the midpoint between two Si atoms. Shaded spheres are OH groups.

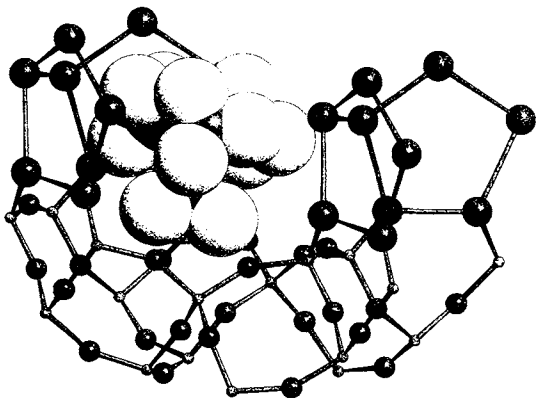

Fig. 3. The TMA ion embedded inside the hydrated silicate layer. The TMA ion is shown as a space-filling model. Small, medium, and large spheres represent Si, O, and OH and H_2O, respectively.

The silicate–hydrate layer is connected to neighboring layers through additional hydrogen-bonded water molecules. Only the oxygen atoms of these molecules have been localized in the structure analysis; they are tetrahedrally coordinated to four neighboring oxygen atoms at distances typical for O-H···O hydrogen bonds (d(O–O) = 2.5–2.9 Å) (Fig. 4 top). The arrangement is only a time- and space-averaged model of the water molecule, which cannot be resolved in the diffraction experiment. For similar reasons the position of the hydrogen atoms cannot be determined because of their very low scattering power. The positive charge of the TMA ion is balanced by the negative charge that is delocalized over the hydrogen bonding system composed of water molecules, hydroxide ions, and terminal silanol groups.

Thus, the structure of RUB-15 is a three-dimensional bonding network consisting of layerlike silicate ions and water molecules or hydroxide ions. The stacking of the silicate layers occurs along the a axis of the unit cell and takes into account the body-centred symmetry. A vacancy located in the center of a group of four TMA ions exist between neighboring silicate layers in the structure. This vacancy is big enough for an additional water molecule (Fig. 4 bottom). Interestingly, the occupation of this vacancy with a water molecule would lead to a hydrate layer, which is topologically equivalent to the silicate layer, and this, in turn, would create a mixed-layer silica–water tetrahedral network. However, our refinement calculations clearly reveal that this water molecule is not present and that a

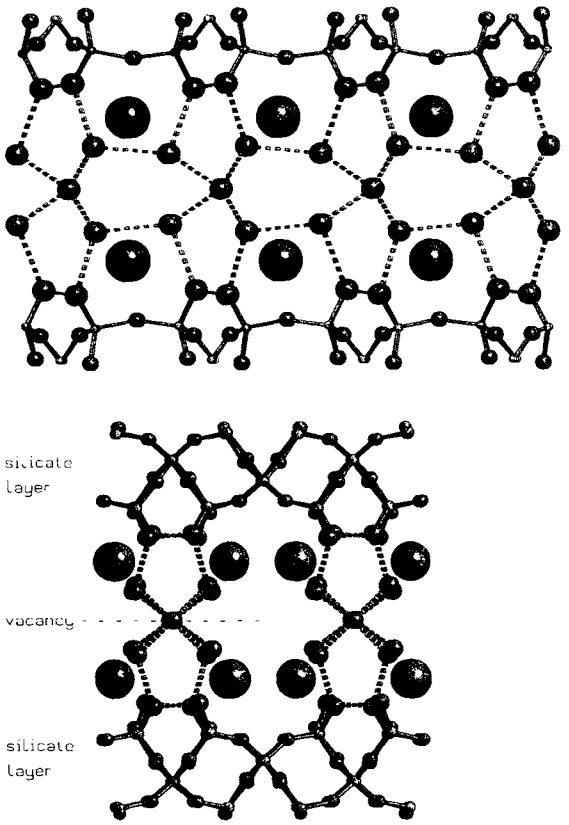

Fig. 4. Hydrogen bonding system in RUB-15: dashed lines are the hydrogen bonds, solid lines are Si–O bonds. Top: Projection along [010], bottom: Projection along [001]. Spheres in order of increasing size represent Si, O, OH and H_2O, and TMA, respectively.

narrow, channel-like void occurs in the structure (Fig. 4 bottom). The structure refinement shows the composition of the unit cell of RUB-15 to be $[N(CH_3)_4]_8[Si_{24}O_{52}(OH)_4]\cdot 20H_2O$.

The layer silicate RUB-15 belongs to the series of inclusion compounds of different composition formed with the TMA ion. The TMA ion is a very effective template cation that yields clathrate-type inclusion compounds in the presence of network-forming molecules and ions (H_2O, $[SiO_4]^{4-}$, $[AlO_4]^{5-}$, $[PO_4]^{3-}$). The structure-directing potential of the TMA ion is demonstrated in Table 2, which shows a selection of clathrate inclusion compounds that have been synthesized in the presence the TMA ion, and that contain TMA as an essential component. In the examples given the TMA ion occupies cagelike voids, which are formed by water molecules, by $[SiO_4]$ tetrahedra, or by different combinations (for example H_2O+$[SiO_4]$ tetrahedra; $[AlO_4]$ and $[PO_4]$ tetrahedra).

Whereas in the TMA + H_2O system only materials with three-dimensional four-connected water frameworks are formed, the addition of SiO_2 leads to TMA–silicate hydrates at room temperature for high concentrations of silica and TMA. Structure analyses revealed that in TMA–silicate hydrates the silicate ions (cubic octamer) together with the hydrate water build a three-dimensional hydrogen bonding network that occludes the TMA ions in cagelike voids.[14]

Furthermore, in the TMA + H_2O + SiO_2 system the synthesis temperature has a decisive influence on the extent of the condensation of the silicate ion. RUB-15, which was obtained at higher temperatures but under otherwise identical synthesis conditions to those used for the room temperature silicate hydrate, contains a two-dimensional silicate ion. This contributes higher bonding energies to the total lattice energy and thus to the higher thermal stability. At the same time, the contributions from the weak hydrogen bonds to the lattice energy decreases. In this case, the TMA ion also occupies cagelike voids, which consist of silicate sodalite semicages and additional water molecules.

From the crystal structure analysis of TMA–sodalite[16] it is known that the TMA ion fills the cage ideally; therefore, the cage with the TMA ion could be regarded as a typical host–guest pair. In analogy to the situation in the TMA–sodalite, the TMA ion in the layer silicate structure of RUB-15 has a template effect on the formation and stabilization of the silicate layer.

A further increase of the synthesis temperature in the TMA + H_2O + SiO_2 system gives the clathrasil Dodecasil 3C, which is the silica analogue of the clathrate hydrate of type II. Thus, RUB-15 could be regarded as a link in the series group-silicate hydrates - layer-silicate hydrates - framework silicates, further illustrating the close relationship between crystalline and non-crystalline compounds of water and silica.[21]

The platelike morphology of RUB-15 crystals suggests that crystal growth is fast at the edge of the silicate layer, but slow perpendicular to the silicate layer; that is, the rate of nucleation of a new layer is slower than the ongoing growth of the unit. The rapid sorption of the TMA ions onto the silicate layer might further stabilize the phase boundary. At the same time these cations serve as a nucleation seed for the new silicate unit.

Sodium layer silicates in their ion-exchanged H-form are useful materials[22] for heterogeneous catalysis because of their acidity and they also serve as ion exchanger in detergent formulations. For instance, the sodium layer silicate kanemite was introduced as a water softener in washing powders a few years ago.[23] Likewise, there are many examples that describe the catalytic properties of layer silicates. As RUB-15 is closely related to the family of sodium layer silicates, similar properties are expected. The presence of acid centers at the surface close to the sodalite half-cavities is of particular interest, since it might lead to form-selective catalysis on the outer surface of the silicate.

Recently two layer silicate structures have been described that are potential zeolite precursors.[24, 25] Careful heating of the

materials causes the condensation of the silicate layers, giving the zeolite structures MCM-22 and ferrierite. Similar behavior can also be expected for RUB-15, since the silicate layer terminated with silanol groups should be the perfect subunit for the formation of the silica framework of the zeolite sodalite.

Experimental Procedure

RUB-15 crystallized from a reaction mixture with the following composition: SiO_2:TMAOH:H_2O = 1.00:0.75:55.52. The solution was filled in Teflon-lined autoclaves (60% filling factor) and kept in an oven at a temperature between 120 and 140 °C for about four weeks. The reaction product was filtered, washed with distilled water, dried at 80 °C, and subsequently identified by X-ray powder diffraction.

Synthesis and Characterization of the Stable Dicarbonyl(cyclopentadienyl)iron Radical $[(C_5R_5)Fe(CO)_2]$ (R = $CHMe_2$)**

Helmut Sitzmann,* Thomas Dezember, Wolfgang Kaim, Frank Baumann, Dietmar Stalke, Joerg Kärcher, Elmar Dormann, Hubert Winter, Christoph Wachter, and Marc Kelemen

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

Thermally labile cyclopentadienyliron halide solvates of the type $[CpFe(X)(thf)_2]$ (X = Cl, Br), which can be obtained in solution under mild conditions, have been known for a long time. As reactive intermediates they are of interest[2c] for the synthesis of triple-decker sandwich complexes,[1] ferrocenes with different ring ligands,[2] and half-sandwich complexes.[2a, 3] When the stabilizing donor ligands are removed, the remaining cyclopentadienyliron(II) chloride decomposes by dismutation, as has been demonstrated recently for the chelate complex $[(C_5Me_5)Fe(Me_2NC_2H_4NMe_2)Cl]$.[4] We report here on the characterization of isolable cyclopentadienyliron(II) halides and of the dicarbonyl(pentaisopropylcyclopentadienyl)iron(I) radical.

Treatment of $[FeBr_2(dme)]$[2a] in tetrahydrofuran with one equivalent of tetra-[5a] or pentaisopropylcyclopentadienide,[5b] led in each case to a dark green solution, the color of which became lighter on evaporation of the solvent. Crystalline, orange-red, extremely air-sensitive products are isolated, which can be stored under inert gas at room temperature (Scheme 1).

We postulate a dimeric structure with bridging bromo ligands for complexes **1** and **2**. A monomeric structure is very unlikely because of the number of valence electrons (14) and the low coordination number of the [CpFeX]-type fragment, and higher nuclearity complexes are not considered because of the extremely bulky five-membered ring ligands. The magnetic properties of complexes **1** and **2** (see below) support this hypothesis (pentamethylcyclopentadienylruthenium chloride is tetrameric and diamagnetic[6]). The strongest argument is supplied by the analogous cyclopentadienyl halides $[\{(C_5R_4H)MX\}_2]$ (R = $CHMe_2$, M = Co,[7a] Ni[7b]), for which a dimeric structure with bridging halide ligands has been confirmed by X-ray crystallography. Complexes **1** and **2** are readily soluble in all common solvents; in acetonitrile a reversible color change to dark violet occurs, in tetrahydrofuran one to dark green. This feature presumably arises from the formation of mononuclear complexes $[(C_5R_4R')Fe(L)_2Br]$ (R = $CHMe_2$, R' = H, $CHMe_2$, L = thf, MeCN) with two loosely coordinated donor molecules.

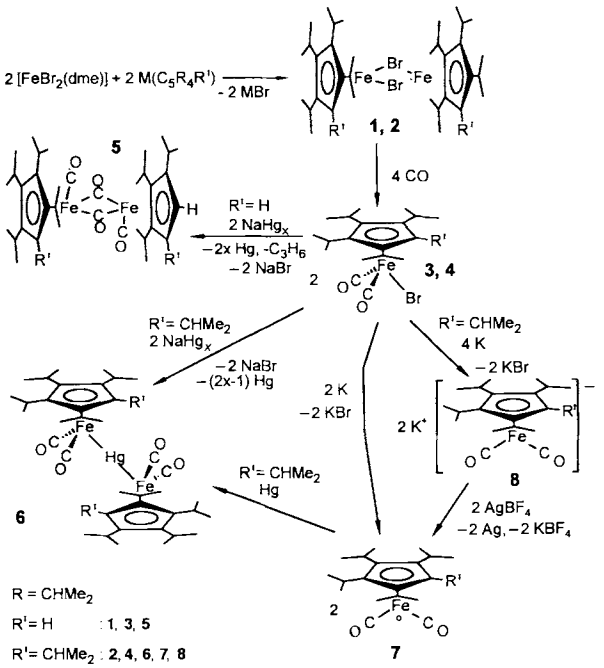
[**] High-Spin Cyclopentadienyl Complexes, Part 1. This work was supported by Fonds der Chemischen Industrie. H. S. is grateful to Prof. Dr. O. J. Scherer, Kaiserslautern, for his generous support, and to Prof. Dr. R. Gleiter, Heidelberg, for recording photoelectron spectra.



Scheme 1. Synthesis of compounds **1**–**8**.

Magnetic susceptibility measurements of **1** in the solid state gave good agreement with the Curie–Weiss law above 125 K (Fig. 1). The effective magnetic moment is 5.15 μ_B and corresponds to a high-spin Fe^{2+} ion (highly unusual for cyclopentadienyliron(II) complexes) with four unpaired electrons and parallel spin coupling of the two d^6-Fe^{2+} centers within one dimer;

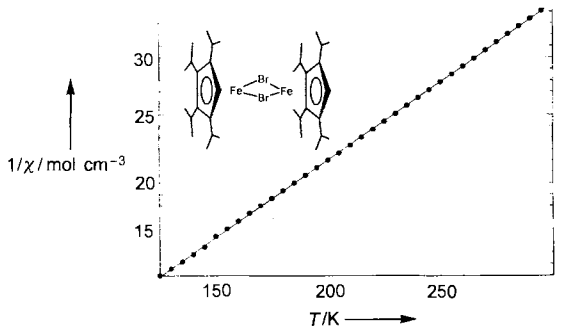


Fig. 1. Reciprocal of the molar magnetic susceptibility of **1** in the solid state as a function of absolute temperature.

the Weiss constant Θ is 45.5 K. The plot of χT (molar magnetic susceptibility × absolute temperature) against the absolute temperature (Fig. 2) shows a steep rise at low temperatures, reaches a maximum dependent on the strength of the magnetic field, and drops away again at very low temperature. This behavior corresponds to parallel spin coupling within the dimers together with absence of long-range magnetic ordering within the crystal.

The ^{1}H NMR spectrum of **1**, which extends from $\delta = 102$ to $\delta = -110.9$ (298 K, C_6D_6), is characterized by very strong broadening and a temperature-dependent shift of the resonance signals. It has not been possible to assign the signals. Dimers **1** and **2** take up carbon monoxide under mild conditions, leading to high yields of the bromo(dicarbonyl)iron complexes **3** and **4**, respectively (see Scheme 1). Reduction of the tetraisopropylcyclopentadienyl derivative **3** with sodium amalgam afforded

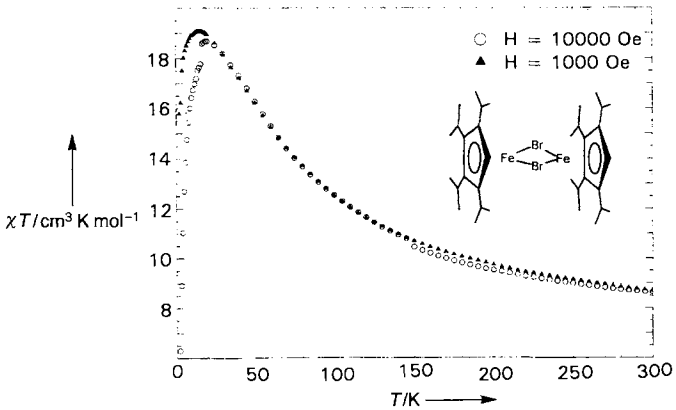

Fig. 2. Product of the molar magnetic susceptibility and the absolute temperature as a function of absolute temperature for complex **1**.

the dimer **5**, which contains one tetra- and one triisopropylcyclopentadienyl ring; the latter is formed by regiospecific propene elimination (Scheme 1).

Precedence for spontaneous diversification of two alkylated cyclopentadienyl ligands lies in the selective formation of $[(C_5R_4H)(C_5R_3H_2)BiCl]$ ($R = CHMe_2$) from $BiCl_3$ and two equivalents of tetraisopropylcyclopentadienide; a reaction that was studied with labeling experiments.[9] That compound **5** does not undergo redistribution of the two different "molecule halves" at room temperature, at least for a period of about an hour, can be deduced from ^{13}C NMR spectra (Fig. 3). ^{1}H NMR spectra of **5** show two superimposed ring CH signals, four septets (two of which are superimposed) and seven doublets with a ratio of integrals 1:2:2:2:1:2:6:6:6:6:6:6:6; as expected one singlet for one ring-H atom, two septets of equal intensity for

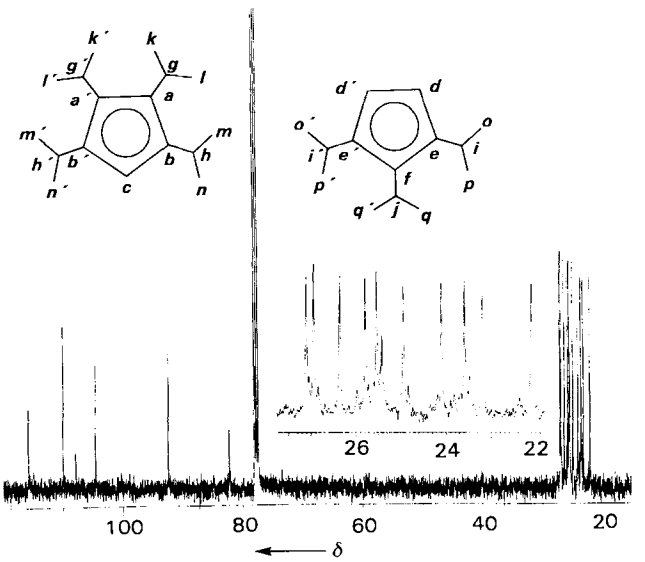

Fig. 3. ^{13}C NMR spectra of **5** showing the region for the alkyl-C and ring-C atoms. Three ring carbon signals, each (*a*–*c* and *d*–*f*) with an intensity ratio 2:2:1, are expected for the two different five-membered rings of **5**. This corresponds exactly to the six signals observed beween $\delta = 80$ and $\delta = 120$. Analogously, four signals with intensity ratio 2:2:2:1 are expected (positions *g*–*j*) for the methine C atoms. The seven pairs of enantiotopic methyl groups (*kk'*, *ll'*, *mm'*, *nn'*, *oo'*, *pp'*, *qq'*) correspond to three pairs of symmetry-equivalent isopropyl groups, each with two diastereotopic methyl positions (*kl* for instance), and one isopropyl group with two enantiotopic methyl positions (*qq'*). Therefore one expects seven signals of intensity ratio 2:2:2:2:2:2:2 for the 14 methyl groups. As expected eleven signals are observed for methine- and methyl-carbon atoms, of which ten signals represent two carbon atoms each and the eleventh signal represents one carbon atom. The signal of highest intensity arises from the solvent $CDCl_3$.

four methine-H atoms of two pairs of isopropyl groups, and four doublets of equal intensity for the total of eight methyl groups (because each pair of symmetry-equivalent isopropyl groups has two diastereotopic methyl positions) are assigned to the tetraisopropylcyclopentadienyl ring. One singlet for two ring-H atoms, two septets (1:2) for three methine-H atoms, two doublets (6:6) for the diastereotopic methyl positions of the two symmetry-equivalent isopropyl groups, and one more doublet for the two enantiotopic methyl positions of the remaining isopropyl group (cf. Fig. 3; for confirmation of the diastereotopic methyl positions of isopropylcyclopentadienyl ligands bound to iron by selective decoupling experiments see reference [5a]) are assigned to the triisopropylcyclopentadienyl ligand. In contrast, the reduction of **4** with sodium amalgam gave only the mercury compound **6** (Scheme 1).[10] Reduction of **4** with two equivalents of potassium afforded the potassium salt of dicarbonyl(pentaisopropylcyclopentadienyl)ferrate(0) (**8**), and subsequent oxidation with one equivalent of silver tetrafluoroborate, or by reduction of **4** with one equivalent of potassium gave a dark green solution for which no IR absorptions are observed in the bridging carbonyl region. The signals observed correspond to the IR bands of the unstable dicarbonyl(pentamethylcyclopentadienyl)iron radical obtained from irradiation experiments,[11] and prove that the dicarbonyl(pentaisopropylcyclopentadienyl) iron radical **7** practically does not dimerize at all in solution (Scheme 1). Measurement of the magnetic susceptibility in solution by using the method employed by Evans[12] gave a magnetic moment of 1.7 μ_B. EPR spectra support the above-mentioned results. Compound **7** is also monomeric in frozen toluene solution ($g_\perp = 2.1215$; $g_\parallel = 2.1534$). The recently investigated pentaphenylcyclopentadienyl derivative shows in addition to the IR bands of the dimer two low intensity absorptions for the monomeric radical, which, however, could not be detected by EPR spectroscopy.[13] A low first ionization energy of 6.88 eV was observed in the photoelectron spectra of **7**. Compound **7** is an olive green powder and could be obtained as compact, completely non-transparent crystals with metallic luster. The crystal structure analysis of **7**[14] shows a carbonyl-bridged dimer with planar cyclopentadienyl rings inclined towards the Fe–Fe axis by 54.6° (Fig. 4).

The Fe–Fe distance (2.60 Å) is somewhat longer than that found in other derivatives (2.49–2.57 Å[15a]) or the sum of the covalent radii of two Fe atoms (2.50 Å[15b]), and significantly less than the Fe–Fe distance (3.138(3) Å) in $[\{(\eta^3\text{-}C_3H_5)\text{-}Fe(CO)_3\}_2]$.[15c] Complete dissociation of **7** in solution confirms that the distance between the two carbonyl-bridged Fe atoms in the crystal does not not allow any conclusions to be drawn on the Fe–Fe bond order. A determination of the electron density by using the X–N method afforded no indication of bond electrons between the Fe atoms also in the case of the C_5H_5 derivative,[16] and is in accordance with MO calculations.[17]

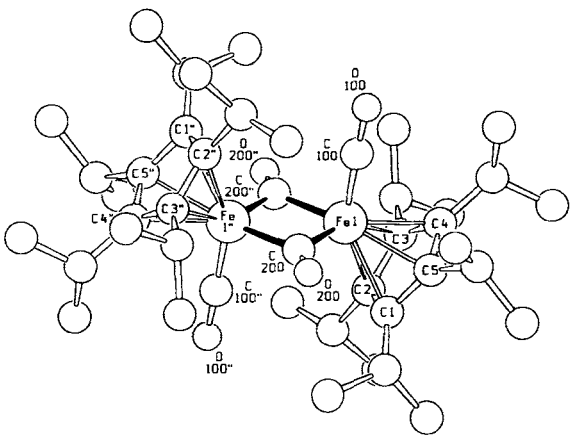

Fig. 4. Crystal structure of **4**. Selected bond lengths [Å] and angles [°]: Fe1–Fe1'' 2.600(2), Fe1–C100 1.725(6), Fe1–C200 1.931(5), C100–O100 1.157(7), C200–O200 1.169(6), Fe1–C1 2.188(5), Fe1–C2 2.198(5), Fe1–C3 2.154(5), Fe1–C4 2.149(5), Fe1–C5 2.150(5), Fe1–Cp(centroid) 1.80; Fe1-C200-Fe1'' 84.4(2), C200-Fe1-C200'' 95.6(2), C100-Fe1-Fe1'' 92.8(2). Only one of the two possible orientations of the pentaisopropylcyclopentadienyl "paddle wheel" in the crystal is shown.

The dicarbonyl radical **7** reacts smoothly in solution with elemental mercury at room temperature to give the yellow mercury compound **6** (see Scheme 1).

In contrast to all other cyclopentadienyl derivatives studied so far, the steric and electronic properties of the pentaisopropylcyclopentadienyl ligand cause the dissociation of complexes of the type $[(Cp^R{}_2Fe_2(CO)_4]$ in solution, leading to the formation of the monomeric radicals of the type $[(Cp^R)Fe(CO)_2]$ with 17 valence electrons. Since **7** exists practically completely as a monomeric radical in solution, interesting prospects for possible follow-up reactions emerge.

Experimental Procedure

1 (**2** was synthesized analogously): $[FeBr_2(dme)]$ (7.23 g, 27.7 mmol) was suspended in DME (100 mL) at −30 °C and treated dropwise with a solution of sodium tetraisopropylcyclopentadienide (6.96 g, 27.1 mmol) in DME (75 mL). After the mixture had been stirred for 2 h, the solvent was evaporated in vacuo, and the residue was taken up in petroleum ether (120 mL). The centrifuged, red-brown solution was evaporated to dryness, and the residue was taken up in pentane (100 mL). After the solution had been centrifuged again, the volume of the solvent was reduced by half. Dimer **1** crystallized at −30 °C from this solution in 33.5% yield (3.35 g, 4.54 mmol). ^{1}H NMR (400 MHz, C_6D_6, external TMS): δ = 94.07, 86.84, 20.89, −82.29.

3: **1** (0.573 g, 0.76 mmol) in diethyl ether (50 mL) was stirred under a CO atmosphere (1 bar) for 1 h at −78 °C, and then a further 12 h at room temperature. The dark red-brown solution was evaporated in vacuo, the crude product taken up in pentane/dichloromethane (3:1), and centrifuged. Red-brown, shiny crystals of **3** (0.404 g, 0.95 mmol, 66%; m.p. 112–115 °C (decomp)) were obtained at −35 °C. ^{1}H NMR (400 MHz, $CDCl_3$, ext. TMS): δ = 4.68 (s, 1H, ring-H), 2.85 (sept, br, 2H, C*H*Me$_2$), 2.73 (sept, br, 2H, C*H*Me$_2$), 1.37 (d, br, 12H, CH$_3$), 1.21 (d, br, 12H, CH$_3$). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$, ext. TMS): δ = 214.5 (2C, CO), 109.1 (2C, ring-CCHMe$_2$), 106.5 (2C, ring-*C*CHMe$_2$), 77.6 (1C, ring-*C*H), 25,2. 25.0, 23.8, 23.3, 22.9 (alkyl C atoms; the signal at δ = 25.2 is particularly intense because of superimposition of two alkyl C signals); IR (toluene): $\tilde{\nu}$[cm^{-1}] = 2024 (s), 1977 (s) (CO).

4: A solution of $LiC_5(CHMe_2)_5$ (5.48 g, 15.4 mmol) in DME (80 mL) was added dropwise over 90 min to a suspension of $[FeBr_2(dme)]$ (4.82 g, 15.8 mmol) in DME (40 mL) at −30 °C, and stirred for a further 30 min at that temperature. The mixture was then stirred under a CO atmosphere for 30 min at −30 °C and allowed to warm slowly to room temperature, while from time to time the consumed CO was replenished. Workup as described for **3** gave **4** (5.02 g, 10.7 mmol, 70%) as a red-brown product that decomposed above 120 °C. ^{13}C NMR (100 MHz, $CDCl_3$, ext. TMS): δ = 215.7 (s, 2C, CO) 107.7 (s, br, 5C, ring-C), 25.9 (d, ^1J(CH) = 127 Hz, 5C, *C*HMe$_2$), 24.5 (q, ^{1}J(CH) = 126 Hz, 10C, *C*H$_3$); IR (toluene): $\tilde{\nu}$[cm^{-1}] = 2021 (vs), 1974 (s) (CO).

5: A solution of **3** (0.457 g, 1.08 mmol) in THF (20 mL) was stirred with potassium (0.045 g, 1.15 mmol) at room temperature for 20 h, then the solution was evaporated to dryness in vacuo. Extraction with diethyl ether (10 mL), reduction in volume to 5–6 mL, and cooling of the solution to −30 °C gave **5** (0.106 g, 0.163 mmol, 30%) as a red-violet, microcrystalline product that decomposed above 120 °C. ^{1}H NMR (400 MHz, C_6D_6): δ = 4.34 (2s, superimposed, 3H, ring-H), 3.15 (sept, 2H, C*H*Me$_2$), 2.78 (2 sept, superimposed, 3H, C*H*Me$_2$), 2.70 (sept, 2H, C*H*Me$_2$), 1.62 (d, ^3J = 7.1 Hz, 6H, CH$_3$), 1.36 (d, ^3J = 6.6 Hz, 6H, CH$_3$), 1.32 (d, ^3J = 7.1 Hz, 6H, CH$_3$), 1.21 (d, ^3J = 6.7 Hz, 6H, CH$_3$), 1.15 (d, ^3J = 6.8 Hz, 6H, CH$_3$), 1.05 (d, ^3J = 6.7 Hz, 6H, CH$_3$), 0.92 (d, ^3J = 6.7 Hz, 6H, CH$_3$); ^{13}C NMR (100 MHz, C_6D_6): δ = 215.1 (s, 2C, CO), 214.4 (s, 2C, CO), 115.7 (s, 2C, ring-*C*-CHMe$_2$), 109.9 (s, 2C, ring-*C*-CHMe$_2$), 107.9 (s, 1C, ring-*C*-CHMe$_2$), 104.6 (s, 2C, ring-*C*-CHMe$_2$), 92.4 (d, ^1J(C,H) = 165 Hz, 2C, ring-*C*H), 82.3 (d, ^1J(C,H) = 172 Hz, 1C, ring-*C*H), 27.1, 26.9, 26.4, 25.8, 25.5, 25.4, 24.9, 24.1, 23.6, 23.2, 22.1 (methine- and methyl-C-atoms, superimposed). IR (nujol): $\tilde{\nu}$[cm^{-1}] = 1924 (s), 1757 (s), (CO).

6: A solution of **7** was stirred with an excess of mercury to give **6** as a yellow, almost insoluble powder in nearly quantitative yield. IR (nujol): $\tilde{\nu}$[cm^{-1}] = 1932 (s), 1894 (s), (CO).

7: A solution of **4** (679 mg, 1.45 mmol) in THF (20 mL) was stirred with finely divided potassium (115 mg, 2.90 mmol) for 20 h at room temperature. The solvent was removed in vacuo and the residue was washed with pentane (3 × 10 mL). Yield:

441 mg (0.90 mmol, 62%) orange-red potassium salt **8**. IR (nujol): $\tilde{\nu}$[cm^{-1}] = 1820 (s, br), 1807 (s, br), 1722 (s, br) [18]. Compound **8** (500 mg, 1.17 mmol) and silver tetrafluoroborate (228 mg, 1.17 mmol) were mixed at -30 °C with precooled THF. The reaction mixture was allowed to warm to room temperature and stirred for 1 h. The dark green solution was filtered over Celite and evaporated to dryness. Compound **7** (409 mg, 1.06 mmol, 90%) was obtained as an olive-green powder that sublimed at 10^{-2} mbar above 70 °C. ^{1}H NMR (400 MHz, 343 K, C_6D_6): δ = 8.67 (br, 15H, CH_3, presumably proximal), 6.51 (br, 5H, CH), 4.50 (br, 15H, CH_3, presumably distal). IR (toluene): $\tilde{\nu}$[cm^{-1}] = 1975 (s), 1901 (s); IR (KBr): $\tilde{\nu}$[cm^{-1}] = 1916 (vs), 1759 (s, br). Crystals suitable for X-ray diffraction were obtained from petroleum ether at -30 °C.

$[As_2(AlCp^*)_3]$—A Compound with a Polyhedral As_2Al_3 Framework**

Carsten K. F. von Hänisch, Christoph Üffing, Markus A. Junker, Achim Ecker, Boris O. Kneisel, and Hansgeorg Schnöckel*

Since the first report on the synthesis[1] of $[(Cp^*Al)_4]$ (Cp^* = pentamethylcyclopentadienyl, C_5Me_5), this versatile reagent has been used for the synthesis of new organoaluminum compounds. For example, reaction with selenium or tellurium provided heterocubane analogues,[2] while that with P_4 led to a compound containing $[P_4(AlCp^*)_6]$ units.[3] These do not have the expected adamantane-like structure with AlCp*-bridged P_4 tetrahedra; instead, they are made up of two face-sharing heterocubanes, each of which lacks one phosphorus atom (see Fig. 2). Halving this molecule would lead to $[P_2(AlCp^*)_3]$, for which a trigonal-bipyramidal structure is expected. Although no geometric parameters could be obtained, a similar structure has been proposed by Roesky et al. for the analogous $[Sb_2(AlCp^*)_3]$ on the basis of preliminary X-ray structure studies.[4] We report here on the analogous arsenic compound $[As_2(AlCp^*)_3]$ (**1**), which, according to X-ray structure analysis, exists as a heteropolyhedron with a trigonal-bipyramidal structure (Fig. 1).

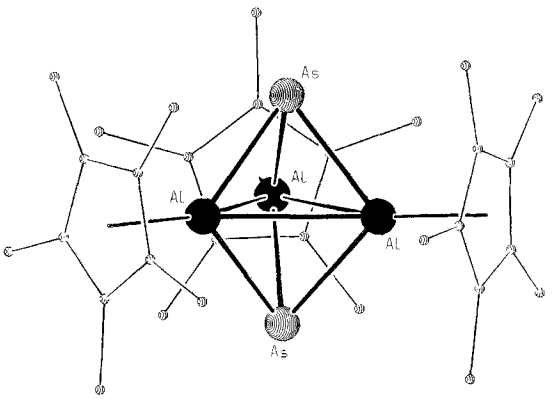

Fig. 1. Molecular structure of $As_2(AlCp^*)_3$ (**1**) in the crystal (hydrogen atoms are not shown).

When $[(Cp^*Al)_4]$ is heated with $[(t\text{BuAs})_4]$ in toluene, **1** is formed together with 2-methylpropane and isobutene. During the reaction, the solution slowly changes color from yellow to orange. After filtration, concentration of the solution, and cooling to -25 °C, **1** can be isolated as yellow crystals. The X-ray crystal structure analysis[5] showed that **1** has an As_2Al_3 framework with approximate D_{3h} symmetry (Fig. 1). The As–Al bond (248 pm) is shorter than that in the organometallic compounds reported so far (249–257 pm).[6]

This shortening of the As–Al bond in **1** is understandable since both arsenic and aluminum have the (higher) coordination number four in all the other known As–Al compounds.[7] However, $(Mes^*AlAsPh)_3$ (Mes^* = 2,4,6-$(t\text{Bu})_3C_6H_2$) was recently

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Dr. R. Köppe for the helpful discussions on the quantum chemical results.

reported, in which both the As and the Al atoms are three coordinate. Consequently, an especially short As–Al bond length of 243 pm is present.[9] The lower coordination number is also responsible for the shorter As–Al bonds in the Zintl anions $[Al_2As_4]^{6-}$ (terminal: 233–235 pm, bridging: 243–245 pm).[10]

The Al–Al distances in **1** (283 pm) are only slightly longer than those, for example, in R_2AlAlR_2 ($R = CH(SiMe_3)_2$, 266 pm)[11] and $[(Cp^*Al)_4]$ (277 pm),[1] indicating the presence of Al–Al bonding. However, in the case of **1**, there are only twelve electrons available for the nine bonds of the As_2Al_3 framework; thus, there is an electron deficient situation, such that the bonding in the As_2Al_3 polyhedron is similar to that in *closo*-boranes.

In contrast to As_2Al_3, the analogous P_2B_3 framework in $P_2[BN(iPr)_2]_3$ (**2**) shows classical two-electron–two-center (2e2c) bonding and, due to the stronger B–N backbonding, only weak B–B interactions.[12] This is supported by the B–B bond lengths (223 pm), which are about 30% longer than a normal B–B single bond (B_2Cl_4: 175 pm),[13] and could further be confirmed by our quantum chemical calculations.[14] Since our calculations are basically in agreement with the recently published results for $[(BX)_n(Y)_2]$ molecules,[15] we will avoid a detailed description of the results here, and only those points that are decisive for the interpretation of the bonding in **1** will be presented.

SCF calculations on the model compound $P_2(BNH_2)_3$[16] confirmed the experimentally observed weak B–B interactions: $d(B–B) = 222$ pm (as in **2**). The extremely long B–B bond length indicates that the bonding can be described solely with 2e2c B–P bonding. Substitution of the NH_2 groups with hydrogen atoms, for which backbonding is no longer possible, results in a shortening of the B–B bond length by 25 pm to 197 pm. This bonding is now better described as a 2e3c interaction (such as that in a *closo*-polyhedron).

According to quantum chemical calculations, the situation in the analogous AlP compound $[P_2(AlH)_3]$ (**3**) is not so clear, since due to the reduced stability of the monomer, owing to the multicenter bonding, the dimer $[P_4(AlH)_6]$ (**4**) must also be considered. Recently, a compound with a P_4Al_6 framework was detected experimentally in the reaction of P_4 with $[(Cp^*Al)_4]$. Two isomers, **4a** (T_d) and **4b** (C_{2h}), are conceivable for this dimeric compound (Fig. 2), although quantum chemical calculations indicate that the T_d structure (**4a**) should be slightly higher in energy.[3]

The calculations reveal that the dimerization of **3** to give the less stable **4a** is strongly exothermic (-184 kJ mol^{-1}).[17] This result is in agreement with the experimental finding that no monomer with the trigonal-bipyramidal structure of **3** has yet been found.

Substitution of phosphorus with arsenic apparently leads to a change in the bonding: only the monomeric unit $[As_2(AlCp^*)_3]$ (**1**) can be detected. Initially, we attributed this to a stabilization by electron delocalization in the As_2Al_3 framework, similar to the Wade description of *closo*-boranes; however, quantum chemical calculations for the H-substituted parent compound $[As_2(AlH)_3]$ (**1a**) and its dimer $[As_4(AlH)_6]$ (**5**) with an adamantane structure show that the dimerization energy (-144 kJ mol^{-1}) is decidedly negative.[18] In order to understand the bonding in monomeric $[As_2(AlR)_3]$ compounds, we have carried out SCF calculations for molecules with R = H, Cl, NH_2, and Cp (**1a–d**).

For the compounds **1a–d** we were able to assign five or six of the highest occupied MOs to the framework electron system, for example, for **1a**: $9a'' = -0.298$, $6e'' = -0.330$, $10e' = -0.383$ a.u. The missing a_1 MO is 0.05 a.u. lower in energy than the fifth bonding MO. However, for **1c** and **1d** there are still two to three MOs, which are higher in energy than the lowest lying a_1 MO of the As_2Al_3 framework and can be assigned to AlR bonding as well as to the lone pairs of electrons on the nitrogen atoms. In all cases, the MOs assigned to lone pairs of electrons on As are separated from the framework electron system by a lowering in energy of 0.18–0.25 a.u. (depending on the substituent). The minimal changes in the electronic structures[19] of **1a–d** indicate similar geometric bonding situations, and the Al–Al bond lengths are barely influenced: 279 (**1a**), 277 (**1b**), 280 (**1c**), and 293 pm (**1d**). The particularly long Al–Al bond lengths on Cp substitution (**1d**) were expected based on earlier results for $[(Cp^*Al)_4]$.

The population analysis for **1a–d** also confirms a clear electron delocalization and, consequently, *closo*-compounds. Therefore, the shared electron number (SEN) values[20] of approximately 0.2 for the Al–Al interaction are expectedly low;[21] however, substantial three-center Al–As–Al population does take place.[22] The partial charges based on the Roby–Davidson population analysis for Al and As vary, according to substituent, from +0.3 to +0.45 and −0.3 to −0.45, respectively.

Based on these experimental and quantum chemical investigations of **1**, its derivatives, and other homologous compounds, it can be concluded that the heavy main group elements can also form heteropolyhedral compounds of the *closo*-borane type. However, the extent of multicenter bonding is significantly lower for molecules with a P_2Al_3 framework and trigonal-bipyramidal structure than for the analogous boron compounds.

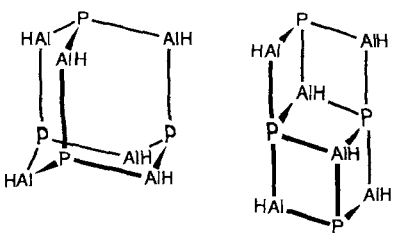

Fig. 2. Structural isomers of $P_4(AlH)_6$: **4a** (left) and **4b** (right).

Experimental Procedure

^{1}H NMR spectra were recorded at room temperature with a Bruker AC250 spectrometer (solvent: C_6D_6, $\delta(C_6D_5H) = 7.16$).

$[(t\text{BuAs})_4]$ [23] (40 mg, 0.077 mmol) was dissolved in toluene (8 mL) and added to $[(Cp^*Al)_4]$ (50 mg, 0.077 mmol) at room temperature. The clear, light yellow solution was tempered alternately at 60°C and 115°C and then cooled to room temperature, leading to an intensification of the color. Filtration and concentration of the solution in vacuo provided an orange solution, from which yellow crystals of **1** were obtained at −25°C. The ^{1}H NMR spectra of the reaction mixture show signals that can be assigned to the starting material as well as isobutene, Cp*H, and 2-methylpropane. A signal, which is shifted downfield by 0.04 with respect to the $[(Cp^*Al)_4]$ signal ($\delta = 1.94$), became more intense at the expense of the $[(Cp^*Al)_4]$ signal and is assigned to compound **1**. No signals could be detected by ^{27}Al NMR spectroscopy. Under high vacuum conditions **1** can be evaporated at about 160°C without decomposition. Mass spectrometry shows 1^+ to be the molecular ion peak at 180°C. MS (EI, 70 eV, 180°C): *m/z* (%): 636 (100, M^+), 501 (10), 474 (18), 399 (4), 324 (15), 162 (27), 121 (14).

[7] In this view, for aluminum only the electronegative ligands, but not the bonding to other Al atoms (as in **1**), has been taken into account. A compound with a particularly short As–Al bond length of 246 pm, despite having four-coordinate As and Al atoms, is $(Me_3Si)_3As \cdot AlCl_3$ [8].

Functionalized Organoimidorhenium(v) Complexes as Potential Radiopharmaceuticals: Syntheses of Glycine Derivatives and the Structure Determination of a Rhenium Analogue of Chlorambucil**

Jeffrey B. Arterburn,* Ian M. Fogarty, Keith A. Hall, Kevin C. Ott, and Jeffrey C. Bryan

Metal-based pharmaceuticals play a prominent role in modern medicine, and new combinations of metals with biologically relevant organic molecules offer versatility in drug design for many potential applications.[1] The coordination chemistry of the metal may be essential, as is the case with cisplatin and related derivatives,[2] while other applications may be based on the existence of radioisotopes of the metal (for example, radioimaging and radiotherapy). In the latter context, diagnostic imaging with ^{99m}Tc complexes has become a routine medical procedure, and current research has focused on finding radiopharmaceuticals that bind selectively to organs or cells.[3] Complexes containing radioisotopes of rhenium (^{186}Re and ^{188}Re) are equally suitable for imaging and radiotherapy of certain cancers.[4]

The linkage used in a metal bioconjugate determines its ease of synthesis, stability, and biological activity of the complex. Multihapto chelating ligands are the most thoroughly investigated ligand class for metal-based drugs, because of favorable complexation kinetics and chelate stability.[5] However, chelating ligands may adversely affect the solubility or lipophilicity characteristics of the complexes, influence target tissue selectivity, and can potentially modify receptor binding. To circumvent these problems, we decided to explore the use of a multiply bonded organoimide linkage (M≡N–biomolecule) that can be easily synthesized for a stable, covalent connection between a metal and a biologically relevant organic molecule as an alternative to chelating linkages.[6, 7] For the purposes of radiopharmaceutical design, ancillary organoimide ligands functionalized with a carboxylic acid would provide a convenient site for the

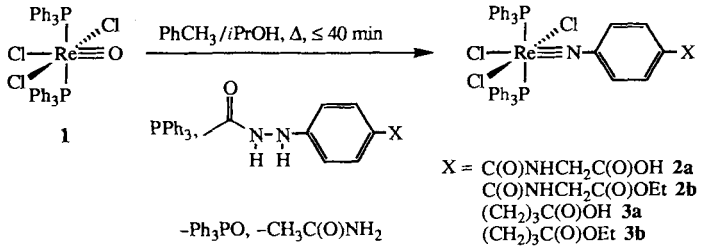
conjugation of biomolecules and permit fine tuning of desirable properties by varying labile ligands in the coordination sphere, an option unavailable to chelates. Here we report the syntheses of a new class of potential metal-pharmaceuticals, a ^{188}Re organoimido analogue of the anti-cancer drug chlorambucil,[8] and its X-ray crystal structure determination, as well as of functionalized imidorhenium complexes containing the amino acid glycine, demonstrating the stability of the imido group in the presence of carboxylic acid, ester, and amide groups.

The oxorhenium(v) complex **1**[9] reacts rapidly with simple, functionalized *N*-acetylarylhydrazine[10] and triphenylphosphane in a refluxing 1:1 mixture of toluene and 2-propanol to give the green, air-stable organoimido complexes **2** and **3** in high yields (≥85%) (Scheme 1). No precautions against air or adventitious water in the reagents were required. The $^{31}P\{^1H\}$ NMR spectra for the complexes are particularly diagnostic and show a characteristic single resonance at about $\delta = -20$ to -22 for the equivalent *trans* phosphane ligands. The FT-IR spectra of the glycine derivatives **2** and chlorambucil analogues **3** display absorptions assigned to the carbonyl groups in the acids, esters, and amides, as well as a strong absorption for the ligated phosphane ligands. Complexes **3** have also been characterized by HPLC.[11]



Scheme 1. Synthesis of functionalized arylimidorhenium(v) complexes from **1**.

To test the viability of this route for radiopharmaceutical syntheses we synthesized complex **3b** labeled with carrier-free ^{188}Re. A CH_2Cl_2 solution containing the ^{188}Re labeled oxo complex **1***[12] reacted with acetylhydrazine (in excess) and PPh_3 to produce **3b*** as determined by HPLC with radiometric detection. The reaction proceeded smoothly at room temperature to produce **3b*** in quantitative radiochemical yields.

Complex **3b** was recrystallized by slow diffusion of ethanol into a dichloromethane solution, and produced crystals suitable for X-ray diffraction.[13] The structure of the complex (Fig. 1) consists of an octahedral arrangement of *mer*-oriented chloride ligands, the *trans*-triphenylphosphane ligands, and the imide ligand. The ligand arrangement around the rhenium is consistent with the spectroscopic data for complex **3b** in solution and similar to that of previously reported phenylimido complexes.[14] The Re–N bond length of 1.713(4) Å and the Re-N-C1 bond angle of 179.0(3)° are typical of rhenium(v) monoimido complexes (1.69–1.75 Å, 156–180°).[7, 16] The Re–Cl and Re–P distances are similar to those reported for the closely related $[Re(NPh)Cl_3(PPh_3)_2]$.[15]

Though organoimide ligands are ubiquitous in the chemistry of transition metals in their higher oxidation states, there are surprisingly very few examples where the alkyl or aryl group has itself been functionalized.[7] To our knowledge, complexes **2a** and **3a** represent the first examples in which an organoimide ligand and free carboxylic acid groups are present within the same molecule. The efficient Re–N π bonding[16] in these

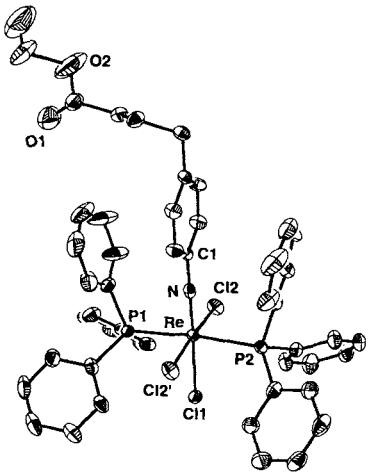


Fig. 1. ORTEP representation of the crystal structure of **3b** (50% thermal ellipsoids). Hydrogen atoms and one set of the pairs of disordered atoms are omitted for clarity [13]. Relevant distances [Å] and angles [°]: Re–N 1.713(4), Re–Cl1 2.447(1), Re–Cl2 2.412(1), Re–P1 2.485(1), Re–P2 2.488(1), Re-N-C1 179.0(3), P1-Re-P2 174.5(1), Cl2-Re-Cl2' 176.9(1), Cl1-Re-N 178.9(1), Cl1-Re-P1 87.0(1), Cl1-Re-P2 87.5(1), Cl1-Re-Cl2 89.0(1).

complexes results in the weak basicity/nucleophilicity of the nitrogen atom and imparts stability to the complexes against hydrolysis in protic media.[11] The solubility, charge, and size of these and related complexes can be modified by making appropriate ligand substitutions without compromising the imido linkage.[7] Since flexibility is important for radiopharmaceutical design, where biodistribution and high receptor specificity are both necessary requirements, this capability is a distinct advantage of the multiply bonded organoimide ligand over chelating linkages.[17]

In conclusion, the use of a covalent organoimido–metal bioconjugate represents a new and potentially powerful methodology in radiopharmaceutical design. The imido-forming reactions proceed readily under mild conditions and are compatible with unprotected carboxylic acids, esters, and amides. They give stable imido complexes and can be adapted to high-yield syntheses utilizing ^{188}Re. The extension of this chemistry to other rhenium organoimido complexes containing biologically relevant organic substrates, and an investigation of the biological stability and potential anticancer activity of the complex **3a** as a bifunctional analogue of chlorambucil[8] with electrophilic DNA crosslinking capability are currently in progress.

Experimental Procedure

Complexes **2** and **3** were prepared by refluxing **1** (716 mg, 0.86 mmol), PPh_3 (451 mg, 1.72 mmol), and the appropriate acetylhydrazine [18] (0.86 mmol) in toluene/2-propanol (60 mL each) for 40 min. The solutions were then concentrated to 5 mL in vacuo, and the products precipitated by the addition of 1:1 ether:hexane (60 mL total). The green solids were filtered, washed with ethanol, and dried in vacuo. Complexes **2a** and **3a** were recrystallized by slow evaporation of a benzene solution, while **2b** and **3b** were recrystallized by slow diffusion of ethanol into dichloromethane solutions of the complexes. $^{31}P\{^1H\}$ NMR spectra were obtained at 161.9 MHz, $CDCl_3$, 22 °C, referenced to an internal capillary containing H_3PO_4 ($\delta = 0$). **2a**: Yield 738 mg, 85%. $^{31}P\{^1H\}$ NMR: $\delta = -21.7$ (s); IR (KBr): $\tilde{\nu} = 3396$ (O–H), 1732 (C=O), 1668 (C=O), 1092 cm^{-1} (P–C). [13] $ReC_{48}H_{45}Cl_3NO_2P_2$ **3b**, $M = 1022.3$, monoclinic, $P2_1/m$, $Z = 2$, $a = 12.550(2)$, $b = 13.6426(8)$, $c = 12.586(2)$ Å, $\beta = 91.380(8)°$, $V = 2154.2(5)$ Å^3, $\rho_{calcd.} = 1.576$ g cm^{-3}, $T = -100$ °C; the structure was solved by direct methods and expanded with Fourier techniques. The Re, P, Cl1, N, and several carbon atoms lie on a crystallographic mirror plane. The methylene carbon atoms of the phenyl(ethylbutanoate) group, which all lie close to this mirror plane, are disordered and were therefore refined at half-occupancy. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included, but not refined. Final refinement on $|F|$, with 296 variables and 3547 independent reflections ($F > 4\sigma_F$) gave an unweighted residual $R = 0.0275$, $R_w = 0.0370$ and a GOF = 1.04. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-125. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: int. code +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).

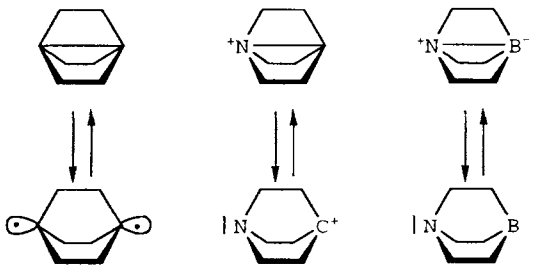
Solvent-Dependent C–N Bond Lengths in a Protonated Orthoamide**

Randolf D. Köhn,* Guido Seifert, and Gabriele Kociok-Köhn

In the early 1970s a new kind of isomerism, in which two isomers differ only in their bond lengths, was proposed by Chatt et al. based on X-ray structure analyses on transition metal complexes,[1] and by Hoffmann et al. based on theoretical studies.[2] The "bond stretch isomers" established to date by crystallography have been critically reviewed by Parkin,[3] and errors were found in most (if not all) interpretations of the X-ray data. This failure to conclusively prove bond stretch isomerism in these complexes, cast doubts on the existence of this type of isomerism.[1]

However, the early theoretical studies indicated the possible existence of bond stretch isomers in organic compounds Scheme 1).[4] The opposing effects of bond energy and ring strain lead to two very different minima; the corresponding isomers differ in their dominant electron configuration (σ and σ^*).



Scheme 1. Theoretically well studied bond stretch isomers in organic compounds.

Based on the difference in polarity, a solvent dependence of the equilibrium between the two isomers was predicted; however, none of the proposed molecules could be prepared because of experimental difficulties and thus the bond stretch isomerism could not be confirmed.

We have tried to prepare complexes from VCl_3 or $FeCl_3$ and the orthoamide **1** analogous to those with $CuCl_2$.[5] However, crystallization of the crude products from CH_2Cl_2/toluene over several weeks resulted in colorless crystals of $\mathbf{2}^+Cl^-$[6] and yel-

lowish crystals of $(3^+)_2[Fe_2Cl_6O]^{2-}$,[7] respectively. These compounds are adducts of **1** with acids that were probably formed from moisture that found its way into the reaction mixture.

In the case of $FeCl_3$, the large and weakly coordinating anion $[Fe_2Cl_6O]^{2-}$ was formed, while the hydrogen-bond-forming Cl^- ion resulted from the reaction with VCl_3. Depending on the interaction with the anion, the ammonium cation 2^+ (Fig. 1) or the amidinium cation 3^+ (Fig. 2) with nearly broken N–C bond

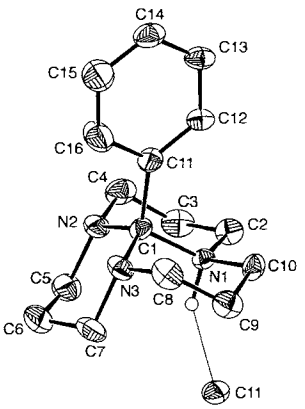

Fig. 1. Structure of 2^+Cl^- in the crystal; selected bond lengths [pm] and angles [°]: C1–N1 159.2(6), C1–N2 143.6(6); N2-C1-N3 113.0(4), N1-C1-C11 112.5(4).

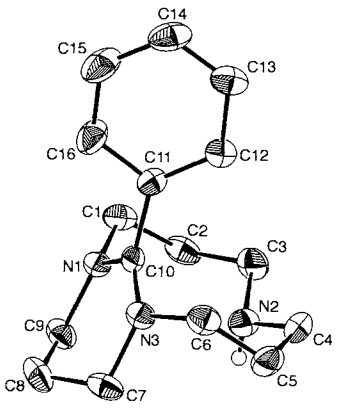

Fig. 2. Structure of the cation 3^+ in the crystal of $(3^+)_2[Fe_2OCl_6]^{2-}$; selected bond lengths [pm] and angles [°]: C2–N10 269(1), C10–N1 133.3(8); N1-C10-N3 123.2(3), N1-C10-C11 115.7(4).

was formed. IR and NMR studies on a similar orthoamide (with a H atom instead of a Ph group) prepared by Wuest et al.[8] revealed that cations analogous to 2^+ and 3^+ can be obtained by protonation depending on the anion and that they are in a fast equilibrium. In 1967 a comparable compound with solvent-dependent C–N bond length was observed, although only in solution, by UV/Vis spectroscopy.[9]

The two cations 2^+ and 3^+ (Fig. 3) are nearly superimposable; however, they differ in one C–N bond and thus in the position of the phenyl group. This situation appears to be similar to the theoretical bond stretch isomers in Scheme 1. The central C–N bond in **1**, which is already extended due to a twofold anomeric effect and some ring strain (155.1(5) pm[5]), is elongated to 159.2(6) pm in 2^+ and to 269(1) pm in 3^+. Thus, both distances are longer than regular C–N bond lengths (147 pm) and shorter than the sum of the van der Waals radii (320 pm).[10] The cation 3^+ is apparently favored when no hydrogen bond is formed to the anion; in contrast, 2^+ is favored by a hydrogen bond between the chloride ion and the NH group. Such a hydrogen bond should also be accessible by a suitable solvent with hydrogen bond acceptor properties. Thus, $(3^+)_2[Fe_2OCl_6]^{2-}$ might close the C–N bond to form the cation 2^+ in polar solvents. In such a case $(3^+)_2[Fe_2OCl_6]^{2-}$ would exist as solvent-dependent isomers with different bond lengths for the same anion. The accidental formation of $(3^+)_2[Fe_2OCl_6]^{2-}$, its probable low solubility in nonpolar solvents, and the paramagnetism of the anion forced us to change to the more suitable anion $[B(3,5\text{-}C_6H_3(CF_3)_2)_4]^-$ (TFPB$^-$), which is a diamagnetic, weakly coordinating anion with higher solubility.

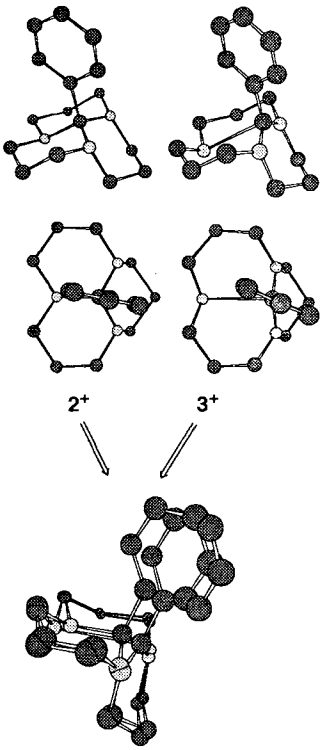

Fig. 3. Superposition of the cations 2^+ (from 2^+Cl^-) and 3^+ (from $(3^+)_2[Fe_2OCl_6]^{2-}$).

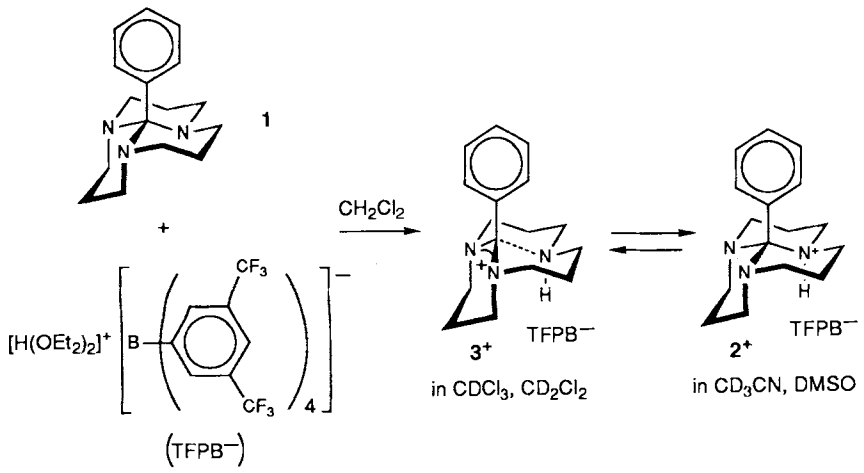
Compound **1** reacts with $[H(OEt_2)_2]$TFPB in CH_2Cl_2 to yield 3^+TFPB$^-$, which is soluble in $CDCl_3$ and CD_2Cl_2 without reformation of the C–N bond. The formation of the amidinium ion was evident from a ^{13}C NMR signal at $\delta = 173.6$. Contrary to the cation investigated by Wuest et al.,[8] the ^1H NMR spectrum of the amidinium ion shows no dynamic exchange. The well-resolved spectrum shows all expected signals for the protons in the three six-membered rings in chair conformation with C_s symmetry; these signals were assigned by $^1H,^1H$-COSY NMR spectroscopy. The coupling patterns feature large J_{gem} and J_{ax-ax} ($J \approx 13$ Hz) coupling constants, including coupling to the amine proton, and show that the conformation of the ten-membered ring is fixed by the weak C^+–N interaction. The chemical shift of the NH protons of $\delta = 0.82$ and the down field shift of the protons adjacent to the amidinium cation confirm the presence of the cation 3^+. The IR spectrum of the solid also indicates the presence of cation 3^+; no ammonium absorption band (<2800 cm^{-1}) is present, but an amine absorption band appears at 3345 cm^{-1}. The ^1H NMR spectra in more polar solvents such as CD_3CN and [D$_6$]DMSO look completely different. The signal for the amine proton at $\delta = 0.8$ is replaced by one for an ammonium proton at $\delta = 8.8$ (in [D$_6$]DMSO). The signals for the propylene bridge are only broad signal groups; the average signal for the protons adjacent to the nitrogen atoms is shifted considerably less down field than that in 3^+. This indicates the absence of the amidinium group. Moreover, no signal for an amidinium C atom was found in the ^{13}C NMR spectrum. Thus, the cation 2^+ exists in these more polar solvents. Removal of the sol-



vent in vacuo and dissolution in $CDCl_3$ regenerates the cation 3^+; therefore, 2^+ and 3^+ can be interconverted depending on the solvent. In DMSO, besides 2^+ approximately 30% of the unprotonated compound **1** and probably H_3O^+ (from water in the DMSO) were observed. The same signals for 2^+ are obtained when 20% [D_6]DMSO are added to a solution of 3^+TFPB^- in $CDCl_3$.

In summary, X-ray crystal structure analysis has revealed very different C–N bond lengths in the isomeric cations 2^+ and 3^+ with two different anions. NMR spectroscopy of compound 3^+TFPB^- has shown that the two isomeric cations can be interconverted depending on the polarity of the solvent; thus, 3^+TFPB^- is a possible candidate for bond stretch isomerism.[11]

Experimental Procedure

3^+TFPB^-: CH_2Cl_2 (2 mL) was condensed to **1** [5] (41 mg, 0.16 mmol) and $[H(OEt_2)_2]TFPB$ [12] (156 mg, 0.15 mmol). After the mixture had been stirred for 10 minutes, the solvent was removed in vacuo. The colorless residue was washed with hexanes (4 mL) and dried in vacuo (124 mg, 74%, m.p. 158–159 °C). Elemental analysis: found (calcd.) (M_r = 1121.61): C 50.25 (51.40), H 3.46 (3.24), N 3.71 (3.75)%; ^{1}H NMR (400 MHz, $CDCl_3$, TMS ext.): δ = 7.70 (m, 9H, Ph + *p*-TFPB), 7.54 (s, 8H, *m*-TFPB), 3.83 (t [13], 2H, H1/6_{ax} [14]), 3.59 (t, 2H, H7/9_{ax}), 3.30 (d, 2H, H3/4_{eq}), 3.23 (d, 2H, H7/9_{eq}), 3.11 (d, 2H, H1/6_{eq}), 3.78 (q, 2H, H3/4_{ax}), 2.25 (t, 1H, H8_{ax}), 2.20 (d, 1H, H8_{eq}), 2.00 (q, 2H, H2/5_{ax}), 1.43 (d, 2H, H2/5_{eq}), 0.82 (br, 1H, N*H*) (similar in CD_2Cl_2); $^{13}C\{^1H\}$ NMR (100 MHz, CD_2Cl_2, TMS ext.): δ = 173.6 (C10), 162.1 (q, J(C,B) = 148 Hz, *ipso*-TFPB), 135.2 (*o*-TFPB), 132.1 (*m*-Ph), 130.9 (*ipso*-Ph), 130.2 (*o*, *p*-Ph), 129.6 (q, J(C,F) = 37 Hz, *m*-TFPB), 125.0 (q, J(C,F) = 267 Hz, CF_3), 117.8 (sept, J(C,F) = 4 Hz, *p*-TFPB), 48.7 (C1/6 + C7/9), 46.1 (C3/4), 26.8 (C2/5), 20.4 (C8) (similar in $CDCl_3$); IR (KBr): $\tilde{\nu}$ = 3345 (N–H), 1599 cm^{-1} (Ph, NCN^+).

2^+TFPB^- was formed by dissolving 3^+TFPB^- in acetonitrile or DMSO: ^{1}H NMR (400 MHz, CD_3CN, TMS ext.): δ = 7.66 (s, 12H, TFPB), 7.70 (m, 2H, *m*-Ph), 7.55 (m, 3H, *o*, *p*-Ph), 3.62 (br, 2H), 2.9–3.2 (br m, 10H), 2.2 (br, 4H), 1.45 (br, 2H) (similar in [D_6]DMSO + 8.8 (br, 1H, N*H*) + signals for **1** [5]); $^{13}C\{^1H\}$ NMR (50 MHz, CD_3CN, TMS ext.): δ = 162.6 (q, J(C,B) = 150 Hz, *ipso*-TFPB), 135.7 (*o*-TFPB), 131.6 (*ipso*-Ph), 131.1 (*o*, *p*-Ph), 129.9 (q, J(C,F) = 32 Hz, *m*-TFPB), 129.8 (*m*-Ph), 125.5 (q, J(C,F) = 272 Hz, CF_3), 118.7 (sept, J(C,F) = 4 Hz, *p*-TFPB), 49 (CCN), 23.5 (*C*CN).
