Energy calculations were carried out both on a representative DOPC–**1** complex and on the crystal structure of the variable portion of the PC–McPC603 complex (Table 1). The binding free energy was factorized as a sum of electrostatic and non-electrostatic contributions.[11] Binding appears to be driven by different contributions in each case: binding of DOPC to **1** in chloroform is enthalpically driven, in agreement with the ΔH° and ΔS values, as a result of the favorable electrostatic contribution to the binding free energy; however, in the binding of PC to McPC603 in water the driving force appears to be the hydrophobic effect, as desolvation of the charged ligand in water greatly reduces the net electrostatic contribution to the binding free energy. This finding highlights the importance of evaluating accurately the energy penalty associated with removing the interacting moieties from water when dealing with molecular associations in aqueous media.[12] The fact that the electrostatic contribution for DOPC–**1** in chloroform and the hydrophobic contribution for PC–McPC603 in water appear to be of the same magnitude is fortuitous. On the other hand, the analysis of the contributions to the binding free energy suggests that it should be possible for a water-soluble derivative of **1** to attain substantially high affinities for biological applications in water, as the hydrophobic and electrostatic contributions to the binding free energy are expected to be similar to those of McPC603. In addition, our calculations suggest that the entropic penalties arising from the fixation of torsional degrees of freedom are also similar in both cases.

Table 1. Binding free energy [kcal mol^{-1}] and its different contributions for PC–McPC603 and DOPC–**1** complexes.

	ΔG_{exp} [a]	ΔG_{tot} [b]	ΔG_{ele} [c]	ΔG_{hyd} [d]	ΔG_{conf} [e]	ΔG_{T+R} [f]
PC–McPC603	-6.6	-5.4	-2.4	-23.0	11.0	9.0
DOPC–**1**	-6.7	-5.6	-25.4	0.0	9.8	10.0

[a] Experimental values at 298 K taken from ref. [3] for PC–McPC603 and from the K_{ass} for DOPC–**1** determined by UV titrations. [b] $\Delta G_{tot} = \Delta G_{ele} + \Delta G_{hyd} + \Delta G_{conf} + \Delta G_{T+R}$; tot = total, ele = electrostatic, hyd = hydrophobic, conf = conformational, T + R = translation and rotation; according to ref. [11]. The bound conformations were the energy-refined crystal structure of PC–McPC603 and a representative average structure [9] of DOPC–**1**. A rigid model for noncovalent complex formation was assumed. [c] The electrostatic contribution to the binding free energy was calculated by solving the Poisson–Boltzmann equation with the program DelPhi [13]. [d] The hydrophobic contribution to the free energy of complex formation was obtained from the solvent-accessible surface [14] of PC and McPC603 buried upon complex formation (400 Å^2) multiplied by a factor of -57.42 cal mol^{-1} Å^{-2} [11]. It is assumed that there is no hydrophobic effect in chloroform. [e] Entropic cost of fixing torsional degrees of freedom in the binding process. A total of eight torsional angles were fixed in DOPC–**1**, each contributing 1.22 kcal mol^{-1} [11]. For PC–McPC603 the lower limit estimated by Novotny et al. [4a, b] was used, which corresponds to nine fixed torsional angles. [f] Entropy less on translation and rotation. For PC, the value of ref. [4a, b] was used. For DOPC, an extra 1 kcal mol^{-1} was added due to the increase in molecular weight [11].

In summary, we have shown that a synthetic non-peptidic receptor displaying the binding properties of a whole antibody can be designed by mimicking the key interactions found in the crystal structure of an hapten–antibody complex. Incorporation of suitable reactive functional groups into the recognition binding site should open a new avenue for research into antibody or enzyme mimics.

[9] MD simulations were carried out using the AMBER 4.0 suite of programs (University of California at San Francisco, **1991**). OPLS parameters were used for chloroform. All distances obtained from the NOE studies were maintained within the expected values during the MD trajectories. The energy-minimized average structure was in agreement with the NOE distances and was chosen to represent the solution structure of DOPC–**1** in the analysis of the contributions to the binding free energy. Full details will be reported elsewhere.

[10] In the direct NMR titration of **1** with DOPC in $CDCl_3$ complete saturation was reached at a ratio of 1:1, indicating $K_{ass} > 50000$ M^{-1}. Thus, binding was measured by UV spectroscopy in $CHCl_3$ by competition with Methyl Orange tetraethylammonium salt ($K_{ass} = 21500 \pm 1000$ M^{-1}). Examination of CPK models suggested that the dye sulfonate group could bind to the guanidinium group of **1** and that the rest of the molecule could easily be encapsulated by the calixarene cavity.

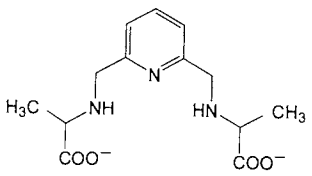
Selection of Different Reactive Sites by Enantiomers in Electron-Transfer Reactions Involving Metalloproteins**

Klaus Bernauer* and Luca Verardo

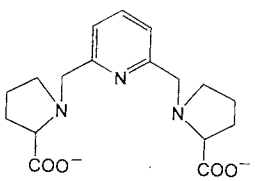
The identification of the exact site of attack in electron-transfer reactions involving metalloproteins has been the object of many studies.[1-3] In the case of plastocyanin ($PcCu^{II}$) two sites have been identified, the "adjacent site" near the copper center and the "remote site" located near a negative patch of the protein, some 16 Å away from the copper center. Negatively charged or neutral metal complexes are thought to react exclusively at the hydrophobic adjacent site, whereas positively charged reagents can react at both the adjacent and/or the remote site.[3] In the latter case the neighboring Tyr83 probably intervenes in the electron transfer pathway. In order to obtain more detailed information on the location of the attack of electron-transfer reagents, we used optically active metal complexes, our aim being the detection of chiral recognition by means of kinetic stereoselectivity.[4-7]

A useful technique to identify electron-transfer sites in inner-sphere reactions is the use of reagents like Cr^{2+}, which form inert reaction products and therefore remain attached to the bridging atom of the electron-transfer precursor complex.[8] This technique has also been applied to metalloproteins, but identification of the exact structure of the reaction products proved to be difficult.[9,10] In the present communication we report the first use of circular dichroism (CD) for the identification of specific sites in the reaction of plastocyanin with optically active Co^{2+} complexes.

In a previous communication we have shown that the electron-transfer reaction between spinach plastocyanin and the optically active Fe^{2+} complexes with **1** and **2** as ligands takes place



1



2

at the hydrophobic adjacent site of this blue copper protein and that significant chiral recognition occurs in the formation of the transition state.[4] From these results the question arose whether the imidazole unit of His87 was involved in the electron transfer. Therefore, plastocyanin was treated with the Co^{2+} complexes of both the (*S*,*S*) and (*R*,*R*) enantiomers of **1** and **2** in phosphate buffer at pH 7 and 20 °C. Under these conditions electron transfer, monitored by the variation of the UV/Vis and CD spectra, is quantitative and occurs at similar rates with all the Co^{II} complexes used. As the reduced protein has no CD activity in the visible range, the CD spectrum of the Co^{III} species formed during the reaction can be obtained by accounting for the remaining Co^{2+} complex in the final spectrum, which was initially present in excess. If the reaction occurs by a His87-bridged transition state, the imidazole moiety would be coordinated to the produced inert Co^{III} complex, which remains attached to the protein. In the case of an outer-sphere reaction, on the other hand, the Co^{III} aqua complex would be formed, and no metal would be bound to the protein. The amount of the fixed Co^{III} is then obtained by comparison of the final CD spectrum with the spectrum of the corresponding Co^{III} complexes containing H_2O or imidazole (or histidine) at the sixth coordination site. The results shown in Figure 1 indicate that *Λ*-[Co((*S*,*S*)-**1**)]

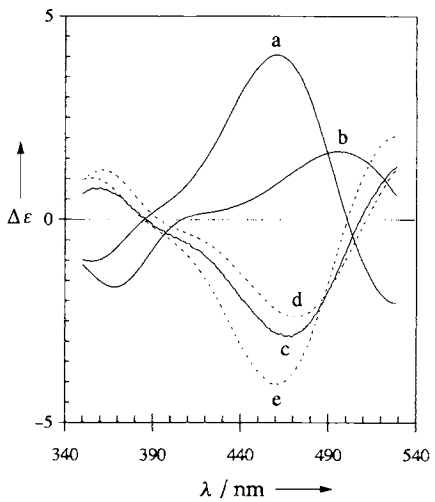


Fig. 1. Circular dichroism spectra of the species involved in the reaction at pH 7 (other reaction conditions as indicated in Table 1) of plastocyanin with complexes of Co^{2+} with both enantiomers of **1** and **2**. The solid lines are the residual spectra of the reaction product of PcCu(II) with *Λ*-[Co((*S*,*S*)-**1**)] (a, identical to the spectrum of *Λ*-[Co((*S*,*S*)-**1**)(imidazole)]$^+$), *Λ*-[Co((*S*,*S*)-**2**)] (b, identical to the spectrum of *Λ*-[Co((*S*,*S*)-**2**)H_2O]$^+$), and *Δ*-[Co((*R*,*R*)-**1**)] (c); the dashed lines are the reference spectra of *Δ*-[Co((*R*,*R*)-**1**)H_2O]$^+$ (d) and *Δ*-[Co((*R*,*R*)-**1**)(imidazole)]$^+$ (e). (The residual spectrum for *Δ*-[Co((*R*,*R*)-**2**)] was omitted for clarity.)

is quantitatively fixed, whereas only the aqua complexes are obtained with both enantiomers of [Co(**2**)]. In the case of *Δ*-[Co((*R*,*R*)-**1**)] an intermediate situation is observed: the final spectrum corresponds to a mixture of the imidazole and the aqua complexes.

When the final solution of the reaction with *Λ*-[Co((*S*,*S*)-**1**)] as the reducing agent is dialyzed, the Co^{III} complex formed is completely retained with the protein. Furthermore, reoxidation by $[Fe(CN)_6]^{3-}$ does not restore the initial CD spectrum of the protein in this case. With the two enantiomers of [Co(**2**)], on the other hand, all the Co^{III} complex is eliminated by dialysis and the initial CD spectrum of the protein is obtained on reoxidation. Again the reaction product obtained with *Δ*-[Co((*R*,*R*)-**1**)] shows intermediate behavior. Only part of the Co^{III} formed is removed by dialysis, and the CD spectrum of the Co^{III} complex retained with the protein is identical to that of the imidazole complex, but the intensity is lower than that expected for the total amount of Co^{III} formed.

The question arises whether the Co^{III} center was attached to the protein in a reaction subsequent to the electron transfer. However, when the protein is reduced in the presence of *Λ*-[Co((*S*,*S*)-**1**)H_2O]$^+$ by ascorbic acid, which does not react with the Co^{III} complex in the time scale of interest, no Co^{III} is bound to the protein. Finally, the reagents leading to the Co^{III} aqua complex do not attack at the remote, negatively charged area of the protein, as the reaction rate with all the reagents used is

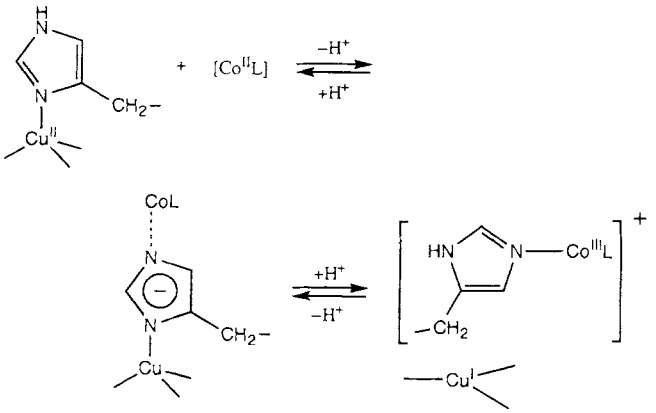
completely unaffected by the presence of highly charged cations like $[Co(NH_3)_6]^{3+}$.

An additional question concerns the exact structure of the transition state involving the bridging imidazole unit of His87. Measurements of the amount of covalently bound Co^{III} at different pH (Table 1) suggest that deprotonation occurs in the transition state and that the metal centers are linked together by the negatively charged imidazole moiety (Scheme 1). This is

Table 1. Relative amount [%] of Co^{III} complexes bound to plastocyanin after electron transfer [a].

pH	Λ-[Co((*S*,*S*)-**1**)]	Δ-[Co((*R*,*R*)-**1**)]	Λ-[Co((*R*,*R*)-**2**)]	Δ-[Co((*S*,*S*)-**2**)]
5.5	80	13	–	–
6.0	>95	21	–	–
7.0	ca. 100	40	0	0
8.0	ca. 100	50	–	–

[a] Determined from CD spectra; error limit ±5%; reaction conditions: $[PcCu^{II}] \approx 10^{-4}$ M, $[Co^{2+}]_{tot} = [ligand]_{tot} = 10^{-3}$ M, [buffer] = 0.1 M (phosphate), $T = 20$ °C.



Scheme 1. Electron transfer reaction between Λ-[Co((*S*,*S*)-**1**)] and $PcCu^{II}$ at His87 (site a) and the possible structure of the transition state.

analogous to what is known for the binding between Cu^{2+} and Zn^{2+} in superoxide dismutase[11] or in corresponding model systems.[12] Even at pH 5.5, 80% of the Co^{III} species still remains attached to the protein in the reaction with the Λ-[Co((*S*,*S*)-**1**)], whereas the reaction with its enantiomer Δ-[Co((*R*,*R*)-**1**)] under the same conditions affords more than 85% of the aqua complex.

From these results some important conclusions can be drawn. Electron transfer at the hydrophobic area of plastocyanin must occur by at least two different pathways, one of them involving the imidazole unit of His87 as a bridging group (site a). Important information about the pathway used in the outer-sphere mechanism (site b) leading to the aqua complexes is obtained from genetically mutated plastocyanin. Site-directed mutations at Leu12 suggest that the reaction with [Co(**2**)] takes place at a position distant from this amino acid.[13]

However, the most important feature in the present case is that the choice of the different pathways can not only be controlled by the structure of different ligands, but also by their chirality. From the data for Δ-[Co((*R*,*R*)-**1**)] and Λ-[Co((*S*,*S*)-**1**)] at pH 5.5 and 20 °C (Table 1), it is concluded that under these conditions the free activation energy for reaction at site (a) is lower by about 3.4 kJ mol^{-1} for Λ-[Co((*S*,*S*)-**1**)], and for the reaction at site (b) by about 4.6 kJ mol^{-1} for Δ isomer than for the other enantiomer investigated in each case. Interestingly, the measured global free activation energy of the reaction at pH 7 and 19 °C is exactly the same for the two enantiomers (crossing point of the Eyring plots; $\Delta G^{\neq} = 72.2$ kJ mol^{-1}).[14] This clearly shows that site (b) is not simply a bypass for the case when site (a) becomes unfavorable, but that each site definitely favors one of the two enantiomers over the other. Apparently, the enantiomers of a chiral reagent can react with high preference at completely different positions on the protein surface.

A Mobility Filter for the Detection and Identification of Charged Species in Complex Liquid Mixtures by ENMR Phase Difference Spectroscopy**

Stefan R. Heil and Manfred Holz*

NMR experiments in the presence of an electric direct current in the sample under observation (DCNMR) can provide interesting information about charged particles in liquid solutions.[1–4] We and later also other groups have shown that by so-called electrophoretic NMR (ENMR)[5] the migration of simple ions, charged molecules, and charged molecular aggregates can be observed and their mobilities can be measured by applying pulsed field gradient spin-echo (PGSE) techniques in one-dimensional (1D)[2, 3, 7] and two-dimensional (2D) ENMR experiments.[5, 6, 8] In particular 2D ENMR spectroscopy proved to be the method of choice for the investigation of complex systems with charged molecular aggregates, since the charged species can be distinguished from the neutral species due to the fact that their NMR lines appear in a second "mobility dimension".

However, 2D ENMR experiments are restricted to nuclides with a high gyromagnetic ratio γ, for example ^{1}H and ^{19}F, and to systems amenable to relatively high electric fields, which results in comparatively high migration velocities v of the charged species. Consequently, 2D ENMR experiments have been performed previously only with the nucleus ^{1}H.[4, 5] 2D ENMR spectroscopy is hardly feasible for other important nuclides such as ^{13}C, ^{29}Si, and ^{31}P. Furthermore, if in a system of interest the ionic concentration is relatively high and exceeds say 0.5 M, the applied electric fields must be reduced to avoid resistive heating of the sample.[4, 5] Both low electric fields and low mobilities, for example of large molecular aggregates, result in low migration velocities during the experiment, which again restrict the applicability of 2D ENMR spectroscopy. Finally, in principle 2D NMR experiments are more time-consuming than 1D NMR experiments and therefore it is generally worthwhile to search for alternative quick 1D NMR experiments.

We report here on a simple 1D ENMR experiment in which a "mobility filter" is generated such that in a complex NMR spectrum of a multicomponent liquid mixture the resonance lines of electrically charged species can be filtered. In this way the electric charge is introduced as a spectral parameter in the 1D NMR experiment. Such an experiment would not only detect charged particles containing the nucleus under observation, but it should simultaneously allow the identification of these particles by their NMR lines. By repeating measurements with varying experimental parameters the mobilities of the detected species can also be measured. In addition, we demonstrate the practicability of ^{13}C ENMR, which results in an extension of possible applications of this special field of NMR spectroscopy. For this reason we have chosen an aqueous solution of three ^{13}C-containing solutes, namely acetonitrile and ethanol as uncharged components, and the formate ion as a charged solute.

We performed the ^{13}C NMR experiments at 25 °C using a Bruker AM 300 spectrometer operating at 75.45 MHz. The gradient unit, the constant current power supply for the electrophoretic cell, and the ENMR probehead are described elsewhere.[7] In the sample cell we used platinated Pt electrodes and applied electric fields of typically $0.5-4\,V\,cm^{-1}$, resulting in pulsed electric currents of 12.5–100 mA in the sample. The simplest PGSE pulse sequence for ENMR experiments is given in Figure 1. The actual values for the gradient pulse sequence were $\delta = 1.5$ ms, $\Delta = 150$ ms, and the gradient strength G could be varied between 0 and approximately $0.5\,T\,m^{-1}$. The composition of the liquid mixture given by the mole fractions x of the four components was: $x(H_2O) = 0.81$, $x(CH_3CN) = 0.06$, $x(CH_3CH_2OH) = 0.05$, and $x(HCOONa) = 0.08$. The measurements were performed in a solution not stabilized by a gelling agent.

The basic idea of our mobility filter is described by the following. In an ENMR experiment only charged particles move with constant drift velocity in an electric field. In a PGSE experiment this drift velocity v results in a phase shift $\Delta\varphi = \gamma G v \delta \Delta$ of the NMR signal at $t = 2\tau$,[4, 5] the time at which the echo maximum appears and when the signal acquisition is started. The quantities G, Δ, δ, and 2τ are shown in Figure 1. (Here the reasons for the previously mentioned restrictions of 2D ENMR spectroscopy are evident. In such an experiment phase shifts $\Delta\varphi$ of at least 360° must be achieved.[4, 5] Since the applicable G, Δ, and δ values are limited owing to the spin-echo signal intensity, successful 2D ENMR experiments require high γ and v values.)

Thus, if we record first an NMR spectrum by using the PGSE sequence in Figure 1, in the absence of an electric field and thus in the absence of an electric current I, and if we then record a second ENMR spectrum in the presence of I and subtract the first spectrum from the second, the resulting difference spectrum should no longer contain NMR signals from uncharged species, since their signals are theoretically equal in both experiments, whereas the signals of charged particles experience a characteristic phase shift $\Delta\varphi$.

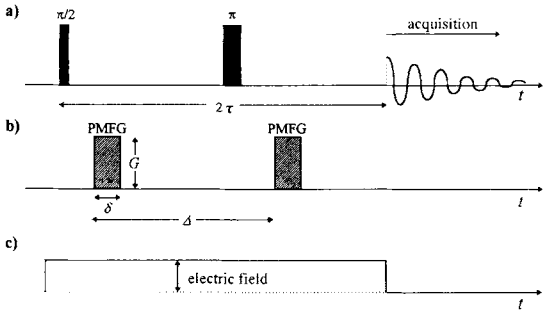

Fig. 1. Pulse sequence for a PGSE experiment in electrophoretic NMR spectroscopy. a) High-frequency pulses; b) magnetic field gradient pulses; c) electric field pulse applied in the sample cell. Signal acquisition starts at 2τ.

Therefore, we applied the following procedure and illustrate it with the results of our ^{13}C ENMR experiment (Fig. 2; the spectra a) and b) show the undecoupled ^{13}C NMR signals of the three aforementioned solutes in the range of higher chemical shifts).

1) Signal acquisition (as in Fig. 1) of the mixture without applied electric field ($I = 0$). If in the very first step (0) an original spectrum is also recorded without gradient pulses, steps 0) and 1) correspond to a normal PGSE experiment for the measurement of self-diffusion coefficients of the different components.[9]

2) Signal acquisition (as in Fig. 1), now with an applied electric field ($I \neq 0$).

3) Fourier transformation and phasing of both spectra. For the phasing procedure a known line of a neutral component in the spectrum from 1) must be used, and finally the spectrum from 2) is phased with identical phasing parameters (Fig. 2a, b). For NMR lines of charged species a phase shift in the spectrum from 2) is evident relative to the spectrum from 1). We emphasize that, as in our case, small phase shifts $\Delta\varphi$ of, for example, 5 to 20° are difficult to observe by simple inspection of the actual spectra.

4) Both spectra are normalized to the same intensity, again using the known line of an uncharged component. We point out that we apply "phase difference spectroscopy" here and thus the absolute intensities play a minor role. (To our knowledge this is the first NMR phase difference spectroscopy experiment, since in common NMR difference spectroscopy line intensity differences are of interest.[10])

5) Spectrum subtraction delivers the difference spectrum (see Fig. 2c). The NMR lines of the neutral species have disappeared and we obtain only non-zero intensities at the position of lines arising from charged species.

6) For a clearer presentation the difference spectrum can be optimized by further data processing, for example further phasing (Fig. 2d).

Inspection of our results given in Figure 2 clearly indicates that the proposed mobility filter works excellently, since in the phase difference spectra c) and d), as expected, only the ^{13}C signal of the formate anion is seen. In spectrum b) the signal-to-noise ratio (S/N) is smaller than that in a) since we had used a smaller number of signal accumulations with $I \neq 0$, with the intention of keeping electrode processes and heating of the sample to a minimum. Convective motion may further reduce

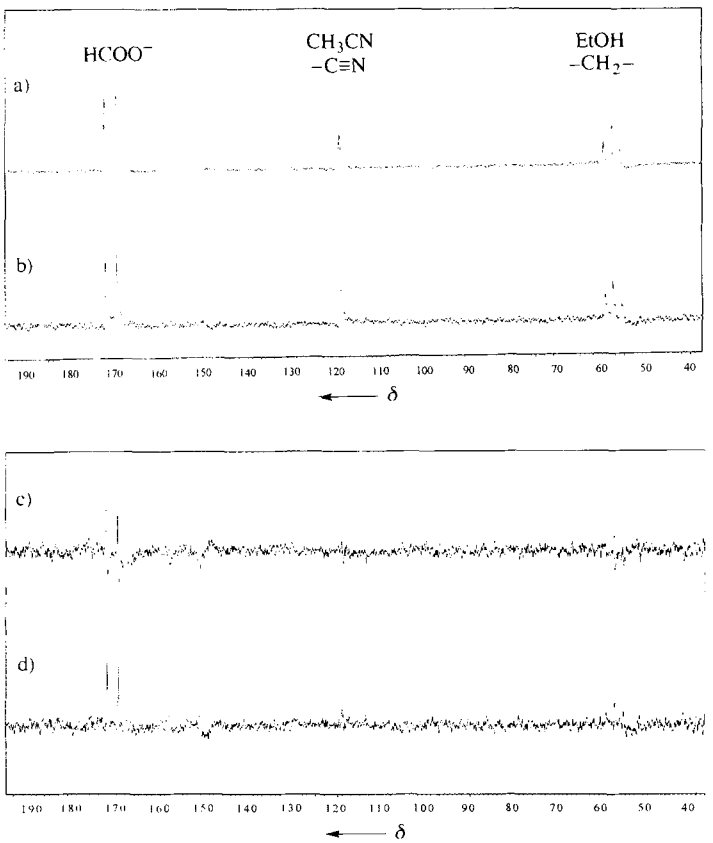

Fig. 2. The high-frequency part of the ^{13}C NMR spectrum of the mixture of water, ethanol, acetonitrile, and sodium formate obtained with the pulse sequence given in Figure 1. a) Electric field off, $I = 0$; b) electric field on, $I \neq 0$; c) phase difference spectrum of a) and b); d) rephased difference spectrum, the "mobility-filtered" spectrum.

the S:N ratio.[11] At the position of the $-^{13}CH_2-$ signal of EtOH and the $-^{13}C\equiv N$ signal of CH_3CN in the difference spectra c) and d) very weak residual signals on the order of the noise intensity can be seen; however, we can state that this small artifact does not affect the effectiveness of the ENMR mobility filter. Of course, in the phase difference spectrum the information about the concentration ratios of the different species in terms of the peak intensities is lost; however, if the lines of the different species are resolved, these ratios can be determined easily from the original spectrum recorded in step 0), by using the assignment gained from the final difference spectrum.

We should add some further general remarks with respect to the phase difference spectroscopy. For this reason we show in Figure 3 a typical NMR line (a) and the phase-shifted line, with varying $\Delta\varphi$ between 0 and 360° (b). The corresponding line shapes in the difference spectrum are also given (c), showing the behavior of the line of interest in the difference spectrum as a function of the shift angle. We recognize two important facts with implications for the application of phase difference spectroscopy. First, the line intensity in the difference spectrum increases with increasing $\Delta\varphi$ between 0 and 180°, reaches twice the intensity of the orignal line at $\Delta\varphi = 180°$, and then decreases at higher angles. Thus, the method has its highest sensitivity when phase shifts of about 180° are produced. Although the typical application of our mobility filter is intended for systems with small shift angles, the experimental aim remains to achieve comparatively high $\Delta\varphi$ values by an appropriate choice of G, Δ, and δ, and the highest applicable electric field (which means the

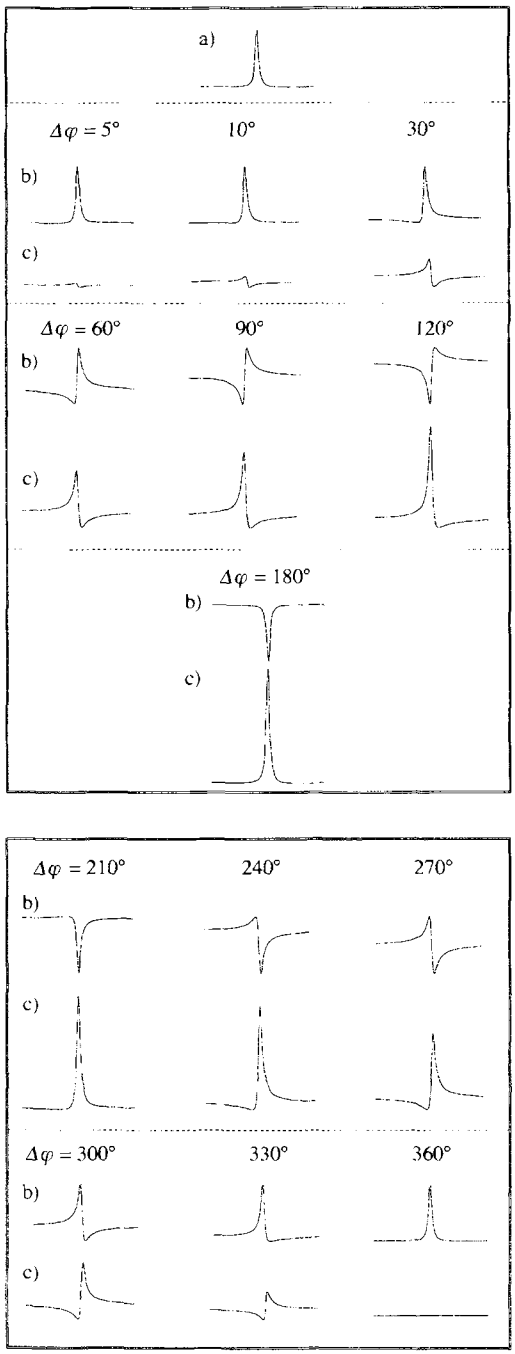

Fig. 3. Signal shapes in NMR phase difference spectroscopy. a) Original typical NMR line; b) the same line as in a) but phase-shifted by $\Delta\varphi$ due to migration of the nucleus-bearing particle in a magnetic field gradient; c) line of interest in the difference spectrum.

highest possible v). Second, we can see from Figure 3 that in those cases in which high phase shifts in the range of 360° can occur, for example with nuclides with high γ values, a problem arises if the phase shift is exactly 360° or generally $n \times 360°$. For this case the intensity is zero in the difference spectrum, and we would not be able to differentiate between neutral and charged species. However, this problem can be easily overcome by performing a second experiment in which one of the parameters—G, Δ, δ, or v—is varied, leading then to a phase shift $\Delta\varphi$ not equal to 360°. But it should be emphasized that in cases with high shift angles the method of choice should be 2D ENMR spectroscopy.

To return to our experiment, it is clear that only charged particles containing carbon are detected in our ^{13}C ENMR experiment. Thus, in the present case the $^{23}Na^+$ ion could not be detected. However, we point out that the sign of the charge of the detected particle is available from the sign of the phase shift generated in the ENMR experiment.[4, 5] In conclusion we can state that the mobility filter described here should provide a good tool for the detection and identification of carbon-containing ions or charged molecules in complex mixtures, in particular if the charged species do not contain hydrogen or only hydrogen atoms that can undergo chemical exchange. In analogy, the same should be valid for charged systems containing ^{29}Si or ^{31}P nuclei. If, as in most organic ions or charged molecular aggregates, suitable hydrogen atoms are present, but the above-mentioned conditions prevent the application of 2D ENMR techniques, an analogous ^1H ENMR mobility filter might even be much better suited than heteronuclear ENMR experiments, due to the sensitivity of ^1H NMR spectroscopy. An interesting additional aspect of the mobility filter is also its possible use for signal assignment. For example, if the charged particles in a mixture are known, a mobility filter with a slightly modified phasing procedure, in which only the lines of charged particles disappear in the difference spectrum, can be used to simplify a complex spectrum and facilitate the assignment of lines of unknown uncharged species.

In these studies we could also demonstrate the feasibility of ^{13}C ENMR spectroscopy, and we will briefly mention the advantages and disadvantages of ^{13}C ENMR. As can be seen in Figure 2 the main advantage is the large chemical shift range in ^{13}C NMR spectroscopy, which results in a well-resolved spectrum even though no sample spinning techniques are applied currently in ENMR studies. (Of course switchable sample spinning[12] during the signal acquisition could in principle be possible, but so far this has not been applied in ENMR.) A further advantage of ^{13}C ENMR spectroscopy lies in the typically long T_2 relaxation times, allowing the application of long Δ values, which are favorable in ENMR experiments.[4, 5] The disadvantage of ^{13}C NMR is its low sensitivity; relatively high signal accumulation numbers are required, which in certain ENMR experiments can lead to problems with electrode processes such as changing concentrations of charged particles during the experiment.

Finally, it should be emphasized that in addition to qualitative results like those described here obtained with the mobility filter, quantitative information can also be derived from the ENMR experiment if required. As already mentioned, information about the single components can be obtained by repeating the experiment, for example, with different G values, which delivers as a byproduct the translational diffusion coefficients D.[9] Moreover, analysis of the phase shift $\Delta\varphi$ as a function of the applied electric current I yields the electrophoretic mobility u.[4, 5] For example, in our experiment we obtain the following results for the previously mentioned mixture at 25 °C: $D(CH_3CN) = 1.4 \times 10^{-9}\ m^2 s^{-1}$, $D(EtOH) = 1.1 \times 10^{-9}\ m^2 s^{-1}$, and $D(HCOO^-) = 1.3 \times 10^{-9}\ m^2 s^{-1}$. The mobility of the formate ion is found to be $u^- = 6.3 \times 10^{-8}\ m^2 s^{-1} V^{-1}$. The data, derived here only for demonstration purposes from experiments with five different G and I values, have a relatively high experimental error of 15%. Unfortunately, our quantitative results cannot be compared with literature data, because this particular mixture has not been investigated previously. However, we want to point out that the diffusion coefficient and in particular the mobility of the formate ion in this multicomponent mixture are unexpectedly high compared with the values in pure water ($u^- = 4.2 \times 10^{-8}\ m^2 s^{-1} V^{-1}$). We ascribe this increased translational mobility of the ion to the influence of the component acetonitrile, since the u and D values in the acetonitrile-free mixture were, as expected, close to those in pure water.

Enzymatic Synthesis of a Characteristic Phosphorylated and Glycosylated Peptide Fragment of the Large Subunit of Mammalian RNA Polymerase II**

Torsten Pohl and Herbert Waldmann*

The transduction of signals from the extracellular space across the plasma membrane into the interior of the cell and ultimately to the cell nucleus in general is achieved by employing covalently modified proteins.[1] Among the different types of covalent protein modification, in particular, the dynamic phosphorylation and dephosphorylation of hydroxyamino acids[2] but also the β-O-glycosidic attachment of single N-acetylglucosamine (O-GlcNAc) residues to serine and threonine units of intracellular proteins[3] mediate the intracellular response to a wide variety of extracellular stimuli. An illustrative example is provided by mammalian RNA polymerase II[4] **1** (Scheme 1). In its cytosolic form the C-terminal domain of its large subunit is heavily glycosylated, probably to facilitate the transport of the enzyme into the cell nucleus. During the intranuclear transition of RNA polymerase II from an initiating to an elongating transcription complex the GlcNAc glycosides are removed and the protein is rapidly and repeatedly phosphorylated. Thus, O-GlcNAc may mask or tag phosphorylation sites, and the covalent modifications with both O-GlcNAc and phosphate fulfil a decisive role in the expression of genes that are transcribed under control of RNA polymerase II.

To study the biological phenomena associated with such covalently modified protein conjugates appropriate tools are needed. The use of characteristic partial structures of the parent proteins that embody both types of modifications as well as

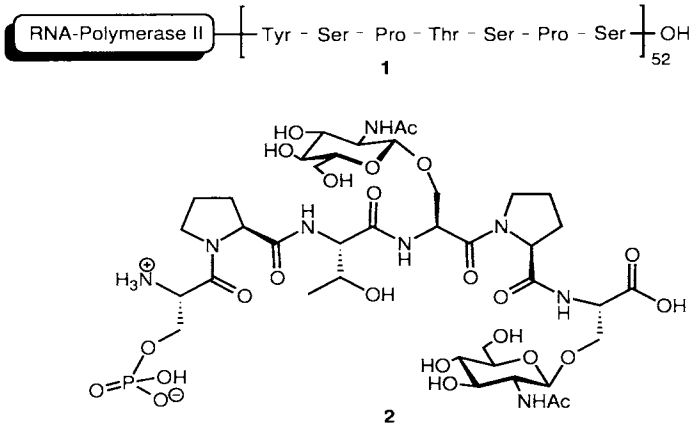


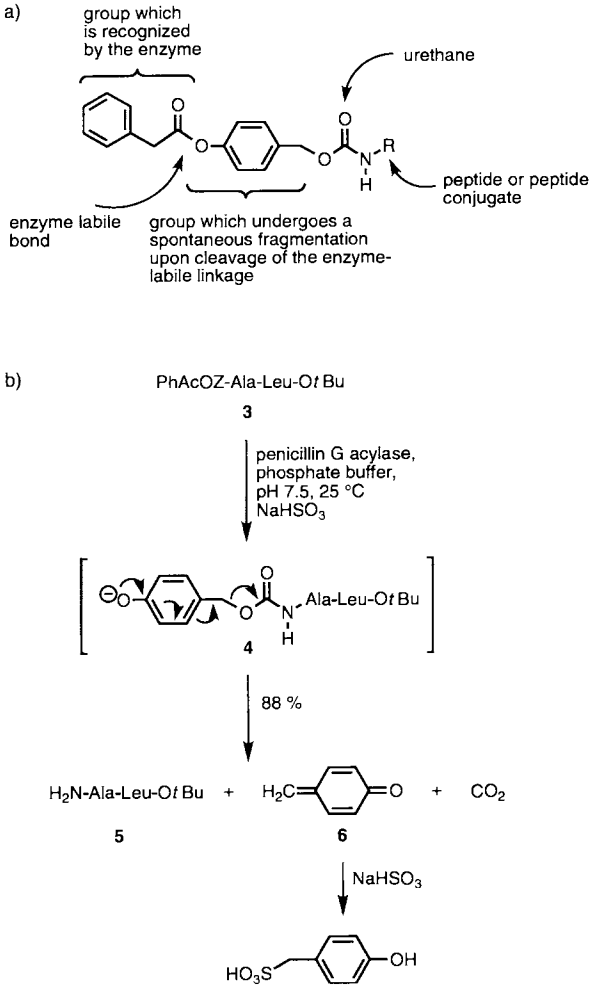
Scheme 1. Repeat sequence **1** of the large subunit of mammalian RNA polymerase II and the structure of the phosphorylated and glycosylated hexapeptide target **2**.

underivatized hydroxyamino acids may open up new opportunities for bioorganic investigations, for example for the generation of monoclonal antibodies (O-GlcNAc-modified peptides are highly antigenic[3]), or for inhibition and microinjection studies. However, the synthesis of phospho-[5] or glycopeptides[6] alone is severely complicated by their pronounced acid and base sensitivity as well as their multifunctionality which make the application of a variety of protecting groups necessary that can be removed selectively under very mild, preferably neutral conditions. In the construction of peptides that embody both modifications these difficulties are potentiated and, consequently to date the synthesis of phosphoglycopeptides has not been described.

We now report that such multifunctional and sensitive peptide conjugates can advantageously be built up under very mild conditions (pH 7.5, 25 °C) by employing enzymatic protecting group techniques.[7] The hexapeptide **2**, which carries one phosphorylated, two glycosylated, and one unmodified hydroxyamino acid, was chosen as biologically relevant target.[8] Compound **2** represents a characteristic partial structure of the repeat sequence of the large subunit of mammalian RNA polymerase II which becomes glycosylated or phosphorylated while the enzyme carries out its biological functions (vide supra).

For the choice of appropriate enzyme-labile blocking functions we have drawn from our previous experience in the biocatalyzed synthesis of multifunctional and sensitive peptide conjugates.[9] As enzymatically removable N-terminal blocking group the *p*-phenylacetoxybenzyloxycarbonyl (PhAcOZ) group was developed, that is a urethane which embodies a functional group (here: a phenylacetate) that is recognized by the biocatalyst (here: penicillin G acylase) and that is bound by an enzyme-labile linkage (here: an ester) to a functional group that undergoes a spontaneous fragmentation upon cleavage of the enzyme-sensitive bond (here: a *p*-hydroxybenzyl urethane) resulting in the liberation of a carbamic acid derivative, which decarboxylates to give the desired peptide or peptide conjugate (Scheme 2).

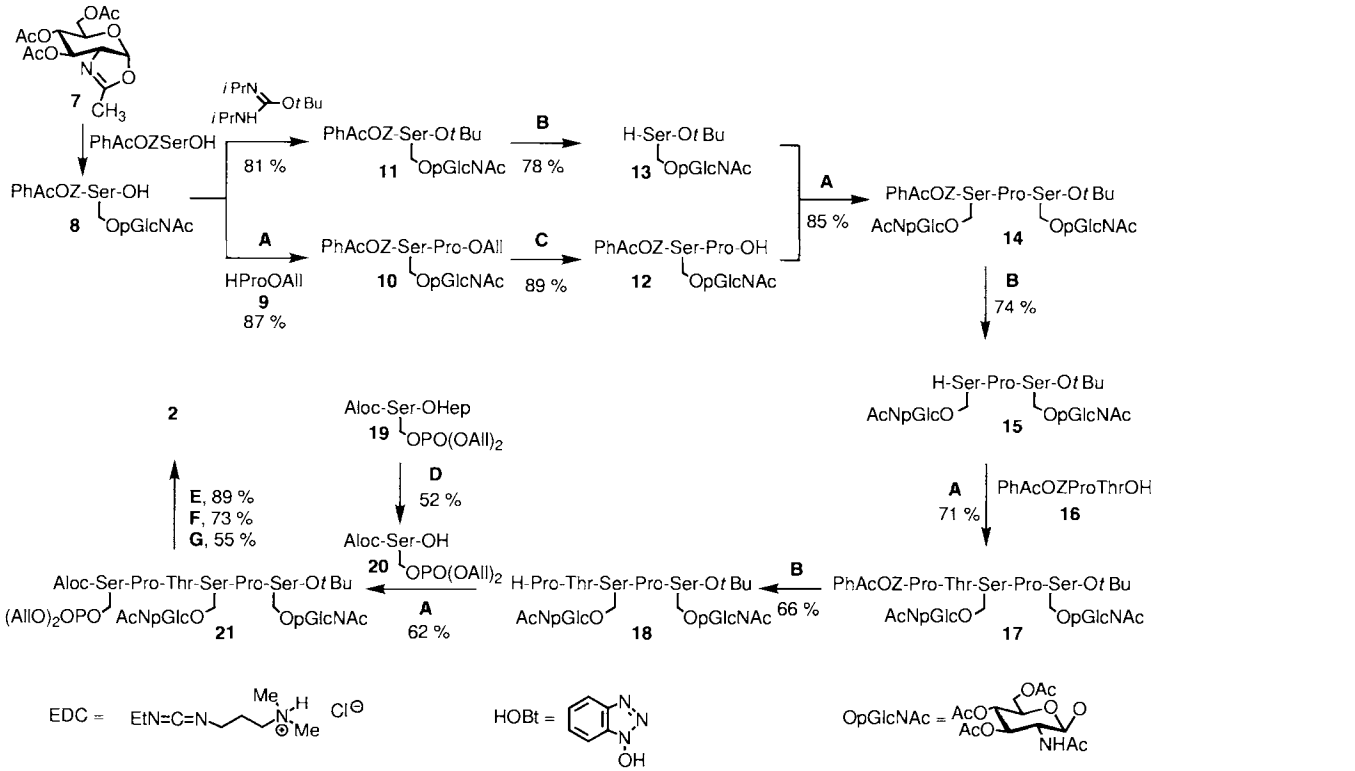
In an orienting experiment the PhAcOZ-protected peptide **3**[10] was treated with penicillin G acylase, that is an enzyme which specifically recognizes and saponifies phenylacetic acid esters and amides under very mild conditions[11] (Scheme 2). In the course of the ensuing enzymatic reaction the phenylacetate **3** was smoothly hydrolyzed to give the phenolate **4**, which spontaneously fragmented and liberated the peptide **5** in high yield. In this process no undesired side reaction was observed. On the one hand, the quinone methide **6**, which was formed from the phenolate, was trapped by water or—more efficiently—by an



Scheme 2. Enzymatic cleavage of the PhAcOZ group with penicillin G acylase. a) Concept for the cleavage; b) cleavage of the PhAcOZ protecting group of **3** leading to the formation of **5**.

added nucleophile like $NaHSO_3$, so that an attack of **6** on the liberated amine **5** was completely avoided. On the other hand, the substrate specificity of penicillin acylase guarantees that exclusively the phenylacetic acid ester is cleaved and that the C-terminal ester group and the peptide bonds are left intact.

To build up the complex phosphoglycohexapeptide **2** by means of this advantageous enzymatic method, the PhAcOZ-protected serine glycoside **8** was synthesized from the oxazoline **7**[12] and PhAcOZ-Ser and then condensed with proline allyl ester **9** to give the completely protected glycodipeptide **10** in high yield (Scheme 3). From **10** the C-terminal ester was selectively removed by Pd^0-mediated allyl transfer to morpholine to give **12**.[13] In addition, **8** was masked as *tert*-butyl ester **11**, which could be deprotected under very mild conditions at the N-terminus by penicillin G acylase catalyzed cleavage of the PhAcOZ-urethane to give **13**. The selectively unmasked glycosylated fragments **12** and **13** were then coupled to give a high yield of the diglycotripeptide **14**, whose N-terminal blocking group was removed by penicillin G acylase induced fragmentation of the PhAcOZ-urethane under virtually neutral conditions. This gave the selectively deprotected diglycotripeptide **15** whose amino acid chain was readily elongated by condensation with the PhAcOZ-masked dipeptide carboxylic acid **16**.[14] Furthermore, from the resulting complex and sensitive diglycopentapeptide **17** the PhAcOZ group was cleaved with penicillin G acylase to



Scheme 3. Enzymatic synthesis of the phosphoglycohexapeptide **2**. A) EDC, HOBt (2 equiv:2 equiv); B) penicillin G acylase, 0.07 M phosphate buffer, 30 vol% methanol, $NaHSO_3$ (500 equiv), pH 7.5, 25 °C; C) $[Pd(Ph_3P)_4]$, morpholine (1.1 equiv); D) lipase from *Aspergillus niger*; 0.2 M phosphate buffer (pH 7, 37 °C); E) $[Pd(Ph_3P)_4]$, formic acid:*n*-butylamine (10 equiv: 6 equiv), room temperature; F) trifluoroacetic acid (TFA), room temperature; G) hydrazine hydrate (3000 equiv), methanol, room temperature.

deliver a satisfactory yield of the selectively unmasked intermediate **18**, which embodies two glycosylated and one unfunctionalized hydroxyamino acid. To guarantee that the PhAcOZ-protected substrates are soluble under the reaction conditions and thereby accessible to the biocatalyst, the enzymatic transformations are most advantageously carried out in the presence of 30 vol% of methanol as cosolvent.

For the subsequent introduction of a phosphorylated, that is differently modified serine residue, the phosphoserine **20** was required. Compound **20** was synthesized by selective saponification of the heptyl ester present in the fully masked phosphoserine derivative **19** with lipase from *Aspergillus niger*[15] under very mild conditions. Finally, **18** and **20** were condensed to give the desired complex multifunctional phosphoglycohexapeptide **21**.[16]

Finally, all allylic protecting groups were removed simultaneously by treatment with formic acid/*n*-butylamine at room temperature in the presence of $[Pd(Ph_3P)_4]$.[17] Subsequently, the *tert*-butyl ester was cleaved with trifluoroacetic acid, and the selective unmasking of the hydroxy groups of the carbohydrates was achieved by employing hydrazine hydrate in methanol.[18]

In all enzymatic and nonenzymatic transformations described above, no undesired side reactions were observed. Thus, the peptide bonds and the O-acetates in the carbohydrates as well as the phosphate remained intact. In addition, an anomerization or cleavage of the glycosidic bonds which may occur under acidic conditions[19] as well as a β-elimination of the phosphate or the carbohydrates which has to be feared under basic conditions[18, 20] could not be detected.

In conclusion, we have developed an enzymatic strategy for the synthesis of differently functionalized complex peptide conjugates and demonstrated its usefulness in the first construction of a phosphoglycohexapeptide that represents a characteristic partial structure of the C-terminal repeating domain of the large subunit of mammalian RNA polymerase II. By using this technique further O-phosphorylated and O-glycosylated peptide conjugates are potentially accessible, which may open up new avenues of research in bioorganic chemistry and biology.

Semisynthesis of Taxol: A Highly Enantio- and Diastereoselective Synthesis of the Side Chain and a New Method for Ester Formation at C13 Using Thioesters**

Cesare Gennari,* Anna Vulpetti, Monica Donghi, Nicola Mongelli, and Ermes Vanotti

Paclitaxel (Taxol, **1**), isolated from the bark of the Pacific yew *Taxus brevifolia*, is considered the most promising cancer chemotherapeutic agent and has recently been approved for treatment of metastatic ovarian and breast cancer.[1] It is also undergoing clinical trials in non-small cell lung cancer, head and neck cancer, glioblastoma, and esophageal cancer. The scarcity of **1** and its highly challenging structure have stimulated interest in its synthesis. Central to all synthetic strategies is the attachment of the C13 side chain to the baccatin III nucleus, since the presence of this side chain has proven to be essential for the biological activity of **1**.[1] Owing to the chemical complexity of Paclitaxel (**1**), its commercial production by total synthesis is not likely to be economical. However, the naturally derived 10-deacetylbaccatin III (**2a**, Scheme 1) is readily available in relatively high yield from the needles of the European yew *T. baccata*. Preparation of quantities of Paclitaxel economically by semisynthesis by condensing suitably protected 10-deacetylbaccatin III (**2b,c**) with suitably protected *N*-benzoyl-(2*R*,3*S*)-3-phenylisoserine (**3**) provides an alternative source of this important natural product and access to semisynthetic analogs. Therefore, the development of short and practical synthetic routes to phenylisoserine derivatives, as well as procedures for attaching the C13 side chain to the baccatin III nucleus, which are adaptable for industrial-scale production, have become very important.

The numerous papers devoted to the preparation of enantiomerically enriched **3** include research on semisynthesis drawing from the chiral pool, enzymatic and/or microbial processes, diastereoselective reactions with covalently bound chiral auxiliaries or with chiral substrates, asymmetric catalysis, and chemical resolution of racemic carboxylic acids.[1] In contrast, only a few reactions have been developed to attach the side chain to the free OH group at C13 of baccatin derivatives. This esterification reaction appears to be hampered by the steric congestion around the C13 OH group. Essentially only two general methods have been developed to solve this problem: the first one relies on the dicyclohexylcarbodiimide protocol by Rhône-Poulenc/Gif/Grenoble,[2, 3] and the second one on the β-lactam protocol by Holton et al. and Ojima et al.[4]

We have developed a very simple, new, straightforward approach to the Paclitaxel side chain using the imine addition reaction of thioester-derived boron enolates bearing chiral ligands.[5–7] The side chain is assembled in one step with the correct relative (*syn*) and absolute stereochemistry (2*R*,3*S*). The easily accessible *tert*-butyl (benzoyloxy)thioacetate (**4**)[8] was enolized with triethylamine and the chiral boron reagent **5** derived from (+)-menthone,[6] and then treated with *N*-(trimethylsilyl)benzaldimine (**6**)[9] (Scheme 2). After quenching and extraction, the crude product was transformed into the amine hydrochloride. Salt formation freed the reaction product from the boron ate complex and all of the by-products could be removed simply by washing the resulting white solid with ether. Treatment with buffered MeOH/H_2O at pH 8.0 caused clean intramolecular COPh migration from oxygen to nitrogen[10] to give the desired compound **7**, which was isolated in practically pure form by simple solvent extraction. The overall yield is around 60% (starting from **4**), and the stereochemical control is high (*syn*:*anti* ≥ 96:4; *ee* ≥ 96%).[11] Treatment of **7** with 2-methoxypropene and pyridinium toluene-4-sulfonate (PPTS)

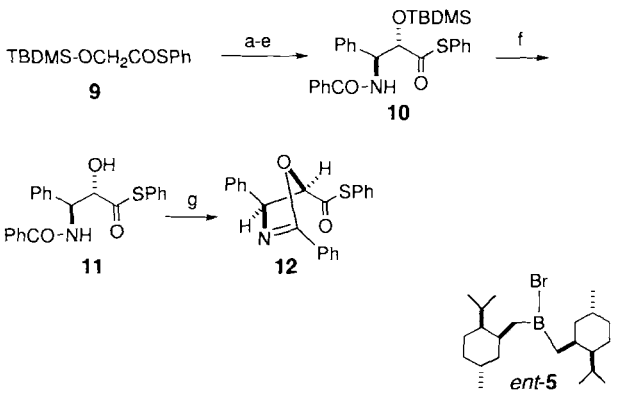
in toluene smoothly furnished oxazolidine **8** (≥90%), and the small amount of the unwanted *anti* diastereomer was removed in this step by chromatography (the *anti* compound does not cyclize under these conditions). The absolute configuration was checked by chemical correlation to known intermediates,[12] and the enantiomeric excess was determined by ^1H NMR analysis of the Mosher ester derivative of **7**.[13]

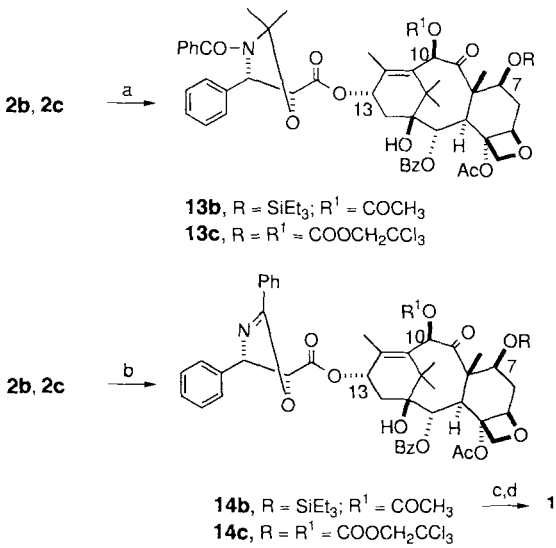
Following a different approach, the easily accessible phenyl (*tert*-butyldimethylsilyloxy)thioacetate (**9**)[14] was enolized with triethylamine and *ent*-**5**, the chiral boron reagent derived from (−)-menthone,[6] and then treated with *N*-(trimethylsilyl)benzaldimine (**6**)[9] (Scheme 3). After quenching and extraction, the



Scheme 3. a) *ent*-**5** [6], Et_3N, CH_2Cl_2, Et_2O, 0 °C → room temperature, 5 h; b) $PhCH{=}NSiMe_3$ (**6**), $-78\,^{\circ}C \rightarrow -5\,^{\circ}C$; c) quenching with phosphate buffer (pH 7), extraction with CH_2Cl_2, concentration to dryness; d) 0.25 N HCl in MeOH/H_2O (1/1), room temperature; concentration to dryness; e) PhCOCl, Et_3N, CH_2Cl_2, 4-dimethylaminopyridine, 0 °C; workup and chromatography (71% yield over steps a–e); f) HF, CH_3CN, H_2O, 100%; g) $SOCl_2$, $CHCl_3$, 45 °C; 1,2-dichloroethane, 100 °C, 65%.

crude product was transformed into the amine hydrochloride to free the reaction product from the boron ate complex. The white solid salt was then treated with PhCOCl, Et_3N, and a catalytic amount of 4-dimethylaminopyridine, and the resulting crude product was purified by filtration through silica gel to give the *anti* compound **10** and traces of the *syn* diastereomer.[11] The overall yield was 71% (starting from **9**), the *anti*:*syn* ratio is 97:3, and the major *anti* compound (**10**) is ≥95% enantiomerically pure (average over several experiments). The *anti* compound **10** (and traces of the *syn* isomer) was then treated with aqueous HF in acetonitrile, and the resulting crude compound **11** (100%; *anti*:*syn* 97:3, average over several experiments)[11] was cyclized by treatment with thionyl chloride in refluxing 1,2-dichloroethane. Oxazoline formation occurred uneventfully with complete inversion of stereochemistry at the C2 stereocenter[10a, 15] to give **12** (65% yield, average over several experiments), and traces of the unwanted *syn* diastereomer were removed in this step by chromatography (the *syn* compound does not cyclize under these conditions). The absolute configuration was checked by chemical correlation with known intermediates,[16] and the enantiomeric excess was determined by ^1H NMR analysis of the Mosher ester derivative of **11**. The synthesis of **12** has an overall yield of 46% (starting from **9**) and requires only two chromatographic purifications.

Thioesters **8** and **12** were attached directly to the baccatin nucleus. By treatment of a mixture of **2b**[2a] or **2c**[17] and **8** or **12** with $LiN(SiMe_3)_2$, the 13-O-acylated compounds **13** and **14** were obtained with high conversion and yield (74–75% for **13** and 89–90% for **14**, Scheme 4).[5] The use of lithium amides for



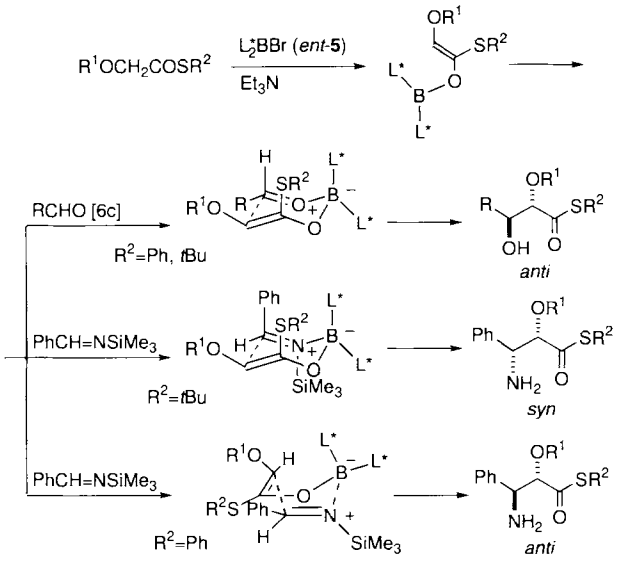
Scheme 4. a) **8** (3.5 equiv), $LiSi(Me)_{32}$ (2.0 equiv), THF, 24 h at 0 °C, 74–75%; b) **12** (3.5 equiv), $LiSi(Me)_{32}$ (4.5 equiv), THF, 15 min at 0 °C, 89–90%; c) 0.04 N HCl in MeOH/H_2O (1.5/1), 60–80 °C; d) $NaHCO_3$, H_2O, pH 7.5, 16 h, room temperature, (80% yield over steps c and d).

metalation of the C13 OH group of protected baccatin III is well precedented.[4a–c] The most surprising, yet gratifying aspect of this new coupling reaction is the high reactivity of the thioester derivatives, given the scarcity of methods for this important transformation and its difficulty. Thioesters have attracted the interest of organic chemists since the discovery that they are used by Nature in enzymatic acylation processes.[18] The resonance overlap of the lone-pair electrons with the carbonyl group is much weaker for the sulfur atom than for the oxygen atom, thus a thioester carbonyl group is much less stabilized by resonance than the carbonyl group of an ester, and is therefore much more reactive.[18] In addition, thioesters **8** and **12** are particularly electrophilic due to presence of electron-withdrawing substituents in both the α and β position.

Compounds **13**[2b–d] and **14**[3] have been deprotected to give Paclitaxel (**1**) in high yields. In our preferred route **14b** is hydrolyzed to give **1** in 80% yield. This represents the third original approach (after the two described in the introduction)[2–4] for the attachment of the Paclitaxel side chain.

From a mechanistic standpoint, the stereochemical divergence of the reactions of aldehydes[6c] and imines was reason-

ably expected based on the different coordination of aldehydes and *trans* imines to the boron atom in chairlike transition state structures (cf. the two chair transition state structures in Scheme 5). However, the stereodivergence caused by the type of thioester (COSPh vs. COS*t*Bu) in the addition to imines is quite surprising. The stereochemical outcome can be rationalized by using corresponding chair and boat transition structures (Scheme 5).[19] However, there is no obvious explanation why this strong stereocontrol is operating as a function of R^2. Experiments not reported here show that the role of the oxygen protecting group R^1 is relatively minor.



Scheme 5. Transition state models for the boron aldol addition to imines. Products with *anti* configuration arise from attack on the *Re* face of the aldehyde or imine, products with *syn* configuration from attack on the *Si* face.

Asymmetric Epoxidation of Enones With Oxygen in the Presence of Diethylzinc and (*R*,*R*)-*N*-Methylpseudoephedrine**

Dieter Enders,* Jiqun Zhu, and Gerhard Raabe

The asymmetric epoxidation of C–C double bonds plays an important role in the synthesis of optically active organic compounds. In 1980 Sharpless et al. reported the titanium-mediated enantioselective epoxidation of allylic alkohols with *t*BuOOH,[1] which was later achieved catalytically by addition of molecular sieves.[2] Based on cationic salen–manganese complexes Jacobsen et al.[3] and Katsuki et al.[4] developed an efficient method for the enantioselective epoxidation of unfunctionalized olefins.

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft (Leibniz Prize), and the European Union (HCM network: Metal Mediated and Catalysed Organic Synthesis). We are obliged to the companies Degussa AG, BASF AG, Bayer AG, Hoechst AG, and Knoll AG for donations of chemicals.

The asymmetric epoxidation of chalcone in high optical yields was achieved by Juliá et al. with H_2O_2/NaOH in a three-phase system over chiral polypeptides.[5] However, the success of this method is as yet usually limited to chalcones.[6] Other methods for the enantioselective epoxidation of α,β-unsaturated ketones, for example by use of benzylquininium chloride,[7] bovine serum albumin,[8] cyclodextrins,[9] or chiral platinum complexes,[10] generally gave only low to moderate enantiomeric excesses.

We now report a new method for the enantioselective epoxidation of α,β-unsaturated ketones **1** with O_2 in the presence of Et_2Zn[11] and (*R,R*)-*N*-methylpseudoephedrine to afford the chiral α,β-epoxyketones (*R,S*)-**2** (Scheme 1). The epoxidation proceeds with excellent yields (94–99%), virtually complete diastereoselectivities (*de* > 99%), and except for one case, with high enantiomeric excesses (*ee* = 61, 82–92%) (Table 1). The

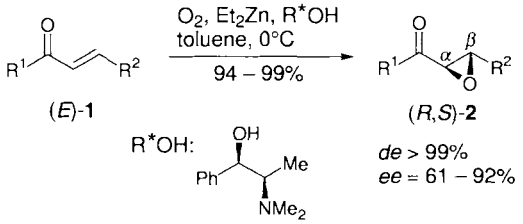
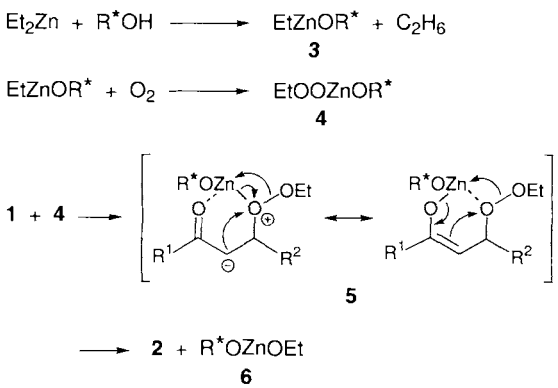
chiral alcohol (*R,R*)-*N*-methylpseudoephedrine employed is readily accessible from cheap (*R,R*)-pseudoephedrine by methylation[12] and can be virtually quantitatively recovered after the reaction by a simple chromatographic elution (Scheme 1).



Scheme 1. Asymmetric epoxidation of enones with O_2 in the presence of Et_2Zn and *N*-methylpseudoephedrine.

The epoxidation, which is carried out as a "one-pot" reaction probably proceeds as follows:[14] Firstly, ethyl zinc alkoxide **3** is formed from diethylzinc and the chiral alcohol.[15] The expected evolution of a gas (ethane) was observed. The substitution of the second ethyl group by an alkoxy ligand is very slow. Therefore, insertion of O_2 into the Zn–C bond between the remaining ethyl ligand and the zinc atom is preferred.[16] In the course of this process the chirally modified alkoxy(ethylperoxy)zinc **4** is formed. The measurement of the absorption of oxygen by a solution of **3** in toluene at room temperature gave a value of 25.8 mL (1.06 mmol). According to the Van der Waals equation absorption of 26.9 mL O_2 was expected for 1.1 mmol **3**. After removal of the solvent in vacuo, **4** remained as a colorless powder. Upon addition of **4** to an aqueous Fe^{II} solution, oxidation to Fe^{III} occurs, which can be proved by the characteristic color change upon treatment with $K_4[Fe(CN)_6]$ and KSCN.[17] It is likely that **4** is the species that actually epoxidizes the α,β-unsaturated ketones asymmetrically. In the epoxidation process the oxygen of the carbonyl function first coordinates the zinc atom in **4**, with concomitant attack of the ethylperoxy anion in β-position to form the intermediate **5**. This reaction constitutes a Michael-type addition. The subsequent cyclization gives the epoxyketone **2** and **6**.[18] In this way, *trans*-epoxides are exclusively formed from (*E*)-α,β-unsaturated ketones (*de* > 99%).[19] Since the reaction rate strongly decreases upon introduction of voluminous groups adjacent to the carbonyl function (see **2f**, **2g**), the formation of **5** is probably the rate-determining step. Upon hydrolysis of **6** the chiral amino alcohol is formed, which can be virtually quantitatively recovered with unchanged enantiomeric purity (Scheme 2).



Scheme 2. Proposed reaction mechanism for the asymmetric epoxidation of enones.

The substituents R^2 in β-position have only a slight influence on the enantioselectivity. Only the phenyl group leads to a significant decrease in the enantiomeric excess (see **2e**). In the scope of this work 35 chiral alcohols such as (*S*)-1-phenylethanol, (*R,R*)-*N*-ethylpseudoephedrine, (−)-menthol, (−)-8-phenylmenthol, (*S*)-2,2-dimethyl-1,3-dioxolan-4-methanol, as well as nine solvents were tested in the asymmetric epoxidation of enones. (*R,R*)-*N*-Methylpseudoephedrine and toluene proved to be best suited. The stereochemical result (that is, the *trans*-(*R,S*) configuration of the epoxyketones **2**) can be explained by means of the transition states **A** or **B** with *R* or *S* configuration at the zinc atom, respectively, which are depicted in Figure 1. In this picture the chiral alkoxy(ethylperoxy)zinc **4** attacks the *si* face of the s-*cis* conformation of the (*E*) enones in the fashion of an oxa-Michael addition. Transition state **A** shows particularly well that the steric hindrance between R^1 and

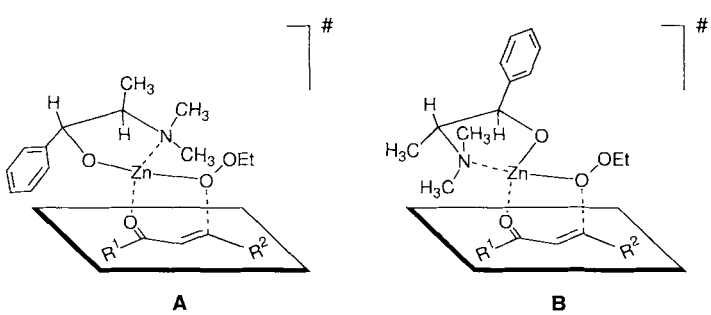


Fig. 1. Postulated transition states for the asymmetric epoxidation.

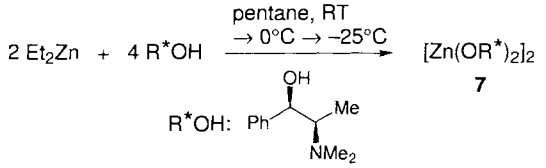
the phenyl group as well as the interaction between R^2 and the dimethylamino group, which are caused by a rotation of the enone plane by 180°, significantly impedes the attack at the *re* face of the enone.

The zinc bis-alkoxide **7** was obtained by the reaction of two equivalents of (*R*,*R*)-*N*-methylpseudoephedrine with diethylzinc in pentane (Scheme 3). However, **7** does not react with the enones **1** under standard conditions. As can be seen from Figure 2, the zinc bis-alkoxide **7** exists as a dimer in the solid



Scheme 3. Preparation of the chiral zinc bis-alkoxide **7**. RT = room temperature.

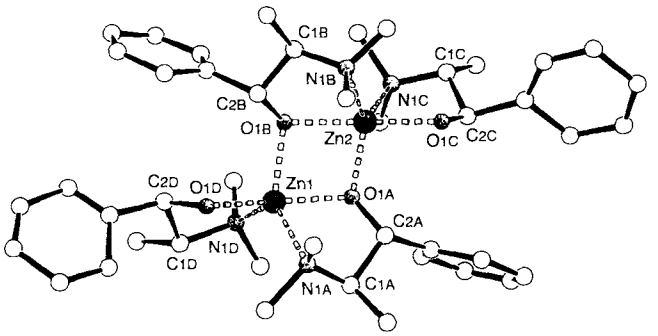


Fig. 2. Structure of the enantiomerically pure zinc bis-alkoxide **7** in the solid state (SCHAKAL plot).

state[20] in which the zinc atoms are surrounded by three oxygen and two nitrogen atoms each to form a distorted trigonal bipyramid (coordination number 5).[21] The structure is C_2-symmetrical and is, to the best of our knowledge, the first crystal structure of a chiral zinc bis-aminoalkoxide.

This new method for the zinc-mediated asymmetric epoxidation of α,β-unsaturated ketones opens an efficient diastereo- and enantioselective access to *trans*-configured α,β-epoxyketones. The use of the cheap chemicals O_2 and Et_2Zn as well as the possibility of recovering the employed chiral additive quantitatively makes this method interesting also in terms of industrial applications. Further work on the optimization of the method and extension to other electron-deficient alkenes is underway.[22]

Experimental Procedure

Asymmetric epoxidation of α,β-unsaturated ketones **1**: A solution of diethylzinc in toluene (1.0 mL, 1.1 M) was added to a stirred solution of (1*R*,2*R*)-*N*-methylpseudoephedrine ([23], 2.4 mmol) in dried toluene (10 mL) in a 50 mL Schlenk flask under an argon atmosphere at 0 °C. After 80 min a slight O_2 pressure was applied from a balloon filled with O_2 so that the argon inside the flask was not removed. After stirring for 2.5 h the reaction mixture was cooled to −78 °C and α,β-unsaturated ketone **1** (1 mmol in 2 mL dried toluene) was added. The reaction mixture was stirred for 30 min at this temperature and then rapidly warmed up to 0 °C (ice/water bath) under constant stirring [24]. At the end of the reaction (TLC control), aqueous phosphate buffer solution (8 mL, pH 7) was added. After the separation of the layers and extraction of the aqueous layer with dichloromethane, the combined organic layers were dried over Na_2SO_4 and concentrated. After purification by flash chromatography (ether/petroleum ether 1/24 to 1/4) the α,β-epoxyketones **2** were obtained [25]. (*R*,*R*)-*N*-Methylpseudoephedrine could be recovered virtually quantitatively with an unchanged enantiomeric purity from the same chromatographic column with a polar eluent (methanol/ether 1/9, mixed with 1 vol% isopropylamine).

[20] X-ray crystal analysis of **7**: monoclinic, space group $P2_1(4)$, $a = 13.988(2)$, $b = 18.846(17)$, $c = 14.141(9)$ pm, $\beta = 106.09(2)^\circ$; 25 reflections, $12.23^\circ < \theta < 16.98^\circ$; $Z = 2$, $V = 3581.8$ Å^3, $M_r = 1202.29$, $\rho_{calcd} = 1.115$ g cm^{-3}. The crystal was measured directly without capillary in a stream of cold nitrogen ($T = 190$ K), $F(000) = 1288$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $\sin\theta/\lambda_{max} = 0.651$, $\mu = 7.32$ cm^{-1} (no absorption correction), $R_{int} = 0.102(30)$, 4963 observed reflections ($I > 2\sigma(I)$) in the range $-18 < h < 17$, $0 < k < 24$, $0 < l < 18$. The structure was solved by the heavy atom method (SHELXS86 [26]), refinement with XTAL3.2 [27]. 4963 reflections in final least-squares full-matrix refinement of 410 parameters. $R = 0.103$, $R_w = 0.077$ ($w = 1/\sigma^2$). $S = 2.717$, residual electron density 1.6 e Å^3. Compound **7** crystallizes with two free molecules of the ligand (disordered) per molecular unit. The poor quality of the crystals allowed only the anisotropic refinement of the Zn atoms and of their immediate environment (O1A–D, N1A–D, C1A–D, C2A–D). All other atomic parameters were refined isotropically. The positions of the hydrogen atoms were calculated. All attempts to prepare crystals of superior quality were unsuccessful. The crystallographic data (without structure factors) of the structure described in this publication were deposited as "supplementary publication no. CCDC-179-57" at the Cambridge Crystallographic Data Centre. Copies of the data can be ordered free of charge from the following address: The Director, CCDC, 12 Union Road, GB-Cambridge CB2 1EZ (fax: Int. code + (1223) 336-033; e-mail: teched(*a*) chemcry.cam.ac.uk)

[21] A related achiral zinc bis-alkoxide structure with C_i symmetry is known: P. L. Orioli, M. Di Vaira, L. Sacconi, *Inorg. Chem.* **1966**, *5*, 400–405.

[22] We have already succeeded in epoxidizing a nitro alkene diastereo- and enantioselectively by the same method: J. Zhu, Dissertation, Technische Hochschule Aachen, **1996**.

[23] The epoxidation carried out with half the amount of (1*R*,2*R*)-*N*-methylpseudoephedrine gave comparable yields at longer the reaction times. However, the enantiomeric excesses fell by several percent in most cases (example **4b**: 17 h, 94% yield, 87% *ee*).

[24] Since extensive exposure to O_2 can have an adverse influence on the reaction, it is recommended to replace the oxygen balloon with an argon balloon after 3.5 h.

[25] In addition, **2g** was prepared by preparative HPLC. All new compounds gave consistent spectroscopic data (IR, NMR, MS) and correct elemental analysis or high-resolution mass spectra.

cis-Sodium Hyponitrite—A New Preparative Route and a Crystal Structure Analysis**

Claus Feldmann and Martin Jansen*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

The family of triatomic molecular 16-electron species has attained an impressive size. Previous studies on these molecules or molecular ions have concentrated on their preparation and structural and spectroscopic characterization.[1] Their electronic structures correspond to a large extent and should, as a result, lead to similar chemical behavior—an aspect that has previously been given scant regard with respect to their use in synthesis. The central atom, being generally positively polarized, should function as a Lewis acid center. This behavior is well-known for CO_2, but otherwise only described for CS_2.[2] Novel interesting tetraatomic complex anions should be accessible by the addition of oxide, nitride, or sulfide ions, for example. To test this idea we studied the effect of laughing gas (N_2O) on Na_2O, which—if the reaction proceeds analogous to that of CO_2—should lead to the formation of sodium nitridonitrate.

At a temperature between 300 and 400 °C, Na_2O does indeed take up an equimolar amount of N_2O. According to the X-ray powder diagrams the reaction goes to completion (no Na_2O reflections were detected), and the elemental analysis confirms the expected composition $Na_2N_2O_2$.[3] The colorless, extremely moisture-sensitive product is obtained as microcrystals. It is thermally stable up to 325 °C; above this temperature quantitative disproportionation occurs with N_2 cleavage and formation of "sodium orthonitrite" [Eq. (a)].[4]

$$3\,Na_2N_2O_2 \longrightarrow 2\,Na_3O(NO_2) + 2\,N_2 \qquad (a)$$

Neither by annealing (due to the low decomposition temperature) nor by recrystallization (due to the insolubility in aprotic solvents and the decomposition in protic solvents) was it possible to obtain single crystals of $Na_2N_2O_2$. The proof of its constitution was therefore undertaken by a crystal structure determination from X-ray powder data without using any a priori knowledge[5] and confirmed spectroscopically (^{15}N MAS-NMR, vibrational spectroscopy).

According to the results of the X-ray structure analysis (Fig. 1),[6] the product of the reaction of N_2O with Na_2O is

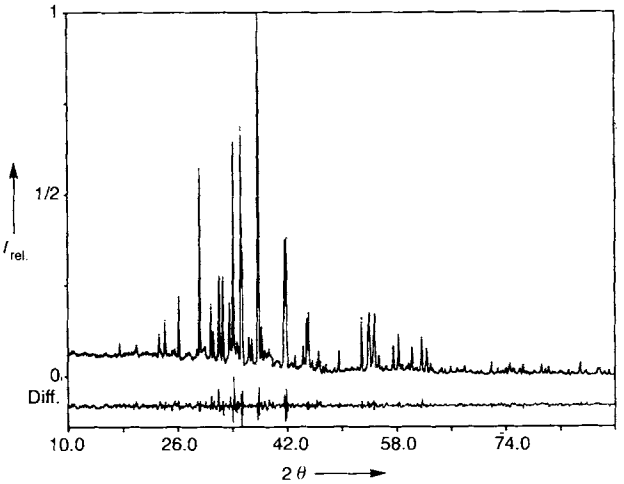

Fig. 1. Profile fitting for *cis*-$Na_2N_2O_2$. Top: measured intensities; bottom: difference.

unexpectedly *cis*-$Na_2N_2O_2$, the constitution of which was thus unequivocally confirmed for the first time. The bond lengths of the *cis*-hyponitrite ion of 1.20(3) (N1–N2), 1.40(3) (N1–O1), and 1.39(3) Å (N2–O2) correspond approximately to those of a N–N double bond (1.15 Å) and two N–O single bonds (1.40 Å).[7] The bond angles of 119.8(4) (O1–N1–N2) and 119.2(4)° (O2–N2–N1) agree with those expected for a pseudo trigonal-planar arrangement.[8] With a dihedral angle (O1–N1–N2–O2) of 0.6(3)°, *cis*-$N_2O_2^{2-}$ is, within the limits of error, planar. The anion has C_1 site symmetry; the measured deviations from the highest possible symmetry (point group C_{2v}) lie within the standard deviations, however.

The ^{15}N MAS-NMR spectrum of *cis*-$Na_2{}^{15}N_2O_2$ (99 % ^{15}N) has, in addition to the rotational side bands, just one isotropic signal ($\delta = 364(1)$). At a line width of $\Delta\delta = 2.0(5)$, the nitrogen atoms can be considered as chemically equivalent, which would agree with the point groups C_{2v} or C_2 for *cis*-$N_2O_2^{2-}$. The vibrational spectra show a clear splitting of all significant peaks, which in accordance with a point or factor group analysis is to be expected (Table 1). Interestingly in this case, the vibrational

			$A_u + B_u$ (2 IR)	IR: 860, 885

[a] The bending vibrations were not detectable because the intensities were too small.

spectroscopy reacts considerably more sensitively to crystal field effects than the MAS nuclear magnetic resonance spectroscopy, which is usually known for its extreme sensitivity.[9]

The *cis*-$N_2O_2^{2-}$ ions are arranged around the Na cations in such a way that each takes on a pseudo octahedral coordination sphere (Fig. 2; if *cis*-$N_2O_2^{2-}$ is coordinated to two adjacent atoms, these are counted as one ligand). A stacking of the *cis*-$N_2O_2^{2-}$ ions along the direction [001] can be considered as the spatial packing principle, whereby the plane of the molecular anions is tilted relative to the *a,b* plane by about 25° (Fig. 3). The cations form linear strings along [001] in the channels remaining between the anions. Astonishingly enough, the packing of *cis*-$Na_2N_2O_2$ has a great deal in common with that of the alkali metal carbonates, in spite of the different symmetries of the anions. If the cations and two of the oxygen atoms are left in almost the same positions as in β-Na_2CO_3 (space group $C2/m$),[10] the crystal structure of *cis*-$Na_2N_2O_2$ is attained by turning the remaining C–O group by 90° and exchanging it for N–N (Fig. 3).

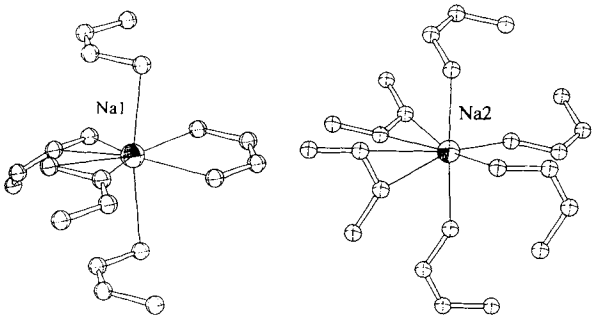

Fig. 2. Coordination spheres around Na (atomic distances: Na–O 2.30 to 2.81 Å, Na–N 2.47 to 3.03 Å).

The hyponitrite class of substances as a whole now appears in a clearer light. Among the three reasonable constitutional isomers for $N_2O_2^{2-}$ (namely, *cis*-hyponitrite, *trans*-hyponitrite, and nitridonitrate), *cis*-$N_2O_2^{2-}$ had only been confirmed structurally as a complex ligand;[11] moreover, the structural suggestions for *cis*- and *trans*-hyponitrite were based on vibrational spectroscopy only (Table 2).[12] Thus, *cis*-$Na_2N_2O_2$ provides the first crystal structure analysis of a simple salt of hyponitrous acid. At the same time, the product of the reduction of NO with Na in liquid ammonia, originally described as sodium nitrosyl, can be recategorized.[13] Based on vibrational spectra of this compound, Goubeau and Laitenberger were able to show that $N_2O_2^{2-}$ ions were present and not NO^- ions. The decision between nitridonitrate and *cis*-hyponitrite fell on the latter.[14] Similarly situated cases such as N_2F_2 and S_2F_2 have shown, however, how difficult a differentiation between these two possible isomers can be, when based solely on vibrational spectra.[15]

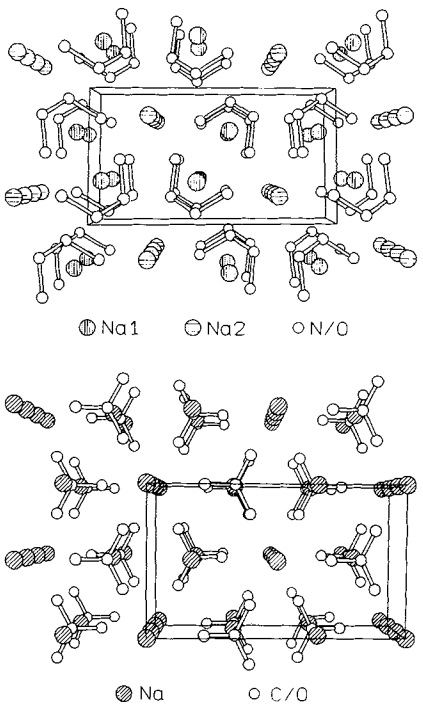

Fig. 3. Packing of the crystal building blocks of *cis*-$Na_2N_2O_2$ (top) and β-Na_2CO_3 (bottom) in the [001] direction (unit cells indicated).

Table 2. Physical and chemical properties of sodium hyponitrite.

point group of the anion	C_{2h}	C_{2v}	C_{2v}

A comparison between the *cis*-$Na_2N_2O_2$ prepared by Goubeau and Laitenberger and that described here shows significant differences in the chemical properties and the vibrational spectra (Table 2, Fig. 4). The fundamentally different temperatures of decomposition and the clearly divergent vibrational spectra irritated us at first, and we assumed that they represented different species. However, the differences are apparently due to the absence of structural order already on a local scale on the one hand and the presence of well-formed long-range crystalline order in the *cis*-$Na_2N_2O_2$ prepared by the solid-state reaction on the other. This is the only convincing explanation for the observation that a local probe such as vibrational spectroscopy in the case of amorphous *cis*-$Na_2N_2O_2$ shows no splitting due to reduced site symmetry. This is an impressive example for different chemical and physical behaviors of solids having the same composition, but different conditioning.

Experimental Procedure

cis-$Na_2N_2O_2$ was prepared by the gas–solid reaction of Na_2O (0.3 g, 4.8 mmol) and excess N_2O (0.77×10^5 Pa at the start of the reaction) in a sealed Duran glass cylinder (l = 425 mm, diameter 45 mm). The cylinder was heated to 360 °C for two hours in a tube furnace. The course of the reaction (complete conversion, start of

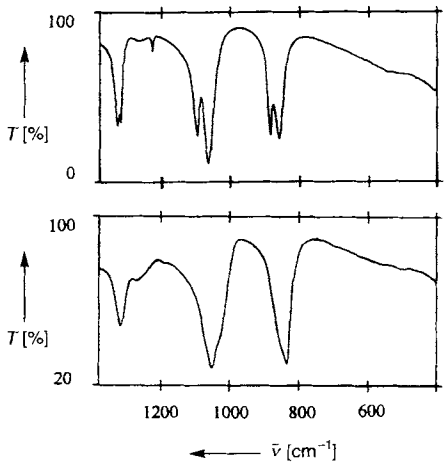

Fig. 4. IR spectra of *cis*-$Na_2N_2O_2$. Top (this paper): $\tilde{\nu}$ = 860/885, 1065/1097, 1320/1329 cm^{-1}; bottom (according to Ref [14]): $\tilde{\nu}$ = 839, 1053, 1316 cm^{-1}.

decomposition) is extremely sensitive to the temperature and duration of reaction, and to the N_2O pressure. The conditions mentioned are the result of careful optimization. The preparation of $Na_2{}^{15}N_2O_2$ was carried out analogously with Na_2O and $^{15}N_2O$ (99 % ^{15}N, Chemotrade, Düsseldorf).

Transition-Metal-Mediated Radical Reactions as an Easy Route to 2-C-Analogues of Carbohydrates**

Torsten Linker,* Klaus Hartmann, Thomas Sommermann, Dieter Scheutzow, and Elfriede Ruckdeschel

Dedicated to Professor Siegfried Hünig on the occasion of his 75th birthday

C-Disaccharides represent an interesting class of compounds in which the glycosidic oxygen atom is replaced by a methylene group.[1] During the last few years the conformational properties of such carbohydrate analogues were investigated intensively.[2] Besides ionic[1a–d, 2] and enzymatic[1e] approaches, radical reactions[3] are especially attractive for the synthesis of *C*-disaccharides. Conveniently, C-analogues of monosaccharides serve as precursors for the different synthetic routes. Carbon substituents can be easily introduced at the anomeric center (synthesis of *C*-glycosides),[4] whereas C-functionalizations at other positions require many steps[2, 5] or the use of toxic tin and mercury compounds.[6] Herein we present a practical protocol, notable for the easy availability of the starting materials, for the synthesis of 2-C-analogues of D-glucose.

Glycals can be prepared on a multigram scale and allow various functionalizations. Epoxidations, cycloadditions, and the introduction of heteroatoms in the 2-position represent the most important transformations.[7] However, the synthetic potential of glycals was not used for intermolecular additions of carbon-centered radicals up to now. In the course of our investigations on manganese(III)-mediated radical reactions,[8] we became interested in the addition of dimethyl malonate (**2**) to tri-*O*-acetyl-D-glucal (**1**, Scheme 1).

Indeed, the C–C bond-formation products **3** and **4** are obtained highly regioselectively in 66% yield. The unsaturated carbohydrates **5** are formed as by-products due to acid-catalyzed Ferrier rearrangement,[9] but are easily separated by column chromatography. The configuration of the C-analogues **3** and **4**, which are obtained as a mixture of diastereomers, was

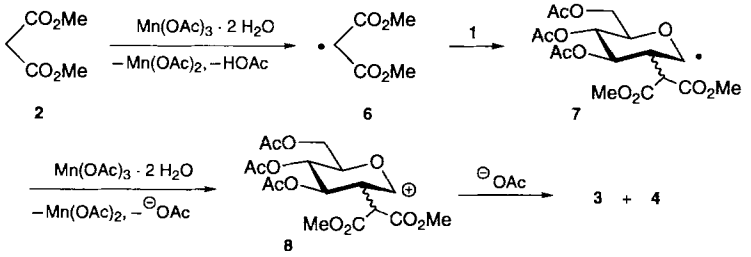
[**] Transition-Metal-Mediated Radical Reactions, Part 3. This work was generously supported by the Deutsche Forschungsgemeinschaft (Li 556/3-1, SFB 347 "Selektive Reaktionen Metall-aktivierter Moleküle") and the Volkswagen-Stiftung. We thank Prof. W. Adam for his constant support. Part 2: [8b].

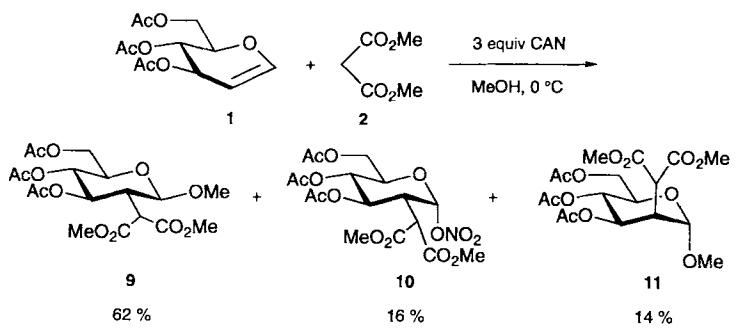
determined by a complete assignment of all ring protons by means of 600 MHz 1D TOCSY NMR spectroscopy.[10] The product ratios and regioselectivities can be rationalized by the mechanism outlined in Scheme 2. In the first step, the malonyl



Scheme 2. Mechanism of the manganese(III)-mediated radical addition of dimethyl malonate (**2**) to tri-*O*-acetyl-D-glucal (**1**).

radicals **6** are generated from dimethyl malonate (**2**) and manganese(III) acetate dihydrate by an inner-sphere electron transfer;[11] these radicals react with tri-*O*-acetyl-D-glucal (**1**) to form the adduct radicals **7**. Oxidation by a second equivalent of manganese(III) affords the cations **8**, which are trapped by the solvent acetic acid to yield the products **3** and **4**. Due to the electrophilic nature of malonyl radicals,[12] the addition is highly regioselective at the 2-position in an orbital-controlled reaction. The preferred formation of *gluco*-configurated products can be rationalized by a *trans* attack at the 3-*O*-acetyl group, which is in accordance with cycloadditions to glucals.[7c-e] Presumably, the same steric effects operate at the anomeric center, where the malonyl substituent controls the reaction. Thus, the *β-gluco* and *α-manno* isomers are obtained predominantly.

In order to suppress the undesired formation of the rearrangement products **5**, we subsequently became interested in additions mediated by ceric(IV) ammonium nitrate (CAN), since the milder reaction conditions are advantageous.[13] For both manganese(III) and cerium(IV) several precedents exist for the generation of electrophilic carbon-centered radicals.[11] However, the application of such radicals in carbohydrate chemistry was hitherto unknown. Indeed, a smooth addition of dimethyl malonate (**2**) to tri-*O*-acetyl-D-glucal (**1**) takes place even at 0 °C, and the formation of the rearrangement products **5** was suppressed completely (Scheme 3). Furthermore, because of the lower reaction temperature higher stereoselectivities are obtained with cerium(IV) than with manganese(III). The methyl glycosides **9** and **11** are formed by trapping of the cationic intermediates **8** (Scheme 2) with solvent, whereas the nitrate **10** results from a ligand transfer reaction with CAN. This ligand transfer offers an explanation for the exclusive formation of the α-anomer **10**,



Scheme 3. Cerium(IV)-mediated radical addition of dimethyl malonate (**2**) to tri-*O*-acetyl-D-glucal (**1**).

since a coordination of the adduct radical to the transition metal is proposed in literature.[14] Thus, the nitrate group should be stereoselectively transferred *cis* to the 2-position, which is indeed the case. Another advantage of the cerium(IV)-mediated reactions is reflected in the easy separation of the *gluco*-configurated main products by column chromatography, which are then isolated in analytically pure form.

In summary, the transition-metal-mediated radical reactions presented herein provide an easy route to 2-C-analogues of D-glucose. Since a broad variety of CH-acidic precursors are available and malonates can be added to glycosyl halides after deprotonation, this methodology should open up interesting prospects for the synthesis of *C*-disaccharides.

Experimental Procedure

A solution of tri-*O*-acetyl-D-glucal (**1**, 1.36 g, 5.0 mmol) and dimethyl malonate (**2**, 6.61 g, 50 mmol) in methanol (10 mL) was cooled to 0 °C under an argon atmosphere. At this temperature a solution of ceric(IV) ammonium nitrate (8.22 g, 15 mmol) in methanol (30 mL) was added dropwise over a period of 4 h. After stirring for 30 min at 0 °C an ice-cold, dilute sodium thiosulfate solution (200 mL) was added, and the mixture was extracted with dichloromethane (4 × 80 mL). The combined organic extracts were dried (sodium sulfate) and concentrated, and the excess of dimethyl malonate was removed at 0.01 mbar. Column chromatography on silica gel (hexane/ethyl acetate 7/3 → 5/5) afforded 370 mg (16%) of **10**, 1.35 g (62%) of **9**, and 350 mg (16%) of **11** containing a small amount of **9**.

9: ^{1}H NMR (600 MHz, $CDCl_3$): δ = 1.98, 1.99, 2.06 (3s, 3H, OAc), 2.57 (ddd, J = 11.6, 8.6, 3.6 Hz, 1H, 2-H), 3.45 (s, 3H, OMe), 3.57 (d, J = 3.6 Hz, 1H, 7-H), 3.69 (ddd, J = 10.0, 4.6, 2.4 Hz, 1H, 5-H), 3.70, 3.73 (2s, 3H, CO_2Me), 4.10 (dd, J = 12.2, 2.4 Hz, 1H, 6-H), 4.28 (dd, J = 12.2, 4.6 Hz, 1H, 6'-H), 4.95 (d, J = 8.6 Hz, 1H, 1-H), 4.98 (dd, J = 10.0, 9.0 Hz, 1H, 4-H), 5.27 (dd, J = 11.6, 9.0 Hz, 1H, 3-H). ^{13}C NMR (151 MHz, $CDCl_3$): δ = 20.5, 20.6, 20.7 (3q, OAc), 46.3, 48.0 (2d, C-2, C-7), 52.4, 52.5 (2q, CO_2Me), 57.5 (q, OMe), 62.2 (t, C-6), 69.8, 71.3, 71.6 (3d, C-3, C-4, C-5), 101.6 (d, C-1), 168.2, 168.5, 169.7, 170.0, 170.7 (5s, OAc, CO_2Me). M.p. 101 °C, $[\alpha]_D^{20}$ = −6.9 (c = 1.08, $CHCl_3$). Anal. Calcd. for $C_{18}H_{26}O_{12}$: C 49.77, H 6.03; Found: C 49.51, H 5.92.

10: ^{1}H NMR (600 MHz, $CDCl_3$): δ = 2.01, 2.03, 2.10 (3s, 3H, OAc), 3.09 (ddd, J = 12.0, 6.1, 3.7 Hz, 1H, 2-H), 3.58 (d, J = 6.1 Hz, 1H, 7-H), 3.76, 3.78 (2s, 3H, CO_2Me), 4.08 (dd, J = 12.6, 2.2 Hz, 1H, 6-H), 4.17 (ddd, J = 10.3, 4.0, 2.2 Hz, 1H, 5-H), 4.33 (dd, J = 12.6, 4.0 Hz, 1H, 6'-H), 5.07 (dd, J = 10.3, 9.3 Hz, 1H, 4-H), 5.45 (dd, J = 12.0, 9.3 Hz, 1H, 3-H), 6.70 (d, J = 3.7 Hz, 1H, 1-H). ^{13}C NMR (151 MHz, $CDCl_3$): δ = 20.4, 20.5, 20.6 (3q, OAc), 42.1, 49.1 (2d, C-2, C-7), 53.0, 53.2 (2q, CO_2Me), 61.3 (t, C-6), 68.9, 69.4, 70.3 (3d, C-3, C-4, C-5), 97.3 (d, C-1), 167.2, 167.4, 169.5, 169.7, 170.5 (5s, OAc, CO_2Me). Syrup, $[\alpha]_D^{20}$ = +138.7 (c = 0.86, $CHCl_3$). Anal. Calcd. for $C_{17}H_{23}NO_{14}$: C 43.88, H 4.98, N 3.01; Found: C 44.12, H 5.14, N 2.79.

Isolation and Characterization of C_{80}**

Frank H. Hennrich, Rudi H. Michel, Achim Fischer, Sabine Richard-Schneider, Stefan Gilb, Manfred M. Kappes,* Dirk Fuchs, Martin Bürk, Kaoru Kobayashi, and Shigeru Nagase

It is well established that fullerenes comprise carbon cage structures consisting of pentagon and hexagon rings.[1] Of the many air-stable fullerene cages (C_{2n}, $n \geq 30$) so far extracted from fullerene soot generated by the Krätschmer–Huffman (K–H) method, all have nonadjacent or "isolated" pentagon rings (isolated pentagon rule, IPR).[2] This has been rationalized on energetic grounds. The smallest fullerene cage that allows such pentagon isolation is C_{60}. Only one form that obeys the IP rule exists for this well-known vertex count (I_h-C_{60}).[3] Beyond C_{60}, the next vertex count that supports an IPR structure is C_{70}. Here again only one IPR isomer is possible (and formed) and has D_{5h} symmetry.[4] After C_{70}, in principle, all C_{2n} cages can have IPR isomers. Furthermore, beyond C_{74} all vertex counts support more than one IPR isomer. Indeed, several IPR isomers of one carbon atom count are often formed in extractable amounts upon fullerene soot generation by graphite arc discharge[5,6] (and by other methods[7]). For example, three of the five theoretically possible C_{78} IPR isomers have been experimentally detected.[8] Furthermore, two of the 24 theoretically possible isomers of C_{84} occur predominantly.[6,9] Study of the symmetries and relative amounts of IPR isomers found for given experimental conditions is of interest towards understanding how the kinetics and energetics of growth and unimolecular dissociation determine fullerene yield in the K–H arc discharge "synthesis". In this work, which has in the meantime led to the isolation and characterization of many IPR C_{2n} fullerenes between C_{76} and C_{96},[10] there have been three notable exceptions. C_{72} (one IPR isomer), C_{74} (one IPR isomer), and C_{80} (seven IPR isomers) have not as yet proven isolable.[11] This has been attributed to their comparatively low abundance in or even outright absence from soot extracts. Herein we report the isolation and characterization of one of these "missing" fullerenes, namely C_{80}.

Apart from inherent questions concerning isomer distribution and relative stability of empty cages, C_{80} is presently also of interest with respect to the mechanism of formation of endohedrally metal doped cages in modified K–H composite arcs. Here it has been found that for several lanthanide metals,[12] the most abundant metallofullerenes after extraction comprise $M@C_{82}$[13] and—remarkably—$M_2@C_{80}$.[14] In both cases the appropriate cage structure still remains to be determined experimentally. Recent ab initio calculations for $La_2@C_{80}$ (which to a first approximation can be described as $(La^{3+})_2@C_{80}^{6-}$) predict an I_h cage derived ground state isomer in contrast to calculations for empty C_{80} which predict a D_2 isomer at the same level of theory (see below).[15]

Fullerene soot formation and extraction was carried out as previously described.[16] The soot extract was fractionated by preparative-scale HPLC in three steps. The optimized protocol consisted of two initial passes using a 250 × 20 mm Cosmosil PYE column (Nacalai Tesque, Kyoto, Japan, toluene eluent), followed by a third pass using a 250 × 21.1 mm Buckyclutcher-1-Prep-Trident-Tri-DNP column (Regis Technologies, Illinois, USA, toluene eluent).[17] The purity of the isolated C_{80} sample (>98%; >1 mg of material) was determined by analytical HPLC and laser desorption time-of-flight mass spectrometry (LD-TOF, N_2-laser). Figure 1 shows the corresponding LD-TOF mass spectrum and the UV/Vis absorption spectrum for the yellow solution of C_{80} in CH_2Cl_2 (main peaks at $\lambda(\varepsilon[\mathrm{L\,mol^{-1}\,cm^{-1}}]) = 860$ (1400), 775 (1400), 714 (1400), 596 (1700), 466 (2100), 420 (2400), 343 (3300) and 276 nm (4200)).

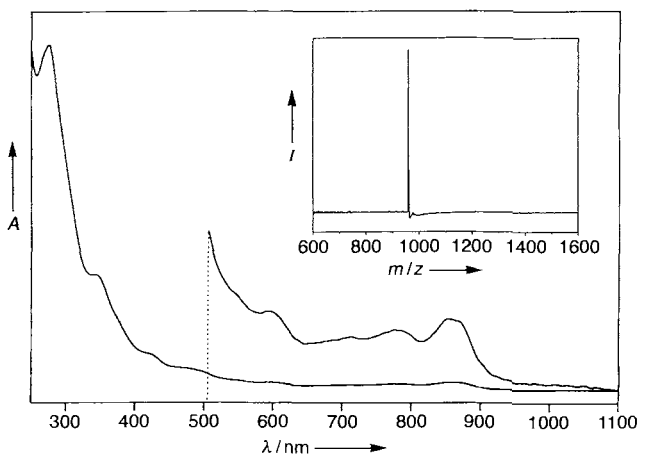

Fig. 1. UV/Vis spectrum of D_2-C_{80} in CH_2Cl_2 (the spectrum enhanced by a factor of 10 is shown in the range from 1100 to about 500 nm). A = absorption. The insert shows the laser-desorption time-of-flight mass spectrum (337 nm) obtained for the purified sample.

Note that the absorption of C_{80} in CH_2Cl_2 (and toluene) solution between 325–335 nm is significantly smaller than that for other previously characterized higher fullerenes.[9,18] In contrast, the solubility of C_{80} in toluene (and CS_2) at room temperature was found to be roughly equivalent to that of C_{78} and C_{82}.

A ^{13}C NMR spectrum of the material dissolved in CS_2 (500 MHz Bruker pulsed FT NMR spectrometer, CCl_3D as internal lock) was obtained after accumulating 60000 scans (measurement time 3.5 days). In the region from $\delta = 129.3$ to 152.9 and at lower resolution the spectrum shows 18 lines with relative intensities between 2.77 and 4.10 and one stronger line of relative intensity 6.00, which at higher resolution splits into two resonances of roughly equal intensity. Considering the signal-to-noise ratio, the measurement is consistent with the presence of 20 groups of four symmetry equivalent carbon atoms (20×4). The experimentally determined chemical shifts and intensities are summarized in Table 1.

Table 1. C_{80} ^{13}C NMR line positions (experimental).

No.	δ [a]	$I_{rel.}$	No.	δ [a]	$I_{rel.}$

[a] Measurements in CS_2 solution at a signal-to-noise ratio of maximally 6. [b] At high resolution this line splits into two signals of roughly equal intensity at $\delta = 144.43$ and 144.45.

C_{80} has been the subject of numerous calculations at various levels.[15,19–22,28] There are seven possible IPR isomers of C_{80} at the level of ring combinatorics, which assumes identical pentagons and hexagons throughout.[1] Their symmetries are: I_h, D_{5d}, D_{5h}, D_3, D_2, C_{2v}, and C_{2v} (interestingly C_{80} is the first fullerene beyond C_{60} to allow an IPR isomer with I_h symmetry—albeit open shell). Several calculations that start from these structures and that allow some level of symmetry relaxation to take into account partially filled electronic levels have been performed.[19–21,28] Of these the most extensive so far predicts a (vibrationless) energy ordering at the HF/AM1 level (energy optimization in AM1 followed by single point HF/3-21G calculations): $D_5(D_{5d}) < D_2$ [+2.3] $< C_{2v}$ [+23.6] $< C_3(D_3)$ [+36] $< C_s(C_{2v})$ [+38.5] $< C_s(D_{5h})$ [+49.9] $< D_2(I_h)$ [+102], where the relaxed symmetry indicated (corresponding to optimized structures only slightly distorted away from the higher symmetry topological cage) derives from that in parentheses, and energies are listed in square brackets [kcal mol^{-1}] relative to the most stable $D_5(D_{5d})$ isomer.[15] Within the limits of error this cage is essentially isoenergetic with the D_2 isomer. In fact at the level of B3P density functional theory, the same study reveals a reversed ordering between these two structures with an even smaller energy difference. Note that in these calculations the optimal I_h derived cage is also found to have D_2 symmetry [$D_2(I_h)$]. The number of symmetry distinguishable carbon atoms corresponding to the seven relaxed structures derived from reference [15] and listed above are: 8 (8×10), 20 (20×4), 23 (6×2; 17×4), 28 (2×1; 26×3), 41 (39×2; 2×1), 44 (8×1; 36×2), and 20 (20×4). In principle, both D_2 structures would be consistent with the 20 distinguishable carbon atoms observed in the ^{13}C NMR spectrum. Furthermore, simple algebra shows that it is not possible to obtain these 20 lines by judicious combination of two or more of the other possible isomers. We therefore conclude on the basis of the calculations in reference [15] that the sample comprises D_2 or $D_2(I_h)$-C_{80}. Given the signal-to-noise ratio and the smaller number of NMR lines expected for the more symmetrical $D_5(D_{5d})$ isomer, we can further state that our isolated sample must contain $< 10\%$ $D_5(D_{5d})$-C_{80}.

While already unlikely on energetic grounds, we can rule out the presence of $D_2(I_h)$-C_{80} on the basis of NMR chemical shift calculations. For this purpose both D_2 isomers were examined with the HF-GIAO chemical shift subroutine implemented in Gaussian 94 using a 6-31G basis set and the HF/3-21G optimized structures of reference [15].[23,24] While not quantitatively predictive, the same procedure has previously been used with some success to calculate NMR chemical shift ranges for a number of higher fullerenes.[25] The ranges predicted here for both D_2 and $D_2(I_h)$ isomers were $\Delta\delta = 21.1$ and 38.9, respectively. Clearly the prediction for the D_2 isomer is in much better agreement with the measured value. Note that the correlation between local cage "surface" curvature (as quantified by π orbital axis vector (POAV) angle[26]) and chemical shift inferred in analogous work on C_{84} isomers[27] fails here—the $D_2(I_h)$ isomer, while predicted to have the larger shift range, is only slightly distorted away from I_h symmetry and therefore more spherical than the D_2 form. This is likely a function of the significantly less homogeneous charge density distribution about the atoms of the $D_2(I_h)$-C_{80} isomer.

In conclusion C_{80} can be isolated from K–H fullerene soot. Only one isomer is observed. This isomer has D_2 symmetry and as such is a chiral molecule. Its topology corresponds to one of the two essentially equienergetic IPR isomeric forms predicted to be the most stable on the basis of (vibrationless) ab initio calculations (Fig. 2).[15] We cannot completely rule out that the other stable $D_5(D_{5d})$-C_{80} form is also present in the soot extract (perhaps coeluting together with and therefore not separable from other much more abundant higher fullerenes). Note, however, that $D_5(D_{5d})$-C_{80} is expected to be more reactive (and perhaps less air-stable) than D_2-C_{80} on the basis of the HOMO–LUMO gap.[15] Furthermore, AM1 calculations performed to calculate hypothetical (isomerization) equilibrium constants K for C_{80} isomers at finite temperatures predict the D_2:$D_5(D_{5d})$ abundance ratio to increase with temperature on entropic grounds ($K > 1$ for $T > 1485$ K—much below arc temperature).[20]

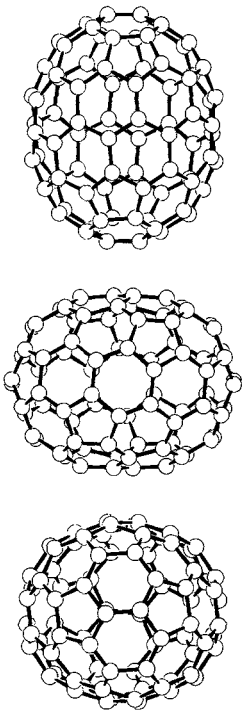

Fig. 2. Inertial axis projections of the D_2-C_{80} molecular structure (as derived from ab initio calculations in ref. [15]; only one enatiomer is shown; relative moments of inertia top:middle:bottom 1:0.95:0.80).

C_{80} appears in positive ion LD-TOF mass spectra of soot extracts with an intensity of less than the 20% of that of the most abundant high fullerene C_{84}.[11] In retrospect it may be that C_{80} has eluded isola-

tion due to an unfortunate combination of relatively low abundance in soot extract (it is the least abundant fullerene ion between C_{76}^+ and $>C_{96}^+$) and small near UV extinction coefficient (typical HPLC separation protocols use absorption detectors set to 330 nm). While a quantitative analysis of raw soot composition is not available, the solubility of C_{80} in solvents used for extraction is not dramatically less than that of other previously isolated cages. This suggests that the apparent low abundance of C_{80} in soot extracts may correlate with a low abundance in the raw material.

While a pronounced lability of C_{80} towards dissociation cannot be postulated on the basis of comparative electronic structure calculations published so far,[28] fragment mass spectra obtained for surface-collisionally activated C_{94}^+ ions, which dissociate by sequential C_2 loss, show an abundance discontinuity at C_{78}^+/C_{80}^+[29] (similar "ledges" occur also at C_{50}^+/C_{52}^+, C_{60}^+/C_{62}^+, and C_{70}^+/C_{72}^+). Such discontinuities have been observed in a variety of carbon cluster ion beam experiments sensitive to metastable decay rates which in turn reflect relative dissociation energies (evaporative ensembles[30]).[31] They generally occur at cluster sizes for which the higher mass is relatively labile and/or the fragment particularly stable. Conceivably then, the reaction

$$C_{80}^{+\bullet} \longrightarrow C_{78}^{+} + C_2 \qquad \text{(a)}$$

may be less endothermic than the corresponding dissociation of $C_{82}^{+\bullet}$ or $C_{78}^{+\bullet}$. There are indications that fullerene formation by graphite/helium arc proceeds at least in part by way of cations—such that these reactions may in fact occur within and at the boundary of the discharge.[32] Might the low abundance of C_{80} (as well as C_{74} and C_{72}?) reflect rate differences in a last evaporative step—before helium collisions freeze out the isomer distribution? Alternative (and perhaps complementary) explanations in terms of cage electron affinity/soot extraction kinetics need to be quantitatively explored.[33]

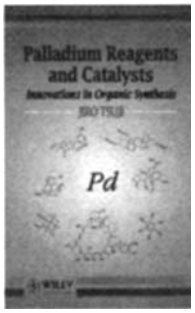
A "Heck" of a Lot of Chemistry

Palladium Reagents and Catalysts. Innovations in Organic Synthesis. By *J. Tsuji*. Wiley, Chichester, 1995. 560 pp., hardcover £125.00.–ISBN 0-471-95483-7

Palladium is justifiably regarded as the transition metal with the greatest variety of potential applications in organic synthesis. Many different reactions are catalyzed or initiated by palladium complexes, and the leading chemistry journals contain articles reporting synthetic uses of palladium in almost every issue. Because of the continuing flood of new publications in this area, much time and effort is absorbed in keeping up with the latest developments. Thus there was certainly a need for an up-to-date monograph on palladium reagents in organic synthesis.



The book by J. Tsuji fulfills this need in exemplary style. Over 2500 literature references, extending up to the beginning of 1994, are treated under the relevant topic areas with succinct commentaries, in a way that ensures lucidity and ease of use despite the vast amount of information. The schemes showing the important reactions and mechanisms are clear and of a high quality.

The subject index lists reagents, substrates, target molecules, and some named reactions. Reactions of a particular type can be found by using the contents list in conjunction with following the systematic arrangement of the subject matter. This system is based on the mechanisms that the reactions are assumed to involve according to current knowledge. It is a pragmatic and effective approach, although one may occasionally question the assumptions, as there still remains much to be learned about the mechanisms of palladium-catalyzed reactions.

The contents are arranged in five chapters of widely differing lengths. Chapter 1 (12 pp.) summarizes the fundamentals and main features of palladium chemistry, including the structures and properties of some important (mostly commercially available) palladium complexes and information about commonly used ligands. Some basic reactions of palladium complexes are described, and the chapter ends with a comprehensive list of references for further reading. Chapter 2 consists of only six pages, giving additional basic information about stoichiometric and catalytic reactions of palladium.

Chapter 3 is much longer (106 pp.), and covers oxidative reactions using palladium(II) compounds. After a short introduction (Section 1), the Wacker process and related reactions are described in Section 2. The following sections are devoted to stoichiometric reactions of π-allyl complexes and to transformations of various compounds (dienes, allenes, alkynes, arenes, and many more) that are induced or catalyzed by palladium(II) compounds.

Chapter 4 is by far the longest (over 400 pp.) and deals with catalytic reactions of palladium(0) and palladium(II). The two main topics are the reactions of organic halides and pseudohalides catalyzed by palladium(0), including examples such as the Heck reaction and the Suzuki coupling (Section 1), and the reactions of allyl compounds, again catalyzed by palladium(0) (Section 2). As an example to illustrate the systematic arrangement of the subject matter adopted throughout the book, let us assume that we wish to find the Stille reaction in Chapter 4. This reaction uses organic halides or pseudohalides as substrates, so we go first to Section 1.1. An organometallic compound is used as the coreactant, which takes us to Section 1.1.4. More specifically this is an organotin compound, so finally we arrive at Section 1.1.4.5. The Stille reaction could actually be found more easily from the contents list, but the same would not be true of the related coupling reactions using organocopper or organozinc compounds, as these are not named reactions–for these one must rely on the system described above.

Chapter 5 (22 pp.) covers other reactions that could not appropriately be included in the preceding chapters, such as the palladium-catalyzed Cope rearrangement and the decarbonylation of aldehydes.

In his preface the author writes that it is better to finish an imperfect book than never to finish a perfect one. In any event this is a very good and useful book which provides a detailed survey of palladium chemistry. There is scarcely a single important publication that is not cited. It should be followed in due course by an updated second edition.

Metals and Ligand Reactivity. By *E. C. Constable*. VCH Verlagsgesellschaft, Weinheim, 1996. 308 pp., hardcover DM 128.00/paperback DM 68.00.—ISBN 3-527-29278-0/3-527-29277-2

What common ground is there between coordination chemistry, a traditional area of inorganic chemistry, and organic chemistry? That is the question addressed by Edwin C. Constable in the new and completely revised edition of the above book; the reader seeking an answer will find it here. The author discusses a large number of examples which show that "inorganic" coordination compounds can certainly undergo "organic" reactions, and that complexation with metal ions alters the reactivity of "organic" molecules. The discussion spans the range from special types of syntheses and aspects of (metallo)supramolecular chemistry—a modern

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

symbiosis of organic and inorganic chemistry—to bioinorganic chemistry.

The first chapter gives a concise but clear and understandable introduction to the basic principles of coordination chemistry, from crystal field theory via MO theory to the thermodynamic and kinetic aspects of coordination compounds. In the second chapter the author begins by discussing the effects of ligands on metal centers, then considers the situation from the opposite standpoint by focusing attention on the effects of coordinated metals on the properties of the ligands, taking into account electronic effects as well as steric and conformational effects. Unfortunately the book is so constructed that these first two chapters have had to be kept rather brief, and consequently they give only a sketchy outline and cannot equip the reader with a detailed understanding.

The chemistry of carbonyl compounds and their derivatives has an important role in organic chemistry, and accordingly it is a central theme of Chapters 3 and 4 (which cover reactions with nucleophiles) and Chapter 5 (reactions with electrophiles). The various types of reactions that can occur are described and illustrated by many examples.

Chapter 6 is concerned with the template effect and the synthesis of macrocyclic ligands. In Chapter 7 the results from the previous chapter are extended to three-dimensional space, which leads to the introduction and detailed discussion of concepts such as supramolecular chemistry, molecular topology, molecular recognition, and self-assembly.

Chapter 8 deals with the chemistry of arenes. The author shows that the typical reactions of aromatic compounds [such as $S_E(Ar)$ and $S_N(Ar)$ reactions] can certainly also occur in the ligand sphere of metal complexes. Chapter 9 is concerned with oxidation and reduction reactions, then the tenth and final chapter emphasizes the importance of the reactive properties of coordination compounds in biological processes, illustrated by a few well-chosen examples. In this chapter the author bridges the gap between coordination chemistry and the area generally called bioinorganic chemistry. Examples drawn from metallo-enzyme chemistry and protein chemistry serve as a brief introduction to this interdisciplinary field between inorganic chemistry and biochemistry.

Regrettably, catalytic reactions of coordination compounds are not included, despite this being a potentially fruitful area for applying the principles of coordination chemistry to organic synthesis. A nice example of this would be the Sharpless epoxidation, illustrating the high catalytic efficiency and degree of stereochemical control that can be achieved using metal complexes.

The book has not been written for the reader whose main interest is in preparing organometallic compounds (e.g. carbene complexes) and in organometallic syntheses. The author has deliberately limited the scope to classical "Alfred Werner" complexes. Thus, the book contains an excellent collection of examples illustrating the "organic chemistry" of coordination compounds, and it is suitable both for students majoring in chemistry and for more advanced readers.

The author's clear and systematic presentation aids the reader's understanding, while the excellent figures and schematic diagrams illustrating chemical principles explain the important relationships very effectively. However, a few small errors in the formulas have slipped through; for example in Figure 2-31 the charges are incorrect, in Figure 3-14 an NH group is missing from the formula of the likely intermediate, and the ligand 7.57 shown on page 220 has two extra methylene groups which should not be present. References to material for further reading enable the reader to follow up selected topics in greater depth. These references concentrate on secondary rather than primary literature, so as to give as broad a range of information sources as possible. The author's comments on the publications cited are an additional aid to selection.

Compared with the first edition (published in 1990 by Ellis Horwood) the most important difference is in the more detailed treatment of supramolecular chemistry. Also the examples discussed and the clear definitions of relevant basic terms are undoubtedly an improvement on the earlier version. I unhesitatingly recommend everyone with an interest in the subject to buy this book.

der Universität Karlsruhe (Germany)

Encyclopedia of Reagents for Organic Synthesis. Vols. 1–8. Supervising editor: *L. A. Paquette*. Wiley, Chichester, 1995. 6223 pp., hardcover £ 1750.00.—ISBN 0-471-93623-5

"Paquette": a reference source on reagents. There can scarcely be a student who, when reading the current literature, does not frequently encounter reagents about which he or she knows little or nothing, often in the form of strange abbreviations above reaction arrows (such as DMTSF, MoOPH, PMDTA, or TMANO), and without even a reference to the original publications. Is it not also true that even experienced synthetic chemists need quick access to information about this or that reagent in their everyday work, especially when they must decide which one to try next for performing a desired transformation? The choice of reagents nowadays available for organic syntheses is enormous. The development of new synthetic methods and the discovery of new applications for familiar reagents has progressed steadily for many decades. In some cases reagents described in the literature have been shown to be dangerous, or their synthetic applications have not developed further and they have disappeared into the back of the filing cabinet. It is becoming increasingly difficult to find one's way through this jungle of information on potential applications, knowledge, and experience.

It is not surprising, therefore, that there is a great demand for easily accessible, concise, and above all reliable sources of information about synthetic reagents. One can well understand the success of "Fieser and Fieser" (*Reagents for Organic Synthesis*), which has served its readers for nearly thirty years, but is now showing its age and becomes more expensive and less convenient with each supplementary volume.

However, thanks to this work edited by L. A. Paquette and a team of well-known American synthetic chemists (S. D. Burke, R. M. Coates, R. L. Danheiser, S. E. Denmark, F. J. Hart, L. S. Liebeskind, D. C. Liotta, A. J. Pearson, H. J. Reich, J. H. Rigby, and W. R. Roush), life is now becoming a little easier. The eight volumes in their brick-red colored bindings contain about 6000 approximately A4-sized pages printed in two-column format, covering over 3500 reagents in alphabetical order (named according to IUPAC rules, from acetaldehyde to zirconium tetraisopropoxide). A comprehensive index is provided at the end of the last volume.

This "Paquette" makes a favorable impression from the start, with its handsome appearance, the very clear typeface with tastefully inserted structural formulas, and a good quality paper which is not too thin and will withstand photocopying. More important, however, is the outstandingly high quality of its contents. All the contributions on individual reagents have been written by carefully chosen experts, often by those whose names one automatically associates with those reagents, and the effort devoted to bring-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3515-1736 $ 15.00+.25/0

ing together the best expert knowledge has paid off handsomely. Altogether more than a thousand scientists from 40 countries were involved, and the editors must be admired and congratulated on the excellent coordination that they have achieved.

Each reagent is treated in a clear and unambiguous style, beginning with the structural formula, the CA Registry number(s), the molecular formula, the molecular mass, and the function of the reagent (in abbreviated form). These details are followed by the main features of its physical properties, solubility, the form in which it occurs and is commercially available, its preparation, purification, and analysis for purity, then information about its handling, storage, possible hazards, and necessary precautions. There is then a brief and succinct description of the reagent's uses, always with references to the original publications. The descriptions are mainly along phenomenological lines; thus, with few exceptions the reaction mechanisms are not discussed.

The lengths of the articles on individual reagents vary from half a page to ten pages; for a few reagents the number of literature references is well over 100. To save space journals are abbreviated according to initial letter codes [e.g., *Angew. Chem. Int. Ed. Engl.* becomes *AG(E)*]; however, these are always easily decoded by referring to a list inside the back cover. Another very useful feature is the general glossary of abbreviations provided on the front inside cover of each volume, which allows one to quickly find the meaning of reagent abbreviations such as those mentioned earlier—for example, DMTSF is dimethyl(methylthio)sulfonium tetrafluoroborate). Both these lists of abbreviations are mentioned at the foot of every other page, alternating with the thoughtful warning "Avoid skin contact with all reagents".

The clear structure and systematic layout of "Paquette" deserve praise, and in this connection one must also mention the index of more than 600 pages, which consists of four parts. If one were looking for a particular reagent (e.g., "Eschenmoser's salt") but did not know its IUPAC name [which in this example would be dimethyl(methylene)ammonium iodide], it could be found easily by searching in one of the other three separate indexes via the molecular formula (under "C_3H_8IN") or the structural class ("Nitrogen reagents: Iminium salts") or the mode of action ("Alkylating reagents: Electrophilic"). Alternatively, however, one could find it in the general subject index (which is itself enormously long) by searching under either the trivial name or the systematic name. This reagent also appears elsewhere in the general index, for example under "Mannich reaction" and under "Amines, tertiary, synthesis". Having then found the actual article, one discovers that the information is not confined to the iodide but also covers other salts such as the chloride (although this is not listed anywhere in the index!). This illustrates another characteristic of "Paquette", namely that although most of the articles belong nominally to a single reagent they often contain information on other closely related reagents. Thus, for example, one finds information on trimethylsilylacetic acid methyl ester in the article on the corresponding *ethyl* ester, and lithium-trimethoxyaluminum hydride is mentioned in the article on lithium-tri-*t-butoxy*-aluminum-hydride.

It is obvious that with these different indexes one has at one's disposal a variety of "navigational instruments". Thus every serious user of the work will quickly learn to find his or her way around within it and obtain answers to different types of questions. In this respect the notes on related reagents included at the ends of many of the articles are very useful, as they allow one to quickly find information about alternatives.

However, care is also needed! For example, a reader wanting information about the asymmetric reduction of ketones will quickly discover that the general subject index cannot always be relied on, despite its comprehensiveness. Thus the CBS reduction method (arguably the most important for enantioselective reductions) can only be found indirectly in this index, by looking up keywords such as "Oxazaborolidines" or "α,α-Diphenyl-2-pyrrolidinemethanol". Evidently, therefore, the user with some previous knowledge would fare better; in fact he or she could also find the CBS reagents by looking in the *Reagent Structural Class Index* under "Boron reagents: Boranes". However, in a case like this it would seem even better to use the *Reagent Function Index*; here, under "Reducing reagents: Chiral", we find a list of 15 reagents, including the one we are looking for under the name "Tetrahydro-1-methyl-3,3-diphenyl-1H,3H-pyrrolo[1,2-c]-[1,3,2]oxazaborole". When we look up the information on this reagent we find an excellent review of the method in question, in an article whose content overlaps considerably with that on "α,α-Diphenyl-2-pyrrolidinemethanol".

It is obvious that a work of this kind cannot be completely encyclopedic in the strict sense of the word. However, the editors have presented an excellent and well-balanced selection which includes most of the important reagents. Transition metal reagents and catalysts are particularly well covered. On the other hand there is far too little on enzymes. The two short articles on bakers' yeast and esterases are all that I could find in this area, and it is unfortunate that other "bioreagents" such as aldolases, alcohol dehydrogenases, lipases, and glycosyl transferases are completely absent. Also, in this era of combinatorial chemistry it would have been desirable to include some articles on support materials for solid phase synthesis, such as Merrifield resins or modified silica gels. Another shortcoming, which "Paquette" has in common with many other large works of reference, is the wide variation in the up-to-dateness of the contributions. A glance at the lists of references shows that in many of the articles the literature coverage extends only to 1992 or 1993. This seems all the more surprising when, on leafing through the volumes, one suddenly (although rarely) comes across references from 1994 or even 1995 (!).

However, on the whole this is an excellent work which fully meets its objectives and comes up to one's highest expectations. It will be of enormous value to both students and practicing chemists. The publication of this new reference source is evidence that even in the age of computerized information media the conventional form of the encyclopedia is still a worthwhile endeavor (although that is not to say that a CD-ROM version would not find a ready market, especially since it would be easier to update).

This "Paquette" should find an honored place in every laboratory engaged in synthesis and in every chemistry library. Chemists working on organic synthesis will gain a competitive advantage by keeping it within easy reach. I fully share the view expressed by L. A. Paquette in his preface that we can "...expect the *Encyclopedia of Reagents for Organic Synthesis* to play a vital role in stimulating creative research in organic chemistry in the years immediately ahead".

Encyclopedia of Inorganic Chemistry. Edited by *R. B. King*. Wiley, Chichester/New York, 1994. Eight volumes. CLXXVI, 4819 pp., hardcover $ 2500.00.—ISBN 0-471-93620-0

During the first four decades of this century inorganic chemistry languished in the doldrums until World War II ushered in the resurgence in the field that the late Sir Ronald S. Nyholm called the "renaissance in inorganic chemistry". Inorganic chemistry encompasses an amazing variety of structurally diverse substances—molecular, ionic, coordination, and organometallic compounds of the roughly one hundred elements now known (with the exception of those compounds of carbon that are the province of organic chemistry) as well as materials such as metallobiomolecules, semiconductors, ceramics, and minerals.

Yet, despite the increased activity in the field during the past half-century, inorganic chemistry has lacked a modern comprehensive encyclopedia, although multivolume treatises on the elements and their compounds such as *Gmelins Handbuch der anorganischen Chemie*, J. N. Friend's *Textbook of Inorganic Chemistry*, J. W. Mellor's *Comprehensive Treatise on Inorganic and Theoretical Chemistry*, P. Pascal's *Nouveau Traité de chimie minérale*, and N. V. Sidgwick's *The Chemical Elements and Their Compounds* have long been available. More recently, modern comprehensive monographs on specialized aspects of inorganic chemistry have appeared, such as Sir Geoffrey Wilkinson, Robert D. Gillard, and Jon A. McCleverty's 7-volume *Comprehensive Coordination Chemistry* (Pergamon, 1987), G. Wilkinson, F. Gordon A. Stone, and Edward W. Abel's 9-volume *Comprehensive Organometallic Chemistry* (Pergamon, 1982), and E. W. Abel, F. G. A. Stone, and G. Wilkinson's 14-volume *Comprehensive Organometallic Chemistry II* (Pergamon, 1995). Perhaps the multivolume set that came closest to the volume under review here is M. Cannon Sneed, J. Lewis Maynard, and Robert C. Brasted's projected 11-volume *Comprehensive Inorganic Chemistry* (only 8 volumes of which were published; 1979 pp., Van Nostrand, 1953–1961), but it was more of a textbook by a limited number of authors (15) than a true encyclopedia. Thus the *Encyclopedia of Inorganic Chemistry* (*EIC*) reviewed here fills a real gap in the literature.

Editor-in-Chief R. Bruce King of the University of Georgia, together with an Editorial Board of five prominent American chemists and an International Advisory Board of 11 chemists from nine countries, including 1987 Nobel laureate Jean-Marie Lehn, has assembled an outstanding group of 304 contributors from 21 countries to produce what should be a definitive reference source for some time to come. The authors, whose names and addresses are listed in Vol. 8, are all prominent authorities who were selected for their expertise in the subjects of their articles, e.g., Robert J. Brotherton (Boron: Inorganic Chemistry), Harold W. Kroto (Carbon: Fullerenes), Stephen J. Lippard (Platinum-Based Anticancer Drugs), Gabor A. Somorjai (Heterogeneous Catalysis by Metals), and Robert C. West (Polysiloxanes and Polysilanes).

For ready reference the *EIC* is arranged alphabetically from Ab Initio Calculations to Zwitterion, with 260 signed main articles (with their contents clearly listed at the beginnings and with numbered sections, subsections, and sub-subsections) dealing with individual topics in a self-contained manner but with frequent references to other articles; 864 short entries defining or explaining important concepts or providing valuable data; and more than 340 cross-reference entries to help locate specific topics. In any article cross-references to definition entries are indicated by italics, while cross-references to other main articles are indicated by bold italics. Abbreviations and terms specific to a given article are defined in the Abbreviations and Glossary sections at the beginning of the article. A list of related main articles is given at the end of each article, followed by extensive, up-to-date literature references, some as recent as 1993 and many to review articles and seminal papers to guide the reader to sources of more detailed information. (For all articles the number of the page on which the references begin is given as a footnote on each right-hand page). A particular subject can be located either directly, by consulting the appropriate alphabetical place, or from the detailed (295 pp.) index in Vol. 8.

The Periodic Table, with the group numbers 1 to 18 as recommended by the International Union of Pure and Applied Chemistry (IUPAC) rather than the older Mendeleev numbers I–VIII and with the symbols for elements 104–109 as endorsed by the Nomenclature Committee of the American Chemical Society (rather than the controversial ones proposed by IUPAC after the *EIC*'s publication) appears on the inside front cover, while four columns of general abbreviations appear on the back endpapers. Each volume contains: Preface; Foreword, which lists the main articles under the six areas of inorganic chemistry assigned to the editors—main group elements, transition metals, organometallics, bioinorganic chemistry, solid state, and physical and theoretical methods (4 pp.); and Table of Contents, which lists alphabetically, with page numbers, all the main and definition articles in the entire *EIC* (10 pp.). Most of the articles are written at an appropriate level for a research student seeking an entry to the literature of an area. The index does not direct readers to authors of references cited in the main articles; an author index of this sort would have been quite useful.

The listing of the articles under the six areas covers the field of inorganic chemistry quite well. This umbrella covers many new areas although it is not, nor could it be, completely exhaustive.

The sections that include main group element chemistry will be particularly useful, since this area has not been reviewed in such detail for many years. It is gratifying to see the excellent treatment of the inorganic chemistry of the noble gases (Boris Žemva) and the discussion of hypervalent compounds (Michael Lattman). The coverage here is reasonably complete and greatly adds to the more classical and narrower focus found in other treatises such as *Comprehensive Coordination Chemistry* and *Comprehensive Inorganic Chemistry*. Of course, the organizational method by bond type generally conceals many of the periodic relationships that already exist and continue to be revealed in this chemistry. Nonetheless, the knowledgeable reader will be able to extract relationships as desired.

The transition metal articles give excellent coverage of inorganic and coordination chemistry of the actinide elements (Grigorii L. Soloveichik), an ambitious undertaking in view of the specialized nature of these elements. The table summarizing "Discovery of the Actinides" is remarkably accurate except for inclusion of a curious reaction to represent the synthesis of plutonium. The table "Main Properties of the Actinides" is generally well done but includes unexpected mistakes (such as in the electronic configuration of Cm^{3+} ions).

Unfortunately, the chemistry of the transactinide elements, rutherfordium (Rf) and hahnium (Ha), is ignored; this is a very interesting area of recent research. Also, a more extensive discussion of the Periodic Table would have been appreciated in view of recent developments at the heavy end.

The sections on organometallics and bioinorganic chemistry cover these areas very well.

Although there are concise and accurate discussions of nuclear matters, a brief discussion of nuclear chemistry might have been appropriate. The use of inorganic chemistry in nuclear studies has a long history and is of continuing importance.

In keeping with the traditional interests of inorganic chemists, most of the theoretical content of the *EIC* concerns bonding models. Three articles on the electronic structures of main-group compounds (Jeremy K. Burdett), organometallics (Thomas A. Albright), and solids (Enric Canadell) all emphasize qualitative, one-electron aspects of bonding. Readers will find much in the first two articles that these authors have previously discussed in books. Canadell expends some effort in weaving the terminology of solid state physics with bonding concepts familiar to many inorganic chemists. Paul T. Czech gives a fairly standard account of qualitative molecular orbital theory in general. The discussion of bonding in clusters given by David J. Wales leans on electron counting and topological schemes, having much in common with his recent book with D. Michael P. Mingos.

It is fair to say that quantitative computational approaches have not yet had as much impact on inorganic chemistry as on organic chemistry, and this is reflected in the coverage in the *EIC*. It is probably also inherently difficult to give an effective treatment of quantitative theoretical approaches in an encyclopedia format aimed at non-theoreticians. Brief accounts tend to be useless; if the reader does not know what the Fock equations are or has not been introduced to density functional theory, the *EIC* is not a realistic place to start. Still, given the pace of change in computing and computational methodology, we suspect that the relatively low profile of quantitative theory in the *EIC* may soon be inappropriate.

Solid state chemistry is much more prominently represented in the *EIC* than in even the most recent textbooks of inorganic chemistry, where the discipline is still given a rather peripheral role. Textbook authors would do well to bear this in mind. Many of the articles are quite good; some are truly outstanding. Klaus Yvon gives a comprehensive and nicely illustrated treatment of solid state hydrides, Hans Georg von Schnering and Wolfgang Hönle present a valuable and authoritative article on phosphides, and William H. McCarroll gives a concise and elegant introduction to solid state oxides. Douglas A. Keszler's article on borates is a fine blend of basic preparative and structural chemistry combined with a useful discussion of physical properties. Indeed, there are several other good articles concerning boron chemistry. The article by Jeremy K. Burdett and John R. Rodgers on structure–property maps is a welcome contribution; such maps seem destined to influence workers who wish to find empirical guides for preparing materials with particular properties in mind. Some connections to topical materials preparation can be found in articles on thin-film synthesis (Chunming Niu and Charles M. Lieber) and organometallic precursors to metallic materials (Herbert D. Kaesz, Alfred Zinn, and Lutz Brandt). Readers will also find good introductory articles on sol–gel synthesis (Jacques Livage) and intercalation chemistry (Allan J. Jacobson). Solid state chemistry tends to have a strong structural emphasis, but many of the articles in the *EIC* will be useful because they also contain good discussions of synthesis and/or properties of compounds.

The encyclopedia is extensively illustrated with photographs, concise tables, line drawings, diagrams, figures, equations, reaction schemes, and computer-drawn structural formulas. Many subjects or terms are defined in only one or two sentences; others are reviewed and referenced in great detail over several pages. This contrast in coverage is to be expected from a comprehensive reference that is less than 5000 pages long. The emphasis on recent developments such as fullerenes, superconductivity, bioinorganic catalysts, and the biology of nitric oxide ensures that the *EIC* will remain topical for many years.

Considering its broad scope and multiple authorships, the *EIC* is exceptionally accurate; the few errors are decidedly minor, such as misspellings (Herault for Héroult, p. 1357), lack of diacritical marks (Delepine for Delépine, p. 985), and the listing of Vaska's complex twice in the Contents (p. XXII). This excellent, up-to-date, comprehensive, easy-to-use, and modestly priced reference work provides more information than is available in single-volume works, without being so large as to be beyond the reach of all but a few well-endowed academic and industrial libraries or affluent individuals. It should be of interest and use not only to inorganic chemists but also to organic, physical, and analytical chemists, biochemists, chemical engineers, materials, earth, and environmental scientists, physicists, biologists, and anyone seeking information on and ideas for new research in one of the most active fields of chemistry today.

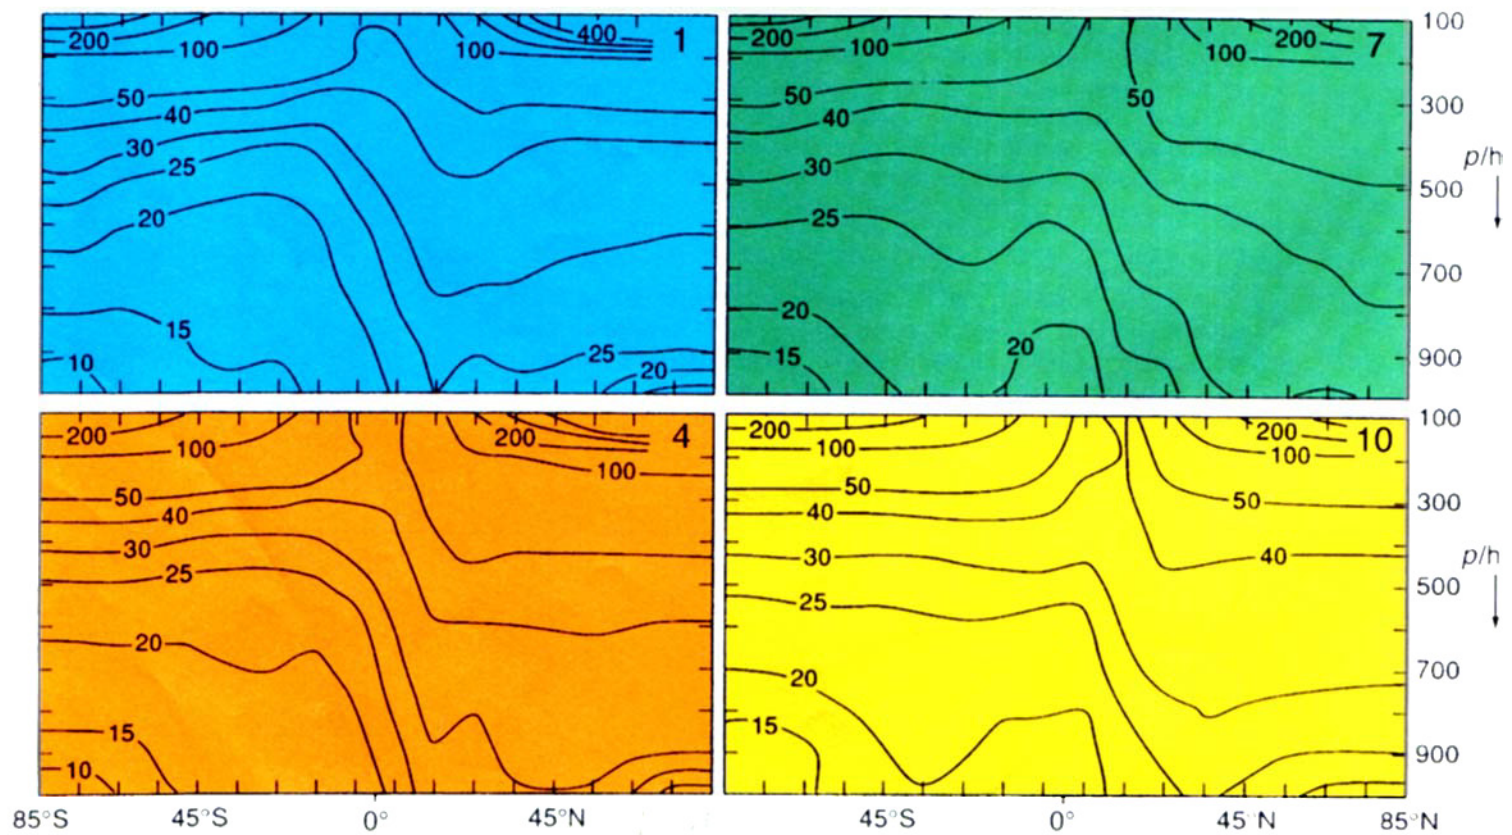
The calculated zonal monthly average concentrations of O_3 in the troposphere have changed substantially from the preindustrial period (top) to 1985 (bottom). Particularly in the northern hemisphere the O_3 concentration has increased substantially as a result of increased emissions of NO, CH_4 and CO.



My Life with O_3, NO_x, and Other YZO_x Compounds (Nobel Lecture)**

Paul J. Crutzen*

To the generation of Jamie Paul and our future grandchildren, who will know so much more and who will celebrate the disappearance of the ozone hole. I hope you will not be disappointed with us.

The Background of an Ozone Researcher

I was born in Amsterdam on December 3, 1933, the son of Anna Gurk and Jozef Crutzen. I have one sister, who still lives there with her family. My mother's parents moved to the industrial Ruhr region in Germany from East Prussia towards the end of the last century. They were of mixed German and Polish origin. In 1929 at the age of 17, my mother moved to Amsterdam to work as a housekeeper. There she met my father. He came from Vaals, a little town in the southeastern corner of the Netherlands, bordering Belgium and Germany and very close to the historical German city of Aachen. He died in 1977. He had relatives in the Netherlands, Germany, and Belgium. Thus, from both parents I inherited a cosmopolitan view of the world. My mother, now 84 years old, still lives in Amsterdam, mentally very alert, but since a few months ago, wheelchair-bound. Despite having worked in several countries outside the Netherlands since 1958, I have remained a Dutch citizen.

Paul Crutzen

In May 1940 the Netherlands were overrun by the German army. In September of the same year I entered elementary school, "de grote school" (the big school), as it was popularly called. My six years of elementary school largely overlapped with the Second World War. Our school class had to move several times to different premises in Amsterdam after the German army had confiscated our original school building. The last months of the war, between the fall of 1944 and Liberation Day on May 5, 1945, were particularly horrible. During the cold "hongerwinter" (winter of famine) of 1944–1945 there was a severe lack of food and heating fuels. Also water for drinking, cooking, and washing was available only in limited quantities for a few hours per day, which caused poor hygienic conditions. Many died of hunger and disease, including several of my schoolmates. Some relief came at the beginning of 1945 when the Swedish Red Cross dropped food supplies by parachute from airplanes. To welcome them we waved our red, white, and blue Dutch flags in the streets. I had, of course, not the slightest idea how important Sweden would become later in my life. We only had a few hours of school each week, but because of special help from one of the teachers, I was allowed, together with two other schoolmates, to continue to the next and final class of elementary school; unfortunately all the others lost a year. More or less normal school education only became possible again with the start of the new school year in the fall of 1945.

In 1946 after a successful entrance exam, I entered the "Hogere Burgerschool" (HBS), Higher Citizen School, a five-year long middle school which prepared scholars for University entrance. I finished this school in June 1951, with natural sciences as my focal subjects. However, we all also had to become proficient in 3 foreign languages: French, English, and German. I was given considerable help in learing languages from my parents: German from my mother, French from my father. During those years, chemistry definitely was not one of my favorite subjects. They were mathematics and physics, but I also did very well in the three foreign languages. During my school years I spent considerable time at sport: football, cycling, and my greatest passion, long distance skating on the Dutch canals and lakes. I also played chess, which in the Netherlands is ranked as a "denksport" (thought sport). I read widely about travels in distant lands, about astronomy, as well as about bridges and tunnels. Unfortunately, because of a heavy fever, my grades in the final exam of the HBS were not good enough to qualify for a university study stipend, which was very hard to obtain at that time, only six years after the end of the Second World War and a few years after the end of colonial war in Indonesia, which had been a large drain on Dutch resources. As I did not want to be a further financial burden on any parents for another four years or more (my father, a waiter, was often unemployed; my mother worked in the kitchen of a hospital), I chose to attend the Middelbare Technische School (MTS), middle technical school, now called the Higher Technical School (HTS), to train as a civil

engineer. Although the MTS took three years, the second year was a practical year during which I earned a modest salary, enough to live on for about two years.

From the summer of 1954 until February 1958, with a 21-month interruption for compulsory military service, I worked at the Bridge Construction Bureau of the City of Amsterdam. In the meanwhile, on a vacation trip in Switzerland I met a sweet girl, Terttu Soininen, a student of Finnish history and literature at the University of Helsinki. A few years later I was able to entice her to marry me. What a great choice I made! She has been the center of a happy family; without her support, I would never have been able to devote so much of my time to studies and science. After our marriage in February 1958, we settled in Gävle, a little town about 200 km north of Stockholm, where I had found a job in a building construction bureau. In December of that same year our daughter Ilona was born. In March 1964, she gained a little sister, Sylvia. Ilona is a registered nurse, now living in Boulder, Colorado. Her son Jamie Paul is 12 years old. Sylvia is a marketing assistant in München, Germany. All were present in Stockholm, Upsala, and Gävle during the Nobel week. We had a happy and unforgettable time.

All this time I had longed for an academic career. One day at the beginning of 1958, I saw an advertisement in a Swedish newspaper by the Department of Meteorology of Stockholm Högskola (from 1961, Stockholm University) announcing an opening for a computer programmer. Although I had not the slightest experience in such work, I applied for the job and had the great luck to be chosen from among many candidates. On July 1, 1959, we moved to Stockholm and I started with my second profession. At that time the Meteorology Institute of Stockholm University (MISU) and the associated International Meteorological Institute (IMI) were at the forefront of meteorological research, and many top researchers worked in Stockholm for extended periods. Only about a year earlier the founder of the institutes, Prof. Gustav Rossby, one of the greatest meteorologists ever, had died suddenly and was succeeded by Dr. Bert Bolin, another famous meteorologist, now "retired" as director of the Intergovernmental Panel on Climate Change (IPCC). At that time Stockholm University housed the fastest computers in the world (BESK and its successor FACIT).

With the exception of participation in a field campaign in northern Sweden, led by Dr. Georg Witt to measure the properties of noctilucent clouds that appear during summer at about 85 km altitude in the coldest parts of atmosphere, and some programming work related to this, I was mainly involved in various meteorological projects until about 1966, especially helping to build and run some of the first numerical (barotropic) weather prediction models. I also programmed a model of a tropical cyclone for a good friend, Hilding Sundquist, now a professor at MISU. At that time programming was a special art. Advanced general computer languages, such as Algol or Fortran, had not been developed, so all programmes had to be written in specific machine code. One also had to make sure that all operations yielded numbers in the range $-1 \leq x < 1$, which meant that one had to scale all equations to stay within these limits; otherwise the computations would yield wrong results.

The great advantage of being at a university department was that I got the opportunity to follow some of the lecture courses that were offered. By 1963 I could thus fulfill the requirement for the "filosofie kandidat" (corresponding to a Master of Science) degree, combining the subjects mathematics, mathematical statistics, and meteorology. Unfortunately I could include neither physics nor chemistry in my formal education, because this would have required my participation in time consuming laboratory courses. In this way I became a pure theoretician. I have, however, always felt close to experimental work, which I have strongly supported during my later years as director of research at the National Center of Atmospheric Research (NCAR) in Boulder, Colorado (1977–1980), and at the Max-Planck-Institute for Chemistry in Mainz, Germany (since 1980).

Being employed at the meteorological research institute, I quite naturally chose a meteorological topic for my filosofie licentiat thesis (comparable to a Ph.D. thesis). Originally, work on the further development of a numerical model of a tropical cyclone had been proposed to me. However, around 1965 I was given the task of helping a scientist from the United States to develop a numerical model of the oxygen allotrope distribution in the stratosphere, mesosphere, and lower thermosphere. This project got me highly interested in the photochemistry of atmospheric ozone, and I started an intensive study of the scientific literature. This gave me an understanding of the status of scientific knowledge on stratospheric chemistry by the latter half of the 1960s, thus setting the "initial conditions" for my scientific career. Instead of the initially proposed research project, I preferred research on stratospheric chemistry, which was generously accepted. At that time the main topics of research at the MISU were dynamics, cloud physics, the carbon cycle, studies of the chemical composition of rainwater, and especially the "acid rain" problem which was largely "discovered" at MISU through the work of Svante Odén and Erik Eriksson. Several researchers at MISU, among them Prof. Bolin and my good friend and fellow student Henning Rodhe, now Professor in Chemical Meteorology at MISU, became heavily involved in the issue, which drew considerable political interest at the first United Nation Conference on the Environment in Stockholm in 1972.[1] However, I wanted to do pure science related to natural processes and therefore I picked stratospheric ozone as my subject, without the slightest anticipation of what lay ahead. In this choice of research topic I was left totally free. I can not overstate how I value the generosity and confidence that were conveyed to me by my supervisors Prof. Georg Witt, an expert on the aeronomy of the upper atmosphere, and the head of MISU Prof. Bert Bolin. They were always extremely helpful and showed great interest in the progress of my research.

Stratospheric Ozone Chemistry

As early as 1930 the famous British scientist Sydney Chapman[2] had proposed that the formation of "odd oxygen" O_x (= O, O_3) is due to photolysis of O_2 by solar radiation at wavelengths shorter than 240 nm [Eq. (1)].

$$O_2 + h\nu \longrightarrow 2O \quad (\lambda \leq 240\ \text{nm}) \tag{1}$$

Fast reactions (2), where M is a mediator, and (3) next lead to the rapid establishment of a steady state for the concentrations of O and O_3 without affecting the concentration of odd

oxygen. Destruction of odd oxygen, counteracting its production by reaction (1), occurs by reaction (4).

$$O + O_2 + M \longrightarrow O_3 + M \quad (2)$$

$$O_3 + h\nu \longrightarrow O + O_2 \quad (\lambda \leq 1180\ nm) \quad (3)$$

$$O + O_3 \longrightarrow 2O_2 \quad (4)$$

Until about the middle of the 1960s it was generally believed that reactions (1)–(4) sufficed to explain the ozone concentration distribution in the stratosphere. However, by the mid 1960s, especially following a study by Benson and Axworthy,[3] it became clear that reaction (4) is much too slow to balance the production of odd oxygen by reaction (1) (Fig. 1). In 1950

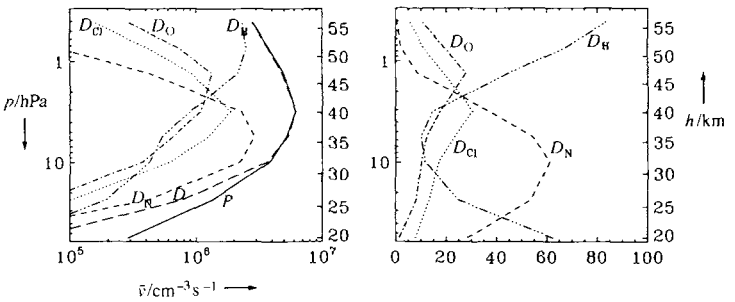

Fig. 1. Dependence of the influence of ozone production and destruction reactions on altitude: D_O = Chapman reaction (4), D_N = NO_x catalysis [Eqs. (11) + (12)], D_H = HO_x catalysis by H, OH, and HO_2, and D_{Cl} = ClO_x catalysis [120]. The calculations neglect the heterogeneous activation by halogen compounds, which becomes very important below 25 km under cold conditions. v = average reaction rate. % k_{tot} = contribution to the total O_3 loss rate. P = production of odd oxygen by reaction (1); D = total ozone destruction.

David Bates and Marcel Nicolet,[4] together with Sydney Chapman, the great pioneers of upper atmospheric photochemistry research, proposed that catalytic reactions involving OH and HO_2 radicals could counterbalance the production of odd oxygen in the mesosphere and thermosphere. Building on their work and on laboratory studies conducted by one of the 1967 Nobel Prize Laureates in Chemistry, Prof. R. Norrish of Cambridge University and his co-workers,[5, 6] the ozone destruction reaction pair (5) and (6) involving OH and HO_2 radicals as catalysts were postulated by Hampson[7] and incorporated into an atmospheric chemical model by Hunt.[8]

$$OH + O_3 \longrightarrow HO_2 + O_2 \quad (5)$$

$$HO_2 + O_3 \longrightarrow OH + 2O_2 \quad (6)$$

$$2O_3 \longrightarrow 3O_2 \quad (5) + (6)$$

The proposed primary source for the OH radicals was photolysis of O_3 by solar ultraviolet radiation of wavelengths shorter than about 320 nm [Eq. (7)], which leads to electronically excited $O(^1D)$ atoms, a small fraction of which reacts with water vapor [Eq. (8)]. Most $O(^1D)$ reacts with O_2 and N_2 to reproduce

$$O_3 + h\nu \longrightarrow O(^1D) + O_2 \quad (\lambda \leq 320\ nm) \quad (7)$$

$$O(^1D) + H_2O \longrightarrow 2OH \quad (8)$$

O_3 rapidly [Eqs. (9) and (2)], producing a null cycle with no effect on the concentrations of ozone or odd oxygen.

$$O(^1D) + M \longrightarrow O + M \quad (9)$$

In the absence of laboratory measurements for the rate constants of reactions (5) and (6), and in order for these reactions to counterbalance the production of odd oxygen by reaction (1), Hunt adopted the rate constants $k_5 = 5 \times 10^{-13}$ cm^{3}molec^{-1}s^{-1} and $k_6 = 10^{-14}$ cm^{3}molec^{-1}s^{-1}, respectively.

In my filosofie licentiat thesis of 1968 I analyzed the proposal by Hampson and Hunt and concluded that the rate constants for reactions (5) and (6) that they had chosen could not explain the vertical distribution of ozone in the photochemically dominated stratosphere above 25 km. Furthermore, I pointed out[9] that the above choice of rate constants would also lead to unrealistically rapid loss of ozone (on a timescale of only a few days) in the troposphere. Anticipating a possible role of OH in tropospheric chemistry, I also briefly mentioned the potential importance of a reaction between OH with CH_4. We now know that reactions (5) and (6) proceed about 25 and 10 times slower, respectively, that postulated by Hunt and Hampson and that the CH_4 oxidation cycle plays a very large role in tropospheric chemistry, a topic to which I will return.

With respect to stratospheric ozone chemistry, I discarded the theory of Hampson and Hunt and concluded "...at least part of the solution of the problem of the ozone distribution might be the introduction of photochemical processes other than those treated here. The influence of nitrogen compounds on the photochemistry of the ozone layer should be investigated."

Unfortunately no measurements of stratospheric NO_x (NO and NO_2) were available to confirm my thoughts about their potential role in stratospheric chemistry. By the summer of 1969 I had joined the Department of Atmospheric Physics at the Clarendon Laboratory of Oxford University as a postdoctoral fellow of the European Space Research Organization and stayed there for a two year period. The head of the research group, Dr. (now Sir) John Houghton, hearing of my idea on the potential role of NO_x, handed me a solar spectrum, taken on board a balloon by Dr. David Murcray and co-workers of the University of Denver, and indicated to me that it might reveal the presence of HNO_3.[10] After some analysis I could derive the approximate amounts of stratospheric HNO_3, including a rough idea of its vertical distributions. I did not get the opportunity to write up the result, because at about the same time, Rhine et al.[11] published a paper, showing a vertical HNO_3 column density of 2.8×10^{-4} atm cm ($\approx 7.6 \times 10^{15}$ molecules per cm^2) above 18.8 km. With this information I knew that NO_x should also be present in the stratosphere as a result of the reactions (10a) and (10b).

$$OH + NO_2(+M) \longrightarrow HNO_3(+M) \quad (10a)$$

$$HNO_3 + h\nu \longrightarrow OH + NO_2 \quad (\lambda \leq 320\ nm) \quad (10b)$$

This gave me enough confidence to submit my paper[12] on catalytic ozone destruction by NO and NO_2, based on the simple catalytic set of reactions [Eqs. (11) + (12)].

$$NO + O_3 \longrightarrow NO_2 + O_2 \quad (11)$$

$$NO_2 + O \longrightarrow NO + O_2 \quad (12)$$

$$O + O_3 \longrightarrow 2O_2 \quad (11) + (12)$$

The net result of reactions (11) and (12) is equivalent to the direct reaction (4). However, the rate of the net reaction can be greatly enhanced by relatively small quantities of NO_x on the order of a few nanomole per mole. I also included a calculation of the vertical distribution of stratospheric HNO_3. As the source of stratospheric NO_x, I initially accepted the proposal by Bates and Hays[13] that about 20% of the photolysis of N_2O would yield N and NO. Subsequent work showed that this reaction does not take place. However, it was soon shown that NO could also be formed to a lesser extent, but still in significant quantities, by the oxidation of nitrous oxide (N_2O) by $O(^1D)$.[14–16] It was further shown by Davis et al.[17] that reac-

$$N_2O + O(^1D) \longrightarrow 2NO \quad (13)$$

tion (12) proceeds about 3.5 times faster than I had originally assumed based on earlier laboratory work. A few years later it was also shown that earlier estimates of O_3 production by reactions (1) and (2) had been too large due to overestimations of both the absorption cross-sections of molecular oxygen[18] and solar intensities in the ozone-producing 200–240 nm wavelength region.[19, 20] As a result of these developments it became clear that enough NO is produced in reaction (13) to make reactions (11) and (12) the most important ozone loss reactions in the stratosphere in the altitude region between about 25 and 45 km (see Fig. 1).

N_2O is a natural product of microbiological processes in soils and waters. A number of anthropogenic activities, such as the application of nitrogen fertilizers in agriculture, also lead to significant N_2O emissions. The rate of increase in atmospheric N_2O concentrations for the past decades has been about 0.3% per year.[21] That, however, was not known in 1971. The discovery of the indirect role of a primarily biospheric product on the chemistry of the ozone layer has greatly stimulated interest in bringing biologists and atmospheric scientists together.

Man's Impact on Stratospheric Ozone

In the fall of 1970, still in Oxford, I obtained a preprint of a study sponsored by the Massachusetts Institute of Technology (MIT), the Study on Critical Environmental Problems (SCEP), which was held in July of that year.[22] This report also considered the potential impact of the introduction of large stratospheric fleets of supersonic aircraft (US: Boeing, Britain France: Concorde, Soviet Union: Tupolev; in the following, supersonic stratospheric transport is abbreviated SST) and gave me the first quantitative information on the stratospheric inputs of NO_x that would result from these operations. By comparing these with the production of NO_x by reaction (13), I realized immediately that we could be faced with a severe global environmental problem. Although the paper in which I proposed the important catalytic role of NO_x on ozone destruction had already been published in April 1970, the participants in the study conference had clearly not taken any note of it, since they concluded "The direct role of CO, CO_2, NO, NO_2, SO_2, and hydrocarbons in altering the heat budget is small. It is also unlikely that their involvement in ozone photochemistry is as significant as water vapour." I was quite upset by the statement. Somewhere in the margin of this text I wrote "Idiots".

After it became quite clear to me that I had stumbled on a hot topic, I decided to extend my 1970 study by treating in much more detail the chemistry of the oxides of nitrogen (NO, NO_2, NO_3, N_2O_4, N_2O_5), hydrogen (OH, HO_2), and HNO_3, partially building on a literature review by Nicolet.[23] I soon got into big difficulties. In the first place, adopting Nicolet's reaction scheme I calculated high concentrations of N_2O_4, a problem that I could soon resolve when I realized that this compound is thermally unstable, a fact not considered by Nicolet. An even greater headache was caused by reactions (14) and (15)

$$N_2O_5 + H_2O \longrightarrow 2HNO_3 \quad (14)$$

$$O + HNO_3 \longrightarrow OH + NO_3 \quad (15)$$

for which the only laboratory studies available at that time had yielded rather high rate coefficients: $k_{14} = 1.7 \times 10^{-18}$ and $k_{15} = 1.7 \times 10^{-11} - 17 \times 10^{-11}$ cm^3 molec^{-1} s^{-1} at room temperatures. A combination of reactions (14) and (15) with these rate constants would provide a very large source of OH radicals, about a thousand times larger than supplied by reaction (8), and would lead to prohibitively rapid catalytic ozone loss. This was a terribly nervous period for me. At that time no critical reviews and recommendations of rate coefficients were available. With no formal background in chemistry, I basically had to compile and comprehend much of the needed chemistry by myself from the available publications, although I profited greatly from discussions with colleagues at the University of Oxford, especially Dr. Richard Wayne of the Physical Chemistry Laboratory, a former student of Prof. R. Norrish in Cambridge. I discussed all these difficulties and produced extensive model calculations on the vertical distributions of trace gases in the $O_x/NO_x/HO_x/HNO_x$ system in a paper which was submitted by the end of 1970 to the Journal of Geophysical Research (received there on January 13, 1971) and which, after revision, was finally published in the October 20 issue of 1971.[15] The publication of this paper was much delayed because of an extended mail strike in Britain. Because of the major problems I had encountered, I did not make any calculations of ozone depletions, but instead drew attention to the potential seriousness of the problem by stating:

> "An artificial increase of the mixing ratio of the oxides of nitrogen in the stratosphere by about 1×10^{-8} may lead to observable changes in the atmospheric ozone level... It is estimated that global nitrogen oxide mixing ratios may increase by almost 10^{-8} from a fleet of 500 SSTs in the stratosphere. Larger increases, up to 7×10^{-8}, are possible in regions of high traffic densities... Clearly, serious decreases in the total atmospheric ozone level and changes in the vertical distributions of ozone, at least in certain regions, can result from such an activity...".

The Supersonic Transport Controversy in the USA

Unknown to me, a debate on the potential environmental impact of supersonic stratospheric transport had erupted in the USA. Initially the concern was mainly enhanced catalytic ozone destruction by OH and HO_2 radicals resulting from the release of H_2O in the engine exhausts.[24] By mid-March 1971, a workshop was organized in Boulder, Colorado, by an advisory board of the Department of Commerce, to which Prof. Harold Johnston of the University of California, Berkeley, was invited. As an expert in laboratory kinetics and reaction mechanisms of NO_x compounds,[25-27] he immediately realized that the role of NO_x in reducing stratospheric ozone had been grossly underestimated. Very quickly (submission 14 April, revision 14 June) on August 6, 1971, his paper appeared in Science[27] with the title "Reduction of Stratospheric Ozone by Nitrogen Oxide Catalysts from Supersonic Transport Exhaust". In the abstract of this paper Johnston stated "...oxides of nitrogen from SST exhaust pose a much greater threat to the ozone layer than does the increase in water. The projected increase in stratospheric oxides of nitrogen could reduce the ozone shield by about a factor of 2, thus permitting the harsh radiation below 300 nanometers to permeate the lower atmosphere." During the summer of 1971 I received a preprint of Johnston's study via a representative of British Aerospace, one of the Concorde manufacturers. This was the first time I had heard of Harold Johnston, for whom I quickly developed a great respect both as a scientist and a human being. Although I had expressed myself rather modestly about the potential impact of stratospheric NO_x emissions from SSTs, for the reasons given above, I fully agreed with Prof. Johnston on the potential severe consequences for stratospheric ozone, and I was really happy to have support for my own ideas from such an eminent scientist. For a thorough resumé of the controversies between scientists and industry, and between meteorologists and chemists (recurring themes also in later years) I refer to Johnston's article "Atmospheric Ozone".[28] It should also be mentioned here that Prof. Johnston's publications in the early 1970s removed several of the major reaction kinetic problems that I had encountered in my 1971 study.[15] It was shown, for instance, that neither reaction (14) nor (15) occur to a significant degree in the gas phase, and that the earlier laboratory studies had been significantly influenced by reactions on the walls of the reaction vessels,[29] advice that was earlier also given to me in a private communication from Prof. Sydney Benson of the University of Southern California.

In July 1971, I returned to the University of Stockholm and devoted myself mainly to studies concerning the impact of NO_x releases from SSTs on stratospheric ozone. In May 1973, I submitted my inaugural dissertation "On the Photochemistry of Ozone in the Stratosphere and Troposphere and Pollution of the Stratosphere by High-Flying Aircraft" to the Faculty of Natural Sciences and was awarded the degree of Doctor of Philosophy with the highest possible distinction, the third time this had ever happened during the history of Stockholm University (and earlier Stockholm "Högskola"). This was one of the last occasions in which the classical and rather solemn "Filosofie Doktor", similar to the Habilitation in Germany and France, was awarded. I had to dress up as for the Nobel Ceremonies. First and second "opponents" were Dr. John Houghton and Dr. Richard Wayne of the University of Oxford, who wore their college gowns for the occasion. Dr. Wayne also served as a most capable, nonobligatory third opponent, whose task it was to make fun of the candidate. Unfortunately, the classical doctoral degree has been abolished (I was one of the last ones to go through the procedure). The modern Swedish Filosofie Doktor degree corresponds more closely to the former Filosofie Licentiat degree.

In large part as a result of the proposal by Johnston[27] that NO_x emissions from SSTs could severely harm the ozone layer, major research programs were started: the Climate Impact Assessment Program (CIAP), organized by the US Department of Transportation,[30] and the COVOS/COMESA[31,32] program, jointly sponsored by France and Great Britain (the producers of the Concorde Aircraft). The aim of these programs was to study the chemical and meteorological processes that determine the abundance and distribution of ozone in the stratosphere, about which so little was known then that the stratosphere was sometimes dubbed the "ignorosphere". The outcome of the CIAP study was summarized in a publication by the US National Academy of Sciences in 1975.[33] "We recommend that national and international regulatory authorities be alerted to the existence of potentially serious problems arising from growth of future fleets of stratospheric airlines, both subsonic and supersonic. The most clearly established problem is a potential reduction of ozone in the stratosphere, leading to an increase in biologically harmful ultraviolet light at ground level."

The proposed large fleets of SSTs never materialized, largely for economic reasons; only a few Concordes are currently in operation. The CIAP and COVOS/COMESA research program, however, greatly enhanced knowledge about stratospheric chemistry. They confirmed the catalytic role of NO_x in stratospheric ozone chemistry. A convincing example of this was provided by a major solar proton event which occurred in August 1972 and during which, within a few hours, large quantities of NO, comparable to the normal NO_x content were produced at high geomagnetic latitudes ($> 65°$), as shown in Figure 2.

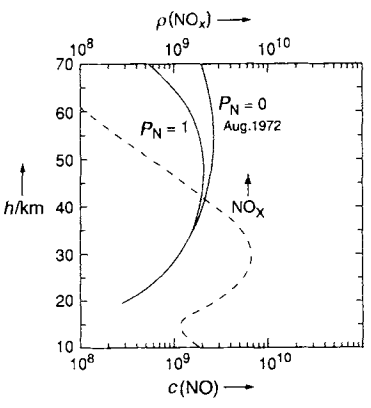

Fig. 2. Production of NO (c in molecules per cm^3; solid line) at high geomagnetic latitudes during the solar proton event of 1972 for two assumptions about the electronic states of the N atoms formed ($P_N = 0$, or 1). Also shown are the average NO_x concentration for these locations (broken line).

With such a large input of NO, a clear depletion of stratospheric ozone was expected,[34] a hypothesis which was confirmed by analysis of satellite observations.[35] Figure 3 shows results of the calculated and observed ozone depletions, the former obtained with a model that also considered chlorine chemistry.[36]

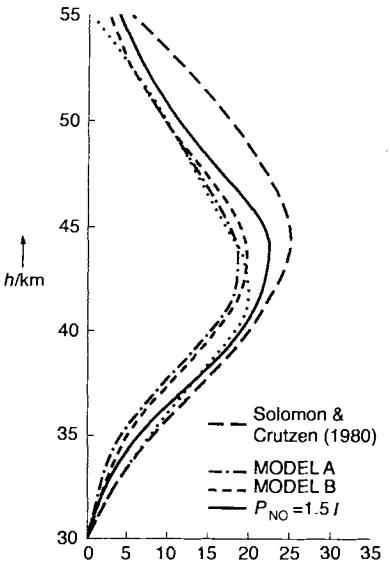

Fig. 3. Observed (····) and calculated percentage depletion of ozone resulting from the 1972 solar proton event. The various calculated curves correspond to assumed values of parameters that were not well known. P = production of NO, I = ionization rate.

Although I had started my scientific career with the ambition to do basic research related to natural processes, the experiences of the early 1970s had made it utterly clear to me that human activities had grown so much that they could compete and interfere with natural processes. Since then this has been an important factor in my research efforts. Already by the end of 1971 I wrote in an article published in the "The Future of Science Year Book" of the USSR in 1972:

> "...the upper atmosphere is an important part of our environment. Let us finish by expressing a sincere hope that in the future environmental dangers of new technological development will be recognizable at an early stage. The proposed supersonic air transport is an example of a potential threat to the environment by future human activities. Other serious problems will certainly arise in the increasingly complicated world of tomorrow."

Tropospheric Ozone

My first thoughts on tropospheric photochemistry go back to about 1968, as discussed briefly above.[9] However, in the following three years, my research was largely devoted to stratospheric ozone chemistry. Then in 1971 a very important paper with the title "Normal Atmosphere: Large Radical and Formaldehyde Concentrations Predicted" was published by Hiram Levy III, then of the Smithsonian Astrophysical Observatory in Cambridge, Massachusetts.[37] Levy proposed that OH radicals could also be produced in the troposphere by the action of solar ultraviolet radiation on ozone [Eqs. (7) and (8)], and that they are responsible for the oxidation of CH_4 and CO, an idea that was also quickly adopted by Jack McConnell, Michael McElroy, and Steve Wofsy[38] of Harvard University. The recognition of the important role of OH was a major step forward in our understanding of atmospheric chemistry. Despite very low atmospheric concentrations, currently estimated at 10^6 molecules per cm^3, corresponding to a mean tropospheric volume mixing ratio of 4×10^{-14},[39] it is this ultraminor constituent—and not the 10^{13} times more abundant O_2—that is responsible for the oxidation of almost all compounds emitted into the atmosphere by natural processes and anthropogenic activities. The lifetimes of most atmospheric gases are, therefore, largely determined by the concentrations of OH and the corresponding reaction coefficients[40] (Scheme 1). Those gases that do not react with OH have very long atmospheric residence times and are largely destroyed in the stratosphere. Examples of the latter class of compounds are N_2O and several fully halogenated, industrial organic compounds, such as $CFCl_3$, CF_2Cl_2, and CCl_4. These play a major role in stratospheric ozone chemistry, an issue to which we will return.

Primary Production of OH Radicals

$O_3 + h\nu\ (\leq 320\ nm) \longrightarrow O(^1D) + O_2$

$O(^1D) + H_2O \longrightarrow 2OH$

Global 24-Hour Average:

$c(OH) \approx 10^6$ molecules per cm^3

molar mixing ratio in troposphere $\approx 4\times10^{-14}$

Reaction with OH Determines the Lifetime of Most Gases in the Atmosphere:

CH_4:	8 years	$(CH_3)_2S$:	2–3 days
C_2H_6:	2 months	CH_3Cl:	≈ 1 year
C_3H_8:	10 days	CH_3CCl_3:	≈ 5 years
C_5H_8:	hours	NO_2:	≈ 1 day

$CFCl_3$, CF_2Cl_2, and N_2O do not react with OH. They are broken down in the stratosphere and have a large influence on ozone chemistry.

Scheme 1. The importance of OH radicals in atmospheric chemistry.

Following Levy's paper my attention turned strongly to tropospheric chemistry. Starting with a presentation at the 1972 International Ozone Symposium in Davos, Switzerland, I proposed that in situ chemical processes could produce or destroy ozone in quantities larger than the estimated downward flux of ozone from the stratosphere to the troposphere.[41,42] Destruction of ozone occurs by reactions (5) + (6) and (7) + (8). Ozone production takes place in environments containing sufficient NO_x by reactions (16), (17), and (2), where R = H, CH_3, or other organoperoxy radicals.

$$RO_2 + NO \longrightarrow RO + NO_2 \quad (16)$$

$$NO_2 + h\nu \longrightarrow NO + O \quad (\lambda \leq 405\ nm) \quad (17)$$

$$O + O_2 + M \longrightarrow O_3 + M \quad (2)$$

$$RO_2 + O_2 \longrightarrow RO + O_3 \quad (16) + (17) + (2)$$

The catalytic role of NO in atmospheric chemistry is, therefore, twofold. At altitudes above about 25 km, where O atom concentrations are high, ozone destruction by reactions (11) + (12) dominates over ozone production by reactions (16) + (17) + (2). The latter chain of reactions is at the base of all photochemical ozone formation in the troposphere, including that taking place during photochemical smog episodes, originally discovered in southern California, as discussed by Johnston.[28] Such reactions can, however, also take place in

background air with ubiquitous CO and CH_4 serving as fuels: in the case of CO oxidation the course is (18)→(19)→(16')→(17)→(2).

$$CO + OH \rightarrow CO_2 + H \quad (18)$$

$$H + O_2 + M \rightarrow HO_2 + M \quad (19)$$

$$HO_2 + NO \rightarrow OH + NO_2 \quad (16')$$

$$NO_2 + h\nu \rightarrow NO + O \quad (17)$$

$$O + O_2 + M \rightarrow O_3 + M \quad (2)$$

$$CO + 2O_2 \rightarrow CO_2 + O_3 \quad (18) + (19) + (16') + (17) + (2)$$

This reaction chain requires the presence of sufficient concentrations of NO. At low NO volume mixing ratios, below about 10 pmol mol^{-1}, oxidation of CO may lead to ozone destruction, since the HO_2 radical then reacts mostly with O_3 [see Eq. (6)]. The result of the participating reactions [(18) + (19) + (6)] is: $CO + O_3 \rightarrow CO_2 + O_2$. In a similar way, the oxidation of CH_4 in the presence of sufficient NO_x will lead to tropospheric ozone production.

Besides reacting with NO or O_3, HO_2 can also react with itself [Eq. (20)] to produce H_2O_2 which serves as a strong oxidizer of S^{IV} compounds in cloud and rain water.

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2 \quad (20)$$

My talk at the International Ozone Symposium was not well received by some members of the scientific establishment of the time. However, in the following years the idea gradually received increased support. In particular, Bill Chameides and Jim Walker,[43] then of Yale University, took it up and went as far as proposing that even the diurnal variation of lower tropospheric ozone could be explained largely by in situ photochemical processes. Although I did not agree with their hypothesis (CH_4 and CO oxidation rates are just not rapid enough), it was good to note that my idea had been taken seriously. (I should also immediately add that especially Bill Chameides in subsequent years add much to our knowledge of tropospheric ozone.) A couple of years later, together with two of my finest students, Jack Fishman and Susan Solomon, we presented observational evidence for a strong in situ tropospheric ozone chemistry.[44, 45] Laboratory measurements by Howard and Evenson[46] next showed that reaction (16) proceeded about 40 times faster than determined earlier, strongly promoting ozone production and increased OH concentrations with major consequences for tropospheric and stratospheric chemistry.[47] A consequence of the faster rate of this reaction is a reduction in the estimated ozone depletions by stratospheric aircraft as the ozone production reactions (16) + (17) + (2) are favored over the destruction reaction (6). Furthermore, a faster reaction (16) leads to enhanced OH concentrations and thus a faster conversion of reactive NO_x to far less reactive HNO_3. Table 1 summarizes a recent ozone budget calculated with a three-dimensional chemical transport model of the troposphere. The results clearly show the dominance of in situ tropospheric ozone production and destruction. With the same model, estimates were also made of the present and pre-industrial ozone concentration distributions (Fig. 4). The calculations indicate a clear increase in tropospheric ozone concentrations over the past centuries.[48] In Figure 5 we also show the meridional cross sections of zonal average ozone, as compiled by Jack Fishman (unpublished data).

Table 1. Tropospheric ozone budgets, globally and for the northern (NH) and southern hemisphere (SH) in 10^{13} mol per year. Only CH_4 and CO oxidation cycles were considered. Calculations were made with the latest version of the global, three-dimensional MOGUNTIA model [48].

	Global	NH	SH
Sources			
$HO_2 + NO$	6.5	4.1	2.4
$CH_3O_2 + NO$	1.7	1.0	0.7
Transport from the stratosphere	1.0	0.7	0.3
Sinks			
$O(^1D) + H_2O$	3.8	2.2	1.6
$HO_2 + O_3$ and $OH + O_3$	2.8	1.8	1.0
Deposition on the surface	2.7	1.8	0.9
Net chemical source [a]	1.6	1.1	0.5

[a] Difference between the two chemical sources and the two chemical sinks.

With the same model we have also calculated the OH concentration distributions for pre-industrial and present conditions. Since pre-industrial times, the CH_4 volume mixing ratio in the atmosphere has increased[49] from about 0.7 to 1.7 ppmv (v indicates a volume/volume comparison). Because reaction with CH_4 is one of the main sinks for OH, an increase in CH_4 should have led to a decrease in OH concentrations. On the other hand, increased ozone concentrations, which enhance OH production by reactions (7) + (8), and the reactions (6) and (16'), both stimulated by strongly enhanced anthropogenic NO production, should exert the opposite effect. Figure 6 shows the zonally averaged, meridional distributions of the diurnally averaged OH concentrations, both for the pre-industrial and industrial periods. They indicate:

a) strong maxima of OH concentrations in the tropics, largely due to high intensities of ultraviolet radiation as a consequence of a minimum in the vertical ozone column. Consequently the atmospheric oxidation efficiency is strongly determined by tropical processes. For instance, most CH_4 and CO is removed from the atmosphere by reaction with OH in the tropics.

b) the possibility of a significant decline in OH concentrations from pre-industrial to industrial conditions.

The results presented in Figure 6, bottom, are of great importance, as they allow estimations of the sink of atmospheric CH_4 by reaction with OH. Prior to the discovery of the fundamental role of the OH radical,[37] estimates of the sources and sinks of trace gases were largely based on guess work without a sound scientific basis. As shown in Scheme 2, this recognition has led to very large changes in the budget estimates of CH_4 and CO. "Authoritative" estimates of the CH_4 budget of 1968 (no reference will be given) gave much higher values for CH_4 releases from natural wetlands. With such a dominance of natural sources, it would have been impossible to explain the annual increase in atmospheric CH_4 concentrations by almost 1% per year. Early estimates of CO sources, on the other hand, were much too low.

The dominance of OH concentrations and the high photochemical activity in the tropics clearly points at the great impor-

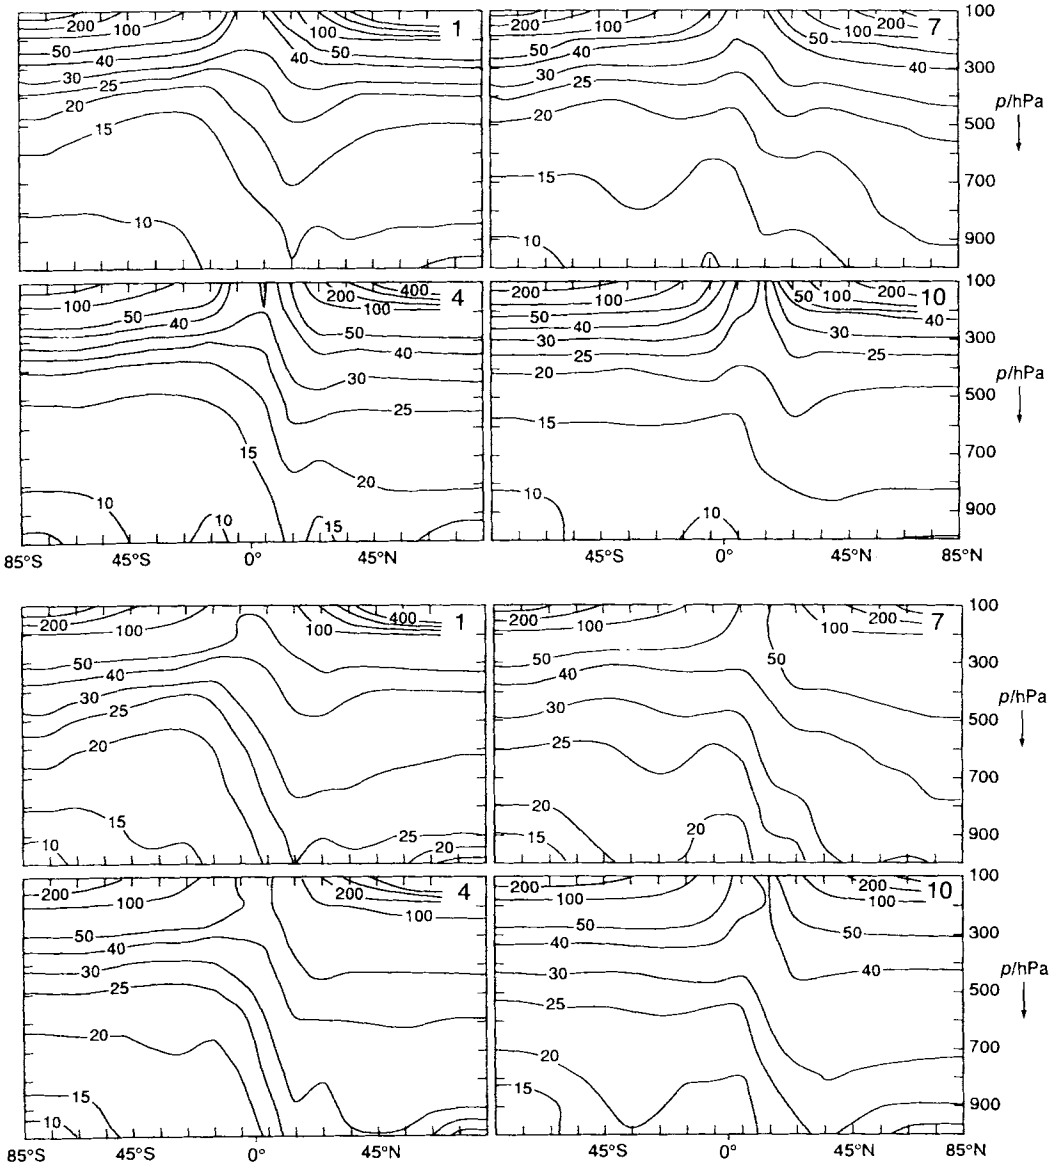

Fig. 4. Calculated zonal average ozone volume mixing ratios in units of nmol per mol for the months January (1 in upper right corner), April (4), July (7), and October (10) in the pre-industrial era (top) and in 1985 (bottom).

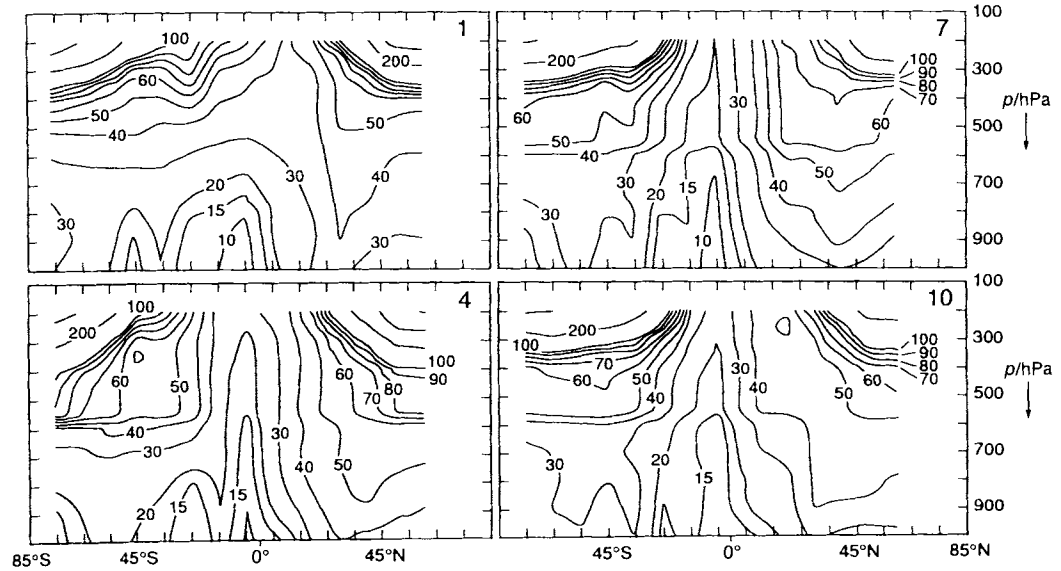

Fig. 5. Compilation of observed meridional ozone distributions (in nmol per molecule) prior to 1989, compiled by Jack Fishman of NASA Langley Research Center, for the months January (1), April (4), July (7), and October (10). It should be mentioned that the data base is very limited and has not improved much for the tropics and subtropics.

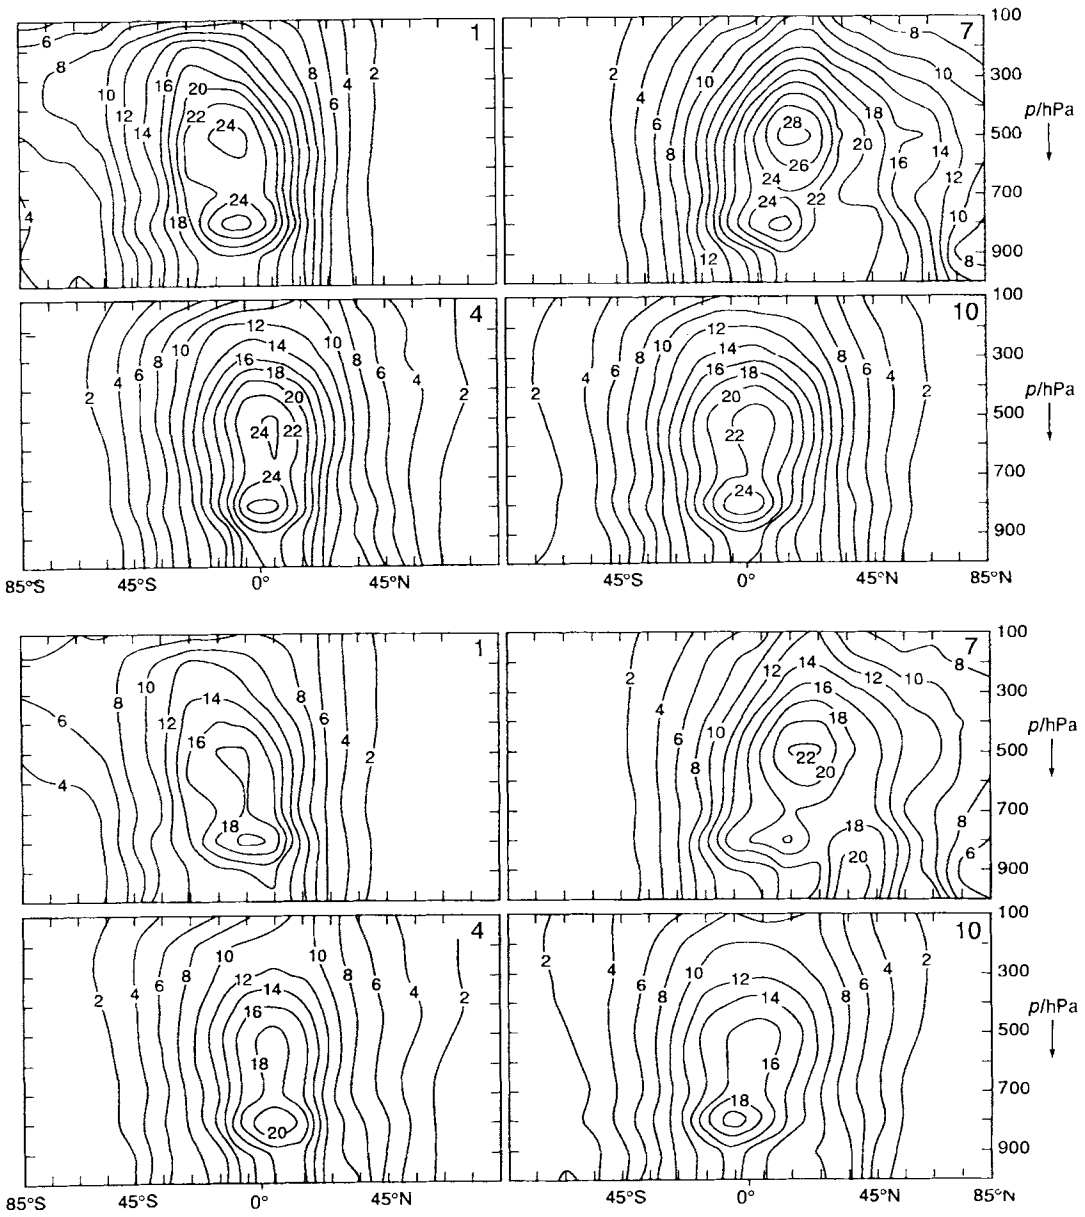

Fig. 6. Calculated zonal and 24-hour average OH concentrations in units of 10^5 molecules per cm^3 for January (1), April (4), July (7), and October (10) in the pre-industrial period (top) and 1985 (bottom).

	1968	1995		1968	1995

tance of the tropics and subtropics in atmospheric chemistry. Despite this fact, research on low latitude chemistry is much neglected, with the consequence that we do not even have satisfactory statistics on the ozone distribution in this part of the world. Tropical chemistry is a topic that has played and will continue to play a large role in my research. Contrary to what was commonly believed prior to the early 1980s, the chemical composition of the tropical and subtropical atmosphere is substantially affected by human activities, in particular biomass burning, which takes place during the dry season. The high temporal and spatial variability of ozone in the tropics is shown in Figure 7. Highest ozone concentrations are observed over the polluted regions of the continents during the dry season, lowest values in the clean air over the Pacific. I will return to the topic of tropical tropospheric ozone, but will first review the stormy developments in stratospheric ozone depletion by halogen compounds that started in 1974.

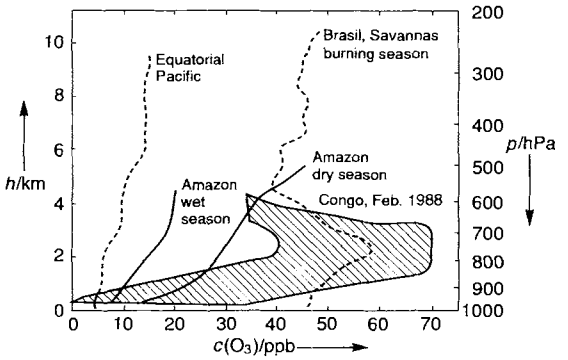

Fig. 7. Variability of ozone profiles in the tropics, displaying the contrast between the dry and the wet season, and between continents and marine sites.

Pollution of the Stratosphere by ClO_x Compounds

Towards the end of the CIAP programme some researchers had turned their interest to the potential input of reactive chlorine radicals on stratospheric ozone. In the most thorough of these studies, Stolarski and Cicerone[50] calculated significant ozone depletions if inorganic chlorine were present in the stratosphere at a volume mixing ratio of 1 nmol per mole of air. Odd oxygen destruction would take place by the catalytic reaction cycle (21) + (22). This reaction sequence is very similar to the

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (21)$$

$$O + ClO \longrightarrow Cl + O_2 \quad (22)$$

$$O + O_3 \longrightarrow 2O_2 \quad (21) + (22)$$

catalytic NO_x cycle (11) + (12) introduced before. The study by Stolarski and Cicerone, first presented at a conference in Kyoto, Japan, in the fall of 1973, mainly considered volcanic injections as a potential source of ClX compounds (their initial interest in chlorine chemistry was, however, concerned with the impact of the exhaust of solid rocket fuels of the space shuttle). Two other conference papers[51, 52] also dealt with ClO_x chemistry. All three papers struggled, however, with the problem of a missing chlorine source in the stratosphere (research over the past 20 years has shown that the volcanic source is rather insignificant).

In the fall of 1973 and early 1974 I spent some time looking for potential anthropogenic sources of chlorine in the stratosphere. Initially my main interest was with DDT and other pesticides. Then by the beginning of 1974 I read a paper by James Lovelock and co-workers,[53] who reported atmospheric measurements of $CFCl_3$ (50 picomol mol^{-1}) and CCl_4 (71 pmol mol^{-1}) over the Atlantic. (Such measurements had been made possible by Lovelock's invention of the electron capture detector for gas chromatographic analysis, a major advance in the environmental sciences.) Lovelock's paper gave me the first estimates of the industrial production rates of CF_2Cl_2 and $CFCl_3$. It also stated that these compounds "are unusually stable chemically and only slightly soluble in water and might therefore persist and accumulate in the atmosphere... The presence of these compounds constitutes no conceivable hazard." This statement had just aroused my curiosity about the fate of these compounds in the atmosphere when a preprint of a paper by M. J. Molina and F. S. Rowland with the title "Stratospheric Sink for Chlorofluoromethanes—Chlorine Atom Catalyzed Destruction of Ozone" was sent to me by the authors. I knew immediately that this was a very important paper and decided to mention it briefly during a presentation on stratospheric ozone to which I had been invited by the Royal Swedish Academy of Sciences in Stockholm. What I did not know was that the press was likewise invited to the lecture. To my great surprise, within a few days, an article appeared in the Swedish newspaper *Svenska Dagbladet*, which drew attention to the topic. This article quickly attracted wide international attention, and soon I was visited by representatives of the German chemical company Hoechst and also by Professor Rowland, who at that time was spending a sabbatical at the Atomic Energy Agency in Vienna. This was the first time I had ever heard of Molina or Rowland, which is not surprising as they had not been active in studies on the chemistry of the atmosphere. Needless to say, I remained highly interested in the topic, and by September 1974, about 2 months after the publication of Molina and Rowland's paper,[54] I presented a model analysis of the potential ozone depletion resulting from continued use of chlorofluoro carbons (CFCs),[55] which indicated the possibility of up to about 40% ozone depletion near 40 km altitude as a result of continued use of these compounds at 1974 rates. Almost simultaneously, Cicerone et al.[56] published a paper in which they predicted that by 1985–1990, continued use of CFCs at early 1970 levels could lead to ClO_x-catalyzed ozone destruction of a similar magnitude to the natural sinks of ozone. Following Molina and Rowland's proposal, research on stratospheric chemistry further intensified, now with the emphasis on chlorine compounds.

By the summer of 1974, together with my family, I moved to Boulder, Colorado, where I assumed two halftime positions, one as a consultant at the Aeronomy Laboratory of the National Oceanic and Atmospheric Administration (NOAA) and the other at the Upper Atmosphere Project of the National Center for Atmospheric Research (NCAR). The NOAA group, which under the able direction of Dr. Eldon Ferguson had become the world leading group in the area of laboratory studies of ion–molecule reactions, had just decided to direct their considerable experimental skills to studies of stratospheric chemistry. My task was to guide them in that direction. I still feel proud to have been part of a most remarkable transformation. Together with Eldon Ferguson, scientists like Dan Albritton, Art Schmeltekopf, Fred Fehsenfeld, Paul Goldan, Carl Howard, George Reid, John Noxon, and Dieter Kley rapidly made major contributions to stratospheric research, including such activities as air sampling with balloon-borne evacuated cans, so-called "salad bowls" for later gas chromatographic analysis, optical measurements of the vertical abundances and distributions of NO_2 and NO_3 (later expanded by Susan Solomon to BrO and OClO), the design and operation of an instrument to measure extremely low water vapor mixing ratios, and laboratory simulations of important, but previously poorly known rate coefficients of important reactions. In later years the NOAA group also devoted itself to studies of tropospheric chemistry, reaching a prominent position in this research area as well. At NCAR the emphasis was more on infrared spectrographic measurements by John Gille and Bill Mankin, work that also developed into satellite-borne experiments. Another prominent activity was the

analysis of the vertical distributions of less reactive gases, such as CH_4, H_2O, N_2O, and the CFCs, employing the cryogenic sampling technique which had been pioneered by Ed Martell and Dieter Ehhalt.

In 1977 I took up the directorship of the Air Quality Division of NCAR, my first partially administrative position. I continued, however, my scientific work, something which many thought would be impossible. Fortunately, in Nelder Medrud I had a highly competent administrative officer. In my position as director I promoted work on both stratospheric and tropospheric chemistry. My own research was mostly devoted to the development of photochemical models, conducted mostly with my students Jack Fishman, Susan Solomon, and Bob Chatfield. Together with Pat Zimmerman we started studies on atmosphere–biosphere interactions, especially the release of hydrocarbons from vegetation and pollutant emissions due to biomass burning in the tropics. I also tried to strengthen interactions between atmospheric chemists and meteorologists to improve the interpretation of the chemical measurements obtained during various field campaigns. To get this interdisciplinary research going was a challenge in those days.

During this period, as part of various activities in the United States and internationally, much of my research remained centered on the issue of anthropogenic, chlorine-catalyzed ozone destruction. However, because I am sure that this topic will be covered extensively by my two fellow recipients of this year's Nobel Prize, I would like to make a jump to the year 1985, when Joe Farman and his colleagues[57] of the British Antarctic Survey published their remarkable set of October total ozone column measurements from the Halley Bay station, showing a rapid depletion on the average by more than 3% per year, starting from the latter half of the 1970s. Although their explanation (ClO_x/NO_x interactions) was wrong, Farman et al.[57] correctly suspected a connection with the continued increase in stratospheric chlorine (nowadays more than five times higher than natural levels). Their display of the downward trend of ozone, matching the upward trend of the chlorofluorocarbons (with the appropriate scaling) was indeed highly suggestive.

The discovery of the ozone hole came during a period in which I was heavily involved in various international studies on the potential environmental impacts of a major nuclear war between the NATO and Warsaw Pact nations, an issue to which I will briefly return in one of the following sections. Because so many researchers became quickly involved in the "ozone hole" research, initially I stayed out of it. Then, in early 1986 I attended a scientific workshop in Boulder, Colorado, which brought me up-to-date with the various theories that had been proposed to explain the ozone hole phenomenon. Although it turned out that some of the hypotheses had elements of the truth, in particular the idea put forward by Solomon et al.[58] of chlorine activation on the surface of stratospheric ice particles, by reaction (23) followed by rapid photolysis of Cl_2 and production of highly reactive Cl atoms [Eq. (24)], I felt dissatisfied with the treatment of the chemistry in the heterogeneous phase. On my flight back to Germany (I hardly sleep on trans-Atlantic flights), I had good time to think it over and suddenly realized that if HNO_3 and NO_x were removed from the gas phase into the particulate phase, then an important defense against the attack of ClO_x on O_3 would be removed. The thought goes as follows: Under normal stratospheric conditions, there are strong interactions between the NO_x and ClO_x radicals, which lead to protection of ozone from otherwise much more severe destruction. Important examples of these are reaction (25) and the pair of reactions (26) + (27), producing HCl and $ClONO_2$,

$$HCl + ClONO_2 \longrightarrow Cl_2 + HNO_3 \quad (23)$$

$$Cl_2 + h\nu \longrightarrow 2Cl \quad (24)$$

$$ClO + NO_2 + M \longrightarrow ClONO_2 + M \quad (25)$$

$$ClO + NO \longrightarrow Cl + NO_2 \quad (26)$$

$$Cl + CH_4 \longrightarrow HCl + CH_3 \quad (27)$$

which do not react with odd oxygen. Because of these reactions, under normal stratospheric conditions most of the inorganic chlorine is present as HCl and $ClONO_2$. Like two Mafia families, the ClO_x and NO_x thus fight each other, to the advantage of ozone. As shown in Figure 8, there are plenty of complex interactions between the OX, HX, NX, and ClX families (for definitions see the legend of Fig. 8). Now, if the NX compounds were removed from the gas phase, reactions (25)–(27) would not occur and most inorganic chlorine may become available in the activated forms. During my return trip to Germany I started to think about this possibility. First, all NO_x compounds are converted to HNO_3 either by reaction (10a) or, especially during the long polar nights, by the night-time reactions (11), (14′), and (28)–(30).

$$NO + O_3 \longrightarrow NO_2 + O_2 \quad (11)$$

$$NO_2 + O_3 \longrightarrow NO_3 + O_2 \quad (28)$$

$$NO_3 + NO_2(+M) \longrightarrow N_2O_5(+M) \quad (29)$$

$$N_2O_5 + H_2O(\text{surface}) \longrightarrow 2HNO_3\,(\text{gas}) \quad (14')$$

$$HNO_3(\text{gas}) \longrightarrow HNO_3(\text{particles}) \quad (30)$$

As noted before, reaction (14) does not occur in the gas phase, but it readily occurs on wetted particulate surfaces. These are always present in the lower stratosphere in the form of sulfate particles, a fact which was first discovered by Christian Junge, a pioneer in atmospheric chemistry and my predecessor as director at the Max-Planck-Institute of Chemistry in Mainz.[59] The sulfate particles are formed by nucleation of gas phase H_2SO_4, which is formed from SO_2, following attack by OH[60, 61] [Eqs. (31)–(33)].

$$SO_2 + OH + M \longrightarrow HSO_3 + M \quad (31)$$

$$HSO_3 + O_2 \longrightarrow SO_3 + HO_2 \quad (32)$$

$$SO_3 + H_2O \longrightarrow H_2SO_4 \quad (33)$$

The sources of stratospheric SO_2 are either direct injections by volcanic explosions[59] or oxidation of OCS, produced at the earth's surface,[62] by reactions (34)–(36).

$$OCS + h\nu \longrightarrow S + CO \quad (34)$$

$$S + O_2 \longrightarrow SO + O \quad (35)$$

$$SO + O_2 \longrightarrow SO_2 + O \quad (36)$$

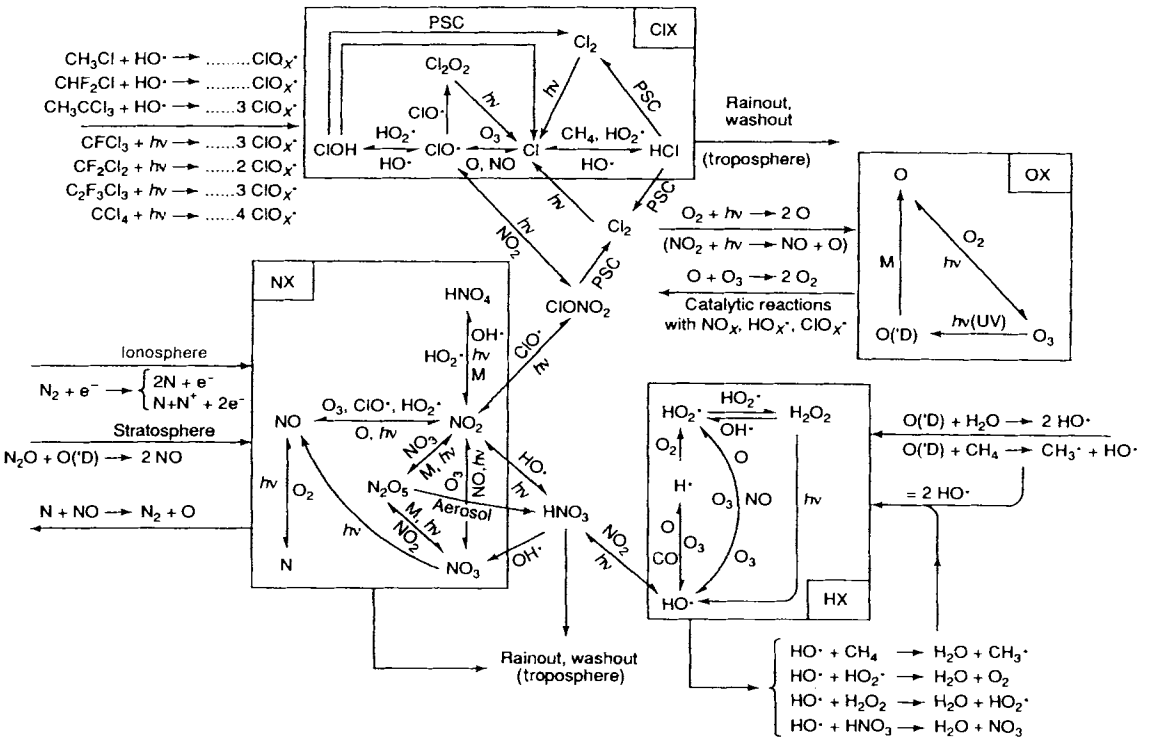

Fig. 8. Schematic presentation of the chemical interactions in the stratosphere. At the start of my scientific career only the OX reactions and some of the HX reactions had been taken into account. Note that OX stands for the odd oxygen compounds, HX for H, OH, HO_2, and H_2O_2; NX for N, NO, NO_2, NO_3, N_2O_5, HNO_3, and HNO_4; and ClX for all inorganic chlorine compounds, Cl, ClO, Cl_2O_2, $ClONO_2$, HCl, OClO, and Cl_2. Not included are the bromine compounds, which likewise play a significant role in stratospheric ozone depletion. PSC = polar stratospheric clouds.

The possibility of HNO_3 formation by heterogeneous reactions on sulfate particles had already been considered in a 1975 paper that I had co-authored with Richard Cadle and Dieter Ehhalt.[63] Based on laboratory experiments, this reaction was for a long while thought to be unimportant, until it was discovered that the original laboratory measurements were grossly incorrect and that reaction (14) readily occurs on H_2O-containing surfaces.[64–66] Earlier tropospheric measurements had, however, already indicated this.[67] The introduction of reaction (14) leads to a significant conversion of reactive NO_x to much less reactive HNO_3, thus diminishing the role of NO_x in ozone chemistry, especially in the lower stratosphere. By including reaction (14), better agreement was obtained between theory and observations.[68] The experience with reaction (14) emphasizes again the importance of high-quality measurements. It is clearly better to have no measurements at all than bad measurements.

As soon as I returned to Mainz, I contacted Dr. Frank Arnold of the Max-Planck-Institute for Nuclear Physics in Heidelberg to explain my idea about NO_x removal from the gas phase to him. After about a week he had shown that under stratospheric conditions, solid nitric acid trihydrate (NAT) particles could be formed at temperatures below about 200 K, that is, a temperature about 10 K higher than that needed for water ice particle formation. The paper about our findings was published in Nature at the end of 1986.[69] Independently, the idea had also been developed by Brian Toon, Rich Turco, and co-workers.[70] Subsequent laboratory investigations, notably by David Hanson and Konrad Mauersberger,[71] then of the University of Minnesota, provided accurate information on the thermodynamic properties of NAT. Next it was also shown that the NAT particles could provide efficient surfaces to catalyze the production of ClO_x by reactions (23) and (24).[72, 73] Finally, Molina and Molina[74] proposed a powerful catalytic reaction cycle involving ClO-dimer formation [Eqs. (21), (37), and (38)], which

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (2\times) \tag{21}$$

$$ClO + ClO + M \longrightarrow Cl_2O_2 + M \tag{37}$$

$$Cl_2O_2 + h\nu \longrightarrow Cl + ClO_2 \rightarrow 2Cl + O_2 \tag{38}$$

$$2O_3 \longrightarrow 3O_2 \qquad (21) + (37) + (38)$$

could complete the chain of events causing rapid ozone depletion under cold, sunlit stratospheric conditions. Note that reaction (37) implies an ozone depletion response that is proportional to the square of the ClO concentration. Furthermore, as chlorine activation by reaction (23) is also nonlinearly dependent on the stratospheric chlorine content, a powerful, nonlinear, positive feedback system is created, which is responsible for the accelerating loss of ozone under "ozone hole" conditions. The "ozone hole" is a drastic example of a man-made chemical instability, which developed at a location most remote from the industrial releases of the chemicals responsible for the effect.

The general validity of the chain of events leading to chlorine activation has been confirmed by both ground-based[75, 76] and airborne, in situ[77] radical observations. Especially the latter, performed by James Anderson and his students of Harvard University, have been very illuminating, showing large enhancements in ClO concentrations in the cold, polar region of the

lower stratosphere, coincident with a rapid decline in ozone concentrations. Together with other observations this confirms the correctness of the ozone depletion theory as outlined above. In the meanwhile the seriousness of this global problem has been recognized by all nations of the world, and international agreements have been signed to halt the production of CFCs and halons from this year on. Although the cause–effect relationship is very clear, for the layperson as well, it is depressing to see that it is, nevertheless, not accepted by a small group of very vocal critics without any record of achievements in this area of research. Some of these have recently even succeeded in becoming members of the U.S. Congress.

And Things Could Have Been Much Worse

Gradually, over a period of a century or so, stratospheric ozone should recover. However, it was a close call. Had Joe Farman and his colleagues from the British Antarctic Survey not persevered in making their measurements in the harsh Antarctic environment for all those years since the International Geophysical Year 1958/1959, the discovery of the ozone hole may have been substantially delayed, and there may have been far less urgency to reach international agreement on the phasing out of CFC production. There might thus have been a substantial risk that an ozone hole could also have developed in the higher latitudes of the northern hemisphere.

Furthermore, while the establishment of an instability in the O_x/ClO_x system requires chlorine activation by heterogeneous reactions on solid or supercooled liquid particles, this is not required for inorganic bromine, which is normally largely present in its activated forms due to gas-phase photochemical reactions. This makes bromine almost a hundred times more dangerous for ozone than chlorine on an atom to atom basis.[52, 78] This brings up the nightmarish thought that if the chemical industry had developed organobromine compounds instead of the CFCs –or alternatively, if chlorine chemistry had behaved more like that of bromine–—then without any preparedness, we would have been faced with a catastrophic ozone hole everywhere and at all seasons during the 1970s, probably before the atmospheric chemists had developed the necessary knowledge to identify the problem and the appropriate techniques for the necessary critical measurements. Noting that nobody had worried about the atmospheric consequences of the release of Cl or Br before 1974, I can only conclude that we have been extremely lucky, which shows that we should always be on our guard for the potential consequences of the release of new products into the environment. Continued surveillance of the composition of the stratosphere, therefore, remains a matter of high priority for many years ahead.

In the meanwhile, we know that freezing of $H_2SO_4/HNO_3/H_2O$ mixtures to give NAT particle formation does not always occur and that supercooled liquid droplets can exist in the stratosphere substantially below nucleation temperatures, down to the ice freezing temperatures.[79] This can have great significance for chlorine activation.[80, 81] This issue, and its implications for heterogeneous processes, have been under intensive investigation at a number of laboratories, especially in the United States, notably by the groups headed by A. R. Ravishankara at the Aeronomy Laboratory of NOAA, Margaret Tolbert at the University of Colorado, Mario Molina at MIT, Doug Worsnop and Chuck Kolb at Aerodyne, Boston, and Dave Golden at Stanford Research Institute in Palo Alto. I am very happy that a team of young colleagues at the Max-Planck-Institute for Chemistry under the leadership of Dr. Thomas Peter is likewise very successfully involved in experimental and theoretical studies of the physical and chemical properties of stratospheric particles at low temperatures. A highly exciting new finding from this work was that freezing of supercooled ternary $H_2SO_4/HNO_3/H_2O$ mixtures may actually start in the small aerosol size range when air parcels go through orographically induced cooling events. Under these conditions the smaller particles, originally mostly consisting of a mixture of H_2SO_4 and H_2O, will most rapidly be diluted with HNO_3 and H_2O and attain a chemical composition resembling that of a NAT aerosol, which, according to laboratory investigations, can readily freeze.[82, 83]

Biomass Burning in the Tropics

By the end of the 1970s considerable attention was given to the possibility of a large net source of atmospheric CO_2 due to tropical deforestation.[84] Biomass burning is, however, not only a source of CO_2, but also of a great number of photochemically and radiatively active trace gases, such as NO_x, CO, CH_4, reactive hydrocarbons, H_2, N_2O, OCS, and CH_3Cl. Furthermore, biomass burning in the tropics is not restricted to forest conversion, but is also a common activity related to agriculture, involving the burning of savanna grasses, wood, and agricultural wastes. In the summer of 1978, on our way back to Boulder from measurements of the emissions of OCS and N_2O from feedlots in Northeastern Colorado, we saw a big forest fire high up in the Rocky Mountain National Forest, which provided us with the opportunity to collect air samples from a major forest fire plume. After chemical analysis in the NCAR Laboratories by Leroy Heidt, Walt Pollock, and Rich Lueb the emission ratios of the above gases relative to CO_2 could be established. Multiplying these ratios with estimates of the global extent of CO_2 production by biomass burning, estimated to be of the order of $2 \times 10^{15} - 4 \times 10^{15}$ g C per year,[85] we next derived the first estimates of the global emissions of H_2, CH_4, CO, N_2O, NO_x, COS, and CH_3Cl, and could show that the emissions of these gases could constitute a significant fraction of their total global emissions. These first measurements stimulated considerable international research efforts. Except for N_2O (for which our first measurements have since proved incorrect) our original findings were largely confirmed, although large uncertainties in the quantification of the various human activities contributing to biomass burning and individual trace gas releases remain.[86] Because biomass burning releases substantial quantities of reactive trace gases, such as hydrocarbons, CO, and NO_x, in photochemically very active environments, large quantities of ozone were expected to be formed in the tropics and subtropics during the dry season. Several measurement campaigns in South America and Africa, starting in 1979 and 1980 with NCAR's Quemadas expedition in Brazil, have confirmed this expectation.[87–92] The effects of biomass burning are especially

noticeable in the industrially lightly polluted southern hemisphere, as is clearly shown from satellite observations of the tropospheric column amounts of CO and O_3 in Figures 9 and 10.[93, 94]

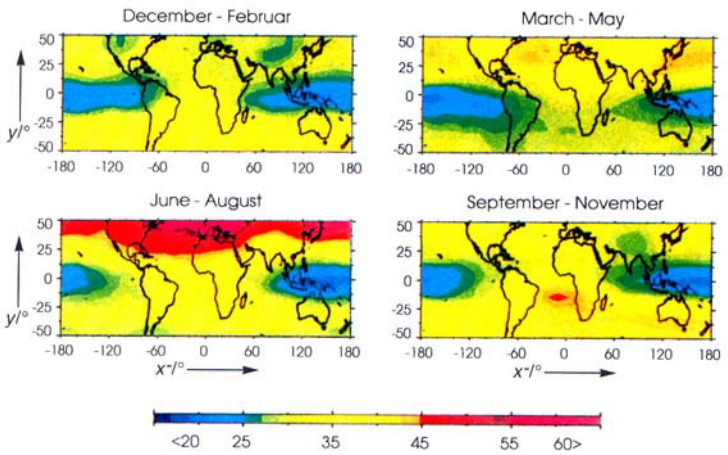

Fig. 9. Observed distributions of vertical column ozone in the troposphere for four seasonal periods in 1994 (from [91, 93]). The color scale is in Dobson units. x = geographic longitude, y = geographic latitude.

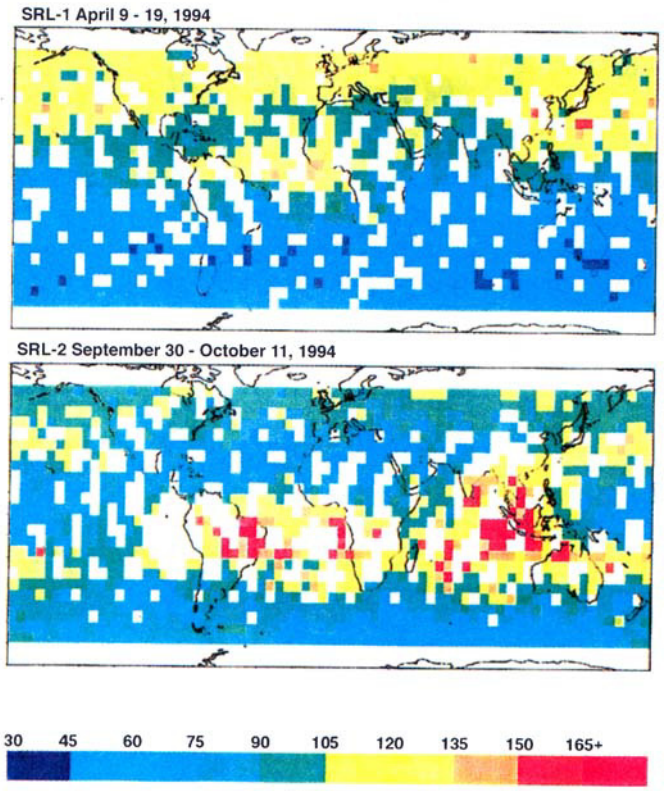

Fig. 10. Observed distribution of vertical column CO in the troposphere, measured on the space shuttle during April and October, 1994 (by courtesy of Dr. Vicki Connors, Dr. Hank Reichle, and the MAPS team [94]). The color scale represents the volume mixing ratios in ppb (1 ppb = 1 nmol per mol).

"Nuclear Winter"

My research interests both into the effects of NO_x on stratospheric ozone and in biomass burning explain my involvement in the "nuclear winter" studies. When in 1981 I was asked by the editor of *Ambio* to contribute to a special issue on the environmental consequences of a major nuclear war, an issue co-edited by Dr. Joseph Rotblat, this year's Nobel Peace Prize awardee, the initial thought was that I would make an update on predictions of the destruction of ozone by the NO_x that would be produced and carried up by the fireballs into the stratosphere.[95, 96] Prof. John Birks of the University of Colorado, Boulder, one of the coauthors of the Johnston study on this topic,[96] who spent a sabbatical in my research division in Mainz, joined me in this study. Although the ozone depletion effects were significant, it was also clear to us that these effects could not compete with the direct impacts of the nuclear explosions. However, we then came to think about the potential climatic effects of the large amounts of sooty smoke from fires in the forests and in urban and industrial centers and oil storage facilities, which would reach the middle and higher troposphere. Our conclusion was that the absorption of sunlight by the black smoke could lead to darkness and strong cooling at the earth's surface, and a heating of the atmosphere at higher elevations, thus creating atypical meteorological and climatic conditions that would jeopardize agricultural production for a large part of the human population.[97] This idea was picked up by others, especially the so-called TTAPS (Turco, Toon, Ackerman, Pollack, Sagan) group,[98] who even predicted that subfreezing temperatures could be possible over much of the earth. This was supported by detailed climate modeling.[99] A major international study of the issue, which was conducted by a group of scientists working under the auspices of SCOPE (Scientific Committee on Problems of the Environment) of the ICSU (International Council of Scientific Unions), also supported the initial hypothesis, and concluded that far more people could die because of the climatic and environmental consequences of a nuclear war than directly because of the explosions.[100, 101]

Although I do not count the nuclear winter idea among my greatest scientific achievements (in fact, the hypothesis can not be tested without performing the "experiment"), I am convinced that, from a political point of view, it is by far the most important, because it magnifies and highlights the dangers of a nuclear war and convinces me that in the long run mankind can only escape such horrific consequences if nuclear weapons are totally abolished by international agreement. I thus wholeheartedly agree in this respect with Joseph Rotblat and the Pugwash organization, this year's recipients of the Nobel Prize for Peace.

Current Research Interests

Realizing the great importance of heterogeneous reactions in stratospheric chemistry, together with my Dutch students Jos Lelieveld (now professor at the University of Utrecht) and Frank Dentener, I have been involved in studies on the effects of reactions taking place in cloud droplets and tropospheric aerosol particles. In general, such reactions result in removal of NO_x and lower concentrations of O_3 and OH.[102, 103] Furthermore, even at high enough NO_x concentrations to allow ozone formation by reactions (16') + (17) + (2), such reactions would be much limited within clouds, because the NO_x molecules, which are only slightly water soluble, stay in the gas phase, while

the HO_2 radicals readily dissolve in the cloud droplets [Eq. (39)], where they can destroy ozone by reaction (40).

$$HO_2(gas) \longrightarrow HO_2(aq) \rightleftarrows H^+ + O_2^- \quad (39)$$

$$O_2^- + O_3 + H^+ \longrightarrow OH + 2O_2 \quad (40)$$

The role of rapid transport of reactive compounds from the planetary boundary layer into the upper troposphere is another topic with which I have been involved with some of my students over the past decade. This may have important effects on the chemistry of the upper troposphere.[104, 105] My great interest in the role of clouds in atmospheric chemistry has brought me in close contact with a major research group at the University of California, San Diego, headed by my good friend Prof. V. Ramanathan.

A new project in which I am currently much interested is the possibility of Cl and especially Br activation in the marine boundary layer. It is already known that Br activation can explain the near-zero O_3 concentrations, which are often found in the high-latitude, marine boundary layer during springtime.[106] In our most recent papers we discuss the possibility that Br activation may also occur in other marine regions and seasons.[107, 108]

The ideas outlined above will be tested by field programs and, if confirmed, introduced in advanced photochemical-transport models. The field programs will be mostly carried out by members of my research division at the Max-Planck-Institute for Chemistry, often in collaboration with other experimental groups. The modeling work is conducted within a consortium of researchers from Sweden, The Netherlands, France, Italy, and Germany. This effort is funded by the European Union and coordinated by Professors Lennart Bengtsson from Hamburg, Henning Rodhe from Stockholm, and Jos Lelieveld from Utrecht.

A Look Ahead

Despite the fundamental progress that has been made over the past decades, much research will be needed to fill major gaps in our knowledge of atmospheric chemistry. In closing I will try to indicate some of those research areas that I consider to be of greatest interest.[109]

Observations of the Tropospheric Ozone

Despite the great importance of tropospheric ozone in atmospheric chemistry, there are still major uncertainties concerning its budget and global concentration distribution. Everywhere, but especially in the tropics and the subtropics, there is a severe lack of data on tropospheric ozone concentrations. Considering the enormous role of tropical ozone in the oxidation efficiency of the atmosphere, the already recognized large anthropogenic impact on ozone through biomass burning, and the expected major agricultural and industrial expansion of human activities in this part of the world, this knowledge gap is very serious. At this stage it is not possible to test photochemical transport models owing to the severe scarcity of ozone observations, especially in the tropics and subtropics. Of critical importance in the effort to obtain data from the tropics and subtropics will be the *training and long-term active participation of scientists from the developing countries.* Besides the ozone measurements at a number of stations and during intensive measurement campaigns, it will be important to also obtain data on reactive hydrocarbons, CO, NO_x, NX, and on chemical constituents in precipitation. Unfortunately, it has been frustrating to note how little response there has been from potential funding agencies to support efforts in this direction.

Long-Term Observations of Properties of the Atmosphere

Two major findings have demonstrated the extreme value of long-term observations of important chemical properties of the atmosphere. One example was the discovery of the rapid depletion of stratospheric ozone over Antarctica during the spring months, as discussed before. Another is the recent, unexpected major, temporary break in the trends of CH_4 and CO. Most surprising were the changes in CO, for which Khalil and Rasmussen[110] derived a downward trend in surface concentrations by $(1.4 \pm 0.9)\%$ per year in the northern hemisphere and by as much as $(5.2 \pm 0.7)\%$ per year in the southern hemisphere between 1987 and 1992. Even larger downward trends, $(6.1 \pm 1)\%$ per year in the northern hemisphere and $(7 \pm 0.6)\%$ per year in the southern hemisphere, were reported for the period between June 1990 and June 1993 by Novelli et al.[111] Although these trends have again reversed (P. Novelli, private communication) into the previous upward trend of $+0.7\%$ per year for CO and almost 1% per year for CH_4,[112, 113] the temporary break is remarkable. The reasons for this surprising behavior are not known. They may consist of a combination of: 1) variable annual emissions from biomass burning, 2) higher concentrations of OH radicals, maybe due to loss of stratospheric ozone, triggered by an increase in reactive aerosol surfaces in the stratosphere following the Pinatubo volcanic eruption in June 1991, 3) a dynamically forced global redistribution of CO, introducing a bias due to the location of the limited number of measuring sites, 4) reduced CO formation from the oxidation of natural hydrocarbons emitted by tropical forests due to globally altered precipitation and temperature patterns, or, most likely, a combination of these and other, yet unknown factors. At this stage we can only conclude that the causes for the surprisingly rapid changes in CO trends are not known, mainly because of incomplete global coverage of the CO measurement network. The same applies for CH_4.

Intensive Measurement Campaigns

Comprehensive field programmes that have been conducted in the past with detailed observations of all factors that influence the photochemistry of the troposphere will also be much needed in the future, especially in various regions of the marine and continental tropics and subtropics, to find out whether we understand the major processes that determine the chemistry of ozone and related photochemically active compounds. Applica-

tions of comprehensive chemical and transport models should be an important part of these activities. Topics in which greatly improved knowledge is necessary are especially the improved quantification of the stratospheric influx of ozone; distributions, sources, and sinks of CH_4, reactive hydrocarbons, CO, NO_x, and NX; and the quantification of natural NO emissions from lightning and soils.

Cloud Transport

The role of clouds as transporters of chemical constituents such as CO, NO_x, reactive hydrocarbons, and their oxidation products from the boundary layer to the middle and upper troposphere (and possibly into the lower stratosphere) should be better understood and quantified, so that they can be parameterized for inclusion in large scale photochemical models of the atmosphere. Similarly the production of NO by lightning and its vertical redistribution by convective storms should also be much better quantified, both for marine and continental conditions. Current uncertainties of NO production by lightning are at least a factor of 4.

Chemical Interactions with Hydrometeors

The interactions of chemical constituents emanating from the boundary layer with liquid and solid hydrometeors in the clouds will be of special importance. There is, for instance, the question of why strong ozone formation has not been noticed around the most convective regions in the continental tropics, in which large amounts of forest-derived reactive hydrocarbons such as isoprene (C_5H_8) and their oxidation products are rapidly lifted to the middle and upper troposphere and mixed with lightning-produced NO to provide favorable conditions for photochemical ozone formation. Could it be that the expected ozone formation is prevented by chemical interactions of the hydrocarbon reaction products and NO_x with the hydrometeors? Could significant ozone destruction take place in cloud water or on the surface of ice particles that may be partially covered by water?[114, 115] Such questions regarding potential loss of ozone by reactions with hydrometeors may be especially relevant in connection with observations of record low O_3 volume mixing ratios often of less than 10 nmol per mol over much of the entire tropospheric column in March 1993 in an extended, heavily convective region between Fiji and Christmas Island over the Pacific Ocean.[116] Although such low ozone volume mixing ratios had been noted on several occasions in the tropical marine boundary layer and can be explained by the ozone-destroying reactions (5)–(8) in the lower troposphere, it should be ascertained whether these reactions alone suffice to explain the extremely low ozone concentrations in such a large volume of air.

Photolysis Rates in Cloudy Atmospheres

Regarding the photochemistry taking place in cloudy atmospheric conditions, recent observations of unexpectedly high absorption of solar radiation in cloudy atmospheres[117] point to the possibility that multiple scattering in broken cloud systems may lead to strongly enhanced photolysis rates and photochemical activity, leading, for example, to much higher O_3 destruction and OH production rates by reactions (7) and (8), or ozone production by reactions (16) + (17) + (2), than thought so far. The influence of clouds on the photochemically active UV radiation field is a potentially very important research topic, which should be pursued by measurements and the development of appropriate radiative transfer models.

Biogenic Sources of Hydrocarbons, CO, and NO

The continental biosphere is a large source of hydrocarbons. Quantification of these sources in terms of geophysical (e.g., temperature, humidity, light levels) and biogeochemical (soil physical and chemical properties, land use) parameters are urgently needed for inclusion in atmospheric models. The hydrocarbon oxidation mechanisms in the atmosphere should also be better understood, so that formation of ozone, carbon monoxide, partially oxidized gaseous hydrocarbons, and organic aerosol can be better quantified. The formation of organic aerosol from hydrocarbon precursors and their capability to serve as cloud condensation nuclei are related, potentially important, subjects that have not been studied in any depth so far.

Potential Role of Halogen Radicals in Ozone Destruction

There are strong indications that tropospheric ozone can be destroyed by reactions in addition to those discussed so far. Observations of surface ozone levels during polar sunrise in the Arctic have frequently shown the occurrence of immeasurably low ozone concentrations, coinciding with high "filterable Br".[106] Further measurements[118] identified BrO as one of the active Br compounds, which, as is well known from stratospheric measurements, may rapidly attack ozone by a series of catalytic reactions, such as the following:

$$2 \times (Br + O_3 \rightarrow BrO + O_2) + (BrO + BrO \rightarrow 2\,Br + O_2) = (2\,O_3 \rightarrow 3\,O_2)$$

or

$$(Br + O_3 \rightarrow BrO + O_2) + (BrO + HO_2 \rightarrow HOBr + O_2) +$$
$$(HOBr + h\nu \rightarrow OH + Br) + (OH + CO + O_2 \rightarrow HO_2 + CO_2)$$
$$= (CO + O_3 \rightarrow CO_2 + O_2).$$

It should be explored whether halogen activation reactions may also occur under different circumstances than indicated above.[105–107]

Heterogeneous Reactions on Aerosol Particles

The issue of interactions between gases and atmospheric aerosol is largely unexplored and very little considered in tropospheric chemistry models. Examples are interactions of dimethylsulfide-derived sulfur compounds with sea salt in the marine boundary layer and reactions of SO_2, H_2SO_4, NO_x, N_2O_5, and HNO_3 on soil dust particles, which remove these

compounds from the gas phase. In the case of industrial SO_2, the neglect of such heterogeneous reactions may well have led to overestimations of the climatic cooling effects of anthropogenic aerosol, as any incorporation of sulfur in soil dust or sea salt will prevent the nucleation of new sunlight backscattering sulfate particles.

Ozone/Climate Feedbacks in the Stratosphere

Ozone is a significant greenhouse gas with an infrared absorption band in the atmospheric window region, centered at 9.6 μm. Although the amount of ozone in the troposphere is only about 10% of that of the stratosphere, the effective long-wave optical depth of tropospheric ozone is larger. Of greatest importance would be any changes that might take place in the ozone concentrations in the tropopause regions as a result of human activities, such as those caused by H_2O, NO, SO_2, and particulate emissions from expanding fleets of civil aircraft flying in the stratosphere and upper troposphere. On one hand this may lead to increasing temperatures in the lower stratosphere. However, increased HNO_3 and H_2O concentrations in the lower stratosphere may increase the likelihood of polar stratospheric particle formation and ozone destruction. Such a course of events is also promoted by cooling of the stratosphere through increasing concentrations of CO_2. This cooling effect also increases with height in the stratosphere and mesosphere. The implications of this for the future dynamics of the stratosphere, mesosphere, and lower thermosphere is likewise a topic deserving considerable attention. Changes in chemical and radiative conditions in the lower stratosphere may, therefore, create feedbacks that we need to understand well. They include understanding their potential impact on tropopause heights and temperatures, stratospheric water vapor, lower stratospheric cloud characteristics, and the tropospheric hydrological cycle. Recent observations of increasing trends of water vapor concentrations in the lower stratosphere over Boulder emphasize this point.[119] All these factors should be taken into account before decisions are taken on vast expansions of aircraft operations in the stratosphere.

In my acknowledgements, I firstly have to thank my parents, my wife, and my family for their love and support, and for creating the personal environment without which nothing will go.

I thank my secretaries Anja Wienhold and Bettina Krüger for their joyful attitude and hard work in sometimes chaotic times, especially in connection with the "Nobel hustle and bustle". Many thanks to Geoff Harris, Mark Lawrence, and Jens-Uwe Grooss for a final reading of the manuscript.

I thank my current and former students, post-docs, and coworkers at the Max-Planck-Institute for Chemistry for their enthusiastic research efforts. Several of them are now professors at universities or directors of major research activities. With most of them I keep a close contact, and we are friends for life.

I also thank the Max-Planck-Society and the various organizations with which I am or have been associated during my scientific career. All of them have been very important in trusting me with long-term funding and in giving me excellent opportunities to do research without major interferences. I am particularly happy to be a member of the NSF Center on the role of Clouds in Atmospheric Chemistry and Climate at the Scripps Institution of Oceanography (SIO) of the University of California, San Diego, where I am learning a lot about clouds, one of the most important elements in the climate system. I thank my good friend Prof. V. Ramanathan and SIO for this great opportunity to rejuvenate myself during a few months of the year.

I thank my director colleagues and the personnel of the Max-Planck-Institute for Chemistry, the University of Mainz, the City of Mainz, and the "Sonderforschungsbereich" for a wonderful welcome and party after my return to Mainz as a fresh Nobel Laureate following a brief vacation in Spain. I will also never forget my "homecoming" at MISU, Stockholm, and the welcome (with illegal fireworks) by my Dutch students and "grandstudents" in Wageningen, The Netherlands.

Finally, I have to thank the many colleagues, all around the world, who have congratulated me on the Nobel Prize award. Many of them have themselves contributed greatly to the remarkable progress in our research field over the past quarter of a century; only a few of these I could recognize in this Novel Lecture. As most of them have written, this is an award to the entire atmospheric chemistry and environmental field. I totally agree and thank you all.

And last but not least, a great Thank You to the Nobel Committee of the Royal Swedish Academy of Sciences. Your decision is an enormous boost for environmental research.

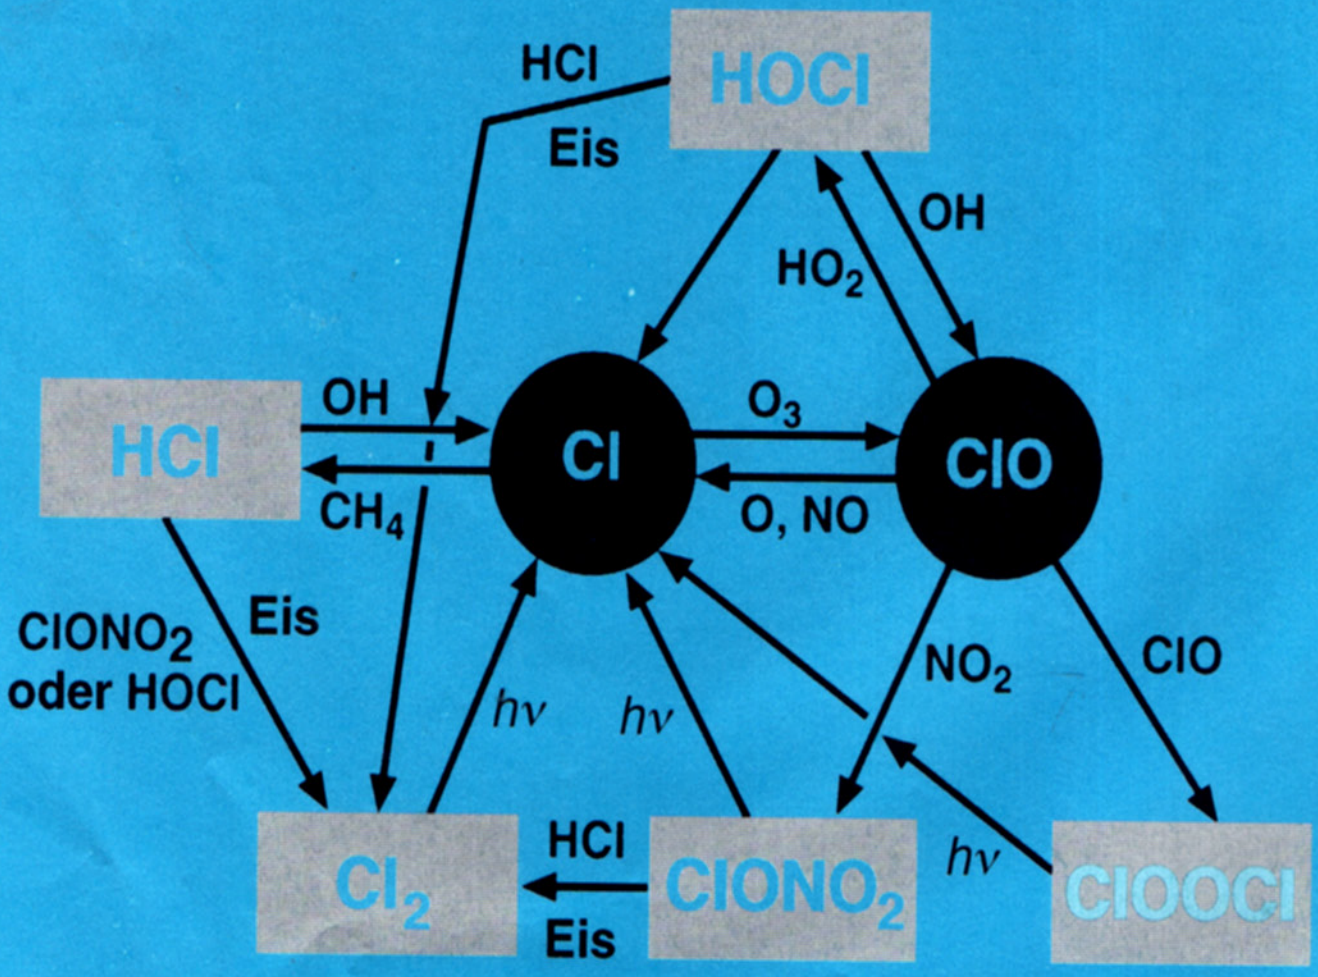
Schematic representation of the chlorine chemistry in the polar stratosphere and the theoretically and experimentally determined structure of the important molecule, chlorine peroxide.



Polar Ozone Depletion (Nobel Lecture)**

Mario J. Molina*

On the rigor of Science

...In that Empire, the Art of Cartography achieved such Perfection that the map of a single Province occupied an entire City, and the map of the Empire an entire Province. With time, those unwieldy maps did not satisfy and the Cartographers raised a Map of the Empire, with the size of the Empire and which coincided with it on every point...

Jorge Luis Borges, *El Hacedor*

Introduction

The ozone layer acts as an atmospheric shield that protects life on earth against harmful ultraviolet radiation from the sun. This shield is fragile: in the past two decades it has become very clear that it can be affected by human activities.

Roughly 90% of the earth's ozone resides in the stratosphere, which is the atmospheric layer characterized by an inverted—that is, increasing—temperature profile that rises typically from about 210 K at its base at 10–15 km altitude, to roughly 275 K at 50 km altitude. The maximum concentration of ozone is several parts per million; it is continuously being produced in the upper stratosphere by the action of solar radiation on molecular oxygen, and continuously being destroyed by chemical processes involving free radicals. Work by Paul Crutzen in the early 1970s[1] established that nitrogen oxides of natural origin, present at parts per billion levels in the stratosphere, are responsible for most of this chemical destruction, which occurs by means of catalytic cycles. Harold Johnston pointed out in 1972[2] that the large fleets of supersonic aircraft, which were being considered at that time, could have seriously affected the ozone layer through their emissions of nitrogen oxides.

In early 1974 F. Sherwood (Sherry) Rowland and I proposed that chlorofluorocarbons (CFCs) would decompose in the stratosphere, releasing chlorine atoms that would catalytically destroy ozone.[3] The CFCs are industrial compounds that have been used as refrigerants, solvents, propellants for spray cans, blowing agents for the manufacture of plastic foams, etc. The two important properties make these compounds very useful: 1) they can be readily transformed from a liquid into a vapor under mild temperature and pressure conditions, as can be seen in Table 1, which displays vapor pressures and boiling points for some of the most common CFCs; and 2) they are chemically very inert and hence nontoxic, nonflammable, and do not decompose inside a spray can or a refrigerator.

Table 1. Physical properties of some common CFCs.

Compound	Formula	Vapor pressure [atm] 260 K	300 K	Boiling point [°C]
CFC-11	$CFCl_3$	0.22	1.12	23.8
CFC-12	CF_2Cl_2	1.93	6.75	−29.8
CFC-113	$CFCl_2CClF_2$	0.08	0.47	47.7

Measurements reported by James Lovelock and co-workers[4] had indicated that the CFCs were accumulating throughout the earth's atmosphere. In our 1974 paper we suggested that the CFCs will not be destroyed by the common cleansing mechanisms that remove most pollutants from the atmosphere, such as rain, or oxidation by hydroxyl radicals. Instead, the CFCs will be decomposed by short wavelength solar ultraviolet radiation, but only after drifting to the upper stratosphere—above much of the ozone layer—where they will first encounter such radiation. Upon absorption of solar radiation the CFC molecules will rapidly release their chlorine atoms, which will then participate in the catalytic reactions (1)–(3).[3, 5]

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (1)$$

$$ClO + O \longrightarrow Cl + O_2 \quad (2)$$

$$O + O_3 \longrightarrow 2O_2 \quad (1) + (2) = (3)$$

These free radical chain reactions are terminated by reactions forming temporary reservoirs, the three most important ones being hydrogen chloride, chlorine nitrate, and hypochlorous acid [Eqs. (4)–(6)]. The free radicals are regenerated by reactions such as (7)–(9).

$$Cl + CH_4 \longrightarrow HCl + CH_3 \quad (4)$$

$$ClO + NO_2 + M \longrightarrow ClONO_2 + M \quad (5)$$

$$ClO + HO_2 \longrightarrow HOCl + O_2 \quad (6)$$

$$HCl + OH \longrightarrow Cl + H_2O \quad (7)$$

$$ClONO_2 + h\nu \longrightarrow Cl + NO_3 \quad (8)$$

$$HOCl + h\nu \longrightarrow Cl + OH \quad (9)$$

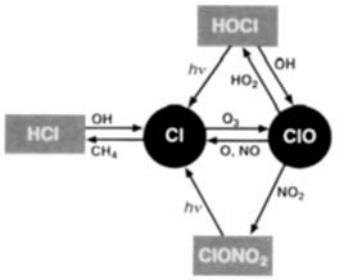

Fig. 1. Schematic representation of chlorine chemistry in the stratosphere at mid and low latitudes.

There are other reactions that affect the chlorine balance in the stratosphere; a schematic representation of the most important ones is shown in Figure 1. The net effect of this chemistry is that the inorganic chlorine produced by the decomposition of the CFCs exists in free radical form—that is, as "active chlorine"—only a few percent of the time. We have published more detailed reviews of stratospheric halogen chemistry; see, for example, Shen et al.[6] and Abbatt and Molina.[7]

In the decade following the publication of our Nature paper, field observations corroborated many of the predictions based on model calculations and on laboratory measurements of reaction rates. However, the effects on ozone were unclear, because the natural ozone levels have relatively large fluctuations.

Ozone Loss in the Polar Atmosphere

The rapid seasonal decline of stratospheric ozone over the South Pole—the so-called Antarctic ozone hole—is a startling phenomenon: a large fraction of the total column ozone (more than a third) disappears in the spring months over an area coinciding largely with the Antarctic continent (Fig. 2). In recent years it has become more severe: in October 1992 and 1993 more than 99% of the ozone disappeared at altitudes between about 14 and 19 km,[8] where concentrations of this species are usually largest; and in 1995, in mid-September, the ozone hole was the largest ever recorded that early in the austral spring.

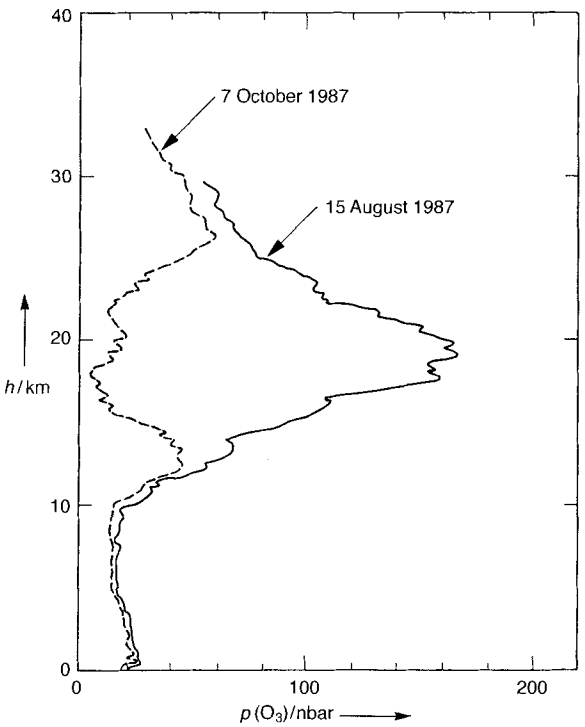

Fig. 2. Balloon measurements of ozone profiles over Halley Bay, Antarctica [30]. $p(O_3)$ = partial pressure of ozone.

Significant ozone depletion over Antarctica started in the early 1980s, but it was not until 1985 that Farman et al.[9] announced their discovery of the ozone hole, suggesting furthermore a possible link with the growth of active chlorine in the stratosphere released by the decomposition of CFCs. Satellite data subsequently confirmed their findings. This discovery was surprising, not only because of the magnitude of the depletion, but also because of its location. We had originally predicted that chlorine-initiated ozone loss would occur in regions of efficient ozone production, that is, predominantly in the upper stratosphere at middle and low latitudes; it is only there that the concentration of free oxygen atoms is large enough for catalytic reactions such as (1) and (2) to occur efficiently. Furthermore, the expectation was that at high latitudes active chlorine would be relatively less abundant, because the reservoir species would be more stable: reactions such as (7) and (8) slow down as a consequence of the decrease in temperature as well as the decrease in solar radiation at the higher zenith angles, that is, the lower sun elevation.

The initial question was, thus, whether the observed polar ozone loss was of human origin, or else merely a periodic natural phenomenon, only never before noticed. A prominent early theory put forth to explain this phenomenon had as a principal cause atmospheric dynamics driven by extreme cold temperatures: the hypothesis was that upon first sunrise in the spring, warming of the Antarctic stratosphere would lead to a net upward lifting of ozone-poor air from the troposphere or lower stratosphere. If so, no ozone destruction would be taking place; it would merely be redistributed periodically. Another theory suggested that the 11-year solar cycle was responsible for the effect: chemical destruction of ozone involving catalytic NO_x cycles would occur, with participation of catalysts generated in the upper stratosphere by high energy particles or by ultraviolet radiation following enhanced solar activity. A third theory suggested that chlorine and bromine free radicals were the catalysts for the chemical destruction of ozone, the source of these radicals being compounds of industrial origin—CFCs and halons (these are compounds containing bromine, which are used as fire extinguishers). This third theory is discussed next in more detail. It is based on our original hypothesis of ozone depletion by CFCs, but it is modified and extended to take into account the peculiar conditions prevailing over Antarctica Figure 3

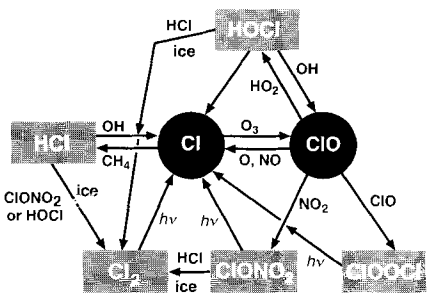

Fig. 3. Schematic representation of chlorine chemistry in the polar stratosphere.

displays schematically the most important reactions of the modified theory (compare to Fig. 1, the original chemistry).

Gas-Phase Chemistry of the Polar Stratosphere

The large solar zenith angle characteristic of the polar stratosphere results in little, if any photodissociation of oxygen, and hence in practically no new ozone production. Similarly, ozone itself photolyzes only rather slowly in those regions, so that the concentration of free oxygen atoms remains very small, particularly in the lower stratosphere where the ozone loss is largest. Consequently, catalytic cycles that require the presence of atomic oxygen are ineffective for ozone destruction, as mentioned above. Several cycles not involving oxygen atoms were proposed after the discovery of the ozone hole, such as the one depicted in Scheme 1, based on the coupling of HO_x and ClO_x radicals.[10]

$$\begin{aligned} &OH + O_3 \longrightarrow HO_2 + O_2 \\ &Cl + O_3 \longrightarrow ClO + O_2 \qquad (1) \\ &ClO + HO_2 \longrightarrow HOCl + O_2 \\ &HOCl + h\nu \longrightarrow OH + Cl \\ &\text{Net: } 2O_3 + h\nu \longrightarrow 3O_2 \end{aligned}$$

Scheme 1. A possible reaction sequence for ozone depletion without the participation of oxygen atoms.

Measurements of the abundance of HOCl in the Antarctic stratosphere indicate, however, that this cycle does not make a major contribution to ozone depletion. McElroy et al.[11] proposed another cycle involving bromine (Scheme 2).

$$\begin{aligned} &Cl + O_3 \longrightarrow ClO + O_2 \qquad (1) \\ &Br + O_3 \longrightarrow BrO + O_2 \\ &ClO + BrO \longrightarrow Cl + Br + O_2 \\ &2O_3 \longrightarrow 3O_2 \end{aligned}$$

Scheme 2. Another possible reaction sequence, which involves bromine, for ozone depletion without participation of oxygen atoms.

The reaction between ClO and BrO regenerates the free atoms in this cycle, but the reaction has actually three channels (Scheme 3). Laboratory investigations have shown that the first and third channels are approximately equally fast, whereas production of BrCl is relatively slow.

$$\begin{aligned} &ClO + BrO \longrightarrow Cl + Br + O_2 \\ &ClO + BrO \longrightarrow BrCl + O_2 \\ &ClO + BrO \longrightarrow Br + OClO \end{aligned}$$

Scheme 3. The three possible reactions between ClO and BrO.

In 1987 we proposed a mechanism involving the self-reaction of ClO to form chlorine peroxide,[12] a compound not previously characterized (Scheme 4, top). The reaction of ClO with itself has three bimolecular channels, as is the case for the ClO + BrO reaction (Scheme 4, bottom). These bimolecular reactions are

$$\begin{aligned} &ClO + ClO + M \longrightarrow Cl_2O_2 + M \\ &Cl_2O_2 + h\nu \longrightarrow 2Cl + O_2 \\ &2Cl + 2O_3 \longrightarrow 2ClO + 2O_2 \qquad 2\times(1) \\ &\text{Net: } 2O_3 + h\nu \longrightarrow 3O_2 \\ &ClO + ClO \longrightarrow Cl_2 + O_2 \\ &ClO + ClO \longrightarrow Cl + ClOO \\ &ClO + ClO \longrightarrow Cl + OClO \end{aligned}$$

Scheme 4. Postulated ozone depletion by participation of Cl_2O_2 (top) and the three possible reactions between two ClO molecules (bottom).

too slow to be of importance in the atmosphere. However, the termolecular reaction that leads to the formation of chlorine peroxide can occur efficiently in the lower stratosphere at high latitudes, as it is facilitated by the lower temperatures and higher pressures prevailing in those regions.

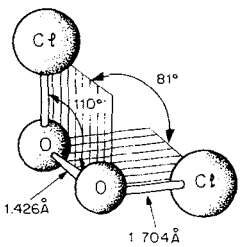

Fig. 4. Structure of chlorine peroxide [14].

The structure of the product formed in the termolecular ClO self-reaction has been shown by both theory[13] and experiment[14] to be indeed ClOOCl, rather than ClOClO (Fig. 4). Furthermore, photodissociation of ClOOCl yields predominantly Cl atoms, rather than ClO radicals, as we and others have shown in laboratory experiments.[15, 16] Formation of ClOO is also possible; however, even under polar stratospheric conditions ClOO rapidly decomposes to yield free chlorine atoms, since the Cl–OO bond strength is only about 5 kcal mol^{-1}.

Polar Stratospheric Clouds

In contrast to the troposphere, the stratosphere is extremely dry and practically cloudless. The concentration of water vapor is measured in parts per million, and is, in fact, comparable to that of ozone. Normally, there is a thin layer of aerosol throughout the lower stratosphere—a haze—first described in 1961 by Junge and co-workers.[17] The aerosol's droplets are mostly liquid and consist of supercooled aqueous sulfuric acid solutions (about 75% H_2SO_4 by weight at mid and low latitudes, with a radius of roughly 0.1 μm). The "background" number density falls typically in the 1–10 cm^{-3} range, but it may increase by between one and two orders of magnitude following the injection of SO_2 directly into the stratosphere by major volcanic eruptions, such as El Chichon in 1982 and Mount Pinatubo in 1991. The SO_2 is oxidized in the stratosphere to form H_2SO_4 on a time scale of months, and the excess particles decay over a period of a few years. SO_2 emitted at the earth's surface by processes such as the combustion of coal is mostly oxidized and removed from the atmosphere (as acid rain) before reaching the stratosphere. The background aerosols arise mainly from OCS, which is also emitted at the earth's surface but is sufficiently

stable to reach the stratosphere, where it photooxidizes to yield SO_2 and subsequently H_2SO_4.

Polar stratospheric clouds (PSCs) form seasonally over the polar regions. Satellite-based instruments have been monitoring these clouds long before the discovery of the ozone hole by observing the attenuation of sunlight, which is scattered at wavelengths characteristic of the size of the cloud particles. In the winter and spring months, sharp increases in the attenuation resulting from the presence of PSCs are evident, followed by a decrease in the summer after the cloud particles evaporate or sediment out.

The PSC particles form by condensation of vapors on the pre-existing sulfuric acid aerosols. Observations have also indicated the existence of different types of clouds, the two most common ones being often referred to as Type I and Type II PSCs. The latter are present only when the temperatures fall below the frost point of water, which is typically about 185–187 K; the particles are roughly 10 μm in diameter and are composed principally of water-ice crystals. The Type II clouds are more prevalent over Antarctica, because of its lower temperatures compared to the Arctic. Type I PSCs are observed more frequently, forming at temperatures above the frost point of water but below 190–195 K, with particle diameters of roughly one micrometer. Thermodynamic considerations coupled with laboratory experiments indicate that Type I PSC particles consist most likely of nitric acid trihydrate (NAT), which is the most stable condensed phase under the conditions leading to the formation of these clouds. However, more recent laboratory experiments indicate that the aerosol particles are not likely to freeze at temperatures above the water frost point.[18] Furthermore, investigations performed in the field[19] and in the laboratory[20, 21] indicate that the liquid sulfuric acid droplets should absorb significant amounts of nitric acid and water vapor under polar stratospheric conditions, and a very rapid change in composition (and hence size) should occur over a narrow temperature range,[22, 23] thus explaining the formation of Type I clouds below a certain temperature threshold. Hence, it appears that Type I PSCs are sometimes liquid—particularly over the Arctic—and sometimes solid.

Chemistry on Cloud Particles

Laboratory experiments, field observations, and atmospheric modeling calculations have now established that chemical reactions occurring on PSC particles play a central role in polar ozone depletion. These reactions have two separate effects, referred to as chlorine activation and nitrogen deactivation: first, chlorine is transferred from the relatively inert reservoir compounds HCl and $ClONO_2$ into forms that can be readily photolyzed (mostly Cl_2); and second, nitrogen oxides are removed from the gas phase, through incorporation of nitric acid into the PSCs, thus preventing the formation of $ClONO_2$, a species that interferes with the catalytic chlorine cycles that destroy ozone. In fact, some PSC particles grow large enough to precipitate, permanently removing nitric acid from the stratosphere; this process is labeled denitrification.

Of the key chlorine activation reactions [Eqs. (10)–(12)], the most important is (10). Our early laboratory experiments indi-

$$ClONO_2 + HCl \longrightarrow Cl_2 + HNO_3 \quad (10)$$

$$ClONO_2 + H_2O \longrightarrow HOCl + HNO_3 \quad (11)$$

$$HOCl + HCl \longrightarrow Cl_2 + H_2O \quad (12)$$

cated that this reaction does not occur in the gas phase at significant rates.[24] However, we noticed in those experiments that this and other reactions involving chlorine nitrate are very sensitive to surface effects; similar observations had been reported by Sherry Rowland's group. In 1986 Solomon et al.[10] suggested that reactions (10) and (11) would be promoted by PSCs, setting the stage for efficient ozone depletion over Antarctica. In 1987 we carried out a series of laboratory measurements showing that reaction (10) is indeed remarkably efficient, requiring only a few collisions of the reactant $ClONO_2$ with ice exposed to HCl vapor.[25] This peculiar chemical reactivity of ice was surprising; in contrast to liquid water—and the well-established chemistry of aqueous ions—reactions promoted by ice at temperatures down to 180 K were unprecedented. Our results were subsequently corroborated by several other groups (for a review, see Kolb et al.[26]).

Mechanism for Chlorine Activation Reactions

The net effect of reactions (11) and (12) occurring sequentially is reaction (10), which suggests that the mechanism for this last reaction involves the two steps (11) and (12). Also, while the high efficiency of reaction (11) on ice is understandable—the reactant H_2O is already in condensed phase—both reactants for reaction (10) are originally in the gas phase; hence, it proceeds most likely through sequential, rather than simultaneous collisions of the reactants with the surface. This implies that at least one of the reactants, most likely HCl, has a high affinity for the condensed phase. Previous measurements had shown, though, that HCl is only sparingly soluble in ice; more recent investigations have indicated, however, that monolayer amounts of HCl are taken up by the ice surface under temperature and HCl partial pressure conditions similar to those prevailing in the polar stratosphere.[26, 27]

Physical adsorption of HCl is expected to incorporate only negligible amounts of HCl on the ice surface,[28] even allowing for a very strong hydrogen bond. These expectations led early on to the suggestion that reaction (10) should not occur on ice under stratospheric conditions of temperature and HCl partial pressure, and the results of laboratory measurements were considered to be artifacts resulting from grain boundary effects.

The high affinity of HCl for the ice surface can be explained, however, by assuming that the HCl solvates, forming hydrochloric acid, as is the case with liquid water. This process is exothermic by about 18 kcal mol^{-1}; in contrast, a hydrogen bond of HCl with ice is estimated to be only 5 kcal mol^{-1}. Solvation can occur because the surface layers of ice are disordered and the water molecules there have much larger mobility than in the bulk crystal. This behavior leads to the formation of a quasi-liquid layer on the ice surface, which can be experimentally observed at temperatures down to about 240 K. The presence of HCl strongly depresses the freezing point (a 9-molal HCl solu-

tion freezes at about 190 K), with the result that formation of a quasi-liquid HCl solution layer appears plausible under polar stratospheric conditions.[28] Furthermore, the large reaction probabilities for reactions (10) and (12) can be understood with the quasi-liquid layer model: the mechanism for these reactions most likely involves aqueous-like ions. In contrast, adsorbed molecular HCl is expected to behave rather similarly to gaseous HCl, and hence should react only very slowly with $ClONO_2$, as noted above.

Laboratory measurements of the uptake of HCl by NAT have also been conducted. For NAT, however, an additional parameter that needs to be taken into account is its H_2O vapor pressure: at any given temperature it can have a range of values, whereas for water-ice it has, of course, only one value. Observations show that when the H_2O vapor pressure of NAT approaches that of ice its surface takes up as much HCl as ice, whereas the amount decreases by more than two orders of magnitude as the H_2O vapor pressure drops. The reaction probabilities for reactions (10) and (12) behave accordingly: they have large values when the H_2O vapor pressure of NAT is within a factor of about 3 of that of ice.[26, 29] It appears that the uptake as well as the reaction probabilities are controlled by the availability of water at the surface.

The chlorine activation reactions (10–12) occur rather slowly on sulfuric acid aerosols at mid latitudes, because HCl is only very sparingly soluble in relatively concentrated H_2SO_4 solutions, and because the water in those solutions is not available for reaction with $ClONO_2$. However, as the temperature drops towards high latitudes and the sulfuric acid solution becomes more dilute, the HCl becomes more soluble, and the efficiency of these reactions increases dramatically over a relatively narrow temperature range: under conditions of thermodynamic stability for Type I PSCs, chlorine activation occurs rapidly on both liquid and solid particles.[20]

Measurements of Key Species over Antarctica

Beginning in 1986, a series of field experiments were designed to test the various hypotheses that had been put forth to explain the Antarctic ozone hole. For example, observations of upward flow in the polar stratosphere would have verified the "dynamics only" theory. The solar cycle theory would have been supported by observations of high NO_x levels in regions where ozone was being depleted; furthermore, according to this theory in years of low solar activity the polar stratosphere would recover to normal pre-ozone hole conditions. In contrast, expectations from the halogen theory were low levels of nitrogen oxides, and high levels of active chlorine.

The first observational campaign designed to test these theories, the National Ozone Experiment (NOZE), was mounted in the winter of 1986. The NOZE scientists, based at McMurdo, Antarctica, and led by Susan Solomon, performed remote sensing measurements of key stratospheric species such as NO_2, O_3, and chlorine free radicals. Their findings provided the first evidence that the chemistry of the Antarctic stratosphere was highly perturbed, and the halogen chemistry mechanism appeared most likely. A second NOZE campaign, as well as the Airborne Antarctic Ozone Experiment (AAOE) were conducted in 1987. This expedition was based at Punta Arenas, Chile: the results from flights conducted over a six week period largely confirmed and extended the results from the NOZE experiment. The observations provided very clear evidence of a strong downward flow within the Antarctic polar vortex, which is the region of the stratosphere where the ozone hole develops: contrary to predictions based on the dynamics only theory, the levels of tracers such as the CFCs, CH_4, and N_2O were typical of air coming from higher altitudes—"aged" air which had been exposed to short-wavelength ultraviolet radiation. Furthermore, the concentration of NO_x was remarkably low, in contrast with expectations from the solar cycle theory.

The chemical CFC–halogen hypothesis received strong support from the results of the field experiments. The measurements conducted by James Anderson and co-workers[31] showed that the ClO concentrations in the polar vortex were greatly enhanced (Fig. 5), revealing that more than half of the

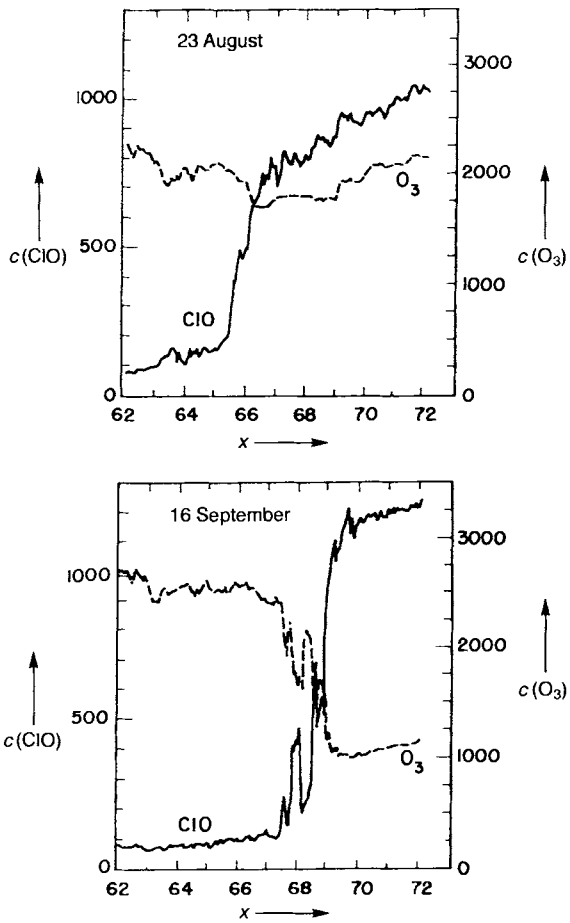

Fig. 5. Mixing ratios c (in ppb) of ClO and ozone measured in 1987 during the AAOE expedition; adapted from Ref. [31]. x = latitude (degrees south).

chlorine was present there as a free radical—chlorine that had been released in the stratosphere at lower latitudes by the decomposition of the CFCs. These measurements, coupled with the observations of the rate of disappearance of ozone, indicated that the chlorine peroxide cycle that we had suggested (Scheme 4, top) was responsible for more than two-thirds of the ozone loss. Most of the rest of the loss resulted from bromine chemistry.

The unique instruments required for all these experiments, as well as the halogen hypothesis itself, were developed in a relatively short time. The community was well prepared for these new developments, since it had vigorously continued for over a decade the pursuit of scientific research on the stratospheric ozone issue.

Conclusions

Much remains to be learned about stratospheric chemistry—and, in more general terms, about the physics and chemistry of the global atmosphere. On the other hand, the cause–effect relationship between human-produced chemicals and ozone depletion is rather well established now: the signals connected with the Antarctic ozone hole are very large indeed. The stratospheric ozone issue has shown us that mankind is quite capable of significantly affecting the atmosphere on a global scale: the most striking effects of CFCs, which are emitted mostly in the north, are seen as far away as possible from the sources, namely over the South Pole. This global problem has also shown us that different sectors of society can work together—the scientific community, industry, environmental organizations, government representatives, and policy makers—to reach international agreements: the Montreal Protocol on Substances that Deplete the Ozone Layer has established a very important precedent for the solution of global environmental problems.

Biographical Notes

Finally, a short resumé of my life. I was born in Mexico City on March 19, 1943, the son of Roberto Molina Pasquel and Leonor Henriquez de Molina. My father was a lawyer in private practice, but he also taught at the National University of Mexico (Universidad Nacional Autonoma de Mexico (UNAM)). In his later years, after I had left Mexico, he served as Mexican Ambassador to Ethiopia, Australia, and the Philippines. I was already fascinated by science before entering high school. Aware of my interest in chemistry, my parents kept with the family tradition of sending children abroad for a couple of years and sent me to a boarding school in Switzerland when I was 11 years old, on the assumption that German was an important language for a prospective chemist to learn. After finishing my undergraduate studies in Mexico with the aim of becoming a research chemist, I spent nearly two years doing research in kinetics of polymerizations at the University of Freiburg, Germany. Subsequently, I returned to Mexico as an Assistant Professor at the UNAM and set up the first graduate program in chemical engineering. Finally, to broaden my background and to explore other research areas, I began my graduate studies in physical chemistry in 1968 at the University of California at Berkeley in the research group of Professor George C. Pimentel. There I met Luisa Tan, a fellow graduate student in Pimentel's group, who later became my wife and close scientific collaborator. We have one son.

M. J. Molina

After completing my Ph.D. degree on the investigation of the distribution of internal energy in the products of chemical and photochemical reactions in 1972, I joined the group of Professor F. Sherwood (Sherry) Rowland as a postdoctoral fellow in 1973 and chose to study the environmental fate of CFCs.

In 1975 I was appointed as a member of the faculty at the University of California, Irvine and set up an independent program to investigate chemical and spectroscopic properties of compounds of atmospheric importance, focusing on those that are unstable and difficult to handle in the laboratory, such as HClO, ClONO, $ClONO_2$, and $HOONO_2$.

Although my seven years at Irvine were very productive, I missed not doing experiments myself because of the many responsibilities associated with a faculty position. I decided to move to a nonacademic position and joined the Molecular Physics and Chemistry Section at the Jet Propulsion Laboratory in 1982. Around 1985 after becoming aware of the discovery by Joseph Farman and his co-workers of the seasonal depletion of ozone over Antarctica, my research group at JPL investigated the peculiar chemistry promoted by polar stratospheric clouds. In 1989 I returned to academic life at the Massachusetts Institute of Technology, where I have continued with research on global atmospheric chemistry issues. Although I no longer spend much time in the laboratory, I very much enjoy working with my graduate and postdoctoral students, who provide me with invaluable intellectual stimulus. I have also benefited from teaching; as I try to explain my views to students with critical and open minds, I find myself continually challenged to go back and rethink ideas. I now see teaching and research as complementary, mutually reinforcing activities.

One of the very rewarding aspects of my work has been the interaction with a superb group of colleagues and friends in the atmospheric sciences community. I truly value these friendships, many of which go back 20 years or more, and which I expect to continue for many more years to come. I feel that this Nobel Prize represents a recognition for the excellent work that has been done by my colleagues and friends in the atmospheric chemistry community on the stratospheric ozone depletion issue. Many colleagues and collaborators have contributed to the work described above; while only some of them have been mentioned here, I would like to express my appreciation to all of them. I am grateful to my past and present students and associates for their dedication in carrying out research in my laboratory. I am especially indebted to my wife, Luisa, who has been my closest collaborator for many years. I also want to acknowledge the sponsors of our research, which have included the National Aeronautics and Space Administration and the National Science Foundation.

These images from the NASA TOMS (Total Ozone Mapping Spectrometer) satellite of October 3, 1979 (top) and October 4, 1992 (bottom) clearly show how the total ozone concentration has changed in spring over the southern hemisphere. The color key (in Dobson Units) interprets the measurements. The data return from October 3, 1979, was flawed, and missing data are shown as irregular white spaces.

Stratospheric Ozone Depletion by Chlorofluorocarbons (Nobel Lecture)**

F. Sherwood Rowland*

Introduction

There is a well-known mathematical exercise called the Konigsberg Bridge Problem in which the solution involves crossing each of the city's bridges once and only once. When my wife and I first visited Stockholm together in April 1974, we had the distinct impression that our host, Paul Crutzen, was trying to illustrate the corresponding solution for Stockholm by leading us across every single bridge, on foot. We were in Stockholm, because I had sent Paul a preprint of our first scientific paper on the chlorofluorocarbon/stratospheric ozone problem,[1] and he had invited me to present a lecture about this work to the Department of Meteorology of Stockholm University.

The starting point for that work was the discovery by Jim Lovelock that CCl_3F, a substance for which no natural sources have been found, was present in the earth's atmosphere in quantities roughly comparable to the total amount manufactured up to that date. Lovelock had earlier invented an extremely sensitive detection system employing electron capture (EC) by trace impurities, and attached it to the column of effluent gases from a gas chromatograph (GC), a device which separates a mixture of gases into its individual components. With this EC-GC apparatus, Lovelock initially established that CCl_3F was always detectable in the atmosphere near his home in western Ireland, and then that it was also present in all of the air samples tested on the voyage of the R.V. Shackleton from England to Antarctica (Fig. 1).[2] The EC-GC instrument is especially sensitive for CCl_3F, as well as for many other similar molecules in this class of chlorofluorocarbons (CFCs).

The appearance in the atmosphere of a new, man-made molecule provided a scientific chemical challenge: Was enough known about the physicochemical behavior under atmospheric conditions of molecules such as CCl_3F to allow prediction of its fate, once released into the environment? In 1973 I included in my yearly proposal to the U.S. Atomic Energy Commission (AEC), which had sponsored my research involving radioactive tracer species since 1956, a predictive study of the atmospheric chemistry of CCl_3F, in addition to the continuation of other

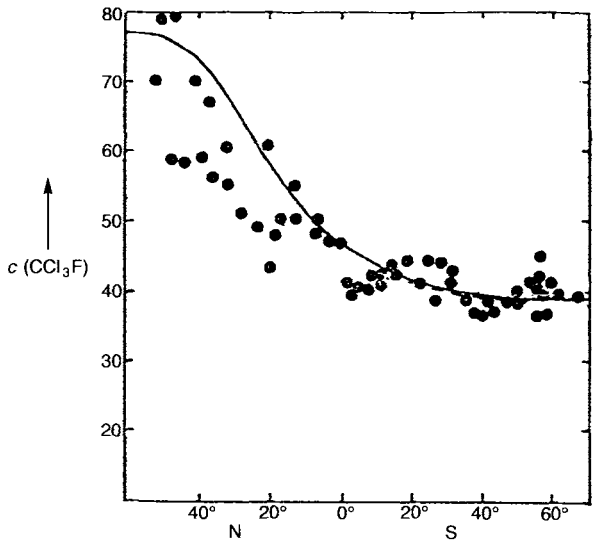

Fig. 1. Mixing ratios of CCl_3F (c in ppbv ($1:10^9$ by volume) measured by James Lovelock [2] on board the R. V. Shackleton in 1971. The x axis represents latitude from 40°N to 60°S.

studies already in progress. The A.E.C. agreed to permit this new venture, subject only to the requirement that I shift some of the funding already scheduled for the studies on radioactivity.

When Mario Molina joined my research group as a postdoctoral research associate later in 1973, he elected the chlorofluorocarbon problem from several offered to him, and we began the scientific search for the ultimate fate of such molecules. At the time, neither of us had any significant experience in treating chemical problems of the atmosphere, and each of us was now operating well away from our previous areas of expertise.

The search for any removal process that might affect CCl_3F began with the reactions that normally affect molecules released to the atmosphere at the surface of the earth. Several well-established tropospheric sinks – chemical or physical removal processes in the lower atmosphere – exist for most molecules released at ground level:

1) Colored species such as the green molecular chlorine (Cl_2) absorb visible solar radiation and break apart, or photodissociate, into individual atoms.

2) Highly polar molecules, such as hydrogen chloride (HCl) dissolve in raindrops to form hydrochloric acid, and are removed when the drops actually fall.

3) Almost all compounds containing carbon-hydrogen bonds, for example CH_3Cl, are oxidized in our oxygen-rich atmosphere, often by the hydroxyl radical [Eq. (1)].

$$CH_3Cl + HO \longrightarrow H_2O + CH_2Cl \quad (1)$$

However, CCl_3F and the other chlorofluorocarbons such as CCl_2F_2 and CCl_2FCClF_2[*] are transparent to visible solar radiation and those wavelengths of ultraviolet (UV) radiation that penetrate to the lower atmosphere, are basically insoluble in water, and do not react with HO, O_2, O_3, or other oxidizing agents in the lower atmosphere. When all of these usual decomposition routes are closed, what happens to such survivor molecules?

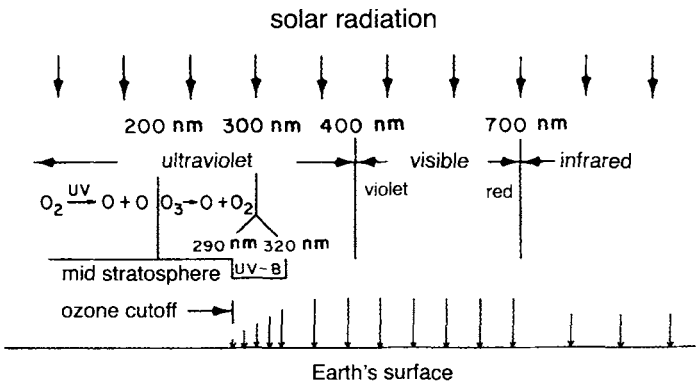

Fig. 2. The solar spectrum, illutrating the absorption of ultraviolet radiation by O_2 and O_3, and the location of the UV-B range between 290 and 320 nm. UV radiation at wavelengths shorter than 290 nm, "the ozone cutoff", does not reach the earth's surface.

Stratospheric Chemical Processes

The radiation from the sun has wavelengths visible to humans from violet (400 nm) to red (700 nm), plus invisible infrared (> 700 nm) and ultraviolet (< 400 nm) wavelengths. The energy of the radiation increases as the wavelengths shorten, and the absorption of highly energetic UV radiation usually causes the decomposition of simple atmospheric molecules.

All multiatom compounds are capable of absorbing UV radiation if the wavelength is short enough, and almost all will decompose after absorbing the radiation. At the top of the atmosphere, the process is so rapid that a CFC molecule would last at most a few weeks if directly released there. However, CFC molecules in the lower atmosphere are protected against this very energetic UV radiation by O_2 and O_3 molecules at higher altitudes. In the upper atmosphere, the UV wavelengths shorter than 242 nm can be absorbed by O_2 (Fig. 2), splitting it into two oxygen atoms [Eq. (2)]. Each of these O atom products normally adds to another O_2 molecule [Eq. (3)] to form ozone (O_3). Collision with some third molecule M is needed to stabilize the O_3 product. These ozone molecules in turn can absorb UV radiation [Eq. (4)] and split off an O atom. Such absorption is especially strong for wavelengths shorter than 290 nm. Again, these O atoms usually reform ozone by reacting with O_2.

$$O_2 + \text{UV light} \longrightarrow O + O \quad (2)$$

$$O + O_2 + M \longrightarrow O_3 + M \quad (3)$$

$$O_3 + \text{UV light} \longrightarrow O + O_2 \quad (4)$$

Ozone is actually quite chemically reactive and sometimes intercepts the O atoms [Eq. (5)]. This set of four reactions involving

$$O + O_3 \longrightarrow O_2 + O_2 \quad (5)$$

O, O_2, and O_3 was already recognized by Chapman in 1930.[3] Through these processes, and others such as the free radical reactions of NO_x and ClO_x described below, a balance of ozone is maintained in the atmosphere by which about 3 parts in 10^7 of the entire atmosphere are present as O_3, versus almost 21% as O_2. About 90% of these ozone molecules are present at altitudes between 10 and 50 km, that is, in the stratosphere, where the mixing ratio of O_3 can rise as high as 1 part in 10^5.

The solar UV energy absorbed in reaction (4) is converted into heat by processes such as energy transfer to M in Equa-

[*]The CFCs are often technically identified by a numerical formula that gives the number of F atoms in the units digit, the number of H atoms plus 1 in the tens digit, and the number of C atoms minus 1 in the hundreds digit: CCl_2FCClF_2 → CFC-113; CCl_3F → CFC-11, dropping the 0 from 011; and CCl_2F_2 → CFC-12. During the past decade, the hydrogen-containing species have been distinguished from the fully-halogenated CFCs by subdivision into the two new categories of HCFCs (e.g., $CHClF_2$ → HCFC-22) and HFCs (e.g., CH_2FCF_3 → HFC-134A; the A distinguishes this molecule from its isomer CHF_2CHF_2).

F. Sherwood Rowland was born on June 28, 1927, in Delaware, Ohio. At not quite sixteen he completed his High School education and then spent two years on an accelerated university course until he was old enough to enlist in the Navy in 1945. After the war he decided to extend the time he still needed to graduate by a year to broaden his studies. In 1948 he enrolled for graduate work in the Department of Chemistry at the University of Chicago. His supervisor was Willard F. Libby, who won the Nobel Prize in 1960 for his work on the ^{14}C dating technique. In his doctoral thesis he worked on the chemical state of radioactive bromine atoms generated in a cyclotron. After attaining his doctorate in 1952 he moved to Princeton University with his wife Joan Lundberg. They have two children. The particularly good facilities for radiochemistry attracted him to the University of Kansas in 1956. From 1964 to 1970 he was the first Chairman of the Chemistry Department at the Irvine campus of the University of California. Since the early 1970s he has devoted his time increasingly to a new research field, atmospheric chemistry, and in particular to the chemistry of chlorofluorocarbons.

tion (3), providing a heat source in the 30–50 km altitude range. This heat source creates the stratosphere, the region between 15 and 50 km in which the temperature increases with altitude. The ozone layer thus performs two important physical processes: it removes short wavelength UV radiation and changes this energy into heat, both creating and maintaining the stratosphere.

Because both O_2 and O_3 can absorb short wavelength UV radiation, no solar radiation with wavelengths shorter than 290 nm penetrates below the stratosphere. The CCl_3F molecule was known from laboratory studies to be able to absorb UV radiation at wavelengths shorter than 220 nm, but to encounter such solar radiation in the atmosphere the molecule must first drift randomly through the atmosphere to altitudes higher than most of the O_2 and O_3 molecules – roughly to 25 or 30 km. More than 98% of the atmosphere and 80% of the ozone lies below 30 km altitude. In this rarefied air, the CFC molecules are exposed to very short wavelength UV radiation and decompose with the release of Cl atoms [Eqs. (6) and (7)]. Because at any

$$CCl_3F + \text{UV light} \longrightarrow Cl + CCl_2F \quad (6)$$

$$CCl_2F_2 + \text{UV light} \longrightarrow Cl + CClF_2 \quad (7)$$

given time, only a very small fraction of CFC molecules are found at altitudes of 30 km or higher, the average molecule survives for many decades before it is decomposed by solar UV radiation.

In 1974 we calculated the vertical profile to be expected for CCl_3F in the stratosphere, using several different sets of eddy diffusion coefficients, the parameter used to simulate vertical motions in these calculations.[4] The resulting vertical profiles for CCl_3F are all quite similar (Fig. 3), because the decomposition rate for this molecule escalates rapidly with increasing altitude in the 20–30 km range. With each of these parameters, the estimated average lifetime in the atmosphere for CCl_3F was in the range from 40 to 55 years, and others extended the lifetime to 75 years. The range of lifetimes calculated for CCl_2F_2 was 75 to 150 years.[1,4]

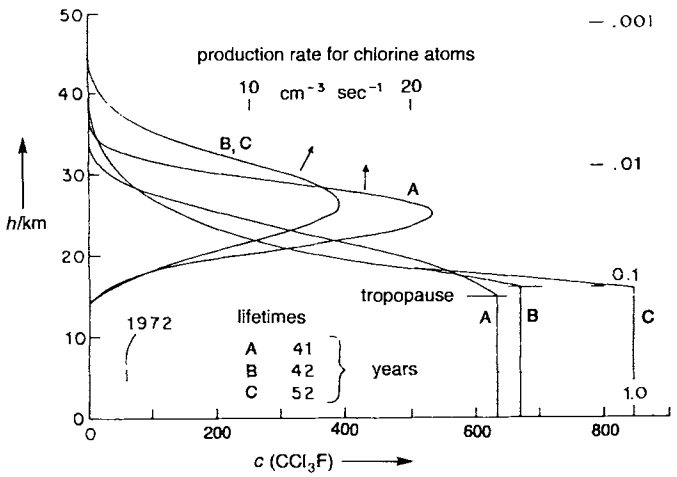

Fig. 3. Vertical profiles of the CCl_3F content c in pptv ($1:10^{12}$ by volume) at steady state, as calculated for three different diffusion models (A, B, C) and the 1972 emission rate [4]. Photolytic destruction of CCl_3F occurs most efficiently at an altitude of 28 kilometers. On the right the pressure is given in atmospheres.

The answer to our original scientific question is that the eventual fate of the CFC molecules is photodissociation in the mid-stratosphere with the release of atomic chlorine, but on a time scale of many decades. What is the fate of these chlorine atoms at an altitude of 30 km?

Chlorine Chemistry in the Stratosphere

The major chemical components of the mid-stratosphere are well known, and their reaction rate constants with atomic Cl have been measured in the laboratory. By combining these data, the conclusion is readily reached that almost all chlorine atoms react with ozone by Equation (8), forming another reactive molecule, ClO. This probability is about 1000 times more likely than reaction with methane according to Eq. (9). The questions of

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (8)$$

$$Cl + CH_4 \longrightarrow HCl + CH_3 \quad (9)$$

the ultimate sinks, first for CCl_3F and then for Cl, have thus been answered, and the question now moves to a third molecule, the ClO product from reaction (8): What happens to ClO at 30 km?

Two important answers appear: reaction with O atoms [Eq. (10)] or with NO [Eq. (11)]. The combination of reactions

$$ClO + O \longrightarrow Cl + O_2 \quad (10)$$

$$ClO + NO \longrightarrow Cl + NO_2 \quad (11)$$

(8) and (10) corresponds to reaction (5) and constitutes a free radical catalytic chain reaction in which the Cl atom alternates between the chemical species Cl and ClO. The first step removes one O_3 molecule, while the second intercepts an O atom which could have become an O_3 by reaction (3), but is instead also converted into O_2. The Cl atom, however, is only a catalyst, and remains to initiate the process once more.

This Cl/ClO cycle can be repeated hundreds or thousands of times, converting back into molecular O_2 one ozone molecule and one oxygen atom. When this catalytic efficiency of about 100000 ozone molecules removed per chlorine atom is coupled with the yearly release to the atmosphere of about one million tons of CFCs, the original question chiefly of scientific interest has now been converted into a very significant global environmental problem – the depletion of stratospheric ozone by chlorine contained in the chlorofluorocarbons.

The ClO_x chain of reactions (8) and (10) was discovered earlier in 1973 by Stolarski and Cicerone, who were interested in the possible natural release of HCl to the atmosphere from volcanoes or from man-made sources in the exhaust of the rockets scheduled for propulsion of the space shuttle.[5] The ClO_x chain has a close analogy with the NO_x free radical catalytic chain of reactions (12) and (13), which also combine to convert

$$NO + O_3 \longrightarrow NO_2 + O_2 \quad (12)$$

$$NO_2 + O \longrightarrow NO + O_2 \quad (13)$$

O and O_3 into two molecules of O_2. This chain can be initiated in the stratosphere by the decomposition of the long-lived mol-

ecule nitrous oxide, N_2O.[6] Alternatively, the NO_x chain can also be triggered by the direct release of NO and NO_2 in the exhaust of high-flying aircraft.[7, 8] The potential effects on stratospheric ozone of NO_x from supersonic transport aircraft such as the Concorde and the proposed Boeing aircraft were discussed in detail during the period 1971 to 1974 under the Climatic Impact Assessment Program.[9, 10]

Reactions such as (9), (11), and (14) show that the distribution of chlorine is closely intertwined with the concentrations of

$$HO + HCl \longrightarrow Cl + H_2O \qquad (14)$$

other stratospheric species, including the nitrogen oxides, methane, and oxides of hydrogen. The most significant homogeneous gas phase interconnections among the active chain species (Cl, ClO) and the reservoir molecules (HCl, HOCl, $ClONO_2$) in the stratosphere above the tropics and the temperate zones are shown in Figure 4. Because of the large-scale mixing processes

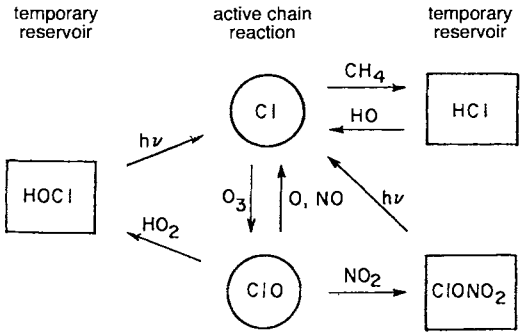

Fig. 4. The most important chemical transformations among inorganic chlorine species in the stratosphere except during the polar winter. Ozone depletion occurs only while chlorine is in the forms of Cl and ClO.

that dominate throughout the troposphere and stratosphere, the total mixing ratio of Cl from any species released at the earth's surface is essentially constant with altitude. However, the fraction in each of the various chlorine-containing chemical forms varies significantly with altitude (Fig. 5).

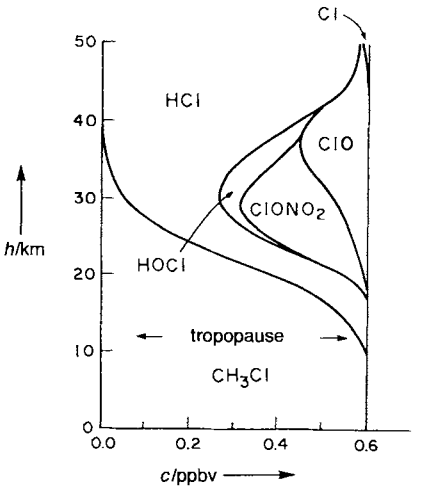

Fig. 5. Schematic illustration of the distribution of chlorine among various chemical forms after release to the atmosphere in the form of methyl chloride. At steady state, the sum of the mixing ratios c at all altitudes is constant and equal to the tropospheric mixing ratios of CH_3Cl.

Our original calculations about the behavior of CFCs in the stratosphere were actually predictions of the vertical distribution, because no measurements were then available for any chlorinated species in the stratosphere, and certainly not for CFCs. During 1975 two different research groups sent evacuated containers equipped with pressure-sensitive values up on high-altitude balloons, and recovered air samples from the stratosphere. The measured mixing ratios for CCl_3F (Fig. 6) were in excellent agreement with the vertical profiles calculated by us in the previous year. This fit between theory and experiment demonstrates both that CFCs reach the stratosphere and that they are decomposed there by solar ultraviolet radiation at the altitudes predicted earlier.[11, 12]

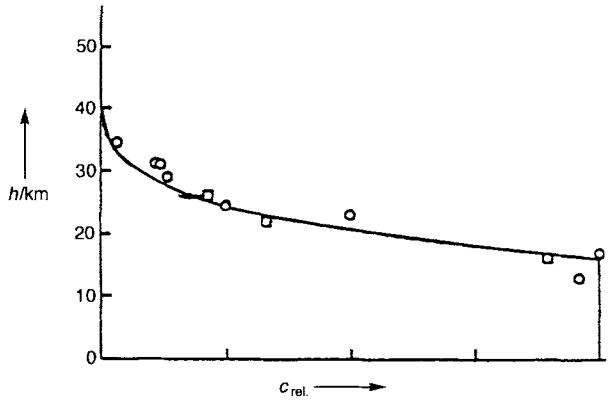

Fig. 6. Relative mixing ratios c_{rel} for CCl_3F, observed in 1975 by research groups from NCAR (○) [12] and NOAA (□) [11] normalized to tropospheric value as 1.0. The solid line was calculated with diffusion coefficient C in Fig. 3 [4].

Growth of Tropospheric CFC Concentrations

When the rate of upward transport of the CFCs into the stratosphere proved to be the same as for all other molecules, attention returned to the possibility of tropospheric sinks. The rapid tropospheric removal processes (photolysis, rainout, oxidation) were readily eliminated. Nevertheless, the calculated 50 to 100 year lifetimes for the various CFCs left room for concern about the possibility of an accumulation of minor sinks, or even of an undiscovered tropospheric sink. While atmospheric and laboratory tests can be conducted appropriate to each proposed individual sink, an even more comprehensive approach is the measurement of the sum for all tropospheric removal processes, including those not yet specifically identified. This can be accomplished by measurement of the actual lifetime of the CFCs in the atmosphere itself, and requires accurate knowledge both of the amounts of a particular CFC released to the atmosphere and of the amount still there.

An electron capture gas chromatographic trace, taken by the same technique originally developed by Lovelock, is shown in Figure 7 for an air sample collected in Tokyo in 1989.

Tokyo is not unusual. Similar high concentrations are found in all major cities, because most of the technological uses of CFCs take place in urban areas. While this is an accurate assessment of the halocarbon impurities found in Tokyo air on that date, it is not very useful for a global assessment of total CFC

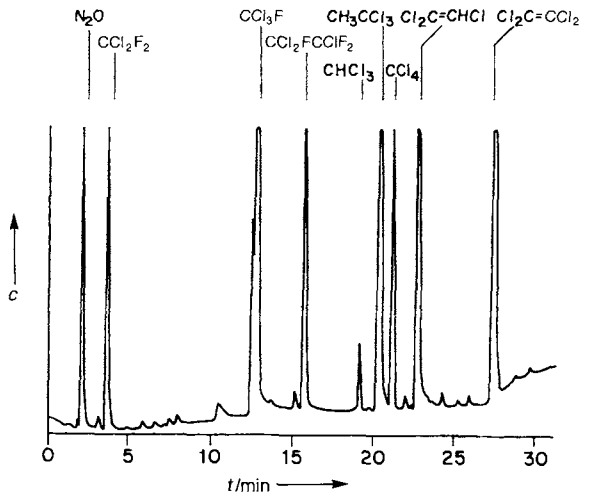

Fig. 7. Analysis by EC-GC of a Tokyo air sample collected on May 20, 1989. Four of the peaks rise above the printed scale values. The detector has a different response for each compound, requiring calibration for each. c = concentration.

concentrations because the measurement is not representative of the whole atmosphere.

The air volume associated with cities, and the amounts of CFCs in that air, represent minuscule fractions of the total atmosphere and of its total CFC content. Instead, what is required are measurements at enough representative remote locations to permit a global assay. A comparable EC-GC display from an air sample collected a few miles from Barrow, Alaska, (71°N Latitude) in 1989 is shown in Figure 8. Although the

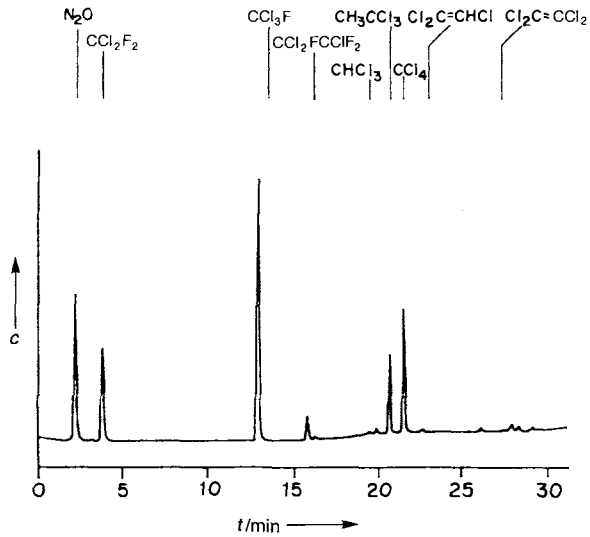

Fig. 8. Analysis by EC-GC of an air sample collected in Barrow, Alaska, on September 15, 1989. The detector has a different response for each compound, requiring calibration for each. c = concentration.

amounts are certainly smaller, the three major CFC molecules are all clearly present near Barrow. Many of the other molecules found in Tokyo (Fig. 7) have atmospheric lifetimes of one year or less, and are detected only in very low concentration or not at all in northern Alaska.

The west-east global mixing processes across longitudinal lines are sufficiently rapid that good estimates can be obtained for molecules as long-lived as the CFCs from a set of air samples collected within a short time period from remote locations across most of the north-south latitudinal spread. The CCl_3F concentration found at such a set of remote locations are illustrated in Fig. 9 for the summer of 1979 (top) and for December

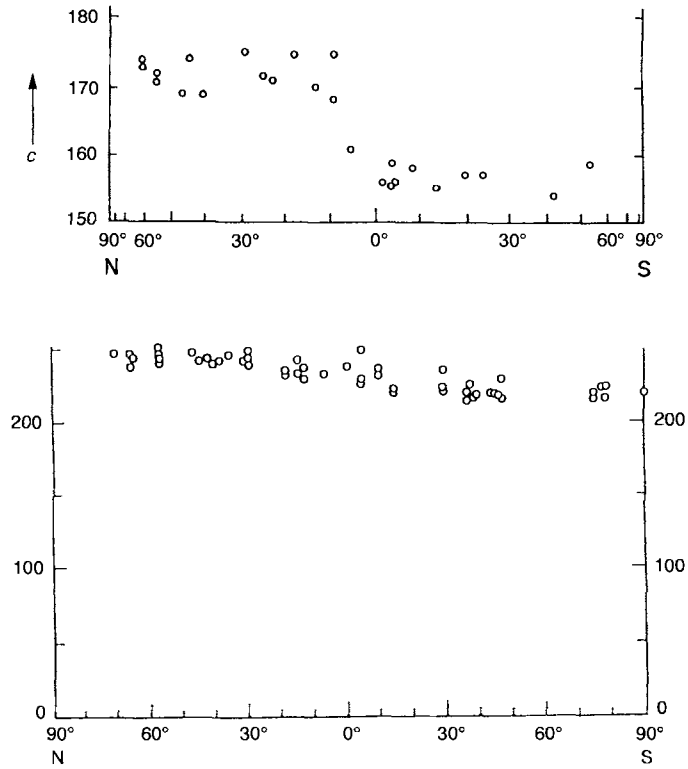

Fig. 9. Mixing ratios c of CCl_3F in pptv for different latitudes, as measured at remote sites in summer 1979 (top) and December 1987 (bottom).

1987 (bottom). Both of these figures illustrate that north-south mixing is quite rapid in the atmosphere, for the gradient from north-to-south is only about 10%, despite the release of about 95% of CCl_3F in the northern hemisphere, mostly between 30°N and 60°N latitudes. The average time for a molecule to mix from the northern to southern hemisphere, or vice versa, has been calculated from the release patterns in comparison with these measured concentrations and is approximately 15 months. The average CFC molecule therefore mixes back and forth between the northern and southern hemispheres 20 to 40 times or more before its ultimate decomposition in the stratosphere. Only the continued injection of CCl_3F into the northern hemisphere maintained the observed north-south concentration gradient from 1971 into the late 1980s.

Comparison of the data in Figure 9 with the Lovelock data demonstrates that the northern hemisphere concentration of CCl_3F increased from about 70 pptv (that is, $1:10^{-12}$) in 1971 to 170 pptv in 1979 and 250 pptv in 1987. This steady increase in concentration with time is precisely what is expected for a molecule with an atmospheric lifetime in the 50 to 100 year range. In 1995 the best estimate for these CFC lifetimes made from a comparison of total atmospheric burden versus total

release is 50 years for CCl_3F and 102 years for CCl_2F_2.[13] Both estimates are well within the ranges of lifetimes calculated 20 years earlier.[1,4] This close agreement between measured lifetimes and those calculated on the assumption that no important tropospheric loss processes exist is a clear indication that this assumption is correct. The ultimate fate for the CFC compounds lies in their photodissociation by solar ultraviolet radiation in the mid-stratosphere.

A typical measurement with the current version of our analytical system for chlorocarbon molecules is shown in Figure 10 for an air sample collected through an external air intake on a C-130 Hercules aircraft 850 miles south of New Zealand on November 15, 1995. Even in this remote location, sixteen different low molecular weight compounds containing Cl or Br atoms were readily detected, together with others such as O=C=S and N_2O (not shown), the molecule whose atmospheric chemistry was considered by Crutzen 25 years ago.[6]

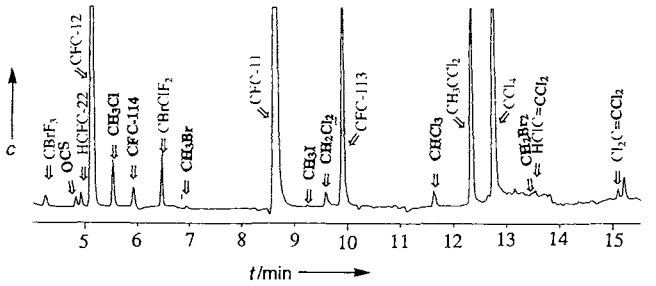

Fig. 10. EC-GC analysis of an air sample collected with an aircraft south of New Zealand on November 15, 1995, at Oh 45 GMT and 800 m altitude. c = concentration.

Springtime Loss of Ozone in the Antarctic

The greatest surprise in the CFC-ozone story was revealed in the spring of 1985 with the discovery by Joe Farman and his colleagues from the British Antarctic Survey of massive springtime losses of ozone over their station at Halley Bay, Antarctica (75.5°S Latitude.[14] This station was established in preparation for the International Geophysical Year of 1957–1958 and was equipped with a Dobson ultraviolet spectrometer for the measurement of total ozone. The principle of this instrument, designed by Dobson in the 1920s, relies on the measurement at the surface of the earth of the ratio of received solar radiation for two UV wavelengths. One of these is moderately absorbed by ozone, and one is almost unaffected, as illustrated in Figure 11. A typical wavelength pair is the C pair that uses 311.45 nm for the former, and 332.4 nm for the latter.

While the absorbing characteristics of most molecules vary continuously with wavelength, the ultraviolet region is often divided for convenience in description into three arbitrary wavelength regions: UV-A, 400 nm to 320 nm (most reaches the earth's surface); UV-B, 320 nm to 290 nm (some reaches the surface); UV-C, shorter than 290 nm (none reaches the surface). The wavelength pairs used with a Dobson spectrometer usually compare one UV-B wavelength against one from the UV-A range. Most concerns about UV effects on biology are directed toward the UV-B range because UV-C radiation does not get

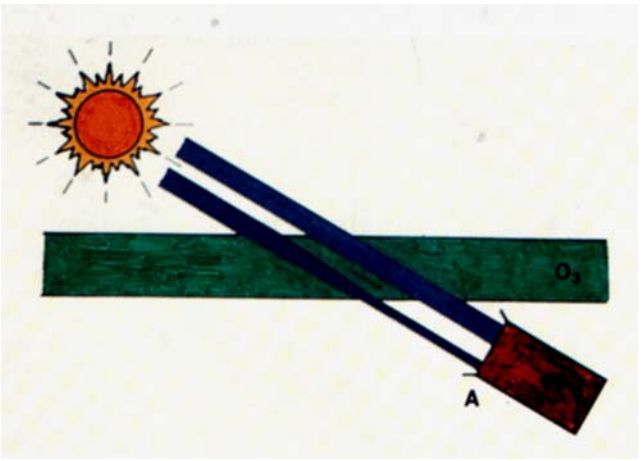

Fig. 11. Standard technique for measurement of ozone with a Dobson ultraviolet spectrometer. The ratio of the intensities at two UV wavelengths is dependent upon the ozone content of the atmosphere and the solar zenith angle.

down to the levels where biological species flourish, and UV-A radiation at the surface is so intense that species without some mechanism for dealing with UV-A would long since have become extinct.

In the northern hemisphere, the highest total ozone concentrations are observed in the polar regions around the spring equinox (March/April), as shown in Figure 12. (The technical

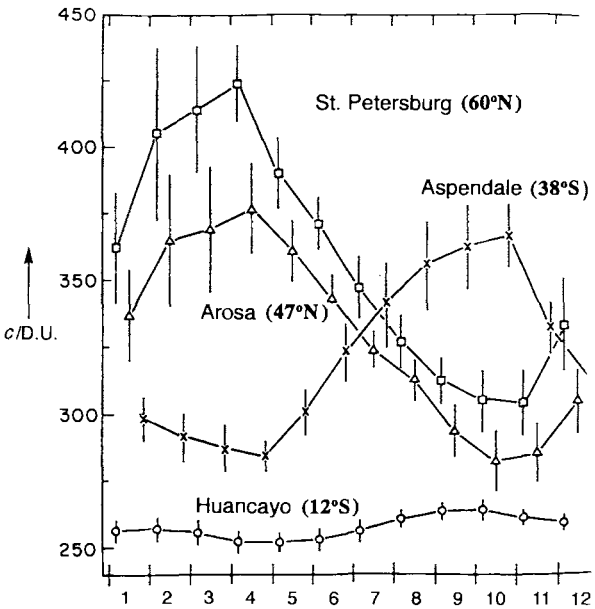

Fig. 12. Seasonal variation of ozone concentrations as measured with a Dobson spectrometer for two stations in the northern hemisphere (St. Petersburg, Russia; Arosa, Switzerland), one station in the tropics (Huancayo, Peru), and one station in the southern hemisphere (Aspendale, Australia). The vertical bars indicate the natural variability of ozone measurements for that location and that calendar month (1 = January, ...12 = December) averaged over 25 years.

unit used to measure total ozone is the milliatmosphere centimeter, but this has been almost universally superseded by its other name, the Dobson Unit (D.U.). The Dobson unit represents approximately 1 part in 10^9 of the atmospheric molecules by volume, and the average global concentration is about 300 D.U.). The spring maximum values are higher at the higher

latitudes, as at St. Petersburg, Russia, versus Arosa, Switzerland, while the highest of all are found in the north polar region. On the other hand, tropical locations have the lowest year-round levels of ozone, with little seasonal variation, as illustrated for Huancayo, Peru.

With no significant prior information about Antarctic meteorology, in 1956 Dobson anticipated finding a spring equinoctial maximum over Halley Bay similar to that previously observed at Spitzbergen, Norway. However, instead of increasing steadily through the autumn and winter, as observed in the north, the southern polar ozone values remained essentially constant through the autumn and winter darkness, and into mid-spring. They then increased sharply to a peak in mid-November, as illustrated in Figure 13 for the summers of 1956–1957, 1957–1958 and 1958–1959.[15] Dobson recognized that this represented the discovery of a very strong Antarctic polar vortex, which until its breakdown in mid-spring prevented the arrival over the polar regions of ozone-richer stratospheric air from the temperate zone.

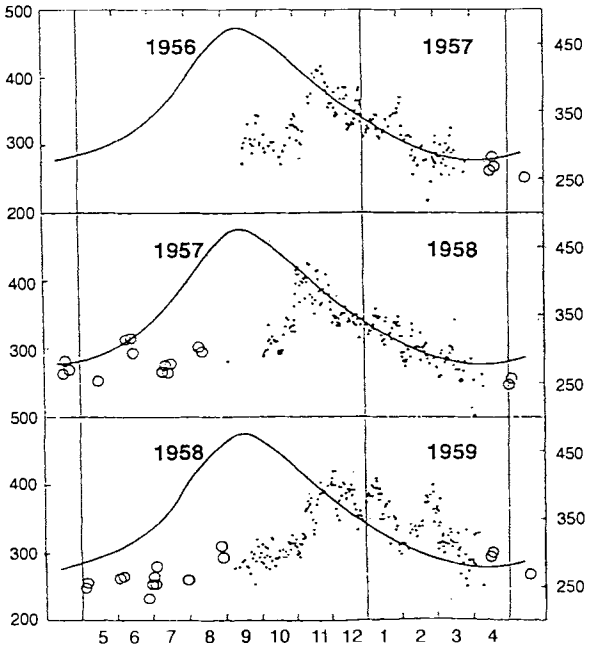

Fig. 13. Daily ozone measurements at Halley Bay, Antarctica, from 1956 to 1959, and, for comparison, the pattern previously observed (solid line) in the north polar region at Spitzbergen, Norway [15]. Dots indicate data using the sun as the UV source, and the less accurate circles those with the moon as the source. Vertical scale: ozone in Dobson units; horizontal axis: months (5 = May, ...4 = April).

This pattern of level ozone values into mid-spring was observed throughout the 1960s and early 1970s. However, in the late 1970s, the average October ozone values over Halley Bay began to decrease, dropping below 200 D.U. in 1984 versus the 300–320 D.U. values of the 1960s (Fig. 14). These data were reported in May 1985, together with the hypothesis that the ozone decrease was correlated with the increasing CFC concentrations in the atmosphere.[14] This loss of ozone begins soon after the end of the polar winter darkness, and proceeds very rapidly for the next six or seven weeks into mid-October.

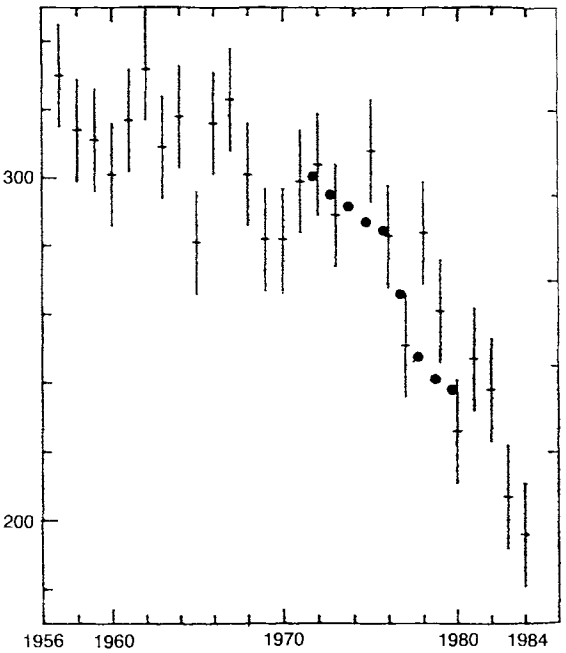

Fig. 14. Average ozone concentrations in Dobson units for October, for the years 1957–1984, at Halley Bay, Antarctica. The black dots indicate on a relative scale the concentrations of CCl_3F versus time, plotted downward from zero at the top.

These substantially smaller ozone values over Halley Bay in October in the 1980s were quickly shown to be characteristic of the entire south polar region by the measurements of the TOMS (Total Ozone Mapping Spectrometer) on the Nimbus-7 satellite.[16] This instrument also measures ozone from the ratio of two UV wavelengths, utilizing solar UV back-scattered from the troposphere through the stratosphere. More than 100000 daily ozone measurements with TOMS over the entire Southern hemisphere are expressed in Figure 15 through a color code for one early October day each in 1979, 1983, 1987, and 1992. In these TOMS displays, the lowest October ozone values fell rapidly from 250 to 175 D.U. and then 125 D.U. between 1979 and 1987. The ozone loss is not confined to the central area: as shown in Figure 15, by 1983 substantial reductions occurred in the areas originally covered by 450–500 D.U. in 1979. A totally different kind of ozone measurement, utilizing its chemical capability for oxidizing the iodide ion to elemental iodine, was used on balloon sondes and demonstrated that most of this ozone loss occurred in the lower stratosphere (Fig. 16). Again, the loss of ozone was observed to be very rapid between late August and October.

Chemistry of the Polar Stratosphere

Numerous theories were suggested for this new observation of ozone loss, and can generally be classified into three groups: a) natural change in the dynamics of the Antarctic stratosphere; b) change in the natural chemistry, e.g. NO_x, of the stratosphere; or c) chemical changes induced by mankind, especially through the introduction of artificial chlorine-containing compounds such as the CFCs. A decrease in the springtime stratospheric temperatures was observed to accompany the observa-

The color code for the measured numerical values in Dobson Units is given to the right. (Missing data is also shown in white.)

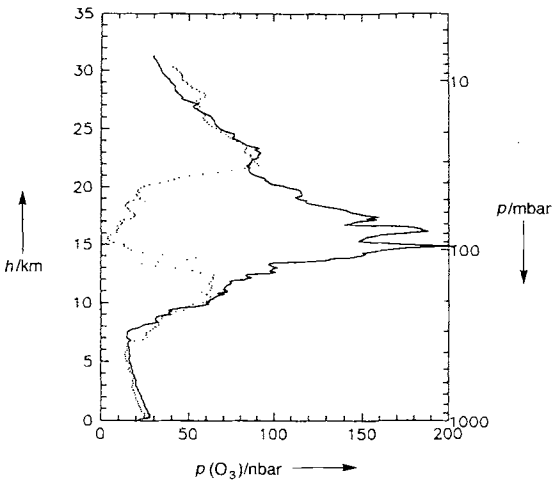

Fig. 16. Dependence of the partial pressures of ozone $p(O_3)$ on altitude, as measured by balloon sondes from McMurdo, Antarctica. Solid line: August 23, 1989, in late winter at the end of the polar night. Dotted line: October 20, 1989, after two months of sunlight. p = approximate total pressure.

tions of lessened quantities of ozone, and was briefly considered as a possible cause for its destruction.[17] However, the lowered temperatures were soon established to be occurring after the ozone loss, and to be the consequence of reduced UV absorption by reduced amounts of ozone, not a cause of the ozone loss. The observed temperature decreases are, in fact, a slower warm-up from the wintertime temperature minimum.

Three polar expeditions in 1986 and 1987 provided the scientific basis for the conclusion that the ozone losses over Antarctica were indeed the consequence of chemical reactions driven by the much higher stratospheric chlorine concentrations of the mid-1980s than those of 1950–1970. Two of these were ground-based expeditions to McMurdo, Antarctica, led by Susan Solomon. Two maxima were detected in 1986 in the vertical profile of the important free radical, ClO, by ground-based millimeter wave spectroscopy.[18] The larger maximum in ClO concentrations, reaching ppbv concentrations ($1:10^9$ by volume), was found in the lower stratosphere coincident with the altitudes of major ozone loss. These results were then followed in 1987 by

in situ measurements of ClO and O_3 within the polar vortex by instruments on the high-flying ER-2 aircraft.[19] These experiments were carried out from a base in Punta Arenas, Chile (53°S latitude), from aircraft which entered the polar vortex over the Antarctic peninsula. The data of Jim Anderson clearly showed levels of 10^{-9} parts by volume of ClO over Antarctica (Fig. 17)

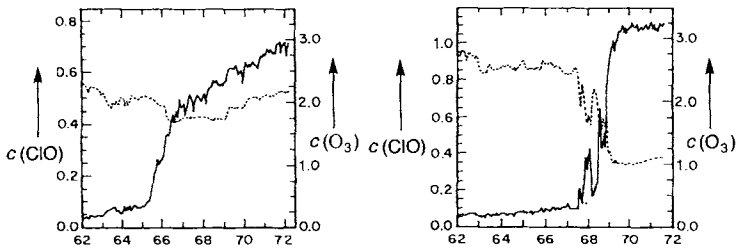

Fig. 17. Chlorine oxide (solid line; scale: parts per 10^9 by volume) and ozone (dotted line; scale: parts per 10^6 by volume) measurements taken on flights with the ER-2 aircraft from Punta Arenas, Chile, over Antarctica [19]. on the first successful flight on August 23. However, the simultaneous ER-2 data for ozone showed little or no change in concentration inside or outside the polar vortex. At this late-winter date, sunlight had only been available in the Antarctic stratosphere for a few days. In contrast, 24 days later on September 16, the ClO levels over Antarctica were again in the same range, but this time approximately two-thirds of the ozone within the polar vortex had already disappeared. The edge of the Antarctic polar vortex was particularly ragged on September 16, and the high values of ClO and low values of O_3 tracked each other in perfect anti-coordination (Fig. 17, right).

The chlorine chemistry of the lower Antarctic stratosphere has some substantial differences from that of the upper stratosphere in the temperate and tropical zones. Because the concentration of O atoms is very low in the polar lower stratosphere, reaction (10) is quite slow and the ClO_x chain of (8) + (10) is no longer effective. At these altitudes, the winter temperatures drop to the −80 °C range, low enough for the formation there of polar stratospheric clouds (PSCs), which can contain both HNO_3 and H_2O.[20–22] Such low temperatures, and the accompanying clouds, are not generally found in the stratosphere of the temperate zone. However, the same air remains trapped in the strong Antarctic polar vortex throughout the total winter darkness, and the temperatures drop low enough for cloud formation.

These polar clouds furnish active surfaces on which chemical reactions can occur, including reactions such as (15) and (16)

$$HCl + ClONO_2 \xrightarrow{PSC} Cl_2 + HNO_3 \quad (15)$$

$$H_2O + ClONO_2 \xrightarrow{PSC} HOCl + HNO_3 \quad (16)$$

involving reservoir molecules HCl and $ClONO_2$.[23–26] surface back into the gas phase, where they are photolyzed when the sun returns from its months-long absence. The HNO_3 from such reactions remains in these clouds, a process which denitrifies the air mass. When cold enough, sufficient water molecules can also add to the PSC particles to make them fall by gravitation, which dehydrates the air mass as well.

An important aspect of the denitrification process is the very low residual concentration of NO and NO_2; the absence of the latter severely curtails the formation reaction for chlorine nitrate by Equation (17). Without this removal process for ClO

$$ClO + NO_2 + M \longrightarrow ClONO_2 + M \quad (17)$$

radicals, the ClO concentrations rise to mixing ratios in the ppbv range and begin to react in significant numbers with other ClO radicals to form Cl_2O_2 by Equation (18).[27] The chlorine oxide dimer, ClOOCl, can then be destroyed by sunlight [Eq. (19)], releasing one Cl atom each in reactions (19) and (20). The sum of reactions 2 × (8) + (18) + (19) + (20) gives (21) by

$$ClO + ClO + M \longrightarrow ClOOCl + M \quad (18)$$

$$ClOOCl + light \longrightarrow Cl + ClOO \quad (19)$$

$$ClOO + M \longrightarrow Cl + O_2 + M \quad (20)$$

$$O_3 + O_3 \longrightarrow O_2 + O_2 + O_2 \quad (21)$$

which two O_3 molecules are transformed into three O_2 molecules. This alternate polar ClO_x chain reaction converts ozone into molecular O_2 without the need for the O atom step of reaction (10). Other reactions involving Br atoms from halon molecules such as $CBrF_3$ and $CBrClF_2$ or methyl bromide are exceedingly efficient in removing ozone as well.

Ozone Losses in the Northern Temperate Zone

In 1985 the several existing statistical evaluations of the combined data from the Dobson stations in the northern hemisphere appeared to indicate that no significant loss in total ozone had occurred there.[28] The longest series of these ozone measurements without any significant breaks has been carried out since August 1931 in the Swiss alpine community of Arosa. In 1986 Neil Harris and I began a reexamination of the Arosa data series, treating it not as a single comprehensive set, but as a collection of twelve separate data sets, one for each calendar month. Interannual ozone comparisons (see Fig. 2) show substantial seasonal differences in the variability of the monthly averages. While each year individually shows the normal north temperate zone pattern of maximum ozone values around the spring equinox, and a minimum at the beginning of autumn, the year-to-year variability in average ozone concentration for each month is much greater for the January-to-April period than it is for July-to-October. When this 56-year data series from Arosa was broken into two periods – the 39 year period 1931–1969, and the 17-year period 1970–1986 – the interesting result emerged that significantly less ozone was measured for several of the autumn-winter months after 1970 than in the previous four decades.[29] Figure 18 shows this Arosa wintertime ozone loss after the inclusion of data from 1987/88.

We then extended this inquiry to two U.S. ozone stations, Caribou (Maine) and Bismarck (North Dakota), and found that these two also exhibited wintertime losses when the data for 1965–1975 were compared with 1976–1986.[29] This comparison of consecutive 11-year periods corresponding to the well-

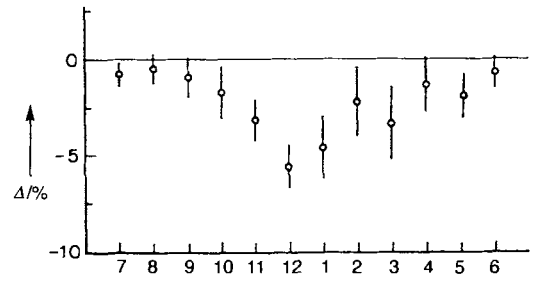

Fig. 18. Changes Δ in monthly average total ozone concentrations measured with a Dobson spectrometer at Arosa for the period 1970–1988 relative to 1931–1969 (updated from [29]). Negative values represent smaller average concentrations after 1970. The x axis represents the months from July (7) to June (6).

known 11-year solar cycle minimizes any influence of variations in UV emission on the evaluation of the long-term trends. Subsequently, the WMO/NASA Ozone Trends Panel confirmed (Fig. 19) that all 18 of the ozone stations between 35°N and

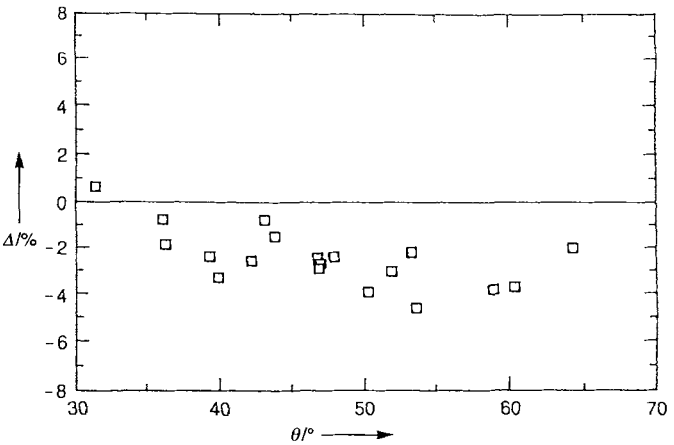

Fig. 19. Changes Δ in average total ozone concentrations in the "winter" season (December to March) for 1976–1986 relative to values for 1965–1975 for all Dobson stations north of 30° North latitude that have a complete 22 year record (two complete solar cycles) [30]. Negative values represent smaller average concentrations after 1975.

60°N latitudes with at least 22 years of data (that is, also covering two complete 11-year solar cycles) had less wintertime ozone in 1976–1986 than in the earlier period.[30] An earlier National Academy of Sciences/National Research Council report had concluded that loss of ozone had already occurred at the altitudes between 35 and 40 km for which the ClO_x chain reaction of (8) + (10) was predicted to be most effective.[31] However, the Ozone Trends Panel report was the first assessment document to assert that significant ozone loss had already been observed over the highly populated areas of North America, Europe, the Soviet Union, and Japan. The combination of very large springtime losses of ozone over Antarctica directly attributable to man-made chlorine compounds introduced into the stratosphere, and measurable ozone losses in the north temperate zone, brought a rapid change in the attitudes of CFC producers and many of the users, and a complete phaseout of CFC production and uses became a widely accepted goal.

The Montreal Protocol for Regulation of CFCs

Regulations for the control of CFC emissions had first been introduced during the late 1970s for the use of CFC-11 and CFC-12 as propellant gases for aerosol sprays, but only in the United States, Canada, Sweden, and Norway. In 1985 a United Nations meeting in Vienna, Austria, had agreed to a convention on the protection of the stratospheric ozone layer. Then, in September 1987 a further agreement, known as the Montreal Protocol, called for actual limitations on the emissions of CFCs, and a 50% cutback in CFC production was scheduled by the end of the century.[32] The terms of the Montreal Protocol called for periodic revisits to the controls, and a meeting in London in 1990 changed the restricted production into an outright phaseout of CFCs by the year 2000. A further meeting in Copenhagen in 1992 accelerated the phaseout to January 1, 1996, for the major industrial countries and included compounds such as 1,1,1-trichloroethane (CH_3CCl_3), carbon tetrachloride (CCl_4), and the bromine-containing halons H-1301($CBrF_3$), H-1211 ($CBrClF_2$), and H-2402 ($CBrF_2CBrF_2$).

Changes in Ultraviolet Flux at the Earth's Surface

Most of the measurements of total ozone, including the Dobson and TOMS data, actually depend upon the ratio of two wavelengths of solar ultraviolet radiation, as described earlier. A change in the amount of ozone along the path of the UV radiation is inferred from a change in the intensity of the wavelengths of the detected radiation. In these cases, the existence of a correlation between ozone and UV-B radiation under clear-sky conditions is a tautology. Less reported ozone means either more UV-B or less UV-A or both, and no mechanisms for significant changes in UV-A radiation intensity have been put forward. However, because actual well-calibrated, precise absolute measurements of ultraviolet radiation over many decades do not exist, no long-term comparison of trends in ozone concentrations and the intensity of UV-B radiation has been possible.

In the past decade, instruments capable of such ultraviolet measurements have been deployed in various locations, especially in the south polar region, including three Antarctic stations – South Pole, McMurdo (78°S), and Palmer (64°S), as well as Ushuaia, Argentina (55°S). Because the Antarctic polar vortex, and its region of low ozone concentrations during recent Octobers, can be very elongated (see Fig. 15 for October 4, 1992), the possibility now exists for much higher UV-B exposures in the southern high latitudes than in previous times.

Comparison of the measured UV-B intensities for the same solar zenith angle in spring (that is, when ozone is depleted) and autumn (relatively normal ozone) allow an experimental confirmation of the anticipated anticorrelation between UV-B and total ozone. The measured correlation in Figure 20 for the South pole in 1991/1992 shows a 150% increase in UV-B for a 50% decrease in ozone content.[33] Furthermore, on October 26, 1993, when a particularly low ozone value existed over Palmer in the Antarctic peninsula, the UV-B intensity exceeded by 25% the highest intensity recorded in San Diego, California, for any day of 1993 (the most intense there was June 21, 1993, Fig. 21).[34] A remarkable further observation was also record-

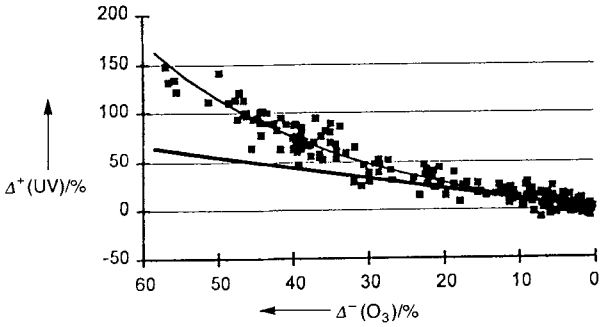

Fig. 20. Percentage increases Δ^+ (UV) in UV-B radiation (erythemally weighted) plotted against percentage decreases in total ozone at the South Pole, 1991/1992 [33]. RAF = 1.1 (RAF = radiation amplification factor).

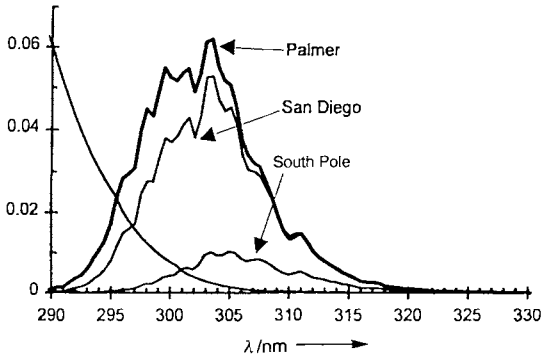

Fig. 21. Maximum UV-B spectral intensities measured at three stations during 1992/1993, weighted by the experimental absorption spectrum of DNA (shown as falling curve at the left of the figure) [34]. At San Diego the maximum intensity occurred on June 21, 1993 (10° solar zenith angle), at Palmer in the Antarctic peninsula (64°S) on October 26, 1993 (52° solar zenith angle), and at the South Pole on November 29, 1992 (68° solar zenith angle). The relative integrated intensities are 0.11 at the South Pole, 0.59 at San Diego, and 0.74 at Palmer.

ed: the most intense weekly UV-B exposure in any single week at any of these stations was recorded at the South Pole. There, even though the sun is low on the horizon, the very low concentrations of ozone in the late Antarctic spring, the general absence of clouds, and the 24 hours per day of continuous sunlight combined to permit a higher weekly dose of UV-B than in any week in San Diego, California.[34] The often-heard statement that UV-B intensities in the Antarctic can never be very large is no longer true. The question of possible biological damage associated with UV-B radiation then requires a separate assessment for each biological species of whether such damage is the result of cumulative UV-B exposure over an entire season or of a single, extremely intense exposure; both circumstances exist elsewhere.

Changing O_3 and CFC Concentrations in the 1990s

Ozone concentrations have continued to fall during the early 1990s. The measured value at the South Pole was only 91 D.U. on October 12, 1993, and the vertical profile data from the corresponding balloon sonde indicated that all ozone had been removed from a 5-kilometer altitude band between 14 and 19 kilometers. The TOMS satellite registered many new daily record low global ozone values in early 1992, and then for nearly 13 months from mid-April 1992, a new daily low global ozone

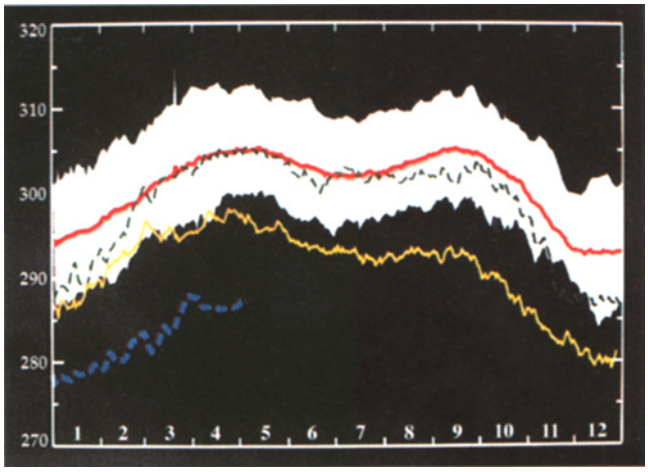

Fig. 22. Global ozone values in Dobson Units as measured with the TOMS on the Nimbus 7 Satellite. The range of values recorded on each day from 1979 to 1990 is outlined in white and the average for these years in red. The values for 1991, 1992, and 1993 are shown in green, yellow, and blue, respectively. The spectrometer failed on May 7. 1 = 1–31 January, etc.

value was measured (Fig. 22). This measurement series ended when the spectrometer finally failed on May 7, 1993. The ozone data interpretations were complicated by the eruption of Mount Pinatubo in the Philippines in June 1991. This volcano, while not providing any significant amount of hydrogen chloride to the stratosphere, did introduce particulate surfaces on which reactions similar to those taking place on the PSCs could occur. The Dobson stations in the northern hemisphere continued to report declining ozone concentrations, with the losses now spreading into the summer. By 1995 the total ozone losses for the north temperate zone approached 10% during winter and spring and 5% in the summer and autumn.[13]

In contrast, the measured tropospheric concentrations of the various halocarbon gases deviated in the 1990s from their earlier pattern of steady increases in response to the restrictions of the Montreal Protocol. The concentrations of the three major CFCs, which had risen almost linearly during the 1980s, markedly slowed their pace of increase. By 1995, the concentrations of CCl_3F measured regularly at seven different stations varying in latitude from the polar Arctic to the South Pole had essentially leveled off (Fig. 23). The CCl_2F_2 and CCl_2FCClF_2

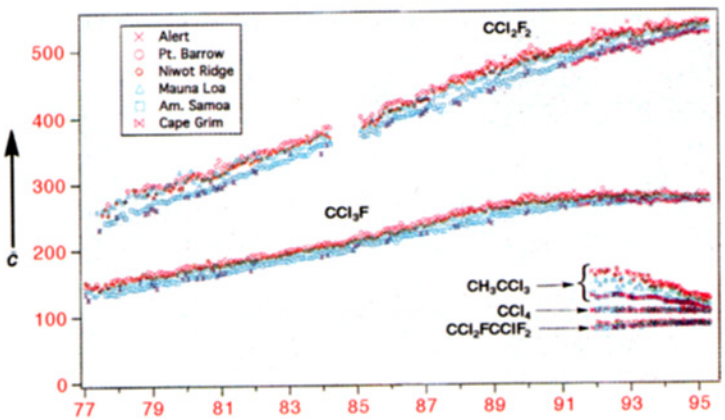

Fig. 23. Measured mixing ratios in pptv for the period 1977–1995 for CCl_3F, CCl_2F_2, CCl_2FCClF_2, CH_3CCl_3, and CCl_4, determined at seven sites. ▽ = South Pole.

concentrations were still rising, but at no more than half the rate of the 1980s. The sharpest changes were observed with the organic solvent 1,1,1-trichloroethane for which controls were added in revisions of the original Montreal Protocol. This substance has three hydrogen atoms that are susceptible to attack by HO radicals in the troposphere, in analogy with reaction (1), and therefore has an average lifetime of only about 5 years. With its rapidly diminishing emission rate under the limitations of the Protocol, the tropospheric concentrations of CH_3CCl_3 reached a maximum in 1992 and have declined significantly since (Fig. 23).

The situation at the end of 1995 is therefore a mixed one. The three most important CFC molecules have atmospheric lifetimes measured from many decades to a century or more, with the consequence that there will be significant quantities of them present in the atmosphere throughout the 21st century. The major springtime losses in the Antarctic will probably continue at least until mid-century. However, because the primary cause of these ozone losses are the man-made chlorine and bromine compounds limited by the Montreal Protocol, the amount of organochlorine in the troposphere will peak soon, if it hasn't already. When the weighted effects of bromine compounds are added in, the peak in tropospheric halocarbons will occur within this decade. Because of the delay time in rising upward, the stratospheric peak will follow within a few years. For the next few decades, the atmosphere will be loaded with chlorine and bromine compounds, so that a really large volcanic explosion with major increases in the particulate surface area of the stratosphere might cause transitory large ozone decreases. Another area for concern is the changing temperature structure of the stratosphere because of the steady increases in the greenhouse gases, especially carbon dioxide. The effect of more carbon dioxide is to decrease temperatures in the lower stratosphere, and this could lead to more extensive cloud formation, and more particulate surface area as well. However, with the limitations just expressed, the threat of extensive further stratospheric ozone depletion during the 21st century appears to be under control.

Generation of Cyclocarbons with 4*n* Carbon Atoms (C_{12}, C_{16}, and C_{20}) by [2+2] Cycloreversion of Propellane-Annelated Dehydroannulenes**

Yoshito Tobe,* Hideki Matsumoto, Koichiro Naemura, Yohji Achiba,* and Tomonari Wakabayashi

Dedicated to Professor Philip E. Eaton on the occasion of his 60th birthday

Recent studies on the spectroscopic, chemical, and physical behavior of carbon clusters revealed that small clusters of C_{10}–C_{20} possess monocyclic form.[1] All-carbon molecules of this type, called cyclo[*n*]carbons,[2] are of particular interest because they play an important role in the formation of fullerenes[3] and because for some of them more than one structure has been predicted by calculations.[4] We and Diederich et al. have synthesized a number of precursors of cyclo[*n*]carbons with well-defined cyclic structures and readily removable groups, which eventually generated *cyclo*-C_{18} (and *cyclo*-C_{24} and *cyclo*-C_{30} as well) by laser desorption induced [4+2] cycloreversion (retro-Diels–Alder reaction),[5a,d] decarbonylation,[5b–d] or [2+2] cycloreversion.[6] The advantage of the [4.3.2]propellane-type precursors lies in their thermal stability and facility to undergo cycloreversion on both laser desorption and ultraviolet irradiation.[6] However, these methods have been only applied so far to generate cyclocarbons with 6*n* carbon atoms (n = 3–5), and no precursors to cyclocarbons of other ring sizes were known despite the importance of these carbon clusters.[7,8] Moreover, cyclocarbons having 4*n* carbon atoms should give dianions by two-electron reduction[9] and form transition metal complexes (in the case of *cyclo*-C_{12}),[10] in view of the chemistry of the dehydroannulenes with 4*n* π-electron systems. In this connection, we report herein the synthesis of hexadehydro[12]annulene **1**, octadehydro[16]annulene **2**, and decadehydro[20]annulene **3** with annelated [4.3.2]propellatriene units and their laser desorption induced fragmentation generating *cyclo*-C_{12}, *cyclo*-C_{16}, and *cyclo*-C_{20}, respectively, by extrusion of indan.

Palladium(0)-catalyzed coupling[11] of dichloro[4.3.2]propellatriene **4**[12] with 2-methyl-3-butyn-2-ol gave mainly the monosubstitution product **5** (70%). Attempted cyclization of **6**, prepared by deprotection of **5**, by Pd^0-catalyzed coupling under a variety of conditions resulted in the formation of dimer **7** (mixture of diastereomers); none of the desired cyclization products were detected. In contrast, when **5** was subjected to phase-transfer conditions for deprotection and subsequent coupling,[15] the dehydroannulenes **1**, **2**, and **3** were obtained in 0.9, 11, and 0.9%, respectively (Scheme 1). Although the dehydroannulenes **1**–**3** are inseparable mixtures of diastereomers (two isomers of **1**, four each of **2** and **3**), only those with the highest symmetry are drawn in Scheme 1 for clarity. The fact that the tetramer **2** is obtained in higher yield than the trimer **1** is explained by the smaller geometrical deformation in the cyclobutene-annelated [16]dehydroannulene ring.[16] The trimer **1** was also prepared in a stepwise manner by three successive Pd^0-catalyzed coupling reactions (Scheme 2). The reaction of diethynylpropellane **8**[17] with an excess of **4** yielded the 1:2 coupling product **9** (50%); **9** was coupled with 2-methyl-3-butyn-2-ol to give monosubstituted **10** (54%); and finally in-

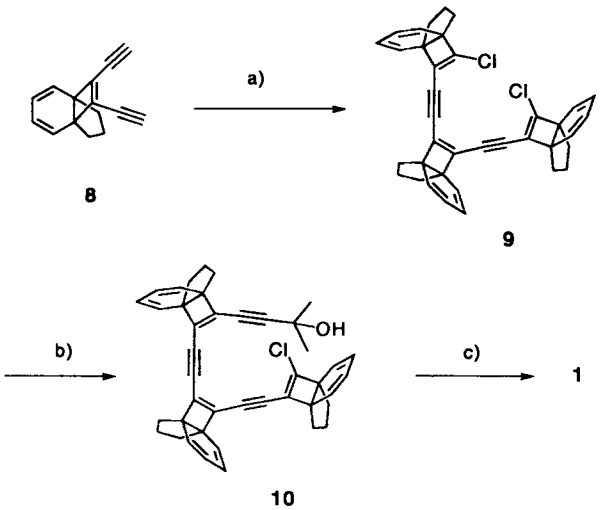

Scheme 2. a) **4** (15 equiv), $[Pd(PPh_3)_4]$, CuI, $BuNH_2$, THF, rt; b) 2-methyl-3-butyn-2-ol, $[PdCl_2(PhCN)_2]$, CuI, piperidine, THF, rt; c) $[Pd(PPh_3)_4]$, CuI, aq NaOH, benzyltriethylammonium chloride, benzene, 80 °C. Compounds **9** and **10** are inseparable mixtures of diastereomers.

tramolecular cyclization of **10** under the phase-transfer conditions provided **1**(14%).

The parent hexadehydro[12]annulene[18] and its benzo[15b, 19] and tris(bicyclo[2.2.2]octeno)[20] derivatives are known and their chemistry has been well studied.[9, 10] However, the properties of **1** might be considerably different, as the triple bonds must be substantially deformed from linearity because of the cyclobutene fusion; the AM1-calculated bond angle of the triple bond is 170.2°. The tetrabenzo[19b, 21] and tetrakis(bicyclo-[2.2.2]octeno)[20] derivatives of octadehydro[16]annulene are known, and both have a nonplanar puckered conformation. We deduce, on the other hand, that dehydroannulene **2** adopts a planar conformation on the basis of the paratropic shift[22] of the signals of the vinyl protons in the ^1H NMR spectrum and long-wavelength absorption maxima in the electronic spectrum (Fig. 1). The dodecadehydro[20]annulene system was previously unknown; the conformation of the pentamer **3** should be nonplanar in view of the small paratropic NMR shift[22] and the absence of long-wavelength absorption maxima.

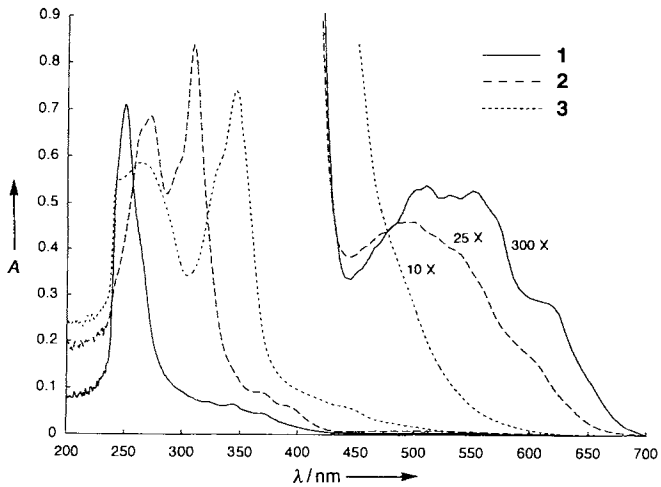

Fig. 1. UV/Vis spectra of **1** (1.04×10^{-6} mol dm^{-3}), **2** (3.43×10^{-6} mol dm^{-3}), and **3** (2.17×10^{-6} mol dm^{-3}) in chloroform. A = absorbance.

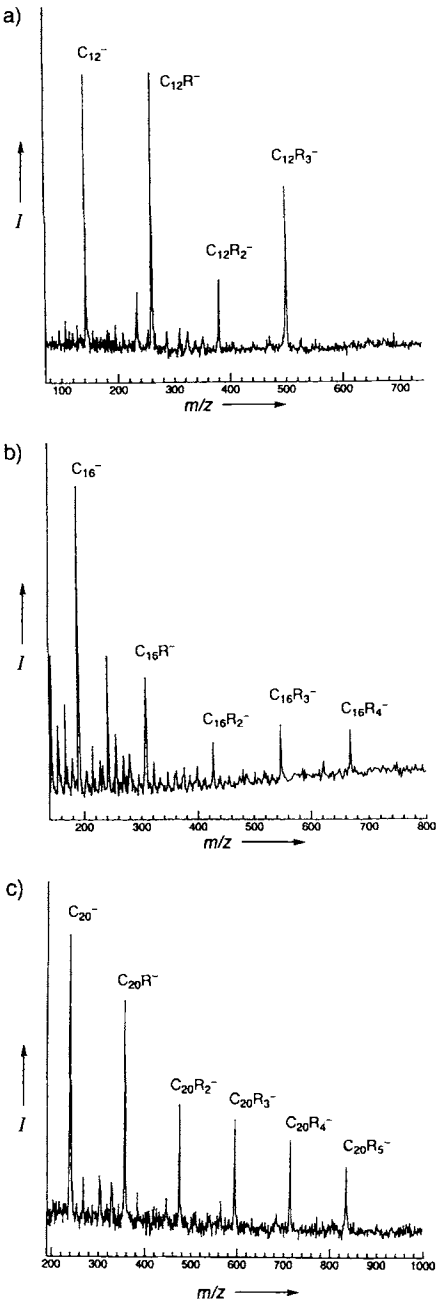

Fig. 2. Laser-desorption time of flight mass spectra of a) **1**, b) **2**, and c) **3** (R = indan). The compounds were dissolved in liquid paraffin as a matrix. For simultaneous desorption and ionization, the fourth harmonic of a Nd:YAG laser (266 nm, typically 0.6 mJ per pulse) was focused on an area of 3 mm^2. The vacuum chamber was maintained at 1×10^{-6} Torr during the operation.

In the positive-ion laser desorption time-of-flight (LD-TOF) mass spectra of **1**–**3**, like that of the related *cyclo*-C_{18} precursor, only the peak due to the indan fragment is observed. However, in the negative-ion mass spectra of **1**–**3** (Fig. 2) the peaks due to the parent ions ($C_{12}R_3^-$, ($C_{16}R_4^-$, ($C_{20}R_5^-$ (R = indan)) and the ions resulting from the successive loss of one, two, and three indan fragments were observed.[23] Thus for the first time cyclo[*n*]carbons with 4*n* carbon atoms have been obtained efficiently from organic precursors with well-defined structures.[7]

Table 1. Physical and spectroscopic properties of compounds **1**–**3**, **9**, and **10**.

1 (mixture of diastereomers): dark purple solid; m.p. 117 °C (decomp); ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 5.77–5.83 (m, 6H), 5.28–5.35 (m, 6H), 1.96–2.06 (m, 3H), 1.50–1.63 (m, 9H), 0.80–0.88 (m, 6H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 139.91 (s), 139.89 (s), 139.78* (s), 139.76 (s), 126.26 (d), 126.19 (d), 126.17 (d), 126.15* (d), 122.00 (d), 121.98* (d), 121.97(d), 121.94 (d), 93.47 (s), 93.35* (s), 93.33 (s), 93.30 (s), 54.47 (s), 54.46* (s), 54.45 (s), 54.41 (s), 32.14 (t), 32.11* (t), 32.08 (t), 32.06 (t), 18.86 (t), 18.81 (t), 18.77* (t). The signals marked by asterisk are due to the C_{3v} isomer, because the intensities of these signals are slightly larger than those expected from the statistical distribution (1:3) of C_{3v} and C_s isomers. UV/Vis ($CHCl_3$): λ_{max} (log ε) = 250 (4.83), 509 (2.24), 550 (2.23), 614 (sh, 1.96) nm; FAB MS: *m/z* (%): 498 (100) [M^+], 261 (30) [$M^+ - 2(C_9H_{10}) - H$]

2 (mixture of diastereomers): dark purple solid; m.p. 218–221 °C (decomp); ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 5.76–5.81 (m, 8H), 5.37–5.44 (m, 8H), 1.68–1.74 (m, 4H), 1.54–1.66 (m, 12H), 0.92–1.01 (m, 8H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 135.65 (s), 135.62 (s), 135.58 (s), 135.54 (s), 135.53 (s), 135.52 (s), 135.51 (s), 135.49* (s), 127.26 (d), 127.25 (d), 127.21 (d), 127.14 (d), 127.01* (d), 121.91 (d), 121.90* (d), 121.87 (d), 121.86 (d), 121.85 (d), 121.81 (d), 89.98 (s), 89.95 (s), 89.93 (s), 89.92 (s), 89.91 (s), 89.91 *(s), 89.90 (s), 89.88 (s), 54.93 (s), 54.90 (s), 54.88 (s), 54.87* (s), 32.49 (t), 32.47 (t), 32.45 (t), 18.73 (t), 18.69, (t), 18.66 (t), 18.65 (t). The signals marked by asterisk are due to the statistically least feasible C_{2v} isomer, because these signals have apparently low intensities. UV/Vis ($CHCl_3$): λ_{max} (log ε) = 272 (4.30), 309 (4.39), 502 (2.72) nm; FAB MS: *m/z* (%): 664 (100) [M^+], 309 (53) [$M^+ - 3(C_9H_{10}) - H$]

3 (mixture of diastereomers): orange solid; m.p. 108 °C (decomp); ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 5.82–5.88 (m, 10H), 5.68–5.65 (m, 10H), 1.84–1.87 (m, 10H), 1.59–1.61 (m, 10H), 1.14–1.22 (m, 10H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 132.99(s), 132.97 (s), 132.95 (s), 132.92 (s), 132.86 (s), 132.82 (s), 132.80 (s), 132.78 (s), 128.35 (d), 128.33 (d), 128.29 (d), 128.25 (d), 128.21 (d), 128.20 (d), 128.18 (d), 128.16 (d), 128.11 (d), 121.96 (d), 121.94 (d), 121.91 (d), 121.89 (d), 121.85 (d), 88.80 (s), 88.79 (s), 88.77 (s), 88.75 (s), 88.74 (s), 88.73 (s), 56.08 (s), 56.07 (s), 56.06 (s), 56.05 (s), 56.04 (s), 56.03 (s), 56.02 (s), 32.94 (t), 18.74 (t), 18.71 (t), 18.67 (t); UV/Vis ($CHCl_3$): λ_{max} (log ε) = 263 (4.43), 345 (4.53) nm; FAB MS: *m/z* (%): 830 (37) [M^+], 357 (100) [$M^+ - 4(C_9H_{10}) - H$], 240 (65) [C_{20}^+, $M^+ - 5(C_9H_{10})$]

9 (mixture of diastereomers): colorless solid; m.p. 68–70 °C; ^{1}H NMR ($CDCl_3$, 270 MHz): δ = 5.77–5.95 (m, 12H), 1.96–2.03 (m, 6H), 1.16–1.67 (m, 12H); ^{13}C NMR ($CDCl_3$, 67.5 MHz): δ = 133.03 (s), 133.01 (s), 132.98 (s), 131.91 (s), 131.90 (s), 131.83 (s), 128.83 (d), 128.44 (d), 127.33 (d), 127.31 (d), 125.67 (s), 122.61 (d), 121.85 (d), 121.58 (d), 86.57 (s), 84.94 (s), 59.64 (s), 56.33 (s), 56.31 (s), 56.16 (s), 33.00 (t), 32.28 (t), 31.83 (t), 18.78 (t), 18.50 (t), 18.48 (t)

10 (mixture of diastereomers): colorless solid; m.p. 97–100 °C; ^{1}H NMR ($CDCl_3$, 270 MHz): δ = 5.76–5.95 (m, 12H), 2.12 (s, 1H), 1.91–1.99 (m, 6H), 1.64–1.16 (m including singlet at 1.55, 10H); ^{13}C NMR ($CDCl_3$, 67.5 MHz): δ = 133.12 (s), 133.09 (s), 133.07 (s), 133.03 (s), 132.98 (s), 132.97 (s), 132.62 (s), 132.60 (s), 132.57 (s), 131.87 (s), 131.85 (s), 131.81 (s), 128.73 (d), 128.71 (d), 128.67 (d), 128.63 (d), 128.57 (d), 128.47 (d), 128.45 (d), 127.29 (d), 125.66 (s), 122.64 (d), 122.59 (d), 121.83 (d), 121.81 (d), 121.68 (d), 121.64 (d), 121.61 (d), 100.31 (s), 87.63 (s), 87.61 (s), 87.60 (s), 87.58 (s), 86.92 (s), 86.09 (s), 86.64 (s), 86.63 (s), 84.87 (s), 84.84 (s), 74.62 (s), 65.65 (s), 59.61 (s), 59.38 (s), 56.31 (s), 56.30 (s), 56.16 (s), 56.14 (s), 56.09 (s), 33.00 (t), 32.87 (t), 32.76 (t), 32.28 (t), 31.80 (t), 31.39 (q), 31.36 (q), 18.73 (t), 18.47 (t)

[20] Recently, bicyclo[2.2.2]octene-annelated dehydro[12]- and -[16]annulenes were synthesized by Komatsu et al. We are grateful to Professor Komatsu for providing us with the unpublished data.

[21] J. D. Bradshaw, D. Solooki, C. A. Tessier, W. J. Youngs, *J. Am. Chem. Soc.* **1994**, *116*, 3177–3179.

[22] While the ^{1}H NMR signals of both of the vinyl protons of **8** appear at δ = 5.8–5.9 [17], those of **1**–**3** were observed at δ = 5.8 and 5.3, 5.8 and 5.4, and 5.85 and 5.65, respectively (Table 1). The signals at higher field are assigned to the protons located closer to the annulene rings, which are shifted upfield due to the paratropicity of the $4n\pi$ ring systems.

[23] In the positive-ion FAB mass spectra of **1**–**3**, peaks due to the loss of the indan fragments were also observed; however, the cyclocarbon cation (C_{20}^+) was observed only in the case of **3** (Table 1).

1,2-Distanna[2]- and 1,2,3-Tristanna[3]-ferrocenophanes**

Max Herberhold,* Udo Steffl, Wolfgang Milius, and Bernd Wrackmeyer

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

[*n*]Ferrocenophanes,[1] in which the two cyclopentadienyl ligands are connected by an intramolecular bridge of $n = 1$, 2, or 3 links, have attracted interest as monomer precursors for the ring-opening polymerization (ROP) to metal-containing polymers.[2, 3] In addition, they can serve as models for the study of molecular dynamics[1a, 4] and for the study of the reactivity of element–element bonds in the bridge[4–8] as a function of the more or less strained bonding situation.

Although 1,1′-disubstituted ferrocene derivatives such as $[Fe(C_5H_4SnMe_3)_2]$[9, 10] and $[Fe(C_5H_4SnMe_2Cl)_2]$ (**1**) (Scheme 1)[10] have been described, their chemistry has not been explored in a systematic manner, and [*n*]ferrocenophanes containing tin directly attached to the two cyclopentadienyl ligands were unknown until very recently: I. Manners and coworkers[20] have succeeded in characterizing the first 1-stanna[1]ferrocenophane $[Fe(C_5H_4)_2(SntBu_2)]$; earlier attempts to synthesize 1-stanna[1]ferrocenophanes had produced only the dinuclear distanna[1.1]ferrocenophanes $[Fe(C_5H_4SnR_2C_5H_4)_2Fe]$ (R = Et[11], *n*Bu[11, 12]) in very low yield in addition to polymeric products. In contrast, sila[*n*]ferrocenophanes such as $[Fe(C_5H_4)_2(SiR_2)_n]$ (R = Me: $n = 1$,[7, 13] 2,[6–8, 14] 3;[8, 14] R = Ph: $n = 1$,[13, 15] R = Cl: $n = 1$[13]) and germa[*n*]ferrocenophanes such as $[Fe(C_5H_4)_2GePh_2]$[16] and $[Fe(C_5H_4GeMe_2)_2]$[14] are well known. We have found a convenient access to 1,1′-bis(chlorodimethylstannyl)ferrocene (**1**),[10] which can be readily converted to the new hydride **2** (Scheme 1).

Both **1** and **2** are useful starting materials for the synthesis of stanna[*n*]ferrocenophanes. Treatment of **1** with bis(trimethylsilyl)mercury affords **3** in moderate yield, whereas the reaction of **2** with bis(diethylamino)dimethyltin liberates two equivalents of diethylamine to give **4** in high yield. However, if other diethylaminotin compounds such as $Et_2Sn(NEt_2)_2$, $nBu_2Sn(NEt_2)_2$, and $Sn(NEt_2)_4$ were treated with **2** under the same conditions, only the distannane **3** was obtained (Scheme 1). The molecular structure[17] of the 1,2-distanna[2]ferrocenophane **3** (Fig. 1) reveals some slight but typical deformations (Fig. 2).

The cyclopentadienyl rings are almost parallel (with a tilt angle α of 0.7° towards the bridge) and adopt a nearly eclipsed conformation (with a twist angle τ of 2.9°). The distance between the cylopentadienyl rings (331.2 pm) is similar to that in ferrocene (332 pm).[18] Both the C(1)–Sn(1) and the C(6)–

[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie.

Sn(2) distances (av 214 pm) and the Me-Sn-Me angles (av 108.8°) are in the expected ranges; the corresponding values in $[Fe(C_5H_4Sn(nBu)_2C_5H_4)_2Fe]$[12] are 212.5(3) and 214.6(3) pm, and 110.1(2)°, respectively. The two $SnMe_2$ units are displaced from the eclipsed arrangement by a torsion angle ε of about 5.3°.

The NMR data of the new stanna[*n*]ferrocenophanes **3** and **4** are consistent with the proposed structures. Of particular interest are the ^{119}Sn NMR spectra, which show typical ^{117}Sn satellite signals of $^1J(^{119}Sn,^{117}Sn) = 5274.0$ Hz (**3**) and 3223.9 Hz (**4**) as well as $^2J(^{119}Sn,^{117}Sn) = 537.2$ Hz (**4**). The bridge consisting of three $SnMe_2$ units in **4** appears to be highly flexible, since no changes were observed in the $^1H(C_5H_4)$ and $^1H(SnMe_2)$ resonance signals, recorded in $[D_8]$toluene between 25 °C and −90 °C.

Evidently, the strain in the [2]ferrocenophanes (Fig. 2) decreases as the E–E bond lengths increase in the order E = $CMe_2 < SiMe_2 < SnMe_2$. Taking into account the well known reactivity of Sn–Sn bonds in distannanes and polystannanes, the new ferrocenophanes **3** and **4** must be considered as model compounds for studying exchange and insertion[21] reactions, opening the way to a rich chemistry of stanna[*n*]ferrocenophanes in general.

Experimental Procedure

All coupling constants to ^{119}Sn are determined from the satellite signals. The ^1H, ^{13}C, and ^{119}Sn NMR spectra were measured at 250, 62.9, and, 93.3 MHz, respectively.

1: A mixture of 1,1′-bis(trimethylstannyl)ferrocene (1.41 g, 2.8 mmol) and dimethyltin dichloride (1.3 g, 5.9 mmol) was heated at 130 °C for 3 h. Trimethyltin chloride was removed from the equilibrium by sublimation onto a cooling finger (15 °C). Traces of further trimethyltin chloride or dimethyltin dichloride were removed in vacuo, and 1.39 g (90%) of **1** was left as a dark-orange oil. Recrystallization from hexane gave an orange solid (m.p. 85 °C). EI MS: *m/z* (%) = 554 (100) $[M^+]$. ^1H NMR (C_6D_6, $J(^{119}Sn,^1H)$): $\delta = 0.55$ (s, 12H, Me_2Sn, $J = 60.9$ Hz); 4.08 (m, 4H, 2,5-H, $J = 9.6$ Hz), 4.25 (m, 4H, 3,4-H); ^{13}C NMR (C_6D_6, $J(^{119}Sn,^{13}C)$): $\delta = -1.1$ (Me_2Sn, $J = 415.6$), 70.7 (C-1, $J = 590.0$ Hz), 74.5 (C-2,5, $J = 66.9$), 72.0 (C-3,4, $J = 51.2$ Hz); ^{119}Sn NMR (C_6D_6): $\delta = 125.5$.

2: A solution of **1** (0.73 g, 1.3 mmol) in ether (20 mL) was slowly added to a cooled (0 °C) suspension of $LiAlH_4$ (0.05 g, 1.3 mmol) in ether, and the mixture was stirred for 3 h at room temperature. Insoluble material was filtered off, and the solvent was removed in vacuo, leaving 0.61 g (96%) of **2** as an orange oil. EI MS: *m/z* (%) = 486 (100) $[M^+]$. ^1H NMR (C_6D_6, $J(^{119}Sn,^1H)$): $\delta = 0.26$ (d, 12H, Me_2Sn, $J = 57.9$ Hz, $^3J(^1H,^1H) = 2.2$ Hz), 3.99 (m, 4H, 2,5-H, $J = 9.4$ Hz), 4.23 (m, 4H, 3,4-H), 5.45 (sept, 2H, HSn, $J = 1824.0$); ^{13}C NMR (C_6D_6, $J(^{119}Sn,^{13}C)$): $\delta = -7.5$ (Me_2Sn, $J = 371.8$ Hz), 65.8 (C-1, $J = 515.4$ Hz), 75.0 (C-2,5, $J = 53.8$ Hz), 71.4 (C-3,4, $J = 42.4$ Hz). ^{119}Sn NMR (C_6D_6): $\delta = -102.4$.

3: From **1** and $Hg(SiMe_3)_2$: To a solution of **1** (0.58 g, 1 mmol) in toluene (20 mL), bis(trimethylsilyl)mercury (0.47 g, 1.3 mmol) was added in one portion. The mixture was stirred at room temperature for 5 h. The toluene was then removed in vacuo and the residue was dissolved in pentane. After filtration and evaporation of most of the pentane, chromatography on silica with hexane/dichloromethane (3:2) gave 0.14 g (29%) of **3** as a yellow, crystalline solid (m.p. 105 °C).

3: From **2** and $R_2Sn(NEt_2)_2$ (R = Et, Bu) or $Sn(NEt_2)_4$: The stoichiometric amount of the diethylaminotin compound was added to a solution of **2** (0.2 g, 0.41 mmol) in ether (20 mL) at 0 °C, and the mixture was heated to reflux for 2 h. After all volatile material had been removed in vacuo the residue was purified by chromatography on silica (vide supra) to give **3** in yields up to 52%. EI MS: *m/z* (%) = 484 (100) $[M^+]$. ^1H NMR (C_6D_6, $J(^{119}Sn,^1H)$): $\delta = 0.40$ (s, 12H, Me_2Sn; $J_1 = 50.2$, $J_2 = 15.4$ Hz), 4.34 (m, 4H, 2,5-H, $J = 9.8$ Hz), 4.22 (m, 4H, 3,4-H); ^{13}C NMR (C_6D_6, $J(^{119}Sn,^{13}C)$): $\delta = -8.2$ Me_2Sn $J_1 = 227.0$, $J_2 = 74.2$ Hz), 77.8 (C-1, $J_1 = 338.9$, $J_2 = 49.9$ Hz), 74.8 (C-2,5, $J = 44.6$ Hz), 69.5 (C-3,4, $J_1 = 32.7$, $J_2 = 4.4$ Hz); ^{119}Sn NMR (C_6D_6, $J(^{119}Sn,^{117}Sn)$): $\delta = -43.4$ ($J = 5274.0$ Hz).

4: A solution of **2** (0.2 g, 0.41 mmol) in ether (20 mL) was cooled to 0 °C, and bis(diethylamino)dimethyltin (0.1 g, 0.41 mmol) was slowly added through a syringe. The mixture was heated to reflux for 3 h, then all volatile material was removed in vacuo. After chromatography on silica with hexane, 0.11 g (43%) of **4** were obtained as a yellow, crystalline solid (m.p. 117 °C). EI MS: *m/z* (%) = 630 (43) $[M^+]$; 467 (100) $[M^+ - SnMe_3]^+$; ^1H NMR (C_6D_6, $J(^{119}Sn,^1H)$): $\delta = 0.53$ (s, 12H, Me_2Sn, $J_1 = 44.6$, $J_2 = 22.6$ Hz), 0.45 (s, 6H, $SnSnMe_2Sn$, $J_1 = 48.7$, $J_2 = 13.8$, $J_3 = 5.0$ Hz), 3.99 (m, 4H, 2,5-H, $J = 10.4$ Hz), 4.26 (m, 4H, 3,4-H); ^{13}C NMR (C_6D_6, $J(^{119}Sn,^{13}C)$): $\delta = -9.0$ ($C_5H_4SnMe_2$, $J_1 = 244.7$, $J_2 = 42.7$, $J_3 = 17.7$ Hz), −13.5 ($SnSnMe_2Sn$, $J_1 = 185.0$, $J_2 = 30.5$ Hz) 72.2 (C-1, $J_1 = 362.9$, $J_2 = 54.1$, $J_3 = 8.3$ Hz), 78.9 (C-2,5, $J_1 = 46.5$, $J_2 = 10.5$ Hz), 74.3 (C-3,4, $J_1 = 35.0$, $J_2 = 5.0$ Hz). ^{119}Sn NMR (C_6D_6, $J(^{119}Sn,^{117}Sn)$): $\delta = -102.5$ ($C_5H_4SnMe_2$, $J_1 = 3223.9$, $J_2 = 537.2$ Hz), −249.3 ($SnSnMe_2Sn$, $J = 3225.7$ Hz).

[17] X-Ray structure analysis of compound **3**: $C_{14}H_{20}FeSn_2$, orange platelet with dimensions $0.42 \times 0.35 \times 0.10$ mm^3; **3** crystallizes in the monoclinic space group $P2_1/c$ with the lattice parameters $a = 1309.0(2)$, $b = 657.5(2)$, $c = 1887.4(2)$ pm, $\beta = 100.76(2)°$, $Z = 4$ and $\mu(Mo_{K\alpha}) = 3.981$ mm^{-1}. On a Siemens P4 diffractometer with $Mo_{K\alpha}$-radiation ($\lambda = 71.073$ pm, graphite monochromator) 4832 reflections were collected in the range $3° \le 2\theta \le 55°$ ($T = 296$K). Solution and refinement (Program SHELXTL PLUS) was done with 3547 independent and observed ($F_0 \ge 0\sigma(F_0)$, no reflections omitted) reflections; the data were corrected empirically for absorption effects by using Ψ scans of ten selected reflections (min./max. transmission factors: 0.3847/0.8034). All non-hydrogen atoms were refined anisotropically, the hydrogen atoms are in calculated positions. The refinement of 155 parameters converged at *R*/*wR*-values of 0.0403/0.0360 with $w^{-1} = \sigma^2(F_0)$; the max./min. residual electron density was 1.09/−0.60 e Å^{-3}. [21] Preliminary results have shown that oxygen, sulfur, and selenium insert into the Sn–Sn bond of **3** to give the 1,3-distanna-2-chalcogena[3]ferrocenophanes.

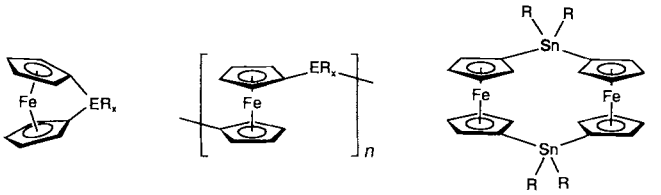
Synthesis and Ring-Opening Polymerization of a Tin-Bridged [1]Ferrocenophane**

Ron Rulkens, Alan J. Lough, and Ian Manners*

[1]Ferrocenophanes **1** possess a single-atom bridge ER_x linking the two cyclopentadienyl ligands. The idea that species such as **1** (E = Si) might exist was (understandably) dismissed by Rosenberg and Neuse in 1970 who stated that such structures would be "impossibly strained."[1] Since the synthesis of the first [1]ferrocenophane **1**, $ER_x = SiPh_2$, in 1975 by the reaction of dilithioferrocene·tmeda (tmeda = tetramethylethylenediamine) with Ph_2SiCl_2,[2] a range of analogous species with Group 14 (Si, Ge),[3,4] Group 15 (P, As),[4-6] Group 16 (S),[7] and Group 4 (Ti, Zr, Hf)[8,9] bridging elements have subsequently been prepared. These molecules possess interesting strained structures with tilt angles between the planes of the cyclopentadienyl ligands between 6° (for **1** (E = Zr)) and 31° (for **1** (ER_x = S)). Recently [1]ferrocenophanes have attracted attention as precursors to novel high molecular weight poly(metallocene)s **2** by ring-opening polymerization (ROP).[10-15]

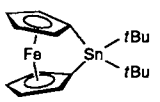


1 **2** **3**

As the properties of the resulting organometallic materials **2** are modified significantly by the nature of the spacer ER_x, the extension of the range of [1]ferrocenophanes by the incorporation of other bridging elements is of considerable interest.[14,16,17] Despite their large covalent radii, the introduction of heavier elements (fifth period and higher) would be expected to be synthetically challenging because of the weakness of the bonds between the *ipso*-carbon atoms and the bridging element. Herein we report on the first [1]ferrocenophane to be bridged by the heavy main group element tin.[18]

Although [1]ferrocenophanes containing silicon and germanium as bridging elements are now well known,[3,4] previous attempts to synthesize stanna[1]ferrocenophanes by the reaction of dilithioferrocene·tmeda with R_2SnCl_2 (R = Me, Et, *n*Bu, or Ph) were unsuccessful and resulted only in low molecular weight oligomers **2** ($ER_x = SnR_2$) ($M_n < 4600$) and cyclic dimers **3**.[4,5,19] The absence of a stanna[1]ferrocenophane in the product mixture was attributed to the high reactivity of the Sn–Cl bonds, which might favor intermolecular condensation reactions over intramolecular cyclizations.[19]

We initially attempted to isolate a tin-bridged [1]ferrocenophane by the reaction of dilithioferrocene·2/3tmeda with nBu_2SnCl_2 in Et_2O at low temperature.[20] Although a color change from amber to orange was detected below −40 °C, warming the reaction mixture led to amber oligomeric products similar to those previously reported.[19] Since the presence of bulkier substituents at the tin atom should stabilize a stanna[1]ferrocenophane, we studied the reaction of dilithioferrocene·2/3tmeda with tBu_2SnCl_2 in diethyl ether. At −35 °C the reaction showed a subtle color change from amber to orange. When it reached −30 °C the reaction mixture was rapidly warmed to 20 °C and filtered to remove LiCl. The filtrate was collected at −78 °C and the stanna[1]ferrocenophane **4** was isolated as orange needles in 65% yield.



4

The structure of **4** was confirmed by ^1H, ^{13}C, and ^{119}Sn NMR, UV/Vis spectroscopy, and by mass spectrometry. NMR and UV/Vis spectroscopic results indicated a less strained structure for **4** compared to that of the Si and Ge analogues **1**, $ER_2 = SiMe_2$ and $GeMe_2$, respectively (see Table 1).[21] For example, the ^1H NMR spectrum of **4** (in $CDCl_3$) shows of a pair of less widely separated pseudo triplets (δ = 4.22 and 4.44) assigned to the α and β protons of the cyclopentadienyl ligands. Thus the splitting between the pseudo triplets, $\Delta\delta$, is 0.22, 0.26, and 0.40 for **4**, **1**, $ER_x = GeMe_2$, and **1**, $ER_x = SiMe_2$, respectively. In the ^{13}C NMR spectrum (in $CDCl_3$) the resonance of the *ipso*-carbon atoms of the cyclopentadienyl ligands of **4** at δ = 34.9 lies at slightly higher field than those of **1** (E = Si, Ge); but these C atoms are still extremely shielded compared to those of unstrained ferrocene derivatives.

Table 1. Comparison of data indicating ring strain in Group 14 bridged [1]ferrocenophanes.

	α [°]	β [a] [°]	λ_{max} [b] [nm]	ε [M^{-1} cm^{-1}]	$\delta_{(ipso\text{-}C)}$ [c]	$\Delta\delta$(H-Cp) [d]
1 ($ER_2 = SiMe_2$)	20.8(5)	37.0(6)	481	341	33.1	0.40

Crystals of the tin-bridged [1]ferrocenophane **4** suitable for a single-crystal X-ray diffraction study were obtained by recrystallization from Et_2O/THF (10:1) at low temperature (< −20 °C). The molecular structure of **4** is shown in Figure 1.[22] The most important structural features indicating ring strain are

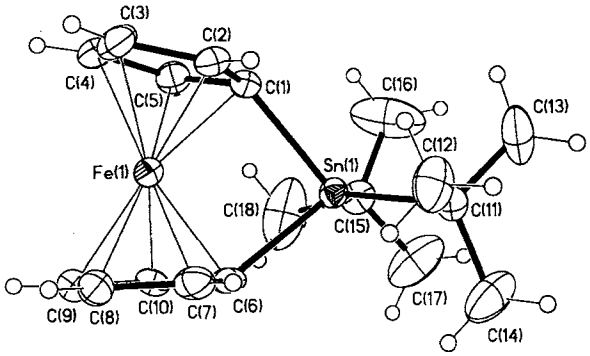

Fig. 1. Crystal structure of **4**. Selected bond lengths [Å] and angles [°]: Sn–C(1) 2.174(4), Sn–C(6) 2.171(5), Sn–C(11) 2.180(5), Sn–C(15) 2.190(6), Sn–Fe 2.9761(8), Fe–C(1) 2.036(5), Fe–C(2) 2.026(5), Fe–C(3) 2.059(5), Fe–C(4) 2.062(5), Fe–C(5) 2.027(5), Fe–C(6) 2.041(5), Fe–C(7) 2.027(5), Fe–C(8) 2.068(5), Fe–C(9) 2.063(6), Fe–C(10) 2.036(6); C(1)-Sn-C(6) 86.5(2), C(11)-Sn-C(15) 115.1(2).

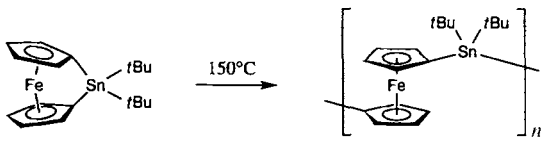
the tilt angle α between the planes of the cyclopentadienyl rings (14.1(2)°) and the angles β between the cyclopentadienyl ring planes and the exocyclic C–Sn bonds (36.2(2)° and 36.1(2)°). The tilt angle α for **4** is the smallest yet reported for a [1]ferrocenophane with a main group element in the bridge and is significantly less than that for silicon- and germanium-bridged analogues (Table 1). The tilting of the cyclopentadienyl ligands is accompanied by a RC1-Fe-RC2 (RC = ring centroid) angle of 168.6(2)° (180° in ferrocene) and a 0.164(6) Å displacement of the iron atom from the line joining the two ring centroids. The tilted cyclopentadienyl ligands maintain an eclipsed conformation. The angle between the *ipso* carbon atoms of the cyclopentadienyl ligands and the tin atom (C1-Sn-C6) is 86.5(2)°; this is smaller than the analogous angles for **1**, $ER_2 = SiMe_2$, and $ER_2 = GeMe_2$, (95.7(4)° and 91.7(3)°, respectively). The average Sn–C bond lengths ($Sn-C_{Cp} = 2.173(4)$, $Sn-C_{tBu} = 2.185(5)$ Å) are typical for Sn–C single bonds. The Sn–Fe distance in **4** is 2.9761(8) Å, which is only 14–17% longer than Fe–Sn bond lengths found in the species $[CpL_2FeSnR_3]$ (2.537–2.605 Å).[23] This indicates that probably there is significant overlap of the orbitals of iron and tin to give a weak bond.[11, 24]



4 **5**

When **4** was heated at 150 °C the amber poly(ferrocenylstannane) **5** was formed,[25] which is soluble in fairly polar and aromatic organic solvents (e.g. THF, CH_2Cl_2, toluene). Analysis by gel permeation chromatography (GPC) in THF versus polystyrene standards showed that the material was of high molecular weight ($M_w = 133000$, $M_n = 83000$, polydispersity index $M_w/M_n = 1.6$). Despite its strained structure, **4** is air-stable over several days in the solid state. However, in solution in $CHCl_3$ ROP occurs at room temperature to form a low molecular weight poly(ferrocenylstannane) **5** ($M_w = 10000$, $M_n = 4700$, polydispersity index $M_w/M_n = 2.2$) and as a side product the cyclic dimer **3** (R = *t*Bu). However, when **4** was dissolved in toluene, high molecular weight **5** ($M_w = 900000$, $M_n = 560000$, $M_w/M_n = 1.6$) and a small amount of the dimer **3** were formed within 3 h.

The tin-bridged species **4** represents the least ring-tilted [*n*]metallocenophane to undergo ROP to date. We have previously prepared [2]metallocenophanes with tilt angles up to 13° that were found to be resistent to ROP.[26, 27] In order to compare the strain energy of **4** to that of other polymerizable [1]ferrocenophanes the thermal ROP was studied by differential scanning calorimetry (DSC) (see Fig. 2). We found that when heated above 100 °C, the sample showed a ROP exotherm but no melt transition. By integration of the ROP exotherm we found that **4** has a strain energy of $36(\pm 9)$ kJ mol^{-1}. This is approximately half the enthalpy of polymerization found by DSC analysis of the ROP of silicon-bridged [1]ferrocenophanes (70–80 kJ mol^{-1}).[10, 28] Analysis of **5** by cyclic voltammetry showed the presence of two reversible oxidation waves (separation $\Delta E = 0.24$ V)[29] consistent with the presence of significant bridge-mediated interactions between the iron atoms.[10, 14, 16, 30–32] Thermogravimetric analysis (TGA) under nitrogen (heating rate of 10 K min^{-1}) revealed that polymer **5** is stable to weight loss below about 230 °C. The ceramic yield at 900 °C was 44%.

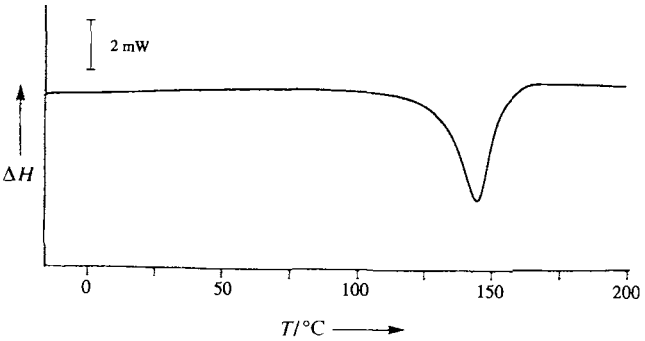


Fig. 2. DSC of the polymerization of **4** (5.8 mg, heating rate: 10 K min^{-1}).

Further studies of **4** and the polymer **5** will allow detailed comparisons with the analogous Si and Ge monomers and high polymers. In addition, the ROP of **4** in solution at room temperature provokes intriguing mechanistic questions. Relevant investigations are now in progress.

Experimental Procedure

4: A solution of tBu_2SnCl_2 (2.32 g, 7.64 mmol) in diethyl ether (20 mL) was added dropwise to a suspension of dilithioferrocene·2/3 tmeda (2.00 g, 7.27 mmol) in diethyl ether (100 mL) that was cooled to −78 °C. The reaction mixture was allowed slowly to warm to −30 °C over 4 h after which it was rapidly warmed to 20 °C and vacuum filtered through a fritted glass disk. The orange filtrate was collected at −78 °C which resulted in the precipitation of the orange product. After the mixture had been cooled for 30 minutes at −78 °C, the solvent was decanted off and the product was dried under vacuum. This gave 1.98 g (65%) of analytically pure orange crystalline needles of **4**. ^{1}H NMR (300 MHz, $CDCl_3$, −20 °C; ps. t: pseudo triplet): $\delta = 4.44$ (ps. t, $J = 2$ Hz, 4H, cyclopentadienyl), 4.22 (ps. t, $J = 2$ Hz, 4H, cyclopentadienyl), 1.48 *t*Bu (s/d, $J(H,^{117/119}Sn) = 75$ Hz, 18H); ^{13}C NMR (75.5 MHz, $CDCl_3$, −20 °C): $\delta = 77.9$ ($J(C,^{117/119}Sn) = 28$ Hz, cyclopentadienyl), 75.7 ($J(C,^{117/119}Sn) = 26$ Hz, cyclopentadienyl), 34.9 (*ipso*-cyclopentadienyl), 32.8 (*ipso*-*t*Bu), 31.8 (*t*Bu); ^{119}Sn NMR (111.8 MHz, $CDCl_3$, −20 °C): $\delta = -23.7$; UV/Vis. (THF): 340 nm (sh.), 418 nm ($\varepsilon = 75\,M^{-1}cm^{-1}$), 485 nm ($\varepsilon = 158\,M^{-1}cm^{-1}$); MS: *m/z* (%): 418 (62) [M^+], 362 (28) [$M^+ - t$Bu], 304 (100) [$M^+ - 2t$Bu], 248 (46) [$Sn(\eta\text{-}C_5H_5)_2^+$], 186 [$Fe(\eta\text{-}C_5H_5)_2^+$]; anal calcd. for $C_{18}H_{26}FeSn$: C 51.85, H 6.29; found: C 51.51, H 6.29; DSC: polymerization exotherm 145 °C (peak), 130 °C (onset), $\Delta H = -36(\pm 9)$ kJ mol^{-1}.

ROP of **4**: The poly(ferrocenylstannane) **5** was obtained from **4** in two ways: 1) Thermal ROP: Solid-state polymerization was carried out by heating crystalline **4** in a sealed evacuated Pyrex tube at 150 °C for 30 min. This resulted in the formation of monomodel high molecular weight poly(ferrocenylstannane) **4** in a quantitative yield. 2) ROP in solution: After the dissolution of **4** (50 mg, 0.10 mmol) in $CHCl_3$ (0.5 mL) at 20 °C, it underwent complete conversion over 3 h to the cyclic dimer **3** (R = *t*Bu) (30%) and to polymeric material **5** (70%), which was isolated by precipitation into hexanes and was shown to have a monomodel low molecular weight. The remaining solution contained the cyclic dimer **3** (R = *t*Bu), which was isolated by recrystallization from pentanes. In toluene, high molecular weight polymer **5** and only a small amount of dimer **3** were formed.

3 (R = *t*Bu): ^{1}H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 4.41$ (ps. t, $J = 2$ Hz, 8H, cyclopentadienyl), 4.18 (ps. t, $J = 2$ Hz, 8H, cyclopentadienyl), 1.18 *t*Bu (s/d, J (H, $^{117/119}$Sn) = 64 Hz, 36H); ^{13}C NMR (50.3 MHz, $CDCl_3$, 20 °C): $\delta = 75.2$ (J ($C,^{117/119}Sn$) = 40 Hz, cyclopentadienyl), 70.2 ($J(C,^{117/119}Sn) = 34$ Hz, cyclopentadienyl), 69.2 (*ipso*-cyclopentadienyl), 31.3 (*t*Bu), 28.1 (*ipso*-*t*Bu); MS: *m/z* (%): 834 (2) [M^+], 777 (73) [$M^+ - t$Bu], 663 (67) [$M^+ - 3t$Bu], 606 (57) [$M^+ - 4t$Bu], 368 (100) [$M^+ - 2Sn(t\text{Bu})_2$], 304 (58) [$[Fe(\eta\text{-}C_5H_5)_2Sn^+$].

5: ^{1}H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta = 4.24$ (s,br., 4H, cyclopentadienyl), 3.97 (s,br., 4H, cyclopentadienyl), 1.34 *t*Bu (s/d, J (H, $^{117/119}$Sn) = 65 Hz, 18H); ^{13}C NMR (75.5 MHz, $CDCl_3$, 20 °C): $\delta = 74.5$ ($J(C,^{117/119}Sn) = 24$ Hz, cyclopentadienyl), 71.1 (J ($C,^{117/119}Sn$) = 32 Hz, cyclopentadienyl), 70.6 (*ipso*-cyclopentadienyl), 31.8 (*t*Bu), 29.0 (*ipso*-*t*Bu); ^{119}Sn NMR (111.8 MHz, $CDCl_3$, 20 °C): $\delta = -45.2$; UV/Vis. (THF): 340 nm (sh.), 452 nm ($\varepsilon = 152\,M^{-1}cm^{-1}$); anal calcd. for $C_{18}H_{26}FeSn$: C 51.85, H 6.29; found: C 51.86, H 6.37; DSC: T_g 120 °C ($\Delta C_p = 28(5)$ J mol^{-1}), T_{decomp} 205 °C; GPC (THF, vs. polystyrene): thermal polymerization $M_n = 83000$ (PDI = 1.6); polymerization in solution (20 °C): $CHCl_3$, $M_n = 4700$ (PDI = 2.2); toluene, $M_n = 560000$ (PDI = 1.6).

Azido and 2,2′-Bipyrimidine Ligands as Useful Tools in Designing Two- and Three-Dimensional Manganese(II) Networks

Giovanni De Munno,* Miguel Julve,* Guillaume Viau, Francesc Lloret, Juan Faus, and Davide Viterbo

Magneto-structural studies on azido-bridged dinuclear copper(II) complexes[1] have shown that the end-to-end and end-on azido bridging ligands are able to mediate large antiferromagnetic[1b–e] and ferromagnetic[1b,f,g] interactions, respectively. The concept of accidental orthogonality[1b] and the theory of spin polarization[2] have been applied by Kahn et al. to account for these magnetic interactions. Calculations have revealed that the interaction between the in-plane π_g HOMOs of the azido ligand and the d_{xy} metal orbitals containing the unpaired electron favors either the singlet (end-to-end azido bridge) or the triplet (end-on azido bridge) as ground state. The extension of these magneto-structural studies to other complexes with transition metal ions such as nickel(II) cation afforded azido-bridged dinuclear,[3] square[4] and cubane[5] tetranuclear, and one-[6] and two-dimensional[7] compounds.

Extensive magneto-structural work has been carried out also with metal complexes that contain 2,2′-bipyrimidine (bpym) ligands, taking advantage of the chelating and bis(chelating) coordination modes of this bis(α-diimine) type ligand. The most striking features of this class of compounds are the easy access to dinuclear complexes,[8] the possibility of tailoring the number of metal atoms in the molecule from the mononuclear species to *n*-dimensional (*n*D) networks ($n = 1-3$),[9] the preparation of novel dicubane type complexes,[10] the rational design of chain-like multinuclear complexes with a regular alternation of ferro- and antiferromagnetic interactions[11] or with two antiferro-

magnetic[12] interactions, and finally, the preparation of new honeycomb layered materials, which exhibit alternating antiferromagnetic interactions within the hexagonal layer.[8c, 13]

In view of the remarkable ability of the end-on azido and bis(chelating) bpym bridging units to mediate relatively strong ferro- and antiferromagnetic interactions, respectively, we tried to prepare honeycomb layered materials with these two types of bridges and first row transition metal ions. Preliminary attempts resulted in the isolation and structural characterization of the sheetlike polymer **1** and the three-dimensional polymeric compound **2**, which both have the same composition.

$[Mn_2(bpym)(N_3)_4]$ **1**, **2**

The crystal structure of **1** reveals parallel sheets of manganese atoms linked by two end-on azido and one bis(chelating) bpym ligands (Fig. 1). Each sheet comprises double azido-bridged manganese(II) chains that are connected by bridging bpym ligands, leading to the formation of a honeycomb network. Each manganese atom is in an highly distorted octahedral MnN_6 environment. If we assume that the equatorial plane is defined by the two bpym nitrogen atoms and the nitrogen atoms N(2) and N(2c) of the azido ligands, the two bonds between the axial azido ligand and the metal are longer than those between the equatorial azido ligands and the metal, and are all significantly shorter than that between the metal and the bpym ligand. The intraring metal–metal separations are Mn(1)···Mn(1a) 6.142(1), Mn(1)···Mn(1b) 3.428(1), Mn(1)···Mn(1d) 6.234(1), Mn(1)···Mn(1e) 8.751(1), Mn(1)···Mn(1f) 8.186(1), and Mn(1b)···Mn(1f) 8.996(1) Å [(a) = x, $1-y$, z; (d) $1+x$, y, z; (e) $1+x$, $1-y$, z; (f) $1.5-x$, $y-0.5$, $-z$]. The distances between Mn centers separated by bpym and azido ligands compare well with corresponding values reported for bpym[8c] or double end-on azido-bridged[14] manganese(II) dimers. Compound **1** is very similar to the parent complex of formula **3**,[8e]

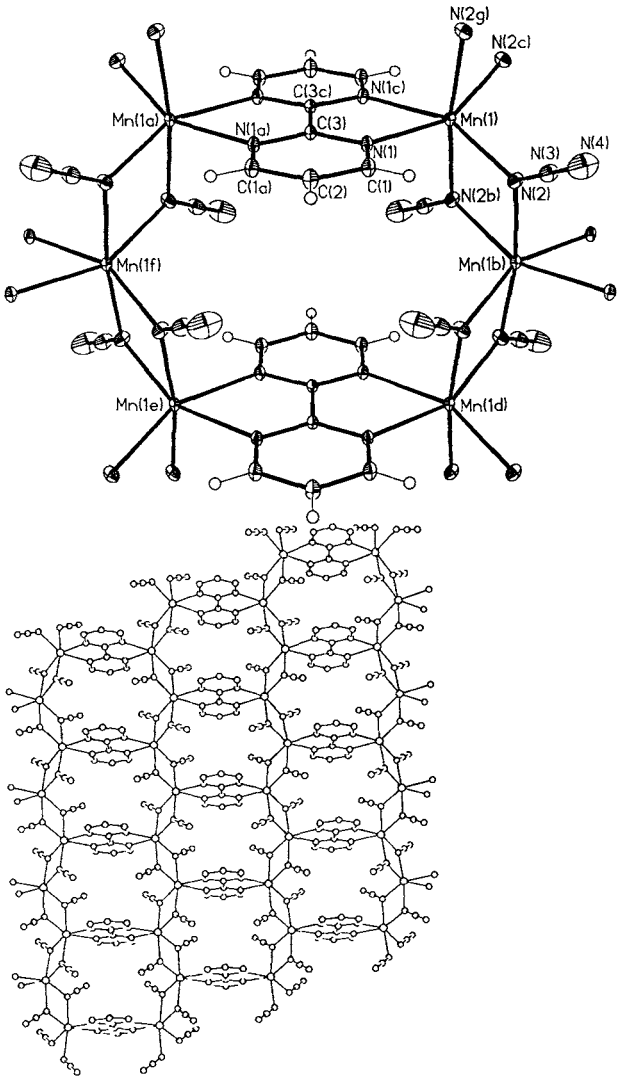

Fig. 1. Crystal structure of **1** (ellipsoids at the 30% probability level). Top: Hexanuclear repeating unit. Bottom: View of a sheet of **1** perpendicular to the xy plane (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°] with standard deviations in parentheses: Mn(1)–N(1) 2.315(1), Mn(1)–N(2) 2.178(1), Mn(1)–N(2b) 2.234(1); N(1)-Mn(1)-N(2) 92.8(1), N(1)-Mn(1)-N(1c) 71.3(1), N(2)-Mn(1)-N(1c) 154.8(1), N(1)-Mn(1)-N(2b) 100.7(1), N(2)-Mn(1)-N(2b) 78.0(1), N(2)-Mn(1)-N(2c) 108.2(1), N(1)-Mn(1)-N(2g) 85.7(1), N(2)-Mn(1)-N(2g) 97.4(1), N(2b)-Mn(1)-N(2g) 172.3(1), Mn(1)-N(2)-Mn(1b) 102.0(1), N(2)-N(3)-N(4) 178.5(2) (symmetry code: (b) $1.5-x$, $1.5-y$, $-z$; (c) $1-x$, y, $-z$; (g) $x-0.5$, $1.5-y$, z).

$[Mn_2(bpym)(ox)_2]\cdot 6H_2O$ **3**

in which the double azido bridge is replaced by the bis(chelating) oxalato ligand. Since the Mn···Mn distances are shortened for the complex with azido ligands in comparison to that with oxalato ligands, the size of the cavity in the hexameric ring of **1** is reduced to such an extent that the inclusion of solvent molecules is precluded. The bpym ligand is planar and its bond lengths and angles are consistent with known values. The distance between the two bpym units within the hexameric ring is 5.876(2) Å.

The crystal structure of **2** consists of chains of manganese atoms; the Mn centers are alternatively bridged by bpym and two end-on azido ligands (Fig. 2). The chains are connected by end-to-end azido ligands in vicinal positions, which ensures linkages along two different directions. Each metal atom is in a highly distorted octahedral MnN_6 environment. If we assume that two bpym-nitrogen atoms occupy two equatorial positions of the octahedron around Mn^{II} (Fig. 2), the other two equatorial positions are occupied by N(6) of the end-on azido ligand and by N(3) of the end-to-end azido ligand, while the axial positions are occupied by N(5c) and N(6b). The axial positions of each Mn^{II} center are connected with the equatorial ones of the adjacent Mn^{II} center (and vice versa) by end-on and end-to-end azido ligands. Although bpym is coordinated to the metal ion in an asymmetrical bis(chelating) fashion, the average Mn–N(bpym) bond length in **2** and the distance between the metal centers separated by the bpym bridge [Mn(1)···Mn(1a) = 6.177(1) Å] are close to that in **1**. The Mn(1)–N(3) bond length is significantly shorter than the other equatorial distances. The bpym ligand is planar and the Mn(1) atom lies 0.036(1) Å out of this plane. The distance between the metal centers separated by end-on azido ligands is somewhat longer that those in **1** and in similar complexes.[14] The structure of **2** is very similar to that of $[Cu_2(bpym)(NCO)_4]$,[9b] because the metal atoms in both compounds are bridged by bpym and end-on and end-to-end pseudohalide ligands. The only remarkable difference concerns the connections of adjacent chains: in the copper complex they are connected in such a way to form a two-dimensional polymer, whereas in **2** a three-dimensional network occurs.

The $\chi_m T$ values (χ_m is the magnetic susceptibility per two Mn^{II} ions) for **1** and **2** at room temperature are similar to one another and lie in the range expected for two $S = 5/2$ ground states. However, the temperature dependence of the $\chi_m T$ values for these compounds is very different: the $\chi_m T$ value for **1** continuously increases as the sample is cooled and reaches a maximum at 25 K (χ_m shows a maximum at 14 K) then decreases very

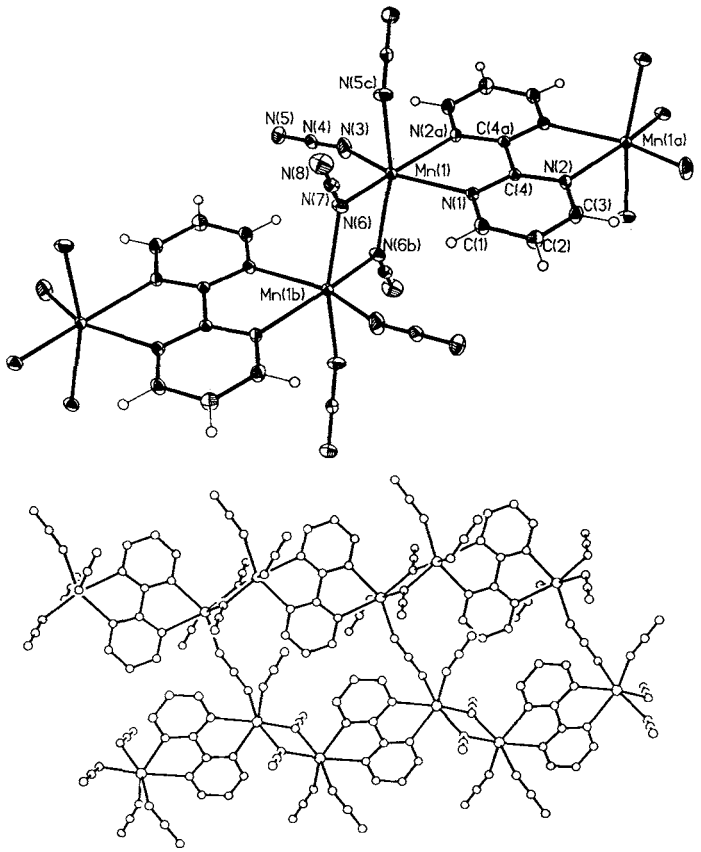

Fig. 2. Crystal structure of **2** (ellipsoids at the 30% probability level). Top: Tetranuclear fragment. Bottom: Best view of two chains in the layer (hydrogen atoms have been omitted for clarity). Selected distances [Å] and angles [°] with standard deviations in parentheses: Mn(1)-N(1) 2.294(2), Mn(1)-N(3) 2.177(2), Mn(1)-N(6) 2.230(2), Mn(1)-N(2a) 2.356(1), Mn(1)-N(5c) 2.217(2), Mn(1)-N(6b) 2.215(2); N(1)-Mn(1)-N(3) 151.8(1), N(1)-Mn(1)-N(6) 97.1(1), N(3)-Mn(1)-N(6) 110.8(1), N(1)-Mn(1)-N(2a) 70.4(1), N(3)-Mn(1)-N(2a) 82.8(1), N(6)-Mn(1)-N(2a) 164.2(1), N(1)-Mn(1)-N(5c) 96.0(1), N(3)-Mn(1)-N(5c) 90.3(1), N(6)-Mn(1)-N(5c) 86.5(1), N(2a)-Mn(1)-N(5c) 85.4(1), N(1)-Mn(1)-N(6b) 91.1(1), N(3)-Mn(1)-N(6b) 91.6(1), N(6)-Mn(1)-N(6b) 75.5(1), N(2a)-Mn(1)-N(6b) 113.2(1), N(5a)-Mn(1)-N(6b) 161.4(1), Mn(1)-N(6)-Mn(1b) 104.5(1), Mn(1)-N(3)-N(4) 161.3(2), N(3)-N(4)-N(5) 178.4(3), Mn(1)-N(5c)-N(4c) 126.6(2), N(6)-N(7)-N(8) 179.2(2) (symmetry code: (a) $1-x, -y, 1-z$; (b) $-x, -y, -z$; (c) $x, 0.5-y, 0.5+z$).

quickly at lower temperatures; the $\chi_m T$ value for **2** continuously decreases as the sample is cooled, and a susceptibility maximum occurs at 35 K. These results correspond to overall ferromagnetic (**1**) and antiferromagnetic behavior (**2**) and can be easily understood by considering the structures. In the case of **1**, the ferromagnetic interaction between the metal ions through the end-on azido bridge is larger (J ca. $+2\ cm^{-1}$)[14] than the antiferromagnetic interaction through the bpym ligand (J ca. $-1\ cm^{-1}$).[8c] This is the first example of a honeycomb layered material with alternating ferro- and antiferromagnetic interactions within the layers. In the case of **2**, the single end-to-end azido ligand and the bridging bpym ligand would provide the pathways for the antiferromagnetic coupling, whereas the double end-on azido ligand mediates the ferromagnetic coupling. The antiferromagnetic interaction through the end-to-end azido ligand should be larger[1d] than the ferromagnetic one and the overall antiferromagnetic coupling results. Additional new compounds and calculations are needed in order to extend these investigations to other spin systems and to get suitable theoretical models to analyze the magnetic properties of these exotic new systems. This kind of compound containing ferro- and antiferromagnetic interactions is very interesting with regard to understanding and designing metamagnetic compounds. Indeed, **1** shows metamagnetic behavior with a critical magnetic field about 2 T.

Experimental Procedure

Synthesis of **1** and **2**: Orange hexagonal needles of **1** (main product) and yellow prisms of **2** were grown by slow evaporation of aqueous solutions (60 mL) containing $Mn(NO_3)_2 \cdot 4H_2O$ (1 mmol), 2,2'bipyrimidine (1 mmol), and sodium azide (2 mmol). The crystals of **2** were separated by hand and dried on filter paper. Crystals of **1** were filtered off, washed with water and dried in air. The crystals obtained in this way were suitable for X-ray diffraction. The main difference in the IR spectra of **1** and **2** is the occurrence of three peaks (**2**) instead of two (**1**) in the region 2120–2040 cm^{-1} (ν_{as} (N_3^-)).

Crystal structure analyses of **1** and **2**: Siemens R3m/V automatic diffractometer, $Mo_{K\alpha}$, $\lambda = 0.71073$ Å, graphite monochromator, 295 K. Data collection, solution, and refinement: ω-2θ scan, standard Patterson methods with subsequent Fourier recycling. SHELXTL-PLUS [15]. **1**: $C_8H_4Mn_2N_{16}$, monoclinic, space group $C2/m$, $a = 6.234(2)$, $b = 15.138(3)$, $c = 8.934(2)$ Å, $\beta = 95.60°$, $V = 839.1(4)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.726\ g\,cm^{-3}$, $3 < 2\theta < 85°$, crystal size $0.12 \times 0.26 \times 0.44$ mm. 3100 unique reflections, and 2259 assumed as observed with $I > 3\sigma(I)$. Refinement of 65 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R = 0.034$, $R_w = 0.038$ and $S = 1.10$ [16]. **2**: $C_8H_4Mn_2N_{16}$, monoclinic, space group $P2_1/c$, $a = 7.695(2)$, $b = 13.114(3)$, $c = 7.813(2)$ Å, $\beta = 111.67°$, $V = 732.7(3)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.977\ g\,cm^{-3}$, $3 < 2\theta < 54°$, crystal size $0.14 \times 0.15 \times 0.18$ mm. 1606 unique reflections, and 1346 assumed as observed with $I > 3\sigma(I)$. Refinement of 127 variables with anisotropic thermal parameters for all non-hydrogen atoms gave $R = 0.022$, $R_w = 0.025$ and $S = 1.19$. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-56. Alternating Ferro- and Antiferromagnetic Interactions in Honeycomb-Like Layers of an Azidomanganese(II) Compound**

Roberto Cortés,* Luis Lezama, J. Luis Pizarro, M. Isabel Arriortua, and Teófilo Rojo*

Alternating ferro-and antiferromagnetic interactions is a rather rare phenomenon in molecular-based magnetic materials. Very few examples are known in one-dimensional (1D) copper(II) compounds[1] and recently this has also been observed in one manganese(II) chain.[2] Interchain interactions in 1D systems are very weak compared with intrachain interactions and, therefore, there is no magnetic ordering except at absolute zero. Thus, in order to obtain high magnetic ordering it appears necessary to increase the dimensionality. To our knowledge, two- (2D) or three-dimensional (3D) systems showing this kind of magnetic alternation have not yet been reported.

Extended lattices of antiferromagnetic or ferrimagnetic systems have been obtained by using adequate superexchange bridging groups such as oxalates or cyanides.[3] Thus, the azido ligand should be a suitable candidate for the design of new magnetic systems because the azido ion has shown great versatility in its coordination modes in different transition metal complexes. Thus, double- or triple-bridged dinuclear complexes,[4–6] square-planar[7] and cubane tetranuclear complexes,[8] and polymeric 1D,[2, 5, 9] 2D,[10] and 3D complexes[11] have been characterized.

The wide variety of molecular architectures obtained has given rise to a broad range of magnetic couplings. In fact, the azido ligand can mediate antiferromagnetic interactions when it bridges end-to-end (EE)[9] or is coordinated through end-on (EO) bridges with angles greater than 108°.[12] In contrast, ferromagnetic coupling is observed through EO bridges with angles less than 108°.[2, 6, 13] Alternating ferro- and antiferromagnetic interactions in a 1D compound containing both types of bridging[2] have also been described.

[**] We thank the University of the Basque Country (UPV EB234/95) for financial support.

In the case of bis(bidentate) ligands such as 2,2′-bipyrimidine (bpym), high-dimensional polynuclear species have been found.[14] This ligand, in its bis(chelating) coordination mode, has a remarkable ability to mediate strong antiferromagnetic exchange interactions between metal ions.[14] Thus, a suitable combination of bpym and the azido ligand (in EO coordination) could therefore lead to the preparation of the desired high-dimensional species with alternating ferro- and antiferromagnetic interactions. Herein we report the results on an unusual polymeric layered system of the formula $[Mn_2(bpym)(N_3)_4]$ **1**, whose molecular structure can be considered as a honeycomb-like layer.

The X-ray crystal structure analysis of the Mn complex **1** (Fig. 1)[15] shows chains of manganese(II) ions connected by

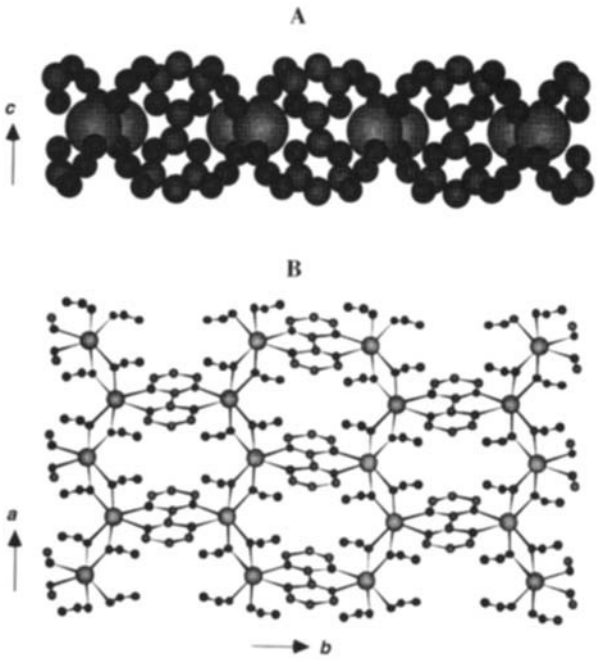

Fig. 1. Crystal structure of **1**. A) Space-filling view of one layer. B) View along the *c* axis of a layer showing the Mn_6^{II} hexagons. The H atoms have been omitted for clarity.

double EO azido bridges. These chains are alternately bridged by bis(bidentate) bpym ligands. The whole structure can be described as parallel honeycomb-like sheets, each consisting of an infinite hexagonal array of manganese(II) ions bridged by bis(chelating) bpym ligands and by double end-on azido bridges. The nearly planar hexagonal units are compressed, with two long and four short edges (Fig. 2). The 2D polymer extends in the *xy* plane by repetition of edge-sharing hexagons. The layers of the polymer are held together by hydrogen bonding between the bpym ligands and the terminal nitrogen atoms of the azido ligands; the interplane separation is 8.88 Å. Each Mn^{II} ion resides in a distorted octahedral environment formed by six nitrogen atoms, four from the azido ligands and two from the bpym ligand. The Mn–N distances range from 2.08 to 2.33 Å. The Mn–N(bpym) distances are slightly larger than those in the dinuclear complex $[Mn_2(bpym)(H_2O)_6(SO_4)_2]$ **2**[14] and as a consequence the value of the bite angle N2-Mn-N1 decreases from 71.5° in the dimer to 70.9(3)° in **1**. Regarding the azido bridges, only the Mn–$N3^I$ distance [2.33(2) Å] can be considered larger than that usually obtained from the azidomanganese compounds. The two EO azido bridges form different angles with the metal centers (98.5(3)° and 107.2(4)°). The distance

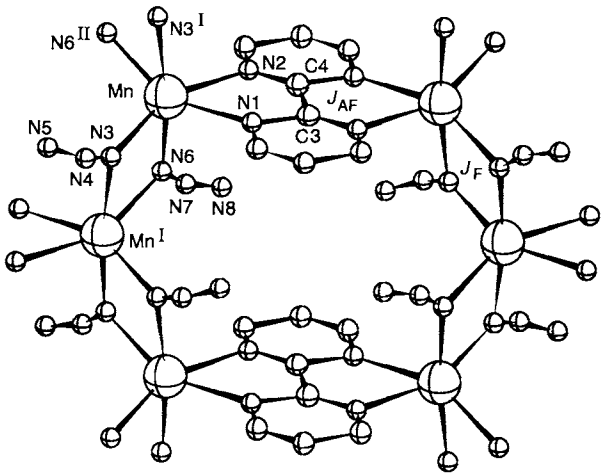

Fig. 2. Compressed hexagonal unit showing selected atom numbering and the exchange coupling constants. Selected distances [Å] and bond angles [°] (standard deviations in parentheses): Mn–N1 2.33(1), Mn–N2 2.289(8), Mn–N3 2.191(9), Mn–N3^{I} 2.33(2), Mn–N6 2.17(1), Mn–N6^{II} 2.08(1); Mn-N3-Mn^{II} 98.5(3), Mn-N6-Mn^{I} 107.2(4), Mn-N1-C4 121.9(4), Mn-N2-C4 114.6(7); symmetry code: I $x-1/2,1/2-y,z$; II $1/2+x,1/2-y,z$.

between the Mn centers separated by the double azido bridge is 3.425(4) Å, that between the Mn centers separated by the bpym ligand 6.127(2) Å.

The variation of the molar magnetic susceptibility χm as a function of the temperature in the temperature range 4–300 K is shown in Figure 3a. When the sample is cooled χ_m gradually increases and reaches a sharp maximum near 12 K after which it rapidly decreases. The value of $\chi_m T$ at room temperature is 9.9 $cm^3 mol^{-1}$ K, which is slightly higher than that calculated for two noninteracting manganese(II) ions (8.76 $cm^3 mol^{-1}$ K). The product $\chi_m T$ continuously increases from room temperature to 22 K and then decreases down to 4 K (see Fig. 3b). This behavior is characteristic of dominant ferromagnetic interactions in the high-temperature range, followed by antiferromagnetic interactions at lower temperatures. The maximum observed is indicative of the existence of two-dimensional antiferromagnetic ordering at temperatures lower than 20 K.

The presence of bridging bpym and EO azido ligands in **1** allows the existence of antiferromagnetic and ferromagnetic interactions through the bpym and EO azido bridges, respectively. This can be explained by the results obtained from other compounds with these kinds of bridges. Thus, the Mn-bpym-Mn fragment is similar to that in the dinuclear compound **2**,[14] which reveals antiferromagnetic interactions with a J value of -1.1 cm^{-1}. On the other hand, ferromagnetic coupling has been observed in the dinuclear compound $[Mn(terpy)(N_3)_2]\cdot H_2O$[13] (terpy = 2,2′-6′,2″-terpyridine) and in the 1D compound $[Mn(bpy)(N_3)_2]$[2] (bpy = 2,2′-bipyridine), which both have EO azido bridges ($J = 1.5$ and 2.5 cm^{-1}, respectively). These data strongly suggest the existence of alternating ferromagnetic and antiferromagnetic interactions in **1**, which to our knowledge, is the first example of a 2D sheetlike molecular compound in which the magnetic interactions alternate in sign. Since no theoretical studies have been carried out on this sort of magnetic behavior in which the magnetic interactions alternate in sign, a detailed analysis of the behavior of **1** is not possible. Two simple models have been employed to evaluate the magnitude of the exchange couplings; however, one should be mindful of their limitations. The first model was based on a Heisenberg type chain in which interchain interactions (J') were treated with

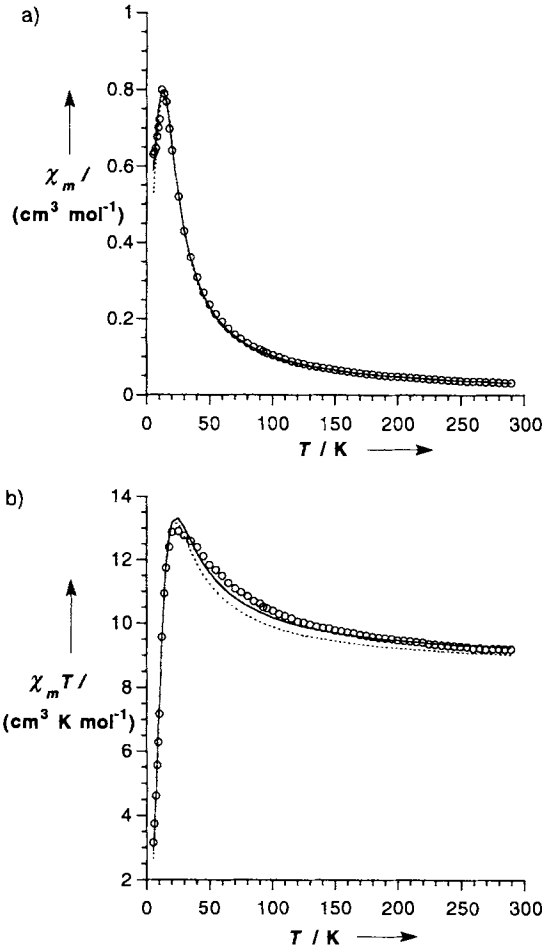

Fig. 3. Temperature dependence of the molar susceptibility χ_m (a), and of the product $\chi_m T$ (b) of **1**. o: experimental values; —: fit for interacting Heisenberg type chain model; - - -: fit for ferromagnetically coupled antiferromagnetic dimer model.

the molecular field approximation.[17] In the second model, antiferromagnetic dimers ferromagnetically coupled to each other were considered.[18] The results for these theoretical models are shown in Figure 3. The best fit for both χ_m and $\chi_m T$ with the first model leads to the parameters $J = -1.06$ cm^{-1} and $zJ' = 1.99$ cm^{-1} and with the second model to $J = -1.18$ cm^{-1} and $zJ' = 1.53$ cm^{-1}. On the basis of these models, and taking their limitations into consideration, the ferromagnetic interactions are predominant in the compound **1** and the magnitude of the exchange parameters obtained are in good agreement with those observed in the literature for both types of bridging.[13, 14]

The connection of 1D compounds through bis(chelating) ligands such as 2,2′-bipyrimidine has been shown to be a good strategy for obtaining 2D systems. The resulting compound **1** shows a honeycomb-like layer structure, which is formed by Mn_6 hexagons and is rather unusual. The bridging ligands between Mn^{II} ions are capable of mediating antiferromagnetic (bpym) and ferromagnetic (EO azide) exchange interactions. This has led to a 2D sheetlike structure with magnetic interactions that alternate in sign. As far as we are aware, this kind of alternating system is unique.

Experimental Procedure

Compound **1** was synthesized by slow addition of bpym (0.158 g, 1 mmol) in methanol (15 mL) to a solution prepared by mixing $Mn(NO_3)_2\cdot 4H_2O$ (0.251 g, 1 mmol) and NaN_3 (0.130 g, 2 mmol) in water/methanol (20 mL). The reaction mixture was stirred continuously at 45 °C. Orange-yellow long prismatic crystals

were obtained from the resulting solution after it had been left to stand at room temperature for two weeks. Elemental analysis: Calc. (found): Mn 25.2 (25.4), N 51.4 (51.3), C 22.0 (22.1), H 1.4 (1.4)%.

[15] X-ray structure analysis: Enraf-Nonius CAD-4 diffractometer. Unit cell parameters were determined from automatic centering of 25 reflections ($12 < 2\theta < 30°$) and refined by least-squares method. Intensities were collected with graphite monochromatized $Mo_{K\alpha}$ (0.71069 Å) radiation using the ω scan technique. Lorentz polarization and extinction corrections were made. The structure was solved by direct methods and successive Fourier difference syntheses, using the SHELXL-93 computing program. $C_8H_6N_{16}Mn_2$ ($M = 436$), monoclinic system, space group $P2_1/a$, $a = 6.229(1)$, $b = 15.104(1)$, $c = 8.923(1)$ Å, $\beta = 95.72(2)°$, $V = 835.3(2)$Å^3, $Z = 4$, $\rho_{calcd} = 1.734\ g\,cm^{-3}$, $\mu = 15.4\ cm^{-1}$, $F(000) = 432$. The refinements by full matrix least-squares gave final $R1(F_o) = 0.028$, $wR2(F_o^2) = 0.1356$ and $S = 0.78$ [16] from 2432 reflections with intensity $I \geq 2\sigma(I)$ for 137 variables. All non-hydrogen atoms were refined anisotropically. The extreme nitrogen atom (N8) of one of the azido bridges is disordered. A strong pseudo-C symmetry is observed in the compound. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-81. Chemoenzymatic Synthesis of Sialyl Lewis^x Glycopeptides**

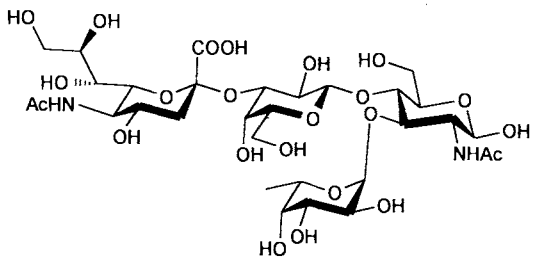
Gabi Baisch and Reinhold Öhrlein*

Invasive leukocytes play a decisive role in acute and chronic inflammation.[1] They reach the site of inflammation through a multistep process initiated by "leukocyte rolling".[2, 3] This "rolling" is caused by the interaction of carbohydrate ligands on the surface of leukocytes and receptors, the E- and P-selectins, which are found on the surface of activated endothelial cells.[4] A disruption of this early interaction is considered to be a promising therapeutic approach.[5] The tetrasaccharide sialyl Lewis^x (SLe^x) and various derivatives have been identified as ligands for selectins.[6] Because monovalent SLe^x shows only



siaα(2-3)galβ(1-4)(fucα(1-3))glcNAc = SLe^x

relatively weak binding to E-selectin ($IC_{50} = 0.75$ mM),[7] it is assumed that the E-selectin–SLe^x interaction is enhanced in vivo through "clustering" (multivalency) by either E-selectin or SLe^x[8] or both. In some early investigations up to 18 preassembled SLe^x moieties were attached with a spacer to bovine serum albumin in order to evaluate this hypothesis.[9] The positive results of assays obtained with these artificial glycoproteins stimulated the search for methods to synthesize well-defined oligovalent SLe^x conjugates. Thus three chemically synthesized SLe^x moieties were linked to nitromethane tricarbonic acids[10] and to cyclopeptide templates.[11] More rigid, divalent SLe^x conjugates were obtained chemoenzymatically with trisaccharide templates.[12]

Up to now there have been no systematic studies concerning the number of SLe^x units necessary and their three-dimensional arrangements. The following strategy for the synthesis of oligovalent SLe^x conjugates enables rapid screening of these parameters. We selected oligopeptide chains as the framework on which to attach the carbohydrate moieties. A proper choice of the monomeric building blocks renders the backbone more rigid or more flexible, thus markedly influencing the presentation of the SLe^x moieties. Additionally, the peptide linker can be optimized by the well-established peptide chemistry.[13, 14]

Complex glycopeptide clusters containing natural hexoses are most efficiently prepared by enzyme-mediated synthesis. With the help of glycosyl transferases, glycosylations can be performed with predictable, excellent stereo- and regioselectivity,[15] thereby circumventing the highly demanding chemical synthesis of the SLe^x tetrasaccharide.[16] The inefficient and cumbersome protecting group manipulations inevitable in the

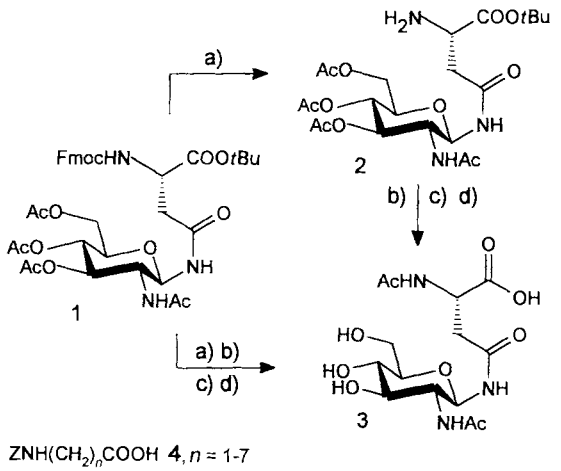
[**] The authors thank Dr. A. Katopodis and Dr. M. Streiff for the biotechnological preparation of α(2-3)sialyl transferase and fucosyl transferase VI.

chemical glycopeptide synthesis are avoided.[17] The enzymes function in aqueous buffer systems without poisonous metal salt promotors.

The scope of the enzymatic methodology is presently limited by the availability of transferases[18] and the necessary activated donor sugars. These have to be synthesized,[19] although they are commercially available on a small scale. Alternatively some donor sugars may be produced in situ.[20]

Our synthesis started with the *N*-acetyl glucosamine building blocks **2** and **3** (Scheme 1). Deprotection of the amino group of the glycoside **1**[21] with morpholine[22] provided the amine **2**, which was subsequently N-acetylated, treated with trifluoroacetic acid to remove the *tert*-butyl ester, and finally deacetylated to yield the building block **3**.

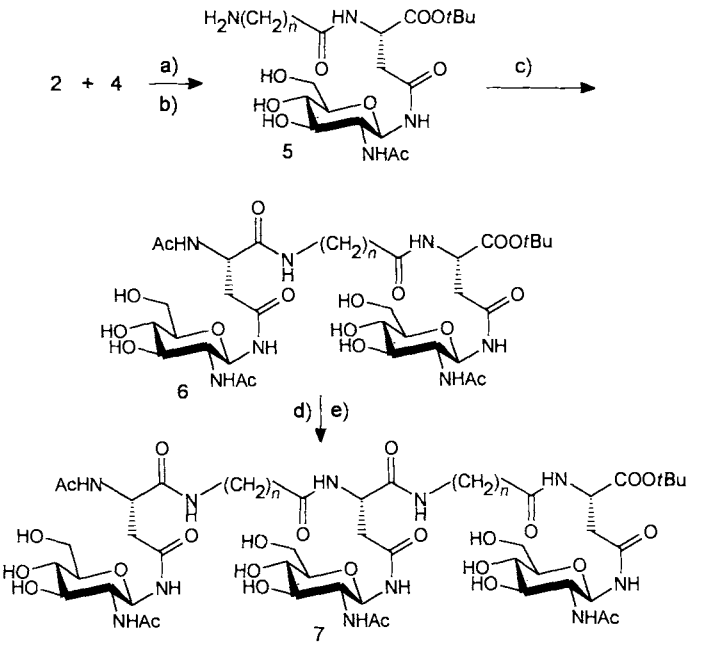


Scheme 1. a) Morpholine, 77%; b) CH_2Cl_2, Ac_2O, py, 96%; c) CF_3COOH, 94%; d) MeOH, MeONa, 76%; Fmoc = 9-fluorenylmethyloxycarbonyl, Z = benzyloxycarbonyl.

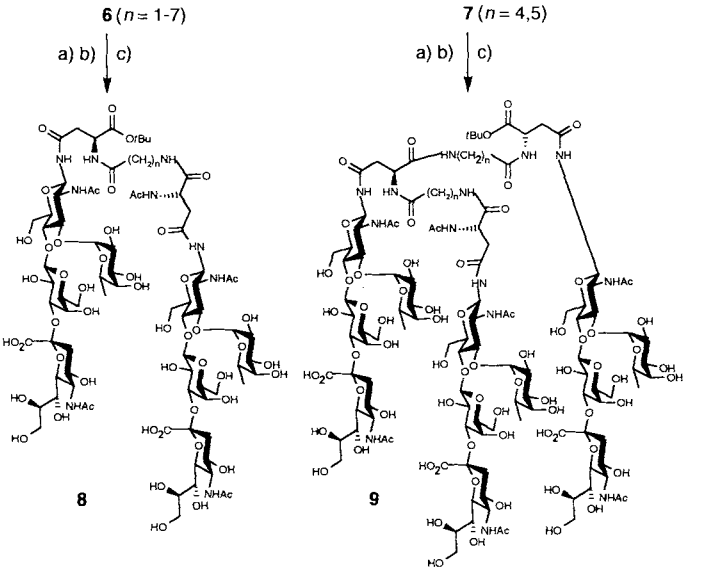
Amino acids **4** of various lengths—flexible spacers—were synthesized according to the Schotten–Baumann procedure from the corresponding free amino acids and benzyloxycarbonyl chloride in quantitative yields.[13] The building blocks **2** and **4** were linked in the presence EDCI[23] and subsequently deacetylated and hydrogenated (Scheme 2). The resulting compounds **5** were connected with building block **3**. DCC/HOBt or BBC proved to be reliable condensing reagents in this case.[24] The trimeric structures **7**[25] were finally reached after deblocking of **6** and subsequent condensation of the resulting acid with **5**. The versatility of this strategy can be exploited through repetition of steps (d) and (e) of Scheme 2 to generate defined "tetravalent" compounds and structures of even higher "valency".

Compounds **6** and **7** were treated with uridine 5′-diphosphogalactose (UDP-gal)[26] and commercially available galactosyl transferase (EC 2.4.1.22)[27] in a sodium cacodylate buffer (pH 7.5) in the presence of calf intestine alkaline phosphatase (CIAP, EC 3.1.3.1) (Scheme 3).[28] The latter enzyme destroys the inhibiting uridine 5′-diphosphate,[29] which is concomittantly formed as a by-product. The completion of the enzymatic reaction can be checked by thin-layer chromatography or preferably by MALDI-TOF (matrix-assisted laser desorption ionization time-of-flight) mass spectrometry of a small sample of the incubation mixture (see Fig. 1).

The galactosylated intermediates were filtered through Sephadex (G-25 superfine (Pharmacia)) and characterized by ^1H and ^{13}C NMR spectroscopy. Subsequently sialic acid was introduced by incubation with cytidine 5′-monophospho-sialic acid (CMP-sia)[30] and α(2-3)sialyl transferase (EC 2.4.99.6)[31] at



Scheme 2. a) THF, EDCI, 62–94%; b) 1% NaOMe in methanol then MeOH, H_2/Pd/C, 93–97%; c) DMF, **3** + DCC/HOBt or **3** + BBC, (56% (n = 1), 47% (2), 54% (3), 80% (4), 67% (5), 84% (6), 97% (7)); d) valid for n = 4–7: CF_3COOH, 0 °C, (43% (n = 4), 82% (5), 53% (6), 55% (7)); e) DMF, **5** + DCC/HOBt or **5** + BBC, 43–53%; EDCI = 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide hydrochloride, DCC = dicyclohexylcarbodiimide, HOBt = hydroxybenzotriazole, BBC = benzotriazolyloxybis(pyrrolidino)carbonium hexafluorophosphate.



Scheme 3. a) 2.2 and 3.3 equiv UDP-gal, gal-t for **8** (75%, 85%, 92%, 70%, 81%, 96%, 64%) and **9**, respectively (88%, 75%); b) 2.2 and 3.3 equiv CMP-sia, α(2-3)sia-t for **8** (73%, 97%, 73%, 99%, 64%, 77%, 77%) and **9**, respectively (85%, 99%); c) 2.2 and 3.3 equiv. GDP-fuc,fuc-t VI for **8** (99%, 85%, 95%, 77%, 73%, 74%, 67%) and **9**, respectively (68%, 67%).

pH 6.5 in the presence CIAP.[29] Filtration of the reaction mixture through Sephadex provided the sialylated saccharides, which were characterized by ^1H NMR spectroscopy and MALDI-TOF mass spectometry. Finally fucose was introduced with guanosine 5′-diphospho-fucose (GDP-fuc)[32] as the fucose donor and fucosyl transferase VI[33] in a cacodylate buffer at pH 6.5, again in the presence of CIAP. Thus the desired compounds **8** and **9** could be obtained in 6–20 mg amounts, which was sufficient for the ensuing biological assays.[34]

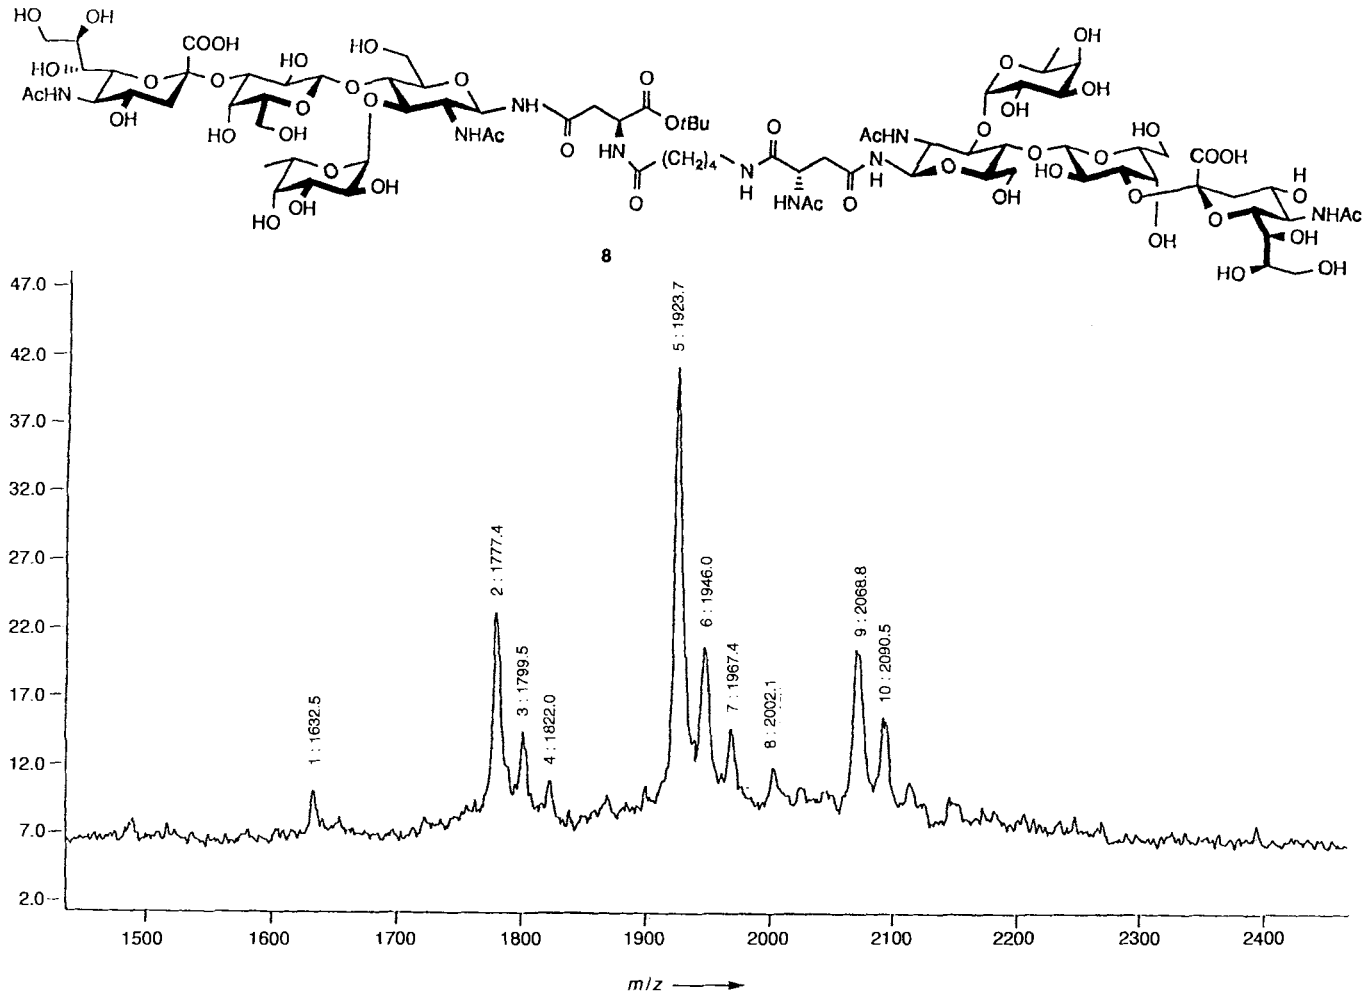


Fig. 1. MALDI-TOF mass spectrum of the reaction mixture from the fucosylation of **6** ($n = 4$); matrix: 0.1 M 2,4,6-trihydroxyacetophenone in ethanol.

All IC_{50} values have been normalized to one SLe^x unit. Although the divalent compounds **8** show varying binding affinities, their overall affinity to E-selectin is not significantly enhanced over that of the monovalent SLe^x, which was attached β-glycosidically to the aglycon (N-acetylated, O-*tert*-butyl protected aspartic acid). In contrast, the affinity of the trimeric compound **9** ($n = 4$) to E-selectin is four times higher than that of the monomer and almost nine times higher than that of the corresponding dimer **8** (Table 1).

For monitoring the progress of the formation of these complex glycopeptides MALDI-TOF mass spectrometry proved to be an indispensable analytical tool.[35] Figure 1 shows a spectrum of a small sample drawn from the incubation mixture from the fucosylation of compound **6** ($n = 4$). All final compounds were additionally characterized by ^1H NMR spectroscopy.[36] In Figure 1 peaks 2–4 arise from nonfucosylated starting material ($M = 1756.7$) with Na^+, $2\,Na^+$, and $3\,Na^+$ ions. Peaks 5–7 correspond to monofucosylated intermediates ($M = 1902.8$) associated similarly with Na^+ ions. Peaks 9–10 arise from the desired difucosylated final compound ($M = 2047.0$), again associated with Na^+ and $2\,Na^+$ ions. The incubation was terminated when no peaks corresponding to either the starting material or intermediates were detected. The final fucosylated glycopeptides were purified by filtration through Sephadex. MALDI-TOF mass spectrometry can also be used to check the purity of the end products.

Table 1. IC_{50} values of the octa- (**8**) and dodecasaccharides (**9**) [34].

Compound	IC_{50} [mM]
SLe^x aglycon	0.60
8 ($n = 1$)	0.46
8 ($n = 2$)	–
8 ($n = 3$)	0.64
8 ($n = 4$)	1.20
8 ($n = 5$)	0.47
8 ($n = 6$)	0.80
8 ($n = 7$)	0.48
9 ($n = 4$)	0.14
9 ($n = 5$)	0.39

Our method, which relies on a set of accessible transferases and activated donor sugars, allows the rapid assembly of oligovalent SLe^x conjugates. The rigidity of the peptide backbone (→ presentation of the SLe^x moieties) and the individual distances of the SLe^x moieties are controlled by the proper choice of amino acid monomers. SLe^x analogues of higher "valency" can be formed sequentially by known peptide chemistry.

The enzymatic methodology is not limited to the formation of the natural SLe^x structure.[37] It has been shown recently that nonnatural substrates (donors and acceptors) are recognized by glycosyl transferases, and glycosides are produced with high regio- and stereoselectivity.[38] The breadth of substrates amenable to glycosyl transferase catalysis is not yet fully investigated. Even pseudo-sugars can be synthesized efficiently with

the help of glycosyl transferases in a stereospecific manner without protecting group manipulations.[38, 39] Thus SLe^x mimetics,[37] some of them showing surprisingly high affinities to E-selectin,[40] may be accessible easily.

Molecular Recognition Analyzed by EPR, ENDOR, and NMR Spectroscopy**

Martin Jäger and Hartmut B. Stegmann*

The formation of complexes between model receptors and substrates is known as molecular recognition.[1] Since natural phenomena like transport, catalysis, and regulation are based on it, extraordinary interest in intermolecular interactions has been aroused. The formation equilibrium and the conformation of all the components of these lock-and-key interdependencies are dynamic systems.

We therefore decided to study these kinds of systems with nuclear magnetic resonance spectroscopy (^{1}H NMR; 250 MHz) in parallel with electron paramagnetic (EPR; 10 GHz) and electron nuclear double resonance (ENDOR) spectroscopy. The difference in time resolution of the methods provides complementary information. The receptor **A** (Scheme 1) proved to be suitable for this investigation because of its converging functional groups, providing a cylinder-lock-like cavity with specific affinity to purine and benzimidazole moieties.[2] To introduce a part of the molecule that can be converted into a paramagnetic state, we modified these heterocycles with suitable phenol-type substituents in sites where they do not hinder the intermolecular interactions. Hence the resulting compounds **1**, **2**, **3** could still be recognized as substrates. One-electron oxidation of the phenols **1**–**3** leads to the paramagnetic complexes **A1***–**A3***.

The spectra of both the diamagnetic and paramagnetic associates depend on concentration and temperature. Since the number of NMR signals remains constant, the chemical shifts repre-

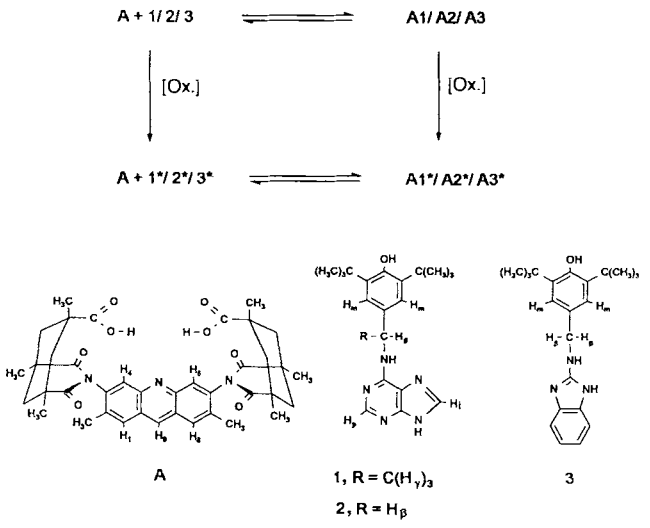

Scheme 1. Interdependence between receptor (**A**) and substrate (**1/1***, **2/2***, **3/3***) and pathways of oxidative radical generation. The nomenclature of the probes is given under the structural formulas.

sent averaged values. On the other hand, characteristic[3, 4] shifts of the signals are observed, which are most distinct for the aromatic protons. Examples of this behavior are demonstrated by the temperature-dependence of the $\Delta\delta$ values in Figures 1 and 2. The difference in the chemical shifts of complexed and free species, $\Delta\delta = \delta_{compl} - \delta_{free}$, eliminates the temperature dependence of the free species, thus takes into account only properties arising from complexation, and therefore indicates the existence of intermolecular interactions. In detail, these shift differences are influenced by association–dissociation equilibria, the complex conformation, and an additional protonation equilibrium, as will be discussed subsequently.

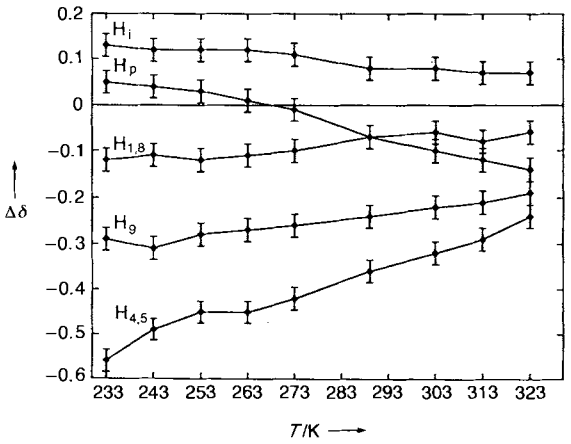

Fig. 1. Chemical shift difference $\Delta\delta$ of H_9, $H_{1,8}$ $H_{4,5}$, H_p, and H_i as a function of the temperature for the equilibrium **A** + **1** ⇌ **A1** in $CDCl_3$.

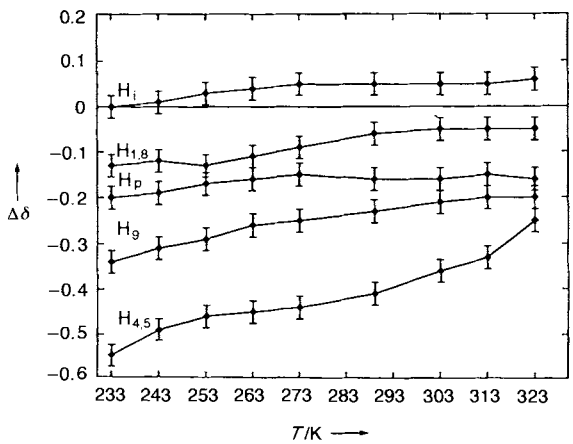

Fig. 2. Chemical shift difference $\Delta\delta$ of H_9, $H_{1,8}$ $H_{4,5}$, H_p, H_i as a function of the temperature for the equilibrium **A** + **2** ⇌ **A2** in $CDCl_3$.

Essentially, the temperature-dependent $|\Delta\delta|$ values converge to zero as shown in Figures 1 and 2. In the same way, if the concentration ratio of the components is systematically varied at constant temperature, the measured chemical shifts approach those of the free species ($lim_{c(comp)\to 0}\Delta\delta_{free} = 0$, $lim_{c(free)\to 0}\Delta\delta_{comp} = 0$) is observed. These results confirm the existence of an equilibrium that is rapid on the NMR time frame.

When complexed, the protons H_9, $H_{4,5}$, and $H_{1,8}$ of the acridine base of **A** are shielded by the purine and benzimidazole moieties and therefore resonate at higher field. In addition, the intramolecular proton transfer equilibrium[5] must be taken into account, as explained below. In the case of the purine derivatives **1** and **2**, the electron density in the imidazole ring is diminished by the "grasp of the carboxyl pincers", causing a downfield shift of the H_i signals. The quantitative investigation of the substrate's concentration dependence (NMR titration) allows an estimation of the association constants. For this purpose, we took the chemical shifts obtained at the experimentally highest receptor–substrate ratio as the chemically induced shifts (CIS)[6] for completely bound substrate at room temperature, because a numerical approximation (curve fitting by means of the nonlinear, least-squares method with a Marquardt algorithm) indicates that they are limiting values. An analysis of the measured data by a Hill plot[7, 8] not only yielded a Hill coefficient of $n_H = 1$ and confirmed the anticipated receptor–substrate complex formation ratio of 1:1, but also enabled the determination of the following association constants: $K_A = 1 \times 10^3\,M^{-1}$ for **A1** and $K_A = 3 \times 10^3\,M^{-1}$ for **A2**. A comparison of these data with those of the unsubstituted heterocyclic bases[3] indicates that the benzyl substituent hardly influences the molecular recognition.

UV, VIS, and fluorescence measurements verify the existence of the equilibrium between the protonated and deprotonated acridine moiety. The fluorescence excitation spectrum of the protonated form of **A** presents a clear bathochromic shift of the transition $S_0 \to S_1$ (band at 410–430 nm) relative to that of the deprotonated form (band maximum at 390 nm). The emission spectrum (excitation at 360 nm) is a composite spectrum superimposing both forms; a series of concentration measurements that determine the proportions of the two forms show that the autoprotolysis of the receptor is suppressed by addition of **1**, **2**, or **3**.

In contrast to the ^1H NMR spectra, EPR and ENDOR spectra are to be interpreted in terms of superposition signals from separate "key" compounds and lock-and-key complex because of the faster time scale of the latter methods. For example, Figure 3 illustrates that in the ENDOR spectra of **1*** new lines appear after addition of **A**, but the number is again reduced to the original seven absorptions with further increase of the receptor concentration, though their frequencies are different.

We attribute the spectrum in Figure 3c to the complex **A1***. Consequently, Figure 3b has to be a superposition of **1*** and **A1***. At $T = 243$ K, the phenoxyl radical **1*** is characterized by the parameters given in Table 1. The addition of the receptor **A** results in a decrease of the β-proton coupling and an increase of a_{H_γ}. The assignment of the coupling constants could be additionally verified by general triple experiments. At $T = 203$ K, new signals are observed in the frequency area of the β-proton

coupling of the complex **A1***. We therefore trace them back to different conformations of the key in the lock according to refs. [3, 4].

Similarly, Figure 4b can be explained as a superimposed spectrum of free and complexed **3***. The signal of the phenoxyl radical **3*** is interpreted with the data in Table 1. The hyperfine structure (hfs) changes on addition of **A** (Fig. 4b). Obviously, a

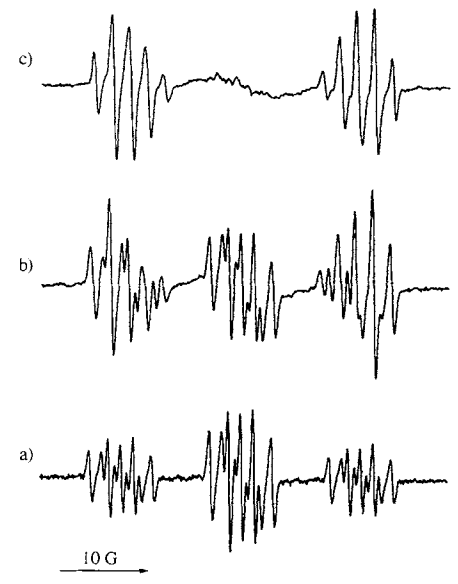

Fig. 4. EPR spectra in CH_2Cl_2 at $T = 293$ K: (a) **3***, (b) **3*** + **A**, (c) difference spectrum b − a.

superposition of the signals of at least two species takes place. In fact, the subtraction of the spectrum of free **3*** leads to the hyperfine structure shown in Figure 4c.

The spectrum can only be understood if complexation influences the intramolecular flexibility of **3***. While in the case of uncomplexed **3*** those processes causing the two β-protons to be equivalent are fast enough to generate a triplet structure, the signals coalesce at the same temperature on interaction with the receptor **A**. The influence of the temperature variation on the molecular dynamics of the substrate at a constant concentration ratio is illustrated for system **A2*** in Figure 5. Whereas the sig-

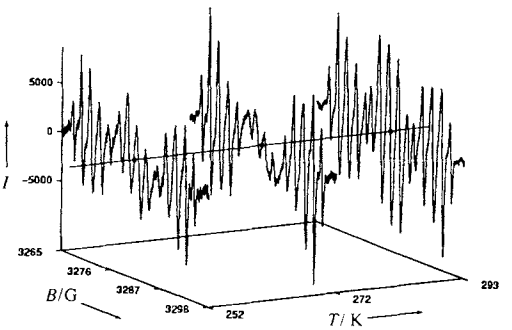

Fig. 5. EPR spectra of **2*** + **A** at different temperatures. I = intensity (arbitrary units).

nal of free **2*** is characterized by a triplet structure with an intensity ratio of 1:2:1 ($a_{H\beta}^{(2)} = 9.18$ G; other hf parameters are shown in Table 1) resulting from an equivalence of the β-protons at $T = 293$ K, the addition of the receptor hinders the flexibility of **2*** even at room temperature; consequently, the three signal groups due to the β-proton coupling have nearly equal intensity. With decreasing temperature, the central hfs components become broader in order to regain intensity after coalescence. The hyperfine coupling constants $a_{H\beta} = 10.90$ G and $a_{H\beta'} = 8.32$ G (all other data given in Table 1) can be deduced from Figure 5 as characteristic for the complex **A2***. Thus, this hfs now provides a quartet pattern. The β-proton coupling ($a_{H\beta}^{(2)} = 9.18$ G) observed for free **2*** is not yet the average of both β-couplings of **A2***. In the absence of **A**, no comparable temperature dependence for **2*** can be found. Thus, the magnetic inequivalence of the β-protons of **2*** at $T < 272$ K is a consequence of the lock-and-key interaction.

The quantitative evaluation of the molecular dynamics of **A2*** according to Arrhenius for a two-jump model yields an activation energy of 8.2 kcal mol^{-1} and $k_{293} = 47$ MHz for the experimentally accessible temperature range between 252 and 333 K.

A two-jump mechanism as interpretation of such a temperature dependence for analogous systems with a tertiary nitrogen atom (Fig. 6) is attributed to hindrance of rotation around the C–C_{aroxyl} bond or to inversion of the nitrogen atom,[9, 10] whereas in this case the magnitude of the activation energy found favors the inhibition of rotation as an explanation. Aroxyls

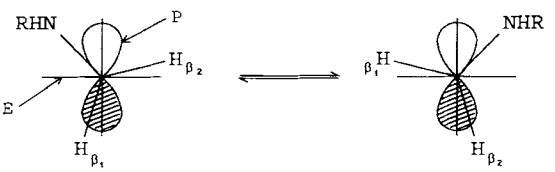

Fig. 6. Illustration of the two-jump mechanism. R = purinyl, E = plane of the arene ring of the phenoxyl radical, P = p orbital perpendicular to E.

substituted with a secondary amino group at the methylene carbon do not show any inequivalence of the β-protons over the whole temperature range. Thus, only the key-in-the-lock possesses the sufficiently large activation energy necessary for the observation of coalescence under the existing conditions.

Experimental Procedure

The receptor **A** is well known [5]. Phenol **1** was synthesized by addition of adenine to 3,5-di-*tert*-butylquinonemethide [11]. Phenols **2** and **3** were obtained by condensation of 4-bromomethyl-2,6-di-*tert*-butylphenol with adenine and with 2-aminobenzimidazole [10], respectively. All compounds were characterized by current methods. The ^{1}H NMR spectra were obtained on a Bruker AC 250 (250 MHz) spectrometer in CDCl3.

The radicals **1***, **2***, and **3*** were generated in CH_2Cl_2 by oxidation of the corresponding phenols with PbO_2; **A** can be added before or after radical generation. Deoxygenation was done by bubbling argon through the samples. The spectra were recorded with a Bruker ESP 300E spectrometer equipped with an ENDOR unit (Bruker ER 810). Typical instrumental parameters for ENDOR investigations: MW power 30 mW; RF power 7 dB, 500 W; modulation 70 kHz.

Bis(bipyridine) Ligands in Manganese Carboxylate Cluster Chemistry: Self-Assembly of a Cluster Complex with Two Butterfly-Like $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ Cores**

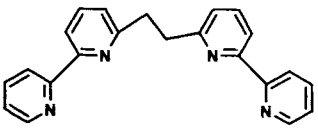
Vincent A. Grillo, Michael J. Knapp, John C. Bollinger, David N. Hendrickson,* and George Christou*

Polypyridyl, oligo-2,2′-bipyridine, and related ligands L have received considerable attention over the last several years.[1–11] The use of such ligands as "programmed" components in self-assembly reactions with metal ions has been a central theme in supramolecular chemistry, and has led to the formation of a variety of metal/ligand supramolecular ensembles. The latter have fascinating structures such as double or triple helices, and "capped", "cylindrical" and "circular" architectures. The resulting redox and photophysical properties have also been of interest. In all the work to date the ligands L have been bound to mononuclear centers and they have also been the only (or in some cases, the majority) ligands to the metals.

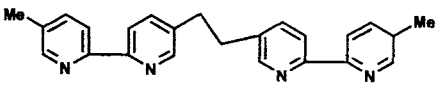
Metal cluster chemistry is another area in which self-assembly of multiple components occurs to produce a "supermolecular" product. We have been interested in carboxylatomanganese clusters for a number of reasons, including the fact that they exhibit highly unusual magnetic properties and, in some cases, are single-molecule magnets.[12, 13]

We report herein the amalgamation of the above two areas, namely the use of bis-2,2′-bipyridine ligands L in carboxylatomanganese cluster formation, in order to explore the influence of the ligand "programming" on both the cluster formed and the nature of the multicomponent assembly; the overall objective is the development of supramolecular chemistry involving metal clusters as components of the supramolecular ensemble.

The two ligands employed were L1[14] and L2.[15] Treatment of $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$[16] (py = pyridine) with L1 in a 1:1.5 molar ratio in MeCN led to a dark brown solution and subsequent isolation of the tetranuclear complex **1** as a perchlorate salt. Similarly, treatment of $[Mn_3O(O_2CEt)_6(py)_3](ClO_4)$[17] with L2 in a 1:1.5 molar ratio in CH_2Cl_2 led to subsequent isolation of the octanuclear complex **2** as a perchlo-



L1



L2

$[Mn_4O_2(O_2CMe)_4(L1)_2](ClO_4)_2$ **1**-$(ClO_4)_2$

$[Mn_8O_4(O_2CEt)_{14}(L2)_2](ClO_4)_2$ **2**-$(ClO_4)_2$

rate salt. The structure of the cation **1** (Fig. 1)[18] consists of two $[Mn_2O(O_2CMe)_2(L1)]^+$ fragments held together by interfragment linkages Mn1–O3′ and Mn1′–O3. The cation is centrosymmetric and mixed-valent (two Mn^{II}, two Mn^{III}) and, on the basis of the structural parameters, the Mn^{II} and Mn^{III} centers are five-coordinate (Mn2) and six-coordinate (Mn1), respectively. Each resulting $Mn^{II}Mn^{III}$ pair is quadruply bridged by O3, two *syn,syn*-$MeCO_2^-$ groups, and the L1 ligand, which is attached to both metals. There are three types of Mn···Mn distances, $Mn^{III}\cdots Mn^{III}$ (2.784(4) Å), intrafragment $Mn^{II}\cdots Mn^{III}$ (3.208(4) Å), and interfragment $Mn^{II}\cdots Mn^{III}$ (3.632(4) Å). The central $[Mn_2O_2]$ unit is asymmetrical; the interfragment Mn^{III}–O bonds (1.8787(6) Å) are noticeably longer than the intrafragment Mn^{III}–O bonds (1.8391(6) Å). Interestingly, all bipyridine (bpy) rings are essentially parallel, providing additional interfragment interactions by π stacking. Complex **1** is a new addition to the family of Mn_4 clusters with a "dimer-of-dimers" structure.[19]

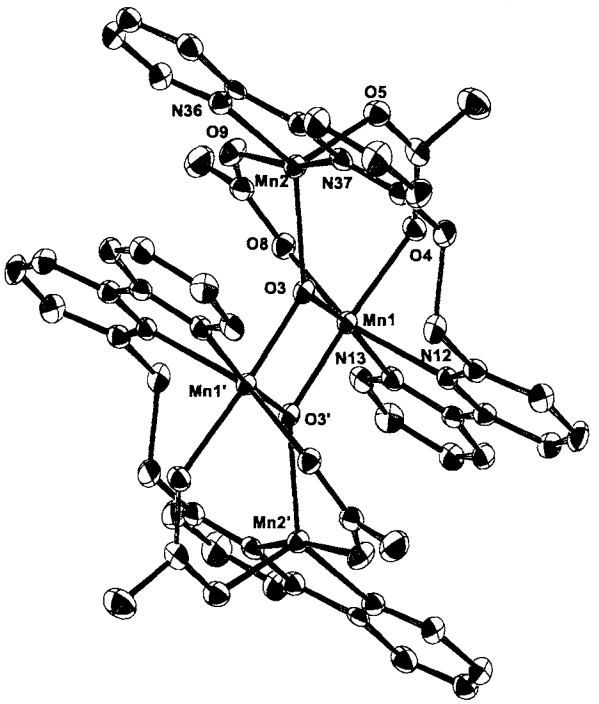

Fig. 1. ORTEP representation of the cation **1**. Selected distances [Å] and angles [°]: Mn1···Mn1' 2.784(4), Mn1···Mn2 3.208(4), Mn1···Mn2' 3.632(4), Mn1–O3 1.839(1), Mn1–O3' 1.879(1), Mn2–O3 2.030(1), O3-Mn1-O3' 83.01(3), Mn1-O3-Mn1' 96.99(3), Mn1-O3'-Mn2' 136.60(3), Mn1-O3-Mn2 111.93(3).

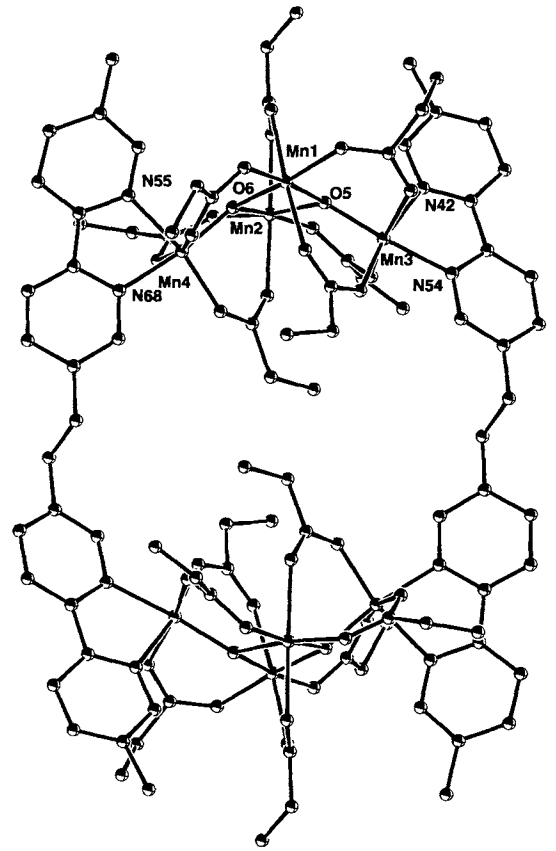

Fig. 2. ORTEP representation of the cation **2**. Selected distances [Å] and angles [°]: Mn1···Mn2 2.843(4), Mn1–O5 1.889(13), Mn1–O6 1.890(12), Mn2–O6 1.893(13), Mn2–O5 1.899(13), Mn3–O5 1.831(13), Mn4–O6 1.845(13), O5-Mn1-O6 81.6(6), O5-Mn2-O6 81.2(6).

The structure of the centrosymmetric cation **2** (Fig. 2)[18] likewise consists of two fragments, but interfragment linkages are now provided by the two L2 ligands. The fragments have $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ (i.e. four Mn^{III}) butterfly-like cores, arranged face-to-face. If the $\text{-}CH_2\text{-}CH_2\text{-}$ linker groups of the L2 ligands were removed, two previously reported $[Mn_4O_2(O_2CEt)_7(bpy)_2]^+$ units result; this shows that **2** can be viewed as a dimer of clusters with butterfly-like cores in which the fragments are only slightly distorted compared with discrete $[Mn_4O_2(O_2CR)_7(bpy)_2]^+$ species.[17] Inspection of a space-filling model shows no cavity in the center of the cluster.

Variable-temperature magnetic susceptibility data were collected on complexes **1** and **2** (SQUID magnetometer, 10.0 kG field) to investigate the degree of interfragment interaction. Complex **1** exhibits an effective magnetic moment (μ_{eff}) per molecule that smoothly decreases from 8.05 μ_B at 320 K to 1.05 μ_B at 2.0 K (Fig. 3). The data were fit to a model in which the exchange interaction between the interfragment $Mn^{II}\cdots Mn^{III}$ pairs was considered to be negligible because of the relatively long separation. The fit (Fig. 3) employed $-2J\hat{S}_i\cdot\hat{S}_j$ terms for exchange interactions and gives $J(Mn^{III}\cdots Mn^{III}) = -3.2\ cm^{-1}$, J(intrafragment $Mn^{II}\cdots Mn^{III}$) $= -2.3\ cm^{-1}$, $g = 1.86$ and a small contamination (4%) by paramagnetic Mn^{II} ions. The value of $J(Mn^{III}\cdots Mn^{III})$ shows that interfragment interactions exist in **1**. The variable-field and variable-temperature data indicate that **1** has an $S = 0$ ground state.

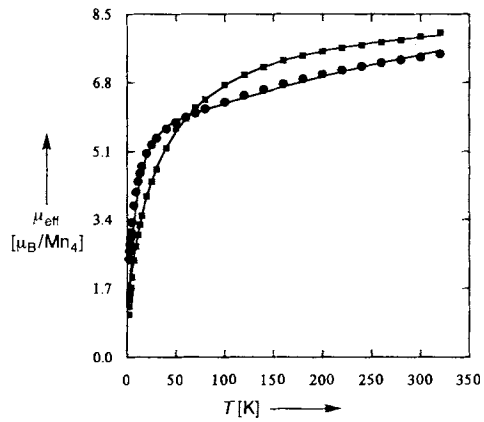

Fig. 3. Plot of the effective magnetic moment, μ_{eff}/Mn_4, vs. temperature for $[Mn_4O_2(OAc)_4(L1)_2](ClO_4)_2$ (**1**, ■) and $[Mn_8O_4(O_2CEt)_{14}(L2)_2](ClO_4)_2$ (**2**, ●) in an applied magnetic field of 10.00 kG. The solid line represents the best fit to the theoretical equation. See text for fitting parameters.

The data for **2** indicate there is negligible exchange interaction between the two butterfly-like $Mn^{III}_4O_2$ fragments. In Figure 3, μ_{eff} per butterfly unit is plotted as a function of temperature. The decrease from 7.51 μ_B (per Mn_4O_2 fragment) at 320 K to 5.82 μ_B at 50.0 K, followed by a rapid decrease to 2.42 μ_B at 2.0 K, parallels what has been seen[17, 20] for other butterfly-like $Mn^{III}_4O_2$ complexes. In fact, the data could be fit assuming the two butterfly-like fragments do not interact to give $J_{wb} = -10.5\ cm^{-1}$, $J_{bb} = -27.4\ cm^{-1}$, and $g = 2.00$, where J_{wb} characterizes the wing-tip-body $Mn^{III}\cdots Mn^{III}$ interaction and J_{bb} the body–body interaction. The rapid decrease in μ_{eff} at low temperatures was accommodated by assuming the $S = 3$ ground state in each butterfly-like core has an axial zero-field splitting with $|D| = 3.0\ cm^{-1}$.

L1 and L2 possess two important properties: 1) the 2,2′-bpy character of each half of the ligands and 2) their overall "linked-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1819 $ 15.00+.25/0

bpy" nature. Given that bpy itself will react with $[Mn_3O(O_2CR)_6(py)_3](ClO_4)$ to afford butterfly-like clusters of the type $[Mn_4O_2(O_2CR)_7(bpy)_2](ClO_4)$,[17] it can be seen that in L2 the 5,5″ linkage results in the above-mentioned properties being independent: property 1) triggers self-assembly of a butterfly-like $[Mn_4O_2]^{8+}$ cluster (as does free bpy), and property 2) yields a resulting "dimer-of-clusters" supramolecular assembly. In contrast, properties 1) and 2) are coupled (not independent) in L1, and the 6,6″ linkage therefore yields the new cluster type in complex **1**.

It is clear that there is great potential for suitably "programmed" polypyridyl and related ligands in this area of supramolecular chemistry involving metal clusters, complementing the current use of mononuclear metal centers. Such an approach might be one potential means of amalgamating, for example, the often unusual magnetic properties of metal clusters and the multidimensional controlled ordering of supramolecular chemistry.

Experimental Procedure

$[Mn_4O_2(O_2CMe)_4(L1)_2](ClO_4)_2$ (**1**). Solid L1 (0.30 g, 0.90 mmol) was added to a stirred red-brown solution of $[Mn_3O(O_2CMe)_6(py)_3](ClO_4)$ (0.52 g, 0.60 mmol) in MeCN (60 mL), which caused a rapid color change to dark red-brown. The solution was stirred for 12 h, filtered, and the filtrate layered with an equal volume of THF. After several days, dark red-brown block-shaped crystals of **1**·2THF had formed; this formulation was indicated crystallographically, but dried solid analyzed as **1**·THF·$2H_2O$. Yield 46%. Anal. calcd (found) for $C_{56}H_{60}N_8O_{21}Cl_2Mn_4$: C 45.70 (45.87), H 4.11 (3.96), N 7.61 (7.67), Mn 14.93 (14.99)%.

$[Mn_8O_4(O_2CEt)_{14}(L2)_2](ClO_4)_2$ (**2**). Solid L2 (0.10 g, 0.30 mmol) was added to a stirred red-brown solution of $[Mn_3O(O_2CEt)_6(py)_3](ClO_4)$ (0.19 g, 0.20 mmol) in CH_2Cl_2 (50 mL). The solution was stirred for 2 h, filtered, and the filtrate layered with an equal volume of hexanes. After several days, dark red crystals of $2\cdot4CH_2Cl_2\cdot xC_6H_{14}$ were collected; this formulation was indicated crystallographically, but dried solid analyzed as solvent free. Yield 65%. Anal. calcd (found) for $C_{90}H_{114}N_8O_{40}Cl_2Mn_8$: C 43.97 (44.04), H 4.67 (4.53), N 4.56 (4.66), Mn 17.88 (17.92)%.

Carbaporphyrins**

Kurt Berlin*

In recent years numerous structural variants of porphyrins have been synthesized[1, 2b] which are not only interesting as 18π arenes, but also because of their diverse applications in medicine,[2] and as catalysts and chromophores.[1, 2b] In most of these porphyrinoids, including porphyrin isomers,[3–5] porphyrin analogs, and expanded porphyrins,[1b, 2b, 4] either a pyrrole ring has been formally replaced by a unit containing a nitrogen or a different heteroatom, or the arrangement of pyrroles and CH groups has been changed. But few porphyrinoids with less than four heteroatoms in the inner cycle have been reported that can bridge the gap to the formally related C-annulenes, which are prepared by completely different synthetic strategies and display strongly contrasting spectroscopic and physical properties.[6]

Novel porphyrin isomers, in particular one with an inverted pyrrole ring and an inner CH unit,[5] were inspiration to proceed further and replace one pyrrole ring of porphine by a five-membered unsaturated all-carbon ring. In these compounds only one nitrogen atom of the porphyrin system is replaced by carbon; thus they are referred to as carbaporphyrins.

Since the replacement of one pyrrole ring of the porphyrin core by 6π arenes was successful,[7] the reaction of a tripyrrane like **2b** (see Scheme 1) with a cyclopentadiene-1,3-dialdehyde appeared to be promising. Unfortunately the latter compound is not known, and it would probably be unstable under the

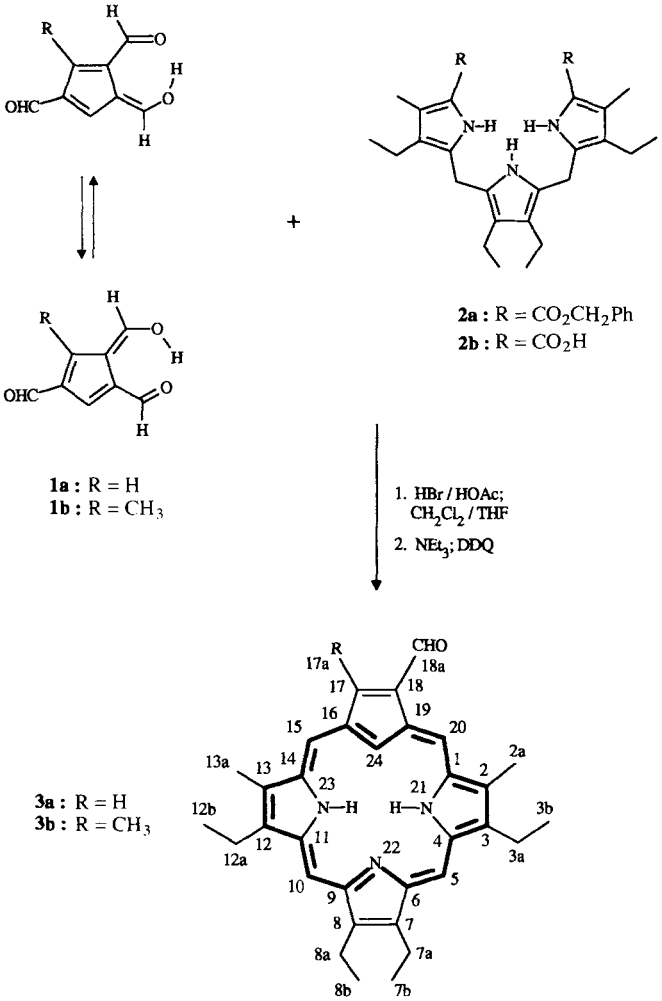
[**] I thank Prof. Dr. E. Breitmaier, Institut für Organische Chemie und Biochemie, Bonn, Germany, for suggesting and supporting this project.

acidic conditions required for cyclization. An alternative approach based on the condensation of 6-(2-pyrryl)fulvenes with dipyrrylmethanedialdehydes to yield carbaporphyrins[8] was thwarted by the instability of the fulvene starting material. An additional electron-withdrawing group attached to an unsaturated five-membered ring dialdehyde should increase the stability of the cyclopentadiene unit and provide a welcome function in the carbaporphyrins for further reactions.

As far back as 1963 Hafner et al. described Vilsmeier formylations of cyclopentadiene[9] that furnished mixtures of isomers in the form of immonium salts. These can be converted into aldehydes by basic hydrolysis. The hydroxyfulvenedialdehyde **1a**, which is stabilized by an intramolecular hydrogen bond,[10] was always isolated regardless of the original substitution pattern. This compound can also be regarded formally as the enol form of cyclopentadienetrialdehyde. The mesomeric stabilization of compounds **1a** and **1b** (Scheme 1) is probably responsible for their sufficient stability even under acidic reaction conditions.



Scheme 1.

The hydroxyfulvenedialdehyde **1a** and compound **1b**, which was prepared analogously from methylcyclopentadiene, reacted as expected with the in situ decarboxylated tripyrranedicarboxylic acid **2b**[11] in dichlormethane/THF with HBr/glacial acetic acid as the catalyst. Oxidation of the products with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) yielded the carbaporphyrins **3a** and **3b**, respectively (Scheme 1), which were obtained from yellow-brown fractions by column chromatography on silica gel. The products were identified unambiguously by two-dimensional NMR spectroscopy (HMQC, HMBC) and high-resolution mass spectrometry.[12]

Table 1. Selected physical and spectroscopic data of **1a**, **1b**, **3a**, and **3b**.

1a: ^{13}C NMR (100 MHz, acetone): δ = 127.8 (C-1/C-2), 138.3 (C-4), 142.3 (C-3/C-5), 182.5(C-2a/C-6), 186.9 (C-4a).

1b: M.p. 131–132 °C; ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.72 (s, 3H, 3a-H), 7.79 (s, 1H, 5-H), 8.77, 8.92 (2d, J = 8.7 Hz, 2H, 2a-H/6-H), 9.99 (s, 1H, 4a-H), 16.87 (t, J = 8.7 Hz, 1H, O-H); ^{13}C NMR (100 MHz, acetone): δ = 12.3 (C-3a), 125.9 (C-2), 127.1 (C-1), 135.8 (C-4), 141.8 (C-5), 144.7 (C-3), 179.6, 181.1 (C-2a/C-6), 187.4 (C-4a).

3a: M.p. > 250 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = −7.23 (s, 1H, 24-H), −4.21 (br. s, 2H, NH), 1.76 (4t, 12H, 3b/7b/8b/12b-H), 3.31 (s, 3H, 13a-H), 3.50 (s, 3H, 2a-H), 3.75 (2q, 4H, 7a/8a-H), 3.82 (q, 2H, 12a-H), 3.88 (q, 2H, 3a-H), 8.39 (s, 1H, 17-H), 9.11 (s, 1H, 15-H), 9.18, 9.26 (2s, 2H, 5-H/10-H), 10.43 (s, 1H, 20-H), 10.59 (s, 1H, 18a-H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 11.4 (C-13a), 11.7 (C-2a), 17.5, 17.6 (C-3b/C-12b), 18.7 (C-7b/C-8b), 19.6 (C-12a), 19.7 (C-3a), 20.1 (C-7a/C-8a), 94.1, 94.8 (C-5, C-10), 103.9 (C-24), 106.4 (C-15), 108.1 (C-20), 132.1 (C-16), 132.4 (C-19), 134.7, 134.8 (C-13/C-14), 135.3 (C-2), 135.6 (C-1), 136.4 (C-18), 137.4 (C-3/C-12), 138.1, 138.5 (C-4/C-11), 143.3 (C-17), 145.0, 145.3 (C-7/C-8), 155.0, 155.4 (C-6/C-9), 188.8 (C-18a); HRMS: m/z = 477.2777 (calcd 477.2780 for $C_{32}H_{35}N_3O$); UV/Vis (CH_2Cl_2): λ_{max} [nm] (lg ε) = 316 (4.12), 366 (4.36), 433 (4.59), 524 (3.77), 564 (3.81), 618 (3.23), 636 (3.25), 704 nm (3.15).

3b: M.p. > 250 °C; ^{1}H NMR (500 MHz, $CDCl_3$): δ = −6.82 (s, 1H, 24-H), −3.71 (br. s, 2H, NH), 1.80 (2t, 6H, 3b/12b-H), 1.83 (2t, 6H, 7b/8b-H), 3.47 (s, 3H, 13a-H), 3.50 (s, 3H, 17a-H), 3.57 (s, 3H, 2a-H), 3.87 (2q, 4H, 7a/8a-H), 3.94 (2q, 4H, 3a/12a-H), 9.50 (s, 1H, 10-H), 9.57 (2s, 2H, 5/15-H), 10.71 (s, 1H, 20-H), 10.96 (s, 1H, 18a-H); ^{13}C NMR (125 MHz, $CDCl_3$): δ = 11.6 (C-13a), 11.8 (C-2a), 12.3 (C-17a), 17.6 (C-3b/C-12b), 18.7, 18.8 (C-7b/C-8b), 19.7, 19.8 (C-3a/C-12a), 20.2 (C-7a/C-8a), 94.3 (C-10), 95.5 (C-5), 102.2 (C-15), 103.7 (C-24), 108.0 (C-20), 131.5 (C-18), 133.7 (C-16), 133.8 (C-19), 134.7 (C-13), 135.1 (C-14), 135.4 (C-1), 135.5 (C-2), 137.6 (C-3), 137.7 (C-4), 137.8 (C-12), 138.6 (C-11), 145.1 (C-8), 145.5 (C-7), 153.1 (C-17), 154.8, 155.5 (C-6/C-9), 188.2 (C-18a); HRMS: m/z = 491.2936 (calcd 491.2937 for $C_{33}H_{37}N_3O$); UV/Vis (CH_2Cl_2): λ_{max} [nm] (lg ε) = 320 (4.22), 371 (4.39), 434 (4.53), 523 (3.91), 564 (3.87), 638 (3.54), 703 nm (3.39).

In the ^{1}H NMR spectrum of **3a** (Fig. 1) the signal of the inner NH protons appears at δ_H = −4.21, whereas the sharp signal

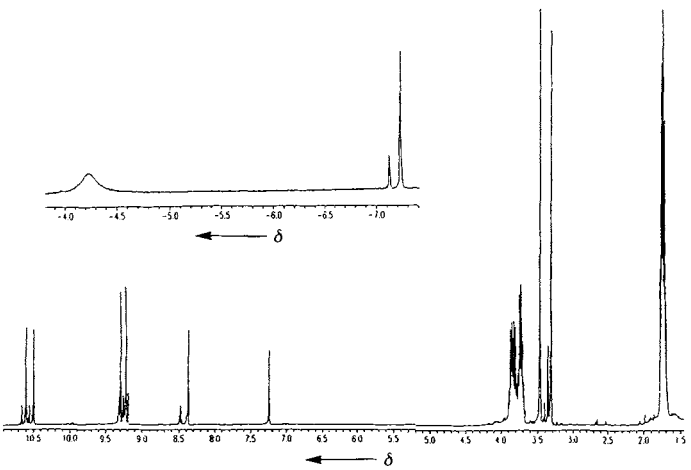


Fig. 1. ^{1}H NMR spectrum ($CDCl_3$) of **3a**.

corresponding to the inner CH group is observed at δ_H = −7.23. Thus the carbaporphyrins exhibit a ring current comparable to that of porphyrins, and there is no doubt that these compounds are 18π arenes. This is also confirmed by the low-field shifts of the signals corresponding to the *meso* protons (between δ_H = 9.1 and 10.7) and by those of the alkyl substituents. The chemical shifts of δ_H = −7.23 and −6.81 for the inner CH group are equivalent to values given by Lash et al. for

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1821 $ 15.00+.25/0

the oxibenziporphyrin[13] and also to those of comparable benzo-condensed carbaporphyrins.[14]

The UV/Vis spectra (Fig. 2) include a characteristic Soret absorption[15] at 433 nm and also resemble the spectra of alkylporphyrins in the visible range. In distinct contrast to porphyrins, the carbaporphyrins do not display a red fluorescence at 366 nm, so that the yellow-brown target compounds look quite unspectacular on the TLC plate.

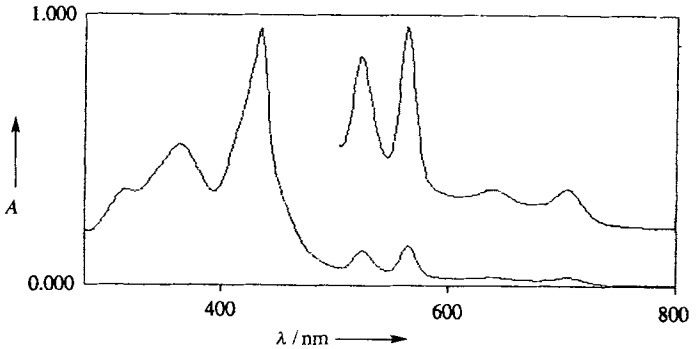

Fig. 2. UV/Vis spectrum of **3a**. A = absorption (arbitrary units).

While the carbaporphyrins appear uniform in the ^{13}C NMR spectra, in the 500 MHz ^1H NMR spectra each signal is accompanied by two weaker ones with identical multiplicity (ca. 13% und 1%). Since they correlate to the same carbon signals in the two-dimensional spectra (HMBC, HMQC), they provide the identical structure information. This confirms that the material is pure with respect to its constitution. Apparently either the three possible tautomers of the carbaporphyrin can be observed on the NMR time scale, or different stable conformations coexist due to steric strain resulting from the three inner protons. It has not yet been possible to achieve coalescence in high-temperature NMR experiments (deuteronaphthalene). In ^{15}N NMR experiments (50 MHz, $CDCl_3$, sample enriched with 5% ^{15}N) the chemical shifts of $\delta_N = 130.4$ and 130.9 (**3a**, NH_3 as a standard) for N-21 and N-23 indicate that the N–H units are located at least predominantly at these positions.[16]

Efforts to synthesize metal complexes (Zn^{2+}, Ni^{2+}) of the carbaporphyrins have not yet been successful. This can probably be attributed to the even lower CH acidity of the carbaporphyrins compared to that of the porphyrin isomers with an inverted pyrrole ring and an inner CH unit; chelates of the latter compounds having a carbon–metal bond are known.[5]

The carbaporphyrins are quite similar to porphyrins with regard to other chemical and spectroscopic properties. Hence carbaporphyrins could be suitable for special applications that require the spectroscopic properties of porphyrins but not their complexation behavior with certain metal ions.

The further development of the synthetic strategy introduced here for the preparation of carbaporphyrins to eventually prepare a tetracarbaporphyrin remains a great challenge and would link annulene and porphyrin chemistry. A dicarbaporphyrin would contain two inner CH units and a total of four inner protons. This would result not only in total cancellation of the tautomerism characteristic of porphyrins, but also in an increase of steric strain which should influence the aromaticity of the molecule. The effects of the inner methylene groups in a tetracarbaporphyrin are the subject of speculation.

Experimental Procedure

The hydroxyfulvenedialdehydes **1a** and **1b** were prepared according to the procedure published by Hafner et al. [9].

3a and **3b**: To a solution of **2a** (635 mg, 1 mmol) in anhydrous THF (80 mL) were added triethylamine (0.1 mL) and palladium on charcoal (200 mg, 10 % Pd, oxidic form, Merck). The mixture was hydrogenated for 3 h at atmospheric pressure. The catalyst was filtered off, and the filtrate was added to a solution of **1a** (150 mg, 1 mmol) or **1b** (164 mg, 1 mmol) in dichloromethane (750 mL). The orange-red solution was degassed with argon and charged with hydrogen bromide in glacial acetic acid (33 %, 1.5 mL) and glacial acetic acid (0.3 mL). The reaction mixture was stirred for 3 h with exclusion of light and neutralized with triethylamine (2.5 mL). DDQ (250 mg) was added and the mixture was stirred an additional 12 h. The solvent was evaporated and the residue purified by column chromatograpy on silica gel (eluent cyclohexane:ethyl acetate 3:1). Yield of **3a**: 37 mg (77.6 μmol, 7.8 %); yield of **3b**: 32 mg (65.2 μmol, 6.5 %) of **3b**. Both are dark green-brown microcrystalline compounds.

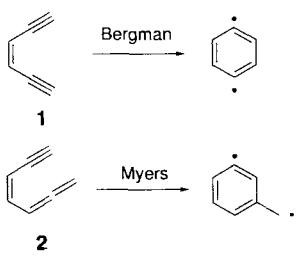
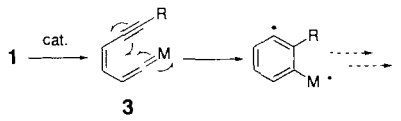
Rhodium(I)-Catalyzed Cycloaromatization of Acyclic 3-Ene-1,5-diynes**

Kouichi Ohe,* Masa-aki Kojima, Koji Yonehara, and Sakae Uemura*

Calicheamicins, esperamicin, dynemicin A, and the neocarzinostatin chromophore belong to a rapidly growing class of anticancer antibiotics from bacterial sources. Their characteristic enediyne subunit, which acts as a "warhead" and induces DNA cleavage, is proposed to be the source of their remarkable antitumor activity.[1] The fascinating mode of the action can be attributed to two types of cycloaromatization, both of which proceed via diradical intermediates (Scheme 1). One is the generation of 1,4-didehydrobenzene from (*Z*)-3-hexene-1,5-diyne (**1**) (Bergman reaction);[2] the other is the cycloaromatization of (*Z*)-1,2,4-heptatrien-6-yne (**2**) producing α,3-didehydrotoluene (Myers reaction).[3] Acyclic enediynes like **1** cyclize only at high temperatures (≈200 °C) and are otherwise quite stable. In contrast, acyclic allene-enynes like **2** undergo facile cycloaromatization at much lower temperatures (≈40 °C).[3a, c] Similar reactions of (*Z*)-1-oxa-2,4-heptatrien-6-yne as an isostructure of **2** have been reported by Moore et al.[4] and by Saito et al.[5] We envisaged a catalytic cycloaromatization of the acyclic enediyne via an intermediary vinylidene–metal complex **3** (Scheme 2).[6]



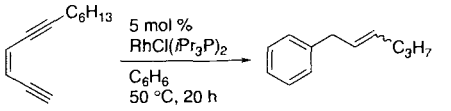
Scheme 1. Bergman and Myers cycloaromatizations.



Scheme 2. Catalytic cycloaromatization of **1**. cat. = transition metal catalyst.

In the course of our study Finn and Wang have reported the cycloaromatization of the isolated vinylidene–ruthenium complex based on the same concept.[7] Here we describe the first rhodium-catalyzed cycloaromatization of an acyclic enediyne.

We examined the reaction of (*Z*)-3-dodecene-1,5-diyne (**1a**) with a coordinatively unsaturated rhodium(I) complex suitable for generating a vinylidene complex.[8] The treatment of **1a** with 10 mol% $[RhCl(iPr_3P)_2]$[9] in the presence of ten equivalents of 1,4-cyclohexadiene as a hydrogen donor in cyclohexane at 80 °C afforded an unexpected product, 1-phenylhex-2-ene (**4a**) (*E*/*Z* = 80/20) in 20% yield (Scheme 3). When 5 mol% $[CpRuCl(PPh_3)_2]$ and NH_4PF_6[10] were used, no reaction took place and **1a** was recovered intact. Even in the absence of 1,4-cyclohexadiene the rhodium(I) complex catalyzed the reaction of **1a** to give **4a** in 22% yield with the same ratio of isomers. Apparently two hydrogens on the alkyl group of **1a** migrate to the phenyl ring. Although the reaction of **1a** was complete, **4a**



Scheme 3. Synthesis of **4a**. In the presence of Et_3N **4a** was obtained in 58% yield (*E*/*Z* = 86/14).

was obtained in low yield because of undesired polymerization. Extensive efforts to improve the yield were made and the addition of triethylamine was found to be effective. Thus, the reaction of **1a** with 5 mol% $[RhCl(iPr_3P)_2]$ and Et_3N in benzene at 50 °C under argon was complete within 20 h and gave **4a** in 58% yield (*E*/*Z* = 86/14) (see Experimental Procedure).

The results of the cycloaromatization of a variety of enediynes under the optimum conditions are listed in Table 1. In all cases

Table 1. Rhodium(I)-catalyzed cycloaromatization of enediynes [a].

Enediyne	Product	Yield [%] (*E*/*Z*)
 **1b**	 **4b**	68 (100/0)
 **1c**	 **4c**	64
 **1d**	 **4d**	10 (88/12)
 **1e**	 **4e**	52 [b]
 **1g**	 **4g**	46 (86/14)

[a] Reaction conditions: 5 mol% $[RhCl(iPr_3)_2]$ and Et_3N (70 μL) in C_6H_6 (4 mL) at 50 °C for 20 h. [b] Yield as the hydrolyzed product $PhCH_2CH_2CO_2CH_2CH_2OH$ after purification of **4e** by column chromatography on silica gel.

the products obtained have a β,γ double bond in the side chain attached to the benzene ring formed. The cyclizations of **1b** and **1c** led to (*E*)-1,3-diphenylpropene (**4b**) and **4c** in yields of 68 and 64%, respectively. Enediyne **1d** bearing an isolated double bond gave diene **4d** in low yield (10%), although **1d** was completely consumed. The formation of 2-alkylidene-1,3-dioxolane **4e** from **1e** demonstrated the tolerance of oxygen functionality, but cycloaromatization of **1f** bearing a cyano group did not proceed

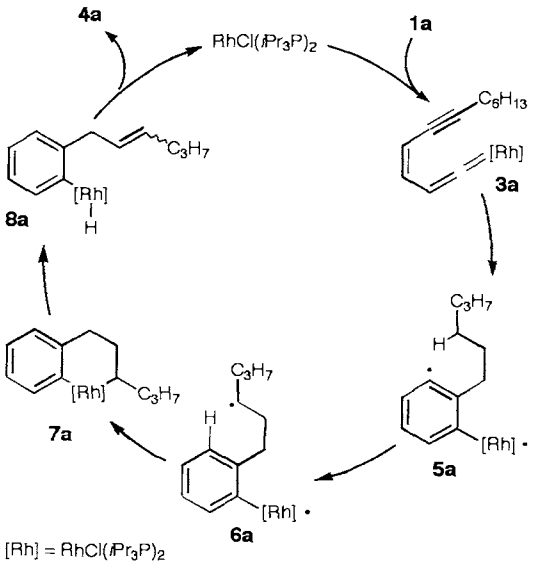
probably due to the strong coordination of the cyano group to rhodium. Similarly, 1-(1-octynyl)-2-ethynylbenzene (**1g**) underwent cyclization to give 2-(2-hexenyl)naphthalene (**4g**) (E/Z = 86/14) in 46% yield.

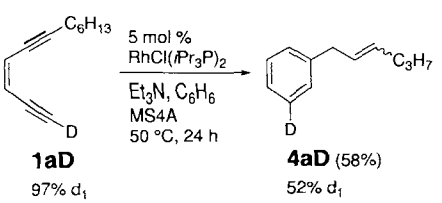
A plausible catalytic cycle for this reaction is shown in Scheme 4. Triethylamine seems to facilitate the rapid formation



Scheme 4. Postulated mechanism for the catalytic cycloaromatization of **1a** to give **4a**.

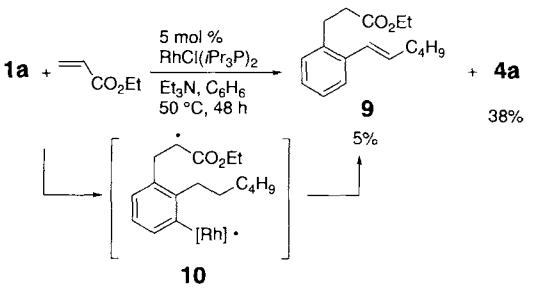
of a vinylidene–rhodium complex [RCH=C=Rh] from an alkynyl(hydrido)–rhodium complex [RC≡CRhH].[11] Thus, this reaction might proceed via the vinylidene–rhodium complex **3a**, which, in analogy to the Myers reaction, cyclizes to afford the 1,4-diradical **5a**. The intramolecular 1,5-hydrogen shift from the hexyl chain to the benzenoid radical takes place to give the intermediate **6a**.[12] Two pathways from **6a** to **8a** might be accessible. The two radical centers in **6a** could couple to form **7a**; subsequent *syn* elimination of the β-hydride ($\rightarrow$ **8a**) followed by reductive elimination would then give **4a**. Alternatively, a second 1,5-hydrogen shift in **6a** from the alkyl chain to the rhodium radical could occur directly to give **8a**, which would lead to **4a**. It is not clear at present by which mechanism the reaction proceeds.

The formation of **3a** was supported by the fact that the reaction of 1-deuterio-3-dodecene-1,5-diyne (**1aD**) (97% deuterium incorporation) afforded 1-(3-deuteriophenyl)hex-2-ene (**4aD**)[15] in 58% yield (52% deuterium incorporation) (Scheme 5).[16] In another experiment diradical **5a** was intercepted intermolecularly with hydrogens from 1,4-cyclohexadiene. In the presence of 25 equiv 1,4-cyclohexadiene, the reaction of **1a** gave 1-hexylbenzene (6%) and **4a** (5%) in addition to recovered **1a** (23%).[17] Interestingly, the reaction of **1a** with two equivalents of ethyl acrylate afforded the (*E*) olefin **9** stereospecifically in 5% yield

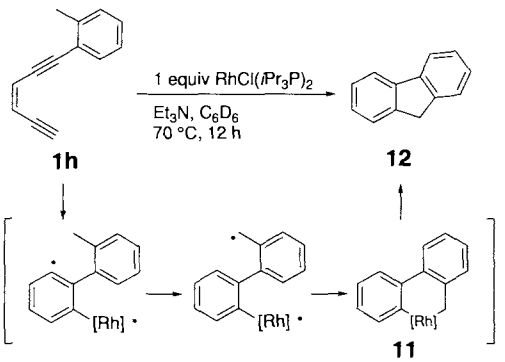


Scheme 5. Conversion of **1aD** into **4aD**. MS4A = molecular sieves 4 Å.

together with **4a** in 38% yield (Scheme 6). The formation of **9** is explained by the addition of the benzenoid radical **5a** to ethyl acrylate producing the 1,6-diradical **10**; abstraction of two vicinal hydrogens of the hexyl group then yields **9**. The intermediacy of the metallacycle **7a** was supported by the reaction of **1h** with a stoichiometric amount of [RhCl(iPr$_3$P)$_2$] (Scheme 7). Fluorene (**12**) formed as a result of reductive elimination from metallacycle **11**, which is analogous to **7a**.



Scheme 6. Cyclization of **1a** in the presence of ethyl acrylate. Only the (*E*) isomer of **9** was obtained.



Scheme 7. Cyclization of **1h** leading to fluorene (**12**) (in quantitative yield).

We have demonstrated the first catalytic cycloaromatization of an enediyne via a vinylidene–rhodium intermediate. It should be noted that the transition metal can act as a trigger for the cycloaromatization of the acyclic enediyne. Applications of this reaction will be reported in due course.

Experimental Procedure

To a solution containing [RhCl(iPr$_3$P)$_2$] prepared in situ from [{RhCl(C$_8$H$_{14}$)$_2$}$_2$] (0.007 g, 0.01 mmol) and iPr$_3$P (10 μL, 0.05 mmol) in benzene (1 mL) were added Et$_3$N (70 μL, 0.5 mmol) and a solution of (*Z*)-3-dodecene-1,5-diyne (**1a**) (0.064 g, 0.4 mmol) in benzene (3 mL). The reaction mixture was stirred under argon at 50 °C for 20 h. Filtration through Florisil and further purification by column chromatography on SiO_2 eluting with hexane afforded 0.037 g (0.23 mmol, 58%) of 1-phenylhex-2-ene (**4a**) (E/Z = 86/14) as a colorless liquid. ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C, TMS): *E* isomer: δ = 0.90 (t, J = 7.3 Hz, 3H), 1.38 (tq, J = 7.3, 7.3 Hz, 2H), 1.97–2.04 (m, 2H), 3.33 (d, J = 5.1 Hz, 2H), 5.50 (dt, J = 15.1, 5.1 Hz, 1H), 5.58 (dt, J = 15.1, 6.2 Hz, 1H), 7.17–7.20 (m, 3H, *o*- and *p*-Ar), 7.25–7.31 (m, 2H, *m*-Ar); *Z* isomer: δ = 0.96 (t, J = 7.3 Hz, 3H), 1.3–1.5 (m, 2H), 2.1–2.2 (m, 2H), 3.40 (d, J = 5.9 Hz, 2H), 5.5–5.6 (m, 2H), 7.1–7.25 (m, 3H), 7.25–7.30 (m, 2H); ^{13}C NMR (67.5 MHz, $CDCl_3$, 25 °C, TMS): *E* isomer: δ = 14.1, 22.9, 35.0, 39.4, 126.1, 128.6, 128.8, 129.2, 132.2, 141.6; *Z* isomer: δ = 14.2, 23.2, 33.8, 36.5, 126.0, 128.5, 128.7, 131.4, 133.0, 142.6. Anal. calcd for $C_{12}H_{16}$: C 89.94; H 10.06; found: C 89.65, H 10.26.

[11] It is known that the addition of pyridine shifts the equilibrium between an alkyne complex [(RC≡CH)Rh] and an alkynyl(hydrido) complex [RC≡CRhH], which is converted to a vinylidene complex: J. Wolf, H. Werner, O. Serhadli, M. L. Ziegler, *Angew. Chem.* **1983**, *95*, 428; *Angew. Chem. Int. Ed. Engl.* **1983**, *22*, 414. However, pyridine deterred the present reaction. *N,N*-Diisopropylethylamine and tetramethylethylenediamine were moderately effective and after two days gave **4a** in 42 and 23% yield, respectively.

[12] The heat of the formation of diradical **6a** is estimated to be about 16 kcal mol^{-1} less than that of **5a** [13]. This value corresponds to the difference in the strength of the secondary alkyl (95 kcal mol^{-1}) and aryl C–H (110 kcal mol^{-1}) bonds. It is less likely that the rhodium center abstracts hydrogen before the benzenoid radical does, because the bond dissociation energy of a secondary C–H bond is greater than that of a Rh–H bond (ca. 54–64 kcal mol^{-1}) [14].

[15] The incorporation of deuterium at the *meta* position was confirmed by comparison of the intensity of ^{1}H NMR signals of the *meta* protons (δ = 7.23–7.32) with those of the *ortho* and *para* protons (δ = 7.12–7.22) in CD_2Cl_2. The ratio of the integrations of the signals in these two regions is 1.48:3.0, which means that one of the *meta* positions had 52% deuterium incorporation. No incorporation of deuterium in the side chain was apparent. The observation of two isotope peaks for [M^+] at m/z = 160 (22.8%) and 161 (24.0%) in the EI mass spectrum (70 eV) of **4aD** also supports the assignment of the product (51.3% deuterium incorporation).

[16] In the absence of molecular sieves 4 Å no incorporation of deuterium into **4a** was observed and recovered **1aD** had a reduced deuterium content. This is probably due to rapid D/H exchange during the isomerization between the alkynyl(hydrido) complex and the vinylidene complex owing to trace amounts of H_2O.

[17] The reaction of **1a** (0.4 mmol) was carried out with 1,4-cyclohexadiene (10 mmol) in benzene (3 mL) in the presence of 5 mol% Rh catalyst and Et_3N (0.5 mmol) at 50 °C for 30 h. The use of greater excesses of 1,4-cyclohexadiene deterred the cyclization.

Ferric Wheels and Cages: Decanuclear Iron Complexes with Carboxylato and Pyridonato Ligands

Cristiano Benelli, Simon Parsons, Gregory A. Solan, and Richard E. P. Winpenny*

The study of polymetallic complexes has recently begun to lead to not only fascinating structures but also interesting properties. In particular the magnetic relaxation and hysteresis effects first shown for a dodecanuclear manganese cluster[1] and recently found in deca-[2] and tetranuclear[3] manganese species are novel and have implications for fundamental science and potential future applications. To understand and exploit these phenomena more examples are required, and therefore the greatest need in this area remains the design of reliable synthetic routes to produce nanoscale clusters with the potential for high-spin ground states.

We have developed the reaction of metal carboxylates with pyridone ligands leading to incomplete replacement of the carboxylates and large polynuclear arrays of copper[4] and nickel.[5, 6] We hoped that this strategy would prove general for the 3d metals, but on examination of the reactivity of $[Fe_3O(O_2CMe)_6(H_2O)_3]Cl$ with pyridones we isolated solids, which on dissolution in MeOH led to the isolation of a yellow powder that analyzed as $[Fe(OMe)_2(O_2CMe)]$. This could be recrystallized from MeOH/THF in low yield, and X-ray structure determination[7] revealed the compound to be complex **1**, which is very similar to the "ferric wheel" **2** reported by Lippard

$[\{Fe(OMe)_2(O_2CMe)\}_{10}]$ **1** $[\{Fe(OMe)_2(O_2CCH_2Cl)\}_{10}]$ **2**

and co-workers.[8] A centrosymmetric cyclic decanuclear array of iron atoms is held together by twenty μ_2-OMe ligands and ten 1,3-bridging acetato ligands (Fig. 1).

[**] This work was supported by the Engineering and Physical Sciences Research Council and the Leverhulme Trust.

Yellow powders with identical elemental composition can be produced from many reactions involving iron(III) and acetate in methanol, for example by mixing ferric chloride with sodium acetate in this solvent, or by refluxing a solution of $[Fe_3O(O_2CMe)_6(H_2O)_3]Cl$ in methanol. Whether the unrecrystallized powder contains exclusively cyclic oligomers is unclear; unfortunately powder diffraction studies failed as the powder is amorphous. We suspect that a polymeric material may be present and that cyclization occurs during crystallization; however, mass spectrometric studies of the powder show an intense high-mass peak at m/z 1710 corresponding to $[\mathbf{1} - O_2CMe]^+$. Only one significant peak is observed at a mass above that of **1**, at m/z 1831, which arises from $[\mathbf{1} + O_2CMe]^+$. This cut-off in the mass spectrum may be coincidental.

The magnetic behavior of the yellow powder is similar to that reported for **2**[8] down to about 50 K, but below this temperature the magnetic susceptibility increases dramatically. Such behavior is not compatible with the existence of rings with an even number of ions having a magnetic moment if only one type of magnetic interaction is present, as would be expected from the molecular structure of **1**. Probably the powder contains some oligomeric impurities that prevent detailed analysis of the low-temperature data at this time. Similar yellow powders result from reactions of other iron carboxylates in MeOH; however, their exact nature is currently unclear.

To synthesize acyclic polynuclear iron complexes we have utilized other precursors and other solvents. The salt $[NEt_4]_2[Fe_2OCl_6]$[9] has proved ideal for such studies.[10, 11] Dissolution of this salt with two molar equivalents of sodium benzoate in acetonitrile, followed by addition of three equivalents of sodium 6-chloro-2-pyridonate, Na(chp), gives a red solution, which we believe contains a dinuclear species of approximate formula $[Fe_2O(O_2CPh)_2(chp)_2(CH_3CN)_4]$.[12] Filtration of the solution followed by mixing with acetone gives, after one week, orange-brown crystals suitable for diffraction studies.[7] The structure in the crystal (Fig. 2) corresponds to a decanuclear iron complex capped by two sodium atoms with the stoichiometric formula **3**.

$[Fe_{10}Na_2(\mu_4\text{-}O)_2(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4(O_2CPh)_{10}(chp)_6(H_2O)_2(Me_2CO)_2]$ **3**

The metal atoms in **3** are held together by a combination of μ_4-oxo groups each bridging three Fe atoms and one Na atom, μ_3-oxo and μ_3-hydroxo units bridging exclusively Fe centers,

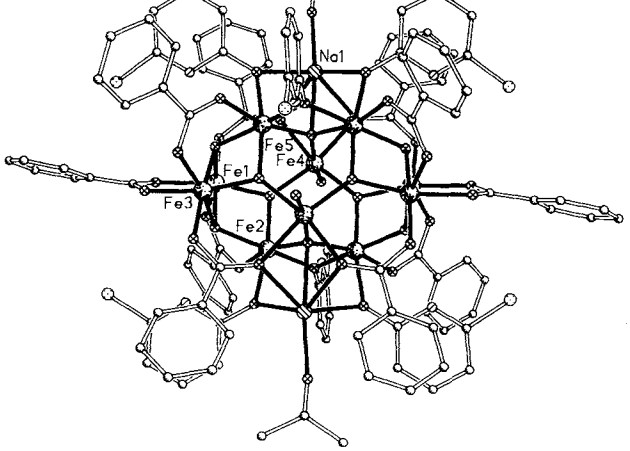

Fig. 2. The structure of the $Fe_{10}Na_2$ cage complex **3** in the crystal.

1,1′,3-bridging and 1,3-bridging benzoates, and chp ligands bridging in a μ_2-fashion through the exocyclic O atom. Terminally bound water molecules are attached to Fe4 and Fe4a, and acetone molecules are bound to the Na atoms. The iron–oxo core can be considered to contain two distorted Fe_6O_6 hexagonal prisms sharing one "square" face containing Fe4, O4, Fe4a, and O4a (Fig. 3). Similar hexagonal prisms are found as segments of other iron–oxo complexes such as $[Fe_{11}(O)_6(OH)_6(O_2CPh)_{15}]$[13] and $[Fe_{16}CoO_{10}(OH)_{10}(O_2CPh)_{20}]$;[14] however, in these complexes the hexagonal prisms do not share faces. Both of these complexes were also synthesized in CH_3CN, starting with $[NEt_4]_2[Fe_2OCl_6]$ and iron benzoate, respectively,[13, 14] possibly indicating an important role for this solvent in the formation of such cage structures. We have not yet been able to produce **3** from the reaction of preformed iron benzoate, for example $[Fe_3O(O_2CPh)_6(H_2O)_3]Cl$ with pyridonate precursors.

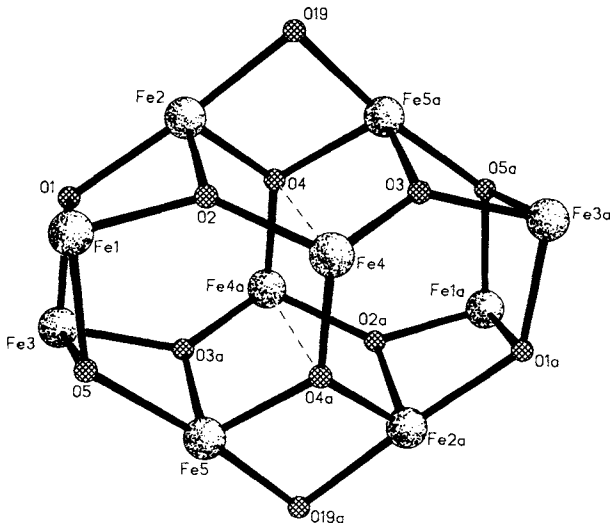

Fig. 3. The central $Fe_{10}O_{12}$ core of **3** showing the atom numbering scheme. Only μ_4-oxo, μ_3-oxo, and μ_3-hydroxo groups are shown. Selected bond angles [°]: Fe2-O1-Fe3 128.7, Fe2-O1-Fe1 91.4, Fe2-O1-Fe1 97.4, Fe1-O2-Fe4 130.2, Fe1-O2-Fe2 100.8, Fe2-O2-Fe4 127.0, Fe-4-O3-Fe3a 130.2, Fe4-O3-Fe5a 126.9, Fe3a-O3-Fe5a 100.6, Fe4a-O4-Fe5a 126.8, Fe4a-O4-Fe2 129.0, Fe2-O4-Fe5a 100.6 (average esd 0.3).

Cluster **3** contains three chemically distinct octahedral iron centers, all of which are bound exclusively to oxygen donors. The first group comprises Fe4 and Fe4a, and they are bonded to oxygen atoms from two benzoato ligands, two μ_3-oxo groups, one μ_4-oxo group, and one terminal aqua ligand. The second group consists of Fe1, Fe1a, Fe3, and Fe3a, each of which is bonded to three benzoato ligands and one μ_3-oxo and two μ_3-OH units. The remaining iron atoms, Fe2, Fe2a, Fe5, and Fe5a, are bonded to one benzoate oxygen, two μ_2-oxygens from chp, and one of each of μ_3-oxo, μ_4-oxo, and μ_3-OH units. The sodium sites are six-coordinate with O-donors derived from one μ_4-oxo, two μ_2-chp ligands, two benzoate groups, and a terminal acetone ligand.

The assignment of groups as oxo or hydroxo was made on the basis of bond length considerations. Fe–O(hydroxo) bonds are known to be significantly longer than Fe–O(oxo) bonds, and in **3** we find that Fe–O distances to such groups fall into two distinct regions. Fe–O(oxo) bonds vary from 1.900 to 1.951 Å, while Fe–O(hydroxo) bonds span the range 2.017 to 2.135 Å (average estimated standard deviation 0.005 Å). The shortest Fe···Fe contact found in **3** is 2.974(2) Å between Fe3 and Fe5. Further evidence of the identity of the O atoms comes from their

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1826 $ 15.00+.25/0

coordination geometry; the μ_3-oxo groups are planar while the μ_3-hydroxides are not. The μ_4-oxo groups have a trigonal-pyramidal geometry and are planar with respect to the three nearest Fe atoms; a Na atom occupies an apical position.

The temperature dependence of the magnetic susceptibility χ_m of **3** was measured between 260 and 2.5 K. The values of χ_m were calculated on the basis of the elemental analysis of the crystals used (C,H, N, Fe), which indicate that the sample has desolvated; hence the molecular weight is about 2900 u rather than 3347 u as indicated in the crystal structure. The observed high-temperature value of the product $\chi_m T$ of approximately 35 emu K mol^{-1} is lower than that calculated for ten non-interacting $S = 5/2$ centers with a g-value of 2 (calcd 43.75 emu K mol^{-1}) (Fig. 4 top). However, the value of $\chi_m T$ increases steadily down to 40 K, where a plateau is reached at a $\chi_m T$ value of roughly 64 emu K mol^{-1}. Such a value is close to that expected for an $S = 11$ spin state (calcd $\chi_m T =$ 66 emu K mol^{-1}). Below 20 K a slight fall in $\chi_m T$ is observed, possibly due to zero-field splitting within the spin ground state or due to intermolecular coupling. This decrease is largely independent of the magnitude of the external magnetic field. In an attempt to clarify the nature of the spin ground state the magnetization of **3** was measured at 2.26 K in an external magnetic field from 0.5 to 7 T. The magnetization shows an increase with the field up to 21.85 μ_B per molecule (Fig. 4 bottom). For a ground state with $S = 11$ a value of 22 μ_B is expected.

A high-spin ground state for **3** could be predicted based on known magneto-structural correlations. Previous work[15] demonstrates that antiferromagnetic exchange between Fe^{III} centers is stronger when mediated by oxo rather than hydroxo groups. This allows us to assume that antiferromagnetic exchange through O2, O3, and O4, and their symmetry equivalents will be dominant, and exchange through O1 and O5 will be of secondary importance (Fig. 3). Secondly, we can assume that

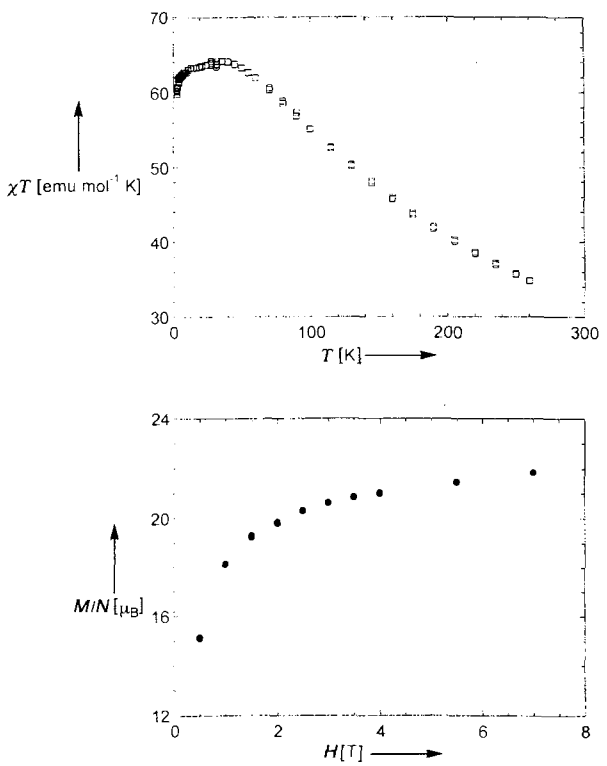

Fig. 4. Top: The temperature dependence of $\chi_m T$ for **3**. Bottom: Magnetization M of **3** at 2.26 K against magnetic field strength. M/N = reduced magnetic moment.

the magnitude of the exchange interaction will be related to the Fe-O-Fe angles at these bridging oxo units; the more obtuse the angle the larger the antiferromagnetic exchange.[16] All the most obtuse angles at oxo groups involve either Fe4 or Fe4a. For example, at O4a the two angles involving Fe4 are roughly 130°; the Fe2a-O4a-Fe5 angle is 100.6(3)°. Therefore we assume the strongest antiferromagnetic exchange interactions within this Fe_3 triangle are between Fe4 $\cdots$ Fe2a and Fe4 $\cdots$ Fe5. Similar considerations lead to all the largest antiferromagnetic exchange interactions coupling Fe4 and Fe4a antiparallel with the other eight spin centers in the molecule.

Although the magnetic susceptibility and magnetization experiments are in good agreement with an $S = 11$ ground state, on the basis of these results we cannot rule out the possibility of a ground state with a higher spin value. The magnetization curve did not reach a saturation plateau and, in any case, in the presence of significant zero-field splitting of ground states with a high spin value the magnetic susceptibility might not attain the expected upper limit. The spin value of the ground state is far from that expected in the presence of simple antiferromagnetic exchange (which would give $S = 15$ and $S = 10$ for a total of six and four $S = 5/2$ centers, respectively). Therefore we believe that some level of spin frustration must exist to explain these preliminary results. Confirmation of the exact spin ground state will require further experiments which we are presently undertaking.

Experimental Procedure

1·2THF: A solution of $[Fe_3O(O_2CMe)_6(H_2O)_3Cl]\cdot 5H_2O$ [17] (0.63 g, 0.9 mmol) in MeOH (30 mL) was stirred at reflux for 3 h to give a yellow precipitate (0.276 g). Yield: 18%. The yellow solid was extracted with a Soxhlet apparatus (40 mL MeOH, 10 mL THF) for 12 h, and the resulting solution was allowed to stand for several weeks to give pale yellow crystals of **1**·2THF. Both the yellow precipitate and crystals analyze satisfactorily for $[\{Fe(OMe)_2(O_2CMe)\}_{10}]$. FAB-MS: m/z: 1832 $[Fe_{10}(OMe)_{20}(O_2CMe)_{11}]^+$, 1739 $[Fe_{10}(OMe)_{19}(O_2CMe)_{10}]^+$, 1711 $[Fe_{10}(OMe)_{20}(O_2CMe)_9]^+$, 1386 $[Fe_9(OMe)_{19}(O_2CMe)_5]^+$, 1357 $[Fe_9(OMe)_{18}(O_2CMe)_5]^+$, 1208 $[Fe_9(OMe)_{19}(O_2CMe)_2]^+$, 1180 $[Fe_9(OMe)_{18}(O_2CMe)_2]^+$, 1031 $[Fe_6(OMe)_{13}(O_2CMe)_5]^+$, 1003 $[Fe_6(OMe)_{12}(O_2CMe)_5]^+$, 854 $[Fe_6(OMe)_{11}(O_2CMe)_3]^+$, 826 $[Fe_5(OMe)_{10}(O_2CMe)_4]^+$, 675 $[Fe_5(OMe)_{11}]^+$.

3·8MeCN·2Me_2CO: A solution of $[NEt_4]_2[Fe_2OCl_6]$ (0.25 g, 0.4 mmol) and $Na(O_2CPh)$ (0.12 g, 0.8 mmol) in MeCN (30 mL) was stirred for 15 min before Na(chp) (0.19 g, 1.2 mmol, 3 equiv) was added. The resultant red solution was stirred for 2 h then filtered and acetone (4 mL) was added. After one week at 253 K orange-brown rhombic prisms of **3**·8MeCN·2Me_2CO had formed. Yield: 15%. The sample analyzed well for $[Fe_{10}Na_2(\mu_4\text{-}O)_2(\mu_3\text{-}O)_4(\mu_3\text{-}OH)_4(O_2CPh)_{10}(chp)_6(H_2O)_2(Me_2CO)_2]\cdot$MeCN. No significant peaks were observed in the FAB mass spectrum.

sion center), $\rho_{calcd} = 1.487\ g\,cm^{-3}$, $T = 150.0(2)$ K, crystal size $0.78 \times 0.58 \times 0.35$ mm, $\mu(Mo_{K\alpha}) = 1.134\ mm^{-1}$. Data were collected with a Stoe-Stadi-4 diffractometer, graphite monochromator, $Mo_{K\alpha}$, $\omega - 2\theta$ scans with on-line profile-fitting (W. Clegg, *Acta Crystallogr. Sect. A* **1981**, *37*, 22). An absorption correction was applied using Ψ-scan data for **3** (min./max. transmission 0.392, 0.560). For both **1** and **3** the crystals were cooled using an Oxford Cryosystems low-temperature device (J. Cosier, A. M. Glazer, *J. Appl. Crystallogr.* **1986**, *19*, 105). Both structures were solved by direct methods and completed by iterative cycles of difference Fourier syntheses and full-matrix least-squares refinement against F^2 (G. M. Sheldrick, SHELXL-93, University of Göttingen, **1993**). Hydrogen atoms were included in both structures in calculated positions, riding on parent C atoms, with $U(H) = 1.2\ U_{eq}(C)$ for chp H atoms and $U(H) = 1.5\ U_{eq}(C)$ for methyl H atoms. For **1** four bridging MeO groups are disordered, and one molecule of THF solvate is also disordered over two positions and was refined with similarity restraints. All iron and fully weighted oxygen atoms (with the exception of O10 which is part of the THF solvate) were refined with anisotropic displacement parameters to give, using 349 parameters, $wR2 = 0.2357$ for 3651 unique data ($2\theta \leq 40^\circ$) [$R1 = 0.0941$ for 1820 observed reflections, $F_o > 4\sigma(F)$]. The largest residual difference peak and hole were 0.977 and $-0.749\ e\,Å^{-3}$, respectively. For **3** all non-hydrogen atoms were refined anisotropically, except atoms in several disordered solvent molecules, which were refined isotropically, to give, using 864 parameters, $wR2 = 0.2236$ for 13157 unique data ($2\theta \leq 50^\circ$) [$R1 = 0.0798$ for 7629 observed reflections, $F_o > 4\sigma(F)$]. The largest residual difference peak and hole were 1.472 and $-1.349\ e\,Å^{-3}$, Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-75. Structural Reorganization of the Doubly Protonated [222]Cryptand through Cation–π and Charge–Charge Interactions: Synthesis and Structure of Its $[CoCl_4]\cdot 0.5\,C_6H_5CH_3$ Salt

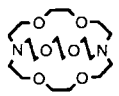
Leonard R. MacGillivray and Jerry L. Atwood*

For molecular recognition processes, understanding the influence of noncovalent interactions on the conformation and corresponding ionophoric properties of macro(poly)cyclic receptors (e.g. crown ethers, cryptands)[1, 2] in solution,[3a, b] the gas phase,[3c] and the solid state[3d] is an area of much current interest. In this context, the cation–π interaction[4] is a stabilizing interaction for the binding of positively charged guests (e.g. ammonium cations) by a number of preorganized electron-rich synthetic hosts (e.g. cyclophanes)[5] and hydrophobic binding sites in proteins (e.g. acetylcholine esterase).[4a, 6] Indeed, both experimental and theoretical studies have determined the interaction energies between $N(CH_3)_4^+$ and NH_4^+ cations and the quadrupole moment of benzene to be 9 and 19 kcal mol^{-1}, respectively,[7] and close contacts between cationic amines and aromatic residues in a limited number of protein structures have been noted.[6, 8]

Extensive work has demonstrated the formation of two-phase liquid clathrate systems[9] resulting from the interaction of a wide range of salts with aromatic solvents.[10] Recently we reported the self-assembly of proton cryptate complexes of the macrobicyclic ionophore [222]cryptand (**1**) with inorganic anions isolated from such liquid clathrate media.[10a, b] In particular, we illustrated the ability of two trifurcated intraionic N^+-H···O hydrogen bonds to reorganize the flexible ligand to a chiral, *in–in* conformation with approximate D_3 symmetry in the solid state.[10b] Furthermore, we also studied its mechanism of protonation and revealed the ability of the oxonium ion (H_3O^+) to interact with the $[\mathbf{1}\text{-}2H]^{2+}$ ion through two strong interionic O^+-H···O hydrogen bonds.[10a]



1

As part of our ongoing studies of liquid clathrate systems we now report the synthesis and X-ray crystal structure of complex **2**, which provides structural insight into the nature of the

$[\mathbf{1}\text{-}2H][CoCl_4]\cdot 0.5\,C_6H_5CH_3$ **2**

ammonium–π interaction. The complex includes a $[\mathbf{1}\text{-}2H]^{2+}$ ion that engages in both a cation–π interaction with a single molecule of toluene and charge–charge interaction with the $[CoCl_4]^{2-}$ ion. Moreover, as a consequence of these interactions, the ligand has undergone a structural reorganization from approximate D_3 symmetry to an elongated *in–in* conformation. To our knowledge, this represents the first case in which an ammonium–π interaction contributes to the structural stability of an ionophore in the solid state.

Addition of anhydrous HCl(g) to a toluene solution of the [2.2.2]cryptand **1** in the presence of an equimolar amount $CoCl_2\cdot 6H_2O$ and a further 2–3 equivalents of H_2O immediately yielded a two-phase liquid clathrate solution. Light blue crystals of **2** suitable for X-ray analysis were obtained from the lower layer by allowing the reaction mixture to stand at room temperature for approximately four weeks. The formula of **2** was confirmed by single-crystal X-ray diffraction,[11] ^{1}H NMR spectroscopy,[12] and analytical data.[13]

An ORTEP perspective of the $[\mathbf{1}\text{-}2H]^{2+}$ ion is shown in Figure 1. As in $[H_3O]_2[\mathbf{1}\text{-}2H][4Cl]\cdot 4H_2O$ (**3**), *endo* protonation of the macrobicycle leads to the formation of two intraionic trifurcated[14] N^+-H···O hydrogen bonds, and hence, an *in–in* conformation is adopted by the cryptate. As a result, all six oxygen atoms are directed inward toward the cavity, as illustrated by NCCO torsion angles, which range from 51(1)° to 53(1)° for N1–CCO and −49(1)° to −53(1)° for N2–CCO. However, unlike the cryptates in **3**, each of which lie on a crystallographic twofold axis,[10b] all atoms of the $[\mathbf{1}\text{-}2H]^{2+}$ ion in **2** are contained within the asymmetric unit. Moreover, the intraionic N^+-H···O interactions in **2** are distinct as revealed by their average N^+···O(cryptate) separations of 2.73(2) and 2.85(2) Å to N1 and N2, respectively. Similarly, the average distances for the edges of the two triangular faces formed by atoms O1,O3,O5 [3.65(2) Å] and O2,O4,O6 [3.89(2) Å] are also different. The

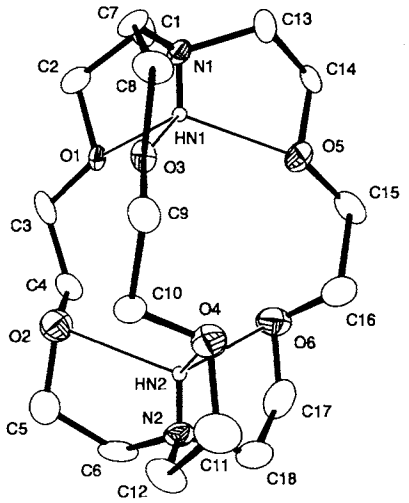

Fig. 1. X-ray crystal structure of the $[1\text{-}2H]^{2+}$ ion. Selected interatomic distances (Å): N1···N2 6.36(2), N1–HN1 1.03, N1···O1 2.75(2), N1···O3 2.71(2), N1···O5 2.74(2), O1···HN1 2.21, O3···HN1 2.25, O5···HN1 2.22, N2–HN2 1.02, N2···O2 2.85(2), N2···O4 2.83, N2···O6 2.87(2), O2···HN2 2.38, O4···HN2 2.31, O6···HN2 2.41.

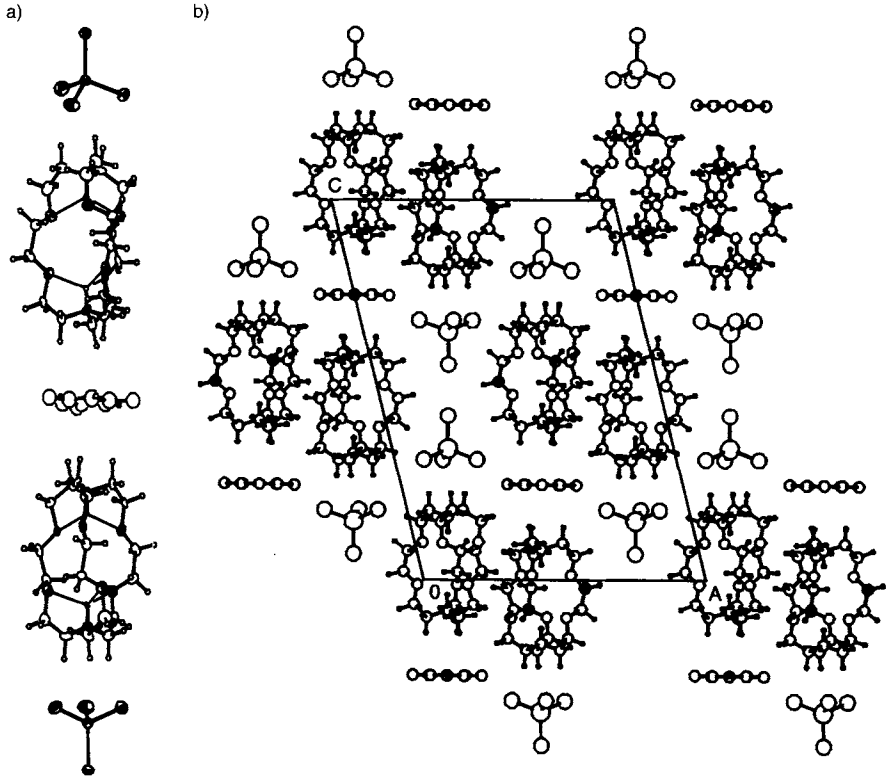

Fig. 2. a) View of the five component supramolecular complex; b) the 2D assembly along the crystallographic *b* axis.

corresponding $N^+\cdots O$ and $O\cdots O$ separations in **3** are 2.77(2) and 3.74(1) Å, respectively.[10b] Furthermore, the nonbonding $N\cdots N$ separation (6.36 Å), which is shorter than that of the empty cryptand (6.87 Å),[15] is substantially longer than in **3** (5.71 Å).[10b, 16]

The surprising geometry of the cavity of the cryptate may be attributed to the contributions of attractive ammonium-π and charge–charge interactions, which induce a structural reorganization upon the flexible macrobicycle causing the ligand to elongate along its $N\cdots N$ axis. Indeed, solution and structural data have suggested the coexistence of both interactions in a number of synthetic and biological receptors.[4] As shown in Figure 2a, the toluene molecule in **2** is sandwiched between two equivalent ends of two symmetry related $[1\text{-}2H]^{2+}$ ions in a position [distance between N1 and the ring centroid: 4.34(1) Å] that facilitates edge-type $C-H^{\delta+}\cdots\pi$ interactions[17] between three α-hydrogen atoms of each dication, each from a different methylene group, and the π face of the aromatic.[18] Similar $C-H^{\delta+}\cdots$ π(arene) interactions have been recently reported in a solid isolated from a liquid clathrate whose composition is water-dependent.[19] The $H\cdots C$(arene) separations in **2**, which range from 2.89(3) to 3.00(3) Å, fall at the upper limit of those calculated in a number of $N(CH_3)_4^+$·n-donor systems[7a] and are consistent with the observation that the interaction energy of such complexes decreases upon increasing the size of the quaternary ion which, in turn, decreases the charge on each proton.[7a] In a similar manner, the $[CoCl_4]^{2-}$ ion, located near N2 [$N2\cdots Co$ 4.54(1) Å], interacts with each cryptate through three $C-H^{\delta+}\cdots Cl$ interactions (2.924(6)–3.029(6) Å) resulting in the formation of a linear five component supramolecular complex.

A view along the crystallographic *b* axis depicting the assembly of **2** is shown in Figure 2(b). Internal protonation results in a deficiency of strong hydrogen-bond donors between constituent ions and molecules; consequently an excess of available hydrogen-bond acceptors are present in **2**.[20] As a result, the assembly process is controlled by weaker electrostatic interactions, which result in the formation of a 2D, layered architecture within the *ac* plane.[21] Interestingly, each layer exhibits pairs of $[1\text{-}2H]^{2+}$ ions surrounded by electron-rich moieties, which lends a measure of support for the proposed model of a liquid clathrate in which cation–cation repulsions are reduced by insulating assemblies of anions and aromatic molecules.[22]

That attractive cation–π and charge–charge interactions may induce a structural reorganization in the flexible $[1\text{-}2H]^{2+}$ ion in a solid isolated from a liquid clathrate medium has been demonstrated. Moreover, such observations provide insight into the ability of noncovalent interactions to impart conformational stability to macro(poly)cyclic hosts. This stability is thought to play an important role in determining their ionophoric properties.

[11] Crystal data for $[1\text{-}2H][CoCl_4]\cdot 0.5C_6H_5CH_3$: crystal size: $0.10\times0.20\times0.20$ mm, monoclinic, space group $C2/c$, $a=19.478(7)$, $b=11.245(1)$, $c=26.43(1)$ Å, $\beta=104.24(2)$, $V=5611(3)$ Å^3, $\rho_{calcd}=1.48$ g cm^{-3}, $2\theta_{max}=46°$; $\mu=0.52$ mm^{-1}, $Mo_{K\alpha}$ radiation ($\lambda=0.71069$ Å) for $Z=8$. Intensity data were collected using the $\omega-2\theta$ scan mode on an Enraf Nonius CAD-4 diffractometer and were corrected for Lorentz, polarization, and absorption effects, but not for extinction. The structure was solved with direct methods. Least-squares refinement based on 1301 reflections with $I_{net}>2.0\sigma(I_{net})$ (out of 4043 unique reflections), and 298 parameters on convergence gave final values of $R=0.081$ and $R_w=0.065$. Methylene and aromatic hydrogen atoms were placed in calculated positions (d(C,H) = 1.08 and 1.00 Å, respectively) with their positional and thermal parameters fixed, temperature factors being based upon the carbon atoms to which they are bonded. Quaternary ammonium hydrogen atoms were located by inspection of a difference Fourier map, and their positional and thermal were fixed, temperature factors being based upon the atoms to which they are bonded. The toluene molecule was observed to lie on a crystallographic twofold axis and exhibit threefold disorder with the carbon atoms of the methyl group displaying site occupancies of 0.4 (CS5) and 0.3 (CS5B). Crystallographic calculations were conducted with the NRCVAX program package (E. J. Gabe, Y. Le Page, J.-P. Charland, F. L. Lee, P. S. White, *J. Appl. Cryst.* **1989**, *22*, 384) on a pentium-based IBM compatible computer. Crystallographic data (excluding structure factors) for the structure reported in this paper have been desposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-83. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).
[12] The ^{1}H NMR spectrum exhibits resonances typical of the $[1\text{-}2H]^{2+}$ ion (see ref. [10b]) and toluene.
[13] Satisfactory elemental analysis was obtained for **2** as formulated.

[16] The N···N separation in **2** is also comparable to that in $[H_3O][1\text{-}2H][(CoCl_3)_2(\mu\text{-}Cl)]$ (6.44 Å)[10a] in which two strong *inter*ionic O^+-H···O hydrogen bonds cause reorganization of the cryptate and result in the formation of two bifurcated *intra*ionic hydrogen bonds within the cavity.
[17] M. A. Viswamitra, R. Radhakrishnan, J. Bandekar, G. R. Desiraju, *J. Am. Chem. Soc.* **1993**, *115*, 4868.
[18] Ab initio calculations involving the $N(CH_3)_4^+$ ion confirm the electrostatic nature of such interactions and demonstrate that a conformation in which three hydrogen atoms are attached to three different alkyl groups is preferred [7].
[19] R. Hunter, R. H. Haueisen, A. Irving, *Angew. Chem.* **1994**, *106*, 588; *Angew. Chem. Int. Ed. Engl.* **1994**, *33*, 566.
[20] L. R. Hanton, C. A. Hunter, D. H. Purvis, *J. Chem. Soc. Chem. Commun.* **1992**, 1134.
[21] We also note the following data: a) an interionic Cl···Cl separation of 3.465(8) Å and a Co-Cl-Cl angle of 179.6(2)° between Cl4 and Cl4a (a: $1.5-x$, $0.5-y$, $-z$), which is indicative of a Cl···Cl interaction [see V. R. Pedireddi, D. S. Reddy, B. S. Goud, D. C. Craig, A. D. Rae, G. R. Desiraju, *J. Chem. Soc. Perkin Trans. 2* **1994**, 2354]; and b) close approach between the methyl group of the disordered toluene molecule and the $[CoCl_4]^{2-}$ ion ($C_{Me}\cdots Cl<3.60$ Å), which suggests the presence of a stabilizing interaction between the hydrogen atoms of the substituent and the anion.
[22] J. L. Atwood, *J. Inclusion Phenom.* **1985**, *3*, 13.
[23] Note added in proof (August 1, 1996): Using data collected on the Siemens SMART system we have recently discovered that **2** may also be solved in the trigonal space group $R\bar{3}c$ with $a=11.2733(5)$, $c=77.002(5)$ Å. The dication and anion lie on a crystallographic threefold axis and the toluene molecule exhibits threefold disorder across a crystallographic *32* site. Interpretation of the assembly process, however, remains the same.

Enantioselective Synthesis of Copper(I) Bipyridine Based Helicates by Chiral Templating of Secondary Structure: Transmission of Stereochemistry on the Nanometer Scale**

Craig R. Woods, Maurizio Benaglia, Franco Cozzi, and Jay S. Siegel*

Achiral oligobipyridines spontaneously wrap around copper(I) ions to create the beautiful secondary structure of a double helix in racemic modification (Fig. 1).[1, 2] In cases where

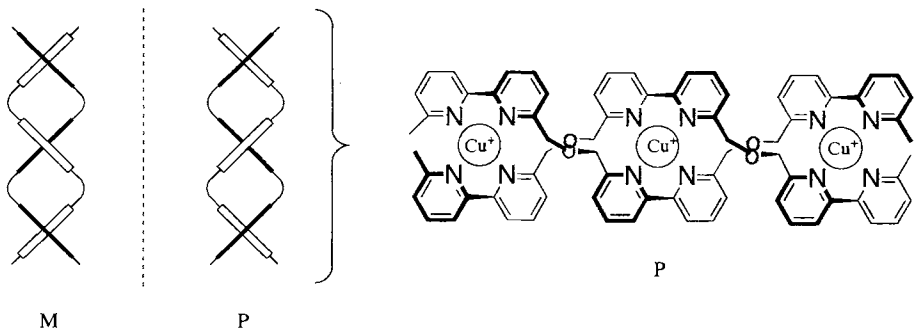

Fig. 1. Enantiomers of helicates.

the bipyridine strands possess a directionality,[3] the pair of enantiomers further speciates into isomers of the head-to-head and head-to-tail variety.[4] Stereoselective control of this secondary structure is an integral component in the synthesis of enantiopure topologically complex supramolecular structures.[5] A classical strategy to such stereocontrol involves altering the parent structure by incorporation of a stereochemical director.[6] Lehn et al. demonstrated this approach by placing chiral linkers between bipyridines which when bound with copper, preferentially formed helicates of one handedness.[7] Less invasive control of stereochemistry can result from an auxiliary template that predetermines stereochemistry and then is removed.[8] Such a scheme opens the possibility of preparing and analyzing specific stereoisomers of the parent helicate in a nonequilibrium mixture. This idea led us to investigate the synthesis and metal complexing behavior of a series of oligobipyridines hybridized to chiral organic templates.

A chiral template provides the necessary symmetry condition for distinguishing right- from left-handed helicates, and the conformational energetics of the chosen template sets the pitch and direction of the helix by restricting the conformational freedom of the bipyridine strands as the metal binds to the ligand. Given sufficient binding strength and helical stability of the helicates, the template can be removed without racemizing the system and the enantiomerically enriched helicate may be used or investigated further. These structural and energetic factors play an important role in determining which template will be an effec-

tive auxiliary. For the copper(I) bipyridine based helicates spirobisindanol **I** and dimethylbiphenic acid **II** presented the necessary match of symmetry, dimensions, and accessibility (Fig. 2). Hybrids of **I** or **II** with oligobipyridine strands thus became our specific synthetic targets. All of these targets contain numerous carbon–oxygen bonds, suitable sites for retrosynthetic disconnection. The pattern of these disconnections can follow various schemes: 1) strand synthesis, followed by hybridization to the template; 2) template modification by linear addition of bipyridine units; 3) convergent combination of an extended template with oligobipyridines. Methods 1 and 3 proved most expedient.

Synthesis of the bipyridine strands **1**-OH–**3**-OH, proceeds, after initial photobromination, by an iterative series of hydrolysis and Williamson etherification steps (Scheme 1). Initially, 6,6′-dimethyl bipyridine (**1**)[9] is brominated to yield the 6-bromomethyl-6′-methyl (**1**-Br) and 6,6′-bis(bromomethyl) (**1**-Br_2) derivatives. Hydrolysis of **1**-Br is effected with potassium carbonate in aqueous dioxane to form the alcohol **1**-OH, the alkoxide of which reacts with **1**-Br_2 to yield the bisbipyridine **2**-Br.[10] The strand is extended by repeating these steps to produce **2**-OH, **3**-Br, and **3**-OH, sequentially. Enantiomerically resolved **I**[11] and **II**[12] were obtained by literature methods. The bipyridine strands are attached to the template at the bromide or alcohol stages depending on the template. The alkoxide of **I** is formed with sodium hydride and reacts with bromomethylbipyridines **1**-Br, **2**-Br, and **3**-Br to form the template/strand hybrids **I-1**, **I-2**, and **I-3**, respectively. The action of oxalyl chloride converts **II** to its acid chloride, and subsequent reaction with the hydroxymethylbipyridines **1**-OH, **2**-OH, and **3**-OH yields the strand/template hybrids **II-1**, **II-2**, and **II-3**, respectively. Additionally, a convergent approach may be taken, in which **I** is combined with **1**-Br_2 to yield **I-1**-Br, which can be subsequently allowed to react with the alkoxide of **2**-OH to give **I-3**. Metal complexation is accomplished by adding copper(I) triflate or trifluoroacetate to a stirred solution of ligand in acetonitrile.[13]

The ^1H and ^{13}C NMR spectra of the strand/template hybrids clearly display discrete regions for each of the respective proton and carbon types. Upon metal complexation specific signal regions of the ^1H NMR spectra undergo significant and telling changes, which make these signals key reporters of helicate formation (Fig. 3). In particular, the methylene region in the spectra of the free ligands appears primarily as a set of singlets ($\delta \approx 5.0-5.2$), due to accidental isochrony of the diastereotopic protons. Only the methylene closest to the template in the **I** series displays a four-line AB pattern. Upon helicate formation all of the methylene signals shift upfield ($\Delta\delta \approx 1$) and the diastereotopism amplifies such that full four-line AB patterns are seen throughout. The proximity of the methylene groups to the shielding cone of the heterocycles is the likely cause of the

upfield shift and the greater manifestation of diastereotopism. The signal for the proton *ortho* to the oxygen in **I** ($\delta = 6.5$) also experiences a strong upfield shift ($\Delta\delta \approx 1.5$) upon complexation. Together these spectral changes indicate helix formation with close participation from the template. Thus, the single stereoelement of the template controls the stereochemistry of the complex throughout a span of 20 Å.

Although the copper(I) complexes of **I** and **II** have complex spectra, the collection of signals can be accounted for by only one species in each case:[13] a single enantiomer of the head-to-head isomer. Previous work on helix reversion excludes the possibility that this set of signals is due to diastereomeric equilibration on the NMR time scale.[1] Chiroptical measurements also support a highly diastereoselective complexation (Table 1). The

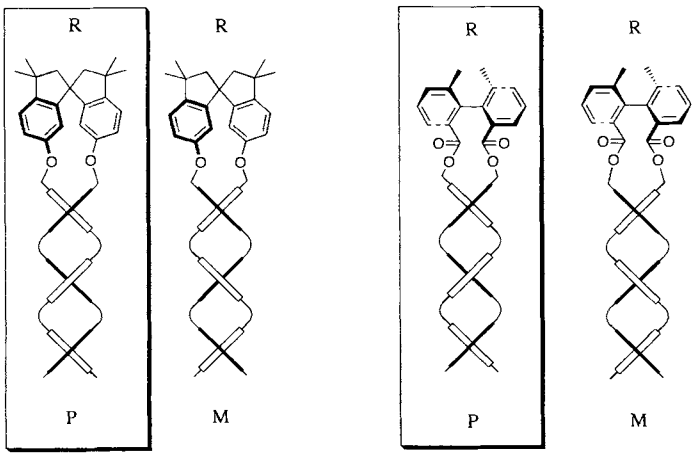

Fig. 5. The possible stereoisomers of the complexes of **I** (left) and **II** (right); the species formed are boxed.

template and the free ligand/template hybrids show $[\alpha]_D$ values that are small in absolute value (<100°); the metal complexes display much greater $[\alpha]_D$ values (ca. +500°). Circular dichroism (CD) spectra (Fig. 4) confirm the helicity of **II**-3-Cu_3.[14]

The absolute configurations of the helicates were deduced by comparison of their CD spectra and $[\alpha]_D$ values with those of Lehn's compound.[7a] The CD spectra show an identical Cotton effect and $[\alpha]_D$ values of the same sign and magnitude.[15, 16] The absolute configurations of the templates have been correlated to the optical rotation in the literature. Thus, for **I**-3-Cu_3 and **II**-3-Cu_3 the absolute configurations must be R-P and R-P, respectively (Fig. 5).

The present results bode well for the general isolation of enantiomerically pure head-to-head double helicates. The stereochemical integrity observed in these compounds demonstrates the ability to transmit stereochemical information over nanometer distances. These complexes will allow direct studies on the mechanism of helicate ligand exchange and recognition processes.[17] Having a general route to the enantiopure helicates with sites for modification opens new avenues for selective bioconjugates involving helicates.[18] From an organic perspective these helicates may provide the foundation for the development of new enantioselective reagents.[19]

Metalloporphyrins as Ligands: Synthesis and Characterization of $[(\eta^6\text{-cymene})\text{-Ru}\{\eta^5\text{-Ni(OEP)}\}]^{2+}$**

Karen Koczaja Dailey, Glenn P. A. Yap, Arnold L. Rheingold, and Thomas B. Rauchfuss*

Interactions between transition metals and heterocycles are relevant to many areas of science and technology. This topic has elicited recent interest in the context of hydrotreating catalysis, the industrial process by which heteroatom-containing contaminants are removed from fossil fuels.[1] Studies to date have focused on two aspects of hydrotreating, hydrodesulfurization (HDS) and hydrodenitrification (HDN), which can be modeled through the study of thiophene–metal[2] and pyridine–metal interactions,[3] respectively.

Hydrotreating also encompasses hydrodemetalation (HDM), which primarily involves the removal of nickel and vanadium from crude oil stocks.[4] These metals are typically found in fossil fuels as metalloporphyrins.[5] Such species arise from the dehydrogenation and transmetalation of chlorophyll and related pigments present in fossil plants. Because HDS and HDN catalysts are poisoned by these metals, HDM reactors typically precede other petroleum processing steps. We have prepared what appear to be the first π–metal complexes of metalloporphyrins as models for the initial stages of HDM catalysis. Since metalloporphyrins are of widespread interest in catalysis,[6] energy conversion,[7] and supramolecular chemistry in general,[8] the new coordination mode may be more broadly applicable, especially as we show that the π complexation strongly affects the structural and spectroscopic properties of the porphyrin.

We have previously demonstrated that the reagent [(cymene)Ru(OTf)$_2$] **1** (cymene = *p*-isopropyltoluene; OTf = $CF_3SO_3^-$) is a potent arenophile, which rapidly forms π complexes with a variety of arenes and heterocycles.[9] We have now found that **1** reacts with octaethylporphyrinatonickel, [Ni(OEP)] **2**, to give the adduct $[(\eta^6\text{-cymene})\text{Ru}\{\eta^5\text{-Ni(OEP)}\}](\text{OTf})_2$ **3** [Eq. (a)].

$$[(R)M(OTf)_2] + [Ni(OEP)] \longrightarrow [(R)M\{\eta^5\text{-Ni(OEP)}\}](OTf)_2 \quad (a)$$

$(R)M^{n+}$ = (cymene)Ru^{2+}, (cymene)Os^{2+}, $(C_5Me_5)Ir^{2+}$

The reaction occurs readily at room temperature and is signaled by a conversion of the magenta color characteristic of the nickel porphyrin to deep green. Addition of hexanes to these solutions precipitates **3**, leaving unconverted **2** in solution. The new compound is air-stable and soluble in a variety of polar organic solvents. Coordinating solvents, such as MeCN, reverse the complexation to give free **2**.

The ^{1}H NMR spectrum of **3** illustrates that the complex lacks the D_{4h} symmetry of **2**. Two methyne singlets are observed at $\delta = 8.13$ and 8.72. These signals are shifted upfield relative to the methyne signal found in **2** at $\delta = 9.7$, indicating the reduced ring current of the metalloporphyrin upon complexation. Homonuclear decoupling experiments show that the methylene hydrogen atoms are diastereotopic, for example the overlapping doublet of quartets at $\delta = 3.83$ is coupled to the overlapping doublet of quartets at $\delta = 3.03$, consistent with C_s symmetry of the π complex. Typical for other π-arene complexes, it is assumed that the $\{\eta^5\text{-Ni(OEP)}\}$, as well as the η^6-cymene ligand, rotates freely about the metal–ring centroid axis. The ^{13}C NMR data are consistent with the ^{1}H NMR spectroscopic results. The lower symmetry of the complex may also be responsible for the broadening of the Soret band, which has shifted from 392 nm to 406 nm, and appearance of a band at 672 nm, which is similar to those exhibited by metallochlorins (Fig. 1).[10]

While **3** did not afford crystals, X-ray quality crystals of the tetrafluoroborate salt, $[(\eta^6\text{-cymene})\text{Ru}\{\eta^5\text{-Ni(OEP)}\}](BF_4)_2$, were obtained, although due to disorder in the anion and solvent, the structure is of limited quality. The crystallographic results confirm that **2** is indeed serving as a π ligand for the Ru dication (Fig. 2).[11] The pyrrolide and π arene deviate from parallel by only 4.13°. The Ni(OEP) ligand is strongly distorted, being folded along the C28-Ni-C46 axis. The planes defined by the pyrrolides containing N1, N3, and N4 are twisted 10°, 28°, and 27°, respectively, from the least-squares plane calculated

The Fluorescence Dynamics Laboratory at the University of Illinois, Urbana-Champaign, is supported by the Division of Research Resources of the National Institutes of Health through grant PHS-P41-RRO3155. OEP = octaethylporphyrin.

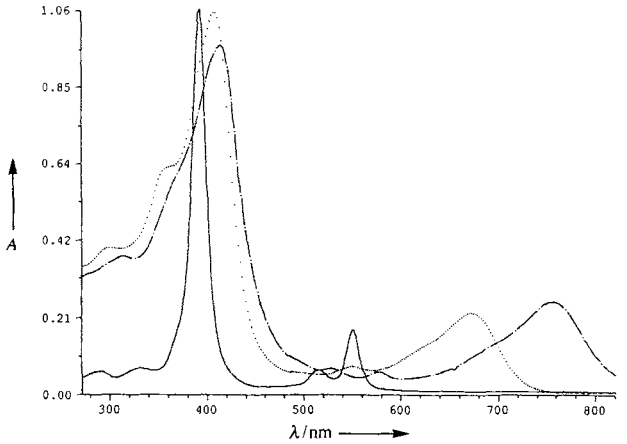

Fig. 1. Absorption spectra of [Ni(OEP)] (—), $[(\eta^6\text{-cymene})Ru\{\mu^5\text{-}Ni(OEP)\}](BF_4)_2$ (····), and $[(\eta^6\text{-cymene})Ru\{\eta^5\text{-}Zn(OEP)\}](OTf)_2$ (–·–·–) in CH_2Cl_2. A = absorption.

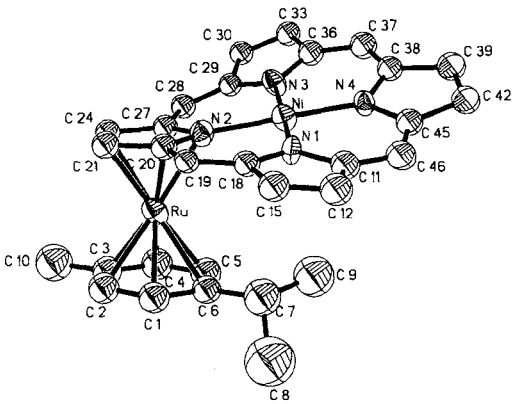

Fig. 2. Structure of the dication in $[(\eta^6\text{-cymene})Ru\{\eta^5\text{-}Ni(OEP)\}](BF_4)_2$ with thermal ellipsoids drawn at the 50% probability level. (Ethyl groups omitted for clarity.) Selected bond lengths [Å]: Ru–N2 2.230, Ru–C20 2.169, Ru–C21 2.216, Ru–C24 2.237, Ru–C27 2.181, Ni–N1 1.922, Ni–N2 1.963, Ni–N3 1.945, Ni–N4 1.924.

for the π-complexed pyrrolide. The competition between Ni and Ru for electron density at N2 is also manifested in the structural data. The Ru–N2 distance is 0.081 Å longer than that in $[(\eta^6\text{-cymene})Ru(\eta^5\text{-}C_4Me_4N)](OTf)_2$ (2.149 Å).[12] The Ni–N2 distance (1.963 Å) in **1** is only slightly longer than that found in the three known crystalline forms of **2**,[13–15] while the remaining three Ni–N bond lengths of the complex are either comparable or slightly shorter. It has been postulated[16] that 1.96 Å is the shortest metal–N bond length necessary to retain a planar macrocycle.[13] Thus, the somewhat shorter Ni–N1, Ni–N3, and Ni–N4 bond lengths are in accord with the severe nonplanarity of the Ni(OEP) ligand in **3**.

The new type of sandwich complex enjoys some the generality. ^{1}H NMR experiments confirm that both $[(C_5Me_5)Ir(OTf)_2]$ and $[(cymene)Os(OTf)_2]$ react with **2** in a manner analogous to **1**. The iridium adduct is deep blue, while the (cymene)Os derivative is green. We investigated the possibility that more than one metal could be attached to the porphyrin ring by treating **2** with an excess of **1**, but only the 1:1 adduct was isolated. We conclude that the first metalation diminishes the basicity of the entire porphyrin.

Interestingly, H_2(OEP) itself does not form a complex with **1**. Stable π complexes derived from pyrroles typically feature the deprotonated heterocycle.[17] We reason that the greater coordinating power of **2** relative to H_2(OEP) reflects the electron-releasing tendency of the electropositive Ni center. Consistent with this view, [Zn(OEP)] forms a very stable adduct with $Ru(cymene)^{2+}$ ions but [VO(OEP)] does not appear to bind at all. Spectroscopic and microanalytical data for $[(cymene)Ru\{Zn(OEP)\}](OTf)_2$ (**4**) suggest that this olive green species adopts a structure similar to that of the cation of **3** [Eq. (b)]. In

$$[(R)Ru(OTf)_2] + [Zn(OEP)] \longrightarrow [(R)M\{\eta^5\text{-}Zn(OEP)\}](OTf)_2 \quad (b)$$
$$(R)M^{n+} = (cymene)Ru^{2+},\ (C_5Me_5)Ir^{2+}$$

contrast to Zn(OEP),[18] whose photophysical properties have been widely studied, neither $[(cymene)Ru\{Zn(OEP)\}]^{2+}$ nor $[(C_5Me_5)Ir\{Zn(OEP)\}]^{2+}$ fluoresces.

The results define a new mode for metal–porphyrin interactions potentially relevant to catalyst–metalloporphyrin interactions in the hydrodemetalation process. The π-complexation strongly perturbs the electronic and structural properties of this important family of heterocycles. This new coordination mode presents new opportunities for the design of metal–metalloporphyrin superstructures.

Experimental Procedure

All preparative operations were conducted under purified nitrogen unless otherwise stated.

$[(cymene)Ru\{Ni(OEP)\}](BF_4)_2$: In a 100 mL Schlenk flask $[(cymene)RuCl_2]_2$ (0.078 g, 0.127 mmol) and $AgBF_4$ (0.098 g, 0.507 mmol) were combined and CH_2Cl_2 (10 mL) was added. After the mixture had been stirred for 2 h at room temperature, the orange solution was filtered to remove AgCl. The solution of $[(cymene)Ru(BF_4)_2]$ was treated with **2** (0.158 g, 0.267 mmol). After about 16 h, the dark purple solution was reduced in volume to about 10 mL and diluted with hexane. The green solid precipitate was washed with hexane until the filtrate was colorless. The green powder was collected and dried under vacuum. Yield: 0.150 g (60%). Single crystals were obtained from a THF/hexane solvent system. ($[(\eta^6\text{-cymene})Ru\{\eta^5\text{-}Ni(OEP)\}][OTf]_2$ was prepared analously using AgOTf, but no crystals were isolated.) Anal. calcd for $C_{46}H_{58}N_4B_2F_8NiRu \cdot 0.6$ THF (found): C 55.70 (54.60), H 6.07 (6.18), N 5.37 (4.48). ^{1}H NMR (CD_2Cl_2): $\delta = 0.54$ (d, 6H), 1.39 (t, 6H), 1.52 (m, 18H), 1.60 (m, 1H), 2.00 (s, 3H), 3.03 (m, 2H), 3.25 (m, 10H), 3.57 (m, 2H), 3.83 (m, 2H), 5.52 (d, 2H), 6.10 (d, 2H), 8.13 (s, 2H), 8.72 (s, 2H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 16.0, 16.3, 16.7, 17.1, 17.8, 18.6, 18.7, 19.0, 19.2, 21.8, 31.0, 86.0, 89.8, 97.3, 102.9, 103.0, 106.2, 106.7, 112.5, 145.9, 148.5, 148.8, 151.1, 154.6, 159.2. FAB-MS: m/z: 826.3 ($[(cymene)Ru\{Ni(OEP)\}]^{2+}$). UV/Vis ($CH_2Cl_2$): λ [nm] (ε[$M^{-1}cm^{-1}$]) 300 (20500), 360 (32400), 406 (55000), 490 (2800), 550 (3700), 624 (6700), 672 (11600).

$[Cp^*Ir\{Ni(OEP)\}](OTf)_2$: The synthesis was carried out as for $[(cymene)Ru\{Ni(OEP)\}](BF_4)_2$ by using $[Cp^*IrCl_2]_2$ (0.038 g, 0.048 mmol), AgOTf (0.051 g, 0.198 mmol), and [Ni(OEP)] (0.060 g, 0.101 mmol). A blue powder was isolated. Yield: 0.070 g (60%). ^{1}H NMR (CD_2Cl_2): δ = 1.26 (s, 5H), 1.58 (m, 24H), 3.16 (m, 2H), 3.37 (m, 10H), 3.60 (m, 2H), 3.84 (m, 2H), 8.36 (s, 2H), 8.64 (s, 2H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 8.4, 15.9, 16.7, 16.9, 17.1, 17.5, 19.1, 19.2, 19.4, 96.7, 96.9, 100.4, 106.0, 108.6, 147.4, 149.7, 150.0, 152.0, 155.7, 159.3. FAB-MS: m/z: 918.4 ($[Cp^*Ir\{Ni(OEP)\}]^{2+}$). UV/Vis (CD_2Cl_2): λ [nm] (ε [$M^{-1}cm^{-1}$]) 312 (16000), 394 (39000), 410 (49000), 550 (6000), 582 (7000), 636 (10000).

4: A solution of **1**, generated from $[(cymene)RuCl_2]_2$ (0.026 g, 0.042 mmol) and AgOTf (0.044 g, 0.170 mmol) in CH_2Cl_2 (10 mL) was treated with [Zn(OEP)] (0.075 g, 0.125 mmol). The slurry was refluxed at 65 °C for about 16 h. After the mixture had been cooled to room temperature, the dark purple solution was filtered (in air) to remove the unconverted, solid [Zn(OEP)]. The remaining [Zn(OEP)] was removed by first precipitating the complex with diethyl ether and washing with this solvent until the filtrate was colorless. The complex was recrystallized from a CH_2Cl_2/hexane solvent system to give olive green microcrystals. Yield: 0.065 g (67%). Anal. calcd for $C_{48}H_{58}N_4F_6O_6RuS_2Zn$ (found): C 50.95 (50.83), H 5.17 (5.50), N 4.95 (4.39). ^{1}H NMR (CD_2Cl_2): δ = 0.92 (d, 6H), 1.29 (m, 6H), 1.54 (m, 18H), 2.09 (s, 3H), 2.43 (m, 1H), 3.30 (m, 14H), 3.44 (m, 2H), 5.7 (dd, 4H), 7.89 (s, 1H), 8.05 (s, 1H). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ = 15.89, 16.51, 16.90, 17.34, 18.67, 18.70, 18.91, 18.92, 19.02, 22.18, 31.40, 86.10, 88.37, 96.63, 102.07, 102.56, 104.98, 108.78, 111.96, 145.81, 147.11, 147.34, 155.78, 163.80, 167.24. FAB-MS: m/z: 832.3 ($[(cymene)Ru\{Zn(OEP)\}]^{2+}$). UV/Vis ($CH_2Cl_2$): λ [nm] (ε [$M^{-1}cm^{-1}$]) 274 (22000), 312 (25000), 370 (41000), 412 (65000), 528 (4000), 576 (3500), 692 (8500), 754 (17000).

$[Cp^*Ir\{Zn(OEP)\}](OTf)_2$: $[Cp^*Ir(OTf)_2]$ was generated from $[Cp^*IrCl_2]_2$ (0.033 g, 0.042 mmol) and AgOTf (0.043 g, 0.166 mmol) in CH_2Cl_2 (10 mL). To this solution, [Zn(OEP)] (0.075 g, 0.125 mmol) was added as a solid. The reaction mixture was heated to reflux for about 16 hours. After cooling to room temperature, the reaction mixture was filtered (in air) to remove the unconverted [Zn(OEP)]. The crude

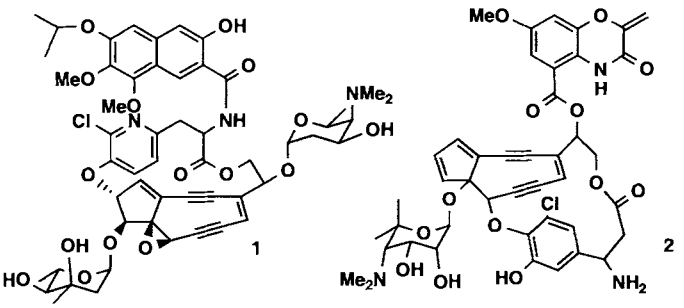
DNA Cleavage by a Nine-Membered Masked Enediyne, an Analogue of the Kedarcidin and C-1027 Chromophores**

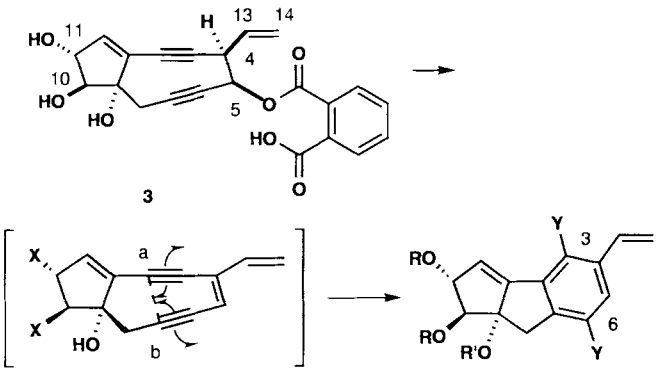
Takashi Takahashi,* Hiroshi Tanaka, Haruo Yamada, Takuyuki Matsumoto, and Yukio Sugiura

Kedarcidin (KD)[1] and C-1027[2] belong to a new class of chromoprotein antitumor antibiotics consisting of a 1:1 complex of apoproteins and cytotoxic nonprotein chromophores. Their chromophores, KD-chr (**1**) and C-1027-chr (**2**), possess a



common nine-membered enediyne core structure. Their biological activities are associated with their ability to cause strong DNA cleavage. The proposed mechanism of the DNA cleavage is that biradical species generated from the highly strained nine-membered enediyne chromophores abstract hydrogens from deoxyribose.[1d,2d] Unlike other enediynes, C-1027 shows predominant DNA-cleaving activity even in the absence of thiols or reducing agents, a valuable implication for its application as a potent cancer chemotherapeutic agent.[3]

The design and synthesis of DNA-cleaving molecules has been a subject of recent synthetic and biochemical investigations.[4,5] We have already reported an approach to the enediyne **4a** (Scheme 1) as a nine-membered esperamicin–calicheamicin



4a: X=H
4b: X=OH

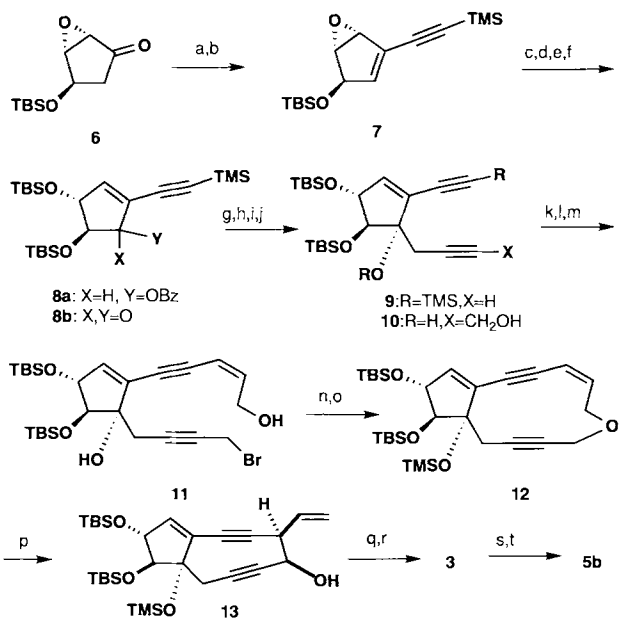
analogue.[6] However, **4a** did not cause any DNA cleavage, probably because it is not soluble in water and not stable enough to be handled at ambient temperature. In this communication we report the design, synthesis, and DNA-cleaving activity of the new nine-membered pro-enediyne **3**, which is sufficiently stable at ambient temperature to allow its isolation and handling and which shows a strong DNA-cleaving activity without addition of thiols.

Compound **3** was designed as a potential precursor for the KD-chr analogue **4b** based on the following considerations. The 1,5-diyne system in **3** should be stable enough to allow isolation and handling at ambient temperature, and the phthalic acid moiety should improve the solubility of **3** in water. Removal[7] of the phthalic acid in **3** in weakly basic buffer solution should lead to the highly reactive nine-membered enediyne **4b**, which based on MM2 calculations (distance between a and b in **4b** is 2.82 Å) should undergo spontaneous Bergman cyclization at room temperature to give the benzenoid biradical **5a**.[8] Thus, like C-1027-chr, the pro-enediyne molecule **3** should cleave DNA without added thiols or reductants. The *trans*-dihydroxy groups at C(10) and C(11) in **3** should also increase its solubility in water and could be used to attach a DNA sequence recognition element in DNA binding studies. In addition, at a later stage of this program the vinyl group at C(4) in **3** could be used to introduce dihydroxy groups at C(13) and C(14), which could be elaborated in analogy to **1** and/or **2**.

The nine-membered diyne **3** was synthesized from the (±)-epoxyketone **6** by using a modification of the general methodology developed previously in our laboratory (Scheme 2).[6,9] Addition of magnesium trimethylsilylacetylide to ketone **6** (80%), followed by treatment of the resultant alcohol with $(CF_3SO_2)_2O$ (Tf_2O) and lutidine gave the enoxide **7** in 70% yield.[10] Palladium-catalyzed ([Pd(OAc)$_2$]/PPh$_3$ in THF) opening of the epoxide ring[11] of **7** in the presence of benzoic acid gave a 4:1 mixture of the 1,4-adduct and 1,2-adduct in 94% combined yield. HPLC and NMR analysis of the products indicate that the major 1,4-adduct is exclusively the α-benzoate but the minor 1,2-adduct is a 2:1 mixture of the α- and β-benzoates. The mixture of isomers was not separated but converted directly to the enone. Protection of the alcohol resulting from the epoxide opening by treatment with *tert*-butyldimethylsilyl chloride (TBSCl)/imidazole, removal of benzoate group in **8a** (MeLi/Et_2O; 83% over two steps), and oxidation of the resultant alcohol with pyridinium chlorochromate (PCC) in CH_2Cl_2 (yield 80%) afforded enone **8b**. 1,2-Addition of propargylmagnesium bromide to **8b** in the presence of $ZnCl_2$ in Et_2O at −78 °C, followed by protection of the alcohol with TMSOTf gave a separable 5:1 mixture of α-trimethylsilyl ether **9** and its β-isomer in 85% yield. Metalation of the alkyne (EtMgBr/THF, at 0 °C), followed by addition of paraformaldehyde gave the alcohol, which was converted to diol **10** by removal of the trimethylsilyl group (K_2CO_3, MeOH) in 97% overall yield. Compound **10** was coupled to (*Z*)-3-iodo-2-propenyl *tert*-butyldimethylsilyl ether with [Pd(OAc)$_2$] and CuI as catalysts[12] (97%). Subsequent bromination of the propargyl alcohol (CBr_4, PPh_3, lutidine/CH_3CN) and selective removal of the primary TBS group (HF_{aq}/CH_3CN, at −20 °C) gave bromide **11** in 57% yield. The cyclization of **11** under high-dilution conditions (10^{-2} M/THF, NaH, room temperature) and protection of the tertiary alcohol (TMSOTf, Et_3N, CH_2Cl_2) gave the cyclic ether **12** in 77% yield. The [2,3]Wittig rearrangement[13] of **12** under our previously described conditions[6,9] (*t*BuLi/THF, at −110 °C) was complete within 10 min. The rearrangement product **13** was obtained in 65% yield with high *cis* selectivity (90%) at the newly formed stereocenters.[14] Alcohol **13** was treated with phthalic anhydride, pyridine, and 4-(dimethylamino)pyridine (DMAP) at room temperature to afford the half ester, which was not isolated but desilylated directly under mild acidic conditions (40% HF_{aq}:CH_3CN = 5:95) at room temperature for 4 h to give the half ester **3**[16] in 47% overall yield after purification by column chromatography.



Scheme 2. Synthesis of **3** and **5b**. a) Trimethysilylacetylene, EtMgBr; b) Tf_2O, lutidine; c) [Pd(OAc)$_2$], PPh_3, BzOH; d) TBSCl, imidazole; e) MeLi; f) PCC; g) propargylmagnesium bromide, $ZnCl_2$; h) TMSOTf, NEt_3; i) EtMgBr, $(CH_2O)_n$; j) K_2CO_3; k) (*Z*)-3-iodo-2-propenyl *tert*-butyldimethylsilyl ether, [Pd(OAc)$_2$], PPh_3, CuI, *t*BuNH$_2$; l) CBr_4, PPh_3, lutidine; m) HF_{aq}, CH_3CN; n) NaH, THF; o) TMSOTf, NEt_3; p) *t*BuLi, THF, −110 °C; q) phthalic anhydride, pyridine, DMAP; r) HF_{aq}, CH_3CN, room temperature; s) DBU, THF, cyclohexadiene; t) Ac_2O, pyridine, DMAP.

As expected, the masked enediyne **3** was readily soluble in 10% MeOH aqueous solution and stable for more than 24 h at room temperature under neutral conditions and for more than one month at −20 °C. But under basic conditions (1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), THF, cyclohexadiene), β-elimination of the phthalate in **3**, followed by cycloaromatization of **4b** proceeded to give the aromatized product (see Scheme 1), which was converted to **5b**[17] in 25% overall yield for structure determination. When the phthalate derivative of **13** was treated with DBU in [D$_8$]THF, deuterium was incorporated at C(3) and C(6) of **5c** to the extent of 67% and 53%, respectively. The hypothesis that the biradical is generated from **3** is supported by deuterium incorporation at these positions.

The DNA-cleaving activity of the masked enediyne **3** was then examined. Supercoiled pBR322 DNA was incubated with **3** at various concentrations in 20 mM Tris-HCl buffer (pH 7.5) at 37 °C for 5 h in the absence of thiol (Fig. 1, lanes 6–8; Table 1). Lane 6 (0.1 mM **3**) indicated single strand DNA cleavage with the formation of Form II DNA. Form III DNA, the result of double strand cleavage, was observed with 1.0 mM **3** (lane 8).

Fig. 1. The concentration- and temperature-dependence of the DNA-cleaving activity of **3**; bands obtained on agarose gel by electrophoretic analysis after DNA strand scission.

Table 1. Percentages of Form I, Form II, and Form III DNA after treatment of pBR322 DNA with **3** under various conditions.

Lane	T [°C]	c(**3**) [mM]	Form I	Form II	Form III
1	[a]		85.9	14.1	0.0
2	4	1.0	16.4	74.7	8.9
3	20	1.0	13.6	77.7	8.7
4	37	1.0	7.9	63.3	28.7
5	50	1.0		fragmentation	
6	37	0.1	33.9	63.3	2.8
7	37	0.5	11.6	75.2	13.2
8	37	1.0	8.0	57.9	34.1
9	37	1.0(+DTT)	25.6	72.2	2.2

[a] Intact DNA.

This is in contrast to other DNA-cleaving molecules that alkylate DNA. In the presence of dithiothreitol (lane 9) the DNA-cleaving activity of **3** was not accelerated, indicating that the masked enediyne **3** is activated even in the absence of thiol. Next, the temperature-dependent DNA-cleaving activity was examined by incubation with 1 mM **3** for 5 h (lanes 2–5). As shown in lane 2, appreciable activity is apparent even at 4 °C. A kinetic study with 1.0 mM **3** showed that single strand DNA cleavage proceeded within 5 min on incubation at 37 °C (Table 2). These results suggest that **3** cleaves DNA through a biradical intermediate, which is generated by Bergman cycloaromatization of the highly strained nine-membered enediyne skeleton.

Table 2. Kinetic study of DNA cleavage by **3** (1 mM).

Incubation time [min]	Form I [%]	Form II [%]	Form III [%]
0	94.9	5.1	0
5	21.9	67.2	10.9
10	23.5	66.7	9.8
30	19.3	75.6	5.1
60	12.5	81.6	5.9

In summary, we have succeeded in the design and synthesis of a nine-membered KD analogue with DNA-cleaving activity in the absence of thiols. The biological properties of the designed analogue may underscore it as a potential lead for the further development of DNA-cleaving molecules. Introduction of DNA recognition sites at C(10) and/or C(11) is under investigation in our laboratory.

Self-Assembly of a Circular Double Helicate**

Bernold Hasenknopf, Jean-Marie Lehn,* Boris O. Kneisel, Gerhard Baum, and Dieter Fenske

Dedicated to Professor Guy Ourisson on the occasion of his 70th birthday

Helicates, metal complexes that form double[1-4] or triple helices[5-7] in solution and/or in the solid state, are generated by self-assembly of two or three ligand strands around suitable metal ions. Whereas the double helix of DNA results from the assembly of two complementary chains of nucleotides through hydrogen bonding, helicates form spontaneously from linear ligands composed of a series of discrete binding subunits through metal ion coordination. The process may be considered as resulting from the operation of a programmed system, in which the steric and interactional information stored in the ligands is read out by the metal ions following the algorithm defined by their coordination geometry.[3] Thus homostranded double[1,3,4] and triple[5,7] helicates have been obtained from chains of 2,2′-bipyridine (bpy) or 2,2′:6′,2″-terpyridine (terpy) groups connected by short covalent bridges, and metal ions having tetrahedral or octahedral coordination geometry. Recently, a heteroduplex helicate based on a tris-bpy strand, a tris-terpy strand, and pentacoordinated Cu^{II} ions has been described.[8]

The DNA double helix is usually acyclic but can also be closed into a cyclic structure, a circular DNA, as found in some viruses. By analogy, it would be of great interest to devise means of generating closed, circular helicates. We describe herein the self-assembly of such a supramolecular architecture. The tris-bpy ligand **L** and iron(II) chloride have been found to form spontaneously and quantitatively a circular double helicate, **cH** (Fig. 1), in other words, a double helicate closed into a ring, as indicated by ^{1}H NMR spectroscopy and mass spectrometry as well as by X-ray crystal structure determination.

The reaction of ligand **L**[5] with an equimolar amount of $FeCl_2$ in ethylene glycol at 170 °C gave a clear red solution, as expected for an iron–bpy complex. Addition of NH_4PF_6 precipitated a red solid, which was separated and analyzed. Its electronic absorption spectrum shows a band at 523 nm in the visible range, which corresponds to the metal–ligand charge transfer (MLCT) band of an "$Fe(bpy)_3$" unit.[9] This agrees with the complexation of three bpy units by each iron(II) ion. In view of the structure of ligand **L**, these three bpy units cannot belong to the same ligand strand. An inspection of molecular models shows that the central and a terminal bpy of one ligand strand cannot be arranged around the same Fe^{II} ion; also the complexation of the two terminal bpys of one ligand by one Fe^{II} ion results in deformation of the central bpy. Therefore, every Fe^{II} ion should complex one bpy from each of three different ligands **L**.

The ^{1}H NMR spectrum of the complex displays a singlet for the methyl groups, pointing to a similar environment for all the ligands in the Fe^{II} complex. The signals of CH_2 groups of the bridges between the bpy units appear as a singlet in the free ligand and as a multiplet in the complex. This splitting agrees with the formation of a helicoidal structure, in which these protons form an AA′BB′ system. The aromatic part of the spectrum shows three singlets and six doublets for the complex, each of which corresponds to two protons. Hence, the complex has a twofold symmetry axis through the C2–C2′ bond of the central bpy. The signals of the protons α to the nitrogens of both the central and the lateral bpys are shifted upfield relative to the signals of the free ligand. This indicates that all the bpy groups of the ligand are coordinated, since octahedral coordination of three bpy units on one metal ion brings these protons in proximity to the aromatic system of another bpy on the same metal center, resulting in the observed upfield shift.

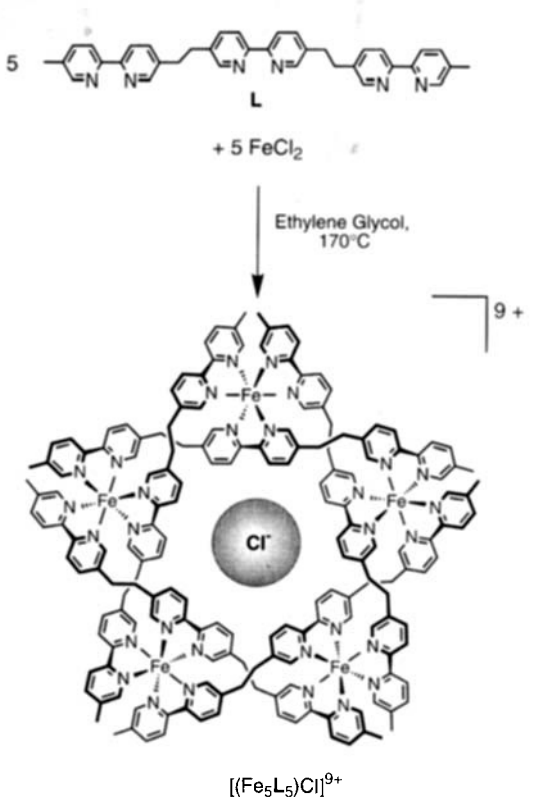

Fig. 1. Self-assembly of the circular helicate $[(Fe_5\mathbf{L}_5)Cl]^{9+}$ from five tris-bpy ligand strands **L** and five equivalents of $FeCl_2$.

All signals have been assigned unequivocally by a series of decoupling and NOE measurements. The NOE measurements allowed a further look into the structure of the complex. One observes interactions between all the protons α to the nitrogens, which must therefore be close in space. This is only possible if central and terminal bpys are coordinated to the same Fe^{II} ion. In view of the limited flexibility of ligand **L** it implies that the central bpy of one strand and the terminal bpys of two other strands are brought into proximity. To assure that all the coordination sites are occupied and open ends are avoided, the whole complex must be closed into a ring.

The electrospray mass spectrum (ESI-MS) indicates a complex with the composition $[(Fe_5\mathbf{L}_5)Cl](PF_6)_9$. The signals of cations arising from an initial complex $[(Fe_5\mathbf{L}_5)Cl](PF_6)_7^{2+}$ through the successive loss of PF_6 anions down to $[(Fe_5\mathbf{L}_5)Cl](PF_6)_2^{7+}$ are observed. The chloride ion must be bound strongly to the complex, since it is found in all fragments.

Single crystals were obtained from nitromethane/benzene and analyzed by X-ray diffraction.[10] The structure determination

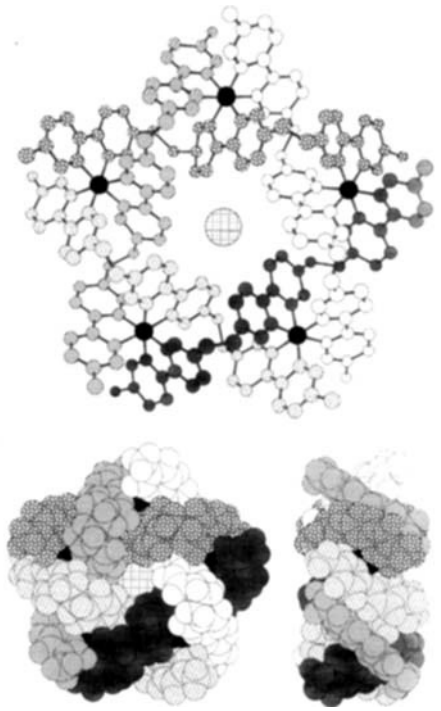

Fig. 2. Top: ball-and-stick representation of the crystal structure of the circular helicate $[(Fe_5L_5)Cl]^{9+}$ in the PF_6 salt. Bottom: CPK representations; left: top view; right: side view. The five ligand strands **L** are shown in different patterns, the Fe^{II} centers are black.

confirms the other results (Fig. 2). The complex consists of five Fe^{II} ions, five ligands **L**, and a chloride ion: $[(Fe_5L_5)Cl]^{9+}$. Each Fe^{II} ion has a distorted octahedral coordination sphere occupied by three bpy groups,[14] two terminal and one central, belonging to three different ligand strands. The metal ions lie almost in one plane and form the corners of a pentagon with an edge length of 8.4 Å (Fe–Fe distance). Neighboring Fe^{II} ions are connected by two strands **L**, which cross each other, resulting in a rotatory sense of the structure. The ligands wrap helically around the connecting line between the Fe^{II} ions. A full turn is completed between three successive metal centers. The rotatory sense between the metals in the complex is the same throughout the structure.

The $[Fe_5L_5]^{10+}$ cation can be described as a *circular double helix* resulting in a torus, with an outer diameter between two opposite carbon atoms of about 22 Å. The inner cavity has a radius of 1.75 Å and contains a chloride ion (ionic radius 1.8 Å). This tight inclusion into a cavity bearing ten positive charges agrees with the strong binding of the chloride ion indicated by the stability of the complex in ESI-MS with respect to the loss of Cl^- and by the fact that no exchange takes place in the presence of a large excess of another anion such as PF_6^- or $CF_3SO_3^-$. The torus $[Fe_5L_5]^{10+}$ is thus a specific receptor for chloride.

The salt of the chiral cation is obtained as a racemic mixture. The unit cell contains two tori of opposite rotatory sense. First attempts at chromatographic separation (Sephadex-SP C-25, 40–120 μm, eluting with an aqueous solution of sodium (+)-tartratoantimonate[15]) yielded two optically active fractions. Their circular dichroism spectra display an opposite Cotton effect at the same wavelength maxima. Full resolution of the two enantiomers was not achieved at this stage.

A number of multinuclear complexes present a circular arrangement of metal centers[16] and may include small atoms or molecules.[17] In these structures the ligands bridge two adjacent metal centers. The supramolecular architecture of $[(Fe_5L_5)Cl]^{9+}$ exhibits unique features: each ligand strand bridges three metal centers and together they form a double helix, which is closed into a torus, representing therefore a circular helicate of fivefold symmetry [5]**cH**, the helicate analog of circular DNA.

The complexation of ligand **L** with Ni^{II} resulted in an architecture also containing octahedrally coordinated metal centers.[5] However, in this case a triple helix formed, in which three ligand strands **L** are wrapped around three Ni^{II} ions. This triple helicate composition $[Ni_3L_3]^{6+}$ was obtained with both $Ni(ClO_4)_2$ and $NiCl_2$ under exactly the same conditions as those leading to the formation of the torus using $FeCl_2$. Thus, different supramolecular architectures are generated with two metal ions which both display octahedral coordination geometry. Preliminary results indicate that the two architectures can be obtained from both metal ions under suitable reaction conditions; the triple helicate is formed first and then converted into the cyclic structure.

Furthermore, the reaction of the ligand **L** with different iron salts yields different complexes. Preliminary results show that $Fe(BF_4)_2$ gives a hexameric $[Fe_6L_6]^{12+}$ complex which could also have a circular structure. The self-assembly is therefore not only determined by the ligand and the coordination geometry of the metal ion, but also by the nature of the counteranion, thus opening the way to a range of novel architectures.

The torus also lends itself to further elaboration. For instance, the covalent connection of the two terminal bpy units of two different strands at each Fe^{II} ion would yield a molecule with the topology of a fivefold knot.[18] The addition of the circular [5]**cH** structure to the linear double[1–4] and triple[5–7] helicates described previously, represents a novel step and warrants further exploration of the developing "helicate world".

The present results are also of much significance from another point of view related to an area of great current activity—combinatorial chemistry. The generation of a defined assembly that depends on the nature of a bound substrate (for example the chloride ion in $[(Fe_5L_5)Cl]^{9+}$) may be considered either as the result of templating by the substrate, or conversely, and much more interestingly, as the result of the spontaneous assembly of a suitable number of components to form a species capable of strongly binding a given substrate. In other words, the latter represents a combinatorial generation of a receptor by self-assembly of a set of components (identical or different) into the entity that most strongly binds the substrate. Thus, the pentameric cyclic structure $[(Fe_5L_5)Cl]^{9+}$ is selected[19] among all possible oligomers when chloride ions are present; other entities may be formed with other anions.

In general terms, such multicomponent self-assembly of a receptor amounts to the generation/selection from a *virtual combinatorial library* (VCL, a library made up of all possible combinations in number and nature of the available components) of that supramolecular entity, among all those possible, that best binds a given substrate, by recruiting the best suited components from the set of those available. Further exploration of this VCL concept is being actively pursued.[21]

Experimental Procedure

The tris-bpy ligand **L** (67 mg, 0.12 mmol) and iron(II) chloride ($FeCl_2 \cdot 4H_2O$, 24 mg, 0.12 mmol) were mixed in ethylene glycol (10 mL) under argon. The red suspension was heated to 170–180 °C overnight. A dark red solution formed. After the reaction mixture had cooled down to room temperature, an aqueous solution of NH_4PF_6 (ca. 1 g in 40 mL) was added. A red gellike solid formed, which was isolated by centrifugation, washed with methanol/ether 1/1, and dried in a desiccator to provide 104 mg of a red powder. Thin-layer chromatography: Al_2O_3, $CH_3CN:H_2O$ (5% NH_4PF_6), $R_f = 0.8$; SiO_2, $CH_3CN:H_2O:KNO_3$ aq. sat. 5:4:1, $R_f = 0.3$;

^{1}H NMR (400 MHz, CD_3CN, 25 °C, TMS): δ = 2.21 (s, 6H; CH_3), 2.6–3.0 (m, 8H; CH_2), 6.47 (s, 2H; 6_A), 6.57 (s, 2H; 6_B), 7.23 (s, 2H; $6'_A$), 7.52 (br. d, 4H; $4_A + 4_B$), 8.08 (d, 7.2 Hz, 2H; $4'_A$), 8.25 (d, 8.3 Hz, 2H; 3_A), 8.47 (d, 8.3 Hz, 2H; $3'_A$), 10.02 (d, 8.3 Hz, 2H; 3_B); A = terminal bpy, B = central bpy; ESI-MS: m/z 2034.24 $[(Fe_5L_5Cl)(PF_6)_7]^{2+}$, 1308.73 $[(Fe_5L_5Cl)(PF_6)_6]^{3+}$, 945.15 $[(Fe_5L_5Cl)(PF_6)_5]^{4+}$, 726.98 $[(Fe_5L_5Cl)(PF_6)_4]^{5+}$, 581.54 $[(Fe_5L_5Cl)(PF_6)_3]^{6+}$, 477.52 $[(Fe_5L_5Cl)(PF_6)_2]^{7+}$; IR (KBr): ν = 3406 (br), 3032 (m), 1602 (m), 1477 (s), 1401 (m), 1247 (m), 1041 (m), 840 (vs), 732 (m), 558 (s) cm^{-1}; UV/Vis (CH_3CN): λ_{max} (ε_{max}): 523 (3.80×10^4), 313 (2.37×10^5), 269 (1.36×10^4), 257 nm (1.38×10^4 $dm^3 mol^{-1} cm^{-1}$); correct C, H, N analysis.

[10] Crystal data for $[\{Fe_5L_5)Cl\}_2](PF_6)_{17.5}Cl_{0.5} \cdot 11\,H_3CNO_2 \cdot 40.5\,H_2O$: diffractometer and data collection: STOE IPDS (−80 °C), graphite-monochromated $Mo_{K\alpha}$ radiation (λ = 0.71073 Å), monoclinic, space group $P2/n$, a = 38.918(8), b = 27.036(5), c = 52.492(11) Å, β = 97.42(3)°, V = 54769(19) Å^3, Z = 2, μ = 0.417 mm^{-1}, $F(000)$ = 20212, ρ_{calc} = 1.208 $Mg\,m^{-3}$, M_r = 19914.16, $2\theta_{max}$ = 45°. Structure solution and refinement: Primary structure solution by direct methods (SHELXS-92) [11a]. Anisotropic refinement for all non-hydrogen atoms (SHELXL-93) [11b], as indicated by R_{free} tests [12]. A riding model starting from calculated positions was employed for the hydrogen atoms; no hydrogen positions were calculated for nitromethane and water molecules. 162803 measured reflections, 69755 independent [R(int) = 0.0874], of which 42481 within a resolution shell of $8.00 \geq d \geq 1.06$ Å were employed in the refinement of 6004 parameters using 126032 restraints, as described in the following. 1) Ligands L: planarity for the aromatic systems and for the coordination spheres around each 1- and 4-position of the pyridyl rings; combined 1,2/1,3 distance restraints for chemically equivalent distances within the bpy units allowing free rotation between the aromatic systems; rigid-bond and similarity restraints for the anisotropic displacement parameters. 2) PF_6 Anions: combined 1,2/1,3 distance restraints for chemically equivalent distances, additional fitting of P···F and F···F distances to target values of 1.60 and 2.24 Å, respectively (e.s.d. 0.03 Å). Rigid-bond and similarity restraints for the anisotropic displacement parameters. Constraints were employed for the anisotropic displacement parameters of opposite fluorine positions. Most of the anions show up to threefold positional disorder, which could not always be resolved and modeled completely. 3) "Free" chlorine anions: the anisotropic displacement parameters were restrained to be approximately isotropic (e.s.d. 0.10 Å). Two positions were treated as being one-fourth occupied. "Anti-bumping" restraints were applied to prevent close contacts between isolated ions and other molecules. 4) Nitromethane: planarity for the coordination spheres around the nitrogen atoms; combined 1,2/1,3 distance restraints for chemically equivalent distances; additionally fitting of N–C, N–O, and O···O distances to target values of 1.55, 1.20, and 2.16 Å, respectively (e.s.d. 0.03 Å). Rigid-bond, similarity, and isotropic restraints for the anisotropic displacement parameters. Some of the solvent molecules show twofold positional disorder, which could be resolved. 5) Water: the anisotropic displacement parameters were restrained to be approximately isotropic (e.s.d. 0.10 Å). Some water positions were treated as half occupied, most water sites were given full occupancies. "Anti-bumping" restraints were applied to prevent close contacts between isolated molecules, and "Babinet's principle" was employed to model diffuse water [13]. The structure was refined against F^2 (full matrix least squares) with the weighting scheme $w^{-1} = \sigma^2(F_o^2) + (0.3526\,P)^2 + 207.5267\,P$, with $P = (F_o^2 + 2F_c^2)/3$, $R1$ = 0.1552 ($F > 4\sigma F$) [$R1$ = 0.2298 (all data)] and $wR2$ = 0.5332 (all data), GooF on F^2 = S = 1.058, max./min. residual density: +1.132/−0.981 e Å^{-3}. ($R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$, GooF = $S = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1/2}$, where n = number of reflections and p = number of parameters). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-46. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).

Planar Bischlorophyll Derivatives with a Completely Conjugated π-System: Model Compounds for the Special Pair in Photosynthesis**

Laurent Jaquinod, Mathias O. Senge, Ravindra K. Pandey, Timothy P. Forsyth, and Kevin M. Smith*

Chlorophylls play a central role in photosynthesis as both antenna arrays and reaction centers. One of the most intriguing problems associated with mimicking their biological function in model systems has been the synthesis of suitable model compounds for the delocalized state of the "special pair" chlorophylls in the reaction center.[1] Numerous attempts have been made to develop model compounds for reaction center chloro-

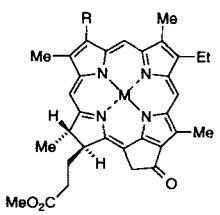
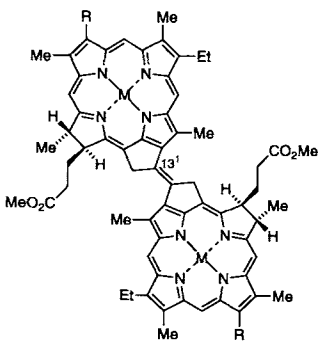
phylls in general.[2] Supramolecular approaches towards the reaction center have yielded promising results,[3a] but only few attempts have been made to address models of the special pair.[2, 3b] Criteria for a good model of the special pair excited state include two chlorin macrocycles in close proximity, a substituent pattern as close as possible to that in natural chlorophylls, and interaction between the π-electron systems of the pair. Even though the special pair itself consists of partly cofacial bacteriochlorophylls overlapping in the ring A area, any kind of electronic coupling between the two components of a pair should produce models worthy of investigation. Along these lines, much recent work has been devoted to the preparation of bismacrocycles in which the two chromophores are coplanar,[4] thereby allowing electronic coupling between the two macrocycles. To date, these systems have consisted of porphyrin subunits. We felt that a more meaningful model for the special pair would consist of a bischlorin in which the two chlorin subunits are coplanar and thus strongly coupled electronically.

We report here the synthesis, spectroscopic properties, and structural analysis of a novel planar bisphaeophorbide system in which the two macrocycles are connected directly by a C=C bridge. The titanium-mediated, reductive coupling of ketones (McMurry reaction)[5] was the key reaction in our approach, and the substrates were derived, initially, from methyl mesopyrophaeophorbide *a* **1**, which possesses a reactive 13^1-carbonyl function, still contains the major structural features of native chlorophyll, and is easily prepared from chlorophyll *a*.[6] McMurry coupling of nickel(II) complex **2** at $-10\,^{\circ}C$ in dimethoxyethane (DME) produced the green nickel(II) bischlorin **3** in 44% yield (61% based on recovered starting material). The ^1H NMR spectrum of **3** indicated a single diastereomer with C_2 symmetry. When the coupling reaction of **2** was performed at $-30\,^{\circ}C$, the formation of the pinacol intermediate could be monitored by disappearance of the Q-band at 638 nm and appearance of another at 620 nm. Chromatography on alumina (Brockmann activity III) or dissolution in dimethyl sulfoxide (DMSO) caused reversion of the pinacol to starting material.[7]

Since attempts to demetalate **3** with concentrated H_2SO_4 led to decomposition, the metal-free bisphaeophorbide **4** was prepared by coupling the zinc(II) monomer **5** in the presence of 3.5 equivalents of pyridine. The zinc(II) ion was removed readily upon treatment with trifluoroacetic acid (TFA) in CH_2Cl_2. After chromatographic purification the free-base bisphaeophorbide **4** was obtained in 46% yield. Hydrogenation (10% Pd/C) of **4** gave quantitatively **6**, and the main Q-band shifted from 752 to 740 nm. Reaction of **6** with $Zn(OAc)_2$ gave the bischlorin **7**.

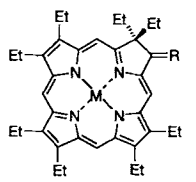


1 M = 2H; R = Et
2 M = Ni; R = Et
5 M = Zn; R = CH=CH$_2$



3 M = Ni; R = Et
4 M = 2H; R = CH=CH$_2$
6 M = 2H; R = Et
7 M = Zn; R = Et

To extend this methodology we examined other chlorin substrates containing ketone groups. When a McMurry coupling of the nickel(II) complex **8**[8] was attempted, the expected bischlorin was not produced. Instead chlorin **9** was obtained in quantitative yield. In the case of the zinc(II) analogue **10**, a similar reduction (in presence of pyridine) could be effected, giving compound **11** in 60% yield. This direct reduction of ketochlorins is unusual, as they have been shown to be unreactive to most reducing agents[8] except for alkyllithiums, though a two-step reduction has been reported.[9] McMurry coupling between acetone and **2** (acetone/**2** = 10/1) gave the isopropylidene adduct in moderate yield; the Q-band of this compound is only slightly blue-shifted ($\Delta\lambda = 14$ nm) compared to that of the starting material.



8 M = Ni; R = O
9 M = Ni; R = 2H
10 M = Zn; R = O
11 M = Zn; R = 2H

The most notable feature of the bischlorins is the large bathochromic shifts of the main Q-band relative to the those of the monomeric chlorins (Fig. 1). For instance **3** shows a 92 nm

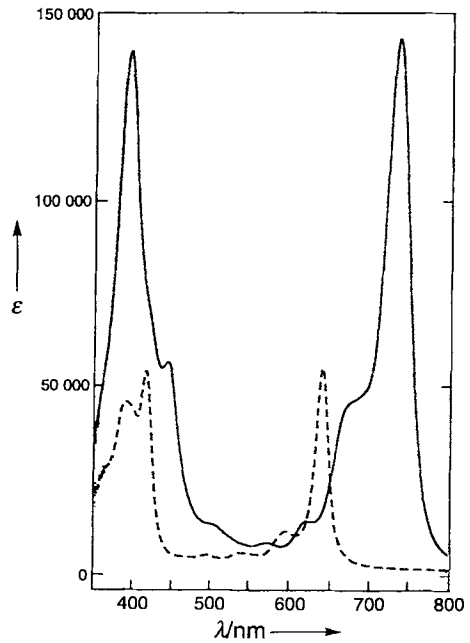


Fig. 1. UV/Vis spectra of **3** (—) and **2** (– – –) in CH_2Cl_2.

red-shift of the highest wavelength absorbance relative to the that of the monomeric nickel(II) compound. The bathochromic shift and the hyperchromic effect displayed by **3** support the hypothesis of "electronic delocalization" within the two phaeophorbide subunits. The Q-bands are sensitive to concentration changes, undergoing a slight blue shift with increased concentration. In the ^1H NMR spectrum of **6** the additional upfield shift for the NH protons ($\delta = -0.95$ and -2.81 versus 0.60, -1.60 for **1**) and the extra downfield chemical shifts of the *meso* protons further support the existence of electronic delocalization.

The molecular structure was established by X-ray crystallography (Fig. 2).[10a] The double bond character of the connecting bridge in **6** is clearly shown by the $C(13^1)-C(13^1)'$ bond length of 1.34(2) Å. With the exception of the reduced pyrrole rings the

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1841 $ 15.00+.25/0

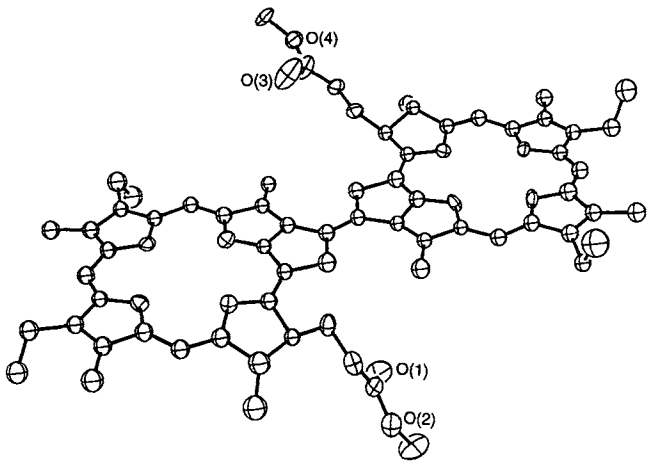

Fig. 2. Molecular structure of **6** in the crystal. Ellipsoids are drawn for 50% occupancy. Hydrogen atoms have been omitted for clarity.

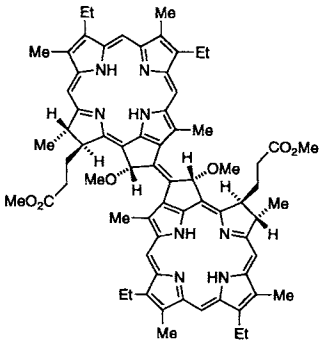
molecule is essentially planar. Deviations from planarity of the macrocycle atoms from their least-squares plane are 0.125 and 0.09 Å for the two phytochlorin units. Delocalization of the electrons in the bischlorin system is also emphasized by the planar arrangement of both phytochlorin systems; the two N_4 planes form an angle of only 2.2°. For steric reasons the two reduced pyrrole rings occupy opposite sides of the plane formed by the ethene bridge and the two propionic ester side chains point to opposite sides of the bischlorin.

The fusion of two chlorophyll derivatives through a direct ethene linkage gives rise to some interesting chemical properties. Both the nickel(II) and zinc(II) bischlorins **3** and **4**, respectively, decompose slowly in solution, whereas the metal-free dimer **6** is quite stable for long periods in solution. But after several months in a chloroform/methanol solution in the presence of air, compound **6** is converted into another compound (Q-band at 726 nm). X-ray crystallography showed the new compound to be the 13^2,$(13^2)'$-dimethoxy derivative **12** (Fig. 3).[10b] Formation of **12** can be explained by an oxygen-promoted double allylic oxidation of **6**, suggesting a lower oxidation potential for **6** than in methyl mesopyrophaeophorbide *a*. The molecular structure of **12** is similar to that of **6**, with an [1.378(12) Å]. One interesting feature is the uniquely *syn* orientation of the methoxy groups at $C13^2$ on one face of the molecule and the C17-propionic ester groups on the other face.



12

Experimental Procedure

Bischlorin **4:** $TiCl_3(DME)_{1.5}$ (1.20 g, 4.12 mmol) and Zn/Cu couple (1.10 g, 15.6 mmol) were added to a dry flask in a dry box. Anhydrous THF (40 mL) was added to the reaction flask, and the resulting mixture was heated at reflux for 3 h under an inert atmosphere. The mixture was then cooled to room temperature; pyridine (0.12 mL, 1.5 mmol, 3.65 equiv) and zinc(II) methyl pyrophaeophorbide *a* **5** (250 mg, 0.41 mmol) were added. The resulting mixture was stirred for 2 h at room temperature and then filtered through a short plug of Grade III alumina, eluting with CH_2Cl_2/THF (10/1). The solvents were evaporated and the residue was redissolved in CH_2Cl_2 (20 mL). TFA (5 mL) was added and the mixture was stirred at room temperature for 0.5 h. The organic phase was washed with water, saturated aqueous sodium carbonate, and again with water, and was concentrated to dryness. The final residue was chromatographed on Grade III alumina, eluting with CH_2Cl_2/cyclohexane (2/1). The main brown fraction was collected and recrystallized from CH_2Cl_2/toluene to give 100 mg (46%) of **4**. M.p. > 330 °C; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 404 (208 500), 486 (87 800), 526 (49 800), 564 (31 600), 600 (19 900), 674 (18 700), 692 (44 500), 752 nm (253 000); ^{1}H NMR (300 MHz, $CDCl_3$): δ = 9.73, 9.68, 8.95 (s, 2H each, *meso* H), 7.91 (dd, 2H, 3^1-CH, J = 18, 12 Hz), 6.02 (m, 4H, 3^2-CH *trans* to 3^1-CH + 2H 13^2-CH_2), 5.83 (d, 2H, 3^2-CH *cis* to 3^1-CH, J = 12 Hz), 5.56 (d, 2H, 13^2-CH_2, J = 18 Hz), 4.78 (m, 4H, 17-CH + 18-CH), 3.91 (q, 4H, CH_2CH_3, J = 7.5 Hz), 4.08, 3.65, 3.42, 3.39 (each s, 6H each), 2.95–2.20 (m, 8H), 2.16 (d, 6H, 18-CH_3, J = 6.9 Hz), 1.83 (t, 6H, CH_3 of Et, J = 7.5 Hz), −1.04 (s, 2H, NH), −2.73 (s, 2H, NH). The compound gave the expected mass spectrum and elemental analysis.

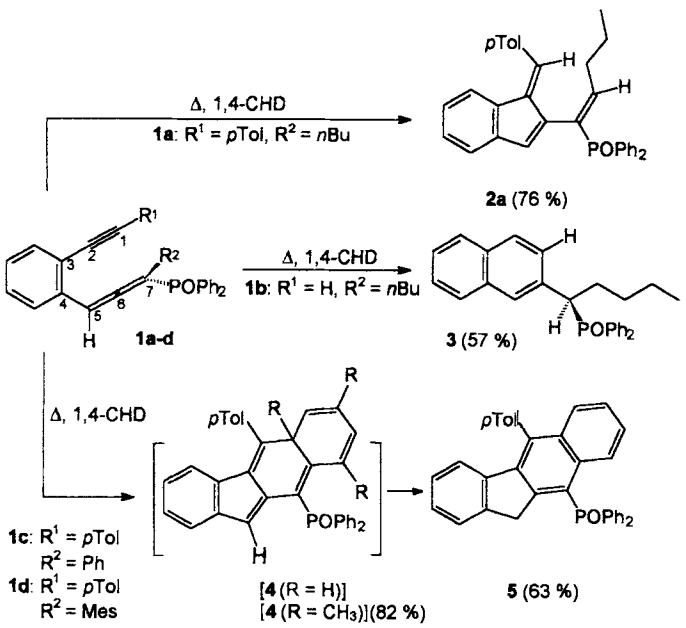
An Unprecedented Biradical Cyclization as an Alternative Pathway to the Myers–Saito Cycloaromatization in the Thermal Reactions of Enyne Allenes**

Michael Schmittel,* Marc Strittmatter, and Susanne Kiau

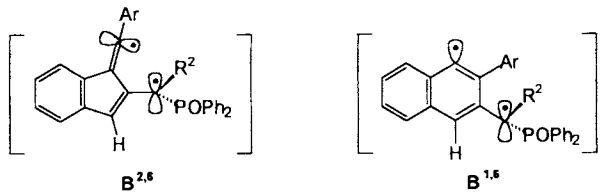
Dedicated to Professor Horst Prinzbach on the occasion of his 65th birthday

During the last few years interest in the thermal biradical cyclizations[1] of enediynes, enyne cumulenes, and enyne allenes has increased dramatically. This trend is due to the fascinating mechanisms of these systems operative in natural antitumor antibiotics[2] as well as their potential in the synthesis of carbocyclic systems.[3] Consequently, numerous derivatives of enyne allenes with various substituents and substitution patterns, which on heating generally furnish the expected Myers–Saito cyclization products,[1b,d] have already been studied.[4] However, we found quite unexpectedly that the simple attachment of an aryl group to the alkyne terminus of the enyne allenes redirects the reaction course to a novel C^2-C^6 cyclization, giving rise to formal ene[5] and Diels–Alder products (Scheme 1).[6]

To account for this surprising C^2-C^6 cyclization of **1a,c,d** we have postulated[5,6] the biradical intermediate $\mathbf{B}^{2,6}$ (Scheme 2), although in principle, **2a**, **4** (R = CH_3), and **5** may also arise from a concerted reaction. However, since aryl groups are known to stabilize vinyl radicals,[7] it was suggested that this stabilizing effect would favor formation of biradical $\mathbf{B}^{2,6}$ over biradical $\mathbf{B}^{1,6}$, which is a key intermediate in the Myers–Saito cyclization.[8]

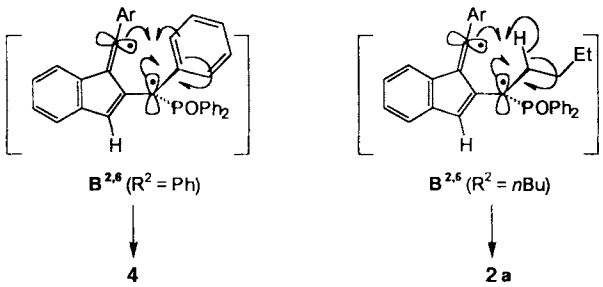


Scheme 1. The switch from the Myers–Saito to a novel C^2-C^6 cyclization in the thermal reaction of enyne allenes (1,4-CHD = 1,4-cyclohexadiene; Mes = 2,4,6-trimethylphenyl).



Scheme 2. Biradicals $\mathbf{B}^{2,6}$ resulting from C^2-C^6 cyclization and $\mathbf{B}^{1,6}$ from the Myers–Saito cycloaromatization of aryl-substituted enyne allenes.

The biradical intermediate $\mathbf{B}^{2,6}$ could easily lead to ene- and Diels–Alder-type products depending on the nature of group R^2 (Scheme 3), and a plethora of other useful reactions should be possible as well. Consequently, we have conducted a series of experiments to elucidate the mechanism of the novel C^2-C^6 cyclization and herein present evidence for a benzofulvene biradical $\mathbf{B}^{2,6}$ intermediate in the cyclizations examined.



Scheme 3. Two follow up reactions of the postulated biradical intermediate $\mathbf{B}^{2,6}$ generated from aryl-substituted enyne allenes.

The first evidence for a stepwise mechanism was provided by the activation barriers for the reactions presented in Scheme 1. The activation data for the formal ene and Diels–Alder reaction (Table 1) proved to be remarkably similar. In addition, the almost identical activation barriers for the formal Diels–Alder reactions of the aryl-substituted enyne allenes **1c** and **1d** are definitely not reconcilable with a concerted reaction. In such a case, the activation energy of **1d** would be expected to be much higher than that of **1c**, since the bulky mesityl group should slow down the pericyclic reaction. Indeed, we are not aware of any examples of an analogous cycloaddition across a mesitylene ring.[9] Even under much more extreme conditions than those applied for the phenyl analogues, cycloaddition does not occur.[10] Another mechanistically significant result is that the rates of the transformations **1a** → **2a** and **1c** → **5** were not affected by the change from an unpolar solvent (mesitylene or benzene) to DMSO. This finding precludes a zwitterion as an alternative intermediate.

Unfortunately, all attempts to trap the postulated biradical $\mathbf{B}^{2,6}$ by an intermolecular reaction (O_2, PhSH, $(Me_3Si)_3SiH$, 1,4-cyclohexadiene 2,2,6,6-tetramethylpiperidine *N*-oxide) failed so far. Thus, in order to obtain information about the lifetime of the presumably short-lived biradical, experiments based on the cyclopropylmethyl radical clock were devised, using the cyclopropyl-substituted enyne allene **1e** (Scheme 4).[11,12] The ring opening of the *trans*-(2-phenylcyclopropyl)benzyl radical is known to be extremely rapid (*k* (80 °C) =

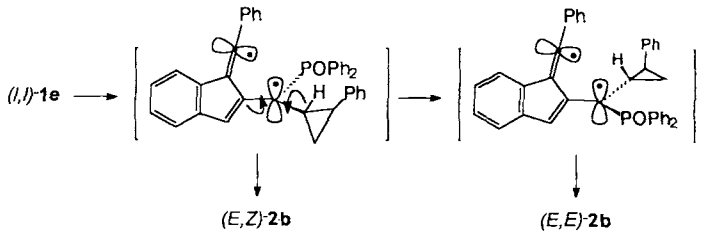
[a] Chiral centers are denoted as C*.

At this point the failure to observe ring-opened products rather seemed to testify against a biradical intermediate. However, we were finally able to separate the two diastereomeric *trans* enyne allenes **1e** ((*u,l*) and (*l,l*))[14] by HPLC. The thermal cyclization of (*u,l*)-**1e** furnished a mixture of (*E,E*)-**2b** and (*E,Z*)-**2b** (33:21, overall yield 54%), while that of (*l,l*)-**1e** provided a mixture of (*E,Z*)-**2b** and (*E,E*)-**2b** (53:7, overall yield 60%) (Scheme 5). Control experiments confirmed that neither



Scheme 5. Proposed mechanism for the thermal cyclization of (*l,l*)-**1e**: Coupled bond rotation in the biradical intermediate.

the enyne allenes (*u,l*)- and (*l,l*)-**1e** nor the products (*E,E*)-**2b** and (*E,Z*)-**2b** interconvert. As a consequence, this ene reaction is not stereospecific, which indicates that a stepwise mechanism proceeding via a reactive intermediate such as biradical **B**[2,6] may be in operation.

Two plausible pathways for the conversion of biradical **B**[2,6] into a mixture of (*E,E*)-**2b** and (*E,Z*)-**2b** are open for discussion: a coupled rotation about the bonds linking the radical center to the cyclopropyl group and to the benzofulvene moiety, and reversible opening of the cyclopropyl ring. PM3 calculations[15] indicate that the activation barrier for the coupled bond rotations should be on the order of 6 kcal mol^{-1}, which is similar to the barrier for cyclopropyl ring opening (E_a = 6.15 kcal mol^{-1}).[13] The rate constant for hydrogen transfer in **B**[2,6] has to be much faster than 10^6 s^{-1} (80 °C), a value found for intramolecular hydrogen transfer from an alkyl group to a vinyl radical via a six-membered ring transition state.[16] At present, however, further investigations are required to obtain a more precise value.

With the assumption of a biradical intermediate all of the experimental results can be readily rationalized: a) The switch from the Myers–Saito cyclization to a novel C^2–C^6 cyclization that occurs when hydrogen or alkyl substituents[3a,b] at the alkyne terminus are replaced by an aryl group results from the stabilization of biradical **B**[2,6] through an adjacent aryl group. b) A biradical intermediate convincingly explains how formally different reactions like the ene reaction and the Diels–Alder cycloaddition can have almost identical activation barriers. c) The almost identical activation barriers for the cycloadditions of **1c** and **1d**, which does not support a concerted reaction pathway due to the different steric demands of the aryl substituents,

is readily explained by a two-step process with formation of $\mathbf{B}^{2,6}$ as the rate-determining step. d) The existence of an intermediate is the only rationalization for the nonstereospecific hydrogen transfer in the reaction of **1e**. e) The lack of solvent effects on the rates of the formal ene and Diels–Alder reactions supports the proposed biradical and excludes a zwitterionic intermediate.

In summary, a novel thermal C^2-C^6 cyclization of substituted enyne allenes has been established for substrates in which an aryl group is affixed to the alkyne terminus. Apparently, aryl substitution raises the barrier for the Myers cycloaromatization and lowers the barrier for the biradical C^2-C^6 cyclization, rendering the latter one the exclusive pathway.[17] Further mechanistic work on this intriguing reaction and its synthetic applications is currently in progess in our group.

Photoinduced Ring-Opening Metathesis Polymerization (PROMP) with Photochemically Generated Schrock-Type Catalysts

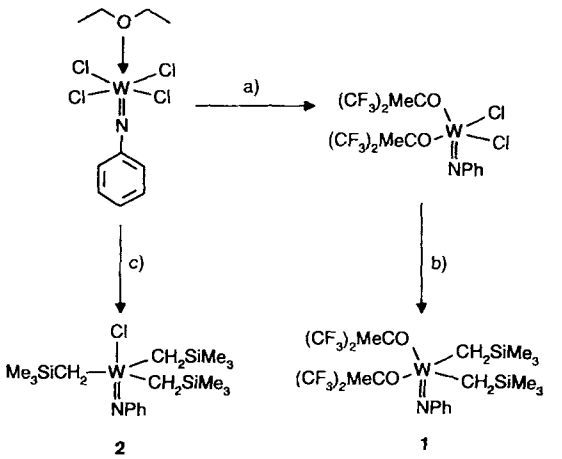
Paul A. van der Schaaf,* Andreas Hafner, and Andreas Mühlebach

Ring-opening metathesis polymerization (ROMP) is a versatile tool for the preparation of a wide variety of polymers.[1] Since the postulated mechanism by Herisson and Chauvin in 1970[2] that metal alkylidenes[3] are the active species in this type of reaction and the discovery by Schrock et al. in 1974 that these are generated by an α-H abstraction reaction between two alkyl substituents,[4] a tremendous amount of effort has been directed, successfully, to the design of well-defined one-component ROMP initiators. To date, a broad range of initiators is known with a versatile range of applications. The best studied initiators are those based on early transition metals, in particular molybdenum and tungsten complexes developed by Schrock et al.[5] These compounds are excellent initiators for a wide variety of monomers, but their main disadvantage is their lack of latency (thermal stability) in the presence of pure monomers. Although there are indications that alkyl complexes of early transition metals can be light-sensitive and even that irradiation can accelerate α-H abstraction reactions,[6] no examples are known, besides our own work on Ru^{II} complexes, using the principle of photoinduced ring-opening metathesis polymerization (PROMP) with well-defined, one-component metal complexes.[7, 8] This is even more surprising when one considers that photoprocesses are known for almost all other polymerization reactions and employed in numerous commercial applications.[9] We report here the first results in the field of photoinduced ROMP (PROMP) reactions using simple alkyl tungsten complexes *and* light for the in situ generation of active ROMP initiators.[10]

Complexes **1** and **2** are easily prepared by standard transmetalation procedures (Scheme 1). Both **1** and **2** are mois-

$[W(=NPh)(CH_2SiMe_3)_2\{OCMe(CF_3)_2\}_2]$ **1**

$[W(=NPh)(CH_2SiMe_3)_3Cl]$ **2**



Scheme 1. Synthesis of the complexes **1** and **2**: a) 2 equiv $LiOCMe(CF_3)_2$ in Et_2O at 0 °C, b) NEt_4Cl and $Zn(CH_2SiMe_3)_2$ in CH_2Cl_2 at 0 °C, c) NEt_4Cl and 1.5 equiv $Zn(CH_2SiMe_3)_2$ in CH_2Cl_2 at 0 °C.

ture-sensitive compounds; **1**, as a crystalline material, can be handled in air for short periods. Both complexes are thermally very stable. Solutions in [D_8]toluene can be heated at 80 °C for at least one day without decomposition products apparent by ^{1}H NMR spectroscopy. The ^{1}H NMR data (see Experimental Procedure) suggest that in both complexes the alkyl groups are *cis* positioned. For direct proof of the stereochemistry an X-ray structural determination of **1** was carried out (Fig. 1).[11]

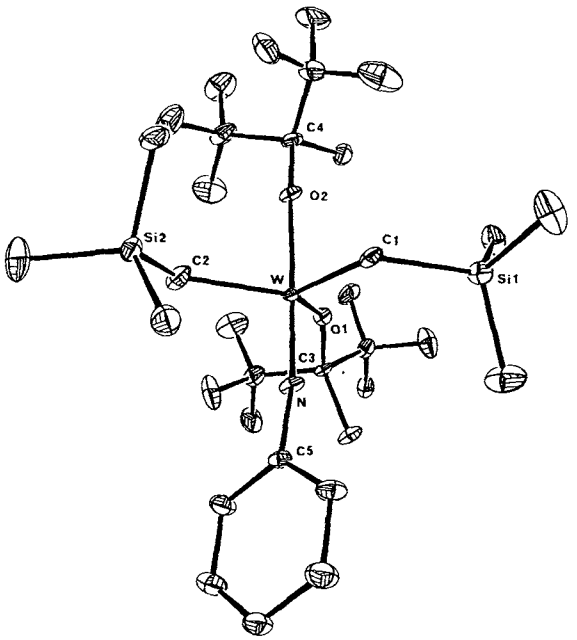

Fig. 1. Molecular structure of **1** (hydrogen atoms are ommited for clarity). Selected bond lengths [Å] and angles [°]: W–C1 2.11(1), W–C2 2.09(1), W–O1 1.919(7), W–O2 1.982(6), W–N 1.753(7); W-C1-Si1 121.7(7), W-C2-Si2 117.2(5), W-O1-C3 137.3(6), W-O2-C4 161.5(7), W-N-C5 171.2(7).

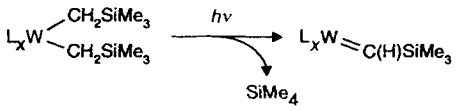
The crystal structure of **1** shows clearly that the two trimethylsilylmethyl groups have a *cis* relationship, as desired for an α-H abstraction reaction. To prove that Schrock-type initiators are formed during irradiation, solutions of **1** and **2** in C_6D_6 were irradiated with UV light and ^{1}H NMR spectra were recorded (Scheme 2). Unfortunately, only decomposition products were observed. However, the in situ formation of an alkylidene metal complex could be proven indirectly by trapping reactions with an aldehyde.[12]



Scheme 2. Schemetic representation of a photoinduced α-H abstraction reaction.

Useful photoinitiators must fulfill several requirements. Firstly, they should, of course, be photoactive, and secondly, they should be latent, that is thermally stable, in the presence of the monomer and initiate the polymerization reaction only when activated with light.

UV irradiation of **1** and **2** in the presence of norbornene or dicyclopentadiene (DCPD) yielded the ring-opening metathesis polymers quantitatively.[13] The photoactivity was demonstrated as well by photo-DSC (DSC = differential scanning calorimetry) experiments and viscosity measurements during UV irradiation of solutions of **1** or **2** in DCPD. The results of the photo-DSC experiments for solutions of 1% of **1** and **2** in DCPD are given in Figure 2. As soon as the light beam is switch on the polymerization is initiated. Whereas the polymerization reaction with **2** is complete after 30 seconds of irradiation, the polymerization reaction with **1** continues when the light is switched off after 3 minutes of irradiation.

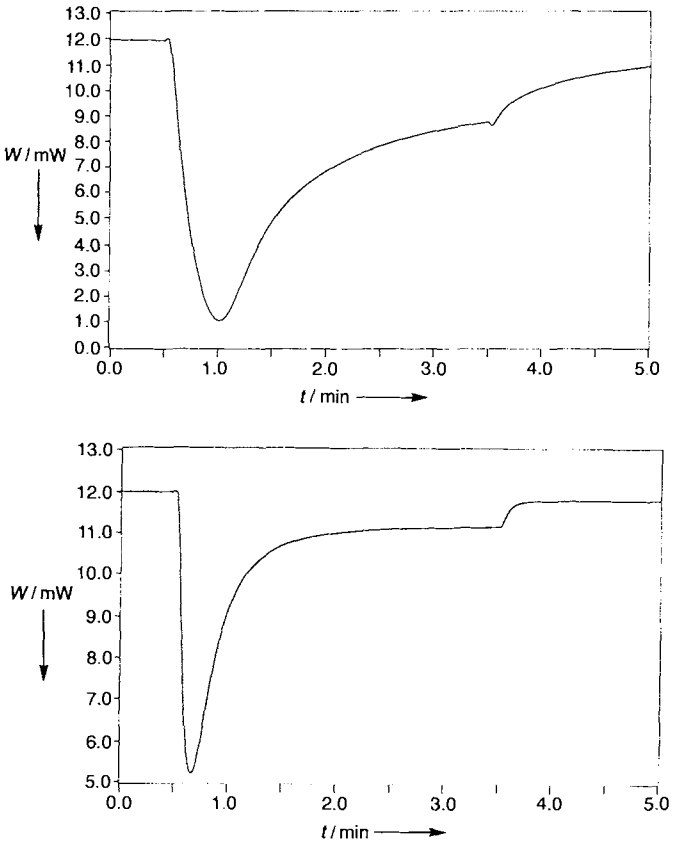


Fig. 2. Results of photo-DSC experiments of **1** (top) and **2** (bottom) in DCPD. *W* = heat flow.

The latency of complexes **1** and **2** in DCPD was tested by using a viscosity apparatus. During these experiments the samples could be either heated or irradiated with a UV lamp. The viscosity of the samples (1% initiator in DCPD containing 5% octane) was determined every minute. The results of the experiments for **1** and **2** are given in Figure 3. Complex **1** slowly polymerizes DCPD at 60 °C in the dark (Fig. 3 top). After 2 h the DCPD starts to gel and after 3 h it is fully polymerized. When the same solution at room temperature is irradiated with a UV lamp, polymerization starts directly and within 15 min the reaction is complete. Surprisingly, complex **2** in DCPD is even more latent (Fig. 3 bottom). Again, irradiation leads to a fast DCPD polymerization. However, when the solution is heated to 80 °C in the absence of light, no polymerization takes place. Moreover, this solution can be stored for days at room temperature without an increase of viscosity, and, even more importantly, without loss of photoactivity.

To our knowledge, these are the first examples of photo-induced ROMP reactions with well-defined early transition metal complexes. With these experiments we showed that simple alkyl tungsten complexes can act as one-component photo-ROMP initiators, and that their photoactivity as well as latency is very

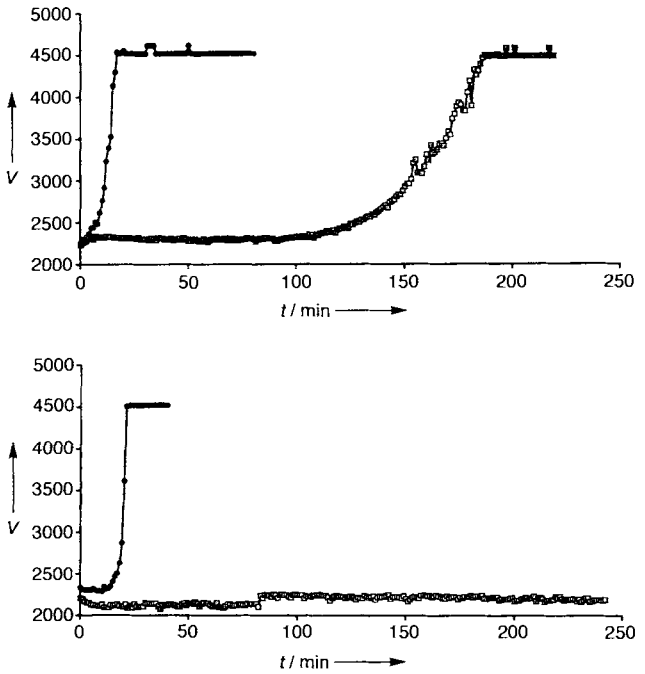

Fig. 3. Plots of real-time viscosimetric measurements of **1** (top) and **2** (bottom) in DCPD, showing the latency of the initiators in the dark. V = viscosity (arbitrary units). Top: ▣: 60 °C, in the dark; ●: 30 °C, UV irradiation. Bottom: ▣: 80 °C, in the dark; ●: 30 °C, UV irradiation.

high. In further studies on these and related complexes we are examining their reactivity with other cyclic olefins as well as the kinetics and quantum yields of these reactions. Applications of this new photopolymerization principle are also being studied.

Experimental Procedure

1: A green solution of $[W(=NPh)Cl_4 \cdot OEt_2]$ (11.58 g, 23.59 mmol) in Et_2O (50 mL) at −78 °C was treated with a solution of $[LiOCMe(CF_3)_2]$ (8.87 g, 47.18 mmol) in Et_2O (50 mL). The brownish reaction mixture was warmed to room temperature, stirred for 30 min, and centrifuged. The orange solution was decanted from a white precipitate (LiCl). Volatiles were removed in vacuo leaving a red solid. The crude product was extracted with hexane (2 × 80 mL). The hexane fractions were combined and dried in vacuo leaving $[W(=NPh)\{OCMe(CF_3)_2\}_2Cl_2]$ as a red powder; yield 16.54 g (90%). To a solution of $[W(=NPh)\{OCMe(CF_3)_2\}_2Cl_2]$ (16.54 g, 21.15 mmol) in CH_2Cl_2 (50 mL) was added NEt_4Cl (4.00 g, 24.14 mmol) as a solid. After 10 min the resulting dark red suspension was cooled to 0 °C and a solution of $Zn(CH_2SiMe_3)_2$ (5.08 g, 21.24 mmol) in CH_2Cl_2 (20 mL) was added within 5 min. Upon addition the color of the reaction mixture turned yellow/orange and a precipitate formed. The reaction mixture was then warmed to room temperature and stirred for an additional hour. Volatiles were evaporated in vacuo leaving a light-yellow solid, which was extracted with hexane (80 and 50 mL). The combined hexane fractions were concentrated to ca. 70 mL and stored at −30 °C. The pure product was obtained, in two crops, as yellow crystalline needles; yield 12.57 g (73.2%). C, H, N analysis: found C 32.61, H 3.89, N 1.79%; calcd C 32.56, H 4.10, N 1.73%; ^{1}H NMR (300 MHz, C_6D_6): δ = 7.22 (d, 2H, *o*-H, NPh), 7.10 (t, 2H, *m*-H, NPh), 6.76 (t, 1H, *p*-H NPh), 2.57 (d, 2H, $^2J(H_a,H_a)$ = 7.5 Hz, $^2J(W,H)$ = 5.1 Hz, CH_aH_aSi), 2.28 (d, 2H, $^2J(H_a,H_a)$ = 7.5 Hz, $^2J(W,H)$ = 5.0 Hz, CH_aH_aSi), 1.87 and 1.37 (2s, 6H, 2 × OCMe), 0.09 (s, 18, $SiMe_3$).

2: A green solution of $[W(=NPh)Cl_4 \cdot OEt_2]$ (8.98 g, 18.29 mmol) in CH_2Cl_2 (60 mL) was treated with powdered NEt_4Cl (3.20 g, 19.31 mmol) and stirred for 30 min. The resulting green suspension was cooled to 0 °C, and a solution of $[Zn(CH_2SiMe_3)_2]$ (6.58 g, 27.44 mmol) in CH_2Cl_2 (25 mL) was added dropwise within 15 min. Upon addition the color of the reaction mixture changed immediately to light brown. The reaction mixture was then stirred for an additional hour. The volatiles were removed in vacuo leaving a sticky light-brown solid. The crude product was extracted with pentane (2 × 60 mL). The combined pentane fractions were concentrated to ca. 50 mL and stored at −30 °C. The pure product was obtained as off-white crystals in 85% yield. C,H,N analysis: found C 37.91, H 6.80, N 2.40%; calcd C 37.79, H 6.70, N 2.45%; ^{1}H NMR (250 MHz, C_6D_6): δ = 7.43 (d, 2H, *o*-H, NPh), 7.09 (t, 2H, *m*-H, NPh), 6.89 (t, 1H, *p*-H, NPh), 2.17 (s, 6H, $^2J(W,H)$ = 4.3 Hz, CH_2Si), 0.20 (s, 27H, $SiMe_3$).

Photo-DSC experiments were carried out at room temperature using a Perkin-Elmer DSC-7 equipped with a Perkin-Elmer DPA-7 light unit. The light source was a 200 W Hg/Xe lamp with 2.5 mW cm^{-2} power. Samples of 1% **1** or **2** in DCPD containing 5% octane were transferred in a sapphire cell under a flow of argon.

Viscosity measurements were performed with a real-time viscosity apparatus of our own construction. Samples of 1% **1** or **2** in DCPD containing 5% octane were heated or irradiated in a pyrex or quartz test tube under a flow of argon while the viscosity was measured every minute. Irradiation was carried out using a 200 W Hg lamp.

Asymmetric Synthesis of Alkyl Aziridine-2-Carboxylates from Chiral 3′-Benzyloxyaminoimides**

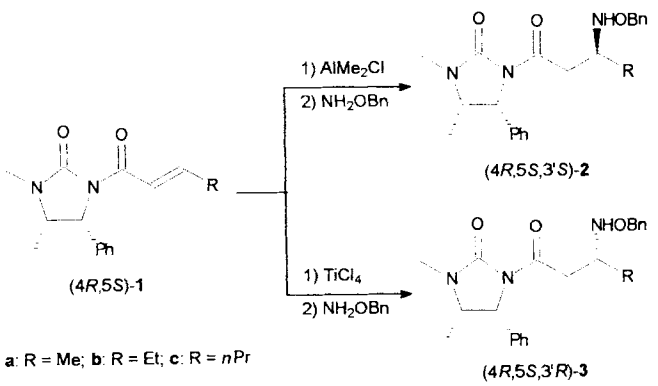
Giuliana Cardillo,* Sonia Casolari, Luca Gentilucci, and Claudia Tomasini

The use of aziridinecarboxylates as intermediates in the synthesis of optically active compounds is a subject of current interest.[1] The ring-opening of aziridines, a consequence of ring strain, is the most important feature of their chemistry and serves as the basis of the synthesis of substituted α- and β-amino acids,[2] which is a topic of interest in our laboratory.[3]

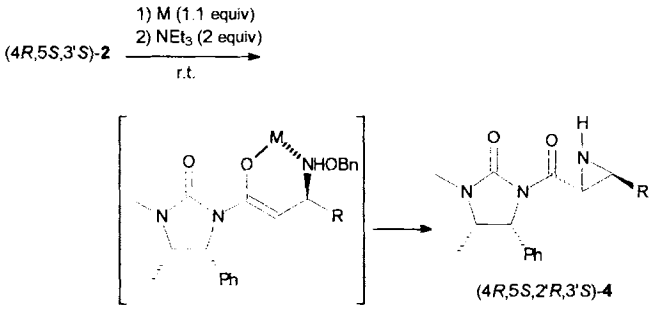
Enantiomerically pure aziridines are available not only by separation of racemic mixtures, successfully performed by enzymatic resolution,[4] but can also be prepared starting from β-hydroxy α-amino acids such as serine or threonine.[4a, 5] Recently Zwanenburg and co-workers reported an interesting synthesis of aziridine-2-carboxylates from the corresponding chiral oxiranes.[6] Furthermore, convenient methods have been reported for the synthesis of this class of compounds from α,β-unsaturated chiral imides relying on the reaction of 2,3-dihalocarboxylic acid derivatives with primary amines or ammonia.[7]

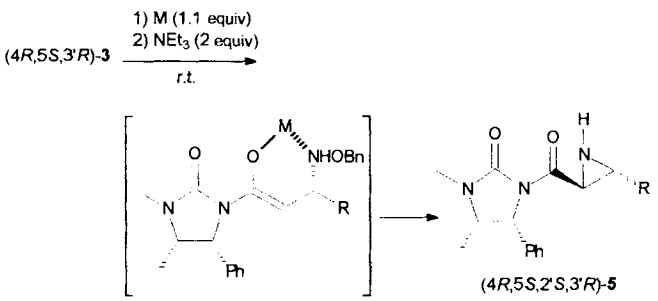
Interestingly, racemic keto aziridines can be prepared from α,β-unsaturated ketones by a two-step procedure: 1,4-addition of *O*-methylhydroxylamine to an unsaturated ketone followed by treatment with two equivalents of sodium methylate in methanol.[8] Under these conditions the *trans* aziridines are formed in excellent yields. Although the mechanism of this reaction is unknown, it is reasonable to assume that the aziridine is formed by cyclization of an intermediate enolate.

We recently reported a new synthesis of β-amino acids[3a] starting from the chiral[9] alkenoylimidazolidin-2-ones **1**, which



undergo selective 1,4-addition of *O*-benzylhydroxylamine promoted by Lewis acids. The predominant (*S*) or (*R*) configuration of the newly introduced stereogenic center depends on the Lewis acid selected as activating agent. Thus, nucleophilic attack on the aluminum-chelated alkenoylimide derivatives results in the formation of (4*R*,5*S*,3′*S*)-**2** as the major product, whereas the titanium-promoted addition of *O*-benzylhydroxylamine affords (4*R*,5*S*,3′*R*)-**3** as the major product. Each compound was obtained in pure form after flash chromatography.





a: R = Me, **b**: R = Et, **c**: R = *n*Pr M = $TiCl_4$, $AlMe_2Cl$

In analogy with the preparation of ketoaziridines, we thought that if an enolate could be prepared from **2** or **3**, the subsequent cyclization would yield the corresponding aziridine. All attempts to prepare the enolate with sodium methylate failed, and a complex mixture of products was obtained without any traces of aziridine derivatives. In contrast, the excellent procedure of Evans et al.[10] for the formation of titanium enolates from the corresponding carbonyl precursors with titanium tetrachloride and a tertiary amine gave satisfactory results. After addition of a titanium complex of **2** or **3** to a solution of triethylamine in CH_2Cl_2 under argon at room temperature, the reaction mixture turned red,[10] thus implying the formation of the desired enolate. The solution was stirred for 30 min at room temperature and the aziridine was isolated after aqueous workup (Table 1). The order of reagent addition has a critical effect on the yield and formation of by-products. Furthermore, the yields are not always reproducible.

Repeating this protocol with $AlMe_2Cl$ as Lewis acid gave better results (Table 1).[11] A clean reaction took place affording a pale yellow solution, and **2** and **3** were converted smoothly to aziridines **4**[7b] and **5**,[12, 13] respectively, in 30 min. The ^1H and

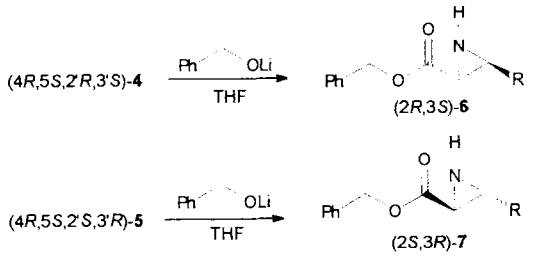
[**] We thank MURST and the CNR for financial support.

^{13}C NMR and HPLC analysis of the crude reaction mixture indicate that the *trans* aziridine, established on the basis of the ^1H NMR coupling constants ($J_{2',3'} = 2.2-2.5$ Hz), is formed exclusively.

The reaction provides better results in CH_2Cl_2 than in ethereal solvents, although the reaction proceeds also in THF in good yield and selectivity. Good to excellent yields of pure aziridines **4** and **5** are obtained after flash chromatography. In the examples given, the stereochemical outcome was uniformly excellent (>99% *de*). Since the configuration at C3′ is known, the configuration of the newly created stereogenic center at C2′ was unequivocally established based on the *trans* relationship of the hydrogens at C2′ and C3′.



A major advantage of this methodology is the efficient and easy removal and recovery of the chiral auxiliary. Reaction of both **4** and **5** in THF with two equivalents of $PhCH_2OLi$[14] (prepared from benzyl alcohol and *n*BuLi) at 0 °C afforded the corresponding esters (2*R*,3*S*)-**6** and (2*S*,3*R*)-**7**, respectively, in good yield[15] after workup with a saturated solution of NH_4Cl (Table 2). Furthermore a small amount of the corresponding aziridine-2-carboxylic acid was recovered from the aqueous layer.[16]

Table 2. Synthesis of enantiomerically pure benzyl *trans*-aziridine-2-carboxylates (2*R*,3S)-**6** and (2*S*,3*R*)-**7**.

Entry	Reagent	Conv [%][a]	Yield [%][b]
1	**4a**	98	75
2	**5a**	96	73
3	**4b**	93	70
4	**4c**	85	75
5	**5c**	87	65

[a] Based on the recovered chiral auxiliary. [b] Yields of **6** and **7** after purification by flash chromatography; the remainder is the corresponding carboxylic acid. No traces of the *cis* epimers were detected by ^1H, ^{13}C NMR and HPLC analysis.

In conclusion, we have developed a practical, straightforward method for the synthesis of (*R*,*S*)- and (*S*,*R*)-aziridine-2-carboxylates, starting from enantiomerically pure (*S*)- and (*R*)-3′-benzyloxyaminoimide derivatives via titanium or aluminium enolate intermediates. The nondestructive removal of the chiral auxiliary was easily performed by treatment with lithium benzyloxide. Studies are in progress in our group to rationalize the high diastereoselectivity observed.

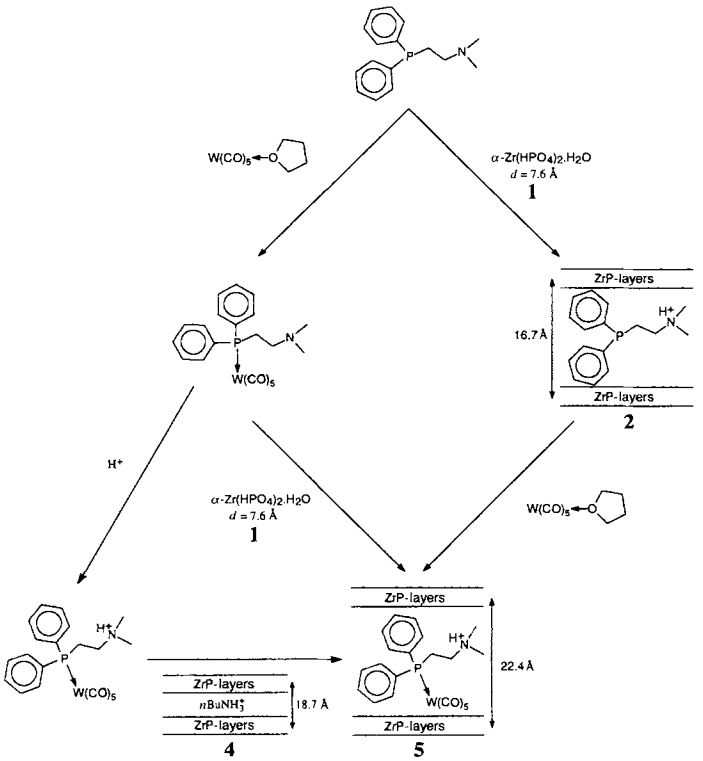
Synthesis of New Hybrid Materials by Intercalation of a Bifunctional Aminophosphane and Its Tungsten Pentacarbonyl Complex in α-Zirconium Phosphate**

Jonathon S. Bone, David G. Evans,* J. John Perriam, and Robert C. T. Slade

In recent years a variety of catalytically active materials has been produced by anchoring transition metal complexes on the surface of insoluble supports such as organic polymers[1] or metal oxides[2] in order to exploit in tandem the well-known advantages of heterogenous and homogeneous systems. If the metal complex can be incorporated in the interlamellar region of a layered solid, the catalytic selectivity is potentially enhanced since the effect of the layers may limit absorption and reaction of substrates based on their size, shape, or polarity. The synthesis of such hybrid materials containing rhodium complexes intercalated in smectite clays has been reported.[3-5] α-Zirconium phosphate $Zr(HPO_4)_2 \cdot H_2O$ (**1**) represents an alternative layered solid, which has a number of advantages as a host lattice arising from the ease of synthesis of high purity material, its high exchange capacity, and chemical and thermal robustness.[6] Crystallographic studies[7] show that each layer consists of almost coplanar zirconium atoms bridged by tetrahedral O_3POH groups alternatively located above and below the plane. The acidic protons of the hydrogen phosphate groups may be readily substituted by other cations, which leads to an expansion of the interlayer distance. A wide variety of transition metal ions[8] and preformed transition metal coordination complexes[9] such as $[Cr(NH_3)_6]^{3+}$ and $[Co(en)_3]^{3+}$ (en = 1,2-diaminoethane) have been intercalated into the α-zirconium phosphate host lattice. An alternative procedure that has been effectively employed[10] is to pre-intercalate a ligand such as 2,2′-bipyridyl or 1,10-phenanthroline and form an intercalated metal complex in situ by subsequent reaction of this material with metal ions such as Rh^{3+}. A third route to intercalation compounds of α-zirconium phosphate involves its reaction with Brønsted bases such as amines, which leads to formation of products containing intercalated alkylammonium ions. If the amino group is incorporated in a suitable bifunctional cyclopentadienyl ligand, its reaction with interlayer acidic protons facilitates the intercalation of organometallic complexes such as $[(\eta^5\text{-}C_5H_5)Fe(\eta^5\text{-}C_5H_4CH_2CH_2NH_2)]$[11] and $[\{(OC)_3Mn(\eta^5\text{-}C_5H_3(CH_3)CH_2)\}_2NH]$[12] in the α-zirconium phosphate host **1**.

Transition metal phosphane complexes are active as both homogeneous and supported catalysts in a variety of important reactions. Herein we report on the synthesis of the first hybrid material containing such a complex incorporated in an α-zirconium phosphate host lattice. Our strategy has been to employ a bifunctional aminophosphane ligand in which the basic nitrogen center facilitates intercalation by reaction with the acidic protons of **1**. With careful choice of experimental conditions, the use of such hybrid ligands allows the incorporation of otherwise hydrophobic metal complexes in the hydrophilic interlayer region. Reaction (methanol solution, 65 °C, 48 h) of mechanically ground (micronized) **1**, prepared by a sol–gel route,[13] with the bifunctional ligand *N*,*N*-dimethylaminoethyldiphenylphosphane[14] afforded a material (**2**), which according to microanalysis and thermogravimetry has the empirical formula $[Zr(HPO_4)_2(Ph_2PCH_2CH_2NMe_2)_{0.46} \cdot 1.1\,H_2O]$ (Scheme 1, Table 1). The powder X-ray diffraction pattern ($\lambda = 1.54178$ Å) of **2** was consistent with the presence of a single crystalline phase and showed (002) and higher order reflections, indicating an expanded interlayer spacing (d_{002}) of 16.7 Å in comparison with the corresponding value of 7.6 Å in **1** (Fig. 1).[6] The increased $H_2O:Zr(HPO_4)_2$ ratio in **2** can be ascribed to the increased



Scheme 1. Methods of intercalation of tungsten complexes with the ligand $Ph_2PCH_2CH_2NMe_2$.

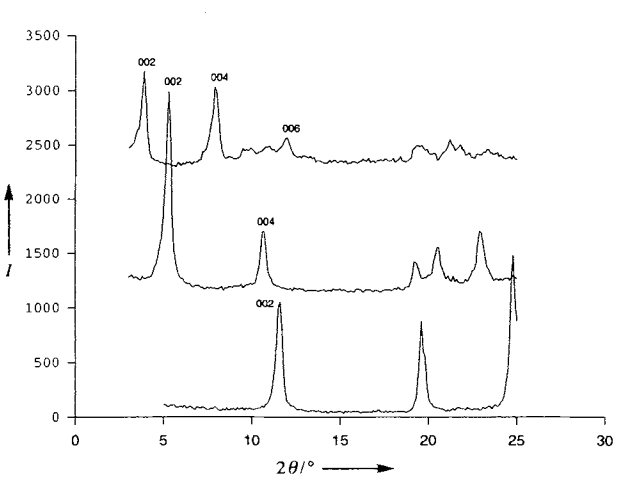


Fig. 1. X-ray powder diffraction patterns ($\lambda = 1.54178$ Å) of **1** (bottom), **2** (middle), and **5** (top). The variation in the position of the low angle reflection (indexed as d_{002}) is consistent with the expansion in interlayer spacing in **1**–**5**.

gallery height, which makes the material more zeolitic in character, thus facilitating uptake of additional water. The ^{31}P MAS NMR spectrum of **2** (Table 1) showed a resonance with a chemical shift close to that observed for the free phosphane in solution[14] and a complex set of resonances indicating[15, 16] that the material contains both hydrogen phosphate ($\delta = -19.2$, -20.0, and -20.7) and phosphate ($\delta = -11.2$) groups. This suggests that it can be correctly formulated as $[Zr(HPO_4)_{1.54}(PO_4)_{0.46}(Ph_2PCH_2CH_2NHMe_2)_{0.46} \cdot 1.1\ H_2O]$. In order to confirm that oxidation of the phosphane had not taken place during the intercalation, reaction of an authentic sample[14] of *N*,*N*-dimethylaminoethyldiphenylphosphane oxide with micronized **1** was carried out under the same conditions as those for the phosphane itself. The product **3** had the empirical formula $[Zr(HPO_4)_2(Ph_2P(=O)CH_2CH_2NMe_2)_{0.43} \cdot 1.5\ H_2O]$ and an expanded interlayer spacing (Table 1). The ^{31}P MAS NMR spectrum of **3** (Table 1) showed resonances consistent with the presence of both hydrogen phosphate and phosphate groups, and in addition a broad resonance with a chemical shift very close to that of the free phosphane oxide in solution, suggesting that **3** can be correctly formulated as $[Zr(HPO_4)_{1.57}(PO_4)_{0.43}(Ph_2P(=O)CH_2CH_2NHMe_2)_{0.43} \cdot 1.5\ H_2O]$. No resonance in the phosphane oxide region of the spectrum is observed in the case of **2**, confirming its formulation as the phosphane intercalate.

The ability of **2** to incorporate metal fragments was investigated by studying its reaction with the labile complex $[W(CO)_5(thf)]$. Such compounds are known[17] to react readily with phosphane ligands in solution to afford complexes of the type $[W(CO)_5(PR_3)]$ that have a characteristic IR spectrum, which is therefore useful for diagnostic purposes. Reaction (THF/methanol, 60 °C, 48 h) of **2** with $[W(CO)_5(thf)]$ led to uptake of the carbonyl moiety by the intercalated phosphane ligand, as shown by the characteristic IR spectrum[12] ($\tilde{\nu}_{CO}$/cm^{-1} 2072 m, 1981 sh, 1936 vs) of the solid and the further expansion of the interlayer spacing to 22.6 Å. A similar material was prepared by direct reaction (THF/methanol, 60 °C, 108 h) of **1** with a solution of the $[(OC)_5W(Ph_2PCH_2CH_2NMe_2)]$ complex[14] (see Scheme 1). The resulting products from these reactions, however, were contaminated with poorly crystalline **1**, and a single phase could not be obtained. The following alternative synthetic strategy did, however, afford single-phase materials.

Reaction of **1** with butylamine vapor is known[18] to afford $[Zr(HPO_4)_2(n\text{BuNH}_2)_2 \cdot 0.7\ H_2O]$ (**4**), which has a greatly expanded interlayer spacing (see Table 1). The interlayer butylammonium cations may be readily replaced by a variety of other cations.[8, 9] Reaction of an ethereal solution of $[(OC)_5W(Ph_2PCH_2CH_2NMe_2)]$ with $HBF_4 \cdot Et_2O$ afforded the isolable salt $[(OC)_5W(Ph_2PCH_2CH_2NHMe_2)](BF_4)$. Reaction of a solution of this salt in methanol with **4** afforded a material (**5**) with the empirical formula $[Zr(HPO_4)_2\{(OC)_5W(Ph_2PCH_2CH_2NMe_2)\}_{0.51} \cdot 1.5\ H_2O]$ (Scheme 1, Table 1). The powder X-ray diffraction pattern contained (002) and higher order reflections, indicating an interlayer spacing of 22.4 Å. The ^{31}P MAS NMR spectrum of **5** (Table 1) showed a complex set of resonances consistent with the presence of both hydrogen phosphate and phosphate groups, and, in addition, two very broad resonances at a chemical shift very close to that of the free tungsten phosphane complex in solution (Table 1), indicating that **5** can be correctly formulated as $[Zr(HPO_4)_{1.49}(PO_4)_{0.51}\{(OC)_5W(Ph_2PCH_2CH_2NHMe_2)\}_{0.51} \cdot 1.5\ H_2O]$. The presence of two resonance signals may indicate that the intercalated phosphane occupies at least two distinct sites in a disordered interlayer region.

It is noteworthy that in the above reaction, two moles of butylamine are quantitatively replaced by 0.51 moles of the aminophosphane complex. In the starting material, $[Zr(PO_4)_2(n\text{BuNH}_3)_2 \cdot 0.7\ H_2O]$, the protonated amine ligands form a bilayer[16, 18] with their alkyl chains making an angle of 55° to the phosphate layers. Although it is to be expected that there will be strong forces between the anionic layers and the cationic guest species, a recent study[19] of quarternary ammonium ion intercalates derived from the closely related host lattice $[\gamma\text{-}Ti(HPO_4)_2 \cdot 2\ H_2O]$ has indicated that the van der Waals forces between the alkyl chains of the guest species make a significant contribution to the overall stability of the material. Replacement of a small amount of butylammonium cation by the intercalating protonated complex will presumably disrupt the bilayer, thus facilitating the expulsion of further butylamine with concomitant reprotonation of the host lattice O_3PO^- groups. A similar high selectivity for cationic transition metal complexes over butylamine has been observed previously.[9] For example, two moles of butylamine were shown to be quantitatively replaced by 0.28 moles of $[Cr(NH_3)_6]^{3+}$ ions or 0.24 moles of $[Co(en)_3]^{3+}$ ions, respectively.

In conclusion, an appropriately functionalized phosphane ligand and its tungsten pentacarbonyl complex may be incorporated into the α-zirconium phosphate host structure. Further studies on other complexes of $Ph_2PCH_2CH_2NMe_2$ and related ligands are in progress.

Experimental Procedure

2: A solution of *N*,*N*-dimethylaminoethyldiphenylphosphane (1.00 g, 3.88 mmol) in dry, degassed methanol (30 mL) was added to a slurry of α-zirconium phosphate (0.50 g, 1.66 mmol) in dry, degassed methanol (20 mL) and the reaction stirred at

65 °C for 48 h. The slurry was cooled and the solid isolated by centrifugation, washed with dried methanol and dried under reduced pressure.

3: The preparation was carried out in the same manner as for **2** starting from *N,N*-dimethylaminoethyldiphenylphosphane oxide.

5: A solution of $[(OC)_5W(Ph_2PCH_2CH_2NHMe_2)](BF_4)$ (0.75 g, 1.07 mmol) [prepared by reaction of $[(OC)_5W(Ph_2PCH_2CH_2NMe_2)]$ (0.80 g, 1.38 mmol) in dry degassed diethyl ether (50 mL) with an 85% solution of $HBF_4 \cdot Et_2O$ in diethyl ether (0.36 g, 1.89 mmol)] in dry, degassed methanol (20 mL) was added to a slurry of **4** (0.10 g, 0.22 mmol) in dry, degassed methanol (20 mL) and the reaction stirred at 60 °C for 48 h. The slurry was cooled and the solid isolated by centrifugation, washed with dried methanol and dried under reduced pressure.

Nonlinear Temperature Behavior of Product Ratios in Selection Processes**

Detlef Heller,* Helmut Buschmann, and Hans-Dieter Scharf

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

For selective reactions it has long been known that a logarithmic plot of the product ratio as a function of reciprocal temperature does not always display linear behavior.[1–3] That the selectivity of a reaction need not fall regularly with decrease in temperature is of considerable practical significance in efforts to attain higher selectivity. In addition, interpretation of the temperature dependence can provide information on the mechanism of a reaction.[3] The temperature dependence has been examined in detail in the case of the Paternò–Büchi reaction, which led to the empirically derived isoinversion principle.[4] Accordingly, at the inversion point of two roughly linear regions, obtained by plotting the logarithm of the product ratios $[\ln(R/S)]$ versus $1/T$, there is a change in dominance between differences in activation enthalpy ($\Delta\Delta H^{\neq}$) and activation entropy ($\Delta\Delta S^{\neq}$) for various selection levels. The difference in the values of $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ before and after the point of inversion—in this case the inversion temperature T_{inv}—leads to the isoinversion temperature T_i [Eq. (a)], which describes the selectivity of a reaction as a characteristic quantity. This is the so-called *isoinversion principle*.

$$\partial\Delta\Delta H^{\neq} = T_i \cdot \partial\Delta\Delta S^{\neq} \qquad \text{(a)}$$

As an "abrupt" change of dominance between $\Delta\Delta H^{\neq}$ and $\Delta\Delta S^{\neq}$ is rather unlikely, according to Ridd,[5] he interpreted the experimentally determined nonlinear temperature dependence of the logarithmic product ratios as a shift in the rate-determining step of the reaction with change in temperature. This alternative interpretation is based on a simulation with empirical energy levels. The shift in the rate-determining step has also been invoked by Sharpless for the asymmetric olefin dihydroxylation with OsO_4 (in the presence of chiral bases).[3]

Common to the two apparently contradictory viewpoints is the consideration of the temperature dependence of the ratio of the overall rate constants in terms of Eyring theory.[6] The subsequent difference in free activation enthalpy $\Delta\Delta G^{\neq}$ resulting from processes leading to selection is also the basis of the stereochemical structure model of Ugi and Ruch.[7]

The aim of the present work was to extend the previous examples and interpretations of the nonlinear temperature dependence in selection processes, and to trace this exclusively back to the nonlinear change in the concentration ratio of the intermediate with the variation in temperature. This should be demonstrated with one of the best understood selection processes, catalytic asymmetric hydrogenation. According to Halpern[8] and Brown,[9] asymmetric catalytic hydrogenation with five-membered Rh chelate complexes proceeds as shown in Scheme 1. All subsequent considerations are based exclusively on two diastereomeric intermediates, which are prepared with chiral C_2-symmetric ligands, for example, Kagan's DIOP ligand (Fig. 1).[10]

As shown in Scheme 1, the diastereomeric substrate complexes E_{ma} and E_{mi} are formed in the first selection level in a preequilibrium. In a series of elementary steps—oxidative addition of hydrogen, insertion, reductive elimination—these react at different rates in the second selection level to give the enantiomers. Under normal conditions the rate of the oxidative addition is recognized to be rate-determining.

The ratio of enantiomers is described by Equation (b). Whereas a plot of $\ln(R/S)$ against $1/T$ gives, in principle, a

$$\frac{R}{S} = \frac{k_{2mi}}{k_{2ma}} \cdot \frac{E_{mi}}{E_{ma}} = \frac{k_{2mi} \cdot \dfrac{k_{1mi}}{k_{-1mi} + k_{2mi}}}{k_{2ma} \cdot \dfrac{k_{1ma}}{k_{-1ma} + k_{2ma}}} \qquad \text{(b)}$$

straight line for established preequilibria ($k_{2ma} \ll k_{1ma}$ or k_{-1ma}; $k_{2mi} \ll k_{1mi}$ or k_{-1mi}), for a nonestablished preequilibrium this

can no longer be the case because of the additive coupling of the rate constants. As the ratio of the rate constants k_{2mi}/k_{2ma} leads in principle to a linear temperature dependence, the experimentally observed nonlinearity must depend on a change in the concentration ratio of the diastereomeric substrate complexes with temperature. This will be explained with an example.

Table 1. Values for $\Delta H^{\ddagger}$ [kcal mol^{-1}] and $\Delta S^{\ddagger}$ [cal mol^{-1} K^{-1}] for the calculation of the rate constants according to Equation (b).

	k_{1mi}	k_{1ma}	k_{-1mi}	k_{-1ma}	k_{2mi}	k_{2ma}
$\Delta H^{\ddagger}$	6.9	4.9	13.0	13.3	8.5	13.5
$\Delta S^{\ddagger}$	−17.0	−24.6	−12.9	−17.9	−27.0	−24.0

Table 1 contains $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for the determination of rate constants according to Equation (b). The rate constants for the preequilibrium are those found for asymmetric hydrogenation.[8] Because the thermodynamically less stable minor substrate complex reacts at a higher rate to give the enantiomer found in excess, as shown by Halpern in terms of the major/minor concept,[8] only the values for calculation of the rate constants of the oxidative addition, k_{2mi} and k_{2ma}, have been simulated. The temperature dependence of the product ratio (R/S) is shown in Figure 2. In the temperature range from roughly −25 °C to about +130 °C a characteristic maximum can be seen.

The upper part of Figure 3 shows the expected linearity in the temperature dependence of the ratio of the rate constants for the oxidative addition as one of the factors on the left-hand side of Equation (b). The temperature dependence of the ratio of the diastereomeric substrate complexes is shown in the lower part of Figure 3. Whereas the curve is still linear at higher temperatures as expected, at lower temperatures the curve deviates increasingly from linearity. Although all rate constants become smaller with decreasing temperature, the displacement of establishment of the preequilibrium becomes more pronounced with decreasing temperature.

Summation of the individual factors from Equation (b) for the temperature dependence shown in Figure 3 gives the temperature dependence of the enantiomer ratio for the overall reaction, as shown in Figure 2. When Figure 3 is considered from this aspect, it is apparent that at higher temperatures the oxidative addition (second selection level) is the major contribution to the enantiomer ratio. In contrast, at very low temperatures the selectivity results predominantly from the ratio of the diastereomeric substrate complexes (first selection level). This increasing dominance of the first selection level is caused exclusively by the increasing deviation, with decreasing temperature, from linearity of the temperature dependence of the ratio of the diastereomer concentrations (E_{mi}/E_{ma}), which is the real cause for the nonlinear temperature dependence of the enantiomer ratio. Thus, both

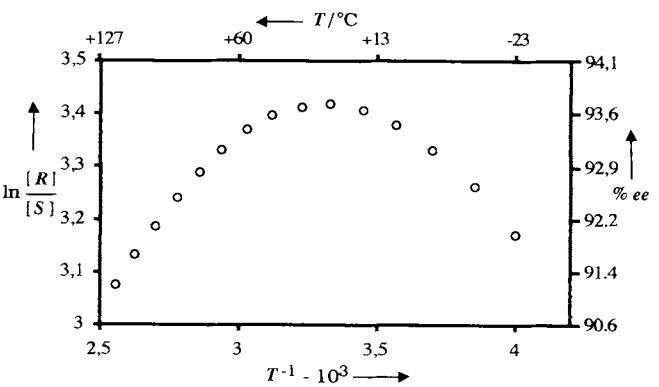

Fig. 2. Temperature dependence of the enantiomer ratio (calculated with the constants from Table 1).

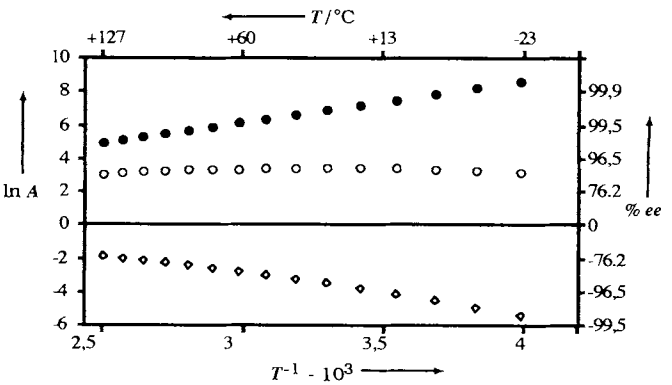

Fig. 3. Temperature dependence of the individual factors from Equation (b) [•: $A = (k_{2mi}/k_{2ma})$; ○: $A = (R/S)$; ◇: $A = (E_{mi}/E_{ma})$].

sides of the maximum can, in principle, be explained as resulting from the dominance of different selection levels in different temperature ranges. This is an essentially empirical statement of the inversion principle.[4]

We will now discuss the nonlinear temperature dependence of the concentration ratio of the intermediates as the cause for the nonlinear behavior of the product ratio in a selection process. In principle, for the asymmetric hydrogenation with C_2-symmetric ligands as an example of a selection process, this behavior can be traced back to two possible causes:[17] 1) displaced (intermolecular) preequilibria and 2) intramolecular equilibria.

The displacement in the establishment of a preequilibrium, the position of which is temperature dependent, means that the stationary concentration of the affected substrate complex will become smaller. Coupling of the diastereomeric substrate complexes through their the common substrate leads to a change in the ratio of the intermediates (see also ref. [12]). The increasing displacement in reaching the preequilibrium through increasingly faster subsequent reactions of the intermediate ultimately results in other steps becoming rate-determining; this corresponds to the "transition region" described by Ridd.[5] The nonlinear temperature dependence of the logarithmic product ratio in this transition region is based on a change in the rate-determining step. In our opinion this is caused by the nonlinear shift of the concentration ratio of the intermediate as a function of temperature.

A second possible cause is the intramolecular exchange between diastereomeric substrate complexes, as described for five-membered chelate rings[13, 14] and recently quantified for seven-membered chelate rings.[15] In principle, even when all equilibria are established, this leads to a nonlinear temperature dependence of the ratio of the diastereomeric substrate complexes (for a derivation, see ref. [16]). This is particularly valid when the intramolecular exchange processes are more dominant than the intermolecular equilibria.

Thus, we have shown that the arguments in the discussion[4, 5] on the interpretation of the nonlinear temperature dependence of logarithmic product ratios are not contradictory. Both interpretations are possible within defined limits. The cause for the experimentally observed dependence can be reduced to the concentration ratio of two intermediates that changes with temperature in nonlinear fashion; further reaction of these two intermediates then leads to selective product formation. The causes of the nonlinear changes in the ratio of intermediates are then displaced intermolecular preequilibria and intramolecular exchange processes of substrate complexes that appear as intermediates.

[17] By the use of C_1-symmetrical ligands (an example is shown in Fig. 1 (**1b**) [11]) formation of individual enantiomers can be the result of two independent processes, because four substrate complexes are possible in principle. This means that the logarithmic product ratio changes with temperature in principle in nonlinear fashion.

Synthesis of New Dialkylmagnesium Compounds by Living Transfer Ethylene Oligo- and Polymerization with Lanthanocene Catalysts

Jean-François Pelletier, André Mortreux,* Xavier Olonde, and Karel Bujadoux

Dedicated to the memory of Professor Francis Petit

Considerable interest has been devoted to oligomerization and polymerization of ethylene on transition metal catalysts. The aim of these reactions is to produce higher olefins (Alfen, Alphabutol, SHOP processes) or polymers of higher molecular weight (Ziegler–Natta catalysis). Such reactions and those with the relatively recently discovered metallocene-based catalysts produce linear, vinyl-terminated chains, which can be transformed by the use of stoichiometric amounts of zirconocene compounds into functionalized compounds.[1] This kind of functionalized oligomers, however, can be obtained by anionic polymerization of ethylene with *n*-butyllithium followed by electrophilic substitution of the resulting living oligomer.[2] In contrast, organomagnesium compounds have been synthesized from olefins by using zirconocene-based catalysts and dialkylmagnesium compounds or Grignard reagents as coreactants,[3] and zirconium tetrachloride has been used as catalyst for the synthesis of dialkylmagnesium compounds from MgH_2 and α-olefins, a process, which could be followed by ethylene addition, but only under severe conditions.[4]

We report herein that the ethylene insertion into a Mg–C bond can be catalyzed under very mild conditions by an alkyl chain transfer through chain growth polymerization on a lanthanocene-based catalyst.[5] This new reaction is a useful method for the synthesis of compounds of the type P-Mg-P′ (P = alkyl chain), in which, depending on the reaction parameters, P or P′ can contain between four and 200 C atoms, and a narrow distribution of products is obtained [Eq. (a)].

$$BuMgEt + (n+m)CH_2{=}CH_2 \xrightarrow[80\,^{\circ}C,\ 1\ atm]{[Cp^{*}_{2}SmCl_2Li(OEt_2)_2]} P\text{-}Mg\text{-}P' \qquad (a)$$

$P = Bu\{CH_2\text{-}CH_2\}_n$; $P' = Et\{CH_2\text{-}CH_2\}_m$.

Typical experiments were conducted at 80 °C in hydrocarbon solvents. Upon introduction of a premixed mixture of the catalyst $[Cp^*_2SmCl_2Li(OEt_2)_2]$[6] (0.1 mmol, $Cp^* = C_5Me_5$) and butylethylmagnesium (20 mmol) into the hydrocarbon solvent (500 mL), the consumption of the ethylene begins immediately and remains constant until the growing alkyl chains of the dialkylmagnesium compound reach such a length that the products precipitate from the solution. The reaction of these new P-Mg-P′ compounds, which were initially obtained from ethylene (0.31 g) and a catalytic solution with a butylethylmagnesium/samarium ratio of 1:100 during 60 s, with CO_2 affords linear carboxylic acids with an odd number of carbon atoms in the chain (between five and 13 C atoms) upon further hydrolysis (FAB^+ MS analysis, $m/z = 101$ to 213).

Table 1 summarises our results obtained by using different Mg/Sm ratios. The lengths of the alkyl chains in the dialkylmagnesium units P-Mg-P′, which are given by the number average molecular weight ($\bar{M}_n$), depend on the Mg/Sm ratio and on the polymerization time. As long as P-Mg-P′ remains in solution (entries 1 to 7), the polydispersity index (PDI) is close to 1. This indicates that a reversible and very efficient transfer reaction occurs, leading to a pseudo-living polymerization process. The number of growing chains (yield/$\bar{M}_n$) is close to the number of Mg–C bonds available. Such transfers between catalyst (Zr or Ti) and trialkylaluminum occur in Ziegler–Natta polymerization, but are effective only at low temperature.[7] The key point in our process is that these transfer reactions are fast and reversible at 80 °C. This is the first example in which a polymerization with transfer reactions between two different metals can be considered as living.

Table 1. Ethylene polymerization with $BuMgEt/[Cp^*_2SmCl_2Li(OEt_2)_2]$ catalysts [a].

Entry	Mg/Sm	Polymerization time [min]	Ethylene consumption [g]	$\bar{M}_n$ [b]	PDI [c]	$N_{exp.}/N_{th.}$ [d]

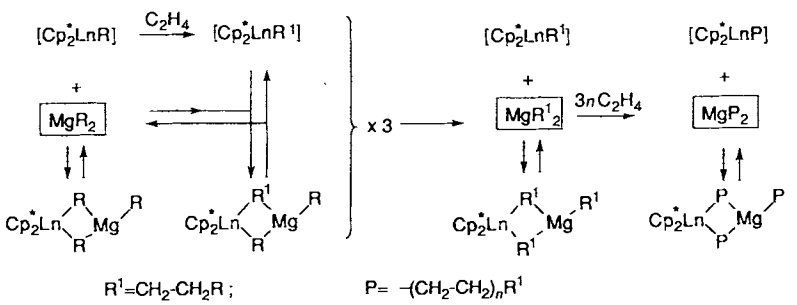
11 [g]	50	220	180.0	2110	2	8.50

[a] Solvent: 500 mL, catalyst: $[Cp^*_2SmCl_2Li(OEt_2)_2]$, (0.1 mmol) 80 °C. [b] Determined by GPC analysis. [c] PDI: polydispersity index = $\bar{M}_w/\bar{M}_n$ of the resulting polymer after hydrolysis. [d] N_{exp}: Experimental chain number [yield (in g)/$\bar{M}_n$]; N_{th}: Theoretical chain number, considering a living polymerization on both Mg (two chains per Mg atom) and Sm. [e] Catalyst: 0.05 mmol. [f] Solvent: xylene. [g] Reaction temperature = 100 °C.

According to our previous observations on the effect of an excess of dialkylmagnesium compound on the ethylene polymerization kinetic profiles,[8] it may be assumed that the polymerization occurs by the formation of a double R-bridged complex (in equilibrium with the free lanthanocene species, which is responsible for the chain growth catalysis, and MgR_2, Scheme 1, left), by which the interchange of the alkyl groups could take place (Scheme 1).



Scheme 1. Proposed reaction mechanism for the synthesis of MgP_2.

If the reaction is allowed to continue after the P-Mg-P′ precipitation, this chain transfer to magnesium is no longer possible, and classical polymerization occurs on the lanthanocene complex with β-H elimination reactions, leading to an increase of the PDI (entry 8).

The $\bar{M}_n$ numbers of each alkyl chain bound to Mg are governed by the solubility of the P-Mg-P′ compound in the reaction medium. A considerable increase in the lengths of the chains could be achieved (entries 10 and 11) by varying the solvent and temperature. However, increasing the temperature to 100 °C gave mainly α-olefins as by-products due to competitive β-H elimination reactions.

In order to check the molecular distribution of the first phase of the polymerization reaction, we performed an experiment with di-*n*-hexylmagnesium. This symmetrical dialkylmagnesium compound was chosen to avoid the possible difference in reactivity that could occur from the BuMg and EtMg moieties in BuMgEt during the initiation step. The distribution of the oligomers obtained by hydrolysis of the reaction products after 9 min (Mg/Sm = 134) is given in Figure 1. As expected, the products are exclusively alkanes with a very low polydispersity ($\bar{M}_w/\bar{M}_n = 1.11$). A Poisson distribution was calculated and is likewise shown. The good agreement between the experimental data and this curve indicates that most of the Mg–C bonds have been exchanged and that the oligomeric distribution can be considered as monodisperse.[9]

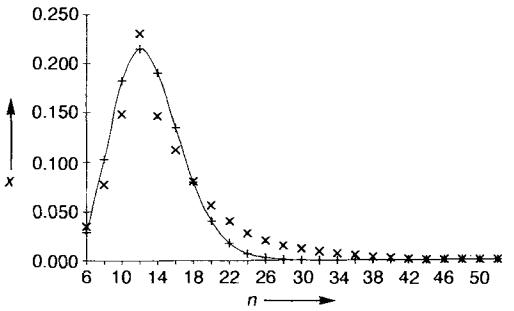


Fig. 1. Comparison of the experimental (×) and calculated (+) distribution of oligomers in the polymerization with di-*n*-hexylmagnesium. The solid line indicates the Poisson distribution. The experimental data were obtained by GC analysis of the products obtained after 9 min from the oligomerization of ethylene (115 mmol) with the catalyst (0.1 mmol) and di-*n*-hexylmagnesium (13.4 mmol) at 80 °C. n = number of C atoms, x = molar fraction. λ = ethylene/Mg–C = 3.54, where λ = average number of ethylene insertions in $Mg(n\text{-hexyl})_2$.

One of the most interesting of the numerous potential applications of these new P-Mg-P′ compounds (Scheme 2) is their use as macroinitiator in diblock copolymerization reactions with some polar monomers.

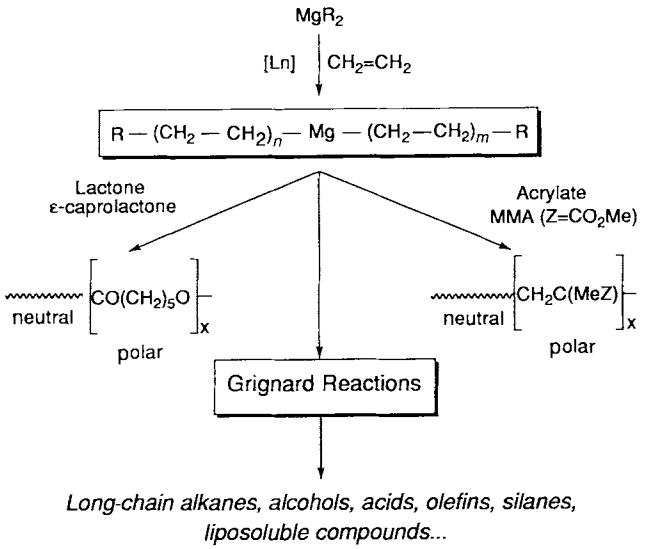

Scheme 2. Synthesis and applications of higher dialkylmagnesium compounds.

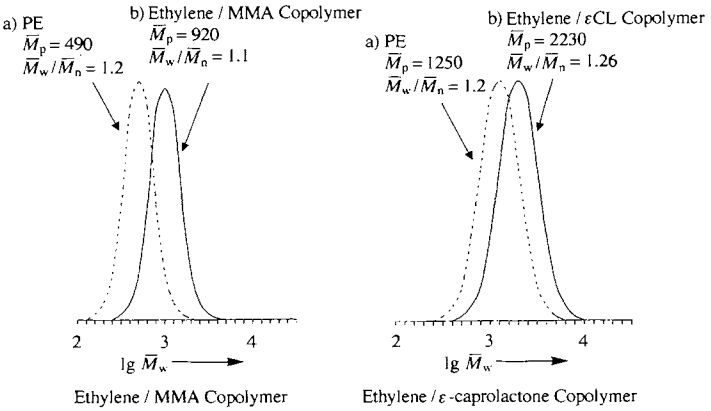

Fig. 2. GPC profiles of diblock ethylene/methylmethacrylate (MMA) and ethylene/ε-caprolactone (CL) copolymers (insoluble fractions after acetone extraction). PE = polyethylene. M_p = peak mass.

Figure 2 shows the gel permeation chromatography (GPC) profiles of polymer samples obtained a) by hydrolysis of P-Mg-P′ compounds, b) by further in situ reaction with ε-caprolactone at 80 °C, and c) by the same consecutive procedure after decreasing the temperature and addition of methyl methacrylate at −78 °C.

As expected, the first ethylene polymerization step occurs in an almost "living" fashion to produce the dialkylmagnesium compound P-Mg-P′. Subsequent addition of the lactone or the acrylate leads to diblock copolymers whose polydispersity index indicates that again, the copolymerization can be considered as living.

We have developed an efficient synthesis of dialkylmagnesium compounds that were hitherto only accessible under severe conditions,[4] and have shown that a living ethylene growth chain transfer reaction between dialkylmagnesium derivatives and lanthanocene complexes is possible. Because of the high reactivity of the Mg–C bond, such dialkylmagnesium compounds with a narrow distribution of molecular weights may eventually be used to introduce lipophilic chains of well-defined lengths in a series of compounds.

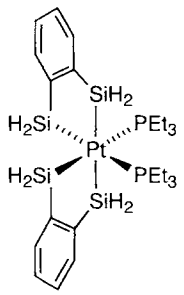
The First Silylpalladium(IV) Complex

Shigeru Shimada, Masato Tanaka,* and Motoo Shiro

Owing to the intense interest in the silicon-based materials, the chemistry of (silyl)metals is a vigorously growing research field. In particular, an understanding of the reactivities of palladium complexes is highly desired, since palladium complexes are versatile catalysts in a number of transformations of hydrosilanes and disilanes.[1] In these reactions, silylpalladium(IV) species are occasionally suggested to be key intermediates, based on the relevant chemistry of silylplatinum(IV)[2, 3] and organopalladium(IV)[4] complexes. However, no unequivocal evidence that substantiates silylpalladium(IV) species has been reported to date. Accordingly, discussions about their intermediacy have usually been speculative, and elementary steps that may involve silylpalladium(IV) species have been often described simply as "metathesis".[5, 6] Our recent paper reporting isolation of a tetrakis(silyl)platinum(IV) complex (**1**)[3] appears to imply that the chelation, rigid conformation, and small steric size of the 1,2-phenylenedisilyl ligand might be ideal for the stabilization of possible palladium(IV) complexes. Here we disclose the very first isolation and characterization of a silylpalladium(IV) complex.



1

After the survey of several palladium complexes,[7] we found that the reaction of [Me_2Pd(dmpe)] (**2**, dmpe = 1,2-bis(dimethylphosphanyl)-ethane)[8] with 3 equivalents of 1,2-disilylbenzene (**3**)[3, 9] in toluene

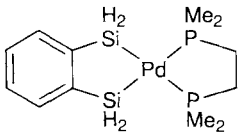
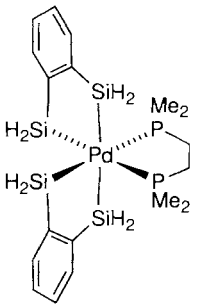
proceeded slowly even at room temperature, and after heating at 50 °C a new complex was isolated as a microcrystalline white solid in 67% yield, which was not a usual bis(silyl)palladium(II) complex like **4** but the tetrakis(silyl)palladium(IV) complex **5**.[10]

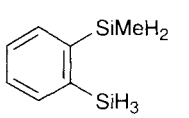


4



5

Several silanes were also formed by methyl-hydrogen exchange processes (according to ^{1}H NMR and GC-MS studies, mainly monomethylsilane **6** (about 30 mol%, based on the consumed **2**), together with dimethyl and trimethyl derivatives of **3**). The ^{29}Si{^{1}H} NMR spectrum (DEPT 45 and 135) of **5** clearly displayed two signals for SiH_2; one SiH_2 group is *cis* to two phosphane ligands (t, ^2J(P,Si) = 17 Hz) and the other *cis* to one and *trans* to another phosphane ligand (dd, $^2J(P_{cis},Si) = 17$ Hz, $^2J(P_{trans},Si) = 162$ Hz). The ^{1}H and ^{13}C NMR spectra similarly displayed two PCH_3 signals. Finally, the structure of **5** was unambiguously confirmed by X-ray diffraction analysis (Fig. 1).[11] Complex **5** is C_2 symmetric, and the Si3–Pd bond is longer than the Si2–Pd bond as a result of the stronger *trans* influence of silicon than that of phosphorus.



6

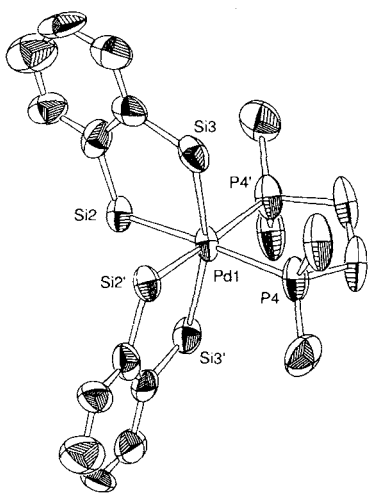


Fig. 1. Molecular structure of **5**. Selected bond lengths [Å] and angles [°]: Pd1–P4 2.337(2), Pd1–Si2 2.345(2), Pd1–Si3 2.394(4); P4-Pd1-P4' 86.1(2), P4-Pd1-Si2 175.5(1), P4-Pd1-Si2' 93.3(1), P4-Pd1-Si3 99.6(1), P4-Pd1-Si3' 93.8(1), Si2-Pd1-Si2' 87.7(2), Si2-Pd1-Si3 84.9(1), Si2-Pd1-Si3' 81.9(1), Si3-Pd1-Si3' 161.6(1).

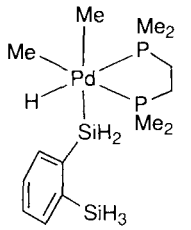
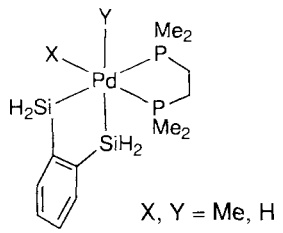
In order to elucidate the mechanism of the reaction, an attempt was made to isolate a possible intermediate (**4**) by treating **2** with 1.1 equivalents of **3**, but the main product that formed was **5**.[12] However, an analogous complex (**7**) was obtained as a dimer[13] by the phosphane exchange reaction of [1,2-$C_6H_4(SiH_2)_2$Pd(PMePh$_2$)$_2$][7] with dmpe. As expected, **7** reacted smoothly with **3** (3 equivalents) at 50 °C to give **5** nearly quantitatively. Based on the above results, we tentatively propose the following mechanism. The formation of **6** and the thermal stability of complex **2**[14] suggest that the initial step is the oxidative addition of one of the Si–H bonds of **3** to **2** to give the silylpalladium(IV) intermediate **8**, which then reductively

[{1,2-$C_6H_4(SiH_2)_2$Pd(dmpe)}$_2$(μ-dmpe)] **7**



8



9

eliminates methane, ethane, or **6**. In the former two cases, further intramolecular oxidative addition of the other Si–H bond gives complex **9**, which then produces **4** by reductive elimination of hydrogen or methane. The next step is presumably the oxidative addition of the Si–H bond of another molecule of **3** to **4** as in the corresponding platinum case,[3] although no evidence was obtained at present.

The results disclosed here emphasize the significance of the intermediacy of silylpalladium(IV) species in the palladium-promoted reactions of hydrosilanes and disilanes. Tetrakis(silyl)-palladium(IV) intermediates, in particular, should be more seriously considered in the metathesis reactions of disilanes catalyzed by palladium complexes.[5a, 5e, 10f, 10g, 15]

Detailed mechanistic aspects as well as the reactivities of complex **5** are now under investigation in our laboratory.

Experimental Procedure

5: To a toluene solution (2 mL) of **2** (177 mg, 0.618 mmol) was added **3** (256 mg, 1.85 mmol), and the resulting mixture was stirred first at room temperature for 78 h and then at 50 °C for 58 h. A large amount of a white precipitate was observed even after the room temperature reaction. After addition of pentane (3 mL), the supernatant was filtered off, and the remaining solid was washed with toluene/pentane (2:1, 2 × 3 mL). After drying under vacuum, **5** was obtained as a microcrystalline white solid, 220 mg (67% yield). The combined mixture of the filtrate and the washings was kept at room temperature to give additional **5** as a hexagonal single crystal suitable for X-ray structure analysis. M.p. 195–220 °C (decomp. under vacuum); ^{1}H NMR (300 MHz, C_6D_6): δ = 0.78 (d, 6H, J = 9 Hz, PCH_3), 0.9–1.2 (m, 4H, PCH_2CH_2P), 1.02 (d, 6H, J = 9 Hz, PCH_3), 4.7–4.8 (m, 2H, SiH_2), 4.83–4.95 (m, 4H, SiH_2), 4.98–5.17 (m, 2H, SiH_2), 7.11–7.21 (m, 4H), 7.75 (d, 2H, J = 7 Hz), 8.04 (d, 2H, J = 7 Hz); ^{13}C{^{1}H} NMR (75.5 MHz, C_6D_6): δ = 11.45 (m, PCH_3), 12.65 (m, PCH_3), 28.69 (t, ^1J(P,C) = 23 Hz, PCH_2CH_2P), 127.5 (2C), 134.22 (t, ^4J(P,C) = 2.5 Hz), 134.89 (s), 147.29 (t, ^3J(P,C) = 3.0 Hz), 150.69 (t, ^3J(P,C) = 2.3 Hz); ^{31}P{^{1}H} NMR (121.5 MHz, C_6D_6): δ = 15.87 (s); ^{29}Si{^{1}H} NMR (59.6 MHz, C_6D_6): δ = −8.31 (t, ^2J(P,Si) = 17 Hz), −6.58 (dd, $^2J(P_{cis},Si) = 17$, $^2J(P_{trans},Si) = 162$ Hz); IR (KBr): $\tilde{\nu}$ = 2070, 2032 cm^{-1} (SiH); C,H analysis: calcd for $C_{18}H_{32}P_2PdSi_4$: C 40.86, H 6.10; found: C 41.21, H 6.01.

[11] Crystal data for **5**: $0.30 \times 0.20 \times 0.20$ mm^3, hexagonal, space group $P6_122$ (No.178), $a = 8.583(1)$, $c = 60.373(3)$ Å, $V = 3851(1)$ Å^3, $Z = 6$, $\rho_{calcd} = 1.37$ g cm^{-3}, $\mu(Cu_{K\alpha}) = 87.9$ cm^{-1}, $T = -70$ °C; Rigaku AFC5R diffractometer, ω scans; 1351 measured reflections, of which 862 with $I > 3.0\sigma(I)$ were used in the refinement. The structure was solved by direct methods (SAPI91) and refined by full-matrix least-squares techniques against $|F|^2$ with teXsan crystallographic software package of Molecular Structure Corporation. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined; $R = 0.035$, $Rw = 0.049$, residual electron density $+0.34/-0.40$ e Å^{-3}. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-55. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[12] The reaction of **2** and **3** in C_6D_6 at 50 °C monitored over 5 days by NMR spectroscopy showed that another complex (^{31}P NMR: $\delta = 16.26$) was generated in the transformation as a transient intermediate. This signal appeared before the emergence of the signal assignable to **5** ($\delta = 15.87$). The amount of the transient species reached its maximum (about 15% by ^{31}P NMR integration) after 10 hours and then gradually decreased. Further characterization or isolation of the transient species was not feasible.

[13] Broad NMR signals appear to indicate that **7** is in equilibrium with monomer **4** in solution. **7**: M.p. 133–137 °C (decomp, under vacuum); ^{1}H NMR (300 MHz, [D$_8$]THF): $\delta = 1.25$–1.37 (br. m, 36H), 1.64 (br. d, 12H, $J = 14$ Hz), 4.94 (s, 8H, $^1J(Si,H) = 160$ Hz, SiH_2), 7.05 (dd, 4H, $J = 3$, 5 Hz), 7.54 (dd, 4H, $J = 3$, 5 Hz); ^{13}C{^{1}H} NMR (75.5 MHz, [D$_8$]THF): $\delta = 14.28$ (br., PCH_3), 29.65 (br. t, $J = 19$ Hz, PCH_2CH_2P), 126.84 (s), 134.37 (s), 152.42 (s); ^{31}P{^{1}H} NMR (121.5 MHz, [D$_8$]THF): $\delta = 2.68$ (br.); ^{29}Si{^{1}H} NMR (59.6 MHz, [D$_8$]THF): $\delta = -18.5$ (br); IR (KBr): $\tilde{\nu} = 2006$ cm^{-1} (SiH); C,H analysis: calcd for $C_{30}H_{64}P_6Pd_2Si_4$: C 38.50, H 6.89; found: C 38.72, H 6.78. The dimeric structure was confirmed by X-ray analysis. The detailed results will be reported separately.

[14] Note that complex **2** is thermally stable at room temperature and slowly decomposes at 90 °C to form methane and ethane; see ref. [8]. Accordingly, generation of palladium(0) species prior to the oxidative addition of **3** is unlikely.

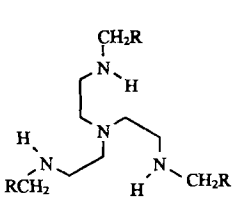
Metallomesogens with Branched, Dendrimeric Amino Ligands**

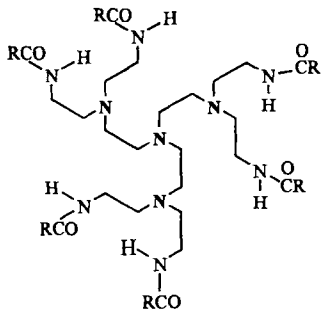
Uwe Stebani, Günter Lattermann,* Michael Wittenberg, and Joachim Heinz Wendorff

In the search for compounds with novel electric or magnetic behavior, the desire to combine the properties of liquid crystals (LC) with those of metal complexes has led to the synthesis of a large number of metallomesogens, mostly with square-planar or linear coordination geometry.[1] However, high-spin transition metal complexes often unavoidably have different geometries whose higher degree of isometry has been regarded for a long time as unsuitable for mesomorphic behavior.[2] Only recently have, for example, liquid-crystalline nickel(II) complexes with paramagnetic properties based on octahedral[3] and tetrahedral coordination[4] been described. The previously known LC complexes with trigonal-bipyramidal configuration have a distorted shape, as in the case of the dimeric zinc alkoxydithiobenzoates[5] and the iron complexes, which have coordination geometries lying between square-pyramidal and trigonal-bipyramidal.[4b, 6]

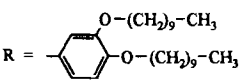
The branched amine ligands $\mathbf{L^1}$ and $\mathbf{L^2}$, which are ethyleneimine dendrimers of the first and second generation and are derivatives of tris(2-aminoethyl)amine (tren), allow access to a novel class of liquid-crystalline transition metal complexes with trigonal-bipyramidal or octahedral coordination geometry. The use of dendrimeric ligands in metallomesogens has not been reported before.



$\mathbf{L^1}$



$\mathbf{L^2}$



The transition temperatures (determined by polarization microscopy and differential calorimetry) of the metal complexes $\mathbf{K^1}$–$\mathbf{K^8}$ are listed in Table 1. Up to $\mathbf{K^3}$ ($\mathbf{L^1} \cdot Ni(NO_3)_2$), all complexes show mesomorphic behavior with relatively low glass transition temperatures. With $\mathbf{K^1}$, $\mathbf{K^4}$, and $\mathbf{K^7}$ there is no crystalline phase, for the other compounds a crystalline phase appears only before the first heating. No double refraction is ob-

Table 1. Transition temperatures [°C] of complexes $\mathbf{K^1}$–$\mathbf{K^8}$ (in parentheses: ΔH [kJ mol^{-1}]).

Complex	T_g	ΔC_p	K		M		I
$\mathbf{K^1}$, $\mathbf{L^1}\cdot CoCl_2$	56	0.37	–		•	85.5 (0.4)	•
$\mathbf{K^2}$, $\mathbf{L^1}\cdot NiCl_2$	40	0.61	•	47.0 (3.4)[a]	•	64.5 (1.7)	•
$\mathbf{K^3}$, $\mathbf{L^1}\cdot Ni(NO_3)_2$	36	0.64	•	46.5 (11.1)[a]	–		•
$\mathbf{K^4}$, $\mathbf{L^1}\cdot CuCl_2$	41	0.57	–		•	75.0 (0.8)	•
$\mathbf{K^5}$, $\mathbf{L^1}\cdot Cu(SCN)_2$	41	0.39	•	48.5 (4.6)[a]	•	75.0 (1.1)	•
$\mathbf{K^6}$, $\mathbf{L^1}\cdot Cu(NO_3)_2$	36	0.88	•	47.5 (12.4)[a]	•	79.0 (1.4)	•
$\mathbf{K^7}$, $\mathbf{L^1}\cdot ZnCl_2$	60	0.41	–		•	126.0 (1.3)	•
$\mathbf{K^8}$, $\mathbf{L^2}\cdot CuCl_2$	49	0.64	–		•	140.0 (2.8)	•

[a] Only on first heating; T_g: glass transition temperature [°C]; ΔC_p [kJ mol^{-1} K^{-1}]; K: crystalline phase, M: mesophase, I: isotropic phase.

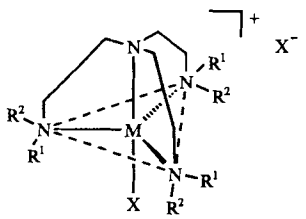
Table 2. X-ray reflections and lattice constants in the mesophase of complexes of $\mathbf{L^1}$ and $\mathbf{L^2}$ and of the ligand $\mathbf{L^2}$.

Complex	d_{10}	d_{11}	d_{20}	d_{30}	a_{hex}
$\mathbf{K^1}$, $\mathbf{L^1}\cdot CoCl_2$	28.67	–	–	–	–
$\mathbf{K^2}$, $\mathbf{L^1}\cdot NiCl_2$	30.13	–	–	–	–
$\mathbf{K^4}$, $\mathbf{L^1}\cdot CuCl_2$	30.48	–	15.37	–	–
$\mathbf{K^5}$, $\mathbf{L^1}\cdot Cu(SCN)_2$	32.63	–	16.34	–	–
$\mathbf{K^7}$, $\mathbf{L^1}\cdot ZnCl_2$	30.78	17.49	15.07	10.16	35.2
$\mathbf{L^2}$	31.09	18.64	15.93	–	36.4
$\mathbf{K^8}$, $\mathbf{L^2}\cdot CuCl_2$	31.98	18.99	16.09	10.57	36.9

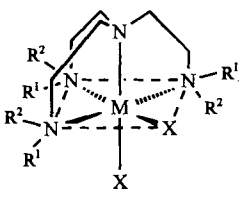
served with the polarization microscope, but $\mathbf{K^7}$ has a fine, needlelike texture.

For the complexes $\mathbf{L^1}\cdot CoCl_2$ ($\mathbf{K^1}$) and $\mathbf{L^1}\cdot NiCl_2$ ($\mathbf{K^2}$), X-ray diffraction of the mesophase (Table 2) gave only a first order reflection apart from a halo at 4.4 Å. For $\mathbf{L^1}\cdot CuCl_2$ ($\mathbf{K^4}$) and $\mathbf{L^1}\cdot Cu(SCN)_2$ ($\mathbf{K^5}$), a second order reflection was observed as well, which is attributed to a lamellar phase. For $\mathbf{L^1}\cdot ZnCl_2$ ($\mathbf{K^7}$), the mixed d_{11} reflection is indicative of a hexagonal-columnar phase (Col_h).

The tren skeleton is in principle able to accomodate two coordination geometries: a) trigonal-bipyramidal (**1**) with fivefold coordination ("azatran geometry" with elements of Groups 1, 2, and 12–15[7] and with transition metals of Groups 3–11[8], resulting in ionic complexes), and b) octahedral geometry (**2**) in the case of neutral complexes of transition metals. The azatran geometry **1** is preferred with most divalent metal centers.[9] Only in the case of the Ni^{II} complex with unsubstituted tren ligands does the octahedral geometry **2** also occur;[8d] with hexamethyl-substituted tren, the trigonal-bipyramidal structure is again favored.[10]



1



2

As the $\mathbf{L^1}$ complexes do not form stable crystalline phases, it was not possible to carry out X-ray structural analysis. However, the complex geometry can be established by comparison with known non-liquid-crystalline analogs. The trigonal-bipyramidal[11] complex formed from the unsubstituted tren ligands and $Cu(SCN)_2$ shows a special feature in the IR spectrum—two sets of two absorption bands corresponding to an isothiocyanato ligand and an ionic thiocyanate group.[12] Comparison of the IR data for this complex with those for $\mathbf{L^1}\cdot Cu(SCN)_2$ ($\mathbf{K^5}$) shows that the absorption bands of the coordinated isothiocyanate group and the thiocyanate anion correspond (Table 3). The trigonal-bipyramidal azatran structure may therefore also be assigned to $\mathbf{K^5}$ (Scheme 1).

Table 3. IR and UV absorption bands of the complexes $\mathbf{K^1}$–$\mathbf{K^6}$ and $\mathbf{K^8}$.

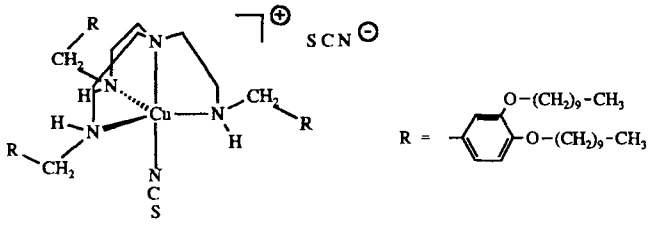

Scheme 1. Structure of [$\mathbf{L^1}\cdot$Cu(NCS)](SCN).

With the other complexes, the geometry cannot be deduced from the IR data. However, important information is available from the UV/Vis spectra (Table 3).[13] The measured wavelengths and molar extinction coefficients of the Co^{II} complex $\mathbf{K^1}$ (Fig. 1) would not expected from octahedral geometry,[13] but correspond to trigonal-bipyramidal coordination.[10] The two or three very intense bands of the Cu^{II} complexes $\mathbf{K^4}$–$\mathbf{K^6}$ cannot be due to an octahedral structure (only one band of low intensity),[13] but confirm the trigonal-bipyramidal coordination that was established by IR spectroscopy for $\mathbf{K^5}$, which can therefore also be assumed for $\mathbf{K^4}$ and $\mathbf{K^6}$. The absorption bands of the Ni^{II} complexes are of only low intensity. Their number, position, and extinction coefficients agree very well with typical values for

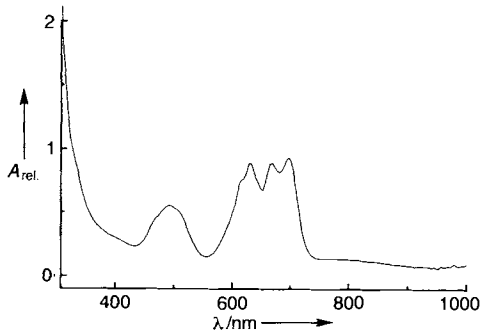

Fig. 1. UV/Vis spectrum of [$\mathbf{L^1}\cdot$CoCl]Cl ($\mathbf{K^1}$) (hexane, $c = 5\times10^{-3}$ mol L^{-1}).

octahedral nickel complexes.[13] No information on the coordination geometry of the complex $L^1 \cdot ZnCl_2$ (K^7) can be derived from the spectroscopic data.

Owing to the very low coordination tendency of the peripheral amide groups, the situation for L^2 is similar to that for L^1. The copper(II) dichloride complex $[L^2 \cdot CuCl]Cl$ (K^8) does not show any crystalline phase; the enantiotropic mesophase is frozen in the glassy state above room temperature (Table 1), and the texture is broken spherolitic (Fig. 2). X-ray diffraction experiments show the presence of a hexagonal-columnar mesophase (Col_h) with $a_{hex} = 36.9$ Å (Table 2, Fig. 3). The lattice constant is only 0.4 Å greater than that of the free ligand, which indicates that complexation has only a negligible influence on the space filling of the molecule. The UV/Vis spectrum of K^8 is almost identical to that of K^4 (Table 3), so that trigonal-bipyramidal coordination may also be assumed for K^8.

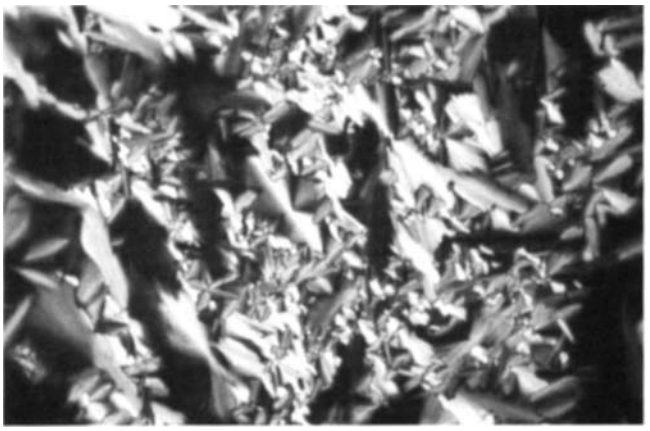

Fig. 2. Texture of the complex $[L^2 \cdot CuCl]Cl$ (K^8) ($T = 132$ C, 120-fold magnification, crossed polarizers).

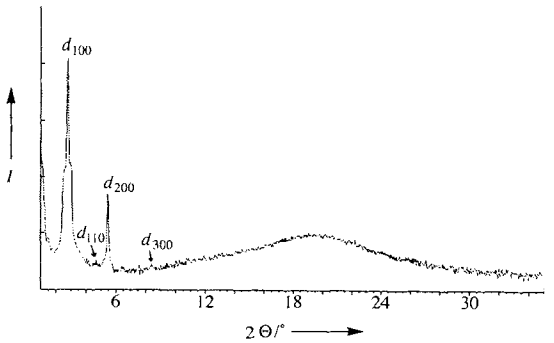

Fig. 3. X-ray diffraction diagram of the complex $[L^2 \cdot CuCl]Cl$ (K^8).

The complexes described here are the first examples of metallomesogens with branched, dendrimeric oligoalkyleneamino ligands. These mesogens are not based on the classical rod or disklike shape. They show a trigonal-bipyramidal coordination geometry; only the nickel complexes studied are octahedral. The transition temperatures of all the complexes—in the absence of a crystalline phase—are relatively low for metallomesogens. The hexagonal-columnar phase appears to be formed when either the larger ligand L^2 or the Zn^{II} ion are present. Initial measurements have shown that the nickel complexes described here are also paramagnetic.

Experimental Procedure

L^1: Tris(2-aminoethyl)amine was allowed to react with 3,4-bis(decyloxy)benzoyl chloride [14], and the product was reduced to the amine [3] (54% yield); IR (KBr): $\tilde{\nu} = 3302\ cm^{-1}$, 2925, 2855, 1606, 1589, 1512, 1467, 1380, 1264, 1231, 1134, 1044, 801, 722; ^1H NMR (250 MHz, $CDCl_3$): $\delta = 6.85$ (s, 1H, arom.), 6.65–6.80 (m, 2H, arom.), 3.95 (m, 4H, OCH_2), 3.65 (s, 2H, $ArCH_2$), 2.60 (m, 4H, CH_2N), 1.75 (m, 4H, OCH_2CH_2), 1.10–1.60 (m, 28H, alkoxy-CH_2), 0.85 (t, 6H, CH_3); EI-MS (70 eV): *m/z* (%): 1352 (11) [M^+], 460 (100); Elemental analysis (%): calcd for $C_{87}H_{150}N_4O_6$ (1354.15 $g\,mol^{-1}$): C 77.17, H 11.61, N 4.14, O 7.09; found: C 77.17, H 11.55, N 4.08.

L^2: This ligand was prepared as described elsewhere [15].

K^1–K^8: To L^1 or L^2 in EtOH at 60 C was added dropwise an equimolar amount of the metal salt dissolved in EtOH. The mixture was stirred for 3 h at 60 C, stored in a refrigerator for 12 h, and then filtered. The residue was recrystallized from EtOH, and the solid dissolved in benzene and freeze-dried. K^5 was synthesized by adding NaSCN in acetone to an equimolar amount of K^4 in acetone at 50 C. After 30 min, this was filtered hot, worked up as described, and recrystallized from benzene (85–92% yield).

Complexes with L^1 (for example: $L^1 \cdot ZnCl_2$): IR (KBr): $\tilde{\nu} = 3193\ cm^{-1}$, 2925, 2855, 1606, 1589, 1515, 1467, 1380, 1265, 1141, 1044, 812, 722; ^1H NMR (250 MHz, $CDCl_3$): $\delta = 7.05$ (br., 1H, arom.), 6.95 (br., 1H, arom.), 6.75 (d, 1H, arom.), 3.8–4.1 (m, 6H, OCH_2, $ArCH_2N$), 2.5–2.8 (br., 4H, NCH_2CH_2N), 1.6–1.9 (m, 4H, OCH_2CH_2), 1.1–1.5 (m, 28H, alkoxy-CH_2), 0.9 (t, 3H, CH_3); Elemental analysis (%): $[L^1 \cdot CoCl]Cl$ (K^1): calcd for $C_{87}H_{156}Cl_2CoN_4O_6$ (1483.99 $g\,mol^{-1}$): C 70.42, H 10.60, N 3.78, Cl 4.78, Co 3.97, O 6.47; found: C 70.25, H 10.60, N 3.94; $[L^1 \cdot NiCl_2]$ (K^2): calcd for $C_{87}H_{156}Cl_2NiN_4O_6$ (1483.75 $g\,mol^{-1}$): C 70.43, H 10.60, N 3.78, Cl 4.78, Ni 3.96, O 6.47; found: C 70.17, H 10.87, N 3.80; $[L^1 \cdot Ni(NO_3)_2]$ (K^3): calcd for $C_{87}H_{156}NiN_6O_{12}$ (1536.85 $g\,mol^{-1}$): C 67.99, H 10.23, N 5.47, Ni 3.82, O 12.49; found: C 68.05, H 10.11, N 5.37; $[L^1 \cdot CuCl]Cl$, (K^4): calcd for $C_{87}H_{156}Cl_2CuN_4O_6$ (1488.60 $g\,mol^{-1}$): C 70.20, H 10.56, N 3.76, Cl 4.76, Cu 4.27, O 6.45; found: C 69.69, H 10.95, N 4.28; $[L^1 \cdot Cu(NCS)](SCN)$ (K^5): calcd for $C_{89}H_{156}CuN_6O_6S_2$ (1533.93 $g\,mol^{-1}$): C 69.68, H 10.25, N 5.48, Cu 4.14, S 4.18, O 6.47; found: C 68.80, H 10.35, N 6.55, Cu 4.30, S 4.10; $[L^1 \cdot Cu(NO_3)](NO_3)$ (K^6): calcd for $C_{87}H_{156}CuN_6O_{12}$ (1541.70 $g\,mol^{-1}$): C 67.78, H 10.20, N 5.45, Cu 4.25, O 12.45; found: C 67.64, H 10.05, N 5.45; $L^1 \cdot ZnCl_2$ (K^7): calcd for $C_{87}H_{156}Cl_2ZnN_4O_6$ (1490.45 $g\,mol^{-1}$): C 70.11, H 10.55, N 3.76, Cl 4.76, Zn 4.39, O 6.44; found: C 68.95, H 10.38, N 4.07.

An Intermolecularly Donor-Stabilized Silanediyl(silyl)nickel Complex: Combined Si–Si Bond Cleavage and Methyl Migration between Silicon Centers**

Sylvain Nlate, Eberhardt Herdtweck, and Roland A. Fischer*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

Cyclopentadienyl derivatives with Lewis bases in the side groups that are capable of binding to hard and soft centers in a hemilabile manner promise a rich coordination chemistry and unusual reactions at the metal center. Prominent ligands include [2-(*N*,*N*-dimethylamino)ethyl]cyclopentadienyl and its tetramethyl-substituted derivative (Cp^N and Cp^{*N}, respectively), and intermolecular adducts of these to various metal centers are known.[1] However, convincing examples in which reactions are specifically controlled by the binding properties of this ligand have not been reported.

The nickel dimer $[Cp^N_2(CO)_2Ni_2]$ can be synthesized quantitatively by the "classical" reaction of $[Cp^N_2Ni]$ and tetracarbonylnickel (the corresponding Cp* compound has been described previously[1b]). Oxidative cleavage of the nickel dimer with iodine, followed by decarbonylation gave the key compound **1** (Scheme 1). The quality of the crystallographic data[3a] (Fig. 1) of **1** is affected by dynamic disorder of the aminoethyl substituent (large anisotropic thermal parameters at C6 and C7). To the best of our knowledge there is only one further structurally characterized example of a nickel complex with intramolecular coordination of the substituent at Cp: $[\eta^5{:}\eta^2$-2,3,4,5-tetramethyl-1-(4-pentenyl)cyclopentadienyl](bromo)-nickel(II).[4]

Reaction of **1** with $[(thf)_3Li\{Si[Si(CH_3)_3]_3\}]$ selectively yields bright yellow, air-sensitive crystals of **2** in 80–90% yield (Fig. 2).[3b] This is the first structurally characterized example of a silanediyl(silyl) metal complex. The occurrence of both π(M=Si) and σ(M–Si) bonds in one molecule permits a direct comparison these two types of bonding. Complex **1** is related to some bissilanediyl complexes, for example $[(\eta^5\text{-}C_5Me_5)Ru(PPh_3)\{\eta^2\text{-}[(\mu\text{-}CH_3O)(SiMe_2)_2]\}]$,[5] which are also stabilized by intramolecular base coordination, but contain identical Si complex fragments. The only other known silanediylnickel complex is [bis(1,3-di-*tert*-butyl-2,3-dihydro-1*H*-1,3,2-diazasilol-2-ylidene)](dicarbonyl)nickel, which was described as a "donor-free" system. However, in this compound silicon is bound to two nitrogen atoms, and π(Si–N) interactions cannot be neglected.[6] Even when the reduced coordination number of three is taken into consideration, the Ni–Si4 bond length in **2** (213.7(1) pm; Fig. 2) is significantly shorter than the corresponding bonds in the above-mentioned $NiSi_2$ complex (220.7(2) pm and 221.6(2) pm).[6] According to T. D. Tilley et al.

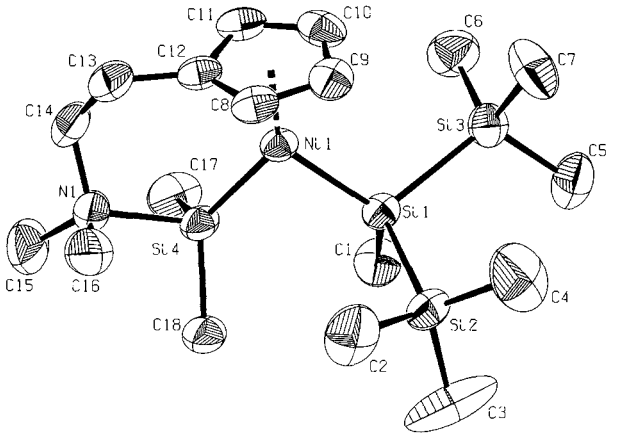

Fig. 2. Crystal structure of **2** (ORTEP, thermal ellipsoids at 50% probability level). Selected bond lengths [pm] and angles [°]: Ni–Si4 213.7(1), Ni–Si1 224.0(1), Ni–C8 211.8(3), Ni–C9 211.6(3), Ni–C10 214.1(3), Ni–C11 214.9(3), Ni–C12 209.3(3), Si1–C1 192.9(3), Si4–C18 188.7(4), Si4–C17 189.2(4), Si4–N1 200.2(3), N1–C14 151.2(4), C12–C13 149.6(5), C13–C14 152.1(5); Si4-Ni1-Si1 88.56(3), C18-Si4-C17 96.7(1), C18-Si4-N1 96.8(1), N1-Si4-Ni1 107.69(8).

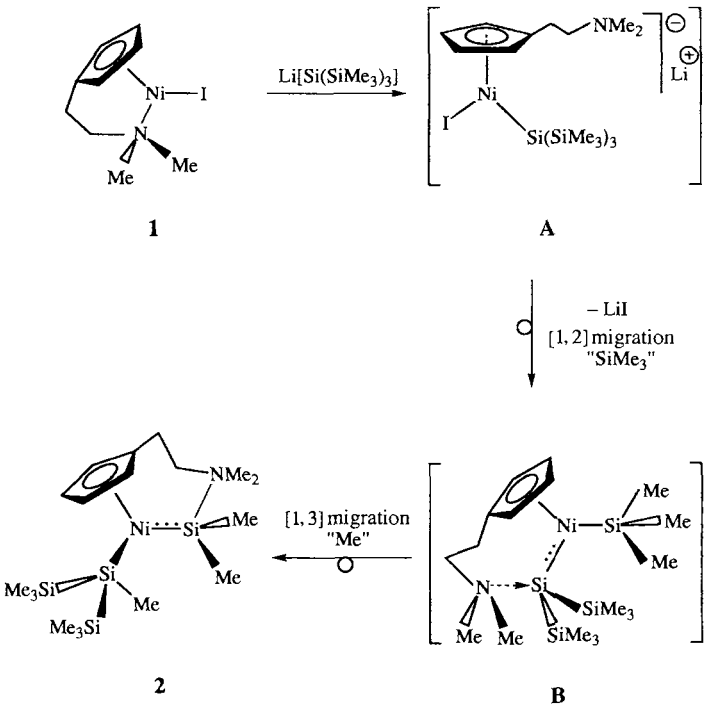
donor stabilization or heteroatom substitution lead to elongated M–Si bonds.[7] Thus, the Ni–Si bond in a donor-free silanediylnickel complex should be shorter than 214 pm. In contrast, the Ni–Si1 bond, which is 10 pm longer, clearly lies in the range of Ni–Si single bonds.[8] Proton-decoupled ^{29}Si NMR spectroscopy shows three types of silicon atoms. The occurrence of a downfield signal for Si1 at $\delta = 107.8$ is consistent with the discussed binding mode.[9] The Si4–N donor–acceptor bond length (200.2(3) pm) is in the range of Si–N bond lengths determined for the related complexes $[(CO)_5Cr{=}Si(Ph)(Ar^N)]$ (204.6(2) pm, Ar^N = 2-(dimethylaminomethyl)phenyl[9b]) and $[\{(\eta^5\text{-}(C_5H_5)(CO)_2Fe{=}Si(CH_3)Ar^N\}^+]$ (194.9(3) pm[10]). The Ni atom in **2** is coordinated to the center of the Cp ligand, whereas in **1** a strongly decentralized binding mode exists. The formation of the bright yellow complex **2** evidently occurs via the primary intermediate **A** (Scheme 2); the aminoethyl substituent is replaced by the incoming nucleophile $\{Si[Si(CH_3)_3]_3\}^-$, a course analogous to that for the reaction of **1** with a phosphane ligand, which is isolobal to the silyl group (Scheme 1, **1** → **3**). The reaction is accompanied by a change of color from greenish black (**1**) to a dark red-purple (**A**). There are examples for the activation of Si–Si bonds at transition metal centers, for example with oligosilanyl systems $[L_nM{-}SiR_2{-}(SiR_2)_n{-}SiR_3]$,[11] and for [1,3] migration of a methyl group between silicon centers in bissilanyl complexes.[12] Intermediates analogous to **2** were claimed, but never isolated. Formation of **2** can be rationalized as follows (Scheme 2): In a first step, complex **B** is formed from intermediate **A** after elimination of LiI and [1,2] migration of a $(CH_3)_3Si$ group. Owing to steric hindrance the bis(trimethylsilyl)-substituted silanediyl center in **B** is apparently not sufficiently stabilized by the aminoethyl group. Then the [1,3] sigmatropic methyl shift from the $(CH_3)_3Si$ unit to Si1 stabilizes the system thermodynamically (**B** → **2**), and the resulting dimethylsilanediyl unit Si4 is trapped by intramolecular adduct formation. We assume that these reaction steps are assisted kinetically by the amino group, giving rise to weak hypervalent interactions with the reactive Si centers. Pentacoordinate intermediates were discussed for Si–Si and Si–C bond cleavage.[13]

The coordinative flexibility of the aminoethyl group thus causes a special reactivity of complex **1**. However, this can be strongly affected. Reaction of complex **1** with $[(thf)_3Li\{Si(CH_3)_3]_3\}]$ in the presence of PMe_3 only yields a stable, "trivial" substitution product **4** (see Scheme 1). In summary, only in the *absence* of strong π acceptors (CO) and soft Lewis bases (PR_3) as competing ligands, do aminoalkyl side chains of Cp ligands participate in the coordination to electron-rich transition metal centers. The aminoalkyl function on the Cp system can then be used to stabilize unusual silanediyl(silyl) complexes such as **2**.



Scheme 2. Hypothetical mechanism of the formation of **2**.

Experimental Procedure

1: I_2 (1.02 g, 4 mmol) in THF (20 mL) was added to a stirred solution of $[Cp^N_2(CO)_2Ni_2]$ (1.8 g, 4 mmol) in THF (20 mL) at −78 °C over 30 min. The mixture was allowed to warm to 25 °C and stirred for 2 h. The solvent was evaporated in vacuo, the residue was washed with *n*-pentane (15 mL), and the product was extracted with toluene. Crystallization from toluene at −30 °C gave **1** (2.2 g, 85% based on Ni). Correct elemental analysis.

2: **1** (0.32 g, 1 mmol) was added to a solution of $(thf)_3Li\{Si[Si(CH_3)_3]_3\}$ (0.47 g, 1 mmol) in THF (20 mL) at −78 °C). The mixture was allowed to warm to 25 °C and stirred for 12 h. The solvent was evaporated in vacuo and the residue was extracted into *n*-pentane (20 mL). Crystallization from *n*-pentane at −30 °C gave **2** (0.38 g, 85%). Correct elemental analysis.

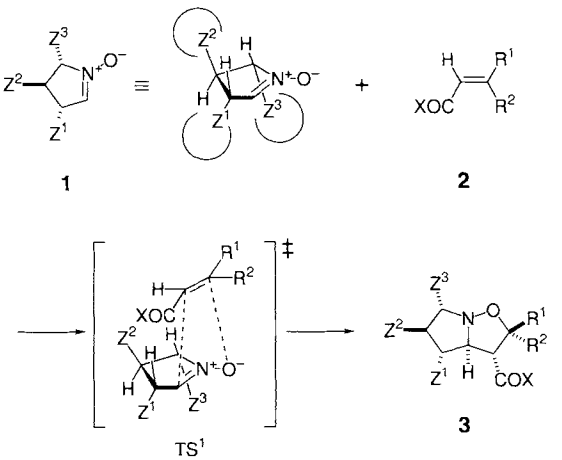
Synthesis and Asymmetric [3+2] Cycloaddition Reactions of Chiral Cyclic Nitrone: A Novel System Providing Maximal Facial Bias for both Nitrone and Dipolarophile**

Teruhiko Ishikawa, Yoshiaki Tajima, Miyuki Fukui, and Seiki Saito*

Asymmetric synthesis through [3 + 2] cycloadditions of chiral nitrones to dipolarophiles provides three contiguous stereogenic centers, the first and third of which are bound to oxygen and nitrogen atoms.[1] In spite of its important role in organic synthesis, a methodology for discriminating the diastereofaces of the nitrone and the enantiofaces of the dipolarophiles at the same time has been lacking.[2]

A cyclic nitrone such as **1** could realize such a high level of stereocontrol (Scheme 1). The role of the three substituents Z^1, Z^2, and Z^3 of **1** seems to be significant. Because Z^1 and Z^3 are located on the same side of the ring (concave space), only the approach to the convex side of dipolarophile (**2**) would be possible. If this is the case, Z^2 would force the smallest substituent



Scheme 1. Nitrone-dipolarophile arrangement in the transition state TS of the reaction of **1** with **2** to form **3**.

of **2** (H atom) to occupy the most demanding space in the transition state (TS^1). We have synthesized **1** by an intramolecular Michael addition of oxime enoates. Furthermore, the reactions of **1** with α,β-unsaturated carbonyl compounds (**2**) have resulted in almost perfect discrimination of the π faces of both **1** and **2**, exclusively affording cycloadducts such as **3**, bearing multiple stereogenic centers.

The cyclic nitrone **1b** that satisfies above-mentioned stereochemical features has been prepared on treatment of a formyl enoate derived from **4b**[3] with hydroxylamine hydrochloride and triethylamine (>99% *de*, Scheme 2). The reaction apparently involves the corresponding oxime enoate as an intermediate. The transition state of the reaction can be depicted as TS^2: TS^3 leading to **1b'** can be ruled out in this case.[4] In contrast, the corresponding formyl enoate derived from **4a** and lacking an α-methyl substituent gave a mixture of **1a** and **1a'** through TS^2 and TS^3, respectively (50% *de*). The structure of **1b** was con-

[**] This work was supported by a Grant-in-Aid for Scientific Research on Priority Areas (No. 07214221) from the Ministry of Education, Science, Sports, and Culture, Japan. We are grateful to "SC-NMR Laboratory of Okayama University" for high-field NMR experiments.

firmed on the basis of spectroscopic analyses, in particular by NOE measurements and mass spectrometry performed on derivative **5**.[5]

The cycloadditions of **1b** to the α,β-unsaturated carbonyl compounds **2a–f** gave the corresponding cycloadducts (**3a–f**, Table 1) in very high diastereomeric excess (>99% *de*).[6] For instance, the diastereofaces of **1b** have been perfectly distinguished by both maleate (**2b**) and maleimide (**2d**) or fumarate

Table 3. Results of the cycloaddition of **1b** to **2** (in C_6H_6 at 70 °C).

Dipolarophile	Equiv. **2**	Time [h]	Cycloadduct [a]	Yield [%]
 **2a**	3	12	 **3a**	82
 **2b**	3	24	 **3b**	85
2c	3	12	 **3c**	84
 **2d**	3	4	 **3d**	89
 **2e**	4	12	 **3e**	62
 **2f**	4	18	 **3f**	60

[a] For chromatographically pure product, the absolute configuration was determined by NOE experiments.

(**2a**), which approach the reaction centers from the convex space exclusively in an *exo* manner and/or enantioselectively (>99% *ee*). The most striking observation is the almost perfect discrimination of enantiofaces of (*E*) and (*Z*) isomeric pairs such as **2e** and **2f**: these dipolarophiles exclusively afforded cycloadducts **3e** and **3f**, respectively. Thus, **1b** is the first chiral, cyclic nitrone capable of achieving an equally high level of face differentiation for the geometric isomers of 1,2-disubstituted and 1,1,2-trisubstituted olefins. The underlying concept for this class of facial bias has significant implications on the design of chiral reagents, catalysts, or ligands.

Experimental Procedure

1b: To a solution of $(COCl)_2$ (0.31 mL, 3.54 mmol, 3 equiv) in CH_2Cl_2 (6 mL) at −70 °C was added a solution of DMSO (0.5 mL, 7.1 mmol) in CH_2Cl_2 (6 mL), and the mixture was stirred for 5 min. To this mixture was added a solution of **4b** (0.511 g, 1.18 mmol) in CH_2Cl_2 (6 mL), the solution stirred for a further 15 min, and Et_3N (1.5 mL, 10.2 mmol, 9 equiv) was added. The mixture was allowed to warm up to 25 °C, quenched with water, and extracted with several portions of hexane/EtOAc (1/1). The combined organic extracts were dried (Na_2SO_4) and concentrated on a rotary evaporator to give the crude aldehyde, which, without purification, was dissolved in CH_2Cl_2 (6 mL). To this solution was added hydroxylamine hydrochloride (0.41 g, 5.90 mmol, 5 equiv) and Et_3N (0.82 mL, 5.90 mmol, 5 equiv) at about 25 °C. The mixture was stirred for 4 h, then poured into water, and extracted with several portions of hexane/EtOAc (1/1). The combined organic extracts were dried (Na_2SO_4) and concentrated on a rotary evaporator to give a crude residue, which was subjected to column chromatography (SiO_2) to give nitrone **1b** as a colorless oil (489 mg, 93%). $[\alpha]_D^{27} = +61.9$ ($c = 5.10$ in chloroform); IR (film): $\tilde{\nu}$ = 1740, 1580, 1460, 1260 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$, 23 °C): δ = 0.069, 0.087, 0.10, 0.17 (each s, each 3H), 0.86, 0.88 (each s, each 9H), 1.11 (d, 3H, J = 7.1 Hz), 1.28 (t, 3H, J = 7.2 Hz), 3.40 (dq, 1H, J = 7.2, 11.8 Hz), 4.13 (br.s, 1H), 4.17 (m, 1H), 4.12 and 4.22 (2 dq, 2H, J = 7.0, 10.8 Hz), 4.54 (d, 1H, J = 2.0 Hz), 6.83 (br. s, 1H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 23 °C): δ = −5.0, −4.8, −4.7, −4.3, 11.2, 14.1, 17.7, 17.8, 25.5, 25.6, 38.2, 61.0, 76.6, 79.3, 82.5, 133.8, 173.2; C,H analysis calcd for $C_{21}H_{43}O_5NSi_2$: H 9.73, C 56.60; found: H 9.85, C 56.45.

3a: A solution of **1b** (1 mmol) and dimethyl fumarate (3 equiv) in benzene (1 mL) was heated at 70 °C. The reaction was continued until **1b** was consumed (monitored by TLC). Then the mixture was concentrated on a rotary evaporator, and the residue was purified by column chromatography (SiO_2) to give **3a**. $[\alpha]_D^{21} = -2.71$ (c = 1.18 in chloroform); IR (film): $\tilde{\nu}$ = 1740, 1260, 1100 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$, 23 °C): δ = 0.055, 0.069, 0.078, 0.107 (each s, each 3H), 0.87 (s, 2 × 9H), 1.20 (d, 3H, J = 7.0 Hz), 1.26 (t, 3H, J = 7.1 Hz), 2.79 (dq, 1H, J = 7.0, 7.2 Hz), 3.61 (dd, 1H, J = 1.9, 7.2 Hz), 3.73 (m, 1H), 3.75 (s, 3H), 3.77 (s, 3H), 4.03 (t, 1H, J = 8.3 Hz), 4.04 (br. s, 1H), 4.12 and 4.17 (2 dq, 2H, J = 7.2, 7.6 Hz), 4.24 (s, 1H), 4.48 (d, 1H, J = 8.3 Hz); $^{13}C\{^1H\}$ NMR (50 MHz, $CDCl_3$, 23 °C): δ = −5.04, −4.96, −4.77, −4.66, 13.7, 14.2, 17.7, 17.8, 25.5, 25.6, 42.1, 52.5, 54.0, 60.3, 76.6, 77.0, 77.6, 79.6, 80.3, 81.0, 170.5, 170.6, 174.4; C,H analysis calcd for $C_{27}H_{51}O_9NSi_2$: H 8.72, C 54.98; found: H 8.77, C 54.88.

[2] An intramolecular [3+2] cycloaddition reaction of a chiral nitrone unit with a prochiral dipolarophile unit in the same molecule has sometimes resulted in almost perfect discrimination of the diastereofaces of the nitrone unit and the enantiofaces of the dipolarophile unit: see ref. [1d].

[3] Compound **4b** was prepared in six steps starting from (2*S*,3*S*)-2,3-*O*-isopropylidene-L-threitol by the sequence of reactions 1) mono-O-*p*-methoxybenzylation, 2) oxidation, 3) Horner–Emmons condensation, 4) cleavage of an acetonide protecting group, 5) TBDMS-protection of a diol group, and 6) cleavage of a *p*-methoxybenzyl protecting group.

[4] For these transition states in which the TBDMSO groups arrange *anti* to each other, see ref. [1f,g] and S. Saito, Y. Hirohara, O. Narahara, T. Moriwake, *J. Am. Chem. Soc.* **1989**, *111*, 4533–4535; S. Saito, O. Narahara, T. Ishikawa, M. Asahara, T. Moriwake, *J. Org. Chem.* **1993**, *58*, 6292–6302 and references therein.

[5] Reduction of **1b** with Pd–charcoal took place at the C=N$^+$ bond to result in subsequent cyclization leading to **5**: the N–O bond was kept intact under the given reaction conditions, as clearly indicated by mass spectrometric analysis of **5**.

[6] Spectroscopic [NMR (^1H, ^{13}C, ^1H-COSY, ^1H-^{13}C-HETCOR, and NOE in some cases), IR, and HRMS] and analytical data for all new compounds were satisfactory.

Black Gold

Hydrocarbon Chemistry. By *G. A. Olah* and *Á. Molnár*, Wiley-Interscience, New York, 1995. 632 pp., hardcover DM 134.90.-ISBN 0-471-11359-X

As a consequence of the increasing consumption of fossil raw materials and fuels – natural gas, oil, and coal – these important sources of hydrocarbons are being rapidly depleted. In the future, therefore, it may become necessary to produce hydrocarbon derivatives using building blocks from less natural sources. This viewpoint is one of the somewhat unconventional thoughts with which George A. Olah and Árpad Molnár introduce their new book *Hydrocarbon Chemistry*.

The book is divided into twelve chapters. After a general introduction describing the origins and uses of hydrocarbons (Chs. 1 and 2) and a short survey of classical synthetic methods based on C_1 sources (Ch. 3), the remaining chapters deal with specific types of reactions: isomerization, alkylation, addition, carbonylation, oxidation and oxygenation, heterosubstitution, reduction and hydrogenation, metathesis, and oligomerization and polymerization. Each of these chapters contains a survey of modern synthetic methods used in the large-scale production of various relevant hydrocarbon derivatives, and explains the most important reaction mechanisms.

Chapter 1 (27 pp., 80 literature references) deals concisely with general aspects, such as the relationship between energy demand and hydrocarbon demand, natural sources of hydrocarbons and extraction processes, the most important available synthetic routes to hydrocarbons, and their uses. Chapter 2 (35 pp., 251 references) describes the most important processes of the petrochemical industry, including cracking, reforming, and dehydrogenation, with their different thermal and catalytic variants, and the technological uses of the most important petrochemical products. Chapter 3 (37 pp., 307 references) describes methods for synthesizing hydrocarbons from C_1 building blocks such as CO_2, CO (Fischer–Tropsch processes), and methanol. Isomerization reactions of alkanes, arylalkanes, and alkenes are then discussed in Chapter 4 (41 pp., 288 references), which also covers some important technological uses such as the manufacture of detergents and polyesters. In Chapter 5 (54 pp., 341 references) the authors deal with methods for the alkylation of hydrocarbons, such as reacting with alkenes, or by the use of various catalysts and reagents such as metal halides (in Friedel–Crafts reactions), Brønsted acids, superacids, or zeolites. These processes are of great technological importance in the manufacture of isoalkanes and alkenes, antiknock fuels, ethylbenzene, cumene, and other alkyl-benzenes. Chapter 6 (68 pp., 558 references) is devoted to additions of electrophilic reagents to alkenes, dienes, and alkynes, with special emphasis on industrial applications. Chapter 7 (22 pp., 205 references) is concerned with carbonylation reactions using CO. These include hydroformylation, oxo reactions, and carboxylation of hydrocarbons using transition metal catalysts; industrial applications are also described. The chapter on oxidation and oxygenation is the longest (Ch. 8, 122 pp., 1041 references). It begins by describing methods for oxidizing saturated hydrocarbons. In addition to the classical methods using free radical initiation these include the use of oxidizing agents such as *m*-chloroperbenzoic acid, dimethyldioxirane, methyl(trifluoromethyl)dioxirane, or hydrogen peroxide in a superacidic medium. Linear alkanes can be converted into primary and secondary alcohols and ketones with regio- and stereoselectivity by using ozone in a superacidic medium or by a dry ozonation reaction using ozone on silica gel. Newer methods are also mentioned, including oxidation by metalloporphyrins and the use of metals as homogeneous oxidation catalysts. The chapter contains detailed explanations of industrial epoxidation processes and the use of oxygen for oxidizing a wide variety of compounds. Chapter 9 (31 pp., 248 references) contains a succinct treatment of heterosubstitution reactions of hydrocarbons. As well as electrophilic halogenation, nitration, and sulfonation reactions of alkanes and arenes the authors discuss free radical and metal-catalyzed reactions for achieving heterofunctionalization. Hydrogenation and reduction reactions and their practical applications are treated in Chapter 10 (56 pp., 345 references). After reviewing heterogeneously and homogeneously catalyzed hydrogenation reactions, the authors go on to discuss chemical and electrochemical reductions, ionic hydrogenations, e.g. using trifluoroacetic acid with trialkyl-silanes, and ionic and metal-catalyzed hydrogenolysis reactions (hydrogenation involving breaking of C–C s-bonds). The chapter ends by describing a number of technological applications, such as the hydro-refining of petroleum fractions and other industrially important hydrogenation processes. Chapter 11 (20 pp., 157 references) is devoted to metathesis reactions and their practical applications. Lastly, in Chapter 12 (70 pp., 500 references), the authors describe the most important methods for oligomerization and polymerization of hydrocarbons. They explain the main reaction mechanisms and discuss stereo- and regioselectivity in relation to industrially important reactions such as Ziegler–Natta polymerization; the effects of varying the catalyst and the reaction conditions are also discussed.

Considering the book as a whole, one particularly impressive feature is the provision of a comprehensive collection of references at the end of each chapter. Thus the interested reader has easy access not only to the earlier original papers extending back up to ten years or so, but also to quite recent publications that have appeared during the last two years. On the other hand, the mediocre quality of the presentation of chemical equations and formulas is disturbing, and is unnecessary with modern technology. Bonds are

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

shown extending into the chemical symbols, making the latter difficult to read. Broken-line bonds are sometimes missing or are printed in varying styles, double bonds in arenes are shown crookedly, ring structures are also crooked in some cases and the rings are often incomplete. The symbols in equations are not all of uniform size. In the main text superscripts and subscripts are a little too small, and the latter are printed too low down. Otherwise, however, the text is very clearly set out and easy to read.

The book provides a detailed and informative survey of synthetic methods for hydrocarbons and their derivatives, including industrial processes. This very useful compilation contains a wealth of literature references. Its special appeal lies in the excellent organization of the subject matter. The most important chemical reactions of hydrocarbons, the mechanisms involved, and the applications of these reactions in industrial processes are linked together and described in a concise and readable form. The book will be useful to all readers with an interest in the reactions of hydrocarbons as applied in industrial processes. It will also serve as an excellent foundation for newcomers to the petrochemical field and the chemistry of hydrocarbons, and for those switching interests in these areas, especially as the industrial processes described are identified by name. Industrial chemists, research chemists, and advanced students will also find useful material in this concise and up-to-date survey of all aspects of hydrocarbon chemistry.

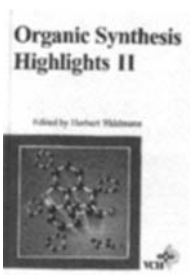
Organic Synthesis Highlights II. Edited by *H. Waldmann*. VCH Verlagsgesellschaft, Weinheim, 1995. 407 pp., hardcover DM 148.00.—ISBN 3-527-29200-4

Organic synthesis is nowadays more than ever before a meeting point of organic chemistry, biochemistry, biology, medicine, physics, and the material sciences. Books concerned with recent developments in this area are therefore of considerable interest to many readers other than synthetic chemists. *Organic Synthesis Highlights II* is a successor to the book *Organic Synthesis Highlights* (J. Mulzer et al.) published in 1990, also by VCH. It contains 40 contributions based on a series of review articles published in the journal *Nachr. Chem. Tech. Lab.* during the period 1989–1993, under the general title "Synthese im Blickpunkt".



Eleven of the articles are by D. Schinzer and twelve are by H. Waldmann, who has also edited this volume. A further six articles are by M. Maier, and K. H. Dötz appears as coauthor in another five. The authors of the remaining contributions are six industrial chemists: R. Bohlmann, T. Brumby, H.-P. Fischer, P. Hammann, R. Henning, and G. Sedelmeier. The book is divided into two parts, the first dealing with new methods and reagents for organic synthesis and the second with their applications in total syntheses of natural products and analogs thereof.

Part 1 is concerned with six topical themes of organic synthesis. The first of these is asymmetric synthesis, to which six chapters are devoted; the subjects range from the Sharpless epoxidation and enantioselective *cis*-dihydroxylation, through asymmetric aza-Diels–Alder reactions, to the use of amines with C_2 symmetry as chiral auxiliaries. The second topic is organometallic chemistry, which is treated at considerable length in seven chapters, reflecting the growing importance of organometallic reactions in synthesis. The wide variety of topics covered includes rhodium-catalyzed carbenoid cyclizations, nickel-activated C_1 building blocks, C–C bond-forming reactions using metallocenes of sub-group 4 metals, and aluminum enolates. The third group of articles is concerned with modern aspects of organosilicon chemistry. In the three chapters in this group the authors report on selective transformations using pentacoordinated silicon compounds, oxidative cleavage of silicon-carbon bonds, and the temporary attachment of silicon-containing groups. The next group of articles has the general heading "Enzymes in Organic Synthesis"; here H. Waldmann reports on applications of enzymatic catalysis in the formation of C-C bonds and in syntheses of *O*-glycosides. The subject of the penultimate section of Part 1 is an "evergreen": the synthesis of heterocycles by cyclization reactions. In four chapters D. Schinzer deals very thoroughly with electrophilic cyclizations of iminium, oxonium, and sulfonium systems, and with the use of polycyclization reactions in the synthesis of alkaloids. Part 1 ends with five articles on "General Methods and Reagents for Organic Synthesis". The methods discussed here are domino reactions and group-selective reactions, and the reagents described are hypervalent iodine species, furan as a synthetic building block, and fluorine.

The articles in Part 2 describe total syntheses of natural products and active agents. The discussions illustrate the impressive capabilities of the techniques now available for organic synthesis, and also emphasize the need to continually develop new methods and reagents. The first of the two sections contains most of the contributions from authors in industry, and is concerned with syntheses of several important classes of natural products and active compounds, including hydroxyethylene-isosteric dipeptides, natural products for plant protection, penems, *O*-glycosides, carbacyclins, mitomycins, ergot and piperidine alkaloids, and taxanes. The concluding part of the book—which I might also describe as its crowning achievement—is an account of the total syntheses of several complex natural products. Here the authors have chosen some very interesting target molecules: CC-1065, morphine, calicheamicin γ_1^I, and rapamycin.

This list of topics is by no means complete, but is sufficient to show that the book covers a wealth of modern developments in organic synthesis. Although the articles treat such a wide variety of topics, the quality is consistently high throughout. All the authors have succeeded in presenting the essentials of their subjects concisely and clearly. The reader needing further details will benefit from the extensive lists of literature references.

Organic Synthesis Highlights II will obviously be of great value for post-graduate students and for everyone interested in modern synthetic methods. It is also eminently suitable as a source for preparing seminars and colloquia for advanced undergraduate students. From the standpoint of students especially, it would of course be helpful if this excellent book could also be published in a cheaper paperback edition.

Theoretical and Physical Principles of Organic Reactivity. By *A. Pross*. Wiley, Chichester, 1995. 294 pp., hardcover £ 42.50.—ISBN 0-471-55599-1

Why do reactions have energy barriers? That is the fundamental question addressed in this monograph by A. Pross,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1866 $ 15.00+.25/0

one of the pioneers in the development and application of the theory of crossing potential curves, usually called the valence bond configurational mixing (VBCM) theory or the curve-crossing model. The book contains ten chapters which are grouped under three main sections: "Theoretical Principles", "Principles of Physical Organic Chemistry", and "Reaction Types". The first section introduces some basic concepts of molecular quantum mechanics. Here the author avoids using mathematical formalism as far as possible. The comparison between the molecular orbital and valence bond theories is well presented and instructive. The fourth chapter starts from simple potential energy curves and develops the theory to discuss reaction profiles using the VBCM method. The three most important "ingredients" of the VBCM theory are explained here, namely the initial excitation energy G, the fraction factor f, and the resonance energy B. Chapter 5 continues this theme with scarcely a perceptible break, explaining a number of well-established reactivity concepts such as the Hammond postulate, the Bell–Evans–Polanyi principle, and the Marcus theory. Both these chapters make easy reading as the arguments follow a clear sequence. However, they could have been improved by including a little more detail, especially in the treatment of the Marcus theory. Chapter 6 discusses empirical structure–reactivity relationships that are not based on a theoretical model, such as the Hammett and Brønsted relationships. In Chapter 7 the author provides the reader with all the theoretical tools needed to apply the VBCM theory qualitatively: the excitation energies, electron affinities, and ionization potentials. Chapter 8 then deals with solvent effects on reaction rates, describing various classical procedures for quantifying such effects, and finally considering solvent effects in terms of the VBCM theory.

The third section of the book is entirely devoted to applications of the VBCM theory to various types of reactions. In accordance with the historical development of the theory it is natural that the greatest emphasis is given to nucleophilic substitution reactions and to general considerations regarding the reactivity of nucleophiles. The last chapter describes recent work by the author on the reactivity of free radicals and carbenes and the application of the VBCM model to pericyclic reactions.

The author writes in an excellent and didactically clear style, both in explaining fundamental concepts and in discussing the many well-chosen examples; thus the central features of the VBCM theory come out especially clearly. Pross confines the discussion to considerations of energy level diagrams and variations in the initial excitation energy, and thus all aspects are treated qualitatively and in a comparative way. This makes the book especially suitable for the readership intended by the author, defined as "advanced undergraduate and graduate students as well as researchers in organic chemistry". The quantitative application of the VBCM theory has already been treated in a monograph by S. Shaik et al. published in 1992 and reviewed in this journal (*Angew. Chem.* **1993**, *105*, 1277; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 1106). Perhaps the only complaint about this excellent introduction is that nearly all the publications on the VBCM theory cited here originate either from the author himself or from S. Shaik. Proposed extensions to the VBCM theory, such as those discussed in the literature by V. Parker, are not mentioned. Also the chosen examples are rather one-sided, in that they illustrate the scope but not the limitations of the VBCM theory. These become especially evident in reactions with very low energy barriers, such as those between nucleophiles and radical cations, and generally in bimolecular reactions where intermolecular attractive forces come into play.

Organomagnesium Methods in Organic Synthesis. (Series: Best Synthetic Methods.) By *B. J. Wakefield.* Academic Press, London, 1995. 249 pp., hardcover £ 50.00.—ISBN 0-12-730945-4

Like the other volumes of this series, the book reviewed here is designed to inform synthetic organic chemists about the capabilities, advantages, and limitations of a particular class of synthetic methods from a practical standpoint. The approach is based not only on describing many examples from the literature but also on giving detailed laboratory procedures for carrying out the preparations. From this the reader can quickly gain a comprehensive picture of the reaction conditions, the techniques used, and the work-up procedures.

The first of the 16 chapters in this volume deals with general aspects, beginning with a fairly brief account of the structures and reactive properties of organomagnesium compounds, then discussing in more detail the methods for handling and using them. The author discusses the different solvents used and describes the techniques for working in an inert environment and performing titrations. This is followed by a chapter of more than fifty pages on the preparation of organomagnesium compounds, including detailed descriptions of 25 laboratory procedures. As well as methods based on activation of magnesium metal, this includes routes that start from other organomagnesium or organolithium compounds, and ligand exchange reactions. The chapters that follow describe applications of organomagnesium compounds in synthesis. The list includes addition reactions of alkenes, alkynes, carbon–nitrogen multiple bonds, carbonyl compounds, and thiocarbonyl compounds, followed by substitutions at carbon atoms, reactions yielding carbenes and arynes, reactions with acidic compounds, methods for forming carbon–nitrogen, carbon–oxygen, carbon–sulfur, carbon–selenium, carbon–tellurium, and carbon–halogen bonds, and methods for synthesizing organoboron, organophosphorus, organosilicon, and various organometallic compounds.

Reaction mechanisms are also explained in some cases, but the emphasis remains firmly on practical synthetic applications. The great value of the book lies in its presentation of the broad scope of applications of organomagnesium compounds, in the wealth of examples that are described, and in the detailed descriptions of experimental procedures. The examples from the literature are closely integrated with the selected laboratory recipes. In addition there are tables referring the reader to other published examples. Unfortunately the laboratory procedures are not easily distinguished at a glance from the main text, which would have made for easier reading. However, a very positive aspect of these descriptions is the attention to the detailed needs of the user, including not only valuable advice about special points concerning the reactions, but also about possible difficulties, such as side-reactions that may occur, or the extent to which the reaction is or is not compatible with the presence of certain functional groups. The coverage of the literature is very thorough, including some references as recent as 1994. The inclusion of the laboratory recipes in the list of contents is a useful aid, but it would also have been helpful to provide in addition a "graphic abstract" for quick access to the information.

To summarize, this should not be regarded as a textbook (nor is it intended to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1867 $ 15.00+.25/0

be), but it can be thoroughly recommended as a very useful reference source for libraries and for all chemists wishing to use organomagnesium compounds in synthetic work.

der Universität Münster (Germany)

Multidimensional NMR in Liquids. Basic Principles and Experimental Methods. By *F. J. M. van der Ven.* VCH Verlagsgesellschaft, Weinheim/ VCH Publishers, New York, 1995. 400 pp., hardcover DM 85.00.— ISBN 1-56081-665-1

This book is an up-to-date introduction to multidimensional NMR spectroscopy as applied to biomolecules. It has been written for chemists, biochemists, and biologists interested in problems of molecular structure, who wish to gain a deeper understanding of NMR spectroscopy and have the necessary background in physical chemistry. The mathematical and physical fundamentals of NMR spectroscopy are presented in an exemplary way, without assuming a great deal of previous knowledge. The theoretical tools introduced are later used repeatedly and consistently in the applications part of the book to describe pulsed NMR experiments, thus enabling the reader to relate them directly to practical situations. A particular peptide (His-Val-Tyr) and a protein (the Pf3-DNA binding protein) appear frequently thoughout the book as standard example molecules to illustrate and explain the various NMR experiments used in determining the structures of biomolecules.

The first of the six chapters begins by explaining the vector formalism used for NMR spectroscopy, and basic concepts such as radiofrequency pulses, the rotating frame, off-resonance effects, the free precession of a spin, and Bloch-Siegert effects. This is followed by a more technically-orientated description of the main components of an NMR spectrometer and of data processing methods. At the end of this chapter the author introduces the density matrix, and discusses the relationship between the quantum-mechanical description of a spin in Liouville space and the vector formalism.

Chapter 2 is concerned with the fundamental properties of multi-spin systems, introducing the scalar coupling and the chemical shift as the dominant parameters. The role of these parameters in the development of a spin system as a function of time is described using the product operator formalism, according to the theory formulated by the author simultaneously with the work of Sørensen, Bodenhausen, and Ernst. The product operator formalism using cartesian basis operators plays a central role in the description of NMR experiments throughout the book. The phenomenological description of relaxation in the product operator formalism is briefly discussed. The chapter ends by introducing and explaining the most important terms in the spin Hamiltonian operator (the chemical shift, the spin-spin coupling, and the interaction with the r.f. field).

Chapter 3 shows how a one-dimensional NMR experiment can be described as an assembly of modules in which the basic building blocks are a 90^0 pulse and a 180^0 pulse. These can produce many different effects, such as refocussing of the precessing spins, modulation of the J-coupling, the appearance of a spin-echo, etc. This chapter also describes experiments for measuring the longitudinal and transverse relaxation times and for calibrating pulses, and various types of experiments using heteronuclear detection, such as the well-known INEPT and DEPT procedures. Lastly some more complicated building blocks are described, such as "composite" pulses and decoupling sequences. Because ever more new and improved pulse sequences are continually being introduced, the author is here less concerned with evaluating the existing sequences than with showing the reader what factors should be considered in assessing the usefulness of any newly developed pulse or decoupling sequence.

Chapter 4 is concerned with two-dimensional NMR spectroscopy. The first 60 pages of the chapter are devoted to the COSY experiment, which was the earliest type of 2D experiment and is the simplest. The underlying philosophy here may have been that once one has understood the COSY experiment one has the key to the whole of 2D NMR spectroscopy. This method serves as an example for explaining various tools of 2D NMR spectroscopy, including phase cycles, field gradients, the BIRD pulse sequence, sign differentiation in indirect dimensions (TPPI, states, states-TPPI, etc.), multiquantum filters, and small flip-angle pulses. The other basic mixing schemes for magnetization transfer are then described: Hartmann-Hahn mixing, NOESY via the nuclear Overhauser effect, then ROESY and TOCSY. This is followed by a discussion of heteronuclear correlation experiments with proton detection (HSQC, HMQC, HMBC). Correlation experiments with heteronuclear detection are now scarcely used at all for applications to biomolecules, and are therefore not discussed further. The chapter ends with a detailed discussion of "coherence order pathways", which form the basis for the design of phase cycles and pulsed gradient sequences for suppressing unwanted signals.

Chapter 5 moves on to n-dimensional NMR spectroscopy. Many different experiments of this kind have been developed during the last six years. The author describes the most useful of these, using the product operator formalism. These are arranged in order of the complexity of the pulse sequences rather than according to the spectral or chemical information that they yield. A number of important experiments are described, including 3D and 4D versions of NOESY-HMQC, HCCH-TOCSY, HNCO, HN(CO)CA, and CBCA(CO)NH. Those treated here are only a selection of the many different methods that can be applied to tasks such as determining the structure of a protein. However, the author clearly explains the principles on which the sequences are based, so as to enable the reader to understand the original publications and to evaluate new sequences. The spectral information yielded by these methods plays only a secondary role in the discussions.

The final chapter is devoted to relaxation. This is undoubtedly the most difficult topic to treat. The author first sets out the fundamental principles of relaxation using the example of stochastic fields, leading to simple derivations of the most important mathematical expressions for dipolar relaxation (NOE, ROE, T_1, and T_2). He then goes on to derive a formalism for relaxation in terms of the density matrix. After a brief résumé of the Wangsness-Bloch-Redfield relaxation theory he then calculates the double commutators needed to describe the most important magnetic interactions, namely the dipolar relaxation and the chemical shift anisotropy, and the cross-correlation between these interactions. In contrast to the previous chapters, this chapter on relaxation devotes relatively little attention to relating the results to spectroscopic practice. However, the bibliography for this chapter includes references to review articles and other publications describing relevant experiments and the types of information that they can give about the dynamic structures of biomolecules.

The book can be thoroughly recommended for everyone who wishes to gain a deeper understanding of the applications of NMR spectroscopy to biomolecules in solution. It is unrivalled in its up-to-date

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1868 $ 15.00+.25/0

coverage, in the thoroughness of the theoretical treatment, and in the skill of presentation.

Frank van der Ven died in March this year. His death is a painful loss for the many people who knew Frank. His scientific ability and, not least, his skill in teaching others in the field of NMR spectroscopy were outstanding. This book is an eloquent testimony to the deep understanding, sharp reasoning, and care that characterized his research.

Chemistry of Waste Minimization. Edited by *J. H. Clark*. Blackie, Glasgow, 1995. 554 pp., hardcover £ 89.00.—ISBN 0-7514-0200-6

Attitudes towards caring for the environment are currently undergoing a shift in many sections of society, away from correcting damage towards preventing it in advance. In order to move towards a sustainable pattern of development that safeguards the future environment, the habits of both producers and consumers must change, and this will require some fundamental changes of attitude and also cause some others. For the chemical industry the future will demand a changeover to an ecologically orientated chemistry. The book *Chemistry of Waste Minimization* is an important contribution on this topic, in which J. H. Clark of the University of York has brought together 22 authors from universities and the chemical industry in Great Britain to cover this complex subject in 16 chapters of widely differing content.

In the introductory chapter T. Lester develops some general principles for the book as a whole, and defines the subject as follows: "Waste minimization involves any technique, process or activity which either avoids, eliminates or reduces a waste at its source, usually within the confines of the production unit, or allows reuse or recycling of the waste for benign purposes."

In the second chapter W. Braithwaite examines the industrial aspects of waste minimization, emphasizing that wherever possible this should be achieved in the production process itself, i.e. at the source. Of course the generation of waste products can never be completely eliminated, but wherever possible they should be recycled. Disposal of wastes into the environment should only be considered in cases where they can be treated in such a way that they have no harmful effects on ecosystems. The waste disposal costs must always be taken into account in the economics of the process. A process that at first sight seems expensive may then be found to be actually cheaper than one that generates a lot of waste which is costly to dispose of. Here it is important that chemists and chemical engineers should work closely together.

In Chapter 3, by P. J. Kinley, the environmental legislation in Great Britain, Europe, and the USA is described, and its effects on the chemical industry are discussed.

After these introductory chapters which are of a fairly general nature, we move on to chemistry. What contributions can chemistry offer in this area? There are undoubtedly many, and the selection presented in Chapters 4–16 often strikes one as rather arbitrary.

Catalysts which allow one to carry out a chemical reaction more selectively can make an important contribution. Chapter 4, by K. Smith, C. V. Fry, and M. Tzimas, deals with clays, zeolites, and other types of catalyst supports, and with the reagents used in this form and their applications to various reactions. As one expects, the examples are chosen on the basis that they are more environmentally friendly than conventional processes. However, no quantitative comparisons are made, nor are there any examples of processes that are already being operated commercially.

Chapter 5 (S. J. Tavener and J. H. Clark) describes the principles and applications of phase transfer catalysis. The authors state that "Phase transfer catalysis clearly has an important role to play in a cleaner future", but regrettably they do not support this by citing quantitative studies or giving an example.

Chapter 6, by D. C. Sherrington, contains a detailed description of the design and application of polymer supports for solid state syntheses. In Chapter 7, B. M. Adger reviews methods for synthesizing chiral compounds and describes several interesting examples of industrial applications. G. Webb and J. M. Winfield then examine in Chapter 8 the alternatives to chlorofluorocarbons and halogenated fire retardants.

Chapter 9 (W. R. Sanderson) is an excellent survey of the use of hydrogen peroxide as an environmentally friendly oxidizing agent for treating chemical wastes and as a reagent in syntheses, including many examples of industrial applications. Chapter 10, by T. J. Mason and S. S. Phull, is concerned with sonochemistry, including sonoelectrochemistry, and the use of these methods in synthesis and in waste water treatment. Chapter 11 (K. Scott) describes the many different applications of electrochemistry in treating chemical wastes; these include the recovery of metals from aqueous effluents, the treatment of effluents containing harmful substances such as cyanides, phenols, or organochloro compounds, and the removal of SO_2, H_2S, NO_x, or Cl_2 from gas emissions. However, electrochemical syntheses are only treated briefly. In Chapter 12, J. H. Atherton and I. K. Jones discuss the problem of choosing the best solvent for a reaction.

Chapter 13, by M. J. Ramsden, discusses the problem of polymer recycling, then in Chapter 14 P. H. Walton deals with the important question of the precipitation of metals from aqueous wastes (already partly covered in Chapter 11), and here includes also biological methods. The topical theme of the decomposition of waste substances in supercritical water is discussed by A. A. Clifford in Chapter 15. In the last chapter A. J. Butterworth, S. J. Tavener, and S. J. Barlow describe some further examples of the use of catalysts in the synthesis of fine chemicals. Enzymes are treated briefly, but more space is again devoted to zeolites and montmorillonite catalysts.

The appearance of this multiauthor work is to be welcomed. It should be available in every library and industrial chemical plant. Practitioners of applied chemistry will find in it many useful ideas for applying to their own operations, and it will help synthetic chemists involved in basic research to devise new synthetic routes that are more environmentally acceptable.

Fifty Years of Free Radicals. (Series: Profiles, Pathways, and Dreams. Series editor: *J. I. Seeman.*) By *C. Walling*. American Chemical Society, Washington, DC, 1995. XXVI, 141 pp., hardcover $ 24.95.—ISBN 0-8412-1830-7

"Cheves Walling is one of the founding fathers of radical chemistry. He helped set the parameters twenty years before the explosive growth of the field. His work pervaded the thinking in radical chemistry... Radicals are not in general very selective, they are unusually reactive; but they are quite valuable in the craft that is synthesis. It just took many years for synthetic

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1869 $ 15.00+.25/0

chemistry to catch up with Walling's contributions."

This statement by Albert Padwa, a professor at Emory University and a former student of Walling's at Columbia University, is not just a tribute to his mentor but a reflection of the fact that the current trend toward using free radicals in synthetic organic chemistry is based on Walling's pioneering contributions. In this 17th and latest volume, one of the shortest, in Jeff Seeman's projected 22-volume series of autobiographies of 20th-century organic chemists, Walling, a whimsical but classical gentleman-scholar with a quirky sense of humor, who often wears outrageously garish neckties and loud Hawaiian shirts to faculty and other professional meetings, modestly describes his life and career, with extensive discussions of the work of his students and of other chemists as well as his own. Thus most of the 52 informal photographs that grace this slim volume are of students and colleagues, with or without Walling, at the various meetings or places that he visited during his extensive travels.

Cheves Thomson Walling was born in Evanston, Illinois on February 28, 1916. His unusual first name derives from his great-great-grandfather, Langdon Cheves, who had been speaker of the U.S. House of Representatives and president of the Bank of the United States during the early 19th century. His parents were relative liberals in a conservative community who impressed upon him that success carried with it an obligation to public service and to those who were less fortunate, a trait that he exhibited throughout his life. Although there were no scientists in his direct family, as a youth he became interested in the physical world around him. His interest in chemistry dated from his encounter with a friend's chemistry set during the summer of 1925, and chemistry was the first branch of science that he encountered that he could actually do something about rather than merely read about. He did not take chemistry in high school and was largely self-taught in science.

In 1933 Walling enrolled in Harvard University, where, as an undergraduate, he worked with Charles H. ("Hap") Fisher, which led to his first two publications—on side-chain reactions of benzene derivatives. After his graduation in 1937, he enrolled in the University of Chicago, where he could work on free radicals with Morris Kharasch and continue his education nearer to home. That year three seminal publications on free radical intermediates that influenced his career appeared—Donald H. Hey and William A. Waters' review of free radical intermediates in solution (*Chem. Rev.* **1937**, *21*, 169); Kharasch's formulation of a bromine atom chain mechanism (*J. Org. Chem.* **1937**, *2*, 288); and Paul J. Flory's analysis of vinyl polymerization as a radical chain reaction (*J. Am. Chem. Soc.* **1937**, *59*, 241). Walling was so impressed with the first article that a half-century later he paid tribute to it in his own article, "Fifty Years of Free Radical Chemistry" (*Chem. Br.* **1987**, *23*, 767), from which the title of the book under review here was undoubtedly derived.

On receiving his Ph.D. degree in 1939, Walling accepted a position at E. I. du Pont de Nemours' Deepwater, New Jersey laboratory, where he worked on azo dyes and other substances. In 1940 he married Jane Wilson, a Vassar graduate whom he had met in Winnetka, Illinois. The couple had four daughters and a son. Frustrated by the largely empirical "Edisonian research" at Du Pont, in 1943 Walling moved to the U.S. Rubber Company in Passaic, New Jersey, where he worked on various aspects of polymer chemistry, which had become vitally important to the war effort, such as structure and reactivity in radical chemistry, emulsion polymerization, free radical additions, polyethylene, and autoxidation. In 1949 he became head of organic research at Lever Brothers Company in Cambridge, Massachusetts, where he was concerned with synthetic detergents and the development of new products and processes.

In 1952 Walling realized his longtime goal of returning to basic research when Louis P. Hammett, who, along with Frank Mayo, Paul Bartlett, and Frank Westheimer, was his scientific hero and role model, invited him to join the faculty of Columbia University. Here, during the 1950s and 1960s, his time in industry helped him to connect fundamental science with commercial practicality and to produce his most significant work—on high-pressure reactions; free radicals in solution (his book with this title appeared in 1957); hypochlorite chemistry and halogen carriers; alkoxy, thiyl, and phosphoranyl radicals; radical cyclizations; and peroxide chemistry. He was also a member of the American Chemical Society's Committee on Professional Training (1962–1975), serving as chairman from 1964 to 1972.

In 1969, disillusioned by the student revolts of the 1960s and because, in his words, "I had always liked the West. I'd gotten restless and felt the need for a change", Walling became Distinguished Professor of Chemistry at the University of Utah at Salt Lake City, where, in addition to continuing his peroxide and hypochlorite studies, he worked on hydroxyl radicals, radical cations, and chemically induced dynamic nuclear polarizations (CIDNP). In predicting the future of his field, he states, "The real frontier... is the understanding of the place of radicals as transient intermediates in living processes."

Walling taught undergraduate organic chemistry and graduate courses in physical organic chemistry and in kinetics as well as an experimental course on science, technology, and society. He also served as editor of the prestigious *Journal of the American Chemical Society* (1975–1981). In 1991 he retired and with his wife moved to their summer home in Jaffrey, New Hampshire.

In his last chapter Walling devotes a 7-page section to a unique insider's view of the cold fusion controversy, the bizarre and frustrating project on which he spent his last two years at Utah. He became involved by offering to assist Stanley Pons, then chairman of the Chemistry Department, and Martin Fleischmann. A compassionate man, Walling felt strongly that the two collaborators, both scientists whom he knew and respected, should be considered innocent before being judged guilty. When they and the university were overwhelmed by inquiries and visitors, many of these were referred to Walling, and he was drawn into the project, serving as consultant and advisor to the National Cold Fusion Institute (NCFI) until it closed and he retired in June 1991. He relates that "Fleischmann and Pons became increasingly secretive and began to consider critics as enemies." When the two learned that he was collecting data on his own, they were furious, demanded that the work stop, and regarded him as an enemy. In Walling's view, "the anomalous heat evolution... seems to be a real phenomenon, although its occurrence is still quite unpredictable", but he concludes, "Currently the field is in such bad repute in the United States that only a rash young investigator or student would touch it, and almost no money is available. I'd like to know the answer even if it does turn out to be trivial."

Although Walling was always available to students, he states, "I was not a demanding research supervisor. Students worked on their own. I was a better supervisor for people who themselves were quite good. Almost all of my students got their degrees." According to Utah colleague Peter Stang, "Walling's high standard of excellence and gentlemanly demeanor served as the role model for

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3516-1870 $ 15.00+.25/0

young faculty as well as students". Walling admits, "I wasn't as much interested in contact with students as I was in understanding physical phenomena and explaining them to other people". He won the 1970 James Flack Norris Award in Physical Organic Chemistry.

Like many of the other authors in Seeman's series, Walling summarizes his career in a few words: "To someone of my temperament, being able to pursue my curiosity through research and reading with freedom and adequate support and to receive some recognition for my work have been all I could ask for. I can't think of anything I'd rather have done... I'm also conscious of the part that chance (or luck) has played in my career."

This entertaining, informative, and attractively priced volume will be of interest to both present and future generations of students and instructors of chemistry and history of chemistry courses as well as to practicing chemists interested in the humanistic aspects of their science.

Symmetry and Structure. Readable Group Theory for Chemists. 2nd edition. By *S. F. A. Kettle*. Wiley, Chichester, 1995. 416 pp., paperback £ 18.99.–ISBN 0-471-95476-4

This book is intended mainly for chemistry students. The title is rather misleading, as the book is not basically about the symmetry of crystal structures. Instead it is an introductory text concerned with the relationship between the geometrical and electronic structures of molecules and their symmetry. Using the chemical bond as an example, the reader is introduced to group theory in a way that is both unconventional and easy to understand. The book consists of 13 chapters and six appendices. The changes that have been made in this second edition are mainly small, but two additional chapters have been included, on space groups and on spectroscopic studies of crystals.

Chapter 1 (9 pp.) describes different models for the bonding in the ammonia molecule. Chapter 2 (25 pp.) contains a lucid elementary introduction to point groups, group tables, character tables, and irreducible representations, using the water molecule as an example. Chapter 3 (28 pp.) then deals with the orthonormality properties of irreducible representations, the separation of reducible representations into their irreducible components, transformation properties of atomic orbitals, symmetry-adjusted combinations of orbitals, interactions between bonds, and orbital energy levels; the examples used for illustration are the electronic structure of water and the point group C_{2v}. Chapter 4 (34 pp.) introduces the point group D_{2h} as the direct product of its normal subgroups C_2 and C_i, then discusses the symmetry of the atomic orbitals in C_2H_6 and B_2H_6, the bonding in these molecules, and the method of projection operators. In Chapter 5 (26 pp.) the author takes the symmetry group C_{4v} of BrF_5 as an example of a fairly complex group, and shows how the orthonormality relationships provide a way of systematically deriving a complete character table. Chapter 6 (12 pp.) discusses again symmetry and bonding in the ammonia molecule. Chapter 7 (42 pp.) is concerned with the symmetry of cubic molecules (example: SF_6) and with octahedral transition metal complexes, and introduces the point groups O, O_h, and T_d together with their character tables. Chapter 8 (11 pp.) is of a more general nature, dealing with the relationships between groups and their subgroups and between the irreducible representations of a given group and those of its subgroups. Chapter 9 (14 pp.) explains how the symmetry of a molecule is related to its vibrational spectrum and introduces the normal modes of vibration. Chapter 10 (22 pp.) deals with the important topics of the direct products of irreducible representations, products of wave-functions, the symmetry of different electronic configurations, and spectroscopic selection rules. In Chapter 11 (18 pp.) the author introduces complex characters, illustrated by the relatively simple example of the π-orbitals of cyclobutadiene with C_4 symmetry, and discusses the occurrence of optical activity. Next, in Chapter 12 (46 pp.), we move from point groups to space groups. The chapter deals in turn with the crystal systems, the Bravais lattices, the crystallographic point groups, symmorphic and asymmorphic space groups, Hermann-Mauguin symbols, and unit cells. The final chapter (15 pp.) is devoted to spectroscopic investigations of crystals. The author shows that because most of the phenomena on which spectroscopic measurements depend are translationally invariant, one can in general limit the discussion to the factor groups of the space groups with respect to their translation subgroups, i.e. to point groups.

Appendices 1 and 2, covering 42 pages, give a brief mathematical introduction to group theory and to the matrix representations of groups. Appendix 3 contains the character tables of the "most important" point groups, namely I_h and I, O_h, O, T_d, T_h and T, D_{nh}, D_{nd}, D_n, C_{nv} and C_n (all with $2 \leq n \leq 6$), C_{2h}, C_{3h}, C_i, S_4, C_s and C_1. Appendix 4 (15 pp.) contains a derivation of the group orbitals with π-symmetry for fluorine in SF_6. Appendix 5 (5 pp.) treats the point groups $C_{\infty v}$ and $C_{\infty h}$. Appendix 6 consists of two tables listing the Schoenflies and Hermann-Mauguin symbols for point groups alongside each other.

With its lucid and unconventional mode of presentation the book makes good reading and is on the whole easily understandable. The number of printing errors is not excessive. Unfortunately, however, these comments do not apply to the last two chapters which have been added for this second edition, and they are especially untrue in the case of Appendix 6, where there is a much higher incidence of errors and the presentation is far from clear. Many of the Hermann-Mauguin symbols are garbled in such a way that it is difficult to identify the groups. These chapters cannot be recommended to anyone as an introduction to space groups. They should be either left out completely or thoroughly rewritten at the earliest opportunity.

Structural Aspects of Nucleic Acid Analogs and Antisense Oligonucleotides

Martin Egli*

Hybridization of complementary oligonucleotides is essential to highly valuable research tools in many fields including genetics, molecular biology, and cell biology. For example, an antisense molecule for a particular segment of sense messenger RNA allows gene expression to be selectively turned off, and the polymerase chain reaction requires complementary primers in order to proceed. It is hoped that the antisense approach may lead to therapeutics for treatment of various diseases including cancer. Areas of active research in the antisense field focus on the mechanisms of cellular uptake of antisense molecules and their delivery to specific cell sites, an improved understanding of how these molecules inhibit the production of proteins, as well as the optimization of the chemical stability of antisense molecules and the thermodynamic stability of the duplexes they form with the mRNA targets. The last two issues in particular have prompted chemists to launch an extensive search for oligonucleotide analogs with improved binding properties for hybridization with RNA and higher resistance toward nuclease degradation. During the last years this research has resulted in a flurry of new chemical analogs of DNA and RNA with modifications in the sugar–phosphate backbone as well as in the nucleobase sites. However, to date little effort has been directed toward uncovering the exact origins of the gain or loss in stability when nucleic acid analogs bind to RNA. Although large amounts of thermodynamic data have been collected, the structural perturbations induced by the modifications in hybrid duplexes are only poorly understood. For many modified oligonucleotides the compatibility of protection, coupling, and deprotection chemistry with standard DNA and RNA synthesis protocols makes it now possible to generate modified nucleic acid fragments or mixed oligonucleotides containing modifications at selected sites in quantities suitable for three-dimensional structure investigations. Such studies should reveal the structural origins of the observed changes in affinity and specificity of binding for particular modifications and may guide the development of second- and third-generation antisense molecules. In addition, the availability of a previously unimaginable variety of modified building blocks and the investigation of their structures provides the basis for a deeper understanding of the native DNA and RNA structures. This contribution will summarize the results of X-ray crystallographic structure determinations of modified nucleic acid fragments conducted in our laboratory during the last three years and the insights gained from them.

Keywords: crystal structure analysis · DNA · hydrogen bonding · RNA

1. Introduction

The precisely ordered strings formed by the four nucleotide bases adenine (A), thymine (T), guanine (G), and cytosine (C), and the formation of complementary, hydrogen-bonded A–T and G–C base pairs provide the foundation for gene structure and expression. In chromosomes the DNA usually exists in the form of an antiparallel double helix composed of the sense strand and the antisense strand. Pairing specificity is the underlying principle of all biological information transfer—replication, recombination, transcription, and translation. In bacteria and viruses hybridization between sense RNA and antisense RNA is a common mechanism for regulation as well as inhibition of gene activity. Both replication and transcription were shown to be controlled by such mechanisms in prokaryotes.[1–4] In order to control replication of the *E. coli* plasmid ColE1, a sense–antisense RNA complex is formed between two complementary loop structures.[5, 6] These initial observations of a natural mechanism to suppress genetic information via nucleic acids were followed by a decade of intense exploration of the possibilities and limits of the antisense approach.

Antisense RNA need not necessarily be administered through expression vectors, but can be injected into cells in the form of short synthetic oligonucleotides. In addition, it was first shown by Zamecnik and coworkers that DNA can also be utilized to effectively inhibit protein expression.[7, 8] Messenger RNA in the unprocessed and processed state is not the only possible target; interference with the protein expression pathway can in

principle also occur at the gene level. However, this approach is thus far restricted largely to homopurine target sites that allow triplex formation with the antigene strand.[9-11] More effective control of gene expression may be exhibited by antisense RNAs with functional properties, for example *trans*-acting hammerhead ribozymes that can cleave a target message after the sequence UH (H = A, C, or U) and will thus not only inhibit but actively degrade the sequence.[12, 13]

The experience gathered in various areas of the antisense field during the last years has indicated several critical points that must be addressed should the antisense technology become applicable in the treatment of human diseases. These obstacles for antisense drug development will only be briefly addressed here; most aspects have been exhaustively treated in a series of excellent recent reviews and books.[14-33] Potential pitfalls to successful application of antisense therapeutics are the often low cellular uptake and the insufficient chemical stability of natural and chemically modified oligonucleotides against degradation by various nucleases. Once resistant against nucleases and efficiently delivered, a modified oligonucleotide may not sufficiently discriminate between a chosen target and other sites. Further complications can arise from the fact that most of the modified DNAs and RNAs do not induce RNase H-mediated cleavage of mRNA,[34] that folding of cellular RNAs into secondary and tertiary structures may render the selected target sites inaccessible, and that the antisense strand and target may not be found in the same location within the cell.

It is anticipated that appropriate chemical modification of oligonucleotides may help overcome some of these problems. In particular, modifications may lead to improved hybridization properties, nuclease resistance, and cell permeation. The structural framework of DNA and RNA allows a multitude of chemical modifications on the phosphate backbone and on the sugar and base moieties. First-generation analogs based on these three constituents include the phosphorothioates,[35, 36] the methylphosphonates,[37, 38] and a range of O2′-modified oligonucleotides.[39-42] The current variety of analogs is overwhelming, and the interested reader is referred to other sources such as the previously mentioned reviews.[14-33]

Among the newer generation of backbone modifications are 3′-allylethers and 3′-allylsulfides,[43] amides,[44] amines,[45] carbon chains,[46] formacetals and thioformacetals,[47, 48] guanidinium linkages,[49] 5′-methyl DNA and RNA,[50] phosphoramidates,[51] phosphorodithioates,[52] sulfides,[53] sulfonamides,[54] and sulfones.[55] The analogs with modifications on the sugar portion comprise carbocyclic compounds,[56, 57] L-2′-deoxyriboses,[58] and hexoses.[59-61] Oligonucleotides in which the pyrimidine rings have propyne substituents at C5 display promising features for antisense applications,[62] and the peptide nucleic acids (PNAs) introduced in 1994 are the analogs with the highest divergence from the native nucleic acids.[63]

The abundant number of modifications is in stark contrast to the handful of detailed structural studies of analogs using either solution NMR or modeling methods. Among those analyzed are amide-linked DNA,[64, 65] formacetal DNA,[66, 67] thioformacetal DNA,[68] urea-linked DNA,[69] phosphorodithioate DNA,[70] 2′-*O*-methyl RNA,[71] 2′-5′-linked RNA,[72] a PNA–RNA duplex,[73] and a PNA–DNA duplex.[74] In addition, structural investigations conducted with PNAs include the crystal structure of a triple-stranded nucleic acid complex, consisting of a homopurine DNA nonamer and two homopyrimidine PNA nonamers, in which the latter strands are linked through six amino acids.[75] Much more structural work will be necessary to interpret the thermodynamic stability data of oligonucleotide modifications, and to begin to understand the complex interplay between enthalpic and entropic effects, including factors such as conformational preorganization, hydration, salt concentration, and cooperativity.[76, 77]

Beyond the search for therapeutically feasible antisense compounds, recent progress in the chemical alteration of DNA and RNA provides numerous opportunities to probe nucleic acid structure[78, 79] as well as interactions between proteins and nucleic acids.[80]

2. The Structures of DNA and RNA

RNA differs from DNA by the additional hydroxyl group at the 2′-position in the ribose. This seemingly subtle difference has important consequences for the chemical and structural properties of RNA and its biological role. DNA is normally a double-stranded molecule, while RNA is single-stranded and can adopt complex folding motifs with a range of structural elements such as double-helical stems, bulges (with unpaired bases), hairpin loops, and pseudoknots.[81] DNA has been observed in two general classes of right-handed duplexes with antiparallel orientation of strands, the A- and the B-form (Fig. 1). One should keep in mind, however, that nucleic acid structure is polymor-

M. Egli was born in 1961 in Schaffhausen, Switzerland. He studied chemistry at the ETH-Zürich, obtaining his diploma in 1984 and his PhD in 1988 under Professors V. Prelog, J. D. Dunitz, and M. Dobler for the structural investigation of the enantioselectivity of simple receptors such as tartrates toward biologically interesting substrates including α-amino alcohol salts. He then joined Professor A. Rich's research group at MIT in Cambridge, MA (USA), where he studied the structure of nucleic acids, their complexes with drugs, and the properties of chimeric RNA–DNA molecules by using X-ray crystallographic methods. In 1992 he moved to the Organic Chemistry Laboratory at the ETH to pursue independent research on the structures of chemically modified DNA and RNA. This account summarizes research conducted by the author while at the ETH. In the fall of 1995 Egli joined the faculty of the Northwestern University Medical School in Chicago, IL (USA), as an assistant professor.

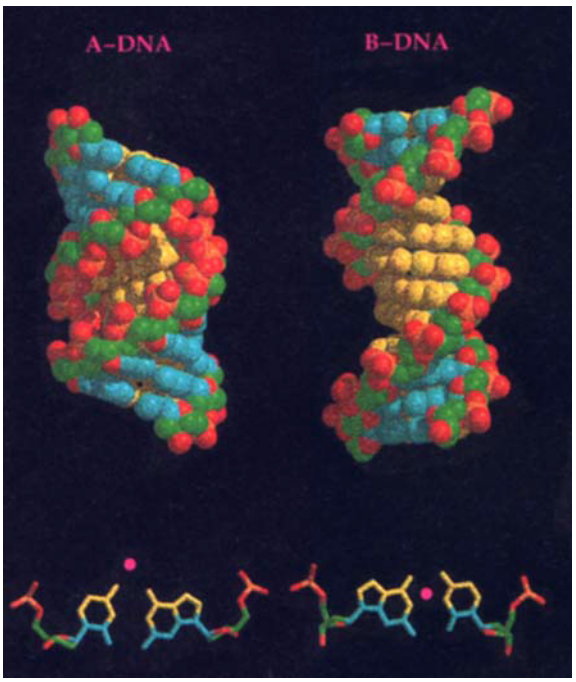

Fig. 1. Top: van der Waals models of the two basic right-handed double-helical conformations of DNA (RNA adopts an A-type duplex). The edges of the base pairs in the major groove are yellow and those in the minor groove are cyan. Bottom: Relative orientations of base pair and helix axis (pink) for A-DNA -RNA (left) and B-DNA (right) in axial projections.

phic; other stable conformations, although not necessarily double-stranded, exist.[82] In this discussion we will analyze DNA and RNA analogs in their right-handed duplex states.

Double-stranded RNA adopts an A-type conformation exclusively and is relatively inflexible. On the other hand, double-stranded DNA displays considerable conformational polymorphism and can exist in a range of conformations featuring both A- and B-like characteristics. These are influenced by the base sequence,[83] hydration state,[84, 85] the lattice contacts in a particular crystal form,[86-89] and the binding motif and interface in protein-DNA complexes,[90] among others. The crystal structure determinations of more than one hundred DNA fragments[91-94] and some four dozen protein-DNA complexes[95-98] have yielded a detailed picture of the DNA double helix. The impact of X-ray crystallography on our understanding of DNA structure and its biological role has thus far not been matched for RNA—apart from the early success with the elucidation of the tRNA structure—because of difficulties in generating highly pure RNA samples.

A- and B-type duplexes are characterized by very different topologies (Fig. 1). The major groove of the A-duplex is narrow and deep, and the minor groove is wide and shallow. The major groove of the B-duplex is wide but not as deep as that of the A-form, and the minor groove is narrower than that in the A-form but of similar depth. The A-duplex has a larger diameter and the helical axis is located in the major groove, whereas it runs through the centers of base pairs in the B-duplex. Several other features distinguish the two duplexes. The base pairs are inclined relative to the helix axis in the A-type duplex, but are more or less normal to the axis in the B-type. Phosphate groups are more closely spaced within strands in the former duplex (5.9 Å on average, B-DNA 7 Å, Fig. 2). These differences in geometry are a direct consequence of the conformational flexibility of the sugar moiety. In the A-DNA form the sugars adopt a so-called C3′-*endo* pucker, and in the B-DNA form the sugar conformation is of the C2′-*endo* type. Sugar conformations that fall into direct neighbor ranges of these two in the furanose pseudo-rotation phase cycle are also observed, but do not drastically change the overall conformations.

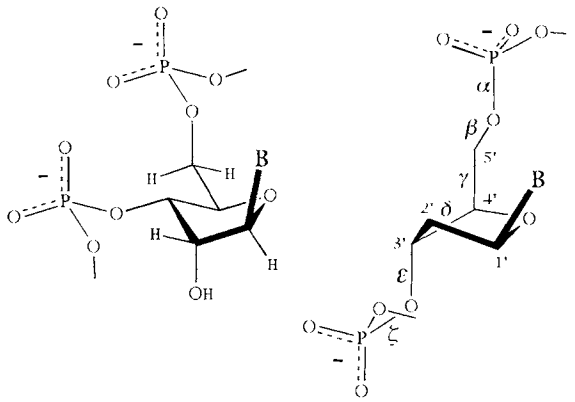

Fig. 2. Schematic diamond-lattice representations of the sugar-phosphate backbone conformations in A- and B-type duplexes. In A-DNA -RNA the six torsion angles α, β, γ, δ, ε, and ζ adopt the conformations sc^-, ap, sc^+, sc^+, ap, sc^-, respectively; in B-DNA, the conformations are sc^-, ap, sc^+, ap, ap, and sc^+. B = nucleobase.

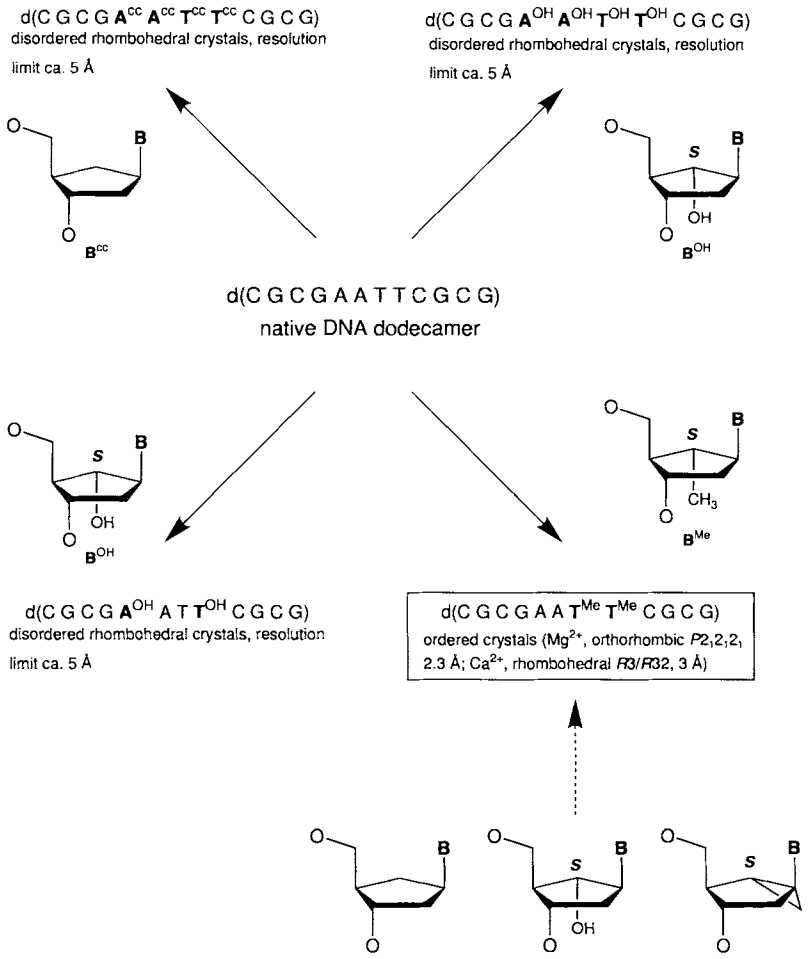
The geometry of the sugar-phosphate backbone of oligonucleotides can be described by six torsion angles, α, β, γ, δ, ε, and ζ; the δ angle describes the torsion angle around the ribose C4′-C3′ bond (Fig. 2). In A-type duplexes δ has a sc^+ conformation, and in B-type duplexes, its conformation is *ap*. All other torsion angles fall into the same ranges in both duplexes. Readers who are not familiar with nucleic acid structure are referred to the excellent review article by Kennard and Hunter[91] for nomenclature and definitions, as well as to Saenger's book on the principles of nucleic acid structure.[99]

3. Crystallization of Oligonucleotide Analogs

3.1. Choosing the Template Sequence and the Sites for Incorporating Modified Nucleotides

A crucial step toward the exploration of chemically modified nucleic acids by X-ray crystallography is the availability of template sequences known to produce crystals that diffract reasonably well (typically to better than 2.5 Å resolution), and the determination of the number and the locations of incorporation sites with a particular nucleotide analog that will preserve crystallization. We have established such sequences and incorporation sites for both modified DNA and RNA oligonucleotides. Scheme 1 illustrates the trial-and-error approach that was used for growing high-resolution crystals of a B-DNA template containing carbocyclic residues. With this d(CGCGAATTCGCG)



Scheme 1. Selection of incorporation sites for carbocyclic nucleotides in a B-DNA dodecamer [107] that will still yield well-diffracting crystals. Placing carbocyclic 6'-α-methylthymidines (T^{Me}) at positions 7 and 8 produced two crystal forms; the orthorhombic crystals are isomorphous with those of the native DNA oligonucleotide. Various carbocyclic analogs can now be incorporated at these sites (see bottom of scheme) with the goal of producing crystals of good diffraction quality and then comparing the structural changes.

or so-called Dickerson–Drew dodecamer, optimal crystallization results were obtained with carbocyclic analogs incorporated at locations T(7) and T(8). The dodecamer was originally selected because of its demonstrated mutation tolerance and lattice conservation in over 35 cases (NDB, Nucleic Acid Crystal Structure Data Base,[100] search December 1994).

It is now widely believed that the targeting of a particular stretch of messenger RNA with RNA analogs may hold certain advantages over the targeting with DNA analogs in terms of stability and selectivity. RNA·RNA duplexes are considerably more stable than the corresponding RNA·DNA hybrids.[101] This suggests that it is important to study RNA modifications within the context of an RNA or A-form double helix. We have relied on two template sequences for the incorporation of RNA analogs: the RNA octamer r(CCCCGGGG)[102,103] and the A-type DNA with sequence d(GCGTATACGC).[104–106]

3.2. Crystal Growth

A comparison of the conditions used to grow crystals of oligonucleotides discloses an amazing similarity between many of them. In probably more than 90% of the cases, the mother liquor components include sodium cacodylate buffer, magnesium chloride, spermine tetrahydrochloride, and 2-methyl-2,4-pentanediol (MPD) as the precipitant. At the onset of crystallization experiments with analogs, it is therefore reasonable to include these components. Obviously, such established techniques[108,109] do not always produce crystals. The conditions for growing protein crystals are considerably more diverse than those for nucleic acids. A common approach is the use of sparse matrix screens[110] that allow efficient sampling of a variety of buffers, cations, and precipitants. These screens are commercially available,[111] and modified versions have recently been applied successfully in the crystallization of medium- and large-sized RNAs .[112,113]

We have used commercial screen kits to crystallize double-helical RNA fragments. Two crystal forms of the octamer r(C_4G_4) could be grown from buffers with pH values between 4.5 and 8.5 and various precipitants, including high concentrations of ammonium sulfate, low molecular weight polyethylene glycols (PEGs), MPD, and others.[102] Successful use of smaller PEGs in the crystallization of RNA oligonucleotides has also been reported by other researchers.[114] The rhombohedral crystal form of the r(C_4G_4) octamer diffracts X-rays to exceptionally high resolution (better than 1.5 Å) and can also be grown from solutions containing 100–250 mM concentrations of various divalent metal cations (Mg^{2+}, Ca^{2+}, Zn^{2+}, etc.). Collection of high-resolution data with these crystals should enable investigation of the RNA binding modes of these ions. The particular arrangement of $[r(C_4G_4)]_2$ duplexes in the rhombohedral lattice displays no close packing contacts for many nucleotides. This renders the r(C_4G_4) sequence an ideal crystallization template for modified RNAs with alterations at a number of sites. Attempts at crystallizing such modified RNAs are under way. This example demonstrates that one should not rely only on classic crystallization ingredients but explore alternatives as well. Modifications alter the physical properties of nucleic acids, and to obtain diffraction-quality crystals of analogs, one will often have to adapt the typical DNA crystallization conditions or even choose an innovative approach.

3.3. Hydration

A deeper understanding of how antisense modifications affect the structure and stability of nucleic acid fragments requires the assessment of modification-induced hydration changes, both at the global and the local level. Besides determining the atomic coordinates, X-ray crystallography permits the visualization of the first hydration shell as well as the thermal motion of molecular fragments and water molecules. Provided atomic-resolu-

tion diffraction data is available, molecular hydration in crystals can be assessed in great detail.[103, 115] Comparison of the hydration of the same oligonucleotide fragment in distinct crystallographic environments can reveal preserved hydration patterns, and crystallization of modified fragments in the lattice of the native molecule can indicate the differences in hydration brought about by the chemical modification.

The so-called "spine of hydration" of B-DNA dodecamers is a conserved hydration pattern that involves backbone and base atoms in the minor groove.[116, 117] Crystallization of such dodecamers with substantial incorporation of nucleotide analogs that affect the topology of the minor groove (Scheme 1, Table 1) should expose alterations in the global hydration, that is, displacements and replacements of water molecules in the spine, caused by the modifications. Similarly, crystallization of oligonucleotides with built-in single modifications allows the consequences for the local hydration to be assessed. Thus, incorporation of a 2′-*O*-methyladenosine into a DNA template provided some clues on the hydration of 2′-O-methylated riboses and its contribution to the exceptional stability of RNAs methylated at the 2′-oxygen.[106]

3.4. The Modifications

Chemical modifications of DNA and RNA affect different areas in the double helix, and Table 1 summarizes the groove locations of selected sugar and base modifications. The nucleic acid modifications thus far analyzed in our laboratory with X-ray crystallography comprise bicyclo-DNA, sulfone-RNA, carbocyclic DNA, and 2′-O-methylated RNA. The chemical alterations associated with each analog are depicted in Figure 3. Three of the modifications concern the ribose moiety, but in sulfone-RNA, the neutral dimethylene sulfone linker replaces the negatively charged phosphate group. The following sections summarize the structural findings based on single-crystal X-ray analyses for each of these nucleic acid analogs.

Table 1. Location of modifications at selected sugar and base sites in the duplex (see Figs. 1 and 2).

Modification site	Location
C2′ (sugar)	minor groove
O4′ (sugar)	minor groove
C5′ (sugar) [50]	minor groove (substituent replacing H^{Re})
C5 (base)	major groove

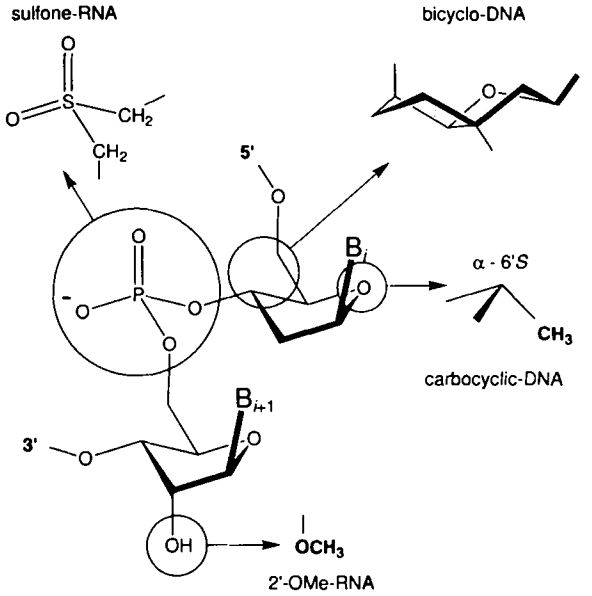


Fig. 3. Four types of DNA and RNA analogs.

4. Bicyclo-DNA

Preorganization and appropriate rigidity of the single strand are critical for the formation of stable duplexes. This was demonstrated by the drastically reduced T_m values of duplexes resulting from incorporation of open-chain glycerol building blocks into oligonucleotides,[118] as well as by the partly entropically stabilized duplexes formed by hexose-DNA.[119] Entropic stabilization of hybridization was tested in several cases. Constrained bicyclic sugar modifications include a neutral riboacetal internucleosidic linkage,[120] bicyclo-carbocyclic analogs,[121, 122] and a DNA analog with an ethylene bridge between C3′ and C5′, the so-called bicyclo-DNA (bcDNA, Fig. 3).[123] Although reduction of the entropy term upon duplex formation was achieved with the latter analogs, the affinity of the oligonucleotides containing bicyclic nucleotides for DNA and RNA was generally lower than that of the native molecules. This indicated that rigidity of the single strand alone is not sufficient for stable duplex formation, but that, in addition, the conformation adopted by the constrained nucleotide must be compatible with that of the target strand in the duplex.

The crystal structure of a bicyclic analog of the deoxycytidylyl-(3′-5′)-deoxycytidine dimer containing intranucleosidyl ethylene bridges between C3′ and C5′ (Fig. 3) was determined by X-ray diffraction at atomic resolution.[124, 125] In the crystal two bcd(CC) strands form a parallel-stranded duplex paired through hemiprotonated C–C^+ base pairs (Fig. 4). The conformations of the two single strands in the duplex deviate only minimally and, therefore, we will focus only on the conformation of the bcd(C1pC2) dimer in our discussion.

The distance between the stacked rings is 3.4 Å, and the right-handed helical twist is 34°. The paired bases display slight propeller twisting (Fig. 4, top). This arrangement leads to extensive overlap between cytosine rings within one strand, and the relative intrastrand positionings of the base carbonyl groups are likely to provide additional stability through dipole–dipole interactions (Fig. 4, bottom). The bicyclic sugars in the dimer adopt different conformations. The pucker of the C(1) deoxyribose moiety is of the C1′-*exo* type, and that of residue C(2) is of the C2′-*endo* type.

The conformations of the two cytidines also differ in their glycosidic torsion angles. Both fall into the *anti* range, but differ by about 40° (Fig. 5). Due to the conformational heterogeneity of residues in the duplex, it is impossible to build an extended parallel-stranded poly(bcdC)–poly(bcdC) duplex with continuous backbones and a single base pair as the repetitive unit.

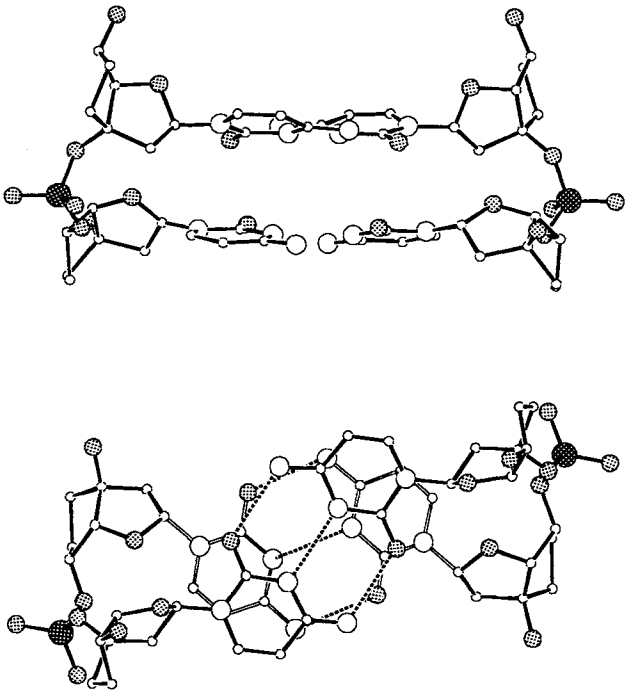

Fig. 4. The parallel-stranded [bcd(CC)]$_2$ duplex viewed along the planes of the base pairs (top), and in the direction of the helix axis (bottom). Here and in the following figures phosphorus atoms are dark gray, oxygen atoms are light gray, and hydrogen bonds are denoted by dashed lines.

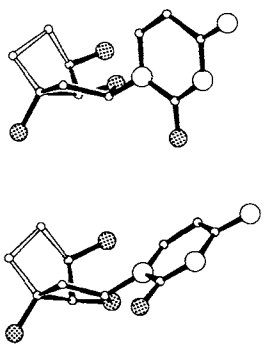

Fig. 5. Conformations of the nucleosides in bcd(CC). The deoxyribose puckers for residues C(1) and C(2) are C1′-*exo* (top) and C2′-*endo* (bottom), respectively. The ethylene bridge linking C3′ and C5′ in bcDNA is highlighted with white bonds.

In the bcDNA dimer the significant deviation from standard B-DNA geometry results in differences in the backbone torsion angles β and γ. These adopt sc^+ and *ap* conformations, respectively, in the bicyclic sugar–phosphate backbone, but are *ap* and sc^+ in B-DNA and A-RNA (where γ in an extended backbone variant can also be *ap*). The opening up of the torsion angle γ is a direct consequence of the modification in the sugar framework of bcDNA.

Cytidine-rich DNA can adopt a four-stranded arrangement composed of two interdigitated duplexes that are paired through hemiprotonated C–C$^+$ base pairs.[126] In this intercalated motif (i-motif) adjacent base pairs are about 6.2 Å apart, allowing for intercalation of base pairs from the second parallel-stranded interpenetrating duplex (Fig. 6). In this arrangement only exocyclic functions overlap, whereas the π-electron systems of the cytosine rings are not directly involved in stacking. Thus, the dipole–dipole interactions between adjacent C2=O2 carbonyl bonds and between adjacent C4–N4 bonds as well as C–H$\cdots$O4′ hydrogen bonds between more closely spaced pairs of sugar–phosphate backbones in intercalated duplexes (Fig. 6) appear to be the main stabilizing factors.[127] In the i-motif neighboring carbonyl bonds are oriented in an antiparallel fashion, while they are parallel in the [bcd(CC)]$_2$ duplex (see Figs. 4 and 6).

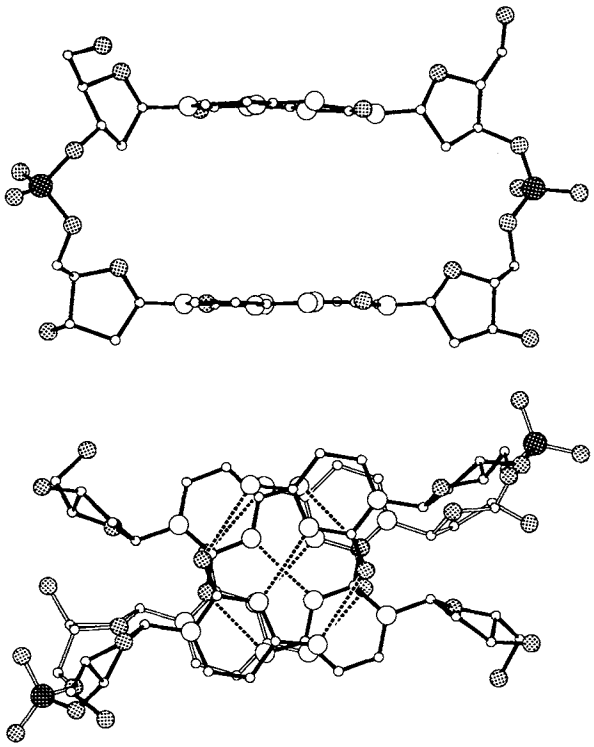

Fig. 6. The C(2)pC(3)·C(6)pC(7) base-pair step in one of the two parallel-stranded intercalated [d(CCCC)]$_2$ duplexes viewed along the planes of the base pairs (top) and in the direction of the helix axis (bottom). In the axial projection the intercalating C–C$^+$ base pair has been included and the C3–C7 base pair is highlighted with white bonds.

About half the deoxyriboses in the i-motif adopt A-type sugar puckers. The increase in the distances between adjacent base pairs in an axial direction is characterized by local changes in the backbone torsion angles. Thus, numerous α,γ pairs are found in the *ap*,*ap* range, a pattern commonly observed in the backbone region around the intercalation sites in DNA–drug complexes.[94]

The geometry of the sugar–phosphate backbone in bcDNA is different from that in B-DNA and in the i-motif. Although the ethylene bridge renders the sugar portion more rigid, the constraints introduced cause a significant deviation in strand conformation from that of a typical B-duplex and abate the entropic stability gains. To date, no diffraction-quality crystals of the native d(CC) dimer have been obtained. This may indicate that stable formation of the intercalated four-stranded motif requires a cytidine section of a minimum length. Perhaps the parallel-stranded zwitterionic bcDNA double helix constitutes an independent pairing structure that does not exist for cytidine-rich oligodeoxynucleotides.

5. Sulfone-RNA

The effect of removing the negative charge carried by phosphodiester backbones in DNA and RNA on the structure of the double helix has been relatively little studied. In duplex DNA the arrangement of negatively charged phosphates along the backbones creates a symmetric charge distribution. Disturbing this balance through neutralization of the negative charges on one face of the DNA bends the DNA toward that face.[78, 128]

With B-form DNA one can expect the degree of deformation to be more severe when the neutralization of charges concerns phosphates arranged on opposite sides of the narrow minor groove than when they flank the wide major groove.

The prospect of improved cell delivery with species that are more lipophilic than DNA and RNA has provided motivation for developing several nonionic nucleic acid analogs. Moreover, the lack of charge repulsion between phosphates in duplexes comprising an uncharged species and RNA may lead to enhanced binding stability of analogs compared with that of DNA and RNA. The methylphosphonates constitute the first uncharged nucleic acid analog. However, replacing one of the nonbridging phosphate oxygens by a methyl group leads to diastereoisomers. The dimethylene sulfone linker was conceived as a roughly isosteric, neutral, and achiral replacement for the phosphate group in DNA (Fig. 3).[55, 129] Synthetic protocols have recently been developed for the synthesis of dimethylene sulfone linked RNA.[130] The consequences of charge removal on the geometry of the RNA double helix were analyzed in the crystal structure of the dimethylene sulfone linked ribodinucleotide analog r(G-SO_2-C).[131] This crystal structure revealed that the neutral RNA analog adopts a relatively regular portion of a right-handed Watson–Crick-type double helix (Fig. 7). Overall,

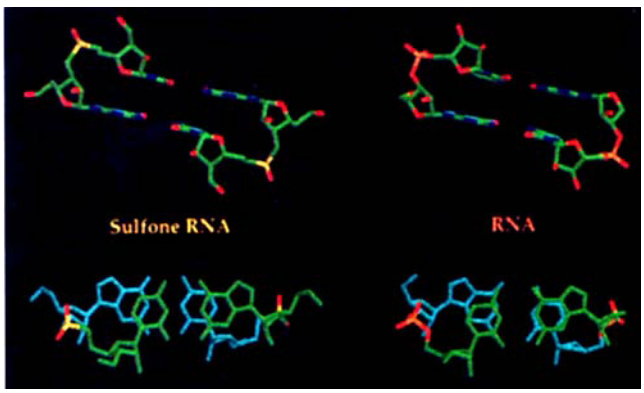

Fig. 7. The double helices formed by the nonionic dimethylene sulfone RNA analog r(G-SO_2-C) and the natural RNA dimer r(GpC) [132,133]. The images in the top half of the figure are projections into the minor groove, approximately along the crystallographic twofold rotation axes, and those in the bottom half are projections along the normal to the plane of the top base pair (green bonds). Sulfur atoms are yellow and phosphorus atoms are orange.

this duplex is quite similar to the one formed by the natural r(GpC) RNA dimer. Although the dimethylene sulfone RNA duplex appears wider at first glance, the actual S···S and P···P distances differ only by 0.3 Å. However, the backbones in the dimethylene sulfone duplex are more inclined relative to the base pair planes than those in $[r(GpC)]_2$. This is accompanied by a pronounced sliding of base pairs relative to one another in $[r(G\text{-}SO_2\text{-}C)]_2$, as well as a concomitant loss of overlap between the aromatic rings of stacked bases and a slightly decreased stacking distance in the sulfone duplex (3.4 Å vs. 3.68 Å in the phosphate duplex, Fig. 7). In addition to these changes, the helical twist in $[r(G\text{-}SO_2\text{-}C)]_2$ is about 14° less than that in $[r(GpC)]_2$, discernable by the angle between the glycosidic bonds of the guanosine and cytidine residues for both dimers (Fig. 7, bottom left and right).

Careful consideration of the possible causes of the structural perturbations in the sulfone-RNA duplex points largely to one of the methylene groups replacing the bridging phosphate ester oxygens, rather than the lack of charge. Notably, all the sugar–sulfone backbone torsion angles lie in the conformational ranges associated with an A-type duplex.[131] Both riboses adopt fairly standard C3′-*endo*-type puckers and the glycosidic bonds are in the *anti* conformation. The lack of *gauche* interactions, which are in natural nucleosides between O3′ and O4′, for 3′-CH_2-substituted (termed C3″ for sulfones) ribonucleosides would stabilize such a sugar pucker. However, the accommodation of the methylene group replacing O5′ (termed C6′ for sulfones) requires an adjustment of the nucleotide conformation (Fig. 8). Thus, the H^{Re} hydrogen of C6′ occupies roughly the position taken by O5′ in the standard phosphate backbone of A-form duplexes. This is achieved by slight changes in the sugar conformation, and in particular, by pushing the δ angle out toward 90° for a more equatorial arrangement of the C4′–C5′ and C1′–N1 bonds relative to the ribose ring. In addition, as a result of the more distinct antiperiplanar conformation of the glycosidic bond, the interaction between the H^{Re} hydrogen of C6′ and the hydrogen of C6 is minimized.

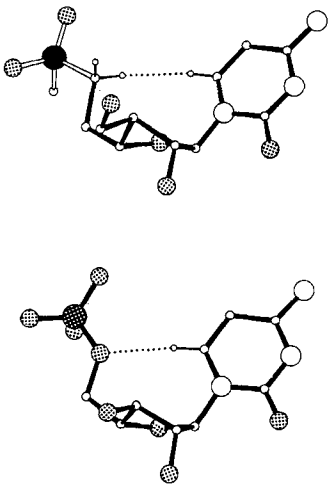

Fig. 8. The conformations of cytidine in the dimethylene sulfone RNA duplex $[r(G\text{-}SO_2\text{-}C)]_2$ (top) and in the natural $[r(GpC)]_2$ duplex (bottom). The dotted lines indicate the distances between H6 and $H6'^{Re}$ in the dimethylene sulfone duplex (2.21 Å) as well as between H6 and O5′ in the natural duplex (2.34 Å). Note the slight difference in ribose puckers in the two nucleotides. The sulfur atom is black, S=O and S–CH_2 bonds are highlighted, and the phosphorus is dark gray.

These changes in the relative positions of sugar and base together with the difference in the P–O and S–C bond lengths (the latter is approximately 0.2 Å longer) are largely responsible for the altered slide in $[r(G\text{-}SO_2\text{-}C)]_2$. Because the C6′–S bond is roughly parallel to the Watson–Crick hydrogen bonds (Fig. 7), the C6′ carbon contributes more substantially to the pronounced slide than the C3″ carbon. The lower twist in the dimethylene sulfone duplex is most likely the consequence of the difference between the S-C6′-C5′ (111°) and the P-O5′-C5′ (120°) bond angles (Fig. 7, bottom). The tighter elbow in $[r(G\text{-}SO_2\text{-}C)]_2$ rotates the green C(2)–G(3) base pair back over the blue G(1)–C(4) base pair.

The almost identical conformations of nucleosides in the dimethylene sulfone dimer allow the construction of an extended oligonucleotide duplex based on the helical twist and rise in $[r(G\text{-}SO_2\text{-}C)]_2$. A comparison between such a duplex and a standard A-RNA duplex is depicted in Figure 9. The sulfone-RNA duplex has about 17 repeats per full turn compared with the 11 repeats in standard A-RNA, and its diameter is 50% larger than that of RNA. This generates a hollow cylinder around the helix axis on the inside. The deep major groove

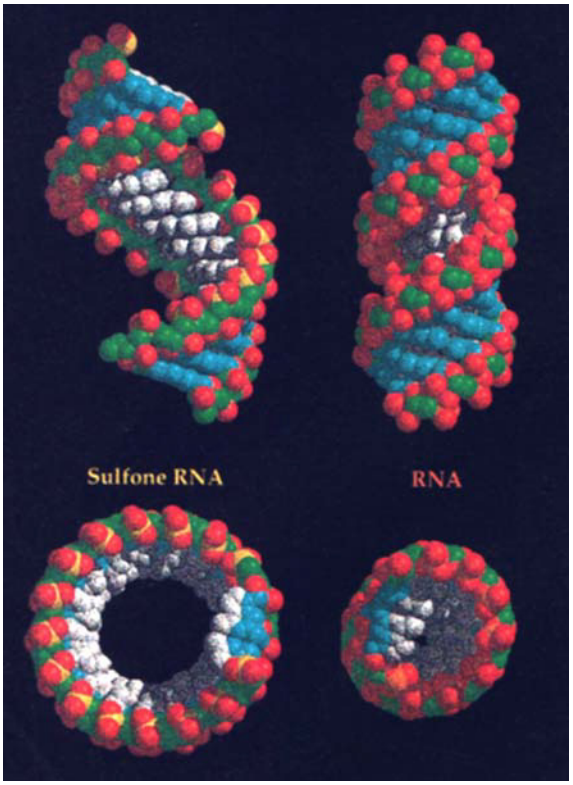

Fig. 9. Projections along the normal to the helix axis (top) and along the helix axis (bottom) of a full turn of a sulfone-RNA double helix (construction of the 17mer is based on the conformation of the $[r(G\text{-}SO_2\text{-}C)]_2$ dimer duplex) and a standard A-RNA of equal length. The edges of base pairs along the major groove are white and those along the minor groove are cyan. Sulfur atoms are yellow and phosphorus atoms are orange.

of A-RNA is opened up greatly in the sulfone duplex, and the distance separating sulfurs of opposite strands across that groove is extended to about 15 Å, or roughly three times the distance between phosphates in standard RNA. The changes in the minor groove are much less severe by comparison.

The reader should note that the rather drastic topological differences between sulfone-RNA and RNA as assessed by the structure determination of the $[r(G\text{-}SO_2\text{-}C)]_2$ duplex may represent a "worst case" scenario. The incorporation of a short stretch of sulfone-RNA into a native or otherwise modified RNA oligonucleotide may have less severe conformational consequences. Likewise, the larger slide and the smaller twist between base pairs in sulfone-RNA could lead to improved stacking beween interstrand purines in 5′-pyrimidine–purine-3′ steps and therefore higher stability. The synthesis of chimeric DNA/sulfone-DNA and RNA/sulfone-RNA oligonucleotides is under way, and it will be interesting to analyze their structures and to assess the consequences of incorporating dimethylene sulfone linked dimers into standard oligonucleotides on thermodynamic stability.

The conformational consequences of the replacement of O5′ by a methylene group have been studied with the r(UpcA) 5′-deoxy-5′-phosphonomethylene dimer,[134] and with r(A-$(pcA)_8$-pcA) 5′-deoxy-5′-phosphonomethylene-adenosine decamers.[135] For the former, circular dichroism experiments indicated that the incorporated methylene group destroyed the stacking in the dimer. However, the stability of triplexes formed by the above 5′-modified homo(A) decamer with two $r(U)_{10}$ strands was similar to that exhibited by the natural RNA oligonucleotides. The contradictory findings may be related to the different lengths and sequences of the molecules investigated. The conformational consequences of replacing O5′ by a methylene group are most likely different for purine and pyrimidine nucleosides. Thus, the methylene group may be more easily accommodated opposite H8 of adenosine than in the vicinity of H6 in cytidine as in $[r(G\text{-}SO_2\text{-}C)]_2$ (Fig. 8). Since the S–C and P–C bond lengths differ only minimally, it is unlikely that phosphonomethylene and dimethylene sulfone linkers lead to much different stacking. Further, an assumed slight loss of intrastrand stacking as observed in $[r(G\text{-}SO_2\text{-}C)]_2$ could affect the stability of double or triple helical arrangements of homopurine strands less severely (cf. the stability of the above-mentioned oligo-5′-deoxy-5′-phosphonomethylene-adenosine) than that of double and triple helices composed of mixed purine–pyrimidine sequences. Recently the synthesis and incorporation in oligonucleotides of a thymidine dimer containing an internucleoside phosphinato linkage (O5′ as well as O3′ replaced by methylene groups) have been reported.[136] It is noteworthy that the hybridization of a DNA with ten consecutive phosphinate nucleotides and its RNA complement resulted in a reduction in the melting temperature of slightly less than 2 °C per modification relative to that of the native hybrid. It remains to be seen how additional replacement of the negatively charged PO_2^- portion by SO_2, as in dimethylene sulfone RNA, will affect the RNA affinity.

The crystal structure of the dimethylene sulfone linked $r(A\text{-}SO_2U)$ dimer in a single-stranded state and a comparison of its conformation to that of the $r(G\text{-}SO_2\text{-}C)$ strand in the duplex state have shed some light on the conformational rearrangements required—in this particular case—for the transformation of a single strand into a duplex.[137] The single-stranded dimer shows an extended conformation, in which all torsion angles in the sugar–sulfone backbone (except δ) adopt an *ap* conformation. Interestingly, the riboses in the $r(ASO_2U)$ dimer have C2′-*exo* puckers (Fig. 10). The *ap* conformation of γ rotates one of the C5′ hydrogens much more toward the β-face of the ribose ring. A standard C3′-*endo* conformation of the ribose as seen in the duplex would cause an unfavorable steric interaction between this C5′ hydrogen and H3′. This is avoided by folding down the C4′-C3′-C2′ elbow in the ribose (Fig. 10). Flipping α

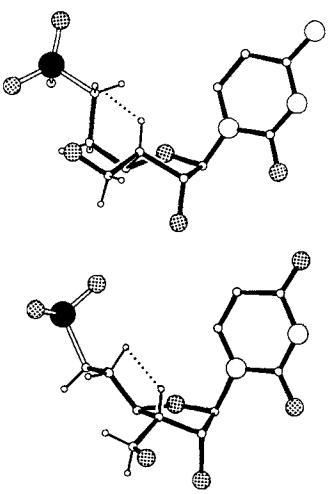

Fig. 10. C3′-*endo* pucker of cytidine in $[r(G\text{-}SO_2\text{-}C)]_2$ (top) and C2′-*exo* pucker of uridine in the $r(A\text{-}SO_2\text{-}U)$ single strand (bottom). The dotted lines mark the distances between H^{Si} of C6′ and H3′ in cytidine (2.16 Å) and between one of the C5′ hydrogens and H3′ in uridine (2.35 Å). Note the different conformations of torsion angle γ in the two nucleotides. Adoption of a C3′-*endo* pucker in uridine would generate an unfavorable interaction between H^{Re} and C5′. The sulfur atom is black.

and γ into a sc^+ conformation could allow the ribose to assume a C3′-*endo* pucker, and additional rotation around ζ would then convert the extended single-stranded conformation in r(A-SO_2-U) to a stacked arrangement similar to the one in the [r(G-SO_2-C)]$_2$ A-type duplex.

6. 6′-α-Substituted Carbocyclic DNA

In carbocyclic analogs the 4′-oxygen of the natural furanosyl nucleoside is replaced by a substituted methylene group (Fig. 3, Scheme 1). Removal of the electron-withdrawing 4′-oxygen in the furanosyl moiety has a significant effect on the basicity of the pyrimidine heterocycle. The carbocyclic analog of 5-methyl-2′-deoxycytidine has a higher pK_a than the parent compound and was shown to increase the stability of Pu·Py–Py type triple helices (requiring protonation of cytidine in the third strand).[156] In addition, the higher stability conferred by carbocyclic residues in the pyrimidine strand may be related to the absence of repulsive interactions between phosphates of the purine strand and the 4′-oxygens of the third strand bound in the major groove.[25] Carbocyclic analogs exhibit greater resistance to enzymatic cleavage of the glycosidic linkage and therefore may be useful in therapeutic applications.[138]

Although oligonucleotides containing carbocyclic building blocks showed favorable RNA-binding properties, it is believed that their stability against nuclease degradation does not suffice for biological applications.[25] Oligonucleotides containing carbocyclic analogs with α-substituents on the CH_2 group (termed C6′, Fig. 3) were found to be more resistant to degradation.[57] However, those analogs with the most significant decrease in DNA/RNA duplex stability are the very ones that show the highest degree of nuclease resistance. The experiences gathered thus far on the stability of DNA homo- and DNA/RNA heteroduplexes containing carbocyclic oligonucleotides are consistent with no particular conformational preference of the cyclopentane ring. Rather, the lack of stereoelectronic effects influencing the conformation in the furanosyl moiety render the five-membered ring much more flexible, and may allow carbocyclic nucleotides to adapt to a variety of induced duplex geometries.

In order to assess the conformational features of carbocyclic nucleotides, we incorporated three types of carbocyclic analogs, both with and without 6′-α-substituents, into a Dickerson–Drew d(CGCGAATTCGCG) template sequence (Scheme 1). Crystals could be grown of all four modified strands synthesized thus far. However, in all but one case, the crystals diffracted to relatively low resolution. To our knowledge, the rhombohedral space group of the carbocyclic dodecamer crystals has never been observed with any of the numerous variants of the dodecamer sequence crystallized during the last 15 years. More than 30 d(CGCxyyyyzGCG)-type (x = G, A, T; y = A, T; z = C, A, T) dodecamers with either sequence alterations, chemical modifications, or minor groove binding drugs complexed to them all crystallized in the orthorhombic $P2_12_12_1$ space group of the native dodecamer.[107] It is noteworthy that an apparently subtle chemical modification like the replacement of O4′ by CH_2 in a few nucleotides causes the dodecamer to pack in a different fashion, perhaps resulting in an altered conformation of the DNA.

The crystal structure of d(CGCGAAT^{Me}T^{Me}CGCG) (T^{Me} = 6′-α-methylthymidine) has been determined at 2.5 Å resolution.[139] The structure is isomorphous to that of the unmodified dodecamer, and the four modified nucleotides per duplex adopt conformations compatible with a B-DNA. Of the twenty sugar units (omitting terminal residues) in the native structure, ten have C1′-*exo*, seven have C2′-*endo*, and two have O4′-*endo* conformations, and one assumes an O4′-*exo* pucker.[140, 141] In the native structure, residues T(7) and T(8) adopt O4′-*endo* and C1′-*exo* puckers, respectively, while they display C2′-*endo* and C1′-*exo* conformations, respectively, in the modified dodecamer (Fig. 11). In the second strand, residues T(19) and T(20) in the native dodecamer both adopt C1′-*exo* puckers, while T^{Me}(19) and T^{Me}(20) in the modified duplex have C2′-*endo* and C1′-*exo* puckers, respectively. Thus, the carbocyclic residues cause only very minor deviations from the standard geometry of the deoxyoligonucleotide duplex, and the cyclopentane rings adjust smoothly to the geometrical constraints posed by the furanosyl–phosphate backbone. This may indicate that the cyclopentane ring of unsubstituted and 6′-α-substituted carbocyclic nucleotides is "conformationally promiscuous", and can comply with a range of geometries dictated by either RNA or DNA backbones.

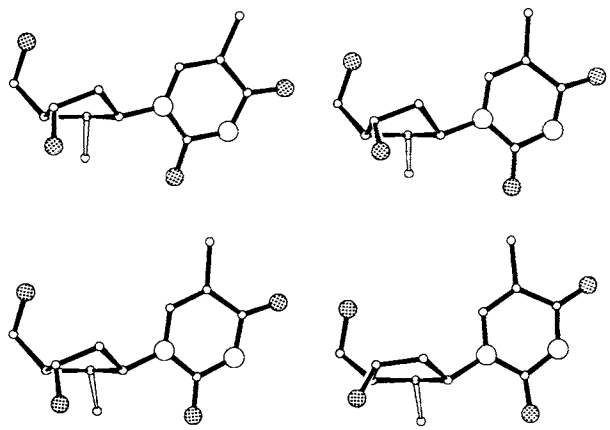

Fig. 11. Conformations of the four carbocyclic 6′-α-methylthymidines in [d(CGCGAAT^{Me}T^{Me}CGCG)]$_2$: T(8) (C2′-*endo*, top left), T(9) (C1′-*exo*, top right), T(19) (C2′-*endo*, bottom left), and T(20) (C1′-*exo*, bottom right). The C6′–C7′ bonds are highlighted.

In the central portion of the minor groove in [d(CGCGAATTCGCG)]$_2$, seven water molecules in the first hydration shell were found to link the guanine N3 or N2, adenine N3, and cytosine and thymine O2 from opposite strands, such that the bridges span two adjacent base pairs (Fig. 12, left). Six water molecules in the second hydration shell then coordinate to those of the first hydration shell with direct contacts to the DNA, thus conferring them with nearly tetrahedral coordination.[116] The ribose 4′-oxygens that line the minor groove stabilize the hydration spine, either through direct hydrogen bonds or by creating a polar environment.[117] It is surprising how little the presence of the methyl groups of the carbocyclic thymidines in the central region of the modified duplex affects the first hydration

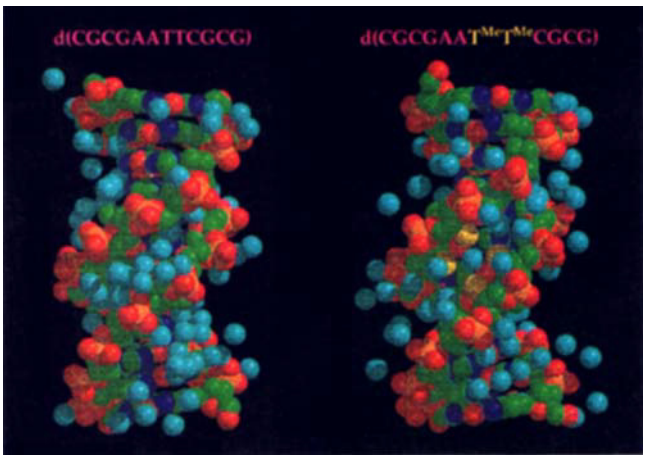

Fig. 12. Hydration of the minor groove in the B-DNA duplexes $[(d(CGCGAATTCGCG)]_2$ (left) and $[d(CGCGAAT^{Me}T^{Me}CGCG)]_2$ (right). Water molecules are represented as blue spheres and the CH_3 carbon atoms of the α-substituents in the modified thymidine residues are highlighted in yellow. The spine of hydration is visible as a chain of water molecules from the first and second hydration shell running down the minor groove in the modified duplex. The view of the central portion of the spine in the native dodecamer is slightly obstructed by water molecules of higher hydration spheres without contacts to the DNA.

shell. As in the native dodecamer, a water molecule bridges the O2 oxygens of residues $T^{Me}(7)$ and $T^{Me}(19)$. This water molecule is sealed off from the outer part of the minor groove by the four methyl groups, one of which forms a contact of 3.12 Å to the water molecule (Fig. 12, right). Two water molecules flanking the central water unit and bridging residues $T^{Me}(8)$ and A(18) as well as A(6) and $T^{Me}(20)$ are also conserved, as is the entire hydration pattern at the floor of the minor groove. However, the lipophilic patch formed by the methyl groups in the center of the minor groove leads to displacement of the water molecules of the second hydration shell that link the three water molecules in the center. In the B-DNA duplex, both the vector defined by the 6′-α-methyl carbon atoms of residues $T^{Me}(7)$ and $T^{Me}(20)$ and the vector defined by those carbons in $T^{Me}(8)$ and $T^{Me}(19)$ are roughly perpendicular to the direction of the minor groove. Thus, the distances between the methyl carbons of these residues across the groove are 1.21 and 0.87 Å, respectively (after subtraction of 4 Å, the sum of the van der Waals radii of methyl groups). The corresponding intrastrand distances between the methyl carbons of residues $T^{Me}(7)$ and $T^{Me}(8)$ and residues $T^{Me}(19)$ and $T^{Me}(20)$ are 1.03 and 0.53 Å, respectively.

The structure demonstrates that 6′-α-substituted carbocyclic nucleotides can mimic the furanosyl conformation in a duplex with B-type geometry. Insertion of isolated 6′-α-methylated building blocks into DNA could destabilize the duplex by distorting the global hydration motif. However, contiguous stretches of ten 6′-α-methylated carbocyclic pyrimidines resulted in duplexes with slightly elevated melting temperatures per incorporated residue compared with that after insertion of isolated analogs ($\Delta T_m = -1.3$ °C vs. -1.7 °C, complement DNA).[139, 142] This cooperative relative stability increase may arise from the release of water molecules in the vicinity of the methyl substituents and the near van der Waals contacts between methyl groups of adjacent intrastrand residues.

7. 2′-O-Methylated RNA

2′-O-Alkylation[40, 62, 143] and 2′-alkyl substitution[144] lead to oligonucleotides with improved metabolic stability. Heteroduplexes composed of 2′-O-alkylated RNA and natural RNA are more stable than those composed of DNA and RNA, and smaller substituents such as methyl, ethyl, and allyl are more stabilizing than longer chain alkyls.[39, 42] The 2′-hydroxyl group of RNA contributes to the thermodynamic stability of the RNA duplex, both enthalpically by improvement of hydration and entropically by conformational preorganization of the ribose.

The crystal structure of the A-RNA duplex $[r(C_4G_4)]_2$ at high resolution[103] and its comparison with the crystal structure of the A-DNA duplex with identical sequence[145, 146] have provided evidence for the superb hydration of the RNA duplex as a result of the 2′-hydroxyl groups in the minor groove (Fig. 13).

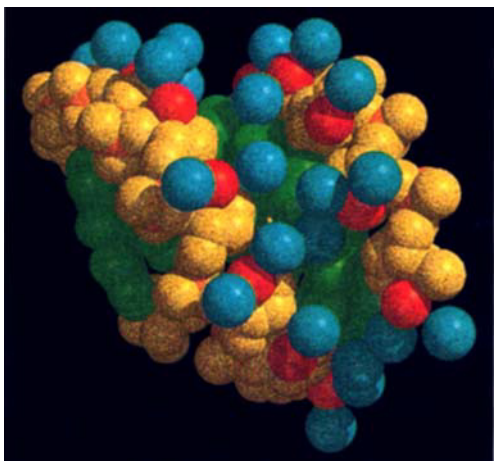

Fig. 13. Hydration of the 2′-hydroxyl groups in the minor groove of the RNA duplex $[r(C_4G_4)]_2$. Each of the water molecules (cyan, partly hidden) lies within 3.4 Å of a 2′-oxygen (red). Phosphorus atoms are orange, the remaining atoms in the ribose–phosphate backbone are yellow, and base atoms are green.

They form hydrogen bonds to two water molecules on average, and most of them serve as donors in an additional internal hydrogen bond to the 4′-oxygen of the adjacent ribose in the 5′ → 3′ direction.

The thermodynamics of hybridization for $r(C_4G_4)$ and $d(C_4G_4)$ were calculated from temperature-dependent UV-spectroscopic data. Perhaps surprisingly, the higher thermodynamic stability of the RNA duplex compared with that of the DNA duplex is not based on a more favorable entropy term, which would be a consequence of the conformational preorganization of the ribose–phosphate backbone in single-stranded RNA for an A-form duplex. Instead, the enthalpy for duplex formation for RNA is more than 30 kcal mol^{-1} higher than for DNA, consistent with the much better hydration of the RNA observed in the crystal (see 2′-OH hydration in Fig. 13). DNA duplex formation may cause a net loss of water molecules, whereas the overall number of water molecules may not be too different in the case of two RNA single strands and an RNA duplex. The very minor loss of hydration (or perhaps even slight increase) for RNA upon duplexation (entropically unfavorable) opposes

Table 2. Thermodynamic data for $r(C_4G_4)$ and $d(C_4G_4)$ based on temperature-dependent UV-hyperchromicity measurements [a].

Oligomer	T_m [°C]	ΔG [kcal mol^{-1}]	ΔH [kcal mol^{-1}]	$-T\cdot\Delta S$ [kcal mol^{-1}]
$d(C_4G_4)$	44.6	−8.4	−54.0	+45.6
$r(C_4G_4)$	70.1	−15.5	−85.1	+69.6

[a] The T_m values were measured in 10 mM sodium cacodylate (pH 7), 100 mM NaCl, 0.1 mM EDTA, at strand concentrations of 8.2 μM. Thermodynamic data are given for 37 °C.

the enthalpy gains due to bound water as well as the contribution from the preorganization of the single strand, which should favorably influence the entropy term. Nevertheless, the gains in enthalpy are higher than the losses in entropy, and the ΔG for duplex formation with RNA is roughly twice that of duplex formation with DNA (Table 2). It is interesting in this context that oligonucleotides containing 2′-alkoxy-substituted carbocyclic building blocks lacking the *gauche* interaction between the 2′-substituent and the 4′-ribose oxygen show reduced RNA-binding affinity relative to that of the corresponding DNA oligonucleotides.[57] Thus, the greater rigidity of RNA relative to DNA due to the *gauche* interaction between O2′ and O4′ in the sugar–phosphate backbone and the resulting entropic advantage for duplex formation are of crucial importance for the higher thermodynamic stability of RNA and 2′-*O*-Me-RNA.

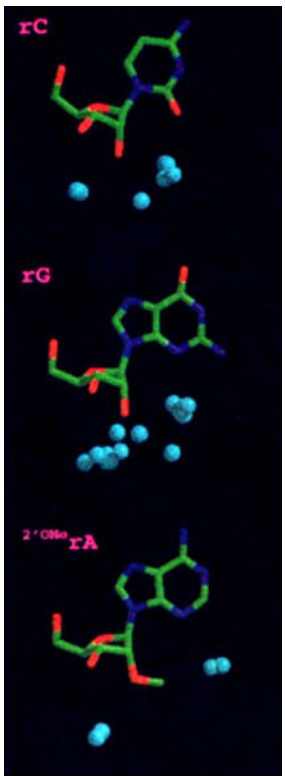

Fig. 14. Consensus hydration pattern of the minor groove in the vicinity of rC (top), rG (middle), and 2′-*O*-Me-rA (bottom). To generate each of the rC and rG pictures, the appropriate eight nucleosides in the $[r(C_4G_4)]_2$ crystal structure (replaced here with a nucleoside with a consensus conformation) and the water molecules around them were superimposed. The hydration pattern of $^{2'OMe}$rA is based on the hydration of the two modified adenosines observed in the crystal structure of a chimeric DNA:2′-*O*-Me RNA decamer duplex [106].

In the crystal structure of the decamer duplex $[d(GCGT)^{O2'Me}r(A)d(TACGC)]_2$, which contains 2′-*O*-methylated adenosines, both methoxy oxygens form a hydrogen bond to only one water molecule.[106] Thus, methylation of the 2′-hydroxyl group leads to a reduced hydration compared with that of native RNA (where 2′-hydroxyl groups are most often bound to two water molecules), and, in addition, disrupts the internal hydrogen bond often observed between O2′ and O4′ of the adjacent intrastrand ribose. The consensus patterns of minor groove hydration for cytidine and guanosine based on the $[r(C_4G_4)]_2$ crystal structure are depicted in the upper portion of Figure 14. There, the 2′-hydroxyl groups stabilize a continous band of water molecules across the groove, which are arranged more or less within the planes defined by the G–C base pairs and link backbones and bases (Fig. 13, foreground). For most of the G–C base pairs, one of the two water molecules hydrogen bonded to the 2′-oxygen atoms is located at the border of the minor groove and forms a bridge between O2′ and the phosphate group. The other water molecule then links O2′ to N3 of guanosine or to O2 of cytidine (Fig. 14). These water molecules are in turn bridged by a fifth water, which normally also forms a hydrogen bond to N2 of guanosine (not included in Fig. 13, as these water molecules do not interact directly with 2′-oxygens).

In the arrangement of water molecules around 2′-O-methylated adenosines it is apparent that the water molecule formerly linking O2′ to N3 (in analogy to G in the RNA duplex) is shifted to the center of the groove by the methoxy group (Fig. 14, bottom). Both the crystal structure and solution NMR experiments[71] provide evidence that the methoxy substituents point into the minor groove, resulting in an approximate *trans* conformation of the C2′–C3′ and O2′–CH_3 bonds. Accordingly, 2′-O-methylation of RNA seems to distort minor groove hydration at the local and the global level, suggesting that the superior stability of 2′-*O*-Me RNA could be mainly entropy driven. This is supported by the even higher thermodynamic stability of hybrids formed between 2′-deoxy-2′-fluorooligonucleotides and RNA.[42, 147] Although hydrogen bonding to covalently bound fluorine atoms has been invoked,[148] fluorine (in contrast to the fluoride anion) is an extremely poor hydrogen bond acceptor.[149] The strong RNA affinity of oligodeoxynucleotides with uniform 2′-fluoro substitution is therefore unlikely to be accounted for by enthalpic stabilization through hydration. However, electronegativity effects that stabilize the C3′-*endo* sugar pucker provide an important contribution to the exceptional RNA affinity.[99] Taken together, the structural and thermodynamic data support the view that 2′-*O*-Me RNA may combine an entropic stabilization similar to that of DNA through loss of water upon duplex formation with the entropic stabilization of RNA through conformational preorganization of the single strand. Additional stability may be provided through hydrophobic contacts between closely spaced O2′-substituents along the strand.[106] Subtle tuning between the gain in entropy and the loss in enthalpy as a consequence of altering the hydration may well be involved in the highly stabilizing effects of a methyl group at C5 in pyrimidines[150] and the exceptional RNA affinity of oligonucleotides comprising pyrimidines with propyne substituents at the C5 position.[62]

8. Sequence-Specific Cleavage of RNA

Hetero duplexes composed of RNA and almost all oligonucleotide analogs with modified sugar and/or phosphate moieties fail to activate the natural mRNA degradation pathway mediated by RNase H. The enzyme cleaves the RNA strand in DNA·RNA hybrids, and the only analogs that do not prevent recognition of the hetero substrate by the enzyme are phosphorothioates, phosphorodithioates, and those with base modifications affecting the major groove (for example 5-propynepyrimidines).[24] This failure to induce RNA degradation may con-

stitute a serious limitation for the therapeutic application of antisense compounds. Functionalized RNAs that can recognize a specific mRNA region and efficiently cleave it,[151] as well as unmodified and chemically modified hammerhead-type ribozymes[13, 41, 152, 153] may prove more potent as antisense therapeutics.

In the ribozyme-catalyzed cleavage of RNA through transesterification of phosphodiesters, the backbone is preoriented for an S_N2-type displacement. Thus, the incoming 2′-OH group and 5′-OH leaving group must both occupy apical positions in the trigonal-bipyramidal transition state formed by the nucleophile and the phosphate group with the scissile P–O5′ bond.[154–156] In an intact A-RNA duplex, the relative positions of the 2′-OH and the adjacent 5′-phosphate group preclude an in-line attack. However, distortions in the backbone geometry around single- or multiple-base bulges appear to provide the conformational freedom necessary for efficient strand cleavage. Quantitative cleavage of an RNA strand was observed at the phosphate adjacent to a "bulged" or unpaired nucleotide in the presence of moderate amounts of Mg^{2+}.[157] The products that result from cutting the 3′-5′-phosphodiester bond between the bulged and adjacent nucleotides in a 5′ → 3′ direction are a cyclic 2′,3′-phosphodiester and a free 5′-hydroxyl group, exactly the same products obtained in the cleavage reaction catalyzed by hammerhead-type ribozymes.[158]

We have determined the crystal structure of a self-complementary RNA–DNA chimera with single adenosine bulges at a resolution of 2.8 Å (Fig. 15).[160] In the crystal the fragment adopts crystallographic twofold symmetry and both adenosines extrude from the duplex (Fig. 16). The deoxyriboses of the bulged nucleotides A(8) and A(19) as well as A(6), T(7), A(17), and A(18) adopt C2′-*endo* puckers, while all others display the C3′-*endo* conformation of A-RNA. The backbone perturbations brought about by the unpaired adenosines kink the fragment by 20° and cause a drastic opening of the narrow major groove to about twice its normal width.

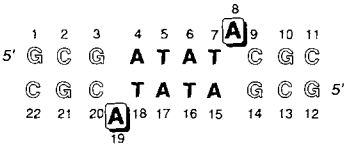

Fig. 15. Sequence of the self-complementary RNA–DNA chimera (units of RNA in outlined letters, those of DNA in filled letters) having two bulged (unpaired) adenosine residues, which was studied by X-ray crystallography. The central portion of the 11mer was originally left as DNA in order to conserve some features of a fully base-paired RNA–DNA chimera that had previously yielded high-resolution crystals [159], and to prevent strand cleavage between residues A(8) and C(9) (or A(19) and C(20)) during attempted crystallization in the presence of divalent metal cations.

In molecular modeling studies based on the crystal structure of this RNA–DNA chimera, a 2′-OH group was introduced at the deoxyribose of the bulged adenosine. As can be seen in Figure 17 (bottom), this hydroxyl group is relatively far removed from the scissile P–O5′ bond (O2′–P 4.2 Å). In addition, it lies approximately within the plane defined by the phosphate oxygens O1P, O2P, and O3′. Thus, the hypothetical O2′-P-O5′ angle of 90° would disfavor cleavage of the phosphodiester bond (Fig. 17, bottom). However, if the C2′-*endo* conformation at the ribose of the bulge residue is flipped into a C3′-*endo* pucker,

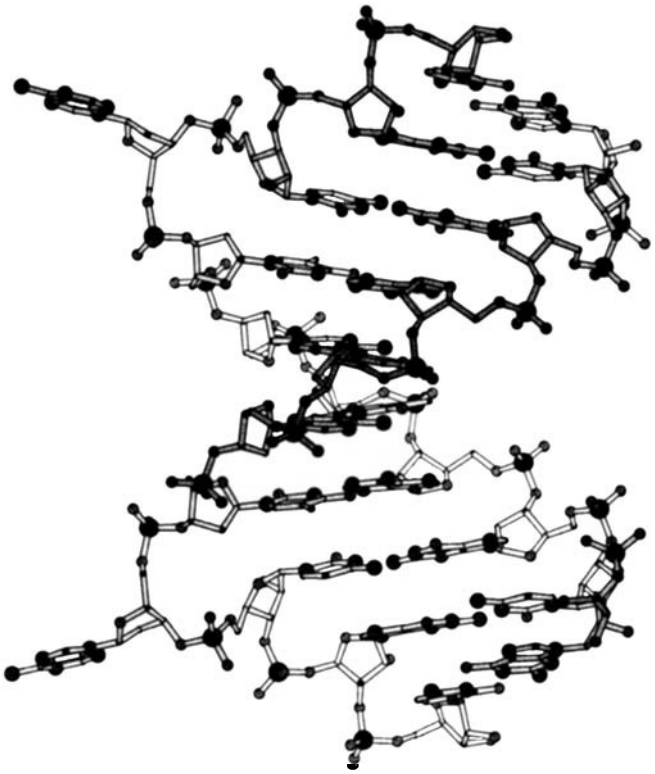

Fig. 16. Overall conformation of the A-RNA-like duplex containing bulged adenosines. Phosphorus atoms are filled circles and darker portions are closer to the viewer. Bulged adenosines are important RNA secondary structure elements and are involved in RNA folding, protein–RNA interactions, and splicing of group I and II introns as well as nuclear pre-mRNA [161–165].

a roughly apical arrangement of the 2′-OH results (O2′-P 3.6 Å, O2′-P-O5′ 150°; Fig. 17, top). This demonstrates that apical positions of incoming and leaving groups at the trigonal-bipyramidal intermediate can be achieved relatively easily as a result of local conformational rearrangements of the backbone around the bulged nucleotide, and is consistent with the efficient metal-assisted cleavage at such sites. The P-$O^{Si}\cdots O^{Re}$-P distance of 3.95 Å for residues C(9) and G(10) adjacent to the bulged nucleotide in the 5′-direction in the crystal structure is the shortest one in the entire duplex, and lies well below the usual intrastrand phosphate–phosphate contacts in A-type duplexes (Fig. 17). These closely spaced phosphate groups may provide a binding site for a Mg^{2+} ion that could activate the phosphate group for the nucleophilic attack and stabilize the 5′-hydroxyl leaving group. It is interesting that in the structure of a second crystal form, determined at a resolution of 1.83 Å,[160] the RNA–DNA chimeric fragment displays a conformation in the region of the bulged nucleotide that is very similar to the one in the modeled structure. In this structure the sugar of the bulged adenosine adopts a C3′-*endo* conformation and the added 2′-OH group assumes a nearly apical orientation relative to the phosphate group (O2′–P 3.8 Å, O2′-P-O5′ 145°).

9. Summary and Outlook

Progress in understanding of nucleic acid structure has always been intimately linked to the advances in the chemical synthesis of DNA and RNA. When milligram amounts of highly pure

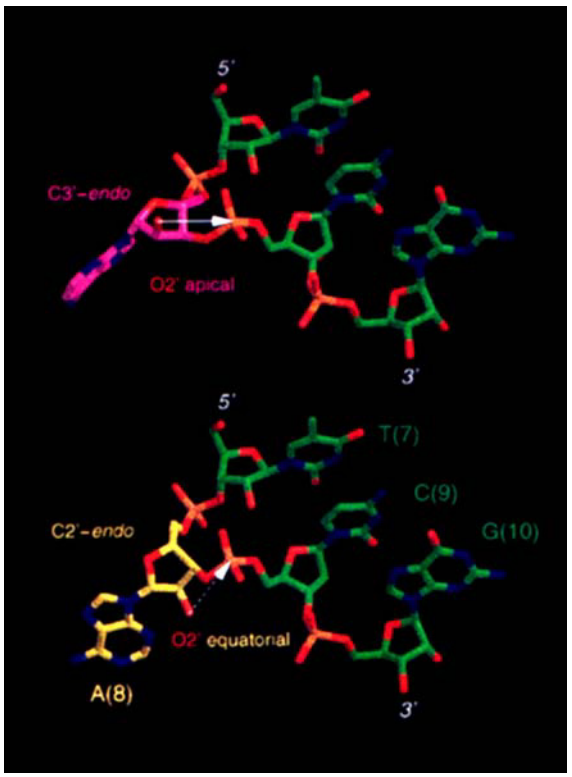

Fig. 17. Backbone conformation around the adenosine bulge (yellow) as observed in the crystal structure (bottom). Modeled backbone conformation around the adenosine bulge (purple) by changing the conformation of the sugar pucker from C2'-*endo* to C3'-*endo* (top). Solid and dashed arrows indicate the vectors between the adenosine 2'-OH, which is depicted here but missing from the crystal structure, and the phosphorus of the 3'-phosphate. The short distance between the phosphate oxygens O^{Si} and O^{Re} of residues C(9) and G(10), respectively, is visible in the foreground.

oligodeoxynucleotides became available in the early eighties, the way was paved for the first high-resolution crystal structures of DNA fragments. In somewhat more than a decade over a hundred crystal structures have given insight into many structural aspects of the double helix. Similar success with RNA has long been hampered by the difficulties encountered in developing synthesis protocols for the large-scale production of oligoribonucleotides. These have now largely been overcome and a dramatic rise in the number of RNA structures in the next years is foreseeable.

The challenge of advancing the antisense technique beyond its use as a research tool toward therapeutic applications has catalyzed the generation of an astounding variety of synthetic nucleic acid analogs. Many of them show improved resistance to cellular nuclease degradation over that of their natural counterparts. Several analogs combine higher chemical stability with increased RNA affinity.[51, 62, 166] However, with very few exceptions, such as the first-generation phosphorothioate analogs, modifications block the natural mRNA degradation pathway based on RNase H. Modified oligonucleotides that form stable complexes with newly transcribed RNA at nuclear sites and do not prevent recruitment of RNase H appear to be particularly effective in shutting down mRNA translation.[167]

Detailed three-dimensional structures provide clues to the origins of the changes in thermodynamic stability incurred by chemical modifications of DNA and RNA. A comparison of the high-resolution crystal structures of a DNA octamer and an RNA octamer duplex with identical sequences illustrates that double-helical DNA and RNA differ fundamentally in their degrees of hydration; the RNA duplex is more extensively hydrated as a result of the additional ribose 2'-hydroxyl groups. Consequently, with respect to bound H_2O, RNA duplex formation is favored enthalpically but disfavored entropically relative to DNA duplexation. The higher rigidity of the ribose moiety contributes positively to the overall thermodynamic stability of the RNA duplex. Hydration changes and the ensuing trade-off between enthalpy and entropy are mostly overlooked in the analysis of the thermodynamic stability data of nucleic acid analogs.[127] Because hydration makes an important contribution to the relative stabilities of native DNA and RNA, it would seem that changes in the solvation as a consequence of chemical modifications are a crucial factor in the altered thermodynamic stability of DNA and RNA analogs. This view is supported by the changes in hydration evident in the crystal structures of derivatives formed by introduction of methyl groups at the 2'-oxygen (2'-*O*-Me-RNA) and the 6'-carbon (carbocyclic DNA). Somewhat simplified, these results point to an equilibration or occasional overcompensation (2'-O-substituted RNA) of the enthalpy losses caused by the altered or reduced hydration in the vicinity of short-chain alkyl groups or heteroatom substituents by the entropy gains due to water loss. The close spacing of such substituents in the minor groove of the A-form duplex is likely to stabilize duplex formation, while longer chain alkyl groups, or in general bulky lipophilic substituents, disrupt hydration in such a way that the enthalpy loss becomes dominant. Hydration effects are probably also involved in the stabilization exerted by substituents at pyrimidine C5 (for example methyl or propyne); stacking and interactions between substituents provide additional contributions.

In addition to providing feedback for the design of further nucleic acid analogs for antisense applications, systematic study of the structures of chemically modified nucleic acids promises deeper insight into the properties of the native DNA and RNA molecules. Just as point mutations with proteins in combination with structural work have permitted the assessment of the individual influences of amino acids in folding and catalysis, specifically modified nucleic acids allow one to analyze the importance of various parameters for the overall structures of DNA and RNA. Thus, analogs may be helpful for an improved understanding of bending, interactions between proteins and nucleic acids, and a variety of other issues.

I wish to thank my collaborators in our laboratory, P. Lubini, S. Portmann, A. Roughton, and C. Richert, as well as those from outside institutions, C. Leumann (University of Berne), K.-H. Altmann, M. Blommers, D. Hüsken, and H. Moser (CIBA, Basel), N. Usman (Ribozyme Pharmaceuticals Inc., Boulder, USA), and F. K. Winkler (Hoffmann LaRoche, Basel) for their contributions and stimulating discussions. I am grateful to A. Roughton for his comments on the manuscript, and I would like to thank the ETH Zürich, the Organic Chemistry Laboratory, The Ciba-Geigy-Jubiläums-Stiftung, and CIBA for their financial support.

Saccharide Sensing with Molecular Receptors Based on Boronic Acid

Tony D. James, K. R. A. Samankumara Sandanayake, and Seiji Shinkai*

The lock-and-key principle of natural systems is based on complex interactions like hydrogen bonding. Many synthetic systems that attempt to mimic natural systems have also used hydrogen bonding as the main binding force and have met with great success in non-hydrogen-bonding solvents that do not compete with the guest for the binding pocket. In contrast, natural systems function in water, a very competitive solvent. Synthetic hydrogen-bonding systems may yet evolve to be successful in water. If this transition can not be made, synthetic answers can nevertheless take inspiration from nature without slavishly following the blue print. This is not an attempt to re-invent the "lock": a new locking mechanism merely replaces the existing one. The inspiration might be the view of the hydrogen bond as an easily reversible "covalent" bond. Screening the literature we rediscovered boronic acids, which have been known for over 100 years. Conveniently, boronic acids rapidly and reversibly form cyclic esters with diols in basic aqueous media. Saccharides and other related "keys" contain a contiguous array of cyclic alcohols. In this work we hope to demonstrate that saccharide "keys" and boronic acid "locks" can open the door to a new and exciting field of research.

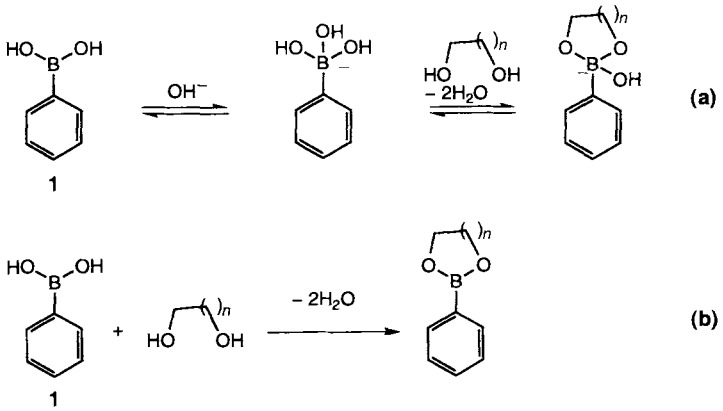
Keywords: boronic acids · fluorescence · electron transfer · saccharides · molecular recognition

1. Introduction

For many years boron-containing compounds have been important in organic synthesis.[1] However, only recently have aromatic boronic acid derivatives been employed in the construction of receptors for molecules such as saccharides.

Phenylboronic acid was first synthesized by Michaelis and Becker in 1880,[2] but 74 years passed before the first binding studies of diols (or saccharides) with boronic acid were published: in 1954 Kuivila et al. noticed that boronic acids solubilized saccharides and polyols, and they postulated the formation of a cyclic ester.[3] This result agreed with the known ability of borates to form complexes with polyhydroxyl compounds.[4] Subsequently it was found that arsenite and tellurate also formed complexes with polyols.[5] The first quantitative evaluation of interactions between saccharides and boronic acid were published by Lorand and Edwards in 1959.[6]

Despite this, the structure of the boronic acid and saccharide complex in aqueous solution is still in dispute.[7] Boronic acids form covalent bonds with 1,2- or 1,3-diols to generate five- or six-membered cyclic esters in nonaqueous or basic aqueous media (Scheme 1). The rigid, vicinal *cis* diols of saccharides form more stable cyclic esters than simple acyclic diols such as ethylene glycol. With saccharides the formation of a particular cyclic ester is complicated by the possibility of pyranose-to-furanose isomerization of the saccharide moiety. The selectivity of phenylboronic acid (**1**) towards saccharides was determined by Lorand and Edwards[6] (Table 1). This selectivity order seems to be common to all monoboronic acids and will be referred to throughout this review.



Scheme 1. Ester formation with boronic acids. Reaction (a) in basic, aqueous milieu; reaction (b) in aprotic milieu in the presence of a dehydrating agent.

The interest in the recognition of biologically important molecular species by synthetic molecular receptors has gained momentum recently. The function of many of these receptors, including several that recognize carbohydrates,[9-10] is based on hydrogen-bonding interactions.[8-10] The efficiency of such interactions has been well demonstrated in nonaqueous systems,

but in aqueous media competitive hydrogen bonding by the solvent is a serious drawback. Boronic acid readily forms covalent interactions with saccharides in aqueous media, and these represent an important alternative binding force in the recognition of saccharides and related molecular species. Although much progress in the construction and design of sensors based on boronic acids has been made, future development will require a greater understanding of the structural and electronic properties of boronic acids.

As the chemistry of saccharides and related molecular species play a significant role in the metabolic pathways of living organisms, detecting the presence and concentration of biologically important sugars (e.g., glucose, fructose, galactose) in aqueous solution is necessary in a variety of medicinal and industrial contexts. The recognition of D-glucose is of particular interest, since the breakdown of glucose transport in humans has been correlated with diseases such as renal glycosuria,[11, 12] cystic fibrosis,[13] diabetes,[14, 15] and also cancer.[16] Industrial applications range from the monitoring of fermenting processes to the establishment of the enantiomeric purity of synthetic drugs. Current enzymatic detection methods for sugars offer specificity for only a few saccharides; additionally, enzyme-based sensors are unstable in harsh conditions. Stable saccharide receptors based on boronic acid can act as saccharide sensors that are selective and sensitive for a particular saccharide.

The development of boronic acid based molecular receptors has been hampered by synthetic difficulties: Since boronic acids can exist as a mixture of acid and anhydride, analytical difficulties arise. Elemental analyses of boronic acid derivatives are complicated by incombustible residues.[17] The cleavage of boronic acids by copper salts,[18] silver salts,[17] and even by hot water have been reported.[17] This review will not discuss these synthetic aspects, and will instead provide a survey of the development of saccharide sensors based on boronic acid.

2. Saccharide Sensing with Circular Dichroism (CD) Measurements

2.1. Homogeneous Systems

Chiroptical properties, known since the mid-nineteenth century, play an important role in analysis in the food and drug industries. Increasingly strict regulations have applied pressure on industry to produce enantiomerically pure drugs because of the potentially devastating effects of the wrong enantiomer. Moreover, CD measurements are useful for the detection and

S. Shinkai

Seiji Shinkai was born in Fukuoka Prefecture, Japan, in 1944 and received his PhD in 1972 from Kyushu University, where he became a lecturer soon afterwards. After postdoctoral work at the University of California, Santa Barbara, with Thomas C. Bruice, he joined Kyushu University in 1975 and became full professor there in 1988. Currently he is also the director of Shinkai Chemirecognics Project (a government-owned project under the Japanese Research Development Corporation (JRDC)). His research interests focus on host–guest chemistry, molecular recognition, liquid crystals, and enzyme models.

K. R. A. Samankumara Sandanayake was born in 1961 in Colombo, Sri Lanka. He received his B. S. in 1985 from the University of Colombo, and his PhD in 1989 from the Queens University of Belfast under A. P. de Silva on fluorescent macrocyclic sensors for alkali and other cations. After postdoctoral work at the University of Liverpool with Professor I. O. Sutherland on chromoionophoric molecular sensors, he joined the Shinkai Chemirecognics Project in 1993. His research interests include host–guest chemistry, molecular design and recognition, and polymers.

Tony D. James was born in Broseley, Shropshire, England in 1964. He received his B. Sc. in 1986 from the University of East Anglia after returning from a one year exchange with the University of Massachusetts. He received his PhD from the University of Victoria under T. M. Fyles on structure–activity studies of ion channel mimics in 1991. He is currently a postdoctoral fellow at the Chemirecognics Project. His research interests include molecular recognition, molecular assemblies, and molecular machines.

the optical purity of a sample. However, the expensive equipment required for CD measurements hampers the practical applications of this method.

The CD properties displayed because of chiral induction of molecular complexes containing chiral guest species such as saccharides provide an important method to determine the chirality of the guest. This is significant for nonchromophoric host molecules.

The presence of hydroxyl groups with only slight reactivity differences creates problems in designing saccharide receptors. On the other hand, the high number of hydroxyl groups is an advantage if these hydroxyl groups are used in the recognition/binding process. When two boronic acid units are arranged in a suitable orientation in a molecule (as in **2**), a saccharide may be bound in a 1:1 complex through the molecule's head and tail boronic acid groups. (Scheme 2). The cooperative binding by two units to monosaccharides and some disaccharides in basic aqueous media creates a rigid cyclic complex. The asymmetric immobilization of two chromophoric benzene rings by ring closure with saccharides can be "read" by CD spectroscopy.[19-21] D- and L-saccharides give positive and negative exciton coupling, respectively (Fig. 1); the highest association constant is 19000 $dm^3 mol^{-1}$ for glucose. Among the D-saccharides tested, D-galactose was the only saccharide to show a negative exciton coupling in the CD spectrum. Table 2 summarizes the CD data and association constants of different saccharide complexes with **2**. These results imply that the absolute configuration of saccharides can be conveniently predicted from the sign of the CD spectra of **2**. The 1,2-diol is widely accepted as the primary binding site of α-glucose with boronic acid (Fig. 1).[6] The pyranose structure of the D-glucose diboronic acid complex (**2**) was suggested by ^{1}H NMR spectroscopy.[20] However, recent ^{11}B, ^{13}C, and ^{1}H NMR investigations indicated that the complex contains the furanose form of D-glucose.[7]

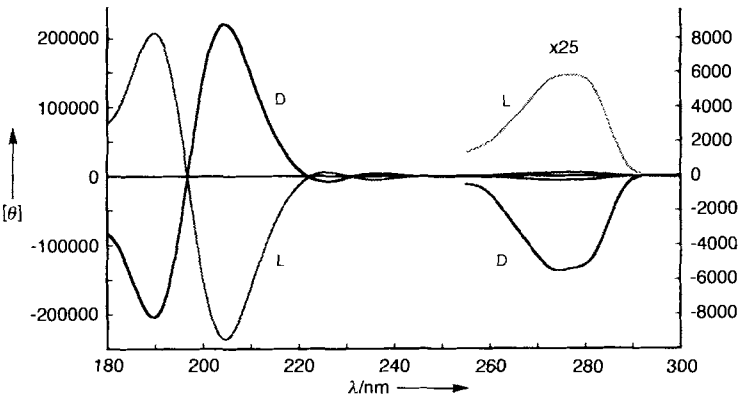

Fig. 1. CD spectra of **2** in the presence of D-glucose (D) and L-glucose (L): c(glucose) = 2.00×10^{-3} mol dm^{-3}, c(**2**) = 1.00×10^{-3} mol dm^{-3}, pH 11.3 with 0.10 mol dm^{-3} carbonate buffer, 25 °C; [θ]: molar ellipticity [° cm^2 $dmol^{-1}$].

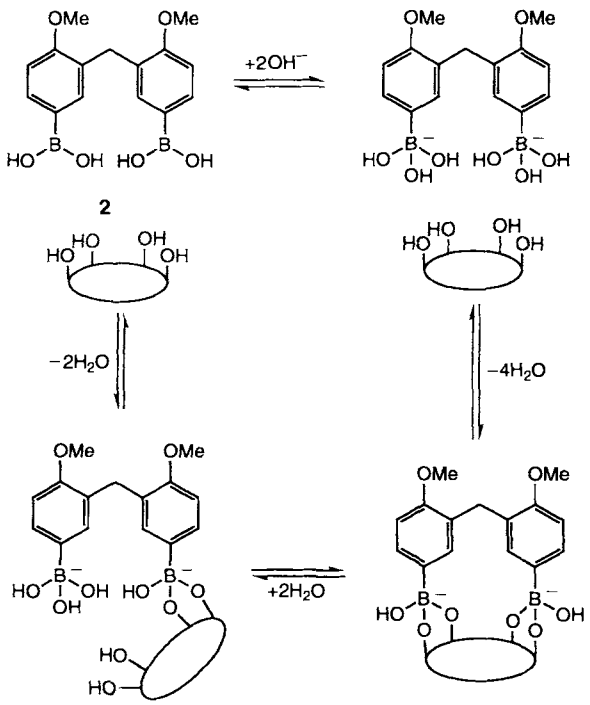
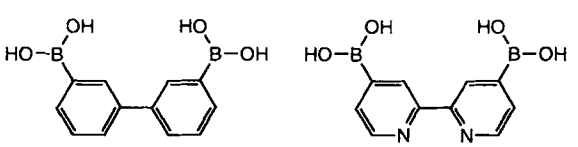
[a] 25 °C, c(**2**) = 1.00×10^{-3} or 2.00×10^{-3} mol dm^{-3}, pH 11.3 with 0.10 mol dm^{-3} carbonate buffer. [b] $[\theta]_{max}$ values are calculated for complete formation of a 1:1 complex. [c] No perceptible CD band could be detected.

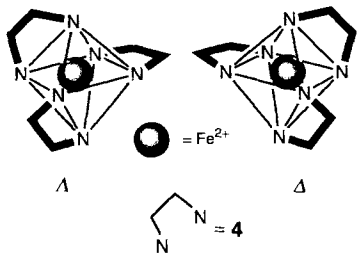


Scheme 2. Formation of the 1:1 complex between a monosaccharide and boronic acid **2**.

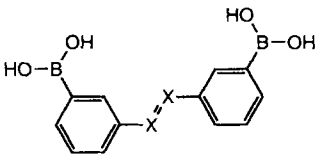
Diboronic acid **3** has a greater distance between the two boronic acid moieties and was expected to associate strongly with disaccharides.[21,22] However, association constants for disaccharides were much smaller than those for the complex formed between monosaccharides and **2**. CPK models revealed that the distance between the two boronic acids in **3** is shorter than the distance between the head and tail hydroxyl groups of the disaccharides. Accordingly, the CD activity was much weaker and was inadequate for the estimation of association constants. The Fe^{2+} complex (as $FeCl_2$) with the related diboronic acid **4** gave CD-active saccharide complexes.[23] The CD activity



3 **4**

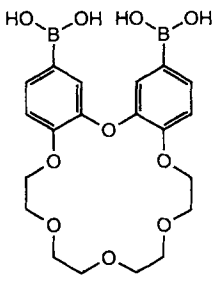


of **4** was derived from the asymmetric immobilization of the two pyridine units on saccharide binding. The Fe^{2+}-**4** complex gave a CD band in the region of the metal-to-ligand charge transfer band. The assignment of *Δ* or *Λ* complexes depended on the saccharide in the complex. For example, the D-maltose complex adopted *Λ* chirality, whereas the D-cellobiose complex adopted *Δ* chirality. The 3,3'-stilbenediboronic acid species **6** similarly gave a CD-active species upon disaccharide complexation.[24] Diboronic acid **5** gave better complexes with disaccharides.[25] The extended chromophore facilitates the detection of CD bands, and the allosteric switching of selectivity by *cis-trans* isomerization of **5** has been investigated.

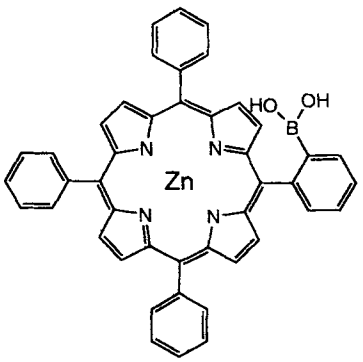


5, X = N
6, X = CH

Nature relies on allosteric (or cooperative) interactions in many biological functions, for instance, the transport of sugars across a cell membrane. In an attempt to mimic these functions, a saccharide-binding diboronic acid unit was combined with a simple crown ether. The strong cooperative binding of **2** prompted the design of such an allosteric system (**7**).[26] The



7



8

change in the angle between two phenyl rings of **2** by some secondary effect contols the sugar binding ability of **2**. Crown ether **7**, with a very similar binding site to **2**, exhibits an even larger association constant for glucose (31 000 $dm^3 mol^{-1}$) in basic $MeOH/H_2O$ solutions (according to CD measurements), since the framework is more flexible with regard to the rotation of the phenyl rings. The binding of metal ions to the crown ether was observed by ^1H NMR spectroscopy. It induces a twist in the crown ether resulting in negative allosterism. Figure 2 shows the decrease of the CD intensity of the D-allose–**7** complex with increasing metal ion concentration.

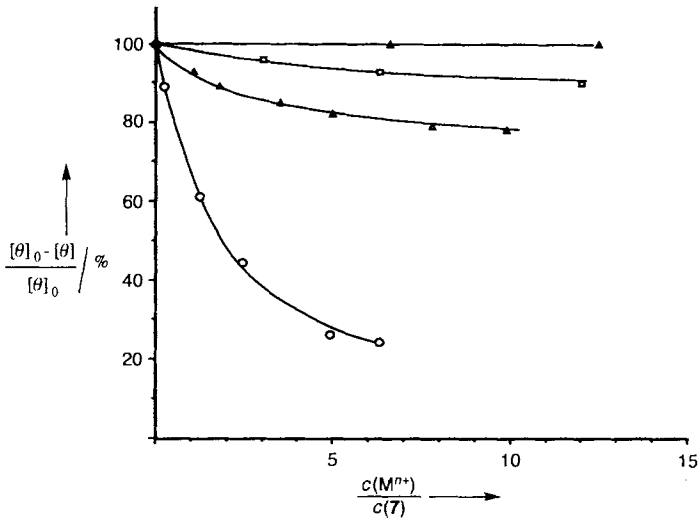


Fig. 2. Decrease in the CD intensity of the D-allose–**7** complex in the presence of metal perchlorates: ○ Ca^{2+}, △ K^+, □ Mg^{2+}, ▲ [Li^+, Na^+, Rb^+, Cs^+]. $c(7) = 1.63 \times 10^{-3}$ mol dm^{-3}, pH = 11.6 with 0.2 % choline hydroxide as the base in 9/1 CH_3OH/H_2O at 25 °C; $[\theta]_0$ and $[\theta]$ are the CD intensity in the absence or presence of metal salt, respectively.

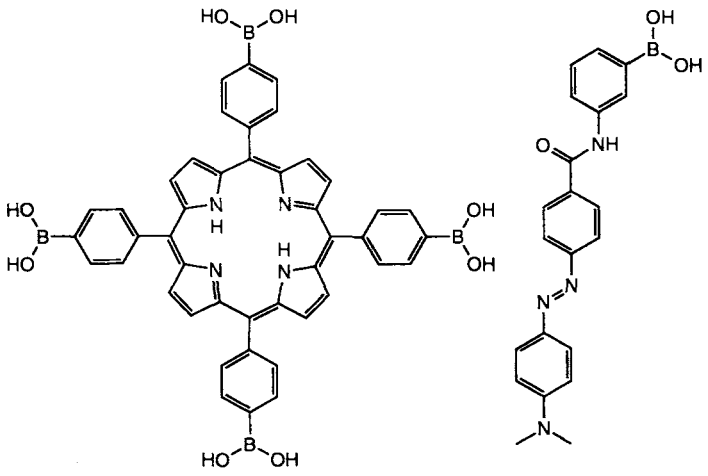
Glucose phosphates are important molecular species in energy storage processes. The metalloporphyrin derivative **8** with a boronic acid appendage selectively distinguishes glucose-6-phosphate from glucose-1-phosphates.[27] The two point binding of glucose-6-phosphate creates a rigid complex that gives a strong exciton coupling signal in the CD spectrum. It is assumed that the strong binding by the primary 1,2-diol binding site of glucose to the boronic acid on one hand, and the subsequent secondary interaction between the phosphate residue and metal center on the other, result in the high affinity for glucose-6-phosphate. The replacement of the 1-hydroxyl group, which is part of the primary binding site of glucose, by a phosphate unit in glucose-1-phosphate weakens the interaction between the saccharide and boronic acid, and hence affects the overall strength of the complex. Binding of phosphate to the metal center was revealed by ^{31}P NMR peak shifts. CD exciton coupling peaks were not found for either metal-free **8** with glucose derivatives or for **8** with glucose itself, which indicates the importance of the two point binding.

2.2. Heterogeneous Systems

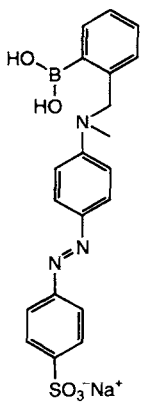
Some chiral molecules are known to form chiral, helical aggregates.[28] Chirality can also be induced in aggregates of nonchiral molecules by interactions with chiral species.[29] The chiral, helical aggregates that are formed when aggregates of a nonchiral tetraboronic acid derivative **9** are treated with monosaccharides[30] can be detected by CD spectroscopy. Furthermore, the sign of the exciton coupling of the sugar-complexed aggregate can be predicted by the sugar-induced, chiral orientation of the complex. The chromophoric boronic acid derivative **10** was also found to aggregate in mixed solvents (water/dimethyl formamide).[31] The aggregate was CD active on addition of glucose.



9 10

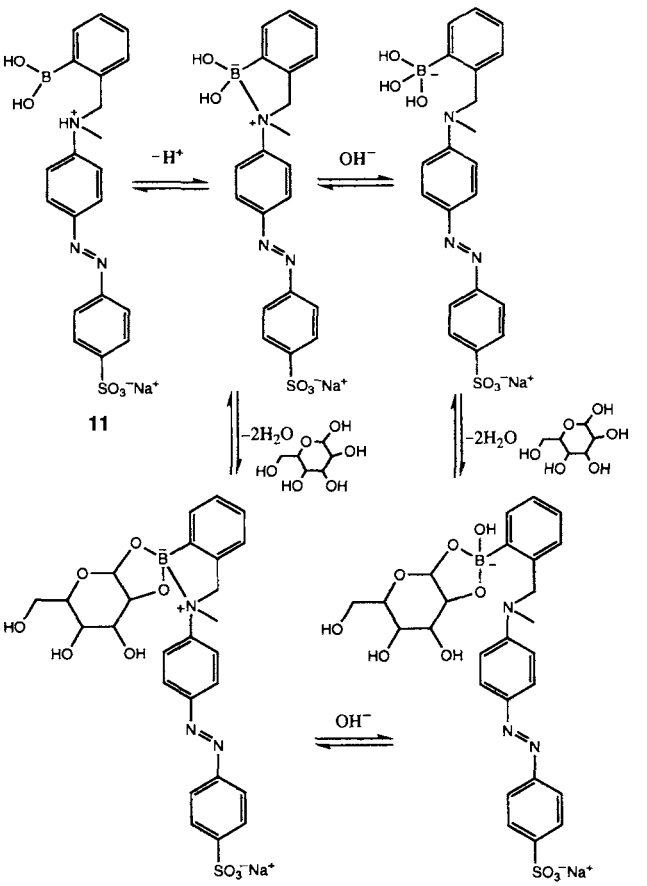
3. Saccharide Sensing with Absorption Spectroscopy

3.1. Homogeneous Systems



11

Although dyes containing boronic acid residues have been known for a long time,[32] the effect of saccharides on the color of these compounds has not been investigated until recently. The molecular internal-charge-transfer sensor **11**[33] is based on the intramolecular interaction between the boronic acid unit and the tertiary amine.[34] The adjacent amine creates a basic environment around the boronic acid moiety, which facilitates the boronic acid saccharide interaction and lowers the working pH of the sensor molecule.[35] The electronic changes associated with the pK_a changes of the boronic acid unit due to the formation of the boronic acid–saccharide complex[6] are directly transmitted to the neighboring amine moiety, thus causing the CT band in the spectrum of the chromophore to shift. The absorption vs. pH profile for **11** in aqueous media with different saccharides is given in Figure 3. The equilibrium processes in different pH regions and the most important species involved are depicted in Scheme 3. The pK_a value dependent on the boron–nitrogen interaction in **11** shifts on addition of saccharides. The pK_a shift was largest for fructose ($\Delta pK_a = 3.31$) and smallest for simple diols such as ethylene glycol ($\Delta pK_a \approx 0$).



Scheme 3. Formation of the complex between **11** and saccharide at different pH values.

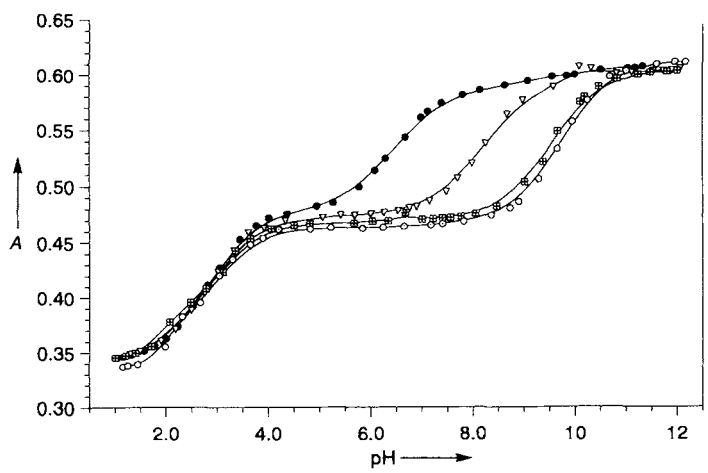


Fig. 3. Changes in absorption in the spectra of **11** (λ_{max} = 468 nm) at different pH values in the presence of 0.05 mol dm^{-3} NaCl and 0.05 mol dm^{-3} D-fructose ●, D-glucose ▽, ethylene glycol ⊞, and without saccharide ⊙.

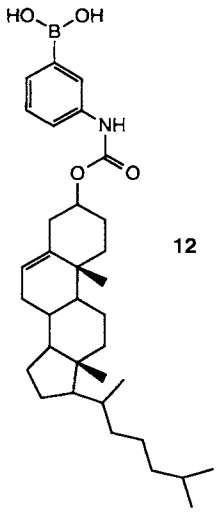
To date, only small color changes have been achieved when saccharides form complexes with boronic acids. With the aid of better chromophores and better receptors it will be possible to develop selective and sensitive color sensors. Such sensory systems will have widespread applications in industry. For example, it should be possible to provide cheap and stable "test strips" for the detection of blood glucose.

3.2. Liquid Crystalline Systems

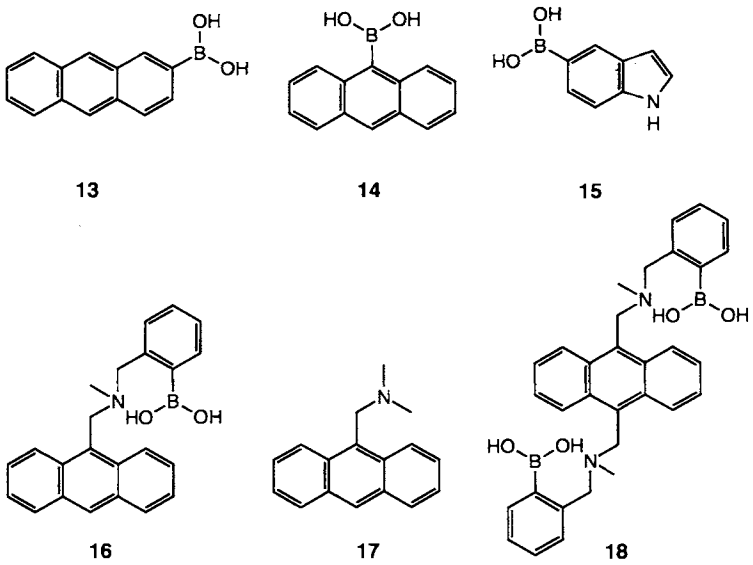
Liquid crystals composed of chiral molecules may possess helical structures in which the pitch determines the color of the liquid crystal. The change in pitch induced by inclusion of molecules results in visible color changes, and the spectral shifts can reflect the absolute configuration of such species. A liquid crystalline composite including cholesteryl boronic acid **12** changes color upon introduction of saccharides.[36] The pitch of the



12

liquid crystal directly reflects the chirality of the bound sugar. For example, the green uncomplexed composite turned red upon introduction of D-glucose and blue upon introduction of L-glucose. A direct correlation between the color and the relative position of the saccharide ring when bound to the boronic acid moieties has been proposed.

As with the absorption spectroscopic techniques this system may find applications in test strips. Unfortunately, the response time may be a serious drawback: to be recognized the saccharide in solution must diffuse from the aqueous layer into the cholesteric liquid crystal layer of the test strip.



13 14 15 16 17 18

3.3. Heterogeneous Systems

Color changes upon introduction of saccharides have been observed in molecular aggregates of **10** in a DMF/water mixed-solvent system.[31] These changes appear to be due to the deaggregation process induced by saccharide binding.

4. Saccharide Sensing with Fluorescence Spectroscopy

An advantage of fluorescence sensors for saccharides is the inherent sensitivity of the fluorescence technique. Because only small amounts of a sensor are required (typically 10^{-6} M), the synthetic costs of such sensors can be offset. Moreover, fluorescence spectrometers are widely available and inexpensive. Fluorescence sensors have also been applied in continuous monitoring with optical fibers for intracellular mapping with confocal microscopy.

4.1. Homogeneous Systems

4.1.1. PET systems

Photoinduced electron transfer (PET) has been widely used as the preferred tool in fluorescent sensor design for atomic and molecular species.[37, 38] PET sensors generally consist of a fluorophore and a receptor linked by a short spacer. The changes in redox potential of the receptor upon guest binding can alter the PET process and generate changes in the fluorescence. The fluorescence of **13** and **14** was quenched by saccharide binding to the boronic acid moiety.[39] The extent of the pK_a shift for **13** induced by the presence of the saccharide in the medium was in line with the inherent selectivity of phenylboronic acid.[6] The PET from the boronate anion is considered to be the source of the fluorescence quenching. However, PET was not efficient although the boronate anion is directly bound to the chromophore (I(with saccharide)/I_0(without saccharide)$\approx$0.7). Catechol derivatives bind to **13** and **14** with even higher affinity, and the PET from the catechol moiety further increased the fluorescence quenching of the anthracene group.

Similarly, 5-indolylboronic acid (**15**) showed fluorescence quenching upon complexation with oligosaccharides.[40] In the pK_a values determined with ^{11}B NMR shifts were consistent with the fluorescence studies. The stability constants of complexes of **15** with monosaccharides correlated with the inherent selectivity of phenylboronic acid for the sugars.[6] The stability constants of oligosaccharides, on the other hand, were generally lower than predicted on these grounds, although higher oligomers were more stable than lower oligomers because of a secondary interaction with the indole N–H.

The lack of sufficiently large electronic changes in the boronic acid or the saccharide moiety upon complexation has hampered the design of fluorescent sensors based on the interaction between boronic acid and saccharide. Boronic acid binds saccharide only at pH values high enough to create a boronate anion. To overcome these disadvantages fluorescence sensor **16** was designed, based on the structure of **17**.[41] The neighboring group participation of the amine group that lowers the working pH of the sensor molecule[35] also provides an electron-rich center for PET.[37, 42] Fluorescence titration of **16** in aqueous media gives rise to a very high pK_a shift together with a very high fluorescence "switch-on" factor on saccharide binding. The increased acidity of the boronic acid moiety strengthens the boron–nitrogen bond and effectively suppresses the PET process. Figure 4 shows the pH titration of **16** in aqueous media with and without saccharides. The very large pK_a shift enables saccharide sensing over a wide pH. The selectivity of **16** is in line with that observed for other phenylboronic acids.[6]

As glucose possesses at least two binding sites that differ from those in other monosaccharides, it should be possible to selectively bind glucose. This has been achieved in the cleftlike structure of **18**[43, 44] with even higher "switch-on" factors than for **16** (Table 3). Upon 1:1 binding of glucose to the large macrocyclic structure **18** the monosaccharide is situated close to the anthracene aromatic face. The most important species involved in the equilibrium process are shown in Scheme 4. The C3 proton of D-glucose, in particular, points towards the π electrons of the anthracene moiety and consequently gives a very large para-

magnetic shift in the ^{1}H NMR spectrum (Fig. 5). Similar paramagnetic shifts have also been observed in complexes of related PET sensor **19** and α,ω-alkanediyldiammonium ions.[45] The existence of a 1:1 complex of **18** and D-glucose was further confirmed by mass spectrometry. Such cooperative binding of saccharides, specifically glucose, occurs at very low saccharide concentrations. Due to the requirements for PET, noncyclic 1:1

19 **20**

complexes could not be detected by fluorescence spectroscopy; only the 1:1 cyclic complexes and 1:2 complexes give fluorescent signals. In human blood three main monosaccharides are present: D-glucose(0.3–1.0 mM), D-fructose (≤0.1 mM) and D-galactose (≤0.1 mM). Competitive binding studies show that **18** is suitable for the detection of glucose at physiological levels.

Diboronic acid derivative **20**, which has a flexible spacer between the two boronic acids, behaves similarly to **18**.[46] Pyrene fluorophores capable of forming excimers give information on both the saccharide concentration and the structure of the complex. The 1:1 binding of a saccharide to **20** leads to an increase in fluorescence intensity over that of the monomer. This increase was produced partially by less excimer formation and partially by the increased overall fluorescence quantum yield because of the suppression of the PET process. The 1:2 binding of **20** to saccharides, on the other hand, increased the excimer:monomer fluorescence intensity ratio. In all cases the formation of a 1:1 complex was observed at low saccharide concentrations, while the predominant complex changed to 1:2 as the saccharide concentration increased. The selectivity of **20** was found to be similar to that of **18** as shown in Table 3. However, the higher concentration of methanol used in the measurements leads to somewhat lower stability constants than for **18**.

The success of these molecular PET systems prompted the design of **21** (*R* and *S*) for chiral recognition of monosaccharides.[47] Work by Irie et al. on the control of intermolecular chiral 1,1'-binapthyl fluorescence quenching by chiral amines[48] and by Cram et al. on the use of 1,1'-binaphthyl in the recognition of chiral amino acids[49] were the inspiration behind the design of **21**. Chiral recognition of saccharides by **21** utilizes both steric and electronic factors. In 1:1 complexes of **21** and D or L saccharides the asymmetric immobilization of the amine groups, which orients them differently relative to the binaphthyl moiety, leads to a difference in PET behavior. This difference is manifested in the maximum fluorescence intensity of the complex. Steric factors arising from the chiral binaphthyl building block are chiefly reflected by the stability constant of the complex. However, the interdependency of electronic and steric factors is not excluded. Figure 6

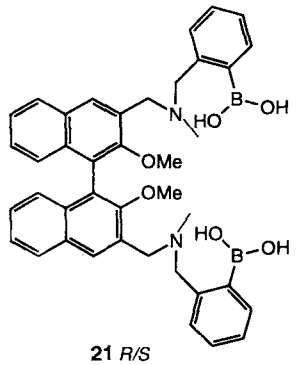
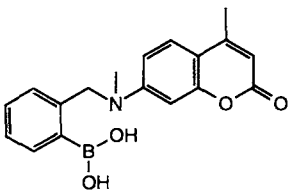
shows the curves for titrations of **21** (*R* and *S* isomers) with D and L saccharides. This new molecular cleft, with a longer spacer unit than that in the anthracene-based diboronic acid **18**, gave the best chiral recognition for fructose. D-fructose was bound best by (*R*)-**21**, which gave rise to a large fluorescence increase. Table 4 shows the stability constants for some D and L monosaccharides. Though chiral recognition of saccharides employing hydrogen bonding by polyhydroxy compounds has been reported,[10] discrimination of isomers in aqueous media by fluorescence, as far as we are aware, had not been achieved before. In this system a combination of steric and electronic factors contributed to the chiral discrimination. Competitive studies with D and L monosaccharides show that selective detection of saccharide isomers is possible with **21**. The availability of both *R* and *S* isomers of this molecular sensor is an important advantage, since concomitant detection of both the D and the L saccharide is possible.



21 *R/S*

4.1.2 *Non-PET Systems*

Disturbing the electron donor or acceptor site of a chromophoric molecule can change its fluorescence properties. This phenomenon has been utilized in the design of fluorescent ionic and neutral compounds.[50] The coumarinium derivative **22** was designed for fluorescence mapping[51] of saccharides in biological samples.[52] The strengthening of the boron–nitrogen bond on saccharide binding was assumed to influence the coumarine internal charge transfer (ICT) chromophore. However, only small fluorescence spectral changes were found on titration of monosaccharides with **22**. In addition, the association constants for simple monosaccharides reveal that the saccharide complexes are considerable less stable. Steric factors together with low basicity of the amino group of **22** are counted as the reasons for this decreased stability.



22

As shown above, diboronic acids can bind monosaccharides selectively, and if the binding is 1:1 a rigid molecular complex

is formed.[20–26] This rigidification effect can also be utilized in designing fluorescence sensors for disaccharides. Diboronic acid species **6** selectively forms cyclic complexes with disaccharides in basic aqueous media, which alter the fluorescence properties of the sensor molecule.[24] Excited stilbene is quenched by radiationless decay as a result of rotation of the ethylene double bond. Obstruction of this rotation leads to increased fluorescence.[53] The rigidification of **6** on binding disaccharide therefore increases the stilbene fluorescence. In particular, **6** shows higher selectivity for the disaccharide melibiose than for other common disaccharides and some trisaccharides (Fig. 7). Small

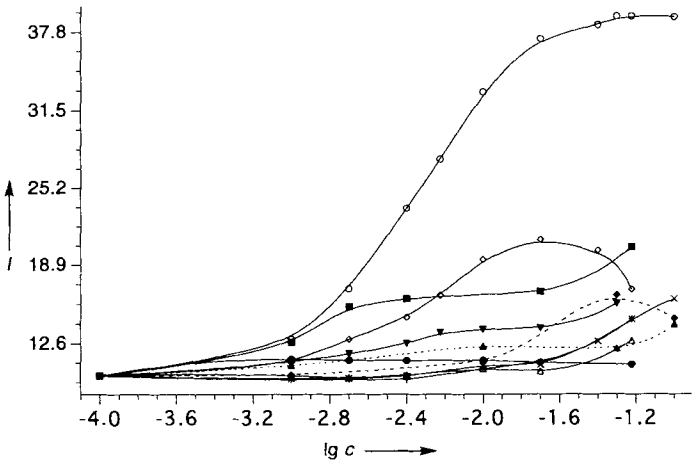


Fig. 7. Fluorescence titration of stilbenediboronic acid **6** (1.0×10^{-5} mol dm^{-3}) at pH 10.6 (0.1 mol dm^{-3} sodium carbonate/sodium bicarbonate buffer) as a function of lg c(disaccharide) (λ_{ex} = 310 nm, λ_{em} = 358 nm); I = relative fluorescence intensity. ○ D-(+)-melibiose, ▼ isomaltose, ◇ gentiobiose, × D-(+)-lactose, +D-(+)-maltose, △ D-(+)-saccharose, ● D-(+)-trehalose, ■ maltotriose, ◆ D-(+)-glucose (dashed line); ▲ D-(+)-mannose (dotted line).

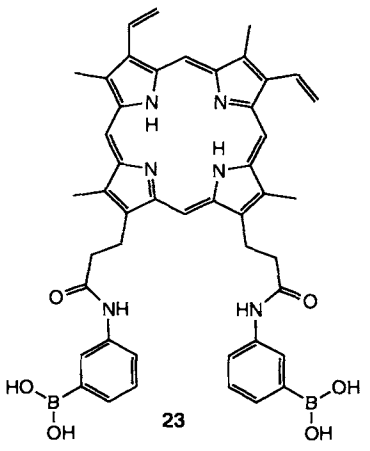
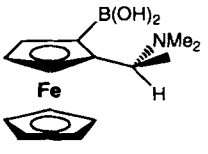
increases of fluorescence intensity found at high concentrations of monosaccharides are believed to derive from 1:2 complex, in which the rotation is restricted by solvent molecules. Increasing viscosity at high saccharide concentration is also believed to increase stilbene fluorescence.[54]

Aggregates of fluorescent molecules do not exhibit fluorescence chiefly because of concentration quenching. Molecular forces which deaggregate such systems can therefore can cause an increase in the fluorescence intensity. Aggregates of porphyrin **23** formed in DMF/water could be dispersed by the



23



24

introduction of saccharides,[55] which leads to a very large fluorescence increase. Some selectivity has been observed in this process.

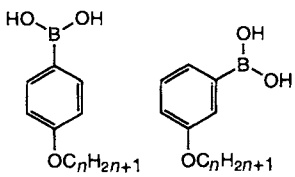
Important from a practical viewpoint is that only those of the fluorescent sensors mentioned above that contain a nitrogen atom adjacent to the boronic acid unit are applicable for physiological glucose detection, since they have a large working pH range, including physiological pH (approximately 7.7).

5. Saccharide Sensing with Electrochemical Detection

Electrochemical detection of saccharides by enzymatic decomposition of sugars is well known.[56] Boronic acid based electroactive saccharide receptors could provide selectivity for a range of saccharides. Chiral ferroceneboronic acid derivatives (−)-**24** and (+)-**24** have been synthesized and tested for electrochemical detection of monosaccharides.[57] D-Fructose, D-mannitol and D-sorbitol gave stability constants of 210, 150, and 500 mol^{-1} dm^3, respectively, with (−)-**24** in methanol/water solution. However, no significant chiral discrimination has yet been achieved with (+)- and (−)-**24**, and the field of electrochemical recognition by receptors based on boronic acid remains unexplored.

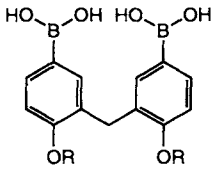
6. Saccharide Sensing at the Air/Water Interface

Molecular assemblies of monolayers and their properties have been well established.[58] The unique characteristics of Langmuir–Blodgett (LB) films have drawn particular attention. The pressure of an LB film sensitively reflects the interaction between its individual constituents on the surface and the guests in the aqueous subphase. The diboronic acids **25** and **26** (n = 16) were prepared in order to demonstrate the effect of



25

26



27 **a**, R = methyl
b, R = 2-octyldodecyl
c, R = 4-*tert*-butylbenzyl
d, R = geranyl

saccharide binding at the air/water interface.[59] The reactivity of the boronic acids was tested by solvent extraction methods (solid/solvent, neutral solvent/solvent, and basic solvent/solvent extraction). The ease of extraction of both compounds by the saccharides decreased in the order D-fructose > D-glucose > D-maltose > D-saccharose. Both the irreproducible pressure–area (π-A) isotherms and the crystalline nature of the monolayer indicated that monolayers formed by **25** were unstable. The *meta*-isomer, **26**, on the other hand, gave very reproducible re-

sults. The π-A isotherm of **26** was affected by the introduction of saccharide into the subphase at pH 10. Fructose was found to give the highest effect upon complexation (Fig. 8). The chiral cholesteryl boronic acid derivative **12**, which should selectively recognize chiral isomers of fructose, behaved similarly.[60]

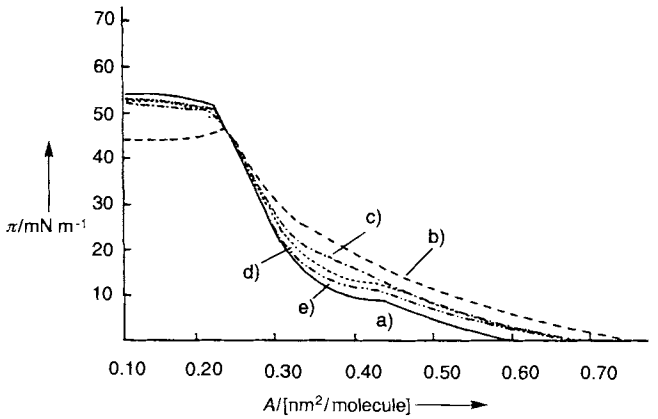


Fig. 8. Influence of saccharide on the π-A isotherms of a monolayer of **26**. The saccharide concentration in the subphase (pH 10.0 with 0.20 mol dm^{-3} carbonate buffer) is 10 mmol dm^{-3}. a) No saccharide, b) D-fructose, c) D-glucose, d) D-maltose, e) D-saccharose.

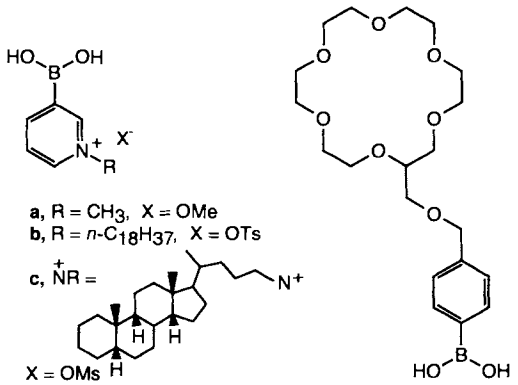
The influence of quaternized amines on the saccharide binding has also been investigated.[61] They facilitate the saccharide detection by the monolayer at neutral pH, probably because ammonium ions located close to the boronate acid enhance its deprotonation. The binding of saccharides to the diboronic acid derivatives **27a–d** on monolayers has also been investigated and found to be similar to that in homogeneous solutions.[62, 63] Molecular recognition in this system also seems to be facilitated by nearby ammonium cations.[63]

7. Saccharide Transport Through Membranes

Efficient transport of saccharide-related, water-soluble, synthetic drugs into cells through the membrane is critical to the future development of drugs. Many biomimetic systems capable of transporting neutral molecules are known, although examples of systems that can transport such species actively are rare.[64]

As formation of the anionic boronate is favored in alkaline pH and disfavored at acidic pH, glucose can be actively transported by a pH gradient. According to this principle, boronic acid and its derivatives have been used as a carrier in the transport of saccharide through membranes.[65] In saccharide transport by phenylboronic acid derivatives, the phenylboronate ions are accompanied by the lipophilic trioctylmethylammonium cation (TOMA).[65] Saccharide-related biologically important molecular species such as uridine can also be effectively transported in this way.[66, 67] The assistance of F^- ions in saccharide transport has been described by Smith et al.[68] Formation of phenylfluoroboronate[69] was proposed as the reason for this observation. Thus saccharide-related molecular species can be actively transported at neutral pH with a fluoride ion gradient. Interestingly, other halogens do not assist in transport through a membrane. The incorporation of a cationic charge into the boronic acid, as in the pyridinium derivatives **28**, could waive the requirement of an accompanying ammonium cation. Indeed, the strongly acidic pyridiniumboronic acid **28c**



28 **29**

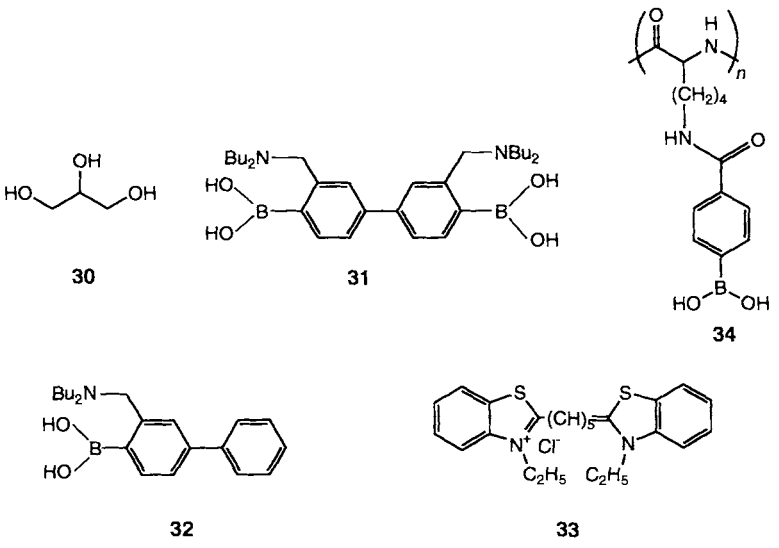
transports saccharide-related species through membranes.[70] The transport of dopamine and its derivatives by the molecular receptor **29** has been reported recently.[71] The cooperative binding by two types of receptor sites is possible in this case. Transport of amino acid derivatives by boronic acid also has been reported.[72]

8. Miscellaneous Applications

Boronic acid derivatives are known to inhibit certain enzymes.[73] For instance, phenylboronic acid inhibits the enzymatic hydrolysis of *N*-benzoyl-L-tyrosine-*p*-nitroanilide by α-chymotrypsin.[74] The inhibitory effect was intensified by the introduction of monosaccharides into the medium. The efficiency of the inhibition by monosaccharides decreases in the following order: D-talose > D-fructose > D-glucose > D-mannose > D-galactose; this differs from the usual order of affinity of phenylboronic acid for monosaccharides. Moreover, the D isomer is more effective than the L isomer. In a separate investigation it was also found that tripodal agents such as **30** can be complexed to boronic acid to regenerate the enzyme activity, thus providing a means of controlling the enzyme activity.[75]

Saccharide-based polymers that retain the inherent chirality of sugars may lead to organized structures such as helices. Diboronic acid **31** has been polymerized with simple monosaccharides or tetrahydroxy compounds.[76] The CD activity of the polymer differs from that of the monomeric structure **32** and is indicative of some type of organized structure. It is impossible to determine whether this polymer has regular head-to-tail or tail-to-head structure. However, the possibility of polymer formation with a C_2-symmetric chiral polyol could provide a means of structure elucidation.

Polymers prepared by imprinting with templates have been used in molecular recognition.[77] Complexes between boronic acid and saccharide have been utilized in this manner to imprint saccharide binding sites into highly cross-linked polymers.[77]



Such systems could be used in the separation of saccharide species.[35, 78]

Poly(D- and L-)lysine modified with boronic acid moieties respond to saccharides by altering the helical structure of the polymer. The helix-coil transition of the polypeptide is induced by subtle forces such as hydrogen bonding, dipole–dipole interactions, and electrostatic repulsion.[79] The boronic acid appended polylysine formed complexes with monosaccharides and altered the pH dependency of the helix-coil transition.[80]

Large ionic dyes are known to form organized inclusion complexes with poly(α-amino acids).[81] The formation of such inclusion complexes of cynene dye **33** with boronic acid appended polylysine is promoted by saccharide binding to the boronic acid moiety.[82] The formation of a boronate anion was facilitated by the inclusion of the cynene dye in a chiral manner and could be monitored by CD spectroscopy. More interestingly, the color of the polymeric assembly changed upon the introduction of saccharides. As an example, increasing D-fructose concentration from 0 to 2.00 mmol dm^{-3} changed the color of the solution from light blue to purple. The change of material properties upon introduction of saccharide related species could be used in molecular sensors and in polymeric materials with interesting physical properties.

9. Conclusions

The interest in boronic acid based molecular receptors for saccharides has grown tremendously during last few years. We believe that this relatively new field will attract the attention of many scientists in the years to come. However, a deeper understanding of the chemistry of boron-containing compounds is imperative for further advances in the development of boronic acid related saccharide receptors and sensing devices.

TDJ would like to thank Dr L. Sarson and Dr P. Linnane for helpful advice and discussions made during the preparation of this manuscript.

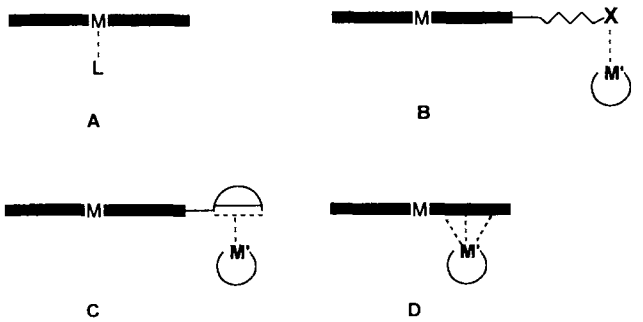
π-Pyrrole–Metal Complexes—The Missing Coordination Mode for Metal–Porphyrin Interactions**

Mathias O. Senge*

The ability of tetrapyrrole systems to coordinate metals is one of the most widely studied areas of porphyrin chemistry. Metalloporphyrins are important natural compounds involved in electron transfer, respiration, and photosynthesis and are gaining industrial importance as catalysts. For a detailed understanding of the mechanisms of catalytic processes performed by metalloporphyrins a thorough study of the interactions between metals and (metallo)porphyrins is necessary.

In theory, four principle coordination modes are possible for metal–porphyrin interactions (Scheme 1): metal σ bonding by



Scheme 1. Types of possible metal–porphyrin interactions.

either the pyrrole nitrogen atoms (A) or through peripheral side chain functionalities (B), and π bonding to metals either through peripheral aromatic systems (C) or by direct involvement of the aromatic porphyrin π system (D).

The best-known coordination type is derived from the intrinsic capability of free base porphyrins to complex almost any known metal ion with the pyrrole nitrogen atoms to yield metalloporphyrins by the formation of N-metal σ bonds.[1] This area of metalloporphyrin chemistry is well developed and encompasses not only the simple chelation of metal centers but also the investigation of metal–metal bonding and organometallic systems. In the latter case the M–C bonds are formed to carbon centers in the axial positions of the metalloporphyrin (type A). So far organometallic porphyrin chemistry has been restricted to this type of "axial coordination chemistry".[2]

Examples for metal coordination by the porphyrin by using functionalities other than the central N atoms are much more scarce. Three different binding motifs have been described for coordination type B. 1) Suitable peripheral substituents may be introduced to establish a second metal chelation site in close vicinity to the metal center of the metalloporphyrin.[3] 2) When heteroatom functionalities are present at the porphyrin periphery, these may serve as ligands for another metal.[4] 3) In a similar manner, the central metal of one metalloporphyrin of type B may form bonds with a second metalloporphyrin by interaction of the heteroatom and the metal, yielding polymeric[5a] or self-organized systems.[5b,c] Typical examples are porphyrins with *meso*-pyridyl or *meso*-nitro substituents as well as chlorophyll-type aggregates.

The structure types A and B are characterized by σ bonds to the metal. In a similar manner, two coordination modes are conceivable that involve π bonding to the metal center. The first example in which the π system of a peripheral substituent of a porphyrin participated in coordination to metal centers was described in 1970 by Gogan and Siddiqui (Scheme 1, type C).[6a] Reaction of zinc(II)tetraphenylporphyrin [Zn^{II}(tpp)] with hexacarbonylchromium(0) yielded the tricarbonylchromium arene complex **1**, in which the tricarbonylchromium(0) species is π-bonded to a *meso*-phenyl substituent. The corresponding [Zn^{II}(tpp){$Cr(CO)_3$}$_2$] complex was also characterized. The second example for type C are ferrocenyl porphyrins, which were prepared directly by reacting pyrrole with suitable aldehydes under the conditions applied by Adler. For instance, use of ferrocenylaldehyde yielded tetraferrocenylporphyrin **2**,[6b] while 4-ferrocenylbenzaldehyde gave tetra(4-ferrocenylphenyl)porphyrin **3**.[6c] Unfortunately, no definite structural data are available for any of these interesting compounds to date.

Examples for coordination type D (Fig. 1), in which the aromatic system of the porphyrin forms π bonds to metal centers, were unknown until recently. In contrast to this the organometallic chemistry of "simple" pyrrole compounds is much better developed. Although N-heterocycles seem to prefer η^1 coordination with metal–nitrogen σ bonds, there are a number of compounds with η^5-heteroatom–metal π bonds.

Most known pyrrole π complexes are obtained from the corresponding azacyclopentadienylanion, which is isoelectronic to cyclopentadienyl (Cp).[7–11] Sandwich complexes with one

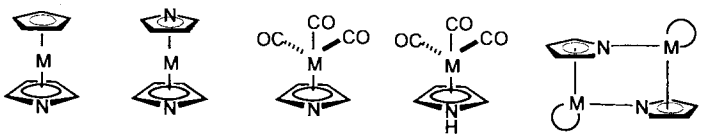
(**4**)[8a,c] or two (**5**)[8b,c] η^5-pyrrolyl groups as well as tricarbonyl(η^5-pyrrolyl) complexes (**6**)[9a] and carborane-stabilized η^5-pyrrolyl double and triple-decker compounds have been prepared.[10] In most cases, stable products of the diazametallocene structure type **5** were obtained only after shielding the nonbonding lone pairs of electrons on the nitrogen atom, for example, by employing sterically demanding α-substituents or by using N-alkylated derivatives.[8, 11] Nevertheless, some π-pyrrole complexes with the neutral pyrrole ligand (**7**) are known,[7, 9e] as are species that contain both nitrogen–metal σ and π bonding (**8**).[9d] An interesting combination of the structure type A with



4 5 6 7 8

an azaferrocene (**5**) has been achieved in an Fe^{II}-porphyrin, which is bisaxially coordinated by the pyrrole nitrogen aotms of azaferrocene.[12]

An intermediary position between organometallic derivatives of pyrrole and those of porphyrins is adopted by metal complexes of porphyrinogens. Porphyrinogens are formally hexahydroporphyrins with four isolated pyrrole units separated by sp^3-hybridized carbon atoms. Such systems have been investigated in detail by Floriani and co-workers.[13] The recurring structural theme in transition metal complexes of octaethylporphyrinogen is the formation of both metal–nitrogen σ bonds and metal–(η^5-pyrrolyl) π bonds, which is facilitated by the free rotation of pyrrole rings around the C_m-C_a bonds, for example as shown for the Zr derivative **9**.[13] The intrinsic differences between the porphyrinogen and the porphyrin ligand are also made evident by a comparison of the respective lithium derivatives **10** and **11**.[14] While the porphyrin derivative **11** consists of a $[Li(thf)_4]^+$ ion and a lithium porphyrin anion, in which the lithium atom is bonded to the four pyrrole nitrogen atoms,[14b] the porphyrinogen complex **10** contains three coordination modes for the four lithium atoms. One lithium atom is bonded solely by the pyrrole nitrogen atoms, while the other three are η^2-bonded to a pyrrole ring (either to a C_a-C_b or $N-C_a$ unit) and σ-bonded to another pyrrole nitrogen atom.[14a]

The first example of the coordination type D (π bonding between the aromatic porphyrin system and a metal) has now been described by Rauchfuss et al.[15] Treatment of [(2,3,7,8,12,13,17,18-octaethylporphyrinato)nickel(II)] [Ni^{II}(oep)] with the arenophiles [(cymene)Ru]$(BF_4)_2$ or [(cymene)Ru]-$(F_3CSO_3)_2$, (cymene = *p*-isopropyltoluene) in CH_2Cl_2 at room temperature yielded a green complex of the composition [{(cymene)Ru}Ni^{II}(oep)]$(BF_4)_2$ (**12**). The single-crystal X-ray analysis clearly showed a sandwich-type structure with (η^6-cymene)Ru(η^5-pyrrole) π bonding involving one of the four pyrrole subunits. The planes of the arene and the π-bound pyrrole ring are almost coplanar and show structural characteristics similar to those found for the complex cation [(η^6-cymene)Ru(η^5-C_4Me_4N)]$^{2+}$.[16] These results were confirmed by NMR spectroscopy, which also indicated a considerably decreased ring current in **12**. This novel type of sandwich complex is air-stable; however, even weakly coordinating solvents like acetonitrile dissociate the complex under liberation of [Ni^{II}(oep)].

Similar arene complexes were formed by reacting [Ni^{II}(oep)] with [(cymene)Os]$^{2+}$ or [(Cp*)Ir]$^{2+}$ (Cp* = C_5Me_5). Reaction of [Zn^{II}(oep)] with these reagents gave rise to compounds **13** and **14**, respectively. The latter compound contained a [(η^5-Cp*)-Ir(η^5-pyrrole)] structural motif, opening a way to combine the rich organometallic chemistry of cyclopentadienyl derivatives with that of porphyrins. The results achieved to date indicate that metalloporphyrins seem to be capable of binding only one [(arene)M]$^{2+}$ unit, since reaction with excess arenophile yielded only the 1:1 adducts.

The spectroscopic characteristics of the products are quite different from those of the porphyrin starting materials. For instance, the UV/vis spectra showed line broadening and bathochromic shifts of the absorption bands. Very characteristic was the formation of a long wavelength band around 680–770 nm [depending on the $[(arene)M]^{2+}$ unit] similar to those found for chlorins. The coordination of $[(arene)M]^{2+}$ completely quenched the fluorescence of $[Zn^{II}(oep)]$. Thus, clearly π complexation has a strong effect on the metalloporphyrin properties. Further investigation of these and related compounds might help to unravel the mechanism of catalytic processes involving metal–metalloporphyrin interactions.

A Novel Approach for Clarifying the Reaction Mechanism of Retaining Glycoside Hydrolases

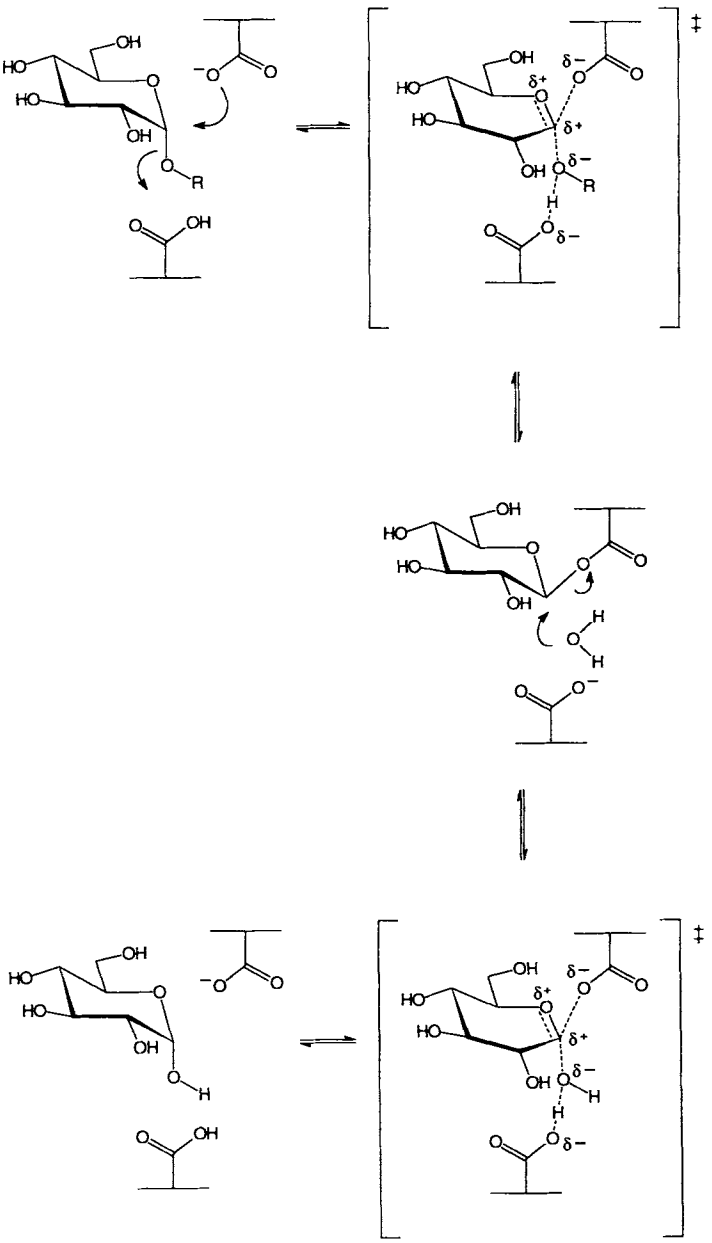
Arnold E. Stütz*

Glycoside hydrolases (glycosidases) are abundant and very important enzymes which degrade poly- and oligosaccharides into monomers or cleave bonds between sugars and non-carbohydrate aglycons. From the degradation of starch to the highly organized and complex process of glycoprotein trimming, glycosidases have many functions essential for the existance and survival of living systems.

Several types of these enzymes have been defined based on their modes of action.[1] Exoglycosidases attack the nonreducing end of a saccharide, while endoglycosidases act somewhere along the polysaccharide chain. In degradation with retaining glycosidases the configuration at the anomeric center is conserved in the product, due to two inversion steps. In contrast, inverting glycosidases mediate a single hydrolysis step with inversion at C-1. In order to fully understand the catalytic properties of glycosidases and to design efficient and highly selective inhibitors for diagnostic as well as therapeutic purposes, their mechanisms have been extensively investigated over the past decades.

Despite extensive efforts it has not been possible to crystallize most of these enzymes, for example numerous interesting exoglycosidases, in order to elucidate their structures and the three-dimensional features of their active sites. Thus, their mechanisms of action have been investigated by indirect methods exploiting substrate analogues such as bromoconduritols, imino sugars, glycosyl fluorides, and related substances as competitive or noncompetitive inhibitors.[2] Mechanistic considerations have been based on work by Koshland[3] and the determination of the structure of hen-egg lysozyme, a small endohexosaminidase, by Phillips and co-workers.[4] According to their results, the reaction follows the pathway depicted in Scheme 1. A catalytically active carboxylic acid function in the active site protonates the glycoside. Subsequently, a carboxylate of the enzyme positioned at the opposite side of the sugar ring stabilizes the cyclic oxocarbonium-like transition state by formation of a covalent bond and inversion of the configuration at the anomeric carbon. This covalently bound glycosyl–enzyme intermediate can be formed from both directions via oxocarbonium-like transition states. Finally, in the hydrolysis step, attack of water at the anomeric center releases the glycoside. For many years it had been generally agreed upon that lysozymes in particular and retaining glycosidases in general had evolved to catalyze the formation of such a cyclic oxocarbonium-like species.[1, 2]

In 1985, on the basis of glycosidase inhibition by imino sugar derivatives, Fleet suggested that glycosidases may follow a reaction pathway in which in the first step the endocyclic bond



Scheme 1. Mechanism of enzyme-catalyzed glycoside hydrolysis proposed by Phillips et al.

between the ring oxygen and the anomeric carbon is cleaved to form an open-chain intermediate[5] (Scheme 2). Such an intermediate was also deemed to be feasable in an invigorating contribution from Post and Karplus[6] on the mechanism of hen-egg lysozyme. This conclusion was based on the experimentally observed absence of substrate distortions on binding with this enzyme,[4] an observation also commented on by Sinnott[1] and Legler,[2] and further supported by molecular dynamics simula-

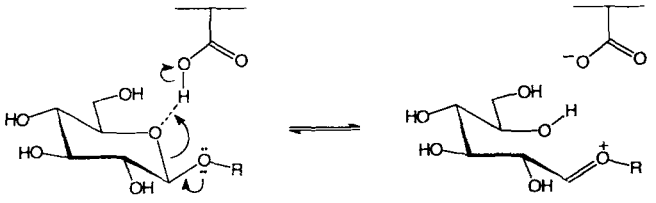
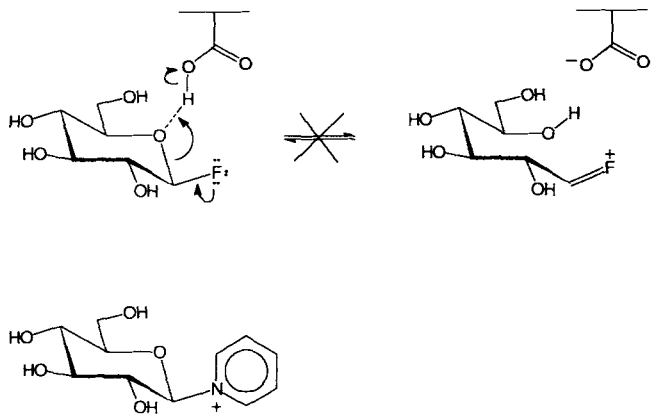


Scheme 2. Mechanism of enzyme-catalyzed glycoside hydrolysis proposed by Fleet.

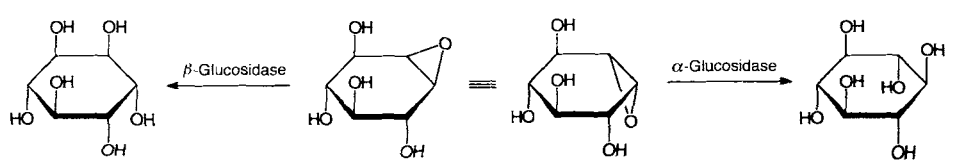
tions combining the concept of "least molecular motions" with the theory of stereoelectronic control.[7] In this approach, the departure of a leaving group from a tetrahedral carbon center, which is functionalized by one or more heteroatoms, is assisted by the antiperiplanar arrangement of the lone pairs of electrons of the heteroatom(s).[8] An example of this type of mechanism is the nonenzymatic, Lewis acid catalyzed reaction of protected α- and β-glucopyranosides with various nucleophiles in an inert solvent; open-chain derivatives were isolated as the kinetically controlled products.[9]

These findings and conclusions prompted a discussion that continues even today. There are strong arguments against the endocyclic bond fission such as the fact that the enzymatic hydrolysis of glycopyranosyl fluorides or glycosyl pyridinium derivatives is not compatible[1] with this mechanism (Scheme 3).



Scheme 3. The hydrolysis of glycopyranosyl fluoride and glycosylpyridinium derivatives does not follow the mechanism proposed by Fleet.

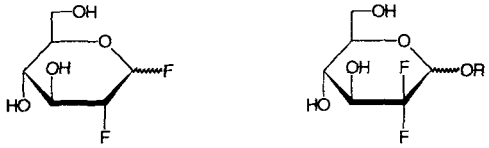
Furthermore, conduritol B epoxide was shown to be opened by both an α-[2, 10] and a β-glucosidase[2, 11] at the oxirane carbon equivalent to C-1 in the naturally occurring substrate and not at the alternative carbon position mimicking O-5 (Scheme 4). Nevertheless, it cannot yet be entirely excluded that during their evolution some glycosidases may have adjusted to changes in the relative basicities of ring oxygen O-5 and anomeric oxygen O-1 as well as to the particular aglycon such that either of these



Scheme 4. Conduritol B epoxide is opened at C-1 by both α- and β-glucosidase.

two reaction pathways, which at first glance appear mutually exclusive, are available.

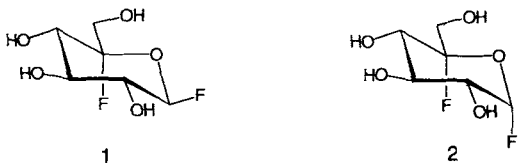
In an attempt to elucidate important mechanistic aspects of retaining glycoside hydrolases, Withers and co-workers synthesized and tested 2-deoxy-2-fluoroglucopyranosyl fluorides[12, 13] and 2-deoxy-2,2-difluoroglucopyranosides[14] as substrate analogues (Scheme 5). The fluorine substituents at C-2 inductively



Scheme 5. 2-Deoxy-2-fluoroglucopyranosyl fluoride and 2-deoxy-2,2-difluoroglucopyranoside.

destabilize the developing positive charge at the vicinal anomeric carbon and thus extend the lifetime of the corresponding glycosyl–enzyme adduct. Though this approach worked well with β-glucosidases, it did not meet with success with various α-glucosidases, which require the original substituent at C-2 for proper recognition and binding.[15] Therefore, *N*-acetylhexosaminidases, for example, which require substrates having an acetylamino group at C-2, cannot be investigated with inhibitors of this type.

Recently, in an innovative contribution, McCarter and Withers have overcome these problems by introducing 5-fluoro-D-glucopyranosyl fluorides **1** and **2** as the first representatives of



1 **2**

a novel class of "pseudo-substrates".[16] In the course of their investigation exciting new evidence was found in support of the classic mechanism originally proposed by Phillips and coworkers.

Following the approach of Ferrier and Tyler,[17] the two anomers **1** and **2** were synthesized by a simple and elegant route. In these stable new compounds the fluorine atom at C-5 replaces a slightly smaller axial hydrogen atom and does not interfere with the steric and electronic requirements important in recognition and binding. This is an advantage over 2-deoxy-2-fluoroglycopyranosyl fluorides, in which fluorine atom at C-2 in some instances takes the position of an essential hydroxyl or acetylamino group of the natural substrate. 5-Fluoro-β-glucopyranosyl fluoride **1** was shown be a strong inhibitor of the β-glucosidase from *Agrobacterium faecalis*. In marked contrast to results with 2-deoxyfluoro sugars, 5-fluoro-α-glucopyranosyl fluoride **2** turned out to be one of the most powerful inhibitors of α-glucosi-

dase from yeast known to date, hence proving the viability and efficiency of this new approach.

As one of the highlights in this report, an electron spray mass spectrum of the β-glucosidase inactivated by compound **1** showed that the mass of the protein had increased by 181 units, equivalent to one defined fluoroglucopyranosyl moiety attached to the catalytic site. This interesting and telling result provides strong, particularly direct support for the classic mechanism of action of this retaining glycoside hydrolase. Cleavage of an endocyclic C–O bond would have generated an unstable geminal fluorohydrin, which would have released hydrogen fluoride forming a 5-oxo sugar species. If this intermediate would be bound to the enzyme at all, the mass of the complex would be distinctly and measurably different. Consequently, exocyclic bond fission is definitely operative at least in this case.

Clearly, due to the versatility of the approach, 5-fluorohexopyranosyl fluorides and analogous derivatives modified at the anomeric center will be accessible and can serve as useful probes for studying the mechanisms of a large variety of glycosyl hydrolases. In terms of understanding complex bioorganic processes and evolutionary aspects of glycoside hydrolases, it will be exciting to learn whether all glycosidase-catalyzed hydrolysis reactions follow the same reaction pathway as that originally proposed for lysozymes, whether enzymes catalyzing endocyclic bond cleavage can be found with the aid of novel designed pseudo-substrates, and even whether certain enzymes can choose either mechanism, as was suggested in a recent review.[18]

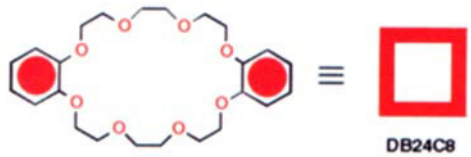
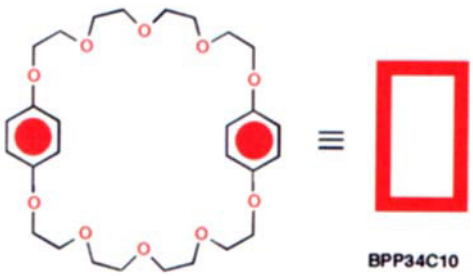
Thermodynamically Controlled Self-Assembly of Pseudorotaxanes and Pseudopolyrotaxanes with Different Recognition Motifs Operating Self-Selectively**

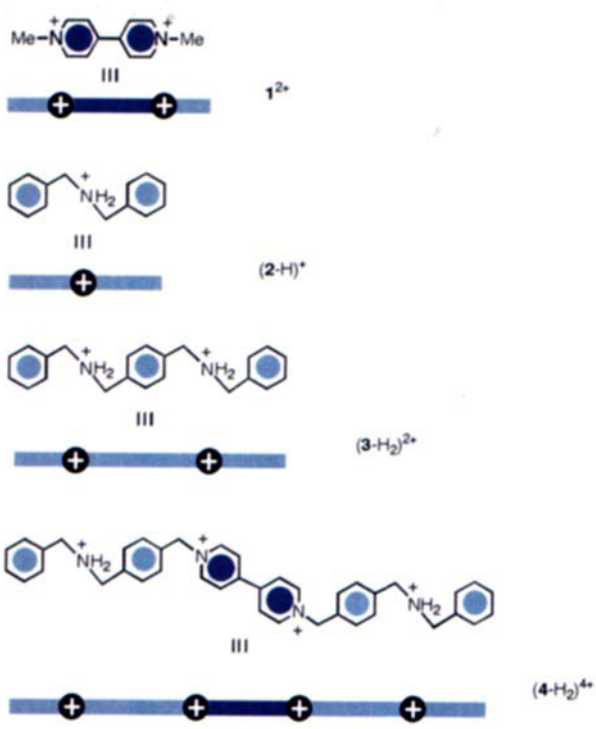
Peter R. Ashton, Peter T. Glink,
M.-Victoria Martínez-Díaz, J. Fraser Stoddart,*
Andrew J. P. White, and David J. Williams

The emergence of self-assembly[1] as a new force in chemical synthesis has led to the appearance of numerous novel molecular assemblies[2] and supramolecular arrays.[3] These structures and superstructures, which are not readily accessible by conventional synthetic methodologies alone, rely on the programming of certain recognition motifs with sufficient information to allow them to interact attractively and selectively as a result of highly stabilizing noncovalent bonding interactions. One particularly successful self-assembling system is that arising[4] from the 1:1 association between π-electron deficient bipyridinium dications like paraquat $\mathbf{1}^{2+}$ and macrocyclic polyethers such as bis-*para*-phenylene[34]crown-10 (**BPP34C10**) containing π-

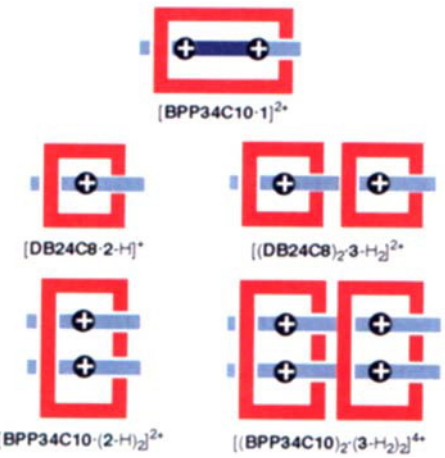




electron rich hydroquinone rings. This system, which can be instructed to operate under kinetic as well as thermodynamic control,[5] has been employed in the self-assembly of pseudorotaxanes,[6] rotaxanes,[7] and catenanes.[8] The requisite molecular recognition depends on π–π stacking augmented by [C–H···O] hydrogen bonding and [C–H···π] interactions. Only last year, a new self-assembling system, which is extremely efficient at producing inclusion complexes with pseudorotaxane-like geometries,[9, 10] emerged on the scene. It relies on the ability of secondary dialkylammonium ion centers, like those in $(\mathbf{2}\text{-H})^+$ and $(\mathbf{3}\text{-H}_2)^{2+}$, to form inclusion complexes with crown ethers, such as dibenzo[24]crown-8 (**DB24C8**) and **BPP34C10**, as a result of primarily [N^+–H···O] and [C–H···O] hydrogen bonding, occasionally supplemented by π–π stacking. The stoi-



chiometries of the complexes are variable and are dictated by the ability of these thermodynamically fashioned supramolecular arrays to maximize their noncovalent bonding interactions (Scheme 1).



Scheme 1. Cartoon representations of the types of pseudorotaxanes that have been characterized previously.

We pose the following questions: What if the rodlike oligocations contained both a bipyridinium unit and NH_2^+ cationic centers? Would they self-assemble selectively and predictably with **DB24C8** and **BPP34C10** in a complementary manner? Here, we report the preparation of the tetracation $(\mathbf{4}\text{-H}_2)^{4+}$ and its complexation with **BPP34C10** and **DB24C8** and with a mixture of these two crown ethers, as probed by X-ray crystallography, NMR spectroscopy, and mass spectrometry.

The salt $\mathbf{4}\text{-H}_2\cdot 4\,PF_6$ was obtained, after counterion exchange, from the reaction of an excess of the hydrochloride salt of *N*-benzyl-*para*-chloromethylbenzylamine[11] with 4,4′-bipyridine in Me_2SO. Orange single crystals suitable for X-ray crystallog-

raphy[12] were obtained from a solution of **BPP34C10** and **4**-$H_2 \cdot 4PF_6$ (4:1 molar ratio) in $MeCN/CH_2Cl_2$ (1:1, v/v), which was layered with *n*-hexane. X-ray structural analysis[13] of a crystal revealed the formation of a complex with an empirical 2:1 stoichiometry, i.e. $[(\mathbf{BPP34C10})_2 \cdot \mathbf{4}\text{-}H_2 \cdot 4PF_6]_n$, in which each $(\mathbf{4}\text{-}H_2)^{4+}$ tetracation is threaded through three **BPP34C10** molecules (Fig. 1). The complex has crystallographic

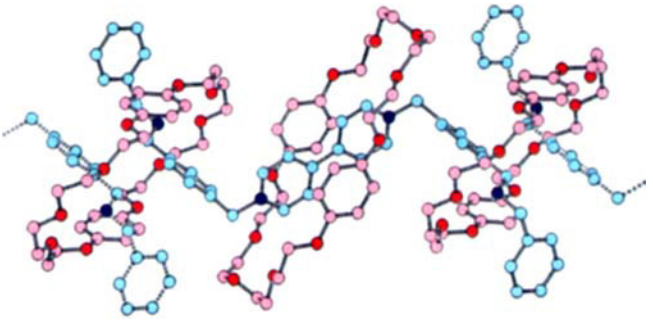

Fig. 1. Ball-and-stick representation of the solid-state structure of the C_i-symmetric "2:1 complex" formed between **BPP34C10** and $(\mathbf{4}\text{-}H_2)^{4+}$. The broken bonds represent portions of lattice-translated tetracationic threads. The π-electron deficient bipyridinium unit is sandwiched between the two hydroquinone rings of the central **BPP34C10** macrocycle (π···π stacking separation of 3.39 Å); the N···N axis of the bipyridinium unit forms an angle of ca. 30° with the OC_6H_4O axes of the hydroquinone rings. Further stabilization is achieved by [C–H···O] hydrogen bonds between one of the hydrogen atoms on each bipyridinium CH_2 group in $(\mathbf{4}\text{-}H_2)^{4+}$ and the central oxygen atoms of the polyether linkages in **BPP34C10**: the [C···O] and [H···O] distances are 3.26 and 2.30 Å, respectively, and the C-H-O angle is 173°. The tetracations are bound to the terminal **BPP34C10** macrocycles through $[N^+-H\cdots O]$ hydrogen bonds between the NH_2^+ centers and the second and fourth oxygen atoms of each polyether linkage: the $[N^+\cdots O]$ and [H···O] distances are 2.94, 2.89, and 1.99, 2.01 Å, respectively, and the N^+-H···O angles are 166 and 151°. The distance between the pair of cothreaded NH_2^+ centers is 8.6 Å, and the separation between the parallel hydroquinone rings in each terminal **BPP34C10** molecule is 6.66 Å (centroid···centroid separation of 6.91 Å).

C_i symmetry; the π-electronsandwich the π-electron deficient bipyridinium unit in the center of the tetracation (cf. $[\mathbf{BPP34C10} \cdot \mathbf{1}]^{2+}$, Scheme 1), while the other two crown ether molecules are positioned around each of the terminal NH_2^+ centers (Fig. 2). Additionally, the terminal dibenzylammonium ion centers are threaded centrosymmetrically with respect to each other through these latter **BPP34C10** molecules in a fashion similar to that observed[9] for the 1:2 complex formed between **BPP34C10** and **2**-H·PF_6 (Scheme 1), producing a pseudopolyrotaxane superstructure (Fig. 2). The pseudopolyrotax-

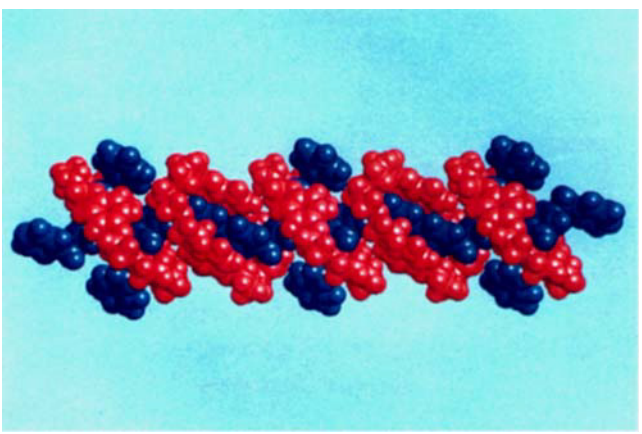

Fig. 2. Space-filling representation of the solid-state structure of a portion of the pseudopolyrotaxane $[(\mathbf{BPP34C10})_2 \cdot \mathbf{4}\text{-}H_2]_n^{4+}$. The **BPP34C10** macrocycle is depicted in red and the threadlike tetracationic component in blue.

ane[14] is stabilized by $[N^+-H\cdots O]$ and [C–H···O] hydrogen bonds as well as by arene–arene π–π stacking interactions.

Crystals of the "2:1 complex" $[(\mathbf{BPP34C10})_2 \cdot \mathbf{4}\text{-}H_2 \cdot 4PF_6]_n$ were also analyzed by liquid secondary ion mass spectrometry (LSIMS),[15] which showed evidence only for a 1:1 complex with intense peaks at *m/z* 1549, 1403, and 1257, corresponding to the loss of one, two, and three PF_6^- ions, respectively, from this species. By contrast, the ^{1}H NMR spectra are markedly dependent upon both the absolute and relative concentrations of the crown ether and the salt. When **BPP34C10** and **4**-$H_2 \cdot 4PF_6$ are present in CD_3COCD_3 in equimolar concentrations, it is the signals for the protons on the bipyridinium unit which experience the largest upfield shifts in this orange-colored solution. However, the addition of a fourfold molar excess of **BPP34C10** relative to **4**-$H_2 \cdot 4PF_6$ leads to small but significant upfield shifts for the $CH_2NH_2^+CH_2$ methylene protons, indicating that, under these conditions,[16] both the terminal dibenzylammonium ion centers and the bipyridinium unit are complexed by **BPP34C10** macrocycles.

The propensity for **4**-$H_2 \cdot 4PF_6$ to form inclusion complexes with the smaller **DB24C8** macrocycle was also investigated by ^{1}H NMR spectroscopy and mass spectrometry. Addition of two molar equivalents of **DB24C8** to a solution of **4**-$H_2 \cdot 4PF_6$ in CD_3COCD_3 resulted in a pale yellow solution. Its ^{1}H NMR spectrum suggested selective complexation of the dibenzylammonium ion centers by the **DB24C8** macrocycles since the signals for the $CH_2NH_2^+CH_2$ methylene and bipyridinium CH_2 and αCH protons of the bound $(\mathbf{4}\text{-}H_2)^{4+}$ tetracation were shifted significantly upfield. On the other hand, the resonances associated with the bipyridinium βCH protons were hardly influenced at all upon complexation, suggesting that it is indeed the NH_2^+ ion centers which are complexed by this crown ether. The spectrum showed separate sets of signals for free **DB24C8**, free **4**-$H_2 \cdot 4PF_6$, and the 2:1 complex $[(\mathbf{DB24C8})_2 \cdot \mathbf{4}\text{-}H_2][PF_6]_4$, indicating slow complexation/decomplexation on the ^{1}H NMR timescale at room temperature (cf. the behavior of $[\mathbf{DB24C8} \cdot \mathbf{2}\text{-}H][PF_6]$ in a variety of solvents[9]). On increasing the molar excess of **DB24C8** in the CD_3COCD_3 solution to sixfold, only signals corresponding to the excess free crown ether and the 2:1 complex were observed[17] in the ^{1}H NMR spectrum. LSIMS[15] confirmed the presence of such a complex with peaks at *m/z* 1910 and 1765 arising from loss of one and two PF_6^- ions, respectively, from the 2:1 complex.

Finally, we investigated the complexation of the $(\mathbf{4}\text{-}H_2)^{4+}$ tetracation by a mixture of **BPP34C10** and **DB24C8**. Orange crystals suitable for X-ray crystallography[12] were obtained from a solution of **DB24C8**, **BPP34C10**, and **4**-$H_2 \cdot 4PF_6$ (6:4:1 molar ratio) in Me_2CO which was layered with *n*-hexane. X-ray crystal structure analysis[18] reveals the formation of the expected 2:1:1 complex (Fig. 3). The central π-electron deficient bipyridinium unit of the tetracation is sandwiched between the π-electron donating hydroquinone rings of the larger **BPP34C10** macrocycle (cf. $[\mathbf{BPP34C10} \cdot \mathbf{1}]^{2+}$, Scheme 1), while the two terminal dibenzylammonium ion centers are encircled by the smaller **DB24C8** macrocycles (cf. $[\mathbf{DB24C8} \cdot \mathbf{2}\text{-}H]^+$ and $[(\mathbf{DB24C8})_2 \cdot \mathbf{3}\text{-}H_2]^{2+}$, Scheme 1). The overall structure has close to a C_i-symmetric arrangement which is broken only by the adoption of an *anti* geometry by one of the $CH_2OC_6H_4OCH_2$ units in the **BPP34C10** and a *syn* geometry for the other. In the case of the bipyridinium·**BPP34C10** recognition site, stabilization is achieved by a combination of π–π stacking and [C–H···O] hydrogen bonding interactions. In the case of the two $CH_2NH_2^+CH_2$·**DB24C8** recognition sites, stabilization arises principally from a mixture of $[N^+-H\cdots O]$ and [C–H···O] hydrogen bonding involving hydrogen atoms on

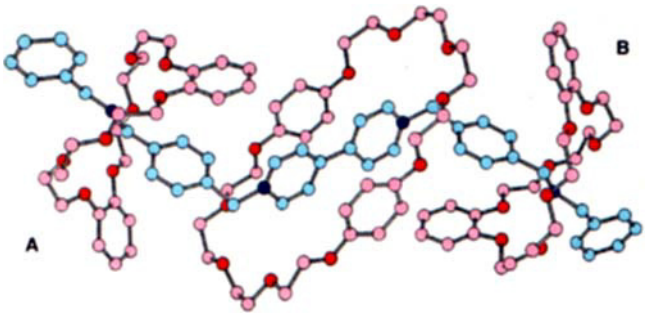

Fig. 3. Ball-and-stick representation of the solid-state structure of the asymmetric 2:1:1 complex formed between **DB24C8**, **BPP34C10**, and $(\mathbf{4}\text{-}H_2)^{4+}$. The distances associated with the $\pi-\pi$ stacking interaction between the bipyridinium unit and the approximately parallel (6° tilt) hydroquinone rings of the **BPP34C10** macrocycle are 3.48 and 3.54 Å. The N···N axis of the former is tilted by ca. 24° to the mean plane of the hydroquinone ring oxygen atoms. Stabilizing [C–H···O] hydrogen bonds are from one of the hydrogen atoms on each bipyridinium CH_2 group in $(\mathbf{4}\text{-}H_2)^{4+}$ to the central oxygen atoms in the polyether linkages in **BPP34C10**: the [C···O] and [H···O] distances are 3.19, 3.28 and 2.27, 2.33 Å, respectively, and the C-H···O angles are 161 and 173°. The $[N^+-H\cdots O]$ and [C–H···O] hydrogen bonding, involving the $CH_2NH_2^+$ centers and the terminal **DB24C8** macrocycles, although essentially the same for both sites (A and B), constitutes an extremely complex pattern. Although the conformations of the two **DB24C8** macrocycles are very similar, there are small differences in the "cleft angles" between the catechol rings: 70° in A and 73° in B. The associated centroid–centroid separations between the catechol rings are 9.23 Å in A and 9.39 Å in B. At end A, the mean separation between the planes of the phenyl rings associated with the terminal benzyl groups in the supramolecular structure shown in Figure 4 is 3.77 Å with a centroid–centroid separation of 4.48 Å, while, at end B, the comparable distances are 3.66 and 3.88 Å, respectively.

the NH_2^+ ion centers and on their adjacent *para*-xylyl methylene groups. As a consequence of the lack of symmetry of the complex, these terminal recognition sites—identified as A and B sites in Figure 3—are not identical. Both of the NH_2^+ hydrogen atoms are involved in bifurcated hydrogen bonds, one to both aryl oxygen atoms of one of the catechol units and the other to the adjacent second and third oxygen atoms of one of the polyether chains in **DB24C8**. One of the *para*-xylyl methylene hydrogen atoms is hydrogen bonded to one of the oxygen atoms of the other catechol unit. In the case of both the A and B sites, the *para*-xylyl units are inclined toward one of the catechol rings of the **DB24C8** macrocycle by about 20° and the distances are too large for any significant $\pi-\pi$ stabilization. In the 2:1:1 pseudorotaxane complex $[(\mathbf{DB24C8})_2\cdot\mathbf{BPP34C10}\cdot\mathbf{4}\text{-}H_2][PF_6]_4$, although there is no double threading of the terminal **DB24C8** macrocycles by the tetracation to produce an intimately linked pseudorotaxane superstructure, both terminal benzyl groups are arranged in a parallel overlapping $\pi-\pi$ stacking relationship with their centrosymmetrically related counterparts. The combination of these intercomplex $\pi-\pi$ interactions, coupled with the intracomplex noncovalent bonding interactions, results in the formation of a loosely bound pseudopolyrotaxane superstructure (Fig. 4).

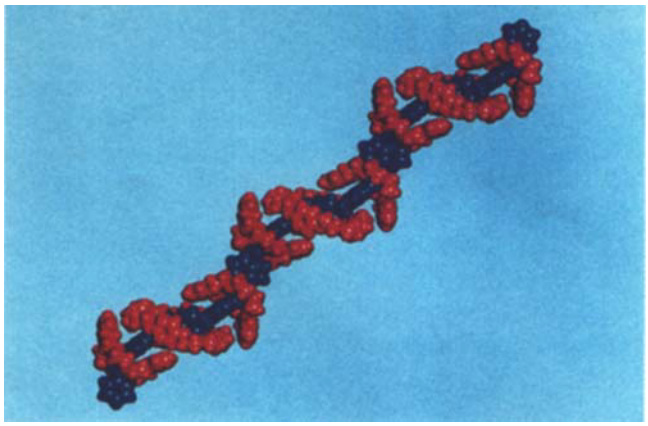

Fig. 4. Space-filling representation of the solid-state structure of a portion of the pseudopolyrotaxane-like $[(\mathbf{DB24C8})_2\cdot\mathbf{BPP34C10}\cdot\mathbf{4}\text{-}H_2]_n^{4+}$ superstructure. The **DB24C8** and **BPP34C10** macrocycles are depicted in red and the threadlike tetracationic component in blue.

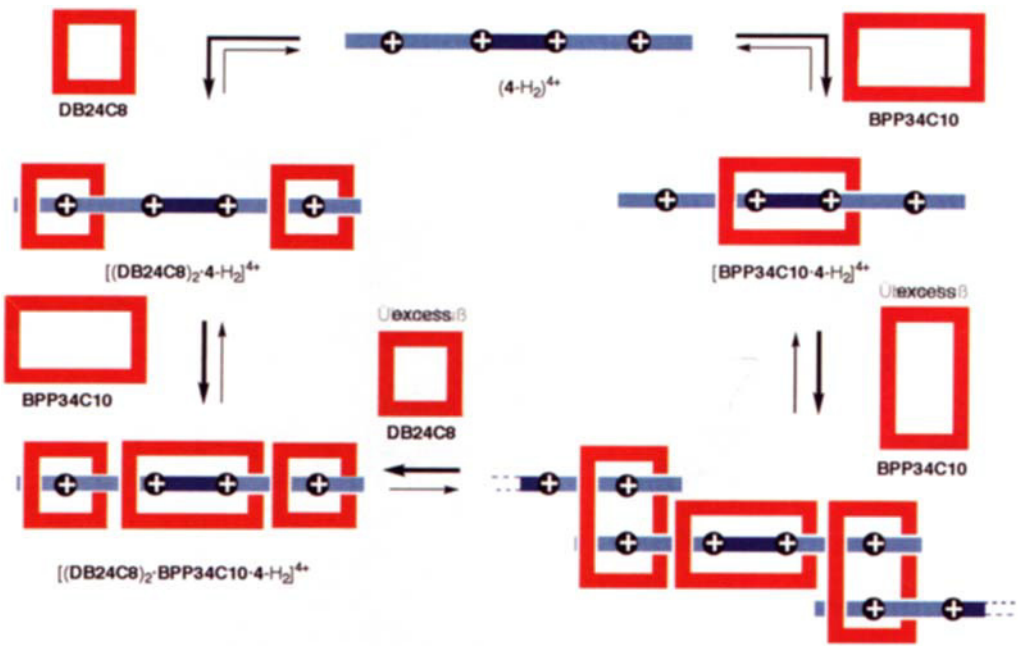
LSI mass spectrometry[15] indicates the very high integrity of the 2:1:1 complex. Intense peaks are observed at *m/z* 2592, 2447, and 2301, corresponding to the supramolecular ion, $[(\mathbf{DB24C8})_2\cdot\mathbf{BPP34C10}\cdot\mathbf{4}\text{-}H_2][PF_6]_4$ and the ions resulting from the loss of one and two PF_6^- ions, respectively. Also, in an ^1H NMR experiment at room temperature[19] a solution of $\mathbf{4}\text{-}H_2\cdot 4PF_6$, a fourfold molar excess of **DB24C8**, and a sixfold molar excess of **BPP34C10** in CD_3COCD_3 produces signals only for the 2:1:1 complex, as well as those for the free crown ethers.

This research has established the principle of thermodynamically controlled self-assembly of matching components in an equilibrium situation where three different molecular recognition motifs experience self-selection, according to a recognition pattern that is entirely in line with expectation. It is evident that bipyridinium units and dibenzylammonium centers bind strongly with the **BPP34C10** and **DB24C8** macrocycles, respectively. The binding of dibenzylammonium ion centers, singly or in pairs by **BPP34C10**, is very much weaker in Me_2CO, and



Scheme 2. The equilibrium processes of self-selection operating between the tetracation $(\mathbf{4}\text{-}H_2)^{4+}$ and the two crown ethers **DB24C8** and **BPP34C10**.

DB24C8 has very little affinity—at least in a threading sense—for bipyridinium units. The selection exercised by the $(\mathbf{4}\text{-}H_2)^{4+}$ tetracation in solution toward **DB24C8** and **BPP34C10**, individually and together in both short supply and in excess, is summarized in Scheme 2.

Experimental Procedure

4-$H_2\cdot 4PF_6$: A solution of 4,4'-bipyridine (72 mg, 0.46 mmol) in Me_2SO (5 mL) was added to a warm solution of the HCl salt (520 mg, 1.84 mmol) of *N*-benzyl-*para*-chloromethylbenzylamine [11] in Me_2SO (5 mL). The reaction mixture was stirred under reflux for 2 d. A white precipitate formed and was filtered off after the suspension had been cooled down to room temperature. The solid **4**-$H_2\cdot 4Cl$ was rinsed with DMF and Et_2O before being dissolved in H_2O. A saturated aqueous solution of NH_4PF_6 was added until no further precipitation occurred. The white solid **4**-$H_2\cdot 4PF_6$ was filtered off and dried (330 mg, 62%, m.p. 240 °C with decomp). Positive-ion LSIMS: *m/z* 1013 $[M-PF_6]^+$; ^{1}H NMR (CD_3COCD_3): δ = 4.63 (s, 4H), 4.70 (s, 4H), 6.21 (s, 4H), 7.40–7.50 (m, 6H), 7.50–7.60 (m, 4H), 7.73 (s, 8H), 8.77 (d, 4H), 9.44 (d, 4H).

[11] The HCl salt of benzyl-*para*-chloromethylbenzylamine was prepared in four steps from the commercially available starting materials benzylamine and methyl 4-formylbenzoate. Condensation of these two compounds in MeOH afforded the imine, which was reduced in situ with an excess of $NaBH_4$ to give the secondary amine. After reduction of the ester function with $LiAlH_4$ in Et_2O and subsequent reaction of the alcohol with an excess of $SOCl_2$, the HCl salt was obtained in good yield overall (58%).

[13] Crystal data for [(**BPP34C10**)$_2\cdot$**4**-H_2][PF_6]$_4\cdot$X [12] (X represents unidentified solvent fragments wherein electron density has been allowed for by distributing six carbon atoms over twelve partial occupancy sites): triclinic, space group $P\bar{1}$, a = 12.603(1), b = 13.276(1), c = 17.983(3) Å, α = 85.00(1), β = 82.26(1), γ = 66.61(1)°, V = 2734.6(4) Å^3, Z = 1 (the complex has crystallographic C_i symmetry), ρ_{calcd} = 1.399 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 15.9 cm^{-1}, T = 183 K, 6850 independent reflections measured, 4971 observed reflections with [$|F_o| > 4\sigma(|F_o|)$, $2\theta \le 110°$] refined on F^2 to R_1 = 0.080, wR_2 = 0.212.

[14] Inspection of the packing of the pseudopolyrotaxane chains does not reveal any strong $\pi-\pi$, [C–H$\cdots\pi$], or [C–H$\cdots$O] interactions between the pseudopolyrotaxanes. The only proximal relationship of note is an approach of the terminal benzyl rings of adjacent threads, suggesting the possibility of cross-linking. However, although the interplanar separation between the terminal benzyl groups is favorable at 3.1 Å, the centroid–centroid separation of 5.3 Å is much too large for any significant $\pi-\pi$ interaction. For a discussion of the term pseudopolyrotaxane, see D. B. Amabilino, I. W. Parsons, J. F. Stoddart, *Trends Polym. Sci.* **1994**, *2*, 146–152.

[15] LSI mass spectra were obtained from a VG Zabspec mass spectrometer equipped with a cesium ion source. Samples were dissolved in a small volume (ca. 1 μL) of *meta*-nitrobenzyl alcohol, which had previously been coated on to a stainless steel probe tip, and spectra were recorded in the positive-ion mode at a scan speed of 10 s per decade.

[16] When **BPP34C10** is present in fourfold molar excess relative to **4**-$H_2\cdot 4PF_6$ (3.3 mM) in CD_3COCD_3, $\Delta\delta$ values (with reference to the free salt) of -0.20, -0.41, -0.04, and $-0.03/-0.05$ are observed in the ^{1}H NMR spectrum for the bipyridinium αCH, βCH, and CH_2 protons and the $CH_2NH_2^+CH_2$ protons, respectively.

[17] When **DB24C8** is present in sixfold molar excess relative to **4**-$H_2\cdot 4PF_6$ (3.3 mM) in CD_3COCD_3, $\Delta\delta$ values (with reference to the free salt) of -0.21, -0.05, -0.30, and $+0.18/+0.16$ are observed in the ^{1}H NMR spectrum for the bipyridinium αCH, βCH, and CH_2 protons and the $CH_2NH_2^+CH_2$ protons, respectively. The 2:1 stoichiometry of the complex [(**DB24C8**)$_2\cdot$**4**-H_2][PF_6]$_4$ was established by integration under the conditions of slow exchange which prevail on the ^{1}H NMR timescale at room temperature.

[18] Crystal data for [(**DB24C8**)$_2\cdot$**BPP34C10**$\cdot$**4**-H_2][PF_6]$_4\cdot 3Me_2CO\cdot H_2O$ [12]: triclinic, space group $P\bar{1}$, a = 13.220(1), b = 22.352(2), c = 23.943(2) Å, α = 87.91(1), β = 78.50(1), γ = 81.99(1)°, V = 6864.9(9) Å^3, Z = 2, ρ_{calcd} = 1.347 g cm^{-3}, $\mu(Cu_{K\alpha})$ = 14.2 cm^{-1}, T = 203 K, 17104 independent reflections accumulated from two crystals of similar overall dimensions, 11145 observed reflections with [$|F_o| > 4\sigma(|F_o|)$, $2\theta \le 110°$] refined on F^2 to R_1 = 0.092, wR_2 = 0.228.

[19] When **DB24C8** and **BPP34C10** are present in four- and sixfold molar excesses, respectively, relative to **4**-$H_2\cdot 4PF_6$ (3.3 mM) in CD_3COCD_3, $\Delta\delta$ values (with reference to the free salt) of -0.35, -0.55, -0.19, and $+0.22/+0.12$ are observed in the ^{1}H NMR spectrum for the bipyridinium αCH, βCH, and CH_2 protons and $CH_2NH_2^+CH_2$ protons, respectively. The 2:1:1 stoichiometry of the complex [(**DB24C8**)$_2\cdot$**BPP34C10**$\cdot$**4**-H_2][PF_6]$_4$ was established by integration under the conditions of slow exchange which prevail on the ^{1}H NMR timescale at room temperature.

Hf_7P_4: A New Binary Phosphide Synthesized by a Surprising Route**

Holger Kleinke and Hugo F. Franzen*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

Despite numerous investigations of binary, ternary, and even quaternary pnictides and chalcogenides of the early transition metals, new binary compounds in these systems can still be found. Most recently, for example, Zr_2P,[1] $Zr_{1+x}Te_2$,[2] Hf_2Se_3,[3] Hf_3Te_2,[4] Nb_2Te_3,[2] Ta_3S_2,[5] Ta_2Se,[6] Ta_2Te_3,[7] and Ta_6Te_5[8] have been synthesized. Thereby, the differences between the metal-rich chemistry of Hf and Zr as well as between Nb and Ta became more and more apparent: none of these compounds have a counterpart among the corresponding homologous metal atom of the other period, and the stoichiometric equivalent phosphides Zr_2P[1] and Hf_2P[9] (or Nb_2P[10] and Ta_2P[11]) crystallize in different structure types; the same is also true for Nb_2Te_3 and Ta_2Te_3, as well as for Zr_2S[12] and Hf_2S.[13] As for some ternary Nb/Ta sulfides[14] and tellurides,[15] the 5d metal atoms prefer the positions with the higher metal–metal bond order. Similarly, the binary chalcogenides of the 5d metal atoms form structures with more metal–metal contacts (compare for example Zr_2S with Hf_2S, and Nb_2Te_3 with Ta_2Te_3).

It was therefore surprising to find that Hf_7P_4[16] is isostructural to Zr_7P_4.[19] Hf_7P_4 was prepared by arc-melting of Hf, Fe, and HfP in the ratio of 5:2:4 by using techniques previously described.[20] The powder diagram obtained from the ground bulk sample contained only the reflections of Hf_7P_4, $HfFe_2$, and Hf_4FeP, which is consistent with a reaction according to Equation (a).

$$5\,Hf + 2\,Fe + 4\,HfP \longrightarrow 6/7\,Hf_7P_4 + 5/7\,HfFe_2 + 4/7\,H_4FeP \qquad (a)$$

Single crystals of Hf_7P_4 were obtained after heating the bulk sample in an induction furnace at a temperature of 1400 °C for six hours. This shows that Hf_7P_4 is thermodynamically stable; its synthesis is only kinetically impeded. Our attempts to prepare Hf_7P_4 without the addition of Fe led only to mixtures of Hf_2P[10] and Hf_3P_2.[21] Thus, since the EDS (*E*lectron *D*ispersive *S*pectroscopy) investigation of the measured single crystal did not show a measurable amount of Fe, we conclude that there is no Fe incorporation into the structure of Hf_7P_4, which is in agreement with the uniformity of the equivalent temperature factors of the structure model of Hf_7P_4. Since the largest void in the structure is surrounded by four Hf and two P atoms at distances of about 2.2 Å, (partial) occupation of this void by iron can be excluded for steric reasons: a Hf–Fe distance of 2.2 Å would correspond to a bond order of 4.7 according to Pauling's Equation (b), using $r_{Hf} = 1.452$ Å and $r_{Fe} = 1.170$ Å

$$d(n) = d(1) - 0.6 \lg n \qquad (b)$$

(n = bond order).[22] Besides the results of the EDS investigation, a statistical presence of other heteroatoms is most unlikely for the following reasons: 1) The high yield argues against significant amounts of impurities in Hf_7P_4. 2) After the arc-melting had been carried out under an argon atmosphere, the annealing was performed under residual pressure of 10^{-7} Torr, thus significant incorporation of heteroatoms is impossible. In addition, if one takes into consideration a stabilization of Hf_7P_4 by oxygen, whereever it might come from, an analysis of the voids in the structure does not show any probable positions for oxygen: either the Hf–O distances would be too short (< 1.76 Å in the Hf_6 octahedra, compared to Hf–O bonds of 2.05 Å in the structure of monoclinic HfO_2)[23] or P–O distances less than 2.4 Å would occur. The latter is very unlikely when P and O are considered as anions with filled shells. In any case, no significant electron density was found in the considered voids.

However, the presence of Fe, which acts as a flux, seems to be essential for the formation of Hf_7P_4. This is presumably the reason why, in spite of studies of the formation of Hf-rich binary[24] and ternary phosphides,[25] the existence of Hf_7P_4 has not been demonstrated up to now. Although the technique of adding a flux material to prepare suitable crystals of metal-rich compounds has been applied successfully in the synthesis of Hf_3Te_2 (using KCl)[4] and Zr_2S (using Cr),[26] most of the previously mentioned pnictides and chalcogenides were prepared by reducing a more metal-poor compound with the corresponding metal, or from the elements directly, which led to very small crystals in most cases. To our knowledge, the synthesis of Hf_7P_4 is the first example in which the use of a flux material has enabled the synthesis of a metal-rich phosphide that has eluded synthesis without using flux.

Hf_7P_4 crystallizes in the Nb_7P_4 structure type, consisting of fragments of the body-centered cubic packing of Hf. The four crystallographically different P atoms are located in singly, two- and three-capped trigonal Hf prisms, and the Hf–P bonds range between 2.57(2) and 3.24(2) Å. Alternatively, this structure can be described in terms of condensed fragments of the M_6X_8 cluster type.[27] Two different variations of the condensed M_6X_8 cluster occur in the structure of Hf_7P_4, both kinds are condensed through common vertex atoms to form infinite chains running parallel to [010]: a Hf_5 fragment of the Hf_6P_8 cluster, in which one Hf atom in the basal plane of the octahedron is missing, is situated between two crystallographically independent Hf_6P_8 octahedra, connected through equatorial Hf atoms to form zigzag chains parallel to [101]. These chains are highlighted by bold lines in Figure 1. Furthermore, these chains are intercon-

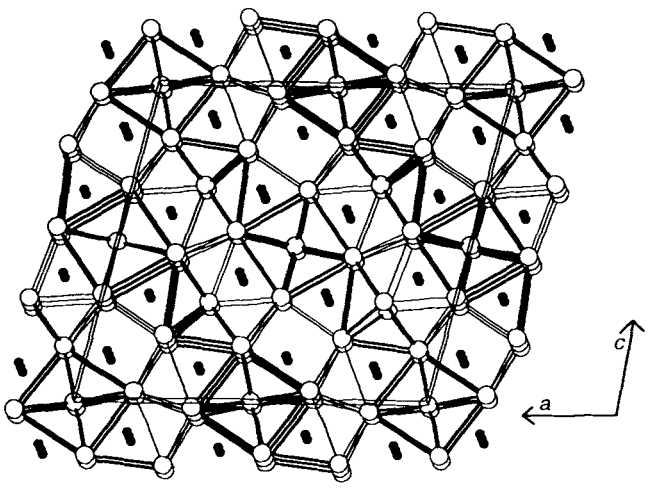

Fig. 1. Projection of the structure of Hf_7P_4 along [010], the Hf_5 and Hf_6 cluster units are highlighted. Small, black circles: P; large, white circles: Hf.

nected by common P atoms and Hf–Hf bonds between the cluster units. Thus, all Hf atoms are either part of the Hf_5 or of the Hf_6 units.

The shortest Hf–Hf bonds occur between the apical and basal atoms of the condensed cluster units (ranging from 3.025(3) to 3.194(2) Å), whereas the distances within the equatorial planes are significantly longer (ranging between 3.437(4) and 3.684(4) Å). As can be seen by the length of the *b* axis, the octahedra are tetragonally compressed, and the Hf–Hf distances between the vertices are 3.5209(9) Å. Therefore a consideration of these units as centered cubes is appropriate, but this model should not be taken too far because the Hf–Hf distances between the cubic units (varying from 3.223(4) to 3.413(4) Å) are even shorter than those within the cubes.

Most unusually, in comparison with other metal-rich systems of neighboring 4d and 5d elements, this metal-rich compound is isostructural to its 4d homologue Zr_7P_4,[19] although, based upon prior comparison of Group 4 and 5 homologues,[28] Hf should prefer a structure with more metal–metal bonding than in the Zr compound.

The observed contraction of the unit cell volume of almost 5% from Zr_7P_4 to Hf_7P_4 cannot be explained only by the different radii of Zr and Hf (1.452 vs. 1.442 Å).[22] Although the differences between the three different crystallographic axes vary between 1 and 3% (*b* axis), no significant trend is observed among the different interatomic interactions. The greatest deviations occur in the Hf–Hf separations parallel to [010], which correspond to the length of *b* and therefore have only weak bonding character. All other types of bonds are about 1.5% smaller in case of Hf_7P_4.

To investigate the consequences of the cell contraction, we calculated the Pauling bond orders with Equation (b)[22] for Zr_7P_4 and Hf_7P_4, and the Mulliken overlap populations (MOP) for Hf_7P_4 and for theoretical Hf_7P_4 with the cell dimensions and atomic positions of Zr_7P_4 by using the extended Hückel method.[29] The parameters for Hf and P were taken from the literature.[4, 30]

The calculated COOP curve (crystal orbital overlap population) consists of two well-separated parts (excluding the phosphorus 3s orbitals below the energy window): at lower energy, between -14.5 and -12 eV, the 3p states of P dominate, leading, by mixing with Hf 6s, 6p and 5d states, to strong bonding Hf–P interactions, whereas in the region of the Fermi level E_F mainly the Hf d bonding states occur. In contrast to more metal-rich compounds[31] not all metal–metal bonding states are filled (Fig. 2).

The calculated COOPs of Zr_7P_4 and Nb_7P_4 (parameters taken from literature)[32] are very similar. Because of the higher electronegativity of Nb its d block is shifted to lower energies and thus overlaps with the 3p block of P. The higher number of valence electrons leads not only to completely filled Nb–Nb bonding states, but also to the occupancy of some antibonding states (Fig. 3). Altogether, the Nb–Nb and Nb–P overlap populations are significantly larger than those of Hf_7P_4.

After the cell contraction from Zr_7P_4 to Hf_7P_4, all atomic sites show the same trend, that is, the metal–metal overlap populations increase by 2.8% from theoretical Hf_7P_4 in the Zr_7P_4 structure (average total $MOP_{Hf-Hf} = 0.996$) compared to those calculated for the structure model of Hf_7P_4 (average $MOP_{Hf-Hf} = 1.024$), and an increase is also found for the metal–nonmetal overlap population (0.948 vs. 0.964, corresponding to an increase of 1.7%). Accordingly, the averaged Pauling metal–metal bond orders changed from 2.56 (Zr_7P_4) to 2.77 (Hf_7P_4) and the metal–P bond orders from 2.44 to 2.70, indicating that

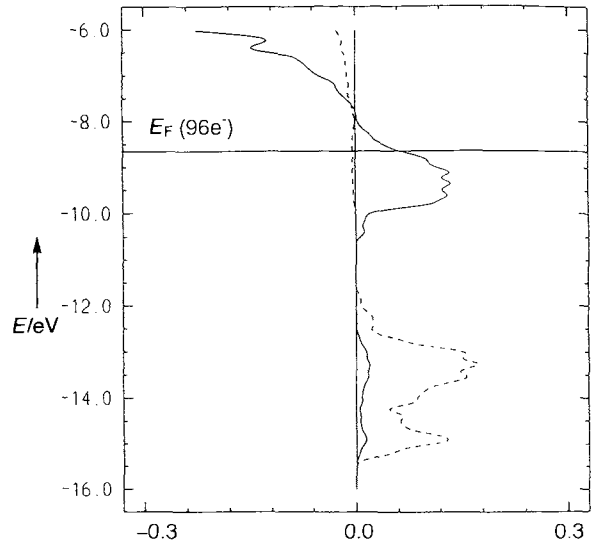

Fig. 2. COOP curve of Hf_7P_4; solid line: Hf–Hf; dashed line: Hf–P interactions. The left half of the diagram covers the antibonding, the right half the bonding interactions.

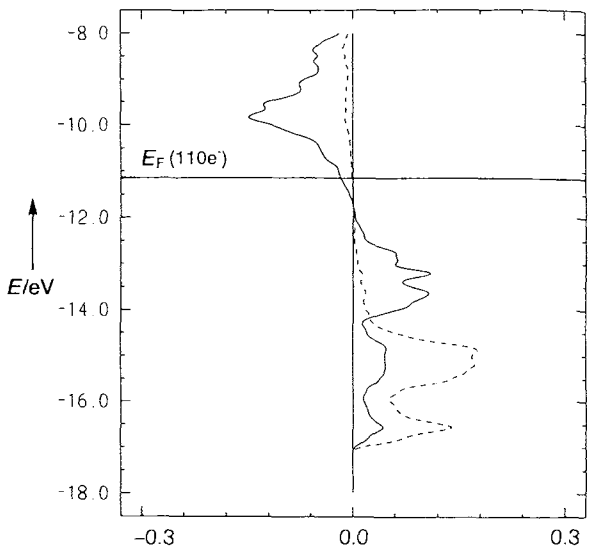

Fig. 3. COOP curve of Nb_7P_4; solid line: Nb–Nb; dashed line: Nb–P interactions. The left half of the diagram covers the antibonding, the right half the bonding interactions.

the cell contraction is not caused by the smaller radius of Hf alone.

The higher metal–metal bond order in the structure of Hf_7P_4 can be explained by the greater extension of the 5d orbitals as well as by the electron concentration rules of Brewer and Engel.[33] According to Brewer and Engel, the s and p conduction electrons determine the structure, and Zr and Hf tend in body-centered cubic structures to the configurations of $d^{2.7}sp^{0.3}$ and $d^{2.5}sp^{0.5}$, respectively; thus, the higher ratio of s and p electrons of Hf enables Hf to form stronger metal–metal bonds.

On the other hand, the increase of metal–metal bonding leads to a lower energy of bonding orbitals centered on Hf, which in turn leads to a higher "back-bonding" covalent character of the Hf–P bonds, corresponding to the higher overlap population. In other words, Hf is more electronegative than Zr and thus forms more covalent M–P interactions.

Relativistic effects in general lead to a radial contraction of the s and p orbitals and to an expansion of the d orbitals;[34] this is particularly true in the case of Hf because of the increase of relativistic effects with Z^2.[35] The result is a volume contraction of the Hf phosphide because of its smaller, structure-determining s and p orbitals. However, since the radii used for calculating the bond orders are based on experimental results, and the experiments are necessarily relativistic, relativistic effects are included by comparisons based on radii. Therefore, the significant higher bond orders of Hf_7P_4 indicate that relativistic effects alone are not responsible for the observed cell contraction.

All viewpoints complement one another and lead to the conclusion that compared with Zr, Hf will be more strongly bonded to itself in metal-rich compounds and more covalently bonded to the nonmetal. In general, these conclusions should also be true for the structural differences of metal-rich compounds of Nb and Ta. In summary, the general trend in the different bonding behavior of Zr and Hf, observed in many examples with very different crystal structures, can also be studied based on isostructural compounds like Zr_7P_4 and Hf_7P_4.

Photoinduced Energy and Electron Transfer in Supramolecular Porphyrin Assemblies**

Christopher A. Hunter* and Robert K. Hyde

Nature uses complex arrays of chromophores to trap solar energy and convert it into the chemical potential that drives the chemistry of photosynthetic organisms.[1] These chromophores are all noncovalently attached to a protein scaffold which holds them at the right separation and orientation for fast energy and unidirectional electron transfer, so that the solar energy conversion process proceeds with a high quantum yield. If we are to mimic the functional properties of these systems, it is likely that we will have to develop strategies for the construction of similarly large but structurally well-defined multichromophore arrays.[2–4] Hydrogen bonding has been successfully employed in the construction of photoactive supramolecular assemblies, but these complexes are relatively unstable with association constants in the region of 10^3 M^{-1}, and this limits the concentration range over which they can be studied as well as their ultimate utility.[3] Complexes assembled through porphyrin coordination chemistry suffer from the same problem, and this has hampered detailed analysis of their photochemical properties.[4] We describe here a new approach that overcomes this problem: the use of cooperative coordination interactions to generate very stable self-assembled chromophore arrays.[5] The porphyrin units employed in these arrays are shown in Scheme 1.

The design of the two complexes shown in Figure 1 is based on the structure of a self-assembling porphyrin "dimer" which we described recently.[6, 7] Zn_2-**2** contains a naphthalenediimide group that can act as an electron acceptor in photoinduced electron transfer reactions with porphyrins.[8] Zn_2-**3** has the same overall dimensions as Zn_2-**2** but has in place of the naphthalenediimide a terephthaloyl diamide, which has a much higher reduction potential and therefore cannot act as an electron acceptor: for our purposes, it behaves as an inert spacer. H_2-**1** is a rigid bifunctional ligand of appropriate dimensions to bridge the two zinc centers in the porphyrin "dimers" as shown in Figure 1.

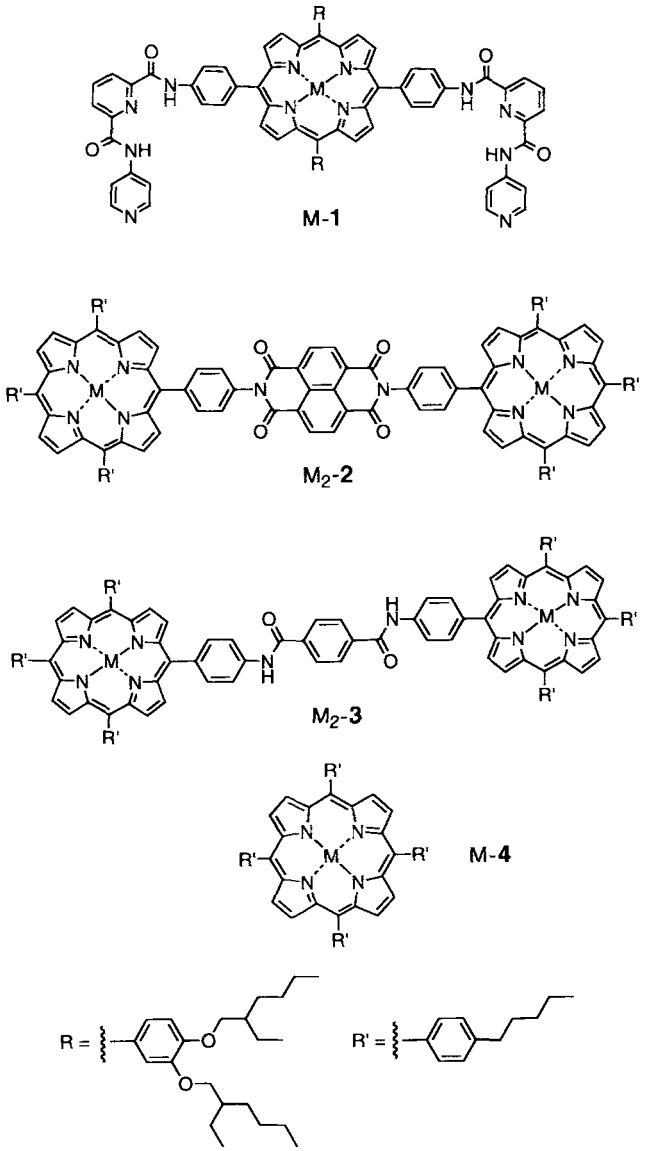

Scheme 1. Porphyrin units used in the construction of the new assemblies. M = H_2, Zn.

On mixing H_2-**1** with either Zn_2-**2** or Zn_2-**3** in organic solvents, exceptionally stable 1:1 complexes formed. Evidence for the structures comes from the following measurements (all in chloroform).

1) Vapor phase osmometry (VPO). The effective relative molecular masses in solution for the pure compounds and equimolar mixtures in solution are listed in Table 1. The results clearly show the presence of discrete 1:1 complexes for both H_2-**1**·Zn_2-**2** and H_2-**1**·Zn_2-**3**.

Table 1. Relative molecular masses in chloroform solution determined by vapor phase osmometry.

Compound(s)	Conc. [mM]	Expt.	Calcd.
H_2-**1**	1.50	1570±150	1606
Zn_2-**2**	1.50	1900±190	2038
Zn_2-**3**	1.50	1880±190	1934
H_2-**1** + Zn_2-**3** (1:1)	0.75	3500±350	3644
H_2-**1** + Zn_2-**3** (1:1)	0.75	3460±350	3540

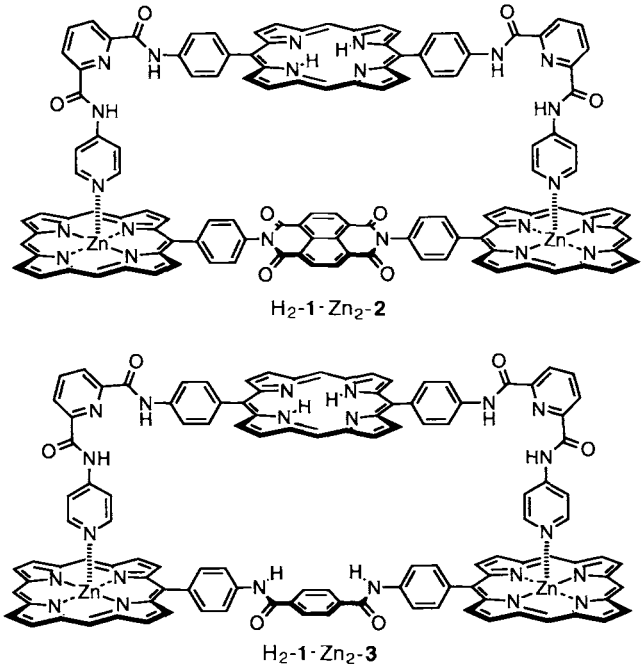

Fig. 1. Structural formulas of the complexes H_2-**1**·Zn_2-**2** and H_2-**1**·Zn_2-**3**. The *meso* substituents are omitted for clarity.

2) ^{1}H NMR spectra. On addition of one equivalent of H_2-**1** to Zn_2-**2** and to Zn_2-**3**, the ^{1}H NMR chemical shifts of several signals changed substantially. The signals of the pyridine a and b protons of H_2-**1** moved 6.0 and 2.5 ppm upfield, respectively, which indicates that they lie over the ring current on the face of a porphyrin π-system. These shifts are diagnostic of a coordination interaction between pyridine and the zinc porphyrin, and their magnitude shows that every pyridine group in the sample is fully bound to a zinc porphyrin under these conditions.[6]

3) UV/Vis absorption spectra. The wavelengths of the H_2-**1**, Zn_2-**2**, and Zn_2-**3** Soret bands are 426, 424, and 424 nm, respectively. However, UV/Vis absorption spectra recorded at 10^{-6} M for 1:1 mixtures of H_2-**1** + Zn_2-**2** and H_2-**1** + Zn_2-**3** both showed a Soret band at 430 nm. This red shift is characteristic of the formation of a zinc porphyrin/pyridine complex: the Soret band of Zn-**4** moves from 422 to 430 nm on coordination of pyridine.[6] Thus in a 1:1 mixture of H_2-**1** and Zn_2-**2** at 10^{-6} M every zinc porphyrin in the sample is coordinated to a pyridine ligand (the same is true for the mixture of H_2-**1** and Zn_2-**3**).

4) Dilution studies. The ^{1}H NMR and UV/Vis absorption spectra of both complexes do not change over the accessible concentration range (10^{-7} to 10^{-2} M); in other words, the complexes remain fully assembled down to concentrations below 10^{-7} M. These complexes are remarkably stable compared to simple zinc porphyrins, which have stability constants in the region of 10^3 M^{-1}, and shows that cooperative self-assembly is taking place.[6]

The spectroscopic results indicate that the structures of the complexes are closed: all of the coordination sites are occupied and there are no free end groups. Thus the complexes are macrocyclic, which also accounts for the observed cooperativity. The only possible structures consistent with these observations and the VPO results are those in Figure 1.

The fluorescence spectra of 1:1 mixtures of H_2-**1** + Zn_2-**2** and H_2-**1** + Zn_2-**3** in dichloromethane are also characteristic of fully bound zinc porphyrin/pyridine complexes at concentrations of

10^{-7} M. However, on dilution both complexes dissociated at a concentration of about 10^{-8} M. Since Zn_2-**2** does not fluoresce (vide infra), the stability constant of the H_2-**1**·Zn_2-**2** complex could be determined by fluorescence titration methods (Fig. 2).

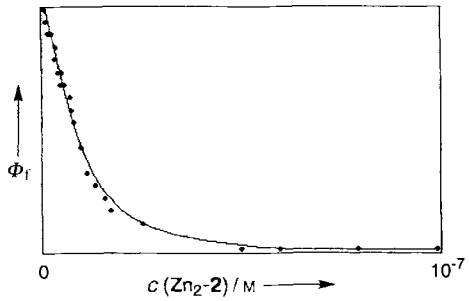

Fig. 2. Fluorescence titration curve for the binding of Zn_2-**2** to H_2-**1** in dichloromethane. The vertical scale is in arbitrary units. H_2-**1** (10^{-9} M) was selectively excited at 520 nm and the emission at 650 nm was recorded. Zn_2-**2** has negligible fluorescent emission at this wavelength at the concentrations used. The curve is the best fit of the 1:1 binding isotherm used to determine the association constant.

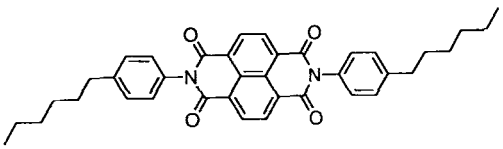
The titration data are approximated very well with an isotherm for 1:1 binding, confirming the VPO results. The stability constant for this complex is $3 \pm 1 \times 10^8\ M^{-1}$, which is very close to the value previously determined for the self-assembled "dimer" on which the design of these complexes were based.[6]

Evidence for electron and energy transfer processes in the complexes was also obtained from the fluorescence spectra. Compared with the Zn-**4** and Zn_2-**3**, Zn_2-**2** has a very weak fluorescent emission at 600 nm. The UV/Vis absorption spectrum of Zn_2-**2** is essentially the sum of the absorption spectra of the two component chromophores, Zn-**4** and **5**, which shows



5

that there is little electronic interaction between the π-systems in the ground state. Thus we ascribe the quenching of the porphyrin emission in Zn_2-**2** to efficient intramolecular electron transfer from the excited singlet state of the porphyrin to the naphthalenediimide.[8]

In the H_2-**1**·Zn_2-**2** complex at a concentration of 10^{-6} M, the intensity of the fluorescent emission from H_2-**1** at 650 nm is 70% less than that of free H_2-**1** (see Fig. 2). Addition of 10^{-6} M **7** and 10^{-6} M Zn-**4** to H_2-**1** caused no change in the fluorescence spectrum. We therefore attribute the fluorescence quenching in the H_2-**1**·Zn_2-**2** assembly to intracomplex electron transfer from the H_2-**1** excited singlet state to the naphthalenediimide electron acceptor. The shortest bonded connection between the chromophores is 24 bonds or roughly 35 Å, whereas the separation of the chromophores in space is 10 Å at most. Thus it is probable that the pathway for the electron transfer is through space or through the solvent occupying the space between the two chromophores. The weak fluorescent emission of Zn_2-**2** is not significantly altered on complexation, which means that fast electron transfer from the zinc porphyrin to the naphthalenediimide also takes place in the complex. The photoinduced electron transfer reactions that take place in the H_2-**1**·Zn_2-**2** complex are summarized in Figure 3a.

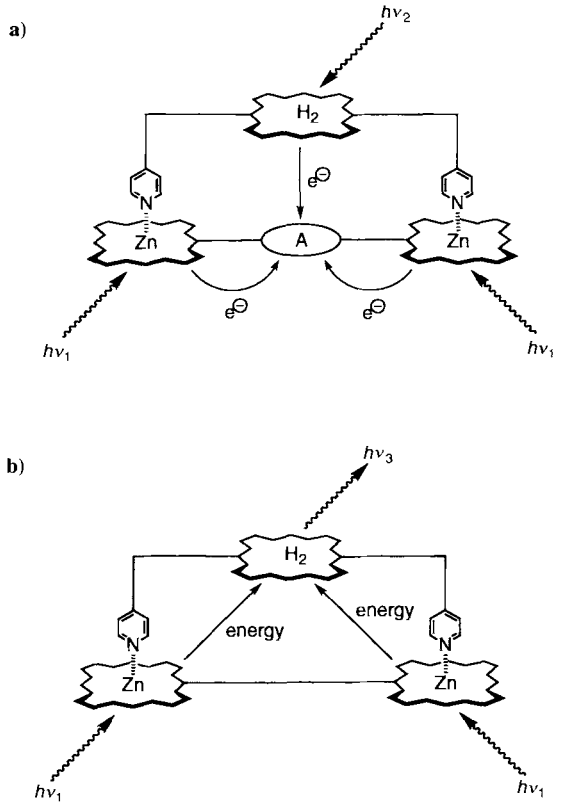


Fig. 3. a) The electron transfer processes assumed for the H_2-**1**·Zn_2-**2** complex. b) The energy transfer process assumed for the H_2-**1**·Zn_2-**3** complex. A = naphthalenediimide acceptor, H_2 = free-base porphyrin in H_2-**1**.

The H_2-**1**·Zn_2-**3** complex was prepared as a control, since it is formed by self-assembly but no electron transfer processes can occur. However, this complex also showed some interesting photochemistry. The intensity of the Zn_2-**3** fluorescent emission in this complex is significantly reduced. This is most clearly seen in Figure 4, which shows the emission spectra for a 1:1 mixture

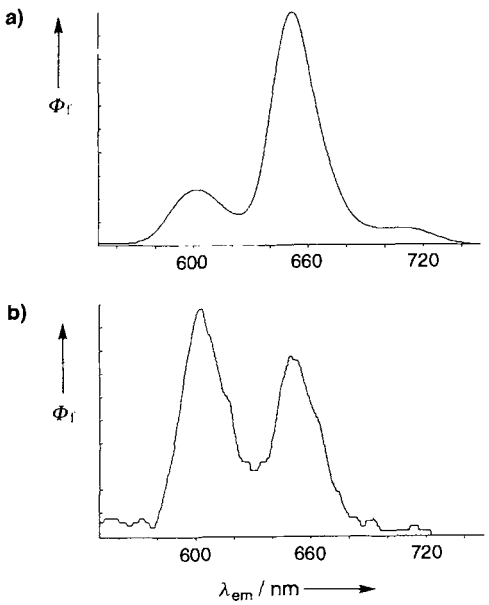

Fig. 4. Fluorescence spectra of a 1:1 mixture of H_2-**1** and Zn_2-**3** in dichloromethane at concentrations of 5×10^{-7} M (a) and 2×10^{-9} M (b); excitation at 426 nm. H_2-**1** fluoresces at 650 nm and Zn_2-**3** fluoresces at 600 nm.

of Zn_2-**3** and H_2-**1** at high concentration (complexed) and low concentration (uncomplexed). In addition, the intensity of the H_2-**1** fluorescent emission increases on adding Zn_2-**3**. Figure 5 shows that the emission from H_2-**1** in the complex is unaffected when the free-base porphyrin is selectively excited at 520 nm;

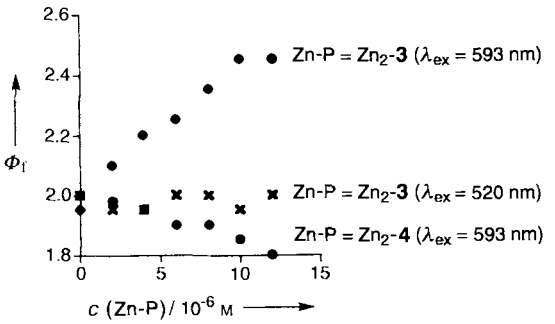

Fig. 5. Fluorescence titration data for the binding of Zn_2-**3** and of Zn-**4** to H_2-**1** (10^{-5} M) in dichloromethane. The vertical scale is in arbitrary units. The emission at 720 nm, which is exclusively due to H_2-**1**, was recorded. The excitation wavelengths are indicated: H_2-**1** absorbs at 520 and 593 nm; Zn_2-**3** absorbs at 593 nm only.

however, excitation at 593 nm, which excites both the zinc and free-base porphyrins, increases the intensity of the free-base emission. Addition of Zn-**4**, which does not complex to H_2-**1** at these concentrations, does not alter the free-base emission. We attribute this to energy transfer from the zinc porphyrins to the free-base porphyrin (Fig. 3b).

The approach described here is a powerful method for the construction of stable complex arrays of chromophores with well-defined three-dimensional structures. These systems represent a significant improvement over related noncovalent complexes, because they remain fully assembled at concentrations as low as 10^{-8} M, and the proportion of uncomplexed chromophore is negligible at higher concentrations. This will greatly facilitate detailed photophysical studies of their properties, and the preliminary fluorescence measurements reported here suggest that this will be a fruitful area for model studies of electron and energy transfer reactions in structurally well-defined yet complex architectures.

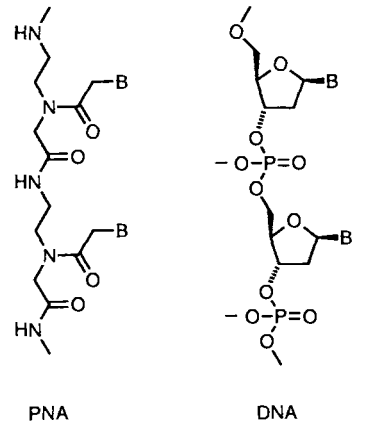
Peptide Nucleic Acids (PNAs) Containing Thymine Monomers Derived from Chiral Amino Acids: Hybridization and Solubility Properties of D-Lysine PNA**

Gerald Haaima, Anders Lohse, Ole Buchardt, and Peter E. Nielsen*

Peptide nucleic acids (PNAs) are DNA mimics containing an achiral, uncharged pseudopeptide backbone.[1–4] PNAs bind strongly and sequence-specifically to both single-stranded DNA and RNA[5,6] as well as to double-stranded DNA.[7,8] Furthermore, PNAs are both chemically and biologically stable.[9] These properties make PNAs attractive leads for the development of gene therapeutics[10–15] and biomolecular tools.[16] The original PNA backbone consists of *N*-(2-aminoethyl)glycine units; the nucleobases are attached to the glycine nitrogens through methylene carbonyl linkers (Scheme 1).[1–4] A number of modified PNAs have been prepared. Extension of the PNA backbone by the insertion of methylene units proved to be deleterious to the DNA-mimicking properties.[16] Introduction of chirality into the backbone has been also been studied, and the results



Scheme 1. Comparison of the backbones of DNA and PNA. B = nucleobases adenine, cytosine, guanine, and thymine.

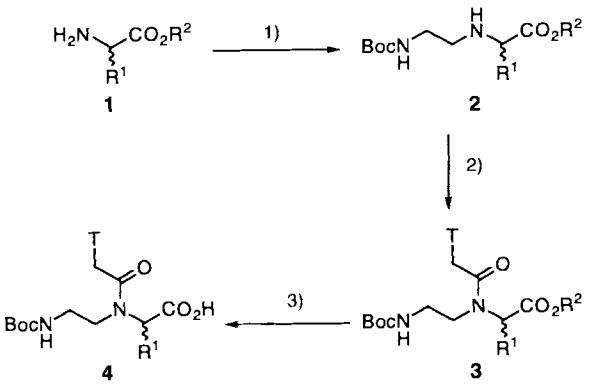
indicate that chirality arising from methyl groups incorporated at various positions along the backbone hardly affects the hybridization properties.[17, 18] However, it is not known whether larger substituents can be accommodated (although NMR studies on PNA–RNA[6] and PNA–DNA duplexes[19] indicate no steric interference of such substituents).

The question of accommodating functionality (and chirality) in the PNA backbone can be answered by constructing PNA monomers from α-amino acids other than glycine. This functionality would provide opportunities to tailor the hybridization behavior of PNA. Other properties such as solubility and cell penetration could also be improved. Finally, functional groups on the PNA backbone could provide convenient attachment points for various biologically active ligands.

We report here on the synthesis of PNA monomers from D- and L-lysine, D- and L-serine, D-glutamic acid, L-aspartic acid, and L-isoleucine with thymine as the nucleobase, as well as the preparation of PNA decamers containing three such monomers. Furthermore, we show that the change in thermal stability of PNA–DNA and PNA–RNA duplexes is −3.0 to +1.0 K per introduced monomer relative to the stability of the original glycine backbone; the D-lysine derivative is the only monomer with a stabilizing effect. Finally, discrimination of mismatched base pairs is generally improved when the monomers are introduced, and the D-lysine monomer is shown to increase the solubility of the PNA oligomer in water.

The synthesis of the chiral PNA monomers containing thymine as the nucleobase is outlined in Scheme 2. The synthetic route is analogous to that used for regular PNA monomers.[21]



Scheme 2. Synthesis of the chiral PNA monomers **4a–g**. 1) $BocNHCH_2CHO$, $NaCNBH_3$; 2) thymin-1-yl-acetic acid, DCC. DhbtOH, DIEA, DMF, 40 °C; 3) for the benzyl ester: H_2, 10% Pd/C, MeOH, 1 h; for the allyl ester: $[Pd(PPh_3)_4]$, morpholine, THF, 30 min. Abbreviations are explained in ref. [20]. See also Table 1.

The protecting group chemistry used at the side chain and α-carboxyl group (Table 1) was designed to maintain the integrity of the stereogenic center during synthesis and subsequent oligomerization.[22] The α-carboxyl group was protected as an allyl ester,[22] a protecting group compatible with those used for the A, C, and G nucleobases of PNA.[21]

Table 1. Amino acids and protecting groups employed and overall yields for the PNAs synthesized according to Scheme 2.

Series	Amino acid	Stereo-chemistry	R^1	R^2	Overall yield [%]
a	Ile	L	*sec*-Bu	benzyl	49
b	Ser	L	CH_2OBn	allyl	44
c	Ser	D	CH_2OBn	allyl	41
d	Asp	L	CH_2CO_2cHex	benzyl	42
e	Glu	D	$CH_2CH_2CO_2Bn$	allyl	46
f	Lys	L	$(CH_2)_4NH$-2-ClZ	allyl	45
g	Lys	D	$(CH_2)_4NH$-2-ClZ	allyl	42

Duplex-forming PNA oligomers were synthesized on MBHA resin following a modified Merrifield solid-phase peptide synthesis.[24] The oligomer sequence was H-$GT_XAGAT_XCACT_X$-$(Lys)NH_2$, where T_X represents the new T monomers.[25] An L-lysine amino acid was included at the beginning of the sequence to facilitate comparisons with previously reported PNAs, except for oligomers incorporating monomers with carboxylic acid side chains. Deprotection and cleavage from the resin were achieved with anhydrous HF or by the "low/high" TFMSA method.[26] All oligomers were purified by HPLC and characterized by MALDI-TOF and/or FAB mass spectrometry.[27]

The thermal stabilities of complexes between the new PNA oligomers and complementary DNA and RNA oligomers were measured (Table 2). The results clearly show that the glycine units in the PNA backbone can be replaced by chiral amino acids with only a moderate loss of stability and, in some cases, an increase in DNA hybridization potency. Furthermore, as is observed for alanine-based PNAs,[17] D-amino acids appear to be better accommodated in the backbone of a PNA–DNA duplex (compare L- versus D-lysine and L- versus D-serine, Table 2). The introduction of negatively charged side chains in the backbone (for example glutamic and aspartic acid) decreases hybridization potency, while a positively charged side chain (L- and D-lysine, Table 2) has a beneficial effect on the DNA hybridization properties of PNA; an increase in T_m of roughly 1 K per lysine unit was observed. A similar increase is found in

Table 2. Melting temperatures [°C] of PNA–DNA and PNA–RNA duplexes [a, b].

Backbone [c]	[f]	T_m (DNA, antiparallel)	ΔT_m DNA [e]	T_m (DNA, parallel)	T_m (RNA)	ΔT_m (RNA) [e]
Gly	$LysNH_2$	52	–	38	55	–
Gly	NH_2	49	–	38	54	–
L-Lys	$LysNH_2$	49	−1.0	41	51	−1.3
D-Lys	$LysNH_2$	55	+1.0	40	55	0
L-Ser	$LysNH_2$	49	−1.0	37	52	−1.0
D-Ser	$LysNH_2$	50	−0.6	38	52	−1.0
D-Glu	NH_2	42	−2.3	28	[d]	[d]
L-Asp	NH_2	38	−3.3	33	[d]	[d]
L-Ile	$LysNH_2$	44	−2.6	38	46	−3.0

[a] Measured in aqueous buffer containing 100 mM NaCl, 10 mM phosphate, 0.1 mM EDTA, pH 7.0; heating rate: 1 K min^{-1}. UV absorbance measured at 254 nm. [b] The PNA sequence was H-$GT_XAGAT_XCACT_X$-R (R = NH_2 or L-$LysNH_2$). The complementary DNA sequence was 5′-d(AGTGATCTAC) for the antiparallel complex and 5′-d(CATCTAGTGA) for the parallel complex. [c] The backbone at the T_X position was constructed with the monomer derived from the indicated amino acid. [d] Not determined. [e] Increase or decrease in T_m [K] per chiral monomer (antiparallel orientation). [f] C-terminal amino acid.

oligonucleotides derived from aminoalkylphosphates.[28, 29] Hybridization of the PNAs to RNA led to similar thermal stabilities; however, the introduction of substituents to PNA resulted in a larger relative destabilization. Thus in this case no change in T_m was observed upon introduction of the D-lysine monomer. As previously noted for the glycine PNA,[5] the PNAs tested here show distinct directional preferences in binding: they bind better to an antiparallel DNA target than to parallel DNA.

We also studied the effect of a single mismatched base pair (T_{PNA}–$G_{DNA/RNA}$) in the middle of the duplex (Table 3). We found that PNAs containing a chiral amino acid discriminate better against base pair mismatches than glycine PNA does.

Table 3. Melting temperatures T_m [°C] of PNA–DNA and PNA–RNA duplexes with one mismatched base pair[a,b].

Backbone [c]	[f]	T_m (DNA)	ΔT_m (DNA) [e]	T_m (RNA)	ΔT_m (RNA) [e]
Gly	$LysNH_2$	37	−15	46	−9
L-Lys	$LysNH_2$	35	−14	40	−11
D-Lys	$LysNH_2$	36	−19	43	−12
D-Glu	NH_2	28	−20	[d]	[d]
L-Ile	$LysNH_2$	28	−16	36	−10
D-Ser	NH_2	33	−17	43	−9

[a] Measured in aqueous buffer containing 100 mM NaCl, 10 mM phosphate, 0.1 mM EDTA, pH 7.0; heating rate: 1 K min^{-1}. UV absorbance measured at 254 nm. [b] The PNA sequence was H-GT$_X$AGAT$_X$CACT$_X$-R (R = NH_2 or L-$LysNH_2$). The complementary DNA sequence with a single mismatched base was 5′-d(AGTGGTCTAC) (antiparallel orientation). [c] The backbone at the T_X position was constructed with the monomer derived from the indicated amino acid. [d] Not determined. [e] Increase or decrease in T_m [K] for the PNA–DNA duplex (antiparallel orientation). ΔT_m for the corresponding DNA–DNA duplex with a base mismatch: 10 K. [f] C-terminal amino acid.

Since the sequence selectivity is increased for both the D- and the L-amino acids, this discrimination is most likely a consequence of the bulky substituent in the α-position, which makes it difficult for the backbone to adopt the conformation required to accommodate the mispaired bases in the helix. Interestingly, the PNA containing D-lysine monomers displays a high sequence specificity ($\Delta T_m = -19$ K), which is approximately equal to that observed for the PNA incorporating D-glutamic acid ($\Delta T_m = -20$ K). Thus the electrostatic attraction between the anionic DNA strand and the cationic PNA apparently does not decrease sequence discrimination.

In general, very purine-rich PNAs are less water-soluble than fully purine–pyramidine mixed sequence PNAs. In order to examine whether the introduction of charged units in the PNA backbone leads to increased solubility, we synthesized the PNA dodecamer H-AGAGTGAGTGAG-NH_2 with T monomers attached to either a glycine or D-lysine backbone, and prepared a saturated solution of the PNA in 140 mM KCl and 10 mM sodium phosphate at pH 7.0 and 37 °C. While the all-glycine PNA was soluble up to a concentration of 40 mM, the D-lysine PNA was five times more soluble (200 mM). Naturally an even greater effect on the solubility is expected if more PNA units contain lysine monomers.

We have shown that PNAs with chiral funtionalized backbones retain strong DNA and RNA hybridization properties. This should provide unique opportunities (not possible with oligonucleotides) to prepare PNAs with specific physical and chemical properties, for example for pharmaceutical applications and for preparing PNA conjugates. For instance, amphiphilic and amphipatic PNAs are both easily constructed. Finally, amino acid functionalized PNAs are formally genuine chimera between proteins and nucleic acids, as functionalities of both are combined. In addition, the monomers may find interesting applications in amide-based combinatorial chemistry.[30]

Experimental Procedure

The general procedure is illustrated by the preparation of monomer **4b** derived from L-serine.

1b: To a stirred solution of L-BocSer(OBn)OH (5.00 g, 16.93 mmol) in dry DMF (60 mL) was added Cs_2CO_3 (5.52 g, 16.94 mmol). After 15 min allyl bromide (4.10 g, 33.88 mmol) was added and the reaction mixture stirred for a further 45 min. The inorganic salts were removed by filtration and the DMF was removed under reduced pressure. The residue was partitioned between ethyl acetate and saturated aqueous $NaHCO_3$. The aqueous layer was extracted several times with ethyl acetate and the combined organic layers were dried (Na_2SO_4). After removal of the solvent under reduced pressure, the light yellow residue was dissolved in benzene (50 mL) and pTSA·H_2O (3.33 g, 17.5 mmol) added. The solution was heated at reflux for 1 h, the volume was reduced to 10 mL, and crystallization was induced by slow addition of diethyl ether. Filtration of the solid material and recrystallization from methanol/diethyl ether afforded 5.68 g (82%) of white crystals (**1b**·pTSA). M.p. 81–82 °C; $[\alpha]_D^{20} = -4.8$ ($c = 5$ in MeOH); ^{1}H NMR ([D$_6$]DMSO, 400 MHz, DMSO reference): $\delta = 8.59$ (br. s, 3H), 7.43 (m, 5H), 7.57, 7.26 (ABq, $J_{AB} = 7.9$ Hz, 4H), 5.97 (m, 1H), 5.44 (m, 1H), 5.34 (dm, $J_{cis} = 10.5$, 1.5 Hz, 1H), 4.78 (m, 2H), 4.66, 4.57 (ABq, $J_{AB} = 12.3$ Hz, 2H), 4.52 (t, $J = 3.5$ Hz, 1H), 3.96 (dd, $J = 10.6$, 3.9 Hz, 1H), 2.37 (s, 3H); ^{13}C NMR ([D$_6$]DMSO): $\delta = 167.37$, 137.67, 137.27, 131.61, 128.29, 128.05, 127.76, 127.70, 118.48, 72.51, 67.30, 66.10, 52.58, 20.82; Anal. calcd. for $C_{20}H_{25}NO_6S$: C 58.95, H 6.18, N 3.36; found: C 58.70, H 6.17, N 3.44.

2b: A solution of **1b** (4.50 g, 11.04 mmol, which was freed from pTSA salts by multiple extraction of a solution of **1b** in aqueous $NaHCO_3$ with CH_2Cl_2) in methanol (40 mL) precooled to 0 °C was treated with Boc-aminoacetaldehyde (2.14 g, 13.28 mmol). The mixture was stirred at 0 °C for 30 min, after which acetic acid (0.75 mL) and sodium cyanoborohydride (0.37 g, 5.89 mmol) were added sequentially. After 30 min solvent was removed under reduced pressure and the resulting oil diluted with ethyl acetate (200 mL). After washing with saturated aqueous $NaHCO_3$ (1 × 100 mL) and brine (100 mL), the organic layer was dried (Na_2SO_4) and the solvent evaporated under reduced pressure to produce a colorless oil. An ethereal solution (80 mL) of this oil was cooled to −20 °C and treated with an equivalent of dry ethereal HCl (1.5 M). Dry hexanes (80 mL) were added and the solid hydrochloride salt was isolated by filtration. Crystallization from methanol/diethyl ether/hexanes produced 3.72 g (91%) of white crystals (**2b**·HCl). M.p. 120–121 °C; $[\alpha]_D^{20} = -11.1$ ($c = 5$ in MeOH);^{1}H NMR ([D$_6$]DMSO): $\delta = 10.22$ (br. s, 1H), 9.60 (br. s, 1H), 7.40 (m, 5H), 7.21 (t, $J = 5.3$ Hz, 1H), 5.96 (m, 1H), 5.43 (dm, $J_{trans} = 17.2$, $J_{gem} = 1.5$ Hz, 1H), 5.32 (dm, $J_{cis} = 10.6$, $J_{gem} = 1.5$ Hz, 1H), 4.78 (m, 2H), 4.68, 4.56 (ABq, $J_{AB} = 12.0$ Hz, 2H), 4.59 (m, 1H), 4.20 (dd, $J = 10.8$, 2.8 Hz, 1H), 4.00 (dd, $J = 10.8$, 3.1 Hz, 1H), 3.42 (m, 2H), 3.14 (m, 2H), 1.46 (s, 9H); ^{13}C NMR ([D$_6$]DMSO): $\delta = 166.78$, 155.77, 137.26, 131.58, 128.29, 127.76, 127.73, 118.55, 78.30, 72.50, 66.33, 66.20, 58.96, 46.21, 36.38, 28.21; Anal. calcd. for $C_{20}H_{31}ClN_2O_5$: C 57.89, H 7.53, N 6.75, Cl 8.54; found: C 57.61, H 7.64, N 6.60, Cl 8.7

3b: To a stirred solution of DhbtOH (2.20 g, 13.5 mmol) and thymin-1-yl-acetic acid (2.48 g, 13.5 mmol) in DMF (40 mL) was added DCC (2.92 g, 14.2 mmol). After 1 h **2b**·HCl (2.50 g, 6.74 mmol) and DIEA (0.88 g, 6.8 mmol) were added. The reaction mixture was stirred at 40 °C until the reaction was complete (typically 15 h). The DMF was evaporated under reduced pressure, the yellow residue taken up in ethyl acetate (120 mL), and the dicyclohexylurea removed by filtration. The organic layer was washed successively with saturated aqueous $NaHCO_3$ (1 × 100 mL), half saturated aqueous $KHSO_4$ (1 × 100 mL), and brine (1 × 100 mL), and then dried with Na_2SO_4. The solvent was removed under reduced pressure to give a light yellow foam, which was purified by silca gel chromatography (2/1 ethyl acetate/hexanes). Further purification by dissolving the product in ethyl acetate (5 mL), adding diethyl ether (100 mL), and stirring overnight afforded 2.04 g (58%) of the analytically pure product. $[\alpha]_D^{20} = -5.2$ ($c = 3$ in MeOH); ^{1}H NMR ([D$_6$]DMSO) (data for the major rotamer only): $\delta = 11.35$ (s, 1H), 7.41 (m, 6H), 6.90 (m, 1H), 5.94 (m, 2H), 5.36 (dd, $J = 17.3$, 1,5 Hz, 1H), 5.26 (dd, $J = 10.5$, 1.5 Hz, 1H), 4.68 (m, 6H), 1.83 (br. s, 3H), 1.47 (s, 9H); ^{13}C NMR ([D$_6$]DMSO): $\delta = 168.27$, 167.43, 164.32, 155.69, 150.92, 142.00, 137.96, 132.25, 128.26, 127.50, 117.69, 108.06, 78.06, 72.21, 67.43, 65.03, 59.76, 47.85, 46.79, 28.19, 11.91; Anal. calcd. for $C_{27}H_{36}N_4O_8$: C 59.55, H 6.66, N 10.29; found: C 59.40, H 6.65, N 10.29.

4b: A solution of ester **3b** (0.50 g, 0.92 mmol) and morpholine (0.80 mL, 9.2 mmol) in THF (9 mL) was treated with [Pd(PPh$_3$)$_4$] (10.6 mg, 0.09 mmol). After 30 min the solvent was removed under reduced pressure and the resulting foam taken up in ethyl acetate (30 mL) and washed with brine (set at pH 3 with aqueous $KHSO_4$). The aqueous layer was further extracted with ethyl acetate (6 × 15 mL) and the combined organic layers washed with brine and dried (Na_2SO_4). The solvent was removed to give a light yellow foam, which was dissolved in ethyl acetate and precipitated by slow addition of hexane. After filtration and drying under high vacuum, 0.386 g (83%) of a white solid was obtained. $[\alpha]_D^{20} = -35.3$ ($c = 3$ in MeOH); ^{1}H NMR ([D$_6$]DMSO): $\delta = 11.28$ (s, 1H), 7.41 (m, 6H), 6.85 (m, 1H),

4.66–4.49 (m, 4H), 3.85 (m, 2H), 1.75 (br. s, 3H), 1.38 (s, 9H); ^{13}C NMR ([D$_6$]DMSO): δ = 167.98, 166.93, 164.39, 155.63, 151.04, 142.09, 138.47, 132.04, 131.54, 128.25, 127.49, 107.94, 77.80, 71.92, 68.14, 61.71, 48.45, 38.19, 28.30, 11.91; FAB HRMS: *m/z* calcd. for $C_{24}H_{33}N_4O_8$: 505.2298; found: 505.2324.

A Stable Methyl Phosphane Oxide/Lithium Amide Complex: a Structural and MO Calculational Investigation of the Mechanism of Proton Abstraction by Alkali Metal Reagents**

David R. Armstrong, Matthew G. Davidson, Robert P. Davies, Helen J. Mitchell, Rachel M. Oakley, Paul R. Raithby, Ronald Snaith,* and Stuart Warren

Lithium alkyls $(RLi)_n$, lithium amides $(R_2NLi)_n$, and their complexes are used extensively in organic synthesis to deprotonate E–H units (E = C, N, O etc.).[1] How such proton abstractions occur is not well understood, although in many cases the preliminary step is presumed to be coordination of the organic compound (through one or more of its functionalities) to the lithium reagent.[2] Presumably also, in such a complex the E–H bond will be in reasonable proximity to the anionic center of the reagent, so facilitating proton transfer and formation of an E–Li bond. Here we describe a species that to some extent tests these presumptions. The methyl phosphane oxide $Ph_2P(=O)CH_3$, which is known to be lithiated by *n*BuLi (and also by *t*BuLi and iPr_2NLi (LDA)) in THF at −78 °C as the first step in Horner–Wittig reactions,[3] is *not* lithiated by lithium bis(trimethylsilyl)amide $(Me_3Si)_2NLi$. Instead, compound **1**

$[(Me_3Si)_2NLi{\cdot}O{=}P(CH_3)Ph_2]_n$ **1**

(n = 2 in the solid state), a complex of the two reagents is isolated. Examination of the structure of **1** indicates why deprotonation is blocked. Prompted by this experimental finding, we report also a MO calculational study of the mechanics and energetics of deprotonation within a related model system, $H_2NLi{\cdot}O{=}P(CH_3)H_2$.

Mixing $Ph_2P(=O)CH_3$ and $(Me_3Si)_2NLi$ in toluene/hexane gave a pale yellow solution at room temperature. Crystals of **1** were obtained in high yield on chilling this solution; a similar yield was gained even after prior heating of the solution to 80 °C for several hours. Adduct **1** was fully characterized by elemental analysis and NMR spectroscopy (see Experimental Procedure), and its solid-state structure was solved by X-ray crystallography[4] (Fig. 1). The observed aggregation of **1** to form a dimer is in itself not surprising. Solid $[(Me_3Si)_2NLi]_n$ is a ring trimer (n = 3), whereas its 1:1 complexes with monodentate Lewis bases such as Et_2O are dimers.[2, 5] Thus $Ph_2P(=O)CH_3$ acts simply as such a Lewis base even though it is a reasonably acidic molecule, deprotonated by reagents such as *n*BuLi at low temperatures. The view of **1** in Figure 1 gives some preliminary stereochemical indication as to why deprotonation is blocked; it shows also the (to us, inexplicable) *cis* arrangement of the methyl groups on the phosphane oxides.[6]

Several published crystal structures are relevant to the discussion of the structure of **1**. Most of them are species obtained after treating the organic compound (for example an amine, an imine, or an enolizable ketone) with a deficiency (less than

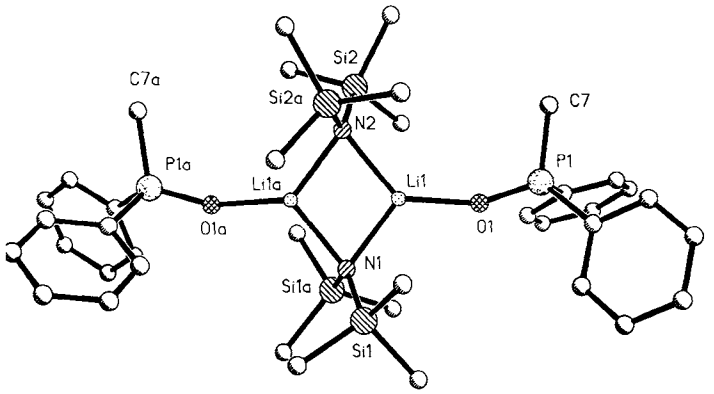

Fig. 1. The molecular structure of **1** in the crystal shown perpendicular to the Li_2N_2 ring (hydrogen atoms omitted for clarity).

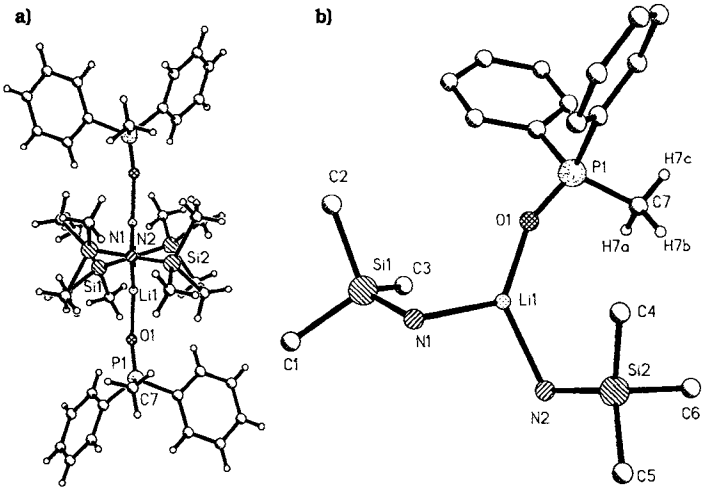

Fig. 2. a) The molecular structure of **1** in the crystal highlighting the relative positions of the $(P)CH_3$ groups and the N centers of the Li_2N_2 ring. b) One-half of the dimer of **1** showing the relative positions of the $(P)CH_3$ and $NSi(CH_3)_3$ groups.

one equivalent) of the metalating reagent. The excess, intact organic precursor then acts as a Lewis base towards the metalated compound, for example as in the monomer [Ph(2-Pyr)NLi]·HMPA·[HN(2-Pyr)Ph] (2-Pyr = 2-pyridyl, HMPA = hexamethylphosphoric triamide),[7a] the tetrameric ladder $[C_5H_{10}NLi \cdot HNC_5H_{10}]_4$ ($C_5H_{10}NH$ = piperidine),[7b] and the tetrameric cubanes $(t\mathrm{Bu_2C{=}NNa})_4 \cdot (HN{=}Ct\mathrm{Bu_2})_2$[7c] and $[t\mathrm{BuC}(=CH_2)ONa \cdot O{=}C(t\mathrm{Bu})CH_3]_4$.[7d] However, all these examples hint at a propagation mechanism: some of the organic precursor has been metalated, whilst the remainder coordinates to the metalation product and awaits subsequent metalation. The case of **1** is fundamentally different. Here, the reactants $Ph_2P(=O)CH_3$ and $(Me_3Si)_2NLi$, taken in 1:1 ratio, do not react but simply form an adduct. This result thus indicates what an initiation step in a deprotonation might be, namely coordination of the wholly intact organic precursor to the metalating reagent. Given this, the only published structure directly relevant to **1** is that of the complex between $(Me_3Si)_2NLi$ and the potentially enolizable ester *tert*-butyl isobutyrate, $[(Me_3Si)_2NLi \cdot O{=}C(t\mathrm{Bu})OCHMe_2]_2$.[8] Here, the failure of the components to react was attributed to the unfavorable position of the enol hydrogen atom, which points directly towards the basic nitrogen; if this hydrogen atom were to be abstracted, delocalization of resulting negative charge into the adjacent carbonyl π orbitals would not be possible. For **1**, however, we ascribe the failure to react to a rather simpler (and probably more general) reason. As Figure 2a makes clear, none of the methyl C–H bonds of the phosphane oxide can approach the negatively polarized N atom of the lithium amide component (key bond angles: Li-O-P 157.7(3)° and O-P-CH_3 112.9(2)°]. Any such proximity is prevented by the large and extensive Me_3Si substituents. In particular, one of the silyl methyl groups is placed between the $N^{\delta-}$ center and the phosphane methyl group (Fig. 2b; one half of the dimer of **1** is shown).

In view of the isolation of **1**, we carried out ab initio calculations to probe how H_2NLi would deprotonate $O{=}P(CH_3)H_2$, and what the energetics of such a reaction would be. All calculations were conducted with the 6-31G basis set (plus, where relevant, a set of d orbitals on phosphorus)[9] by means of the program GAMESS.[10] Species were optimized without imposed geometric constraints, and absolute energies are reported.[11] The precursors—$O{=}P(CH_3)H_2$ and H_2NLi—and the potential products—$LiOP(CH_2)H_2$, a planar ring with both Li–O and Li–C bonds, and NH_3—were optimized first. Formation of the complex $H_2P(CH_3)O \cdot LiNH_2$ (Fig. 3a) is highly favorable; the complex is 32.3 kcal mol^{-1} lower in energy than the

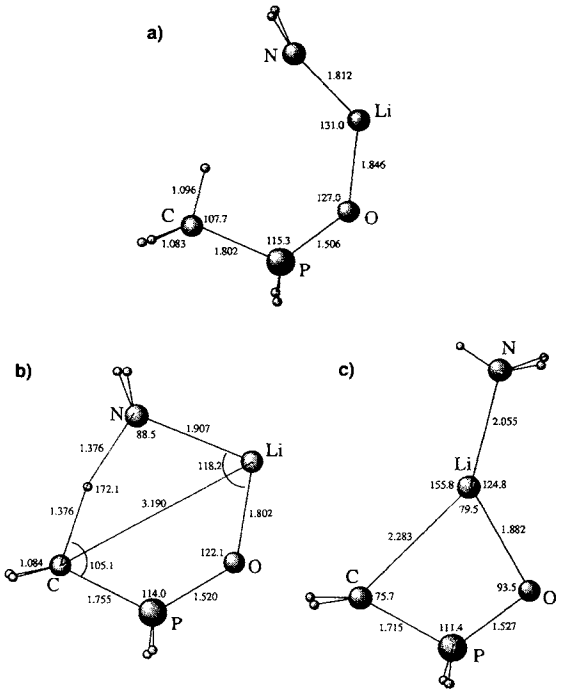

Fig. 3. Structures optimized by ab initio calculations (bond lengths in Å, bond angles in degrees) for a) the initial complex between $H_2P(CH_3)O$ and $LiNH_2$, b) the transition state for proton transfer from CH_3 to NH_2^-, and c) the resulting NH_3 complex of $H_2P(CH_2)OLi$.

separate components. Rotation of the CH_3 group is barrier-free (< 0.1 kcal mol^{-1}), so that none or one or two of its H atoms can point towards the H_2N unit. In the configuration shown in Figure 3a, the $(C)H \cdots N(H_2)$ and $(H_3)C \cdots Li$ distances are 2.368 and 3.383 Å, respectively. The calculated transition state for proton transfer is shown in Figure 3b. Here the transferable methyl proton is equidistant (1.376 Å) between C and N in a near-linear (C-H-N 172.1°) arrangement, it is significantly polarized (charge +0.44, cf. +0.17 for the remaining CH_2 protons), and the Li–C bond is beginning to form ($Li \cdots C$ 3.190 Å). Progression from the reactants' complex to this transition state requires an energy increase of only 8.7 kcal mol^{-1}. It is accomplished almost exclusively by a decrease in the O-Li-N angle (131.0° in the complex, 118.2° in the transition

state) and much of this reflects movement of the Li–N unit towards the carbon atom; the P-O-Li angle decreases from 127.0 to 122.1°, whereas the OPC angle changes little (115.3 to 114.0°). Complete proton transfer affords an ammonia complex of the lithiated phosphane oxide (Fig. 3c). This is 16.5 kcal mol^{-1} lower in energy than the transition state and so 7.8 kcal mol^{-1} more stable than the initial reactant complex. The complexation of NH_3 to the lithiated phosphane oxide is associated with a stabilization of 23.8 kcal mol^{-1}.

These calculational results quantify (to our knowledge, for the first time) the energetics of proton transfer from an acidic organic compound to a lithium reagent, and may have significance on several counts. 1) When the organic compound contains an electronegative functionality, its complexation to the lithium reagent seems a likely first step. 2) The activation energy for proton transfer is quite low in the model we have used; however, this is the least sterically demanding system possible. Progression to the transition state appears to require for the most part movement of the anionic center of the lithium reagent towards the acidic organic center. One would readily expect that this activation energy would be prohibitively high when groups on one or both centers are large (as found for **1**). 3) For lithium amide reagents in particular, the initial product of deprotonation is likely to be an amine complex (witness here the quite strong complexation of NH_3 to the lithiated phosphane oxide). Several post-enolization amine/lithium enolate complexes have been detected,[12] and this "secondary amine effect" can influence the subsequent reactivity of the lithium enolate.[13] It can also result in reprotonation of the enolate by the attached amine, so reducing final yields.[12a, 13a, c, 14] In our model calculations the step from the initial reactant amide complex to the ammonia-complexed product affords a modest 7.8 kcal mol^{-1} drop in energy. Within this step, the more substantial NH_3 complexation energy (23.8 kcal mol^{-1}) plays a determining role. Thus, poorly complexing amines such as $(Me_3Si)_2NH$[13, 14] might well affect the position of the equilibrium between the reactant amide complex and the amine-complexed product. The failure of $(Me_3Si)_2NLi$ to lithiate $Ph_2P(=O)CH_3$ might therefore be due to this phenomenon rather than due to the precise stereochemical features of the isolated product **1**.

Calculations have also been carried out on the model dimers $[H_2NLi\cdot O{=}P(CH_3)H_2]_2$, which are more akin to **1**. The findings are in line with those recorded above for the monomer and will be reported in a full paper.

Experimental Procedure

Synthesis of **1**: Solid methyldiphenylphosphane oxide (0.54 g, 2.5 mmol) and lithium bis(trimethylsilyl)amide (0.42 g, 2.5 mmol) were taken up together in chilled hexane/toluene (5 mL/5 mL). Brief warming of the resulting white suspension afforded a pale yellow solution, which was chilled (5 °C, 2 d) to give colorless crystalline blocks of **1**. First batch yield: 0.68 g, 71%; m.p. 148–152°C; satisfactory analysis for $C_{19}H_{31}LiNOPSi_2$; ^1H NMR (C_6D_6, 250 MHz, 25 °C): $\delta = 7.58$(m, 4H), 7.09 (m, 6H), 1.62 (d, $J = 13.2$ Hz, 3H, $Ph_2P(O)CH_3$), 0.56 (s, 18H, LiN[Si(CH_3)$_3$]$_2$).

[4] X-ray crystal data for **1**: $C_{38}H_{62}Li_2N_2O_2P_2Si_4$, $M = 767.08$, monoclinic, space group $C2/c$, $a = 23.217(5)$, $b = 11.181(2)$, $c = 18.351(4)$ Å, $\beta = 105.98(3)°$, $V = 4580(2)$ Å^3, $F(000) = 1648$, $\lambda(Mo_{K\alpha}) = 0.71073$ Å, $\mu(Mo_{K\alpha}) = 0.231$ mm^{-1}, $T = 153(2)$ K, $Z = 4$, $\rho_{calcd} = 1.113$ Mg m^{-3}. Data were collected on a Stoe-Siemens diffractometer in the range $3.56° \le \theta \le 22.50°$ (3330 reflections collected, 2969 independent ($R_{int} = 0.0556$)). The structure was solved by direct methods, and refinement, based on F^2, was by full-matrix least-squares techniques (SHELXL93, G. M. Sheldrick, Universität Göttingen); all non-hydrogen atoms were refined anisotropically, and hydrogen atoms were included in calculated positions and allowed to ride on the relevant carbon atom. Final residuals were $R1 = 0.0517$ for 2320 unique data with $I > 2\sigma(I)$, and $wR2 = 0.181$ (all data). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-42. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).

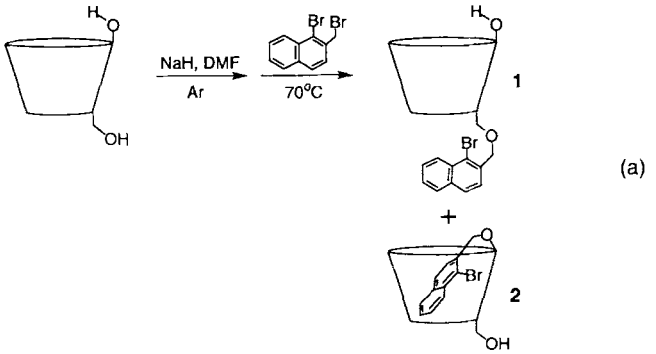
Regioisomeric Effects on the Excited State Processes of a Cyclodextrin Modified with a Lumophore**

Mark A. Mortellaro, Wanda K. Hartmann, and Daniel G. Nocera*

Supramolecular topologies may be exploited to engender novel physical and chemical processes. Of the many diverse architectures offered by supramolecules,[1] the cylindrical cavities of cyclodextrins (CDs) have been intensively investigated. The six, seven, or eight $\alpha(1\rightarrow4)$ linked D-glucose units (α-, β-, and γ-CD, respectively) of these cyclic oligosaccharides allow for water solubility while maintaining a hydrophobic interior suitable for substrate binding. The hydroxyl groups on the outer rims of the CD offer a site for the derivitization that might promote biomimetic transformations on substrates included within the cavity.[2] Typically the primary hydroxyls provide the most convenient points of attachment to the CD, because the reactivity of the secondary hydroxyl groups is diminished. However, when CDs are derivatized on the primary and secondary OH groups with the same functional group,[3-5] substantial differences in thermal reactivity have been observed.

In recent years, the use of CDs to control molecular processes has been extended to reaction pathways proceeding through excited states. As a complement to the macromolecular fluorescent schemes designed for ion sensing,[6] lumophores have been appended[7, 8] onto CDs to afford supramolecules that produce a luminescent signal upon association of neutral substrates. An important and outstanding issue in the design of photoactive CD supramolecules is whether regioisomeric effects on reactivity, so prominent in ground state processes, are manifested in excited state processes as well. The synthesis of photoactive CD regioisomers is rare,[9] and to date no significant differences have been observed in the photophysics or photochemistry of these congeners. We now report an unusual example of differences in the excited state properties of regioisomers and in the chemistry of a bromonaphthalene lumophore appended to the primary (**1**) and secondary OH groups (**2**) of β-cyclodextrin.

Compounds **1** and **2** were prepared in one step from the reaction of β-CD with 1-bromo-2-bromomethylnaphthalene and sodium hydride [Eq. (a)]. The sites of attachment of the bromonaphthalene lumophore to the CD are clearly distinguished by ^{13}C NMR data (see Experimental Procedure). The carbon resonance at $\delta = 69.5$ in the spectrum of **1** is indicative of alkylation at a primary C6 hydroxyl. For regioisomer **2**, the appearance of a carbon resonance at $\delta = 80.1$ attests to alkylation at the secondary face of the β-CD; the downfield shift of the C4′ signal ($\delta = 81.6$) identifies reaction at the more acidic C2 hydroxyl group, which is the usual site of reaction under strongly basic conditions.[10] The emission spectra of **1** and **2** in aqueous, air-saturated solutions are presented in Figure 1. Whereas both molecules fluoresce at about 350 nm with nearly equal quantum yields, the phosphorescence of **2** at 530 nm is more than 10^2 times more intense than that observed for an equimolar solution of **1** ($\phi_e^{530}(\mathbf{1}) \leq 10^{-4}$; $\phi_e^{530}(\mathbf{2}) = 0.05$ in aerated H_2O; $\phi_e^{530}(\mathbf{1}$ and $\mathbf{2}) \approx 0.06$ in the absence of oxygen). Furthermore, deoxygenation of these solutions by freeze-pump-thaw or nitrogen purging results in a dramatic increase in the phosphorescence intensity of **1** but only a slight increase in the phosphorescence of **2**; the fluorescence intensity of both compounds is largely unaffected by deoxygenation. These results suggest that whereas the bromonaphthalene moiety of **2** is protected from oxygen quenching, the bromonaphthalene moiety of **1** is not.



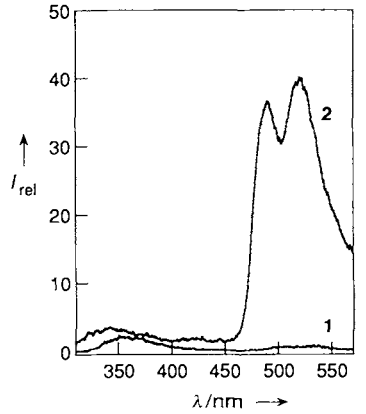


Fig. 1. Emission spectra of of **1** and **2** (each 1.0×10^{-4} M) in air-saturated, aqueous solution (excitation wavelength $\lambda_{ex} = 290$ nm).

The disparate luminescence properties of regioisomers **1** and **2** may be ascribed to the latter's forming an intramolecular complex in which the appended bromonaphthalene is protected from oxygen as a result of inclusion within the CD cavity. To assess this conjecture, we studied the phosphorescence quenching of **2** by oxygen in the presence of dodecyltrimethylammonium bromide (DTAB), which is a water-soluble, organic substrate that forms inclusion complexes with β-cyclodextrin.[11] Titration of an aqueous solution of **2** with DTAB results in the decrease of emission intensity at 520 nm (Fig. 2). The phosphorescence intensity approaches zero as the concentration of DTAB increases (the concentration of DTAB was maintained below the critical micelle concentration of 5–15 mM). A least squares fit[12] of the dependence of the phosphorescence intensity on DTAB concentration at 22 °C yields a K_{assoc} value of $1600 \pm 160\ M^{-1}$, which is greater than the association of DTAB to β-CD.[11]

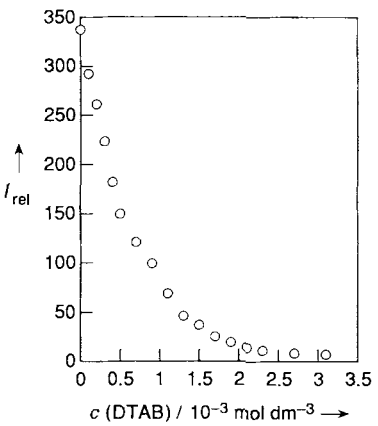

Fig. 2. Relative phosphorescence intensity at 520 nm of an air-saturated, aqueous solution of **2** (concentration 5.0×10^{-5} M) as function of the concentration of DTAB ($\lambda_{ex} = 290$ nm).

Cyclodextrins modified on the secondary face show a greater tendency to bind aromatic residues owing to additional hydrophobic interactions and solvent shielding.[13] The increased stability of **2** therefore results in an attenuated binding of DTAB to the CD cup. These titration results can be attributed to the quenching of 1-bromonaphthalene phosphorescence when the lumophore is forced outside the CD cavity by the addition of a competitive guest.

To define the quenching kinetics of **1** and **2** better, the water-soluble solid, $[Co(NH_3)_6]Cl_3$, was employed as a quencher of bromonaphthalene phosphorescence in deoxygenated solution.[14] Table 1 lists the rate constants k_q for luminescence quenching in the systems **1**, **2**, **2** in the presence of DTAB and free 1-bromonaphthalene (1-BrNp), and the binary complex formed between 1-BrNp and glucosyl-β-CD (1-BrNp/Gβ-CD).[15] The rate constants were determined from Stern–Volmer analysis of phosphorescence decay as a function of the concentration of $[Co(NH_3)_6]^{3+}$; all plots are linear and exhibit an intercept of unity. Several important conclusions can be drawn from the data in Table 1. First, the large and similar rate

Table 1. Rate constants k_q for the luminescence quenching by $[Co(NH_3)_6]^{3+}$ in systems containing bromonaphthalene and/or β-cyclodextrin, in deaerated aqueous solution at 25 °C [a].

Compound	$k_q/M^{-1}s^{-1}$
2	1.5×10^3
1-BrNp/Gβ-CD [b]	1.9×10^6
1	8.2×10^7
2/DTAB	1.7×10^8
1-BrNp [c]	1.8×10^8

[a] Emission lifetimes were measured at 520 nm; excitation wavelength 309 nm. [b] A binary complex formed from glucosyl-β-CD and 1-BrNp (Ref. [15]). [c] 1-BrNp in methanol/water (1/1).

constants for the luminescence quenching of **1** and 1-BrNp indicate that the bromonaphthalene moiety of **1** is afforded no protection by the CD cavity but is exposed to bulk solution. Since the inclusion of 1-BrNp into β-CD circumvents luminescence quenching by $[Co(NH_3)_6]^{3+}$, as is observed for the 1-BrNp/Gβ-CD binary complex, these data are consistent with the inability of **1** to form an intramolecular inclusion complex.[16] Second, the quenching of **2** is 10^4 times slower than that of **1**. However, when **2** is saturated with DTAB, the resultant complex is quenched by $[Co(NH_3)_6]^{3+}$ with a rate constant commensurate with that observed for **1** and for free 1-BrNp in solution. We interpret these results as evidence that the bromonaphthalene moiety of **2** includes within the cyclodextrin cavity by intramolecular complexation and that addition of the competitive guest DTAB displaces the bromonaphthalene moiety from the CD, where it is quenched at rates approaching the diffusion-controlled limit.

Examination of CPK molecular models suggest that whereas the side of β-CD with secondary OH groups is wide enough for an appended bromonaphthalene to enter the cavity, the side with primary OH groups is too narrow for unimpeded intramolecular inclusion to occur. Consequently, only derivative **2** forms an intramolecular complex in which its appended bromonaphthalene lies inside the cyclodextrin cavity, giving rise to novel room temperature phosphorescence in oxygenated and aqueous environments. These results show that regioisomeric effects can control reactions of the excited state of photoactive CDs. Such issues will play an especially prominent role in the design of CD-based supramolecules for optical sensing, especially those that derive their function from equilibria of appended lumophores inside and outside the CD cup.

Experimental Procedure

β-Cyclodextrin (1.00 g, 0.881 mmol, dried at 120 °C in vacuo overnight) and NaH (38.0 mg, 0.95 mmol, 60% in mineral oil) were stirred in anhydrous DMF (40 mL) overnight under a stream of argon. 1-Bromo-2-bromomethylnaphthalene (292 mg, 0.973 mmol) was added, and the solution heated to about 70 °C under argon for 5 h. This solution was poured into 450 mL of acetone, and the resulting precipitate was washed with an additional 100 mL of acetone. ^{1}H NMR analysis of this sample indicated the presence of a 1:1 mixture of **1** and **2** in about 60% yield along with unchanged β-CD. This solid mixture was stirred in 20 mL of water for 30 minutes, filtered, washed with 10 mL of water, and the aqueous solutions were combined. Within 12 h, a white precipitate of pure **2** (82 mg, 6.9%) was isolated from the filtrate. Semipreparative reverse phase HPLC of the remaining crude material on a C-18 column with elution with a step gradient of 20% CH_3CN(aq) to 30% CH_3CN(aq) afforded pure **1** and **2**. Physical data for **1**: ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 8.22 (d, 1H; ArH), 8.00 (d, 2H; ArH), 7.70 (d, 2H; ArH), 7.60 (t, 1H; ArH), 5.95–5.65 (br, 14H; C2-OH, C3-OH), 4.88 (d, 1H; H-1′), 4.8 (s, 6H; H-1), 4.78 (s, 2H; $ArCH_2$), 4.60–4.40 (br, 6H; C6-OH), 3.89–3.80 (m, 2H), 3.72–3.15 (m, 42H); ^{13}C NMR (500 MHz, [D$_6$]DMSO): δ = 136.2 (ArH), 133.5 (ArH), 131.2 (ArH), 128.3 (ArH), 127.8 (ArH), 127.7 (ArH), 126.6 (ArH), 126.1 (2 × ArH), 120.9 (ArH), 102.4 (Cl′), 101.9 (C1), 82.2 (C4′), 81.5 (C4), 73.0–72.0 (C2, C3, C5), 70.5 ($ArCH_2$), 69.5 (C6′), 59.9 (C6): FABMS: m/z 1376.0 [M^+ + Na]. Physical data for **2**: ^{1}H NMR (300 MHz, [D$_6$]DMSO): δ = 8.25 (d, 1H; ArH), 8.02 (dd, 2H; ArH), 7.82 (d, 1H; ArH), 7.71 (t, 1H; ArH), 7.65 (t, 1H; ArH), 6.10–5.60 (br, 13H; C2-OH, C3-OH), 5.14 (s, 2H; $ArCH_2$), 5.10 (s, 1H; H-1′), 4.85 (s, 6H; H-1), 4.59–4.35 (br, 7H, C6-OH), 3.95 (t, 2H), 3.90–3.15 (m, 42H); ^{13}C NMR (500 MHz, [D$_6$]DMSO): δ = 135.3 (ArH), 133.4 (ArH), 130.9 (ArH), 128.0 (ArH), 127.6 (ArH), 127.5 (ArH), 126.5 (ArH), 126.4 (ArH), 126.0 (ArH), 121.5 (ArH), 101.6 (C1), 99.6 (C1′), 81.6 (C4′), 81.1 (C4), 80.1 (C2′), 72.8–71.4 (C2, C3, C5, $ArCH_2$), 59.5 (C6); FABMS: m/z 1353.8 [M^+], 1376.4 [M^+ + Na].

[16] At the concentration of our complexes (50 μm), the extent of the association of BrNp to β-CD is too small (K_{assoc} = 700 M^{-1} [15]) for intermolecular complexes to be observed.

A Three-Dimensional Molecular Ferrimagnet Based on Ferricyanide and $[Ni(tren)]^{2+}$ Building Blocks**

M. Salah El Fallah, Eva Rentschler, Andrea Caneschi, Roberta Sessoli, and Dante Gatteschi*

Prussian blue analogues are components of a large variety of magnets, some of which are magnetically ordered at high temperatures.[1-10] The origin of the magnetic behavior is associated with the three-dimensional structure of the compounds, in which the metal ions are connected by efficient cyanide bridges that transmit strong ferro- or antiferromagnetic interactions. These materials can be considered as molecular-based magnets because they can be synthesized by applying the techniques of molecular chemistry, but they more closely resemble ionic magnets in terms of the possibility of tuning the magnetic properties. In fact they can only be varied by altering the pairs of interacting metal ions, like in ionic lattices, while for molecular magnets the tuning can be achieved by varying the organic part of the molecule.

Recently several research groups have employed a hybrid approach, in which $[M(CN)_6]^{n-}$ building blocks have been combined with transition metal ion complexes in order to exploit the features of the ligands to give different structures. For instance, $[Ni(en)_2]_3[Fe(CN)_6]_2 \cdot 2H_2O$[11] (en = ethylenediamine) and $[Ni(pn)_2]_2[Fe(CN)_6]ClO_4 \cdot 2H_2O$[12] (pn = propylenediamine) have been obtained as variations of $Ni^{II}_3[Fe^{III}(CN)_6]_2$, which have a rope-ladder or a two-dimensional structure. Both compounds seem to undergo magnetic phase transitions at lower temperatures than the Prussian blue analogue. We have now found that by using the nickel complex of the tetradentate ligand tris(2-aminoethyl)amine) (tren) the compound $[Ni(tren)]_3[Fe(CN)_6]_2 \cdot 6H_2O$ **1** is obtained, which has a three-dimensional structure and orders to a bulk ferrimagnet at about 8 K.

The structure of **1** was determined by X-ray structure analysis.[13] The asymmetric unit contains four iron ions, which are localized at the special equivalent positions (1/2,0,0), (0,0,0), (0,1/2,0), and (1/2,0,1/2), connected to nickel ions by bridging cyanide groups (Figs. 1 and 2). The Ni–Fe separations range between 4.958(2) and 5.119(3) Å. Each Ni^{II} center is octahedrally coordinated by four nitrogen atoms of the tren ligand and two nitrogen atoms of cyanide groups. The Ni–N distances range between 2.08(1) and 2.13(1) Å for Ni–N(tren) and between 2.01(1) and 2.15(1) Å for Ni–N(CN). The Fe–C distances range from 1.91(1) to 1.97(1) Å, whereas, as expected, the Fe-C-N bond angles only vary in the small range between 175(1) and 179(1)°. The Ni-N-C bond angles, on the other hand, deviate significantly from linearity and lie between 149(1) and 177(1)°. There are two types of $[Fe(CN)_6]^{3-}$ groups, one bridges four $[Ni(tren)]^{2+}$ groups, the other only two; we have labeled these as $Fe_\square$ and Fe_Λ, respectively. The three-dimensional structure of **1** can be described by Ni–Fe chains parallel to the three cell axes. As can be seen from Figure 2, the chains parallel to the *a* axis are built up from Ni–$Fe_\square$ units, whereas the chains parallel to the *b* axis and the *c* axis are composed of -Ni-$Fe_\square$-Ni-Fe_Λ-Ni- units. Each $Fe_\square$ group belongs to two different orthogonal chains.

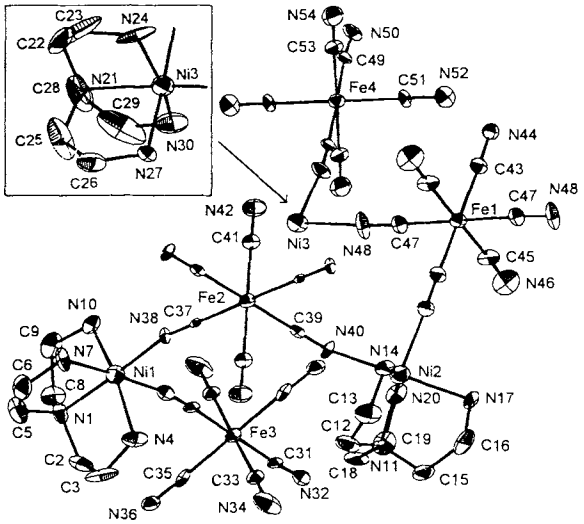

Fig. 1. ORTEP plot of the structure of **1** (without H_2O molecules). Selected distances [Å] and angles [°] (standard deviation in parentheses): Ni1–N38 2.042(11), Ni1–N32 2.055(11), Ni2–N44 2.056(11), Ni2–N40 2.149(11), Ni3–N48 2.008(12), Ni3–N50 2.061(11), Fe1–C45 1.91(2), Fe1–C47 1.913(14), Fe1–C43 1.946(14), Fe2–C41 1.945(14), Fe2–C37 1.950(13), Fe2–C39 1.965(14), Fe3–C35 1.915(14), Fe3–C31 1.921(13), Fe3–C33 1.933(2), Fe4–C51 1.905(13), Fe4–C53 1.928(14), Fe4–C49 1.931(14); C31-N32-Ni1 171.4(10), C37-N38-Ni1 165.6(9), C39-N40-Ni2 148.7(9), C43-N44-Ni2 163.3(10), C47-N48-Ni3 177.5(13), C49-N50-Ni3 170.0(10), N38-Ni1-N32 91.0(4), N44-Ni2-N40 89.4(4), N48-Ni3-N50 89.8(4), N46-C45-Fe1 179(2), N48-C47-Fe1 175.2(13), N44-C43-Fe1 176.3(11), N40-C39-Fe2 169.8(10), N42-C41-Fe2 179.3(11), N38-C37-Fe2 177.8(9), N32-C31-Fe3 177.2(10), N36-C35-Fe3 177.6(11), N34-C33-Fe3 178.1(11), N54-C53-Fe4 178.0(12), N52-C51-Fe4 178.3(11), N50-C49-Fe4 174.5(11).

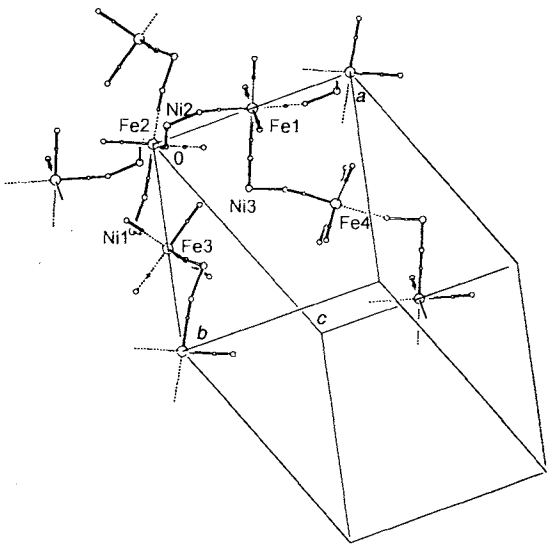

Fig. 2. Simplified cell-packing diagram of the building blocks of $[Ni(tren)]_3[Fe(CN)_6]_2$, in which only the Ni, Fe, and CN groups are shown for clarity.

The magnetic behavior of **1** in a field of 1 T[14] is shown in Figure 3. The $\chi_M T$ value of 4.96 emu mol^{-1} K at 225 K, which is close to the value expected for uncoupled Ni_3Fe_2 (4.88 emu mol^{-1} K with $g_{Ni} = 2.3$ and $g_{Fe} = 2.2$), increases gradually with decreasing temperature to reach a maximum of 12.19 emu mol^{-1} K at about 8.4 K and then decreases below this temperature. The same behavior has been observed in many compounds like $[Ni(en)_2]_3[Fe(CN)_6]_2 \cdot 2H_2O$ and $[Ni(pn)_2]_2$-

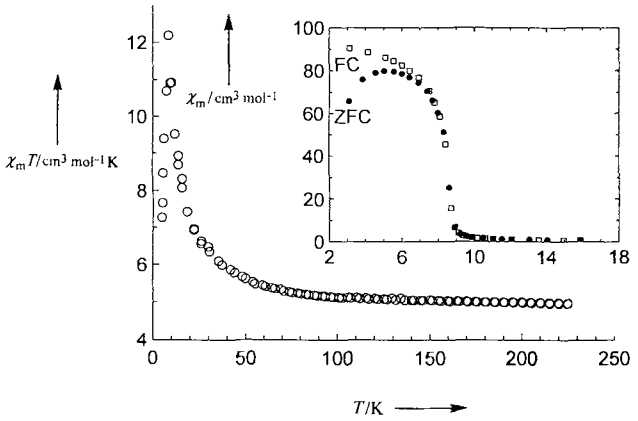

Fig. 3. Plot of $\chi_m T$ vs. T of a polycrystalline sample of **1** at an applied field of 1 T. The χT curves at zero-field-cooled (ZFC) and field-cooled (FC) magnetization are shown in the insert.

$[Fe(CN)_6]ClO_4 \cdot 2H_2O$, which order ferromagnetically[11, 12] at a maximum critical temperature of about 10 K. The ferromagnetic interaction between the Fe^{III} and Ni^{II} ions has been rationalized by the strict orthogonality of the magnetic orbitals of the Ni^{II} and the low-spin Fe^{III} centers.

In order to characterize the magnetic ordering of **1**, the magnetization has been measured between 3 and 16 K (see insert in Fig. 3). The zero-field-cooled (ZFC) magnetization, measured by cooling the sample under zero field and then warming it up under an applied field of 80 G, shows a maximum at 5.5 K and decreases rapidly above 8 K with increasing temperature. When the sample is cooled down again, the curve diverges below 8 K, tending to a plateau, thus confirming the transition to a magnetically ordered phase.

The course of the reduced magnetization $M/N\mu_\beta$ (Fig. 4) shows a spontaneous magnetization close to zero field, which reaches a value of 1.98. This corresponds to an $S = 1$ spin state.

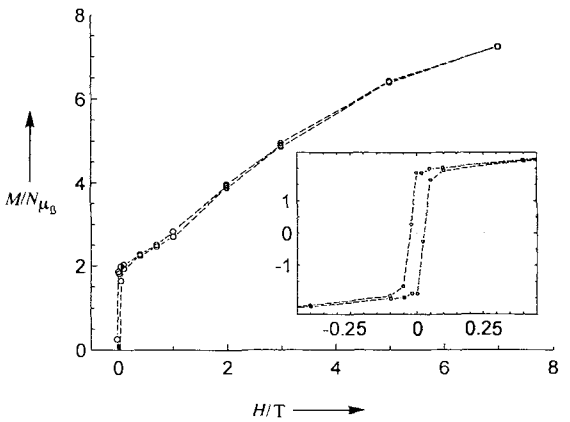

Fig. 4. Plot of $M/N\mu_\beta$ vs. H of a polycrystalline sample of **1** at 3 K. The hysteresis loop is shown in the insert.

When the applied field is increased to 1 T, the magnetization curve increases slower than expected. Above 1 T the curve becomes steeper and reaches a value of 7.2 at 7 T. A hysteresis loop was observed with a coercive field smaller than 30 G. This seems to indicate a small magnetic anisotropy and the absence of irreversible movements of the domain walls, which, had they been present, would have led to large hysteresis effects.[15]

The rapid saturation of the magnetization at a value of $S = 1$ in low field, the sharp increase in fields of about 2 T, and the slow increase for higher fields suggest ferrimagnetic order. This is determined by a weak antiferromagnetic interaction, which is flipped by external fields larger than 1 T. Ni–Fe interactions are normally ferromagnetic; however, taking into account the structural parameters of **1**, we find that the bond lengths of one CN^- bridging group (C39, N40) to the metal ions Fe2 and Ni2 is elongated with respect to the others. If we assume that at very low field the alternating -Ni-$Fe_\square$-Ni-Fe_Λ-Ni- chains are already ferromagnetically ordered and Ni2 and Fe2 are very weakly antiferromagnetically coupled, a noncompensated spin of $S = 1$ is obtained, which is in agreement with the observed value of 1.98 for the reduced magnetization.

Compound **1** is an example of a three-dimensional molecular ferrimagnet; however, since the three-dimensional lattice arises from the interaction of chains, the magnetic connectivity is low and the critical temperture is lower than in $Ni^{II}_3[Fe^{III}(CN)_6]_2 \cdot xH_2O$.[5] The weak interaction, which is mediated by one CN^- group, further depresses the critical temperature.

Experimental Procedure

To a solution of $Ni(ClO_4)_2 \cdot 6H_2O$ (3 mmol) in water (50 mL) was added tren (3 mmol). After the mixture had been stirred for a few minutes, the resulting solution was mixed with potassium ferricyanide (2 mmol) dissolved in water (30 mL). Slow evaporation of the resulting solution gave crystals suitable for X-ray diffraction. The elemental analysis gave satisfactory results.

Prominent Gelation and Chiral Aggregation of Alkylamides Derived from *trans*-1,2-Diaminocyclohexane

Kenji Hanabusa,* Manabu Yamada, Mutsumi Kimura, and Hirofusa Shirai

The design of building blocks that can assemble into supramolecules of nanoscale dimensions has received a great deal of attention.[1, 2] We have been investigating gelling agents for hardening organic fluids, and have become particularly interested in self-complementary molecules in which functional binding groups of one molecule interact with complementary groups of a neighboring molecule,[3–6] since our previous results indicate that self-complementary interactions, which lead to macromolecule-like aggregates, are essential for gelation. Herein we report on the remarkable gelation ability of alkylamides derived from *trans*-1,2-diaminocyclohexane and the resulting chiral aggregates in organic solvent.

Several recent reports have described the thermoreversible gelling properties of low molecular weight organic compounds.[7–13] We have studied gelling agents that form thermoreversible physical gels; the main driving forces of these reactions are intermolecular hydrogen bonding and van der Waals interactions. Three important features for development of gelling agent are 1) the existence of intermolecular interactions for building up macromolecule-like aggregates, 2) the occurrence of intertwining of the aggregates, and 3) the presence of some factor for preventing the crystallization of the metastable gel. We have now focused on a simple diamide compound, **1**, in the expectation that it may form interlocked macromolecule-like aggregates as a result of two cooperating noncovalent forces, the intermolecular hydrogen bonding between the amide groups of adjacent molecules and the hydrophobic interaction of the long hydrocarbon tails. The (1*R*,2*R*)-1,2-cyclohexane derivative **1** was prepared by the reaction of (1*R*,2*R*)-(−)-1,2-diaminocyclohexane and lauroyl chloride in THF in the presence of triethylamine.

A typical procedure for testing the gelation is as follows: A weighed sample of **1** was mixed with an organic liquid (1 mL) in a septum-capped test tube and the mixture was heated until the solid dissolved. The resulting solution was cooled at 25 °C for 1 h and then the gelation was checked visually. Once the gel is formed, it is stable and the tube can be inverted without changing the shape of the gel. The resulting gels were so stable that they were not converted to viscoelastic fluids or crystals even after six months. The minimum gel concentrations of **1** necessary for gelation are summarized in Table 1. Surprisingly, **1** can form physical gels and harden a wide variety of organic fluids, including hydrocarbons, alcohols, ketones, esters, ethers, aprotic polar compounds, aromatic compounds, mineral oils, and edible oils. The only other universal gelling agent of this kind known to date is the octadecylamide of *N*-benzyloxycarbonyl-L-valyl-L-valine.[7] For example, the amounts of **1** necessary to gel one liter of hexane, ethanol, ethyl acetate, acetonitrile, tetrachloromethane, toluene, and *N*,*N*-dimethylformamide are 6 g, 33 g, 8 g, 5 g, 23 g, 12 g, and 10 g, respectively. This means that one molecule of **1** interacts with about 600 molecules of hexane, 200 molecules of ethanol, 600 molecules of ethyl acetate, 1800 molecules of acetonitrile, 200 molecules of tetrachloromethane, 400 molecules of toluene, and 600 molecules of *N*,*N*-dimethylformamide. It is important to note that the corresponding *cis* isomer prepared from *cis*-1,2-diaminocyclohexane forms no gels with any of the liquids. Furthermore, the racemate consisting of **1** and the *S*,*S*-enantiomer **2** only formed an unstable gel, which was converted to cocrystals after several hours, though **2** itself revealed the same gelation behavior as **1**. The introduction of a hydrophobic group longer than hexanoyl into (1*R*,2*R*)-(−)-1,2-diaminocyclohexane is essential for gelation, since gels fail to form when the chain of the lipophilic tail group is shortened to four carbon atoms.

Table 1. Minimum gel concentration *c* of **1** (in g per L solvent) necessary for gelation at 25 °C.

Solvent	*c* (**1**)	Solvent	*c* (**1**)
hexane	6	1,4-dioxane	12
cyclohexane	11	benzene	20
methanol	20	toluene	12
ethanol	33	chlorobenzene	22
1-propanol	44	nitrobenzene	12
2-propanol	40	dimethylsulfoxide	12
ethyl acetate	8	N,N-dimethylformamide	10
acetone	10	N,N-dimethylacetamide	11
2-butanone	15	soybean oil	7
cyclohexanone	13	kerosene	7
acetonitrile	5	light oil	8
pyridine	25	silicone oil	2
tetrachloromethane	23	liquid paraffin	3

The FT-IR spectrum of a cyclohexane gel formed by **1** or **2** is characterized by broad bands at 3279 and 1637 cm^{-1}, which are assigned to N–H and C=O intermolecular hydrogen bonding stretching vibrations, respectively. The FT-IR spectrum of **1** in KBr also contains bands in these regions at 3286 and 1638 cm^{-1}, indicating the presence of similar hydrogen bonding. These spectroscopic results are consistent with what one would expect if association by self-complementary intermolecular hydrogen bonding occurs between two equatorially positioned amide units of **1** in both the gel and the solid, thus forming long sequences of hydrogen bonds. The FT-IR spectrum of a homogeneous cyclohexane solution of the *cis* isomer of **1** showed broad bands at 3300 and 1671 cm^{-1}, which can be

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3517-1949 $ 15.00+.25/0

assigned to groups not undergoing hydrogen bonding. The data for the *cis* isomer can be explained by taking into account that macromolecule-like aggregates fail to form because the amide unit in an axial position cannot form hydrogen bonds; thus, the *cis* isomer has no gelation ability.

The sol–gel process of **1** is temperature-dependent; the minimum gel concentrations necessary to form the gel increase with temperature. From the sol–gel phase diagram, in which the minimum gel concentration is plotted against temperature, the thermodynamic parameters[14] for the sol to gel of **1** in toluene are calculated as follows: $\Delta H(40\,^{\circ}C) = -65\,kJ\,mol^{-1}$ and $\Delta S(40\,^{\circ}C) = -160\,J\,K^{-1}\,mol^{-1}$. These values indicate that the enthalpic contribution compensates for the undesirable entropic change in the gelation. The value of ΔH suggests that two hydrogen bonds per molecule are formed when the gel is built up in toluene. The thermodynamic parameters are consistent with the FT-IR spectroscopic findings.

To study the chiral structure of the aggregate in the gel, circular dichroism (CD) spectra were measured. The CD spectra of loose gels (1 mM; 0.0677 wt %) for **1** and **2** in acetonitrile are shown in Figure 1. Importantly, for the interpretation, it was

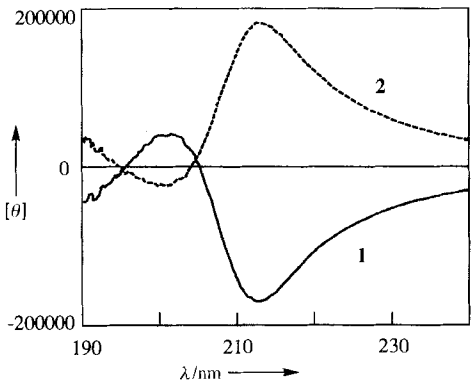

Fig. 1. CD spectra of **1** and **2** in acetonitrile; c (**1**) = c (**2**) = 1.0 mM. The molar ellipticity $[\theta]$ is given in $^{\circ}cm^2\,dmol^{-1}$. $T = 20\,^{\circ}C$.

confirmed that the contributions of linear dichroism (LD) spectra to the true CD spectra were almost negligible. The CD spectrum of **1** at 20 °C exhibited markedly strong peaks for the amide unit: $[\theta]_{201} = +4.20 \times 10^4$ and $[\theta]_{213} = -1.73 \times 10^5\,^{\circ}cm^2\,dmol^{-1}$. The corresponding values for the *S,S*-enantiomer **2** are $[\theta]_{201} = -2.69 \times 10^4$ and $[\theta]_{213} = +1.82 \times 10^5\,^{\circ}cm^2\,dmol^{-1}$. These strong peaks decreased with increasing temperature and disappeared at 50 °C as the loose gel was transformed to an isotropic solution. The disappearance of the CD signal in the isotropic solution led us to conclude that the CD bands originate from a chiral aggregate of **1** and not from a chiral conformation of **1**. Considering that such a much-enhanced CD is derived from exciton coupling among the organized chromophore, the observed CD indicates that the aggregate formed from **1** is cooperatively organized for helical stacking.

The results of CD spectroscopic studies prompted us to investigate the chiral aggregate by electron microscopy. In fact, helical superstructures built up from chiral low molecular weight compounds were observed by electron microscopy[15–19] and optical microscopy.[20, 21] The transmission electron micrographs (TEMs) of a **1**-acetonitrile gel negatively stained by osmic acid are shown in Figure 2. Numerous intertwined aggregates were formed from helical fibers with widths of 40–70 nm. The helicity of fibers was always right-handed for **1**, and left-

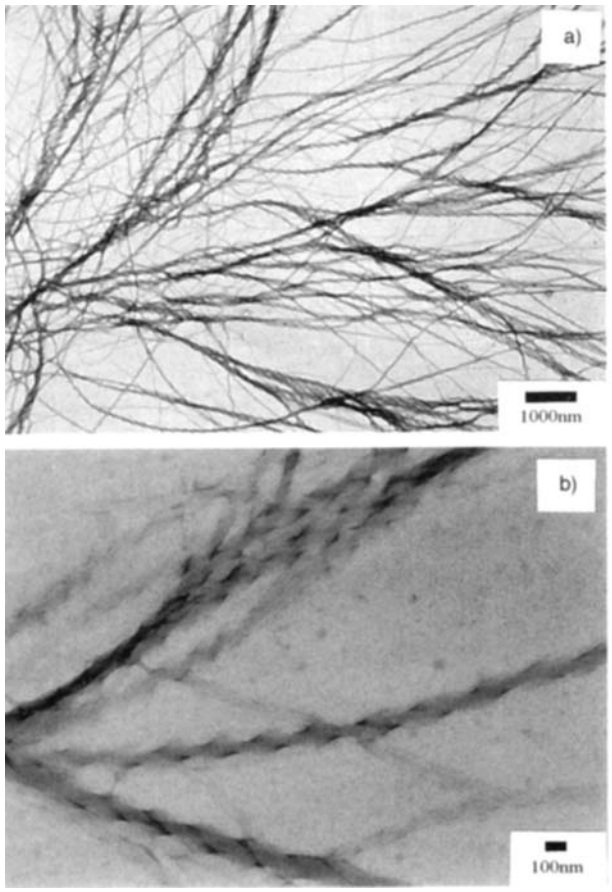

Fig. 2. TEM images of a loose **1**-acetonitrile gel (1 mM **1**) stained by osmic acid. Magnification: a) × 7000, b) × 30000.

handed for the *S,S*-enantiomer **2**. The pitches of the helices in Figure 2 are very similar (ca. 150 nm, Fig. 2b). It is unknown at this time whether the helical fiber observed in the TEM represents the "unit" of helical structure causing the strong CD band.

Molecular modeling studies suggest that the two equatorial amide-NH and amide-CO of **1** can direct themselves antiparallel to each other and perpendicular to the cyclohexyl ring, therefore, an extended molecular tape (for example **3**) stabilized by two intermolecular hydrogen bonds between each molecule is formed. The resulting asymmetric tape may be responsible for the chiral superstructure observed in the CD spectra and the TEM images. It is assumed that the tapelike molecular aggregates are formed by intermolecular hydrogen bonding. Subsequently these are interlocked through van der Waals interactions and transformed to the helical fiberlike aggregates, which finally immobilize the organic fluids.

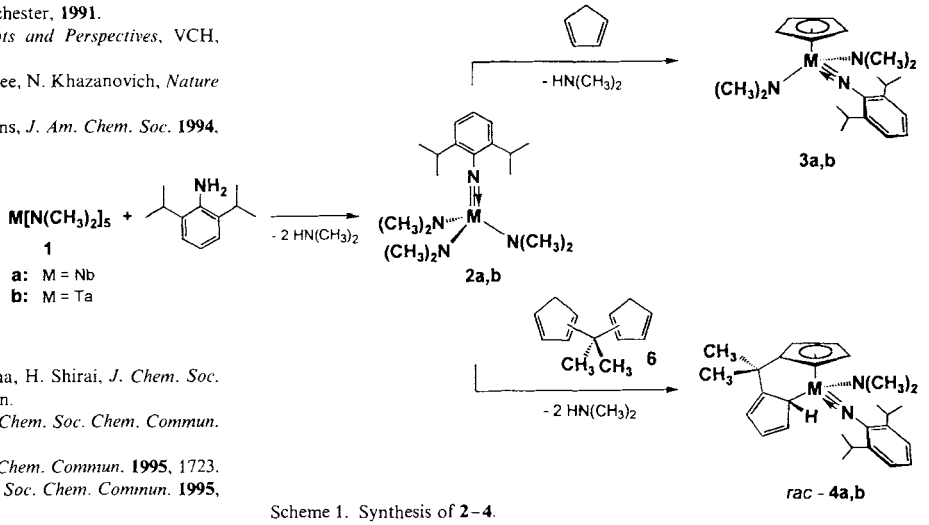

Scheme 1. Synthesis of **2**–**4**.

tion of two equivalents of amine in the reaction of di(2,6-isopropyl)aniline with pentakis(dimethylamido)niobium **1a** and -tantalum **1b** (Scheme 1). The single-crystal X-ray structure analysis of the niobium derivative **2a**[6] exhibits a pyramidal geometry of the NbN_4 core (Fig. 1) with three almost planar metal amide groups. The metal–nitrogen distances reflect the individual bonding situations (Nb–N_{imide}: 179.4(2) pm; Nb–N_{amide}: 197.4(2)–202.3(2) pm).

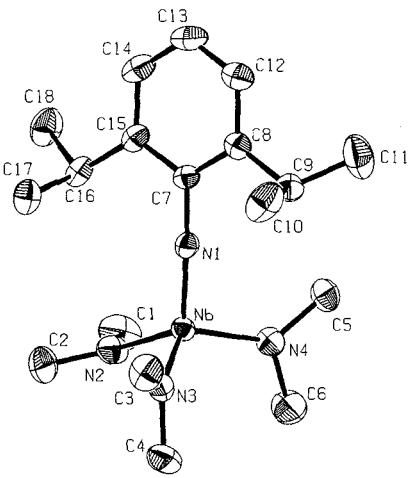

Fig. 1. ORTEP drawing of the crystal and molecular structure of **2a**. Thermal ellipsoids are at the 50% probability level. Selected bond lengths [pm] and angles [°]: Nb–N1 179.4(2), Nb–N2 202.3(2), Nb–N3 197.4(2), Nb–N4 197.9(2); N1-Nb-N2 116.6(1) N1-Nb-N3 108.1(1), Nb-N1-C7 167.4(2).

When the complexes **2a,b** are treated with cyclopentadienyl in toluene, dimethylamine is eliminated and the η^5-cyclopentadienyl complexes **3a,b** are obtained in >70% yield (Scheme 1); cleavage of one further equivalent of amine could not be forced, even with an excess of the CH-acidic ligand.[7]

However, *two* of the amido ligands in **2a,b** can be exchanged for a doubly deprotonated hydrocarbon in boiling toluene by using the diprotic 2,2-bis(cyclopentadienyl)propane (**6**) as ligand precursor (Scheme 1). The resulting products **4a** and **4b** were obtained as orange and yellow crystals, respectively, and proved[8] to be thermally surprisingly stable (decomp. ≫200 °C), but highly sensitive to moisture.

Structure Dynamics in Novel *ansa*-Metallocenes of Niobium and Tantalum**

Wolfgang A. Herrmann,* Walter Baratta, and Eberhardt Herdtweck

Dedicated to Professor Rudolf Taube on the occasion of his 65th birthday

ansa-Metallocenes of zirconium have founded a new era of industrial polyolefin chemistry.[1] However, whereas a large number of zirconocene derivatives have been synthesized since the first publication in this area,[2] most[3] derivatives of the neighboring elements niobium and tantalum have remained unknown. An extended redox chemistry, resulting from the combination of high-valent metals (Nb^V, Ta^V) with π-unsaturated organic ligands, complicates the access to this class of compounds, which serve as possible catalysts for the polymerization of olefins.[4] We report herein on novel niobocene and tantalocene derivatives with bridged cyclopentadienyl ligands and show that additional strong donor ligands are essential for the existence of these compounds.

The new trisamido complexes **2a** and **2b** of the imido-type[5] can be obtained in 79% and 86% yield, respectively, by elimina-

[**] Multiple Bonds between Main Group Elements and Transition Metals, Part 156. This work was generously supported by the Alexander-von-Humboldt-Stiftung (research scholarship for W. B.), the Bayerische Forschungsstiftung (IPDS structure analysis), and the Volkswagenstiftung. Part 155: W. A. Herrmann, J. D. G. Correia, G. R. J. Artus, R. W. Fischer, C. C. Romão, *J. Organomet. Chem.*, in press.

A single-crystal X-ray structure analysis[9] of the niobium derivative **4a** revealed a pseudo-tetrahedral geometry at the Nb center; the structurally most interesting feature is the $\eta^1:\eta^5$ coordination of the metallocene-forming hydrocarbon ligand (Fig. 2). The dimethylamido and the (nearly linearly coordinated) arylimido ligand show no remarkable bonding modes ($\sphericalangle$Nb-N2-C3 = 167.4(1)°), but the *ansa*-ligand forms an asymmetric bridge in which the two bonds to the metal are almost perpendicular to the N1-Nb-N2 plane. One of the cyclopentadienyl rings is π-coordinated (average Nb–C(15–19) distance: 246.3 pm), while the other is η^1-coordinated to the metal (Nb–C27 229.1(2) pm). A crystallographic study of the analogous tantalum compound **4b** confirmed the structural characteristics observed for **4a**.

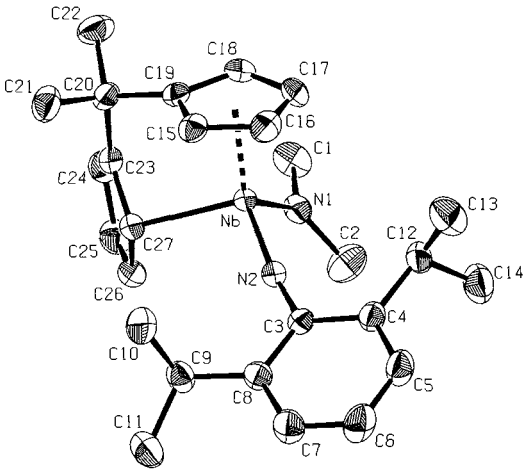

Fig. 2. ORTEP drawing of the crystal and molecular structure of **4a**. Thermal ellipsoids are at the 50% probability level. Selected bond lengths [pm] and angles [°]: Nb–N1 197.4(2), Nb–N2 178.6(2), Nb···C23 289.7(2), Nb···C24 369.0(2), Nb···C25 379.1(2), Nb···C26 308.2(2), Nb–C27 229.1(2), Nb–Cp(centroid) 215.0, N2–C3 138.9(2); N1-Nb-N2 102.13(7), N1-Nb-C27 105.04(7), N2-Nb-C27 102.78(7), Cp(centroid)-Nb-N1 122.4, Cp(centroid)-Nb-N2 119.6, Cp(centroid)-Nb-C27 102.5, Nb-N2-C3 167.4(1). Cp(centroid) corresponds to the calculated center of the π-coordinated ring ligand C(15–19).

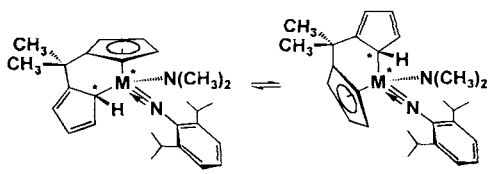
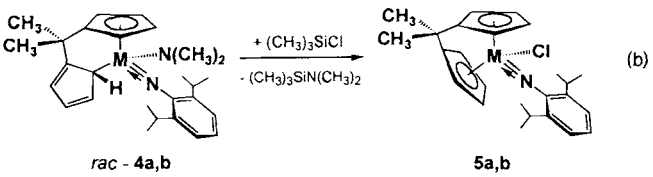
The η^1-coordinated cyclopentadienyl ligand shows exactly the C–C bond length variations expected for a 1,3-diene system: short distances for C23–C24 and C25–C26, and long distances for the remaining three interligand bonds. The angle formed between the centroid of the planar ring C(23–27) and the single bond (C27–Nb) to the metal center is 111°.

The results of NMR experiments confirmed that the coordination of the *ansa*-ligand was maintained in solution until −80 °C. However, an $\eta^1:\eta^5 \rightleftharpoons \eta^5:\eta^1$ coordination exchange equilibrium was observed with a rather low activation barrier [Eq. (a)] evidently because of the minor changes in the ring geometry associated with the exchange process. The fluctuational equilibration of **4a,b** leads to a (*S,R*)/(*R,S*) racemate.



(a)

Consecutive reactions performed with the metallocenes **4a,b** provoke slight modifications in the coordination, but do not change the overall structure of the complexes. A quantitative amide/chloride exchange is achieved by the use of chlorotrimethylsilane [Eq. (b)]. The resulting complexes **5a,b** exhibit $\eta^5:\eta^5$-metallocene structures (based on NMR spectroscopy, and a single-crystal X-ray structure analysis[10]), which is further proof that the chloro ligand is a poorer π donor than the amido ligand. Treatment of **4a** with $[HNMe_3][B(C_6H_5)_4]$ leads to the new cationic complex $[ansa\text{-}(\eta^5:\eta^5\text{-}C_5H_4\text{-}CMe_2\text{-}C_5H_4)\text{-}Nb(=NR)(HNMe_2)]^+$, which has also been isolated and characterized by ^1H and ^{13}C NMR and FAB-MS.



(b)

rac - **4a,b** **5a,b**

Like the conventional chloro systems, amide derivatives of zirconocene complexes are catalytically active in stereoregular propene polymerization. Therefore, the niobocene and tantalocene complexes described herein for the first time provide realistic prerequisites for catalytic applications. In particular, the use of the readily accessible arylimido complexes **2a,b** as precursors holds promise as a generalized synthetic route to niobocene and tantalocene complexes. Importantly, disadvantages arising from the notorious redox chemistry of homoleptic, high-valent metal amides like **1a,b**[11] are overcome by our synthetic concept.

Experimental Procedure

4a: A solution of 2,2-bis(cyclopentadienyl)propane (480 mg, 2.78 mmol) in toluene (20 mL) was added dropwise to a solution of tris(dimethylamido)(2,6-diisopropylphenylimido)niobium(v) (**2a**) (1092 mg, 2.72 mmol) in toluene (10 mL) at −30 °C. The solution was then allowed to warm up to 20 °C and then heated to reflux for 3 h. The volatiles were removed in vacuo and the oily residue was redissolved in *n*-pentane (6 mL). An orange solid (**4a**) precipitated at −78 °C and was dried in vacuo. Yield 980 mg (74%). The tantalocene derivative **4b** was prepared analogously (yield 59%).

Glycocoating of Oligovalent Amines: Synthesis of Thiourea-Bridged Cluster Glycosides from Glycosyl Isothiocyanates**

Thisbe K. Lindhorst* and Christoffer Kieburg

Many cell adhesion phenomena are based on the specific interactions of carbohydrates and proteins.[1] Important examples include the transfer of leucocytes to areas of acute or chronic inflammation, which is initiated by the interaction of selectins with the sialyl Lewis^x tetrasaccharide,[2] and the phagocytosis of bacteria, which is prompted by carbohydrate–protein interactions.[3] Microbial adhesion is in many cases also dependent on the recognition of carbohydrates on the surface of the host cells by specific lectins.[4] The so-called mannose-binding protein (MBP),[5] an acute phase protein of immune response, recognizes a broad array of oligosaccharide moieties on the surface of bacteria, which it is able to distinguish from its own sugar epitopes.[6] There is even evidence that carohydrate–lectin interactions are a key requirement for processes leading to neuronal outgrowth.[7]

Suitable glycomimetics that are able to compete with or even perform better than the naturally occurring carbohydrate ligands are needed for the elucidation and manipulation of carbohydrate–protein interactions.[8] For this purpose the clustering of glycosides has proved to be advantageous in many instances, as the multipresentation of specific sugar epitopes in one molecule can result in remarkably increased avidities in the adhesion systems examined.[9] This phenomenon has been termed the cluster effect and was first shown for the galectin on hepatocytes.[10] Since then the clustering of glycosides has been examined in particular for the inhibition of the influenza virus hemagglutinin.[11] Copolymerization reactions[12] or telomerizations[13] have often been used to incorporate several oligosaccharides; meanwhile an increasing number of dendrimers has appeared as core molecules for the synthesis of clustered glycosides with exactly defined structures.[14] Recently the clustering of the sialyl Lewis^x tetrasaccharide has been also investigated for the control of leucocyte trafficking.[15]

We have lately described a facile method for the preparation of glycosyl isothiocyanates, which gives access to these versatile carbohydrate derivatives on a multigramm scale.[16] We now demonstrate that glycosyl isothiocyantes are ideally suited for the preparation of cluster glycosides. The ease of the transformation of isothiocyanates and amines to thiourea derivatives can generally be applied to the reaction of glycosyl isothiocyanates with oligovalent, multibranched amines to yield oligoantennary, thiourea-bridged glycoconjugates directly.

We have tested the reaction with the trivalent tris(2-aminoethyl)amine (**1**) and mono- as well as disaccharide glycosyl isothiocyanates of different configurations and obtained the triantennary products in very good yields. The sugar units can be deprotected easily in a Zémplen reaction with sodium methanolate in methanol without attack on the thiourea bridges (Scheme 1). Thus the acetylated *gluco*-, *manno*-, *galacto*-, *cellobio*-, and *lacto*-configurated glycosyl isothiocyanates were

Scheme 1. Reaction of tris(2-aminoethyl)amine (**1**) with glycosyl isothiocyanates to yield triantennary thiourea-bridged cluster glycosides **2**–**6**.

converted in two steps into the tris(2-glycosylthiourea-ethyl)-amines **2**–**6** in overall yields of 70–85%.[17]

The anomeric sugar configuration is determined by the glycosyl isothiocyanate used and does not change during the reaction. However, the base-catalyzed O → N migration of the acyl groups from the acetyl-protected glycosyl isothiocyanates onto the amino termini of the core molecules was troublesome. If the reaction was not carried out carefully enough, only the divalent bis(glycosylthiourea) cluster was formed, while the third amino group was acetylated and therefore blocked. This unwanted side reaction resulted in lower yields and structural defects in the periphery of the cluster. It was suppressed by an appropriate reaction procedure: a diluted solution of the oligovalent core molecule was added dropwise to a solution of the glycosyl isothiocyanate in dichloromethane at reflux temperature.

This method can also be applied to the synthesis of higher branched clusters, in which dendritic polyamines serve as suitable core molecules. These core molecules are easily obtained by the exhaustive Michael addition of methyl acrylate to initial amines and the subsequent amidation of the resulting esters with an excess of ethylenediamine to afford amidoamines. The reiteration of this two step reaction sequence results in the doubling of peripheral animo funtionalities; thus higher branched structures are assembled in each developing generation. This construction principle leads to the so-called PAMAM (polyamidoamine) dendrimers as in the work of Tomalia et al.[18] In this way the hexavalent amine **8** was synthesized from tris(2-aminoethyl)amine (**1**) as well as the tetravalent amine **7** and the next octaantennary generation **9** starting from ethylenediamine.

For the synthesis of bigger clusters we focused on the application of mannosyl isothiocyanate for the coupling reaction, as we were especially interested in clustered mannosides for the investigation of mannose-sensitive adhesion systems.[19] As expected 2,3,4,6-tetra-*O*-acetyl-α-D-mannosyl isothiocyanate reacted easily with the tetrafunctional amine **7** to give the tetraantennary cluster **10**, with the hexafunctional core **8** to yield the hexaantennary conjugate **11**, and with the octavalent dendrimer **9** to afford the octaantennary cluster mannoside **12** in very good yields of 76, 69, and 55%, respectively. The reaction can be carried out following the same basic protocol for a variety of clusters. Bigger clusters have to be dissolved in DMF instead of dichloromethane, and the reaction times lengthened. The purification of all presented products was successfully performed on

silica gel. The acetylated compounds yielded glasses; the water-soluble, deprotected cluster glycosides were obtained as white powders after lyophylization.

All products were examined by means of ^1H and ^{13}C NMR spectroscopy and mass spectrometry. The NMR spectra show a single signal pattern for all sugar units; the ratios of the integrals for these signals and for the signals of the methylene protons of the core are correct for each product as formulated. The NMR spectra of the acetylated clusters were recorded in DMSO, where the required number of NH resonances for every compound were observed between $\delta = 7.2$ and 9.5.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3517-1955 $ 15.00+.25/0

The dynamic behavior of the aliphatic core chains resulted in signal broadening in the ^{1}H NMR spectra of the synthesized cluster glycosides, especially for the thioamide protons, the methylene peaks of the core region, and the anomeric protons of the sugar antennae. For the same reason some signals in the ^{13}C spectrum, for example the signals related to the methylene groups were hardly or not at all detected when the spectrum was recorded at room temperature. These effects were less intense for the deprotected compounds and when D_2O was used as the solvent. High-temperature measurements led to an improved resolution of the multiplets in the ^{1}H NMR and to the detection of the complete signal pattern in the carbon spectrum (Table 1). In the case of the octaantennary compound **12**, the methylene carbon atoms of the central ethylenediamine moiety can only be seen with a highly concentrated sample.

MALDI-TOF mass spectrometry was a well-suited method for the mass analysis of the largest cluster **12** (M_r = 3199.69 g mol^{-1}). The protonated molecular ion peak was the only signal in the MALDI-TOF MS spectrum of **12**.

We have shown here that glycosyl isothiocyanates can be linked with dendritic polyamines to give thiourea-bridged cluster glycosides with defined structures. The method requires simple starting materials, two reaction steps only, and easily permits the variation of the carbohydrate epitopes, as well as the number of branches, by choice of different core molecules. It facilitates the rapid preparation of cluster glycosides of different kinds on a multigramm scale.

Experimental Procedure

12: A solution of generation 1 PAMAM dendrimer **9** (40 mg, 0.028 mmol) in DMF (10 mL) was added dropwise to 2,3,4,6,-tetra-*O*-acetyl-α-mannopyranosyl isothiocyanate (122 mg, 0.31 mmol, 11.2 equiv) in dichloromethane (50 mL) at reflux temperature. It was stirred at reflux for 6 h, then the solvent was removed by distillation, and the residual syrup was purified by flash column chromatography (silica gel 0.04–0.063 mm; CH_2Cl_2/MeOH, 9/1). The acetylated reaction product was dissolved in dry methanol (80 mL), and the solution was adjusted to pH 8–9 with a freshly prepared 1 N sodium methanolate solution. The reaction mixture was stirred at 40 °C until the reaction was complete, then it was neutralized with ion exchange resin (Dowex, H^+ W50x8), and the ion exchanger was filtered off and washed with water. The resulting solution was distilled to remove the methanol and lyophilization. The octaantennary cluster mannoside **12** was obtained as a white lyophilizate (49 mg, 0.015 mmol).

[19] In collaboration with the research center in Borstel we are currently testing the dependence of the inhibitory properties of cluster mannosides in the agglutination of type 1 fimbriae from *Escherichia coli* and yeast cells on the structure and number of antennae of the examined compounds (cf. N. Firon, S. Ashkenazi, D. Mirelman, I. Ofek, N. Sharon, *Infect. Immun.* **1987**, *55*, 472–476). In addition, cluster mannosides are needed for the investigation of the biological functions of glycoproteins from the CD66 gene cluster (cf. S. L. Sauter, S. M. Rutherford, C. Wagener, J. E. Shively, S. A. Hefta, *J. Biol. Chem.* **1993**, *268*, 15510–15516).

Synthesis of a Water-Soluble Conjugated [3]Rotaxane**

Sally Anderson* and Harry L. Anderson*

Organic molecules with extended conjugated π-systems have many potential applications, for example as dyes for nonlinear optics and in electroluminescent displays.[1] However, the small HOMO–LUMO energy gaps that are responsible for the special electronic properties of these compounds also make them reactive, so chemical instability often limits the usefulness of

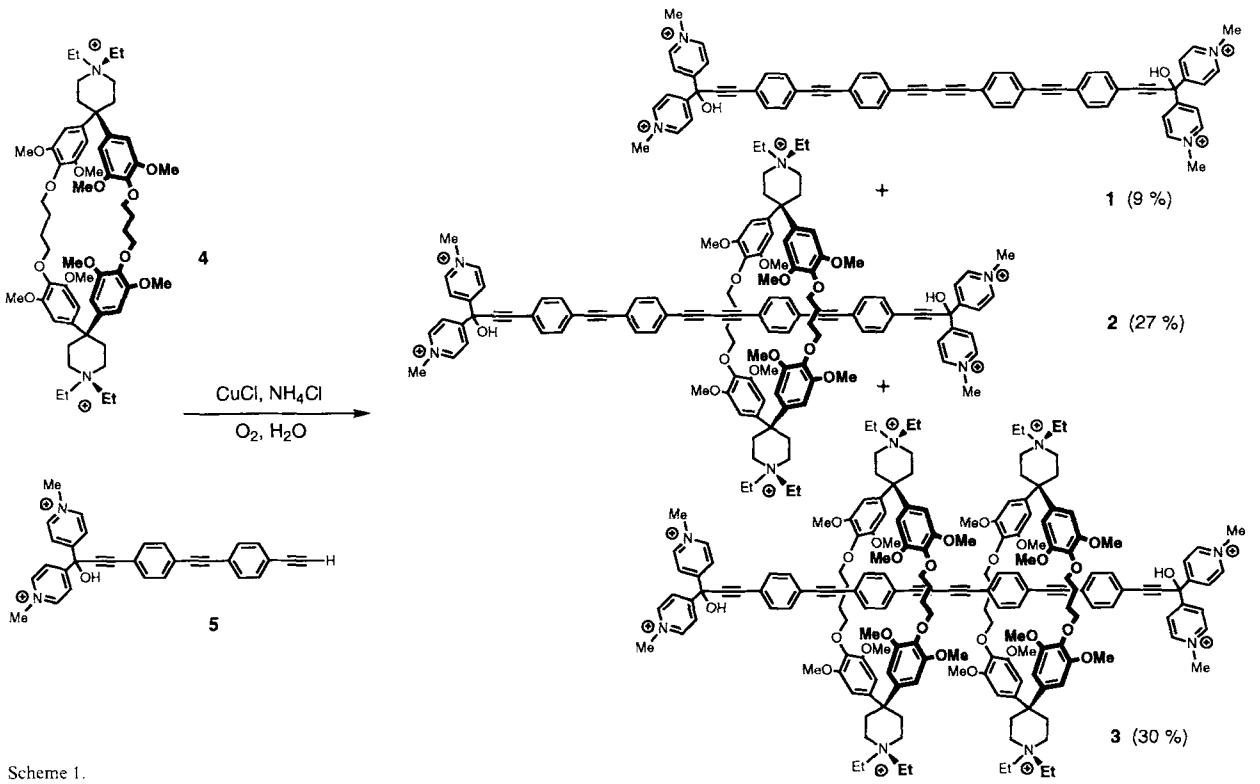

Scheme 1.

these materials. The threading of a conjugated dumbbell through one or more macrocycles to form a rotaxane should protect the π-system from attack. Rotaxane formation may also protect the excited state of the chromophore from quenchers and thus increase its fluorescence efficiency, which could be relevant to electroluminescent applications. Here we present a synthetic approach to conjugated rotaxanes in which the hydrophobic effect is used to direct rotaxane formation. Comparison of the "naked" dumbbell **1** with its [2]rotaxane **2** and [3]rotaxane **3** shows that threading macrocycles increases its fluorescence yield.

Many rotaxanes have been synthesized[2] but this is the first synthesis of rotaxanes with conjugated backbones.[3] We chose to use the hydrophobic effect to direct the formation of our rotaxanes because, as most of the monomers used for synthesizing conjugated structures are hydrophobic, this avoids the need to build specific binding sites into our components. Many water-soluble macrocycles bind 1,4-disubstituted benzenes in water.[4] We chose to use Diederich's cyclophane **4** because of its convenient solubility, binding properties, and synthesis.[5] Our approach was to couple the stopper **5**[6] in the presence of one equivalent of **4** as shown in Scheme 1.

^{1}H NMR titrations showed that **5**·2Cl forms a stable complex with macrocycle **4**·2Cl in water, despite the fact that both units are dications.[7] Complexation is accompanied by large upfield shifts in the ^{1}H NMR signals of the aromatic protons of **5** ($\Delta\delta_{sat}$ = 0.13, 0.49, 1.72, and 2.04 ppm for H_C, H_D, H_F and H_G; for assignments see Fig. 1). In contrast, the pyridine resonances are not significantly shifted ($\Delta\delta_{sat} < 0.015$ ppm), indicating that only the phenylene ethynylene region of **5** binds inside the cavity of the cyclophane. Job plot analysis confirmed the 1:1 stoichiometry. The binding constant at 298 K is $(4.1 \pm 0.5) \times 10^4\ M^{-1}$. Titrations at several temperatures between 298 and 348 K gave a linear van't Hoff plot with ΔH and $T\Delta S_{298}$ of 12 and 6 kcal mol^{-1}, respectively, showing that the hydrophobic binding is enthalpically driven as is typical for receptors of this type.[5, 8]

Glaser coupling[9] of a 1:1 mixture of **5** and **4** at 3 mM concentration in water (Scheme 1) gave a product mixture containing 38% [3]rotaxane **3**, 36% [2]rotaxane **2**, and 26% dumbbell **1**.[10] These compounds were isolated after chromatography and recrystallization as PF_6^- salts in yields of 30, 27, and 9%, respectively. The ratio of [3]rotaxane to dumbbell is less than that predicted based on the stability of the **4**·**5** complex; its binding constant of $4.1 \times 10^4\ M^{-1}$ implies that at 3 mM concentration 91% of the stoppers should be bound to cyclophane, whereas the yields indicate that only 56% of the stoppers are bound to **4** when they couple. This implies that binding under coupling conditions is weaker than in pure water or that free **5** couples faster than the **4**·**5** complex.

The structures of the [3]rotaxane **3** and the [2]rotaxane **2** were established by mass spectrometry and by ^{1}H and ^{13}C NMR spectroscopy (Table 1). The electrospray ionization mass spectrum (ESI-MS) of **3**·8PF_6 in acetonitrile shows peaks at *m/z* 360.2, 411.5, and 479.9 due to M^{8+}, $(M - H)^{7+}$, and $(M - 2H)^{6+}$, as well as a peak at *m/z* 500.5 due to $\mathbf{4}^{2+}$ formed by fragmentation of **3** during electrospray ionization.[11]

The ^{1}H NMR spectrum of the [3]rotaxane **3**·8Cl in D_2O (Fig. 1) was fully assigned by NOESY and COSY experiments. Many NOEs were observed within the dumbbell, within the cyclophane, and between the two components;[12] some of these are illustrated in Figure 1. Both the NOEs and the large upshield shift of the $H_{F/G}$ resonance ($\Delta\delta$ = 1.97 ppm) show that the cyclophanes prefer to reside on the central phenylene rings, away from the stoppers. The rims of the cyclophane are nonequivalent in **3** so the diastereotopic protons of the methylenes in the $O(CH_2)_4O$ chain, such as H_N, give pairs of multiplets. However, the aromatic H_E and methoxy H_I protons of the cyclophane give rise to singlets at room temperature, showing that the aromatic rings of the cyclophane are rotating fast on the

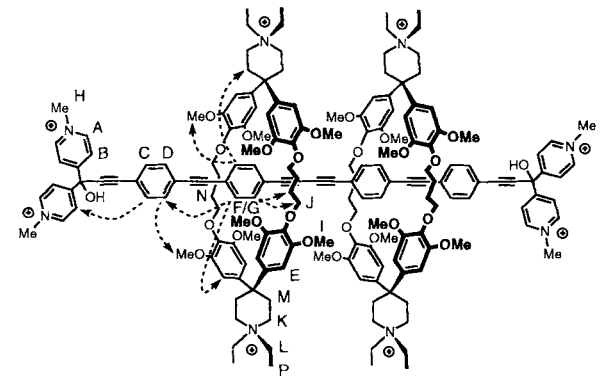
[a] Signal hidden by solvent resonance. [b] Two overlapping signals.



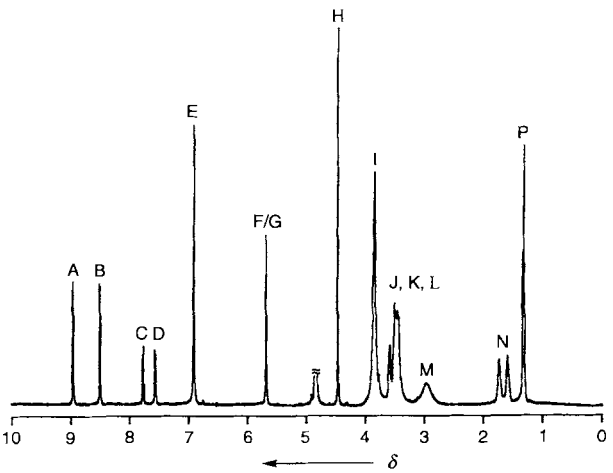


Fig. 1. 500 MHz ^{1}H NMR spectrum of **3**·8Cl in D_2O. The broken arrows indicate some negative NOEs that were important for the structure assignment. The truncated peak is due to HOD.

chemical shift timescale. At 278 K this process is slow and split signals are observed. In the ^{1}H NMR spectrum of the [2]rotaxane **2** the rims of the cyclophane are equivalent and there are only two phenylene environments, which implies that the cyclophane shuttles rapidly along the dumbbell at room temperature;[13] the signals are broader at 278 K but the shuttling process does not go into slow exchange.[14]

The electronic absorption and emission spectra of **1**, **2**, and **3** are compared in Figure 2. The absorption spectra in the 300–400 nm region are very similar because the cyclophane does not absorb significantly at wavelengths greater than 250 nm.

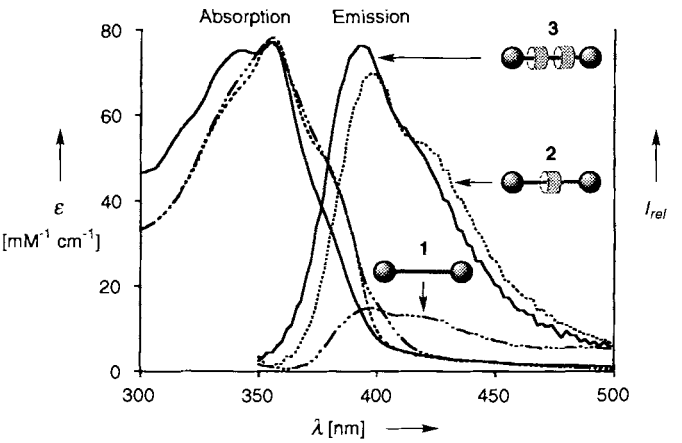

Fig. 2. UV absorption and emission (excitation 300 nm) spectra for **3**·8Cl (– –), **2**·6Cl (· · ·), and **1**·4Cl (– · · · –) in water at 20 °C at 1.0 μM concentration.

All three compounds show emission at around 400 nm when they are excited at 300 nm, but the emission intensity of **3** and **2** is about six times greater than that of **1**. The presence of the cyclophane rings in these rotaxanes appears to increase the fluorescence efficiency of the dumbbell by hindering quenching and increasing the kinetic stability of the excited state.[15] We plan to apply this methodology to synthesize conjugated polyrotaxanes as "insulated molecular wires", in which the macrocycles increase the kinetic stability of the ground state.

Experimental Procedure

1, **2**, and **3**: A solution of **4**·2Cl (210 mg, 0.196 mmol) and **5**·2Cl (100 mg, 0.196 mmol) in water (15 mL) was added to a solution of copper(I)chloride (12.9 g, 0.13 mol) and ammonium chloride (20.92 g, 0.39 mol) in water (50 mL), and the mixture was stirred under oxygen for 48 h [9]. The reaction was quenched by the addition of hydrochloric acid (50 mL, 2 N). NH_4PF_6 was added to the resulting green solution until no further precipitation occurred, and the solid product was collected by centrifugation. The crude product mixture was analyzed at this stage [10], and the three components were separated by flash column chromatography on silica eluting with methanol/2 N aqueous ammonium chloride/nitromethane [13] (7:2:1 v:v) for dumbbell **1** and [2]rotaxane **2**. The polarity was increased to methanol/2 N aqueous ammonium chloride/nitromethane (5:3:2 v:v) to elute the [3]rotaxane **3**. Each fraction was then treated with excess NH_4PF_6 to precipitate the cationic product. Each product was then recrystallized from methanol/acetone (1:1) by layering with diethyl ether, and then dried under vacuum to yield [3]rotaxane **3**·8PF 120 mg (30%), **2**·6PF_6 57 mg (27%), and dumbbell **1**·4PF_6 13 mg (9%).

[9] Our Glaser coupling conditions are derived from those of J. B. Armitage, E. R. H. Jones, M. C. Whiting, *J. Chem. Soc.* **1952**, 2014–2018.

[10] The ratios of **1**:**2**:**3** were determined by integration of the ^{1}H NMR spectrum of the crude reaction mixture. No other products were detected.

[11] The amount of fragmentation of **3** to give **4** increased with increasing cone voltage. ESI MS measurements were carried out on a VG-Bio Q instrument. We are very grateful to Dr R. T. Aplin for recording these mass spectra.

[12] The NOEs from H_C to H_B and from H_D to $H_{F,G}$ were small and could be detected reliably only with a double pulsed field gradient spin echo-Gradient NOESY experiment. We are very grateful to Dr T. D. W. Claridge for measuring these spectra.

[13] This behavior contrasts with that of some of Stoddart's molecular shuttles, which exhibit slow translational isomerism: D. B. Amabilino, P.-L. Anelli, P. R. Ashton, G. R. Brown, E. Córdova, L. A. Godínez, W. Hayes, A. E. Kaifer, D. Philp, A. M. Z. Slawin, N. Spencer, J. F. Stoddart, M. S. Tolley, D. J. Williams, *J. Am. Chem. Soc.* **1995**, *117*, 11142–11170.

[14] The ^{1}H NMR spectra of **2**·6Cl in [D$_4$]methanol give evidence of fast exchange down to 193 K. Cyclophane aryl rotation in **3**·8PF$_6$ in [D$_4$]methanol/[D$_6$]acetone gives rise to fast exchange evident in ^{1}H NMR spectra down to 233 K. The dynamic behavior of both rotaxanes is diminished in water due to hydrophobic binding between the cyclophane and the dumbbell.

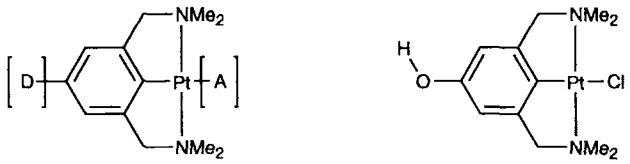
[15] The fluorescence yields of **1**·4Cl, **2**·6Cl, and **3**·8Cl in water were measured by comparison with anthracene in cyclohexane as 0.04, 0.2, and 0.2%, respectively. See: *CRC Handbook of Organic Photochemistry*, (Ed.: J. C. Scaiano), CRC Press, Boca Raton **1989**. These quantum yields are independent of concentration for concentrations of less than 5 μM. The enhanced fluorescence of these rotaxanes appears to be similar to that of cyclodextrin complexes. See R. Corradini, A. Dossena, R. Marchelli, A. Panagia, G. Sartor, M. Saviano, A. Lombardi, V. Pavone, *Chem. Eur. J.* **1996**, *2*, 373–381; M. Hoshino, M. Imamura, *J. Phys. Chem.* **1981**, *85*, 1820–1823; F. Cramer, W. Saenger, H.-C. Spatz, *J. Am. Chem. Soc.* **1967**, *89*, 14–20.

Organoplatinum Building Blocks for One-Dimensional Hydrogen-Bonded Polymeric Structures

Philip J. Davies, Nora Veldman, David M. Grove, Anthony L. Spek, Bert T. G. Lutz, and Gerard van Koten*

The exploitation of the hydrogen bond in the assembly of molecules in the solid state is a topic of current interest.[1] Crystal packing of molecules can take place in a very precise manner, since the hydrogen bonds introduce a high degree of directionality and confer unique properties on the resulting molecular material.

We set out to synthesize organoplatinum complexes possessing hydrogen-bond donor (D) and hydrogen-bond acceptor (A) groups at either end of the molecule, separated by a rigid aryl spacer (**1**, Fig. 1). These features could then promote self-orga-



1 **2**

Fig. 1. Complex **2** possesses both hydrogen-bond donor [D] and hydrogen-bond acceptor [A] groups.

nization in the solid state through intermolecular hydrogen bonding to form a self-assembled organometallic polymeric structure containing directed, noncovalent bonds. Here we present primarily the synthesis and solid-state structure of the *para*-hydroxyaryldiamineplatinum complex **2**. This complex has all the properties required for the formation of intermolecular hydrogen bonds, namely a *para*-hydroxyl group and a potential hydrogen bond acceptor in the chloride ligand.

The synthetic strategy relies on initial synthesis of the required organic ligand (**3**) (Scheme 1) in which the hydroxyl group is protected as its *tert*-butyldimethylsilyl (TBDMS) ether.[2] The ligand **3** was isolated in 45% yield based on the starting compound, 5-hydroxyisophthalic acid.

Reaction of **3** with *n*-butyllithium in hexane afforded **4** (Scheme 2) in which exclusively the position *ortho* to both CH_2NMe_2 arms was lithiated. This was established by quenching a sample of the lithiated compound with D_2O and deducing the position of deuterium incorporation by ^{1}H NMR spectroscopy. We propose a dimeric structure for **3** in both the solid state and in solution, based on studies of similar species.[3]

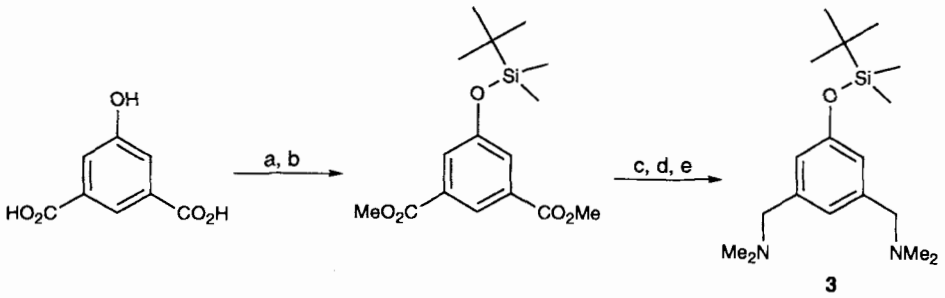
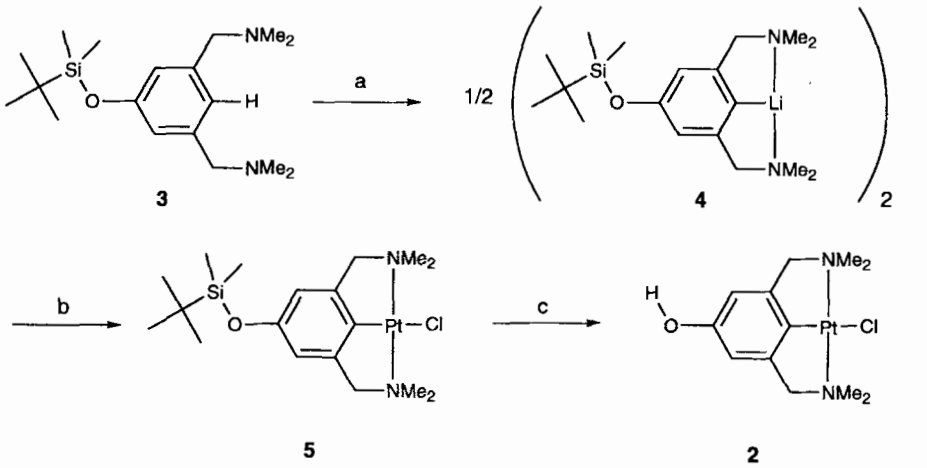


Scheme 1. Synthesis of the TBDMS-protected aryldiamine ligand **3** [2b]. a) MeOH, H_2SO_4, Δ; b) *t*BuMe$_2$SiCl, NEt_3, THF, Δ; c) $LiAlH_4$, Et_2O; d) $MeSO_2Cl$, NEt_3, CH_2Cl_2, Δ; e) $NHMe_2 \cdot HCl$, NEt_3, DMF.



Scheme 2. Lithiation, transmetalation, and deprotection of the aryldiamine ligand **3**. a) *n*BuLi, C_6H_{14}, −78 °C; b) $[PtCl_2(SEt_2)_2]$, Et_2O; c) NBu_4F, THF, H_2O.

Transmetalation of **4** with $[PtCl_2(SEt_2)_2]$ afforded the protected aryldiamineplatinum complex **5**. Reaction of **5** with tetrabutylammonium fluoride trihydrate in THF/water then afforded the *para*-hydroxyaryldiamineplatinum complex **2**.

Complex **2** self-assembles to form, in the solid state, neutral, linear, regularly repeating, one dimensional arrays through the formation of intermolecular hydrogen bonds from the phenolic hydrogen atom to the chloride ligand of an adjacent molecule of **2** (Fig. 2).[4] A cooperative hydrogen bonding motif in which oxygen acts as both hydrogen bond donor and acceptor is not observed. All aryldiamineplatinum molecules align in the same direction in each polymer chain as a consequence of the hydrogen bonding. An equal number of individual polymer chains are, however, oriented in opposite directions, and macroscopic directionality throughout the whole crystal is therefore cancelled out. The hydroxyl hydrogen atom was located in the difference Fourier map and included in the refinement. The environment around the oxygen atom has been examined for close C–H···O contacts, and none shorter than 2.600(14) Å (O1···H9b) were found, that is, only one type of hydrogen bond motif is present. Variable-temperature infrared spectroscopic studies of **2** have been carried out to obtain further insight into the nature of the intermolecular hydrogen bonding. In the solid state at ambient temperature (296 K, Poflu mull) an O–H stretching band at 3284 cm^{-1} shows a red-shift upon cooling (3277 cm^{-1} at 180 K and 3270 cm^{-1} at 87 K), a phenomenon characteristic of hydrogen bonding (Fig. 3).[5] This temperature effect is due to a strengthening of the intermolecular hydrogen bond on cooling with concomitant weakening of the O–H bond. Shoulders on each side of the OH band originate from coupling interactions with lattice vibrations, which occur at low wavenumber (<150 cm^{-1}).[6] Upon cooling, the intensities of the shoulders decrease and that of the O–H mode increases significantly; this behavior is characteristic of hydrogen bonding. An IR spectrum of **2** in chloroform solution at 296 K shows a non-hydrogen-bonded O–H mode at 3598 cm^{-1}, which can be assigned to an unassociated phenolic hydroxyl group.[7] In this spectrum there is also a residual hydrogen-bonded O–H mode at 3284 cm^{-1}. This indicates that, even in solution, there is a degree of hydrogen bonding present that can lead to the formation of dimers or higher oligomers. It is possible to calculate an approximate hydrogen-bond enthalpy (ΔH°) from the difference in stretching frequency between the O–H bond observed in the solution spectrum and that in the solid-state spectrum;[8] the value of −22.7 kJ mol^{-1} obtained is indicative of a moderately strong hydrogen bond.

Here we have demonstrated the usefulness of the intermolecular hydrogen bond in the self-assembly of an organometallic compound in the solid state to form one-dimensional polymeric structures. Research is currently in progress to introduce chiral, identi-

cally configurated substituents into the aryldiamine skeleton to give a noncentrosymmetric space group on crystallization, as this could give rise to desirable macroscopic properties such as optical nonlinearity.

Experimental Procedure

2: Tetrabutylammonium fluoride trihydrate (0.076 g, 0.24 mmol) was dissolved in THF (20 mL). The chloroplatinum compound **5** (0.131 g, 0.24 mmol) was added as a solid, and the mixture was stirred for 2 h at room temperature. Water (0.2 mL) was then added, and the reaction mixture stirred at room temperature for another 12 h. The precipitate that formed was collected by filtration, washed with hexane, and dried in vacuo to yield a colorless solid (0.060 g, 58%). A water-free sample for elemental analysis was obtained by drying the sample in vacuo over calcium oxide. Single crystals suitable for X-ray crystallography were grown by slow evaporation of a solution of **2** in dichloromethane/dimethylsulfoxide. Elemental analysis: calcd for $C_{12}H_{19}ClN_2OPt$: C 32.92, H 4.37, N 6.40%; found: C 33.06, H 4.42, N 6.36%; ^{1}H NMR (200 MHz, [D$_1$]chloroform/[D$_6$]DMSO, 25 °C, TMS): $\delta = 2.55$ (s, ^3J(Pt,H) = 37.4 Hz, 12H, NMe_2), 3.49 (s, ^3J(Pt,H) = 45.8 Hz, 4H, CH_2), 5.88 (s, 2H, aromatic), 8.00 (s, 1H, OH); ^{13}C NMR (50 MHz, [D$_1$]chloroform/[D$_6$]DMSO, 25 °C, TMS): $\delta = 154.3$ (C_{para}), 143.4 (^2J(Pt,C) = 81.0 Hz, C_{ortho}), 133.1 (^1J(Pt,C) not observed, C_{ipso}), 106.7 (^3J(Pt,C) = 38.3 Hz, C_{meta}), 77.3 (^2J(Pt,C) = 62.0 Hz, CH_2), 54.0 (^2J(Pt,C) = 15.0 Hz, NMe_2).

[4] Crystal data for **2**: $C_{12}H_{19}ClN_2OPt$, $M_r = 437.83$, colorless, transparent, needle-shaped crystals (0.63 × 0.05 × 0.05 mm), orthorhombic, space group $Pna2_1$ (no.33) with $a = 24.2238(14)$, $b = 10.1986(8)$, $c = 5.4483(14)$ Å, $V = 1346.0(4)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.161$ g cm^{-3}, $F(000) = 832$, $\mu(Mo_{K\alpha}) = 106.1$ cm^{-1}, 6631 reflections measured, 2936 independent ($1.7° < \theta < 27.5°$, ω scan, $\Delta\omega = 0.87 + 0.35 \tan\theta$, $T = 150$ K, $Mo_{K\alpha}$ radiation, graphite monochromator, $\lambda = 0.71073$ Å) on an Enraf-Nonius CAD4-T diffractometer on a rotating anode. Data were corrected for Lorentzian polarization and for a linear decay of 8% of the reference reflections (212, 220, 2$\bar{2}$0) during 13 h of X-ray exposure time; empirical absorption correction (DIFABS) applied as implemented in PLATON (transmission range 0.579–1.000). The structure was solved by Patterson methods and subsequent difference Fourier techniques (DIRDIF-92). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93); no observance criterion was applied during refinement. Final $R1$ value 0.0376, for 2340 reflections with $F_o > 4.0\sigma(F_o)$, $wR2 = 0.0793$ for 2934 data, $w = 1/[\sigma^2(F_o^2) + (0.0311P)^2]$, where $P = (\mathrm{Max}(F_o^2, 0) + 2 \times F_c^2)/3$, $S = 1.024$, for 161 parameters. Maximum and minimum residual density: 0.84, −1.08 e Å^{-3}. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined with a fixed isotropic thermal parameter related to the value of the equivalent isotropic thermal parameter of their carrier atoms, by a factor of 1.5 for the methyl groups, and 1.2 for the other hydrogen atoms. The hydroxyl hydrogen was found in the difference Fourier map and allowed to refine freely. Weights were refined in the final refinement cycles. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-70. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: Int. code Int. +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).

[5] Infrared studies have also been carried out on a KBr disc. In this case, partial halogen exchange occurs as evidenced by the appearance of a new O–H band at 3309 cm^{-1} (90 K), which was assigned to the Pt-Br···H–O hydrogen bond motif; the intensity of this new band increases as a function of the grinding time. This phenomenon does not, however, occur with KCl discs, which is in accord with the proposed explanation. The shift to higher wavenumber relative to the Pt–Cl···H–O motif indicates that the hydrogen bond to bromide is weaker.

Coordination Chemistry of Polyoxometalates: Rational Synthesis of the Mixed Organosilyl Derivatives of Trivacant Polyoxotungstates α-A-$[PW_9O_{34}(t\mathrm{BuSiO})_3(\mathrm{RSi})]^{3-}$ and α-B-$[AsW_9O_{33}(t\mathrm{BuSiO})_3(\mathrm{HSi})]^{3-}$**

Agnès Mazeaud, Najib Ammari, Francis Robert, and René Thouvenot*

Derivatized polyoxometalates are expected to play an increasingly greater role in catalysis, chemotherapy, and molecular science.[1] In particular, heteropolyoxometalates with an organic, organometalloid, or organometallic group anchored to the oxometalate backbone are attractive precursors for the synthesis of organic–inorganic hybrid materials. They were among the very first organometallic derivatives of polyoxometalates to be reported.[2, 3a, 3b, 4a] A number of organotin derivatives of the Lindqvist,[5] Keggin,[3, 4] and Dawson-type[4] structures have now been characterized. In contrast, organosilicon derivatives have received comparatively less attention. However, "Keggin-type" derivatives of general formula $[SiW_{11}O_{40}(RSi)_2]^{4-}$

(R = Et, $CH{=}CH_2$, $N{\equiv}N(CH_2)_3$, Ph, $C_{10}H_{21}$), in which an $(RSi)_2O^{4+}$ unit replaces a WO^{4+} unit, have been described.[3a, 6] We are currently investigating the reactions of chlorosilanes with trivacant polyoxotungstates.[7] Under phase-transfer conditions, dichlorosilanes, R_2SiCl_2, react with α-A-$[XW_9O_{34}]^{n-}$ ions (X = Si, $n = 10$, X = P, $n = 9$) to give the ions **1** and **2**,

α-A-$[SiW_9O_{34}(R_2Si)_3]^{4-}$ **1a**: R = Me, **1b**: R = Ph

α-A-$[PW_9O_{34}(R_2Si)_3]^{3-}$ **2a**: R = Me, **2b**: R = Ph

respectively, which have been characterized by multinuclear NMR spectroscopy.[7a] The proposed structure with C_{3v} symmetry has been confirmed by the X-ray analysis of $(nBu_4N)_4$-**1a**.[7c] Under similar conditions, reactions with trichlorosilanes, $RSiCl_3$, yield the ions **3** and **4**, respectively. The structure of **3**

α-A-$[SiW_9O_{34}(RSiO)_3(RSi)]^{4-}$ **3a**: R = H, **3b**: R = Me

3c: R = Et, **3d**: R = *n*Bu

α-A-$[PW_9O_{34}(RSiO)_3(RSi)]^{3-}$ **4a**: R = H, **4b**: R = Me

4c: R = Et, **4d**: R = *n*Bu

(C_{3v} symmetry proposed on the basis of a thorough multinuclear NMR study of **3a**)[7b] has been confirmed by the X-ray analysis of α-A-$(nBu_4N)_3(Me_2NH_2)$-**3c**.[7c] These studies have now been extended to some other chlorosilanes, for example $tBuSiCl_3$, and other trivacant polyoxotungstates, for example α-B-$[HAsW_9O_{33}]^{8-}$.

Whereas $nBuSiCl_3$ reacts with α-A-$[PW_9O_{34}]^{9-}$ ions to give **4d**, the analogous reaction with $tBuSiCl_3$ yields only **5** pre-

α-A-$[PW_9O_{34}(tBuSiOH)_3]^{3-}$ **5**

sumably because of steric crowding. The ion **7** has been obtained in a similar manner by reacting $tBuSiCl_3$ with α-B-$[HAsW_9O_{33}]^{8-}$ ions. The two ions **5** and **7** have been characterized by X-ray crystallography as their tetrabutylammonium salts.[8] Both anions display approximate C_{3v} symmetry and the structure of the parent trivacant polyoxotungstate is retained.[9] Each of the three chemically equivalent *t*BuSi(OH) units is attached to the polyoxotungstate backbone through two W-O-Si bridges (Fig. 1). The difference in composition between organosilicon and organotin derivatives, for example α-A-$[PW_9O_{34}(tBuSiOH)_3]^{4-}$ vs. $[\{\alpha\text{-A-}(PW_9O_{34})\}_2(PhSnOH_2)_3]^{9-}$[3d] or $[\{\beta\text{-A-}(PW_9O_{34})\}_2(PhSnOH)_3]^{12-}$[4b] can be ascribed to different coordination preferences between Si and Sn. ^{29}Si and ^{183}W NMR data indicate that the structures of **5** and **7** are maintained in solution (Tables 1 and 2).

The "open-structure" anions **5** and **7** react cleanly with $RSiCl_3$ in DMF to yield **6** and **8**, respectively. In the first case, the

α-A-$[PW_9O_{34}(tBuSiO)_3(RSi)]^{3-}$ **6a**: R = H, **6b**: R = Me, **6c**: R = Et

6d: R = $CH{=}CH_2$,

6e: R = CH_2-CH_2-CH_2Cl

α-B-$[AsW_9O_{33}(tBuSiOH)_3]^{3-}$ **7**

α-B-$[AsW_9O_{33}(tBuSiO)_3(RSi)]^{3-}$ **8a**: R = H

reaction has been monitored by ^{31}P NMR spectroscopy, and the reactivity of $RSiCl_3$ has been seen to decrease in the order: H > Me > Et. The ions **6** and **8** have been characterized by multi-

nuclear NMR spectroscopy (Tables 1 and 2). The ion **6a** provides a typical example. Its ^{29}Si NMR spectrum in solution exhibits two signals with a multiplicity of 3:1 (Fig. 2). The low-frequency doublet (1Si, $\delta = -96.86$, $^{1}J_{Si,H} = 299.7$ Hz) is assigned to the silicon center of the capping group HSi, and the high-frequency signal (3Si, $\delta = -59.06$) appears as a poorly resolved multiplet due to coupling with the nine protons of the *t*Bu group ($^{3}J_{Si,H}$ ca. 6.7 Hz) and to the one H atom of the capping HSi group: this signal reduces to a doublet ($^{3}J_{Si,H} = 3.8$ Hz) in the selectively decoupled spectrum (Fig. 2b).

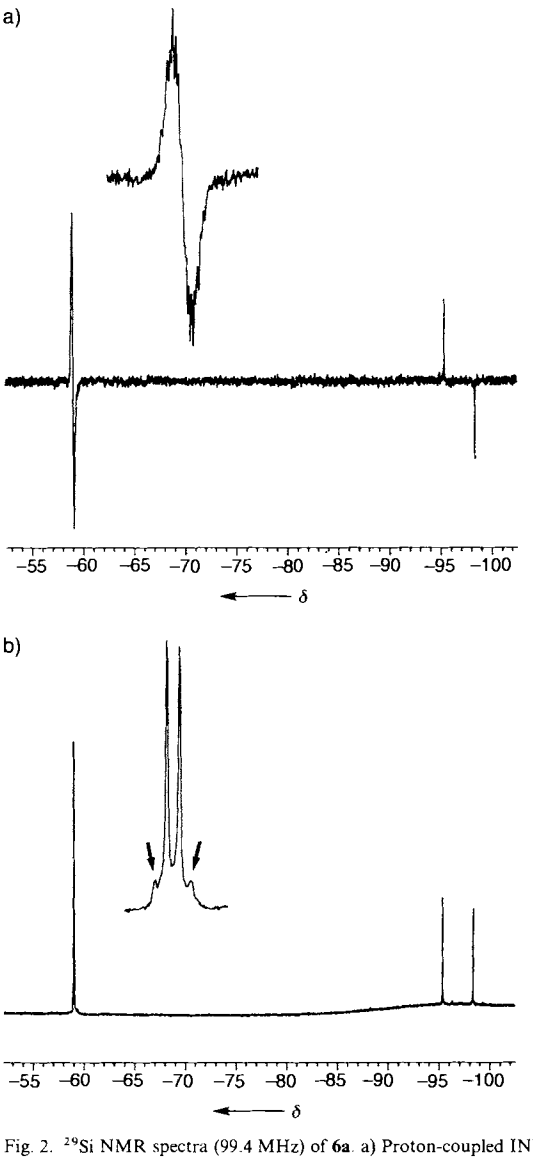

Fig. 2. ^{29}Si NMR spectra (99.4 MHz) of **6a**. a) Proton-coupled INEPT spectrum, with abscissa expansion of the high-frequency *t*BuSi signal. b) Inverse-gated selectively decoupled spectrum, with abscissa expansion of the high-frequency *t*BuSi signal showing the tungsten satellite signals (arrows).

Tungsten satellite signals appear around the high-frequency signal in the proton-decoupled spectrum ($^{2}J_{Si,W}$ ca. 7 Hz). The ^{183}W NMR spectrum of **6a** displays two signals with a multiplicity of 2:1 and a mutual coupling $^{2}J_{W,W}$ of about 22 Hz (Fig. 3); in addition, each line is split into a doublet due to coupling with the phosphorus atom ($^{2}J_{P,W} \approx 1.6$ and 1 Hz, respectively). Taken together these data are consistent with a "closed-structure" with C_{3v} symmetry, similar to that of **3**.[7b]

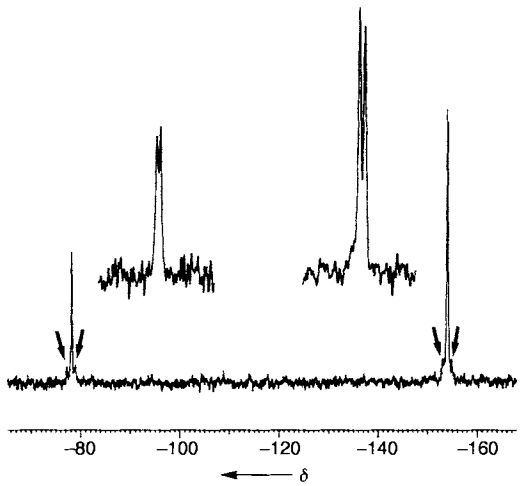

Fig. 3. ^{183}W NMR (12.5 MHz) spectrum of **6a**. Tungsten satellite signals are marked by arrows. The abscissa expansions (after resolution enhancement) clearly show the doublet structure due to the $^{2}J(W,P)$ couplings.

The characterization of **5** and **7**, and the formation of **6** and **8** from **5** and **7**, respectively, support the reaction pathway shown in Scheme 1 for the reactivity of trichlorosilanes with trivacant polyoxotungstates.

$$3\,RSiCl_3 + 9\,H_2O \longrightarrow 3\,RSi(OH)_3 + 9\,HCl$$

$$\alpha\text{-A-}[PW_9O_{34}]^{9-} + 3\,RSi(OH)_3 \longrightarrow \alpha\text{-A-}[PW_9O_{34}(RSiOH)_3]^{3-} + 6\,OH^- \text{ (heterogeneous)}$$

$$\alpha\text{-A-}[PW_9O_{34}(RSiOH)_3]^{3-} + R'SiCl_3 \longrightarrow \alpha\text{-A-}[PW_9O_{34}(RSiO)_3(R'Si)]^{3-} + 3\,HCl \text{ (homogeneous)}.$$

Scheme 1.

These results open up new perspectives in the chemistry of organosilicon derivatives of polyoxotungstates. Indeed, it may be possible to construct interconnected polyoxometalate networks through reaction of "open-structure" species, such as **5** and **7**, with polysilanes. These reactions are currently under investigation.

Experimental Procedure

$(n\text{Bu}_4\text{N})_3$-**5**·0.5 MeCN: To a well-stirred suspension of α-A-$K_9[PW_9O_{34}]\cdot 16H_2O$ [10a] (10 g, 3.48 mmol) in dry MeCN (200 mL) under argon were added solid $n\text{Bu}_4\text{NBr}$ (6 g, 18.6 mmol) and then *t*BuSiCl$_3$ (2.1 g, 10.1 mmol); the mixture was stirred overnight at 0 °C. After separation of the white solid (KCl + KBr), white crystals of $(n\text{Bu}_4\text{N})_3$-**5** formed upon slow evaporation of the resulting solution in an open vessel at room temperature. The crude compound was recrystallized from MeCN. Yield: 7.8 g (67 %). Compound $(n\text{Bu}_4\text{N})_3$-**7** was similarly obtained in 60 % yield from α-B-$K_8[HAsW_9O_{33}]\cdot x H_2O$ [10b].

$(n\text{Bu}_4\text{N})_3$-**6a**: **5** (3 g, 0.91 mmol) was dissolved in dry DMF (10 mL) under argon and $HSiCl_3$ (0.2 mL, 2 mmol) was added. The solution was stirred overnight at room temperature and then was set aside. White crystals of $(n\text{Bu}_4\text{N})_3$-**6a** formed within a few days. Yield: 1.43 g (70 %). $(n\text{Bu}_4\text{N})_3$-**6b**–**e** were similarly obtained from $MeSiCl_3$, $EtSiCl_3$, $CH_2{=}CHSiCl_3$ and $CH_2ClCH_2CH_2SiCl_3$, respectively, and $(n\text{Bu}_4\text{N})_3$-**8a** was similarly prepared by reaction of $HSiCl_3$ on $(n\text{Bu}_4\text{N})_3$-**7**.

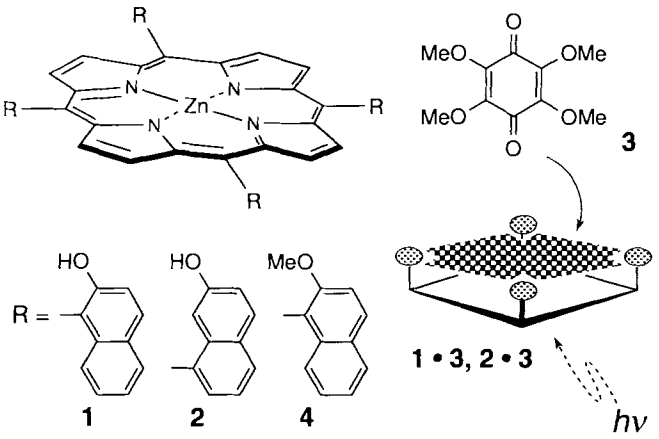
Photoinduced Electron Transfer between Multifunctional Porphyrin and Ubiquinone Analogues Linked by Several Hydrogen-Bonding Interactions**

Takashi Hayashi,* Takashi Miyahara, Shigeichi Kumazaki, Hisanobu Ogoshi,* and Keitaro Yoshihara

In the last decade, electron transfer (ET) has received a great deal of attention due partly to its importance in biological systems. Particularly, the quinone–linker–porphyrin triad seems to be one of the most suitable combinations to elucidate the mechanism of ET, and many unique porphyrin–quinone compounds have been designed and discussed.[1, 2] However, studies on noncovalently linked porphyrin–quinone systems with specific donor–acceptor interactions such as hydrogen bonding remain quite limited,[3, 4] although in nature ET often proceeds in an assembly of several chromophores that are noncovalently connected.[5] Recently we reported the molecular recognition of face-to-face pairing between porphyrin and ubiquinone through several hydrogen bonds.[6] In this paper, we wish to report the intracomplex ET for specific porphyrin–quinone complexes in which weak chemical interactions hold the donor and acceptor in a cofacial orientation.

We prepared two zinc porphyrins, zinc(II) *meso*-α,α,α,α-tetra(2-hydroxy-1-naphthyl)porphyrin (**1**) and zinc(II) *meso*-α,α,α,α-tetra(7-hydroxy-1-naphthyl)porphyrin (**2**) from each free-base porphyrin.[6a, d, 7] The face-to-face interaction between zinc porphyrin and tetramethoxy-*p*-benzoquinone (**3**) has been characterized by ^{1}H NMR and visible absorption spectroscopy,



and these affinities were determined by titrimetric measurement of visible spectra in the region of 550–700 nm which gave clear isosbestic points ($K_a(\mathbf{1}\cdot\mathbf{3}) = 2.5 \times 10^5\ \mathrm{M}^{-1}$ and $K_a(\mathbf{2}\cdot\mathbf{3}) = 2.2 \times 10^3\ \mathrm{M}^{-1}$ in toluene at 298 K). The Stern–Volmer plots indicate efficient fluorescence quenching of **1** and **2** in the low concentration range of quinone ($c(\mathbf{3}) < 5 \times 10^{-3}$ M). In contrast, no fluorescence quenching of zinc(II) *meso*-α,α,α,α-tetra(2-methoxy-1-naphthyl)porphyrin (**4**) was detected in the same concentration range of quinone. These findings indicate that static quenching of fluorescence of **1** and **2** occurs by ET from the photoexcited state to **3** in the face-to-face mode. From CPK molecular models the distances between porphyrin and the quinone rings are estimated to be 3.5 (for **1**·**3**) and 6.0 Å (for **2**·**3**).[8]

The time-resolved fluorescence measurements of **1** and **2** in dry toluene reveal monoexponential decay with a lifetime of 2.0 ± 0.1 and 2.2 ± 0.1 ns, respectively.[9] Figure 1a shows the transient absorption spectra of **1** excited by dye laser pulses (570 nm, fwhm ≤ 3 ps).[10] The spectra display a broad excited state absorption in the 615–750 nm region with a dip at 650 nm due to stimulated emission. These features are characteristic of a zinc porphyrin singlet excited state. There was no substantial change in the spectra recorded with between 5 and 45 ps delays after excitation by a laser pulse, which is consistent with the lifetime of the fluorescence. Qualitatively similar results were obtained for **2**.

The transient absorption spectra of **1** and **2** in the presence of **3** (Fig. 1b) show a significant time-dependent positive absorption at 640 nm, which is distinctly different from those without **3** (Fig. 1a). The spectra are characteristic of zinc porphyrin

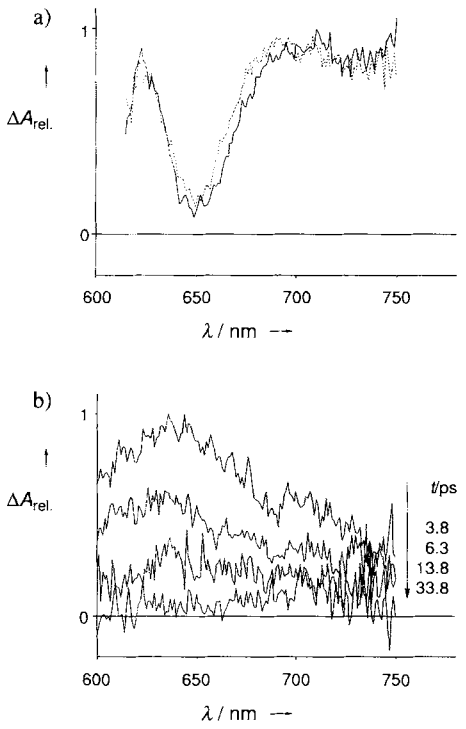

Fig. 1. a) The transient spectra upon excitation (570 nm) of porphyrin **1** in toluene (1.69×10^{-4} M) at 5.0 ps (solid line) and 45.0 ps (broken line) delays. b) Transient spectra of the porphyrin **1** (1.69×10^{-4} M) at 3.8, 6.3, 13.8, and 33.8 ps after excitation at 570 nm in the presence of quinone **3** (8.94×10^{-3} M) in toluene, showing the disappearance of the cation radical.

cation radical.[5b, 11, 12] Immediately after the excitation, the spectra are already free of the dip at 650 nm characteristic of excited state of zinc porphyrin. Forward ET rate constants were estimated to be greater than or equal to 4×10^{11} s^{-1} (limited by the pulse width and signal-to-noise ratio) for both samples. The decays of the radical pairs monitored at 650 nm (Fig. 2)

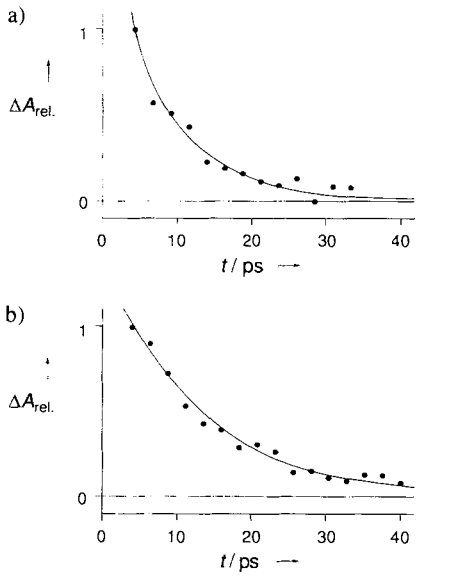

Fig. 2. Transient absorption kinetics after the full rise of the signal at 650 ± 2 nm for **1** (1.69×10^{-4} M) (a) and **2** (2.36×10^{-4} M) (b) in toluene following a 570 nm laser flash in the presence of **3** (concentration for (a) 8.94×10^{-3} M and for (b) 9.33×10^{-3} M).

were fitted to monoexponential curves with time constants of $(1.1 \pm 0.4) \times 10^{11}$ s^{-1} for **1** and $(6.8 \pm 0.3) \times 10^{10}$ s^{-1} for **2**. In contrast, the transient absorption spectra of zinc(II) *meso*-α,α,α,α-tetra(2-methoxy-1-naphthyl)porphyrin (**4**) even in the presence of a large excess of **3** exhibited no radical species (data not shown).

In conclusion, our present work demonstrates the first example of an ET complete in the picosecond range between zinc porphyrin and quinone linked in face-to-face mode by specific noncovalent interaction. The forward and backward ET rate constants in this work are at least as large as those reported in covalently bridged porphyrin–quinone systems.[13] The rate of ET is not limited by diffusion processes of donor or acceptor, and the association by hydrogen bonding seems to be stable during the period of excitation, charge separation, and recombination processes. Further work on the kinetics of ET reaction to elucidate the mechanism by use of different quinones and porphyrins is in progress.

[8] According to the X-ray crystal structure analysis of free base of **1** and **3** complex, the face-to-face distance between the porphyrin and the quinone is 3.3 Å.

[9] The lifetimes were obtained on a Hamamatsu Picosecond Lifetime Measuring System type C4780, Hamamatsu Photonics equipped with a N_2 laser-pumped dye laser, LN100C2, Laser Photonics INC (λ_{ex} = 550 nm).

[10] The measurement system consisting of laser and transient absorption spectrometer was described previously [14]. The excitation laser was operated at 10 Hz, the center wavelength was at 570 nm, and the single pulse energy for excitation was 300–500 μJ. The absorbance change was proportional to the excitation pulse energy in the energy range studied. The sample was flowed by peristatic pumping in a cell (10 mm light path) in which pump and probe pulses overlapped at an angle of 5°. The magic angle polarization condition was selected. No difference was observed in absorption spectra of the sample after the measurement. The instrumental response time, which was measured by 10–90% rise time of oxazine 750 in ethanol, was 5 ± 1 ps.

Reactions of β,γ- and γ,δ-Unsaturated Esters with the Reagent Ti(O*i*Pr)$_4$/2*i*PrMgCl: Formation of β-Titanated Esters, β-Titanated Cyclobutanones, and Acyltitanium Compounds

Aleksandr Kasatkin, Takanori Yamazaki, and Fumie Sato*

Recently, we have found that substituted allylmalonic esters undergo deallylation on treatment with complex **1**,[1] which

$[(\eta^2\text{-}CH_3CHCH)Ti(OiPr)_2]$ **1**

is readily generated in situ from Ti(O*i*Pr)$_4$ and two equivalents of *i*PrMgCl. This reaction thus makes it possible to use the allyl group as a protective group for the acidic hydrogen of malonic esters.[2] The plausible mechanism of the deallylation involves the exchange of the coordinated propene ligand in **1** with an olefinic moiety of the substrate and subsequent β-elimination of malonate carbanion.

With these results in hand, we anticipated that the reaction of **1** with substituted propargylmalonic esters **2** would result in depropargylation.[3] However, treatment of diethyl 2-butynylmethylmalonate (**2a**) with **1** followed by hydrolysis afforded the olefinic ester **3a** in addition to the expected depropargylation product **4** [Eq. (a) and entry 1 in Table 1]. Similarly, diethyl

[a] All reactions were carried out with 2.0 equiv Ti(O*i*Pr)$_4$ and 4.0 equiv *i*PrMgCl in Et_2O between −45 and −40 °C (1 h). [b] Yields of isolated products based on starting unsaturated esters unless stated otherwise. [c] Deuterolysis of the reaction mixture gave the product with > 95% D incorporation. [d] According to ^{1}H NMR data of the crude product using an internal standard. [e] Combined yield of diastereomers according to ^{1}H NMR analysis.

methyl(propargyl)malonates **2b,c** provided mixtures of **4** and the corresponding diethyl α-alkylideneglutarates **3b,c** (entries 2 and 3 in Table 1). This new reductive rearrangement of propargylmalonates into α-alkylideneglutarates can be explained by the mechanism shown in Scheme 1. The titanacyclopropene intermediate **5**[4] generated from **1** and **2** undergoes intramolecular carbonyl addition to give **6**; subsequent cleavage of the cyclobutane ring then gives **7** through elimination of the titanium enolate. The presence of the alkenyltitanium compounds **7** in the reaction mixture was confirmed by deuterolysis to afford doubly deuterated **3a** with >95% D incorporation at both the alkenyl and α-positions (entry 1 in Table 1). Although the yields of **3** are only moderate, the high synthetic utility of the products and the easy access to the starting compounds make this methodology promising.[5] Furthermore, the opportunity for

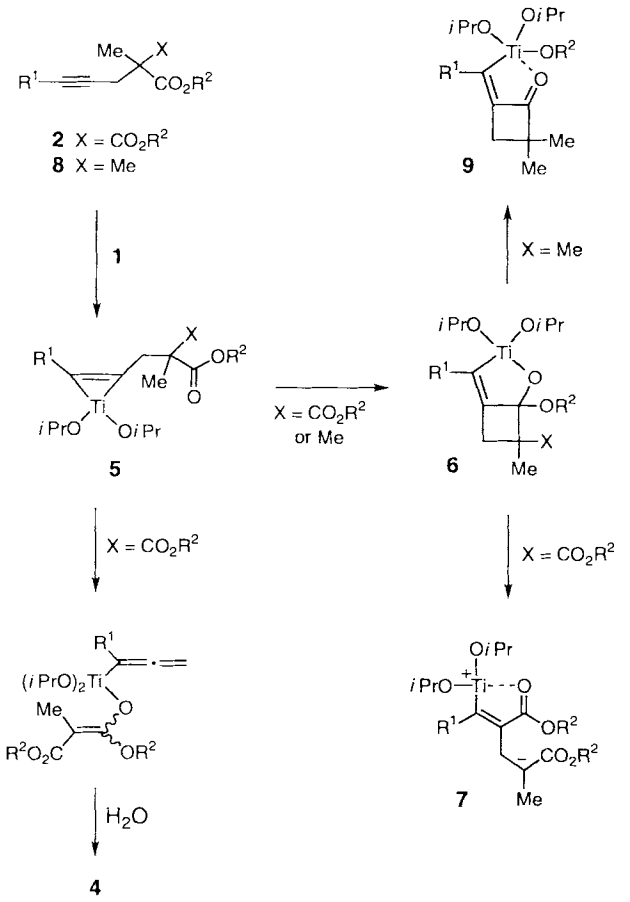
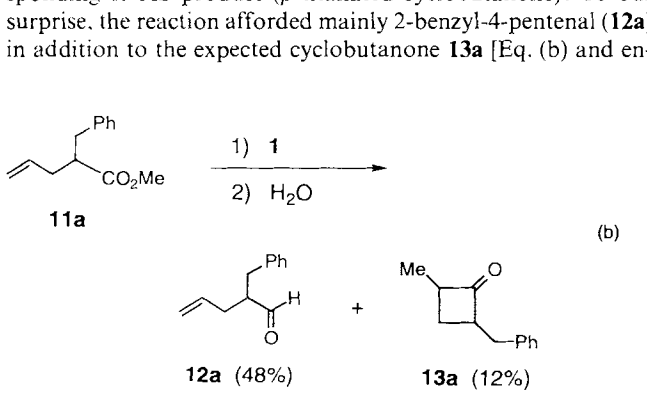


Scheme 1.

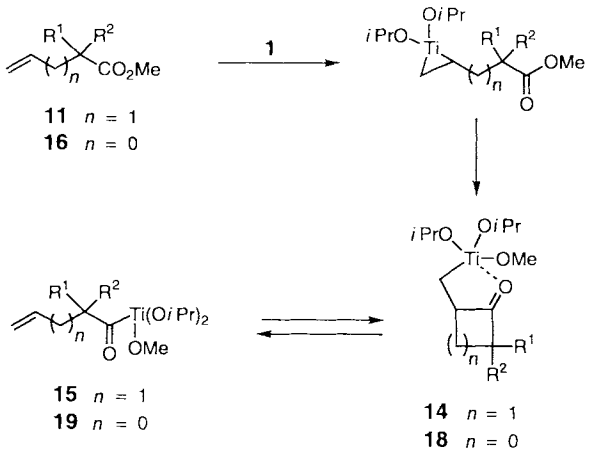
functionalization through manipulation of the carbon–titanium bonds in **7** serves to enhance the attractiveness of the reaction.[6]

Since the generation of relatively stable titanium enolate derivatives seems to be essential for the present rearrangement, we anticipated that alkynyl monoesters **8** would give the corresponding alkenyltitanium compounds **9**, which have a cyclobutanone unit, via **6** through an intramolecular nucleophilic acyl substitution (INAS) reaction as shown in Scheme 1.[7] As expected, the reactions of **1** with the alkynyl esters **8a,b** furnished after hydrolysis the α-alkylidenecyclobutanones **10a,b** in high yield (entries 4 and 5 in Table 1). Deuterolysis of the reaction mixture obtained from **8a** gave deuterated **10a** (entry 4).

Next, we investigated the reaction of **1** with methyl 2-benzyl-4-pentenoate (**11a**) and anticipated formation of the corresponding INAS product (β-titanated cyclobutanone). To our surprise, the reaction afforded mainly 2-benzyl-4-pentenal (**12a**) in addition to the expected cyclobutanone **13a** [Eq. (b) and entry 6 in Table 1]. Similarly, the α,α-disubstituted ester **11b** gave a mixture of cyclobutanone **13b** and γ,δ-unsaturated aldehyde **12b** (entry 7). The formation of **12** can be explained by ring-opening of the expected β-titanated cyclobutanone **14** to give the acyltitanium compound **15** as shown in Scheme 2.[8, 9]



(b)



Scheme 2.

In accordance with this explanation, deuterolysis of the reaction mixture led to deuterated **12a** with >95% D incorporation (entry 6 in Table 1). The reaction of **1** with the α-heteroatom substituted esters **11c,d**, however, afforded only the corresponding cyclobutanones **13c,d** in high yield (entries 8 and 9). Although the factors influencing the equilibrium between **14** and **15** are not clear at this time, the smooth preparation of α-O- and α-N-substituted cyclobutanones from readily accessible starting compounds is noteworthy from a synthetic point of view.[10] The reaction of **1** with the vinylic ester **16**, in which the double bond and the ester group are separated by one less carbon than in substrates **11**, however, afforded the β,γ-unsaturated aldehyde **17** exclusively (Scheme 2 and entry 10 in Table 1). Complete ring-opening of the β-titanated cyclopropanone **18** yielding **19** reflects the higher strain of the three-membered cycloalkanone fragment compared to that of the four-membered unit in **14**.[8, 11]

Experimental Procedure

The following procedures for preparation of **3a**, **4** (entry 1 in Table 1) and **12b**, **13b** (entry 7) are representative.

3a, **4**: To a solution of $Ti(OiPr)_4$ (284 mg, 1.00 mmol) and **2a** (113 mg, 0.50 mmol) in Et_2O (7.5 mL) was added dropwise *i*PrMgCl (1.53 mL, 1.31 M in ether, 2.00 mmol) at −50 °C. The reaction mixture was stirred at −45 to −40 °C for 1 h and hydrolyzed by addition of 1 N HCl (3.0 mL). After warming up to 20 °C and stirring for 15 min, the organic layer was separated and the aqueous layer was extracted with ether. The combined organic layers were dried over $MgSO_4$ and concentrated under reduced pressure. The yield of **4** (32%) was determined by ^1H NMR analysis of the crude reaction mixture with trichloroethylene as an internal standard. After separation by column chromatography (silica gel, hexane:ether = 6:1), **3a** (47 mg, 0.21 mmol) was isolated in 42% yield as a colorless oil. ^1H NMR (300 MHz, $CDCl_3$): $\delta = 1.17$ (d, $J = 7.5$ Hz, 3H), 1.28 (t, $J = 7.1$ Hz, 3H), 1.32 (t, $J = 7.1$ Hz, 3H), 1.84 (d, $J = 7.5$ Hz, 3H), 2.42 (dd, $J = 15.7$, 8.3 Hz, 1H), 2.70 (m, 2H), 4.10 (q, $J = 7.1$ Hz, 2H), 4.19 (q, $J = 7.1$ Hz, 2H), 6.96 (q, $J = 7.5$ Hz, 1H); ^{13}C NMR (300 MHz, $CDCl_3$): $\delta = 14.13$, 14.17, 14.42, 16.73, 30.23, 38.80, 60.17, 60.32, 130.77, 139.09, 167.37, 176.19.

12b, **13b**: To a solution of $Ti(OiPr)_4$ (284 mg, 1.00 mmol) and **11b** (109 mg, 0.50 mmol) in Et_2O (7.5 mL) was added dropwise *i*PrMgCl (1.35 mL, 1.48 M in ether, 2.00 mmol) at −50 °C. The reaction mixture was stirred at −45 to −40 °C for 1 h, then a solution of water (1.2 mL) in THF (30 mL) was added. After warming up to 20 °C and stirring for 30 min, the organic layer was decanted and the white solid was washed thoroughly with ether. The combined organic layers were dried

Enhancing DNA Triple Helix Stability at Neutral pH by the Use of Oligonucleotides Containing a More Basic Deoxycytidine Analog**

Stefan Hildbrand and Christian Leumann*

High-affinity, sequence-specific recognition of double-stranded DNA by oligonucleotide analogs is important in the selective control of gene expression.[1] Triple-helix formation of oligodeoxynucleotides with duplex DNA according to the py–pu:py binding motif,[2] however, is hampered at neutral pH because the cytosine residues in the third strand must be protonated. The pK_a of this base in the corresponding free nucleoside is 4.3. In the past, attempts to overcome this obstacle mainly focused on the design and use of (deoxy)ribonucleosides carrying charge-neutral bases that display a H-bonding pattern isomorphous to that of N^3-protonated cytosine. Examples of such altered bases investigated in triple-helix formation include pseudoisocytosine,[3] the "base P",[4] 4-amino-5-methyl-2,6-[1*H*,3*H*]-pyrimidione,[5] 8-oxoadenine[6] and its N^6-methyl derivative,[7] N^7-deoxyguanine,[8] and the base "pyrazine-ADD".[9]

In an alternative approach to increase the affinity of oligonucleotides to target DNA at neutral pH, the cytidine nucleosides could be replaced by analogs that ideally were completely protonated at physiological pH. A limited increase in basicity can be achieved by replacing the furanose sugar in 2′-deoxycytidine by the corresponding carbocyclic sugar. Carbocyclic 5-methyldeoxycytidine is more basic than 5-methyldeoxycytidine by 0.45 pK_a units.[10] Oligonucleotides containing this analog showed increased triple-helix stability by 3.9 °C per substitution (relative to 5-methyldeoxycytidine). The more obvious way to increase basicity consists in replacing the base cytosine by an aromatic heterocycle that is intrinsically more readily protonated. Oligonucleotides containing 6-amino-2′-*O*-methylcytidine (pK_a = 6.8) were therefore recently prepared and incorporated into oligonucleotides.[11] Their pairing to duplex DNA, however, was inhibited, most probably as a result of unfavorable conformational properties around the nucleosidic bond in this 2,6-substituted pyrimidine nucleoside.

In our design of a more readily protonated cytosine substitute we started from the basic idea that replacement of the nitrogen atom N^1 in the pyrimidine ring by carbon and concomitant removal of the 2-oxo function should result in a more basic pyridine derivative without perturbing the hydrogen-bonding pattern relevant for triple-helix formation. This concept seemed to be applicable because of the relative differences in basicity for 4-aminopyrimidine (pK_a = 5.71) and the analogous heterocycle 2-aminopyridine (pK_a = 6.86), containing only one ring nitrogen.[12] Here we report on the synthesis of the target C-nucleoside analogs **5** and **7**, as well as on the incorporation of **7** into oligonucleotides and their properties with respect to binding to double-stranded DNA. Although an alternative synthesis of the C-nucleoside **7** recently appeared in the literature,[13] the concept of using **7** as a protonated cytidine equivalent in oligonucleotides is unprecedented.

Our synthesis of the C-nucleosides **5** and **7** (Fig. 1) starting from the readily obtainable 2,3,5-tri-*O*-benzyl-*D*-ribono-1,4-lactone (**3**)[14] and the commercially available 2-amino-

5-bromopyridine (**1**) essentially followed the syntheses of C-glycosides by Krohn et al.[15] and Kraus et al.[16] Protection of the amino group in **1** with 1,2-bis(chlorodimethylsilyl)ethane lead to compound **2**, which was suitable for coupling with the sugar component. In situ bromo–lithium exchange in **2** with *n*-BuLi at −75° furnished the nucleophile, which readily added to the lactone **3**. The resulting mixture of hemiacetals was subsequently reduced with $Et_3SiH/BF_3 \cdot Et_2O$ to provide **4** (only β-configured isomer was obtained), which after debenzylation with BBr_3 yielded the ribonucleoside **5** in its hydrobromide form. The corresponding N-protected 2′-deoxynucleoside was obtained from **4** in five consecutive steps starting with benzoylation of the exo amino group, followed by debenzylation, selective protection of the 3′ and 5′ hydroxyl group, subsequent removal of the 2′ hydroxyl group by Barton chemistry, and finally desilylation to give **6**. Compound **6** was then either converted into the phosphoramidite building block **8** by standard methods[17] or to the free 2′-deoxynucleoside **7** by treatment with 40% aqueous CH_3NH_2. The ^1H NMR data of **7** were identical to those already reported.[13]

The pK_a values of the cytidine nucleoside analogs are 6.15 for the ribonucleoside **5** and 6.26 for the deoxyribonucleoside **7**.[18] These values are about 0.6 pK_a units lower than that reported for 2-aminopyridine but more importantly, about two pK_a units higher than that of natural cytidine. As expected, the difference in the basicity of **5** and **7** is only 0.1 pK_a unit, thus confirming that the presence or absence of a hydroxyl group on C(2′) in the ribose ring has negligible influence on the pK_a of these C-nucleosides.

Fig. 2. Sequences of the 21-mer target DNA-duplex and the oligonucleotides **9**–**12** for triple-helix formation (X = 7; ^{Me}C = 5-methyldeoxycytidine).

Once the building block **8** had been prepared, the oligonucleotides **10** and **11** (Fig. 2) were synthesized on a solid support according to standard phosphoramidite chemistry.[19] Coupling efficiencies were estimated from trityl assays and were in the range of 95% per step (including those with the phosphoramidite **8**). After chain assembly and final detritylation the oligomers were detached from the solid support and freed from protecting groups with 25% NH_3 (55 °C, 12 h), followed by 40% aqueous CH_3NH_2 (70 °C, 26 h). Methylamine treatment was absolutely necessary because of the poor ammonolysis of the benzoyl group in residues of **6**. The crude material obtained in this manner was purified by DEAE ion exchange chromatography (DEAE = diethylaminoethyl), its purity determined by reversed phase HPLC and the structural integrity of the oligomers analyzed by matrix-assisted laser desorption ionization—time of flight (MALDI-TOF) mass spectrometry.[20] The oligonucleotides **9** and **12** were prepared for comparison.

Binding to duplex DNA was monitored by UV melting curves in the pH interval 6.0–8.0 and at salt concentrations of 200 mM and 1 M NaCl. Melting transition data (T_m) for third-strand dissociation of **9**–**12** from the chosen target 21-mer duplex (Fig. 2) are summarized in Table 1. Representative melting curves

Table 1. T_m values [°C] and hyperchromicity [%] (in parentheses) of the dissociation of the third strand **9**–**12** from UV-melting curves (λ = 260 nm). Triple helix concentration 1.5–1.7 μM in 10 mM NaH_2PO_4.

Strand	200 mM NaCl [a]				1 M NaCl [b]			
	pH 6.0	pH 7.0	pH 7.5	pH 8.0	pH 6.0	pH 7.0	pH 7.5	pH 8.0
9	42.5 (10)	20.3 (3)	9.8 (2)	<4	42.9 (10)	20.7 (8)	13.0 (6)	4.0 (3)
10	44.3 (9)	25.7 (3)	15.3 (2)	7.8 (1)	47.2 (10)	26.3 (7)	16.4 (6)	8.0 (4)
11	50.3 (11)	39.0 (6)	31.3 (4)	23.1 (3)	[c]	43.4 (5)	33.2 (4)	28.5 (4)
12	53.3 (12)	31.5 (5)	20.1 (2)	12.2 (1)	55.1 (11)	31.4 (7)	21.2 (6)	12.5 (5)

[a] T_m of target duplex melting: 61 ± 1 °C. [b] T_m of target duplex melting: 69 ± 1 °C. [c] Only one T_m value for triplex and duplex melting (69.4 °C) was observed.

(pH 7.5, 200 mM NaCl) are depicted in Figure 3.[21] From the data in Table 1 it becomes clear that oligomer **11**, in which all cytosine bases were replaced by the 2-aminopyridyl residue, shows a dramatic increase in T_m relative to **9** incorporating the natural base cytosine, and **12** containing 5-methylcytosine. The increase in stability relative to the controls is most pronounced at pH > 7.0. Even replacement of only one deoxycytidine residue has a strong stabilizing effect as can be seen from the binding data of **10**. The average increase in T_m per residue at pH 7.5 is 4.3 K relative to cytosine and 2.2 K relative to 5-methylcytosine. Interestingly, replacement of only one residue, as in **10**, has a stronger effect on triplex stability than expected from the average values.

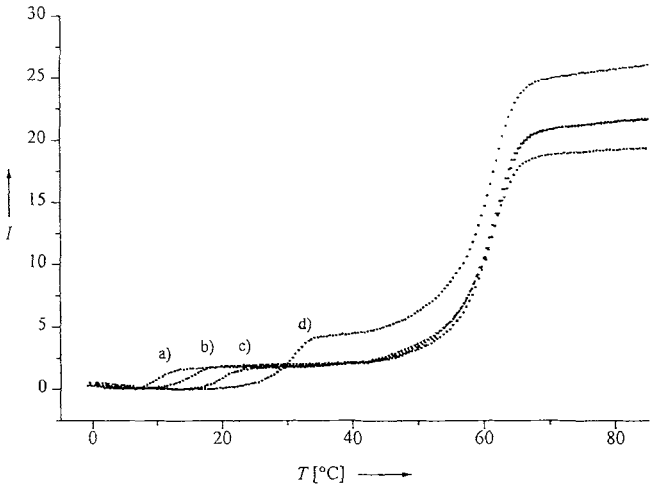

Fig. 3. UV-melting curves ($\lambda = 260$ nm) of **9** (a), **10** (b), **11** (d), and **12** (c) with the target duplex sequence (T_m of the duplex 61 ± 1 °C). Conditions: 10 mM NaH_2PO_4, 200 mM NaCl, pH 7.5; triplex concentration 1.5–1.7 μM. I = hyperchromicity (%).

The results clearly demonstrate that the nucleoside analog **7**, due to its enhanced basicity relative to natural cytidine, is an excellent substitute for the latter in DNA duplex recognition at physiological pH through the py:pu–py motif. Furthermore, the lack of the 2-oxo function present in cytidine does not perturb third-strand binding in the major groove of DNA. This opens the possibility for chemical modifications of the base in **7** at positions 2 and 5 (cytidine numbering) for various purposes, for example, further increasing the pK_a, optimizing stacking properties, or attachment of functional units.

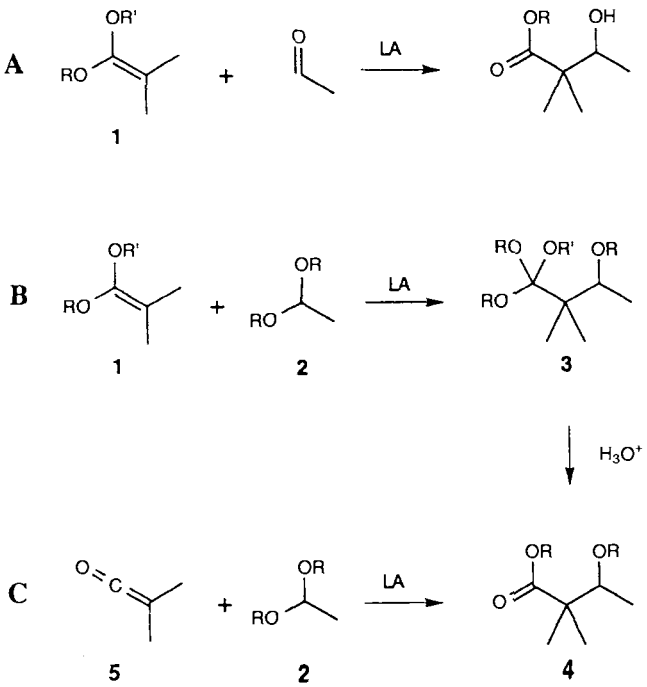
[21] Melting curves were recorded for a consecutive heating-cooling-heating protocol with a linear gradient of 1 K min^{-1}. Consecutive heating cycles were superimposable while cooling cycles showed slight hysteresis for the dissociation of the third strands **9**–**12**.

Stereoselective Insertion of Ketenes into O,O-Acetals: Synthesis of β-Alkoxy Esters and 1,4-Dioxepan-5-ones

Johann Mulzer,* Dirk Trauner, and Jan W. Bats

Lewis acid (LA) mediated aldol additions of carboxylic acid derivatives can be performed either by the reaction of ketene acetals with aldehydes and ketones (path A; Mukaiyama aldol addition[1]) or with acetals (path B[2]). Path B can be regarded as the insertion of **1** in one of the C–O bonds of **2** followed by hydrolysis of the resulting orthoester **3** to yield β-alkoxy ester **4**.



[*] Prof. Dr. J. Mulzer, Dipl.-Chem. D. Trauner, Dr. J. W. Bats

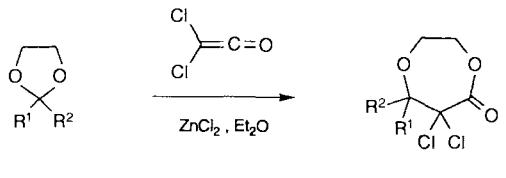
A logical extension would be a reaction in which ketene **5** instead of ketene acetal **1** directly inserts into one of the C–O bonds of acetal **2** (path C). Known examples of reaction C are largely restricted to unsubstituted ketene and acyclic aldehyde acetals.[3]

We used the experimentally convenient Staudinger conditions,[4] which have not been employed in this context before, to generate the ketene and the necessary Lewis acid, $ZnCl_2$, simultaneously. Thus dichloroketene was prepared in situ from trichloroacetyl chloride and commercially available zinc–copper couple and treated with 1,3-dioxolanes **6a–g** to yield the corresponding 6,6-dichloro-1,4-dioxepan-5-ones **7a–g** (Table 1).

Table 1. Reaction of dichloroketene with 1,3-dioxolanes.



6a-g **7a-g**

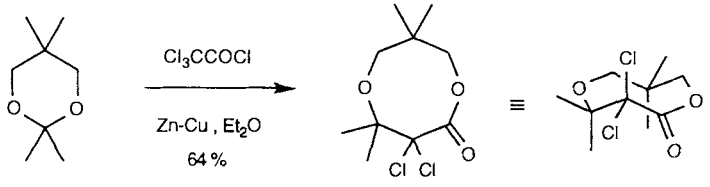
1,3-Dioxanes like **8** also underwent the reaction. The product, the achiral, eight-membered 1,5-dioxocan-2-one **9**, displays four broadened methyl signals in its ^{13}C and ^1H NMR spectra,[5] indicating slow conformational interconversion.



8 **9**

The variability of the ketene component **11** was investigated with anisaldehyde dimethyl acetal **10** (Table 2). The first step in the ketene insertion[6] is probably the nucleophilic attack of an acetal oxygen on the ketene, which is activated by the Lewis acid. The dipolar intermediate **13** is formed, which dissociates into enolate **14a** and carboxonium ion **14b** (a zwitterion in the case of cyclic acetals). These components recombine to give the α,β-alkoxyester **15**.

Accordingly, the rate of the reaction is strongly dependent on the inductive and mesomeric effects exerted by the substituents R^1 and R^2. Since di- and polymerization of the ketenes dominate with decreasing rate of the insertion, the yields also reflect this electronic influence. The parent 1,3-dioxolane **6a** gave dioxepanone **7a** in only 7% yield (Table 1), whereas the *p*-anisyl-substituted compound **6g** furnished **7g** in 92% yield. Doubly

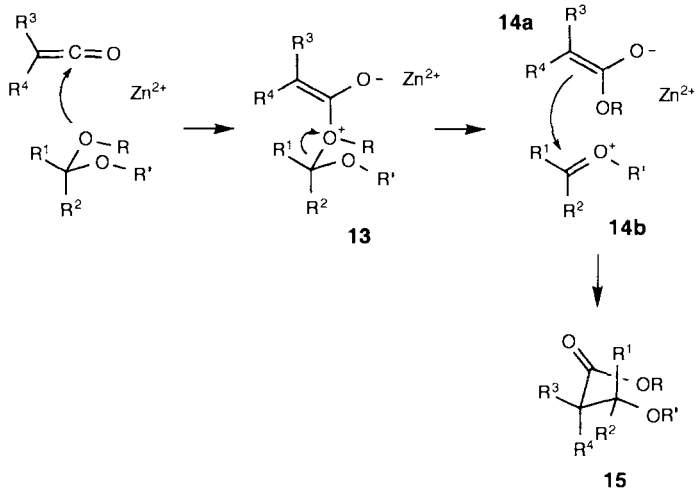
[a] Not optimized. [b] Combined yield of diastereomers.



alkylated dioxolanes **6b–d** also reacted with good yields. Sterically hindered substrates, for example camphor ethylene ketal, did not react for the reasons mentioned above.

The ketene substituents have less influence on the reaction. The strongly electrophilic dichloroketene **11a** gave the best yield (94%) of insertion product **12a** (Table 2). Ketene itself (**11b**) furnished **12b** in 42% yield under the chosen conditions. Even monosubstituted ketenes, which have a strong tendency to di- or polymerize, like methylketene **11d** or phenylketene **11e**, underwent the reaction. The aldol-type products **12d** and **12e** were formed in modest yields as 3:1 and 2.2:1 mixtures of diastereomers, respectively. Sterically hindered diphenylketene (**11f**) also inserted cleanly, probably due to its low tendency to dimerize.

For an asymmetric version of the ketene insertion we chose the chiral dioxolane **16** (Table 3), which displays a nonstereogenic chirotopic acetal center. Reaction of **16** with ketenes **17a–d** led to compounds **18a–d** with >95% stereoselectivity. The structures of **18a–d** were elucidated by crystal structure analysis[7] and NMR spectroscopy (NOESY). Comparably high stereoselectivities have been observed in analogous reactions with silyl ketene acetals.[8] Products **18a** und **18b** were formed as the sole detectable isomers. In the case of both **18c** and **18d**, a second diastereomer was isolated in less than 5% yield (based on **18c,d**); the structures of these side products were not fully secured. Products **18b–d** contain the structural element of an *anti*-configurated aldol, and all four compounds **18** display the same relative configuration at the benzylic center with

respect to the two preexisting stereocenters. The induced diastereoselectivity is quantitative; the simple diastereoselectivity is high. The crystal structure of compound **18c** is shown in Figure 1.

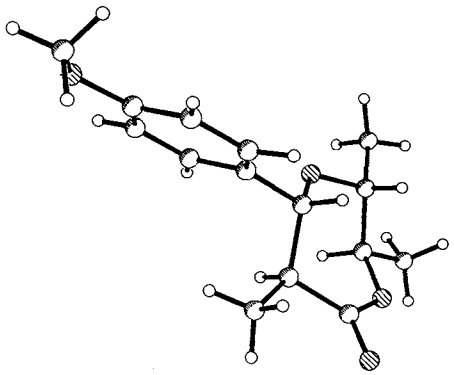

Fig. 1. Crystal structure of **18c**. The oxygen atoms are hatched.

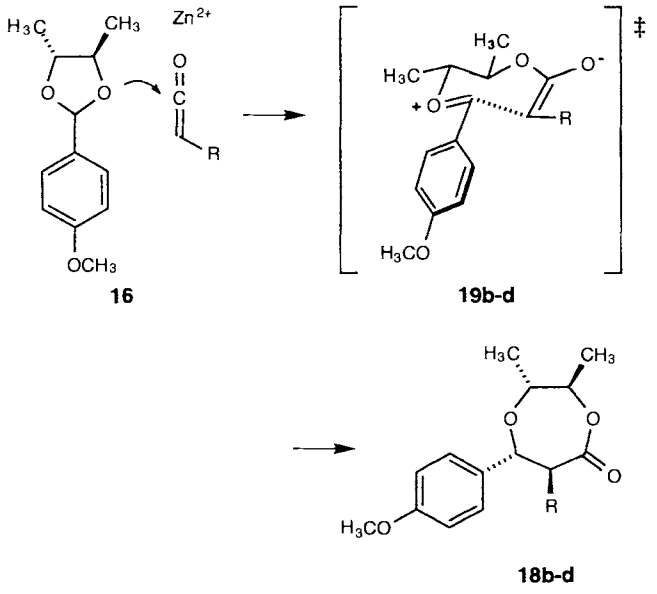
Attack of either oxygen of dioxolane **16** on the ketene leads to the same intermediate of type **14**. Since monosubstituted ketenes such as methyl ketene (**17c**) are attacked by nucleophiles in the plane of the molecule and preferentially on the side opposite to the substituent,[8] the (*Z*) enolate is selectively formed. The seven-membered transition state **19b–d** leading to the main diastereomer **18b–d** is presumably favored as a consequence of the pseudo-equatorial positions of all four residues, which are also observed in the product (Fig. 1).



Experimental Procedure

A solution of trichloroacetyl chloride (1.5 mL, 13 mmol) in anhydrous ether (25 mL) was added dropwise within 1 h to a mixture of **16** (1 g, 4.5 mmol) and Zn–Cu couple (1 g, 15 mmol) in refluxing anhydrous ether (25 mL). The mixture was refluxed for an additional hour and stirred at room temperature for ca. 15 h. Subsequently, it was diluted with ether (50 mL), filtered, and extracted twice with water (50 mL), once with saturated bicarbonate solution (50 mL), and twice with brine (50 mL). The organic phase was dried ($MgSO_4$) and concentrated to dryness. The residue was purified by column chromatography (silica; hexanes:ethyl acetate = 10:1; $R_F = 0.2$) to yield 1.15 g (82%) of diastereomerically pure **18a** as colorless crystals [5].

An Unsymmetrical Dinuclear Iron(III) Complex with Peroxidase Properties**

Burkhard Eulering, Michael Schmidt,
Ulrich Pinkernell, Uwe Karst, and Bernt Krebs*

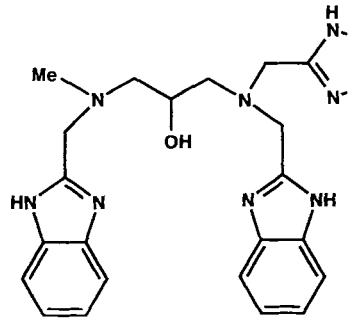
Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

The use of heptadentate dinucleating ligands is a promising strategy for the synthesis of dinuclear iron complexes that serve as model compounds for metalloproteins. To imitate the respective active sites as well as possible, unsymmetrical ligands are required. The crystallization of the corresponding unsymmetrical iron complexes has proven to be extremely difficult, and to date only two examples, both based on the use of μ-phenoxo-bridged ligands, have been described. Latour et al. have successfully synthesized an unsymmetrical $Fe^{II}Fe^{III}$ complex with terminal phenolato coordination as a model for purple acid phosphatases[1] and also prepared a semimet-hemerythrin analogue.[2] We report here on the synthesis and X-ray structure analysis of the first unsymmetrical μ-alkoxo-bridged dinuclear iron complex and on its peroxidase activity.

Compound **1** was synthesized by reacting the unsymmetrical hexadentate chelating ligand *N*-methyl-*N*,*N*′,*N*′-tris(2-benzimidazolylmethyl)-2-hydroxy-1,3-diaminopropane (Hmtbpo)[3] with equimolar amounts of $Fe(ClO_4)_3 \cdot 9H_2O$, $FeCl_3$, and $NaO_2As(CH_3)_2 \cdot 3H_2O$ in methanol.

$[Fe_2(mtbpo)\{O_2As(CH_3)_2\}Cl_2(CH_3OH)](ClO_4)_2 \cdot 4CH_3OH$ **1**

Hmtbpo =



The X-ray structure analysis shows that (Fig. 1) the metal centers in **1** are linked by a dimethylarsinato-*O*,*O*′ bridge and by the deprotonated alkoxo oxygen atom O1. This results in a (μ-alkoxo)(μ-dimethylarsinato)diiron(III) center, which was also recently reported in a complex with the symmetrical heptadentate chelating ligand *N*,*N*,*N*′,*N*′-tetrakis(2-benzimidazolylmethyl)-2-hydroxy-1,3-diaminopropane (Htbpo).[5] Complex **1** is a structural model for the active site of the arsenato inhibitor complex of the purple acid phosphatase ($Fe^{III}Fe^{III}$ form) from porcine uterus (uteroferrin), since both the type of bridging and the number of arsenato groups in **1** correspond to the postulated situation in uteroferrin. The environment of Fe1 in the complex

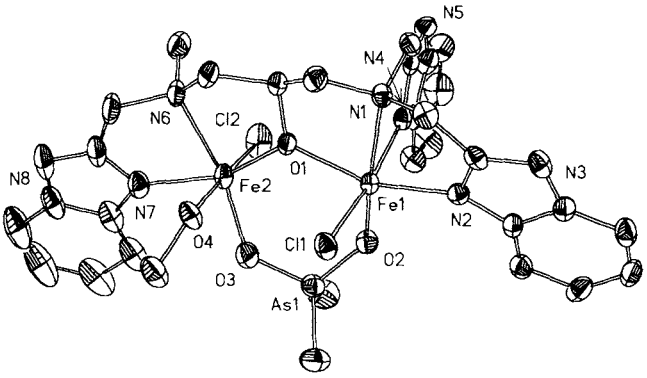


Fig. 1. Structure of one of the crystallographically independent cations $[Fe_2(mtbpo)\{O_2As(CH_3)_2\}Cl_2(CH_3OH)]^{2+}$ of **1** in the crystal. Selected distances [Å] and interatomic angle [°]: Fe1 ··· Fe2 3.535(1), Fe1 ··· As1 3.269(1), Fe2 ··· As1 3.297(1), Fe1–Cl1 2.367(1), Fe1–O1 2.021(2), Fe1–O2 1.906(3), Fe1–N1 2.309(3), Fe1–N2 2.075(3), Fe1–N4 2.102(3), Fe2–Cl2 2.261(1), Fe2–O1 1.972(2), Fe2–O3 1.912(3), Fe2–O4 2.247(3), Fe2–N6 2.268(3), Fe2–N7 2.066(3), As1–O2 1.694(3), As1–O3 1.689(3); Fe1-O1-Fe2 124.5(1).

cation of **1** is completed by the facial coordination of two benzimidazole nitrogen atoms, a tertiary nonaromatic nitrogen donor atom of the ligand $mtbpo^-$, and a chloro ligand. The distorted octahedral coordination at Fe2 is completed by two nitrogen donor atoms of the ligand $mtbpo^-$, a chloro ligand, and a methanol group. Thus, different coordination spheres are obtained for the two iron atoms: Fe1 is surrounded by a N_3O_2Cl and Fe2 by a N_2O_3Cl donor set. The Fe ··· Fe and Fe ··· As distances in **1** with average values for both crystallographically independent complex cations of 3.54 Å and 3.28 Å, respectively, are in the same order of magnitude as those of the complex with the symmetrical ligand Htbpo (3.58 and 3.31 Å, respectively).[5]

The catalytic properties of **1** in oxidations have been investigated by using hydrogen peroxide. The reaction of H_2O_2 and **1** in methanol can be monitored photometrically. A peroxide adduct is formed that is stable over several hours and that has an absorption maximum at 578 nm. The labile chloro ligands at Fe1 and Fe2 and the methanol ligand at Fe2 are coordination partners that can be substituted easily by H_2O_2. Complex **1** exhibits very limited catalase properties (catalytic decomposition of H_2O_2 to O_2 and H_2O). In contrast, the high stability of the adduct suggested that **1** may be suitable to activate peroxides for oxidations.

In the study of this peroxidase behavior, we observed the catalytic oxidation according to Equation (a). The diammoni-

$$H_2O_2 + \text{substrate}_{red} \longrightarrow H_2O + \text{substrate}_{ox} \quad \text{(a)}$$

um salt of 2,2'-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) proved to be particularly suitable as substrate; it is commonly applied for the quantification of the enzymatic activity of peroxidases. The reduced form of ABTS is colorless; in contrast, when ABTS is oxidized to the radical cation, several characteristic absorption bands appear at 415, 650, 735, and 815 nm, and the resulting solution is green. Similar investigations have been performed with iron–porphyrin complexes.[8] Peroxidase properties of dinuclear complexes, however, have not been observed yet.

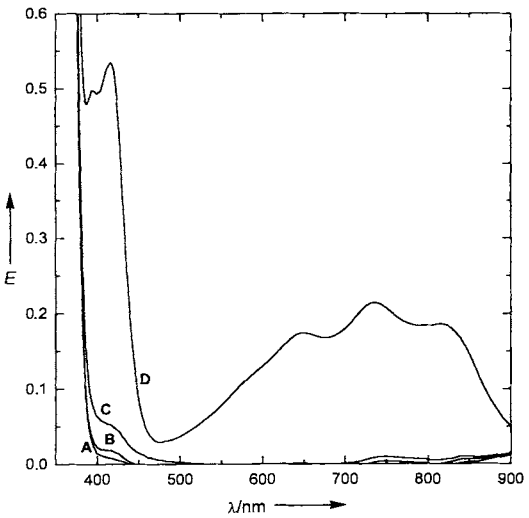

Fig. 2. UV/Vis absorption spectra of ABTS (A), ABTS + H_2O_2 (B), ABTS + **1** (C), ABTS + **1** + H_2O_2 (D), each recorded 10 min after mixing the solutions.

In the reaction of ABTS with H_2O_2 in the presence of **1**, the characteristic absorption bands of $ABTS^{\cdot+}$ were established immediately after mixing (Fig. 2). Without **1**, the oxidation of ABTS by H_2O_2 did not occur. The further oxidation to the corresponding dication[7] was also not observed. Thus, **1** can be considered as a functional model for peroxidase.

Experimental Procedure

1: $Fe(ClO_4)_3 \cdot 9H_2O$ (0.104 g, 0.20 mmol) and $FeCl_3$ (0.033 g, 0.20 mmol) were dissolved in methanol (5 mL) and added to a solution of Hmtbpo (0.1 g, 0.20 mmol) in methanol (5 mL). Sodium dimethylarsinate (0.043 g) in methanol (5 mL) was added to the deep red solution. The red product crystallized after a few days. Correct elemental analysis. UV/vis (methanol): λ_{max} (ε[L mol^{-1} cm^{-1}]) = 211 (38210), 240 (23660), 271 (26530), 278 (24430), 351 nm (4860). Cyclic voltammogram (in acetonitrile with 0.1 M tetrabutylammonium perchlorate; three-component system: mercury disk working electrodes, platinum wire auxiliary electrodes, and a Ag/AgCl 3 M NaCl reference electrode): quasi-reversible one electron transfer transition at −830 mV. Magnetic susceptiblity (SQUID measurement, 5.1–299.5 K) [9]: $H = -2JS_1S_2$ ($S_1 = S_2 = 5/2$): J [cm^{-1}]: −10.8(1). Mössbauer spectra at 4.2 K (doublet) [9]: δ [mm s^{-1}], ΔE_Q [mm s^{-1}]: 0.34, 0.27.

Oxidation of ABTS with H_2O_2 in the presence of **1**: An aqueous solution of ABTS (50 μL; 5 mg mL^{-1}) and a methanolic solution of **1** (10 μL; 1 mmol L^{-1}) were added to water (3 mL). The oxidation of ABTS starts immediately after addition of an aqueous solution of H_2O_2 (50 μL; 10 M).

[3] The ligand Hmtbpo can be synthesized by the reaction of an aqueous, alkaline solution of iminodiacetic acid with an equimolar amount of epichlorohydrine, followed by subsequent reaction with an alkaline solution of sarcosine. The ligand is obtained by the reaction of the free acid with 1,2-phenylenediamine. A complete description of the synthesis and characterization of the ligand will be described elsewhere [10]. The synthesis of the N-methyl derivative of the ligand Hmtbpo was recently achieved by another synthetic route [11].

Cationic Iridium(III) Carbonyl Complexes: $[Ir(CO)_6]^{3+}$ and $[Ir(CO)_5Cl]^{2+}$**

Christian Bach, Helge Willner,* Changqing Wang, Steven J. Rettig, James Trotter, and Friedhelm Aubke*

Neutral homoleptic carbonyl complexes of iridium such as the tetranuclear cluster $[Ir_4(CO)_{12}]$ have been known for some time.[1–3] More recently the highly reduced carbonylate $[Ir(CO)_3]^{3-}$ was reported,[4] and it has since become a challenge to synthesize the homoleptic carbonyl cations $[Ir(CO)_6]^{3+}$. Its existence as a thermally stable species would complete a series of carbonyl cations of the 5d block metals that stretches from linear $[Au(CO)_2]^+$[5] over square-planar $[Pt(CO)_4]^{2+}$[6] to octahedral $[Ir(CO)_6]^{3+}$. We report here the synthesis and spectroscopic characterization of $[Ir(CO)_6][Sb_2F_{11}]_3$ and the molecular structure determination of $[Ir(CO)_5Cl][Sb_2F_{11}]_2$.

Since $[Au(CO)_2][Sb_2F_{11}]$[5] and $[Pt(CO)_4][Sb_2F_{11}]_2$[6] are obtained from the fluorosulfate precursors $[Au(CO)SO_3F]$[7] and *cis*-$[Pt(CO)_2(SO_3F)_2]$,[8] respectively, by solvolysis in liquid SbF_5 under a CO pressure of about 1 atm, the recent discovery of $[Ir(CO)_3(SO_3F)_3]$[9] provides a promising starting material for the synthesis of $[Ir(CO)_6][Sb_2F_{11}]_3$. Our recent report on the compounds $[M(CO)_6][Sb_2F_{11}]_2$, M = Ru or Os,[10] suggests that in addition to the well-known cations $[M(CO)_6]^+$ (M = Mn, Tc, and Re)[11] multiply charged homoleptic octahedral metal carbonyl cations exist and display unexpectedly high thermal stabilities. The molecular structure of $[Hg(CO)_2][Sb_2F_{11}]_2$[12] indicates that the $[Sb_2F_{11}]^-$ ion plays an important role in stabilizing the linear $[Hg(CO)_2]^{2+}$ ion through $SbF\cdots CO$ secondary contacts. The use of liquid antimony(v) fluoride as reaction medium for (reductive) carbonylations has been reviewed very recently.[13]

While the synthesis of $[Ir(CO)_3(SO_3F)_3]$[9] proceeds smoothly, the preparation of the starting material $[Ir(SO_3F)_3]$ by metal oxidation with $S_2O_6F_2$ in HSO_3F at 120–140 °C[14] is more difficult. Hence only small amounts (250 mg) of $[Ir(SO_3F)_3]$ are available for a subsequent carbonylation to $[Ir(CO)_3(SO_3F)_3]$. Solvolysis of $[Ir(CO)_3(SO_3F)_3]$ in an excess of SbF_5 under a CO atmosphere at 60 °C produces an inseparable mixture of $[Ir(CO)_6][Sb_2F_{11}]_3$ and at least one other species, judging by the complexity of the vibrational spectra in the CO region. When crystalline *mer*-$[Ir(CO)_3(SO_3F)_3]$[9] was dissolved in magic acid (65 mol% SbF_5 in HSO_3F) at 25 °C under 0.5 atm CO and the solution was allowed to stand for about nine weeks, pale yellow crystals form, which were identified by X-ray single-crystal diffraction as $[Ir(CO)_5Cl][Sb_2F_{11}]_2$[15] (Fig. 1). Fluorochloro-

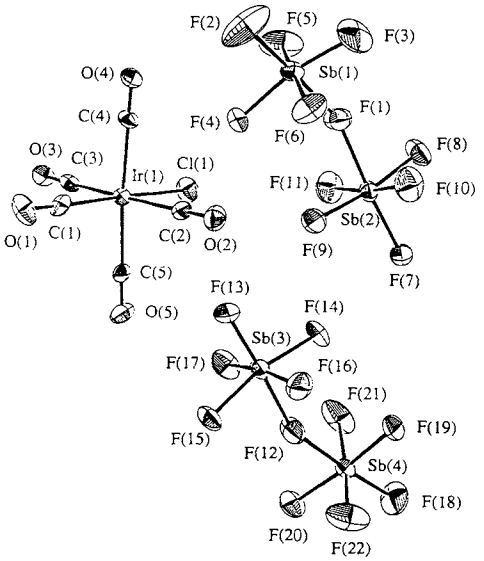

Fig. 1. Molecular structure of $[Ir(CO)_5Cl][Sb_2F_{11}]_2$ (50% probability thermal ellipsoids are shown).

carbon grease is considered to be the most likely source for the chloride ion.

The $[Ir(CO)_5Cl]^{2+}$ ion is unique in carbonyl complex chemistry. $[Fe(CO)_5Cl]^+$[16] and the isoelectronic species $[Re(CO)_5Cl]$[1–3] provide remotely related precedents. The Ir–C distances of 202(2) pm are long compared to the q_u value of 189.8 pm, which was calculated based on 148 examples.[17a] As expected, the C–O distances of 108(2) pm are very short, but the large standard deviations do not permit a meaningful discussion. Both sets of data are comparable within standard deviations to those reported for *mer*-$[Ir(CO)_3(SO_3F)_3]$[9] and for $[Ir(CO)_3F_3]$ from EXAFS data.[17b] As found for *mer*-$[Ir(CO)_3(SO_3F)_3]$[9] and for $[Hg(CO)_2][Sb_2F_{11}]_2$[12] there are significant secondary interionic $SbF\cdots CO$ contacts (ca. 280 pm, two for each C atom), which are less than the sum of the van der Waals radii (317 pm).[18]

These interionic interactions are comparable in strength but not in number to those found for $[Hg(CO)_2][Sb_2F_{11}]_2$, in which the C atoms of the linear $[Hg(CO)_2]^{2+}$ ion appear to be more accessible and where four interionic $SbF\cdots CO$ contacts are observed.[12] Consequently the Sb-F_b-Sb angle of 147.6(3)° in the anion $[Sb_2F_{11}]^-$ is more acute in the mercury compound than in $[Ir(CO)_5Cl][Sb_2F_{11}]_2$ (153.2(6)° and 156.2(6)°). Reduced secondary interionic interactions within the iridium compound are also reflected in the Sb–F distances, which range from 178 to 188 pm. The corresponding bondlengths in $[Hg(CO)_2][Sb_2F_{11}]_2$ lie between 185 and 189 pm.[12]

Since the synthesis of $[Ir(SO_3F)_3]$ is difficult[9, 14] and $IrCl_3$ is found to be unreactive in SbF_5 when CO is also present, a different synthetic approach to $[Ir(CO)_6][Sb_2F_{11}]_3$ was developed: the reductive carbonylation of IrF_6 in SbF_5 [Eq. (a)].

$$2\,IrF_6 + 12\,SbF_5 + 15\,CO \xrightarrow[60\,^\circ C,\ 12\ h]{SbF_5(l)} 2\,[Ir(CO)_6][Sb_2F_{11}]_3 + 3\,COF_2 \qquad (a)$$

IrF_6 was prepared by fluorination of iridium metal powder at 250 °C by a published procedure.[19] The white, extremely moisture-sensitive complex $[Ir(CO)_6][Sb_2F_{11}]_3$ remained after removal of all volatiles in vacuo. The isotopomer $[Ir(^{13}CO)_6][Sb_2F_{11}]_3$ was obtained in an identical manner by using ^{13}CO. The product was identified by the mass balance of the reaction, by its vibrational spectra, and by the ^{13}C MAS NMR spectrum (Table 1).[20]

The vibrational data for $[Ir(CO)_6][Sb_2F_{11}]_3$ and its ^{13}C isotopomer clearly indicate that the $[Ir(CO)_6]^{3+}$ ion is strictly octahedral. Consistent with this finding, a single line resonance at $\delta = 121$ is found in the ^{13}C MAS NMR spectrum, and coupling to either ^{191}Ir or ^{193}Ir (both with a nuclear spin of 3/2) is not observed.

With the inclusion of the two carbonylates $[Hf(CO)_6]^{2-}$[4] and $[Ta(CO)_6]^-$[21] a correlation of spectroscopic properties for six octahedral carbonyl species ranging from $[Hf(CO)_6]^{2-}$ to $[Ir(CO)_6]^{3+}$ is now possible (Table 1). In addition to the ^{13}C

Table 1. Vibrational spectra ($\tilde{\nu}_{CO}$ region), force constants f_{CO}, and ^{13}C chemical shifts for homoleptic, isoelectronic, and octahedral $[M(CO)_6]$ species of the 5d block metals.

chemical shifts, the frequencies of the asymmetric CO stretches $\tilde{\nu}_{CO}(f_{1u})$ are given in Table 1, because Raman spectra have so far not been reported for the two carbonylate anions. For the remaining four molecular species from $[W(CO)_6]$ to $[Ir(CO)_6]^{3+}$ complete vibrational data are available.[10, 20–23]

The trend shown by the f_{1u} vibrations, that the CO bond strength increases with increasing formal charge of the metal, is quantified by the increasing stretching force constants f_{CO} (Table 1). The value of the force constant for $[Ir(CO)_6]^{3+}$ (20.8×10^2 Nm^{-1}) is only slightly below that for $[Hg(CO)_2]^{2+}$ (21.0×10^2 Nm^{-1})[12] and that for HCO^+ (21.3×10^2 Nm^{-1}).[5] The ^{13}C chemical shift of $\delta = 121$ is the lowest that has been measured for carbonyl complexes. The rather smooth trend in both $\tilde{\nu}^{CO}(f_{1u})$ and ^{13}C chemical shifts illustrates that for the six isostructural and isoelectronic $(d^6)[M(CO)_6]$ species π back donation gradually decreases with a concomitant increase in σ donation as the formal charge on the metal gradually increases from -2 to $+3$. For $[Ir(CO)_6]^{3+}$, π back bonding makes only a small, insignificant contribution to the Ir–CO bonding. A similar correlation can be made for carbonyl derivatives of iridium where $\tilde{\nu}_{CO}$ for terminal CO groups increases from 1642 cm^{-1} for $[Ir(CO)_3]^{3-}$[14] to 2295 cm^{-1} for the a_{1g} mode of $[Ir(CO)_6]^{3+}$. Both trends clearly demonstrate the great versatility of the CO ligand, which coordinates to metallic centers of formal charges from -3 to $+3$ form stable metal carbonyl species.

As more cationic carbonyl complexes like $[M(CO)_6]^{2+}$ (M = Ru, Os)[10], $[Ir(CO)_5Cl]^{2+}$, and $[Ir(CO)_6]^{3+}$ become known, together with accurate structural and vibrational data, and as smooth correlations between the formal charge on the metal and the bonding characteristics in the CO ligands emerge, it becomes increasingly obvious that any arbitrary subdivision using vague terms like "classical" and "nonclassical (σ-only)" carbonyl complexes as proposed sometime ago for the thermally unstable $[Ag(CO)_n]^+$ ($n = 1, 2$) species[24] is incorrect, inappropriate, and unnecessary. The first metal carbonyl derivative $[Pt(CO)_2Cl_2]$ reported in 1868[25] with an average $\tilde{\nu}_{CO}$ value of 2175 cm^{-1} [well above that (2143 cm^{-1}) for free CO[26]] would be assigned "nonclassical", which is in our view absurd.

Achieving Stable, Reverse Water-in-Fluorocarbon Emulsions**

Véronique M. Sadtler, Marie Pierre Krafft, and Jean G. Riess*

Macroemulsions are thermodynamically unstable systems that tend to separate irreversibly into the component phases upon aging. Their kinetic stability can, however, be increased by counteracting the processes by which they break down, that is, coalescence and molecular diffusion (Ostwald ripening).[1] Preparing stable water-in-fluorocarbon "reverse" emulsions is a stimulating challenge from both fundamental and applied standpoints.

Fluorocarbons are unique due to the extreme position of fluorine in the Periodic Table.[2] Liquid fluorocarbons display very

weak intermolecular (van der Waals) interactions, and this results in the lowest possible associative character.[3] Water-in-fluorocarbon emulsions are thus a most unnatural combination of the least associated of liquids with one of the most strongly associated ones. Their formation and stabilization presuppose that very high interfacial tensions have been overcome.

Molecular diffusion was shown to be the predominant mechanism of particle size increase in direct, fluorocarbon-in-water emulsions.[4] We have now found that the same mechanism is effective for water-in-fluorocarbon emulsions. According to the Lifshitz–Slyozov equation [Eq. (a)][5] that describes this

$$v = \mathrm{d}(\bar{a}^3)/\mathrm{d}t = 8\gamma_i CDV_m/9RT \qquad \text{(a)}$$

mechanism, the rate v of particle volume increase ($\bar{a}$ = average radius of the particle) over time t through molecular diffusion is proportional to the molar volume of the dispersed phase (V_m), to the interfacial tension γ_i between continuous and dispersed phase, and to the solubility and diffusivity coefficients (C and D) of the dispersed phase in the continuous phase.

Molecular diffusion of water through the continuous fluorocarbon phase in a reverse water-in-fluorocarbon emulsion is expected to be faster than that of the same fluorocarbon through water, on two accounts: 1) although no data appear to be available on mutual solubilities of water and fluorocarbons, water should be more soluble in the fluorocarbon than vice versa because of its smaller molar volume and the easier formation of holes capable of hosting the water molecules in the loosely associated fluorocarbon. According to Hildebrand's theory, the solubility of water in a fluorocarbon is actually expected to be higher by several orders of magnitude than that of the same fluorocarbon in water, as it varies exponentially with the molar volume.[6] 2) The diffusivity of water in the fluorocarbon should also be larger than that of the fluorocarbon in water as indicated by the Hayduk–Laudie equation, although the difference is not expected to be as great.[7] Coalescence of water droplets in a fluorocarbon phase should be favored by the large difference in densities and by the higher fluidity of the fluorocarbons utilized here relative to that of water.

In spite of these unfavorable premises we have prepared stable water-in-fluorocarbon emulsions with submicrometer particles and a narrow size distribution. The key to meeting this challenge lay in the selection of an effective surfactant system. Because the continuous phase is fluorinated, the surfactant needs to have definite affinity for fluorocarbons, and hence needs to be fluorinated. A number of single- and double-chain perfluoroalkyl surfactants, among those that have been synthesized in this laboratory in recent years,[8] were therefore screened. Their modular molecular design allows stepwise modifications of their hydrophilic, lipophilic, and fluorophilic properties, which, in turn, have a considerable impact on their ability to form and stabilize colloidal systems.

Potential applications of reverse fluorocarbon emulsions can be envisaged in pulmonary administration of drugs and other agents. The agents to be delivered (which include surfactants, antibodies, antioxidants, steroids, nucleic acids, vasoactive agents, and cytotoxic drugs) are usually insoluble in fluorocarbons in significant amounts. Contrary to the presently investigated dispersions of micronized solid drugs in liquid fluorocarbons,[9] water-in-fluorocarbon emulsions should allow uniform, reproducible distribution of the agents, including to the deeper parts of the lungs; this presupposes, however, that emulsion stability has been achieved. Controlled release and reduced toxicity are also expected; in the hydrocarbon series, for example, water-in-oil emulsions of doxorubicin that allowed controlled delivery of the drug have been prepared, and fewer side-effects were experienced than with dispersions of solids.[10]

Perfluorooctyl bromide and perfluorooctylethane were chosen for this study, because they satisfy the criteria required for liquid breathing, a procedure investigated for treatment of acute respiratory distress. The former compound is in Phase II/III clinical trials for this procedure;[11] its fluorocarbon-in-water emulsions are in Phase II clinical trials as injectable oxygen carriers (blood substitutes).[12] The emulsifying agent utilized for the reverse fluorocarbon emulsions was eventually selected from a homologous series of fluorinated surfactants (*F*n*C*m*DMP*) derived from dimorpholinophosphate.[13]

$C_nF_{2n+1}(CH_2)_mOP(O)[N(CH_2CH_2)_2O]_2$

FnCmDMP; $n = 4, 6, 8, 10$ and $m = 2, 5, 11$

FnCmDMP are indeed highly fluorophilic; the potential for spontaneous formation of membranes with low curvature is indicated by the presence of elongated rather than spherical self-assemblies when dispersed in water.[14] Various spacer (m) and fluorocarbon chain lengths (n) were investigated. The best results, that is, the obtention of stable emulsions with small droplet size and long shelf-life, were achieved with F8C11DMP. It is noteworthy that no stable reverse emulsions could be prepared with the phospholipids used to prepare direct fluorocarbon-in-water emulsions, nor with the hydrocarbon dimorpholinophosphate $C_{15}H_{31}OP(O)[N(CH_2CH_2)_2O]_2$.

The preparation of the reverse fluorocarbon emulsions involved first the dispersion of the perfluoroalkylated surfactant in the fluorocarbon, followed by the addition of the aqueous phase, which may contain an active component. Emulsification was initiated with a low-energy mixer and completed with a high-pressure mechanical homogenizer. A series of water-in-fluorocarbon emulsions was thus prepared with water contents ranging from 1 to 30% v/v.

A typical example of a reverse emulsion containing perfluorooctyl bromide (95% v/v), NaCl (2.5% solution in water; 5% v/v), and F8C11DMP (2% w/v) was prepared as follows: F8C11DMP (40 mg) was dispersed in perfluorooctyl bromide (1.9 mL) by gentle stirring. The aqueous 2.5% solution of NaCl (0.1 mL) was added to the fluorocarbon phase, and the mixture was shaken by hand. The resulting coarse pre-emulsion was homogenized under high pressure (Emulsiflex B3, Avestin, 4.1×10^7 Pa, 12 cycles); the temperature was maintained below 40 °C.

The final emulsion was highly fluid and bluish. The average particle diameter, as measured by photosedimentation (Horiba Capa 700) immediately after preparation, was 0.15 ± 0.01 μm; this emulsion was stable enough to withstand heat sterilization conditions (121 °C, 15 min, 15 $N m^{-2}$) without significant particle size increase (0.16 ± 0.02 μm). As an alternative, the emulsion can also be filtered through a 0.22 μm sterilizing membrane without detectable change (0.15 ± 0.01 μm). The reverse nature of the water-in-fluorocarbon emulsion is unequivocally supported by the high fluidity (comparable to that of the fluorocarbon), by the absence of electrical conduction, and by the fact that the emulsions can easily be diluted with a fluorocarbon but not with water. The possibility of having reverse surfactant vesicles was excluded by an epifluorescence microscopy experiment in which 5,6-carboxyfluorescein was incorporated into the aqueous phase (2×10^{-3} M); it clearly showed uniformly fluorescent droplets rather than the fluorescent rim that was seen in the case of reverse vesicles.[15] Furthermore, as much as 30% by weight (45% by volume) of water can be incorporated into our reverse emulsions, with a surfactant/water ratio as low as 0.03

by weight, which is definitely incompatible with the formation of reverse vesicles.

The shelf stability of the reverse fluorocarbon emulsions was monitored at 25 °C by photosedimentation. After about 4.5 months, the average particle diameter of the above emulsion was still only 0.27 ± 0.02 μm, and the particle size distribution remained reasonably narrow as shown in Figure 1. That the

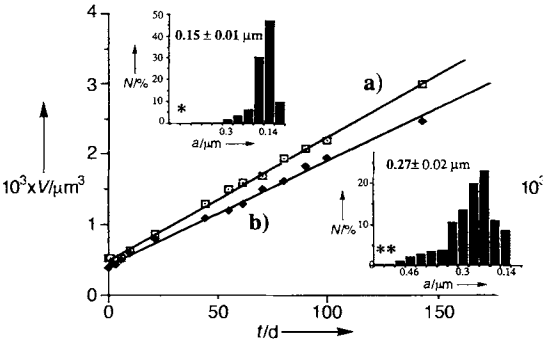

Fig. 1. Linear variation with time of the average volume V of water droplets at 25 °C in a reverse water-in-fluorocarbon emulsion (95% v/v perfluorooctyl bromide, 5% v/v saline, 2% (perfluorooctyl)undecyldimorpholinophosphate F8C11DMP) after heating at 121 °C for 15 min (a) and after filtration on a 0.22 μm sterilizing membrane (b). Insets: Size distribution histograms measured for the heated emulsion immediately after preparation (*) and after 140 days at 25 °C (**). N = percentage of particles with radius a. The quoted values give the average radii $\bar{a}$.

mechanism of particle growth in reverse fluorocarbon emulsions is molecular diffusion is strongly indicated by the following findings: a) the average volume of the water droplets increases linearly with time, as seen in Figure 1 for both heated and filtered emulsions; b) the distribution function, that is, the ratio $a_i/\bar{a}$ of particle radius a_i to the mean radius $\bar{a}$, is time-in variant;[4, 5] and c) the addition of NaCl contributes to stabilizing the emulsions by reducing the solubility of water in the fluorocarbon.

A series of drugs, including antibiotics (doxycycline, gentamycin, erythromycin), vasoactive bronchodilators (epinephrine, tolazoline), mucolytic agents (acetyl cysteine), antituberculosis agents (ethambutol, pyrazinamide), cholinergic (acetylcholine chloride), glucocorticoid (prednisone), and antitumor agents (cyclophosphamide), could be incorporated into such reverse fluorocarbon emulsions without inducing significant loss of stability.

For example, a reverse fluorocarbon emulsion otherwise formulated as in the example given above was prepared by adding 0.1 mL (5% v/v) of an aqueous solution of tolazoline (3% w/v in a 2.5% aqueous solution of NaCl). The average particle size, as measured by photosedimentation was 0.15 μm after preparation, 0.17 μm after heat-sterilization, and 0.23 μm after a month at 25 °C.

Preliminary toxicity data on water-in-fluorocarbon emulsions are encouraging. Intravenous administration of a dispersion of F8C11DMP in NaCl (0.9% solution) showed no acute toxicity at concentrations as high as $2\,g\,kg^{-1}$ body weight in mice (limit of protocol; all ten animals treated survived) indicating an i.v. LD_{50} value greater than $2\,g\,kg^{-1}$. Intraperitoneal administration of the same compound dispersed in perfluorooctyl bromide yielded an i.p. LD_{50} value around $4\,g\,kg^{-1}$. In the case of F8C2DMP all ten animals survived a $2\,g\,kg^{-1}$ body weight dose i.p. No hemolytic activity was detected either for these surfactants. A reverse emulsion (perfluorooctyl bromide, 95% v/v; NaCl 0.9% in water, 5% v/v; F8C11DMP, 1% w/v) was injected intraperitoneally into 10 mice (25 mL kg^{-1} body weight); after one month all the animals were still alive; no significant perturbation in their growth or behavior was observed during this period.

Ruthenium-Catalyzed Metathesis of Polymer-Bound Olefins**

Matthias Schuster, Josef Pernerstorfer, and Siegfried Blechert*

Olefin metathesis has experienced a remarkable renaissance through the development of catalysts[1] that remain active even in the presence of many functional groups. This impetus is reflected in the numerous publications on ring closing and ring opening metathesis, and cross metathesis.[2, 3] Since the development of combinatorial synthesis,[4] in particular with the aim of discovering drugs, much interest is devoted to efficient synthesis processes on solid phases. We therefore studied metathesis reactions of polymer-bound, functionalized olefins. Here we present some ruthenium-catalyzed olefin metatheses with polymer-bound olefins. Whereas the examples of ring closing metathesis of diolefins suggest applications in the construction of functionalizable heterocyclic frameworks, cross metathesis between a polymer-bound and a dissolved olefin is an interesting concept for the catalytic immobilization.

Figure 1 shows the results of the ruthenium-catalyzed ring closing metathesis of a series of diolefins. After gel-phase ^{13}C NMR spectra[5] revealed that the tentacle-polymer-bound diallyl amide **2**[6] could be converted into **3** in high yield with **1a**[1a]

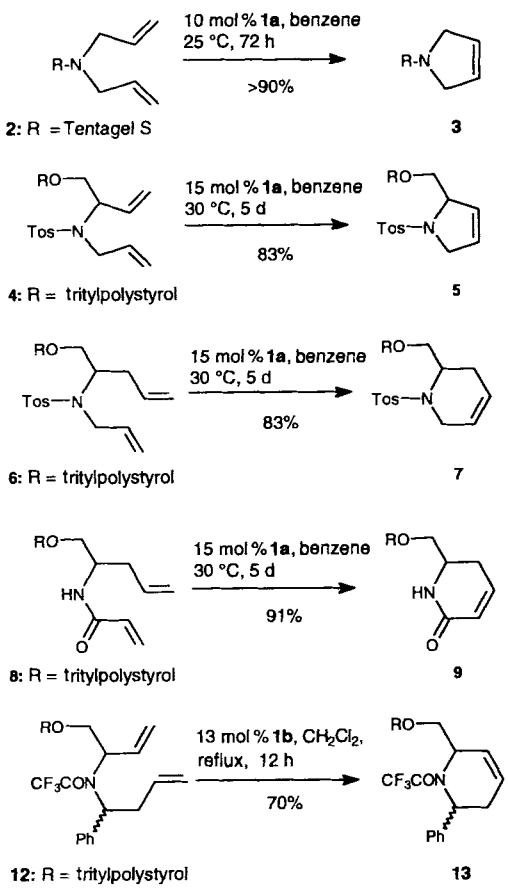

Fig. 1. Results of the ruthenium-catalyzed ring closing metathesis of polymer-bound substrates.

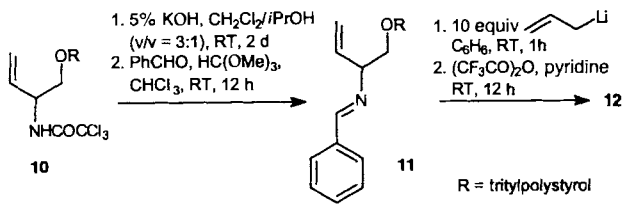
$[Cl_2(PCy_3)_2Ru{=}CH{-}CH{=}CPh_2]$ **1a**

(Cy = cyclohexyl), the following experiments were performed on the inexpensive polystyrene resins. Olefins **4** and **6** were obtained by *N*-allylation of polymer-bound racemic *N*-tosyl-*C*-vinylglycinol and *N*-tosyl-*C*-allylglycinol, respectively, in quantitative yield;[7] olefin **8** was prepared by binding *N*-acryloyl-*C*-allylglycinol to chlorotritylpolystyrene.[8] The loading in all cases was between 0.4 and 0.6 mmol g^{-1} resin.[9] The quoted yields were determined by HPLC analysis of the metathesis products obtained by acid cleavage from the trityl resin. The distinctly faster transformation of **12** into **13** in high yields catalyzed by **1b**[1b] emphasizes that α,α′-substituted nitrogen

$[Cl_2(PCy_3)_2Ru{=}CHPh]$ **1b**

heterocycles, which are ubiquitous in nature as bioactive compounds, are also accessible in polymer-bound form. After acid cleavage of **13** and subsequent basic workup of the soluble product, 2-hydroxymethyl-6-phenyl-1,2,5,6-tetrahydropyridine (**13b**) was isolated in an overall yield of 60%, based on **10**, with a *syn-anti* ratio of 3:5 and characterized.[10] The sequential preparation of the metathesis precursor **12** from polymer-bound *C*-vinylglycinol, benzaldehyde, and allyllithium (Scheme 1) should make α,α′-substituted hydropyridines readily accessible by variation of the components.



Scheme 1. RT = room temperature.

Besides ring closure reactions, intermolecular metathesis reactions between two different olefins interest us. In the course of such reactions the cross metathesis competes with the dimerization of the two starting alkenes. We hoped to prevent the dimerization by binding one of the olefin components to a polymer and thus also to achieve better reaction control. Since both tritylpolystyrene-bound 4-pentenol and allyl alcohol dimerize on the polymer surface by macrocyclic ring closure under metathesis conditions,[11] sterically demanding hydroxyolefins were immobilized and subjected to metathesis. In the case of polymer-bound *N*-trichloroacetyl-*C*-vinylglycinol (**10**), although as expected no dimerization was observed, the ruthenium-catalyzed metathesis gave only slight conversion despite higher catalyst concentrations. On use of the less sterically demanding *N*-Boc-*N*-allylglycinol (**14**), a slow dimerization was detected at a loading of 0.6 mmol g^{-1} polymer, which could, however, be suppressed by reducing the loading to 0.2 mmol g^{-1} polymer. All experiments were therefore performed with this loading. The results of binding a series of olefins to **14**, as well as to the isomeric *N*-Boc-*C*-allylglycinol resin **19** are summarized in Figure 2.[12] *cis*-Hexene was used as only slightly volatile propene equivalent. The examples demonstrate that cross metathesis between soluble and immobilized olefins can be

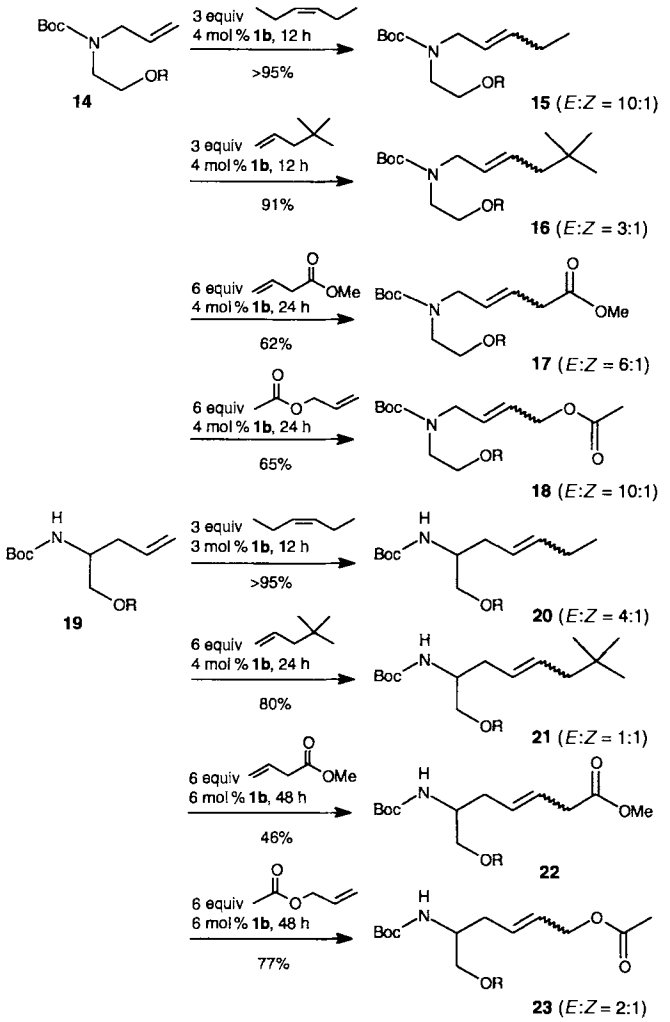

Figure 2. Results of the catalytic immobilization of olefins on tritylpolystyrene-bound *N*-Boc-*N*-allylglycinol (**14**) and *N*-Boc-*C*-allylglycinol (**19**). Boc = *tert*-butoxycarbonyl.

performed in viable yields. This reaction is interesting, because it enables a catalytic immobilization of dissolved compounds by C,C bond linkage. The tolerance of the applied catalysts to nitrogen- and oxygen-containing functional groups suggests that very diverse substrates can be coupled with this principle.

Experimental Procedure

General procedure for ruthenium-catalyzed ring closing metathesis: Under exclusion of moisture and air the tritylpolystyrene-bound diolefin (200–500 mg) was treated with the catalyst in the given solvent (10 mL g^{-1} resin). At the end of the reaction the resin was washed five times alternately with chloroform and methanol. For the cleavage the resin was suspended in a solution of trifluoroacetic acid (25% in chloroform) and shaken for 5 min. After addition of methanol (1 mL) and 5 min shaking, the liquid phase was separated off, and the resin again washed twice with 2 mL portions of a mixture of chloroform and methanol (1:1 v/v). The liquid phases were combined and concentrated under vacuum. The conversion was determined by analytical reversed-phase HPLC or GC. Finally the metathesis product was purified by chromatography and characterized.

General procedure for the ruthenium-catalyzed cross metathesis [12]: After addition of the soluble olefins the reactions were performed as already described. The catalyst was added in two steps, at the beginning of the reaction and after half the quoted reaction time had elapsed. After thorough washing the polymer was suspended in chloroform (10 mL g^{-1} resin). After addition of a drop of trifluoroacetic acid (intense red coloration of the globules of resin), the mixture was briefly shaken, and the reaction quenched with methanol (2 mL g^{-1} resin). After two subsequent washings with chloroform/methanol (1:1 v/v) the liquid phases were combined, treated with saturated $NaHCO_3$ solution and extracted three times with chloroform. Thin-layer chromatography confirmed that the urethane function was retained in the process of cleaving the product from the resin. The products were purified by chromatography and characterized.

[9] Loading was determined by a comparison by HPLC or GC of the filtrate after cleavage with trifluoroacetic acid from a defined amount of resin (5–20 mg) with a standard solution of the authentic compound.

[10] Compound **13** was treated several times with trifluoroacetic acid (10% solution in dichloromethane). The combined extracts were treated with methanol and an excess of K_2CO_3, shaken, and washed with water. The organic phase was dried over $MgSO_4$, filtered, and concentrated under vacuum. Compound **13b** was isolated by chromatography in an overall yield of 60% and characterized. The assignment of the diastereomers was achieved by NOE measurements. Selected spectroscopic data: **13b**-*syn*: ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.44-7.24$ (m, 5H), 5.94–6.01 (m, 1H), 5.63 (ddd, 1H, $J = 10$ Hz, 4 Hz, 2 Hz), 3.97 (dd, 1H, $J = 10$ Hz, 5 Hz), 3.82–3.76 (m, 1H), 3.69 (dd, 1H, $J = 10.5$ Hz, 3.5 Hz), 3.60 (dd, 1H, $J = 10.5$ Hz, 5 Hz), 2.31–2.15 (m, 2H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 144.5$ (C), 128.5 (CH), 128.0 (CH), 127.4 (CH), 127.0 (CH), 126.7 (CH), 65.8 (CH_2), 57.6 (CH), 57.1 (CH), 34.5 (CH_2); MS: *m/z* (%) 189 (0.5) [M^+], 188 (2), 170 (2), 158 (100), 141 (18), 131 (8), 115 (17), 106 (35), 91 (32), 77 (12), 65 (5), 55 (7); high resolution MS: calcd. for $C_{12}H_{14}NO$ [M^+-H]: 188.1075, found: 188.1075. **13b**-*anti*: ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.42-7.24$ (m, 5H), 6.05–5.98 (m, 1H), 5.69 (ddd, 1H, $J = 10$ Hz, 4 Hz, 2.5 Hz), 3.96 (dd, 1H, $J = 10$ Hz, 4 Hz), 3.61–3.48 (m, 3H), 2.38–2.19 (m, 2H); ^{13}C NMR (50.32 MHz, $CDCl_3$): $\delta = 143.7$ (C), 128.5 (CH), 127.9 (CH), 127.2 (CH), 126.6 (CH), 126.1 (CH), 62.9 (CH_2), 55.1 (CH), 50.9 (CH), 32.6 (CH_2); MS: *m/z* (%) 189 (0.5) [M^+], 188 (1), 170 (2), 158 (100), 141 (18), 131 (6), 115 (15), 104 (10), 91 (25), 77 (7), 65 (6), 53 (4); high resolution MS: calcd. for $C_{12}H_{14}NO$ [M^+-H]: 188.1075, found: 188.1075.

[11] The corresponding dimers, 4-octenediol and 2-butenediol, were isolated after cleavage from the resin as *E*/*Z* mixtures.

[12] The quoted amounts of catalyst refer to the components in solution. After acid cleavage the yield, based on the immobilized components, was determined by GC. The *E*/*Z* rations were likewise determined by gas chromatography, and the isomers, purified by chromatography on silica gel, were assigned by ^{1}H NMR spectroscopy.

Dioxygen Activation by a Manganese Complex Containing a Schiff Base: Selective Oxidation of an Imino to an Amido Group within the Salophen Ligand and Formation of a Hydroxy-Bridged Mn^{III}-Polymer**

Emma Gallo, Euro Solari, Nazzareno Re, Carlo Floriani,* Angiola Chiesi-Villa, and Corrado Rizzoli

The manganese-assisted oxygen transfer from dioxygen to substrates remains a rather uncommon process,[1] even though investigations on the interaction of manganese with dioxygen are very extensive over several classes of complexes.[2] However, the reactions are carried out in situ on poorly defined products that were not previously isolated and under protic conditions. The products of such reactions are almost exclusively μ-oxo complexes,[3] which are supposed to be reactive oxidizing agents. The oxygen transfer ability belongs essentially to the [Mn=O] functionality,[4] formed from oxidizing agents other than dioxygen, or to much rarer peroxo-[5] or superoxomanganese[6] derivatives, which come from dioxygen.

Tetradentate Schiff bases, particularly those having the salen skeleton (H_2salen = bis(salicylidene)ethylenediamine),[7] were ligands of choice in this field, whereas only minor attention was given to the salophen dianion[8] (H_2salophen = N,N'-*o*-phenylenebis(salicylideneimine)).

This report concerns the reaction the Schiff base (SB) complexes depicted in Scheme 1 with dioxygen under very controlled conditions. The reaction products vary, depending on the solvent (*n*-hexane, thf, or pyridine).

The reaction of **1** and **3** with oxygen in hydrocarbon solvents or thf gave polymeric **5** and **6**, respectively, which underwent cleavage to **7** and **8** when pyridine was added. However, the reaction of **2** and **4** with oxygen in pyridine led directly to **7** and **8**, which formed in a yield consistently lower than 50% at a constant O_2 uptake in the Mn/O_2 molar ratio of 2/1.[10] Even when the reaction is run in pyridine, these data support the intermediacy of **5** and **6** and rule out the further oxidative conversion of the undetected monomeric hydroxy-Mn moiety. In pyridine the oxygenation of **2** and **4**, which have been isolated from neat pyridine and structurally characterized as dimers, probably occurs on the dimeric form. We proposed that the formation of a superoxo complex is followed by hydrogen abstraction from the imino carbon (Scheme 2). The cleavage of the resulting hydroperoxo moiety generates a Mn-O· radical which couples with the radical at the imino carbon. The reaction very probably occurs intramolecularly within the dimer. Although the relatively slow oxygenation of **1** and **3** was carried out both at -78 and $-40\,^{\circ}C$, we were unable to detect any peroxo-type intermediate in the UV/Vis spectrum. The overall result of the dioxygen reaction with **1** and **3** is the conversion of one imino group of the dimer into an amido with the concurrent formation of a OH-bridged Mn^{III} dimer.

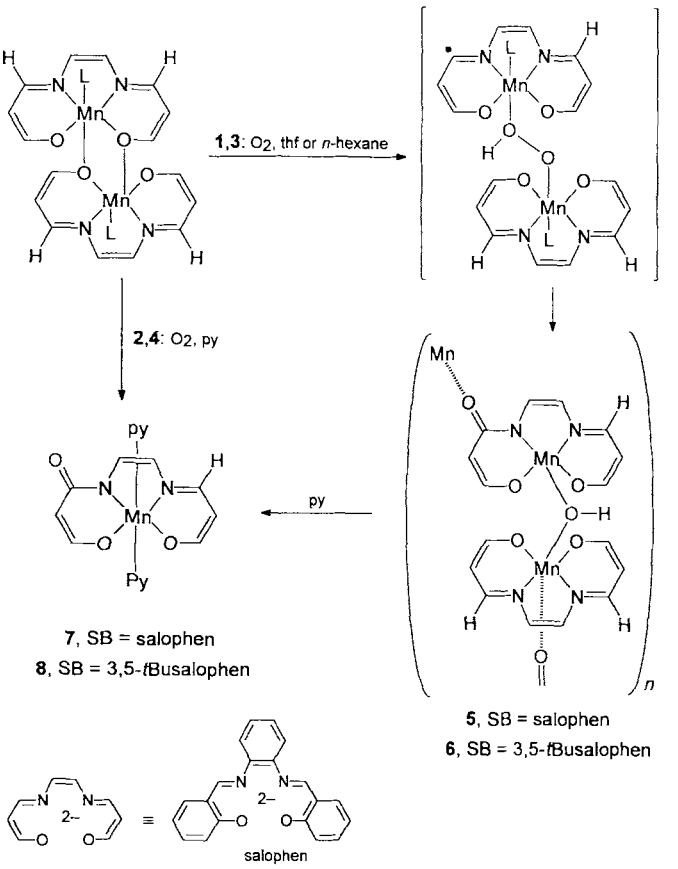
1 [9]: SB = salophen, L = thf
2: SB = salophen, L = pyridine (py)
3: SB = 3,5-*t*Bu salophen, L = thf
4: SB = 3,5-*t*Bu salophen, L = py

Scheme 1. 3,5-*t*Busalophen = dianion of *N,N*-*o*-phenylene-bis(3,5-di-*tert*-butylsalicylidenimine).



Scheme 2.

Complexes **2** and **6**–**8** have been structurally characterized, but details are given only for **6**,[11] which is a rare[12] Mn^{III} dimer bridged by a single hydroxy group. Its structure is shown in Figure 1. The hydroxy group asymmetrically bridges the two Mn^{III} atoms [unit A: Mn1–O4 2.009(8) Å; unit B: Mn1–O4 2.082(8) Å], and the Mn–O distances are much longer than those of corresponding oxo-bridged analogues [1.78–1.84 Å]. The coupling constant for **6** ($-24.0\ cm^{-1}$) shows a significant antiferromagnetic coupling between the two Mn^{III} units ($S = 2$) within the dimer, in agreement with the wide Mn-O-Mn angle [Mn1(unit A)-O4-Mn1(unit B) 147.2(4)°], whereas the interdimer coupling is irrelevant. The coupling constant value is close to that found in the single (μ-hydroxy)Mn^{III}–Mn^{III} dimer reported very recently.[12] Besides the electronic properties, a major reason for the difference between the salophen and salen skeletons stems from the much more rigid, square-planar coordination that the salophen imposes on the metal. Thus, for the case of salophen, the evolution of a superoxo and subsequently peroxo type of intermediate to a *cis* bis-μ-oxo arrangement becomes much less favorable, since other evolution pathways are possible.

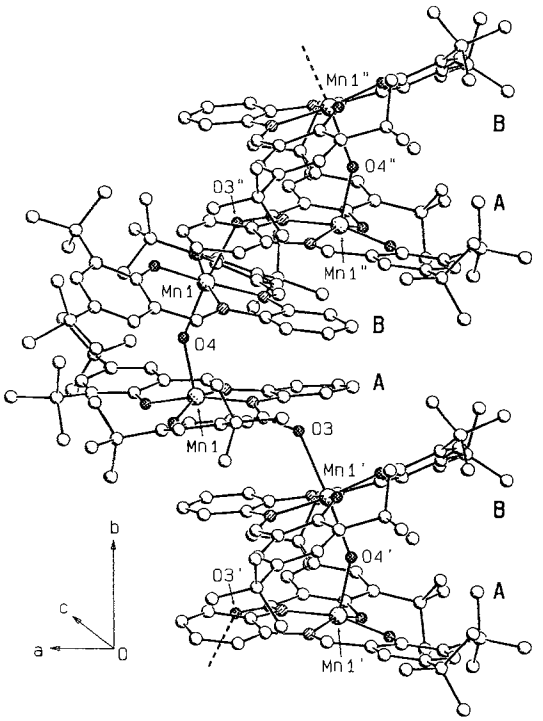

Fig. 1. SCHAKAL view of the chaining of complex **6** along the [010] direction. Selected bond lengths [Å] and angles [°] for moiety A [B in square brackets]: Mn1–O4, 2.009(8) [2.082(8)]; Mn1B–O3″, 2.373(7); O3–C7, 1.257(10); N1–C7, 1.343(12) [1.292(14)]; N2–C14, 1.291(12) [1.292(13)]. Selected bond angles [°]: C7-O3-Mn1B′, 132.6(6); Mn1A-O4-Mn1B, 147.2(4). Disorder omitted for clarity. Prime and double prime denote a transformation from x,y,z to $-x, -0.5+y, 0.5-z$ and $-x, 0.5+y, 0.5-z$, respectively.

The reactions with **1** and **3** have been carried out under strictly nonprotic conditions. Thus, the imino hydrogen plays a major role as a source of peroxo hydrogen. By replacing the hydrogen atom at the imino functionality with a methyl group as in **9**,[9]

[Mn(Me–salophen)(thf)]$_2$ **9**

a very different reaction pathway was observed, which also varied depending on the nature of the solvent. In fact, the reaction of O_2 with **9** in thf was strikingly different from that with **1** and **3**. The O_2:Mn ratio changes from 0.5:1 for **1** and **3** to 1:1 for **9**.[10] Therefore, in the case of **9**, we propose the formation of a superoxo species, which in the absence of the imine proton cannot evolve in the same manner as for **1** and **3**.[13] We should also emphasize that, in general, the genesis of the OH ligand in manganese complexes is from either hydrolysis[14] or protonation of μ-oxo compounds[15] rather than from the activation of a carbon–hydrogen bond.

Experimental Procedure

6: **4** (2.01 g, 1.51 mmol) was dissolved in thf (100 mL), nitrogen was removed from the red solution by evacuation, and oxygen dried over P_2O_5 was allowed to enter at room temperature. The resulting brown solution was stirred for 12 h at room temperature under an oxygen atmosphere. The mixture was then evaporated to dryness, and the resulting brown solid extracted with Et_2O (50 ml). The extract was filtered to collect the product and the resulting red solid was then dried in vacuo (65%). Elemental analysis calcd for $[C_{72}H_{92}Mn_2N_4O_6]_n$: C 70.92, H 7.60, N 4.59; found: C 70.53, H 7.76, N 4.17. Recrystallization of the powder from heptane yielded red crystals suitable for X-ray diffraction. IR (Nujol): $\tilde{\nu}$ = 1602(s), 1576(m), 1548(w), 1525(s) 1419(w), 1358(m), 1315(m), 1256(m), 1172(m), 836(m), 741(s), 540(m) cm^{-1}.

8: **6** (1.04 g, 0.85 mmol) was dissolved in pyridine (30 mL), and the resulting red solution was stirred for 12 h at room temperature and then evaporated to dryness. The residue was extracted with Et_2O (50 ml) to give a suspension of the red solid product in Et_2O. The product was then filtered off and dried in vacuo (31%). Recrystallization of the powder from Et_2O:pyridine (90:10) yielded red crystals suitable for X-ray diffraction. Elemental analysis calcd for $C_{46}H_{55}MnN_4O_3$: C 72.04, H 7.23, N 7.31; found: C 71.57, H 7.30, N 7.08. μ = 4.63 μ_B at 293 K.

[10] O_2 uptake has been measured in thf and py at 298 K, according to a modified version of the apparatus reported in F. A. Cotton, F. Calderazzo, *Inorg. Chem.* **1962**, *1*, 30. The expected error in the O_2 uptake volume is lower than 5%.

[11] Crystal data for **6**: $C_{72}H_{92}Mn_2N_4O_6 \cdot 2C_6H_{14}$, M = 1391.8, monoclinic, space group $P2_1/c$, a = 17.395(4), b = 13.083(3), c = 34.904(6) Å, β = 103.61(2)°, V = 7720(3) Å^3, Z = 4, ρ_{calcd} = 1.197 g cm^{-3}, $F(000)$ = 3000, $Cu_{K\alpha}$ radiation (λ = 1.54178 Å), μ = 30.72 cm^{-1}; crystal dimensions 0.15 × 0.27 × 0.38 mm. The structure was solved by the heavy atom method and anisotropically refined for all the non-H atoms except for those affected by disorder. One butyl group (C33 ··· C36) in unit A was found to be disordered over two positions with a site occupation factor of 0.5 on isotropic refinement. The two *n*-hexane solvent molecules of crystallization showed high isotropic thermal parameters indicating the presence of disorder. The best fit was obtained on isotropic refinement by splitting the C2, C3, C10, and C11 atoms over two positions with site occupation factors of 0.6 and 0.4, respectively. The H4 hydrogen atom associated with the hydroxo group was located from a difference Fourier map and isotropically refined. All the other hydrogen atoms except those associated with disordered atoms (which were ignored) were located from difference Fourier maps or put in geometrically calculated positions and introduced as

fixed contributors in the last stage of refinement (U_{iso} = 0.08 Å^2). During the refinement the C–C bond distances within the disordered butyl group and *n*-hexane molecules were constrained to be 1.54(1) Å. For 5086 unique observed reflections [$I > 2\sigma(I)$] of a total of 11 208 collected at T = 173 K on a Rigaku AFC6S diffractometer ($6 > 2\theta > 140°$) and corrected for absorption, R is 0.073 ($wR2$ = 0.178). All calculations were carried out on an IBM PS2/80 Personal Computer and an ENCORE E91 computer. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, as supplementary publication no. CCDC-179-62. $BaYbSi_4N_7$—Unexpected Structural Possibilities in Nitridosilicates**

Hubert Huppertz and Wolfgang Schnick*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

Recently we developed a novel synthetic approach to ternary nitridosilicates by reacting alkaline earth or rare earth metals with silicon diimide in a specially developed high-frequency (HF) furnace.[1–3] These reactions may be interpreted as the dissolution of an electropositive metal in a nitrido-analogous, polymeric acid accompanied by the evolution of hydrogen [Eqs. (a) and (b)]. A specific advantage of this method is the possibility of varying the metals and the fact that preparative amounts of nitridosilicates are accessible as coarse crystalline and single-phase products in short reaction times.[4]

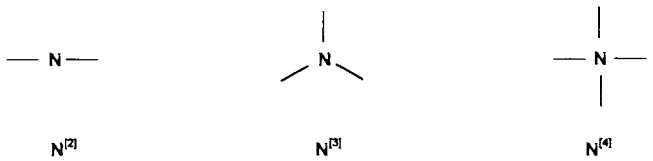
$$2M + 5Si(NH)_2 \xrightarrow[\text{HF-furnace}]{1500–1650\,^\circ C} M_2[Si_5N_8] + N_2 + 5H_2 \quad (a)$$
M = Ca, Sr, Ba

$$3M' + 6Si(NH)_2 \xrightarrow[\text{HF-furnace}]{1650\,^\circ C} M'_3[Si_6N_{11}] + {}^1/_2\,N_2 + 6H_2 \quad (b)$$
M' = Ce, Pr

SiO_4 and SiN_4 tetrahedra are characteristic structural elements in oxo- and nitridosilicates, respectively. These tetrahedra are connected through corner-sharing to give network structures. In oxosilicates a maximum cross linkage is reached in silicon dioxide, in which the molar ratio of tetrahedral centers to bridging atoms is Si:O = 1:2. All bridging atoms ($O^{[2]}$) are bonded to two Si atoms. In nitridosilicates built up from the SiN_4 tetrahedra, bridging atoms ($N^{[3]}$) were found for molar ratio of Si:N > 1:2 for the first time. These bridging atoms each connect three silicon atoms (for instance $^3_\infty[(Si_6^{[4]}N_9^{[2]}N_2^{[3]})^{9-}]$ and $^3_\infty[(Si_5^{[4]}N_4^{[2]}N_4^{[3]})^{4-}]$).

Accordingly, nitridosilicates extend the structural possibilities of silicates and lead with a molar ratio Si:N > 1:2 to higher condensed network structures, for which there are no analogues in the oxosilicates. The maximum cross linking is reached in Si_3N_4,[5] in which according to $^3_\infty[Si_3^{[4]}N_4^{[3]}]$ all nitrogen atoms ($N^{[3]}$) are connected to three Si atoms.

In the Si–N networks we have examined to date, no nitrogen atoms simultaneously connected to four Si tetrahedral centers ($N^{[4]}$) were observed. In condensed tetrahedral structures such a structure motif is only expected to occur when the molar ratio of tetrahedral centers T to bridging atoms X lies in the range of $1.0 \geq T:X \geq 0.75$. In the case of nitridosilicates(IV), this would require partial cationic Si–N structures, which have not been observed so far.[6] Herein we report on $BaYbSi_4N_7$, the first compound in which one nitrogen atom connects four silicon atoms (cf. Scheme 1).



Scheme 1. In nitridosilicates, nitrogen atoms covalently connect two, three, or four Si tetrahedral centers.

The new nitridosilicate $BaYbSi_4N_7$ was synthesized by reacting stoichiometric amounts[7] of Ba and Yb metal with silicon diimide $Si(NH)_2$ in a HF furnace[1] under nitrogen atmosphere [Eq. (c)]. This process leads to the formation of $BaYbSi_4N_7$ as a single-phase,[8] coarse crystalline, colorless solid. Similar to all the other nitridosilicates we have synthesized so far, $BaYbSi_4N_7$ is stable up to 1600 °C and resistant to hot acids and alkalines.

$$Ba + Yb + 4Si(NH)_2 \xrightarrow[\text{HF-furnace}]{900–1650\,^\circ C,\ 18\,h} BaYbSi_4N_7 + {}^1/_2\,N_2 + 4H_2 \quad (c)$$

According to the X-ray structure determination on single crystals,[9] $BaYbSi_4N_7$ contains a network structure of corner-sharing SiN_4 tetrahedra $^3_\infty[(Si_4^{[4]}N_6^{[2]}N^{[4]})^{5-}]$. Although a stoichiometric ratio of Si:N = 4:7 should lead to $^3_\infty[(Si_4^{[4]}N_5^{[2]}N_2^{[3]})^{5-}]$, no $N^{[3]}$ atoms were found. Instead, there is a corresponding number of $N^{[4]}$ bridges, which connect four Si tetrahedral centers. As expected the bond lengths to the $N^{[4]}$ atoms in $BaYbSi_4N_7$ are significantly longer (Si–N: 188–196 pm) than those to the $N^{[2]}$ atoms (Si–N: 170–172 pm).

The Si–N network structure in $BaYbSi_4N_7$ is built up from starlike $[N(SiN_3)_4]$ building blocks (Fig. 1). By connecting these groups through common

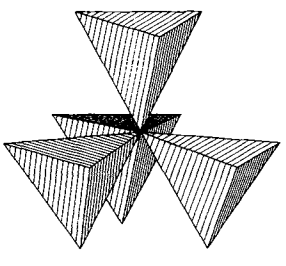


Fig. 1. Four SiN_4 tetrahedra are connected through a common nitrogen atom to give a $[N(SiN_3)_4]$ building block. The entire network structure of $BaYbSi_4N_7$ is built up by these starlike-shaped building blocks.

[**] This work was supported by the Fonds der Chemischen Industrie and the Deutsche Forschungsgemeinschaft (Schwerpunktprogramm "Nitridobrücken", project SCHN 377/7-1 and 2, and the Gottfried Wilhelm Leibniz program).

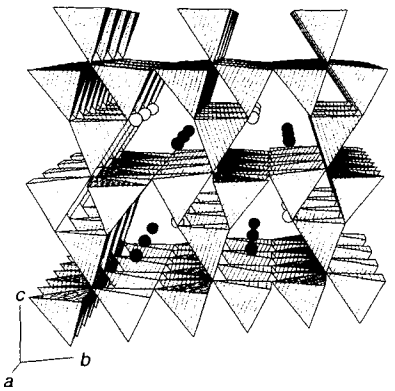

Fig. 2. Crystal structure of $BaYbSi_4N_7$. The SiN_4 tetrahedra are shown as closed polyhedra, the Ba^{2+} ions as grey and the Yb^{3+} ions as black spheres.

N atoms a stacking variant of the wurtzite-analogous aluminum nitride structure type is formed (Fig. 2). Systematic elimination of tetrahedra from this arrangement along [100], leads to the formation of sechser ring channels, in which the Ba^{2+} and Yb^{3+} are positioned. The Ba^{2+} and Yb^{3+} metal ions show anticuboctahedral and octahedral coordination, respectively, by nitrogen atoms of the Si_4N_7 network. The Ba–N and Yb–N contact distances (298–305 pm and 229–231 pm) approximately correspond to the sum of the ionic radii.[10]

$BaYbSi_4N_7$ provides the first example of $N^{[4]}$ connections between four Si tetrahedral centers. This extends the structural possibilities in nitridosilicates by a surprising dimension. Thoroughly cross-linked Si–N network structures, particularly in highly condensed nitridosilicates (Si:N $>1:2$), should be possible for which attractive material properties (high mechanical, thermal, and chemical stability) can be predicted. While the structural chemistry of oxosilicates is limited to terminal oxygen atoms and simple bridging $O^{[2]}$ atoms, the nitridosilicates show extended structural possibilities with $N^{[2]}$, $N^{[3]}$, and $N^{[4]}$ connections of Si tetrahedral centers. These variations have not as yet been found in oxosilicates and may not be possible with silicon and oxygen.[11]

[4] Meanwhile some rare earth nitridosilicates $Ln_3Si_6N_{11}$ (Ln = La, Ce, Pr, Nd) and $LnSi_3N_5$ (Ln = Ce, Pr, Nd) are synthesized by reaction of the silicides $LnSi_2$ and "$LnSi_3$" with N_2: M. Woike, W. Jeitschko, *Inorg. Chem.* **1995**, *34*, 5105. A problem with this procedure is the avoidance of metallic impurities.
[5] W. Schnick, *Angew. Chem.* **1993**, *105*, 846; *Angew. Chem. Int. Ed. Engl.* **1993**, *32*, 806.
[6] Well-known examples for $N^{[4]}$ connections in nitrides are BN and AlN.
[7] In a typical charge 1 mmol of the metals were thoroughly mixed with $Si(NH)_2$ under inert gas atmosphere in a glove box and transferred in a tungsten crucible into the HF reactor. Under nitrogen atmosphere the reaction mixture was slowly heated up to 1650 °C, maintained at that temperature for 2 h, and then cooled down to 1400 °C within 15 h. At the end of the reaction the product was quenched to room temperature.
[8] The composition of $BaYbSi_4N_7$ was confirmed to be in agreement with the structure analysis by energy dispersive X-ray microanalysis (Ba,Yb,Si) and quantitative determination by Pascher (Remagen). The absence of hydrogen (NH) was checked by IR spectroscopy.
[9] $BaYbSi_4N_7$: $P6_3mc$, $a = 603.07(2)$, $c = 981.98(4)$ pm, $Z = 2$, Siemens P4 diffractometer, $Mo_{K\alpha}$ radiation, graphite monochromator, $F(000) = 462.0$, $\mu(Mo_{K\alpha}) = 22.07\ mm^{-1}$, ω scan, 11456 measured reflections in the range $2° \le 2\theta \le 95°$, 1144 unique reflections with $F_o^2 \ge 0\sigma(F_o^2)$, empirical absorption correction (ψ scans), $R_{int} = 0.0728$, the crystal structure was solved by direct methods (SHELXTL-Plus, Vers. 5.03) and anisotropically refined by a least-squares procedure against F^2 with all data, 32 refined parameters, $R1 = 0.0210$, $wR2 = 0.0475$, GOF = 1.06. The absolute structure was determined, Flack parameter $x = 0.151(8)$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-405194.

[11] Indeed there are $O^{[3]}$ connections in stishovite according to $^3_\infty[Si^{[6]}O^{[3]}_2]$ but at the same time the coordination number of the Si atoms in this high-pressure modification is raised from four to six. Also compare: F. Liebau, *Structural Chemistry of Silicates*, Springer, Berlin, **1985**.

LUCY—A Program for Structure Elucidation from NMR Correlation Experiments**

Christoph Steinbeck*

With the introduction of gradient-supported NMR spectroscopy, the time and effort required to record two-dimensional C,H correlations has now reached such a level that they can be considered as routine applications. Thus, long-range C,H correlation (HMBC[1]), long appreciated as a very valuable tool for determining the constitution, is also widely available. The idea of using this spectroscopic information for computer-supported, automated structure elucidation was close at hand. Although Lindley et al.[2] demonstrated the use of 2D information in a computer program for generating structures as early as 1983, it was not until the beginning of the 1990s that useful attempts in CASE systems (*c*omputer *a*ssisted *s*tructure *e*lucidation) were published.

We now introduce the program LUCY with which one can determine the constitution of an unknown compound based on the results of an HMBC experiment by using a standard personal computer. The information required for this task is the empirical formula, the broadband-decoupled ^{13}C, the DEPT-90, the DEPT-135, and the C,H COSY spectra (HMQC,[3] HSQC[4]). The H,H COSY diagram is optional, but useful. Here $^3J_{H,H}$ couplings are used exclusively. Evaluation of the DEPT spectrum and the C,H COSY diagram permits the user to exclude geminal coupling in the H,H COSY spectrum for diastereotopic protons of CH_2 groups. Furthermore, statements can be made as to whether or not a C atom is attached to a heteroatom, as evidenced by its chemical shift or its C,H coupling constants.

The authors of programs that use 1D NMR, mass, and IR spectra for structure elucidation have also reported recently on the use of HMBC data.[5, 6] However, new modules were always added to existing systems. LUCY, on the other hand, has been specifically designed to make use of HMBC data.

Our process uses these data to generate larger fragments of the carbon skeleton already in the first step of the structure elucidation. The CH_x ($x = 0-3$) fragments and the heteroatoms obtained from the DEPT experiments are combined in a recur-

sive process [analyse coloc( )] to give all possible interpretations of the long-range C,H coupling in question. The use of $^3J_{H,H}$ couplings leads to a marked reduction in the number of combinations to be carried out. The algorithm is based on the hypothesis that the HMBC cross signals are representations of $^2J_{C,H}$ or $^3J_{C,H}$ couplings. Two atoms C_A and B (where B can be a carbon atom or a heteroatom bearing a proton) between which a correlation $C_A \rightarrow B{-}H$ exists, are connected to each other either directly ($^2J_{C,H}$) or through an optional heavy atom in the matrix ($^3J_{C,H}$). $^4J_{C,H}$ Couplings have not been considered, which appears to be justified given the statistical rarity of such cross signals and the enormous increase in computing time that would result were these couplings taken into account. Generation of these fragments from HMBC data leads to an extremely effective limitation in the number of solutions and the time required for structure elucidation is considerably reduced in comparison with that required for one based on selected HMBC data *after* the structure generation. In this way, a selection by applying other rules can be largely avoided.

During evaluation of the HMBC data, if a valid interpretation (in terms of the rules defined above) of all HMBC signals is found, the structure generator make bond( ) is used to complete the connectivity matrix. The resulting structure is subjected by the routine test global( ) to a number of user-defined selection criteria (for example, exclusion of rings of a certain size) and then displayed as a structure formula (an algorithm[8] developed by Ugi is used for the display).

The program consists of two parts (Fig. 1). The user interface LUCY (structure e*LUCI*dation), which runs under MS-Windows 3.1, Windows 95, and Windows NT, allows the convenient

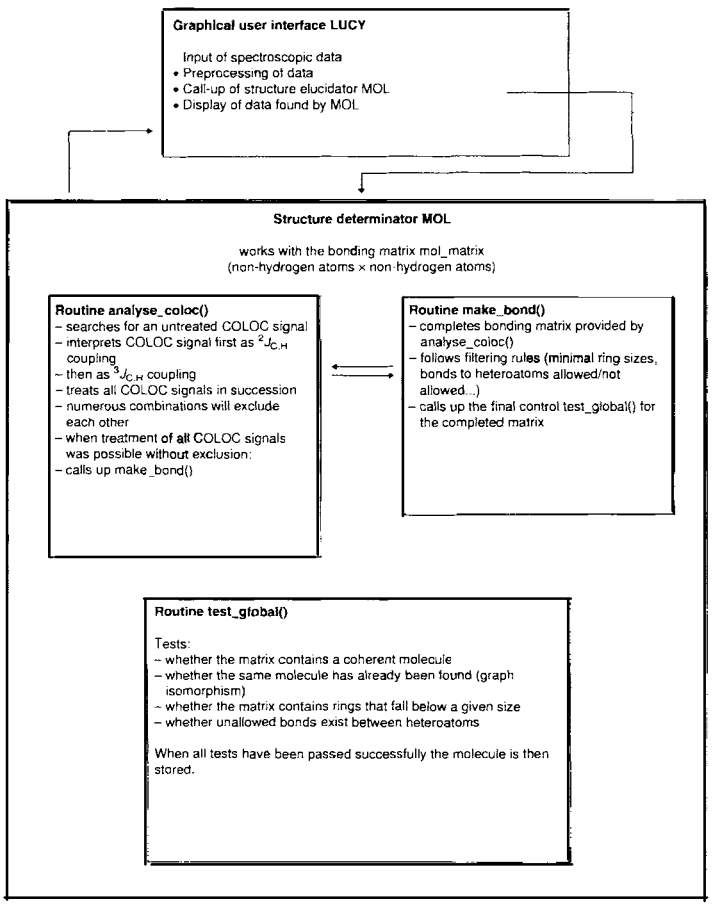

Fig. 1. Structure of the program LUCY.

introduction of data, whilst the calculation is carried out by the module MOL. Every modern PC (minimum requirement: an Intel 80486 processor) can be used. The structure elucidation can be transferred to another computer, for example, a work station, because the program can be divided into two parts.

The performance of the system is demonstrated with two examples. In 1991 Munk and Christie[5] determined the structure of monochaetin ($C_{18}H_{20}O_5$) by using DEPT, H,H COSY, and C,H COSY spectra, together with long-range C,H correlation with the system COCOA/INFER2D. The constitution of this fungal metabolite had already been elucidated in 1986 by conventional means.[7] Munk and Christie obtained six structures, including the correct one.

The same experimental data[5] were used for a structure elucidation with LUCY (Table 1, Fig. 2). The program effected a

Table 1. Data used for calculating the monochaetin structure [a]

C-18	CH_3	11.45	0.97		1.81/1.48

[a] The shifts of the diastereotopic protons, which belong to the same CH_2 group, are separated by a backslash. [b] The δ values in the column H,H COSY are the coordinates of the cross signals, for which the matching values can be found in the column C,H COSY. This is also valid for the data given in Table 2.

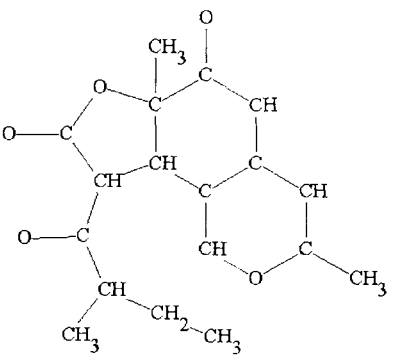

Fig. 2. Results calculated with LUCY on the monochaetin problem

minimal preprocessing in which it assigned, on the basis of the ^{13}C chemical shift, the signal at $\delta_C = 169$ to a carboxylic acid derivative (COO function) and the signals at $\delta_C = 205$ and $\delta_C = 191$ to two keto functions (>C=O). This preprocessing cannot be switched off at the moment, but can be adjusted. LUCY obtained the correct structure as the only result within about one minute using Windows95 with a Pentium PC operating at 100 MHz.

[a] See footnote [b] in Table 1.

The program is being tested on numerous other examples in the course of our daily work.[10] Figure 3 shows the six solutions to the polycarpol problem[9] calculated by LUCY with data from Table 2, the largest matrix tested by us to date. The program requires two hours for the calculation (same conditions as above).

An Unusually Stable Pentaethynylcyclopentadienyl Radical**

Norbert Jux, Karoly Holczer,* and Yves Rubin*

A major research goal of fullerene chemistry has been to encapsulate atoms or metal ions within the carbon framework of C_{60}.[1,2] Schwarz et al. and Saunders et al. have shown that inert gases like helium can be inserted into fullerenes, albeit with

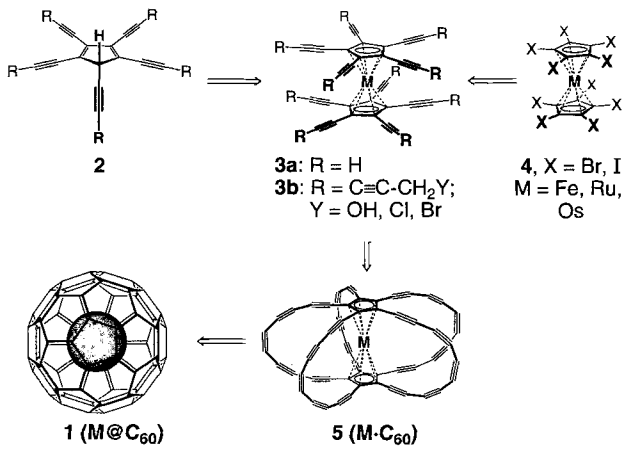
H. thanks the National Science Foundation for an instrumentation grant (DMR-9404166) and for support of a Bruker ESP380e spectrometer equipped with a 360D Dice ENDOR unit. N. J. thanks the Deutsche Forschungsgemeinschaft for a postdoctoral fellowship.

low efficiency, to give $He@C_{60}$.[3] Endohedral metal complexes of fullerenes are generated by evaporation of carbon rods filled with lanthanide oxides or nitrides yielding, for example, $La@C_{82}$.[2] A significant limitation of this procedure is that none of these compounds can be obtained in reasonable amounts, and so far no endohedral transition metal complexes of C_{60} itself (**1**, $M@C_{60}$) have been isolated.[4] The properties of the latter are potentially the most rewarding with regard to their superconductivity, ferromagnetism, and other interesting physical properties.

As part of a three-front approach to a rational synthesis of endohedral metal fullerene complexes such as **1** based on the multiple bond reorganization of alkyne-rich cyclophanes,[5–8] we have been investigating ways to incorporate the metal early on in the synthesis in the form of the D_{5h}-symmetric metallocene cyclophane **5**, isomeric to $M@C_{60}$ **1** (Scheme 1). Although we do not expect to isolate **5**, it may be an intermediate in flash vacuum pyrolytic or solution-phase reactions of the decakis-

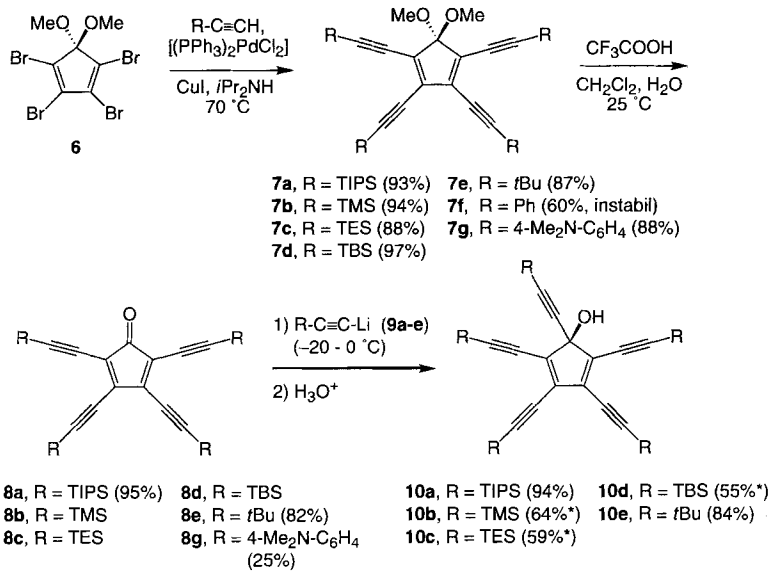


Scheme 1.

(1,3-pentadiynyl)metallocenes **3b**. The logical precursor of **5** is the decaethynylmetallocene **3a**, but little is known about this class of compounds. Bunz et al. have reported the synthesis of the half-sandwich pentaethynylcymantrenes (cymantrene = $CpMn(CO)_3$) through alkynylation of the corresponding pentaiodide.[9] In our hands similar ethynylation reactions of the decahalogenated precursors **4** have failed so far.[10] An alternate approach to decaethynylmetallocene **3a** is by deprotonation of a pentaethynylcyclopentadiene **2** and reaction with a metal halide.

In pursuit of this goal, we have developed a straightforward approach to the alcohols **10a–e**, halides **11a–c**, and the tautomeric fulvene-allenes **12a**, **12e**, and **13**. The preparation and characterization of the surprisingly stable pentaethynylcyclopentadienyl radical **14** is also presented.

1,1-Dimethoxy-2,3,4,5-tetrabromocyclopentadiene (**6**)[11] was ethynylated with various substituted acetylenes using a modified Sonogashira reaction (Scheme 2).[12] Substituents on acetylene include the trimethylsilyl (TMS), triethylsilyl (TES), triisopropylsilyl (TIPS), *tert*-butyldimethylsilyl (TBS), *tert*-butyl, phenyl, and 4-dimethylaminophenyl groups. The resulting ketals are obtained as yellow (**7a–e**), orange (**7f**), or red (**7g**)



Scheme 2. Preparation of the pentaethynylcyclopentadienols **10a–e**; the yields marked with an asterisk are based on corresponding ketals.

crystals and are highly fluorescent in solution. The compounds we describe here are limited mainly to those protected with the triisopropylsilyl group (TIPS), because of the large kinetic stability it provides them (Table 1). However, the same reactions have been carried out on most of the other members of this series without significant alterations.

Acidic cleavage of the ketals **7a–e** and **7g** with trifluoroacetic acid/water (9:1) in CH_2Cl_2 afforded the cyclopentadienones

Table 1. Selected physical data for compounds **7a**, **8a**, **10a**, **12a**, **13**, and **14**.

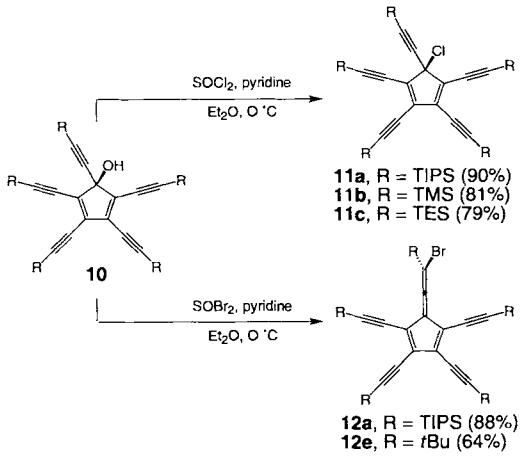
12a: M.p. 214–216 °C (decomp); ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.09–1.16 (m, 105H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 11.48, 11.51, 11.83, 18.59, 18.74, 18.78, 84.68, 100.31, 100.33, 101.48, 102.54, 114.30, 122.96, 130.28; IR (KBr): $\tilde{\nu}$ = 2136, 1911 cm^{-1}; HR-MS (FAB): *m/z* 1046.6250 (M^+), calcd. for $C_{60}H_{105}{}^{81}BrSi_5$: 1046.6225; UV/Vis (cyclohexane): λ_{max} (ε) = 255 nm (26900), 302 (39500), 332 (15800), 377 (16800), 390 (16600), 511 (1900), 636 (520).

13: M.p. 258–260 °C; ^{1}H NMR (400 MHz, $CDCl_3$): δ = 1.08–1.19 (m, 105H), 5.88 (s, 1H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 11.41, 11.47, 11.91, 18.51, 18.75, 18.78, 18.80, 18.81 (more than three signals due to hindered rotation), 81.39 (^1J(C,H) = 154.7 Hz), 99.12, 99.48, 100.73, 100.98, 109.40 (^3J(C,H) = 7.7 Hz), 123.96, 127.26, 207.41 (^2J(C,H) = 8.1 Hz); IR (KBr): $\tilde{\nu}$ = 2136, 1901 cm^{-1}; HR-MS (FAB): *m/z* 967.7249 (M^-), calcd for $C_{60}H_{107}Si_5$: 967.7219; UV/Vis (cyclohexane): λ_{max} (ε) = 297 nm (46800), 300 (41900), 327 (16900), 358 (16000), 375 (18300), 394 (14600), 466 (4600), 638 (30).

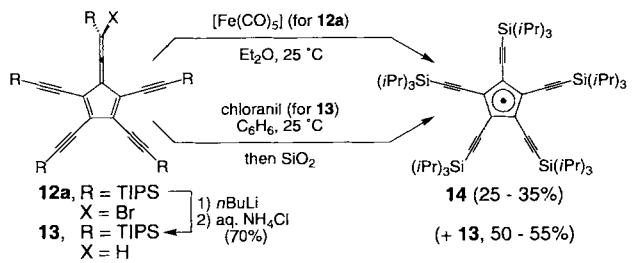
14: M.p. > 145 °C (decomp); ^{1}H NMR (400 MHz, C_6D_6): δ = 2.86 (br. s, 90H), 1.37 (s, 15H); IR (KBr): $\tilde{\nu}$ = 2126, 1896 cm^{-1}; HR-MS (FAB): *m/z* 966.7131 (M^+ + H), calcd for $C_{60}H_{106}Si_5$: 966.7141; UV/Vis (cyclohexane): λ_{max} (ε) = 289 nm (46800), 308 (41400), 421 (4000), 529 (1200), 564 (3100), 595 (6100), 614 (4100), 640 (14200).

8a–e and **8g**. The TIPS and *tert*-butyl derivatives **8a** and **8e** are stable purple crystalline solids which show no tendency to dimerize, while the other ketones can be stored only in dilute solution.[13,14] Reaction of **8a–e** with the corresponding lithiated acetylenes **9a–e** gave the stable alcohols **10a–e**. These alcohols could be converted smoothly to either the chlorinated pentaethynylcyclopentadienes **11a–c** or their brominated fulvene-allene tautomers **12a** and **12e**, depending on whether $SOCl_2$ or $SOBr_2$ was used (Scheme 3).



Scheme 3. Formation of the halogenated pentaethynylcyclopentadienes **11a–c** and their fulvene-allene tautomers **12a** and **12e**.

On addition of *n*-butyllithium to bromide **12a** (Scheme 4) in THF or Et_2O at $-78\,^{\circ}C$ the red color of the fulvene-allene disappeared and a yellow suspension of the lithium salt formed. Addition of anhydrous iron(II) chloride did not lead to the formation of the ferrocene **3a** (M = Fe). Instead, quenching of the reaction mixture with saturated NH_4Cl gave the dehalogenated fulvene-allene **13** rather than the cyclopentadiene tautomer **2** (R = TIPS). In another attempt to prepare the ferrocene **3a**



Scheme 4.

(M = Fe), bromide **12a** was treated with $[Fe(CO)_5]$[15] in ether at $25\,^{\circ}C$ to yield a new compound with an intense blue-green color, along with some orange-red **13**. Column chromatography on silica gel with hexanes in air gave the surprisingly stable cyclopentadienyl radical **14**.[16] Alternatively, radical **14** was prepared by oxidation of fulvene-allene **13** with chloranil or 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) in benzene at $25\,^{\circ}C$; interestingly this reaction required treatment with silica gel to induce formation of the radical.[17]

The surprising stability of radical **14** is in striking contrast with that of pentaaryl- or pentaisopropylcyclopentadienyl radicals,[16] which, although stable at $25\,^{\circ}C$, are all described as being highly sensitive to oxygen. Remarkably, radical **14** is stable in contact with air for weeks in the solid state and for days in hexane solution. This stability is even more peculiar because the steric shielding provided by the aryl or isopropyl substituents around the cyclopentadienyl radical must be considerably greater than that in the pentaethynyl system **14**, where the cyclopentadienyl ring remains very accessible to small molecules like oxygen.

The ^1H NMR spectrum of **14** shows two broad signals at $\delta = 2.86$ (90H; 350 Hz half-width) and $\delta = 1.37$ (15H) indicating the effect of the paramagnetic system on the proton resonances of the remote TIPS hydrogens. These two signals are well-separated in contrast to the usual TIPS-C≡C resonances which coincide at $\delta = 1.1$. The signal at $\delta = 2.86$ is shifted about 1.8 ppm downfield, indicating the effect of the paramagnetic system on the methyl protons of the TIPS groups. The paramagnetic shielding in **14** is less pronounced than that in the pentaisopropylcyclopentadienyl radical[16b,c] due to the larger distances of the CH and CH_3 groups from the radical center in the pentaethynylated system.

Confirmation of the radical nature of **14** was provided by an intense (unresolved) ESR signal at $25\,^{\circ}C$ in methylcyclohexane (MCH). For further evaluation of the structure of **14**, we performed a hyperfine-correlated ENDOR (HYEND) experiment (ENDOR = electron nuclear double resonance) at 20 K (Fig. 1).[18] This method is applicable to disordered spin systems

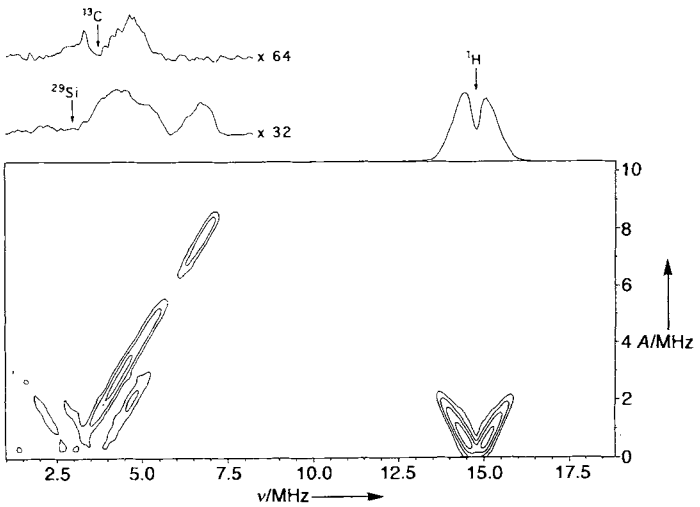


Fig. 1. Hyperfine-correlated ENDOR (HYEND) spectrum of radical **14** in methylcyclohexane at 20 K. The signals in the 1–8 MHz portion on the ENDOR axis are represented at 32 times higher intensity than those in the right-hand portion, and the corresponding projections are multiplied by 32 and 64 for ^{29}Si and ^{13}C, respectively. The spin flip angle of the applied radio-frequency pulses drop linearly below ≈3 MHz, resulting in an artificial loss of signal intensity. ν = ENDOR frequency, A = hyperfine splitting.

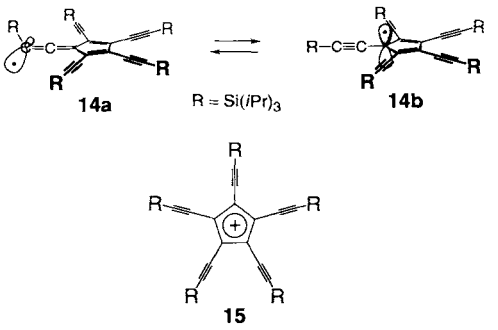
such as frozen solutions, and correlates hyperfine splitting to the nuclear transition frequencies in a 2D experiment. HYEND allows the separation of the ENDOR contributions of the three spin-active nuclei (^1H, ^{13}C, and ^{29}Si), the distinction of ^{13}C and ^{29}Si being especially important. These signals are centered around the free Larmor frequencies for these elements on the ENDOR frequency scale (^1H, 14.902 MHz; ^{13}C, 3.748 MHz; ^{29}Si, 2.963 MHz at 0.35 T); the projections show their separated ENDOR spectra. Note that the integrated intensities[19] are compatible with the elemental composition of **14** and the natural abundances of these elements. Interestingly, the silicon signal

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3517-1988 $ 15.00+.25/0

is split into two parts with integration ratios close to 4:1. The higher frequency part can be assigned to a silicon atom with high spin density, that is, to a hyperfine tensor with an isotropic part of about 8 MHz. The remaining broad contribution does not allow us to distinguish between the other four silicon atoms; assuming similar anisotropy, the isotropic part can vary between 2 and 4 MHz, implying two to four times less spin density on these atoms. This indicates that the D_{5h} structure of the radical is Jahn–Teller distorted in the MCH matrix at 20 K in favor of the C_s-symmetric equilibrium structure **14a** (Scheme 5).



Scheme 5.

Strain release by bringing one of the bulky TIPS groups out of plane from the other four, occurring by passing from equilibrium form **14b** to **14a**, could be one factor accounting for this observation. Permanent Jahn–Teller distortion was also observed for the pentafluorocyclopentadienyl radical, but only below 8 K.[20]

The UV/Vis spectrum of radical **14** shows strong, sharp absorption bands with vibrational fine structure in the long-wavelength region (Fig. 2), whereas the corresponding ketone **8a**

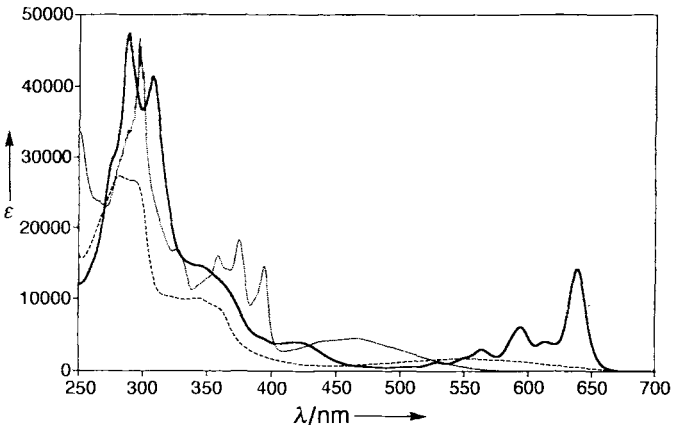


Fig. 2. UV/Vis absorption spectra of compounds **8a** (– – –), **13** (——), and **14** (——).

and fulvene-allene **13** have broad visible absorptions, implying that **14** has a more rigid structure in solution at 25 °C. The highly structured visible absorption region for radical **14** differs from the broad bands centered around 580 nm observed for the pentaarylcyclopentadienyl radicals,[16a,d,21] where the out-of-plane aryl rings are subject to bond rotation affecting conjugation.

The considerable bulk of the TIPS groups in the anion corresponding to **14** prevents coupling of two units to form a metallocene **3** (R = TIPS)[16c] even with larger metals such as Sn or Pb,[16d,22] and further studies will determine if smaller end groups can be used for that purpose. Cyclic voltammetry of radical **14** (CH_2Cl_2, 0.1 M $[nBu_4N][PF_6]$, 100 mVs^{-1}) reveals that it has a remarkable propensity to lose one electron to form the potentially antiaromatic cation **15** ($E_{ox1/2}$ = 0.15 V vs Fc/Fc^+). The pentaisopropylcyclopentadienyl radical is somewhat harder to oxidize ($E_{ox1/2}$ = 0.58 V).[16b] The facile oxidation of **14** reflects a significant propargylic/allenic resonance stabilization by the silylalkyne moieties. We believe that the cyclopentadienyl cation **15** should be stable at room temperature, and the isolation and characterization of this unusual species will be the subject of further studies.

Experimental Procedure

7a: Ketal **6** (4.42 g, 10 mmol) [11], $[(PPh_3)_2PdCl_2]$ (560 mg, 0.8 mmol), CuI (300 mg, 1.6 mmol), and $(iPr)_3Si\text{-}C\equiv CH$ (8.21 g, 45 mmol) were added in this order to 200 mL of degassed $(iPr)_2NH$. The mixture was heated at 70 °C for 12 h under argon. After evaporation of the solvent, the residue was dissolved in CH_2Cl_2 and filtered through silica gel. Column chromatography (SiO_2, hexanes/CH_2Cl_2 5:1) and recrystallization from CH_2Cl_2/methanol afforded **7a** as yellow needles (7.88 g, 93%).

8a: A solution of ketal **7a** (6.78 g, 8 mmol) in 400 mL of CH_2Cl_2 was allowed to react with was treated with CF_3COOH (20 mL) and H_2O (5 mL) for 30 min. After aqueous workup, the organic layer was washed with aq. $NaHCO_3$, dried over $MgSO_4$, and concentrated to dryness. Column chromatography (SiO_2, hexanes/CH_2Cl_2 5:1) and recrystallization from CH_2Cl_2/methanol afforded **8a** as small purple needles (6.09 g, 95%).

10a: *n*-Butyllithium (5.5 mmol) was added to a solution of $(iPr)_3Si\text{-}C\equiv CH$ (1.0 g, 5.5 mmol) in dry Et_2O (50 mL) at 0 °C. The reaction mixture was stirred 30 min, then a solution of ketone **8a** (4.01 g, 5 mmol) in Et_2O (100 mL) was added dropwise at 0 °C. The reaction mixture was stirred for a further 1 h then treated with sat. NH_4Cl. The organic layer was washed with H_2O and dried ($MgSO_4$). Evaporation of the solvent, column chromatography (SiO_2, CH_2Cl_2/hexanes 3:1), and recrystallization from hexanes afforded **10a** as yellow needles (4.62 g, 94%).

12a: $SOBr_2$ (0.842 g, 4.05 mmol) was added dropwise to a solution of alcohol **10a** (3.94 g, 4 mmol) and pyridine (0.316 g, 4 mmol) in dry Et_2O at 0 °C. The reaction mixture was stirred for 30 min then quenched with H_2O. The organic layer was treated with 2 M HCl, washed with H_2O, and dried ($MgSO_4$). Evaporation of the solvent, column chromatography (SiO_2, hexanes), and recrystallization from CH_2Cl_2/methanol afforded **12a** as shiny purple needles (3.68 g, 88%).

13: *n-Butyllithium (1 mmol) was added to a solution of bromide* **12a** *(1.05 g,* 1 mmol) in dry Et_2O (50 mL) at −78 °C. After 30 min the reaction mixture was treated with sat. NH_4Cl, and the organic layer was washed with H_2O and dried ($MgSO_4$). Evaporation of the solvent, column chromatography (SiO_2, hexanes), and recrystallization from CH_2Cl_2/methanol afforded **13** as small red needles (678 mg, 70%).

14: a) $[Fe(CO)_5]$ (294 mg, 1.5 mmol) was added to a solution of **12a** (523 mg, 0.5 mmol) in dry, degassed Et_2O. After 4 h the solvent was removed and the residue dissolved in hexanes. Column chromatography (SiO_2, hexanes) gave **14** as blue-green waxy crystals (170 mg, 35%) in addition to **13** (242 mg, 50%).
b) Chloranil (1.23 g, 5 mmol) was added to a solution of **13** (968 mg, 1 mmol) in benzene (50 mL). The reaction mixture was stirred for 2 h at 25 °C, poured onto silica gel, and extracted with hexanes. Evaporation of the solvent and column chromatography (SiO_2, hexanes) afforded **14** (339 mg, 35%) in addition to **13** (483 mg, 50%).

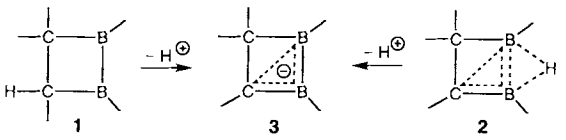
1,2-Diboretanides: Homoaromatic 2π-Electron Compounds with High Inversion Barriers**

Dirk Steiner, Heinz-Jürgen Winkler, Christian Balzereit, Thorsten Happel, Matthias Hofmann, Govindan Subramanian, Paul von Ragué Schleyer, Werner Massa, and Armin Berndt*

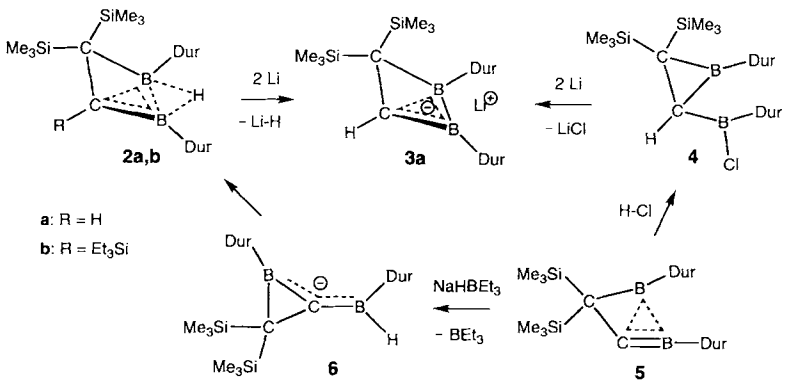
Dedicated to Professor Kurt Dehnicke on the occasion of his 65th birthday

1,2-Diboretanes with amino substitutents on the boron atoms have the classical structures **1**.[1] When such π-donor groups are absent the nonclassical form **2**, which contains two three-center-two-electron (3c,2e) bonds, is more stable.[2] We describe herein the corresponding anions of **1** and **2**, 1,2-diboretanides **3**, which have one 3c,2e bond and serve as a link between classical and nonclassical 1,2-diboretanes (Scheme 1).



Scheme 1.

The lithium 1,2-diboretanide **3a** is formed by the reaction of the nonclassical 1,2-diboretane **2a**[2] or of the chloroborylborirane **4**[3] with lithium in diethyl ether (Scheme 2). Compound **2a** can be obtained almost quantitatively from the methyleneborane **5**[4] in two steps. Treatment of **5** with $NaHBEt_3$ in toluene gives the hydride adduct **6**, which is then allowed to react with cyclopentadiene to yield **2a**. The constitution of **3a** is deduced from the NMR data (Table 1) by means of the NMR/GIAO/ab initio method.[5] Note the agreement of the chemical shifts of the framework atoms with values computed at the GIAO-MP2/tzp level for unsubstituted **3u** and **3u'** (Table 2).[6] Figure 1 shows the structure of **3a** in the crystal.[7]



Scheme 2.

The geometry of the four-membered ring in the 1,2-diboretanide **3a** strongly resembles those of the nonclassical 1,2-diboretanes **2u** and **2b**;[2] the lithium ion coordinated by one di-

Table 1. Some physical properties of compounds **3a** and **6**.

3a: Solid, m.p. 157 °C (decomp.), yield: 75%. ^1H NMR (300 MHz, C_6D_6, 25 °C): δ = 0.09, 0.32 (each s, each 9H, $SiMe_3$), 2.05, 2.14, 2.28, 2.43, 2.61 (each s, total of 24H, *o*- and *m*-CH_3), 4.69 (s, 1H, CHB), 6.72, 6.77 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, C_6D_6, 25 °C): δ = 1.6, 2.7 (each q, each 3C, each $(CH_3)_3Si$), 19.8, 20.5, 20.8, 21.0, 21.3, 21.5 (each q, total of 8 C, *o*- and *m*-CH_3), 32.0 (br. s, 1 C, CSi_2), 84.8 (br. d, 1 C, CHB, ^1J(C,H) = 161 Hz), 130.0, 131.7, 132.5, 133.9, 134.1, 137.1, 137.4 (total of 10 C, *o*-, *m*- and *p*-C), 139.2, 146.5 (each br. s, each 1 C, each *ipso*-C); ^{11}B NMR (96 MHz, C_6D_6, 25 °C): δ = 5, 58.

6: yellow solid, m.p. 170 °C (decomp.), yield ca. 90%. ^1H NMR (500 MHz, [D$_8$]THF, −30 °C): δ = −0.02 (s, 18H, $SiMe_3$), 2.07, 2.10, 2.27, 2.38 (each s, each 6H, *o*- and *m*-CH_3), 5.65 (br. s, 1H, BH), 6.48, 6.70 (each s, each 1H, *p*-H); ^{13}C NMR (125 MHz, [D$_8$]THF, −30 °C): δ = 2.0 (q, 6C, $SiMe_3$), 19.5, 20.6, 20.8, 21.0 (each q, each 2C, *o*- and *m*-CH_3), 106.1, (br. s, 1 C, BCB), 127.1, 132.0 (each d, each 1 C, *p*-C), 130.1, 131.4, 134.8, 142.5 (each s, each 2C, *o*- and *m*-C), 138.1, 155.8 (each br. s, each 1 C, *ipso*-C), the signal of the C atom carrying the trimethylsilyl groups could not be observed; ^{11}B NMR (96 MHz, [D$_8$]toluene, 25 °C): δ = 44 ($\nu_{1/2}$ = ca. 2600 Hz).

[a] MP2(FU) 6-31G*-optimized geometries. ^{11}B and ^{13}C NMR computations with GIAO-MP2 tzp.

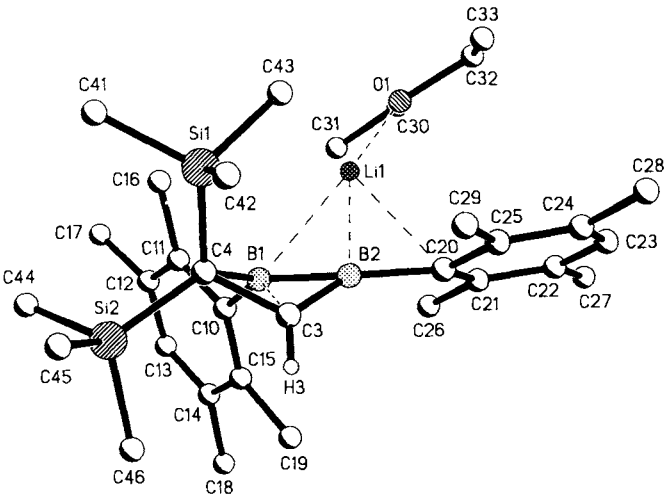

Fig. 1 Structure of **3a** in the crystal. Important interatomic distances [pm] and angles [°]: B1–B2 165.5(4), B1–C3 171.1(4), B1–C4 162.9(4), B1–C10 160.9(4), B2–C3 146.0(4), B2–C20 157.8(4), C3–C4 154.2(4), Li1–B1 250.8(7), Li1–B2 224.6(7), Li1–C20 259.8(7), Li1–O1 187.2(6), C4–Si1 186.2(2), C4–Si2 187.9(3); B2-B1-C4 97.5(2), B2-B1-C10 136.1(2), C4-B1-C10 123.1(2), B1-B2-C3 66.3(2), B1-B2-C20 151.8(2), C3-B2-C20 138.7(2), B2-C3-C4 110.7(2), C3-C4-B1 65.2(2), Si1-C4-Si2 116.7(1). Folding angle at B1–C3 140.0(2).

ethyl ether molecule adopts the position of the bridging H atom in **2u** and **2b**. However, the B1–B2 distance of 165.5(4) pm in **3a** (computed[8] to be 162.2 pm for **3u'**, Table 2) is considerably shorter than the corresponding distances in **2b** (179.9(3) pm) and **2u** (171.7 pm): the interaction of the B–B bond with the Li^+ ion in **3a** is electrostatic, whereas that with the H^+ ion in **2b** and **2u** is multicenter covalent. The Wiberg bond indices (WBIs) and charges obtained by natural population analysis (NPA) of the HF/6-31G* wavefunction clearly characterize the B-H-B bridge as a covalent 3c,2e bond, while the Li^+ ion in **3u'** is bound essentially electrostatically (Fig. 2).

The short B1–C3 distance (**3a**: 171.1(4) pm, **3u'**: 171.8 pm) and the corresponding WBI (0.528) indicate a strong 1,3-interaction, which also is consistent with the high barrier of ring inversion of **3a**. Two sharp signals for the geminal trimethylsilyl groups in the ^1H and ^{13}C NMR spectra at 25 °C broaden at higher temperatures. The barrier of 19.5 kcal mol^{-1}, determined from the coalescence temperature (130 °C in [D_{10}]*o*-xylene) in the ^1H NMR spectrum and the difference of the chemical shifts at slow exchange ($\Delta\delta = 100$ Hz), is considerably higher than all barriers reported for the homoaromatic 2π-electron compounds **7**–**9** (Fig. 3).[9]

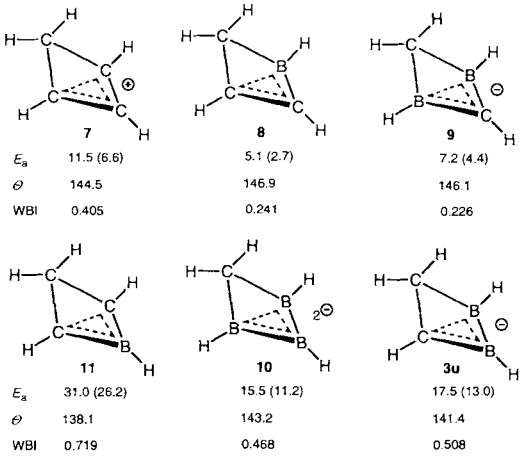

Fig. 3. MP2(FU)/6-31G*//MP2(FU)/6-31G* + ZPE inversion barriers E_a [kcal mol^{-1}], dihedral angles θ [°], and Wiberg bond indices (WBIs) for isoelectronic homoaromatic 2π-electron compounds. Inversion barriers at B3LYP/6-311 + G**//B3LYP/6-311 + G** + ZPE level are given in parentheses for comparison.

MP2/6-31G* calculations gave inversion barriers of 17.5 and 20.4 kcal mol^{-1} (Fig. 3) for the unsubstituted **3u** and **3u'**, respectively. Hence, such high barriers are characteristic for 1,2-diboretanides. Two related members of the family of homoaromatic 2π-electron compounds are still unknown, the homotriborirane dianion **10** and the borabicyclobutane **11**; their computed barriers are 15.5 and 31.0 kcal mol^{-1}, respectively (Fig. 3).

The inversion barriers given in Figure 3 reflect the degree of cyclic delocalization and the magnitude of homoaromaticity in the four-membered rings. The barriers correlate both with the folding angles between the two planes of the three-membered rings (correlation coefficient 0.98) and with the WBI of the transannular bonds (correlation coefficient 0.96).

The method was implemented in ACESII: ACESII is an ab initio program system written by J. F. Stanton, J. Gauss, J. D. Watts, W. J. Lauderdale, R. J. Bartlett, *Quantum Theory Project*, University of Florida, FL, USA, **1991**, **1992**). The abreviation tzp stands for "triple zeta plus polarization" basis sets: A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571–2577.

[7] X-ray structure analysis: colorless crystals of **3a** ($C_{28}H_{45}B_2Si_2Li\cdot Et_2O$) were investigated with a four-circle diffractometer (CAD4, Enraf-Nonius) at −70 °C with $Cu_{K\alpha}$ radiation ($\lambda = 154.178$ pm). Crystal dimensions $0.6 \times 0.3 \times 0.3$ mm^3, monoclinic, space group $P2_1/c$, $Z = 4$, $a = 1287.5(3)$, $b = 1536.0(3)$, $c = 1745.2(3)$ pm, $\beta = 90.88(3)°$, $V = 3450.9 \times 10^{-30}$ m^3, $\rho_{calc} = 1.040$ g cm^{-3}; a total of 4630 reflections were measured up to $2\theta = 110°$ with $\omega/2\theta$ scans; 4329 independent reflections were used after LP correction in subsequent calculations; no absorption correction ($\mu = 10.7$ cm^{-1}). The structure was solved by direct methods and refined with full matrix against the F^2 data. Some of the H atoms could be localized from difference Fourier syntheses, the rest were calculated. Anisotropic temperature factors were used for all other atoms. $wR_2 = 0.1489$ resulted, corresponding to $R = 0.0517$ for 3614 reflections $> 4\sigma(F_o)$, the maximum residual electron density was 0.31 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-67. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched(@ chemcrys.cam.ac.uk).

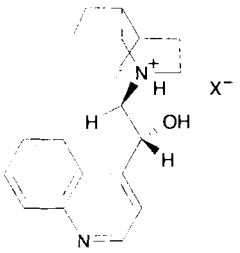
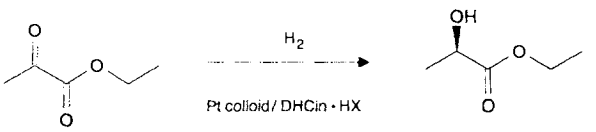
Enantioselective Hydrogenations on Platinum Colloids**

Helmut Bönnemann* and Gerhard A. Braun

Metal colloids with dimensions of a few nanometers are important for catalysis research because of their high proportion of surface atoms.[1] These colloids can either be employed as catalysts in quasi-homogeneous phases[2] or serve as precursors for heterogeneous catalysts.[3] Their stabilization in solution at concentrations necessary for catalysis is achieved by polymers,[4] ligands,[5] or surfactants.[6] In several cases it was possible to show that the stabilizer affects the catalytic selectivity.[7] Herein, we report on a chiral induction by the stabilizer in a colloid-catalyzed hydrogenation. Using as an example a platinum sol stabilized by the protonated alkaloid dihydrocinchonidine (DHCin), we examined the influence of the stabilizer on the enantioselective hydrogenation of ethylpyruvate to (*R*)-ethyllactate [Eq. (a)] in a quasi-homogeneous phase.



DHCin · HX:
X = Cl, AcO, HCO_2



(a)

The enantioselective hydrogenation of α-oxoesters on heterogeneous platinum catalysts in the presence of cinchona alkaloids was reported for the first time by Y. Orito.[8] Over the last few years, these chirally modified heterogeneous catalysts have been systematically studied with respect to catalyst preparation,[9a] catalyst structure,[9b, c, d] reaction conditions,[9e, f, g] and kinetics.[9h, i] The structure of the modifier has been varied,[10a] and the interaction between the substrate and the alkaloid has been modeled.[10b, c]

In order to synthesize colloidal platinum, an aqueous solution of a platinum salt is reduced in the presence of protonated DHCin. The normally water-insoluble alkaloid is initially transformed into the water-soluble hydroformate, and then added by syringe to an aqueous platinum tetrachloride solution. The formate reacts to yield carbon dioxide, and the resulting platinum sol (**2**) is stabilized by the hydrochloride of DHCin [Eq. (b)].

$$PtCl_4 + (2-n)\ DHCin\cdot HCO_2H + n\ HCO_2H \rightarrow Pt_{colloid}\ [DHCinH^+\ Cl^-]_{2-n} + (2+n)\ HCl + 2\ CO_2 \quad \text{(b)}$$

[**] This work is part of the planned thesis of G. Braun, RWTH Aachen. It was supported by the Bundesministerium für Bildung, Forschung, Technologie, und Wissenschaft, Bonn (FKZ 03 D 00007 A2), and the Funds der chemischen Industrie, Frankfurt. We thank Dr. Helmut Cölfen, Max-Planck-Institut für Kolloid- und Grenzflächenforschung/Teltow-Seehof, for the studies employing the analytical ultracentrifuge.

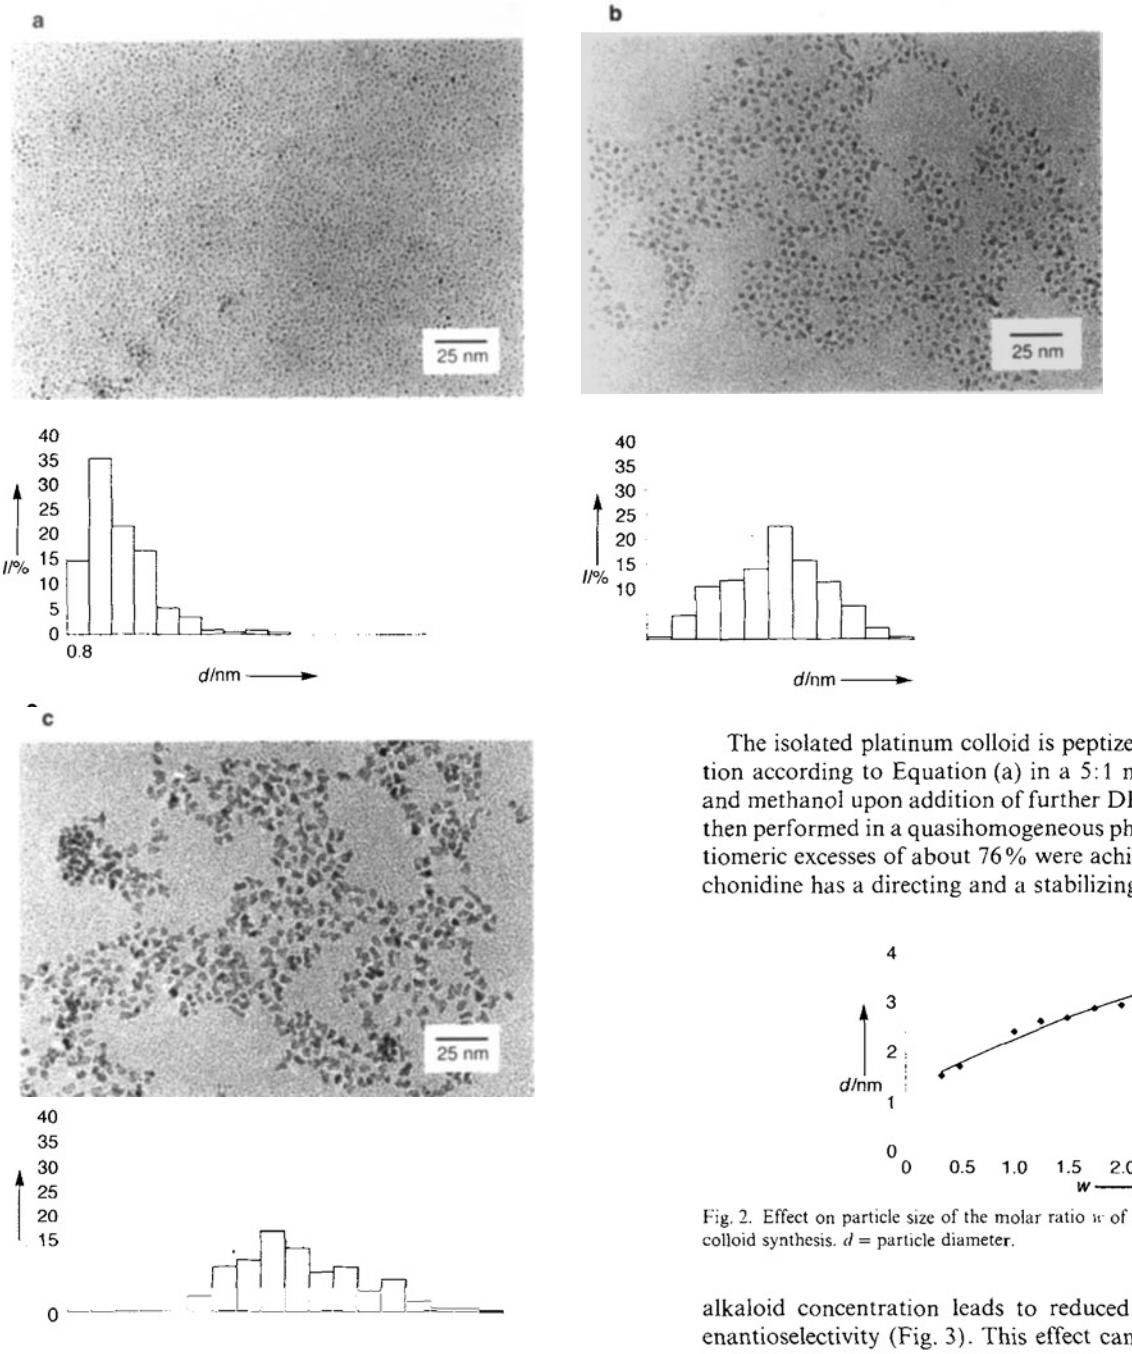

Fig. 1. Particle size distribution of DHCin-stabilized platinum colloids as a function of stabilizer concentration. Molar ratios of platinum to DHCin during the synthesis: a) 0.5, b) 1.25, c) 3.5. The distribution was determined by measuring at least 230 particles at different locations in the sample. d = particle diameter; I = relative abundance.

The colloids were examined by high-resolution electron microscopy (Fig. 1).[11] The molar ratio of platinum to dihydrocinchonidine during the synthesis determines the size of the resulting colloid; the particle size can by varied from 1.5 to 4 nm (Fig. 2).

The platinum sol (**2**) is precipitated by using sodium hydrogencarbonate, filtered off, washed, taken up in dilute acetic acid, and finally freeze-dried. The resulting black powder can be stored in the air and can be completely peptized in water or acetic acid upon the addition of methanol. The isolated platinum colloids exhibit a metal content of 40–50% by weight and are virtually free of chlorine.

The isolated platinum colloid is peptized for the hydrogenation according to Equation (a) in a 5:1 mixture of acetic acid and methanol upon addition of further DHCin. The catalysis is then performed in a quasihomogeneous phase. In general, enantiomeric excesses of about 76% were achieved.[12] Dihydrocinchonidine has a directing and a stabilizing effect: a decrease in

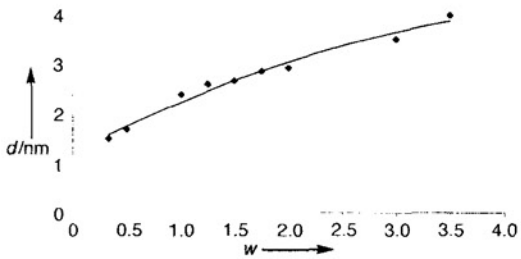

Fig. 2. Effect on particle size of the molar ratio w of platinum to DHCin during colloid synthesis. d = particle diameter.

alkaloid concentration leads to reduced activity at constant enantioselectivity (Fig. 3). This effect can be attributed to the agglomeration of the colloid in solution, which can be demonstrated by UV/Vis spectroscopic studies.[13] This agglomeration reduces only the accessible surface area, while the chiral induction at the remaining catalytically active sites is not affected. In

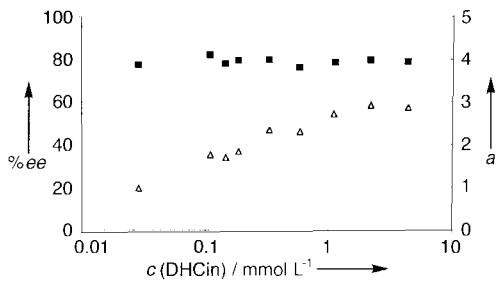

Fig. 3. Activity a (△) of colloidal platinum and enantiomeric excess (■) during the hydrogenation reaction (a) as a function of the concentration c of DHCin in the reaction medium [16].

order to avoid this agglomeration during catalysis, DHCin was added in 25 molar excess to platinum. UV/Vis spectroscopy, electron microscopy, and analytical ultracentrifuge studies before and after the reaction showed that under these conditions, no agglomeration takes place.[14] Thermostatically controlled glass reactors with flow breakers and gas addition stirrers were used for the hydrogenation. These reactors yield a very good material transport from the gas phase into the liquid. The hydrogenation was performed at 12 °C under atmospheric pressure; the course of the reaction was monitored by observing the consumption of hydrogen. Table 1 lists the colloid catalysts employed, their selectivities, as well as the turnover frequencies (TOF).

Table 1. Enantiomeric excess and TOF values for the catalytic hydrogenation according to Equation (a) on DHCin-stabilized platinum colloids of varying particle sizes.

w [a]	d_{TEM} [nm] [b]	d_s [nm] [c]	Dispersion [d]	TOF [s^{-1}]	% *ee*
0.5	1.5	2.0	0.57	1.1	76
1.25	2.6	3.0	0.38	1.1	74
3.5	3.9	4.7	0.22	0.9	78

[a] w is the molar ratio of platinum to DHCin during colloid synthesis. [b] d_{TEM} is the average particle diameter as determined by transmission electron microscopy. [c] d_s is the mean particle diameter, as averaged over the entire surface [15]. [d] The dispersion of the particles was calculated as outlined in ref. [15].

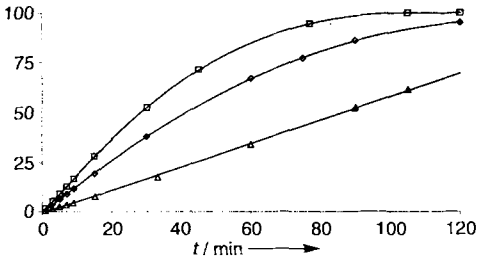

Fig. 4. Hydrogenation of ethylpyruvate on DHCin-stabilized platinum colloids of varying sizes. ▵: d_{TEM} = 3.9 nm, ◇: d_{TEM} = 2.6 nm, □: d_{TEM} = 1.5 nm [16]. The turnover [%] is plotted on the ordinate axis.

The activity of DHCin-stabilized platinum colloids decreases with increasing particle sizes (Fig. 4) as a result of decreasing dispersion. The dispersion is defined as the ratio of the number of surface atoms to the total number of atoms. It was calculated by using a surface density of platinum atoms estimated according to the method by Scholten et al.[15] and their mean diameter, as averaged over the entire surface. For the calculation of the TOF, all surface atoms were assumed to be catalytically active. The particle size had *no* effect on the TOF (Table 1) or on the enantiomeric excess (76 ± 2 % *ee*). The use of heterogeneous catalysts, on the other hand, has been reported to be associated with a distinct structure sensitivity.[9b]

DHCin-stabilized platinum colloids can be adsorbed on activated charcoal and silica. The thus obtained carrier catalysts show, for the hydrogenation according to Equation (a) at a hydrogen pressure of 100 bar in acetic acid, enantioselectivities (80 % *ee*) comparable to those reported for modified conventional heterogeneous catalysts.[9]

Experimental Procedure

Synthesis of the platinum colloid: Into a 250 mL two-neck flask, previously rinsed with aqua regia and a H_2SO_4/H_2O_2 mixture, was placed $PtCl_4$ (0.208 g, 0.6 mmol) dissolved in distilled water (160 mL). The flask was fitted with a reflux condenser and a septum, and the mixture was heated to reflux in an oil bath. During the synthesis, the bath temperature was maintained at 140 °C (± 5 °C). A solution of dihydrocinchonidine (0.355 g, 1.2 mmol) in 0.1 M aqueous formic acid (15 mL) was added rapidly by syringe. Initially, the reaction mixture became turbid and began to turn black after a few minutes. About ten minutes after the color change to black, the reaction was complete. The reaction mixture was poured into a saturated $NaHCO_3$ solution (200 mL), and the resulting precipitate was removed by a G4 fritted glass filter. The residue was washed first with a half-saturated $NaHCO_3$ solution (400 mL), then with water. The black solid was taken up in 1 M acetic acid (50 mL), and subsequently freeze-dried to remove the solvent. In this way a black powder (0.216 g) was obtained, which could be completely peptized in water and acetic acid/methanol. The metal content was found to be 41 % by weight, which indicated a yield of 71 % based on platinum. The chlorine content was below 0.5 % by weight. For the preparation of colloids with different particle sizes, the amount of platinum salt used was kept constant, while the amount of dihydrocinchonidine was reduced.

Enantioselective hydrogenation of ethylpyruvate on platinum colloids: Dihydrocinchonidine (150 mg) was dissolved in a 5:1 mixture of acetic acid and methanol (70 mL). Subsequently, platinum colloid (10 mg; particle size 1.5 nm, 41 % platinum by weight) was peptized in this solution and the dispersion was treated for 90 min in an ultrasonic bath. The resulting catalyst dispersion was a clear yellow-brown liquid. This liquid was cooled to 12 °C in a closed reactor fitted with a stirrer, degassed three times, and finally saturated with hydrogen. Using a hydrogen counterflow, ethylpyruvate (5 mL, 48 mmol) was added. The reaction was initiated by turning on the stirrer at a speed of 2000 revolutions per minute and was performed at atmospheric pressure. The course of the reaction was monitored by using the hydrogen consumption as an indicator; the reaction was complete after 120 minutes. The enantiomeric excess was determined by gas chromatography (6-*tert*-butyldimethylsilyl-2,3-dimethyl-β-cyclodextrin/SE54 as stationary phase) to be 76 % *ee*.

Pays-Bas* **1994**, *113*, 465–474.

[11] The electron microscope studies were performed with a Hitachi high-resolution transmission electron microscope, type HF 2000. The TEM samples were prepared by peptizing the colloid in water, followed by a dropwise addition of the solution onto a copper sample mesh covered with carbon. The colloidal dispersion was removed after two minutes using cellulose and the sample was transferred to the microscope. We thank the electron microscopy department of the Max-Planck-Institut für Kohlenforschung for the critical discussion of these results.

[12] a) After the study reported herein was completed, we received a personal communication form H. U. Blaser (October 5, 1995) that polyvinylpyrrolidone (PVP)-stabilized platinum colloids yield 65% *ee* for reaction (a) (at a hydrogen pressure of 100 bar and with 2-propanol as solvent). b) Collier et al. report the enantioselective hydrogenation of ethylpyruvate (up to 40% *ee* at 17% turnover) on 2-butanone-stabilized platinum colloids after the addition of DHCin. The colloids were prepared by metal evaporation and are highly agglomerated: P. J. Collier, T. Goulding, J. A. Iggo, R. Whyman in *Chiral Reactions in Heterogeneous Catalysis* (Eds.: G. Jannes, V. Dubois), Plenum Press, New York, **1995**, 105.

[13] The absorption of metal sols in the UV/Vis range is determined by the shape and size of the metal particles. The agglomeration of the colloids was confirmed by UV/Vis spectroscopy. More details about the UV/Vis spectroscopy of metal sols can be found in G. D. Duff, P. P. Edwards, B. F. G. Johnson, *J. Phys. Chem.* **1995**, *99*, 15934–15944, and references therein.

[14] The TEM studies on the agglomeration of the colloids during catalysis were performed by conserving 5 mL of the reaction solution from before and after the reaction in an aqueous solution of the polymer PVP. Details regarding the conservation of metal colloids in PVP can be found in the literature cited in ref. [13].

[15] The surface density of platinum atoms in the colloid is $\rho_s = 1.25 \times 10^{19}$ atoms per m^2, assuming equal proportions of (100), (110), and (111) surfaces: J. J. F. Scholten, A. P. Pijpers, A. M. L. Hustings, *Catal. Rev. Sci. Eng.* **1985**, *27*, 151–206. The surface-averaged diameter d_s is obtained from the expression $d_s = \sum_i n_i d_i^3 (\sum_i n_i d_i^2)^{-1}$, where n_i is the number of particles having the diameter d_i. The dispersion is calculated from $D = 6fM(\rho\sigma N d)^{-1}$, where f is the percentage of the freely accessible surface of the particle, M the relative atomic mass of platinum, ρ the density of platinum, $\sigma = \rho_s^{-1}$ the mean surface area occupied by an atom, and N is Avogadro's number: J. L. Lemaitre, P. G. Menon, F. Delannay in *Characterization of Heterogeneous Catalysts* (Ed.: F. Delannay), Dekker, New York, **1984**, 299.

[16] The hydrogenation according to Equation (a) was performed in all cases using colloidal platinum metal (ca. 4 mg), AcOH/MeOH (70 mL), and ethylpyruvate (5 mL). For the calculation of the activity a, the consumption of hydrogen per minute (in mL) was compared to the mass of platinum (in mg) employed. The hydrogen consumption during the first ten minutes of the hydrogenation reaction was used as the basis for this calculation.

Corrigendum

In the communication "Discovery of Chiral Catalysts through Ligand Diversity: Ti-Catalyzed Enantioselective Addition of TMSCN to *meso* Epoxides" by M. L. Snapper, A. H. Hoveyda, et al. (*Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 1668–1671) the entries in Table 1 under the column heading "Ligand" were inadvertantly cut off. Table entries 1, 3, and 5 were obtained with ligand **10**, entries 2, 4, and 6 with ligand **15**.

Furthermore, the citations in the text beyond no. 10 are incorrect. On page 1670 they should read "...as yellow crystalline solids.[11] In a manner similar to "positional scanning",[12]..." On page 1671 the passages should be "...enantioselectivity is improved from 40 to 86% *ee*.[13]" and in the Experimental Procedure at the top of the second column "...subjected to a ninhydrin test[14]...".

A New Angle on Asymmetric Synthesis

Stereoselective Synthesis. By *R. S. Atkinson*. Wiley, Chichester, 1995. 529 pp., paperback £29.95.—ISBN 0-471-95250-8/0-471-95419-5

The subject of stereoselective synthesis has recently inspired quite a number of authors. In the case of the book *Stereoselective Synthesis* by R. S. Atkinson, published last year in a first edition, we even find that there are "cousins" with the same name: the Houben-Weyl volumes E 21 a–f and a book by M. Nógrádi, both of which bear the same title.

A glance at the contents of this latest addition to the family shows that it covers all the subject areas expected in a work of this size (see below). The description of each class of reactions begins with a precise explanation of the underlying principle, based on mechanistic considerations and a transition state model, and this is followed by a detailed discussion with suitable examples. This should provide the reader with a thorough understanding of the causes of the observed stereoselectivity.

When it comes to the arrangement of the subject matter the author takes a more exotic line than in his choice of title, as will appear below. One of the main purposes of the book is to promote a new way of classifying stereoselective reactions. This is based on comparing the number of chiral centers formed in the product molecule with the number that were present in the starting molecule, resulting in a classification into five reaction types from 0 to IV. A reaction of type 0 does not form any new chiral centers, whereas a type I reaction involves the breaking of one bond at a chiral center and the stereoselective formation of one new bond. Type II reactions are those in which two or more chiral centers are formed simultaneously from achiral reagent molecules (e.g., simple diastereoselection). In type III reactions one or several stereocenters are formed under the influence of an already existing stereocenter. The latter reactions are further divided into several different sub-groups (types $III_{s.c.}$, $III'_{s.c.}$, $III_{r.c.}$, $III_{s.c./r.c.}$, and $III_{cat.enant.}$). Type IV reactions are those in which no chiral centers are generated but diastereomers can be formed (e.g, diastereoselective formation of an enolate). Last but not least, it is also necessary to introduce type II/III reactions, which do not fit clearly into the above groups. The system has other weaknesses, which are particularly well illustrated by the fact that the author himself has not consistently followed this classification as a basis for the structure of the book! Instead of devoting one chapter to each reaction type with subdivisions where necessary, the author has arranged the contents in 16 chapters, all of equal status. In some cases a chapter corresponds to a single type, whereas elsewhere one reaction type is distributed through up to eight chapters!

Chapter 1 explains the meanings of the terms used in the book, such as chemo-, regio-, diastereo-, and enantioselectivity, chirality, prochirality, homotopy, enantiotopy, and diastereotopy. In Chapter 2 the author briefly explains the system of classification mentioned above (which is treated in greater depth in the later chapters). Chapter 3 is concerned with reactions of type 0. The most important part of this chapter is a table listing enantiomerically pure compounds that are readily obtainable. The author decribes how these can be converted into other enantiomerically pure synthetic building blocks in which the chiral centers are retained. Still following a logical sequence, Chapter 4 deals with type I reactions, beginning with inversion by means of S_N2 reactions and continuing through double inversion (equivalent to retention of configuration) and 1,2-rearrangements, both with inversion and with retention of configuration, and leading finally to Still's carbanions with a stable configuration. In Chapter 5 we find the first deviation from the system of classification, since instead of type II reactions this is devoted to some special type $III_{s.c.}$ reactions. Specific reactions discussed here are 1,3 chirality transfers via S_N2' reactions, [2,3]-sigmatropic and [3,3]-sigmatropic rearrangements, and the ene reaction.

Type II reactions are now taken up in Chapter 6, in which the discussion covers 1,2-additions to olefins, electrocyclic reactions, Diels-Alder reactions, and 1,3-dipolar cycloadditions. Even here, however, the author is innovative, introducing the terms "inherent diastereoselectivity" and "occasional diastereoselectivity", which have never appeared previously. In Chapter 7 the topic of "occasional diastereoselectivity" is treated in more detail, discussing as examples photochemical [2+2]-cycloadditions, photochemical 1,3-additions of arenes, 1,3-diyl additions, palladium-catalyzed trimethylenemethane additions to olefins, and again [2,3]- and [3,3]-sigmatropic rearrangements.

Chapter 8 deals with the aldol addition and related reactions (still belonging to type II). Type III reactions are then treated, along with others, in Chapters 9-12. Here we again find mentions of nearly all types of reactions in which asymmetric induction is known to occur, ranging from epoxidation through alkylation reactions to carbonyl addition reactions. For the first time the author explains the concepts of $A_{1,2}$- and $A_{1,3}$-strain, already mentioned several times in earlier discussions. Chapter 13 treats the hybrid type II/III reactions along with [4+2]-cycloadditions, 1,3-dipolar cycloadditions, aldol additions, and [3,3]-sigmatropic rearrangements.

Chapter 14 returns to type III reactions, and provides examples of catalytic enantioselective reactions (type $III_{cat.enant.}$). Particular topics treated here are the Sharpless epoxidation, CBS reduction of ketones, homogeneously catalyzed hydrogenations, chiral Lewis acids for Diels-Alder and ene reactions, the Sharpless dihydroxylation, cyclopropanation reactions, carbonyl additions, and Michael additions. Type $III_{s.c./r.c.}$ reactions are covered in Chapter 15, which explains double stereo-differentiation and the meaning of terms such as "matched" and "mismatched".

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

The sixteenth and final chapter is again concerned with type III reactions. Here the focus of attention is the distinction between enantiotopic and diastereotopic atoms or groups. In addition about 19 pages are devoted to the use of enzymes in stereoselective synthesis.

At the end of each chapter there is a summary of the most important points occupying about half a page. There is an adequate index containing about 500 entries which include all the important keywords. However, it is annoying that for some keywords not all the relevant page-numbers are listed; for example, the entry for the Diels-Alder reaction fails to refer to page 477. Altogether there are about 700 literature citations extending up to 1992.

The author's use of the word "echt", presumably borrowed from German, as in "the design of *echt* type $III_{r.c.}$ reactions" (p. 361) struck me as odd. Apart from a few minor inconsistencies of the kind that always slip through in the first edition of any book, I have found only three serious errors: on pages 217, 233, etc. allyl metal compounds are repeatedly referred to as "alkenyl metal compounds"; in Scheme 14b on page 372 the wrong olefin is shown; thirdly, instead of *syn* and *anti* as introduced by Masamune, the prefixes *cis* and *trans* are incorrectly used.

In any discussions involving stereochemistry the quality of the structural diagrams is of paramount importance. The perspective formula diagrams used here for the transition states are clear, but the mushroom-like appearance of the oxygen atoms at the ends of the backward-directed bonds (e.g. on p. 27) takes a little getting used to. The "lassos" that are occasionally shown around bonds whose movement is indicated by arrows (e.g. on p. 81) convey an odd sense of urgency.

The author's decision to abandon the usual order of presentation, based on either the stereoselective synthesis of a particular class of compounds or the stereochemical aspects of individual reactions (e.g. the Diels-Alder reaction), has its disadvantages. For example, it results in the various stereochemical aspects of the Diels-Alder reaction being treated in a fragmented way in seven different chapters. The numerous cross-references to other chapters are therefore really essential. On the other hand, the arrangement of the subject matter adopted here emphasizes principles of stereoselection that are common to different reactions, which has the advantage of focusing the reader's attention on an interesting new perspective and helping him or her to discover new relationships. Thus, on pages 148ff the common features linking the epoxidation, aziridination, and cyclopropanation of alkenes are discussed, then the reactive properties of the compounds concerned are correlated with those of intermediates in the halogenation of alkenes and of sulfonium and selenium ions in three-membered rings. However, as explained above this interesting sequence of topics is not directly derived from the proposed new system of classification, and therefore the usefulness of the latter is called into question.

To sum up, the above inconsistency means that the book is not very suitable for newcomers to the subject of stereoselective synthesis; on the other hand, for readers who already have a basic knowledge of the subject it offers new ideas and insights. It remains to be seen whether this attempt at a new classification of stereoselective reactions will gain acceptance.

Analytical Electrochemistry. By *J. Wang*. VCH Publishers, New York, 1994. 193 pp., hardcover $ 59.95.—ISBN 1-56081-575-2

It is pleasing to note that during the last few years the VCH group has devoted much effort, with considerable success, to remedying the relative neglect of electrochemistry in the available literature. Examples of successes in this field are the new series *Frontiers in Electrochemistry*, the journal *Electroanalysis*, and several monographs. The latest monograph from this publishing house is devoted to the very interesting and highly topical area of analytical electrochemistry, where new methods, especially the use of electrochemical sensors, are becoming increasingly important. The choice of this currently highly interesting topic, together with the expertise of the publishers in this field and the high reputation of the author, hold out to users of the methods and to students the promise of an interesting and valuable book. Regrettably, however, the reality does not quite come up to these expectations.

Already in the first short chapter on the fundamentals we find that there is no treatment of the electrochemical potential nor of equilibrium considerations. In the sections on kinetics one occasionally comes across mathematical equations that are incomplete, derivations that are not quite correct, and statements that are rather superficial. The poor quality of the figures is especially noticeable. The potential is shown increasing either from right to left or in the opposite sense depending on the original source. Dimensions are only partly standardized, and the symbols used for the same quantity vary from page to page. For example, A is first introduced to represent the electrode surface area, but two pages later is unashamedly used as a probability factor. Several examples of computations are given, which at first seems impressive, but is less helpful than expected: whereas the user's difficulties are most likely to be concerned with dimensions and orders of magnitude, the computational problem of electroanalysis (e.g. on p. 103) is cleverly reduced to the dimensionless problem of the rule of three.

Chapter 2 is mainly concerned with potential-controlled methods. Here the practitioner will find a collection of information on important instruments, relationships, and new systems. This presentation is a considerable step forward compared with the more conventional books by Plambeck and others. Chapter 3 contains much valuable practical information, including even the addresses of equipment suppliers. The sections on modern electrodes are also very useful; aspects such as special modifications, microelectrodes, and methods for producing these are included. A chapter on potentiometry is followed by a discussion of biosensors and chemical sensors; this is interesting and up-to-date, but not very systematic. The last 30 pages describe many new developments, in areas ranging from cyclovoltammetry to scanning tunneling microscopy. The information on the role of electrochemistry as a modern tool of interfacial science is useful, but is not easy to understand if one is not familiar with the principles.

Thus the book presents in an unusual way both the successful and the less successful aspects of applied research in this area. For the practitioner it has a certain value as a source of information. On the other hand, the reader who wishes to gain an understanding of the fundamentals of electroanalysis and modern electrochemistry will be better served by the more established works on the subject.

Multidimensional Solid-State NMR and Polymers. By *K. Schmidt-Rohr* and *H. W. Spiess*. Academic Press, London, 1994. 478 pp., hardcover $ 65.00—ISBN 0-12-626630-1

Klaus Schmidt-Rohr and Hans Wolfgang Spiess have certainly written an impressive monograph. While always keeping polymers in mind, they clearly put the emphasis on the methodology of modern solid-state NMR, much of which has originated in the last decade in the laboratory of H. W. Spiess. Accordingly, the heading of Chapter two is "principles of NMR of Organic Solids", and only a short descriptive chapter is devoted specifically to the structure and dynamics of solid polymers.

One may ask, as the authors also do, for whom the book is written. Actually, the intention is to address a broad readership including beginners in solid-state NMR, typically students starting their work for a diploma or master's degree in a solid-state NMR laboratory. Although K. S.-R. and H. W. S. have tried to provide a self-contained text which can be read without constantly being forced to consult the cited literature (statement in the preface), I think that a beginner will need guidance for the study of this monograph, and I hasten to add: why not—after all it is through the interplay between reading, discussing, and doing experiments oneself that one's learning in science progresses.

With guidance, the beginner will recognize that from this monograph she or he can learn all that is needed to thoroughly understand spin gymnastics, Fourier theory in one and two dimensions, and all about the magic of magic-angle sample spinning, including the facts that it really is advantageous to introduce a bewilderingly large number of different reference frames and seemingly complicated functions, and that DOR and DAS, beautiful as they are conceptually and technically, have only limited applications. No word, though, about Floquet theory.

For the reader with some experience the monograph will prove to be a mine of treasures where countless "experiments", serving a wide range of purposes in polymer science and elsewhere, can be found. (Note that the usage of the word experiment is quite different in NMR from that in, for example, high energy physics. In NMR, already a new pulse sequence which can be implemented through the keyboard of a commercial spectrometer is termed a new "experiment".) The practitioner in the laboratory will appreciate the numerous helpful remarks on very practical everyday problems.

The expert will enjoy the fresh approach by the authors to some simple questions and the deep thought they give to some classical problems. For example, how many of us know whether our pulses rotate the nuclear magnetization to the left or to the right? K. S.-R. and H. W. S. at least *care*. They make considerable efforts to clarify important concepts and terms that are often carelessly used. Examples are the distinctions between homogeneous and inhomogeneous line-broadening, homogeneous and inhomogeneous Hamiltonians, and coherent and stochastic processes.

Much consideration is given to the question of the basic information content of various multidimensional spectra. In this context the reader leans about the usefulness of various joint and conditional probabilities, and that certain multidimensional spectra will exactly correspond to them. The close relationship between exchange NMR spectra and correlation functions in neutron scattering is discussed. Everyone who has performed a multidimensional solid-state NMR experiment would be well advised to consult this monograph as to whether or not the information contained in the spectra has been fully recognized and correctly interpreted. And this advice is certainly also pertinent to those who have questions about a material, be it a polymer or not, and wonder what kind of NMR experiment might give the answer. Even more: the monograph provides guidance to ask the right questions in the first place.

The sections and chapter on spin diffusion and its applications for characterizing polymers and polymer blends are particular highlights. It is refreshing to see that the monograph even serves as a platform for scientific controversy. Here one becomes very conscious of the personal involvement of K. S.-R. and of how much original work he has contributed to the subject.

I am sure that the monograph will soon become a standard reference source, a *classic*, simply "the SRS". It will be a *must* for all who work in solid-state NMR. I am the happy owner of two copies, one for the bedside and one for the office.

Two-Metal Ion Catalysis in Enzymatic Acyl- and Phosphoryl-Transfer Reactions

Norbert Sträter, William N. Lipscomb,* Thomas Klabunde, and Bernt Krebs*

Numerous studies, both in enzymatic and nonenzymatic catalysis, have been undertaken to understand the way by which metal ions, especially zinc ions, promote the hydrolysis of phosphate ester and amide bonds. Hydrolases containing one metal ion in the active site, termed mononuclear metallohydrolases, such as carboxypeptidase A and thermolysin were among the first enzymes to have their structures unraveled by X-ray crystallography. In recent years an increasing number of metalloenzymes have been identified that use two or more adjacent metal ions in the catalysis of phosphoryl-transfer reactions (R-OPO_3 + R′-OH → R′-OPO_3 + R-OH; in the case of the phosphatase reaction R′-OH is a water molecule) and carbonyl-transfer reactions, for example, in peptidases or other amidases. These dinuclear metalloenzymes catalyze a great variety of these reactions, including hydrolytic cleavage of phospho-mono-, -di- and -triester bonds, phosphoanhydride bonds as well as of peptide bonds or urea. In addition, the formation of the phosphodiester bond of RNA and DNA by polymerases is catalyzed by a two-metal ion mechanism. A remarkable diversity is also seen in the structures of the active sites of these di- and trinuclear metalloenzymes, even for enzymes that catalyze very similar reactions. The determination of the structure of a substrate, product, stable intermediate, or a reaction coordinate analogue compound bound to an active or inactivated enzyme is a powerful approach to investigate mechanistic details of enzyme action. Such studies have been applied to several of the metalloenzymes reviewed in this article; together with many other biochemical studies they provide a growing body of information on how the two (or more) metal ions cooperate to achieve efficient catalysis.

Keywords: catalysis · enzymatic catalysis · metallohydrolases

1. Introduction

Enzymes containing two metal ions separated by about 3 to 5 Å in the active site, termed dinuclear metalloenzymes, catalyze a wide variety of chemical reactions in nature. Prominent examples are the dinuclear iron proteins hemerythrin, ribonucleotide reductase, and methane monooxygenase,[1] or the copper proteins superoxide dismutase, hemocyanin, tyrosinase, and cytochrome c oxidase, all of which are involved in transport or activation of oxygen. Examples for nonredox-active dinuclear metalloenzymes include enolase, xylose isomerase, and arginase. An active role in catalysis (or oxygen binding in the case of hemerythrin and hemocyanin) has been assigned to both metal ions, and none of the closely neighboring metal ions seems to have a purely structural role. Increasing numbers of dinuclear metalloenzymes that catalyze hydrolytic reactions are now recognized (Table 1). However, it has only been in the last few years that detailed three-dimensional structural information became available for some of these enzymes.

Two-metal ion catalysis is now found in several biological transfer reactions of phosphoryl and acyl or other carbonyl groups, mostly to water molecules (phosphatases, peptidases, amidases). In view of the similarities of these reactions a comparative review of the presumed reaction mechanisms and their structural basis seems desirable. Therefore the scope of this article covers structural and mechanistic aspects of the catalysis of metalloenzymes that utilize two or more catalytic metal ions in phosphoryl- and carbonyl-transfer reactions. No limitation is made to a specific metal ion (e.g. Zn^{2+}) employed for catalysis in vivo, especially since for most of these enzymes activity is seen with several divalent metal ions. The enzymes are discussed and compared mainly on the basis of structural investigations, including also kinetic and spectroscopic results of relevance to the two-metal ion mechanism. Considering the number of enzymes included here, it is evident that a comprehensive coverage of the available literature on each one could not be achieved. However, for most of these enzymes a recent and more comprehensive review article is cited. We also regret that studies on small-molecule dinuclear metallocatalysts, many of which were

synthesized as structural or functional models for the enzymes discussed here, could not be included. For zinc enzymes containing two or more adjacent metal ions, termed cocatalytic zinc motifs, a recent analysis with respect to their structural and biochemical properties is available.[2]

2. Phosphoryl-Transfer Reactions

Phosphoryl-transfer mechanisms have been intensively studied both in enzymatic and nonenzymatic reactions because of their fundamental biological importance. Consequently, several comprehensive reviews are available on these reactions in general[3–5] and on the role of metal ions.[6] A main step in the classification of an enzyme-catalyzed phosphoryl-transfer reaction concerns the question of whether the reaction proceeds via a covalent phosphoenzyme intermediate or whether the phosphoryl group is directly transferred to the final acceptor. Provided that each elementary step yields an inversion of the chiral

N. Sträter

W. N. Lipscomb

T. Klabunde

B. Krebs

Norbert Sträter was born in Soest, Germany, in 1965. He studied Chemistry at the University of Münster, Germany, and obtained his PhD in 1994. In the group of Bernt Krebs he worked on the X-ray crystal structure of purple acid phosphatase. As a postdoctoral researcher in the laboratory of William N. Lipscomb at Harvard he is currently studying the two-metal ion mechanisms of leucine aminopeptidase and aminopeptidase A by X-ray crystallography.

William N. Lipscomb was born in Cleveland, Ohio, in 1919. After obtaining his BS in Chemistry at the University of Kentucky, he earned a PhD in Chemistry at the California Institute of Technology for X-ray and electron diffraction studies in the group of Linus Pauling. He then joined the faculty of the University of Minnesota, where he studied the structure and bonding of volatile boron hydrides by low-temperature single-crystal X-ray diffraction. He pursued this work after 1959, when he became Professor of Chemistry at Harvard, and was awarded the Nobel Prize in Chemistry in 1976 for these research studies. X-ray studies on enzyme structure and function, focussing on metalloenzymes and allosteric enzymes, started in 1962. His research on metalloenzymes has included work on carboxypeptidase A, carbonic anhydrase, leucine aminopeptidase, and fructose-1,6-bisphosphatase.

Thomas Klabunde was born in Lüdenscheid, Germany, in 1968. After studying Chemistry at the University of Münster, Germany, he joined the group of Bernt Krebs. He obtained his PhD in 1996 for biochemical and crystallographic studies on purple acid phosphatase and has now joined the research group of James C. Sacchettini at Texas A & M University for postdoctoral research in crystallography.

Bernt Krebs was born in 1938 in Gotha, Germany. He studied Chemistry at the University of Göttingen, Germany, and received his PhD in 1965 for studies on the crystal structure and chemistry of trithiocarbonic acid under supervision of G. Gattow. Thereafter followed postdoctoral research at Brookhaven National Laboratory (X-ray and neutron diffraction on biological macromolecules), Habilitation in Inorganic Chemistry in Göttingen, and faculty positions in Kiel, Bielefeld, and Münster, where he has been a full Professor since 1977. His primary research interests include chemical and structural studies on thio- and seleno-compounds, chalcogen halides, chalcogenide solid-state compounds, transition metal oxygen compounds, cis-platinum analogues, and metalloproteins as well as model complexes for these metalloproteins.

configuration around the phosphorus atom (see below), a direct transfer would result in an inverted configuration, whereas one phosphoenzyme intermediate would yield a retention of the configuration, and so forth. Of the nucleophilic amino acid side chains available to the enzyme to form a phosphoenzyme intermediate, histidine, serine, threonine, cysteine, and tyrosine are known to become phosphorylated. However, aspartate, glutamate, and lysine may also act as nucleophiles. An enzyme-bound intermediate may be trapped at a certain pH or in a metal-exchanged enzyme form, as was shown for Cd-substituted alkaline phosphatase.[7]

A second main characteristic of the mechanism concerns the nature of each elementary step. Each displacement step may proceed either by a largely dissociative mechanism via a metaphosphate-like intermediate[8] or by an associative pathway through a pentacoordinate intermediate or transition state (Fig. 1). Both possibilities have been demonstrated to occur in nonenzymatic phosphoryl-transfer reactions.[3, 9, 10]

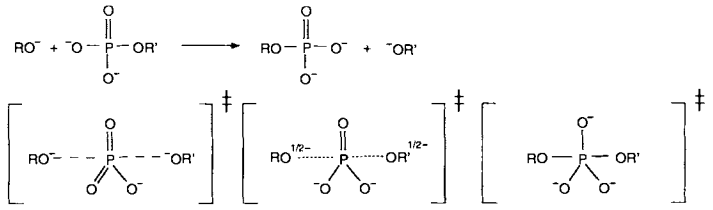

Fig. 1. Phosphoryl-transfer reaction of a phosphomonoester dianion with a deprotonated nucleophile (top). Structure of the transition state for a dissociative (bottom left), intermediate (bottom middle), and associative (bottom right) mechanism.

Inversion of the configuration around the phosphorus atom is a characteristic of an associative in-line S_N2 displacement step as long as no rearrangement of the ligands in the pentacoordinate intermediate takes place. Whereas such rearrangements like the Berry pseudo-rotation[10] are possible in nonenzymatic reactions, they have not been observed in enzymatic catalysis so far.

The experimental differentiation between a reaction pathway via a short-lived metaphosphate-like intermediate and an associative pathway is extremely difficult. If the rate constant can be determined as a function of the pK_a value of the attacking nucleophile or the leaving group, a plot of $\lg(k)$ against pK_a usually yields a linear relationship (Brønsted plot).[11] A large dependence of the rate constant on the nucleophilicity of the attacking group can be expected for an associative mechanism, whereas no dependence is expected for a purely dissociative pathway. Both pathways are influenced by the nucleophilicity of the leaving group.

It is evident from Figure 1 that the bond order to the equatorial phosphoryl oxygen atoms changes for an associative and a dissociative pathway in the transition state relative to the ground state. Isotopic substitution of these oxygen atoms can thus influence the rate constant.[9, 12, 13] Substitution of ^{18}O in an associative pathway will slow down the reaction (normal secondary isotope effect), whereas the same substitution leads to a rate enhancement for dissociative mechanisms (inverse secondary isotope effect). Likewise, the influence of an isotopic substitution of the ester oxygen atom can indicate the degree of bond cleavage in the transition state.[12, 13] Studies on the isotope effect have been applied to the reactions catalyzed by alkaline phosphatase, calcineurin, and phosphotriesterase (see Sections 2.1, 2.2.2, and 2.9).

In addition, a number of well-founded considerations have been put forward by various authors on the basis of the energetics of enzymatic catalysis to assess the factors favoring each pathway. These criteria operate mainly on the interactions between enzyme and substrate and between enzyme and transition state or intermediate and can thus most thoroughly be applied on the basis of a detailed structural analysis, preferably of complexes of the enzyme with reaction coordinate analogues. One structural consideration concerns the distance between the intermediate and the final acceptor: Since even a stabilized metaphosphate intermediate is a highly reactive chemical species it has to be separated by a minimum distance from the enzyme-bound nucleophile in order to be stable for a limited lifetime. Mildvan and Fry[14] estimated that a distance of more than 4.9 Å is necessary for a dissociative path.

Several significant conclusions can be drawn from studying the possible interactions between the participating reactants (Fig. 2). Because of the high reactivity of a metaphosphate intermediate, an activation of the attacking nucleophile is not necessary and would favor an associative pathway. Activation of the leaving group promotes both pathways and is thus of little diagnostic use, although it has a greater influence on a metaphosphate path. Interaction of the equatorial phosphoryl oxygen atoms with positively charged amino acid side chains or metal ions stabilizes the intermediate of both pathways by reducing the negative charge on the oxygen atoms. However, it becomes apparent from Figure 1 that an associative pathway increases the negative charge on the equatorial oxygen atoms of the intermediate, whereas in a dissociative pathway the magnitude of the negative charge of the metaphosphate intermediate is reduced compared to that of the substrate. The interaction of metal ions or positively charged amino acid side chains with the phosphoryl oxygen atoms thus stabilizes the substrate more than it stabilizes a metaphosphate intermediate, so that the metaphosphate ion is destabilized relative to the ground state by these interactions, whereas the pentacoordinate intermediate is stabilized relative to the ground state. Neglecting the influence of the different geometrical structures of ground state and transition state (see below), electrostatic interactions of the equatorial phosphoryl oxygen atoms with positively charged species may therefore favor an associative pathway.

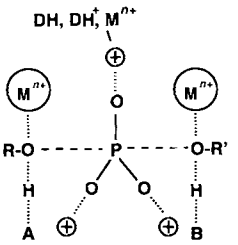

Fig. 2. Possible interactions in the stabilization of a transition state of an in-line displacement step for a phosphomonoester with metal ions (M^{n+}), general acids (AH), general bases (B), and hydrogen-bond donors (DH). OR is the leaving group and OR' the incoming nucleophile.

Partly because of the aforementioned reasons most authors assume an associative phosphoryl-transfer mechanism, since positively charged metal ions or amino acid side chains are frequently found in interaction with the phosphoryl oxygen atoms in enzyme active sites. However, the nonenzymatic hy-

drolysis of phosphomonoesters, of phosphodiesters,[5] and of the γ-phosphoryl group of ATP[15] takes place largely or in part via a metaphosphate pathway in solution. Does an enzyme change the dissociative character of these reactions by employing metal ions or positively charged side chains in catalysis, or does it enhance catalysis by further stabilizing the same transition state of the reaction in solution? Metal ions evidently do not change the transition state character of nonenzymatic reactions and they have little effect on the rate constant.[15, 16] Thus, it was argued that coordination of metal ions to the phosphoryl oxygen atoms has a much smaller effect than generally assumed and does not change the character of the transition state.[15] Also, the metal ions are usually coordinated by one or more negatively charged ligands (most often carboxylate groups), which can reduce the overall charge toward neutrality. The role of the metal ions may primarily be to achieve a favorable orientation of the reactants. Furthermore, the assumption that a metaphosphate-like transition state is destabilized relative to the substrate in a positively charged electrostatic field neglects geometrical factors such as the different structures of the tetrahedral phosphate group of the substrate and of the trigonal-planar metaphosphate. These factors could result in a stabilization of a metaphosphate by a more perfect fit of the intermediate to the enzyme active site. Orbital interactions, in particular, may be very sensitive to the complementary geometry of intermediate and active site.

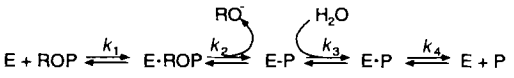
Figure 2 summarizes possible interactions of protein groups and metal cofactors in the stabilization of a transition state of a phosphoryl-transfer reaction. Metal ions (M^{n+}) lower the pK_a value of the nucleophile (HOR') such that it can be deprotonated to the much stronger nucleophile OR'^-, possibly with the help of a general base B (B = Glu^-, Asp^-, His) as a proton acceptor. Expulsion of the leaving group (OR^-) is facilitated by protonation by a general acid AH (AH = Glu, Asp, His^+) and/or by reducing the nucleophilicity of OR^- by metal coordination. The energy of the transition state can be minimized by interaction of the equatorial phosphoryl oxygen atoms with hydrogen-bond donors DH (DH = amide NH, Thr, Ser, Tyr, Cys, Asn, Gln, His, H_2O), which may also be positively charged (DH^+: His^+, Arg^+, Lys^+), or with metal ions.

2.1. Alkaline Phosphatase

Alkaline phosphatase (AP) is certainly the most intensely studied enzyme of all dinuclear metallohydrolases described in this article.[17] The enzyme is a nonspecific phosphomonoesterase found in prokaryotes and eukaryotes. Hydrolysis to produce free inorganic phosphate competes with the transfer of the phosphoryl group to other alcohols, for example 2-amino-2-(hydroxymethyl)-1,3-propanediol (Tris), if present in the buffer. Although its specific function in mammals is not known at present, the biological importance is indicated by the widespread use of AP activity in human serum as an enzymatic signal for a variety of disease states.

The homodimeric AP (94 kDa) from *E. coli* contains two Zn^{2+} and one Mg^{2+} ion in each active site. Activity has a sigmoid pH-rate profile with a pK_a of 7.5 which involves a change in the rate-determining step from release of phosphate at high pH to dephosphorylation at low pH.[18, 19]

The reaction proceeds via a phosphoenzyme intermediate (E–P), in which Ser-102 is phosphorylated (Scheme 1).[18, 20] This intermediate could be isolated at acid pH (below 5.5), where the



Scheme 1. Reaction pathway for the hydrolysis of phosphate esters by alkaline phosphatase.

E–P$\rightleftharpoons$E·P equilibrium favors the phosphorylated intermediate. E·ROP and E·P refer to the noncovalent complexes with substrate and product, respectively. R can vary from a methyl group to a large protein molecule with almost no influence on the overall reaction constant k_{cat} as long as the pK_a value of the leaving group is less than 10.[21] This finding reflects the fact that the dissociation of P_i, the product phosphate, is the rate-limiting step at alkaline pH, as demonstrated by a variety of NMR spectroscopic methods.[22, 17] In addition, at pH 8.0 the overall second-order rate constant k_{cat}/K_m for the hydrolysis of phosphate esters was found to be dependent on the viscosity of the solution, indicating that the maximum activity of AP is also limited by the diffusion-controlled encounter with the substrate.[23]

The alkaline phosphatase reaction proceeds with retention of configuration around the phosphorus atom.[24] This result suggested that the reaction consists of two in-line S_N2 nucleophilic attacks: the first by Ser-OH (or Ser-O^-) on the substrate and the second by solvent H_2O (or OH^-) on the phosphoserine intermediate. Brønsted correlations that probe the nature of the transition state have been applied by different groups and have yielded conflicting results. The first such study on AP revealed a small value of $\beta_{lg} = -0.2$ for a series of aryl and alkyl monoesters.[25] A β_{lg} value of -0.6 for the leaving group was determined for a series of phosphomonoesters with a pK_a value of less than 15 for the alcohol group.[21] The fact that this value was found to be only -0.3 for a mutant in which the nucleophilic serine residue was mutated to a cysteine residue was, together with the 50-fold lower rate constant for this mutant, interpreted as indicative of a largely associative phosphorylation step. In contrast, a β_{lg} value of -0.8 for a series of aryl phosphorothiolates led, in comparison with a value of β_{lg} of -1.1 for the nonenzymatic reaction that is known to follow a dissociative pathway, to the suggestion that there is considerable dissociative character in both enzymatic and nonenzymatic transition states.[26] An inverse secondary ^{18}O kinetic isotope effect on the hydrolysis of glucose 6-phosphate by AP also indicated a dissociative mechanism.[27] Studies on the isotope effects using *p*-nitrophenyl phosphate as substrate yielded values near unity, indicating that a nonchemical step is rate-limiting for the hydrolysis of this substrate.[28]

The metal atoms in native Zn1-Zn2-Mg3-AP can be exchanged for various divalent metal ions.[17] The native enzyme has maximal activity, but the Mg^{2+} ion in binding site 3 has only a minor influence on the activity of bacterial APs.[17, 29] However, the presence of magnesium in this binding site influences the activity in mammalian APs, possibly because a histidine

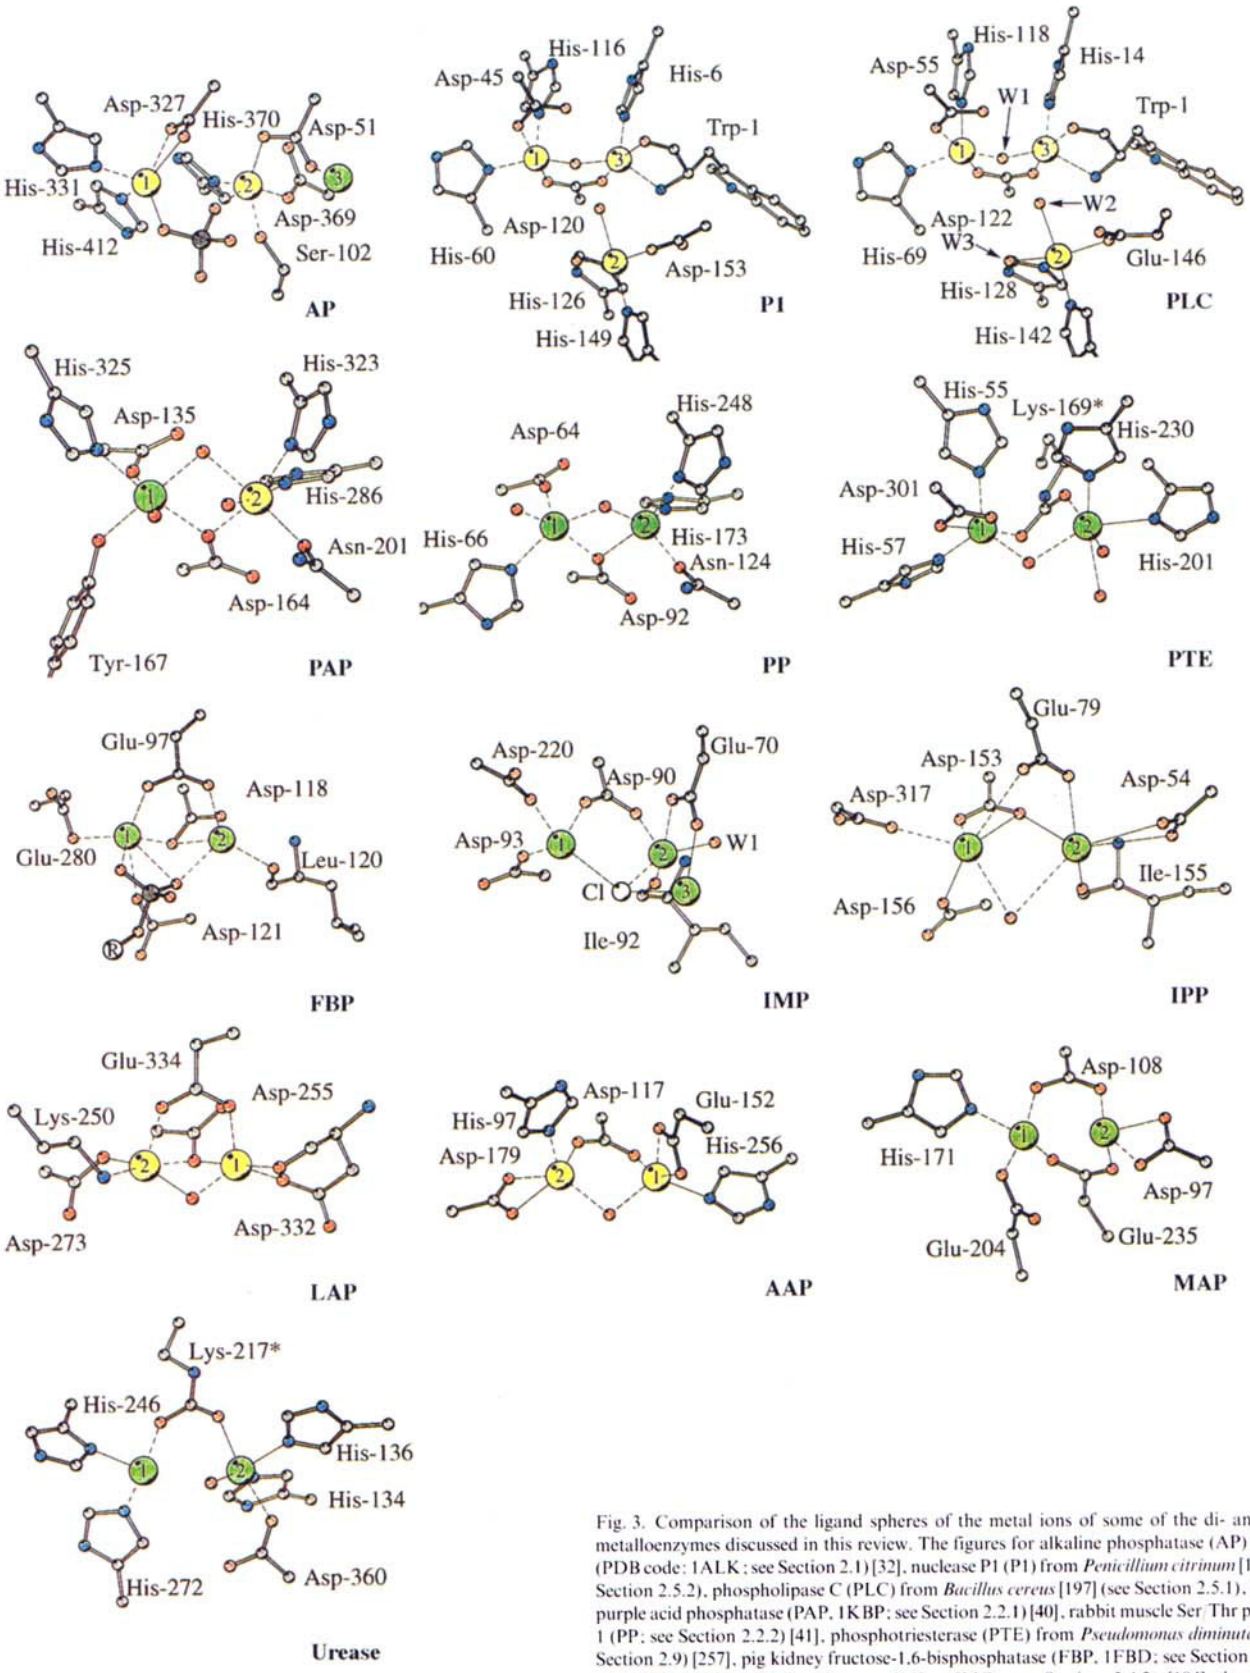


Fig. 3. Comparison of the ligand spheres of the metal ions of some of the di- and trinuclear metalloenzymes discussed in this review. The figures for alkaline phosphatase (AP) from *E. coli* (PDB code: 1ALK; see Section 2.1) [32], nuclease P1 (P1) from *Penicillium citrinum* [196, 212] (see Section 2.5.2), phospholipase C (PLC) from *Bacillus cereus* [197] (see Section 2.5.1), kidney bean purple acid phosphatase (PAP, 1KBP; see Section 2.2.1) [40], rabbit muscle Ser/Thr phosphatase-1 (PP; see Section 2.2.2) [41], phosphotriesterase (PTE) from *Pseudomonas diminuta* (1PSC; see Section 2.9) [257], pig kidney fructose-1,6-bisphosphatase (FBP, 1FBD; see Section 2.4.1) [169], human inositol monophosphatase (IMP, 1IMC; see Section 2.4.2) [184], bovine inositol polyphosphate 1-phosphatase (IPP, 1INP; see Section 2.4.3) [151], bovine lens leucine aminopeptidase (LAP, 1LAM; see Section 3.1.1) [284, 286], aminopeptidase (AAP) from *Aeromonas proteolytica* (1AMP; see Section 3.1.2) [292], methionine aminopeptidase (MAP) from *E. coli* (1MAT; see Section 3.1.3) [300], and urease (1KAU; see Section 3.2) [260] have been generated from the atom coordinates. Zinc ions are shown in yellow, all other metal ions in green [320], carbon atoms in grey, oxygen atoms in red, and nitrogen atoms in blue.

residue in the mammalian enzymes replaces a Asp-153.[30] The exchange of one or both of the zinc ions in sites 1 and 2 by Mg^{2+}, Co^{2+}, or Mn^{2+} ions results in a considerably reduced activity. Substitution of Zn^{2+} by Cd^{2+} has a drastic effect on the dephosphorylation of E–P, and allows the isolation of the E–P intermediate.[7] This finding can be readily explained by the diminished ability of the "softer" and larger Cd^{2+} ion to generate an OH^- nucleophile or to stabilize the transition state.

Structures of native AP at 2.8 Å resolution, of the complex with phosphate (E·P) at 2.0 Å resolution, and of the Cd-substituted enzyme with covalently bound phosphate (E–P) at 2.5 Å resolution have been determined.[31, 32] The structure of the native enzyme complexed with phosphate at 2.0 Å resolution provided the most detailed insight into the active site structure (Figs. 3 and 4). The Zn1 center is pentacoordinated by His-331,

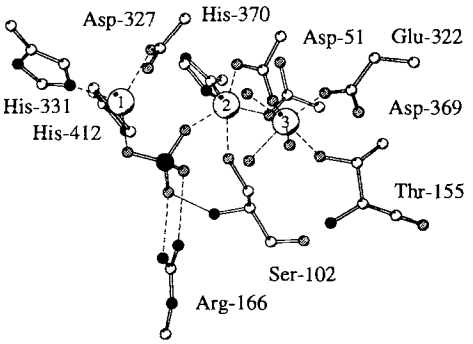

Fig. 4. Structure of the active site of the alkaline phosphatase with a bound phosphate ion (generated from the coordinate file 1ALK) [32]. The Ser-102 side chain, which is modeled in coordination to Zn2, is disordered in this structure (see Fig. 6). Sites 1 and 2 are occupied by Zn^{2+} and site 3 binds Mg^{2+}.

His-412, the two carboxylate oxygen atoms of Asp-327, and one oxygen atom of the phosphate group. Several water molecules were found in the active site region but no water coordination to Zn1 was reported. Water relaxation measurements[33] as well as ^{113}Cd and ^{35}Cl NMR data[34] suggested that one or two water molecules are coordinated to the site 1 metal in the absence of phosphate. The Zn2 center is coordinated tetrahedrally by an oxygen atom of His-370, two oxygen atoms of monodentate carboxylate side chains (Asp-51 and Asp-369), and another oxygen atom of the phosphate group. Thus, the phosphate ion bidentately bridges the two zinc ions. The other two phosphate oxygen atoms are tightly held by the guanidinium group of Arg-166. Asp-51, Glu-322, Thr-155, and three water molecules coordinate Mg at site 3. Asp-51 bidentately bridges Zn2 and Mg3. The distances between the metal ions are 4.1 Å between Zn1 and Zn2, 4.8 Å between Zn2 and Mg3, and 7.1 Å between Zn1 and Mg3.[35] The side chain of the Ser-102 residue was found to be disordered. This structure serves as a model for the product complex E·P as well as for the complex with bound substrate (E·ROP), since the enzyme evidently builds no specific interactions to the leaving group.

Exchange of the two zinc ions by cadmium ions enabled the structural characterization of the E–P intermediate at pH 7.5 at 2.5 Å resolution.[32] Figure 5 shows a schematic drawing of the interactions of the phosphorylated Ser-102 side chain with the

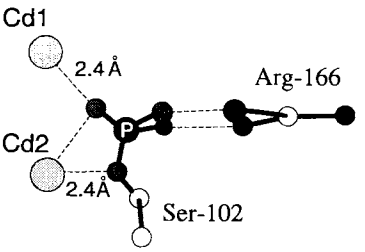

Fig. 5. Schematic drawing of the interactions in the phosphoserine intermediate of the Cd Cd form of alkaline phosphatase [32]. This structure is also considered to model the binding mode of the phosphorylated Ser-102 side chain to a catalytically active Zn Zn cluster (see Fig. 6).

cadmium ions and Arg-166. A similar model is considered to be applicable for the zinc ions.

The substrate probably binds to both zinc ions with its ester oxygen atom coordinated to Zn1 and opposite to Ser-102 (Fig. 6b).[32, 17] Coordination of the serine oxygen atom to Zn2 facilitates deprotonation of this side chain to yield the attacking Ser-O^- nucleophile. The Zn1 center activates the leaving alcohol group. After the phosphoenzyme intermediate (E–P) has formed (Fig. 6d), the alkoxide leaves and its coordination site

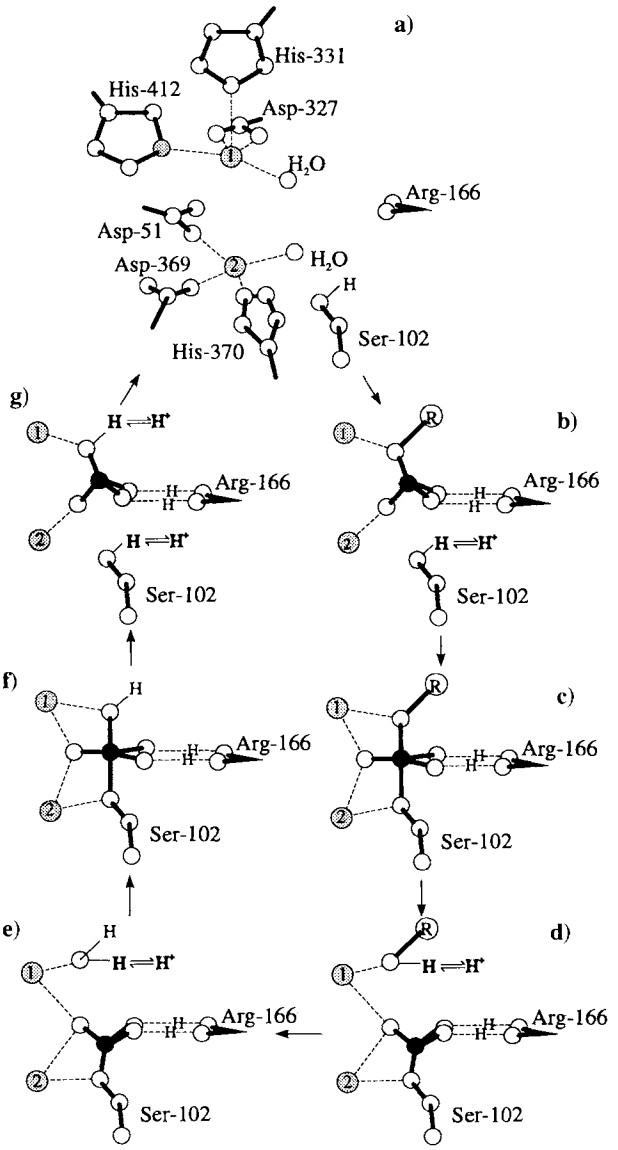

Fig. 6. Proposed mechanism for the hydrolysis of a phosphomonoester by alkaline phosphatase on the basis of the X-ray crystal structures [32] and biochemical data.

on Zn1 is substituted by a water molecule that dissociates a proton to form the Zn-OH^- nucleophile for the hydrolysis of the phosphoserine intermediate (Fig. 6e). The structure of this intermediate is known from the X-ray crystal structural analysis. Dephosphorylation of the E–P intermediate occurs in a displacement step in which the two metal ions have reversed roles: the oxygen atom of the leaving group (Ser-O^-) is now activated by Zn2 and the remaining oxygen atoms are coordinated to both metal ions or hydrogen-bonded to Arg-166 in order to enhance the electrophilicity of the phosphorus atom.

Besides the two metal ions the side chains of Ser-102 and Arg-166 evidently play major roles in AP catalysis. Mutation of Ser-102 to the nonnucleophilic residues alanine or leucine resulted in a greatly reduced activity in the hydrolysis of phosphate monoesters.[36] Values for $k_{cat} \approx 1/1000$ and $\approx 1/500$ of the wild-type activity were determined for both mutant forms, respectively, with only a minor influence on K_m. Although the activity of these mutants is significantly reduced, the hydrolysis of *p*-nitrophenylphosphate is still enhanced by a factor of about 10^7 compared to the rate for the uncatalyzed reaction.[36] Hydrolysis by these mutants probably proceeds by a different mechanism, for example, by direct attack of a zinc-activated water molecule similar to mechanisms seen in other phosphatases. Replacement of Arg-166 against serine, alanine, lysine, and glutamine demonstrated that Arg-166 is important for activity but not essential.[37] Loss of Arg-166 results in an increase of K_m and in a diminished k_{cat} (2.4% of wild-type for R166A).

The proposed mechanism contains dissociative character in the activation of the leaving group by one metal ion; however, the nucleophile is also activated by deprotonation by a metal ion. A remarkably unique feature of the AP mechanism is the reversed role of the two metal ions in the two displacement steps: the second step of the reaction is almost a mirror image of the first step.

2.2. Family of $\beta\alpha\beta\alpha\beta$ Metallophosphoesterases

Even before any structural information for the purple acid phosphatases (PAPs) or the Ser/Thr protein phosphatases (PPs) were available, a phosphoesterase signature motif, DX[G/H]-$(X)_n$-GDXX[Y/X]-$(X)_n$-GNH[E/D] (motif A), had been identified in a large group of phosphoesterases (Fig. 7). This motif is found in the sequences of PAP, the PPs, diadenosine tetraphosphatases, exonucleases, 5′-nucleotidases, sphingomyelin phosphodiesterases, and other phosphoesterases.[38,39] In these enzymes the core structure is formed by two sandwiched β-sheets with the metals located at the C-termini of central parallel strands as shown by the X-ray crystal structures of PAP[40] and the PPs.[41–44] In kidney bean PAP, motif A contains four of the metal coordinating residues: Asp-135, Asp-164, Tyr-167, and Asn-201. In all other phosphoesterases the tyrosine residue of the second loop appears to be exchanged, and the corresponding position in the coordination sphere is filled by the histidine residue of the first loop (which is a glycine in PAP). Based on the structure of PAP, sequence alignments revealed a second signature motif (motif B), H-$(X)_n$-[G/A]HX[H/X], comprising His-286, His-323, and His-325 in PAP.[45]

2.2.1. Purple Acid Phosphatase

Purple acid phosphatases (PAPs) represent a group of widely distributed phosphomonoesterases characterized by their low pH-optima, by their insensitivity to tartrate inhibition, and by their intense purple color, which results from a tyrosine → Fe^{III} charge transfer. A role in degradative biological processes such as in the phagocytosis of aged erythrocytes[46] and in active bone resorption[47] has been implicated for the mammalian PAPs, possibly including phosphorylated proteins as substrates. The monomeric 35-kDa mammalian PAPs all contain a Fe^{III}–Fe^{II} center in their active form. This diiron center has attracted considerable interest and is now spectroscopically well characterized by Mössbauer,[48,49] EPR,[48,50–53] NMR,[53,54] EXAFS,[55] magnetic,[48,56,57] electrochemical,[58] and resonance Raman[59] studies. Most of these studies used bovine spleen PAP and porcine uterus PAP (also known as uteroferrin), which share a sequence homology of 90%.

In contrast to the mammalian PAPs, the divalent metal binding site in kidney bean PAP is occupied by zinc.[60] This plant enzyme is a homodimeric glycoprotein (111 kDa) with a disul-

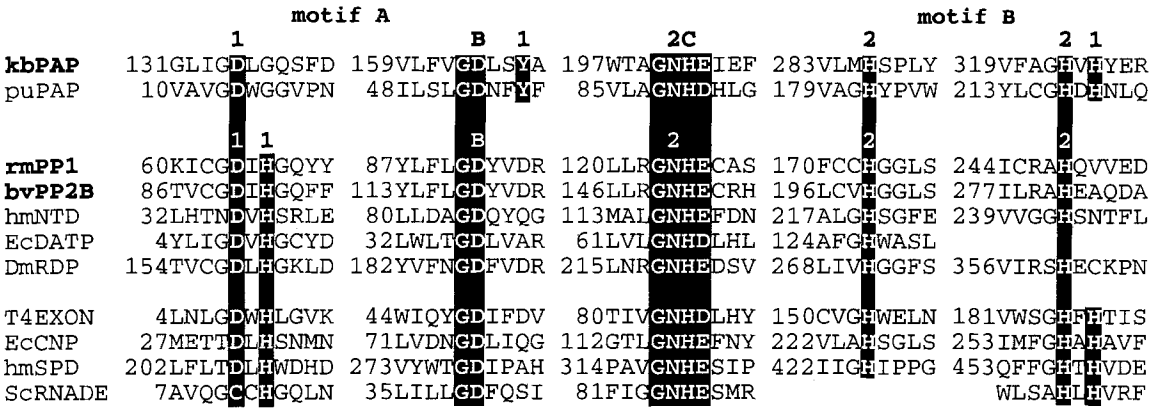

Fig. 7. Sequence alignment of the metal-coordinating motifs of some members of the family of $\beta\alpha\beta\alpha\beta$ metallophosphoesterases (more complete analyses can be found in refs. [38,39,45]). The sequences of kidney bean PAP (kbPAP), rabbit muscle PP1 (rmPP1), and bovine calcineurin (bvPP2B), for which X-ray crystal structures are available, are aligned to those of porcine uterus PAP (puPAP), human 5′-nucleotidase (hmNTD), *E. coli* diadenosine tetraphosphatase (EcDATP), *Drosophila melanogaster* retinal degeneration protein (DmRDP), bacteriophage T4 exonuclease protein GP47 (T4EXON), *E. coli* 2′,3′-cyclic nucleotide 2′-phosphodiesterase (EcCNP), human sphingomyelin phosphodiesterase (hmSPD), *Saccharomyces cerevisiae* RNA debranching enzyme (ScRNADE). Those residues coordinated to metal ions 1 and 2, as well as the bridging apartate (B) and the conserved catalytic histidine (C) are marked. Motif A comprises the first three blocks and motif B the last two blocks.

fide bridge connecting both monomers.[60, 61] The zinc ion in kidney bean PAP can be exchanged against other divalent metal ions, yielding almost the same (Fe^{2+} or Co^{2+}) or reduced activity.[62] After exchange of Zn^{2+} for Fe^{2+} the kidney bean enzyme shows nearly identical spectroscopic and kinetic behavior to the mammalian PAPs.[62, 63] In spite of a low overall sequence homology, significant local sequence similarities could be identified especially in the regions of active site residues, suggesting that the mammalian enzymes and kidney bean PAP are evolutionary related and have a similar three-dimensional core structure.[64] In addition, all metal-ligating residues are conserved between the plant and mammalian PAPs.

A small antiferromagnetic coupling constant in the mixed-valent iron center ($S = 1/2$) has been revealed by the temperature dependence of the intensities of the EPR signals,[48] and by ^1H NMR spectroscopic[65] and magnetic susceptibility[56] measurements. This small coupling constant suggests the presence of a μ-hydroxo bridge, but not a μ-oxo bridge. The oxidized enzyme displays stronger antiferromagnetic coupling; however, the existence of a μ-oxo bridge in the $Fe^{III}-Fe^{III}$ enzyme is still not clear.

The existence of water molecules coordinated to the dinuclear cluster has been demonstrated by electron spin echo envelope modulation (ESEEM) spectroscopy and electron nuclear double resonance (ENDOR) spectroscopy,[51] and by electrochemical[58] studies. Based on the observed decrease of the activity at lower pH values, as well as on the pH-dependence of the EPR spectra a solvent molecule bound to the ferric iron with an apparent pK of around 4.5 has been proposed.[50] Stopped flow measurements on uteroferrin indicate a rapid binding of phosphate to the Fe^{2+} center.[66, 67] For substrates a similar fast binding to the Fe^{2+} center is proposed and the Fe^{3+}-bound hydroxide ion can attack the phosphorus atom of the substrate. A direct in-line transfer of the phospho group to the water molecule is supported by the inversion of the absolute configuration around the phosphorus atom for phosphomonoester hydrolysis by PAP.[68] Furthermore, a recent study found no evidence for the formation of a phosphoenzyme intermediate.[69]

The X-ray crystal structure of kidney bean PAP at 2.9 Å resolution showed the Fe^{3+} ion to be coordinated by Tyr-167, His-325, and Asp135, whereas the Zn^{2+} center is ligated by His-286, His-323, and the amide oxygen atom of Asn-201 (see Fig. 3, Section 2.1).[40] Also, Asp-164 monodentately bridges the two metal ions, which are 3.1 Å apart. Although positions of water molecules could not be determined in the X-ray crystal structure because of the moderate resolution, the authors placed three exogeneous ligands into the coordination sphere of the dinuclear metal cluster based on biochemical evidence (see above) and the observed coordination geometry:[40] the presumed OH^- nucleophile bound to the Fe^{3+} center, a terminal water molecule coordinated to the Zn^{2+} center, and a μ-hydroxo bridge (see Fig. 3, Section 2.1). The coordination sphere of the Fe^{3+} ion is then almost perfectly octahedral and that of the Zn^{2+} ion matches a more distorted octahedron. An X-ray crystal structure of kidney bean PAP in the presence of phosphate showed that the phosphate ion bidentately bridges the two metal ions (Fig. 8).[45] The two noncoordinated phosphate oxygen atoms are hydrogen-bonded to His-202 and His-296, which move by about 1 Å relative to their positions in the phosphate-free enzyme.

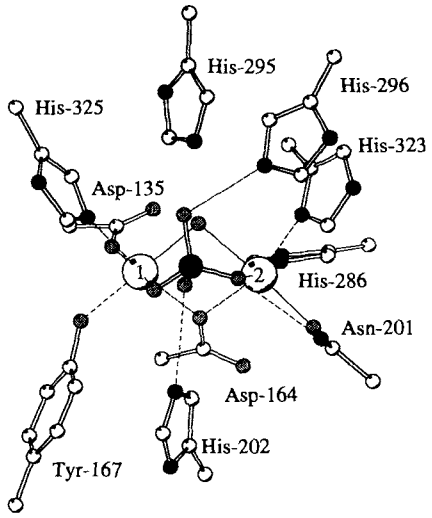

Fig. 8. Structure of the active site of PAP with a bound phosphate ion (generated from coordinate file 4KBP) [45]. The Fe^{3+} ion is bound to site 1 and the Zn^{2+} ion to site 2. The position of the bridging water molecule was not determined from the X-ray crystal data; it was modeled on the basis of biochemical evidence and the observed coordination geometry.

In a plausible mechanism (Fig. 9)[40, 50, 66] the phosphate group of the substrate binds to the divalent metal ion, which together with the histidine ligands preorients the phosphate group and enhances the electrophilicity of the phosphorus center. Then a nucleophilic attack occurs by the hydroxide ligand bound to the Fe^{3+} center, and the configuration at the phosphorus center is inverted through a pentacoordinate transition state in which the leaving group and the attacking nucleophile are in the apical positions. In addition to the metal ions the protonated side chains of His-202 and His-296 reduce the energy of the pentacovalent transition state through the formation of hydrogen bonds. After a small movement, His-295 may also interact with the substrate and His-296 may then protonate the leaving alcohol group.

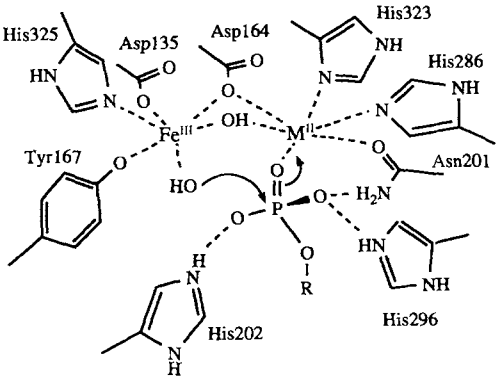

Fig. 9. Substrate binding mode and attack of the Fe^{3+}-bound nucleophile for the proposed reaction mechanism of phosphomonoester hydrolysis by PAP [40, 45, 50, 66].

2.2.2. *Serine/Threonine Protein Phosphatases*

Protein phosphorylation plays a cardinal role in regulating many cellular processes in eukaryotes. The phosphorylation of a protein is a dynamic process controlled by protein kinases and protein phosphatases (PPs). The serine/threonine phosphatases are unrelated in sequence and structure to the tyrosine phosphatases, and have been classified into four groups (1, 2A, 2B, 2C) on the basis of their biochemical properties.[70] Protein phosphatases 1, 2A, 2B (also known as calcineurin) have highly homologous catalytic domains,[38] but differ in their interactions with regulatory subunits and in their substrate specificity.[71]

Calcineurin, a heterodimer of a catalytic 60-kDa subunit (calcineurin A) and a 19-kDa calmodulin-like regulatory subunit (calcineurin B), is activated by several divalent metal ions,[72, 73] but the native enzyme probably contains a dinuclear Fe–Zn center in the active site.[72] Conflicting results have been reported concerning the oxidation state of the iron ion.[74] Manganese-activated calcineurin exhibits a broad pH-optimum around 7.[75] A solvent isotope effect of 1.35 in deuterated water on V_{max}/K_m is consistent with one or two proton transfer steps in the enzyme reaction.[76] Furthermore, several kinetic and chemical data support a mechanism without the formation of a phosphoenzyme intermediate.[75–77]

X-ray crystal structure analyses for Ser/Thr protein phosphatases are now available for the catalytic subunit of rabbit muscle PP-1 complexed with the toxin microcystin (2.1 Å resolution),[41] for human PP-1 and its complex with tungstate (both 2.5 Å resolution),[44] for bovine brain calcineurin complexed with the immunophilin-immunosuppressant FKBP12-FK506 complex (2.5 Å resolution),[42] and for human calcineurin with and without bound FKBP12-FK506 (3.5 and 2.1 Å resolution, respectively).[43] In agreement with the substantial sequence homologies between these proteins the overall folding architecture of the homologous domains of the three structures seems to be the same.

In the crystal structure of rabbit PP-1 both metal sites are probably occupied by Mn^{2+} ions, which is required to restore the full activity of the recombinant protein and was present in the crystallization buffer.[41, 78] However, a recent study indicates that PP1, like calcineurin, might be a Fe–Zn metalloenzyme in vivo.[79] Metal ion 1 is coordinated by Asp-64, His-66, and Asp-92, metal ion 2 by Asp-92, Asn-124, His-173, and His-248 (Fig. 3, Section 2.1 and 10).[41] Two exogeneous solvent molecules, one coordinated to metal ion 1 and one bridging the two metal ions, provide two additional ligands for the metal ions. A third water molecule has been located at a larger distance of 3.4 Å to metal ion 2. The coordination geometries of the two metal ions, which are 3.3 Å apart, are approximately square-pyramidal for site 1 and trigonal-bipyramidal for site 2. Proton-induced X-ray emission (PIXE) spectroscopy data and the X-ray crystal structure indicate that in human PP-1 metal site 1 contains iron and site 2 manganese.[44] Interestingly, the metal–metal distance for unliganded human PP-1 was refined to 4.0 Å on the basis of a data set collected on a frozen crystal in the presence of 30% glycerol. In the complex with tungstate this distance is reduced to 3.5 Å.

A very similar arrangement of the metal-ligating protein residues has been found in the two calcineurin structures.[42, 43]

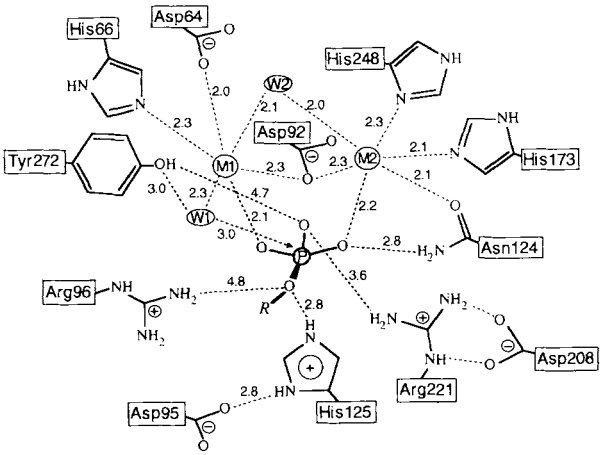

Fig. 10. Active site structure of rabbit muscle PP-1 and modeled binding mode of a phosphomonoester [41]. W1 might be the nucleophile that attacks the phosphorus center. A similar bidentate binding mode (as proposed here for the substrate) of a tungstate ion to the metal ions was determined for human PP-1 [44]. The latter structure implied that also W2 might be the nucleophile. His-125 could protonate the leaving group in both mechanisms.

Here the distance between the two metal ions was refined to 3.0 Å for the enzyme from bovine brain and to 3.1 Å for human calcineurin. In both calcineurin structures metal ion 1 has been modeled as an iron ion and metal ion 2 as a zinc ion, based on the homology to PAP. A phosphate ion, which was present in the crystallization buffer, bidentately bridges the two metal ions in the bovine calcineurin structure.[42] Furthermore, there is a weak electron density feature consistent with a water molecule bridging the two metal centers. In human calcineurin, three metal-bound water molecules were found: a bridging water molecule and a Fe^{3+}-bound water molecule similar to those found in PP-1 and an additional Fe^{3+}-bound water molecule, which is also hydrogen-bonded to His-151 (Fig. 11). This latter water molecule is not seen in the PP-1 structure, possibly because the nearby bound microcystin inhibitor sterically precludes binding

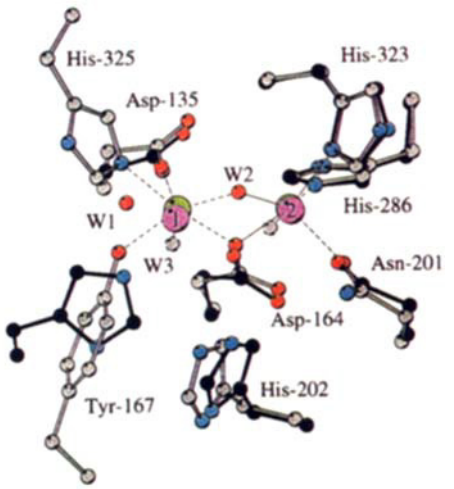

Fig. 11. Superposition of the dimetal clusters and the catalytic histidine residues of rabbit PP-1 (C atoms black) [41] and PAP (C atoms grey) [40]. Labels for the protein side chains and metal-coordinating bonds are only shown for PAP. The Fe^{3+} ion binds to site 1 and the Zn^{2+} ion to site 2 in kidney bean PAP. The water molecules W1 and W2 shown in red (labeled as in Fig. 10) belong to PP-1. The two terminal metal-bound water molecules shown in grey are proposed to be present as ligands in PAP in addition to a bridging water molecule at the position of W2.

of this water. A bidentate bridging binding mode to the dimetal center was found for a tungstate ion bound to human PP-1.[44]

Mutational analysis on Ser/Thr phosphatases has been employed on the smallest family member, the bacteriophage λPP.[39] Mutation of the catalytic histidine residue (marked C in Fig. 7) that is proposed to interact with the substrate phosphate group has a deleterious effect on activity, decreasing k_{cat} by a factor of 10^5. Mutagenesis of one of the two arginine residues in the active site (Arg-53 in PP-1) supports a role for this residue in binding of the substrate and stabilization of the transition state.

In spite of the similarity of the active site structures of the three Ser/Thr phosphatase structures, the putative reaction mechanisms discussed by the authors differ considerably. In the bovine calcineurin structure the μ-hydroxo bridge is within 2.9 Å of the phosphorus atom of the bidentately bound phosphate and colinear with one of the P–O bonds. Assuming that the substrate phosphate group binds in the same way as a phosphate ion does to the active site, the bridging hydroxide ion (W2 in Fig. 11) could be the attacking nucleophile in an in-line mechanism.[42] A similar mechanism based on the tungstate binding mode is assumed by Egloff et al.[44] The negative charge of the intermediate is supposed to be stabilized by interactions with both metal ions, and by Arg-122 and Arg-254, which were found to be in hydrogen-bonding distance with two of the phosphate oxygen atoms. His-151, which is hydrogen-bonded to the most solvent-exposed oxygen atom, is proposed to protonate the leaving alcohol group. A similar assistance of the corresponding two arginine residues and the conserved histidine residue in stabilization of the transition state and protonation of the leaving group is also proposed in an alternative mechanism (see Fig. 10).[41] The substrate phosphate group is assumed to bind in a bidentate way. However, based on the modeled binding mode of the phosphate group an in-line attack of the terminal water molecule W1 coordinated to M1 is discussed. A third alternative assumes that water molecule W3 in Figure 11 is the catalytically active nucleophile.[43] The catalytically active histidine residue may act here as a general base to accept a proton from this iron-coordinated water molecule.

2.2.3. Comparison of the Structures of Purple Acid Phosphatase and the Ser/Thr Protein Phosphatase

Superposition of the active sites of kidney bean PAP and rabbit PP-1 shows that the conserved ligands of the metal ions and also the catalytically active histidine residue (His-202 in PAP) have identical conformations and superimpose very well (see Fig. 11). The Fe^{3+}-coordinated tyrosine group is replaced by a histidine group in the Ser/Thr PPs and the position of the Fe^{3+}-bound histidine group in PAP is occupied by a water molecule (W1) in PP-1 and in the calcineurin structures. The bridging water molecule proposed for PAP probably also has a similar position to that of the bridging water in the PPs (W2). One additional water molecule has been proposed to occupy the sixth ligand position at each of the two metal ions in PAP. This sixth ligand to Fe^{3+} is indeed seen in the human calcineurin structure (W3). In bovine calcineurin this position is occupied by the bound phosphate group, whereas in rabbit PP-1 this position is empty, possibly due to the influence of the nearby bound inhibitor microcystin. The zinc ions are only five-coordinate in all PP structures. The main differences between the structures of the active sites of PAP and the PPs are thus the additional water molecule at Fe in the PPs, which is substituted by a histidine residue in PAP, and the presence of two arginine groups in the PPs, which might interact with the phosphate group. His-295 and His-296 in PAP might serve similar roles.

Phosphate as the reaction product as well as the analogue inhibitor tungstate bind in a bidentate bridging mode to both metal ions, as seen in structures of PAP, bovine calcineurin, and human PP1. Several possible mechanisms have been proposed for PAP and the PPs, differing mainly in the substrate binding mode and the identity of the water nucleophile, which may be any one of the water molecules W1, W2, and W3 as seen in the human calcineurin structure. All mechanisms proposed for the PPs assume that the substrate binds in the same bidentate bridging mode as seen in product–enzyme complexes, whereas in PAP the substrate is assumed to bind monodentately to the divalent metal ion. It therefore remains to be seen if PAP and the Ser/Thr PPs, despite the similarity of the structures of their active sites, actually employ a different mechanism in catalysis.

2.3. RNA and DNA Polymerases and Other Nucleotidyl-Transferases

Their role in the faithful transmission of genetic information make the RNA and DNA polymerases some of the most important enzymes for all living organisms.[80, 81] These enzymes often contain one or more nuclease activities besides the polymerase activity. DNA polymerase I from *E. coli*, for example, catalyzes template-directed DNA synthesis, 3′,5′-DNA hydrolysis, and 5′,3′-DNA hydrolysis on three separate domains of one polypeptide chain of 103 kDa. All three activities are dependent on divalent metal ions. Furthermore, the polymerase and 3′,5′-exonuclease activity and possibly also the 5′,3′-nuclease activity are accomplished by a two-metal ion mechanism (see below). Human immunodeficiency virus 1 reverse transcriptase (HIV-RT) also contains, besides the polymerase active site, ribonuclease H (RNase H) activity. It remains to be shown whether RNase H and HIV-RT from *E. coli* or other organisms, use one or two metal ions in catalysis.

In addition to the activities present on the polymerases a two-metal ion mechanism is discussed for other nucleotidyl-transferases, such as the restriction endonucleases. A common characteristic of all these active sites is the low metal-binding affinity in the absence of substrates. The two metal ions are bound through two or three carboxylate side chains upon substrate binding. This feature distinguishes these enzymes from other nucleases such as nuclease P1.

However, a word of caution is appropriate here concerning the question of whether or not all these enzymes mentioned in this section actually use two metal ions. In most cases the presence of some conserved carboxylate side chains and a requirement for divalent metal ions is, sometimes together with a homology to another enzyme which presumably uses two metal ions for catalysis, the only evidence for a two-metal ion mechanism. Studies of metal binding to the apoenzyme have led to conflicting results in some cases, possibly because of the use of crystallographic difference Fourier techniques in the location of

metal ions without further refinement. Biochemical and crystallographic studies with substrate analogues or products in the presence of various metal ions may clarify more mechanistic details. Considering that many enzymes catalyze a similar nucleotidyl-transfer reaction with only one or no metal ion it may well be that some of the enzymes discussed here use only one metal and a free carboxylate side chain to act as a general base.

2.3.1. *Polymerase Active Sites*

Several structures of enzymes containing a polymerase active site have been determined to date, including the Klenow fragment of *E. coli* DNA polymerase I (pol-I),[82-87] reverse transcriptase from the human immunodeficiency virus HIV-1 (HIV-RT),[88-91] rat DNA polymerase-β (pol-β),[92-94] bacteriophage T7 RNA polymerase (pol-T7),[95] and *Thermus aquaticus* DNA polymerase (*Taq* pol).[96] Although these polymerases are of significantly different size and complexity and some of them show very limited or no overall sequence homology,[97] the core catalytical units of all polymerases show a strikingly similar molecular architecture.[81, 91, 96, 98, 99] Sequence alignments among many polymerases revealed the presence of three similar sequence motifs A–C containing three highly conserved carboxylate residues and a lysine group.[81, 100] However, pol-β is most likely not related to the other polymerases by a common ancestor.

What role do these carboxylic acid side chains play in the polymerase mechanism? Site-directed mutagenesis of many of the conserved amino acids demonstrated that mutations of these three carboxylate groups of motifs A and C cause the most dramatic effect on catalytic activity.[101, 102] A crystal structure of HIV-RT complexed with an oligonucleotide showed that the 3′-hydroxyl group of the DNA primer terminus binds near the three catalytic aspartate side chains.[89] Divalent metal ions, especially Mn^{2+} and Mg^{2+} ions, are known to activate polymerase activity.[103-105] Some polymerases, including *E. coli* RNA polymerase, contain tightly bound zinc ions, but also need other divalent cations as activators.[103, 106] The nature of the metal ion also influences the fidelity of the polymerase reaction.[107, 108] As a result, some metal ions, like Mn^{2+} and Ni^{2+}, are considered to be mutagenic or carcinogenic. The Mg^{2+} ion might therefore be the active metal ion in vivo for most polymerases.[104, 108]

Based on kinetic and magnetic resonance studies of metal ion and substrate binding to pol I, a two-metal ion mechanism has been proposed for the polymerase reaction.[103, 109, 110] Indeed, the crystal structure of rat pol-β complexed with a DNA template-primer and dideoxycytidine triphosphate (ddCTP) in the presence of 10 mM $MgCl_2$ showed two metal ions coordinated to the three conserved carboxylate groups.[93] ddCTP lacks the nucleophilic 3′-OH group of the natural 2′-deoxycytidine 5′-triphosphate (dCTP) substrate; thus, after one catalytic cycle of incorporation of this polymerase inhibitor into the growing primer strand, no 3′-OH group of the primer is available for the next catalytic cycle. In the X-ray crystal structure the 3′-carbon atom of the primer strand, which would bear the nucleophilic hydroxyl group in a catalytically active arrangement, and the phosphate groups of ddCTP are bound in the immediate vicinity of the metal ions (Fig. 12). The magnesium ion B (Mg B), which is near the 3′-carbon atom of the primer strand, is coordinated by Asp-256, Asp-190, Asp-192, one of the nonesterified phosphoryl oxygen atoms of the α-phosphate of ddCTP, and possibly a water molecule (Fig. 12). In the complex with an intact

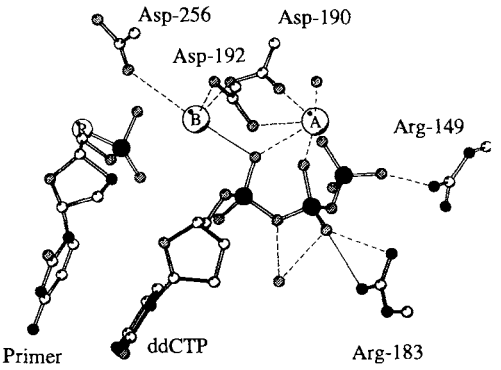

Fig. 12. Binding mode of ddCTP and the 3′-ddCTP of the primer strand to the dimetal cluster of pol-β (generated from coordinate file 2BPF) [93]. The carbon atom shown in black of the 3′-ddCTP group of the primer bears the nucleophilic 3′-OH group in a catalytically active arrangement with a normal dNTP nucleotide instead of ddCTP at the 3′-primer end.

primer terminus, the 3′-OH group of the primer would probably also be coordinated to Mg B. The magnesium ion A (Mg A) is liganded by Asp-190, Asp-192, three phosphoryl oxygen atoms of the α-, β-, and γ-phosphate groups of ddCTP, and one water molecule (Fig. 12). Both metal ions, which are 4.7 Å apart, have a distinct coordination sphere that cannot be easily described in terms of more symmetrical coordination polyhedrons. Also, the coordination sphere of Mg B is characterized by a number of relatively long metal–ligand distances. Interestingly, in this structure there are no protein side chains interacting with the oxygen atoms of the α-phosphate group. The transition state may thus be solely stabilized by the metal ions, water molecules in the region of the active site, and weaker van der Waals forces.

The structure of rat pol-β was also independently solved by another group.[92] Soaking experiments with Mn^{2+} ions revealed two metal ion binding sites in the native enzyme[111] and in a complex with 2′-deoxythymidine 5′-triphosphate (dTTP). Surprisingly, both metal ions were described as being coordinated by only one bidentate bridging carboxylate chain (Asp-190) in the native enzyme, but these structures have not been refined at this stage. Most of the other polymerase structures[82-96] also have either been determined in the absence of divalent metal ions in the crystallization buffer and thus contain no bound metal ions, or the metal-ion binding sites have not yet been fully refined. We will thus not describe these structures here, since more detailed results may be expected in the near future.

On the basis of the rat pol-β structure a polymerase mechanism has been proposed in which Mg B helps to deprotonate the primer 3′-OH nucleophile and stabilizes the transition state by coordination to one of the equatorial phosphoryl oxygen atoms (Fig. 13).[93] In this mechanism Mg A is neither involved in the stabilization of the pentacoordinate transition state nor in the activation of the leaving group by coordination to the oxygen

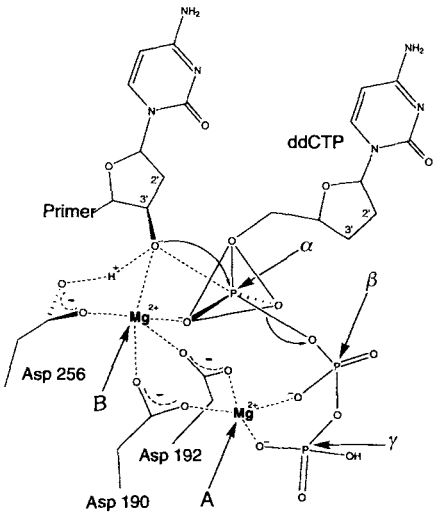

Fig. 13. Mechanism for the polymerase reaction as proposed on the basis of the ternary complex of pol-β, DNA primer, and ddCTP as shown in Fig. 12 [93]. In a similar alternative polymerase mechanism [112] the Mg^{2+} ion at site A also participates in the activation of the leaving group by coordinating to the anhydride oxygen atom between the α- and β-phosphate groups.

atom between the α- and the β-phosphate groups. Instead, Mg A binds and orients the β- and γ-phosphate groups. In an alternative polymerase mechanism, which resembles that of one in-line displacement step in AP, Mg A has additional interactions to one of the equatorial phosphoryl oxygen atoms and to the bridging oxygen atom of the leaving group in the transition state.[112] So far, all stereochemical studies have found an inversion of the phosphorus configuration in the polymerase reaction,[113] in agreement with the proposed one-step in-line mechanisms. A role in the polymerase mechanism could be demonstrated by mutagenesis studies for several active site residues, including the conserved lysine side chain of motif B.[101, 114]

2.3.2. 3',5'-Exonuclease Active Site of DNA Polymerase I

The Klenow fragment of *E. coli* DNA polymerase I contains besides the polymerase activity also a 3',5'-exonuclease active site, which is located about 33 Å away from the polymerase active site.[82, 115–117] The two active sites function independently and have separate binding sites for DNA. The exonuclease activity serves to remove polymerase errors by excision of mismatched base pairs. Other polymerases also contain homologous domains that have 3',5'-exonuclease activity.[97, 118] A number of crystallographic studies make the exonuclease reaction pathway one of the best-studied two-metal ion mechanisms by structural means.[81–86, 110, 117]

The exonuclease reaction takes place with inversion of the configuration around the phosphorus atom,[119] consistent with one in-line displacement step. Divalent metal ions (Mg^{2+}, Mn^{2+}, Zn^{2+}, or Co^{2+}) are essential for exonuclease activity,[120] and two metal-binding sites were located in crystal structures of the enzyme complexed with the products 2'-deoxycytidine monophosphate (dCMP) or 2'-deoxythymidine monophosphate (dTMP).[84, 85] The presence of more than one metal binding site was also implicated by NMR spectroscopic studies[105] and by a cooperative effect of metal binding on the exonuclease activity.[120] In the dTMP–product complex these two metal ions are 3.9 Å apart and are bidentately bridged by Asp-355 and by one of the phosphoryl oxygen atoms (Fig. 14). Site A has a distorted tetrahedral ligand sphere, whereas the metal ion in site B is octahedrally coordinated. The complex was crystallized in the presence of 20 mM $MgSO_4$ and 1 mM $ZnSO_4$ and it was shown that under these conditions a Zn A – Mg B site is formed,[85] consistent with the preferred coordination geometries of zinc and magnesium.

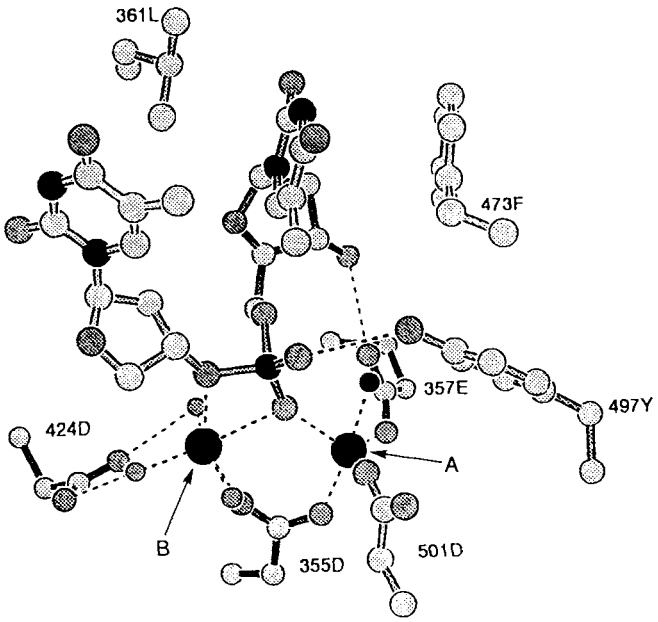

Fig. 14. A dinucleoside phosphate bound to the 3',5'-exonuclease active site of pol-I (taken from ref. [85]). The coordinates of the dinucleoside phosphate are taken from the structure analysis of the inactive D424A mutant enzyme, with an Mg^{2+} ion in site A, no metal ion in site B, and with a bound tetranucleotide. These coordinates are shown together with the structure of the protein with two bound metal ions taken from a complex of the wild-type enzyme with dTMP (dTMP not shown). The water molecule (in black) coordinated to the metal ion in site A is well positioned for attack on the phosphorus atom.

Metal binding site B is not occupied in the absence of bound dNMP in the native enzyme crystallized in the presence of divalent metal ions.[82, 85] This finding suggests that metal ions bind to site B together with or after substrate binding to form a catalytically active complex. In contrast, metal binding site A is occupied also in the native enzyme when crystallized in the presence of metal ions, and has a strong preference to bind zinc ions.[82, 85] Mutation of the site B ligand Asp-424 to alanine yielded an inactive enzyme with no metal bound to site B.[82, 84] This inactive mutant allowed the structure determination of a complex with a bound tetranucleotide $(dT)_4$ substrate in the presence of Mg^{2+} ions bound to site A (Fig. 14).[85] The 3'-terminal nucleotide of the tetranucleotide binds in the same way as dTMP of the product complex.

Assuming that the substrate binding mode in the catalytically active complex in the presence of a metal ion in site B is the same as that found in the structure with bound $(dT)_4$, this study provides detailed insight into the arrangement of the reactants prior to the transition state (Fig. 14). The water molecule coordinated to metal ion A is opposite to the leaving group and

therefore in an ideal position for the nucleophilic attack. Both metal ions are coordinated to one of the nonesterified phosphoryl oxygen atoms and metal ion B is also coordinated to the oxygen atom of the leaving group. A remarkable result of the crystallographic study of the substrate binding in the D424A mutant is that the loss of metal ion B results in an almost complete loss of activity (of at least five orders of magnitude),[84] even though the electrophilic phosphorus atom is presumably still correctly positioned and activated by metal ion A with respect to the nucleophile bound to metal ion A. This finding stresses the importance of the stabilization of the transition state and the activation of the leaving group by metal ion B.

Figure 15 shows a plausible mechanism for the exonuclease reaction. The roles of the metal ions resemble those in each

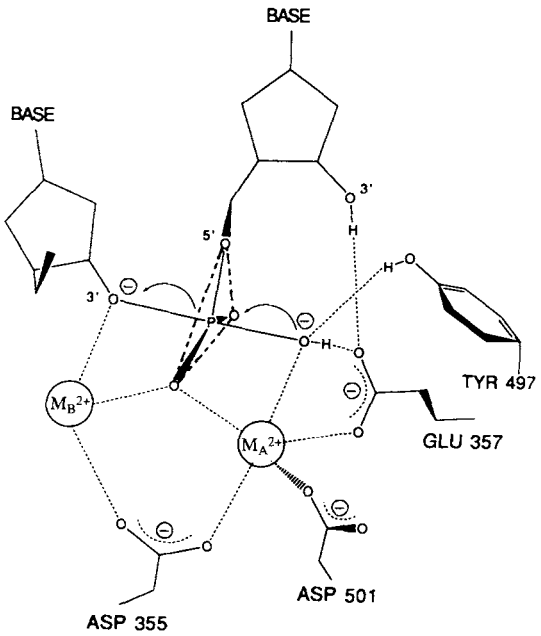

Fig. 15. Proposed interactions of the transition state with the protein for the 3',5'-exonuclease reaction of pol-I [85].

displacement step in AP. Metal ion A helps to generate the attacking hydroxide ion nucleophile, which is further stabilized by hydrogen bond interactions with Glu-357 and Tyr-497. Since Glu-357 is also coordinated to metal ion A, its pK_a value is lowered and it is not assumed to act as a general base. This assumption is supported by structure–energy calculations that make use of the empirical valence bond method.[121] Also, Tyr-497 is unlikely to function as a proton acceptor since its mutation to a phenylalanine residue resulted in a similar dependence of the rate on the pH value as in the native enzyme, and in only a modest reduction in activity.[116] A remarkable feature of this mechanism in contrast to that of alkaline phosphatase is that no protein side chains have significant roles in the stabilization of the transition state similar to that of Arg-166 in AP. The main task of the protein ligands seems to be the binding and orientation of the two metal ions and of the reactants. This mechanism is thus consistent with the finding that mutations of Asp-355, Asp-424, and Asp-501 have the largest effects on exonuclease activity.[116]

2.3.3. 5',3'-Nuclease Activity of the Polymerase from *Thermus aquaticus*

Thermus aquaticus DNA polymerase (*Taq* pol), famous for its use in the polymerase chain reaction,[122] is homologous to pol-I and also contains a 5',3'-nuclease activity in its N-terminal domain, but no 3',5'-exonuclease activity. The crystal structure of *Taq* pol revealed one metal binding site I, when the crystals were soaked in a solution containing Zn^{2+} ions (1 mM).[96] Soaking the crystals in a solution containing Mn^{2+} ions (20 mM) revealed two additional metal binding sites, II and III. I and II are 5 Å apart, whereas III is displaced by 10 Å from I and from II. The metal-containing structures have not yet been fully refined and are therefore not described here in more detail. However, the localization of two adjacent metal binding sites in the 5',3'-nuclease domain of *Taq* pol suggests that this activity might also use two metal ions in catalysis.

2.3.4. Ribonuclease H

HIV-RT possesses ribonuclease H (RNase H)[123] activity, acting as an endonuclease to degrade the viral RNA template strand during DNA synthesis.[124] The RNase H active site is located on a separate domain of the 66-kDa subunit; the distance to the polymerase active site is about 60 Å.[81, 88] The crystal structure of the isolated domain, which is stable but devoid of catalytic activity,[125] was determined at 2.4 Å resolution.[126, 127] Divalent metal ions are essential for RNase H activity.[128] In the presence of a solution of $MnCl_2$ (45 mM) two metal ion binding sites, which are approximately 4 Å apart, were located in 2.8 Å difference electron density maps (Fig. 16).[126] The side chains of Asp-443, Glu-478, Asp-498, and Asp-549 are near the two metal ions. These four carboxylate groups were also found to be highly conserved among retroviruses.[129]

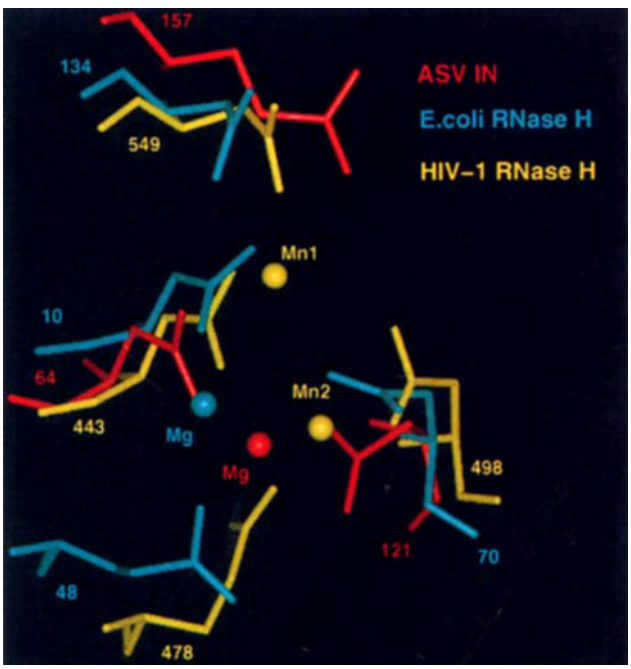

Fig. 16. Comparison of the metal ion binding sites in *Avian sarcoma* virus integrase (red) and RNase H from *E. coli* (blue) and HIV-1 (yellow) (taken from ref. [136])

The RNase H domain of HIV-RT displays significant sequence and structural homology to *E. coli* RNase H.[130,131] The residues Asp-443, Glu-478, Asp-498, and Asp-549 of HIV-RT RNase H that coordinate the metal ions correspond to Asp-10, Glu-48, Asp-70, and Asp-134 of *E. coli* RNase H. Mutagenesis of Asp-10, Glu-48, and Asp-70 of the bacterial enzyme also resulted in a significant loss of activity.[132] In contrast to the viral enzyme, only one Mg^{2+} binding site was found in *E. coli* RNase H by crystallographic[131] and NMR spectroscopic[133] studies (Fig. 16), even in the presence of nucleotides. These results support a one-metal ion mechanism for RNase H, in which one carboxylate side chain serves as a general base to deprotonate a water nucleophile and the metal ion coordinates to the two nonesterified phosphoryl oxygen atoms of the polynucleotide.[131] Thus, the question as to whether RNase uses one or two metal ions in catalysis, or if homologous RNases have different reaction mechanisms, remains open.

The crystal structures of the integrases from HIV-1[134] and *avian sarcoma* virus (ASV),[135,136] bacteriophage Mu transposase, MuA,[137] as well as the Holliday junction resolvase RuvC from *E. coli*[138] show a structural similarity to RNase H from HIV and *E. coli*.[139] Three highly conserved carboxylate side chains in their active sites and the fact that all enzymes depend on divalent metal ions, mainly Mg^{2+} and Mn^{2+} ions, for activity suggest that these nucleotidyl-transferases need one or more metal ions for activity. One metal ion binds to ASV integrase in the presence of Mg^{2+} or Mn^{2+} ions, close to the homologous metal ion position in *E. coli* RNase H (Fig. 16).[136] More detailed insight into the catalytic pathways of these enzymes can be expected for the future, when more structures with bound substrate analogues or products in the presence of metal ions become available.

2.3.5. *Restriction Endonucleases*

Restriction endonucleases, which cut the phosphodiester bond of DNA at specific sequences, require Mg^{2+} ions as a cofactor for catalysis. There is also biochemical and structural evidence that these nucleases, which show conserved carboxylate residues in the active site region, despite weak or no primary sequence homologies, might employ a two-metal ion mechanism.[140-143] The crystal structure of an enzyme–product–Mg^{2+} ion complex of *Eco*RV endonuclease showed the presence in the active site of two adjacent magnesium ions, which were bidentately bridged by the product phosphate group.[141,144] Also, the structures of *Eco*RI,[145] *Pvu*II,[146] *Bam*HI,[140] and *Cfr*10I[143] support a possible two-metal ion mechanism based on structural similarities of the active sites, although some differences exist (see ref. [143] for a superposition).

2.3.6. *Ribozymes*

Despite the absence of functional groups that have pK_a values and chemical properties similar to protein amino acid side chains, RNA can catalyze chemical reactions, for example as a nuclease or in RNA splicing.[147] The requirement for divalent metal ions and a comparison to other nucleases utilizing a two-metal ion mechanism led to the hypothesis that these RNA enzymes also catalyze nucleic acid hydrolysis or RNA splicing with the help of two metal ions.[148]

2.4. The Lithium-Sensitive Metallophosphatases Fructose-1,6-bisphosphatase, Inositol Monophosphatase, and Inositol Polyphosphatase

The three structurally characterized phosphatases fructose-1,6-bisphosphatase (FBP), inositol monophosphatase (IMP), and inositol polyphosphatase (IPP) form a group of distinctly related enzymes. FBP was the first enzyme of this group to have its three-dimensional structure unraveled by X-ray crystallography.[149] This structure analysis revealed a characteristic fold of five layers of secondary structural elements of alternating $\alpha\beta\alpha\beta\alpha$, which was later also found in the structures of IMP[150] and IPP.[151] The structural similarity also extends to the active sites, where all but one (which is an Asp/Glu exchange) of the metal binding residues are conserved.[152] These conserved residues have been grouped into three motifs, which contain the ligands of the metal ions and other active site residues (Fig. 17).[152,153] All three enzymes also share common bio-

The weak homology extends to a core structure of five α-helices and 11 β-strands. Those residues coordinated to the metal ions 1 and 2 and the bridging aspartate side chain (B) are marked.

chemical characteristics, such as their sensitivity to inhibition by monovalent ions, especially lithium, and their dependence on divalent cations for activity. Although active enzyme forms are observed in the presence of several ions, including Zn^{2+} and Mn^{2+} ions, the metal binding constants as well as the much higher concentration of magnesium in the cell favor magnesium as the bound metal ion in vivo; however, FBP may prefer zinc ions.[154]

2.4.1. *Fructose-1,6-Bisphosphatase*

Fructose-1,6-bisphosphatase (FBP) is a key regulatory enzyme in the gluconeogenic pathway.[155-157] It converts D-fructose-1,6-bisphosphate to D-fructose-6-phosphate with maximum activity at pH 7.6 for the rabbit liver enzyme. The presence of divalent metal ions (Mg^{2+}, Mn^{2+}, Zn^{2+}, or Co^{2+}) is essential for catalytic activity.[154,156,158-160] One to three zinc binding sites were found in each monomer in the presence or absence of substrate, product, or their analogues.[154,159,161] One Mn^{2+} ion binds per monomer in the absence of substrate, whereas two metal ions bind in the presence of substrate or analogues.[159,162] Consistent with one in-line displacement step, the hydrolysis takes place with inversion of the configuration at the phosphorus atom.[163]

Substrate fructose-1,6-bisphosphate exists in solution as a mixture of 15% α-form, 81% β-form, 2% keto form, and 1.3% *gem*-diol (Fig. 18).[164] Rapid quench kinetic studies indicate that the α-anomer is the real substrate.[165] In contrast, 2,5-anhydro-D-mannitol-1,6-bisphosphate (AhM-1,6-P_2), a β-substrate analogue inhibitor (Fig. 18), displays a 20-fold lower inhibition constant toward FBP than does the corresponding α-analogue inhibitor.[166]

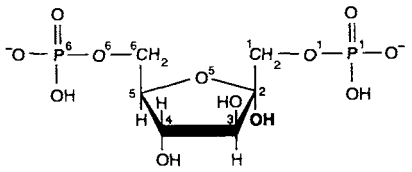

Fig. 18. Structure of the α-anomer of fructose-1,6-bisphosphate. In the analogue inhibitor AhG-1,6-P_2 the 2-OH group (printed bold) is replaced by a hydrogen atom. In the β-anomer and its analogue AhM-1,6-P_2 the chiral configuration around C2 is inverted.

The mammalian enzymes are regulated by adenosine monophosphate (AMP) at an allosteric site and by fructose-2,6-bisphosphate at the active site. Crystal structures of FBP from pig kidney,[149, 167–171] human liver,[172] and spinach chloroplast[173] are available. The 144-kDa pig kidney enzyme is a homotetramer of 222 symmetry. One side chain of the neighboring monomer, Arg-243, contributes to substrate binding at the interface between two monomers.

In the crystal structure of the complex from Mn–Mn FBP and the α-analogue inhibitor the two metal ions are separated by 3.7 Å and are bridged by two bidentate carboxylate groups of Glu-97 and Asp-118, and bidentately by the 1'-phosphate group of the inhibitor (Fig. 19 and Fig. 3, Section 2.1).[169] Other ligands of the metal ions are Glu-280 to Mn1 and the backbone carbonyl group of Leu-120 to Mn2. Disregarding metal-coordinated water molecules, which could not be located in the 2.9 Å electron density maps, the coordination spheres around both metal ions match a distorted tetrahedron. In addition to the bonds to the metal center one of the phosphoryl oxygen atoms of the inhibitor's 1-phosphate group interacts with the Arg-276 side chain, and the ester oxygen atom forms a hydrogen bond to the NH group of Gly-122 (Fig. 19). In the absence of metal ions,

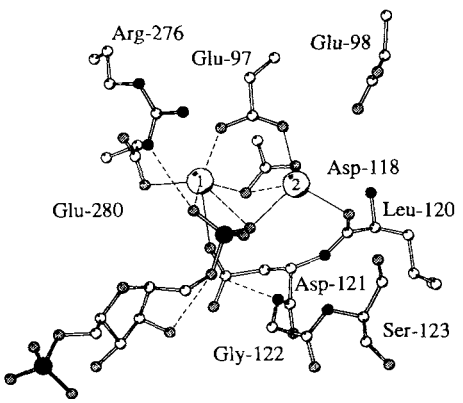

Fig. 19. Substrate analogue inhibitor AhG-1,6-P_2 (see Fig. 18) bound to the active site of FBP (generated from coordinate file 1FBD) [169].

the substrate fructose-1,6-bisphosphate in the α-form binds in a similar way as AhG-1,6-P_2, indicating that this inhibitor provides a good model for the binding mode of the substrate.

In the presence of Zn^{2+} or Mn^{2+} ions, two binding sites were found for the unliganded enzyme, one of which is identical to metal ion site 1, while the second metal ion site, designated as metal ion site 3, is near but different from metal ion site 2 found in the presence of substrate analogue.[172] The binding mode of the product was revealed by a crystal structure analysis of FBP cocrystallized with fructose-6-phosphate and Mn^{2+} or Zn^{2+} ions.[155] Under these conditions only the metal ion site 1 is occupied, and no metal binding is observed at site 2 or site 3. These results suggest that binding of Mn^{2+} or Zn^{2+} ions to metal ion site 2 requires the presence of the 1-phosphate group of the substrate, and that binding to metal ion site 3 is inhibited by the presence of substrate analogue or product. Thus, the first metal ion and the substrate bind independently to the active site, followed by binding of the second metal ion. It also seems likely that after hydrolysis the metal ion at site 2 leaves the active site before the product.

A putative mechanism assumes that the substrate binds in a bidentate bridging mode, as observed in the crystal structure with the AhG-1,6-P_2 inhibitor. The two metal ions M_1 and M_2 orient the substrate for attack of the nucleophile and stabilize the transition state (Fig. 20).[169] Deprotonation of the water

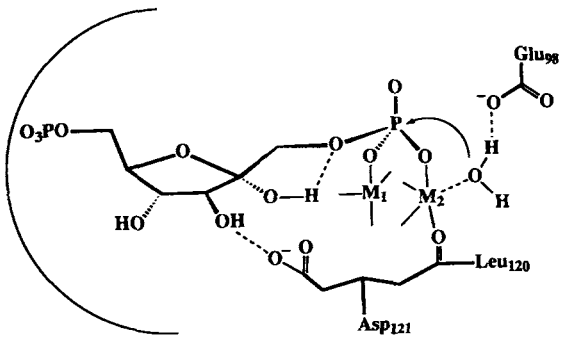

Fig. 20. Substrate binding mode and attack of a water molecule coordinated to the metal ion M_2 in the proposed mechanism for FBP [169].

nucleophile is facilitated by coordination to the metal ion M_2 and by interaction with Glu-98, which acts as a general base. Additional interactions of protein residues with other substrate atoms orient the substrate in a conformation in which the 2-hydroxyl group can interact with the ester oxygen atom of the 1-phosphate group. The importance of this interaction for catalysis is demonstrated by the resistance of substrates lacking the 2-hydroxyl group to enzymatic cleavage.[166] In addition, the backbone NH group of Gly-122 and the side chain of Arg-276 might play a role in the stabilization of the transition state. In agreement with the X-ray crystallographic studies, mutational analysis showed that substitution of Arg-276 by methionine reduces k_{cat} to less than 1%,[175] whereas Asn-212, Arg-243, Tyr-244, Tyr-264, and Lys-274 are primarily involved in substrate binding.[176] A mutation of the catalytic base Glu-98 to glutamine reduces k_{cat}/K_m 12000-fold.[177]

Binding of AMP to the allosteric site, 28 Å away from the active site, results in the catalytically inactive T-form of the

enzyme. The allosteric transition is accompanied by a 15–17° rotation of the two dimers of the tetramer relative to each other.[168] As a result, a displacement of residues Glu-97, Asp-118, and Leu-120 takes place, which also displaces metal ion 2 by 1.4 Å.[171] This metal ion is thereby no longer appropriately positioned to coordinate to the 1-phosphate group of the substrate in a catalytically productive position. In addition, FBP activity is modified by monovalent ions: K^+ and Tl^+ ions are activators, whereas Li^+ ions are inhibitors.[178] The activators bind to three positions in the active site, two of which are very close to the catalytic metal binding sites 1 and 2.[170] The third binding site is 3.8 Å away from one of the oxygen atoms of the substrate's 1-phosphate group and may be the activation site. Interestingly, in the absence of K^+ or Tl^+ ions, site 3 is occupied by the guanidinium group of Arg-276. The activators might therefore substitute efficiently for Arg-276 in catalysis.[170] The Li^+ ion inhibits FBP by binding to site 1; this finding provides a model for the role of lithium in treatment of manic depression, in which it inhibits inositol monophosphatase (see Section 2.4.2).

2.4.2. *Inositol Monophosphatase*

Inositol monophosphatase (IMP) participates in the phosphatidylinositol cell signaling pathway by hydrolyzing the inositol monophosphates Ins(1)P, Ins(3)P, and Ins(4)P to give *myo*-inositol.[179] Since human IMP is inhibited by therapeutically relevant concentrations (0.5–1.0 mM) of lithium ions, the putative role of the enzyme in the lithium therapy of manic depression has raised considerable interest.

IMP requires the presence of Mg^{2+} ions for activity, though other divalent metal ions such as Mn^{2+}, Zn^{2+}, and Co^{2+} also promote catalysis.[180, 181] The cooperative binding behavior of the Mg^{2+} ion to IMP with a Hill coefficient of 1.9 was originally interpreted on the basis of two nonadjacent metal binding sites in the homodimeric IMP (molecular mass 60 kDa).[182, 183] On the basis of the X-ray crystal structure analysis[184] and metal titration experiments,[181] these results have now been reinterpreted in the light of a cooperative binding to two adjacent metal binding sites within each active site. The fact that the structurally homologous bovine inositol polyphosphatase, despite its monomeric structure, also shows cooperative metal binding supports this view.[151, 185] IMP catalyzes the exchange of ^{18}O from H_2O to phosphate only in the presence of inositol,[183] indicating that the reaction does not proceed via a phosphoenzyme intermediate. In addition, attempts to isolate such an intermediate failed,[183, 186] and the X-ray crystal structures show no suitable nucleophilic side chain positioned to attack the phosphoryl group.[150]

Several crystal structures of IMP have been determined in the presence of different metal ions and substrate analogues in order to characterize the reaction pathway and the mode of lithium inhibition.[150, 184, 187] The structure of the free (unliganded) enzyme in the presence of manganese ions revealed three metal ion binding sites (see Fig. 3, Section 2.1).[184] The Mn1 and Mn2 ions are 3.9 Å apart and bridged bidentately by Asp-90.[45] Mn2 is further coordinated by Glu-70, the backbone oxygen atom of Ile-92, one terminal water molecule (W1), and a chloride ion which is at a distance of about 2.8 Å from all three metal ions. Additional ligands to Mn1 are Asp-93 and Asp-220. Besides $O_\varepsilon 1$ of Glu-70 and the chloride ion there are only three water ligands present in the coordination sphere of the metal ion at site 3. This site is not occupied in the product complex with phosphate and is probably a very low affinity binding site, which is not involved in catalysis.

In addition to the structure of the free enzyme, structures of complexes with either of the D- or L-form of *myo*-inositol 1-phosphate[187] and with product phosphate[184] contributed detailed insight into the catalytic pathway. Both substrate molecules could be bound to an enzyme inactivated by the presence of Gd^{3+} and Li^+ ions in the crystallization buffer. The Gd^{3+} ion binds to the metal binding site 2 and the Li^+ ion probably to site 1.[188] Figure 21 shows a superposition of the binding

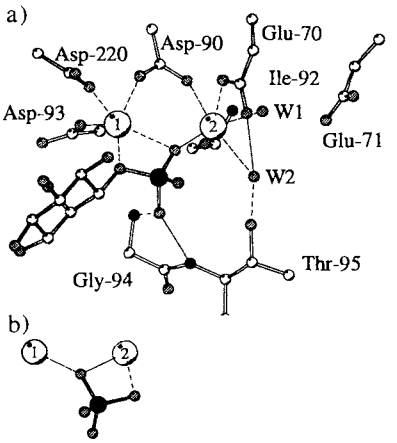

Fig. 21. a) Superposition of the binding mode of D-Ins(1)P as seen in Li1-Gd2 inactivated IMP onto the structure of the active Mn1–Mn2 enzyme (generated from coordinate files 1IMA and 1IMC) [184, 321]. Water molecule W2 is proposed to be the nucleophile coordinated to the metal ion in the mechanism of IMP [184]. b) Binding mode of a phosphate ion to Mn1–Mn2 IMP (PDB file 1IMD).

mode of the substrate D-Ins(1)P complexed to the inactivated enzyme onto the structure of active Mn–Mn IMP, thus yielding a plausible model of the catalytically productive substrate binding mode.[187] The phosphate group interacts with the metal ions, the backbone NH groups of Gly-94 and Thr-95, and two water molecules. A phosphate ion binds to Mn-Mn IMP such that the phosphate group is inverted compared to the substrate (Fig. 21).[184] Such an inverted binding mode of the product phosphate ion can be expected after attack on the substrate phosphate group by a water nucleophile apical to the inositol leaving group.

The wealth of biochemical and structural data available for IMP catalysis has been interpreted to be consistent with a direct displacement mechanism in which W2, the water molecule coordinated to the site 2 metal ion, is the nucleophile.[179, 181] This water molecule is also stabilized by hydrogen bonds to Glu-70 and Thr-95. The importance of Thr-95 for catalysis was demonstrated by mutation of this residue to an alanine, which reduced the enzyme activity by a factor of 14000.[189] Also, mutation of Glu-70 to a glutamine, which may not affect the enzyme's metal binding ability, resulted in a 7000-fold reduction in activity. The metal ion at site 1 possibly binds after the substrate is bound, since some of its ligands are substrate atoms: the two phosphate

oxygen atoms and possibly the 6-OH group of inositol, as suggested by modeling studies on the mechanism.[181] The importance of the 6-hydroxy group of the substrate in the mechanism has also been implicated by the inability of IMP to cleave 6-deoxyinositol 1-phosphate.[190] Stabilization of the transition state might be achieved by the interaction of the equatorial phosphoryl oxygen atoms with both metal ions and with the backbone NH groups of Gly-94 and Thr-95. The release of the leaving group may be facilitated by coordination of the esterified oxygen atom to the metal ion at site 2.

2.4.3. Inositol Polyphosphate 1-Phosphatase

Inositol polyphosphate 1-phosphatase (IPP) is another enzyme of the phosphatidylinositol signaling pathway[191] that removes the 1-phosphate from inositol 1,4-bisphosphate and inositol 1,3,4-trisphosphate.[192, 193] IPP requires Mg^{2+} ions for activity and is inhibited by lithium and calcium ions.[185, 192] Binding of magnesium ions shows cooperativity that has a Hill coefficient of 1.9, indicating the presence of two or more binding sites for Mg^{2+} ions.

The crystal structure analysis of bovine IPP at a resolution of 2.3 Å in the presence of magnesium ions showed two metal binding sites separated by 3.9 Å.[151] Both metal ions have an unusual coordination sphere with very long metal–ligand distances (see Fig. 3, Section 2.1). Only two ligands are less than 3 Å away from the coordinated metal. If one generously defines a ligand sphere of 4 Å around the metal ions, both magnesium ions are surrounded by six ligands in a distorted octahedral fashion. As in IMP, a crystal structure of the enzyme complexed with Gd^{3+} ions showed that this cation is located at metal binding site 1. The hydroxyl group of Thr-158, which is highly conserved between the phosphatases of this group, is hydrogen-bonded to the water molecule near the two Mg^{2+} ions and to the nearby side chain of Lys-37. Both residues are essential for catalytic activity, as demonstrated by mutagenesis studies.[194]

2.4.4. Comparison of the Structures of the Active Sites of Fructose 1,6-Bisphosphatase, Inositol Monophosphatase, and Inositol Polyphosphatase

A superposition of the active sites of FBP, IMP, and IPP based on the C_α coordinates of the five conserved coordinating ligands (see Fig. 17) and the two metal ions shows that these residues superimpose with (root mean square) deviations of 0.7–0.8 Å (Fig. 22).[195] Thus, the conserved side chains and the metal ions within this protein family show larger positional deviations than the conserved residues in PAP and the PPs (see Fig. 11). However, most of the residues have similar conformations, and they coordinate to the metal ions in a similar way. Glu-280 in FBP has a different conformation than it has in the homologous residues in IMP and IPP. Although the ligands are similarly arranged in the three proteins, the displacements of ligands and metal ions lead to some unusually long metal–ligand distances in IPP. Similar positions occur for Glu-98 in FBP, which is proposed to act as a general base, and the homologous glutamate side chains in IMP and IPP.

For FBP and IMP models of the substrate binding mode could be derived from co-crystal structures containing a bound substrate analogue, or a substrate bound to the inactivated enzyme (Figs. 19 and 21, respectively). These studies implicate a different binding mode of the substrate for the two enzymes: in FBP the phosphoryl group binds in a bidentate fashion through two nonesterified oxygen atoms, whereas in IMP one metal ion interacts with the ester oxygen atom of the leaving group, reminiscent of one displacement step in AP. Despite the significant structural homology of the active sites and the similarity of the catalyzed reactions, the two enzymes might therefore employ different mechanisms.

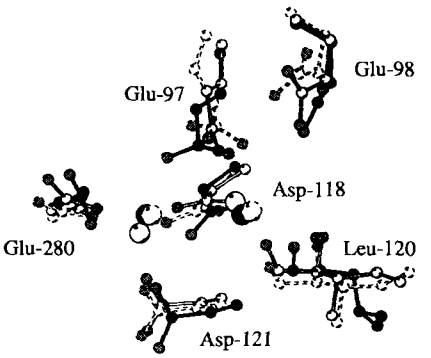

Fig. 22. Superposition of the active sites of FBP (C atoms black), IMP (C atoms white), and IPP (broken lines) [195]. The labels refer to the residues in FBP.

2.5. The Trinuclear Zinc Phosphodiesterases Phospholipase C and P1 Nuclease

Although phospholipase C (PLC) from *Bacillus cereus* and P1 nuclease (P1) from *Penicillium citrinium* display only low sequence homology in the zinc binding regions, the crystal structure analysis of P1[196] revealed a structure of similar fold and active site arrangement as found previously in phospholipase C.[197] By using 145 C_α atoms, the two structures can be superimposed with a (root mean square) deviation of 1.8 Å. They show 18% sequence homology in the superimposed regions.[196] The arrangement of the zinc ions and their coordination sphere including the positions of the three water molecules is very similar, and all ligands are conserved with the exception of Asp-153, which is Glu-146 in PLC (see Fig. 3, Section 2.1).

2.5.1. Phospholipase C

Phospholipase C (PLC) hydrolyses phosphatidylinositol and phosphatidylcholine and participates in the generation of second messengers in mammalian cells. The monomeric 28-kDa PLC from *Bacillus cereus*[198] is similar to the mammalian enzymes, and serves as a model for the hitherto less-characterized mammalian PLCs.[199] Determination of its metal content as well as removal and exchange of the metal ions characterized *B. cereus* PLC as a zinc enzyme containing two tightly bound zinc ions per molecule.[200] A third zinc ion was revealed by the X-ray crystal structure (1.5 Å resolution) of PLC.[197] The zinc ions can be exchanged for cobalt, manganese, and magnesium ions to give enzymes of reduced activity and altered substrate specificity.[200, 201] Spectroscopic studies indicated that in the cobalt(II)-substituted enzyme, two metal ions are present in a

distorted octahedral environment.[202] However, in the X-ray crystal structure of the native enzyme, all three zinc ions have a distorted trigonal-bipyramidal environment (see Fig. 3, Section 2.1).[197] The three metal ions are relatively close together: Zn1–Zn3 3.3, Zn1–Zn2 6.0, and Zn2–Zn3 4.7 Å. Zn1 and Zn3 are bridged bidentately by Asp-122 and by a water molecule (W1). Zn1 is further coordinated by His-69, His-118, and Asp-55. The ligand sphere of Zn3 is completed by His-14 and by the backbone carbonyl oxygen atom and the terminal amino group of Trp-1. Zn2 is coordinated by His-142, His-128, Glu-146, and two water molecules (W2 and W3).

In addition to the structure of the native enzyme the three-dimensional structures of complexes with a phospholipid substrate analogue, phosphate, iodate, iodide, and Tris have been determined.[203–205] In the phosphonyl group of a nonhydrolyzable substrate analogue inhibitor,[206] one of the ester oxygen atoms of the substrate's phosphate group is replaced with a methylene group. This analogue binds such that one of the free phosphonyl oxygen atoms bridges Zn1 and Zn3, whereas the other phosphonyl oxygen atom is coordinated to Zn2 (Fig. 23).[203] All three water ligands to the metal cluster are

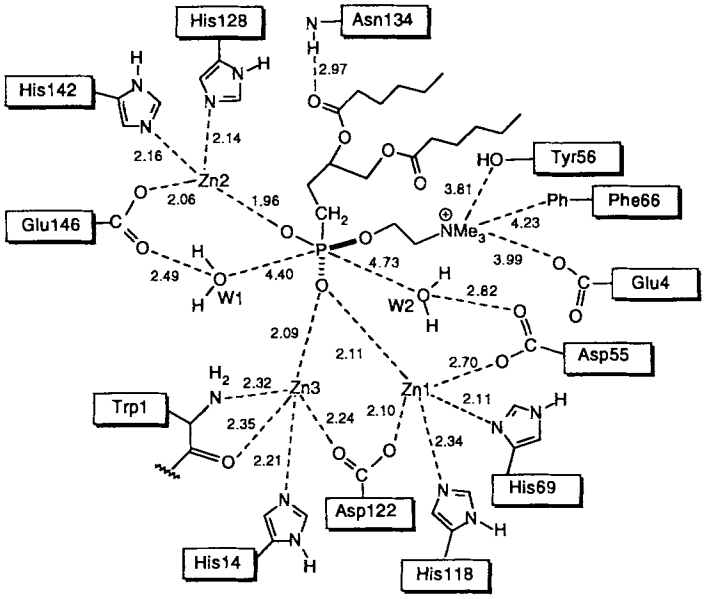

Fig. 23. Schematic drawing of the binding mode of the substrate analogue inhibitor 3(*S*),4-dihexanoyloxybutyl-1-phosphonylcholine to the active site of PLC (taken from ref. [206]; bond lengths given in [Å]). The labeling of the water molecules W1 and W2 does not correspond to that in Fig. 3.

displaced upon inhibitor binding, since the 1.9 Å electron density maps give no indication of zinc-coordinated water molecules. It was therefore proposed that the nucleophile is not generated by coordination to one of the zinc ions. A water molecule, which is 4.4 Å from the phosphorus atom and in an apical position to the diacylglycerol leaving group, may function as the water nucleophile. This water molecule is hydrogen-bonded to one carboxylate oxygen atom of the Zn2-coordinated Glu-146, which is proposed to function as a general base. All three zinc ions probably play a role in the stabilization of the transition state, but in this mechanism these zinc ions do not participate in the generation of the nucleophile, but possibly in the activation of the leaving group. There are no protein side chains positioned to protonate the diacylglycerol leaving group or interacting with the phosphoryl oxygen atoms, except for the metal-coordinated Asp-55 and Glu-146 side chains. Thus, all three metal ions evidently play a dominant role in catalysis by PLC. A computational evaluation of the binding energy of the substrate in different conformations to the enzyme yielded a different proposal for the substrate binding mode.[207] Here, the substrate binds to Zn2 and the nucleophile is the Zn1–Zn3 bridging water molecule. This study suggests that the binding mode of the substrate analogue inhibitor (Fig. 23) might not model the catalytically productive substrate binding. A phosphate ion binds like the phosphonyl group of the substrate analogue to all three zinc ions.[204]

2.5.2. *Nuclease P1*

Nuclease P1 (P1) is a phosphodiesterase that cleaves the bond between the 3′-hydroxyl and 5′-phosphate group of preferably single-stranded RNA and DNA under inversion of the configuration at the phosphorus center.[208] P1 also acts as a phosphomonoesterase on the 3′-terminal phosphate group of a (poly)nucleotide,[209] thus generating 5′-mononucleotides as the final cleavage products. Both activities require the presence of three zinc ions per molecule and are rather unspecific with respect to the nucleotide sequence.[210] The X-ray crystal structure of the monomeric 36-kDa *Penicillium citrinium* P1 nuclease was solved at a resolution of 2.8 Å.[196] Three zinc ions were found in the active site of P1, which are 3.2 Å (Zn1–Zn3), 5.8 Å (Zn1–Zn2), and 4.7 Å (Zn2–Zn3) apart (see Fig. 3, Section 2.1). All three zinc ions have three oxygen and two nitrogen ligands in a trigonal-bipyramidal coordination geometry.

To determine the substrate binding mode the crystal structure analysis of P1 liganded with the (*R*)-diastereomer of the thiophosphodinucleotide dA·P(S)·dA, a supposedly uncleavable substrate analogue,[211] was determined at 3.0 Å resolution.[196] This compound binds to two sites, which are about 20 Å apart, but for both binding sites only one mononucleotide could be found in the electron density map. The second half of the dinucleotide is presumably disordered or was cleaved off by the enzyme (Fig. 24).[212] The phosphate group of the mononucleotide is coordinated to Zn2 and has no contacts to the other two zinc ions. Arg-48 is hydrogen-bonded to one or two phosphate oxygen atoms. In contrast to the presumed substrate binding mode to PLC on the basis of the PLC-inhibitor complexes,[203, 204] the phosphate group of the mononucleotide binds differently to P1 than to PLC. Therefore, the authors discuss a different reaction mechanism for P1, in which one of the two Zn2-coordinated water molecules is the nucleophile.[196] However, more recent results suggest that the water molecule bridging Zn1 and Zn3 is the nucleophile.[212] This mechanism is thus similar to that for PLC which was proposed on the basis of the computational study (see Section 2.5.1).[207] Arg-48 and Zn2 evidently stabilize the transition state and/or activate the leaving group.

Nuclease P1 shows 50% sequence identity to nuclease S1 from *Aspergillus oryzae*. Nuclease S1 also needs three zinc ions for activity,[213] and the nuclease activity inverts the configuration at the phosphorus atom.[214] The two nucleases might therefore employ similar mechanisms for phosphate ester hydrolysis.

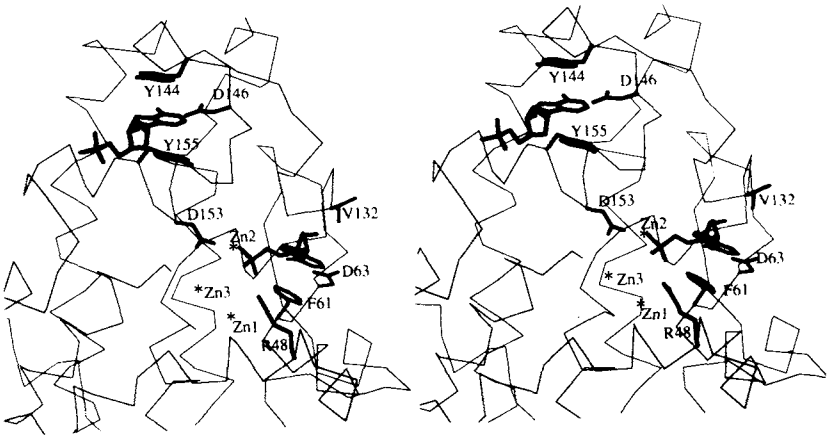

Fig. 24. Stereoview of two mononucleotide binding sites of the nuclease P1 (taken from ref. [196]).

2.6. Inorganic Pyrophosphatase and the *Mut*T Enzyme

The cleavage of pyrophosphate shifts the equilibrium of several, mainly ATP-dependent, biosynthetic reactions, including protein, DNA and RNA synthesis towards the products. This hydrolysis reaction is catalyzed by inorganic pyrophosphatase (IPY) in the presence of divalent metal ions.[215] Highest activity is seen with Mg^{2+} ions, but Mn^{2+}, Zn^{2+}, and Co^{2+} ions also promote catalysis.[216] The best studied IPYs are those from *E. coli* and yeast, *Saccharomyces cerevisiae*. X-ray crystal structures are available for the homohexameric *E. coli* enzyme,[217–219] the homodimeric yeast IPY,[220] and for the homohexameric IPY from *Thermus thermophilus*.[221] The structures of the homologous monomers of all three IPYs show a great similarity (for a superposition see reference [219]).[222] Furthermore, the catalytic mechanisms of the enzymes from *E. coli* and yeast seem to be very similar.

Inversion of the configuration around the phosphorus atom indicates a direct phosphoryl-transfer to the water molecule, in which the first phosphate released from the enzyme contains the oxygen atom from the solvent.[223] Studies on *E. coli* IPY showed that three to five Mg^{2+} ions participate in the reaction, depending on the protonation state of the enzyme.[224] Yeast IPY binds two Mn^{2+} ions per subunit in the free enzyme and three Mn^{2+} ions in the presence of phosphate.[225] Mutational analysis of residues in the active site of the *E. coli* enzyme showed that these mutations influence the activity by increasing the pK_a value of a catalytically important basic group.[226] This group probably is a metal-bound hydroxide ion nucleophile.

In the X-ray crystal structure of yeast IPY with three Mn^{2+} ions and two phosphate ions (P1 and P2), M1 is coordinated by Glu-58 and one oxygen atom of P2, M2 by Asp-116, Asp-119, Glu-48, and P2, and M3 by Asp-114, Asp-151, one oxygen atom each from P1 and P2, and by one water molecule.[220] M2 and M3 are 3.5 Å apart, whereas M1 is separated by 4.2 Å and 5.3 Å from M2 and M3, respectively. Three positively charged side chains, Lys-56, Lys-153, and Arg-77, are near the two phosphate groups and might assist in substrate binding and transition state stabilization.

Mechanistically related to IPY is the *Mut*T enzyme, a pyrophosphohydrolase of 129 residues, that catalyzes the hydrolysis of nucleoside triphosphates to nucleoside monophosphates and pyrophosphate. The structure determined by NMR spectroscopy of the *Mut*T protein, which requires two divalent cations for activity,[227] shows a cluster of five glutamate residues (41, 53, 56, 57, and 98), which might bind one or both metal ions.[228] More detailed information on the metal binding sites is not yet available. *Mut*T and IPY have a similar $\alpha + \beta$ fold, although they show no significant sequence homology.

2.7. (*S*)-Adenosylmethionine Synthetase

(*S*)-adenosylmethionine synthetase (AMS) catalyzes the formation of the sulfonium compound (*S*)-adenosylmethionine (AdoMet), which serves as an important methylation reagent in biological systems, from L-methionine and ATP (Fig. 25).[229] This synthesis proceeds by a unique two-step process: in the first step the complete tripolyphosphate chain of ATP is displaced by methionine to yield AdoMet and tripolyphosphate (PPP_i). Kinetic isotope effects characterized this step as an S_N2-type reaction with attack of the sulfur nucleophile at the C5′ of ATP. In a second step tripolyphosphate is hydrolyzed to pyrophosphate (PP_i) and phosphate (P_i) before AdoMet leaves the active site first.[230]

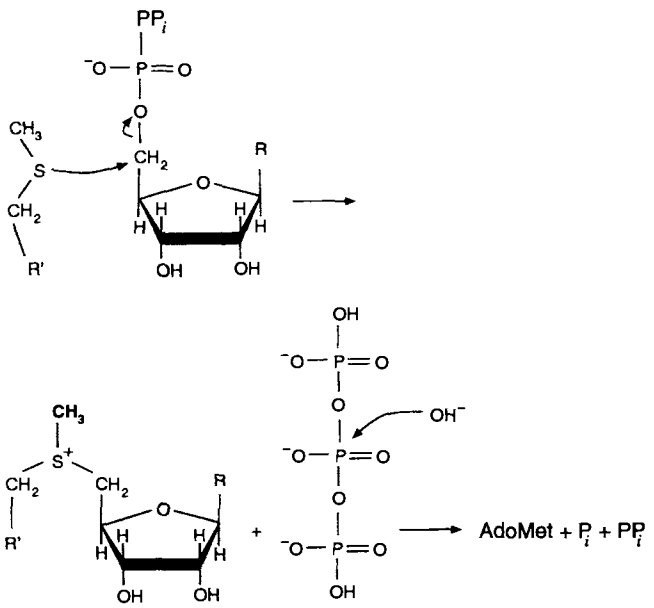

Fig. 25. Two-step reaction catalyzed by AMS. R′ denotes the missing part of methionine group and R is the adenyl group of ATP.

Divalent metal ions (Mg^{2+}, Mn^{2+}, Zn^{2+}, Co^{2+}, or Ni^{2+}) are required for AMS activity.[231] Since a vanadyl cation (VO^{2+}) binds to these divalent metal sites, it could be used as a spectroscopic probe.[232] In addition, a spatial proximity of two Mn^{2+} binding sites was demonstated by EPR spectroscopy.[233]

Monovalent cations (mainly K^+) also activate AMS. According to ^{205}Tl NMR spectra, Tl^+ ions bound to this monovalent site were not influenced by the presence of methionine, an ATP analogue, or pyrophosphate, indicating that substrates and products do not coordinate to the monovalent metal activator.[234] Binding of two phosphate ions to the dimetal center was implicated by the inhibition profile of this product.[230]

In good agreement with these biochemical results the 3.0 Å X-ray crystal structure of AMS in the presence of Mg^{2+}, K^+, and phosphate ions showed two magnesium sites, which are 5 Å apart, and one potassium ion in the active site.[235] The two divalent metal ions are bridged by two phosphate ions such that each metal ion is coordinated to two oxygen atoms of one phosphate and to one oxygen atom of the other phosphate. In addition, crystal structures of the enzyme with ADP and phosphate and with pyrophosphate and phosphate have been determined in the presence of Mg^{2+} ions.[236] In all of these structures two Mg^{2+} ions were found in the active site. ADP and phosphate, which were products of AMS-catalyzed cleavage of ATP, bind such that all three phosphate groups bridge the two metal ions in a bidentate fashion (Fig. 26). Further ligands are Asp-A271 to Mg1 and Asp-B16 to Mg2 (A and B refer to different subunits of the homotetramer). The positively charged side chains of His-B14, Lys-B165, Lys-A265, Arg-B244, and Lys-B245 interact with the products and thus may play important catalytic roles.

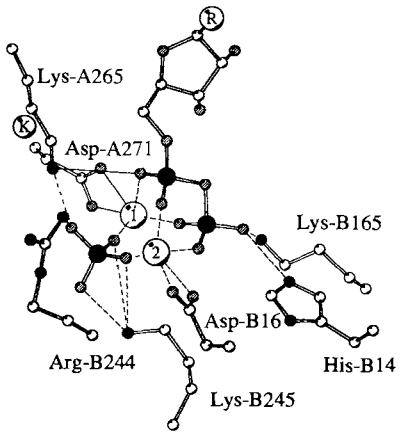

Fig. 26. Structure of ADP and phosphate bound to the active site of AMS [236]. R denotes the adenyl group of ADP.

The current data clearly implicate a two-metal ion mechanism for one or both steps of the reaction pathway of AMS. A possible mechanism of the second step, the hydrolysis of triphosphate, includes a role of Lys-265 in the protonation of the α-β-bridging oxygen atom and subsequently in the deprotonation of the water nucleophile.[236] However, further biochemical and structural studies are needed in order to clarify details of the unusual two-step catalysis of this enzyme.

2.8. Glutamine Synthetase

Glutamine synthetase (GLS) catalyzes the synthesis of glutamine from ammonia, glutamate, and ATP (Fig. 27). The reaction takes place via an enzyme-bound tetrahedral intermediate.[237] Divalent metal ions (Mg^{2+}, Mn^{2+}) are necessary for activity.[238] X-ray crystal structures of native GLS from *Salmonella typhimurium* and of complexes with substrate, product, and intermediate analogue compounds, including L-methionine-*S*-sulfoximine phosphorylated by the enzyme, yielded structural models for several stages of the reaction pathway (Fig. 28).[239, 240]

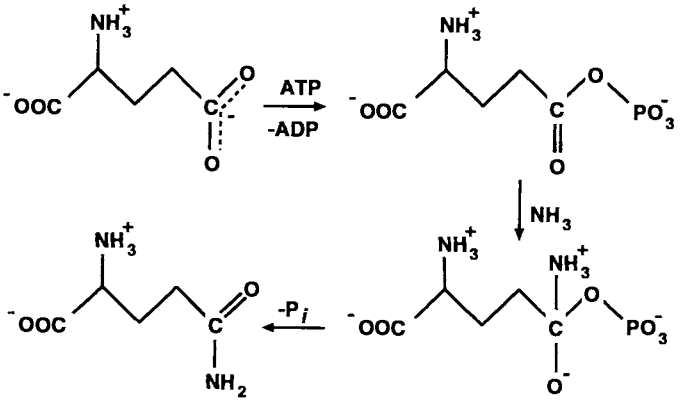

Fig. 27. Reaction catalyzed by glutamine synthetase.

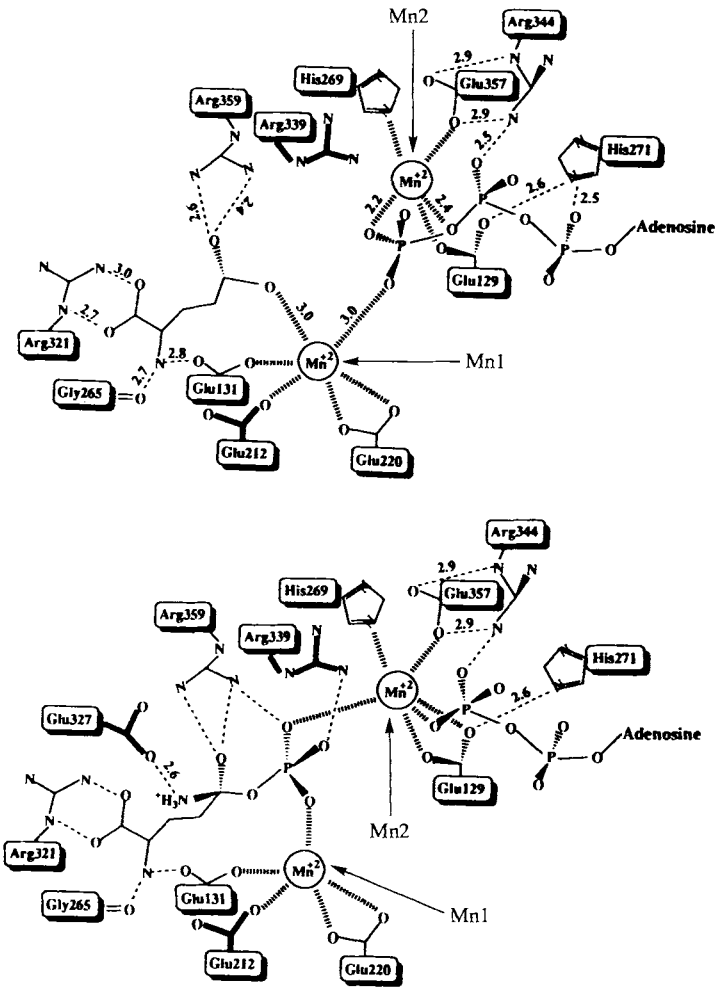

Fig. 28. Structural models for the phosphoryl-transfer step of the reaction pathway of glutamine synthetase (taken from ref. [240]).

Mn1, which is coordinated by three glutamate residues (131, 212, and 220), binds the nucleophilic carboxylate group of the substrate glutamate. The γ-phosphoryl group of ATP is polarized by both metal ions, but more strongly by Mn2, which has His-269, Glu-357, and Glu-129 as protein ligands (Fig. 28 top). The two metal ions are 5.8 Å apart, consistent with spectroscopic results.[241] Mn2 also activates the AMP leaving group. After the phosphoryl group has been transferred to the substrate carboxylate group, an ammonium ion attacks the carboxylate carbon atom, and the tetrahedral intermediate is formed (Fig. 28 bottom). In the last step the phosphate group leaves by cleavage of the carbon–oxygen bond. Arg-339 and Arg-359 may stabilize the transition-state of the phosphoryl-transfer reaction. Mutation of either of these two arginine residues severely diminishes the catalytic activity.[242] Interestingly, GLS also catalyses the arsenolysis of glutamine, probably by a mechanism in which phosphate is replaced by arsenate in the reversal of glutamine synthesis.

2.9. Phosphotriesterase

Organophosphate triesters are not naturally occurring compounds, but they are released in quantities on the order of millions of kilograms every year into nature by man's use as pesticides and insecticides. In addition, several nerve agents belong to this group of compounds and are stockpiled as chemical warfare agents. Resistance of some insects to insecticides and the degradation of pesticides by soil microbes led to the detection of phosphotriesterases that catalyze hydrolysis of many organophosphate triesters.[243–245] The enzyme from the soil bacteria *Pseudomonas diminuta* is by far the best characterized phosphotriesterase (PTE). It is a 39-kDa monomeric metalloprotein that exhibits a fairly broad substrate specificity and hydrolyzes P–O, P–F, P–CN, and P–S bonds between the phosphorus center and the leaving group.[244, 246] However, phosphomonoesters and phosphodiesters are not cleaved by PTE.[247] Although PTE shows comparable activity with Zn^{2+}, Co^{2+}, Ni^{2+}, Cd^{2+}, or Mn^{2+} ions in the active site, its binding affinity for metal ions and atomic absorption measurements on the native enzyme indicate that it is a dinuclear zinc enzyme in vivo.[244, 248] The environment of the metal ions has been characterized by EPR[249] and ^{113}Cd NMR spectroscopy [250] as a mixed N,O ligand sphere with one or more ligands bridging the two metal ions. Some of these ligands as well as other active site residues were identified as histidine residues by the use of histidine-modifying agents and by mutagenesis studies.[251, 252]

Hydrolysis of phosphotriesters by PTE occurs upon inversion of the configuration at the phosphorus atom, consistent with an in-line displacement reaction.[253] The pH-dependence of the activity indicates that one ionizable residue with a pK_a value of 6.1 plays a role in the mechanism of the catalysis.[251] Brønsted plots on the influence of the pK_a value of the leaving group on the rate constants, which yielded β values around -1.8,[254] as well as primary and secondary ^{18}O isotope effects[255] indicate a largely broken bond to the leaving group in the transition state (very late transition state). Although the PTE-catalyzed reaction is thus not as associative as the alkaline hydrolysis in solution, these data were interpreted as consistent with an S_N2-like concerted associative mechanism in both enzymatic and nonenzymatic hydrolysis of phosphotriesters.

Crystal structures of the apoenzyme[256] and the Cd–Cd form[257] revealed the molecular structure of the enzyme and the active site. The two cadmium ions are 3.8 Å apart and are located at the C-terminus of the β-strands of the α/β-barrel structure. The two metal ions are bridged by the carbamylated side chain of Lys-169 and by a water molecule (see Fig. 3, Section 2.1). In the structure of the apoenzyme[256] Lys-169 is not carbamylated. It has been subsequently demonstrated that CO_2 is required for the assembly of the two-metal site.[258] A carbamylated lysine side chain has also been found as a ligand to magnesium in ribulose-1,5-bisphosphate carboxylase/oxygenase[259] and as a bidentate bridging ligand to the two nickel ions in urease.[260] Cd1 is further coordinated by His-55, His-57, and Asp-301 in a trigonal-bipyramidal geometry, whereas Cd2 is also coordinated by His-201, His-230, and two terminal water molecules. Interestingly, assembly of the dinuclear cluster in PTE also induces drastic changes in the course of the polypeptide chain in some regions, yielding a (root mean square) deviation of 3.4 Å for the superposition of the C_α atoms of the apoenzyme and the holoenzyme.

3. Acyl- and Other Carbonyl-Transfer Reactions

Carbonyl-transfer reactions share many features with the chemistry of phosphoryl-transfer. In principle, an associative mechanism via a tetrahedral *gem*-diolate intermediate and a dissociative pathway via an acylium ion ($R-CO^+$), which is assumed to be an intermediate in the mechanism of Friedel–Crafts acylation,[261] are possible.[262] However, due to the polarity and electrophilicity of the carbonyl group nucleophilic substitutions via a tetrahedral transition state or intermediate dominate in enzymatic and nonenzymatic reactions of carbonyl compounds. Isotope effects and structure–activity correlations support such a tetrahedral transition state structure.[13]

3.1. Aminopeptidases

Aminopeptidases are ubiquitous in nature and are of critical biological and medical importance because of their key role in protein modification and degradation, and in the metabolism of biologically active peptides.[263, 264] These enzymes catalyze the hydrolysis of amino acid residues from the amino terminus of a peptide and generally have a broad substrate specificity. X-ray crystal structures are available for three aminopeptidases: leucine aminopeptidase, aminopeptidase from *Aeromonas proteolytica*, and methionine aminopeptidase. These three proteins have no detectable sequence homology, and thus constitute different prototypes of proteolytic enzymes.

A number of natural and synthetic reaction coordinate analogue inhibitors have been characterized for aminopeptidases. These inhibitors can be used to study mechanistical aspects of the hydrolytic reaction by biochemical and structural means. Examples include bestatin and amastatin,[265, 266] aminoboronates,[267, 268] aminophosphonates,[269] aminoaldehydes,[270] methyl ketones,[271] chloromethyl ketones,[272] and

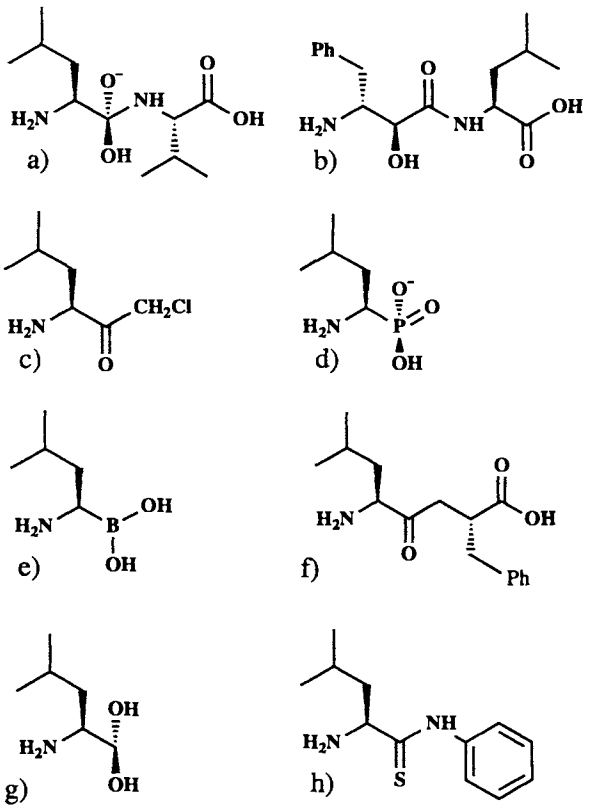

Fig. 29. Structures of a putative *gem*-diol intermediate for hydrolysis of substrate L-leucyl-L-leucine (a) and some reaction coordinate analogue inhibitors for aminopeptidases. The inhibition constants for porcine kidney LAP are: bestatin (b), 0.6 nM [265]; DL-leucylchloromethylketone (c), 12 μM [323]; L-leucylphosphonic acid (d), 0.23 μM [324]; DL-leucylboronic acid (e), 20 nM (IC_{50}) [267]; L-Leu-CO-CH_2-(DL)Phe (f), 57 μM [273]; L-leucinal (g), 60 nM [325]; L-leucylthioanilide (h), 0.19 mM [274].

peptides containing a ketomethylene amide bond replacement[273] as transition state analogues of an associative acyl-transfer reaction (Fig. 29). Thionopeptides may serve as substrate analogue compounds.[274]

3.1.1. Leucine Aminopeptidase

A number of biochemical and X-ray crystal structural studies make leucine aminopeptidase (LAP) currently the best characterized aminopeptidase containing a dinuclear metal center.[275] Bovine lens LAP is a hexameric enzyme with a molecular mass of 324 kDa and shows maximum activity at pH 8–9. Each of the six identical 54-kDa subunits contains two zinc ions[276] that are essential for catalytic activity and display different exchange kinetics. The readily exchangeable site 1 binds Zn^{2+}, Mn^{2+}, Mg^{2+}, or Co^{2+} ions[276–279] and has been identified as Zn1 in the X-ray crystal structure by the structure determination of the Zn^{2+}–Mg^{2+} metallohybrid enzyme.[280] The zinc ion in the tight binding site 2 can be exchanged for a Co^{2+} ion only when both binding sites are not occupied.[278, 279] In contrast to some earlier results, it is now apparent that metal substitution in both binding sites significantly affects both K_m and k_{cat}.[279] Thus, both metal ions participate in substrate binding and activation, including a possible role in the activation of the nucleophile. Although Mg^{2+} and Mn^{2+} ions hyperactivate LAP,[281] the enzyme has a significantly higher affinity for Zn^{2+} than for Mn^{2+} or Mg^{2+} ions,[277] and the isolated enzyme contains zinc ions.[282] Bovine LAP shows 31% sequence identity to aminopeptidase A from *E. coli*,[283] which serves a role as an accessory protein in Xer site-specific recombination in *E. coli*. The homology is 52% in the catalytic domains and all active site residues are conserved between LAP and aminopeptidase A.

The X-ray crystal structure of bovine lens LAP at a resolution of 1.6 Å showed that the two zinc ions are 3.0 Å apart and are bridged bidentately by Glu-334, monodentately by Asp-255, and by an exogenous water or hydroxide ion ligand (see Fig. 3, Section 2.1).[284–286] Further ligands are one carboxylate and the carbonyl oxygen atom of Asp-332 to Zn1, and Asp-273 and the amino group of Lys-250 to Zn2. Both zinc ions are thus five-coordinate in an arrangement best described as octahedral with one vacant position.

X-ray crystal structures of LAP with four transition state analogues have been determined: the natural inhibitors bestatin[285, 287] and amastatin,[288] L-leucinephosphonic acid,[289] and L-leucinal.[286] All transition state analogues bind in a similar way to the active site of LAP (Fig. 30). Even bestatin, which has a D-configuration at the N-terminal phenylalanine residue and contains an additional carbonyl group next to the hydroxyl group (Fig. 29), differs in its binding mode only by the absence of a fourth coordination bond to Zn1. Together these structures provide a reasonable model for the binding mode of the transition state. In all of these inhibitor structures the terminal amino group is coordinated to Zn2. Upon binding of the inhibitor, the zinc–zinc distance widens to about 3.3 Å, but no rearrangements of the ligand spheres of the metal ions take place.

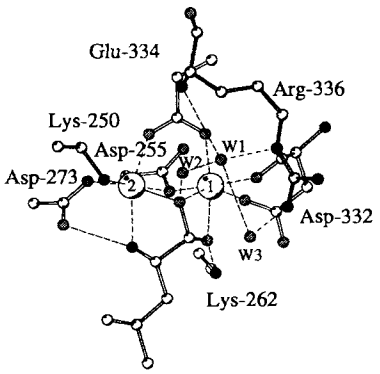

Fig. 30. Binding mode of the transition state analogue inhibitor L-leucinal to the active site of LAP (generated from coordinate file 1LAN) [286]. Binding sites 1 and 2 are occupied by zinc ions.

Leucinal resembles the presumed tetrahedral *gem*-diolate intermediate of an associative acyl-transfer mechanism more closely than do any of the other inhibitors. The positions of the two *gem*-diol oxygen atoms of the hydrated aldehyde group probably correspond to the positions of the two *gem*-diol oxygen atoms of the intermediate (Fig. 30). One of these oxygen atoms bridges the two metal ions, whereas the other oxygen atom is coordinated only to Zn1. The binding modes of bestatin and amastatin, which show the peptide leaving group in a position pointing away from the dizinc center toward the central solvent channel of the LAP hexamer, are in agreement with this model of the intermediate binding mode. There are no protein residues in the active site positioned to act as a general base. Furthermore, the X-ray crystal structure of the unliganded enzyme[286] at 1.6 Å resolution showed that only one exogenous solvent ligand is coordinated to the dizinc cluster: a water or hydroxide ion ligand that symmetrically bridges the two metal

ions (see Fig. 3, Section 2.1). The position of this water ligand is identical to the position of the bridging oxygen ligands in the inhibitor structures.

Based on the X-ray crystal structures and the biochemical data a reaction mechanism was proposed in which the bridging hydroxide ion acts as the nucleophile (Fig. 31).[286, 289] In this mechanism both metal ions participate in substrate binding and

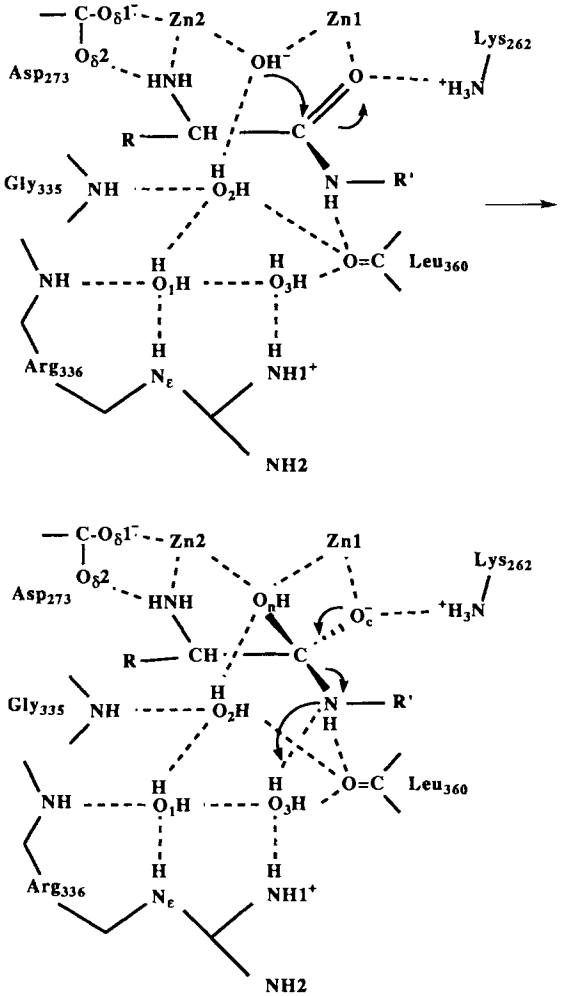

Fig. 31. Reaction mechanism proposed for LAP based on X-ray crystal structures and biochemical evidence [286].

in catalysis. Zn2 binds the terminal amino group, activates the water nucleophile, and stabilizes the transition state. Zn1 polarizes the carbonyl group, activates the water nucleophile, and stabilizes the transition state by coordination to both *gem*-diolate oxygen atoms. In addition, two amino acid side chains probably play an important role in catalysis: Lys-262 in the polarization of the carbonyl group and in the stabilization of the transition state, and Arg-336, which interacts with the substrate and intermediate through three water molecules. These water molecules may lower the transition state energy through the formation of hydrogen bonds. One of these water molecules probably protonates the leaving group (see also Section 3.1.4).

3.1.2. *Aminopeptidase from Aeromonas proteolytica*

In contrast to the mammalian aminopeptidases, *Aeromonas proteolytica* aminopeptidase (AAP) is a small monomeric protein (29.5 kDa).[290] As isolated from the bacteria, APP contains two zinc ions. In addition to Zn^{2+} ions, Co^{2+}, Ni^{2+}, and Cu^{2+} ions are capable of restoring activity to the inactive apoenzyme.[291] These metal exchanged enzymes display a higher activity towards certain substrates than does the native Zn–Zn enzyme. An even higher hyperactivity is obtained for the mixed Ni–Zn and Cu–Zn forms of AAP. Again, the hyperactivation strongly depends on the type of the substrate and on the order of metal addition: the more active forms were obtained by adding one equivalent of Cu^{2+} or Ni^{2+} ions before adding Zn^{2+} ions, consistent with the existence of two nonidentical metal binding sites. As in LAP, substitutions of both metal ions influence both k_{cat} and K_m.

The X-ray crystal structure analysis (1.8 Å resolution) of the Zn–Zn form of unliganded AAP showed the presence of two zinc ions, 3.5 Å apart.[292] Both Asp-117 (bidentate) and a water molecule bridge the two zinc ions, which are five-coordinate if one includes the slightly more distant second carboxylate oxygen atoms of Glu-152 to Zn1 (2.4 Å) and Asp-179 to Zn2 (2.3 Å) (see Fig. 3, Section 2.1). In addition to the bridging ligands Zn1 is coordinated by Glu-152 and His-256, and Zn2 by His-97 and Asp-179. A striking feature of this metal center is the similarity of the coordination spheres of the two zinc ions. The bridging water molecule is hydrogen-bonded at a distance of 3.3 Å to the carboxylate group of Glu-151.

3.1.3. *Methionine Aminopeptidase*

Most proteins are synthesized beginning with methionine (in eukaryotes) or formylmethionine (in prokaryotes) at the N-terminus. Removal of the N-terminal methionine group may be catalyzed by methionine aminopeptidase (MAP), depending on the identity of the adjacent residue. MAPs purified from different mammalian and microbial sources display similar substrate specificities, showing cleavage when the penultimate residue is small.[293, 294] For MAP isolated from several of these sources, the enzyme, which requires divalent metal ions, is most active in the presence of cobalt ions. However, it remains to be shown whether MAP is a cobalt enzyme in vivo. MAP is a soluble monomer with optimal activity at neutral pH. The prokaryotic and yeast MAPs display a significant degree of sequence homology, and all ligands are conserved, with the exception of a replacement of a glutamate residue for a glutamine residue in yeast MAP. Furthermore, sequence comparisons among other proteins indicated that aminopeptidase P,[295] proline dipeptidase,[296] and p67[297] have a similar fold as that of MAP and probably also contain a two-metal active site.[298, 299]

The X-ray crystal structure analysis (2.4 Å resolution)[300] of *E. coli* MAP[293] revealed the presence of two metal ions separated by 2.9 Å. These metal ions are located at the center of the central curved antiparallel β-sheet of the mixed α/β structure. Residues Glu-235 and Asp-108 bridge the two metal ions bidentately (see Fig. 3, Section 2.1). Further ligands are Glu-204 and His-171 to Co1 and both carboxylate oxygen atoms of Asp-97 to Co2. Thus, Co1 and Co2 both have four protein ligands. The coordination geometry of both metal ions may be described as

octahedral, in which one of the vacant ligand positions is occupied sterically by the other cobalt ion.[300] Weak electron density features suggest that solvent ligands may occupy the remaining two ligand positions, one at each cobalt ion. These water ligands would then interact with His-178 or Thr-99, which may thus also play important roles in the catalysis. The short distance between the two metal ions may, alternatively, permit a bridging water molecule or hydroxide ion.

3.1.4. Comparison of the Aminopeptidase Structures

AAP and the carboxy-terminal, catalytic domain of LAP have similar folds, despite only insignificant sequence homology.[292] However, this similarity does not extend to the precise location or structure of the active site. The metal coordination spheres of the two zinc aminopeptidases are significantly different. Also, the active site cavity in AAP contains neither a lysine nor an arginine side chain, in order to serve similar roles as Lys-262 and Arg-336 in LAP. A common feature of AAP and LAP is the presence of a dinuclear metal center, which contains one water ligand bridging the two metal ions. In addition, both metal ions in both structures are five-coordinate, thus having a vacant ligand position at each zinc ion. The two active sites may thus be superimposed on the basis of the zinc ions and the bridging water molecule, in such a way that the more buried Zn2 of AAP is superimposed onto the more buried Zn2 of LAP, which also coordinates the amino terminus of the substrate (superposition not shown). Interestingly, this superposition also maps the hydrophobic binding pocket for the N-terminal side chain of LAP onto the presumed specificity pocket for this residue of AAP. In detail, Met-270, Met-454, and Thr-359 of LAP have similar positions as Met-180, Phe-244, and Met-242 of AAP, respectively. Furthermore, the carboxylate group of Glu-151 of AAP is at a position that is occupied by water molecules or a carbonate ion near Arg-336 in the structures of LAP. There is indirect evidence that two of these water molecules in LAP are actually a $H_3O_2^-$ ion stabilized in the active site of LAP to serve a functional role.[286] This role could be similar to that of Glu-151 in AAP, including a function as a general base. However, Lys-262 of LAP has no similar residue in AAP in this superposition, since the side chain of Ile-255 takes its place in AAP.

Both metal ions in MAP also have four protein ligands, similar to the situation in AAP and LAP. Unfortunately, the crystallographic resolution did not allow an unambiguous determination of coordinated water molecules. Whether AAP, LAP, and MAP employ similar reaction mechanisms despite the pronounced differences in their metal coordination geometries and active site structures remains to be shown, for example by structure determination of suitable enzyme-inhibitor complexes.

3.2. Urease

Urease is a metalloenzyme that catalyses the hydrolysis of urea to ammonia and carbamate.[301–304] This enzyme allows bacteria, fungi, and higher plants to use urea as a nitrogen source. In 1975 urease was identified as the first nickel metalloenzyme,[305] and nickel has since been found in all ureases characterized so far. Thus, nickel evidently has a unique role in the catalysis by urease. Considering the similarity of urea hydrolysis to other hydrolytic reactions, it is surprising that this role can not be fulfilled by other more readily available divalent "hydrolytic ions" such as zinc, cobalt, magnesium, manganese, or iron ions. Indeed, Zn^{2+}, Cu^{2+}, and Co^{2+} ions do not restore activity to the apoenzyme of the urease from *Klebsiella aerogenes*.[306] Only the Mn protein possesses 2% of the activity of the Ni-activated apoprotein. Spectroscopic studies and titration experiments with a tight-binding inhibitor further characterized the active site as a dinuclear nickel center.[307, 308] Urease is also interesting because of its selectivity in the assembly of the metal ion center: several accessory proteins, encoded by adjacent genes of the urease gene cluster in bacteria,[302, 309] are needed to incorporate nickel into the apoenzyme in vivo. Furthermore, the discovery that carbon dioxide is necessary for nickel binding to urease[310] can now be readily explained by the presence of a carbamylated lysine side chain as a ligand to both metal ions.[260] Nickel binding and the carbamylation of this lysine residue (Lys-217) is a synergistic process; in the apoenzyme Lys-217 is not carbamylated despite the presence of CO_2.[260]

Crystals of urease from the jack bean were obtained in 1926 by Sumner.[311] These were the first crystals of a then recognized enzyme. This crystallization was an historic landmark in enzymology, because it demonstrated that enzymes are well-defined chemical compounds. The crystal structure[260] (2.2 Å resolution) of urease from *Klebsiella aerogenes*[312] shows a tightly associated trimer of $(\alpha\beta\gamma)_3$ stoichiometry. Since other ureases share about 50% sequence homology with the enzyme from *K. aerogenes* possibly all known ureases have a similar trimeric structure.[260] The two nickel ions are 3.5 Å apart and bridged bidentately by the carbamylated Lys-217 side chain (see Fig. 3). Further ligands to the metal ions are His-246 and His-272 to Ni1, and His-134, His-136, Asp-360, and a water molecule to Ni2. Thus, Ni1 is coordinated by three ligands in a tetrahedral geometry in which one ligand is missing. The coordination geometry of Ni2 may be described as a distorted trigonal bipyramid.

The side chains of His-219, Cys-319, and His-320 delineate—among other residues—a putative urea binding pocket.[260] Chemical modification and mutagenesis studies demonstrated that these three residues influence the catalytic efficiency.[313–315] Site-directed mutagenesis of His-219 suggested a role of this residue in substrate binding, whereas His-320 was proposed to act as a general base.[314] Cys-319 is not essential for activity but its mutation or modification to larger side chains can greatly reduce the activity.[313]

A mechanism has been proposed for catalysis by urease in which one nickel ion binds the hydroxide ion nucleophile and the other nickel ion binds and polarizes the carbonyl group of the substrate (Fig. 32).[316] The X-ray crystal structure of urease supports this model in

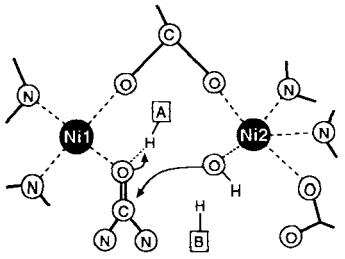

Fig. 32. Mechanism proposed for urease based on biochemical data and the X-ray crystal structure [260, 304, 316] A = general acid, B = general base.

that the Ni2-coordinated water molecule (or hydroxide ion) may be the nucleophile, and Ni1 has a vacant ligand position to coordinate the carbonyl oxygen atom.[260] Furthermore, His-219 would then be within hydrogen-bonding distance to the carbonyl oxygen atom, and thus able to assist in polarizing the carbonyl group and stabilizing the negatively charged tetrahedral intermediate, which is formed after the attack of the hydroxide ion. Except for $O_\delta 1$ of the Ni1-coordinated Asp-360 side chain there is no other residue in a position to function as a general base. For structural studies with mechanism-based inhibitors, a number a suitable compounds have been shown to inhibit urease. Phosphate inhibits urease in a strongly pH-dependent way.[307, 317] Boric and boronic acids are also possible reaction coordinate analogues, but it is not clear whether they bind as substrate analogues with a trigonal planar $R-B(OH)_2$ group or as transition state analogues as tetrahedral $R-B(OH)_3^-$ ions.[307, 318] Another strong binding inhibitor is phenylphosphorodiamidate, inhibiting *K. aerogenes* urease with an overall dissociation constant of 94 pM.[307]

The urease structure revealed a striking similarity[260] of its $(\alpha\beta)_8$ barrel in the catalytic α domain to that in adenosine deaminase (ADA), a mononuclear zinc enzyme.[319] This homology also extends to the location of the active site: Ni2 has a position close to Zn in ADA and three of the Ni2 ligands in urease coordinate in a way which is similar to the corresponding ligands of zinc in ADA (Fig. 33). Also, the position of the water

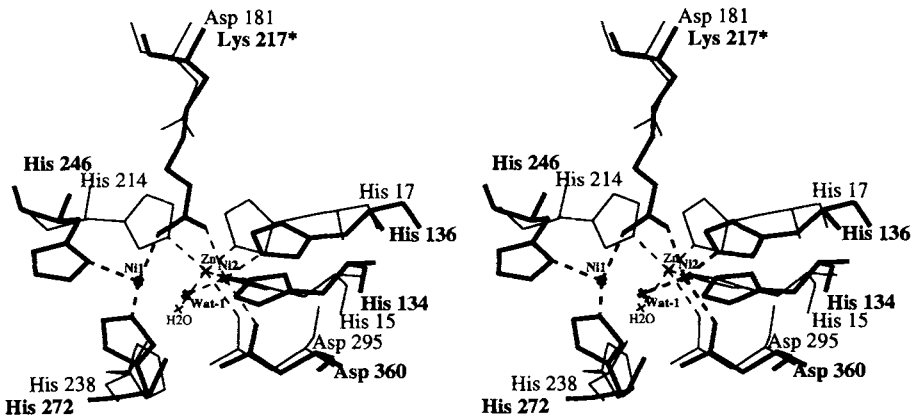

Fig. 33. Superposition of the active site structures of urease (bold lines) and the mononuclear zinc enzyme adenosine deaminase (thin lines) (taken from ref. [260]).

(or hydroxide ion) nucleophile is similar in these two enzymes. One of the ligands to Ni1 in urease, His-246, has a different position in ADA (His-214) in which it is coordinated to zinc. The relationship between ADA and urease provides an instructive example of how a dinuclear metal center (here of urease) has evolved from a possible ancestor protein containing a mononuclear metal site (here similar to ADA). It was proposed that the mutation to and carbamylation of Lys-217, which is an aspartate residue in ADA, was necessary to provide a side chain long enough to bridge the two metal ions (the corresponding Asp-181 side chain in ADA is not metal-coordinated).[260]

4. A Common Structural or Mechanistic Theme?

The two adjacent metal ions are in most cases separated by a distance of between 3 and 4 Å (this is also true for the centers containing three metal ions if we consider only the two closest metal atoms in these centers). A longer distance is seen in structures of pol-β (4.7 Å),[93] 5′-nuclease of *Taq* pol (5 Å),[96] AMS (5 Å), and GLS (5.8 Å).[235, 240] In these three enzymes both metal binding sites have a very low binding affinity for metal ions, or are only occupied in the presence of substrate or analogues (as seen in the structures). Usually one or more bridging carboxylate side chains or carbamylated lysine residues facilitate the assembly of such a di- or trinuclear metal cluster. No such bridge is seen in the dimetal centers of AP, AMS, and GLS. In contrast to those enzymes in which at least one of the bridging carboxylate groups is bidentate, PAP and the PPs contain only one monodentate metal-bridging carboxylate side chain. A great diversity is seen in the type of ligands and the geometry of the coordination spheres of the metal ions, even in enzymes that catalyze similar or identical reactions, such as the aminopeptidases. With respect to the zinc enzymes, a tendency to coordination numbers higher than four (three protein ligands and one water nucleophile), as seen in many mononuclear zinc hydrolases, is noted.[2]

For some enzymes reviewed in this article, structures could be obtained with substrates, products, intermediates, or reaction coordinate analogue compounds bound to the active site. These yield reasonable models for the possible interactions activating the reactants and stabilizing the transition state. These studies indicate that in all of the metalloenzymes containing two adjacent metal ions in the active site, both metal ions participate in catalysis, and none of them serves a mere structural role. Also, in the phosphodiesterases P1 and PLC, all three metal ions are probably involved in the binding and activation of the reactants. However, the magnesium ion in AP probably serves a more indirect role in catalysis. AP is also unique among all enzymes discussed here in its two-step mechanism with the formation of a phosphoenzyme intermediate. All other enzymes evidently directly transfer the phosphoryl group to the water molecule (or the acceptor) in one in-line displacement step. However, the mechanism of each of the two displacement steps in AP is a prototype of a two-metal ion mechanism, which is also thought to be realized in a similar form in other enzymes (see below). A possible pitfall in the determination of the substrate binding mode by the use of phosphate or substrate analogues containing a phosphate group is that the binding mode of the inhibitor might resemble a product binding mode or might be a thermodynamically most stable binding mode, but not the catalytically productive substrate binding mode (see Sections 2.2.1–2.2.3 and 2.5.1).

Table 2 shows that each of the possible interactions of the reactants with metal ions or protein residues as mentioned in

Table 2. Residues that activate the nucleophile or leaving group, or stabilize the transition state (or intermediate) as implicated from suitable enzyme-inhibitor structures. M = metal ion.

Enzyme	Transition state stabilization	Leaving group activation	Nucleophile activation
AP	Zn1, Zn2, Arg-166, NH_{102}	Zn1 / Zn2 [a]	Zn2 / Zn1 [a]
PAP	M^{II}, His-202, His-296	His-296	Fe^{III}
PP-1	Zn2, Fe1	His-125	Fe1, or Fe1 and Zn2
Pol-β	MgB	(H_2O)	MgB, Asp-256 [b, c]
Pol-I	Mg1, Mg2	Mg2	Mg1
EXO	M_A, M_B	M_B	M_A, Glu-357 [b], Tyr-497
FBP	M1, M2, Arg-276	2'-OH of the substrate, NH_{122}	M2, Glu-98 [c]
IMP	M1, M2, NH_{94}, NH_{95}, (H_2O)	M2	M1, Glu-70 [b, c], Thr-95
PLC	Zn1, Zn2, Zn3	Zn2 (?)	Glu-146 [b, c]
P1	Zn2, Arg-48	Zn2 (?)	Zn1 and Zn3, or Zn2
GLS	Mg1, Mg2, Arg-339, Arg-359	Mg2	Mg1
LAP	Zn1, Zn2, Lys-262, (H_2O)	(H_2O)	Zn1 and Zn2

[a] In the first/second phosphoryl-transfer step. [b] Ligand at metal ion. [c] The residue is proposed to act as a general base (proton acceptor).

Section 2 (see Fig. 2) is thought to be realized in one or more of the presumed two-metal ion mechanisms. In the mechanisms of AP, PAP, the PPs, FBP, and LAP positively charged side chains (Arg, His, or Lys) evidently participate in the stablization of the transition state in addition to the metal ions. In contrast, in the polymerases, 3',5'-exonuclease, IMP, and PLC the metal ions appear to provide most of the transition state stabilization alone, since no other protein residues are positioned to interact with the phosphoryl oxygen atoms. In IMP, two backbone NH groups may also help in the stabilization of the transition state.

For all di- and trinuclear metalloenzymes discussed here, a metal ion is proposed to help in the deprotonation of the nucleophile. For LAP, the Ser/Thr PPs, and nuclease P1, a deprotonation of the nucleophile by two metal ions is discussed (metal-ion-bridging nucleophile). Since two metal ions may lower the pK_a value of a coordinated water molecule even more than one metal ion, such a bridging water molecule may be deprotonated more easily without the help of a protein residue acting as a general base. However, the Lewis acidity of the metal ion(s), modulated by the coordinating ligands, should be strong enough to just generate a metal-bound hydroxide ion at the pH value of the natural enzyme environment, but not stronger since the Lewis acidity will also reduce the nucleophilicity of the generated hydroxide ion. An open question remains on the issue as to whether a carboxylate group coordinated to a metal ion is likely to accept a proton from the nucleophile, as proposed for the mechanisms of pol-β and IMP. A computational study on the 3',5'-exonuclease activity of pol I indicated that the Glu-357 side chain coordinated to the metal ion is unlikely to become protonated during the reaction, since the basicity of a carboxylate group is significantly lowered by metal coordination.[150] Also, an activation of the leaving group by metal ions or protein side chains is proposed for most enzymes (Table 2). Often water molecules are seen at hydrogen-bonding distance to phosphoryl or ester oxygen atoms (e.g. in IMP, or pol-β), or to the *gem*-diolate oxygen atoms of the transition state analogue inhibitors for LAP. These water molecules may also significantly stabilize the transition state or protonate the leaving group. Such catalytically important water molecules may be present in X-ray crystal structures, although at lower resolution (greater than about 2.5 Å) they may not be seen in the electron density maps.

The data in Table 2 indicates that both metal ions play a dominant role in most of the the catalytic pathways. In an attempt to simplify the proposed two-metal ion phosphoryl-transfer mechanisms we might therefore compare them on the basis of the binding mode of the reactants to the metal ions, as shown in Figure 34, in which all interactions with other protein residues are neglected. A substrate binding mode, in which one metal ion generates the deprotonated nucleophile and the other metal ion activates the leaving group and both metal ions polarize the phosphoryl group, is implicated for both displacement steps of AP, as well as for IMP, 3',5'-exonuclease, and as one possibility for the RNA/DNA polymerases (Fig. 34a). This kind of mechanism is supported by several structural studies for these enzymes and thus appears to be a prevalent two-metal mechanism. A mechanism, in which one metal ion binds the substrate phosphoryl group and the other metal ion deprotonates the nucleophile is discussed for PAP, and in a modified form as one possibility for P1, assuming that the nucleophile is the water molecule that bridges Zn1 and Zn3 (Fig. 34b). In a third alternative substrate binding mode, the phosphoryl group bridges the two metal ions in a bidentate fashion (Figs. 34c and d). The nucleophile might be a terminal ligand to one metal ion, as proposed for FBP and for PP-1, or a bridging water molecule, one possibility for the mechanism of the Ser/Thr PPs.

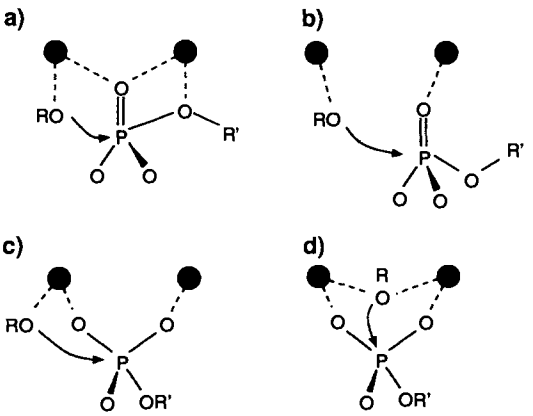

Fig. 34. Simplified scheme showing four possible binding modes of a phosphomonoester and a nucleophile to a dimetal center. In mechanisms a) and b) the substrate binds monodentate bridging or terminal with one nonbridging phosphoryl oxygen atom to the metal ions, whereas in mechanisms c) and d) the substrate binding mode is bidentate bridging.

We do not know how close these mechanistic models approach the actual reaction pathways, nor do we know the extent that further structural or other studies will modify these proposed mechanisms. Nevertheless, it appears as if significantly different mechanisms can be achieved with a two-metal ion arrangement. Even for evolutionary related enzymes, such as PAP and the PPs, FBP and IMP, or P1 and PLC, differences in the pathways with respect to the identity of the nucleophile or the substrate binding mode are observed or at least implicated or possible. We know that three-dimensional structures are more conserved than protein sequences, but it remains to be shown how well enzyme mechanisms are conserved.

We are grateful to Hazel Holden, Fusao Takusagawa, Dietrich Suck, Edward Hough, Sissel Hansen, Zdenek Hostomsky, Andy Karplus, Stephen Martin, Alexander Wlodawer, Harold Wyckoff, Tom Steitz, Jonathan Goldberg, and John Kuriyan for providing figures and coordinates for the generation of figures prior to release by the Protein Data Bank. Huguette Pelletier, Fusao Takusagawa, and Dietrich Suck are thanked for sharing results before publication and for helpful comments. B. K., N. S., and T. K. thank Herbert Witzel for advice and many helpful discussions. Research in the laboratories of the authors was supported by grants NIH GM06920 to W. N. L. and DFG 406/13/15 and BMFT(BMBF) 05648PMA to B. K. N. S. thanks the Deutsche Forschungsgemeinschaft for financial support.

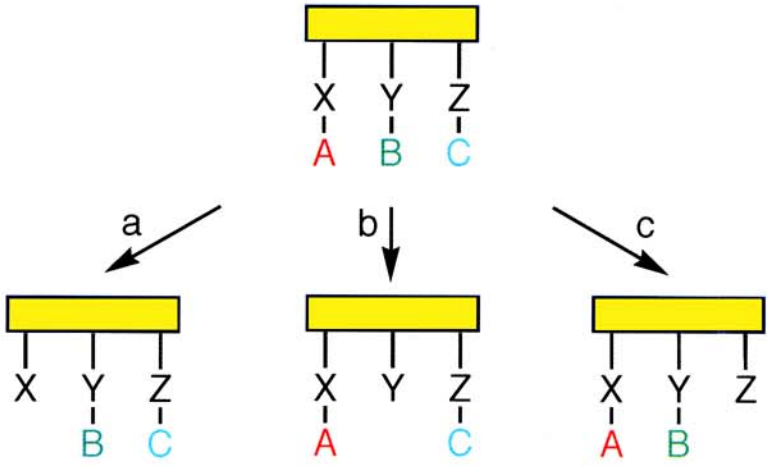
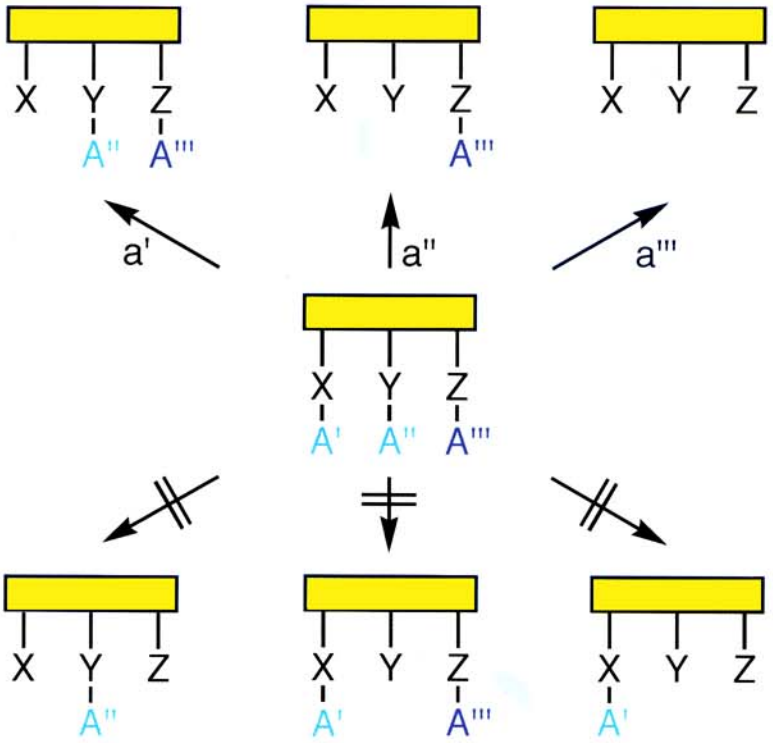
Orthogonal Stability



Modulated Lability



Orthogonal stability and modulated lability are protecting group strategies often employed in combination in complex syntheses.

Protecting Group Strategies in Organic Synthesis

Michael Schelhaas and Herbert Waldmann*

Dedicated to Professor Leopold Horner on the occasion of his 85th birthday

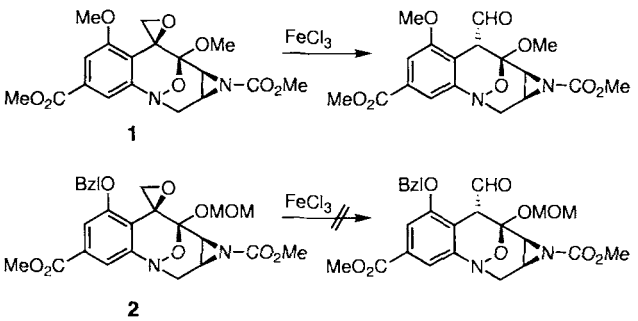
The choice of protecting groups is one of the decisive factors in the successful realization of a complex, demanding synthetic project. The protecting groups used influence the length and efficiency of the synthesis and are often responsible for its success or failure. A wide range of blocking groups are currently available for the different functional groups; however, an overall strategy combining these different masking techniques in an advantageous and reliable manner has never been proposed or at best only for individual cases. This review attempts to make a contribution to filling this gap. First a very short overview of the most commonly used protecting groups will be given, in which they are classified according to their lability and not according to the functional group they protect. This classification clarifies coherent concepts for the development of blocking strategies. On the basis of this brief summary reliable strategies will then be illustrated and developed with selected examples from the recent literature by which protecting groups may be combined successfully and advantageously in synthetic projects of differing degrees of complexity and difficulty.

Keywords: protecting groups · retrosynthetic analyses · synthetic methods · total syntheses

1. Introduction

Today, organic synthesis has reached a remarkable level of competence and even the most complex molecules are accessible.[1] The prerequisites for this success are both the availability of a wide range of efficient synthetic methods[2] and reagents,[3] and the fact that "retrosynthetic analysis"[4] can provide a framework for the design of a synthetic strategy leading to the desired product in the most efficient and logical way.

These strategies include tactics for the construction of the molecular framework, for the establishment of the absolute configuration of any stereocenters present, for the efficient formation of rings, and for the reduction of the number of synthetic steps. The complex synthetic intermediates and products contain, in general, a multiplicity of functional groups, most of which must be blocked and, at an appropriate point in the synthesis, liberated. The correct choice of protecting groups is often decisive for the realization of the overall operation. This is exemplified by the recently published total synthesis of the mitomycin analog FR-900482. In model studies Danishefsky et al. had shown that the basic skeleton of this natural product can be accessed by $FeCl_3$-mediated opening of the epoxide in **1** (Scheme 1).[5] However, the synthesis could not be concluded successfully, because cleavage of the methyl ether was accompanied by decomposition of the aziridine. To avoid this problematic situation, the hydroxyl groups in **2** were not protected as methyl ethers but rather as benzyl and methoxymethyl ethers. Unfortunately, after this seemingly innocuous[6] alteration in the protecting group pattern, the selective $FeCl_3$-mediated cleavage of the oxirane failed owing to the higher lability of the newly introduced ether functions. The authors were forced to find an entirely new reagent to complete the synthesis.[6]



Scheme 1. Protecting group problems in the synthesis of mitomycin analog FR-900482 by S. Danishefsky et al. [5]. MOM = methoxymethyl, Bzl = benzyl.

Another unexpected protecting group problem appeared during the total synthesis of taxol, again by Danishefsky et al.[7] The advanced intermediate **3** was converted into the epoxide **4**, but the robust *tert*-butyldimethylsilyl (TBDMS) ether could not be removed in the next steps (Scheme 2). Thus the TBDMS in **3** was replaced by the more labile triethylsilyl (TES) ether. Compound **5** was converted into the corresponding epoxide **6**, which was then successfully transformed into the complex natural

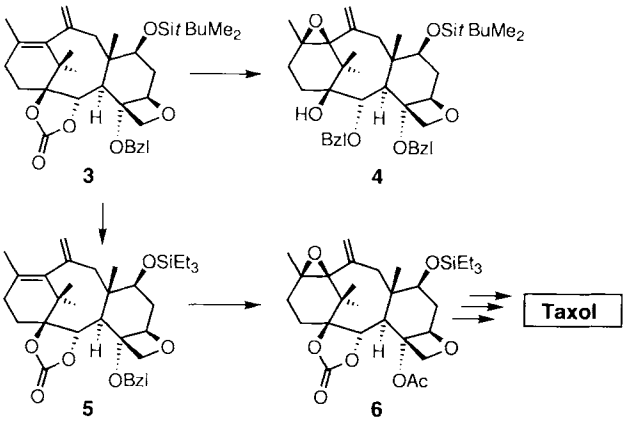


Scheme 2. Protecting group problems in the synthesis of taxol by S. Danishefsky et al. [7].

product. The TES group was removed only after construction of the correctly functionalized polycycle.

These examples make it obvious that a successful synthesis requires both basic retrosynthetic planning and a separate protecting group strategy that takes into account different requirements such as the lability of the intermediates and of the reagents to be used.

As a consequence of the great importance of protecting groups in organic chemistry, a multitude of blocking techniques have been developed for a wide range of functional groups. Here the chemist has numerous choices. However, when giving a detailed description of a successfully completed total synthesis, authors rarely comment on why they selected particular protecting group patterns.[8] Similarly, in the monographs[9, 10] and reviews[11] concerning protecting group chemistry, the emphasis lies in the presentation of the various possibilities that exist for the blocking and deprotection of the function in question. Strategies that can be used to combine protecting groups in appropriate ways and that have proved their capability and reliability in complex syntheses have never been published or only for isolated cases.[12] The protecting groups will be classified according to their lability (for a more comprehensive treatment see refs. [9–11]) instead according to the functional group they block. This has the advantage that the sensitivity of the compounds to be protected and the required reaction conditions can be accounted for in the planning of a synthesis.

Experience shows that the critical parameters are generally the stability and the cleavage of the protecting group rather than its introduction. For most of the typically required functional groups, protecting groups are known that are labile under different, often alternative, conditions. Furthermore, unified concepts for the development of new blocking possibilities become clear as a consequence of this approach. As an example, the N-*tert*-butyloxycarbonyl (Boc) group, the *tert*-butyl ester, and the *tert*-butyl ether can be cleaved under acidic conditions, the trimethylsilylethoxycarbonyl (Teoc) group and the trimethylsilylethyl (TMSE) ether are cleaved by fluoride ions through β-elimination, and allyloxycarbonyl (Aloc) urethane, allyl (All) ester, allyl ether, and 5-methylene-1,3-dioxane acetal,[13] which is used for the protection of carbonyl groups, can all be removed by noble metal catalyzed reactions. Following this short overview, selected examples from the recent literature will be used to illustrate proven strategies for the successful and advantageous combination of protecting groups in synthetic projects of varying complexity and difficulty. This review should provide simple guidelines for the the development of successful tactics and strategies for organic synthesis.

2. Lability and Cleavage of Protecting Groups

For a protecting group to find wide application in organic synthesis, it must fulfill several criteria. In particular, it must

be introduced into the molecule to be protected under mild conditions in a selective manner and in high yield; functional groups other than that to be protected must not be attacked.

H. Waldmann

M. Schelhaas

Herbert Waldmann was born in 1957, studied chemistry at the University of Mainz, and received his doctorate in 1985 under the supervision of Horst Kunz. After a postdoctoral appointment at Harvard University with George Whitesides, he returned to the University of Mainz in 1986 and completed his habilitation in 1991. He was Professor of Organic Chemistry at the University of Bonn from 1991 to 1993 before taking up a chair of Organic Chemistry at the University of Karlsruhe. His work has been recognized by the award of the Friedrich-Weygand-Preis, the Dozentenstipendium of the Fonds der Chemischen Industrie, and the Carl-Duisberg-Preis of the Gesellschaft Deutscher Chemiker. His research encompasses diastereo- and enantioselective synthesis, the chemistry of peptides, carbohydrates, and alkaloids, and the use of enzymes in organic synthesis. One of his current research topics is the preparation of new tools by the methods of organic chemistry for addressing biological questions such as the control of signal transduction.

Michael Schelhaas was born in 1967, studied chemistry at the University of Bonn, and completed his degree in 1993. He then moved to Karlsruhe with Herbert Waldmann's group, where he is currently working on his doctoral thesis in the field of chemoenzymatic syntheses of lipid-modified peptide conjugates. He won the Heinrich-Hörlein-Preis for his degree and the Wolf-und-Sohn-Preis for further work.

be stable under all the conditions used during the synthesis, including those of the purification steps, up to the step in which the protecting group is removed, it should, as far as possible, have a stabilizing effect on the molecule and should suppress racemization or epimerization.
- be cleavable under very mild conditions in a highly selective manner and in high yield; other protecting groups present in the molecule and unprotected functionalities should not be affected by the cleavage conditions.

In addition to these minimum requirements, the protecting group should also
- be introduced and removed with the help of readily available reagents, such that in both transformations the products can be easily purified.
- introduce no additional stereocenters.
- lend the protected intermediates advantageous physical properties; for example the compounds should be easily crystallized and/or readily soluble.

Only a few protecting groups meet all of these demands, and in most cases a compromise must be found, in which the most important criteria are addressed. In most cases guaranteeing that the protecting group is very stable and, at the same time, readily liberated (an apparent contradiction) is the crucial problem and overshadows the requirements for efficient introduction and the provision of desirable physical and chemical properties. In the next sections the most important protecting groups will be presented briefly according to their lability and their ease of cleavage.

2.1. Acid-Labile Protecting Groups[9-11]

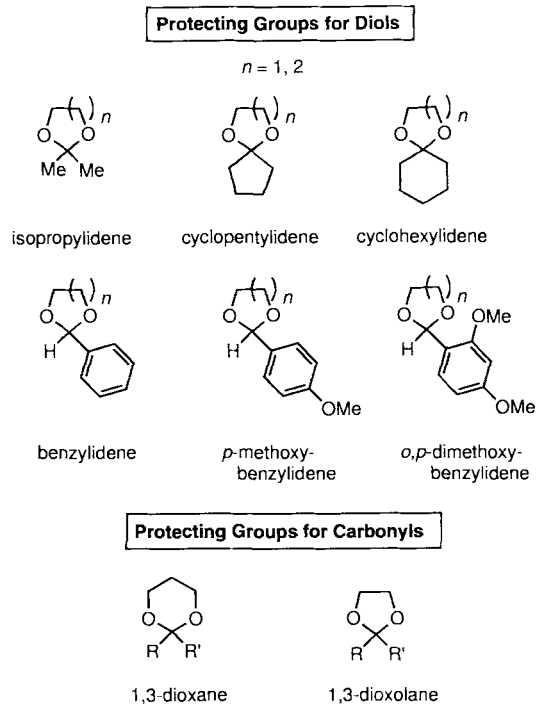
The cleavage of protecting groups by acid-mediated hydrolysis is one of the best established methods in protecting group chemistry and forms one of the central pillars of the subject. Nevertheless, only those protecting groups that can be removed under sufficiently mild (but not too mild) conditions find widespread use.

2.1.1. Acetal Protecting Groups

Acetals are formed and cleaved under acid catalysis. They are generally stable towards nucleophiles and bases, and are thus suitable for the protection of alcohols, diols, and carbonyl compounds. Furthermore, N,N- and N,O-acetals are utilized for the protection of amino groups.

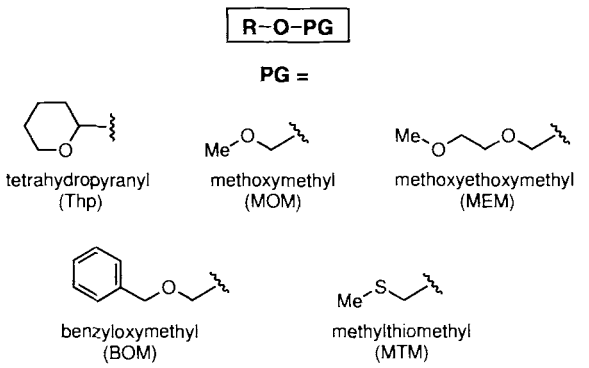
Cyclic O,O-acetals can be considered as protecting groups for either carbonyl groups or diols, depending on which component is of interest. Carbonyl groups are normally protected as the 1,3-dioxolane or -dioxane by condensation with ethylene glycol or propylene glycol (Scheme 3). Similarly, 1,2- and 1,3-diols are masked by reaction with acetone, (substituted) benzaldehyde, and cyclic ketones (cyclopentanone, cyclohexanone, cycloheptanone) as isopropylidene, (substituted) benzylidene, and cycloalkylidene acetals. Recently, the dispiroketal (DISPOKE)[14] and the cyclohexane-1,2-diacetal (CDA) groups[15] have been proposed as two promising new acetal protecting groups (see Section 5).

Acyclic O,O-acetals are normally used for the protection of alcohols. Most commonly used are the tetrahydropyranyl (THP),



Scheme 3. Examples of cyclic O,O-acetals as protecting groups for 1,2-diols, 1,3-diols, and carbonyl compounds.

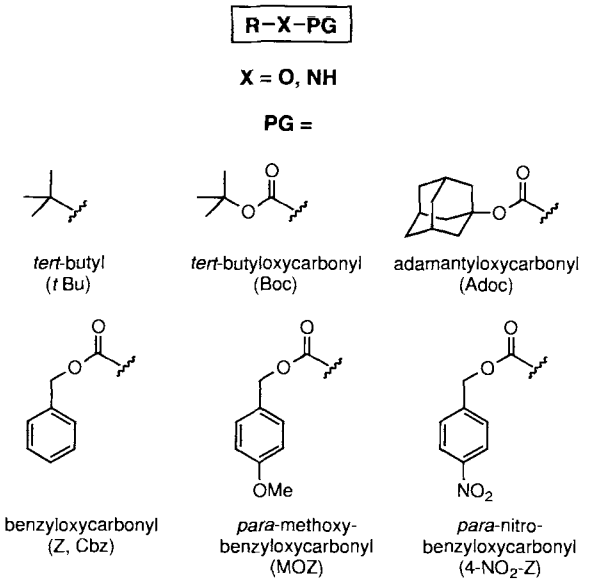
the methoxymethyl (MOM), the benzyloxymethyl (BOM), and the methoxyethoxymethyl (MEM) protecting groups (Scheme 4). They can be cleaved readily under mildly acid conditions, and their complexing ability can also be used to control the stereochemical course of a transformation (see Section 3.5).



Scheme 4. Examples of acyclic O,O-acetals and O,S-acetals as protecting groups for alcohols.

2.1.2. Formation of Stabilized Cations

The second large class of acid-labile protecting groups is characterized by the formation of stabilized cations upon cleavage. The *tert*-butyl ether along with the corresponding ester and urethane (Boc protecting group) are examples of this class, which find use in the protection of alcohols, thiols, amines, and carboxylic acids (Scheme 5). In each case, their cleavage liberates the *tert*-butyl cation. By analogy, benzyl cations are generated on the cleavage of benzyl protecting groups, which are also common blocking groups for hydroxyl groups, thiols, esters, and amino groups. By introduction of additional substituents,



Scheme 5. Examples of acid-labile protecting groups that are cleaved with formation of stabilized cations.

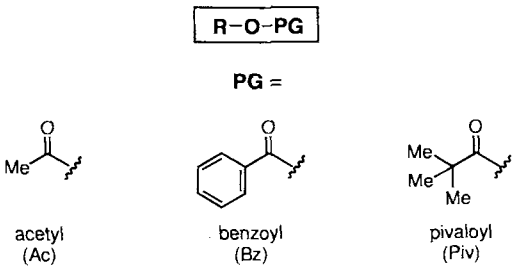
the stability of the cation can be increased or reduced, and thereby the acid sensitivity of the protecting group can be fine-tuned. Thus, the adamantyloxycarbonyl (Adoc) and the *para*-methoxybenzyloxycarbonyl (MOZ) groups are more acid-labile than the respective parent Boc and Z groups. The 4-NO_2-Z group is, however, significantly more stable than the Z-urethane. It should be noted that the silyl ether protecting groups, which are usually removed by treatment with fluoride ion (see Section 2.3), are also labile under mild acidic conditions.

2.2. Base-Labile Protecting Groups[9–11]

The removal of protecting functions under basic conditions is also one of the tried-and-true methods in protecting group chemistry. On the basis of mechanistic considerations, two categories can be distinguished: basic hydrolysis and based-induced β-elimination.

2.2.1. Basic Hydrolysis

This method applies to practically all esters, with the exception of the *tert*-butyl ester mentioned in Section 2.1.2. Carboxylic acids are typically protected as (substituted) alkyl esters. Alcohols are often esterified with acetic acid, benzoic acid, or pivalic acid (Scheme 6). The rate of hydrolysis can be modified by adjusting steric and electronic factors. For example, trifluoroacetate can be removed selectively in the presence of acetate, and acetate can be cleaved in the presence of pivalate.

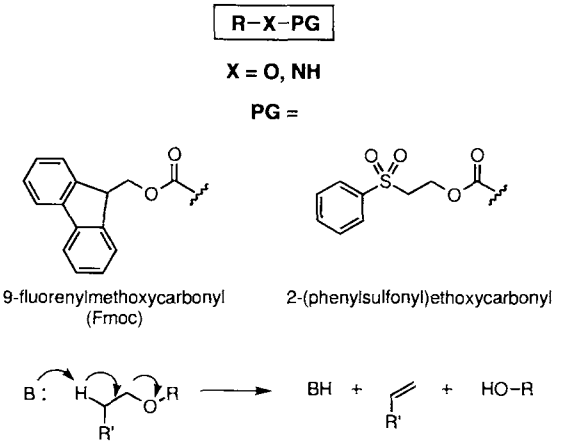


Scheme 6. Examples of base-labile acyl protecting groups.

Basic cleavage of amides to liberate amines is only seldom used on account of the generally harsh conditions required. The phthaloyl group is one exception; it can be cleaved with hydrazine under mildly basic conditions. Again, it should be noted that the silyl ethers can be removed by basic hydrolysis (however, see Section 2.3).

2.2.2. Cleavage by Base-Induced β-Elimination

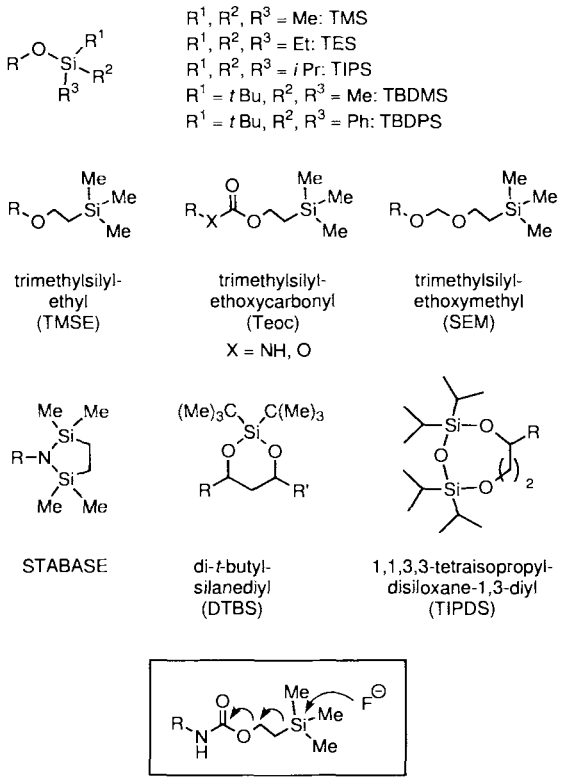
Protecting groups such as the fluorenylmethoxycarbonyl (Fmoc) urethane, which has established itself as one of the standard protecting functions for amino groups in solution-phase and solid-phase peptide synthesis, and the phenylsulfonylethyl group are cleaved by the abstraction of an acidic proton and subsequent β-elimination, with the formation of a vinyl system (Scheme 7). Direct attack of the base on a carbonyl function is thus avoided. This type of protecting group has found many applications.



Scheme 7. Examples of protecting groups that are cleaved by β-elimination.

2.3. Fluoride-Labile Protecting Groups[9–11]

Silyl protecting groups can be cleaved by treatment with fluoride ion under conditions that affect nearly no other functionalities. They thus make up an essential chapter in protecting group chemistry (Scheme 8). Variation of the substituents on silicon allows modification of their stability towards acids and bases, as well as the selectivity of the cleavage with fluoride ion (see Section 3.2.2 and Scheme 37). A simple rule of thumb holds—the greater the steric demand, the higher the stability. Alcohols are typically protected as trialkylsilyl ethers; the order of stability for the ethers is TMS < TES < TBDMS < TIPS[16] $\approx$ thexyl. For particularly challenging cases, a further level of fine-tuning can be achieved with, for example, isopropyldimethylsilyl,[17] diisopropylmethylsilyl,[18] and diethylisopropylsilyl (DEIPS)[19] groups. 1,3-Diols can be masked as silanediyl derivatives (see also Scheme 44) or by introduction of the tetraisopropyldisiloxane-1,3-diyl (TIPDS) group. Silyl groups are rarely used for the protection of esters and amines due to the high lability of the resulting derivatives (the STABASE protecting group[20] for amines is an exception, see Scheme 8). For this purpose, trialkylsilylethyl esters and carbamates have been

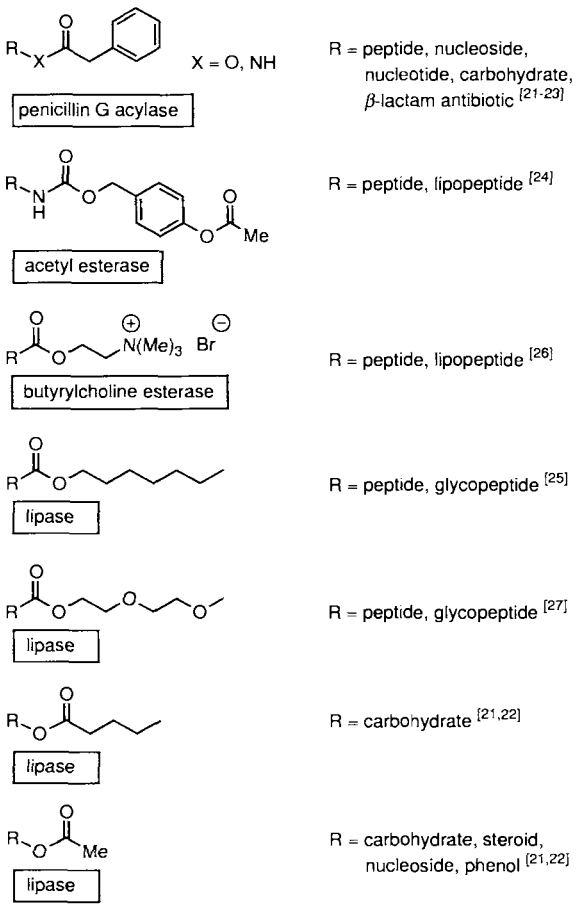


Scheme 8. Examples of protecting groups that are cleaved with fluoride ions.

developed, which can be removed by fluoride ion promoted fragmentation analogous to the previously described β-elimination (Section 2.2.2; Scheme 8). The same principle is also behind the trimethylsilylethyl (TMSE) and trimethylsilylethoxymethyl (SEM) protecting groups for alcohols.

2.4. Enzyme-Labile Protecting Groups[21, 22]

In many cases the selective removal of different acyl protecting groups from amines and alcohols and the targeted deblocking of carboxylic acids under mild conditions is most readily achieved with biocatalysts. Enzymes typically function in the pH range 5–9 and at room temperature; they may display a high specificity for the structures they recognize and the reactions they catalyze, and at the same time they may tolerate a wide range of substrates. Thus enzymes enable the targeted removal of protecting groups (which may in principle also be removed by classical chemical methods) under mild conditions and with a chemo- and regioselectivity that is hardly, if at all, possible by classical chemical techniques. Although the development of enzymatic protecting group techniques has been intensively studied only in the last few years, a number of interesting enzyme-labile protecting groups have been developed for organic synthesis (Scheme 9). Thus, for example, the phenylacet (PhAc) amide[23] and the 4-acetoxybenzyloxycarbonyl (AcOz) urethane[24] have been used as enzyme-labile protecting functions for amino groups, and carboxylic acids can be selectively demasked through enzyme-mediated cleavage of heptyl[25] and choline esters.[26] Hydroxyl groups protected as the acetate, benzoate, butyrate, and even pivalate can be liberated enzymatically.[21, 22] In this way such conversions can be carried out in



Scheme 9. Selected enzyme-labile protecting groups.

polyfunctional carbohydrates, nucleosides, steroids, alkaloids, and phenolic natural products, often with astonishingly high regioselectivity not achievable with classical chemical techniques. The ability of enzymes to function in organic solvents opens up new possibilities for the introduction of protecting groups.

2.5. Reduction-Labile Protecting Groups[9–11]

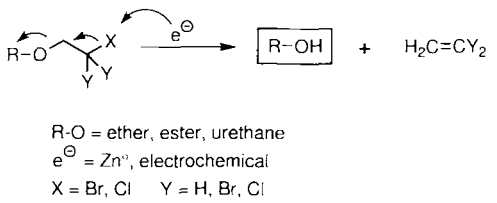
Reductive conditions can be used to cleave a variety of protecting groups that are used more or less frequently in organic synthesis.

2.5.1. Cleavage by Hydrogenolysis

Benzyl groups, which can be present as ethers, esters, urethanes, carbonates, or benzylidene acetals, and are used for the protection of alcohols, carboxylic acids, amines, and diols, can be removed under mild conditions by hydrogenolysis. The rate of hydrogenolysis can be influenced by introducing electron-donating or -accepting substituents in the aromatic ring. Benzyl groups are frequently used.

2.5.2. Cleavage by Reductive Elimination

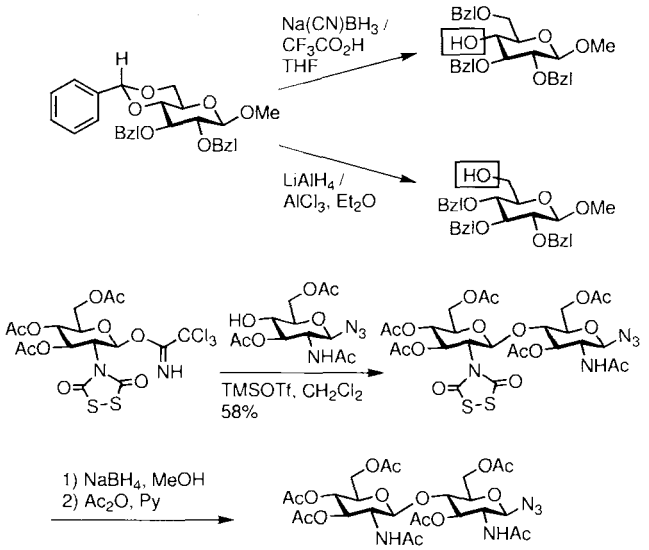
Protecting groups of the 2-haloethyl type can be cleaved by a mechanism involving the donation of electrons into the carbon–halogen bond, leading to a fragmentation corresponding to the β-elimination discussed in Sections 2.2.2 and 2.3 (Scheme 10).



Scheme 10. 2-Haloethyl protecting groups that can be cleaved by reduction.

Zinc is the preferred electron donor, but electrochemical methods are also successfully used.

The reduction of, for instance, ester protecting groups with complex hydrides, reagents that also will attack a pivalate ester, is rarely used, owing to the poor selectivity of these reagents. An exception worth mentioning is the regioselective opening of benzylidene acetals in carbohydrate chemistry[28] (Scheme 11). The



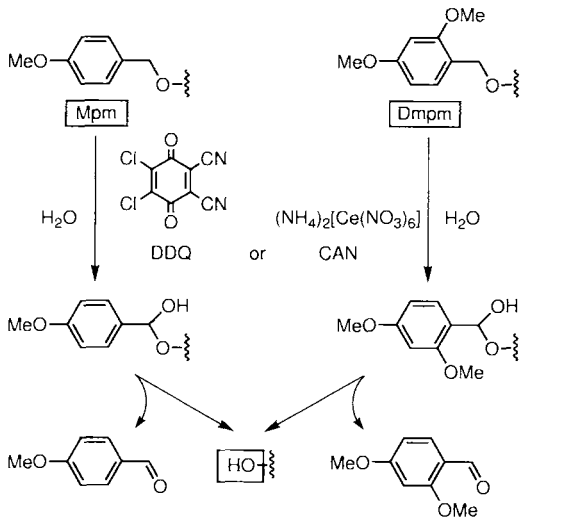
Scheme 11. Regioselective opening of benzylidene acetals and reductive cleavage of the dithiasuccinimide (Dts) protecting group in carbohydrate chemistry.

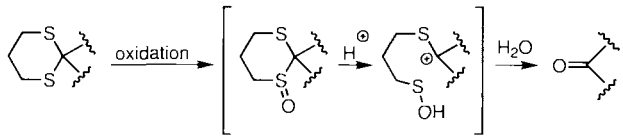
reductive cleavage of disulfides with thiols or complex hydrides is also seldom used. However, an interesting application of this deblocking technique for the liberation of amino groups from dithiasuccinimides (Dts protecting group) in saccharide synthesis was recently published[29] (Scheme 11).

2.6. Oxidation-Labile Protecting Groups[9-11]

The choice of oxidation-labile protecting groups is very limited. The 4-methoxybenzyl (Mpm) and the more labile 2,4-dimethoxybenzyl (Dmpm) ethers have proved their worth as reagents in the synthesis of complex molecules. Both of these functions are easily removed under mild conditions with dichlorodicyanoquinone (DDQ) or with cerium(IV) ammonium nitrate (CAN) (Scheme 12), or under acidic conditions (see Section 2.1.1).

It is also worth mentioning that S,S-acetals of carbonyl compounds, such as 1,3-dithianes, can be cleaved after oxidation of the sulfur (Scheme 12).



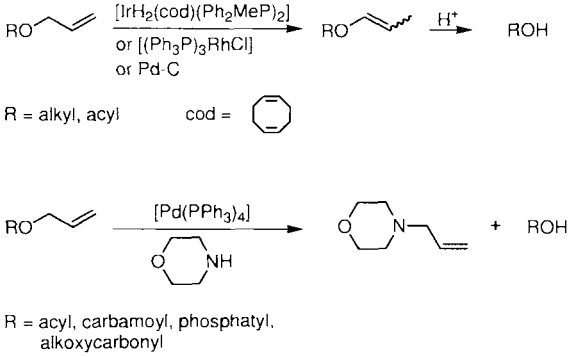


Scheme 12. Examples of oxidation-labile protecting groups.

2.7. Cleavage of Protecting Groups Assisted by Heavy Metal Salts or Complexes[9-11]

The activation of protecting groups with noble metals often offers an advantageous alternative for the targeted deblocking of functional groups. Thus, carbonyl compounds masked as 1,3-dithianes can be hydrolytically regenerated easily by treatment with stoichiometric amounts of Hg^{II}, Ag^{I}, Cu^{II}, or Tl^{III} salts or alternatively by reaction with other electrophiles or by oxidation of the sulfur (see Section 2.6).

Catalytic amounts of Rh^{I}, Ir^{II}, and Pd^{0} complexes and even Pd–C suffice for the removal of protecting groups containing the allyl group. Thus, allyl ethers in carbohydrates and peptides can be selectively isomerized to the acid-labile prop-1-enyl system through the action of catalytic quantities of Pd–C or Rh^{I}, or Ir^{II} complexes. Hydrolysis of this group is achieved under mild conditions. (Scheme 13). The allyloxycarbonyl (Aloc)

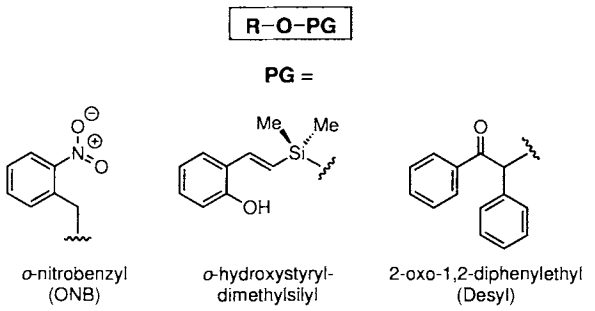


Scheme 13. Cleavage of allyl ethers, allyl esters, allyl urethanes, and allyl carbonates by using heavy metal complexes.

group, allyl esters, and allyl phosphates can be cleaved under mild conditions by Pd^0-mediated allyl transfer to a variety of nucleophiles such as amines and C–H-acidic compounds (Scheme 13). As a consequence of its ready removal and its compatibility with a range of other functional groups, the allyl protecting group has become established in protecting group chemistry and is finding increasing application in the synthesis of complex natural products (see Sections 3.1.3, Schemes 23–27). 1,3-Dithianes and allyl protecting groups can also be viewed "two-stage" protecting groups (see Section 2.9).

2.8. Photolabile Protecting Groups[9–11]

Photolabile protecting groups contain a chromophore of high chemical stability that can be selectively activated by irradiation with light of a suitable wavelength. Of the many known photolabile protecting groups, the *o*-nitrobenzyl group[30] has been used repeatedly in the form of ethers, esters, carbonates, carbamates, and acetals (Scheme 14, see also Section 3.1.5). Two

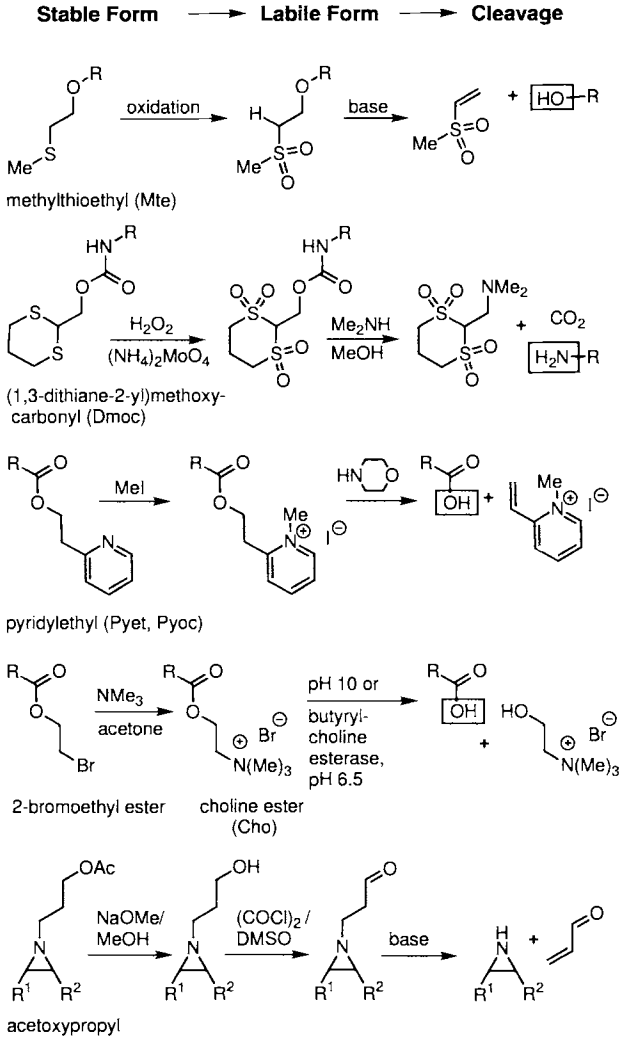


Scheme 14. Examples of photolabile protecting groups.

further interesting photolabile protecting groups are the 2-oxo-1,2-diphenylethyl (Desyl) group[31] and the *o*-hydroxystyryldimethylsilyl group[32] (Scheme 14). Photolabile protecting groups can be cleaved under mild conditions with light of a suitable wavelength, and highly selective cleavage in the presence of other functional groups is possible by the choice of an appropriate chromophore. Despite these advantages, photolabile protecting groups are used much less frequently than other types of protecting groups.

2.9. "Two-Stage" and "Safety-Catch" Protecting Groups

The inherent (and deliberately employed) reactivity of, for example, acid- and base-labile protecting groups is often the source of undesired side reactions. Thus, masking can be (partially) lost at the wrong point in the synthesis. If several protecting groups of comparable reactivity are present in one molecule, selective removal of a single protecting group can be difficult. This problem can be avoided by the use of protecting functions that initially exist in a chemically stable form and can be converted into a labile group when their cleavage is required; these are the "two-stage" protecting groups.[33] Examples include the methylthioethyl (Mte) and the 1,3-dithianylmethoxycarbonyl (Dmoc) groups, which are insensitive towards acid and base, but which, after oxidation of the sulfur to sulfone, fragment by

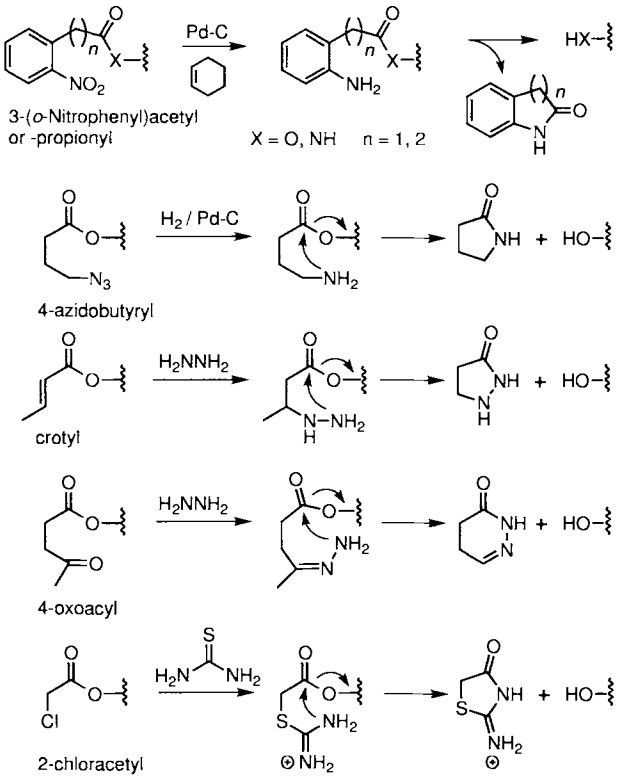


Scheme 15. Selected "two-stage" protecting groups.

base-induced β-elimination (Scheme 15). The same principle applies to the 2- and 4-pyridylethyl protecting groups, which, after alkylation of the pyridine nitrogen, can be cleaved even with morpholine (Scheme 15). 2-Bromoethyl esters can be transformed into salts of the corresponding choline esters by reaction with trimethylamine. The protecting group can then be cleaved either with base or under milder conditions with the enzyme butyrylcholine esterase (see Sections 2.4 and 3.1.4). Removal of another interesting protecting group, the acetoxypropyl protecting group for amines, requires hydrolysis of the acetate, subsequent oxidation of the liberated hydroxyl group to give the aldehyde, and finally base-induced elimination (Scheme 15). This proved to be a useful alternative to classical acyl protecting groups in the total synthesis of mitomycin C.[34] Other examples of this method of protecting group cleavage are 1) the removal of 1,3-dithianes by reaction with electrophiles (or oxidation of sulfur) and subsequent hydrolysis (see Sections 2.6 and 2.7), and 2) the removal of allyl groups by a) isomerization of the allyl system followed by acid hydrolysis or by b) formation of a π-allylpalladium complex and subsequent reaction with a nucleophile (see Sections 2.7 and 3.1.3).

Closely related to the two-stage protecting groups are the "safety-catch" protecting groups.[35] In these systems a chemi-

cally stable precursor is introduced, which is converted into an activated intermediate directly before cleavage. In this case no additional reagent, such as a base or a nucleophile, is required in order to remove the protecting groups. The activated intermediate itself carries a reactive functional group, typically a nucleophile, which intramolecularly attacks the bond to the blocked function and thus causes the cleavage of the protecting group. Several examples of this technique are presented in Scheme 16. Thus, reduction of the nitro-substituted aromatic



Scheme 16. Selected "safety-catch" protecting groups.

precursor generates the aniline derivative, which then cyclizes to give the amide with liberation of the deprotected functional group. The same principle applies for azidobutyrates. Crotyl and 4-oxoacyl protecting groups react with hydrazine by addition to the α,β-unsaturated system and by formation of a hydrazone, respectively, thereby placing the nucleophile in the correct position. Analogously, chloroacetates are converted to substituted α-thioacetates by reaction with thiourea; subsequent cyclization releases the unprotected functional group.

3. Strategies for the Choice of Protecting Groups

When a synthesis is planned, the choice of suitable protecting groups is inseparable from the consideration of how one will construct the basic structure of the target molecule and how the stereochemistry will be established. The first step in planning a synthesis is the retrosynthetic analysis of the target molecule, which designates the fragments containing the groups to be protected. On the basis of the inherent lability of these intermediates one can, even at this early stage, already exclude certain protecting group strategies. For example, if a fragment contains a C–C double bond, one would not consider using benzyl ethers or esters as protecting groups, which must be removed by hydrogenolysis. After a successful analysis, concrete reactions, the required reagents, and protecting groups are chosen simultaneously. Functional groups, which, after they are introduced or formed, should remain blocked throughout the entire synthesis, will be protected with permanent protecting groups, whereas those that will be liberated at an early stage in the synthesis will be blocked with temporary protecting groups. In practice, it is often neccessary to try out alternative approaches in the course of the synthesis. One must remain alert to the fact that in such cases other protecting groups may be required. For example, if an aldol reaction is planned and strong base is required to deprotonate the carbonyl compound, any protecting groups required should be base-stable but may be acid-labile. However, if this aldol reaction does not prove satisfactory, for example because of low or undesired stereoselectivity, an alternative would be Mukaiyama's variant of the aldol reaction, in which the corresponding silyl enol ether is activated by a Lewis acid (such a case has been described by Reetz et al.[36]). Now the requirements for successful protecting groups would be completely reversed, and exchange of the previously used protecting groups for others might thus be required. It should be noted that the type of blocking can also affect the course of the planned synthesis (see Section 3.5). This example illustrates that each synthetic alternative (here an aldol reaction under basic or acidic conditions) can require its own pattern of protecting groups (base-stable or acid-stable as the case may be).

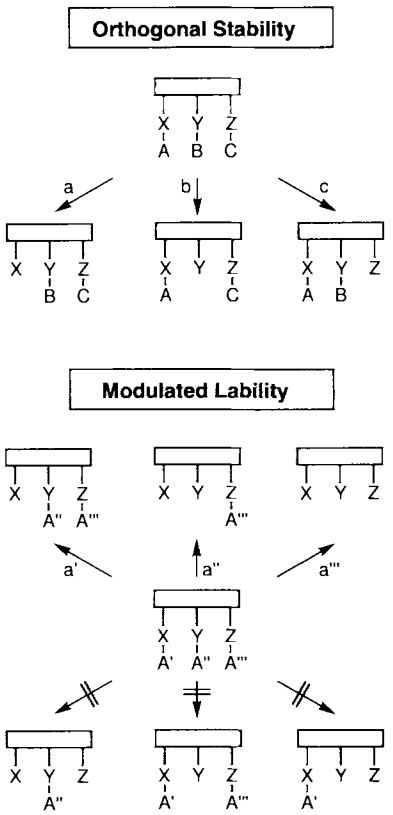
In the development of a protecting group strategy two fundamental concepts are available (Scheme 17):

- the use of orthogonally stable protecting groups
- the use of protecting groups with modulated lability

The principle of orthogonal stability[37] requires that only those protecting functions should be used that can be cleaved under (as a rule totally) different reaction conditions without affecting the other functions present (Scheme 17). For example, three protecting groups A, B, and C, which are attacked by acid, by base, and by hydrogenolysis, respectively, could therefore be selectively removed in any sequence at any point in a synthesis.

In following the principle of modulated lability, the protecting groups are all sensitive to one set of conditions, but to differing extents. Consider three protecting groups A', A'' and A''', all of which are acid-labile. The most acid-sensitive group, A', can be removed without affecting the other two. However, the least labile A''' cannot be removed selectively in the presence of one or both of the others (Scheme 17).

A strategy based upon the concept of orthogonal stability guarantees a great degree of flexibility in the execution of a synthesis. However, it is often not possible to find and use the requisite number of orthogonally stable protecting groups, particularly in the case of multifunctional molecules, since cleavage of one protecting group requires not only the stability of all the other protecting groups but also of the masked molecule itself under a wide range of reaction conditions. Additionally, in the last steps of a synthesis it is often not necessary that all protecting groups have strictly orthogonal stability, since only a few groups must be selectively liberated and a series of selective



Scheme 17. Orthogonal stability and moldulated lability as basic concepts for the development of protecting group strategies.

deblockings extend the synthesis significantly. These disadvantages do not exist if one uses a set of protecting groups of similar but modulated stability. In practice, a combination of the two strategies is often employed, in which the earlier stages rely more heavily on orthogonal stability and in the latter stages the concept of similar lability is more important.

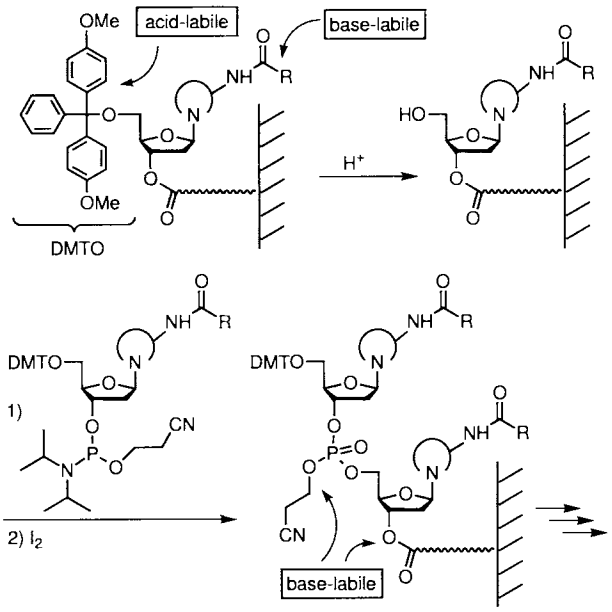
These two fundamental strategies can be augmented by auxiliary strategies, including:
- the earliest possible unification of a protecting group pattern
- the introduction of "stand-ins"
- the use of protecting groups to direct reactions.

3.1. The Use of Orthogonally Stable Protecting Groups

The protecting groups discussed in Section 2 of differing lability can be used in a wide variety of combinations. In this case again, there are numerous possibilities. A general answer to the question of the most convenient combinations is not available. However, from the many published syntheses one can sift out some combinations that have proved effective time and again.

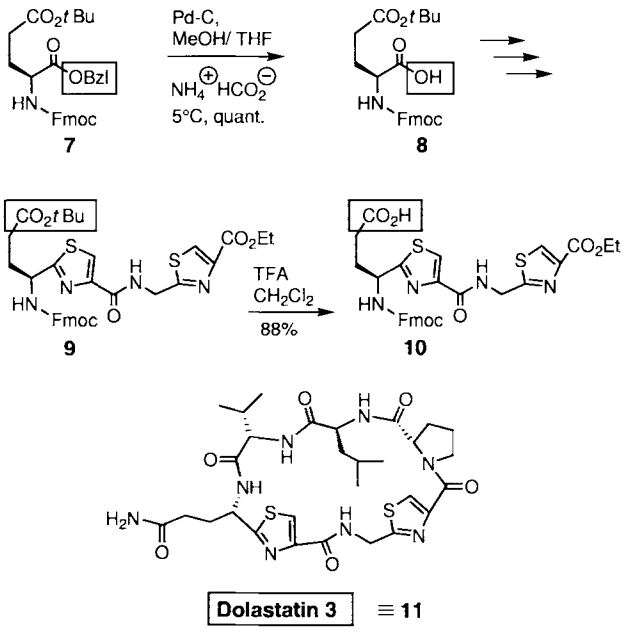
3.1.1. Acid Hydrolysis/Base Hydrolysis/Hydrogenolysis

The combination of acid-labile, base-labile, and hydrogenolytically labile protecting groups is a frequently used protecting group strategy. In oligonucleotide chemistry, for instance, the acid-labile dimethoxytrityl ether is typically used to protect hydroxyl functions, base-labile amides mask the amino groups of the nucleobases, and base-labile phosphate esters block the phosphate groups (Scheme 18). Similarly, in solid-



Scheme 18. Oligonucleotide synthesis with acid-labile alcohol protecting groups and base-labile linkers and amino protecting groups. R = phenyl, isobutyl, etc.

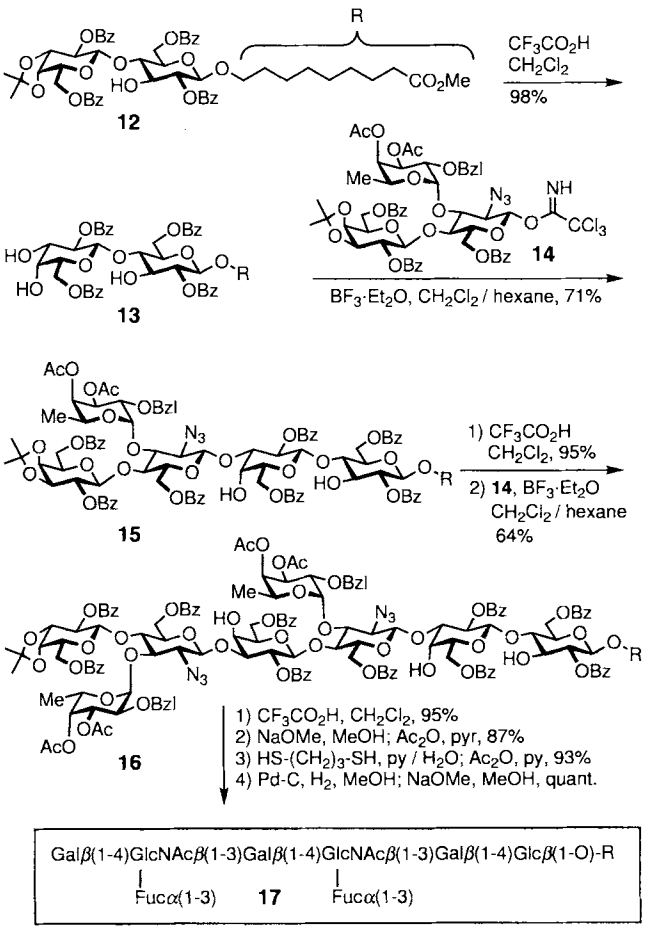
phase peptide synthesis the base-labile Fmoc group is frequently used to block the N-terminus, while an acid-sensitive function links the C-terminal carboxylic acid and the polymeric carrier (that is, an acid-labile, polymeric protecting group). The orthogonal stability of all three types of protecting groups has, for example, been employed in the synthesis of a precursor of the dolastatin cytostatics by R. C. Kelly et al. (Scheme 19).[38a]



Scheme 19. The combination of acid-labile, base-labile, and reduction-labile protecting groups in the synthesis of a precursor of dolastatin 3 (**11**) by R. C. Kelly et al. [38a].

selectively protected glutamic acid derivative **7** the α-benzyl ester was selectively removed by hydrogenolysis and then the desired bisthiazole unit was constructed. Acid-mediated cleavage of the γ-*tert*-butyl ester in **9** opened up the possibility of converting the γ-carboxyl group of glutamic acid into the amide. In both steps the Fmoc group remained intact. This group can be removed under basic conditions, if required, and the amino acid N-terminus can be extended.[38b]

Among the classical combinations of protecting groups is the simultaneous use of acid-labile acetals for the protection of carbonyl groups or 1,2-diols, base-labile esters, and reductively cleavable benzyl groups. This strategy is often used, particularly in the field of carbohydrate chemistry, as illustrated by the synthesis of the dimeric Lewis^x antigen described by R. R. Schmidt et al. (Scheme 20).[39] In this case, the isopropylidene group of



Scheme 20. Synthesis of the dimeric Lewis^x antigen by R. R. Schmidt et al. [39].

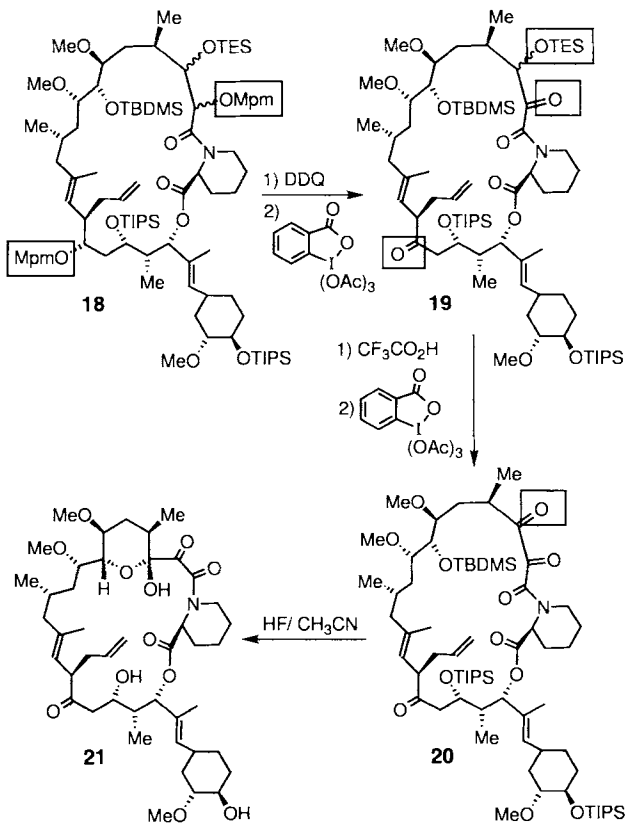
the lactoside **12** was initially removed by acid hydrolysis. Of the two liberated hydroxyl groups present in **13**, only the equatorial reacts in the subsequent glycosylation with the activated trisaccharide **14**. A combination of base-labile esters (acetate and benzoate), a benzyl ether, and, again an acid-labile acetal are present in the resulting pentasaccharide **15**. The benzyl group in the fucose unit of **15** ensures that the correct stereochemistry is produced in the introduction of this monosaccharide (see also Section 3.5); the acetates increase the stability of the O-fucosidic bond towards acidic conditions.[40] The acetal protecting group was again selectively removed from the complex pentasaccharide **15** by acidic hydrolysis. This made possible repeated glycosylation with the trisaccharide unit **14**, leading to the complete octasaccharide **16**. Finally, all the protecting groups were successively removed from **16**.

As demonstrated in this example, acetals are commonly employed as temporary protecting groups, whereas benzyl and acyl protecting functions are preferred as permanent protecting groups. When all such groups are removed to give the target compound, the acyl groups are typically removed before the benzyl ethers, in order to minimize steric hindrance in the final heterogeneous catalytic hydrogenolysis. For this reason, it can be advisable to exchange benzyl for acyl protecting groups as early in the synthesis as possible (see Section 3.3).

Examples of alcohols protected as acyclic O,O-acetals are given in Schemes 40, 45, and 50. Oxidation-labile and acid-labile protecting groups can also be advantageously combined. In the example in Scheme 41 the oxidatively cleavable (but also acid-labile) Mpm and Dmpm ethers were combined with an acid-labile dimethyl acetal.

3.1.2. Fluoride-Labile Protecting Groups in Combination with Oxidation-Labile Functions

The 4-methoxybenzyl (Mpm) and 2,4-dimethoxybenzyl (Dmpm) ether groups, which are cleaved by oxidation to quinone methides, can be favorably combined with a range of different protecting groups. Their combination with fluoride-labile silyl ethers has proved to be particularly effective. This combination rarely gives problems, since the substituted benzyl ethers are completely inert towards the fluoride ion. The

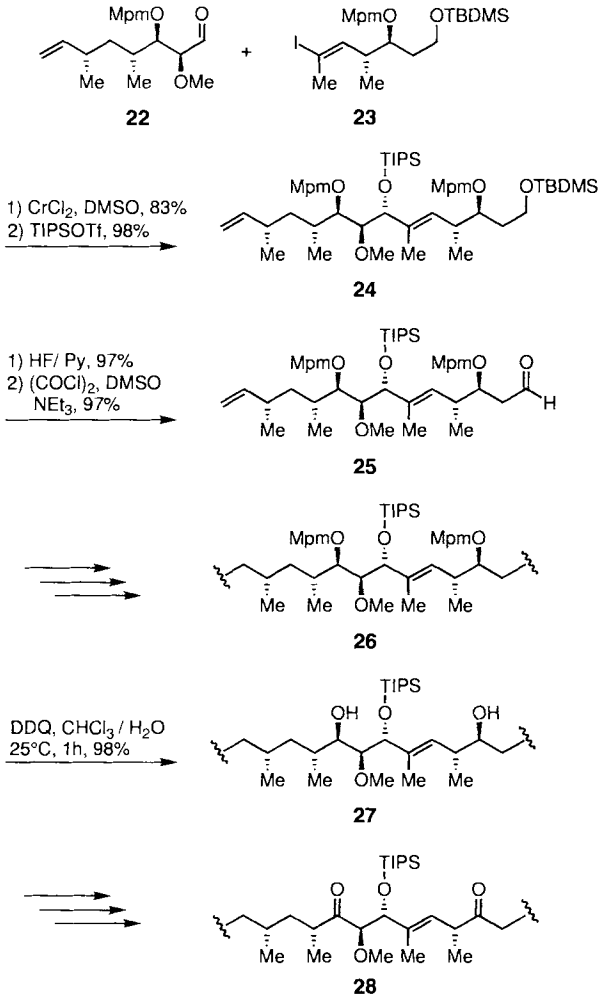


Scheme 21. Final transformations in the synthesis of the immunosuppressant FK506 (**21**) by S. L. Schreiber et al. [41].

oxidants DDQ and CAN (see Section 2.3), which are used for the oxidative cleavage of the Mpm and Dmpm groups, can in the worst case attack only the most labile silyl ethers such as the TMS group, which is seldom used in any case due to its high hydrolytic lability.

An illustration of the use of Mpm ethers in concert with various silyl ethers is provided by the synthesis of the immunosuppressant FK506 (**21**) by S. L. Schreiber et al. (Scheme 21).[41] Two hydroxyl groups are masked as substituted benzyl ethers and four others as different silyl ethers in the advanced intermediate **18**. Oxidation with DDQ cleaved the alkoxybenzyl ethers selectively, and the hydroxyl group thus liberated was then oxidized with Dess–Martin periodinane to give the corresponding diketone **19**. Of the various silyl groups in **19** (for a discussion of their relative stabilities see Section 3.2.2), the most labile was removed by treatment with acid and the selectively demasked hydroxyl group was then oxidized to give triketone **20** (see Section 3.4 for the strategy of masking carbonyl groups by the temporary introduction of hydroxyl groups as "stand-ins"). The synthesis was completed by the simultaneous cleavage of the remaining silyl groups.

The combination of Mpm and silyl ethers also proved its worth in the synthesis of the immunosuppressant rapamycin by K. C. Nicolaou et al. (Scheme 22).[42] In this case, the hydroxyl group in the product obtained from the Cr^{II}-mediated addition of vinyl iodide **23** to aldehyde **22** was blocked as a TIPS ether. The TBDMS group was cleaved selectively (see Section 3.2.2) and the deblocked hydroxyl group was oxidized to give aldehyde **25**, which enabled a subsequent aldol reaction (**25** → **26**). Intermediate **26** carries both Mpm groups and a TIPS ether, and the methoxybenzyl ethers were selectively removed by oxidation. The resulting diol **27** was oxidized to provide the dicarbonyl compound **28**. The TIPS ether remained intact in this reaction sequence and was removed only at the end of the synthesis.

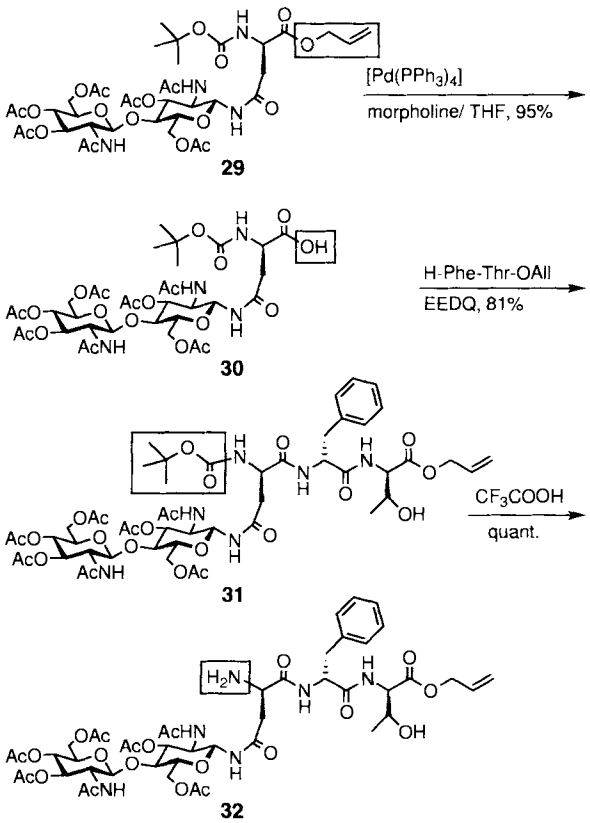


Scheme 22. Sections of the synthesis of the immunosuppressant rapamycin by K. C. Nicolaou et al. [42].

3.1.3. *Allyl Groups with Acid- and Base-Labile Protecting Groups*

Allyl groups can be profitably utilized in combination with a wide variety of other protecting groups, in particular acid- and base-labile blocking groups, as they are readily cleaved by means of Pd-, Rh-, and Ir-catalyzed reactions (see Section 2.7). Carboxylic acids, amines, and alcohols can be blocked as allyl esters, allyl urethanes, allyl ethers, and allyl carbonates. In the past ten years the increasing number of examples in which allylic groups are removed in crucial deblocking steps proves that this protecting group has assumed a permanent position in protecting group chemistry.

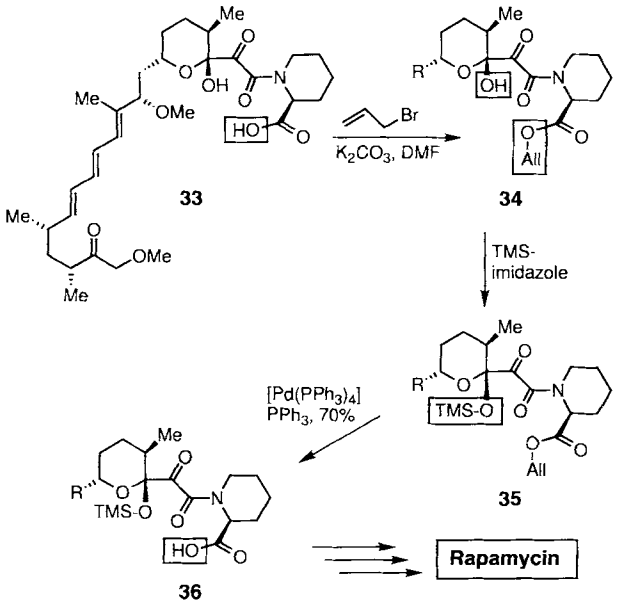
One of the first demonstrations of the effectiveness of allyl protecting groups in the synthesis of complex molecules was provided by the synthesis of glycopeptide **32** by H. Kunz et al. (Scheme 23).[43] The allyl group in the glycosylated allyl ester of asparagine **29** was transferred to morpholine in almost quantitative yield in a Pd^0-catalyzed reaction. Neither the acid-labile *tert*-butylurethane, nor the glycosidic bond, nor the base-labile



Scheme 23. Application of allyl esters in a glycopeptide synthesis by H. Kunz et al. [43]. EEDQ = ethyl-2-ethoxy-1,2-dihydroquinoline-1-carboxylate.

acetates of the carbohydrate moiety were attacked under these conditions.

The especially mild conditions for the cleavage of allyl esters were also used to advantage by S. Danishefsky et al. in the synthesis of the immunosuppressant rapamycin[44] (Scheme 24). Attempts to activate the carboxyl group in the advanced intermediate **33** prior to a condensation reaction resulted in lactonization at the tertiary OH group of the tetrahydropyranyl

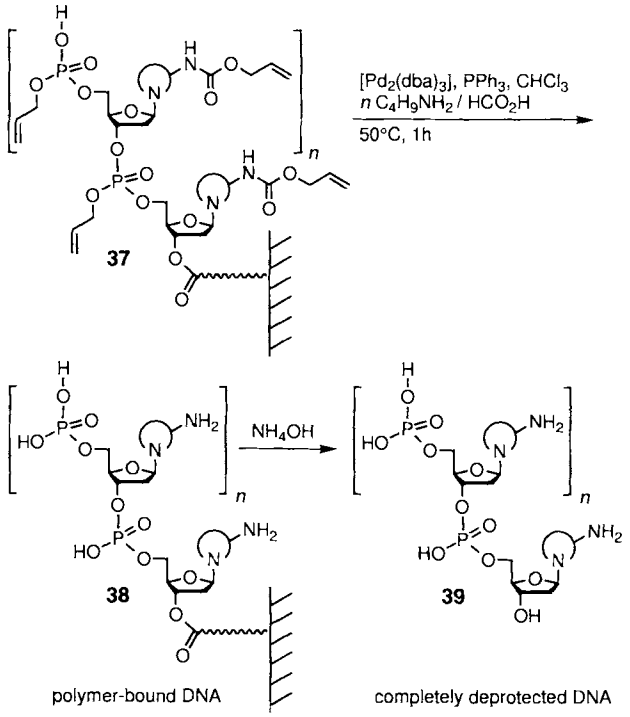


Scheme 24. Section of the synthesis of rapamycin by S. Danishefsky et al. [44].

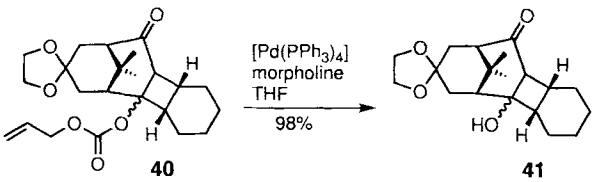
ring. The OH group therefore had to be protected. To avoid side reactions, it was necessary to mask the carboxylic acid as an allyl ester and then to silylate the remaining free hydroxyl group in **34**, leading to the doubly protected **35**. At this point the carboxyl group could be deprotected. The Pd^0-mediated removal of the allyl ester in **35** proceeded under such gentle conditions that neither the complex molecular framework (including the α-ketoamide) nor the acid- and base-labile TMS ether were lost or damaged.

R. Noyori et al. relied on allyl groups to protect amines and phosphates in the preparation of oligonucleotides[45] (Scheme 25). They employed O-allyl-masked phosphoroamidites as condensation reagents and allyloxycarbonyl (Aloc) protected nucleobases for the construction of oligonucleotides **37** on the solid phase. When the synthesis was complete, all of the allyl protecting groups in the polymer-bound oligonucleotide were removed in a single step. The DNA oligomers **38** thus obtained, which are still bound to the polymer carrier, can be used directly for biological tests or can be cleaved from the solid phase. In one example, the simultaneous cleavage of 104 allyl groups led to the 60mer **39** in an overall yield of 25% and in high purity. (When conventional protecting groups were used an overall yield of 6% was obtained.)

Blechert et al. incorporated the targeted cleavage of an allyl carbonate into the synthesis of a biologically active analog of the antitumor alkaloid taxol[46] (Scheme 26). The allyl carbonate in **40** was cleaved in almost quantitative yield without attack at the ketal or ring expansion by fragmentation of the base-labile β-hydroxyketone unit.

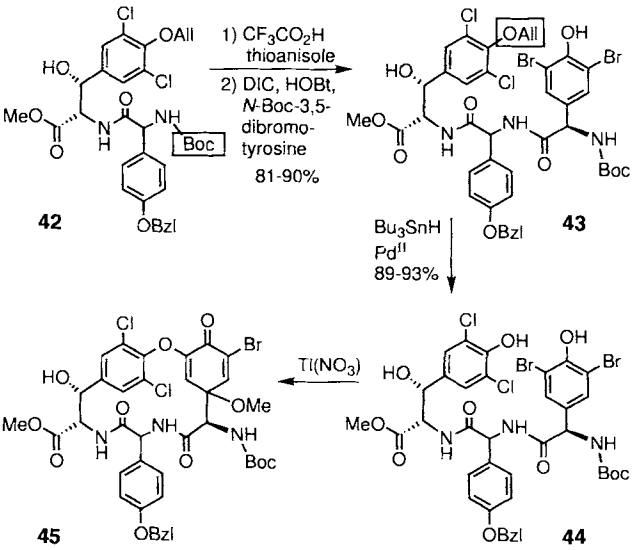


Scheme 25. Application of allyl protecting groups in the synthesis of oligonucleotides by R. Noyori et al. [45]. dba = dibenzylideneacetone.



Scheme 26. Cleavage of an allyl carbonate in the synthesis of a taxol analog by S. Blechert et al. [46].

The selective cleavage of an allyl ether was employed by D. A. Evans in the synthesis of vancomycin[47] (Scheme 27). The Boc group in peptide **42** was specifically removed with retention of



Scheme 27. Section of the synthesis of vancomycin by D. A. Evans et al. [47]. DIC = diisopropylcarbodiimide, HOBt = 1-hydroxybenzotriazole.

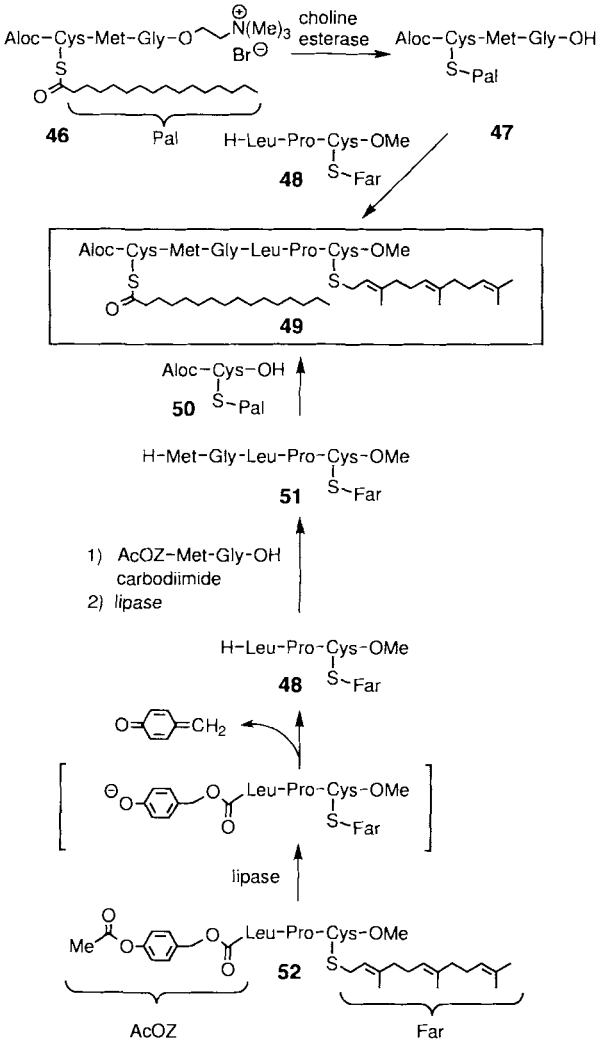
the phenolic allyl ether, thus enabling selective extension of the amino acid chain to give **43**. Removal of the allyl group under mild conditions provided phenol **44**, and subsequent oxidative ring closure yielded the cyclic product **45**.

3.1.4. Enzyme-Labile Protecting Groups with Acid- and Base-Labile Groups

Owing to the often distinct chemo-, regio-, and stereoselectivity of enzyme-mediated transformations, enzyme-labile protecting groups can be combined with other protecting groups that can be removed by classical chemical techniques (see Section 2.4). Enzyme-catalyzed reactions are invaluable especially when

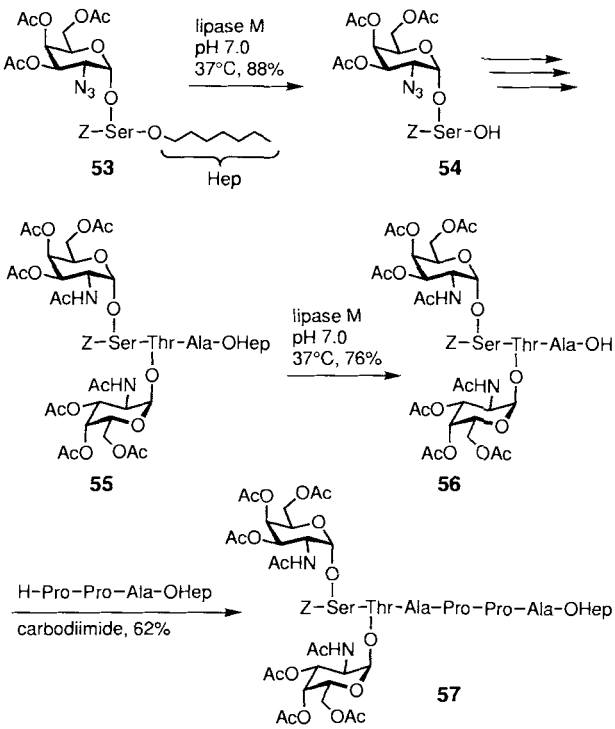
- the substrate is so labile that only the most gentle deblocking methods are tolerated.
- the chemo-, regio-, and stereoselectivity of the enzyme imparts orthogonality to protecting groups which, under classical deblocking methodology, would have similar or even inverted lability.

Both principles were utilized in the chemoenzymatic synthesis of the S-palmitoylated and S-farnesylated C-terminal lipohexapeptide of the human N-Ras protein **49**[24, 26] (Scheme 28). This type of modified lipoprotein cannot be deblocked under basic conditions because the labile palmitic acid thioester group would be preferentially hydrolyzed. Under acidic conditions the double bonds of the farnesyl moiety are attacked. However, the C-terminus of the peptide chain was successfully deprotected by selective enzymatic hydrolysis of the choline ester in **46** without attack on the palmitic acid thioester. The observed chemoselectivity here is exactly opposite to that found in the nonenzymatic conversion. Extension of the peptide chain in **47** with the farnesylated tripeptide **48** yielded the desired lipopeptide **49**. Alternatively, the N-terminal AcOZ protecting group in **52** could be removed by lipase-initiated spontaneous fragmentation under neutral conditions and without attack on the C–C double bonds. After extension of the peptide chain in **48** with a further AcOZ-protected dipeptide and enzymatic deprotection, the lipopentapeptide **51** was obtained, which afforded the acid- and base-labile Ras peptide **49** after treatment with the S-palmitoylated cysteine **50**. In these enzyme-catalyzed deprotections of urethane protecting groups, the biocatalyst differentiates between the C-terminal methyl ester and the aryl acetate incorporated in the urethane group.



Scheme 28. Chemoenzymatic synthesis of the S-palmitoylated and S-farnesylated C-terminal lipohexapeptide of the human N-Ras protein by H. Waldmann et al. [24, 26].

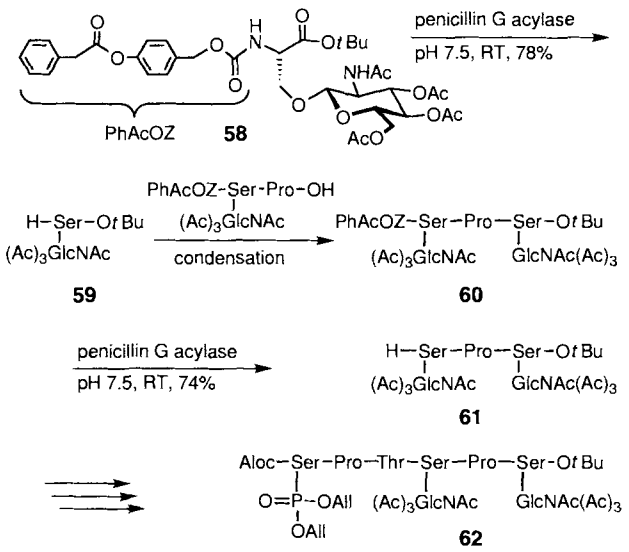
The advantageous properties of the enzyme-labile protecting groups also makes possible the chemoenzymatic synthesis of base- and acid-sensitive O-glycopeptides.[48, 49] Thus, the C-terminal heptyl ester of the glycosylated serine derivative **53** could be selectively cleaved by lipase-mediated hydrolysis[48] (Scheme 29). Glycopeptide **54** was condensed with an N-terminal deblocked glycodipeptide to give **55**, and enzymatic removal of the heptyl ester was still efficient. Compound **56**, accessible in this way in high yield, was subsequently extended to provide the glycohexapeptide **57**. This compound represents a characteristic



Scheme 29. C-terminal enzymatic deprotection of glycopeptide heptyl esters by H. Waldmann and H. Kunz et al. [48].

fragment of a tumor-associated antigen that appears on the surface of human breast cancer cells.

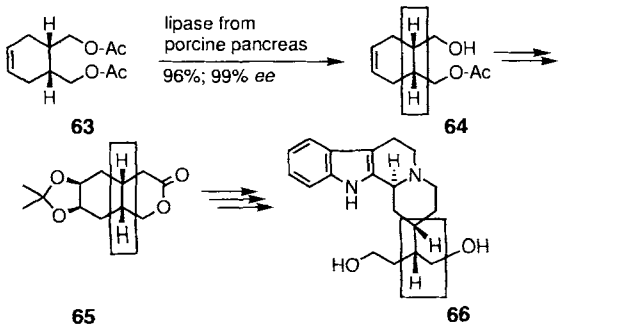
Selective N-terminal cleavage of a phenylacetoxybenzyloxycarbonyl (PhAcOZ) urethane group (analogous to the AcOZ group) in O-glycopeptides was accomplished by action of penicillin G acylase[49] (Scheme 30). The enzymatic cleavage of this



Scheme 30. Use of the enzyme-labile PhAcOZ group in the synthesis of a hexapeptide sequence of a partially processed RNA polymerase by H. Waldmann et al. [49]. RT = room temperature.

urethane protecting group in **58** yielded **59**, which was condensed with a further glycosylated dipeptide to give **60**. The N-terminal protecting group in **60** was removed enzymatically in a selective manner, and the peptide **61** thus liberated was finally converted into the phosphorylated and glycosylated peptide conjugate **62**, a characteristic sequence of a partially processed RNA polymerase. In the enzymatic transformations described in Schemes 29 and 30, no undesired attack on the acetate esters in the carbohydrates was observed, and neither β-elimination of the carbohydrate moiety nor anomerization of the glycosidic bonds take place.[48–50]

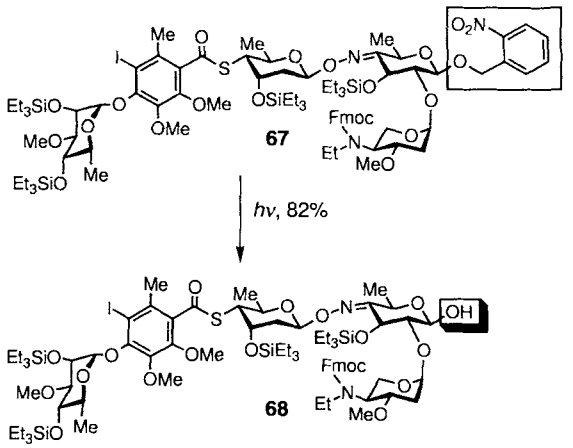
The stereoselectivity of enzyme-mediated reactions can also be used advantageously for the preparation of specifically functionalized and protected synthetic intermediates. An example of this is the desymmetrization of the *meso* diacetate **63** in the enantioselective synthesis of the indole alkaloid (−)-anthirin (**66**) by G. Lesma et al.[51] (Scheme 31). Diester **63** was converted into the monoprotected diol **64** with essentially complete selectivity by treatment with porcine pancreatic lipase. The configuration remained intact throughout the construction of the target compound **66** via intermediate **65**. Further applications[52] of such biocatalyzed transformations include syntheses of showdomycin,[53] biotin,[54] an analog of thromboxane A_2,[55] rhizoxin,[56] neplanocin A,[57] nicardipin,[58] chrysanthemic acid, permethric acid and caronic acid,[59] rifamycin,[60] compactin,[61] (+)-disparlure,[62] and aphanorphin.[63]



Scheme 31. Example of an enzymatic conversion in the synthesis of (−)-anthirin (**66**) by G. Lesma et al. [51].

3.1.5. *Photolabile Protecting Groups with Other Protecting Groups*

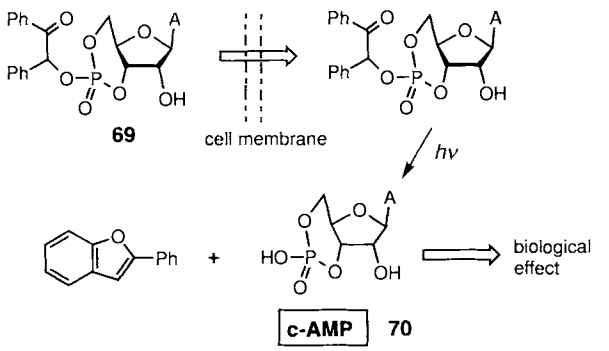
The cleavage of protecting groups by irradiation with light of a suitable wavelength lends itself well to an orthogonal protection strategy.[64] Many other protecting groups are not affected by these conditions, and thus no particularly advantageous combinations have emerged. One of the most impressive applications of this technique is found in the synthesis of the enediyne antitumor antibiotic calicheamicin γ_1^I by K. C. Nicolaou et al.[65] (Scheme 32). To activate the complex oligosaccharide of



Scheme 32. Application of a photolabile *o*-nitrobenzyl protecting group in the synthesis of calicheamicin γ_1^I by K. C. Nicolaou et al. [65].

the natural product towards the coupling reaction with the aglycone, the anomeric center of the terminal carbohydrate part of the fully protected intermediate **67** had to be liberated. The *o*-nitrobenzyl ether function proved to be a suitable protecting group. Due to its high stability, it could be introduced at an early point in the synthesis and remained intact even under drastic conditions such as treatment with methoxide, tetrabutylammonium fluoride, bromine, and diisobutylaluminum hydride. However, it was easily cleaved from **67** in high yield by photolytic conditions, under which the oxime group, the glycosidic bond, the thioester, the Fmoc group, and the silyl ether all remained intact.

The rate and selectivity of the photochemical deblocking is also an integral part of the "caging" technique used in biological studies[66] (Scheme 33). In this context a inactive substrate such as **69** having a photolabile protecting group is introduced into a biological system, for example, a cell. The protecting group is removed by an intense flash of light and the active compound, in this case **70**, is thereby liberated. The advantage of this method is the precise triggering of the deprotection and libera-



Scheme 33. Application of a photolabile protecting group in the "caging" method. A = adenine.

tion of the active species, making pharmacokinetics measureable, even for fast processes. The prerequisite for the use of the "caging" technique is that the photodecomposition products have minimal toxicity. The required excitation wavelength and intensity should also not damage the cell. The photolabile protecting group most frequently employed in synthesis is the *o*-nitrobenzyl group. Since the photochemical cleavage of this species leads to the production of the toxic *o*-nitrobenzaldehyde, other photolabile groups such as 1-pyrenylethyl[67] and the benzoin group[68] are commonly used for biological applications (see Scheme 33). An exception was described by W. Mäntele et al.,[69] who monitored the progress of a reaction by following the decomposition of an *aci*-nitro intermediate by IR spectroscopy.

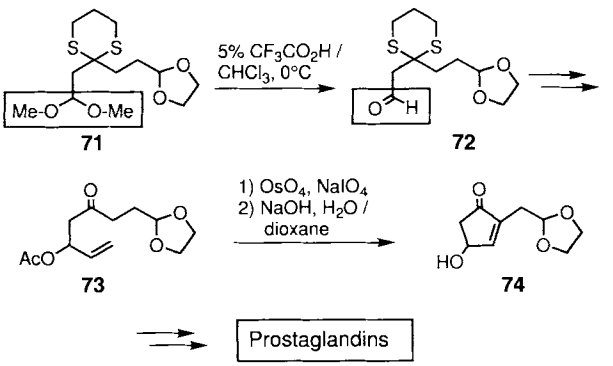
Although photochemically cleavable protecting groups offer many advantages, their use is restricted since the substance to be deblocked may not itself contain any photoexcitable functional groups. For this reason this protecting group strategy was not widely applied for a long time. In more recent developments, for example the establishment of anchor groups in combinatorial chemistry (see Section 5), photolabile protecting groups may play an increasingly important role.

3.2. Protecting Groups with Modulated Lability

Protecting groups with modulated lability are often utilized in organic synthesis, although they do not provide the same degree of safety offered by orthogonally stable functions. In particular, this strategy is applied when several of the same type of functional group are present in the molecule to be protected for which an insufficient number of orthogonal groups is available, or when the removal of the most stable protecting group could lead to undesired side reactions. In principle, protecting groups of modulated lability can be developed for each of the classes discussed in Section 2. Acid-labile, base-labile, and fluoride-labile protecting groups have proved to be particularly suitable; oxidatively cleavable functions have more limited scope. The modulated lability of many protecting groups can be referred to in, for example, ref. [9].

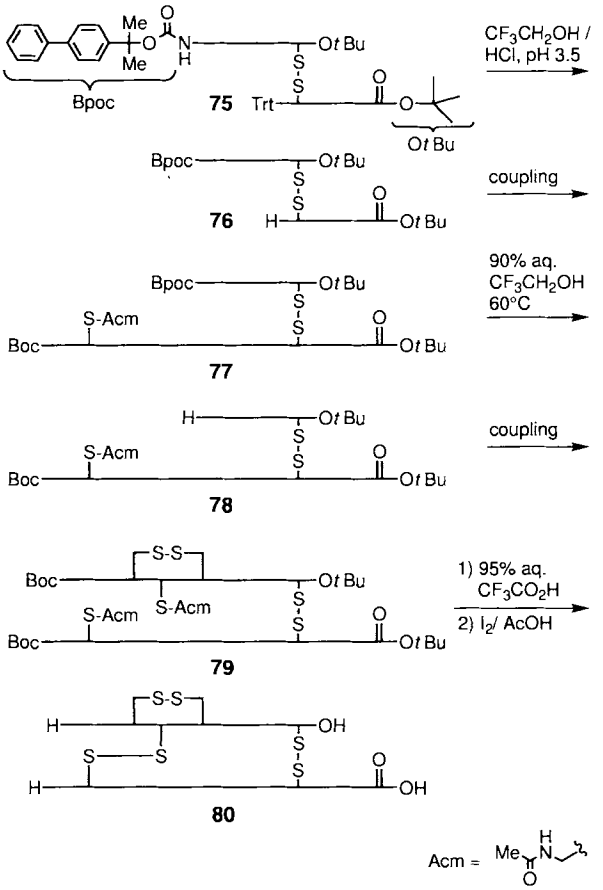
3.2.1. Modulated Acid- or Base-Lability

In many cases acetals have different labilities towards acids. For instance, acyclic acetals are more sensitive than their cyclic equivalents to acidic conditions. This property was utilized by R. Ellison et al. in the synthesis of a prostaglandin precursor[70] (Scheme 34). The selective removal of the dimethyl acetal in **71** proceeded in almost quantitative yield and provided the liberated aldehyde **72**, which was used in chain extension. After the removal of the dithiane group, **73** was ready for ring closure, which yielded the desired functionalized prostaglandin precursor **74**.



Scheme 34. Use of acid-labile protecting groups with modulated lability in the synthesis of a prostaglandin precursor by R. Ellison et al. [70].

The principle of using protecting groups with modulated acid-lability has found repeated application in peptide chemistry (see Sections 2 and 4). This is exemplified by the synthesis of human insulin carried out by P. Sieber et al.[71] and sketched in Scheme 35. Compound **75** bears three protecting groups of

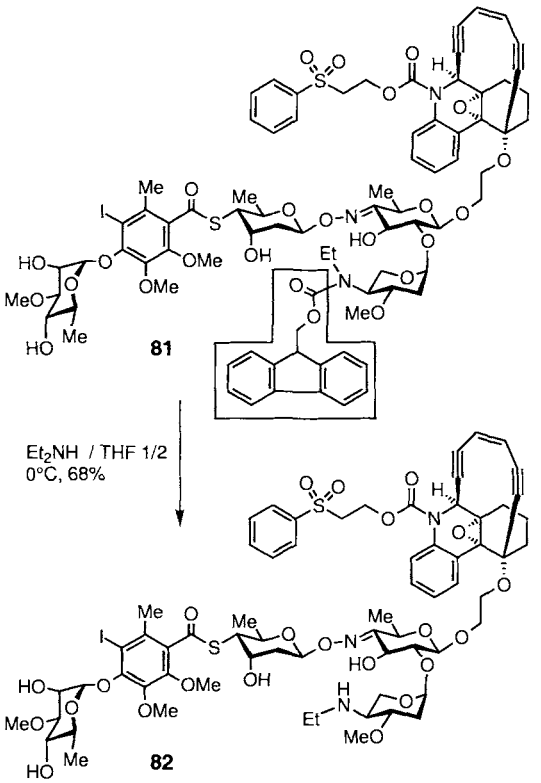


Scheme 35. Use of acid-labile protecting groups with modulated lability in the synthesis of human insulin by P. Sieber et al. [71].

varying lability—the *tert*-butyl ester and the Bpoc and trityl (Trt) groups. First the trityl group was removed selectively in the presence of the Bpoc group, which is likewise very acid-sensitive. After extension of the B chain (**76** → **77**), the Bpoc group was selectively removed. The A chain was completed by coupling **78** with a similarly Boc-protected peptide. All the *tert*-butyl protecting groups in **79** were then simultaneously cleaved. After the cysteine side chain was deblocked, ring closure provided insulin **80**.

While the synthesis shown in Scheme 35 proves that this methodology can be quite successful, it has not found widespread use in peptide chemistry due to the potential of losing protecting groups required later in the synthesis. Owing to their greater reliability, orthogonal protecting strategies are generally preferred.

The modulated based-lability of two urethane protecting groups was used by K. C. Nicolaou et al. in the synthesis of a calicheamicin–dynemicin hybrid[72] (Scheme 36). The 2-fluorenylmethoxycarbonyl (Fmoc) group was removed from the complex glycoside **81** by treatment with diethylamine, without attack at the similarly base-labile 2-phenylsulfonylethoxycarbonyl (Psec) group. The cleavage of this group under basic conditions later triggered the liberation of the "warhead", which is buried in the dynemicin aglycone of **82**.



Scheme 36. Use of amino protecting groups of differing lability in the synthesis of a calicheamicin–dynemicin hybrid by K. C. Nicolaou et al. [72].

3.2.2. *Modulated Lability of Silyl Protecting Groups*

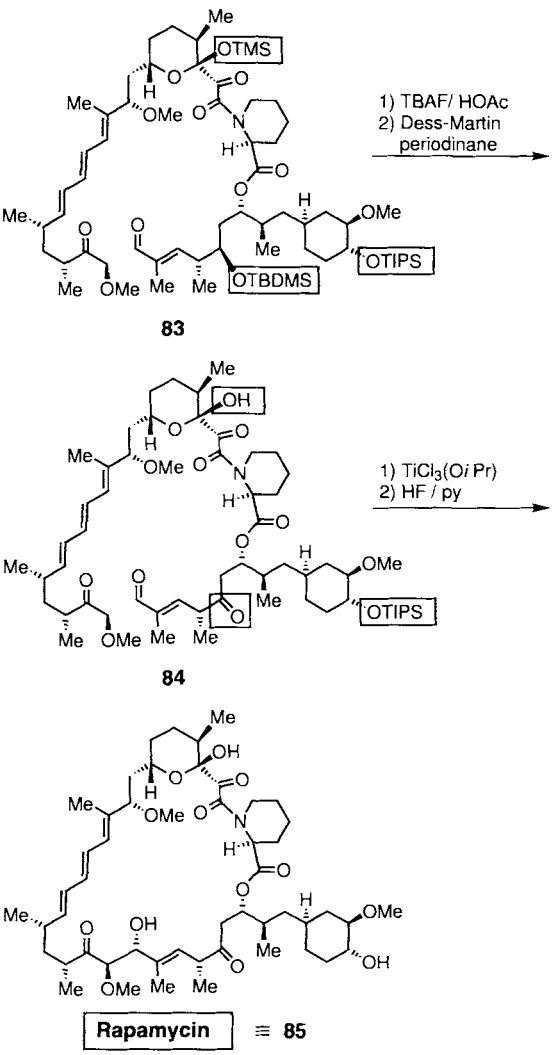
The lability of silyl groups towards acids, bases, and fluoride ions can be specifically tuned by varying the substituents on silicon. Scheme 37 indicates the relative rates of hydrolysis of various silyl ethers under acidic and basic conditions. (The order of the cleavage rates on treatment with fluoride ions is similar.) As a consequence of this range of activities, silyl ethers with modulated solvolytic activity are now commonly used in synthesis.

Relative stability of silyl ethers	R–O–SiR'$_3$
Acidolysis:	R'$_3$Si: Me_3Si (1) < Et_3Si (64) < tBuMe$_2$Si (20000) < iPr$_3$Si (700000) < tBuPh$_2$Si (5000000)
Basic solvolysis:	R'$_3$Si: Me_3Si (1) < Et_3Si (10-100) < tBuMe$_2$Si ≈ tBuPh$_2$Si (20000) < iPr$_3$Si (100000)

Scheme 37. Relative rates of hydrolysis for silyl ethers R–O–SiR'$_3$ (k_{rel}^{-1}).

tert-Butyldimethylsilyl (TBDMS) ethers can be cleaved with, for example, tetrabutylammonium fluoride (TBAF), while the cleavage of the more stable triisopropylsilyl (TIPS) and the *tert*-butyldiphenylsilyl (TBDPS) protecting groups requires solutions of HF in pyridine, acetonitrile, or even water.

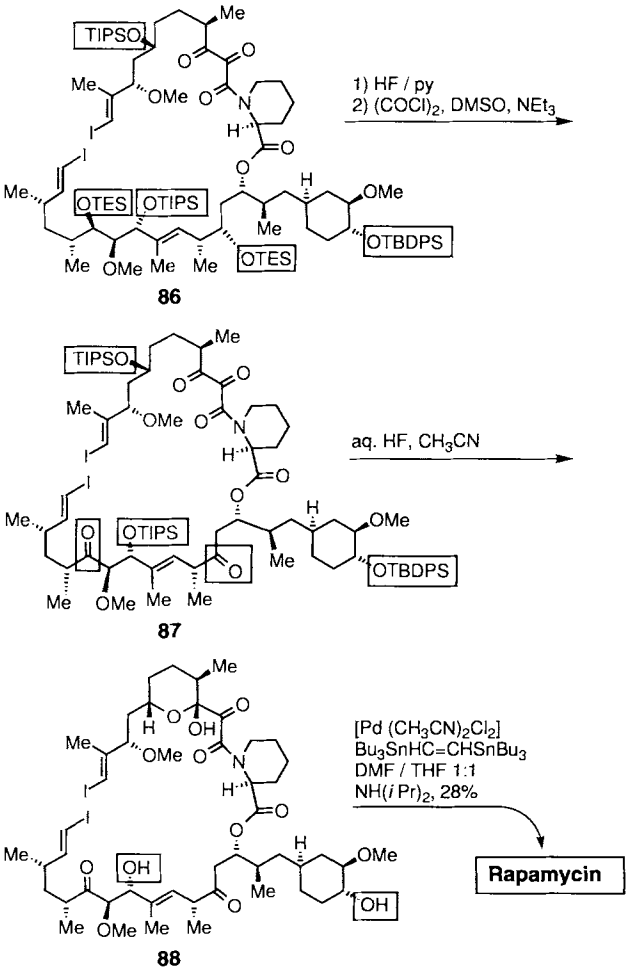
These clear differences in reactivity were employed by Danishefsky et al. in the synthesis of the immunosuppressant rapamycin[44] (Scheme 38). When intermediate **83**, which con-



Scheme 38. Use of silyl protecting groups of modulated lability in the synthesis of rapamycin (**85**) by S. Danishefsky et al. [44].

tains a TMS, a TBDMS, and a TIPS ether, was treated with TBAF, the TMS and the TBDMS ethers were cleaved, but the TIPS ether remained intact. After oxidation of the liberated secondary hydroxyl group, the macrocyclic ring was closed, and finally the TIPS ether in the cyclohexane moiety in **84** was cleaved with a solution of HF in pyridine to yield the natural product **85**.

The different stabilities of silyl ethers was also utilized by K. C. Nicolaou et al.[42] in their synthesis of rapamycin. Scheme 22 indicates that treatment of **24** with HF/pyridine removed only the TBDMS protecting group, while the TIPS-protected secondary hydroxyl group remained intact. A similar strategy was used in the last steps of this synthesis (Scheme 39).

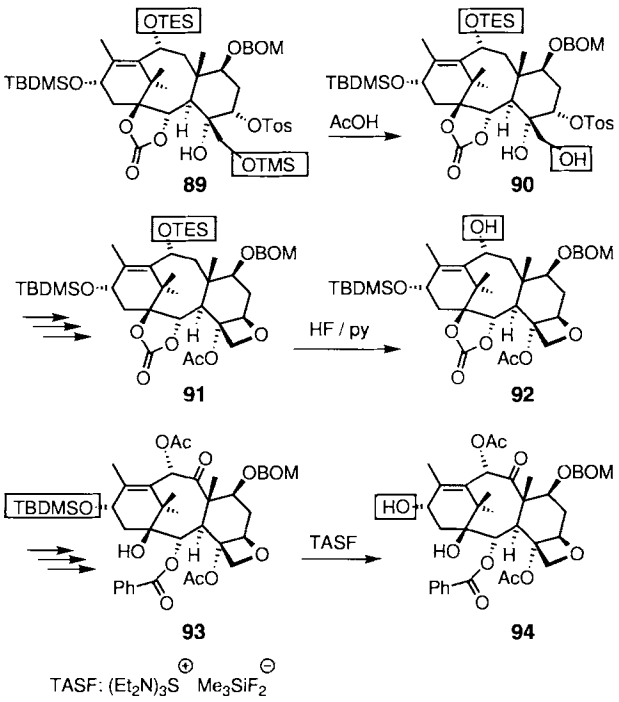


Scheme 39. Use of silyl protecting groups of modulated lability in the synthesis of rapamycin by K. C. Nicolaou et al. [42].

Of the five silyl protecting groups present in **86**, only the TES ethers were cleaved by HF/pyridine. Thus the selective oxidation of the liberated secondary hydroxyl groups to give the corresponding carbonyl groups could be carried out. The remaining, more stable silyl ethers were cleaved by treatment with HF in CH_3CN/H_2O, and the synthesis was subsequently concluded by Pd^0-mediated coupling of the two vinyl iodides.

The differing acid sensitivity of silyl ethers allowed S. Schreiber et al. to selectively deblock an advanced intermediate in the synthesis of FK506[41] (Scheme 21). Macrocycle **19** contains TIPS, TBDMS, and TES protecting groups, of which only the TES group was removed by treatment with aqueous trifluoroacetic acid, allowing the selective oxidation of only one of the four hydroxyl groups.

R. A. Holton et al. took advantage of the varying lability of silyl ethers towards both bases and different sources of fluoride ions in the synthesis of the antitumor agent taxol[73] (Scheme 40). Thus, treatment of **89** with acetic acid cleaved only

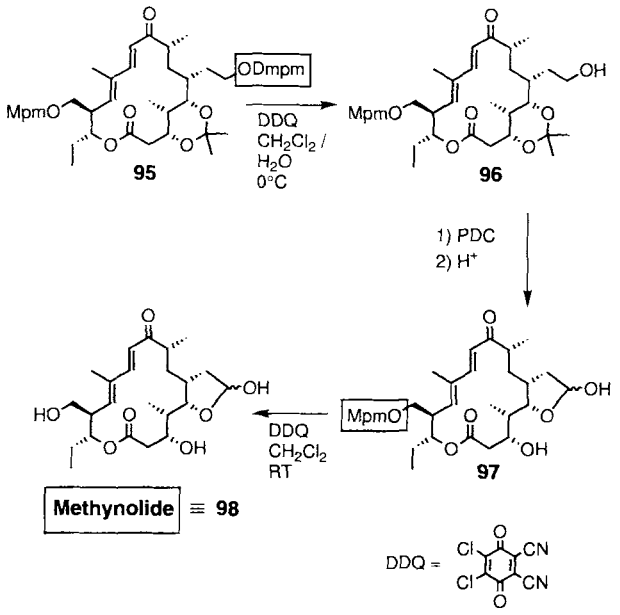


Scheme 40. Use of silyl protecting groups of modulated lability in the synthesis of taxol by R. A. Holton et al. [73].

the TMS ether; the other acid-labile groups, the BOM acetal and the other silyl groups, remained intact. After transformation of **90** into the oxetane **91**, the TES group was selectively removed by treatment with HF/pyridine. The central eight-membered ring was oxygenated as required in the position adjacent to the free hydroxyl group. Finally, the remaining TBDMS protecting group was removed with the reagent TASF (see Scheme 40; this conversion failed with TBAF) to allow the attachment of the side chain.

3.2.3. Modulated Oxidation-Lability

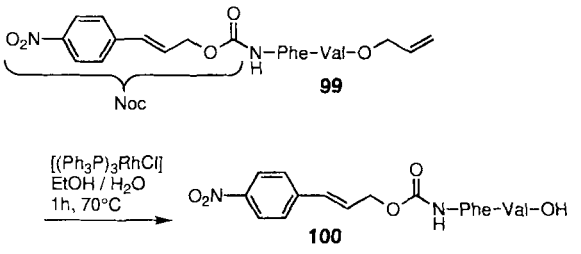
The oxidation-labile Mpm and Dmpm ethers (see Section 2.6) are attacked at different rates by dichlorodicyanoquinone (DDQ) at 0–5 °C. This modulated lability can be employed advantageously in the synthesis of polyfunctional target compounds, including those containing C–C double bonds. Thus, in the course of a total synthesis of methynolide (**98**), O. Yonemitsu et al. cleaved the more electron-rich, and therefore more easily oxidized Dmpm group in **95** in the presence of an Mpm group by treatment with DDQ at 0 °C (Scheme 41).[74, 75] The hydroxyl group in **96** thus liberated was then oxidized to the



Scheme 41. Selective oxidative cleavage of the Dmpm group in the presence of the Mpm group in the synthesis of methynolide (**98**) by O. Yonemitsu et al. [74, 75]. PDC = pyridinium dichromate. RT = room temperature.

aldehyde, which cyclized to give the hemiacetal **97** following the acid-catalyzed hydrolysis of the adjacent acetal protecting group. Finally, the desired natural product was obtained by oxidative cleavage of the Mpm ether at room temperature.

Such fine-tuning of lability through the introduction of substituents can also be achieved for other types of protecting groups. Thus, for example, when a nitrophenyl substituent is attached to the allyl system of an allyloxycarbonyl (Aloc) group, cleavage of the resulting 4-nitrophenylallyl (Noc) urethane with Pd^0 and Rh^I catalysts is significantly slower than that of the simple unsubstituted allyl protecting groups.[76] As can be seen from Scheme 42, the allyl ester in dipeptide **99** can be cleaved selectively without attack on the Noc group.

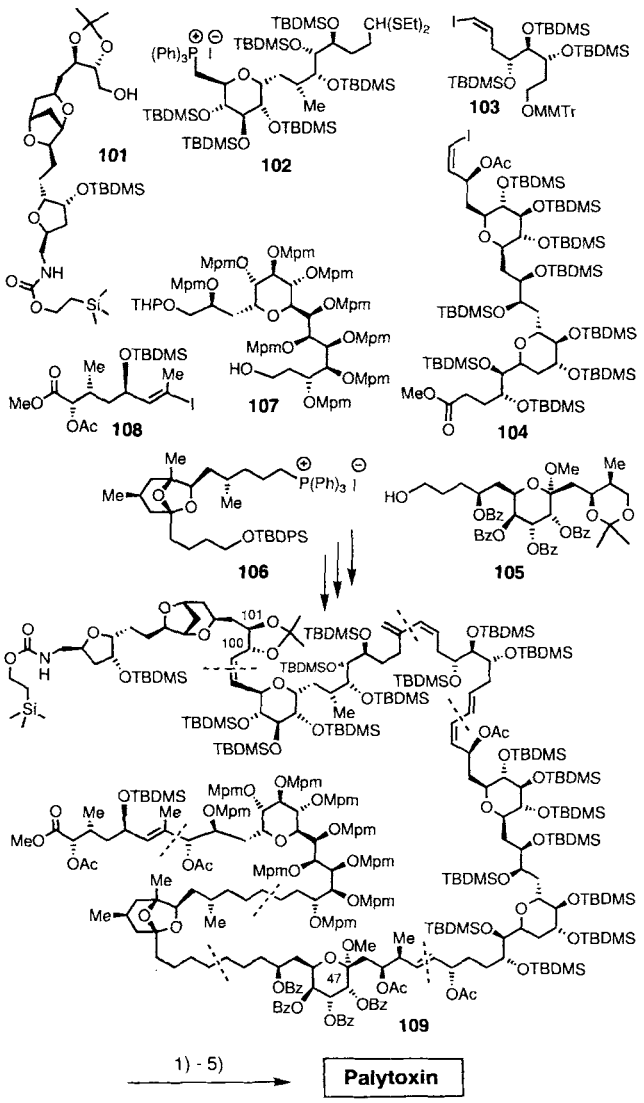


Scheme 42. Selective cleavage of an unsubstituted allyl ester in the presence of a nitrophenylallyl group by H. Kunz et al. [76].

3.3. Unification of Protecting Groups

In the construction of polyfunctional molecules the tactic of using several protecting groups that must be removed under drastically different reaction conditions can lead to problems in the late stages of a synthesis, for example after successful construction of the molecular framework. First, the molecule must be stable under all of the conditions used for deblocking. This stipulation must be made in the selection of protecting groups for each subunit in the whole molecule. It is thus possible that only a few—and under certain circumstances too few—of the available protecting groups fulfill this criterium. Second, such a strategy can lead to a significant increase in the number of steps required at the end of the synthesis, even to the point that the associated losses become crippling.

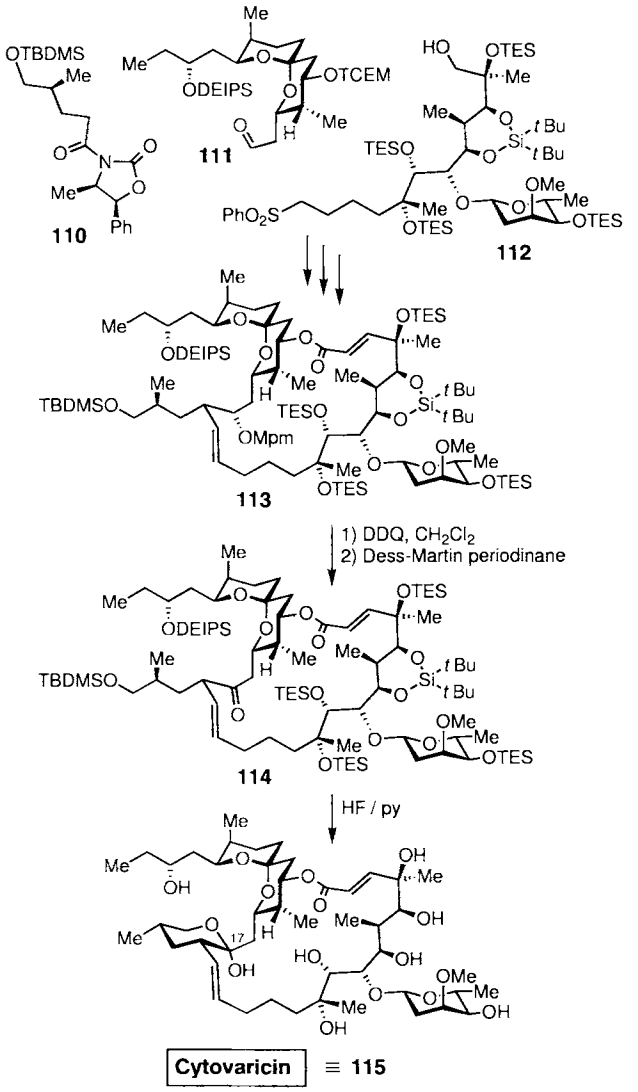
To avoid these problems, the following strategy is often followed, in particular in complex multistep syntheses. As early as possible in the synthesis, protecting groups are used that can be removed under the same conditions in order to unify the protecting group pattern as much as possible. For example, intermediates having a single type of protecting group can be designed and used from the beginning of a synthesis, thus automatically simplifying the problem. This strategy cannot be used if specific reactivities in the intermediates are eliminated in the course of the synthesis, or the directing effect of particular protecting groups is required (see Section 3.5). Then protecting groups in the intermediates must be removed and replaced with others that correspond to the type remaining in the molecule. Under certain conditions this can increase the length of the



Scheme 43. Part of the synthesis of palytoxin by Y. Kishi et al. [77]. 1) DDQ, tBuOH/CH_2Cl_2, room temperature (RT), then Ac_2O, DMAP in pyridine; 2) $HClO_4$ (1.18 N) in THF, 25 °C, 8 d; 3) 0.08 N LiOH, H_2O/THF (1:2:8), 25 °C, 20 h; 4) nBu$_4$NF in THF, 22 °C, 20 h; 5) AcOH/H_2O (1:9), RT, 12 h.

synthesis; however, the risk of losses is shifted toward earlier stages in the synthesis with the simpler and more readily available early intermediates.

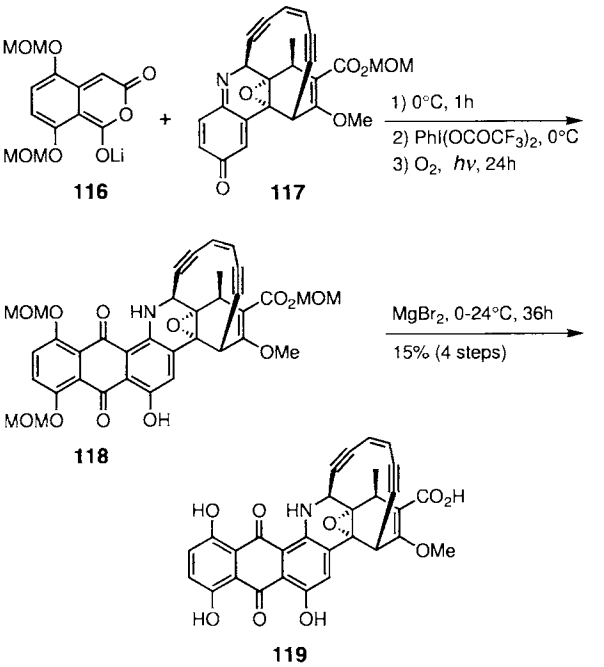
The strategy of creating the uniformly protected intermediates, which can be completely deblocked in only a few steps at the end of the synthesis, was followed by Y. Kishi et al. in the synthesis of the marine natural product palytoxin[77] (Scheme 43). The size of the molecule, sheer number of groups needing protection, and the long list of synthetic problems to be overcome made it very difficult to use only one type of protecting group. Intermediate **109** (Scheme 43) contains the complete and still completely protected molecular framework of palytoxin, which was formed by the coupling of fragments **101**–**108**. In **101**, **102**, **103**, and **104** the protecting groups are almost exclusively fluoride-labile, **105** and **108** incorporate esters of differing base-lability, and in **107** the hydroxyl groups are protected as oxidation-labile Mpm ethers. In addition, it was necessary to protect the hemiacetal at C-47 and the diol unit at C-100 and C-101 as acid-labile acetals. This significant unification of the types of protecting groups enabled efficient deblocking in only five steps at the end of this extremely arduous synthesis (Scheme 43).



Scheme 44. Synthesis of cytovaricin (**115**) by D. A. Evans et al. [78]. DEIPS = diethylisopropylsilyl, TCEM = trichloroethoxymethyl.

The strategy of choosing all the permanent protecting groups from the same class was demonstrated by D. A. Evans et al. in the synthesis of cytovaricin (**115**)[78] (Scheme 44). The intermediates **110**–**112** used to construct the protected form of the natural product **114** carried exclusively silyl protecting groups, all of which were removed in high yield in a single step at the end of the synthesis. The conditions required were so mild that the hemiacetal formed at C-17 remained stable and did not lose water and form a diene.

S. Danishefsky et al. used the same principle in the synthesis of the enediyne antibiotic dynemicin A[79] (Scheme 45). Thus

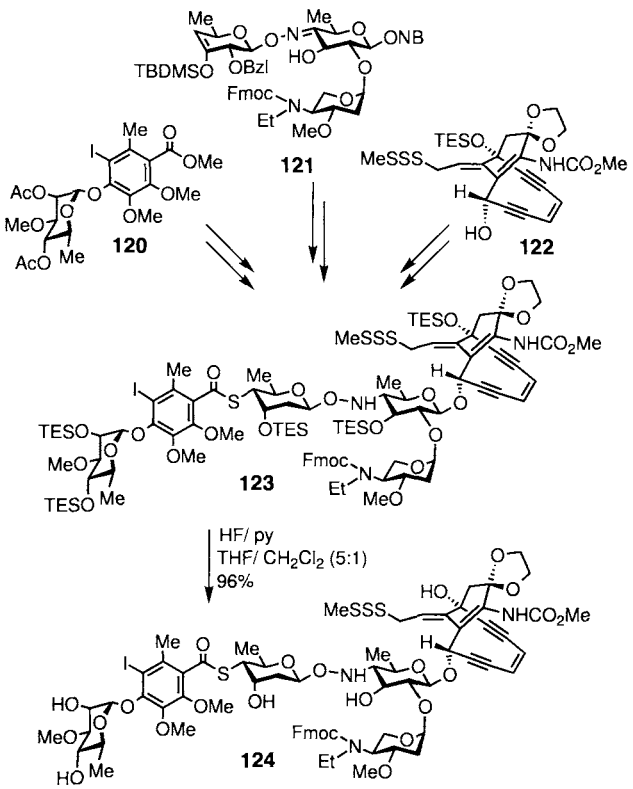


Scheme 45. Use of a single type of protecting group in the synthesis of dynemicin by S. Danishefsky et al. [79]. MOM = methoxymethyl.

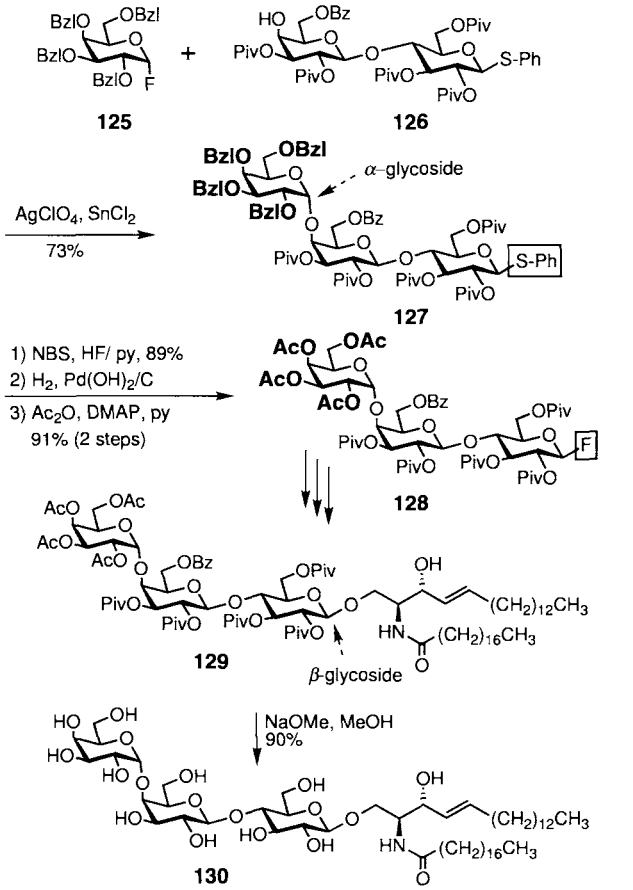
116 and **117** were fused to give compound **118** with three MOM acetal protecting groups, from which the sensitive natural product **119** was liberated.

The protecting group pattern of an advanced intermediate was changed by K. C. Nicolaou et al. in the synthesis of calicheamicin γ_1^I[65] (Scheme 46). The complex glycoside **123** was formed from the predominantly acyl-protected unit **120** and the intermediates **121** and **122**. After the coupling, the acetates were transformed into silyl ethers, which were cleaved in the same step as the silyl ethers originating from **121** and **122** by treatment with HF/pyridine in almost quantitative yield.

In the synthesis of the glycosphingolipid Gb_3 (**130**), K. C. Nicolaou et al.[80] swapped the reduction-sensitive benzyl ethers for the base-labile acetates and thus unified the pattern of protecting groups (Scheme 47). Because the galactosylfluoride **125** carried benzyl groups, its coupling with the partially deblocked glycosyl acceptor **126** yielded the trisaccharide **127** predominantly as the α-anomer. Intermediate **126** carried acyl protecting groups, guaranteeing a high degree of β-selectivity in the introduction of the sphingosine group (see also Section 3.5). At the stage of trisaccharide **127** the benzyl protecting groups were



Scheme 46. Change in the pattern of protecting groups in the synthesis of calicheamicin γ_1^1 by K. C. Nicolaou et al. [80]. NB = nitrobenzyl.

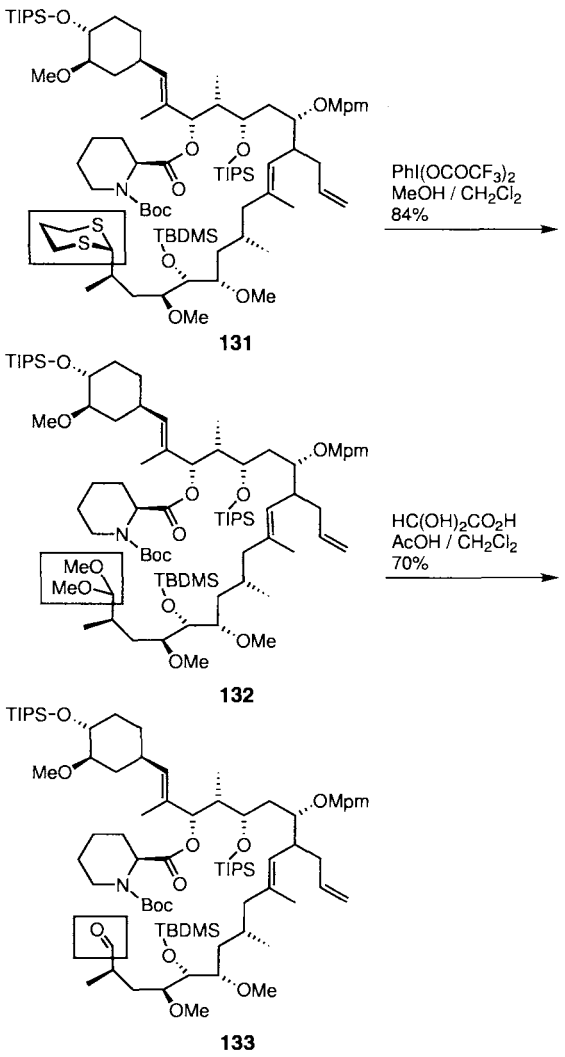


Scheme 47. Unification of the protecting group pattern in the synthesis of the glycosphingolipid Gb_3 (**130**) by K. C. Nicolaou et al. [81].

removed by hydrogenolysis and the hydroxyl groups thus liberated were immediately protected as acetates. The complete trisaccharide unit thus contained exclusively base-labile acyl protecting groups, which, at the end of the synthesis, were removed simultaneously in high yield. This strategy also proved to be very effective in the construction of the trimeric Lewis^x nonasaccharide.[81]

3.4. Introduction of "Stand-Ins"

In the synthesis of polyfunctional compounds, two factors can make the choice of protecting group strategy particularly difficult: the lability of the intermediates and the fact that sufficiently different enough protecting groups might not be available for a given type of functional group. Aldehydes and ketones are generally protected as thioacetals or O,O-acetals. An example of this is given by the synthesis of FK506 by S. Schreiber et al.,[41] a section of which is shown in Scheme 48. The terminal aldehyde was masked as a 1,3-dithiane in **131**; however, all attempts to liberate the protected carbonyl group by established methods afforded the desired product in very low



Scheme 48. Application of 1,3-dithiane and dimethyl acetal protecting groups in the synthesis of the immunosuppressant FK506 by S. L. Schreiber et al. [41].

yields. Only dethioacetalization employing a hypervalent iodine reagent as a mild oxidant gave satisfactory results. Even so, the aldehyde thus liberated was not isolated directly in the free state, but rather as the dimethyl acetal **132**. This very sensitive compound yielded **133** with the free aldehyde group after transacetalization with glyoxylic acid under mildly acidic conditions. This approach is practically identical to that employed by T. K. Jones et al. in the synthesis of FK506.[82]

The example just given illustrates that, despite the effectiveness of thioacetals and acetals as protecting groups, the conditions necessary for their removal often hinder their use. 1,3-Diols can also be protected as silylene derivatives, which are useful replacements for the acid-labile acetals (see **114** in Scheme 44). When such choices are not available, a completely different tactic must be used.

In one increasingly popular alternative strategy a "stand-in" is introduced for the required functional group. In the case of a carbonyl group, a masked alcohol can be used, which can be deprotected and subsequently oxidized to give the required aldehyde or ketone. Although a further protecting group must be introduced in following this strategy, many more masking groups are established for the hydroxyl function.

This methodology is illustrated by the synthesis of FK506 by S. Schreiber et al.[41] sketched out in Scheme 21. The very sensitive and reactive tricarbonyl unit in **20** was constructed right at the end of the synthesis by the deprotection and oxidation of the corresponding hydroxyl groups. The successive deblocking and oxidation prevented the formation of mixtures of products resulting from incomplete oxidation. TES- and Mpm-protected hydroxyl groups were employed as the "stand-ins" for the carbonyl groups, while the hydroxyl groups found in the final product (**20**) were masked as TIPS and TBDMS ethers.

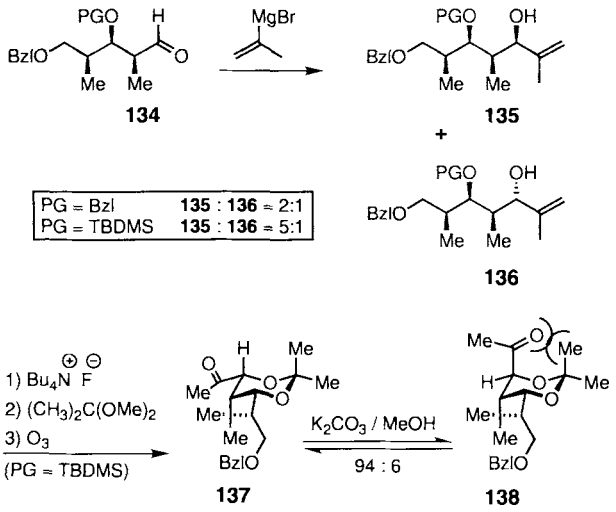
Similarly, in the synthesis of rapamycin by S. Danishefsky et al.[44] (Scheme 38) at a step close to the end of the synthesis, one of the three protected hydroxyl groups in **83** is selectively deblocked and oxidized to give a carbonyl group.

D. A. Evans et al. also used this strategy in the synthesis of cytovaricin[47] (Scheme 44). The hydroxyl group to be oxidized in **113** was present as the Mpm ether, whereas all other alcohols were blocked as silyl ethers. After cleavage of the benzylic protecting group with DDQ, the required carbonyl group was formed and finally the silyl groups removed. This approach was necessary because the hemiacetal formed in the last step is very sensitive (see Section 3.3.).

3.5. The Influence of Protecting Groups on the Course of Syntheses

One factor that should always be taken into account when planning a protecting group strategy is the potential of the protecting group, under certain circumstances, to actively influence the course of the synthesis.

For example, the ability (or lack of) of a protecting function to complex metal ions can be utilized to direct the stereochemical course of a reaction. This use of "(non)chelating" protecting groups is one of the best established tools of asymmetric synthesis.[83] Such an effect was used by J. Mulzer et al.[84] in the synthesis of erythronolide B (Scheme 49). The diastereomeric

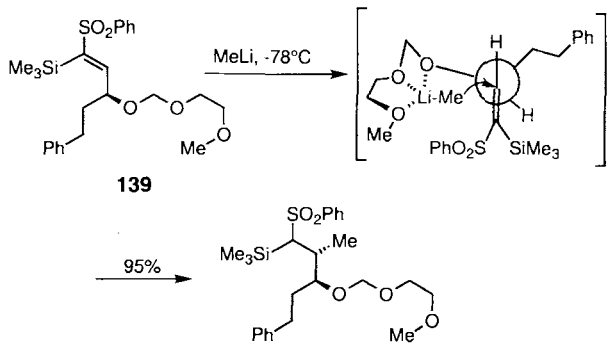


Scheme 49. Stereochemical directing effects of protecting groups in the synthesis of erythronolide B by J. Mulzer et al. [84].

ratio of **135** and **136** formed from the addition of propenylmagnesium bromide to the aldehyde **134** was dependent upon the type of ether function present in **134**. When the secondary hydroxyl group was protected as its benzyl ether, this ratio was 2:1; however, the corresponding silyl ether led to a 5:1 ratio of **135** and **136**. The silyl group hindered the formation of a 1,3-chelate leading to *anti*-**136** and favored the development of a Felkin–Anh transition state leading to the *syn*-diol. The diastereomeric ratio could be increased further by manipulation of the protecting groups. The mixture of **135** and **136** was converted to the acetonides **137** and **138**. An unfavorable 1,3-diaxial interaction of the ketone with one of the methyl groups of the acetal protecting group came into play in **138**, which meant that **138** could be equilibrated to the more stable **137** by treatment with K_2CO_3 in methanol.

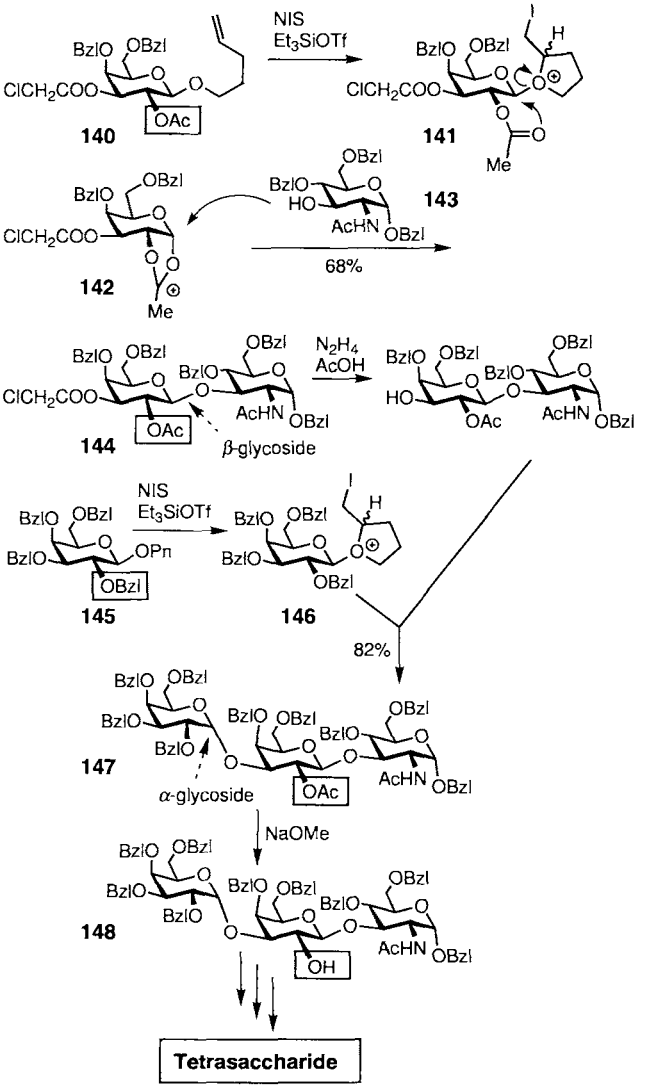
BOM, MOM, and MEM ethers are typically used as chelating protecting groups (see Section 2.1.1.). Thus, for example, M. Isobe et al. employed the directing effect of a MEM group for the stereoselective construction of a precursor to maytansin[85] (Scheme 50). In the reaction of **139** with methyllithium, the oxygen atoms of the protecting group complex the lithium cation and thus force the attack of the organometallic reagent onto the *Re* side of the double bond in the vinyl sulfone.

The directing effect of protecting groups is typically used in the synthesis of oligosaccharides, where the course of the glyco-



Scheme 50. Directing influence of the MEM protecting group in the synthesis of a precursor of maytansin by M. Isobe et al. [85].

sylation can be affected. In glycosyl donors such as **140** (Scheme 51) the ester function in the 2-position shields the underside of the glycosyl cation **142** formed during the glycosylation reaction. Thus, the glycosyl acceptor **143** attacks from above to form the β-glycoside **144**.[86] If the 2-position of the



Scheme 51. Control over α/β-selectivity by choice of suitable protecting groups in the synthesis of the blood group B tetrasaccharide by B. Fraser-Reid et al. [86]. Pn = pentenyl, NIS = *N*-iodosuccinimide.

glycosyl donor is not blocked by an acyl group capable of neighboring group participation, as is the case in the benzyl-protected donor **145**, then the α-glycoside, in this case **147**, is preferentially formed. This directing effect was used highly effectively by B. Fraser-Reid et al. in the synthesis of **147**, en route to the tetrasaccharide characteristic of the human blood group B. A further example is given in the preparation of the Gb_3 glycolipid by K. C. Nicolaou et al. sketched in Scheme 47.

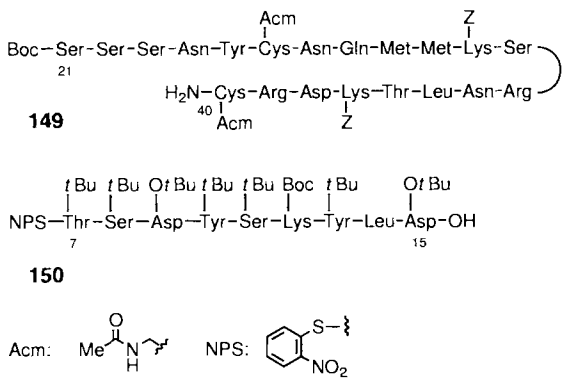
The type of protecting group determines not only the stereochemical course of glycoside synthesis, but also affects the reactivity of the glycosyl donor. Since esters are better electron acceptors than ethers, the formation of glycosyl cations is less favored from an acyl-protected glycosyl donor like **140** than from an alkyl-protected donor such as **145**. The nucleophilicity of the leaving group at the anomeric center is also less in the ester case than in the alkyl-protected system. To characterize this finding, B. Fraser-Reid et al. described these acyl-masked glycosyl donors as "disarmed" with respect to activation by electrophiles, while alkyl-masked donors were viewed as being "armed".[87] This concept of armed/disarmed groups has proved useful for a wide variety of different glycosyl donors.

4. The Best Protecting Group Is No Protecting Group

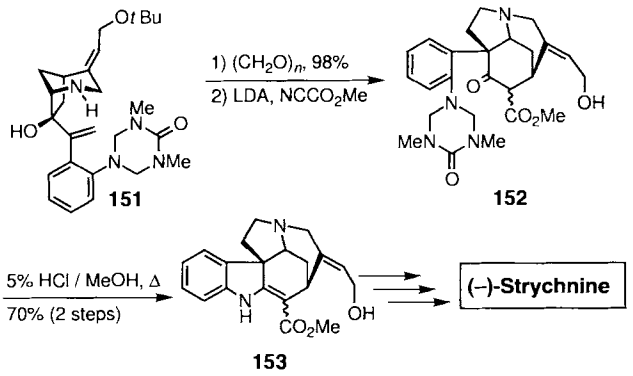
The examples discussed in the foregoing sections illustrate the capabilities of the protecting group techniques available today and indicate that protecting groups can also be used to influence the course of reactions. Nevertheless, an unavoidable consequence of the introduction and removal of protecting groups is that the synthesis is lengthened, and that the use of protecting groups is thus often seen as "unproductive".[84]

The number of protecting group manipulations can be kept to a minimum through the use of the differences in reactivity of similar or identical functional groups. In certain cases this can determine the course of the entire synthesis and the chosen protecting group pattern. This approach is chosen again and again in the synthesis of glycosides, for example, because reliable information is available concerning the reactivity of the various hydroxyl groups in carbohydrates. R. R. Schmidt et al. applied this strategy in the synthesis of the dimeric Lewis^x determinant illustrated in Scheme 20.[39] In **12** and **15**, the hydroxyl groups at C-3 and C-4 of the terminal carbohydrate were protected together as an acetal. After cleavage of the isopropylidene acetals of **12** and **15**, the glycosyl donor **14** reacted regioselectively in both cases with the equatorial groups at C-3 to give the pentasaccharide **15** and the octasaccharide **16**, respectively. The introduction of a protecting group at C-4 was thus unneccessary. R. R. Schmidt et al.[88] also utilized the difference in reactivity of the C-3 and C-4 hydroxyl groups in the syntheses of the tri- and tetrameric Lewis^x glycosphingolipids.

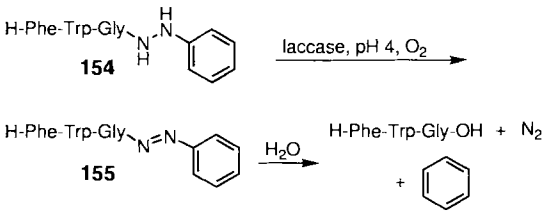
Differences in the reactivity of functional groups have also been utilized in the synthesis of oligopeptides. An example of this tactic of "minimal protection" was also used in impressive fashion by R. Hirschmann and D. F. Veber et al.[89] in the synthesis of the S-protein of ribonuclease A. This peptide consists of 103 amino acids and contains all of the trifunctional amino acids with the exception of tryptophan. As indicated in Scheme 52 for the masked 21–40 fragment **149**, only the ε-amino groups of lysine and the β-mercapto group of the cysteine were masked, while the side chains of arginine, aspartic acid, and the hydroxyamino acids serine, threonine, and tyrosine remained unprotected. This strategy stands in contrast to the concept of "maximum protection", in which the maximum number of functional groups are masked in order to avoid side reactions. E. Wünsch et al. followed this strategy in the synthesis of the peptide hormone glucagon[90] and protected the side chains of all the hydroxyamino acids, histidine, lysine, and aspartic acid with acid-labile protecting groups. The resulting 7–15 intermediate **150** (Scheme 52) indicates that a distinctly greater effort must be made to prepare such synthetic intermediates than is demanded by the "minimal protection" tactic.



Scheme 52. The "minimal protection" tactic in the synthesis of the S-protein of ribonuclease A (21–40 fragment **149**) by R. Hirschmann and D. F. Veber et al. [89] and the "maximum protection" tactic in the synthesis of glucagon (7–15 fragment **150**) by E. Wünsch et al. [90].



Scheme 53. Use of the triazone protecting group in the synthesis of strychnine by L. E. Overman et al. [92].



Scheme 54. Enzymatic cleavage of phenylhydrazides from peptides by A. N. Semonov et al. [93].

While the danger of side reactions is greater when one uses minimal protection, and the number of compatible coupling techniques is reduced, the tactic of maximum protection has the disadvantage that losses in yield can occur during the removal of protecting groups, and that the protected peptide fragments are often poorly soluble or difficult to purify.

5. New Developments

Most of the protecting groups discussed in Sections 2 through 4 have been known for some time. Their usefulness has been demonstrated in a multitude of complex syntheses and they can be considered to be well-established[10, 11] (this conclusion cannot yet be drawn for the enzyme-labile protecting groups). Nevertheless, the development of new protecting group techniques and the improvement of existing methods continues to be the subject of intensive research in organic synthesis. The following trends can be distinguished from the large number of new developments.

5.1. Development of Protecting Groups with New Lability/Stability

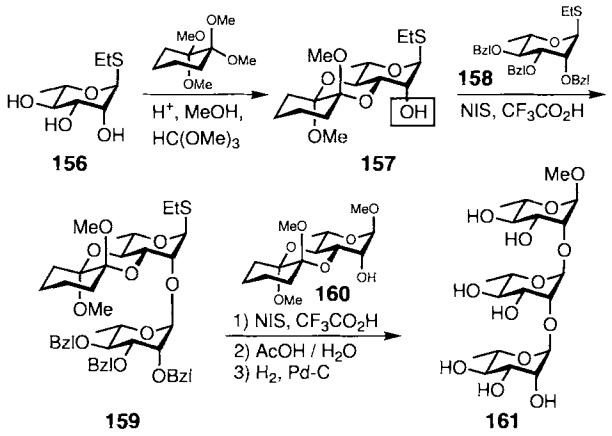
New developments on protecting groups with modulated reactivity have been described for silyl ethers, in particular (see Section 2.3), but new acid-labile groups have also been successfully developed and applied. An example is the triazone protecting group for amines developed by S. Knapp et al.,[91] which blocks two N–H positions and can be easily cleaved with dilute acid. This protecting group was essential in studies by L. E. Overman et al.[92] on the synthesis of the strychnine alkaloids, as illustrated by the synthesis of strychnine itself (Scheme 53). In the precursor **151** the amino group of the aniline was masked as a triazone, which, after a domino sequence consisting of Mannich reaction and aza-Claisen rearrangement, could be removed from **152**, enabling the subsequent ring closure to give **153**. If the *tert*-butylurethane (Boc) group or a pivalinamide is used in place of the triazone, the selective cleavage is not successful.

The application of biocatalysts has given the area of orthogonally stable protecting groups new impetus. An example of this is given in Scheme 54. Peptides such as **154**, which carry a phenylhydrazide at the C-terminus, are oxidized by the enzyme laccase to give the diimide, in this case **155**, which spontaneously hydrolyzes and liberates the desired peptide.[93] Phenylhydrazides can be cleaved by classical chemical methods only under much more drastic conditions.

5.2. Development of Protecting Groups that Induce Alternative Selectivities in Reactions

The number of blocking/deblocking steps in a synthesis can be reduced by employing protecting groups which, upon introduction, can distinguish between several functional groups of similar reactivity. Examples of such protecting groups are the recently developed dispiroketal (DISPOKE) and cyclohexane-1,2-diacetal (CDA) protecting groups,[14, 15, 94] which selectively mask diequatorial 1,2-diols. In the synthesis of the trisaccharide unit **161** of a streptococcal antigen, the two OH groups in the 3- and 4-positions of the glycosyl acceptor **156** were selectively blocked and thus the axial hydroxyl group at C-2 was made available for the coupling reaction with the glycosyl donor **158** (Scheme 55).[15] The disaccharide **159** thus formed was ready for a further glycosylation; its coupling with **160** and subsequent cleavage of the CDA and the benzyl groups completed an efficient synthesis of the trisaccharide **161**.

The development of reagents for the introduction of protecting groups under alternative conditions is of great interest. Recent results in this area include the introduction of allyl, benzyl, and *tert*-butyl ethers via the corresponding trichloroacetimidate[95] under acidic, rather than the usual basic, conditions. The formation of benzylidene acetals, normally introduced under acidic conditions, with the help of benzylidene-1,2-dibromide under basic conditions[96] is also a valuable alternative.

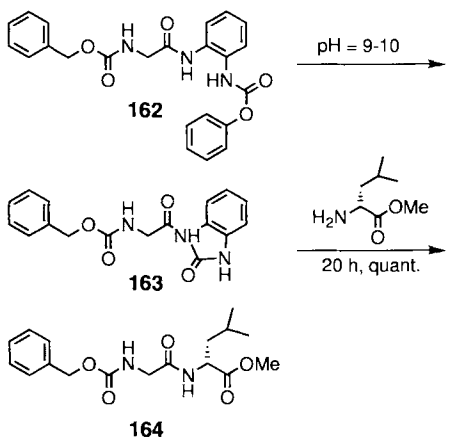


Scheme 55. Synthesis of a rhamnotrisaccharide by S. V. Ley et al. [15] using the CDA protecting group. NIS = *N*-iodosuccinimide.

5.3. Development of Protecting Groups that Can Be Converted into Activated Groups

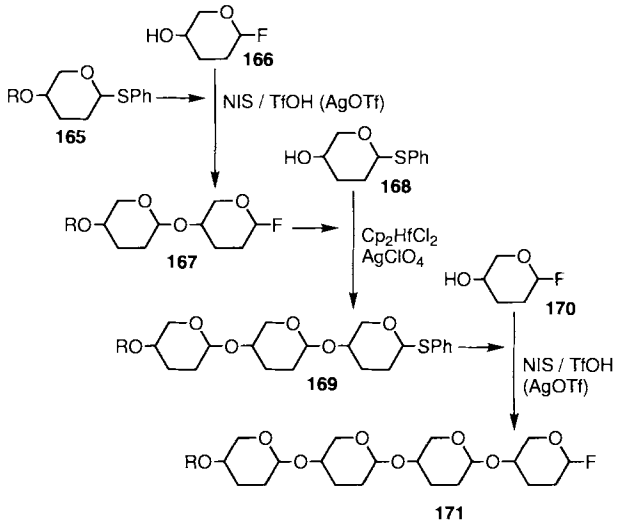
If it is possible to use a protecting group that can be converted into a form that actually activates the molecule for the next transformation, then protecting groups become more than just a "necessary evil" and can be seen to play an active, positive role.

An example of the successful realization of such a principle is given by the use of protecting groups based on *o*-phenylenediamine[97] in peptide synthesis (Scheme 56). Under basic conditions peptide derivatives such as **162** react at the urethane function to form 1-acylbenzimidazolin-2-ones such as **163**. These activated compounds can then be coupled directly with amino acid esters and peptide esters. A further example is the use of *n*-pentenyl groups in carbohydrate chemistry[98] (see Section 3.5, Scheme 51). In **140** and **145** the anomeric center is protected as a pentenyl ether. Treatment with *N*-iodosuccinimide and triethylsilyl triflate converts the stable, protected **140** and **145** into the activated glycosyl donors **141** and **146**, respectively.



Scheme 56. Use of protecting groups capable of activation based on *o*-phenylenediamine in the synthesis of peptides by R. Pascal et al. [97].

If the principle of converting protecting groups to activating groups can also be applied to doubly orthogonal systems, then one would have a very effective tool for the synthesis of oligomers. T. Ogawa et al.[99] have recently described such a system for the construction of oligosaccharides. They exploited the possibility of orthogonally activating thioglycosides and glycosyl fluorides (Scheme 57). The thioglycosides **165** and **169** were converted into reactive glycosyl donors with *N*-iodosuccinimide and trifluoromethane sulfonic acid or with silver(I) trifluoroacetate. The configuration of the anomeric center of the fluorosugar remained stable under these conditions. However, when bis(cyclopentadienyl)hafnium dichloride and silver(I) perchlorate were used, only the glycosyl fluorides **167** and **171** were activated. This switchable activation and direct glycosylation allows a rapid and elegant synthesis of oligosaccharides. The strategy is highly efficient, and it can be expected that further combinations of protecting groups capable of orthogonal activation will find use.



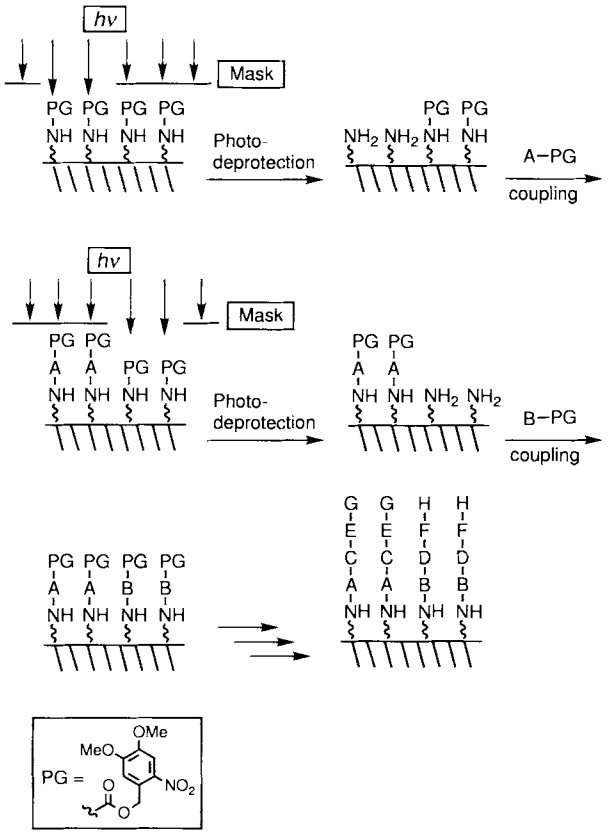
Scheme 57. Construction of oligsaccharides by T. Ogawa et al. [99] using orthogonal activation. NIS = *N*-iodosuccinimde, TfOH = trifluoromethanesulfonic acid.

5.4. Development of New Anchor Groups for Solid-Phase Synthesis

In the synthesis of oligopeptides and nucleotides on polymeric supports, the terminal monomer is attached to the solid phase by an anchor group. The anchor groups are generally derived from protecting groups developed for solution-phase applications. Solid-phase synthesis can thus be understood as synthesis with polymer-modified protecting groups.

Synthesis on polymeric supports has found particular interest due to the development of combinatorial chemistry.[100] The anchor groups used in solid-phase oligopeptide and nucleotide chemistry often cannot be directly applied to the synthesis of other types of compounds. With the growing application of combinatorial techniques, the demand for new anchor groups will increase, which will be defined by the requirements of combinatorial chemistry in general, as well as by the properties of the target compounds. A representative example is given by the

work of S. Fodor et al.,[101] who have combined modern protecting group chemistry with photolithographic methods for the parallel synthesis of oligopeptides and oligonucleotides on spatially well-defined regions of a solid support (Scheme 58). The



Scheme 58. Light-directed parallel synthesis of oligomers developed by S. P. A. Fodor et al. [101].

surface of the support was initially derivatized with photolabile protected amino functions. Certain areas of the surface were then covered with a mask and the whole was then irradiated. Only the protecting groups in uncovered areas of the surface were removed, leaving free amino functions. These were chemically coupled with photolabile animo acid derivatives. By using another mask, other regions can be selectively deblocked and converted. This process allows a defined sequence to be prepared on a given area of the surface.

6. Outlook

The continuous development of new protecting group techniques over the last decades resulted in most of the strategies discussed in this review and has contributed substantially to the impressive achievements in organic synthesis today. The successful applications of the silyl and allyl protecting groups in complex syntheses are particularly good examples. The authors are of the opinion that the potential of biocatalysts is equally vast. Basic methods relying on these systems have been developed in many areas and all that is lacking is definitive proof of their performance in demanding synthesis.

The development of more efficient protecting group techniques, relying, for example, on differences in reactivity between similar functional groups (see Section 4) and on new reagents with alternative reactivities, stabilities, and selectivities, continues to be the focus of attention (see Section 5) and will certainly lead to new protecting group strategies. Protecting group chemistry will thus continue to provide organic synthesis with great impetus in the future and open up new possibilities.

The basis and motivation for this review was research carried out at the Universities of Mainz, Bonn, and Karlsruhe aimed at developing and establishing enzymatically cleavable protecting groups (see ref. [21]). Active participants in this work were (in alphabetic order): Peter Braun, Alain Cotté, Stephanie Gabold, Simone Glomsda, Axel Heuser, Volker Jungmann, Thomas Kappes, Bruno Klaholz, Karsten Kuhn, Edgar Nägele, Torsten Pohl, Armin Reidel, Jörg Sander, Bernd Sauerbrei, Michael Schelhaas, Dagmar Sebastian, and Paul Stöber. We are grateful to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, the Bundesministerium für Bildung und Forschung, BASF AG, Boehringer Mannheim GmbH, and Degussa AG for funding our research.

[8] Peptide and nucleotide chemistry are, however, exceptions. The most advantageous combinations of protecting groups and strategies for the synthesis of oligopeptides and oligonucleotides have often been commented on in the relevant publications and textbooks (for examples see Schemes 35 and 52). Because the types of functions requiring protection in these classes of compounds is limited and the number of reactions to be carried out is restricted, the problem is more easily defined in this area of synthesis than in the stereoselective synthesis of a complex natural product. For discussions of protecting group strategy in peptide synthesis see for examples refs. [35, 37], and references therein, or J. Jones, *The Chemical Synthesis of Peptides*, Clarendon, Oxford, **1992**; *Method in Molecular Biology, Vol. 35: Peptide Synthesis Protocols* (Eds.: M. W. Pennington, B. M. The New Inductees in the "Hall of Phane"—No Phane, No Gain

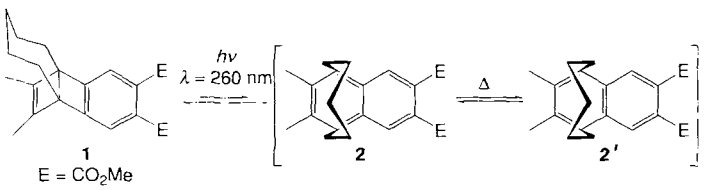
Graham J. Bodwell*

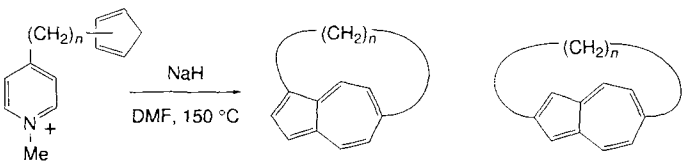
Since their emergence as a distinct class of compounds in the 1950s, the general appeal of cyclophanes has shown no signs of waning. They possess unusual and aesthetically pleasing structures. They pose unique synthetic challenges. They undergo interesting conformational processes. They exhibit peculiar chemical reactivity, spectroscopic properties, and physical properties. They can also be designed to be chiral. From the ever smaller and more strained cyclophanes to the ever larger and more complex cyclophanes, chemists continue to push back the frontiers of all aspects of this captivating field of chemistry.

The [*n*]cyclophanes are the archetypal small cyclophanes; of these, the [*n*]paracyclophanes have received by far the most attention. A detailed computational study of [4]paracyclophane,[1] which has only been prepared as a transient species by matrix isolation,[2] was recently reported. An energy difference of 9 kcal mol^{-1} between it and its Dewar benzene isomer was predicted. This paper also provides a comprehensive summary of the literature of the [*n*]paracylophanes. [5]Paracyclophane, which exists as the minor component of an equilibrium with its valence isomeric Dewar benzene, is the smallest member of this series to exhibit sufficient stability to be studied directly.[3] To further stabilize the [5]paracyclophane unit, Bickelhaupt et al.[4] recently synthesized a benzoannelated version, namely [5](1,4)-naphthalenophane **2** (Scheme 1). Even though this compound also exists in equilibrium with the Dewar naphthalene **2** from which it was produced, the proportion of the cyclophane (35% of the mixture) is higher than in any previously reported photochemical aromatization of a Dewar isomer. A particularly interesting feature of this system is that two bridge conformers (**2** and **2'**) are observed in solution in a ratio of 95:5. Unfortunately, despite considerable effort, assignment of the two conformers was not possible.



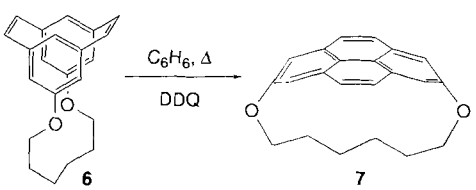
Scheme 1. Synthesis of the benzoannelated [5](1,4)naphthalenophane **2** by Bickelhaupt et al. [4].

Over the years, a number of [*n*]cyclophanes based on polycyclic aromatic hydrocarbons have been prepared.[5] However, the limits to which any of these systems can be bent has not been systematically investigated. Hafner's [*n*](1,6)- (**4**) and [*n*](2,6)-azulenophanes (**5**, $n = 11-13$) are a promising step in this direction.[6] They were produced by an intramolecular azulene-forming reaction of the 4-(ω-cyclopentadienylalkyl)-1-methylpyridinium salts **3** (Scheme 2). The crystal structure of [13](2,6)-azulenophane **5** ($n = 13$) revealed a 3.7° angle between the mean planes of the two rings. Hopefully, lower homologues of this series will soon be prepared.



Scheme 2. Synthesis of the [*n*](1,6)- and [*n*](2,6)azulenophanes **4** and **5** by Hafner et al. [6].

Our group were able to impart much greater deviations from planarity in the pyrene framework.[7] The remarkably distorted 1,8-dioxa[8](2,7)pyrenophane **7** was prepared by the valence isomerization and dehydrogenation of the tethered [2.2]metacyclophanediene **6** (Scheme 3). In the crystal the overall bend is nearly 90°. The curvature of the aromatic surface approximates that expected for a fragment of the D_{6h}-symmetric C_{84} molecule. Bond angles of up to 119° were observed in the aliphatic bridge, as well as a very high field proton resonance at $\delta = -1.47$. Although the next smaller member of this series, [7](2,7)pyrenophane, could not be prepared in this way, this compound has since been isolated.[8]



Scheme 3. Synthesis of the 1,8-dioxa[8](2,7)pyrenophane **7** from [2.2]metacyclophanediene **6** by Bodwell et al. [7]; DDQ = 2,3-dichloro-5,6-dicyanobenzoquinone.

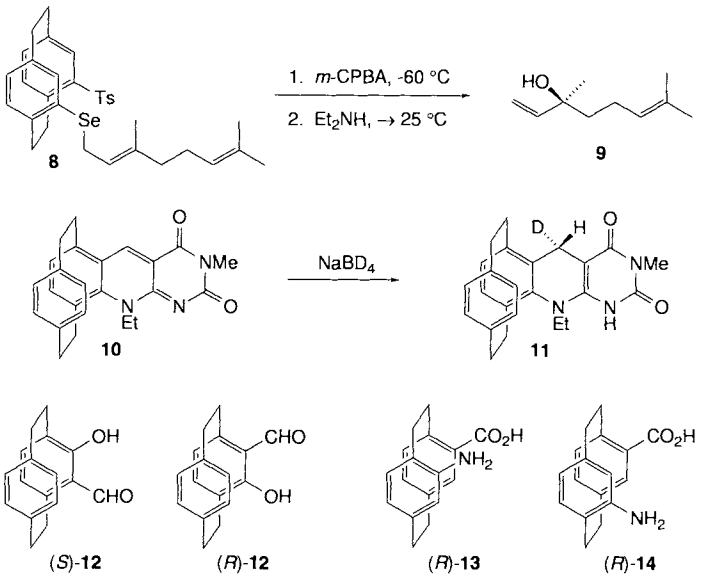
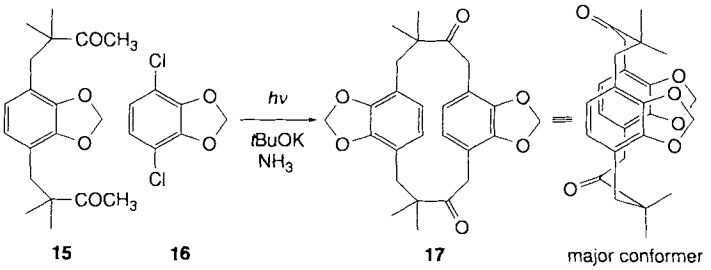
It has long been known that appropriately substituted [2.2]paracyclophanes are chiral, chemically stable, and do not racemize under normal reaction conditions. Considering these seemingly ideal prerequisites for use in chiral synthesis, it is surprising that only three examples have appeared in the literature, all of them in recent years (Scheme 4). Reich et al. employed [2.2]paracyclophane-substituted selenides such as **8** to achieve chirality transfer through [2,3]sigmatropic rearrangements of the selenoxide. Using this methodology, he was able to synthesize optically active linalool **9** (*S*:*R* ratio = 5:1).[9] Yanada, Yoneda et al. constructed the deazaflavinophane **10**, which exhibits complete regioselectivity when oxidized or reduced, for example, in the reduction with $NaBD_4$ to afford **11**.[10] Belokon, Rozenberg et al. used scalemic 4-formyl-5-hydroxy[2.2]paracyclophane (**12**) in the synthesis of α-amino acids (*ee* = 45–98%).[11] An alternate synthesis of **12** was more recently reported by Hopf and Barrett.[12] Another interesting advance in the area of chiral cyclophanes was the synthesis of the homochiral [2.2]paracyclophane amino acids **13** and **14**.[13]



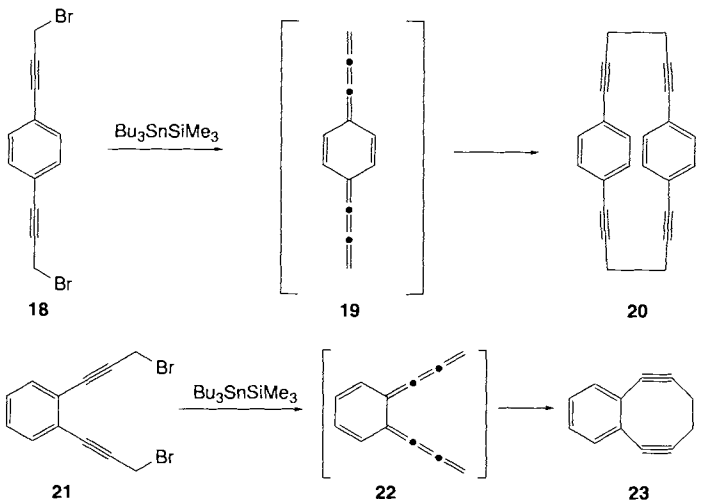
Scheme 4. Examples of the application of chiral [2.2]paracyclophanes in organic synthesis.

Many cyclophanes are conformationally mobile, and the study of their behavior in solution has proved to be one of their most intriguing features. A particularly striking example is the conformational analysis of [4.4]paracyclophane derivative **17**, synthesized by Fukazawa et al.[14] through a photoinduced double $S_{RN}1$ reaction of the precursors **15** and **16** (Scheme 5). Signals due to three conformers appear in the low temperature ^1H NMR spectrum of **17**. The crystal structure of the major conformer corresponded to the calculated lowest energy conformer. When crystals of **17** were dissolved in precooled (−80 °C) solvent, the ^1H NMR spectrum of the resulting solution exhibited signals arising only from the major conformer of the previous mixture.



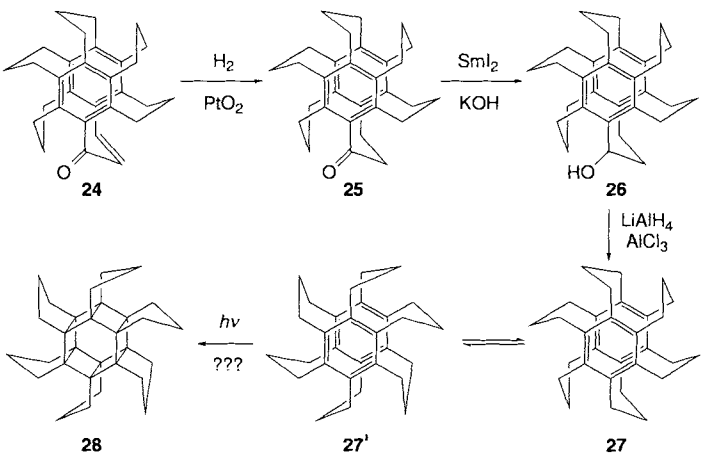
Scheme 5. Synthesis of the [4.4]paracyclophane derivative **17** by Fukazawa et al. [14].

The [6.6]paracyclophanetetrayne **20** was synthesized by Hopf et al. by the reaction of dibromide **18** with $Bu_3SnSiMe_3$ (Scheme 6).[15] The intermediacy of the novel cumulated *para*-quinodimethane **19** was invoked. Reaction of the *ortho*-substituted isomer **21** under the same conditions presumably gave the intermediate **22** to yield the highly strained 3,4-benzocyclooct-3-en-1,5-diyne **23**.



Scheme 6. Synthesis of the [6.6]paracyclophanetetrayne **20** and 3,4-benzocyclooctene-1,5-diyne **23** by Hopf et al. [15].

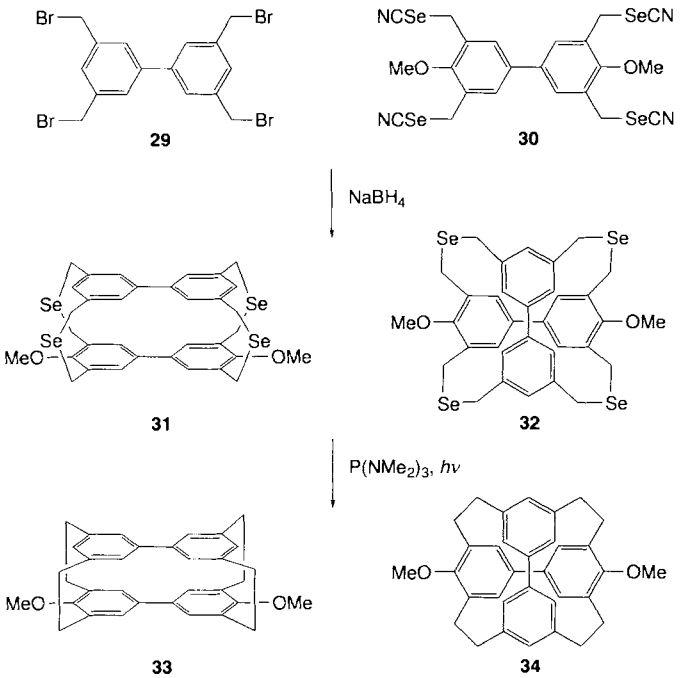
Seventeen years after Boekelheide et al.'s landmark synthesis of $[2_6](1,2,3,4,5,6)$cyclophane (termed superphane),[16] Shinmyozu et al. very recently described the synthesis of the homologous $[3_6](1,2,3,4,5,6)$cyclophane **27** (Scheme 7).[17] Formation of the final bridge of this "molecular pinwheel" was accom-



Scheme 7. Synthesis of the $[3_6](1,2,3,4,5,6)$cyclophane **27** by Shinmyozu et al. [17].

plished with an intramolecular aldol condensation. While the double bond of enone **24** could be easily hydrogenated, the carbonyl of the resulting ketone **25** proved to be quite inert towards reduction. The action of SmI_2/1 M KOH finally yielded the alcohol **26**, which on treatment with $LiAlH_4/AlCl_3$ afforded cyclophane **27**. The well averaged ^1H NMR signals of the bridge protons are consistent with a correlated inversion of all six trimethylene bridges in solution at room temperature. News about whether this molecule fulfills predictions[18] of a photochemical isomerization to the [6]prismane derivative **28** is eagerly awaited.

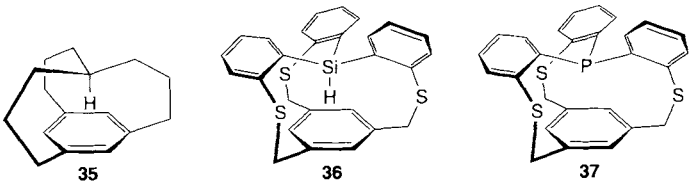
Tani et al. recently described the coupling of the tetrabromide **29** with the tetraselenocyanate **30** to give the parallel and crossed tetraselenabiphenylophanes **31** and **32** in a ratio of 1:3 (Scheme 8).[19] The thia analogue of **32** was synthesized earlier



Scheme 8. Synthesis and deselenation of the tetraselenaphenylophanes **31** and **32** by Tani et al. [19].

through a thiol-bromide coupling,[20] but the isomer corresponding to **31** was not formed. While the thia analogue of **32** could not be desulfurated, **31** and **32** were successfully deselenated in 40–50% yield upon photolysis in the presence of $P(NMe_2)_3$ to give the structurally interesting bridge-contracted phanes **33** and **34**.

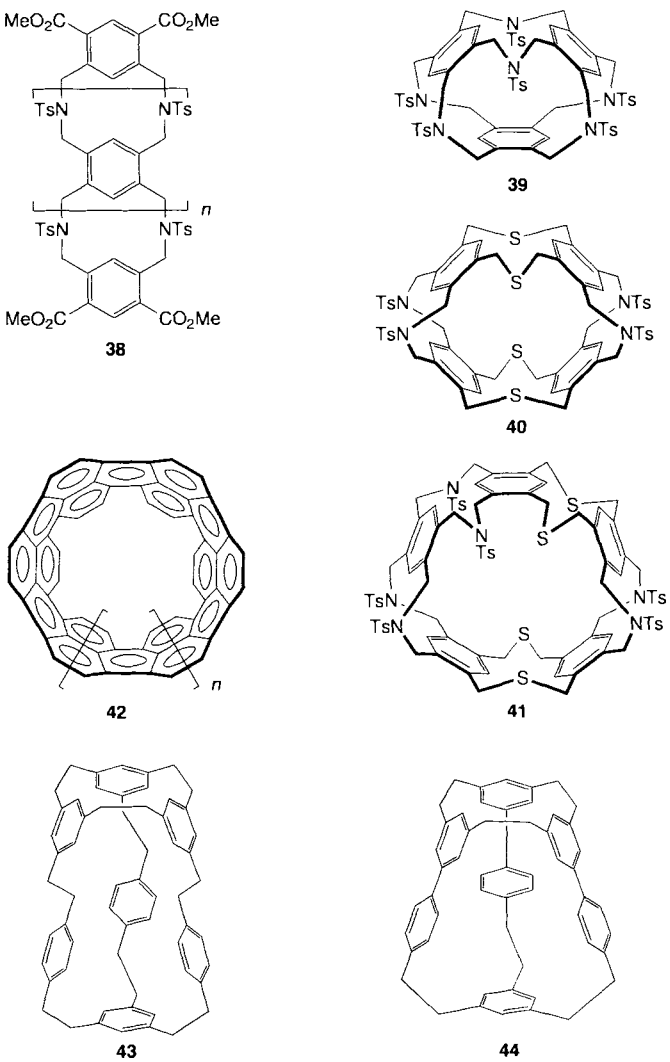
The *in*-cyclophanes **35**–**37** described by Pascal, Jr, et al. are excellent vehicles for the study of functional group interactions resulting from enforced proximity (Scheme 9). While original work was directed towards compounds containing alkane CH groups projected towards the center of an aromatic ring (for example **35**, $\delta_H = -4.03$),[21] it now includes second row elements. Silaphane **36**[22] exhibits a proton resonance at ($\delta = 1.04$), some 5 ppm upfield from that of an acyclic model compound. In addition there is a 280 cm^{-1} hypsochromic shift of the infrared Si–H stretching frequency arising from steric compression. For the phosphaphane **37**,[22] which is resistant to



Scheme 9. Examples of *in*-cyclophanes.

protonation with HBr, the ^{13}C and ^{31}P NMR spectra indicate that there is an electronic interaction between the phosphane P atom and the basal ring. However, the presence of a bonding attraction between them could not be determined. Subsequent functionalization of the basal ring with a nitro or amino substituent enabled HPLC resolution of the enantiomers, which exhibit exceptionally high optical activity.[23]

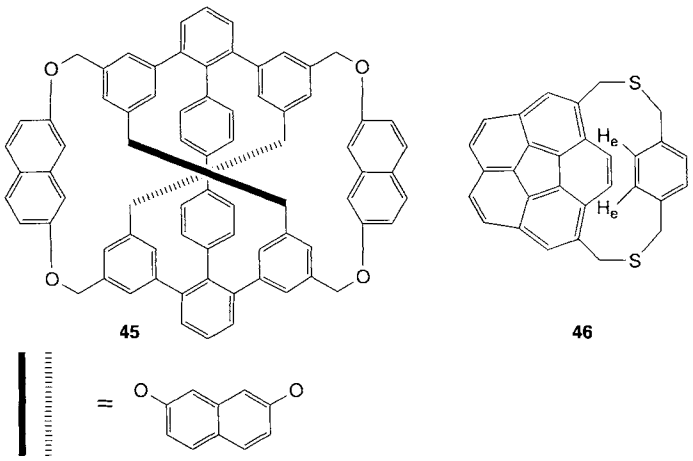
Vögtle's group continues to produce a steady stream of fascinating cyclophanes. Among these are the nanometer-scale molecular ribbons **38** (Scheme 10), which were synthesized with an iterative approach.[24] The longest yet, ribbon **38** ($n = 5$), has seven layers. The conversion of some of these ribbons into molecular belts such as **39**–**41** has also been described.[25] Cyclic



Scheme 10. Examples of cyclophanes in ribbon and belt form.

side-products containing up to 40 (!) benzene rings were observed by Plasma Desorption Mass Spectrometry, although none of these higher oligomers has been isolated. Conversion of these macrocycles into fully aromatic belts **42** should provide an entry to nanotube fullerene fragments. The "spheriphanes" **43** and **44** were also prepared by the same group.[26] Spheriphane **43** exhibits a high affinity for silver cations and, by virtue of its sixty carbon framework, may serve as a direct precursor to C_{60}.[27]

One of the most spectacular cyclophanes to be prepared in recent years is the "Kuratowski cyclophane" **45** (Scheme 11).[28] This nanodimensional multicyclophane is the



Scheme 11. The "Kuratowski-cyclophane" **45** [28] and the first corannulenocyclophane, **46** [29].

first example of an achiral molecule possessing nonplanar $K_{3,3}$ topology. The straightforward synthesis of this intricately entwined macrocyclophane should pave the way to a new family of molecules possessing novel architecture and vast dimensions. A further contribution from Siegel's group is the synthesis of the first corannulene cyclophane **46**.[29] A striking feature of its ^{1}H NMR spectrum is the *endo* aromatic protons (H_e) of the benzene ring, which are positioned almost directly over the center of the corannulene system, appear at remarkably high field ($\delta = 1.89$). Furthermore, since no peak broadening was observed up to 148 °C, dynamic conformational processes in the thioether bridges and bowl-to-bowl inversion of the corannulene moiety both have lower limits of 18 ± 1 kcal mol^{-1}.

From its rudimentary beginnings over four decades ago, cyclophane chemistry has developed into an ever-evolving, multifaceted discipline that overlaps with many other areas of chemistry. A rough cross-section of some of the recent developments in the mainstream of this field, as highlighted here, certainly attests to that.

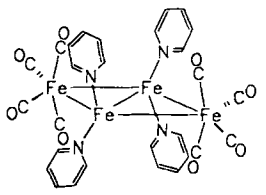
"Strangelove" in Cluster Chemistry: A New Class of Open-Shell Transition Metal Clusters

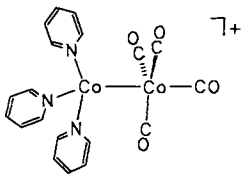
Lutz H. Gade*

The way we view (and teach!) transition metal cluster chemistry is based on its partition into the two paradigms of metal–metal-bonded systems, as established by the pioneering work of Cotton, Dahl, Lewis, Chini, and others:[1] "The two general types of metal cluster compounds, which may be loosely called the 'lower halide' type and the 'carbonyl' type, differ from each other in many ways, and there is little in the way of chemical reactions to interrelate them."[2] The exceptional cases in which complex fragments of the two regimes are directly bonded to each other have attracted some attention but on the whole remained at the margin of an otherwise mature field of research.

One such class of compounds comprising the so-called "early-late heterobimetallics" that contain unsupported metal–metal bonds has received increasing attention over the past decade and is a field of research that is rapidly expanding.[3] Another type of metal–metal bonded compounds, which occupies the gap between the two regimes of "classical" clusters, is *formally* composed of cationic transition metal centers stabilized by "hard" donor ligands that are directly bonded to carbonylmetalate fragments. The first well-characterized example of such a species were reported by Fachinetti and co-workers almost a decade ago[4, 5] and stemmed from a variation of the well-known redox disproportionations that some metal carbonyls undergo in the presence of donor bases. Although such reactions were among the first to be studied in the early days of metal carbonyl chemistry,[6] by careful control of the stoichiometry and reaction conditions a hitherto undiscovered class of metal–metal-bonded compounds emerged. From the reactions of $[Fe(CO)_5]$ and $[Co_2(CO)_8]$ with pyridine the truly remarkable complexes $[\{(py)_2FeFe(CO)_4\}_2]$ (**1**)[4] and $[(py)_3CoCo(CO)_4]^+$ (**2**)[5] could be isolated and structurally characterized.



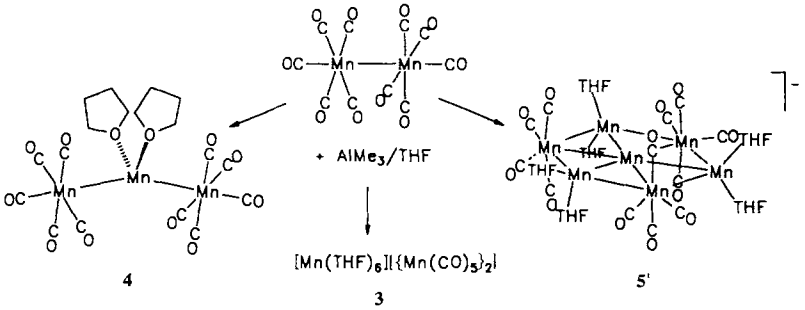
1



2

Both complexes **1** and **2** are paramagnetic and highly electron-deficient on the basis of EAN-electron counting, and their reactivity indicated that they dissociate heterolytically in solution. In their first reports Fachinetti et al. therefore interpreted them as "homonuclear ion-pair clusters"; however, an Extended Hückel Molecular Orbital study (EHMO) of **1** published a few years later supported the notion of essentially covalent donor–acceptor metal–metal bonding with almost equal charge distribution between the $\{(py)_2Fe\}$ and $\{(CO)_4Fe\}$ centers.[7] The good match of the donor and acceptor capabilities of the two metal fragments is responsible for this bonding situation, which is not unlike that of equally dissimilar complex fragments directly bonded to each other in, for instance, $[(R_2N)_3TiFeCp(CO)_2]$.[8]

This earlier work has most recently received renewed attention due to the remarkable results from the treatment of another neutral metal carbonyl, $[Mn_2(CO)_{10}]$, with the Lewis acid $AlMe_3$ in the polar donor solvent THF (Scheme 1).[9] Depending on the reaction conditions chosen the products of redox disproportionations that Whittlesey et al. identified were $[Mn(thf)_6][\{Mn(CO)_5\}_2]$ (**3**), $[(thf)_2Mn\{Mn(CO)_5\}_2]$ (**4**), and $[Mn\{Mn_7(thf)_6(CO)_{12}\}_2]$ (**5**).



Scheme 1. Products of the disproportionation reaction of $[Mn_2(CO)_{10}]$ in THF in the presence of $AlMe_3$. **5'** is the anionic cluster fragment in **5**.

While the trinuclear cluster **4** is related to **2**, complex **5** turned out to be a high-nuclearity cluster. A crystal structure analysis of the latter revealed a metal–metal-bonded array unique in metal cluster chemistry (Fig. 1). The compound may be viewed as consisting of two $[Mn_7(thf)_6(CO)_{12}]$ units, each containing an almost planar metal core. These are coordinated through isocarbonyl linkages to a central manganese atom that has an octahedral coordination geometry.

The most remarkable feature of the structure is the central unligated manganese atom of the Mn_7 moiety, which is surrounded by a hexagonal planar arrangement of alternating $Mn(thf)_2$ and $Mn(CO)_4$ fragments. The planar cluster structure is reminiscent of the hexagonal planar compound $[Ni\{PtBu_3\}_6]$[10] and the pentagonal dianion $[In\{Mn(CO)_4\}_5]^{2-}$ (Fig. 2).[11] Hoffmann et al. have offered a qualitative rationale for the bonding in these interesting complexes based on the isolobal relationship between RP and $Mn(CO)_4$.[12] However, the presence of $Mn(thf)_2$ fragments linking the $Mn(CO)_4$ units

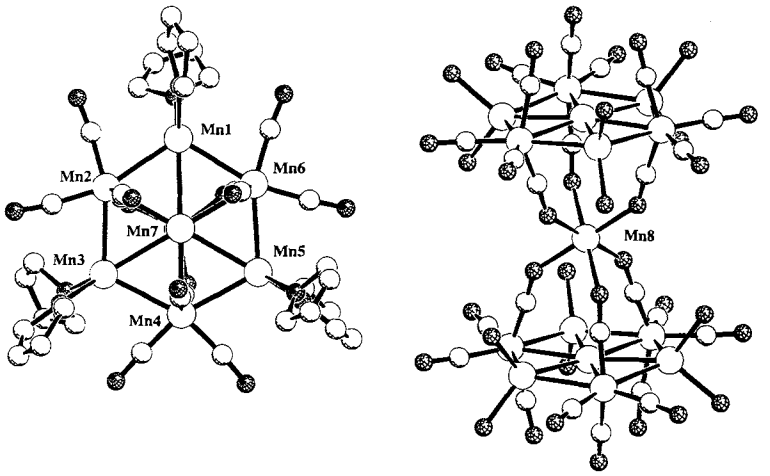

Fig. 1. Molecular structure of **5** in the crystal. Left: view of the virtually planar $[Mn_7(thf)_6(CO)_{12}]$ cluster monoanions. Right: view of the whole aggregate with the central Mn^{2+} ion octahedrally coordinated by six isocarbonyl ligands through the O atoms.

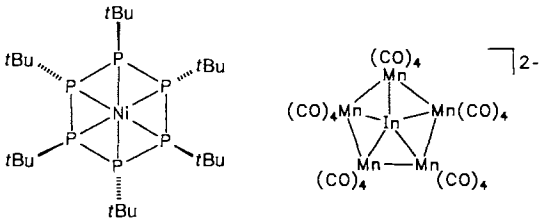

Fig. 2. Molecular structures of $[Ni(PtBu]_6]$ (left) and $[In\{Mn(CO)_4\}_5]^{2-}$ (right).

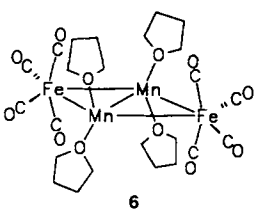
present in **5** makes an analysis of the bonding along the same lines less straightforward.

There is strong evidence from infrared spectroscopy that the aggregate observed in the crystal dissociates in solution, partially breaking down to $[Mn(CO)_4]^{3-}$ units. The isolation of **3** and **4** from reaction mixtures containing $[Mn\{Mn_7(thf)_6(CO)_{12}\}_2]$ suggests that these clusters form from the ions $[Mn(thf)_6]^{2+}$ and $[Mn(CO)_5]^-$, which are the products of a redox disproportionation of $[Mn_2(CO)_{10}]$ in THF[13] and which aggregate upon simultaneous displacement of THF and CO.

The planar manganese cluster may serve as a starting material in the synthesis of heterometallic clusters, as was also shown by Whittlesey and Harakas.[14] From the reaction of **5** with $[Fe(CO)_5]$ the MnFe-heterobimetallic analogue of **1**, $[(thf)_2MnFe(CO)_4]_2$ (**6**) could be isolated in moderate yield.



6

Whereas the magnetic behavior of **1** is consistent with a triplet ground state, the more open-shell complex **6** appears to have a quintet ground state. This implies the presence of substantial covalent bonding between the metal centers in **6** involving three of the five valence d-electrons of the Mn centers. Comparison of the position of the ν(CO) infrared bands of the $Fe(CO)_4$ units in both compounds reveals (not unexpectedly!) a somewhat more polar nature of **6**.

With the structural characterization of **1**, **2**, and **4**–**6** a new type of open-shell transition metal cluster is emerging. Whittlesey proposed the term xenophilic ("stranger-loving") for this class of clusters to characterize the nature of the combining complex fragments. A more detailed theoretical investigation into their metal–metal bonding is clearly required to categorize them meaningfully.

The thermal lability of these systems in solution and their partial break down in polar solvents have thus far prevented the development of their reaction chemistry. In pursuing the aim of stabilizing such polynuclear complexes the focus will be on the fragments containing the Werner-type coordination sphere, since they are the primary points of attack in solution. As in the chemistry of early-late heterobimetallics[3g, h] the judicious choice of, for example, chelating ligands, which stabilize these metal centers kinetically (without causing complete dissociation into solvent separated ion pairs!), may provide the entry into the systematic development of this area of cluster chemistry. Modern coordination chemistry offers a whole armory of ligands for that purpose!

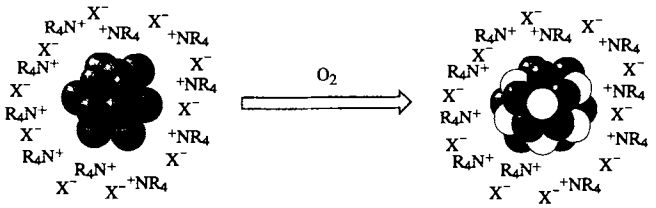
Nanostructured Metal Oxide Clusters by Oxidation of Stabilized Metal Clusters with Air

Manfred T. Reetz,* Stefan A. Quaiser, Martin Winter, Jörg A. Becker, Rolf Schäfer, Ulrich Stimming, Andrea Marmann, Roland Vogel, and Toyohiko Konno

Dedicated to Professor Heinz A. Staab on the occasion of his 70th birthday

Nanostructured metal sulfides and oxides are useful as catalysts in organic and inorganic chemistry, and as materials with special electronic and optical properties.[1] The size-dependent semiconductor properties of these materials are of special interest in microelectronics (quantum dots). Metal chalcogenides are usually obtainable by precipitation or sol–gel processes, in which a wide variety of compounds, for example, polyphosphate, can be used as stabilizers.[1, 2] Although there are several interesting approaches to control the particle size of metal sulfides and oxides in the nanometer range, it is usually necessary to use chromatographic enrichment to obtain monodisperse materials.[1]

We have recently described two electrochemical methods for preparing $R_4N^+X^-$-stabilized metal and bimetal clusters.[3, 4] In some cases it was possible to control the size of the clusters within the range 1.5–6 nm by varing the current density and solvent.[3, 5] It was shown by high resolution transmission electron microscopy (HRTEM) and scanning tunneling microscopy (STM) that the metal clusters are stabilized by a monomolecular layer of the ammonium salt.[6] We now report that in the case of fairly readily oxidizable metals such as cobalt, iron, or nickel the $R_4N^+X^-$-stabilized clusters can be quantitatively converted into the corresponding nanostructured metal oxide clusters (Scheme 1).



Scheme 1. Idealized representation of the oxidation of $(C_8H_{17})_4N^+X^-$-stabilized metal clusters with O_2 (dark spheres, metal atoms; light spheres, oxygen atoms).

If a 0.5 M solution of $(C_8H_{17})_4N^+Br^-$-stabilized cobalt clusters[7] (3.6 nm mean diameter by TEM) is allowed under exclusion of moisture to react slowly with oxygen, the color of the solution changes from blackish-brown to olive-green within a few hours. To exclude the possibility that only a surface layer of oxide on the cobalt clusters is formed, the progress of the oxidation reaction was monitored by measuring the oxygen consumption. Accordingly, the amount of oxygen consumed turned out to be exactly that required for the stoichiometric formation of cobalt(II) oxide.[8] The UV/Vis spectra of the material before and after the reaction with O_2 also indicate complete oxidation (Fig. 1). The solution of Co clusters shows unstructured absorption in the UV/Vis spectrum (359–800 nm), increasing with increasing wavelength, which is typical for metal clusters (Fig. 1a). This decreases by a factor of 10 during the course of the oxidation, and additional bands appear between 600 and 750 nm (Fig. 1b).

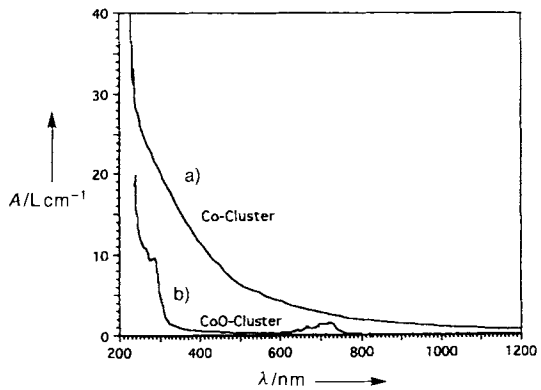


Fig. 1. UV Vis spectra of $(C_8H_{17})_4N^+Br^-$-stabilized Co clusters (a) and CoO clusters (b) in THF.

To obtain a better insight into the oxidation process, the magnetic properties of the Co clusters were investigated. Since $R_4N^+Br^-$-stabilized Co clusters are superparamagnetic,[7] this property should change during the oxidation. Indeed, the magnetic susceptibility, as measured by a magnetic (Gouy) balance, falls away completely during the course of the reaction with O_2 (Fig. 2), parallel to the O_2 uptake.[9] After complete oxidation the THF solution of CoO clusters is diamagnetic.

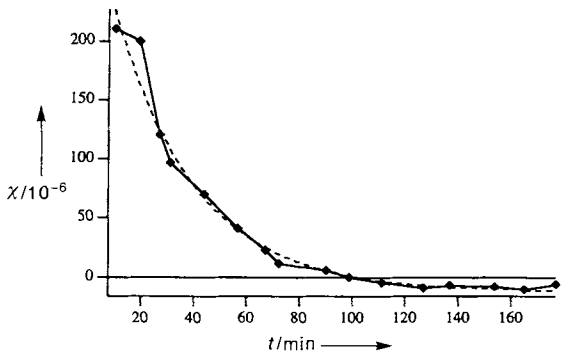

Fig. 2. Change of magnetic susceptibility χ with time in the reaction of $(C_8H_{17})_4N^+Br^-$-stabilized Co clusters in THF with air (◆, —); exponential interpolation (- - -).

For further characterization, the cobalt oxide clusters were investigated by HRTEM. In the TEM images (Fig. 3) single clusters are visible, which are similar in mean diameter and shape to the Co clusters in their initial state.[10] The lattice planes are also clearly visible. In the electron diffraction image the diffraction rings characteristic of nanocrystalline materials can be identified (Fig. 3 inset). Analysis of these revealed the presence of a face-centered cubic structure. Of the known bulk

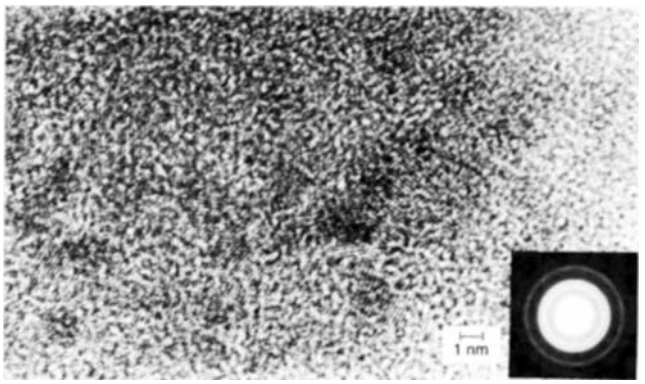

Fig. 3. TEM image of oxidized Co clusters. The inset shows the electron diffraction image.

cobalt oxides CoO, Co_2O_3, and Co_3O_4, only the unit cell of the monoxide is face-centered cubic. The lattice constant found from the electron diffraction rings (Fig. 3 inset) was found to be 4.249 Å, which agrees well with the known value for bulk CoO (4.2495 Å).[11, 12]

To answer the question whether the cobalt oxide clusters in solution are in fact stabilized by a layer of ammonium salt (Scheme 1),[13] an STM study was carried out. The oxidized metal clusters were deposited on a specially prepared, faceted gold surface[6] by dip coating. The STM image shows that the cobalt oxide clusters are located on the steps of the surface (Fig. 4). The clusters have an average diameter of 6.0 nm. As the corresponding TEM images for the metal oxide core gave a diameter of approximately 3.6 nm, the result of the combined STM/TEM study is consistent with the existence of a stabilized outer layer of surfactant.[6]

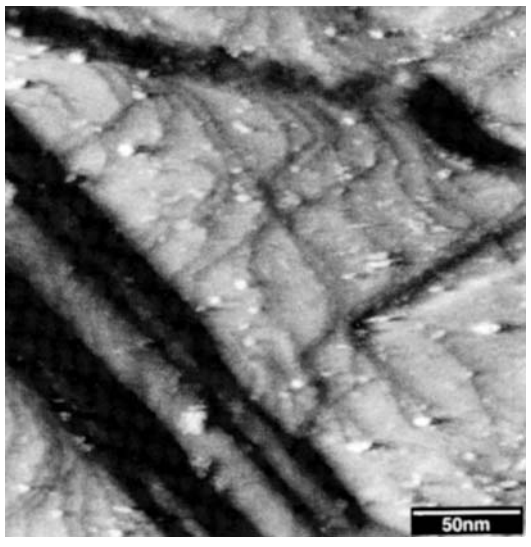

Fig. 4. STM image of CoO clusters.

If solutions of CoO clusters are allowed to come into contact with moisture in the air, light green precipitates are formed. TEM images reveal particles 100 nm to several millimeters in size formed by agglomeration of cobalt oxide clusters.

Both the preformed Co clusters and the CoO clusters can be immobilized on solid supports. For example, if dried Al_2O_3 pellets (Johnson Matthey 11838) are immersed in solutions of Co clusters in THF, the clusters become efficiently fixed onto the support. Within 45 min the impregnation is complete, as shown by photographs of sections of the pellets (Fig. 5, top). During and after the immobilization, the Co clusters are oxidized by air, resulting in an olive-green coloration. Fixation of preformed CoO clusters on a support proceeds differently, penetration being only slight even after 45 min, (less than 200 μm; Fig. 5, bottom). This corresponds to a morphology that is desirable for shell catalysts.[14, 15] It is likely that the Co clusters do not migrate very far into the pores of the Al_2O_3 particles on a microscopic scale (cortexlike morphology),[14] although this still needs to be clarified.

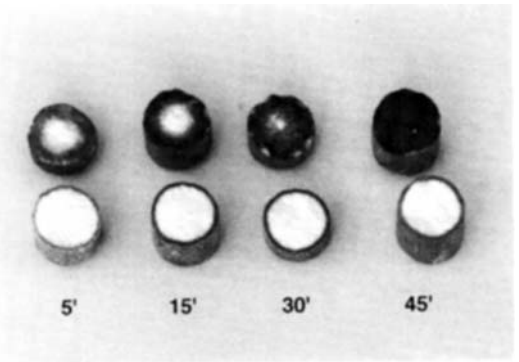

Fig. 5. Section through Al_2O_3 pellets (diameter 3.2 mm) after immersion in 0.5 M THF solution of $(C_8H_{17})_4N^+Br^-$-stabilized Co clusters (top) and CoO clusters (bottom) for 5, 15, 30, and 45 min.

Other readily oxidizable $R_4N^+X^-$-stabilized metal clusters can also be converted by oxygen into the corresponding metal oxide clusters without forming insoluble bulk metal oxides. Examples include $(C_8H_{17})_4N^+Br^-$-stabilized iron oxide clusters (2–3 nm) and nickel oxide clusters (2–3 nm), which respectively form reddish-brown and green solutions in THF. Finally, bimetal clusters (for example, Fe/Co)[3] can also be oxidized by oxygen. The exact characterization of these materials and their possible use in catalysis are subjects of further investigation.

[8] It is also possible intentionally to oxidize the Co clusters partially with substoichiometric amounts of O_2.
[9] We thank C. Herwig, H. Petersen, S. Zahn, and M. Becker (University of Marburg) for performing the measurements.
[10] A slight increase in particle size (by about 18%, estimated from the properties of bulk Co and CoO) would be expected, but such small differences cannot be detected with certainty within the limits of accuracy of the TEM analysis.
[11] N. C. Trombs, H. P. Rooksby, *Nature* **1950**, *165*, 412.
[12] In bulk CoO the proportion of cobalt is usually substoichiometric because of lattice defects, and the required charge neutralization is achieved by an increase in the oxidation state of a few cobalt ions in the lattice from +2 to +3. This material is thus a homeotopic mixed crystal of CoO and a little (green) Co_2O_3 (N. Wiberg, *Lehrbuch der Anorganischen Chemie*, de Gruyter, Berlin, 91st–100th ed., **1985**, p. 127, 1148). We cannot exclude the presence of small amounts of Co_2O_3 in the CoO clusters. Interestingly, the electron diffraction images show the presence of not only Co and CoO but also Co_2O_3 (corundum structure, hexagonal close packing) in the samples obtained by partial oxidation (extent, for example, 50%) [8].

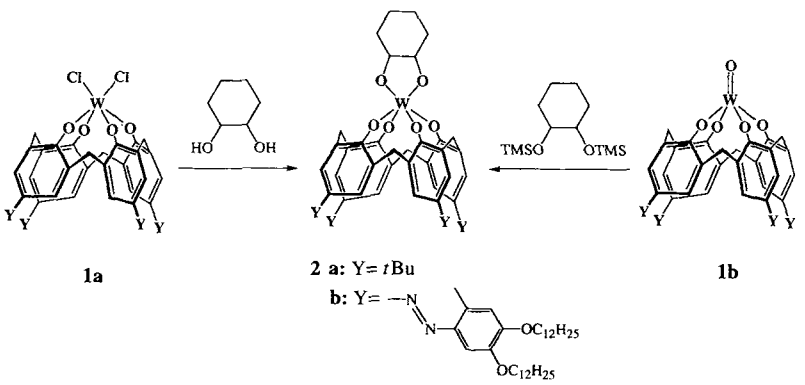
Chiral Metallocalix[4]arenes: Resolution by Diastereomeric Tungsten(VI) Alkoxides**

Bing Xu, Partrick J. Carroll, and Timothy M. Swager*

Efficient preparations of chiral supramolecular systems are critical to the design of new materials and catalysts. Calixarenes[1] present one of the most versatile platforms for the construction of supramolecular receptor assemblies with well-defined structures and specific functions.[2] Recent applications include the use of calixarenes as highly specific ligands,[3] sensors,[4] nonlinear optical chromophores,[5] porous monolayers,[6] and bowlic liquid crystals.[7] Chiral calix[4]-arenes have been produced by unsymmetric substitution of the lower rim,[8] by the addition of chiral appendages,[9] and by the incorporation of unsymmetric substitution patterns on the phenyl rings.[10] *meta*-Substituted systems with C_4 symmetry of the latter type have been prepared as racemates,[10b] and a route to analogs with a variety of functional groups has recently been reported.[11] In spite of the interest in chiral calix[4]arenes, few resolutions have been developed. We have been investigating transition metal containing calix[4]arenes[12] with rigid well-defined receptor cavities for the development of supramolecular materials and catalysts. We report herein the first resolution of chiral metallocalix[4]arenes. This method makes use of tungsten alkoxides,[13] which may be efficiently transformed into Lewis acidic oxotungsten(VI) calix[4]arene complexes or dichlorotungsten(VI) calix[4]arenes.[7a, 12a]

Among many resolution methods, we have concentrated on the use of diastereomeric intermediates to resolve the chiral metallocalix[4]arenes. Since the racemic $R_4W{=}O$ complex can be considered as a conceptual analog of a $R_2C{=}O$, the complex $R_4W(OR^*)_2$ was chosen to provide separable diastereomers similar to classical resolutions of chiral ketones via diastereomeric ketals. After separation, removal of the alkoxy groups produces resolved enantiomers. To test the accessibility and stability of cyclic tungsten(VI) calix[4]arene alkoxides,[14] we synthesized *trans*-1,2-cyclohexanediol-based chelates to produce complexes **2a** and **2b**. Two synthetic procedures were developed (Scheme 1). In one route, dichlorotungsten(VI) *p*-*t*Bu-calix[4]-arene (**1a**) was heated to reflux with doubly deprotonated cyclohexanediol in toluene for four hours to give **2a** in 96% yield. Alternatively, oxotungsten(VI) calix[4]arene (**1b**) is transformed to **2b** in 10% yield when treated with silylated cyclohexanediol in refluxing toluene for two days. The



Scheme 1. Synthesis of **2**.

^{1}H NMR spectra displayed by these calix[4]arenes are diagnostic for the formation of **2**. Due to lower symmetry of **2**, the methylene groups of the calix[4]arene core are inequivalent and produce two sets of coupled geminal protons for a total of four doublets. Both **2a** and **2b** can be purified by chromatography on a silica gel column without any decomposition.

With methods to prepare tungsten(VI) dialkoxy calix[4]arenes in hand, we endeavored to synthesize diastereomeric complexes in which both the calix[4]arene and dialkoxy ligands are chiral (Scheme 2). We employed 3,4-dimethylcalix[4]arene, which had been previously reported by Böhmer et al., since it has an interesting inherently chiral structure with C_4 symmetry.[10b] Reaction of 3,4-dimethylcalix[4]arene with WCl_6 in benzene produced the dichlorotungsten(VI) complex **3** in 81% yield. The ^{1}H NMR spectrum contained four doublets for the calix[4]arene methylene protons, which is consistent with **3** having a elliptical cone conformation with C_2 symmetry.[12a] Racemic **3** reacts with (1*S*,2*S*)-*trans*-1,2-cyclohexanediol under the same conditions used to prepare **2a** to give a mixture of the diastereomers **4** and **5**. The diastereomeric relationship is apparent from the ^{1}H NMR resonances for the methylene protons (eight doublets, Fig. 1). The two diastereomers **4** and **5** can be separated by

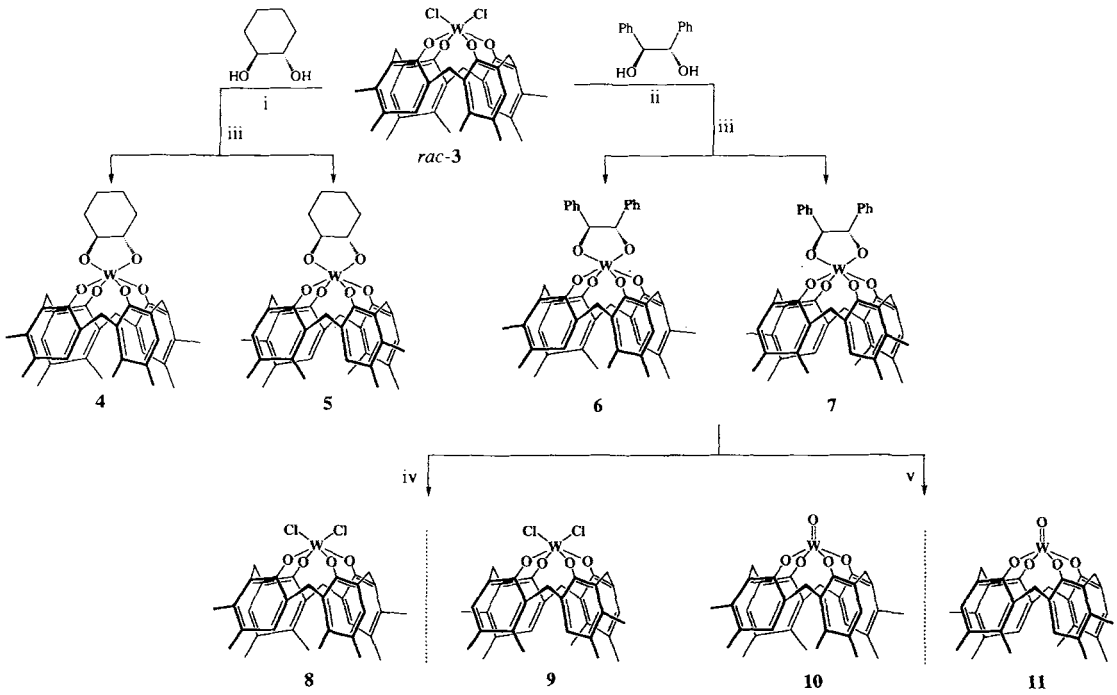

Scheme 2. Conditions: i) *n*BuLi, toluene, 4 h, 96%; ii) *n*BuLi, toluene, 4 h, 75%; iii) HPLC; iv) $AlCl_3$, $CHCl_3$, reflux, 3 min, 98%; v) trimethylsilyl triflate (TMSOTf), toluene, reflux overnight, 76%.

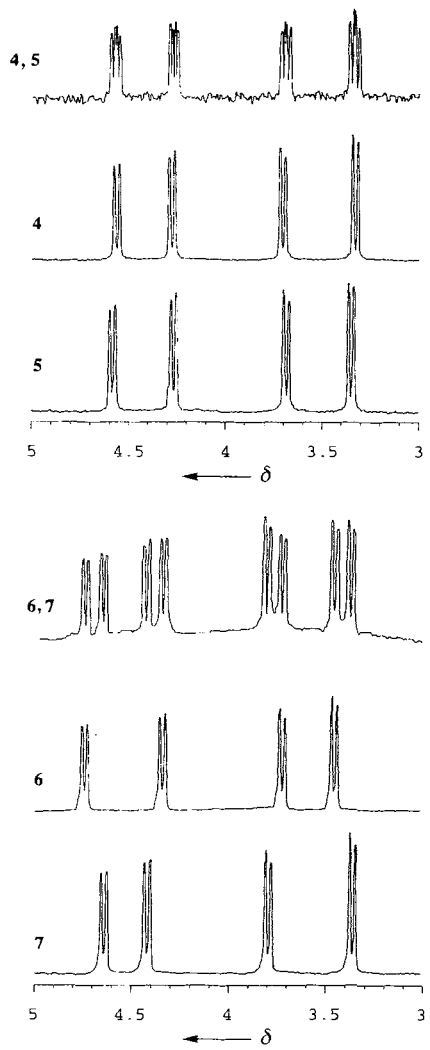

Fig. 1. ^{1}H NMR spectra of the characteristic calix[4]arene methylene protons of the diastereomeric mixtures (**4**, **5** and **6**, **7**), the first components from HPLC (**4** and **6**), and the second components from HPLC (**5** and **7**).

chromatography on silica gel (HPLC; eluent, *n*-hexane:CH_2Cl_2 3:1), and each compound has the expected four methylene doublets (Fig. 1).

After separation of **4** and **5**, we tried to complete the resolution and produce pure enantiomers **8** and **9** or oxo analogs **10** and **11**. However, a variety of deprotection protocols (H_2O, HCl, $AlCl_3$, BBr_3) proved ineffective. This difficulty is likely due to the inert nature of the W–O′ bond, which is considered to be very strong.[14c] We considered that a more productive approach would use dialkoxy groups in which the C–O bond may be cleaved. We prepared a (*S*,*S*)-(−)-hydrobenzoin-based diastereomeric mixture, **6** and **7**, in 75% yield (Scheme 2). Similar to **4** and **5**, the diagnostic calix[4]arene methylene protons of the diastereomeric mixture display eight pairs of doublets in the ^{1}H NMR spectrum. However, in this case we observe a greater dispersion in chemical shift (Fig. 1), which suggests that **6** and **7** have larger variations in their properties. Indeed their chromatography properties reflect this; **6** and **7** are more easily separated (silica: flash or HPLC) than **4** and **5**.

In order to assign the absolute configuration of the chiral tungsten(VI) calixarenes, we performed a crystal structure determination[15a] of compound **7** (the second component from the HPLC separation). In the crystal structure (Fig. 2), the tungsten(VI) center is approximately octahedral,[15b] and the calix[4]arene phenyl rings define an elliptical cone similar to that reported for dichlorotungsten(VI) *p*-*t*Bu-calix[4]arene.[12a] Crystals of **7** exhibit a noncentrosymmetric highly polar structure (Fig. 3).

The higher reactivity of the C–O bonds facilitates the transformation of **6** and **7** to enantiomeric metallocalix[4]arenes. Indeed, **6** and **7** are converted to the respective dichlorotungsten(VI) complexes **8** and **9** in near quantitative yield when treated with excess $AlCl_3$ (in refluxing $CHCl_3$, 3 min). The short reaction time was necessary since **8** and **9** were observed to decompose with longer reaction times. The CD spectra of compounds **8** and **9** are mirror images (Fig. 4), thereby confirming that they are indeed optical isomers. The strong Cotton effects observed

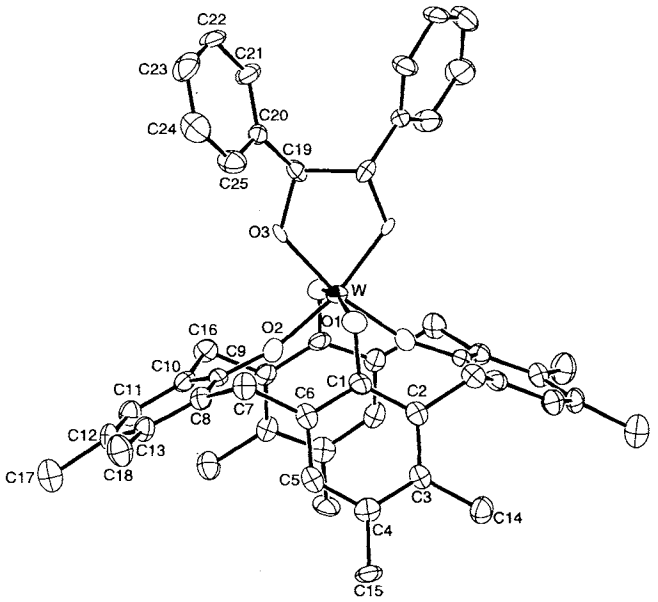

Fig. 2. X-ray structure of compound 7 [15b].

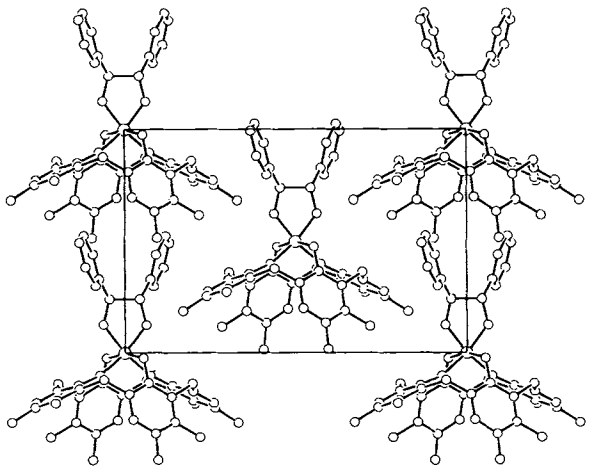

Fig. 3. Crystal packing of 7.

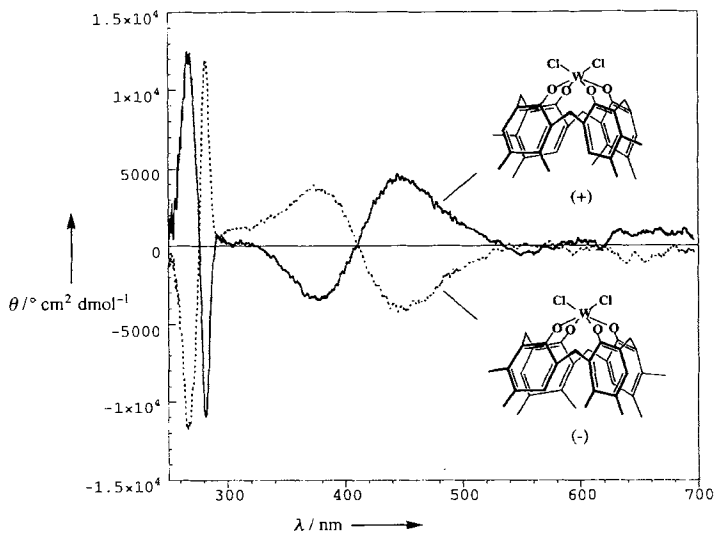

Fig. 4. CD spectra of resolved **8** and **9**.

at 250–300 nm are similar to what has been observed in other optically pure chiral calix[4]arenes[17] and likely result from exciton coupling of the aromatic chromophores.[16] The Cotton effects at 375–450 nm are most probably ligand–metal charge transfer in character. At λ_{max} (280 nm), θ is quite large (+12540), indicating that these chiral metallocalix[4]arenes have very strong rotary power. On the basis of the X-ray structure of **7**, we can assign the absolute configurations of **8** and **9** (Fig. 4).

To prepare Lewis acidic chiral oxotungsten(VI) calix[4]arenes with C_4 symmetry, we first investigated the method applied by Floriani et al.[12a] for the transformation of the dichlorotungsten(VI) group of **3** to an oxotungsten group. However, in contrast to other dichlorotungsten calix[4]arenes such as **1a**, which is hydrolytically sensitive, **3** has remarkably high stability and is even stable to chromatography on silica. To prepare oxotungsten calix[4]arenes **10** and **11**, we treated **6** and **7** with trimethylsilyl triflate followed by an aqueous workup (Scheme 2). Presumably, the initial product is a ditriflate, which is hydrolyzed to give the oxo compound. The calix[4]arene methylene protons in the ^{1}H NMR spectrum collapse to a pair of doublets at $\delta = 4.55$ and 3.59, indicating the C_4 symmetry of compounds **10** and **11**. The CD spectra of **10** and **11** again indicate that these complexes are optical isomers (Fig. 5). It is also interesting to note that **10** and **11** have yet stronger rotary power than **8** and **9** ($\theta = +45100$ at 265 nm (λ_{max})). The absolute configurations of **10** and **11** are shown in Figure 5.

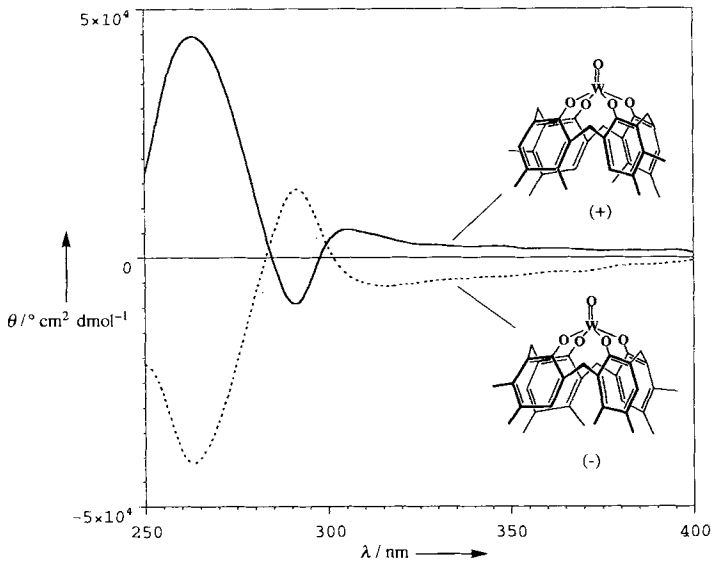

Fig. 5. CD spectra of optical isomers of **10** and **11**.

In summary, we have demonstrated the first resolution of metallocalix[4]arenes. The Lewis acidity and rigid chiral cavity of the oxotungsten(VI) calix[4]arenes present opportunities for the development of catalytic and liquid crystalline systems. Such applications are the subject of ongoing investigations in our laboratory.

Experimental Procedure

2a: *trans*-1,2-Cyclohexanediol (0.064 g, 0.56 mmol) in dry toluene (20 mL) was treated with *n*BuLi (1.1 mL, 1.6M) at room temperature under an argon atmosphere. After the solution had been stirred for 1 h, it was transferred to a suspension of dichlorotungsten(VI) *p*-*t*Bu-calix[4]arene (0.56g, 0.56 mmol) in toluene [12a]. The resulting dark purple suspension was heated to reflux for 4 h to give a clear orange-red solution. After the toluene had been evaporated, the residue was

purified by flash chromatography (*n*-hexane:dichloromethane 3:1) to give an orange solid (0.51 g, 96%). positive-ion FABMS: *m/z*: 943 [*M* + 1]; ^{1}H NMR (CDCl$_3$, 200 MHz): δ = 1.18 (s, 18H, *t*Bu), 1.29 (s, 18H, *t*Bu), 1.30 (m, 2H, CH$_2$), 1.71 (m, 2H, CH$_2$), 1.85 (m, 2H, CH$_2$), 2.16 (m, 2H, CH$_2$), 3.30 (dd, ^2J = 14.02, ^3J = 4.02 Hz, 4H, ArCH$_2$Ar), 4.62 (dd, ^2J = 13.38, ^3J = 5.08 Hz, 4H, ArCH$_2$Ar), 5.17 (m, 2H, OCH), 7.01 (s, 4H, ArH), 7.18 (s, 4H, ArH).

2b: *trans*-1,2-Cyclohexanediol (0.022g, 0.19 mmol) was dissolved in THF (5 mL) under an argon atmosphere, excess TMSCl (0.2 mL) and Et$_3$N (0.2 mL) were added at room temperature. The reaction mixture was allowed to stir until TLC showed the disappearance of cyclohexanediol, then THF, excess TMSCl, and Et$_3$N were removed under reduced pressure. Then **1b** (0.40 g, 0.171 mmol) [7a] in dry toluene (20 mL) was added to the residue, and the reaction mixture was heated to reflux for two days. Purification by flash chromatography (*n*-hexane:dichloromethane 3:1) gave an orange-red solid 50 mg (10%). Positive-ion FABMS: *m/z*: 2666 [*M* + 1], ^{1}H NMR (CDCl$_3$, 250 MHz): δ = 0.85 (t, 24H, CH$_3$), 1.10–2.00 (m, 166H, alkyl and CH$_2$), 2.20–2.30 (m, 2H, CH$_2$), 2.56 (s, 6H, ArCH$_3$), 2.74 (s, 6H, ArCH$_3$), 3.63 (dd, ^2J = 13.52, ^3J = 4.52 Hz, 4H, ArCH$_2$Ar), 3.89 (t, 4H, OCH$_2$), 3.97 (t, 4H, OCH$_2$), 4.00–4.10 (m, 8H, OCH$_2$), 4.71 (dd, ^2J = 13.62, ^3J = 6.42 Hz, 4H, ArCH$_2$Ar), 5.35–5.45 (m, 2H, OCH), 6.65 (s, 2H, ArH), 6.79 (s, 2H, ArH), 7.11 (s, 2H, ArH), 7.36 (s, 2H, ArH), 7.67 (s, 4H, ArH), 7.88 (s, 4H, ArH).

3: 3,4-Dimethylcalix[4]arene (0.501 g, 0.93 mmol) [10b] and WCl$_6$ (0.40 g, 1.0 mmol) were stirred in dry benzene (10 mL) overnight. After the solvent had been removed, the residue was purified by flash chromatography (*n*-hexane:dichloromethane 3:1) to give **3** as dark purple product (0.59 g, 81%). positive-ion FABMS: *m/z*: 787 [*M* + 1], ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 2.06 (s, 6H, CH$_3$), 2.37 (s, 6H, CH$_3$), 2.39 (s, 6H, CH$_3$), 2.58 (s, 6H, CH$_3$), 3.52 (d, ^2J = 14.19 Hz, 2H, ArCH$_2$Ar), 3.91 (d, ^2J = 14.19 Hz, 2H, ArCH$_2$Ar), 4.43 (d, ^2J = 14.16 Hz, 2H, ArCH$_2$Ar), 4.70 (d, ^2J = 14.17 Hz, 2H, ArCH$_2$Ar), 6.83 (s, 2H, ArH), 7.13 (s, 2H, ArH).

4 and **5**: These compounds were prepared in 92% yield by using the same procedure as for **2a**. Positive-ion FABMS: *m/z*: 831 [*M* + 1]. The mixture was separated by HPLC to give **4** and **5**. (Rainin preparative silica column, *n*-hexane:dichloromethane 3:1, flow rate 20 mL min^{-1}). First component: ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 1.36 (m, 2H, CH$_2$), 1.70 (m, 2H, CH$_2$), 1.84 (m, 2H, CH$_2$), 2.06 (s, 6H, CH$_3$), 2.15 (m, 2H, CH$_2$), 2.17 (s, 6H, CH$_3$), 2.353 (s, 6H, CH$_3$), 2.347 (s, 6H, CH$_3$), 3.33 (d, ^{2}J = 13.79 Hz, 2H, ArCH$_2$Ar), 3.71 (d, ^2J = 13.8 Hz, 2H, ArCH$_2$Ar), 4.28 (d, ^2J = 13.83Hz, 2H, ArCH$_2$Ar), 4.57 (d, ^2J = 13.68 Hz, 2H, ArCH$_2$Ar), 5.17 (m, 2H, OCH), 6.76 (s, 2H, ArH), 7.01 (s, 2H, ArH); second component: ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 1.36 (m, 2H, CH$_2$), 1.71 (m, 2H, CH$_2$), 1.85 (m, 2H, CH$_2$), 2.07 (s, 6H, CH$_3$), 2.15 (m, 2H, CH$_2$), 2.17 (s, 6H, CH$_3$), 2.354 (s, 6H, CH$_3$), 2.344 (s, 6H, CH$_3$), 3.35 (d, ^2J = 13.80 Hz, 2H, ArCH$_2$Ar), 3.69 (d, ^2J = 13.80 Hz, 2H, ArCH$_2$Ar), 4.27 (d, ^2J = 13.77 Hz, 2H, ArCH$_2$Ar), 4.59 (d, ^2J = 13.78 Hz, 2H, ArCH$_2$Ar), 5.16 (m, 2H, OCH), 6.75 (s, 2H, ArH), 7.01 (s, 2H, ArH).

6 and **7**: These compounds were also prepared by the same procedure as for **2a** (75% yield). positive-ion FABMS: *m/z*: 929 [*M* + 1]. Again separation by HPLC (*n*-hexane:dichloromethane 3:1) afforded **6** and **7**. First component: ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 2.09 (s, 6H, CH$_3$), 2.20 (s, 6H, CH$_3$), 2.325 (s, 6H, CH$_3$), 2.344 (s, 6H, CH$_3$), 3.45 (d, ^2J = 13.91 Hz, 2H, ArCH$_2$Ar), 3.72 (d, ^2J = 13.81 Hz, 2H, ArCH$_2$Ar), 4.34 (d, ^2J = 13.83 Hz, 2H, ArCH$_2$Ar), 4.74 (d, ^2J = 13.79 Hz, 2H, ArCH$_2$Ar), 6.52 (s, 2H, ArH), 6.80 (s, 2H, ArH), 7.02 (s, 2H, ArH), 7.29–7.38 (m, 10H, ArH); second component: ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 2.08 (s, 6H, CH$_3$), 2.20 (s, 6H, CH$_3$), 2.334 (s, 6H, CH$_3$), 2.345 (s, 6H, CH$_3$), 3.36 (d, ^2J = 13.84 Hz, 2H, ArCH$_2$Ar), 3.79 (d, ^2J = 13.86 Hz, 2H, ArCH$_2$Ar), 4.42 (d, ^2J = 13.94 Hz, 2H, ArCH$_2$Ar), 4.64 (d, ^2J = 13.72 Hz, 2H, ArCH$_2$Ar), 6.51 (s, 2H, ArH), 6.81 (s, 2H, ArH), 6.99 (s, 2H, ArH), 7.29–7.38 (m, 10H, ArH).

8 and **9**: Compound **6** (or **7**) (1.2 mg) was dissolved in CHCl$_3$ (2 mL), then AlCl$_3$ (10 mg) was quickly added to the solution, and the solution was heated to reflux for about 3 min, upon which the color of the solution changed from orange to dark purple. The reaction was quenched with water (0.5 mL) and dried under reduced pressure. The residue was purified by HPLC (*n*-hexane:dichloromethane 3:1) to give the dichlorotungsten(VI) calix[4]arene (1 mg) **8** (or **9**), as a dark purple solid (98%). Positive-ion FABMS: *m/z*: 787 [*M* + 1], ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 2.06 (s, 6H, CH$_3$), 2.36 (s, 6H, CH$_3$), 2.39 (s, 6H, CH$_3$), 2.58 (s, 6H, CH$_3$), 3.52 (d, ^2J = 14.20 Hz, 2H, ArCH$_2$Ar), 3.91 (d, ^2J = 14.19 Hz, 2H, ArCH$_2$Ar), 4.43 (d, ^2J = 14.11 Hz, 2H, ArCH$_2$Ar), 4.70 (d, ^2J = 14.17 Hz, 2H, ArCH$_2$Ar), 6.83 (s, 2H, ArH), 7.13 (s, 2H, ArH).

10 and **11**: Excess trimethylsilyl triflate was added to a solution containing compound **6** (or **7**) (2 mg) in toluene (10 mL). The solution changed from orange to red-orange under heating to reflux overnight under argon. The reaction was quenched with water (1 mL) and neutralized by the addition of triethylamine. The solvent was removed and the residue was purified by flash chromatography (AcOH:CH$_2$Cl$_2$ 5:95) to give the oxotungsten(VI) calix[4]arene **10** (or **11**) (1 mg) as a yellow solid (76%). Positive-ion FABMS: *m/z*: 733 [*M* + 1], ^{1}H NMR (CDCl$_3$, 500 MHz): δ = 2.14 (s, 12H, CH$_3$), 2.31 (s, 12H, CH$_3$), 3.59 (d, ^2J = 13.46 Hz, 4H, ArCH$_2$Ar), 4.55 (d, ^2J = 13.40 Hz, 4H, ArCH$_2$Ar), 7.04 (s, 4H, ArH).

Boron–Carbon Chains Stabilized in Rare Earth Metallic Frameworks

Denis Ansel, Josef Bauer,* François Bonhomme, Ghania Boucekkine, Gilles Frapper, Patrick Gougeon, Jean-François Halet,* Jean-Yves Saillard,* and Bachir Zouchoune

Ternary and higher order phases comprising a rare earth metal, boron, and carbon show a particularly rich and varied structural chemistry. These structure types can be classified in three different families according to the dimensionality of the boron–carbon sublattice: two-dimensional (2D) networks, one-dimensional (1D) zigzag chains, or finite, linear units of various lengths.[1] Such compounds are attractive not only as new materials with interesting physical properties, but also simply as solid-state analogues of molecular organic and organometallic compounds containing all-carbon ligands.[2]

Finite boron–carbon units stabilized in metallic lattices are rather scarce and limited in length to three or four atoms as demonstrated in the metal- and carbon-rich compounds Sc_2BC_2,[3] $Ce_5B_2C_6$,[4] $La_3BC_2Br_2$, and $Ce_6B_2C_3Br_3$.[5] We report herein on the characterization of chains with up to 13 atoms that are contained in new cerium, lanthanum, and neodynium boride carbide materials. $La_{15}B_{14}C_{19}$, $M_{10}B_9C_{12}$ (M = La, Ce, Nd), and $Ce_5B_4C_5$ are obtained as lustrous black pellets by arc melting and subsequent annealing of the elements for several days.[6]

In all compounds, the metallic sublattice can be described as resulting from an irregular stacking of slightly corrugated 2D square nets, which gives rise to a three-dimensional (3D) framework with metal–metal separations between 3.40 and 4.10 Å.[9] This leads to the formation of small channels of different sizes in which roughly linear B_xC_y units are inserted (Fig. 1). Two kinds of eleven-membered units, B_4C_7 and B_5C_6, are embedded in the structure of $La_{15}B_{14}C_{19}$, corresponding to the formula $La_{15}(B_4C_7)(B_5C_6)_2$. $Ce_{10}B_9C_{12}$ contains a thirteen-membered B_5C_8 chain (the longest so far observed in these materials) and an eight-membered B_4C_4 chain, corresponding to the $Ce_{10}(B_5C_8)(B_4C_4)$ formula. $Ce_5B_4C_5$ contains eight-membered B_4C_4 and six-membered B_3C_3 units, in addition to single C atoms and the already known BC_2 group, giving rise to the formula $Ce_{10}(B_4C_4)(B_3C_3)(BC_2)(C)$. These tightly bonded boron–carbon "molecules" and their metal environments are shown in Figures 2–4. The boron atoms are generally attached to two carbon atoms and often located in a distorted cube of metal atoms, whereas the carbon atoms are generally accomodated in $[M_4B_2]$ or $[M_5B]$ octahedra.[11] The B–B, B–C, and C–C bond lengths vary between 1.57 and 1.68, 1.43 and 1.58, and 1.33 and 1.35 Å, respectively. They suggest some double-bond character.[3–5] The associated bond angles vary from 180° to about 140° (Figs. 2–4).

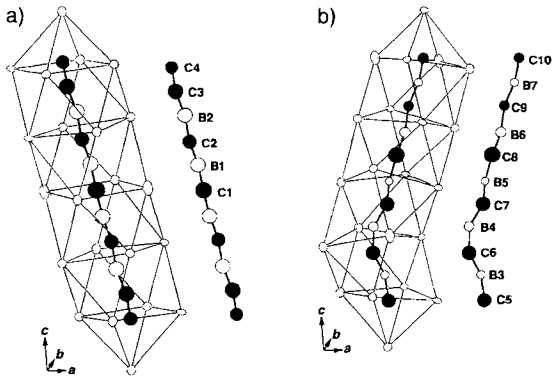

Fig. 2. Environments of the centrosymmetric B_4C_7 (a) and noncentrosymmetric B_5C_6 (b) chains in $La_{15}B_{14}C_{19}$. Selected interatomic distances [Å] and angles [°]: B_4C_7: C1–B1 1.46(3), C2–B1 1.46(4), C2–B2 1.47(3), C3–B2 1.51(4), C3–C4 1.35(3); B1-C1-B1′ 180, C1-B1-C2 167(2), B1-C2-B2 162(2), C2-B2-C3 160(3), C4-C3-B2 164(3); B_5C_6: C5–B3 1.44(3), C6–B3 1.50(3), C6–B4 1.50(3), C7–B4 1.50(3), C7–B5 1.40(3), C8–B5 1.51(3), C8–B6 1.58(3), C9–B6 1.49(3), C9–B7 1.49(3), C10–B7 1.43(3); C5-B3-C6 153(2), B3-C6-B4 148(2), C6-B4-C7 149(2), B4-C7-B5 153(2), C7-B5-C8 157(2), B5-C8-B6 148(2), C8-B6-C9 145(2), B6-C9-B7 156(2), C9-B7-C10 163(2).

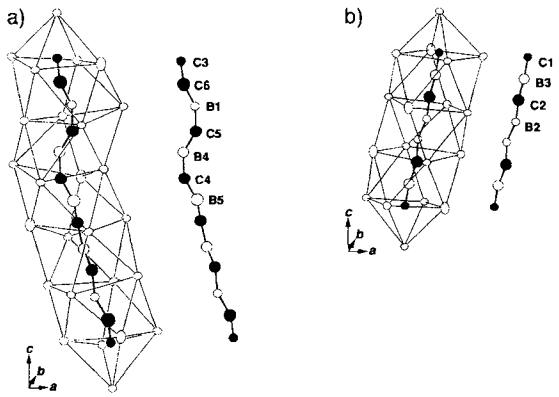

Fig. 3. Environments of the centrosymmetric B_5C_8 (a) and B_4C_4 (b) chains in $Ce_{10}B_9C_{12}$. Selected interatomic distances [Å] and angles [°]: B_5C_8: C3–C6 1.33(2), C6–B1 1.52(2), B1–C5 1.51(2), C5–B4 1.49(2), B4–C4 1.55(2), C4–B5 1.44(1); C3-C6-B1 156(2), C6-B1-C5 151(1), B1-C5-B4 145(2), C5-B4-C4 148(2), B4-C4-B5 149(2), C4-B5-C4′ 146(2); B_4C_4: C1–B3 1.46(2), B3–C2 1.53(2), C2–B2 1.41(2), B2–B2′ 1.57(3); C1-B3-C2 167(2), B3-C2-B2 158(2), C2-B2-B2′ 152(2).

Previous theoretical studies on rare earth metal boride carbides have shown that their structures can be rationalized within the approximation of a purely ionic bonding mode between the metal and the nonmetal centers.[1, 3, 12–14] For instance, Sc_2BC_2 can be described in a first approximation as being built of $(BC_2)^{5-}$ ions surrounded by not fully oxidized $Sc^{2.5+}$ ions.[3] The same approach is used here to tackle the chemical bonding in the new materials $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$.

The first question that arises concerns the assignment of formal ionic charges to account for the cumulene-like character of

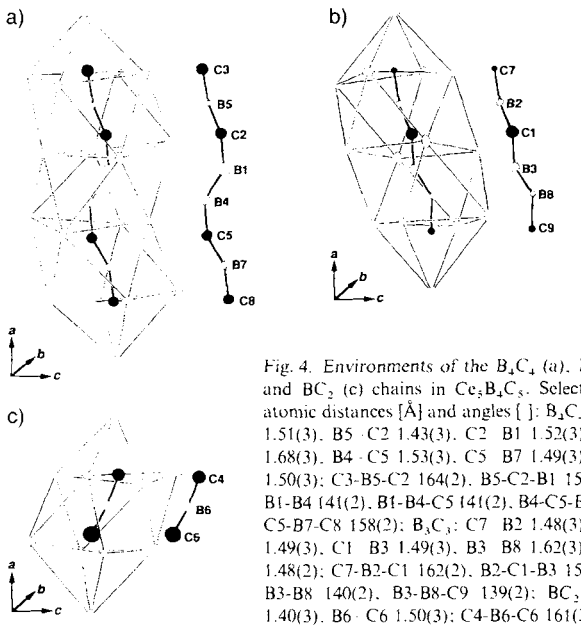

Fig. 4. Environments of the B_4C_4 (a), B_3C_3 (b), and BC_2 (c) chains in $Ce_5B_4C_5$. Selected interatomic distances [Å] and angles [°]: B_4C_4: C3–B5 1.51(3), B5–C2 1.43(3), C2–B1 1.52(3), B1–B4 1.68(3), B4–C5 1.53(3), C5–B7 1.49(3), B7–C8 1.50(3); C3-B5-C2 164(2), B5-C2-B1 158(2), C2-B1-B4 141(2), B1-B4-C5 141(2), B4-C5-B7 154(2), C5-B7-C8 158(2); B_3C_3: C7–B2 1.48(3), B2–C1 1.49(3), C1–B3 1.49(3), B3–B8 1.62(3), B8–C9 1.48(2); C7-B2-C1 162(2), B2-C1-B3 152(2), C1-B3-B8 140(2), B3-B8-C9 139(2); BC_2: C4–B6 1.40(3), B6–C6 1.50(3); C4-B6-C6 161(2).

the boron–carbon units in these materials. The usual oxidation state for the La and Ce is 3+, but can be lower as demonstrated for Sc in Sc_2BC_2.[3] In this compound the formal charge of 5− was found to be the energetically most favorable for an isolated BC_2 unit, since this provides a large HOMO/LUMO gap separating the low-lying bonding and nonbonding levels from the high-lying antibonding levels. The extended Hückel molecular orbital[15] (EHMO) diagrams of the various B_xC_y groups encountered in $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$ are shown in Figure 5; they are based on averaged linearized geometries. As for the BC_2 case, only one favored electron count, which leads to a significant HOMO/LUMO gap and corresponds to $[B_5C_6]^{9-}$, is possible for B_5C_6. In the case of the B_3C_3 and the B_4C_4 units two, and for the B_4C_7 and B_5C_8 units four π-type orbitals of intermediate energy (~9 eV) lie in the middle of a large energy gap. This is a typical situation for the existence of a range of possible electron counts corresponding to a partial or complete occupation of these intermediate levels.

A clearer answer to the question concerning which of the possible electron counts is closer to the real situation in $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$ can be gained by analyzing the band structure of these materials, calculated within the extended Hückel tight-binding (EHTB) formalism.[16] This analysis reveals that in all of these compounds, the states lying in the vicinity (above and below) of the Fermi level (ε_F) result from the overlap of the bottom of the metallic d band with bands generated by the intermediate MOs of the B_3C_3, B_4C_4, B_4C_7, or B_5C_8 units. This is exemplified by the density of states (DOS) of $Ce_{10}B_9C_{12}$ shown in Figure 6. The analysis of the states around ε_F reveals a significant participation of all the components (Ce, B_4C_4, and B_5C_8). The contributions from B_4C_4 and B_5C_8 come essentially from their $3\pi_u$ and $4\pi_g + 4\pi_u$ levels, respectively. It follows that the intermediate levels of the B_4C_4 and B_5C_8 units in $Ce_{10}B_9C_{12}$ are calculated to be roughly half-occupied. A similar situation is found for the other chains B_3C_3, B_4C_4, and B_4C_7 in $Ce_5B_4C_5$ and $La_{15}B_{14}C_{19}$. This leads to the approximate formal charges $(B_3C_3)^{7-}$, $(B_4C_4)^{8-}$, $(B_5C_6)^{9-}$, and $(B_5C_8)^{9-}$. By assuming these charges, the EHMO Mulliken overlap populations calculated on the isolated anions are in reasonably good agreement with the observed bond lengths.

Geometry optimization with ab initio calculations[17] has been also performed on $(BC_2)^{5-}$, $(B_3C_3)^{7-}$, $(B_4C_4)^{8-}$, $(B_5C_6)^{9-}$, and $(B_5C_8)^{9-}$ to ascertain the proposed assignment of the anionic charges. A cumulene-like character (formal double bonds along the chains) is confirmed for these charges.[18] As mentioned previously, the nonmetal chains encountered in these new rare earth metal boride carbides are not rigourously linear. Deviation from linearity is well-established in organic cumulene and cumulenone molecules.[19] It is known that a small bending of these molecules is not costly in energy and is facilitated as they become longer.[19] The same phenomenon might occur for the boron–carbon "molecules". Larger distortion is observed experimentally for the longest B–C chains. For instance, ab initio calculations on a bent and linear $(BC_2)^{5-}$ ion show almost no change in the B–C distances (ca. 1.50 Å) and only a small increase of the total energy (0.59 eV) for a C-B-C bending angle of 150° compared to 180°.[20] Clearly, small constraints of the surrounding metal matrix must be sufficient to allow a small distortion of the B–C chains without modifying their electronic structure too much.

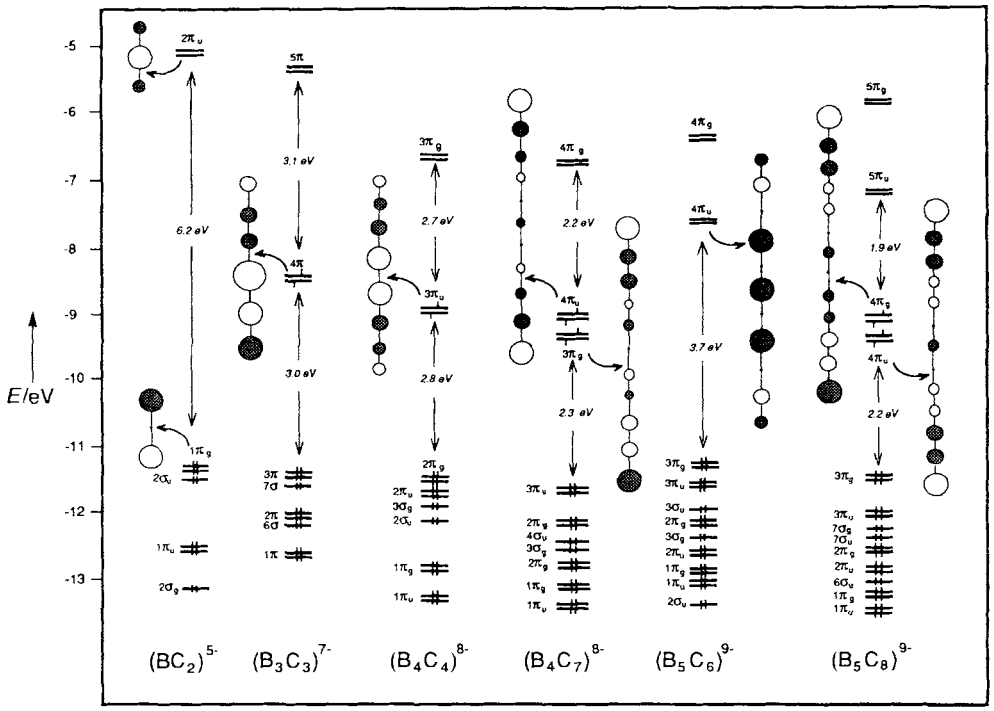

Fig. 5. EHMO diagrams of the boron-carbon units $(BC_2)^{5-}$, $(B_3C_3)^{7-}$, $(B_4C_4)^{8-}$, $(B_4C_7)^{8-}$, $(B_5C_6)^{9-}$, and $(B_5C_8)^{9-}$ (linear models of $C_{\infty v}$ or $D_{\infty h}$ symmetry were assumed).

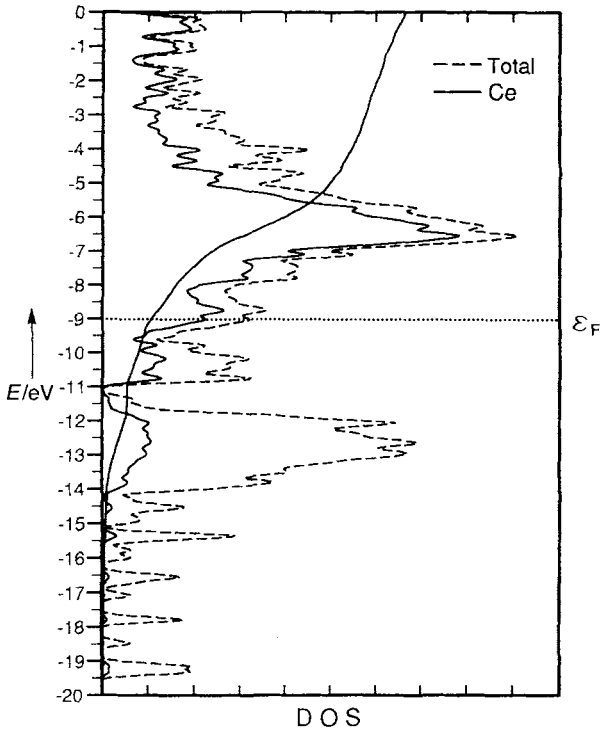

Fig. 6. Total density of states (solid line) and metal contribution (dashed line) for $Ce_{10}B_9C_{12}$ obtained from EHTB calculations.

Within the first-order approximation of an ionic model, $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$ can then be written as $(La^{1.73+})_{15}(B_4C_7)^{8-}[(B_5C_6)^{9-}]_2$, $(Ce^{1.7+})_{10}(B_4C_4)^{8-}(B_5C_8)^{9-}$, and $(Ce^{2.4+})_{10}(BC_2)^{5-}(B_3C_3)^{7-}(B_4C_4)^{8-}(C^{4-})$, respectively. Similarly, Sc_2BC_2,[3] and $Ce_5B_2C_6$[4] can be written as $(Sc^{+2.5})_2(BC_2)^{5-}$ and $(Ce^{2.8+})_5[(BC_2)^{5-}]_2(C_2)^{4-}$, respectively. It is noteworthy that all the B_xC_y anions are isoelectronic to cumulene- or carbyne-like C_x^{4-} anions, satisfying the octet rule, some of which such as C_2^{4-} and C_3^{4-} have been characterized in the solid state.[10] The question of the stability of rare earth metal-boron-carbon phases containing oligomeric or polymeric chains longer than 13 atoms remains open.[21]

Significant covalent interaction occurs between the metallic framework and the boron–carbon units. This is exemplified by the significant metallic participation below ε_F in the states generated by the occupied levels of the $(BC_2)^{5-}$, $(B_3C_3)^{7-}$, $(B_4C_4)^{8-}$, $(B_5C_6)^{9-}$, and $(B_5C_8)^{9-}$ ions (see Fig. 6 for the example of $Ce_{10}B_9C_{12}$). Such an interaction is associated with an electron transfer into the empty levels of the metallic d band. This reduces somewhat the anionic charge on the boron–carbon "ligands" trapped in the metallic matrix, consequently contributing to their stabilization.[22]

Since the metal atoms are not fully oxidized and their band structures exhibit the same features as that described in Figure 6 for $Ce_{10}B_9C_{12}$, all these new materials are expected to exhibit metallic properties.[23] They do not show any superconducting properties, despite the coexistence of metallic and nonmetallic states around ε_F, which might favor such properties as observed in related compounds such as $La_5B_2C_6$[4] or $LuNi_2B_2C$.[24]

[6] Preparation: Cold-pressed pellets of different mixtures of powders prepared from commercially available pure elements were arc-melted in a water-cooled copper furnace under purified argon. They were turned over and remelted several times to ensure homogeneity. Subsequent annealing at 1000 °C for four days was carried out with a high-frequency furnace under purified argon. Single crystals of $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$ were obtained from slowly cooled samples. Crystallographic data: $La_{15}B_{14}C_{19}$, $P2_1/c$, $a = 8.671$ (3), $b = 8.656(1)$, $c = 19.953$ (8) Å, $\beta = 94.45(1)°$ $V = 1493.2$ (8) Å^3, $Z = 2$, $\mu = 210.53$ cm^{-1}, $R(F) = 0.036$, $R_w(F) = 0.049$ (based on 1941 reflections with $I > 3\sigma(I)$). $Ce_{10}B_9C_{12}$, $P4_12_12$, $a = 8.4785(7)$, $c = 25.350(4)$ Å, $V = 1822.3(3)$ Å^3, $Z = 4$, $\mu = 248.41$ cm^{-1}, $R(F) = 0.028$, $R_w(F) = 0.039$ (based on 1247 reflections with $I > 2\sigma(I)$). $Ce_5B_4C_5$, $Pna2_1$, $a = 24.426(5)$, $b = 8.4636(7)$, $c = 8.5007(7)$ Å, $V = 1757.3(4)$ Å^3, $Z = 4$, $\mu = 257.59$ cm^{-1}, $R(F) = 0.040$, $R_w(F) = 0.042$ (based on 1755 reflections with $I > 2\sigma(I)$). Data were collected at room temperature on an Enraf-Nonius CAD-4 diffractometer equipped with graphite-monochromatized $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å). Accurate cell parameters were obtained by least-squares refinement of the setting angles of 25 reflections. Structures were solved with the aid of MULTAN 11/82 [7] and subsequent difference Fourier syntheses. All the calculations were performed with the SDP programs [8]. Further details of the crystal structure investigations may be obtained from the Fachinformationszentrum Karlsruhe, D-76344, Eggenstein-Leopoldshafen, on quoting the depository numbers CSD-402368 ($Ce_5B_4C_5$), CSD-402387 ($Ce_{10}B_9C_{12}$), and CSD-402390 ($La_{15}B_{14}C_{19}$).

[9] The unit cell parameters a and b in $La_{15}B_{14}C_{19}$, a in $Ce_{10}B_9C_{12}$, and b and c in $Ce_5B_4C_5$, are nearly identical and comparable to those measured in $La_5B_2C_6$ [4]. The stacking parameter (c in $La_{15}B_{14}C_{19}$ and $Ce_{10}B_9C_{12}$, a in $Ce_5B_4C_5$) depends only on the number of metal layers (separated by ca. 3 Å) needed to accomodate the boron–carbon anions. They can be derived from the defect NaCl structure of the rare earth metal monocarbides as in Sc_3C_4 for instance [10].

[22] The EHTB computed atomic net charges are the following: $(La^{1.19+})_{15}(B_4C_7)^{6.67-}$ $[(B_5C_6)^{5.59-}]_2$ for $La_{15}B_{14}C_{19}$, $(Ce^{1.12+})_{10}$ $(B_4C_4)^{4.2-}$ $(B_5C_8)^{7.00-}$ for $Ce_{10}B_9C_{12}$, and $(Ce^{1.33+})_{10}(C)^{2.31-}$ $(BC_2)^{2.72-}$ $(B_3C_3)^{3.72-}$ $(B_4C_4)^{4.51-}$ for $Ce_5B_4C_5$.

[23] Preliminary electrical resistivity measurements indicate that $La_{15}B_{14}C_{19}$, $Ce_{10}B_9C_{12}$, and $Ce_5B_4C_5$ are good metallic conductors. According to magnetic susceptibility measurements, no superconductivity is observed down to 2 K (H. Noël, personal communication).

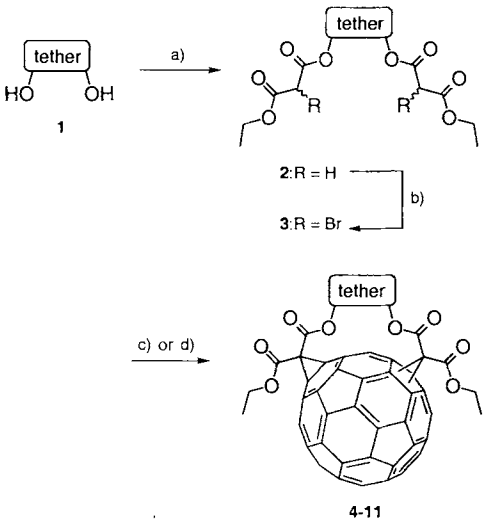
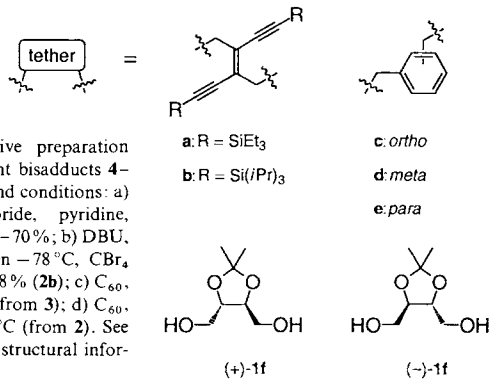
Regio- and Diastereoselective Bisfunctionalization of C_{60} and Enantioselective Synthesis of a C_{60} Derivative with a Chiral Addition Pattern**

Jean-François Nierengarten, Volker Gramlich, Francesca Cardullo, and François Diederich*

Although a rich variety of methods for the preparation of covalent monoadducts of C_{60} are known,[1] the development of selective routes to isomerically pure multiple adducts of the fullerene is still in its infancy.[2–4] We recently described a versatile strategy for the regioselective preparation of specific bis-through hexakisadducts of C_{60} based on the concept of tether-directed remote functionalization.[4] We now report a similar, yet much simpler, direct bisfunctionalization of C_{60} based on a cyclization reaction of the carbon sphere with bis(malonate) derivatives in a double Bingel addition.[5] A short synthetic route led to a variety of specific fullerene bisadducts with high regio- and diastereoselectivity. Starting from optically pure bis(malonate) derivatives, the new method also permitted the preparation of enantiomerically pure bis(cyclopropanated) C_{60} derivatives whose chirality results exclusively from the addition pattern.[6, 7]

During the synthesis of precursors to polytriacetylenes with pendant C_{60} moieties,[8] we found that reaction of C_{60} with bis(2-bromomalonates) **3a** and **3b**, which were prepared in two steps from the corresponding diols **1a,b**[9] via **2a,b** (Scheme 1), yielded the macrocyclic bisadducts **4** and **5**, respectively, resulting from double Bingel addition to one carbon sphere (Table 1, Fig. 1). Since the linker between the two malonate moieties in **3a,b** acted as a directing tether, the bisfunctionalization of C_{60} was highly regioselective and only one of the possible isomeric bisadducts was formed in 16% (**4**) and 10% (**5**) yield. The general character of this facile methodology for the selective preparation of C_{60} bisadducts was subsequently established by





Scheme 1. Regioselective preparation of macrocyclic covalent bisadducts **4**–**11** of C_{60}. Reagents and conditions: a) ethyl malonyl chloride, pyridine, CH_2Cl_2, 0 to 20 °C, 60–70%; b) DBU, THF, 0 to 20 °C, then −78 °C, CBr_4 (2 equiv), 52% (**2a**), 48% (**2b**); c) C_{60}, DBU, toluene, 20 °C (from **3**); d) C_{60}, DBU, I_2, toluene, 20 °C (from **2**). See Table 1 for additional structural information and yields.

Table 1. The diols and derived bis(malonate) derivatives, which were used in the addition to C_{60}, along with the addition products. All products are out–out stereoisomers [a].

Diol	Bis(malonate)	Bisadduct (symmetry, add. pattern, yield) [b]
1a	**3a**	**4** (C_1, *cis*-2, 16%)
1b	**3b**	**5** (C_1, *cis*-2, 10%)
1c	**2c**	**6** (C_s, *cis*-2, 33%)
1d	**2d**	**7** (C_s, *cis*-2, 32%)
1e	**2e**	**8** (C_s, *trans*-4, 33%)
		9 (C_1, *e*, 8%)
(+)-**1f**	(−)-**2f**	**10a** (C_1, *cis*-2, 20%)
		11a (C_2, *cis*-3, 13%)
(−)-**1f**	(+)-**2f**	**10b** (C_1, *cis*-2, 21%)
		11b (C_2, *cis*-3, 15%)

[a] All new compounds were fully characterized by ^1H and ^{13}C NMR, UV/Vis, FT-IR, FAB-MS data, and, except for **9**, by elemental analysis. [b] For the position notation in the bisaddition patterns, see ref. [3a] and Fig. 1. For identical addends, a second attack into *e-face* or *e-edge* positions leads to identical products [4c].

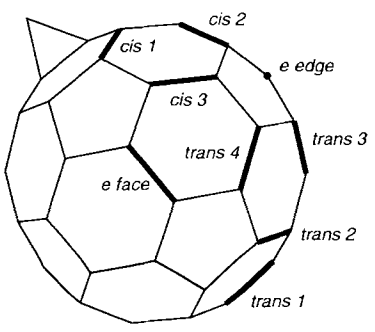


Fig. 1. Position notation for bisadducts of C_{60}.

[**] This work was supported by the Swiss National Science Foundation and by a postdoctoral fellowship (Human Capital and Mobility) from the EU (J.-F. N.). We thank Dr. M. Sebova and J. Cuntze for NMR measurements, T. Granier for help with the CD measurements, and A. Herrmann for help in the HPLC analysis.

starting from the three isomeric benzenedimethanols **1c–e**. In a typical procedure, diols **1c–e** were treated with ethyl malonyl chloride in the presence of pyridine in CH_2Cl_2 at 20 °C to give the bis(ethyl malonyl) derivatives **2c–e**, respectively, in 60–70% yield. The corresponding halomalonates were prepared in situ with iodine,[10] and the one-pot reaction of C_{60} with compounds **2c–e**, I_2, and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene at 20 °C afforded the corresponding bisadducts **6–9** (Scheme 1 and Table 1).

For each macrocyclic bisadduct **4–9**, the relative position of the two cyclopropane rings on the C_{60} surface was determined based on the molecular symmetry (Table 1) deduced from the ^1H and ^{13}C NMR spectra as well as on its UV/Vis spectra. Stepwise double Bingel reaction with diethyl 2-bromomalonate had previously been shown by Hirsch and co-workers to yield a total of seven out of eight possible regioisomers, with the *trans*-3-and *e*-isomers (Table 1, Fig. 1) being the dominant products.[3a] They found that the UV/Vis spectra of the bisadducts are highly dependent on the addition pattern and characteristic for each regioisomer. The UV/Vis spectra (CH_2Cl_2) of **4–9** are totally consistent with those previously reported for the analogous tetraethyl esters.[3a, 3e]

In theory, each cyclic regioisomer could form as a mixture of different diastereoisomers, depending on how the two ethoxycarbonyl residues at the two methano bridge C atoms are oriented with respect to each other (in–in, in–out, and out–out isomerism).[11] Actually, for cyclic bisadducts such as **6–9** with a simple symmetrical linker, there exist, in theory, 37 possible different constitutional isomers and stereoisomers. Nevertheless, bisadducts **4–9** were all isolated either as achiral, isomerically pure compounds or as single racemic mixtures; therefore, the second intramolecular Bingel addition occurs not only regio- but also diastereoselectively. Because of the length of the linker between the two cyclopropane rings, only the out–out diastereoisomer appeared reasonable for the bisadducts **8** and **9**. Two C_s-symmetrical *cis*-2 diastereoisomers (in–in and out–out) are possible for **6** and **7**.[11] Due to the additional chirality arising from the presence of the *trans*-alkene fragment in the macrocyclic bridges, four different C_1-symmetrical *cis*-2 diastereoisomers are possible for **4** and **5**. However, steric considerations based on molecular and computer modeling indicated that the two cyclopropane rings on the C_{60} surface in all *cis*-2 bisadducts should be linked in a similar (out–out) manner to that determined by X-ray crystal structure analysis for compound **6** (Fig. 2a).[12] The crystal packing analysis showed that the molecules are assembled in a dimeric arrangement (Fig. 2b). The phenyl ring of one molecule is stacked above the C_{60} moiety of the second molecule at an intermolecular distance of 3.30 Å between the center of the aromatic ring and the closest C_{60} C atom.[13] Noteworthy are the two short intermolecular $C(sp^3)$–$H\cdots O$ contacts between the benzylic CH and the ester C=O groups of neighboring molecules ($H\cdots O$ distance: 2.68 Å; C-$H\cdots O$ angle: 139.4°).[14]

Using the same methodology, the two enantiomeric *cis*-2 bisadducts **10a** and **10b** as well as the two enantiomeric *cis*-3 bisadducts **11a** and **11b** were prepared from the commercially available optically pure diols (+)- and (−)-**1f**, respectively (Scheme 1, Table 1). The cyclization reaction is highly diastereoselective and only one of the possible diastereoisomers could be detected in each case.[15] The *cis*-3 addition pattern on the C_{60} surface is chiral;[7] therefore transesterification (K_2CO_3, EtOH/THF) of **11a** yielded the *cis*-3 tetraethyl ester **12** as an enantiomerically pure compound (Fig. 3). The other enantiomer *ent*-**12** was prepared in a similar way starting from **11b**. The circular dichroism (CD) spectra of the two enantiomers (^fC and ^fA; f = fullerene, *C* = clockwise, *A* = anticlockwise)[16] are depicted in Figure 3. As previously described, the CD spectra show pronounced Cotton effects due to strong chiroptical contributions from the chirally functionalized fullerene chromophore.[6, 16] The enantiomeric excess (*ee*) determined by HPLC[17] was higher than 97% for both enantiomers of **12**.

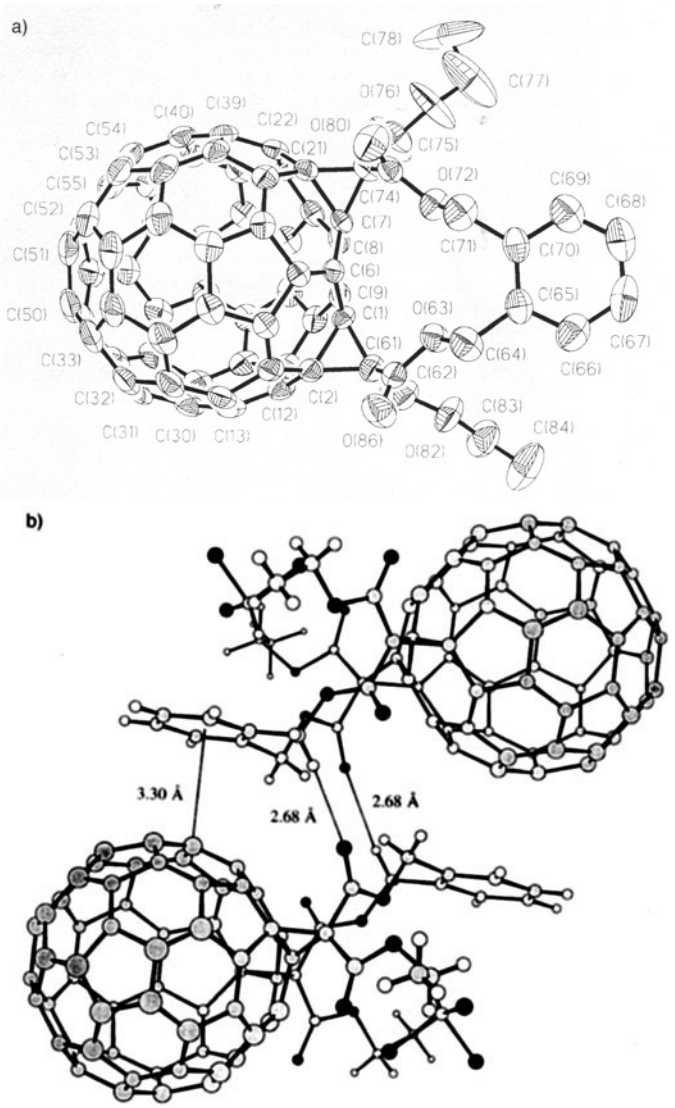

Fig. 2. a) X-ray crystal structure of **6**. The $CHCl_3$ molecule located in the crystal lattice has been omitted. b) Crystal packing of **6** showing the face-to-face dimeric arrangement of the C_{60} derivatives. Each pair of molecules is surrounded on top and bottom by cocrystallized $CHCl_3$ molecules (shown in dark).

With similar efficiency to that of the asymmetric Sharpless dihydroxylation of C_{60},[6] the addition of the chirally tethered bismalonate enables an enantioselective synthesis of optically active C_{60} bisadducts in which the chirality results exclusively from the addition pattern. Additionally, it should be noted that all macrocyclic C_{60} bisadducts described above are topologically nontrivial molecules; in other words, they cannot be represented by planar molecular graphs.[18]

Experimental Procedure

Preparation of **10b**, **11b**, and *ent*-**12**: DBU (0.43 mL, 2.913 mmol) was added under Ar at 20 °C to a stirred solution of C_{60} (350 mg, 0.485 mmol), I_2 (271 mg, 1.068 mmol), and (+)-**2f** (208 mg, 0.534 mmol) in toluene (700 mL). The mixture was stirred for 7 h, and filtered over a plug of silica, first with toluene to remove the unreacted C_{60}, then with CH_2Cl_2/MeOH 99:1. Column chromatography (SiO_2)

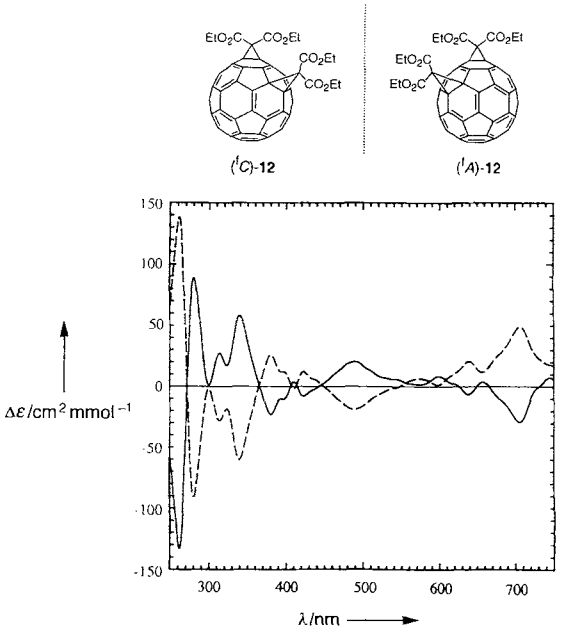

Fig. 3. CD spectra for both enantiomers of tetraethyl ester **12** in CH_2Cl_2 ($c = 0.8 \times 10^{-5}$ M). Solid line: enantiomer resulting from the transesterification of **11a**; dashed line: enantiomer resulting from the transesterification of **11b**.

eluting with CH_2Cl_2/hexane 9:1 followed by precipitation from CH_2Cl_2/hexane yielded **10b** (114 mg, 21%). Dark red solid, m.p. >280 °C; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 258 (108500), 320 (sh, 32500), 374 (sh, 10700), 437 (2700), 468 (2300); ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 1.36 (t, J = 7.1 Hz, 3H), 1.37 (t, J = 7.1 Hz, 3H), 1.46 (s, 3H), 1.47 (s, 3H), 4.05 (m, 1H), 4.15 (m, 1H), 4.22 (m, 1H), 4.33–4.47 (m, 4H), 4.60 (m, 1H), 4.84 (m, 1H), 4.98 (m, 1H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 14.12, 14.13, 28.48, 28.55, 48.90 (2C), 63.46 (2C), 66.89, 67.08, 67.16 (2C), 70.10, 70.17, 78.25, 78.29, 111.35, 133.55, 137.55, 137.73, 137.83, 138.06, 138.33, 138.48, 138.55, 140.92, 140.95, 141.30, 141.33, 141.88, 142.09, 142.42, 142.45, 143.15, 143.20, 143.64, 143.66, 143.89, 143.94, 144.19, 144.25, 144.39, 144.57, 144.58, 144.69, 144.72, 144.90, 145.03, 145.18, 145.19, 145.21, 145.31, 145.33, 145.35, 145.64, 145.71, 145.75, 145.77, 146.00, 146.04, 146.15, 146.19, 147.33, 147.43, 147.53, 149.38, 149.51, 162.63, 162.68, 162.92, 162.99; FAB-MS (*meta*-nitrobenzyl alcohol (NOBA)): m/z: 1107 (100, MH^+), 720 (42, C_{60}^+).

Elution with CH_2Cl_2 followed by precipitation from CH_2Cl_2/hexane yielded **11b** (84 mg, 15%). Brown solid, m.p. >280 °C; UV/Vis (CH_2Cl_2): λ_{max} (ε) = 255 (110200), 317 (36400), 399 (sh, 4750), 408 (sh, 4000), 454 (1800), 468 (1750), 697 (280), 632 (490); ^{1}H NMR ($CDCl_3$, 500 MHz): δ = 1.44 (t, J = 7.1 Hz, 6H), 1.50 (s, 6H), 4.31–4.36 (m, 2H), 4.39–4.44 (m, 2H), 4.44–4.57 (m, 4H), 4.70–4.75 (m, 2H); ^{13}C NMR ($CDCl_3$, 125 MHz): δ = 14.16, 27.70, 48.82, 63.54, 64.80, 68.90, 71.75, 75.77, 109.75, 129.92, 136.11, 139.15, 139.42, 140.97, 141.00, 141.06, 141.65, 141.80, 142.17, 142.35, 143.61, 143.63, 144.18, 144.37, 144.43, 144.68, 144.87, 145.00, 145.04, 145.18, 145.20, 145.32, 145.56, 145.63, 146.43, 146.66, 163.25, 163.36; FAB-MS (NOBA): m/z: 1107 (100, MH^+), 720 (18, C_{60}^+).

K_2CO_3 (314 mg, 2.276 mmol) was added to a stirred solution of **11b** (35 mg, 0.031 mmol) in THF/EtOH 1:1 (34 mL) under Ar. The mixture was stirred at 20 °C for 1.5 h, then filtered, and evaporated to dryness. Column chromatography (SiO_2, toluene) followed by precipitation from CH_2Cl_2/hexane yielded *ent*-**12** (28 mg, 83%). Brown solid, m.p. >280 °C; UV/Vis, IR, ^{1}H NMR, and mass spectra identical to those of *rac*-**12** previously prepared by Hirsch and co-workers [3a,e].

[11] For the concept of in–in, in–out, and out–out stereoisomerism, see G. Quinkert, E. Egert, C. Griesinger, *Aspekte der Organischen Chemie: Struktur*, VHCA, Basel, **1995**, p. 28. For *cis*-1, *cis*-2, and *trans*-4 bisadducts, there exist two C_s-symmetrical (in–in, out–out) and one C_1-symmetrical (in–out) isomers. For *cis*-3, *trans*-2, and *trans*-3 bisadducts, two C_2-symmetrical (in–in, out–out) and one C_1-symmetrical (in–out) isomers can form. The *e* bisaddition yields two C_1-symmetrical isomers (out–out, in–out), and *trans*-1 addition gives one C_{2h}-symmetrical (out–out) and one C_2-symmetrical (in–out) isomer. Taking into consideration the pairs of enantiomers in C_1- and C_2-symmetrical compounds, a total of 37 bisadducts can theoretically be formed.

[12] X-ray crystal data for **6** ($C_{78}H_{18}O_8 \cdot CHCl_3$, M_r = 1202.3): dark red prisms of **6** were obtained by slow diffusion of hexane in a $CHCl_3$/benzene solution of **6**. Monoclinic space group $P2_1/c$, Z = 4, ρ_{calcd} = 1.688 g cm^{-3}, a = 17.469(14), b = 14.471(9), c = 19.51(2) Å, β = 106.41(7)°, V = 4732(7) Å^3, Picker-Stoe diffractometer, $Cu_{K\alpha}$ radiation using ω scans, λ = 1.54178 Å. The structure was solved by the PATSEE method and refined by full-matrix least-squares analysis (SHELXTL PLUS; heavy atoms anisotropic, H atoms fixed, whereby H positions are based on stereochemical considerations) to give $R(F)$ = 0.0637 and $R_w(F)$ = 0.0925 for 811 variables and 3984 observed reflexions with $F > 4.0\sigma(F)$ and $3.0 \le 2\theta \le 100°$. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-92. Thioenols from Peptidyl Cysteines: Oxidative Decarboxylation of a ^{13}C-Labeled Substrate**

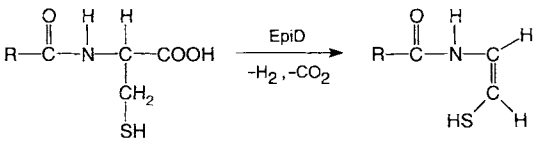
Christoph Kempter, Thomas Kupke, Dietmar Kaiser, Jörg W. Metzger, and Günther Jung*

Dedicated to Professor Anton Rieker on the occasion of his 65th birthday

Epidermin, a tetracyclic peptide antibiotic with therapeutic activity against acne, is produced by the Gram-positive bacterium *Staphylococcus epidermidis*. It contains the uncommon amino acids 2,3-didehydroaminobutyric acid, *meso*-lanthionine, β-methyllanthionine, and C-terminal *S*-[(*Z*)-2-aminovinyl]-D-cysteine.[1] The prepeptide EpiA, consisting of 52 amino acids, is synthesized ribosomally and transformed into the biologically active 22mer peptide by posttranslational modifications. These modification reactions comprise oxidative decarboxylation, dehydration, formation of four thioether bridges, and cleavage of the leader peptide[2] (Fig. 1). Complementation studies of epidermin-negative mutants and DNA sequencing have revealed that the genes *epiB*, *epiC*, *epiD*, and *epiP* encode the enzymes for the biosynthesis of epidermin.[3] The enzyme EpiD has been isolated and characterized. In this novel flavoprotein (20.8 kDa) flavinmononucleotide (FMN) is a noncovalently bound coenzyme that reacts with the precursor peptide EpiA under reducing conditions.[4] The modified polypeptide exhibits increased hydrophobicity, increased absorbance at 260 nm, and a decrease in molecular mass by 46 Da relative to the starting polypeptide.[5] EpiD catalyzes the oxidative decarboxylation ($-H_2$, $-CO_2$) of the C-terminal cysteine residue of EpiA and thus takes part in the formation of *S*-[(*Z*)-2-aminovinyl]-D-cysteine (Scheme 1). Although the mechanism



Scheme 1.

has not yet been studied in detail, it can be assumed that the first step is the oxidation leading to the formation of the double bond followed by decarboxylation to form the thioenol.[5] Flavin coenzyme that has been reduced during the reaction is reoxidized probably by aerial oxygen.

The substrate specificity of the new enzyme has been investigated by using synthetic peptides and peptide libraries.[6] It was found that peptides with the C-terminal consensus sequence AA1-AA2-Cys (AA1 = Val/Ile/Leu/(Met)/Phe/Tyr/Trp; AA2 = Ala/Ser/Val/Thr/Cys/(Ile, Leu)) show a decrease in molecular mass of 46 Da after reaction with EpiD.[7] The MS–MS fragmentation pattern of the substrate Ser-Phe-Asn-Ser-Tyr-Thr-Cys after reaction with EpiD revealed that only the C-terminal cysteine was modified, presumably by conversion into a C-terminal thioenol by oxidative decarboxylation. In this paper, we report on the structure determination of the product of this unusual enzymatic reaction.

The heptapeptide SFNSYTC was prepared by solid-phase synthesis with fluorenylmethoxycarbonyl/*tert*-butyl protecting groups.[8] After treatment with 5,5′-dithiobis(2-nitrobenzoic acid) (Ellman's reagent), both the purified peptide and the peptide modified by EpiD showed an increase in molecular mass by 197 Da in the electrospray ionization mass spectrum (ESI-MS). This corresponds to the formation of asymmetric disulfides from the thiol groups of the peptide and of 5-thio-2-nitrobenzoic acid. These disulfides could be reduced by addition of *n*-propanethiol and partly converted into the asymmetric disulfide with *n*-propanethiol. The addition of Ellman's reagent to the assumed double bond in the product, which would lead to an increase in molecular mass by 199 Da, has not been observed.

Previous two-dimensional NMR experiments failed to help in determining the structure of the peptides obtained by modification of SFNSYCC and SFNSYTC, because the products are not stable long enough in solution. According to ESI-MS experiments, the thioenol derivatives are substantially degraded after only one hour. Since the modification product of the peptide SFNSYTC turned out to be more stable than SFNSYCC, a peptide with the C-terminal sequence Thr-Cys was used in the subsequent NMR experiments as a substrate for EpiD. The enzymatic reaction was carried out in the NMR spectrometer, enabling us to monitor the process and to observe the unstable reaction product in situ. Due to the complexity of the spectra, the introduction of a ^{13}C isotope in the cysteine was necessary in order to extract the interesting signals by heteronuclear correlation experiments. Hence, the peptide KKSFNSYTC was synthesized by solid-phase synthesis using cysteine labeled with ^{13}C

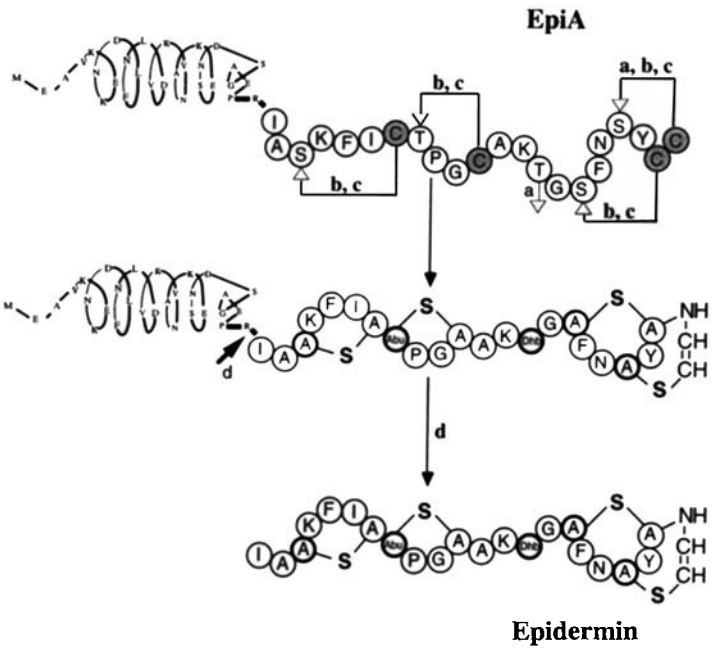


Fig. 1. Model of the biosynthesis of epidermin. The ribosomally synthesized prepeptide EpiA is converted into the antimicrobially active, tetracyclic lantibiotic epidermin by the following posttranslational modifications: a) oxidative decarboxylation of the C-terminal cysteine residue, b) dehydration of serine and threonine residues, c) formation of thioether bridges (lanthionine and β-methyllanthionine), and d) cleavage of the leader peptide (30 residues). Abu = 2-aminobutyric acid; Dhb = α,β-didehydrobutyric acid; cysteine residues are shaded in gray, modified amino acids are marked with bold circles.

at the β-carbon atom. The two lysine residues at the N-terminus were introduced to increase the solubility of the substrate in water.

Two crosspeaks at $\delta(^1H) = 2.83$, $\delta(^{13}C) = 29.1$, and $\delta(^1H) = 3.58$, $\delta(^{13}C) = 63.3$ occur in the HSQC spectrum[9] of the starting peptide KKSFNSYTC. The first signal is due to the ^{13}C-labeled β-carbon, while the second stems from the methyl groups in tris(hydroxymethyl)aminomethane (Tris buffer). In the one-dimensional ^{13}C NMR spectrum of the starting peptide, there are two peaks for the β-carbon atom at $\delta = 29.1$ and 29.2 from the two epimers, which cannot be resolved in the two-dimensional experiment. After only 15 min a third signal emerges at $\delta(^1H) = 6.01$ and $\delta(^{13}C) = 120.5$, the intensity of which increases over time. Figures 2 and 3 show projections of the HSQC spectra onto the F2 (^1H) and F1 (^{13}C) axes, respectively, recorded over a period of 825 min; an increase in intensity of the product signal is clearly visible. Because of the high substrate concentration, the enzymatic reaction is slower than in previous experiments (substrate inhibition). On the other hand, the constant supply of new product in this experiment gives the impression that the product is fairly stable. After 16 h a HSQC-TOCSY experiment[10] was conducted to determine the chemical shift of the α-proton in the cysteine residue. The spectrum shows an additional signal at $\delta(^{13}C) = 120.5$ and $\delta(^1H) = 6.59$. The observed chemical shifts for H_α and H_β ($\delta = 6.59$ and 6.01, respectively) as well as for C_β ($\delta = 120.5$) are characteristic of a double bond. The NMR data, the MS–MS experiments, the observed reaction product with Ellman's reagent, and the fact that the difference in mass between starting material and product is 46 Da, all indicate that the product contains a C-terminal thioenol. The (Z) configuration of the double bond in the reaction product was determined from the ^3J coupling constant of H_α and H_β. In the 1D ^1H NMR spectrum the signal for the β-proton at $\delta(^1H) = 6.01$ is a doublet of doublets with the coupling constants $^1J(H_\beta, C_\beta) = 170$ Hz and $^3J(H_\alpha, H_\beta) = 7.3$ Hz, which is typical for a double bond with (Z) configuration and comparable to the coupling constant observed in epidermin[1] (Fig. 4).

After 16 h the ^{13}C spectrum still contains two signals at $\delta = 29.1$ and 29.2; however, the latter signal has only about 50% of its initial intensity, and after 40 h this signal vanishes completely. Therefore the enzyme EpiD only modifies the epimer with L-cysteine. In this spectrum no signal was evident in the region around $\delta = 250$, which is the typical ^{13}C chemical shift for a carbon atom in a thioaldehyde. In contrast to the corresponding enols, the thermodynamic stability of the thioenols is similar to that of the thioaldehydes and they tautomerize only slowly.[11]

After the unusual thioenol in the modified peptide had been proved, one question still remained: What are the degradation products of the initially formed thioenols? With the present NMR and MS data no distinct conclusions are possible, because the concentration of the secondary products is too low to be detected by NMR spectroscopy.

The present results imply that in the biosynthesis of epidermin the oxidative decarboxylation of the precursor protein takes place before and not, as previously assumed,[2] after the formation of the thioether bridges. Work is in progress to fully label the novel enzyme EpiD with ^{13}C and ^{15}N in order to determine the three-dimensional solution structure of the enzyme and the enzyme–substrate complex by NMR spectroscopy. It is safe to assume that the posttranslational modification described in this work also occurs during the biosynthesis of the natural epidermin analogues gallidermin,[12] mersacidin (a novel inhibitor of the biosynthesis of cell walls),[13] and the new peptide antibiotic cypemycin.[14]

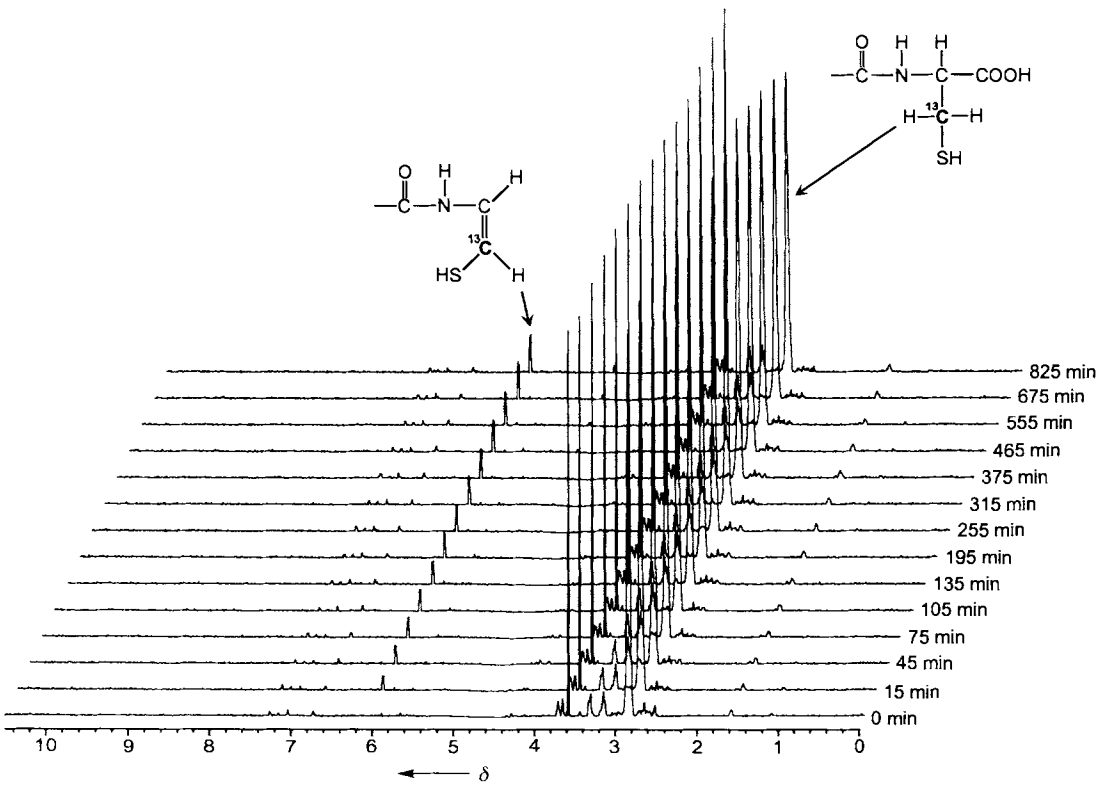

Fig. 2. Reaction of the labeled substrate KKSFNSYTC with the enzyme EpiD. Shown are projections along the F2 (^1H) axis of the HSQC spectra recorded during the course of the reaction. The product signal at $\delta(^1H) = 6.01$ increases in intensity with time. The signal at $\delta(^1H) = 2.83$ corresponds to the protons at the ^{13}C-labeled C_β atom of cysteine. The signal at $\delta(^1H) = 3.58$ stems from the methyl groups of the Tris buffer.

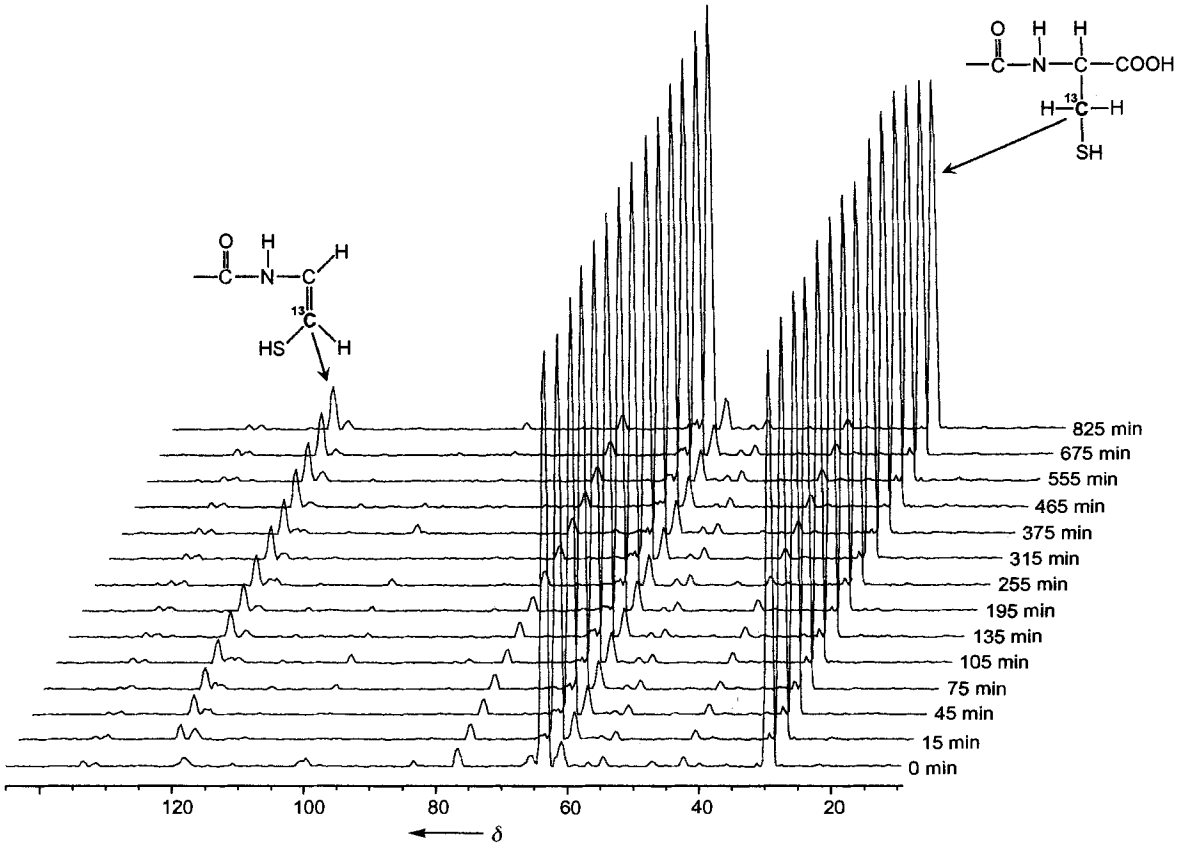

Fig. 3. Reaction of the labeled substrate KKSFNSYTC with the enzyme EpiD. Shown are the projections along the F1 (^{13}C) axis of the HSQC spectra recorded during the course of the reaction. The product signal at $\delta(^{13}C) = 120.5$ increases in intensity with time. The signal at $\delta(^{13}C) = 29.1$ corresponds to the C_β atom of the cysteine residue in the starting material, while the signal at $\delta(^{13}C) = 63.3$ can be assigned to the methyl groups of the Tris buffer.

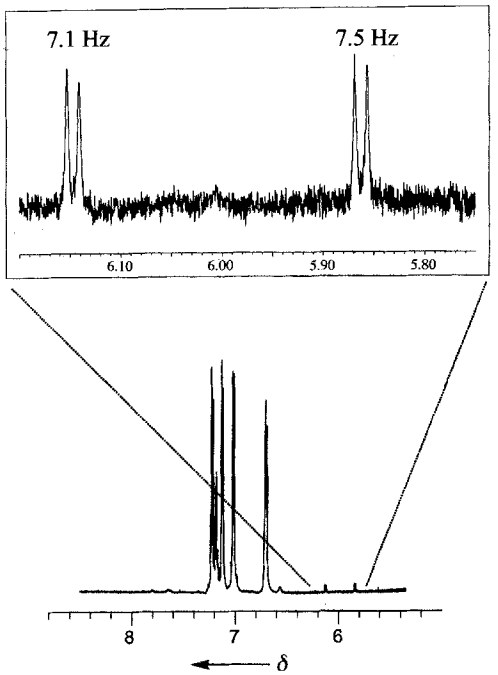

Fig. 4. ^1H NMR spectrum of the reaction mixture of KKSFNSYTC and EpiD after 16 h. The signal at $\delta(^1H) = 6.01$ corresponds to the proton at the C_β atom of the former C-terminal cysteine after the modification by EpiD; the signal is a doublet of doublets with the coupling constants of $^3J(H_\alpha,H_\beta) = 7.3$ Hz and $^1J(H_\beta,C_\beta) = 170$ Hz. The homonuclear coupling constant of 7.3 Hz between H_α and H_β is typical for a double bond with (*Z*) configuration in the reaction product [1, 3, 15].

Experimental Procedure

DL-Cysteine was purchased from Isocom (Landshut, Germany) and trimethoxybenzaldehyde from Aldrich (Steinheim, Germany). N,S-protected 3-^{13}C-labeled DL-cysteine was synthesized as follows: The thiol group of DL-cysteine (3-^{13}C) was protected with a 2,4,6-trimethoxybenzyl (Tmob) group by reaction with 2,4,6-trimethoxybenzaldehyde in the presence of trifluoroacetic acid [16]. The amino group was protected by reaction with 9-fluorenylmethyloxycarbonyl-*O*-succinimide (Fmoc-OSu) in a solution of Na_2CO_3 in H_2O/THF. Fmoc-3-[^{13}C]-DL-Cys(Tmob) was attached to 2-chlorotrityl chloride resin and the peptide KKSFNSYTC synthesized with a peptide synthesizer (MultiSynTech, Bochum). Fmoc-protected amino acids were coupled with diisopropylcarbodiimide/1-hydroxybenzotriazole (DIC/HOBT) (1:1). The enzyme EpiD was purified after overexpression in *Escherichia coli* as described in ref. [4].

ESI-MS and MS–MS spectra were recorded on an API III triple-quadrupole mass spectrometer (Sciex, Thornhill, Canada). The NMR experiments were performed at 305 K on a AMX600 spectrometer (Bruker, Karlsruhe) equipped with a $^{13}C,^{15}N$ triple resonance probe at a proton frequency of 600.13 MHz. The nonapeptide KKSFNSYTC (2.7 mg) labeled with ^{13}C at C_β of the cysteine residue was dissolved in 20 mM Tris buffer (Tris/HCl, pH 8.0, 0.5 mL) containing 10 mM dithiothreitol and 10% D_2O. This solution was transferred to an NMR tube and 6 μg of EpiD was added. HSQC spectra, with a measuring time of 10 min each, were recorded every 20 min over the course of the enzymatic reaction.

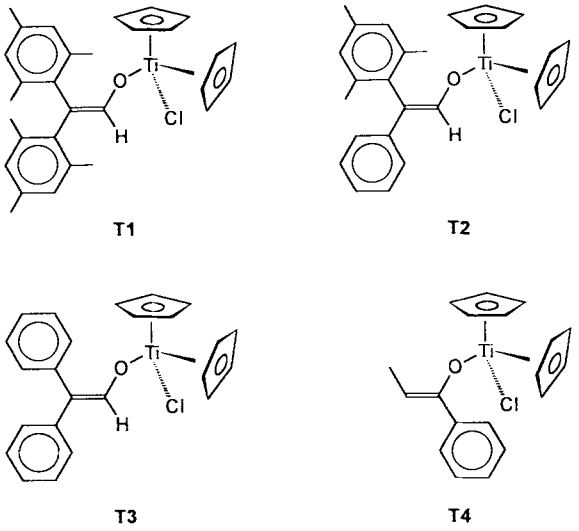
First Characterization of a Titanium Enolate Radical Cation in Solution: Carbon–Carbon Bond Formation and the Kinetics of the Mesolytic Ti–O Bond Cleavage**

Michael Schmittel* and Rolf Söllner

Ever since their first successful use in 1981[1] titanium enolates have had an important standing as versatile synthetic carbon nucleophiles in stereoselective aldol[2] and Michael reactions,[3] in particular because they allow for higher stereoselectivites than lithium enolates. Most importantly, the incorporation of chiral ligands at the titanium center opened the way for enantioselective aldol reactions with excellent *ee* values.[4] Surprisingly, the umpolung of titanium enolates through one-electron oxidations is hitherto completely unknown,[5] although such radical cations should offer interesting electrophilic features that could be exploited in carbon–carbon bond formation, quite in analogy to the recent chemistry of silyl[6] and stannyl[7] enol ether radical cations. Here we report for the first time on titanium enolate radical cations in solution, their characterization by cyclic voltammetry and ESR, as well as on the kinetics of the mesolytic[8] Ti–O bond cleavage. In addition, our exploratory investigations reveal that oxidative carbon–carbon bond formation from titanium enolates is possible.

In view of the significance of titanium enolates in organic synthesis it is quite astonishing how little is known about their structural and spectroscopic properties. The lack of data is mainly because these reactive compounds are usually prepared in situ and have only been isolated in a few cases,[9] as a result of their high sensitivity toward hydrolysis. Hence, a pivotal prerequisite for our investigations on the corresponding radical cations was the availability of stable and pure titanium enolates, a problem that could be solved by using some well-known stabilizing structural motifs from the design of simple stable enols.[10] Accordingly, we have synthesized the sterically shielded model compounds **T1**–**T3** as well as the sterically unimpeded **T4**.[5a]



T1 **T2** **T3** **T4**

The novel titanium enolates **T1**–**T3** were prepared in analytically pure form in 32–53% yield as dark red solids from the corresponding stable enol or carbonyl precursor by quantitative deprotonation with sodium hydride followed by reaction with dichlorotitanocene in tetrahydrofuran at room temperature.

While **T4** could only be handled under rigorous exclusion of water in Schlenk glassware, **T1**–**T3** exhibited a remarkable stability against hydrolysis. For instance, **T1** could be exposed to atmospheric water and oxygen for three months without significant decomposition.

In standard cyclic voltammetry (cv) investigations irreversible oxidation waves were monitored for titanium enolates **T1**–**T4** in acetonitrile at a scan rate of 100 mVs^{-1} (Table 1); they indicated that a rapid follow-up reaction occurred. The oxidation potentials E_{pa} (0.4–0.6 V vs. Fc[11]) are in a range where chemical one-electron oxidations should easily be realized in the pres-

Table 1. Oxidation potentials E_{pa} and half-wave potentials $E_{1/2}$ of titanium enolates determined by cyclic voltammetry (potentials referred to the ferrocene/ferrocenium redox couple; electrolyte: tetra-*n*-butylammonium hexafluorophosphate).

Titanium enolate	E_{pa} [a]	$E_{1/2}$

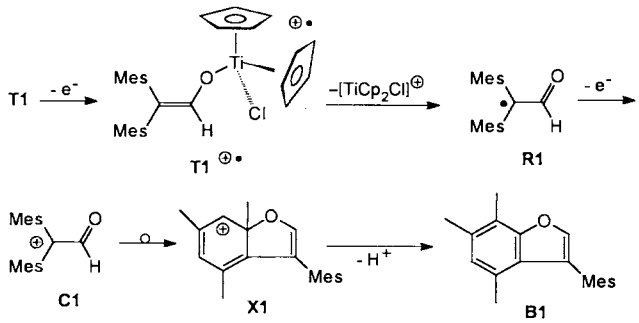
ence of many other common functional groups.[12] For **T1** and **T3** the thermodynamic half-wave potentials $E_{1/2}$ were determined with fast scan cyclic voltammetry at ultramicro electrodes; for instance, **T1** exhibited a reversible wave in dichloromethane at scan rates v greater than 20 Vs^{-1}.

Besides the first oxidation wave at $E_{pa1} = 0.44$ V, titanium enolate **T1** displays an additional irreversible oxidation wave (at $v = 100\ mVs^{-1}$) at $E_{pa2} = 1.08$ V[13] that is caused by the benzofuran **B1** (Scheme 1),[14] formed as product of the one-elec-

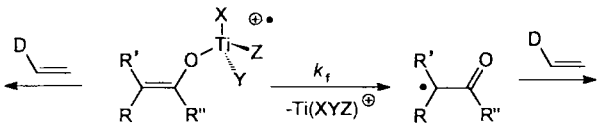


Scheme 1. Mechanism of the formation of the benzofuran. On 1,2-methyl-migration with proton loss **X1** forms **B1**. Mes = mesityl.

tron oxidation of **T1** already on the time scale of the cv run. In order to support this assignment, we oxidized **T1** with 200 mol% of $[Fe(phen)_3](PF_6)_3$ (phen = 1,10-phenanthroline), a well defined outer-sphere one-electron oxidant, and obtained benzofuran **B1** in 93% yield. The cyclic voltammogram of **B1** indeed exhibited an irreversible oxidation wave at $E_{pa} = 1.06$ V. The formation of product **B1** clearly indicates that a clean Ti–O bond cleavage must have taken place in the course of the one-electron oxidation. The most likely mechanism, following the pathways of the corresponding enol[15] and silyl enol ether[16] oxidations, is depicted in Scheme 1. The alternative mechanism (that is, direct cyclization within $\mathbf{T1}^{+\bullet}$) can be excluded on steric grounds.

Another mesolytic cleavage pathway[17] involving fragmentation of $\mathbf{T1}^{+\bullet}$ directly to **C1** and $Ti^{III}Cp_2Cl$ could be postulated. However, such a cleavage mode seems highly implausible, because the oxidation potential of $Ti^{III}Cp_2Cl$ ($E_{pa} = -0.68$ V)[18] is much lower than that of **R1** ($E_{pa} = +0.37$ V).[19]

Since chiral titanium enolate radical cations can potentially be used in enantioselective carbon–carbon bond formation (Scheme 2), it was important to investigate the kinetics of the



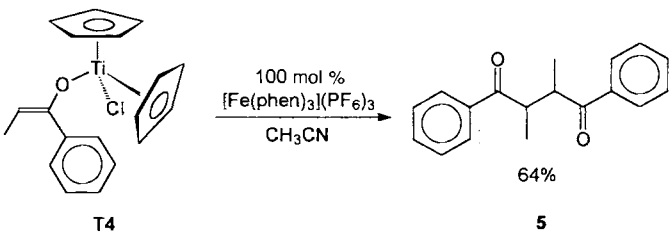
Scheme 2. Conceivable reaction pathways of the titanium enolate radical cations. D = donor.

Ti–O bond cleavage process. Obviously, if the Ti–O bond fragmentation (k_f) is too rapid, α-carbonyl radical intermediates and not the desired chiral titanium enolate radical cations would be the pivotal species in the bond formation process.

Consequently, we determined the rate of Ti–O bond rupture in $\mathbf{T1}^{+\bullet}$ in acetonitrile using cv with scan rates between 200 and 3000 Vs^{-1}. According to the method of Nicholson and Shain,[20] a first-order rate constant of $k_f = 850\ s^{-1}$ was obtained for the fragmentation in acetonitrile at room temperature on applying a working curve for an $EC_{irr}E$ mechanism[21] (electron transfer/chemical reaction/electron transfer). This rate constant is similar to that of the O–$SiMe_2t$Bu fragmentation in silyl enol ether radical cations ($k_f = 1300\ s^{-1}$).[22] Notably, O–$SiMe_2t$Bu silyl enol ethers have already been used successfully in oxidative C–C couplings.[6]

The first ESR spectra of titanium enolate radical cations,[23] generated through one-electron oxidation of the neutral precursors **T1**–**T3** with tris(*p*-bromophenyl)aminium hexachloroantimonate in dichloromethane, were recorded at −100 °C. Whereas for $\mathbf{T1}^{+\bullet}$ ($g = 2.0043$) only unresolved spectra were obtained in spite of measurements at different concentrations, the spectra of $\mathbf{T2}^{+\bullet}$ ($g = 2.0036$) and $\mathbf{T3}^{+\bullet}$ ($g = 2.0038$) exhibited hyperfine splitting caused through mesityl, phenyl, and vinyl hydrogen atoms. No spin density seems to reside on the titanocene fragment, which qualifies such radical cations as electrophilic radicals that are most likely to react at the β-carbon.

While such carbon–carbon bond formation is highly unlikely with $\mathbf{T1}^{+\bullet}$ due to the extreme steric shielding of the β-carbon, one-electron oxidation of **T4** with 100 mol% of $[Fe(phen)_3](PF_6)_3$ in acetonitrile gave rise to dimer **5** (64%, *meso*:D,L = 1:1, Scheme 3). Although some mechanistic details of this new carbon–carbon bond formation reaction are open to discussion, cv investigations suggest that C–C bond formation is much more rapid than Ti–O bond cleavage in $\mathbf{T4}^{+\bullet}$.[24] Therefore, the dimerization most likely is initiated by the nucleophilic attack of **T4** on the titanium enolate radical cation $\mathbf{T4}^{+\bullet}$.



Scheme 3. Synthesis of **5** by dimerization.

In summary, we have synthesized three remarkably stable titanium enolates and investigated for the first time titanium enolate radical cations in solution. Since the mesolytic Ti–O bond cleavage is rather slow, sterically unshielded titanium enolate radical cations (for example, $\mathbf{T4}^{+\bullet}$) undergo direct carbon–carbon bond formation processes with π-nucleophiles.

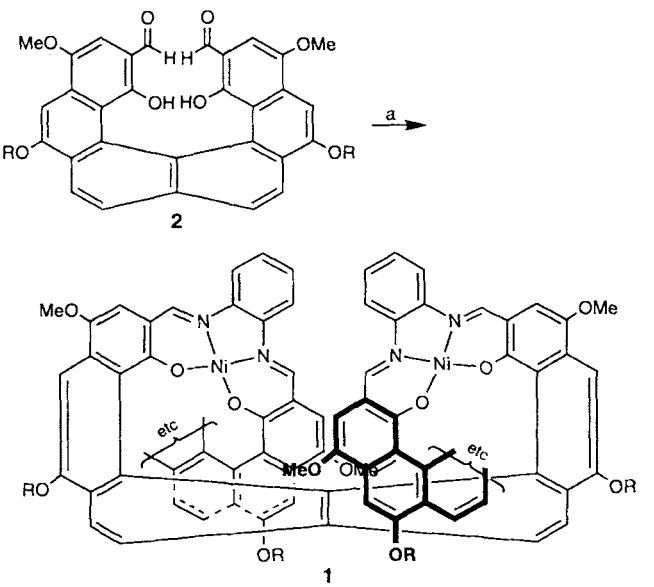
[23] The signals of $\mathbf{T1}^{+\bullet}$ and $\mathbf{T2}^{+\bullet}$ persisted for several hours, whereas that of $\mathbf{T3}^{+\bullet}$ decayed within 1 hour.

[24] Thermochemical cycle calculations[17] indicate that the free energy for the Ti-O-bond cleavage in $\mathbf{T1}^{+\bullet}$–$\mathbf{T4}^{+\bullet}$ should differ by less than 2 kcal mol^{-1} as a consequence of the small differences in the oxidation potentials of the titanium enolates. Accordingly, the kinetics of the mesolytic bond cleavage is not expected to differ vastly. Nevertheless, **T1** is reversibly oxidized at scan rates greater than 20 Vs^{-1}, whereas **T4** shows no sign of reversibility at scan rates smaller than 40000 Vs^{-1}, which is indicative of an alternative follow-up reaction, for example, dimerization.



Scheme 1. Synthesis of the helical conjugated ladder polymer **1**. a) *o*-phenylenediamine in refluxing ethanol, then $Ni(OAc)_2$ in refluxing THF/EtOH (95%). R = CH_2CH_2OnBu.

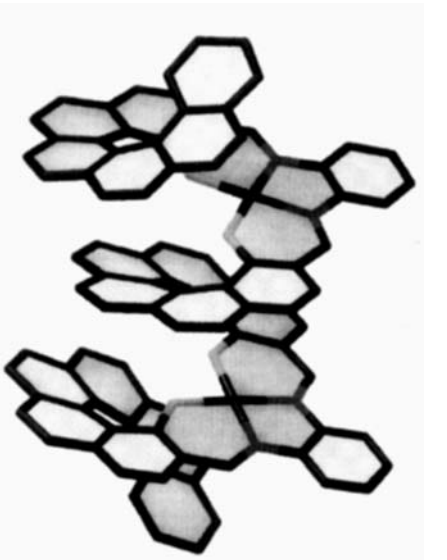


Fig. 1. A portion of structure **1**, consisting of three helicene rings and two salophens. The side chains have been deleted for clarity.

Synthesis of a Helical Conjugated Ladder Polymer**

Yujia Dai, Thomas J. Katz,* and David A. Nichols

Reported here is the synthesis of the first polymer (**1**) with an unbroken network of double bonds that winds in one direction along a helix.[1, 2] The key step is the union of a [6]helicene possessing salicylaldehyde functionality at each end, 1,2-phenylenediamine, and nickel acetate (Scheme 1). In the resulting structure (Fig. 1) "nickel salophen"[5, 6] units bind adjacent helicenes,[7] provide a conjugated link from one ring system to the next, and constrain the p-orbitals of the rings they unite to be nearly parallel.[8] Unlike other ladder polymers,[9] **1** is chiral, and unlike other optically active conjugated polymers (such as polythiophenes), its helical shape is preserved by unaggregated molecules in solution.[10]

Helical bis(salicylaldehyde) **2**, which was used for the experiments, was synthesized from optically active helical bis(quinone) **3**[11] by the procedures outlined in Scheme 2. Noteworthy is the selectivity of two steps, the addition of HBr that converts **3** into **4**[12, 13] and the removal of half the acetate functions that converts **5** into **6**.[4]

The dark red product **1** that formed in the reaction shown in Scheme 1 was purified by dissolution in CH_2Cl_2 and precipitation by the addition of hexane. The material is soluble in $CHCl_3$, CH_2Cl_2, THF, benzene, acetone, and CH_3OH. Thus it does not suffer the insolubility that is a major deficit of many planar ladder polymers.[9]

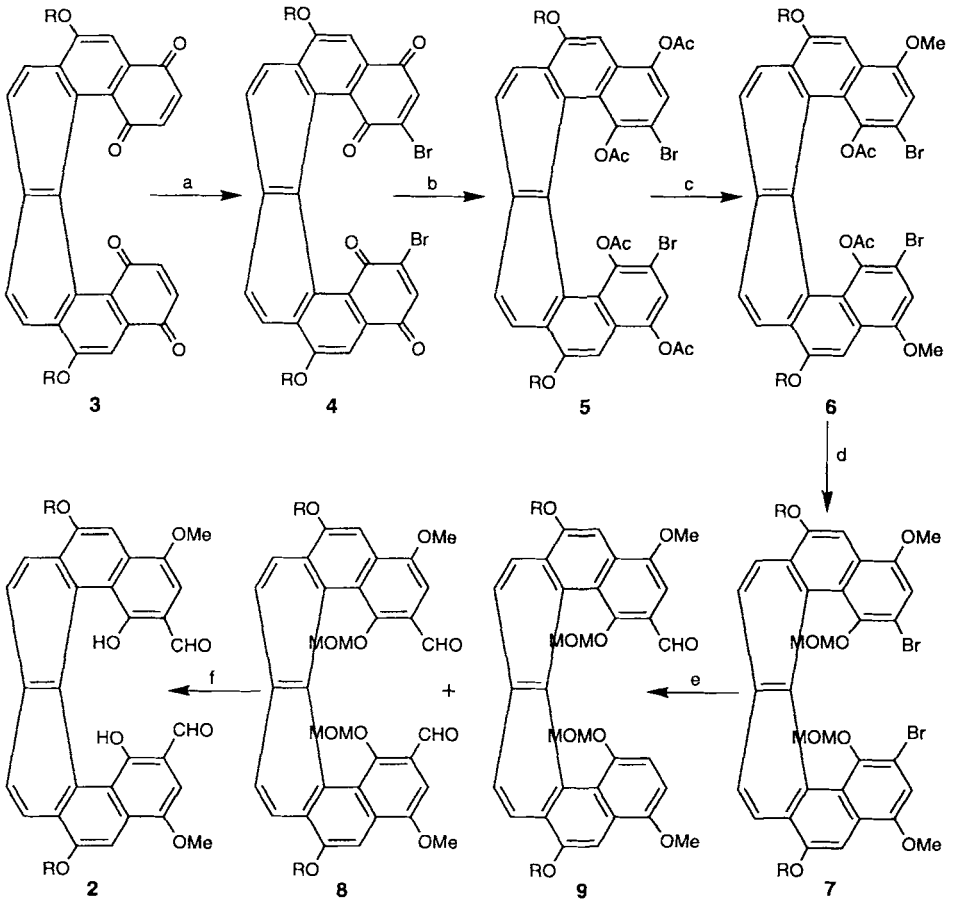
[**] This work was supported by grants from The National Science Foundation (CHE92-24634) and The Kanagawa Academy of Science and Technology. We thank Dr. Y. Itagaki (Suntory Institute for Bioorganic Research, Osaka, Japan) for the mass spectrum of **1**, Dr. James C. Carnahan (General Electric Co., Schenectedy, New York) for its GPC analysis, and Dr. Ullrich Scherf for informing us of his related work on ladder polymers.



Scheme 2. Route to optically active helical bis(salicylaldehyde) **2**. a) HBr in $EtCO_2H$, then chloranil (25–30%); b) $Na_2S_2O_4$, nBu_4NBr, H_2O/CH_2Cl_2, then Ac_2O, Et_3N, CH_2Cl_2 (78–82%); c) K_2CO_3, MeOH, 25 °C, then MeI, K_2CO_3, acetone, reflux (81%); d) KO*t*Bu, THF, 25 °C, then $MeOCH_2Cl$ (MOMCl), THF, 25 °C (92%); e) *n*BuLi, THF, −78 °C, then Me_2NCHO, −78 → 25 °C (80% **8**, 16% **9**); f) H_2SO_4, HOAc, H_2O, 60 °C (100%). R = CH_2CH_2OnBu.

Evidence that the product has structure **1** includes the following. 1) The procedure used is expected to give this structure.[6, 7a–c] 2) The ^1H NMR spectrum of the product in $CDCl_3$ shows four clearly defined broad peaks—broad, probably, because of the viscosity. The signal intensities are those required[14] and their positions are, with the exception of the resonances of the outermost portions of the side chains,[15] shifted upfield, most likely by electron currents in nearby rings,[16] by $\Delta\delta \approx 1$ from their positions in the spectra of **2** and of nickel salophen itself. The intensities of resonances related to the CHO and OH resonances in **2** are tiny. 3) The ^{13}C NMR spectrum of **1** in $CDCl_3$, although it consists of broad and multiple peaks (presumably because the material is a mixture of oligomers and because in small polymers some carbons are nearer the ends while others are nearer the middle), exhibits resonances that match those of **2**, with these differences: the aldehyde resonance, which in **2** appears at $\delta = 193.7$, is barely visible, and one of the low-field resonances of **2** (attributable to the carbon next to the phenoxide $C_{ar}-O^-$) is shifted.[17] Resonances at $\delta = 124$ and 143 may be attributable to the phenylene moiety. 4) The infrared spectrum of **1** (KBr) shows a band at 1596 cm^{-1}, appropriate for the C=N stretch of a nickel salophen.[18] No bands are evident for either a C=O or an OH stretching absorption. 5) The Matrix-Assisted Laser Desorption/Ionization Time-of-Flight (MALDI-TOF) mass spectrum[19] consists of two peaks separated by 90.0 ± 0.2 Da that repeat ten times with decreasing intensity at intervals of 837.6 ± 0.2 Da. This last figure is exactly the mass of the repeat unit of **1** ($C_{48}H_{46}N_2NiO_8$).

The mass spectrum also identifies the end groups. The repeating motif of two peaks distinguishes two series of polymers. The signal for the lowest mass member of one series corresponds to ($2 + NiO \cdot H_2O$), implying that one end has the *o*-hydroxybenzaldehyde functionality of **2** and the other the functionality of its hydroxynickel salt. The ions of the second, and probably predominant,[20] series have the additional mass (90.1) of one phenylenediamine unit less water, expected for a Schiff base derivatives. Two small but prominent resonances in the ^1H NMR spectrum of the oligomers, at $\delta = 4.6$ and 4.5, are at lower fields than the other OCH_2 resonances and at a position characteristic of the hydrogens on one of the OCH_2 groups in precursor **2** (undoubtedly the one closest to the benzene rings). Their integration suggests that the number average molecular mass is approximately 7000.[23] This agrees with the value $M_n \approx 7400$ obtained by GPC analysis of a solution in THF and the assumption that a published correction applies that relates the molecular masses of certain rigid rod polymers and polystyrenes.[24, 25]

The optical properties of **1** (Fig. 2) differ from those of simpler molecules. The feature at longest wavelength in the UV spectrum (in CH_2Cl_2) is a band at 594 nm, with $\varepsilon = 9300$. Although its position corresponds to that of d–d transitions in simple salophens,[26] the intensity (calculated per unit monomer concentration as if the polymer were infinite)[27] is roughly 60 times larger. Accordingly, we suppose the peak to be related to the "metal-to-ligand" charge transfer band of nickel salophen, but shifted to longer wavelength by 114 nm from its position in the spectrum of the parent compound (480 nm),[26b, 28] possibly because the energy of the HOMO is raised by the electron-donating substituents. The circular dichroism (CD) at this wavelength is very large. At the maximum at longest wavelength

(595 nm, there is no exciton splitting), $\Delta\varepsilon$[27] is 105, much higher than the value of around 3 shown by the simpler metal Schiff base complexes studied previously.[26b, 29, 30]

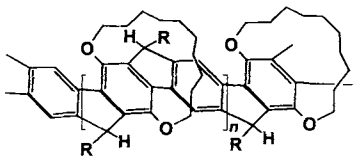
Synthesis of an Optically Active Poly(*para*-phenylene) Ladder Polymer**

Rainer Fiesel, Joachim Huber, and Ullrich Scherf*

The synthesis of optically active conjugated polymers is an exciting challenge from the point of view of both the synthesis itself and also its potential for applications based on nonlinear optical and chiroptical effects.[1] If, in addition, these materials are efficient luminophores, they are also of importance for generating polarized photo- and electroluminescence. Until now, such compounds have usually been synthesized by introducing chiral side groups, which induced a helical formation of the single-stranded main polymer chain.[1, 2] We describe here a new approach to the preparation of optically active conjugated polymers such as **1**, in which planar chirality elements (cyclophane building blocks) are bonded together to form flat nonhelical poly(*para*-phenylene) (PPP) ladder polymers.



1

The achiral analogs of **1** (PPP ladder polymers LPPP with two alkyl or alkoxy substituents instead of the $OC_{10}H_{20}O$ bridges) have been thoroughly described.[3] They are characterized by unusual optical and electronic properties such as extremely small Stokes shifts (about 30 meV[4]) and high photoluminescence quantum yields,[5] and can be used as emitter materials in light-emitting diodes.[6]
