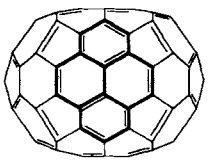
1,8-Dioxa[8](2,7)pyrenophane, a Severely Distorted Polycyclic Aromatic Hydrocarbon**

Graham J. Bodwell,* John N. Bridson, Tom J. Houghton, Jason W. J. Kennedy, and Michael R. Mannion

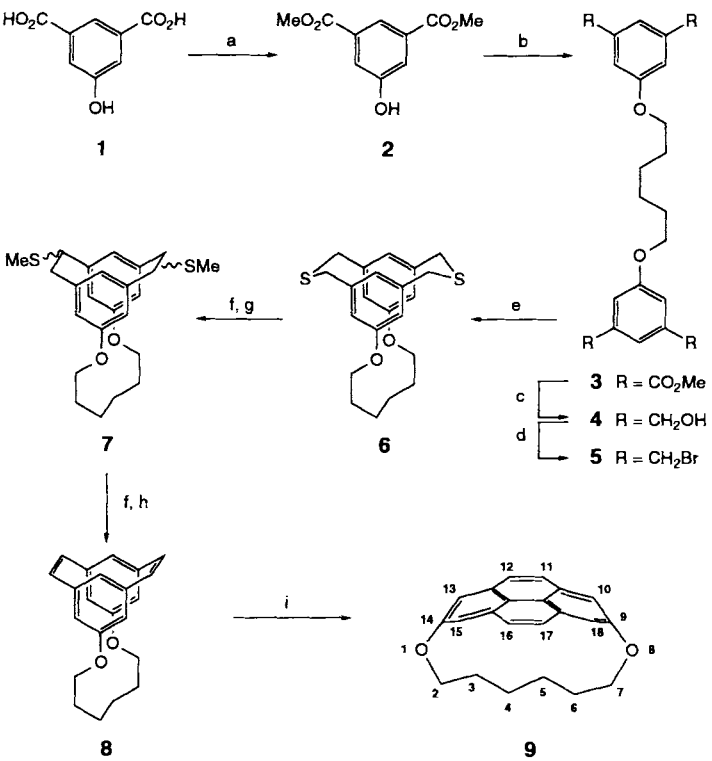
One of the distinguishing features of the smaller cyclophanes is the presence of nonplanar aromatic rings. The introduced distortions often lead to unusual spectroscopic properties as well as unusual chemical behavior. The extent to which an isolated benzene ring can be bent and still remain stable has been investigated thoroughly (for example, for [*n*]paracyclophanes[1, 2] and [*n*]metacyclophanes[2]) both from an experimental and a theoretical point of view. Although several [*n*]cyclophanes that contain polycyclic aromatic hydrocarbons have been reported, most of these (for example, [*n*](1,3)-[3] and [*n*](1,4)naphthalenophanes,[4] and [*n*](9,10)anthracenophanes[5]) can be viewed as benzannelated [*n*]paracyclophanes and [*n*]metacyclophanes. That is, the distortions from planarity are primarily localized to one ring. We are aware of no instance in which the tolerance of any polycyclic aromatic hydrocarbon to bending over its entire aromatic surface has been systematically investigated (by, for instance, pushing it to the limit).[6] Since a variety of nonplanar polycyclic aromatic hydrocarbons are subunits in the surfaces of the fullerenes (Fig. 1), we became interested in preparing and studying such compounds. We now report our initial results of this work, namely the tolerance of pyrene (a subunit of D_{5h} C_{70} (Scheme 1) and D_{6h} C_{84}, among others) towards distortions from planarity.



Scheme 1. The pyrene subunit of D_{5h} C_{70}.

In order to impart nonplanarity over the entire pyrene framework, our first choice of targets were the [*n*](2,7)-pyrenophanes. The synthetic approach is based upon the well-known valence isomerization of [2.2]metacyclophane-1,9-dienes to 10b,10c-dihydropyrenes, which normally occurs under mild conditions.[7] Theoretical and experimental studies have concluded that the dihydropyrene is usually the energetically more favorable valence isomer.[8] When the cyclophanediene bears internal hydrogen substituents, loss of hydrogen from the dihydropyrene to give a pyrene derivative often takes place readily.[9]

The title compound **9** was prepared as shown in Scheme 2.[10] Readily available 5-hydroxyisophthalic acid (**1**) was esterified and then converted into the tetraester **3** by reaction with sodium hydride/1,6-dibromohexane/TBAI (tetra-*n*-butylammonium iodide). Reduction of **3** with $LiAlH_4$ afforded tetraol **4**, which was brominated crude with a mixture of HBr and H_2SO_4 (2/1) to yield tetrabromide **5**. Reaction of **5** with Na_2S/Al_2O_3[11] readily furnished the [8.3.3](1,3,5)dioxadithiacyclophane ("tethered *syn*-dithia[3.3]metacyclophane") **6** (67%). In its 300 MHz ^{1}H NMR spectrum, the internal and external protons of **6** (*para* and *ortho* to the ether oxygen) appear as broad singlets at $\delta = 6.71$ and 6.39, respectively. Since **6** cannot undergo a *syn* to *syn'* conformational flip, it is not surprising that the thioether



Scheme 2. Reagents and conditions: a) MeOH, H_2SO_4, Δ, 3 h, 94%; b) $Br(CH_2)_6Br$, NaH, TBAI, THF, Δ, 3 h, 80%; c) $LiAlH_4$, THF, room temperature (RT), 16 h; d) HBr/H_2SO_4 2/1, RT, 1 h, 46% based on **3**; e) Na_2S/Al_2O_3, 18% $EtOH/CH_2Cl_2$, RT, 24 h, 67%; f) $(MeO)_3CHBF_4$, CH_2Cl_2, RT, 2 h; g) *t*BuOK, THF, Δ, 3 h, 66% based on **6**; h) *t*BuOK, *t*BuOH/THF 1/1, RT, 3 h, 83% based on **7**; i) DDQ, benzene, Δ, 12 h, 67% (and 26% of **8**).

bridge protons appear as an AB system ($J = 14.7$ Hz) at $\delta = 3.79$ and 3.75. Methylation of **6** with Borch reagent followed by Stevens rearrangement gave the bridge-contracted cyclophane **7** as a mixture of isomers. Methylation of **7** with Borch reagent followed by Hofmann elimination cleanly afforded tethered [2.2]metacyclophanediene **8**. The internal and external protons are observed at $\delta = 6.95$ and 6.11, respectively. The bridge alkene protons appear at $\delta = 7.15$, which is closely comparable with other etheno-bridged cyclophanes.[12] Diene **8** can be stored on the bench in air for at least three months without significant decomposition, although considerable decomposition occurs in solution ($CDCl_3$) in the space of a day. Treatment of **8** with DDQ (2,3-dichloro-5,6-dicyanobenzoquinone) in benzene at reflux resulted in smooth conversion into 1,8-dioxa[8](2,7)pyrenophane **9**.[13] Some unchanged starting material was also recovered. This reaction proceeds very slowly in the absence of DDQ under the same conditions. The aromatic region of the ^{1}H NMR spectrum of **9** contains singlets at $\delta = 7.84$ (H11, H12, H16, H17) and 7.44 (H10, H13, H15, H18).[14] The corresponding signals of 2,7-dimethoxypyrene are observed at $\delta = 7.97$ and 7.69.[14, 15] The bridge protons are observed as symmetrical multiplets centered at $\delta = 3.58$ (H2, H7), 0.10 (H3, H6) and −1.47 (H4, H5). This suggests that the bridge undergoes a rapid pseudorotation at room temperature. Relative to the signals of cyclophane precursor **5** as reference, $\Delta\delta$ is 0.40 for H2/H7, 1.72 for H3/H6, and 3.02 for H4/H5. By comparison, the highest field protons in [6]paracyclophane (the smallest isolable [*n*]paracyclophane) appear at $\delta = -0.6$.[16] Pyrenophane **9** exhibits similar stability to **8**.

A single crystal X-ray structure analysis of **9**[17] revealed a number of unusual structural features (Fig. 1). The distortions

Selected bond lengths [Å]: C1 - C2 1.377(7), C2 - C3 1.399(6), C3 - C4 1.419(6), C4 - C10 1.420(6), C3 - C7 1.439(7), C7 - C8 1.346, O1 - C1 1.394(6), O1 - C17 1.457(6), C17 - C18 1.518(7), C18 - C19 1.506(6), C19 - C20 1.520(6).

Table 1. Bend angles [ ] between planes in the pyrene moiety of **9**.

Planes defined by [a]		Angle
C1, C2, C6	C2, C3, C5, C6	16.2
C2, C3, C5, C6	C3, C4, C5	13.3
C3, C4, C5	C3, C5, C9, C11	15.6
C3, C5, C9, C11	C9, C10, C11	15.4
C9, C10, C11	C9, C11, C14, C16	13.1
C9, C11, C14, C16	C14, C15, C16	14.3
C1, C2, C6	C14, C15, C16	87.8

[a] The crystallographic numbering shown in Fig. 1 is employed.

in the pyrene moiety are spread out more or less equally over the entire carbon skeleton. Angles formed by adjacent planes of carbon atoms are between 13.1° and 16.2° and average 14.6° (Table 1). The corresponding angles in D_{5h} C_{70}[18] and D_{6h} C_{84} should average 18° and 15°, respectively. The pyrene unit in **9** can thus be viewed as a close approximation of part of the surface of D_{6h} C_{84}. Further distortions are observed at the termini of the pyrene unit, where the two C_{aryl}–O bonds are bent out of the planes defined by C1, C2, C6 and C14, C15, C16 by 8.8°. The total bend of the pyrene unit (angle between the C1-C2-C6 and C14-C15-C16 planes) is 87.8°. There is also a fair correlation between the aromatic C–C bond lengths in **9** with those observed[18] and calculated[19] for D_{5h} C_{70}. The severe bend of the aromatic portion of the molecule is accompanied by stretching of the aliphatic chain. The C-C-C bond angles are between 115.0° and 119.4°, whereas the bond angles at oxygen are 110.5° and 110.6°. Given that arene bends of over 20° and aliphatic C-C-C bond angles of up to 126.5° have been observed in derivatives of [6]paracyclophane,[20] we are optimistic that even more distorted [*n*](2,7)pyrenophanes are obtainable.

A Triple Anion Complex Containing Enolate, Amide, and Halide—A New Structural Type in Lithium Chemistry**

Kenneth W. Henderson, Andrea E. Dorigo, Paul G. Williard,* and Peter R. Bernstein

The growing use of lithium bases as reagents for organic and organometallic transformations has led to a realization of the role that aggregation plays in their reactivity and selectivity.[1-3] Complexes of lithium bases, including mixed anion and mixed cation combinations, have been intensely investigated in solution and in the solid state.[2] An important example of altering aggregation to tailor reactivity and stereoselectivity is the use of lithium halide additives in enolization and addition reactions.[3] Combining crystal structure data with theoretical calculations, we recently investigated a reaction sequence for enolization and subsequent aldol addition involving halide-containing mixed anion complexes.[4] As further support for the involvement of halides in organolithium aggregates we now provide the structure of an aggregate containing lithiated amide, enolate, and halide ligands. This compound has several unique features leading to a new structural category for a tetranuclear lithium compound containing mixed anions.

Complex **1** crystallized from a solution containing a 1:1:1:2 ratio of LiBr, $LiN(SiMe_3)_2$, $LiOC(tBu)=CH_2$ and $Me_2NCH_2CH_2NMe_2$ (TMEDA). An X-ray crystallographic study revealed that **1** consists of four lithium cations, one amide anion, one bromide ion, and two enolate residues (Fig. 1).[5] Formation of complexes that do not reflect the ratio of reactants used is commonplace for reactions involving lithium.[2,6] A feature of the structure is a novel "butterfly" arrangement, in which all four metal atoms lie in the same plane (Li1 and Li2 are 0.180 Å and 0.234 Å, respectively, out of the plane formed by all ligating atoms of the anions and the cations). Alternative tetrameric frameworks that have been observed are mostly cubanes (stacks) or edge-to-edge ladders,[2] although open octagons[7] and a bicyclo[2.4.0]octane system[8] have also been reported (Fig. 2). Complex **1** can be viewed as a three rung ladder trimer of lithium bromide, lithium pinacolate, and lithium hexamethyldisilazide in which a second lithium pinacolate residue is complexed 'side-on' to the ladder. Another bromide-containing tetranuclear aggregate (**2**) has been identified.[9] In this instance the structure is a cubane.

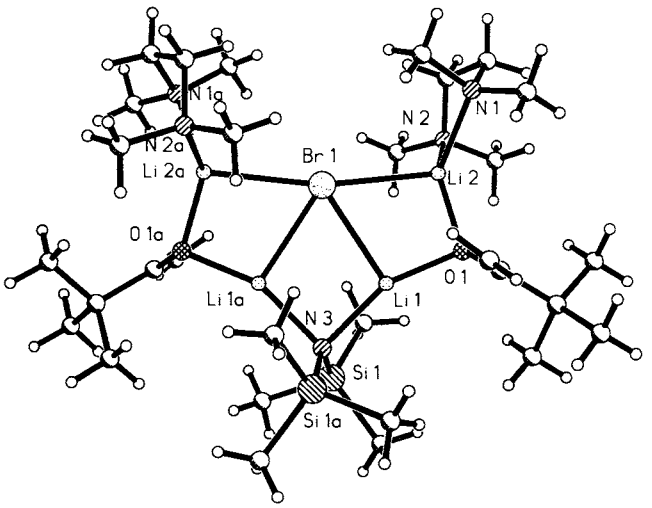

Fig. 1. Molecular structure of **1** with hydrogen atoms omitted for clarity. Key bond lengths [Å] and angles [°]: Li1–Br1 2.604(7), Li1–O1 1.845(7), Li1–N3 2.001(7), Li2–Br1 2.613(6), Li2–O1 1.843(7), Li2–N1 2.094(7), Li2–N2 2.084(7), Li2-Br1-Li2a 167.8(3), Li1-Br1-Li2 64.3(2), Li1-Br1-Li1a 65.2(3), Br1-Li1-N3 102.9(3), Br1-Li1-O1 98.9(3), Br1-Li2-O1 98.6(3), Li1-O1-Li2 97.7(3), Li1-N3-Li1a 89.1(4).

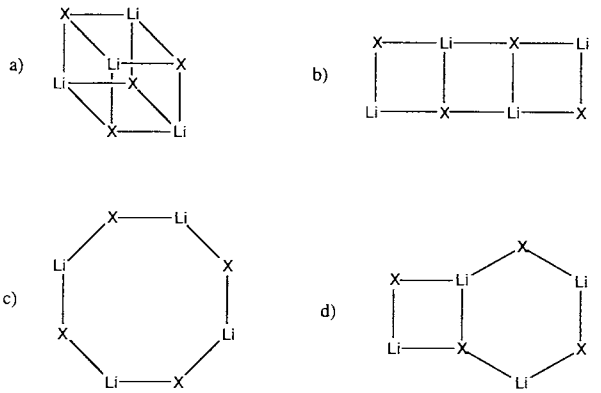

Fig. 2. Known structural types for lithium tetramers. a) Cubane, b) ladder, c) octagon, and d) bicyclo[2.4.0]octane system.

$[LiBr \cdot LiN(SiMe_3)_2 \cdot \{LiOC(tBu)=CH_2\}_2 \cdot (TMEDA)_2]$ **1**

$[LiBr \cdot (PhLi)_3 \cdot (Et_2O)_3]$ **2**

Another unique feature of **1** is that it contains three different types of anion in the aggregate. To our knowledge, **1** is the only crystallographically characterized example of an alkali metal complex that is composed of three distinct anions. This is remarkable, since over 1500 crystal structures containing lithium are reported in the Cambridge Structural Database. In part, the lack of information on such systems is due to the experimental difficulty in preparing mixed anion complexes.[4]

There are two distinct types of lithium atom present in the structure of **1**. Li1 and Li1a are three-coordinate and trigonal planar, bridging three anion types, whereas Li2 and Li2a are four-coordinate and tetrahedral, bonding to the bromine ion, an enolate ion, and a TMEDA molecule. However, the Li–O and Li–Br bond lengths are almost identical for both types of metal coordination (Li1–Br1 2.604 Å and Li2–Br1 2.613 Å; Li1–O1 1.845 Å and Li2–O1 1.843 Å). There is also a short contact distance between the three-coordinate lithium center and the α-carbon of the enolate (Li1–C8 2.586 Å, whereas Li1–C7, the distance to the β-carbon, is 3.016 Å).

Ladder structures are common in organolithium chemistry;[2] however, no reports on structures such as **1**, in which an anionic center bridges four *in-plane* lithium atoms, have been published. Clearly, this is a consequence of the nature of the electronegative center, bromine, but the bulk of the substituents and ligands present also plays a part. To demonstrate this, we performed semi-empirical PM3[10] calculations on two isomers—"ladder"-shaped and "butterfly"-shaped—of the model systems **I**–**III** (Fig. 3). We found that both factors influence the

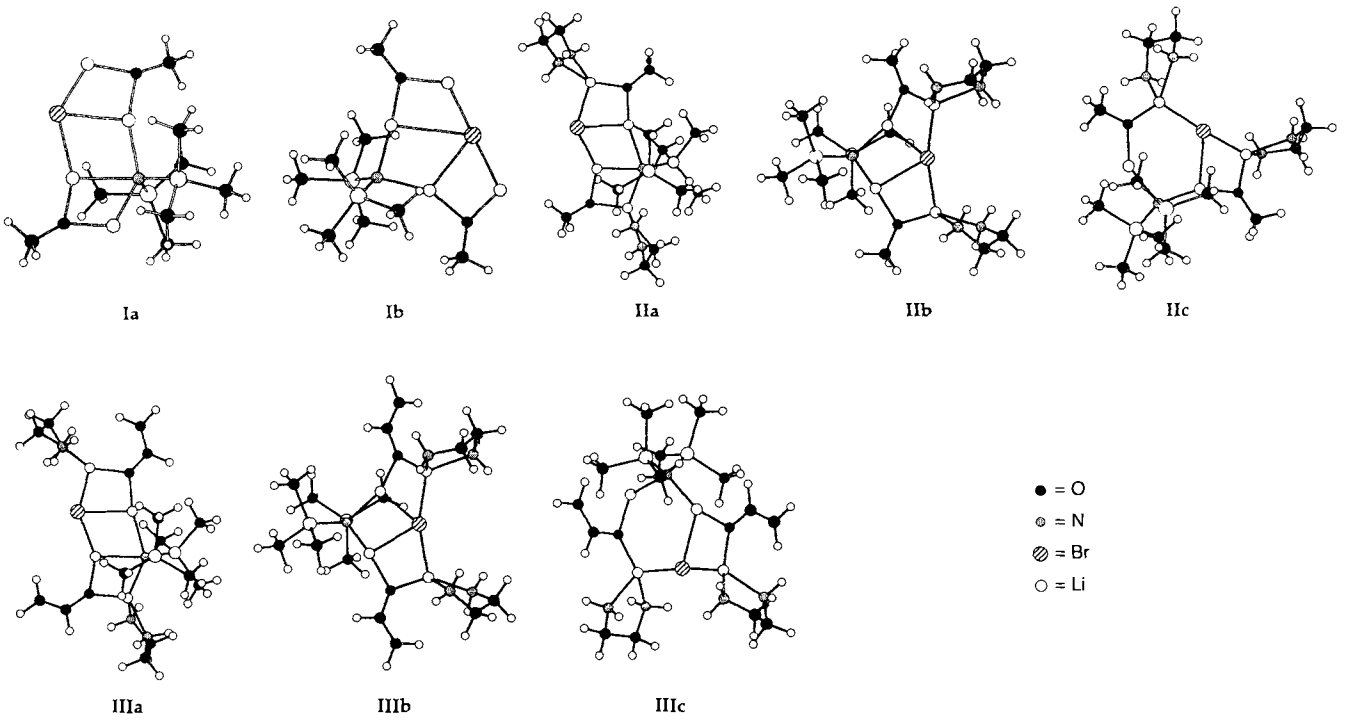

Fig. 3. PM3-optimized structures **I**–**III**. Calculated heats of formation [kcal mol^{-1}]: **Ia** −361.8, **Ib** −354.7, **IIa** −411.2, **IIb** −414.6, **IIc** −416.7, **IIIa** −377.8, **IIIb** −382.9, **IIIc** −385.7. Absolute HF/LANL2DZ energies [Hartree]: **Ia** −571.62484, **Ib** −571.63637, **IIa** −950.12458, **IIb** −950.15169, **IIc** −950.12620.

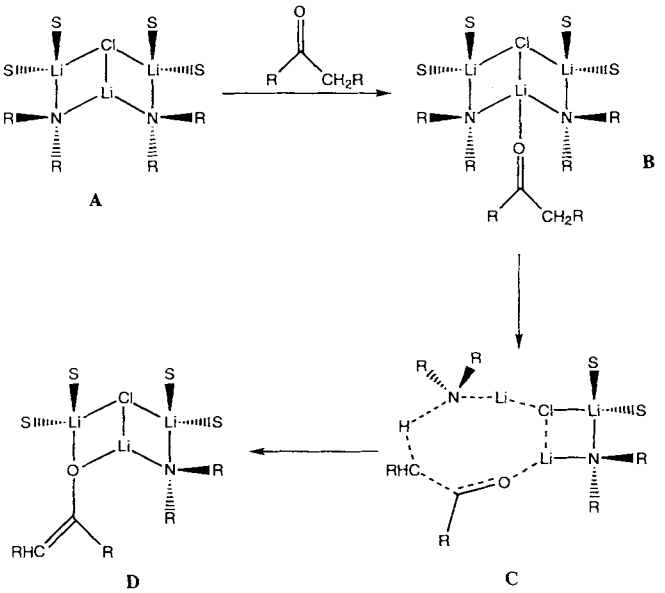
relative energies of the two isomers. Thus, the ladder structure **Ia**, in which the substituent on oxygen is a methyl group and neither lithium center has a ligand, is 7.1 kcal mol^{-1} more stable than the butterfly form **Ib**. However, coordination of two lithium centers with diaminoethane renders **IIa** less stable than **IIb** by 3.4 kcal mol^{-1}. Remarkably, a third structure, **IIc**, is even more stable than **IIb**, by 2.1 kcal mol^{-1}. This structure is best described as a bicyclic system formed by the fusion of a four-membered and a six-membered ring. A tetramer of LiCl solvated by TMEDA was recently found to have a similar structure.[8] Finally, replacement of the methoxy groups with acetaldehyde enolate residues gives a 2.8 kcal mol^{-1} preference for **IIIc** over **IIIb** and a 7.9 kcal mol^{-1} preference for **IIIc** over **IIIa**.

In all models (except for the simplest structures **Ia** and **Ib**) the ladder structure is clearly disfavored. It is still not clear why PM3 gives a lower energy for the bicyclic structure. To clarify the issue regarding the relative energies of the two systems, we performed single-point ab initio calculations[11] on **Ia**, **Ib**, **IIa**, **IIb**, and **IIc** at the HF/LANL2DZ[12] level using the PM3 geometries. At this level, **Ib** becomes favored over **Ia** by 7.2 kcal mol^{-1}. Structure **IIb** is favored by 16.0 and 17.0 kcal mol^{-1} over **IIc** and **IIa**, respectively. The large discrepancy between the relative stabilities determined with PM3 and ab initio calculations of the butterfly forms is probably due to the use of minimal basis sets in PM3, which are not flexible enough to describe the bonding of the tetracoordinate bromine center in **Ib** and **IIb** properly. It therefore appears that, at the highest level of theory, the butterfly-shaped structures are more stable than alternative geometries.

The crucial element in the stabilities of the butterfly and ladder forms is the nature of the amido nitrogen. We have formerly established that, due to a combination of electronic and steric factors, hexamethyldisilazide ions are poor μ_3-bridging anions.[13] As a consequence, the second lithium enolate group prefers to bond to bromine, leaving the amido nitrogen tetracoodinate.

We previously theorized that complexes similar to **1** may be involved during enolization reactions and will affect selectivity (Scheme 1).[4] In fact, **1** is very similar to complex **D** in Scheme 1, which supports this hypothesis (compounds



Scheme 1. Postulated mechanism of enolization in the presence of lithium complexes. For details, see text.

analogous to **A** are known, and transition state **C** is energetically viable according to ab initio calculations). Interestingly, the enolization of 3-pentanone gives an optimium *E*/*Z* selectivity when 0.3–0.4 equivalents of LiCl per lithium amide are present.[14] Such a ratio is consistent with the structure of **1**. Complex **1** also demonstrates the important fact that triple anion aggregates of lithium are stable species.

Experimental Procedure

To a cooled mixture (approx. 0 °C under an argon atmosphere) containing *n*BuBr (2 mmol), hexamethyldisilazane (4 mmol), and TMEDA (4 mmol) in 2 mL of pentane was added *n*BuLi (6 mmol, from a 2 M solution in pentane). The mixture was stirred for five minutes, after which pinacolone (2 mmol) was added over a period of one minute. The opaque solution was warmed to 20 °C and concentrated to half volume in vacuo. After gentle heating, the clear colorless solution was kept at −20 °C. Upon standing for several weeks, a small crop of crystalline **1** was deposited. Although the yield of these crystals varied with the crystallization conditions, it was reproducible and not insignificant.

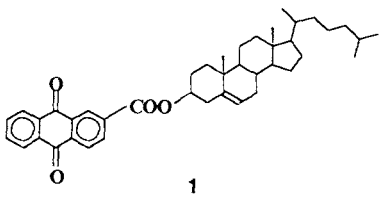
Novel X-ray Method for In Situ Determination of Gelator Strand Structure: Polymorphism of Cholesteryl Anthraquinone-2-carboxylate**

Emanuele Ostuni, Peter Kamaras, and Richard G. Weiss*

We report a novel method to discern the packing of molecules within fibers, and demonstrate its application to thermally reversible gels that employ cholesteryl anthraquinone-2-carboxylate (CAQ[1–3]) (**1**) as gelator. It is shown that the morph responsible for the fibers in this case is not the one obtained by "normal" crystallization. Although the method may not be applicable to all gels, it offers the possibility for determining in situ the molecular packing arrangement of gelator fibers and other assemblies of this generic type.



1

CAQ (**1**) and many structurally related gelators form thermotropic liquid-crystalline phases[1, 4, 5] and, in some cases, the gels are birefringent like lyotropic phases.[1a, 5] The length and thickness of the gelator fibers can be influenced strongly by solvent properties[1b, 2, 6, 7] and by the rate of formation of the fiber networks.[5, 7] Terech et al. have exploited elegantly small angle neutron scattering (SANS) and small angle X-ray scattering (SAXS) data to deduce information about the dimensions of fibers and the types of junctions between them in various gel phases.[3, 8, 9] Yet, some important structural questions remain unanswered. For instance 1) how do molecules pack within a fiber? and 2) what, if any, is the relationship between bulk crystals and "fiber crystals"?

Our method addresses these questions by relating structural information from powder and single-crystal X-ray diffraction data from different sample phases without losing the correlation among them.[10] First, the X-ray powder diffraction pattern of a gel is subtracted from that of the neat liquid component measured under identical conditions.[11] The difference is thus the diffraction from the solid-like fibers that are composed primarily of gelator molecules since virtually all of the liquid component of the gel is disordered (as it is in its neat state).[1, 8, 9] If the subtracted diffraction pattern and the powder diffractogram from a crystalline form of the neat gelator are virtually the same, molecular packing in gelator fibers can be related to that in bulk single crystals.

Differential scanning calorimetry (DSC) thermograms of neat CAQ and its X-ray powder diffractograms (vide infra) show that the solid obtained upon cooling from the mesophase is different from that from the crystals from solution (solvent:

[**] We are indebted to Prof. Timothy Swager and Mr. Bing Xu of the University of Pennsylvania for their generosity in allowing us to use their powder diffractometer and for helpful discussions. The National Science Foundation is gratefully acknowledged for its support of this work (CHE-9422560) and for its partial support of the purchase of the single-crystal diffractometer (CHE-9115394).

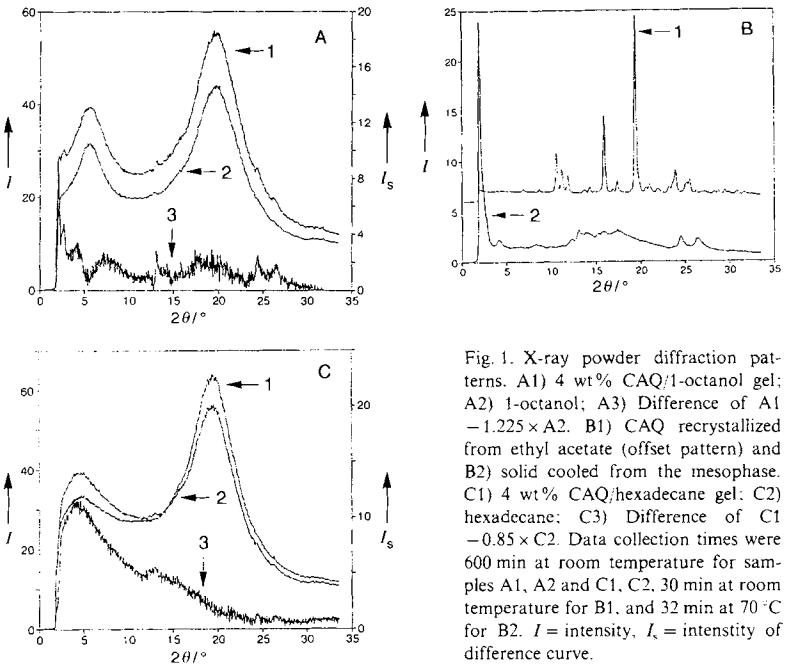

Fig. 1. X-ray powder diffraction patterns. A1) 4 wt% CAQ/1-octanol gel; A2) 1-octanol; A3) Difference of A1 $-1.225 \times$ A2. B1) CAQ recrystallized from ethyl acetate (offset pattern) and B2) solid cooled from the mesophase. C1) 4 wt% CAQ/hexadecane gel; C2) hexadecane; C3) Difference of C1 $-0.85 \times$ C2. Data collection times were 600 min at room temperature for samples A1, A2 and C1, C2, 30 min at room temperature for B1, and 32 min at 70 °C for B2. I = intensity, I_s = intenstity of difference curve.

ethyl acetate or 1-butanol/toluene)—CAQ is a polymorphous solid, like several other gelators we have studied.[1, 4, 12] Thus, the melting temperature and heat of transition for the first heating thermogram (166 °C and 55 $J g^{-1}$) are different from those of all subsequent heating cycles (169.7 °C and 25.9 $J g^{-1}$). Fibers are apparent in electron micrographs of CAQ/silicone oil gels[2] and they offer the best explanation for SANS and SAXS data derived from CAQ/1-alkanol and CAQ/alkane gels.[3] The diffraction pattern of a CAQ/1-octanol gel (Fig. 1 A1) is, as expected, very similar to that of the neat liquid component (Fig. 1 A2), since it is isotropic on a mesoscopic scale.[1] However, it includes barely discernible peaks whose intensity can be amplified by subtracting the diffraction pattern of a capillary filled with 1-octanol from that of the corresponding CAQ/1-octanol gel. The resultant pattern (Fig. 1 A3) is very similar to that of solid CAQ cooled from its mesophase (Fig. 1 B2), but not to that of recrystallized CAQ (Fig. 1 B1). The pattern for the liquid phase was multiplied by 1.225, an empirical factor, before subtraction since the ability of the liquid to diffract is different from that of the gel. These data provide compelling evidence that the strands of the gelator network in 1-octanol consist primarily of CAQ molecules packed like those in the neat solid cooled from the mesophase.

An analogous treatment of diffraction data from a CAQ/hexadecane gel results in a pattern that cannot be related as easily to one of the gelator dimorphs (Fig. 1C). Nevertheless, the peaks at about 13° and those at 24–28°, characteristic only of CAQ cooled from the mesophase, are evident; thus, CAQ/hexadecane gels may consist of fibers whose molecular packing is also like that of neat solid CAQ cooled from its mesophase.

The presence of broad diffuse features in subtracted patterns from both gels, corresponding to diffraction of the isotropic liquids, is consistent with the conclusions from SANS and SAXS analyses[3] that some liquid-component molecules are incorporated in or anisotropically associated with the fibers near junction zones. As yet, our technique is not capable of assessing quantitatively the degree of liquid participation.

Although the dimorph from the mesophase has not been obtained yet in a form amenable to single-crystal diffraction, we assume (on the basis of the low-angle peak in the powder pattern and the parallel arrangement of molecules in the mesophase) that the fibers contain CAQ molecules in lamellar-like arrays.

The packing arrangement of CAQ molecules in a single crystal[13] (obtained from 1-butanol/toluene) was determined by an X-ray structural analysis (Fig. 2). Its powder diffraction pattern simulated from the single-crystal packing information[14] is virtually superimposable with that in Figure 1 B1, providing further evidence that recrystallization from ethyl acetate and 1-butanol/toluene produces the same dimorph. The molecular packing displays none of the characteristics expected of gelator fibers. There are no apparent (strongly) attractive interactions. Individual molecules have neighbors whose long axes are parallel, but each is staggered so that there are no lamellae. Also, π-π interactions[1, 5] between anthraquinonyl groups and steroidal–steroidal interactions[15] are not apparent: neighboring aromatic groups are canted with respect to each other by 19°; the nearest approach (3.14 Å) is between an oxygen atom of an anthraquinonyl group of one molecule and the carbonyl oxygen atom of the ester group of a neighboring molecule; all other intermolecular distances are at least 3.9 Å. Within a molecule, the angle between the non-weighted least-squares plane defined by the carbon atoms of the aromatic ring nearer the steroidal group and by the carbon atoms at the 1, 3, and 5 positions in the steroidal A-ring is about 55°. Whatever layering does exist is not expected to impart the mechanical strength necessary to construct a colloidal network of fibers.

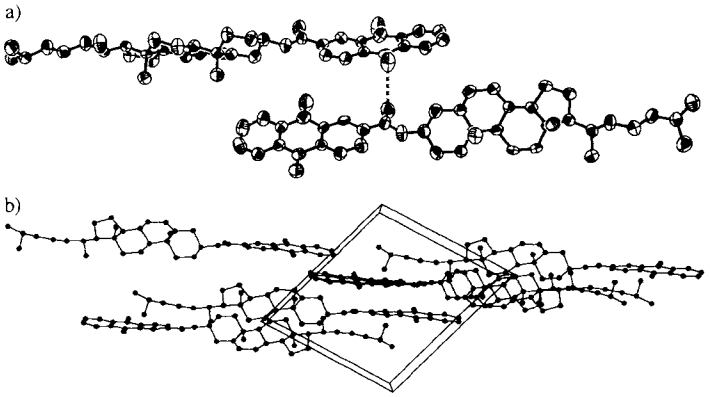

Fig. 2. Molecular packing of CAQ in crystals obtained from 1-butanol/toluene. a) ORTEP plot (50% probability; hydrogen atoms removed for clarity); the dashed line shows the shortest intermolecular interaction. b) Molecular packing within the unit cell.

In summary, we have described a methodology for ascertaining the molecular packing of gelator molecules in strands constituting colloidal networks in physical gels and have presented examples of its application using CAQ. The method takes into consideration the potential polymorphous character of many gelator molecules and, for that reason, it maintains direct relationships among data sets derived from the various states of matter. The fact that the CAQ morph in the gel fibers is *not* the one obtained upon a "normal" crystallization indicates the caution necessary in relating molecular packing in gel and neat phases.

[10] Recently, Menger et al. made the guarded claim in this journal [10a] to have determined for the first time the packing arrangement of molecules at the atomic level in a self-assembled gel fiber. They attempted to examine fibers of gels from dibenzoyl-L-cystine (DBC) in mixtures of water and ethanol. Unfortunately, their molecular packing arguments are based upon single-crystal diffraction data from a *related* molecule, di(*p*-toluoyl)-L-cystine (DTC), that precipitated from water/ethanol mixtures, and then was recrystallized from yet a *different* solvent (methanol ethyl acetate) before being analyzed! Considering that polymorphism of gelator molecules is common (contrary to assumption [10a]), that different strand types can be found in gels of one gelator and different liquid components [1b,6–8], and that subtle structural changes (such as addition or subtraction of even one carbon atom on a chain) can have drastic consequences on molecular packing in crystals [10b] and gelation ability [7], we consider the extrapolation from DBC gels to DTC recrystallized from a different solvent to be compromising in the best scenario and a source of erroneous conclusions in the worst one. a) F. M. Menger, Y. Yamasaki, K. K. Catlin, T. Nishimi, *Angew. Chem.* **1995**, *107*, 616; *Angew. Chem. Int. Ed. Engl.* **1995**, *34*, 585; b) B. M. Sheikh-Ali, M. Rapta, G. B. Jameson, R. G. Reversible Encapsulation of Guest Molecules in a Calixarene Dimer**

Blake C. Hamann, Ken D. Shimizu, and Julius Rebek, Jr.*

Dedicated to Professor C. David Gutsche on the occasion of his 75th birthday

A molecular capsule[1] based on the hemispherical substructure of a calix[4]arene was recently described.[2] Urea functions placed on the "upper" rim of the calix[4]arene permit dimerization to occur through a head-to-tail hydrogen bonding pattern (Fig. 1), a pattern which is remniscent of those observed for

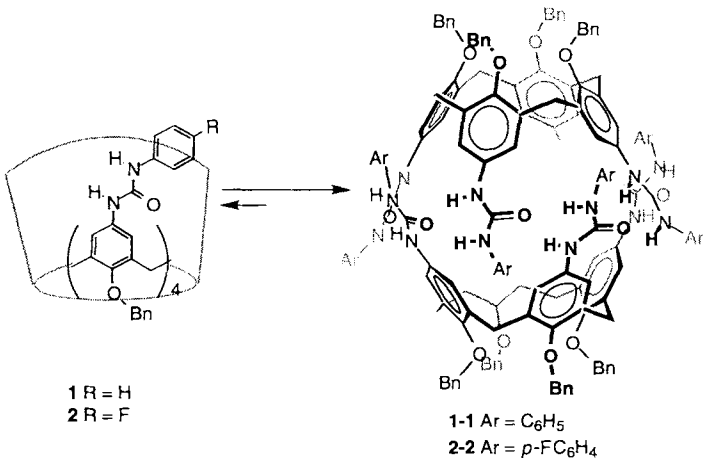

Fig. 1. The dimerization of the urea-substituted calix[4]arene through the formation of intermolecular hydrogen bonds. Bn = benzyl.

diaryl ureas in the solid state.[3] The direct observation of guests within the capsule has now been achieved, and permits a measure of the stoichiometries and exchange rates of guests into and out of the capsule. We report here on these developments and apply a computational method to estimate the interior volume of the capsule.

The capsule **2-2** was prepared from the appropriate tetraamine as previously described[1, 4] for **1-1** but using *p*-fluorophenyl isocyanate as the electrophile in the final step of the synthesis. The signals of the fluorine atoms in **2-2** serve as an internal standard for ^{19}F NMR spectroscopy. The compound is monomeric in [D_6]DMSO but a well-behaved dimer in [D_{10}]-*p*-xylene solution, and its ^1H NMR spectra are recorded in Figure 2. The characteristic features of the spectrum—two different calixarene proton resonances at $\delta = 5.78$ and 7.95, the meta coupling between them ($J = 2.4$ Hz), the widely separated AB system for the methylene protons of the calixarene (characteristic of a cone conformation),[5] and the AB quartet for the benzyl protons (which reflects the asymmetry imparted by the "direction" of the circle of urea functions)—leave little doubt that the structure is the dimeric **2-2** shown in Figure 1.[6]

[**] We thank Professors David Reinhoudt, George Whitesides, and Volker Böhmer for suggestions and advice, and Professor Philip Eaton for a sample of cubane. The National Institutes of Health provided financial support.

[+] Address after July 1, 1996: Institute for Chemical Biology, The Scripps Research Institute, 10550 N. Torrey Pines Road, La Jolla, CA 92037 (USA).

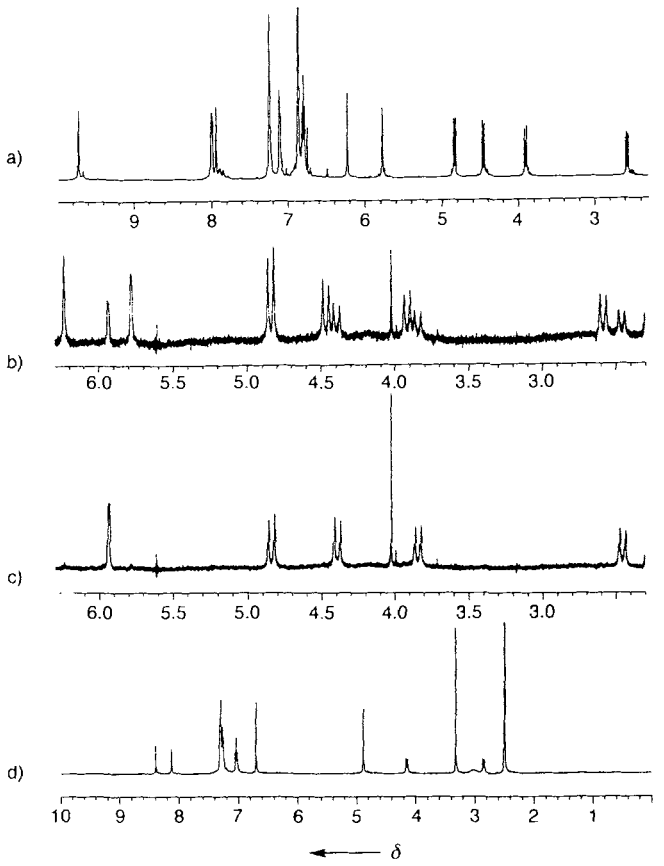

Fig. 2. ^{1}H NMR spectra of **2-2** in [D_{10}]*p*-xylene. a) Without addition of benzene. b) 4 minutes after the addition of 5 μL benzene, and c) 40 minutes after the addition of 5 μL benzene. d) ^{1}H NMR spectrum of **2** in [D_6]DMSO.

When fluorobenzene is added to the solution of **2-2**, a new signal emerges upfield in the ^{19}F NMR spectrum. The integration indicates an approximately 1:1 stoichiometry, and implies that encapsulation of fluorobenzene has occurred.[7] On addition of other ureas such as the phenyl-α-phenylethyl derivative **3** to the latter solution, the fluorobenzene is liberated and the signals of a new calixarene species appear in the ^{1}H NMR spectrum. This most likely results from the "denaturation" of the calixarene dimer **4** by the urea derivative through competitive hydrogen bonding (Fig. 3), a process analogous to the denaturation of proteins with urea. One of the many posssible structures for the denatured product is **5** (Fig. 3).

Direct observation of the encapsulated guests by ^{1}H NMR spectroscopy is also possible, given some time. For example, when excess benzene is added to the solution of **2-2** (Fig. 2a), a new singlet appears at $\delta = 4.02$ and grows over the course of about 40 minutes (Fig. 2b and 2c). Integration again indicates an approximately 1:1 ratio of benzene to the capsule **2-2**, and the half-life for the uptake is about eight minutes. Equilibrated solutions of benzene and the dimeric calixarene in [D_{10}]*p*-xylene indicate an association constant K of 230 M^{-1} for benzene encapsulation.[8]

The encapsulation of other guests such as fluorobenzene, *p*-difluorobenzene, and pyrazine has also been directly monitored by NMR spectroscopy (Fig. 4a–c). Particularly striking

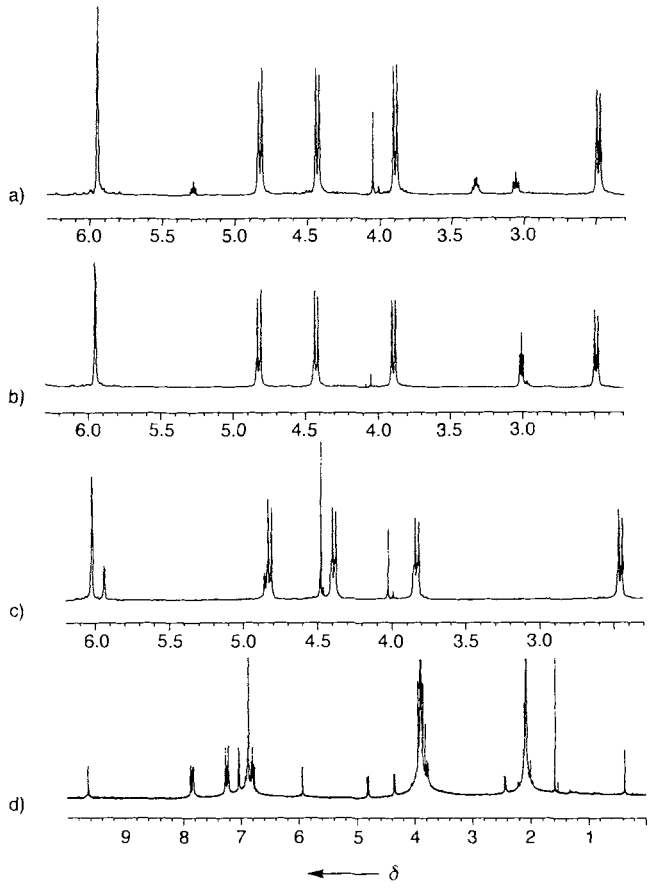

Fig. 4. ^{1}H NMR spectra of solutions of **2-2** in [D_{10}]*p*-xylene (2.94×10^{-3} M) with benzene (22×10^{-3} M) and a) fluorobenzene, b) *p*-difluorobenzene, and c) pyrazine (each 22×10^{-3} M); d) ^{1}H NMR spectrum in [D_{10}]*p*-xylene with excess cubane.

are the different chemical shifts observed for the *ortho*-, *meta*-, and *para*-hydrogen atoms of encapsulated fluorobenzene; the *para*- and *ortho*-hydrogen atoms are separated by more than 2 ppm! This is evidence that a particular orientation is favored by this guest within the cavity. The orientation of fluorobenzene in **4** shown is consistent with the chemical shifts observed. The *ortho*- and *meta*-hydrogen atoms are directed at the π-electron systems of the phenyl rings of the calixarene, while the *para*-hydrogen atom and the fluorine atom are directed at the encircling urea groups. Competition studies of other guests were undertaken and the affinity of the calixarene dimer for these (relative to benzene) is given in Table 1. The high affinity observed for pyrazine also hints at

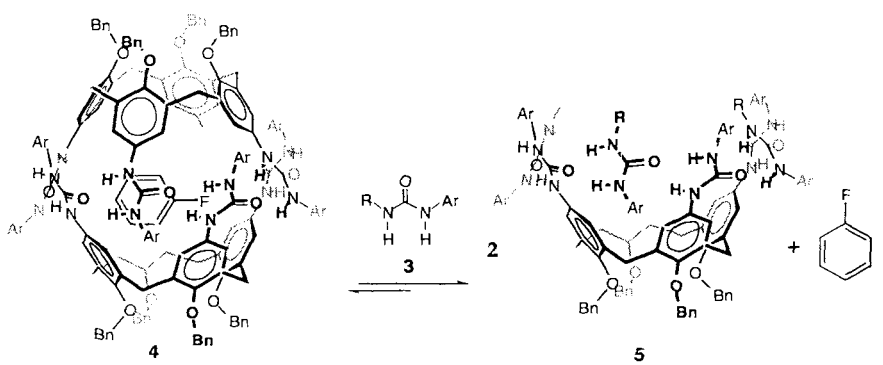

Fig. 3. The "denaturation" of capsule **4** on addition of urea derivative **3**, resulting in the liberation of *p*-fluorobenzene.

Table 1. Relative affinities of **2-2** for guests in competition with benzene [a]

Guest	Affinity

a conformation that directs the lone pairs of electrons on the nitrogen atom toward the urea hydrogen atoms in the complex.[9]

Determination of "negative volume", the cavity size inside of a molecule, has been particularly **difficult.**[10] Low-tech methods, such as physically building a space-filling model and measuring the amount of plaster that can be pressed into its interior, have been used with practical results.[11] We have found that the modeling program MacroModel can measure the negative volume of a cavity through a simple series of calculations. MacroModel calculates the positive volume of a molecule and does so without calculating overlapping volumes twice. For the case of **2-2**, the volume that the host occupies was calculated. Next, the cavity was "stuffed" with smaller overlapping arbitrary molecules in a way that no unoccupied space remained inside the cavity. Care was taken to avoid ruptures, that is, penetration of the stuffing through the outer van der Waals (VDW) surface of the dimeric capsule. The calculation was repeated on the filled capsule, and subtraction of the first volume from the second gives the volume of the cavity.

In this manner, the volume of **1-1** was calculated to be ≈ 210 Å^3. In addition, the volumes of several guests were measured for comparison (Table 2). These measurements show that most guests appear to fill $\approx 50\%$ or less of the available space in the cavity. By comparison, in a liquid 70% of space is filled.

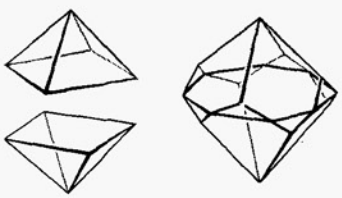

Fig. 5. Schematic representations of the cavity formed by the dimerization of **2**. The two square pyramids (left) represent the separate calix[4]arenes and the geometric figure (right) the assembled cavity.

The shape of the cavity within **2-2** is not easy to visualize. A geometric simplification is shown in Figure 5. Each calix[4]arene is represented by a square pyramid with its triangular facets corresponding to the phenyl rings of the macrocycle. In the dimer, the pyramids are offset by 45°, and the corners are cut off to simulate the eight interleaved urea groups that mark the equator of the structure.

A horizontal slice through the plane of the urea group yields an octagonal cavity, a vertical slice gives a diamond-shaped cavity, having different angles and lengths for the top and bottom sections. Overall the cavity has a height of ≈ 10 Å and a width of 7–8 Å, measured from VDW surface to VDW surface (Fig. 6). Modeling shows that guests such as benzene, cyclohexane, and chloroform can be easily accommodated.

As the cross sections in Figure 6 show, cubane would fit well in the cavity. The energy-minimized structures for the complexes with cubane are shown in Figure 7, in which the cavity walls

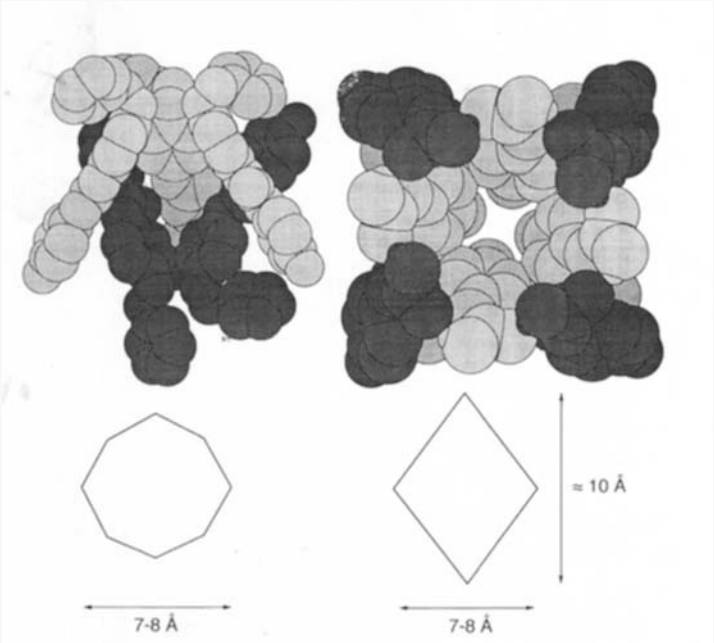

Fig. 6. Horizontal and vertical cross sections of van der Waals surfaces of **2-2**. In each view half of the dimer has been cut away.

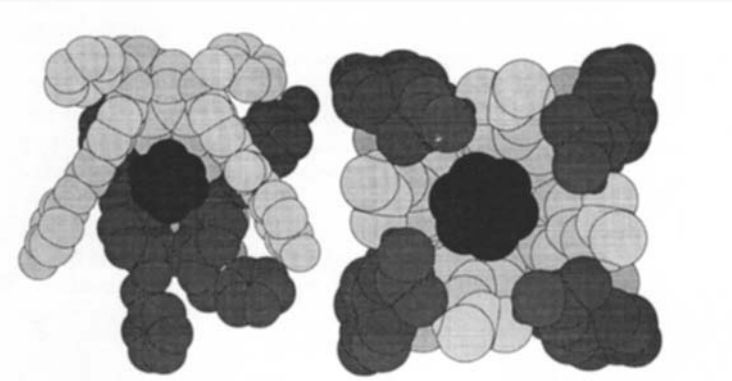

Fig. 7. Views of CPK representations of **2-2** with encapsulated cubane from side and top views. Only half of the dimer is shown in each case

Table 2. Volume V [Å^3] and length of the longest axis L of various guests [a]

Heterogeneous Palladium-Catalyzed Regioselective Hydrostannation of Alkenes**

Mark Lautens,* Sophie Kumanovic, and Christophe Meyer

Hydrometalation of carbon–carbon multiple bonds is a powerful method for the generation of useful organometallic compounds.[1] We have previously described the nickel-catalyzed hydroalumination and ring opening of oxabicyclic systems such as **1** leading to the cycloalkenol **2** (Scheme 1).[2] Recently we reported the palladium-catalyzed hydrostannation of **1**,[3] leading to the organostannane **3** in which the tin occupies a distal position. Transmetalation of the latter with methyllithium afforded the regioisomeric ring-opened product **4**.

We were interested in extending the scope of the hydrostannation reaction to a wider variety of alkenes. It is well-known that palladium complexes catalyze the hydrostannation of alkynes to yield vinylstannanes.[4] However, the corresponding reaction of unactivated alkenes has not been reported to our knowledge. This reaction should, in principle, lead to tetraalkylstannanes. Although simple tetraalkylstannanes fail to undergo efficient tin–lithium exchange, an appropriately located heteroatom shifts the equilibrium due to coordination to the newly formed organolithium compound, thus allowing the exchange

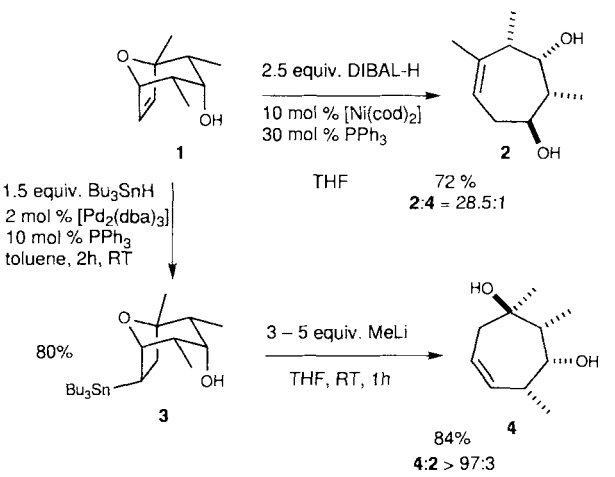
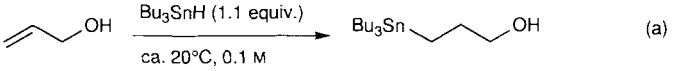


Scheme 1. Hydrometalation–ring opening sequences of oxabicyclic compound **1**. RT = room temperature, DIBAL-H = diisobutylaluminum hydride.

to proceed.[5] Interestingly, 3-tributylstannyl-1-propanol has been shown by Seebach and Meyer to be transmetalated to 3-lithioalkoxypropyllithium,[6a] and the dramatic influence of the alkoxy moiety in a related process has been nicely illustrated by Carpenter and Newman-Evans.[6b] More recently, Knochel et al. have applied this tin–lithium exchange reaction to the synthesis of chiral, γ-functionalized secondary alcohols.[6c]

Hydrostannation of double bonds has mostly been achieved under radical conditions by heating the compounds in neat tin hydrides, sometimes in the presence of a radical initiator.[7] Activated alkenes including styrene react rapidly, but this reaction lacks generality. Since addition of stannyl radicals onto a carbon–carbon double bond is reversible,[7b] a high concentration of tin hydride is required to achieve an efficient quench of the initially formed β-stannyl radical. Alternatively, ultrasound-promoted radical hydro- and hydroxystannations of activated double bonds have also been described.[7e]

When we attempted to perform the hydrostannation of allyl alcohol [Eq. (a)] with the homogeneous Pd catalyst that worked



(a)

efficiently for the conversion of **1** to **3**, the corresponding 3-tributylstannyl-1-propanol was produced in no more than 5% yield (Table 1, entry 1). Similarly, other allylic alcohols failed to give high yields of hydrostannated products in the presence of the commonly used soluble catalyst [$Pd(PPh_3)_4$].

However, we have found that this reaction can be performed in high yield under heterogeneous catalysis. Pd/C was the first

Table 1. Hydrostannation of allyl alcohol according to Equation (a).

Entry	Catalyst	Solvent	Time [a]	Yield [%] [b]
1	[$Pd_2(dba)_3$] 2.5 mol % PPh_3 10 mol %	THF	ca. 12 h	4
2	·	EtOH abs.	ca. 12 h	23 [c]
3	Pd/C 10 mol %	AcOEt	ca. 12 h	35
4	[$Pd(OH)_2$]/C [d, e]	EtOH abs.	2 h	50
5	[$Pd(OH)_2$]/C [d]	THF	1 h	82

[a] Total time elapsed before workup. [b] Yield of isolated product. [c] No reaction occurs if the solvent is degassed, or if galvinoxyl is added. Galvinoxyl = 2,6-di-*tert*-butyl-α-(3,5-di-*tert*-butyl-4-oxo-2,5-cyclohexadien-1-ylidene)-*p*-tolyloxy (free radical). [d] 10 mol % Pd from Pearlman's catalyst (dry weight basis). [e] Addition of galvinoxyl has no effect on this reaction.

catalyst we examined (entry 3), but $[Pd(OH)_2]/C$ (Pearlman's catalyst, entries 4 and 5) was more efficient at promoting the hydrostannation of a variety of alkenes, provided that Bu_3SnH was added slowly over one or more hours. Transition metals are known to catalyze the decomposition of tributyltin hydride to hexabutyldistannane and molecular hydrogen,[7a] and this was the main side reaction we had to overcome. The major side product of the reaction is Bu_6Sn_2, which is easily removed by column chromatography.

The catalytic influence of palladium hydroxide is demonstrated by the fact that in its absence, 3-tributylstannyl-1-propanol is produced in only 23% yield, because of an inefficient radical pathway (entry 2). The latter pathway can be completely inhibited by degassing the solvent or by adding radical scavengers such as galvinoxyl. THF was the optimum solvent for this heterogeneously catalyzed hydrostannation (entry 5), although ethanol gave good yields as well.

The reaction has been successfully applied to a wide variety of alkenes (Table 2). The allylic alcohols can be either secondary or tertiary (entries 1 and 2). The presence of a coordinating group located at the allylic position is not required for the reaction to proceed, since 3-buten-1-ol, 10-undecen-1-ol (entry 3), acrolein diethyl acetal (entry 4), and vinylacetic acid (entry 5) are regioselectively hydrostannated in good yields. In the case of acrylonitrile (entry 6), both heterogeneously and previously reported homogeneously catalyzed hydrostannations afford the α adduct,[8] confirming that the reaction follows a polar pathway. *N*-Vinylphthalimide (entry 6) is hydrostannated in acceptable yield, and the resulting compound is of significant interest, since α-phthalimidostannanes can function as α-aminostannane equivalents in Stille-type coupling reactions.[9]

Allyl amine derivatives (entry 7) are also hydrostannated in excellent yields under the same conditions, which provides an efficient route to γ-aminostannanes.

1,1-Disubstituted alkenes react efficiently (entry 8), but unactivated 1,2-dialkyl-substituted alkenes give low yields of hydrostannated products under these conditions. However, aryl substituted alkenes react smoothly, leading to benzylstannanes (entries 9 and 10). Interestingly, in the case of 1,2-dihydronaphthalene, we have found that radical-initiated addition of Bu_3SnH proceeds with the opposite regiochemistry in 88% yield.

In conclusion, we have shown that a wide variety of alkenes can be efficiently hydrostannated under heterogeneous conditions, providing easy access to organostannanes that are not easily prepared by other routes. This reaction can also be complementary to the radical-based hydrostannation reactions in terms of the regioselectivity of the addition. Further developments on this reaction, especially in the design of diastereo- and enantioselective hydrostannations, are currently underway.

[a] Conditions: 1.5 equiv Bu_3SnH, 10 mol% Pd from Pearlman's catalyst, THF (0.1 M), room temperature, 1 h. [b] Yields of isolated products. [c] Reaction performed in absolute ethanol. [d] An 84:1 ratio of the linear and branched isomers was observed.

Experimental Procedure

General procedure for the heterogeneous, palladium-catalyzed hydrostannations of alkenes: Tributyltin hydride (1.5 mmol) was added over 1 hour by syringe pump to a well-stirred mixture of the alkene (1 mmol) and $[Pd(OH)_2]/C$ (Pearlman's catalyst, 53 mg, 0.1 mmol of Pd) in THF (10 mL). The reaction mixture was stirred for an additional hour and then filtered through a pad of celite. Flash chromatography on silica gel (hexanes:ethyl acetate mixtures as eluent) gave the product.

1-Phenyl-3-(tributylstannyl)propan-1-ol (entry 1): Purified by flash chromatography (hexanes:ethyl acetate 100:0 to 10:1), colorless oil (yield 96%). ^1H NMR (400 MHz, $CDCl_3$) $\delta = 7.36-7.24$ (m, 5H), 4.53 (m, 1H), 1.96–1.83 (m, 3H), 1.52–1.20 (m, 12H), 0.89–0.59 (m, 17H); ^{13}C NMR (100 MHz, $CDCl_3$) $\delta = 144.5$, 128.3, 127.4, 125.9, 77.7, 36.2, 29.2, 27.4, 13.7, 8.80, 4.20.

Molecular Structure of $[Pd_6Cl_{12}]$ in Single Crystals Chemically Grown at Room Temperature**

Daniela Belli Dell'Amico,* Fausto Calderazzo,* Fabio Marchetti, and Stefano Ramello

$[Pd_2Cl_4(CO)_2]$, which according to spectroscopic data is a centrosymmetric chloro-bridged dimer ($\tilde{\nu}_{CO} = 2163\ cm^{-1}$ in thionyl chloride(solv.)), can be prepared by carbonylation of palladium(II) chloride.[1] The thermodynamic data of the equilibrium (a) were established as $\Delta H^0 = -(56.9 \pm 1)\ kJ\,mol^{-1}$ and $\Delta S^0 = -(128.7 \pm 3)\ J\,mol^{-1}\,K^{-1}$).

$$2\,PdCl_{2(s)} + 2\,CO_{(solv.)} \rightleftharpoons [Pd_2Cl_4(CO)_2]_{(solv.)} \qquad (a)$$

We reckoned that slow decrease of the partial pressure of CO over a solution of the dimer could give single crystals of palladium(II) chloride. This experiment could be of interest for many reasons. It should provide a) information about the crystal phase in equilibrium with the carbonyl compound; b) the possibility of adjusting our earlier estimate of the bond dissociation energy (BDE) for the Pd^{II}–CO bond;[1] and c) the possibility of growing single crystals of $PdCl_2$ at room temperature, an experiment which had no precedent in the literature. Furthermore, as both α-[2] and β-$PdCl_2$[3] are reported to sublime as $[Pd_6Cl_{12}]$, as confirmed by mass spectrometric experiments,[3, 4] growing crystals from the experimental setup based on Equation (a) would exploit a well-established dinuclear precursor, different from that operating in the $Pd_{(s)} + Cl_2$ experiments at high temperature[1, 5] (in the range 400–600 °C). Further points of interest are that the bonding parameters of $[Pd_6Cl_{12}]$ are still unknown, since the original structural assignment[3] was based on a Guinier data collection on a microcrystalline sample. Moreover, the data of the α-modification, reported by A. F. Wells[2] to be composed of infinite, linear chains of chloro-bridged square-planar palladium atoms, were collected with a less sophisticated X-ray diffractometer than those available nowadays.[6]

A solution of $[Pd_2Cl_4(CO)_2]$ (about 3×10^{-2} M) in thionyl chloride in a Schlenk tube open to the atmosphere over several days at room temperature, deposited well-formed single crystals of $PdCl_2$ (elemental analysis), which were only sparingly soluble in thionyl chloride.[8] The single-crystal X-ray structure analysis showed the compound to be the hexanuclear $[Pd_6Cl_{12}]$ compound, described by H. Schäfer and co-workers[3] and classified as the β-modification, to distinguish it from the α-one.[2] The molecular structure (Fig. 1) is similar, but not identical, to that of $[Pd_6Cl_{12}]$, prepared by G. Thiele and co-workers[9] by vapor-phase recrystallization of microcrystalline $PtCl_2$ at 550 °C in the presence of dichlorine.[10]

The hexanuclear $[Pd_6Cl_{12}]$ molecule can be described as a cube whose edges are approximately 4.62 Å long; the central points of faces and edges are occupied by the palladium atoms and by the chlorine atoms, respectively. The coordination around the palladium atoms is almost exactly square-planar; the most notable deviations are the short Pd–Cl(1) distance of 2.304(1) Å and the distance of the palladium atom from the plane Cl(1)-Cl(1′)-Cl(2)-Cl(2″) (0.028(1) Å). The bond angles at the chloro ligands range between 90.70(5) and 92.04(5)°. The average Pd–Cl distance of 2.310(4) Å, which is the same as that observed in α-$PdCl_2$[2] (2.31 Å), corresponds to a rather strong palladium–chlorine bond, taking into consideration that for a considerable number of known crystal structures the average Pd^{II}–Cl distance is 2.43(6) Å (for bridging chloro ligands with bond angles at palladium of approximately 90°).[12] A value of 2.36 Å was reported for $[Pt_6Cl_{12}]$, alias β-$PtCl_2$,[9] as expected for metal cations with very similar ionic radii.[13] The six palladium atoms define an octahedron, whose tetragonal planes contain four bridging chloro ligands each; the shortest intramolecular Pd···Pd distances of 3.283(1) and 3.329(2) Å are considerably longer than the distance in palladium metal (2.750 Å).[14]

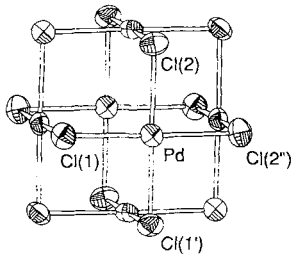

Fig. 1. The molecular structure of $[Pd_6Cl_{12}]$. The ellipsoids are represented at 50% probability. ′ = y, z, x; ″ = $-z, -x, -y$; ‴ = z, x, y; ⁗ = $-y, -z, -x$. Bond lengths [Å] and angles [°]: Pd–Cl(1) 2.304(1), Pd–Cl(1′) 2.310(1), Pd–Cl(2) 2.314(1), Pd–Cl(2″) 2.312(1); Cl(1)-Pd-Cl(1′) 90.26(9), Cl(1′)-Pd-Cl(2) 178.40(3), Cl(1)-Pd-Cl(2) 90.37(5), Cl(1′)-Pd-Cl(2″) 90.13(5), Cl(1)-Pd-Cl(2″) 178.65(3), Cl(2)-Pd-Cl(2″) 89.18(3), Pd″-Cl(1)-Pd 90.70(5), Pd-Cl(2)-Pd⁗, 92.04(5).

Polycrystalline samples of the palladium(II) chloride that had been prepared from the carbonyl derivative were subjected to X-ray diffraction experiments with a Gandolfi camera: the diffraction pattern corresponded satisfactorily to that calculated[15] from the single-crystal structure (Table 1), thus showing that the bulk of the palladium chloride in equilibrium with the carbonyl-chloropalladium complex is $[Pd_6Cl_{12}]$.

On the basis of these new findings on the nature of the palladium(II) chloride involved in equilibrium (a), a ΔH_f^0 value of $-(478 \pm 10)\ kJ\,mol^{-1}$ was calculated[17] for $[Pd_2Cl_4(CO)_2]_{(g)}$; the Pd^{II}–CO BDE in the dinuclear carbonyl derivative was estimated as $104 \pm 4\ kJ\,mol^{-1}$, thus confirming the earlier results.[1]

In conclusion, we have confirmed that palladium(II) chloride, which plays a role as a precursor in several catalytic processes,[19] if prepared at room temperature is the hexanuclear compound $[Pd_6Cl_{12}]$, regardless of the method of preparation.[4] Furthermore we have established its metrical parameters. The best method for preparing $[Pd_6Cl_{12}]$ appears to be equilibration of palladium(II) chloride suspended in thionyl chloride with CO at atmospheric pressure and room temperature. The result is, of course, independent of the nature of the chloride initially used. The Pd–CO bond is confirmed as atypical[20] and is characterized by a moderate bond strength and by a high $\tilde{\nu}_{CO}$ stretching frequency, comparable to that of $[BH_3(CO)]$[21] ($\tilde{\nu}_{CO} = 2165\ cm^{-1}$ in the gas phase) and $[CaCp^*_2(CO)]$[22] ($\tilde{\nu}_{CO} = 2158\ cm^{-1}$, toluene), suggestive of a predominant σ-contribution.

Experimental Procedure

In a Schlenk tube, $PdCl_2$ (1.06 g, 6.0 mmol) [as obtained by evaporation under reduced pressure of an aqueous acidic solution of $[PdCl_4]^{2-}$ followed by treatment of the resulting solid with $SOCl_2$ at room temperature (satisfactory Pd, Cl analyses)] was suspended in $SOCl_2$ (100 mL) and stirred under CO at atmospheric pressure at 18 °C for 70 h. This resulted in a red solution of $[Pd_2Cl_4(CO)_2]$. The container was

[a] Similar results were obtained on a microcrystalline sample sealed in a glass capillary, or on a small polycrystalline aggregate of almost spherical shape glued at the end of a glass fiber. The sample for the X-ray powder diffraction experiment should not be milled. Although crystalline palladium(II) chloride is apparently stable in air over extended periods of time, milling in air resulted in the appearance of spurious lines, similar to those attributed in the literature to commercial palladium chloride [16], alias the low-temperature form [5], alias γ-$PdCl_2$ [11c,4].

left open to the atmosphere for 22 days; the red-brown crystalline deposit of $[Pd_6Cl_{12}]$ was collected by filtration and dried in vacuo (0.52 g, 49% yield). The crystals of $[Pd_6Cl_{12}]$ were small reddish-black rhombohedra bounded by six faces of the form $\{100\}$. A crystal of approximate dimensions $0.14 \times 0.14 \times 0.072$ mm was glued at the end of a glass fiber and its X-ray diffraction pattern was studied with a Weissenberg camera. It showed trigonal symmetry without systematic absences. Cell parameters were measured and intensity data were collected on a Siemens P4 single-crystal automatic diffractometer equipped with graphite-monochromatized $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å). Cell parameters were calculated based on the accurately centered setting angles of 21 strong reflections with $12.6 \leq \theta \leq 19.2°$. Crystal data: Pd_6Cl_{12}, $M_r = 1063.9$, $T = 296(2)$ K, space group $R\bar{3}$ (no. 148), $a = 8.0600(9)$ Å, $\alpha = 108.07(2)°$, $V = 422.63(8)$ Å^3, $Z = 1$, $\rho_{calcd} = 4.180$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 8.115$ mm^{-1}, $F(000) = 480$. The collected intensities of 1477 reflections with $3 \leq \theta \leq 35°$, on merging the equivalent ones and after correction for Lorentz and polarization effects, resulted in an internal R value of 0.16; the application of a Gaussian absorption correction [23] based on crystal shape and size reduced it to 0.025. The diffraction symmetry indicated the space groups $R\bar{3}$ or $R3$. We placed the Pd and Cl atoms in the positions the appropriate atoms have in $[Pt_6Cl_{12}]$ [9], and first tried to refine the structure in the $R\bar{3}m$ space group, that is the same as that for $[Pt_6Cl_{12}]$. The R factor decreased to 0.192; then the mirror planes were removed, refinement was continued in the $R\bar{3}$ space group, and anisotropy in the thermal motion was introduced: the R value dropped to 0.022; 29 parameters were refined based on 806 independent reflections $\{R_1 = 0.022 = \Sigma||F_o| - |F_c||.\Sigma|F_o|; wR_2 = 0.055 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}; w = 1/[\sigma^2(F_o^2) + (0.0164P)^2 + 0.33P]$ where $P = [MAX(F_o^2, 0) + 2F_c^2]$, $S = 1.143 = [\Sigma w(F_o^2 - F_c^2)^2/(N - P)]^{1/2}\}$ [23]. All calculations and drawings were performed by using the SHELXTL [24a] and ORTEPII [24b] programs, respectively. For the X-ray diffraction experiments on polycrystalline samples (Table 1) a small polycrystalline aggregate of $[Pd_6Cl_{12}]$ of almost spherical shape was glued at the end of a glass fiber and the diffraction pattern was measured with a Gandolfi camera (114.6 mm) and Ni-filtered $Cu_{K\alpha}$ ($\lambda = 1.54178$ Å) radiation. The positions of the lines were measured with a precision caliper equipped with an optical alignment device [25].

[8] Although it may appear so, this is not a fortuitous experiment: slow diffusion of moisture in the air into the reactor has the beneficial effect of decreasing the partial pressure of CO on the solution due to the formation of SO_2 and HCl from the solvent. The preparation has been repeated several times successfully. Depending on the rate of admission of air into the reactor single crystals or microcrystalline samples can be obtained.

[10] Another modification of $PtCl_2$, a polynuclear compound, classified as α-$PtCl_2$, was identified on the basis of both Guinier data on a microcrystalline sample [11c] and X-ray diffraction data on a single crystal [11c]; this substance was obtained [11] by heating $[Pt_6Cl_{12}]$ for 1–2 days at 500 °C or by treating platinum metal with dichlorine (3 atm) in several temperature gradients ranging between 520 and 440 °C and 800 and 780 °C. The α-modifications of palladium(II) and platinum(II) chlorides were reported [11c] not to be isotypic.

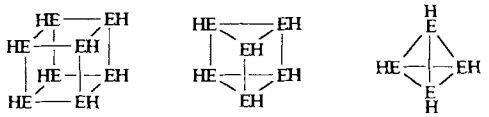
[25] After submission of this paper, we learned that Prof. G. Thiele, Universität Freiburg, Germany, and his group had obtained complementary crystallographic data on single crystals of solvated (benzene or chloroform) $[Pd_6Cl_{12}]$, grown at room temperature from the corresponding solutions. Satisfactory agreement has been found between the sets of data obtained independently in the two laboratories. We thank Prof. G. Thiele for communicating his results prior to publication.

Tetrakis(tri-*tert*-butylsilyl)-*tetrahedro*-tetragermane $(t\mathrm{Bu_3Si})_4\mathrm{Ge_4}$—The First Molecular Germanium Compound with a $\mathrm{Ge_4}$ Tetrahedron**

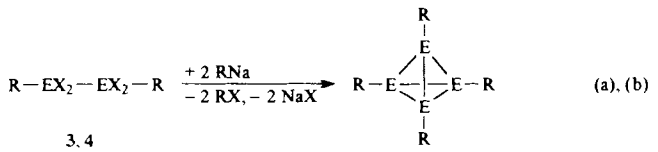
Nils Wiberg,* Walter Hochmuth, Heinrich Nöth, Andrea Appel, and Martin Schmidt-Amelunxen

According to ab initio calculations,[1, 2] the strain energy of $(EH)_n$ polyhedra (E = Si, Ge) increases with the number of the three-membered rings in the framework of the polyhedron, thus in the order *hexahedro*-octasilane (-germane) **A**, *triprismo*-hexasilane (-germane) **B**, and *tetrahedro*-tetrasilane (-germane) **C**.[3]



A **B** **C**

Consequently, initially the hexahedranes $(ER)_8$ (E/R = Si/$SiMe_2t$Bu,[4a] Si/CMe_2iPr,[4b] Si/2,6-$C_6H_3Et_2$,[4c] Ge/$CMeEt_2$,[4c] Ge/2,6-$C_6H_3Et_2$[4c]) and triprismanes $(ER)_6$ (E/R = Si/2,6-$C_6H_3i\mathrm{Pr}_2$,[4e] Ge/$CH(SiMe_3)_2$,[4d] Ge/2,6-$C_6H_3i\mathrm{Pr}_2$[4e]) were obtained. We synthesized the first molecular silicon compound **1** with a Si_4 tetrahedron[5, 6] by the reaction of tetrabromo-1,2-bis(supersilyl)disilane $t\mathrm{Bu_3Si-SiBr_2-SiBr_2-Si}t\mathrm{Bu_3}$ (**3**) with supersilylsodium $t\mathrm{Bu_3SiNa}$ in tetrahydrofuran (THF) [Eq. (a); supersilyl = $Si t\mathrm{Bu_3}$[7]].



(a) E = Si; X = Br
(b) E = Ge; X = Cl

R = $Si t\mathrm{Bu_3}$

1, E = Si
2, E = Ge

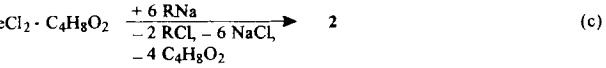
[**] Compounds of Silicon and Its Group Analogues Part 108; Sterically Overloaded Supersilyl Compounds, Part 10. This work was supported by the Deutsche Forschungsgemeinschaft. Part 107 and 9: Ref. [3].

In an effort to obtain a molecular germanium compound with a Ge_4 tetrahedron by an analogous route, we treated tetrachloro-1,2-bis(supersilyl)digermane $t\mathrm{Bu_3Si-GeCl_2-GeCl_2-Si}t\mathrm{Bu_3}$ (**4**), which formed from $GeCl_4$ and $t\mathrm{Bu_3SiNa}$ in THF at room temperature along with other products ($t\mathrm{Bu_3SiGeCl_3}$, $(t\mathrm{Bu_3Si})_2GeCl_2$, $(t\mathrm{Bu_3Si})_2$, $t\mathrm{Bu_3SiCl}$), and was characterized by X-ray crystallography, with $t\mathrm{Bu_3SiNa}$ in THF at −78 °C. This reaction led to the *tetrahedro*-tetragermane **2** in low yield [Eq. (b)] together with other products containing supersilyl groups that are also formed in the reaction of $GeCl_2 \cdot C_4H_8O_2$ and $t\mathrm{Bu_3SiNa}$ (see below). Compound **4** reacts with sodium in C_6D_6 at room temperature initially to give the tetrahedrane **2**, which is, however, attacked by sodium; one of the resulting products, namely $t\mathrm{Bu_3SiNa}$, reacts as described with unconverted **4**.[8] $t\mathrm{Bu_3SiNa}$ reacts with $GeCl_2 \cdot C_4H_8O_2$ in THF via a series of—in part isolable—intermediates[9] likewise to give **2** and additional products [Eq. (c)].



(c)

The tetragermane **2** forms intense red crystals, which are hydrolyzed slowly by water, and are rapidly oxidized by air. Compound **2** can be reduced with sodium; among the products of the reaction is $t\mathrm{Bu_3SiNa}$, which can be identified by conversion with Me_3SnCl into $t\mathrm{Bu_3Si-SnMe_3}$.

So far we have only been able to obtain crystals suitable for X-ray diffraction[12] from solutions prepared according to Equation (c) after exchanging THF by pentane. However, in addition to **2** these contain superdisilane $t\mathrm{Bu_3Si-Si}t\mathrm{Bu_3}$,[11] which fills the large holes between the almost spherical molecules of **2** in the crystal, and thereby stabilizes the structure of the crystal. The monoclinic unit cell of the crystals with the composition $2(t\mathrm{Bu_3Si})_4Ge_4 \cdot (t\mathrm{Bu_3Si})_2$ (**2a**) contains four molecules of **2** and—in the cavities—two molecules of $t\mathrm{Bu_3Si-Si}t\mathrm{Bu_3}$ (Fig. 1). The building unit **2** in the crystal of **2a** contains almost regular Ge_4 tetrahedra (Fig. 2). The Ge–Ge (av. 2.44 Å) and Ge–Si (2.38 Å) distances are slightly longer than those in $H_3Ge-GeH_3$ (2.41 Å[13]) and $H_3Ge-SiH_3$ (2.36 Å[13]), respectively; for comparison Si–Si distances in **1** are 2.35 (*endo*) and 2.37 Å (*exo*),[3] in $H_3Si-SiH_3$ and $Me_3Si-SiMe_3$ 2.331 and 2.338 Å, respectively[13]. The fact that $t\mathrm{Bu_3Si-Si}t\mathrm{Bu_3}$ in crystals

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3512-1333 $ 15.00+.25/0

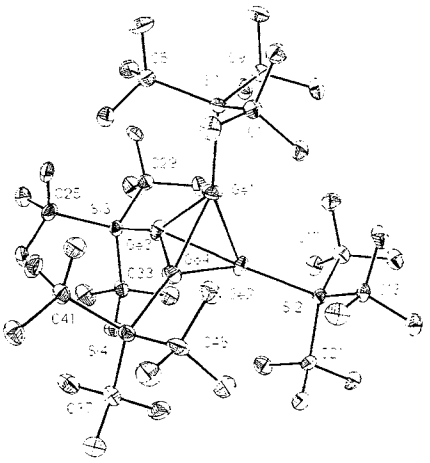

Fig. 2. Structure of **2** in the crystal **2a** (ORTEP plot). Selected bond lengths [Å] and angles [°]: Ge1-Ge2 2.447(2), Ge2-Ge3 2.446(2), Ge3-Ge4 2.443(3), Ge1-Ge4 2.431(2), Ge1-Ge3 2.447(2), Ge2-Ge4 2.435(2), Ge1-Si1 2.385(4), Ge2-Si2 2.385(4), Ge3-Si3 2.378(4), Ge4-Si4 2.383(4), Si-C (av) 1.94; Ge-Ge-Ge 59.62(7)–60.10(7), Si1-Ge1-Ge4 142.3(1), Si2-Ge2-Ge4 141.4(1), Si1-Ge1-Ge2 155.8(1), Si1-Ge1-Ge3 132.9(1), Si2-Ge2-Ge3 156.7(1), Si2-Ge2-Ge1 132.5(1), Si3-Ge3-Ge4 145.6(1), Si4-Ge4-Ge1 144.9(1), Si3-Ge3-Ge2 131.0(1), Si3-Ge3-Ge1 153.7(1), Si4-Ge4-Ge2 146.1(1), Si4-Ge4-Ge3 142.7(1), C-Si-C (av) 112.8.

of **2a** has a slightly larger Si–Si distance (2.719(8) Å) than that in superdisilane crystals (2.697(2) Å[11]) is possibly attributed to van der Waals attractions between supersilane and **2** in **2a** (see below). Although the Ge_4 tetrahedron suggests a symmetrical (radial) arrangement of the supersilyl groups, they are slightly bent; the Si-Ge4-Ge bond angles differ by up to only 3.4°, the Si-Ge2-Ge angles by up to 24.2°. The reason for this might be the proximity of tBu$_3$Si–SitBu$_3$; the center of the Si–Si bond lies on a crystallographic inversion center.

Experimental Procedure

tBu$_3$SiNa (0.69 mmol) [11] in THF (1.3 mL) was added dropwise to a solution of $GeCl_2 \cdot C_4H_8O_2$ (0.050 g, 0.22 mmol) in THF (1 mL) at room temperature. After 12 h, the THF was removed under vacuum from the resulting red-brown suspension, the oily residue was taken up in pentane (2 mL), and filtered to remove insoluble material. Intense red crystals of the composition $2(t\text{Bu}_3\text{Si})_4\text{Ge}_4 \cdot (t\text{Bu}_3\text{Si})_2$ (**2a**) (0.008 g, 11 % yield) crystallized from the filtrate at −25 °C over a long period. M.p. >360 °C (above 280°C slow decomposition). ^{1}H NMR (C_6D_6, TMS, internal): $\delta = 1.374$ (4 SitBu$_3$); ^{13}C{^{1}H} NMR (C_6D_6, TMS, internal): $\delta = 31.87$ (12 CMe_3), 26.17 (12 CMe_3); ^{29}Si{^{1}H} NMR (C_6D_6, INEPT, TMS, external): $\delta = 59.0$ (4 SitBu$_3$); UV (heptane): $\lambda_{max} = 501$ nm.

[2] According to calculations (N. Matsunaga, M. S. Gordon, *J. Am. Chem. Soc.* **1994**, *116*, 11407) *triprismo*-hexasilane and -hexagermane $(EH)_6$ are considerably more stable than their isomers, hexasila- and hexagermabenzene. *tetrahedro*-Tetrasilane and -tetragermane [1] $(EH)_4$ are more stable than their isomers, planar tetrasila- and tetragermacyclobutadiene, but slightly less stable than $(EH)_4$ compounds with puckered E_4 rings. Of course, sterically demanding substituents contribute to the stabilization of the tetrahedrane structure.

[12] Crystal structure analysis of **2a**: A single crystal (0.4 × 0.3 × 0.25 mm) was mounted in perfluoroether oil under argon, placed in a Lindemann capillary, and centered on a Siemens P4 diffractometer at −70 °C. The data was collected with a Siemens SMART area detector, the monoclinic unit cell calculated by using reflections ≥10 $I/\sigma(I)$. After reduction of the data, the structure was solved by direct methods (SHELXTL). Whereas the molecular structure of $(t\text{Bu}_3\text{SiGe})_4$ was refined without difficulty, tBu$_3$Si–SitBu$_3$ showed rotational disorder within the tBu$_3$ groups. As a result some of the anisotropic temperature parameters of these C atoms are very large and the bond lengths not meaningful. All non-hydrogen atoms were included in the refinement with anisotropic temperature parameters, the H atoms in calculated positions with a riding model. Nevertheless, a comparatively high residual electron density remains for three atoms (1.816, 1.39, 0.96 e Å^{-3}) in the space between two $(t\text{Bu}_3\text{SiGe})_4$ molecules. The following weighting scheme was applied: $w^{-1} = \sigma^2 F_o^2 + (xP)^2 + yP$ with $P = (F_o^2 + 2F_c^2)/3$. Crystallographic data: $C_{60}H_{135}Ge_4Si_5$, $M_r = 1027.34$, $a = 18.1997(2)$, $b = 16.8809(2)$, $c = 25.0074(4)$ Å, $\beta = 97.949(1)°$, $V = 7609.1(2)$ Å^3, $Z = 8$, $\rho_{calcd} = 1.124$ Mg m^{-3}, $\mu = 1.674$ mm^{-1}. Data collection: $2\theta \leq 46.6°$, $-18 \leq h \leq 17$; $-18 \leq k \leq 18$, $-12 \leq l \leq 27$; measurement rate: 10 s per setting, 11463 measured relections, 8256 of which symmetry-independent. Refinement with 8248 reflections and 601 variables, weighting scheme: $x/y = 0.0753/138.2605$, GOF = 1.193, $R1$ (4σ) = 0.0927, $wR2 = 0.2676$. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-405202.

Formation of Macrocyclic Lactones by Enantioselective Intramolecular Cyclopropanation of Diazoacetates Catalyzed by Chiral Cu^{I} and Rh^{II} Compounds**

Michael P. Doyle,* Chad S. Peterson, and Dann L. Parker, Jr.

Macrocyclization is an essential synthetic element in the preparation of large ring compounds, and a variety of transformations have been reported for this process.[1] Only one, however, the macrocyclization of an ω-alkynal in the synthesis of the

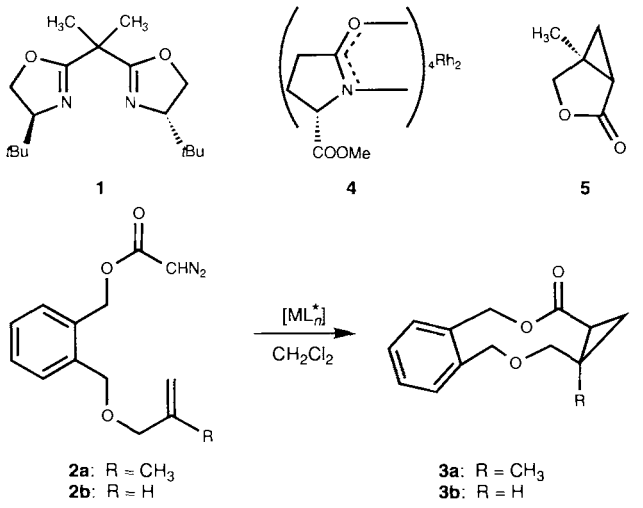
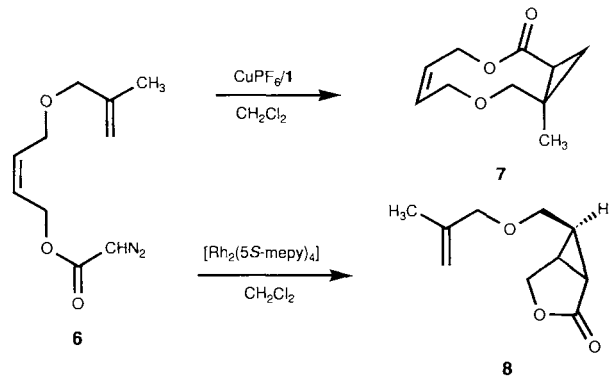
16-membered ring of (*R*)-(−)-muscone, has been reported to occur with high levels of asymmetric induction in a catalytic process.[2] With unlimited chain length between reacting partners, enantio- and diastereoselectivity for a specific macrocyclization should be the same as that in the corresponding intermolecular process. However, at least in metal carbene catalyzed transformations, there is ordinarily a dramatic fall-off in stereocontrol with increasing ring size.[3] We recently reported that catalytic intramolecular cyclopropanation of diazoacetates is an effective methodology for macrocyclization in select cases, promoted by electrophilic dirhodium(II) catalysts, even when placed in direct competition with the normally favored allylic cyclopropanation.[4] We now report that high stereocontrol (enantioselectivity and diastereodifferentiation) has been achieved in catalytic intramolecular cyclopropanations, leading to the formation of macrocycles.

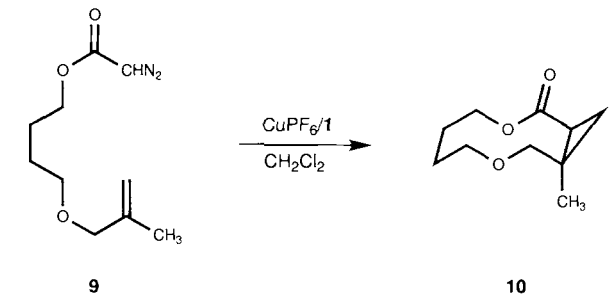
The reaction of conveniently handled and prepared[5] $[Cu(MeCN)_4](PF_6)$ and Evans's chiral bis(dihydrooxazole) (**1**)[6] with diazoacetate **2a** in refluxing dichloromethane led to a single macrocyclic cyclopropane, identified as **3a**, with 90% *ee* in 82% yield. For comparison, intramolecular cyclopropanation of 2-methyl-2-propen-1-yl diazoacetate under the same conditions gave **5** with 87% *ee* in 82% yield. By using the chiral complex $[Rh_2(5S\text{-mepy})_4]$ (**4**) (5*S*-mepy = methyl (5*S*)-2-pyrrolidone 5-carboxylate anion), which for 2-methyl-2-propen-1-yl diazoacetate resulted in **5** with only 7% *ee*,[7] diazo decomposition of **2a** produced the macrocycle **3a** with 47% *ee* (77% yield). Similar results were obtained with allyl diazoacetate **2b** by using $[Cu(MeCN)_4](PF_6)$/**1** (**3b**: 80% *ee*, 71% yield). In contrast to intermolecular reactions of diazo esters, in which the predominant product is generally the *trans* diastereoisomer,[8] these macrocyclizations provide only the *cis* isomer (NOE NMR experiments). All reactions were performed under standard conditions[7] without high dilution. The yields given are those of the purified products, and enantiomeric excesses were determined by GC with baseline resolution.



With the (*Z*)-2-buten-1,4-diyl diazoacetate derivative **6**, macrocycle formation was the predominant intramolecular reaction with $[Cu(MeCN)_4](PF_6)$/**1** (**7**: 87% *ee*, 43% yield; **8**: 41% *ee*, 19% yield), whereas allylic cyclopropanation was the sole result of the $[Rh_2(5S\text{-mepy})_4]$-catalyzed reaction (**8**: 96% *ee*, 84% yield).[9]

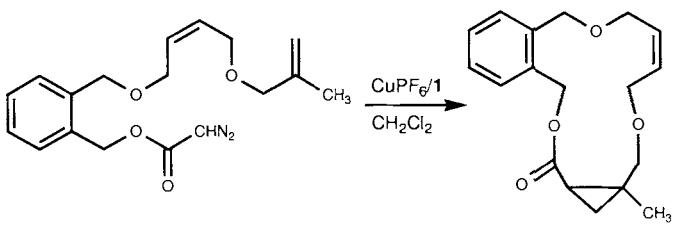
To determine if macrocycle formation is due primarily to conformational restrictions placed on the metal carbene intermediate formed from **2** or **6**, the saturated derivative **9** was also subjected to diazo decomposition. Surprisingly, use of $[Cu(MeCN)_4](PF_6)$/**1** resulted in the formation of the macrocycle **10** as the only isolable product with 91% *ee* in 43% yield.





Thus the restricted degrees of conformational freedom afforded by **2** and **6** are not the a priori cause of these facile macrocyclizations, although the relative rigidity of **2** and **6** may account for increased reactivity in intramolecular cyclopropanations.

With the diazoacetate **11** there is a competition between the intramolecular cyclopropanations to give the bicyclo[10.1.0] and bicyclo[15.1.0] ring systems, but in reactions catalyzed by $[Cu(MeCN)_4](PF_6)$/**1** the bicyclo[15.1.0] product **12** (90% *ee*, 61% yield) was formed with greater than 25:1 regiochemical preference for the larger macrocycle. With $[Cu(MeCN)_4](PF_6)$ alone, **12** was formed with a 6:1 regiochemical preference. The ability of diazo esters to undergo macrocyclization, even to form 15-membered rings, with high enantioselectivity and diastereocontrol suggests the amazing versatility of this methodology.



Experimental Procedure

In a typical procedure, $[Cu(CH_3CN)_4](PF_6)$(3.6 mg, 9.6 mmol) and ligand **1** (3.4 mg, 11.5 μmol) were added to an oven-dried two-neck round-bottom flask fitted with a reflux condenser and a rubber septum. To this flask was added freshly distilled CH_2Cl_2 (10 mL), and the homogeneous solution was stirred at reflux for 5 min. Diazoacetate **2a** (250 mg, 960 mmol) was dissolved in CH_2Cl_2 (10 mL) and added over 5 h by syringe pump to the clear catalyst solution. Upon completion of addition, the entire solution was passed through a plug of silica gel, and the solvent

was removed under reduced pressure. The resulting solid material was purifed by flash chromatography on silica gel (5:1 hexanes:ethyl acetate) to yield pure **3a** (183 mg, 82%) as a white solid (90% *ee*, GC analysis, 145 °C, Chiraldex G-DA (Alltech and Assoc., Inc.); $[\alpha]_D^{25} = -9.2$ ($c = 1.0$ in MeOH)).

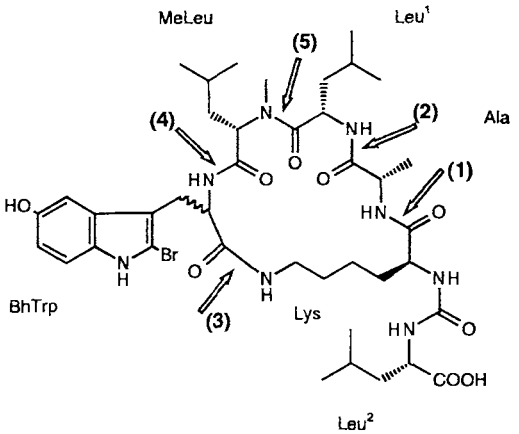
What is the Structure of the Calmodulin Antagonist Konbamide from *Theonella* sp.? Synthesis of Two Isomers by Direct Biomimetic Introduction of Bromine in Hydroxytryptophan-Containing Cyclic Peptides**

Ulrich Schmidt* and Steffen Weinbrenner

Many marine plants and animals store halogens. Their peptidic components often include halogenated tyrosine[1] and tryptophan. For example, the nonribosomal amino acid 6-bromotryptophan is incorporated into clionamide[2] and celenamide,[3] which are isolated from algae. Similarly, the cyclic natural product jaspamide[4] contains 2-bromo-*N*-methyltryptophan as a ring element. 2-Bromo-5-hydroxytryptophan is a component of the cyclic peptides konbamide,[5] orbiculamide A,[6] and keramamides B–D,[7] which are isolated from the sea sponge *Theonella*, and we have synthesized the halogenated compound by direct bromination of hydroxytryptophan derivatives.[9] Both the amino acid and its *N*-acyl derivatives are unstable and therefore cannot be used in natural product synthesis.

In the biosynthesis of bromine-containing peptides the bromination of the peptide in the last step is a subject of debate; even electrophilic, nonenzymatic substitution by bromine (formed from oxidation of Br^- ions, perhaps by symbiotic algae) seems plausible. In the following, we describe our experiments on the biomimetic synthesis of konbamide by electrophilic bromination of a preformed cyclic peptide. Konbamide has structural characteristics (Scheme 1) that complicate its synthesis: the sensitive 2-bromo-5-hydroxytryptophan, lysine in which the ε-amino group is a ring member, and the urea side chain.



Scheme 1. Postulated structure of konbamide. Strategic bonds in retrosynthetic analysis are marked with arrows.

Intramolecular acylation at the alanine (position 1) or leucine (position 2) nitrogen atoms were both possibilities for the ring closure. Both positions seem to be unhindered and both activated alanine and lysine are quite configurationally stable. Based on our experience in the synthesis of glidobaktin,[9] ring closure at the ε-amino group of lysine (position 3) is not promising. Ring closure at the hydroxytryptophan (position 4) or *N*-methylleucine (position 5) nitrogen atoms was ruled out because of the difficulty in acylating secondary nitrogen centers and the facile racemization of activated *N*-methylleucine.

The linear pentapeptide **5**, which could undergo ring closure at the alanine nitrogen atom, was obtained by straightforward reaction of **2** and **4** (Scheme 2). From this point on, all protective groups had to be compatible with 2-bromo-5-tryptophan, which was to be formed after ring closure. For protection of the phenolic OH group we chose a pivaloyl ester, which had already been used successfully in synthesis of 2-bromo-5-hydroxytryptophan. It prevents 4- and 6-substitution of hydroxytryptophan during bromination, is conserved during hydrolysis of the methyl ester **6**, and can be cleaved from **11** without destruction of the sensitive tryptophan functionality.

Ring closure of **8** at position 1 was achieved with the pentafluorophenyl (PFP) ester method, which we developed, in a biphasic system to produce **9** in 63% yield. The corresponding ring closure at the leucine nitrogen atom proceeded in 60% yield. The ring closure could be performed by the same method without protection of the phenolic group, but this had a yield of

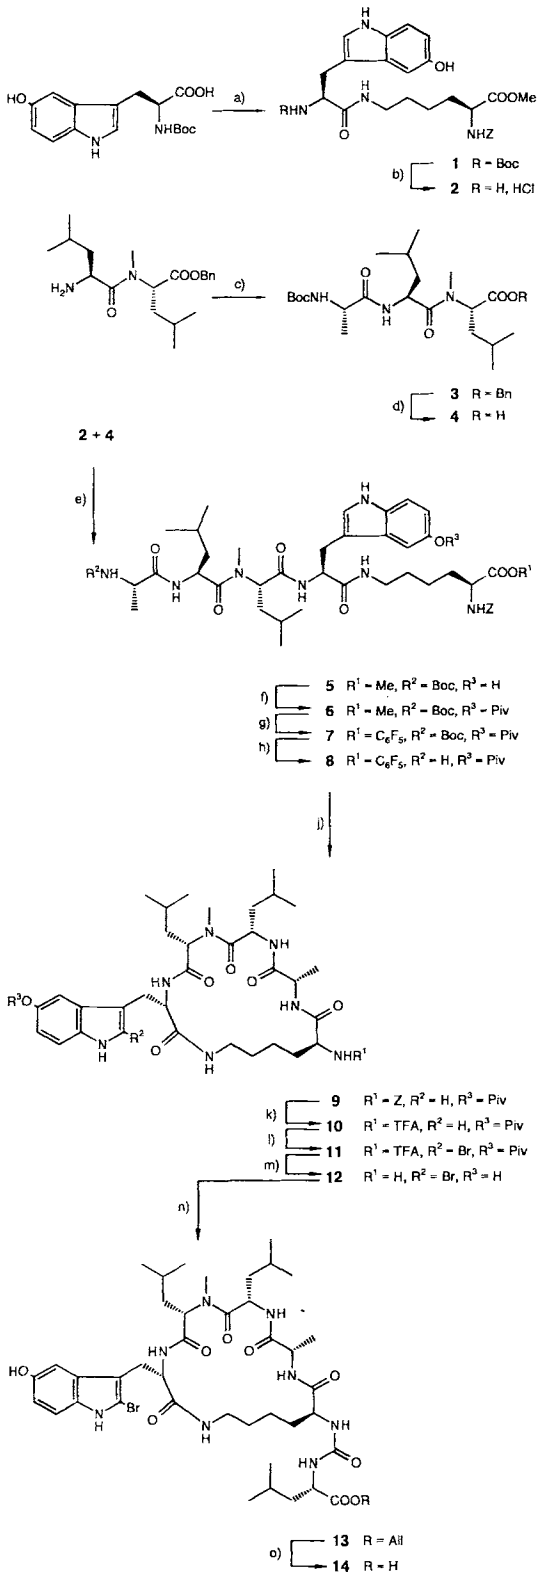

Scheme 2. Synthesis of "konbamide" **14**. a) THF, Z(H, HCl)-(*S*)-Lys-OMe, Bop-Cl, Et_2NH, 0 °C, 16 h, 80%; b) HCl, dioxane, room temperature (RT); 2 h; c) CH_2Cl_2, Boc-(*S*)-Ala-OH, TBTU, Et_2NH, 0 °C, 3 h, 88%; d) MeOH, Pd/C/H_2, RT, 3 h, 98%; e) DMF, 2-(diphenylphosphoryl)azide, −20 °C, 48 h, 86%; f) CH_2Cl_2, PivOCl, Et_3N, RT, 3 h, 97%; g) dioxane, H_2O, NaOH, RT, 97%; CH_2Cl_2, 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC), PFP, −20 °C → RT, 16 h; h) HCl, dioxane, RT, 2 h; j) $CHCl_3$, $NaHCO_3$, RT, 5 h; g)–h): 63%; k) MeOH, Pd/C/H_2, RT, 16 h; THF, TFA anhydride, RT, 16 h, 93%; l) CH_2Cl_2, NBS, RT, 30 min, 75%; m) MeOH, H_2O, NaOH, RT, 24 h; n) THF, allyl (*S*)-2-isocyanato-4-methylpentanoate, RT, 24 h; m)–n): 40%; o) THF, $[Pd(PPh_3)_4]$, RT, 5 h; 75%.

only 30%. Exchange of the Z-protective group for a trifluoroacetyl (TFA) protective group gave substrate **10**, which was brominated with *N*-bromosuccinimide (NBS) without a radical starter or light in a straightforward reaction. The TFA and pivaloyl protective groups were removed from the resultant bromide **11** by careful alkaline hydrolysis to produce **12**. The urea side chain was formed by using allyl (*S*)-2-isocyanato-4-methylpentanoate[10] (from leucine). Finally, the allyl ester **13** was cleaved with Pd^0[11] to afford the acid **14**.

Minor differences between the synthetic product and the natural compound were evident by HPLC.[12] Similarly the optical rotation and the NMR spectra of the synthetic product and the natural substance were not completely identical. In particular, there were noticeable differences in the α-H and NH signal regions (Table 1). In contrast, the mass spectra were the same.[13]

Table 1. Comparison of characteristic NMR data for natural konbamide [5] and **14**.

14	Konbamide	Assignment [5]
4.01–4.08 (m, 1H)	3.93 (m, 1H)	Lys-α-NH
4.10–4.18 (m, 1H)	4.03 (dd, J = 9.0, 5.0 Hz, 1H)	Leu^2-α-H
4.28–4.30 (m, 1H)	4.18 (m, 1H)	Ala-α-H
4.61–4.65 (m, 1H)	4.61 (ddd, J = 11.3, 9.0, 3.5 Hz, 1H)	BhTrp-α-H
4.71–4.78 (m, 2H)	4.72 (m, 2H)	MeLeu-α-H Leu^1-α-H
6.20 (d, J = 7.9 Hz, 1H)	6.26 (d, J = 9.0 Hz, 1H)	Leu^2-NH
6.33 (d, J = 8.3 Hz, 1H)	6.42 (d, J = 7.4 Hz, 1H)	Lys-α-NH
7.41 (d, br., 1H)	7.44 (dd, J = 7.8, 3.3 Hz, 1H)	Lys-ε-NH
8.26 (d, J = 5.6 Hz, 1H)	6.99 (d, J = 5.7 Hz, 1H)	Ala-NH
8.43 (d, J = 9.0 Hz, 1H)	8.29 (d, J = 9.0 Hz, 1H)	BhTrp-NH
8.84 (d, J = 5.9 Hz, 1H)	8.74 (d, J = 6.2 Hz, 1H)	Leu^1-NH

One possible explanation is that the natural compound and the synthetic product are diastereomers. During their investigation of the natural substance by 2D-NMR, FAB-MS analysis, and total hydrolysis, the Japanese authors[5] determined that the amino acids are L-configurated after the hydrolysis, by using GC and HPLC on chiral phases. Bromohydroxytryptophan decomposes during hydrolysis and thus its configuration was left open.

The amino acids resulting from hydrolysis of the synthetic product also proved to be L-configurated. To exclude a different configuration at bromohydroxytryptophan as the reason for the difference between the synthetic product and the natural substance, we also synthesized the diastereomer of **14** with D-bromohydroxytryptophan. However, the HPLC retention time of this product also deviated from that of the natural substance. Thus the proposed structure of konbamide cannot be correct.

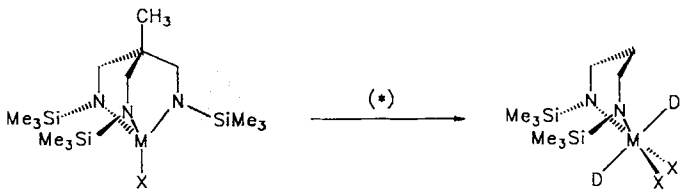
A Chelate-Amidozirconium Fragment as Building Block for Unsupported Trinuclear ZrM_2 Heterobimetallic Complexes (M = Fe, Ru, Co)**

Stefan Friedrich, Lutz H. Gade,* Ian J. Scowen, and Mary McPartlin

With the recent development of halide complexes with tripodal amido ligands, monofunctional building blocks for the generation of directly metal–metal bonded M′–M heterobimetallic compounds (M′ = Ti, Zr, Hf; M = late transition metal) of unprecedented stability have been made available[1, 2] and have enabled a systematic investigation into their chemical reactivity.[3] We have now extended this strategy to the development of difunctional building blocks (Scheme 1), which may be employed in the synthesis of stable trinuclear complexes containing two equivalent Zr–M bonds, thus opening up the possibility of extending the cooperative reactivity of early–late heterobimetallic compounds to involve three complex fragments.



Scheme 1. Relationship between monofunctional and difunctional amidohalide complexes of the metals of the titanium triad used as building blocks for heteronuclear compounds. (*): Formal removal of an anionic "amido-arm" in a tridentate ligand.

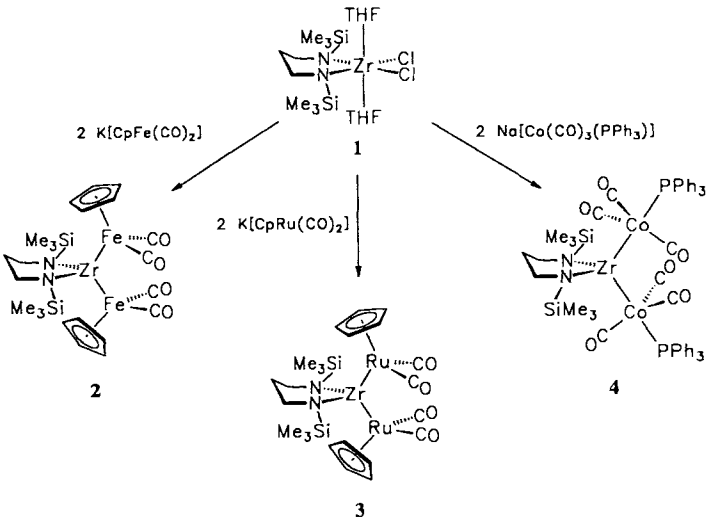
[**] This work was supported by the Deutsche Forschungsgemeinschaft (L. H. G., S. F.), the Engineering and Physical Science Research Council (M. McP., I. J. S), the Deutscher Akademischer Austauschdienst, and the British Council (ARC grant). We thank Professor Werner for his support and Degussa AG for a gift of basic chemicals.

This type of trinuclear complex possessing two highly polar metal–metal bonds is particularly rare; the only fully characterized and studied example is Casey's $ZrRu_2$ complex $[Cp_2Zr\{Ru(CO)_2Cp\}_2]$ ($Cp = C_5H_5$).[4] More recently, Pályi et al. have given a preliminary account of the generation of $[Cp_2Zr\{Co(CO)_4\}_2]$ by salt metathesis or alkane elimination.[5] Based on early work by Bürger et al.[6] we synthesized the difunctional amidozirconium complexes of the type $[CH_2(CH_2NSiMe_3)_2ZrCl_2(D)_2]$ (D = thf, pyridine),[7] which have proved to be ideally suited for the synthesis of such trinuclear complexes. Reaction of the complex $[CH_2(CH_2NSiMe_3)_2ZrCl_2(thf)_2]$ **1** with two molar equivalents of the carbonyl metalates $K[CpM(CO)_2]$ (M = Fe, Ru) and $Na[Co(CO)_3(PPh_3)]$ yields the corresponding trinuclear $ZrFe_2$, $ZrRu_2$, and $ZrCo_2$ compounds **2**–**4** (Scheme 2). While both **2** and **3** are stable in



Scheme 2. Synthesis of the ZrM_2 heterobimetallic complexes **2**–**4**.

solution, the $ZrCo_2$ complex **4** slowly decomposes generating $[Co(CO)_3(PPh_3)]_2$ and an intractable Zr-containing material. The existence of metal–metal bonds in **2**–**4** was initially deduced from the IR spectra, in which the ν(CO) bands are shifted to higher wavenumbers relative to those of the alkali metal salts of the anions (Table 1). It is interesting to compare the position of the asymmetric ^{12}CO stretching vibration of **3** with that of $[Cp_2Zr\{Ru(CO)_2Cp\}_2]$.[4] For **3** $\Delta\tilde{\nu}(\nu(CO)_{as})$ was found to be 97 cm^{-1} relative to the free carbonyl metalate [$\tilde{\nu}(\nu(CO_{as}))$ = 1896, 1811 cm^{-1}], while the value for Casey's $ZrRu_2$ compound is only 71 cm^{-1}.[8] The greater Lewis acidity of the amidozirconium fragment in comparison to that of the Cp_2Zr unit apparently induces a higher degree of charge redistribution from the late transition metal to the early transition metal through the metal–metal bond, which therefore assumes a more covalent character.

This difference in the IR spectroscopic data should be reflected in the molecular structures of the compounds. To establish such a relationship, and in order to structurally characterize a $ZrFe_2$ species for the first time, single-crystal X-ray structure analyses of **2** and **3** were carried out (Fig. 1).[9] The compounds are isomorphous and their gross features are identical. In each, the central Zr atom adopts a distorted terahedral coordination geometry (**2**: N(1)-Zr-N(2) = 97.5(3), Fe(1)-Zr-Fe(2) = 116.2(1)°; **3**: N(1)-Zr-N(2) = 97.6(2), Ru(1)-Zr-Ru(2) = 115.84(2)°) and links to iron or ruthenium complex fragments through direct unsupported metal–metal bonds.

Table 1. Selected spectroscopic data [a].

[a] NMR spectra recorded at 200.13 MHz (^{1}H), 50.32 MHz (^{13}C), and 81.03 MHz (^{31}P) in C$_6$D$_6$. IR spectra were recorded in toluene. Correct elemental analyses obtained for all compounds.

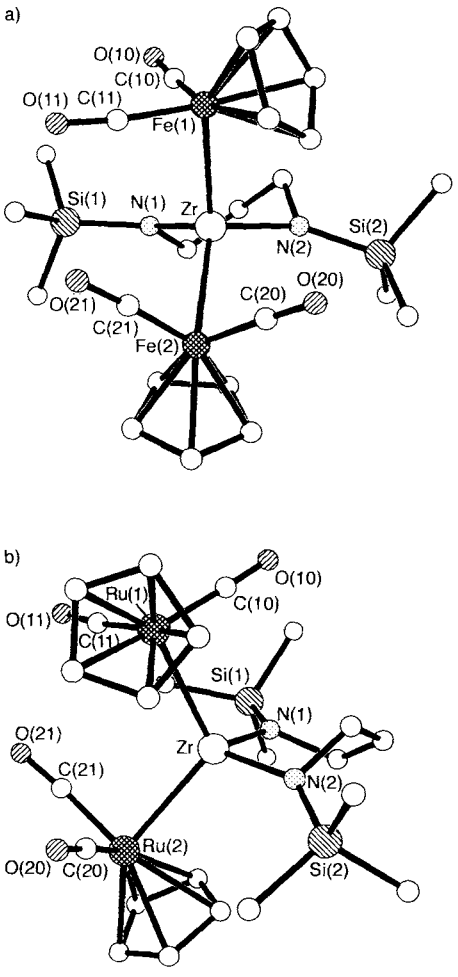

Fig. 1. Crystal structures of the nearly isostructural complexes [CH$_2$(CH$_2$NSiMe$_3$)$_2$Zr{M(CO)$_2$Cp}$_2$]. a) **2** (M = Fe). Selected bond lengths [Å]: Zr–Fe(1) 2.665(2), Zr–Fe(2) 2.664(2), Zr–N(1) 2.036(7), Zr–N(2) 2.040(7), Fe(1)–C(10) 1.720(11), Fe(1)–C(11) 1.720(11), Fe(1)–Cp 2.095(10)–2.111(11), Fe(2)–C(20) 1.722(12), Fe(2)–C(21) 1.712(12), Fe(2)–Cp 2.086(9)–2.121(11). b) **3** (M = Ru). Selected bond lengths [Å]: Zr–Ru(1) 2.7372(7), Zr–Ru(2) 2.7452(7), Zr–N(1) 2.042(5), Zr–N(2) 2.025(5), Ru(1)–C(10) 1.851(8), Ru(1)–C(11) 1.857(9), Ru(1)–Cp 2.258(7)–2.296(8), Ru(2)–C(20) 1.841(8), Ru(2)–C(21) 1.846(7), Ru(2)–Cp 2.255(7)–2.305(7).

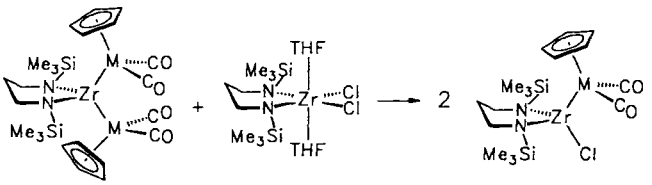
The Zr–Fe distances in **2** of d[Zr–Fe(1)] = 2.665(2) and d[Zr–Fe(2)] = 2.664(2) Å lie in the range between those found in [MeSi{SiMe$_2$N(4-CH$_3$C$_6$H$_4$)}Zr–Fe(CO)$_2$Cp][3] and [CH$_2$(CH$_2$NSiMe$_3$)$_2$(Cp)Zr–Fe(CO)$_2$Cp][7] [d(Fe–Zr) = 2.605(2) and 2.745(1) Å, respectively]. The Zr–Ru bonds in **3** (d[Zr–Ru(1)] = 2.7372(7), d[Zr–Ru(2)] = 2.7452(7) Å) are by far the shortest found in unsupported Zr–Ru complexes. The corresponding bonds in [Cp$_2$Zr{Ru(CO)$_2$Cp}$_2$] (d[Zr–Ru(1)] 2.938(1), d[Zr–Ru(2)] = 2.948(1) Å)[4] and [Cp$_2$Zr(O*t*Bu)-Zr–Ru(CO)$_2$Cp] (d(Zr–Ru) = 2.910(1) Å)[10] are significantly longer. In a theoretical study on the metal–metal bonding in Zr–M complexes Wolczanski et al. have pointed out that the Zr–M bond length critically determines the degree of metal–metal π-bonding and thus the degree of charge relocalization between the two metal centers.[11] The different positions of the $\tilde{\nu}$(CO) IR bands in the amido complexes and the Cp$_2$Zr derivatives is thus manifested in their structural data. The comparatively "open" coordination of the Zr centers in **2** and **3** and, consequently, the reduced steric interaction between the {CpM(CO)$_2$} fragments in both compounds is particularly remarkable and is reflected in the rapid internal rotation around the Zr–M bonds, which is not frozen out even upon cooling NMR samples to 180 K.[12]

Upon reaction of **2** and **3** with **1** in a molar ratio of 1:1, a quantitative complex fragment redistribution is observed that generates the dinuclear compounds **5** and **6**, respectively.[13]



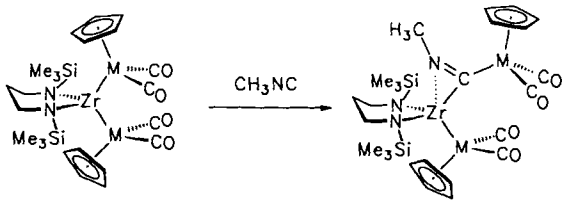
2, M = Fe; **3**, M = Ru — **1** — **5**, M = Fe; **6**, M = Ru

Attempts to generate a ZrFeRu heterotrimetallic complex by reacting **5** with [CpRu(CO)$_2$]$^-$ or **6** with [CpFe(CO)$_2$]$^-$ led to product mixtures in which the target compound could not be unambiguously identified. The facility of the Zr-bonded {CpM(CO)$_2$} fragment to be displaced by a nucleophile, thus

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3512-1339 $ 15.00+.25/0

competing with Cl^-, is the underlying reason for this observation. That this is indeed a kinetic phenomenon and not a consequence of a redistribution equilibrium of the trinuclear complexes is inferred from the unsuccessful attempts to generate a trimetallic species through conproportionation of **2** and **3** even upon heating such mixtures.

The stability of **2** and **3** enables the systematic investigation of the reactivity of systems containing two symmetry-related Zr–M bonds. In view of our previous studies on insertion reactions of polar unsaturated molecules into the Zr–M bonds of dinuclear systems[3] it was of particular interest to assess how the transformation at one Zr–M bond would affect the other. Since in contrast to $[Cp_2Zr\{Ru(CO)_2Cp\}_2]$,[4] both **2** and **3** proved to be completely inert to CO (1 atm), we chose methyl isocyanide as substrate. Compounds **2** and **3** react with one molar equivalent of CH_3NC to yield the mono-insertion products **7** and **8**, respectively, which proved to be inert towards a further equivalent of the substrate or even a large excess of it.



2, M = Fe
3, M = Ru

7, M = Fe
8, M = Ru

The IR spectra of **7** and **8** display a significant shift of the ν(CO) bands in comparison to those of the starting materials (Table 1): the C-bonded $\{CpM(CO)_2\}$ fragments are shifted to higher wavenumbers and the Zr-bound $\{CpM(CO)_2\}$ unit is shifted to significantly lower wavenumbers. The latter is particularly interesting since it indicates that insertion into one Zr–M bond influences the second Zr–M bond. The charge redistribution between the directly metal–metal bonded donor and acceptor complex fragments in **7** and **8** appears to be significantly reduced and thus the residual electron density at the $\{CpM(CO)_2\}$ fragment greater, as reflected in the IR data.

In order to obtain detailed information of the structural consequences of the isocyanide insertion a crystal structure analysis of **8** was carried out (Fig. 2).[14] Similar to the structures of **2** and **3** the central zirconium atom in **8** adopts a distorted tetrahedral coordination with the η^2-"metallaiminoacyl ligand" occupying one coordination site. The most remarkable feature is the increased length of the remaining Zr–Ru bond (d[Zr–Ru(2)] = 2.8639(6) Å) compared to those in the starting material. The resulting reduction of the π-donor–acceptor interaction between the two metal centers is probably responsible for the higher remaining electron density at Ru(1), as manifested in the position of the ν(CO) bands in the IR spectrum. An increase in the metal–metal bond length should imply an enhanced reactivity towards a second equivalent of the substrate, a notion which apparently contradicts the observed reactive behavior. Since **7** and **8** are sterically less crowded than **2** and **3** this situation must be due to changes in the electronic structure of the compounds, an aspect we are currently investigating.

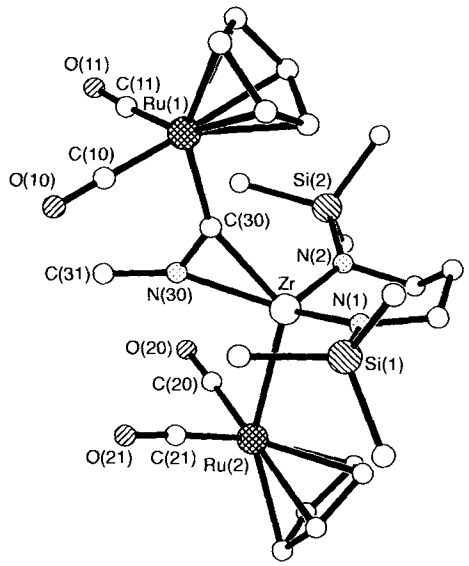


Fig. 2. Crystal structure of **8**, the isocyanide insertion product of $[CH_2(CH_2NSiMe_3)_2Zr\{Ru(CO)_2Cp\}_2]$. Selected bond lengths [Å]: Zr–Ru(1) 2.8639(6), Zr–N(1) 2.066(4), Zr–N(2) 2.025(4), Zr–N(30) 2.185(4), Zr–C(30) 2.237(4), Ru(1)–C(10) 1.858(6), Ru(1)–C(11) 1.835(6), Ru(1)–Cp 2.274(5)–2.309(5), Ru(2)–C(20) 1.866(6), Ru(2)–C(21) 1.865(6), Ru(2)–Cp 2.264(14)–2.303(8), Ru(2)–C(30) 2.040(4).

Experimental Procedure

2–4: To a mixture of solid $[CH_2(CH_2NSiMe_3)_2ZrCl_2(thf)_2]$ (**1**) (550 mg, 1.05 mmol) and solid alkali metal carbonylate [15] toluene (20 mL) and THF (2 mL) were added at ambient temperature. After the mixture had been stirred for 1 h, Na powder (20 mg) was added to the reaction mixture. The mixture was stirred for another 2 h, the solvent was then removed in vacuo, and the residue extracted with pentane (25 mL). After filtration, the solvent of the filtrate was again removed in vacuo, and the residue recrystallized from diethyl ether (4 mL) at −78 °C. Compounds **2–4** were obtained as yellow crystalline solids in yields of 37, 65, and 31%, respectively.

5, **6**: Solid **2** or **3** (0.5 mmol) and **1** (260 mg, 0.5 mmol) was dissolved in C_6H_6 (10 mL) and stirred for 24 h after which the conversion to **5** and **6**, respectively, was complete. The solid products were isolated in almost quantitative yields after removal of the solvent in vacuo and washing of the residue with cold pentane.

7, **8**: To a solution of $[CH_2(CH_2NSiMe_3)_2Zr\{M(CO)_2Cp\}_2]$ (M = Fe: **2**, Ru: **3**; 0.29 mmol) in toluene (5 mL) was added CH_3NC (16.5 μL, 0.29 mmol). After the mixture had been stirred at room temperature for 5 min, the solvent was removed in vacuo and the solid residue extracted with diethyl ether (5 mL). Upon filtration the solution was concentrated to 3 mL and stored at −60 °C. Compounds **7** and **8** were obtained as yellow crystalline solids in yields of 62 and 67%, respectively. The same materials were isolated in the presence of an excess of CH_3NC.

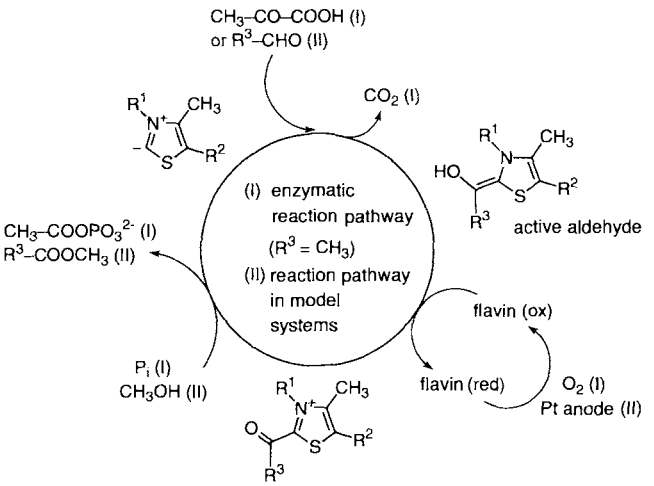
A Flavo-Thiazolio-Cyclophane as a Functional Model for Pyruvate Oxidase**

Patrizio Mattei and François Diederich*

Pyruvate oxidase is a flavin adenine dinucleotide (FAD) and thiamine diphosphate (ThDP) dependent enzyme found in lactobacteria,[2] whose X-ray crystal structure has recently been determined.[3] The enzyme catalyzes the reaction from pyruvate to acetyl phosphate (Scheme 1, pathway I). ThDP-mediated decarboxylation of pyruvate generates an active aldehyde, which is oxidized by FAD. The resulting reduced flavin ($FADH_2$) is reoxidized by dioxygen under formation of H_2O_2. Finally, the 2-acetylthiazolium intermediate produced by oxidation of the active aldehyde reacts with inorganic phosphate producing the energy storage metabolite acetyl phosphate and regenerating the thiazolium ylide.



Scheme 1. Catalytic cycles in the conversion of pyruvate to acetyl phosphate catalyzed by pyruvate oxidase (pathway I) and in the oxidation of a carboxaldehyde to a methyl ester in model systems (pathway II).

In a similar reaction sequence, aldehydes are oxidized in water or alcohols to carboxylic acids and esters, respectively (Scheme 1, pathway II). These conversions have been catalyzed by simple thiazolium ions,[4] thiazolium micelles,[5] and thiazolio-cyclodextrins[6] in the presence of oxidizing agents such as nitrobenzene,[4a–d] ferricyanide,[6] and flavins.[4e, 5] We recently reported the catalytic use of thiazolio-cyclophane **1**, which con-

tains a binding site for aromatic substrates.[1] In basic methanolic solution, a bound aromatic aldehyde reacts to give the active aldehyde,[7] which subsequently is oxidized, by transfer of a hydride equivalent to a flavin derivative,[8] to an acylthiazolium intermediate. This intermediate rapidly reacts with the solvent to afford a methyl ester, while the thiazolium ylide is regenerated. The dihydroflavin formed is reoxidized electrochemically at low anodic potential (-300 mV vs. Ag/AgCl). This catalytic cycle is a mild preparation of aromatic esters with high turnover rates. We felt that these rates could be further enhanced by incorporating the flavin directly into the receptor molecule, since CPK model examinations suggested that the active aldehyde intermediate encapsulated in the cavity was not easily accessible for intermolecular oxidation by an external flavin molecule. Efficient trapping of the active aldehyde by the oxidizing agent helps prevent side reactions such as the benzoin condensation and prevents the oxidation step from becoming rate-limiting.[1]

Scheme 2. We describe herein the synthesis and preliminary evaluation of the catalytic performance of the novel cyclophane **2**, the first functional model of pyruvate oxidase that combines a well-defined binding site with flavin and thiazolium prosthetic groups. The flavo-thiazolio-cyclophane **2** will be compared to our previously published system {**1** + external flavin},[1] the non-macrocyclic bis(coenzyme) derivative **3**, and the simple system {*N*-benzylthiazolium ion **4** + flavin **5**}.

	R^1	R^2	R^3	R^4
5	2-CH_3O-C_6H_4	H	C_4H_9	C_4H_9
22	Br	H	C_4H_9	C_4H_9
26	CH_3	CH_3	CH_3	Tetra-*O*-acetylribityl

Unlike earlier tetraoxa[*n*.1.*n*.1]paracyclophane receptors,[1, 9] **2** is nonsymmetric, that is the four benzene rings have three different substitution patterns; as a result a novel synthetic approach had to be developed. The cyclization precursors **15** and **16** were prepared from the tertiary alcohol **6**[11] (Scheme 2).[10] The 2-nitrobenzyl ether was selected as a phenol protecting group in compounds **8**–**14** because of its excellent stability towards $BF_3 \cdot OEt_2$ needed in the construction of the two diphenylmethane units in **15** and **16** (steps c and g in Scheme 2). Simple benzyl ethers are cleaved under similar Friedel–Crafts reaction conditions.[11] Photolytic deprotection[12] of **13** and **14** succeeded without affecting the sensitive C–Br bonds.

The formation of target compound **2** from cyclization precursors **15** or **16** is shown in Scheme 3. The ω-bromoalkylated phenol **15** underwent an intramolecular macrocyclization to give **17** in 83% yield! Alternatively, cyclophane **17** was obtained in 41% yield in a bimolecular macrocyclization of bis(phenol) **16** with 1,4-dibromobutane. Hydrolysis of **17** to the bis(secondary amine) **18**, followed by acylation with hexanoyl chloride gave **19**, which was reduced with $BH_3 \cdot THF$ to afford the bis-(tertiary amine) **20**. The boronic acid **21** was prepared from bromocyclophane **20** by metalation with *n*BuLi/TMEDA, followed by treatment with excess trimethylborate and aqueous workup. Suzuki-coupling[13] of **21** with the 7-bromoflavin **22**[14] afforded **23** in 56% yield (from **20**). This key step in the preparation of **2** is general and provides a convenient access to 7-arylflavins. Quaternization of **23** followed by ion exchange led to the flavo-cyclophane **24**. Chloromethylation of **24** with CH_2O/HCl in AcOH/conc. aq. HCl[1] yielded the benzyl chloride **25** which, upon heating in 4-methylthiazole and chromatography on reversed-phase silica gel (C_{18}), furnished the water-soluble flavo-thiazolio-cyclophane **2**.

The complexation of 2-naphthaldehyde with flavo-cyclophane **24** and flavo-thiazolio-cyclophane **2** was investigated in ^1H NMR binding titrations in D_2O/CD_3OD (3:2) at 300 K (Table 1). The binding free energy measured for the complex of **24** was in the same range as that determined for a similar cyclophane lacking the flavin moiety.[1] The stability of the com-

Table 1. Association constants K_a and binding free energies $-\Delta G^\circ$ from ^{1}H NMR spectroscopy (binding titrations) for 1:1 complexes of 2-naphthaldehyde at $T = 300$ K [a].

Host	K_a [L mol^{-1}]	$-\Delta G$ [kcal mol^{-1}]	Solvent	Degree of saturation [%]
24	5300	5.1	D_2O/CD_3OD (3:2)	93
2	2900	4.8	D_2O/CD_3OD (3:2)	88
2	26	1.9	CD_3OD	71
3	- [b]	-	CD_3OD	-

[a] For titrations in D_2O/CD_3OD, [2-naphthaldehyde] = 0.5 mM, [cyclophane] varied. For titrations in CD_3OD, [host] = 10 mM, [2-naphthaldehyde] varied. The association constants were obtained by nonlinear least-squares curve fitting of the titration data. Accuracy of the K_a values about ±15%. Also shown is the degree of saturation reached in the titrations. [b] No appreciable complexation detected.

plex with **2** is somewhat lower, presumably owing to self-complexation of the thiazolium ring within the cavity as was found for **1**.[1]

The oxidation of 2-naphthaldehyde in methanol to methyl 2-naphthoate is catalyzed by **2** in the presence of Et_3N. The reaction was initiated by adding Et_3N (50 mM) to a degassed solution of **2** (0.5 mM) and 2-naphthaldehyde (2–50 mM) in MeOH under argon. The course of the reaction was followed by monitoring the decrease in absorbance of the flavin chromophore upon reduction to the colorless dihydro form. Initial velocities were determined by standard linear regression analysis of the linear portion of the plot of absorbance versus time. For comparison, this oxidation was also studied under similar conditions with **3** and {**4** +**5**}.[15]

Saturation kinetics was observed with cyclophane **2** (Fig. 1, Table 2). A Lineweaver–Burk plot ($1/v$ vs. 1/[2-naphthaldehyde])[15] gave $v_{max} = 1.2 \times 10^{-4}$ M s^{-1} and $K_M = 23$ mM. The

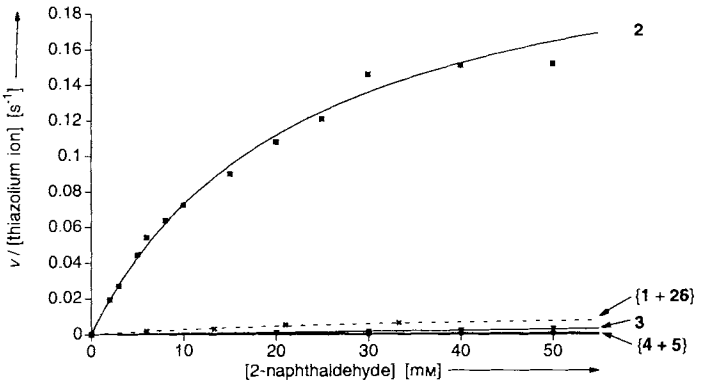

Fig. 1. Plot of relative initial rates versus substrate concentrations for the oxidation of 2-naphthaldehyde to methyl 2-naphthoate catalyzed by **2**, **3**, and {**4** +**5**} [15] as well as {**1** +**26**} [1]. For meaningful comparison, v/[thiazolium ion] rather than v is plotted, since experimental conditions required different concentrations of the various catalysts [15].

Table 2. Oxidation of 2-naphthaldehyde to methyl 2-naphthoate in the presence of Et_3N in methanol.

Catalyst	Second-order rate constant [M^{-1} s^{-1}]
flavo-thiazolio-cyclophane **2**	$k_{cat}/K_M = 10$ [a]
thiazolio-cyclophane **1** and flavin **26**	$k_{cat}/K_M = 0.36$ [b]
flavo-thiazolio-cleft **3**	$k_2 = 0.058$
thiazolium ion **4** and 7-arylflavin **5**	$k_2 = 0.015$

[a] $k_{cat} = 0.24$ s^{-1}, $K_M = 23$ mM. [b] $k_{cat} = 0.013$ s^{-1}, $K_M = 36$ mM.

Michaelis constant is slightly lower than the dissociation constant (K_a^{-1}) measured by ^{1}H NMR titration (38 mM), which can be attributed to unproductive conformations of the host–guest complex.[16] The turnover number $k_{cat} = v_{max}/[\mathbf{2}]$ was calculated to be 0.24 s^{-1}; this value represents approximately a twentyfold acceleration in comparison to the reaction with the bimolecular system {**1** +**26**},[1] and is one of the highest turnover numbers reported for artificial enzymes.[17] Since the bimolecular reaction is already zero order in the oxidizing agent,[1, 5, 6] the acceleration obtained with **2** cannot be expressed in terms of an effective molarity. Although we actually measured the disappearance of the oxidized flavin and thus the initial formation rate of the 2-acylthiazolium intermediate, we can equate its appearance to the formation of the methyl ester, since the reaction of this intermediate with MeOH is fast under basic conditions.[18] In contrast, rates in the presence of **3** and {**4** +**5**} increased in a linear fashion with increasing substrate concentration (Fig. 1).

A comparison of the apparent rate constant k_{cat}/K_M for **2** with the calculated second-order rate constants for the catalyst systems **3** and {**4** +**5**}, which lack the macrocyclic binding site revealed that the reaction with **2** is 170-fold and 670-fold, respectively, faster than with **3** and {**4** +**5**}. The large increase in the reaction rate with **2** is a result of the intramolecularity of all key steps in the catalytic cycle. The formation of the methyl ester was confirmed by ^{1}H NMR spectroscopy. Comparison with authentic samples of 2-naphthaldehyde and methyl 2-naphthoate showed that no by-product was formed.

Unfortunately, attempts to run the reaction under aerobic conditions in order to reoxidize the flavin (as is the case for the reaction with pyruvate oxidase, Scheme 1) largely led to the oxidative destruction of the thiazolium catalyst **2**, and no more than 1.1 equivalents of methyl ester were formed with one equivalent of catalyst.[19] A higher number of catalytic cycles was observed with the more reactive 4-cyanobenzaldehyde. There-

fore, in our future preparative-scale studies with **2**, we will apply the electrochemical regeneration of the oxidized flavin under anaerobic conditions[1] in order to complete the catalytic cycle. These studies with **2**, which has been prepared in gram quantities, will also explore the interesting catalytic oxidation of aldehydes into carboxamides. In parallel, we are investigating the monooxygenase activity of the novel flavo-cyclophane **24** in the hydroxylation of phenolic compounds.[20]

Determination of the Enantiomeric Ratio of Unprotected Amino Acids by NMR Spectroscopy with C_2-Chiral Palladium Compounds

Bernd Staubach and Joachim Buddrus*

α-Amino acids are important compounds in chemistry and biochemistry. Current syntheses focus on compounds with *S*- or *R*-configuration and with additional substituents in α- or other positions.[1–3] In most cases, for the determination of the enantiomeric ratio the chiral amino acid is chemically modified and subjected to NMR spectroscopy or chromatography. NMR analysis[4] is carried out by reacting the amino acid with chiral carboxylic acid chlorides under Schotten–Baumann conditions[5] or with chiral phosphonates;[6] in each case a workup procedure of the diastereomeric mixture is necessary prior to NMR analysis. NMR analysis is also feasible with water-soluble chiral lanthanoid shift reagents, however, line broadening due to paramagnetic relaxation is often observed.[7] For gas chromatographic analysis the amino acid is converted in two steps to its corresponding N-acyl ester and investigated on a chiral stationary phase.[8,9] Liquid chromatographic analysis is carried out with diastereomeric derivatives (from chiral isothiocyanate[10]) under normal phase conditions on an achiral stationary phase, or with free amino acids under reversed-phase conditions in the presence of chiral auxiliaries either in the mobile[11] or in the stationary phase;[12] analysis with free amino acids by liquid chromatography may suffer from problems concerning UV detection.[11b] Analysis by capillary electrophoresis is accomplished after derivatization with *o*-phthaldialdehyde/cysteine.[13] Here we report on a NMR spectroscopic method that permits determination of the enantiomeric ratio of the unprotected amino acid by using chiral palladium compounds.[14]

$[Pd(H_2NCH_2CH_2NH_2)(H_2O)_2(NO_3)_2]$ (**1a**) is known to react with α-amino acids **2** in water to yield the square-planar bicyclic compounds **3a**.[15] Starting from optically active C_2-chiral 1,2-diamines, we prepared aqueous solutions of the chiral palladium compounds **1b–e** and subsequently treated them with amino acids to give the diastereomeric palladium complexes **3b–e** (*cis*/*trans* isomers). The NMR analysis of the diastereomeric complexes yielded the enantiomeric ratio of the amino acid directly.

The equilibrium (a) lies predominantly but not completely to the right, and is slow on the NMR time scale, as indicated by NMR signals of both the free and the complexed amino acid. However, complexation is completed by adding NaOD (ca. 0.75 equiv). The addition of larger amounts was avoided to

prevent dimerization of **1**[16] or ring opening of **3**[17] in alkaline solution. The NMR signals of the two diastereomers are separated both in the ^1H and ^{13}C NMR spectra. The amino acid residue yields two sets of NMR signals, whereas the diamine residue leads to four sets of signals (two pairs of diastereomeric atoms). Figure 1a and 1b show the ^{13}C and ^1H NMR spectrum of **3d**, which is obtained from DL-alanine and **1d**. To test the ability of the chiral palladium compounds **1** as suitable auxiliaries, alanine with different *R*/*S* ratios was prepared by weighing the pure enantiomers and examining the products of the reaction with **1d**. NMR spectroscopic analysis gives the same ratio within the experimental error (±1%; Fig. 1c). Evidently, kinetic resolution (if any) is below the NMR detection limit.

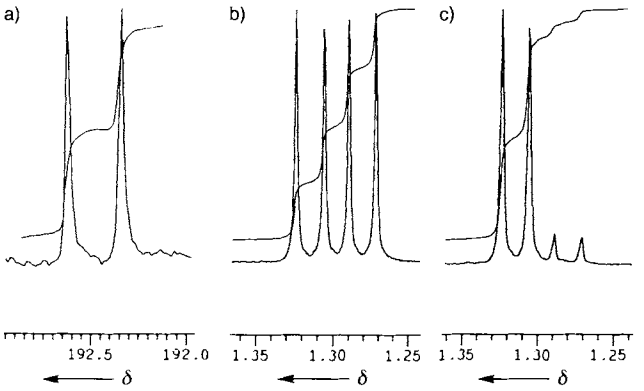

Fig. 1. NMR spectra of **3d** (R′ = CH_3) in D_2O; a) ^{13}C NMR spectrum (100 MHz, carbonyl region); b) and c) ^1H NMR spectrum (400 MHz, methyl region) from DL-alanine and L-alanine with 80% *ee*, respectively.

To investigate the influence of the substituent R in **3b–e** on the magnitude of the NMR signal separation, several optically active 1,2-diamines were tested:[18] (2*S*,3*S*)-2,3-diaminobutane, (1*R*,2*R*)-1,2-diphenylethylenediamine, (1*R*,2*R*)-1,2-diaminocyclohexane, (2*R*,3*R*)-2,3-diamino-1,1,4,4-tetradeuterio-1,4-dimethoxybutane, and in addition to these C_2-chiral diamines (*R*)-1,2-propylenediamine. The results obtained with DL-alanine as analyte are presented in Table 1. The largest signal separation

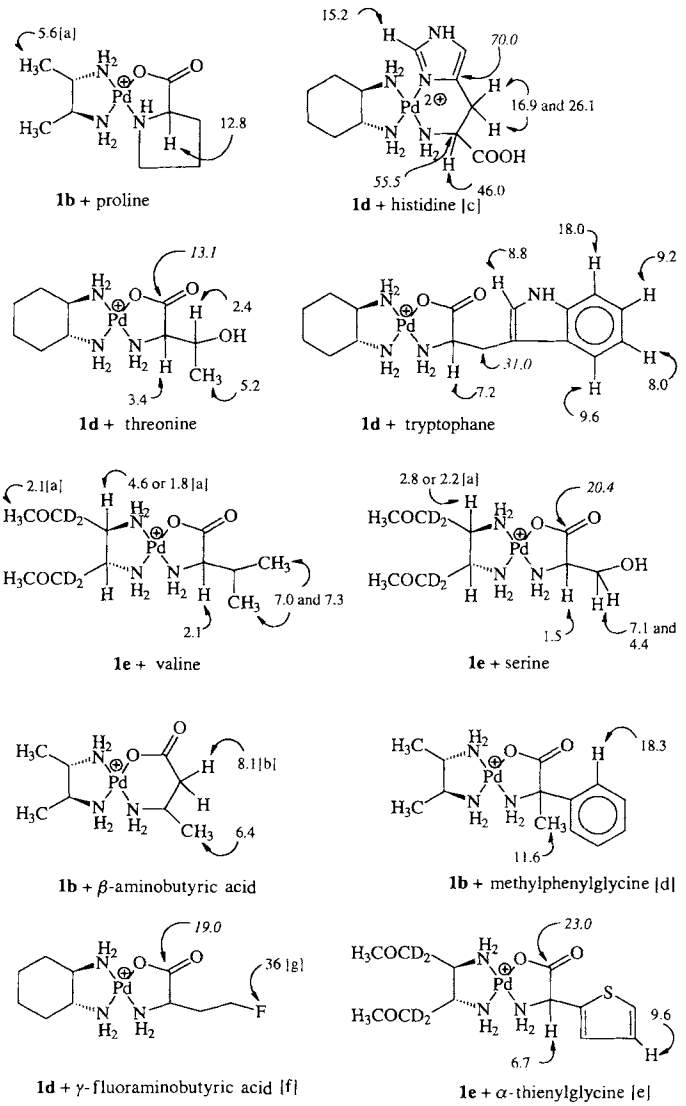
Table 1. ^1H NMR signal separation of the diastereomeric mixture of type **3**, obtained from the auxiliaries **1b–f** and DL-alanine.

Auxiliary	**1c**	**1d**	**1b**	**1e**	**1f** [b]
$\Delta\delta$ [Hz][a]	22.4	14.0	10.8	8.2	7.0

[a] Separation of the CH_3 signals in the alanine residue at 400 MHz. [b] Obtained from (*R*)-1,2-diaminopropane [19].

was observed with **1c** (R = phenyl), which can be explained by the magnetic anisotropy of the benzene ring. Unfortunately, compound **1c** is only sparingly soluble in D_2O, necessating longer NMR measuring time. Most experiments were performed with the auxiliary **1b**, because this compound is sufficiently water-soluble and gives simple ^1H NMR spectra. Several natural α-amino acids, three artificial α-amino acids (one of them alkylated in α-position), and one β-amino acid, all of them unprotected, were investigated; selected ^1H and ^{13}C NMR signal separations are given in Scheme 1.

In summary, the enantiomeric ratio of a chiral α- or β-amino acid can be easily determined: The free amino acid is simply added to an aqueous solution of one of the optically active palladium compounds **1b–e**, and the diastereomeric mixture is



Scheme 1. Diastereomeric ^1H (400 MHz) and ^{13}C (100 MHz) signal separations (in Hz) of some palladium/DL-amino acid complexes (^{13}C NMR signal separations in italics). a) Separation arbitrarily assigned to one of the two constitutopic groups; b) separation arbitrariliy assigned to one of the diastereomeric protons; c) structure proposed according to ref. [20]; d)–f) compounds kindly provided by Prof. M. Schneider, Prof. H. J. Altenbach, Wuppertal, and Prof. G. Haufe, Münster, respectively; g) ^{19}F NMR at 360 MHz.

directly analyzed by ^1H or ^{13}C NMR spectroscopy. In contrast to line widths obtained with paramagnetic lanthanoid shift reagents, the line width of all compounds of type **3** is less than 1 Hz. We are currently preparing further auxiliaries of type **1** with a view to increasing the magnitude of the separations of the NMR signals. Even larger separation of the NMR signals are obtained with the C_2-chiral compound **1a** (NH_2 replaced by (*R*)-$NHCH(CH_3)C_6H_5$): 98 Hz (400 MHz) for the protons of the methyl group in DL-alanine.

Experimental Procedure

The chiral diamines [18] were treated with $[K_2PdCl_4]$ to give the corresponding $[Pd(diamine)Cl_2]$ complexes [21]. $[Pd(diamine)Cl_2]$ (0.02 mmol) and $AgNO_3$ (0.04 mmol) were suspended in D_2O (1 mL) and stirred for 30 minutes. After removal of the precipitated AgCl by centrifugation, a clear yellow solution of $[Pd(diamine)(D_2O)_2(NO_3)_2]$ (**1**), which is stable at room temperature for several months, was obtained [16]. Free amino acid **2** (0.017 mmol) and NaOD (0.015 mmol) were added and the mixture was stirred until it became clear (1 to 10 minutes). The solution was analyzed by ^1H NMR spectroscopy. For analysis by ^{13}C NMR

spectroscopy the concentrations of the reactants were chosen 15 times higher (about 0.3 M), which is the upper limit of solubility for the compounds **1b**, **1d**, and **1e**.

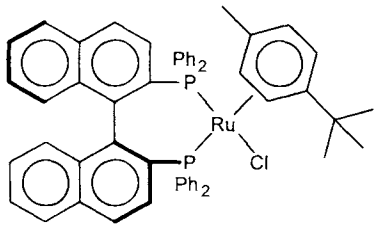
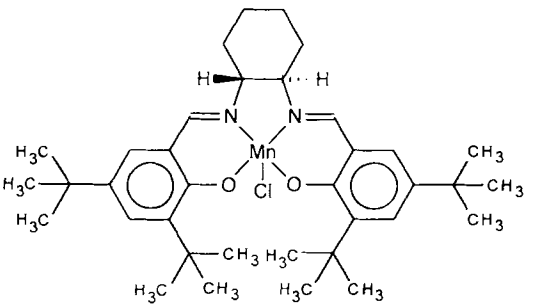
Chiral Catalytic Membranes**

Ivo F. J. Vankelecom,* Diedrik Tas, Rudy F. Parton, Valérie Van de Vyver, and Pierre A. Jacobs

The easy separation of a solid catalyst from the reaction mixture is one of the main advantages offered by heterogeneous catalysts and an essential prerequisite for their regeneration. Since the cost of most chiral homogeneous catalysts is very high, their heterogenization is highly desirable. Chiral complexes are the most important class of homogeneous enantioselective catalysts.[1] Typical examples are the Ru-BINAP complex [2,2′-bis(diphenylphosphanyl-1,1′-binaphtyl]chloro(*p*-cymene)-ruthenium[2] (**1**) and the Jacobsen catalyst *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)chloro-1,2-cyclohexanediaminemanganese[3] (**2**), which catalyze hydrogenation and epoxidation reactions, respectively. For the Jacobsen catalyst (**2**), no successful hetero-



1



2

genization procedure has been published, and regeneration does not seem possible. In only one case was a homogeneous chromium-containing Jacobsen catalyst successfully recycled 5 times.[4] However, this was in the enantioselective ring opening of epoxides, a reaction that involves no oxidants and thus avoids oxidative destruction of the complex, a major deactivation route for salen complexes. In the case of BINAP-based catalysts, only a triphasic system consisting of a solid support, the sulfonated form of the complex dissolved in an ethyleneglycol phase, and an immiscible phase containing the substrate has been reported.[5]

Here we present the preparation, catalytic characterization, and regeneration of the heterogeneous chiral catalysts by means of a new, versatile, and generally applicable method for complex immobilization. The above-mentioned BINAP complex **1** and

chiral Schiff base complexes **2** were occluded in an elastomeric type polydimethylsiloxane (PDMS) membrane. In both cases, a perfectly regenerable catalytically active membrane was obtained that provided essentially the same catalytic activity, product, and enantiomeric selectivity as the homogeneous case. In contrast to earlier polymer-supported catalysts in which complexes were immobilized through electrostatic interactions,[6] covalent bonds,[7] or coordinative[8] bonds, the complex is captured here in the elastomer network merely by steric restrictions. In the epoxidations the bimolecular oxidation between active Jacobsen complexes is prevented here by the reduced diffusivity of the immobilized complexes in the membrane matrix.

The complexes **1** and **2** were occluded in a PDMS membrane (see Experimental Procedure), and the activity of the resulting catalytic membranes was tested in the hydrogenation of methyl acetylacetate (for **1**) or in the epoxidation of olefins (for **2**). The results of catalysis with free Jacobsen catalysts and those occluded in membranes are summarized in Table 1. Our experimental results for activities, product selectivities, and enantiomeric selectivities with the homogeneous catalysts agree well with published data (entries 1 and 5).[3, 9–13] No significant differences are obtained with the catalytic membranes (entries 2 and 6), apart from a reduced selectivity in entry 2. This is attributed to the formation of phenylacetaldehyde and 1-phenyl-1,2-ethanediol, probably formed at the membrane edges. The (*S*,*S*) form of the salen complex gives the same results as its (*R*,*R*) form (compare entry 8 with 9). Moreover, the catalytic membranes are regenerable by a simple washing procedure (entries 3, 4, and 7). The reaction mixture was analyzed by atomic absorption spectrometry (AAS) after evaporating the organics and subsequently redissolving the Mn complexes in water. Of a total amount of 112 ppm Mn in the original membrane, negligible concentrations of 1.2 and 0.8 ppm Mn were obtained in the solution after the epoxidation of cyclooctadiene and styrene, respectively. As the catalytic results obtained do not vary significantly with membrane thickness, it is not very probable that diffusion in the membrane is controlling the rate of the catalytic reaction (entries 6 and 10). It should be stressed that the homogeneous complex is a much more selective catalyst for epoxidation of *cis*-alkenes than for the epoxidation of *trans*-alkenes, giving very high *ee* values for the former olefins. Preliminary work seems to indicate that the same is true for the corresponding chiral catalytic membrane.

Table 1. Epoxidation of olefins with NaOCl at 4 °C with a PDMS-occluded (*S*,*S*)-salen complex **2**.

[f] After one regeneration consisting of washing with acetone and air-drying of the membrane at 60 °C. [g] After a second regeneration of the membrane. [h] With the (*R*,*R*)-salen complex. [i] Using a membrane 0.4 mm thick.

The hydrogenation of methyl acetoacetate was chosen as a test reaction in the case of the membrane-occluded Ru-BINAP complex. Until recently, the catalytic asymmetric hydrogenation of ketones suffered from low activity and/or enantioselectivity. However, Noyori and co-workers performed the enantioselective hydrogenation of β-ketoesters in an efficient manner (more than 98% *ee*) using Ru^{II}-BINAP complexes. This opens opportunities for producing functionalized alcohols in synthetically useful enantiomeric excesses.[14, 15] Regeneration of the expensive catalyst requires a complex procedure though. Therefore, a membrane occluded Ru-BINAP complex was assayed here for the hydrogenation of methyl acetoacetate. Results on the hydrogenation of methyl acetoacetate with a membrane-occluded Ru-BINAP catalyst are summarized in Table 2. Complex leaching was absent in all cases. The ruthenium content in the reaction mixture was below the AAS detection limit (0.16 ppm), indicating less than 0.2% leaching. In agreement with earlier reports, very low activity and enantiomeric selectivity results when the solvent is water (entry 1).[5] With ethyleneglycol, polyethyleneglycol, or glycerol as solvent, the activity and enantioselectivity can be improved (entries 2–4). Conversions could be increased further at higher temperatures (entry 5) with only a slight loss in *ee* (still without leaching). After regeneration the catalytic activity of the chiral membrane was almost unchanged (entry 6).

Table 2. Results of the hydrogenation of methyl acetoacetate with a PDMS-occluded Ru-(*S*)-BINAP catalyst (**1**) in different solvents at 60 or 80 °C.

Entry	Solvent	*T* [°C]	TOF [a]	ee [%]

[a] Turnover frequency [min^{-1}], based on conversions after 48 hours. [b] After regeneration by air drying at 60 °C.

In conclusion, a new versatile and general way of immobilizing complexes is presented, which can be applied to a broad variety of catalysts. The method is interesting, especially for chiral complexes, becauses the chirality of the catalyst is kept intact by occlusion in a dense polymer in the absence of any supplementary chemical bonding. The chiral catalytic membranes remain heterogeneous under a wide range of conditions and show good to excellent activity and enantioselectivity in hydrogenation as well as in partial oxidation reactions. It is clear that the present two-phase system is more generally applicable and versatile than any three-phase system.[5] Further improvement of activity by systematically changing the membrane thickness, its degree of cross-linking, and the nature of functional groups is within the scope of our future research.

Experimental Procedure

Immobilization of the chiral complexes **1** and **2** by occlusion in a PDMS membrane: A 20 vol% solution in chloroform of a 10/1 weight ratio of prepolymer (RTV-615A, linear polydimethylsiloxane chains with terminal vinyl groups) and crosslinker (RTV-615B, linear polydimethylsiloxane chains carrying several hydride groups) from General Electric was stirred in an oil bath at 70 °C for 1 hour. The chiral complex (obtained from Aldrich) was then added (0.5 wt% for **1** and 2 wt% for **2**), and the mixture was further stirred at room temperature for another 2 hours. The solvent was then allowed to evaporate. Finally, the membrane was cured under vacuum at 150 °C for 1 h. For catalyst **1**, the whole procedure took place in a nitrogen atmosphere. The average thickness of the catalyst membrane was 0.2 mm.

which corresponds to a loading of approximately 0.108 μmol cm^{-2} for **1** and of 0.629 μmol cm^{-2} for **2**. Before use, the catalytic membranes were washed with toluene.

Hydrogenation of methyl acetoacetate (MAA) (molar ratio MAA/catalyst/solvent = 5000/1/40000) with occluded complex **1** was performed in a 100 mL modified Parr autoclave equipped with a turbine-type stirring device rotated at 600 rpm. Hydrogen was admitted just below the turbine at 6 MPa at 60 °C. The membrane was fixed between the turbine and the hydrogen outlet to provide optimum gas transfer to the membrane.

Epoxidation of olefins was performed in a countercurrent membrane reactor, with separate streams of oxidant and substrate (as a 0.6 vol% solution in heptane) on each side of the catalytic membrane (diameter of approximately 15 cm). An aqueous solution of NaOCl was used as oxidant. The olefin/metal complex/oxidant molar ratio was 25/1/100.

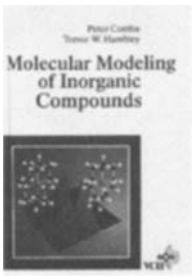
The Shape of Things to Come

Molecular Modeling of Inorganic Compounds. By *P. Comba* and *T. W. Hambley*. VCH Verlagsgesellschaft, Weinheim, 1995. 197 pp., hardcover DM 188.00.—ISBN 3-527-29076-1



If the maturity of a subject can be judged by the number of textbooks describing it, then this contribution by Comba and Hambley certainly marks a most distinguished start for inorganic molecular modeling. It is a nicely produced, extensive, and readable account of empirically based computational approaches to the structure and energetics of inorganic species although, by their own definition, the title should have been "Molecular Mechanics for Inorganic Compounds", since there is no coverage of electronic structure methods whether semi-empirical or ab-initio.

The text is essentially divided into three sections. After a general introduction, Part I (Chapters 1–5) deals with the theoretical/mathematical basis of molecular mechanics (MM), Part II (Chapters 6–14) with various applications, and Part III (Chapters 15–17) with a series of practical tips and guidelines for doing calculations and interpreting results. References are collated independently for each part and are comprehensive, although the layout leads to repetition and Refs. 288 and 289 from Part II are missing.

The material in Part I is reasonably straightforward but is nicely presented, well organized and absolutely necessary for a text which assumes no prior knowledge of the subject. Probably the most salient point which emerges in Part I (and is consistently repeated throughout) is that individual force field (FF) parameters need bear no relationship to their spectroscopically determined counterparts. The FF parameters need to be taken as a whole and judged on their ability to reproduce global quantities such as molecular structure. The individual 'ideal' bond lengths, 'ideal' angles, force constants, etc. are not physically meaningful in themselves.

The real meat of the text is contained in Part II where an astonishing diversity of applications is sampled, ranging from computing structures for molecular visualization, through to estimating enantioselectivities; from racemate separations and stereoselective synthesis to metal ion selectivity; from combining MM calculations with spectroscopic measurements to electron transfer reactions; from the Jahn–Teller effect to bioinorganic chemistry, organometallics, and s-, p-, and f-block systems.

The applications naturally focus on the authors' own contributions, mainly in transition metal chemistry, but this still gives a remarkably wide and varied coverage—a testimony to their pioneering role in this area. Together with selected examples from organometallic, main group and f-block chemistry, the reader can certainly get a feel for the kinds of systems and properties which can be modeled.

In many ways most of Part III becomes almost self-evident from reading Parts I and II, but the authors take the time to discuss some of the practical pitfalls encountered when attempting to apply MM to inorganic molecules, especially transition metal systems, and while not being an out-and-out plug for their program system MOMEC, one assumes it would be a good vehicle for putting their philosophy into practice.

The ultimate message is clear and definitely upbeat. MM can work even within the richness and diversity of inorganic chemistry provided you recognize its interpolative nature and work within this constraint. This may be restrictive and may also require the user to develop a force field if none already exists for the systems of interest. While this may not always be for the faint-hearted, the authors make a compelling justification for the success of MM and it is encouraging to see just what can be achieved.

Overall, this book will appeal both to the active research scientist and to the intellectually curious and is required reading for all those with an interest in theoretical approaches to inorganic systems.

On Being a Scientist: Responsible Conduct in Research. *Committee on Science, Engineering, and Public Policy; National Academy of Sciences; National Academy of Engineering; Institute of Medicine.* National Academy Press, Washington, D.C., 1995. VIII, 27 pp., paperback $ 5.00 (single copy); $ 4.00 each (2–9 copies); $ 2.50 each (10 or more copies) plus $ 4.00 for shipping and handling.—ISBN 0-309-05196-7

According to Frank Press, past president of the U.S. National Academy of Sciences: "Traditionally, young scientists have learned about the methods and values of scientific research from personal contact with more experienced scientists, and such interactions remain the best way for researchers to absorb what is still a largely tacit code of professional conduct". Recently, however, the increasing size of research teams and the accelerating pace of research have rendered such informal transmission of values insufficient.

Furthermore, the familiar "mad scientist" image is a false stereotype fostered and encouraged by films, television, literature, and the sensation-seeking mass media. From the unrealistically optimistic view of science and scientists as purveyors of unlimited "better things for better living" (the motto of E. I. du Pont de Nemours and Company), a backlash against science has come to pass with a

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to Dr. Illenora Beckmann, Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

vengeance, as scientists are blamed for technological disasters such as Three Mile Island, Bhopal, Chernobyl, and current environmental problems such as pollution, the greenhouse effect, acid rain, the erosion of the ozone layer by CFCs, oil spills, and the proliferation of pesticides and nuclear weapons and nuclear wastes. In addition to all the above negative views, recent allegations of fraud in scientific disputes at the highest levels have provoked a questioning of the ethics of scientists and technologists, as what the public regards as their presumptuous curiosity and search for scientific truth lead to disaster, when scientists allegedly fail to foresee and take responsibility for the results of their research and development.

To deal with these problems, in 1989 the U.S. National Academy of Sciences published a short but important booklet, *On Being a Scientist*, prepared by the academy's Committee on the Conduct of Science. Written primarily for beginning graduate and undergraduate research students and printed in a run of more than 200000 copies, the largest ever commissioned by the academy, it sought "to describe some of the basic features of a life in contemporary research and some of the personal and professional issues that researchers will encounter in their work".

In order to incorporate the important developments in science ethics during the past half dozen years, such as new policies and procedures established by research institutions and government agencies for dealing with unethical behavior, a new, updated version of the original booklet has been prepared. For example, it includes new material on guidelines for research conduct and related matters taken from *Responsible Science: Ensuring the Integrity of the Research Process* (National Academy Press, Washington, D.C., Vol. 1, **1992**, Vol. 2, **1993**), a thorough analysis of scientific misconduct prepared by the Panel on Scientific Responsibility and the Conduct of Research under the Committee on Science, Engineering, and Public Policy of the National Academy of Sciences, National Academy of Engineering, and Institute of Medicine. It reflects suggestions from readers of the first booklet, instructors who used it in classes and seminars, and graduate students and professors who commented on drafts of the revision.

This booklet of practical advice answers questions that are fundamental, but usually neglected in courses, such as: how should anomalous data be treated? how much confidence must a researcher have in the results of a particular experiment before publishing a paper? how much of a contribution should a researcher or faculty adviser make before being listed as coauthor? how can scientists avoid self-delusion in making observations? how should errors in papers be corrected? what are the borderlines between honest error, negligent error, and misconduct? what should a researcher do when he or she suspects a colleague of scientific misconduct?

Among the topics discussed are scientific method, treatment of data, the relation between hypotheses and observations, peer review, recognition and priority in discovery, replication and the openness of communication, scientific progress, the social foundations of science, experimental techniques, values in science, publication and openness, allocation of credit, authorship practices, error and negligence, misconduct, responding to violations of ethical standards, the scientist in society, and patent procedures. To be sure, these topics are dealt with in greater detail in specialized monographs, such as those listed in the booklet's three-page annotated bibliography, but rarely are they found in a general pamphlet short enough to be read from cover to cover in an hour or two. Science is depicted throughout as a human endeavor with all its virtues and defects; historical examples abound—from Galileo to scientists who release their results directly to the public through a press conference (cold fusion is discussed, although Pons and Fleischmann are not mentioned by name).

A very useful, provocative, and effective means of illustrating research ethics that was lacking in the first version is the inclusion of nine hypothetical scenarios, ranging in length from one to three paragraphs. These deal with conflicts arising when the black-and-white, clear-cut areas of science meet the gray, more ambiguous areas of human values and biases. Each scenario is followed by three questions on how to deal with the problems and issues portrayed, viz., selection of data, conflict of interest, industrial sponsorship of academic research, sharing of research materials, allocation of credit, publication practices, fabrication in grant applications, plagiarism, and informing on a colleague ("whistle-blowing"). A three-page appendix at the end of the booklet offers guidance in thinking about, discussing, or debating the scenarios, but the scenarios remain open-ended, and no definitive answers or specific ways of dealing with the situations are given. This stance is in accordance with the authors' belief that "research ethics is not a complete and finalized body of knowledge. These issues are still being discussed, explored, and debated, and all researchers have a responsibility to move the discussion forward".

This attractive and well-planned booklet deals with fields of science from astronomy to zoology and abounds with provocative case studies such as the discovery of pulsars, the location of spiral nebulae, eugenics, the rejection of Mendelian genetics in the USSR, and polywater. Pertinent quotations from scientific authorities such as Albert Einstein, Barbara McClintock, Peter Medawar, Alvin Weinberg, and John Ziman are included, usually in sidebars. The booklet's contents will undoubtedly be used as a basis for discussion and debate in undergraduate or graduate classes or seminars on research ethics, research methods or statistics, and the history, sociology, or philosophy of science as well as in meetings of scientific societies in general, or those that aim to develop ethics policies or guidelines.

Although this booklet was written largely with an American audience in mind, it deals with matters of vital concern to the global scientific community. Moreover, in addition to being a *sine qua non* for scientific novices, it provides lessons of great value to all scientists at all stages of their scientific careers. As the preface points out, "in particular, senior scientists have a special responsibility in upholding the highest standards for conduct, serving as role models for students and young scientists, designing educational programs, and responding to alleged violations of ethical norms. Senior scientists can themselves gain a new appreciation for the importance of ethical issues by discussing with their students what had previously been largely tacit knowledge". Furthermore, in view of the current prevalence of anti-scientific prejudice among citizens who are increasingly called upon to vote on issues with a considerable scientific or technological component, the general public could certainly benefit from the booklet's lucid explanation of the nature of science as process as well as product and the limitations of science and the provisional nature of its findings.

In the past, our department has presented our graduating chemistry majors with a year's subscription to a scientific periodical. This booklet should make a gift of equal or even greater value.

Enzyme Catalysis in Organic Synthesis. A Comprehensive Handbook. Volumes 1 and 2. Edited by *K. Drauz* and *H. Waldmann*. VCH Verlagsgesellschaft, Weinheim, 1995. 1050 pp., hardcover DM 498.00, $ 475.00.— ISBN 3-527-28479-6

Enzyme-catalyzed reactions are now an important part of the armory of modern organic synthesis. These reactions proceed under mild conditions, with high substrate specificity and with high stereo-, regio-, and chemoselectivity. The main area of application of enzymatic reactions is in the synthesis of enantiomerically pure and polyfunctional compounds. Because of the enormous developments that have occurred in this area during the past decade, it seemed an appropriate time to bring together the current state of knowledge in the form of this substantial multiauthor work. The articles in this handbook have been written by 53 recognized international experts. They cover the literature up to the beginning of 1994, with over 4000 references, and the subject index of more than 70 pages serves as a very effective key to the contents.

The work is divided into three parts. The first, consisting of about 160 pages, contains an introduction followed by chapters on the production and isolation of enzymes, their immobilization, process engineering for enzyme-catalyzed biotransformations, and microbiological transformations using growing and resting cells. This part of the book introduces the basic principles of enzyme-catalyzed reactions, including enzyme kinetics and the standard techniques for preparing, purifying and using enzymes.

The second part (about 800 pages) begins with eight chapters that are essentially devoted to different types of enzyme-catalyzed reactions that can be used in synthesis. These are followed by four shorter chapters dealing with special applications of enzymes. The first chapter (about 200 pages) covers the hydrolysis and formation of CO bonds. This includes esterase- and lipase-catalyzed kinetic racemate separation processes based on the hydrolysis of carboxylic acids and the esterification of alcohols. Asymmetrization reactions of *meso* and prostereogenic carboxylic acid derivatives and alcohols are also treated in detail. This chapter also deals with the hydrolysis of epoxides by epoxide-hydrolases and the use of glycosidases and glycosyl-transferases for forming and breaking glycosidic bonds. The following chapter (240 pages) is concerned with the formation and hydrolysis of CN bonds including, for example, the hydrolysis of nitriles using nitrilases, and the use of nitrile-hydratase to catalyze amide formation followed by the protease-catalyzed hydrolysis of the amides. The use of proteases for the hydrolysis and formation of peptide bonds is treated in detail, and considerable space is devoted to the synthesis of amino acids and peptides using proteases. Next is a chapter of 40 pages on the formation and breaking of PO bonds. This is followed by a chapter of about 50 pages on the formation of CC bonds using aldolases, transketolases, or transaldolases, or by addition of hydrogen cyanide to aldehydes and ketones using oxynitrilases. The following chapter (about 70 pages) deals with the application of dehydrogenases to the reduction of aldehydes, ketones, carboxylic acids, C=N bonds, and C=C bonds. A chapter of over 130 pages is devoted to a survey of oxidation reactions, including hydroxylations, epoxidations, *cis*-dihydroxylations of arenes, oxidations of alcohols, Baeyer–Villiger oxidations, oxidations of sulfides, and halogenations, using mono- and dioxygenases, oxidoreductases, and peroxidases. A 40-page chapter then covers enzyme-catalyzed isomerizations such as the racemization of amino acids by racemases. Next is a chapter discussing numerous examples where enzyme-catalyzed reactions have played a valuable role in the use of protecting groups. These methods achieve selective protection of amino, thiol, carboxyl, and hydroxyl groups, mainly in polyfunctional molecules. The next chapter reviews the use of catalytic antibodies in organic synthesis. This second part ends with three shorter chapters on enzymatic analysis and biosensors, protein engineering, and enzymes derived from highly thermophilic and hyperthermophilic archaeabacteria and eubacteria. The third part contains tables giving information about commercially available enzymes and suppliers.

This handbook is an indispensable source of information about all types of enzyme-catalyzed reactions that can be used in syntheses. The many examples of the use of enzymes in organic synthesis are in themselves enough to make this two-volume work an enormously valuable resource. The wealth of information is presented in a very clear form; in particular the presentation of results in tables enables the reader to quickly find the essential data, and also provides stimulating ideas for following up. The work is intended for synthetic chemists in academic and industrial research, and for biochemists, microbiologists, and biotechnologists whose work involves biotransformations. It is very clearly set out, easy to read, and sturdily bound. It should be in every library.

Glycals in Organic Synthesis: The Evolution of Comprehensive Strategies for the Assembly of Oligosaccharides and Glycoconjugates of Biological Consequence

Samuel J. Danishefsky and Mark T. Bilodeau

This review provides a personal account of the explorations of a research group in oligosaccharide and glycoconjugate construction. The journey began twenty years ago with the study of Diels–Alder reactions of complex dienes. By extending this methodology to aldehydo-type heterodienophile equivalents, access to unnatural glycals was gained (LACDAC reaction). From this point a broad-ranging investigation of the use of glycals in the synthesis of oligosaccharides and other glycoconjugates was begun. Mobilization of glycals both as glycosyl donors and glycosyl acceptors led to the strategy of glycal assembly. Several new glycosylation techniques were developed to provide practical underpinning for this logic of glycal assembly. Glycal-based paradigms have been shown to be nicely adaptable to solid phase supported synthesis. Moreover, glycal assembly—both in solution and on solid phases—has been used to gain relatively concise and efficient entry to a variety of biologically interesting and potentially valuable constructs. Some of these syntheses, particularly in the field of tumor antigens, have led to novel compounds which are in the final stages of preclinical assessment. This review presents an account of the chemical reasoning at the center of the program.

Keywords: glycals · glycoconjugates · glycosylations · oligosaccharides · synthetic methods

1. Background and Settings

The synthesis of carbohydrate-based structures is emerging as a major frontier area for organic chemistry. In addition to their well-appreciated roles in supporting structural matrices, in energy storage, and as biosynthetic starting materials, carbohydrates are cast in a variety of interesting settings as glycoconjugates, for example as antibiotics,[1] antitumor agents,[2] and cardiotonic glycosides.[3] The gangliosides are being increasingly implicated as tumor antigens and cellular differentiation markers.[4] The importance of the carbohydrate domains in glycoproteins and glycolipids as elements in cell surface recognition is manifested by their role in cellular adhesion[5, 6] and as determinants in blood group typing.[7] Another incentive for focusing on carbohydrates is their usefulness as enantiomerically pure starting materials for the synthesis of various natural products and other types of target molecules.[8]

Our first encounter with carbohydrate chemistry arose from happenstance rather than through careful planning. A slight digression may be appropriate. From 1974 to 1981 we had been investigating the synthetic potential of the uncatalyzed Diels–Alder reaction of siloxydienes with electrophilic dienophiles.[9, 10] Actually the problem that triggered those studies was a proposed synthesis of vernolepin.[11] For that purpose we thought that intermediate **4** might be useful (Scheme 1). It seemed to have all of the functionality necessary to allow for a plausible route to our target (the dotted arrows highlight transformations that were eventually achieved). At the time, however, there was no known route to efficiently introduce the $\Delta^{1,2}$ conjugated double bond via a saturated 3-ketone in the *cis*-fused series of compounds.

This problem prompted the idea of using the parent version of diene **1** (R^1, $R^2 = H$) in a Diels–Alder reaction with dienophile **3** (itself the product of the Diels–Alder reaction of 1,3-butadiene with methyl propiolate). The synergism of the 1,3-substituents on **1** (R^1, $R^2 = H$) facilitated reaction with the sluggish dienophile **3**. Furthermore the adduct could be easily transformed into the desired **4**.

The matching of electronically complementary Diels–Alder components did indeed favor many otherwise difficult cycloadditions. By taking advantage of functional groups in the diene component at the points of linkage (for example in **3**, Scheme 1), we were able to realize the total synthesis of a variety of natural products, including vernolepin. Some of the other targets were also quite challenging, and their total syntheses were not without instructional value (cf. prephenic acid (Scheme 1), pentalenolactone, and griseofulvin).

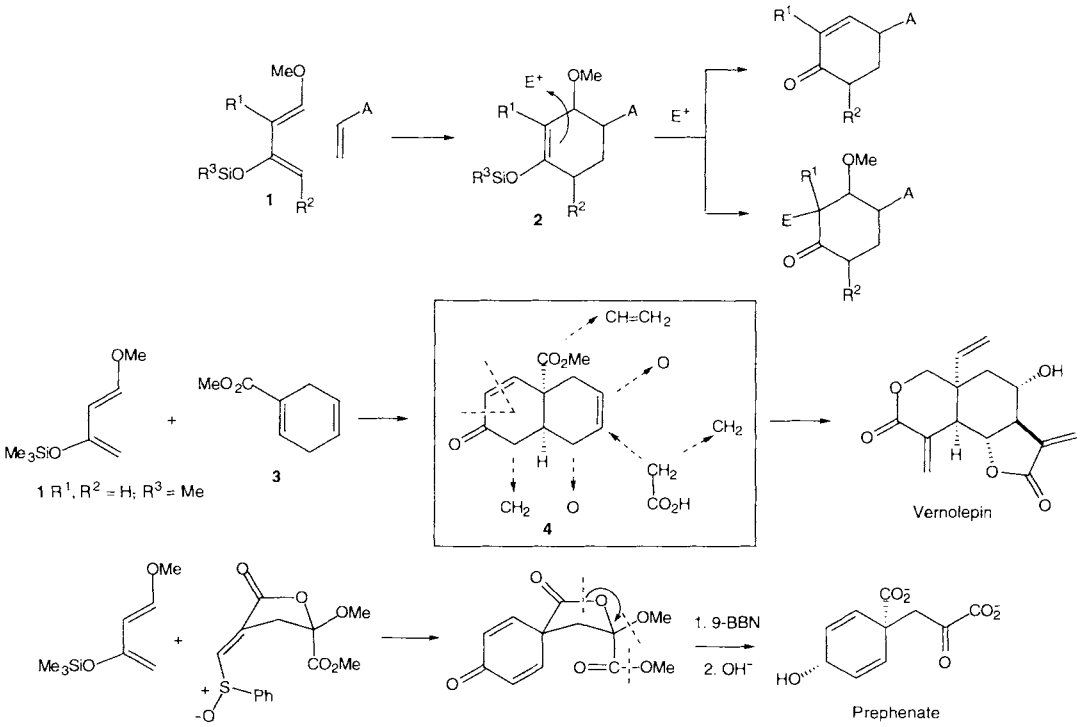
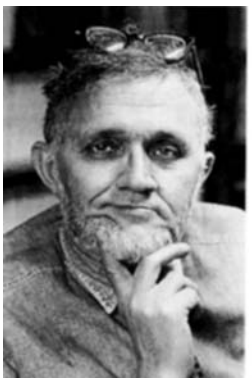


Scheme 1. Diels–Alder reactions of siloxydienes with electrophilic dienophiles (A = electron-withdrawing substituent, E^+ = electrophile, including H^+).

Perhaps the most enduring aspect of this early work in Pittsburgh was the interest it spawned in diene **1**, in the broad class of siloxydienes and, more generally, in the concept of heavily functionalized dienes in the Diels–Alder reaction. While these ideas are now taken for granted, much follow-through work was needed for them to gain wide acceptance and usage.[12]

As the use of functionalized dienes in all-carbon Diels–Alder reactions was developing in many other laboratories,[13] we cast our attentions toward a new departure. We came to wonder about the possibility of the cycloaddition of siloxydienes with aldehydes. Elsewhere we have related the early history of this reaction.[14] While it was known that aldehydes especially activated by adjacent electron-withdrawing groups (e.g. α-dicarbonyl systems or α-polyhaloaldehydes) would undergo cycloaddition with "nucleophilic" dienes,[15] analogous processes were not realizable with typical aldehydes under thermal conditions. It remained for James Kerwin, then a graduate student in our laboratory at Yale University, to discover that under appropri-

Samuel J. Danishefsky received a Bachelor of Science degree from the Yeshiva University, New York, NY (USA), and a Ph.D. from Harvard University, Cambridge, MA, under the direction of Peter Yates. He did a postdoctoral tour with Gilbert Stork as an NIH Fellow at Columbia University, New York, NY. He began his independent career at the University of Pittsburgh, Pittsburgh, PA, from 1964 to 1979. He was Professor of Chemistry at Yale University, New Haven, CT, from 1980 to 1993. At Yale he was Chairman of the Department from 1981 to 1987 and was named Sterling Professor in 1990. He is currently the Director of the Laboratory for Bioorganic Chemistry at the Sloan-Kettering Institute for Cancer Research. He returned to Columbia University as Professor of Chemistry in 1993. He is a member of the National Academy of Science and co-recipient of the 1996 Wolf Prize in Chemistry.



S. J. Danishefsky

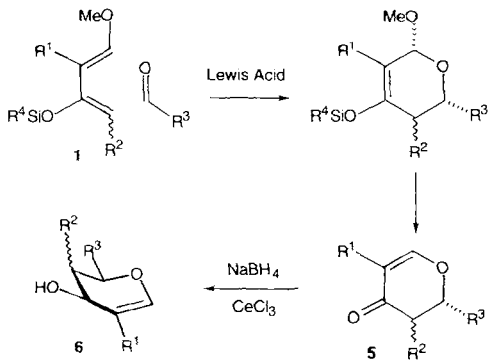
M. T. Bilodeau

Mark T. Bilodeau received his B. S. degree in chemistry in 1988 from Boston College, Chestnut Hill, MA, where he worked in the laboratory of T. Ross Kelly. In 1993 he earned his Ph.D. in organic chemistry from Harvard University under the guidance of David A. Evans. After receiving his degree he moved to the Sloan-Kettering Institute for Cancer Research, where he was an NIH postdoctoral fellow with Samuel J. Danishefsky. While at the Sloan-Kettering Institute he focused on the synthesis of a human breast tumor antigen and the carbohydrate domain of asparagine-linked glycopeptides. He has since assumed a position in the Medicinal Chemistry Department of Merck & Co. in West Point, PA.

ate Lewis acid catalysis, cyclocondensation between suitable siloxydienes and aldehydes was in fact a general and reliable reaction.[16] After several years of investigation the cyclocondensation reaction emerged as a central element in a new strategy for the synthesis of polyoxygenated natural products.[17]

2. The Synthesis of Enantiomerically Enriched Artificial Glycals and Applications to Total Synthesis

The Lewis acid catalyzed diene–aldehyde cyclocondensation (LACDAC) reaction provided a rapid route to novel dihydropyrones of the type **5** (Scheme 2). It was subsequently shown, first



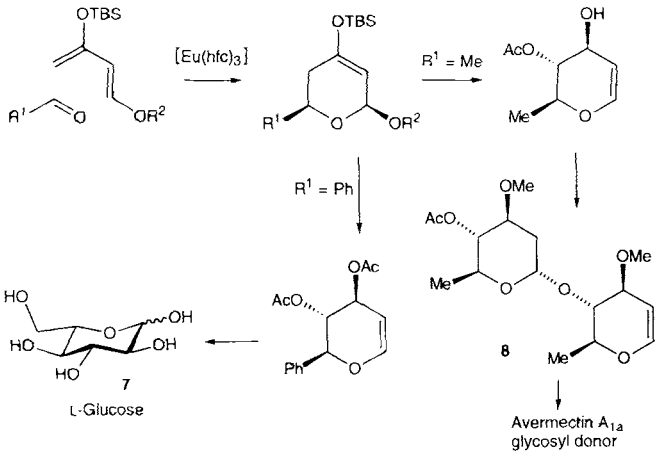
Scheme 2. Synthesis of glycals by the LACDAC reaction (β-R^2: gluco series; α-R^2: galacto series).

by Toby Sommer, that 1,2-reduction of such dihydropyrones with sodium borohydride mediated by cerium(III) chloride gave alcohols such as **6** in which the hydroxyl group is in equatorial position (Scheme 2).[18] We began to refer to such compounds as "glycals." The term had been reserved by carbohydrate chemists for naturally derived pyranose or furanose systems bearing a C1–C2 double bond. The possibility that racemic compounds such as **6**, derived by purely synthetic means, might be described as "glycals" was greeted not surprisingly with reservation by some in the community of traditional carbohydrate chemists, but to us, the connection seemed obvious.

Four pathways have subsequently been followed to produce enantiomerically enriched or enantiomerically pure dihydropyrones and glycals by means of the LACDAC reaction.[14] We review them here chronologically.

Early, but only modest success was achieved by using enantiomerically pure oxophilic lanthanide complexes as Lewis acid catalysts in the cyclocondensation reaction.[19] Lanthanides bearing chiral ligands had, of course, previously been used as chemical shift reagents. It is often overlooked but perhaps worth remembering that the experiments of Mark Bednarski, wherein [Eu(hfc)$_3$] imparted enantioselectivity in the LACDAC reaction, were among the first examples of decent enantiotopic induction in the metal-catalyzed formation of carbon–carbon bonds (hfc = 3-(heptafluoropropyl(hydroxymethylene)-D-camphorato).

In the next phase we investigated the effects of mounting an enantiomerically pure auxiliary on the diene component. Here, only painfully modest seletivities were realized. However, dramatic diastereomeric excesses were obtained by combining the use of a chiral auxiliary with an enantiomerically pure lanthanide complex.[20] After separation of the diastereomeric products, enantiomerically pure versions of dihydropyrones were available. This strategy was used in the synthesis of L-glucose (**7**)[21] and in the construction of the carbohydrate fragment of avermectin A_{1a} (**8**, Scheme 3).[22] An interesting feature here is that the effects of the catalyst and auxiliary are nonmultiplicative. Indeed, Bednarski's best results were obtained when the enantioselective tendencies of the auxiliary and catalyst components of the "*ee* enrichment package" veered in opposite directions.

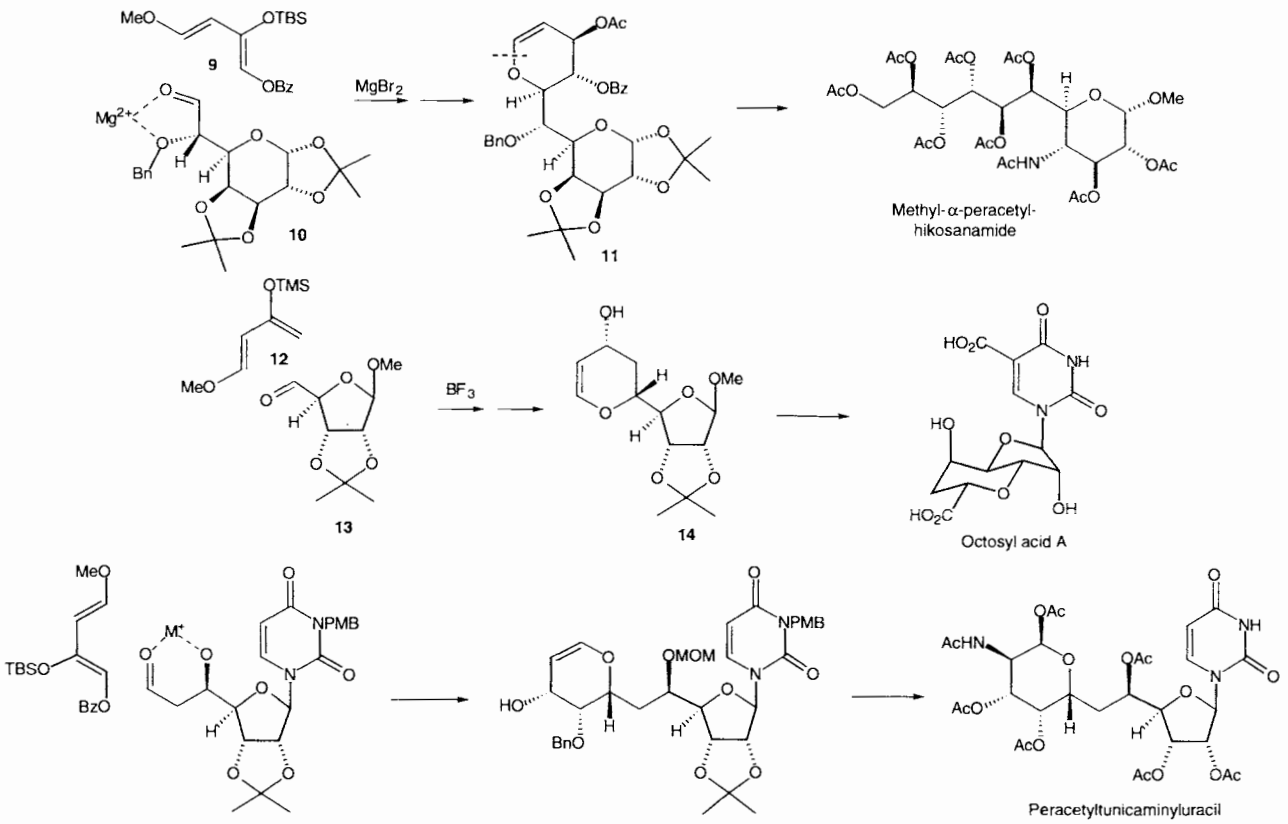


Scheme 3. Enantioselective LACDAC reactions (R^2 = L-8-phenylmenthyl).

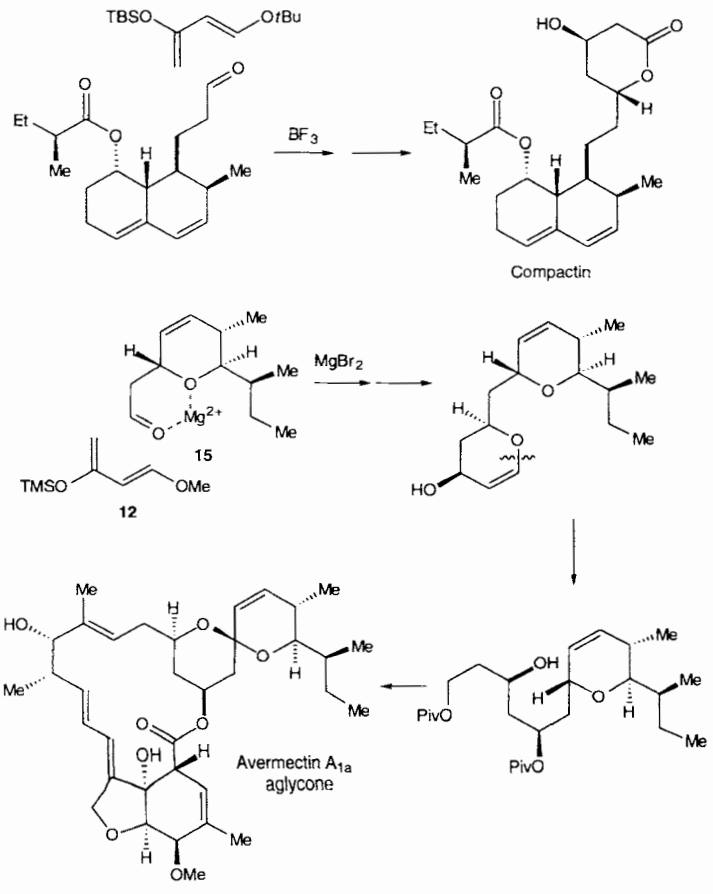
It is well to note that H. Yamamoto and co-workers have pioneered the use of enantiomerically pure BINAP-based Lewis acid catalysts (BINAP = 1,1'-binaphthalene-2,2'-diylbis(diphenylphosphane), which confer high enantioselectivity on the LACDAC reaction.[14, 23] This chemistry, in conjunction with the stereoselective reduction of dihydropyrones by the Luche system ($NaBH_4/CeCl_3$), constitutes an excellent route for the formation of novel enantiomerically pure artificial glycals.

Unlike these methods, in which the de novo induction of chirality in the dihydropyrone was attempted, the third approach started with enantiomerically pure aldehydes. The proximal stereogenic center in these aldehyde heterodienophiles imparted face selectivity to the LACDAC reaction. In this way various complex optically pure glycals were obtained from precursors that were formed in high diastereomeric excesses. This chemistry allowed us to achieve synthetic routes to the higher order monosaccharides[24] including lincosamine,[25] *N*-acetylneuraminic acid,[26] *rac*-3-deoxy-*manno*-2-octulosonic acid (KDO),[26] hikosamine,[27] and octosyl acid A.[28] In some cases (**11** → α-methylhikosanamide and **14** → octosyl acid, Scheme 4) the pyrone substructure served as a temporary locus for establishing configurational relationships which were unveiled upon opening of the ring.

Most of our advances in systems bearing resident chirality were achieved with aldehydes in which the stereogenic centers contain electron-withdrawing groups α to the formyl function (cf. **9** + **10** → **11**; **12** + **13** → **14**, Scheme 4). However, some striking successes were realized even when the resident chirality was more remote from the site of induction. In our syntheses of tunicaminyluracil (Scheme 4)[29] and compactin (Scheme 5)[30]

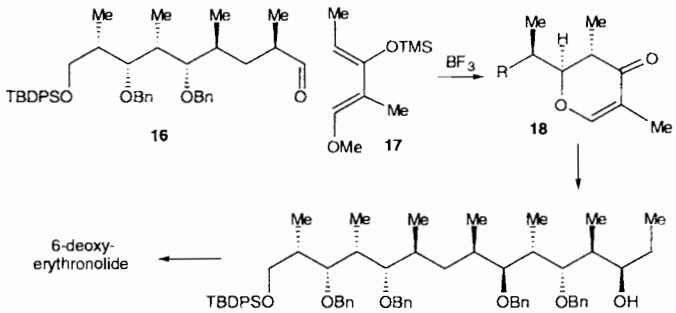


Scheme 4. Applications of the LACDAC reaction to total synthesis.



Scheme 5. Applications of the LACDAC reaction to total synthesis.

significant diastereoselectivities were attained in the absence of an α-directing function. Another important case of strong selectivity, involving resident chirality at some distance from the site of bond formation, arose during the LACDAC reaction of **12** and **15**. This was an important step en route to our total synthesis of the aglycone of avermectin A_{1a} (Scheme 5).[22] Another particularly important demonstration was realized during our synthesis of 6-deoxyerythronolide B (**16** + **17** → **18**, Scheme 6),

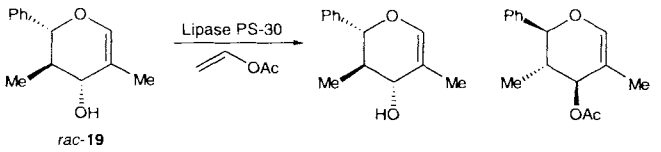


Scheme 6. Application of the LACDAC reaction to the synthesis of 6-deoxyerythronolide.

wherein the stereogenicity seems to be enhanced by stereocenters remote from the aldehyde.[31] It appears probable that new potentials for face selectivity in the LACDAC reaction still remain to be identified and tapped.

As previously mentioned, Sommer had demonstrated that reduction of dihydropyrones with the Luche system ($NaBH_4$/$CeCl_3$) is quite selective for formation of an equatorial hydroxyl

group at C3 and is not significantly complicated by 1,4-addition.[18] This chemistry paved the way for the fourth and most general route to enantiomerically pure artificial glycals.[32, 33] Thus, David Berkowitz found that racemic compounds of the type **19** could be kinetically resolved by enantioselective acetylation exploiting the Wong method (lipase PS-30 and vinyl acetate as the acylating agent, Scheme 7).[34]

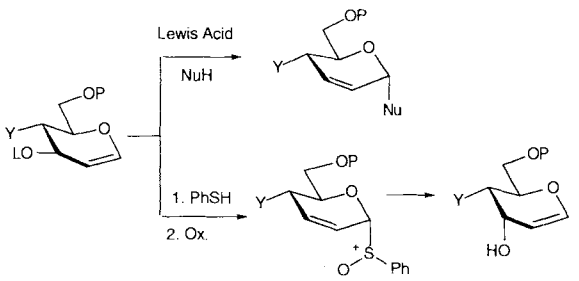


rac-**19**

Scheme 7. Enzymatic resolution of a racemic glycal.

Our enthusiasm for the LACDAC methodology notwithstanding, naturally occurring sugars are still the best source of glycals bearing the usual hexose functionality at C3, C4, and C6. In particular, glycals closely related to D-glucal, D-galactal, and D- or L-fucal are readily accessible from commercially available precursors. It is only when the required functionality of the target glycal is not reasonably accessible from carbohydrates that total synthesis by means of LACDAC chemistry can be superior to partial synthesis.

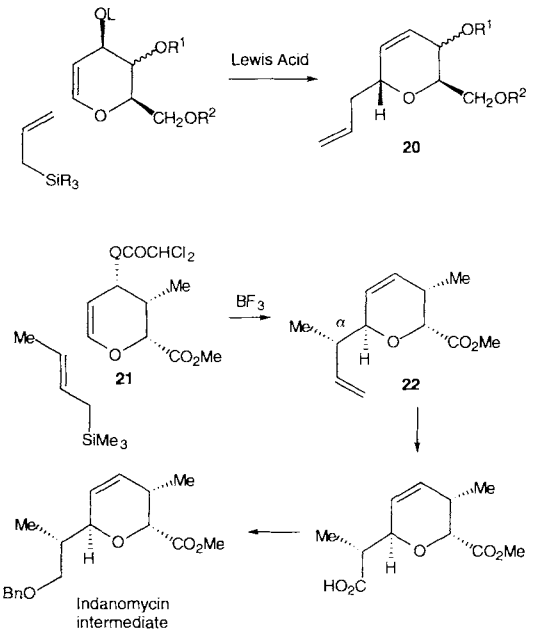
The synthesis of glycals from carbohydrate precursors bearing a axial hydroxyl group at C3 (for example D-allal and D-gulal) can be achieved by reductive elimination of hetero groups at C1 and C2.[35] However, in several important instances the starting hexoses bearing axial hydroxyl groups at C3 were themselves accessible only with extreme difficulty. A route was devised to deal with this type of situation. Our method exploits a form of the Ferrier-type displacement of glycals.[36, 37] As will be seen, the classical Ferrier rearrangement leading to pseudoglycals was valuable to our developing program (Scheme 8).



Scheme 8. Ferrier rearrangements of glycals and utilization of subsequent sulfoxide rearrangements (LO = leaving group, Y = α-OR for allals, Y = β-OR for gulals).

For the case at hand, reaction of a C3 equatorial glycal with thiophenol gives rise to an axial thiophenyl "pseudoglycal," which is converted by oxidation into a C3 axial glycal, presumably by rearrangement of its sulfoxide.[38, 39] While the scope, limitations, and mechanism of this reaction have not been fully defined, it has already found application in our total synthesis of the trisaccharide sector of esperamicin and the aryltetrasaccharide sector of calicheamicin (see Schemes 59 and 60, respectively).

As access to glycals was being significantly improved, and as our syntheses of many of the higher order monosaccharides were being concluded, we began to explore new options for using glycals as synthetic building blocks in the construction of various glyconjugates. Before turning to the main theme of this report, we will review the application of glycals to the stereoselective synthesis of C-glycosides. A key reaction developed can be regarded as a Lewis acid promoted "carbon-Ferrier" process.[40] Thus reactions of allyltrimethylsilane with activated glucal or galactal derivatives afforded C-glycosides bearing axial allyl functions (**20**, Scheme 9).

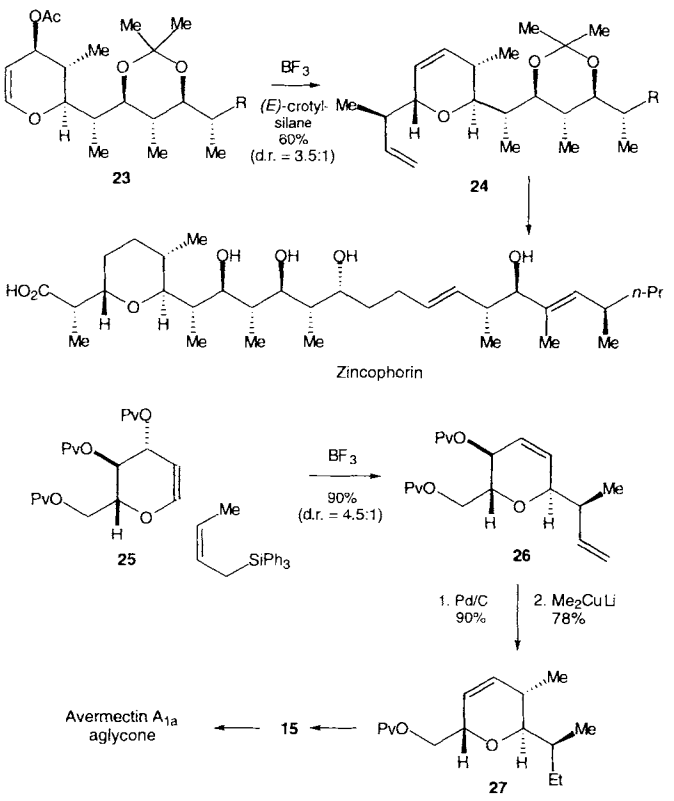


Scheme 9. Allylsilanes employed in the Ferrier rearrangement (OL = leaving group, α-OR^1: gluco series, β-OR^1: galacto series).

Subsequently, it was found that reaction of various glycals with *cis*- and *trans*-crotylsilanes affords methallylated glycosides with good stereoselectivitiy at C_α. The resulting configuration is a function of the geometry of the crotyl group. This capability was used to good effect in our syntheses of indanomycin,[41] zincophorin,[42] and avermectin A_{1a}.[22] Thus, reaction of *trans*-crotylsilane with glycals **21** (Scheme 9) and **23** (Scheme 10) gave rise to **22** and **24** as the major products, respectively. However, triphenyl(*cis*-crotyl)silane reacted with glycal **25** to give rise to **26** (Scheme 10). The latter was reduced then treated with lithium dimethylcuprate to provide **27**, from which we were able to reach the avermectin aglycone via **15**.

3. Glycals in the Synthesis of Oligosaccharides—Some Early Notions

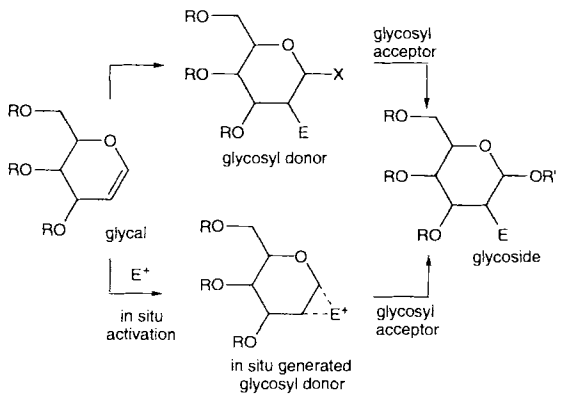
We now turn to the use of glycals in the general construction of oligosaccharides and other glyconjugates. To facilitate discourse, we make reference to a useful terminological distinction that has evolved to describe the two components entering into a glycosylation reaction. Thus, the component that contributes



Scheme 10. The use of the allylsilane Ferrier rearrangement in total synthesis.

the anomeric carbon of the resultant glycoside is described as the glycosyl donor (Scheme 11). The donor reacts with a glycosyl acceptor to establish a glycoside. In the overwhelming majority of glycosylation reactions, the acceptor is a nucleophile that furnishes the oxygen of the resultant glycoside by replacement of a leaving group at the anomeric carbon of the electrophilic glycosyl donor. However, the novel glycosylations of Schmidt,[43] David and Lubineau,[44] Vasella,[45] and Kahne[46] attest to the need to decouple the terms "glycosyl donor" and "glycosyl acceptor" from mechanistic descriptors such as "nucleophile" and "electrophile".

It is also well to distinguish two modalities by which glycals can function as glycosyl donors (Scheme 11). In one motif the glycal is first converted, through a reaction or sequence of reactions, into an isolable or at least identifiable glycosyl donor (for



Scheme 11. Glycals as glycosyl donors.

instance, by epoxidation, azidonitration,[47] or sulfonamidoglycosylation, vide infra). In essence the glycal is a precursor to a structurally defined glycosyl donor. Alternatively, in situ electrophilic activation might mobilize the glycal to function as the donor in the form of a substoichiometric nonisolable intermediate rather than as a defined reaction component.

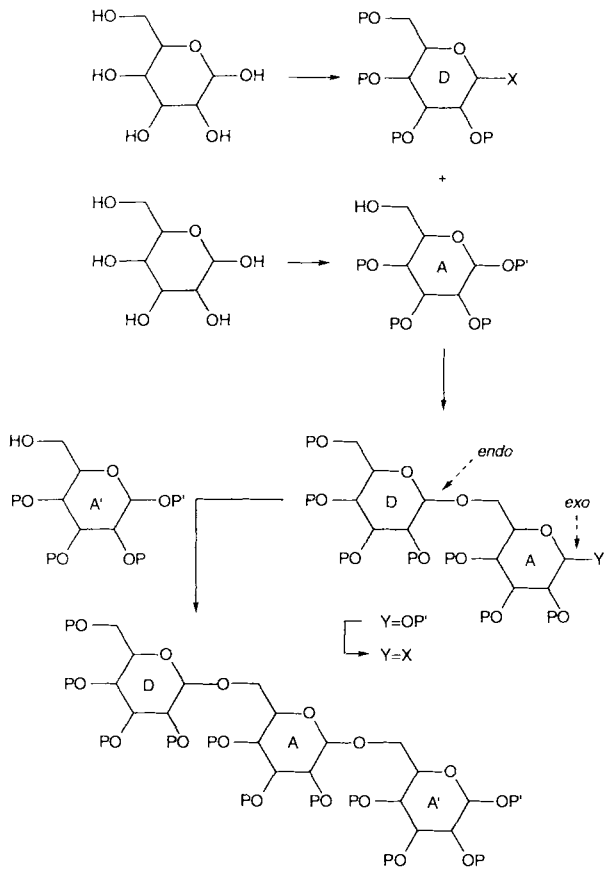
The possibility of utilizing glycals as glycosyl donors in disaccharide synthesis had been demonstrated in the pioneering research of Lemieux[48] and Thiem[49] by halonium-mediated coupling to suitably disposed acceptors. These particular reactions had been shown by Thiem[49] to have a high proclivity for *trans*-diaxial addition and provided a crucial route to α-linked disaccharides bearing an axial 2-iodo function on the nonreducing end. Owing to the difficulty in effecting nucleophilic displacement of the iodine in such systems,[50] the Thiem chemistry has thus far found its most useful application in the synthesis of 2-deoxyglycosides.[49, 51]

Our chemistry, directed toward assembly of glycoconjugates and oligosaccharides, came to be organized around four questions: 1) Could a glycal linkage at the terminating end of a di- or oligosaccharide serve as a useful glycosyl donor (by either of the modalities discussed above)? 2) Could glycals also function as glycosyl acceptors? Surprisingly, prior to our investigation this question had not been examined. 3) Could unnatural glycals available through LACDAC chemistry serve as stereoselective glycosyl donors and acceptors? 4) Would the glycal-based methodology be of sufficient scope to find useful application in the total synthesis of complex multifunctional targets? The translatability of advances from the relatively sheltered world of "synthetic demonstrations" to the often harsh and more demanding realities of the total synthesis of complex targets cannot be assumed as a matter of course!

If glycals could serve both as glycosyl donors and as glycosyl acceptors in a broad range of couplings, a reiterative strategy for the syntheses of complex glycoconjugates, including oligosaccharides, could be contemplated. A potentially important advantage of glycal-based glycosylations was to be the simplification of achieving differentiated hydroxyl protection and presentation. This is readily appreciated by comparison of Schemes 12 and 13.

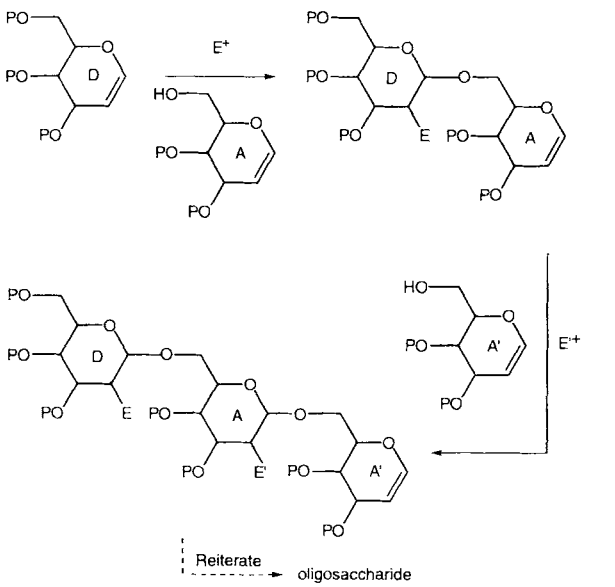
Scheme 12 portrays the classical strategy of glycosylation[52] using fully oxygenated pyranose donors and acceptors. In the very simple case of coupling hexoses D (donor) and A (acceptor) to produce the protected DA disaccharide, several challenges must be overcome. The anomeric hydroxyl function in the eventual donor sugar must be distinguished as a leaving group from the other four hydroxyls. In the eventual acceptor, a particular free hydroxyl (one of five such groups) must be identified for glycosylation, while the anomeric area of the "acceptor" system is properly protected. If one is to proceed toward the DAA′ trisaccharide, the "*exo*" glycoside moiety of the DA disaccharide must be distinguished from its "*endo*" counterpart. With this accomplished, a leaving group (a glycosyl-donating function) is installed on the erstwhile A sugar, and this ensemble must be appended to glycosyl acceptor A′, in which one of five hydroxyls has been identified as the acceptor for the glycosylation.

We contrast this situation with the projected formation of the DAA′ trisaccharide by reiterative coupling of glycals



Scheme 12. Synthesis of a trisaccharide (DAA') by conventional methods. (The stereochemistry of glycosidic linkages is not implied.) A, A' = acceptor unit, D = donor unit, P = protecting group, X = leaving group.

(Scheme 13). The activatable olefinic linkage of uniformly protected glycal D functions as the donor. One of three hydroxyls of acceptor glycal A is to be presented for glycosylation to give the DA disaccharide. After coupling, the glycal linkage of DA is



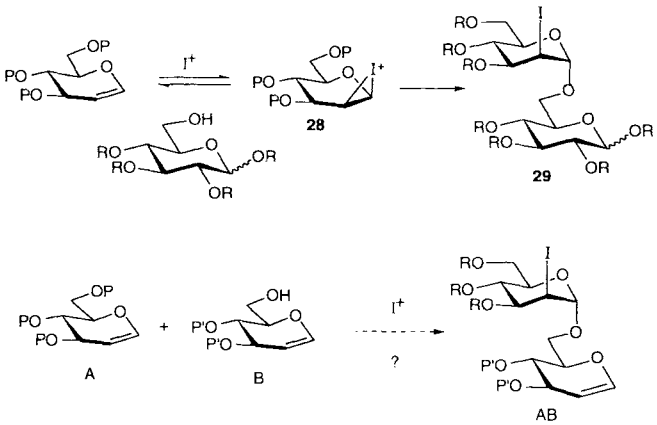
Scheme 13. Synthesis of a trisaccharide (DAA') by a glycal assembly strategy. (The stereochemistry of glycosidic linkages is not implied.) Reiteration of the glycosylation sequence leads to oligosaccharides.

activated (either in situ or in a discrete process) to produce a DA donor vis à vis a new acceptor glycal, A'. In this way, trisaccharide DAA' is obtained. It can be readied for elongation by priming the glycal in the A' sector en route to tetrasaccharide or higher oligomers.

For the reiterative method described in Scheme 13 to be viable and widely applicable, glycals must also function as glycosyl acceptors. Furthermore, for the sorts of extended applications we had begun to contemplate, it would be necessary for glycal linkages at the putative reducing end of larger oligosaccharides to also function as viable donors. For maximum applicability, it would be necessary to fashion a menu of coupling methods in which glycals serve both as donors and as acceptors. To use these concepts in the construction of unnatural glyconjugates and oligosaccharides, unnatural glycals, obtained by synthesis, must be amenable to the methodology being developed.

4. Haloglycosylation

The iodoglycosylation reaction developed by Lemieux[48] and Thiem[49] seemed to represent a particularly difficult challenge to the concurrent use of glycals as acceptors and donors. Classically, iodoglycosylation is carried out with a glycal serving as a donor. The glycal linkage is attacked by an "I^+ equivalent" reagent, for example *N*-iodosuccinimide or *sym*-collidine iodonium perchlorate. In the ordinary case, the presumed substoichiometric intermediate **28** (Scheme 14), arising from the attack of I^+ on the glycal, is attacked by coexisting non-glycal acceptor, in which the reducing end is suitably capped. The stereochemistry of glycosylation is governed by *trans*-diaxial addition and the α-linked disaccharide **29** is produced.

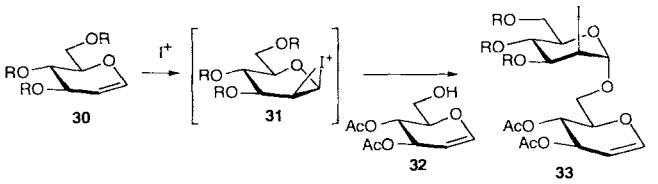


Scheme 14. Iodonium salt mediated coupling of glycals.

We first considered the coupling of two glycals through iodoglycosylation. Such a coupling had apparently not been previously attempted. The problem is controlling the roles of the glycals. Since species **28** is generated as a fleeting intermediate, it seemed very unlikely that the sequential introduction of the two nonidentical glycals (A and B, Scheme 14) and the iodinating agent would control the outcome. Indeed the order of addition of glycals does not determine which one serves as the donor and which as the acceptor en route to the desired AB glycal.

In the case of nonidentical glycals, a particular glycal can be prevented from functioning as a glycosyl acceptor by blocking all of its hydroxyl functions. However, owing to the presence of glycal functionality in the putative acceptor, it can serve as glycosyl donor (see Scheme 14). Therefore, even if one of the two glycals were ineligible as a glycosyl acceptor, significant problems (symmetrical coupling and polymerization) could be encountered in regulating the glycosyl acceptor.

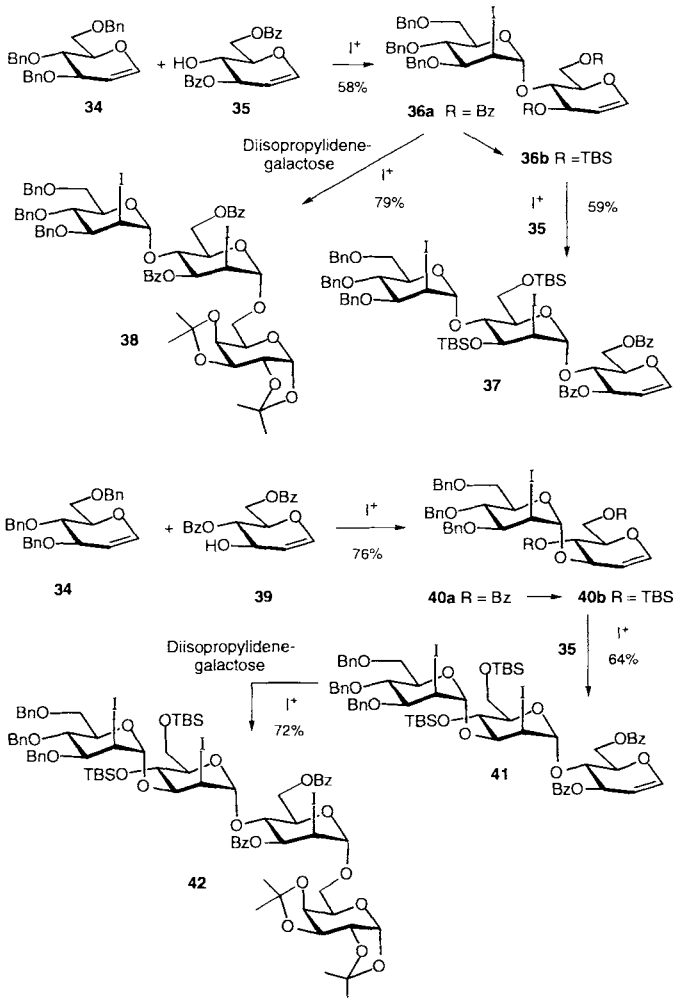
An interesting possible solution presented itself. The thought was that the pattern of protecting groups of the glycal might be used to direct the reaction. While it had long been known that acyl protecting groups lower the reactivity of glycosyl donors,[53a] the idea of exploiting this effect in the coupling of two glycosyl donors had not been conceptualized until the seminal experiments of Fraser-Reid et al.[53b, 54] For the case at hand, consider the two glycals, projected donor **30** and projected acceptor **32** (Scheme 15). The oxygen atoms of **32** are acylated, while those of **30** are alkylated (or silylated). It seemed likely that **30** would be more nucleophilic than **32** towards the iodonium electrophile. Hence, I^+ will attack **30**, thereby generating the mechanistically operative glycosyl donor **31**. Furthermore, as **30** does not have a free hydroxyl group, it cannot act as an acceptor. Glycal **32**, which is equipped with a hydroxyl group, can function as the glycosyl acceptor, giving rise to iodoglycoside **33**. For reduction of this concept to practice, it is necessary that the rate of formation and the effective concentration of **31** be much greater than that of the corresponding species derived from **32** or from the disaccharide product **33.**



Scheme 15. The use of glycal donors and acceptors in iodoglycosylations (R = alkyl).

The realization of this possibility was achieved by Richard Friesen (**34** + **35** → **36**, Scheme 16).[55] To reiterate the strategy, it was necessary to enhance the nucleophilicity of the disaccharide glycal toward I^+ so that it would function as a glycosyl donor to the next acceptor, hydroxy diester **35**. For this purpose, **36a** was converted to **36b**. Indeed, iodinative coupling of **36b** with **35** gave rise to **37**. The analogous coupling of glycal **36a** with the capped (non-glycal) acceptor diisopropylidenegalactose was of interest. This case, which led smoothly to **38**, again demonstrated (as was already well known from earlier studies) that glycals bearing acyl protecting groups are certainly competent donors in iodoglycosylation reactions with non-glycal acceptors. The essence of Friesen's finding was that the otherwise active 1,2-double bond of the diester-protected glycal substrate does not compete with the analogous double bond in the triether for attack by the iodonium species.

We have not yet elucidated in detail the quantitative effects of the glycal substituents on the iodonium-mediated coupling. The most obvious position where the electronic difference between

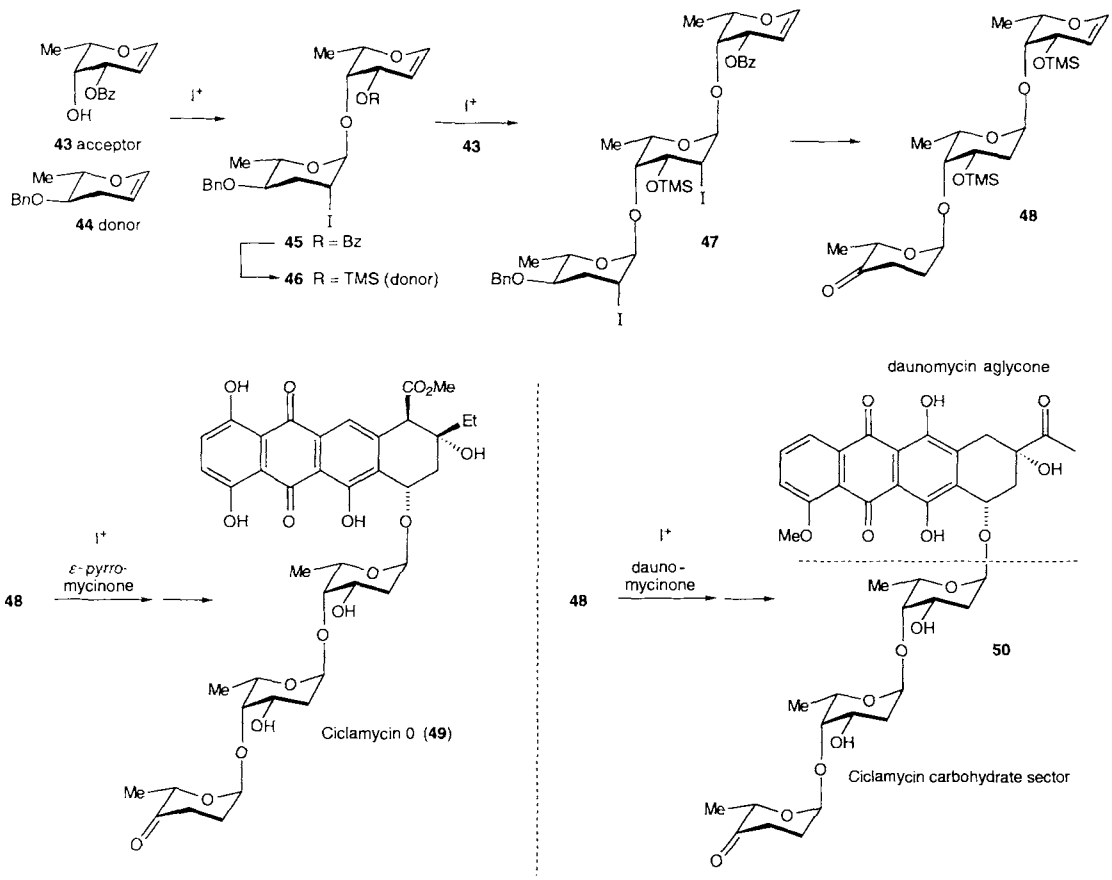


Scheme 16. Polysaccharide assembly employing the iodoglycosylation reaction.

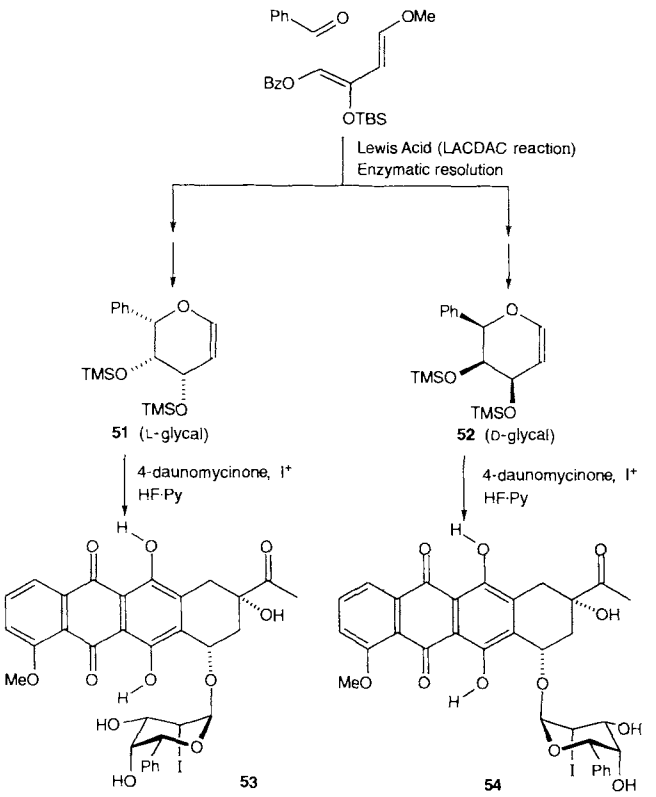
an acyloxy and an alkoxy group would be likely to be decisive would seem to be at the C3 center allylic to the double bond. However, the clean and successful coupling of **34** and **39** to give **40a** (Scheme 16) indicates that even without an acyloxy group at C3, subtle effects can be exploited to bring about an orderly progression leading to glycosylation. The disaccharide thus obtained was subjected to the aforementioned procedure (**40a** → **40b** → **41**) to provide trisaccharide glycal **41**. The trisaccharide **41** was also extended by reaction with diisopropylidenegalactose to give rise to the tetrasaccharide **42**.

We were then in a position to exploit this control of glycal-glycal coupling in a synthesis of ciclamycin 0 (Scheme 17).[56, 57] The key coupling steps to prepare trisaccharide glycal **48** are shown. Fortunately, it was feasible to use **48** to iodoglycosylate the ciclamycin 0 aglycone (ε-pyrromycinone), leading after a few steps, to the natural product itself (**49**). Also, iodonium-mediated coupling of **48** and daunomycinone afforded, after deiodination, the hybrid anthracyclinone **50**.

The synthesis of novel anthracyclines using unnatural glycals **51** and **52** (by the LACDAC reaction) has been developed further (Scheme 18).[33] The handedness of the sugar domain (e.g. in **53** and **54**) has a profound effect on the DNA binding properties of the modified daunomycinone. This experiment provid-



Scheme 17. Synthesis of ciclamicin 0.



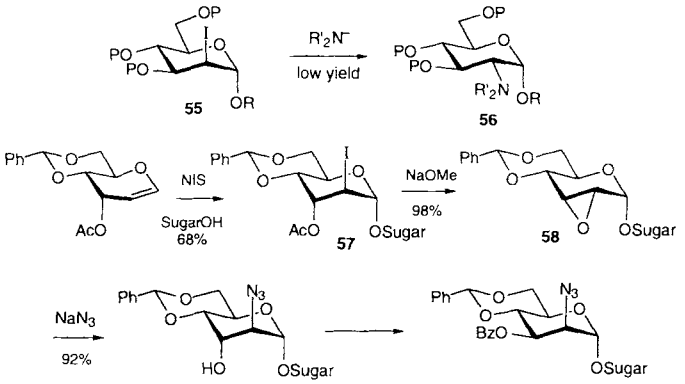
Scheme 18. Enzymatically resolved glycals attached to the daunomycin aglycone. The carbohydrate domain of **53** exhibits the "natural" configuration and is strongly bound to DNA, that of **54** has the opposite configuration and is weakly bound to DNA. Py = pyridine.

ed us with the first sense of the potentially important role of the carbohydrate sector in mediating interactions in the DNA–drug effector region. This critical lesson was not forgotten when we worked in the calicheamicin series (see Section 9).

By combining access to unnatural glycals in optically pure form (in either enantiomeric series), with the capacity for iodoglycosylation, it will be possible to explore in detail the role of the carbohydrate sector in DNA recognition and in the cytotoxicity of the anthracycline antitumor agents. Work in this general direction is now in progress in our laboratory.

5. Azaglycosylation of Glycals

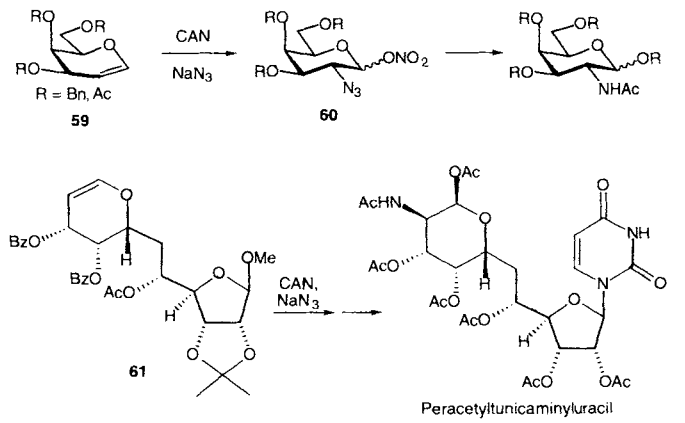
Given the excellent access to natural and unnatural glycals by either total synthesis or partial synthesis (see Section 2), it seemed appropriate to investigate the possibility of their use as precursors to glycosides of 2-acylaminosugars. Of course, in the light of the iodoglycosidation chemistry discussed in Section 4, the most obvious approach to introduce an equatorially disposed nitrogen at C2 would entail displacement of the axial iodo substituent (**55** → **56**, Scheme 19). However, S_N2 reactions at centers with (axial) leaving groups in a 1,2-*anti* relationship to an axial glycoside bond tend to be low yielding. A different approach to this problem for the case of an *N*-acetylmannosamine glycoside, developed in our laboratory, involved exploiting an intramolecular hydroxy nucleophile at C3 (**57** → **58**).[55] While interesting, this method is rather lengthy and, in any case does not address the critical series of glycosides



Scheme 19. Synthesis of an α-mannosamine from a glycal.

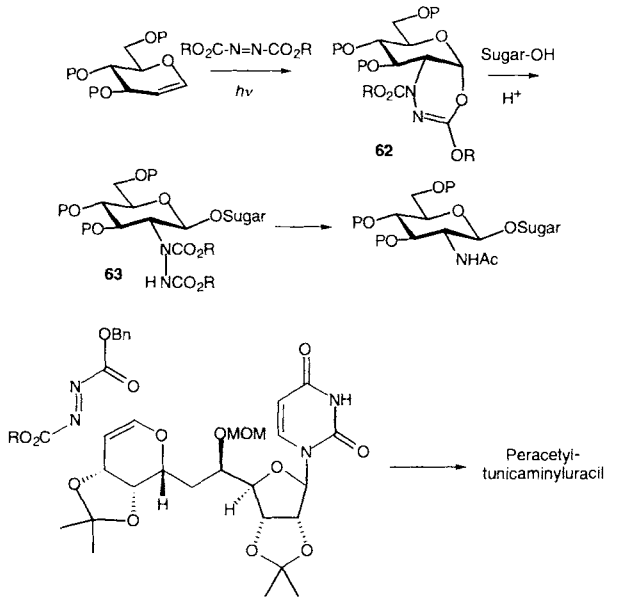
corresponding to *N*-acetylglucosamine. Such glycosides appear, for instance, in asparagine-linked glycoproteins (see Section 10).[58]

Two methods for introducing a nitrogen at C2 via a glycal had been studied earlier by Lemieux. An important first advance employed nitrosochlorination of glycals.[59] While this route constituted significant progress at the time, the methods to convert the oximino products to desired goal structures were not fully optimal as regards to yield and stereoselectivity. Better results were achieved by azidonitration (**59** → **60**, Scheme 20).[47] Indeed, this method led to the synthesis of various goal systems. For instance, in our first synthesis of tunicaminyluracil, we made recourse to azidonitration of glycal **61**, which had been derived from the LACDAC methodology.[29a]



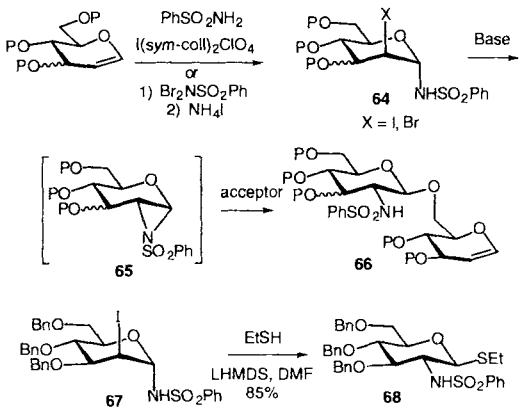
Scheme 20. Azidonitration of glycals. CAN = cerium ammonium nitrate.

A very interesting solution to the problem of converting glycals to such goal systems was developed by Fitzsimmons, Le Blanc, and co-workers.[60] It starts with the cycloaddition of azodicarboxylates with glycals, giving **62** (Scheme 21). Under various forms of acidic mediation, systems such as **62** can function as glycosyl donors (**62** → **63**). Several protocols were developed such that the hydrazodicarboxylate linkage can be reductively cleaved and the resulting products converted to desired 2-acetamido targets. Indeed, we took advantage of this chemistry in our second and more effective synthesis of tunicaminyluracil (Scheme 21).[29b]



Scheme 21. Cycloaddition of azodicarboxylates with glycals.

For reasons that will become clear when we discuss the total synthesis of allosamidin,[61] we sought a new method to reach glycal **66** (Scheme 22). The condition was that stereoelectronic factors rather than issues of local steric hindrance should govern product formation. In other words, application of the method to be developed to either a glucal or an allal bearing a C3 axial hydroxyl, or protected hydroxyl group, should result in the C2-α-acetamido product.



Scheme 22. Iodosulfonamidation of glycals. P = protecting group or sugar, LHMDS = lithium hexamethyldisilazide.

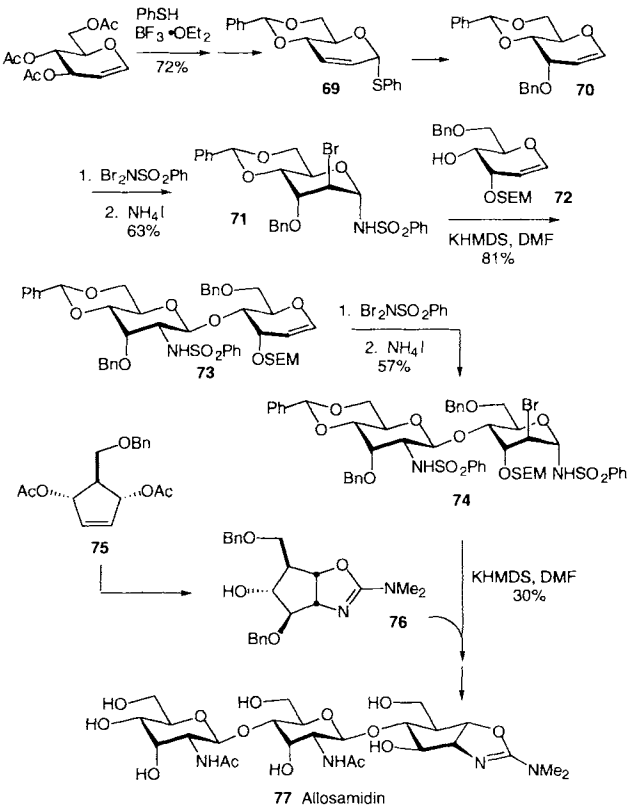
The key reaction developed by David Griffith to deal with this problem was that of sulfonamidoglycosylation.[62] The method, which involves *trans*-diaxial addition of an *N*-halobenzenesulfonamide to a glycal, leads to **64**. Under appropriate conditions, a range of nucleophiles can be used to convert **64** to glycosides of 2-α-benzenesulfonylglycosamine derivatives. The incoming acceptor can be a pyranose with a suitably differentiated hydroxyl group, or it can be a glycal (e.g. **66**) thus allowing for reiteration of the process. Also, the donor can be a di- or oligosaccharide terminating in a glycal linkage to undergo sulfonamidoglycosylation.

While we have not succeeded in properly characterizing the intermediate between the 2β-halo-1α-sulfonamidopyranosides (e.g. **64**), and the product **66**, we have reason to believe that the 1,2-sulfonylaziridine **65** is, in fact, the active glycosylating entity. This moiety functions as a very powerful electrophile, prompting clean β-attack by the nucleophile at the anomeric carbon. Several protocols have been developed for liberating the amino system from its 2-sulfonamide precursor (see Section 10). Furthermore, an iodosulfonamide can be readily converted to the corresponding ethyl thioglycoside (see **67** → **68**, Scheme 22). The latter can subsequently be employed as an azaglycosyl donor to some advantage. This conversion has been proven to be very useful in several important cases where the direct glycosylation of iodosulfoamides fails (see Schemes 53 and 54).

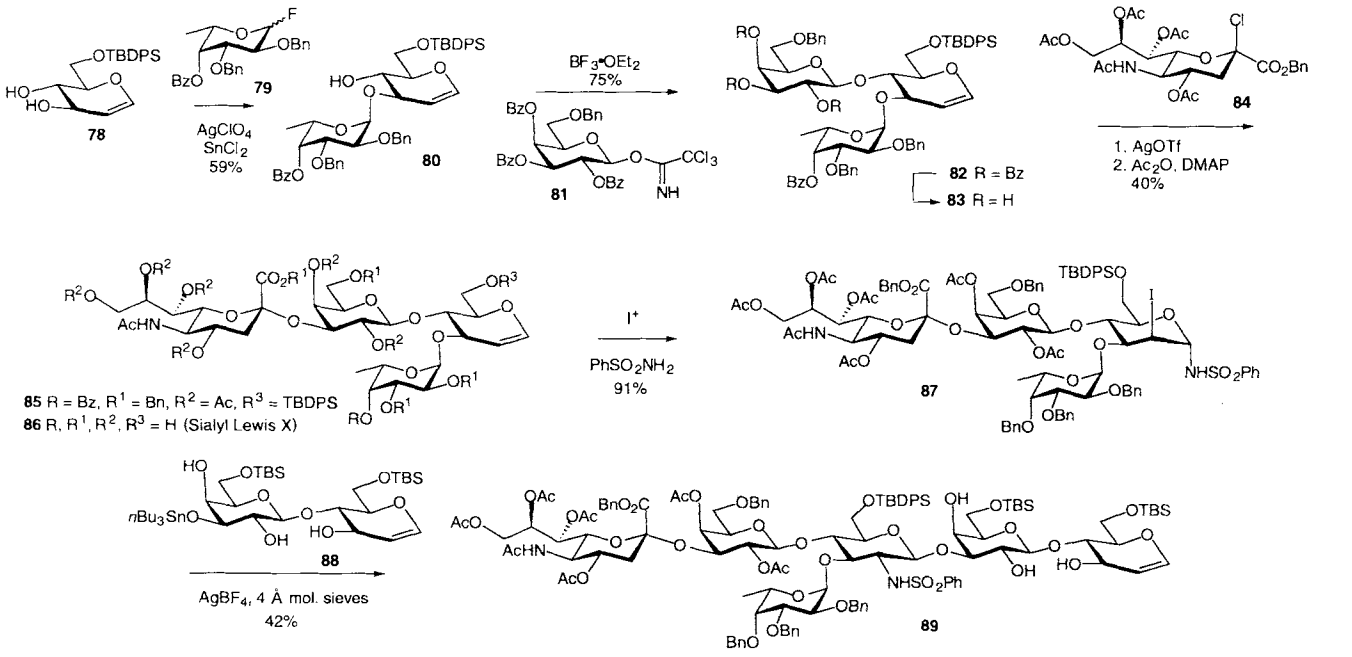
Below we describe three of the early applications of the sulfonamidoglycosylation of glycals. The first application of this new chemistry was in the total synthesis of the very powerful chitinase inhibitor allosamidin.[51] The route to allosamidin exploited sulfonamidoglycosylation at two stages. In the first application, the allal-type glycal **70** was used (Scheme 23). This glycal is available either from allose or, more interestingly, by rearrangement of the α-thiophenyl derivative **69** (in turn available by a sequence starting with the Ferrier transformation of D-glucal triacetate).[36] Bromosulfonamidation of **70** afforded **71**, which was coupled to glycal **72** in the presence of potassium hexamethyldisilazide (KHMDS) to give **73**. The latter then functioned as an azaglycosyl donor. Bromosulfonamidation of **73** afforded **74**. Reaction of **74** with aglycone derivative **76** afforded, after several steps, allosamidin (**77**). Incidentally, the synthesis of **76** was accomplished by enantioselective desymmetrization of the *meso* compound **75**,[64] thus enabling a pleasing route to the natural enantiomer.

A second early application came in the important field of sialyl Le^x glycosides.[64-66] The sialyl Le^x substructure at the nonreducing end of glycoproteins on the cell surface is the key recognition element in E-selectin and P-selectin mediated adhesion.[67] This discovery has spurred interest in the field of sialyl Le^x chemistry.[68] The goals, as we defined them from a combined chemistry–biology perspective, focused on the synthesis of an intermediate that could serve as a launching point to reach various glycosides of sialyl Le^x. Such glycosides could be screened as potential inhibitors of the natural ligand.

Toward this end, we identified sialyl Le^x glycal derivative **85** as a suitable target (Scheme 24). We also hoped to study the



Scheme 23. The synthesis of allosamidin. SEM = trimethylsilylethoxymethyl.



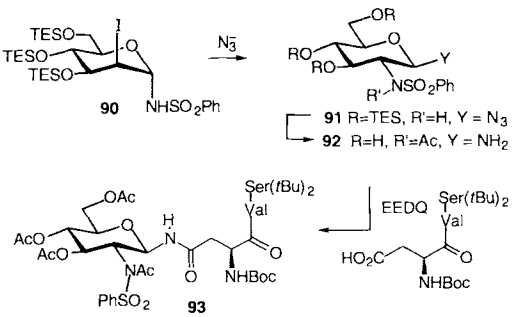
Scheme 24. Synthesis of a sialyl Le^x glycal.

properties of the fully deprotected derived glycal **86** in an ELAM binding assay. Moreover, if the azaglycosylation chemistry described above could be extended to the protected system **85**, we could gain access to a range of more extended oligomers from a late stage in the synthesis. In this way we would obviate the need for a separate lengthy synthesis for each assay candidate.

A key discovery in this regard, first registered by Jacquelyn Gervay and John Peterson, was that glycal **78**, containing silyl protection only at the primary (C6) hydroxyl group, undergoes selective fucosylation with **79** at the allylic alcohol center (C3) (Scheme 24). Conveniently, after fucosylation, the C4 hydroxyl was available to serve as the acceptor toward the galactosyl trichloroacetimidate donor **81**, thus affording Le^x derivative **82** (and, after deprotection, **83**). Sialylation of **83** with the known sialyl donor **84** and acetylation led to protected product **85**, and eventually to the deprotected sialyl Le^x glycal **86**.

Furthermore, **85** underwent iodosulfonamidation to afford **87** (Scheme 24). This compound served as an *N*-sulfonylglucosaminyl donor toward stannyl-activated glycosyl acceptors (e.g. **87** + **88** → **89**). The prospect of exploiting the glycal linkage for still further derivatization is obvious. A further simplification in reaching the Le^x glycal series employing a 1,2-anhydrogalactose derivative has been achieved, and this is described later in this review (see Scheme 50).[56]

The possibility of using a glycal linkage in the construction of glycopeptides by sulfonamidoglycosylation presented itself. In the event, iodosulfonamide **90** was treated with sodium azide to produce, cleanly, the anomeric β-azide **91**, which was converted to **92** (Scheme 25).[69] The anomeric amine was acylated by

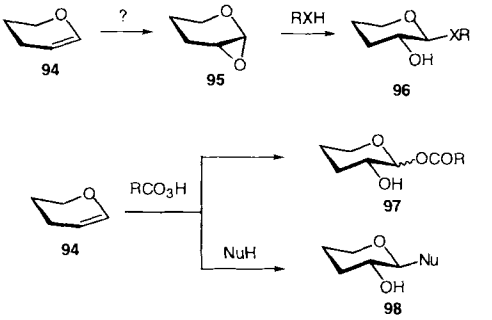


Scheme 25. Synthesis of N-linked glycopeptides from iodosulfonamides. TES = triethylsilyl.

suitable aspartate residues, including that of a tripeptide, using 2-ethoxy-*N*-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ) to afford **93**. At that stage, deprotection of the sulfonamide in the presence of the sensitive glycopeptide bond, even at the level of a monosaccharide tripeptide was problematic. Given our rapidly developing methodology for the synthesis of oligosaccharides terminating in glycals (see Section 6), the ability to convert such compounds to asparagine-linked glycopeptides was seen to constitute an important goal in synthesis of large complex oligosaccharide–peptides. We shall return to the dramatic progress achieved in this area after addressing the matter of solid-phase oligosaccharide synthesis (see Schemes 73 and 74).

6. Applications of 1,2-Anhydrosugars to Glycoside Synthesis

While iodoglycosylation and sulfonamidoglycosylation provide valuable capabilities for the conversion of glycals to various glycosides, there was a need for a very general route to convert glycals into common glycosides of glucose, galactose, and mannose. Ideally the new methodology would embrace both α- and β-glycosides. In search of this type of method, we considered the possibility of directly converting glycals **94** to glycal epoxides **95** (Scheme 26). At the time we undertook this



Scheme 26. Direct epoxidation of glycals.

investigation, two serious impediments to the broad applicability of 1,2-anhydrosugars presented themselves. First, there had been no reported methodology for the direct conversion of a glycal to its 1,2-oxirane derivative. While such systems were well known for 60 years (for example Brigl's anhydride),[70] they had hitherto been prepared only after somewhat lengthy protocols from hexose derivatives. However, given our focus on glycals, we considered the possibility that such epoxides might be readily obtained directly from glycals. Previous attempts to prepare 1,2-anhydro systems from the reactions of various peracids with glycals led, not to the 1,2-oxiranes, but to products of their heterolysis (**97** and **98**).[71] Certainly, the indications were that glycal epoxides were exceedingly sensitive to opening of the oxirane ring by nucleophilic attack at the anomeric carbon.

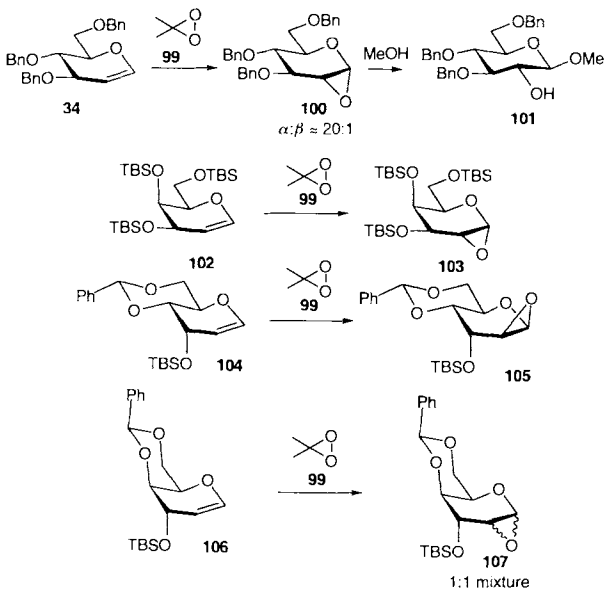
Also, the record of using α-epoxides such as **95** as stereoselective β-glycosylating agents for the formation of compounds such as **96** was none too promising.[72] Previous attempts to prepare disaccharides by employing a 1,2-oxirane as a glycosyl donor with various acceptors often resulted in nonstereoselective glycoside formation, although the application of such a donor in the historic Lemieux construction of sucrose[73] was certainly a milestone accomplishment in synthetic organic chemistry.

Owing to the difficulties associated with synthesizing 1,2-oxiranes, in most of their applications as glycosylating agents the systems contain acyl protecting groups at positions 2, 3 and 4. We wondered whether such resident groups might participate in the ring opening of the epoxide, thereby compromising clean inversion in the glycosidation reaction. In this connection, we were struck by reports from the laboratories of Schuerch and co-workers,[74] wherein perbenzylated 1,2-anhydroglucose underwent stereoregular polymerization under the influence of protic acids. It was recognized that in principle epoxy polymer-

ization of a 1,2-anhydrosugar corresponds to a reiterative glycosidation. If the polymer were indeed being produced in a stereodefined fashion with regular 1β linkages, it seemed that, at least in the polymerization case, the glycosylation reactions were stereospecific.

We therefore focused on several tasks. We sought a general method for the conversion of a glycal to a 1,2-anhydrosugar. The second emphasis was investigating whether glycals, which do not bear potential neighboring group participants of their resident functionalities, might serve as more stereoselective and efficacious donors in the formation of β-glycosides. Furthermore, we would investigate whether suitably differentiated glycals could function as glycosyl acceptors in glycosylations using glycal epoxide donors. We were not unmindful that should such a step be accomplished, the product would itself be a candidate for further elongation through reiteration of the sequence of epoxidation and coupling.

A major advance in our technology was contributed by Randall Halcomb. He found that a variety of glycals react smoothly with 2,2-dimethyldioxirane (**99**, DMDO),[75] prepared as a solution in dichloromethane according to the protocol of Murray.[76] For instance, glucal derivative **34** reacted smoothly with **99** to afford **100** in near-quantitative yield (Scheme 27). Solvolysis of **100** with neat methanol provided methyl glycoside **101**, whose structure was confirmed unequivocally by NMR analysis. Based on configuration of the methanolysis products, we estimate the stereoselectivity of epoxidation to be at least 20:1 in favor of the α-isomer. We emphasize, however, that with resident acetyl protecting groups, the stereoselectivity of epoxidation is much reduced (cf. Scheme 46). Epoxidation of galactal derivative **102** provided **103**.

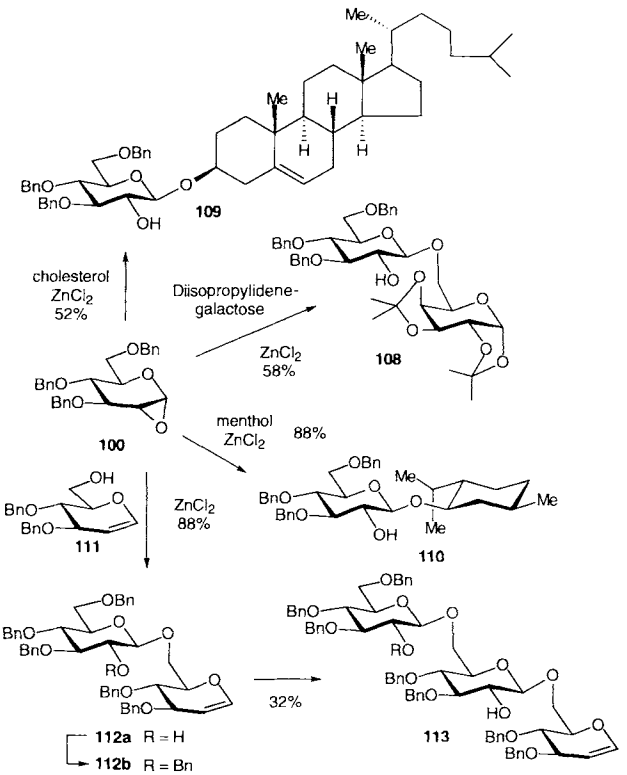


Scheme 27. Epoxidation of glycals by 2,2-dimethyldioxirane (**99**).

It was of interest to probe the allal series. In the event, glycal **104** bearing the axial 3-TBSO function undergoes quite selective epoxidation from its β-face, providing **105**. On the other hand, the gulal derivative **106**, with hindering substituents on both faces of the double bond, gave a 1:1 mixture of epoxides **107**.

Armed with these results, we investigated the glycosyl-donating properties of these epoxides, particularly those derived from glucose and galactose. We soon discovered that the glycosylation of acceptors more complex than methanol and present to a roughly stoichiometric degree was slow and required promotion. A universal promoter has not been discovered. With moderately acidic acceptors such as phenols[77] and indoles[78] (vide infra) best results were obtained under basic conditions. Presumably under these conditions the kinetically active form of the acceptor is the alkoxide. With ordinary alcohol acceptors, including those in which the hydroxyl group is part of a saccharide, the most widely used promoter has been anhydrous zinc chloride. In some special applications (for example the synthesis of gangliosides) stannyl derivatives generated in situ gave the best results (vide infra).

Our earliest results with **100** as a donor are summarized in Scheme 28. Subsequent to these experiments, it was found that this particular oxirane is among the poorest of the donors[79, 80]

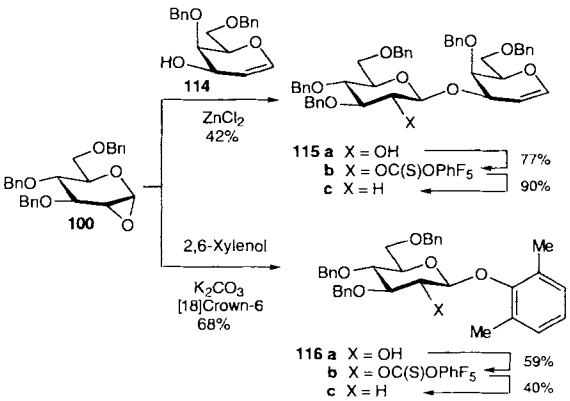


Scheme 28. Coupling of an anhydrosugar with representative acceptors.

and, depending on the case, some α-glycoside is produced. It has since been learned that glycosylation yields can be improved by constraining the C3 and C4 or C4 and C6 oxygen functions into a cyclic motif (see Schemes 37 and 80). Nonetheless, the method had already enabled an easily executed two-step pathway from glucal derivatives to β-glycosides. That these products are fashioned with a uniquely distinguished free hydroxyl group adjacent to the β-glycosidic bond became a crucial element in our synthesis of complex branched saponins and the blood group determinants (vide infra). Also, the finding that the glycosyl acceptor for the glycal epoxide can itself be a glycal (see formation of **112**) had indeed established the basis for a reiterative

strategy for the synthesis of repeating β-glycosides such as **113**. This type of reiterability was in turn a central component of our solid-phase synthesis of oligosaccharides, in which the glycosyl donor is mounted to a solid matrix (see Section 10).

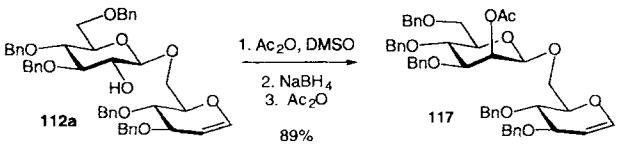
We also demonstrated the applicability of the glycal epoxide method to the synthesis of 2-deoxy-β-glycosides.[77, 81a] Here we took advantage of the uniquely placed free hydroxyl group at C2 as a target for deoxygenation. This was accomplished by free radical reduction of the derived pentafluorophenylthiocarbonate (Scheme 29).[81b] This demonstrates the feasibility of



Scheme 29. Coupling of epoxides with secondary alcohols and phenols as acceptors.

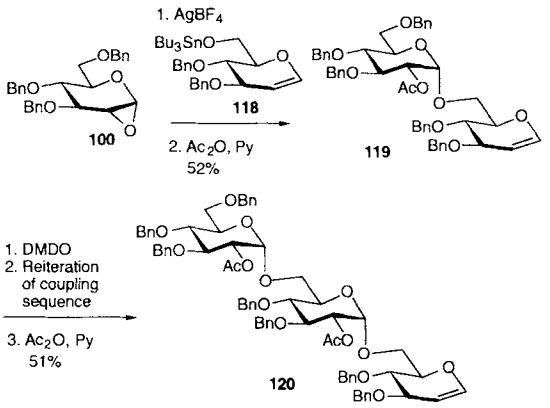
a Barton deoxygenation in the presence of a glycal linkage. Again, the basis for ready reiterability of the sequence is seen in the progression **100** + **114** → **115**. The glycosylation of 2,6-xylenol by donor **100** leading to **116a** set the stage for the synthesis of β-aryloxyglucosides and, following deoxygenation, the corresponding 2-deoxyaryloxyglucosides such as **116c**.

The uniquely generated 2′-hydroxyl group arising from opening of the 1,2-epoxide donor has also been exploited in the synthesis of β-mannosides by means of the Garegg oxidation/reduction protocol (Scheme 30).[82] Thus, oxidation of **112a** with acetic anhydride and DMSO followed by reduction of the unpurified product with $NaBH_4$ and acetylation provided selectively the β-mannoside **117** in 89% yield.



Scheme 30. Creation of β-mannosides by oxidation/reduction.

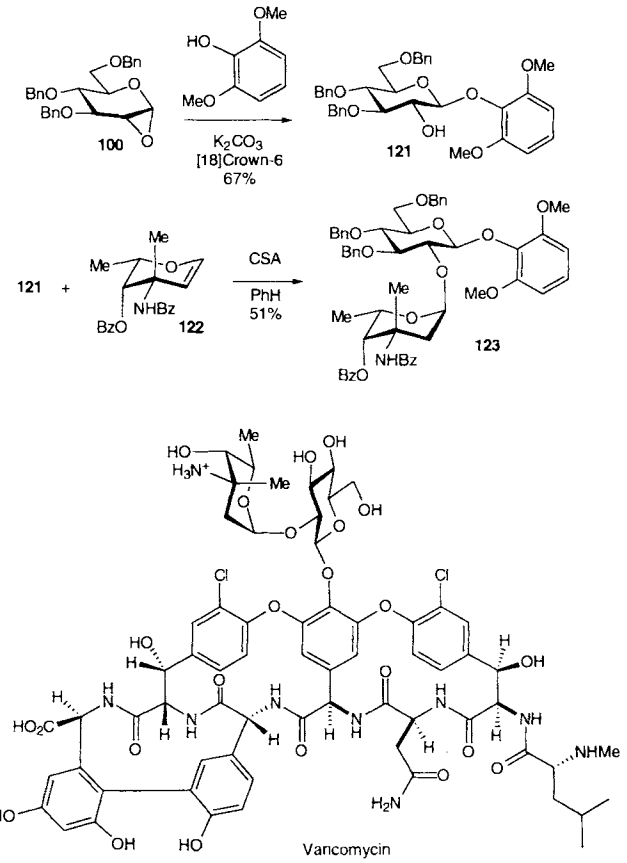
In addition, we have shown that in certain cases an α-glucoside can be obtained directly from a glucal epoxide (Scheme 31).[83] Reaction of the epoxide **100** with stannylether **118**, promoted by $AgBF_4$, followed by acetylation afforded the α-glycoside **119**. The process was readily reiterated to provide the trisaccharide **120**. Reactions with secondary acceptors proceeded in lower yields and exhibited sharply diminished stereoselectivities. This method is presently limited to primary



Scheme 31. Direct formation of α-linked glucose linkages. Py = pyridine, DMDO = dimethyldioxirane (**99**).

hydroxyl acceptors and certainly does not constitute a comprehensive solution to the challenging problem of generating α-glycosides. A solution to the conversion of glucals to α-glucosides was attained by transformation of the α-epoxides to known α-glucoside donors (see Scheme 40).

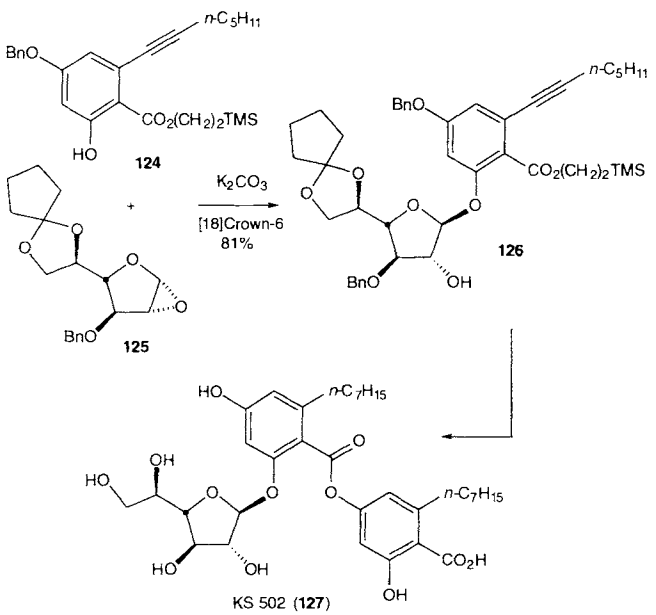
In Scheme 32 we demonstrate the applicability of the glycal epoxide method to the facile construction of a complex 2-branched β-aryl glycoside.[84] Compound **121** was constructed from **100** and 2,6-dimethoxyphenol. In the original approach **123** was to be prepared by iodinative glycosylation of **121** and **122** followed by reduction. As matters transpired the one-step



Scheme 32. Synthesis of a branched β-aryl disaccharide. CSA = 1-(*S*)-(+)-camphorsulfonic acid.

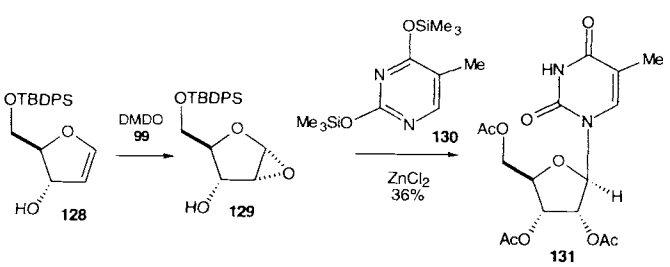
proton-mediated coupling of **121** and **122** proceeded stereospecifically. We note that product **122** encapsulates the salient features of the branched aryl glycoside domain of the potent antibiotic vancomycin.

It was of interest to attempt to extend these ideas to the synthesis of β-glycosides of furanose derivatives. Russel Dushin took up this possibility in the context of the first total synthesis of the calmodulin-dependent phosphodiesterase inhibitor KS 502 (**127**, Scheme 33).[85] The salicylate glycosyl acceptor **124** was assembled in a straightforward way. The furanoid 1,2-glycal epoxide **125** was synthesized from D-talonic acid via the corresponding glycal. Coupling of **124** and **125** gave **126** with high stereoselectivity. The steps from **126** to KS 502 (**127**), while not trivial, proved to be manageable.



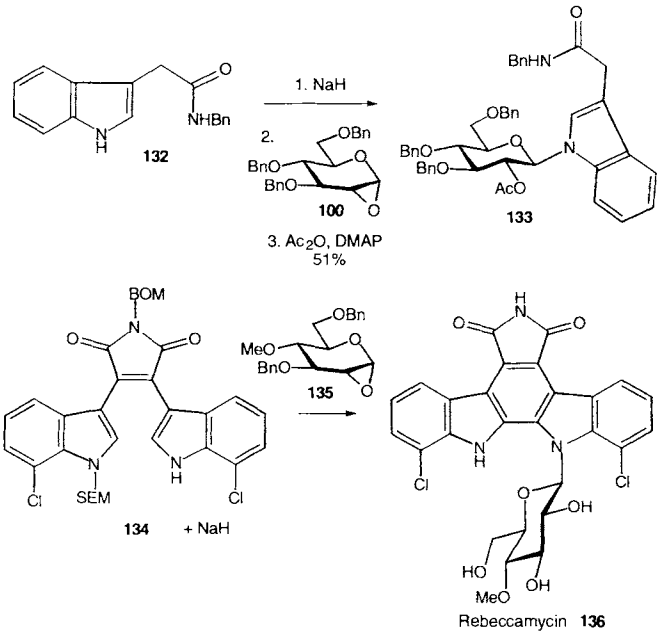
Scheme 33. Synthesis of KS 502 (**127**).

The possibility of utilizing 1,2-oxiranes derived from furanoid epoxides in the synthesis of nucleosides was briefly examined.[86] Interestingly, the furanoid glycal **128** underwent smooth epoxidation with dimethyldioxirane to produce, in 9:1 selectivity, the α-epoxide **129** (Scheme 34). Thus, at least in the furanoid glycal series, "hydroxyl direction" in the epoxidation seems to be operative. Interesting in this regard is the recent report of Murray which demonstrates that in nonpolar solvents the epoxidation of 2-cyclohexen-1-ol with 2,2-dimethyldioxirane does exhibit directivity.[87] In our case, the labile **129** was used as a glycosyl donor in a Vorbrüggen-type reaction[88] with pyrimidine derivative **130** to give stereospecifically **131**. The yield for fashioning of the nucleoside bond is somewhat disappointing and has not yet been improved.



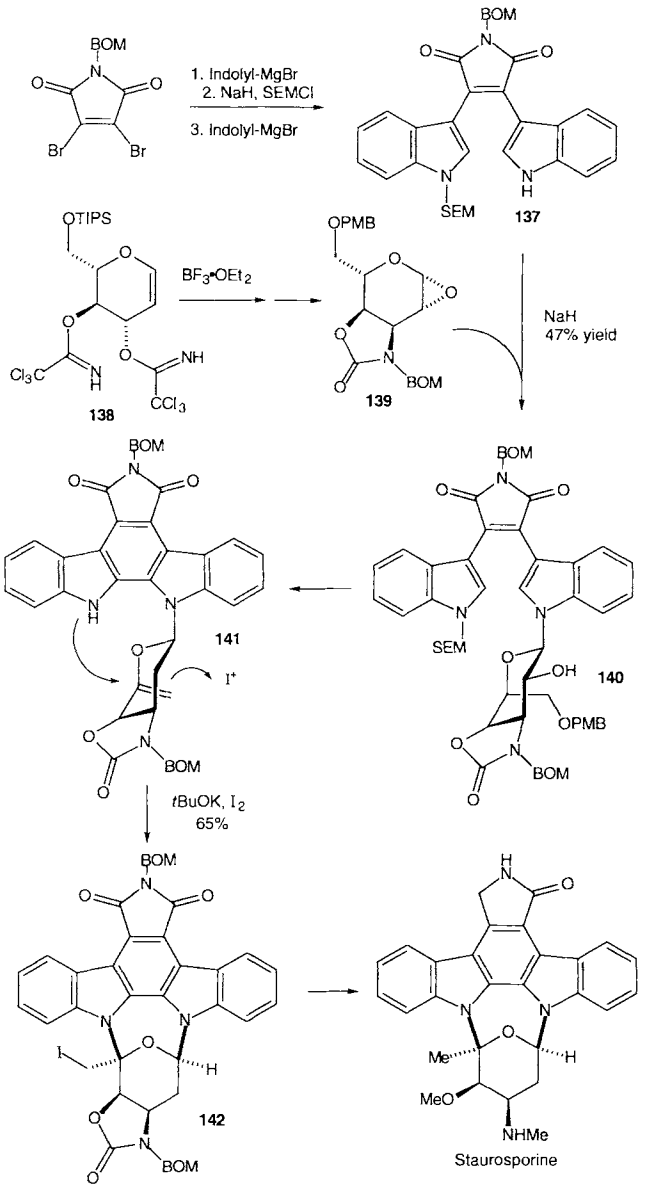
Scheme 34. Synthesis of nucleoside **131** (d.r. = 4:1).

Another area of inquiry was the possibility of using glycal epoxides to glycosylate indoles. Michel Gallant took up this problem. He found that deprotonation of **132** with sodium hydride followed by glycosylation with **100** and acetylation gave rise to model system **133** (Scheme 35).[78] Our motivation in studying the N-glycosylation of indoles with such oxiranes was the potential application of such reactions to the synthesis of natural products. Gallant and J. T. Link first brought our newfound capability to bear in the synthesis of the antitumor agent rebeccamycin (**136**). They took recourse to differentiated secoimide **134** as the acceptor and the differentiated oxirane **135** as the donor.

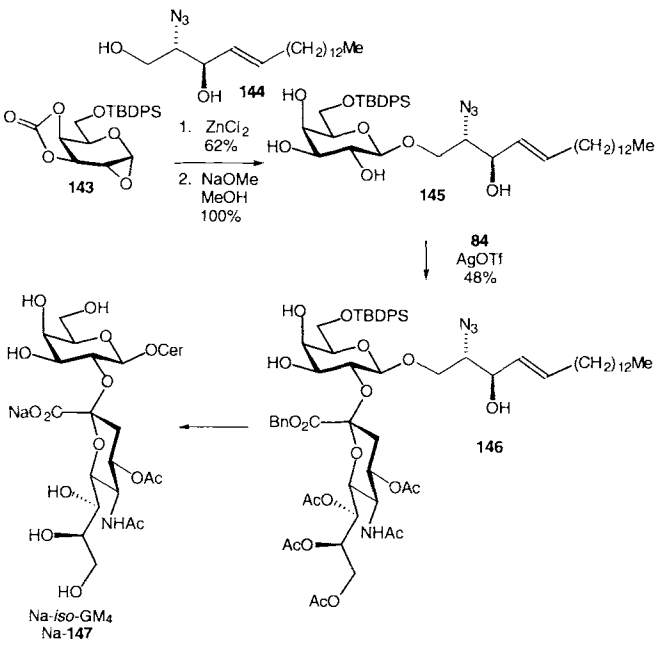


Scheme 35. Indole glycosylation by anhydrosugars. DMAP = 4-dimethylaminopyridine.

A more adventurous, yet related project was apparent: a total synthesis of the premier protein kinase-C inhibitor, staurosporine. Link, Subha Raghavan, and Gallant rose to the challenge. They noted the possibility that staurosporine might be constructed by formation of two indolyl glycoside bonds. Accordingly, the aglycone **137** and glycosylating agent **139** were assembled (Scheme 36).[89, 90] The former was assembled from *N*-benzyloxymethyl 3,4-dibromomalemide and indolylmagnesium bromide through the modular motif previously used in the rebeccamycin effort. The synthesis of the hexose portion started with the mono(triisopropylsilyl) (mono-TIPS) protected L-glucal, which was converted to bis(trichloroacetimidate) **138**. A rather interesting vinylogous Schmidt glycosylation was employed, in which the "leaving group" is the trichloroacetimidate function at C3 "donor" carbon. This led, eventually, to the 1,2-epoxy donor **139**. Coupling of the sodium salt of **137** with



Scheme 36. The synthesis of staurosporine. BOM = benzyloxymethyl.



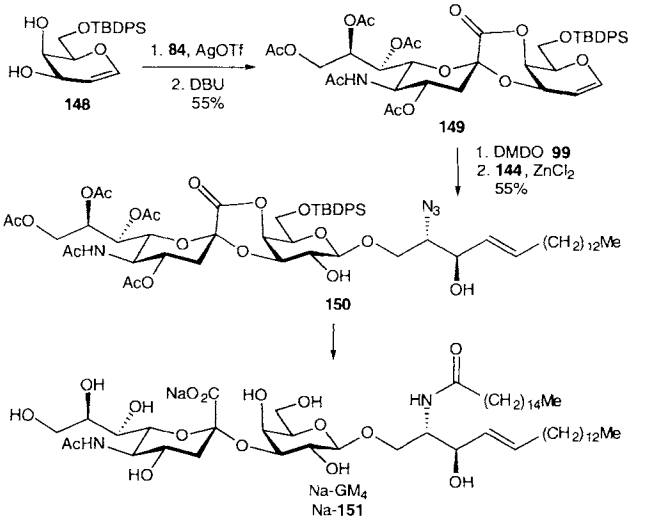
Scheme 37. Synthesis of "iso-GM_4." Cer = ceramidyl.

139 afforded **140**. Several further steps yielded **141**, the potassium salt of which underwent smooth intramolecular "indolo"-N-glycosylation to afford **142** and, after a number of steps, staurosporine was obtained.

The possibility of using glycal epoxides in the construction of gangliosides was examined.[91,92] An important advance in this area relied on the use of galactal-derived epoxide **143** (Scheme 37). Previously, in many cases, galactal-derived epoxides did not function well as stereospecific β-galactoside donors. The use of a cyclic carbonate protecting group engaging the C3 and C4 oxygens (see structure **143**) can lead to favored β-galactosylation in a variety of situations. In the event, reaction of Schmidt construct **144** with **143** resulted in a high degree of selectivity for β-glycoside formation at the primary alcohol. Cleavage of the carbonate gave rise to tetraol **145**. Contrary to many apparent precedents, **145** underwent sialylation at the C2 rather than the C3 hydroxyl group. This surprise was uncovered when the product, later known to be **146**, was carried through several steps to produce **147**, whose spectroscopic properties were inconsistent with formulation as GM_4. We have referred to **147** as "iso-GM_4."

Even today we are unable to explain this remarkable departure from the precedents of Hasegawa et al.[93] and our own experience in the sialyl Le^x series (see Scheme 24, formation of **85**).[66] It must be a special consequence of the presence of the pre-ceramide side chain, although the particular functional group responsible for an apparent activation at C2 cannot be specified.

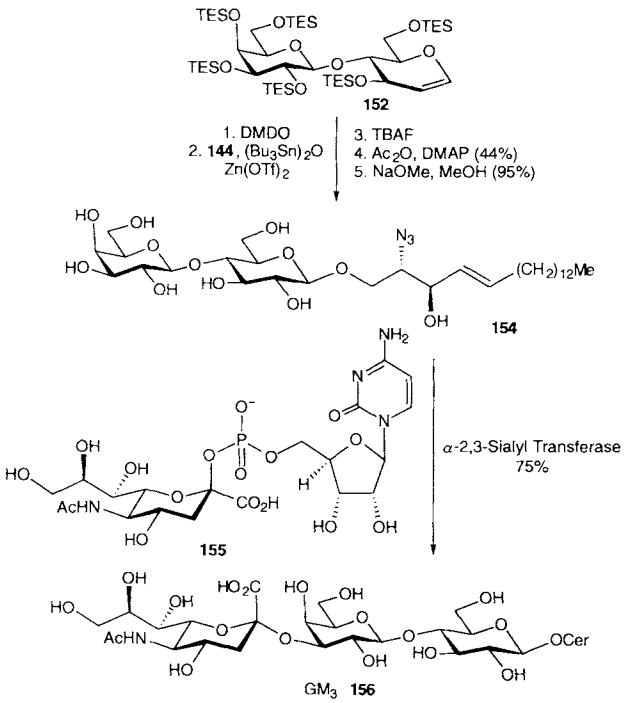
Fortunately, however, a straightforward way of circumventing this difficulty presented itself to Gervay and Peterson. Thus, glycal **148** was directly submitted to sialylation with **84** (Scheme 38). Coupling occurred smoothly at the allylic hydroxyl group, generating a 3-sialylated galactal derivative which, upon treatment with 1,8-diazabicyclo[5.4.0.]undec-7-ene



Scheme 38. Synthesis of GM_4.

(DBU), provided the 3,4-spirolactone, glycal **149**. Epoxidation with dimethyldioxirane and glycosylation with ceramide precursor **144** produced glycoside **150**. This compound was, indeed, converted to the pure sodium salt of GM_4 (**151**).

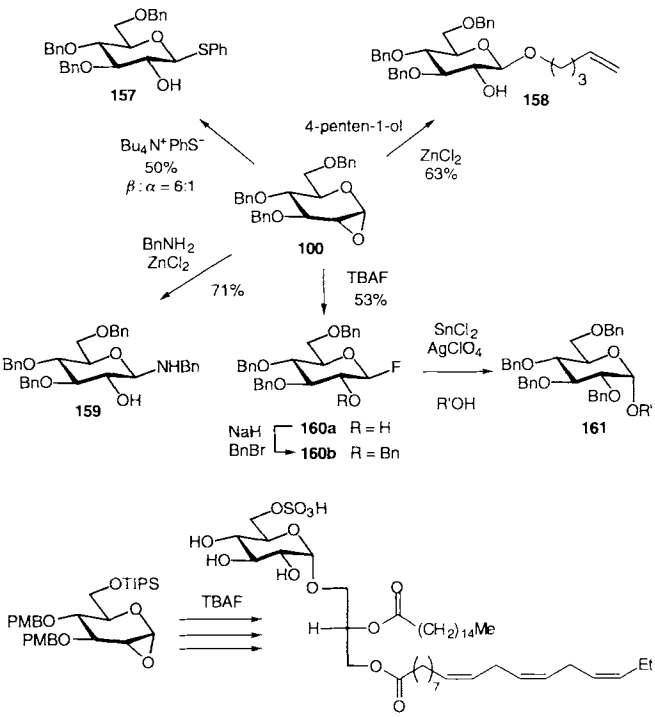
A combination of chemical and biological methods was used by Kevin K. C. Liu in a particularly straightforward synthesis of the important ganglioside GM_3 (**156**).[91] Thus, lactal was uniformly protected with triethylsilyl groups to produce **152** (Scheme 39). The latter underwent epoxidation and coupling



Scheme 39. Synthesis of GM_3.

with the stannylated version of the Schmidt diol **144**, followed by desilylation to produce, in high yield and high specificity, compound **154**. This compound responded to enzymatic sialylation with cytidine monophosphate (CMP) sialic acid (**155**) under mediation by a 2,3-sialyl transferase. After total deprotection, GM_3 (**156**) was in hand. Though cofactors were not regenerated in our experiments, this chemoenzymatic approach provides the most direct route to GM_3.

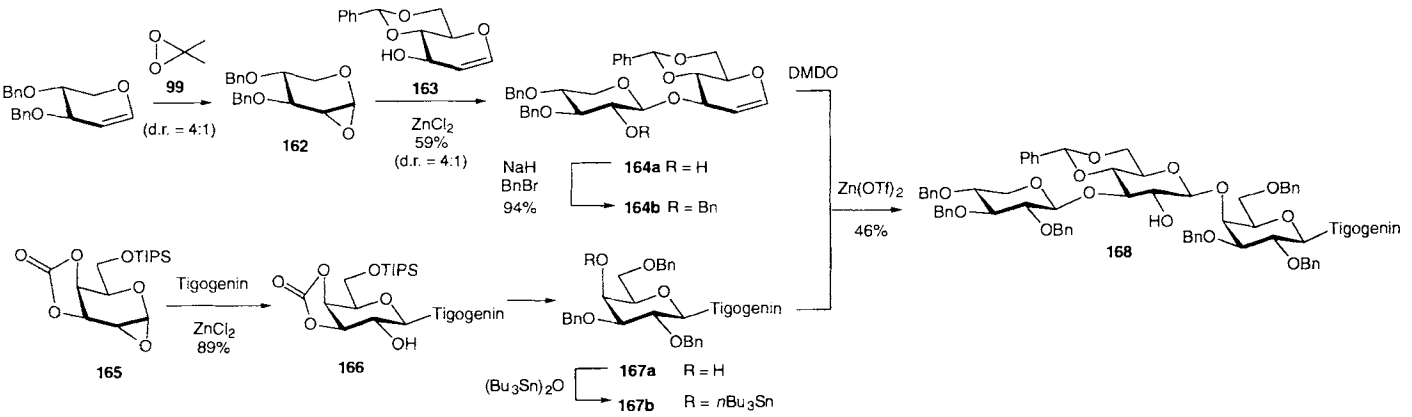
Thus far we have focused on the use of glycal epoxides in the synthesis of β-glycosides. It is also possible to convert such epoxides to other glycosylating agents (Scheme 40).[94] For instance, Dana Gordon found that compound **100** could be converted to the thiophenyl glycoside **157**, the pentenyl glycoside **158**, the benzylaminoglucoside **159**, and fluoroglycoside **160**. Compound **160a**, upon benzylation of the single free hydroxyl group at C2, gave rise to **160b**, which served as a glycosyl donor in a conventional Mukaiyama reaction[95] to produce α-glycoside **161**. The route from glycals to α-glycosides found important application in Gordon's synthesis of the cyanobacterial sulfolipid, a compound alleged to have anti-HIV activity (Scheme 40).[96] Still another application arose during our synthesis of the carbohydrate section of acarbose.[97]



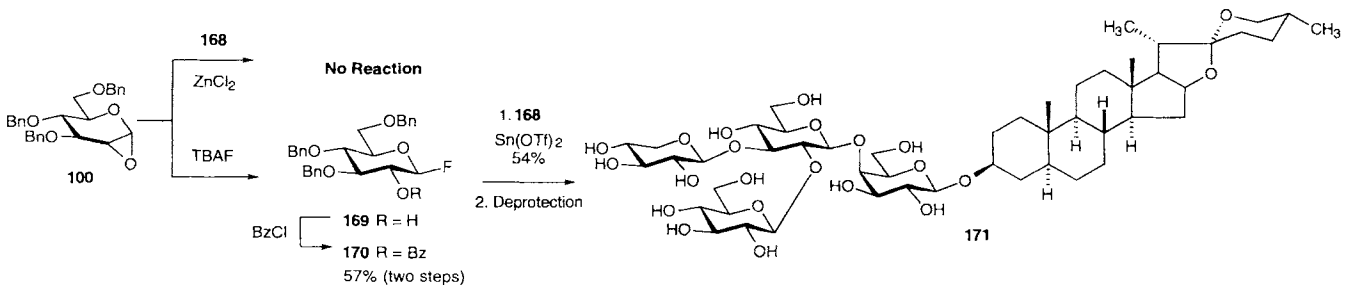
Scheme 40. Conversion of anhydrosugars to other donors, and synthesis of a cyanobacterial sulfolipid.

At this stage we could perceive the emergence of a comprehensive strategy for oligosaccharide construction based on glycal acceptors and glycal-derived donors. We began to field-test the concepts of glycal assembly in the context of specific biologically active and important goal systems. It is almost indisputable that the "combat worthiness" of new concepts in synthesis and new synthetic methodology are best evaluated in the context of multifaceted target structures (for example natural products), where unanticipated difficulties are apt to arise.

An advance in the development of the logic of glycal assembly was achieved in our synthesis of the complex saponin, desgalactotigonin (Schemes 41 and 42).[98, 99] John Randolph took note of the collection of β-glycoside linkages in this target. In particular, we focused on the branched glucose ring in the carbohydrate sector, which is β-linked to the axial hydroxyl group at C4 of a galactose. Particularly intriguing is the branching of this glucose: its C2-hydroxyl is β-linked to another glucose, while at C3 it is β-linked to a xylose. The introduction of this central glucose ring in the form of glycal derivative **163** brought forth major simplifications in protecting group strategy. The free hydroxyl at C3 served as an acceptor toward the xylal-derived epoxide **162** to afford, after benzylation, **164b**. The acceptor for coupling to this donor was fashioned from galactal cyclic carbonate derivative **165**. Epoxidation of **165** followed by coupling to the tigogenin aglycone afforded **166**. Once again this type of epoxide had served us very well as a β-galactosylating agent (cf. **143** in Scheme 37). Several steps were required on the resultant glycoside: 1) cleavage of the cyclic carbonate, 2) engagement of the 4- and 6-hydroxyls in a benzylidene protecting group, 3) benzylation at C2, 4) cleavage of the benzylidene linkage, and 5) rebenzylation at C6 and stannylation at C4 to produce acceptor **167b**. Coupling of **167b** with the epoxide of **164b** under



Scheme 41. Synthesis of desgalactotigonin (part 1).



Scheme 42. Synthesis of desgalactotigonin (part 2).

mediation by zinc triflate afforded, albeit in only 46% yield, the steroidal trisaccharide **168**. The glycal epoxide coupling method had targeted a unique hydroxyl group at C2 of the central glucose for branching.

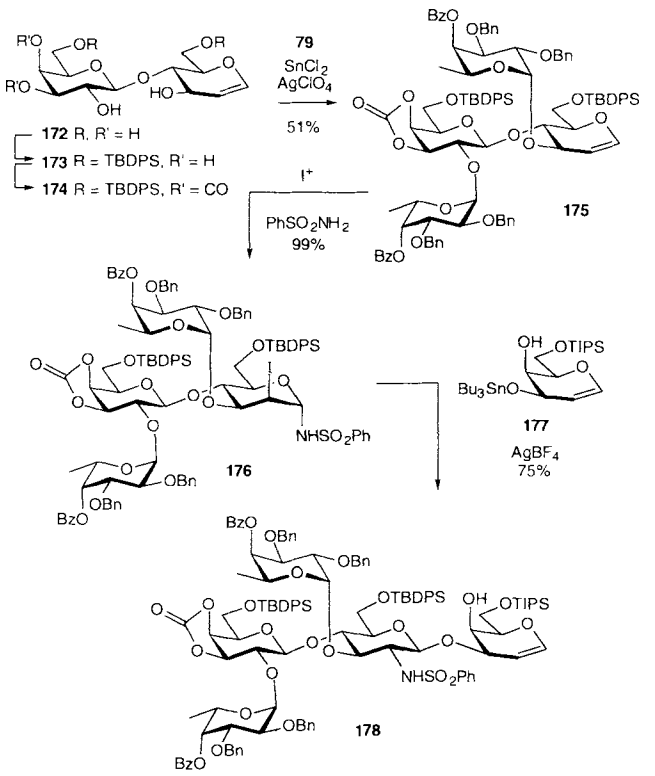
At this stage, however, the free hydroxyl group in **168**, flanked as it was by glycosidic bonds at C1 and C3, did not lend itself to glycosylation with epoxide donors (cf. **100**, Scheme 42). However, we were readily able to fashion a competent donor from **100**. Thus, fluoridolysis[94] afforded **169**, which was converted to its benzoate **170**. The latter functioned with apparent α-face participation to heavily favor β-glycoside formation. Indeed, coupling of **170** with **168** was smoothly accomplished, and was followed by deprotection to provide desgalactotigonin (**171**).

In summary, the logic of glycal assembly had allowed for a high degree of convergence in assembling the complex branched target system. Glycal epoxide opening had been used to expose a unique hydroxyl group to function as a glycoside acceptor (see **169**) and to install a participating neighboring group in a regiospecific fashion. The participating group could be used to direct a fluoroglycosyl donor toward β-glycoside formation (en route to **171**).

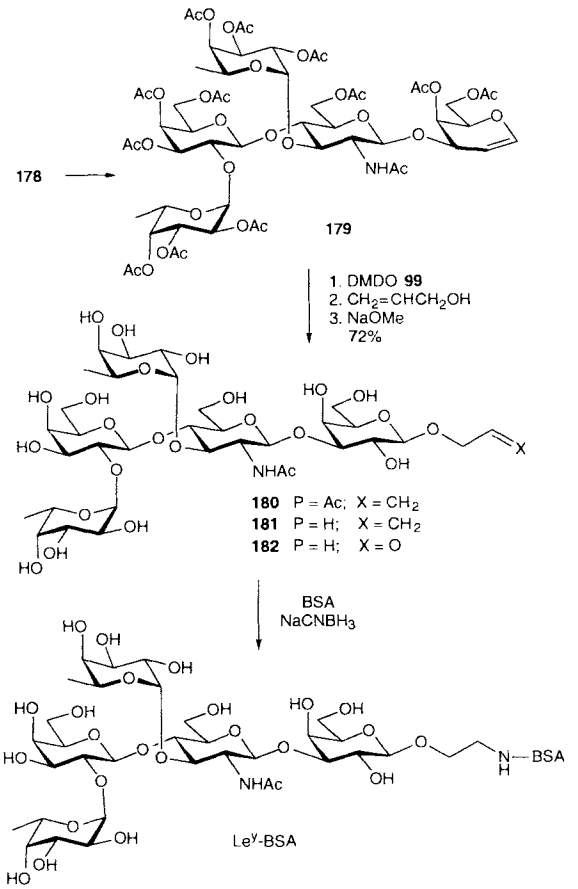
7. Lewis Determinants, Blood Group Determinants, and Tumor Antigens

The grounds seemed to be sufficiently secure to apply the glycal assembly logic to the synthesis of Lewis and blood group determinants. In so doing we would be drawing from glycal epoxides and halosulfonamides in the same synthesis. The glycal epoxide methodology would be used to install β-glycosidic linkages and the azaglycosylation methodology would be used to incorporate the *N*-acetyl glucosamine substructure. John Randolph and Victor Behar took up this problem in earnest. In the synthesis of the first target, the Le^y determinant,[100,101] the objective was not only to prepare the carbohydrate sector of the determinant, but also to conjugate it to a carrier protein such that it would more closely approximate the realities in biological systems. The Le^y determinant was of particular interest to us because it had been previously identified as an important epitope for eliciting antibodies against colon and liver adenocarcinoma cell lines.[102] It has recently been implicated as a marker in metastatic prostate cancer.[103] We hoped to simulate this capacity with fully synthetically derived antigen. For this purpose it would be necessary to conjugate this synthetic product to a carrier of the type used to stimulate immune response. To preserve the integrity of the core epitope sector, it would be insulated from the carrier through a spacer domain.

Inspection of the Le^y structure points toward the possibility of building from a central lactose core for this purpose. Given our preference for exploring the chemistry of glycals, lactal (**172**) was identified as the lactose equivalent (Scheme 43). The two primary hydroxyl groups were silylated to produce the bis-TBDPS derivative **173** (TBDPS = *tert*-butyldiphenylsilyl). At this point we took advantage of the *cis* relationship of C3′ and C4′ of **173** by engaging these hydroxyl substituents in the form of cyclic carbonate **174**. Thus, the required two hydroxyl groups at C3 and C2′ of the galactose moiety were readily designated in two steps to function as glycosyl acceptor sites. Fluorosugar **79** was employed as the glycosyl donor. It bears a nonparticipatory benzyl ether at C2 and a potentially participating benzoate



Scheme 43. Synthesis of a Le^y glycal.



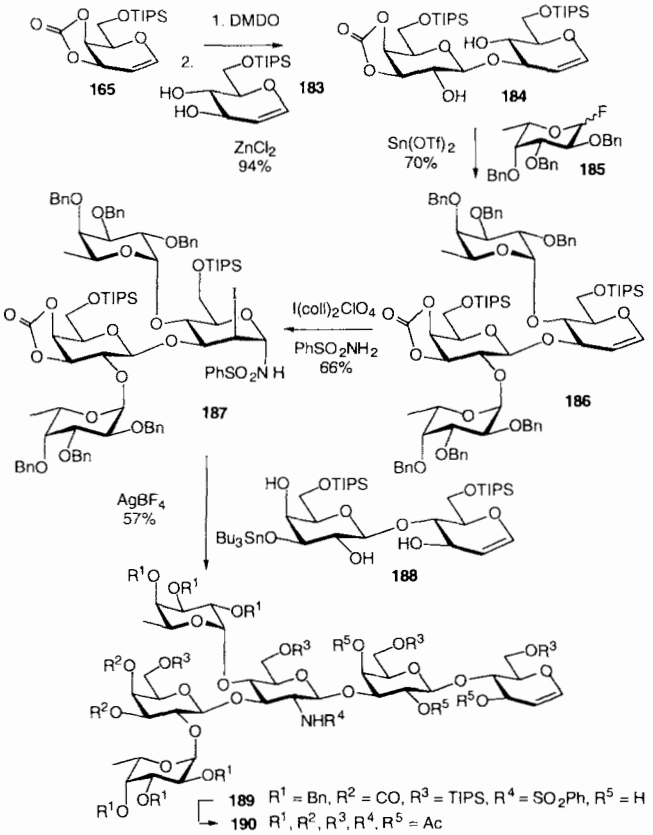
Scheme 44. Conjugation of Le^y to a protein carrier.

at C4. In the event, treatment of **174** with **79** under suitable conditions results in clean incorporation of two fucose residues with formation of compound **175**. The glycal double bond was then subjected to iodosulfonamidation under the usual conditions to give rise to **176**, which functioned as a masked azoglycosyl donor. The critical coupling of **176** with the mono-TIPS stannylated galactal derivative **177** gave the bisfucosylated compound **178** in 75% yield. Thus the tetrasaccharide determinant was efficiently constructed such that it still contained an exploitable double bond.

Before we proceeded to the final glycosylation, it was strategically useful to convert the benzenesulfonamide function to an acetamido group as well as to regularize all of the protecting groups as acetates (Scheme 44). This goal was accomplished and led to compound **179**, which was subjected to the action of dimethyldioxirane. The epoxide thus produced functioned as a competent donor with allyl alcohol as the acceptor to provide **180**. Removal of all acetate groups, affording **181**, was accomplished by the action of sodium methoxide. Thus the logic of glycal assembly combined with the powerful technologies of azaglycosylation and of glycosylation via glycal-derived 1,2-anhydrosugars allowed for a highly concise and convergent synthesis of **181**. We were then ready for the conjugation phase and relied on the reductive amination method developed Bernstein and Hall in a much simpler context.[104] In practice, the double bond of the allyl group of **181** was cleaved to give the uncharacterized aldehyde **182**. The latter was conjugated to bovine serum albumin (BSA) through the action of sodium cyanoborohydride. Amino acid and carbohydrate analysis of the pseudo-glycoprotein indicated the incorporation of approximately 15 pentasaccharide units into the 38 lysine residues theoretically available. Immunization studies of conjugates of **182** in mice are currently in progress, and the earliest results are promising.

It is possible that oligosaccharide domains will someday be synthesized from non-carbohydrate building blocks. At the present time, however, this prospect is virtually unimaginable. Therefore, the basic challenges of synthetic design lie in selecting the molecular components of the synthesis in such a fashion that their assembly in the desired sense is least complicated. Conciseness is the goal in the orchestration of the diverse functionalities and in chemically identifying those loci destined to serve as the glycosyl acceptors and donors in the coupling steps. In both the syntheses of **171** and **181** the use of glycals toward these goals had been demonstrated.

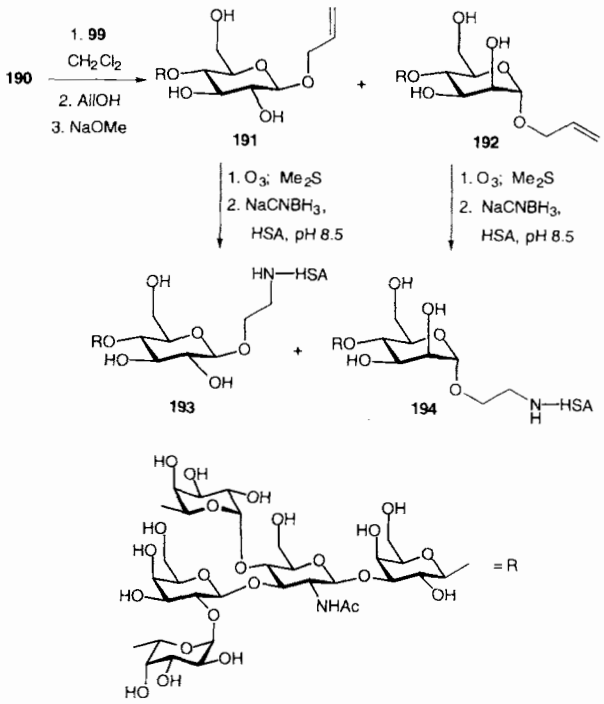
John Randolph accomplished the synthesis of the Le^b determinant, again in bioconjugatable form.[101, 105] This determinant is more challenging from the synthetic standpoint than the Le^y target, because lactal (**172**), trivially available from lactose, cannot serve as a starting material. We proceeded as follows: the TIPS galactal derivative **165** was converted to its epoxide through the agency of dimethyldioxirane (Scheme 45). The acceptor **183** was readily fashioned from glucal itself. Here we could take advantage of another enormous simplification of the glycal method. Coupling of **183** with the epoxide of **165** occurred exclusively at the C3 hydroxyl of **183** to provide **184**, in which the particular hydroxyls to be fucosylated (at C4 of the glucose and C2′ of the galactose) have been smoothly distin-



Scheme 45. Synthesis of a Le^b glycal.

guished from other functions. Twofold fucosylation did, indeed, occur using the readily available donor **185** and the tetrasaccharide glycal **186** was efficiently obtained. Compound **186** was prepared for azaglycosylation through iodobenzenesulfonamidation to afford **187**. The latter reacted with lactal derivative **188**, which was prepared from lactal (**172**) in two steps. Coupling of **188** and **187** provided **189**. Thus, the critical tetrasaccharide recognition domain of the Le^b determinant had been assembled in a highly convergent fashion and insulated, through a disaccharide spacer, from the implement to be used in bioconjugation. For this purpose, all silyl groups were removed through the action of tetra-*n*-butylammonium fluoride (TBAF) and the benzyl groups were cleaved by sodium in ammonia. The crude product was peracetylated to give **190**, which was converted to its 1,2-anhydrosugar derivative, as a mixture of isomers, and thence to the corresponding allyl glycosides (Scheme 46). This serious breakdown in the stereochemistry of epoxidation arose from the presence of a resident acetate protecting group in the terminal glucose residue. As described earlier (see Scheme 26), triacetyl glucal is also a poor substrate for stereoselective epoxidation. Since conjugation occurs at some distance from the epitope domain, it is not clear that the stereochemistry of the glycoside bond leading to the carrier domain is of consequence at the biological level.

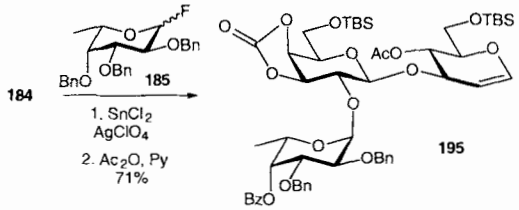
Cleavage of all acetate groups gave rise to **191** and **192**. These oligosaccharides were separately ozonolized and the resultant glycolic aldehyde products were reductively coupled to human serum albumin (HSA) by the Bernstein–Hall protocol[104] to provide adducts **193** and **194**.



Scheme 46. Conjugation of Le^b to a carrier protein. All = allyl.

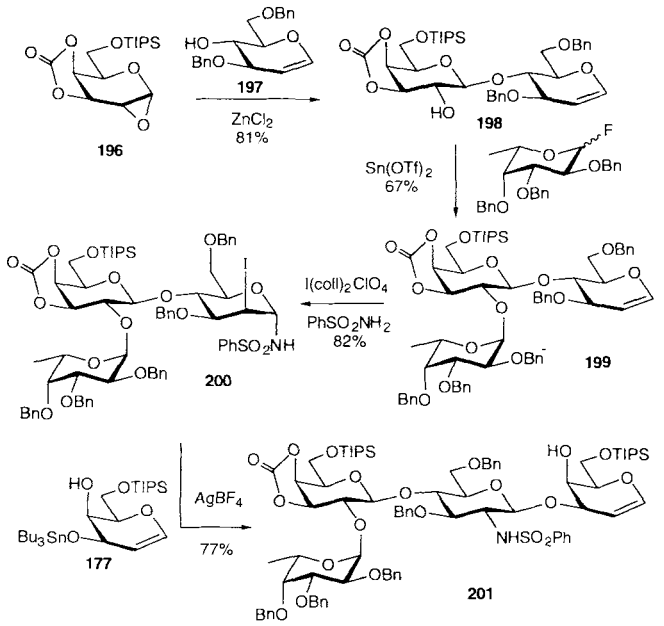
Approximately 33 carbohydrate hexamer units were incorporated, presumably by linkage to side chain amino groups of lysine. This construct is of particular interest to us because it incorporates the recognition domain implicated in the binding of *Helicobacter pylori* to gastric epithelial cells.[106] This form of infection is claimed to be one of the major causative elements of gastric ulcer and possibly gastric cancer. The possibility of synthesizing soluble binding agents for *H. pylori* constitutes an exciting goal for the glycal assembly methodology.

The chemistry described here can readily be accommodated into a synthesis of an H-type I tetrasaccharide as well.[101] This is accomplished by a selective α-fucosylation of the disaccharide unit **184** (Scheme 47). Fucosylation with donor **185**, as before, occured with a 5.5:1 selectivity at the 2′-hydroxyl in preference to reaction at the 4-hydroxyl, providing **195**.



Scheme 47. Synthesis of an H-type I glycal.

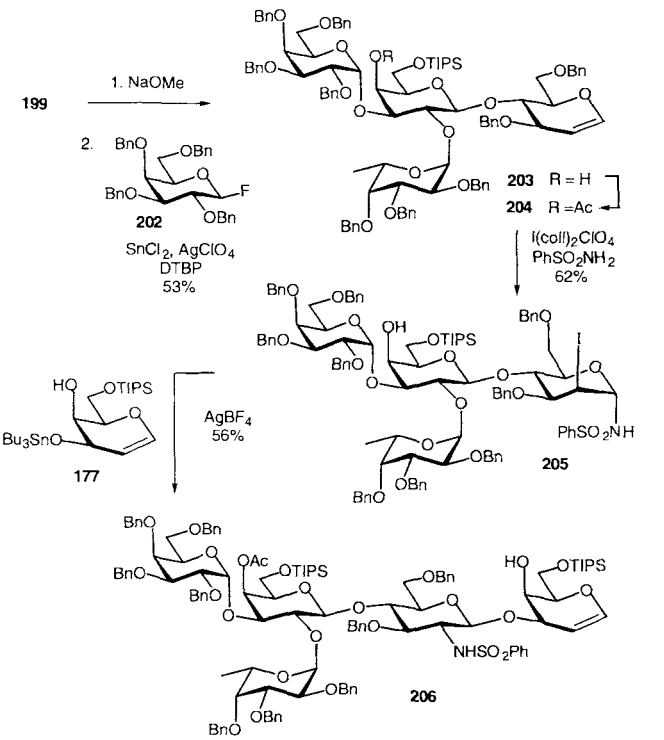
Furthermore, we have synthesized a tetrasaccharide having the H-type II structural domain (Scheme 48).[101] Reaction of epoxide **196** (derived from **165**) with the glucal **197** provided the differentiated lactal **198**, in which the newly presented C2′-hydroxyl is available for the requisite fucosylation. $Sn(OTf)_2$-promoted coupling yielded trisaccharide **199** bearing the H-type II domain. We further demonstrated that the structure



Scheme 48. Synthesis of an H-type II glycal.

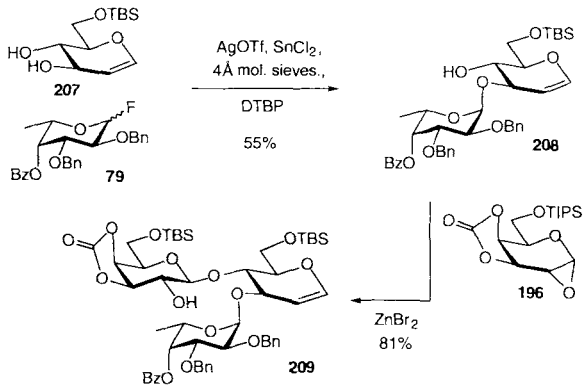
can be extended to a tetrasaccharide, employing the standard iodosulfonamide chemistry, to provide **200**. The latter, upon reaction with **177**, afforded **201**.

We have extended glycal chemistry toward the synthesis of the human A and B blood group determinants, which govern the ABO typing system. The synthesis of the core structure of the B determinant is shown in Scheme 49.[107] In the described case, trisaccharide **199** (Scheme 48) with the H-type II domain was used as the starting point. The carbonate was cleaved and the resulting diol was glycosylated with fluorosugar **202** to provide tetrasaccharide **203** containing the B-type domain. After acetylation, standard iodosulfonamide chemistry was employed to provide **205**. This B-type II structure was extended to the pentasaccharide **206** by utilizing the standard coupling conditions with acceptor **177**. The pentasaccharide **206** was readily deblocked to provide the unprotected version of the compound. Considerable progress in the A group series has also been accomplished at this writing, but the project is not yet complete (see Section 11).[107]



Scheme 49. Synthesis of a B-type II glycal. DTBP = di-*tert*-butylperoxide.

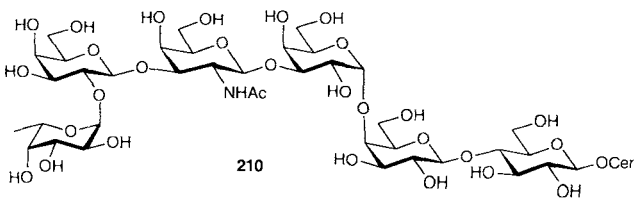
Returning to the series of Lewis determinants, our synthesis of the Le^x domain, previously described in Scheme 24, was greatly simplified by the use of a 1,2-anhydrosugar donor (Scheme 50).[66] Fucosylation of monoprotected glucal **207** afforded the disaccharide **208**, which is analogous to the acceptor employed in the earlier synthesis (cf. **80** in Scheme 24). In this later case, however, the acceptor was found to react under optimized conditions with the epoxide **196** to give Le^x trisaccharide **209** in 81% yield. Epoxide **196** is far more accessible than donor **81** was in the earlier work.



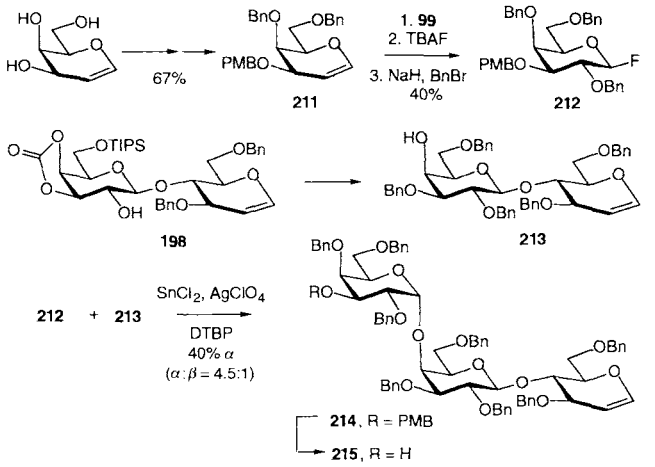
Scheme 50. A concise synthesis of the Le^x domain (cf. Scheme 24, compound **82**).

8. Total Synthesis of the Breast Tumor Antigen: Challenges and Solutions

The glycal assembly method has culminated in the recently completed synthesis of a hexasaccharide glycosphingolipid, which is a breast tumor associated antigen of potential clinical importance. Compound **210** was isolated from breast cancer cell line MCF-7 and was immunocharacterized by the monoclonal antibody MBr1 (Scheme 51).[108] Our synthesis of **210** involved the construction of two trisaccharide domains, which were then brought together to provide the hexasaccharide.[109] Galactal **211** was converted into the fluorosugar **212** (Scheme 52). The desired acceptor **213** was fashioned from disaccharide **190** (itself



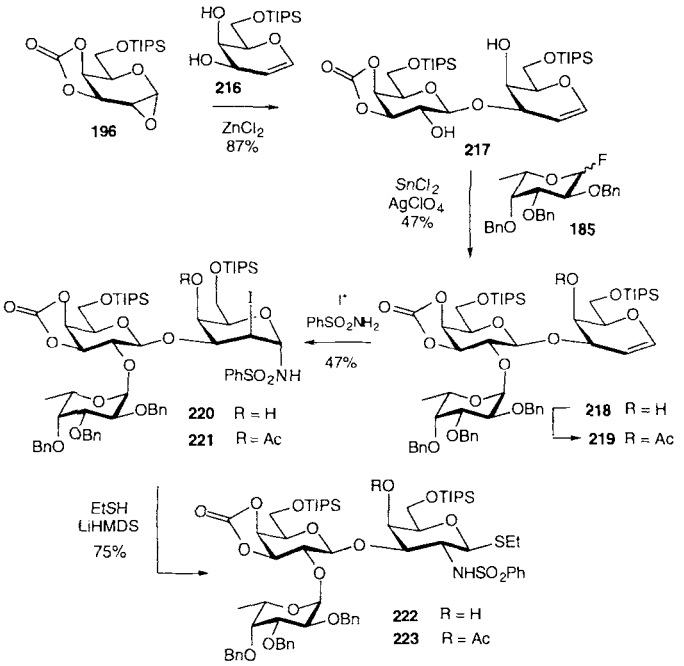
Scheme 51. Structure of the MBr1 carbohydrate antigen.



Scheme 52. Synthesis of a trisaccharide acceptor.

obtained by glycal coupling, see Scheme 49) after protecting group manipulations. Coupling of **212** and **213** afforded the trisaccharide **214**. Deprotection of the PMB ether provided **215**, setting the stage for merger with a suitable trisaccharide donor.

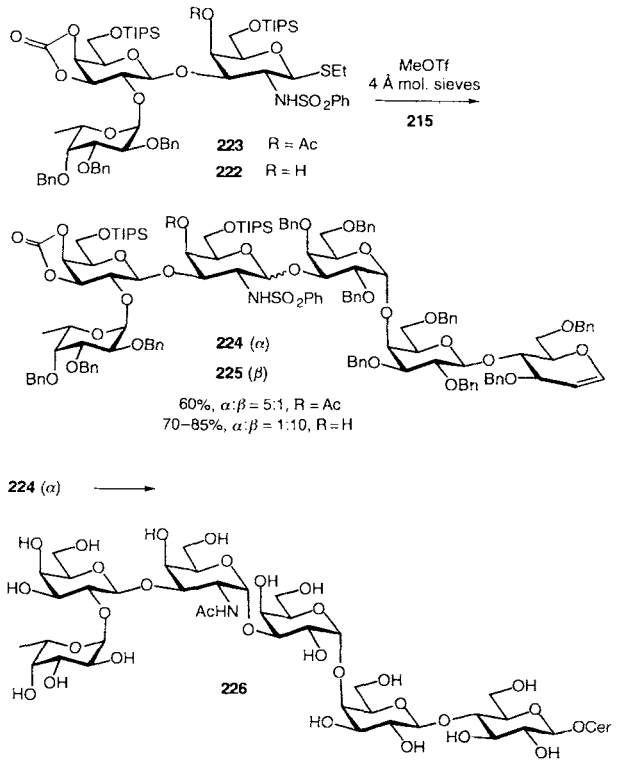
Construction of the donor began with **196**, which was glycosylated with acceptor **216** to afford the disaccharide **217** with excellent selectivity (Scheme 53). Regioselective fucosylation of the equatorial hydroxyl of **217** with donor **185** provided the trisaccharide **218**. This trisaccharide was acetylated to produce **219** which, after now standard treatments, was transformed to iodosulfonamide **221**. Unfortunately, iodosulfonamide donors of this type were not competent in the desired direct coupling reaction (see Scheme 22) with various trisaccharide acceptors. A large excess of difficultly available acceptor would be necessary, and this requirement is certainly not appropriate. We therefore



Scheme 53. Synthesis of a trisaccharide donor. LiHDMS = lithium hexamethyldisilazide.

examined the conversion of **221** to thioglycosides donors (see Scheme 22). Treatment of iodosulfonamide **221** with lithium ethanethiolate indeed afforded exclusively the β-ethyl thioglycoside **223**. Such compounds, under promotion by methyl triflate, function as azaglycosyl donors in coupling reactons with even complex donors. (In Section 11 we discuss some limitations in the projected merger of highly hindered partners.)

Precedent established in our program had suggested that, in coupling reactions, donors of this type would give the β-configurated product, presumably due to sulfonamide participation.[110] In the event, the reaction of **223** with the acceptor **215** afforded a hexasaccharide, which was advanced through the remaining manipulations in the synthesis (Scheme 54). However, the spectral properties of the ultimate product **226** did not

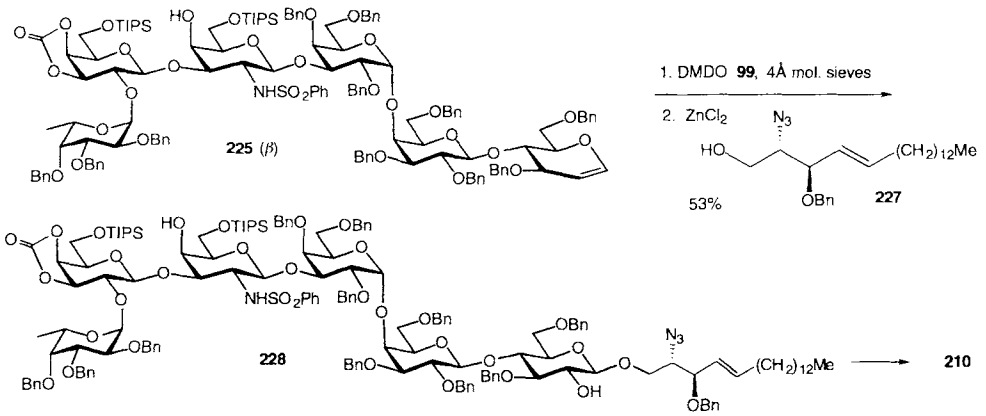


Scheme 54. Synthesis of the hexasaccharide glycal **226**.

correspond to those reported by Hakomori for the natural antigen, assumed to be properly represented by structure **210**. On this basis, and on the basis of self-consistent spectral analysis, we concluded that the material obtained from the coupling of the two trisaccharides had arisen from selective formation of the unexpected (and undesired) α-linked product **224**. We subsequently found that when the trisaccharide donor **222** (obtained by the sequence **218** → **220** → **222**) was employed in the key coupling reaction, the desired β-configurated product **225** was indeed obtained with high selectivity. Thus, there may be an unsuspected electronic or participatory effect biasing the system towards formation of the α-linked product when the 4-hydroxyl group is substituted . Alternatively, there may be a positive β-directing effect exerted by the 4-hydroxyl group of the donor. We emphasize that the occurrence of α-glycosylation and the remarkable turnover in selectivity has not yet been fully general-

ized, though it has been observed in several other cases (see synthesis of asialo-GM_1 in Section 11). This matter is being currently investigated and should be codified in due course. It does serve to once again underline the subtlety of the influences on the stereochemistry of glycosylation. The outcome is not merely a function of the type of donor and the type of reaction conditions employed. In complicated cases it can be much influenced by specific molecular interactions between donor and acceptor.

The properly configured hexasaccharide **225** was epoxidized and coupled with ceramide precursor **227** to provide **228** (Scheme 55). This ceramide attachment can be conducted more

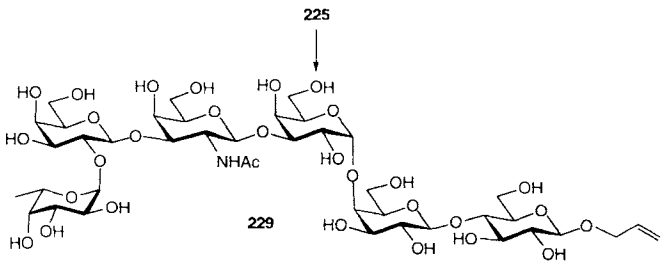


Scheme 55. Completion of the synthesis of the MBr1 antigen.

efficiently on trisaccharide **214**. For reasons that are not yet clear, this alternate route, which is being investigated, presently gives a lower β/α ratio in the (3 + 3) coupling when the acceptor already contains the lipid fragment at the reducing end.

Compound **228** was elaborated and deprotected to afford the natural material **210**. The fully synthetic antigen **210** has been shown to bind to monoclonal antibody MBr1 in the enzyme linked immunosorbent assay (ELISA) and in immune thin layer chromatography assays, while the unnatural isomer **226** exhibits very weak binding in the same assays. Also, MBr1 is strongly reactive with human breast cancer cell line MCF-7 by flow cytometry. Preincubation of MBr1 with glycosphingolipid **210** completely inhibits this reactivity with MCF-7.

Hexasaccharide **225** was also converted to the corresponding allyl glycoside **229** and through this to protein conjugates, as described previously for Le^b and Le^y (Scheme 56). Early studies indicate that our synthetic constructs are immunogenic in vivo. The usefulnesss of the antibodies thus produced against cancer



Scheme 56. Formation of an MBr1 allyl glycoside for protein conjugation.

cells is currently being evaluated (see Section 11). The ultimate goal is to develop compounds suited for vaccinelike applications in cancer treatment.

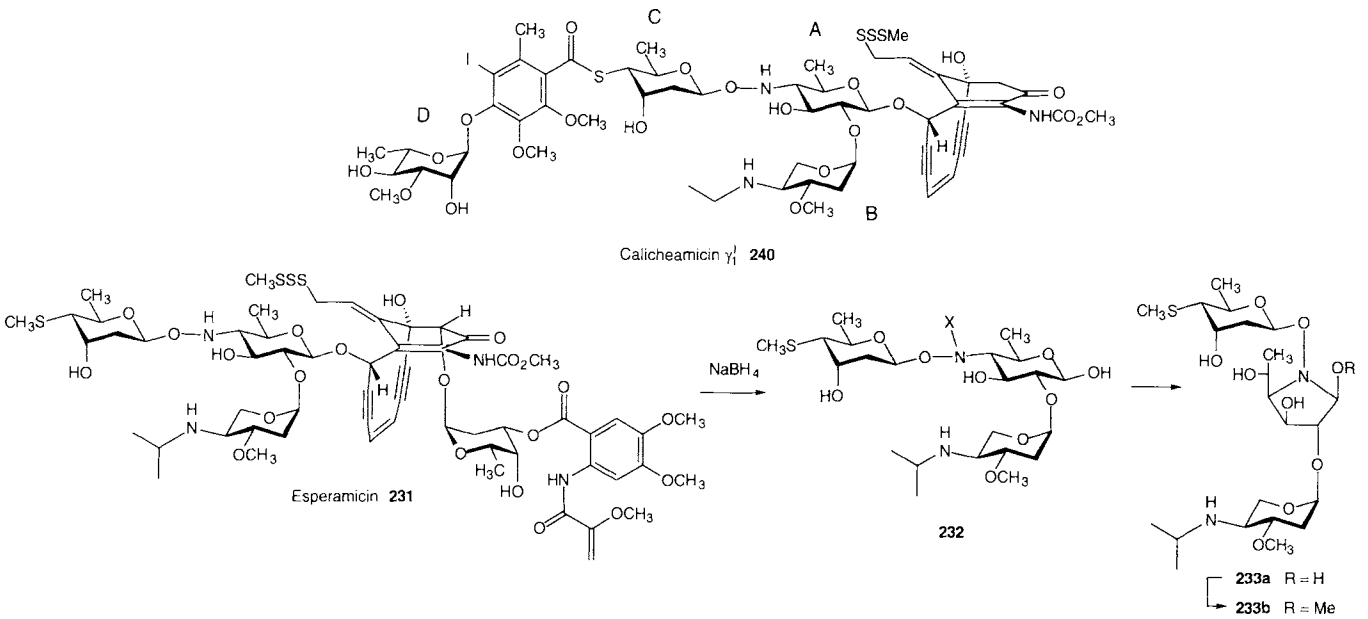
9. The Calicheamicin Problem

In the examples of glycal assembly discussed thus far ensembles were created from familiar carbohydrate building blocks. One of the large advantages of the glycal assembly method has been a reduction in the number of protecting group manipulations necessary to bring about the synthesis of complex target structures. A challenging extension of the glycal assembly method, in which several of the building blocks were far from conventional, was in the construction of the carbohydrate domains of the enediyne antibiotics calicheamicin (**230**, Scheme 57) and esperamicin (**231**).[111-115]

These investigations had several goals. First, we wanted to synthesize these sugar domains so that their biological properties could be examined in the absence of the effector feature of the drugs. Since the intact carbohydrate domains had not been successfully retrieved by degradation of the drugs, this objective seemed to be attainable only by synthesis. The realization of this synthesis through glycal assembly chemistry would confront us with some fresh challenges not encountered with conventional carbohydrate domains.

Moreover, we hoped to accomplish a total synthesis of calicheamicin γ_1^I itself. We had previously synthesized the aglycone domain, calicheamicinone, in racemic as well as enantiomerically pure form.[116] For a total synthesis it was our goal to deliver a fully synthetic carbohydrate domain, as a glycosyl donor, to an appropriate aglycone construct functioning as the acceptor. It seemed likely that the viability of the glycosyl donor would require extensive protecting group manipulations for the hydroxyl, alkylamino, and hydroxylamino functions. Thus, it would be crucial that deprotection of the carbohydrate domain be feasible with survival of this and the aglycone domain. Correspondingly, it would be desirable if the aglycone sector were in a maximally advanced state when functioning as the acceptor. In that way, the burden of dealing with the myriad of sensitive functionality subsequent to coupling would be minimized.

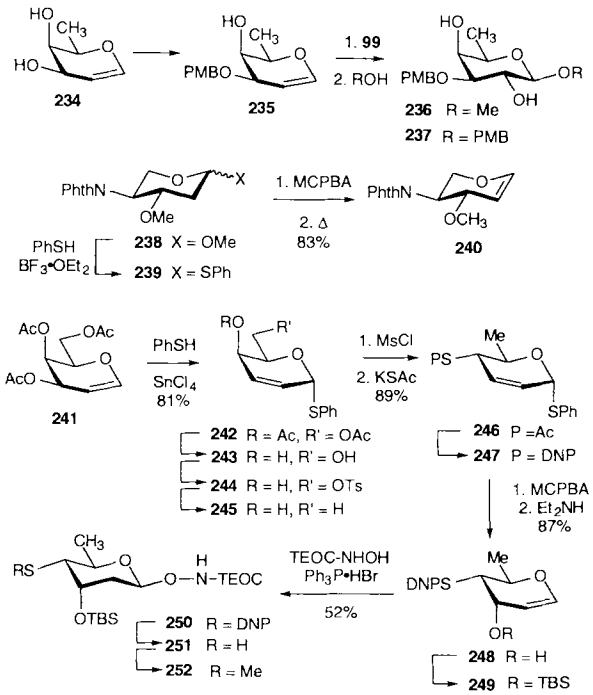
With these goals in mind, we started work on the core carbohydrate domain of esperamicin (**231**). Chemists at Bristol Myers Squibb with access to the drug had found that treatment of **231** with sodium borohydride led to **233a**, in addition to uncharacterized aglycone product (Scheme 57).[117] This reaction implied that reduction of the drug was producing **232** en route to **233a**, which was characterized as methyl glycoside **233b**. Obviously, a perception of the approximate rate of this rearrangement was of great interest to us. Presumably, our eventual car-



Scheme 57. Structures of calicheamicin and esperamicin.

bohydrate sector glycosyl donor (in the calicheamicin series) would be fashioned from **233a** through manipulations at a free hydroxyl group at the anomeric carbon of its reducing end. The Bristol Myers result suggested that the concurrent presence of a free reducing end and a free NH group on the hydroxylamino spacer might well be incompatible. If this restriction were indeed the case, protection of the latter would be necessary as we passed through a construct with a free reducing end.

For the synthesis of the esperamicin carbohydrate domain, three glycals were mobilized (Scheme 58). Thus, D-fucal (**234**) was readily converted to **235**. The second glycal, **240**, was prepared from the previously reported methyl glycoside **238** via the anomeric thiophenyl compound **239** by pyrolysis of its derived sulfoxide.



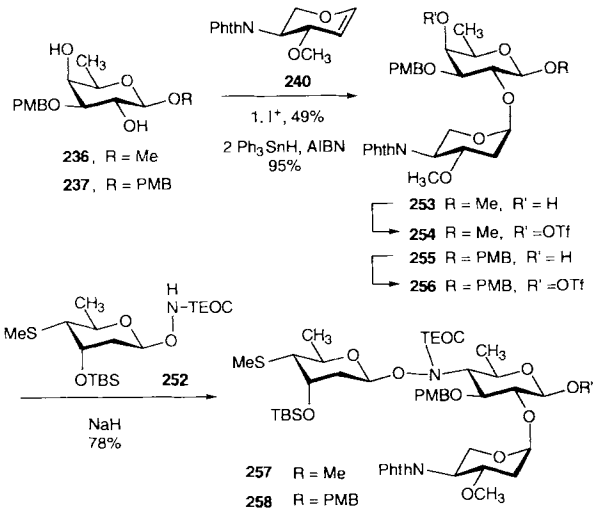
Scheme 58. Synthesis of the esperamicin carbohydrate domain (part 1). MCPBA = *m*-chloroperbenzoic acid, Ms = methanesulfonyl, Phth = phthaloyl, Ts = toluenesulfonyl.

The fashioning of the required thiosugar-containing glycal was challenging. D-galactal triacetate **241** was converted to **242** by thiophenyl Ferrier rearrangement.[36] After formation of diol **243** and thence tosylate **244**, reduction afforded **245** and soon thereafter **246** and **247**. Following rearrangement of the derived sulfoxide and suitable protection, **249** was in hand. This compound served as a donor with *N*-trimethylsilylethyloxycarbonyl (TEOC) hydroxylamine to afford **250**. The chemoselectivity of the addition reaction was only 1.5:1 (the minor product was the *N*-glycoside). The stereoselectivity, however, was very high in favor of the β-glycoside. Presumably this exclusive β-face attack is a consequence of the resident α-axial-OTBS function (TBS = *tert*-butyldimethylsilyl). Removal of the dinitrophenyl (DNP) group and methylation provided **252**.

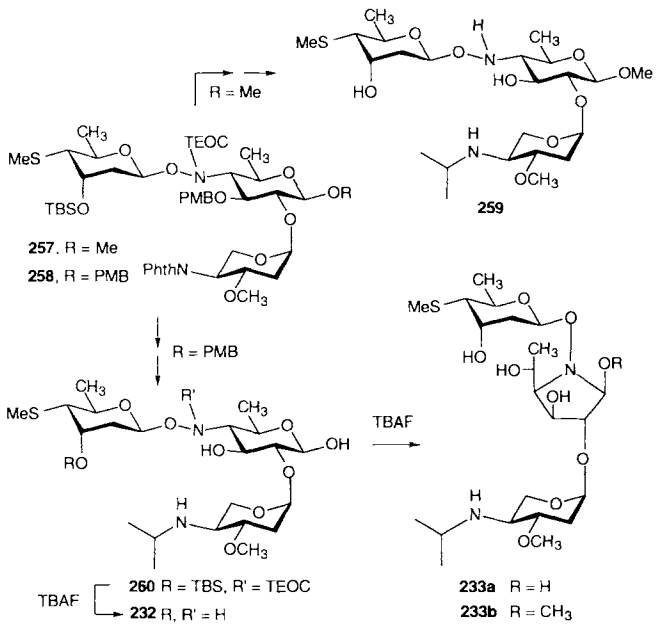
The assembly process started with epoxidation of **235** along conventional lines. Reaction of the resultant anhydrosugar with methanol and alternatively *p*-methoxybenzyl alcohol afforded **236** and **237**, respectively (Scheme 59). Iodoglycosylation of **240** with **236** and **237** occurred quite selectively at the C2 (equatorial) hydroxyl to afford, after deiodination, disaccharides **253** and **255**, respectively. Thus, the epoxide opening and iodoglycosylation strategies had been choreographed to provide rapid routes to the unusual disaccharides **253** and **255**. These compounds were in turn converted to triflates **254** and **256**, which were smoothly coupled to the carbamate sodium salt derived by deprotonation of **252**.[118] In this way, tricyclic compounds **257** and **258** were in hand.

In the methyl glycoside series (**257**) the phthalimide was cleaved and an *N*-isopropylamine linkage fashioned by reductive amination with acetone. Cleavage of the TEOC and TBS protecting groups afforded methyl glycoside **259** (Scheme 60).

Similarly, in the *p*-methoxybenzyl (PMB) case (**258**), once again the phthalimide was cleaved and the *N*-isopropyl group introduced. We next exposed the free reducing end by cleaving



Scheme 59. Synthesis of the esperamicin carbohydrate domain (part 2). AIBN = 2,2'-azobisisobutyronitrile, Tf = trifluoromethanesulfonyl.

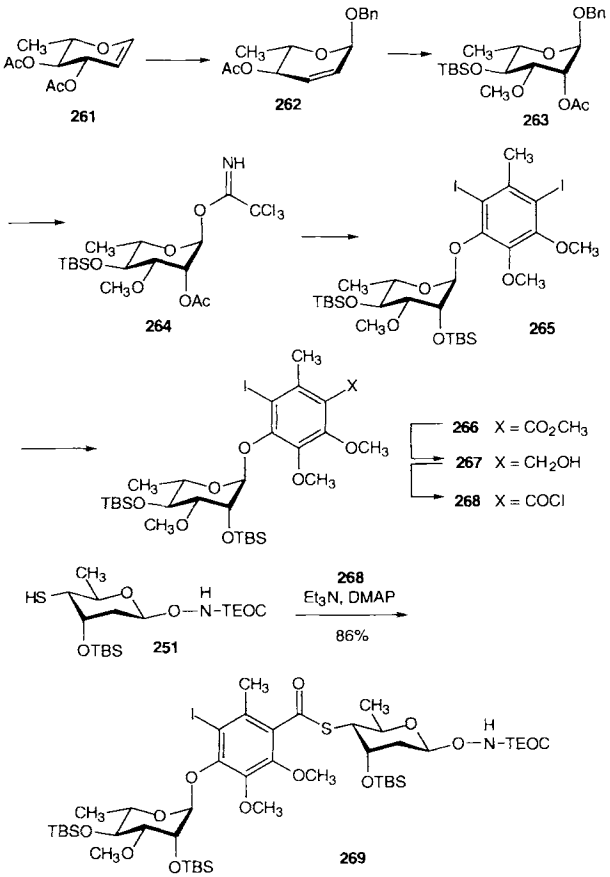


Scheme 60. Synthesis of the esperamicin carbohydrate domain (part 3).

the PMB groups. At this point, compound **260** was in hand. The *N*-TEOC group at the hydroxylamine linkage prevented the ensemble from rearranging to an azafuranose. Indeed, when construct **260** was exposed to the action of TBAF all silyl-based protecting groups were cleaved. However, compound **232**, which would correspond to the fully deprotected core trisaccharide domain of esperamicin, was not isolated or observed. Rather, the isolated product was the azafuranose **233a** and was best characterized as the methyl glycoside **233b**. This compound proved to be identical with a sample that had been derived from esperamicin by the chemists at Bristol Myers (vide supra).

At this stage, it was clear that for the core trisaccharide to maintain viability either the spacer hydroxylamine or the anomeric center at the reducing end must be protected. Since preparation of a glycosyl donor to serve as a calicheamicin-directed construct would probably require the intermediacy of a construct with a free reducing end, it would be necessary to maintain protection of the NH group of the hydroxylamine spacer center during this fashioning stage.

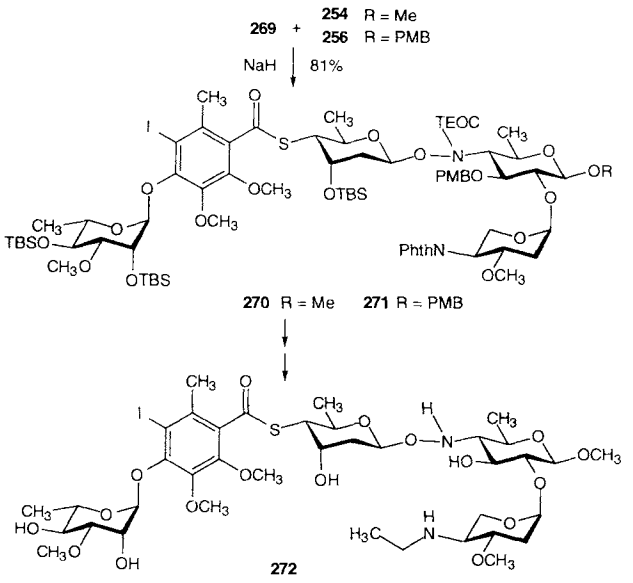
Our attention was next directed to the aryltetrasaccharide domain of calicheamicin. Of course, the synthesis of the ABC sector of **230** would be closely patterned after the program followed in the esperamicin series. Thus, we focused on the CD sector of the domain (Scheme 61). We started with glycal **261**,



Scheme 61. Synthesis of the calicheamicin carbohydate domain (part 1).

which was available from L-rhamnal. Ferrier rearrangement with benzyl alcohol afforded **262**, which was converted by osmylation, monomethylation (of the derived stannylene), and silylation to provide **263**. After debenzylation, the trichloroacetimidate donor function was introduced, affording **264**. Schmidt coupling of **264** to 2,4-diiodo-5,6-dimethoxy-3-methylphenol afforded **265**. Regioselective palladium-mediated carbonylation furnished **266**, which upon reduction (to **267**), followed by oxidation and formation of the acid chloride, provided **268**.[119] The previously described C-ring thiol-containing glycal **251** underwent acylation with **268** to afford aryl disaccharide **269**.

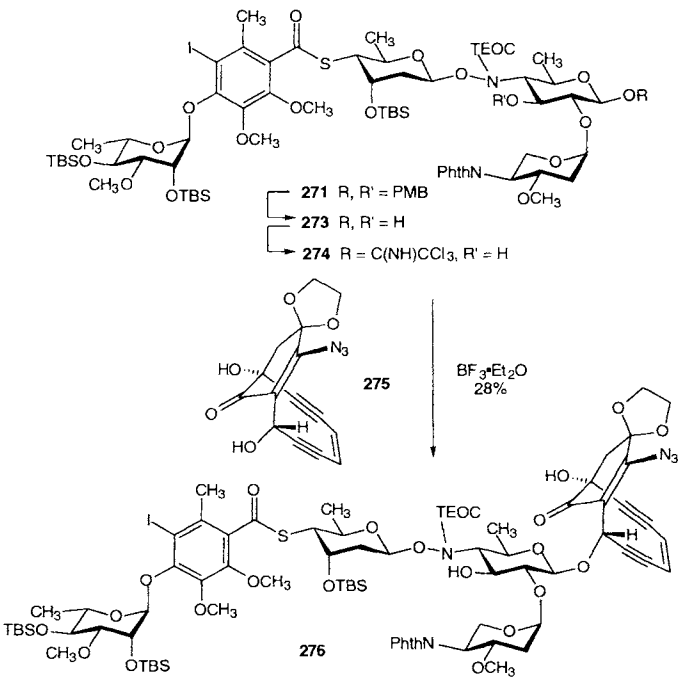
Kahne coupling[118] of the anion of **269** with the triflate **254** produced the aryl tetrasaccharide **270** (Scheme 62). Removal of the phthalamide group was followed by reductive ethylation and cleavage of all silyl-based blocking groups and the PMB ether to provide **272**. A variety of independent investigations by our group[120-122] and by Nicolaou et al.,[123, 124] who had earlier synthesized the carbohydrate domain,[125] revealed that



Scheme 62. Synthesis of the calicheamicin carbohydrate domain (part 2).

the recognition attribute of calicheamicin is, in fact, vested in the aryltetrasaccharide domain embodied in **272**.

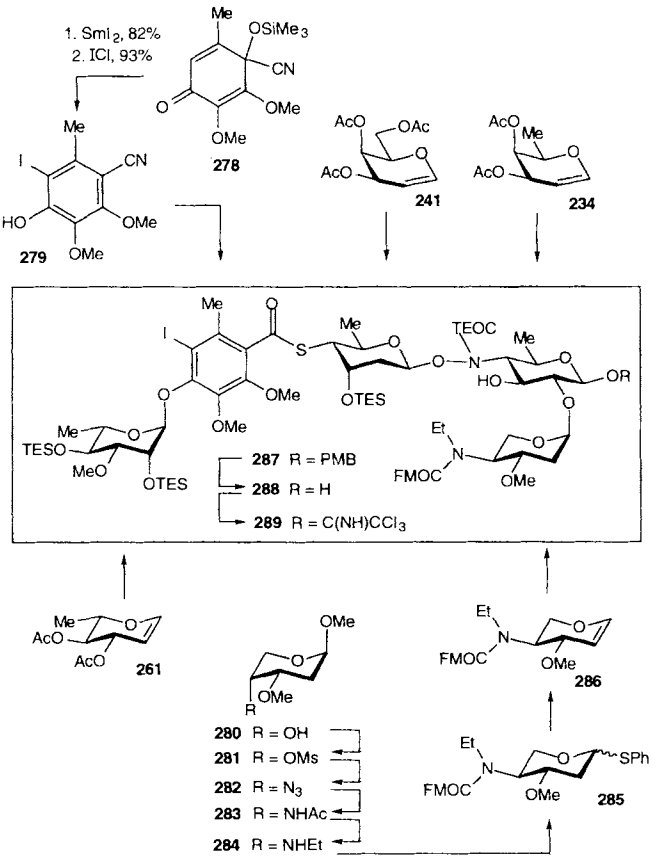
Our next goal was to demonstrate that a competent glycosyl donor could be fashioned from **272** and, above all, delivered to a reasonably advanced version of the aglycone domain. For this purpose, **269** and **256** were coupled to provide aryl tetrasaccharide **271** (Scheme 62). Deprotection of **271** with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ) afforded **273**, which was converted to the trichloroacetimidate donor **274**. Among the aglycone acceptors screened was **275**. Schmidt coupling of **274** and **275** indeed gave rise to a 3:1 mixture of **276** and the corresponding α-glycoside, which were readily separable (Scheme 63). This was the first such demonstrated glycoside coupling of two fully synthetic domains in the calicheamicin series.[126]



Scheme 63. Coupling of the carbohydrate sector to an enediyne core.

While the result was certainly pleasing, it soon became clear that compound **276** was insufficiently developed for advancement to fully synthetic calicheamicin. During this era of the program, several valuable insights were garnered. A key finding was that hydrazine-induced cleavage of the phthalimide group was not possible in the presence of the cyclic enediyne functionality. Under various conditions, destruction of the enediyne network (albeit in an uncharacterizable way) occurred far more rapidly than liberation of the amine from the phthalimide. Similarly to be taken to heart, was the finding that cleavage of the axial TBS protecting groups with TBAF was a problematic step. When the final deprotection was conducted on various constructs containing these protecting groups, the rhamnose D ring was seriously damaged or lost. This loss could be minimized at low temperatures (−10 °C), but under these conditions deprotection of the axial TBS groups took roughly seven days. Based on the results of experiments in which the "survival times" of these functional groups were determined, it seemed unlikely that an enediyne moiety could withstand the action of these conditions for the period of time required for freeing of the alcohol from its TBS derivative.

In response to these problems, and taking cognizance of the first total synthesis of calicheamicin by Nicolaou and colleagues,[111] we changed our pattern of protecting groups to that shown in Scheme 64. In preparing for the final push toward calicheamicin γ_1^I, several processes were improved. The route to

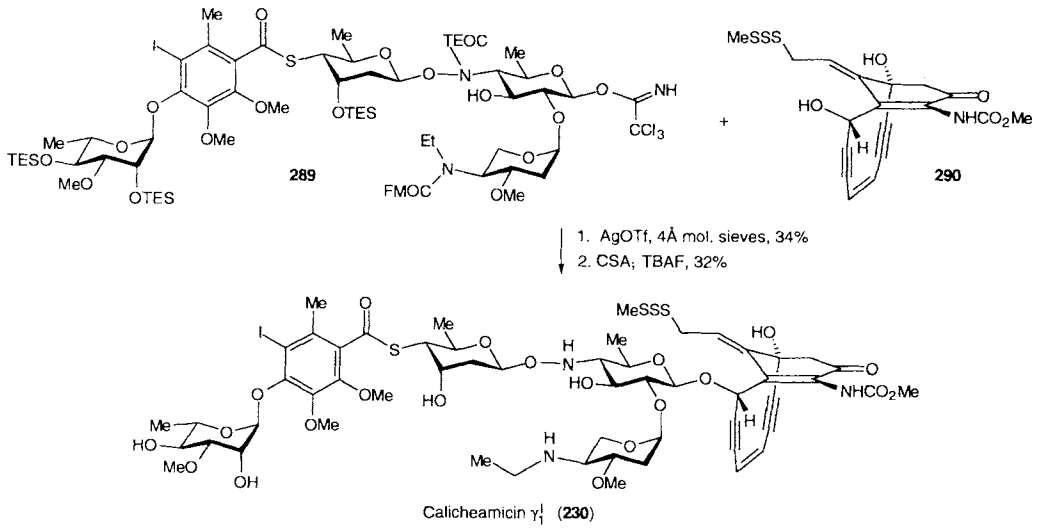


Scheme 64. Improved synthesis of the calicheamicin carbohydrate domain. FMOC = 9-fluorenylmethyloxycarbonyl.

the aromatic sector was totally revamped and streamlined. A key finding, per se unrelated to carbohydrate chemistry, was registered by Steven Olson. He found that mono-TMS cyanohydrin derivatives of quinones (e.g. **278**) are converted to *p*-hydroxybenzonitriles (e.g. **279**) through the action of samarium(II) iodide.[127] D-fucal (**234**), D-galactal triacetate (**241**), and L-rhamnal diacetate (**261**) were the building blocks for the A, C, and D rings, essentially as before, with the exception that triethylsilyl groups were employed instead of TBS functions as the protecting groups for the hydroxyl groups.

The starting material for the 9-fluorenylmethyloxycarbonyl (FMOC)-containing glycal was mesylate **281**, derived from differentiated methylglycoside **280**. Serge Boyer found that azide displacement upon **281** afforded **282** and, in seriatum, the acetamide **283** and then the *N*-ethyl derivative **284** were fashioned. Thiophenol displacement at the anomeric center provided **285**, which upon oxidation and thermolysis afforded **286**. Glycal assembly in analogy to our first calicheamicin synthesis used **237** for the iodoglycosylation with **286**, en route to the AB section. Continuation of the sequence led to tetrasaccharide **287**, thence to **288**, and finally to **289**.

At this stage Steven Hitchcock was able to investigate a most exciting possibility. Glycosylation could be conducted with **289** as the projected donor and **290** as the acceptor (Scheme 65). The feasibility of employing such a structurally advanced acceptor arose from the use of donor **289**. Since no oxidations or reductions would be necessary to bring the projected product to the state required in the drug, one would hope to use the otherwise vulnerable acceptor **290**, in which the allylic trisulfide functionality is already present. Fortunately, reaction under particularly mild conditions (AgOTf, 4Å molecular sieves)[128] allowed for glycosylation. All blocking groups were discharged in two steps, and calicheamicin γ_1^I (**230**) was in hand. Thus, an ultimately convergent synthesis had been accomplished.



Scheme 65. The ultimately convergent synthesis of calicheamicin.

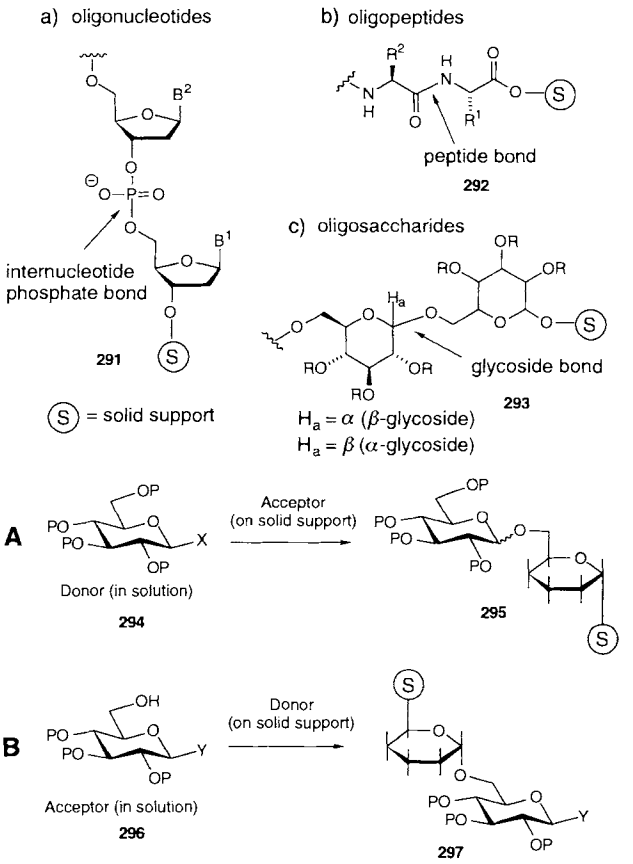
10. Solid-Phase Oligosaccharide Synthesis

Progress in the synthesis of oligosaccharides and glycoconjugates by the solution-based methodology described in the previous sections was certainly reassuring. Yet because of the importance of this field, these advances prodded us to seek still greater levels of simplicity and efficiency. It was instructive to think about this problem in the broader context of biooligomer synthesis, thus inviting analogies between oligosaccharide synthesis and the synthesis of oligonucleotides and peptides. Of course, impressive advances had been registered in the solution-phase synthesis of these latter biooligomers. However, it is clear that the major upsurge in their synthesis arose only after solution-based coupling methods were adapted to the solid phase. While polymer-supported synthesis of oligopeptides[129] and oligonucleotides[130] is not a panacea, it has certainly been of enormous benefit in improving yields, simplifying procedures, and obviating the need for purification at each stage. Obviously, in solid-phase methodology the potential advantage of such purification after each elongation is substantially forfeited. Hence the chemistry of the various reiterations must be sufficiently efficient that a single purification at the final stage affords product of the required homogeneity.

In polypeptide and oligonucleotide synthesis, it is the high yields in the individual coupling steps that seem to render the final-stage purification strategy viable. Excellent yields arise from the inherent quality of the coupling steps and are further "amplified" by the capacity to employ excess solution-based coupling partner, which is removed from the solid phase by filtration.

By contrast, solid-phase synthesis of oligosaccharides is much less developed.[131] This assessment is in no sense intended as a critique of the practitioners of the field; rather it reflects the fact that the problem of oligosaccharide synthesis is intrinsically far more complicated than the corresponding problem in oligonucleotide and oligopeptide synthesis (Scheme 66).

Consider the synthesis of oligonucleotides, particularly oligo-2-deoxynucleotides (Scheme 66). Assuming the availability of the individual nucleosides, each elongation involves the fashioning of an internucleotide phosphate bond. For this purpose it is necessary to distinguish between the 5′- and 3′-hydroxyl groups and to discover a high-yielding coupling step. The fashioning of the internucleotide bond does not create a new chiral center. Similarly, in fashioning a peptide the α-amino and α-carboxyl groups must be distinguished from any such or related functionality (for example thiol and hydroxyl groups) present on various side chains. An efficient coupling is necessary for amide bond forma-



Scheme 66. Solid-phase synthesis of biopolymers. B^1, B^2 = nucleobases.

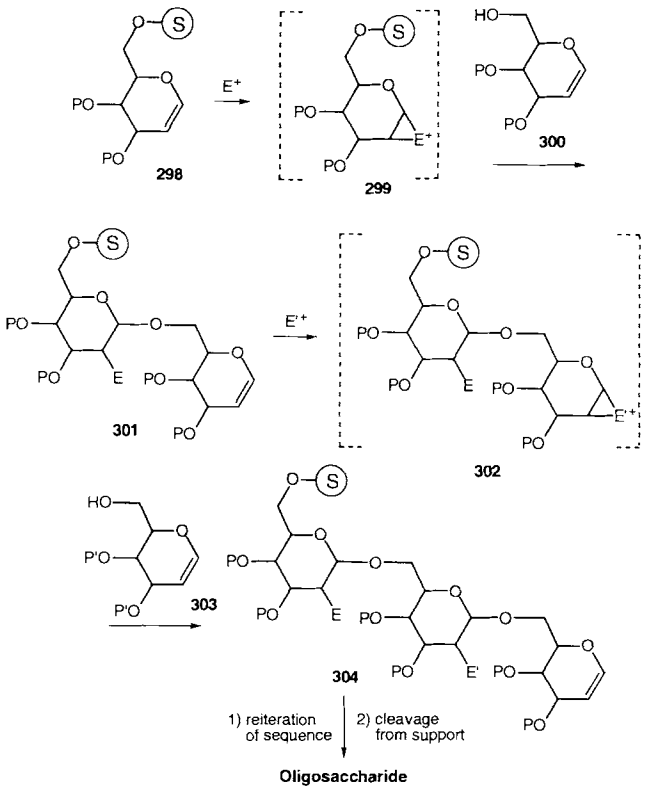
tion. Once again, no new chirality arises in the elongation of the oligopeptide. The two strategies for elongation of these biopolymers on solid supports are implied in structures **291** and **292** in Scheme 66. Clearly, in contemplating the synthesis of an oligosaccharide on solid support (cf. **293**) the complexity level rises markedly.

Thus, in fashioning the repeating units from an aldohexose, one must distinguish the anomeric region of one of the components to serve as the donor region (see **294**). In the case of combining hexose units, one must also differentiate one of five rather closely related hydroxyls to serve as the glycosyl acceptor center (see **296**). Most demanding is the need to control the configuration at each newly emerging glycosidic bond. Unlike the synthesis of the other biooligomers, the linkage of saccharide monomers through formation of a glycoside bond has serious stereochemical consequences. Given the enormously more complicated nature of the problem of oligosaccharide synthesis on a solid support, the dramatic progress that has been registered is indeed amazing and speaks eloquently for the creativity and tenacity of its founding practitioners.

In contemplating the syntheses of oligosaccharides on a solid support, two overall strategies can be entertained. In one instance (Case A) a glycosyl acceptor is mounted to a support, and solution-based donor (**294**) as well as promoter are administered for the coupling step leading to glycoside **295**. To reiterate the process, a new acceptor must be fashioned on the support. This would generally involve cleavage of a specific protecting group (P) to generate a new acceptor center in a defined position.

In the alternative strategy (Case B) the polymer-bound glycosyl donor reacts with the solution-based acceptor (**296**). For reiteration, the donor functionality must be unveiled from the terminal anomeric functionality (Y) on the support-bound structure (**297**). Also, positionally defined glycosyl acceptors must be synthesized for each iteration such that acceptor character is manifested at a particular hydroxyl center and donor character can be fashioned at the anomeric center of the product. The incremental complexities of oligosaccharide synthesis on a solid support relative to that associated with the other classes of biooligomers is virtually palpable upon analysis of the problem.

It was in dealing with the problem of solid-phase carbohydrate synthesis that we felt that glycal-based constructions might prove to be particularly valuable.[132, 133] The guiding paradigm was that shown in Scheme 67. Polymer-bound glycal

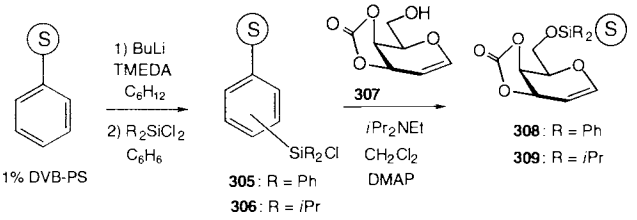


Scheme 67. Solid-phase carbohydrate synthesis employing glycals. P, P′ = protecting groups; E^+, E'^+ = electrophiles.

298 would be synthesized by attaching the requisite glycal to a suitable solid support. The system would be activated by unspecified electrophile E^+ to furnish polymer-bound donor **299**. In principle **299** can be a substoichiometric intermediate (cf. iodoglycosylation) or a characterizable chemical entity (cf. 1,2-epoxide). Coupling of **299** with solution-based glycal acceptor **300** would give rise to the elongated polymer-bound glycal **301**. Reiteration of the process generates **304** via new polymer-bound donor **302** and solution-based acceptor **303** (which may or may not be identical to **300**).

Several decisions, starting with the choice of polymer, were necessary to study the implementability of the scheme. We elect-

ed a silicon-based attachment of the growing carbohydrate domain to the solid support and turned to commercially available polystyrene (cross-linked with 1% divinylbenzene). Fortunately, we were able to take good advantage of the findings of Chan[134] registered in a totally different context. Thus, metalation of the polymer leads to formation of the aryllithium species. When exchange is followed by silylation with a difunctional silane of the type R_2SiCl_2, a silyl chloride functionalized resin is obtained (Scheme 68).

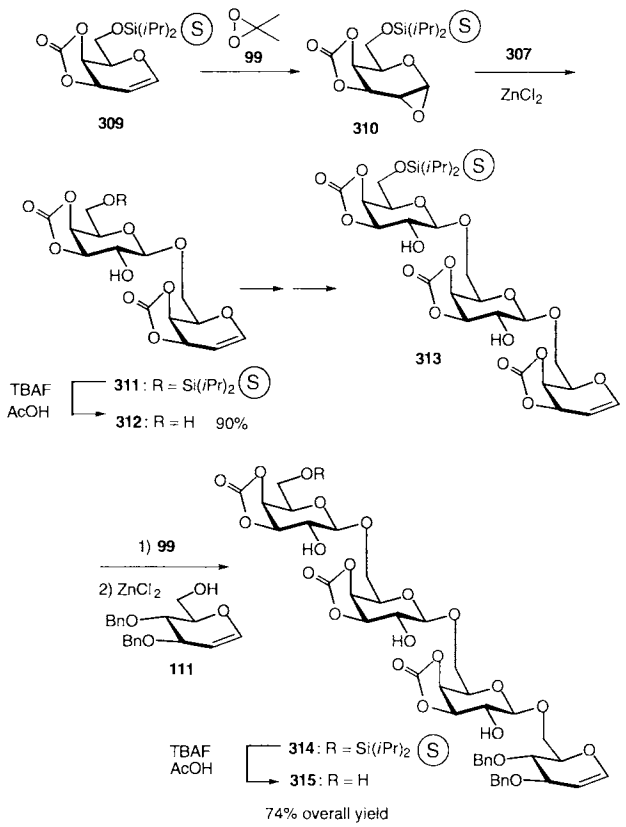


Scheme 68. Preparation of a polymer-linked glycal. TMEDA = tetramethylethylenediamine. 1% DVB-PS = polystyrene cross-linked with 1% divinylbenzene.

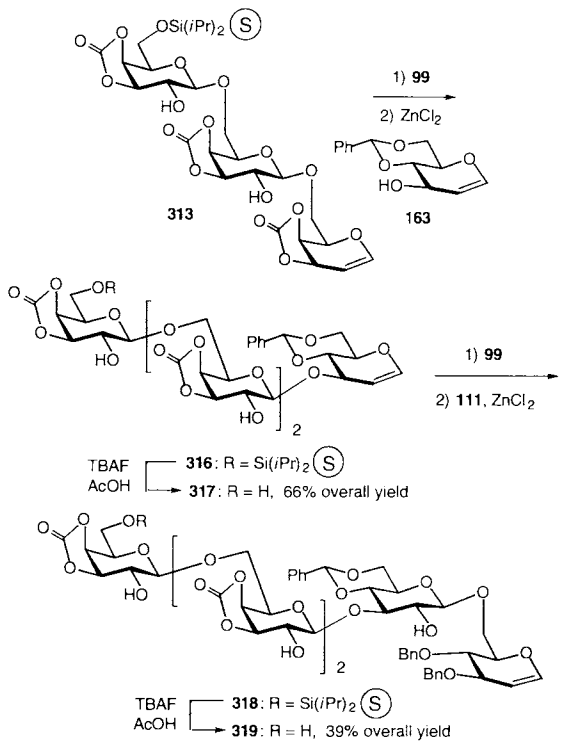
In our initial explorations[132] we silylated with diphenyldichlorosilane and attached the first glycal (**307**) through a conventional silylether forming reaction to provide **308**. Subsequent studies revealed that the spacer in the products arising from elongation of **308** lacked the needed hydrolytic stability. Accordingly, we turned to the use of diisopropyldichlorosilane as the silylating agent, which led us to **309** as our support-bound donor of choice. We determined the loading of carbohydrate to be in excess of 0.9 mmol per gram of **307**. The activation method we developed at first was that of glycal epoxidation using 2,2-dimethyldioxirane as the oxidant. Of course, from this point on the support-bound compounds (e.g. **310**) were generally not fully characterizable (Scheme 69). Reaction of **310** with glycal acceptor **307** mediated by zinc chloride afforded **311**. We could establish the actual presence of **311** by treatment with tetra-*n*-butylammonium fluoride (TBAF), which provided **312** in roughly 90% yield. Reiteration of the sequence, twice more, using acceptors **307** and **111** in sequence followed by removal from the polymer with TBAF led to tetrasaccharide **315** in 74% overall yield (approximately 90% average yield per coupling step). The reader will recognize that in these early forays we relied heavily on galactose epoxide donors of the type **310**. These tend to offer high margins of β-product formation (see Scheme 37). That galactosylation is also an important capability in fashioning biologically important oligosaccharides had not escaped our attention.

Several features of the method should be emphasized. First, the polymer-bound donors in which the C3 and C-4 hydroxyl groups are engaged as a cyclic carbonate are, in fact, highly stereoselective galactosylating agents. Single purification at the tetrasaccharide stage was a straightforward matter. Another feature was the "self-policing" nature of failed couplings. While the average coupling yields are only about 90%, the uncoupled epoxide is apparently destroyed by hydrolysis. Thus, we do not encounter entities with deletions in the interior of the chain.

Glycosyl acceptors with secondary hydroxyl groups are also accommodated by this method (Scheme 70). Compound **313**,



Scheme 69. Solid-phase synthesis of 1,6-linked polysaccharide residues.



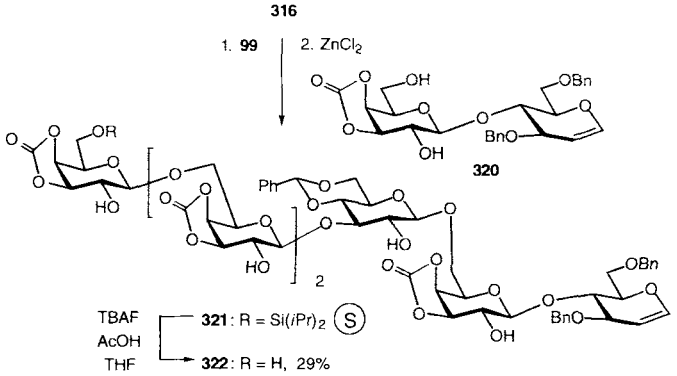
Scheme 70. Synthesis of a pentasaccharide on a solid support.

following epoxidation with **99**, reacted with D-glucal derivative **163** to give **316**. Tetrasaccharide **317** was retrieved from the support by the action of TBAF in a 66% overall yield based on **309**. Assuming 90% yield per coupling in the synthesis of **313**,

glycosidation of **163** had occurred in roughly 80% yield. An additional example demonstrating the use of glycals with secondary hydroxyl groups is the coupling of solution-based 3,6-dibenzylglucal with **310** to give the corresponding 1,4-linked disaccharide product.

Compound **316** was oxidized with **99** to give a polymer-bound glucosyl donor. This epoxide reacted with $ZnCl_2$ and a solution of **111** in THF to provide **318**, which was cleaved from the support to give pentasaccharide **319** in 39% overall yield from **309**. This glycosylation, which had been achieved in approximately 60% yield based upon **316**, also occurred with a high degree of stereoselectivity. However, in this particular case, a minor component, believed to be the α-glycoside, was detected in the ^{1}H NMR spectrum. The ratio of the desired all-β-glycoside product to this unknown component was in excess of 10:1. This apparent erosion from strict β selectivity using this glucal-derived donor can perhaps be controlled by appropriate modification of the as yet unoptimized conditions.

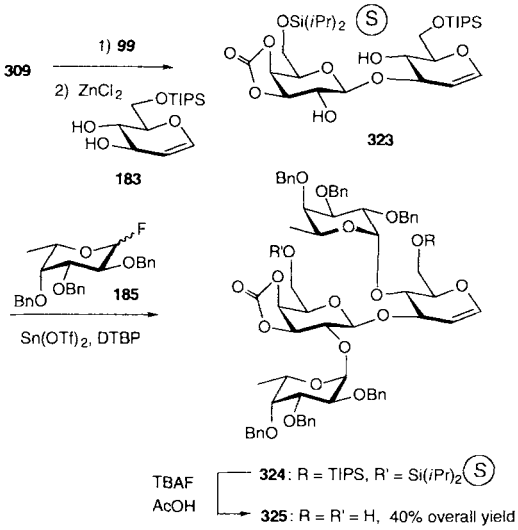
The scheme can be rendered more convergent through recourse to disaccharide and higher oligomer acceptors (Scheme 71). Thus, epoxidation of polymer-bound tetrasaccharide glycal **316** followed by zinc chloride mediated coupling with disaccharide acceptor glycal **320** and retrieval from the support (TBAF) afforded **322** in a 58% overall yield (29% overall from **309**, 45% yield from **316**).



Scheme 71. Synthesis of a hexasaccharide on a solid support.

It should be noted that this last coupling involves the regioselective glycosylation of a diol acceptor. This element of "site direction" in the use of polymer-bound donors with solution-based acceptors can be a significant advantage since protecting group manipulations can be minimized.

The solid-phase method is also applicable to the synthesis of branched structures through the logic of glycal assembly (see Schemes 41 and 42). We demonstrated the principle with support-bound glycal **309**, which was epoxidized and coupled to acceptor **183** to afford disaccharide **323** (Scheme 72). The latter served as a polymer-bound glycosyl acceptor in a reaction with fluorosugar **185** mediated by stannous triflate. Tetrasaccharide **324** was retrieved from the polymer with TBAF to afford **325**, a glycal precursor of Lewis b. Thus, it was demonstrated that branching at the C2 hydroxyl could be achieved in a growing chain by exploiting the hydroxyl group unveiled in the epoxide donor based glycosylation.



Scheme 72. Synthesis of branched sugars on a solid support. DTBP = di-*tert*-butylperoxide.

We note that at this stage direct sulfonamidoglycosylation of solution-phase carbohydrate acceptors with polymer-bound donors (cf. Scheme 22) was not possible. While halosulfonamide adducts of glycals can be formed on supports, the glycosidation failed. Thus, we were unable to make our way from polymer-bound **324** to the full Lewis b determinant. Instead, we had to revert to solution-phase methods (see **325**) and complete the Lewis b synthesis by the previously discussed procedure. More recently we have developed a two-stage protocol for conducting sulfonamidoglycosylation on support-bound substrates (see Scheme 81).

Another of our goals was to build upon the capabilities attained in glycal assembly to synthesize glycopeptides. Our first objective was to reach asparagine-linked glycopeptides. Brilliant advances in glycopeptide synthesis have been achieved by many researchers,[135] including notably, Paulsen, Kunz,[135e] Meldal, and Lansbury.[135c] The strategy we hoped to implement would be radically different and maximally convergent.

It was envisioned that a terminal glycal of a synthetic oligosaccharide domain would be subjected to iodosulfonamidation. As demonstrated earlier in a simpler model (see **90** → **91**, Scheme 25), treatment of such an intermediate with azide results in formation of β-anomeric azide with suprafacial movement of the α-sulfonamide from C1 to C2. Reduction of the azide and acylation of the resultant anomerically pure β-aminosugar provided a protected glycopeptide (**93**, Scheme 25). Fortunately, this capability was tranferable to the solid phase (vide infra).

This was to serve as the cornerstone of our strategy. First, however, a cautionary note is appropriate. While the synthesis of glycopeptide ensembles is a complex undertaking, the most difficult part of the enterprise may actually be the final maneuvers required to produce the fully deprotected entity. Thoughtful planning and corresponding care must be exercised since the *N*-asparagine-linked glycopeptide can be a rather vulnerable construct.

Jacques Roberge took up the problem in great detail and was subsequently joined by Xenia Beebe. In this presentation we spare the reader the description of the many setbacks encoun-

tered in implementing the seemingly straightforward design with provision for full deprotection. We will first present the solution synthesis of glycopeptides by this method[136] and then demonstrate its compatibility with synthesis on solid supports.

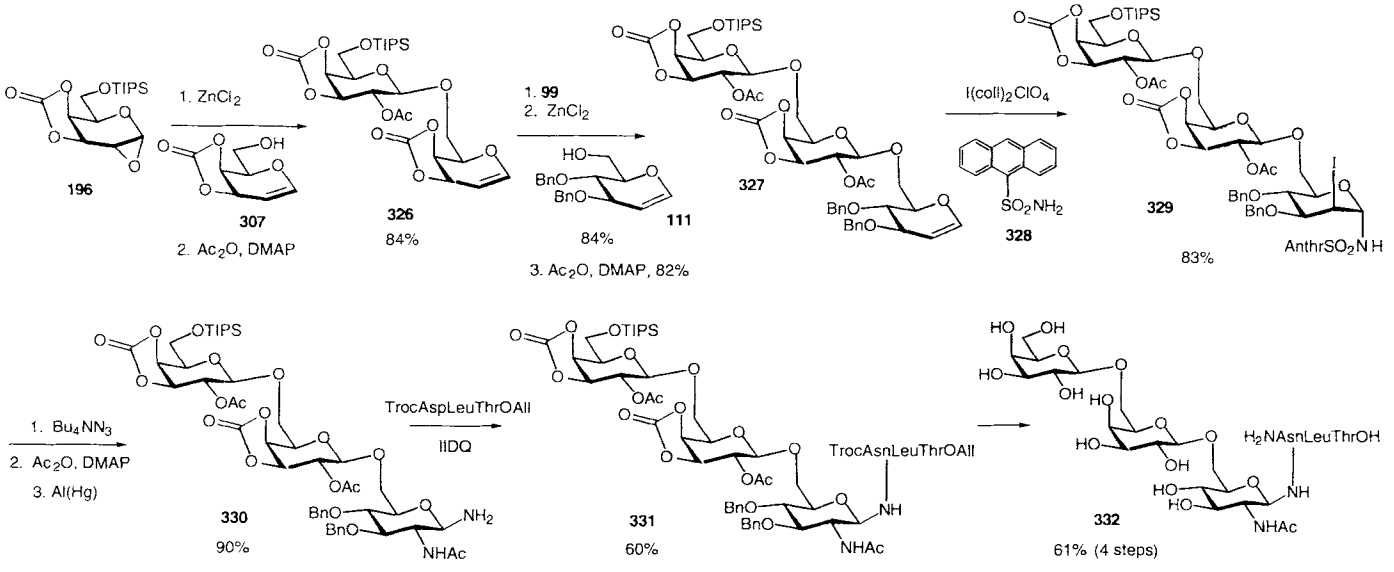
In synthesizing the carbohydrate domain of the glycopeptide we focused on a target structure amenable to the most straightforward methodology we had developed. For this purpose, we relied on the galactal epoxide **196**, which reacted with **307** to give, after acetylation, disaccharide **326** (Scheme 73). Epoxidation of **326** followed by reaction with acceptor **111** furnished, after acetylation, the trisaccharide glycal **327**. This set the stage for functionalization of the glycal linkage with a view to glycopeptide formation. In pursuit thereof, we eventually settled on the use of 9-anthracenylsulfonamide (**328**) in the iodosulfonamidation reaction. We have demonstrated that this protecting group can be readily removed under a variety of mild reducing conditions.

Treatment of **327** with **328** and di-*sym*-collidine iodonium perchlorate gave rise to **329**. Reaction of the latter with tetra-*n*-butylammonium azide triggered the expected relocation of the sulfonamide. The resulting azidotrisaccharide was then acetylated. Azide reduction and reductive cleavage of the sulfonamide was accomplished with aluminum amalgam to afford **330**. Acylation of the β-amine was conducted with the ω-carboxyl group of the tripeptide TrocAspLeuThrOAll in the presence of IIDQ, giving rise to **331**. Deprotection was accomplished by desilylation, removal of the allyl group, reductive removal of the Troc group, and hydrogenolysis of the benzyl groups. Lastly, the two cyclic carbonate linkages were cleaved by KCN/ethanol and the free N-linked glycopeptide **332** was in hand. We view this synthesis of the trisaccharide tripeptide ensemble as an important plateau in aspiring to the synthesis of glycopeptides.

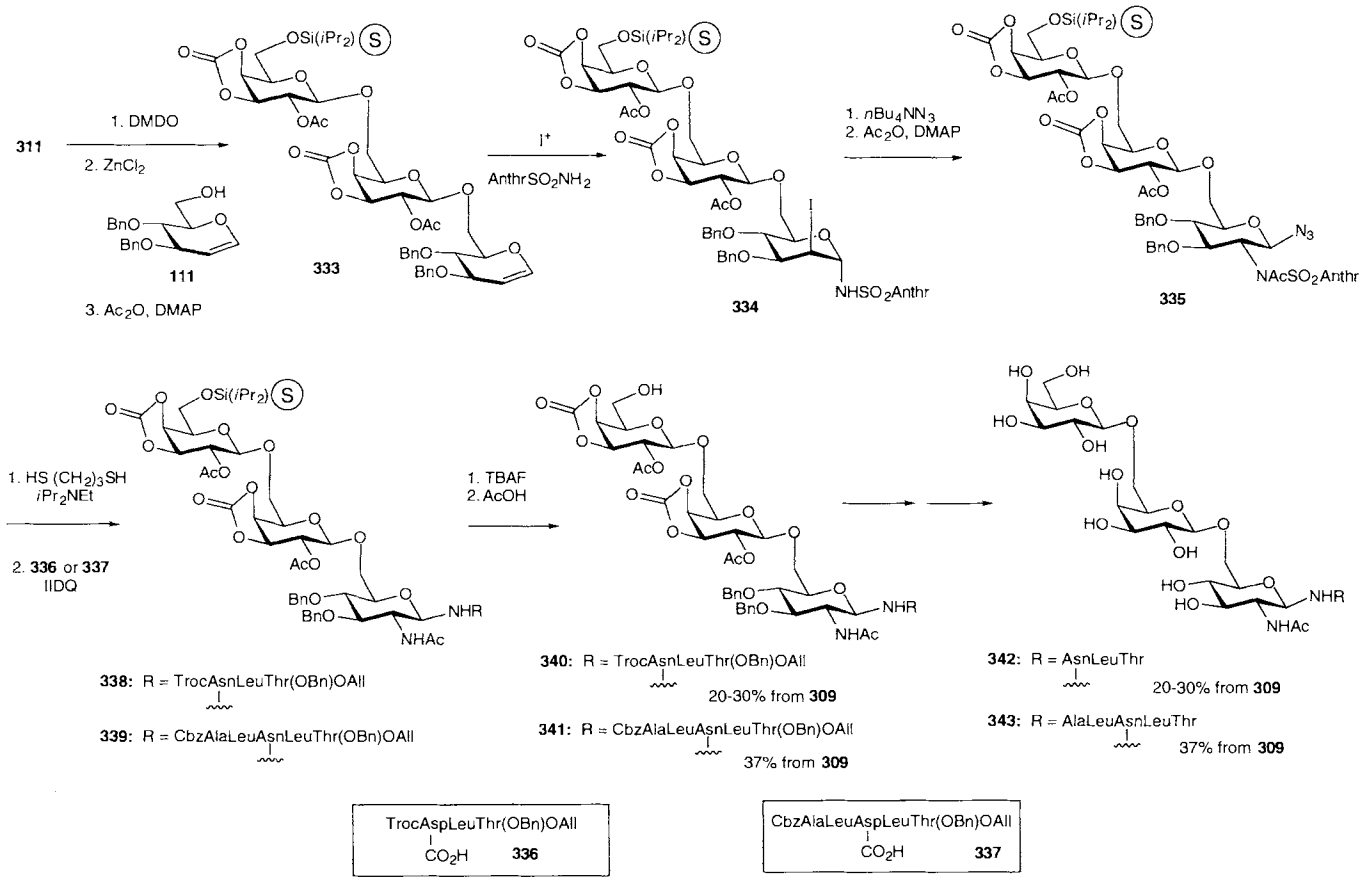
Having demonstrated the feasibility of the synthesis in solution, we next turned to conducting it on the solid support (Scheme 74).[137] Polymer-supported disaccharide **311** was extended by epoxidation, reaction with **111**, and acetylation to provide trisaccharide **333**. After treatment of **333** with anthracenesulfonamide and I(*sym*-coll)$_2$ClO$_4$, the clean formation of **334** was inferred from subsequent steps. Reaction of this material with tetra-*n*-butylammonium azide followed by acetylation provided the anomeric azide **335**. This success is in contrast to our inability to achieve polymer-based sulfonamidoglycosylation of carbohydrate acceptors (see Scheme 71).

The principal advantage in using the anthracenesulfonamide linkage is that it can be cleaved by a variety of mild methods. For instance, we developed the use of thiophenol or 1,3-propanedithiol and Hünig's base for the removal of the anthracenesulfonyl group. These protocols are compatible with synthesis on solid supports. Also, anthracenesulfonamide itself is more soluble than benzenesulfonamide in THF, which is a good swelling solvent for the polymer. Thus, the use of the anthracene-based agent results in a more efficient and complete iodosulfonamidation reaction. Treatment of **335** with 1,3-propanedithiol and iPr$_2$NEt effected both the reduction of the azide and removal of the sulfonamide. The resulting amine was coupled with tripeptide **336** and alternatively with pentapeptide **337** in the presence of IIDQ to afford the protected glycopeptides **338** and **339**, respectively. Removal from the solid support with HF·pyridine provided the glycopeptides **340** and **341** in overall yields of 30 and 37%, respectively. For the synthesis of **341** this constitutes an average yield of approximately 90% per step over the ten steps from polymer-bound glycal **309**. Chromatography on a short column of reversed-phase silica gel (C-18) was sufficient to obtain **340** and **341** in pure form. This ready purification can be attributed to the previously described "self-policing" feature of the solid-phase glycal assembly method (see Scheme 70) and illustrates the efficiency in the conversion of the terminal glycal to the terminal glucosylamine.

The remaining protecting groups in both **340** and **341** were cleaved under standard conditions to provide the completely deblocked glycopeptides, **342** and **343**, in yields of 61 and 48% (from **340** and **341**), respectively. Structural characterization of the glycopeptides by NMR spectroscopy confirmed the β-con-



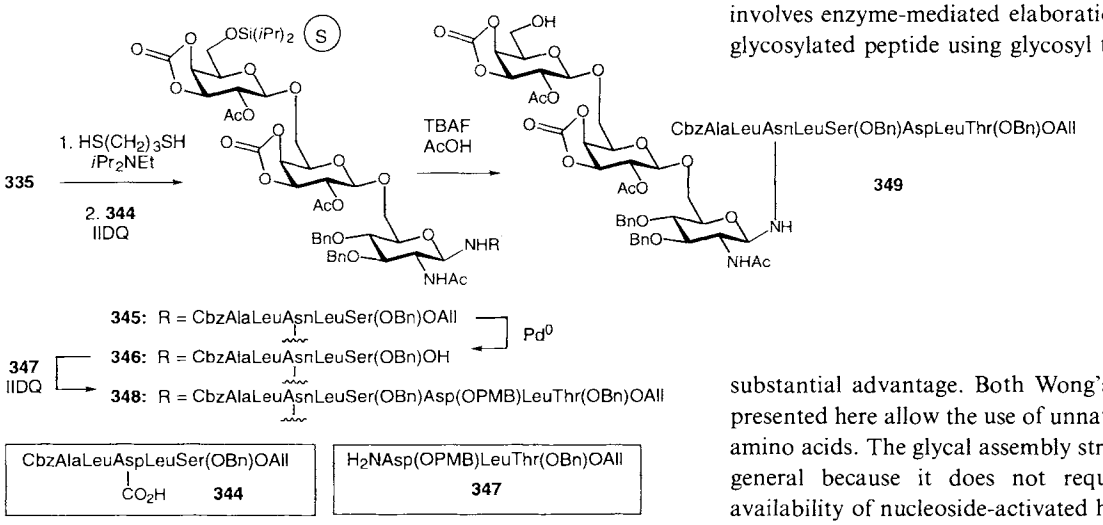
Scheme 73. Synthesis of N-linked glycopeptides. All = allyl, Anthr = anthracenyl, Troc = trichloroethoxycarbonyl, IIDQ = 2-isobutoxy-1-isobutoxycarbonyl-1,2-dihydroquinoline.



Scheme 74. Synthesis of N-linked glycopeptides on a solid support. Cbz = benzyloxycarbonyl.

figuration of all the anomeric linkages. The structures were further corroborated by mass spectroscopy.

The presence of orthogonal protecting groups on the C- and N-termini of the peptide provides the opportunity to extend the peptide chain while the ensemble is bound to the solid support. Alternatively, after removal from the support, the liberated peptide terminus may provide a functionality for linking to a carrier molecule to generate other glycoconjugates. Scheme 75 shows how the peptide portion of the glycopeptide was extended while still bound to the polymer support. The solid phase bound trisaccharide pentapeptide **345** was assembled as previously described from **335** by employing pentasaccharide **344** in the coupling reaction. The C-terminus of **345** was deprotected to give acid **346**, which was then coupled to tripeptide **347** with a free N-terminus to give glycopeptide **348**. Retrieval from the solid support afforded the trisaccharide–octapeptide **349** in an 18% overall yield from polymer-bound galactal carbonate.



Scheme 75. Synthesis of N-linked glycopeptides on a solid support.

In contemplating the future of glycopeptide synthesis, one should take particular note of the method of Wong,[138] which involves enzyme-mediated elaboration of a solid phase bound glycosylated peptide using glycosyl transferases to append unprotected nucleoside phosphate activated monosaccharides in the elongation phase. The conjugate is retrieved from the solid support by protease action. Protecting group manipulations are not necessary in enzymatically mediated chemistry, which can be a substantial advantage. Both Wong's method and the method presented here allow the use of unnatural amino acids and non-amino acids. The glycal assembly strategy is in principle totally general because it does not require transferases and the availability of nucleoside-activated hexoses. It can also accommodate the inclusion of unnatural (artificial) sugars in the

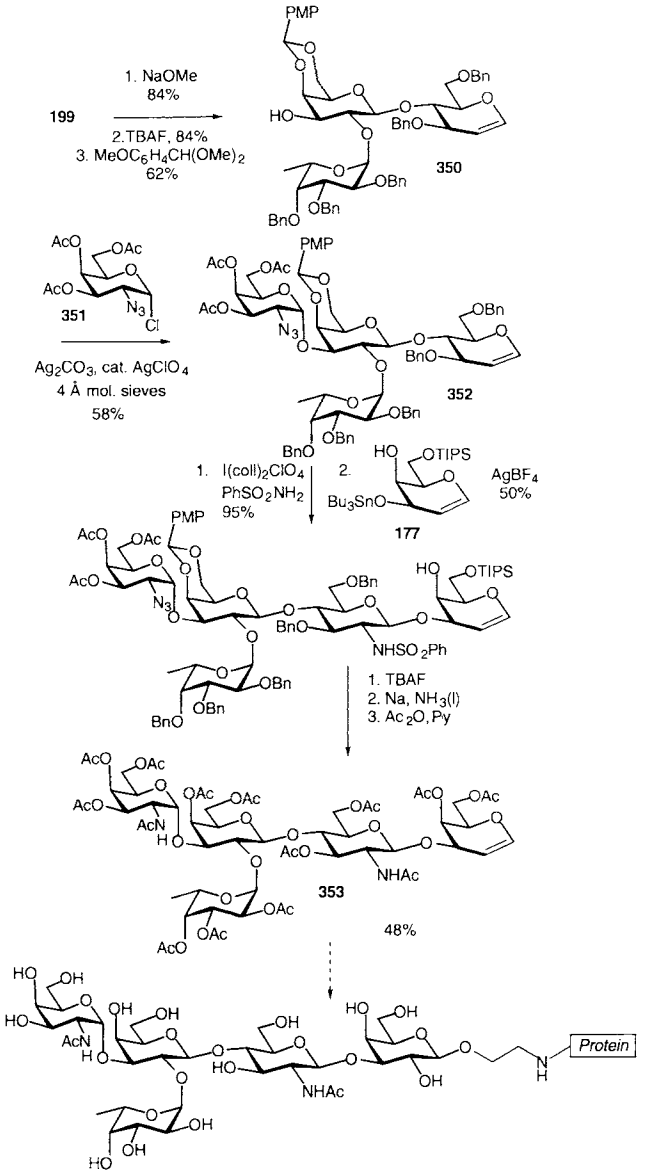
construction. Such building blocks are available from the Lewis acid catalyzed diene–aldehyde cyclocondensation reaction (Scheme 2). All workable approaches, whether purely chemical or chemo-enzymatic, are complementary for reaching the common goal of carefully designed, fully synthetic glycopeptides.

11. Studies in Progress

Thus far we have confined ourselves to a review of programs that have been completed and published. It is well to bring the reader up to date on current efforts in our laboratory. This update will help to underscore the sorts of chemical and biological problems we are addressing through the strategy of glycal assembly.

11.1. Synthesis of Blood Group A (Type 2) Determinant

We have been continuing our work in the total synthesis of human blood group determinants using glycal assembly. An important recent target has been the blood group A (type 2) determinant.[7] While we have not yet reached this goal, in the sense of producing a fully deprotected, suitably conjugated blood group A substructure, the substantial progress realized[139] suggests that this will be achieved shortly. The synthesis started with previously described compound **199**, which was converted to glycal **350** such that the C3′-hydroxyl of the galactose moiety could subsequently function as the glycosyl acceptor site (Scheme 76). Fortunately, this coupling could be accomplished by using the anomerically pure C2-azido chloride **351**, as pioneered by Paulsen.[140] The resulting **352** has now been converted by our standard protocols to the pentacyclic glycal **353**. The latter awaits suitable conjugation to provide the synthetic human blood group A determinant and immunological investigation.



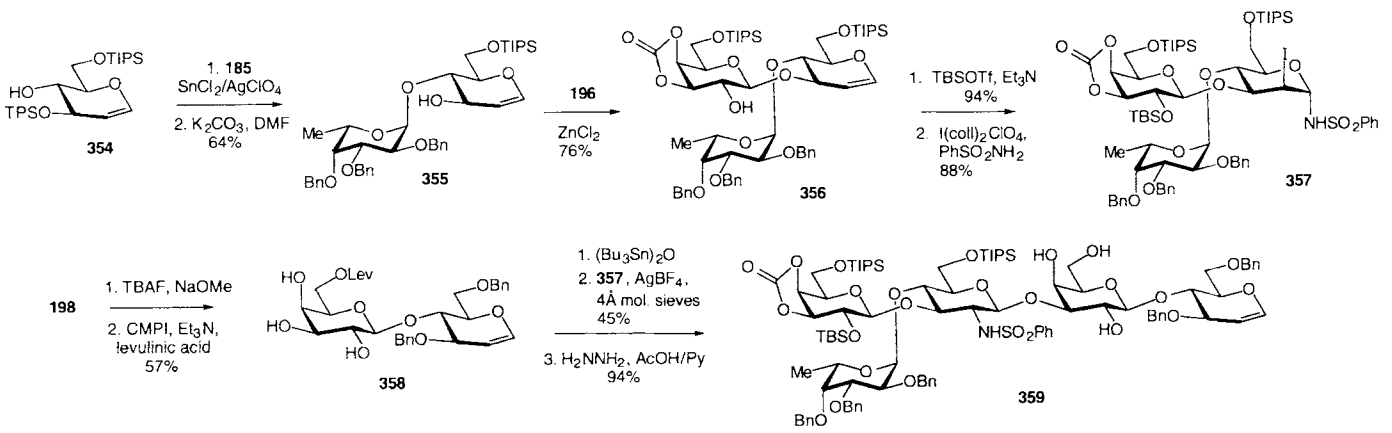
Scheme 76. Synthesis of a glycal of the blood group A (type 2) determinant.

11.2. An Approach to the N3 Antigen

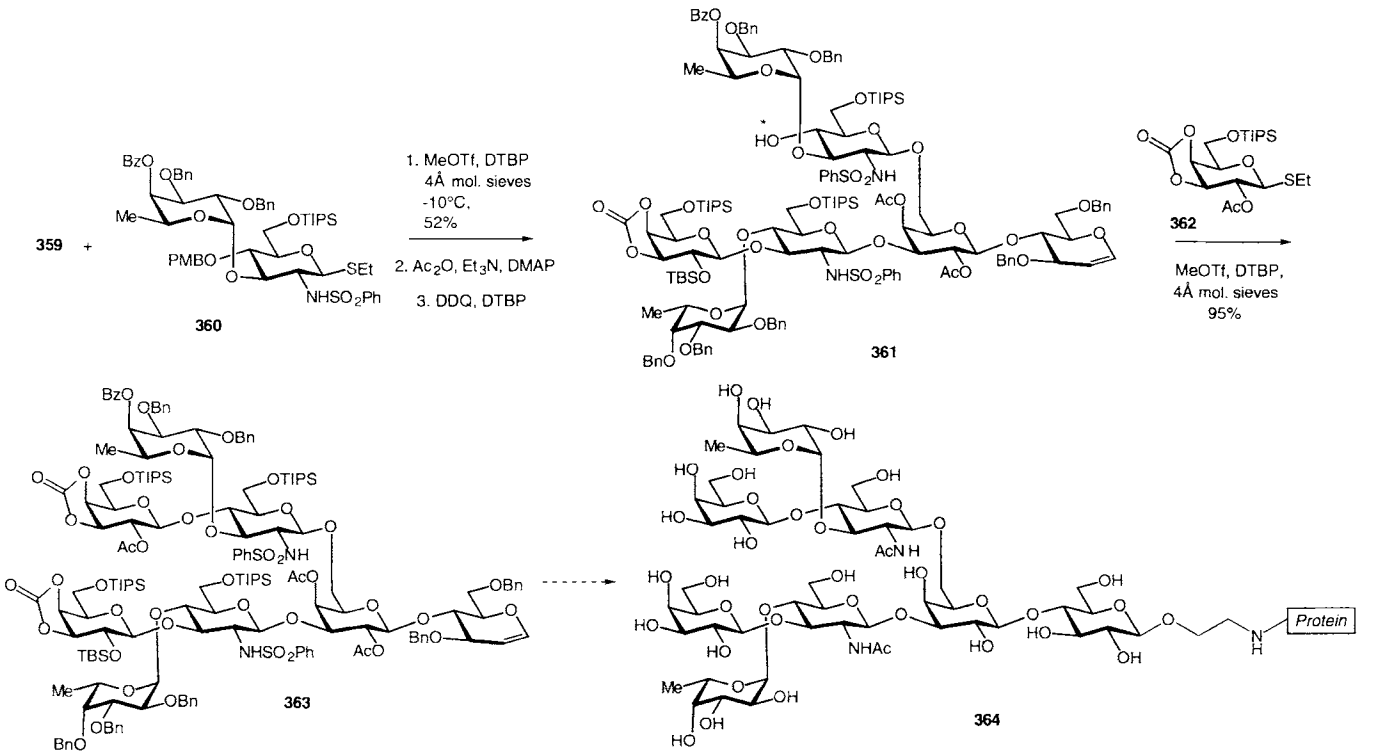
Our synthesis of the N3 antigen is now nearing completion. We, as well as others,[141] have high hopes that a suitably conjugated version of this antigen can be used to detect even minuscule amounts of the N3 antibody, which appears to be specifically produced in response to gastrointestinal cancer.

The realization of this synthetic goal by glycal assembly methodology turned out to be more complicated than might have been expected. The exercise has been valuable in exposing some limits of the technology described earlier in this report. It was found that sulfonamidoglycosylation, either directly (cf. Scheme 22) or by the two-stage protocol employing a saccharide having an ethylsulfanyl substituent at the anomeric center (cf. Scheme 54), can be undermined if the combined steric demands of the donor and acceptor are too high. At the present time we have developed a sense as to when such coupling reactions may fail, but we do not have firm guidelines for predicting what levels of congestion may be tolerated for specific combinations of donors and acceptors. Clearly, such insight will be necessary if this already powerful method is to reach full fruition in applications to complex settings.

For the synthesis of the N3 antigen, we proceeded as described in Schemes 77 and 78.[142] Glycal **355** was used to construct the key building block **356**, which was further converted to the complex azaglycosylation donor **357**. The acceptor triol **358** bearing a levulinoyl protecting group was assembled from glucal and galactal. Fortunately, the 3′,4′,5′-triol in **358** was sufficiently noncongested that the coupling with **357** by direct "rollover" of the sulfonamido group was possible. Upon unveiling of the primary hydroxyl by hydrazine-induced cleavage of levulinoyl protecting group, acceptor **359** was in hand. Starting with D-glucal, following conversions that the reader will at this stage anticipate, donor **360** bearing a strategic *p*-methoxybenzyl protecting group at C4 of the GlcNAc ring was assembled (Scheme 78). The components met the anticipated requirements for coupling at the relatively unhindered primary acceptor site in **359** flanked by a free hydroxyl at C4′. Successful coupling was followed by acetylation of the axial C4′ hydroxyl site on the galactose. We then exposed a unique acceptor site by cleavage of the PMB group (see asterisk **361**). We had recog-



Scheme 77. Synthesis of the N3 antigen (part 1). CMPI = 2-chloro-1-methylpyridinium iodide, Lev = levulinoyl.



Scheme 78. Synthesis of the N3 antigen (part 2).

nized the steric congestion at this acceptor site and had accordingly simplified the demands on the coupling process through the use of a more reactive thioethyl donor. Indeed, **361** underwent successful coupling with donor **362**, fashioned from D-galactal, to produce the N3 glycal precursor **363** in 95% yield. We are currently completing the total synthesis of the N3 antigen and preparing useful N3 conjugates, which may find use as immunostimulants or as diagnostic agents.

This successful preparation of the protected N3 glycal **363** emphasizes an important dimension to the synthesis complex oligosaccharides not often recognized by students of general organic chemistry. Although the basic building blocks are in a broad sense generally defined in advance, there are many opportunities for ingenuity and creativity in how they are brought together. The problems can be quite challenging in the synthesis of compounds with increasing degrees of branching.

Note that in compound **361** one out of 19 potential hydroxyl groups[143] has been identified as the acceptor site. Moreover, it is located in a sterically congested region of the molecule. Yet coupling occurs smoothly because the acceptor center is being merged with a rather reactive donor (**362**). For those who are willing to labor at mastering the "grammar" of complex oligosaccharide synthesis, there is ample opportunity to author a new "literature" of large proportions.

11.3. Synthesis of Asialo-GM_1

In this vein we turn to our recently completed total synthesis of asialo-GM_1.[144] The biological rationale for conducting this project is clear: Al-Awqati and co-workers have implicated membrane-bound asialo-GM_1 as a primary infection site of cys-

tic fibrosis associated pathogens.[145] Indeed, the interior GalNAc-Gal sector of asialo-GM_1 had earlier been claimed to be a general carbohydrate bioligand for pathogenic association in a variety of other infections.[146] Our hope is to generate soluble, cell-permeable versions of these substructures to study their potential as infection decoys.

The full power of azaglycosylation methodology has been brought to bear on the synthesis.[147] Our route started with the previously described **217**, which was suitably upgraded to produce the azaglycosyl donor **365** featuring a free axial hydroxyl in the donor ring (Scheme 79). As noted in the synthesis of the human breast tumor antigen (see Scheme 54), this arrangement tends to favor β-glycoside formation in the sulfonamidoglycosylation reaction. In the case at hand, **365** was coupled to the suitably differentiated and previously described glycosyl acceptor **213** to give **366**. This reaction constituted a severe challenge to our technology, as it required linkage at the very hindered axial bond of the lactal-derived construct. From this achievement, the steps to asialo-GM_1(**368**) followed the protocols that had been well worked out in previous demonstrations. Synthetic **368**, as well as other constructs derived from the terminal glycosidic sites does, indeed, bind to cystic fibrosis associated pathogens.[148]

11.4. Synthesis of the Polysaccharide Core of a Glycopeptide

Our long-term program of synthesizing a natural-type (high mannose containing), fully competent and deprotected asparagine-linked glycopeptide has been progressing well (Scheme 80).[149] Thus, dibenzylglucal epoxide **34** was converted to the ethylsulfanyl-substituted **369** and further to the mannosyl donor **370** (cf. Scheme 30). The azaglycosyl donor **372** was fashioned from **371** as shown and successfully coupled to **197** to produce **373**.

A key element of our strategy was the use of the epoxide derived from glycal **374** protected at C4 and C6 by a *p*-methoxybenzylidene group. This compound was derived from D-glucal in the usual way. The epoxide derived from **374** was transformed to the ethylsulfanylglycoside **375**, which was coupled smoothly with **373** and **375**. Glycal **376** was eventually obtained. Reductive opening of the benzylidene linkage and desilylation pin-

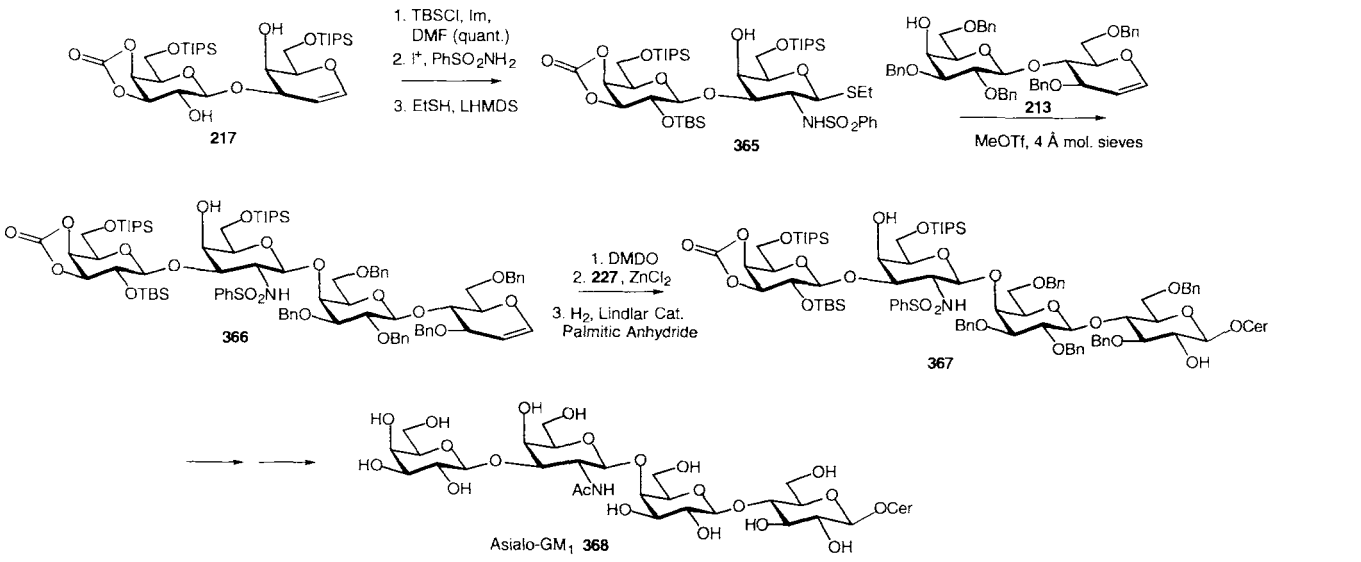


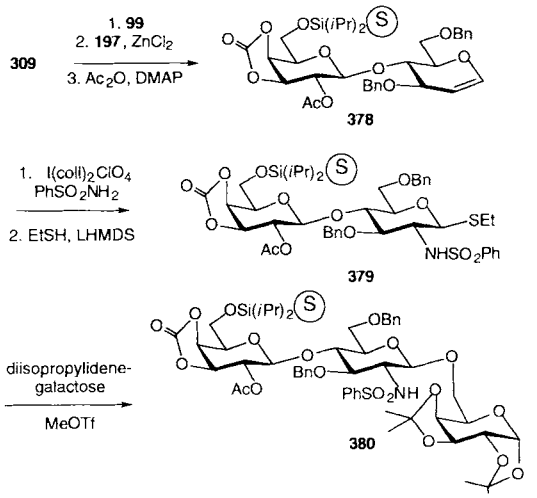
Scheme 79. Synthesis of asialo-GM_1. Im = imidazole.

pointed the α-mannosyl acceptor sites en route to the "high mannose region glycal" **377**. The assembly of the full mannose region in the construct containing an explotiable glycal constitutes a significant advance. Upon refinement of this technology, the stage will be set for introduction of the asparagine-linked peptide by previously described methods (see Scheme 75).

11.5. Solid-Phase Synthesis of a 2-Sulfonamido-2-Deoxyglycoside

Of course, our long-term goal is to synthesize the entire glycopeptide, including the mannose-rich region, on a solid support. The carbohydrate section of the glycopeptide would, eventually, culminate in presentation of blood group or tumor antigen epitopes at the nonreducing end of the construct. Previously, we had noted that azaglycosylation was not successful in our solid-phase protocols, save for introduction of an azido group at the anomeric center (see discussions associated with Schemes 72 and 73).

A significant advance in our technology has now arisen from the demonstration that the polymer-bound **378**, prepared from the previously described **309** in the usual way, can be used to furnish a competent azaglycosyl donor (Scheme 81).[150] Thus,



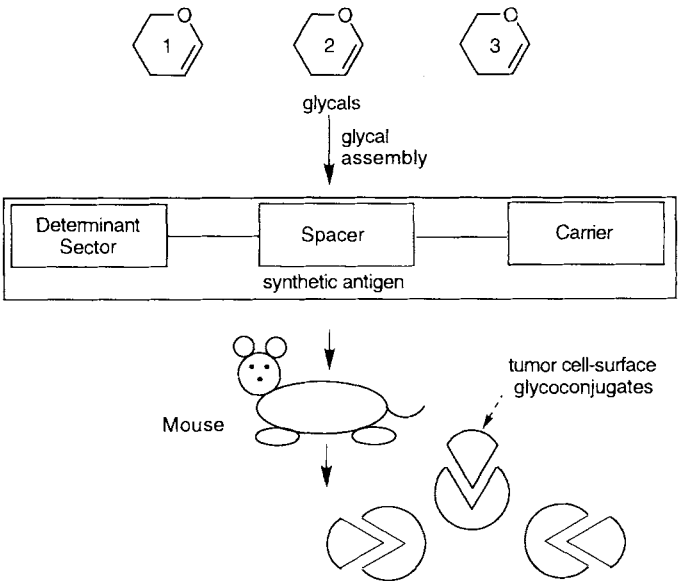
Scheme 81. Lactosamine synthesis on a solid support.

378 was converted to the polymer-bound donor **379**, which reacted with solution-phase diisopropylidenegalactose to produce **380**. Thus, though the generality of azaglycosidation of polymer-bound donors is not yet fully established, certainly the prospects for achieving a strictly solid-phase synthesis of glycopeptide-linked tumor antigens are now quite promising.

11.6. Preclinical Assessments

At present we are focusing on protein conjugates of the human breast tumor (MBr1) and Le^y antigens. In each case, synthetic conjugates bind to appropriate antibodies. These studies clearly implicate the carbohydrate sectors as the key immunological recognition sites. Mapping efforts are well underway to ascertain the key contributions to binding in the carbohydrate domain.

Most encouraging is the fact that our fully synthetic constructs in both series, when injected in mice, generate antibodies that bind in vitro to target cell lines (Scheme 82). These promising findings invite the next question, whether such constructs will provide clinically useful immunological protection or even regression in a human setting. The protocols needed to put such large and important questions to the test are now being developed.



Scheme 82. Inoculation of mice with synthetic antigens. Mouse antibodies bind to tumor-transformed cell lines.

12. Conclusions and Futuristic Perceptions

In this article we have shown, by example, the power of glycal assembly. Of course, ours is only one of several laboratories addressing the synthesis of complex oligosaccharides. We cannot claim these methods to be indispensable; all of the target molecules described in this review could probably have been reached by other coupling methods or assembly strategies. A fair number of the syntheses shown here have in fact been achieved through more conventional carbohydrate chemistry. We do, however, feel that glycal assembly may offer large advantages in synthetic conciseness. These stategies may obviate many of the onerous protecting group manipulations that have dominated this field. Glycal assembly has stimulated the development of new coupling technologies, and the methods are constantly improving. Those who maintain an open mind about carbohydrate technology would be well advised to consider ways in which glycals might be useful for their purposes.

We are confident that solid-phase oligosaccharide synthesis, our methods and others,[138] will be expanded, and that substantial progress in this regard is in the offing. We expect major new advances in glycopeptide synthesis to be realized by our methods, by other chemical methods, and, indeed, by enzymatically assisted methods. Certainly, the goal of adapting solid-phase methodology to include assembly of the mannose-rich regions of glycopeptides is high on our list of priorities.

Ultimately, the test of the success at the chemical level will be whether complex oligosaccharides and glycoconjugates can be synthesized effectively by even nonspecialists. Despite the success of the methods described here, this is currently far from the case and further developments are needed. The challenges and the opportunities of oligosaccharide synthesis are immense and many solutions are possible, including some which await creative formulation by future practitioners.

We venture the opinion that even as progress is made on the chemical issues, the "really decisive" terrain may be shifting. In the past chemists have lavished a great deal of time and energy in developing a host of glycosylation methods and strategies. These advances have spawned a new and very serious challenge – the conceptualization of valuable targets. Though many unsolved chemical problems continue to arise, the time is already at hand to prepare and evaluate new constructs to test important possibilities in structural biology, immunology, and medicine. In our own work it is only in the last year that our glycal methodology has produced ample amounts of carrier protein conjugated carbohydrate-based tumor antigens for preclinical and, hopefully, clinical evaluation. At this time no one can safely predict the full impact of such carbohydrate–protein constructs on either the diagnosis or the treatment of cancer. The most we can safely assert is that this clinical issue will be probed in detail. Thus, the largest challenges may now lie in choosing synthetic targets and in marshaling the multidisciplinary resources for systematic evaluation of the products of such efforts.

We close this review with some thoughts concerning life on the chemistry–biology frontier. In this account we have shown by historical progression how our laboratory, starting with fascinating problems in the field of "small molecule" natural products, has become involved in issues of tumor expression and tumor immunology. One of the singular contributions which we and like-oriented research groups bring to such coalitions is a sensitivity for precisely defined structures. When collaborating with biologists in identifying bioactive compounds and charting their functions, the chemist insists that the compounds in question be demonstrably pure and that the structural assignments, down to each stereogenic center, be corroborated. But chemistry's contribution to the enterprise is certainly more than restraints arising from insistence on thoroughness and intellectual exactitude. Methodical building upon the principles of our science leads to the magic of synthesis—with its unique capability to prepare molecules of virtually any shape and juxtaposition of functional groups. Creative synthesis is the indispensable talent that the chemist will bring to the many exciting struggles and opportunities in the future.

The research reviewed in this paper was possible only through the dedication, enthusiasm, and creativity of scores of co-workers, whose names are acknowledged on the publications cited from our laboratory. In a few instances we identified individual colleagues who were involved at particularly sensitive points of the journey. However, it is to all our associates on these papers, and to other members of the laboratory (who were available for the extensive discussions that helped to fashion these experiments) to whom the program is lastingly indebted.

Needless to say, external funding was also necessary! This support was provided largely by the National Institutes of Health (AI 16943, CA 28824, HL 25848). In addition, M. T. B. gratefully acknowledges the NIH for a Postdoctoral Research Fellowship (GM 16291). We also note and express our thankfulness for generous inputs over these twenty years from various public-spirited supporters in the pharmaceutical industry, particularly the Merck Corporation and, more recently the Pfizer Foundation for Graduate Fellowships.

[53] a) H. Paulsen, *Angew. Chem.* **1982**, *94*, 184; *Angew. Chem. Int. Ed. Engl.* **1982**, *21*, 155; b) D. R. Mootoo, P. Kondradsson, U. Udodong, B. Fraser-Reid, *J. Am. Chem. Soc.* **1988**, *110*, 5583. This paper introduced the concept of "armed" and "disarmed" *n*-pentenylglycosides. In the work of Friessen [55], which was virtually complete before this landmark paper was published, there is no analog to the disarmed substrate. Glycals bearing acyloxy groups function perfectly well as glycoxyl donors. Such donors simply react with acceptors slower than their triether counterparts do.

How ceramics and glasses can be synthesized by new procedures and which organic building blocks and transition metal fragments these can contain, is described by herein.

Recent Developments of Molecular Chemistry for Sol–Gel Processes

Robert J. P. Corriu* and Dominique Leclercq

This review focuses on some aspects of the chemistry involved in the preparation of oxides by sol–gel methods. This field is opening interesting possibilities for molecular chemistry and among those presented herein are: 1) the use of precursors containing functional groups for the preparation of solids with specific chemical reactivity; 2) the non-hydrolytic gelation (NHG) route, a new general method for the synthesis of oxides that allows the use of oxygen donors (ethers, alcohols, alkoxides) other than water; the mechanism is based on oxygen–carbon bond cleavage; 3) organic–inorganic hybrid solids containing covalent bonds for which the chemical reactivity is used to demonstrate the presence of substructure in the globally amorphous solid; the substructure greatly depends on the geometry of the organic moiety.

Keywords: materials design · molecular chemistry · organic–inorganic hybrid composites · sol–gel process

1. Introduction

Organic and inorganic molecular chemistry has made great progress during the last few decades. Nowadays, chemists can construct almost every conceivable structure. The next goals for chemistry are the synthesis of biomolecules and planned synthesis of solids with specific properties.

Apart from polymer materials, most ceramic and glass materials are prepared by solid-state reactions. The main exceptions, in which the synthetic methods are based on a molecular chemistry approach, are the synthesis of ceramics by pyrolysis of organometallic polymers, for example the preparation of silicon carbide fibers from the Yajima process,[1] and the preparation of oxides by sol–gel processes.[2]

Clearly, the planned synthesis of solids whose properties can be controlled at the molecular scale is one of the challenges of molecular chemistry. From this viewpoint, organosilicon chemistry has a very great future, since it is an ideal link between molecular and solid-state chemistry. Silicon–carbon bonds are very stable and silicon-containing moieties can be included in many different sites in organic molecules; they can induce the formation of many kinds of polymers and can also lead to a wide variety of solid materials including oxides, silicides, and thermomechanical ceramics.

For these reasons, since 1986 we have been interested in organosilicon compounds as potential precursors for the synthesis of solids. This review will focus mainly on the chemistry and not on the physics and materials science of sol–gel processing. The molecular chemical aspect is emphasized by the presentation of new precursors, a new chemical route in the sol–gel process, and the report of hybrid organic–inorganic materials, which are a new class of materials.

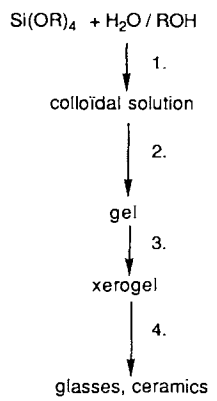
2. Sol–Gel Chemistry: General Remarks

Sol–gel processes have been well studied and developed in materials science since they are well-suited to preparing materials and to designing devices with very specific properties.[2] The sol–gel processes may be divided into two classes depending on the nature of the precursors; inorganic precursors (chlorides, nitrates, sulfides, etc.) and alkoxide precursors. The route that involves the use of alkoxide precursors appears as the more versatile one.[3] The most important step in this route is the formation of an inorganic polymer by hydrolysis reactions, during which the molecular precursor is transformed into a highly crosslinked solid in a one-pot procedure (Scheme 1).



Scheme 1. Sol–gel process. 1. Hydrolysis/condensation, 2. Sol–gel transition. 3. Drying. 4. Densification.

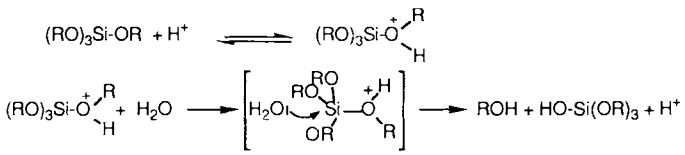
Hydrolysis of a solution of tetraalkoxysilanes in an organic solvent such as alcohol leads to the formation of products with silanol functions, which form a sol (colloidal dispersion of particles in a liquid) by condensation polymerization.[2] The continuation of the process gives a gel (continuous solid skeleton enclosing a continuous liquid phase). This transformation is designated the sol–gel

transition. Gels may exhibit spontaneous shrinkage, called syneresis, on ageing. The network is initially supple and allows further condensation and bond formation induces contraction of the network and expulsion of liquid from pores. Drying of the gel by evaporation under normal conditions gives a dried gel, called a xerogel. Xerogels are interesting materials because of their porosity and high surface area, which make them useful as catalyst substrates, filters, etc. They are also useful in the preparation of dense ceramics by sintering (the densification is driven by the interfacial energy).[2] The advantage of the molecular approach to the synthesis of materials is based on the fact that the precursors can be obtained in the form of monoliths, films, fibers, and monosized powders directly from the gel state. The transformation from xerogel to ceramic is mainly the concern of material scientists, whereas the transformation of the molecular precursors to gels is the domain of molecular chemists.

Metal alkoxides are very sensitive to hydrolysis.[4] Thus, because of the low reactivity of tetraalkoxysilanes, their hydrolysis, which is usually catalyzed, has been more extensively studied. At this point, it is important to point out that in aquo-organic solvents, the pH value is not well defined. It is merely a measured value and not the exact one of the acidity (or basicity) of the mixture. The H_0 function introduced by Hammet[5] is the only true value of the proton activity that depends strongly on the water/organic solvent ratio. Since we have discussed this in detail elsewhere it will not be developed here.[6]

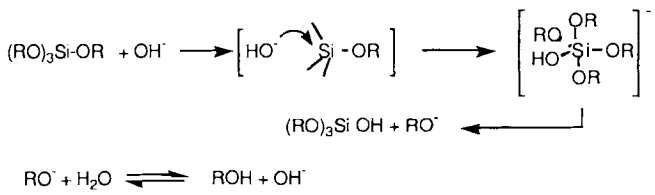
Even in the case of alkoxysilanes, only the mechanism of the first steps of the sol–gel process are well known.[7] It involves a nucleophilic attack by water at the silicon center. The detailed mechanism, however, is dependent on the catalyst used. Three kinds of catalysis are possible: acid, basic (OH^-), and nucleophililic (F^-, *N*-methylimidazole, hexamethyl phosphoramide (HMPA), etc.)

1) Acid catalysis: The first step is the reversible protonation of the alkoxy group which confers to it a better leaving character (Scheme 2). Nucleophilic substitution by water (or by silanol) occurs via a pentacoordinate intermediate.



Scheme 2.

2) Basic catalysis: The nucleophilic hydroxide ion reacts with the alkoxysilane by nucleophilic substitution via the formation of a pentacoordinate intermediate and elimination of the alkoxide RO^- (Scheme 3). The catalyst re-forms by reaction with water. However, this mechanism has been recently questioned, since bases could act as nucleophilic catalysts [see 3].[8]



Scheme 3.

3) Nucleophilic catalysis: The nucleophilic catalyst (F^-, HMPA, *N*-methylimidazole, *N*,*N*-dimethylaminopyridine) coordinates to the alkoxysilane giving rise to a pentacoordinate silicon intermediate that is more reactive toward nucleophilic

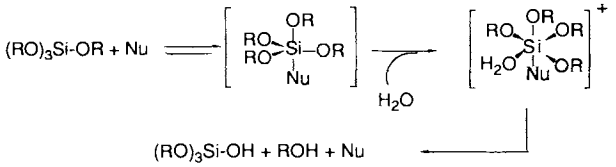
R. J. P. Corriu

D. Leclercq

Robert Corriu, born in 1934 in Port-Vendres, France, obtained his Docteur es Sciences Physiques in 1961 from the Université de Montpellier. He became Assistant Professor at the Université de Perpignan in 1963, Associate Professor at the Université de Poitiers in 1964, and Professor at the Université de Montpellier in 1969. His research interests in organometallic chemistry are focused on organosilicon, organogermanium, and organophosphorus compounds, transition metal complexes, and hypercoordinate silicon and phosphorus compounds. He is currently concentrating his research efforts into the chemistry of organometallic polymers as precursors to materials. He has obtained awards from the French Chemical Society (Prix Sue in 1969 and Prix Lebel in 1985), from the CNRS (silver medal in 1982), and from the American Chemical Society (Kipping Award in 1984). He was elected to the French Academy of Sciences in 1991 and obtained the Alexander von Humboldt Research Award in 1992, and the Max Planck Research Award in 1993.

Dominique Leclercq, born in 1952 in Fourmies, France, obtained his Docteur es Sciences Physiques in 1984 from the Université de Montpellier II with a thesis on the mechanisms of nucleophilic substitution on organophosphorus compounds. After a postdoctoral position at the Centre de Recherche Rhône-Poulenc, Aubervilliers, he studied the chemistry of organometallic compounds as precursors to materials. He is currently interested in the preparation of non-oxide ceramics by pyrolysis of polycarbosilanes and polysilazanes as well as in synthesis of oxide ceramics by the sol–gel process.

substitutions (by water or silanol) than the tetracoordinate one (Scheme 4). The nucleophile coordinates to this pentacoordinate intermediate, leading to a hexacoordinate intermediate or transition state, which subsequently gives rise to the formation



Scheme 4. Nu = nucleophile.

of alcohol and silanol and re-formation of the catalyst. The mechanism of this reaction has been evidenced by kinetic and stereochemical studies[9] and is supported by theoretical calculations.[10] The hydoxide ion could also act as nucleophilic catalyst.[8]

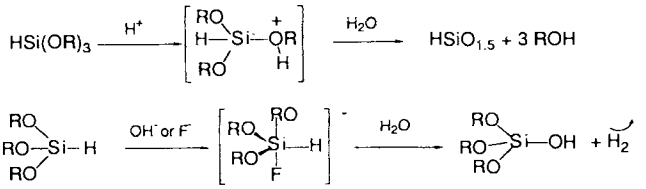
These mechanisms, however, address only the first step of a very complex process. Many kinetic studies have been devoted to the first stage of the sol–gel process. Kinetic analyses were performed by using a functional group model, which allows the evaluation of global rate constants.[11] The only study on the determination of the rate constants of individual component reactions of the acid-catalyzed hydrolysis of silicates was reported by Chojnowski et al.[12] This work emphasizes the role of alcoholysis reactions in the overall process. Many simulations have been done, based on different hypotheses, permitting an explanation of the shape of the solids formed under some experimental conditions.[13] However, these are only empirical procedures for the synthesis of solids with defined structures. Every small change in the experimental conditions (temperature, solvent, concentrations, nature and concentration of catalyst, and external factors such as sonication or pressure, etc.) modifies drastically the texture (specific surface area, size and distribution of pores, density, processibility, etc.) of the solid obtained. A detailed knowledge of the chemical mechanisms, which permits prediction and control of the properties of the final amorphous material at the molecular scale, is an exciting challenge for molecular chemists.

In this review, we will not give a detailed account of the chemistry of building blocks[14] or mechanistic studies of the sol–gel transition.[2] Instead, we focus on 1) new precursors, 2) new chemical routes for the sol–gel process, and 3) hybrid organic–inorganic solids.

3. New Precursors

3.1. $HSi(OR)_3$

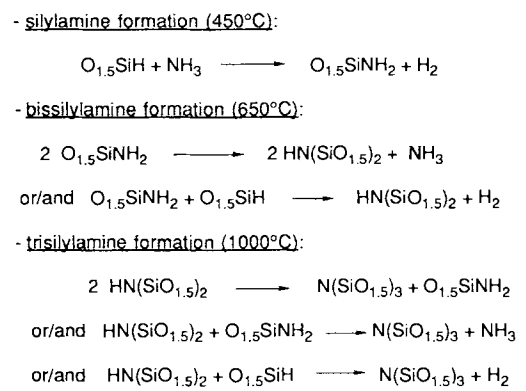
The hydrolysis of $HSi(OR)_3$ (R = Me, Et, *i*Pr) performed under acid conditions avoids the hydrolysis of the Si–H bonds and leads to a gel of composition $HSiO_{1.5}$.[15] Under nucleophilic or basic conditions silica is formed with evolution of H_2 (Scheme 5).[15] Indeed, nucleophilic substitution of hydridosilicates $[HSi(OR)_4]^-$ leads only to cleavage of the Si–H bond.[16] This reaction parallels the nucleophilic activation of the Si–H bond, which permits selective and efficient reduction.[17]



Scheme 5. Hydrolysis of trialkoxysilanes.

The $HSiO_{1.5}$ gel shows spectroscopic features similar to those of the crystalline octahydrosilsesquioxane $[HSiO_{3/2}]_8$ ($\tilde{\nu}_{Si-H}$ = 2250 cm^{-1}, $\delta_{Si} = -85$).[18] In contrast to silica gels, these gels are not hydrophilic. This is easily explained by the absence of silanol groups in the gel and by the presence of the hydrophobic Si–H groups at the surface of the gel, instead of hydrophilic Si–OH groups in the case of silica.

The thermal treatment of these solids is interesting. Under an oxidizing atmosphere, as expected, the Si–H bonds are oxidized leading to an increase in weight (10%) due to the formation of silica.[15, 19] Under an NH_3 atmosphere silicon oxynitrides are formed with a high content of nitrogen (3 wt%).[20] The mechanism of nitridation, which was determined by IR and NMR spectroscopy and by thermogravimetric analysis coupled with mass spectrometry (TGA/MS), is a three-step process (Scheme 6).[19, 20] The first step is the formation of silylamine



Scheme 6. Mechanism of nitridation of $HSiO_{1.5}$.

functions at about 450 °C as a result of the reaction of the Si–H bond with ammonia. Condensation of silylamine functions with each other or with Si–H functions above 650 °C leads to the formation of silazane groups. These then undergo condensation reactions with each other and/or with silylamine and/or with Si–H at 1000 °C, leading to the formation trisilylamines. This illustrates that the Si–H group can be considered as a functional group.

Other interesting reactions take place upon heating under argon. At 350 °C, a very unexpected rearrangement takes place that leads to the evolution of SiH_4, which was detected by a mass spectrometer coupled with the TGA apparatus.[19, 21] The solid-state MAS ^{29}Si NMR spectrum of the gel heated at 400 °C under argon shows two additional peaks at $\delta = -50$ and $\delta = -110$ corresponding to H_2SiO_2 and SiO_4 units, respectively (Fig. 1). On heating to a higher temperature (570 °C), the signal

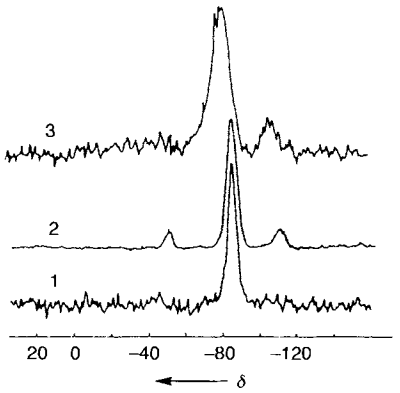


Fig. 1. ^{29}Si CP/MAS NMR spectra of a $HSiO_{1.5}$ gel heat treated at 1) 150 °C, 2) 405 °C, and 3) 565 °C.

for the H_2SiO_2 structural unit disappears. The formation of SiH_4 arises from redistribution reactions that occur in the solid (Scheme 7), regardless of the atmosphere under which the reactions were performed (air, ammonia, or argon).[19] Nitridation of the gel begins at 450 °C, following the loss of silane at 350 °C.

$$2\ HSiO_{1.5} \rightleftharpoons H_2SiO + SiO_2$$
$$H_2SiO + HSiO_{1.5} \rightleftharpoons H_3SiO_{0.5} + SiO_2$$
$$H_3SiO_{0.5} + HSiO_{1.5} \rightleftharpoons SiH_4 + SiO_2$$

Scheme 7. Redistribution of the Si–H and Si–O bonds in $HSiO_{1.5}$.

On heating in air, the formation of silane is not observed. However, the dissymmetrical exothermic peak observed by differential thermal analysis (DTA), as well as the presence of water detected by mass spectrometry indicate that SiH_4 is formed, but that it is rapidly oxidized in an exothermic reaction.[22]

At temperatures between 450 and 900 °C, evolution of H_2 is detected. Taking into account what would be expected in solution, the formation of Si–Si bonds leading to silicon sesquioxide Si_2O_3 has been proposed (Scheme 8).[23] Furthermore, X-ray diffraction showed the formation of cristobalite and crystalline silicon at 1600 °C, which was attributed to disproportionation of Si_2O_3 (Scheme 9).[23]

$$O_{1.5}Si\text{-}H \longrightarrow O_{1.5}Si^{\cdot} + H^{\cdot}$$
$$2\,H^{\cdot} \longrightarrow H_2$$
$$2\,O_{1.5}Si^{\cdot} \longrightarrow O_{1.5}Si\text{-}SiO_{1.5}$$

Scheme 8. Formation of Si_2O_3 by dehydrogenation of $HSiO_{1.5}$.

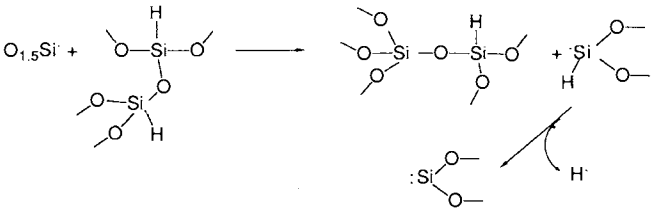
$$2\,Si_2O_3 \longrightarrow Si + 3\,SiO_2$$

Scheme 9. Disproportionation of silicon sesquioxide.

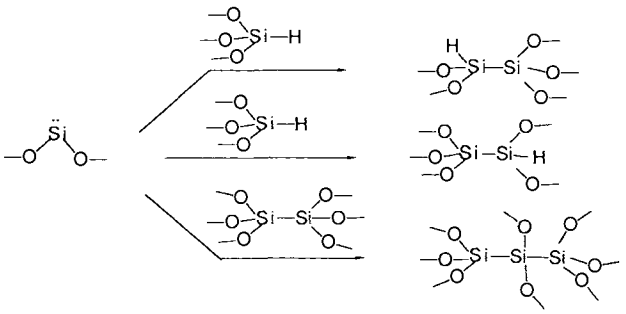
ESR spectra between 400 and 1200 °C show that the pyrolyzed gel contains $O_3Si^{\cdot}$, $O_2SiSi^{\cdot}$, $OSi_2Si^{\cdot}$, $Si_3Si^{\cdot}$ radicals (10^{17} unpaired electrons per g gel).[18] Furthermore, an X-ray absorption near-edge structure (XANES) spectroscopic study reveals that the product obtained by heating at 500 °C contains predominantly regions with Si–Si bonds and those with Si–O. Thus, during the thermal dehydrogenation of $HSiO_{1.5}$ between 400 and 900 °C, Si–Si bond formation competes with a formal redistribution of Si–Si and Si–O bonds. The ESR signals can thus be assigned to the resulting tetrahedral $Si(Si_xO_{4-x})$ units.

The Si–Si bond formation can be interpreted according to the mechanism of the thermolysis of alkoxydisilane in solution, in which a redistribution of Si–Si and Si–O bonds occurs via silylene intermediates.[24] Indeed, due to the restricted mobility of the $O_3Si^{\cdot}$ radicals in the solid state, a recombination reaction is less likely than a reaction with an oxygen atom of the neighboring $HSiO_{1.5}$ network (Scheme 10). The resulting silylene reacts to form Si–Si bonds by insertion into Si–H, Si–O, or Si–Si bonds (Scheme 11).

$$HSiO_{1.5} \longrightarrow H^{\cdot} + {}^{\cdot}SiO_{1.5}$$



Scheme 10. Formation of silylenes.



Scheme 11. Insertion reactions of silylene.

The thermal dehydrogenation of hydrosilsesquioxide gels does not lead directly to the formation of the stable silicon and silica phases but to the silicon sesquioxide phase that consists of a mixture of tetrahedral $Si(Si_zO_{4-z})$ units.[18]

3.2. Si_2Cl_6

The synthesis of a definite compound Si_2O_3 with only one tetrahedral $Si(Si_3O)$ site necessitates formation of Si–Si bonds at low temperature. A simple method has been proposed that employs hexachlorodisilane as a precursor (Scheme 12).[25]

$$Cl_3Si\text{-}SiCl_3 \xrightarrow[-95°C]{3\,H_2O\,/\,Et_2O} Si_2O_3 + 6\,HCl$$

Scheme 12. Synthesis of Si_2O_3.

Neutral or acid hydrolysis does not cleave the Si–Si bonds.[25] The hydrolysis of Si_2Cl_6 gives rise to an evolution of HCl, which provides acidic conditions. The reaction affords a white amorphous powder (with a specific surface area of 600 m^2g^{-1}) in which most of the Si–Si bonds are preserved (more than 90% of the theoretical ones). The silicon sesquioxide product has been characterized by IR spectroscopy (very weak Si–H stretching band at 2265 cm^{-1}, $\tilde{\nu}(SiO_{1.5}) =$ 875 cm^{-1}), ^{29}Si MAS NMR spectroscopy ($\delta = -71$, half

height width 954 Hz), and X-ray absorption spectroscopy (absorption edge at 1840.5 eV, those of silicon and silica are at 1836 eV and 1844 eV, respectively).[25] The representation of the average interatomic distances in Si_2O_3 in the bulk material obtained by extended X-ray absorption fine structure (EXAFS) spectroscopy is given in Figure 2. Thus, Si_2O_3, prepared in this

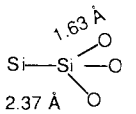


Fig. 2. Average environment determined by EXAFS spectroscopy of the silicon atoms in Si_2O_3 in the bulk material.

way is a defined compound in which each silicon atom is bonded to three oxygen atoms and one silicon atom rather than a random mixture of Si-like and SiO_2-like tetrahedra.[25] However, this product contains quite a few absorbed water molecules as shown by IR spectroscopy.

The thermal evolution of this compound was studied by TGA/MS and by ^{29}Si MAS NMR spectroscopy. Above 200 °C water and hydrogen are evolved. The presence of water arises from desorption and from condensation of silanol groups, which are formed by hydrolysis of the Si–Si bonds (see below). The formation of H_2 is attributed to the hydrolysis of Si–Si and Si–H bonds (Scheme 13). The NMR spectrum of the remaining

$$O_{1.5}Si{-}SiO_{1.5} \xrightarrow{H_2O} O_{1.5}Si{-}OH + O_{1.5}Si{-}H$$

$$2\,O_{1.5}Si{-}OH \longrightarrow 2\,SiO_2 + H_2O$$

$$O_{1.5}Si{-}OH + O_{1.5}Si{-}H \longrightarrow 2\,SiO_2 + H_2$$

Scheme 13. Hydrolysis of the Si–Si bond in Si_2O_3.

solid corresponds to hydrated silica. Hydrolysis of the Si–Si bonds, which leads to the formation of silica, occurs during heating due to absorbed water in the gel. Similar cleavage of Si–Si bonds by adsorbed NH_3 was encountered in the synthesis of triimidodisilane by ammonolysis of Si_2Cl_6.[26] The hydrophilic character of silicon sesquioxide Si_2O_3 does not allow its metastability to be studied.

3.3. Organosilicon Precursors

Silicon oxycarbide species have been characterized by X-ray photoelectron spectroscopy (XPS) [27, 28] and by high-resolution solid-state ^{29}Si MAS NMR.[28–38] The system may be described as a composite material formed by a silicon oxycarbide phase of the composition $SiC_xO_{(1-x/2)}$, and free carbon (arising from an excess carbon phase). In this phase the carbon atoms are only linked to silicon atoms under the formation of $C(Si_4)$ sites, and the oxygen atoms are involved in Si-O-Si bridges.

Silicon oxycarbides were reported at the interface between silicon carbide substrates and the silica surface layers formed by oxidation.[34] Nicalon ceramic fibers, which are obtained by pyrolysis of a polycarbosilane crosslinked by oxidation, consist of β-silicon carbide and graphite crystallites embedded in a continuous phase of glassy silicon oxycarbide.[35] The pyrolysis of polysiloxane gels, which were obtained by hydrolysis of organosilanes, appears to be a versatile route to silicon oxycarbide glasses or silicon carbide, because of the carbothermal reduction that takes place above 1400 °C.[31, 33, 42, 43]

A great variety of polysiloxane precursors with varied compositions and structures has been prepared by hydrolysis/condensation (or co-hydrolysis/condensation) of alkoxy- or chlorosilane monomers (or co-monomers) bearing non-hydrolyzable substituents such as methyl, ethyl, vinyl, phenyl, or hydro groups (Scheme 14). However, in the case of alkyl groups, carbon is lost during the pyrolysis by β-elimination; thus, the final carbon content is the same as obtained by starting from methyl precursors. The use of precursors with unsaturated substituents such as phenyl and vinyl groups leads to a high final carbon content but as a free carbon phase.

$$n\,R_{4-x}SiX_x + n\,(x/2)\,H_2O \longrightarrow (R_{4-x}SiO_{x/2})_n + nx\,HX$$

X= MeO, EtO, Cl ; R= Me, Et, Vi, Ph, H....

Scheme 14. Preparation of polysiloxane precursors. Vi = vinyl.

To date, only the composition of one oxycarbide has been studied in detail. It does not depend on the C/Si ratio in the precursors, since a large fraction of the carbon atoms belongs to a phase formed from excess carbon. The O/Si ratio in the oxycarbide, however, is always slightly higher than that in the gel, since in addition to the formation of Si-O-Si bridges, thermal redistribution reactions between Si–C and Si–O bonds take place, leading to the formation of volatile organosilicon species and SiO_4 groups (Scheme 15).[20, 39] Most of the polysiloxane precursors described have O/Si ratios close to 1.5; they give rise, after pyrolysis in argon at about 1000 °C, to silicon oxycarbide phases with O/Si ratios between 1.5 and 1.8.

$$2\,CH_3SiO_{1.5} \rightleftharpoons (CH_3)_2SiO + SiO_2$$

$$CH_3SiO_{1.5} + (CH_3)_2SiO \rightleftharpoons (CH_3)_3SiO_{0.5} + SiO_2$$

$$2\,(CH_3)_3SiO_{0.5} \rightleftharpoons (CH_3)_3SiOSi(CH_3)_3$$

Scheme 15. Redistribution of Si–C and Si–O bonds.

A change in the composition of the silicon oxycarbide phase may be achieved by simply decreasing the O/Si ratio. However, a decrease of the O/Si ratio entails a decrease in the number of siloxane bridges; thus, the level of crosslinking in the precursor decreases, which favors the formation of volatile organosilicon compounds during pyrolysis. This, in turn, may change the composition of the gel and lead to a low pyrolysis yield. For instance, linear polysiloxanes (O/Si = 1) such as polydimethylsiloxane $(Me_2SiO)_n$ give a negligible ceramic yield, because of the loss of volatile cyclic oligomers. Thus, to prepare good precursors with low O/Si ratios, the Si-O-Si bridges have to be replaced by other bridges in order to decrease the O/Si ratio without decreasing the level of crosslinking in the precursor.[28, 31]

This approach has been developed starting from precursors containing Si–Si bonds such as dimethyltetrachlorodisilane

$MeCl_2SiSiCl_2Me$, or "disilane residue" ("S" mixture), $(CH_3)_xCl_{6-x}Si_2$, a product arising from the direct synthesis of methylchlorosilanes (reaction of methyl chloride with copper/silicon),[31] and bridging alkyl groups such as polydichlorosilylethylene $(Cl_2SiCH_2CH_2SiCl_2)_n$, obtained by hydrosilylation of vinyldichlorosilane ($ViHSiCl_2$).[28] Starting from $ViHSiCl_2$, two precursors of unknown composition **A** and **B** have been prepared: hydrosilylation followed by hydrolysis/condensation led to **A**, whereas hydrolysis followed by hydrosilylation led to **B** (Scheme 16). In this way, silicon oxycarbide phases have been

$$n\ ViHSiCl_2 \xrightarrow{\varepsilon\text{-}H_2PtCl_6} (Cl_2SiCH_2CH_2SiCl_2)_{n/2} \xrightarrow{H_2O} \mathbf{A}$$

$$ViHSiCl_2 \xrightarrow{H_2O} (ViHSiO)_n \xrightarrow{\varepsilon\text{-}H_2PtCl_6} \mathbf{B}$$

Scheme 16. Preparation of precursors **A** and **B**. Vi = vinyl.

prepared with compositions in the range O/Si = 1.3 to 1.14. The higher oxygen content of the oxycarbide glass that was obtained from the disilane precursors is due to partial hydrolysis of the Si–Si bonds and chiefly to redistribution reactions, which lead to the formation of silica and volatile carbon-rich oligomeric silanes. Indeed the loss of silicon compounds during pyrolysis is in the range 2 to 20%.[31] Thus the composition of the oxycarbide phases may be varied depending on the nature of the precursors (Table 1).

Table 1. Composition of oxycarbide phases synthesized from different precursors.

Precursor	T [°C] [a]	Composition of the gel	Composition of the oxycarbide phase
$MeSiO_{1.5}$	900	$SiO_{1.69}C_{0.8}$	$SiO_{1.69}C_{0.15}$ (+ 0.65 C)
SiO_2/Me_2SiO	970	$SiO_{1.75}C_{0.37}$	$SiO_{1.75}C_{0.12}$ (+ 0.25 C)
$MeSiO_{1.5}/Me_2SiO$	970	$SiO_{1.57}C_{0.66}$	$SiO_{1.57}C_{0.21}$ (+ 0.45 C)
$Me_2Si_2O_2$	1000	$SiO_{1.29}C_{0.77}$	$SiO_{1.29}C_{0.36}$ (+ 0.41 C)
"S" [b]	1000	$SiO_{1.26}C_{0.76}$	$SiO_{1.26}C_{0.37}$ (+ 0.39 C)
A [c]	900	$SiO_{1.29}C_{1.42}$	$SiO_{1.29}C_{0.36}$ (+1.06 C)
B [c]	900	$SiO_{1.14}C_{1.74}$	$SiO_{1.14}C_{0.43}$ (+1.31 C)

[a] T = Pyrolysis temperature. [b] "S" = disilane residue. [c] For **A** and **B** see Scheme 16.

The ^{29}Si MAS NMR and XPS spectra show that the distribution of the five tetrahedral SiO_xC_{4-x} sites changes with the composition of the oxycarbide phase.[28, 40] As the O/Si ratio decreases, the relative amount of Si–C rich tetrahedra increases. A comparison of the measured and calculated spectra (Fig. 3) revealed that in fact the silicon oxycarbide phase may be described as a purely random distribution of Si–O and Si–C bonds that forms an independent single phase regardless of the composition.[38] The nature of the precursor governs the composition of the glass; however, the environment of the silicon atoms depends only on the O/Si ratio and is not related to the structure of the precursor.

On heating the sample, the distribution of the SiO_xC_{4-x} sites of the oxycarbide glasses is greatly altered; the ^{29}Si NMR spectra show that the intensity of the peaks corresponding to SiO_4 and SiC_4 sites increases between 1200 and 1350 °C, immediately prior to the occurrence of the carbothermal reduction.[40] This behavior underlines the metastability of silicon oxycarbide

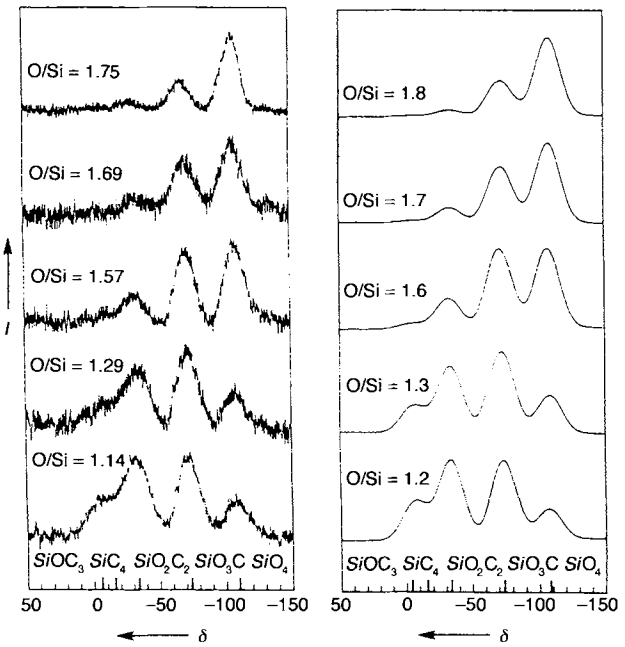

Fig. 3. ^{29}Si MAS NMR spectra of silicon oxycarbide glasses with various O/Si ratios; left: experimentally determined spectra; right: simulated spectra for a purely random distribution of Si–O and Si–C bonds.

phases, which tend to give the thermodynamically stable silicon carbide and silica phases. This phase separation has been ascribed to a continuation of the redistribution reactions of Si–O and Si–C bonds. This rearrangement to a mixture of silicon carbide and silica shows that the formation of silicon carbide by carbothermal reduction above 1400 °C involves the reduction of silica by the excess carbon rather than the reduction of the silicon oxycarbide phase. It has been reported that gaseous silicon monoxide SiO is the intermediate species of the reaction (Scheme 17).[41, 42]

$$SiO_2(s) + C(s) \longrightarrow SiO(g) + CO(g)$$
$$SiO(g) + 2\,C(s) \longrightarrow SiC(s) + CO(g)$$
$$SiO_2 + 3\,C \longrightarrow SiC + 2\,CO$$

Scheme 17. Carboreduction of SiO_2.

For silicon glasses containing an excess of carbon (more than 1.5 C per O), SiO_2 is converted to silicon carbide and the excess carbon remains in the residue.[33] That means that the reaction of gaseous SiO with carbon is very fast. When the excess of carbon is very low (less than 0.2 C), the carboreduction reaction does not occur; the pure silicon oxycarbide phase is thermally stable up to 1500 °C.[43] When the carbon excess is too low to allow the total conversion of SiO into SiC, a large amount of silicon monoxide is lost during this reaction.[38]

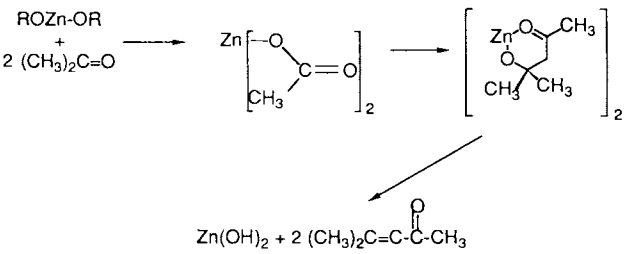
4. New Chemical Routes in Sol–Gel Processing

Hydrolysis and condensation of tetraalkoxysilanes $(RO)_4Si$ readily gives monolithic gels (that is, gels formed from one piece that do not exhibit internal cleavage). However, metal alkoxides

are much more reactive toward hydrolysis and condensation, and generally lead to the formation of precipitates.[3] Sophisticated processes based on decreasing the reactivity of the metal alkoxide precursors by chemical modification (alcohol exchange, addition of carboxylic acids or β-diketones) or on controlling the local concentration of water (alcohol dehydration, esterification, micelles microemulsions) have been developed to achieve monolithic gels.[3, 44, 45]

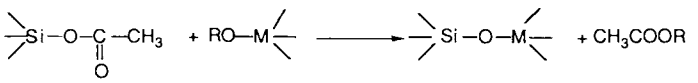
Furthermore, the different reactivities of alkoxysilanes and transition metal alkoxides toward hydrolysis and condensation also make it difficult to control the composition and the homogeneity of binary oxides by the sol–gel process.[46]

To counter the extreme hydrolytic reactivity of metal alkoxides, new condensation reactions have to be developed that permit the formation of metal-oxygen-metal (M-O-M) bridges without hydrolysis. One such method is based on the reaction of acetone with a zinc alkoxide, which results in the formation of a gel, via the decomposition of the intermediate ketolate complex, followed by liberation of zinc oxide, the alcohol, and mesityl oxide (Scheme 18).[47] This reaction is restricted to basic metal alkoxides that are capable of inducing ketolization of ketone.



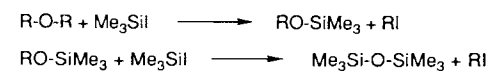
Scheme 18. Reaction of ketone with zinc alkoxides.

The condensation reaction of an acetoxysilane with metal alkoxides under liberation of ester molecules likewise leads to M-O-M bridges (Scheme 19).[48]



Scheme 19. Synthesis of Si-O-M units by ester elimination.

A third method has been developed that is based on well-established organic chemistry; that is, ethers are cleaved by iodotrimethylsilane to give alkyl iodide and hexamethyldisiloxane (Scheme 20).[49] In this reaction, the alkoxysilane formed



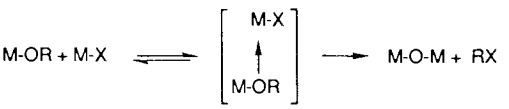
Scheme 20. Cleavage of ethers by Me_3SiI.

from the ether and iodosilane reacts with further iodosilane to give a siloxane. This reaction has already been reported by Gerrard et al, who showed that silica can be formed by heating tetrachlorosilane with tetrabenzyloxysilane (Scheme 21).[50] The alkoxy groups may also be formed in situ by reaction of metal halides with benzaldehyde (Scheme 22).[51]

Scheme 21. Formation of silica from tetrachlorosilane and tetrabenzyloxysilane.

Scheme 22. Reaction of metal halides with benzaldehyde.

These reactions show that products containing M-O-M bridges may be synthesized starting from metal halides and different oxygen donors such as alkoxides, ethers, or benzaldehyde. The mechanism of the condensation reaction involves the coordination of the oxygen atom of the metal alkoxide to the metal center of the metal chloride. This complex reacts further to give M-O-M bridges (Scheme 23). The general principle of



Scheme 23. Condensation of metal alkoxides with metal halides.

this nonhydrolytic process is to induce cleavage of the carbon–oxygen bond instead of the metal–oxygen one. This nonhydrolytic route has been applied to the preparation of monocomponent as well as bicomponent gels.[52]

4.1. Monocomponent Gels

4.1.1. Silica Gels

Silicon tetrachloride does not react with tetraethoxysilane (TEOS), diethyl ether, or diisopropyl ether, but with oxygen donors in which the alkyl group has a greater electron-releasing capacity.[50, 53, 54] Silica nonhydrolytic gels (NHG) can be obtained from silicon tetrachloride and dibenzyl ether, benzaldehyde, or tetrabenzyloxysilane (Table 2).

Table 2. Specific BET surface areas S [$m^2 g^{-1}$] of silica obtained by the NHG process by treating tetrachlorosilane with organic oxygen donors at 110 °C in sealed tubes.

Oxygen donor	t [a]	S
$PhCH_2OCH_2Ph$	15	731
PhCHO	2	265
$Si(OCH_2Ph)_4$	8	500

[a] t = gel time [d].

The main drawback of this NHG process is the large weight loss during calcination, which can be attributed to the large proportion of residual organic components. For example, the weight loss observed during the calcination of the gel derived from $SiCl_4$ and $Si(OCH_2Ph)_4$ was 73%. However, this process may be improved by using a Lewis acid as catalyst. In this way, commercially available materials such as tetraethoxysilane (TEOS) and diethyl ether can be used as starting materials in the

nonhydrolytic condensations.[55] In the presence of $FeCl_3$ as catalyst, silica NHG were obtained by reacting silicon tetrachloride with tetraisopropoxysilane, tetraethoxysilane, diisopropyl ether, or diethyl ether as oxygen donors.[55]

4.1.2. *Alumina Gels*

When a solution of aluminum chloride and either aluminum triisopropoxide (in stoichiometric amounts), or diisopropyl ether (1.5 equiv) is heated, monolithic alumina gels are formed (Scheme 24).[56] Aluminum chloride was solubilized by formation of an addition complex with ether. It is noteworthy that gelation occurs faster with diisopropyl ether than with aluminum triisopropoxide (Table 3).

$$AlCl_3 + Al(OiPr)_3 \xrightarrow[110\,^\circ C,\ 24\,h]{Et_2O/CCl_4} \text{Monolithic gel} \xrightarrow{\text{calcination}} \text{Alumina NHG}$$

$$AlCl_3 + 1.5\,iPrO \xrightarrow[110\,^\circ C,\ 2\,h]{CH_2Cl_2} \text{Monolithic gel} \xrightarrow{\text{calcination}} \text{Alumina NHG}$$

Scheme 24. Preparation of nonhydrolytic alumina.

Table 3. Specific BET surface areas S [$m^2 g^{-1}$] of alumina obtained by the NHG process by treating $AlCl_3$ with oxygen donors.

Oxygen donor	t [a]	$\Delta m/m$ [%] 200–1000 °C	Yield [%]	XRD	S [b]
$Al(OiPr)_3$	24	35	86	amorphous	370
$1.5\,iPr_2O$	2	45	92	amorphous	400

[a] t = gel time [h]. [b] Determined at 650 °C. XRD = X-ray powder diffraction pattern of samples calcined at 500 °C.

The weight loss during calcination measured by TGA and the yields of alumina are similar regardless of the oxygen donor used. More interesting is the amorphous character of the resulting alumina. Hydrated crystalline alumina gels are formed when the hydrolytic sol–gel process is used.[57] Under the conditions employed by ourselves, the crystallization of hydrated phases such as boehmite (AlO(OH)) is not possible. The alumina remained amorphous even after 5 h calcination at 750 °C; at this temperature the specific surface area of calcined samples is quite high, around 300 $m^2 g^{-1}$. The formation of crystalline γ-Al_2O_3 was observed after heating samples at 850 °C for 5 h. For comparison, hydrated alumina gels obtained by hydrolysis of alkoxide precursors usually crystallize to give γ-Al_2O_3 below 500 °C.[57]

Another difference to the hydrated alumina is the presence of a high proportion of pentacoordinate aluminum atoms in alumina gels prepared from $AlCl_3$ and aluminum triisopropoxide, as determined by ^{27}Al NMR spectroscopy.[58] In most cases the aluminas contain tetracoordinate or hexacoordinate Al atoms, whereas pentacoordinate Al atoms have been found in only a very few examples.[59] The regions with pentacoordinate Al atoms are retained in the calcined samples up to the crystallization of γ-Al_2O_3 above 750 °C. The pentacoordination is attributed to the fact that aluminum chloride and aluminum triisopropoxide form a trinuclear aluminum complex in which one aluminum atom is pentacoordinate and the other two are tetracoordinate (Fig. 4).[60] This structure is maintained in solution even after heating for up to 3/4 of the gelation time.[58]

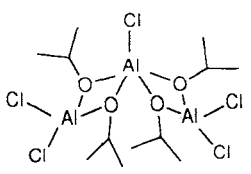


Fig. 4. Stucture of the trinuclear complex obtained from aluminum chloride and aluminum triisopropoxide.

4.1.3. *Titania Gels*

The role of the oxygen donor in the nonhydrolytic gel process was investigated by reacting titanium tetrachloride with titanium tetraisopropoxide or with a stoichiometric amount of an ether such as tetrahydrofuran (THF), di(*n*-propyl) ether, di(isopropyl) ether, diethyl ether, and dimethoxyethane (DME) without solvent.[61] The addition of oxygen donors to $TiCl_4$ gives solids of the composition $ROTiCl_3$ (Scheme 25), which melt below 110 °C; thus, the reactions took place in the homogeneous liquid phase.

$$TiCl_4 + ROR \longrightarrow Cl_3TiOR + RCl$$

Scheme 25.

Gelation occurs in all cases at much longer times than under hydrolytic conditions (Table 4). The gel time is dependent on the oxygen donor and increases in the order: $Ti(OiPr)_4 \approx iPr_2O < Et_2O < THF < nPr_2O < DME$. The analysis of the syneresis liquid confirms the formation of alkyl chlorides as the by-product (with isomerization of the propyl chloride in the case of di-*n*-propyl) ether).

Table 4. Properties of titania obtained from $TiCl_4$ and ethers at 110 °C in a sealed tube.

Oxygen donor	t [b]	Alkyl chloride	$\Delta m/m$ [%]	Yield [%]	XRD [c]	XRD [d] %A	XRD [d] %R
THF	60	$Cl(CH_2)_4Cl$	18	89	A	57	43
nPr_2O	70	*n*PrCl (86%) *i*PrCl (14%)	16	81	A	89	11
iPr_2O	12	*i*PrCl	16	95	A	86	14
Et_2O	17	EtCl	22	74	A	42	58
DME	85	-	47	80	A	0	100
$Ti(OiPr)_4$	12	*i*PrCl	14	90	A	100	0

[a] A: anatase, R: rutile. [b] t = gel time [h]. [c] Samples calcined at 500 °C. [d] Samples calcined at 1000 °C.

The absence of dichloro-1,2-ethane as syneresis liquid (methyl chloride is too volatile to be isolated) in the gel formed with DME and the weight loss ($\Delta m/m$ = 47%) during calcination is attributed to the fact that $TiCl_4$ reacts only with the end groups of DME, leading to a hybrid organic–inorganic gel (ethylene-bridged TiO_2) (Scheme 26).

$$2\,M\text{-}Cl + CH_3\text{-}O\text{-}CH_2CH_2\text{-}O\text{-}CH_3 \longrightarrow M\text{-}O\text{-}CH_2CH_2\text{-}O\text{-}M + 2\,CH_3Cl$$

Scheme 26. Preparation of a hybrid organic–inorganic gel.

The titania yields after calcination (above 500 °C) were large (74–95%). Titania calcined at 500 °C crystallizes in the anatase form. By heating to 1000 °C (without holding time), a proportion of anatase was transformed to rutile; complete transformation was only observed for the sample prepared from DME, whereas the transformation had not yet begun at this temperature for the sample derived from $Ti(OiPr)_4$. This result is of particular interest because the transformation of anatase to rutile is crucial for the porosity and the surface area of the material.[62] For example, in membrane applications the anatase–rutile transformation is inhibited by doping.[62]

Table 6. Properties of aluminosilicate gels obtained by the NHG process, and specific BET surface areas S [$m^2 g^{-1}$] of the calcined gels.

No.	t [a]	Al/Si [b]	Al/Si [c]	$\Delta m/m$ [d] [%]	Yield [%]	S [e]

4.2. Bicomponent Gels

4.2.1. General Aspects

In the synthesis of bicomponent gels problems arise with respect to the composition and the homonegeity of gels because of the difference in the rates of hydrolysis and condensation of the various metal alkoxides used.[63]

Owing to the mechanism of its mode of condensation, the nonhydrolytic sol–gel process appears well suited to the preparation of binary oxides.[64] Furthermore, any composition is theoretically attainable by several chemical combinations, provided that the number of chloride substiuents is equal to the number of alkyl groups R (in the alkoxides $M(OR)_n$ or in the ether R_2O). However, redistribution reactions between metal chlorides and metal alkoxides could give rise to heterogeneous gels, the compositions of which may be difficult to control.

4.2.2. SiO_2/Al_2O_3 System

SiO_2/Al_2O_3 gels with different compositions, in which the Al/Si ratio varied from 0.39 to 10.52, were prepared from metal chlorides and an ether or from a metal chloride and a metal alkoxide (Table 5).

Table 5. Molar composition of aluminum- and silicon-containing solutions that were used for the gelation.

No.	$AlCl_3$	$Al(OiPr)_3$	$SiCl_4$	$Si(OiPr)_4$	iPr_2O	Solvent
1	2	0	1.86	3.31	0	CH_2Cl_2
2	6	0	2.4	0	12.7	CCl_4/Et_2O
3	3	3	1.04	0.99	0	CCl_4/Et_2O
4	10.5	0	1	0	17.8	CH_2Cl_2

Monolithic gels were obtained for all the compositions (Table 6). The overall yields of binary oxide, determined after calcination in air, were very large (92–100%) (Table 6). Based on X-ray diffraction patterns, the gels remained amorphous after calcination up to 700 °C. Their specific surface areas in the amorphous state were determined by the Brunauer–Emmet–Teller (BET) method. As expected from the high yields, the compositions of the calcined gels, determined by energy-dispersive X-ray spectroscopy (EDX), are rather close to those of the initial solution. Thus, in the NHG process, the composition of the binary oxides can be controlled by the stoichiometry of the starting solution.

The homogeneity of the binary oxides has been investigated by ^{29}Si solid-state MAS NMR spectroscopy. The ^{29}Si chemical shifts of the silicon atom of a given SiO_4 tetrahedron are quite sensitive to the number of further silicon atoms attached at the vertices. Thus, a downfield shift of the signal of $\Delta\delta = 5$ is observed for each substitution of a Si atom by an Al atom, generating the five possible local environments of silicon Si[4Si], Si[Al, 3Si], Si[2Al, 2Si], Si[3Al,Si], and Si[4Al].[65]

The ^{29}Si NMR spectra of various silicoaluminates prepared reveal a large distribution of chemical shifts (Fig. 5). A comparison of the ^{29}Si chemical shift observed for the Si-rich oxide (gel 1, signal centered at $\delta = -102$) with that of the Al-rich oxide (gel 4, signal centered at $\delta = -84$), reveals a regular downfield shift, which is attributed to the formation of Si-O-Al bonds. This downfield shift reflects the increase in the number of Si-O-Al bridges; however, the distribution of Si and Al atoms in the oxides is purely random.

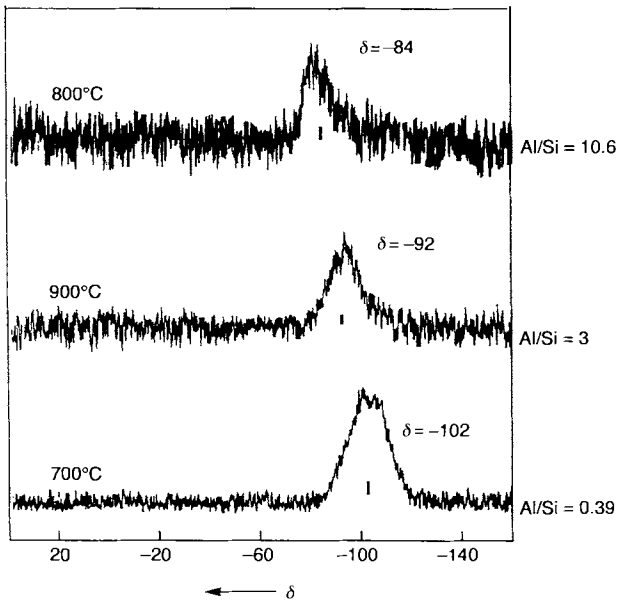

Fig. 5. ^{29}Si MAS NMR spectra of silicoaluminates with various Al/Si ratios.

Another way to determine the homogeneity of bicomponent gels is to study their crystallization. The crystallization tem-

perature of a binary oxide of known composition strongly depends on the homogeneity of the starting gel. For example, in the Al_2O_3/SiO_2 system, mullite, $3Al_2O_3 \cdot 2SiO_2$, is the only compound with a stoichiometric composition. The crystallization of pre-mullite gels is known to be influenced by ultrastructure, giving a clear insight into the scale of mixing between aluminum and silicon.[66] Indeed, when the homogeneity is achieved at the atomic level, crystallization of tetragonal mullite occurs at 980 °C. When the gel is homogeneous only on the namometer scale, a spinnel phase crystallizes at the same temperature (980 °C), whereas mullite is obtained at 1200 °C.

In order to study the homogeneity of nonhydrolytic gels with stoichiometric mullite composition,[67] two gels were prepared in which diisopropyl ether or aluminum triisopropoxide were used as oxygen donor (Scheme 27). Their conversion to mullite

$$6\,AlCl_3 + 2\,SiCl_4 + 13\,iPr_2O \xrightarrow[110°C]{CH_2Cl_2} \text{Gel} + 13\,iPrCl$$

$$5/3\,AlCl_3 + 13/3\,Al(OiPr)_3 + 2\,SiCl_4 \xrightarrow[110°C]{Et_2O/\,CCl_4} \text{Gel} + 13\,iPrCl$$

Scheme 27. Preparation of premullite gels for the synthesis of mullite.

was followed by DTA, X-ray diffraction (XRD), and MAS NMR spectroscopy. The DTA curves indicated a sharp exothermic peak near 1000 °C for the gel prepared with the ether, corresponding to the crystallization of tetragonal mullite. The other gel showed a broad peak near the same temperature due to the appearance of spinel. The ^{29}Si MAS NMR spectra of both samples calcined at 900 °C are very similar. The broad signal centered at about $\delta = -92$ corresponds to that expected for a random distribution of Al and Si in the oxides. Thus, DTA appears a more accurate probe for homogeneity of premullite gels than solid-state NMR spectroscopy.

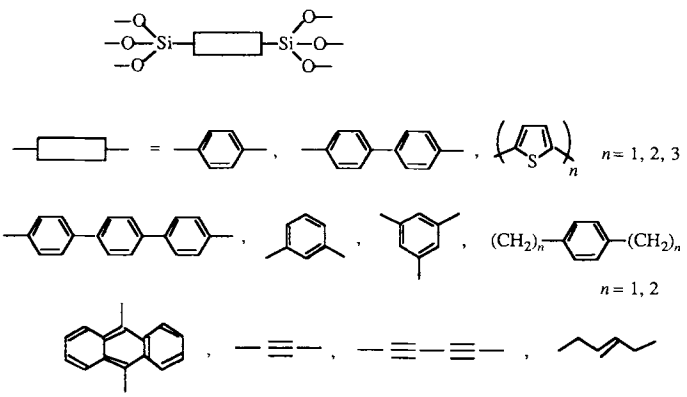
The nonhydrolytic sol–gel process, in which the metal chloride reacts under condensation with oxygen donors, is a quite general procedure, which is only limited by the insolubility of some metal chlorides in organic solvents.

The main advantages expected from this route are: 1) the preparation of non-hydrated oxides and oxides with a low number of hydroxyl groups at low temperatures; 2) improved control over the molecular level homogeneity and stoichiometry of multicomponent oxides; 3) access to new structures by retaining the complex molecular framework of precursors in solution.

5. Organic–Inorganic Hybrid Materials

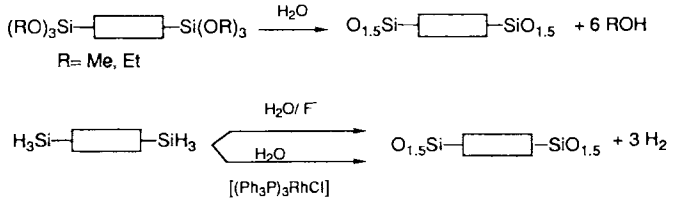
Organic–inorganic hybrid materials are a very wide field of growing interest.[68, 69] They encompass inorganic oxides that function as fillers in organic polymers, and also solids consisting of polymers or organic molecules included in inorganic oxide networks.

The preparation of hybrid materials in which organic molecules are covalently bound to silica is opening interesting perspectives for chemists. The organic moieties can be located inside the solid or only at its surface.[70–72] When only one organic substituent in the silicon alkoxide precursor is linked by C–Si bond, the hydrolysis of the $Si(OR)_3$ group leads to a crosslinked solid in which most of the organic groups are located at the surface. A review on this kind of hybrid polymer was recently published.[69e] The incorporation of an organic spacer inside an inorganic matrix can be performed when at least two covalent bonds are formed between the organic molecule and the solid. The organic spacers used are given in Scheme 28.



Scheme 28. Organic spacers in polysiloxane hybrid gels.

In most cases the gels were obtained by hydrolysis of $Si(OMe)_3$ or $Si(OEt)_3$ groups; however, SiH_3 groups, which were hydrolyzed with fluoride ions or $[(Ph_3P)_3RhCl]$ as catalyst, have also been used (Scheme 29).[71b] The solid was identified



Scheme 29. Gelation of bridged bissilyl precursors.

by cross polarization magic angle spinning (CP-MAS) NMR spectroscopy: ^{13}C NMR spectroscopy showed that the organic groups remain intact in the gel. ^{29}Si NMR spectroscopy showed that the Si–C bonds are still present, since the cleavage of these bonds would lead to the formation of easily detectable $RO\text{-}Si(OSi)_3$ and $Si(OSi)_4$ units. These units are named in conformity with usage in silicone chemistry; thus, the names used are based on the functionality of the precursor (Me_3SiOR [M], $Me_2Si(OR)_2$ [D], $MeSi(OR)_3$ [T] and $Si(OR)_4$ [Q]) and on the number of Si-O-Si bonds ($T^2 = CSi(OSi)_2OR$).[39] The degree of condensation has been quantitatively determined by ^{29}Si CP-MAS NMR spectroscopy, [70b] and is largely dependent on the catalyst used for polycondensation. The use of an acid catalyst leads to a lower degree of condensation (65–75%) than a basic one (89–90%). As previously pointed out, the specific surface area of the solid is highly dependent on the experimental conditions (solvent, concentration of reagents, catalyst, functionality

Table 7. Gelation conditions for the various hybrid precursors and specific BET surface areas S [$m^2 g^{-1}$] of the calcined gels.

of the silane precursor).[71] In the case of hybrid solids (e.g. organo-bridged polysiloxanes), the nature of the organic moiety becomes an important parameter. The influence of the organic moiety on the specific surface area is illustrated in Table 7.

Some of these solids behave as highly porous materials with very high specific surface areas (up to 1260 $m^2 g^{-1}$). For precursors with an aliphatic chain, the specific surface area and the porosities are highly dependent on the length of the chain. Long chains (more than ten CH_2 groups) lead to solids that behave as resins with no specific surface area or porosity. Under specific conditions, shorter chains (less than ten CH_2 groups) lead to mesoporous solids. However, it is impossible to predict the porosity of the resulting solid from the nature of the organosilane precursor. All the parameters capable of modifying the kinetics of the substitution reactions taking place at the silicon center during the polycondensation process control the formation of the solid and are of importance for the porosity of the material. These include concentrations of reagents, solvent, functionality at silicon, catalyst, external parameters (sonication, pressure etc...), and nature and geometry of the organic moiety, etc. The influence of the experimental conditions on the structure (texture) of the polycondensate is evident from Table 7.

5.1. Potential Applications

Since the field of organic–inorganic hybrid materials is very new, only a few possible applications have been explored up until now. Porous hybrid solids such as polysiloxanes with phenylene bridges have been used as the confinement matrix for inclusion of semiconductor particles of CdS: nanosized CdS particules have been deposited uniformly in the hybrid matrix. Likewise by complexation of $Cr(CO)_3$ groups on the phenylene-bridged groups included in the hybrid matrix, followed by thermal treatment, it is possible to produce a gel that includes Cr^0 crystalline nanoclusters.[70c]

Fluorescent xerogels have been prepared starting from terphenylene- and anthracene-bridging organosilanes.[70b] Films exhibiting interesting nonlinear optical (NLO) properties have been prepared starting from precursors containing organic dye molecules as bridging units.[70f]

The hydrolysis of a mixture of 1.1-bistrimethoxysilylferrocene with tetramethoxysilane has led to the formation of a gel containing ferrocene bridge units.[72a] This material was used as an electrode that is stable toward various solvents under aerobic conditions.

5.2. Short-Range Order in Organic–Inorganic Hybrid Materials

Besides the intrinsic physical properties (electronic, optical, magnetic, etc.) that are possibly afforded by the organic molecules embedded in the solid, there is one interesting question that concerns the structure of the amorphous solid: Does the molecular structure give rise to some short-range order in the amorphous solid?

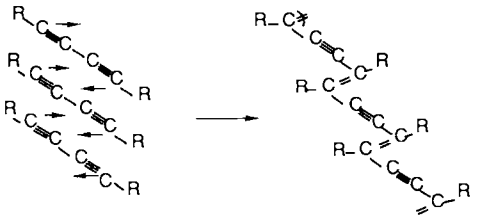
At present, it is difficult to answer this question since there are not many tools available that permit characterization of amorphous systems. Multinuclear NMR and X-ray absorption spectroscopy (XANES, EXAFS) provide information about only the basic unit and whether the basic unit is present or not in the solid; however, they do not provide any information about the medium-range structure of the solid. Similarly, the X-ray diffraction method is useful only for long-range structured solids that are crystalline. The small angle X-ray scattering (SAXS) method allows the study of medium-range structure (or substructure); however, up until now, this method has been used only for studies on the fractal dimensions of hybrid solids.[69d,g]

To circumvent the lack of physical methods, the chemical reactivity of the organic moiety of hybrid solids has been used to obtain some chemical evidence of short-range order in the amorphous hybrid silica network for hybrid solids having a substructure (a structure intermediate between an amorphous one and one with long-range crystalline order).[71,72,82,85,86] To achieve this goal, hybrid organic–inorganic solids containing organic moieties covalently bonded to at least two $Si(OMe)_3$ groups have been prepared. The organic moieties undergo a specific and selective reaction with each other or with external reagents, which may be easily evidenced by spectroscopic means. In all the cases considered, the general procedure involves the preparation of precursors with selected organic moi-

eties and their gelation by hydrolysis. The presence of the organic component in the hybrid solid without chemical transformation or Si-C bond cleavage has been determined by ^{13}C and ^{29}Si CP MAS NMR spectroscopy.

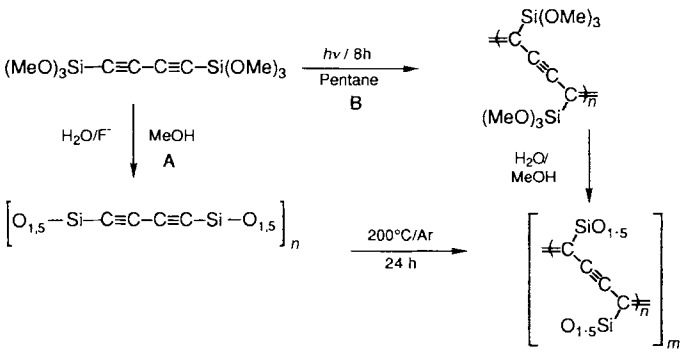
5.2.1. *Crosslinkage of Diynes in the Gel*

Diyne units have been chosen as functional bridges because of their very selective reactivity. The polymerization of the diacetylene groups occurs topochemically,[73-75] that is a particular arrangement of the triple bonds to one another is required. As illustrated in Scheme 30, the 1-4 addition, leading to enyne formation, requires the diacetylene units to be parallel to each other.[76]



Scheme 30. Topochemical polymerization of diacetylene units.

A gel containing diacetylene units has been prepared from 1,4-bis(trimethoxysilyl)buta-1,3-diyne (^{13}C NMR: $\delta = 79.4$, and 87.8 (C-*C*≡*C*-Si), IR: $\tilde{\nu} = 2202$ and 2091 cm^{-1}). After the mixture had been heated at 200 °C under argon, the formation of enynes, and the associated crosslinking in the solid was detected by spectroscopy (^{13}C NMR: $\delta = 133$, ^{29}Si NMR: $\delta = -74$, IR: $\tilde{\nu} = 2169$ cm^{-1}).[77] Moreover, the same spectroscopic features have been found regardless of whether gelation is performed before the crosslinking (route A) or whether the crosslinking is induced by irradiation before the gelation (route B) (Scheme 31).



Scheme 31. Sythesis of gels containing acetylene units.

It is interesting to compare this polymerization with the crosslinkage observed in the case of polymers [-SiR_2-C≡C-C≡C-]$_n$ for which the DTA curve is highly dependent on the organization in the solid.[76] In the DTA curve of crystalline polymers of this type (R = Me,Et), a sharp peak occurs at 200 °C that can be attributed to the crosslinking reaction. In contrast, the poorly crystalline (R = Ph) or noncrystalline polymers (R = $SiMe_3$) are crosslinked only between 250 °C and 350 °C. In the case of gels the crosslinking reaction starts at lower temperatures as shown in Figure 6: The DTA curve exhibits an exothermic transformation between 120 and 350 °C with a maximum at 250 °C.

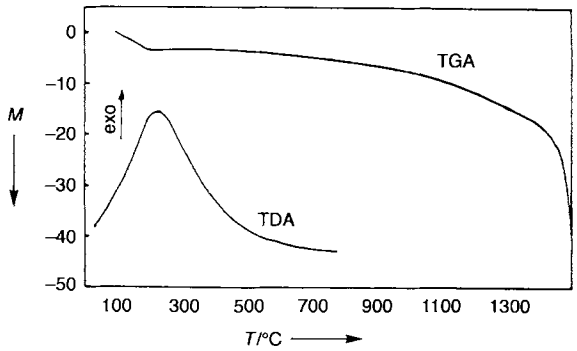


Fig. 6. TGA and TDA curves of a gel containing diyne units. M = loss of mass [%].

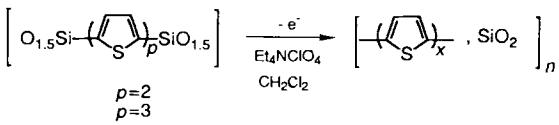
The facile reaction between the diyne fragments at a relatively low temperature within the amorphous gel may be indicative of a favorable arrangement of the diyne moieties. The enyne formation involves parallelism between several diacetylene units inside the solid. These results suggest the formation of "substructures" in the silica network that permit the 1-4 addition between the organic units.

5.2.2. *Polymerization of Thiophene Units Inside the Matrix*

Polythiophenes are obtained by electropolymerization,[78] and silylated thiophenes have been shown to be very efficient precursors for this polymerization,[79, 80] leading to polymers in which the thiophene units are bonded to each other mainly in the α position.[84] Gels containing bissilylated mono-, bis-, and terthiophene have been prepared.[82] ^{13}C and ^{29}Si CP MAS NMR spectra show that the structure of the precursor remains intact in the solid without cleavage of the Si–thiophene bond. The electrochemical oxidation of the gels deposited as films at the electrode leads to a fast polymerization reaction of the thiophene units included in the hybrid matrix (Scheme 32).[82] The



Scheme 32. Electropolymerization of gels containing silylated thiophenes.

same reaction is also possible by chemical oxydation using $FeCl_3/CHCl_3$ as oxidising agent.[82] The polythiophene formed in situ cannot be separated from the solid; it was identified in the film by Raman spectroscopy ($\tilde{\nu} = 1458$, 1220, 1171, 1047, 700, 682, and 652 cm^{-1}).[82]

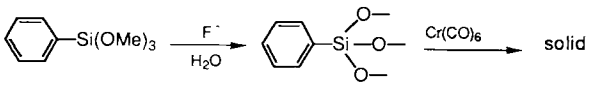
The mechanism of oxidative polymerization known for silylated thiophenes requires the thiophene units to be close to each

other.[81] Thus, the fast polymerization inside the gels suggests the formation of thiophene aggregates with some regular geometry. Furthermore, it is impossible to separate the polymer from the solid, which is attributed to the presence of $O_{1.5}Si$ end groups in the polymer. The thiophene units are present in the gel in a more or less aggregated state, and oxidation leads to the formation of polymeric segments by coupling of proximal thiophene units.

Since the mobility in the solid is restricted, and since the polymerization is known to take place by coupling of two radicals with precise steric requirements, it has been concluded that the polymer formation occurs only because of the presence of thiophene aggregates with some regular geometry, which are formed during the gelation process.[82]

5.2.3. Complexation of Aromatic Groups Bound to Silica

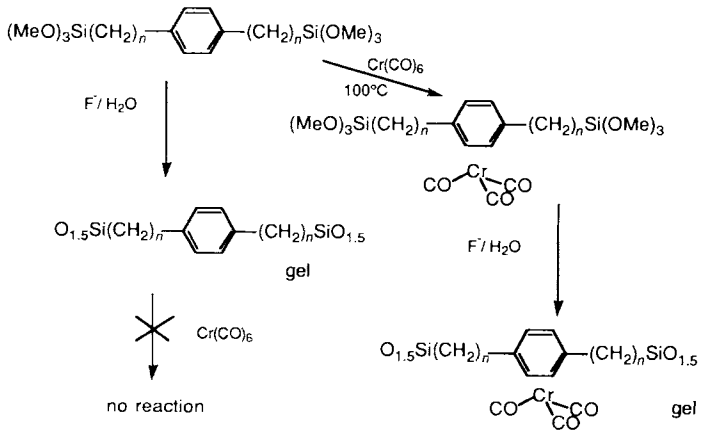
Aromatic organosilanes react readily with $Cr(CO)_6$ to form $Cr(CO)_3$ complexes.[83, 84] This reaction was used to test the reactivity of phenyl groups attached to a silica network.[85] In the case of monosilylated phenyl systems, the introduction of $Cr(CO)_3$ in gels, which had been prepared from monosilylated phenyl compounds, is possible (Scheme 33) since most of the



Scheme 33. $Cr(CO)_3$-containing phenylsilasesquioxane.

phenyl groups are accessible because they are located at the surface of silica.[85] The presence of the phenyl groups at the surface also explains the high hydrophobicity of these solids. The complexation has been monitored by IR and NMR spectroscopy and quantitatively determined by TGA and EDX investigations.[85]

On the other hand it is possible to prepare gels containing $Cr(CO)_3$-complexed phenylene groups from bis-silylated phenylene compounds,[70, 71] but the complexation must take place prior to gelation (Scheme 34).[85] However, the operation is not commutative: when the gelation is performed first, it is impossible to introduce the $Cr(CO)_3$ moieties to the phenylene



Scheme 34. Reactions of gels containing bissilylated phenylene groups.

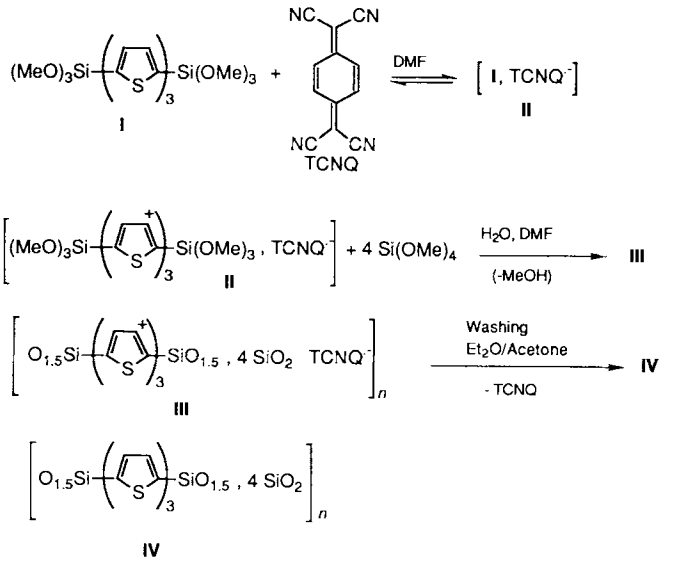
ring. It has been concluded that most of the phenylene groups are located in the core of the solid and are thus not accessible for chemical reactions. This is consistent with the high hydrophilicity observed for gels containing *p*-phenylene units.[85]

However, the chemical behavior of these gels is highly dependent on the nature of the precursor. When the precursor contains rigid phenylene units, the resulting solid is hydrophilic (Si–OH at the surface), and the organic units, located in the core of the solid, are not accessible for chemical reactions. When more flexible organic groups such as phenylene-1,4-bis(ethylene) are introduced, the properties of the product are completely different: The solid is hydrophobic and reacts with $Cr(CO)_6$ since the phenylene groups are present at the surface.

The constitution of the starting materials influences the spatial arrangement of the organic units in the resulting condensation polymers.

5.2.4. Solids Containing Charge Transfer Complexes

The importance of the interactions between the organic units on the structure of the solid obtained during the gelation process is illustrated by the inclusion of charge transfer complexes in gels.[82] Scheme 35 shows the inclusion in silica of the charge transfer complexes formed between bissilylated terthiophenes



Scheme 35. Charge transfer complex from terthiophene and TCNQ in a polysiloxane gel.

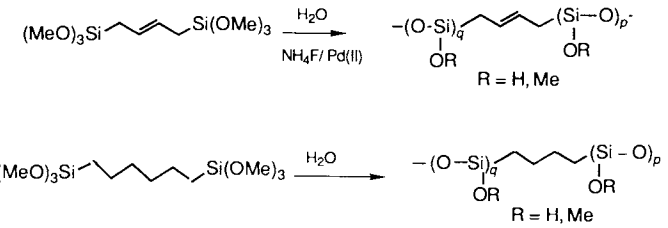
and 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ). These complexes remain unchanged after gelation as shown by absorption spectroscopy (λ = 855, 752, 684 nm) and by conductivity measurements ($\varkappa = 10^{-6}\,S\,cm^{-1}$). Even though these interactions are very weak, they are evidently strong enough to control the structure in the amorphous solid.

5.2.5. Control of Solid Formation by Intermolecular Interactions

All the factors capable of modifying the course of polycondensation reactions are of importance. In order to illustrate

the drastic effect of the kinetic factors on the formation of the solid, the influences of a template effect on the rate of gelation and on the structure of the solid obtained have been investigated.

The polycondensation of an olefinic trialkoxysilane $(MeO)_3Si\text{-}(CH_2)_n\text{-}CH{=}CH\text{-}(CH_2)_n\text{-}Si(OMe)_3$ ($n = 1,2$) by the sol–gel process has been studied in the presence of Pd^{II} complexes (Scheme 36).[71, 86] This system was chosen because of the



Scheme 36. Gelation with unsaturated and saturated trialkoxysilanes.

pronounced ability of C–C double bonds to coordinate around Pd centers[87] (template effect) and the behavior was compared to that of the corresponding saturated precursors $(MeO)_3Si\text{-}(CH_2)_6Si(OMe)_3$.

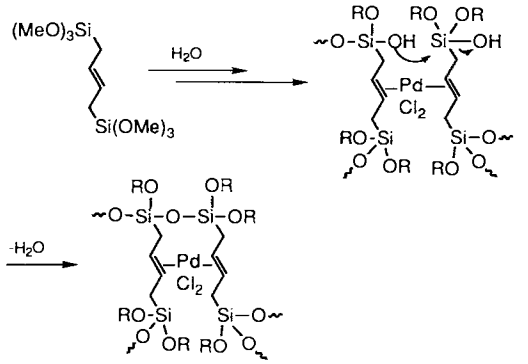
In all cases, a transparent gel was formed, and ^{13}C and ^{29}Si NMR spectroscopic analysis clearly established that the Si–C bond is retained in the solid. Whereas differences in the experimental conditions did not produce significant changes in the hybrid network at the molecular level, drastic differences appeared in the kinetics of gelation. In the presence of Pd^{II} compounds the gel time was reduced by almost two orders of magnitude (Table 8). In contrast, the reaction of the saturated

Table 8. Preparation of gels with unsaturated and saturated bis(trimethoxysilyl) precursors.

Precursor	Additive	Amount [a]	t [min] [b]
$(MeO)_3Si$–⁄\⁄–$Si(OMe)_3$	NH_4F	10^{-3}	29×10^3
	NH_4F/Li_2PdCl_4	$10^{-3}/5 \times 10^{-2}$	90
	Li_2PdCl_4	5×10^{-2}	75
	NH_4F/LiCl	$10^{-3}/10^{-1}$	50×10^3
	$NH_4F/(CH_3CN)_2PdCl_2$	$10^{-3}/5 \times 10^{-2}$	30
$(MeO)_3Si$–⁄\⁄\–$Si(OMe)_3$	NH_4F	10^{-3}	1×10^4
	NH_4F/Li_2PdCl_4	$10^{-3}/5 \times 10^{-2}$	120
$(MeO)_3Si$–⁄\⁄\⁄\–$Si(OMe)_3$	NH_4F	10^{-3}	2.9×10^3
	NH_4F/Li_2PdCl_4	$10^{-3}/5 \times 10^{-2}$	2.9×10^3

[a] Added amount of additive [mol] based on amount of precursor used. [b] t = gel time.

precursor is totally insensitive to the presence of Pd^{II} compounds. Most probably Pd^{II} activation proceeds by a template effect of the metal. As shown in Scheme 37, the formation of an η^2-olefin complex with unsaturated units allows an intramolecular condensation within the coordination sphere of the Pd center. While held in the complex, the monomer is ideally positioned for condensation and siloxane bridge formation. The

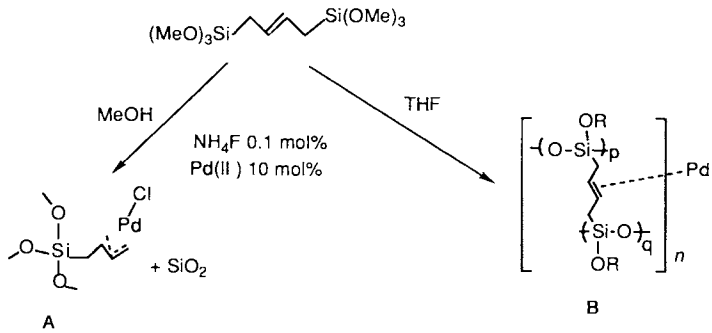


Scheme 37. Pd^{II}-activated gelation.

acceleration of the polycondensation can thus be attributed to the template effect of the palladium center.

The influence of Pd on the composition and properties of the resulting gel has been described.[86] For the gel prepared from unsaturated monomer, 80–100% of Pd was trapped in the hybrid network and remained in the xerogel. Conversely only a few Pd centers were retained in the gel prepared from the saturated C_6 monomers.

The gels containing Pd revealed no catalytic activity in hydrogenations, since the Pd center is not accessible but rather is completely embedded inside the network (Scheme 38 compound



Scheme 38. Influence of the solvent on the catalytic activity of Pd^{II} catalysts. For A and B see text.

B). The condensation proceeded quite differently in MeOH than in THF. In methanol, the Si–C bond was cleaved and η^3-allylpalladium species were formed.[88] The resulting solid with η^3-allylpalladium complexes at the surface behaves as a very efficient catalyst for hydrogenation reactions (Scheme 38 compound **A**)

In conclusion, the results observed illustrate that the structure of the solid obtained during the gelation of hybrids of organosilanes with at least two $C\text{–}Si(OR)_3$ bonds depends greatly on the nature of the organic moieties included. These organic units can be located at the surface or in the core, and can lead to the formation of a substructure in the amorphous network. Furthermore, the chemical reactivity of the organic components appears as a very useful tool for the study of these systems, D. which show a degree of order.

6. Summary and Outlook

The field of research opened by the chemistry associated with the sol–gel process, which can be considered as sol–gel chemistry, is very wide. The chemistry of building blocks or new oxide synthesis with a particular attention to the chemistry of hybrid organic–inorganic solids are only two of the many research areas that have opened up for molecular chemists working in this field.

In this review we have focused on three main topics: 1) We have described the possibilities opened by new functional precursors, which allow the introduction of reactive centers in a solid at moderate temperature (300–450 °C). The polycondensates synthesized in this way undergo subsequent reactions which involve the same mechanisms as in solution; however, the restricted mobility of reactive centers in the solid changes dramatically the progress of the reaction. Metastable phases, silicon sesquioxide Si_2O_3, silicon oxynitride, and siliconoxycarbide have been obtained by this route. 2) A new general route for the synthesis of oxides has been described. In this sol–gel process, instead of H_2O, which is usually used in the inorganic polymerization, other oxygen donors such as ethers R_2O are employed. This method seems particularly attractive for the synthesis of multicomponent oxides homogeneous in the atomic region. 3) The field of hybrid organic–inorganic solids was considered with the aim of studying the possible organization in the solid, induced by the structure of the organic component of the hybrid precursor. Investigations into the chemical reactivity revealed the presence of aggregates between the organic components in the core of the solid. The structure and the texture of the products obtained are also highly dependent on the nature of the organic moiety.

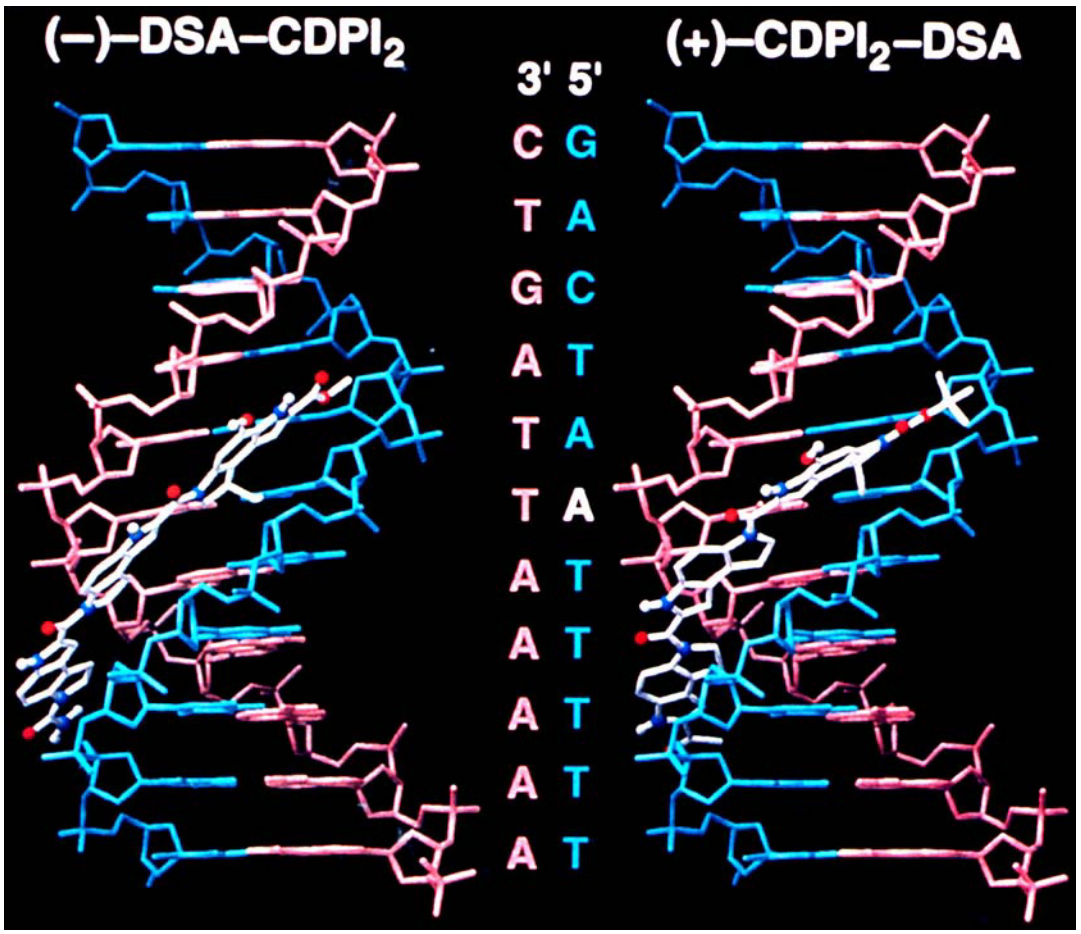
Merely reversing the arrangement of the DNA-binding structural elements (DSA-$CDPI_2$→$CDPI_2$-DSA) causes a DNA alkylating agent to behave like the enantiomer of the natural product, although the alkylation unit has the configuration found in nature. Model studies on the binding of the enantiomers to DNA provide an explanation.



CC-1065 and the Duocarmycins: Understanding their Biological Function through Mechanistic Studies**

Dale L. Boger* and Douglas S. Johnson

We review here studies defining the DNA alkylation properties of a class of potent antitumor antibiotics that includes CC-1065 and the duocarmycins, as well as investigations that delineate fundamental relationships between their structure, functional reactivity, and biological properties. In conjunction with the study of the natural products themselves, the examination of synthetic agents containing deep-seated structural changes, the unnatural enantiomers of the natural products, and related analogs has defined the structural basis for the sequence selective alkylation of duplex DNA and proved to be the key to understanding the fundamental relationships between chemical structure, functional reactivity, and biological properties. The characteristic DNA alkylation proceeds by reversible, stereoelectronically controlled adenine-N3 addition to the least substituted carbon of the activated cyclopropane within AT-rich minor groove sites. Both the natural and unnatural enantiomers alkylate DNA, and the sequence selectivity of both is controlled and dominated by the preferential noncovalent binding of the agents within the narrower, deeper, AT-rich minor groove and the steric accessibility to the alkylation site on penetration of this groove. Among the fundamental relationships between structure and properties, the most striking is the direct relationship between chemical or functional stability and biological potency. Within a short time, simplified and readily accessible synthetic agents rationally based on the natural product leads have been developed, which exhibit comparable and exceptional biological potency (IC_{50} = 50 to 51 pM) and improved efficacy. The fundamental relationships that have been defined to date can be expected to provide the foundation for future developments and advances.

Keywords: antibiotics · antitumor agents · DNA alkylation · duocarmycins

1. Introduction

Substantial progress has been made toward understanding the origin of the sequence-selective recognition of duplex DNA by small organic molecules[1-5] including a wide range of naturally occurring antitumor antibiotics. Major factors contributing to the interest include the desire to define the basis for the therapeutic properties of the naturally occurring antitumor antibiotics that have been shown to bind DNA, to define the nature of DNA lesions induced by toxic, mutagenic, or carcinogenic materials,[6] and to alter transcription, translation, or protein expression and exploit the ramifications for therapeutic purposes.

Three fundamental issues to be addressed in the examination of DNA binding agents are the origin of binding affinity, binding selectivity, and reaction selectivity including DNA alkylation or cleavage. Each can independently exert control on the apparent sequence-selective recognition of DNA, and the relative importance and origin of these effects remain an important objective of most investigations. The emergence of experimental techniques for the rapid sequencing of DNA,[7-10] for the determination of DNA binding selectivity and affinity including footprinting and affinity cleavage techniques,[11,12] and for the determination of sites of DNA modification[13] coupled with the structural characterization of DNA complexes at defined sites by X-ray crystallography,[14,15] NMR spectroscopy,[16,17] and molecular modeling[18,19] has advanced the understanding of the molecular interactions responsible for the sequence-selective recognition of DNA.

A powerful complement to such tools in the examination of naturally derived DNA binding agents is the preparation and subsequent examination of key partial structures, agents containing deep-seated structural modifications in the natural product, and their corresponding unnatural enantiomers. Well-conceived, deep-seated structural modifications may be used to directly address and define both the structural basis for the sequence-selective recognition of DNA and fundamental relationships between structure, functional reactivity, and biological properties. This is especially important in the case of natural products that are identified by directed screening efforts. In contrast to the study of the biological role of primary metabo-

lites, the presence of secondary metabolites and the perceived origin of the identified lead is often misrepresented. Nature, with its vast array of secondary metabolites, provides a diverse library of small organic molecules for random screening. Not always, and perhaps only rarely, is the role of the identified natural products related to the biological basis of the screening efforts responsible for their detection and identification. Consequently, it may be a mistake to assume that nature has optimized or even devised the agent for purposes related to the biological process for which the screening assay was set up. Rather, it is more accurate to recognize that nature has only provided a novel lead or solution that has not yet been optimized. A challenging problem remains: to understand the beautiful solutions and subtle design elements that nature has provided in the form of a natural product and to extend this solution through rational design elements to provide more selective, more efficacious, or more potent agents designed specifically for the problem or target under investigation.

One of the newest class of agents shown to alkylate DNA includes (+)-CC-1065 (**1**),[20–23] (+)-duocarmycin A (**2**),[24–29] and (+)-duocarmycin SA (**3**)[30–33] (Fig. 1). Because of their remarkable cytotoxic potency, substantial efforts have been devoted to defining their properties.[34–50] These studies show that the agents exert their biological effects through a sequence-selective alkylation of DNA. The reversible, stereoelectronically controlled adenine-N3 addition to the least substituted cyclopropane carbon has been found to occur within selected AT-rich sites in the minor groove, and extensive efforts have been devoted to determining the origin of the DNA alkylation selectivity, to establishing the link between DNA alkylation and the ensuing biological properties,[51] and to defining the fundamental principles underlying the relationships between structure, chemical reactivity, and biological activity. The initial limited studies conducted with naturally derived duocarmycin SA (**3**), the most recent addition to this class of agents, revealed a combination of properties that make it the most exciting of the natural products identified to date. In addition to lacking the characteristic of delayed toxicity of (+)-CC-

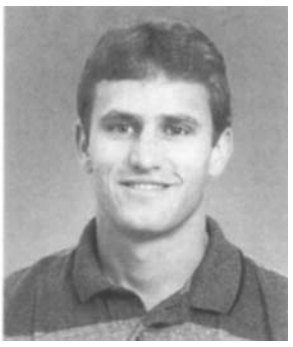
D. L. Boger



D. S. Johnson

Born August 22, 1953 in Hutchinson, Kansas, Dale L. Boger received his BSc in chemistry from the University of Kansas (1975, with highest distinction and honors in chemistry) and Ph.D. in chemistry from Harvard University (1980). He immediately returned to the University of Kansas as a member of the faculty in the Department of Medicinal Chemistry till 1985, when he moved to the Department of Chemistry at Purdue University. In 1991 he joined the faculty at The Scripps Research Institute as the Richard and Alice Cramer Professor of Chemistry. His research interests span the fields of organic and bioorganic chemistry and include the development of synthetic methodology, the total synthesis of natural products, heterocyclic chemistry, bioorganic chemistry, medicinal chemistry, the study of DNA–agent and protein–ligand interactions, and antitumor agents.

Douglas S. Johnson was born August 24, 1969 in Roseville, Minnesota. He received his BSc in chemistry from the University of Minnesota (1991, summa cum laude), where he conducted research in the laboratory of Professor T. R. Hoye. He is presently a graduate student in chemistry at The Scripps Research Institute, where he is studying the synthesis and evaluation of antitumor and DNA binding agents under the direction of Professor D. L. Boger. His research interests include the synthesis of biologically important molecules as well as designed analogs to study their mechanism of action.

1065,[52] it is the most stable and most potent member of this class of agents. In fact, the name duocarmycin SA is an abbreviation of its original name, duocarmycin Stable A, which was introduced before its structure was established. As detailed herein, this combination of properties is not fortuitous, but rather the enhanced functional stability of duocarmycin SA is directly responsible for its increased biological potency. The studies complement those conducted on other DNA alkylating agents including the nitrogen mustards, the mitomycins, aflatoxin, epoxides of polyaromatic hydrocarbon diols, azinomycin, saframycin, anthramycin and related agents, and dichloroplatinum and related agents.[1-6]

2. DNA Alkylation Properties

2.1. DNA Alkylation Selectivity of the Natural Products

The event, sequence selectivity, quantitation, reversibility, and structure determination of the predominant DNA alkylation by **1**–**3** have been defined.[53-72] The identification of the alkylation site and the assessment of relative selectivity were achieved by thermally induced depurination and strand cleavage of labeled DNA after exposure to the agents (Scheme 1). The selectivity in alkylations by (+)-duocarmycin A (**2**) and (+)-duocarmycin SA (**3**) proved nearly indistinguishable.[54, 56] In each case alkylation took place at an adenine residue that was flanked by two 5′-A or -T bases, and the preferred order of these three-base sequences proved to be 5′-AAA > 5′-TTA > 5′-TAA > 5′-ATA. In addition, A or T dominated over G or C as a fourth 5′ base, and this feature distinguished high-affinity sites from low-affinity sites. An additional weak preference for a purine (Pu) over pyrimidine (Py) at the 3′ base preceding the adenine alkylation site was detected, which was more prominent in the low-affinity sites. Table 1 summarizes the consensus sequence derived from the evaluation of alkylations with **2**[56] and **3**.[54] Although these agents alkylated the same sites, two important distinctions were defined. The least reactive of the agents, (+)-duocarmycin SA (**3**), alkylated DNA with a greater efficiency (10–100×) and a greater selectivity among the available sites. In addition, the selectivity of the related naturally occurring agents **4**–**7** (see Fig. 1) was indistinguishable from that of **2**, which may be attributed to their facile cyclopropane ring closure under the conditions of assay.[54, 56] This behavior of **6**–**7** requires that they first close to form **2** prior to alkylating DNA, and that this is the biologically relevant and more potent form of the agent. These observations with **4**–**7** are general throughout the set of agents examined to date. In fact, not only are the selectivities in DNA alkylation of such seco agents indistinguishable, but often the DNA alkylation efficiencies and biological potencies are also the same, which indicates that the cyclopropane ring closure is not a limiting factor. Only in the cases of the more difficult or slower spirocyclizations have distinguishing features in DNA alkylation efficiency or biological potency been observed.[33, 56]

The preceding studies of (+)-CC-1065 (**1**) revealed a selectivity for a similar, but more extended five-base-pair, AT-rich alkylation site.[53, 64-72] Table 1 summarizes the consensus sequence derived from our evaluation of (+)-CC-1065.[53, 71-72] Each site of alkylation proved to be an adenine residue flanked by two

[a] The numbers listed in the table give the percentage of the indicated base located at the designated position relative to the adenine-N3 alkylation site. [b] The numbers in parentheses give the percentage composition within the DNA examined.

5′-A or -T bases. The sequence preference for the three-base, AT-rich alkylation site followed a similar order: 5′-AA<u>A</u> = 5′-TT<u>A</u> > 5′-TA<u>A</u> > 5′-AT<u>A</u>. In addition, the agent exhibited a strong preference for the fourth 5′ base to be A or T, a weaker preference for the fifth 5′ base to be A or T, and a weak preference for the 3′ base preceding the alkylation site to be a purine. These preferences for the fourth and fifth 5′ bases distinguished the high- from the low-affinity sites, and the preference for a 3′ purine over pyrimidine was more prominent in the lower affinity sites. The strict AT requirement within the first three base pairs represents a combination of the initial 3′ adenine-N3 alkylation site and an adjacent 5′ two-base AT site required to accommodate the central subunit binding. The weaker preferences for A or T as the fourth and fifth 5′ bases reflect, as observed with the high-affinity sites, a preferential AT-rich site for the third subunit also bound in the minor groove. A study of shorter and more extended analogs of CC-1065 revealed that this selectivity for AT-rich sites corresponds nicely to the length of the agent and, hence, the size of binding site required to accommodate the agent.[53, 71]

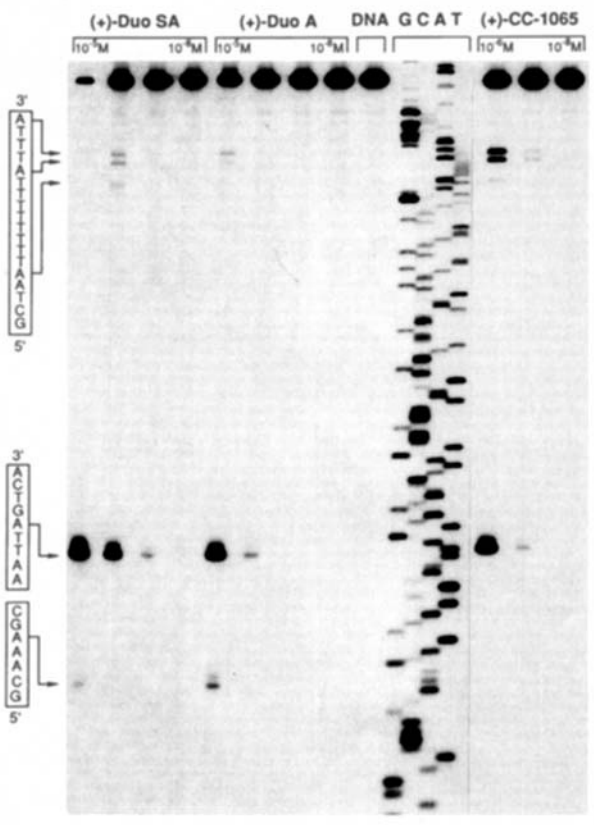

Fig. 2. Thermally induced strand cleavage (by heating to 100 °C for 30 min) of double-stranded DNA (SV40 DNA fragment, 144 base pairs, nucleotide no. 5238-138, clone w794) after 24 h incubation of DNA with the agent at 25 °C and removal of unbound agent by EtOH precipitation followed by denaturing PAGE (8%) and autoradiography. Lanes 1–4: **3** (1×10^{-5} M–1×10^{-8} M); lanes 5–8: **2** (1×10^{-5} M–1×10^{-8} M); lane 9: control DNA; lanes 10–13: Sanger G, C, A, and T reactions; lanes 14–16: **1** (1×10^{-6} M–1×10^{-8} M).

Figure 2 illustrates the similarities of **2** and **3** and their subtle distinctions from **1** in their behavior toward DNA. According to the concentrations required to detect alkylation, (+)-duocarmycin SA (**3**) is approximately ten times more efficient at alkylating the DNA than (+)-duocarmycin A (**2**) and subtly more efficient than (+)-C-1065 (**1**). Although **3** and **2** alkylate the same sites, **3** exhibits a greater degree of discrimination among the available sites. This is evident from the relative concentrations required to detect the minor and major alkylation sites for the two agents. Similarly, while CC-1065 and the duocarmycins both alkylate the same high-affinity site in this segment of DNA, distinctions in the alkylation of the minor sites are apparent, including the lack of alkylation by (+)-CC-1065 at the shorter three-base AT-rich site 5′-GCAA<u>A</u>.

The sequence selectivity observed with intracellular SV40 DNA is essentially identical to that observed with purified SV40 DNA except that higher concentrations of **1** are required.[74–76] Thus, in vitro analyses with purified DNA reflect the sequence-selective reactivity of **1** with intracellular DNA.

2.2. DNA Alkylation Selectivity of the Unnatural Enantiomers

One of the more revealing discoveries that was made possible through use of synthetic materials was that the unnatural enantiomers may also constitute effective DNA alkylating agents and potent cytotoxic agents.[53, 54, 68, 71] Moreover, the ability to compare the behavior of the two enantiomers proved to be the key to understanding the structural origin of the sequence selectivity in DNA alkylations. Consistent with its relative cytotoxic potency, *ent*-(−)-duocarmycin SA was found to alkylate DNA at concentrations approximately ten times that required for the natural enantiomer;[54] Table 1 summarizes its consensus alkylation sequence. Each alkylation site detected was an adenine residue, and essentially each alkylation site was flanked by a 5′- and 3′-A or -T base and exhibited the following sequence preference: 5′-A<u>A</u>A > 5′-A<u>A</u>T > 5′-T<u>A</u>A > 5′-T<u>A</u>T. An additional strong preference for A or T as the second 3′ base from the alkylation site was observed. In this regard, the (−)-duocarmycin SA alkylation was analogous to the natural enan-

tiomer with the exception that the binding orientation is reversed (5′ → 3′) over an AT-rich, 3.5-base-pair site. However, whereas the bound natural (+)-enantiomer covers an AT-rich, 3.5-base-pair site extending from the adenine-N3 alkylation site in the 3′ → 5′ direction across the adjacent two to three 5′ bases (that is, 5′-AAAA), the AT-rich, 3.5-base-pair site for the unnatural (−)-enantiomer extends in the reverse 5′ → 3′ direction starting at the first 5′ base site preceding the adenine-N3 alkylation site and extending across the alkylation site to the first and second adjacent 3′ bases (that is, 5′-AAAA). The reversed binding orientation is required to permit adenine addition to the least substituted cyclopropane carbon, and the alkylation selectivity for an offset AT-rich site is the natural consequence of the diastereomeric relationship of the adducts.

Similarly, preceding studies had shown that (−)-CC-1065 alkylates DNA with an efficiency equivalent to that of the natural enantiomer, but the alkylation rate is slower.[68, 71] Consistent with these observations, the unnatural and natural enantiomers of CC-1065 have been found to exhibit indistinguishable cytotoxic potency and in vivo antitumor activity.[68, 71] Table 1 summarizes the consensus alkylation sequence for (−)-CC-1065, which proved similar to (−)-duocarmycin SA but which exhibits an AT selectivity that extends across five base pairs.[53, 68] Each alkylation site proved consistent with 5′-adenine-N3 alkylation and agent binding in the minor groove in the 5′ → 3′ direction from the alkylation site covering five base pairs across an AT-rich region. All alkylation sites detected in the sequencing studies proved to be adenine, and nearly all of the 3′ and 5′ bases flanking the adenine-N3 alkylation site proved to be A or T. The preferred order for the sequence of these bases is as follows: 5′-AAA > 5′-TAA > 5′-AAT, 5′-TAT. There also proved to be a substantial preference for A or T as the second and third 3′ base.

Unlike duocarmycin SA, the unnatural enantiomer of duocarmycin A proved to be 100 or more times less effective than the natural enantiomer at alkylating DNA and 100 or more times less potent in cytotoxic assays.[59] Although these observations initially appeared confusing, they could be attributed to well-defined differences in the diastereomeric adducts derived from the two enantiomers, for which duocarmycin A is especially sensitive.[54, 73] Inversion of the configuration at C6 of **2**, which leads to **11** (Fig. 3), had no effect on the DNA alkylation

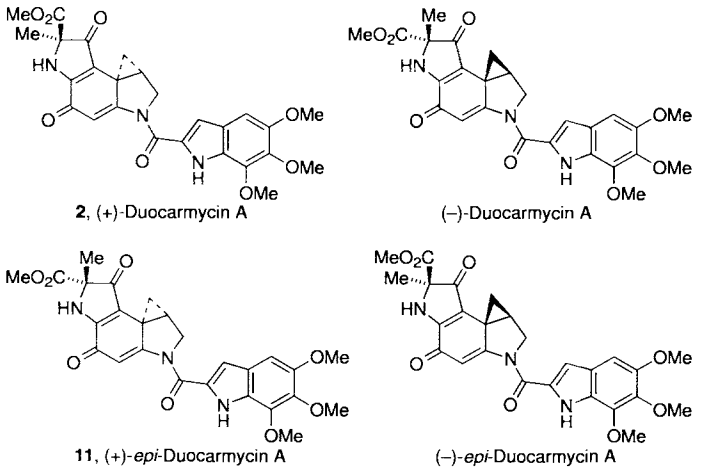

Fig. 3. Stereoisomers of (+)-duocarmycin A (**2**).

Table 2. Cytotoxic potencies of **1**–**3** and their isomers and the relative DNA alkylation efficiencies.

Agent	IC_{50}, L1210 [pM]	Rel. Alkylation Efficiency
(+)-**3**, (+)-duocarmycin SA	10	1
(−)-**3**, *ent*-(−)-duocarmycin SA	100	0.1
(+)-**2**, (+)-duocarmycin A	200	0.05
(−)-**2**, *ent*-(−)-duocarmycin A	>22000	<0.0005
(+)-**11**, *epi*-(+)-duocarmycin A	1600	0.01
(−)-**11**, *ent*,*epi*-(−)-duocarmycin A	>24000	<0.0005
(+)-**1**, (+)-CC-1065	20	0.5
(−)-**1**, *ent*-(−)-CC-1065	20	0.5

sequence selectivity and only a small impact on the DNA alkylation efficiency and cytotoxic potency of the agent (Table 2).

As detailed in the following sections, the DNA alkylation properties and selectivity of the unnatural enantiomers have proven uniquely valuable in establishing the key recognition elements and structural features responsible for polynucleotide recognition. Ultimately their preparation and subsequent evaluation alongside the natural enantiomers provided deeper insights into the behavior of the natural products themselves and led to the evolution of models that clearly delineate the requirements for DNA alkylation and the origin of the selectivity.

2.3. Adenine-N3 Alkylation

Since the thermally induced cleavage of DNA employed to identify the alkylation sites only detects adducts susceptible to thermal glycosidic bond cleavage (adenine-N3 and guanine-N3 or -N7 alkylation), the occurrence of additional alkylation reactions would not be detected under such conditions. Thus, the quantitation of the adenine-N3 alkylation, confirmation of its structure through isolation and characterization of the thermally released adducts, and the search for undetected alkylation sites have been conducted. In these studies, the adenine-N3 alkylation of DNA present in excess by (+)-duocarmycin A (**2**), (+)-duocarmycin SA (**3**), (−)-duocarmycin SA, and (+)-CC-1065 (**1**) accounts for 86–92%,[57] 90–100%,[54] 86–92%,[54] and 80–90%,[66] respectively, of their consumption and constitutes the virtually exclusive alkylation event (Scheme 1, p. 1441). The full characterization of the adducts led to the unambiguous assignment of the structures **8**–**10** (see Scheme 1) in which addition of the adenine-N3 atom to the unsubstituted cyclopropane carbon of the agents was established. The demonstration that **6** and **7** also provide the adduct **8**[56, 57] requires that they first convert to **2** prior to alkylating DNA.

2.4. Adenine-N3 and Trace Guanine-N3 Alkylation

All three agents and their corresponding seco precursors provide predominantly or exclusively adenine-N3 adducts (>90%). However, a minor guanine-N3 alkylation has been detected with **2** and to a lesser extent with **1**, but only upon isolation of the thermally released adduct following treatment of DNA with excess agent,[61, 62] within oligodeoxynucleotides lacking a high-affinity adenine-N3 alkylation site,[62] or when the adenine alkylation sites within AT-rich regions of DNA were

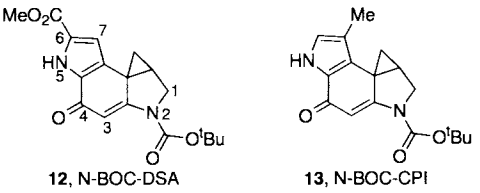
protected from alkylation with agents (including distamycin) that bind with high affinity in the AT-rich minor groove.[63] A study of this minor guanine-N3 alkylation with **2** revealed that as the agent-to-base-pair ratio in the reaction mixture was varied from 1:10 to 1:160, the ratio of adenine-N3 to guanine-N3 alkylation steadily increased from 1.4:1 to 11:1 (92:8),[61] which clearly indicates that adenine-N3 alkylation is preferred when available.[57] In contrast, duocarmycin SA showed no evidence of guanine-N3 alkylation when subjected to similar or more forcing reaction conditions.[54] Even under vigorous conditions, unchanged agent was recovered, and the selectivity (adenine-N3/guanine-N3 alkylation) was greater than 25:1. This enhanced selectivity of **3** may be attributed to its decreased reactivity. Notably, under the relevant conditions of limiting agent even **2** provided nearly exclusive adenine-N3 alkylation.[57] Since **3** is much more potent than **2**, the minor guanine-N3 alkylation cannot be uniquely important to the biological properties of the agents and may represent a nonproductive competitive event.

Thus, the relative reactivity of the agents may influence the DNA alkylation selectivity. Under the conditions of limiting agent and excess DNA, where little or no guanine-N3 alkylation is detected, the studies have illustrated that the more stable and less reactive agents are both more efficient and more selective among the available alkylation sites. These distinctions would appear to be most important to exploit.

2.5. Reversibility of the DNA Alkylation Reaction: Binding-Driven Bonding

Although the duocarmycin DNA alkylations have proven similar to those of CC-1065, one important feature distinguishes the agents. Unlike **1**, which irreversibly alkylates DNA, duocarmycins **2** and **3** alkylate DNA reversibly.[54, 58] The ease of reversibility proved dependent upon the relative reactivity of the agent and hence the stability of the adduct, as well as on the extent of the noncovalent binding interactions (Fig. 4). Consistent with the relative reactivity of the agents and the expected stability of the adducts, the (+)-duocarmycin A (**2**) retroalkylation reaction was slower than that of (+)-duocarmycin SA (**3**). In addition, the rate of retroalkylation was faster, and the adduct was much less stable with N-BOC-DSA (**12**) (see Fig. 5) than with **3**, which may be attributed to the lack of stabilization from the trimethoxyindole binding. (+)-CC-1065 (**1**) is less reactive than **2** but more reactive than **3**. The lack of detection of a reversible alkylation by **1** under comparable conditions may be taken as a further indication of the dependence of reversibility on the extent of the noncovalent binding stabilization. Consistent with this interpretation, analogs of CC-1065 possessing the same alkylation subunit but simpler and smaller binding subunits were the first such agents shown to alkylate DNA reversibly.[70]

Thus, dominant forces stabilizing the DNA alkylation reaction are not only the covalent bond but also the stabilizing noncovalent interactions derived from hydrophobic binding and van der Waals contacts. That is, the alkylation reaction is rendered less reversible or irreversible by noncovalent binding stabilization. The importance of these observations becomes clear when the properties of the agents are compared. The exceptionally potent cytotoxic activity of the natural products relative to that of the simple derivatives of the alkylation subunits themselves (Fig. 5) may be attributed in part to the simple event of noncovalent binding stabilization of the inherently reversible DNA alkylation reaction.



12, N-BOC-DSA **13**, N-BOC-CPI

Fig. 5. Structures of derivatives of the alkylation subunits.

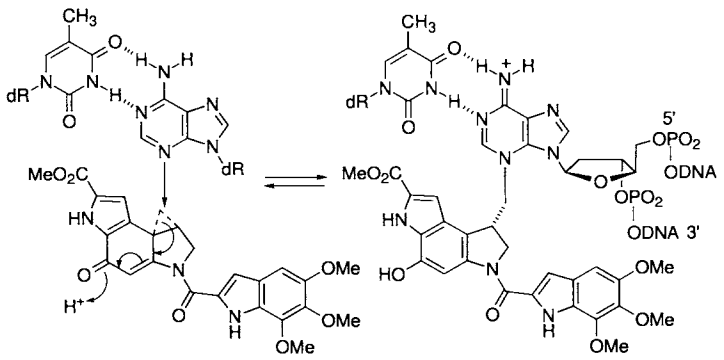


Fig. 4. Reversible DNA alkylation reaction, exemplified with **3**. The characteristics of the reversible reaction are as follows: The rate of the reverse reaction increases with increasing pH, temperature, and ionic strength. It is greater for duocarmycin SA than for duocarmycin A, showing the general decrease with increasing stability of the adduct and increasing agent reactivity. It is greater for the duocarmycins than for CC-1065 and even larger for N-BOC-DSA indicating a general decrease with increasing stabilization provided by the noncovalent binding interactions.

This reversible nature of the alkylation reaction itself along with the equilibrium binding requires that four rate constants be addressed in assessing the sequence-selective alkylation [Eq. (a)]. The large differences in the extent of reversibility sug-

$$\text{substrate} + \text{DNA} \underset{k_d}{\overset{k_a}{\rightleftharpoons}} \text{substrate}\cdot\cdot\text{DNA} \underset{k_{retroalk.}}{\overset{k_{alk}}{\rightleftharpoons}} \text{substrate-DNA} \qquad \text{(a)}$$

gest that treatments to date have neglected two of the more important rate constants,[43, 46] namely the relative rates of retroalkylation at competing or potentially nonobserved sites and the dissociation rates (off rates) for the available binding sites. The off rates for some noncovalent adducts have been shown qualitatively to be quite slow.[82]

These observations coupled with studies indicating that the noncovalent binding equilibrium is established through decomplexation, not through procession along the minor groove, suggest that dissociation rates and not simply association rates or $K_b (= k_a/k_d)$ may be especially important.[96] Defined oligonucleotides that contain sites capable of noncovalent binding but incapable of alkylation have been shown to inhibit the rates of

DNA alkylation. This would suggest that the rates of equilibrium binding may be slow and that the dissociation rate or relative K_b, not the association rate or rate of alkylation, may be rate-determining. Moreover, this inhibition of DNA alkylation was the same whether the competitive site for noncovalent binding was inter- or intramolecular. These studies would seem to demonstrate that the first binding equilibration in Equation (a) may be slow relative to alkylation and that the off rates or relative K_b are significant and should not be neglected.

2.6. Models of the DNA Alkylation for Enantiomeric Agents

The examination of the natural products, their synthetic unnatural enantiomers, and key partial structures not only resulted in the unusual observation that the unnatural enantiomers constitute effective DNA alkylating agents and potent antitumor antibiotics, but has also led to the emergence of a detailed model[53, 54] of the structural features responsible for their selective alkylation of DNA. The characterization of **8**–**10**, the unambiguously established absolute configuration of the agents, and the definition of the alkylation consensus sequences for both enantiomers of **1**–**3** provided the necessary information for the construction of accurate models of the adenine-N3 alkylation. Figure 6 illustrates models of the (+)- and (−)-duocarmycin SA alkylation at a common site in w794 DNA (5′-CTAATT), which is a high-affinity site for the unnatural enantiomer, and a minor site for the natural enantiomer.[54]

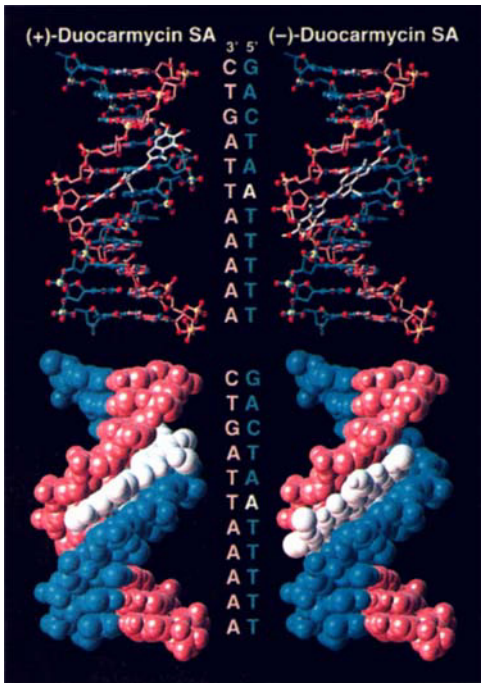

Fig. 6. Stick and space-filling models illustrating the alkylation at the same site within w794 DNA (duplex 5′-d(GACTAATTTTT)) by (+)-duocarmycin SA (left) and (−)-duocarmycin SA (right). The binding of the natural enantiomer extends in the 3′ → 5′ direction from the adenine-N3 alkylation site across the sequence 5′-CTAA, that of the unnatural enantiomer in the reverse 5′ → 3′ direction across the site 5′-AATT.

Similar models of the (+)- and (−)-CC-1065 alkylations may be found in Figure 7.[53] For both the duocarmycins and CC-1065 the hydrophobic face of the agent is imbedded deeply in the minor groove, the polar functionality lies on the outer face of the complex, and the bound helical conformation of the agent complements the topological curvature and pitch of the minor

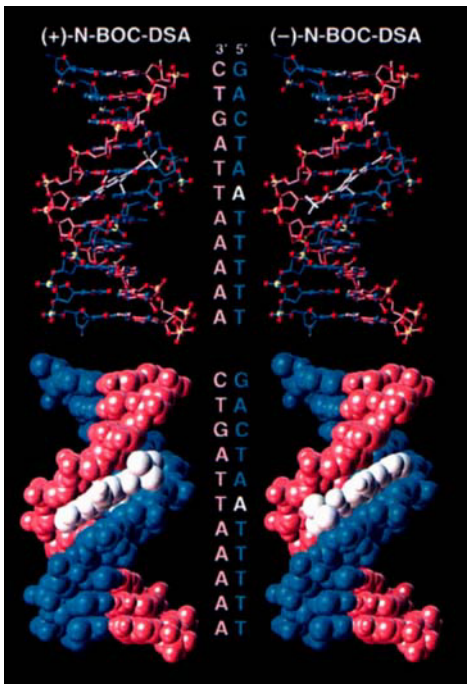

Fig. 7. Stick and space-filling models illustrating the alkylation at the same site within w794 DNA (duplex 5′-d(GACTAATTTTT)) by (+)-CC-1065 (left) and (−)-CC-1065 (right). The binding of the natural enantiomer extends in the 3′ → 5′ direction from the adenine-N3 alkylation site across the sequence 5′-ACTAA, that of the unnatural enantiomer in the reverse 5′ → 3′ direction across the site 5′-AATTT.

groove spanning an AT-rich, 3.5- or 5-base-pair site, respectively. For (+)-duocarmycin SA, the binding spans 3.5 base pairs starting with the 3′-adenine alkylation site and extends in the 3′ → 5′ direction over two to three adjacent 5′ base pairs (5′-CTAA). For the enantiomer, the binding similarly spans a 3.5-base-pair, AT-rich site, but one which necessarily starts at the 5′ base adjacent to the alkylation site and extends in the 5′ → 3′ direction over the alkylation site and one to two adjacent 3′ base pairs (5′-AATT). This alkylation selectivity within an offset AT-rich site is the natural consequence of the diastereomeric relationship of the adducts, and the reversed binding orientation (with respect to the alkylation site) in the minor groove is required to permit addition of the adenine-N3 atom to the least substituted carbon of the electrophilic cyclopropane. The importance of the fourth base (A/T > G/C) in the binding sequences is the reason why this site constitutes a high-affinity site for the unnatural enantiomer but only a minor site for the natural enantiomer. Similarly, the CC-1065 models[53] accommodate the larger size of the more extended five-base-pair, AT-rich binding site of the enantiomeric agents, their reversed binding orientation in the minor groove, and their AT-rich selectivity offset relative to the alkylation site.

The apparently confusing distinctions in the relative efficiency of DNA alkylations by the natural and unnatural enantiomers were found to correlate with the extent of the stabilization of the inherently reversible noncovalent binding in the adducts, as well as with the degree of steric bulk surrounding the C7 center of the agent. Consistent with expectations based on the models, the unnatural enantiomers are especially sensitive to the steric bulk around this C7 center.[53, 54, 73]

3. Key Partial Structures

3.1. N-BOC-DSA: A DNA Alkylating Agent Whose Selectivity and Efficiency Are Independent of Its Absolute Configuration

The accuracy of the models were revealed when they were found to provide a beautiful explanation for the unusual observation that both enantiomers of simple derivatives of the alkylation subunit, for example N-BOC-DSA (**12**)[54] or N-BOC-CPI (**13**, see Fig. 5),[53, 68] alkylate the same sites in DNA. In addition to illustrating that the DNA alkylation reactions of (+)- and (−)-**12** are both substantially less efficient (about $10^4\times$) and less selective (selectivity: 5′-A<u>A</u> > 5′-T<u>A</u>), and proceed with a different profile from that of (+)- or (−)-duocarmycin SA or CC-1065, the studies have shown that both enantiomers of **12** alkylate the same sites with essentially the same efficiency independent of the absolute configuration.[54] This feature of such simple agents is general, and the *N*-acetyl derivatives have been shown to behave similarly. Figure 8 illustrates these features nicely, and the consensus alkylation selectivity for both (+)- and (−)-N-BOC-DSA and -N-BOC-CPI is summarized in Table 3. Although these observations may appear unusual, they are a natural consequence of the diastereomeric relationship of the adducts. The natural enantiomer binds in the 3′ → 5′ direction from the site of alkylation extending over the adjacent 5′ base. The unnatural enantiomer binds in the reverse 5′ → 3′ orientation but with binding that also covers the same adjacent 5′ base. These alkylation site models,[53, 54] which are illustrated in Figure 9, nicely accommodate the observed selectivity of 5′-A<u>A</u> > 5′-T<u>A</u> for both enantiomers. The apparent preference of 5′-A<u>A</u> over 5′-T<u>A</u> (about 2:1) observed when examining one strand of single end-labeled DNA at a time is statistical rather than structural in nature. The unlabeled complementary partner strand of a 5′-TA sequence contains an identical competitive site, whose alkylation diminishes the apparent alkylation efficiency of the labeled strand. The factor controlling alkylation is simply the depth of penetration into the minor groove achieved by the agent, which is essential for the adenine-N3 alkylation of the electrophilic cyclopropane. For simple agents such as **12** and **13**, it is sufficient when the adjacent 5′ base is A or T, and models of an unobserved 5′-G<u>A</u> alkylation support this proposal.[53, 54] For **3** or **1**, a larger 3.5- or 5-base-pair, AT-rich region surrounding the alkylation site is required to permit sufficient groove penetration for alkylation, which is further facilitated by the preferential noncovalent binding of the agents within the narrower, deeper, AT-rich minor groove.[82]

These distinctions are important but not uniformly accepted in the work conducted to date. Whereas our studies revealed

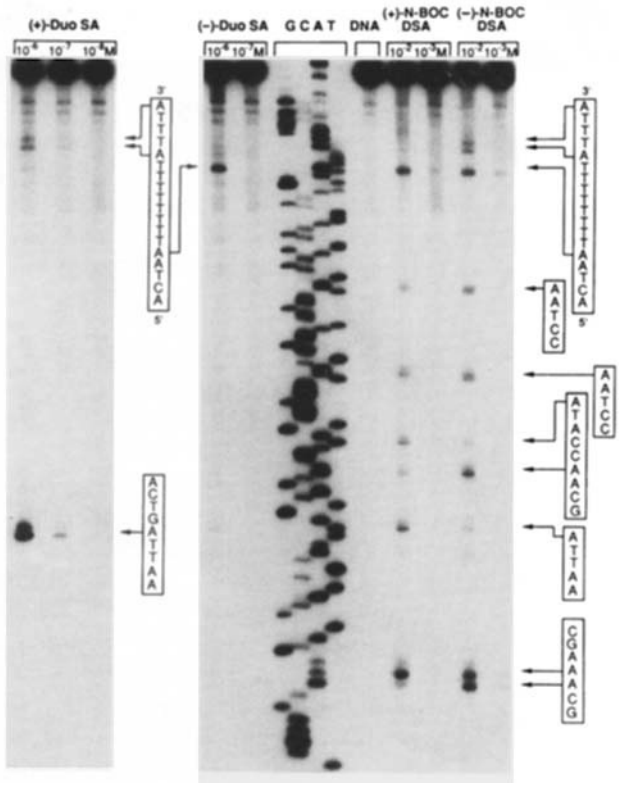

Fig. 8. Thermally induced strand cleavage (by heating to 100 °C for 30 min) of w794 DNA (SV40 DNA segment, 144 base pairs, nucleotide no. 5238-138) after 24 h incubation of DNA with (+)- or (−)-duocarmycin SA at 25 °C and with (+)- or (−)-N-BOC-DSA at 37 °C and removal of unbound agent by EtOH precipitation followed by denaturing PAGE (8%) and autoradiography. Lanes 1–3: **3** (1×10^{-6}–1×10^{-8} M); lanes 4 and 5: ***ent*-3** (1×10^{-6}–1×10^{-7} M); lanes 6–9: Sanger G, C, A, and T reactions; lane 10: control DNA; lanes 11 and 12: (+)-**12** (1×10^{-2}–1×10^{-3} M); lanes 13 and 14: (−)-**12** (1×10^{-2}–1×10^{-3} M).

distinctions between the natural products and simple derivatives of the alkylation subunit in the extent of the alkylation selectivity, the collaborative efforts of the Hurley and Upjohn groups with CPI-derivatives report an indistinguishable or subtly distinguishable alkylation selectivity between (+)-CC-1065 and (+)-N-acetyl-CPI.[43, 46, 47, 67, 68] This premise has led them to the conclusion that all the structural requirements for observation of the alkylation selectivity by (+)-CC-1065 are embodied in the CPI alkylation subunit.

Despite the similarities in the behavior of N-BOC-DSA (**12**) and N-BOC-CPI (**13**), two important differences were observed. First, both the natural and unnatural enantiomers of **12** are more efficient at alkylating DNA and are biologically more potent than the corresponding enantiomers of **13**. These differences may be attributed to the enhanced stability of **12**, which leads to more productive DNA alkylation. Secondly, while little or no distinction was observed in the DNA alkylation efficiencies of the natural and unnatural enantiomers of **12**, the natural enantiomer of **13** was found to be both more efficient and more cytotoxic than its unnatural enantiomer by a factor of between 10 and 100. As detailed later, this apparently confusing behavior of enantiomeric pairs may be attributed to the degree of steric bulk surrounding the C7 center, for which the diastereomeric adducts derived from the unnatural enantiomers are especially sensitive.

[a] The numbers listed in the table give the percentage of the indicated base located at the designated position relative to the adenine-N3 alkylation site. [b] The numbers in parentheses give the percentage composition within the DNA examined.

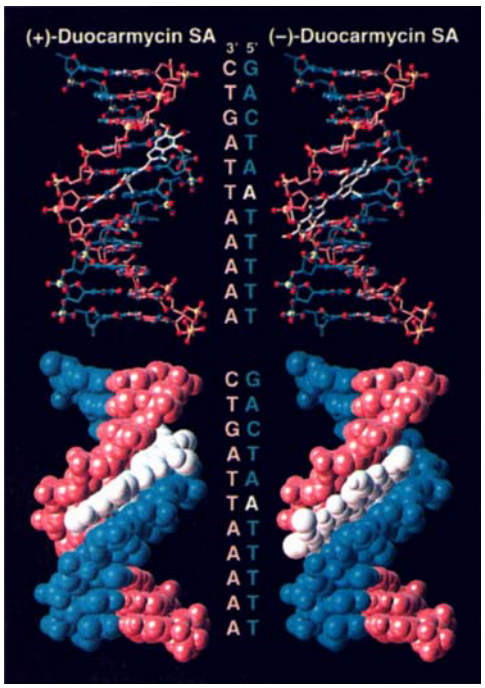

Fig. 9. Stick and space-filling models illustrating the alkylation of the same site within w794 DNA (duplex 5′-d(GACTAATTTTT)) by (+)-**12** (left) and (−)-**12** (right). The binding of the natural enantiomer extends in the 3′ → 5′ direction from the adenine-N3 alkylation site across the site 5′-AA, that of the unnatural enantiomer in the reverse 5′ → 3′ direction but across the same 5′-AA site.

3.2. CPI-PDE-I$_1$: A Key Substructure of CC-1065

In early efforts to establish the role of each of the subunits of CC-1065, both enantiomers of CPI-PDE-I$_1$ (**14**, Fig. 10) were prepared for evaluation.[71] Although a number of interesting

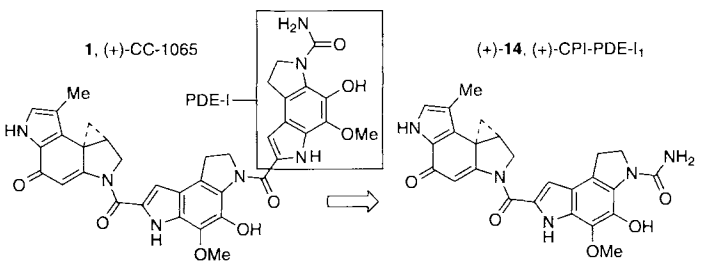

Fig. 10. CPI-PDE-I$_1$ (**14**), a key substructure of CC-1065.

observations were made in this early study, only two of the more seminal are described below. First, (+)-CPI-PDE-I$_1$ displayed in vitro cytotoxic activity indistinguishable from (+)-CC-1065, indicating that the entire righthand subunit framed in Figure 10 was unnecessary for observation of the full biological potency of the natural product. The subsequent discovery of the duocarmycins, which also lack this third subunit, provided indepen-

dent confirmation of its relative unimportance to the biological properties of the natural enantiomers. In addition, the natural enantiomer of **14** exhibited a similar, although perceptibly altered DNA alkylation selectivity from that observed with (+)-CC-1065. Table 3 (Section 3.1) summarizes the consensus alkylation sequence found for (+)-**14**. Like (+)-CC-1065, each alkylation site detected proved to be adenine, and each site was flanked by two 5′-A or -T bases. The same order of preference as in the case of **1** was observed for this three-base, AT-rich alkylation region: 5′-AA<u>A</u>≈5′-TT<u>A</u>>5′-TA<u>A</u>>5′-AT<u>A</u>. The distinctions between (+)-**14** and (+)-CC-1065 were found to lie in the AT preference extended to the fourth and fifth 5′ bases. With (+)-**14**, a weaker preference for the fourth 5′-A or -T base was observed, and unlike (+)-CC-1065, no preference for the fifth 5′ base was observed. Thus, like the subsequent observations made with duocarmycin A and SA, (+)-**14** exhibits alkylation selectivity for a shorter 3.5-base-pair, AT-rich site. Consequently, the presence of the DNA binding subunits were found to influence the sequence selectivity of DNA alkylation, and a full study of shorter and more extended analogs of CC-1065 revealed that this AT-rich selectivity corresponds nicely to the length of the agent and the size of the region surrounding the alkylation site required to bind the agent (see Table 3).[53, 71]

The relative cytotoxic potencies of related agents, including those that lack the DNA binding subunits altogether, suggested an additional important functional role for the DNA binding subunits. (+)-N-BOC-CPI and (+)-N-acetyl-CPI, which lack an attached DNA binding subunit, proved to be approximately 1000 to 10000 times less potent than (+)-CC-1065. In contrast, the natural enantiomers of the agents **14**–**17** (see Figs. 10 and 12), which possess one to three DNA binding subunits, proved equipotent with the natural product (Table 4). Similarly, (+)-N-BOC-CPI and (+)-N-acetyl-CPI were substantially less efficient (1000–10000×) at alkylating DNA, whereas **14**–**17** and **1** exhibited comparable efficiencies but different DNA alkylation rates and subtly distinguishable selectivities for AT-rich alkylation sites, corresponding to their relative sizes. This, in conjunction with computational studies, quantitative molecular modeling studies, and an appreciation of the intrinsic stability of the agents, suggested to us that the DNA alkylation was inherently reversible but stabilized by the noncovalent interactions provided by the DNA binding subunits. Furthermore, it suggested that a single DNA binding subunit would provide this stabilization for the natural enantiomers and that it was the simple event of the stabilization that provided the full potentiation of the biological properties. At this time the reversible nature of the DNA alkylation was not recognized, and the Hurley and Upjohn groups, in their complementary efforts, proposed that the distinctions were due to the rates of DNA alkylation and the kinetic aspects of the formation of the DNA adducts.[46] These varying proposals led to the subsequent discovery that the DNA alkylation reactions are indeed reversible and that the adducts are increasingly stabilized by the presence and size of the DNA binding subunits.[58, 70]

3.3. CPI-$CDPI_2$: A Precise Functional Analog of CC-1065

Among the first analogs of CC-1065 examined, that which was derived from removal of the methoxy and hydroxy substituents from the central and righthand subunits proved especially revealing (Fig. 11). CPI-$CDPI_2$ proved particularly important to examine because of the growing perception at the time that the polar functionality on CC-1065 was contributing significantly to the properties of the agents. Its examination addressed three important questions. The first was the contribution that the substituents may make to DNA binding, the resulting alkylation properties of the natural product, and their contribution to the biological properties. Although the substituents were initially expected to influence the DNA alkylation properties significantly, extensive molecular modeling studies did not support such a role.[38, 41] Secondly, the C4 hydroxy group had been suggested to facilitate DNA binding by hydrogen bonding to the carbonyl group of the linking subunit, thereby stabilizing

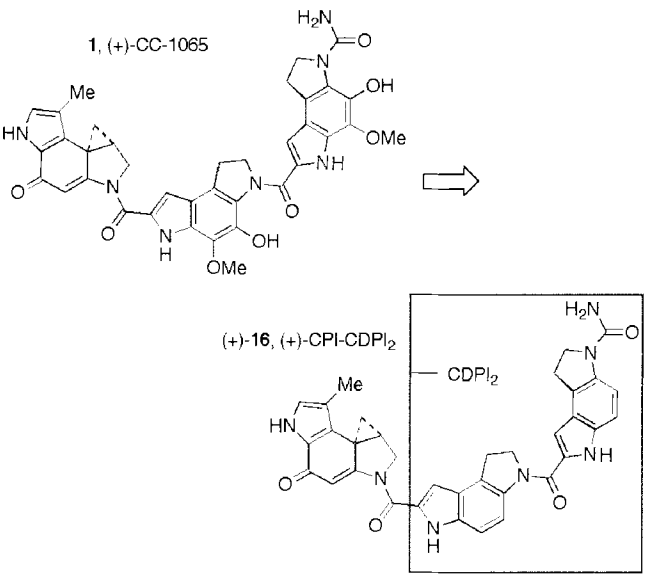

Fig. 11. CPI-$CDPI_2$ (**16**), a precise functional analog of CC-1065.

a curved and helical conformation required for groove binding. However, this intramolecular hydrogen bonding introduced an exaggerated pitch to the helical conformation of CC-1065, and the less pronounced inherent pitch of the helical conformation of (+)-**16** more closely followed that required for minor groove binding.[38, 77, 78] Finally, oxidation of the central and righthand subunits to an extended *para*-quinone imine was thought potentially to contribute to the delayed toxicity of (+)-CC-1065.[80]

The preparation of both enantiomers of CPI-$CDPI_2$[77] and their comparison with the enantiomers of CC-1065 revealed that the two agents were indistinguishable.[71] The cytotoxic activity, in vivo antitumor activity, and DNA alkylation efficiencies and selectivities of both enantiomers of CPI-$CDPI_2$ were identical to those of the corresponding CC-1065 enantiomer. Moreover, (+)-CPI-$CDPI_2$ exhibited the delayed toxicity characteristic of (+)-CC-1065, whereas both the unnatural enantiomers lacked this property.[79] Thus, the examination of **16** established that the hydroxy and methoxy substituents on the central and righthand subunits of CC-1065 do not contribute to the properties of the natural product. Some of the conclusions drawn from a complementary and concurrent study were initially distinct from this[79] but later revised.[46]

The indistinguishable profiles of DNA alkylation proved particularly revealing when compared to those of the series of structurally related agents detailed in the next section. The studies were facilitated through introduction of a useful protocol for rapidly securing substantial quantities of DNA labeled at one end with ^{32}P.[72]

3.4. CPI-$CDPI_n$: Extended and Shortened Analogs of CC-1065

In initial efforts to establish the functional roles of each of the CC-1065 subunits, the full set of shortened and extended agents **15**–**17** were prepared for comparative examination (Fig. 12).[71] In these studies, CPI-$CDPI_1$ and CPI-PDE-I_1 proved indistinguishable, and the natural enantiomers of CPI-$CDPI_n$ ($n = 1-3$) and CPI-PDE-I_n ($n = 1-2$) exhibited the same cytotoxic potency. Pertinent to defining the origin of the DNA alkylation selectivity of (+)-CC-1065 is the observation that the natural enantiomers of (+)-CPI-$CDPI_1$ and (+)-CPI-PDE-I_1, as well as (+)-CPI-$CDPI_3$, were distinguishable from natural product and (+)-CPI-$CDPI_2$. The former exhibited a selectivity for shorter 3.5-base-pair, AT-rich alkylation sites, while the latter favored a more extended, 6.5–7-base-pair, AT-rich site.[53] Table 3 summarizes the consensus alkylation sequences for both the natural and unnatural enantiomers of these key substructures of CC-1065.

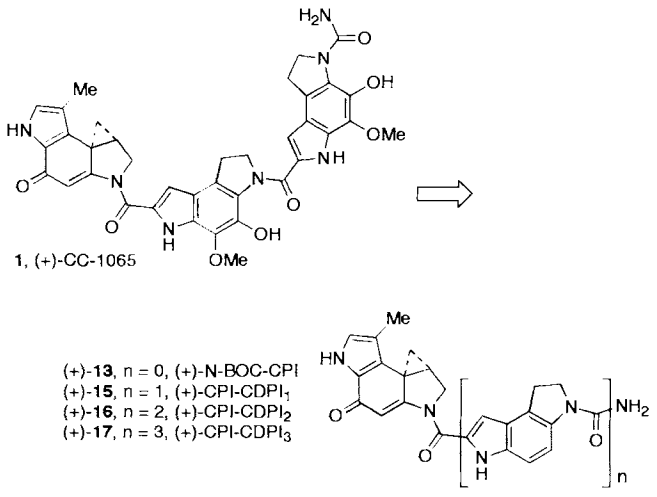

Fig. 12. CPI-$CDPI_n$, extended and shortened analogs of CC-1065.

One of the initially confusing observations was that the unnatural enantiomers of CPI-$CDPI_1$ and CPI-PDE-I_1, unlike (−)-CC-1065, failed to alkylate DNA productively and were relatively nonpotent cytotoxic agents (Table 4). Although this was not easily rationalized at the time the observations were made, it now can be attributed to the extent of stabilization provided by the noncovalent contacts and the degree of steric bulk surrounding the C7 center of the CPI or DSA alkylation subunit (**12** or **13**, respectively). For the unnatural enantiomer, this results from destabilizing steric interactions with the 5′ base preceding the alkylated adenine residue on the alkylated strand of DNA, which decelerate the rate of DNA alkylation and destabilize reversible adduct formation. A single DNA binding subunit is necessary to stabilize reversible adduct formation for the natural CPI alkylation subunit, whereas the unnatural CPI enantiomer requires two such DNA binding subunits. In sharp contrast, a single DNA binding subunit is required for both the natural and unnatural enantiomers of DSA, since the destabilizing steric interactions at C7 unique to the unnatural enantiomer adducts have been reduced.

Further simplifications in the DNA binding subunits have been accomplished and studies with agents containing deep-seated modifications in this region have been described. These are discussed in more detail in Section 10.

4. Noncovalent Binding Affinity and Selectivity

4.1 PDE-I_n, $CDPI_n$, $ACDPI_n$, and $TACDPI_n$

Important early insights into the structural origin of the sequence-selective DNA alkylation were derived from the examination of the characteristics of the noncovalent binding to DNA of **18**–**21**, key partial structures of **1**–**3** that were not capable of the covalent bond formation (Fig. 13). Although the studies have been conducted with a range of agents and various DNA,[81–84] only the seminal aspects of the studies are summarized in Figure 13. Both relative and absolute DNA binding constants have been established, and the agents exhibited a substantial selectivity for binding to the AT-rich minor groove (Table 5).[82, 83] In addition, $CDPI_3$ was the optimum binding agent within the $CDPI_n$ series (Fig. 13, bottom). The minor groove binding of $CDPI_3$ spans five base pairs or half a helix turn, which constitutes the largest site accessible for synchronous binding of both ends of the rigid agent. Partially bound forms of the larger agents, for instance $CDPI_4$ bound through a $CDPI_2$ subunit only, constitute productive and stable noncovalent complexes, and $CDPI_4$ and $CDPI_5$ were not as effective as $CDPI_3$. The removal of the hydroxy and methoxy substituents (PDE-$I_n \rightarrow CDPI_n$) had only a small impact on the

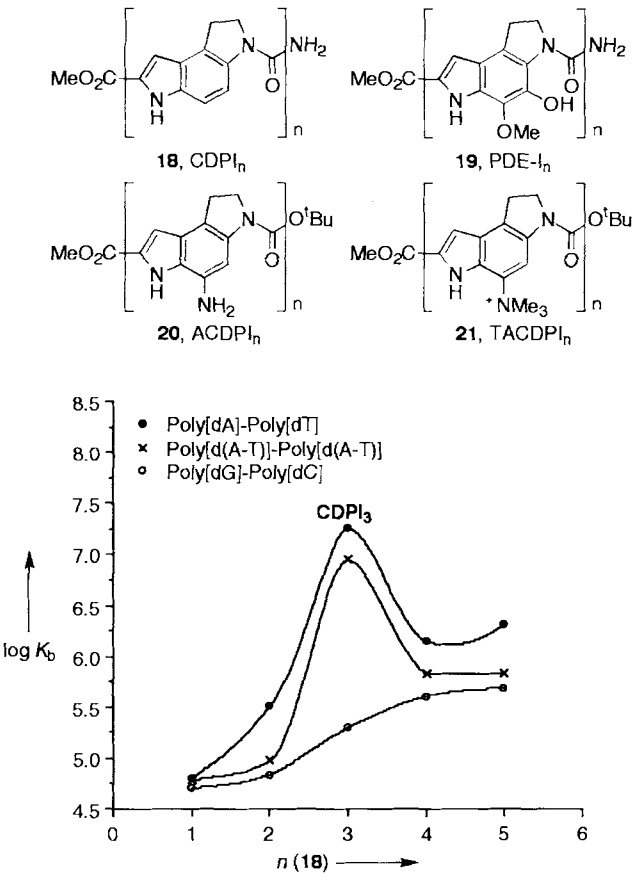

Fig. 13. Structures (top) and binding constants (bottom) of substrates that bind noncovalently to DNA.

binding affinity and no apparent impact on the selectivity for AT-rich binding sites.[82] Since there is no CDPI$_n$ functionality that would provide hydrogen bonding or electrostatic stabilization, the affinity is derived principally from stabilizing van der Waals contacts. The preference for AT-rich minor-groove binding is probably due to the deeper penetration of the agents into the narrower, AT-rich minor groove, where the stabilizing contacts are maximized.

Consequently, the studies suggested that (+)-CC-1065 is best represented as a selective alkylating group superimposed upon the rigid CDPI$_3$ skeleton[82] rather than as a reactive alkylating agent (CPI) attached to a DNA binding agent (PDE-I$_2$). The agents exhibit a substantial preference for noncovalent binding at AT-rich regions in the minor groove, which is optimal with the rigid trimer. Among features that contribute to minor-groove binding selectivity, at least two structural characteristics of an A-T base pair and of a run of A-T base pairs are important to agents that rely on stabilizing van der Waals contacts and hydrophobic binding. First, the amino substituent of a G-C base pair that extends into the minor groove has no counterpart in an A-T base pair (Fig. 14). This results in a sterically more accessible region adjacent to an A-T base pair that permits the deeper penetration of an agent into the minor groove and enhances the stabilization derived from van der Waals contacts. In addition, X-ray crystallographic studies of oligodeoxynucleotides that contain a run of A-T base pairs in the center of their structure have revealed characteristic features including the constricted width of the AT-rich minor groove.[14, 15] Illustrated in Figure 14 (bottom) is a plot of the effective width of the minor groove of four such oligodeoxynucleotides that highlights this

narrower, AT-rich minor groove. This important conformational feature of DNA possessing runs of A-T base pairs contributes prominently to the selectivity of the agents that depend on stabilizing van der Waals contacts for noncovalent binding. The noncovalent complexes of such agents may be expected to form preferentially within the narrower, sterically more accessible, AT-rich minor groove, where the stabilizing van der Waals contacts are most effectively provided.

More recently the DNA binding properties of ACDPI$_n$ (**20**, $n = 1-4$) and TACDPI$_n$ (**21**, $n = 1-3$) have been described.[83] As with the CDPI$_n$ series, ACDPI$_3$ proved to be the optimal minor groove binding agent and exhibited a selectivity for AT- rather than GC-rich DNA. Similarly, TACDPI$_n$ exhibited a substantial selectivity for AT-rich DNA binding sites ($n = 3$, $\Delta\Delta G = -2.7$ to -3.5 kcal mol^{-1}). The comparison of CDPI$_n$ substrates with ACDPI$_n$ substrates illustrated that the introduction of a strong electronegative substituent onto the outer face of the agent reduced the binding affinity through introduction of destabilizing electrostatic interactions with the phosphate backbone. In contrast, the behavior of TACDPI$_n$ substrates revealed that the introduction of a C5 quaternary amine substantially enhanced the binding affinity through introduction of stabilizing electrostatic interactions with the phosphate backbone (Fig. 15).

Finally, the terminal urethane of CC-1065 was found not to contribute to the minor-groove binding affinity or selectivity.[82]

4.2. Affinity Cleavage: The Sites for Noncovalent Binding and for Alkylation Coincide

A study of the efficiency and selectivity of DNA cleavage by the Fe^{III} complex of the affinity cleavage agent **22**[85] (Fig. 16)

has provided further direct evidence that for both (+)- and (−)-CC-1065 all DNA alkylation sites coincide with AT-rich regions suitable for noncovalent binding.[86] Importantly, no DNA alkylation sites were observed to lie outside such preferred noncovalent binding regions. To a first approximation, the relative alkylation efficiencies between sites paralleled the relative cleavage efficiencies of Fe^{III}-**22** at the competing sites. As the affinity cleavage agent **22** provided clean cleavage at both ends of a five-base-pair binding site, it must bind in both orientations in the site. The offset H-abstraction sites leading to DNA cleavage confirm minor-groove binding. This relationship of the DNA cleavage sites for **22** surrounding the w794 five-base-pair, AT-rich, high-affinity alkylation site for CC-1065 is illustrated in Figure 17. Notably, (+)-CC-1065 can only alkylate one site and strand in this sequence, since in its reversed bound orientation the activated cyclopropane is placed adjacent to the two 3′ T bases on the left strand.

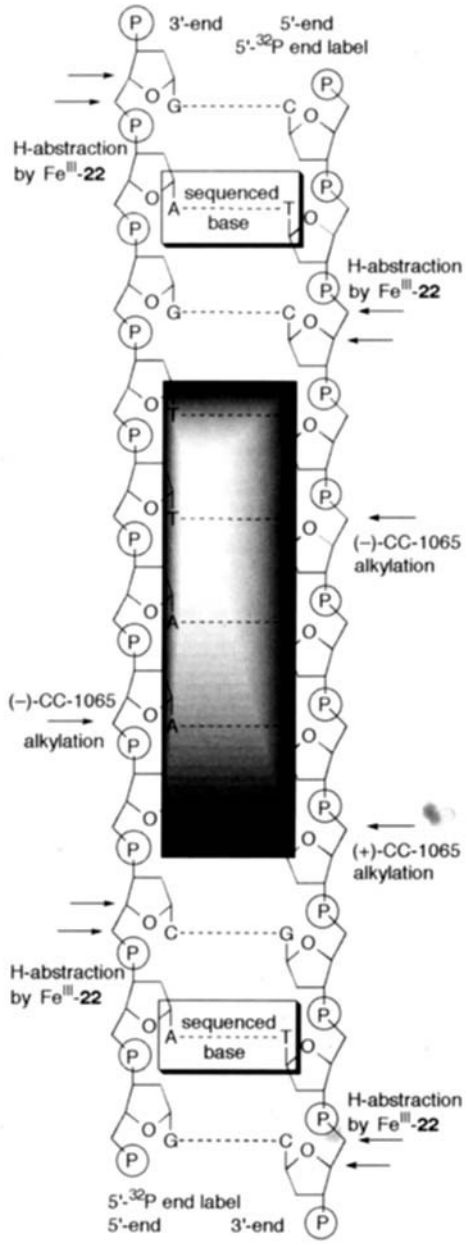

Fig. 17. Model illustrating the relationships between the sequenced cleavage sites for Fe^{III}-**22**, its C4′ and C5′ H-abstraction sites, the five-base-pair, AT-rich site for noncovalent binding, and the sites of adenine-N3 alkylation by (+)- and (−)-CC-1065 in w794 DNA.

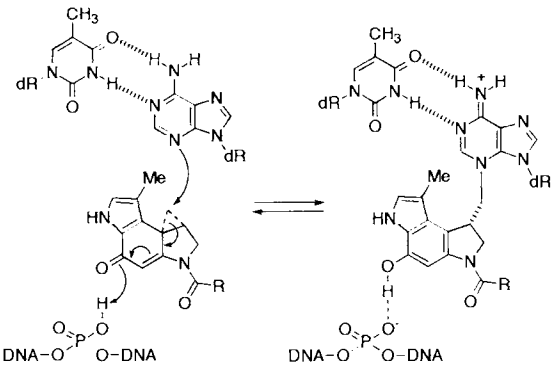
4.3. Circular Dichroism Studies

Difference circular dichroism studies initially demonstrated that CC-1065 binds in the AT-rich regions of the minor groove in double-stranded B DNA.[87–97] This technique has also shown that (+)-CC-1065 forms a stable noncovalent complex with the Dickerson dodecamer d(CGCGAATTCGCG)$_2$.[91, 92, 96] In fact, all adenine-containing duplex deoxyoligonucleotides initially bind (+)-CC-1065 noncovalently, as evidenced by a transient absorption at 390 nm, and then react to produce a covalent adduct, which shows a maximum ellipticity at 370 nm.[89–97] In the exceptions, which bind but do not react with CC-1065, the binding sites do not contain an adenine properly positioned to permit alkylation. For example, the activated cyclopropane of (+)-CC-1065 is placed proximal to the two 3′-T bases of the Dickerson dodecamer in both bound orientations, and thus no accessible nucleophilic site is available for alkylation. Contrary to assertions of the uniqueness of the alkylation reaction, the positioning of this nucleophilic adenine-N3 site need not be exquisite but must be on the right end of the binding site. Consistent with this, the unnatural enantiomer of CC-1065 readily alkylates the Dickerson dodecamer, and its activated cyclopropane is oriented toward the opposite strand proximal to the two 5′-A bases. It is misleading to suggest that such studies illustrate that noncovalent binding cannot dominate or control DNA alkylation, if only a single mismatched binding site is examined.[46, 96] As the studies with the affinity cleavage agent **22** illustrate, noncovalent binding at an AT-rich site in the minor groove may not guarantee alkylation, but it is a prerequisite to the observation of DNA alkylation.

5. Proposals for the Origin of Polynucleotide Recognition

In the course of studies on CC-1065 and the duocarmycins, the alkylation selectivity of the natural enantiomers has been attributed to a sequence-dependent activation of the reaction through C4 carbonyl protonation by a strategically positioned phosphate in the DNA backbone,[43–47, 67–69] to the conformational variability of DNA and alkylation at junctions of bent DNA,[98–103] or to preferential noncovalent binding and subsequent alkylation within the narrower, deeper, AT-rich minor groove of DNA (Scheme 2).[34–42] Central to the different interpretations are the perceived similarities[43–48, 64–68] or dis-



Alkylation Model:
- (+)-CPI and (+)-CC-1065 alkylation selectivities are identical
  - selectivity is inherent in the CPI alkylation subunit and the alkylation reaction
- Alkylation selectivity is independent of binding selectivity
- Different features control the (−)-CC-1065 alkylation
- Conformational flexibility of DNA with alkylation at junctions of bent DNA
- Sequence-dependent activation by C4 carbonyl protonation by the phospate backbone
  - C4 carbonyl is required for activation and alkylation selectivity

Noncovalent Binding Model:
- (+)-CPI and (+)-CC-1065 alkylation selectivities are different
  - CPI is a modest electrophile superimposed on a five-base-pair, AT-rich binding agent
- Alkylation selectivity is controlled by binding selectivity and steric accessibility to the alkylation site
- Same features control the (−)-CC-1065 alkylation
- Alkylation within appropriate AT-rich binding sequences
- Phosphate activation does not control the alkylation selectivity
  - C4 carbonyl is not required

Scheme 2. Summary of the key features of the proposed models.

tinctions[34-42, 53, 54] in the alkylation selectivity of simple derivatives, including **12** and **13** and the natural products **1**–**3**. The former two proposals advocated by the Hurley and Upjohn groups are based on the premise that (+)-**13** and (+)-**1** alkylate the same sites and that the alkylation subunit or alkylation reaction controls the selectivity irrespective of noncovalent binding. In contrast, the latter proposal advocated in our studies requires that the selectivity of the agents for AT-rich noncovalent binding sites and their steric accessibility to the alkylation site that accompanies deep penetration into the AT-rich minor groove control the sequence selectivity. This latter model accommodates nicely the reverse and offset 3.5- (for **3**) or 5-base-pair (for **5**), AT-rich, adenine-N3 alkylation selectivities of the natural and unnatural enantiomers of **3** and **1** and requires that **12** and **13** and **1**–**3** exhibit distinct alkylation selectivities (see Fig. 8 and Table 3).[53, 54, 71]

All groups have concluded that the DNA alkylation selectivity displayed by the unnatural enantiomer is dominated by the selectivity of the agents for AT-rich noncovalent binding, as advanced in our studies.[45, 53, 54, 68] However, the Hurley–Upjohn proposal for the natural enantiomers requires that different fundamental polynucleotide recognition elements are operative for the natural and unnatural enantiomers.[68] Because of such distinct interpretations, we set out to unambiguously test the proposed models with the intention of establishing the origin of the DNA alkylation selectivity. This has proven to be especially important to address at this juncture, since the (+)-CC-1065 alkylation of duplex DNA has been suggested to be, and is often cited as, a prototypical example of sequence-dependent DNA reactivity.[43, 46, 47] Before such a proposal should be widely accepted, experimental support and verification should be provided.

5.1 Definitive Tests of Proposed Models for the Origin of the CC-1065 and Duocarmycin DNA Alkylation Selectivity

5.1.1. Test of the Importance of C4-Carbonyl Protonation for Sequence-Selective DNA Alkylation

Although the proposal that a sequence-dependent activation through C4 carbonyl protonation by a strategically placed phosphate in the DNA backbone is attractive, a direct test of its viability indicates it cannot be the source of the DNA alkylation sequence selectivity. In the key study[104, 105] it was shown that **23**–**26** (Fig. 18) exhibited identical alkylation selectivities (5′-AA > 5′-TA) irrespective of their absolute configuration, and the selectivities were identical to those of both enantiomers of **12** and **13**. In addition, the natural enantiomers of **27**–**30** exhibited DNA alkylation selectivities identical to (+)-CC-1065 (Fig. 19)[104] and were much more selective and efficient than **23**–**26**. Because **25**/**26** and **29**/**30**, which lack the C4 carbonyl, alkylate the same sites as **23** or **27**, respectively, a sequence-dependent phosphate protonation and activation cannot be the event that determines the alkylation selectivity. In addition, the much more selective DNA alkylation by **27**–**30**/**1**–**3** than by **23**–**26**/**12**–**13**—independent of the nature of the electrophile—is not consistent with the assertions that the alkylation reaction

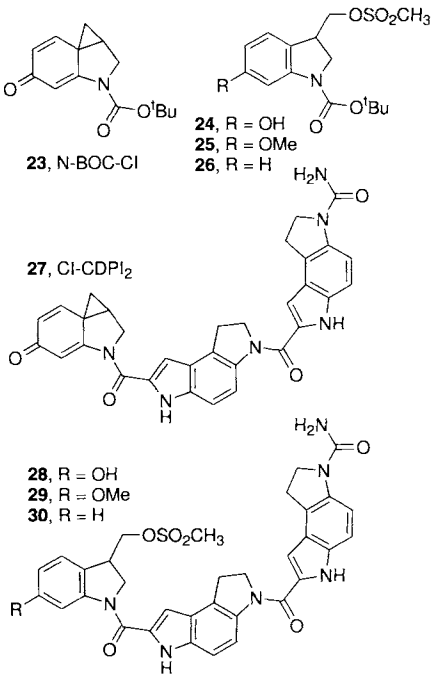


Fig. 18. Structures of the agents **23**–**30**.

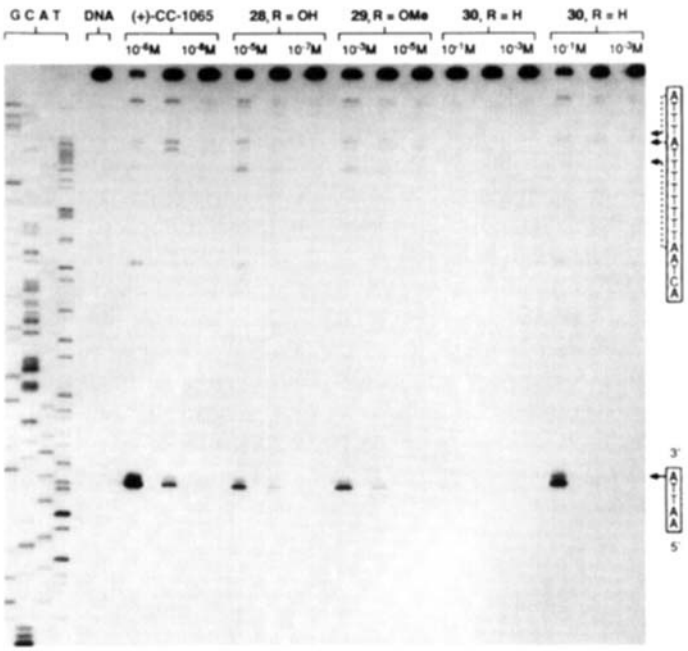

Fig. 19. Thermally induced strand cleavage (by heating to 100 °C for 30 min) of double-stranded DNA (SV40 DNA fragment, 144 base pairs; nucleotide no. 138-5238, clone w794) after 24 h incubation at 4 °C or 37 °C and removal of unbound agent by EtOH precipitation followed by denaturing PAGE (8%) and autoradiography. Lanes 1–4: Sanger G, C, A, and T reactions; lane 5: control DNA; lanes 6–8, (+)-CC-1065 (**1**, 2.5×10^{-6}–2.5×10^{-8} M, 4 °C); lanes 9–11: **28** (2.5×10^{-5}–2.5×10^{-7} M, 4 °C); lanes 12–14: **29** (2.5×10^{-3}–2.5×10^{-5} M, 4 °C); lanes 15–17: **30**, (2.5×10^{-1}–2.5×10^{-3} M, 4 °C); lanes 18–20: **30** (2.5×10^{-1}–2.5×10^{-3} M, 37 °C). The results shown here for the racemates of **28**–**30** are identical to those under analogous conditions for the pure natural enantiomers.

and nature of the alkylation subunit control the alkylation selectivity, but are consistent with the noncovalent binding model.

In addition, the DNA alkylation reaction is not likely to be acid catalyzed at pH 7–7.6 as advocated by Warpehoski,[106]

but rather Lewis acid catalyzed by virtue of metal cations associated with the deprotonated phosphate backbone. Attempts to derive rate accelerations for the DNA alkylation reaction must be tempered by this consideration of a Lewis acid or Brønstedt acid catalyzed reaction.

5.1.2. A Switch in the Inherent Alkylation Selectivity of an Enantiomer by Reversal of the Agent Orientation: A Definitive Demonstration of the Origin of the DNA Alkylation Selectivity

Key to the second and definitive study[108] was the disclosure that both the natural and unnatural enantiomer of duocarmycin SA alkylate DNA efficiently.[54] One unique feature of **3** is the methyl ester at C6 on the lefthand side of the alkylation subunit that complements the righthand side linking amide. This provides the ability to introduce DNA binding subunits on either side of the duocarmycin SA alkylation subunit. In the studies, both the natural and unnatural enantiomers of the extended and reversed duocarmycin SA analogs **31** and **32** (Fig. 20) were examined. We anticipated that (+)- and (−)-DSA-$CDPI_2$ (**31**) would, in general, exhibit alkylation selectivity for a more extended (five-base-pair) site than the site favored by **3** and, in particular, behave identically to (+)-CC-1065 (that is, 5′-AAAAA selectivity) and (−)-CC-1065 (that is, 5′-AAAAA selectivity), respectively.[53] From the noncovalent binding model, the reversed agents (+)- and (−)-$CDPI_2$-DSA (**32**) were projected to exhibit a similar five-base-pair, AT-rich alkylation selectivity, but one that extends in the atypical reverse direction from an alkylation site. Moreover, the alkylation sites for the natural enantiomer of the reversed agent (+)-**32** should coincide with those of *ent*-**1** and (−)-**31**, and analogously those of the unnatural enantiomer (−)-**32** with (+)-CC-1065 or (+)-DSA-$CDPI_2$ (**31**). In contrast, the alkylation site model, in which the natural enantiomer alkylation selectivity is embodied in the alkylation subunit and the DNA alkylation reaction is independent of binding selectivity, would require that the two natural enantiomers (+)-**31** and (+)-**32** alkylate the same sites. Thus, the examination of the DNA alkylation selectivities of both enantiomers of **31** and **32** provided an unambiguous test of the models with a definitive resolution.

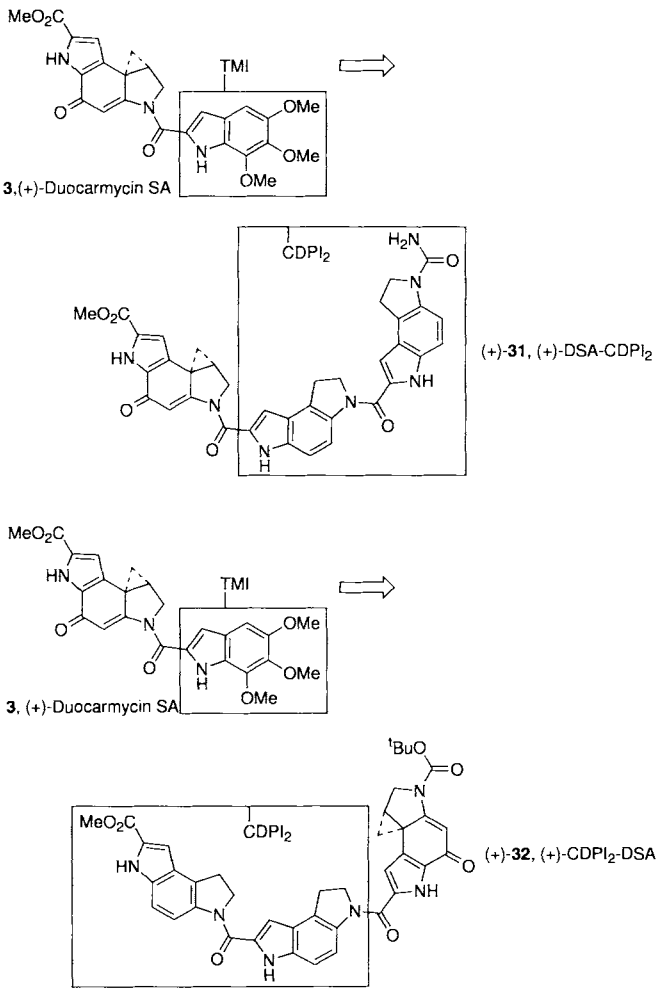

Fig. 20. Extended (top) and reversed (bottom) analogs of (+)-duocarmycin SA (**3**).

Both (+)- and (−)-**31** were found to alkylate DNA with the same selectivity as (+)- and (−)-**1**, respectively (Table 6).[109] The natural enantiomer of the reversed agent (+)-**32** alkylated DNA with the same selectivity as (−)-**31** and *ent*-**1**.[108, 109] This is illustrated beautifully in Figure 21, which highlights the comparisons between the alkylation selectivities not only of the typ-

[a] The numbers listed in the table give the percentage of the indicated base located at the designated position relative to the adenine-N3 alkylation site. [b] The numbers in parentheses give the percentage composition within the DNA examined.

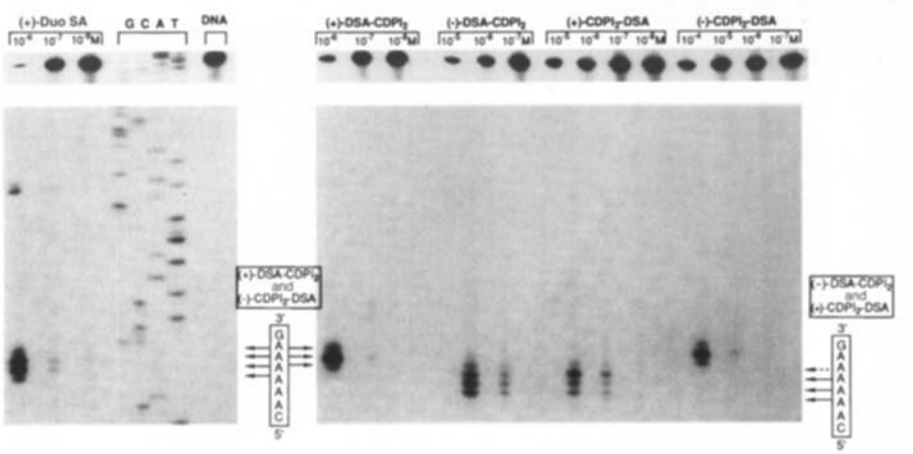

Fig. 21. Thermally induced strand cleavage (by heating to 100 °C for 30 min) of w836 DNA (146 base pairs, nucleotide no. 5189-91) after incubation at 25 °C, removal of unbound agent by EtOH precipitation followed by denaturing 8% PAGE and autoradiography. Lanes 1–3: (+)-**3**, 1×10^{-6}–1×10^{-8} M; lanes 4–7: Sanger G, C, A, and T sequencing standards; lane 8: control DNA; lanes 9–11: (+)-**31**, 1×10^{-6}–1×10^{-8} M); lanes 12–14: (−)-**31**, 1×10^{-5}–1×10^{-7} M; lanes 15–18: (+)-**32**, 1×10^{-5}–1×10^{-8} M; lanes 19–22: (−)-**32**, 1×10^{-4}–1×10^{-7} M.

ical natural and unnatural enantiomers of **31** but also of the two enantiomers of the reversed agents **32**. This incorporation and conversion of a natural enantiomer of the duocarmycin SA alkylation subunit into an agent that exhibits the DNA alkylation selectivity of a typical unnatural enantiomer by simple reversal of the orientation of the DNA binding subunits is only consistent with a model in which the binding selectivity and the depth of minor groove penetration in the vicinity of the alkylation site is controlling the sites of alkylation. Moreover, the observations are definitively inconsistent with alternative models based on the premise that the natural enantiomer's alkylation subunit controls the alkylation selectivity. Similarly, the unnatural enantiomer of the reversed agent (−)-**32** was found to alkylate the same sites as (+)-**31** and **1**, typical natural enantiomers. Thus, this switch in the inherent enantiomeric alkylation selectivity that accompanies the simple reversal of agent orientation is general and confirms that the same fundamental recognition features are operative for both the natural and unnatural enantiomers (Fig. 22).

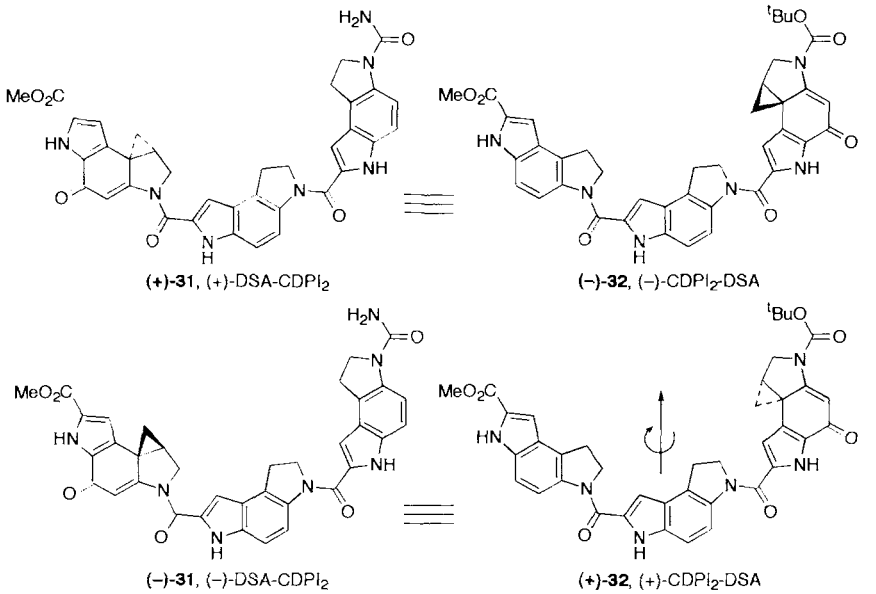

Fig. 22. Representations of the enantiomers of **31** and **32** that highlight the similarities in their experimental behavior. The arrow indicates the rotation of 180° in the horizontal plane (see text).

Although this behavior of the agents may not be obvious from the two dimensional representations of **31** and **32**, a simple rotation of **32** in the horizontal plane reveals the remarkable structural similarities between the two classes of agents and illustrates that it is the pairs of natural and unnatural enantiomers of different substrates **31** and **32** that orient the cyclopropane in comparable directions relative to the DNA binding subunits. Illustrated in Figure 23 are models of the alkylation by (+)-**31** and (−)-**32** at the high-affinity site 5′-AATTA and in Figure 24, models of the alkylation by (−)-**31** and (+)-**32** at the high-affinity site 5′-AATTT. The significance of these comparisons should not be underestimated. The results not only require that the same recognition features are affecting both enantiomers, but also represent an unambiguous demonstration that noncovalent binding in an AT-rich region is controlling and determining the sites of DNA alkylation for both the natural and unnatural enantiomers. In addition, since the DNA alkylation selectivities of (+)-**31**/(−)-**32** or (−)-**31**/(+)-**32** are identical despite the distinctions in the positioning of the cyclopropane, the positionings need not be precise, just accessible.

5.1.3. "Sandwiched" Analogs of Duocarmycin SA: A Class of Agents Whose DNA Alkylation Selectivity Is Independent of Absolute Stereochemistry

In a subsequent and further elegant verification of these observations, the natural and unnatural enantiomers of **33** were prepared by attaching a single DNA binding subunit to both sides of the duocarmycin SA alkylation subunit (Fig. 25) and subjected to examination.[109] Consistent with the noncovalent binding model, both (+)- and (−)-**33** exhibited identical DNA alkylation selectivities, which were distinct either from the natural or from the unnatural enantiomers of the extended or reversed agents **31** and **32** (Table 7).

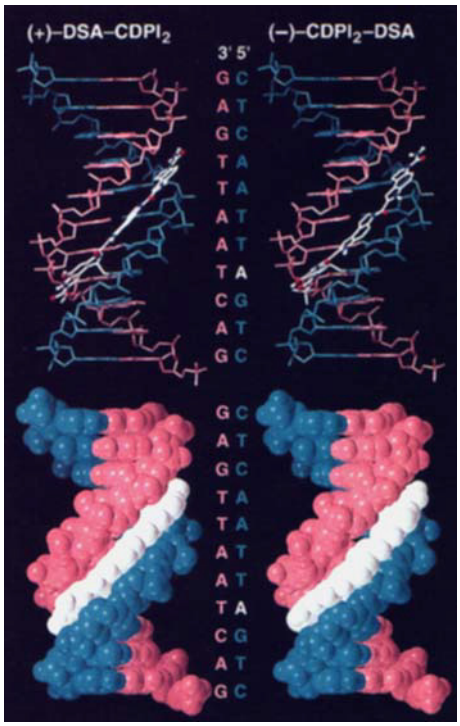

Fig. 23. Stick and space-filling models of the alkylation at a high-affinity site in w794 DNA (5′-CTCAATTAGTC) by (+)-**31** (left) and (−)-**32** (right). The natural enantiomer extends in the 3′ → 5′ direction from the adenine N3 alkylation site across the five-base, AT-rich site 5′-AATTA. The unnatural enantiomer of the reversed agent binds in the same 3′ → 5′ direction across the identical five-base, AT-rich site 5′-AATTA.

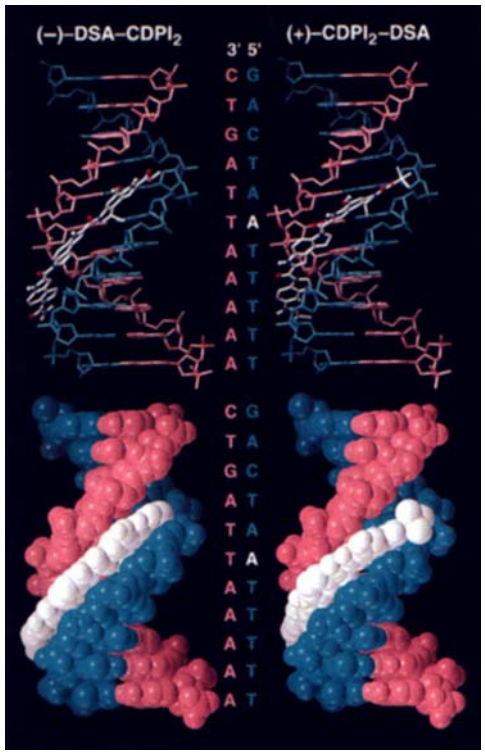

Fig. 24. Stick and space-filling models of the alkylation at a high-affinity site in w794 DNA (5′-GACTAATTTTT-3′) by (−)-**31** (left) and (+)-**32** (right). The unnatural enantiomer binds in the 5′ → 3′ direction across the five-base, AT-rich site 5′-AATTT. The natural enantiomer of the reversed agent binds in the same 5′ → 3′ direction across the identical five-base, AT-rich site 5′-AATTT.

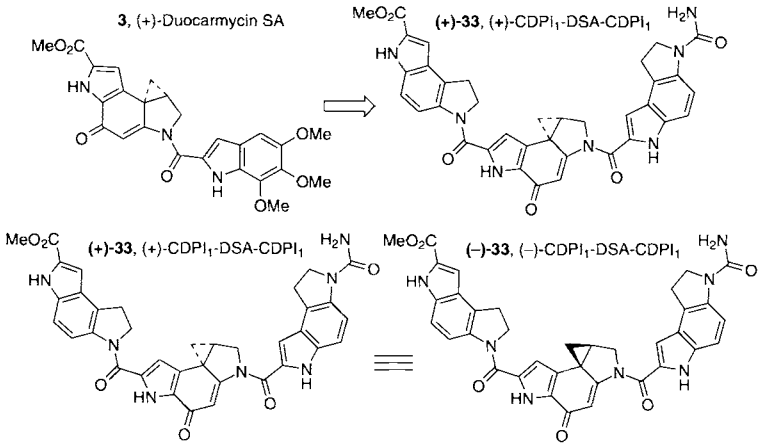

Fig. 25. Sandwich analogs of duocarmycin SA.

6. Structural Characterization of Oligo-Agent Complexes

Spectroscopic studies of complexes of the agents within defined sites of deoxyoligonucleotides have established the accuracy of the models and have begun to reveal subtle elements present in the structures. Most prominent is the confirmation of the binding orientation within the minor groove of the natural and unnatural enantiomers relative to the alkylated strand and the offset nature (relative to the alkylation site) of the binding site occupied by the agent.

A detailed NMR study of the complex formed between the duplex d(GACTAATTGAC)·d(GTCAATTAGTC), which contains the sequence of the high-affinity

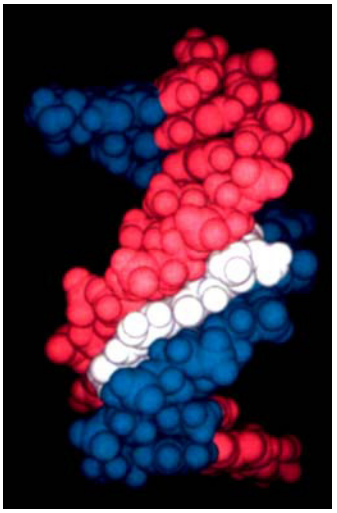

Fig. 26. Space-filling model of the covalent complex between (+)-duocarmycin SA and d(GACTAATTGAC)·d(GTCAATTAGTC) produced by molecular dynamics simulations restrained by NMR-derived distance constraints [110].

alkylation site found in w794 DNA, and (+)-duocarmycin SA has been conducted.[110] The studies, which have provided a high-resolution solution structure of the covalent complex, confirm the accuracy of the original models by disclosing the adenine-N3 alkylation and 3′ → 5′ binding in the minor groove across the 5′-ATTA site (Fig. 26).

A complex of (+)-CC-1065 with d(CGATTAGC)·d(GCTAATCG) has been studied by NMR.[111] The agent is covalently attached to the N3 atom of the A6 residue and binds in the 3′ → 5′ direction across five base pairs in the minor groove. A complex of (+)-CC-1065 with d(GGCGGAGTTAGG)·d(CCTAACTCCGCC) has also been characterized.[69, 112] In these studies, the alkylated adenine was shown to exist in the protonated form in which the two hydrogens were located on the exocyclic C6-amino group.[112] Since no phosphate in the backbone lies close enough to have protonated the C4 carbonyl, it was suggested that an intervening water molecule mediates this protonation by bridging the phenolic proton of CPI and the phosphate between A16 and A17. A very small ^{17}O (H_2O^{17}) isotope effect on line broadening of this phenolic proton NMR signal was observed and used to support this proposal[69] and the suggestion that this interaction may provide a molecular basis for the DNA alkylation sequence selectivity of (+)-CC-1065 and its analogs. However, it was later shown that the results of the ^{17}O experiments cannot be simply attributed to a purported tightly bound water molecule as earlier proposed.[47] Following adduct formation, the 12-mer duplex becomes bent (17–22°) about a locus lying between T8 and T9, which leads to a narrowing of the minor groove in this region.

A complex of (+)-CPI-$CDPI_2$ with $d(CGCTTAAGCG)_2$ has also been studied.[113] The NMR data support formation of a major adduct at A7 in which the agent binding is oriented toward the 5′ end of the alkylated strand.

A site-specific covalent adduct of duocarmycin A with an intramolecular DNA triple helix has been examined.[114] In this complex, duocarmycin A was found to bind and alkylate in the minor groove at a single adenine in the sequence 5′-AAAA-3′ in a manner analogous to duplex DNA alkylation. The bound duocarmycin A in the minor groove does not expel the third pyrimidine strand from the major groove of the triplex at low temperature and acidic pH. However, it did lower the pK_a for protonation of the third strand cytidines in the major groove by 1.8 pH units.

7. Modified Alkylation Subunits

As distinctions in the importance of the alkylation subunits of **1**–**3** and their contribution to the DNA alkylation profile surfaced, studies of modified alkylation subunits were initiated to address the problem directly. Agents containing deep-seated modifications in the alkylation subunit not accessible by simple derivatization could be anticipated to define the structural features contributing to functional reactivity and regioselectivity, to define the extent and contributing structural features effecting DNA alkylation selectivity or efficiency, and to delineate key fundamental relationships between structure, functional reactivity, and biological properties.

7.1. CI: Minimum Potent Pharmacophore of the Alkylation Subunits and Common Pharmacophore in the Natural Products

One of the first class of agents examined incorporated the parent alkylation subunit 1,2,7,7a- tetrahydrocyclopropa-[*c*]indol-4-one (CI, Fig. 27). Consistent with expectations, the CI-based agents proved to be exceptionally reactive electrophiles. In spite of this large change in the structure and relative reactivity of the alkylation subunit, the DNA alkylation selectivities of the agents **27** and **34** were remarkably similar to the natural products **1** and **2**/**3**, respectively, and their examina-

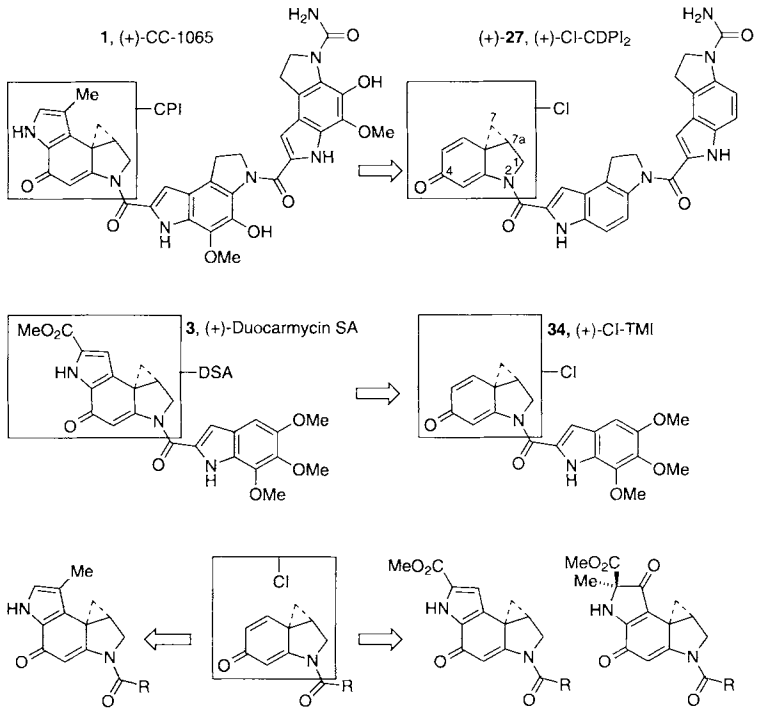

Fig. 27. CI: the minimum potent pharmacophore of the alkylation units of CC-1065 (top, including the atomic numbering for CI) and duocarmycin (center) and thus the common pharmacophore of CC-1065 and the duocarmycins (bottom).

tion provided more insight into the relative importance and role of the alkylation subunit than anticipated.[55, 56, 72, 115, 116] At the time the studies were conducted, the purported importance of the alkylation subunit was so heavily emphasized that the simple removal of the CPI C7 methyl group, much less the entire pyrrole segment, was arguably considered detrimental to the DNA alkylation selectivity.

The CI alkylation subunit was shown to constitute the minimum potent pharmacophore of the natural products' alkylation subunits and the common pharmacophore of CC-1065 and the duocarmycins. The exceptionally reactive CI-based agents alkylated the same sites as the corresponding CPI- or duocarmycin-based agents, but did so with lower efficiency and less selectivity among the available sites. Importantly, no new adenine-N3 alkylation sites were detected despite a 1000 × increase in reactivity. This observation provided the initial indication that the nature of the alkylation reaction was not as critical to DNA alkylation selectivity as suggested by others.[46] Consistent with their instability the CI agents alkylated DNA less efficiently and exhibited a pronounced decrease in cytotoxic potency.

7.2. CBI: A Simplified and Improved Alkylation Subunit

Similarly, the examination of the class of agents containing the 1,2,9,9a-tetrahydrocyclopropa[*c*]benz[*e*]indol-4-one (CBI) alkylation subunit, in which the deep-seated change is the replacement of the fused pyrrole with a fused benzene ring (Fig. 28), proved important and timely.[115–125] The anticipated release of strain that accompanies the ring expansion of the fused aromatic ring led to decreased reactivity and increased stability relative to the CPI alkylation subunit (4 ×) and increased cytotoxic potency (4 ×) without affecting the DNA alkylation selectivity. The CBI-based agents alkylated the same sites as the corresponding CPI or DSA-based agents and with an efficiency and relative selectivity consistent with their reactivity. They were more efficient and more selective among the available alkylation sites than the corresponding CPI-based or DA-based agents and comparable to the DSA-based agents. Despite their diminished reactivity, the CBI-based agents alkylated DNA at a faster rate than the corresponding CPI-based agent[119, 120] and at a rate comparable to that observed with the corresponding DSA-based agent.[73] This has suggested that the degree of steric bulk surrounding the C7 center of CPI or DSA may affect both the rate and relative efficiency of DNA alkylation and that the CPI C7 methyl group, once projected as important, may actually diminish the inherent properties of the CPI-based agents.

An examination of the CBI- and CI-based agents led to the proposal that a direct relationship exists between cytotoxic potency and functional stability. At the time these observations were made, the prevailing expectation was that the reverse relationship between functional reactivity (not stability) and cytotoxic potency was important[46, 159] and that even modest changes in the alkylation subunits would adversely, not productively, influence the DNA alkylation and biological properties of the agents. Consequently, the results from the CBI-based agents led to a shift in the paradigms of the field. Most importantly, it also revealed that in vivo antitumor efficacy[121, 166] may be observed in agents containing deep-seated and simplifying structural changes in the alkylation subunit and that the potency of the naturally derived materials may be enhanced by simply enhancing chemical stability. Although the sites of DNA alkylation are not altered, the rate and efficiency are increased, and the inherent selectivity among the available sites may be increased by increasing the functional stability of the agent.

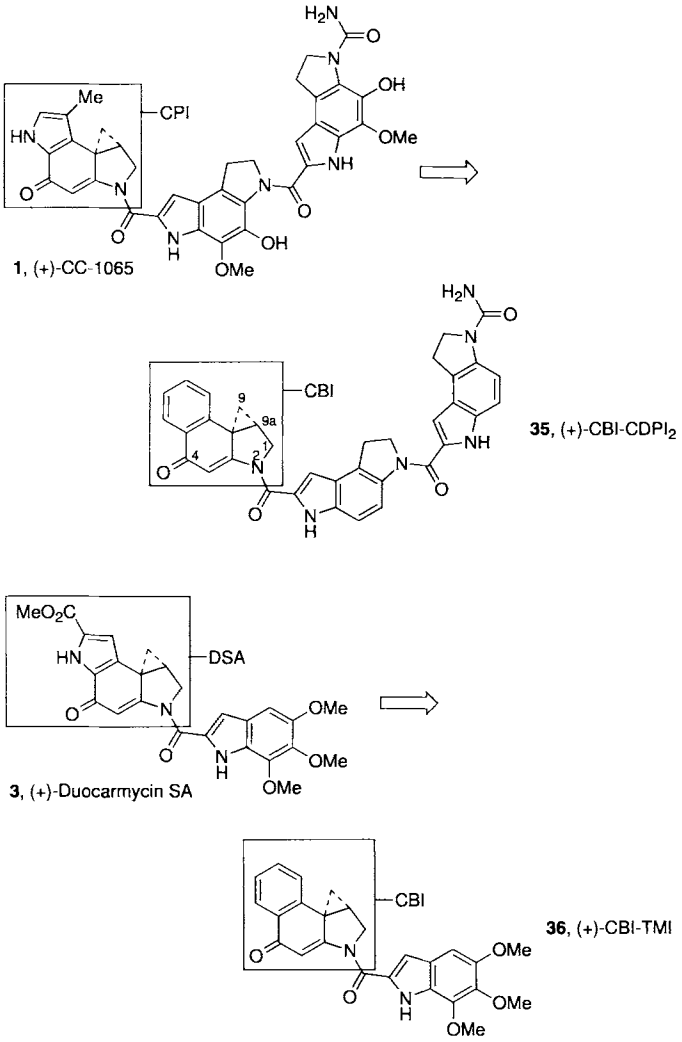

Fig. 28. CBI analogs of CC-1065 (top) and duocarmycin SA (bottom). The atomic numbering for CBI is shown in **35**.

7.3. MCBI and CCBI: Electronic Effects on Functional Reactivity

In the continued examination of the structural features that affect reactivity, the substituted CBI derivatives, MCBI (**37**)[126] and CCBI (**38**),[127] in which a C7 methoxy or cyano substituent has been placed *para* to the C4 carbonyl, have been recently prepared (Fig. 29). Their preliminary and ongoing examination has revealed an important and surprisingly small impact of the C7 substituent on the functional reactivity of the agents. This is discussed in detail in Section 8.

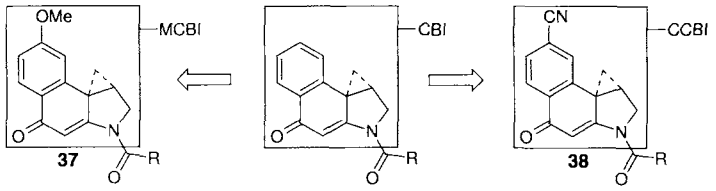

Fig. 29. MCBI and CCBI: structural elements used in the study of the electronic effects on the functional reactivity.

7.4. CBQ: An Exceptionally Reactive Alkylation Subunit

The ring expanded 2,3,10,10a-tetrahydrocyclopropa[*d*]-benzo[*f*]quinol-5-one (CBQ) alkylation subunit was prepared and incorporated into analogs of the natural products (Fig. 30).[128–130] Their examination revealed a surprising but

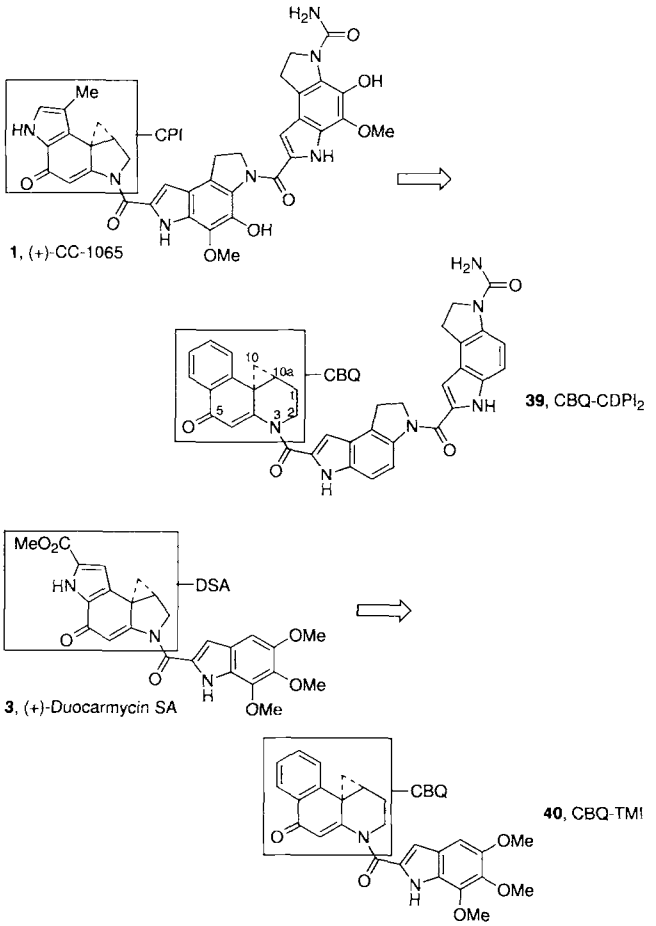

Fig. 30. CBQ-CDPI$_2$ (**39**) and CBQ-TMI (**40**): an alkylation unit showing exceptional reactivity.

normal level of functional reactivity and a number of subtle structural features that impact this reactivity,[128, 129] reaction regioselectivity,[129] and mechanism of acid catalyzed solvolysis and nucleophilic addition,[129] as well as subtle factors contributing to the adenine-N3 alkylation regioselectivity.[130] These are discussed in detail in Section 8.

7.5. C_2BI-CDPI$_2$ and C_2BI-TMI: Exquisitely Designed Adenine–Adenine Cross-Linking Agents

The core structure of C_2BI-CDPI$_2$ and C_2BI-TMI and their achiral precursors **41** and **42** (Fig. 31) was taken from the CBI-based agents, which are exceptionally stable and synthetically more accessible than the core structures of the natural alkylation subunits.[131, 132] In addition, the acyclic agents **41** and **42** lacking the preformed cyclopropane ring could be expected to

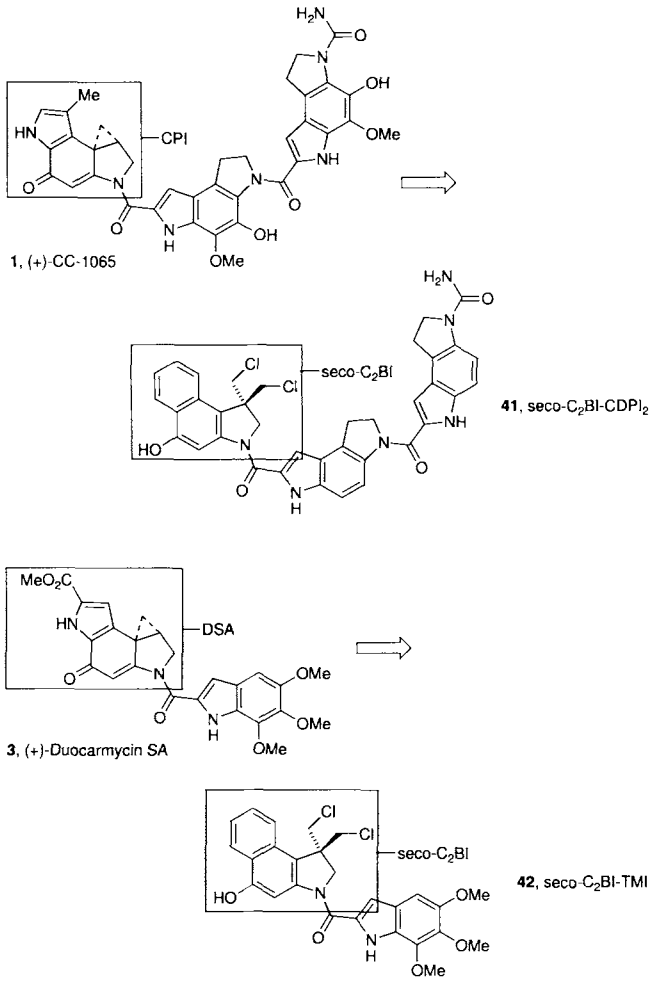

Fig. 31. Achiral precursors of C_2BI-CDPI$_2$ (**41**) and C_2BI-TMI (**42**): DNA cross-linking agents.

display properties identical to C_2BI-CDPI$_2$ and C_2BI-TMI, but are achiral. This simple feature of **41** and **42** not only provided attractive synthetic candidates that did not require resolution or asymmetric synthesis, but also a single agent for biological evaluation free of the necessity of documenting the behavior of both enantiomers.

In addition, the bis-alkylating capabilities of **41** and **42** provided the opportunity to cross-link DNA in which their two alkylating groups act independently as the individual enantiomers. When this occurs within a sequence such as d(AT-TA)·d(TAAT), the adenine-N3 alkylation by the natural enantiomer component of **42** occurs at its high-affinity site of 5′-ATTA-3′ with agent binding in the 3′ → 5′ direction relative to

the strand it alkylates, across a 3.5 base, AT-rich site. The alkylation by the unnatural enantiomer component of **42** is directed to the complementary strand, leading to cross-linking with adenine-N3 alkylation at its high-affinity site of 3′-TAAT-5′ with agent binding in the reversed 5′ → 3′ direction relative to the strand it alkylates, across a 3.5 base AT-rich site (Fig. 32).

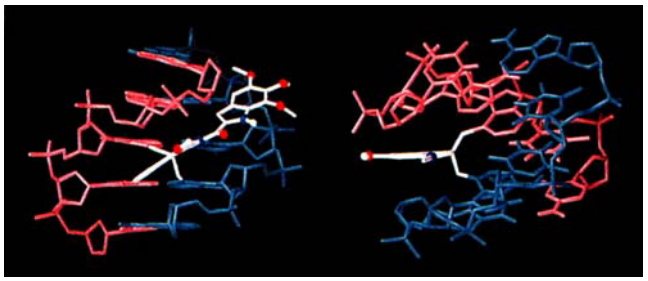

Fig. 32. View from the front and from the groove of the product of the cross-linking reaction of C_2BI-TMI in the w794 DNA high-affinity site (5′-(ATTAG)·5′-(CTAAT)). For details, see text.

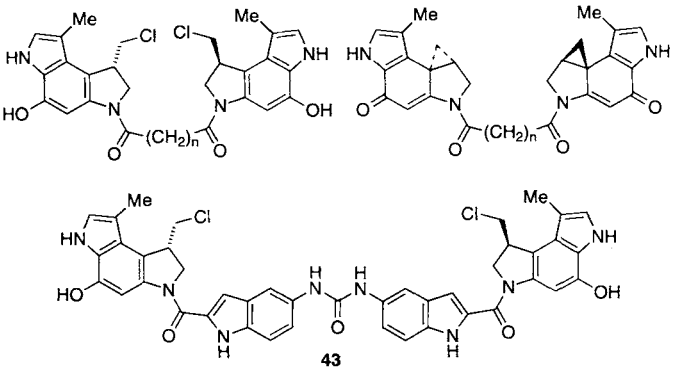
Consistent with the fact that the reversed binding orientation and the offset AT-rich binding sites relative to the alkylated adenine of both enantiomers coincide in a single binding and cross-linking site, **41** and **42** were found to be efficient cross-linking agents.[131, 132] Figure 32 gives an alternative depiction of DNA alkylations by the natural and unnatural enantiomers, where complementary strand reactions occur from one binding orientation.

Additional cross-linking agents have been disclosed, including **43**, which is based on the CC-1065 structure and constructed by linking two CPI units together (Fig. 33).[133–142]



43

Fig. 33. Structures of additional DNA cross-linking agents.

7.6. Other Modifications in the DNA Alkylation Subunits

A number of agents incorporating additional modifications in the DNA alkylation subunits are shown in Figure 34. These include agents with alteration of the duocarmycin A and B_2 alkylation subunits,[143] furan analogs of CC-1065[144] and duocarmycin SA,[143] substituted CI analogs,[145] a simplified cyclopropyl derivative,[146] a gramine analog related to the CPI unit,[147] the 9,9-difluoro-CBI derivative,[148] and an isomeric cyclopropacyclohexadienone that combines the features of both CC-1065 and the mitomycins.[149]

8. Fundamental Relationships Between Structure, Functional Reactivity, and Biological Properties

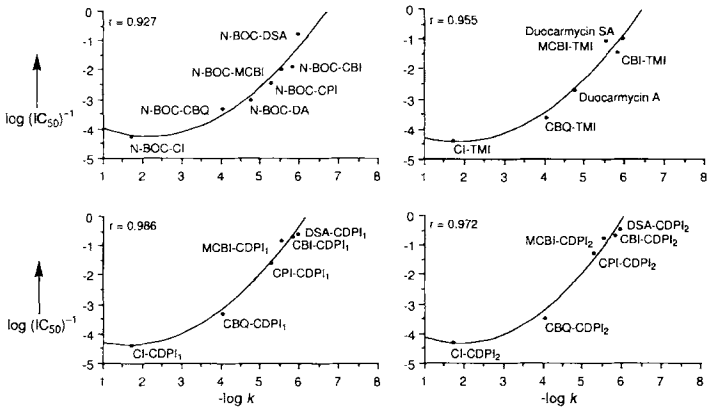
In addition to the total synthesis of the natural products (CC-1065 (**1**),[77, 150–152] duocarmycin A (**2**),[153, 154] and duocarmycin SA (**3**),[155–157]) and the extensive number of investigations directed at the authentic subunits of the natural products[41, 50] and their analogs,[158–162] studies that have provided agents containing deep-seated structural modifications have proven valuable in defining the relationships between structure, functional reactivity, and biological properties.[34–38]

8.1. Definition of a Fundamental Relationship Between Functional Reactivity and Biological Activity

The proposed acid catalyzed activation of the DNA alkylation reaction led to the expectation that a direct relationship may exist between the reactivity and cytotoxic activity of the

agents and to the proposal that the biological potency may be enhanced as the electrophilic reactivity is increased.[159] However, studies conducted with the agents **44**–**51** revealed the reverse relationship and that the most stable agents may be expected to exhibit the most potent cytotoxic activity (Fig. 35). Moreover, a well-defined, direct relationship between stability toward solvolysis and biological potency (IC_{50}, L1210) has been observed and proved to be general with both simple and full analogs of the natural products.[118–121, 126, 129, 163, 166]

	k [s^{-1}]	$t_{1/2}$ [h] (pH 3)	IC_{50} [nM]
N-BOC-DSA	1.08×10^{-6}	177	6
N-BOC-CBI	1.45×10^{-6}	133	80
N-BOC-MCBI	1.75×10^{-6}	110	100
N-BOC-CPI	5.26×10^{-6}	37	330
N-BOC-DA	1.75×10^{-5}	11	1000
N-BOC-CBQ	9.07×10^{-5}	2.1	2000
N-BOC-Cl	1.98×10^{-2}	0.01	18000



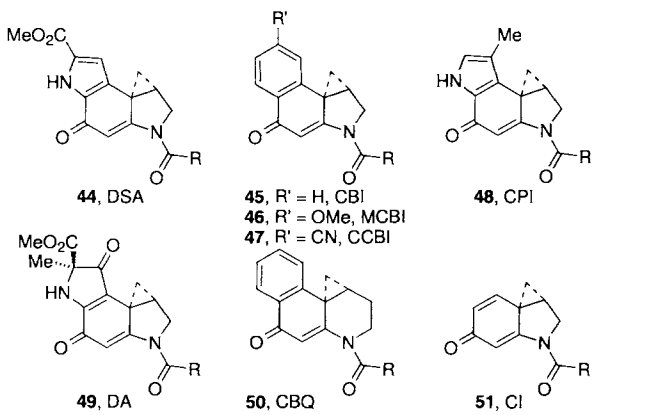


Fig. 35. Direct correlation between chemical or functional stability and cytotoxic potency of analogs of the natural products. R represents BOC, TMI, CDPI, or $CDPI_2$ shown in the graphs. N-BOC-**44** is identical to **12**. The unit for IC_{50} in the top right plot is nM; in all the other plots it is pM.

8.2. Establishment and Verification of a Fundamental Relationship between Functional Reactivity and Biological Activity

Examination of the properties of **52**–**55**,[163] simple derivatives of CBI, led to the validation of this direct relationship between solvolysis stability and cytotoxic potency (Fig. 36). Their examination revealed a direct, linear relationship between

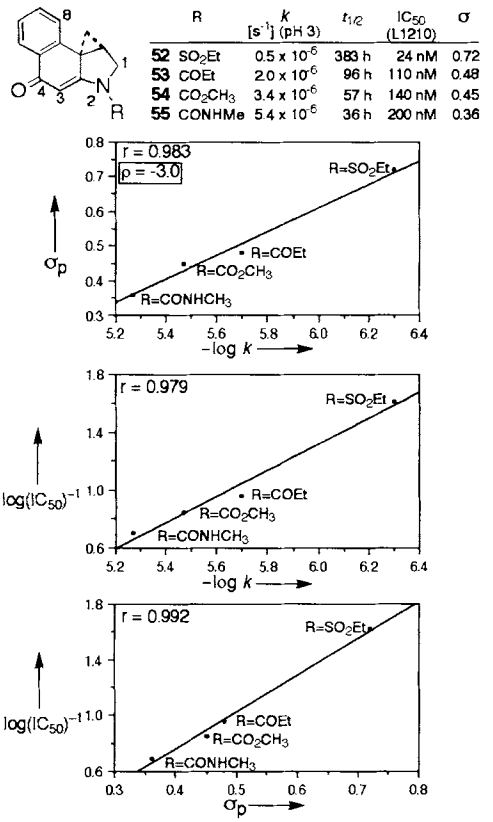

Fig. 36. Effect of the N2 substituent on the cytotoxic activity and the rate of solvolysis.

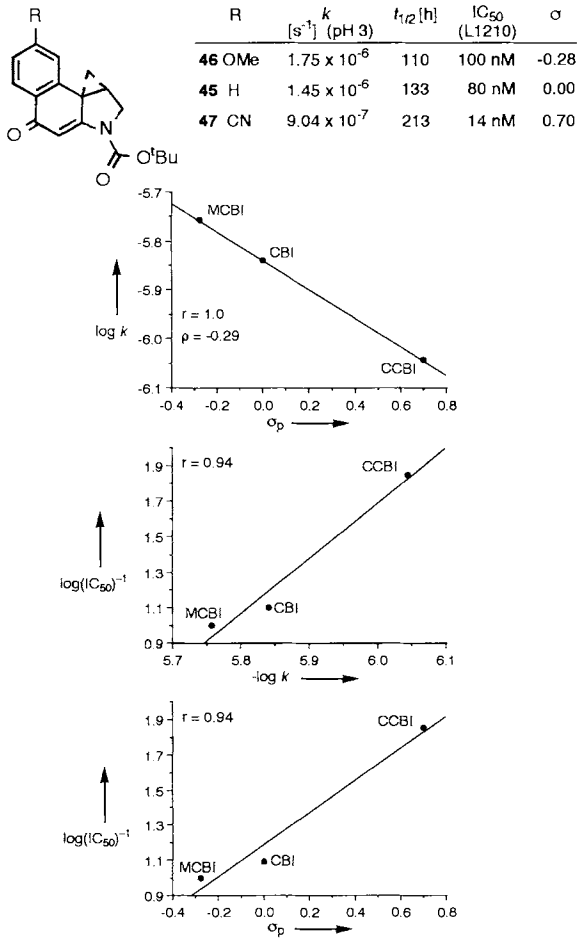
the cytotoxic potency (L1210, $\log 1/IC_{50}$) and the solvolytic stability ($-\log k$, pH 3) within the reactivity range examined. Similarly, a linear relationship was found between the electron-withdrawing properties of the N2 substituents (Hammet σ_p constant) and the solvolysis reactivity ($-\log k$, pH 3) in which the strongest electron-withdrawing substituents provide the most stable agents. This latter relationship reflects the influence of the N2 substituent on the ease of C4 carbonyl protonation required for catalysis of solvolysis, and those with the stronger electron-withdrawing substituents exhibit the slower solvolysis rates. Moreover, the slope of the plot of σ_p versus $\log k$ revealed a remarkably large ρ value of -3.0. This large negative ρ value is indicative of the strong vinylogous amide conjugation and suggests that the reactivity may be greatly influenced by the nature of the N2 substituent and its interaction with the cyclopropylcyclohexadienone. Less obvious but more fundamental, the observations follow a predictable linear relationship between the cytotoxic potency (L1210, $\log 1/IC_{50}$) and the electron-withdrawing properties of the N^2 substituent (σ_p). The agents with the strongest electron-withdrawing substituents proved to be the most potent agents (Fig. 36).

These fundamental correlations between the functional reactivity of the agents and their biological potency should prove useful in designing new analogs. For agents that possess sufficient reactivity to alkylate duplex DNA, the chemically more stable agents are predicted to be the biologically more potent agents. Presumably this may be attributed to the more effective delivery of the more stable agents to their intracellular target.

8.3. Substituted CBI substrates: Magnitude of Electronic Effects on Functional Reactivity and the Verification of the Fundamental Relationship between Functional Reactivity and Biological Activity

In efforts to address the structural features of **1**–**3** that contribute to their functional reactivity, the substituted CBI agents **46** and **47** (see Fig. 35) and a full set of analogs of the natural products that incorporate these modified alkylation subunits have been prepared.[126, 127] Against expectations, the nature of the C7 substituent, which is *para* to the C4 carbonyl, had only a very modest effect on the functional reactivity of the agents. On using acid catalyzed solvolysis as a measure of their relative reactivity, **46** was found to be only 1.2 to 1.05 times more reactive than the parent **45**, and **47** less than twice as stable at pH = 3 or 2 (Fig. 37). These studies provided a clear validation of the direct relationship between functional stability and cytotoxic potency and revealed a predictable direct relationship between the electronic properties of the C7 substituent (σ_p constant) and the functional reactivity ($-\log k$, pH 3), a direct relationship between the cytotoxic potency (L1210, $\log 1/IC_{50}$) and functional stability ($-\log k$, pH 3), and a fundamental, direct relationship between cytotoxic potency (L1210, $\log 1/IC_{50}$) and the electronic properties of the C7 substituent (σ_p constant); again the strongest electron-withdrawing substituent provided the most potent agent (Fig. 37). Importantly, the very modest effect of the C7 substituent on the functional reactivity was reflected in the determination of the exceptionally small ρ value of -0.3.



R	k [s^{-1}] (pH 3)	$t_{1/2}$ [h]	IC_{50} (L1210)	σ
46 OMe	1.75×10^{-6}	110	100 nM	-0.28
45 H	1.45×10^{-6}	133	80 nM	0.00
47 CN	9.04×10^{-7}	213	14 nM	0.70

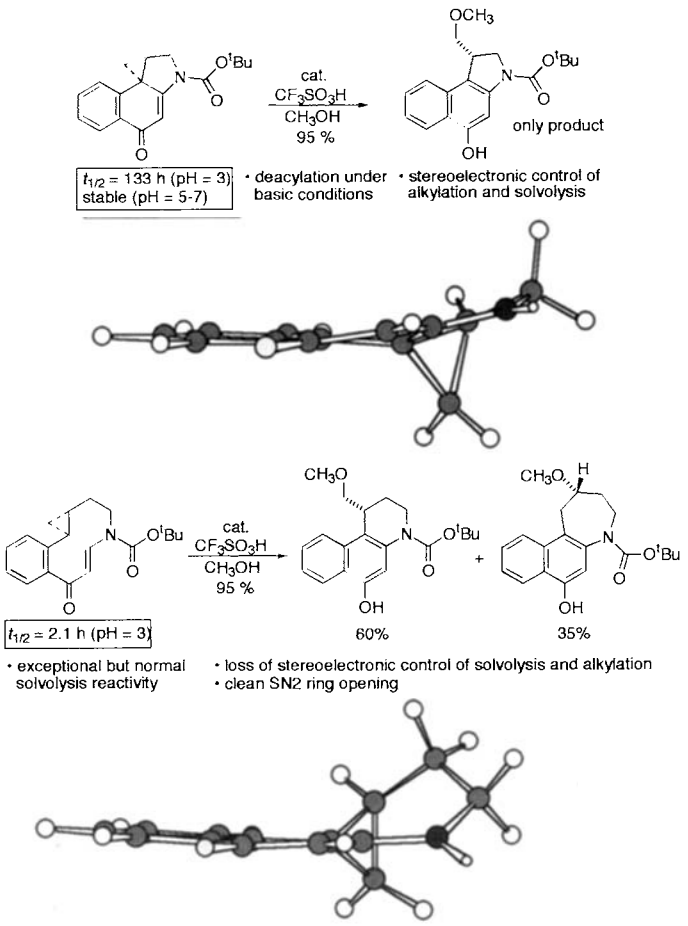
Fig. 37. Electronic effects of the substituted CBI analogs **45**–**47**.

This surprisingly modest effect of the *para* C7 substituent suggests that protonation of the C4 carbonyl may not be the rate-limiting step of solvolysis or acid catalyzed nucleophilic addition and that little charge buildup at the substitution site occurs in the transition state ($\rho = -0.3$). Further study with these agents (Section 8.6) also supports the proposal that the cyclopropane ring opening requires the presence and assistance of a nucleophile (S_N2 mechanism). No doubt this contributes to the DNA alkylation selectivity and is consistent with the expectation that the positioning of the nucleophile (adenine-N3) and not C4–O protonation is the rate-determining event. This remarkably small electronic effect on the solvolysis rate had no impact on the solvolysis regioselectivity, and stereoelectronically controlled nucleophilic addition to the least substituted cyclopropane carbon was observed exclusively.

8.4. Stereoelectronic Control

Two characteristics of the alkylation subunits **44**–**51** have proven important in the studies to date. The first is the stereoelectronically controlled, acid catalyzed opening of the cyclopropane, which dictates addition of a nucleophile to the least substituted carbon. The second is the rate of acid catalyzed solvolysis and the demonstration of a direct relationship between solvolysis stability and cytotoxic potency. A recent comparison of the chemical and structural properties of N-BOC-**50** and N-BOC-**45** confirmed the stereoelectronic control of the solvolysis or alkylation reactions of **44**–**51** and revealed an unappreciated but fundamentally important stability for the duocarmycin and CC-1065 alkylation subunits and its structural origin.[128, 129] The solvolysis reactivity of **50** along with that of **44**–**51** are summarized in Figure 35. In addition to the increased reactivity of **50** (63 ×) relative to that of N-BOC-**45**, the solvolysis of **50** occurs with nucleophilic addition to both C10 and C10a, while that of **45** occurs exclusively at the least substituted cyclopropane carbon atom (Scheme 3).[129]

The X-ray structure of N-BOC-**50**[128, 129] provided the structural insights into this difference in solvolysis reactivity and regioselectivity (Scheme 3). It is clear from the X-ray structure of CBI[118, 128] that the bent orbital of the cyclopropane bond extending to the least substituted carbon is nearly perpendicular to the plane of the cyclohexadienone and consequently overlaps nicely with the developing π system of the solvolysis product phenol (Fig. 38), whereas the cyclopropane bond extending to the tertiary carbon is nearly in the plane of the cyclohexadienone, and its orbital is nearly orthogonal to the π system of the product phenol. Thus, opening of the cyclopropane occurs with addition of a nucleophile to the least substituted carbon, and the stereoelectronic control responsible for this addition selectivity overrides the intrinsic electronic preference for ring-expansion ring opening. In contrast, N-BOC-CBQ exhibits different characteristics. The cyclopropane is ideally conjugated with the cyclohexadienone π system, the plane defined by the



Scheme 3. Comparison of the solvolysis reactivity and X-ray structures of N-BOC-**45** (top) and N-BOC-**50** (bottom).

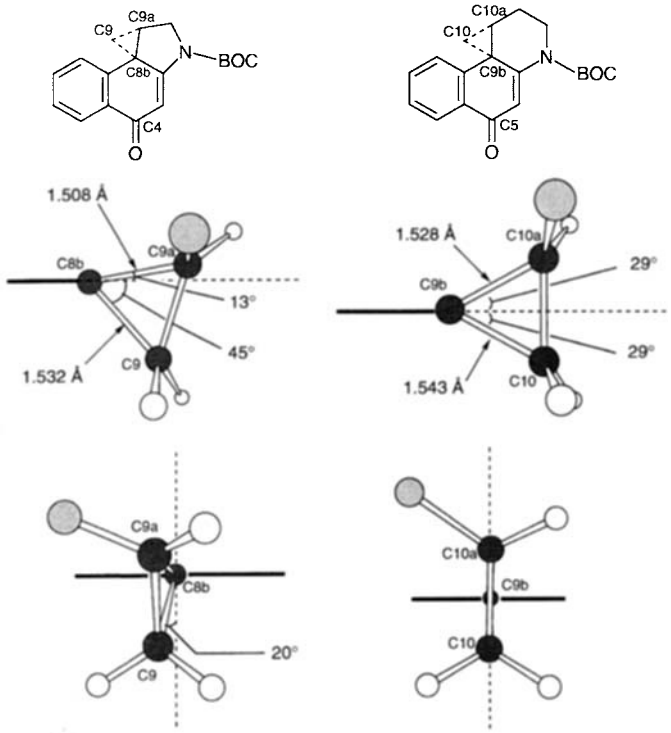


Fig. 38. Side and rear views of the activated cyclopropane rings of **45** and N-BOC-**50**, illustrating data taken from the X-ray crystal structures and highlighting the idealized overlap and alignment of the cyclopropane ring of N-BOC-**50** with the cyclohexadienone π-system.

cyclohexadienone ideally bisects the cyclopropane, and the bonds extending to the secondary and tertiary cyclopropane carbon atoms are equally aligned with the π system. Thus, the two available cyclopropane bonds are equally aligned for cleavage, and addition to both occurs.[129] The subtle differences in the relative amounts of the ring-expanded solvolysis product may be attributed to destabilizing torsional strain that accompanies nucleophilic attack at the more substituted center.

In contrast to the CBI-based agents, which react regiospecifically to provide exclusively one acid catalyzed addition product under a wide variety of reaction conditions, both N-acyl-CPI and N-acyl-DA agents (including duocarmycin A) have been shown to provide variable amounts of the abnormal ring expansion solvolysis products depending on the reaction conditions. To date, this has not been investigated in detail, and the structural origin of the minor ring expansion reaction with CPI or DA has not been established. It may be related to their increased reactivity or different degrees of stereoelectronic alignment derived from subtly altered cyclopropane conjugation. The delineation of the structural origin of these distinctions may, no doubt, be derived from comparative crystallographic studies of the respective alkylation subunits, and such detailed studies are in progress.

8.5. Structural Origin of an Unappreciated but Productive Stability of the Natural Alkylation Subunits: Extent of Cyclopropane Conjugation and Activation

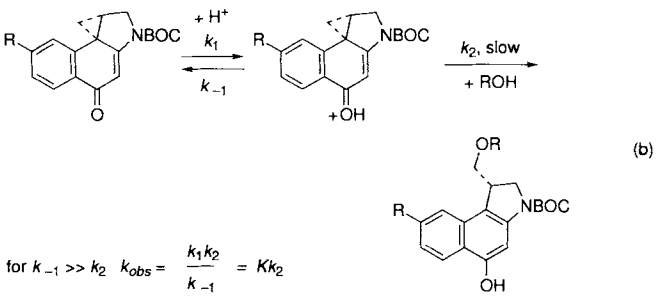
The rapid solvolysis of N-BOC-CBQ was initially surprising; however, important insights into this enhanced reactivity are clear from the X-ray structures. Although they reside in a cyclopropane fused to a six- rather than a five-membered ring, the lengths of the CBQ C9b–C10a (1.528 Å) and C9b–C10 (1.543 Å) bonds are greater than those found in CBI (1.508 and 1.532 Å, respectively) and nicely reflect the enhanced cleavage reactivity[128] (Fig. 38). This lengthening of the cyclopropane bonds may be attributed to the idealized conjugation or π delocalization of both the C9b–C10a and C9b–C10 cyclopropane bonds with the cyclohexadienone π-system. Contributing to this enhanced conjugation is the ideal geometrical alignment of C10 and C10a with C9b, C5, and the carbonyl oxygen atom. For CBI, the constraints of the fused five-membered ring place its C9 and C9a at a 20° angle off this plane and prevent ideal alignment and overlap of either the C8b–C9a or C8b–C9 bond with the cyclohexadienone π system. This idealized cyclopropane conjugation with the cyclohexadienone π system in N-BOC-**50** results in the observed longer and weaker bonds and higher solvolysis reactivity.

Thus, the geometrical constraints of the fused five-membered ring found in the CC-1065 or duocarmycin alkylation subunits impose stereoelectronic control on the nucleophilic cleavage of the cyclopropane dictating addition to the least substituted carbon atom. In addition, the nonideal alignment and overlap of the cyclopropane with the cyclohexadienone π system found in the naturally occurring alkylation subunits result in diminished electrophilic reactivity. The fundamental insight derived from these comparisons is not the solvolysis reactivity of N-BOC-**50**, but rather the surprising stability of the CBI, DSA, and CPI

alkylation subunits. In spite of structural features that intuitively suggest high reactivity, the latter agents are uncharacteristically stable. This unusual stability is imposed by fusion of the cyclopropane to the five-membered ring, which constrains it to a nonideal alignment and overlap with the cyclohexadienone π system.

8.6. Mechanism of Acid Catalyzed Solvolysis and Nucleophilic Addition

Studies with N-BOC-CBQ (**50**) also resulted in an unambiguous determination of the mechanistic course of the acid catalyzed solvolysis reaction. Both the racemate and the pure (+) isomer of **50** were subjected to acid catalyzed methanolysis (0.1 equiv CF_3SO_3H, CH_3OH, 25 °C, 1 h, 95%). The abnormal, ring-expanded solvolysis product derived from optically active **50** was formed with exclusive inversion of the configuration at the reacting center, which indicates an S_N2 ring-opening reaction.[129] The demonstration was unambiguous and contrasts the conclusions of Warpehoski and Harper[107] in which a free carbocation and an S_N1 mechanism has been invoked to account for the minor CPI ring expansion solvolysis products. These and related studies[127] with the CBI-based agents have also shown that the acid catalzyed nucleophilic addition displays a first-order dependence on both the acid and nucleophile concentration. Together, these studies illustrate that the slow step is not C4 carbonyl protonation, but rather nucleophilic addition to the activated cyclopropane following rapid and reversible protonation of the C4 carbonyl oxygen atom [Eq. (b)].



These studies have significant implications on the rate-determining step of the DNA alkylation reaction and, thus, the origin of the DNA alkylation sequence selectivity. Even though both of the CBQ cyclopropane bonds are equally aligned for cleavage, the acid catalyzed cyclopropane ring-opening reaction still occurs with a slight preference for normal rather than ring-expansion solvolysis. This latter pathway would be strongly preferred if substantial positive charge were to develop at the reacting cyclopropane carbon atom (secondary rather than primary carbocation character). The fact that it is not preferred and that reaction at the more substituted center occurs with full inversion of configuration by a strict S_N2 reaction mechanism further supports the prior kinetic evidence that the slow step of the reaction is not carbonyl protonation but rather the attack (or positioning) of the nucleophile, which preferentially occurs at the least hindered cyclopropane carbon.

8.7. Additional Subtle Features Contributing to the DNA Alkylation Regioselectivity

The examination of the DNA alkylation properties of CBQ-TMI (**40**) and related agents showed that they alkylated the same sites as the corresponding enantiomers of the agents incorporating the DSA, DA, CPI, CBI, or CI alkylation subunits.[130] Consistent with their reactivity, they exhibited less selectivity among the available sites and alkylated DNA with a lower efficiency. Importantly, only adducts derived from adenine-N3 addition to the least substituted cyclopropane carbon atom were detected under the relevant conditions of limiting agent concentrations. The adenine-N3 adduct obtained by thermal depurination was isolated, characterized, and shown to be derived only from addition to the least substituted cyclopropane carbon atom of CBQ-TMI (**40**). Since the CBQ-based agents exhibit nonselective solvolysis regioselectivity with cleavage of both the usual external and unusual internal cyclopropane bonds, the observations suggest that the clean regiochemical course of the characteristic adenine-N3 alkylation may benefit not only from stereoelectronic effects, but from additional features that complement the normal addition as well. These include the preferential adoption of binding orientations that favor the normal adenine-N3 addition (proximity effects), destabilizing torsional strain and steric interactions that accompany the abnormal adenine-N3 addition (Fig. 39), and a potential binding-induced conformational change in CBQ that imposes the stereoelectronic preference for adenine-N3 addition to the least substituted cyclopropane carbon (Fig. 40). Of these, the destabilizing torsional and steric interactions that accompany the abnormal adenine-N3 addition might be most significant and contribute similarly to the regioselectivity of the DNA alkylation reactions of **1**–**3** and related agents.[130]

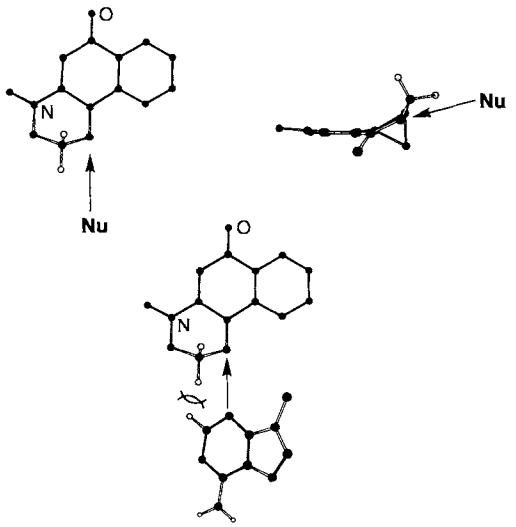


Fig. 39. Top and side views of the atypical nucleophilic addition to the most substituted cyclopropane carbon of CBQ. Top: Illustration of the eclipsing interaction between a nucleophile Nu and the C1-H^a, and the torsional strain that results from it. Bottom: The relative orientation of the reactants in the adenine-N3 addition taken from a model of a noncovalent complex of DNA and CBQ-TMI[130] when constrained in the minor groove. The diagram highlights the additional destabilizing steric interaction between Ad-C2-H and C1-H^a. The other hydrogen atoms and the trimethoxyindole subunit have been removed for clarity. In some formulas the cyclopropane ring is obscured.

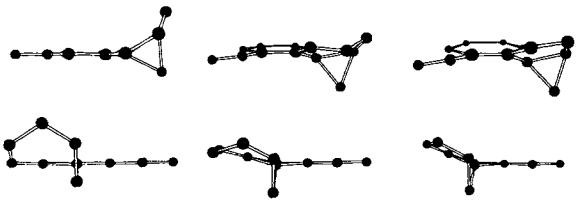

Fig. 40. Side and rear views of the CBQ boat (left, X-ray structure analysis [128,129]), CBQ half chair (middle), and CBI (right, X-ray structure analysis [118]) conformations, illustrating the relative orientations of the cyclopropane ring. Like in the case of CBI, the higher energy half-chair conformation of CBQ ($\Delta E = 1.0-1.5$ kcal mol^{-1}) would impose stereoelectronic control of the addition to the least substituted cyclopropane carbon atom. (Hydrogen atoms have been removed for clarity.)

8.8. Experimental Verification of Vinylogous Amide Stabilization: A Stable, Isolable *para*-Quinomethide

Because of the significant contribution of the vinylogous amide stabilization of the structures **44**–**51**, the *para*-quinomethide **56** and its stable precursors were prepared and examined (Fig. 41).[164] Unlike *para*-naphthoquinomethides, which are

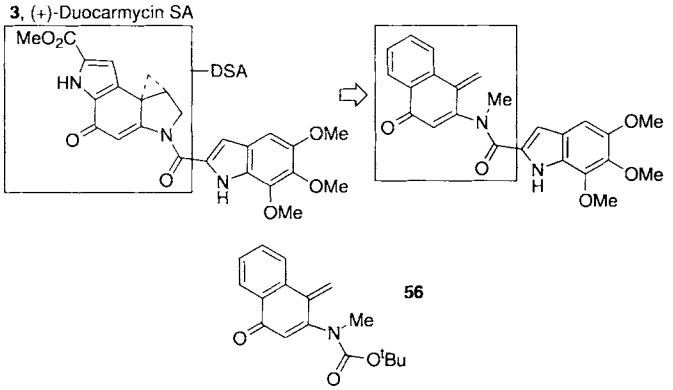

Fig. 41. *para*-Quinomethide (**56**) rendered isolable by vinylogous amide stabilization. For further information on **56**, see text.

not sufficiently stable for isolation, characterization, or detection and are inferred reaction intermediates, the *para*-quinomethide **56** was isolated (with SiO_2 chromatography!) and characterized. Although **56** is still exceptionally reactive and substantially more reactive than **44**–**51**, the unusual stability that permits its isolation may be attributed to this key vinylogous amide stabilization, which is lost upon aromatization.

8.9. Additional Key Features

A number of additional unique structural features of **44**–**51** also contribute to their stability. The stability ordering **44**–**48** > **49** > **51** can be attributed to the diminished gain in delocalization energy that accompanies aromatization in a system that bears a fused aromatic ring.[116,156] The increased stability ordering **44** > **48**, **47** > **45** and **49** > **51** can be attributed to the conjugated electron-withdrawing group which diminishes C4 carbonyl protonation required of solvolysis and alkylation.[126,127,156] The increased stability of **45** > **48** can be attributed in part to the release of strain that accompanies the substitution of a fused six-membered for a fused five-membered arene ring.[118,122] Finally, the vinylogous amide stabilization of the cyclohexadienone structure, which is lost upon aromatization, contributes significantly to the stability of **44**–**51**.[164]

8.10. Relationship Between Alkylation Subunit Structure and DNA Alkylation Selectivity

The agents containing the natural (CPI, DSA, or DA) or modified (CI, CBI, CBQ, CFI) alkylation subunits attached to the same DNA binding subunits have been found to alkylate the same sites. Notably, no new or unique sites or alterations in the DNA alkylation sequence selectivity attributable to structural changes in the alkylation sites have been disclosed. In such sequencing studies, the alkylations are conducted with a large excess of DNA and limiting agent concentrations, and consequently, minor or forced additional reactions are not observed (for instance, minor guanine-N3 alkylation). These selectivities, which have been experimentally derived and summarized elsewhere,[56,71,105,122,130,144] can also be extrapolated from the data presented in Tables 1, 3, and 6 for the DSA, DA, or CPI-based agents. The distinctions between the agents lie in the greater selectivity among the available sites observed with the chemically more stable agents (DSA ≥ CBI > CPI > DA > CBQ > CI). In addition, it is notable that the corresponding precursor agents lacking the cyclopropane (i.e., **4**–**7**) also alkylate the same sites. Although in most cases this may be attributed to their facile closure to the cyclopropane-containing agents under the conditions of the assay, important and key studies have shown that this is not necessarily required.[55,56,104,105]

8.11. Relationship Between Functional Reactivity, DNA Alkylation Rate or Efficiency, and Biological Properties

To date, the relative efficiency of DNA alkylation follows closely the relative cytotoxic potencies observed with the agents. As the alkylation subunit reactivity diminishes, the relative efficiency of DNA alkylation increases. This was presumed to be attributable to the nonproductive consumption of the more reactive agents. The assumption was confirmed in the initial[56] studies with duocarmycin A and reestablished in more recent investigations with duocarmycin A[61,62] and CBQ-TMI (**40**).[130] Similarly, as the size of the DNA binding subunits increase, the relative efficiencies of DNA alkylation increase to a maximum and then level off for agents that possess the same alkylation subunit. This is consistent with the expectation that an increase in the noncovalent binding affinity within the minor groove provided by the DNA binding subunits increases both the rate and efficiency of DNA alkylation. The maximum plateau in cytotoxic potency occurs at approximately the same point at which the relative efficiencies in DNA alkylation also reach a plateau, even though the DNA alkylation rates vary widely. Thus, although the relative cytotoxic potencies have been suggested to be directly related to the relative rates of DNA alkylation,[46] we have suggested that the cytotoxic potencies may more closely follow the trends in relative DNA alkylation

efficiencies.[71, 120] Since the DNA alkylation reactions are inherently reversible, it is attractive to suggest that the maximum plateau in the DNA alkylation efficiency and cytotoxic activity may be achieved only when the inherently reversible adduct formation is fully stabilized by a sufficiently strong noncovalent binding. This would seem to be validated in the recent studies with the 7-MCBI derivatives.[126]

Although the careful comparisons are limited in the studies conducted to date, the chemically more stable agents have not only been determined to alkylate DNA more efficiently but also to do so more rapidly. It is not intuitively obvious that this would be expected for a Brønsted acid or Lewis acid catalyzed reaction and may be a consequence of the limited number of agents examined to date. For example, the most reactive of the agents carefully examined to date are the CBQ-based agents, which have been shown qualitatively to alkylate DNA slower than the CPI-, CBI-, or DSA-based agents. Similarly, the CPI-based agents alkylate DNA with both a lower efficiency and lower rate than the CBI-based agents even though they are four times more reactive (Fig. 42). In contrast, the CBI-based agents alkylate DNA with efficiencies and rates that are both only slightly lower than those of the exceptionally stable DSA-based agents (Fig. 42). Thus, the chemically most stable class of agents examined to date also alkylate DNA at the fastest rate. It is also the class of agents that possess the smallest degree of inherent steric bulk on the inside concave face of the alkylation subunit especially surrounding the DSA C7 position. Thus, it may be that steric bulk surrounding this C7 center diminishes the inherent rate of DNA alkylation, and the agents examined carefully to date follow this trend (DSA > CBI > CPI).

9. Structural Origin of the Distinctions between Enantiomers: Sensitivity to C7 Steric Interactions

The studies have suggested an attractive explanation for the sometimes confusing behavior (relative DNA alkylation efficiency and relative biological potency) of pairs of enantiomeric agents that may be traced to a single structural feature: the degree of steric bulk surrounding the CPI or DSA C7 center within the alkylation subunit for which the unnatural enantiomers are especially sensitive. The distinctions between enantiomers have proven readily detectable with the simple alkylation subunits themselves (that is, N-BOC-DSA (**12**), -CI (N-BOC-**51**), -CPI (**13**), and -CBI (N-BOC-**45**)), are most prominent with the dimer-based agents (like duocarmycin SA, duocarmycin A, CBI-CDPI$_1$, CPI-CDPI$_1$ (**15**), and CPI-PDE-I$_1$ (**14**), Table 8, Fig. 43), and are less prominent with the larger trimer- or tetramer-based agents (CC-1065, CPI-CDPI$_2$ (**16**), CBI-CDPI$_2$, and CPI-CDPI$_3$ (**17**)).[54, 73] In general, less distinction in the biological potency and relative DNA alkylation efficiency has been observed with the CI and duocarmycin SA enantiomeric pairs, both of which lack substituents or steric bulk at this position within the alkylation subunit. Moreover, the distinctions among enantiomeric CI-based agents, which lack the pyrrole ring altogether, are generally smaller than those observed with the duocarmycin SA-derived agents (DSA > CI). In contrast, the CPI-, CBI-, and duocarmycin A-based agents generally exhibit more pronounced distinctions within enantiomeric pairs (CPI > duocarmycin A > CBI). This suggests that the behavior of the unnatural enan-

[a] The relative concentrations of the (unnatural/natural) enantiomers required to detect DNA alkylation.

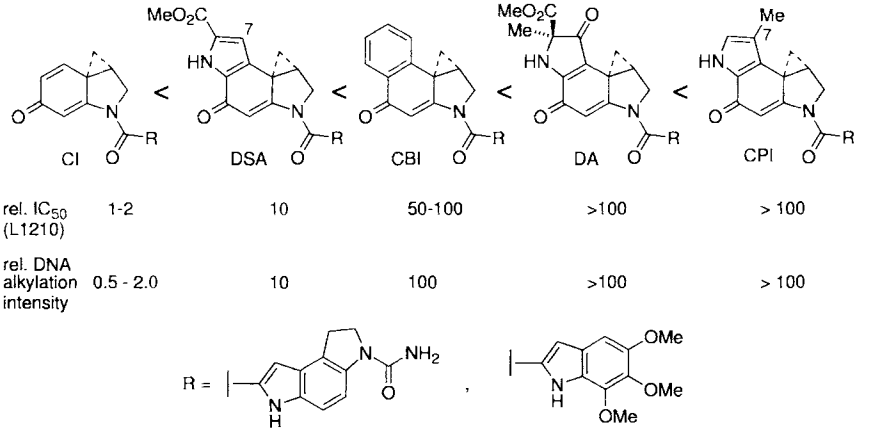

Fig. 43. Origin of the distinctions between the behavior of pairs of enantiomers toward DNA alkylation: steric bulk surrounding the DSA and CPI C7 center.

tiomer of duocarmycin SA as well as that of all agents studied to date is derived from a pronounced steric interaction of the C7 center with the 5′ base adjacent to the adenine N3 alkylation site necessarily present with the 5′ → 3′ binding of the unnatural enantiomer. The 3′ → 5′ binding model for the natural enantiomers benefits from a less substantial but still potentially significant sensitivity to steric bulk at this same C7 position.

Consistent with the empirical observations to date and in agreement with models of the alkylation adducts, the studies suggest that agents lacking steric bulk surrounding the position occupied by a CPI or duocarmycin SA C7 substituent are predictably more effective at alkylating DNA, that the unnatural enantiomers of such agents are especially sensitive to steric bulk at this position, and that as this steric bulk is reduced, the distinctions between the enantiomers diminish. The only exception to these generalizations was observed with the MCBI-based agents, where the properties of the two enantiomers are more similar than those of the enantiomers of the CBI-based agents.[126] This has suggested that such distinctions may be reduced or overcome by the introduction of additional noncovalent binding stabilization into the alkylation subunit itself.

10. Modified DNA Binding Subunits

One of the earliest and easiest structural features of the agents subjected to examination was the DNA binding subunits attached by an amide linkage to the naturally occurring alkylation subunits. These studies confirmed that hydrophobic righthand subunits convey binding affinity for the DNA minor groove, confer selectivity for binding at an AT-rich site in the minor groove, stabilize covalent adduct formation, accelerate the rate of DNA alkylation, contribute to and/or dominate the sequence selectivity of DNA alkylation,[108,109] and affect the physiochemical properties of the naturally occurring agents. Many of these issues are discussed in the context of the key analogs of CC-1065 and the duocarmycins described in Sections 2–5.

10.1. Systematic Substructure Examination of the CC-1065 DNA Binding Subunits

Early studies defined the degree of simplification and the optimum DNA binding subunits for analogs of CC-1065 that maintain the full potency of the natural product but improve in vivo antitumor efficacy. The PDE-I_2 subunits of CC-1065 could be reduced to $(indole)_2$ with full maintenance of cytotoxic potency and with significant enhancements in the in vivo antitumor activity (Fig. 44).[158–162] Further simplifications or reductions in the size of the DNA binding subunits (for example, $(indole)_1$) resulted in diminished properties, although the attachment of the trimethoxyindole (TMI) subunit of the duocarmycins has provided a potent agent.[165] This suggests that an appropriately substituted, single DNA binding subunit (for example, TMI or CDPI$_1$) may provide fully potent cytotoxic agents. Similar studies with the CBI-based agents have been conducted and have extended these observations (Fig. 44).[73,117–127,166]

Notably, this latter class of agents incorporating the synthetic and simplified CBI alkylation subunit and the simplified, synthetic $(indole)_2$ (**57**, Fig. 45) or TMI DNA binding subunits constitute synthetic, designed analogs of the natural products that possess potent and efficacious antitumor activity.[73,121,166] Consequently, a large degree of variation may be tolerated in this portion of the structure for optimization of the biological and physiochemical properties of the agents (Fig. 45).

We have advanced the proposal that it is not the kinetic rates of DNA alkylation[46] that are responsible for the difference in the cytotoxic potencies of the agents bearing a common alkylation subunit, but rather the relative efficiency of DNA alkylation and thermodynamic stability of the adducts.[38] Consistent with this proposal the cytotoxic potencies plateau for agents bearing a common alkylation subunit when sufficient noncovalent binding provides stable adducts. Moreover, this maximum potency is directly related to the functional stability of the agents. The chemically more stable agents provide the greatest

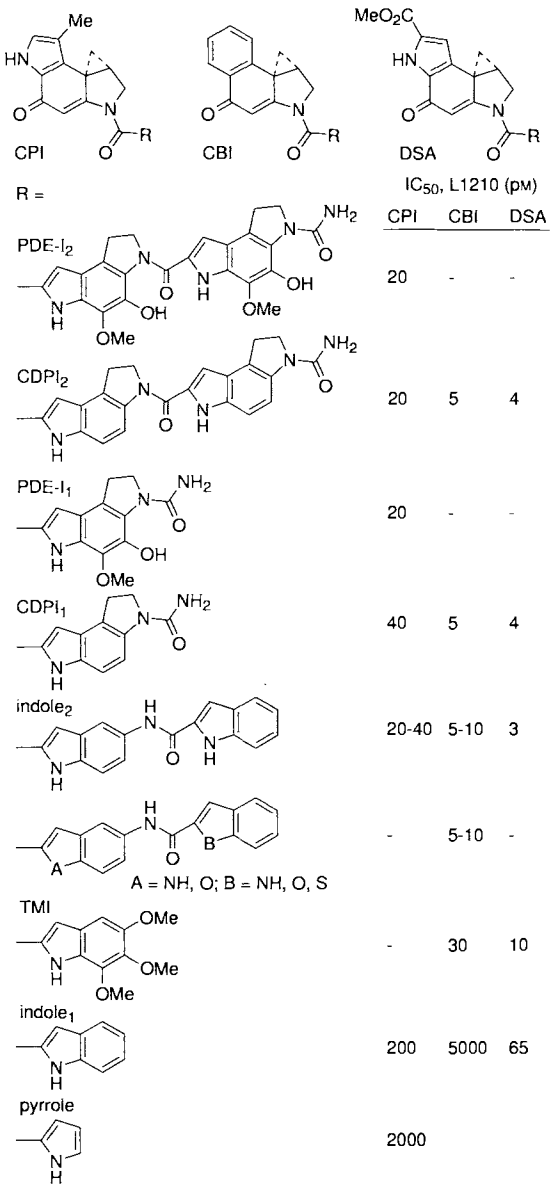

Fig. 44. Influence of the structure of the DNA binding subunits on the cytotoxic activity of CPI, CBI, and DSA analogous. The numbers on the right are the IC_{50} values (L1210) in pM.

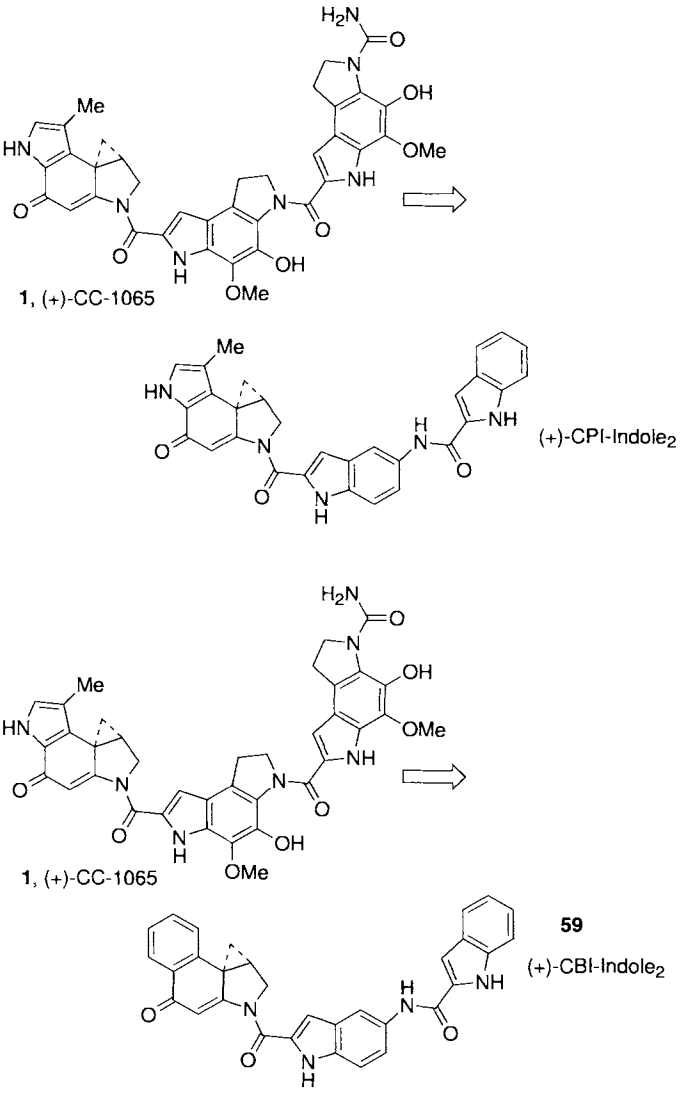

Fig. 45. (+)-CPI(indole)$_2$ and (+)-CBI(indole)$_2$: potent antitumor agents.

potency (CPI: 20pM, CBI: 5pM, DSA: 3–4pM). This is presumably because the chemically more stable agents reach their intracellular target more effectively.

10.2. Systematic Substructure Examination of the Duocarmycin DNA Binding Subunit

More recent studies systematically examined the role of the three methoxy substituents on the trimethoxyindole DNA binding subunit of duocarmycin SA.[109] The C6 and C7 methoxy substituents, which lie on the outer or peripheral face of the DNA–agent complexes, individually contribute only a small or no enhancement to cytotoxic potency and the relative efficiency of DNA alkylation (C6>C7), while the C5 methoxy substituent, which is deeply imbedded in the minor groove, contributes fully to such properties (Fig. 46). In fact, the agent with a single C5 methoxy substituent proved indistinguishable from the natural product indicating that it alone is sufficient for full potentiation of the properties. Consistent with the results of modeling studies detailed in early studies on CC-1065,[41] this may be attributed to the additional noncovalent binding stabilization provided by the C5 methoxy substituent imbedded in the minor groove.[82]

Importantly, the studies provided further key evidence supporting the proposal that the full potentiation of the cytotoxic potency of the agents is derived from noncovalent binding stabilization of an inherently reversible DNA alkylation rather than differences in the relative rates of DNA alkylation.[109]

10.3. Deep-Seated Modifications in the DNA Binding Subunits

Two interesting deep-seated modifications in the DNA binding subunits of the natural products have been detailed. The first was based on the disclosure that electropositive substituents placed on the outer face of the DNA binding subunits substan-

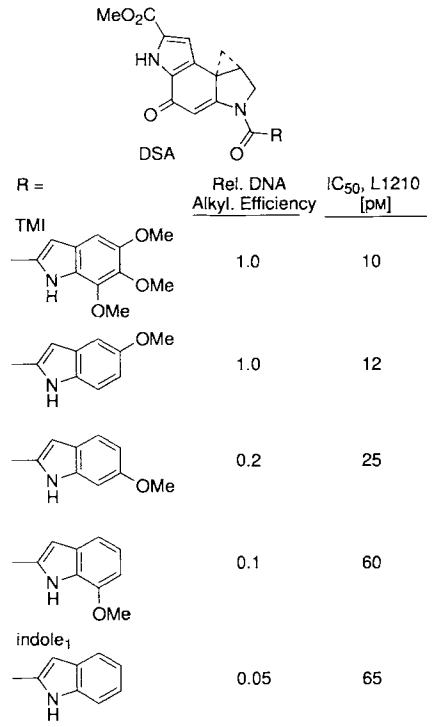

Fig. 46. The effect of methoxy substituents on the activity of duocarmycin SA analogs. Eff_{rel} = relative efficiency of the DNA alkylation.

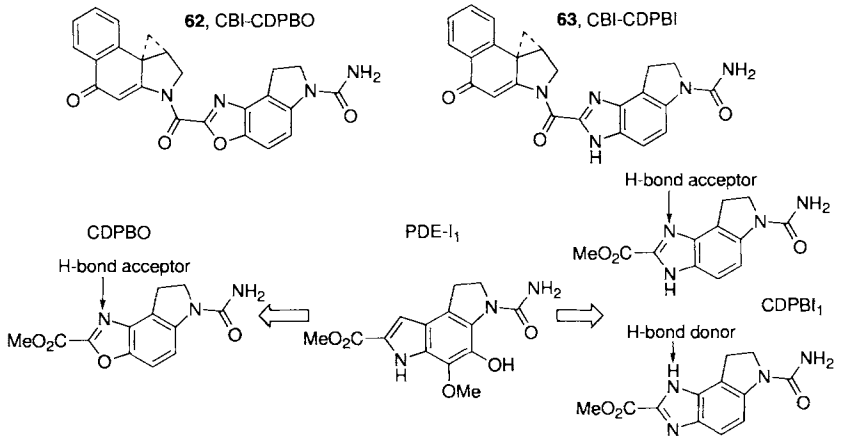

Fig. 48. CBI-CDPBO and CBI-CDPBI: model compounds with modified structural elements for DNA binding.

tially increase DNA binding affinity without affecting DNA binding selectivity and simultaneously increase water solubility. This may be attributed to a spatially well-defined stabilizing electrostatic interaction with the negatively charged DNA phosphate backbone.[83] These studies have been extended to **59–61** (Fig. 47) containing a quaternary ammonium salt on a single indole DNA binding subunit capable of providing this same strong electrostatic binding stabilization.[84] Consistent with expectations, the water soluble agents **59–61** alkylated DNA with the same efficiency as **1** or **3** and were one hundred times more effective than **58**, which lacks the positively charged group.

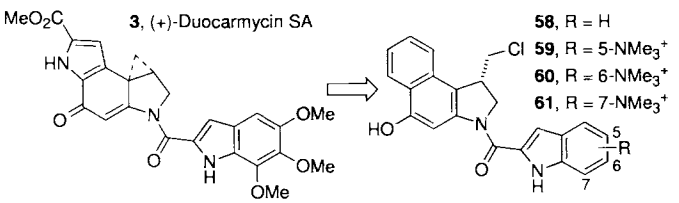

Fig. 47. Structures of **59–61**, the ammonium derivatives of **58**, as analogs of **3**.

The second important modification was based on the observations of Dervan[12, 167] and Lown[168] that the AT-rich, noncovalent binding selectivity of distamycin could be altered to accommodate a G-C base pair through introduction of a nitrogen into the backbone structure to serve as a hydrogen bond acceptor from a guanine C2-amine.[169] In analogy to such studies, the agents **62** and **63** were designed and prepared (Fig. 48).[170] They contain deep-seated modifications in the DNA binding subunits with incorporation of a nitrogen capable of serving as a hydrogen bond acceptor (CDPBO, CDPBI) or hydrogen bond donor (CDPBI) on their inside concave face, which is in intimate contact with the minor groove floor. The DNA alkylation selectivities of **62** and **63** are identical to those of CBI-CDPI$_1$ but with a substantially diminished efficiency (100×). Thus, the introduction of a single nitrogen atom had a pronounced and detrimental effect on the relative efficiency of DNA alkylation, but no apparent effect on DNA alkylation selectivity.

11. Biochemical Studies: Mechanism of Action

11.1. Apoptosis: A Link Between DNA Alkylation, Cytotoxic Activity, and Antitumor Properties

The first step in defining the link between DNA alkylation and effective antitumor activity was detailed in studies demonstrating that sensitive tumor-cell lines including L1210 and Molt-4 are triggered to undergo apoptotic cell death at agent concentrations (100 pM) below that required for typical cell death by necrosis observed in nonsensitive cell lines.[51] Apoptosis is a specific mechanism of cell death different from necrosis: cells undergo morphological changes including a characteristic heterochromatin condensation, degradation of genomic DNA, nuclear disintegration, and packaging of cell remains into apoptotic bodies that are removed by macrophages.

11.2. Cell Cycle Effects

The fundamental features of the cell cycle include growth, DNA replication, mitosis, and cell division. The cell cycle is divided into two parts—interphase and mitosis (M). The S phase (DNA synthesis) occurs in the middle of interphase and is preceded by G_1, the gap between mitosis (M) and DNA synthesis (S) and followed by G_2, the gap between replication and mitosis. The extent to which an antitumor agent affects these events has important implications on its mechanism of action. (+)-CC-1065 blocks progression of cells at G_2 and M.[49, 171–173] No effect was observed in the transitions

from M to G_1 or G_1 to S. At agent concentrations low enough to arrest the cell cycle at G_2 and M, cells were able to pass slowly through S phase even though CC-1065 inhibits DNA synthesis. Similarly, adozelesin (**65**, see Fig. 49) was found to cause G_2 arrest.[174, 175]

11.3. DNA Processing Enzymes

The alkylation of duplex DNA by CC-1065 and related agents inhibits many DNA processing enzymes[176] (including the S1 nuclease responsible for digestion of single strand DNA,[88] T4 ligase,[177] helicase[178–181]) and terminates DNA polymerase catalyzed DNA synthesis (replication) at the adduct sites.[182] The CC-1065 adenine-N3 adduct produces a pronounced inhibition and enhancement patterns of DNA cleavage upon DNase I or MPE-Fe^{II} footprinting.[183] Attempts to correlate agent structure with the extent of both the mutagenic effects of the adenine-N3 alkylation [184–191] and resistance[192–194] have been disclosed.

12. Delayed Toxicity

A serious limitation in the use of agents related to (+)-CC-1065 (**1**) is the characteristic, delayed fatal toxicity of the natural product.[52] When the toxicity of **1** was examined in non-tumor-bearing mice, an unusual form of lethal, delayed hepatoxicity was observed at therapeutic antineoplastic doses. At single dose levels of 12.5 $\mu g\,kg^{-1}$ administered intravenously (iv), delayed deaths were observed at 50 days, and at 10 $\mu g\,kg^{-1}$ single dose (ip) administration, delayed deaths were observed at 70 days. The mouse LD_{50} value (iv) was determined to be 9 $\mu g\,kg^{-1}$ single dose and 0.3 $\mu g\,kg^{-1}$ per day, five daily doses. These delayed deaths were accompanied by dramatic changes in the morphology of hepatic mitochondria. Animal pretreatment with agents that induce cytochrome P-450 metabolism was unsuccessful in preventing the toxicity of **1**. Importantly, the unnatural enantiomer of CC-1065, which is equally potent in vitro and equally efficacious in vivo, does not embody this property suggesting it is not inherent in the structure or a required consequence of the mechanism of action responsible for the productive antitumor activity. Similarly, most but not all CC-1065 analogs do not display this delayed toxicity nor do the duocarmycins and their analogs reported to date. Much speculation on the origin of this unusual property has been detailed.[47, 97, 176] Among the more intriguing is the suggestion that the delayed toxicity may be related to the degree of DNA alkylation reversibility and consequently the extent of the noncovalent binding stabilization of the reversible adduct.[37, 58] The agents whose absolute configuration (adducts of the natural enantiomers are more stable than those of unnatural enantiomers) and extent of noncovalent binding render the alkylation irreversible may be prone to this delayed toxicity. This suggests that the optimal agents may be those that form stable but not irreversible adducts. Regardless of whether this impacts on the delayed toxicity, this proposal implies that there may be inherent benefits to the use of the chemically most stable alkylation subunits whose degree of reversibility is greatest and whose nondiscriminant alkylation reactivity is diminished coupled with their attachment to an appropriately sized DNA binding subunit capable of providing stable but not irreversible adduct formation.

13. Clinical Candidates

Four agents that are analogs of **1** and contain the authentic CPI alkylation subunit or a seco precursor have been put forward as clinical candidates.[195, 196] The first two, **64** (U-71,184) and **65** (adozelesin), were derived from the first stage of studies on analogs of **1** in which systematic modifications, simplifications, and optimization of the DNA binding subunits were conducted (Fig. 49).[197–199] Carzelesin (**66**) is a prodrug that after

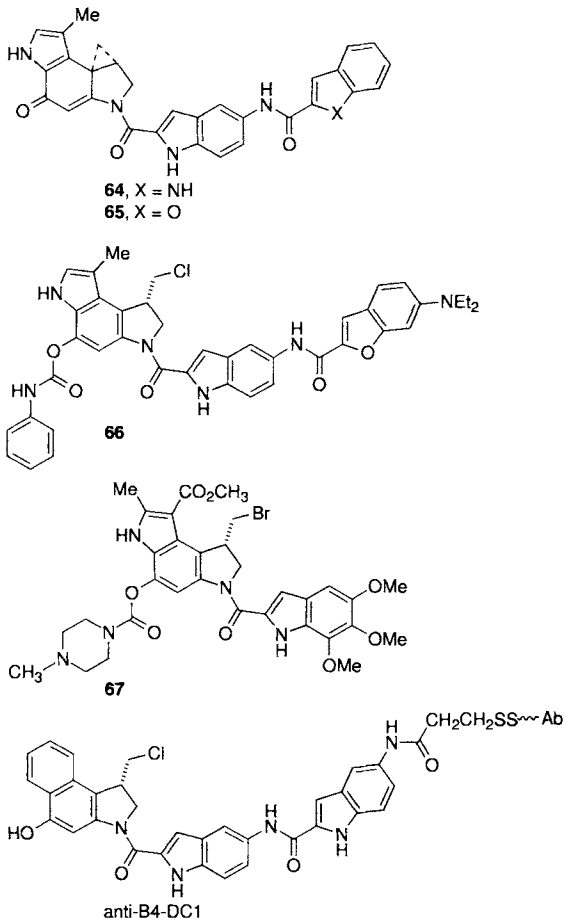

Fig. 49. Candidates for clinical trials.

releasing the free phenol upon carbamate hydrolysis ($t_{1/2}$ = 18–52 min in plasma; $t_{1/2}$ = 40 min in cell culture) readily cyclizes to the corresponding agent containing the cyclopropane.[200] Bizelesin (**43**) is a DNA cross-linking agent incorporating two CPI alkylation subunit precursors and is approximately 20 to 30 times more potent than **1** (IC_{50}(L1210) = 1 pM vs 20 pM).[201]

From the duocarmycin class of agents, KW-2189 (**67**) has been selected for clinical trials in Japan.[202–205] It is a semisynthetic duocarmycin B_2 derivative, which possesses improved antitumor activity, water solubility, and stability.

When conjugates of (+)-CBI-(indole)$_2$ (Fig. 45) that were first prepared with materials from our laboratory were linked by a cleavable disulfide to humanized versions of the antibodies (mAbs) anti-B4 and N901 and directed against the tumor-associated antigens CD19 and CD56, respectively, they proved to be extremely potent and antigen-selective in killing target cells in culture.[206] The anti-B4 disulfide conjugate with (+)-CBI-(indole)$_2$ showed antitumor efficacy in an aggressive, in vivo, metastatic, human B-cell lymphoma model and completely cured animals bearing large tumor burdens. It was shown to be considerably more effective than doxorubicin, cyclophosphamide, etoposide, or vincristine at their maximum tolerated doses. Such tumor-selective targeting of the potent cytotoxic agents related to **1** and the duocarmycins by reversible linkage to tumor-directed antibodies thus improved their inherent selectivity. Because of the potentially low delivery of the antibody-linked agents, which is limited by the number of cell surface cognate antigens, such approaches require that the linked cytotoxic agent be exceptionally potent. Only a limited number of agents including **1**–**3** and their synthetic analogs possess such required potencies.

14. Summary and Future Prospects

In a remarkably short period the definition of the DNA alkylation properties and the basis for the sequence-selective recognition and alkylation of DNA by this new class of antitumor antibiotics have been described. This may well represent the best understood and most thoroughly investigated class of sequence-selective DNA alkylating agents examined to date. Major issues in understanding the polynucleotide recognition and functional reactivity of the agents and their potential utility have been detailed. Nonetheless, several fundamental unresolved issues remain, including a consensual agreement on the origin of the DNA alkylation selectivity, the importance of the rates or efficiencies of DNA alkylation relative to the thermodynamic stability of the reversible adducts, the origin of the characteristic but unique delayed toxicity of **1**, the extent and origin of catalysis of the DNA alkylation reaction, and the link between DNA alkylation and selective antineoplastic activity. Importantly, the present understanding of the origin of the properties of the natural products emerged principally through the design and evaluation of synthetic substructures and agents containing deep-seated structural changes (as well as their unnatural enantiomers), rather than through extensive studies conducted solely on the natural products themselves. Speculation on the origin of properties, which may result in misconceptions or misrepresentations, may and should be addressed by direct and often unambiguous tests employing well-devised synthetic agents. Some such agents have also proven much more efficacious than the natural products themselves, which illustrates that their productive properties may be enhanced by well-founded and designed structural changes. The fact that such structural changes may also often simplify the target analog suggest that it will be a synthetically designed rather than naturally derived agent in this class that will ultimately become clinically significant. No doubt, the fundamental principles defined in the studies conducted to date may provide the foundation for such future developments and advances.

Abbreviations

DSA: duocarmycin SA alkylation subunit
DA: duocarmycin A alkylation subunit
CPI: 1,2,8,8a-tetrahydro-7-methylcyclopropa[*c*]pyrrolo[3,2-*e*]indol-4-one
CBI: 1,2,9,9a-tetrahydrocyclopropa[*c*]benz[*e*]indol-4-one
MCBI: 1,2,9,9a-tetrahydro-7-methoxycyclopropa[*c*]benz[*e*]indol-4-one
CCBI: 1,2,9,9a-tetrahydro-7-cyanocyclopropa[*c*]benz[*e*]indol-4-one
CI: 1,2,7,7a-tetrahydrocyclopropa[1,2-*c*]indol-4-one
CBQ: 2,3,10,10a-tetrahydro-1*H*-cyclopropa[*d*]benz[*f*]quinol-5-one
C_2BI: 9a-(chloromethyl)-1,2,9,9a-tetrahydrocyclopropa[*c*]benz[*e*]indol-4-one
CDPI: 3-carbamoyl-1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate
TMI: 5,6,7-trimethoxyindole-2-carboxylate
CDPBO: 3-carbamoyl-1,2-dihydro-3*H*-pyrrolo[3,2-*e*]-benzoxazole-7-carboxylate
CDPBI: 3-carbamoyl-1,2,-dihydro-3*H*-pyrrolo[3,2-*e*]benzimidazole-7-carboxylate
TACDPI: 5-trimethylammonio-3-carbamoyl-1,2-dihydro-3*H*-pyrrolo[3,2-*e*]indole-7-carboxylate
ACDPI: 5-amino-3-carbamoyl-1,2-dihydro-3*H*-pyrrolo-[3,2-*e*]indole-7-carboxylate
IC_{50}: the concentration of agent required to inhibit by 50% the growth of the indicated cell line (L1210) in a 72 h assay.

[78] Consistent with this proposal, the observed induced circular dichroism upon DNA binding and alkylation by (+)-CC-1065 is much larger than that of (+)-**16**, indicating a greater conformational change upon binding for CC-1065. This larger induced circular dichroism for CC-1065 was mistakenly attributed to a higher binding and alkylation efficiency in early studies [79].

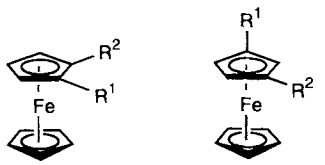
Planar-Chiral Ferrocenes: Synthetic Methods and Applications

Antonio Togni*

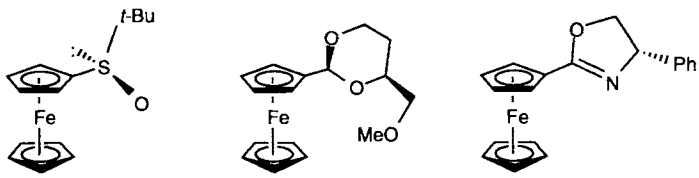
Since its discovery, and because of its stability and the wealth of methods for its derivatization, ferrocene has played an important role in many areas of synthetic and materials chemistry. Thus ferrocene has been incorporated into more complex structures, which then displayed, for example, nonlinear optical, liquid crystalline, or ferromagnetic properties.[1] From a stereochemical point of view, however, one of the most important attributes of, for example, 1,2- or 1,3-disubstituted ferrocenes such as **1** and **2** is that they are planar-chiral, and thus potentially available in enantiomerically pure form.[2]



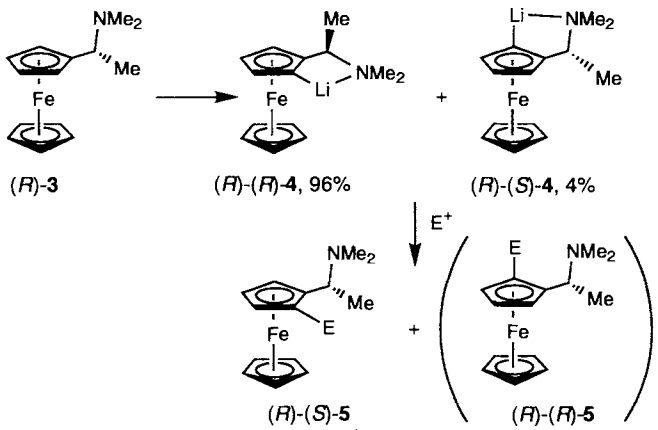
1 **2**

So far, the most important method for preparing enantiopure (or enantiomerically enriched) planar-chiral ferrocene derivatives relies upon a diastereoselective *ortho*-lithiation and subsequent reaction with an appropriate electrophile. The most prominent example of this methodology is based on the pioneering work of Ugi and co-workers (Scheme 1).[3]

Thus, lithiation of ferrocenylamine (*R*)-**3** with BuLi generates the two possible diastereoisomers of **4** (for simplicity formulated here as monomeric, nonsolvated species) in a ratio of 96 to 4. Following the reaction with the electrophile, the diastereoisomeric side-product is usually easily separated by crystallization and/or chromatography. This strategy, which involves the use of stereogenic *ortho*-directing groups, has been further developed in more recent years by several research groups. Thus, the sulfoxide **6**,[4] the acetal **7**,[5] and the oxazoline **8**[6] have been found to afford high diastereoselectivities. These functional groups, however, are not necessarily those one may want to incorporate into the final planar-chiral product; that is, they may need to be removed or modified. An exception to this observation is the oxazoline fragment in compound **8** that has been demonstrated to fulfill both the role of a diastereoselective *ortho*-directing functionality and of a ligand for transition metals in homogeneous-catalyzed reactions (see below).



6 **7** **8**



Scheme 1. Diastereoselective *ortho*-lithiation of (*R*)-**3**.

Since amines of type **3** (or the corresponding alcohols as synthetic equivalents) still remain the most versatile starting materials for diastereoselective lithiation processes, and because the amino group can easily be substituted in a stereoretentive process,[3a] methods have been developed for their enantioselective preparation. Recent work includes the amino alcohol catalyzed addition of dialkylzinc reagents to ferrocene-carbaldehyde,[7] and the 1,2-addition of organolithium compounds to the corresponding SAMP-hydrazone,[8] as illustrated in Scheme 2. Further methods involve the enantioselective reduction of ferrocenyl ketones using chiral oxazaborolidine boranes[9] and lipase-mediated desymmetrization of acetoxymethyl derivatives.[10] All these procedures make use of chiral auxiliaries (or catalysts) for the generation of the α-stereogenic center bearing a heteroatom functionality. Among these methods those starting from ferrocenyl ketones are more straightforward and do not involve, for example, cumbersome operations for the removal of chiral auxiliaries, or complex work-up and separation procedures. Therefore, they are anticipated to become even more significant in the near future.

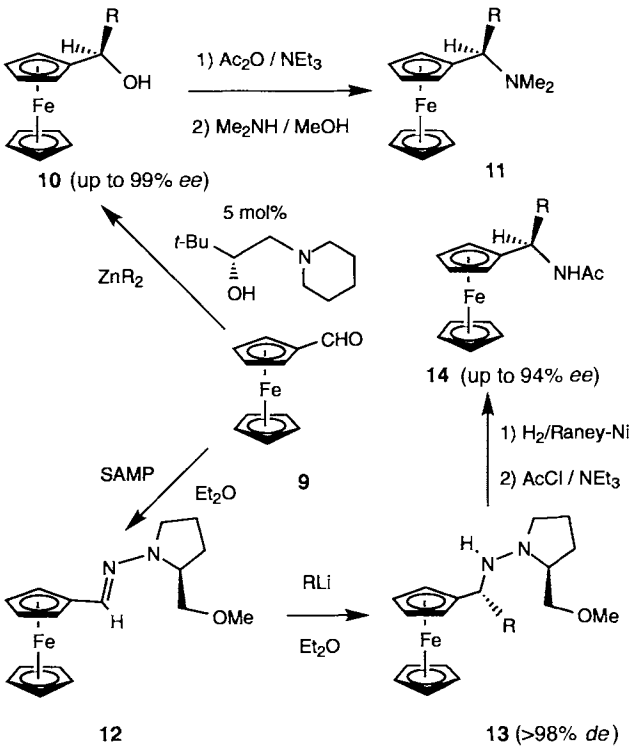
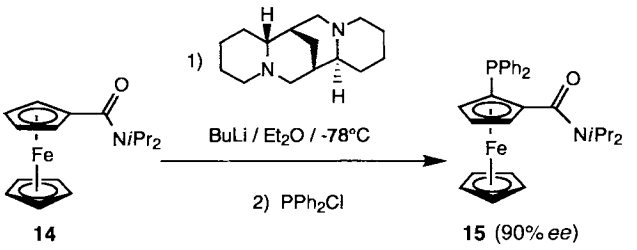


Scheme 2. New syntheses of chiral ferrocenylamines. SAMP = (*S*)-1-amino-2-(methoxymethyl)pyrrolidine.

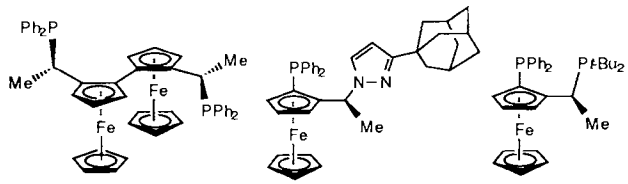
A completely different approach for the preparation of planar-chiral ferrocenes, which represents an important development in this area, was reported recently by Snieckus and co-workers.[11] Indeed it was shown that the enantioselective *ortho*-lithiation of ferrocenylamides of type **14** is effectively achieved by utilizing the alkaloid (−)-sparteine as a chiral inducing agent (see example in Scheme 3). The novelty of the



Scheme 3. Sparteine-mediated enantioselective synthesis of **15**.

method lies in the fact that for the first time planar-chiral ferrocenes have been generated highly selectively and without the need of introducing a stereogenic directing group. The application of the reagent BuLi/sparteine in ferrocene chemistry is a welcome extension of the concept of enantioselective deprotonation developed inter alia by Hoppe and co-workers in recent years.[12] Despite the impressive results (the phosphane **15** can be obtained in 90% *ee* and in 82% yield, whereas other electrophiles, for example TMSCl or benzophenone afford optical yields up to 98% and 99% *ee*, respectively), it remains to be seen whether or not the method may be applied so successfully also to ferrocenes bearing substituents other than amides. Furthermore, will there be a chance to overcome the disadvantage of the single enantiomeric form of (−)sparteine?[13]

Probably the most important class of planar-chiral ferrocenes accessible by the techniques delineated above is that of chelating ligands for transition metal catalyzed asymmetric reactions.[1] Progress in this area is characterized, among others, by ligands of type **16**,[14] **17**,[15] and **18**.[16]

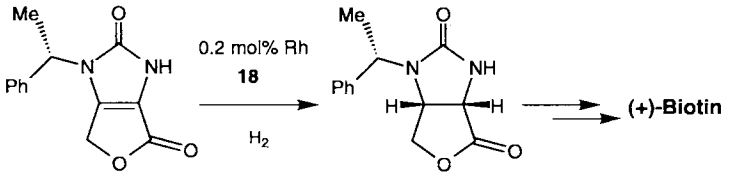


The C_2-symmetric biferrocene **16** has been reported by Ito and co-workers to behave as a *trans*-spanning chelating ligand. The combination of C_2-symmetry and *trans* coordination geometry is conceptually new in the field and is promising for future development. TRAP (the abbreviation for this kind of compounds) affords high enantioselectivities in the Rh-catalyzed asymmetric Michael reaction of 2-cyanopropionates, the hydrosilylation of simple ketones, and the hydrogenation of β,β-disubstituted *N*-acetylaminoacrylic acid derivatives.

The P,N ligand **17** represents a class of chiral auxiliaries that are amenable to easy steric and electronic tuning, an aspect that is anticipated to play an important role in the further development of asymmetric catalysis. Thus, ligands of this type have been shown to afford the highest enantioselectivities reported so far for the Rh-catalyzed hydroboration of styrenes with catecholborane (up to 98.5% *ee*) and for the Pd-catalyzed substitution of allylic acetates and carbonates with benzylamine (up to >99% *ee*). The advantage offered by these ligands is the ease of their synthetic modification, which relies upon the simple idea of a construction kit. The latter comprises 1) the carrier of the chiral information (the amine **3**), 2) a set of chlorophosphanes (for the generation of the planar-chiral phosphane-amine intermediate), and 3) a series of substituted pyrazoles to be used as nucleophiles. The assembly of these three fragments occurs in two consecutive synthetic steps, and allows the ligand to be adapted to the needs of a particular reaction in an unprecedented way.

The same type of considerations apply to diphosphanes of the Josiphos type such as **18**.[16] This specific compound, containing the bulky $t\mathrm{Bu}_2\mathrm{P}$ group, has been found to be the only ligand that affords a very high diastereoface selectivity in the hydrogenation of compound **19** to give **20**, an intermediate in a new synthesis of (+)-biotin[17] (Scheme 4). The analogous achiral starting material containing a benzyl protecting group, instead of a stereogenic phenethyl group, affords under the same reaction conditions 90% *ee*. This quite remarkable process, which involves the hydrogenation of a fully substituted C=C bond, is currently being applied on a commercial scale by Lonza AG.

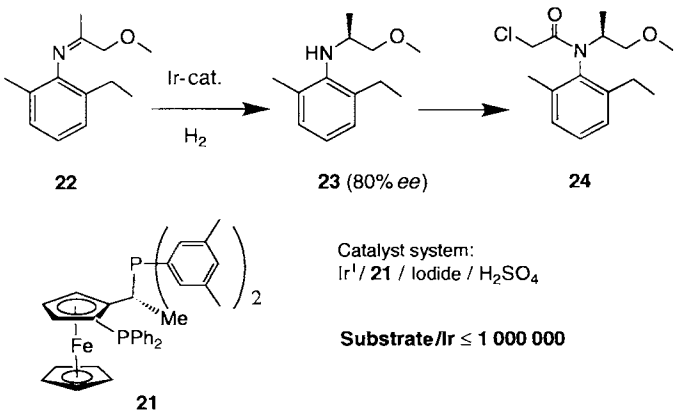
A second and probably more important technical application of this type of ligands has recently been disclosed by Ciba-Geigy. Derivative **21** constitutes the chiral component of the excep-



19 20 (99% ds)

Scheme 4. Asymmetric hydrogenation of **19** to give **20**, which is used for the preparation of (+)-biotin.

tionally highly active iridium catalyst used for the enantioselective hydrogenation of imine **22**, an intermediate in the synthesis of the herbicide (*S*)-Metolachlor (**24**)[18] (Scheme 5).



Scheme 5. Asymmetric imine hydrogenation in the production process of the herbicide (*S*)-Metolachlor (**24**).

The relatively low selectivity obtained in this catalytic reaction (80% *ee*) is tolerable for an agrochemical product. Much more important in this specific case are the activity and productivity of the catalyst. Besides a decisive co-catalytic effect of added acids (the exact role of the added iodide salt and of the acid are still unclear), one of the key features of this large industrial process is the use of ferrocenyl ligand **21**, which turns out to be superior to all commercially available chiral chelating diphosphanes with respect to a combination of several important aspects.

To our knowledge, the latter two examples constitute the first industrial applications of chiral ferrocenyl ligands and are a clear demonstration of the potential of this class of compounds. Any improvement of their synthetic versatility will mirror not only their fundamental interest, but shall be welcome also by the practitioner in the fine-chemical industry who is willing to extend the scope of homogeneous catalysis as a powerful synthetic method.

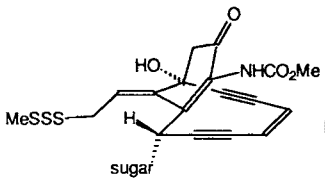
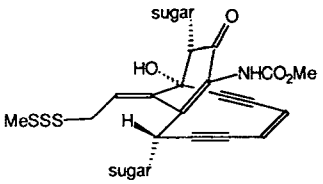
Design of Diradical-based Hydrogen Abstraction Agents**

Peter Chen*

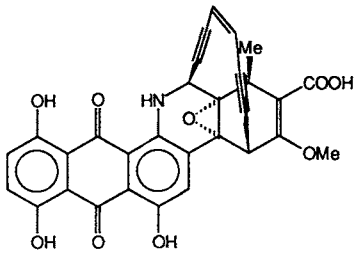
Interest in the chemistry of diradicals has undergone a vigorous resurgence over the last decade, in large part due to the putative intermediacy of arene diradicals in the DNA-cleaving activity of the enediyne family of antitumor antibiotics. There were early indications from the Masamune[1] and Sondheimer[2] groups, but the first unambiguous demonstration of the presence of arene diradicals produced by the cyclization of enediynes was reported by Bergman and co-workers.[3] The field lay fallow for many years until the discovery of the remarkable polyunsaturated ring structures for esperamicin, dynemicin, and calicheamicin.[4]



calicheamicin



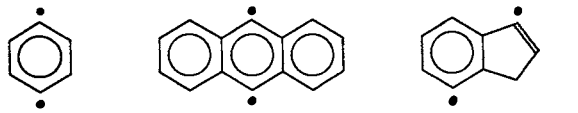
esperamicin



dynemicin

It became evident that the enediyne antitumor antibiotics cycloaromatized to form a substituted 1,4-didehydrobenzene (*p*-benzyne) diradical, which could initiate DNA cleavage by hydrogen abstraction from the sugar phosphate backbone of duplex DNA. Further studies have elucidated the design principles behind the various functional domains of the natural products: the triggering by the trisulfide moieties[4] in calicheamicin and esperamicin, the DNA recognition function of the pendant oligosaccharide chains,[5] the control of cycloaromatization through complexation by the apoprotein in kedarcidin[6] and neocarzinostatin,[7] etc. One marvels at the elegance and modular design of the natural products. Nevertheless, it is almost a truism to state that the natural products are highly optimized under some set of constraints for some biological function, which may or may not bear much relationship to the constraints or function that the enediynes find as therapeutic agents. It is therefore highly desirable to understand the ways in which organic chemists may re-engineer the functionalities of the natural products to effect a rational modification in properties.[8] The modular design of the enediyne series of compounds makes this enterprise particularly attractive. In this report, perspectives on the redesign of the "warhead" part of the enediyne drugs are discussed with an emphasis on recent developments in the field of arene diradicals that provide handles for alteration of function.

The diradicals that form from the natural products are all 1,4-diradicals: either substituted *p*-benzynes or 3,7-dehydroindenes. The functional significance of this restricted range of structures is not altogether clear, although suggestions (see below) can be made. Arene diradicals for which spectroscopic, thermochemical, and/or kinetic data have recently appeared include *p*-benzyne,[9, 10] 9,10-dehydroanthracene,[11, 12] and the larger condensed species, which form by tandem cyclizations.[13, 14]



p-benzyne 9,10-dehydroanthracene 3,7-dehydroindene

In the older literature, there are also structures such as the presumed cyclization product of Sondheimer's tetrayne.[2] While there are many reasons to study diradicals, the key questions in the present context are: What would happen if one were to use one of the nonnaturally occurring diradicals in a DNA-cleaving agent? What would the advantages and disadvantages be relative to *p*-benzyne, for example? What handles does one have, from an engineering point-of-view, to modify the chemistry?

In this light, the preparation and characterization of arene diradicals with connectivity or substitution different from those occurring in the natural products is of high interest. The recent report of the clean preparation, under matrix-isolation conditions, of 1,3-didehydrobenzene (*m*-benzyne),[15] opens the way to the physical characterization of an arene diradical which, while never implicated in the activity of a natural product, may have desirable properties from the engineering point-of-view.

A comparison of the results obtained by IR spectroscopy with those from ab initio calculations confirms the identity of the common product that is formed from different precursors by flash vacuum pyrolysis (FVP) and photolysis (Scheme 1). Noteworthy is the survival of *m*-benzyne under the conditions employed for FVP, which is in marked contrast to *p*-benzyne, which has been trapped, but never isolated. The earlier reports that pyrolysis of 1,3-diiodobenzene[16] or isophthaloyl diiodide[17] produced hex-3-ene-1,5-diyne do indicate that there

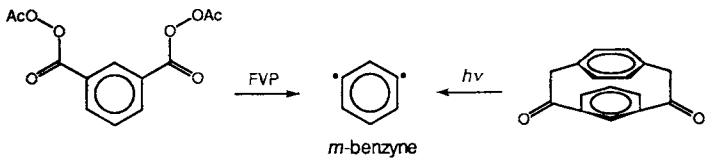
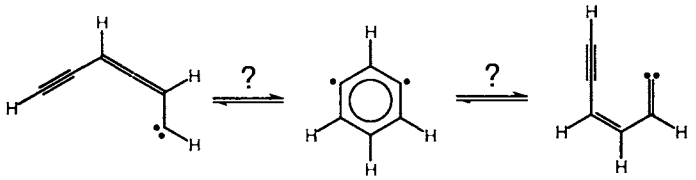


Scheme 1. Formation of *m*-benzyne.

is a rearrangement/ring-opening pathway, but with an activation energy that must be higher than the barrier of 19.8 kcal mol^{-1}[10] for the ring-opening of *p*-benzyne. One can write plausible mechanisms, based on carbene isomers of the enediyne, which rationalize the rearrangement (Scheme 2).



Scheme 2.

However, given that *m*-benzyne has a heat of formation 15 kcal mol^{-1} lower[9] than *p*-benzyne, and the vinylidene isomer of the enediyne, for example, should lie perhaps 40 kcal mol^{-1} above the enediyne, the greater kinetic stability of *m*- versus *p*-benzyne is not difficult to understand. With information gleaned from the experiment, one is almost in a position to make a prediction as to the effect of replacing *p*-benzyne by *m*-benzyne as a hydrogen abstraction agent. To close the argument, one needs only to know something about 1,4-diradicals as abstraction agents.

We have reported the absolute rates of hydrogen abstraction from acetonitrile and isopropyl alcohol by the 9,10-dehydroanthracene diradical[12] as a model for the reaction by *p*-benzyne or any other 1,4-arene diradical. The second-order rate constants for the hydrogen abstraction obtained at room temperature by measuring the transient absorption after flash photolysis and trapping of the reactive intermediate are $k_{MeCN} = (1.1 \pm 0.2) \times 10^3\,M^{-1}s^{-1}$ and $k_{iPrOH} = (6.5 \pm 0.6) \times 10^3\,M^{-1}s^{-1}$, and thus 100–200 times lower than the corresponding rate constants for the phenyl radical[18] or the 9-anthryl radical.[19] A reduced rate in hydrogen abstraction reactions for *p*-benzyne relative to that for the phenyl radical was also found by ab initio calculations at the CASPT2N/6-31G** level.[20] The lowered reactivity of a singlet ground-state diradical relative to that of a reference monoradical was rationalized by a valence-bond promotion energy argument that correlated the singlet–triplet splitting in the diradical to the magnitude of rate reduction. The singlet–triplet splitting in the arene diradicals, in turn, is determined primarily by the extent of through-bond coupling between the two radical sites. Accordingly, by choosing a diradical whose structure favors or disfavors through-bond coupling, or by tuning the energies of the σ and/or σ^* orbitals by way of substituents on the σ-framework, it should be possible to tune the rate of hydrogen abstraction to optimize the process for a particular set of constraints. The heats of formation for *o*-, *m*-, and *p*-benzyne, determined experimentally within the last two years,[9, 10] indicate a much larger coupling in *m*-benzyne than in *p*-benzyne. Ab initio calculations confirm the effect as manifested by a larger singlet–triplet splitting.[21] One would expect, therefore, that the rate of hydrogen abstraction by *m*-benzyne should be even lower than that by *p*-benzyne. Conversely, the diradicals formed by tandem cyclizations, by virtue of greater separation of the two radical centers, should be more reactive than *p*-benzyne.

Accordingly, the substantial stabilization from the 1,3-through-bond interaction in *m*-benzyne should impose both thermodynamic and kinetic barriers to hydrogen abstraction which could be very useful. From the heat of formation,[9] it is clear that abstraction of hydrogen by *m*-benzyne from donors with C–H bonds stronger than 94 kcal mol^{-1} would be endothermic. Even for those donors with a weak enough C–H bond, the promotion energy argument above suggests that there should be a substantial additional component to the activation energy which would nevertheless slow the hydrogen abstraction. The diradical should be long-lived, and presumably, selective in its attack.

It remains only to consider the possible functional significance of arene diradicals in the natural products, given their rather low rate of hydrogen abstraction, and the possible modification in that function upon replacement by a different diradical. Of course, it is conceivable that there is no special reason at all for the occurrence of such diradicals in Nature, but given that there are now many examples of radical-based biological processes,[22] one can imagine that, if it were to be advantageous to have a better abstraction agent, it would have been possible to have one. Greater selectivity, associated in general with lower reactivity, is one possible reason for the choice of a diradical agent versus a monoradical one. A more interesting possibility comes from the differential reactivity between an arene diradical and the phenyl radical. The first hydrogen abstraction by a *p*-benzyne-type diradical proceeds rather slowly (and presumably selectively) and yields the two-hundredfold more reactive phenyl radical. Reaction at the same target site is then likely, in this case meaning that two hydrogen atoms are abstracted from closely spaced positions, rather than from widely separated locations. For DNA cleavage, one would presume that this would lead to more double-stranded breaks, as has been shown to be the case in DNA cleavage by calicheamicin.[23] The exploitation of the differential rates of hydrogen abstraction between diradicals and monoradicals to enhance the likelihood for double-stranded breaks represents an elegant use of intrinsic reactivity to achieve a functional goal. The differential is further enhanced if *m*-benzyne is substituted for *p*-benzyne. While the former should be even slower and more selective than the latter in the first hydrogen abstraction, both diradicals produce the same phenyl radical for the second abstraction. DNA need not even be the target. The general motif associated with diradical-based hydrogen abstractions would be the use of an activated C–H bond, for example benzylic, allylic, etc., to direct the attack on a neighboring, unactivated C–H bond.

Some consequences of recent studies of the chemistry of arene diradicals have been discussed with an view to identifying the factors responsible for the particular choice of diradicals in natural products, and the advantages and disadvantages that

would be incurred if an alternative structure were to be substituted. Important structural features for rational modification of the diradical "warhead" have been suggested.

Template Assembled Synthetic Proteins (TASP) as Functional Mimetics of Proteins**

Manfred Mutter,* Pascal Dumy, Patrick Garrouste, Christian Lehmann, Marc Mathieu, Cristina Peggion, Stéphane Peluso, Alain Razaname, and Gabriele Tuchscherer

The use of peptidomimetics and topological templates has become an important tool in protein design and mimicry.[1-4] By introducing these elements in the design process, the synthetic chemist aims to unravel the complex interplay between protein structure and function. In order to avoid the well-known protein folding problem, we have introduced the concept of template assembled synthetic proteins (TASP); here, templates serve as built-in devices for directing the intramolecular assembly of covalently attached peptide blocks into characteristic folding topologies.[5-8] So far, problems with the synthesis have prevented the development of the full potential of this approach.[5] According to the TASP approach, the functional part of a protein, for example the antigen binding site of an antibody or the ligand binding site of a receptor, is detached from the rest of the molecule and assembled on a topological template, which mimics the loop supporting structural framework of the native protein (Fig. 1). Here, we elaborate the methodologies for the synthesis of this novel generation of functional TASP compounds.

The approach comprises two key elements: 1) peptide sequences (loops) containing C- and N-terminal functional-

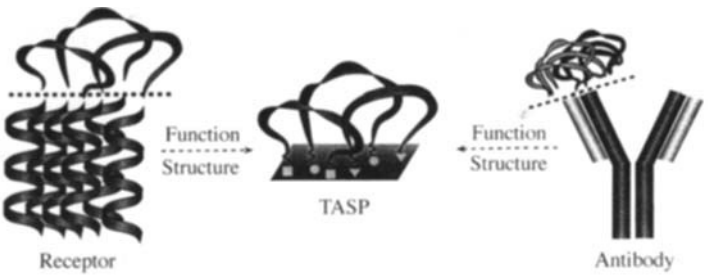

Fig. 1. Concept of template assembled synthetic proteins as mimetics of the binding region of receptors and antibodies.

groups (sticky ends) for chemoselective ligation[9-12] and 2) topological templates for the regioselective assembly of the loops. A prototype template consists of two antiparallel β-sheet peptides linked through β-turn-inducing dipeptides or nonpeptidic β-turn mimetics.[13-15] NMR spectroscopic investigations and molecular dynamics calculations confirm the preferred conformations of the TASP templates shown in Figures 2a and b; the attachment sites, for example the ε-amino groups of the lysine side chains, are all directed to one side of the β-sheet plane.Choosing from a variety of orthogonal protecting groups for peptide synthesis, we have developed a set of cyclic peptides as templates for the selective attachment of loop sequences.[13-15] In tailoring the flexibility of the backbone and side chains, this template motif may dispose any desired number and geometry of attachment sites.

The stepwise condensation of peptide sequences (loops, $\mathbf{L}^i$) onto these topological templates $\mathbf{T}^i$ (Table 1) is achieved by amide, oxime, and thioether formation[9-12] or combinations thereof.

In strategy A (Scheme 1), the C-terminally activated (step 1) fully protected loop $\mathbf{L}^i$ is fixed to the template $\mathbf{T}$, which contains one single reactive attachment site after removal of the protecting group Y^i (step 2, amide 1). Selective deprotection of the

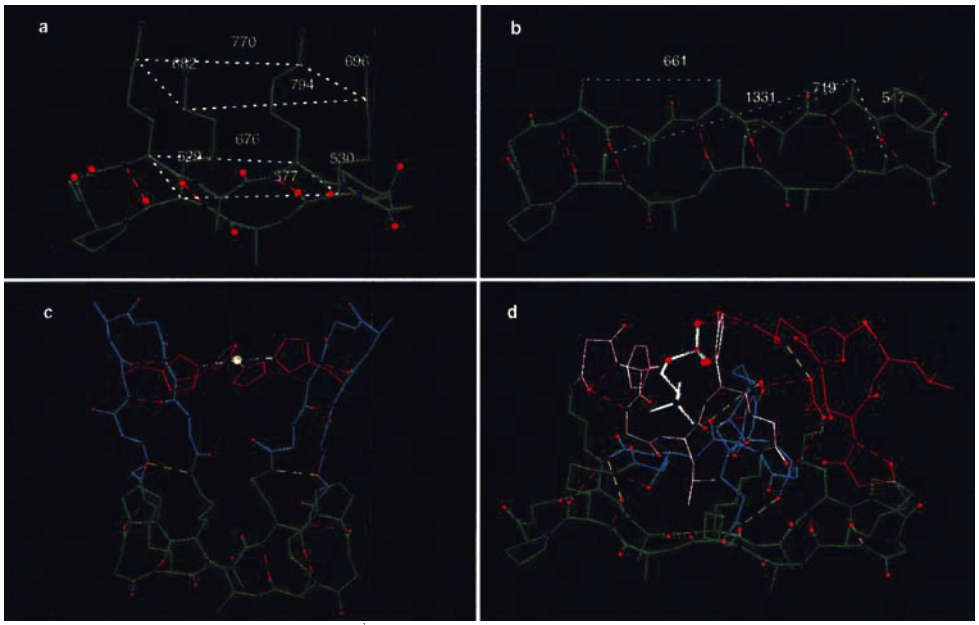

Fig. 2. Design of TASP compounds as functional protein mimetics. a) A cyclic $(ProGlyLysAlaLys)_2$ β-sheet mimetic (template $\mathbf{T}^2$) generated as a full structure from a regularized protein Cα-trace by using the program MOLOC [23,24]. Recent NMR/RMD investigations [15] reveal that the cyclopeptide adopts an antiparallel β-sheet structure spanned between two β-turns of type II. The given idealized $C_\alpha - C_\alpha$ distances [pm] indicate that the mean longitudinal distances are approximately 1.4 Å larger than the transannular ones, whereas the distances on the level of the attachment sites $C_\varepsilon - C_\varepsilon$ may adjust through a type of "crankshaft" motion along the $C_\gamma - C_\delta$ bond into distances suitable to accommodate a structural unit as exemplified below [25]. b) The extension of the chain of a cyclic peptide to a 14-mer unit $(ProGlyLysAlaLysAlaLys)_2$ ($\mathbf{T}^1$) increases the number of potential attachment sites and range of accessible distances. Thus larger distances become accessible to span functional loops that may even mimic an enzymatic binding cavity. c) Two-loop TASP **TASP II** with a square-planar metal binding site that is formed by condensation of two identical HisAlaGlyHisGly sequences on an 10-mer template ($\mathbf{T}^2$). The conformation was optimized by MAB force field calculations [24]; the metal binding geometry was deduced by weighted superposition of the histidine side chains onto the X-ray crystal structure of tetrakis(imidazole)copper(II) sulfate [26]. d) Representation of one of the eight possible directional isomers of a three-loop TASP as a mimetic for the antigen binding site of the phosphorylcholine specific antibody McPC603 [18,19]. In this model selected side chains were considered to be flexible; zero-distance and weak hydrogen bond constraints are sufficient to retain the shape of the binding cavity to enable it to host the amphiphilic zwitterionic species.

N-terminal amino group of the loop $\mathbf{L}^i$ (step 3) and activation of the carboxyl group on the template (step 4) completes the cyclization of the loop (amide 2). Alternatively, the selective attachment of the N-terminal end may proceed by the formation of an oxime bond after the aminooxy group on the template has been deprotected (step 2 in strategy B). The condensation of peptides containing the same functional groups at both chain ends (for example carboxyl or aldehyde groups, strategies A′ and D, respectively) proceeds in one step and results in a mixture of two isomers with differently oriented loops. These strategies are very suitable for preparing TASP compound libraries for functional screening.[16] Chemoselective ligation procedures[9–12] allow for the condensation of completely unprotected peptides in aqueous solution or solvent mixtures (strategies C and D). Here, the regioselective attachment of a loop peptide to the template in one single condensation step (strategy C) can be achieved by the combination of two orthogonal ligation techniques (e.g. oxime and thioether formation).

The individual strategies (Scheme 1) were evaluated by fixing peptide loops $\mathbf{L}^i$ of different chain length and sequence to cyclic peptides (see Fig. 2a and b) as regioselectively addressable templates $\mathbf{T}^i$ (Table 1). The kinetics of the reaction were monitored by analytical HPLC (Fig. 3) and the target molecules were characterized mainly by ES mass spectrometry, amino acid analysis, and NMR spectroscopy. Typically, the condensation proceeds

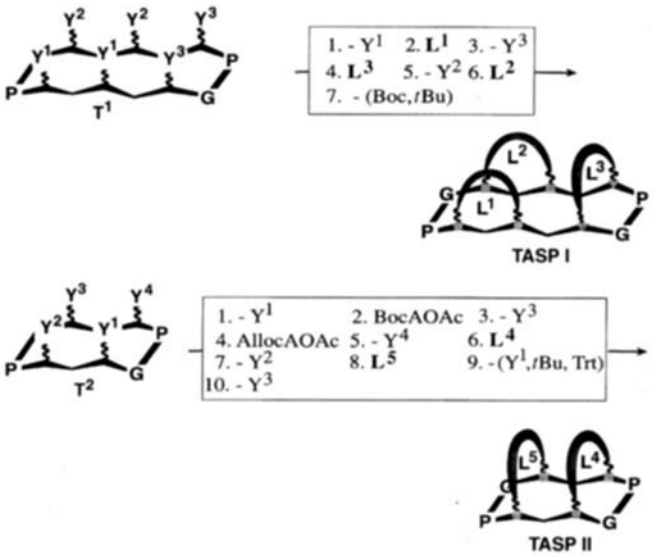
to completion within less than two hours by applying equimolar amounts of L^i and **T** (Fig. 3a, b). In strategy A′ and D, the reaction between L^i and **T** is performed at high dilution ($<10^{-3}$ M) in order to enhance intramolecular loop cyclization. Under these conditions, we observe a pronounced difference in the reaction kinetics of the first and second attachment step: after fixation of one chain end of the loop L^i to the template, the loop cyclization reaction proceeds very fast, as indicated by the absence of the intermediate noncyclized molecule. Apart from the selective fixation of the C- and N-terminal end of a loop L^i as in strategies A–C, the noncyclic intermediate (Fig. 3a in brackets) is only detected when the cyclization is sterically hindered due to the presence of several loops on the template. However, even the condensation of a designed 18-mer peptide to a bifunctional template by oxime bond formation (L^7, strategy D) proceeded without detectable amounts of the intermediate species (Fig. 3b). The increased tendency for loop cyclization on topological templates compared to the regular head-to-tail cyclization reactions is in accord with the theory of peptide macrocyclization.[17]

Starting from a pool of *n* orthogonal amino or carboxyl protecting groups, up to *n* different loops can be selectively fixed according to the individual strategies depicted in Scheme 1. By extending the palette of orthogonal protecting groups and by combining various ligation techniques, TASP compounds of higher structural and functional complexity (including TASP compound libraries) become accessible.

As a first example of a potentially ligand (metal, substrate, antigen, transition state analogue) binding TASP compound, peptides derived from the CDR (complementarity-determining region) loop sequences of the phosphorylcholine binding monoclonal antibody McPC603[18, 19] were covalently attached to a topological template (Fig. 2d, **TASP I** in Scheme 2). Starting from a cyclic peptide with pairs of selectively addressable reactive sites, the stepwise condensation of three peptides (L^1–L^3) by amide bond formation according to strategy A′ provided **TASP I** in high yield and purity (Fig. 3c, left). It is noteworthy that even in the presence of two loops on the template, the condensation of the third loop proceeded smoothly as shown by the HPL chromatogram. Interestingly, the isomers (exhibiting the same molecular mass, Fig. 3c, center) with differently oriented loops were obtained in nonequimolar amounts, indicating an energetic nonequivalence of the different loop orientations. The CD spectra (Fig. 3c, right) show the characteristic features of a loop cluster conformation.[15, 20]



Scheme 2 Synthetic strategies for the assembly of **TASP I** (Fig. 2d) and **TASP II** (Fig. 2c). **TASP I**: L^1–L^3, T^1; **TASP II**: L^4, L^5, T^2 (Table 1).

The regioselective fixation of loops (strategy B) for TASP compounds with defined chain topology was illustrated by the design and synthesis of a potentially metal binding 2-loop TASP (Fig. 2c, **TASP II** in Scheme 2). To this end, two amino groups of the template T^2 were transformed into aminooxy groups as chemoselectively addressable attachment sites (steps 2 and 4 in Scheme 2). Subsequently, two peptides, each containing two histidine residues as metal binding sites (L^5, L^6), were fixed step by step by C-terminal amide and N-terminal oxime bond formation according to strategy B.

These prototype TASP compounds proved to be readily soluble in aqueous buffer solutions and polar organic solvents, and thus allowed a variety of biochemical investigations of the structure. Preliminary investigations on the conformational and binding properties support the hypothetical structures of T^2 suggested by molecular modeling studies (Fig. 2c, d).[21]

In summary, the presented strategies provide a synthetic entry to a new generation of TASP compounds, thereby extending the template concept[5] in protein design and mimicry. Most notably, the stepwise condensation of peptide loops to regioselectively addressable templates may be performed in aqueous solution and proceeds to completion within hours. The envisaged reattachment of the topological templates to the solid support will further simplify the multistep synthesis of differential loop cyclizations for generating TASP compound libraries. The state-of-the-art in chemoselective ligation and orthogonal protecting techniques determines the number of selectively attachable loops and thus the complexity of the TASP compounds. However, by exploiting the immense repertoire of synthetic organic chemistry for the incorporation of functional groups (sticky ends) into peptide chains, the scope of the present approach will be rapidly expanded. For example, ligand-directed assembly of helices, β-sheets, and loops onto tailor-made templates represents a new tool for studying supramolecular assembly and molecular recognition processes. Furthermore, this novel concept opens the way for a new generation of functional protein mimetics with a pivotal role in drug design.

Experimental Procedure

The templates and loop sequences (Table 1) were synthesized according to standard procedures in solid-phase peptide synthesis [22] by using orthogonally protected Lys, Glu, and Cys residues in the template sequence **T** as selectively addressable attachment sites for the loops. The N-terminal carboxyl group of L^1–L^3 was introduced by treating the resin-bound peptide with succinic anhydride. The aminooxyacetyl group (Y^6 in T^4) was introduced by coupling Y^iHNOCH_2COOH to the ε-NH_2 group of the lysine residue [9,11]. The aldehyde function in the loop sequences (**L**) was generated by mild oxidation ($NaIO_4$) of a serine residue attached either at the N-terminus (L^4, L^5, strategy B) or at the side chain of a lysine residue (L^6, L^7, strategies C, D). Coupling of maleoyl-β-alanine (Mal) with PyBop (PyBop = benzotriazol-1-yloxytris(pyrrolidino)phosphonium hexafluorophosphate) at the N-terminus (L^6) provided the functional group Mal applied in strategy C [12]. For the condensation of the loops L^i to the templates T^i, 1.1 equivalents of L^i were added to a 1 mM solution of T^i. Amide bond formation (A, B) was achieved by using PyBop as coupling reagent in DMF, oxime formation in acetate buffer, pH 4.5 (C,D), and thioether formation in buffer pH 7 (in combination with oxime pH 4; C). In general, the condensation reaction proceeded to completion within less than two hours at room temperature.

TASP I was synthesized by sequential removal of the Boc (TFA), Alloc ($[(Ph_3P)_2PdCl_2]/Bu_3SnH$), and Dde (2% $H_2NNH_2 \cdot H_2O$ in DMF) amino protecting groups in the template T^1 and subsequent ligation of L^1–L^3 in DMF through the activated N- and C-terminal carboxyl groups (1 equiv PyBop; strategy A′). After the final deprotection step (TFA), the target molecules were purified by reversed-phase HPLC (Vydac, C18) and characterized by ES-MS (Fig. 3c).

For the synthesis of **TASP II** (Scheme 2), the Boc amino protecting group in the template T^2 was removed (TFA) and the amine coupled with $BocHNOCH_2COOH$ (PyBop, DMF). In the second step, the Alloc group of T^2 was removed with

[$(Ph_3P)_2PdCl_2$]/Bu_3SnH] and AllocHNOCH$_2$COOH coupled to the ε-NH_2 group of the lysine residue (PyBop, DMF). After removal of the Fmoc group with 20% piperidine in DMF, L^4 was ligated through its C-terminal carboxyl group to the free ε-NH_2 group of lysine in T^2 (PyBop, 1 equiv); after removal of the Dde protecting group with 2% $H_2NNH_2 \cdot H_2O$ in DMF, L^5 was attached in the same manner. Subsequently, all acid-labile protecting groups were removed with TFA, the N-terminal serine residue in L^4 was oxidized with $NaIO_4$, and the first oxime bond was formed. Finally, Aloc was cleaved with [$(Ph_3P)_2PdCl_2$]/Bu_3SnH and the N-terminal serine residue in L^5 transformed to an aldehyde ($NaIO_4$), which readily formed the second oxime bond. The target molecules were characterized by ES-MS and amino acid analysis.

[17] According to cyclization theory, the cyclization equilibrium constant K is proportional to the volume density $W(r)$ of the head to tail vectors $\langle r \rangle$ (where $\langle\ \rangle$ denotes the statistical mechanical average of r over all accessible loop conformations). Assuming in a first approximation a random coil conformation of the flexible loop sequence and a Gaussian distribution of $\langle r \rangle$, $W(r)$ at a fixed distance r_1 of the reacting chain ends (r_1 corresponds to the distance between the loop attachment sites on the template) approaches a maximal value for $r_1 \approx \langle r \rangle$. Consequently, the tendency for ring closure in loop condensation reactions (where $r_1 \rightarrow \langle r \rangle$) is predicted to be higher than in regular cyclization reactions (where $r_1 \rightarrow 0$). see: M. Mutter, *J. Am. Chem. Soc.* **1977**, *99*, 8307.

Synthesis, Crystal Structure, and Magnetic Properties of an Octanuclear Nickel(II) Complex with a *hexahedro*-Ni_8 Core**

Juan Faus,* Francisco Lloret, Miguel Julve, Juan M. Clemente-Juan, M. Carmen Muñoz, Xavier Solans, and Mercedes Font-Bardía

There is currently great interest in polynuclear complexes of transition metals, a large and structurally diverse class of compounds.[1] Polynuclear high-spin nickel(II) complexes have been isolated with a large number of ligands, and much attention has been devoted to the study of their magnetic properties.[2] Most of them are dinuclear, but several trinuclear and cubane-like tetranuclear species have been studied.[2–4] Complexes of higher nuclearity are very scarce, although a few pentanuclear aggregates are known.[5] Very recently, a undecanuclear and a cyclic dodecanuclear species have been characterized.[4, 6]

The violurate anion H_2vi^- (H_3vi = violuric acid or 5-(hydroxyimino)-2,4,6-(1*H*,3*H*,5*H*)-pyrimidinetrione) is a strong-field, bidentate ligand, which coordinates to transition metal ions through the oxime-N atom and the O atom of a vicinal carbonyl group to form a five-membered chelate ring (Fig. 1).[7] Potentially, H_2vi^- is an ambidentate ligand, since it might bind the metal ions through the oxime-O atom and the O atom of the other vicinal carbonyl group to form in this case a six-membered chelate ring; it therefore might also be a bis(bidentate) bridging ligand (Fig. 1). However, these coordination modes have not been characterized up to now.

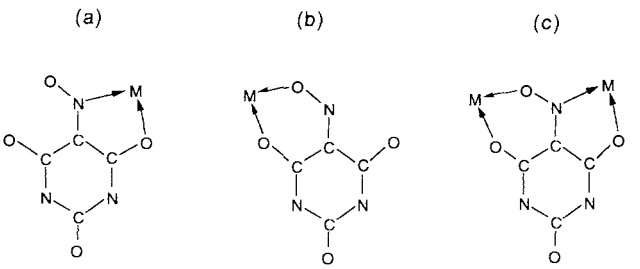

Fig. 1. Possible coordination modes of the violurato ligand (hydrogen atoms are not shown): a) bidentate-*N*,*O*; b) bidentate-*O*,*O* (unknown); c) bis(bidentate), bridging (this work).

Metal ion coordination increases the acidity of H_2vi^- considerably, which undergoes deprotonation much more easily than as a free acid.[8] The resulting Hvi^{2-} anion should exhibit a greater tendency to act as a bridging ligand, but although the deprotonation of some violurato complexes was investigated,[8] no polynuclear species is known.

[**] This work was supported by the Spanish Dirección General de Investigación Científica y Técnica (DGICYT) (Projects PB94-1002 and PB94-0998) and the Human Capital and Mobility Program (Network on Magnetic Molecular Materials from EECC) through Grant ERBCHRX-CT920080.

Studies of complex formation between Ni^{2+} and H_2vi^- in a mixture of dimethylsulfoxide (DMSO) and water (80/20) as solvent showed the stepwise formation of mononuclear 1:1, 1:2, and 1:3 complexes.[9] The neutral 1:2 species is insoluble in water and precipitates quantitatively as $[Ni(H_2vi)_2(H_2O)_2]\cdot 3H_2O$; the anionic complex $[Ni(H_2vi)_3]^-$ has been isolated from ethanolic solutions as a sodium salt.[10] Although deprotonation products of these complexes were also reported,[9, 10] their molecular structures remain unknown.

We report here the synthesis, crystal structure, and magnetic properties of **1**, a compound that contains an octanuclear Ni^{II}

$K_4[Ni(H_2O)_6][Ni_8(Hvi)_{10}(H_2vi)_2]\cdot 20H_2O$ **1**

complex ion consisting of a cubic aggregate of nickel atoms linked by twelve μ-violurato ligands. A planar, octagonal, diamagnetic thiolatonickel(II) complex was characterized some years ago,[11] but **1** is the first paramagnetic octanuclear Ni^{II} complex. As far as we know, the only precedent for a *hexahedro*-Ni_8 geometry is found in the compounds $[Ni_8(\mu_4\text{-}PPh)_6(CO)_8]$, $[Ni_8(\mu_4\text{-}PPh)_6(CO)_4(PPh_3)_4]$, and $[Ni_8(\mu_4\text{-}PPh)_6Cl_4(PPh_3)_4]$, three closely related metal clusters with Ni–Ni bonds along the edges of the cube.[12]

Beautiful, black prisms of **1** are obtained in high yield in a one pot synthesis by slow precipitation of aqueous solutions of potassium acetate containing Ni^{2+} and H_2vi^- in a ligand-to-metal ratio of less than 2. Its formula could not be established by elemental analysis, but was determined by crystal structure analysis by X-ray diffraction.

Crystals of **1** consist of octanuclear $[Ni_8(Hvi)_{10}(H_2vi)_2]^{6-}$ complex anions, $[Ni(H_2O)_6]^{2+}$ and K^+ cations, and many molecules of water of crystallization. Each anion is formed by eight Ni^{2+} ions arranged at the vertices of a cube (edge length 4.8 Å) and linked through twelve bis(bidentate) violurato ligands (Fig. 2). There are no terminal ligands. Two ligands are coplanar with each face of the cube in such a way that the oximato bridges span two opposite edges in opposite directions. The N–O bonds cut the edges with angles varying between 23° and 53°, connecting two nickel atoms in a *trans* conformation. As far as we know, this is a new coordination mode for a μ-oximato ligand and causes a much longer metal–metal distance than the usual *cis* conformation.[13] The electric charge on the anion of 6 – is defined by the number of countercations, namely one $[Ni(H_2O)_6]^{2+}$ and four K^+ ions, which implies that ten of the twelve violurato ligands are Hvi^{2-} and two are H_2vi^- ions. Most likely, crystal packing effects dictate the incomplete deprotonation of the ligands. Each nickel(II) ion is coordinated to three ligands to give an octahedral geometry. Two different metal environments (NiN_3O_3 and NiO_6) alternate at the vertices of the cube. However, the complex unit has only a ternary axis and no twofold axis, with the result that four metal ions and four ligands are nonequivalent by symmetry.

We can rationalize the formation of this polynuclear complex as the result of the interaction between monomeric complexes $[Ni(Hvi)_3]^{4-}$ and Ni^{2+}. $[Ni(Hvi)_3]^{4-}$ can act as a tris(bidentate) O-donor ligand (μ_3-ligand) binding three Ni^{2+} cations. In this tetranuclear fragment the lines joining the central metal ion with the peripheral ones are mutually perpendicular, defining the corner of a cube. On the other hand, one Ni^{2+} can bind three of ligand complexes with the same Ni_4 geometry as above. Thus, the formation of a discrete *hexahedro*-Ni_8 species is a natural consequence of the spatial arrangement of three bidentate ligands around the metal ion in an octahedral complex and the relative position of the two pairs of donor atoms in a violurato bridge. It should be possible to synthesize similar homo- or even heterometallic cubic complexes with other metal ions.

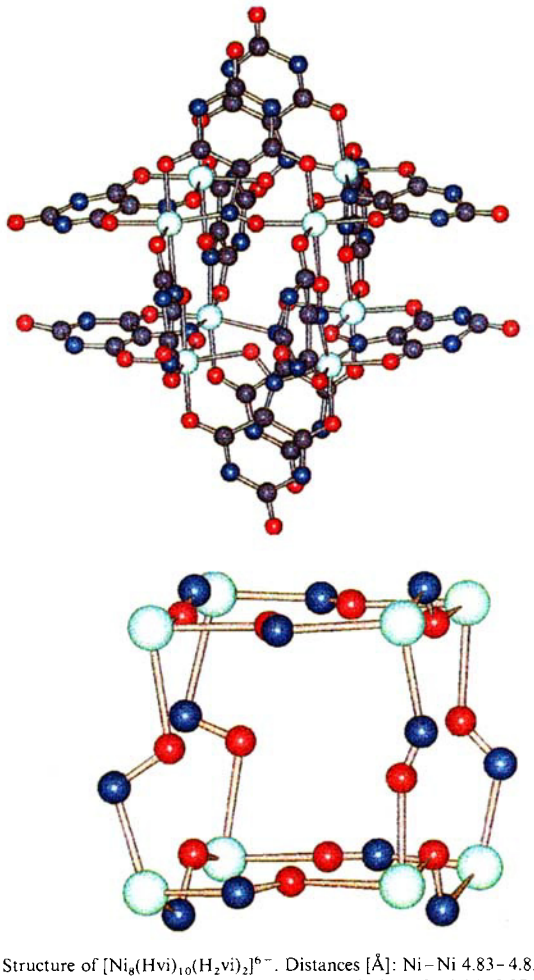

Fig. 2. Top: Structure of $[Ni_8(Hvi)_{10}(H_2vi)_2]^{6-}$. Distances [Å]: Ni–Ni 4.83–4.85, Ni–O 1.97–2.22, Ni–N 2.01–2.30. The nickel atoms are displaced by 0.06–0.07 Å above and below the mean planes of the square faces, which form dihedral angles of 90°. The dihedral angles between the mean planes of the violurato ligands and the faces of the cube vary between 4 and 7°. Bottom: A detail of the structure of $[Ni_8(Hvi)_{10}(H_2vi)_2]^{6-}$ showing only the nickel ions and the oximato groups of the violurato ligands.

The magnetic properties of **1** are shown in Figure 3. The product of the molar magnetic susceptibility by the absolute temperature (χT) decreases quickly on cooling, and a plot of this product against temperature gives a smooth sigmoidal curve. The value of χT at room temperature (7.5 $cm^3 mol^{-1} K$) is significantly smaller than that calculated for nine noninteracting Ni^{II} ions. This decrease reveals that a strong antiferromagnetic coupling is occurring among nickel(II) centers at distances of 4.8 Å. The value of χT at 4 K of 1 $cm^3 mol^{-1} K$ is due exclusively to the isolated $[Ni(H_2O)_6]^{2+}$ countercation; the cubic octanuclear complex has become diamagnetic.

Magnetic data have been analyzed with the spin Hamiltonian $\hat{H} = -J\sum S_i S_j$ ($i<j$, $i=1-8$). Calculations have been performed with a general program that takes into account the isotropic exchange interactions between the eight magnetic centers with the same spin, $S=1$. The effective Hamiltonian has been written in terms of irreducible tensors by applying the Wigner-Eckart theorem and the usual method of successive couplings. The theoretical curve fits the experimental data very well with $J = -60\ cm^{-1}$ and $g = 2.27$. A fixed χT contribution of 1.2 $cm^3 mol^{-1} K$ has been considered for the $[Ni(H_2O)_6]^{2+}$ ion. The limiting value at infinite temperature with uncoupled

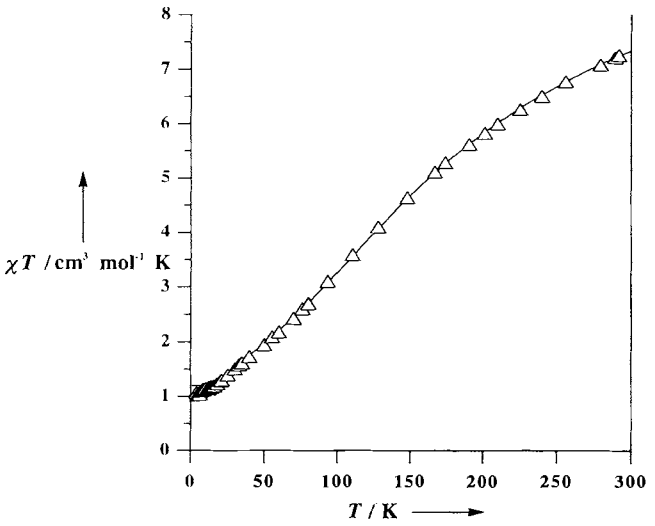

Fig. 3. Temperature dependence of χT for **1**. Triangles represent experimental points and the continuous line is the theoretical curve.

magnetic centers is 11.3 $cm^3 mol^{-1}$ K. This strong coupling is in agreement with the magnetic behavior of other oximato ligands[13] and clearly shows the special ability of a *trans* μ-oximato group to transmit electronic effects between distant metal ions.

The energy level diagram is complicated. It consists of 1107 different spin states associated with nine different values of total spin, from $S = 0$ to $S = 8$. The ground state is a singlet, the most excited state the only one with $S = 8$, and the energy gap between them about 1600 cm^{-1}.

Experimental Procedure

Synthesis of **1**: Potassium acetate (10 g) and nickel(II) acetate tetrahydrate (249 mg, 1 mmol) were dissolved in water (100 mL) under gentle heating. Violuric acid monohydrate (232.75 mg, 1.33 mmol) and LiOH (55.86 mg, 1.33 mmol) dissolved in water (50 mL) were then added. On standing, a black crystalline solid separated from the resulting dark solution. Precipitation began in a few hours and was complete in about two days. The solid was filtered, washed with water, and dried in the air (yield 85%). Anal.: C 18.7, N 16.39, H 1.95%; calcd: C 19.12, N 16.7, H 2.18%. The crystals obtained were suitable for X-ray diffraction studies.

Crystal structure analysis: Prismatic crystal, $0.1 \times 0.1 \times 0.2$ mm, crystal system trigonal, space group $R\bar{3}$, with $a = b = 16.007(2)$, $c = 36.284$ Å, $\alpha = \beta = 90°$, $\gamma = 120°$, $V = 8051(2)$ Å^3, $Z = 3$, $\rho_{calcd} = 1.840$ g cm^{-3}, $1.57° < \theta < 27°$, $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å), $T = 293(2)$ K. Of 4351 independent reflections measured ($\omega/2\theta$ scan), 2691 were assumed as observed ($I > 2\sigma(I)$). Lorentz polarization corrections but no absorption corrections were made. Absorption coefficient $\mu = 1.826$ mm^{-1}. The structure was solved by direct methods with the SHELXS computer program [14], 518 parameters refined by full-matrix least-squares method with the SHELXL-93 program [15], 3349 reflections used (very negative intensities not included). Hydrogen atoms were not found. $R = 0.0709$, $wR = 0.175$ (on $|F|^2$). Max./min. peaks in final difference synthesis 0.820/ − 0.580 e Å^{-3}, respectively. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-61. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (Fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk.)

Sequence-Specific Recognition of DNA by a Major and Minor Groove Binding Ligand**

Jason W. Szewczyk, Eldon E. Baird, and Peter B. Dervan*

Two nonbiological approaches for the sequence-specific recognition of double helical DNA that target a broad repertoire of sequences are oligonucleotide-directed triple helix formation[1] and pyrrole/imidazole polyamide–DNA complexes.[2] For recognition of the major groove of DNA, a pyrimidine oligonucleotide binds parallel to the purine Watson–Crick strand.[1] Specificity is derived from thymine (T) recognition of adenine–thymine base pairs (T·AT base triplets) and protonated cytosine (C^+) recognition of guanine–cytosine base pairs (C^+·GC base triplets).[1] For recognition of the minor groove of DNA, polyamides containing *N*-methylimidazole (Im) and *N*-methylpyrrole (Py) amino acids are combined side-by-side and the DNA sequence-specificity is controlled by the linear sequence of pyrrole and imidazole amino acids.[2–4] Antiparallel pairing of imidazole (Im) opposite pyrrolecarboxamide (Py) targets a GC base pair, while pyrrolecarboxamide opposite imidazole targets a CG base pair.[2] A pyrrole/pyrrole pairing combination is partially degenerate and targets both TA and AT base pairs.[2, 3] A pyrrole/imidazole polyamide "hairpin" with γ-aminobutyric acid (γ) serving as a "turn monomer" provides a versatile motif for high-affinity recognition of a wide variety of sequences in the minor groove of DNA.[5] A key issue is to determine if the models of both major and minor groove binding

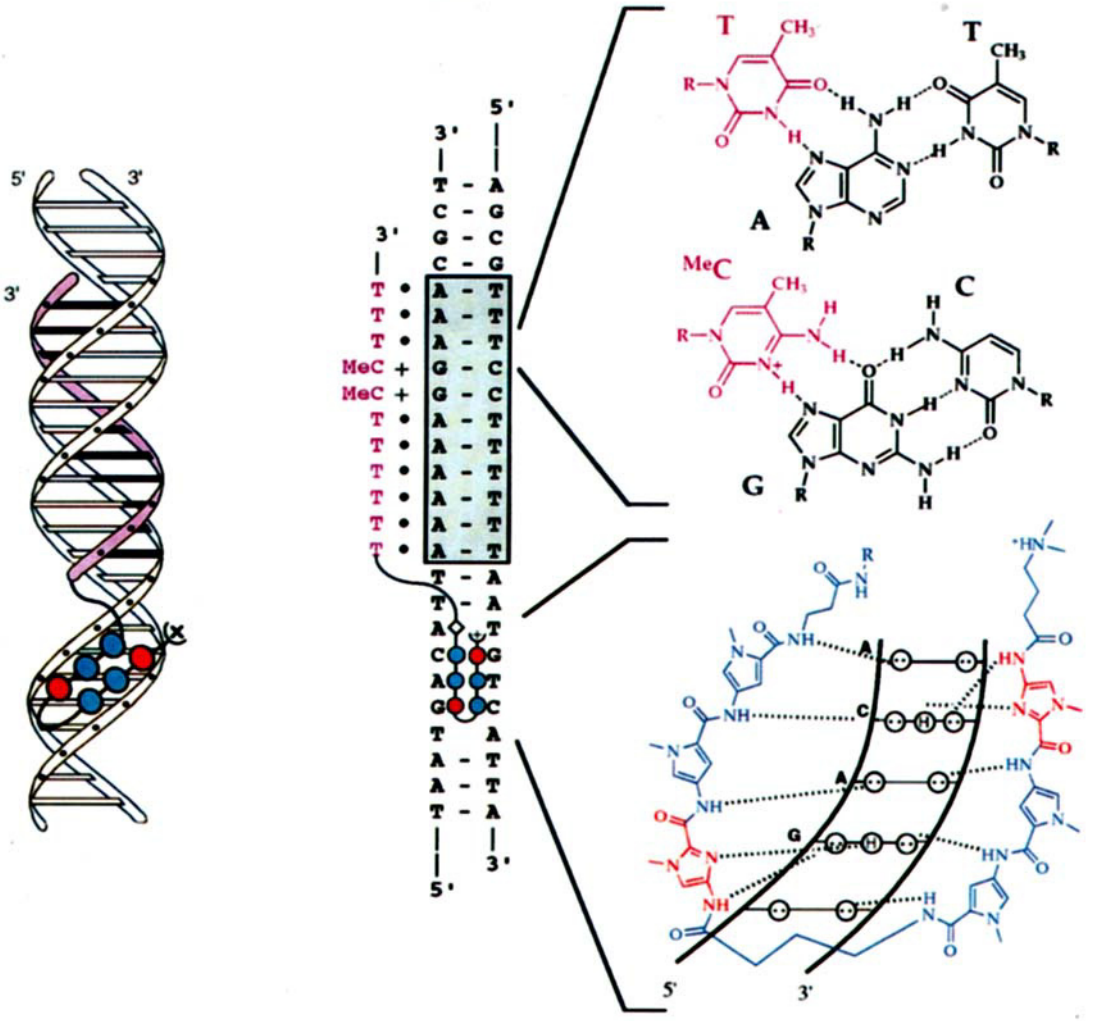

Fig. 1. Left: A ribbon model depicting a hairpin pyrrole/imidazole polyamide–oligonucleotide simultaneously binding the major and minor grooves of double helical DNA. The red and blue circles represent *N*-methylimidazole and *N*-methylpyrrole rings, respectively, and the diamond represents β-alanine. Right: Two-dimensional models depicting the molecular interactions responsible for sequence-specific recognition. Top right: The TAT and CGC base triplets formed by Hoogsteen hydrogen bonding of T to a Watson–Crick AT base pair and protonated ^{Me}C to a Watson–Crick GC base pair, respectively. The bases in the third strand are depicted in lavender, the bases in the Watson–Crick strand are depicted in black. Bottom right: Expected complex of ImPyPyγImPyPyβ with the binding site 5′-TGACA-3′. Circles with dots represent lone pairs on N3 of purines and O2 of pyrimidines, and circles containing an H represent the N2 hydrogen on guanine. Putative hydrogen bonds are illustrated by dashed lines.

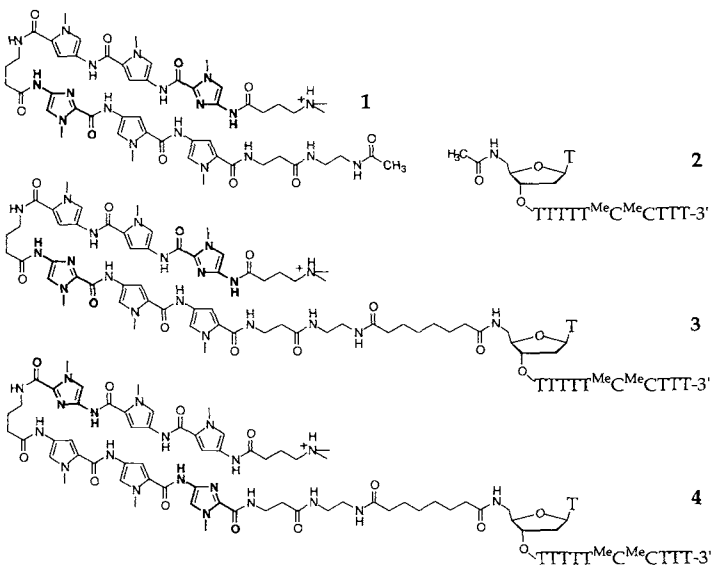
recognition can be combined within a single molecule without compromising the sequence specificity of either recognition domain.

We report that a hairpin polyamide linked to an 11-mer oligonucleotide specifically and simultaneously binds the major and minor grooves of DNA at subnanomolar concentration. A pyrimidine oligonucleotide, 5′-TTTTTT^{Me}C^{Me}CTTT-3, covalently tethered by a twelve-atom linker to the polyamide of sequence composition ImPyPyγImPyPyβ (β = β-alanine) binds to 16 base pairs of double helical DNA by formation of a specific hairpin pyrrole/imidazole polyamide–DNA complex in the minor groove and a specific triple helix in the major groove (Fig. 1). According to the two binding models, the hybrid ligand–DNA complex affords 10 discrete hydrogen bonds for recognition of 5 base pairs in the minor groove (5′-TGACA-3′) and 22 discrete hydrogen bonds for recognition of 11 base pairs in the major groove (5′-AAAAAAGGAAA-3′).

The polyamide ImPyPyγImPyPyβ, modified with a free primary amino group at the C terminus, was prepared by solid-phase methods[6, 7] and allowed to react with either acetic anhydride to provide control hairpin **1**, or with a support-bound *N*-hydroxysuccinimide ester of a suitably 5′-modified 11-mer oligonucleotide 5′-TTTTTT^{Me}C^{Me}CTTT-3′ to provide the conjugate, ImPyPyγImPyPyβ-(linker)-TTTTTT^{Me}C^{Me}CTTT-3′ **3** upon deprotection.[8] Similarly, a control conjugate **4** was synthesized with a "reverse" polyamide sequence composition PyPyImγPyPyImβ. Polyamide–oligonucleotides **3** and **4** were purified by reverse-phase HPLC and the molecular composition



was verified by MALDI-TOF mass spectrometry,[9] UV spectroscopy,[10] and HPLC analysis of the products of enzymatic phosphodiester hydrolysis. A DNA fragment was constructed that contains the 18 base pair site 5′-*TGACA*T-*TAAAAAAGGAAA*-3′ composed of a 5 base pair polyamide binding site separated by two base pairs from an 11 base pair triple helix site. For controls, isolated 5 base pair polyamide and

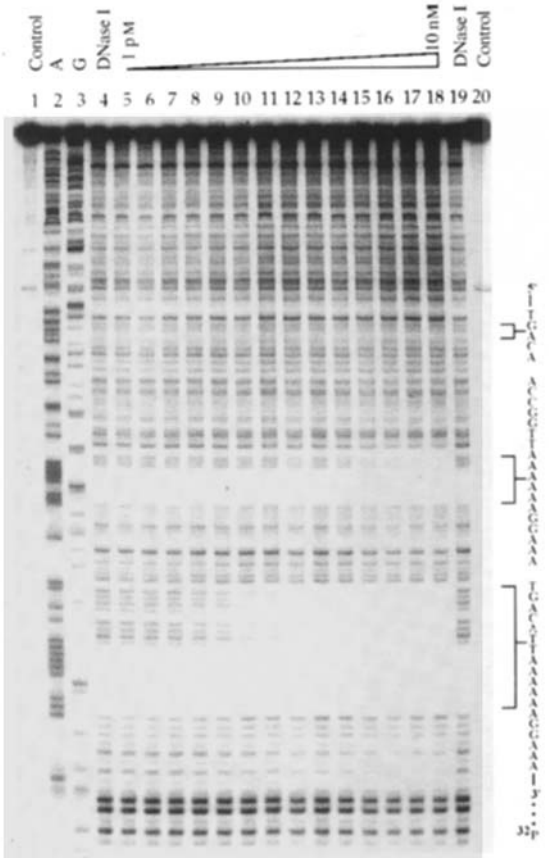


Fig. 2. DNaseI footprinting titration of pyrrole/imidazole polyamide–oligonucleotide **3** with a ^{32}P end-labeled 302 base pair restriction fragment. Gray scale representation of a storage phosphor autoradiogram of a 8% denaturing polyacrylamide gel representing a tenfold change in the signal from the lowest (5 arbitrary units, white) to highest (50 arbitrary units, black) intensities. The binding site is shown to the right of the autoradiogram. Lanes 1 and 20: intact DNA; lane 2: A reaction; lane 3: G reaction; lanes 4 and 19: DNaseI standard; lanes 5–18: 1, 5, 10, 20, 50, 100, 150, 250, 400, and 650 pM, and 1.5, 2.5, 6.5, and 10 nM polyamide–oligonucleotide **3**, respectively.

11 base pair triple helix binding sites were also present on the fragment.[11]

Quantitative DNaseI footprint titration experiments[12] on a 302 base pair restriction fragment afford the binding affinities of the designed ligands (Fig. 2). Polyamide **1** binds to five base pairs of the target site 5′-TGACATTAAAAAAGGAAA-3′ with an equilibrium association constant, $K_a = (1.3 \pm 0.3) \times 10^8\ M^{-1}$. Unmodified oligonucleotide **2** binds eleven base pairs 5′-TGACATTAAAAAAGGAAA-3′ with an equilibrium association constant, $K_a = (2.5 \pm 0.8) \times 10^5\ M^{-1}$. The hybrid polyamide–oligonucleotide **3** binds the designated target site 5′-TGACATTAAAAAAGGAAA-3′ with an apparent first-order equilibrium association constant, $K_a > 2 \times 10^{10}\ M^{-1}$,[13] representing at least a 150-fold increase in binding affinity relative to the unlinked subunits. In controls, the binding affinity of **3** at either the five base pair polyamide binding site, 5′-TGACATTAGCTCGTAATG-3′, ($K_a < 1.0 \times 10^5\ M^{-1}$) or the oligonucleotide eleven base pair site, 5′-ACCGGTTAAAAAAGGAAA-3′, ($K_a = 1.9 \times 10^9\ M^{-1}$) is reduced by approximately tenfold relative to binding at the designated match site. Mismatch polyamide–oligonucleotide **4**, binds the 18 base pair target, 5′-TGACATTAAAAAAGGAAA-3′, ($K_a = (6.1 \pm 0.2) \times 10^7\ M^{-1}$) with 300-fold reduced affinity relative to the match conjugate **3**.

Polyamide–oligonucleotide **3** binds with subnanomolar affinity only at the designated target site, indicating that the 3.0 kcal mol^{-1} binding enhancement results from *simultaneous* expand the repertoire of sequences targeted by artificial methods and create a new motif for the design of molecules for the sequence-specific recognition of both grooves of the DNA double helix.

[10] The UV spectrum of the polyamide–oligonucleotide is a summantion of the spectra of the individual components: λ_{max} (ε) [H_2O] = 260 nm (138000), 310 nm (54000).

[11] The plasmid pCON1 was prepared by hybridization of two complementary sets of synthetic oligonucleotides 5′-d(CCGGGAACGTAATGACATTAGCTCG-TAATGTTATTAGCTCGCTAAGGT-CATTACCGGTTAAAAAAGGAA-ACGCTCGA)-3′,5′-d(GGCGTCGAGCGTTT-CCTTTTTTAACCGGTA-ATGACCTTAGCGAGCTAATAACATTACGAGCTAATGTC-ATTACG-TTC)-3′ and 5′-d(CGCCGCTAATGACATTAAAAAAGGAAACGCTC-GAGCTCGTGGGCCCTAGCGTCGTAGCTAGCGTCGTCTTAAG)-3′,5′-(TCGA-CTTAAGACGACGCTAGCTACGACGCTAGGGCCCACGAGC-TCGAGCGTTTCCTTTT-TTAATGTCATTAGC)-3′, which were subsequently ligated into pUC19 previously cleaved with *Ava*I and *Sal*I. The plasmid was digested with *Afl*II, labeled at the 3′ end, and digested with *Fsp*I. The 302 base pair restriction fragment was isolated by nondenaturing gel electrophoresis and used in all experiments described here.

[12] The quantitative footprint titration experiments were executed in a total volume of 400 μL with a final concentration of each species as indicated. The ligands were added to solutions of radio-labeled restriction fragment, NaCl (10 mM), Bis Tris·HCl (10 mM, pH 7.0), and spermine (250 μM), and incubated for 24 h at 22 C. Footprinting reactions were initiated by addition of 10 mL stock solution of DNaseI (2.4 units mL^{-1}) containing $MgCl_2$ (200 mM), $CaCl_2$ (200 mM), Bis Tris·HCl (10 mM), and glycerol (20%), and allowed to proceed for 6 min at 22 C. The reactions were quenched by addition of 50 μL of a solution made up of 107 μL of water, 788 μL of NaCl (4 M), 425 μL of EDTA (0.5 M, pH 8.0), 40 μL of calf thymus DNA (1 mM base pairs), 40 μL of glycogen (20 mg mL^{-1}). The DNA was precipitated by addition of ethanol, resuspended in 80% formamide loading buffer, and analyzed by electrophoresis on an 8% polyacrylamide denaturing gel at 2000 V for 1 h. Data analysis were performed as previously described [5a].

[13] Equilibrium association constants. $K_a > 1 \times 10^{10}\ M^{-1}$ determined by quantitative DNaseI footprint titration experiments represent lower estimates.

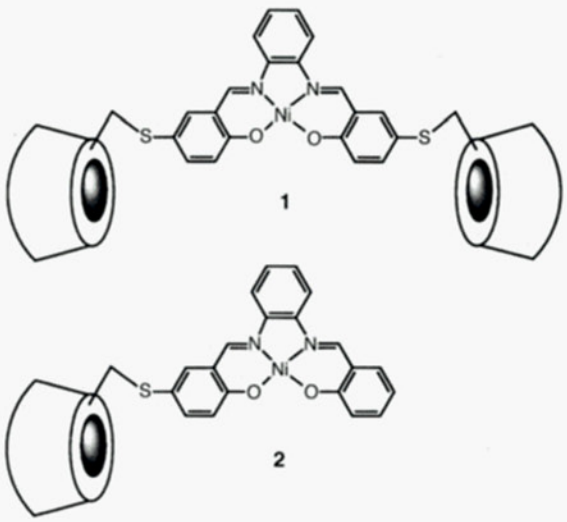
Selective Binding of the Dipeptides L-Phe-D-Pro and D-Phe-L-Pro to β-Cyclodextrin**

Milana Maletic,* Helma Wennemers,* D. Quentin McDonald, Ronald Breslow, and W. Clark Still

Over the past three decades inclusion complexes of cyclodextrins have emerged as one of the paradigms of host–guest chemistry.[1] The hydrophobic effect, which determines the binding of substrates to enzymes and antibodies to antigens, also drives the binding of hydrophobic molecules to cyclodextrins.[2] Although it is known that many biologically important molecules form stable inclusion complexes with cyclodextrins in water, the search for new substrates is continuing. Among the known cyclodextrin substrates are the hydrophobic amino acid residues: phenylalanine, tyrosine, and tryptophan. Their complexes with cyclodextrins have been exploited in enzyme modeling,[3] in drug delivery,[4] and in peptide separations.[5] However, cyclodextrin binding to small peptide fragments is still not well understood. In this report we study the binding of β-cyclodextrin to di- and tripeptides using a combinatorial chemistry approach.

In recent years combinatorial chemistry has become a major tool in the search for suitable substrates for a given receptor and vice versa.[6] By using such methods it has become possible to detect subtle differences in host–guest association, including binding selectivities that could not have been predicted by modeling or easily detected by conventional experiments.[7]

The orange-colored nickel salophen complexes **1** and **2** having two and one β-cyclodextrin substituents, respectively, were screened against a tripeptide library on hydrophilic poly(ethyleneglycol)polystyrene (TentaGel)[8] in water. The library was prepared by encoded split synthesis and had the general structure AA3-AA2-AA1-NH$(CH_2)_2$-Tent aGel.[9] At each position 29 different amino acids were used. Thus, the library contained maximally 29^3 (24389) different tripeptides.[10]



The bis(cyclodextrin) receptor **1** showed remarkably selective binding when screened against the tripeptide library in water at pH 7. After equilibration for 24 h, about 1 out of every 200 beads picked up the orange color of the receptors at a receptor concentration of roughly 2 mM. The same observation was made with the mono(cyclodextrin) receptor (Fig. 1), indicating that a single cyclodextrin unit is sufficient for the observed binding. Addition of sodium 4-*tert*-butylbenzoate as a competitive inhibitor for cyclodextrin caused desorption of the dye from the beads, suggesting the cyclodextrin to be the major locus of peptide binding.

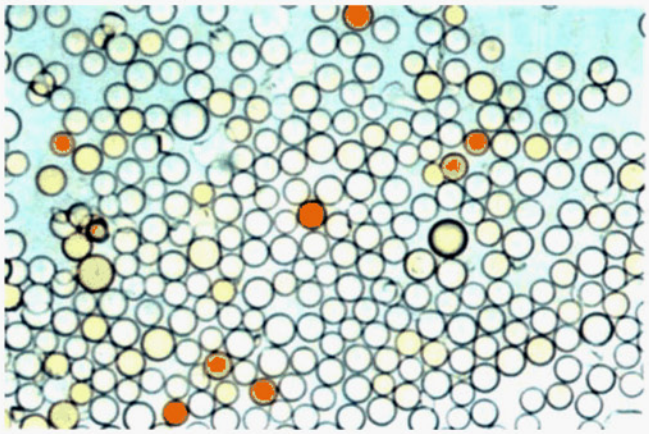


Fig. 1. Picture of a typical binding assay of receptor **2** to the described peptide library.

Decoding the tripeptides on the colored beads by using electron capture gas chromatography revealed a remarkable selectivity: *all* of the selected beads when receptor **1** was used and most of the selected beads when receptor **2** was used bore a sequence containing either L-Phe-D-Pro or D-Phe-L-Pro (Table 1). None of the other possible phenylalanine-containing dipeptides were found, and more interestingly, the diastereomeric, homochiral dipeptides L-Phe-L-Pro or D-Phe-D-Pro were not selected.

Table 1. Sequences selected by receptors **1** and **2** in the assay of the tripeptide library[a].

AA3	AA2	AA1	Frequency of occurrence [%] with 1	2
L-Phe	D-Pro	X	36	46
X	L-Phe	D-Pro	16	8
D-Phe	L-Pro	X	28	31
X	D-Phe	L-Pro	20	0

[a] X represents the third amino acid of the tripeptide.

In order to study this highly selective binding we synthesized the two dipeptides **3** and **4** and determined their binding energies

TFA·H_2N-L-Phe-D-Pro-CONHCH$_3$ **3**

TFA·H_2N-L-Phe-L-Pro-CONHCH$_3$ **4**

to β-cyclodextrin in aqueous solution by NMR-monitored titration. All binding studies were carried out at a constant concen-

tration of 2.0 mM of the dipeptide and with eight different amounts of β-cyclodextrin (0.0–13 mM) in D_2O. The binding curves were fit using KaleidaGraph and the standard iteration procedure.[11]

In the ^1H NMR spectrum of L-Phe-D-Pro mainly (>95%) one conformer, the *s-trans* conformer,[12] is visible and the signals of several protons shift significantly upon addition of β-cyclodextrin. The binding constant was found to be $180 \pm 20\ M^{-1}$ ($\Delta G = -3.0 \pm 0.1$ kcal mol^{-1}). Large upfield shifts are observed for three protons (H3′, H4′, H5′) of proline from one face of the pyrrolidine ring, whereas the three alkyl protons (H3, H4, H5) on the other proline ring face do not shift measurably. This finding is consistent with a binding mode where one face of proline fits over cyclodextrin as a "cap" and the phenyl ring of phenylalanine is fully inserted into the hydrophobic β-cyclodextrin cavity, allowing the more hydrophilic functional groups of the dipeptide to reside in water (see Fig. 2). Both the hydrophobic interaction between the pyrrolidine ring and the cyclodextrin cavity, and the encapsulation of the phenyl ring by the cavity account for the high stability of this complex. The binding constant of the *s-cis* conformer could not be determined due to its small population (< 5%).

The ^1H NMR spectrum of L-Phe-L-Pro shows that two conformers are present in a ratio of 5:1 in favor of the *s-trans* conformer.[12] In contrast to the D-L heteroisomer, the *s-trans* conformer of L-Phe-L-Pro binds to β-cyclodextrin only with low affinity. However, several peaks of the minor *s-cis* conformer exhibit large shifts when β-cyclodextrin is added, accounting for a binding constant of $120 \pm 5\ M^{-1}$ ($\Delta G = -2.8 \pm 0.1$ kcal mol^{-1}). During the binding titration the *s-trans*:*s-cis* ratio changes from 5:1 to 3:1, which is in agreement with the observed binding constant. The binding mode of the minor *s-cis* conformer to β-cyclodextrin seems to be analogous to that of the major *s-trans* conformer of the heterochiral dipeptide; all hydrophilic functional groups are exposed to the solvent. In contrast, the major *s-trans* L-Phe-L-Pro conformer binds more weakly to β-cyclodextrin because some of its hydrophilic functional groups cannot escape exposure to the hydrophobic cyclodextrin cavity. Its binding constant was estimated by NMR to be $20 \pm 5\ M^{-1}$ (saturation ca. 20%), which is on the same order of magnitude as the binding constant of phenylalanine alone to β-cyclodextrin.[4]

As the more tightly binding conformer of L-Phe-L-Pro is present at only 21%, it is not surprising that beads carrying L-Phe-L-Pro never picked up the deep orange color in the solid-phase binding assay.

To further investigate the structure of the dipeptide complexes with β-cyclodextrin, we performed extensive conformational searches using the MacroModel 5.0 program. The calculations used the united atom AMBER* force field[13] and the GB/SA model for water.[14] Searching was performed using the MCMM[15] method in blocks of 5000 steps and was continued until no further low-energy structures (<3 kcal mol^{-1} higher in energy than the global minimum) were located in any block (giving a total of 15000 steps for each complex). The search took account of all rotatable bonds in the peptide as well as rotation and translation of the peptide relative to β-cyclodextrin. The starting geometry of β-cyclodextrin was taken from its X-ray crystal structure.[16]

The conformational searches yielded low-energy structures that support the binding modes of the two dipeptides suggested by our NMR experiments. In the lowest energy structures of L-Phe-D-Pro and β-cyclodextrin, the phenyl and pyrrolidine rings are in close proximity and form a hydrophobic plug that is able to associate strongly with the cavity of the β-cyclodextrin (Fig. 2).

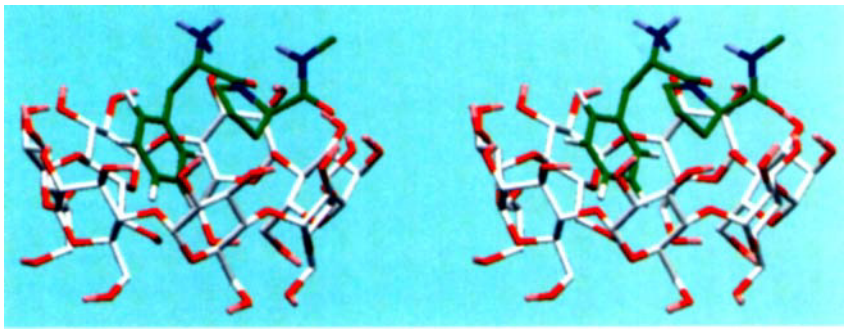

Fig. 2. Stereoview of the lowest energy structure of the complex between L-Phe-D-Pro and β-cyclodextrin as calculated with MacroModel 5.0.

The conformational search of L-Phe-L-Pro and β-cyclodextrin yields a similar structure for the *s-cis* conformer, but there are additional lower energy structures in which only the phenyl ring is included in the cavity and the hydrophobic proline ring is partially exposed to solvent at the cavity entrance.

In summary, by combinatorial means a remarkable binding selectivity of β-cyclodextrin to the enantiomeric dipeptides L-Phe-D-Pro and D-Phe-L-Pro was discovered. With the help of NMR spectroscopy it was possible to propose a binding mechanism. This selectivity could be exploited for the design of novel sequence-specific peptide-cleaving catalysts based on β-cyclodextrin.

Experimental Procedure

3: D-Pro-$NHCH_3$ (90 mg, 0.70 mmol) and *N*-Boc-L-Phe (186 mg, 0.70 mmol) were dissolved in 3 mL of CH_2Cl_2 and coupled with EDC (372 mg, 1.40 mmol). The *N*-Boc protected dipeptide was purified by flash chromatography on silica gel (CH_2Cl_2:acetone 5:1 then 2:1) and crystallization (Et_2O/hexanes). TFA (1 mL) was added to a solution of the *N*-Boc protected dipeptide (200 mg, 0.32 mmol) in 4 mL of CH_2Cl_2. Removal of all volatiles at reduced pressure after 1.5 h afforded 210 mg (80%) of TFA·L-Phe-D-Pro-$NHCH_3$ as a colorless solid. (TFA·L-Phe-D-Pro-$NHCH_3$ **4** was obtained analogously.)

3: TFA·L-Phe-D-Pro-$NHCH_3$ (*trans* conformer): ^1H NMR (500 MHz, D_2O, 25 C, CH_3CN): δ = 1.40 (m, 1H; Pro-H4′), 1.68 (m, 2H; Pro-H3 and Pro-H4), 1.90 (m, 1H; Pro-H3′), 2.60 (m, 1H; Pro-H5′), 2.61 (s, 3H; CH_3), 3.02 (dd, J = 13.4, 9.0 Hz, 1H; Phe-βH), 3.11 (dd, J = 13.4, 6.3 Hz, 1H; Phe-βH′), 3.38 (m, 1H; Pro-H5), 4.14 (dd, J = 4.6, 8.3 Hz, 1H; Pro-αH), 4.41 (dd, J = 6.3, 9.0 Hz, 1H; Phe-αH), 7.21 (m, 2H; arom.), 7.32 (m, 3H; arom.); ^{13}C NMR (75.4 MHz, CD_3OD, 25 C): δ = 25.24, 26.35, 30.78, 38.29, 48.45, 54.19, 61.65, 129.05, 130.07, 130.24, 130.37, 130.61, 135.44, 168.53, 174.55; high-resolution MS calcd for $C_{15}H_{21}N_3O_2$ (M^+): m/z: 275.1534; found: 275.1644.

4: TFA·L-Phe-L-Pro-$NHCH_3$: ^1H NMR (500 MHz, D_2O, 25 C, CH_3CN): *trans* conformer: δ = 1.77 (m, 1H; Pro-H3′), 1.85 (m, 2H; Pro-H4 and Pro-H4′), 2.13 (m, 1H; Pro-H3), 2.64 (s, 3H; CH_3), 2.99 (dd, J = 14.5, 7.5 Hz, 1H; Phe-βH′), 3.21 (dd, J = 14.5, 6.2 Hz, 1H; Phe-βH), 3.25 (m, 1H; Pro-H5′), 3.61 (m, 1H, Pro-H5), 4.27 (dd, J = 6.3, 8.1 Hz, 1H; Pro-αH), 4.43 (pseudo-t, J = 7.3 Hz, 1H; Phe-αH), 7.24 (m, 2H; arom.), 7.30 (m, 3H; arom.); *cis* conformer: δ = 1.56 (m, 3H; Pro-H3, Pro-H3′ and Pro-H4), 1.70 (m, 1H; Pro-H4), 2.60 (s, 3H; CH_3), 2.90 (dd, J = 13.2, 9.8 Hz, 1H; Phe-βH), 3.05 (dd, J = 13.2, 5.4 Hz, 1H; Phe-βH′), 3.29 (m, 1H; Pro-αH), 3.33 (m, 1H; Pro-H5), 3.42 (m, 1H; Pro-H5′), 3.80 (dd, J = 9.8, 5.4 Hz, 1H; Phe-αH), 7.13 (m, 2H; arom.), 7.27 (m, 3H; arom.); ^{13}C NMR (75.4 MHz, CD_3OD, 25 C): δ = 23.08, 26.00, 26.36, 26.66, 30.45, 32.62, 37.70, 38.90, 54.41, 61.38, 61.85, 128.89, 129.11, 130.13, 130.51, 130.81, 135.36, 135.43, 168.65, 174.15; high-resolution MS: calcd for $C_{15}H_{21}N_3O_2$ (M^+): m/z: 275.1534; found: 275.1633.

Compound **1** was prepared in analogy to known procedures [17]. ^{1}H NMR (400 MHz, [D$_6$]DMSO, 25 °C): δ = 8.98 (s, 2H; CH), 8.09 (m, 2H; CH), 7.74 (s, 2H; CH), 7.39 (m, 4H; CH), 6.87 (d, J = 8.8 Hz, 2H; CH), 5.74 (m, 28H; OH), 4.82 (m, 14H; CH), 4.48 (m, 12H; OH), 3.65 (m, 56H; 4CH, 2CH$_2$), 3.30 (m, 28H; CH). ^{13}C NMR (75.4 MHz, [D$_6$]DMSO, 25 °C): δ = 164.6, 156.2, 142.2, 139.3, 137.3, 128.0, 121.7, 120.7, 120.5, 116.3, 102.5, 102.0, 101.7, 84.9, 81.6, 81.4, 73.1, 72.9, 72.4, 72.1, 70.1, 60.0, 59.6. FAB-MS calcd for $C_{104}H_{151}N_2O_{70}S_2Ni$ ([M + H]$^+$): m/z: 2671.7; found: 2672; UV/Vis (H_2O): λ_{max} (ε) = 374 (20000), 273 (55000) nm.

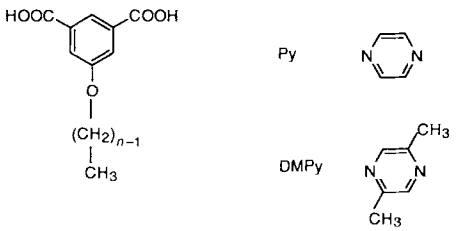
Self-Assembly of a Two-Component Hydrogen-Bonded Network: Comparison of the Two-Dimensional Structure Observed by Scanning Tunneling Microscopy and the Three-Dimensional Crystal Lattice**

Katrin Eichhorst-Gerner, Andreas Stabel, Georg Moessner, Dries Declerq, Suresh Valiyaveettil, Volker Enkelmann, Klaus Müllen,* and Jürgen P. Rabe*

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

The self-assembly of molecules to form well-defined supramolecular structures under the influence of weak forces such as hydrogen bonds, electrostatic interactions, and hydrophobic effects in the solid state[1] and in solution[2] has been explored in detail. *Single-component* two-dimensional hydrogen-bonded networks of small molecules[3] and polymers[4] have previously been studied by scanning tunneling microscopy (STM); however, no molecular-scale images of monolayers of *stoichiometric* assemblies with *two or more components* have been reported. Having explored the self-assembly of 5-alkoxy isophthalic acids of the general formula C_nIsA (Scheme 1) in the bulk,[5–7] we



C_nIsA, n = 12, 16

Scheme 1. Left: General formula of the isophthalic acid derivatives discussed in the text. n gives the total number of C atoms of the alkoxy substituents. Right: Py = pyrazine, DMPy = 2,5-dimethylpyrazine.

present here STM images of these molecules and their 2:1 stoichiometric donor–acceptor complexes with the bifunctional bases pyrazine (Py) and 2,5-dimethylpyrazine (DMPy) with submolecular resolution. We compare the structural data obtained on the two-dimensional (2D) crystals by STM with those from X-ray structural analysis of the three-dimensional (3D) crystals.

STM images of highly ordered monolayers of C_{16}IsA (Fig. 1 top), C_{12}IsA · 0.5Py (Fig. 2 top), and C_{16}IsA · 0.5DMPy (Fig. 2 bottom) have been obtained with submolecular resolution.

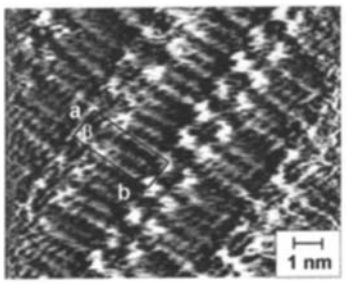

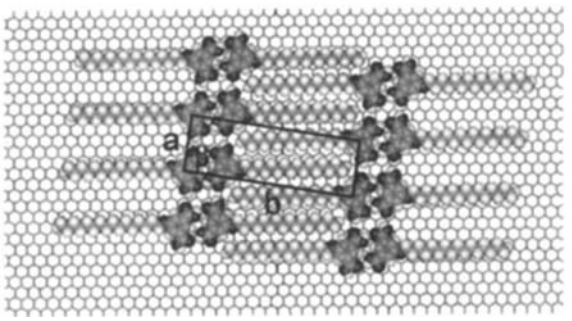

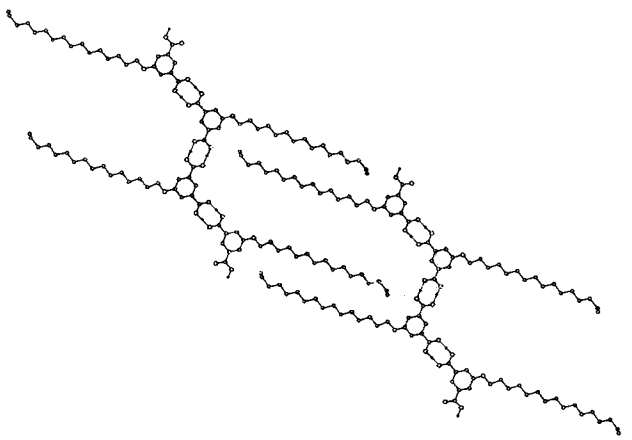

Fig. 1. Top: STM image of an ordered monolayer of C_{16}IsA on graphite with unit cell; $U_T = 0.6$ V, $I_T = 1.5$ nA. Middle: Schematic representation of 2D crystal lattice of C_{16}IsA as deduced from STM images. Bottom: 2D cut through the 3D crystal structure determined by single-crystal X-ray analysis; the hydrogen-bonded strands lie in the plane of the page

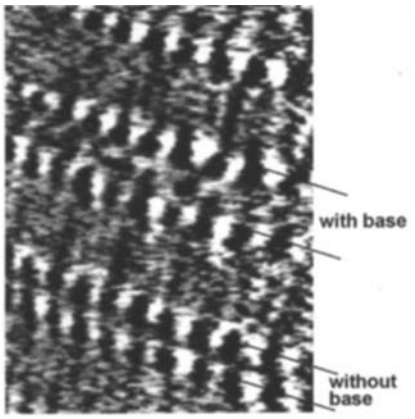
The unit cell data for the 2D crystals (see also Fig. 1 bottom) are summarized in Table 1. The 2D data were obtained by in-situ comparison with the underlying graphite lattice, the lattice constants of which are known. Refinement of the data was achieved by evaluating the Moiré pattern.[8] To allow a direct comparision of the 2D and 3D structures, another 2D unit cell with the parameters a, b, and β was defined for a 2D cut through the 3D crystal structure (see also Fig. 1 bottom).

In both the 2D and the 3D structures the pure acid (C_{16}IsA) forms closely packed arrays of interdigitating hydrogen-bonded ribbons. In the 3D structure two sets of planes are of interest: the first is defined by the hydrogen-bonded strands (see the plane of the drawing Fig. 1 bottom), and the second contains the alkyl chains; the two planes form an angle of 51°. However, in the 2D structure, the hydrogen-bonded strands and alkyl chains must lie in one plane. As a result, the hydrogen bonding pattern in the 2D structure is different from the one in the 3D crystal lattice. A proposal for the 2D hydrogen bonding pattern is depicted in Scheme 2.



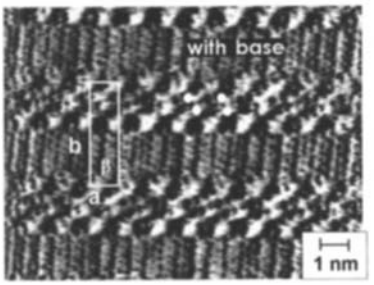


Fig. 2. Top: STM image of C_{12}IsA · 0.5Py on graphite; $U_T = 0.7$ V, $I_T = 1$ nA. No length scale is given because the image is slightly distorted (see text) in the horizontal direction. Bottom: STM image of an ordered monolayer of C_{16}IsA · 0.5DMPy on graphite with unit cell; $U_T = 0.6$ V, $I_T = 0.7$ nA

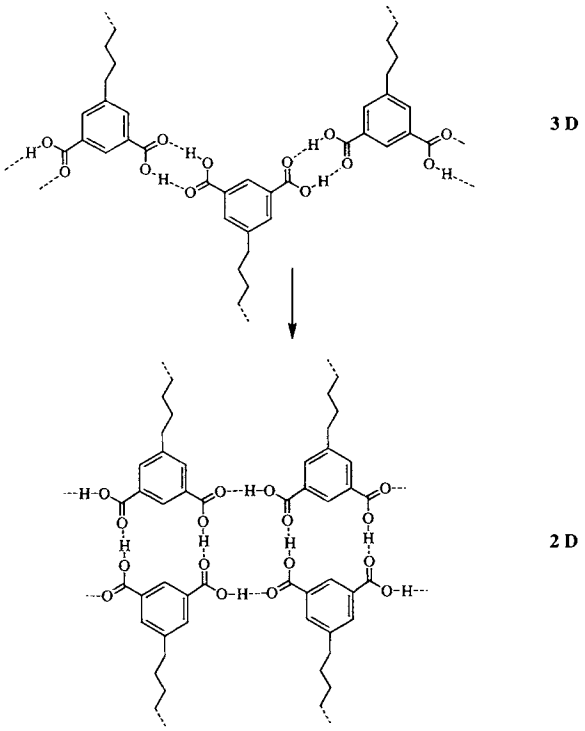
Table 1. Unit cell data of the 2D and 3D structures of the investigated compounds.

	2D Structure	2D cut through 3D structure [a]
C_{16}IsA		
a	0.93 ± 0.015 nm	1.572 nm [b]
b	3.3 ± 0.2 nm	2.654 nm
β	90 ± 2	104
C_{12}IsA · 0.5Py		
a	0.93 ± 0.015 nm	0.88 nm
b	3.44 ± 0.3 nm	3.36 nm
β	90 ± 2	93
A	3.20 nm²	2.95 nm²
C_{16}IsA · 0.5DMPy		
a	0.93 ± 0.015 nm	[c]
b	3.77 ± 0.2 nm	
β	90 ± 2	

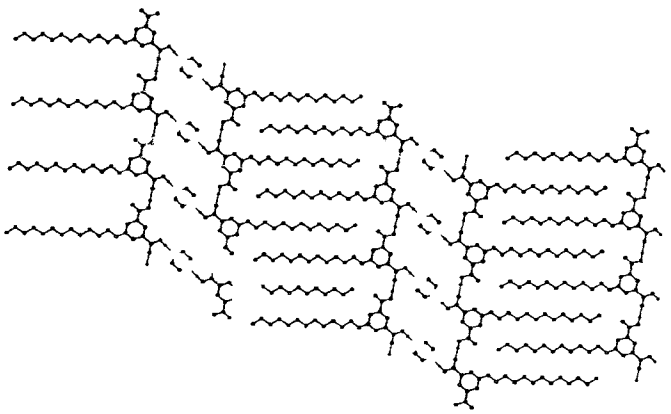
[a] Determined from single-crystal X-ray structure [5] (see Fig. 3 top). [b] The 3D crystal structure of C_{16}IsA does not consist of flat planes, hence no 2D cut through this 3D crystal represents the structure completely. [c] X-ray powder diffractograms show that C_nIsA · 0.5 Py and C_nIsA · 0.5DMPy ($n = 12, 14, 16, 18, \ldots$) form homologous series of structures, in which the lattice parameters change by regular increments for each CH_2. CH_2 unit added [12].

The introduction of a bifunctional aromatic base such as pyrazine leads to strong hydrogen bonding between the COOH group and the N atom of the diazine, which, in turn, changes the self-assembly pattern.[9]

For the system C_{12}IsA · 0.5Py in 3D this results in a hydrogen-bonded network as was previously shown.[5] A cut through the 3D crystal (see Fig. 3 top) reveals a nearly close-packed structure. The STM image of a monolayer (see Fig. 2 top) shows that the structure corresponds closely to this crystal plane (see also Table 1). From the width of the lamellae one must con-



Scheme 2.



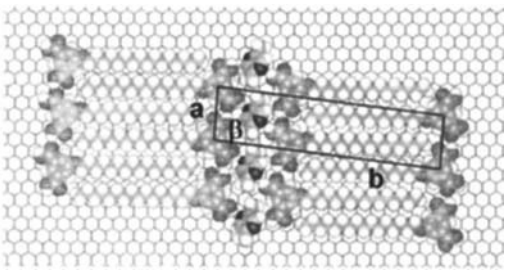


Fig. 3. Top: 2D cut through the 3D crystal structure of C_{12}IsA · 0.5Py. Bottom: Schematic representation of the 2D crystal lattice of C_{16}IsA · 0.5DMPy as deduced from STM images (see Fig. 2 bottom).

clude, however, that not all dimers contain a pyrazine acceptor molecule. This coexistence of two similar 2D crystal structures can be explained by the fact that the monolayer is in a dynamic equilibrium with the supernatant solution, which contains both acid and base. The relatively low resolution of Figure 2 top is attributed to some molecular mobility, which occurs because the plane is not completely close-packed along the row of the pyrazine molecules (see Fig. 3 top). Accordingly, the corresponding 2D packing observed by STM is less stable than a truly close-packed arrangement would be. Hence monolayer formation is not particularly favorable, and therefore almost saturated solutions are required in order to push the equilibrium between solvation and monolayer formation towards the latter. The beginning of bulk precipitation may then cause increased friction for the tip ploughing through, thereby causing some image distortion along the fast scan direction (here from right to left).

From studying the 2D-packing behavior of the complex with CPK models it can be deduced that the use of the 2,5-dimethyl-substituted pyrazine would lead to a more close-packed structure and hence to monolayers of higher stability. Another method for obtaining more stable monolayers of alkyl-substituted molecules at the solution–graphite interface is to increase the length of the alkyl chain.[10, 11] The system meeting these requirements, C_{16}IsA · 0.5DMPy, indeed displayed a greater monolayer stability, and therefore better quality STM images could be obtained (see Fig. 2 middle). It was also observed that the addition of DMPy stabilized the C_{16}IsA monolayer considerably. We attribute this phenomenon to the greater strength of the acid–base hydrogen bond as compared to the acid–acid hydrogen bond, which it replaces.[2c]

The 2D structure of C_{16}IsA 0.5DMPy consists of hydrogen-bonded strands of acid molecules. The alkyl side chains of two neighboring strands interdigitate and the resulting lamellae are cross-linked by diazine molecules. This structure is analogous to a projection plane of the 3D crystal structure of C_{16}IsA · 0.5Py. The 2D structure of C_{16}IsA · 0.5DMPy and a molecular sheet projection plane of the 3D structure of C_{12}IsA · 0.5Py are schematically depicted in Figure 3. They can be compared directly because the powder diffraction X-ray analysis of C_{16}IsA · 0.5Py reveals that it is isostructural to C_{12}IsA · 0.5Py.[12] A similar analogy between 2D and 3D crystal structures has previously been reported for long-chain alkanes,[13] fatty alcohols, and diols.[3c] In the case of C_{16}IsA · 0.5DMPy, the methyl substituents of the base DMPy occupy the existing free volume as anticipated, but leave the structure otherwise unaltered. The methyl groups are visible in the STM images (see Fig. 2 middle) and are highlighted by white dots in four illustrative cases.

In summary, we have presented STM images with submolecular resolution of monolayers of pure 5-alkoxyisophthalic acid and a donor–acceptor complex of the latter. Based on data from the X-ray crystal structure analysis, it has been possible to increase the stability of the monolayer by utilizing a space-filling base as an acceptor. Whereas the 2D structure of the pure acid shows little resemblance to its 3D structure, the 2D molecular sheet of the supramolecular assembly from a 2:1 mixture of the diacid and diazine is identical to a projection plane of the corresponding 3D crystal. We are currently extending the concept of donor–acceptor complex formation on graphite with a view to creating controlled two-dimensional molecular patterns and to designing monolayers that are two-dimensionally cross-linked by hydrogen bonding.

Experimental Procedure

The synthesis of C_nIsA has been described elsewhere [5]. Samples of highly oriented pyrolytic graphite (HOPG) (12 × 12 × 2 mm, quality ZYB) were obtained from Advanced Ceramics, Cleveland, USA.

A drop of solution (2 mM) of C_nIsA in phenyloctane was applied to a vertically placed slab of freshly cleaved HOPG with a Pasteur pipette. The drop slipped off the substrate leaving an approximately 20 μm thick liquid film on the surface [14], into which the tunneling tip was immersed. The physisorbed two-dimensional crystals

were investigated in situ at the solid–liquid interface using a scanning tunneling microscope (STM) constructed in our institute [15]. The tunneling tips were electrochemically etched (2 N KOH + 6 N NaCN) from a 0.25 mm Pt/Ir (80:20) wire. After the investigation of the pure C_nISA solution, a drop of pure Py or DMPy was added. After a few minutes, images of the stoichiometric compound could be recorded. Unless mentioned otherwise, the STM images were obtained in constant height mode under ambient conditions (scan rate: 0.3 Hz per image, positive tip bias, $U_T = 0.1$ to 1.0 V, $I_T = 0.5$ to 1 nA). They were recorded on videotape in real time and digitized later. Data are reported as recorded without digital image processing.

Single crystals suitable for X-ray crystal structure analyses [5, 6] were grown by slow evaporation of THF solutions. Crystal structure analyses were performed on an Enraf–Nonius CAD4 diffractometer, by using graphite-monochromated $Cu_{K\alpha}$ radiation ($\lambda = 1.5405$ Å). The structures were solved by direct methods (SIR 88, Molen) and refined by full-matrix least squares analyses with anisotropic temperature factors for C, N, and O. The H atoms were refined in the riding mode with fixed isotropic temperature factors.

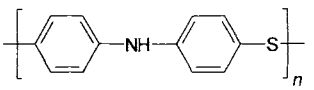
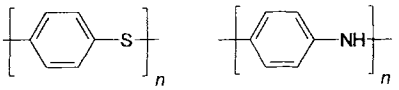
Poly(phenylenesulfidephenylenamine) (PPSA)—the "Compound" of Polyphenylenesulfide with Polyaniline

Li Xiang Wang, Thomas Soczka-Guth, Edsko Havinga, and Klaus Müllen*

Polyphenylenesulfide (PPS) **2**[1] and polyaniline (PAni, pseudo leucoemeraldine form) **3**[2] are two remarkable polymers containing aromatic building blocks. Whereas PPS is notable for its chemical stability, the outstanding characteristic of PAni



PPSA **1**

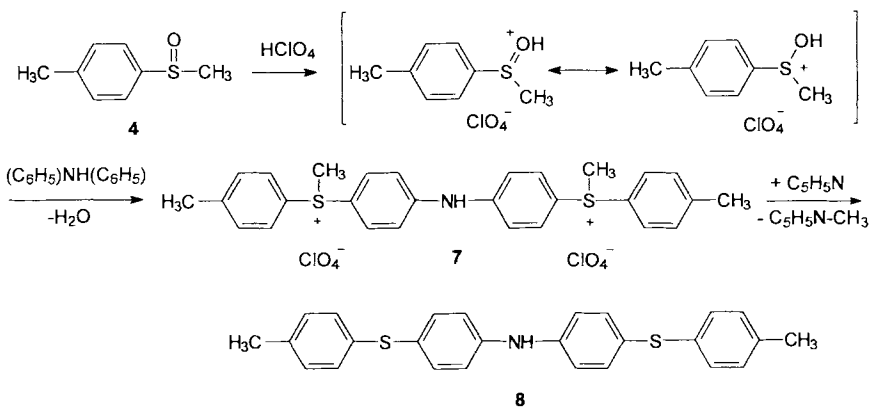


PPS **2** PAni **3**

is its ability to form electrically conducting films. The wide distribution of these two materials is attributed not only to their special properties but also to their ready accessibility: PPS can be prepared from 1,4-dichlorobenzene and sodium sulfide by the Philips process,[1] and PAni by the anodic or chemical oxidation of aniline.[2] We have combined PAni and PPS by the simple synthesis of poly(phenylenesulfidephenylenamine) (PPSA) **1**, which has promising electronic, mechanical, and optical properties.

In principle, **1** can be synthesized by forming either amino bridges or sulfide bridges; the latter method has been found to have certain advantages.[3] However, the condensation of methylsulfoxyarenes with another arene, with intermediate formation of a sulfonium cation, appears to be a particularly attractive method for producing diphenylsulfide units.[4]

We first investigated the suitability of this reaction for the condensation with diphenylamine units by synthesizing the model compound 4,4′-di(4-tolylsulfanyl)diphenylamine **8** (Scheme 1).



Scheme 1. Synthesis of **8** from **4**.

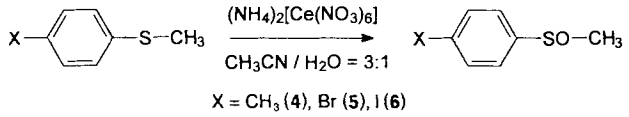
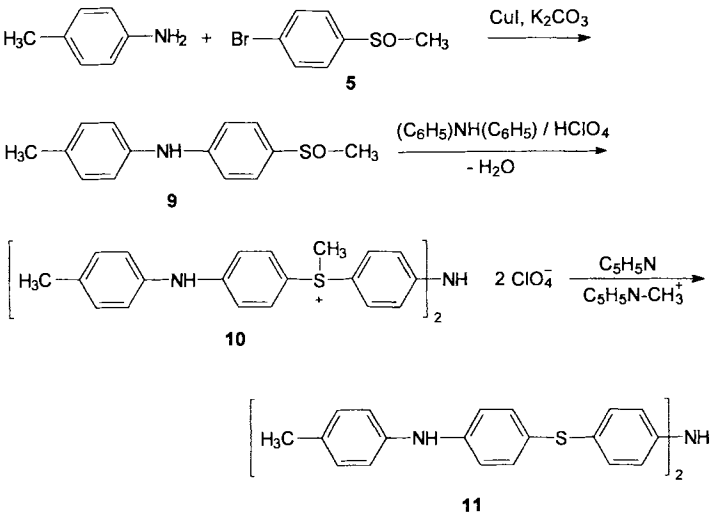
The required methyltolyl sulfoxide **4** is prepared in high purity and in yields of 70–80% by the oxidation[5] of 4-methylthioanisole with Ce^{IV} (Scheme 2). The acid-induced condensation of **4** with diphenylamine leads quantitatively to the sulfonium salt **7**, which is demethylated by heating in pyridine to give **8** (95–98% yield).

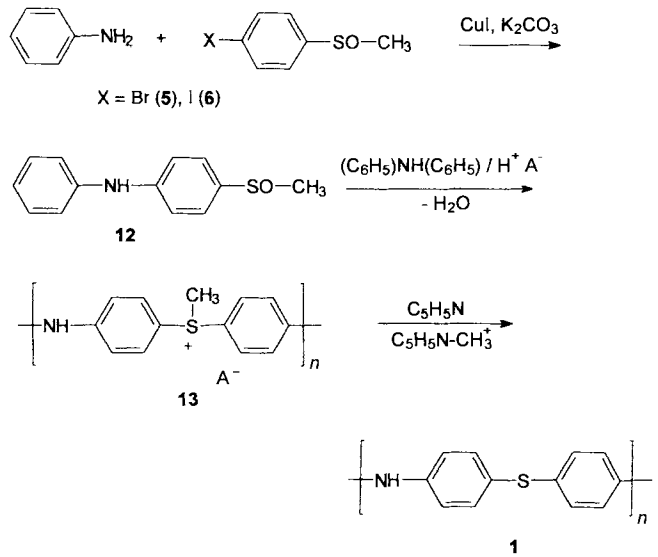


Scheme 2. Synthesis of **4**, **5**, and **6**.

Another model compound 4,4′-di(4′-methyldiphenylamine-4-sulfanyl)diphenylamine **11** can be obtained analogously to **8** by the reaction of 4-methylsulfinyl-4′-methyldiphenylamine **9**[6] with diphenylamine by first forming the sulfonium salt **10** and then demethylating this in 91% yield (Scheme 3). The monomer **12** required for the polymer synthesis can be obtained by the Cu^{I}-catalyzed reaction of 4-iodomethylsulfinylbenzene[5, 7] or of 4-bromomethylsulfinylbenzene[5] with aniline analogously to that with **9** (Scheme 4).[6]



Scheme 3. Synthesis of **11**.



Scheme 4. Synthesis of **1** from the precursors **12** and **13**.

The precursor polymer **13**[8] is obtained in 94% yield by adding **12** to a strong acid. This polysulfonium salt **13** is soluble in pyridine, DMF, and *N*-methylpyrrolidone (NMP) at room temperature. A determination of the molar mass by size-exclusion chromatography was not possible because of interactions with the column material.

The title compound **1**, which is obtained in 98% yield by the demethylation of **13**,[9] is, unlike PPS and PAni, structurally well-defined and very soluble. In the ^{13}C NMR spectrum ([D_6]DMSO, 75 MHz) only the expected four signals (δ = 118.0, 125.7, 132.6, 142.7) were observed (IR (KBr) ν = 820 cm^{-1}; UV (quartz) λ_{max} = 204, 333 nm; fluorescence emission maxima (excitation 350 nm, THF) at 390, 410 nm). The molar mass was determined to be M_n = 109000 and M_w = 206000 by size-exclusion chromatography in THF,[10] and to be M_n = 110000 by membrane-osmometric measurements in DMF.[11] Thermogravimetric analysis showed that **1** is stable up to 380 °C.

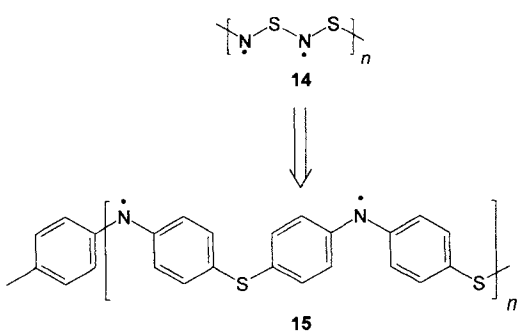
The very high solubility of PPSA compared with that of PPS and PAni is surprising. Reasons for this could be the low crystallinity of PPSA and the lack of cross-linking in the structure.

Optically clear, free-standing films can be prepared from the solution of the polymer. The modulus of elasticity E of the polymer film was determined to be 1.3 GPa (PPS: E = 3.8 GPa). It is especially remarkable that films of **1** adhere very well to metals, especially gold.

The structural similarity between **1**, polyaniline, and polyphenylenesulfide raises the question of the electrochemical properties and dopability of the polymer. Investigations by cyclic voltammetry show that **8** is a substituted diphenylamine, since the half-wave potentials lie in the same range as those for 4,4′-disubstituted diphenylamines.[12] The half-wave potentials of **1** ($E_{1/2}$ = 0.67 V, $E_{1/2}$ = 1.17 V) correspond to those of **8**; the increase in current with the number of measured cycles is attributed to the increase in ionic concentration in the polymer film during the measuring process.[13]

Preliminary doping tests were carried out on free-standing films of **1**. Such films doped with $SbCl_5$ had a conductivity of 0.2 $S cm^{-1}$ and those doped with $FeCl_3$ 0.9 $S cm^{-1}$, and retained their flexibility even after doping.[14] The conductivity of the black films remains unchanged for several weeks in dry air. The conductivity, which is low in comparison to that of PPS (up to 200 $S cm^{-1}$)[15] and that of PAni (up to ca. 100 $S cm^{-1}$),[16] is likewise attributable to the low crystallinity of the PPSA.

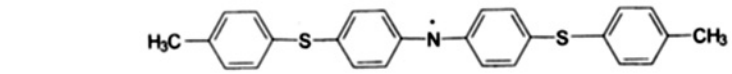
An important aspect of this is the structural similarity of the dehydrogenation product of **1**, the polyaminyl radical **15** (polyphenylenesulfurnitride, PPSN), to the polysulfazene **14**, which has metallic conductivity properties.[17]



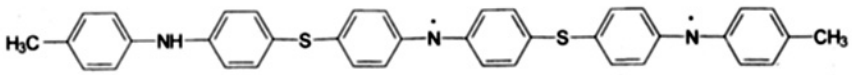
We have prepared the aminyl radical **16** of the model compound **8** by UV irradiation of a solution of **8** in toluene containing dibenzoyl peroxide, and have characterized this by ESR

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1496 $ 15.00+.25/0

spectroscopy. The low g value (2.00374) and the coupling constants ($a_{H_o} = 0.338$ mT, $a_{H_m} = 0.133$ mT, $a_N = 0.802$ mT), which are typical of aminyl radicals, enabled the presence of a nitroxyl radical to be ruled out.[18] The diradical **17** (g = 2.00374) prepared by dehydrogenation of the model compound **11** could be confirmed by ESR spectroscopy. Zero field splitting at 135 K (toluene, glass) was determined to be 1.76 mT. The distance of 1.17 nm found from this by point dipole estimation is in good agreement with the calculated distance between the aminyl centers of 1.02 nm.[19]



16



17

The new polymer PPSA has a well-defined structure and a high molecular weight. It is colorless, stable at temperatures up to 380 °C, very soluble in many common organic solvents, and dopable. Continuing investigations into its optical and electronic properties and into the conversion of **1** into the polyradical **15** are in progress.

Synthesis and Structure of a Discrete Hexanuclear Uranium–Phosphate Complex**

Ladd M. Mokry, Norman S. Dean, and Carl J. Carrano*

Multinuclear complexes form a widespread group of inorganic materials that have both theoretical and practical importance.[1] They have added not only to our understanding of chemical bonding but they are also excellent models for many intermediates in heterogeneous catalytic processes.[2] Indeed some complexes have been prepared that are so large that the dividing line between discrete molecules and extended solids has become blurred.[1c, 3] While there are many representatives of this class of compound among both the p- and d-block metals, there seem few if any examples among the heavy f-block elements such as the actinides.[4] In the course of trying to prepare new phosphate-based chelating agents for extraction of the uranyl ion from aqueous waste streams (of importance to the nuclear power industry and environmental chemistry), we have prepared and characterized a novel hexanuclear uranium complex, which we believe to be the first high nuclearity "cluster" of this element ever reported.[5]

Reaction of one equivalent of [TpVCl$_2$(dmf)], where Tp = hydridotris(pyrazolyl)borate, with three equivalents of sodium diphenylphosphate and half an equivalent of uranyl acetate in aqueous acetonitrile under inert atmosphere produced a deep green solution. The deep green color is attributed to the initial formation of the μ-oxo-bis-(μ-acetato)divanadium(III) dimer, as determined by UV/Vis spectroscopy.[6] Over the course of several hours this solution turns light green and deposits a pale green solid (**1**). IR spectroscopic analysis of the product indicated the absence of the uranyl oxo groups and the trispyrazolylborate capping ligand, while demonstrating the presence of diphenylphosphate. Fortunately under high dilution conditions large green crystals of **1** were formed which allowed a detailed X-ray structural determination to be undertaken.[7]

The single-crystal structure of **1** is characterized by an octahedral array of uranium atoms, in which each face is capped by a μ_3-oxo (hydroxo) group (Fig. 1). Each uranium atom is further coordinated by four diphenylphosphate groups, which form bridges with its four nearest uranium neighbors. Thus, the uranium atoms are overall eight coordinate with approximate square anitiprism geometry (Fig. 2). All of the U–O bonds are essentially equivalent in length and lie in a narrow range between 2.30–2.42 Å. The U–U distances of about 3.85 Å are larger than the sum of the covalent radii, hence no metal–metal bonds are evident. Although the X-ray analysis allows an unequivocal determination of the overall structure, it provides no information concerning the protonation state of the capping ligands (i.e. oxo or hydroxo) since hydrogen atoms are not visible on the difference map in the presence of uranium, nor does it give a clue as to the oxidation sate of the uranium atoms. Simple charge

considerations predicts an average uranium valence of 4.67 (formally two U^{VI} and four U^{IV}) if one assumes μ_3-oxo capping ligands. For μ_3-hydroxo capping ligands an average valence of 3.33 (formally four U^{III} and two U^{IV}) is expected. In either case the valences appear to be completely delocalized as all the uranium atoms are structurally equivalent. Several lines of evidence led us to favor the the presence of μ_3-hydroxo capping ligands. First, the thermal ellipsoids of the μ_3-oxygen atoms are all elongated normal to the trigonal face such as might be expected if there were unaccounted for electron density due to a bound proton. The analytical data also fit best to a formulation with hydroxo groups, and the presence of a sharp band at 3581 cm^{-1} in the IR spectrum is readily assigned as a non-hydrogen bonded O–H stretching vibration. Finally, we have also undertaken a bond valence sum (BVS) analysis, a procedure that has found widespread utility in assigning ambiguous oxidation states in metal clusters.[9] The BVS analysis gives an average valence of 3.33, a value consistent only with the hydroxo formulation. In any event it is clear that the vanadium(III) must provide the reducing equivalents, as the well-characterized vanadium(IV) complex $[\{TpVO(C_6H_5O)_2PO\}_2]_2$ is the only other identifiable product produced.[10] The room temperature magnetic moment has been measured but appears to be less than that expected for either of the valence formulations, suggesting perhaps some superexchange mediated spin coupling.[11] However, the interpretation of magnetic data for the actinides is very complex and a complete analysis will require a variable temperature study.

The results presented here demonstrate that there is nothing inherently unstable about high nuclearity actinide complexes, and we expect to see the number of such well-characterized complexes grow rapidly because of their potential applications. The emerging chemistry of uranium hydroxides and alkoxides represents, for example, important models for the complexes likely to be present in aqueous solutions of the actinides, which may be environmentally important species involved in transporting these elements in ground waters.[12] In addition these high nuclearity complexes may have useful roles to play as X-ray contrast and protein labeling agents.[13]

Experimental Procedure

1: To a mixture of $[TpVCl_2(dmf)]$ (0.41 g, 1 mmol) and uranyl acetate (0.2 g, 0.5 mmol) dissolved in acetonitrile (30 mL) was added a solution of the sodium salt of diphenylphosphate (0.72 g, 3 mmol) in H_2O (1 mL). After the mixture had been stirred overnight, the pale green precipitate was filtered off and washed with water and acetonitrile to yield 0.21 g (54% based on uranium) of product. Elemental analysis: Found: C 38.06, H 2.89%; calcd: C 38.09, H 2.83%. IR (KBr): $\nu[cm^{-1}]$ = 3581(w), 3071(w), 1591(m), 1491(m), 1213(s), 1095(s), 951(s), 780(m), 683(m), 533(m), 510(m). Magnetic moment at 298 K is 2.3 BM mol^{-1}. UV/Vis (dichloromethane): λ[nm] = 432, 468, 492, 510, 550, 636, 652, 670.

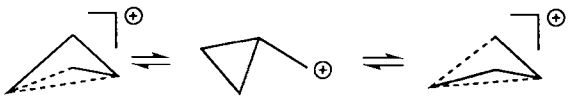
2-Triaxanemethyl Cation and 2,10-*para*-[3².5⁶]Octahedranedimethyl Dication**

George A. Olah,* Herwig A. Buchholz,* G. K. Surya Prakash,* Golam Rasul, James J. Sosnowski, Roger K. Murray Jr.,* Mikhael A. Kusnetsov, Shelue Liang, and Armin de Meijere*

Dedicated to Professor Ivar Ugi on the occasion of his 65th birthday

Cyclopropylmethyl cations are among the most extensively studied class of carbocations. The rapid interconversions of cyclopropylmethyl, cyclobutyl, and homoallyl derivatives via carbocation intermediates have attracted considerable attention.[1] Historically cyclopropylmethyl cations were the first carbocations to be named "nonclassical",[1, 2] and many interesting and intriguing studies concerning the direct observation of cyclopropylmethyl cations under stable ion conditions by NMR spectroscopy have recently been reviewed.[2g]

The parent primary cyclopropylmethyl cation $C_4H_7^+$ was characterized by ^1H and ^{13}C NMR spectroscopy under stable ion conditions by Olah and co-workers as early as 1970.[3] Subsequent low-temperature NMR evidence on ^{13}C-[4, 5] and ^2H-labeled[6] systems, including solid-state NMR measurements[7a] and high-level ab initio calculations,[7b] excluded classical cyclopropylmethyl or cyclobutyl ion structures. Rather, the cyclopropylmethyl cation is a rapidly equilibrating mixture of nonclassical bicyclobutonium cations (**1** and **3**) and the bisected cyclopropylmethyl cation **2**.[5, 6, 7]



1 **2** **3**

The only known example of a "static" bisected primary cyclopropylmethyl cation was prepared by Schmitz and Sorensen by ionizing 1-nortricyclanemethanol (**4**) with SbF_5 in SO_2ClF at low temperature.[8] In **4** the cyclopropyl moiety is locked in a norbornane framework.

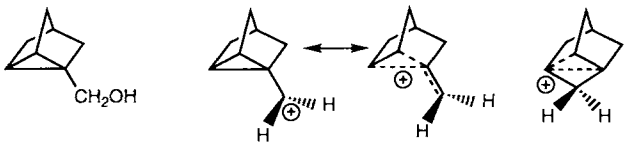
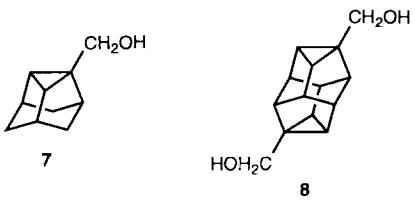
[**] Stable Carbocations, Part 298. This work was supported at University of Southern California by the Loker Hydrocarbon Research Institute and the National Science Foundation, at University of Delaware by the University of Delaware Research Foundation, and at the Universität Göttingen by the Fonds der Chemischen Industrie. The systematic name of 2-triaxanemethyl cation and 2,10-*para*-[3².5⁶]octahedranedimethyl dication are 2-tetracyclo[3.3.1.0^{2,4}.0^{3,7}]nonanemethyl cation and 2,10-heptacyclo[6.4.0.0^{2,4}.0^{3,7}.0^{5,12}.0^{9,11}]dodecanedimethyl dication, respectively. The latter skeleton has also been termed ditriaxane [21], but we prefer the more descriptive trivial name *para*-[3².5⁶]octahedrane for the parent hydrocarbon and hence also for its derivatives. For Part 297 see N. J. Head, G. K. S. Prakash, A. B. Hashimi, G. A. Olah, *J. Am. Chem. Soc.* **1995**, *117*, 12005.

The static bisected ion structure **5a** seems to be almost exclusively populated and is the only spectroscopically observable species. This has been rationalized by considering the contribution of a vinyl-bridged 2-norbornyl cation structure (**5b**) to the resonance hybrid.[9] Involvement of an alternative bicyclobutonium ion type structure **6** was ruled out.



4 **5a** **5b** **6**

In the cyclopropylmethanol derivatives, 2-triaxanemethanol (**7**)[10] and 2,10-ditriaxanedimethanol (**8**),[11] the cyclopropyl moieties are also rigidly locked in oligocyclic hydrocarbon frameworks. We explored under stable ion conditions the behavior of **7** and **8** as potential precursors to related cyclopropylmethyl cations. The observed intriguing mono- and dications were characterized by low-temperature ^{13}C NMR spectroscopy. IGLO calculations (IGLO = Individual Gauge for Localized Orbitals) on density functional theory (DFT)[12] optimized structures helped resolve the nature of the monocation.



7 **8**

2-Triaxanemethanol (**7**) was ionized at −78 °C in SO_2ClF with SbF_5 and gave an orange solution.[13] The 75 MHz proton-decoupled ^{13}C NMR spectrum[14] of this species at −80 °C shows only seven resonances (assigned on the basis of multiplicities and coupling constants): $\delta^{13}C$ = 147.9 (s), 97.6 (d, $J_{C,H}$ = 187.1 Hz), 52.7 (t, $J_{C,H}$ = 134.7 Hz), 47.3 (t, $J_{C,H}$ = 168.3 Hz), 43.4 (d, $J_{C,H}$ = 151.4 Hz), 38.7 (t, $J_{C,H}$ = 136.5Hz), and 36.6 (d, $J_{C,H}$ = 149.9 Hz) in a ratio of 1:2:1:1:1:2:2. The chemical shifts remain constant over the temperature range of −100 to −40 °C. This is in accordance with either a single ground-state structure for the ion or a set of rapidly equilibrating unsymmetrical bicyclobutonium ion structures. Similar studies on the parent cyclopropylmethyl cation had already established the fast, temperature-dependent, degenerate equilibration of the cyclopropylmethyl cation and bicyclobutonium ion.[4] Since the ion has apparent C_s symmetry, possible structures include the static, classical, bisected cyclopropylmethyl cation **9**, a fast equilibrium of the nonclassical, unsymmetrical, bridged bicyclobutonium ions **10a** and **10b**, or a fast equilibrium of the classical 2,5-dehydro-3-protoadamantyl cations **11a** and **11b**.

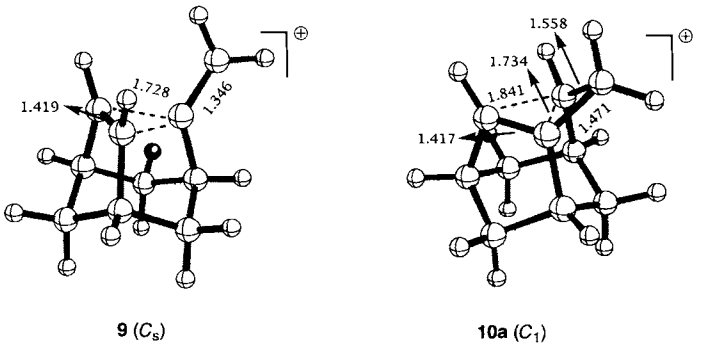
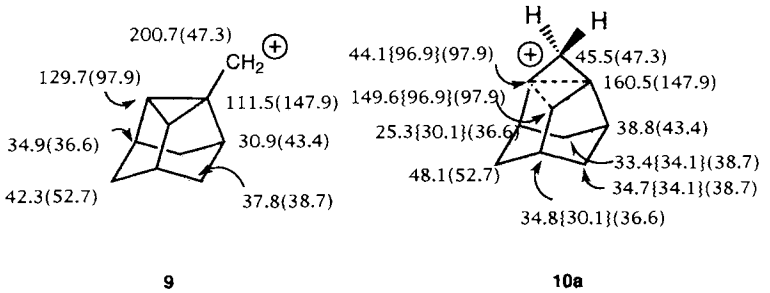
Geometry optimizations of the possible ions were carried out at the Becke3LYP/6-31G* level by using the Gaussian 94[12b] program package (Fig. 1). ^{13}C NMR chemical shifts were calculated by IGLO[15] with the standard DZ basis set and the



9 (C_s) **10a** (C_1)

Fig. 1. Selected Becke3LYP/6-31G*-optimized parameters [Å] of **9** and **10a**.

Becke3LYP/6-31G* geometries. The calculated chemical shifts for the carbocationic center of the static bisected ion **9** ($\delta^{13}C = 200.7$, Scheme 1) lie in the same range as that for Sorensen's nortricyclylmethyl cation **5** ($\delta^{13}C = 191.4$). Undoubtedly the difference of $\Delta\delta = 153$ between the calculated and



9 **10a**

Scheme 1. Calculated ^{13}C NMR chemical shifts of **9** and **10a**. Experimental values are given within parentheses and averaged values for **10a/b** within braces.

the experimentally measured ^{13}C NMR chemical shift excludes **9** as the major species in the equilibrium. On applying the empirical ^{13}C chemical shift additivity concept[16] the difference of $\Delta\delta^{13}C = 226$ between the total sum of the ^{13}C NMR chemical shifts of the ion ($\sum\delta = 638$) and the total sum of the ^{13}C chemical shifts of the corresponding hydrocarbon ($\sum\delta = 412$[17]) further supports a nonclassical structure. Typically, a difference of 350 or greater indicates a classical carbocationic nature, whereas $\Delta\delta$ values for nonclassical carbocations are significantly smaller.[16] The most likely structure for the cation from **7** is a set of rapidly equilibrating bicyclobutonium ions (**10a/b**) with apparent C_s symmetry.

Since ion **10a** is only 0.6 kcal mol^{-1} more stable than **9** at the B3LYP/6-31G* level, **10a/b** probably lies on a rather flat potential energy surface. Rearrangements of carbocations involving low energy barriers are common.[1e] In fact by taking the average IGLO calculated ^{13}C NMR chemical shifts of the two optimized, degenerate structures **10a** and **10b** a good agreement with the experimental values is obtained (Scheme 1). Thus the ionization product of **7** can be best described as a set of rapidly equilibrating (with a low energy barrier) nonclassical unsymmetrically bridged bicyclobutonium ions **10a/b**.

Structurally similar to **7** is the diol 2,10-*para*-[$3^2.5^6$]octahedranedimethanol (**8**). In **8** two cyclopropylmethanol units are locked into a rigid hydrocarbon framework. Because its geometry resembles that of **7**, similar spectroscopic features to those of **10a/b** for the ionization product derived from **8** can be expected. On the other hand, formation of a distonic[18] primary cyclopropylmethyl dication gives a considerably higher atom-to-charge ratio than the cation from **7**, which could lead to a lower extent of σ delocalization into the strained cyclopropyl moieties.

Ionization of **8** with SbF_5 in SO_2ClF at $-78\,^\circ C$ resulted in a dark yellow solution.[13] The 75 MHz proton-decoupled ^{13}C NMR spectrum of this solution at $-80\,^\circ C$ shows only five absorptions, indicating the presence of a highly symmetric dication: $\delta^{13}C = 135.7$ (s, C_{quat}), 118.9 (t, $J_{C,H} = 174$ Hz, methylene groups), 105.0 (d, $J_{C,H} = 193.2$, four β CHs), 66.4 (d, $J_{C,H} = 148.8$, two belt CHs), and 53.3 (d, $J_{C,H} = 156.1$, four belt CHs) in a ratio of 1:1:2:1:2. Considering the similar geometry and a correlation between charge density and ^{13}C NMR chemical shifts,[19] the downfield shift of the methylenes by $\delta = 71$ relative to that of **10a/b** clearly indicates higher positive charge density on the methylene groups in the dication from **8** and less charge delocalization into the cyclopropylmethyl moieties in the framework. On the other hand, this positively charged carbon atom is still relatively shielded relative to that of Sorenson's nortricyclylmethyl cation **5** (upfield shift for this dication: $\Delta\delta = 72.5$), which indicates still substantial positive charge delocalization into the cyclopropane moiety and clearly rules out the static bisected structure **12** for the ionization product of **8**.

A test for the temperature dependence of the NMR spectrum showed no significant changes in the range from -100 to $-30\,^\circ C$.[20] Application of the empirical ^{13}C NMR chemical shift additivity rule also supports the assignment of a bridged structure for this ion. The difference between the total sum of the ^{13}C NMR chemical shifts for this ion ($\sum\delta = 1275.6$) and the total sum for the structurally closely related parent hydrocarbon 2,9-dimethylditriaxane ($\Delta\delta = 774.6$)[21] is 250 ppm per unit of positive charge. Comparison of this value with related monocharged systems such as the highly delocalized cyclopropylmethyl cation ($\Delta\delta = 283$) and the static, bisected nortricyclylmethyl cation ($\Delta\delta = 470$) supports the bicyclobutonium type nonclassical structures **13a/b/c**[22] for the ionization product of **8**.

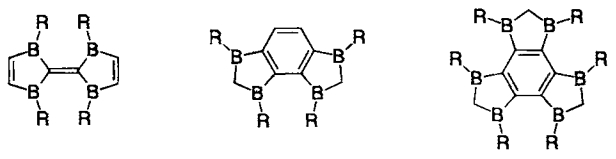
Hexaborylbenzene and Tetraborylethene Derivatives**

Andreas Maderna, Hans Pritzkow, and Walter Siebert*

Dedicated to Professor Marianne Baudler on the occasion of her 75th birthday

Functionalized tetraborylethenes and tetra- and hexaborylbenzene derivatives are potential precursors for new boron heterocycles. Tetraborafulvalenes **A** and benzobis- and benzotris(1,3-diborole) derviatives **B** and **C**, respectively, are suitable for the synthesis of doubly and triply stacked complexes with



A **B** **C**

1,3-diborolyl bridging ligands. Additionally, tetra- and hexaborylbenzenes can be used for synthesizing band and sheet polymers. In this way a graphite analogue $(C_3B)_n$, in which every boron atom is surrounded by three C atoms, could be made by polycondensation of $C_6(BR_2)_6$ under elimination of BR_3. We report here on the first synthesis of perborylated C–C multiply bonded systems by transition metal catalyzed reactions of bi(1,3,2-benzodioxaborolyl)acetylene (**1**).[1] Cyclotrimerization of **1** provides **2a**, the first example of a hexaborylbenzene derivative. Diboration of **1** with 2,2'-bi(1,3,2-benzodioxaborolyl)-borane (**3**) leads to the tetraborylethene compound **4a**. The boron–oxygen bonds in **2a** and **4a** can be cleaved with methyllithium and trimethylaluminum (Scheme 1).

[**] This work was supported by the Deutsche Forschungsgemeinschaft (SFB 247) and the Fonds der Chemischen Industrie.

The synthesis of substituted arenes by cobalt-catalyzed trimerization of alkynes is well known and has found broad applications in organic synthesis.[2] In an analogous manner, the diborylacetylene **1**[1] can be cyclotrimerized with (η^5-cyclopentadienyl)dicarbonylcobalt in refluxing toluene to give the hexaborylbenzene **2a** in 67% yield. Compound **2a** is only slightly soluble in most solvents; in methanol a slow reaction takes place leading to the formation of $H_4C_6O_2BOMe$. Purification of **2a** is accomplished by multiple washings with THF and CH_2Cl_2. Subsequent drying provides analytically pure, air-stable **2a**. The ^{11}B NMR spectrum in [D_8]toluene at 372 K shows a broad signal at $\delta = 33$; the chemical shift of the boron-bound C atoms in the ^{13}C NMR spectrum ($\delta = 143$) appears in the range expected for 1,2-diborylbenzene derivatives.[3]

In analogy to the cleavage of the B–O bonds in 2-alkyl-1,3,2-benzodioxaborole derivatives with Grignard reagents,[4] a solution of **2a** in toluene reacts with methyllithium in diethyl ether to form a yellow solution of the methyl derivative **2b**. After separation of the precipitated $C_6H_4O_2Li_2(OEt_2)_n$, **2b** was identified by GC-MS analysis to be the only product. Surprisingly, the ^{11}B NMR spectrum of the yellow solution shows a broad signal at $\delta = 6$, which indicates a donor–acceptor interaction between the oxygen atoms of dissolved $C_6H_4O_2Li_2$ and the boron atoms. Additionally, two signals of lower intensity appear in the highfield region at $\delta = -17.4$ and -20.6, which we assign to the boranates **2b**·$(LiMe)_n$ and $LiBMe_4$.[5] Addition of an excess of pyridine results in an orange-red solution from which a crystalline, lithium-containing product precipitates. NMR and mass spectra indicate a compound based on **2b**, dilithio-1,2-dioxabenzene, and pyridine.

The crystal structure analysis indicated the formation of compound **2c** (Fig. 1), in which two oxygen atoms from two $Li_2O_2C_6H_4$ units each bridge two BMe_2 groups. The boron

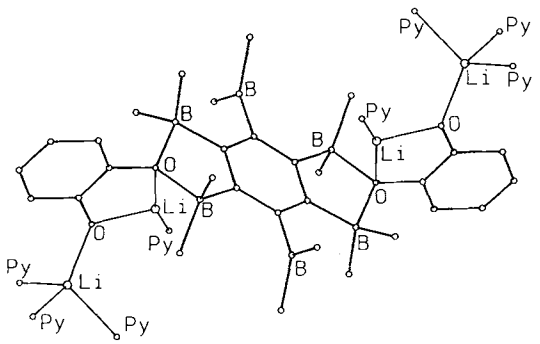

Fig. 1. Structure of **2c** in the crystal. Py = C_5H_5N.

atoms of the other two boryl groups, which are *para*-positioned with respect to one another, are planar coordinated. The BC_2 planes are perpendicular to the central benzene plane. However, no satisfactory refinement of the structure analysis was possible, due to the poor quality of the crystal, resulting from disordered solvent and/or pyridine. The ^{11}B NMR spectrum of **2c** shows a broad signal at $\delta = 0$. No signals for the BMe_2 groups were found in the lowfield region. From this it can be concluded that only four-coordinate boron atoms are present in solution.

Concentration of the yellow toluene/diethyl ether solution of **2b** resulted in the formation of a yellow precipitate. Further removal of solvent provides a yellow, insoluble, air-sensitive powder. The ^{11}B NMR spectrum of a saturated solution of this in CH_2Cl_2 shows a broad signal at $\delta = 85$ as well as a signal at $\delta = 6$, which indicates the presence of **2b**. In the EI mass spectrum of the yellow product, the highest mass appears at 317 (M^+ for **2b**). The reaction of a suspension of **2a** in hexane with trimethylaluminum also results in **2b**; removal of the insoluble components by filtration provides a yellow filtrate whose ^{11}B NMR (only one signal at $\delta = 85$) and EI-MS ($m/z = 317$, M^+) spectra confirm that this product is formed.

According to Suzuki and Miyaura[6] alkynes react catalytically with 2,2'-bi(4,4,5,5-tetramethyl-1,3,2-dioxaborolanyl)-platinum and tetrakis(triphenylphosphane)platinum to give *Z*-1,2-diborylethenes. Heating a solution of the diborylacetylene **1** and the diborane(4) **3** in toluene in the presence of bis(triphenylphosphane)(ethene)platinum[8] for 24 h results in the tetraborylethene derivative **4a** in 50% yield (see Scheme 1). Compound **4a** is an air-stable solid that is very poorly soluble. The first $C_2(BX_2)_4$ compound (X = F) was obtained by gas-phase reaction of carbon with B_2F_4.[13] The ^{11}B NMR spectrum of **4a** in [D_4]methanol shows a broad signal at $\delta = 34$ and a signal of lower intensity at $\delta = 18$ that can be assigned to $C_6H_4O_2BOCD_3$, which is formed by the methanolysis of **4a**. The ^{13}C NMR signal of the boron-bound C atoms could not be detected due to the poor solubility of the compound.

Different reactivity is seen upon the stoichiometric addition of bis(triphenylphosphane)(ethene)platinum. In addition to traces of **4a**, the corresponding substituted 1,1,2,2-tetraborylethene derivative is obtained in 8% yield.[9] Its synthesis is probably due to the intermediate formation[11] of 1,3,2-benzodioxaborole and subsequent double hydroboration of **1**.

The reaction of **4a** with methyllithium already occurs at $-5\,^\circ C$; however, due to the enhanced reactivity of the boryl groups compared to those in **2b**, the resulting **4b** could not be identified by GC-MS analysis. Upon addition of pyridine, the ^{11}B NMR spectrum of the red-brown solution shows, just as for **2c**, a signal at $\delta = 0$ as well as a signal for $LiBMe_4$ ($\delta = -19.5$). We assume that a product analogous to **2c** is formed from **4b**, $Li_2O_2C_6H_4$, and pyridine. The ^{13}C NMR spectrum, like that of **2c**, shows a broad signal for the BMe_2 groups ($\delta = 13$) and a broad signal for the boron-bound, sp^2-hybridized carbon atoms ($\delta = 158$). Attempts to synthesis donor-free **4b** from **4a** and trimethylaluminum provided a yellow solution whose ^{11}B NMR spectrum shows a signal for **4b** at $\delta = 82$ and for trimethylborane at $\delta = 87$. The isolation and characterization of **4b** has not yet been successful.

Electronic as well as steric features of **1** are decisive for the formation of **2a** and **4a**. The Lewis acidity of the boron atoms is reduced due to the donor function of the oxygen atoms. The C–C triple bond is only minimally lengthened[1] to allow the necessary coordination at the metal center during the catalytic cycle. The planar benzodioxaborolyl substitutents are advantageous in that they are able to rotate with respect to one another and allow the approach of several alkynes to the reactive metal center. Transition metal catalyzed cyclotrimerization and diboration of **1** offers a pathway to unsaturated, perborylated compounds, which can be used for the synthesis of new boron heterocycles. These can, in turn, be used for organic synthesis as well as applications as hydride[12] and fluoride acceptors.

Experimental Procedure

2a: **1** (1.234 g, 4.7 mmol) and (η^5-cyclopentadienyl)dicarbonylcobalt (0.042 g, 0.23 mmol, 5 mol%) in toluene (25 mL) were heated under reflux for 24 h. Afterwards, the precipitate was isolated by filtration, washed several times with THF and CH_2Cl_2 and dried in vacuum. Yield: 0.827 g (67%), m.p.: >310 °C, ^1H NMR (200 MHz, [D_8]THF): $\delta = 6.4$–6.8 (m); ^{13}C NMR (50 MHz, [D_4]MeOH): $\delta = 146.2$, 120.8, 116.3 (C_6H_4), 143 (CB, br.); ^{11}B NMR (64 MHz, [D_8]toluene, 373 K): $\delta = 33$ ($\Delta\nu_{1/2} = 580$ Hz); HR-MS (EI): m/z 785.1879 (M^+ calcd. $^{12}C_{42}{}^1H_{24}{}^{10}B_1{}^{11}B_5{}^{16}O_2$: 785.1862); correct C, H analysis.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1502 $ 15.00+.25/0

4a: **1** (473 mg, 1.8 mmol), **3** (430 mg, 1.8 mmol), and bis(triphenylphosphane)-(ethene)platinum (83 mg, 0.12 mmol, 6.2 mol%) in toluene (15 mL) were heated under reflux for 24 h. Afterwards, the precipitate was isolated by filtration, washed several times with THF and CH_2Cl_2, and dried in vacuum. Yield: 455 mg (50.6%), m.p.: >310 °C, ^{1}H NMR (200 MHz, [D$_4$]MeOH): δ = 6.5–6.9 (m); ^{13}C NMR (50 MHz, [D$_4$]MeOH): δ = 146.3, 120.9, 116.4 (C_6H_4), CB not observed; ^{11}B NMR (64 MHz, [D$_4$]MeOH): δ = 34 ($\Delta\nu_{1/2}$ = 524 Hz), 18 ($\Delta\nu_{1/2}$ = 58 Hz, $C_6H_4O_2BOCD_3$); HR-MS (EI): *m/z* 500.1209 (M^+, calcd $^{12}C_{26}{}^1H_{16}{}^{10}B_4{}^{16}O_8$: 500.1217); correct C, H analysis.

2b, **2c**: A suspension of **2a** (785 mg, 1 mmol) in toluene (15 mL) and methyllithium (8 mL of a 1.5 M solution in diethyl ether, 12 mmol) was first stirred for 1.5 h at −5 °C and then for 8 h at 25 °C. After removing the insoluble components, a yellow solution of **2b** was obtained which contained minor amounts of boranates. ^{11}B NMR (64 MHz): δ = 6 ($\Delta\nu_{1/2}$ = 466 Hz), −17.4 ($\Delta\nu_{1/2}$ = 87 Hz), −20.6 ($\Delta\nu_{1/2}$ = 29 Hz); GC-MS: *m/z* (%) 317 (100) [M^+], 302 (17.4) [M^+ − Me], 41 (92.4) [BMe_2^+]. An excess of pyridine was added to the yellow solution. Crystalline **2c** precipitated from the resulting orange-red solution at room temperature. Yield: 296 mg (33%), m.p.: >250 °C (decomp), ^{1}H NMR (200 MHz, $CDCl_3$): δ = −0.3 to 0.3 (m, BMe), 5.8–6.9 (m, C_6H_4), 7.0 (m, Py), 7.5 (m, Py), 8.2 (m, Py); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 13.0 (BMe, br), 114.6, 116.5, 118.2, 120.0, 153.6, 160.0 (C_6H_4), 123.7, 136.6, 149.6 (Py), 168.0 (CB, br); ^{11}B NMR (64 MHz, $CDCl_3$): δ = 0.3 ($\Delta\nu_{1/2}$ = 204 Hz); MS (FD): *m/z* 982 [M^+ − Py − 4Me].

Synthesis of Naturally Occurring, Conformationally Restricted Oxazole- and Thiazole-Containing Di- and Tripeptide Mimetics**

Georgi Videnov, Dietmar Kaiser, Christoph Kempter, and Günther Jung*

Residues that restrict the peptide backbone are synthesized in Nature inter alia by the following modifications: N- and α-alkylations,[1] α,β-didehydroamino acid and sulfide ring formations,[2] and synthesis of aromatic five-membered heterocycles.[3] The unusual amino acids of most peptide antibiotics are incorporated by multienzyme complexes.[1] However, an increasing number of posttranslational modifications originating from enzymatic, ribosomally synthesized precursor proteins has been detected.[2] Thus, the fascinating 43-peptide antibiotic microcin B17, which inhibits DNA-gyrase, contains four oxazole and four thiazole rings,[3b] which arise by cyclizations and dehydrogenations from di- and tripeptide units containing Gly, Ser, and Cys residues of the precursor protein (69 residues) followed by cleavage of a leader peptide (26 residues). A wide variety of oxazole-, thiazole-, and thiazoline-containing natural products has also been isolated from marine organisms[4a–i] and microorganisms.[4j–m] The reported syntheses of oxazole[5,6] and/or thiazole[7] derivatives include only few examples of aminoalkyl- or aminoaryloxazolecarboxylic acids.[6a,g,i]

Substituted five-membered heterocycles are pharmacophores of many natural and synthetic, bioactive compounds. In particular, the amino- and carboxy-functionalized heterocycles found in microcin B17 (Scheme 1) are valuable building blocks for peptidomimetics, which restrict the ω,ψ-conformational freedom in peptides. As a part of our efforts towards the total synthesis of microcin B17,[3] we developed efficient procedures for the preparation of Boc- and Fmoc-protected amino acids derived from oxazole, thiazole, bisthiazole, oxazolyl-thiazole, and thiazolyl-oxazole, which can be considered as di- and tripeptide mimetics. We also discovered a novel, useful procedure for the oxidative conversion of intermediate oxazoline into corresponding oxazole rings with 1,8-diazabicyclo[5.4.0]undec-

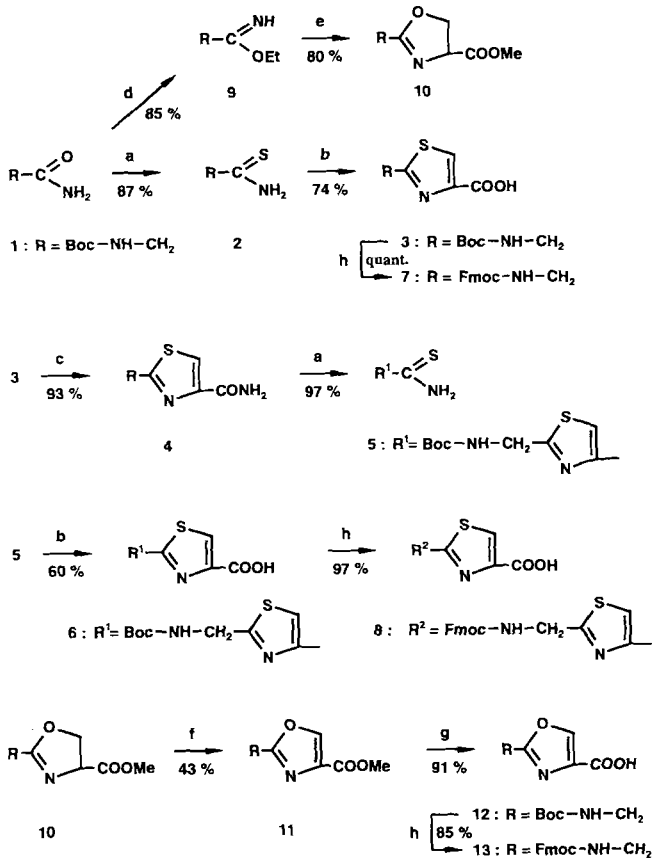
7-ene (DBU)/CCl_4/acetonitrile/pyridine. This reagent proved to be superior to the known reagent $CuBr_2$/DBU/hexamethylenetetramine (HMTA).

For the synthesis of 2-aminomethylthiazole-4-carboxylic acid (Scheme 2), *N*α-Boc-glycinamide (**1**) was converted into thioamide **2** by Lawesson's reagent.[8] Cyclocondensation of **2** with 3-brom-2-oxo-propionic acid[9] leads to **3** in 74% yield. After

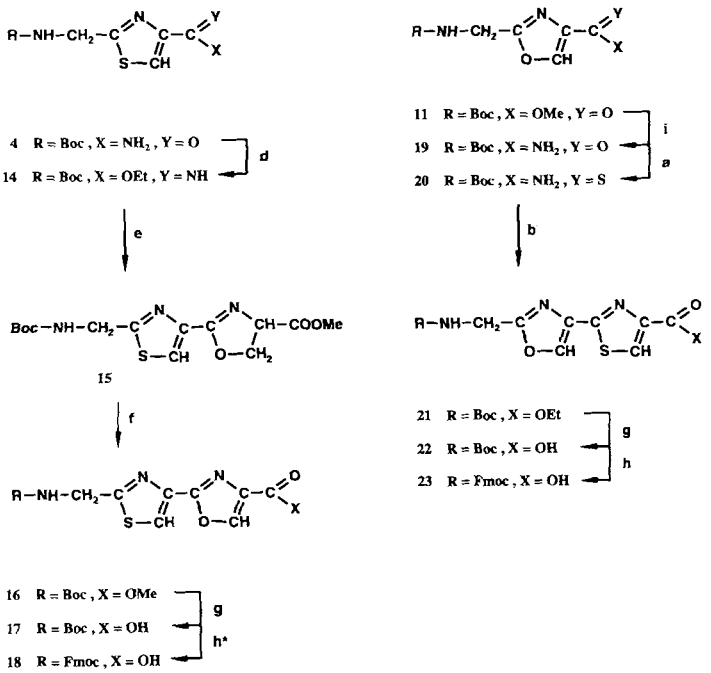


Scheme 2. a) Lawesson's reagent [8] ; b) 3-brom-2-oxo-propionic acid [4a–c,9]; c) *i*BuOCOCl, MeMorph, NH_4OH ; d) Et_3OPF_6 [10]; e) serine-OMe·HCl [11b]; f) DBU, CCl_4, CH_3CN, Py; g) NaOH; h) TFA then Fmoc-OSu.

Boc deprotection (50% trifluoroacetic acid (TFA)/CH_2Cl_2) the Fmoc protecting group was introduced by Fmoc-OSu (9-fluorenylmethoxycarbonyl-*O*-succinimide) to give **7**. The acid **3** was converted via amide **4** into thioamide **5** with isobutyl chloroformate/aqueous ammonia in THF. Reaction of the thioamide **5** with 2-bromopyruvic acid yielded the Boc-bisthiazole **6** (60%), which was converted into the Fmoc compound **8**.

The synthesis of the building block 2-aminomethyloxazole-4-carboxylic acid was accomplished by a novel route (Scheme 2). Treatment of the amide **1** with triethyloxonium hexafluorophosphate gave the imino ether **9**.[10] The intermediate oxazoline **10** was obtained in high yield (80%) by cyclization of the imino ether **9** with serine methyl ester in CH_2Cl_2.[11] Oxidation of **10** with the reagent DBU/CCl_4/acetonitrile/pyridine gave the oxazole **11** (43%), which was saponified to give **12**. Removal of the Boc group and reprotection with Fmoc-OSu afforded **13**.

The Boc- and Fmoc-protected 2-(2′-aminomethylthiazole-4′-yl)oxazole-4-carboxylic acids were synthesized according to Scheme 3. The amide **4** was converted into the imino ether **14** as described for **9**. Formation of the thiazolyloxazoline derivative



Scheme 3. For a), b), and e)–h) see Scheme 2; i) MeOH–NH_4OH.

15 occurs in high yield (72%). Oxidation of **15** with the novel procedure described for **10** yielded the ester **16**, which was saponified without problems to give **17**. Deprotection of the aminomethyl group and introduction of the Fmoc group afforded **18**.

For the synthesis of Boc- and Fmoc-protected 2-(2′-aminomethyloxazole-4′-yl)thiazole-4-carboxylic acid (Scheme 3) **11** was converted into amide **19** with methanol/ aqueous ammonia and to the thioamide **20**. The condensation of thioamide **20** with ethyl bromopyruvate (modified Hantzsch reaction[4a, b, j]) yielded the ethyl ester **21**. Basic hydrolysis of **21** gave the acid **22**, which was treated successively with 50% TFA/CH_2Cl_2 and Fmoc-OSu to obtain **23**.

The preparation of the oxazole- and/or thiazole-derived amino acids described above enabled us to synthesize fully active microcin B17,[13] and the use of these and related building blocks for the synthesis of further bioactive products is the object of intense research. During our experiments, we developed a novel method for the oxidation of oxazolines to oxazoles, which we hope will prove useful for the synthesis of related heterocycles. A report on X-ray structures, ab initio calculations, NMR spectroscopy studies and molecular dynamics simulation (MDS) studies summarizes the structural properties of the novel amino acids.[14]

Experimental Procedure

Thin-layer chromatography: glass sheets coated with silica gel (E. Merck, Darmstadt); solvent systems: A = $CHCl_3$/MeOH/H_2O (80/30/5); B = $CHCl_3$/MeOH/AcOH (95/5/3); C = $CHCl_3$/MeOH (9/1); D = EtOAc/*n*-hexane (1/1); E = *n*BuOH/AcOH/H_2O (4/1/1). Silica gel for flash chromatography was from J. T. Baker (Deventer, Holland). Instrumentation and conditions: Mass spectrometry: API III triple quadrupole mass spectrometer with an electrospray ion source at atmospheric pressure (Sciex, Thornhill, Canada); electrospray ionization mass spectra (ESI-MS) were taken in the positive mode; samples were dissolved in 10% HCOOH/MeOH (1/1). NMR spectroscopy: Bruker AC 250 spectrometer (Bruker Physics, Karlsruhe, Germany); solutions in $CDCl_3$ and [D_6]DMSO (c = 40 mg mL^{-1}); chemical shifts referenced to the solvent peaks [δ(^{13}C, CDCl3) = 77, δ(^{13}C, [D_6]DMSO) = 39.5 and δ(1H, [D_6]DMSO) = 2.49].

1: Gly-NH_2·HCl (22.0 g, 0.2 mol), triethylamine (28.0 mL, 0.2 mol) and di-*tert*-butyl dicarbonate [12] (48.0 g, 0.22 mol) in THF/water (4/1) (300 mL) were stirred

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1504 $ 15.00+.25/0

at room temperature (RT) until the starting material was consumed (TLC system A). Yield 31.0 g (89%); homogeneous (TLC systems A and C).

2: Lawesson's reagent [8] (30.0 g, 75 mmol) and a solution of **1** (17.4 g, 100 mmol) in dimethoxyethane (400 mL) was stirred at room temperature until **1** was consumed (TLC system C). The solvent was removed in vacuo. A solution of the residue in EtOAc was extracted with 10% $NaHCO_3$, and the aqueous phase reextracted with EtOAc (2×). The combined organic phases were washed with brine and dried. Evaporation and crystallization from EtOAc/*n*-hexane afforded a yellow solid. Yield 17.0 g (89%); homogeneous (TLC systems B and C). ^{1}H NMR ([D$_6$]DMSO): δ = 1.38 (s, 9H; $3CH_3$), 3.81(d, ^3J(H,H) = 6.07 Hz, 2H; CH_2), 7.82 (t, ^3J = 5.92 Hz, 1H; NH), 9.0, 9.66 (br s, 1H; $CONH_2$); ^{13}C NMR ([D$_6$]DMSO): δ = 28.2 (Boc-CH_3), 50.5 (CH_2), 78.3 (Boc-C_q), 155.5 (Boc-CO), 204.0 (C=S).

3: 3-brom-2-oxo-propionic acid (1.93 g, 11.6 mmol), thioamide **2** (1.52 g, 8 mmol), and $CaCO_3$ (2.3 g, 23 mmol) were added to dry ethanol (60 mL) and stirred at room temperature under Ar for 5 h. The reaction mixture was filtered, and the solid washed with ethanol (2×20 mL). The combined filtrate was evaporated, and the residue dissolved in EtOAc (150 mL), the solution washed with 5% $KHSO_4$ and brine, and then dried. After evaporation the solid **3** was crystallized from EtOAc/*n*-hexane. Yield 1.48 g (74%); homogeneous (TLC system A). ^{1}H NMR ([D$_6$]DMSO): δ = 1.41 (s, 9H; $3CH_3$), 4.39 (d, ^3J(H,H) = 5.87 Hz, 2H; CH_2), 7.82 (t, ^3J(H,H) = 5.86 Hz, 1H; NH), 8.34 (s, 1H; CH_{Thz}), 12.94 (br s, 1H; COOH); ^{13}C NMR ([D$_6$]DMSO): δ = 28.6 (Boc-CH_3), 43.1 (CH_2), 80.9 (Boc-C_q), 129.1 (C^5_{Thz}), 148.2 (C^4_{Thz}), 158.2 (Boc-CO), 164.0 (C^2_{Thz}), 173.7 (COOH). ESI-MS: *m/z*: 259 $[M+H]^+$, 276 $[M+NH_4]^+$, 281 $[M+Na]^+$.

4: To **3** (5.2 g, 20 mmol) and *N*-methylmorpholine (2.2 mL, 20 mmol) in THF (100 mL) was added isobutyl chloroformate (5.2 mL, 20 mmol) at −20 °C. After 4 min aqueous ammonia (6 mL, 0.1 M) was added. After 3 h at room temperature and subsequent evaporation, the residue was precipitated with 10% $NaHCO_3$, filtered, and the solid was washed with water, dried, and crystallized from ethanol/ether/*n*-hexane. Yield 4.77 g, (93%); homogeneous (TLC systems A and C); X-ray structure analysis [14]. ^{1}H NMR ([D$_6$]DMSO): δ = 1.41 (s, 9H; $3CH_3$), 4.41 (d, ^3J(H,H) = 6.03, 2H; CH_2), 7.53, 7.65 (s, 1H; $CONH_2$), 7.8 (t, ^3J(H,H) = 5.66, 1H; NH), 8.14 (s, 1H; CH_{Thz}); ^{13}C NMR ([D$_6$]DMSO): δ = 28.1 (Boc-CH_3), 42.0 (CH_2), 78.7 (Boc-C_q), 124.0 (C^5_{Thz}), 150.0 (C^4_{Thz}), 155.8 (Boc-CO), 162.2 (C^2_{Thz}), 171.5 ($CONH_2$). ESI-MS: *m/z*: 258 $[M+H]^+$, 275 $[M+NH_4]^+$, 280 $[M+Na]^+$.

5: Prepared from **4** (4.33 g, 16.85 mmol) as described for **2**. Crystallization from ethanol/*n*-hexane. Yield 4.4 g (97%); homogeneous (TLC systems B and C); X-ray structure analysis [14]. ^{1}H NMR ([D$_6$]DMSO): δ = 1.41 (s, 9H; $3CH_3$), 4.4 (d, ^3J(H,H) = 5.94 Hz, 2H; CH_2), 7.85 (t, ^3J(H,H) = 5.83, 1H; NH), 8.35 (s, 1H; CH_{Thz}), 9.41, 9.94 (br s, 1H; $CONH_2$); ^{13}C NMR ([D$_6$]DMSO): δ = 28.2 (Boc-CH_3), 42.1 (CH_2), 78.8 (Boc-C_q), 127.0 (C^5_{Thz}), 153.4 (C^4_{Thz}), 155.8 (Boc-CO), 171.3 (C^2_{Thz}), 189.2 (C=S). ESI-MS: *m/z*: 274 $[M+H]^+$.

6: Prepared from **5** (2.0 g, 7.3 mmol) as described for **3**. Crystallization from EtOAc/ether. Yield 1.5 g (60%); homogeneous (TLC system A); X-ray structure analysis [14]. ^{1}H NMR ([D$_6$]DMSO): δ = 1.43 (s, 9H; $3CH_3$), 4.46 (d, ^3J(H,H) = 6.05 Hz, 2H; CH_2), 7.86 (t, ^3J(H,H) = 5.9, 1H; NH), 8.25, 8.48 (s, 1H; C^5_{Thz}, $C^{5'}_{Thz}$), 13.11 (br s, 1H; COOH); ^{13}C NMR ([D$_6$]DMSO): δ = 28.2 (Boc-CH_3), 42.0 (CH_2), 78.7 (Boc-C_q), 117.9 ($C^{5'}_{Thz}$), 128.9 (C^5_{Thz}), 147.3 (C^4_{Thz}), 148.2 (C^4_{Thz}), 155.8 (Boc-CO), 162.0 ($C^{2'}_{Thz}$), 162.2 (C^2_{Thz}), 172.8 (COOH). ESI-MS: *m/z*: 342 $[M+H]^+$, 359 $[M+NH_4]^+$, 364 $[M+Na]^+$.

7: **3** (1.3 g, 5 mmol) was deprotected quantitatively in 50% TFA/CH_2Cl_2 (20 mL) for 45 min. Fmoc-OSu (2.0 g, 6 mmol) in THF (30 mL) was added to the TFA salt and Na_2CO_3 (1.0 g, 10 mmol) in water (15 mL). After 12 h at room temperature THF was removed in vacuo, and the aqueous phase was diluted with water, acidified (1 N HCl) to pH 3 and filtered. The solid product was recrystallized from ethanol/ether. Yield 1.9 g (100%); homogeneous (TLC system A). ESI-MS: *m/z*: 381 $[M+H]^+$, 403 $[M+Na]^+$, 425 $[M+2Na]^+$.

8: Prepared from **6** (1.0 g, 2.9 mmol) as described for **7**. Crystallization from ethanol/ether. Yield 1.3 g (97%). ESI-MS: *m/z*: 464 $[M+H]^+$, 486 $[M+Na]^+$, 508 $[M+2Na]^+$.

9: The imino ether **9** was prepared from **1** (3.5 g, 20 mmol) according to ref. [10], obtained as a oil, and used without purification. Yield 3.4 g (85%). IR (Nujol): $\tilde{\nu}$ = 1653 cm^{-1} (C=N); ESI-MS: *m/z*: 203 $[M+H]^+$, 220 $[M+NH^4]^+$, 225 $[M+Na]^+$.

10: Oxazoline **10** was prepared according to ref. [11b] starting from **9** (3.4 g, 17 mmol) and H-Ser-OMe·HCl (3.1 g., 20 mmol) in CH_2Cl_2 (100 mL). Oxazoline **10** was obtained as a oil and used without purification. Yield 3.5 g (80%). ^{13}C NMR ($CDCl_3$): δ = 28.3 (Boc-CH_3), 27.9 (CH_2), 52.7 ($OOCH_3$), 67.7 (C^4_{Oxa}), 70.1 (C^5_{Oxa}), 79.9 (Boc-C_q), 155.5 (Boc-CO), 167.7 (C^2_{Oxa}), 171.2 (COO). ESI-MS: *m/z*: 259 $[M+H]^+$, 281 $[M+Na]^+$, 297 $[M+K]^+$.

11: DBU (3 mL, 30 mmol) was added to **10** (2.0 g, 7.75 mmol, about 80% purity) in a mixture of CCl_4 (10 mL), pyridine (15 mL), and acetonitrile (15 mL). After 3 h at room temperature the solvent was removed in vacuo, the residue dissolved in EtOAc, the solution extracted with 0.5 N HCl and the aqueous phase reextracted with EtOAc (2×). The EtOAc phase was washed with brine, dried, and the solvent evaporated. Chromatography on SiO_2 (EtOAc/*n*-hexane, 1:1) afforded oxazole **11**. Yield 0.85 g (43%). X-ray structure analysis [14]. ^{1}H NMR ([D$_6$]DMSO): δ = 1.4 (s, 9H; $3CH_3$), 3.86 (s, 3H; OCH_3), 4.45 (d, ^3J(H,H) = 5.77, 2H; CH_2), 5.34 (br t, 1H; NH), 8.16 (s, 1H; CH_{Oxa}); ^{13}C NMR ([D$_6$]DMSO): δ = 28.3 (Boc-CH_3) 38.0 (CH_2), 52.2 ($OOCH_3$), 80.4 (Boc-C_q), 133.4 (C^5_{Oxa}), 144.2 (C^4_{Oxa}), 155.1 (Boc-CO), 161.4 (C^2_{Oxa}), 162.3 (COO). ESI-MS: *m/z*: 257 $[M+H]^+$, 274 $[M+NH_4]^+$ 279 $[M+Na]^+$.

12: NaOH (0.24 g in 10 mL of water) was added to ester **11** (0.78 g, 3 mmol) in dioxane (30 mL). After 1 h at room temperature the solution was neutralized with 10% $KHSO_4$ to pH 6. Removal of the dioxane in vacuo was followed by acidification to pH 3 and extraction with EtOAc (3×). The extract was dried, and the solvent removed in vacuo. Crystallization from EtOAc/*n*-hexane. Yield 0.66 g (91%); homogeneous (TLC systems A and C). ^{1}H NMR ([D$_6$]DMSO): δ = 1.37 (s, 9H; $3CH_3$), 4.25 (d, ^3J(H,H) = 5.92 Hz, 2H; CH_2), 7.53 (t, ^3J(H,H) = 5.75 Hz, 1H; NH), 8.66 (s, 1H; CH_{Oxa}), 13.02 (br s, 1H; COOH); ^{13}C NMR ([D$_6$]DMSO): δ = 28.1 (Boc-CH_3), 37.2 (CH_2), 78.5 (Boc-C_q), 133.2 (C^5_{Oxa}), 145.1 (C^4_{Oxa}), 155.6 (Boc-CO), 162.0 (C^2_{Oxa}), 162.4 (COOH). ESI-MS: *m/z*: 243 $[M+H]^+$, 260 $[M+NH_4]^+$, 265 $[M+Na]^+$, 281 $[M+K]^+$.

13: Prepared from **12** (0.27 g, 1.1 mmol) as described for **7**. Crystallization from ethanol/ether/*n*-hexane. Yield 0.34 g (85%); homogeneous (TLC system A); ^{13}C NMR ([D$_6$]DMSO): δ = 37.6 (CH_2), 46.7 (Fmoc-C9), 65.9 (Fmoc-CH_2O), 120.0 (Fmoc-C4,C5), 125.2 (Fmoc-C1, C8), 127.1, 127.6 (Fmoc-C3,C6,C2,C7), 133.7 (C^5_{Oxa}), 140.7 (Fmoc-C4a,C4b), 143.8 (Fmoc-C8a,C9a), 145.0 (C^4_{Oxa}), 156.3 (Fmoc-CO), 162.0 (C^2_{Oxa}), 162.1 (COOH); ESI-MS: *m/z*: 365 $[M+H]^+$, 387 $[M+Na]^+$.

14: The imino ether **14** was prepared from **4** (4.8 g, 18.7 mmol) as described for **9**. The product was obtained as a oil and used without purification. Yield 5.1 g (95%). ESI-MS: *m/z*: 286 $[M+H]^+$.

15: The thiazolyl-oxazoline **15** was obtained from **14** (5.1g, 18 mmol) and Ser-OMe·HCl (1.55 g, 10 mmol) by heating under reflux for 3 h; after additional 12 h at room temperature, work up as described for **10**. Compound **15** was recrystallized from EtOAc/*n*-hexane. Yield 4,4 g (72%). ^{13}C NMR ([D$_6$]DMSO): δ = 28.1 (Boc-CH_3), 41.9 (CH_2), 52.2 ($OOCH_3$), 7.14 (CH_{Oxa}), 69.6 (CH^2_{Oxa}), 78.7 (Boc-C_q), 125.6 (CH_{Thz}), 142.2 (N-C_{Thz}), 155.8 (Boc-CO), 160.3 (C=N_{Oxa}), 171.3 (C=N_{Thz}), 172.2 (COO); ESI-MS: *m/z*: 342 $[M+H]^+$.

16: The thiazolyl-oxazole **16** was prepared from **15** (2.1 g, 6.1 mmol) as described for **11**. After purification on SiO_2 with EtOAc/*n*-hexane (2/1) as eluent, **16** was obtained as a colorless solid and recrystallized from EtOAC/*n*-hexane. Yield 1.1 g (55%); homogeneous (TLC systems B and C). ^{1}H NMR ([D$_6$]DMSO): δ = 1.41 (s, 9H; $3CH_3$), 3.83 (s, 3H; CH_3), 4.44 (br s, 2H; CH_2), 7.88 (br t, 1H; NH), 8.39 (s, 1H; CH_{Oxa}), 8.93 (s, 1H; CH_{Thz}); ^{13}C NMR ([D$_6$]DMSO): δ = 28.1 (Boc-CH_3), 42.0 (CH_2), 78.7 (Boc-C_q), 122.8 (CH_{Thz}), 133.3 (N-C_{Thz}), 141.3 (N-C_{Oxa}), 145.4 (CH_{Oxa}), 155.8 (Boc-CO), 157.2 (CH_{Oxa}), 161.0 (CH_{Thz}), 173.0 (COO); ESI-MS: *m/z*: 340 $[M+H]^+$, 362 $[M+Na]^+$.

17: The acid **17** was obtained from **16** (0.47 g, 1.4 mmol) as described for **12**. Crystallization from EtOAc/ether. Yield 0.42 g (92%); homogeneous (TLC system A). ^{1}H NMR ([D$_6$]DMSO): δ = 1.42 (s, 9H; $3CH_3$), 4.41 (d, ^3J(H,H) = 5.67 Hz, 2H; CH_2), 7.86 (br t, 1H; NH), 8.36 (s, 1H; CH_{Oxa}), 8.82 (s, 1H; CH_{Thz}); ESI-MS: *m/z*: 326 $[M+H]^+$, 348 $[M+Na]^+$.

18: Fmoc derivative **18** was prepared from **17** (0.55 g, 1,7 mmol) as described for **7**. Crystallization from ethanol/ether. Yield 0.7 g (92%); homogeneous (TLC system A); ESI-MS: *m/z*: 448 $[M^+]$, 465 $[M+NH4]^+$, 470 $[M+Na]^+$, 486 $[M+K]^+$.

19: Aqueous ammonia (10 mL) was added in one portion to **11** (0.51 g, 2 mmol) in methanol (30 mL) and stirred at room temperature for 15 h. After evaporation in vacuo 10% $NaHCO_3$ (50 mL) was added to the residue, which was then filtered off and washed with water. The solid was recrystallized from EtOAc/*n*-hexane. Yield 0.46 g (96%); homogeneous (TLC systems B and C); ^{1}H NMR ([D$_6$]DMSO): δ = 1.38 (s, 9H; $3CH_3$), 4.26 (d, ^3J (H,H) = 5.90 Hz, 2H; CH_2), 7.46 (br s, 2H; $CONH_2$), 7.21 (t, ^3J (H,H) = 5.58 Hz, 1H; NH), 8.49 (s, 1H; CH_{Oxa}), ^{13}C NMR ([D$_6$]DMSO): δ = 28.2 (Boc-CH_3), 37.3 (CH_2), 78.5 (Boc-C_q), 136.2 (C^5_{Oxa}), 141.9 (C^4_{Oxa}), 155.5 (Boc-CO), 161.7 (C^2_{Oxa}), 161.8 ($CONH_2$).

20: Prepared from **19** (0.84 g, 3.5 mmol) as described for **2**. The thioamide **20** was crystallized from EtOAc/*n*-hexane. Yield 0.76 g (84%); homogeneous (TLC systems B and C); ^{1}H NMR ([D$_6$]DMSO): δ = 1.37 (s, 9H; $3CH_3$), 4.26 (d, ^3J (H,H) = 5.65 Hz, 2H; CH_2), 7.54 (br t, 1H; NH), 8.57 (s, 1H; CH_{Oxa}), 9.25, 9.79 (br s, 1H; $CSNH_2$); ^{13}C NMR ([D$_6$]DMSO): δ = 28.1 (Boc-CH_3), 37.4 (CH_2), 78.5 (Boc-C_q), 140.9 (C^5_{Oxa}), 143.7 (C^4_{Oxa}), 155.5 (Boc-CO), 161.7 (C^2_{Oxa}), 187.5 (C=S).

21: Ester **21** was prepared from **20** (0.75 g, 2.9 mmol), $KHCO_3$ (1.5 g, 15 mmol) and ethyl bromopyruvate (1.25 mL, 10 mmol) in DME (50 mL) according to refs. [4a,b,j]. After purification on SiO_2 with EtOAc/*n*-hexane (2/1) as eluent **21** was crystallized from EtOAc/*n*-hexane. Yield 0.57 g, (57%); homogeneous (TLC systems B and C); ^{13}C NMR ([D$_6$]DMSO): δ = 14.2 (OCH_3), 28.2 (Boc-CH_3), 37.4 (CH_2), 60.9 (OCH_2), 78.5 (Boc-C_q), 129.1 (C^5_{Thz}), 134.5 (C^5_{Oxa}), 137.2 (C^4_{Oxa}), 147.2 (C^4_{Thz}), 155.7 (Boc-CO), 159.9 (C^2_{Oxa}), 160.6 (C^2_{Thz}), 162.9 (COO); ESI-MS, *m/z*: 354 $[M^+]$.

22: The Boc compound **22** was prepared from **21** (0.42 g, 1.2 mmol) as described for **12**. Crystallization from EtOAc/*n*-hexane. Yield 0.36 g (92%); homogeneous (TLC systems B and C); ^{1}H NMR ([D$_6$]DMSO): δ = 1.4 (s, 9H; $3CH_3$), 4.32 (br d, 2H; CH_2), 7.59 (br t, 1H; NH), 8.49 (s, 1H; CH_{Oxa}), 8.78 (s, 1H; CH_{Thz}); ^{13}C NMR ([D$_6$]DMSO): δ = 28.2 (Boc-CH_3), 37.4 (CH_2), 78.6 (Boc-C_q), 128.6 (C^5_{Thz}), 134.6 (C^5_{Oxa}), 137.0 (C^4_{Oxa}), 148.4 (C^4_{Thz}), 155.7 (Boc-CO), 159.6 (C^2_{Oxa}), 161.9 (C^2_{Thz}), 162.9 (COOH).

23: The Fmoc compound **23** was prepared from **22** (0.32 g, 1 mmol) as described for **7**. Crystallization from ethanol/ether. Yield 0.42 g (93%); homogeneous (TLC system A); ESI-MS: m/z 448 $[M^+]$, 470 $[M + Na]^+$, 492 $[M + 2Na]^+$.

Synthesis of the DNA Gyrase Inhibitor Microcin B17, a 43-Peptide Antibiotic with Eight Aromatic Heterocycles in its Backbone**

Georgi Videnov, Dietmar Kaiser, Marc Brooks, and Günther Jung*

Dedicated to Professor Helmut Zahn on the occasion of his 80th birthday

The complete structure elucidation of the most unusual polypeptide microcin B17 (McB17),[1,2] a DNA gyrase inhibitor, reveals that it contains four oxazole and four thiazole rings within its backbone of 43 amino acids. McB17 inhibits DNA replication with remarkably high biological activity.[3] The glycine-rich peptide antibiotic is ribosomally synthesized by *Escherichia coli* strain LP 17,[4] and posttranslational enzymatic backbone modifications of glycine, serine, and cysteine residues in the 69 amino acid precursor lead to the formation of 2-aminomethylthiazole-4-carboxylic acid [gly(Thz)] and 2-aminomethyloxazole-4-carboxylic acid [gly(Oxa)], as well as the bicyclic 2-[2′-amino-methyloxazole-4′-yl]thiazole-4-carboxylic acid [gly(OxaThz)] and 2-[2′-amino-methylthiazole-4′-yl]-oxazole-4-carboxylic acid [gly(ThzOxa)] (Fig. 1). The synthesis of these novel constraint amino acids and their Boc and Fmoc derivatives is described separately.[6] Here we summarize details of the total synthesis of McB17 that we first reported in 1995.[5]

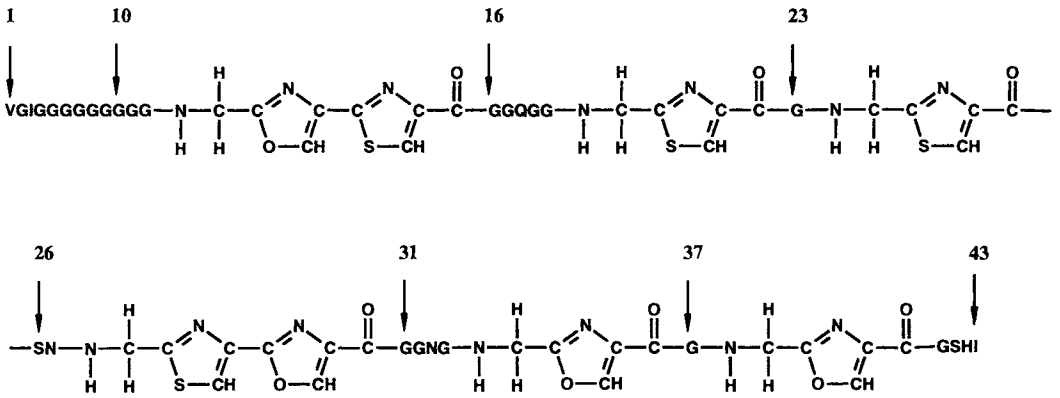

Fig. 1. Formula of the glycine-rich peptide antibiotic microcin B17 containing eight heterocyclic modifications that constrain the backbone [1,2]. Protein amino acids are abbreviated in the one-letter code and numbered according to the unmodified precursor protein.

McB17 was built up by 9-fluorenylmethoxycarbonyl (Fmoc) solid-phase synthesis starting from Fmoc-Ile-Wang resin. Fmoc-protected amino acids were coupled with an equimolar ratio of 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate (TBTU), *N*-hydroxybenzotriazole (HOBt), and diisopropylethylamine (DIEA), and the reaction was monitored for completion with ninhydrin. Due to problems in the stepwise synthesis of the glycine-rich N-terminal part, we used Fmoc-Gly-Gly-OH, Fmoc-Gly-Gly-Gly-OH, Fmoc-Ile^3-Gly^4-OH, and Boc-Val^1-Gly^2-OH in the appropriate positions (Fig. 1). In particular, Boc-Val^1-Gly^2-OH, Fmoc-Ile^3-Gly^4-

OH, and Fmoc-Gly^5-Gly^6-OH had to be coupled twice. The assembled peptide was cleaved from the resin with a 3:3:3:91 mixture of dimethylsulfide, *meta*-cresol, ethanedithiol, and trifluoroacetic acid (TFA) for 1 h at room temperature and precipitated with ether. The raw synthetic McB17 was about 50% pure and was chromatographed to high purity (>95%) by semipreparative HPLC (Nucleosil 300C18 5 μm, 8 × 250 mm; CH_3CN/H_20 containing 0.1% TFA). The structural identity of purified McB17 was confirmed by HPLC (Fig. 2), electrospray mass spectrometry (ESI-MS), and 2D NMR spectroscopy. The mass spectrum of the synthetic microcin B17 shows peaks having the expected mass of doubly and triply charged molecular ions (Fig. 2). The enantiomeric purity of HPLC purified McB17 has been determined by gas chromatography of a derivatized hydrolysate (48 h) on a Chirasil-Val to be within the usually tolerated values (<1%).

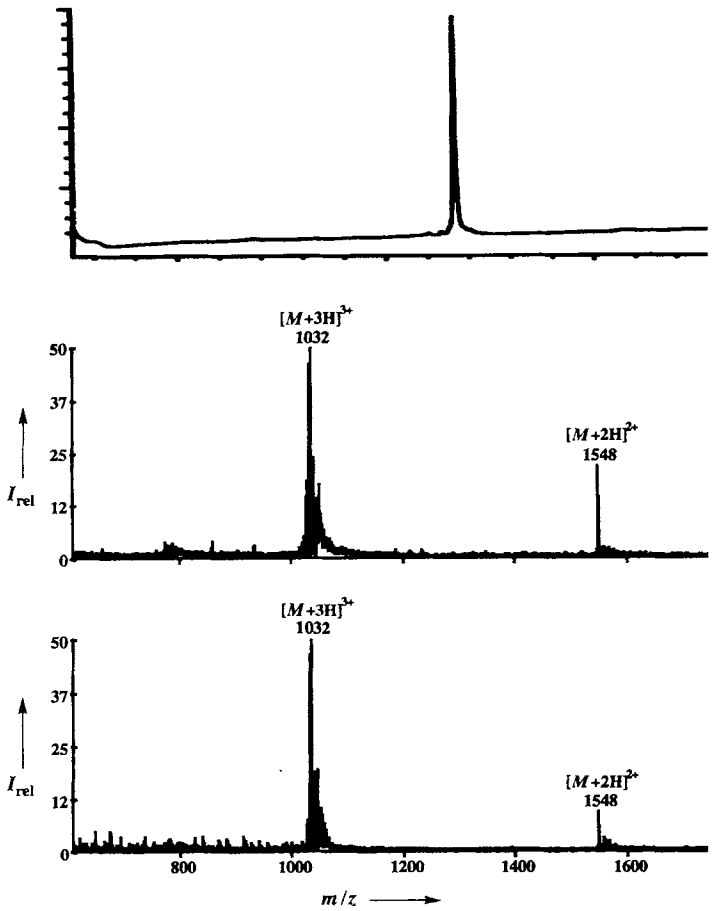

Fig. 2. HPLC chromatogram of purified synthetic microcin B17 (top) and ESI-MS spectra of the synthetic (center) and the purified natural (bottom) microcin B17 (M_r = 3094).

2D $^1H,^{13}C$ HSQC spectra (HSQC = heteronuclear single quantum coherence) were recorded to confirm the structure of the synthetic peptide originating from 43 amino acids, since we could rely on our complete NMR signal assignments of both the ^{15}N- and $^{13}C,^{15}N$-labeled natural McB17.[2] As expected the region for arene protons shows, besides the histidine signals, eight carbon signals that can be assigned to the CH groups of the eight five-membered heteroarenes. Thiazole rings show ^{13}C chemical shifts between δ = 125 and 130 and the oxazole ring between δ = 140 and 146. The spectrum of the synthetic product clearly exhibits the signals of the heteroaromatic modifications, which correspond exactly to those of natural McB17 (Fig. 3). Only the signal of the CH group in position 29 shows small deviations from the corresponding signal of the $^{13}C,^{15}N$-labeled sample, probably due to the strong pH dependence of signals of this moiety. Such a dependence was also observed in the natural sample.[2] The imidazol CH signals are broadened in both the synthetic and natural sample and are not visible in Figure 3 due to the particular level chosen for the illustrated 2D spectrum. The aliphatic signal region is in full agreement with the signals of the natural sample.[2]

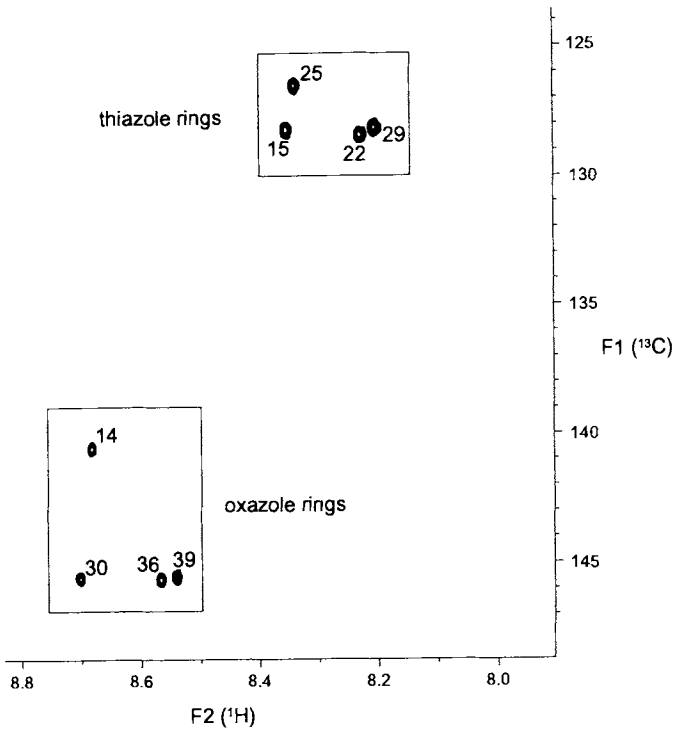

Fig. 3. Arene region of the $^1H,^{13}C$ HSQC spectrum of synthetic microcin B17 (c = 8 mg mL^{-1}, [D_6]DMSO) showing CH signals of the eight heterocycles (see Fig. 1). The signals were assigned according to ref. [2], and the numbering of heterocyclic residues relates to the sequence of the unmodified precursor protein.

An *Escherichia coli* (rec A$^-$) strain was used as a microcin B17 indicator strain in an agar diffusion assay. The lyophilized synthetic microcin was dissolved in urea buffer and spotted on an agar plate. After incubation the inhibition zones revealed the same antibacterial activity as the natural McB17.

The synthesis of McB17 confirms our previously published structure elucidation[1, 2] and represents a solid basis for our ongoing studies of structure–activity relationships of this gyrase inhibitor.

Experimental Procedure

NMR: 2D NMR spectra were taken at 600.13 MHz (^1H) on an AMX-600 (Bruker, Karlsruhe) with an inverse triple resonance probe. McB17 was dissolved in [D_6]DMSO (c = 8 mg mL^{-1}; reference DMSO: ^1H, δ = 2.50; ^{13}C, δ = 43.5; 305 K). For $^1H,^{13}C$ HSQC spectra at natural isotope abundance we used a pulse sequence of enhanced sensitivity applying gradients for coherence selection [7,8]. The offset frequency was set at δ = 135 (arene region) and δ = 45 (aliphatic region) in the ^{13}C dimension, and the experiment was carried out with a spectral band width of δ = 30 and 70, respectively, in the indirect dimension.

Antibacterial assays: The activity of McB17 was tested by the limited dilution assay [9]. The dissolution of the lyophilized sample in a TRIS buffer (pH 8) containing 50% urea and 1 mM EDTA resulted in a concentration of 1 mg McB17 per mL. Samples (each 5 μL) of a dilution series were spotted on M 63 glucose plates that were covered with 3 mL of minimal soft agar freshly seeded with 2×10^7 indicator

bacteria. After overnight incubation at 37 °C, the diameters of the halos were measured. The reciprocal of the minimum mass of McB17 that produced a clear halo of growth inhibition was defined as activity. The indicator strain was *E. coli* K12 16-19 Ufr/recA⁻/B1/T1, T5 sensitive (laboratory collection of the University of Tübingen, Microbiology Department), which is hypersensitive to McB17 due to its mutation in the SOS regulated recA⁻ gene [10].

$[Sb_{12}\{(2\text{-MeO})C_6H_4N\}_{18}]\cdot 6THF$; A Twenty-Four Membered Imidoantimony(III) Metallacycle**

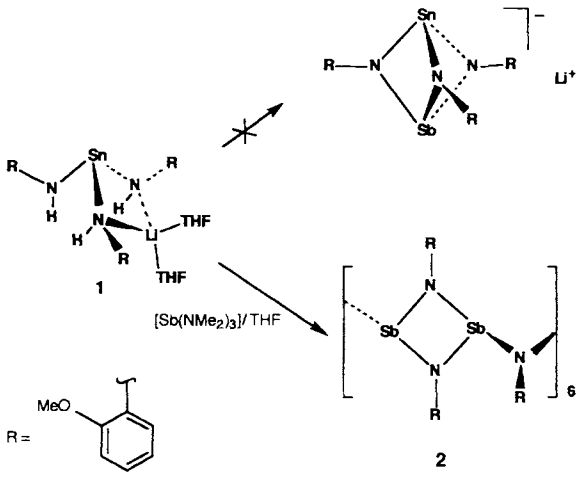
Michael A. Beswick, Maxwell K. Davies, Michael A. Paver, Paul R. Raithby, Alexander Steiner, and Dominic S. Wright*

Dimethyl amido complexes of p block metals $[E(NMe_2)_x]$ (E = Sb and Bi, $x = 3$;[1] Sn, $x = 2$[2]) are highly potent deprotonation reagents. Thus, the reactions of $[Sb(NMe_2)_3]$ with primary amines RNH_2 in the molar ratio 1:1 at low temperature give the dimeric imidoantimony(III) complexes $[\{(Me_2N)Sb(\mu\text{-}NR)\}_2]$ in which the amine ligands have been doubly deprotonated.[1b] The further reaction of the terminal Me_2N groups of $[\{(Me_2N)E(\mu\text{-}NR)\}_2]$ with [RNHLi] (E = Sb, Bi; R = C_6H_{11} (Cy), *t*Bu) in the molar ratio 1:2 produce cage complexes containing dianions such as $[E_2(NR)_4]^{2-}$.[1d, e] Such polyimido anions of elements of Group 15,[1c, d] which can be generated by similar "mixed-metallation" reactions, have an interesting coordination chemistry; they undergo both transmetallation[3a] and cocomplexation with metal salts.[3b] Our interests have broadened to encompass the syntheses and coordination chemistry of a range of anionic and neutral p block metallaligands.[4] We report here that the mixed-metallation reaction of $[Sb(NMe_2)_3]$ with the tris(amido)stannate complex **1** (ma = 2-methoxyanilino dianion, $(2\text{-OMe})C_6H_4N^{2-}$) leads to the formation of **2**, an imidoantimony(III) metallacyclic complex.

$[(Hma)Sn(\mu\text{-}Hma)_2Li\cdot 2THF]$ **1**

$[Sb_{12}(ma)_{18}]\cdot 6THF$ **2**

The reaction of **1** with $[Sb(NMe_2)_3]$ (1:1 equiv) was carried out in an attempt to prepare a mixed-metal complex containing the trigonal bipyramidal anion $[Sn(\mu\text{-}ma)_3Sb]^-$. However, the product of this reaction is not the simple species that was originally sought but the imidoantimony(III) metallacyclic complex **2** (Scheme 1). Although the mechanism of this reaction is not clear, the presence of the Sn^{II} reagent appears to be important, since attempts to prepare **2** by direct reaction of $[H_2ma]$ with $[Sb(NMe_2)_3]$ (3:2 equiv) were unsuccessful (see Experimental Procedure).



Scheme 1.

The low-temperature X-ray structure analysis of **2** (Fig. 1 top) shows that the reaction of **1** with $[Sb(NMe_2)_3]$ does not follow a simple deprotonation reaction pathway.[5] Molecules of **2** are composed of six Sb_2N_2 rings linked by bridging imido groups into a planar twenty-four membered metallacyclic ring. In addition there are six THF molecules in the lattice. The orientation of the Sb_2N_2 moieties, perpendicular to the macrocyclic core of **2**, produces an overall toroid structure (Fig. 1 bottom). Several metallacyclic complexes containing transition metals linked by O-centered ligands have structural arrangements related to that of **2**.[6] Although metallacyclic complexes containing main group elements are known[7] and other twenty-four membered rings based on phosphorus–nitrogen backbones have been characterized,[8] complex **2** is the largest structurally characterized metal imido complex of Group 15 and the first p block metal metallacyclic imido complex.

The planar Sb_2N_2 units from which the metallacyclic ring is constructed are a distorted rhombic shape (N-Sb-N av 77.2°, Sb-N-Sb 102.8°). There is surprisingly little variation in the Sb–N bond lengths throughout the whole molecule (Sb–N av 2.070 Å within the dimer units; cf. av 2.044 Å for the bridging imido groups connecting them). The angles and bond lengths found within the Sb_2N_2 units are similar to those which have

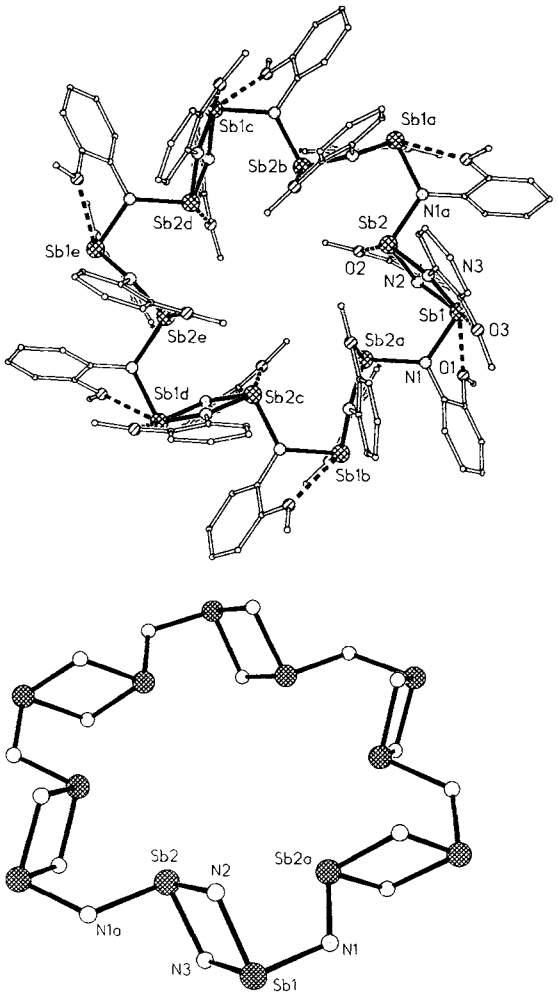

Fig. 1. Top: Structure of **2** in the solid state. Hydrogen atoms and THF lattice solvation have been omitted for clarity. Important bond lengths [Å] and angles [°]: Sb1–N1 2.04(1), Sb1–N2 2.10(1), Sb1–N3 2.07(2), Sb2–N2 2.06(1), Sb2–N3 2.10(1), Sb2a–N1 2.05(1), Sb1–O1 3.08(2), Sb1–O3 2.71(1), Sb2–O2 2.76(2), Sb2···Sb2e ca. 7.8; Sb2a-N1-Sb1 120.2(6), N1-Sb1···Sb2 100.1(4), Sb1···Sb2-N1a 100.3(4). Bottom: Toroid structure of the core of **2**.

been previously observed in the structures of isolated dimeric $Sb^{III,V}$ complexes.[1a, b, f] The formation and stability of the metallacyclic structure, as opposed to the alternative formation of a polymer, may conceivably be due to the presence of strong Sb–O interactions which hold the cyclic framework of **2** together. One of the Sb centers of each Sb_2N_2 unit interacts with a methoxy group from a bridging ma ligand within the Sb_2N_2 unit (Sb–O 2.76 Å), whereas the second Sb has an intra-Sb_2N_2 contact to the other bridging methoxy group (Sb–O 2.71 Å) and an inter-Sb_2N_2 contact to a methoxy group of a bridging ma ligand (Sb–O 3.08 Å). These interactions are well within the sum of the van der Waals radii of Sb and O (3.70 Å) and are considerably shorter than the weak intermolecular Sb···O contacts observed in the structure of $[\{(Me_2N)Sb[\mu\text{-}NC_6H_2\text{-}3,4,5\text{-}(OMe)_3]\}_2]$ (av 3.500 Å). The result of these interactions is a cyclic $Sb_{12}N_{18}$ backbone in which alternating highly distorted four-coordinate and five-coordinate Sb^{III} centers are present.

As a result of the inter-Sb_2N_2 interaction of one of the bridging methoxy groups with the four-coordinate Sb centers of **2**, the associated aromatic ligands are distorted significantly out of the planes of each of the Sb_2N_2 moieties. The six attached methoxy ligands of these are directed towards the center of the metallacycle (three above and three below the $Sb_{12}N_{18}$ ring), giving rise to an almost perfectly octahedral macrocyclic cavity (distance between diametrically opposite Sb centers ca. 7.8 Å; Sb-N-Sb 120.2(6)° and Sb···Sb-N av 100.2°). This arrangement presents the exciting prospect of selective complexation of metal ions by this new type of metallacyclic ligand. In addition, there is also the possibility of anion complexation by the Lewis acidic Sb^{III} centers.

We are currently investigating the syntheses of other Group 15 metallacyclic complexes using a similar synthetic approach to that used in the synthesis of **2** and the applications of **2** as a novel macrocylic ligand to transition and main group metals. The variation in the functionalities of the imido (and potentially phosphido and arsenido) ligands in these species may introduce further possiblities for site-selective metal complexation.

Experimental Procedure

1: H_2ma (0.74 g, 6 mmol) in THF (20 mL) was treated with *n*BuLi (4.0 mL, 1.5M, 6 mmol) at 0 °C. To the yellow solution of the lithiate was added $[Cp_2Sn]$ (2.5 mL, 0.8M in THF, 2 mmol) [9] at room temperature. The reaction mixture was briefly heated to reflux (which resulted in changing the color of the mixture to a more intense yellow) and the solvent was reduced in vacuo to about 8 mL, whereupon a yellow solid precipitated. The solid was redissolved by heating gently, and storage at room temperature (24 h) gave a crop of yellow crystalline blocks of **1**. The low-temperature X-ray structure of **1** shows that the complex has the formula $[(Hma)Sn(\mu\text{-}Hma)_2Li\cdot 2THF]\cdot 0.5\,THF$. The THF in the lattice was removed when the complex was placed under vacuum (ca. 15 min, 10^{-1} atmos) during isolation. The following analytical and spectroscopic data refer to the dry amorphous powder produced; yield 0.98 g (77%); m.p. 226 °C; IR (nujol): $\tilde{\nu}_{max}[cm^{-1}] = 3327$ (w, N–H str), 1588 (m, arene str), 1223 (s, C–O str), 734 (s, *o*-substituted Ph ring); ^1H NMR (+ 25 °C, 250 MHz, $(CD_3)_2SO$): $\delta = 6.67$ (3H, dd, C(3)-H), 6.55 (3H, dd, C(6)-H), 6.46 (3H, td, C(4)-H), 6.09 (3H, td, C(5)-H), 3.72 (3H, s, N-H), 3.64 (9H, s, MeO), 3.57 (24H, m, THF), 1.73 (24H, m, THF); elemental analyses: Calc. C 54.7, H 6.3, N 6.6; found C 53.4, H 6.3, N 6.4.

2: A solution of **1** (1.59 g, 2.5 mmol) in THF (25 mL) was treated with $[Sb(NMe_2)_3]$ (1 mL, 2.5M in THF, 2.5 mmol) at 0 °C. Warming the reaction mixture to room temperature followed by briefly heating to reflux caused the initial yellow solution to intensify in color to give a lemon-yellow solution. The solution was filtered (Celite) and the solvent was reduced in vacuo to about 7 mL, whereupon a yellow solid precipitated. The precipitate was redissolved by warming gently and lemon-yellow crystals of **2** were formed by storage at room temperature (24 h); yield 0.22 g (26%); m.p. decomp 180 °C; IR (nujol): $\tilde{\nu}_{max}[cm^{-1}] = 1586$ (m, arene str), 728 (s, *o*-substituted Ph ring); ^1H NMR (+ 25 °C, 250 MHz, $(CD_3)_2SO$): $\delta = 6.60$ (48H, m, aryl C-H), 3.72 (36H, s, MeO), 3.57 (24H, m, THF), 1.74 (24H, m, THF); elemental analyses: Calc. C 44.2, H 4.3, N 6.2; found C 42.5, H 4.2, N 6.4. The analytical and spectroscopic data confirm that, unlike **1**, the lattice solvation by THF is robust.

Metastable Reverse Globular Micelles and Giant Micellar Wires from Block Copolymers**

Joachim P. Spatz, Stefan Mößmer, and Martin Möller*

Amphiphilic molecules such as surfactants and lipids associate in aqueous solution to form rather well-defined globular, rodlike, and platelet micelles, continuous structures, bilayers, and bilayer vesicles. These can partly transform from one to another when the solution conditions such as the ionic strength, the concentration, pH, or temperature are changed.[1] For block copolymers (that is, macromolecular amphiphiles) different structure variations are known in the bulk, depending on the length of the constituent blocks. In solution, however, block copolymers tend to form globular micelles.[2-7] Their size depends on the solvent and on the absolute and relative length of the blocks. In quantitative agreement with theoretical predictions, experimental evidence indicates that the cores are not spherical but have the shape of ellipsoids.[8, 9]

Only recently Eisenberg et al. observed for the first time different morphologies of polystyrene(PS)-*block*-poly(acrylic acid) associates in aqueous solution, namely, spheres, rods, lamellae, vesicles, and complex aggregates of reverse micelles.[8-10] An essential condition for the formation of these structures was that the PS core block was long relative to the outer poly(acrylic acid) block. Dispersion in water was achieved by dissolving the block copolymer in DMF-rich solvent mixtures, followed by addition of water and dialysis. Because of the vitrification of the PS core, the structure can be frozen in a nonequilibrium state.

This work deals with polystyrene-*block*-poly(2-vinylpyridine)s with a poly(2-vinylpyridine) (P2VP) block that is significantly longer than the PS block. In a dilute solution of toluene these block copolymers are expected to form reverse globular micelles, which, however, become unstable as the solvent evaporates, that is, the solution concentration increases. Transmission electron microscopy (TEM) and scanning force microscopy (SFM) is employed to study how preservation or transformation of the metastable structures upon formation of thin films depends on the block lengths and the ionic character of the core block. In a similar study we recently demonstrated that intact globular micelles are deposited from a dilute solution of a symmetrical polystyrene-*block*-poly(2-vinylpyridine) in toluene.[11-16] Transformation of the globular micelles to the lamellar bulk equilibrium structure could be inhibited by neutralization of the poly(2-vinylpyridine) block with $HAuCl_4$, which establishes a stabilizing dipole–dipole interaction.

Two polystyrene-*block*-poly(2-vinylpyridine) samples differing in their absolute molecular weight but having a similar styrene:P2VP ratio (R) were used. Table 1 summarizes the molecular characteristics. The polymers have been treated with different equivalents of $HAuCl_4$ per pyridine group in a dilute solution of toluene. The absolute molecular weight, the R ratio, and the degree of neutralization L ($L = n_{HAuCl_4}/n_{P2VP}$) are the parameters that effect the kinetic stability of a structure formed in dilute solution (in this case, globular micelles) when the solvent is evaporated. The rate of evaporation will also influence the structure transformation, as the stability is only kinetically controlled. The rate of evaporation will be subject of a subsequent paper; in the present work it was kept constant for all investigations.

Table 1. Molecular characteristics of the block copolymers.

Sample	M_n(PS) [a] [g mol^{-1}]	M_n(P2VP) [b] [g mol^{-1}]	M_n (total) [c] [g mol^{-1}]	M_w/M_n [c]
PS80-P2VP320	7.900	34.900	57.600	1.10
PS180-P2VP700	19.000	74.000	108.300	1.19

[a] Molecular weight measured by GPC for the polystyrene block before addition of the second monomer. [b] Molecular weight calculated from the styrene/2-vinylpyridine composition obtained by ^{1}H NMR in relation to the length of the PS block. [c] Molecular weight measured by GPC for the block copolymer according to narrow molecular weight polystyrene standards.

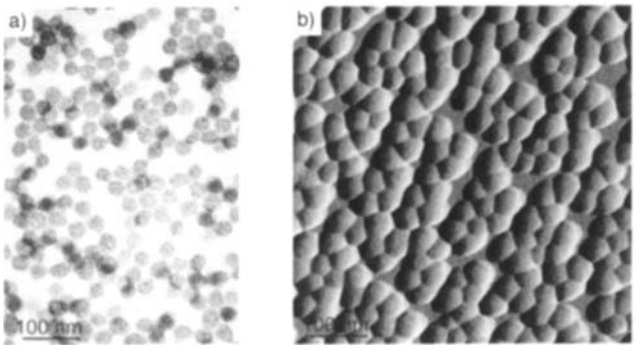

Fig. 1. Transmission electron and scanning force micrographs of spherical micelles formed of PS80-P2VP320, $R = 0.24$, $L = 0.7$. a) TEM reveals the core of the micelles (small black dots). b) SFM depicts the outer contour with the corona of the micelles, which cannot be seen by TEM. a) and b) have the same scale.

in the TEM image represent agglomerations of small gold particles, which form upon irradiation by the electron beam (electron irradiation stimulates reduction of Au^{III} ions).[12, 16] The arrangement of the gold particles indicates that the globular micelles were preserved in the solvent-free state. The gold particles mark the micelle core. The outer contours of the micelles can also be seen in the SFM picture in Figure 1b. Comparison of the TEM picture with the SFM picture reveals that the core remained less affected by the close packing of the micelles within the thin film, whereas the PS shell was significantly deformed and approached a honey comb structure as flat contact areas were formed between the micelles.

Figure 2 shows TEM pictures of a film that was formed under identical conditions from the same block copolymer, which, however, had been treated with a smaller amount of $HAuCl_4$ ($L = 0.3$). In coexistence with the globular micelles a new structure, giant cylindrical micelles, were formed. Again, the gold-loaded core of the micelles is depicted by the black areas in the TEM pictures. The ratio of the length of the cylinder to its diameter (the aspect ratio) exceeded values of 2000. While the diameters of the disks is (32 ± 3) nm, the diameter of the stripes is uniformly (21 ± 3) nm.

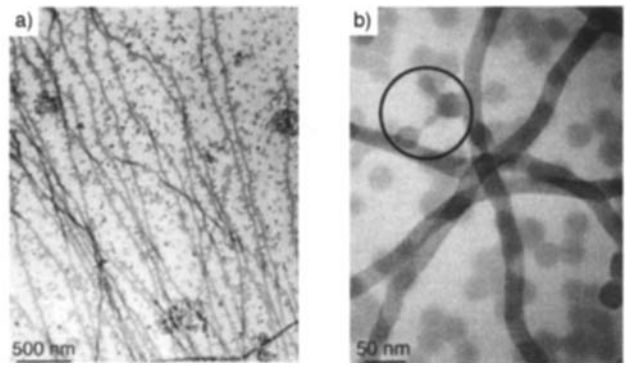

Fig. 2. The TEM images show a) the formation of cylindrical micelles with an aspect ratio a of about 2000 and b) cylindrical micelles in direct contact. The circle marks the initial step of the transformation from cylinders to wires.

Very obviously a number of the spherical micelles coagulated to form the long isolated cylinders, which are known for low molecular weight surfactants,[18] but have only been observed once for block copolymers in solution.[9] As shown in Figure 2b, these micellar wires cross each other without the integrity of the cylinders being affected by the direct contact. The initial step of the transformation from cylinders to wires is marked by the circle in Figure 2b. Apparently the transformation occurs on surface contact of the spherical micelles.

Figure 3 shows a scanning force micrograph of the micellar wires. The image displays the amplitude control signal, emphasizing rather small features in height.[17] Apparently, the corona of the cylinders is still corrugated with a periodic structure similar to the dimensions of globular micelles. Comparison of the contacts between spheres and wires demonstrates that the contour of the latter is less deformed by the contact.

Fig. 3. SFM amplitude control signal (length of one side corresponds to 2 μm) of a monolayer of spherical micelles on top of which cylindrical micelles were formed.

Neither the cylinders nor the globules represent the bulk equilibrium structure for the strongly unsymmetric block copolymers in the solvent-free state.[19] Apparently the formation of the micellar wires is controlled by the decrease in the kinetic stability of the spherical micelles as the degree of ionization of the core block is lowered from 0.7 to 0.3. This is consistent with the observation that no micellar wires were formed when at the same time the R ratio was increased. At $L = 0.3$, a PS110-P2VP280 ($R = 0.39$) did not yield cylindrical structures.

A second, important point is the observed contraction of the core radius upon formation of the micellar cylinders. This is in agreement with expectations and can be regarded as the driving force of the transformation. At the R ratios employed here, the core blocks have to stretch in order to form globular micelles with a minimum total interface area, which depends on the size and the number of micelles.[4, 5, 7] The penalty in entropy for the stretching is balanced by the reduced contacts between the ionic and nonpolar units. As the solvent evaporates, the balance is disturbed and the cylindrical micelles represent a more favorable structure with respect to the free energy. Thus, diminishing L to 0.3 accelerates the transformation kinetics to the more favorable micellar wires.

This is also demonstrated by the comparison of the two block copolymer samples that have the same composition but different absolute molecular weights (Table 2). The obtained decrease in the core diameter can be correlated to the increase in kinetic stability on transforming the globule to cylinders and depends on the absolute molecular weight. The smaller the ratio D of the diameter of the spheres to that of the cylindrical micelles, the smaller the free energy gain by the transformation. A higher molecular weight results in slow relaxation times, which have a direct influence on the transformation kinetics. This argument is consistent with the observation that the aspect ratio of the

Table 2. Dimensions of spherical and cylindrical wires.

Dimensions	PS80-b-P2VP330 $R = 0.24$, $L = 0.3$	PS180-b-P2VP700 $R = 0.26$, $L = 0.3$
D_1 [nm] [a]	32	35
D_2 [nm] [b]	21	27
D [c]	1.52	1.30
a	2×10^3	2×10^2

[a] D_1 = diameter of the spherical micelle. [b] D_2 = diameter of the micellar wire. [c] $D = D_1/D_2$. [d] a = aspect ratio = (micellar length)/(micellar diameter)

molecular wires was reduced considerably as D decreased from 1.52 to 1.30 on changing from PS80-P2VP320 to PS180-P2VP700.

Summarizing, we emphasize the following points (Fig. 4): 1) Coagulation of spherical micelles is explained by the reduced chain stretching. 2) This results in an increased grafting density in the corona and a higher shape stability. 3) The ends of the cylinders are particularly activated because of a reduced grafting density. Points 2) and 3) explain the coexistence of spheres and cylinders and the linear growth of the cylinders.

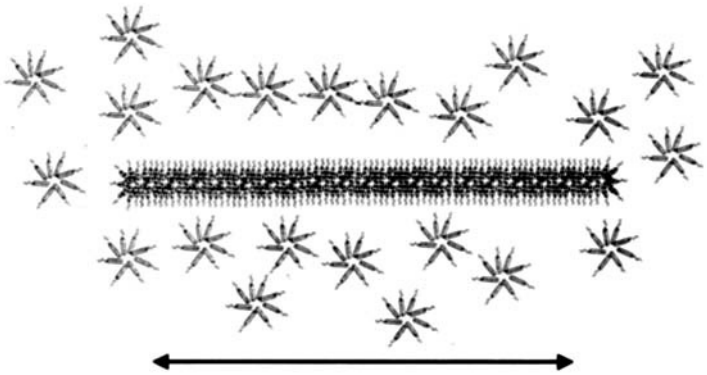

Fig. 4. The formation of micellar cylinders. Globular micelles can only join the ends of a cylinder. The arrow indicates the direction of growth. However, micellar transformations can be blocked by kinetic stabilization of the structure during the evaporation process.

Experimental Procedure

Sample preparation: The polystyrene-*block*-poly(2-vinylpyridine) block copolymers were synthesized by anionic polymerization [20, 21]. A solution of block copolymer (0.5 wt% in toluene) was mixed with different amounts of $HAuCl_4 \cdot H_2O$, depending on the molar concentration of pyridine groups (L = $HAuCl_4$/P2VP). The mixture was stirred for at least 24 h to allow complete dissolution of the gold salt within the cores of the block copolymer micelles. The solutions were diluted to 1–3 mg block copolymer per milliliter. Thin films were prepared by putting a drop of the solution onto an electron microscopy grid coated with a thin layer of carbon, which was in direct contact with a soaking tissue to remove the solution immediately. The film thickness was controlled both in this way and by varying the concentration.

Bright-field TEM images were recorded with a PHILIPS EM400T microscope operated with 80 kV. In order to minimize the destruction of the polymer by the electron beam, the electron beam intensity was kept as low as possible (second condenser lens: 50 Pt, lens: 30 Au). Scanning force microscopy with the same samples (grids) that were used for electron microscopy were performed with a Nanoscope III [17] operating in the tapping mode [22].

Synthesis, Structure, and Bonding of a Mixed-Valent Tetraphosphete**

Walter Frank,* Volker Petry, Elmar Gerwalin, and Guido J. Reiss

Investigations of compounds of the general formula P_4R_4 have so far been concerned exclusively with cyclotetraphosphane $(PH)_4$ and its derivatives.[1] Neither experimental nor theoretical studies exist that deal with the valence-isomeric $1\lambda^5,3\lambda^5$-tetraphosphete $(H_2PP)_2$ and its derivatives, although two conceptual approaches are possible to such a mixed-valent 4π-electron four-membered ring system (**A**): First, it may be considered an analogue of the diphosphetes **B**[2] and the isovalence-electronic cyclodiphosphazenes **C**;[3] second, it is evidently related to the phosphinylidene-σ^4-phosphoranes[4] and in

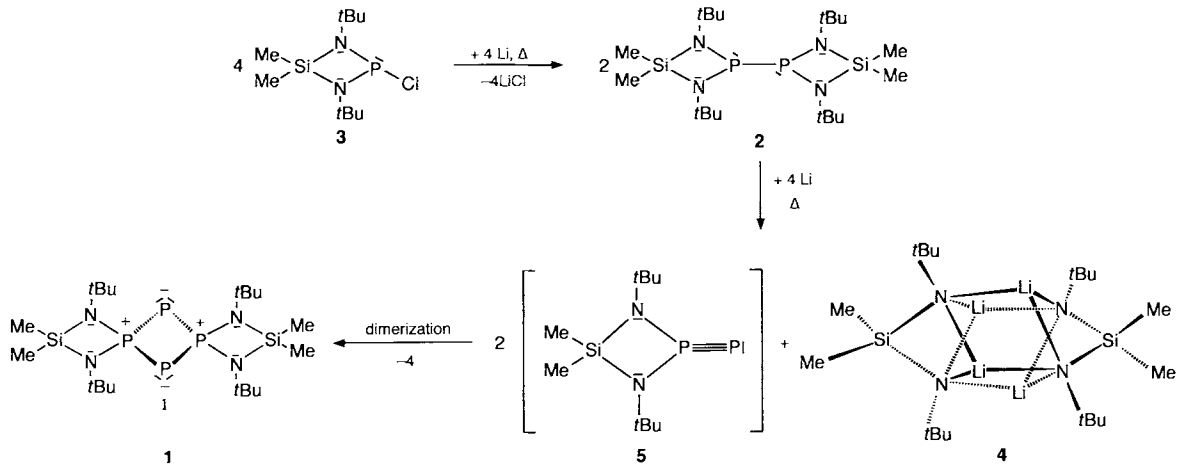

Scheme 1. Postulated mechanism for the formation of 1.

particular to those having acyclic "monounsaturated" λ^5P-λ^3P-λ^5P structural units.[5] Recently we have developed a simple route to compound **1** (see Scheme 1), which contains a $1\lambda^5,3\lambda^5$-tetraphosphete four-membered ring as the central structural unit of a dispirocyclic system.

Compound **1** is formed, in addition to the tetrakis(amino)-diphosphane **2**, in the reduction of the bis(amino)chlorophosphane **3**[6] with lithium. The reaction was monitored by NMR spectroscopy, which suggested that **1** is formed as a secondary product from **2** (Scheme 1). Since more complex mechanisms may also be contemplated under the reaction conditions given, and direct evidence for an intermediary phosphidophosphorane **5** has not been obtained, further investigations will be necessary to show whether or not **1** is actually formed by a "head-to-tail" type dimerization (Scheme 1). The lithium amide **4**[7] was identified by ^{7}Li NMR as well as by ^{1}H NMR spectroscopy and by the molecular ion M^+ in the EI mass spectrum as the only other lithium-containing compound in addition to dissolved lithium chloride.

The intense yellow compound **1**, which can be handled in air for long periods of time without decomposition, has been characterized by elemental analysis, mass spectrometry, ^{1}H NMR and ^{31}P NMR spectroscopy, and by a crystal structure investigation.[8] It is poorly soluble in both nonpolar and polar solvents. Therefore, ^{1}H NMR and ^{31}P NMR spectra could be recorded only in dioxane at elevated temperature. Under such conditions, the spectra are consistent with D_{2h} symmetry of the molecule. While the ^{31}P NMR chemical shift of the σ^4-P atoms is in good agreement with the values found in comparable compounds, that of the σ^2-P atoms has a rather unusual value lying between the ranges usually obtained for phosphinylidene-σ^4-phosphoranes and diphosphenes.

Upon crystallization, the point symmetry of the molecules of **1** is lowered (to C_i), as might be expected, while the D_{2h} symmetry is roughly conserved for the spirocyclic skeleton of Si, N, and P atoms (Fig. 1). The extent of rhombic distortion of the central P_4 ring is remarkable, exhibiting an unusually acute P1-P2-P1a angle of 79.4°. All of the P–P bonds in the ring are approximately equal in length (Table 1); the distances are typical of monounsaturated λ^5P-λ^3P-λ^5P structural units.[5]

In the EI mass spectrum of **1**, M^+ is the peak with the largest m/z observed. In addition to the cyclic $[Me_2Si(NtBu)_2P]^+$ ion and its characteristic fragments, the radical cation of the monomeric phosphidophosphorane **5** and its decomposition products are observed with higher source temperatures.

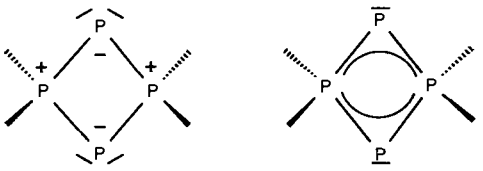
[a] The structure of **1** was determined by X-ray structure analysis, those of the model compounds **6** and **7** by ab initio calculations (RHF6-31G*).

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1513 $ 15.00+.25/0

Ab initio quantum chemical calculations[9] revealed a very good agreement of the structural parameters of the model compound **6**, in which each of the CH_3 groups is replaced by a H atom (the conformational arrangement of the resulting methyl groups is like that of the *tert*-butyl groups in Fig. 1),[10] with those in **1** obtained by crystal structure investigation (Table 1). The important structural features of **1** (equivalent P1–P2 and P1–P2a distances, rhombic distortion) are basically accounted for by formulations as a bis(ylide) **I** or as a system with delocalized double bonds **II**. From the two canonical π-MOs schematically represented in Figure 2, it can be seen immediately that pπ-pπ bond contributions are considered in **1**, whereas the 3c/2e interactions in comparable cyclodiphosphazenes are formulated in terms of pπ-dπ fractions.[4b] The calculated charge distributions in the P_4 ring of **1** and in the P_2N_2 ring of its phosphazene analogue $[\{NP(NMe)_2SiH_2\}_2]$ **8** show that the ylidic character is predominant in each case (natural charges:[14] **6**: P1 +1.40, P2 −0.45, N −1.34; **8**: P1 +2.49, N_{ring} −1.55, N_{term} −1.38), but is reduced in **1** as compared to **8**. In contrast, the π-bond fraction calculated by Mulliken population analyses and NLMO analyses[14] is significantly higher in **1** than in **8**. According to our MP2/6-31G* calculations,[9] the parent compound $1\lambda^5,3\lambda^5$-tetraphosphete **7** is less stable by 109.2 kJ mol^{-1} than the valence-isomeric cyclotetraphosphane $(PH)_4$ in its most stable conformation (all-*trans*, D_{2d} symmetry).



I II

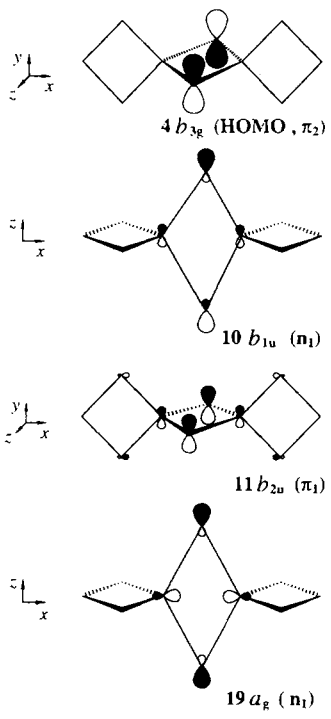


Fig. 2. π and n orbitals relevant for the discussion of the bonding in the P_4 ring of **1**; calculated orbital energies of the nine highest occupied orbitals [eV]: π_2(HOMO) −6.81, n_2 −8.38, π_1 −8.78, $7b_{2g}$ −9.51, $2a_u$ −10.40, $9b_{1u}$ −11.73, $16b_{3u}$ −11.82, n_1 −12.40.

Experimental Procedure

1,3,7,9-Tetra-*tert*-butyl-2,2,8,8-tetramethyl-1,3,7,9-tetraaza-$4\lambda^5$,5,$6\lambda^5$,10-tetraphospha-2,8-disiladispiro[3.1.3.1]deca-4,6(10)-diene (**1**) and 1,3,1′,3′-tetra-*tert*-butyl-4,4,4′,4′-tetramethyl-[2,2′]-bis(1,3,2,4-diazaphosphasiletidinyl) (**2**): Lithium (0.37 g, 53.3 mmol) was suspended in a solution of **3** (10.7 g, 40.0 mmol) [6] in THF (150 mL), and the mixture was heated to reflux. After two days, complete conversion of **3** to yield the diphosphane **2** and the tetraphosphete **1** was established by ^{31}P NMR spectroscopy. From the orange filtrate of the reaction mixture, 1.89 g (18%, based on **3**) of yellow plates of **1** crystallized in the course of two weeks at −35 °C. The solvent was removed from the mother liquor in vacuo, and a yellow oil was distilled at 54 °C/10^{-2} mbar from the highly viscous red residue. The oil congealed almost completely, often only after several days, with crystallization of colorless plates of **2** (5.65 g, 61%, m.p. 30 °C).

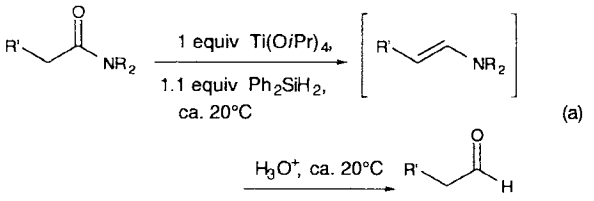
A Mild General Procedure for the One-Pot Conversion of Amides to Aldehydes**

Shelley Bower, Kristina A. Kreutzer, and Stephen L. Buchwald*

Functional group manipulation is fundamental to synthetic organic chemistry and, hence, the development of new transformations remains of great interest. The conversion of an amide to an aldehyde is an underdeveloped transformation; few good general methods are available.[1] Existing techniques usually utilize aluminum or boron hydrides.[2] Many such reactions are substrate specific, the outcome of the reaction being dependent upon the nature of the nitrogen substituents.[3] The high reactivity of some reagents is manifested by low functional group tolerance, overreduction to amines, or the formation of other byproducts.[2b, 4] Herein, we describe a general procedure for the conversion of amides to aldehydes that employs readily available, inexpensive reagents, and operates under mild conditions at room temperature.

Recently we have reported a number of catalytic and stoichiometric titanium-mediated hydrosilylations of carbonyl compounds, including procedures for the reduction of esters[5] and lactones.[6] Herein we describe the reactions of a stoichiometric quantity of $Ti(OiPr)_4$ and Ph_2SiH_2 with amides [Eq. (a)]. In most instances an enamine is the initial product (see below).[7] Subsequent aqueous workup then affords the aldehyde.



(a)

Typically, the reaction is carried out neat, using 1.0 equivalent $Ti(OiPr)_4$ and 1.1 equivalents Ph_2SiH_2 at room temperature, although the reaction can be carried out in THF or benzene if desired. Examination of the ^1H NMR spectrum of the crude reaction product with anisole as an internal standard shows the yields of enamine to be in the range 80–95%. No overreduction to amine is observed. The enamine may be easily hydrolyzed in situ by using a simple aqueous workup (2:1 THF/1 M HCl or wet silica gel/THF for acid-sensitive compounds) to yield the desired aldehyde, usually in excellent yields.[8] While the reaction does not proceed with any significant catalytic turnover,[9] the cost of $Ti(OiPr)_4$ is insignificant for most applications.

To explore the scope of this method, the reduction of a number of substrates was investigated (Table 1). The results shown in entries 1–4 demonstrate that the reaction can be carried out using both tertiary amides with aliphatic nitrogen substituents of varying steric demands (entries 1–3) or with aromatic substituents (entry 4). In this latter case hydrosilylation afforded a mixture of enamine and a hemiaminal, both of which could be hydrolyzed to the desired aldehyde. In addition, secondary amides with a bulky N-substituent are efficiently processed (entry 5), although, while 1.1 equiv of Ph_2SiH_2 was sufficient for complete conversion to the enamine, an additional equivalent of Ph_2SiH_2 caused the reaction to proceed much faster. The reaction tolerates a number of different functional groups including internal and terminal C–C double bonds (entries 6 and 7), and even terminal C–C triple bonds (entry 8). No competitive reduction of a nitrile moiety (entry 9) was observed. An epoxide

Table 1. Titanium-mediated conversion of amides to aldehydes [a].

[a] All reactions were carried out neat at room temperature using 1.0 equiv $Ti(OiPr)_4$ and 1.1 equiv Ph_2SiH_2 except where indicated. [b] Workup A: 2/1 THF/1 M HCl, room temperature, 30 min to 3 h. Workup B: 2/1 THF/H_2O, excess silica gel, room temperature, 2–5 h. [c] Yields refer to products isolated after column chromatography. All compounds were characterized by ^1H NMR, ^{13}C NMR, and IR spectroscopy, and determined to be >95% pure by ^1H NMR spectroscopy and gas chromatography. [d] 2.5 equiv Ph_2SiH_2 were used. [e] This reaction was performed in THF. [f] Crude aldehyde was treated with excess MeMgBr, Et_2O, 0 °C. [g] Product contaminated with ≈5% $Ph_2Si(OH)_2$.

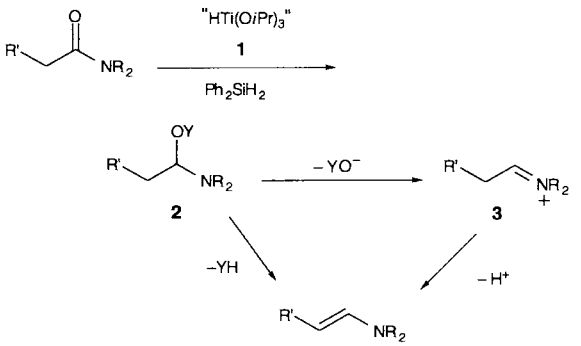
(entry 10) and two ethers (entries 11 and 12) were also successfully transformed under these conditions. The crude aldehydes derived from amides containing a thiophene moiety (entry 13) and from an aromatic bromide (entry 14), while not isolable in pure form,[10] could be treated directly with an excess of MeMgBr to afford secondary alcohols. This demonstrates that isolation of the aldehyde is not necessary for the application of this procedure.[11]

Limitations of this methodology include that aldehydes derived from optically active α-chiral amides, which would be produced via enamine intermediates, would be formed with complete epimerization at the α-stereogenic center. Additionally there is a requirement of an aliphatic α-hydrogen atom in the amide substrate for successful enamine formation; for instance, *N*,*N*-dimethyl cinnamide, upon treatment under our standard conditions, afforded a complex mixture of unidentified products. When no α-hydrogen was present, a mixture of aldehyde and the corresponding alcohol was obtained after aqueous work-up. Primary amides also afforded a mixture of unidentified products.

At present, detailed mechanistic studies have not been undertaken and the exact process of enamine formation is unclear. It has been proposed that a titanium hydride-like complex (**1**), which is obtained by a σ-bond metathesis reaction[12] between Ph_2SiH_2 and $Ti(OiPr)_4$, is the active reductant (Scheme 1). However, the exact structure of this species is not known. Initial insertion of the amide into the titanium–hydrogen bond of **1** affords hemiaminal **2**, which may then convert to the enamine, either directly by elimination or indirectly via an iminium ion (**3**).



Scheme 1. Proposed mechanism of enamine formation. Y = $Si(H)Ph_2$ or $Ti(OiPr)_3$.

In summary, we have developed a mild and efficient one-pot method for the conversion of amides to aldehydes that proceeds at room temperature and employs readily available, air-stable reagents. The reaction is general for a variety of tertiary and secondary, aliphatic and aromatic amides and tolerates a wide range of different functional groups. The simplicity of this method makes it an attractive new tool to the organic chemist. Studies to further elucidate the scope of this and other related transformations are currently underway.

Experimental Procedure

Undecenal (entry 7 in Table 1): To a dry flask containing neat *N*,*N*-diethyl undecenamide (0.155 mL, 0.65 mmol) under argon was added Ph_2SiH_2 (0.135 mL, 0.72 mmol) and $Ti(OiPr)_4$ (0.196 mL, 0.65 mmol). Initial effervescence was observed **[caution!]** and the reaction mixture was stirred at room temperature until analysis by thin layer chromatography showed complete consumption of the starting material (ca. 5 h). The mixture was diluted with THF (20 mL), treated with 1 M HCl (10 mL), and after stirring for 1 h, poured into ether (80 mL). The organic layer was washed with 1 M HCl (3 × 10 mL), saturated sodium bicarbonate solution (2 × 10 mL), and brine (10 mL), then dried ($MgSO_4$) and concentrated in vacuo. Flash column chromatography on silica gel (15% hexane/ether) afforded 99 mg of undecenal (90%) [CAS registry number 1337-83-3]. An alternative workup for acid-sensitive compounds proceeds as follows: The mixture was treated with THF (20 mL), H_2O (10 mL), and silica gel (ca. 2 g), and stirred for 3–5 h at room temperature, then poured into ether (80 mL). The organic layer was washed with H_2O (3 × 10 mL) and brine (10 mL), dried (Na_2SO_4), and concentrated in vacuo. The residue was purified by flash column chromatography.

[8] Occasionally, a deep blue color was noted in the reaction mixture but there was no significant correlation with either the rate or efficiency of the reaction.
[9] These reactions were found to be catalytic in $Ti(OiPr)_4$ (5 mol%) with $(EtO)_3SiH$ **[caution!]** K. A. Kreutzer, PhD Thesis, Massachusetts Institute of Technology, **1992**. However, due to the undesirable toxicity of $(EtO)_3SiH$ and the potential to form pyrophoric derivatives under certain conditions (for more details see ref. [5]), this method was not developed further.
[10] Both 2-thiophenebutanal and *para*-bromophenylethanal proved difficult to isolate cleanly from the reaction mixture, either by column chromatography or by kugelrohr distillation. Contamination with silicon-derived impurities was usually observed.
[11] In addition, α-branched amides could also be reduced: *N*,*N*-dimethyl-2,2-diphenylacetamide was reduced cleanly to enamine under the reaction conditions, although purification of the resultant aldehyde in this instance proved problematic.

tions.[1] Conversely, increasing the electron count of a cluster by the addition of electrons, either by reduction or by addition of a ligand, usually leads to the breaking of metal–metal bonds.[2] Here we describe an unusual reversible reaction in which the addition of an innocent two-electron donor to a metallic center in a tetranuclear complex leads to the formation of three new metal–metal bonds by the migration of a metal fragment. Thus, the metal fragment has a choice of donor sites in a cluster, and hops from one to another by the addition or removal of a two-electron donor.

Recently we described the preparation and structure of the 60-electron clusters **1** (cod = 1,5-cyclooctadiene) and **2** (tfb = tetrafluorobenzobarrelene)

$[Rh_4(\mu\text{-}p\text{-}MeC_6H_4N)_2(\text{diolefin})_4]$

2, diolefin = tfb

in which the organoimido ligands bridge a metallic triangular core having one nonbonded edge; the fourth metal atom is η^5-coordinated to one arene ring and is not involved in cluster bonding.[3] Reactions of **1** and **2** with carbon monoxide under atmospheric pressure in toluene at 55 °C and room temperature, respectively, unexpectedly give the clusters **3** and **4** (Scheme 1), which were isolated in 85% yield as dark-red crystalline solids. The structure of **4** (Fig. 1) consists of an essentially planar butterfly arrangement of the metal atoms in which two triangles of Rh atoms share a common edge.[4] One of these triangles is bicapped by two *para*-tolylimido ligands, forming a trigonal bipyramid comprising three Rh and two N atoms. The second adjacent triangle of Rh atoms results when the fourth Rh atom bridges a Rh–Rh edge. Each of the Rh atoms in the bicapped triangle has two terminal CO ligands, while the fourth Rh atom completes a distorted trigonal bipyramidal coordination sphere, bonding to a further terminal CO ligand and a chelating tfb ligand. The metal–metal separations of between 2.758(2) and 2.895(2) Å are all clearly within the range expected for metal–metal single bonds. Complex **4** can be considered as a 62-electron system, consistent for a butterfly geometry,[5] and represents the first structurally characterized

planar tetrarhodium cluster with a raftlike structure (dihedral angles of 178.4(1)° and 171.5(1)° for the two independent molecules in the asymmetric unit). Other remarkable features include the coexistence of formally seven-coordinate and five-coordinate rhodium atoms, and the presence of carbonyl and diolefin ligands on the same rhodium center. This structure is maintained in solution, as shown by the $^{13}C\{^1H\}$ and ^1H NMR spectra of **3** and **4** at low temperature; however, complexes **3** and **4** undergo a fluxional process at room temperature that is probably associated with the pentacoordination of one rhodium atom (Table 1). Cooling a hot solution of **3** or **4** under an atmosphere of carbon monoxide leads to the replacement of the diolefin ligand to give **5**. These reactions can be reversed simply by plac-

$[Rh_4(\mu\text{-}p\text{-}MeC_6H_4N)_2(CO)_9]$ **5**

ing complex **5** in the presence of cod or tfb under an inert atmosphere. Complex **5** is a purple solid, which can be isolated in 70% yield. A comparison of the spectroscopic data in the fingerprint regions shows that **5** has a raftlike structure similar to that found for **4**. In addition, complex **3** slowly loses CO on standing in solution in toluene at room temperature to give black crystals of **6**. Complex **6** is a 60-elec-

[a] [a] Denotes the [η^5-(*p*-MeC_6H_4N)Rh(cod)] fragment.

pletes the stepwise carbonylation from **1** to **5**, since it reacts with CO to give **3** (or **5** depending on the reaction conditions). The implications of the reversible reaction **3**⇌**6** (Scheme 1) are quite remarkable. On addition of CO to complex **6** the [Rh(cod)(CO)] fragment migrates from the η^5-arene coordination site to the trimetallic core. This metal mobility involves the unprecedented formation of three metal–metal bonds in spite of the increase in the electron count of the cluster by two. Conversely, the loss of a CO ligand, usually associated with an increase in the number of metal–metal interactions, leads to a reformation of the trimetallic core and the η^5-arene site. In this process three metal–metal bonds are broken. These facts can be explained in terms of a recognition of two donor sites in the cluster by the metallic fragment that is controlled by the addition of a two-electron donor ligand. The 12-electron fragment $[Rh(cod)]^+$ prefers to coordinate to the arene ring to achieve electronic saturation. Following the introduction of a CO ligand, however, the resulting 14-electron T-shaped fragment $[Rh(cod)(CO)]^+$ prefers to be coordinated to two Rh atoms of the trimetallic core. This implies the remarkable behavior of two metal atoms of an open-edged trimetallic core as donors. Indeed, the trinuclear imido metal core could be considered as a "ligand" that has two potential donor sites to engage a mononuclear fragment. A different, but related, proposal for the bonding of a Pt_3 face as a donor to the $Re(CO)_3$ fragment in the cluster $[Pt_3\{\mu\text{-}Re(CO)_3\}(\mu\text{-dppm})_3]^+$ has been recently reported.[6] Further work on the reactivity of these organoimido clusters and the extension to higher nuclearity clusters is in progress.

$LiCHCl_2 \cdot 3$ Pyridine, Structure of a Carbenoid with a Tetrahedral C Atom**

Achim Müller, Michael Marsch, Klaus Harms, John C. W. Lohrenz, and Gernot Boche*

Recently we described the first X-ray crystal structure of a Li/Cl[1] and a MgBr/Br carbenoid;[2] however, both cases deal with vinyl carbenoids, which are more stable because of their C_{sp^2}–halogen bond[3] (decomposition above − 60 °C) than carbenoids with a tetrahedral carbon atom. For instance, studies by Matteson[4] have shown that dichloromethyllithium $LiCHCl_2$ (**2**)[5] "is not stable much above −100 °C". We were interested in whether it is also possible to obtain single crystals and an X-ray crystal structure analysis even from such extremely labile organolithium compounds. The results of the X-ray crystal

structure determination of $LiCHCl_2 \cdot 3$ pyridine ($2 \cdot 3$py) reported herein reveal that this is possible.

$LiCHCl_2$ (**2**) was generated by deprotonation of dichloromethane (**1**) in a mixture of tetrahydrofuran, *tert*-butyl methyl ether, diethyl ether, and pyridine between $-78\,^{\circ}C$ and $-90\,^{\circ}C$ with *n*-butyllithium (Scheme 1). During the crystallization of the pyridine complex $2 \cdot 3$py, the temperature has to be kept

$$\underset{\mathbf{1}}{CH_2Cl_2} \xrightarrow{n\text{-BuLi, py}} \underset{\mathbf{2} \cdot 3\,py}{LiCHCl_2 \cdot 3\,py}$$

Scheme 1. Synthesis of $2 \cdot 3$py. py = pyridine.

strictly in the range between $-100\,^{\circ}C$ and $-98\,^{\circ}C$. The transfer of crystals by using a cold copper "tongue"[1, 2, 6] to the diffractometer was not always successful because of the extreme thermolability of the crystals, which often decomposed rapidly. Figure 1 shows the solid-state structure of $2 \cdot 3$py determined at $-123\,^{\circ}C$.[7]

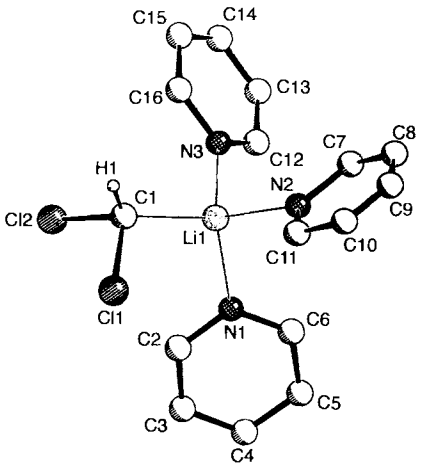

Fig. 1. Crystal structure of $2 \cdot 3$py.

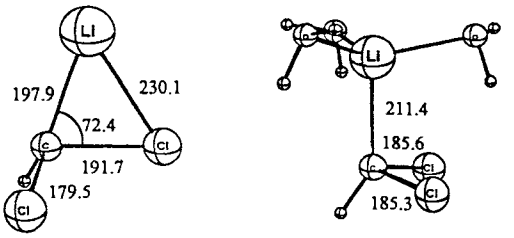
Figure 1 reveals that Li1 coordinates to C1 (Li1–C1 210.5(9) pm) and to the nitrogen atoms of three pyridine molecules (Li1–N1 207.7(8), Li1–N2 201.7(9), Li1–N3 203.3(8) pm). The C–Cl bond lengths (C1–Cl1 185.7(5) pm and C1–Cl2 183.2(5) pm) are especially significant for the carbenoid structure in that *both* C–Cl bonds are approximately 10 pm longer than the C–Cl bonds in **1** (174.6 pm).[14] An elongation of the C–halogen bond was also observed in the vinyl carbenoids mentioned above.[1, 2] This bond lengthening is consistent with the results of calculations[15] and confirms the conclusion drawn by Seebach et al.[16] from NMR investigations, according to which the C–Li bond in carbenoids should have a higher s character and all other bonds a higher p character. The sum of the angles Cl2-C1-Cl1 (105.3(2)°), Cl1-C1-H1 (96(3)°), and Cl2-C1-H1 (107(3)°) of 308°, which is significantly smaller than the tetrahedral value (328°), is in addition to the elongation, further evidence for the increased p character of the C–Cl bonds in $2 \cdot 3$py. This essentially is the reason for the strong electrophilic character of carbenoids, which for a long time was not understood.[3, 15g, h, 17]

How significant is the solvation of the metal cation for the thermal stability and other properties of carbenoids? Model calculations on **2** and on the trihydrate $2 \cdot 3H_2O$ have provided further insight. Figure 2 shows the results of the MP2(fc)/6-31G(d) structure investigations and of the IGLO/II + sp//MP2(fc)/6-31G(d) calculations of the ^{13}C chemical shifts of **2** and $2 \cdot 3H_2O$.



2 $\quad\quad$ **2** · $3H_2O$

$\delta = 62.8$ $\quad\quad$ $\delta = 49.5$

$\delta_{exp} = 50.0$ [16d]

Fig. 2. Calculated structural parameters and NMR shifts of **2** and $2 \cdot 3H_2O$ [18].

In the nonsolvated **2** the bridged structure (like in all other carbenoids[15]) is the most stable one. The Li-bridged C–Cl bond is elongated to 191.7 pm, whereas the other C–Cl bond (179.5 pm) shows only an insignificant elongation compared to the C–Cl bonds in **1** (176.9 pm).[14c] "Bad" external solvation of the Li^+ ion thus supports, through Li-bridging of the C–Cl bond, the Li^+-induced cleavage of this carbenoid bond, which is consistent with experimental observations.[3c] In contrast, if the Li^+ ion is "well" solvated ($2 \cdot 3H_2O$ was chosen as a model for $2 \cdot 3$py) the bond of the Li^+ ion to the Cl atom is broken. The lengths calculated for the C–Cl bonds in $2 \cdot 3H_2O$ (185.3 and 185.6 pm) correspond closely to the values determined in $2 \cdot 3$py (183.2(5) and 185.7(5) pm) as is also the case for the C–Li distance ($2 \cdot 3H_2O$ 211.4 pm; $2 \cdot 3$py 210.5(9) pm). The results of the IGLO calculations are also of particular interest. The calculated ^{13}C chemical shift of the C atom in the Li^+-bridged **2** is $\delta = 62.8$, whereas it is $\delta = 49.5$ in the solvated $2 \cdot 3H_2O$: the Li^+-bridged **2** with the larger downfield ^{13}C chemical shift shows the stronger carbenoid character. Since the measured shift of **2** in THF is $\delta = 50.0$,[16d] the structure of the THF-solvate of **2** should be nearly the same as that of $2 \cdot 3H_2O$ and $2 \cdot 3$py. Thus, investigations of the type shown above even allow conclusions to be drawn on the structure of carbenoids in solution.

Experimental Procedure

Preparation of single crystals of $2 \cdot 3$py: To a mixture of THF (1.70 mL) *tert*-butyl methyl ether (0.80 mL), diethyl ether (0.50 mL), and pyridine (0.50 mL, 489 mg, 6.18 mmol), dichloromethane **1** (0.25 mL) in THF (0.031 M, 0.775 mmol) was added. After the solution had been cooled ($-78\,^{\circ}C$ to $-90\,^{\circ}C$), **1** was deprotonated to **2** with *n*BuLi (0.49 mL, 0.78 mmol, 1.60 M solution in hexane) under constant shaking within 30 min. At $-98\,^{\circ}C$ to $-100\,^{\circ}C$ colorless crystals of $2 \cdot 3$py suitable for X-ray crystal structure analysis had formed after 16 h.

[18] All geometries are optimized at the MP2(fc)/6-31G(d) level with the programs GAUSSIAN92 [19] and TurboMole [20–25]. The nonsolvated species were fully optimized, whereas the solvated ones were optimized on the assumption of local C_3 symmetry for the three water molecules in which the C–Li bond is the rotational axis. The chemical shifts were calculated with the DIGLO program [26–28] using the IGLO/II basis [29] with additional diffuse functions [30] (II + sp).

Porphyrinoid Macrocycles Based on Thiophene—The Octaethyltetrathiaporphyrin Dication

Emanuel Vogel,* Michael Pohl, Adalbert Herrmann, Torsten Wiss, Christoph König, Johann Lex, Maurice Gross,* and Jean Paul Gisselbrecht

Dedicated to Professor Giorgio Modena on the occasion of his 70th birthday

The aromatic heterocycle thiophene[1] has gained significance as a useful building block for the development of advanced materials (e.g., conducting polymers[2] with possible applications in microelectronics,[3] and electroluminescent[4] and other functional dyes[5]). In that light, porphyrinoid macrocycles based on thiophene become challenging synthetic targets. While mono- and dithiaporphyrins have been known for some time,[6] the true sulfur analogue of porphyrin, the tetrathiaporphyrin dication with thiophene instead of pyrrole units (as its perchlorate), yielded to synthesis by our group only recently.[7] Unfortunately, this dication does not lend itself readily to the desired chemical exploration because of its limited accessibility and poor solubility in common organic solvents. Our efforts, therefore, focused on the preparation of the octaethyltetrathiaporphyrin dication (**1**, as its perchlorate), taking advantage of experience acquired in the porphyrin,[8a] tetraoxaporphyrin,[8b,c] and corrole series,[8d] in which the more soluble octaethyl derivatives serve as versatile model compounds.

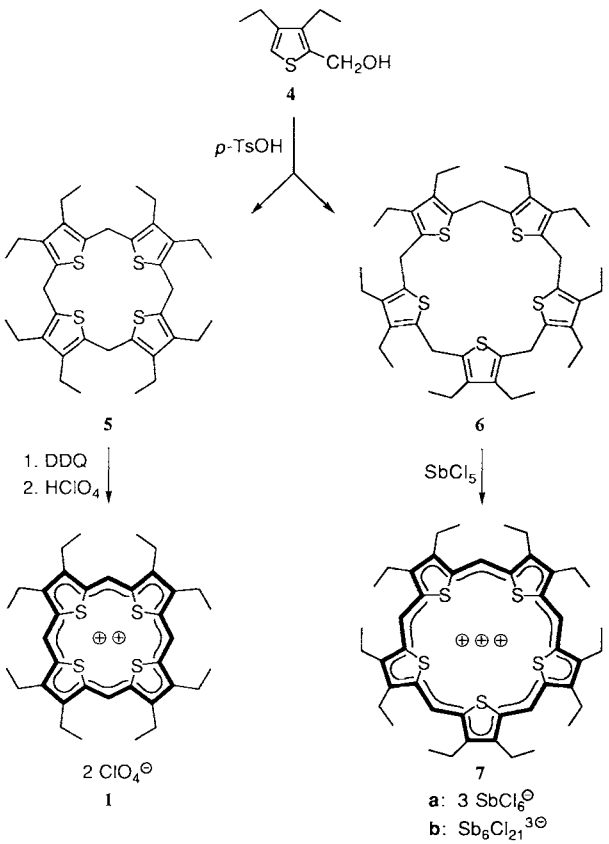
Among the various chemical transformations the dication **1** might undergo, its two-electron reduction to give the intriguing [20]annulene octaethyltetrathiaisophlorin (**2**)[9] appeared particularly attractive. Due to the presence of a $4n\pi$ conjugation pathway and proper symmetry of the molecule, **2** should possess a small HOMO–LUMO gap and be subject to an isodynamic π-bond shift. Moreover, annulene **2** contains structural features of the intensively studied poly(thienylenemethines) **3**,[10] for which a small gap between the valence (HOMO) and conduction band (LUMO) is predicted.[11] In this communication we report the synthesis of **1** (accompanied by the isolation of a higher order homologue), spectroscopic evidence supporting the formation of octaethyltetrathiaisophlorin (**2**), and the synthesis and characterization of a stable derivative of **2**.

The most obvious approach to the octaethyltetrathiaporphyrin dication **1** is via the previously unknown octaethyltetrathiaporphyrinogen (**5**) (Scheme 1; for selected physical data



Scheme 1. DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.

of this and the other new compounds, see Table 1), that is, by methodology well-established in porphyrin chemistry. Intermediate **5** should be available by either an oxygen–sulfur exchange reaction from octaethyltetraoxaporphyrinogen[8b] under the conditions of the Jurjew reaction,[12] or by a biomimetic, acid-catalyzed cyclocondensation of 3,4-diethyl-2-hydroxymethylthiophene (**4**).[13]

The oxygen–sulfur exchange reaction that was highly successful in the case of unsubstituted tetraoxaporphyrinogen[7] failed completely when applied to the octaethyl derivative, presumably for steric reasons. Furthermore, under typical biomimetic conditions, the cyclocondensation of **4** proved to be unsatisfactory. However, we found that **5** could be obtained in relatively good yield (30%) on treatment of **4** with one equivalent of *para*-toluenesulfonic acid in nitromethane at 100 °C. Under these conditions another interesting compound, the pentacyclocondensation product **6**, was formed in addition to **5** and isolated in 16% yield. Purification of **5** and **6** was achieved by column chromatography on silica gel with a ternary mixture of hexane/toluene/acetonitrile (50/9/1) as the mobile phase. After recrystallization from ethanol, each compound was obtained as colorless needles, with melting points of 196–198 °C and 175–176 °C for **5** and **6**, respectively. The ^{1}H NMR spectra of **5** and **6** are—as expected for such closely related compounds—nearly superimposable, with the result that only mass spectra allowed the correct assignments of their structures.

Table 1. Selected physical data for **1**, **4**–**6**, **10**, and **13**–**15**. ^{1}H NMR: 300 MHz; ^{13}C: 75.5 MHz [a].

1: ^{1}H NMR (CD_3NO_2): δ = 12.53 (s, 4H, H-*meso*), 4.58 (q, 16H, H-2a,3a,7a,8a,12a,13a,17a,18a), 1.98 (t, 24H, H-2b,3b,7b,8b,12b,13b,17b,18b); ^{13}C NMR (CD_3NO_2): δ = 160.53, 160.40, 130.88, 24.35, 18.35; MS (FAB): *m/z* (%) 605 (80), 604 (100) $[M - 2ClO_4]^{\bullet+}$, 603 (30), 589 (10); IR (CsI): $\tilde{\nu}$ = 2970, 2932, 2873, 1519, 1450, 1419, 1373, 1310, 1260, 1192, 1083, 929, 869, 728, 624, 527, 458 cm^{-1}; UV/Vis (CH_2Cl_2, 1% CF_3CO_2H): 266 (15000), 293 (14400), 452 (159000), 613 (11300), λ_{max} (ε) = 667 nm (6700)

[a] Correct elemental analyses were obtained for all compounds, except for the sensitive compounds **10** and **13**, which gave correct high-resolution mass spectra.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1521 $ 15.00+.25/0

The remarkably high tendency of **4** to afford the cyclocondensation products **5** and **6** most likely results from a helical effect of the ethyl groups in the 3 and 4 positions of thiophene, as demonstrated by Franck et al.[14] in the porphyrin series. The occurrence of significant amounts of product **6** in the acid-mediated condensation of **4** can best be explained by the fact that thiophene exhibits a wider angle between the exocyclic bonds at the α positions than pyrrole or furan (147° vs. 131° and 126°, respectively[15]). It is interesting to note that the homologues **5** and **6** readily interconvert under the conditons of their formation. For instance, upon heating either pure **5** or **6** to 100 °C in the presence of *para*-toluenesulfonic acid, mixtures of the two compounds in an approximate ratio of 2:1 were obtained. Almost certainly, interconversion between **5** and **6** is initiated by protonation of a thiophene moiety in an α position followed by macrocyclic ring opening.

Oxidation of octaethyltetrathiaporphyrinogen (**5**) to give the octaethyltetrathiaporphyrin dication (**1**, as its perchlorate) could be achieved under conditions similar to those employed in the synthesis of the parent dication,[7] that is, by successive treatment of **5** with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ, 3.3 equiv, 2 h, 60 °C) in acetic acid and with 70% perchloric acid (1:10 in acetic acid, 5 equiv, 0.5 h, 80 °C). The intensely colored crystals that separated from the cold reaction mixture were recrystallized from acetic acid, affording blue needles with a metallic luster. As evidenced by the ^{1}H NMR spectrum as well as by elemental analysis, the target compound **1**, which contains 1.5 equivalents of acetic acid enclosed within the crystal lattice, was obtained (70% yield). The acetic acid can be removed by heating this clathrate under vacuum (60 °C, 0.01 mm); the acid-free **1** (as its perchlorate) is left as a green powder.[16] The ethyl groups confer good solubility on **1** in organic acids as well as in dichloromethane, acetonitrile, and nitromethane. On the other hand, when alcohols are used as solvents, instantaneous nucleophilic addition to two adjacent *meso* positions in **1** occurs, resulting in the formation of derivatives of tetrathia-5,10-dihydroisophlorin (**10**).[17]

The ^{1}H NMR spectrum of **1** (in CD_3NO_2), which shows no significant temperature dependence, corresponds to that expected for a dicationic aromatic porphyrinoid, since the *meso* protons (H_m) appear as a singlet at very low field ($\delta = 12.53$). The location of this signal almost coincides with that of the *meso* protons in the unsubstituted dication ($\delta = 12.46$, albeit in 68% $DClO_4/CH_2Cl_2$ int.).[7] When the ^{1}H NMR spectrum of **1** was recorded in the less polar solvent dichloromethane, its resolution decreased (accompanied by a shift of $\Delta\delta = 0.3$ of the signal for the *meso* protons to higher field), an observation indicative of the formation of aggregates.[18]

A comparison of the ^{1}H NMR data of **1** with those of its oxygen analogue **8** (Table 2) reveals that the resonance of the *meso* protons of the thia compound has shifted to lower field ($\Delta\delta = 0.68$). This finding is best explained as arising primarily from a heteroatom effect of the sulfur atoms rather than from an unusually strong diamagnetic ring current in **1**. A similar difference in chemical shift is observed (Table 2) on going from tetrathia-5,10-dihydroisophlorin (**10**) with interrupted cyclic conjugation to its oxygen counterpart **11**. To some extent, the noticeable deshielding of H_m of **1** may also be attributable to the localization of the positive charge at the *meso* carbon atoms, which is more pronounced in **1** than in **8**, as inferred from the relation $\delta^{13}C_m(\mathbf{1}) > \delta^{13}C_m(\mathbf{8})$. The slight puckering of the ring skeleton of **1** (see below) should have only a minor influence on the strength of the aromatic ring current, since even in the starkly nonplanar dication **9** the *meso* protons still resonate at very low field. The UV/Vis spectrum of **1** has experienced the

Table 2. Selected ^{1}H and ^{13}C NMR data (300 MHz and 75.5 MHz, respectively) for the dications **1**, **8**, and **9** as their perchlorates (CD_3NO_2), and the 5,10-dihydroisophlorins **10**–**12** ($CDCl_3$).

anticipated bathochromic shift relative to that of the parent dication[7] [$\Delta\lambda_{max}$(Sôret) ≈ 25 nm].

According to an X-ray crystallographic analysis of the octaethyltetrathiaporphyrin dication (**1**),[19] the steric demand of the sulfur atoms causes the ring skeleton of the molecule to deviate from planarity, albeit slightly (Fig. 1). Dication **1**, like the unsubstituted compound, is centrosymmetric in the crystal, but differs from the latter in conformation. While in the parent dication two diagonal thiophene rings are tilted, in opposite directions, by 23° out of the plane defined by the four *meso* carbon atoms,[7] a *syn,syn,anti,anti* arrangement with twist angles of 19° is found for **1**. Both compounds exhibit distances between adjacent sulfur atoms nearly 1 Å less than the sum of

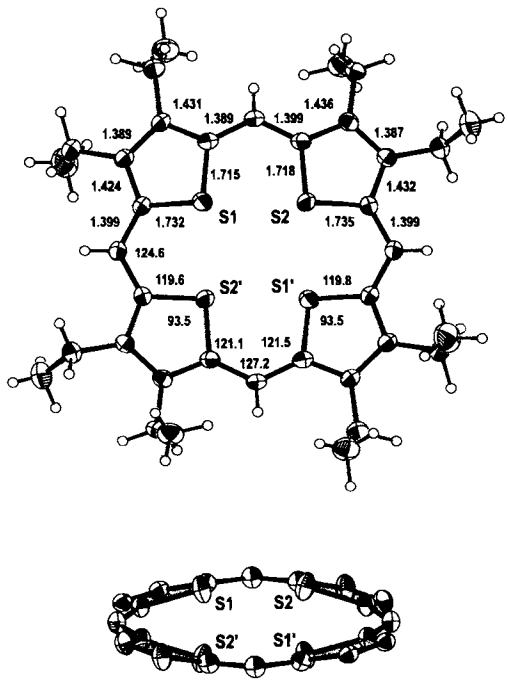

Fig. 1. Structure of octaethyltetrathiaporphyrin dication (**1**, as its perchlorate) in the crystal (top: top view; bottom: perspective view). Vibrational ellipsoids represent 40% probability. With selected bond lengths [Å] and angles [°] (standard deviation approximately 0.009 Å and 0.5°). The thiophene subunits are shaded, and the ethyl groups and hydrogen atoms omitted in the perspective view to visualize the deviation of **1** from planarity better.

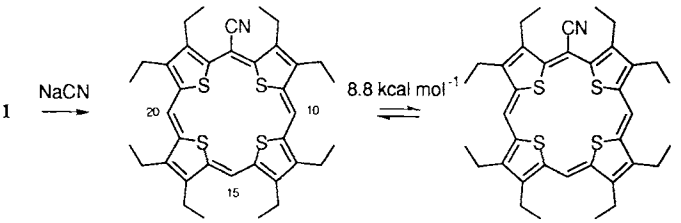
their van der Waals radii. Thus attractive S···S interactions appear to be involved. In solution, the five-membered heterorings of **1** are presumed to exchange sites rapidly by inversion. Indirect evidence in support of this process may be gathered from the ^{1}H NMR spectrum, in which no splitting of the resonances of the diastereotopic CH_2 protons is observed as the temperature is lowered (to $-100\,^\circ C$). Such a splitting is, indeed, found in the case of the conformationally less mobile *N,N',N'',N'''*-tetramethyl compound **9**.[7]

An electrochemical study of the dication **1** was performed with the main purpose of evaluating the possibility of generating the isophlorin **2** by reduction of **1**. This study, carried out in 0.1 M solutions of tetrabutylammonium hexafluorophosphate ($TBAPF_6$, as supporting electrolyte) in dichloromethane at a platinum electrode,[20a] afforded two defined half-wave potentials at $+0.37$ V and $+0.07$ V vs. Ag/AgCl. As confirmed by cyclic voltammetry measurements in the same solvent,[20b] these potentials should be ascribed to two one-electron reductions leading to the radical cation and to tetrathiaisophlorin **2**, respectively. At scan rates $<1\ Vs^{-1}$ the intensity of the second wave decreased with respect to the first, while at the same time an additional reduction wave at -0.32 V appeared. These findings indicate that in the reduction of **1**—in contrast to that of octaethyltetraoxaporphyrin dication (**8**)—the products are not stable under the conditions of the measurements. Further reduction steps that could give rise to the formation of the radical anion or the 22π dianion were not observed up to the cathodic limit of the measurement range. Accordingly, generation of **2** by chemical means seemed feasible.

Attempts to convert **1** into **2** with alkali metals or other conventional reducing agents did not yield defined products. However, when samarium(II) iodide[21] was employed, which is reasonably soluble in organic solvents and possesses a sufficiently negative reduction potential ($\varepsilon_o = -1.5$ V)[21c] without giving rise to overreduction, we were able to record NMR spectra of **2** at low temperatures. Specifically, this was accomplished by adding a solution of SmI_2 in tetrahydrofuran to a suspension of **1** in the same solvent under rigorous exclusion of oxygen at $-40\,^\circ C$. After passing the reaction mixture through a short alumina column (activity grade I) at $-78\,^\circ C$ followed by removal of the solvent, an amorphous solid was obtained. This contained as the major component the tetrathiaisophlorin **2** as an extremely oxygen-sensitive compound, which spontaneously polymerizes at temperatures above $-20\,^\circ C$ (apart from **2**, minor amounts of oligomers were present). The ^{1}H NMR spectrum (300 MHz, [D$_8$]THF, $-50\,^\circ C$) of **2** shows—in accord with the assumption that the compound undergoes an isodynamic π-bond shift that is rapid on the NMR time scale—only one singlet for the *meso* protons ($\delta = 5.26$), one quartet for the methylene protons ($\delta = 2.05$), and one triplet for the methyl protons ($\delta = 0.95$). In parallel herewith, the ^{13}C NMR spectrum (75.5 MHz, [D$_8$]THF, $-50\,^\circ C$) exhibits five signals at $\delta = 145.5$, 142.0, 108.1, 19.9, and 15.1. The presence of a paramagnetic ring current in **2**, though weaker than in tetraoxaisophlorins[8b, 9a] for steric reasons, is evident from the high-field shift of the signal of H_m relative to that of the dihydro compound **10** ($\Delta\delta^1H_m = 1.35$, see also Table 1). Unfortunately, a more detailed spectrosopic characterization of **2** was hampered by the high reactivity of the compound.[22]

Remarkably, replacement of only one of the *meso* hydrogen atoms of **2** by an electron-withdrawing substituent is sufficient to allow the preparation of stable octaethyltetrathiaisophlorins. A case in point is 5-cyanooctaethyltetrathiaisophlorin (**13**), which by analogy to the conversion of **9** into *N,N',N'',N'''*-tetramethyl-5-cyano-octaethylisophlorin,[9b] is produced when a solution of **1** in dry ethanol is treated with sodium cyanide at $-20\,^\circ C$ (Scheme 2). After chromatography on basic alumina (ether/THF 20/1, $-20\,^\circ C$), followed by concentration of the eluate under vacuum and subsequent slow addition of *n*-hexane, **2** is obtained as a blue microcrystalline powder (moderately stable in air when kept in the dark); decomp. above 160 °C, 45% yield.



13

Scheme 2.

The ^{1}H NMR spectrum of **13** at room temperature, due to its relative simplicity (effective C_{2v} symmetry), is indicative of a rapid π-bond shift—also isodynamic in this case—and a rapid inversion of the thiophene rings. The *meso* protons give rise to only two singlets at $\delta = 5.98$ (H10,20) and $\delta = 5.84$ (H15), which, owing to the presence of the electronegative nitrile group, are shifted to lower field than the signal of the *meso* protons of **2** ($\Delta\delta = 0.72$ and 0.58, respectively). In order to freeze the π-bond shift of **13** to such an extent that the singlet of the *meso* protons at positions 10 and 20 splits into two signals, it was necessary to cool the sample to $-110\,^\circ C$. From the temperature of coalescence of these signals ($-83\,^\circ C$) a free energy of activation ($\Delta G^{\ddagger}_{190}$) of 8.8 kcal mol^{-1} for the dynamic process was derived. This energy value appears realistic when compared with the corresponding values of the π-bond shifts of the strongly distorted *N,N',N'',N'''*-tetramethyloctaethylisophlorin and the practically planar tetraoxaisophlorin ($\Delta G^{\ddagger}_{298} = 13.2$ kcal mol^{-1}[9b] and $\Delta G^{\ddagger}_{138} < 6$ kcal mol^{-1},[9a] respectively).

The occurrence of the thiaporphyrinogen homologue **6** as a by-product from the cyclocondensation of **4** was anything but an undesired result. On the contrary, compound **6** invited oxidation experiments that ultimately might lead to the decaethylpentathiapentaphyrin trication **7**, a potentially aromatic 22π-electron system.[23] As is evident upon inspection of the resonance structures of **7** (not shown here) with the positive charges located on sulfur, the trication **7** bears the same relationship to pentaphyrin[24] as the tetrathiaporphyrin dication does to porphyrin. In its trisprotonated form, pentaphyrin is in fact isoelectronic with **7**. The first evidence for the formation of **7** was obtained when **6** was treated with DDQ in benzene, and the amorphous precipitate thus produced dissolved in [D$_2$]sulfuric acid. The ^{1}H NMR spectrum of the resulting intensely cherry-red solution proved to be fully consistent with the generation of the obviously highly symmetric aromatic trication **7**, since it contained only three broadened signals at $\delta = 14.66$ (5H, H-*meso*), $\delta = 5.69$ (20H, CH_2), and $\delta = 2.70$ (30H, CH_3). Subsequently, antimony pentachloride ($SbCl_5$) was found to be particularly effective in oxidizing **6** to the trication **7**. On addition of this antimony agent to **6** in dichloromethane, **7** was produced as a mixture of salts from which small amounts of crystals of **7a**, the expected trishexachloroantimonate, and of **7b**—with a polymeric chloroantimonate(III) as the counterion (containing $[Sb_6Cl_{21}]^{3-}$ as repeat unit)—could be separated mechanically.[25] As already revealed by preliminary results of X-ray analyses of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1523 $ 15.00+.25/0

7a and **7b**, the trication **7** is planar. Further details regarding the structures of **7a** and **7b** will be reported in a forthcoming publication as soon as the as yet unsatisfactory means of isolation can be improved.

[15] Calculated from the values given by C. W. Bird, G. W. H. Cheeseman in *Comprehensive Heterocyclic Chemistry, Volume 4, Part 3* (Eds.: A. R. Katritzky, C. W. Rees), Pergamon, Oxford, **1984**, p. 3.

[16] A crystalline acid-free form of **1** was obtained by crystallization from chloroform/dichloromethane (5/1); blue rods of the composition $\mathbf{1}\cdot 2CHCl_3$.

[17] The UV/Vis spectrum of **1** in dry methanol (λ_{max} = 251, 324, 439sh, 463, 492 nm) is nearly superimposable on that of **10**. The latter compound was obtained on reaction of **1** with either $NaBH_4$ or $LiAlH_4$ in THF; microcrystalline, yellow needles from ethanol, decomp. above 150 °C, 90% yield; for spectroscopic data see Table 1.

[18] For formation of aggregates of **1** with π donors see: A. Mahammed, M. Rabinovitz, I. Willner, E. Vogel, M. Pohl, *J. Phys. Org. Chem.* **1995**, *8*, 647; A. Mahammed, M. Rabinovitz, R. E. Hoffman, I. Willner, E. Vogel, M. Pohl, *ibid* **1995**, *8*, 659.

[19] Data of the crystal structure of $\mathbf{1}\cdot 2CHCl_3$: $C_{36}H_{44}S_4Cl_2O_8\cdot 2CHCl_3$, M_r = 1042.59, crystals from $CHCl_3/CF_3CO_2H$, decomp. above 230 °C; crystal dimensions 0.4 × 0.35 × 0.35 mm, monoclinic, space group $P2_1/n$, a = 8.062(2), b = 21.218(6), c = 13.759(4) Å, β = 102.89(2)°, V = 2294.3 Å^3, Z = 2, ρ_{calcd} = 1.509 g cm^{-3}, $F(000)$ = 1076; μ_{Mo} = 7.22 cm^{-1}; θ_{max} = 27°; 5331 reflections measured; 4989 independant reflections; 3730 reflections observed ($F_o^2 > 2\sigma F_o^2$); $R1$ = 0.0698, $wR2$ = 0.1995. Enraf-Nonius CAD4 diffractometer (room temperature, $Mo_{K\alpha}$ radiation, λ = 0.71069 Å). The structure was solved by direct methods and refined by F^2 with all observed reflections (heavy atoms with anisotropic, H atoms with isotropic temperature factors); $wR2 = [\sum w(F_o^2 - F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$. Programs used: structure determination by MolEN (Enraf Nonius) and refinement by SHELXL-93 (G. M. Sheldrick, University of Göttingen). Calculations were performed at the regional computational center of the University of Cologne. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-41. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[20] a) Dichloromethane was dried over CaH_2 and stored under an argon atmosphere. $TBAPF_6$ (Fluka-electrochemical grade) was used as supporting electrolyte. A platinum rotating disc electrode was employed. The logarithmic analysis of the signals resulted in a slope of 0.058 V lg^{-1} for each reduction step. Ferrocene was used as the internal standard at +0.375 V vs. Ag/AgCl. b) Measurements were carried out at scan rates between 0.01 and 20 Vs^{-1} at a platinum electrode. Potentials were measured against an Ag/AgCl electrode as reference.

Template-Driven Syntheses of Polymeric Metal Cyanides: A Chiral Nanoporous Host for the nBu$_4$N$^+$ Ion**

Peter Schwarz, Stefan Eller, Eric Siebel, Tarek M. Soliman, R. Dieter Fischer,* David C. Apperley, Nicola A. Davies, and Robin K. Harris*

Dedicated to Professor Erwin Weiss on the occasion of his 70th birthday

Molecular recognition refers to the phenomenon of specific interaction between a receptor and a substrate or a host system and its potential guest.[1] An "intelligent" receptor or host can also adapt structurally to suit different substrates or guests.[2] We have discovered that the guest cations G^{n+} that the anionic 3D network of **1** can accommodate in its lipophilic cavity are as dissimilar as methyl viologen dications (MV^{2+}), cobaltocenium ions ($[CoCp_2]^+$, Cp = η^5-C_5H_5), and Et_4N^+ ions: the topology of the host framework in the host/guest compounds **2**[3a] and **3**,[4] which formally resembles that of **1**, differs significantly depending on the G^{n+} ion used.[3b] Also in the case of compound **4** ($G^+ = Et_4N^+$), which belongs to the same type as **2** and **3**, the results of vibrational[5] and solid-state NMR spec-

$[(Me_3Sn^{IV})_3M^{II}(CN)_6^-] \equiv {}^3_\infty[M^{II}(\mu\text{-}CNSn^{IV}Me_3NC)_3^-]$ (M = Fe, Ru) **1**

${}^3_\infty[(G^{n+})_{1\,n} \subset \mathbf{1}]$ **2**: $G^{2+} = MV^{2+}$; M = Ru
3: $G^- = [CoCp_2]^+$; M = Fe
4: $G^- = Et_4N^+$; M = Fe

troscopy[4] suggest a structurally optimally adapted host system. Here we report that with the larger nBu$_4$N$^+$ ion as the guest the resulting host/guest compound **5** even adopts a different stoichiometry that also has unexpected impact on the structure.

$[(n\text{Bu}_4\text{N})_{0.5}(\text{Me}_3\text{Sn})_{3.5}\text{Fe(CN)}_6 * \text{H}_2\text{O}]$ **5**

Both ion exchange[5] [Eq. (a)] and spontaneous self-assembly[4] [Eq. (b)] afford **5** in virtually quantitative yield (based on the amount of nBu$_4$NCl used).[6] The product is sparingly sol-

$$[(\text{Me}_3\text{Sn})_4\text{Fe(CN)}_6] \xrightarrow[-0.5\,\text{Me}_3\text{SnCl}]{0.5\,n\text{Bu}_4\text{NCl}/\text{H}_2\text{O}} \mathbf{5}\downarrow \quad \text{(a)}$$

$$3.5\,\text{Me}_3\text{SnCl} + 0.5\,n\text{Bu}_4\text{NCl} \xrightarrow[-4\text{KCl}]{\text{K}_4[\text{Fe(CN)}_6]/\text{H}_2\text{O}} \mathbf{5}\downarrow \quad \text{(b)}$$

uble in water as well as in organic solvents. The crystal structure analysis of **5**[7] clearly reveals that the modified composition leads to the formation of a 3D network with a larger cavity than that in **3**.[4] The building blocks are an infinitely long, helical chain A and a 15 atom long chain B (Fig. 1). As in **1**–**4**, all Sn atoms in **5** also have fivefold coordination. Every Fe atom belongs to three discrete strands (A, A', and B); possibly, weak hydrogen bonds between the O atom of every B chain and the

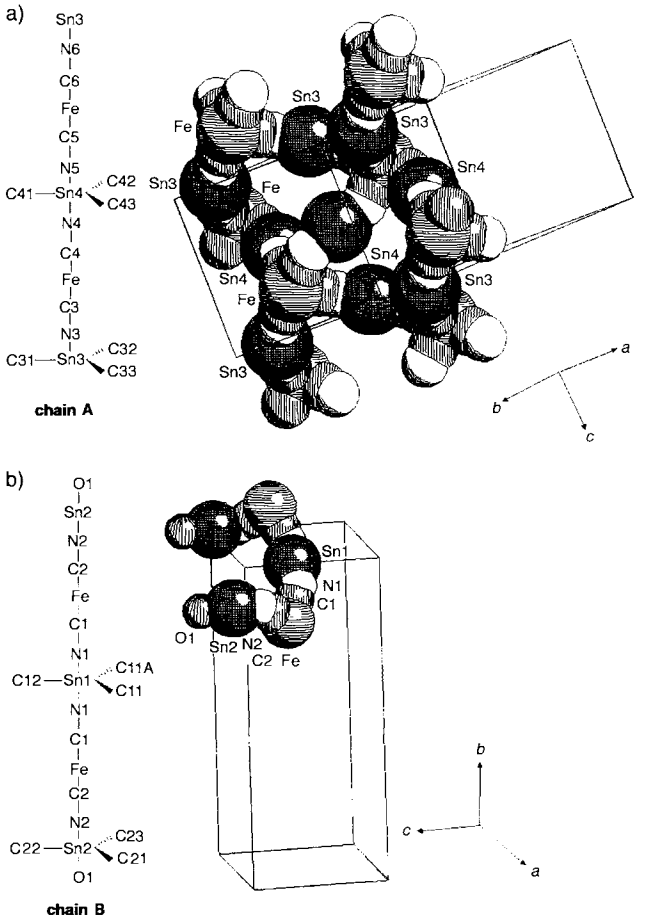

Fig. 1. a) Section of the network of **5**: SCHAKAL representation of the chains of type A only (without CH_3 groups) with complete numbering of the atoms for the vertical A helices. b) SCHAKAL representation and numbering of the atoms of a chain of type B (without CH_3 groups. Interatomic distances [pm] and angles [°] for A: Sn3-N3 229.2(14), Sn3-N6 231.7(14), Sn4-N4 224.8(14), Sn4-N5 248.0(12); C3-N3-Sn3 156.8(11), C6-N6-Sn3 154.8(13), C4-N4-Sn4 156.7(12), C5-N5-Sn4 133.6(11); C4-Fe-C6 89.9(6); C3-Fe-C5 176.9(6); B: Sn1-N1 233.6(13), Sn2-N2 218.7(13), Sn2-O1 266.4(13); C1-N1-Sn1 147.2(12), C2-N2-Sn2 137.6(12), C1-Fe-C2 90.8(6), N2-Sn2-O1 175.3(5); A/B linkage: C1-Fe-C6 178.7(6), C2-Fe-C4 174.9(6).

CN groups[8] of adjacent B' and B'' chains also contribute to the cross-linking (shortest distances [pm]: O1 ··· N1' 320, O1 ··· C1' 323; Fig. 2).

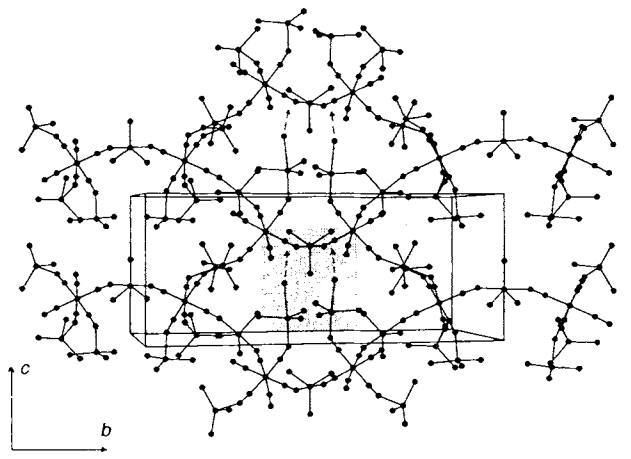

Fig. 2. View of the three-dimensional network of **5** down the a axis. Two adjacent Sn2–O1 ··· (N2–C2) fragments (O–H ··· NC hydrogen bonds) are highlighted by a grey background: nBu$_4$N$^+$ ions and methyl-H atoms have been omitted.

[**] This work was supported by the Deutscher Akademischer Austauschdienst and the British Council (ARC Cooperation), the Deutsche Forschungsgemeinschaft (Program "Nanoporous Crystals"), the Egyptian Ministry of Education ("Channel System"), and the UK EPSRC (through the National Solid-State NMR Service based at Durham).

Figure 3 depicts the approximately rectangular, nanometer-sized channels extending along the *c* axis. The nBu$_4$N$^+$ ions that are located in the channels with an almost perfect fit (C74···C78

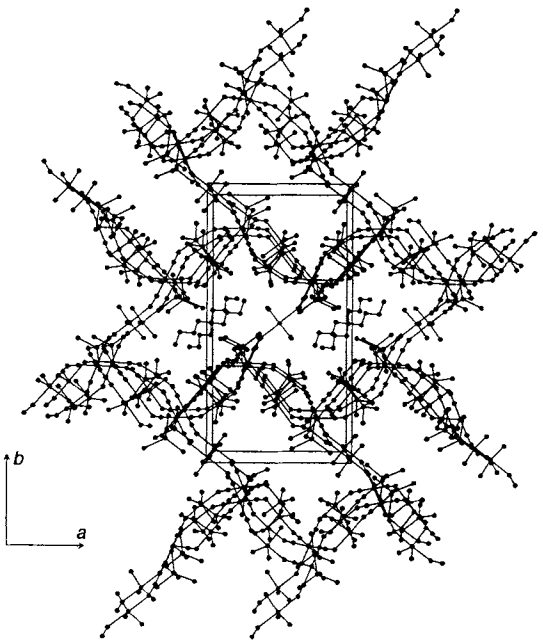

Fig. 3. View of the three-dimensional network of **5** (without methyl-H atoms) down the channels (along the *c* axis). Only in two channels are the nBu$_4$N$^+$ ions depicted.

1.013(4), H741···H781 1.151(4) nm) are not disordered (Fig. 4). The axes of part of the A helices, which are the major constituents of the walls of the channels, also run parallel to the *c* axis (see Fig. 1a). Helical chains in polymeric metal cyanides like **5** (that is, $\{M-CN-E-NC\}_n$ where M = Cu, Mo, W; E = SnR$_3$[9, 10] and $\{M-NC-E-CN\}_n$ where M = Co, Zn: E = Au[11, 12]) are a new structural motif that has only recently attracted increasing attention.[12] In **5** every distorted octahedral Fe(CN)$_6$ unit is, moreover, enantiomorphic, independent of the helicity of the chain.[13] The appearance of six separate ν_{CN} bands in each of the IR and Raman spectra is quite unusual[14] and indicates that different vibrational force constants can be attributed to the six CN ligands, which are at least crystallographically nonequivalent.[15]

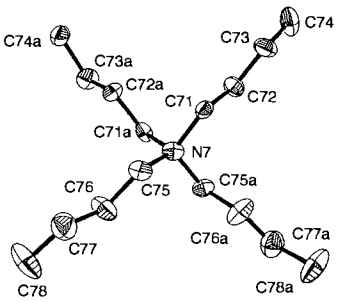

Fig. 4. ORTEP plot of the nBu$_4$N$^+$ ion of **5** (view along the *b* axis; 30% probability).

The CP/MAS NMR spectra (CP = cross polarization, MAS = magic angle spinning) of **5** recorded at 25 °C often display fewer signals or different relative intensities than expected for the number of nonequivalent atoms in the asymmetric unit.[16] Although the four expected ^{119}Sn resonances appear as discrete singlets (Table 1), even after ^{15}N enrichment (to about 50% or 95%[17]) only five (cyanide) ^{15}N and four ^{13}C signals were observed, whereas the asymmetric unit contains six nonequivalent atoms of each. Instead of eleven possible methyl ^{13}C resonances, the spectra show only two (δ = 2.3, 3.5; I_{rel} = 1/2); these split at −115 °C into six singlets δ = −1.9, 0.9, 1.1, 3.1, 3.6, 7.0; I_{rel} = 10, 4, 32, 30, 10, 10). Apparently even then the rapid rotation on the NMR time scale of only one of the four Me$_3$Sn groups about the N-Sn-X axis (X = N, O) is frozen.[18] The α-, β-, and γ-C atoms of the nBu$_4$N$^+$ ion each give rise to a relatively broad ^{13}C NMR signal (δ = 57.4, 25.7, 21.0), whereas two sharper δ-methyl ^{13}C NMR resonances (δ = 16.4, 15.5) appear. In each case, according to the asymmetric unit, two signals are anticipated. The ^{15}N NMR chemical shifts of the guest cations of **4** (δ = −372.6) and **5** (δ = −308.2; one signal predicted from the asymmetric unit) differ significantly. The above discussion of the NMR results seems justified, since the experimentally determined X-ray powder diffraction diagram is in satisfactory agreement with the calculated[7] pattern (Fig. 5).

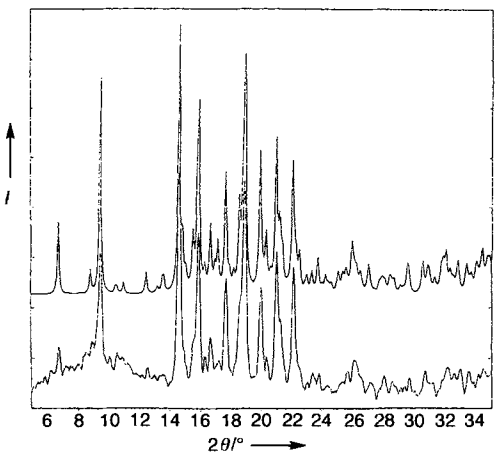

Fig. 5. Calculated (top) and experimental (bottom) X-ray powder diagram of **5**.

A notable feature resulting from the involvement of nBu$_4$N$^+$ is the formation of the {C2-N2-Sn2Me$_3$·OH$_2$} fragment that resembles an only loosely solvated, stanna-isocyanide ligand coordinated to Fe.[19] Striking evidence is a) the relatively short Sn2–N2 contact (218.7 pm), b) in contrast to this, the extremely long Sn2–O1 distance (266.4 pm),[20, 24] c) the nonplanarity of the Me$_3$Sn2 fragment (C21/C22/C23-Sn2-N2 angle: 94.8/97.3/94.4°), d) the ^{119}Sn resonance of δ = +6 (Table 1) that is attributable to a four-coordinate rather than a five-coordinate Sn atom,[25] e) the ^{13}C NMR shift of δ = 196 that displays quite a high frequency for a "classical" cyanide ligand,[26] and f) the ν_{CN} value of 2026 cm^{-1} that is relatively low for a normal Fe–CN → Sn bridge.[14] Complexes with strictly terminal CNER$_3$ ligands (E = Sn, Pb) have not yet been characterized structurally according to our knowledge;[27] thus, for the present the question whether the appearance in **5** of Fe-C2-N2 and C2-N2-

Sn2 angles that deviate significantly from 180° (171.4 and 137.6°) is mainly attributable to very pronounced Fe→C2 π backbonding must remain open.[28]

The results presented here are specific for the guest (template) ion nBu$_4$N$^+$: with no other $(C_mH_{2m+1})_4N^+$ ion ($m = 1-3,5$) did we obtain a product of the composition $[(R_4N)_x(Me_3Sn)_{4-x}Fe(CN)_6(H_2O)_y]$ with $x = 0.5$ that would be strictly homologous with **5**.[29]

[6] Synthesis of **5**: a) A suspension of **6** (450 mg, 0.519 mmol) in a solution of nBu$_4$Cl (273 mg, 1.034 mmol) in water (35 mL) was stirred for about 15 h. Filtration and washing with small portions of water (3×) and drying under vacuum yielded 401 mg (0.442 mmol, 85%) of **5**. Correct C, H, N, O, and Sn analyses, pale green–white, decomp. >260° with darkening. TG/DTA/DTG (in a stream of argon): between 60 and 140 °C a continuous decrease in mass of only about 0.7% (H_2O content of **5**: 1.7%). b) Syntheses of **5** with about 50% [^{15}N]cyanide: To a stirred aqueous solution of $K_4[Fe(CN)_6\cdot 3H_2O]$ (81.3 mg, 0.192 mmol), $K_4[Fe(C^{15}N)_6\cdot 3H_2O]$ (79.0 mg, 0.192 mmol), and nBu$_4$Cl (203 mg, 0.769 mmol) in water (8 mL), a clear solution of Me_3SnCl (306 mg, 1.536 mmol) in water (12 mL) was added dropwise. After workup as above the yield was 320 mg (0.352 mmol, 92%). Single crystal growth of **5** according to Equation (b), but with three- to fivefold more dilute solutions. An analytically and spectroscopically indistinguishable isotopomer of **5** $[(n\text{Bu}_4)_{0.5}(Me_3Sn)_{3.5}Fe(CN)_6\cdot D_2O]$ was obtained in D_2O according to Equation (b).

[25] The relative abundances of Sn deduced from the asymmetric unit, Sn1:Sn2:Sn3:Sn4 = 0.5:1:1:1, deviate from the data in Table 1.

[26] Chemical shift values of $\delta \approx 190$ have actually been measured in the ^{13}C NMR spectra of some $CNSnR_3$ and $CNPbR_3$ complexes [19].

[27] The principal reason for this is the very attractive coordination number of 5 for many Me_3Sn^{IV} derivatives.

[28] Interestingly it is the Fe-C2 bond that is slightly shorter than the other Fe-C bonds of **5** (Fe–C2 187.6(13) pm, otherwise 189.7(15)–193.2(14) pm).

[29] For $m = 1$ [5] as well as for $m = 3$ and 5 we found x values of between 0.5 and 1; it is also remarkable that no strict Ru homologue of **5** forms with M = Ru instead of Fe.

The Effect of the Surrounding Medium on the Interaction of Nitriles with Boron Trifluoride**

Ian R. Beattie* and Peter J. Jones

In a series of elegant papers, Leopold et al. have examined the interaction of acetonitrile or hydrogen cyanide with boron trifluoride.[1–3] The observations demonstrate a remarkable change in the boron–nitrogen bond length between those bonds in the free molecules (in a pulsed molecular beam of argon) and those in the crystalline solids.[3, 4] In the case of $CH_3CN\cdot BF_3$, the change in bond length was 0.381 ± 0.011 Å. The isolated molecule can be regarded[1] as "structurally quite intermediate between a covalent molecule and a weakly bound complex" although energetically it is much more like a van der Waals molecule.[5] The results of ab initio calculations[6] on the isolated molecule were in good agreement with the microwave data and indeed helped to guide the microwave search initially. Very recently the (calculated) B–N bond length was examined as a function of the dielectric constant of the surrounding medium, by using the self-consistent reaction field (SCRF) method.[7] For $HCN\cdot BF_3$ the critical dielectric constant was approximately 10 D. Media having a dielectric constant higher than this value gave the short B–N distance, as found in the solid. These and related papers[8] have led to a resurgence of interest in such Lewis acid–base complexes.

The compound $CH_3CN \cdot BF_3$ is well characterized, stable at room temperature, and easily sublimed in a vacuum. Laubengayer and Sears[9] found from vapor density measurements that in the temperature range 50 to 103 °C dissociation is "virtually complete"; however, the photoelectron spectrum of the vapor has been reported.[10, 11] In view of these apparently conflicting results, we examined the IR spectrum of a completely vaporized sample at 50 °C using a long path-length (ca. 90 cm) borosilicate glass cell with sealed-in silicon windows and no taps or joints. The resultant spectrum was a superposition of the spectra due to acetonitrile[12] and boron trifluoride,[13] and no bands due to complex formation were detected. An early study of the IR spectrum of solutions of $CH_3CN \cdot BF_3$ in benzene indicated a solubility of the order of 0.25 M.[14] As benzene has a dielectric constant of only about 2.3 D while that of xenon near the critical point is about 1.8 D,[15] we decided to attempt experiments in liquid and supercritical xenon, since these media have the advantage of being transparent to IR radiation. Unfortunately the solubility was too low to obtain either proton NMR[16] or IR spectra.[17] A redetermination of the solubility in benzene by using ^{19}F NMR spectroscopy with $C_{10}F_8$ as a reference compound gave a value of 0.023 M, an order of magnitude lower than that found previously.

Because of this discrepancy and the importance of studies in media of low dielectric constant, we examined the "CN stretching frequency" of $CD_3CN \cdot BF_3$ in benzene (CD_3CN was used because of problems[18] of Fermi resonance in CH_3CN). Using a borosilicate cell with fused-in silicon windows wedged to give path lengths between 0.0 mm and about 1.0 mm, we were able to verify a new band at 2353 cm^{-1}. Solutions of BF_3, CD_3CN, or $CH_3C^{15}N \cdot BF_3$ did not show this band; however, much of this region is obscured by solvent bands. In nitrobenzene (dielectric constant ca. 35 D), $CH_3CN \cdot BF_3$ showed[19] a "CN stretching frequency" at 2360 cm^{-1}, only a few wave numbers away from that for the corresponding solution in benzene and again close to the solid-state value of 2376 cm^{-1}.[20] Although the observation of a particular frequency does not define a bond length, nonetheless there is considerable evidence that "ν_{CN}" is related to the strength of the interaction of CH_3CN with Lewis acids.[21] Certainly the shift of greater than 100 cm^{-1} from the free ligand in solution in benzene (2248 cm^{-1}) to the complex $CH_3CN \cdot BF_3$ in solution in benzene (2353 cm^{-1}) suggests an interaction in solution comparable to that found in the solid state.

The ^{19}F NMR spectrum of $CH_3CN \cdot BF_3$ in benzene[22] showed one signal at $\delta \approx -139$ relative to $CFCl_3$. (To retain the integrity of the system, no internal standard was used, so δ values are only approximate.) In earlier work[23] in a solution in CH_2Cl_2 (with a dielectric constant of about 9 D), a solution composed of a 1:3:60 mol ratio of BF_3:CH_3CN:CH_2Cl_2 gave a signal at $\delta = -144.2$. The chemical shift value for BF_3 has been reported[24] as $\delta = -125$, and in our experiments[22] we found a solution (ca. 0.2 M) in benzene gave a signal at $\delta = -124$.

All of the above results can be interpreted in terms of the presence of a largely undissociated molecular species in benzene, dichloromethane, or nitrobenzene, whose geometry is similar to that found in the solid state. Attempts to study solutions in *n*-hexane (with a dielectric constant of about 1.9 D) failed due to lack of solubility. It is apparent that the solubility of $CH_3CN \cdot BF_3$ is highly dependent on the dielectric constant of the medium, and we note that the complex is very soluble in excess ligand (CH_3CN).

Matrix isolation is an attractive technique for studying molecular species as solid solutions in a relatively inert environment such as argon (with a dielectric constant of 1.56 D[15]). In order to increase the likelihood of complex formation while minimizing the possible formation of aggregates, we used a bulb containing a 1:10:500 mol ratio of CD_3CN:BF_3:argon, heated to 60 °C to ensure that all the material was in the vapor. The highest product concentration would then be 1:500. The small excess of BF_3, while ensuring that the CD_3CN would "see" the BF_3, has no dipole. Furthermore, the "ν_{CN}" band was expected to be more intense in the complex than in free CD_3CN.[25] Although the resultant IR spectra were inevitably complicated by combination bands of BF_3, there was clear evidence of a product band at 2380 cm^{-1}. It is logical to attribute this band to the $CH_3CN \cdot BF_3$ complex with a structure similar to that found in the solid state, with a band at 2373 cm^{-1}. Figure 1 shows a difference spectrum in the "CN stretching region" between a matrix consisting of a 1:10:500 mol ratio of CD_3CN:BF_3:argon; and a matrix consisting of a 1:50 mol ratio of BF_3:argon.

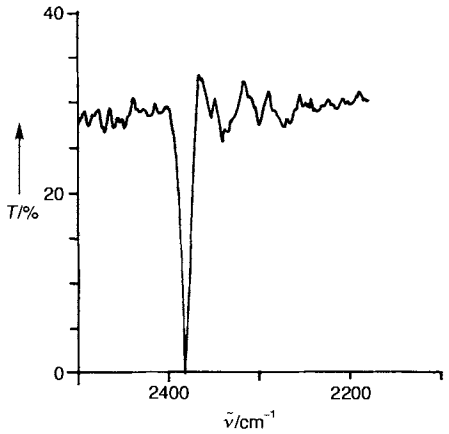

Fig. 1. Difference IR spectrum between a matrix of CD_3CN:BF_3:argon at 1:10:500 and a matrix of BF_3:argon at 1:50 mol ratio. T = transmittance.

The case of $HCN \cdot BF_3$ is complicated by the fact that a) this complex is less stable than $CH_3CN \cdot BF_3$ (HCN is a weaker donor than CH_3CN. Thus the dissociation pressure of $HCN \cdot BF_3$ is 400 Torr at 19 °C,[26] while for $CH_3CN \cdot BF_3$ this pressure is only attained at about 90 °C[9]), and b) there is an acidic proton that can form a hydrogen bond with the fluorine atom or the nitrogen atom of another molecule, or interact with the surrounding medium. A very recent paper[27] discusses the importance of such "a cooperative mechanism" in crystalline $HCN \cdot BF_3$.

When a gas mixture of $HCN \cdot BF_3$ in a 1:1 ratio was condensed at about 12 K and annealed at 100 K, the IR spectrum showed bands [cm^{-1}] at: 3193 (ms), 2209 (s, sharp), ca. 1200 (vs, broad), 863 (s), 803 (w), 653 (s), 512 (ms, sharp). The bands in the region between 3,300 and 1,000 cm^{-1} can reasonably be assigned, in order of decreasing frequency, as ν_{CH}, ν_{CN} and ν_{BF}. They may be compared with ν_{CH} at 3205 and ν_{CN} at 2192 for solid $HCN \cdot AsF_5$[28] and with ν_{BF} of solid $MeCN \cdot BF_3$, "a strong band at about 1200 cm^{-1}".[20]

In a matrix isolation experiment analogous to that for $CH_3CN \cdot BF_3$ (i.e. HCN:BF_3:argon at 1:10:500) product bands appeared at 3246, 2217, and about 1200 cm^{-1}. These correspond closely with those in the solid and identify the matrix-isolated species as $HCN \cdot BF_3$ in the form with short B–N linkage.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1528 $ 15.00+.25/0

A matrix isolation experiment using an excess of HCN (HCN:BF_3:argon at 10:1:500) gave spectra in which ν_{CN} occurred at 2167 cm^{-1}, with no evidence for a band around 2210 cm^{-1}. Furthermore, condensing a gas mixture of HCN:BF_3 (ca. 5:1) at 12 K showed a strong product band at about 2180 cm^{-1}, together with a broad band at about 1200 cm^{-1}. Annealing at 150 K led to a decrease in intensity of the band at 2180 cm^{-1}, while a band at 2210 cm^{-1}, corresponding to ν_{CN} of solid HCN · BF_3, grew in. Clearly the excess HCN is interacting with the HCN · BF_3. The corresponding solution chemistry is complicated by preferential loss of boron trifluoride. When cold toluene, which contains crystals of HCN · BF_3, is allowed to warm to room temperature, a gas is evolved as the crystals "dissolve". The IR spectrum of the resultant solution shows the presence of free HCN, coupled with a weak broad band at 2167 cm^{-1} analogous to that found in the solid (5 HCN: 1 BF_3) and in the matrix containing excess HCN. A solution in toluene which was about 0.025 M in HCN and had a pressure of approximately two atmospheres of BF_3 above that solution, in addition to free HCN, showed only the 2167 cm^{-1} band, even on cooling to −70 °C.

It is interesting to compare these results with those on gaseous HCN · BF_3, where ν_{CH} is almost unchanged from that of free HCN,[29] showing a very small perturbation of the HCN by the (distant) BF_3. We also note that the van der Waals molecule OC · BF_3 (isoelectronic with HCN · BF_3) shows frequency shifts of the order of 10 cm^{-1} for ν_{CO} and ν_{BF} (antisymmetric stretch).[30, 31] The corresponding ν_{BF} shifts for strong adducts[20] are nearer to 200–250 cm^{-1}, similar to those proposed here for HCN · BF_3. In a matrix isolation experiment, it is always possible for polymerization to occur, notably at the interface with the condensing gas. However, we note: a) that in a separate experiment on HCN in argon at a 1:500 matrix ratio, we found only a trace of dimer, in agreement with a very recent paper by Beichert et al.;[32] b) that to form (RCN · BF_3)$_2$ in a matrix requires two RCN and two BF_3 molecules to come together in the correct orientation. This seems unlikely in our experiments in which the maximum product ratio wuld be 1:1000 and no annealing was carried out after the condensation at 12 K. However, we should emphasize that this does not *exclude* the possibility of polymer formation.

Intramolecular Movements of Lithium in Crystals

Michael Veith,* Michael Zimmer, Kira Fries, Jutta Böhnlein-Maus, and Volker Huch

In certain molecular structures, metal atoms can undergo definite movements without actually leaving the molecule. The lithium atom in the silylamide $(Me_3Si)_4N_4(SiMe_2)_2InLi$, for example, orbits around the central indium atom—its nitrogen coordination changing continually.[1] These movements are accompanied by large framework vibrations of the ligands, however, so that the process is only observed in solution. Model calculations confirm the interpretation of the experimental findings.[2]

We subsequently extended our search to include compounds in which intramolecular movements of lithium atoms can be identified in the *solid state*, and our search proved successful in the case of the lithium salt **1**, which we used as starting material for a series of metal amides.[3, 4] Compound **1** can be prepared according to Scheme 1 with a total yield of 81 %.[5]

According to molar mass determinations, **1** is dimeric in solution. Depending on the temperature, **1** forms three crystalline phases, in which the symmetry of the crystal lattice increases with increasing temperature. The changes in volume and lattice constants with increasing temperature are depicted in Figure 1;

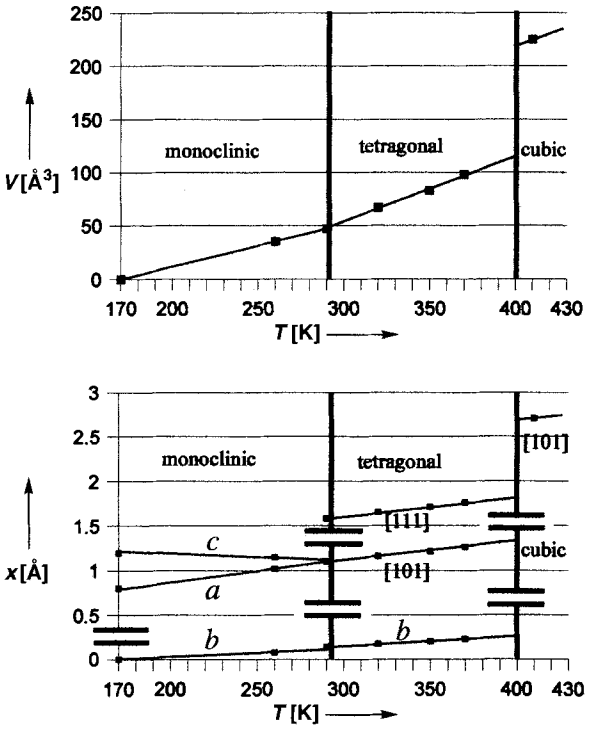

Fig. 1. Change in volume V (top) and lattice constants x (bottom) of crystalline **1** with increasing temperature.

the corresponding space groups and crystal dimensions are listed in Table 1. Whereas the changes in the lattice parameters are only small for the transition from the monoclinic phase to the tetragonal phase (for which a small amount of heat absorption ($\Delta H = +0.45\ \mathrm{kJ\,mol^{-1}}$) was determined by differential scanning calorimetry (DSC) measurements), they are rapid and conspicuous in the second phase transition (tetragonal to cubic), which is accompanied by a considerably higher heat loss

($\Delta H = -3.06\ \mathrm{kJ\,mol^{-1}}$). X-ray structure analyses were carried out on single crystals for both the monoclinic and tetragonal phases, but it was only possible to determine the cubic phase by means of powder methods (heatable Guinier camera).[6] The latter phase only leads to few diffraction lines, the intensities of which drastically decrease with increasing diffraction angle, just as is known for *plastic phases*.[7, 8] The phase transitions are reversible; the results of differential thermoanalysis (DTA) studies and temperature-dependent Guinier photographs indicate a small amount of hysteresis.

The results of the X-ray structure analyses are shown as ORTEP diagrams in Figures 2 and 3. In the monoclinic phase

all atoms occupy an unequivocal position and a typical molecular structure is obtained. The two lithium atoms are each bonded to both alkoxysilazyl ligands, which results in the formation of a central four-membered Li_2N_2 ring. Apart from the two nitrogen atoms, the lithium atoms are each additionally coordinated to the oxygen atoms of the alkoxy groups and thus attain a coordination number (CN) of four. Both *t*BuO–Si(Me)$_2$–N–Si(Me)$_2$–O*t*Bu ligands are largely planar and arranged in such

a fashion that they almost fulfill an $S_4(\bar{4})$ symmetry operation. Four N_2O_2 coordination polyhedra of almost equal size are thus formed (cf. Fig. 3), of which two are occupied by lithium atoms.

Structure determinations were carried out on the tetragonal phase at three different temperatures (22, 45, and 80 °C; Fig. 3 and the details given in the literature[6] relate to 45 °C). The changes observed in the displacement parameters, and alternative model calculations indicate that the crystal structure is to be interpreted as a superposition of different atomic positions and is not the result of the formation of a twin crystal. It can be deduced from the solid-state NMR spectra (see below) that the cause of the split atomic positions is a special dynamic process in the molecular crystal that becomes more intense after the monoclinic/tetragonal phase transition. The lithium atoms have the largest extreme values for split positions, which give an electron density of Li/2 in the centers of the four N_2O_2 coordination polyhedra described previously. The formal point symmetry of the molecule increases for the monoclinic/tetragonal phase transition from C_1 (one of the three pseudo C_2 axes runs through both nitrogen atoms) to D_{2d} ($\bar{4}2m$). The tetragonal space group of **1**, $P4_2/nmc$, is a higher class (but not a maximum[9]) in the symmetry tree of the monoclinic space group $P2_1/n$, the volume of which is twice as large.

On the transition to the high-temperature phase (that is from tetragonal to cubic) the point symmetry of the molecule **1** increases once more and achieves, depending on the choice of space group, O_h ($m3m$) or T_d ($\bar{4}3m$) symmetry. The amount of exothermic heat energy measured in the DSC experiment is consistent both in size and in sign with an anticipated melting process, which is what the plastic phase represents. The molecules of **1** thus undergo oscillations about their cubic close-packed centers of gravity in the high-temperature phase, which leads to the formation of threefold and fourfold crystallographic axes that are not present in the molecule.

The cause of the phase transition from tetragonal to cubic is thus of a dynamic nature. We have therefore also interpreted the positional disorder in the tetragonal phase as being a direct result of molecular movement. This assumption was in fact confirmed by powder solid-state ^{6}Li, ^{7}Li, ^{13}C, and ^{29}Si MAS NMR (MAS = magic angle spinning) and broad-line NMR spectra, which were recorded at the same temperature intervals as the X-ray experiments.[5, 10] All spectra are consistent with one another and confirm the crystallographically found phase transitions as well as the movements. This is exemplified in the following with the aid of selected spectra.

^{13}C CP/MAS NMR spectra (CP = cross polarization) of **1** were recorded over and above both of the phase transitions (Fig. 4). In the low-temperature monoclinic phase the ^{13}C CP/MAS NMR spectra of **1** has eight signals from methyl groups for the four $SiMe_2$ groups, corresponding to the number expected for the lower molecule symmetry (crystallographically: C_1, pseudo D_2); three of these could not be resolved and are superimposed. The methyl groups of the four crystallographically different *tert*-butyl groups were only split into two signals, whereas the quaternary carbon atoms only gave a single signal corresponding to the low resolution of the chemical shift. At the phase transition monoclinic/tetragonal the group of signals for the eight $SiMe_2$ groups merges to give a singlet. The two signals from the *tert*-butyl groups also degenerate to give a single resonance. The increase in symmetry indicates a reinforced ligand dynamism in the tetragonal phase. The line widths of the *tert*-butyl groups and the $SiMe_2$ group signals increase with increasing temperature and at 343 K the signal from the quaternary carbon atom disappears.[10–12] The attainment of the plastic phase is indicated by the development of new sharp signals in the spectrum at 403 K, the positions of which are different from those in the tetragonal phase. This is in agreement with the crystallographic observation that a completely new lattice build-up is found (immediate surroundings of a particular molecule: tetragonal, CN = 10; cubic, CN = 12).

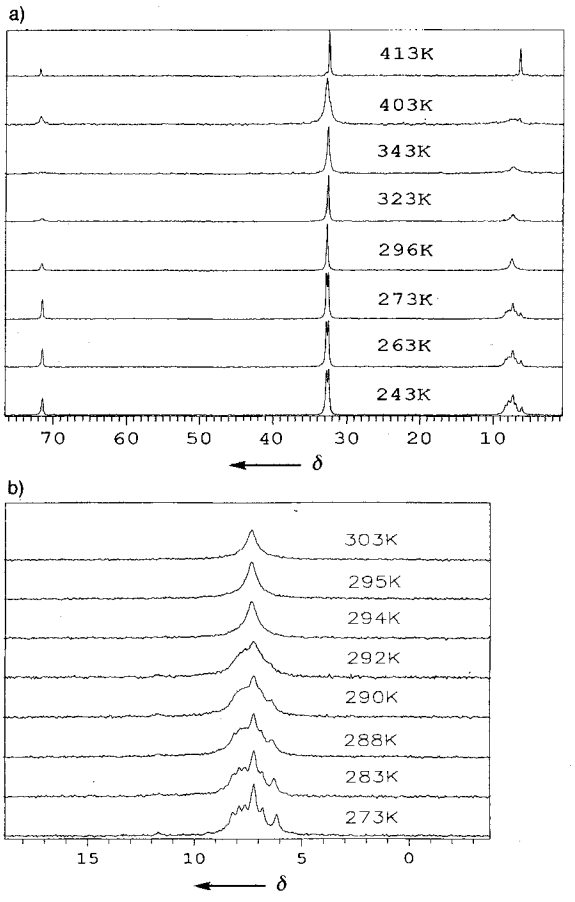

Fig. 4. a) ^{13}C CP/MAS NMR spectra of **1** in the temperature range from 243 K to 413 K. b) The monoclinic/tetragonal phase transition based on the signals of the $SiMe_2$ groups (expanded). Note the abrupt change between 292 and 294 K!

Parallel to the ^{13}C CP/MAS NMR spectra, the temperature-dependent ^{6}Li and ^{7}Li solid-state NMR spectra of **1** show significant changes at the monoclinic/tetragonal phase transition (Fig. 5a). In the low-temperature monoclinic phase, the ^{7}Li MAS NMR spectrum shows the typical line shape resulting from first-order quadrupolar splitting. Comparison with simulated spectra leads to an estimated quadrupolar coupling constant of 100 ± 2 kHz and an asymmetry parameter η of 0.4.[13] The transition to the tetragonal phase is coupled with an immediate disappearance of the rotational side bands of the satellite transitions; only the central line is still observed. The typical line shape with first-order quadrupolar splitting is first registered again at a temperature of about 373 K with the reappearance of the rotational side bands. The distribution of side bands of the satellite transitions at 383 K indicates a quadrupolar coupling constant of 88 ± 2 kHz with an asymmetry parameter $\eta = 0.1$,[13] that is close to cylindrical symmetry.

In agreement with this, the temperature-dependent ^{6}Li CP/MAS NMR spectra of **1**—isotopically enriched to 95 % ^{6}Li—follow an analogous course (Fig. 5b). In the ^{6}Li MAS NMR experiment the line shape also changes considerably and (as in the case of the ^{7}Li MAS NMR experiment) an area with homogeneous line broadening is encountered with corresponding reduced efficiency of the MAS NMR experiment;[14] this is an

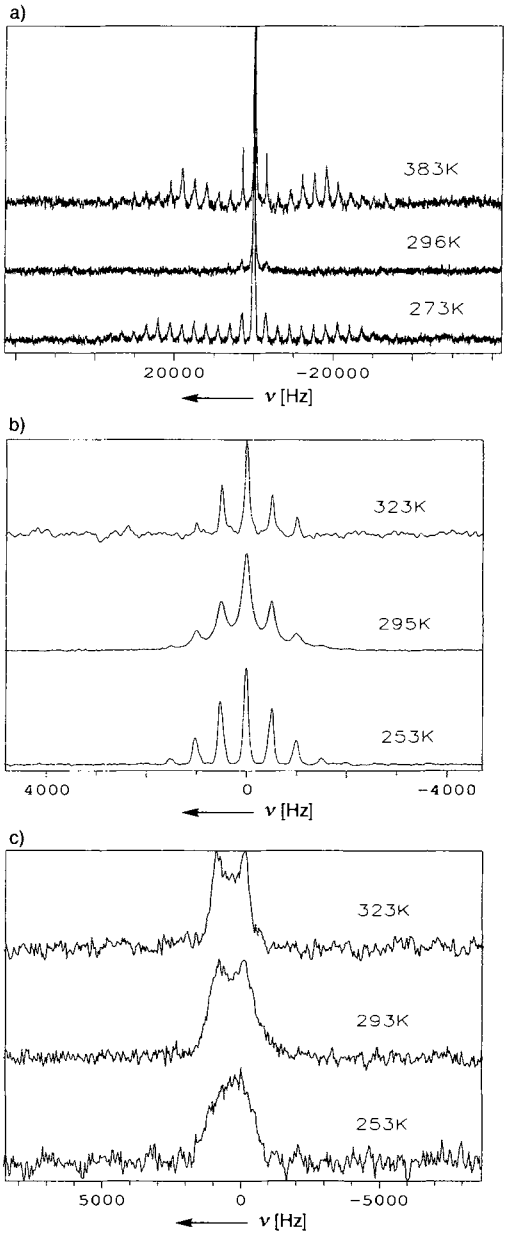

Fig. 5. a) ^{7}Li SPE/MAS NMR spectra (3 kHz) of the monoclinic (273 K) and tetragonal (296, 383 K) phases. b) ^{6}Li CP/MAS NMR spectra (500 Hz) of **1** in the region of the monoclinic/tetragonal phase transition. c) The corresponding ^{6}Li broad line NMR spectra over the same temperature interval.

unequivocal confirmation of dynamic exchange. The simulation of the line shape of the static ^{6}Li broad line NMR spectrum (Fig. 5c) at 323 K in the tetragonal phase suggests a quadrupolar coupling constant of 1.5 kHz and an asymmetry parameter η of 0.1. An effective quadrupolar coupling constant of 87 kHz has thus been calculated for ^{7}Li at 323 K from the ratio of the quadrupolar moments of ^{6}Li and ^{7}Li.[15, 16] This value agrees well with the value of 88 kHz found in the ^{7}Li MAS NMR experiment at 383 K, and thus confirms that the change in the quadrupolar interaction is primarily dependent on the phase transition and not on the temperature. The transition to the high-temperature plastic phase is indicated by the appearance of a sharp peak on the central line of the ^{7}Li solid-state NMR signal, the intensity of which increases with increasing temperature and is activated before the phase transition actually occurs.

The results of our experiments can be summarized as follows. Stronger vibrations of the molecular framework in **1** are stimulated by increases in temperature. The higher amplitudes of the vibrations of the framework atoms are carried over to the two lithium atoms from the tetragonal phase onward. The lithium atoms vibrate out of their distorted tetrahedral N_2O_2 potential minima and, for electrostatic reasons, fall cooperatively into the neighboring potential minima. An alternative movement of the entire molecule around one of the C_2 axes can be excluded on the basis of the data from the X-ray structure analysis. One enantiomer thus changes into its mirror image (in the low-temperature monoclinic phase both enantiomers are present and coupled with one another through inversion centers). Investigations are currently being carried out into how far these movements of the lithium atoms occur chaotically on an intermolecular basis. However, the intramolecular orbital movements of the lithium atoms are coupled to a phase transition, and the positions of the center of gravity of the molecules change only negligibly (Table 1). At very high temperatures the framework vibrations are so large that the molecules then start to slide past one another (a new stacking arrangement of the molecules takes place, Table 1) until more room is available for movement. The molecules begin to sway around their centers of gravity in a disordered fashion and a new plastic phase is formed.

$P4_2/nmc \xrightarrow{t2} (Pmmn) \xrightarrow{t2} (P2_1/m) \xrightarrow{k2} P2_1/n\ (a' = a + c;\ b' = c - a)$.

[10] The ^{13}C CP/MAS NMR spectra were recorded at a sample rotation speed of 3 kHz and a contact time of 1 ms. The measurements at higher temperatures (above 50 °C) were carried out by in a single pulse excitation (SPE) experiment. The B_1 field strength of the proton decoupler was varied between 41 and 83 kHz to confirm the line width decoupling strength relationship [11,12]. The best resolution in the ^{29}Si CP/MAS NMR spectra was obtained for the sample enriched to 95 % with the ^6Li isotope. In order to confirm the quadrupolar splitting by ^{14}N [17], the ^{29}Si CP/MAS NMR spectrum was additionally recorded at a field strength of 9.45 T (79.4 MHz). The ^7Li MAS NMR spectra were recorded by using the SPE experiment. In order to avoid saturation, recycle delays of 30 s were used. All ^6Li NMR spectra of the 95 % isotopically enriched compound were recorded by using the cross-polarization method with contact times of 5 to 10 ms. All measurements were performed by using dipolar ^1H decoupling and carried out on a Bruker MSL 200 S spectrometer equipped with a B-VT 2000 temperature control unit. Air-tight Kel-F inserts which fit into 7 mm MAS rotors were used for the preparation of the samples. See ref. [5] for the solid-state NMR data.

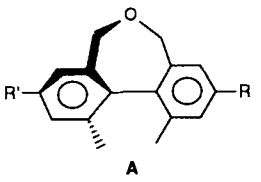
New Family of Enantiomerically Pure Liquid Crystals Containing a Chiral Biphenyl Core

Guy Solladié,* Philippe Hugelé, Richard Bartsch, and Antoine Skoulios

Many applications of liquid crystals (LC) require chiral and optically active materials. Large-pitch cholesterics obtained by doping nematics with chiral and enantiomerically pure molecules give better response in displays, as shown by Schadt and Helfrich.[1] It is also well known that ferroelectric properties of smectic LC are only observed with chiral mesogenic molecules.[2]

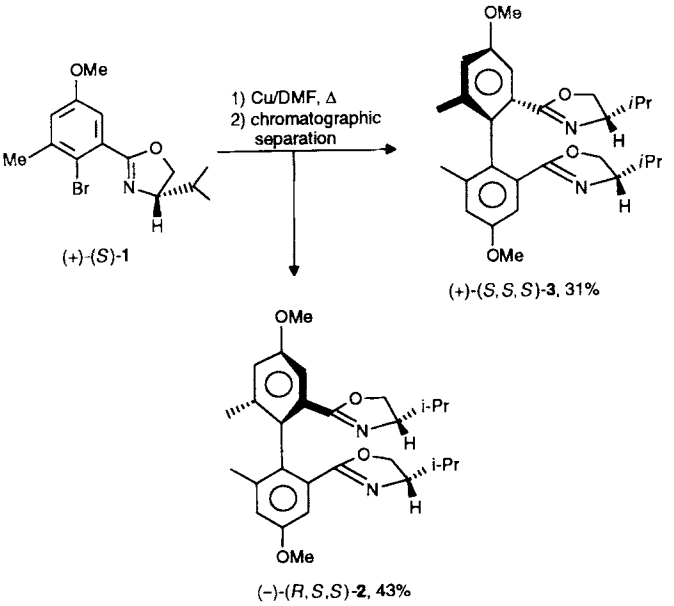
Biphenyls without substituents in the *ortho* position have been used as nematic phases in a huge variety of applications. Most of the time the chirality was obtained by incorporating an asymmetric carbon in a chain linked to the core of the mesomorphic molecule.[2] Although a 2,2',6,6'-tetrachlorobiphenyl derivative in its racemic form was shown to be nonmesomorphic, tetra-*ortho*-substituted biphenyls with axial chirality were found to form cholesteric liquid crystals when they are enantiomerically pure.

For the past several years we have been interested in chirality in liquid crystals.[3] We reported on enantiomerically pure 1-biphenylyl-2-cyclohexylidenethanone derivatives, the first examples of LC with axial chirality in the core of the mesogenic molecules.[4] In that case the presence of a biphenyl substituent was necessary to induce mesomorphic properties, and therefore these compounds can be considered as biphenyl derivatives having axial chirality in the chain. Later on we showed[5a] that racemic substituted *trans*-stilbene epoxides, in which the two aryl groups are in a rigid, nonplanar, and slightly twisted conformation, have mesogenic properties. Recently new examples of this family were reported.[5b] We describe here a new family of enantiomerically pure LC of type **A** and show that molecules containing a rigid twisted biphenyl core with axial chirality can form cholesteric mesophases.



A

The synthesis of the optically active targets (+)-(*R*)-**6** and (−)-(*R*)-**8** started from the chiral dihydrooxazole (+)-(*S*)-**1**, which was dimerized by means of an Ullmann reaction to give a mixture of the two diastereomeric biphenyl derivatives (−)-(*R,S,S*)-**2** and (+)-(*S,S,S*)-**3**, which



were easily separated by silica gel chromatography. This is the first report of the optical resolution of a biphenyl compound through diastereomeric dihydrooxazole derivatives. The absolute configuration of the biphenyl moiety was established by chemical correlation of (−)-(*R,S,S*)-**2** with the known phenol (+)-(*R*)-**9**[6] (Py = pyridine, DMSO = dimethyl sulfoxide, *m*CPBA = *m*-chloroperbenzoic acid). Comparison of the optical rotation of the sample of (+)-(*R*)-**9** obtained from (−)-(*R,S,S*)-**2** with the literature value[6] attests to the high enantiomeric purity of our synthetic sample.

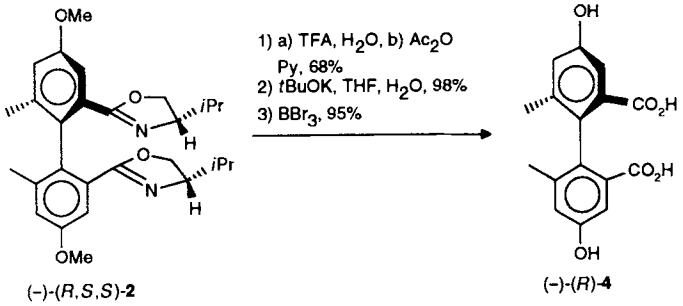
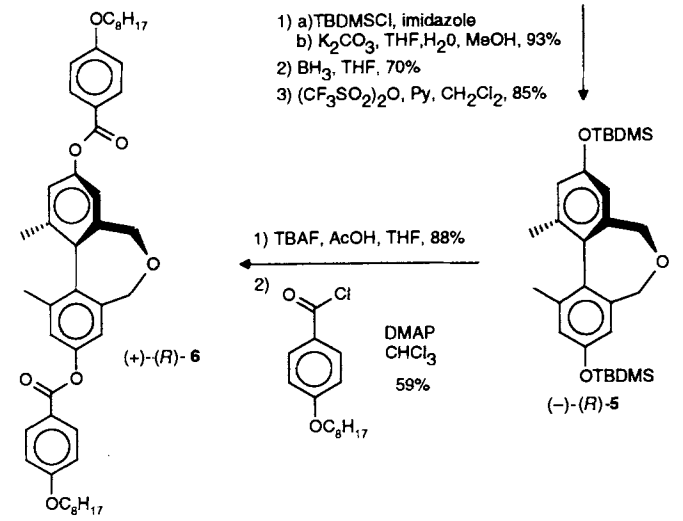
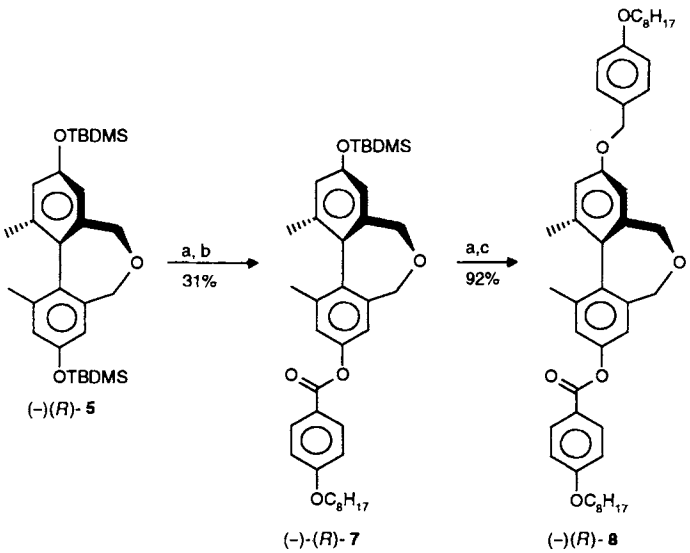
The oxepine (−)-(*R*)-**5** was obtained in a few steps from (−)-(*R*,*S*,*S*)-**2**. Opening of the dihydrooxazole rings with trifluoroacetic acid (TFA) to give the corresponding amino esters followed by acetylation of the amino groups, saponification of the esters with *t*BuOK, and hydrolysis of the methoxy groups with BBr_3 furnished the dicarboxylic acid (−)-(*R*)-**4** (m.p. 228 °C; $[\alpha]_D = -20$ ($c = 2$ in ethanol)). Protection of the hydroxyl groups of the phenols with *tert*-butyldimethylsilyl groups, reduction of the carboxyl groups with BH_3·THF (70% yield), and cyclization with triflic anhydride gave the oxepine (−)-(*R*)-**5**. Finally after the silyl groups were removed with tetrabutylammonium fluoride (TBAF), esterification with 4-(octyloxy)-benzoyl chloride afforded the mesogenic chiral biphenyl target (+)-(*R*)-**6**. The enantiomeric purity of the sample was checked by recording its ^{1}H NMR spectrum in presence of tris[3-(trifluoromethylhydroxymethylene)-*d*-camphorato]praseodimium.





The second mesogenic compound, (−)-(*R*)-**8**, was obtained by deprotecting one phenol group of (−)-(*R*)-**5** and esterifying with 4-(octyloxy)benzoyl chloride to get (−)-(*R*)-**7** (m.p. 76 °C; $[\alpha]_D = 14.8$ ($c = 2$ in acetone). The remaining silyl protecting group in (−)-(R)-**7** was removed by treatment with TBAF, and subsequent etherification 4-(octyloxy)benzyl iodide afforded (−)-(*R*)-**8** (Scheme 1). The configurational stability of compounds **6** and **8** is very high; racemization was not observed at temperatures below 110 °C (determined by the absence of coalescence of the AB systems of the OCH_2 protons).

The liquid crystal behavior of molecules **6** and **8** was briefly investigated by differential scanning calorimetry, polarizing microscopy, and X-ray diffraction. Both molecules were found to produce a cholesteric phase as expected (fluidity; fine schlieren texture; presence of a broad cybotactic ring instead of sharp



Scheme 1. a) TBAF, AcOH, THF; b) 4-$C_8H_{17}OC_6H_4COCl$, DMAP; c) 4-$C_8H_{17}OC_6H_4CH_2I$.

small-angle Bragg reflections). The phase transition is enantiotropic in nature for **6** (K 75 Ch 105 I) and monotropic for **8** (K (Ch 60) 78 I) (K = crystalline, Ch = cholesteric, I = isotropic). In both cases crystallization proved to be particularly slow, lasting many days when the melt was cooled to room temperature.

Molecular modeling of oxepine **6** (MOPAC software, CAChe work station from Oxford Molecular) showed a dihedral angle of 56° between the aryl rings of the biphenyl. This value is similar to the 57° found by UV analysis for 1,11-dimethyl-5,7-dihydrodibenz[*c*,*e*]oxepine.[7].

These results show for the first time that a rigid, nonplanar, and enantiomerically pure biphenyl derivative can display liquid crystal properties and that the axial chirality of the biphenyl moiety induces a cholesteric mesophase. This is in sharp contrast with the previous studies on racemic noncyclic 2,2′,6,6′-tetrachlorobiphenyl derivatives[8] (torsional angle close to 90°) and on an enantiomerically enriched oxepine[9] very similar to compound **6** with two *ortho*-nitro groups (torsional angle of 58°) in place of the two methyl groups; none of these compounds showed mesogenic properties. We are currently investigating new derivatives of these biphenyl oxepines which may form smectic phases.

Experimental Procedure

2 and **3**: A mixture of **1** (5 g, 16 mmol) and freshly activated copper (5 g) in 30 mL of freshly distilled DMF was heated at reflux for 3 h. After cooling, the mixture was diluted with CH_2Cl_2 and washed with aqueous ammonia until the copper was completely removed. The organic layer was washed with water, dried ($MgSO_4$), and concentrated to give a yellow oil, which was purified by flash chromatography (flow rate = 40 mL min^{-1}, ether/hexane 20/80) over pretreated silica gel. (400 g of silica gel was stirred overnight in 800 mL of ether/hexane (20/80) and 20 mL of Et_3N and the column was filled up with this solution under a small pressure.) 1.6 g (43%) of the atropisomer (−)-(*R*,*S*,*S*)-**2** ($R_f = 0.22$) and 1.1 g (31%) of (+)-(*S*,*S*,*S*)-**3** ($R_f = 0.32$) were obtained.

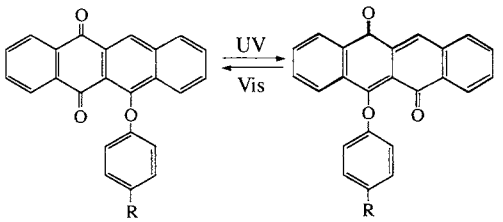
An Electroactive Photoisomerizable Monolayer-Electrode: A Command Surface for the Amperometric Transduction of Recorded Optical Signals**

Amihood Doron, Eugenii Katz, Moshe Portnoy, and Itamar Willner*

The development of molecular switching assemblies has attracted extensive research efforts recently, as they provide the basis for molecular electronic and optoelectronic devices.[1, 2] Optical,[3, 4] electrochemical,[5] thermal,[6] and pH[7] triggering signals have been used to activate switchable molecular functions. Electrochemical translocation of molecular components[5] in supramolecular complexes was reported as a mechanism for electroactivated molecular switches. Light-controlled association of ions to photoisomerizable molecular receptors[8] and activation of ion–transport systems[9] represents optical switching at the molecular level. Similarly, light-signaled formation or dissociation of donor–acceptor complexes (like the association of the *cis*-azobenzene 4,4′-bipyridinium salt to the eosin dye, which acts as electron donor) represents an optical molecular switch.[10]

The assembly of molecular switching devices requires the transduction of the molecular switching function by a secondary physical signal. This allows the application of the molecular switching assembly as a Read/Write memory device. Recently, photoisomerizable dithienylethene with two phenol substituents was used for the amperometric transduction of optical signals.[11] In this system one of the photoisomeric states revealed electroactivity that enabled the amperometric transduction of the optical signal and its storage. Similarly, photoisomerizable monolayers assembled on electrodes were applied as optical recording interfaces and command surfaces for electrochemical transduction of the optical signal.[12–14] Specific association (or dissociation) of redox proteins like cytochrome c,[13a] electrically "wired" enzymes like ferrocene-modified glucose oxidase,[13b] and antibodies[14] to the photoisomerizable monolayer electrodes enabled the electrochemical transduction of the optical signals recorded by the photoactive monolayer. Here we wish to report on the assembly of a photoisomerizable electroactive monolayer electrode that enables the amperometric transduction of the optical signals recorded at the monolayer electrode.

Phenoxynaphthacenequinone (**1a**) undergoes reversible photochemical isomerization between the "*trans*"-quinone (**1a**) isomeric state and the "*ana*"-isomer **1b**[15] [Eq. (a)]. Accordingly, 6-[4-(carboxymethyl)phenoxy]-5,12-naphthacenequinone (**2a**)



(a)

"*trans*" **1a, 2a** "*ana*" **1b, 2b**

1, R = H
2, R = CH_2CO_2H

was assembled as a monolayer on a gold electrode as outlined in Scheme 1. A cystamine monolayer was assembled on the gold electrode, and **2a** was coupled to this monolayer. Figure 1 (curve a) shows the cyclic voltammogram of the resulting monolayer-electrode. The ill-defined redox-wave is characteristic of a monolayer of the quinone that is not densely packed. Different orientations and configurations of the quinone components (relative to the electrode) in the flexible configuration of the monolayer result in different electron-transfer rates and the ill-defined electrochemical wave.[16] Treatment of the **2a**-modified monolayer electrode with 1-tetradecanethiol results in the association of the thiol to the pinhole defect sites on the electrode surface.[17] This yields a densely packed monolayer with a rigidified orientation of the quinone units in the monolayer assembly. Figure 1 (curve b) shows the cyclic voltammogram of

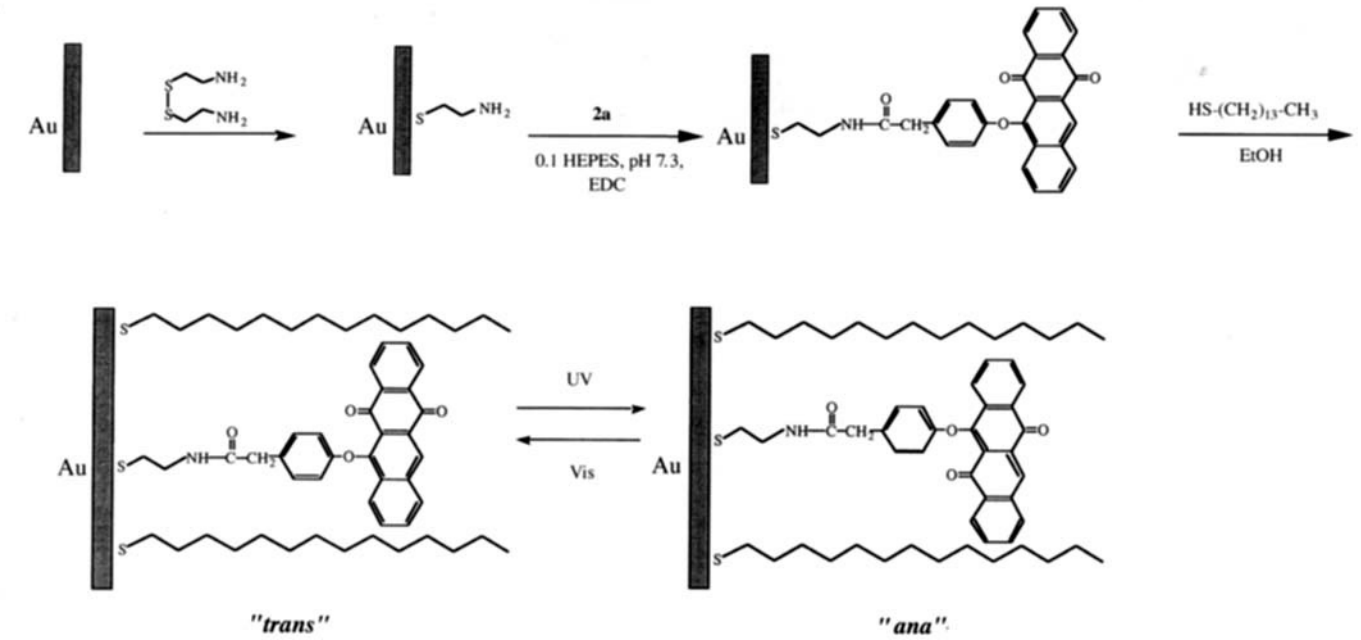

Scheme 1. Assembly of the photoisomerizable quinone **2a** on a gold electrode. EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide; HEPES = *N*-[2-hydroxyethyl]piperazine-*N'*-[2-ethanesulfonic acid].

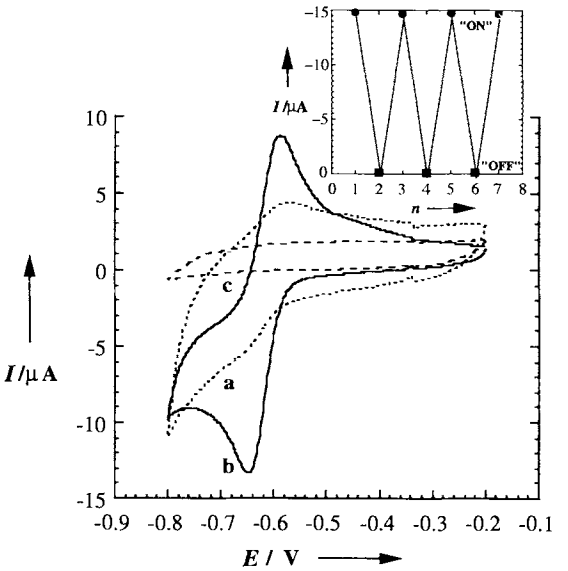

Fig. 1. Cyclic voltammograms of a) **2a**-modified monolayer Au-electrode, b) **2a**-monolayer electrode after treatment of the electrode with an ethanolic solution of $C_{14}H_{29}SH$ (5×10^{-3} M) for 30 min, c) **2b**-monolayer electrode obtained by photoisomerization of the **2a**-monolayer electrode treated with $C_{14}H_{29}SH$ (340 nm $< \lambda <$ 360 nm). All experiments were performed in 0.01 M phosphate buffer and 0.1 M Na_2SO_4, pH 7.0 under Ar, scan rate, 50 mV s^{-1}. Inset: Cyclic amperometric responses at $E = -650$ mV (vs. SCE) of the photoisomerizable monolayer electrode upon reversible optical switching of the monolayer between the *trans*-quinone state **2a** (●), and the *ana*-state **2b**, (■). The transformation of the monolayer-electrodes to the respective isomer states was accomplished by irradiation of the electrode with the appropriate light source for 1 min. n = number of cycles [20].

the **2a**-monolayer electrode after treatment with the long-chain thiol. The quinone is characterized by a well-defined, quasi reversible redox-wave ($E^\circ = -0.62$ V vs. SCE, pH = 7.0). Note that the capacity current of the **2a**-monolayer electrode after treatment with 1-tetradecanethiol is substantially lower than that of the primary **2a**-monolayer electrode, which implies that a densely packed assembly is formed after the treatment of the monolayer with the thiol. Coulometric analysis of the **2a**-monolayer redox wave yields a surface density of the quinone on the electrode surface of 2×10^{-10} mol cm^{-2}. The rate constant for electron transfer from the electrode to the quinone units in the densely packed monolayer configuration was calculated from Laviron's theory[18] to be $k_{et} = 2.5\ s^{-1}$. The *trans*-quinone compound (**1a**) is reduced in a dry dimethylsulfoxide (DMSO) solution at a bare Au electrode with 0.05 M tetrabutylammonium tetrafluoroborate as supporting electrolyte by two successive one-electron reduction processes ($E_1^\circ = -0.91$ and $E_2^\circ \approx -1.46$ V (vs. SCE). In water, **1a** yields an ill-defined redox-wave corresponding to a two-electron reduction process.

Irradiation of the **2a**-monolayer electrode (340 nm $< \lambda <$ 360 nm) in air results in isomerization of the monolayer to the *ana*-state (**2b**). Figure 1, curve (c), shows the cyclic voltammogram of the resulting **2b**-monolayer electrode. The electrode reveals only the background current of the electrolyte. Further illumination of the **2b**-monolayer electrode ($\lambda > 450$ nm) regenerates the **2a**-monolayer electrode, and the voltammetric wave of the *trans*-quinone electroactive monolayer is restored. By cyclic photoisomerization of the monolayer electrode between the *trans*-quinone state **2a** and the *ana*-quinone state **2b**, reversible amperometric transduction of the optical signal recorded by the monolayer-modified electrode is observed (Fig. 1, inset). It should be noted that the absorbance maxima of **2a** in dry dimethylsulfoxide are observed at $\lambda = 245$ and 398 nm, whereas the **2b** shows absorption maxima at $\lambda = 483$, 452, and 248 nm. The photochemical conversion of **2a** to **2b** in a DMSO solution is about 70%. The complete conversion of **2a** to **2b** in the monolayer assembly is attributed to the hydrophobic environment. The photoisomerization of **2a** to **2b** in hydrophobic solutions could not be followed due to limitations in solubility.

The cyclic voltammogram of the **2a**-monolayer electrode is pH-dependent (Fig. 2). As the pH of the electrolyte is increased,

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1536 $ 15.00+.25/0

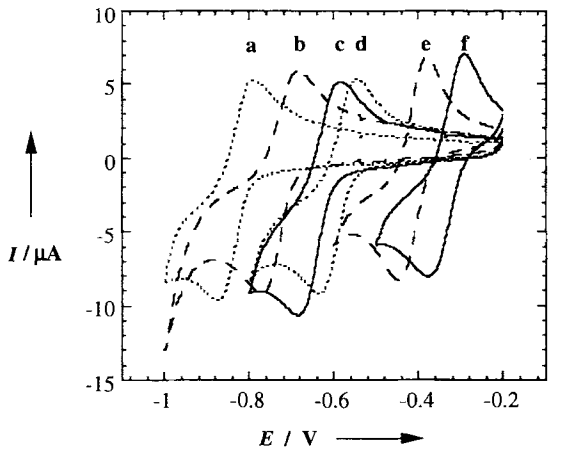

Fig. 2. Cyclic voltammograms of the **2a**-monolayer electrode at different pH values: a) 10.82, b) 8.93, c) 7.27, d) 6.48, e) 3.32, f) 1.93.

a negative shift in the redox potential of the quinone units is observed. The relationship between E° and pH is linear, and the slope of the line is 56 mV per pH unit. This indicates that the reduction of the *trans*-quinone unit involves two electrons and two protons. This pH dependence implies that the quinone units within the monolayer assembly are exposed to the aqueous phase.

We conclude that organization of a photoisomerizable phenoxynaphthacenequinone **2a**-monolayer electrode generates an active surface for optical recording.[19] Photoisomerization of the *ana*-state of the monolayer electrode to the *trans*-state enables the amperometric transduction of the recorded optical signal. Furthermore, reduction of the *trans*-quinone moiety to the hydroquinone form stores the optical signal and reoxidation of the monolayer to the *trans*-quinone state allows the reactivation of the optically recording interface.

[20] The cyclic voltammogram does not coincide with that expected for a surface-confined species, where zero peak-to-peak separation is expected. Also, the cathodic wave does not return to the background level due to the cathodic discharge of the solvent at this potential. For similar observations see also K. Weber, S. E. Creager, *Anal. Chem.*, **1994**, *66*, 3164; L.-H. Guo, J. S. Facci, G. McLendon, *J. Phys. Chem.* **1995**, *99*, 8458.

Pyranosyl-RNA: Base Pairing between Homochiral Oligonucleotide Strands of Opposite Sense of Chirality**

Ramanarayanan Krishnamurthy, Stefan Pitsch, Mark Minton, Christian Miculka, Norbert Windhab, and Albert Eschenmoser*

Pyranosyl-RNA (p-RNA) is the structural isomer of RNA[1, 3–5] in which the ribose units exist in the pyranose form and are linked together repetitively by phosphodiester groups between positions C-2′ and C-4′ (Fig. 1). The properties of this *unnatural* oligonucleotide pairing system are considered to be relevant to the problem of the origin of *natural* RNA.[6] Previous investigations[1, 4, 6] have shown that base pairing in p-RNA is not only *stronger* but also *more selective* than in RNA or DNA. The selectivity refers to the pairing mode. So far, only Watson–Crick (WC) pairing and neither Hoogsteen (H) nor

Noe for generous hospitality to his satellite research group at the Institut für Pharmazeutische Chemie der Universität Frankfurt. Dr. Thomas Carell, ETH-Zürich, translated the German manuscript. Part 2 and Part 17: ref. [1] and ref. [2].

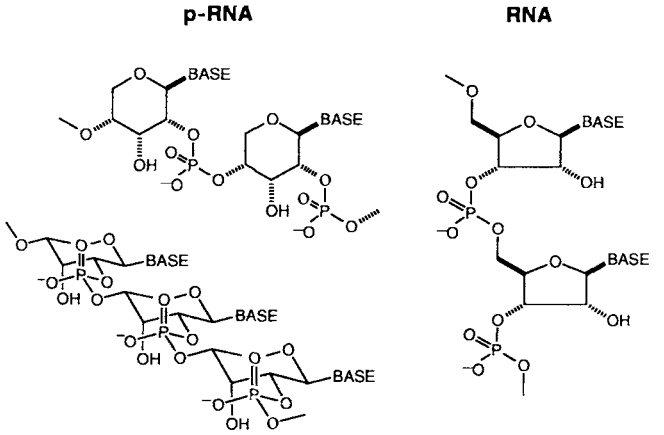

Fig. 1. Constitution of p-RNA and RNA and (idealized) pairing conformation of p-RNA [3, 4].

reverse-Hoogsteen (RH) pairing has been observed. This is in sharp contrast to the behavior of RNA and DNA[7] as well as of synthetic homo-DNA.[11] Probably the most important consequence of the selectivity is the ability of p-RNA to replicate without enzymes.[1] p-RNA oligonucleotides do not suffer from the replication handicap characteristic of RNA-type oligonucleotides caused by the self-deactivation of guanine-rich template strands through guanine self-pairing,[14] as shown by Orgel.[12, 13]

Owing to the constitutional relationship between p-RNA and RNA, the extraordinary pairing properties, and especially the potential of this pairing system for nonenzymatic replication of combinatorial structural information, we are conducting a comprehensive investigation of the chemistry of p-RNA as part of an experimental program directed at a chemical etiology of the structure of the *natural* nucleic acids.[4, 6] In this context the question arises if and how *homochiral* p-RNA strands could be derived from ribopyranosyl mononucleotides, which—from an etiological point of view—would have to be *racemates*. This prompted us to search for the existence of base pairing between homochiral p-RNA strands of opposite sense of chirality.[18]

In p-RNA both purine–pyrimidine and purine–purine WC pairing[21] show high strand enantioselectivity[1] (Fig. 1, see Table 2). WC pairing between *homochiral* oligonucleotides of

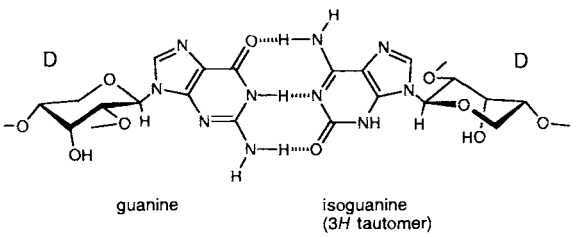

Fig. 2. Constitution of guanine–isoguanine pairing (Watson–Crick mode) [3, 23].

opposite sense of chirality would require either a parallel strand orientation[25] with *anti* conformation of the nucleobases on both sides of a base pair or, in the case of antiparallel strand orientation, *syn* conformation[27] of one of the nucleobases (Table 1). Both types of pairing are "forbidden" in the p-RNA series for reasons analoguous to those put forward to explain the nonoccurrence of H and RH pairing.[1, 4] However, symmetry and model considerations suggest that these restrictions

Table 1. Relationships between pairing mode and strand orientation for homochiral p-RNA strands having the same or the opposite sense of chirality.

Pairing mode	Conformations at the nucleosidic bond	Orientation of homochiral strands with same sense of chirality	opposite sense of chirality
Watson–Crick (WC)	*anti*/*anti* or *syn*/*syn*	antiparallel	parallel
	syn/*anti* or *anti*/*syn*	parallel	antiparallel
Reverse-Watson–Crick (RWC)	*anti*/*anti* or *syn*/*syn*	parallel	antiparallel
	syn/*anti* or *anti*/*syn*	antiparallel	parallel
Hoogsteen (H)	*anti*/*anti* or *syn*/*syn*	parallel	antiparallel
	syn/*anti* or *anti*/*syn*	antiparallel	parallel
Reverse Hoogsten (RH)	*anti*/*anti* or *syn*/*syn*	antiparallel	parallel
	syn/*anti* or *anti*/*syn*	parallel	antiparallel

should vanish with homochiral p-RNA strands of opposite sense chirality, provided that the constitution of the base combinations is such that it corresponds to base pairing in the reverse-Watson–Crick mode (RWC). The topology of the RWC mode allows for a centrosymmetric arrangement of homochiral, but enantiomorphic oligonucleotide backbones and antiparallel strand orientation and *anti* conformation at all nucleosidic bonds. For symmetry reasons such quasi-racemic p-RNA duplexes should have a strictly linear ladder structure, provided that the base pairs, such as purine–purine pairs, are composed of isomorphous bases. Figure 3 features a selection of such quasi-centrosymmetric (tridentate) base combinations in the RWC mode, which are expected to give rise to pairing between homochiral p-RNA strands of opposite sense of chirality.[28] Incidentally, noncanonical base combinations such as isoguanine–cytosine, guanine–isocytosine, and diaminopurine–xan-

[h] $c = 50 + 50$ μM; the values in parentheses refer to cooling curves. [i] $c = 50 + 50$ μM, 1.5 M NaCl; the values in parentheses refer to cooling curves.

Homochiral strands of pr(isoG$_n$) and pr(C$_n$) ($n = 6$ or 8) with the *same* sense of chirality show neither self-pairing nor pairing in 1:1 mixtures above 0 °C under standard conditions,[1] as determined by temperature-dependent UV and CD spectroscopy. In contrast, L-pr(isoG$_n$) and D-(pr(C$_n$) ($n = 6$ or 8) in equimolar mixtures under otherwise identical conditions, *do* form duplexes. For the octamers the duplex was characterized by temperature-dependent UV and CD spectra (Fig. 4a–c) and by its gel electrophoretic behavior under nondenaturing conditions (Fig. 4d). For the hexamers, the 1:1 stoichiometry of the quasi-racemic complex was established by UV spectroscopy by its mixing curve.[31] Homochiral L-pr(G$_8$) and D-pr[(5-methyl-isoC)$_8$] strands were analoguously shown to form a corresponding purine–pyrimidine duplex which, however, is somewhat less stable than the one formed by L-pr(isoG$_8$) and D-pr(C$_8$) (see Table 2).[32]

Homochiral strands of D- and L-pr(isoG$_n$) ($n = 6$ or 8, Fig. 5), while not showing self-pairing at room temperature, react in equimolar mixtures to form quasi-racemic purine–purine complexes which are easily recognized by their conspicuously strong UV hyperchromicity (Fig. 5a and Table 2). The mixing curve determined for the case $n = 8$ (Fig. 5b)[31] demonstrates the formation of a 1:1 complex; the observed deviation from linearity in the correlation between extinction and composition points to an additional aggregation in which the 1:1 complex associates with either itself, or with one of the (enantiomeric) single strands ($c = 15$ μM, 5 °C, otherwise standard conditions). The pairing of enantiomeric isoguanine strands is also demonstrated by gel electrophoresis under nondenaturing conditions (Fig. 4d).

Homochiral strands of D- and L-pr(G$_8$), neither of which shows self-pairing at room temperature,[1] form a quasi-racemic 1:1 complex (Fig. 6a–c) like that of the isoguanosine strands. However, this complex has an unusually low hyperchromicity and its pairing/depairing curves reproduceably show a hysteresis (Fig. 6a and b). In addition, the mixing curve (5 °C) does not indicate further aggregation of the (1:1) complex (Fig. 6c),

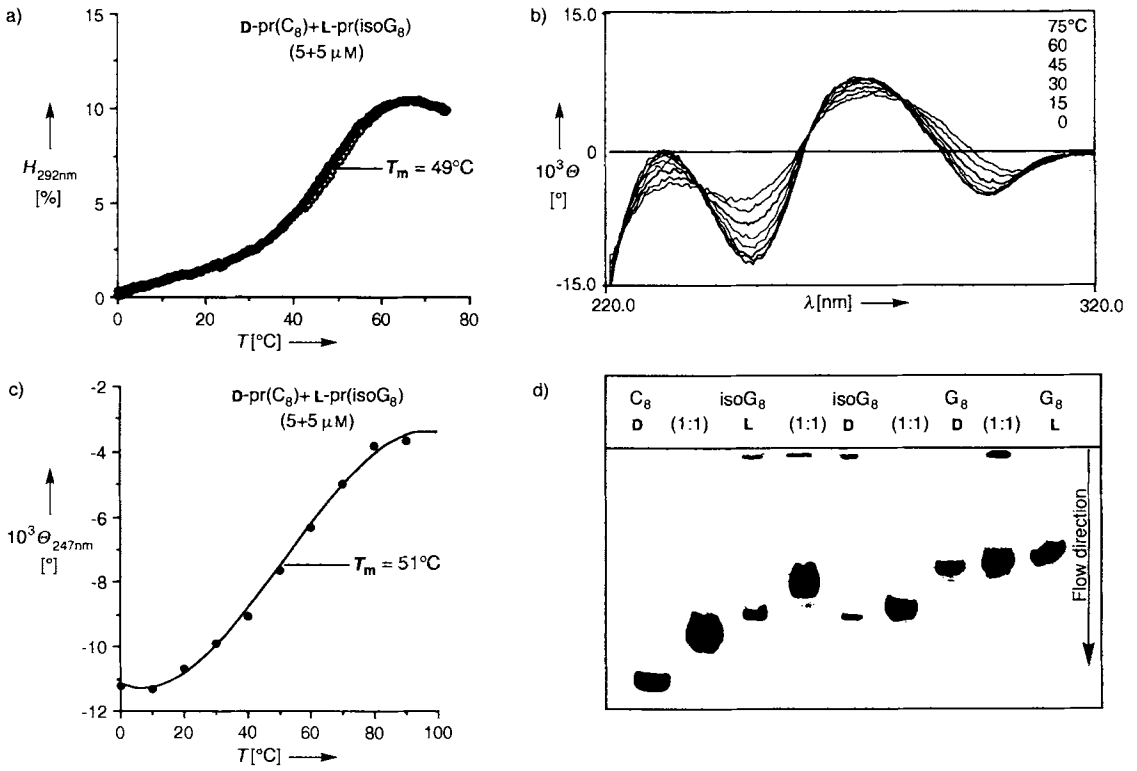

Fig. 4. Pairing between D-pr(C$_8$) and L-pr(isoG$_8$) [30] ($c = 5 + 5$ μM, 0.15 M NaCl, 0.01 M Tris buffer, pH 7). a) UV spectroscopic determination of T_m, $\Delta T = 1$ K min^{-1}, H = hyperchromism; b) temperature dependence of CD spectrum; c) CD spectroscopic determination of T_m; d) gel electrophoresis under nondenaturing conditions (20% acrylamide, 0.09 M Tris·B(OH)$_3$, 0.005 M MgCl$_2$, 6 W, 2 °C, 2.5 h, detection "stains all").

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1539 $ 15.00+.25/0

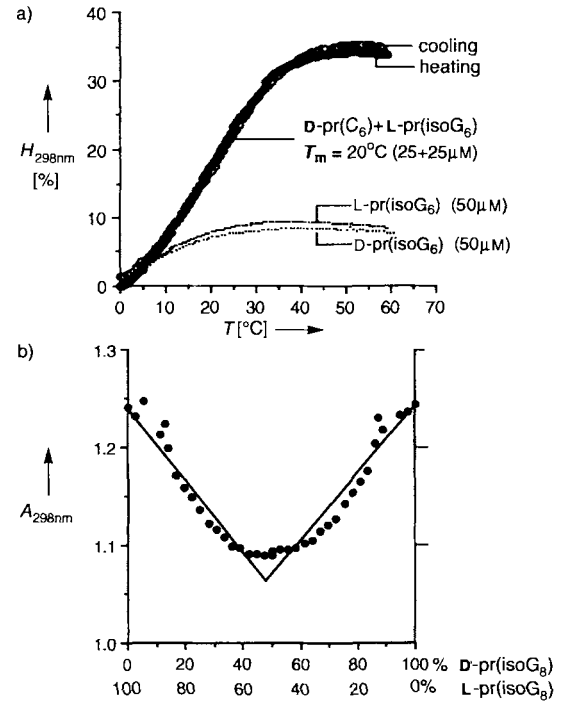

Fig. 5. Pairing between D-pr(isoG$_n$) and L-pr(isoG$_n$) (n = 6 and 8) [30]. a) UV spectroscopic determination of T_m (for conditions see caption of Fig. 4); b) mixing curve [31] of D- + L-pr(isoG$_8$) at 5 °C, c(D + L) = 15 μM (for other conditions see caption of Fig. 4).

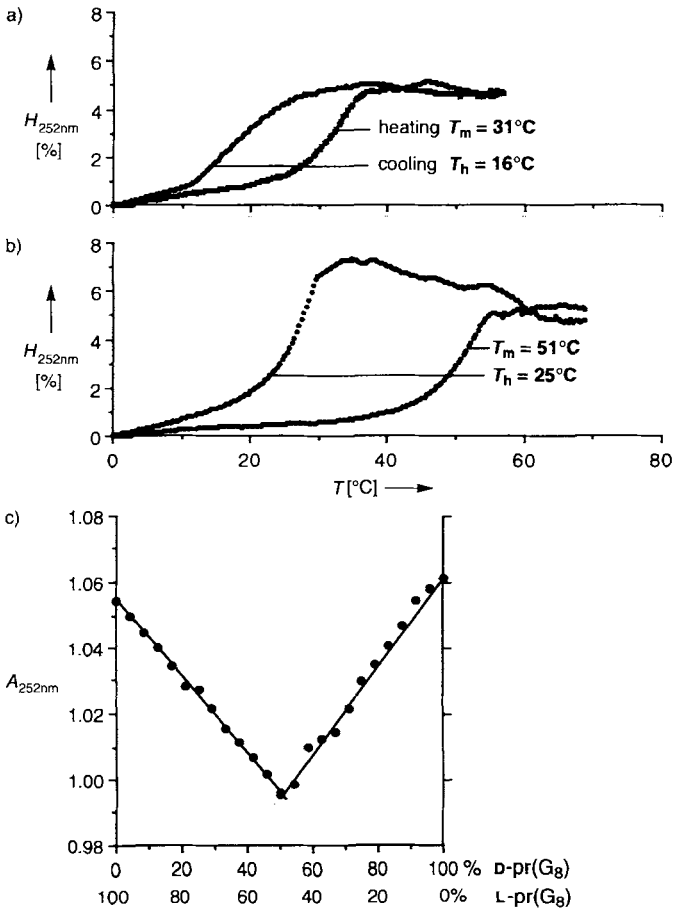

Fig. 6. Pairing between D-pr(G$_8$) and L-pr(G$_8$) [30]. a) UV spectroscopic determination of T_m at normal salt concentration (ΔT = 1 K min^{-1}; b) determination of T_m at high salt concentration; c) mixing curve [31] at 5 °C, c(D + L) = 100 μM (for other conditions see caption of Fig. 4).

in contrast to the isoguanine case. Moreover, the T_m values are more strongly dependent on salt concentration than in the isoguanine series.

Our expectations regarding the pairing of homochiral p-RNA strands of *opposite* sense of chirality (Fig. 3) appear confirmed by observation, at least from a phenomenological point of view: we observe the pairing both of guanine with isocytosine[33] (but not with cytosine), and of isoguanine with cytosine (but not with isocytosine[33]). While neither all-guanosine, nor all-isoguanosine p-RNA strands undergo *isochiral* self-pairing at temperatures above 0 °C,[1] they do feature *heterochiral* pairing. The question must remain open whether the coincidence of expectation and observation is just phenomenological, or whether it also refers to the constitutional assignment of the RWC pairing mode. We think that, at least in the cases of the quasi-racemic purine–pyrimidine duplexes L-pr(isoG$_8$)/D-pr(C$_8$) and L-pr(G$_8$)/D-pr[(5-methyl-isoC)$_8$], the assignment of the RWC pairing mode (Fig. 3 top, middle) is probably correct, simply because we cannot see a *convincing* constitutional alternative.

The proposal of a quasi-centrosymmetric isoguanine–isoguanine pairing in the tridentate RWC mode (Fig. 3 bottom) requires the isoguanine base to engage its 1*H* as well as its 3*H* tautomer in the pairing process. We consider this requirement to be fulfilled, as otherwise no rationale can be offered for the proven occurrence of isochiral guanine–isoguanine pairing in both homo-DNA[22–24] and p-RNA[1] (Table 2) as well as the heterochiral pairing of isoguanine with cytosine in p-RNA (Table 2 and Fig. 3).[34] Nevertheless, the assignment for the D/L isoguanosine pair remains uncertain, since four *didentate* centrosymmetric pairing modes can be considered beside the *tridentate* RWC mode, all formally compatible with the topological constraints of the p-RNA backbone. Of these four, the double-Hoogsteen (DH) mode[35] deserves special attention. It could give rise to a centrosymmetric duplex structure with the potential for further strand aggregation in the RWC mode; this could also be described by saying that the quasi-centrosymmetric RWC duplex has the potential for additional strand aggregation through DH pairing (Fig. 7 top). An alternative aggregation pattern of the RWC duplex is depicted at the bottom of Figure 7.

In contrast to isoguanine there is, to our knowledge, no evidence that tautomers play a role in guanine pairing, as would be required if guanine were to pair with itself in the RWC mode. In fact, the striking differences between the observed properties of the quasi-racemic complexes D/L-pr(G$_8$) and D/L-pr(isoG$_8$) indicate that they quite probably do not have the same pairing mode. Symmetry and model considerations suggest that a quasi-racemic guanine tetrade consisting of alternating D and L strands of pr(G$_8$) in antiparallel orientation (H mode) should be topologically forbidden, for reasons similar to these used to rationalize the strict non-occurrence of H pairing in the isochiral series.[1, 4] On the other hand, duplex formation in the quasi-centrosymmetric RH mode would seem to be topologically allowed; it would require one of the guanines within a (G–G) pair to assume the *syn* conformation at its nucleosidic bond, a requirement that might explain the hysteresis observed for the pairing process. The phenomenon of the quasi-racemic guanine–guanine pairing (and not only this) certainly demands, as well as deserves, further investigation.

The observations described here demonstrate the existence of purine–pyrimidine and purine–purine pairing between homochiral p-RNA strands with opposite sense of chirality. The selection rules for this type of pairing (Table 3) are different from those valid for pairing between homochiral strands of the same sense of chirality (heterochiral versus isochiral pairing).

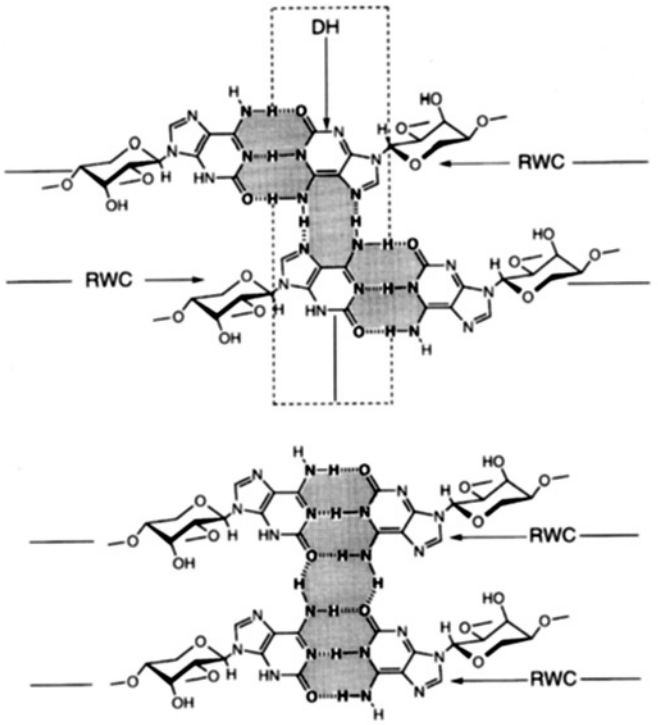

Fig. 7. Hypothetical constitutional models for aggregation of a racemic RWC duplex D-pr(isoG$_8$) + L-pr(isoG$_8$).

Table 3.

Base pairs	Conformations at the nucleosidic bonds [a]	Pairing mode [a]
isoG/isoG	*anti/anti*	RWC and/or DH
G/G	*syn/anti*	RH
isoG/C	*anti/anti*	RWC
G/isoC	*anti/anti*	RWC
Dp/T	*anti/anti*	RWC

[a] Hypothetical.

Observations made so far show that isochiral pairing is uniformly stronger than heterochiral pairing and, in both cases, purine–pyrimidine pairing is stronger than purine–purine pairing. *Of all four variants, the isochiral purine–pyrimidine pairing that dominates pairing in the natural nucleic acids is strongest.* Establishing relationships of this kind would appear to be a prerequisite for the design of conceptual and experimental models of the origin of homochirality in the natural nucleic acids.

[32] A sterically induced propeller twist in the duplex L-pr(G$_8$)/D-pr[(5-methyl-isoC)$_8$] could explain why it is less stable than L-pr(isoG$_8$)/D-pr(C$_8$). This may also explain our (surprising) observation that D-pr(isoG$_8$) and D-pr[(5-methyl-isoC)$_8$] do not form a duplex (in contrast to the DNA series [33]).
[33] We did not use isocytosine itself but its 5-methyl derivative for stability reasons. For the (isochiral) pairing between isoguanine with isocytosine in the DNA series see ref. [36] and: A. Rich in *Horizons in Biochemistry* (Eds.: M. Kasha, B. Pullmann), Academic Press, London, **1962**, pp. 103–126; C. Y. Switzer, S. E. Moroney, S. A. Benner, *Biochemistry* **1993**, *32*, 10489–10496.
[34] According to the literature (J. Sepiol, Z. Kazimierczuk, D. Shugar, *Z. Naturforsch. C* **1976**, *31*, 361–370; R. S. Norton, R. P. Gregson, R. J. Quinn, *J. Chem. Soc. Chem. Commun.* **1980**, 339–341), N-9 substituted isoguanine derivatives in aqueous solution exist in, beside the enol form, mainly the 1*H* lactam form (see also F. Seela, C. Wei, Z. Kazimierczuk, *Helv. Chim. Acta* **1995**, *78*, 1843–1854). The pairing behavior of isoguanine in both the homo-DNA and the p-RNA series suggests that the 1*H* and the 3*H* lactam forms are the predominant tautomers present in aqueous medium (see ref. [23]).
[35] Two of the remaining possibilities (which we consider to be less important) would be didentate variants of the tridentate RWC mode, in which two identical isoguanine tautomers could form a base pair. The third possibility would be centrosymmetric didentate self-pairing of the lactam group of the 3*H* tautomer (sterically hindered).

Chemical Double-Mutant Cycles for the Measurement of Weak Intermolecular Interactions: Edge-to-Face Aromatic Interactions**

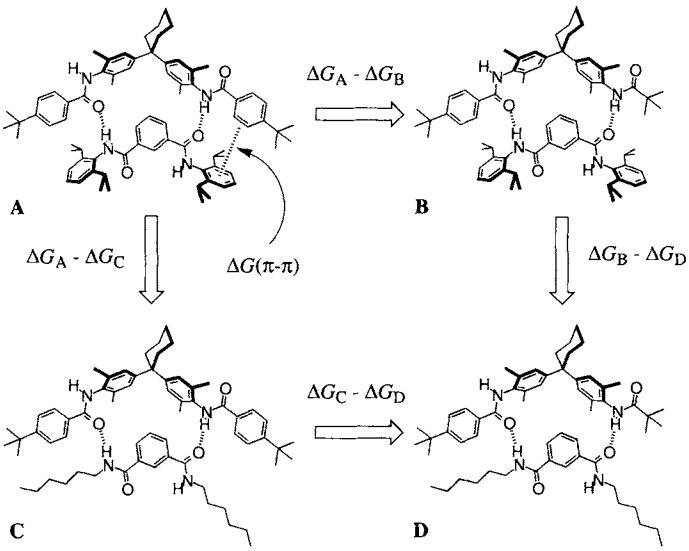
Harry Adams, Fiona J. Carver, Christopher A. Hunter,* Juan Carlos Morales, and Eileen M. Seward

Weak noncovalent interactions are of fundamental importance in determining the three-dimensional structures and functional properties of molecular systems in biology, chemistry, and materials science. If we are to develop the ability to predict and understand the complex behavior of these systems, we will require good models for the forces that control them. One interaction of particular importance is that between two aromatic rings ($\pi-\pi$ interaction).[1-4]

Qualitative models that account for the properties of $\pi-\pi$ interactions have been developed based on simple electrostatic arguments. However, good quantitative computational models for weak interactions of this type require good quantitative experimental data against which the models can be tested.[5, 6]

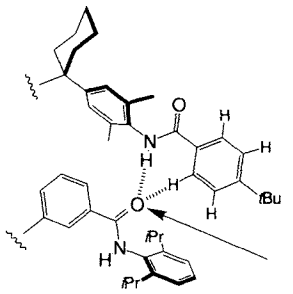
The quantitative determination of the energies of weak noncovalent interactions is fraught with difficulties. Direct measurement at room temperature in solution is not possible because the interactions are not strong enough to cause intermolecular complexation in a well-defined orientation. They can therefore only be measured as a perturbation of a stronger interaction. However, any changes to a system that affect one interaction are likely to affect other neighboring interactions. A solution to this problem, which has been used to measure interactions between side chains in proteins, is to apply thermodynamic cycles in combination with structure variation (mutagenesis).[7] In this communication we describe the application of the double-mutant cycle concept to a synthetic supramolecular system for the measurement of an intermolecular edge-to-face aromatic interaction.

We recently described a molecular zipper, a 1:1 complex of two amide oligomers held together by hydrogen bonds and edge-to-face $\pi-\pi$ interactions.[8] This structure is ideally suited to the measurement of noncovalent interactions using the double-mutant approach.[9] Since the molecules are essentially rigid, the experiments are not complicated by losses of conformational mobility on complexation.[10] This rigidity also ensures that the $\pi-\pi$ interactions in complex **A** are fixed in edge-to-face orientations by the covalent structures of the molecules and the hydrogen bonds (Scheme 1). The linear array of interaction sites means that chemical mutations at the terminal functional groups can be used to probe the interactions on the ends of the complex without perturbing the structure of the core.



Scheme 1. Chemical double-mutant cycle for measuring the terminal $\pi-\pi$ interaction in complex **A**.

The magnitude of the terminal $\pi-\pi$ interaction in complex **A** could be estimated by removing one of the interacting aryl groups, as in complexes **B** and **C**. However, these single chemical mutations not only remove the interaction of interest, they also remove other secondary interactions, for example those between the amides and the terminal aromatic rings (Scheme 2). The change in the secondary interactions can, however, be quantified by using the double mutant, complex **D**. Comparing complexes **C** and **D** allows us to quantify the change in the secondary interactions that occurs when the **A** → **B** mutation is made. Thus the difference between the two horizontal mutations in Scheme 1, $(\Delta G_A-\Delta G_B)-(\Delta G_C-\Delta G_D)$, gives the magnitude of the terminal $\pi-\pi$ interaction in the absence of secondary effects.[11, 12] Comparing the vertical mutations in Scheme 1 yields the same result [Eq. (a)].



Scheme 2. A possible secondary interaction (marked with an arrow) between the terminal aromatic group and the amide core of complex **A**. A C–H···O hydrogen bond is shown, but other secondary interactions are also possible.

$$\Delta G(\pi-\pi) = \Delta G_A - \Delta G_B - \Delta G_C + \Delta G_D \quad \text{(a)}$$

Compounds **1**–**5** were synthesized in high yield by means of simple amide coupling reactions.[13] The structure of complex **A** in chloroform was determined by ^{1}H NMR spectroscopy. Job's method of continuous variations gave results consistent with a 1:1 stoichiometry.[14] A ROESY experiment on a 1:1 mixture of

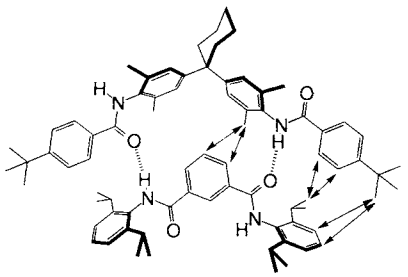
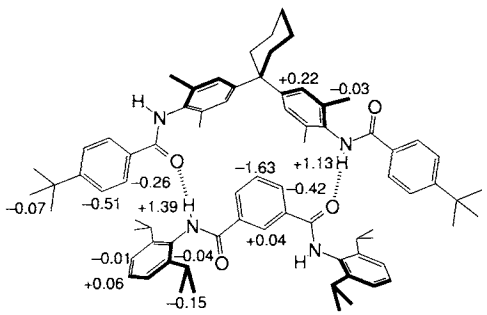


Scheme 3. Intermolecular NOEs observed for a 1:1 mixture of **1** and **4** in a ROESY experiment.

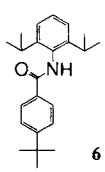
1 and **4** gave the intermolecular NOEs illustrated in Scheme 3, which show that the isophthaloyl group of **4** binds into the aromatic pocket of **1** and that the terminal benzoyl and aniline groups are in close contact. Dilution experiments show that none of the compounds dimerize significantly in chloroform ($K < 1\ \text{M}^{-1}$), and so titrations were analyzed using a simple 1:1 binding isotherm. Titrations were performed using both **1** and **4** as the fixed concentration host, so that accurate limiting complexation-induced changes in chemical shift could be obtained for both components of the complex (Scheme 4). These changes in shift confirm



Scheme 4. Limiting complexation-induced changes in ^{1}H NMR chemical shifts for complex **A** in chloroform.

that the $\pi-\pi$ interactions are edge-to-face in the complex: the benzoyl and isophthaloyl protons (with the exception of that at C2) experience large upfield ring current induced shifts, because they lie over the faces of neighboring aromatic rings; the other aromatic protons experience small or downfield shifts, indicating that they sit at the edges of neighboring aromatic rings. The signal due to the isopropyl methyl groups of **4** experiences an upfield shift, because these groups project over the faces of the benzoyl rings of **1**. The large downfield shifts observed for the signals due to the amide NH protons are evidence for the hydrogen-bonding interactions.

Although we have not crystallized the complex formed by **1** and **4**, we have obtained an X-ray crystal structure of the related model compound **6**, which provides strong supporting evidence for the structure of complex **A**.[15] A dimer of **6** is effectively half of complex **A**, and the hydrogen bonds and edge-to-face $\pi-\pi$ interactions proposed for complex **A** are clearly present in the crystal structure of **6**. There are two different edge-to-face $\pi-\pi$ interactions in the structure, and in both, the benzoyl and aniline aromatic rings are in van der Waals contact, oriented at 86° to one another. The distances between the ring centers are 5.02 and 4.94 Å, and the shortest carbon–carbon distances are 3.79 Å in each case.[16]



6

Titrations were carried out for the other combinations of compounds **1**–**4** (Table 1). The complexation-induced changes in chemical shift were similar to those observed for complex **A** (Scheme 4), which shows that all four complexes **A**–**D** have

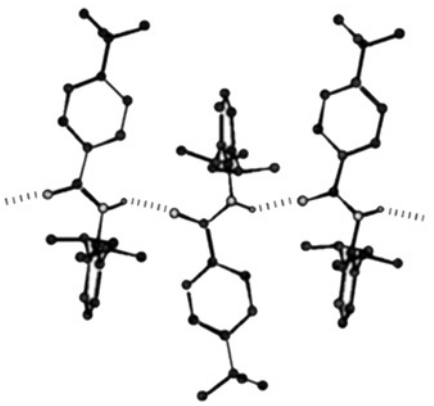


Fig. 1. X-ray crystal structure of **6**. The N–O distances in the hydrogen-bonded amides are 2.83 Å.

essentially the same structure in solution; in other words, the chemical mutations do not perturb the structure of the core of the complex. Table 1 shows the association constants derived from fitting the experimental data to a 1:1 binding isotherm.

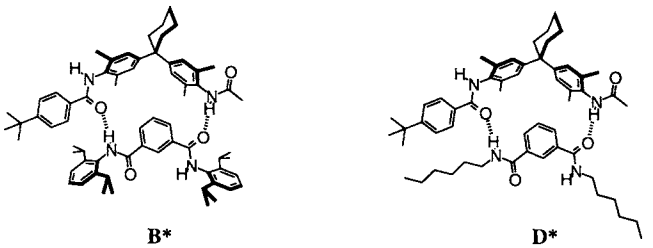
Table 1. Association constants K_a in chloroform at 298 K [a].

Complex	Composition	K_a [M^{-1}]	ΔG [kJ mol^{-1}]
A	**1** + **4**	48 ± 2	− 9.6 ± 0.1
B	**2** + **4**	17 ± 2	− 7.1 ± 0.3
C	**1** + **5**	15 ± 3	− 6.8 ± 0.5
D	**2** + **5**	10 ± 2	− 5.7 ± 0.5
B*	**3** + **4**	14 ± 2	− 6.6 ± 0.4
D*	**3** + **5**	8 ± 2	− 5.2 ± 0.5

[a] Average values from at least three experiments. Titration data for four to six different signals were used to determine the association constant in each experiment. Errors are quoted as twice the standard error from the weighted mean (weighting based on the observed change in chemical shift).

Complexes **B**–**D**, which do not contain the terminal $\pi-\pi$ interaction, are clearly less stable than complex **A**. This indicates that this interaction is attractive and makes a significant contribution to the binding energy in chloroform. The results also show that secondary interactions operate in these systems: complex **D**, which does not have these secondary interactions, is less stable than all of the other complexes. Thus the double-mutant cycle is required for accurate quantitation of the edge-to-face $\pi-\pi$ interaction, which according to Equation (a) is -1.4 ± 0.8 kJ mol^{-1}.[17] Chloroform is a competitive solvent for this kind of nonpolar interaction, so the van der Waals and solvophobic contributions to binding are likely to be small, and the interaction measured is probably electrostatic in origin.

Wilcox et al. used a molecular torsion balance to measure an intramolecular edge-to-face $\pi-\pi$ interaction in chloroform, and their estimate (1.0 kJ mol^{-1}) is comparable to ours.[18] However, they also showed that a *tert*-butyl group interacts even more strongly with the face of a π system than an aromatic ring does. This is clearly inconsistent with our results: complex **B** is significantly less stable than complex **A**. To measure the effect of the *tert*-butyl group on our results, we constructed another double-mutant cycle using the methyl mutant **3** in place of the *tert*-butyl mutant **2**, specifically, using complexes **B*** and **D*** in place of complexes **B** and **D** (Scheme 5, Table 1). With this cycle the $\pi-\pi$ interaction is determined to be -1.4 ± 0.8 kJ mol^{-1}. This result is identical to that obtained with the first cycle, and we can detect no significant *tert*-butyl–π interaction in these complexes.



B* D*

Scheme 5. Complexes **B*** and **D***, which use the methyl mutant **3** in place of the *tert*-butyl mutant **2**.

This is consistent with an interaction that is electrostatic in origin, since aromatic protons have a larger net positive charge than alkyl protons.[2] The difference between the torsion balance and the zipper may be due to subtle differences in geometry or solvation.

The double-mutant approach is a powerful method for quantifying weak interaction energies, and the molecular zippers have an ideal structure for exploiting this potential. In principle, the method can be applied to investigate any noncovalent interaction, provided the two interacting functional groups can be attached to the ends of the zippers in an appropriate orientation. The results described here show that very weak interactions can be measured by this method: the edge-to-face $\pi-\pi$ interaction in this system is -1.4 ± 0.8 kJ mol^{-1}. This is not a universal value for edge-to-face $\pi-\pi$ interactions; it is accurate for the particular system we have used and provides an estimate of the likely magnitude of such interactions in other systems. The perceived noncovalent interaction in any system will be affected by secondary interactions and sensitive to solvent and the relative orientation and substitution pattern of the two aromatic rings.

[11] One limitation of the approach is that for intermolecular complexes, the entropy of complexation partially compensates the enthalpy of complexation, and the extent to which this occurs may differ in each of the four complexes. It is not clear how significant this effect is in practice, but the implications for our experiments are that the value for the $\pi-\pi$ interaction determined using Equation (a) is a lower limit for the maximum possible interaction that would occur in a system in which all intermolecular modes have been eliminated. [17] The error takes no account of systematic errors inherent in measurements on such weakly binding complexes. Different titration procedures give small but significant changes in the measured association constants, but systematic errors of this type are reduced in a thermodynamic cycle provided all four experiments in the cycle are carried out under identical conditions.

μ_3-Imido-Functionalized Chevrel–Sergent-Type Molecular Clusters, a New Class of Inorganic–Organic Hybrid Compounds: Preparations and Alkylation Reactions

Santiago Uriel, Kamal Boubekeur, Patrick Batail,* and Jesús Orduna

In 1995 we reported on the synthesis of chalcogen-enriched, μ_3-heteroatom-substituted hexanuclear chalcohalide cluster dianions $(n\mathrm{Bu_4N})_2[\mathrm{Re_6Q^i_5(\mu_3\text{-}E)Cl^i_2(Cl^a_6)}]$ (Q = S, Se; E = O, S, Se, Te; *i* stands for an inner ligand capping a face of the Re_6 octahedron and *a* for an apical, terminal ligand linked to a single rhenium atom) by reaction of the cluster monoanions $(n\mathrm{Bu_4N})[\mathrm{Re_6Q^i_5Cl^i_3(Cl^a_6)}]$ with silylated reagents $(\mathrm{Me_3Si})_2\mathrm{E}$ at room temperature.[1] We now report efficient reactions in which one face-capping μ_3-chloro core ligand (Cl^i) is displaced by amino substituents upon treatment of the generic cluster monoanions with bis(trimethylsilyl)amine derivatives. Furthermore, and most importantly, it is demonstrated that the μ_3-imido-functionalized cluster cores $[\mathrm{Re_6Q_5(\mu_3\text{-}NR)Cl_2}]^{4+}$, which

are isostructural and isoelectronic with the Chevrel–Sergent cluster cores $[Mo_6Q_8]^{4-}$,[2a,b] react with electrophiles—an important and long-cherished goal in this chemistry.[2c–2h]

The reaction of $(n\mathrm{Bu_4N})[Re_6Q_5Cl_9]$ (Q = S, Se) with $(Me_3Si)_2NR$, (R = Me, CH_2Ph), followed by addition of an excess of $n\mathrm{Bu_4NCl}$ affords **1**–**4** in good yields (Scheme 1). As demonstrated earlier in the halide/chalcogenide substitution–functionalization chemistry,[1,3] the driving force of the present substitution reactions, in addition to the formation of Me_3SiCl, is the formation of the cluster dianions, the thermodynamically most stable cluster forms. Thus, besides convincing elemental analysis data, negative liquid secondary ion mass spectrometry[4] (LSIMS data see Table 1) proved extremely valuable in determining the composition, and hence the charge of the new compounds. All fragmentations characteristic of the dianionic clusters in $(n\mathrm{Bu_4N})_2[Re_6Q_5ECl_8]$ (E = O, S, Se, Te)[1] are observed for **1**–**4**. However, several additional peaks are identified, properly assigned, and found to be specific for the amine substituent (R-specific fragmentations, Table 1). Thus, **1**–**4** generate the gas-phase anions, $[Re_6Q_5Cl_6]^-$, $[Re_6Q_5Cl_5]^-$, and $[Re_6Q_5Cl_4]^-$ (Table 1), as a result of the loss of their N-methyl or N-benzyl ligands. Collision-induced dissociation (CID) experiments unambigously demonstrate the formation of these species by gas-phase reactions rather than matrix processes. The precursor-ion spectra of $[Re_6Q_5Cl_6]^-$ ions (m/z = 1489.4 for Q = S; m/z = 1725.1 for Q = Se) show that these species are generated from $[Re_6Q_5(\mu_3\text{-NR})Cl_8]^-$ ions. Likewise, the daughter-ion spectra of $[Re_6Q_5(\mu_3\text{-NR})Cl_8]^-$ ions issued from compounds **1**–**4**, and illustrated in Figure 1 for **3**, indicate the loss of N–R, albeit associated with the concomitant loss of either one or two chlorine atoms.

These results are substantiated further by the X-ray structure determination[5] for **1** (Fig. 2). It should be noted that within the

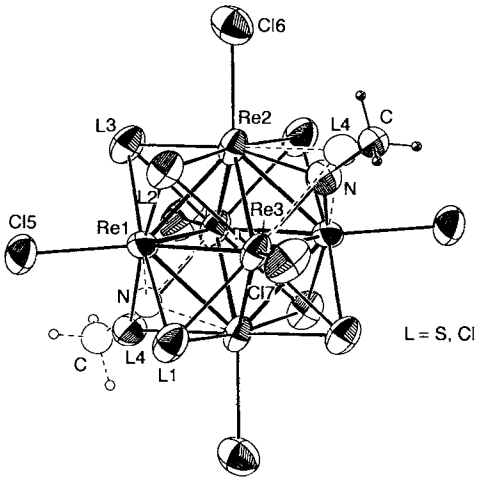

Fig. 2. Crystal structure of the $[Re_6S_5(\mu_3\text{-NMe})Cl_8]^{2-}$ dianion in **1**, showing 50% probability ellipsoids and the atom labeling scheme.

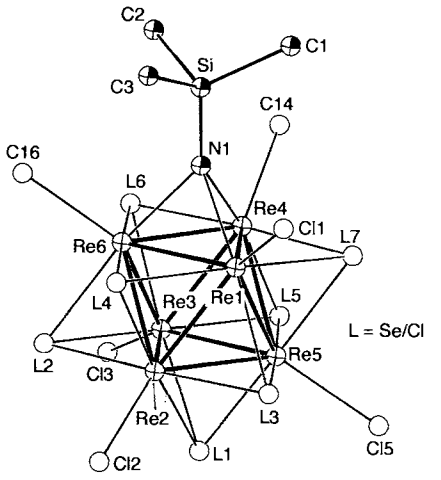

Fig. 3. Representation of the solid-state structure of the $[Re_6SeS_5(\mu_3\text{-}NSiMe_3)Cl_8]^{2-}$ dianion in **6**.

crystal lattice the μ_3-NMe group is found disordered onto two opposite faces of the Re_6 octahedron. There is no apparent distortion of the latter upon coordination by the imido group. On the other hand, the disordered, mixed μ_3-sulfido and μ_3-chloro ligands L4 (Fig. 2) appear to be further away from their Re_3 faces than the other mixed sulfido and chloro ligands L1, L2, and L3. The elevation of the ligands L1–L3 from their respective cluster face is, in fact, comparable to that observed in the structure of $(nBu_4N)_2[Re_6S_6Cl_8]$.[3b] Conversely, the disordered μ^3-N atoms lie closer to their corresponding Re_3 face (av Re–N 2.013(45) Å) than the μ_3-oxygen atom does in the structures of $(nBu_4N)_2[Re_6S_5OCl_8]$[1] (av Re–O 2.087(6) Å) and $(Pr_4N)_2[Re_6Se_4O_2Cl_8]$[3a] (av Re–O 2.083(14) Å and 2.094(19) Å, for the α and β isomers, respectively). However in $(nBu_4N)_2[Re_6S_5OCl_8]$, the Re_3 face capped by an oxygen atom is contracted, while the opposite, sulfur-capped face is expanded. This suggests that the seemingly nondistorted cluster core in **1** in fact corresponds to an average of two distorted opposite cluster faces capped by either a μ_3-N or a μ_3-S atom, that is a contracted and an expanded one, amounting to no apparent net effect. The average Re–Cl^a distance, specific for the charge of the cluster motif, is 2.374(5) Å, as expected for a cluster dianion.[1, 3b]

The trimethylsilylamine-derivatized compounds **5** and **6** were obtained from reactions of $(nBu_4N)[Re_6Q_5Cl_9]$ with $(Me_3Si)_2NH$ (Scheme 1), and were fully characterized by elemental analysis, LSIMS (Table 1), and X-ray diffraction (only for **6**).[6] The structure of the anion of **6** is shown in Figure 3. Remarkably, and in contrast to **1**–**4**, the cluster ions of **5** and **6** do not lose their silylamino ligands under LSIMS conditions. In this case the most characteristic fragmentation is the loss of one methyl radical to give a series of peaks (Table 1) at 15 mass units below those corresponding to successive losses of chlorine atoms. The loss of one methyl group is confirmed by CID experiments.

The trimethylsilyl groups may be removed readily by using fluoride anions as nucleophile.[7] Thus, reaction of **5** and **6** with nBu_4NF affords the long-sought after compounds **7** and **8**, respectively, in high yields. Again the compounds were characterized by elemental analysis and LSIMS (Table 1). Compounds **7** and **8**, as well as **3** and **4** are extremely soluble in organic solvents; thus, good quality single crystals suitable for X-ray diffraction have not yet been obtained.

Finally, we have also been able to demonstrate that the μ_3-NH-functionalized cluster cores readily react with electrophiles. Thus, for example, **5** and **6** react with benzyl chloride and catalytic amounts of triethylamine to give **3** and **4**, respectively. As mentioned earlier **3** and **4** were also obtained independently by the direct substitution–functionalization reactions.

Thus, opportunities are now offered to extend the chemistry of inorganic–organic hybrid compounds. The molecular cores of these compouds are prepared by high-temperature solid-state synthesis only and are subsequently converted to new compounds at room temperature with modern inorganic reactions—in this case, by reactions of imido ligands with electrophiles.

Experimental Procedure

A suspension of $(nBu_4N)[Re_6Q_5Cl_9]$ (Q = S, Se) (100 mg, ca. 50 μmol) [3b] in dry CH_3CN (50 mL) under an argon atmosphere was treated with an excess (ca. 20-fold) of either $(Me_3Si)_2NMe$, $(Me_3Si)_2NCH_2Ph$, or $(Me_3Si)_2NH$. The mixture was stirred at room temperature until complete dissolution of the starting material (5–8 h). An excess of solid $(nBu_4N)Cl$ was then added and the solution was stirred for two hours. The solution was evaporated to dryness in vacuo, the orange residue washed with ethanol and recrystallized from acetonitrile (ca. 15 mL).

1: Yield 68 mg, 60%. Elemental analysis for $C_{33}H_{75}N_3Re_6S_5Cl_8$ (M = 2075.1): Calcd. C 19.1, H 3.64, N 2.02, S 7.72, Cl 13.67; found C 18.75, H 3.32, N 2.26, S 7.83, Cl 13.34.

2: Yield 76 mg, 69%. Elemental analysis for $C_{33}H_{75}N_3Re_6Se_5Cl_8$ (M = 2309.6): Calcd. C 17.16, H 3.27, N 1.82, Cl 12.28; found C 17.01, H 3.05, N 1.96, Cl 12.52.

3: Yield 71 mg, 61%. Elemental analysis for $C_{39}H_{79}N_3Re_6S_5Cl_8$ (M = 2151.2): Calcd. C 21.77, H 3.70, N 1.95, S 7.45, Cl 13.18; found C 22.1, H 3.31, N 2.07, S 7.22, Cl 12.97.

4: Yield 77 mg, 67%. Elemental analysis for $C_{39}H_{79}N_3Re_6Se_5Cl_8$ (M = 2385.7): Calcd. C 19.63, H 3.34, N 1.76, Cl 11.89; found C 20.01, H 3.15, N 1.96, Cl 11.62.

5: Yield 67 mg, 58%. Elemental analysis for $C_{35}H_{81}N_3Re_6S_5Cl_8Si$ (M = 2133.3): Calcd. C 19.71, H 3.83, N 1.97, S 7.51, Cl 13.30; found C 19.35, H 3.47, N 2.04, S 7.69, Cl 13.53.

6: Yield 62 mg, 55%. Elemental analysis for $C_{35}H_{81}N_3Re_6Se_5Cl_8Si$ (M = 2367.8): Calcd. C 17.75, H 3.45, N 1.77, Cl 11.98; found C 17.81, H 3.34, N 1.71, Cl 12.01.

Nucleophilic substitution reactions of the trimethylsilylamine-derivatized cluster cores: A solution of **5** or **6** (100 mg, ca. 50 μmol) in CH_3CN (50 mL) was treated with an excess (ca. 10-fold) of nBu_4NF supported on silica gel 1%. The reaction mixture was stirred for 6 h at room temperature, filtered off, and evaporated to dryness in vacuo. The residue (**7** or **8**, respectively) was washed with ethanol and recrystallized from acetonitrile.

7: Yield 84 mg, 87%. Elemental analysis for $C_{32}H_{73}N_3Re_6S_5Cl_8$ (M = 2061.1): Calcd. C 18.65, H 3.57, N 2.04, S 7.78, Cl 13.76; found C 18.82, H 3.49, N 2.31, S 7.47, Cl 13.42.

8: Yield 86 mg, 89%. Elemental analysis for $C_{32}H_{73}N_3Re_6Se_5Cl_8$ (M = 2295.6): Calcd. C 16.74, H 3.21, N 1.83, Cl 12.36; found C 17.03, H 3.76, N 2.05, Cl 12.48.

Alkylation reactions: A solution of **5** or **6** (50 mg) in CH_2Cl_2 (30 mL) was treated first with nBu_4NF, then with an excess of benzyl chloride and catalytic amounts of

triethylamine. The reaction mixture was stirred for 18 h and evaporated to dryness in vacuo. The residue was washed with ethanol, dissolved in a 1/1 ethanol/acetonitrile solution and treated with an excess of nBu$_4$NCl in order to ensure complete exchange of any other possible ammonium cations such as Ph(Me)$_3$N$^+$. The solution was evaporated to dryness in vacuo, washed with ethanol and recrystallized from acetonitrile. The LSI mass spectra of the resulting products were identical to those of **3** and **4**.

[4] The LSI mass spectra were recorded as described previously [1]. Helium was used as the collision gas in CID experiments [8] and the pressure was adjusted to reduce the main beam intensity to 50% of its original value. The spectra were recorded by linked scans [9] at constant B/E and B^2/E for daughter-ion and precursor-ion spectra, respectively.

[5] X-ray crystal structure analysis for **1**: $C_{33}H_{75}N_3S_5Cl_8Re_6$, $M_r = 2075.13$, orange crystals, monoclinic, space group $P2_1/n$, $a = 12.895(3)$, $b = 11.468(5)$, $c = 18.365(4)$ Å, $\beta = 90.87(2)°$, $V = 2715.5(1.5)$ Å^3, $Z = 2$, $\rho_{calcd} = 2.54$ g cm^{-3}, $Mo_{K\alpha}$ radiation, empirical absorption corrections ($\mu = 141.2$ cm^{-1}), 5943 independent reflections with ω-2θ scans were measured up to $\theta = 27°$ at 230 K on an Enraf–Nonius CAD4 diffractometer. The structure was solved by the Patterson method. The full matrix least-squares refinements of 266 parameters for 3056 reflections with $I \geq 3\sigma(I)$ converged at $R = 0.036$ and $R_w = 0.045$ (GOF = 1.297). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-51. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[6] Preliminary crystallographic data for **6**: $C_{35}H_{81}N_3SiCl_8Se_5Re_6$, $M_r = 2365.78$, orange platelike crystals, monoclinic, space group $P2_1/c$, $a = 24.948(1)$, $b = 11.7636(6)$, $c = 22.279(1)$ Å, $\beta = 111.287(1)°$, $V = 6092(1)$ Å^3, $Z = 4$, $\rho_{calcd} = 2.58$ g cm^{-3}; 20696 reflections were measured with $Mo_{K\alpha}$ radiation up to $\theta = 27°$ at 295 K on a Siemens CCD-area detector based SMART X-ray diffractometer. The structure was solved by direct methods. Experiments to determine the precise structure and its triclinic low-temperature modification, are currently in progress and will be published separately.

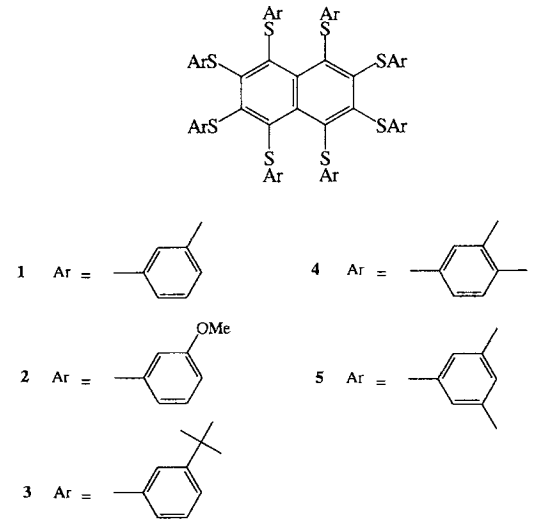
Octakis(3,4-dimethylphenylthio)naphthalene: A Designed Spider Host of Unparalled Versatility**

Gary A. Downing, Christopher S. Frampton, James H. Gall, and David D. MacNicol*

The exactly D_2-symmetric conformation of the spider host[1] octakis(*m*-tolylthio)naphthalene **1** is instrumental in maintaining an open tetragonal host lattice, which, remarkably, is stable even in the absence of a guest.[2] This key conformation is of the *aabbaabb* type[2] where *a* and *b* denote side chains projecting above and below the mean plane of the naphthalene core, respectively. Based on a knowledge of the crystal structure of **1**, we have sought to reproduce this key conformation by judicious modification, with a view to producing related clathrates with larger cavities suitable for versatile storage of guests[3] and lattice-controlled reactivity studies.[4] Salient results from this line of enquiry are now reported.

Initial studies involved replacement of the *meta*-methyl group in the side chains of **1** by the polar methoxy function[5] or the bulky *tert*-butyl group,[6] as in **2** and **3**; however, these changes



were found to attenuate severely inclusion ability, highlighting the importance of the specific nature of the *meta* substituent in controlling host packing. In view of this, the *meta*-methyl group was retained, and octakis(3,4-dimethylphenylthio)naphthalene **4** and octakis(3,5-dimethylphenylthio)naphthalene **5**, both possessing an additional methyl group in their side chains, were targeted and prepared. Compounds **4** and **5** were found to be at the opposite ends of the inclusion ability spectrum, a direct reflection of their molecular conformations, as described below.

The introduction of a second *meta*-methyl substituent, as in **5**, is incompatible with a D_2 conformation analogous to that of **1**

owing to severe *trans*-ring interactions arising from the second methyl group. This leads to the formation of a highly asymmetric *abbaabab* conformation, previously uncategorized,[2] in which two of the *peri*-related side chains have a *syn*-arrangement.[7] Compound **5** has shown no evidence of inclusion compound formation. By contrast, the sterically undemanding introduction of a *para*-methyl substituent as in **4** leaves the parent D_2 host conformation of **1** essentially unperturbed (see below), and the new compound **4** possesses truly versatile inclusion properties.

The first indication of the remarkable inclusion behavior of **4** became apparent during its isolation in the course of which ruby-red cubes containing components of the solvent (40–60° petroleum ether) were obtained on evaporation of chromatographic fractions overnight. Host **4** rapidly revealed an impressive ability to include guest species and these ranged in size from thiophosgene to squalene (Table 1). Moreover, guest classes

ranged through hydrocarbons, ethers, alcohols, ketones, amines, amides, and halocarbons, for example. Particularly significant, however, is the propensity of **4** to enclathrate volatile, reactive and toxic materials, such as THF, CCl_4, thiophosgene, tri-*n*-butylphosphane, hexamethylphosphoramide (HMPA), and tetraethyllead. In order to elucidate the origin of the novel properties displayed by **4**, which indicated unusual host packing and void geometry, single-crystal X-ray analyses of the 1,4-dioxane, *t*BuOH, $PbEt_4$, and $(CH_3)_3SiC{\equiv}CSi(CH_3)_3$ adducts were carried out.[8] The adducts of **4** crystallize in the cubic space group $Pn\bar{3}$, a transformation from the tetragonal packing of **1**, which is unique for any pure organic molecular system, as established by reference to the Cambridge Crystallographic Data Base.[9]

The host molecule of **4**, located on a point of 222 symmetry, is constrained to have exact D_2 symmetry, and both enantiomeric conformations are present in the crystal. Figure 1 shows the atomic numbering scheme of the asymmetric unit, and Figure 2 the $PbEt_4$ adduct with a view along one of the twofold rotation axes. The close correspondence of this *aabbaabb* conformation[2] to that of **1** (1,4-dioxane adduct) is indicated by comparison of the related torsion angles [°] (values for **1** in parentheses): C1-C9-C9′-C1′ − 27 (− 27), C9-C1-S1-C11 + 45 (+ 42), C-1-S1-C11-C12 + 49 (+ 50), C1-C2-S2-C22 + 94 (+ 94), and C2-S2-C21-C22 + 11 (+ 11).[9b] There are two large, enantiomerically related, cavities per unit cell; these voids are chiral with symmetry 23(T), and each void is capable of including one bulky guest such as tetraethyllead or up to six[10] medium-sized guests, for example, 1,4-dioxane or 1,4-thioxane.

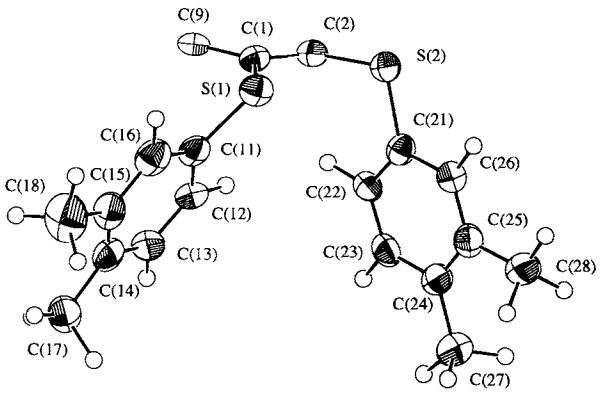

Fig. 1. View of the asymmetric unit in crystals of **4** showing atom numbering scheme. The thermal ellipsoids are drawn at the 50% probability level; hydrogen atoms are drawn as small circles of arbitary radius. Selected bond lengths [Å] and angles [°]: C(1)–C(2) 1.377(8), C(2)–C(2′) 1.42(1), C(1)–C(9) 1.444(7), C(9)–C(9′) 1.44(2); C(2)-C(1)-C(9) 120.4(6), C(1)-C(2)-C(2′) 120.2(4), C(1)-C(9)-C(9′) 116.8(4), C(1)-C(9)-C(1′) 126.3(8), C(9)-C(1)-S(1) 121.0(5) [8b].

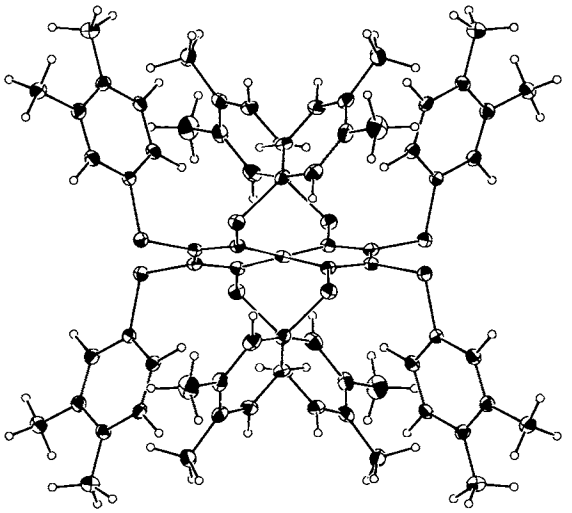

Fig. 2. Structure of **4** in its Et_4Pb clathrate. The view along the twofold rotation axis, which is coincident with the central C–C bond, illustrates the D_2-symmetric conformation of **4**.

The host–guest packing in the $PbEt_4$ adduct of **4** is shown in Figure 3. The six host molecules of **4** shown are centred round a point of $\bar{3}$ symmetry; there are, however, four such equivalent $\bar{3}$ points surrounding each cavity and, as a consequence, guest escape is blocked in all directions. The lead atom of the guest is located on a crystallographic twofold axis, hence, owing to statistical disorder, it appears as an octahedral distribution in Figure 3; the ethyl groups of the guest are highly disordered and are not shown.[11]

Recent work in the literature has described the effective control of reactions involving single molecules as well as dimerizations and polymerizations by the lattice.[4] The availability of discrete nanoscale cavities in **4**, capable of including several guest molecules, opens up the exciting possibility of carrying out controlled oligomerizations and related processes. Work along these lines is currently in progress.

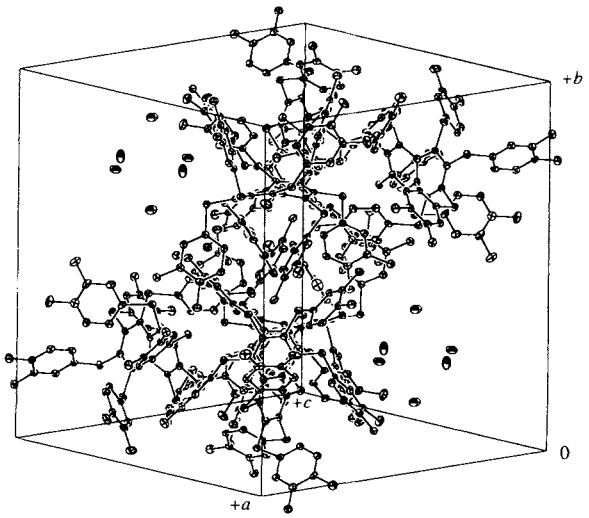

Fig. 3. Host–guest packing in the Et_4Pb clathrate of **4**. The octahedron of (partially occupied) lead atom positions arises from the 23(T) symmetry of the cavity. The highly disordered ethyl groups of the guest are not shown.

Experimental Procedure

4: Perfluoronaphthalene (0.26 g, 0.96 mmol) and sodium 3,4-dimethylbenzenethiolate (2.45 g, 15.3 mmol), prepared from 3,4-dimethylbenzenethiol and sodium in absolute ethanol, were stirred in dry, degassed 1,3-dimethylimidazolidin-2-one (DMEU) (20 mL) for 3 h at ambient temperature, under N_2. The red reaction mixture was then added to toluene (200 mL), washed with water (250 × 10 mL), and evaporation of the solvent gave a red oil which was chromatographed (dry column) on silica gel (60–80° petroleum ether/diethyl ether, 10/1) to afford 0.96 g (82%) of **4** as red cubelike crystals, m.p. 131–133 °C (petroleum ether adduct). ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.00 (s, 12H), 2.08 (s, 12H), 2.09 (s, 12H), 2.17 (s, 12H), 6.18 (dd, 4H, J = 8.0, 1.9 Hz), 6.44 (dd, 4H, J = 8.0, 1.9 Hz), 6.63 (d, 4H, J = 8.0 Hz), 6.66 (d,4H, J = 1.9 Hz), 6.81 (d, 4H, J = 8.0 Hz), 6.83 (d, 4H, J = 1.9 Hz); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 19.3, 19.5, 19.6, 19.7, 125.0, 125.7, 129.1, 129.7, 129.8, 129.9, 133.8, 134.1, 134.4, 136.1, 136.5, 136.8, 139.9, 140.4, 144.7; FAB MS: m/z: 1216.34 (±0.12) [M^+]; $C_{74}H_{72}S_8$ calculated 1216.34.

5: Perfluoronaphthalene (0.25 g, 0.92 mmol) and sodium 3,5-dimethylbenzenethiolate (2.16 g,13.5 mmol), prepared from 3,5-dimethylbenzenethiol and NaH in THF, were stirred in dry, degassed DMEU (20 mL) for 3 h at ambient temperature, under N_2. The red reaction mixture was then added to toluene (200 mL), washed with water (250 × 10 mL), and evaporation of the solvent gave a red oil, from which compound **5** was obtained on recrystallization from 1,4-dioxane/methanol; yield 0.98g (88%), red crystals, m.p. 180–181 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.06 (br. s, 24H), 2.07 (br. s, 24H), 6.37 (m, 8H), 6.47 (m, 8H), 6.62 (m, 4H), 6.64 (m, 4H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 21.2, 21.3, 124.4, 125.3, 127.3, 127.7, 137.2, 138.0 (overlapping resonances), 138.3, 139.9, 143.3, 146.9; elemental analysis [%]: Calcd for $C_{74}H_{72}S_8$: C 73.02, H 5.92, S 21.06; found C 72.93, H 5.87, S 21.06.

[8] Crystal data: **4**·0.3(Et_4Pb): $C_{74}H_{72}S_8$·0.3($(CH_3CH_2)_4Pb$), M_r = 1325.03, cubic, space group $Pn\bar{3}$, a = 22.2343(13) Å, V = 10991.8(3) Å^3, Z = 6, ρ_{calcd} = 1.201 g cm^{-3}, $Cu_{K\alpha}$ radiation, λ = 1.54178 Å, cell parameters from 25 reflections, 29.72° ≤ 2θ ≤ 99.32°, μ = 40.04 cm^{-1}, T = 123 K, bright red prism, 0.25 × 0.20 × 0.10 mm. Data Collection: Rigaku AFC7R diffractometer, $2\theta_{max}$ = 139.9°, ω-2θ scans, 5804 reflections collected, 3788 unique, R_{int} = 0.048, 2095 reflections observed, ($I \geq 2\sigma(I)$). Ψ scan absorption correction applied, (transmission factor range 0.65–1.00). The structure was solved by direct methods using SHELXS-86 [12] and refined on F to R = 0.075, R_w = 0.081 and S = 3.56 with $w = 1/\sigma^2(F)$ for the 2095 observed reflections. Hydrogen atoms for the host molecule were placed in calculated positions but not refined. The carbon atoms of the $(Et)_4Pb$ guest molecule were severely disordered and the model is the best fit to the residual electron density. Least-squares refinement was carried out using the teXsan package [13]. Crystal data for **4**·1.2(tBuOH): $C_{74}H_{72}S_8$·1.2($(CH_3)_3COH$), M_r = 1306.81, cubic, space group $Pn\bar{3}$, a = 22.2220(24) Å, V = 10973.6(6) Å^3, Z = 6, ρ_{calcd} = 1.186 g cm^{-3}, $Mo_{K\alpha}$ radiation, λ = 0.71069 Å, cell parameters from 25 reflections, 18.78° ≤ 2θ ≤ 21.73°, μ = 2.87 cm^{-1}, T = 123 K, bright red cube, 0.25 × 0.25 × 0.25 mm. Crystal data for **4**·0.6($(CH_3)_3SiC{\equiv}CSi(CH_3)_3$): $C_{74}H_{72}S_8$·0.6($(CH_3)_3SiC{\equiv}CSi(CH_3)_3$), M_r = 1320.10, cubic, space group $Pn\bar{3}$, a = 22.2223(18) Å, V = 10974.1(4) Å^3, Z = 6, ρ_{calcd} = 1.198 g cm^{-3}, $Mo_{K\alpha}$ radiation, λ = 0.71069 Å, cell parameters from 25 reflections, 14.35° ≤ 2θ ≤ 20.69°, μ = 3.05 cm^{-1}, T = 123 K, bright red prism, 0.20 × 0.18 × 0.10 mm. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-43. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Telefax: Int. code Int. Code +(1223) 336-033; e-mail: teched@chemcrys. cam.ac.uk).
[9] a) For an example of a metal-containing system with space group $Pn\bar{3}$, $[Et_4N]_6[Na_{14}Mo_{24}P_{17}O_{97}(OH)_{31}]$·$xH_2O$, see R. C. Haushalter, F. W. Lai, *Angew. Chem. Int. Ed. Engl.* **1989**, *28*, 743; *Angew. Chem.* **1989**, *101*, 802; b) Symmetry transformation used to generate equivalent atoms marked with a ('): $x, 3/2 - y, 1/2 - z$.
[10] Since there are six host molecules of **4** and two cavities per unit cell, uniform occupancy of each cavity by six guest molecules would correspond to a host–guest ratio of 1:2. The 75.4 MHz ^{13}C CP MAS spectrum (for which we thank Dr. D. C. Apperley, Univeristy of Durham) of the 1,4-dioxane adduct of **4** clearly indicates its nonstoichiometric composition (Table 1). Deconvolution of the methyl region reveals that one of the four lattice-symmetry-independent methyl carbon atoms is cleanly split into two components with a ratio close to 2:1; $\delta(CH_3)$ (relative weights in parentheses): 17.7 (1), 18.3 (1), 18.6 (1/3), 19.0 (2/3), and 20.9 (1). This is consistent with sixfold occupancy of two out of each three cages in the crystal, the third containing only five 1,4-dioxane guests, and is in keeping with the observed host–guest ratio of about 1:1.9, measured by ^{1}H NMR spectroscopy for a solution in $CDCl_3$ (see Table 1).
[11] The guest molecules 1,4-dioxane, tBuOH, and $(CH_3)_3SiC{\equiv}CSi(CH_3)_3$ all exhibit a high degree of disorder in their respective inclusion compounds with host **4**. Preliminary experiments have indicated the inclusion of C_{60} (the I_h symmetry of which is compatible with the T cage symmetry) by **4**, though single crystals suitable for X-ray diffraction analysis have not yet been obtained.

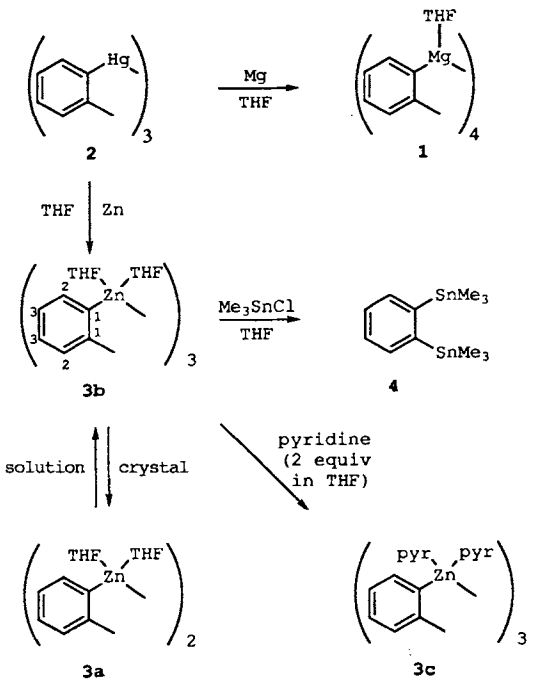
Synthesis and Structure of *ortho*-Phenylenezinc**

Marcel Schreuder Goedheijt, Tom Nijbacker, Otto S. Akkerman, Friedrich Bickelhaupt,* Nora Veldman, and Anthony L. Spek

Dedicated to Professor Erwin Weiss on the occasion of his 70th birthday

In the context of our interest in polymetalated compounds,[1] we had previously prepared *ortho*-phenylenemagnesium (**1**)[2] from *ortho*-phenylenemercury (**2**)[3] (Scheme 1). It turned out



Scheme 1. Synthesis of **1**, **3a–c**, and **4** from **2**.

that **1** has an unusual tetrameric structure in which four magnesium atoms are arranged in the form of a distorted tetrahedron. Similar structures are also observed for the related compounds diphenylvinylenemagnesium and 1,8-naphthalenediylmagnesium,[2] and overall the situation resembles that for tetrameric organolithium clusters. Since **2** has a trimeric structure with linear C-Hg-C bonds[3b] and zinc in many ways assumes a position intermediate between that of magnesium and mercury, it was of interest to investigate the analogous zinc derivative *ortho*-phenylenezinc (**3**). Recently, the corresponding *ortho*-phenylenedizinc diiodide (o-$C_6H_4(ZnI)_2$) was prepared by Tagaki et al. in good yield from *ortho*-diiodobenzene and zinc powder in the presence of *N,N,N',N'*-tetramethyl-1,2-ethylenediamine (TMEDA) and tetramethyl urea (TMU) under irradiation with ultrasound;[4] however, structural information has not been reported.

Analogous to the synthesis of **1**, we prepared **3** by stirring **2** with metallic zinc in THF. The progress of the reaction was monitored by the disappearance of the sparingly soluble **2**. After six hours at room temperature, a clear solution of **3** was obtained; it is remarkable that this process is much faster than the conversion of **2** with magnesium to give **1** which requires two weeks to go to completion.[1] After careful decantation from the resulting amalgam, **3** was obtained in 92% yield (determined by titration after hydrolysis);[5] the compound was further characterized by ^1H and ^{13}C NMR spectroscopy (Table 1) and by derivatization with chlorotrimethylstannane which gave **4**.

Table 1. NMR data (δ, J [Hz]) of **3b,c** [a].

	3b [b]		**3c** [c]	
	δ	J	δ	J

derived with sufficient confidence. The solid-state structure of **3** (molecule **3a**) consists of two *ortho*-phenylenezinc units; it is located on a crystallographic inversion center, has approximate D_{2h} symmetry, and may be described as a (practically) planar 9,10-dihydro-9,10-dizincaanthracene in which each zinc atom is surrounded by two aromatic rings and by two THF molecules in a distorted tetrahedral fashion; note that the dimerization is achieved by covalent bonding between each metal and one carbon atom of each of the two phenylene units, and not by electron-deficient two-electron–three-center bonding that has been observed for organozinc compounds only twice,[8] but more often in organomagnesium[2, 9, 10] and especially in organolithium chemistry.[10, 11] The central six-membered ring appears to be slightly distorted, but only seemingly so, as the Zn–C bonds (Zn1–C1 1.991(16) Å, Zn1–C6a 1.963(13)) lie in the expected range and are equalivalent in length within the standard deviation. The molecule is clearly strained because the angle at zinc is unusually small (cf. C1-Zn1-C6a 130.3(6)° versus normal values of about 140–160°[12, 13]), while those at the *ipso* carbon atoms (C2-C1-Zn1 127.9(12)°, C6-C1-Zn1 116.2(11)°) similarly deviate from the usual value of about 122°.[12] Note that a (beneficial) increase of the angle at zinc would lead to a (detrimental) further distortion around the *ipso* carbon atoms. The planarity of the central ring, too, can be understood as a consequence of the large valence angle at zinc: boat-shaped folding as occurs in normal dihydroanthracenes would cause additional reduction of this angle.

Although the solubility of **3** is low (about 0.1 M), it is sufficient to determine the molecular weight by stationary isothermal distillation,[14] which furnished a concentration-independent degree of association of 3.0(±0.1)! Thus, one is confronted with the astounding fact that in the crystalline state, **3** is a dimer (**3a**), but in solution a trimer (**3b**) without discernible tendency towards dissociation. Nevertheless, it is evident that the two forms must be linked by the equilibrium 3 **3a**⇌2 **3b** which is strongly shifted towards **3b** in solution. As a dimer, **3a** is favored over **3b** by entropy, but this is apparently overcompensated by strain. The strain is relieved in **3b** because the C-Zn-C angle can be larger and adopt a normal value without causing angle distortions at the *ipso* carbon atoms; once this is achieved, the driving force for oligomerization is absent, so that entropy protects the system against further association. A similar situation has been encountered for the monomer/dimer equilibrium of magnesacyclohexane in THF.[15]

At present, the exact structure of **3b** is not known. It is unlikely that in analogy to **2** (which also is a trimer),[3b] **3b** has linear carbon-metal-carbon angles. Since zinc is a stronger Lewis acid than mercury, it is assumed that the zinc atom in **3b** will be coordinated by two THF molecules like in **3a** and thus achieve a normal, distorted tetrahedral arrangement. This assumption is supported by the observation that on addition of an excess of pyridine to a solution of **3b** in THF, a yellow precipitate is formed that has the composition of **3c** (^{1}H and ^{13}C NMR spectroscopy); exactly two molecules of pyridine are coordinated to each zinc atom, and the new species **3c**, like **3b**, is trimeric in THF solution according to association measurements.

Surprisingly, **3a** crystallizes from a solution of **3b** although the latter apparently is present in large excess and is thermodynamically more stable. We suggest that in solution, **3a** is present in minute amounts and crystallizes preferentially due to favorable packing effects; it is relevant to point out that the crystallization process at −20 °C took about two weeks.

Finally, one may ask why the *ortho*-phenylene derivatives of zinc (**3a**: dimer; **3b**: trimer; both with a mononuclear metal environment) are so different from that of magnesium (**1**: tetrameric cluster). Of course, the metal–carbon bond is much more polar in the case of magnesium, and apparently, electrostatic contributions to bonding are prominent enough for clustering to become feasible.[2] This is in analogy to organolithium chemistry where high polarity is well-known to favor electron-deficient clusters.[10, 11] In contrast, the Zn–C bonds (as in **3**), and even more so the Hg–C bonds (as in **2**), have sufficient covalent character to facilitate, under the same circumstances, directed bonding.

Experimental Procedure

ortho-Phenylenemercury (**2**) [3] (2.38 g, 8.6 mmol) and zinc (5.23 g, 80 mmol) in THF (50 mL) were stirred for 6 h at room temperature. A light brownish solution with a fine black precipitate was formed. The clear solution was decanted; titration of an aliquot (HCl and EDTA) [5] indicated the formation of **3** in 92% yield. Concentration of this solution and slow cooling (over about 1 day) to −20 °C afforded colorless crystals of **3a** (7.3 mmol, 85%, determined by titration after hydrolysis) after about two weeks.

When an excess of pyridine (1 mL) was added to a solution of **3** (0.42 mmol) in THF (10 mL), the color of the solution changed immediately from colorless to bright yellow. After 3 min, a yellow precipitate of **3c** formed; it was filtered off, dissolved in [D$_8$]toluene and characterized by ^{1}H and ^{13}C NMR spectroscopy.

[6] Crystal data for **3a**: $C_{28}H_{40}O_4Zn_2$, M_r = 571.40, colorless, transparent (0.18 × 0.38 × 0.50 mm), triclinic, space group P (no. 2), with a = 8.184(4), b = 8.887(4), c = 10.952(3) Å, α = 93.71(3), β = 112.39(3), γ = 105.34(6)°, V = 697.9(5) Å^3, Z = 1, ρ_{calcd} = 1.360 g cm^{-3}, $F(000)$ = 300, $\mu(Mo_{K\alpha})$ = 17.5 cm^{-1}, 2143 reflections measured, 1970 independent (2.0° < θ < 25.0°, ω scan, $\Delta\omega$ = 1.30 + 0.35 tanθ°, T = 293 K, $Mo_{K\alpha}$ radiation, graphite monochromator, λ = 0.71073 Å) on an Enraf-Nonius CAD4-T diffractometer with rotating anode; 5 h of X-ray exposure time. Data were corrected for Lorentz polarization. The structure was solved by automated Patterson methods (SHELXS86). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL-93); no observance criterion was applied during refinement. Final $R1$ value 0.121, for 979 reflections with $F_o > 4.0\sigma(F_o)$, $wR2$ = 0.297 for 1970 data, $w = 1/[\sigma^2(F_o)^2 + (0.1000P)^2]$, with $P = (\mathrm{Max}(F_o^2, 0) + 2F_c^2)/3$, S = 1.430, for 154 parameters. Mean and maximum shift over error: 0.000 and 0.000. Maximum and minimum residual density: 1.22, −0.73 e Å^{-3}. Crystals invariably showed broad reflection profiles of 3° that even increased to 6° at low temperature. As a result, only data of limited quality could be obtained. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were refined riding on their carrier atoms with a fixed isotropic thermal parameter related to the value of the equivalent isotropic thermal parameter of their carrier atoms by a factor of 1.2.

The $[Mn_2^{IV}(\mu\text{-}O)(\mu\text{-}PhBO_2)_2]^{2+}$ Unit: A New Structural Model for Manganese-Containing Metalloproteins**

Ursula Bossek, Helga Hummel, Thomas Weyhermüller, Karl Wieghardt,* Stephen Russell, Lodewijk van der Wolf, and Uwe Kolb

The structural motif of the μ-oxo(hydroxo)-di-μ-carboxylatodimanganese unit has been discovered in the active centers of some metalloproteins containing manganese. For example, in the catalases from *Lactobacillus plantarum*[1] and *Thermus thermophilus*[2] as well as in a ribonucleotide reductase from *Brevibacterium ammoniagenis*;[3] this structural motif has also been proposed for the tetranuclear manganese cluster in photosystem II (PS II).[4] These proposals were supported by the synthesis of dinuclear model complexes, in which the oxidation state of the two Mn ions was varied in one-electron steps from Mn_2^{II}[5] over $Mn^{II}Mn^{III}$[6] and Mn_2^{III}[7] to $Mn^{III}Mn^{IV}$.[8] The Mn_2^{IV} state was so far not accessible. Complexes of this type are very important for the calibration of the spectroscopic methods that are employed in the characterization of biomolecules. We report here that the corresponding Mn_2^{IV} complexes can be obtained if boronato ligands RBO_2^{2-} are used as bridging ligands instead of carboxylate groups. Surprisingly, the coordination chemistry of boronic acids has aroused little interest to date.[9]

The treatment of 1,4,7-trimethyl-1,4,7-triazacyclononane (L) and phenylboronic acid with $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ in acetone in the presence of air leads to green crystals of **1**. Figure 1 shows

$[LMn^{III}(Ph_2B_2O_3)(ClO_4)]$ **1**

the structure of the octahedral, neutral complex in **1**,[10] which has a monodentate ClO_4^- ion, a cyclic triamine, and the bidentate dianion $[Ph_2B_2O_3]^{2-}$ as ligands; the latter can be regarded as an analog of the pentane-2,4-dionato ion ($acac^-$): In the complex $[LMn^{III}(acac)(OH_2)](ClO_4)_2$[11] the two $Mn^{III}-O_{acac}$ bonds are somewhat longer (1.88 Å) than the corresponding bonds in **1** (1.845 Å).

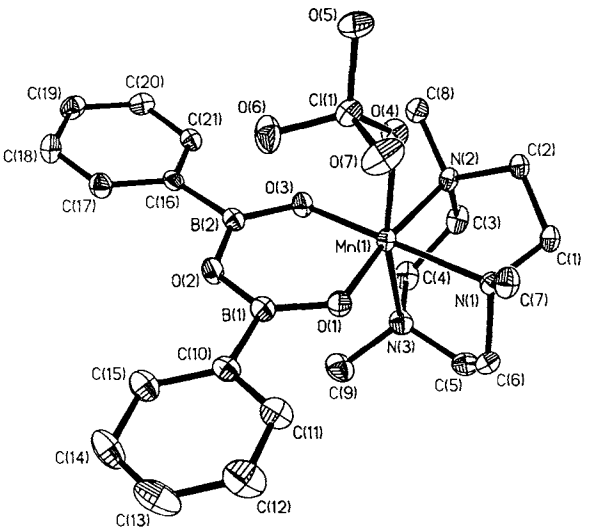

Fig. 1. Structure of the neutral complex in crystals of **1**. Selected bond lengths [Å]: Mn-O1 1.844(3), Mn-O3 1.846(3), Mn-O4 2.354(3), Mn-N1 2.116(3), Mn-N2 2.115(3), Mn-N3 2.272(3), B1-O1 1.348(4), B1-O2 1.386(4), B1-C10 1.574(5), B2-O3 1.348(4), B2-O2 1.382(4), B2-C16 1.572(5).

Hydrolysis of **1** in the presence of air in a mixture of ethanol/water/acetone (3:1:2) to which solid $NaClO_4$ was added gave deep red crystals of **2** after two to three days. The X-ray crystal

$[L_2Mn_2^{IV}(\mu\text{-}O)(\mu\text{-}PhBO_2)_2](ClO_4)_2 \cdot 2Me_2CO$ **2**

structure analysis[10] (Fig. 2) reveals that the dication in **2** consists of two Mn^{IV} ions with octahedral environments; they are linked together by two *syn,syn-O,O'*-coordinated phenylboronic acid dianions and a bent oxo bridge. Thus the structure of **2** corresponds very closely to that found in the μ-oxo-di-μ-carboxylatodimanganese complexes (Table 1).

The missing member of this series, a hydroxo-bridged, mixed-valent $Mn^{II}Mn^{III}$ complex, was also prepared: Treatment of L

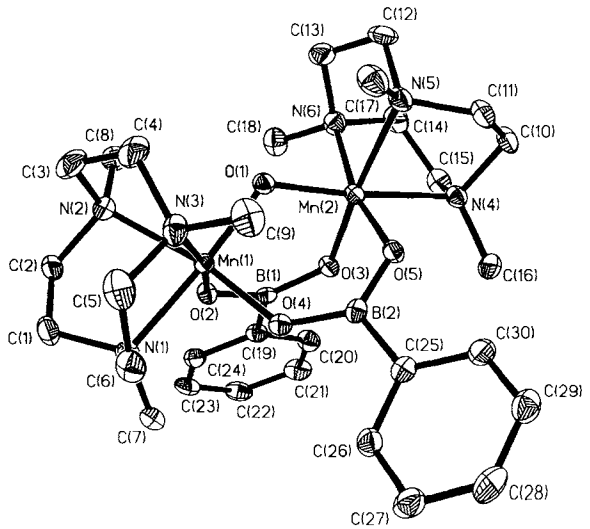

Fig. 2. Structure of the dication in crystals of **2**. Selected bond lengths [Å] and angles [°]: Mn1-N1 2.137(4), Mn1-N2 2.111 (4), Mn1-N3 2.103(4), Mn1-O1 1.823(3), Mn1-O2 1.821(3), Mn1-O4 1.829(3). Die entsprechenden Abstände an Mn2 sind innerhalb der Fehlergrenzen gleich. B1-O2 1.365(6), B1-O3 1.360(6) B2-O4 1.359(6), B2-O5 1.359(7); Mn1 ··· Mn2 3.184(1), Mn1-O1-Mn2 121.9(2).

Table 1. Structural parameters and magnetism of dinuclear $[LMn(\mu\text{-}X)(\mu\text{-}Y)_2MnL]^{n+}$ complexes (X = O, OH; Y = RCO_2^- or RBO_2^{2-}).

Complex	Mn^nMn^m	Mn–X [Å]	Mn–Y [Å]	Mn-X-Mn [°]	Mn···Mn [Å]	J [cm^{-1}] [a]	Ref.
$[L_2Mn_2(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2]^+$	Mn_2^{II}	2.053(4)	2.17	109.4(3)	3.351(3)	−9	[5]
3	$Mn^{II}Mn^{III}$	1.932(5)	2.05	119.3(2)	3.449(1)	−9	[b]
		2.065(5)	2.09				
4	Mn_2^{III}	1.83	2.05	121.8(2)	3.193(1)	+5.4	[b]
$[L_2Mn_2(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2]^{3+}$	$Mn^{III}Mn^{IV}$	1.82	1.97	125.1(3)	3.230(3)	−40	[8]
2	Mn_2^{IV}	1.82	1.83	121.9(2)	3.184(1)	+10	[b]

[a] $H = -2JS_1 \cdot S_2$. [b] This work.

and pivalic acid with $Mn^{II}(ClO_4)\cdot 6H_2O$ in acetone in the presence of air leads to light brown crystals of **3**. The oxidation of **3** by O_2 in a basic medium gave red-violet crystals of **4**. The

$[LMn^{II}(\mu\text{-}OH)(\mu\text{-}(CH_3)_3CCO_2)_2Mn^{III}L](ClO_4)_2$ **3**

$[L_2Mn_2^{III}(\mu\text{-}O)(\mu\text{-}(CH_3)_3CCO_2](ClO_4)_2$ **4**

X-ray structural analyses[10] of **3** and **4** (Fig. 3) show that the valences in **3** are localized and that an OH group forms a bridge between a Mn^{II} and a Mn^{III} ion. In **4** the two Mn^{III} ions are linked by an oxo bridge.

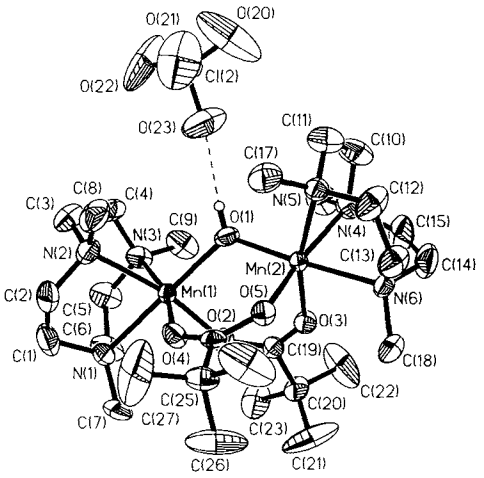

Fig. 3. Structure of the dication in **3** (that of the dication in **4** is very similar and is not shown). Selected bond lengths [Å] and angles [°] (values for **4** are given in parentheses): Mn1···Mn2 3.449(1) (3.193(1)), Mn1-N1 2.262(6) (2.153(4)), Mn1-N2 2.258(7) (2.183(5)), Mn1-N3 2.270(7) (2.268(5)), Mn1-O1 2.065(5) (1.833(3)), Mn1-O2 2.068(5) (2.017(3)), Mn1-O4 2.117(5) (2.090(3)), Mn2-N4 2.169(6) (2.157(4)), Mn2-N5 2.301(5) (2.296(4)), Mn2-N6 2.164(6) (2.141(4)), Mn2-O1 1.932(5) (1.821(3)), Mn2-O3 2.102(4) (2.095(3)), Mn2-O5 1.997(5) (1.997(3)), O1···O23 2.948(9); Mn1-O1-Mn2 119.3(2) (121.8(2)).

The electronic structure of the complexes **1**–**4** was determined from measurements of the temperature dependency of the molar magnetic susceptibility.[12] For **1** a temperature-independent magnetic moment of 4.80 μ_B (40–295 K) was determined, which corresponds to an $S = 2$ ground state for a high-spin Mn^{III} ion (d^4). In contrast, the magnetic moment of **2**, which contains two Mn^{IV} ions (d^3), is temperature-dependent; it increases monotonically from 5.82 μ_B at 300 K to 6.76 μ_B at 4.2 K. Using the formalism of the isotropic Heisenberg–Dirac–van Vleck model ($H = -2JS_1 \cdot S_2$; $S_1 = S_2 = 3/2$) gave a g value of 1.99(2) and a ferromagnetic coupling constant J of $+10(1)$ cm^{-1}. Therefore, the ground state of **2** is $S = 3$. This is surprising, because antiferromagnetic couplings were found for the isostructural and isoelectronic complexes $[L_2Cr_2^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](BPh_4)_2$[13] and $[LCr^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}(tacn)](PF_6)_3$[14] (tacn = 1,4,7-triazacyclononane).

The exchange couplings in **3** and **4** were calculated analogously. The coupling between the $Mn^{II}(d^5)$ and the $Mn^{III}(d^4)$ ion in **3** is weakly antiferromagnetic, as has been reported for two analogous phenolato-bridged complexes.[6] In **4** the $Mn^{III}(d^4)$ ions are weakly antiferromagnetically coupled—in agreement with earlier observations.[7]

With the complexes $[L_2Mn_2^{II}(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2]PF_6\cdot CH_3OH$,[5] **3**, $[L_2Mn_2^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](ClO_4)_2$,[7] $[LMn^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2Mn^{IV}L](ClO_4)_3]$,[8] and **2** there is now an "isostructural" series available, in which the oxidation level increases stepwise by one electron per two manganese ions. The energy of the manganese K X-ray absorption edge serves as a measure of the degree of oxidation of the manganese cluster in PS II.[15–17] The present series of complexes can now be used for the experimental verification of the fundamental supposition that the Mn K-edge energy increases linearly with the oxidation level of the Mn ions given that the structure of the complex remains the same. The protonation or deprotonation of the oxo and hydroxo bridge, respectively, does not have any influence on the Mn K-edge energy.[18]

As can be seen from Figure 4, the XANES experiments (*X*-ray *a*bsorption *n*ear *e*dge *s*pectroscopy) carried out on the five

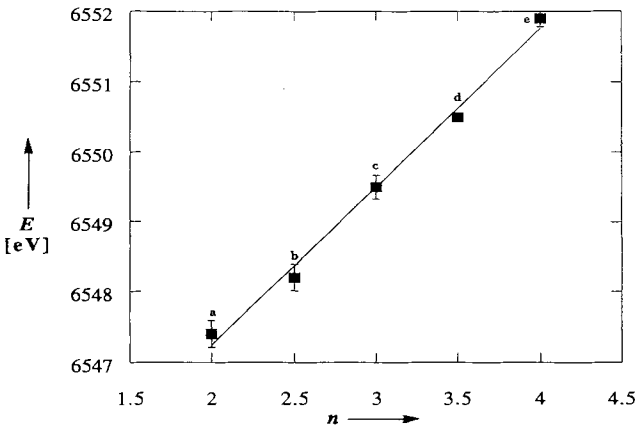

Fig. 4. The Mn K-edge energy E for the complexes a) $[L_2Mn_2^{II}(\mu\text{-}OH)(\mu\text{-}CH_3CO_2)_2]PF_6\cdot CH_3OH$: 6547.4 ±0.4 eV, b) $[L_2Mn_2^{II/III}(\mu\text{-}OH)(\mu\text{-}(CH_3)_3CCO_2)_2](ClO_4)_2$: 6548.2 ±0.4 eV, c) $[L_2Mn_2^{III}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](ClO_4)_2$: 6549.5 ± 0.3 eV, d) $[L_2Mn_2^{III/IV}(\mu\text{-}O)(\mu\text{-}CH_3CO_2)_2](ClO_4)_3$ [19]: 6550.5 eV, e) $[L_2Mn_2^{IV}(\mu\text{-}O)(\mu\text{-}PhBO_2)_2](PF_6)_2$: 6551.9 ±0.2 eV as a function of the average oxidation state n of the Mn ions ((■) measured values; (—) fitted line).

complexes show clearly that, within the error limit, the Mn K-edge energy increases linearly with increasing oxidation level. In particular, the oxidation state of IV is confirmed for the two Mn ions in **2**.

Experimental Procedure

1: 1,4,7-Trimethyl-1,4,7-triazacyclononane (L) (0.50 g) and phenylboronic acid (0.70 g) were dissolved in acetone (40 mL) and treated with $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ (1.0 g). The solution turned green within 60 min on stirring in air. Slow evaporation of the solvent in air gave large green crystals of **1** within one to two days. Yield: 0.81 g (53%). UV/Vis (CH_3CN): λ_{max} (ε [L mol^{-1} cm^{-1}]) 219 (2.26×10^4), 237 (2.0×10^4), 293 (8.7×10^3), 412 (265), 688 nm (19).

2: A solution of **1** (0.50 g) in a mixture of ethanol/water/acetone (3:1:2) (40 mL) was treated with $NaClO_4$ (0.30 g). After the mixture was left to stand in air for two to three days, the solvent was removed and the red-brown residue recrystallized from acetone. Yield: 0.19 g (40%). Alternatively, **2** could also be obtained from the above solution after addition of H_2O_2 (0.5 mL, 30% H_2O_2) and NaOH (0.10 g) in H_2O (2 mL). UV/Vis (CH_3CN) λ_{max} (ε[L mol^{-1} cm^{-1}]) = 222 (3.0×10^4), 274 (1.9×10^4), 370 sh, 693 (137), 710 sh (150), 763 (50), 790 sh (36), 865 nm (21).

3: To a solution of L (0.50 g) and pivalic acid (0.40 g) in acetone (40 mL) was added $Mn^{II}(ClO_4)_2 \cdot 6H_2O$ (1.0 g). The mixture was left to stand in air for about 6 h at 20 °C, during which time the mixture turned brown. After addition of solid $NaClO_4$ (0.90 g) to this solution, brown crystals of **3** precipitated. Recrystallization from acetone. Yield: 0.90 g (70%). UV/Vis (CH_3CN) λ_{max} (ε[L mol^{-1} cm^{-1}]) = 288 (5.8×10^3), 431 (620), 472 nm (517).

4: To a solution of **3** (0.50 g) in acetone (40 mL) in air were added ten drops of triethylamine and solid $NaClO_4$ (0.80 g). On concentration of the red reaction solution, red crystals of **4** formed. Yield: 0.30 g (61%). UV/Vis (CH_3CN) λ_{max} (ε[L mol^{-1} cm^{-1}]) = 312 (1.4×10^4), 400 sh, 485 (719), 522 (691), 730 (136), 990 nm (67).

All new complexes gave satisfactory elemental analyses (C, H, N).

[19] The XANES experiments were carried out on the Mn-K edge at the experimental station BN3 of the storage ring ELSA at the Universität Bonn. The edge positions were determined by using their first turning points. The experimental error was calculated from the resolution of the monochromator and the reproducibility of the edge positions of a Mn metal foil (6539.0 eV) directly before and after the measurements.

Screw-Sense-Selective Polymerization of Isocyanides by Dinuclear μ-Ethynediyl Complexes**

Fumie Takei, Koichi Yanai, Kiyotaka Onitsuka, and Shigetoshi Takahashi*

Macromolecular asymmetry, which originates from the helical structure of a polymer backbone, has recently attracted a great deal of interest, and some optically active polymers with helical chirality have been synthesized for methacrylates, chloranils, and isocyanates.[1] Such artificial polymers, which contain a stable, single-handed helical conformation, are of special interest in view of their potential as new materials and because of their relation to biomolecules.[2]

Poly(isocyanide)s have a 4_1 helical structure[3] and usually exist in a 1:1 mixture of two conformational isomers with right-handed (*P*) and left-handed (*M*) helices due to the restricted

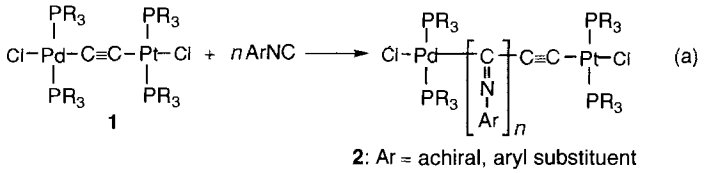
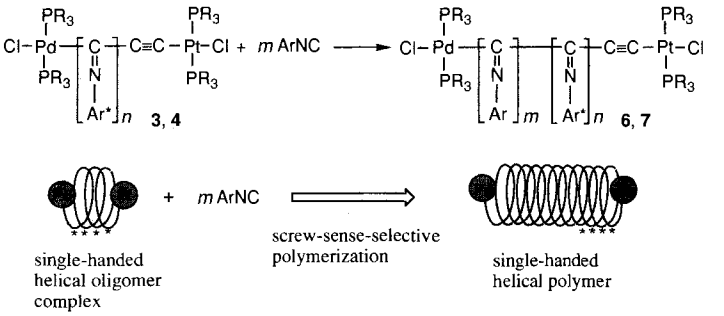
rotation about the C–C single bond in the polymer backbone. The screw-sense-selective (SSS) polymerization of isocyanides should give optically active poly(isocyanide)s with *P* or *M* helical structure. Indeed, some attempts at the SSS polymerization of isocyanides have been made using transition metal catalysts modified with chiral amine,[4] phosphane,[5] and acetato ligands, [6] as well as by using chiral isocyanides.[7]

Recently we showed[8] that the dinuclear μ-ethynediyl complex **1** undergoes successive multiple insertions of isocyanides exclusively into the Pd–C bond. This leads to a novel living polymerization of aryl isocyanides; however, mononuclear acetylides of the type $[(PR_3)_2PdX(C{\equiv}CR)]$ are inactive to the polymerization. We have now applied the catalytic properties of **1** to the SSS polymerization of isocyanides by utilizing the living nature of the process.

The reaction of **1** with *n* equivalents of phenyl, *p*-tolyl, or 4-*n*-butylphenyl isocyanides [Eq. (a)], led to oligomers **2** (e.g., $n = 10$) as well as polymers **2** (e.g., $n = 100$) in almost quantitative yields. Since these compounds still contain the active end-group $[CPd(PR_3)_2Cl]$, they can be reused as initiators for further polymerization of isocyanides.[8] If a chiral isocyanide is employed, the reaction with **1** may produce chiral oligomer complexes like **3**, which probably can be brought into play for the polymerization of further isocyanide monomers. Our approach to a generally applicable SSS polymerization of isocyanides is based on this characteristic feature of the complexes and the use of a block-copolymerization technique as illustrated in Scheme 1.

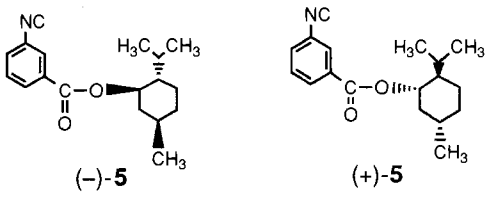


(a)



Scheme 1. Screw-sense-selective polymerization of isocyanides.

To prepare the chiral oligomer complex **3**, we treated **1** with 2, 10, 20, and 30 equivalents of the chiral isocyanide *m*-$CNC_6H_4CO_2R^*$ (–)-**5** ($R^* = (-)$-menthyl,[9] $[\alpha]_D^{20} = -83$ ($c = 0.21$ in $CHCl_3$)) and obtained the oligomer complexes **3a** ($n = 2$, $m/z = 1440$, $[\alpha]_D^{20} = +2$), **3b** ($n = 10$, $M_n = 3720$, $[\alpha]_D^{20} = +22$), **3c** ($n = 20$, $M_n = 6580$, $[\alpha]_D^{20} = +176$), and **3d** ($n = 30$, $M_n = 10080$, $[\alpha]_D^{20} = +228$), respectively, which were identified, for example, based on their ^{31}P NMR and circular dichroisum (CD) spectra, and molecular weight measurements.[10] Similarly, the related chiral oligomer complexes **4** were prepared by reactions of **1** with *m*-$CNC_6H_4CO_2R^*$ (+)-**5** ($R^* = (+)$-menthyl, $[\alpha]_D^{20} = +82$ ($c = 0.13$ in $CHCl_3$)).[9] Complex **4d** ($n = 30$) has an $[\alpha]_D^{20}$ value of -225, and the CD spectrum is the same as the mirror image of that of **3d**, indicating that **3d** and **4d** are a pair of enantiomers.



Like **1**, the chiral complexes **3** smoothly polymerized the chiral monomer (–)-**5** in THF under reflux to give polymers with a narrow polydispersity index ($M_w/M_n < 1.08$). Although the monomer shows a negative optical rotation, the polymers and the oligomers exhibit a large positive one. The specific rotation increases proportionally with the increase in the molecular weight of **3** and reaches a constant value of $[\alpha]_D^{20} = +260$ at a molecular weight of more than about 20000, which corresponds to the degree of polymerization P_n of about 70. The large optical rotation clearly arises from macromolecular asymmetry caused by the helical chirality of the polymer backbone and not by the chiral menthyl groups attached to the backbone. Since no appreciable change in the $[\alpha]$ value was observed after heating **3e** ($n = 100$) at reflux in THF for 5 h, the helical structure can be regarded as being stable in solution. Polymers **4** prepared similarly from (+)-**5** exhibit a negative optical rotation; the same relationship as for **3** is observed between the $[\alpha]$ value and the molecular weight. In addition, the CD spectra of, for example, **3e** ($n = 100$) and **4e** ($n = 100$) are mirror images of each other, suggesting that the polymerization of the chiral isocyanide **5** proceeds with a screw-sense selectivity and that polymers **3** and **4** are a pair of enantiomers. The screw sense (*P* or *N*) of the helical enantiomers, however, has not been assigned yet.

Furthermore, we have investigated the SSS polymerization of achiral isocyanides initiated by chiral oligomer complexes **3** and **4**. The screw-sense selectivity of the polymerization has been estimated on the basis of the specific rotation of the resulting polymers. Thus, the oligomer complex **3d** was treated with *m* equivalents of 3-propoxycarbonylphenyl isocyanide to yield polymers **6d-Pr**, the molecular weight and specific rotation of which are listed in Table 1. The relationship between M_w and $[\alpha]$ suggests that a SSS polymerization of the achiral isocyanide occurs at the initial stage of the reaction, but the selectivity

gradually falls as the degree of polymerization increases. When **3b** and **3c** were used as initiators, the loss of selectivity took place at an early stage of the reactions. Similar results were obtained when *n*-butylphenyl isocyanide was polymerized with **3** as an initiator. The loss of selectivity in the propagation step is probably due to a rather weak steric interaction between the incoming isocyanide monomers and the active site $\{Cl(PEt_3)_2Pd[C(=NAr)]_n\}$ bearing the helical chirality. We therefore chose to investigate the polymerization of the monomer 3,5-dipropoxycarbonylphenyl isocyanide **8**.

Chiral complexes **3** smoothly polymerized the sterically demanding monomer **8** to give polymers **6-diPr** in almost quantitative yields. A summary of the molecular weights and rotation values are given in Table 1. Polymers **6b-diPr** show a rather small specific rotation, indicating the low stereoselectivity of the polymerization. In contrast, polymers **6c-diPr** exhibit a relatively large [α] value, which decreases slightly with increasing molecular weight. The polymers **6d-diPr** maintain very large [α] values even for high molecular weight polymer of at least $M_w = 29000$. As expected, polymers **6**, produced by initiation with **3**, exhibit a negative rotation, while use of **4** as initiator afforded polymers **7-diPr**, which have specific rotations of the opposite sign, but the same absolute values as the corresponding **6-diPr** polymers. These findings suggest that the chiral complexes **3** and **4** are capable of initiating the SSS polymerization of sterically demanding achiral isocyanides with a high stereoselectivity and that the helical chirality of the initiator is preserved during the SSS polymerization. Since the polymerization initiated by **3c** proceeded with a slight decrease of the selectivity, the SSS polymerization of achiral isocyanides seems to require chiral oligomer complexes that possess at least seven turns of single-handed helices as an initiator.[11]

The SSS polymerization of achiral isocyanides described here reveals that chiral transition metal complexes that have been modified by chiral isocyanides can act as effective initiators and provides a new method for preparing poly(isocyanide)s with a single-handed helix.

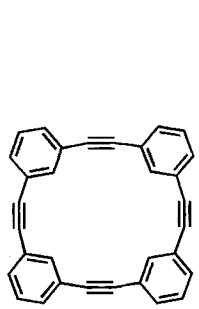
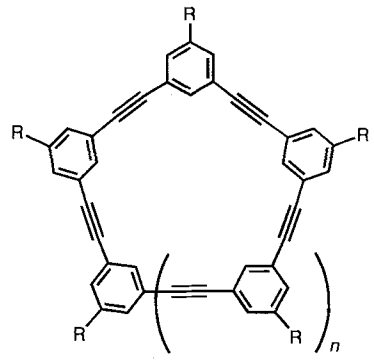
[2.2.2.2]Metacyclophane-1,9,17,25-tetrayne**

Takeshi Kawase, Noriko Ueda, Hossein Reza Darabi, and Masaji Oda*

Although a number of [2.$_n$]metacyclophane-*n*-ynes have been synthesized, the tetrayne **1** has remained unknown.[1, 2] While unsubstituted[1] and substituted[2] compounds are known for the hexayne **3**, only substituted compounds are known for the pentayne **2** and the heptayne **4**.[2] These compounds were synthesized by coupling reactions of acetylenic precursors; however, this method proved unsuitable for synthesizing **1**.[2] We here report the synthesis, properties, and structure of **1**, the smallest member of this class of compounds known to date.



1



2: $n = 1$ (R = COO*n*Bu)
3a: $n = 2$, R = H
3b: $n = 2$, R = H, *t*Bu alternately
4: $n = 3$ (R = COO*n*Bu)

The strain energy of **1** has been estimated to be about 11 kcal mol^{-1} from a molecular mechanics calculation.[2] This strain energy, though sizable, should be dispersed over the molecule so that each triple bond is only slightly strained. Thus, **1** is expected to be stable enough to avoid undergoing ready addition of nucleophiles, thus allowing the application of the base-promoted dehydrohalogenation method for constructing the triple bonds. Wennerström et al. achieved the synthesis of the (Z^4)- and (Z^3,*E*)-[2.$_4$]metacyclophanetetraenes **6a** and **6b**, respectively, potential precursors to **1**, by a double Wittig reaction.[3] However, the yields of **6a** and **6b** were too low for them to be of use as synthetic intermediates for **1**. We recently reported that the reductive coupling of 4,4′-(*Z*)-stilbenedicarbaldehyde with low-valent titanium reagents affords a mixture of [2.$_4$]paracyclophanetetraenes (including a new *E,Z,E,Z* isomer) in better yields than with the double-Wittig method.[4] We therefore examined the Ti-mediated coupling of the 3,3′-(*Z*)-stilbenedicarbaldehyde (*Z*)-**5**,[5] and obtained the coupling products **6** in improved yields (Scheme 1).

Treatment of (*Z*)-**5** with the low-valent titanium compound, prepared from $TiCl_4$ and Zn in dimethoxyethane (DME),[6] afforded a mixture of **6b**, the new (*E,Z,E,Z*) isomer **6c** (20–50% of the mixture), and a small amount of other isomers in 35–40% yield. The (Z^4)-isomer **6a** and the intramolecular coupling product **7** were not detected. Similar treatment of the (*E*)-isomer

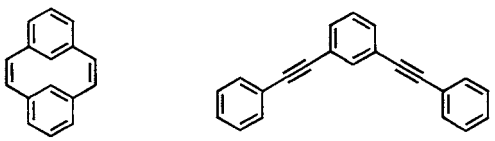
a = (Z⁴); b = (Z³,E),
c = (E,Z,E,Z)

Scheme 1. Synthesis of **1** via **6b** and **6c**.

(*E*)-**5** gave only a trace amount of the cyclic compounds. The new tetraene **6c**, which is the third known member of the six possible stereoisomers, was isolated from the mixture by fractional recrystallization from CH_2Cl_2/hexane. The reaction of the tetraene mixture **6** with bromine and subsequent treatment of the crude octabromide mixture with *t*BuOK gave the tetrayne **1** as a stable crystalline substance in 55% yield (Scheme 1).



7 **8**

The ^1H and ^{13}C NMR spectra of **1** and **6c** are fairly simple, consistent with the high symmetry of the molecules (see Table 1). The inner protons of **1** are observed at the lowest field ($\delta = 8.07$) among the aromatic protons and at lower field than

Table 1. Physical and spectroscopic data for **1** and **6c**.

1: colorless crystals, decomp >300 °C; MS (FAB): *m/z* 400 (M^+); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 7.35$ (m, 12H), 8.07 (m, 4H); ^{13}C NMR (67.8 MHz, $CDCl_3$): $\delta = 92.20$ (sp-C), 123.78, 128.20, 128.95, 141.85; UV (cyclohexane): λ_{max} (ε) = 214 (50100), 271 (61700 sh), 286 (115000), 303 (67600), 319 (6300), 324 nm (5800 sh); fluorescence (cyclohexane): λ_{max} = 327, 338, 350 nm; Raman (KBr): $\tilde{\nu} = 2202\ cm^{-1}$ (C≡C).

6c: colorless crystals, m.p. 196–197 °C; MS (FAB): *m/z* 408 (M^+); ^1H NMR (270 MHz, $CDCl_3$): $\delta = 6.47$ (s, 4H), 6.50 (s, 4H), 6.99 (dt, $J = 7.6$, 1.7 Hz), 7.10 (dt, $J = 7.6$, 1.7 Hz, 4H), 7.17 (t, $J = 7.6$ Hz, 4H), 7.28 (t, $J = 1.7$ Hz, 4H); ^{13}C NMR (67.8 MHz, $CDCl_3$): δ = 124.80, 127.59, 128.65, 128.84, 130.12, 130.86, 136.73, 137.72.

the corresponding proton of 1,3-di(phenylethynyl)benzene **8** ($\delta = 7.72$[7, 8]), an acyclic homologue of **1**. Since the chemical shifts of the outer protons of **1** are comparable to those of **8**, the low-field shift of the inner protons may be due to greater anisotropic effects from the neighboring triple bonds and benzene rings. The sp carbon atoms of **1** ($\delta = 92.20$) also resonate at slightly lower field than those of diphenylacetylene ($\delta = 89.4$), **2** ($\delta = 89.6$), and **3b** ($\delta = 88.6$ and 89.8), which is consistent with higher ring strain in the molecule; however, the degree of the low-field shift is much smaller than that for strained cycloalkynes.[9, 10]

The absorption spectrum of **1** is similar to those of diphenylacetylene, the *meta*-diyne **8**, and the cyclic hexaynes **3** with the exception of the absorption coefficients which are roughly proportional to the number of diphenylacetylene units. The tetrayne **1** emits remarkably intense fluorescence ($\Phi = 0.16$[11]). The Raman frequency of the triple bonds of **1** ($\tilde{\nu} = 2202\ cm^{-1}$) is a little lower than that of **3a** ($\tilde{\nu} = 2212$ and $2223\ cm^{-1}$)[1], reflecting the deformation of the triple bonds from linearity (more sp^2 character).[9, 10]

The X-ray structure analysis of a single crystal of **1** revealed two important features (Fig. 1).[12] First, the molecule is nearly

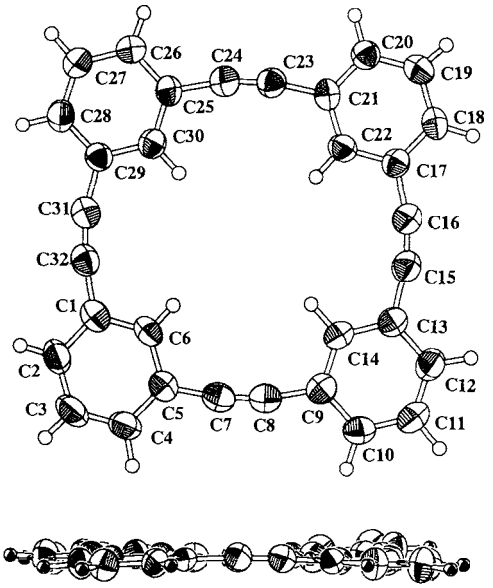


Fig. 1. Crystal structure of **1**. Top: Plan view; bottom: Side view (ORTEP; 50% probability). Selected bond lengths [Å] and angles [°] (standard deviation in parentheses): C5–C7 1.436(7), C7–C8 1.189(6), C8–C9 1.441(6), C13–C15 1.434(6), C15–C16 1.189(6), C16–C17 1.445(6), C21–C23 1.443(6), C23–C24 1.195(5), C24–C25 1.440(6), C29–C31 1.447(6), C31–C32 1.189(6), C32–C1 1.438(6); C5-C7-C8 169.5(6), C7-C8-C9 169.9(6), C13-C15-C16 168.2(5), C15-C16-C17 167.7(5), C21-C23-C24 169.4(5), C23-C24-C25 169.0(5), C29-C31-C32 168.6(5), C31-C32-C1 167.7(5).

planar; the twist angles of the benzene rings from the plane formed by the four triple bonds are less than 2°. Second, the triple bonds are no longer linear but bent (167.7–169.9°), which indicates the strained nature of the molecule. Similar angles occur at the triple bonds in cyclononyne (169.7°)[13] and [2.2](4,4')tolanophane (169°).[14] Although the molecular structure of **1** thus shows some strain around the triple bonds, the molecule is remarkably stable and is inactive towards cyclopentadiene and furan at room temperature.

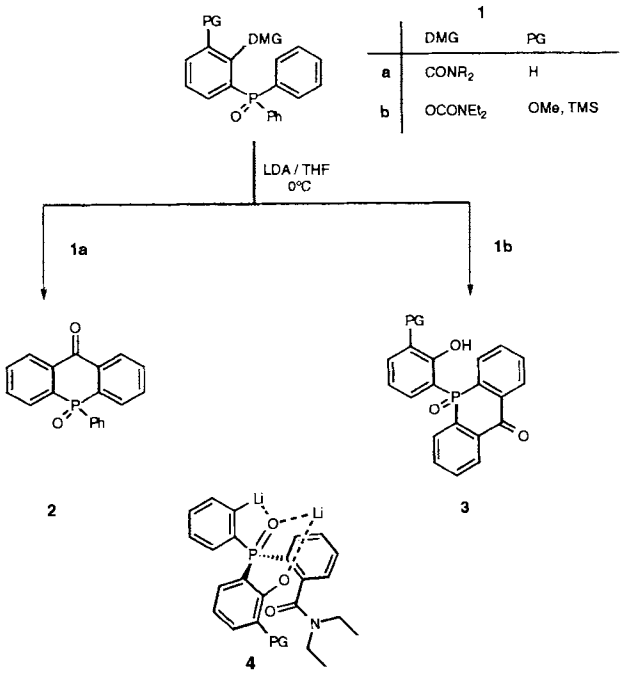
Carbanion-Mediated Heterocyclizations: Regiospecific, General Route to Dibenzo-[*b*,*e*]phosphininones by Synthetic Anionic Equivalents of Friedel–Crafts Reactions and Remote Fries Rearrangement**

Matthew Gray, Brian J. Chapell, Nicholas J. Taylor, and Victor Snieckus*

We report on the first carbanion-mediated synthesis of diverse dibenzo[*b*,*e*]phosphininones **2** and **3** from carbamoyl and carbamoyloxy triarylphosphane oxides, **1a** and **1b** respectively (Scheme 1), which, conceptually, represent synthetic equivalents of anionic Friedel–Crafts and remote Fries rearrangements. This fundamental new chemistry of triarylphosphane oxides, suggested by the Complex Induced Proximity Effect (CIPE),[1] is part of an emerging general class of lithiation-induced regiospecific heterocyclizations,[2] which allows mild and regioselective access to substituted, condensed, and heterocycle-fused phosphininones (Table 1). Moreover, this sparsely investigated class of P-heterocycles,[3] of significance to fundamental



Scheme 1. LDA = lithium diisopropylamide, TMS = trimethylsilyl.

Table 1. Carbanionic route to dibenzo[*b*,*e*]phosphininones. PG = protecting group.

Entry	Substrate	Equiv LDA	Product	Yield [%] [a] (m.p. [°C])
1		2.2		X = NEt2; 81
2		2.2		X = N*i*Pr2; 98[b]
3		3.4	**2**	X = OH; 75 (220-222)[c]
4		2.9		76 (167-167.5)
5		4.0	 **5**	80 (278-279.5)
6		2.2		99 (160-161)
7		2.2	 **3**	PG = OMe; 78 (252-253)
8		2.5		PG = TMS; 41[d] (187-187.5)

[a] Yields are of chromatographed material. [b] With Li(tmp) (tmp = 2,2,6,6-tetramethylpiperidin-1-yl), yield = 87%. [c] Published m.p. 220–222 °C [6a], 222–223 °C [7b], 223 °C [7c]. [d] The product of remote carbamoyl migration, (2-diethylcarbamoylphenyl)(2-hydroxy-3-trimethylsilylphenyl)phenylphosphane oxide, was also obtained in ca. 50% yield.

studies of phosphorus bonding,[4] turnstile geometry,[5] and the aromaticity of phosphacycles,[6] has previously been inaccessible, mainly due to limitations inherent in the classical Friedel–Crafts technology.[4–7] Added interest stems from the current popularity of atropisomeric diarylphosphane ligands (e.g. binap) in asymmetric synthesis and homogeneous catalysis.[8]

Encouraged by documentation on the effective properties of $P(O)Ph_2$ in directing metalation [Directed Metalation Group (DMG) properties],[9] we subjected the carbamoyl triarylphosphane oxides **1a** (R = Et, *i*Pr), prepared by $ClP(O)Ph_2$ treatment of the corresponding *ortho*-lithiated benzamide (Table 1),[10] to lithium diisopropylamide (LDA, 2.2 equiv/THF/0 °C) and observed their smooth cyclization to give the parent dibenzo[*b*,*e*]phorphorinone **2** (Table 1, entries 1 and 2). The recent important observation by Mortier[11] suggested cyclization of the corresponding carboxylic acid, which, in the event, led to the same product in somewhat lower yield (entry 3). In entry 4, the potential competition between three sites for metalation and cyclization to form either phosphininone or two types of fluorenone (arrows a, b, and c) is not observed, and only a phosphininone is obtained. The structure was confirmed by X-ray crystallographic analysis.[12a] Double anionic cyclization of a dicarboxamide-substituted triaryl phosphane oxide (entry 5) leads efficiently (47% overall yield based on starting benzamide) to 5*H*,9*H*-phosphinolino[3,2,1-*de*]-14-λ^5-acridophosphine-5,9,14-trione (**5**), a polycyclic system previously prepared by lengthy Friedel–Crafts approaches (overall yield less than 10%).[4] Its X-ray crystal structure (Fig. 1) shows

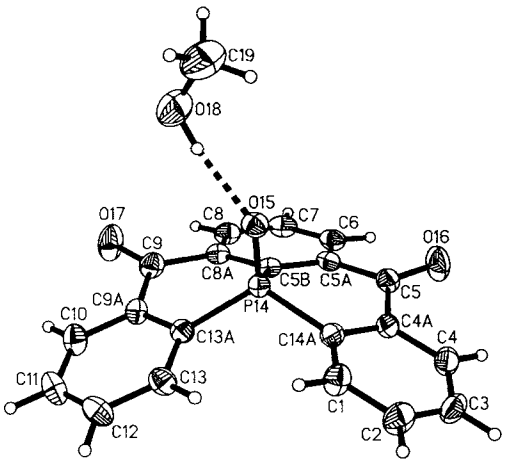

Fig. 1. Structure of **5** in the crystal.

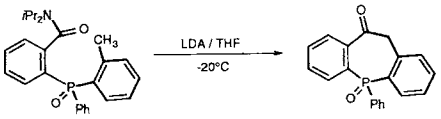
a puckered pentacyclic structure in contrast to the parent **2**, which exhibits only slight deviations from planarity. However, the constraints of the pentacycle reduce pyramidality at phosphorus (sum of C-P-C bond angles, 319.9°; cf. 316.8° in **2**).[12a, b] The scope of this new methodology is illustrated by the preparation in quantitative yield of an indole-fused phosphininone (entry 6), a new ring system.[10, 13]

Tandem remote anionic Fries rearrangement[2a] and anionic Friedel–Crafts reactions are observed on *ortho*-carbamoyloxy triarylphosphane oxides (entries 7,8), leading to hitherto unknown P-phenyl functionalized phosphininones **3** (Scheme 1). The regiochemistry of the second deprotonation leading to intermediate **4** may be dictated by factors of higher electron density in the phenolic ring and OLi ··· O = P coordination effects.

In analogy to observations from other heteroatom-bridged biaryls,[2] the *ortho*-tolyl phosphane oxide **6** (Scheme 2),[14]



Scheme 2.

when subjected to slightly modified cyclization conditions (2.2 equiv LDA/THF/ − 20 °C), furnished the phosphepine **7** (ca. 50% yield), a ring system with meager literature and potential antidepressant activity.[15]

To probe the potential involvement of CIPE[1] in the anionic Friedel–Crafts reaction, **1a** (R = Et) was subjected to LDA (1.1 equiv; THF/0 °C/40 min) to give a mixture of phosphininone **2** and starting material in 61:39 ratio (by ^1H NMR spectroscopy; respectively, 65% and 27% yields of isolated product). Exposure of **1a** (R = Et) to LDA/TMSCl (2.2 equiv/2.5 equiv; THF/ −70 °C → 0 °C) under in situ conditions[16] provided **2** in 58% yield and only trace amounts of silylated material. Thus cyclization appears to be fast with respect to external electrophile trapping under the assumed thermodynamic conditions, but the relative contributions from amide CIPE and P(O)Ph DMG effects require further investigation.

In summary, a general, convenient, and regiospecific entry into benzo[*b*,*e*]phosphininones, including functionalized, polycyclic, and heterocyclic analogues, has been achieved by directed metalation tactics. The chemistry of this P-heteroatom class,[17] previously inadequately explored because of synthetic inaccessibility, may now be investigated, perhaps with emphasis on development of new phosphane ligands for asymmetric synthesis.[18] Furthermore, this and related studies[2] suggest that carbanion-mediated cyclizations may provide fruitful new methodology for the construction of other dibenzoannelated six- and seven-membered ring heterocycles.

Experimental Procedure

2: *N*,*N*-Diisopropylamine (0.21 mL, 1.52 mmol) in dry THF (12 mL) at temperatures below −70 °C under argon was treated with *n*-butyllithium (0.90 mL, 1.61 M solution in hexanes, 1.45 mmol) by dropwise addition, and the mixture was stirred at 0 °C (20 min). (2-Diethylcarbamoylphenyl)diphenylphosphane oxide (250 mg, 0.66 mmol) in THF (3.5 mL) was added dropwise to this solution at be < 2 °C by cannula over 5 min, and the resulting brown suspension was stirred at 0 °C for 30 min. Saturated aqueous NH_4Cl was added, and the mixture extracted with ethyl acetate, washed with brine, dried ($MgSO_4$), and concentrated in vacuo. Purification by column chromatography (97/3 CH_2Cl_2/MeOH eluent) afforded 10-phenyl-9,10-dihydro-10-λ^5-acridophosphine-9,10-dione (163 mg, 81%): colorless needles, m.p. 220–222 °C (MeOH), (published m.p. 220–222 °C, see Table 1); IR (KBR, cm^{-1}): $\tilde{\nu}$: 3055, 1666, 1200; ^1H NMR (250 MHz, $CDCl_3$): δ = 8.49–8.40 (m, 2H), 8.08–7.96 (m, 2H), 7.78–7.68 (m, 4H), 7.64–7.54 (m, 2H), 7.49–7.33 (m, 3H); ^{31}P NMR (81 MHz, $CDCl_3$, ext. ref. $P(OMe)_3$ in C_6D_6): δ = 4.0; MS (EI): *m*/*z* (%): 304 (44) [M^+]; anal. calcd for $C_{19}H_{13}O_2P$: C 75.00; H 4.31; P 10.18. Found: C 75.26; H 4.46; P 9.96.

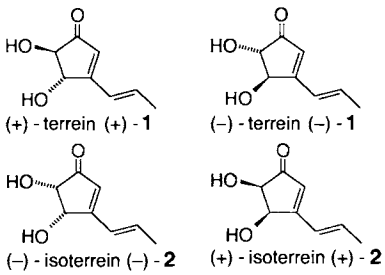
The First Synthesis of Enantiopure (−)- and (+)-Isoterrein from Optically Inactive *meso*-Tartaric Acid**

Marian Mikołajczyk,* Maciej Mikina, Michał W. Wieczorek, and Jarosław Błaszczyk

Dedicated to Professor Leopold Horner on the occasion of his 85th birthday

(+)-Terrein (+)-**1**, a metabolite of the mold *Aspergillus terreus*, was first isolated by Raistrick and Smith in 1935.[1] Twenty years later its correct structure was established independently by Grove[2] and by Barton and Miller,[3] who also determined the configuration of the *trans*-diol moiety by conversion of (+)-**1** into a derivative of (+)-tartaric acid. Although the structure of terrein **1** is simple, its synthesis is not trivial because of its sensitivity to acids and bases. Therefore, only after a lapse of twenty years were three synthetic approaches to racemic terrein **1** reported.[4–6] In addition to the synthesis of **1**, Barton and Hulshof[5] also described the preparation of racemic isoterrein **2**, the more stable isomer of **1**, in which the hydroxyl groups are *cis* oriented.



Only recently, two research groups succeeded in synthesizing optically active terrein. Kolb and Hoffmann[7] prepared first racemic terrein **1** by ring contraction of 6-alkoxy-2,3-dihydro-6*H*-pyran-3-one. Then after resolving racemic precursors of **1**, they completed the total synthesis of natural (+)- and unnatural (−)-terrein. Altenbach and Holzapfel[8] devised an elegant and short synthesis of (+)-**1** from L-(+)-tartaric acid utilizing the chemistry of bis(β-oxophosphonates). The synthesis and reactivity of this new class of phosphonates was independently and intensively investigated in our laboratory.[9] As a result of our studies we report here the first synthesis of both enantiopure forms of isoterrein, (−)-**2** and (+)-**2**.[10]

In developing the strategy for the synthesis of both enantiomers of isoterrein we noted that both (+)-terrein and (+)-tartaric acid used in the synthesis of (+)-terrein have the same configuration at the *trans*-diol moiety. Since isoterrein has a *cis*-diol unit, *meso*-tartaric acid would appear to be a suitable starting material; however, it is optically inactive. Therefore, it was necessary to first seek a way to convert *meso*-tartaric acid into an optically active derivative such that the configurational

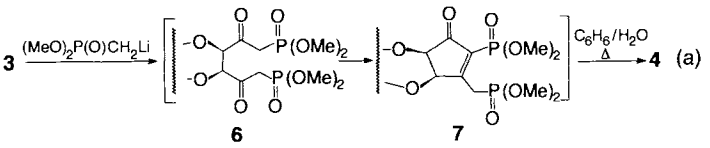
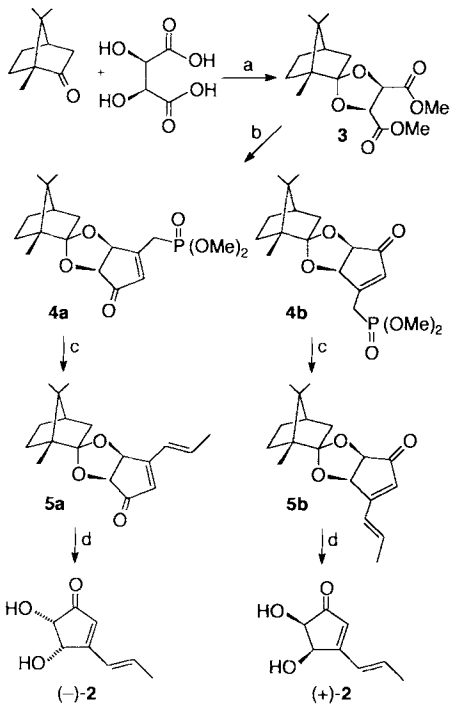
relationship at both chiral carbon atoms is preserved. It was gratifying to find that the acid-catalyzed reaction of *meso*-tartaric acid with (+)-camphor and methyl orthoformate in methanol resulted in the formation of a single diastereomer [m.p. 95 °C (hexane), $[\alpha]_{589} = -2.17$ ($c = 20$ in acetone)] of the protected dimethyl *meso*-tartrate **3** in 76% yield (Scheme 1). The X-ray structure determination of **3** (Fig. 1)[11] revealed that this fully diastereoselective desymmetrization reaction led to the diastereomer with *R* and *S* absolute configuration at C11 and C12, respectively.

Starting from **3**, which is easily available in multigram quantities, both enantiomers of isoterrein **2** were obtained as shown in Scheme 1. Thus, treatment of **3** with dimethyl lithiomethanephosphonate produced the protected 3-phosphonomethylcyclopentenone **4** in 59% yield as a mixture of diastereomers **4a** and **4b** in a 55:45 ratio (^{1}H NMR analysis). In accord with our previous studies[9] this one-pot conversion of **3** to **4** involves initial formation of the bis(β-oxophosphonate) **6**, which undergoes fast cyclization to give the kinetically controlled Knoevenagel product **7** (a mixture of two diastereomers) [Eq. (a)]. The latter is transformed then, without isolation, into the Horner–Wittig product **4** by heating in a basic benzene–water mixture at reflux.





Scheme 1. a) $(MeO)_3CH$, MeOH, H_2SO_4 cat., room temperature (rt), 5 d. b) $(MeO)_2P(O)CH_2Li$ (4 equiv), THF, −78 °C → rt; benzene–H_2O, reflux 3 h, chromatography (silica gel, petroleum ether/acetone 5/1); separation [crystallization from acetone/hexane and chromatography (silica gel, petroleum ether/acetone 5/1)]. c) BuLi, THF, −78 °C, CH_3CHO, rt, 2 h, chromatography (silica gel, petroleum ether/acetone 10/1). d) H_2O/dioxane, aq HCl (36%), 50 °C, 3–4 h, chromatography (silica gel, petroleum ether/acetone 2/1).

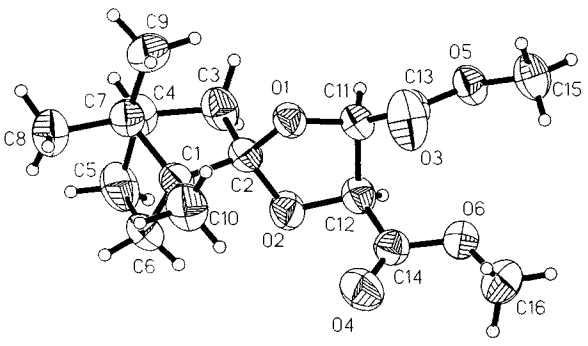


Fig. 1. X-ray crystal structure of **3**. Selected bond lengths [Å] and angles [°]: C2–O1 1.427(3), C2–O2 1.434(4), O1–C11 1.415(4), O2–C12 1.401(4), C11–C12 1.549(3), C11–C13 1.524(4), C12–C14 1.522(3); O1-C2-O2 103.9(2), C2-O1-C11 104.6(2), C2-O2-C12 109,6(2), O1-C11-C12 102.0(2), O2-C12-C11 103.5(2), O1-C11-C13 110.1(2), O2-C12-C14 110.8(2).

Fractional crystallization from hexane/acetone and subsequent column chromatography led to separation of the pure diastereomers **4a** [m.p. 112 °C, $[\alpha]_{589} = -19.7$ ($c = 6$ in acetone)] and **4b** [m.p. 103 °C, $[\alpha]_{589} = +5.4$ ($c = 5.8$ in acetone)]. X-ray crystal structure determinations carried out on single crystals of both **4a** (Fig. 2)[11] and **4b** indicated unequivocally

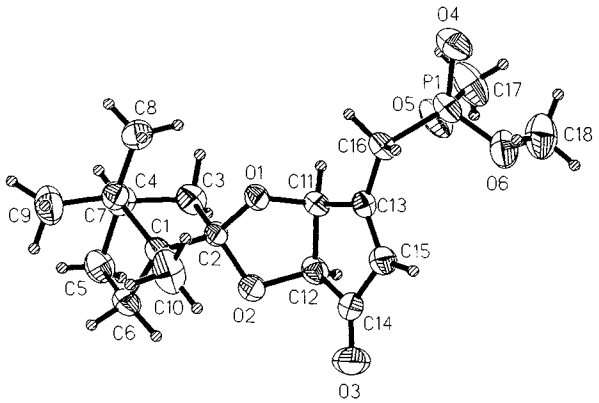

Fig. 2. X-ray crystal structure of **4a**. Selected bond lengths [Å] and angles [°]: C(2)–O1 1.431(3), C2–O2 1.443(4), O1–C11 1.428(4), O2–C12 1.411(3), C11–C12 1.543(3), C11–C13 1.517(3), C12–C14 1.526(4), C13–C15 1.337(4), P1–O4 1.455(3); C12–C14 1.526(4); O1-C2-O2 104.1(2), C2-O1-C11 106.3(2), C2-O2-C12 108.0(2), O1-C11-C12 102.2(2), O2-C12-C11 105.9(2), O1-C11-C13 109.3(2), O2-C12-C14 111.8(2).

that the configurations of the diol moieties in **4a** and **4b** are 11*S*,12*S* and 11*R*,12*R*, respectively. The Horner–Wittig reaction of **4a** with acetaldehyde furnished the protected isoterrein **5a** [m.p. 39–42 °C, $[\alpha]_{589} = -135$ ($c = 5.38$ in hexane)] in 62% yield. Similarly, **3b** afforded the corresponding dienone **5b** [m.p. 144.5–145.5 °C, $[\alpha]_{589} = +142.5$ ($c = 1.19$ in hexane)]. Deprotection of the diol moiety in **5a** and **5b** by acidic hydrolysis afforded in 80% yield both (−)-**2** [m.p. 122–123 °C, $[\alpha]_{589} = -113$ ($c = 2.31$ in acetone)] and (+)-**2** [m.p. 122–122.5 °C, $[\alpha]_{589} = +111$, ($c = 2.19$ in acetone)] in enantiopure form.[12] Since in the last two steps the chiral diol fragment is not affected, (−)-**2** can be assigned the *S*,*S* configuration, and (+)-**2** the *R*,*R* configuration.

It is interesting to note that in the ^{1}H NMR spectra (200 MHz, $CDCl_3$) of the enantiomerically pure isoterreins **2** in addition to the characteristic coupling between the *cis* protons ($J = 5.7$ Hz)[13] further coupling of these protons with the hydroxyl protons is evident visible ($J = 3.1$ and 3.2 Hz). Accordingly, the resonance signals of the hydroxyl protons appear as

Table 1. Selected spectroscopic data for compounds **2**–**5** [a].

2: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.76 (dq, 1H, J = 15.7, 6.7 Hz, =CH(CH_3)), 6.51 (dd, 1H, J = 15.7, 1.4 Hz, =CH), 6.00 (s, 1H, =CH), 5.00 (dd, 1H, J = 5.7, 3.1 Hz, CH), 4.18 (dd, 1H, J = 5.7, 3.2 Hz, CH), 3.09 (d, 1H, J = 3.2 Hz, OH), 2.97 (d, 1H, J = 3.1 Hz, OH), 1.99 (dd, 3H, J = 6.7, 1.4 Hz, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 206.1, 170.1, 140.5, 126.3, 126.0, 71.9, 68.2, 19.3

3: ^{1}H NMR ($CDCl_3$, 200 MHz): δ = 4.78 (d, 1H, J = 7.6 Hz, CH), 4.64 (d, 1H, J = 7.6 Hz, CH), 3.73 (s, 3H, CH_3O), 3.72 (s, 3H, CH_3O), 1.9–2.1 (m, 2H), 1.6–1.8 (m, 2H), 1.35–1.55 (m, 2H), 1.1–1.3 (m, 1H), 0.99 (s, 3H, CH_3), 0.91 (s, 3H, CH_3), 0.86 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 171.3, 168.5, 120.5, 75.8, 74.2, 72.9, 52.1, 51.9, 44.9, 44.0, 43.2, 29.6, 26.7, 20.3, 20.0, 9.3

4a: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.02 (d, 1H, J = 4.3 Hz, =CH), 5.20 (dd, 1H, J = 5.4, 3.1 Hz, CH), 4.32 (d, 1H, J = 5.4 Hz, CH), 3.79 (d, 6H, J = 11.1 Hz, CH_3O), 3.06 (d, 1H, J = 22.4 Hz, PCH), 3.03 (d, 1H, J = 23.7 Hz, PCH), 1.1–2.1 (m, 7H), 0.95 (s, 3H, CH_3), 0.81 (s, 3H, CH_3), 0.63 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 199.7 (d, J = 2.6 Hz), 166.4 (d, J = 9.9 Hz), 131.0 (d, J = 9.1 Hz), 124.1, 79.8 (d, J = 3.4 Hz), 75.5, 52.8 (d, J = 11.7 Hz), 52.7 (d, J = 11.2 Hz), 49.4 (d, J = 181.1 Hz), 44.8, 44.2, 29.1, 28.4, 26.4, 25.6, 20.0, 19.8, 9.1; ^{31}P NMR (81 MHz, $CDCl_3$): δ = 25.5

4b: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.04 (d, 1H, J = 4.3 Hz, =CH), 5.07 (dd, 1H, J = 5.5, 2.9 Hz, CH), 4.46 (d, 1H, J = 5.5 Hz, CH) 3.80 (d, 3H, J = 11.1 Hz, CH_3O), 3.79 (d, 3H, J = 11.1 Hz, CH_3O), 3.07 (d, 1H, J = 22.5 Hz, PCH), 3.05 (d, 1H, J = 23.7 Hz, PCH), 1.10–2.15 (m, 7H), 0.97 (s, 3H, CH_3), 0.82 (s, 3H, CH_3), 0.63 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 199.9, 165.9 (d, J = 10.2 Hz), 131.1 (d, J = 8.8 Hz), 123.9, 77.8 (d, J = 3.7 Hz), 77.1, 52.6 (d, J = 7.4 Hz), 52.5 (d, J = 8.5 Hz), 49.2 (d, J = 188.4 Hz), 44.7, 44.0, 29.3, 28.3, 26.4, 25.5, 19.9, 19.8, 8.8; ^{31}P NMR (81 MHz, $CDCl_3$): δ = 25.5

5a: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.70 (dq, 1H, J = 15.7, 6.7 Hz, =CH(CH_3)), 6.45 (d, 1H, J = 15.7 Hz, =CH), 5.79 (s, 1H, =CH), 5.27 (d, 1H, J = 5.8 Hz, CH), 4.33 (d, 1H, J = 5.8 Hz, CH), 1.96 (d, 3H, J = 6.7 Hz, CH_3), 1.1–2.2 (m, 7H), 0.97 (s, 3H, CH_3), 0.82 (s, 3H, CH_3), 0.62 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 200.8, 168.2, 140.3, 126.2, 125.8, 123.6, 77.6, 75.9, 53.6, 51.2, 47.5, 44.8, 44.1, 29.0, 26.5, 20.0, 19.1, 9.0

5b: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.68 (dq, 1H, J = 15.7, 6.8 Hz, =CH(CH_3)), 6.47 (dd, 1H, J = 15.7, 1.3 Hz, =CH), 5.81 (s, 1H), 5.13 (d, 1H, J = 5.8 Hz, CH), 4.47 (d, 1H, J = 5.8 Hz, CH), 1.98 (dd, 3H, J = 6.8, 1.3 Hz, CH_3), 1.1–2.15 (m, 7H), 0.99 (s, 3H, CH_3), 0.82 (s, 3H, CH_3), 0.64 (s, 3H, CH_3); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 201.5, 168.1, 140.6, 126.7, 126.1, 124.1, 77.9, 75.9, 51.6, 47.8, 45.2, 44.5, 29.7, 26.9, 20.4, 20.2, 19.3, 9.3

[a] All compounds described here provided correct C,H,P analytical data.

doublets at δ = 2.97 and 3.09. This indicates that the proton exchange in **2** is very slow. Moreover, the ^{1}H NMR spectrum of (−)-**2** measured in the presence of (+)-(*R*)-*tert*-butyl(phenyl)phosphinothioic acid as a chiral solvating agent confirmed its full enantiomeric purity.[14]

In summary, we have developed a short and efficient synthesis of both enantiomers of isoterrein **2** from the easily accessible, optically active derivative of *meso*-tartaric acid **3**. The latter as well as the diastereomeric 3-phosphonomethyl cyclopentenones **4** are promising precursors of other biologically active, chiral, nonracemic cyclopentanoids. Further studies in this direction are in progress.

Alkylation of 1-Naphthol with Alcohols over an Iron Oxide Catalyst **

Hanna Grabowska, Włodzimierz Miśta, Ludwik Syper, Józef Wrzyszcz,* and Mirosław Zawadzki

The two naphthol isomers, 1- and 2-naphthol, are commonly used as intermediates in the production of azo dyes, pigments, insecticides, and drugs. The selective alkylation of these compounds is an important reaction in industrial organic chemistry, and there is increasing pressure to find cleaner, more environmentally friendly methods. Heterogeneous catalysis is one possibility.

When Brinner et al. and Plüss alkylated naphthols with methanol in the presence of Al_2O_3, they obtained oils containing methylnaphthalenes.[1] When higher alcohols were used longer chain alkyl derivatives of naphthols formed. The alkylation of naphthols with methanol in the presence of Al_2O_3 of varying acidity was systematically investigated by Klemm et al.[2] Depending on reaction temperature, four types of products formed: naphthyl ethers (O-alkylation), methylated naphthols, methylated oxodihydronaphthalenes, and methylnaphthalenes. The complex product mixtures could not be separated or used in further applications.

In studies conducted in the 1970s phenol was methylated to yield *ortho*-cresol and 2,6-dimethylphenol with catalysts consisting mainly of Fe_2O_3 or Cr_2O_3.[3-5] Many other formulations based on these fundamental systems have also been investigated.[6, 7] Inoue and Enomoto[8] employed a Fe_2O_3 catalyst for the alkylation of 1-naphthol with methanol and obtained 2-methyl-1-naphthol in 57% yield and with 100% selectivity. These experiments were carried out in the liquid phase in an autoclave under a pressure of about 100 bar.

We report here that an oxide catalyst composed of mainly iron and additives of chromium, silicon, and potassium can mediate the alkylation of 1-naphthol with methanol carried out in a flow system to provide 2-methyl-1-naphthol in 90% yield. The main component can be separated easily from the product mixture.[9]

During experiments lasting 500 h resin- or tar-type deposits did not form or accumulate on the iron catalyst. When the experiments were interrupted, the reactor allowed to cool, and the system restarted, a stationary equilibrium was again established within roughly one hour and results identical to those recorded previously were obtained. The catalyst can be regenerated repeatedly without loss of activity by passing air through the catalyst bed heated at 743 K. The main component of the catalyst, α-Fe_2O_3, was reduced when the catalyst bed was treated with alcohol vapors or an alcohol solution of 1-naphthol starting at 473 K. During the reduction α-Fe_2O_3 is transformed into magnetite. The oxidative regeneration causes partial oxidation of magnetite into hematite. Owing to the high yield per pass, with liquid hourly space velocities (LHSV) of 1.5–3.0 $L L^{-1} h^{-1}$, 1 L of catalyst can furnish about 250–500 g of products per hour. This indicates the possibility of industrial-scale applications.

The alkylation of 1-naphthol begins at 520 K and accelerates with increased temperature. Up to 570 K the yield of the 2-alkyl-1-naphthol products amounts to more than 50%, and the selectivity of their formation is close to 100%. At higher temperatures 4-alkyl- and 2,4-dialkyl derivatives of 1-naphthol are also formed, albeit in low yield. The products obtained at higher reaction temperatures (640–660 K) also contain trace amounts of compounds having alkyl chains shorter than that of the alcohol used for alkylation.

Figure 1 shows the temperature dependence of the yield of the reaction products and the selectivity of the formation of the main product in the alkylation of 1-naphthol with ethanol. 2-Ethyl-1-naphthol (**1a**) is formed with a yield exceeding 95% and a selectivity of 95–96%. The reaction mixture also contains 4-ethyl-1-naphthol (**2a**) (up to 4%), traces of 2-methyl-1-naphthol (less than 1%), and 2,4-diethyl-1-naphthol (**3a**) in the amounts indicated in the figure. It is interesting that in the presence of the catalyst only C-alkylation occurs. In the whole range of temperatures investigated formation of ethers as a result of O-alkylation was not observed.

Table 1 shows the results of the alkylation of 1-naphthol with ethyl alcohol at different loads and with different molar ratios

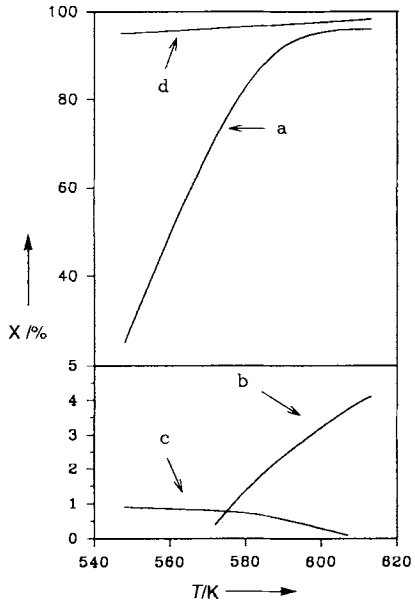

Fig. 1. Alkylation of 1-naphthol with ethyl alcohol. Molar ratio 1-naphthol:alcohol = 1:10, LHSV = 1.5 $L L^{-1} h^{-1}$; X = yields of **1a** (curve a), **2a** (b), **3a** (c), and selectivity for formation of **1a** (d).

Table 1. Results of the alkylation of 1-naphthol with ethyl alcohol at different reaction parameters.

Reaction temp. [K]	608	614	616	616
Molar ratio 1-naphthol:alcohol	1:10	1:10	1:5	1:5
LHSV[$L L^{-1} h^{-1}$]	1.5	3.0	1.5	3.0
Conversion of 1-naphthol[%]	≈100	99.3	99.1	93.1
Selectivity of formation of main product **1a**[%]	96.7	96.8	96.6	97.7
Product components[%]				
2-methyl-1-naphthol	traces	traces	0.4	0.1
2-ethyl-1-naphthol (**1a**)	96.7	96.1	95.7	91.0
4-ethyl-1-naphthol (**2a**)	3.2	3.1	0.4	traces
2,4-diethyl-1-naphthol (**3a**)	traces	–	2.6	1.9
unidentified	0.1	0.1	–	0.1

of reactants. The yield and selectivity of the formation **1a** were not influenced significantly by changes in the load and composition of starting materials. At a molar ratio of 1-naphthol to ethanol of 1:5 the diethyl product **3a** was predominant. The data presented indicate that the selectivity of this reaction can be improved by appropriate choice of parameters.

The product fraction with a boiling point lower than that of 1-naphthol contains mainly unreacted alcohol and traces of aldehydes, ketones, and esters. At reaction temperatures over 620 K naphthalene is also among the products.

1-Naphthol was also alkylated with *n*-propyl and *n*-butyl alcohol in the temperature range of 540–680 K. Table 2 lists the results of experiments carried out under different parameters in which highly selective alkylation was observed in the 2-position. In both cases the corresponding 2-alkyl derivatives **1b** and **1c** were obtained in yields exceeding 85% and with selectivities of about 90%. Small amounts of the 4-alkyl derivatives **2b** and **2c**, the 2,4-dialkyl compounds **3b** and **3c**, 2-methyl-1-naphthol, and **1a** were also detected in the reaction mixture. The last two compounds could have been formed by thermal decomposition

Table 2. Results of the alkylation of 1-naphthol with *n*-propyl and *n*-butyl alcohol at different reaction parameters.

unidentified	3.2	2.0	1.5	1.5

of the main products. In analogy to the alkylation of 1-naphthol with ethanol, O-alkylation yielding ethers did not occur. Some products found in trace amounts were not identified.

When higher alcohols were used as alkylating agents, the yield and selectivity of the reaction decreased with increasing chain length. In the case of *n*-pentanol up to 80% yield of 2-*n*-pentyl-1-naphthol (**1d**) was obtained, but the reaction with *n*-hexanol furnished 2-*n*-hexyl-1-naphthol in only 25% yield. The latter reaction also afforded significant amounts of undecanone-6 and the ester $C_6H_{13}CO_2C_5H_{11}$, which formed from alcohol by aldol condensation[10, 11] and Tishchenko reaction,[12, 13] respectively. Since *n*-hexanol and higher alcohols react above all with each other, the amount of alkylated product decreases.

We have also found that 1-naphthol reacts with primary branched alcohols to furnish the *ortho*-alkylated products in low yields and selectivities, and that secondary alcohols are inactive in this reaction.

An explanation of the high activity and selectivity of the iron oxide catalyst in the alkylation of 1-naphthol is that the alcohols are transformed into reactive electrophiles by β-hydride transfer.[14, 15]

In general the selectivity of oxide catalysts is governed by how naphthol is adsorbed on the catalyst surface, which depends on the surface acidity. On more acidic catalysts the naphthols rings take a position parallel to the surface, thus decreasing the likelihood of substitution in the *ortho* position, and as a result many products are formed. In the case of catalysts in which a basic function predominates, the naphthol rings assume a position vertical to the surface. Attack in the *ortho* position is thus preferred and the formation of ethers and others naphthol derivatives is excluded.[16, 17]

Experimental Procedure

The catalyst consisted of iron, silicon, chromium, and potassium oxides in the molar ratio 100:2:1:0.1. Chromium and silicon were used as additives to prevent sintering, and potassium served as an activator [18].

Preparation of catalyst: A solution of 202 g of $Fe(NO_3)_3 \cdot 9H_2O$ in 0.5 L of water and a solution of 2 g of $Cr(NO_3)_3 \cdot 9H_2O$ in 12.5% aqueous ammonia were prepared separately and introduced simultaneously to a vessel containing 0.5 L of water. The mixture was maintained at pH 7 and stirred vigorously at room temperature for ca. 1 h. Then a solution of sodium silicate (3.4 g containing 27% SiO_2) in 100 cm^3 of water was added. After 2 h of stirring the precipitate was filtered off and washed with water to remove nitrate ions. The obtained solid was dried at 383 K for 24 h, powdered, and pelletized with addition of 3 wt%. The pellets were crushed and sieved to give particles with diameters of 0.6–1.2 mm. A 50 g portion of these particles was impregnated with a solution of 0.05 g of K_2CO_3 in 30 cm^3 of water, then dried and calcined at 723 K for 5 h in air. Some of the physico-chemical properties of the catalyst are given in Table 3.

Table 3. Important properties of the catalyst.

	Catalyst		
	Fresh	Used	Regenerated
Iron oxide phases[a]	α-Fe_2O_3	Fe_3O_4	α-Fe_2O_3, Fe_3O_4

[a] From X-ray diffraction and magnetic measurements.

The alkylation reactions were carried out at atmospheric pressure in flow reactors with a fixed bed of 30 g or 3 g of the catalyst. After condensation the reaction products were analyzed chromatographically (FID detector, columns: Silicon Oil DC550 on Chromosorb W and Silicone OV-1 on Chromosorb W-AW-DMCS). Samples were additionally analyzed using a gas chromatograph (HP 5890A) coupled with a mass spectrometer (HP 5971A with a mass-selective detector).

The main products were isolated from the products mixture by middle-pressure column chromatography with silica gel (Kieselgel 60 finer than 230 mesh "Merck") as the adsorbent and mixtures of CH_2Cl_2/petroleum ether 3:7 and 5:5 as eluant. The amounts of isolated main products (**1a–1d**) were in good agreement with the results obtained by GC. The products were further purified by crystallization from hexane. **1a**: M.p. 70–71 °C, **1b**: M.p. 47–48 °C, **1c**: M.p. 73–74 °C, **1d**: M.p. 57–58 °C. The identity of the compounds was confirmed by comparing their melting points and spectroscopic properties (IR, MS, and NMR) with those of authentic samples, which were prepared as follows: 1-Methoxy-naphthalene was *ortho*-lithiated and reacted with appropriate alkyl iodide [19, 20]. The methoxymethyl group was removed by treatment with hydrogen chloride in a methanol–water mixture.

Compounds **2a–c** and **3a–c** were identified by GC using synthetized standards and in addition by means of their MS spectra. Compounds **2a–2c** were obtained from 1-methoxy-4-naphthaldehyde [21], which was reacted with the appropriate alkyl Grignard reagent. The resulting alcohols were reduced with a mixture of $LiAlH_4$ and $AlCl_3$ [22]. The final naphthols were generated by treating suitable methyl ethers with BBr_3 in dichloromethane. Compounds **3a–3c** were obtained from **2a–c** by the procedure described for **1a–c**. 2-Methyl-1-naphthol was obtained earlier [15] by alkylation of 1-naphthol with methanol.

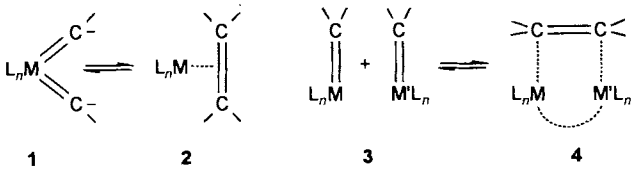
Intermolecular Carbene–Carbene Coupling of a Nucleophilic Vinylidene and an Electrophilic 1-Methoxyethylidene Ligand**

Rüdiger Beckhaus,* Jürgen Oster, Rhett Kempe, and Anke Spannenberg

Dedicated to Professor Max Herberhold on the occasion of his 60th birthday

The formation and cleavage of carbon–carbon bonds is one of the basic problems in organometallic chemistry. Experimentally and theoretically intriguing are both intramolecular coupling of carbene ligands forming olefinic species (**1** → **2**) and the possibility of breaking carbon–carbon double bonds in the coordination sphere of transition metals (**2** → **1**).[1–6] Examples for intermolecular C–C coupling (**3** → **4**) on a heterodinuclear complex fragment are still unknown.[7]



1 **2** **3** **4**

Our investigations concerning the titanaallene species [Cp$^*_2$Ti=C=CH$_2$] (**5**), preferably generated by selective methane elimination from [Cp$^*_2$Ti(CH=CH$_2$)CH$_3$] (**6**) demonstrate the nucleophilic character of the α-carbon atom in **5**, which is responsible for the regiochemistry observed in the preparation of cycloaddition product **7**[8] and for the reactions of **5** with electrophiles.[8e, 9] Here we contrast the reactivity of **5** with that of a classical Fischer-type carbene complex exhibiting an inverse M=C polarity.

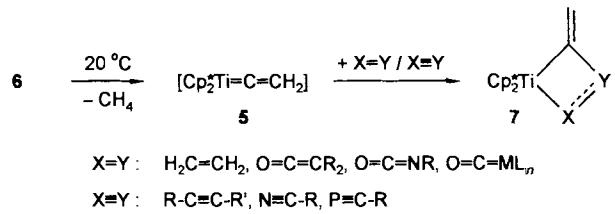
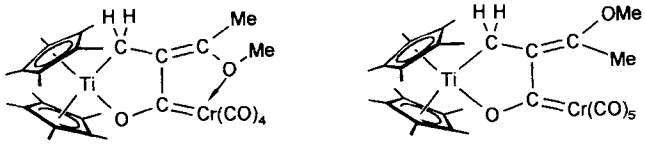
[**] This work was supported by the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. G. E. Herberich for his continuing interest and Prof. Dr. U. Rosenthal and his co-workers for the X-ray structure determination. Stimulating remarks from the referees are gratefully acknowledged.



Treatment of [(CO)$_5$Cr=C(OCH$_3$)CH$_3$] (**8**) with **6** in *n*-hexane at a temperature between −30 and 25 °C gives the new heterodinuclear complexes **9** and **10** by an unusual coupling of the Fischer-carbene complex **8** with the intermediate Schrock-carbene complex **5**. The C–C bond formation occurs between carbon atoms of vinylidene, carbene, and carbonyl ligands. After chromatographic workup the separated complexes **9** and **10** can be isolated as air-stable red crystals. Cycloaddition products of type **7**, for example those typical with metal carbonyls,[8c] were not detected.



9 **10**

The constitution of **9** and **10** follows from NMR and IR spectroscopic data. The carbene carbon atoms show typical resonances at δ = 336.7 (**9**) and 328.0 (**10**). Characteristic differences can be noted for the substituents of the C=C bond and for the Cr(CO)$_n$ fragment. As a result of the change of configuration at the exocyclic double bond, the methyl resonance shows a remarkable shift from δ = 1.90 (**9**) to 2.89 (**10**) in the ^{1}H NMR spectra. The methoxy coordination is documented by the shift of the OCH$_3$ carbon resonance to lower field (δ = 65.6 (**9**), 54.6 (**10**)). In the infrared spectra of **9** typical signals for a C_{2v} symmetry are observed, whereas a C_{4v} pattern can be detected for the Cr(CO)$_n$ fragment of **10**.

The X-ray structure determination of **9** shows two symmetry-independent molecules (**9**, **9'**) in the asymmetric unit (Fig. 1,

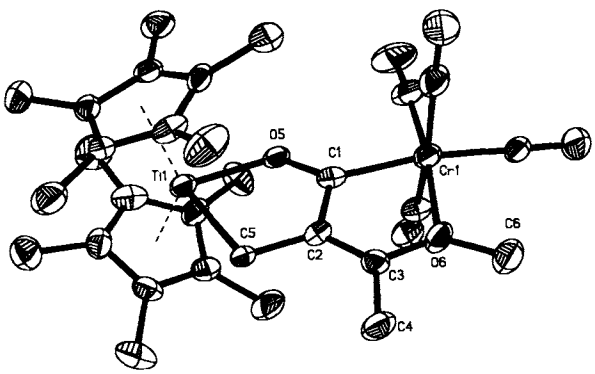


Fig. 1. Molecular crystal of **9**, selected distances [Å] and angles [°] (Cp(1) and Cp(2) represent the centers of the Cp* ligands of the titanocene fragment; in square brackets values of **9'**: Ti–Cp(1) 2.105 [2.114], Ti–Cp(2) 2.090 [2.108], Ti–C5 2.202(7) [2.187(7)], Ti–O5 2.002(5) [2.008(5)], O5–C1 1.299(8) [1.288(8)], C1–C2 1.506(9) [1.465(9)], C5–C2 1.506(9) [1.527(8)], C2–C3 1.337(10) [1.325(9)], C3–C4 1.512(9) [1.483(9)], C3–O6 1.381(8) [1.400(7)], O6–C6 1.470(9) [1.447(8)], O6–Cr 2.204(5) [2.182(5)], C1–Cr1 2.020(8) [2.025(8)]; C5-Ti-O5 78.8(2) [80.1(2)], Ti-O5-C1 125.8(4) [122.6(4)], O5-C1-C2 110.1(7) [113.4(6)], C5-C2-C1 118.4(7) [118.2(6)], C6-O6-C3 121.2(6) [119.1(6)], C4-C3-O6 116.6(7) [118.1(7)].

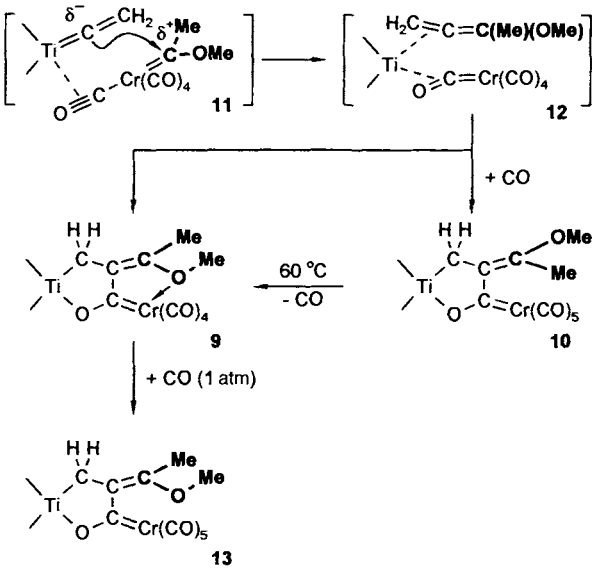
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1565 $ 15.00+.25/0

data for **9'** are given in brackets).[10] The formation of a chelate ring by OCH_3 coordination leads to a distortion of the octahedral symmetry at the chromium center. Noteworthy in this connection is a small O6-Cr-C1 angle of 76.1(3)°. The Cr–O6 distance of 2.204(5) [2.182(5)] Å is similar to that of bonds in anisyl–carbene complexes[11] and significantly longer than the Cr–O bond in $[(CO)_5Cr(thf)]$ (2.123(3) Å).[12] A Cr–C1 distance of 2.020(8) [2.025(8)] Å can be related to short carbene bonds;[13] acyl resonance forms[14] for **9** can be neglected. In agreement with this, a C1–O5 distance of 1.299(8) [1.288(8)] Å is found. The planes of the bicyclic system are almost coplanar (max. deviation < 0.06 Å).

The formation of the reaction products **9** and **10** is in accordance with a carbene–carbene coupling via the intermediate allene complex **12**.[15] This reaction step can be explained by the



primary interaction of the nucleophilic and the electrophilic carbene carbon atoms shown in **11**, which is supported by coordination of CO to the oxophilic titanium center. Titanium-centerd cycloaddition of the allene molecule with the remaining $Cr(CO)_5$ fragment leads directly to **9** and, after fast CO addition from **8**, to **10**. ^{1}H NMR spectroscopy confirms that **10** is the preferred product rather than **9** (**10**:**9** = 4:1).

Under a CO atmosphere the OCH_3 coordination to the Cr center is reversed, and **13** is formed. In solution **10** can be converted thermally (60 °C) into **9** by elimination of one CO. This reaction is much faster in the presence of PMe_3. No products could be isolated because of the lability of these phosphane adducts. However, the substitution of one CO ligand by PMe_3 is detectable spectroscopically. The formation of an equilibrium between **10** and **12** or the removal of the exocyclic C=C double-bond character by contribution of ionic resonance forms of the vinylcarbene moiety[16] can explain the isomerization of the double-bond system during thermolytic formation of **9** from **10**. The conversion of **13** into **10** is not observed.

The described reaction represents, to our knowledge, the first example of an intermolecular coupling of inversely polarized carbene ligands. The metal-centered coupling of several carbon atoms of different substrates[17] is thereby enlarged by an additional reaction type, which opens up a new potential for synthesis.

Experimental Procedure

9 and **10**: *To a solution of* **6** *(280 mg, 0.778 mmol) in n-hexane (40 mL) was* added **8** (140 mg (0.560 mmol) [18] at −30 °C. After warming to room temperature the reaction mixture was stirred for 3 h. The color changed from yellow to red, and **9**/**10** was obtained as a red-brown precipitate. The solid was dissolved in CH_2Cl_2 (3 mL) and chromatographed on alumina (neutral, 100–125 mesh). With *n*-hexane a yellow solution of unchanged **8** was obtained. Elution with CH_2Cl_2/*n*-hexane (3/1) produced a red solution of **10**. After further elution with tetrahydrofuran a red solution of **9** can be separated. The volume of the solvent was reduced to 2 mL in vacuo. Addition of *n*-hexane (10 mL) gave **9** and **10** as red solids. Crystallization from benzene afforded red crystals of the products.

9: Red crystals, yield 90 mg, 27%, correct elemental analysis. IR (KBr): $\tilde{\nu}$ = 1987 s, 1873 sh, 1865 vs, 1821 s (CO), 1341 cm^{-1} s. IR (CH_2Cl_2): $\tilde{\nu}$ = 1994 s, 1878 vs, 1828 s, 1343 cm^{-1} s. ^{1}H NMR ($CDCl_3$, 500 MHz, 25 °C): δ = 1.87 (s, 2H, CH_2), 1.90 (s, 3H, CH_3), 1.96 [s, 30H, $C_5(CH_3)_5$], 3.97 (s, 3H, OCH_3). ^{1}H NMR (C_6D_6, 500 MHz, 25 °C): δ = 1.26 (s, 3H, CH_3), 1.72 [s, 30H, $C_5(CH_3)_5$], 1.77 (s, 2H, CH_2), 3.34 (s, 3H, OCH_3). ^{13}C{^{1}H} NMR ($CDCl_3$, 125 MHz, 25 °C): δ = 12.1 [$C_5(CH_3)_5$], 13.0 (CH_3), 55.7 (CH_2), 65.3 (OCH_3), 125.7 [$C_5(CH_3)_5$], 145.9 [C=$CCH_3(OCH_3)$], 169.3 [C=$CCH_3(OCH_3)$], 218.8, 230.3, 235.4 [*cis*-$Cr(CO)_4$], 336.7 (C=Cr). Epothilone A and B—Novel 16-Membered Macrolides with Cytotoxic Activity: Isolation, Crystal Structure, and Conformation in Solution**

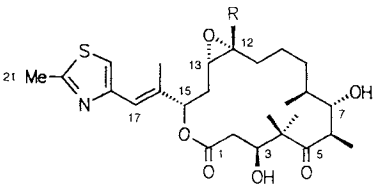
Gerhard Höfle,* Norbert Bedorf, Heinrich Steinmetz, Dietmar Schomburg, Klaus Gerth, and Hans Reichenbach

Myxobacteria of the genus *Sorangium* have proved in the last few years to be extremely versatile producers of biologically active secondary metabolites.[1] This diversity is true both for the basic structures, which are generally new, and for the biological effects and their underlying mechanisms. Sorangia very frequently produce antifungal compounds, which may be explained by the fact that these cellulose-degrading organisms have to compete with fungi for the same ecological niche. Also, the *Sorangium cellulosum* strain So ce90 was identified during screening by its antifungal activity, which guided the isolation of two new, structurally unrelated classes of compounds, the epothilones **1**[2, 3] and the spirangiens.[4] When isolated in the pure form, epothilones A and B (**1a** and **1b**, respectively) showed broad activity against eukaryotic cells; the efficiency of the methyl derivative B was mostly a factor of 2 greater than that of the derivative A.



1a R = H

1b R = CH_3

The antifungal activity of **1** against oomycetes (*Plasmopara viticola*, *Phytophthora infestans*), in vitro and in the greenhouse,[5] is noteworthy, as is its cytotoxicity against mouse fibroblasts (cell line L929, **1b**: IC_{50} 2 ng mL^{-1}), which results in disintegration of the cell nucleus and r apoptosis (programmed cell death) within three days.[3] The epothilones also showed noticeable activity and selectivity against breast and colon tumor cell lines in the in vitro antitumor screening program of the National Cancer Institute (NCI).[6, 7] In addition, epothilones were discovered independently by Bollag et al. by a tubulin polymerization assay.[8] This assay, and subsequent detailed studies of their cytotoxicity and inhibition of mitosis show that the epothilones have an almost identical activity and mode of

[**] Antibiotics from Gliding Bacteria, Part 77. Part 76: D. Schummer, E. Forche, V. Wray, T. Domke, H. Reichenbach, G. Höfle, *Liebigs Ann.* **1996**, 971–978. We thank Dr. A. Ross and colleagues at the Bio Pilot Plant of the GBF for help with fermentations, Dr. V. Wray and colleagues from Instrumental Analytics Group for recording the NMR and mass spectra, and B. Pluta, A. Ritter, and K. Schicht for technical assistance. This work was supported by the Fonds der Chemischen Industrie.

action to that of taxol and, according to the results of displacement experiments, apparently compete for the same binding site on microtubules. These discoveries resulted in much interest in the production of epothilones, their three-dimensional structure, and potential homology to taxol, which will be reported herein.

For the synthesis of the epothilones on a gram scale, the extract (46 g) from 230 L of production strain culture[3] is fractionated on Sephadex LH-20 (20 × 100 cm column, 20 mL min^{-1} methanol). Chromatography of the epothilone-containing fractions (R_t = 265–295 min, 12 g) on RP-18 silica gel (Prep-bar system, Merck, 40 × 10 cm column, 180 mL min^{-1} methanol/water 3:1) and rechromatography of the mixed fractions gave a total of 4.8 g epothilone A (**1a**) and 2.1 g epothilone B (**1b**), as colorless oils. Both compounds crystallize on trituration with ethyl acetate.

Elemental analysis and physical data give the empirical formula $C_{26}H_{39}NO_6S$ for **1a** and $C_{27}H_{41}NO_6S$ for **1b**, and ^1H and ^{13}C NMR spectra (Tables 1 and 2) and their 2D correlation are

Table 1 Physical and spectroscopic data for compounds **1a** and **1b**.

in agreement with the epothilone structures. This was confirmed by an X-ray structural analysis of **1b**,[9] which also gave the absolute configuration of the eight stereogenic centers (Fig. 1).[10] The crystals obtained from dichloromethane (spatial group $P2_1$) contain two molecules of **1b** and a disordered molecule of dichloromethane in the unit cell. Intermolecular hydrogen bonds are present between 3-OH and the epoxide oxygen atom, and between 7-OH and the C-5 carbonyl group. The carbon backbone of the macrocycle is largely flat, with maximum deviation from the best-fit plane for C-6 (– 0.96 Å) and C-3 (0.85 Å). The methyl groups C-22, C-25, and C-26 adopt an approximately axial position and the side chain with the thiazole ring an equatorial position; 1,3-diaxial interactions are avoided. Only the *cis* configuration of the epoxide[11] produces strain that the molecule cannot avoid.

Information about the conformation in solution was obtained from the vicinal coupling constants of the ring protons, which are compared to the values expected for the crystal structure in Table 2.[12] Since the expected and measured values are consistent, it can be concluded that the conformation of **1a** and **1b** in solution is similar to that in the crystal.[13] Significantly higher values than expected are only found in the spin system 2-H$_2$/3-H with $J_{2b,3}$ = 3.0 (**1a**) and 4.5 Hz (**1b**). Since the neighboring C atoms do not carry protons, it is not possible to give a more exact description of the difference in conformation in this ring segment.

Larger variations can be ruled out, however, since the NOE relations given in Figure 2 are in good agreement with the presumed conformation. There is apparently no preferred conformation for the side chain with the thiazole moiety. In addition, the NOE effects confirm the assignment of the proton signals and indirectly confirm the ^{13}C NMR assignments in Tables 1 and 2. ^1H NMR experiments with **1b** in [D$_4$]methanol and [D$_6$]DMSO with addition of 10 to 50 vol% D$_2$O indicate that the original conformation is maintained in biological media.

A number of structural similarities are apparent on comparison of the epothilones with taxol: both compounds contain a geminal dimethyl group, a β-hydroxyoxo unit, and a small ether ring. Also, the size of the 14-membered perimeter of the diterpene part of taxol corresponds approximately to that of the

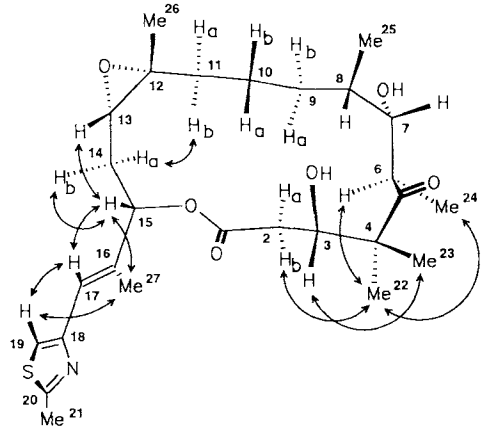

Fig. 2 Selected NOE relations for **1b**.

lactone ring in the epothilones. However, if taxol is reduced to the structural elements required for its biological activity[15] and the spatial orientation of the corresponding functional groups is taken into account, there are no remaining similarities. Furthermore, the spatially distant, essential phenyl residues at the 2- and 13-positions of taxol are only matched by *one* of this type of side chain in the epothilones. From this it has to be concluded that the epothilones and taxol occupy different but possibly overlapping binding sites on microtubules.

Whether the in vivo activity of the epothilones is equivalent or even better than that of taxol has not yet been demonstrated. Advantages which are already apparent are their much higher activity against P-glycoprotein-forming, multiresistant tumor lines,[8] their better solubility in water by a factor of about 30, and their almost unlimited availability by fermentation in a technical culture medium.[3]

[13] In a recent preliminary communication by Victory et al. [14] attempts were made to derive the relative configuration and conformation in solution of **1a** on the basis of the ^1H NMR data. The two proposals for the relative configuration are incorrect, and the conformations in solution differ essentially from our own proposal; however, they can first be evaluated conclusively when the spatial assignment of the methylene protons and the atomic coordinates or the dihedral angles of the ring skeleton are known.

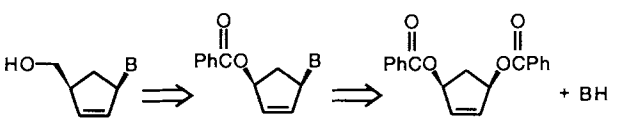
A Short Enantioselective Synthesis of Carbanucleosides**

Barry M. Trost,* Robert Madsen, Simon G. Guile, and Andrew E. H. Elia

The intense interest in the potential therapeutic applications of carbanucleosides continues to stimulate synthetic efforts.[1, 2] Palladium-catalyzed reactions have become an important tool in their synthesis.[3] A potentially very short asymmetric synthesis of carbanucleosides could evolve by the use of purines (or pyrimidines) as nucleophiles BH in the palladium-catalyzed asymmetric desymmetrization of diesters[4, 5] as illustrated in Scheme 1. In comparison to our first approach for the enantioselective preparation of these compounds such a reaction sequence could reduce the number of steps by a factor of two. In principle, the enantiodiscriminating step in the palladium-catalyzed desymmetrization of *meso*-diesters should be independent of the nucleophile. With simple nucleophiles like malonate,[4] sulfinate,[6a] azide,[6b] and amine,[4] this expectation was fulfilled. Contrary to these results, employment of purines shows a remarkable effect on this enantiodiscriminating step.



Scheme 1. Retrosynthesis of carbanucleosides. BH = nucleobase (nucleophile).

[**] We thank the National Science Foundation and the General Medical Sciences Institute of the National Institutes of Health for their support of our programs. R. M. thanks the Thomas B. Thriges and Knud Højgaards Fonds and the Danish Technical Research Council for partial support. Johnson Matthey Alfa Aesar provided a generous loan of palladium salts. Mass spectra were provided by the Mass Spectrometry Facility at the University of California-San Francisco supported by the NIH Division of Research Resources.

Herein we report our results obtained with purines as nucleophiles as well as the application of this strategy in a four-step synthesis of (−)-carbovir.[7]

Previous work established that the diphenylacetate **1a** and the dibenzoate **1b** gave the respective alkylation products with similar *ee* values.[5b] Furthermore, both 1,2-diphenylethyl (e.g., **7**) and cyclohexyl (e.g., **8**) type ligands gave comparable results. Solubility problems with adenine (**2a**) dictated the use of a mixed DMSO/THF solvent system. Reaction of diester **1a** with adenine (**2a**) in the presence of $[Pd_2(dba)_3]\cdot CHCl_3$ **4** and ligand **8** at room temperature led to the desired alkylation product **3a** but in low conversion (Scheme 2). Most disappointingly, hydrolysis (NaOH, CH_3OH, room temperature) and esterification

with (*S*)-O-methylmandelic acid (dicyclohexylcarbodiimide (DCC), 4-(dimethylamino)pyridine (DMAP), CH_2Cl_2) to give **6a** indicated the alkylation proceeded only in 9% *ee*. Other work in which N-methylbenzylamine was employed as nucleophile established that use of a DMSO/THF mixture rather than THF alone should not be the reason for such a drastic decrease in enantioselectivity. This observation is further verified herein (see below).

The switch from adenine (**2a**) to 6-chloropurine (**2b**) had a dramatic effect on the reaction. Addition of a tertiary amine such as triethylamine in conjunction with the purine resolves the conversion problem. Thus, the reaction with the 1,2-diphenylethyl ligand **7** and **4** as the palladium(0) source gave better results than that with the cyclohexyl ligand **8** and **5** as the palladium(0) source. When the reaction was performed with 7.6 mol% **7**, 2.5 mol% **4**, and **1b** in THF at room temperature, the crystalline adduct **3b** was obtained in 63% yield[8] (m.p. 90–92°; Table 1). Hydrolysis with sodium hydroxide in methanol gave **3** (X = OH, Y = OCH_3), which was esterified with (*S*)-O-methylmandelic acid (DCC, DMAP, CH_2Cl_2, room temperature) to give **6b**. Examination of the crude product **6b** by NMR spectroscopy revealed the diastereomeric excess to be 97%; the main diastereomer has the absolute configuration depicted in Scheme 2.[9, 10]

Table 1. Physical and spectroscopic data of the compounds **3b**, **11c**, and **14**.

3b: M.p. 90–92 °C; for material of 93% *ee*, $[\alpha]_D^{25} = -106.8$ ($c = 1.71$, CH_2Cl_2). Scheme 3. Synthesis of **11** and **12**. **a**: Y = Cl, Z = NH_2; **b**: Y = $OCH_2CH_2SiMe_3$, Z = NH_2; **c**: Y = $OCONPh_2$, Z = NHAc.

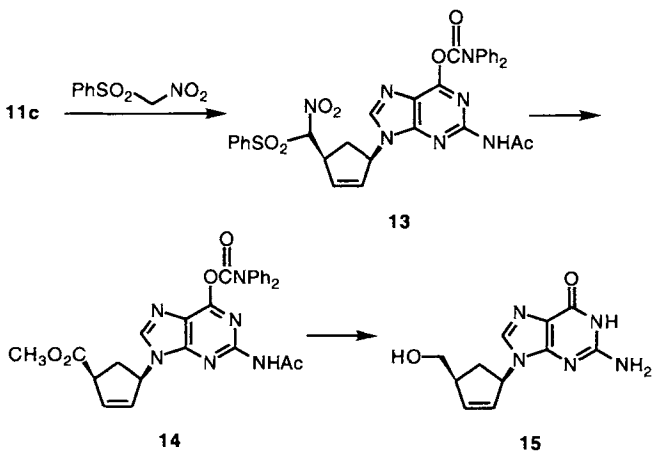
With the aim of finding a guanine equivalent, we turned to 2-amino-6-chloropurine (**10a**) (Scheme 3). In this case, the products of alkylation both at N-9 (i.e. **11a**[8]) and N-7 (i.e. **12a**[8]) were observed, presumably as a result of electronic effects. The choice of the base used played a significant role in this conversion; tertiary amine bases were superior to inorganic bases. In the series triethylamine, dicyclohexylethylamine, diisopropylethylamine, and 1,2,2,6,6-pentamethylpiperidine (pempidine), the yield of the alkylation product increased from 32 to

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1570 $ 15.00+.25/0

73%. With ligand **7** and four equivalents of pempidine as base, a mixture of **11a** and **12a** (3:1 ratio) was isolated in a combined yield of 52% (71% based on recovered starting material (brsm)). The $[\alpha]_D$ value of **11a** was -95.[11] The use of the cyclohexyl ligand **8** instead of **7** led to inferior results on all counts, conversion (only 60%), ratio of **11a**:**12a** (1.4:1), and enantioselectivity ($[\alpha]_D = -48$). On the other hand, with the bicyclic ligand **9**, which presumably has a larger P-Pd-P bite angle, improved results with respect to yield (60%, 66% brsm) and *ee* ($[\alpha]_D = -132$) were achieved, although the selectivity of the N alkylation was still unsatisfactory (**11a**: **12a** = 0.9:1.0). Increasing the steric hindrance associated with the C-6 substituent in an effort to sterically block the N-7 position as in **10b** does lead to a single product but only in 12% yield (21% brsm). If in addition the electron-donating ability of the 2-amino group is reduced by acetylation (as in **10c**[12]), under the same conditions the products **11c**[13] and **12c** were obtained in a combined yield of 62% (71% brsm; **11c**:**12c** = 3.8:1, *ee* 90%). Lowering the temperature from room temperature to 0° increased the ratio of **11c**:**12c** to 8.4:1 and the *ee* to 93–96%.[13] In addition, the doubly alkylated product[8] was obtained in 16% yield.[14] The above-mentioned reaction was carried out as follows: dibenzoate **1b** (1.0 equiv) and purine **10c** (1.2 equiv) in DMSO containing 1,2,2,6,6-pentamethylpiperidine (3 equiv) was added to a solution of 1.5 mol% **5** and 4.5 mol% **9** in THF at 0 °C. After 8 h at 0 °C and the normal work-up, **11c** was isolated in 50–59% yield (54–70% brsm) with 93–96% *ee* (Table 1).[13] Recrystallization from ethyl acetate enhanced the *ee* to >98%.

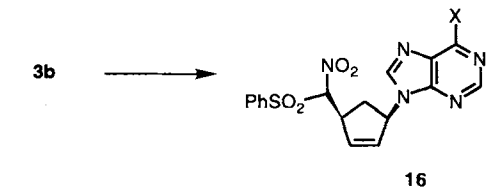
Access to enantiopure **11c** sets the stage for a short synthesis of (−)-carbovir (**15**). Introduction of the remaining one carbon side chain requires substitution of the benzoate with retention of configuration; this again calls for a Pd(0)-catalyzed reaction. In the event, treatment of **11c** with phenylsulfonylnitromethane (1.2 equiv) and triethylamine (2.5 equiv) in THF at room temperature in the presence of 1.5 mol% **4** and 12 mol% triphenylphosphane gave **13** in 97–99% yield (Scheme 4).



Scheme 4. Synthesis of (−)-carbovir **15**.

Chemoselective oxidative cleavage to give the ester **14** in 71% yield (Table 1) was achieved by treating the tetramethylguanidine salt in methanol/dichloromethane with tetrabutylammonium-oxone[15] buffered with sodium carbonate. Reduction with calcium borohydride[16] in THF followed by an aqueous ammonia work-up generated (−)-carbovir (**15**) in 61% yield (m.p. 255–7 °C, $[\alpha]_D^{25} = -60.1$ ($c = 0.4$, CH_3OH)).[7]

The surprising dependence of the palladium-catalyzed desymmetrization of *meso*-diesters on the nature of the purine base unlike a myriad of other nucleophiles including secondary amines, azides, sulfones, carboxylates, malonates, etc., may derive from their ability to serve as competitive ligands thereby disrupting the normal coordination of the palladium. The requirement for the hindered tertiary amine base may stem from its stabilization of the pronucleophile by hydrogen bonding, thereby disfavoring any equilibrium involving coordination of the pronucleophile or nucleophile to the metal and, at the same time, preventing it from serving as a ligand due to the steric hindrance. Thus, the nature of the nucleophile cannot be totally dismissed in this metal-catalyzed desymmetrization. These results clearly indicate that our normally preferred ligand **8** is not suitable for reactions with these nucleophiles and that better results can be achieved with either **7** or **9**. The ability to use the Pd(0)-catalyzed desymmetrization has resulted in a four-step synthesis of (−)-carbovir from dibenzoate **1b**. Since the first two steps employ Pd(0)-catalyzed alkylations that may be combined into a single event, a three-stage synthesis may evolve. In addition, **3b** was converted analogously in quantitative yield to **16a** (Scheme 5). Ammonolysis gave **16b**, an intermediate in the synthesis of the carbanucleoside (−)-aristeromycin.[3a] This strategy should hold great promise for making carbanucleosides of either enantiomeric series, both of which are of biological interest, more readily available.



Scheme 5. Synthesis of **16**. **a**: X = Cl; **b**: X = NH_2.

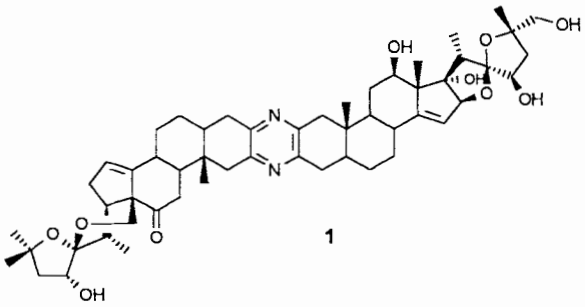
Directed Synthesis of Nonsymmetrical Bis-Steroidal Pyrazines and the First Biologically Active Cephalostatin Analogues**

Michael Drögemüller, Rolf Jautelat, and Ekkehard Winterfeldt*

Dedicated to Professor Ernst Mutschler on the occasion of his 65th birthday

Cephalostatin 1 (**1**) is the prototype of the cephalostatins and the ritterazins, a family of 30 trisdecacyclic pyrazines, isolated by Pettit and his co-workers since 1988 from the Indian Ocean marine worm *Cephalodiscus gilchristi*[1] and by the group of Fusetani from the tunicate *Riterella tokioka*.[2] The extraordinarily strong cytostatic activity,[1b,3] together with the new and interesting structure and very limited availability,[1a] immediately led to attempts at syntheses in various laboratories.[4–6] Although recently Fuchs et al. reported quite impressive achievements in the total synthesis of cephalostatins and ritterazins, the crucial problem of a direct synthesis of nonsymmetrical bis-steroidal pyrazines was not properly solved. Fuchs and his co-workers prepared the cephalostatins 7 and 12 together with ritterazin K from two precursors in a statistical way and had to separate the three products.[5b] For the first synthesis of nonsymmetrical pyrazines from α-acetoxy ketones and α-amino oximethers, which was not yet been applied to $\Delta^{14,15}$ steroids, Heathcock et al.[4] reported high reaction temperatures (145 °C) paired with low yields and regioselectivity problems.



1

Systematic investigations in our laboratories indicated two independent routes to easily accessible cephalostatin analogues, which can provide information on the substructures essential for cytostatic activity. One approach, called the *symmetrical route*, aimed at the straightforward synthesis of symmetrical bis-steroidal pyrazines by dimerization of the usual α-amino ketone precursor.[7] These pyrazines have then to be desymmetrized and further functionalized at a later stage of the synthesis. The other approach, called the *nonsymmetrical route*, called for the direct synthesis of unsymmetrical bis-steroidal pyrazines by coupling of two different steroids.

At the beginning we elaborated the symmetrical route, which afforded in a short and efficient seven-step synthesis the symmetric diketone **3a** from easily available hecogenine acetate **2**.[6] Desymmetrization of this diketone by diastereoselective reduction with L-Selectride afforded the α-hydroxy ketone **4α**, while borohydride reduction provided the β-hydroxy ketone **4β**. These reduction processes under proper conditions also gave rise to the α-diol **5α** and β-diol **5β** (see Scheme 1).

Submitting the selected compounds **3a**, **3b**, **4β**, and **5β** to the U. S. National Cancer Institutes (NCI) in vitro, human-cancer-focused evaluation system,[8] we found that the symmetrical and saturated diketone **3b**[9] (affecting only 4 of 58 cell lines; GI_{50}: MG MID (MG MID = *m*ean *g*raph *mid*point; that is mean activity over all cell lines) > -4.0) showed weak activity. In contrast the symmetrical but unsaturated substances diketone **3a** (affecting 32 of 58 cell lines; GI_{50}: MG MID > -4.3) and β-diol **5β** (affecting 21 of 58 cell lines; GI_{50}: MG MID > -4.2) showed moderate tumor-inhibiting capacity. Finally the nonsymmetrical and unsaturated β-hydroxy ketone **4β** (affecting 58 of 58 cell lines; GI_{50}: MG MID $= -5.3$) revealed significant cytostatic action on all tested tumor cells.[10] Therefore the β-hydroxy ketone **4β** reaches affecting concentrations of standard chemotherapeutics (e.g., cyclophosphamide GI_{50}: MG MID $= -3.7$; 5-fluorouracil GI_{50}: MG MID $= -4.7$; cisplatin GI_{50}: MG MID $= -5.7$; adriamycin GI_{50}: MG MID $= -6.9$).[11] Their activities are similar to those of tamoxifen (GI_{50}: MG MID $= -5.3$)[11] and 4000 times weaker than that of the very potent cephalostatin 1 (**1**) (GI_{50}: MG MID $= -8.9$),[1c] which itself shows a tenfold stronger tumor-inhibiting activity than taxol (GI_{50}: MG MID $= -7.9$).[11]

By comparison to the noncytostatic saturated cephalostatin analogues[4,5a] we recognized that the $\Delta^{14,15}$ double bond is indispensable for the biological activity in general and that the nonsymmetrical structure is of particular importance for the broad scope of this action. Therefore we focused our efforts on

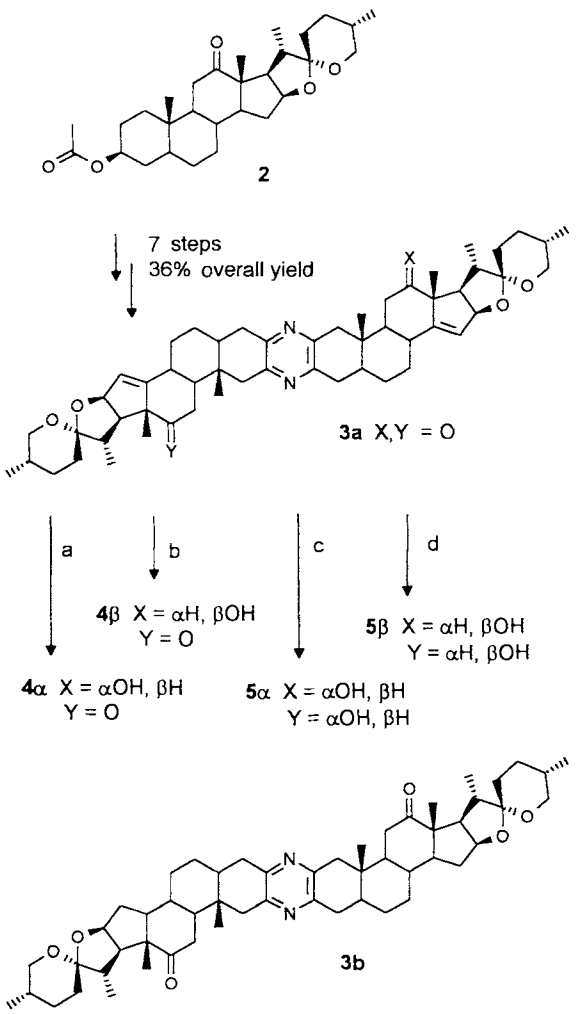
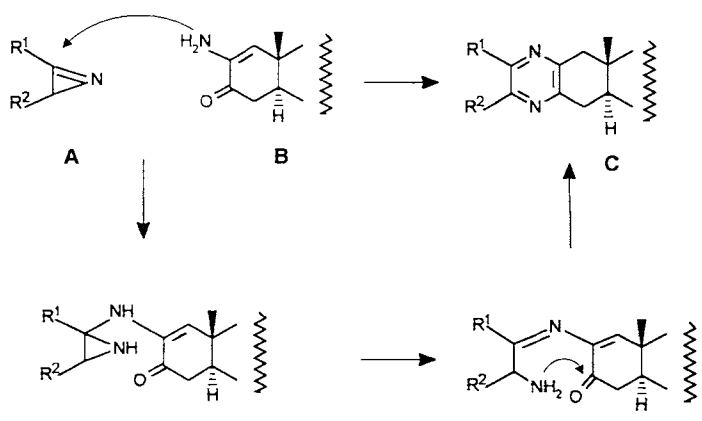


Scheme 1. Synthesis of compounds **4α**, **4β**, **5α**, and **5β**. a) 0.7 equiv L-Selectride, dry toluene, −78 °C, (49% in one step, 82% with recovery of starting material); b) 0.7 equiv $NaBH_4$, CH_2Cl_2/MeOH, −78 °C (47% in one step, 81% with recovery of starting material); c) L-Selectride, dry toluene, −78 °C (96%); d) $NaBH_4$, CH_2Cl_2/MeOH, −78 °C (98%).

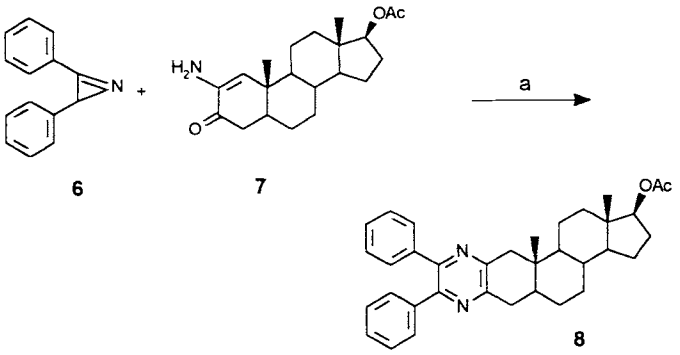
a direct formation of nonsymmetrical compounds of this type by the already mentioned nonsymmetrical route.

Having noticed that enamino ketones of type **B** are stable under thermal conditions and do not undergo dimerization, we expected that reaction of **B** with azirines **A** as nondimerizing analogues of α-amino ketones could give an easy access to nonsymmetrical pyrazines **C** (see Scheme 2).



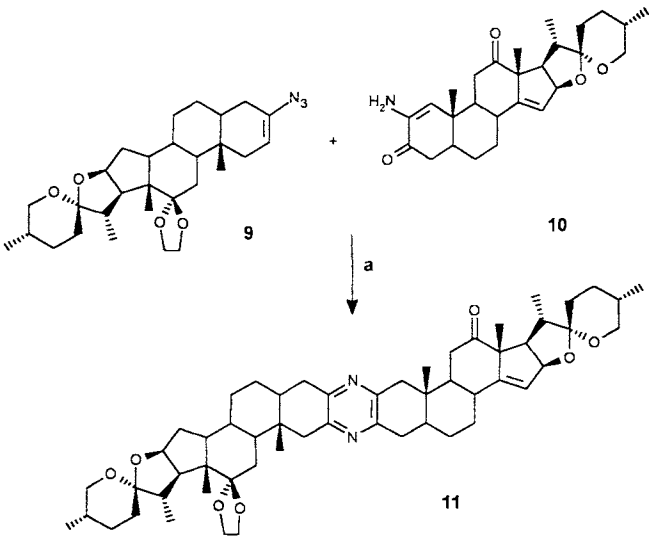
Scheme 2.

As expected treatment of azirine **6**, easily prepared from *trans*-stilbene,[12] with enamino ketone **7** and trifluoracetic acid (TFA) at 0 °C in THF gave pyrazine **8** in 63% yield (see Scheme 3).



Scheme 3. Preparation of pyrazine **8**. a) THF, TFA, 0 °C, 3 h (63%).

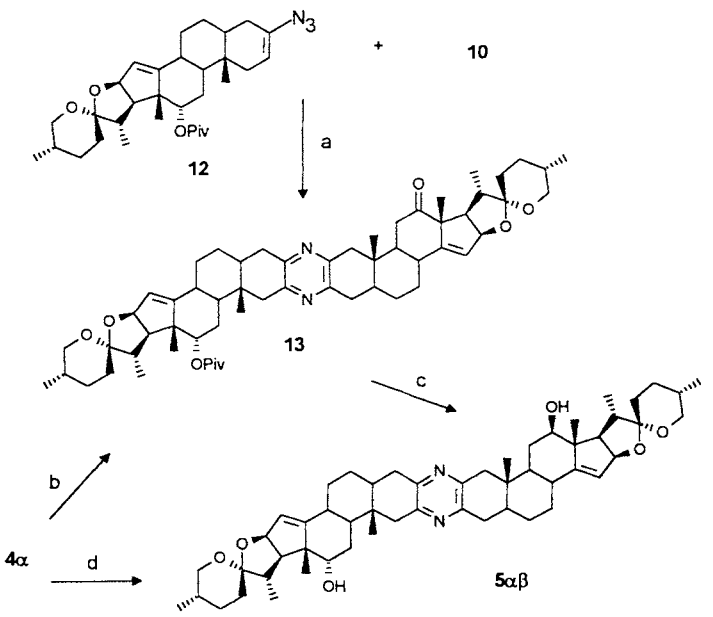
With the intention of combining two steroids we applied—after substantial improvements[13]—Zbiral's[14] method to prepare steroidal vinyl azides as precursors for the corresponding azirines.[15] However, all attempts to generate and isolate these ring-fused azirines failed. When a literature survey[16] confirmed that this kind of compound is indeed highly strained and less stable than monocyclic azirines like **6**, we conducted the azirine formation in the presence of enamino ketone **10** in order to capture in situ the formed azirine. In the event the decomposition of the vinyl azide **9** in refluxing dioxane in the presence of **10** and pyridine-*para*-toluenesulfonate (PPTS) as a mild proton source did generate the unsymmetrical pyrazine **11** in 67% yield (see Scheme 4).



Scheme 4. Synthesis of pyrazine **11**. a) Dioxane, PPTS, 90 min at reflux (67%).

By this method we prepared pyrazine **13** from vinyl azide **12** and enamino ketone **10** in 51% yield and obtained cephalostatin analogues with promising biological activity.[17] Pyrazine **13** was also available independently by the symmetrical route described above, followed by an esterfication of the α-hydroxy ketone **4α** (96% yield). Both products were identical (according

to TLC and IR, ^1H, ^{13}C spectroscopy) and verified the regioselectivity of this new pyrazine-forming reaction. Reduction of pyrazine **13** with sodium borohydride and diisobutylaluminum hydride (DIBAH) gave the α,β-diol **5αβ**, which was also prepared by reduction of α-hydroxy ketone **4α** with sodium borohydride (see Scheme 5).[18]



Scheme 5. Synthesis of compounds **13** and **5αβ** a) PPTS, dioxane, 3 Å molecular sieves, reflux (51%); b) pivaloyl chloride, dimethylaminopyridine, pyridine, 100 °C (96%); c) 1) $NaBH_4$, CH_2Cl_2/MeOH, −78 °C; 2. DIBAH, toluene (68%); d) $NaBH_4$, CH_2Cl_2/MeOH, −78 °C (96%).

In conclusion, we were successful in preparing easily accessible, biologically active cephalostatin analogues and in developing a novel method for the directed and flexible synthesis of nonsymmetrical bis-steroidal pyrazines.

Experimental Procedure

13: A degassed solution of **10** (51 mg, 0.11 mmol), **12** (64 mg, 0.12 mmol), PPTS (5 mg), and 3 Å molecular sieves (23 mg) in dry dioxane (2 mL) was heated at reflux under an argon atmosphere for 2 h. After filtration through silica, the solvent was removed and the residue purified by flash chromatography (silica, light petroleum/ethyl acetate = 2/1) to yield 55 mg (51%). White crystals, m.p. 269 °C; UV/Vis (CH_3OH): λ_{max} = 305 (sh), 288, 210 nm; IR (KBr): $\tilde{\nu}$ = 2956, 2932, 2872, 1716(br), 1400, 1376, 1192, 1156, 980, 908 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$): δ = 0.77–1.03 (m, 24H), 1.18 (s, 9H), 1.20–2.43 (m, 32H), 2.47–2.92 (m, 8H), 3.31–3.53 (m, 4H), 4.78 (dd, J = 8.1 and 2.0 Hz, 1H), 4.90 (dd, J = 7.9 and 2.0 Hz, 1H), 4.93 (s, 1H), 5.49 (s, 1H), 5.52 (s, 1H); ^{13}C NMR (100.6 MHz, $CDCl_3$): δ = 11.52, 11.75, 13.76, 14.10, 17.14, 18.79, 20.75, 26.08, 27.14, 27.85, 27.95, 28.74, 28.77, 30.31, 30.39, 31.09, 31.26, 33.95, 34.20, 35.15, 35.21, 35.68, 36.36, 37.20, 38.91, 41.24, 41.65, 44.21, 44.52, 45.17, 45.75, 49.75, 49.89, 49.92, 53.14, 53.60, 62.29, 67.09, 67.12, 77.71, 83.93, 85.00, 106.64, 107.05, 120.67, 121.56, 148.09, 148.10, 148.58, 148.64, 153.85, 154.28, 177.60, 210.73; FAB-MS (nitrobenzyl alcohol matrix): m/z (%): 932 (100) [MH^+], 818 (27); $C_{59}H_{82}O_7N_2$ (931.31): found C 76.09, H 8.60, N 3.16; calcd C 76.09, H 8.87, N 3.01.

Macmillan, New York, 1990. 339 pp., paperback $ 13.00.—ISBN 0-0200-9801-4

The publication in 1995 of *Révélations gastronomiques* by Hervé This gives one an opportunity to compare it with three other books that are also concerned with the relationships between food preparation and chemistry. These relationships need to be looked into critically, since it is nowadays fashionable to complain that the food we eat is full of chemicals. We are told that pesticides, artificial fertilizers, irradiation, fumigation, artificial aromas, flavor additives, and other "works of the devil" are likely to make us all ill. This sends many people to obscure natural food shops where allegedly "biodynamically grown" products are sold at high prices. However, there are also many, often actually the same people, who buy convenience foods such as soups, sauces, puddings, baking mixtures, etc. which are ready to eat or need only some quick preparation such as adding water and heating. One only needs to look in any supermarket to see the innumerable varieties of joghurts and of sauces made for noodles. Of course there are also simple products such as natural joghurt or curd cheese, and one could buy rice, milk, tomatoes, and onions and make all these concoctions for oneself. The large consumption of ready-prepared meals and pre-processed foods is a social phenomenon that has much to do with "self-fulfillment", leisure activities, and social pressures. However, that is a huge field that has scarcely been studied yet.

The truth is that foodstuffs have never before been so pure, so varied, and so fresh as they are today. Our forebears often used large amounts of salt and pepper to mask the flavor of food that had been spoiled. From medieval times right up to the 18th century it was quite usual for bread, wine, milk, and other commodities to be horribly adulterated. These facts emerge clearly from the chapter on "Food Additives" in the most interesting of the books reviewed here, Harold McGee's *On Food and Cooking – The Science and Lore of the Kitchen*. The book is sturdily bound, although regrettably printed on paper of indifferent quality. It is easily the best of this genre, not only because of the wealth of information provided but also in the arrangement of the material and the thoroughness and soundness of the treatment. It contains a brief introduction followed by Part I, "Foods" (500 pp.), then two shorter parts on "Food and the Body" and "The Principles of Cooking". The first and main part is divided into ten chapters dealing with different types of foods. For example, under "Milk and Milk Products" we learn about the importance of milk in the Bible, and the chemical background relating to casein, whey, cream, and joghurt. On cheese too we find much historical information, but also there are electromicrographs showing its structure and answers to such questions as why mozzarella contains long fibers and why wine is used in making fondue. The chapter on "Eggs" not only answers the perennial question "Which came first, the chicken or the egg?" but also gives a lucid explanation of the very complex chemistry of the cooking of eggs.

History plays an important role throughout McGee's book, and we find this again in the chapters on meat. Domestication of animals, the consumption of meat, the relationship between structure and quality, and the processes of slaughtering, maturing, boiling, and roasting are all treated thoroughly. Here it becomes apparent that the author is an American, as the "cuts" of meat (sirloin, rib, etc.) are quite different from those in Germany. The chapter on "Fruit and Vegetables" mentions many geographical and geohistorical aspects, but also covers topics such as cell structure and the formula of chlorophyll. Here, however, I have to make one of my very few critical comments, as the formulas are poorly drawn, and remind one of the elongated benzene hexagons in old German chemistry textbooks. However, we go on to more excellent stuff, with occasional historical anecdotes such as that concerning the work of Szent-Györgi on vitamin C, and the publication in 1910 of the observations that bananas ripen faster when stored next to oranges and that various green fruits turn red more quickly when near a kerosene stove. Although we now know that these effects are caused by ethylene, its mode of action is still not fully understood.

Everyone knows that eating asparagus causes one's urine to smell foul, and it has long been known that this is due to methyl mercaptan formed by the degradation of methionine. However, until 1960 it was thought that the variation in perception of the intensity of the odor from one individual to another was caused by genetic differences in metabolization. However, we now know that all humans have similar amounts of methyl mercaptan in their urine after eating asparagus, but their perception of it differs widely due to partial anosmia. In the chapter on "Cereals and Nuts" we learn that in "parboiled" rice the vitamin B is completely retained, as the process causes it to move from the husk into the grain itself. Under "Bread" we find much information about baking. The microbiology of the sour dough is discussed in great detail, whereas the history of the noodle is recounted poetically. There is a long chapter on "Sauces". We read about Antoine Carême (1784–1833), who was the greatest cook of his day and invented the excellent sauces or gravies based on meat juices and roux (lightly fried and browned flour), and about Escoffier who by 1910 had a reper-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1575 $ 15.00+.25/0

toire of about 200 sauces. The action of starch in thickening sauces is explained with simple but informative diagrams showing the hydrogen-bonding of the amylose component. The other group of sauces is based not on starch but on water-in-oil or oil-in-water emulsions stabilized by the lecithin present in egg-yolk or by cholesterol as emulsifying agents. There are detailed references to a debate which took place between 1977 and 1979 in the pages of *Nature* and the *New England Journal of Medicine* on the multiphase colloidal system in sauce béarnaise.

In the chapter on sugar and chocolate the author clears up the widespread misconception that honey, unlike sugar, is "natural" and "healthy". The amounts of vitamins and minerals in honey are negligibly small! Also so-called "raw sugar", or more accurately brown sugar, is not an unrefined and therefore more natural product, but is normal white sugar onto which a film of molasses has been sprayed. With regard to chocolate we learn that the name "praline", dating from about 1650, originates from that of the Duke of Plessis-Praslins, an army commander under Louis XIII and Louis XIV.

In the chapter on wine, beer, and spirits we have some real chemistry. The process of fermentation is treated rather briefly but in a way that is easily understandable by non-chemists. Distillation, a basic operation in chemistry, is then described. However, the formulas given for the various alcohols (p. 486) are not well drawn. Under beer the author mentions the Bavarian purity regulations of 1516 and also the absurdity of the American "light beers", commenting on the latter that "the more closely the beer resembles water the more of it one can drink". On the other hand, Dickens and Hogarth are quoted with regard to the effects of gin.

In Part 2, "Food and the Body", the author describes how, encouraged by advertising and all types of media, people nowadays pay out millions for "organic" and "macrobiotic" foods, for "energy-giving" vitamins, and for special fiber supplements. According to McGee, it is very difficult to persuade people against this kind of nonsense, even though a simple and varied diet tastefully and carefully prepared from good raw food products, enjoyed in moderation, would make all this charlatanism unnecessary.

Part 3 is a comprehensive account of the basic principles of food science. The chemistry and physics of water is clearly explained, including its special characteristics such as the density anomaly and its high specific heat. In discussing carbohydrates the roles of amylose and amylopectin are well described, and the author explains why we differ from many animals in being unable to feed on hay or wood. Under proteins the main emphasis is on their denaturation by the action of salts, acids, or heating. Some important properties of fats are discussed, starting from the structure of the triglycerides. For example, it is explained why cocoa butter, in contrast to all other fats, has a clearly defined melting point, and what causes fats to go rancid.

There is an appendix of a few pages in which some basic principles of chemistry such as atomic models, the Periodic System, bond strengths, and crystal lattices are explained. This seems rather inappropriate and is not really necessary. It is superfluous for the scientist reader, whereas the non-scientist will be unable to make much use of it. The book ends with a very well set out and comprehensive bibliography. Apart from the minor reservations mentioned above the book deserves the highest praise. It contains a clear, competent, thorough, and factual account of all that is worth knowing about this fascinating subject, enlivened by historical information and by simple but informative illustrations. I look forward to the appearance soon of a new edition and, hopefully, a German translation, followed by a wide circulation among all who are interested in cooking.

A few years after the above book the same author wrote *The Curious Cook – More Kitchen Science and Lore*, a very sparsely illustrated paperback forming a kind of supplement to the former book. Its structure follows the pattern of its larger predecessor with three parts, each divided into chapters. Part 1 is called "Playing with Food: Experiments", and begins with a chapter entitled "The Searing Truth". This is a very illuminating description of how one can fry a steak under various experimental conditions such that the juice of the meat does not escape. In precise detail the author dismisses the myth that quick frying on one side "seals the pores" and causes the juice to stay in. This is followed by an examination of why it is that during the frying the fine droplets of oil condense of the *inner* surface of the cook's glasses; the answer is related to the geometry of their trajectories.

The interesting chapter "Green and Brown" explains the well-known but puzzling observations that leaves of basil turn brown so quickly, and why sprinkling vinegar and oil onto lettuce makes it wilt much quicker than it otherwise would. With regard to white butter sauce (beurre blanc) scientific investigations have been carried out to determine the exact ratio of fat to water. It is explained, with reference also to historical precedents, why one cannot use margarine instead of butter for this purpose. In the chapter on fruit ices the author discusses the lowering of the freezing point and the sugar and acid content of fruits. He gives very complicated formulas (not meant to be taken too seriously) for determining the acidity and adjusting it by adding lemon juice; the results must, of course, be evaluated with the help of a computer! We learn that lemons have the lowest ratio of sugar to acid (0.2) and pears have the highest (110). Recipes are given for many different types of ice-cream, including such enticing and exotic kinds as rose ice or avocado-and-pineapple ice. Part 1 ends with a chapter on "The Pleasures of Merely Measuring" which addresses such important problems as how to avoid having the soup burn one's tongue (one has to measure the rate of cooling as a function of viscosity and rate of stirring).

Part 2, "Making the Good Life Better", includes much discussion of the connection between fats and heart disease and of carcinogens in food. The worries about cholesterol, which are especially prevalent in the USA, are put into perspective. The chapter on food and cancer is fascinating. It is emphasized here that grilling meat over wood charcoal, which is nowadays so popular, generates large quantities of carcinogens. The incidence of cancer is certainly very dependent on eating habits. For example, the incidence of intestinal and breast cancer is below average in Japan and among members of certain churches and religious sects in the USA. Bruce Ames, the famous biochemist who has developed well-known tests for carcinogens, claims that with a normal diet one's daily intake of "natural pesticides" present in plants is in the order of grams, about 10^4 times more than the traces of synthetic pesticides we receive! Nevertheless, one should not be afraid to eat fruit or mushrooms. On the whole nature balances things out very well. Cancer can result from changes in the DNA caused by certain compounds such as polycyclic aromatic hydrocarbons, which are present not only in barbecue smoke (and, of course, tobacco smoke), but also in toast and in caramel. However, the body has an inbuilt ability to neutralize such toxins by metabolization. Thus a "cancer-causing" menu made up of beef gravy, grilled steak, and mushrooms can be "detoxified" if it is accompanied by Brussels sprouts, brown rice, a salad with garlic, and apple pie.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1576 $ 15.00+.25/0

Part 3 seems rather unrelated to the foregoing. However, in the last chapter we again find some useful information under the title "From Raw to Cooked: The Transformation of Flavor". Here we find a discussion of the Maillard reaction, which is difficult to understand even for specialists, but the chapter also deals with aroma-bearing substances such as heterocyclic oxygen, sulfur, and nitrogen compounds. This book can be thoroughly recommended for everyone who wishes to know as much as possible about the processes such as boiling, roasting, and many others that are used in food preparation.

The first of the books by Hervé This is *Les secrets de la casserole*, published in 1993. It is very nicely produced with many instructive illustrations and pretty decorative panels on a pale gray background. The introduction of about 30 pages deals with the main physical and chemical principles involved in food preparation, discusses the relationship between cooking and science, describes the physiology of taste, and considers how color and aroma are related to taste. We learn much that is interesting here, such as why peeled apples quickly turn brown and why lobster meat turns red when boiled.

The main part of the book consists of more than 30 sections of about five pages each, dealing with different foodstuffs such as milk, eggs, meat, vegetables, fruit, bread, etc., and with the various methods of preparation such as boiling, roasting, grilling, and frittering. Each section is subdivided under headings such as "Pineapples which make the food tender", or "Meat from its initial hanging to becoming rotten", or more often under interestingly phrased questions that are then answered briefly or at some length. Examples are: "Why does the crust of the loaf have more flavor than the inside?", "Why is human milk more easily digestible than cows' milk?", "How much mayonnaise can be made from one egg-yolk?", "Why should cauliflower not be boiled too long?", "Why does every little bean produce a little sound?" The answer to the latter question is that beans contain raffinose, a trisaccharide made up of fructose, glucose, and galactose; the last of these passes through the stomach without being absorbed and is digested only in the small intestine by *E. coli*, which breaks it down into carbon dioxide, methane, and hydrogen. Other questions: "Is béarnaise a warm mayonnaise?", "Why must roux be cooked for a long time?", "Why should dough be left to stand?". The answers to all these are expressed clearly, succinctly, and in a form that impresses itself on one's memory, and are illustrated by good diagrams.

In the chapter on wines their evaluation by eye, nose, and tongue is described in clear and thorough detail, as one would naturally expect of a French author. The chemist's attempts at "improving" wines are also discussed. If the wine is too light one can add ethanol. A lack of flavor may be remedied by adding a little vanilla essence or cassis (blackcurrant extract). A wine of recent origin can be "aged" by adding port, and a "vin ordinaire" can be moved a little closer to Bordeaux, as it were, by adding minute quantities of 1-octanol and 3-isobutyl-2-methoxypyrazine. Also the awkward question of why alcohol makes one intoxicated is not avoided. In conclusion the author draws attention to some questions for which there is as yet no answer, and invites his readers to help. For example, why can a mixture of oil and butter be heated to a higher temperature than butter alone? How can apple-juice be prevented from turning dark? Why must one not leave parsley in a marinade for a day or two? Is it true that putting a teaspoon in the neck of a champagne bottle helps to retain its fizz, even after standing for a long time, and if so why? Finally a good index completes this very enjoyable and readable book.

The most recent of these books, *Révélations gastronomiques*, is a particularly handsome work. Like the book described above it is well printed on high quality paper with an excellent binding. Both the chemist who enjoys cooking for pleasure and the cooking enthusiast with an interest in chemistry will find here something quite special, with 55 first-class recipes. It begins with a general introduction and a chapter on good kitchen equipment, in which both the text and the illustrations are very informative. These are followed by five longer chapters containing detailed descriptions of the recipes, each in a separate section with its own logo. The chapters deal separately with aperitifs (5 recipes), starter dishes (16), fish and shellfish (6), meat dishes (13), and desserts (15). Each recipe is treated in five to six pages, beginning with an appropriate vignette, followed by the main title, a suitable quotation from Brillat-Savarin, Verlaine, Racine or some other writer, then a paragraph of introduction giving the ingredients in precise detail, with visual highlighting for clarity. In many cookbooks one finds that the quantities are given with variable and inconsistent precision which makes little sense, as for example in: "take 110 g of flour, 85 g of sugar, and 3 eggs". What exactly does "3 eggs" mean? In contrast, Hervé This keeps consistent precision throughout, as in the experimental section of a report in *Liebigs Annalen* or *Helvetica Chimica Acta*.

The operations are then described in separate steps, varying from 5 to 15 according to the degree of difficulty. Each of these subsections consists of a few lines of clear instructions and a longer commentary, often with diagrams or photographs, describing the chemical processes. All this is presented in a relaxed and witty style. For example, in the recipe for preparing dough we find: "Mix 10 g of yeast with a teaspoonful of sugar and 30 cL of lukewarm water and allow the mixture to stand for a quarter of an hour. – The cube of yeast that you have bought from your baker for a small sum consists of a large number of microorganisms called yeast cells. In the presence of sugar and water these yeast cells begin to develop, multiply themselves by cell division, and release CO_2 which causes the dough to rise. The yeast cells are most active at temperatures of 25–35 °C. If they are too cold their biological machine works more slowly, like that of hibernating marmots in winter. On the other hand, if they are too hot they risk dying. Bear in mind that the yeast cells are not greatly different from the cells that make up your body."

On the whole the recipes are demanding enough to satisfy the enthusiastic amateur cook, but are nevertheless described in sufficient detail to ensure that those with less experience will also succeed. Moreover, they are quite delectable ... goose liver with grapes and apples, poached trout with white butter sauce, roast quail with potato purée, pears with sabayon of Gewürztraminer ...

This excellent book ends with a four-page epilog, an index, and a bibliography. The epilog might be given the rather pompous title "A philosphical view of the art of cooking past and present, in the context of the interaction of art, craft, and science". The essential message of Hervé This is that we should use the opportunity now offered to us by science and technology to reach a better understanding of cooking, so as to do it even better and to increase our enjoyment of life. I have nothing to add to that.

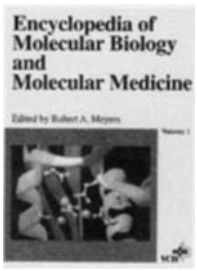
Encyclopedia of Molecular Biology and Molecular Medicine. Vol. 1. Edited by *R. A. Meyers*. VCH Verlagsgesellschaft, Weinheim, 1996. 462 pp., hardcover DM 460.00 (single vol.)/DM 2550.00 (set).–ISBN 3-527-28471-0/ISBN 3-527-28478-8 (set)

Is there something in molecular biology that you have always wanted to know? Are you familiar with the Achilles cleavage? No? Then do you know of the importance of the plant *Arabidopsis thaliana* in genome research, or of the worm *Caenorhabditis elegans* in the physiology of development? Or would you like to learn more about these two organisms? Are you looking for a quick up-to-date overview of the molecular biological aspects of Alzheimer's disease, of recent developments in the area of therapeutic treatments for AIDS and antisense oligonucleotides, or of chirality?



You might go to your library and search, search, search. Or instead you might simply reach for the *Encyclopedia of Molecular Biology and Molecular Medicine* by Robert A. Meyers. Volume 1 of this six-volume work has now appeared, and contains many detailed and expertly written review articles on topics such as those mentioned above. The editorial committee contains many eminent names including seven Nobel laureates (W. Arber, E. J. Corey, R. Huber, A. Klug, L. Pauling†, B. Samuelsson, P. Sharp), and the list of authors of individual articles resembles a hall of fame of modern molecular biology. Consequently the quality of the contributions is everything that one could wish for. Each article contains very useful cross-references to related topics.

In this first volume (A to C) there is a strong emphasis on the fields of molecular biology and genome research. However, all the other related topics within this area are covered under their general headings. Volume 1 contains relatively few articles on molecular medicine, but a glance at the publishers' list of all the keywords covered shows that this is just an accidental consequence of the alphabetical arrangement of topics. Diabetes, Drug Addiction, Drug Synthesis, Drug Targeting, etc. will appear in Volume 2. The literature references given in the individual articles are restricted to a few important ones, and are quite recent in most cases, extending up to 1993 and 1994, and in a few instances even to 1995. With regard to the degree of up-to-dateness it must be borne in mind that the publishers have set themselves the very ambitious goal of completing the six-volume work, with over 300 articles, within one year. Thus, for example, we only have to wait until autumn 1996 for the currently highly topical keyword "Prions", and "Zinc Fingers" will appear in January 1997. The publication of the whole work within a short space of time means that all the articles will be approximately contemporaneous in their coverage, a great advantage in a field that is developing so rapidly.

A work as large as this covering such a wide range of subjects cannot be expected to be absolutely perfect when first published. Nevertheless, it is pleasing to note that errors are comparatively rare. One can excuse the few inconsistencies in formulas (examples: arginine on the inside front cover; NH-*i*Pr instead of NH-*t*Bu in Ro 31-3959, Fig. 5, p. 39–cf. also p. 17; L-Tyr instead of L-Trp in formula 45 on p. 58; missing double bonds in the indoles in Fig. 12, p. 200) and some printing errors in compound names (e.g., "sequinavir" instead of saquinavir on p. 18, and "benzpyrine" instead of benzpyrene on p. 437). The article on Bioorganic Chemistry contains many errors; for example the formulas in Figure 7a on page 164 (explanation of hydrogen-bonding) and in Figure 12 on page 168 (natural substrate, enalapril) contain serious errors, and on pages 168 and 169 (Fig. 13) it is incorrectly stated that acetylsalicylic acid reacts irreversibly with an amino group of the enzyme cyclooxygenase (this should instead be the hydroxy group of Ser-530 in cyclooxygenase). Many structural formulas, such as those of the amino-acids shown on the front jacket flap, are drawn in a rather outdated style, and unfortunately without indicating their stereochemistry. Also, to make it easier to find subject headings in the series later on, it would have been useful to print the letters range A-C on the spine of the volume in addition to "Volume 1". At the price of DM 460 for Volume 1 (or the subscription price of DM 2550 for the entire work, valid until June 30, 1996) the encyclopedia is by no means cheap, but it seems not unreasonable for a work of this size and quality. Within its 462 closely printed large-format pages this first volume contains an enormous wealth of information. A good indication of how useful and interesting the contents are is the fact that after studying it for a short time I was reluctant to put it down; also that I now feel an urgent need for the other five volumes. The rather indifferent quality of the paper seems inappropriate for a book of this price, as also does the annoying practice (now increasingly common with many publishers) of placing all the color figures together in the middle of the book, in this case 13 figures on eight pages. Admittedly this reduces the cost of production, but in a work of this magnitude the small difference would hardly have mattered.

Up to now the *Encyclopedia of Molecular Biology and Molecular Medicine* has no rival to compete with it. It should appeal to a very wide readership, who will find it not only interesting and informative but also an indispensable aid in their everyday work. Chemists, biochemists, molecular biologists, pharmacologists, toxicologists, biologists, geneticists, and medical scientists should all have access to this encyclopedia, as also should everyone whose work is concerned with the molecular basis of diseases or with drug research, whether in universities or in the pharmaceutical industry. I have no hesitation in recommending that one should buy it.

Active Metals. Preparation, Characterization, Applications. Edited by *A. Fürstner*. VCH Verlagsgesellschaft, Weinheim/New York, 1996. 464 pp., hardcover $ 155.00—ISBN 3-527-29207-1

Metals and their derivatives are indispensable auxiliaries in preparative chemistry and catalysis. The book *Active Metals*, edited by Alois Fürstner, contains many examples of organic reactions in which the key step—electron transfer and reduction, cleavage or formation of a chemical bond—is only made possible by the aid of a metal species. Among the various coupling processes that are metal-promoted, special attention has been paid to those of the McMurry type which are immensely useful in organic synthesis; details of their mechanism are presented, as well as their recent applications to the preparation of diols, alkenes, 1,5-dienes and bibenzyls, with emphasis on the large ring and natural products. Not surprisingly we find many examples in this book where the reactions of metals with organic substrates, especially the halides, lead to the formation of well-defined organometallics which are themselves valuable tools in synthetic chemistry. In this context, the preparation and applications of allylic barium reagents and functionalized

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3513-1578 $ 15.00+.25/0

organozinc reagents are treated in more detail. The former, which can be generated stereospecifically, react with a variety of electrophiles with remarkable regio- and stereoselectivity. Organozinc reagents, which have been neglected for a long time because of their low reactivity, can be transformed by transmetallation into unique polyfunctional copper, palladium, or titanium intermediates which, here again, undergo highly selective reactions and are quite interesting in assymetric synthesis.

Active Metals, because of the diversity and wide scope of the reagents and applications described, offers a good entry into the study of organic synthesis by means of metal species, and should convince the reader, if still necessary, of their major importance. It will also satisfy the specialist who will certainly find new information and ideas regarding many transformations. Although obviously not exhaustive—that is not the aim of the monograph—the list of reagents and reactions includes beautiful examples of what is possible by using properly synthesized and defined materials. In fact, it is often a problem for the chemist to control the preparative tricks for obtaining suitable and efficient reagents which will induce successful and reproducible reactions. Undoubtedly, Fürstner's book is without precedent in providing the complete and detailed procedures enabling the chemist to prepare and use active metals. The more conventional route to these is the chemical reduction of metal salts, which can be accomplished by several methods, using alkali metals, manganese-anthracene or magnesium hydride, hydrotriorganoborates, and also electrolysis. Another approach is the physical dispersion of the element, by ultrasonically induced activation or metal evaporation. The principles of each method are clearly presented, as well as the scope and limitations of the different procedures. The details of typical experiments are provided, with essential informations on the handling of specific chemicals, equipment and apparatus.

The active metals thus obtained exist in a variety of physical forms—ultrafine powders, clusters or colloids, intermetallics and alloys—depending, for each preparative method, upon the experimental conditions. Clearly, the symbol M* does not represent a simple real species; moreover, an active metal is often a "living" material which undergoes variations in its physical properties and is not stable enough to be stored indefinitely. These difficulties can be circumvented by immobilizing the active metal on a support. In addition to the improved stability and ease of use, supported metals, especially the metal – graphite combinations, give higher efficiency and selectivity, due to the synergism between the reagent and its carrier. Metal colloids can also be stabilized by tetraalkylammonium or phosphonium salts. It is evident that a reaction will follow a different course depending on the morphology, bulk density, and grain or particle size of the so-called M* species. The contributors to the monograph are leading experts in their special fields, some dealing mainly with the characterization and others with the synthetic applications of the active metals; their diverse approaches brought together in this book are an example of the value and necessity of interdisciplinary studies. Indeed, further significant progress in metal-induced reactions will become possible when the phenomenon of activation and the relationship between the structure of the metal and its reactivity are better understood. The first exciting achievements in this direction open up promising perspectives. Our knowledge of the factors influencing particle growth and the clustering process has been much improved. The characterization of the materials is becoming more accurate, facilitated by the development of suitable techniques (X-ray diffraction and absorption, electron microscopy, scanning tunneling microscopy, and atomic force microscopy), as shown by the elucidation of the morphology of metal – graphite compounds. These studies will attract the attention not only of organic and inorganic chemists but also of materials scientists, who are likely to be interested by the unusual physical properties of these nanostructured materials, such as superparamagnetism. Here again, interdisciplinary collaboration is highly desirable.

Because it is a unique guide to many experiments and an enormous source of valuable information, *Active Metals* should be at the disposal of everyone in a preparative chemistry laboratory. Moreover, as well as practical details and up-to-date references, the book is teeming with stimulating ideas, a lot of new facts and problems that must be known and shared for taking up numerous challenges in various fields of chemistry. I believe that *Active Metals* will have historical importance, since it makes the chemist want to get work in the laboratory and helps him or her to build the science of tomorrow.

Many fascinating inorganic polymers including dendrimers such as the organoplatinum complex shown here have been recently synthesized

Polymers and the Periodic Table: Recent Developments in Inorganic Polymer Science

Ian Manners*

Dedicated to the memory of Daisy Maud Manners

Polysiloxanes $[-R_2Si-O-]_n$, polyphosphazenes $[-R_2P=N-]_n$, and polysilanes $[-R_2Si-]_n$ illustrate that the incorporation of inorganic elements into a polymer main chain can lead to useful properties. These include low temperature flexibility, high thermal and oxidative stability, flame retardancy, novel forms of chemical reactivity, and intriguing electrical and optical characteristics arising from unusual electronic effects such as the delocalization of σ electrons. However, until recently, the development of inorganic polymer science has been held back by the synthetic problem of finding ways to join atoms of inorganic elements together into long chains. This review surveys many of the exciting advances in the field of inorganic polymers over the past decade and focuses mainly on the new inorganic polymer systems that have been prepared during this period. These include random-network polysilynes, poly(carbophosphazene)s, sulfur–nitrogen phosphorus polymers, poly(organooxothiazene)s, and, very recently, the first examples of polystannanes that possess a main chain of tin atoms. Transition metal based polymer science has also experienced a number of synthetic breakthroughs and new materials include high molecular weight metallocene-based polymers, polymetallaynes incorporating elements such as iron, nickel, and rhodium, liquid crystalline organocobalt and organochromium polymers, and lanthanide-based polymers.

Keywords: inorganic polymers · liquid crystals · main group elements · semiconductors · transition metals

1. Introduction

Despite the fact that carbon is not a particularly abundant terrestrial element, carbon-based or "organic" macromolecules form the basis of life on our planet, and natural or synthetic macromolecules based on carbon chains fill the world around us.[1, 2] Organic polymers are used as plastics and elastomers, films, and fibers in areas as diverse as clothing, car tires, compact discs, packaging materials, and prostheses.[2] Moreover, exciting new applications in electroluminescent and integrated optic devices and sensors are also now under development.[3] The massive growth in the use of organic polymeric materials in the past 50 years can mainly be attributed to their ease of preparation, lightweight nature, and unique ease of fabrication. Their ease of preparation is a consequence of not only the advanced state of organic synthesis, which reflects both the intrinsic logic of this subject and the creativity of scientists interested in the area, but is also due to the accessibility of cheap petroleum-derived monomers.[2]

In contrast to organic chemistry, the chemistry of inorganic elements is generally at a much more primitive state of development. Even seemingly simple small molecules can be surprisingly elusive,[4] and the development of routes to long polymer chains constructed mainly or entirely from inorganic elements has been a particular challenge.

2. The Construction of Long Inorganic Chains: A Synthetic Problem

One might anticipate that application of the techniques that have worked so well for the preparation of organic polymers would allow similarly facile access to inorganic macromolecules. However, consideration of the main synthetic routes to organic polymers (Scheme 1) illustrates the problems associated with this approach. Traditional synthetic protocols that involve a chain-growth mechanism such as addition polymerization (Scheme 1, Route A) are very difficult to use for inorganic polymer synthesis, since suitably reactive but stable multiple bonds involving inorganic elements are generally difficult to prepare. In contrast to the situation for unsaturated organic molecules (α-olefins, acetylenes, nitriles, etc.), the isolation of stable species with multiple bonds between inorganic elements usually requires the presence of sterically demanding, oligomerization-inhibiting ancillary groups.[5] Most of the early attempts to prepare inorganic polymers focused on the use of polycondensations (Scheme 1, Route B). These step-growth routes work well

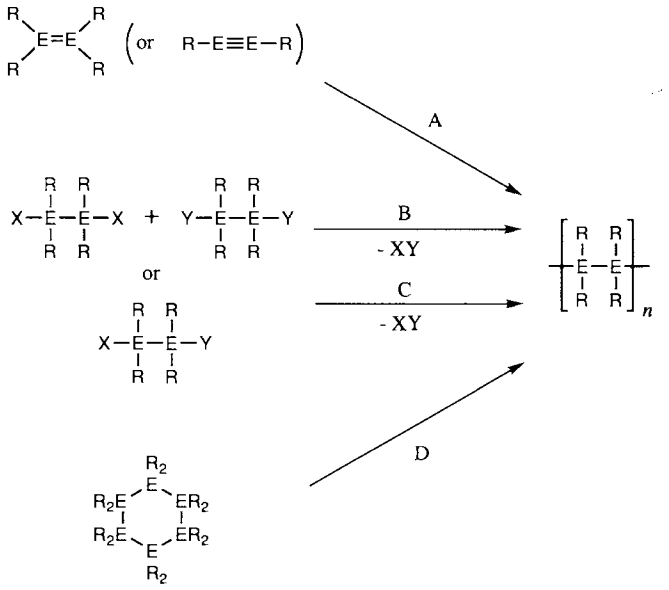
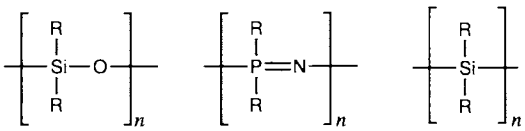


Scheme 1. Syntheses of inorganic polymers (E = inorganic element).

for the synthesis of carbon-based polymers when difunctional organic monomers are used because such species are generally easily accessible in a high degree of purity.[6] This allows the stringent stoichiometry and conversion requirements which need to be fulfilled for the formation of high molecular weight condensation polymers to be satisfied.[7] However, inorganic functional group chemistry is poorly developed and difunctional inorganic monomers (dilithiated species, for example) are often so reactive that they are difficult to prepare and purify. Thus, exact reactant stoichiometries for polycondensation reactions cannot be achieved.[7] This generally results in the formation of low molecular weight oligomeric products, which are well below the critical molar mass (typically M_n = ca. 10000) needed to obtain the necessary interchain entanglement and materials mechanical strength for fabrication into free-standing films, fibers etc. The advantageous processability characteristics associated with macromolecules, which generally constitute the major motivation for making polymers in the first place, cannot therefore be realized.[8] A very promising variant on this type of condensation polymerization is to use monomers that possess groups X and Y, which can be eliminated from the same molecule (Scheme 1, Route C). This circumvents the need for careful control of reaction stoichiometry and, in certain cases, polymerization of monomers of this type can follow a chain-growth-type mechanism, which leads to polymers with high molecular weights much more naturally.[6] Another chain-growth approach that appears very promising is ring-opening polymerization (ROP) (Scheme 1, Route D). Inorganic ring chemistry is very well-developed and thus many potential ROP monomers are available.[9]

As a result of the synthetic difficulties, until recently only three well-characterized inorganic polymer systems existed: polysiloxanes or "silicones" **1**, polyphosphazenes **2**, and polysilanes **3**.[10] Significantly, these materials all possess remarkable properties, which differ substantially from those of conventional organic macromolecules.



1 **2** **3**

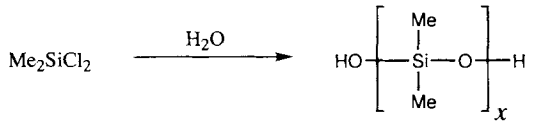
This review aims to provide an overview of the current status of inorganic polymer science[10–14] and will focus mainly on recent developments in the field with particular attention given to the new, well-characterized polymer systems prepared in the last 10 years. Excellent reviews and books have been published that describe the synthesis, properties, applications, and technology of polysiloxanes, polyphosphazenes, and polysilanes in detail. In this article, the main features of these three well-established polymer systems are briefly summarized, as their unique properties help provide the motivation for the further expansion of inorganic polymer science to elements other than Si, P, O, and N in the periodic table. Recent developments concerning new classes of inorganic polymers based on main group elements and transition metals are then described.

Ian Manners was born in London, England in 1961. He received his BSc degree in Chemistry in 1982 at the University of Bristol where he also completed his PhD (in 1985) with Professor Neil Connelly on organotransition metal radicals. From 1986–87 he was a Royal Society European Postdoctoral Fellow at the RWTH, Aachen, Germany working with Professor Peter Paetzold on the chemistry of iminoboranes. Following work as a Research Associate on polyphosphazenes and poly(heterophosphazene)s with Professor Harry R. Allcock at the Pennsylvania State University, USA, he joined the Faculty at the Department of Chemistry, University of Toronto, Canada in July 1990. He became an Associate Professor in 1994 and a Full Professor in 1995 and he is currently a Fellow of the Alfred P. Sloan Foundation (1994–1996) and is the recent recipient of the Rutherford Memorial Medal in Chemistry (1996). His research interests focus on the synthesis, properties, and applications of novel inorganic molecules, polymers, and solid-state materials. He is the author or coauthor of over 120 publications and holds or coholds five patents.

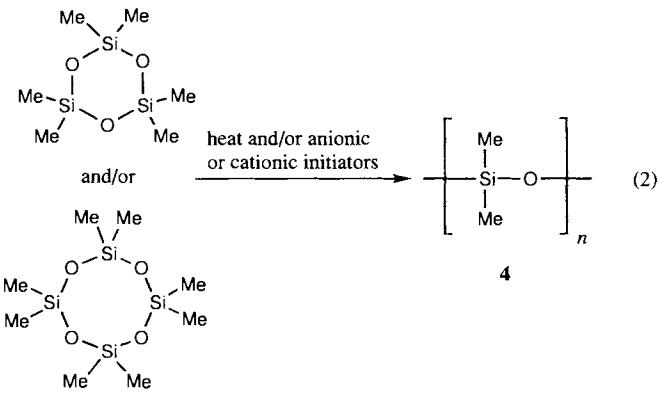
3. Well-Established Inorganic Polymer Systems

3.1. Polysiloxanes or Silicones

Polysiloxanes, which were first developed in the 1930s and 1940s, currently represent the most commercially important inorganic polymer system and comprise a billion dollar global industry.[15,16] Indeed, these materials are now often regarded as commodity polymers rather than specialty products. The main methods of synthesis involve condensation and anion- or cation-induced ring-opening routes and these are illustrated for the synthesis of the most common siloxane polymer, poly(dimethylsiloxane) (**4**) [Eqs. (1) and (2)]. The starting materials



(1)



(2)

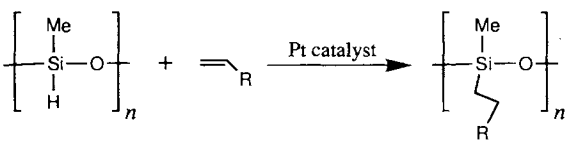
are organodichlorosilanes of which the most common, Me_2SiCl_2, is readily available by the Rochow–Müller process. The cyclic starting materials used in the ROP route are available by controlled hydrolysis of the corresponding organodichlorosilane.

The exceptional properties of polysiloxanes are a direct result of their inorganic backbone of silicon and oxygen atoms and have resulted in their widespread use as high performance elastomers and fluids, surface modifiers, adhesives, and biomedical materials.[10,15–18] The siloxane backbone, which contains long Si–O bonds (1.64 Å compared to 1.54 Å for a C–C bond), the absence of substituents on every other skeletal atom (oxygen), and a wide bond angle at oxygen (Si-O-Si 143° compared to C-C-C 109°), possesses unique dynamic flexibility. This leads to materials that retain elasticity and do not become brittle even at very low temperatures. For example, poly(dimethylsiloxane), the most common polymer, has a glass transition temperature (T_g) of −123 °C, and for poly(methylhydrosiloxane) the T_g value is even lower (−137 °C). In addition, Si–O bonds are stronger than C–C bonds (bond energies: Si–O ca. 450 kJ mol^{-1}, C–C ca. 348 kJ mol^{-1}) and are more stable to oxidation and UV radiation. This results in higher thermooxidative stability and leads, for example, to the use of polysiloxanes in oil baths found in most chemical laboratories. Poly(dimethylsiloxane) crystallizes at T_m = −40 °C, and for many elastomer applications the introduction of a small percentage of phenyl substituents by random copolymerization is necessary to ensure amorphous character. Crosslinking for elastomer applications can be achieved by a variety of techniques including heating with peroxides or vulcanization at room temperature by which crosslinking can be induced by the transition metal catalyzed hydrosilylations between vinyl substituents and Si–H groups introduced along the polymer chain. In general, the addition of reinforcing agents or fillers such as high surface area silica is also necessary to improve mechanical properties.[10]

Polysiloxanes also have a variety of other useful properties such as hydrophobicity and their exceptionally high permeability to gases. Indeed, snails can live submerged beneath the surface of low molecular weight poly(dimethylsiloxane) fluids for up to 72 h by breathing oxygen that diffuses through the material.[17] Other applications in the biomedical field that take advantage of the high permeability of polysiloxanes include uses as soft contact lenses and artificial skin. However, the leakage of silicone-based materials through polysiloxane membranes in breast implants has raised considerable public concern. Nevertheless, claims of health problems arising from the consequential presence of silicones in the body appear unproven to date.[18]

Although poly(dimethylsiloxane) is the most well-studied example, a wide variety of other polysiloxanes with aliphatic or aromatic side groups are known and these are accessible either by condensation or by cationic- or anionically-induced ROP routes. These other polysiloxanes also have very interesting properties and many have been the subjects of recent studies. For example, the morphology of simple high molecular weight (M_w = ca. 10^5–10^6) *n*-alkyl-substituted polysiloxanes that are available by ROP has been studied in detail.[19] Many, such as poly(di-*n*-pentylsiloxane), poly(di-*n*-hexylsiloxane), and poly(di-*n*-decyl)siloxane, are liquid crystalline and each forms a disordered mesophase. Polysiloxanes with fluoroalkyl substituents (e.g. trifluoropropyl), also known as fluorosilicones, possess novel surface properties and are technologically important with a range of applications.[17] The living anionic ROP of strained cyclic siloxanes such as $(Me_2SiO)_3$ is also important as this permits access to block copolymers with organic monomers.[20]

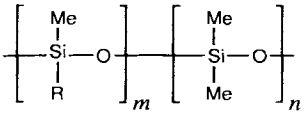
A very versatile methodology for controlling the properties of polysiloxanes involves hydrosilylation [Eq. (3)]. Reaction of



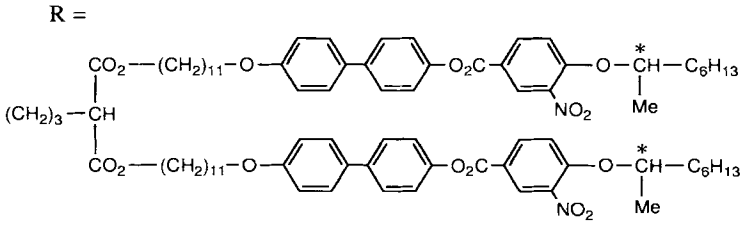
(3)

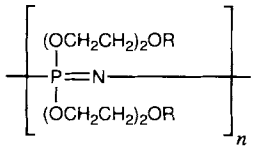
poly(methylhydrosiloxane) or poly(methylhydrosiloxane)–poly(dimethylsiloxane) copolymers with vinyl-capped species allows the introduction of side groups that give rise to a variety of interesting properties.[21,22]

For example, ferroelectric side-chain liquid crystalline polysiloxanes **5** with short switching times have recently been reported.[23] Another exciting recent development involves the

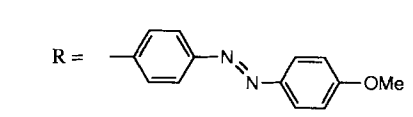


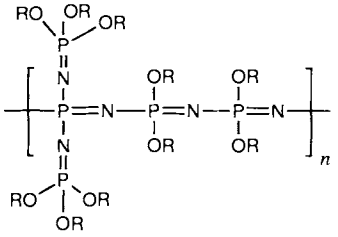
5



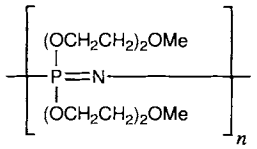


7





8

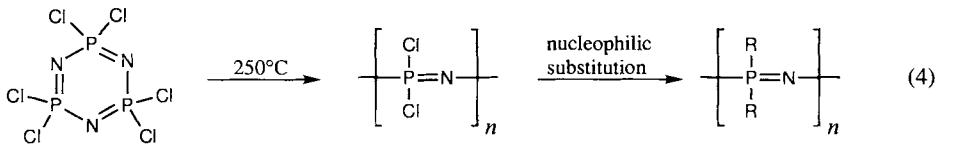


9

use of polysiloxanes functionalized with polar cyanopropyl and crosslinkable methacryloxypropyl groups as the matrices of Na^+ sensing membranes for chemically modified field-effect transistors (CHEMFETs).[24] The advantages of polysiloxanes for this type of application revolve around their high diffusion and permeability coefficients.

3.2. Polyphosphazenes

Polyphosphazenes **2** have a phosphorus–nitrogen backbone. The first example, poly(dichlorophosphazene) (**6**) [Eq. (4)], was prepared in crosslinked form by Stokes at the end of the last century by the thermal ROP of the cyclic trimer $(Cl_2PN)_3$.[10] However, this material, referred to as "inorganic rubber," remained only a chemical curiosity due to its intractability and hydrolytic instability. The key developments concerning this polymer system took place in the mid-1960s when it was shown by Allcock and Kugel that if the ROP of pure $(Cl_2PN)_3$ is carried out carefully, uncrosslinked **6** is formed which is soluble in organic solvents.[25] This permitted replacement of the halogen substituents by reaction with nucleophiles to yield hydrolytically stable poly(organophosphazene)s [Eq. (4)].[10, 26–28]



(4)

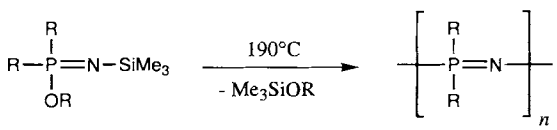
6

R = OR, OAr, NHR, etc.

The unique reaction sequence comprising ROP followed by nucleophilic substitution with oxygen- or nitrogen-based nucleophiles (generally alkoxides, aryloxides, or primary amines) has been pioneered by Allcock and co-workers, and permits the immense structural diversity of poly(organophosphazene)s and allows the properties to be tuned and specific properties to be introduced.[10] Recent highlights concerning the use of the macromolecular substitution route with **6** and related materials include the introduction of side groups which lead to liquid crystallinity (see polymer **7**),[29] photochromism,[30] photocrosslinkability,[31–33] and the preparation of novel polymers such as **8** with short chain branching.[34]

The phosphazene backbone also inherently possesses a unique range of unusual properties. For example, it is extremely flexible, and poly(alkoxyphosphazene)s such as the *n*-butoxy derivative have glass transitions of below $-100\,^{\circ}C$.[10] Furthermore, it is thermally and oxidatively stable, optically transparent from 220 nm to the near IR region, and it imparts flame-retardant properties. Some of the most important polymers are fluoroalkoxy derivatives and amorphous copolymers are very useful as flame-retardant, hydrocarbon-solvent and oil-resistant elastomers and have found aerospace and automotive applications. Polymers such as the amorphous comb polymer poly[bis(methoxyethoxyethoxy)phosphazene] **9** are of considerable interest as components of polymeric electrolytes in battery technology.[10] Polyphosphazenes are also of interest as biomedical materials, and bioinert, bioactive, membrane-forming, and bioerodable materials and hydrogels have been prepared.[10]

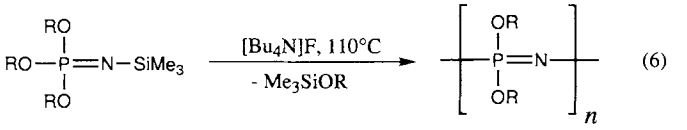
The reaction of poly(dichlorophosphazene) with organometallic reagents such as Grignard or organolithium reagents generally leads to chain cleavage as well as substitution and does not provide a satisfactory route to polymers with only alkyl and aryl side groups bound by direct P–C bonds.[10] In the early 1980s a solution to this problem was provided by the discovery by Neilson and Wisian-Neilson of a condensation route to poly(alkyl/arylphosphazene)s from phosphoranimines [Eq. (5)].[35] The polymerization is in fact a chain-growth reaction, and allows access to high molecular weight polyphosphazenes such as poly(dimethylphosphazene) and poly(methylphenylphosphazene).



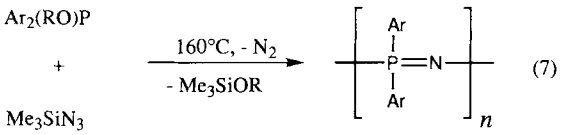
(5)

R = alkyl or aryl

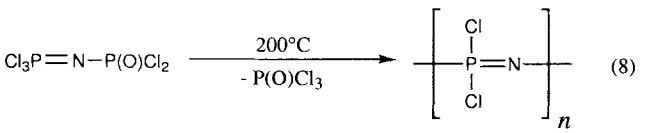
Although several polyphosphazenes have been commercialized, recent work has focused on the development of cheaper and more convenient methods for making these materials. The thermal ROP route requires the synthesis and careful purification of the cyclic trimer $(Cl_2PN)_3$ and the use of elevated temperatures where control of molecular weight is difficult and crosslinking can take place at high conversion which can limit the yield. Recently, condensation reactions have been developed by Matyjaszewski and co-workers that provide an alternative, direct route to fluoroalkoxy phosphazene polymers and aryl derivatives, and also permit access to block copolymers [Eqs. (6) and (7)].[36, 37] The development of condensation routes to poly(dichlorophosphazene) have also been reported. De Jaeger and co-workers have described a promising route that operates at 200 °C [Eq. (8)].[38] Very recently Manners and Allcock and their respective co-workers reported details of a synthesis of poly(dichlorophosphazene) that operates at room temperature and allows molecular weight control [Eq. (9)].[39] These developments offer the prospect of improved routes to phosphazene polymers that may well facilitate more rapid and extensive commercialization.[40]



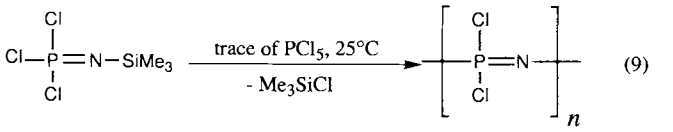
(6)



(7)



(8)

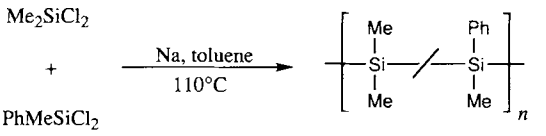


(9)

3.3. Polysilanes

Since the first reports of soluble and processable polysilanes **3** in the late 1970s, these macromolecules have attracted tremendous interest from both a fundamental and an applied perspective.[10, 41–43] The backbone of silicon atoms gives rise to unique electronic and optical properties as a result of the delocalization of σ electrons. Several polysilanes also function as useful thermal precursors to silicon carbide fibers and these materials have also attracted attention with respect to microlithographic applications and as polymerization initiators.[10, 41, 42]

The first report of a soluble polysilane by West and co-workers appeared in 1978, and the material was prepared by the treatment of a mixture of organodichlorosilanes with sodium metal.[44] Instead of only the expected cyclic oligomers, a polymeric product, termed "polysilastyrene" (**10**), was formed [Eq. (10)]. Poly(dimethylsilane) had been previously prepared



(10)

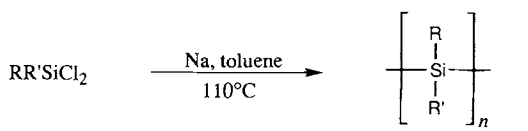
10

as a highly crystalline insoluble material.[10, 41, 42] The introduction of phenyl groups in the random copolymer reduces the crystallinity and allows the material to be soluble and processable.

The use of this Wurtz coupling route has allowed the preparation of a range of high molecular weight polymers ($M_n > 10^5$) with alkyl or aryl subtituents at silicon. Since 1980 the interest in these polymers has grown tremendously and they have been found to possess a variety of fascinating properties.

One of the most remarkable features of the all-silicon backbone is that it leads to the delocalization of σ electrons, a phenomenon that is virtually unknown in carbon chemistry.[45] This can be understood in terms of the nature of the molecular orbitals associated with the Si–Si σ bonds. These are more diffuse than those associated with C–C σ bonds, since they are constructed from higher energy 3s and 3p atomic orbitals. This leads to significant interactions between the adjacent Si–Si σ bonds along a polysilane chain, a situation analogous to that for the π bonds in π-delocalized polymers such as polyacetylene. Thus a band model rather than a localized model is more appropriate.[10, 42] As a consequence of the delocalization of σ electrons, the σ-σ* transition, which occurs at 220 nm in $Me_3Si-SiMe_3$, moves to lower energy as the number of silicon atoms in the chain increases. In the high polymers the σ-σ* band-gap transitions occur in the near UV region at about 300–400 nm.[46] The electron delocalization also leads to appreciable electrical conductivity following doping. For example, conductivities of up to 0.5 Scm^{-1} have been reported for **10**, after doping with AsF_5.[10] In addition, many of the polymers are thermochromic as the conformations adopted by the polymer change with temperature, which alters the degree of σ delocalization along the main chain. Due to their low energy σ-σ* transitions, polysilanes are photosensitive and have attracted considerable attention as photoresist materials in microlithography.[10, 41, 42]

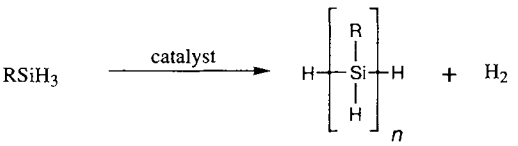
The main method used to synthesize polysilanes involves the thermally induced Wurtz coupling reaction of organodichlorosilanes with alkali metals [Eq. (11)]. Although improvements in



(11)

this process have been reported, for example the use of ultrasound, the harsh conditions for this reaction tend to limit the side groups that can be successfully introduced to nonfunctionalized alkyl and aryl units and makes scale up unattractive.[10]

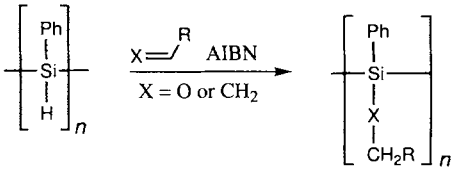
Because of these limitations, considerable effort has been focused on the development of new synthetic routes to polysilanes. The dehydrogenative coupling process catalyzed by early transition metals, which was discovered by Harrod and co-workers in 1985 [Eq. (12)], is potentially very attractive; however, the



(12)

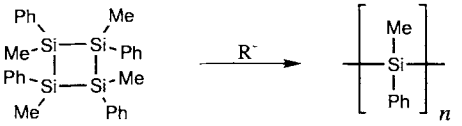
molecular weights of the polysilanes formed to date are generally quite low ($M_n < 8000$).[47] The catalysts used for these coupling reactions are usually titanocene or zirconocene derivatives.[47,48]

The catalytic dehydrogenation route yields novel polysilanes with Si–H functionalities that are of interest as ceramic precursors.[49] In addition, Waymouth and co-workers have recently shown that a variety of new side groups can be introduced by using a derivatization approach [Eq. (13)].[50]



(13)

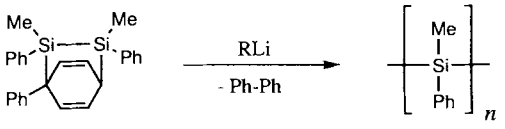
In 1991 Matyjaszewski and co-workers reported a novel ROP route to polysilanes [Eq. (14)].[51] The key to this approach is to



(14)

take readily accessible octaphenylcyclotetrasilane, which is too sterically crowded to undergo ROP, and to replace some of the phenyl groups by smaller methyl substituents (by a two-step process) to make the ring polymerizable.

Sakurai and co-workers have also recently described another novel route to polysilanes that involves the anionic polymerization of disilabicyclooctadienes, which function as masked disilenes [Eq. (15)].[52]



(15)

Recent exciting developments in polysilane research include the use of these materials as hole transport layers in electroluminescent devices.[53] In addition, the photoconductivity of poly(methylphenylsilane) doped with C_{60} is comparable with the best materials currently available.[54] Remarkable, optically active[55] and dendritic polysilanes with extensively σ-delocalized structures[56,57] have also recently been prepared.

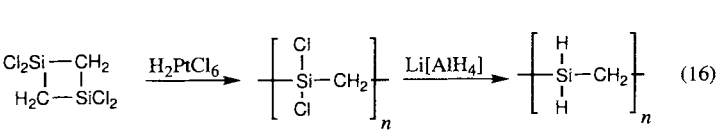
4. New Polymers Based on Main Group Elements

Polysiloxanes, polyphosphazenes, and polysilanes illustrate that incorporation of main group elements within a polymer main chain can influence chain flexibility, flame retardancy, and electron delocalization, and can also permit access to new synthetic avenues for the control of polymer microstructure and hence properties. Over the last decade, attention has also focused on the development of a range of new polymer systems based on p-block elements, and these are now reviewed.

4.1. Poly(carbosilane)s

Polymers with a carbon–silicon backbone have been known since the 1960s.[58,59] Thermal and transition metal catalyzed ROP routes were used to prepare these materials. A range of polymers with silicon and unsaturated hydrocarbon linkages in the backbone are also known and several of these materials exhibit significant electrical conductivity upon doping.[60–65] Dendritic poly(carbosilane)s have also been prepared recently.[66,67] Over the past 10 years the main interest in poly(carbosilane)s has focused on their use as precursors to silicon carbide ceramics.[41,42,68–70]

One of the recent highlights of this area is the synthesis and study of the properties of poly(silaethylene) (**11**), a novel analogue of polyethylene, by Interrante and co-workers.[71] This polymer was prepared by the platinum-catalyzed ROP of 1,1,3,3-tetrachlorodisilacyclobutane to yield poly(dichlorosilaethylene), followed by reduction with $LiAlH_4$ [Eq. (16)].[72]

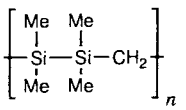


(16)

11

Poly(silaethylene) is air-stable, soluble in organic solvents, and has been well-characterized. In contrast to polyethylene, which is a fairly high melting point solid ($T_m = 138\,°C$), this material is a viscous liquid at room temperature but on cooling to just below room temperature forms a translucent white solid. Below the T_m at about 25 °C the powder X-ray diffraction pattern shows no obvious similarity to that for any of the known forms of polyethylene. The T_g for this material is extremely low (ca. −135 to −140 °C). Significantly, poly(silaethylene) converts to stoichiometric silicon carbide in excellent yield (87%) on pyrolysis to 1000 °C.

Very recent work by Isaka et al. suggests that "saturated" poly(carbosilane)s may possess interesting electronic properties.[73] Periodic poly(carbodisilane)s **12** were prepared by Wurtz coupling and



12

show evidence of significant σ conjugation despite the presence of a saturated carbon atom in every repeat unit. Indeed, ab initio calculations for poly(carbodisilane)s indicated that the effective hole masses at the valence band edge were inbetween those in polysilanes and polyethylene.

4.2. Random-Network Polymers of the Group 14 Elements: Polysilynes and Polygermynes

In 1989 Bianconi and Weidman prepared the first members of a class of random-network silicon polymers termed polysilynes $[RSi]_n$.[74] These yellow, film-forming materials (**13**) were synthesized by the Wurtz coupling reaction of organotrichlorosilanes promoted by high intensity ultrasound [Eq. (17)].

$$RSiCl_3 \xrightarrow[\text{THF, ultrasound}]{\text{Na/K}} \left[\begin{array}{c} R \\ | \\ -Si- \end{array}\right]_n \qquad (17)$$

13

Polysilynes **13** are soluble in organic solvents, providing that the organic group R attached to silicon has at least four carbon atoms, and have molecular weights (M_w) of between 10000–15000 by gel permeation chromatography (GPC). Differential scanning calorimetry (DSC) and X-ray powder diffraction studies showed that the materials are amorphous, and NMR studies are consistent with the presence of a randomly constructed rigid network of monosubstituted sp^3-hybridized silicon units (Fig. 1). The electronic properties of these materials are particularly interesting and are significantly different from those of linear polysilanes.[75, 76] Poly(*n*-hexylsilyne), for example, shows an intense near-UV absorption band edge that tails into the visible region up to 450 nm, which is associated with σ conjugation extended in three dimensions (Fig. 2). The three-dimensional structure of these materials leads to additional photostability in comparsion to that for polysilanes. In air, insoluble polysiloxanes are formed by insertion of oxygen atoms into the Si–Si bonds. Potential applications of these materials as photoresists are under investigation; exposure to air or light leads to a pattern that remains after dissolution of unoxidized polymer.

Fig. 1. Random-network structure of the polysilyne **13** (R = *n*-hexyl) (adapted from ref. [75] with permission).

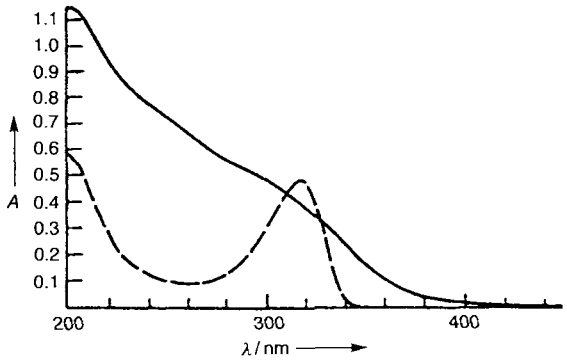


Fig. 2. UV/Vis spectra in cyclohexane of the polysilyne **13** (R = *n*-hexyl) (filled line) compared to that of the polysilane **3** (R = *n*-hexyl) (broken line) (reproduced from ref. [75] with permission). *A* = absorption (arbitrary units).

Very recently random-network polymers have been made for other Group 14 elements.[77] Polygermynes **14** are coffee-colored materials prepared from organotrichlorogermanes by a similar synthetic methodology [Eq. (18)]. These materials have UV/Vis absorptions that tail into the visible region up to 800 nm. Copolymers with polysilynes have also been prepared by using mixtures of $RSiCl_3$ and $RGeCl_3$ and have properties intermediate between those of the homopolymers. For example, $[(n\text{BuSi})_{0.8}(\text{PhGe})_{0.2}]_n$ shows a UV/Vis absorption band that tails up to about 650 nm.[77]

$$RGeCl_3 \xrightarrow[\text{THF, ultrasound}]{\text{Na/K}} \left[\begin{array}{c} R \\ | \\ -Ge- \end{array}\right]_n \qquad (18)$$

14

4.3. Linear Polymers Containing Heavier Group 14 Elements: Polygermanes and Polystannanes

The remarkable properties of polysilanes has led to considerable interest in the development of polymer chains based on the heavier Group 14 elements germanium and tin. Polygermanes were prepared in the mid 1980s by Wurtz coupling techniques similar to those used to prepare the silicon polymers [Eq. (19)].

$$RR'GeCl_2 \xrightarrow[110^\circ C]{\text{Na, toluene}} \left[\begin{array}{c} R \\ | \\ -Ge- \\ | \\ R' \end{array}\right]_n \qquad (19)$$

Studies of these materials indicated that the σ delocalization is even more extensive than for polysilanes and that the σ-σ* band-gap transition for the high polymers is significantly red shifted by about 20 nm in comparison to that for the silicon analogues.[78, 79]

Polystannanes would be expected to have even more σ delocalized structures.[80-82] Indeed, elegant work by Dräger and co-workers in 1987 showed that linear oligostannanes with up to six tin atoms can be prepared and that the σ-σ* transition moves dramatically to lower energy as the chain length is increased. This led to the proposed term "molecular metals" for prospective high molecular weight analogues.[80] However, attempts to generate high polymers by Wurtz coupling of organodichlorostannanes have yielded only low molecular weight oligomers and reduction products. A key breakthrough in this area was reported in 1993 by Tilley and co-workers who showed that transition metal catalyzed dehydrogenative coupling reactions, which had been extensively applied to the synthesis of polysilanes (see Section 3.3), could be applied to secondary stannanes R_2SnH_2 [Eq. (20)].[83] Yellow polystannanes **15** (R = e.g.

$$R_2SnH_2 \xrightarrow[25^\circ C]{\text{Zr catalyst}} \left[\begin{array}{c} R \\ | \\ -Sn- \\ | \\ R \end{array}\right]_n \qquad (20)$$

15

n-butyl, *n*-hexyl, or *n*-octyl) of substantial molecular weight (up to M_w = ca. 96000, M_n = ca. 22000) were prepared by using various zirconocene catalysts. These materials indeed possess σ electrons that are extensively delocalized, as illustrated by the band-gap transition that occurs at 384–388 nm (in THF). In addition, exposure of thin films of the polymers to the oxidant AsF_5 leads to significant electronic conductivities of about 0.01 - 0.3 $S\,cm^{-1}$.[84]

The properties of these remarkable materials are now under detailed scrutiny. They are highly photosensitive and exhibit photobleaching behavior, and on irradiation with UV light depolymerize to yield cyclic oligomers (Fig. 3). The materials are thermally stable to temperatures between 200 and 270 °C in air, and at more elevated temperatures function as interesting precursors to SnO_2.[84]

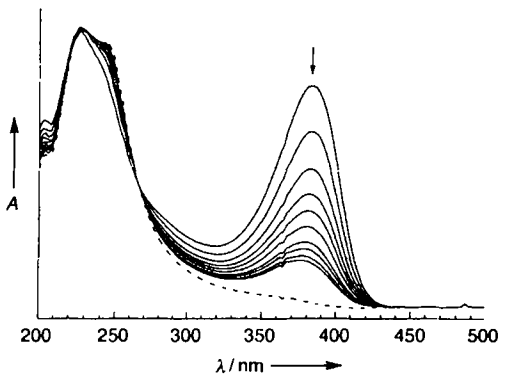

Fig. 3. UV/Vis spectrum of polystannane **15** (R = *n*Bu) illustrating photobleaching behavior in pentane upon irradiation by room light. Measurements were taken every 30 s. The final spectrum is given by the dotted line. (reproduced from ref. [84] with permission). *A* = absorption (arbitrary units).

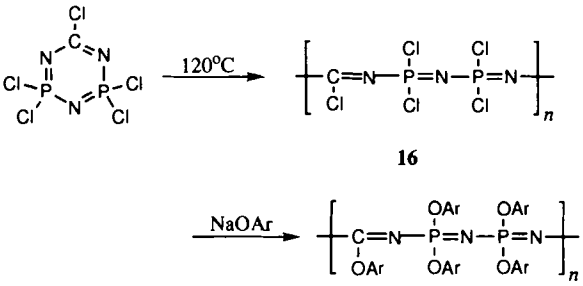
4.4. Poly(carbophosphazene)s

Poly(carbophosphazene)s have a backbone comprising phosphorus, nitrogen, and carbon atoms and can be regarded as derivatives of classical polyphosphazenes **2** in which every third phosphorus atom is replaced by carbon. The first examples of these materials were discovered in 1989 by Allcock, Nuyken and co-workers.[85] Thermal ROP of a cyclic carbophosphazene was used to prepare the chlorinated polymeric species **16**, which undergoes halogen replacement reactions with nucleophiles such as aryloxides to yield hydrolytically stable poly[(aryloxy)carbophosphazene]s **17** (M_w = ca. 10^5, $M_n = 10^4$) [Eq. (21)].[85-88] The polymer backbone in these materials is



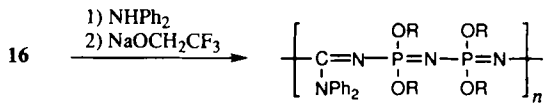
16

(21)

17

less flexible than in classical polyphosphazenes. For example, the halogenated polymer **16** has a T_g value of −21 °C compared to a value of −66 °C for poly(dichlorophosphazene) (**6**).

The reaction of **16** with alkylamines has also been studied.[88] The resulting poly[(alkylamino)carbophosphazene]s are sensitive to hydrolysis. However, arylamino derivatives are moisture-stable, and, in addition, a novel, regioselectively substituted polymer **18** was successfully prepared by the sequential reaction with $NHPh_2$ and trifluoroethoxide anions [Eq. (22)].



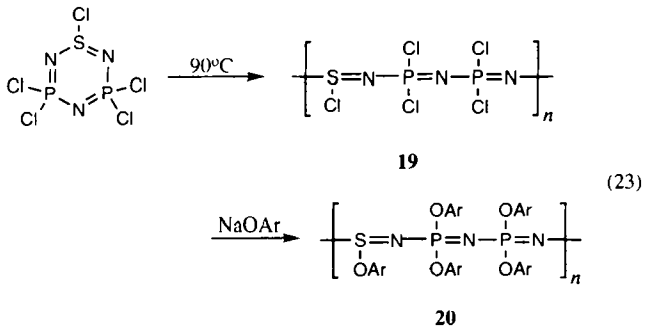
$OR = OCH_2CF_3$

18

(22)

4.5. Sulfur–Nitrogen–Phosphorus Polymers

Sulfur–nitrogen–phosphorus polymers have backbones that can be regarded as compositional hybrids of those present in sulfur–nitrogen polymers, such as the solid-state polymer poly(sulfur nitride) $[SN]_x$ or poly(oxothiazene)s $[RS(O)=N]_n$ (see Section 4.6), and classical polyphosphazenes, $[R_2P=N]_n$ (**2**).[89, 90] The first well-characterized examples of these materials, poly(thiophosphazene)s, were also reported by Allcock, Nuyken and co-workers.[91] These polymers were prepared by the thermal ROP of a cyclothiophosphazene [Eq. (23)]. This yielded the hydrolytically sensitive poly(thiophosphazene) **19** with a backbone comprising three-coordinate sulfur(IV), nitrogen, and phosphorus atoms. Although reaction of **19** with nucleophiles such as aryloxides yielded polymers of the type **20** with improved hydrolytic stability, degradation was still rapid except where very bulky substituents such as *o*-phenylphenoxy were present.

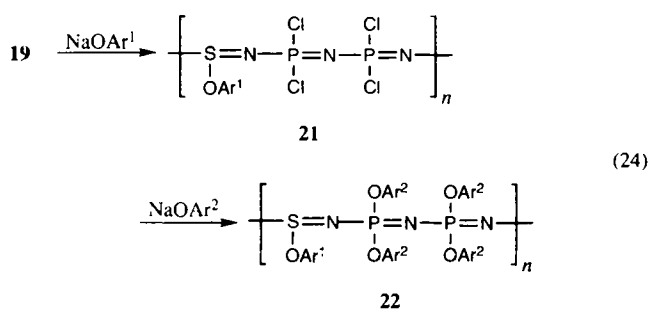


19

20

(23)

Although the backbone of poly(thiophosphazene)s appears to be quite fragile, a particularly interesting feature of the substitution reactions of **19** is that the S–Cl bond is much more reactive than the P–Cl bonds. Regioselective substitution is possible at the sulfur center, yielding macromolecules **22** with different aryloxy substituents at sulfur and phosphorus [Eq. (24)].[91,92]

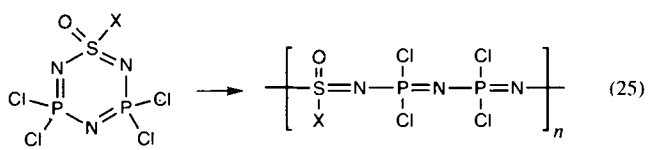


21

22

(24)

In 1991 another class of sulfur–nitrogen–phosphorus polymers, poly(thionylphosphazene)s, were reported by Manners and co-workers.[93,94] These materials, which possess four-coordinate sulfur(VI) atoms in the backbone, have considerably improved stability and were prepared by a thermal ROP of cyclic thionylphosphazenes **23** with either chlorine or fluorine at the sulfur(VI) center [Eq. (25)].[95]

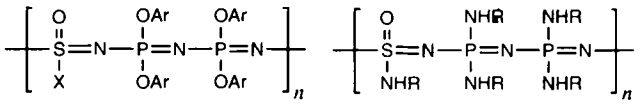


(X = Cl, F) 165°C (X = Cl); 185°C (X = F)

23 24

(25)

The halogenated poly(thionylphosphazene)s **24** that are formed in these ROP reactions (together with small quantities of macrocyclic by-products) are quite sensitive to hydrolysis but a variety of moisture-stable derivatives have been prepared by reaction of this species with aryloxides or amines.[96–98] Mixed-substituent aryloxy–alkoxy polymers have also been prepared.[89] Interestingly, with aryloxides, regioselective substitution at phosphorus is observed and in the resulting polymers (**25**), the sulfur(VI)–halogen bond remains intact. Remarkably, this regioselectivity is the exact reverse of that detected for the poly(thiophosphazene) **19** described above, in which the sulfur(IV) halogen bond is more reactive. In contrast to the reactions with aryloxides, reaction with amine nucleophiles leads to substitution at both the phosphorus and the sulfur(VI) centers to give poly(aminothionylphosphazene)s **26**.[98]



(X = Cl, F) R = Alkyl, Aryl

25 26

Ab initio calculations on isotactic poly(thionylphosphazene)s (**24**; X = Cl or F) indicate a localized electronic structure for the polymer backbone and predict that a *cis*–*trans* helical conformation is the most energetically favorable for isolated macromolecules (Fig. 4).[99] This is in contrast to the analogous classical polyphosphazene **6** in which a *cis*–*trans*-planar conformation is preferred. Studies of the properties of the poly(thionylphosphazene)s also reveal significant differences in thermal transition behavior and polymer morphology compared to that for the classical polyphosphazenes. For example, the polymer $[NSOF\{NP(OPh)_2\}_2]_n$ is an amorphous elastomer (T_g = −15 °C), whereas the analogous classical polyphosphazene $[NP(OPh)_2]_n$ is a microcrystalline thermoplastic (T_m = 390 °C, T_g = −6 °C). The T_g values of the fluorinated poly(thionylphosphazene)s are lower than those of the analogues with chlorine at sulfur. For example, for **24** (X = F) T_g = −56 °C, whereas for **24** (X = Cl) T_g = −46 °C.[97]

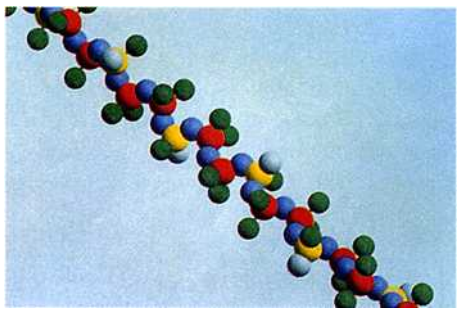


Fig. 4. Helical structure of the poly(thionylphosphazene) **24** (X = Cl) according to ab initio calculations. S: yellow, N: blue, P: red, O: white, Cl: green (picture courtesy of R. Jaeger and G. J. Vancso).

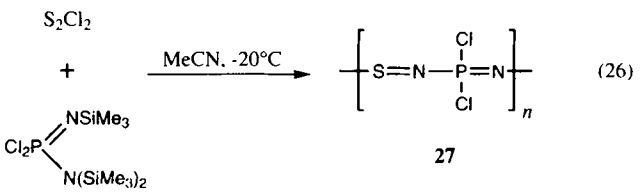
Recently preliminary reports of the first poly(thiazylphosphazene)s **27**, which possess three-coordinate sulfur(III) atoms, have appeared [Eq. (26)].[100] These materials would represent true hybrids of poly(sulfur nitride) and polyphosphazenes and further developments in this area should prove to be particularly interesting.

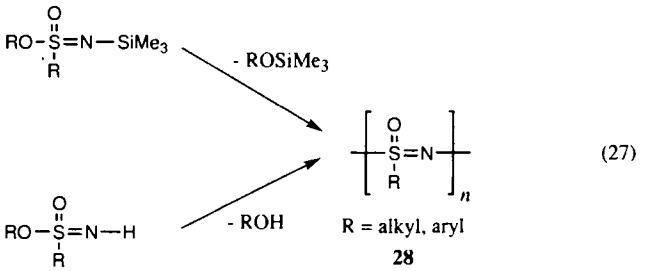


27

(26)

4.6. Poly(oxothiazene)s

Partially characterized poly(oxothiazene)s were briefly reported in the early 1960s.[101] However, in 1992 the first well-characterized examples (**28**) with alkyl or aryl substituents at sulfur were described by Roy.[102] These polymers, which have estimated molecular weights of M_w of about 10^5 and M_n of about 10^4, were synthesized by the condensation polymerization of *N*-silylsulfonimidates at 120–170 °C over two to eight days [Eq. (27)]. These reactions are catalyzed by added Lewis acids



(27)

28

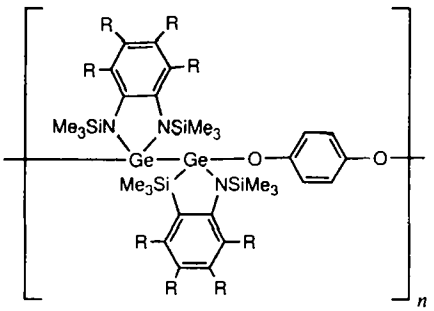
(e.g. $BF_3 \cdot OEt_2$) and bases (e.g. fluoride). By using a mixture of different sulfonimidates, copolymers such as $[MeS(O)=N]_n$-$[PhS(O)=N]_m$ were also successfully prepared. Free sulfonimidates also thermally condense to yield poly(organooxothiazene)s at lower temperatures than their *N*-silyl analogues [Eq. (27)].[102, 103]

Poly(oxothiazene)s appear to be very polar. For example, $[MeS(O)=N]_n$ is soluble in DMF, DMSO, hot water, and concentrated H_2SO_4. Studies of the thermal transition behavior of these materials have indicated that they are amorphous, which is consistent with an atactic structure. Interestingly, the T_g value of $[MeS(O)=N]_n$ is about 60 °C, which is dramatically higher than that for $[Me_2P=N]_n$ ($T_g = -46$ °C). This suggests a much less flexible backbone for poly(oxothiazene)s than for polyphosphazenes, as might be expected from studies on poly(thionylphosphazene)s (see Section 4.5). Thermogravimetric analysis (TGA) showed that the polymers are stable to weight loss up to about 270 °C (at a heating rate of 10 °C min^{-1}). Theoretical studies on $[MeS(O)=N]_n$ have indicated that a *cis-trans* helical conformation is the most stable for this polymer.[103]

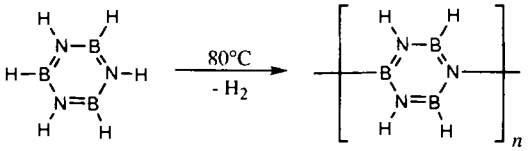
4.7. Other Polymers Based on Main Group Elements

The use of new synthetic methodologies has provided access to a range of other polymers incorporating main group elements in the main chain. Examples include interesting 2:1 periodic copolymers **29** prepared by Kobayashi and co-workers by the reaction of cyclic germylenes with *para*-benzoquinones.[104]

Boron-containing polymers are of considerable interest as reactive intermediates and as precursors to boron-based ceramics.[105–110] Sneddon and co-workers have synthesized polyborazines **30** (M_w up to about 7600, M_n up to about 3400) by thermally induced dehydropolymerization of borazines [Eq. (28)].[109] The polymers were isolated as white solids and characterization suggested the presence of a significantly branched structure. Pyrolysis at 1200 °C yielded white boron nitride in 85–93% yield.



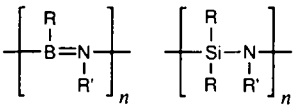
29



(28)

30

Poly(iminoborane)s **31**, boron–nitrogen analogues of poly(acetylene), have also been briefly reported as white insoluble materials, which swell in certain solvents.[111] These materials are clearly worthy of further investigation. Cyclodiborazane-based polymers have also been prepared and well-characterized.[112] In addition to boron-based systems, polymers with a silicon–nitrogen backbone, polysilazanes **32**, have also attracted considerable attention as precursors to ceramics such as Si_3N_4.[113] Novel, well-characterized polymers with backbones of silasesquioxane cages, which in some cases possess spacer groups containing transition elements such as zirconium, have also been prepared recently by Lichtenhan et al, and these materials have high stability and also exhibit preceramic potential.[114]



31 **32**

5. Transition Metal Based Polymers

Transition metal complexes and metal-containing solid-state materials display a diverse array of interesting and useful redox, magnetic, optical, electrical, and catalytic properties.[115, 116] The incorporation of transition metals into a polymer main chain therefore clearly offers considerable potential for the preparation of processable materials with properties that differ significantly from those of conventional organic polymers.[117–119] In addition, the diverse range of coordination numbers and geometries that exist for transition elements offer the possibility of accessing polymers with unusual conformational, mechanical, and morphological characteristics. Transition metal based polymers might also be expected to function as convenient and processable thermal or photochemical precursors to metal-containing ceramic films, fibers, and coatings with high stability and desirable and useful physical properties.[120] However, once again the development of this area of inorganic polymer science has been held up by considerable difficulties associated with the synthesis of these materials.

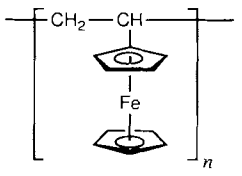
Much of the early work in the field utilized polycondensation routes in which the difunctional precursors were often impure, making low molecular weight, poorly defined materials the logical products. In addition, the resulting products were often insoluble and poorly characterized. Indeed, at the end of a comprehensive review of the field of metallocene-based polymers in 1970 the authors made the critical analysis that many of the structures assigned to the polymers in the article were "hypothetical and need rigorous analytical verification, and the description of experimental procedures and polymer properties more often than not has been superficial or has been lacking altogether".[121]

Over the past five years or so, however, a number of significant synthetic breakthroughs have taken place which have paved the way to the establishment of several examples of soluble, high molecular weight materials that have been well-characterized.

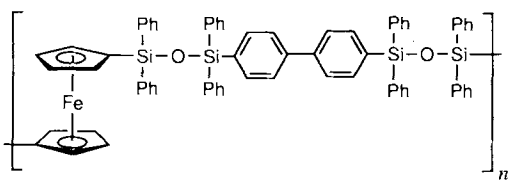
5.1. Metallocene-Based Polymers

5.1.1. Early Work on Ferrocene-Based Polymers

The excellent thermal stability and interesting physical (e.g. redox) properties associated with the ferrocene nucleus have led to extensive efforts aimed at the incorporation of this moiety into polymer structures. The inclusion of this moiety in the side group structure of polymers has been very successful because the synthesis of such materials generally requires only minor modifications of previously established synthetic methodologies. For example, poly(vinylferrocene) (**33**) can be prepared by the free radical addition polymerization of vinylferrocene.[122] The incorporation of ferrocene moieties into the main chains of polymers in which the metal atoms are separated by a considerable distance has also been achieved. Here, by exploiting the extensive organic chemistry of the metallocene nucleus, well-defined difunctional ferrocenes have been prepared, and controlled polycondensation reactions have then been used to yield well-defined products of appreciable molecular weight. Examples of products derived from such reactions include the poly(arylene-siloxane-ferrocene)s (e.g. **34**),[123] ferrocene-containing polyesters,[124] and novel "accordian" type polymers.[125, 126]



33

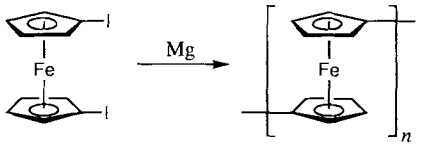


34

In contrast, very few examples of polymers with ferrocene units in close proximity have been prepared. Such materials are desirable if advantage is to be taken of interactions beween the metal atoms. The development of materials with interesting physical (e.g. electronic and/or magnetic) properties might be anticipated based on the properties of molecular species in which two ferrocene units are linked close together. Thus, in such systems the iron atoms can interact and in some cases yield delocalized, mixed-valent species upon one-electron oxidation, even when the metal atoms are up to 7 Å apart.[127, 128] Until recently, work in this field had only yielded materials of low molecular weight ($M_n < 10000$) that were often poorly defined.[121, 129]

5.1.2. Poly(ferrocenylene)s

A typical early route to poly(ferrocenylene)s **35** with $M_n < 5000$ involved polycondensation processes such as the recombination of ferrocene radicals generated by the thermolysis of ferrocene in the presence of peroxides. However, these materials possess other fragments such as CH_2 and O in the main chain.[130] More structurally well-defined poly(ferrocenylene)s such as **35** ($M_n < 4000$) have been prepared by Neuse et al.[131] by the condensation reaction of 1,1-dilithioferrocene·tmeda with 1,1-diiodoferrocene and, significantly, the reaction of 1,1′-dihaloferrocenes with magnesium [Eq. (29)] has



(29)

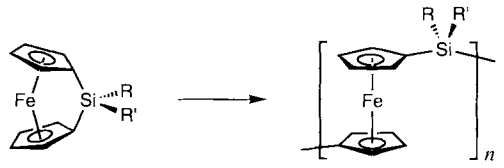
35

been shown to afford low molecular weight materials (M_n = 4600 for soluble fractions) with appreciable crystallinity.[132] In the latter case, oxidation with 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) afforded doped polymers that were delocalized on the Mössbauer timescale (ca. 10^{-7} s) at room temperature and which exhibited electrical conductivities of up to 10^{-2} S cm^{-1}.

5.1.3. Poly(ferrocenylsilane)s Prepared by Ring-Opening Polymerization

Early attempts to prepare macromolecules in which the ferrocene units are separated by an organosilane spacer group also focused on the use of polycondensation reactions.[133, 134] Impure, partially characterized poly(ferrocenylsilane)s were prepared by the reaction of dilithioferrocene with organodichlorosilanes at subambient temperature.[133] The molecular weights of 1400–7000 reported for these materials are characteristic of those obtained from polycondensation processes in which exact reaction stoichiometries are virtually impossible to achieve because one reactant, in this case dilithioferrocene, cannot be readily prepared in pure form.

In 1992 Manners and co-workers reported the first synthesis of high molecular weight poly(ferrocenylsilane)s **37** (M_w = 10^5–10^6, $M_n > 10^5$) by a thermal ROP route.[135] This process involved heating silicon-bridged [1]ferrocenophanes **36** in the melt at 130–220 °C [Eq. (30)]. The presence of a single atom



36 R, R' = Alkyl, Aryl, Ferrocenyl 37 (30)

bridging the ferrocene unit in the monomer leads to a strained structure in which the planes of the cyclopentadienyl rings are tilted with respect to one another by an angle of about 21°; in ferrocene the cyclopentadienyl rings are parallel. The presence of strain in the ferrocenophane, which has been measured to be about 80 kJ mol^{-1} for **36** (R = R' = Me), is believed to provide the driving force for the ROP process.

Since this initial discovery, a wide range of silicon-bridged [1]ferrocenophanes with either symmetrically or unsymmetrically substituted silicon atoms have been prepared and similarly polymerized.[136-146] Considerable effort has also been directed towards investigating and understanding the properties of the resulting poly(ferrocenylsilane) materials, the vast majority of which are soluble in organic solvents despite their very high molecular weights.[141] It was initially noted that the electrochemistry of the high polymer **37** (R = R' = Me) showed two reversible oxidation waves in a 1:1 ratio.[135] This provided clear evidence for the existence of interactions between the iron atoms and led to the proposal that initial oxidation occurred at alternating iron sites along the main chain. Recent work on model oligomers has provided clear evidence in support of this postulate.[142] Similar electrochemical behavior has subsequently been detected for a range of other poly(ferrocenylsilane)s.[141, 143-145] The polymers also exhibit interesting morphology and several of the symmetrically substituted derivatives will crystallize. For example, the dimethyl derivative **37** (R = R' = Me) is an amber, film-forming thermoplastic with a T_m of 122 °C and a T_g of 33 °C (see Fig. 5), whereas, the *n*-hexyl analogue **37** (R = R' = *n*-hexyl) is an amber, gummy amorphous material with a T_g of −26 °C.[141, 147]

Poly(ferrocenylsilane)s exhibit excellent thermal stability to weight loss (up to 350–400 °C) and yield interesting ferromagnetic Fe/Si/C ceramic composites at 500–1000 °C.[148-150] Oxidative doping of poly(ferrocenyldimethylsilane) with I_2 yields semiconducting materials (σ = ca. 10^{-7} S cm^{-1}).[141] Significantly, a recent report by Garnier and co-workers indicated that several tetracyanoethylene (TCNE)-oxidized low molecular weight poly(ferrocenylsilane)s (M_w = ca. 1500) show electron delocalization on the Mössbauer timescale (ca. 10^{-7} s) and also ferromagnetic ordering at low temperatures.[151] This discovery should certainly stimulate further research efforts on these materials in the future.

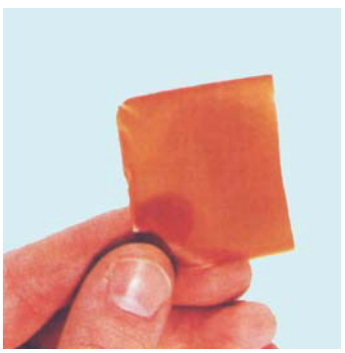


Fig. 5. A solvent-cast film of the poly(ferrocenylsilane) **37** (R = R' = Me).

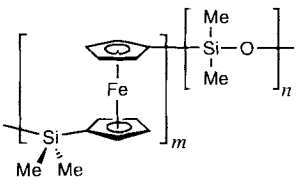
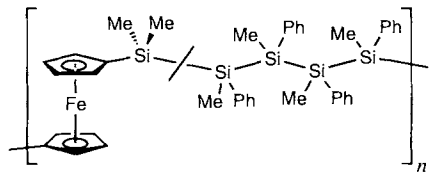
It was recently shown that silicon-bridged [1]ferrocenophanes undergo "living" anionic ROP at 25 °C by using initiators such as *n*BuLi in THF.[152] This has permitted the synthesis of poly(ferrocenylsilane)s with controlled molecular weights and narrow polydispersities and has also allowed the preparation of the first block copolymers such as **38** containing skeletal transition metal atoms. Very recently the transition metal catalyzed ROP of silicon-bridged [1]ferrocenophanes, which occurs in solution at room temperature, has also been reported.[153, 154]



38

Novel random copolymers **39** with oligosilane spacers have been prepared by Matyjaszewski, Manners, and their co-workers by using a thermal copolymerization process.[155] These polymers, which possess backbones containing transition metal atoms together with σ-delocalized polysilane segments, are expected to exhibit interesting photophysical and charge transport properties. Indeed, the materials are photosensitive and the skeletons of the polysilane segments can be selectively cleaved by using UV light.

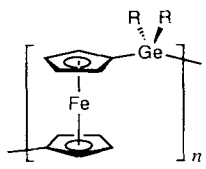


39

Polymerization of a mixture of different silicon-bridged [1]ferrocenophanes also yields random copolymers.[140] In addition, ROP of silicon-bridged [1]ferrocenophanes with silicon-bridged bis(benzene)chromium complexes[156] has very recently been shown to yield unusual bimetallic poly(ferrocenylsilane)–poly(chromarenosilane) copolymers.[157]

5.1.4. *Other Polymetallocenes Prepared by Ring-Opening Polymerization*

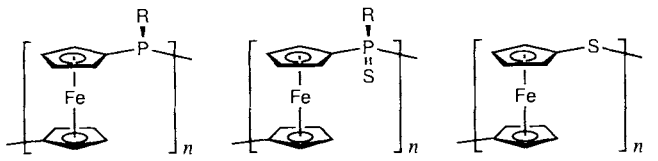
The ROP route has also been extended to the synthesis of other polymers from [1]ferrocenophane precursors. Poly(ferrocenylgermane)s **40** were first reported in 1993 and have been well-characterized and exhibit quite similar thermal transition behavior, morphology, and electrochemical behavior to the analogous poly(ferrocenylsilane)s.[158-160]



R = Me, Et, *n*Bu, Ph

40

Poly(ferrocenylphosphane)s **41** (and the corresponding phosphane sulfides **42**) are also accessible by the thermal ROP of phosphorus-bridged [1]ferrocenophanes.[161] Polymers of type **41** have been previously prepared by condensation routes and the catalytic potential of some of their transition metal derivatives has already been noted.[162, 163] In addition, very recently the

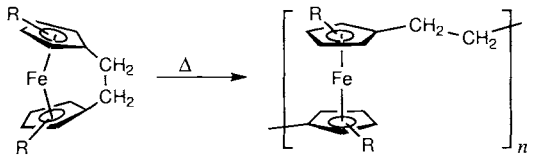


R = alkyl, aryl R = alkyl, aryl

41 **42** **43**

first sulfur-bridged [1]ferrocenophanes have been prepared and polymerized to give poly(ferrocenylsulfide)s such as **43**.[164]

Although disilane-bridged [2]ferrocenophanes have very small ring-tilt angles (ca. 4–5°) and are insufficiently strained to undergo thermal ROP, hydrocarbon-bridged [2]ferrocenophanes **44** have strained ring-tilted structures (tilt-angles = ca. 21°) as a result of the smaller atomic radius of carbon compared to that of silicon.[141] These species yield poly(ferrocenylethylene)s **45** by ROP at 250–300 °C [Eq. (31)].[165] As a



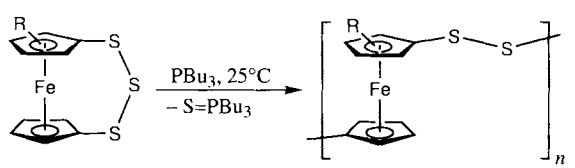
44 **45**

consequence of the presence of a more insulating bridge, the interactions between the iron atoms in these polymers are much smaller than those in poly(ferrocenylsilane)s.[143]

The inclusion of the larger ruthenium atom into a metallocenophane structure gives rise to even more tilted and strained molecules, and hydrocarbon-bridged [2]ruthenocenophanes (tilt-angles = ca. 29–30°) undergo thermal ROP to yield poly(ruthenocenylethylene)s.[166] These materials exhibit significantly different electrochemistry from their iron analogues.

5.1.5. Poly(ferrocenylene persulfide)s Prepared by Atom Abstraction Induced Ring-Opening Polymerization

In early 1992 Rauchfuss and co-workers reported that [3]trithiaferrocenophanes, which are essentially unstrained, function as precursors to poly(ferrocenylene persulfide)s by a novel atom abstraction polymerization route [Eq. (32)].[167] Thus, reaction of [3]trithiaferrocenophanes **46** with PBu_3 led to the formation of the phosphane sulfide, $S{=}PBu_3$, and the polymers **47**.



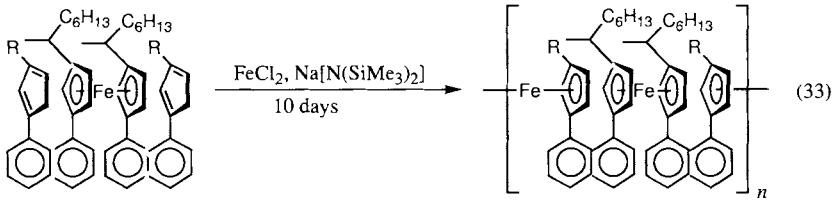
46 **47** (32)

The presence of a butyl substituent on the cyclopentadienyl ring is necessary for the polymer to be soluble. The molecular weights (M_w) of **47** (R = *n*Bu) have been determined to be between 12000 and 359000 (by GPC), depending on the solvent used for the desulfurization reaction. The [3]ferrocenophanes **46** (R = H) and **46** (R = *n*Bu) can be copolymerized to give soluble copolymers with $M_w = 25000$.

Poly(ferrocenylene persulfide)s exhibit a range of very interesting properties.[167–170] They are photosensitive in air, and the S–S bonds can be reversibly reductively cleaved with $Li[BEt_3H]$ and then regenerated upon oxidation with I_2. Their electrochemical behavior is similar to that detected for poly(ferrocenylsilane)s except that the interaction between the iron sites appears to be even greater. The atom abstraction route using PBu_3 as a desulfurization agent has very recently been extended to the preparation of other poly(ferrocenylene persulfide)s with *tert*-butyl substituents, and also to high molecular weight (M_w = 50000–1000000) network polymers by the use of [3]ferrocenophanes with two trisulfido bridges as monomers.[168] Linear poly(ferrocenylene perselenide)s have also been prepared but these materials are of lower molecular weight.[169]

5.1.6. Face-to-Face Metallocene Polymers

The development of rigid-rod metallocene polymers with a multistacked structure has been reported by Rosenblum and co-workers by using condensation routes.[171–175] Palladium-catalyzed coupling of chlorozinc ferrocenes with 1,8-diiodonaphthalene yielded low molecular weight materials ($M_n < 4000$), as the sensitivity of the ferrocene reagent made the accomplishment of exact stoichiometries very difficult. With this in mind, an improved coupling procedure was developed [Eq. (33)] in which treatment of the ferrocene monomers **48** with

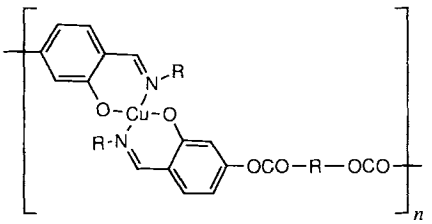


48 **49** (33)

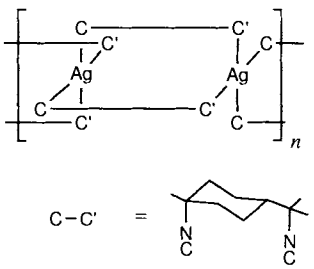
$FeCl_2$ and $Na[N(SiMe_3)_2]$ yielded purple polymers **49** with molecular weights up to $M_n = 18000$; higher molecular components components were also present. Novel mixed-metal copolymers containing Ni and Fe whose soluble fractions were of low molecular weight ($M_n < 3000$) were also obtained by using $[Ni(acac)_2]$ instead of $FeCl_2$.[171] The electrical and magnetic properties of these novel polymers and copolymers have been investigated and conductivities up to $6.7 \times 10^{-3}\ S\,cm^{-1}$ have been determined for I_2-doped materials.[173] Interestingly, structural work on well-defined oligomers suggests that the stacked metallocene units in the polymer form a helical structure.[175]

5.2. Coordination Polymers

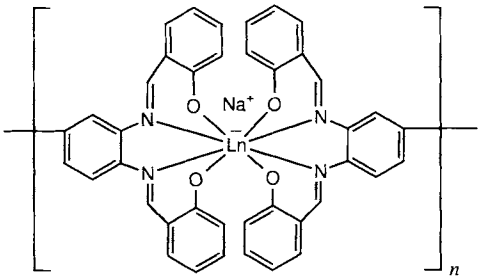
In the past, attempts to prepare coordination polymers have been hindered by the insolubility and consequent intractability of the products. These problems arise from the inherent skeletal rigidity of these materials, and the introduction of solubilizing or flexibilizing groups either in the polymer backbone or side group structure is necessary for useful products to be obtained. Recent work has yielded a range of interesting and well-characterized materials with intriguing properties. For example, novel liquid crystalline polymers **50** containing paramagnetic Cu^{II} centers have been prepared by Serrano and co-workers, and soluble, luminescent silver-containing polymers **51** have been reported by Harvey, Michel and co-workers.[176, 177]



50



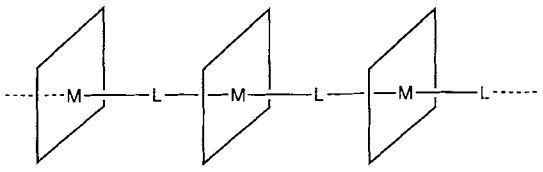
51



Ln = La, Gd, Y, Yb

52

In addition, well-characterized lanthanide-containing polymers such as **52**, which show polyelectrolyte behavior and which should exhibit interesting photophysical properties, have been reported by Archer and Chen.[178] Several of the polymers are soluble in polar organic solvents such as DMSO, and molecular weights (M_n) up to 18000 have been established. Polymers containing cerium in the main chain possess M_n values up to 30000.[179]



= phthalocyanine L = bipy, CN^-

M = Fe, Ru, Os, Co, Rh, Mn, Cr

53

Phthalocyanine-based polymers, such as the "shish-kebab" polymers **53**, are also of considerable interest and significant electrical conductivities of up to about 0.1 Scm^{-1} have been detected for chemically or electrochemically doped materials.[180, 181] If flexible organic substituents are present on the periphery of the phthalocyanine ring these materials can also be soluble (at least low molecular weight fractions).

The generation of dendrimeric coordination polymers has also been an area of significant recent activity and imaginative routes to novel Ru- or Pt-polypyridyl systems (Fig. 6) have been reported.[182–186] These materials are of interest with respect to their photophysical and electrochemical properties and possibly their catalytic behavior.

5.3. Rigid-Rod Organometallic Polymers

Together with several of the classes of ferrocene-based polymers described above, macromolecules with backbones that contain conjugated C≡C units and transition metal atoms, termed polymetallaynes, represent the best-characterized examples of transition metal based polymers prepared to date.[187] The synthesis and study of these materials is currently an exciting and active area of polymer science.

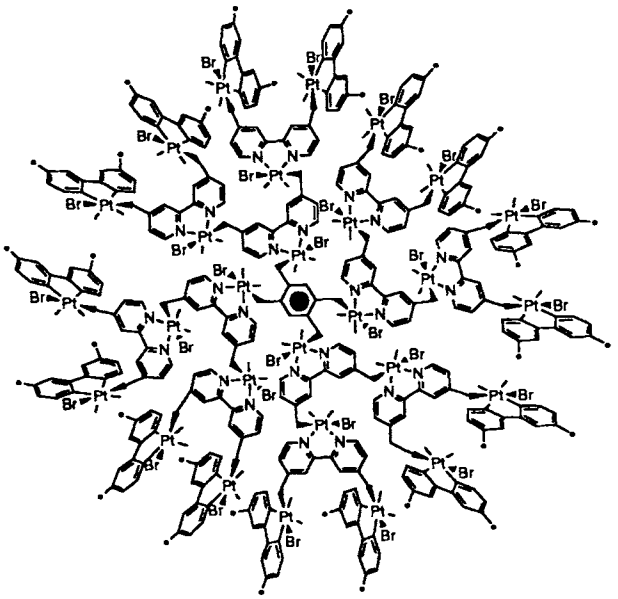


Fig. 6. Structure of a dendrimeric organoplatinum complex (reproduced from ref. [183] with permission).

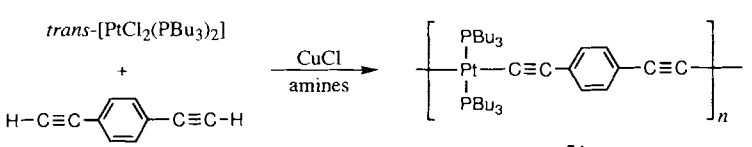
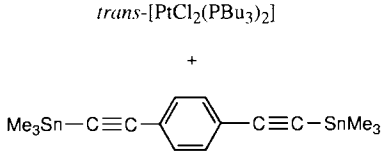
The first polymetallaynes contained nickel, palladium, or platinum atoms in the main chain and were isolated in 1977 by Sonogashira, Hagihara, and Takahashi as yellow, film-forming materials.[188–190] These were prepared by efficient copper halide catalyzed coupling processes [Eq. (34)] and have estimated molecular weights (M_w) between 13000 and 120000.



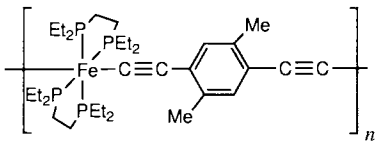
54 (34)

The last few years have seen an important expansion in this area that has yielded a range of new rigid-rod materials by the creative use of a variety of new and well-defined polycondensation strategies. For example, Lewis and co-workers reported a new route to the polyplatinynes **54** based on the reaction of *trans*-$[PtCl_2(PR_3)_2]$ complexes with bis(trimethylstannyl)diynes [Eq. (35)].[191] These rigid-rod polymers possessed estimated weight-average molecular weights up to about 100000 according to GPC measurements.

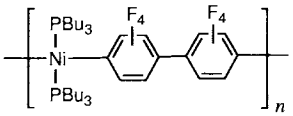


$\xrightarrow{-ClSnMe_3}$ **54** (35)

Lewis and co-workers have also shown that this synthetic procedure could be extended to allow the incorporation of other transition elements such as iron into the polymer main chain (to give **55**) by using $[FeCl_2(Et_2PCH_2CH_2PEt_2)_2]$ as the transition



55



56

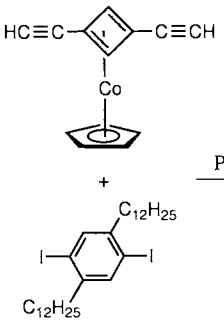
metal containing reactant.[192] In addition, Hunter and co-workers have devised condensation routes to the unusual organonickel polymers **56**, and interesting organocobalt and organozirconium polymers containing metallacyclopentadiene moieties in the main chain have been recently reported by the groups of Nishihara and Endo, and by Tilley and co-workers, respectively.[193–196]

In another interesting synthetic development, Marder and co-workers showed that a range of rhodium-containing polyynes **57** are accessible by the reaction of the unsubstituted diynes with $[Rh(PR_3)_4Me]$ in a reaction that involves reductive elimination of methane and the loss of a phosphane ligand [Eq. (36)].[197] In the case where trimethylphosphane ligands are attached to the rhodium center, the polymers are insoluble but the tri(*n*-butyl)phosphane analogues are soluble and yield free-standing solvent-cast films from THF.

Over the past 10 years the physical properties of polymetallaynes have received continued attention because of their novel rigid-rod structures and their conjugated backbones.[198–207] Thus, polyplatinaynes form ordered, liquid crystalline mesophases in solvents in which they are soluble such as trichloroethylene,[198] and these materials also possess novel, third-order nonlinear optical properties,[199] which are of intense current interest for electrooptic device applications. Optical absorption and photoluminescence spectroscopic studies and extended Hückel calculations have shown that polymetallaynes possess a delocalized polymer backbone whose electronic structure is modified by the nature of the transition metal, coligands, and the unsaturated hydrocarbon spacer.[200–202] For example, optical band gaps for a series of polyplatinaynes with platinum centers joined by π-conjugated acetylide–arene linkages of varying length have been measured to be in the range of 2.5–3.1 eV, which is lower than for model complexes and is consistent with conjugation through the metal centers.[201]

Other recent highlights in the area of rigid-rod transition metal based polymers include the synthesis by Bunz and Altmann of a range of interesting thermotropic liquid crystalline organocobalt polymers such as **58** in which the metal is bound to skeletal cyclobutadiene units [Eq. (37)].[208] Novel analogues of such materials in which thiophene units are also incorporated in the polymer main chain have also been prepared and these can form smectic lyotropic liquid crystalline phases.[209]

In addition, the preparation and characterization of novel lyotropic liquid crystalline aramides **59** with complexed chromium (tricarbonyl) units have been reported by Dembek et al.[210] These materials are soluble in organic solvents, which leads to potential processing advantages for the uncomplexed organic



$\xrightarrow{Pd^{II}, CuI}$

L = PBu_3

57

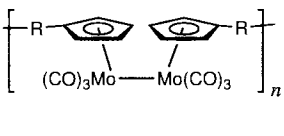
polymer, since the $Cr(CO)_3$ groups can be easily added and removed, and poly(*p*-phenyleneterephthalamide) is only soluble in concentated sulfuric acid.[210–212]

Related to polymetallynes are polymeric metal nitrides (e.g. **60** M = Mo or W).[187, 213, 214] Examples of these materials are known in the solid state but these generally dissociate into monomers with M≡N bonds in solvents in which they are soluble. To date, reports of soluble polymers such as **61** and

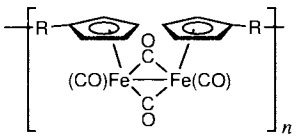
related species have been very brief[214] but such materials are of considerable interest and warrant further study.

5.4. Polymers with Metal–Metal Bonds in the Main Chain

Polymers containing metal–metal bonds in the polymer backbone might be expected to have novel conductive and photochemical properties.[115] In general, little work has been carried out in this area; however, in 1989 Tyler and co-workers reported polycondensation routes to polyurethanes containing Mo–Mo bonds (**62**) (R = urethane linkage) or $Fe(\mu\text{-}CO)_2Fe$ units (**63**) in the polymer backbone.[215, 216] These polymers



62



63

have M_n values between 5000 and 20000, and are of interest as photoreactive materials since the metal–metal bonds could be cleaved photochemically by visible light. In contrast, existing polymers generally require ultraviolet light for photodegradation. The quantum yields for the degradation of the polymers were found to decrease with increasing molecular weight.

Interestingly, Morán, Cuadrado, and Mosada and co-workers have recently reported the synthesis of a further class of polymers of structure **63** in which the R group is an oligosiloxane linkage, and these materials display interesting electrochemical properties.[217]

6. Future Prospects

Inorganic polymer science represents an area that until recently has been held back by the synthetic problem of constructing macromolecular chains. Even ten years ago relatively few well-characterized polymer systems were known. Recent advances have led to the preparation of a variety of new polymers that contain main group elements, transition metals, and even lanthanides. In the next few years it will be critical to examine the physical properties of these new materials in detail in both solution and in the solid state. New fundamental science can be expected to emerge as structure–property correlations are established for these novel polymer structures. It is also plausible that some of these new materials with properties that are difficult or impossible to achieve with existing organic materials may fulfill the requirements of niche markets, providing that their synthesis is straightforward and the reactants cheap. Polysiloxanes, and to a lesser extent polyphosphazenes and polysilanes, have already found applications in this way.[10] Ferrocene-based polymers have also attracted significant interest, both as electrode mediators and as materials for the construction of electronic devices.[217–220]

With the whole periodic table available there is clearly almost infinite scope for the design and synthesis of new inorganic polymer materials. For example, preliminary synthetic developments targeting polymers based on metal clusters,[221] metal–metal quadruple bonds,[222] multidecker sandwiches,[223] and metal–carbon multiple bonds[224] illustrate the remarkable potential for inorganic and organometallic chemists to make exciting and important synthetic contributions towards the development of new inorganic macromolecules with unprecedented structures and exciting properties. It is clear that considerable opportunities for both fundamental scientific studies and also applications-oriented work exist for the future.

[90] Poly(sulfur nitride), $[SN]_x$, possesses remarkable properties such as electrical conductivity at room temperature and superconductivity below 0.3 K; see M. M. Labes, P. Love, L. F. Nichols, *Chem. Rev.* **1979**, *79*, 1. $[SN]_x$ is insoluble and has a polymeric structure in the solid state with interchain S···S interactions. As these interactions are crucial to the properties of the material, $[SN]_x$ is best regarded as a solid-state polymer rather than a polymeric material with discrete macromolecular chains of the type discussed in this review article.

Chemistry and biology are both required in order to determine the importance of individual structure elements in zaragozic acid A.

Chemistry and Biology of the Zaragozic Acids (Squalestatins)**

Alan Nadin and K. C. Nicolaou*

New natural products seldom arouse much excitement. However, with their unprecedented and heavily oxygenated molecular structure, and potentially lucrative biological activity, the zaragozic acids (squalestatins) provoked a flurry of activity among academic and industrial chemists and biologists in the early 1990s. Since they are powerful inhibitors of squalene synthase, the enzyme catalyzing the first committed step on the biosynthetic pathway to cholesterol, hopes were high that the zaragozic acids would follow the huge commercial success of the mevinic acids by becoming second-generation cholesterol-lowering drugs. The unusual and characteristic 2,8-dioxabicyclo[3.2.1]octane-3,4,5-tricarboxylic acid "core" structure of the zaragozic acids stimulated a large number of diverse synthetic studies, ranging from the traditional to the avant garde. In this review we attempt to bring together for the first time the chemistry and biology of this fascinating class of molecules.

1. Introduction

Cardiovascular disease (CVD) remains the largest cause of human death in industrialized nations. In the U. S. in 1992, 915000 deaths were recorded as resulting from CVD, compared with 521000 from all forms of cancer combined, 86000 from accidents, and 23000 from AIDS.[1] Therefore, even though the relative incidence of CVD has almost halved since the 1950s,[2] there remains keen interest in the pharmaceutical industry for developing better drugs for the treatment of CVD.

The majority of CVD mortalities (79% in 1992)[1] are due to coronary heart disease (CHD) or coronary artery disease (CAD).[3] The main cause of both CHD and CAD is atherosclerosis, a disease colloquially known as "hardening of the arteries". It is characterized by the formation of atherosclerotic plaques composed of cholesterol esters, lipids, and other cellular debris on the inside walls of large and medium-sized arteries.[2] This has the consequence of hardening the artery wall and reducing the cross-sectional area of the lumen, which results in reduced blood flow.[4] Atherosclerosis is also implicated in other mortalities and illnesses, owing to the reduced blood flow to the brain, kidneys, and intestine.[5] Atherosclerosis can be treated in some cases by bypassing the damaged area (coronary bypass surgery), by opening the lumen by balloon angioplasty, or by removing the offending plaques by surgical andarectomy. However, in a landmark ten-year study completed in 1984, the Lipid Research Clinics Program showed that by lowering serum cholesterol levels, the incidence of fatal heart disease could be decreased significantly.[6] This and subsequent studies[7] established abnormal serum cholesterol levels as a major risk factor for heart disease. Today, everyone knows about cholesterol, although there continues to be debate about the issue.[8]

The human body satisfies about half of its requirement for cholesterol by endogenous biosynthesis, which occurs mainly in the liver.[9] The remaining amount is obtained from the diet. Consequently, one often effective way of reducing serum cholesterol levels (and by implication the risk of heart disease) is to reduce the dietary intake of cholesterol.[10] As a result of government-sponsored "healthy eating" campaigns[11] and a greater public awareness of cholesterol, the average dietary consumption of cholesterol in the U. S. has decreased from a peak of about 550 mg per person per day in the 1950s[12] to about 283 mg per person per day in 1988.[13]

However, in many instances dietary regulation is impractical, insufficient, or unpopular. Consequently, extensive efforts have focused on finding effective therapeutic agents for lowering serum cholesterol levels by controlling certain key steps in the cholesterol biosynthetic pathway.[14] Those currently available can be divided into two main classes: bile acid sequestrants and HMG-CoA reductase inhibitors.[15] In response to the search for more effective medicines, emphasis has been placed on finding inhibitors of other key steps in the pathway. These investigations recently led to the isolation of a fascinating class of natural products, named the zaragozic acids or squalestatins. This review gives an overview of the chemistry and biology of these compounds.

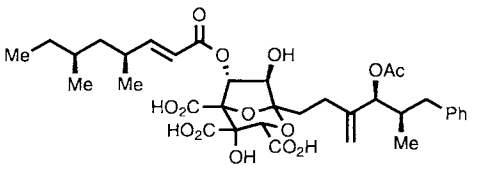
[**] A list of abbreviations frequently used in this review can be found at the end of the article.

In 1991 and 1992 three groups independently and almost simultaneously reported the isolation of the zaragozic acids (squalestatins). The group at Merck[16] refer to them as the zaragozic acids; the groups at Glaxo[17] and Tokyo Noko University/Mitsubishi Kasei Corporation[18] refer to them as squalestatins. We will refer to these compounds as zaragozic acids throughout this review. All three groups isolated zaragozic acid A (squalestatin S1) (**1**, Fig. 1). Merck isolated zaragozic



1: zaragozic acid A / squalestatin S1

acid A from the uncharacterized sterile fungus ATCC 20986, isolated from filtrates of the Jalon River in the province of Zaragoza in Spain (hence the name zaragozic acid). Glaxo isolated the same compound from a different fungus, *Phoma* sp. C2932, found in a soil sample from Armacao de Pera, Portugal, and the Japanese group from yet another fungus, *Setosphaeria khartoumensis*. In addition to zaragozic acid A, a number of other zaragozic acids have been found by Merck and Glaxo (Tables 1 and 2).

Glaxo's approach to identifying other naturally occurring zaragozic acids was to extract very minor components from large-scale fermentations of the original producer organism *Phoma*.[19] Besides the three main components (squalestatins S1, H1, and S2), this approach yielded 24 additional squalestatins (Table 1). Each squalestatin can be named by a two-character code, composed of a letter and a number correlated to the structure of the R^1 and R^2 side chains, respectively (Table 1). Some of these minor components could possibly be artifacts from the extraction techniques. It can be seen that with five exceptions (which lack oxygen functions at the C6 and C7 positions, see footnote [b] in Table 1) all the squalestatins and zaragozic acids (Tables 1 and 2) contain the same basic 2,8-dioxabicyclo[3.2.1]octane-3,4,5-tricarboxylic acid "core" with two lipophilic "arms" attached either as an acyl group on the C6 hydroxyl or as an alkyl group on the C1 carbon.

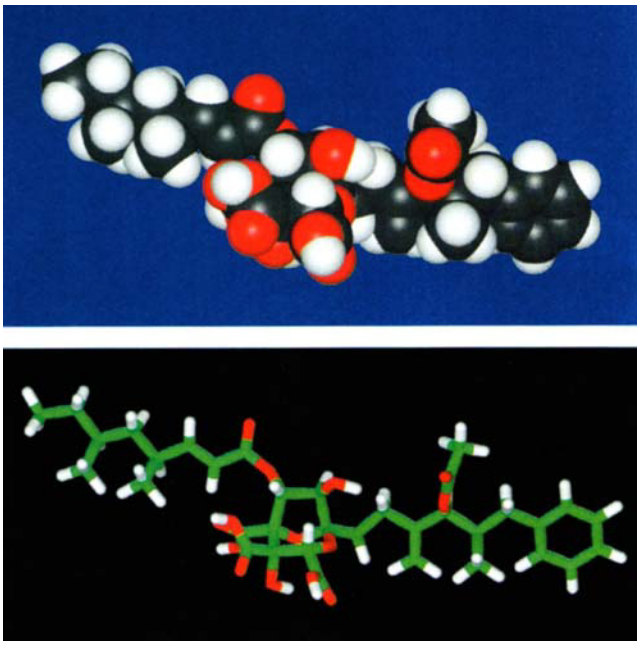


Fig. 1. Space-filling model (top) and ball-and-stick model (bottom) of zaragozic acid A/squalestatin S1 (**1**).

Merck screened a wider variety of fungi from quite different ecosystems (Table 3) and made the remarkable finding that many different fungi (from eleven different taxa of the genus *Ascomycotina*) produce zaragozic acids.[20] The main zaragozic acid produced by each fungus appears to be a characteristic of the particular fungus. For example, *Spororomiella intermedia*, from a variety of ecological sites around the world, produced mainly zaragozic acid B. Zaragozic acid C was produced by *Leptodontidium elatius*,[21] zaragozic acids D and D_2 by *Amauroascus niger*.[22] It is interesting to note that the variety of the side chains in the zaragozic acids (Table 2) is wider than in the squalestatins (Table 1), which might reflect the more diverse origins of the zaragozic acids.

The zaragozic acids appear to be relatively easy to obtain and purify. Glaxo has performed fermentations of *Phoma* on the 5000 L scale;[19] Merck has fermented ATCC 20986 on the 11000 L scale.[107] The unusual tricarboxylic acid function of

K. C. Nicolaou's biography can be found in issue 6/1996 on p. 590. The latest additions to his list of honors include the presentation of this year's Inhoffen lecture sponsored by the Biotechnologische Forschung and the Technische Universität Braunschweig and membership of the U. S. National Academy of Science.

Alan Nadin was born in London, England, in 1968 and received his BA from the University of Cambridge in 1990. He remained there and completed his PhD in 1994 under the direction of Dr. A. B. Holmes on the molecular self-recognition of medium-ring lactams. In 1994 he joined the research group of Professor Nicolaou at The Scripps Research Institute, where he worked on the zaragozic acid and maitotoxin projects. In 1996 he joined Merck, Sharp and Dohme in Harlow, England.

the zaragozic acids makes initial purification of the crude fermentation extract by ion exchange chromatography relatively easy.

The structure of zaragozic acid A was determined independently by a standard combination of NMR spectroscopy, mass spectrometry, and X-ray structure analysis. Merck established the relative configuration of nine of the ten stereocenters by X-ray analysis of the rearranged derivative **2**; the configuration of the C4′ stereocenter was determined by X-ray analysis of another intermediate.[23] The absolute configuration was determined by circular dichroism measurements on a 6,7-bis(4-bromobenzoate) derivative.

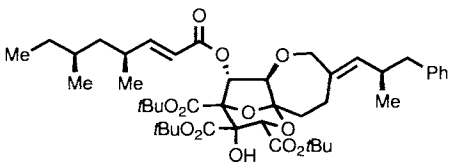
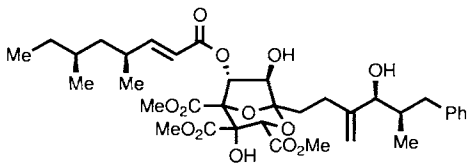
Glaxo determined the relative configuration of the zaragozic acids by X-ray crystal structure analysis of **3**.[17b] The absolute



2

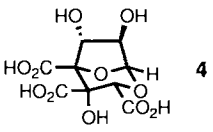


3

configuration was rigorously established by comparing the optical rotation of a derivative of the C6 acyl side chain (obtained by degradation of **1**) with a previously reported value for the same compound. The structure of zaragozic acid A has also been confirmed by three total syntheses.[74c, 81, 92]

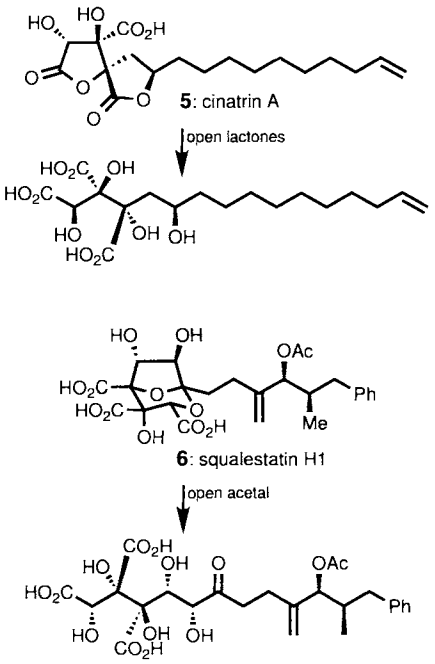
The structures of the other zaragozic acids/squalestatins have been established through similar spectroscopic, semisynthetic, and total synthetic methods.[21, 22, 85, 90] However, many of the remote stereocenters in the side chains of the minor squalestatins remain undefined.

The most remarkable feature of the zaragozic acids is the highly oxygenated core structure present in virtually all of the naturally occurring zaragozic acids/squalestatins (see Tables 1 and 2). If the two side chains are replaced by hydrogens, then the resulting "naked" fragment **4** has the molecular composition $C_9H_{10}O_{11}$ and contains 59.8% oxygen by mass. To put this stoichiometry into perspective, this figure should be compared with those of glucose ($C_6H_{12}O_6$, 53.3% oxygen), citric acid ($C_6H_8O_7$, 58.3%), and oxalic acid ($C_2H_2O_4$, 71.1%).



4

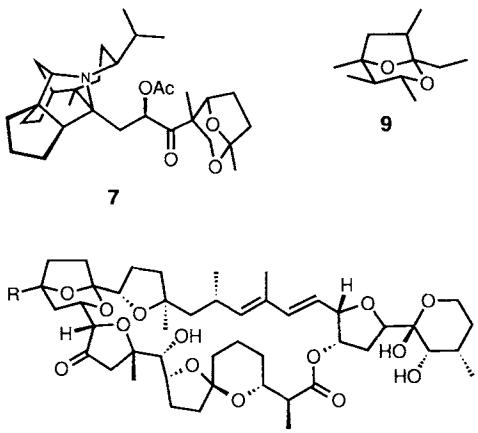
The closest relatives to the zaragozic acids appear to be the cinatrins (for example cinatrin A (**5**), Scheme 1), a family of



Scheme 1. Structural relationship between the zaragozic acids and the cinatrins.

natural products isolated from the fungus *Circinotrichum falcatisporum* RF-641.[24] These natural products are characterized by a polyoxygenated head attached to a long, linear C_{10} lipophilic tail. The oxygenation pattern of the head bears a very close pseudo-enantiomeric relationship to that of the zaragozic acid core (for example squalestatin H1 (**6**)); if the C_{10} side chain is removed, the "naked" head has the composition $C_8H_{12}O_{10}$ (59.7% oxygen by mass), which is quite comparable to that of the zaragozic acid core. Unfortunately, the cinatrins have received little attention from chemists, which is probably a result of their rather modest biological activity (they are weak inhibitors of phospholipase A_2).

The ring system of the zaragozic acids is officially designated as a 2,8-dioxabicyclo[3.2.1]octane system, and although not unknown, it is decidedly uncommon. It has been found in the alkaloid daphniphylline hydrochloride (**7**),[25] in a family of diarrhetic fish toxins (pectenotoxins 1–3, **8a–c**),[26] and recently in sordinin (**9**), the banana weevil pheromone.[27] It has also



7 **9**

8a: R = CH_2OH PTX1

8b: R = CH_3 PTX2

8c: R = CHO PTX3

been used as a synthetic intermediate en route to other compounds.[28] However, nothing approaching the oxygenated complexity of the zaragozic acid core, which contains six contiguous chiral centers, three of which are quaternary, had ever been seen before.

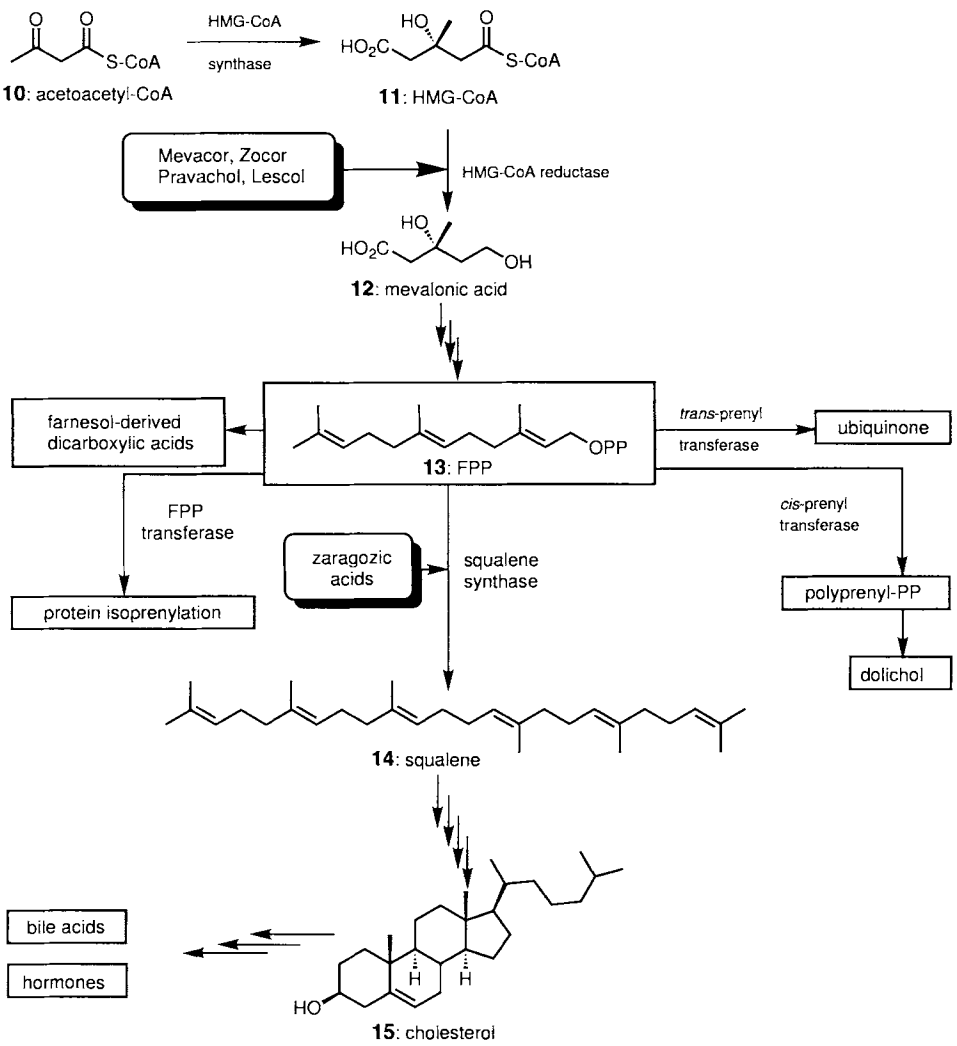
The role of the zaragozic acids in nature is not clear. However, it is interesting to note that the HMG-CoA reductase inhibitors (see Section 2.1.1) and the HMG-CoA synthase inhibitor L-659699 are all (fungally derived) potent and specific inhibitors of early steps in the sterol synthetic pathway. It has been suggested that because of their antifungal activity (see Section 2.2), the particular zaragozic acid produced by one fungus may be used to defend the colony against an invading colony.[20] This hypothesis suffers from the observation that many producers do not excrete the zaragozic acid they produce. However, the observation that the zaragozic acids are widely found in the fungal kingdom implies that they do serve some general purpose.

2. Biological Role of the Zaragozic Acids

2.1. Background

2.1.1. The Sterol Biosynthetic Pathway

The sterol biosynthetic pathway is one of many catabolic pathways that start from acetyl-coenzyme A (acetyl-CoA), but is unique in being responsible for producing cholesterol and other important terpenes.[29] The main routes are shown in Scheme 2. The pathway starts with acetyl-CoA and acetoacetyl-



Scheme 2. Simplified sterol biosynthetic pathway. HMG = 3-hydroxy-3-methylglutaryl. FPP = farnesyl pyrophosphate. Mevacor, Zocor, Pravachol, and Lescol are drugs that block mevalonic acid synthesis.

CoA (**10**) (also obtained from acetyl-CoA), which are joined together by HMG-CoA synthase to form hydroxymethylglutaryl-CoA (HMG-CoA) (**11**). HMG-CoA is then reduced under the influence of HMG-CoA reductase to give mevalonic acid (**12**). HMG-CoA reductase is believed to be the major control point for the sterol pathway and accordingly has been the subject of many studies. HMG-CoA reductase is regulated by a number of late-stage products of the sterol pathway, including cholesterol and a hydroxylated derivative, which act at the transcriptional level. A number of steps then convert mevalonic acid into farnesyl pyrophosphate, FPP (**13**). FPP is the last common intermediate for the synthesis of all the end products of the sterol synthetic pathways. Apart from its role in cholesterol biosynthesis, the intracellular pool of FPP is used directly in the synthesis of dozens of other natural products.[30] For example, FPP is used by FPP transferase as the source of farnesyl groups for the farnesylation of certain proteins. This covalent attachment of a farnesyl group is necessary for the biological activity of many of proteins (see Section 2.2). FPP can also be reductively dimerized to give geranylgeranyl pyrophosphate, which plays a similar role in protein isoprenylation. It has been estimated that 2% of all eukaryotic proteins carry isoprenyl units.

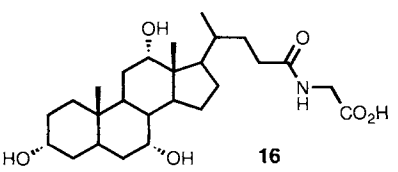
FPP is also a substrate for *trans*-prenyl transferase, an enzyme that catalyzes the formation of long-chain all-*trans* polyisoprenes. These are used in the synthesis of ubiquinone, which is the only endogenously synthesized antioxidant, and therefore very important. Similarly, *cis*-prenyl transferase catalyzes the formation of polyprenyl pyrophosphate, a precursor for the biologically important dolichols.

The fourth branch point enzyme, squalene synthase (SS) [E. C. 2.5.1.21], which controls the first committed step en route to cholesterol, is responsible for the synthesis of the sterols. SS catalyzes the reductive head-to-head dimerization of FPP to give squalene (**14**). The few established details of the mechanism of this transformation are given in Section 2.3. A long series of enzyme-catalyzed reactions, involving at least two separate pathways, finally produce cholesterol (**15**). Although important in its own right (it helps to maintain the fluidity of cell membranes), cholesterol is an important building block for the biosynthesis of other sterols such as the fecal steroids, steroid hormones, and bile acids.

2.1.2. Ways of Inhibiting Cholesterol Biosynthesis

In principle, the inhibition of any enzyme in the sterol pathway could lead to a reduction in cholesterol biosynthesis. There have been three main fronts in the search for cholesterol-lowering drugs: a) drug-induced removal of cholesterol from the serum, b) inhibition of the key regulatory enzyme, HMG-CoA reductase, and c) inhibition of squalene synthase. Moderately effective inhibitors of other sterol enzymes are known, for example HMG-CoA synthase,[31] mevalonate pyrophosphate decarboxylase,[32] and acylCoA:cholesterol acyltransferase[33].

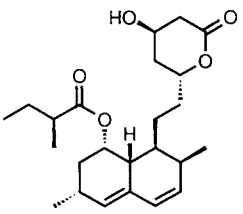
If the patient's compliance with dietary restrictions is poor, and if serum cholesterol levels are not satisfactorily lowered, a bile acid sequestrant is often prescribed.[15] Bile acid sequestrants (for example cholestyramine (Bristol-Myers-Squibb) and Cholestipol (Upjohn)) are basic amine anion exchange resins. They work by sequestering sterol-derived bile acid anions, for example glycocholic acid (**16**), in the intestine as an insoluble complex, which



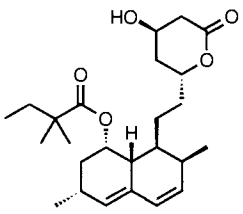
16

is excreted. Although this is often an effective form of treatment, large dosages are required (10–20 g daily), socially unpleasant side effects sometimes arise, and patient response and compliance is often poor and/or attenuates with time.[15]

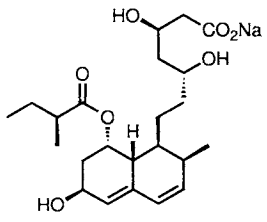
Shortly after the link between high serum cholesterol levels and atherosclerosis was first proposed, the search for inhibitors of the sterol biosynthetic pathway began. In 1980 Goldstein, Brown, and Faust[34] suggested the "flow diversion hypothesis" for sterol regulation. This model predicted that a decrease in cellular FPP levels would affect only SS, since the other branch point enzymes all have a higher affinity for FPP. Consequently, changes in FPP levels would affect only the pathway leading to cholesterol, and it was therefore hoped that inhibitors of HMG-CoA reductase (which decrease levels of FPP) would not cause serious side effects. These assumptions have largely been proven correct after many years of successful clinical use of HMG-CoA reductase inhibitors. However, there are a few instances of decreased ubiquinone levels in rats and humans[35] treated with high levels of Lovastatin (17) and some other side effects that may have resulted from decreased FPP levels.[36] An excellent review on HMG-CoA reductase inhibitors has been published recently,[37] and we will only outline the main points here. A number of inhibitors of HMG-CoA reductase are known, some of which have become the pharmaceutical industry's best-selling products (Scheme 3). Mevacor (17) (also known as Lovastatin, Mevinacor, Mevlor, Mevinolin, and Monacolin K), first approved by the U. S. Food and Drug Administration (FDA) in 1989, had annual worldwide sales of $1.285 billion in 1992.[38]



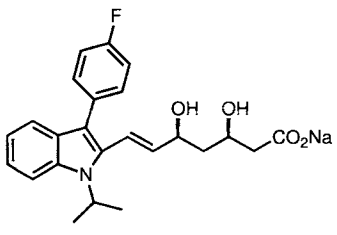
17: Mevacor (Merck)



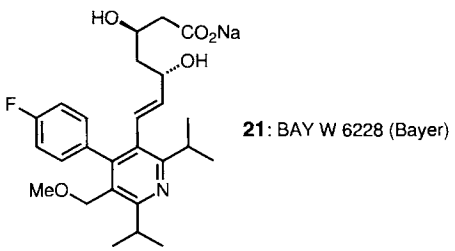
18: Zocor (Merck)



19: Pravachol (Sankyo/Bristol-Myers-Squibb)



20: Fluvastatin (Sandoz)



21: BAY W 6228 (Bayer)

Scheme 3. HMG-CoA reductase inhibitors applied as cholesterol-lowering drugs.

The closely related analog Simvastatin (**18**) (Zocor, Zocord, Synvinolin), licensed in 1991, also by Merck, had sales of $475 million in 1992.[38] Pravastatin sodium (**19**) (Mevalotin, Pravachol) from Bristol-Myers-Squibb/Sankyo had sales in 1992 of $824 million.[38] Fluvastatin (Lescol) (**20**) developed by Sandoz was launched in April 1994 at half the price of its competitors, and rapidly captured a substantial portion of the market.[39] Amongst many second-generation analogs of the mevinic acids, Bayer's BAY W 6228 (**21**), currently undergoing clinical trials, looks particularly promising with a potency in dogs some 200 times greater than that of Lovastatin (**17**).[40]

2.2. Biological Activity of the Zaragozic Acids

The biological activity of the zaragozic acids can be grouped into three types. They can be: a) inhibitors of mammalian squalene synthase (cholesterol lowering), b) antifungal agents, and c) farnesyl transferase inhibitors. The first two categories are essentially the same, since the antifungal activity of the zaragozic acids is a result of their inhibition of fungal squalene synthase. However, since cholesterol lowering and antifungal activity are separate therapeutic areas, we will discuss them separately.

The zaragozic acids are the most potent inhibitors of SS known to date. The squalene synthase (cholesterol-lowering) activity of the zaragozic acids has recently been covered in the review by Procopiou and Watson,[41] so we will only outline the main points here. In vitro data has been reported from assays with rat microsomal squalene synthase, Hep-G2 (a human liver cell line) microsomes, and isolated rat hepatocytes (tissue functionally equivalent to liver). In all instances, zaragozic acids were potent and selective inhibitors (Table 4). It should be noted that because of different assay conditions, the IC_{50} values reported by Merck are always lower (apparently more potent) than those given by Glaxo.[41]

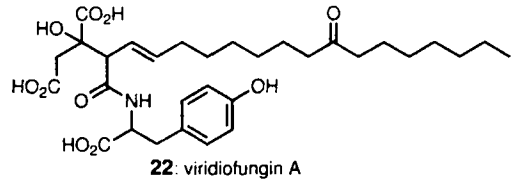
Table 4. Biological activities of zaragozic acids/squalestatins.

Compound	IC_{50}[nM] [a]	[b]	MIC[$\mu g mL^{-1}$] [c]
zaragozic acid A/ squalestatin S1	0.5 (Merck) 12 (Glaxo)	250 –	8 –
zaragozic acid B	0.2	1000	–
zaragozic acid C	0.4	150	8–16
zaragozic acid D	6	100	–
zaragozic acid D_2	2	100	–
squalestatin S2	5	–	125
squalestatin H1	26	–	>125

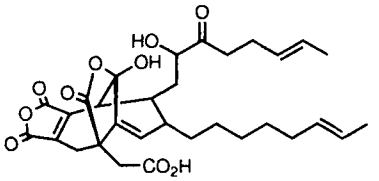
[a] Inhibition of rat squalene synthase. [b] Inhibition of bovine brain farnesyl protein transferase. [c] Minimum inhibitory concentrations against *Candida albicans*.

In vivo studies have also been performed. Glaxo reported that when rats were dosed intravenously with zaragozic acid A (**1**) at levels of 0.1 mg per kg of body weight, cholesterol biosynthesis was reduced by 50%.[42] When marmosets (which apparently have a similar lipoprotein profile to man[43]) were dosed orally with 10 mg per kg per day of zaragozic acid A, serum cholesterol levels fell by up to 75% for eight weeks, with no attenuation of response.[42] Merck reported similar findings with mice.[16a]

Recently other naturally occurring, fungally derived SS inhibitors have been reported. The viridiofungins, for instance **22**,[44] have been isolated by Merck from *Trichoderma viride* (ATCC 74084), and CP-225917 (**23**)[45] has been isolated by

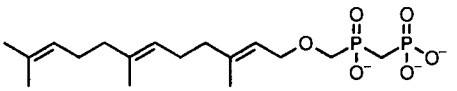


22: viridiofungin A



23: CP-225 917

Pfizer from an uncharacterized fungus (ATCC 74256). The viridiofungins (IC_{50} = 0.4–15 μM) are much less potent than the zaragozic acids; the potency of CP-225917 has not been reported. It is interesting to compare the structural similarities between the three families of natural products: both zaragozic acid A and CP-225917 have two lipophilic side chains flanking a polar bicyclic core. Squalestatin H1 (**6**) contains only one side chain attached to a tricarboxylic acid core; the viridiofungins contain a similar tricarboxylate function attached to a lipophilic tail. In addition to the naturally occurring inhibitors, a large number of designed inhibitors have been made (e.g. **24**), most of which are of modest potency.[46]



24

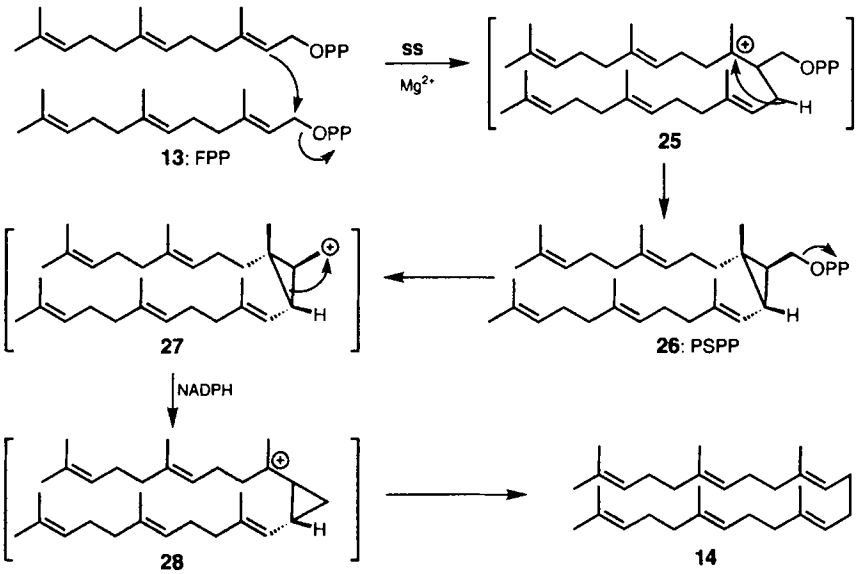
Glaxo has reported the antifungal activity of zaragozic acid A against a variety of yeasts and fungi. MICs (minimum inhibitory concentrations) varied between 0.5 and 16 μg mL^{-1} (see Table 4).[41]

The ras proteins are a family of proteins that regulate cell proliferation and differentiation. Ras, the protein of the *ras* oncogene, is implicated in many cancers.[47] It appears, however, that tumorigenesis requires posttranslational modification of ras. This involves attachment of the farnesyl group of FPP to a cysteine residue of ras, which is catalyzed by ras farnesyl:protein transferase (FPTase).[48] There is evidence that inhibitors of FPTase have the potential to be antitumorigenic agents.[49] Scientists at Merck discovered that the zaragozic acids are powerful inhibitors of FPTase (see Table 4),[22] with potency similar to that of other naturally occurring inhibitors.[50] Zaragozic acids D and D_2 are the most potent inhibitors;[22] however, one synthetic analog is the most potent FPTase inhibitor currently known.[50]

2.3. Mechanism of Action of the Zaragozic Acids

Unfortunately, very few papers deal with the interesting question of how the zaragozic acids inhibit SS. This is probably because the mechanism of action of SS is not clearly understood, owing in part to the difficulties in purifying the enzyme and the consequent lack of crystal structure data.[51] As shown in Scheme 4, in the presence of Mg^{2+} and NADPH, SS converts two molecules of FPP (**13**) through two half-reactions into one molecule of squalene (**14**), via presqualene pyrophosphate (PSPP) (**26**). It is now accepted that SS sequentially binds two molecules of FPP, one into a donor site and one into an acceptor site.[52] The order of these events is not known. Reaction of the donor FPP with the acceptor FPP results in the loss of PPi (inorganic pyrophosphate) and the formation of the putative carbocationic intermediate **25**. Loss of a proton then gives PSPP, which can dissociate or remain bound to the enzyme. The second half-reaction (reduction of PSPP to squalene) requires NADPH. It has been shown that NADPH binds to the enzyme after the formation of PSPP.[53] Loss of PPi generates initially carbocation **27**, which is ultimately reduced with NADPH. A stereoelectronic barrier prevents reductive opening of the cyclopropane by NADPH with retention of configuration. It has been suggested that the intermediate **27** undergoes rearrangement to give the tertiary carbenium ion **28**, which can then be reduced by NADPH to give squalene. In the absence of NADPH a number of hydrolysis and elimination products (capable of arising from the carbocation **28**) were isolated.[53] It is still not clear whether the active sites for the two half-reactions overlap or are in the same region on the enzyme.

The first brief suggestion of a mechanism for the inactivation of SS by zaragozic acid A was in the original publication by the



Scheme 4. Proposed steps in the formation of squalene (**14**) catalyzed by squalene synthase (SS)

Merck group.[16] They concluded that zaragozic acids A–C were competitive inhibitors of SS, which worked by possibly acting as PSPP mimics. The structures of zaragozic acid A and PSPP show striking similarities: in both two lipophilic side chains flank a trianionic core.

Glaxo later postulated from medicinal chemistry studies that analogs of zaragozic acid A possessing an acyl side chain at C6 act as FPP mimics, whereas those having both side chains are mimics of PSPP.[54]

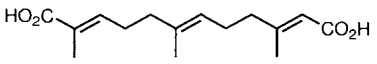
Hasumi and co-workers[18] were the first to demonstrate that zaragozic acid A (**1**) inhibits *both* half-reactions of SS: the first (synthesis of PSPP) with a K_i of 14 nM, the second (conversion of PSPP to squalene) with a K_i of 33.4 nM. Under the same conditions the K_i for the overall reaction was 1.6 nM. Merck reported a value of 78 pM for the overall reaction.[16]

The most detailed investigation of the mechanism of action of zaragozic acid A (**1**) was conducted by Harwood and Lindsey at Pfizer.[55] They provided several lines of evidence consistent with inactivation of the enzyme resulting from *competitive inhibition followed by mechanism-based irreversible inactivation*, rather than just strong, reversible competitive inhibition. In other words, zaragozic acid A binds competitively (with respect to FPP) to SS and then reacts covalently with the enzyme to irreversibly inactivate it ("suicide inhibition").[56] It was suggested that the α,β-unsaturated ester of the C6 acyl side chain was the likely site of reaction, presumably by Michael addition of a nucleophilic residue in the active site. This hypothesis was supported by detailed analysis of the kinetics of inhibition of SS by two synthetic analogs. It should be noted, however, that zaragozic acids B and C and many of the potent analogs do not possess an α,β-unsaturated ester. This suggests the intriguing possibility that zaragozic acid A is a mechanism-based irreversible inhibitor of SS, but that other members of the family are simple competitive inhibitors.

2.4. Toxicity of the Zaragozic Acids

Some brief reports on the toxicity of the zaragozic acids have been published. It should be noted that the effect of cholesterol-lowering drugs in vivo can be very species-specific: for example, lovastatin is an effective and nontoxic agent in humans and dogs, but ineffective in rats and mice.[57]

One possible consequence of blocking SS is that FPP accumulates, since it cannot be processed through the cholesterol pathway. It appears that this is the case. It has been shown that in rats treated with zaragozic acid A (**1**), FPP levels increase[58] and HMG-CoA reductase is upregulated.[59] The excess levels of FPP appear to be rapidly catabolized in the liver to a range of farnesyl-derived dicarboxylic acids (FDDCAs) such as **29**, which are excreted in the urine.[60] The same effect can be produced by feeding the rats large quantities of farnesol. When rats were treated with a dosage of 15 mg per kg per day of zaragozic acid A and a bile acid sequestrant, the levels of FDDCAs in the urine rapidly became very high and the animals became very moribund,[59b] which is a symptom of acidosis. Acidosis is a disease associated with abnormal serum pH levels. It was therefore suggested that the toxic effects associated with zaragozic acid A are a result of the acidosis caused by massive overproduction of FDDCAs from an increased pool of FPP.[59b, 61]



29

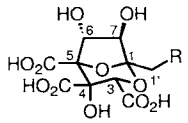
When dogs were dosed subcutaneously at 3 mg per kg, both zaragozic acids A and C caused extreme toxicity after one to two weeks.[61] With three other zaragozic acids, the effect depended on the dose and on the potency of the individual zaragozic acid. Even so, little or no lowering of cholesterol levels was observed. However, the toxicity was totally eliminated by co-dosage with a HMG-CoA reductase inhibitor. In the presence of the HMG-CoA reductase inhibitor alone, cholesterol levels were lowered by 50%, and by an additional 20% when both drugs were used. In this case, too, large amounts of FDDCAs were detected. It was suggested that the initially observed toxicity was a result of acidosis. In contrast, rhesus monkeys dosed orally with zaragozic acid A at 10 mg per kg per day for two weeks showed 50–60% lower cholesterol levels and much lower levels of FDDCAs. The reasons for this difference are not clear.

3. Chemistry of the Zaragozic Acids

3.1. Syntheses of Model Systems of the Bicyclic Core

In the last three years a number of research groups have successfully synthesized the zaragozic acids and a number of related model systems. Numerous approaches have been used, and it is very instructive to compare the different strategies and the variety of reactions employed. Table 5 lists the C–C bond connections that each research group has used to synthesize the bicyclic core. For example in the Evans synthesis[90] the C6–C7 bond was made by an aldol reaction, the C4–C5 bond by an enolate addition reaction, and the C1–C1′ bond by an alkyllithium addition—strategies that have all been used in part by

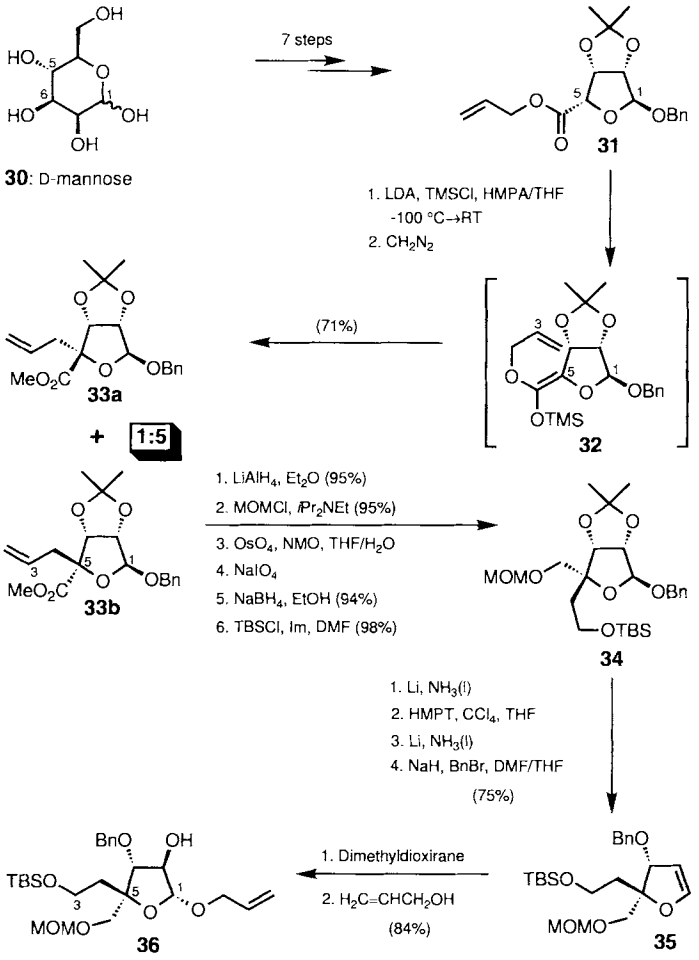
Table 5. Strategic C–C bond connections in syntheses of the bicyclic core of zaragozic acid.



Bond	Research group (method)
C1–C7	Nicolaou (dithiane addition) Armstrong (dithiane addition) Carreira (acetylide addition) Koyama (1,3-dipolar cycloaddition)
C3–C4	Gurjar (Wittig reaction)
C4–C5	Aggarwal (enolate addition) Evans (enolate addition) Roberts (2-lithiofuran addition) Nicolaou (Stille coupling) Armstrong (Stille coupling)
C5–C6	Koyama (1,3-dipolar cycloaddition) Carreira (acetylide addition) Nicolaou (Wittig reaction)
C6–C7	Kraus (modified Mukaiyama reaction) Evans (Evans aldol reaction)
C1–C1′	Evans (alkyllithium addition) Rizzacasa (Grignard addition) Heathcock (organocerium addition)

other research groups. It can also be seen that some retrosynthetic steps are more popular than others. Indeed, every research group except one,[75] has made the bicyclic core by retrosynthetic disconnection of the C1–O8 and O2–C3 bonds, with assembly by an anticipated acid-catalyzed ketalization. To most people, the polyoxygenated core structure looks like a heavily oxidized carbohydrate, and the majority of the syntheses use carbohydrate-based starting materials. Only two syntheses of enantiomerically enriched targets, that by Nicolaou and co-workers[77, 78] and the closely related one by Armstrong and Barsanti,[82] rely on asymmetric catalysis to obtain the core structure.

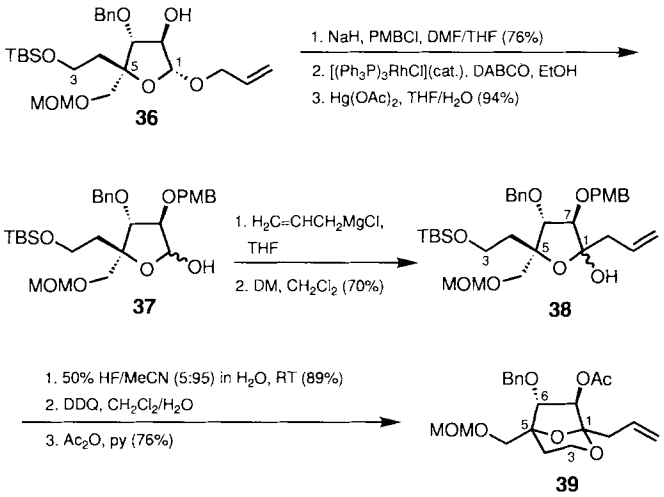
In the fall of 1993 four groups published successful syntheses of differently functionalized models of the zaragozic acids. The one by Rizzacasa and co-workers[62] is described in Schemes 5



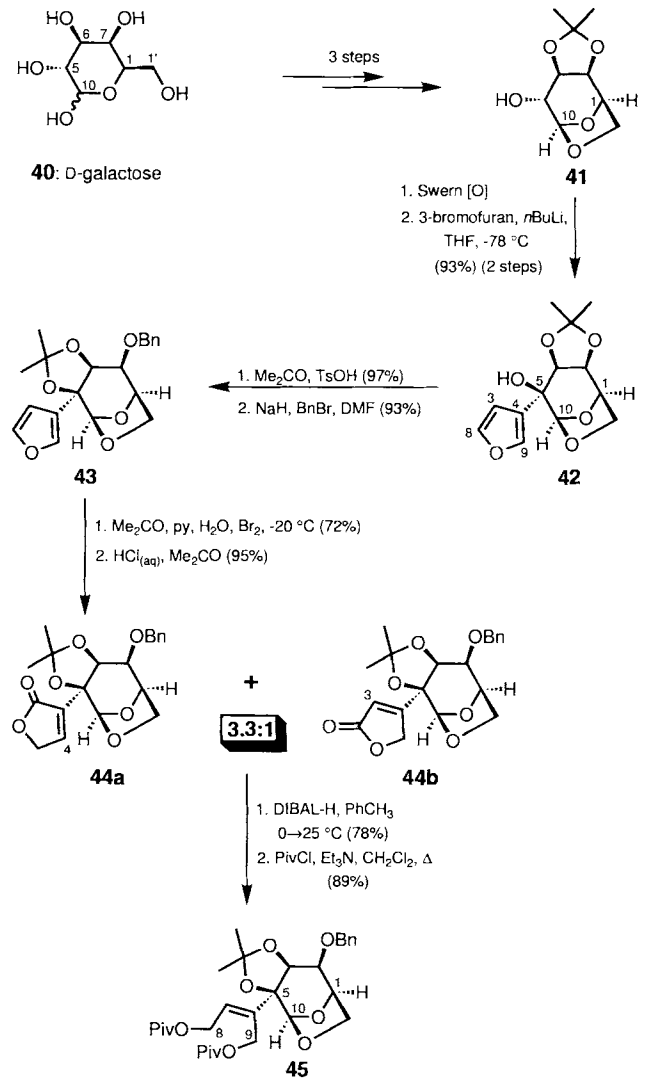
Scheme 5. Early stages of Rizzacasa's synthesis of a zaragozic acid model compound. TMS = trimethylsilyl, RT = room temperature, MOM = methoxymethyl, Im = imidazole, Bn = benzyl.

and 6. Starting with D-mannose (**30**), seven well-precedented steps gave the allyl ester **31**. Note that the "back" five-membered ring has already been constructed. The next few steps establish the correct configuration at the C5 stereocenter and invert the hydroxyl-bearing stereocenter at C7.[*] The C5 quaternary stereocenter was made with an Ireland–Claisen rearrangement,[63] which gave the diastereomers **33a** and **33b** as

[*] Here and in the following discussions the atomic numbering in the synthetic building blocks refers to positions in the final zaragozic acids.



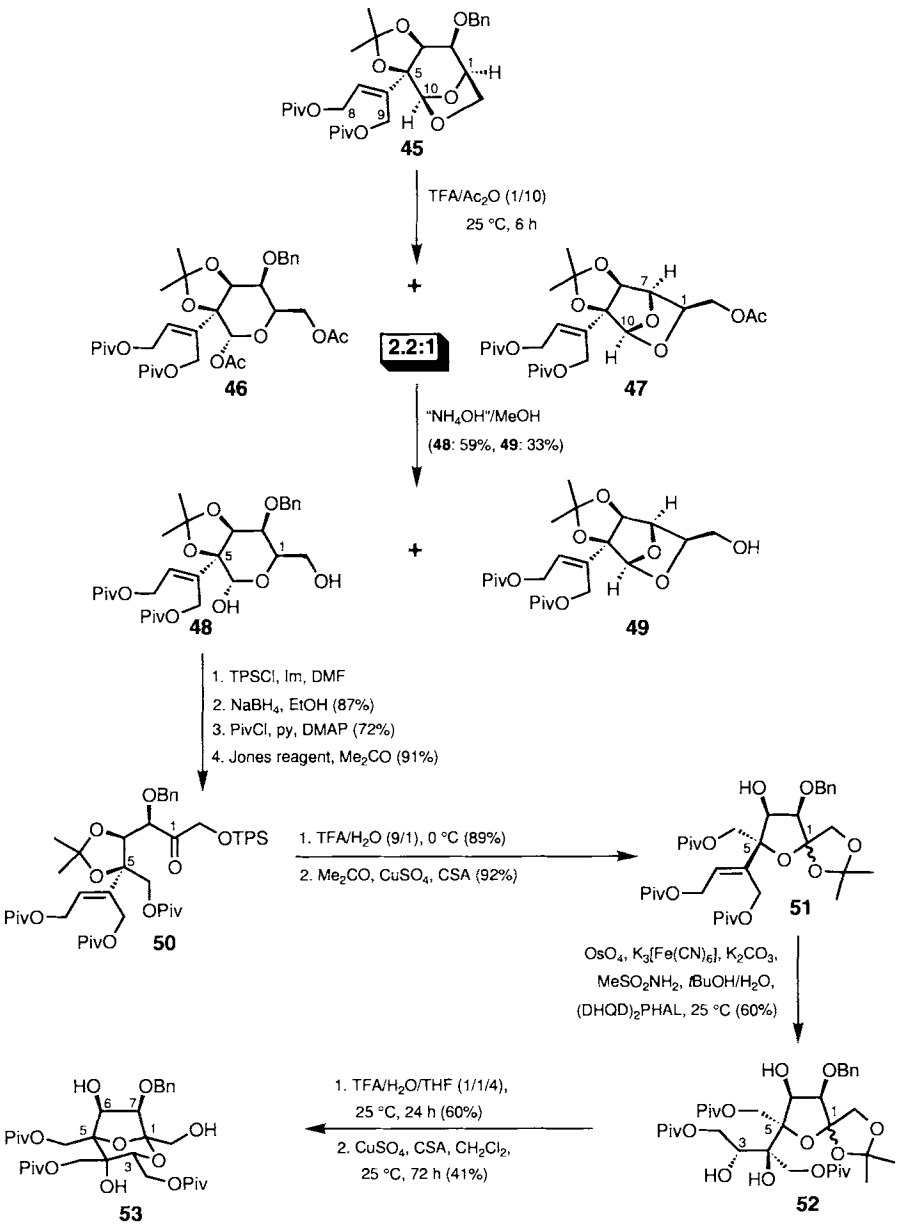
Scheme 6. Final stages of Rizzacasa's synthesis of a zaragozic acid model compound. DABCO = diazabicyclooctane, DDQ = 2,3-dichloro-5,6-dicyano-1,4-benzoquinone.



Scheme 7. Early stages of Roberts's synthesis of a zargozic acid model compound. Ts = *para*-toluenesulfonyl. DIBAL-H = diisobutylaluminum hydride.

a 1:5 mixture, via mixed silyl ketene acetal **32**. The major isomer was separated and a series of functional group interconversions furnished the TBS ether **34**. The next six steps were necessary to invert the C7 stereocenter and differentiate the C6 and C7 hydroxyl groups. Reduction of **34** with Li/NH_3 removed the benzyl ether to give a lactol, which was transformed into a glycosyl chloride by treatment with CCl_4 and HMPT. Reductive elimination gave the glycal and freed the C6 hydroxyl group to be protected as a benzyl ether in **35**. Epoxidation with dimethyldioxirane then occurred from the face opposite to the benzyl ether (selectivity >9:1). Regioselective opening of the epoxide with allyl alcohol afforded the allyl ether **36** in 84% yield. The C7 hydroxyl group was protected as a PMB ether and the allyl group was removed to give lactol **37** (Scheme 6). As a model for the C1 side chain, allyl magnesium chloride was added to lactol **37**, and subsequent oxidation yielded the lactol **38**. Note that Evans et al. used the same strategy,[90] but the order of the oxidation and addition steps was reversed in their total synthesis (steps 1 and 2 in the transformation of **196** into **197** in Scheme 40). The key cyclization of **38** to furnish the bicyclo[3.2.1]octane framework was achieved with $HF/MeCN/H_2O$, which removed the silyl protecting group and catalyzed the ketalization. Two protecting group manipulations gave the final derivative **39**.

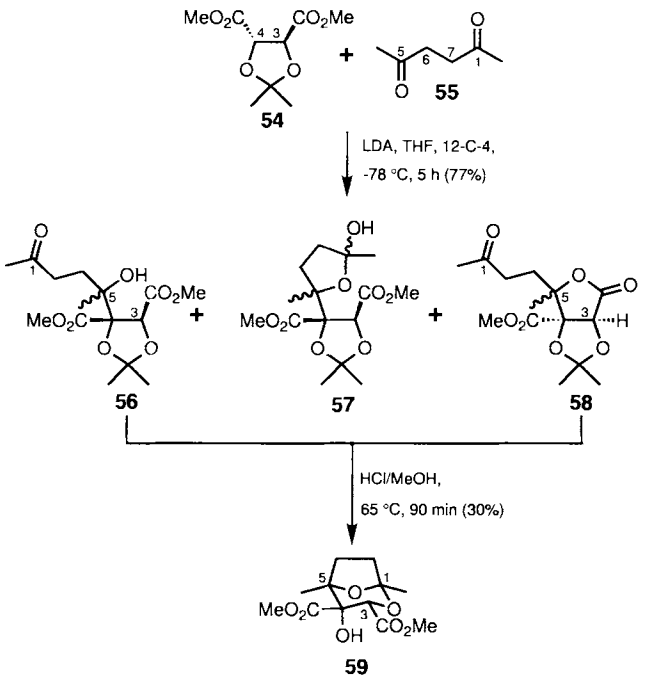
The Roberts–Glaxo route[64] (Schemes 7 and 8) produced the more highly functionalized derivative **53**. Starting from D-galactose (**40**), three steps gave the anhydropyranose structure **41**. Swern oxidation and addition of 3-lithiofuran to the resulting ketone gave the diastereoisomerically pure alcohol **42** in 93% yield. The C7 and C6 hydroxyl groups were differentiated by shifting the acetonide to C5/C6 with acetone/TsOH and protecting the C7 hydroxyl group as a benzyl ether to give **43**. The furan ring represents the C3/C4 fragment and is essentially a reduced form of the tartrate enolate fragment used by Aggarwal et al.[66] and Evans et al.[90] (Schemes 9 and 40, respectively). Accordingly, the furan ring was oxidized to the dilactol by treatment with bromine, and subsequent acid-catalyzed rearrangement afforded a mixture of the α- and β-substituted butenolides **44a** and **44b**. Although the butenolides could be manipulated further, it was found to be more expedient to homogenize the mixture of regioisomers by reducing both butenolides to the (same) diol with DIBAL-H and protecting the hydroxyl groups as pivaloate esters to give **45**. Acetolysis (cf. **93** → **94** in Scheme 16) afforded a mixture of the desired pyranoside **46** and the novel tricycle **47**, in which the C7 benzyl ether had been removed (Scheme 8). Hydrolysis of the acetate esters then gave the diol **48** after purification. The next four steps (protection of the primary hydroxyl group, reduction of the lactol, protection of the new primary hydroxyl group, and oxidation of the secondary hydroxyl group) gave the protected acyclic ketone **50**. Removal of the C5/C6 acetonide revealed the C5 hydroxyl group, enabling the tetrahydrofuranyl ring of the bicyclic core to form. Formation of another acetonide in a second step gave the spirolactol **51**. The next step was a dihydroxylation of the double bond. This is a crucial step because it generates two stereocenters. Fortunately, Sharpless asymmetric dihydroxylation (AD)[65] with a slightly modified reagent, gave, after 3.5 days, the diol **52** as a single diastereoisomer in 60% yield. Other groups have used asymmetric dihy-



Scheme 8. Final stages of Roberts's synthesis of the zaragozic acid model compound **53**. TFA = trifluoroacetic acid, DMAP = 4-dimethylaminopyridine, $(DHQD)_2PHAL$ = dihydroquinidine 1,4-phthalazinediyl diether (see also Scheme 33).

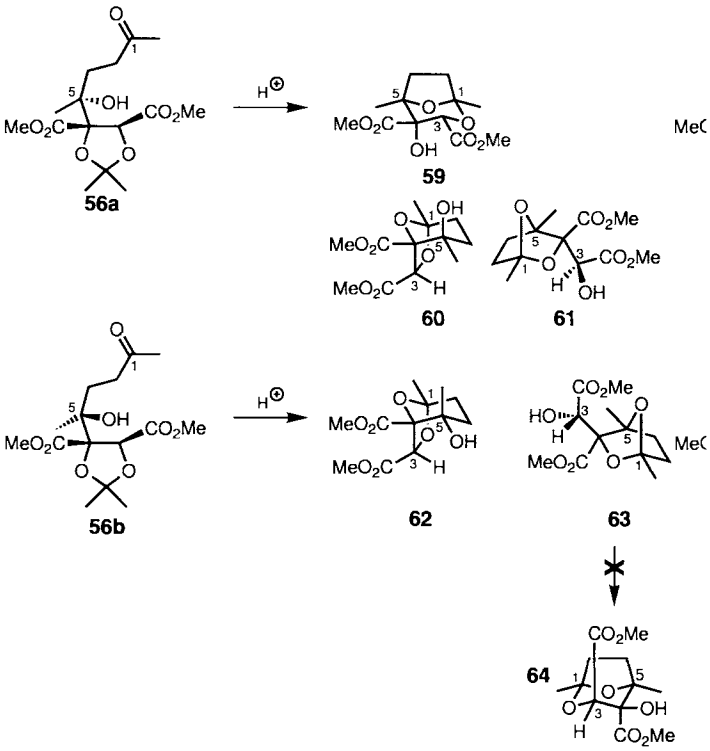
droxylation to control other stereocenters in the zaragozic acids, with varying degrees of success (see Schemes 22, 29, and 33). Finally, removal of the acetonide and dehydrative ketalization gave the target molecule **53** in 24% overall yield from **52**. The bicyclic structure **53** is a realistically functionalized model system. In principle, correction of the configuration at C6, oxidation of the three pivaloate esters, and introduction of side chains at C1 and C6 should lead to the natural product itself.

The shortest synthesis of a model of the bicyclic core is the two-step preparation described by Aggarwal and co-workers (Scheme 9).[66] By identifying the C3/C4 fragment as an intact



Scheme 9. Aggarwal's synthesis of a model compound. 12-C-4 = [12]crown-4.

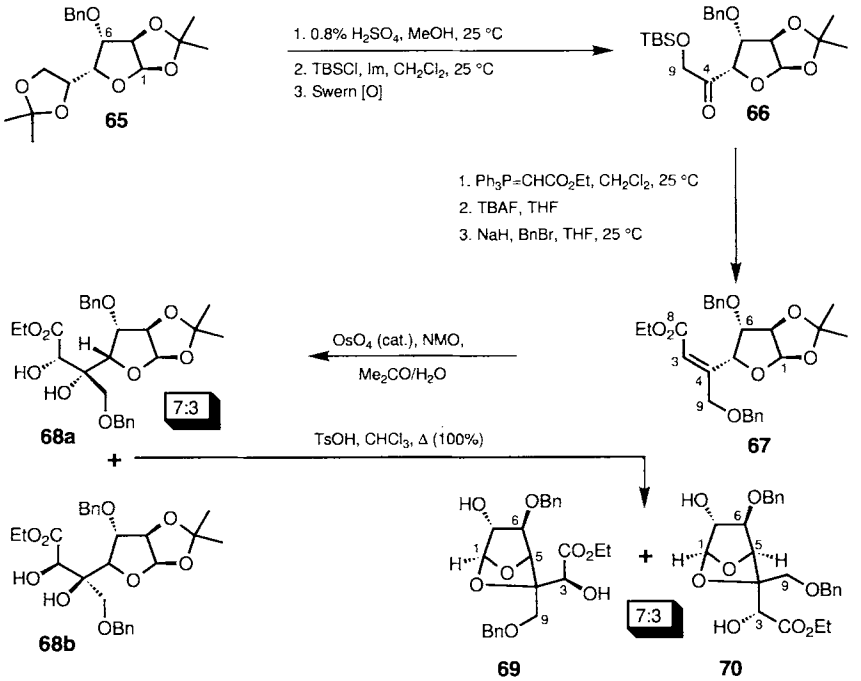
tartrate unit, the simple model system **59** was rapidly assembled. Formation of the lithium enolate of **54**, which was derived from (+)-tartaric acid,[67] and condensation with the symmetrical ketone **55**, in the presence of [12]crown-4, gave a mixture of several products in an unselective aldol reaction. Not only were C4 and C5 diastereoisomers produced, but the initial products reacted further to give lactones **57** and lactols **58**. The yield was estimated at 77%, and no attempt was made to purify the reaction mixture. Instead, treatment of the mixture obtained in the first step with refluxing HCl/MeOH for around 90 minutes gave the bicyclic core **59** in an optimal yield of 30%; NMR evidence excludes the alternative structures **60** und **61**. It was suggested that the (5*R*) diastereoisomer **56a** could easily cyclize to afford the desired product **59** (Scheme 10), but that the (5*S*) diastereoisomer would prefer to form bicyclic ketals **62** and **63** rather than the diaxial dimethyl ester **64**, which was assumed to be less stable than **59**. Unfortunately the side products from the reaction were not investigated to support this theory. Although the reactions are low-yielding and unselective, the approach clearly has potential: by using an appropriately functionalized dicarbonyl compound, a strategy for introducing a carboxyl



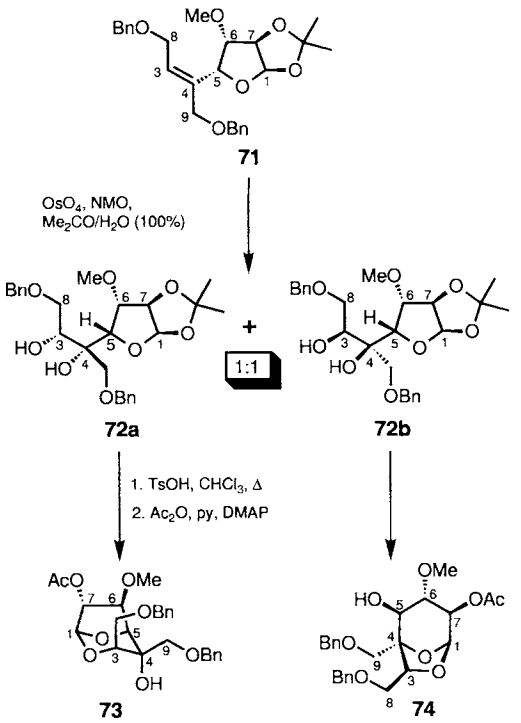
Scheme 10. Proposed intermediates in the rearrangement of **56a** and **56b** (Aggarwal et al.).

substituent at C5, and a method for controlling the aldol reaction, more functionalized zaragozic acid models could be made. Indeed, Evans et al. made use of such improvements in their total synthesis (see Schemes 40 and 41).

Gurjar et al. were the first to discover that the acid-catalyzed ketalization might not be as trivial as initially thought (Scheme 11).[68] Starting with the diacetonide **65**, which was derived from D-glucose, selective hydrolysis of the side chain acetonide, protection of the primary alcohol, and Swern oxidation gave the ketone **66**. A Wittig reaction and protecting group interchange gave the alkene **67**. Dihydroxylation with the Upjohn conditions then gave an inseparable mixture of diols **68a** and **68b** in a 7:3 ratio. It should be noted that because the double bond in **67** is of (*Z*) configuration, one of the stereocenters introduced in the dihydroxylation is destined to be wrong. Moreover, refluxing the mixture of diols with TsOH in chloroform resulted in the formation of not the desired bicyclo[3.2.1]octane skeleton but the bicyclo[2.2.1] systems **69** and **70** in quantitative yield. Unfortunately, it was not shown whether these were kinetic or thermodynamic products. This outcome could be a consequence of the lack of substituents at the C1 center (see Scheme 18), but was suggested to arise from the presence of the ethoxycarbonyl group, which reduced the nucleophilicity of the adjacent C3 hydroxyl group. Accordingly, ester **67** was reduced to give **71** (Scheme 12), and the corresponding diols **72a** and **72b** (with a different protecting group on the C6 hydroxyl group) were submitted to the rearrangement conditions. This time, one diastereoisomer (**72a**) gave the desired bicyclo[3.2.1]octane (anhydrofuran) **73**; the other gave the anhydropyran **74**. This unusual stereochemical dependence was not explained. Note that **73** is pseudo-enantiomeric to the zaragozic acids.

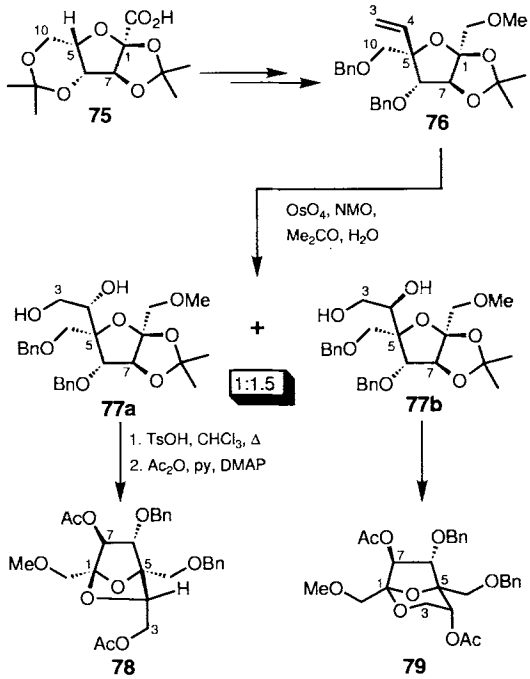


Scheme 11. Gurjar's model study (part 1).



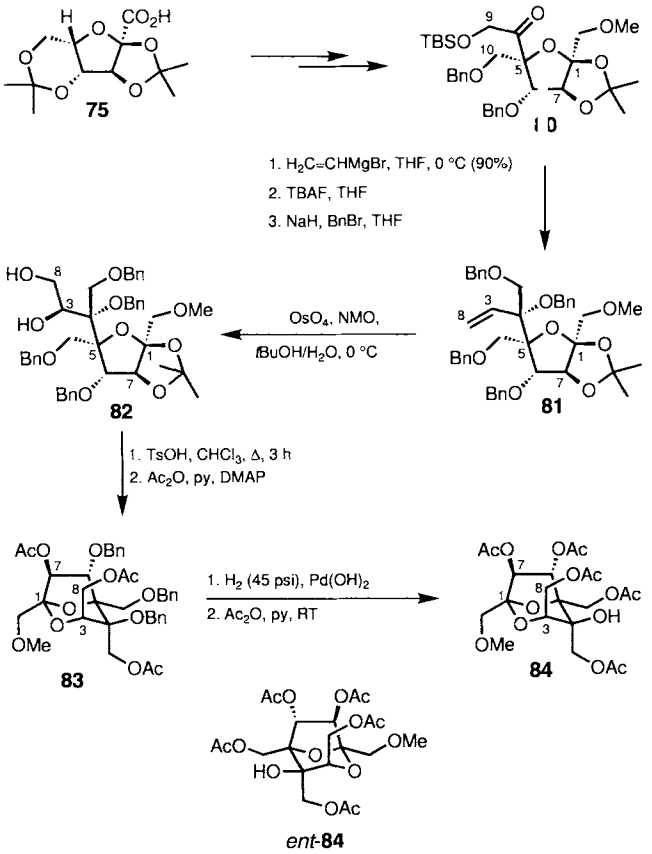
Scheme 12. Gurjar's model study (part 2).

Two later papers[69, 70] described the transformation of a C1-substituted substrate **75** into the vinyl derivative **76** by a standard sequence of reactions (16 steps, Scheme 13). Dihydroxylation gave a 1:1.5 mixture of epimers **77a** and **77b** in quantitative yield. Refluxing this mixture with TsOH in chloroform gave, after acetylation, the two isomers **78** and **79**. It is clear that isomer **77a** forms the [2.2.1] ring system preferentially, while the other affords the [3.2.1] system. Finally, in their most sophisticated model, Gurjar and co-workers found a substrate that yielded only one isomer in the cyclization reaction. Starting with the same acid **75** (Scheme 14), a number of steps gave the ketone **80**. Addition of vinylmagnesium bromide to **80** resulted in one diastereomerically pure alcohol (unfortunately with the wrong relative configuration), which was then protected as a benzyl ether to give **81**. Dihydroxylation gave, also as a single diastereoisomer, diol **82**. As predicted from earlier studies (Scheme 12), acid-catalyzed cyclization and subsequent acetylation then gave the desired bicyclo[3.2.1]octane skeleton **83**. Debenzylation and acetylation furnished the pentaacetate **84**. Note by examination of the enantiomer *ent*-**84** (Scheme 14), it is readily apparent that only two stereocenters (C3 and C4) have the wrong configuration relative to the rest of the molecule. The configuration at C3, which is installed by a dihydroxylation, could probably be easily controlled by using the Sharpless method. The three carboxylic acid functions present in zaragozic acid A are usefully represented by acetoxymethyl groups, and the hydroxyl groups at C6 and C7 are also conveniently differentiated.

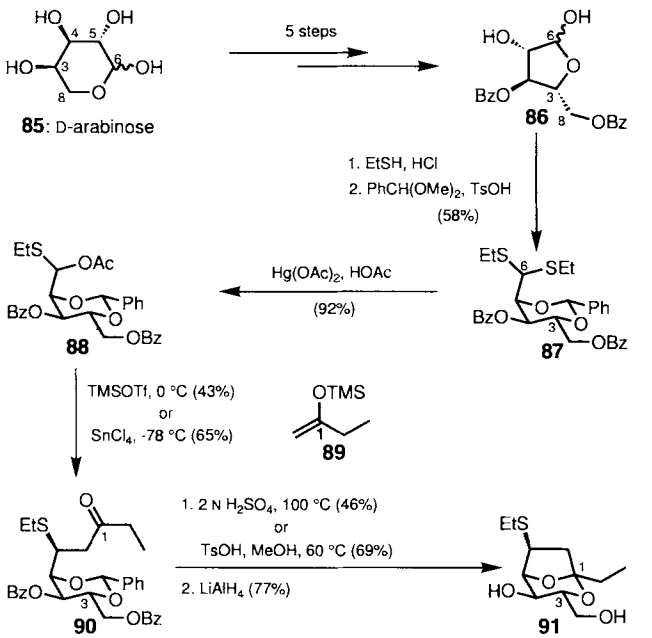


Scheme 13. Gurjar's model study (part 3).

Kraus and Maeda[71] also started their synthesis of a simplified model of the zaragozic acid core from a carbohydrate (Scheme 15). Starting with D-arabinose (**85**), five precedented steps gave the lactol **86**. Treatment of the lactol **86** with ethanethiol and HCl, followed by acetalization with benzaldehyde dimethyl acetal afforded the acetal **87**. They then attempt-



Scheme 14. Gurjar's model study (part 4). 1 psi = 6900 Pa ≈ 52 Torr.



Scheme 15. Synthesis of a zaragozic acid model compound by Kraus and Maeda.

ed to hydrolyze the dithioacetal, but this could not be readily achieved. However, treatment of **87** with mercuric acetate and acetic acid gave the α-acetoxysulfide **88** in 92% yield as a single diastereoisomer, which can, in principle, serve as an aldehyde equivalent. To demonstrate this, a modified Mukaiyama aldol reaction[72] between the silyl enol ether **89** and an appropriate Lewis acid ($SnCl_4$ was found to be the best) was performed. This furnished the sulfide **90** as a single diastereoisomer in 65% yield (but unfortunately with the wrong stereochemistry at C6). Transketalization and reduction of the esters then gave the diol **91** in moderate yield.

Heathcock and co-workers[73] examined in detail the acid-catalyzed ketalization step previously taken for granted by most groups (Scheme 16). In model studies they noticed a substantial

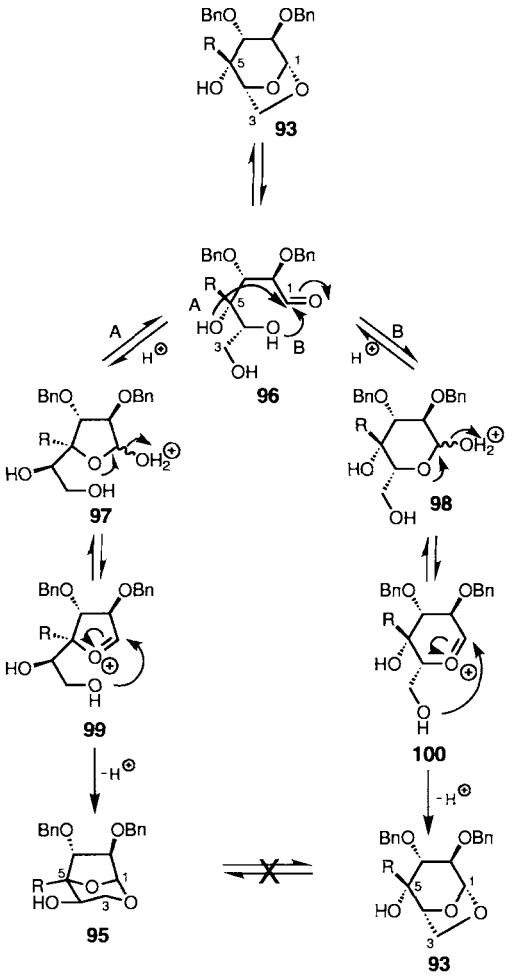
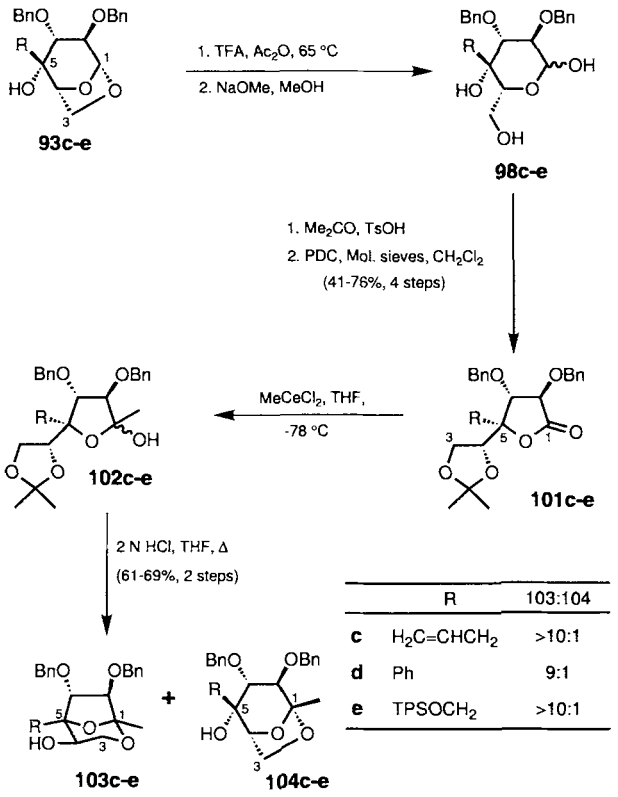
dependence of the outcome of the cyclization of **94** on the nature of the R substituent at C5. Starting from D-galactose (**40**), a series of standard operations gave the anhydropyranose **92**. Oxidation of the C5 hydroxyl group, followed by addition of a variety of Grignard reagents gave, with complete control of diastereoselectivity, alcohols **93a–f**. Acetolysis and solvolysis of the anhydro linkage (see Scheme 8), followed by acid-catalyzed acetalization in refluxing benzene gave mixtures of the desired anhydrofuranoses **95a–f** and starting material (**93a–f**). The ratio was found to be dependent on the C5 substituent; electron-withdrawing groups such as CO_2Et led to preferential formation of the undesired product. Appropriate control experiments established that the observed ratios were subject to kinetic not thermodynamic control. These findings were rationalized by the events shown in Scheme 17. Assuming that the first step in the acid-catalyzed rearrangement is the opening of the acetal to the aldehyde **96**, one of two productive pathways can occur. Path A, attack of the C5 hydroxyl group, gives the five-membered lactol **97**; path B gives the six-membered lactol **98**. Both of these intermediates can eliminate water to form oxonium ions **99** and **100**, respectively. However, it was suggested that the presence of an electron-withdrawing group at C5



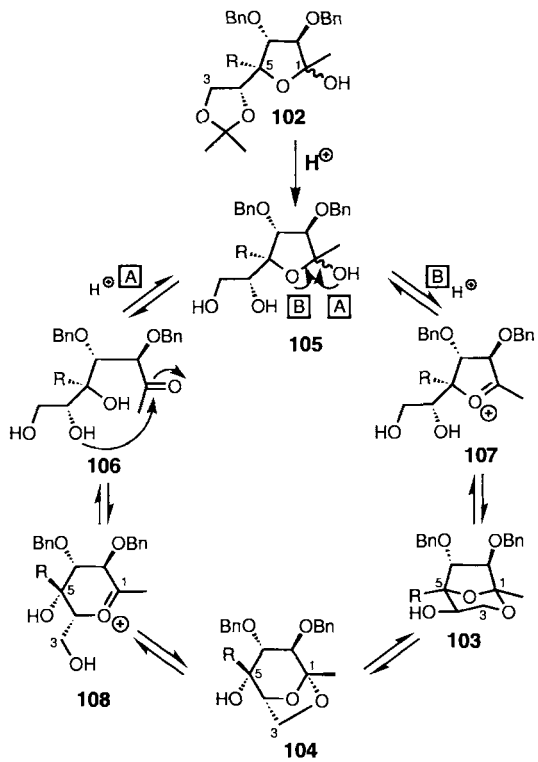
Scheme 17. Rearrangement of C5-substituted anhydrofuranoses (Heathcock et al.). Left: path A; right: path B.

would destabilize the five-membered cyclic oxonium ion **99** relative to **100**, and the reaction would proceed preferentially by path B. Moreover, since the ring closures of each oxonium ion are essentially irreversible under the reaction conditions, the kinetic product cannot equilibrate to yield a thermodynamic mixture of products.

As the zaragozic acids are substituted at C1, the effect of C1 substitution on the acid-catalyzed cyclization was also investigated (Scheme 18). The necessary functionalization of **93c–e** at C1 was achieved efficiently. The six-membered lactols **98c–e** were synthesized and converted into the corresponding lactones **101c–e** by ring opening and formation of the five-membered lactol, introduction of the C3/C4 acetonide, and oxidation. Addition of the organocerium reagent derived from methylmagnesium bromide gave the lactols **102c–e** in good yield. Conventional Grignard reagents caused elimination of the C6 benzyl group. Rearrangement of the lactol then produced a mixture of the two [3.2.1] ring systems, furanoses **103c–e** and pyranoses **104c–e**, but the ratio was less dependent on R and always in favor of the desired furanose form. This time, too, control experiments established that the ratio was subject to kinetic control. After longer reaction times the relative amount of the pyranose form increased until equilibrium was reached, which depended on the nature of R. This was rationalized by the events shown in Scheme 19. Hydrolysis of the acetonide functionality



Scheme 18. Introduction of functionality at C1 (Heathcock et al.). PDC = pyridinium dichromate.

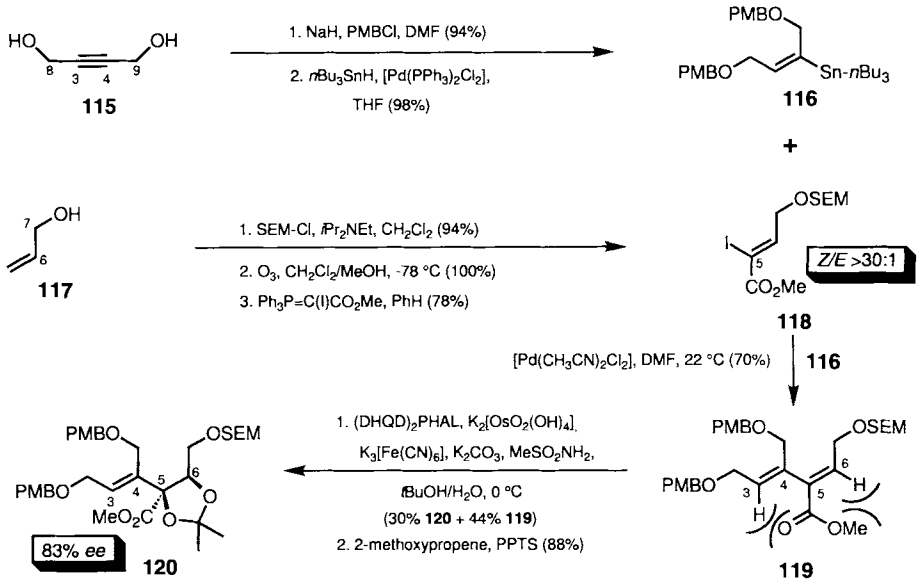


Scheme 19. Rearrangement of lactol **105** (Heathcock et al.).

was assumed to give diol **105**, which could either lead to ketone **106** and oxonium ion **108** (path A) or to the oxonium ion **107** (path B). The facile trapping of oxonium ion **107** to give product **103** is faster than the cyclization of ketone **106** to yield the

oxonium ion **108**, which accounts for the kinetic preference for the furanose form. Oxonium ions **107** and **108** are more stable intermediates (since they are substituted at C1) and the ring-closing steps from each are therefore not irreversible. Thus the two end products can equilibrate via **106** to afford a mixture whose ratio is apparently dependent on the size of R. This methodology was recently used by Heathcock et al. to complete the synthesis of zaragozic acid A,[74] although details have not yet been published.

The most imaginative synthesis of a model of the zaragozic acid core was described by Koyama and coworkers at Merck (Scheme 20).[75] Whereas all the other approaches to the synthesis of the zaragozic acids rely on a ketalization to form the bicyclic core, these researchers used a tandem cyclization–cycloaddition reaction, first developed by Padwa,[76] to assemble the core from two acyclic precursors in a single step. Starting with the diazoketone **109**, rhodium tetraacetate induced decomposition gave the presumed carbonyl ylide **110** by carbene insertion into the C=O bond of the ester. Intermediate **110** then undergoes an intermolecular 1,3-dipolar cycloaddition with an enol ether dipolarophile to give the bicyclic core **111**. The yields, however, are rather modest and the products of course are racemates. In contrast, when ketone **112** was used (Scheme 21), the products **114**, carbocyclic

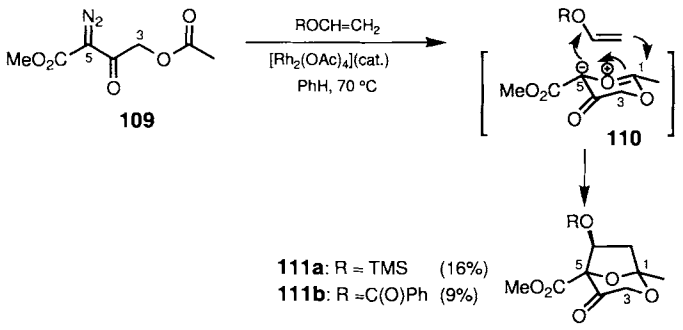


Scheme 22. Early stages of our synthesis of the model compound **130a**. PPTS = pyridinium *para*-toluenesulfonate.

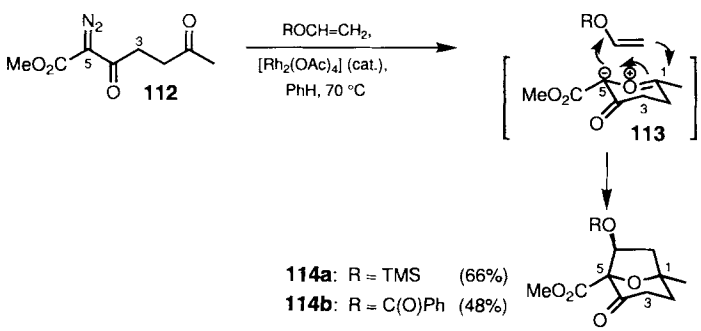
analogs of the zaragozic acids, were obtained in much greater yields.

One of only two syntheses to use asymmetric catalysis to synthesize an enantiomerically enriched model of the core of the zaragozic acids is that by our group (Schemes 22–28).[77, 78] Starting with two readily available starting materials, butyne-1,4-diol (**115**) (an intermediate in the industrial synthesis of THF) and allyl alcohol (**117**), the vinylstannane **116** and the vinyl iodide **118** were synthesized (Scheme 22). Since the alkyne **115** has two identical substituents, the regioselectivity of the *cis*-hydrostannylation was not important. The configuration of the double bond in the vinyl iodide was controlled by a Wittig reaction to give **118** with >30:1 *Z*/*E* selectivity. A Stille coupling[79] of **116** and **118** then formed the diene **119** as a single isomer without any pre-isomerization, a problem that can affect some Stille couplings. It should be noted that the control over the configuration of the double bond was crucial at this stage, since four of the six stereocenters in the core ultimately arise from dihydroxylations of double bonds. The first of two dihydroxylations was conducted under Sharpless conditions,[65] and, remarkably, gave a single regioisomer **120** in around 83% *ee* but only 30% yield. The success of this reaction was found to depend critically on the size of the protecting groups at C7, C8, and C9. The surprising regioselectivity was explained as resulting from a subtle balance of steric and electronic effects.[78] After removal of the PMB protecting groups from **120**, a second dihydroxylation (which was accompanied by spontaneous translactonization) gave triol **123** as a single diastereoisomer in 83% yield (**121** → **123**, Scheme 23). A series of sequential oxidations and protecting group manipulations was then performed to increase the oxidation states at C7, C8, and C9 to the correct levels (**124** → **125**, Scheme 24).

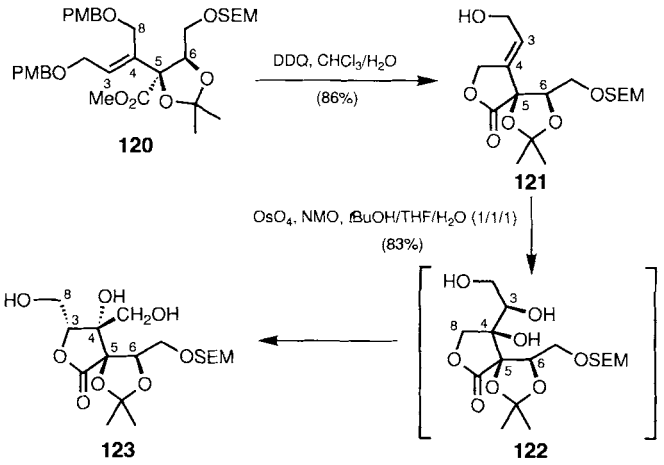
As a model for the alkyl side chain at C1, the anion of 2-methyl-1,3-dithiane (**126**) was added to the aldehyde **125** (Scheme 25). Unfortunately, a (separable) 1:1 mixture of C7 diastereoisomers resulted. The desired diastereoisomer **127a** was desilylated with 2% HCl in MeOH and the dithiane protecting group was removed with $Hg(ClO_4)_2/CaCO_3$ to provide



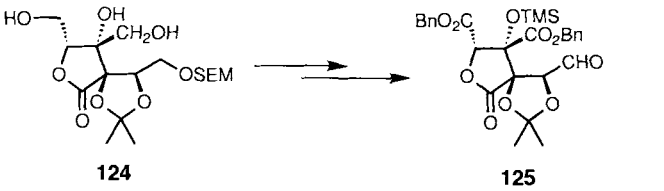
Scheme 20. Approach to the zaragozic acids based on a tandem cyclization–cycloaddition reaction (Koyama et al.).



Scheme 21. Synthesis of carbocyclic analogs of zaragozic acid (Koyama et al.).



Scheme 23. Synthesis of the model compound **130a**: the second dihydroxylation. **123** is obtained as a single diastereomer.



Scheme 24. Synthesis of the model compound **130a**: oxidation of **124** (≙ **123**) to give **125**.

128 in 72% yield. In the tricyclic structure **128a** each carbon atom is at the correct oxidation state, so that an acid-catalyzed removal of the three cyclic protecting groups and subsequent ketalization should give the desired [3.2.1]bicycle **129a**. These predictions proved to be correct, and by refluxing **128a** in 2% HCl in MeOH, **129a** was obtained in 56% yield. The C3 and C5 carboxyl groups had also been usefully differentiated from the C4 benzyl ester in the form of methyl esters. Hydrolysis of the two methyl esters with lithium hydroxide gave the corresponding dicarboxylic acid, which was converted to the tricarboxylic acid **130a** in quantitative yield by hydrogenolysis. The same experiments on the diastereoisomer **127b** (obtained from the dithiane addition reaction) gave the corresponding triacid–triol **130b**, epimeric at C7. The high yield in the rearrangement of **128a** and **128b** is remarkable, particularly in light of Heathcock's studies[73–74] discussed previously and calculations by Evans and co-workers (vide infra).[90]

Two by-products could be isolated from reactions that had not reached completion, methyl glycoside **131** and the alternative [3.2.1] system **132**, both of which could be converted to the desired product **129b** (Scheme 26). This suggested that in this system at least, the desired product was the thermodynamically more stable one.

In an attempt to overcome the poor selectivity obtained in the addition of dithianes to **125**, we replaced the aldehyde derivative **125** with **136**.[78] Starting from intermediate **133** (an analog of **123** with a different protecting group on the C7 hydroxyl group), selective silylation, oxidation, and esterification with DCBI (**137**) gave the ester **134** (Scheme 27). DCBI and its relatives such as DITBI (**176**) have seen widespread use in derivatizing the zaragozic acids.[80] Desilylation of the C8 silyl ether and cleavage of the MEM group with NaI/TMSCl in acetonitrile

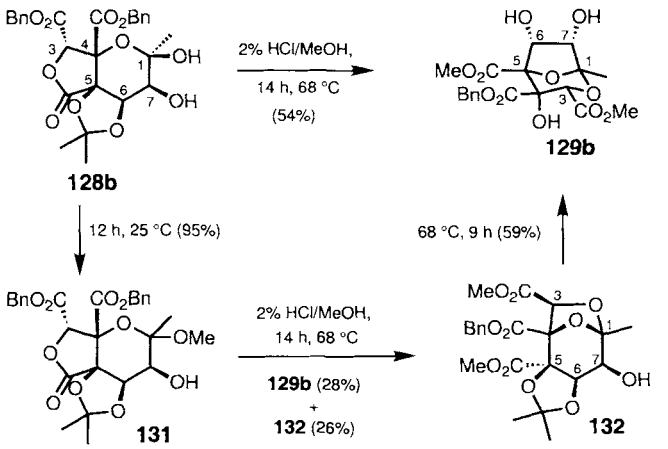
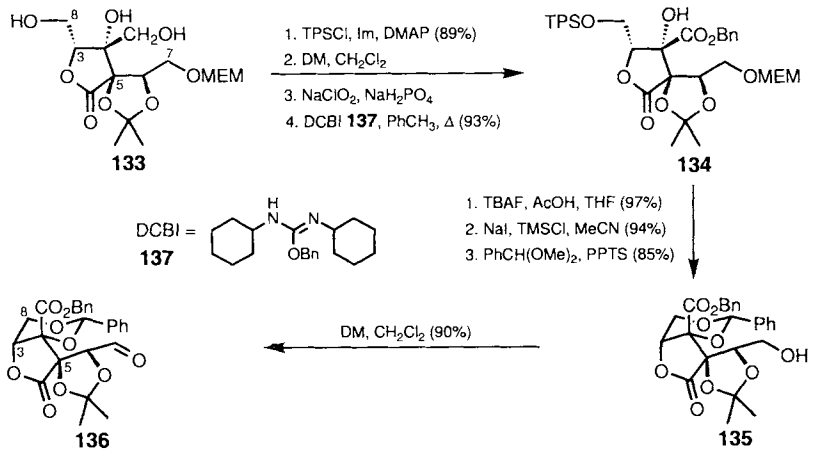
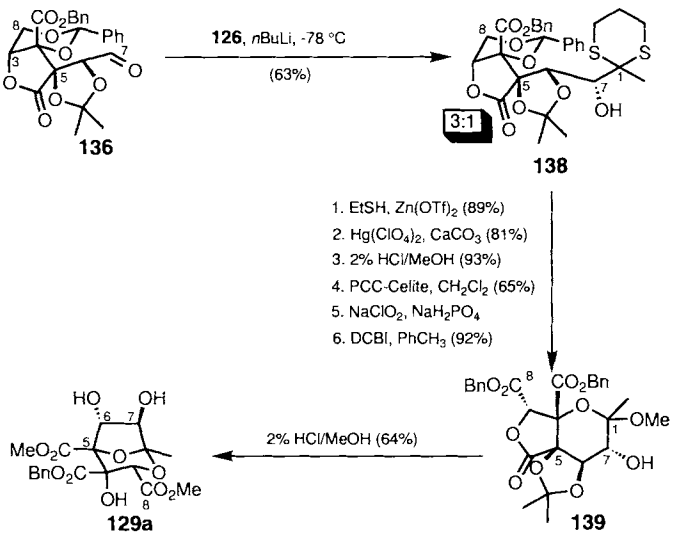


Scheme 26. Rearrangement of the anhydropyran **132**.



Scheme 27. Synthesis of **136**, an alternative to **125**. MEM = 2-methoxymethyl.

gave the corresponding triol in excellent yield. Subsequent treatment with benzaldehyde dimethyl acetal afforded the benzylidene acetal **135**, and finally, oxidation gave the aldehyde **136**. Addition of the anion of 2-methyl-1,3-dithiane (**126**), the nucleophile used previously, then proceeded with improved diastereoselectivity to give the dithiane **138** as the major product (Scheme 28, ratio of diastereoisomers 3:1). A standard se-



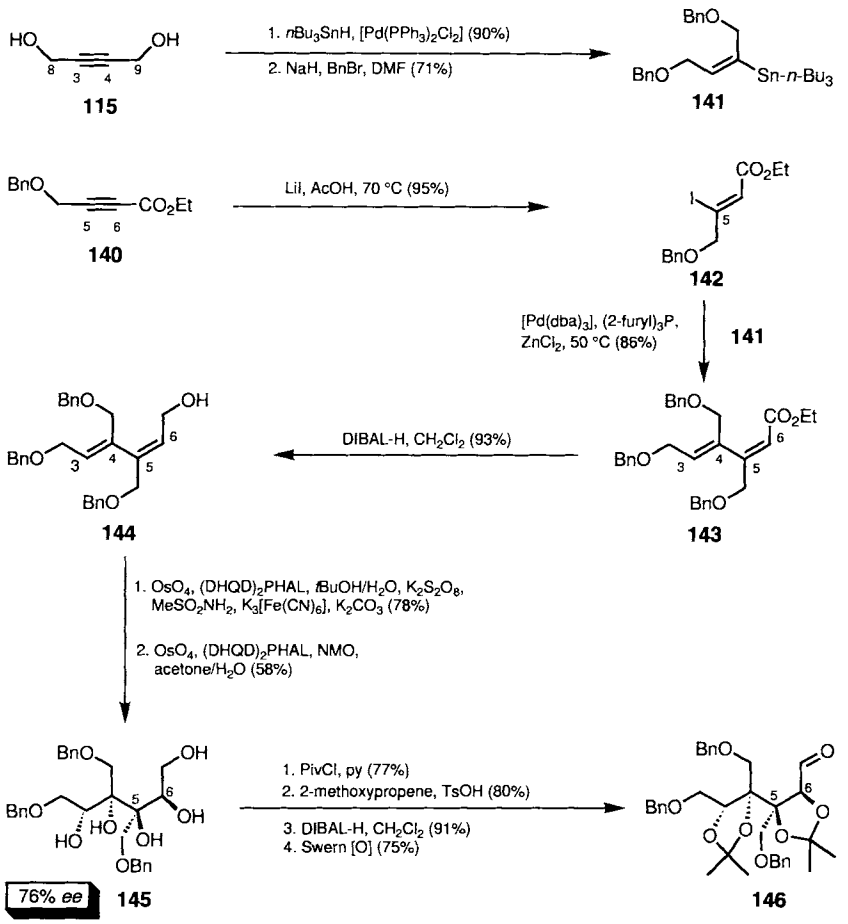
Scheme 28. Final stages of our alternative synthesis of **129a**. PCC = pyridinium chlorochromate.

quence of reactions then provided the methyl glycoside **139**. As before, the methyl glycoside **139** underwent rearrangement to give the previously obtained triester **129a** in 64% yield. Some of these results were later applied in the first synthesis of zaragozic acid A (vide infra).[78, 81]

A very similar approach was described by Armstrong and Barsanti in a recent report (Schemes 29 and 30).[82] Essentially the same strategy was used, but on substrates with lower oxidation states. The same two carbon–carbon bond forming reactions (a Stille coupling and a dithiane–aldehyde coupling) were used to construct the same bonds, and sequential dihydroxylations of a diene were used to introduce the four contiguous hydroxylated stereocenters from C3 to C6. Starting from alkyne **140** (Scheme 29), conjugate addition of lithium iodide gave vinyl iodide **142** in 95% yield. Vinylstannane **141** was synthesized from butyne-1,4-diol (**115**) by sequential *cis*-hydrostannylation and bis(benzylation) reactions. The vinyl iodide and the vinylstannane were then joined together in a Stille reaction employing an exotic mixture of reagents to afford diene **143** in 86% yield. Zinc chloride was added to the reaction mixture to accelerate the transmetalation of the vinylstannane moiety. Reduction of the ethyl ester functionality with DIBAL-H gave the allylic alcohol **144**. This was dihydroxylated under slightly modified Sharpless conditions[65] to afford a mixture of regioisomeric triols. Potassium peroxodisulfate was added to this reaction mixture as an additional stoichiometric re-oxidant. The mixture of triols was then dihydroxylated once more (with the NMO-based version of the AD) to afford pentaol **145** in an overall yield of 45% from **144** and in 76% *ee* as a 9:1 mixture of diastereoisomers. The dihydroxylations could be performed all in one step if the NMO variant was used first, but the *ee* of the resulting pentaol **145** was low (24%), although the yield was good (74%). Protection of the primary hydroxyl group of **145** as a pivaloate ester, bis(acetonide) formation, deprotection of the primary alcohol, and Swern oxidation[83] afforded aldehyde **146**.

As a simple model for the C1 alkyl side chain, the anion of 2-methyl-1,3-dithiane (**126**) was added to aldehyde **146** (Scheme 30). This addition, as in our synthesis (see Scheme 25), was essentially stereorandom. The desired isomer **147b** was separated and the dithiane grouping was removed in 92% yield with $Hg(ClO_4)_2/CaCO_3$. Treatment of the resulting ketone **148** with 2% HCl in MeOH, first at room temperature and then at 50 °C for 5 h, afforded the bicyclic structure **149**, plus an approximately equimolar amount of the anhydropyranose isomer **150**, in a combined yield of 92%. The undesired pyranose form was reported to be the thermodynamically more stable of the two isomers. Clearly, only introduction of the relevant side chains and oxidation of the three benzyloxymethyl groups to carboxyl functions need to be achieved to complete the total synthesis.

The last model study included in this review is that by the late R. E. Shaw and co-workers at Glaxo (Scheme 31).[84] It is included with some license, since they did not attempt to synthesize the bicyclic core. Indeed, the aim was to prepare monocyclic analogs for biological testing. Nevertheless, the synthesis shares some of the features and problems encountered in syntheses of the natural product, and it is included here for completeness. Starting with the bis(acetonide) of D-glucose **151**, three steps gave the cyanohydrin **152**. Oxidation of the cyanohydrin, formation of the methyl ester, hydrolysis of the side chain acetonide, and oxidation of the primary hydroxyl group gave the acid **153** in good overall yield. Standard manipulations then afforded the lactone **154**. Methanolysis of the *para*-nitrobenzyl ester gave the dimethyl ester **155**. Treatment of this with $Ph(CH_2)_6CH(OMe)_2$, a model for the side chain, under acidic dehydrating conditions gave the 1,3-dioxane **156** in 48% yield



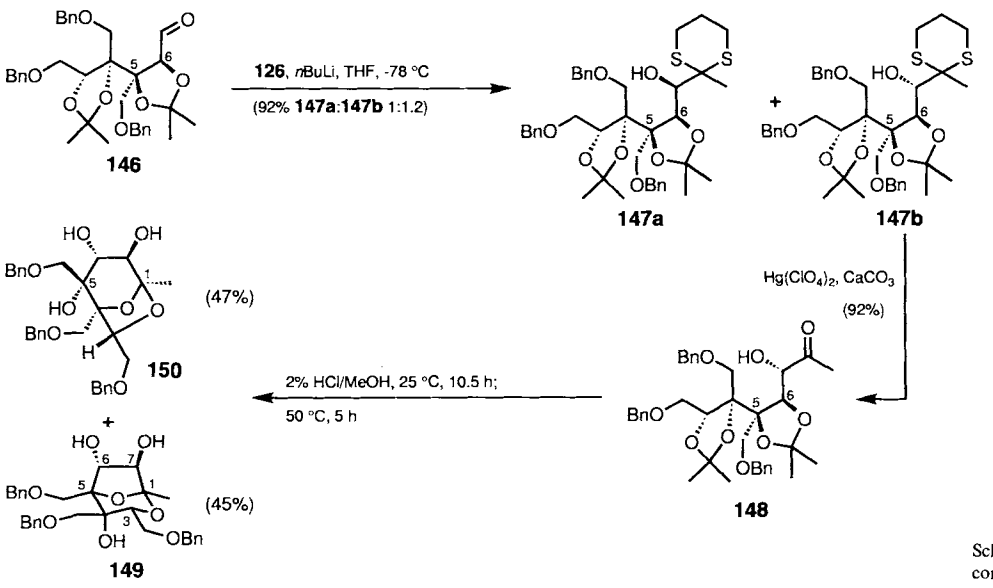
Scheme 29. Armstrong's synthesis of model compound **149** (part 1).

3.2. Total Syntheses of Zaragozic Acids A and C

The first synthesis of zaragozic acid C was reported by Carreira and Du Bois at the end of 1994 (Schemes 32–39).[85, 86] Of the three published syntheses of naturally occurring zaragozic acids, that by Carreira accesses the bicyclic core structure most rapidly. Starting from D-erythro-γ-lactone **162** (which is expensive but can be made readily from ascorbic acid in three steps), three standard reactions gave the amide **163** (Scheme 32). Formation of the C5 stereocenter required the construction of two carbon–carbon bonds and this was achieved in a particularly neat, one-pot reaction. Sequential addition of one equivalent of ethoxyvinyllithium and one equivalent of the Grignard reagent derived from trimethylsilylacetylene afforded an intermediate vinyl ether, which after ozonolysis gave the ester **164** in excellent yield. The diastereoselectivity was >20:1 and was postulated to have arisen through magnesium ion mediated chelation of the intermediate keto group with the neighboring benzyl ether. Reduction of the ethyl ester in **164**, deprotection of the alkyne, and protection of the hydroxyl groups at C10 and C5 with a TBS and a TMS group, respectively, then gave the intermediate **165**.

Unlike the Evans synthesis and our synthesis, Carreira introduces the C1 alkyl side chain at an early stage. Thus the anion of alkyne **165** was added to the aldehyde **166** (see Scheme 46) in the presence of LiBr to form the C1–C7 bond in 93% yield (Scheme 33). Reduction of the alkyne to the necessary *trans* alkene proved difficult, but eventually with a new reagent combination diol **168** could be

and a small amount of the 1,3-dioxolane **157**. However, with the zaragozic acid A side chain equivalent **158** (as a mixture of racemic diastereoisomers) the results were inferior, resulting partly from isomerization of the allylic acetate, and the desired compound **159** could only be isolated in very low yields.



Scheme 30. Armstrong's synthesis of model compound **149** (part 2).

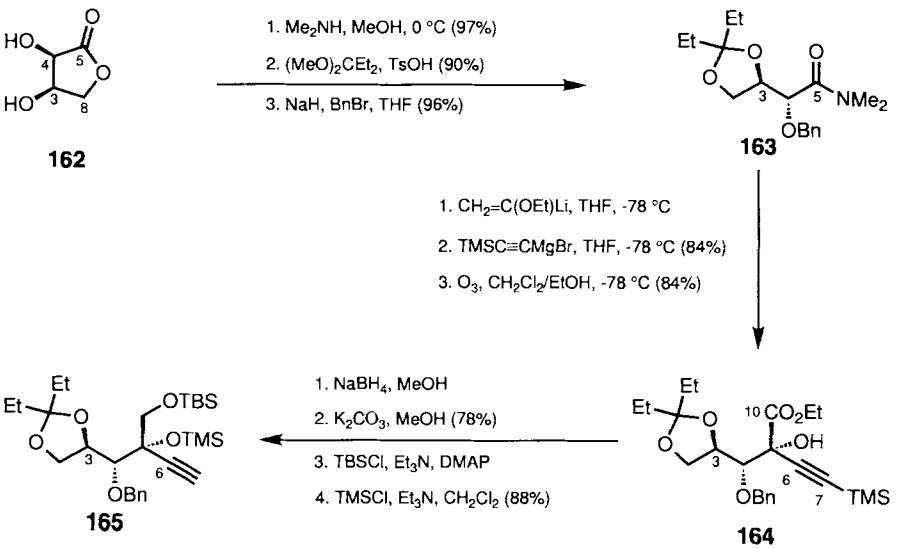

Scheme 32. Early stages of Carreira's synthesis of zaragozic acid C.

obtained in good yield after desilylation. The C6 and C7 stereocenters were then set by a dihydroxylation, which proved more difficult than expected. Under standard catalytic dihydroxylation conditions the substrate favored formation of the undesired diastereoisomer **169b**, and under the standard Sharpless asymmetric dihydroxylation conditions no reaction was observed. However, with a slightly modified set of reagents (NMO instead of $K_2CO_3/K_3[Fe(CN)_6]$ as the stoichiometric oxidant) the desired diastereoisomer **169a** was formed with a slight preference (1.7:1).[65] Remarkably, this ratio was the same regardless of which pseudo-enantiomeric ligand was used in the reaction, a result also encountered recently by Smith and co-workers.[87] The mixture of dihydroxylation products **169a,b** was then treated with HCl in MeOH at room temperature, resulting in the efficient formation of the bicyclic core structure. Protection of the two primary hydroxyl groups as TBS ethers afforded **170**, which was separated from the undesired C7 epimer by chromatography.

The remaining tasks in the synthesis at this point were: a) the introduction of functionality at C4, b) the oxidations, and c) the differentiation of the C6 and C7 hydroxyl groups. To accomplish the first task, the C6 and C7 hydroxyl groups were protected as pivaloate esters, the benzyl ether was removed, and the resulting alcohol was oxidized under Swern conditions to give the C4 ketone **171**. Three different approaches to introduce the C9 carbon atom were tested (Scheme 34). Ultimately, addition of TMSC≡CLi under very carefully optimized conditions gave the best results (→**174**) in terms of yields and selectivity.[88] Other routes (**171** →**172** and **171** →**173**) were less successful.

As in our route, the oxidations initially formed a large part of the synthesis (Scheme 35). Deprotection of alkyne **174**, removal of the pivaloate units and replacement with acetyl groups, selective hydrolysis of the C8 TBS ether, and partial reduction of the alkyne gave the alcohol **175**. Oxidation, esterification, carefully buffered deprotection of the C10 hydroxyl group (to prevent migration of the acetyl group at C6), and a three-step oxidation–esterification of the C10 hydroxyl group gave the diester **177**. Ozonolysis of the double bond in **177** gave the corresponding aldehyde, which was converted into the triester **178**.

Fortunately, this tedious sequence of reactions could be replaced by a more elegant and far more efficient approach, in which the oxidations are performed almost simultaneously (Scheme 36).[86] Starting with the triacetate **179**, hydroly-

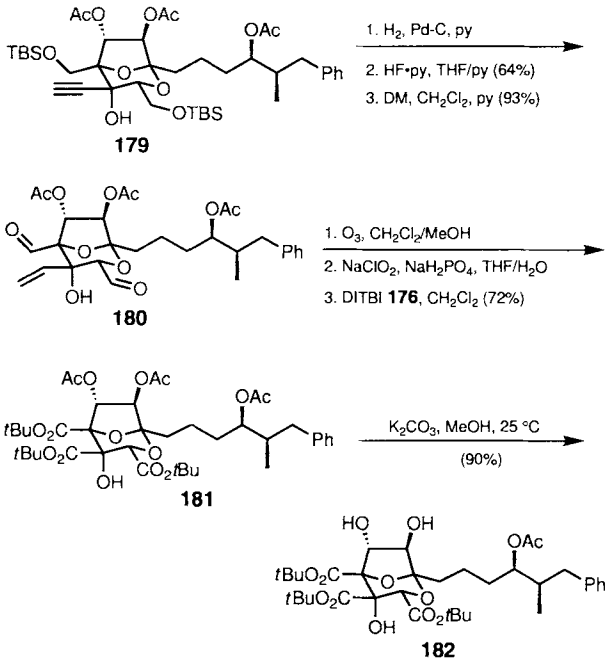
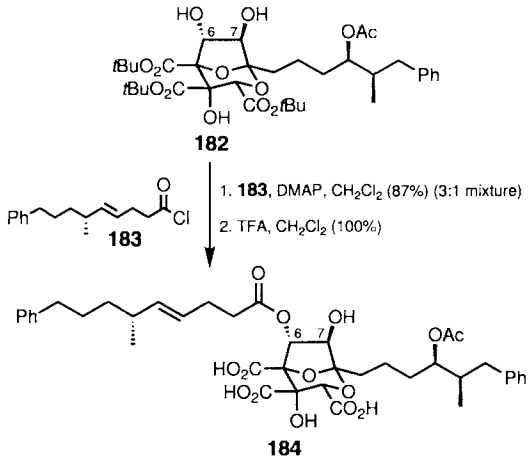


Scheme 36. Simultaneous oxidations to form the tricarboxylate moiety **181** (= **178**) of zaragozic acid C (Carreira et al.).

sis of both TBS ethers, and oxidation with the Dess–Martin reagent[89] gave the dialdehyde **180**. Ozonolysis then gave the trialdehyde (!), which was oxidized further with $NaClO_2$ and esterified as before to give the triester **181**. Finally, a remarkably selective deprotection revealed the C6 and C7 hydroxyl groups and afforded **182**.

Initially, Carreira and Du Bois completed the synthesis of zaragozic acid C (**184**) by esterifying **182** with the acid chloride of the C6 acyl side chain **183** (see Scheme 50), separating the mixture of C6 and C7 regioisomers, and deprotecting the three *tert*-butyl esters (Scheme 37).[85] However, a few model studies



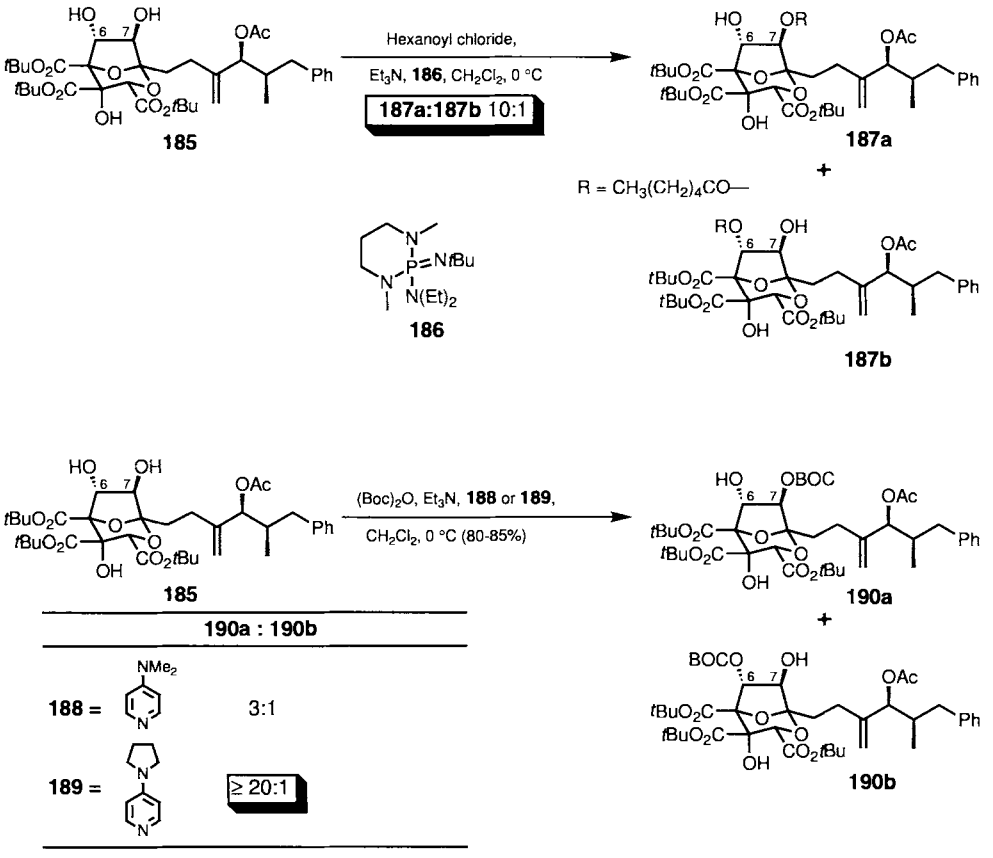
Scheme 37. Conclusion of the synthesis of zaragozic acid C (**184**) (Carreira et al.).

conducted with zaragozic acid A suggested that a much more satisfactory end to the synthesis could be found.[86] Initial studies with **185**, derived from zaragozic acid A (**1**), showed that acylation with hexanoyl chloride in the presence of the exotic phosphorus base **186** gave a mixture of regioisomers **187a** and **187b** in a 10:1 ratio (Scheme 38). This was improved still further by using $(Boc)_2O$ as the acyl source and 4-(1-pyrrolidinyl)pyridine (**189**) as the catalytic base, which afforded **190a**:**190b** in a ratio of >20:1. Remarkably, when the reaction was repeated with DMAP (**188**) in place of **189** the ratio fell to 3:1.

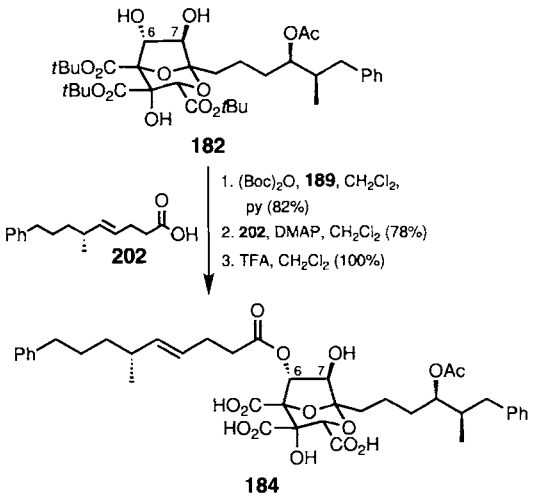
With this procedure to differentiate the C6 and C7 hydroxyl groups, it was a simple matter to introduce the C6 acyl side chain **202** and simultaneously deprotect the three *tert*-butyl esters and the Boc carbonate to give zaragozic acid C (**184**) (Scheme 39).

The synthesis of zargaozic acid C by the Evans group[90] (Schemes 40 and 41) is notable for its efficiency and the complete control exerted over each newly formed chiral center. Two of the key C–C bond forming reactions are coincidentally similar to those reported by other groups: the addition of the C1 alkyl side chain (**198** + **199** → **200**) is similar to the Rizzacasa and Heathcock routes, and the use of a tartrate fragment for the C3/C4 unit is similar to that reported by Aggarwal.

Starting with *N*-acyl oxazolidinone **191**, an Evans aldol reaction[91] with cinnamaldehyde gave the *syn* aldol **192** as a single diastereoisomer, which was converted to the aldehyde **193** in three standard reactions (Scheme 40). The di-*tert*-butyl ester **194** of (+)-tartaric acid was protected as a cyclopentylidene acetal. This protecting group is more labile than the more common acetonide and probably accounted for the mildness of the rearrangement conditions used later in the synthesis (**200** → **201**; Scheme 41). A Mukaiyama aldol reaction between silyl ketene acetal **195** and aldehyde **193** promoted by



Scheme 38. Selective acylation of the C6 and C7 hydroxyl groups of **185** (Carreira et al.). Boc = benzyloxycarbonyl.



Scheme 39. Selective introduction of the C6 acyl group (Carreira et al.).

(iPrO)$TiCl_3$ gave **196** as a single diastereoisomer. Oxidation of **196** with the Dess–Martin reagent and addition of vinylmagnesium bromide generated the stereocenter at C5 (selectivity >10:1) and introduced the C10 carbon atom. The diastereoselectivity was found to be strongly solvent-dependent. Selective cleavage of the disubstituted double bond gave a lactol, which was oxidized to the lactone **197** with tetra-n-propylammonium perruthenate (TPAP). The tri-*tert*-butyl ester **198** was then obtained by standard methods (Scheme 41). It should be noted that **198** is functionally identical to our aldehyde **125**. Addition of the side chain was achieved by adding the lithio derivative of **199** to the lactone **198**. The PMB protecting group was removed and replaced with an acetyl group to give **200**, which underwent rearrangement at room temperature to yield the bicyclic ketal. Following re-introduction of some of the *tert*-butyl esters and hydrogenolysis of the C6 benzyl ether, alcohol **201** was obtained. Some desilylation of the silyl ether at C7 was encountered during the ketalization step, but this was corrected by resilylating. The final three steps all proceeded without incident: introduction of the C6 acyl side chain (**202**), desilylation of the C7 silyl ether, and deprotection of the three *tert*-butyl esters gave zaragozic acid C (**184**) in an overall yield of 80%. The high degree of convergency of this route owing to the late-stage coupling of the two side chains has also enabled the facile synthesis of zaragozic acid A (**1**).[92]

Our synthesis of zaragozic acid A[81,93] (Schemes 42–44) closely followed the model studies previously described (see Schemes 22–28). Addition of the anion of dithiane **203** to aldehyde **125** gave, as before, an approximate 1:1 mixture of diastereoisomers epimeric at C7 (Scheme 42). The dithiane grouping in the undesired isomer **204** was removed to give the lactol **205**. Unfortunately, during the attempted conversion of lactol **205** to intermediate **206**, the TPS protecting group at C4′ was cleaved and spiroketal **207** was obtained.[78] Interestingly, the spiroketal **207** could not be transformed further to give the bicyclic core **206**.

Accordingly, the more acid-stable di-*tert*-butylmethylsilyl group was used to protect the hydroxyl group at C4′ (**125** + **208** → **209**, Scheme 43). This time the protecting group remained intact during the acid-catalyzed rearrangement, and the bicycle **210** was formed in 40% yield. Removal of the DTBMS

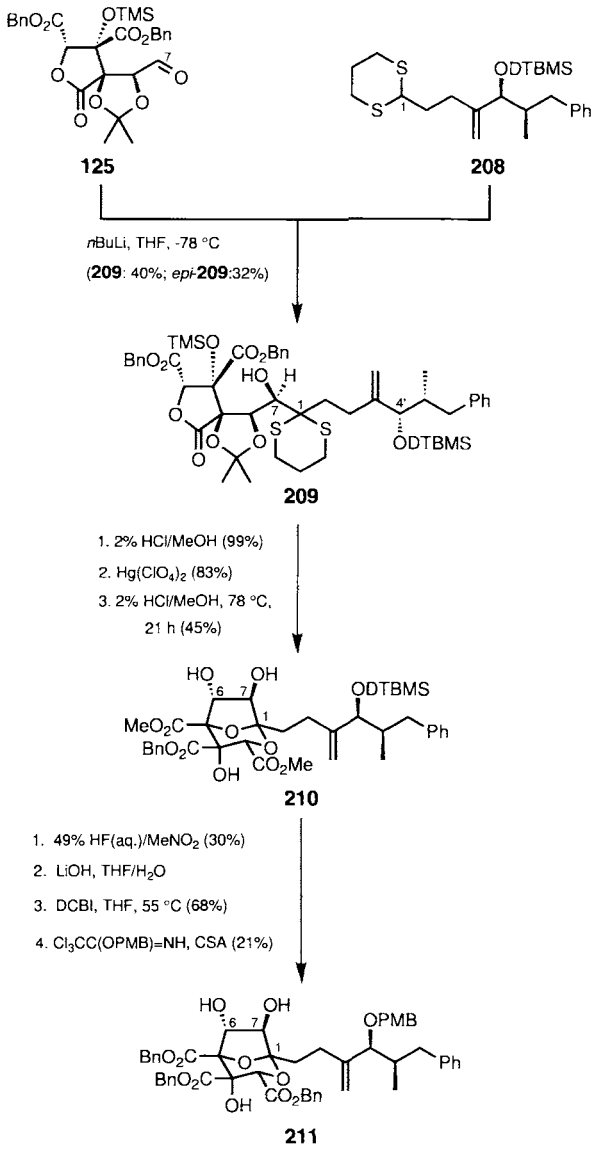


Scheme 43. Our synthesis of intermediate **211**.

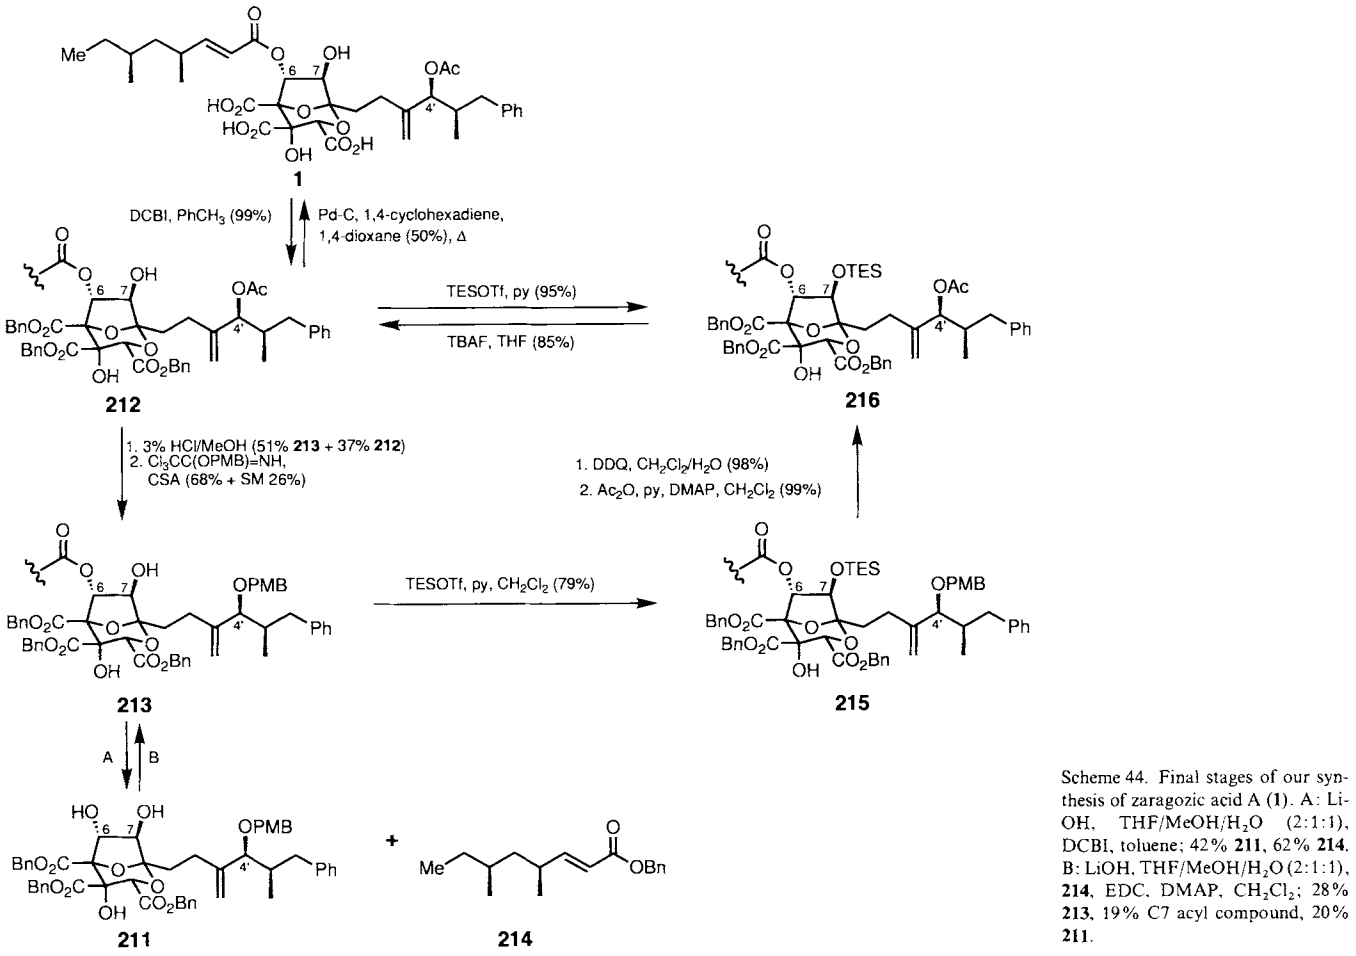
protecting group, exchange of the two methyl esters for benzyl esters, and selective protection of the C4′ hydroxyl group as a PMB ether gave the triol **211**, which had been established as an intermediate in earlier degradative studies. The exchange of the methyl esters for benzyl esters was necessary in order to avoid concomitant hydrolysis of the C6 acyl side chain at the end of the synthesis.

Intermediate **211** was converted to zaragozic acid A (**1**) as shown in Scheme 44.[93] Introduction of the C6 acyl side chain (with **214**) was achieved with only modest selectivity (3:2) to give the intermediate **213**. The undesired isomer could be separated by chromatography, hydrolyzed, and recycled. Protection of the C7 hydroxyl group as a TES ether (**215**), deprotection and acetylation of the C4′ hydroxyl group (**216**), and subsequent desilylation gave tribenzyl ester **212** in 77% overall yield. Finally the three benzyl groups were removed, without affecting either the exocyclic double bond or the α,β-unsaturated ester, by transfer hydrogenolysis to give zaragozic acid A (**1**). Furthermore, **211** can be prepared from zaragozic acid A (**1**) by the following route (Scheme 4): a) esterification with DCBI to give the tribenzyl ester **212**, b) selective hydrolysis of the acetate at C4′ under the conditions described by Merck, c) selective protection of the C4′ hydroxyl group with PMB trichloroacetimidate, and d) hydrolysis of the side chain to give (after replacement of some of the benzyl esters) the intermediate **211**.

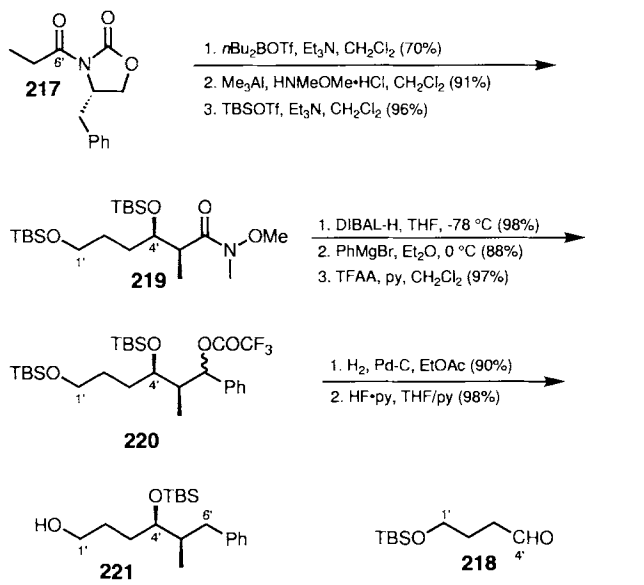
3.3. Synthesis of the C1 Alkyl Side Chains of Zaragozic Acids A and C

The comparatively simple C6 acyl and C1 alkyl side chains have received less attention than the bicyclic core. Nonetheless, efficient syntheses of both pieces are necessary for total syntheses and for the synthesis of analogs. A common feature of several syntheses of the enantiomerically pure side chains is the use of the Evans oxazolidinone as a chiral auxiliary. In contrast, asymmetric catalysis is used only twice. It should be noted that the exact composition of the C1 alkyl side chain varies slightly. Depending on the synthetic strategy, C1 is sometimes included in the side chain fragment and sometimes in the bicyclic core. The oxidation state of the C1 or C1′ terminal atom also varies with the synthetic plan.

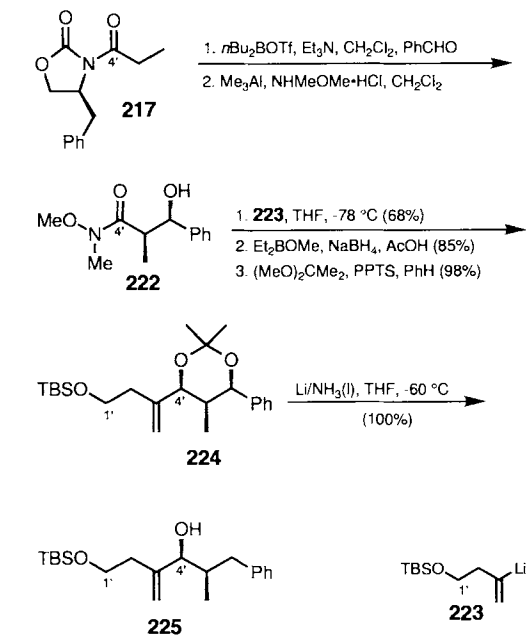
The synthesis of the C1 alkyl side chain of zaragozic acid C by Merck is described in Scheme 45.[94] Starting from *N*-propionyloxazolidinone **217**, an Evans aldol reaction with **218** followed by cleavage of the auxiliary by the Weinreb amide method[95]



Scheme 44. Final stages of our synthesis of zaragozic acid A (**1**). A: LiOH, THF/MeOH/H_2O (2:1:1), DCBI, toluene; 42% **211**, 62% **214**. B: LiOH, THF/MeOH/H_2O (2:1:1), **214**, EDC, DMAP, CH_2Cl_2; 28% **213**, 19% C7 acyl compound, 20% **211**.



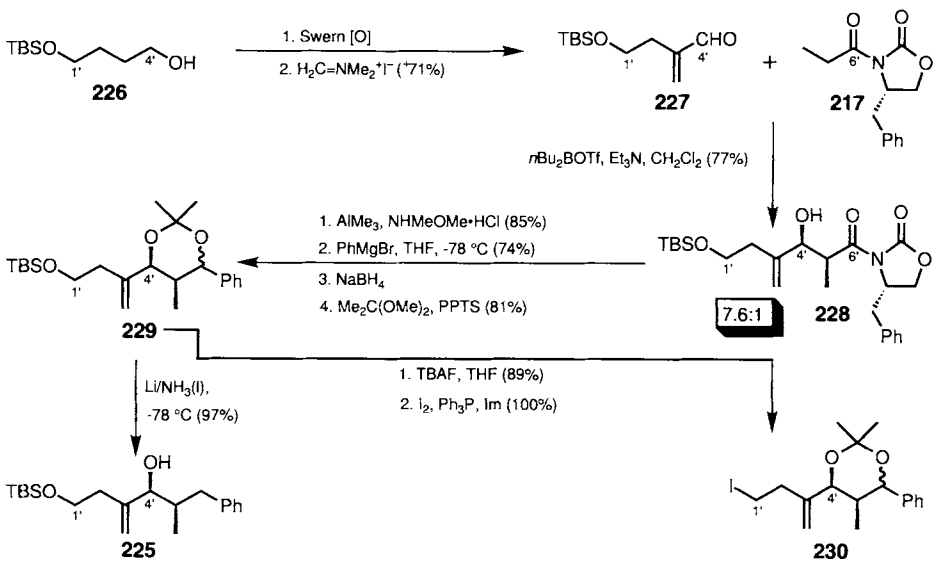
Scheme 45. Synthesis of the C1 alkyl side chain of zaragozic acid C (Merck).



Scheme 46. Synthesis of the C1 alkyl side chain of zaragozic acid A (Merck).

and protection of the resulting hydroxyl group gave the amide **219**. Reduction of the amide, addition of phenylmagnesium bromide, and treatment of the resulting alcohol with trifluoroacetic anhydride gave the trifluoroacetate **220**. Hydrogenolysis removed the benzylic oxygen substituent and selective deprotection with HF in pyridine gave the primary alcohol **221**.

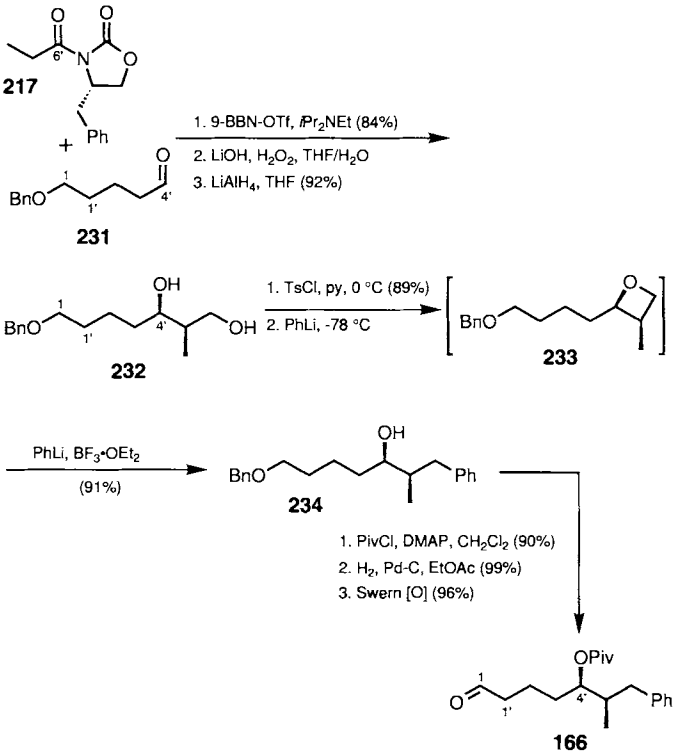
The synthesis of the C1 alkyl side chain of zaragozic acid A is described in Scheme 46.[94] The known Weinreb amide **222** was prepared from **217**. Addition of the vinyllithium derivative **223**, *syn*-selective reduction of the β-hydroxy ketone, and protection



Scheme 47. Synthesis of the C1 alkyl side chain of zaragozic acid C (Rizzacasa et al.).

of the 1,3-diol afforded the acetonide **224**. The benzylic hydroxyl substituent was then efficiently removed by treatment with Li/NH_3 to give the partially protected C1′,C4′ diol **225**.

The same fragment was synthesized independently in a similar fashion by Rizzacasa and co-workers (Scheme 47).[96] The alcohol **226** was oxidized and the resulting aldehyde was treated with Eschenmoser's salt, $H_2C_2{=}NMe_2^{+\ -}$, to yield the α,β-unsaturated aldehyde **227**. This was joined to the C5′/C6′ fragment **217** by an Evans aldol reaction to give the *syn* aldol product **228** as the major component in a 7.6:1 mixture of diastereoisomers.

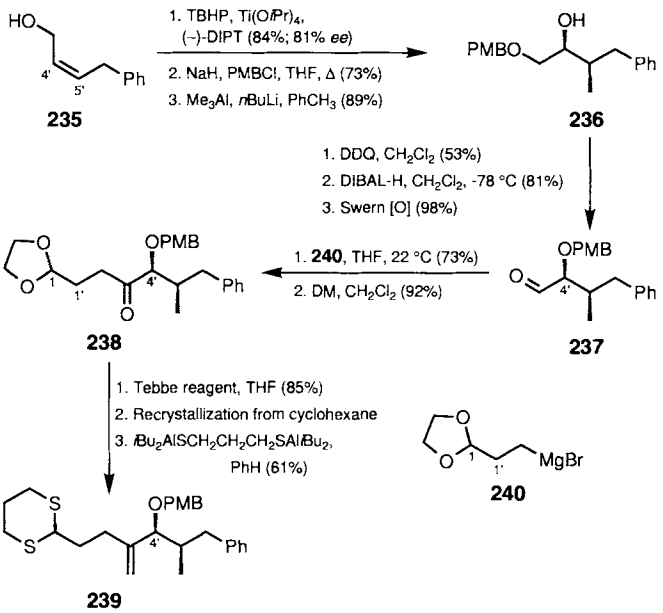


Scheme 48. Synthesis of the C1 alkyl side chain of zaragozic acid C (Carreira et al.). 9-BBN = 9-borabicyclononyl.

Curiously, the Merck group had earlier reported that this route to the alkyl side chain of zaragozic acid A was unsuccessful.[95] Four standard operations then gave the acetonide **229**, which could be converted into the desired iodide derivative **230** of the C1 alkyl side chain fragment or reduced with Li/NH_3 to provide the allylic alcohol **225**.

Carreira's synthesis of the C1 alkyl side chain of zaragozic acid C also relied on an Evans aldol reaction, this time to make the diol **232** (Scheme 48).[86] To introduce the phenyl group, the primary hydroxyl group in **232** was first tosylated selectively. Subsequent treatment with phenyllithium gave the oxetane intermediate **233**. Reaction with a further equivalent of phenyllithium and $BF_3{\cdot}OEt_2$ induced opening of the oxetane at C6′ to furnish intermediate **234**. Three standard manipulations gave the aldehyde **166**.

Our synthesis of the alkyl side chain of zaragozic acid A began with allylic alcohol **235** (Scheme 49).[93] Sharpless asymmetric epoxidation[97] gave the corresponding epoxide (81% *ee*,

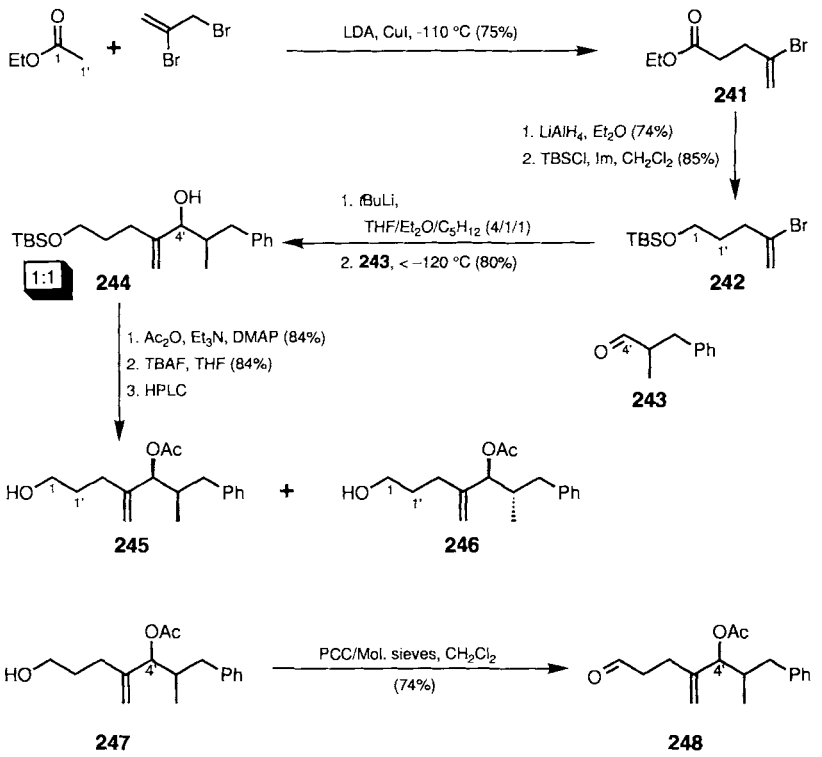


Scheme 49. Our synthesis of the C1 alkyl side chain of zaragozic acid A.

84% yield), which was protected as a PMB ether and opened regioselectively at C5′ with trimethylaluminum to give the alcohol **236** as a single regioisomer. The PMB protecting group was shifted from the primary to the secondary hydroxyl group by oxidation in the absence of water to yield the PMB acetal and then reductive cleavage with DIBAL-H. Swern oxidation then gave aldehyde **237**. Homologation was achieved by addition of the Grignard reagent **240** and oxidation to give the

ketone **238**. Three standard manipulations, including a recrystallization to improve the enantiomeric purity, gave the dithiane **239**.

The shortest synthesis of the alkyl side chain of zaragozic acid A was reported by Shaw and co-workers at Glaxo (Scheme 50).[84] The vinyl bromide **241** was obtained by alkylation of ethyl acetate with 2,3-dibromopropene. Reduction of the ester to the alcohol and silylation gave **242**. Halogen–metal exchange at $-120\,^{\circ}C$ and addition of racemic aldehyde **243** gave **244** as a 1:1 mixture of racemic diastereoisomers. Acetylation and desilylation afforded primary alcohols **245** and **246**, which were separable by preparative HPLC on a cyclodextrin column. Oxidation of the mixture (**245** + **246** ≙ **247**) provided the aldehyde **248**, which was used in the synthesis of monocyclic analogs of zaragozic acid A.



Scheme 50. Synthesis of the C1 alkyl side chain of zaragozic acid A (Glaxo). LDA = lithium diisopropylamide.

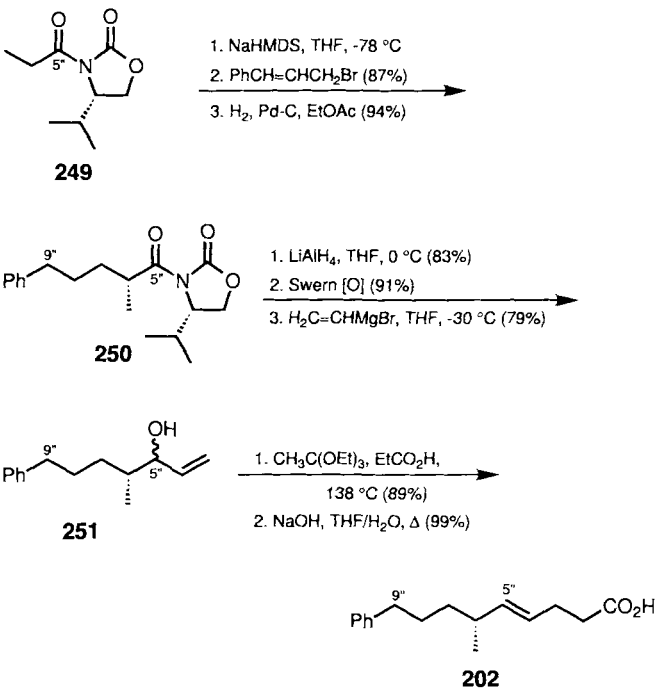
diastereoisomers. Heating **251** with triethylorthoacetate in the presence of a catalytic amount of acid effected [3,3]sigmatropic rearrangement to give, after saponification, the carboxylic acid **202**.

The synthesis by Carreira et al. (Scheme 52) generates the same allylic alcohol **251** but by a different sequence.[86] Starting with 5-phenylpentyne (**252**), alkylation with formaldehyde and reduction of the resulting propargylic alcohol gave the allylic alcohol **253**. Sharpless asymmetric epoxidation then provided the epoxide **254** in 98% yield (>95% *ee*). The epoxide was then regioselectively opened at C6″ and the resulting diol was cleaved to afford the aldehyde. Addition of vinylmagnesium bromide then gave allylic alcohol **251**, which was converted to the acid chloride **183**.

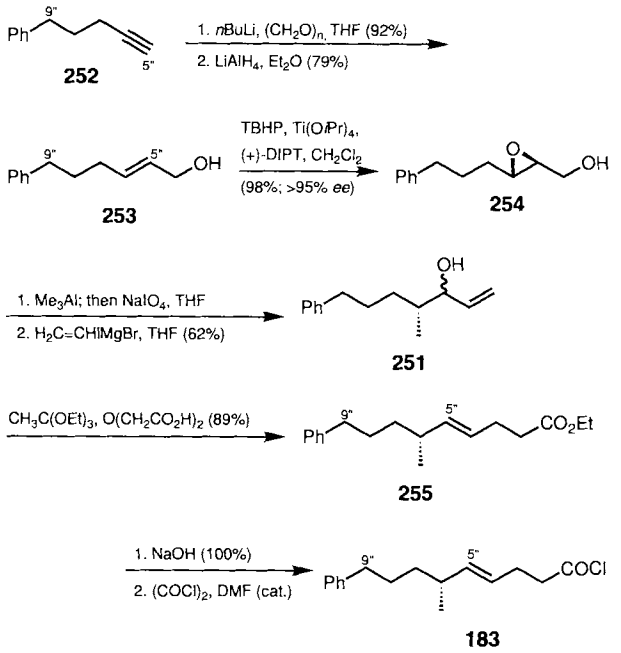
The only synthesis of the acyl side chain of zaragozic acid A was conducted by our group (Scheme 53).[93] Owing to the ready availability of zaragozic acid A, supplies of the side chain have been easily obtained by degradation of the natural product. The synthesis, however, is remarkably short and can provide substantial amounts of the side chain **260**. Starting with enantiomerically pure hydrazone **256**,[100] made from propionaldehyde, alkylation with commercially available and optically pure iodide **257** gave **258** (92% *de*). Ozonolysis yielded the aldehyde **259**, which was homologated by a Wittig reaction. Hydrolysis of the ester furnished carboxylic acid **260** in 27% overall yield from **256**.

3.4. Synthesis of the C6 Acyl Side Chains of Zaragozic Acids A and C

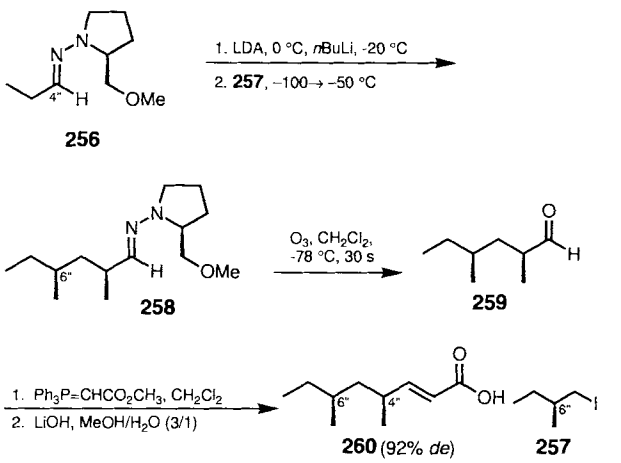
The two syntheses of the acyl side chain of zaragozic acid C[86,98] both employ a Johnson–Claisen orthoester rearrangement[99] as the key step. This transformation can be particularly effective at generating a remote chiral center adjacent to a *trans* double bond. The synthesis of the zaragozic acid C side chain by Merck[98] (Scheme 51) provided the first proof of the absolute configuration of zaragozic acid C. Intermediate **250** was synthesized by alkylation of **249** with cinnamyl bromide, followed by hydrogenation. Three standard functional group interconversions gave allylic alcohol **251** as a mixture of



Scheme 51. Synthesis of the C6 acyl side chain of zaragozic acid C (Merck).



Scheme 52. Synthesis of the C6 acyl side chain of zaragozic acid C (Carreira et al.).

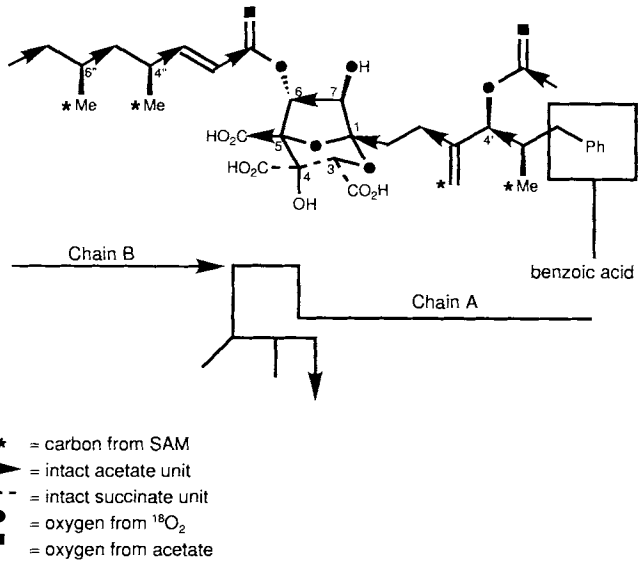


Scheme 53. Our synthesis of the C6 acyl side chain of zaragozic acid A.

3.5. Biosynthesis of the Zaragozic Acids

The biosynthetic origin of zaragozic acid A has been established independently by Merck and Glaxo.[101, 102] The results of standard feeding experiments with isotopically labeled substrates led to the following conclusions regarding the biosynthesis of zaragozic acid A (Scheme 54):

1. Zaragozic acid A is biosynthesized from two polyketide chains (labeled A and B), which comprise the C1 alkyl side chain and the core, and the C6 acyl side chain, respectively.
2. The biosynthesis of the A chain begins with an aromatic nucleus (derived from phenylalanine via benzoic acid). Five intact acetate units are then added in a standard fashion. The final four atoms (C3, C4, C8, and C9) arise from incorporation of an intact succinate unit. However, it was not possible to rule out the possibility that all three carboxyl groups originate from an intact citrate unit.



Scheme 54. Biosynthesis of zaragozic acid A (1). SAM = *S*-adenosylmethionine.

3. The C4′ acetyl group stems from an acetate unit.
4. The two one-carbon substituents on the C1 alkyl side chain (C5′-Me and C3′-CH_2) come from *S*-adenosylmethionine (SAM).
5. The B chain is made by successive linkages of four acetate units. The C4″-Me and C6″-Me substituents arise from SAM.
6. The two oxygens attached to C1 and those at C6, C7, and C4′ stem from atmospheric oxygen.
7. The oxygens of the carbonyls of the C4′-acetate and the C6-acyl groups come from acetate.

The elucidation of the biosynthetic origins of the zaragozic acids was not only of academic interest but also necessary in order to design and predict the outcome of feeding experiments aimed at generating analogs biosynthetically.[103–106] A number of minor secondary metabolites, which appear to be precursors of the A chain, have recently been isolated from the fermentation broth of ATCC 20986.[107]

4. Medicinal Chemistry (Structure–Activity Relationships)

A large body of information on structure–activity relationships has been collected by the testing of analogs obtained from the natural product, biosynthetic feeding, biotransformation, and total synthesis. The medicinal chemistry[108–126] has been the subject of an excellent and thorough review by Procopiou and Watson,[41] so we will only outline the main findings here. Figure 2 shows the structure of zaragozic acid A with comments on the importance of various parts of the structure in the assay with rat microsomal squalene synthase. It should be emphasized that many changes are not completely independent. For example, the nature of the C6 acyl side chain influences the effect of many substitutions elsewhere in the molecule. This could result from zaragozic acid A binding either as a PSPP mimic or an FPP mimic (see Section 2.3).

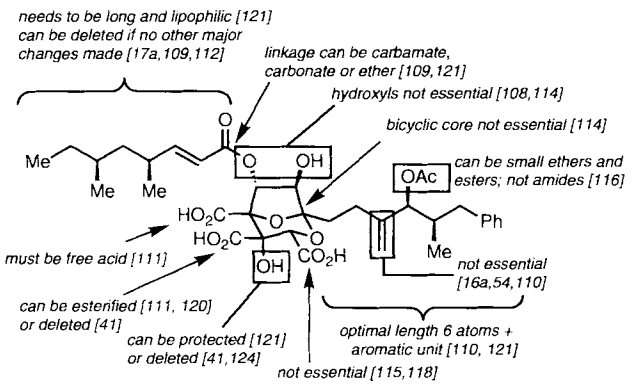


Fig. 2. Important structure–activity relationships of zaragozic acid A and the corresponding references.

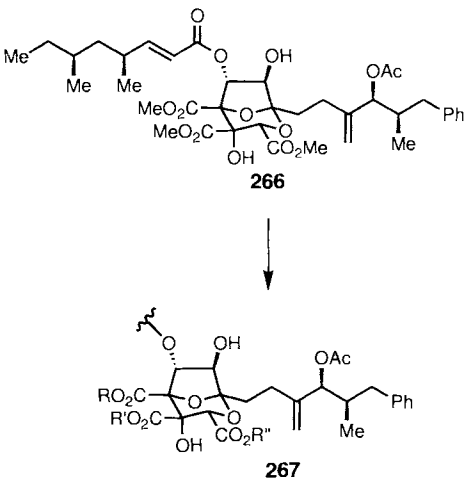
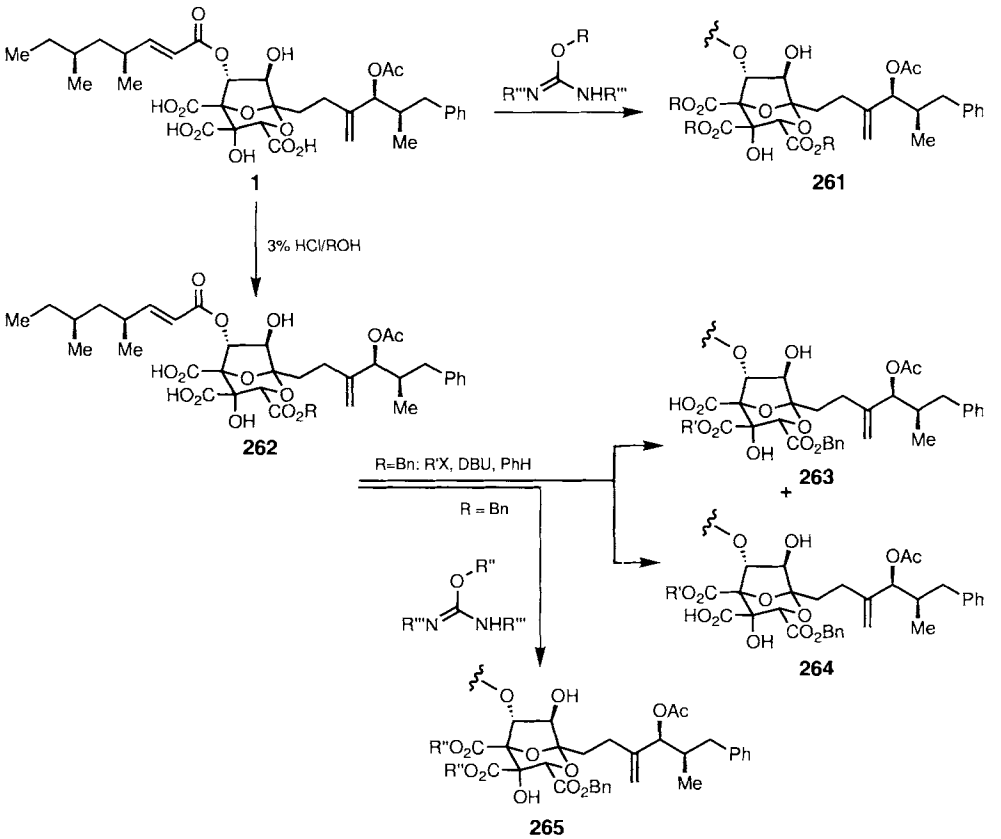


Scheme 56. Selective manipulations of the carboxyl groups of zaragozic acid A (Glaxo).

4.1. Important Manipulations with Zaragozic Acid A

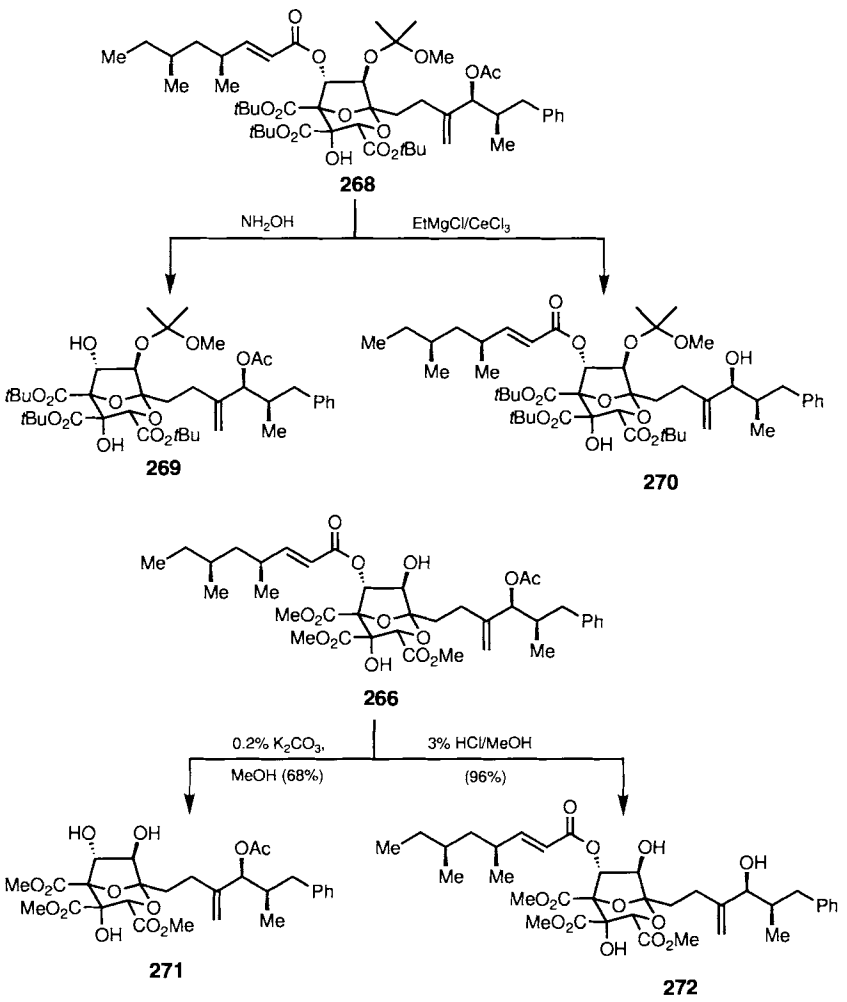
In order to generate analogs efficiently from the natural product, two selective manipulations were required. Firstly, the three carboxyl groups had to be differentially protected, and secondly, methods were needed for the selective manipulation of the C4′-acetyl and C6-ester.

All three carboxyl groups of zaragozic acid A (**1**) can be esterified with a variety of isoureas (e.g. **1** → **261**, Scheme 55)[23, 120] or with *N*,*N*′-dimethylformamide-di-*tert*-butyl acetal.[108] The former method of esterification, originally developed by Mathias,[80] is particularly mild and convenient, particularly for *tert*-butyl esters, and has been used in all of the total syntheses of the zaragozic acids. The C3 carboxyl group can be selectively esterified under Fischer conditions with a variety of alcohols (**1** → **262**, Scheme 55).[111, 120] The benzyl ester derivative was monoesterified further (but only with moderate selectivity) to give a mixture of the C5 monocarboxylic acid **263** and the C4 monocarboxylic acid **264**. Both the C3 and C4 carboxyl groups can be esterified with the isourea method to yield **265**.[120] The benzyl ester function(s) were removed by transfer hydrogenation, and the *tert*-butyl esters with trifluoroacetic acid.[120] By choosing different ester protecting groups, all possible combinations of ester and carboxyl groups are accessible. Alternatively, the trimethyl ester **266** can be selectively deprotected at the C5 carboxyl with LiI/collidine or at the C3 position with one equivalent of sodium hydroxide (Scheme 56).[111]



Scheme 55. Selective manipulation of the carboxyl groups of zaragozic acid A (Merck). DBU = 1,5-diazabicyclo[5.4.0]-undec-5-ene. R = R′ = Bn, Me, $Me_3SiCH_2CH_2$, $Me_2CHCH_2CH_2$; R″ = *t*Bu, Me.

The selective cleavage of the α,β-unsaturated C6 acyl side chain can be achieved by treatment with either hydroxylamine[108, 119] or with 0.2% potassium carbonate in methanol[23] (**268** → **269**, **266** → **271**, Scheme 57). The latter reagent causes transesterification of the C3 carboxyl group and therefore is probably not suitable for esters other than *tert*-butyl or methyl. Cleavage of the C4′ acetyl group can be achieved either with EtMgCl/$CeCl_3$[119] or with 3% HCl in MeOH[23] (**268** → **270**, **266** → **272**, Scheme 57).



Scheme 57. Selective cleavage of the C4 acetyl and the C6 acyl groups of zaragozic acid A.

4.2. Cleavage of the Bicyclic Core of Zaragozic Acid A

To assess the importance of the bicyclic core for biological activity, and also out of scientific interest, Merck and Glaxo have investigated reactions that break up the bicyclic ketal. It is notable that molecular mechanics calculations and experiments by Evans et al.[90] and others have suggested that the core may be kinetically extremely stable under the conditions used for its formation, but thermodynamically less stable than other alternative structures. Schemes 58–60 show some of the transformations possible once the bicyclic core is opened,[108, 113, 127–128] and provide a challenging set of examples for a problems class in elementary organic chemistry.

5. Summary and Outlook

Of the hundreds of new natural products that are isolated every year, very few cause any excitement. Interest occasionally increases when a natural product is found that contains a functionality or set of functionalities not normally associated with natural products chemistry. Examples from recent years include the brevetoxins,[129] the enediynes,[130] and the manzamines.[131] The excitement is heightened further if these novel structures are accompanied by profound biological activity. The zaragozic acids, with their unprecedented heavily oxygenated core structure and picomolar-level inhibition of squalene synthase, fulfill both conditions. Consequently, in just three years and in around 100 publications,[132] the chemistry, biology, and medicinal potential of the zaragozic acids has been substantially elucidated. The next adventure in natural products chemistry cannot be far away.

A list of frequently used abbreviations:

Bz	benzoyl
CSA	10-camphorsulfonic acid
dba	*trans,trans*-dibenzylidene-acetone
DCBI	*N,N'*-dicyclohexyl-*O*-benzyl-isourea
DET	diethyl tartrate
DHP	3,4-dihydro-2*H*-pyran
DIPT	diisopropyl tartrate
DITBI	*N,N'*-diisopropyl-*O*-*tert*-butylisourea
DM	Dess–Martin periodinane
DTBMS	di-*tert*-butyl-methylsilyl
EDC(I)	1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride
HMPA	hexamethylphosphoric triamide
NaHMDS	sodium bis(trimethylsilyl)-amide
NMO	4-methylmorpholine *N*-oxide
Piv	pivaloyl
PMB	4-methoxybenzyl
py	pyridine
SEM	2-(trimethylsilyl)ethoxymethyl
TBAF	tetra-*n*-butylammonium fluoride
TBHP	*tert*-butyl hydroperoxide
TBS	*tert*-butylmethylsilyl
TES	triethylsilyl
Tf	trifluoromethanesulfonate
TPAP	tetra-*n*-propylammonium perruthenate
TPS	*tert*-butyldiphenylsilyl

We wish to thank our collaborators S. La Greca, J. E. Leresche, Z. Yang, and E. W. Yue for useful discussions; Dr. Alan Armstrong (Bristol, UK) and Dr. Panayiotis Procopiou and Dr. Nigel Watson (Glaxo, UK) for preprints of their work; and John Trujillo (Scripps) for the color pictures. We thank the NIH, Merck, Sharp & Dohme, Schering Plough, Pfizer, Hoffman La Roche, Glaxo, Rhône-Poulenc Rorer, and the ALSAM Foundation for financial support.

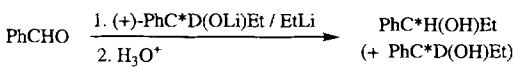
Asymmetric Autocatalysis with Amplification of Chirality**

Carsten Bolm,* Frank Bienewald, and Andreas Seger

Asymmetric metal catalysis has been intensively studied in recent years, and some efficient catalytic methods for the synthesis of enantiomerically pure compounds have been developed.[1] With suitable metal/ligand combinations excellent enantioselectivities and high conversion rates have frequently been achieved. Normally the catalyst must remain unaffected by the continually formed new product in order to achieve a constant, high stereoselectivity. How does it behave, however, when the product itself is a catalyst and, moreover, catalyzes its own asymmetric synthesis? Wynberg recognized very early the great potential of such "asymmetric autocatalysis" for synthesis and as early as 1989 had formulated the challenge that asymmetric autocatalysis could constitute the next generation of asymmetric synthesis.[2] In spite of great efforts the discovery of the first autocatalytic system operating with high enantioselectivity has only recently been made.[3] Two important contributions from Soai et al.[3,4] take pride of place here, but before introducing them we will describe some other fundamental studies.

Seebach, Dunitz et al. first drew attention to the fact that in stereoselective reactions with organometallic reagents differing diastereo- and enantioselectivities could arise because of the formation of various mixed complexes during the course of product formation.[5,6] This led Alberts and Wynberg to investigate the asymmetric additions of organometallic carbon nucleophiles (e.g. ethyllithium) to benzaldehyde (Scheme 1), and they showed that the stereochemical course of both stoichiometric and catalyzed reactions were influenced by metal-containing product molecules (here lithium alcoholates).[7] The product itself is not a catalyst but nevertheless ensures that the newly formed product is optically active. Alberts and Wynberg coined the term "enantioselective autoinduction" for this effect.



Scheme 1. Asymmetric addition of ethyllithium to benzaldehyde [7]. Chirality centers are identified by a star.

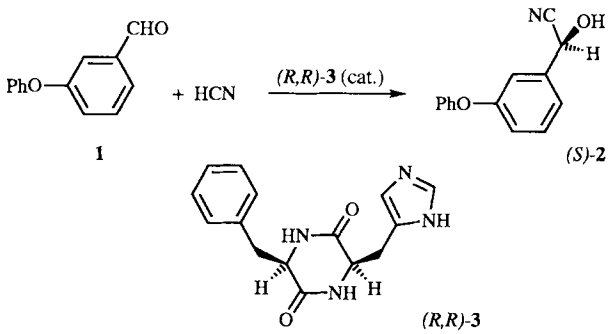
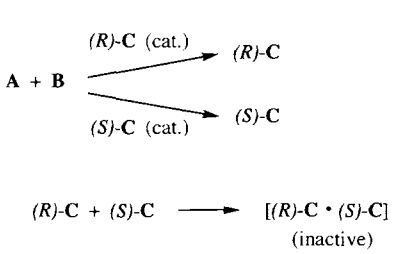
Danda et al. established that the product powerfully influenced the catalyst in the *metal-free* catalyzed asymmetric hydrocyanation of 3-phenoxybenzaldehyde **1** to (*S*)-**2** by the cyclic dipeptide (*R,R*)-**3**.[8] In the presence of the product the reaction-accelerating effect of the cyclic dipeptide was enhanced. (*R,R*)-**3** alone showed little catalytic activity at first, and with increasing reaction time the enantiomeric excess of (*S*)-**2** increased. If a small amount of (*S*)-**2** was added to the reaction mixture at the start the product was formed with an almost constant, high *ee* value. Here (*S*)-**2** itself is *not* a catalyst and only the interaction between the correct product enantiomer and the cyclic dipeptide leads to better catalysis. In addition asymmetric amplification occurred only in the presence of the product.[9] Thus, 2.2 mol% (*R,R*)-**3** with 2% *ee* at 43% conversion yields the cyanohydrin (*S*)-**2** with 81.6% *ee* when 8.8 mol% (*S*)-**2** with 92% *ee* is added at the start of the reaction. If (*S*)-**2** is not added at the start, the conversion and enantiomeric excess are 4% and 3.4%, respectively. It is also interesting that in this asymmetric amplification the absolute configuration of the product is not determined by the configuration of the catalyst but by that of the added cyanohydrin.



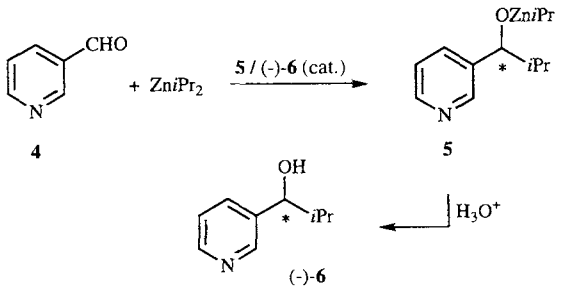
In the examples quoted the product influences stereoselectivity or has a positive effect on an existing catalysis.[10] Things become especially interesting, however, when the chiral product itself is a catalyst for its own formation from achiral precursors. This area of asymmetric autocatalysis was hardly developed for a long time, though in 1953 Frank had already formulated a mathematical model that indicated that "spontaneous asymmetric synthesis", as he called the process, is quite possible.[11] As a natural property of life this could be of fundamental importance in the genesis of asymmetry in nature.[12-14] In the scenar-

io described by Frank two achiral substances, **A** and **B**, react to form optically active products (*R*)-**C** and (*S*)-**C**, each of which can catalyze its own synthesis (Scheme 2a). This corresponds to the working of conventional autocatalysis. If one imagines that the two enantiomeric catalysts mutually reduce (or destroy) their effects (Scheme 2b), the system would show flip-flop

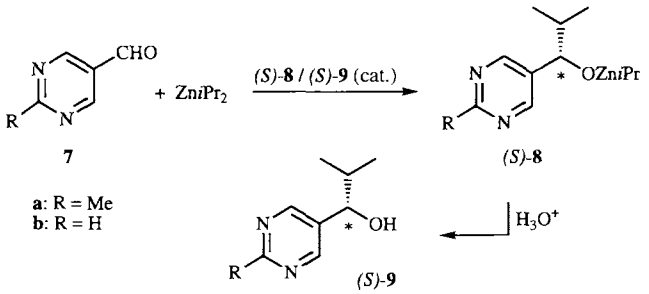


Scheme 2. a) Model for "spontaneous asymmetric synthesis" according to Frank [11]. b) Deactivation of the catalytically active chiral product.

switching properties: even a small statistical fluctuation (for example, if the reaction catalyzed by (*R*)-**C** were preferred for a short time) would have the effect of reducing the catalytic activity of (*S*)-**C** and new (*R*)-**C** would be formed ever more quickly. In such an "aggressive" system a trace of a chiral substance would be enough to ensure its own production in large quantities by autocatalysis. The inductor does not even need to be enantiomerically pure since the model implies the principle of asymmetric amplification. In his article Frank pleaded for the development and testing of simple autocatalytic systems.[11] The first successful reactions with a "chiral autocatalyst" were reported by Soai et al. in 1990.[15] They found that the pyridinyl alcohol **6** catalyzed its own formation from pyridine-3-carbaldehyde (**4**) and diisopropylzinc via the isopropylzinc alcoholate **5**. With 20 mol% (−)-**6** (86% *ee*), workup afforded (−)-**6** in 67% yield with an *ee* of 35%.



Similarly, in other enantioselective additions of organozinc compounds asymmetric autocatalyses were also demonstrated,[16] though they always gave a product with a much lower *ee* value than that of the catalyst used. Only at the end of 1995 was an important breakthrough achieved[3, 4] when Soai et al. showed that the presence of 20 mol% of the pyrimidyl alcohol (*S*)-**9a** (94.8% *ee*) in the reaction between the corresponding aldehyde **7a** and diisopropylzinc led to the formation of (*S*)-**9a** in 48% yield with an *ee* of 95.7%. The product underwent automultiplication *without* a significant change in the enantiomeric excess.



As if this were not enough, Soai et al.[4] also used this system to demonstrate for the first time the asymmetric amplification during autocatalysis that is inherent in the Frank model. Thus, 20 mol% of (*S*)-**9b** with an *ee* of only 2% gave, with autocatalysis, (*S*)-**9b** with an *ee* of 10%. In further reaction cycles the enantiomeric excess rose from 10 through 57 to 81 and finally to 88% (Fig. 1). There was a 942-fold increase in the amount of product after four cycles. The asymmetric amplification shown by this simple self-replicating system behaved, in fact, as predicted by the simple, theoretical Frank model.

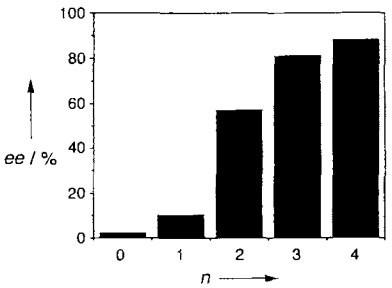


Fig. 1. Increase in the enantiomeric excess of (*S*)-**9b** with the number of reaction cycles *n*.

As the mechanism of the reaction and possible intermediates in solution are still unknown, the phenomenon described here cannot yet be used for the targeted development of further reactions. It is, nevertheless, clear that complex formation with the organometallic reagents is essential to autocatalysis with asymmetric amplification. For this reason a deeper understanding of the behavior of chiral compounds during the formation of complexes would be very useful for the design and discovery of new autocatalytic processes.

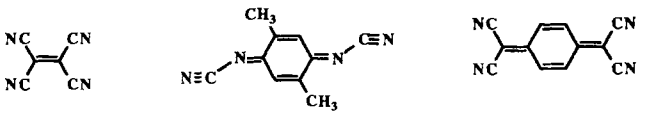
Organocyanide Acceptor Molecules as Novel Ligands

Kim R. Dunbar*

Pioneering research carried out at Dupont in the 1950s and 1960s established a wealth of interesting chemistry for conjugated organic molecules with cyanide functionalities.[1] Forty years later, research involving organocyanide molecules continues to flourish, owing to their promise as precursors for molecule-based materials. Among the organocyanide materials demonstrated to exhibit unusual properties is a class of ionic materials that consists of paramagnetic transition metal metallocene cations and radical anions of tetracyanoethylene (TCNE, Scheme 1a).[2] The compounds $[M(Cp)_2^*][TCNE]$ (M = Mn, Fe) crystallize in columns of donors and acceptors,



TCNE **DM-DCNQI** **TCNQ**

Scheme 1. Important organocyanide acceptor molecules.

$D^+A^-D^+A^-$, ($D^+ = [M(Cp^*)_2]^+$; $A^- = TCNE^-$) and are remarkable in that they order ferromagnetically at Curie temperatures T_c of 4.8 K (Fe) and 8.8 K (Mn). These results are quite surprising in the context of classical magnets, considering that the materials are not three-dimensional and that the properties are based on spins of organic molecules.

Solids containing transition metals cations σ-bonded to the nitrile groups of polycyano anions are an entirely different category of organocyanide materials than the ionic, stacked systems.[3] A primary motivation for coassembling metal centers and organic radicals in this manner is to achieve new pathways for electronic coupling through $p_\pi - d_\pi$ overlap in addition to the usual p_π overlap of the organic acceptors. With the proper energy match of metal and organic orbitals it may be possible to achieve an interplay between superexchange and charge-transport pathways, perhaps leading to a synergistic state wherein superconductivity and ferromagnetism coexist. At the very least it appears that this strategy holds promise for the design of highly conducting organometallic polymers, as evidenced by the work of Hünig and co-workers, who synthesized a new family of organic acceptors known as dicyanoquinodiimines (DCNQIs, Scheme 1). These DCNQIs form crystalline network solids with copper that exhibit extraordinarily high conductivities that persist to the lowest temperatures.[4] The structures of $[Cu(2,5\text{-}Me_2\text{-}DCNQI)]_2$ (Fig. 1, 2,5-Me_2-DCNQI = DM-DCNQI)

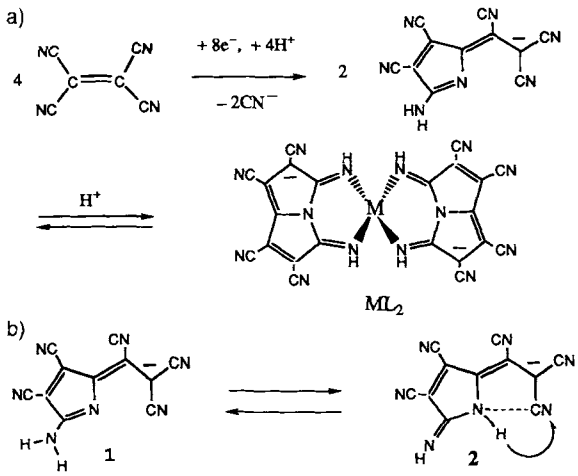
consist of an infinite array of tetrahedrally ligated Cu cores bridged by four independent DCNQI ligands, which stack in 1-D columns. The unusual charge-transport properties of these compounds are attributed to the existence of an isotropic 3-D conduction pathway from Robin–Day class III, mixed-valent behavior for the $Cu^{I/II}$ ions bridged by DCNQI in addition to the usual 1-D pathway through stacks of DCNQI radicals.[4b]

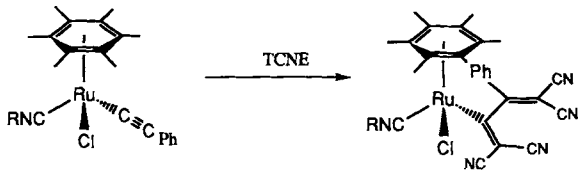
In addition to the DCNQI conductors, the most remarkable discovery in the context of polycyano radical chemistry in recent years is that a coordination compound of TCNE formulated as $[V(TCNE)_x]\cdot yCH_2Cl_2$ behaves as a bulk ferromagnet with a T_c above room temperature.[5] Unfortunately, no structural information is available for this fascinating binary TCNE compound. In fact, although they date back several decades,[6] the only structurally characterized example of a *binary* metal/TCNX (X = E or Q) compound is $[Ag(\mu_4\text{-TCNQ})]_n$ (TCNQ = tetracyanoquinodimethane).[7] In the absence of structural information on the simple phases, which are insoluble and therefore quite difficult to crystallize, researchers have turned to mixed-ligand model compounds, whose structures are more easily determined.[3b, 8, 9] In this way, researchers are building the fundamental structure–property relationships that are essential, not only for the full understanding of the physics behind the properties, but for the rational design of new materials with predictable behavior. Among the crystallographically determined TCNE and TCNQ coordination compounds that have been reported in the past few years are novel 1-D and 3-D polymeric structures incorporating μ_2-TCNX and μ_4-TCNX.[8, 9]

In addition to the well-known acceptors depicted in Scheme 1, a number of more exotic organocyanide molecules are also being used as novel ligands for transition metals. Several of these are decomposition products unearthed in the course of investigating the complexation chemistry of TCNE: for example, the unprecedented reductive coupling of TCNE molecules on a metal center to give two pyrrolizinato ligands (L = $[C_{11}N_7H_2]^-$) (Scheme 2a).[10a] The resulting $[ML_2]$ compounds (M = Fe, Ni, Cu, Zn) are of considerable interest in materials applications owing to their similarities to the metal phthalocyanines. The free ligand (LH) was also prepared and crystallized,[10b] as was the free anion, which exists in two tautomeric forms **1** and **2** (Scheme 2b).[10c]



Scheme 2. a) Reductive coupling of TCNE molecules on a metal center to give two pyrrolizinato ligands (L = $[C_{11}N_7H_2]^-$). b) Tautomeric forms **1** and **2** of the free anion $[C_{11}N_7H_2]^-$.

In another report, the new organocyanide $\{C[=C(CN)_2]\text{-}CPh=C(CN)_2\}$ was synthesized from an insertion reaction of TCNE into the acetylide group in $[Ru(\eta^6\text{-}C_6Me_6)\text{-}Cl(C\equiv CPh)(CNR)]$ (Scheme 3).[11] The ligand is bound only through Ru–C bonds, but there are four uncomplexed nitrile groups that are open for possible coordination to other metal centers.



Scheme 3. Insertion of TCNE into the acetylide group in $[Ru(\eta^6\text{-}C_6Me_6)\text{-}Cl(C\equiv CPh)(CNR)]$.

The cyanocarbon ligand $[C_{10}N_7]^-$ (1,1,2,4,5,5-hexacyano-3-azapenta-1,4-dienide) and its 1:1 complex with Ag^I were first reported in 1958[1] but were only recently subjected to X-ray studies by Pala et al., who determined the structures of $[Et_4N][C_{10}N_7]$ and the intriguing coordination polymer $[\{Ag(C_{10}N_7)\}_n]$.[12] In the latter compound, $[C_{10}N_7]^-$ behaves as a tetradentate bridging ligand to two distinctly different types of silver ions, namely with tetrahedral and with a highly unusual square-planar geometry. Figure 2 depicts a single plane in which

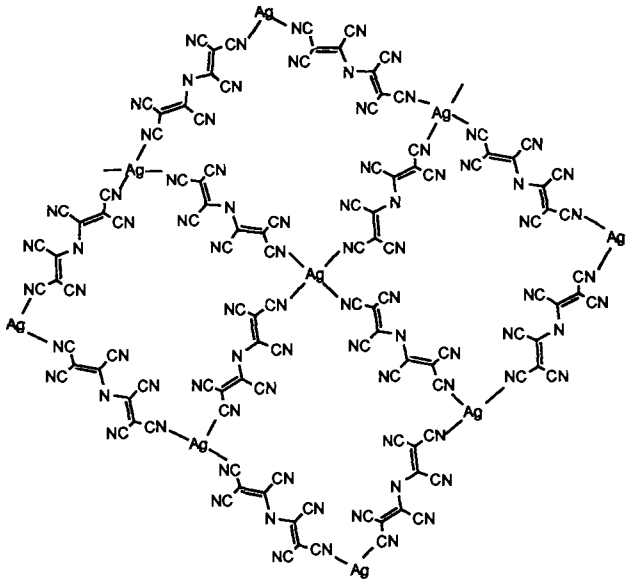


Fig. 2. Schematic representation of polymeric $[\{Ag(C_{10}N_7)\}_n]$ in the (001) plane emphasizing the square-planar Ag sites.

the $[C_{10}N_7]^-$ ions are bonded to square-planar Ag^I ions, which stack along the (001) direction at a distance of 3.15 Å and are linked by the tetrahedral Ag^I ions located between the layers. A comparison of the anion unit in $[Et_4N][C_{10}N_7]$ and $[\{Ag(C_{10}N_7)\}_n]$ reveals that coordination to a metal center does not significantly alter the geometry of the ligand. Electrochemical studies indicate that $[C_{10}N_7]^-$ exhibits two reversible, one-electron reduction processes, the first of which corresponds to the radical species $[C_{10}N_7]^{2-}$, as verified by EPR spectroscopy.

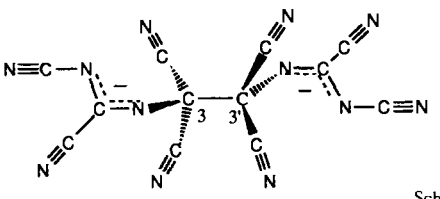
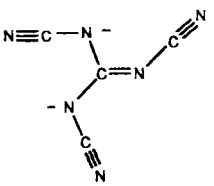
A recent attempt to prepare $[Mn^{IV}(CN)_6]^{2-}$ from $[Mn^{III}(CN)_6]^{3-}$ led Miller and co-workers to the serendipitous discovery of the novel cyanocarbon {(1,1,2,2-tetracyano-1,2-ethanediyl)bis[imino(cyanomethylene)]}bis[cyanamide] ion $[C_{12}N_{12}]^{2-}$, which was characterized by a single crystal X-ray study.[13] The dianion is centrosymmetric about the central C–C bond and is planar except for the C3 and C3′ cyano groups (Scheme 4). The authors reason that the oxidative decomposition of $[Mn^{III}(CN)_6]^{3-}$ leads to CN^- and $CN^{\bullet}$, which react in a complicated series of reactions that most likely involve cyanogen $(CN)_2$. Cyanide is known to dimerize to cyanogen, which reacts with CN^- to form several products, among them the anion $[C_7N_7]^-$, which can undergo electropolymerization reactions with cyanogen to yield low molecular weight polycyanogen $[C_nN_n]$. Clearly there are many possibilities for the preparation of new cyanocarbons from reactions of cyanogen and CN^- that lead to various combinations of C–C, C–N, and N–N bonds.



$[C_{12}N_{12}]^{2-}$

Scheme 4. The new cyanocarbon $[C_{12}N_{12}]^{2-}$.

The aforementioned results hint at a wealth of untapped potential for the use of organocyanides as ligands in new complexes and materials. Noncentrosymmetric molecules are of particular interest owing to their potential for exhibiting extensive second-order nonlinear optical effects, as was recently found for the tricyanoguanylidine dianion synthesized by Rasmussen and coworkers (Scheme 5).



$[C_4N_6]^{2-}$

Crystallization of Supramolecular Materials: Perhydrotriphenylene (PHTP) Inclusion Compounds with Nonlinear Optical Properties**

Ralf Hoss, Olaf König, Vera Kramer-Hoss, Urs Berger, Peter Rogin, and Jürg Hulliger*

A prerequisite for the design and synthesis of materials with nonlinear optical (NLO) properties is a molecular building block that can be incorporated into a solid in an appropriately functionalized and oriented manner. To obtain new, single-crystal materials that exhibit electrooptical (EO) effects more pronounced than those of the currently known organic NLO crystals,[1-4] stable molecules showing hyperpolarizabilities β_z of up to 10000×10^{-40} $m^4 V^{-1}$ and having dipole moments that can be aligned in a parallel manner within the solid are required. While a large number of target compounds can be envisioned based on these known criteria,[3, 5] the probability is low that during the crystallization of pure NLO compounds a crystal structure with a parallel arrangement of the β_z axes is realized (about 25% for an acentric space group, less than 5% for a nearly parallel packing[1, 3]). Hence, the question of alternatives for the formation of crystalline and structurally optimized EO materials arises. In this study it is shown that perhydrophenylene (PHTP)[6] forms inclusion compounds with electronically optimized NLO species, in which the guest molecules can attain a parallel arrangement; materials with polar properties on a macroscopic level are formed about 90% of the time.

Approaches to incorporating NLO molecules in a parallel fashion into supramolecular host–guest systems have been tried more than ten years ago.[7] Starting with β-cyclodextrin,[8] a number of known clathrate-forming compounds[9, 10] such as urea and thiourea, tri-*o*-thymotide, cyclophosphazene, deoxycholic acid, and PHTP[6] were examined with respect to the formation of inclusion compounds with small organic as well as organometallic species. These host and guest molecules provided a high proportion of polar structures for the inclusion compounds (63–85%) as well.[11] Zeolites have been loaded with NLO compounds with the same goal in mind.[12, 13] The successful incorporation of two strongly hyperpolarizable species (**5**, **8**; see Table 1) into racemic (±)-PHTP was reported only recently.[14] This led to the assumption, that relative to urea, thiourea, and tri-*o*-thymotide, PHTP is particularly well suited to incorporate NLO target molecules of various compositions. The equatorial protons of layered, disk-shaped PHTP molecules form continuous, apolar channels in which the guest molecules are arranged in a parallel fashion (Fig. 1). The formation of inclusion compounds was first studied with the oblong, unbranched, conjugated species **I**–**VI**, which exhibit different patterns of donor (D) and acceptor (A) substituents. These molecular frameworks have already been used to create NLO molecules with large β_z values.[5] In this group, the thiovinyl moiety **IV** was of particular interest due to its strong delocalization of π electrons. Table 1 summarizes the compounds discussed below and some details regarding the synthesis and the detection of polar PHTP-guest materials.

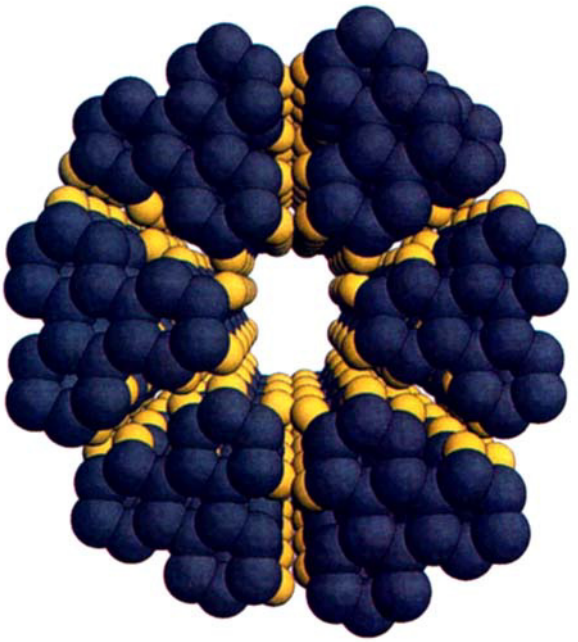

Fig. 1. Van der Waals surface of a PHTP channel (without guest molecules) according to a recent structure elucidation [20]; the van der Waals radii are shown reduced by 30%; carbon grey, hydrogen yellow; computer program employed, ATOMS (Shape Software).

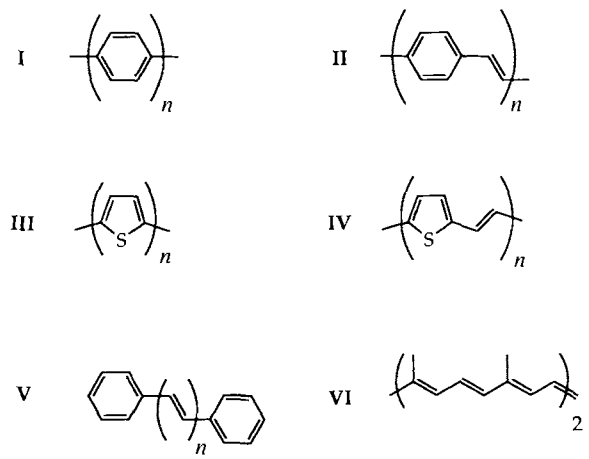

According to the literature,[6] crystals of PHTP–guest complexes can be obtained from solutions as well as from melts. While during crystallizations from solutions the co-inclusion of solvent must be avoided, the formation of crystals from melts is limited to a few, thermally stable NLO guest components. 2-Butanone, in which PHTP is just soluble enough, has been reported as suitable in this context.[6] However, a ^{1}H NMR spectroscopic analysis of the inclusion compounds studied showed co-inclusion of 2-butanone in about ten cases. For a homogeneously colored single crystal of PHTP-**16** that showed no macroscopically visible inclusions, the ratio of **16** to 2-butanone was 1:15. The crystallization of PHTP-**16** and other systems from paraldehyde, on the other hand, yielded solvent-free inclusion complexes. Paraldehyde, with a van der Waals diameter of about 8 Å, is too big to fit into the PHTP channels, which have an inner diameter of about 5 Å. The inclusion compounds could also be prepared, independent of solvents, by solid state reactions and by crystallizations from the gas phase. PHTP-**5**, for example, is formed already during mixing of the powdered starting materials.

X-ray oscillation photographs of single crystals exhibited, apart from Bragg reflections stemming primarily from the PHTP host lattice, diffuse X-ray scattering phenomena that are caused by, among other things, a one-dimensional periodic arrangement of the guest molecules.[14] In the cases studied (**2**–**9**, **12**, **15**–**18**), the translational periods agree well with the calculated lengths of the corresponding molecules;[15] in some cases, the formation of hydrogen bonds is observed. The guest species that absorb visible light were all observed to exhibit a strong dichroism ($\alpha_{\parallel} \gg \alpha_{\perp}$), clearly indicating parallel charge-transfer axes.[16] A "closest packing" of guest molecules is important for two reasons: 1) the dilution of dipoles, caused by the host–guest lattice, is not further enhanced; 2) the observed intermolecular interactions along the D-π-A···D-π-A chains support the assumption that photoconduction might be possible upon a judicious choice of the D and A substituents. A new pathway for the formation of organic photorefractive crystals could be opened in this way.[1, 17]

The number of the obtained PHTP-guest systems exhibiting macroscopic polar properties was also determined. Frequency doubling experiments on polycrystalline samples[18] or small single crystals showed that 18 of the 20 systems studied exhibit a second-order NLO effect, while only four crystalline samples of the pure guest species were SHG active (SHG = *s*econd *h*armonic *g*eneration). A contribution to the SHG effect by crystallites of pure NLO species can be excluded for all samples obtained by solid-state reactions, as only crystal modifications that are SHG inactive were used. With respect to the high proportion of SHG-active PHTP-guest systems it remains to be examined how much the theoretically maximum NLO or electrooptic effect is reduced by orientational disorder or by domain formation (regions showing antiparallel orientations of the β_z axes). The EO characterizations of PHTP-**5** performed so far allow the exclusion of domains that are substantially larger than the wavelength of visible light. For the PHTP–guest complexes with **5**, **8**, **9**, **13**, **14**, as well as **16**–**20**, the 2ω response was sufficiently intense relative to that of pure 4′-dimethylamino-*N*-methyl-stilbenazolium-*p*-tosylate[1] to assume a primarily parallel arrangement of dipoles. In terms of potential crystallization mechanisms it is surprising that even solid-state reactions between PHTP and apolar crystalline samples of the guest species lead to polar PHTP–guest materials, as does the co-inclusion of 2-butanone.

With a representative sample of compounds we could show that racemic PHTP forms stable channel-inclusion lattices with many electronically interesting guest molecules. Through the supramolecular approach, the use of D-π-A guest molecules yields crystals exhibiting macroscopic polar properties in about 90% of

the cases studied. For now, the question why the formation of a polar arrangement for PHTP inclusion complexes is so strongly preferred over a pure NLO species remains unanswered.

Experimental Procedure

The guest species were purified by chromatography before cocrystallization and characterized with the usual analytical techniques. Of the large number of NLO compounds [1–4] only the 20 D-π-A systems described herein were available to us. The crystallizations by controlled isothermal evaporation of 2-butanone or paraldehyde were performed as described [14,19]. When solid starting materials were employed, the first step was grinding with a mortar and pestle, followed by isothermal annealing at 80–100 °C. Crystallization from the gas phase can be performed (e.g., for PHTP-**5**) according to reference [19] (evaporation from Knudsen cells) or in sealed ampules with $\Delta T < 1$ K, $T = 60$–120 °C, depending on the vapor pressure of the guest species.

The PHTP–guest systems were detected and characterized by gas chromatography and ^{1}H NMR spectroscopy in solution, as well as by single crystal X-ray structure analysis. The melting points of these systems were above that of pure PHTP (125.2 °C). Oscillation photographs show a system of diffuse layer lines perpendicular to the channel axis [14]. From this data, the translational periods of the guest molecules were calculated. In all studied cases this period corresponded well to the calculated length of the molecule (e.g., $\mathbf{15}_{obs}/\mathbf{15}_{calc} = 22.9(3)/22.8(5)$ Å, $\mathbf{16}_{obs}/\mathbf{16}_{calc} = 27.1(5)/28.8(7)$ Å, $\mathbf{18}_{obs}/\mathbf{18}_{calc} = 18.0(4)/19.2(6)$ Å).[15] The lattice constant c of the host lattice was also determined from oscillation photographs and was always found to be 4.75(5) Å. Precession photographs indicated a host unit cell with either orthorhombic C-centered (**5**, **8**, **15**) or monoclinic symmetry (**16**, **17**, **18**).

As summarized in Table 1, polycrystalline samples and small single crystals of the PHTP–guest complexes were examined for SHG at 1064 or 1300 nm (for **1**–**6** and **7**–**20**, respectively). To eliminate potential effects of trapped solvents, measurements involving guest species that do not show SHG effects as pure solids were performed on samples from solid-state reactions.

Oscillating Crystallization of (+) and (−) Enantiomers during Resolution by Entrainment of 2-Azabicyclo[2.2.1]hept-5-en-3-one**

Gerard A. Potter, Chantal Garcia, Raymond McCague, Brian Adger, and André Collet*

The (−) enantiomer of the bicyclic lactam **1** is a key synthon for the preparation of enantiopure carbocyclic nucleosides[1, 2] used as chemotherapic agents for the treatment of viral infections (HIV, herpes) and as coronary vasodilatators[3] in certain cardiac diseases.[4, 5] At present the manufacture of this important compound is effected by biocatalytic resolution of the racemate with suitable microbial strains.[6] We recently discovered that (±)-**1** is a conglomerate (a feature that had not been reported before),[7] and this finding led us to focus on the possibility of resolving this compound by the preferential crystallization (or entrainment) method,[8–11] which is well suited to large scale applications. In this communication we report an amazing observation made during the development of a practical entrainment process for **1**; we found that the crystallization of supersaturated solutions of this lactam proceeds by a series of oscillations of their enantiomeric composition (the optical rotation value varies from (−) to (+) and back), until the final racemic composition corresponding to the solubility equilibrium is attained. This unprecedented physical phenomenon provides a new insight into some of the factors that determine the kinetics of crystallization of enantiomeric mixtures remote from their solubility equilibrium.

(+)-**1** (−)-**1**

We first examined the crystallization and solubility properties of lactam **1** in various solvents. This compound crystallizes well from diisopropyl ether, in which it is sparingly soluble at 20 °C (racemate: $S_R = 3.56$ wt %, enantiomer: $S_A = 1.1$ wt %).[12] In this apolar solvent, however, the solubility ratio $\alpha = S_R/S_A$ has an anomalously high value ($\alpha = 3.24$), indicating that each enantiomer of **1** enhances the solubility of its mirror image beyond what is usually observed. The same solubility properties were observed in other ethereal solvents such as *tert*-butyl methyl ether (TBME, $\alpha = 3.4$). In most conglomerates there is not normally such mutual solubility enhancement, and the racemate is usually about twice as soluble as the individual enantiomers (that is, α is close to 2).[13] The amide structure of **1** lends itself to the formation of strong intermolecular hydrogen bonds, and the enhancement of the racemate solubility is possibly due to the existence of preferential heterochiral H-bonding in solution. This is substantiated by the observation that addition of an alcoholic solvent to diisopropyl ether, which can disrupt the intermolecular H-bonding, increases the solubility of **1** and significantly decreases α. Since a high value of α is not favorable for the method of enantiomeric resolution by preferential crystallization,[14] we attempted carrying out the entrainment experiments in a 90:10 (w/w) mixture

of diisopropyl ether and 2-propanol at 20 °C, where S_R and $S_A = 12.71$ and 4.54 wt%, respectively, and α is reduced to 2.8. This value is still too high, but we could not improve on this. Figure 1a displays the ternary phase diagram of (+)- and (−)-**1** at 20 °C in this mixed solvent system, and Figure 1b) focuses on the region of this diagram located in the vicinity of the

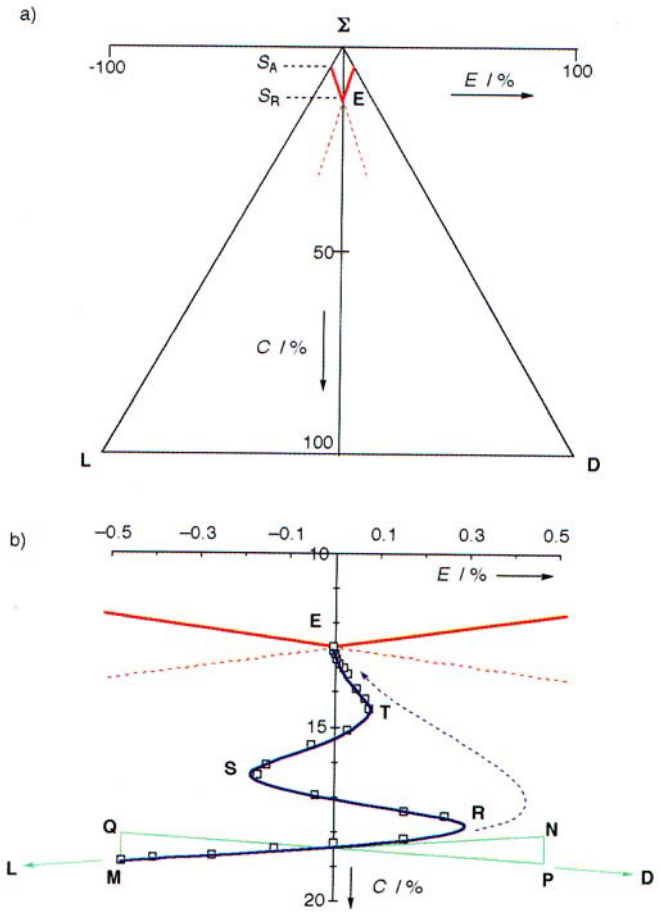

Fig. 1. a) Solubility isotherm at 20 °C of mixtures of (+)-**1** (**D**) and (−)-**1** (**L**) in solvent Σ (diisopropyl ether/2-propanol 90:10 w/w); b) enlargement of the region of diagram (a) situated below the eutectic **E**, showing the oscillating crystallization path (□ represent the experimental points); units for C and E in wt%.

eutectic **E**. In the area situated below the red dotted lines, which represent the extensions of the solubility isotherms beyond **E**, both enantiomers are supersaturated; this is the region suitable for the preferential crystallization method, and by way of example, the indicated paths **M** → **N** or **P** → **Q** represent the expected variation of the composition of a supersaturated solution during the crystallization of a pure enantiomer in a typical entrainment process. Note that segments **N** → **P** and **Q** → **M** correspond to the addition of racemate after each crystallization cycle, and that the extensions of **NM** and **QP** intersect the **L** and **D** apexes of the triangle of Figure 1a.

We then sought conditions that allow a supersaturated solution to follow path **M** → **N** after addition of seeds of (−) enantiomer. Typically, 500 g of a batch solution with composition **M** ($C_0 = 18.9$ wt% and $E_0 = -0.47$ wt%) were stirred at 360 rpm and seeded at 20 °C with 50 mg of finely ground (−)-**1**. The composition of the solution was derived from its rotation α_{436}^{30} (E) and index of refraction n_D^{30} (C), which were recorded every 2 minutes during the initial period (24 min), then every 10 minutes or more at the end. Plots of E vs. C and of α_{436}^{30} vs. the time t are shown in Figure 1b and 2, respectively.

During the first 10 minutes, the composition of the solution closely followed line **MN**, indicating that crystallization of pure (−)-**1** was taking place. Sign inversion from (−) to (+) occurred at the end of 8 minutes; what we then expected was that the solution would attain a maximum positive rotation, followed by a slow decrease eventually reaching zero at the eutectic point **E** (dotted curve in Figs. 1b and 2); this normal behavior

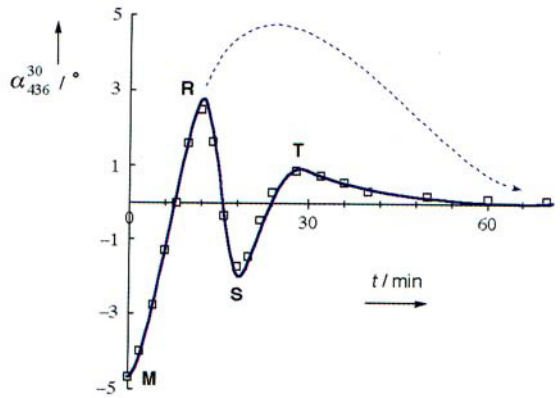

Fig. 2. Optical rotation of the solution vs. time during the oscillating crystallization (□ represent the experimental points).

corresponds to the spontaneous nucleation of the nonseeded enantiomer, which then starts to crystallize along with the seeded enantiomer until the thermodynamic equilibrium is attained. Instead of this, we observed after 12 min a sharp turn (**R**) followed by a straight segment **RS** parallel to **PQ** and corresponding to the crystallization of pure (+)-**1**. This was followed after 16 min by a second change of sign of the solution from (+) to (−), then by a second turn (**S**, 18 min) where (−)-**1** started to crystallize again; a third change of sign from (−) to (+) occurred after 24 min and a last turn at the end of 28 min (**T**). After this point the equilibrium state **E** was finally attained by the end of 1 h, and no further oscillation was observed. This phenomenon was observed consistently and proved to be perfectly reproducible.[15]

An explanation of this behavior can be provided on consideration of two factors. 1) As stated above, the α value is high; that is, one enantiomer aids the solubility of the other. Therefore, as one enantiomer crystallizes from a supersaturated solution, the other enantiomer becomes critically supersaturated, and has a much greater tendency to crystallize than in the racemic solution. This is not sufficient, however, to explain the oscillations. 2) It must be assumed that the conglomerate crystals are *twinned*, and that one enantiomer (+) can grow on the surface of the other (−) (and vice versa) in such a way that the apparent handedness of the seeds is periodically inverted during the crystallization process. This inversion occurs at **R**, **S**, and **T** on the crystallization path displayed Figures 1b and 2. The twinning hypothesis is substantiated by the fact that, although the compound is a conglomerate, individual crystals sorted from the racemate only show weak rotations, and a well formed (apparently) single crystal was found to be almost racemic. Examples of lamellar twinning of (+) and (−) enantiomers in conglomerates have previously been reported, and the case of [6]-helicene is well documented.[16] Along these lines, we explain the observed oscillations as follows. The (−) enantiomer crystallizes rapidly first, on the (−) seeds added. A point is reached (**R**)

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3515-1667 $ 15.00+.25/0

where the (−) enantiomer has crystallized to the extent that the (+) enantiomer left in solution is now in excess and becomes critically supersaturated. At this point the (+) crystals start to grow on the surface of the (−) crystals that have already formed, which stops the crystallization of the (−) enantiomer; a point is then reached (**S**) where the (+) enantiomer has crystallized to the extent that the (−) is now left in solution in excess and becomes critically supersaturated. The (−) enantiomer then starts to grow on the surface of the (+) crystals, and so on. The process repeats until the solubility equilibrium is attained (**E**). If this explanation is correct, then the crystals thus formed would consist of distinct alternating layers of (−)/(+)/(−)/(+) enantiomers, as has been observed in [6]-helicene.

In order to test the hypothesis that one enantiomer of the bicyclic lactam **1** can grow on the surface of the opposite enantiomer, an experiment was conducted in which a supersaturated solution of **1** containing a small excess of the (−) enantiomer was seeded with crystals of the *opposite* (+) enantiomer. Indeed, in this experiment carried out on a 500 g scale with an initial composition of $E_0 = -0.42$ wt% and $C_0 = 17.12$ wt% by seeding with 50 mg of (+) enantiomer and collecting the crystals thus formed just before the first oscillation, it was possible to obtain 4.0 g of the (−) enantiomer having 86% *ee*! Following on from this result, seeding with crystals of the racemate was examined. From a solution with the same starting composition as the previous experiment and seeded with 50 mg of racemic seed crystals, 3.9 g of the (−) enantiomer of 90% *ee* was obtained. For seeding with the opposite enantiomer and racemate to be successful, the initial enantiomeric excess (E_0) needed to be greater than about 0.35 wt% (ca. 2 % *ee*) at the initial concentration employed. Thus above a certain critical enantiomeric excess, which is dependent upon the degree of supersaturation, the enantiomer in excess crystallizes on the surface of the seed crystals, irrespective of which enantiomer it is, verifying that one enantiomer of **1** can grow on the surface of its opposite enantiomer.

The fact that oscillating crystallizations of this kind have not been observed earlier is not surprising. The conditions that must be fulfilled are in fact very difficult to meet: conglomerates represent only 5–10 % of crystalline racemates, the vast majority of these display normal solubility behavior (α close to 2), and lamellar twinning of enantiomers is not so common. Moreover, the region of the phase diagram where such oscillations can take place is very narrow (compare the scales of Figure 1a and b).

Although the crystallization of **1** was observed to proceed in this oscillating manner, successful resolution by a cyclic entrainment process was found to be possible by seeding with the desired enantiomer and collecting the crystals formed just before the onset of the first oscillation through careful monitoring of the crystallization process.

Experimental Procedure

Suitable operating conditions for entrainment were as follows: solvent 90:10 (w/w) mixture of diisopropyl ether and 2-propanol; $T = 20\,^{\circ}C$; 1 kg of batch solution having $C_0 = 16.6$ to 17.1 wt% and $E_0 = +$ or -0.28 wt%; stirring speed 500 rpm; seeding with 50 mg of enantiomer per cycle; crystallization duration from 30 to 60 min; yield *ca.* 6 g of enantiomer per cycle, with 85-90 % *ee*. Under these conditions, a series of ten successive cycles furnished 31.9 g of (−)-**1** and 31.1 g of (+)-**1** having 86 % *ee*, which after one recrystallization yielded 25.6 and 24.8 g, respectively, of pure lactam enantiomers.

[12] The following units are used throughout this paper: in a quantity σ g of solvent, the solubility (S) or concentration C of a mixture of d g of (+) and l g of (−) enantiomers is defined as $(d+l)/(d+l+\sigma)$ in wt % and the excess of enantiomer E as $(d-l)/(d+l+\sigma)$ also in wt %. Note that C and E define the vertical and horizontal axes of the ternary phase diagram of Fig. 1, and that E/C corresponds to *ee*, the usual enantiomeric excess of the considered mixture.
[13] There are very few reported examples of conglomerates with α greater than 3: in water at 30 °C *N*-acetyl- and *N*-butyrylproline have $\alpha = 3.34$ and 3.24, respectively: C. Hongo, M. Shibazaki, S. Yamada, I. Chibata, *J. Agric. Food Chem.* **1976**, *24*, 903.
[14] See Ref. [9] pp. 233–235; a value of α greater than 2 reduces the size of the region of the phase diagram suitable for the entrainment (lower productivity), and has a detrimental effect on the stability of the supersaturation of the nonseeded enantiomer, which leads to spontaneous nucleation of the undesired enantiomer.
[15] The oscillation frequency was found to increase with the degree of supersaturation and the rate of stirring, but this dependence is complex, and was not investigated further in this work.

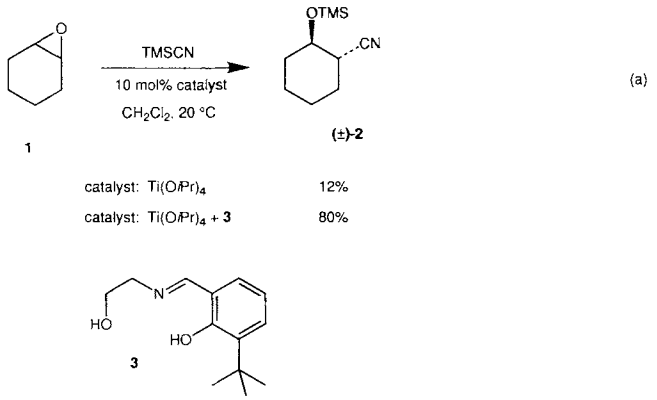
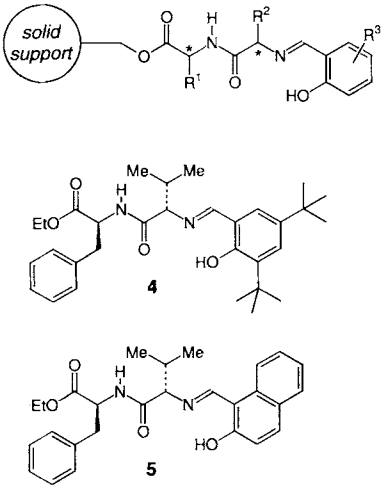
cesses,[1] and leads to the discovery of low molecular weight ligands that effect formation of chiral molecules efficiently. This research was undertaken since we judged that, given the ability of enzymes to serve as asymmetric catalysts,[2] potent stereoselective reactions catalyzed by transition metal peptide complexes may be uncovered. As the search for an optimal ligand was inspired by combinatorial and related strategies, peptide-derived ligands represent an attractive option: they have modular structures within which asymmetry can be easily varied. Furthermore, amino acid building blocks are environmentally benign, readily available in optically pure form, and inexpensive.[3] We thus present the first enantioselective formation of β-cyanohydrins achieved by the asymmetric opening of *meso* epoxides.[4] Our studies demonstrate that diverse peptide-based structures can be rapidly synthesized and screened collectively for their ability to induce appreciable levels of enantiocontrol.

The Ti-catalyzed addition of trimethylsilylcyanide to epoxides is facilitated by the presence of an alkoxide Schiff base [Eq. (a)].[5] Reaction of **1** with 10 mol% $Ti(OiPr)_4$ provided



(a)

(±)-**2** in only 12% yield (18 h), whereas when **3** was also present (10 mol%), (±)-**2** was isolated in 80% yield. We surmised that if ligands such as **3** are effective in accelerating C–C bond formation, dipeptide Schiff bases with the general structure shown in Scheme 1 may also give rise to effective *chiral* catalysts. The availability of two amino acid residues presents opportunities for fine-tuning catalyst efficiency; the aromatic Schiff base allows for electronic adjustment of the ligand.[6] Similar ligand systems have been used by Inoue et al. for catalytic enantioselective cyanohydrin synthesis;[3] however, these studies followed



Scheme 1. General structure of support-bound dipeptide Schiff bases, and ligands **4** and **5**. R^1 and R^2 can contain stereogenic centers.

the classical approach to catalyst optimization: ligands were modified in a serial manner.

To establish the efficacy of dipeptide Schiff bases, the reaction illustrated in Equation (a) was performed in the presence of **4** (see Experimental Procedure): at 4 °C (9 h, CH_2Cl_2), **2** was isolated in 68% yield (6% *ee*); with **5** present (toluene, 4 °C), a 58% yield of **2** was achieved (40% *ee*). Reasonable levels of reaction acceleration can thus be expected from this class of chiral ligands. This transformation and the variety of related ligand systems render the aforementioned strategy for catalyst development attractive, because solid-support techniques can be used for the high-throughput search for an effective catalyst. It is notable that since reactions are accelerated by the dipeptide Schiff base,[7] adventitious side products present from ligand synthesis on solid support should not provide a serious hindrance to accurate analysis (impurities are less likely to serve as ligands).[8]

Dipeptide Schiff bases can be prepared rapidly and efficiently in a parallel manner by standard methods (Scheme 2).[9,10] Schiff base **8** is prepared by subjecting the polymer-bound **7** to the requisite aromatic aldehyde. Accordingly, more than twenty different ligands can be prepared in the course of a single day, a feat that would be difficult by traditional techniques.

Next, we established whether the levels of selectivity observed for the dipeptide Schiff base bound to the solid support correspond to those of reactions with the free ligand. With support-

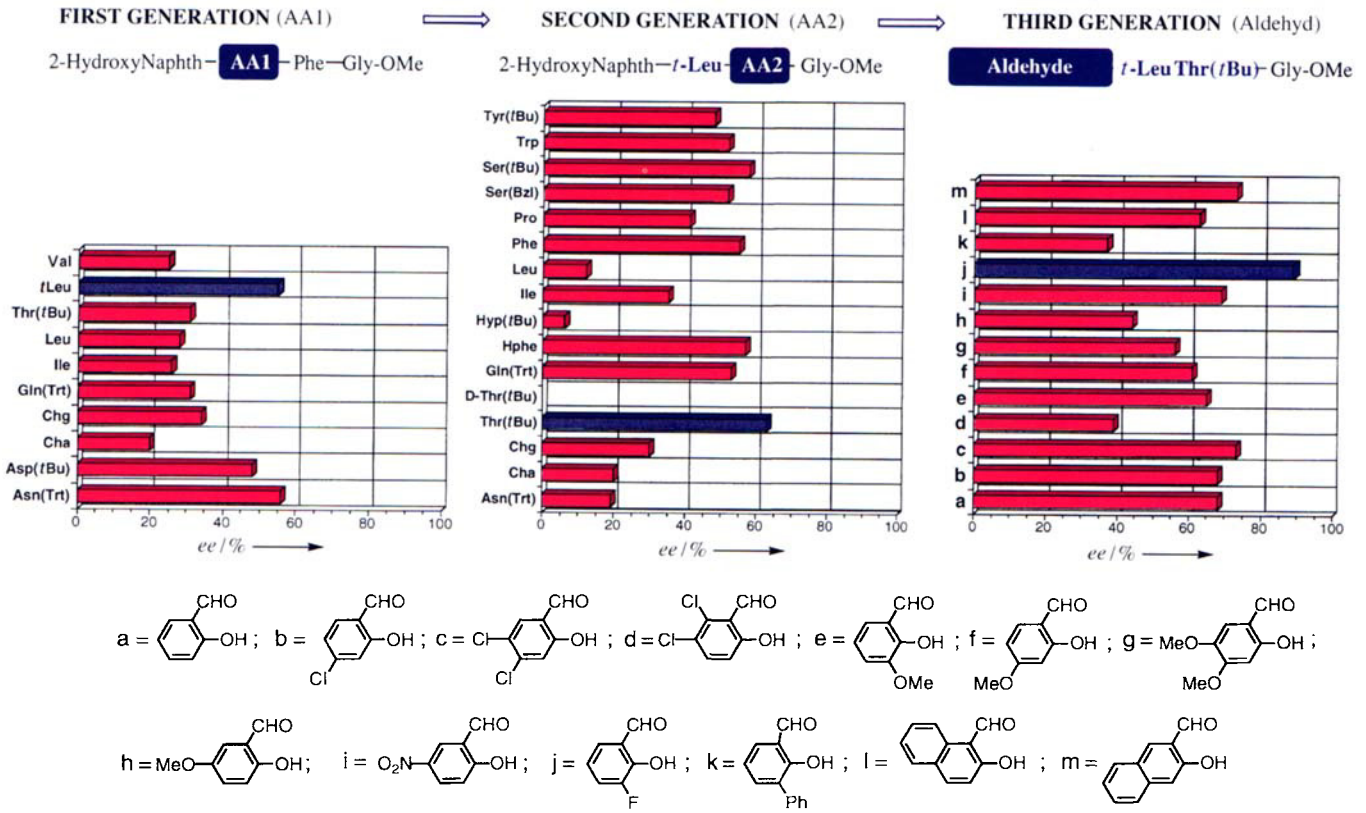

Fig. 1. Ligand optimization by variation of the ligand components AA1 (first generation), AA2 (second generation), and aldehyde (third generation). Asn(Trt) = *N*-β-trityl-L-asparagine; Asp(*t*Bu) = L-aspartic acid β-*tert*-butyl ester; Cha = L-cyclohexylalanine; Chg = L-cyclohexylglycine; D-Thr(*t*Bu) = *O*-*tert*-butyl-D-threonine; Gln(Trt) = *N*-γ-trityl-L-glutamine; Hphe = L-homophenylalanine; Hyp(*t*Bu) = *O*-*tert*-butyl-L-hydroxyproline; Ile = L-isoleucine; Leu = L-leucine; Phe = L-phenylalanine; Pro = L-proline; Ser(Bzl) = *O*-benzyl-L-serine; Ser(*t*Bu) = *O*-*tert*-butyl-L-serine; Thr(Bzl) = *O*-benzyl-L-threonine; Thr(TBS) = *O*-*tert*-butyldimethylsilyl-L-threonine; Thr(*t*Bu) = *O*-*tert*-butyl-L-threonine; Thr(Trt) = *O*-trityl-L-threonine; *t*-Leu = L-*tert*-leucine; Val = L-valine; trityl = triphenylmethyl.

bound **4**, reaction of **1** with TMSCN affords cyanohydrin **2** in 56% *ee* (vs 6% *ee* with the free ligand). When **5** is tethered to the solid support with the longer chain 6-amino caproic acid linker, (±)-**2** is obtained (vs 58% *ee* with a glycine linker). Thus, enantioselective processes are possible with immobilized ligands, but it appeared that, at least initially, a more reliable approach for discovery of catalysts in solution would require cleavage of the ligand from the polymer support, a process that delivers ligands in excellent yields as yellow crystalline solids.[7]

In a manner similar to "positional scanning",[8] each of the basic structural modules of the chiral ligand system was modified systematically (Fig. 1). Because in our preliminary studies **5** led to the highest enantioselectivities (40% *ee*), we decided to use it as our starting system. To determine the best candidate for the amino acid unit AA1, ten ligand systems were prepared on solid support (other two components were retained), cleaved, and screened in a parallel fashion as catalysts for the enantioselective formation of **2** (10 mol% ligand and $Ti(OiPr)_4$). *t*Leu emerged as a superior AA1 unit. With *t*Leu as AA1 and 2-hydroxy-1-naphthaldehyde (2-hydroxynaphth) as the Schiff base, the search for the most appropriate AA2 unit (second-generation ligands, sixteen different amino acids) led us to Thr(*t*Bu). It is noteworthy that the unnatural enantiomer D-Thr(*t*Bu) did not afford any of the desired product. With *t*Leu as AA1 and Thr(*t*Bu) as AA2, thirteen aldehydes with a range of steric and electronic properties were selected, synthesized, and screened; 3-fluorosalicaldehyde stood as the best choice (third-generation ligand). Hence, through rapid screenings of three ligand classes each consisting of ten to seventeen members, a ligand structure (AA1 = *t*Leu, AA2 = Thr(*t*Bu), aldehyde = 3-fluorosalicaldehyde) was found that effects enantioselective formation of **2** in 89% *ee*.

Dipeptide Schiff base **10** is therefore implicated to be an effective chiral ligand for the Ti-catalyzed addition. Indeed, conversion of **1** to **2** in the presence of **10** proceeds in 86% *ee* (Table 1,

Table 1. Ti-catalyzed enantioselective addition of TMSCN to *meso* epoxides [a].

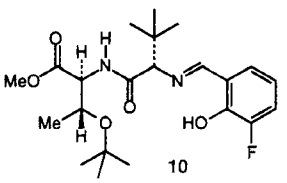
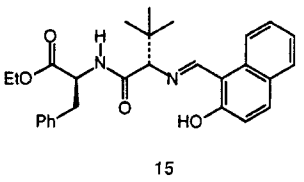
entry 1). However, **10** is not the most suitable ligand for the reaction of **11**. In the presence of **10**, addition product **12** is obtained in 64% *ee* (entry 3), whereas with **15** as the chiral ligand, **12** is obtained in a higher 75% *ee* (entry 4). In direct contrast, **15** is an inferior ligand for Ti-catalyzed TMSCN addition to **1**; **2** is formed in 70% *ee* (vs 86% *ee* with **10**). This



10



15

substrate specificity in asymmetric induction as a function of the ligand structure is a notable attribute of the present method (similar to what is found in enzyme-catalyzed reactions). Ligand optimization can be carried out for *each* particular class of substrates, since the best chiral ligand for six-membered epoxides may not be the most effective for reactions of five-membered ring substrates (compare entry 1 to 3 or entry 2 to 4). The outcome of the Ti-catalyzed asymmetric opening of **13** (entries 5 and 6) supports this contention.

The present report delineates several advances. 1) We put forth the first example of a catalytic and enantioselective method for the addition of TMSCN to *meso* epoxides. 2) We illustrate that peptide-based systems are amenable to high-throughput screening. The reaction outcomes observed in the initial screening correlate well with the subsequent solution chemistry. 3) We demonstrate a novel strategy for the development of new catalysts for asymmetric transformations; stepwise modification of the modular ligand structure leads to the identification of a system that affords high enantioselectivity. In the case of **1** → **2**, reaction enantioselectivity is improved from 40 to 86% *ee*.[9] The present strategy does not allow for an exhaustive examination of every ligand structure; our iterative approach, however, allows one to eliminate—quickly and logically—certain combinations. We have scanned much of the conformational space at each position of the modular ligand by varying various subunits in a random fashion and combining the best set of building blocks. The described strategy assumes that the influence of each ligand subunit is independent and additive; it is impossible to rule out cooperative effects without individually testing each combination. Nonetheless, additivity effects are apparent from the above data and our studies corroborate that if ligand **10** is optimized in the reverse fashion (i.e. aldehyde→AA2→AA1), the same ligand structure is identified. The dipeptide-based ligands discussed here, the attendant method for examination of their efficiency, and the catalytic enantioselective addition of TMSCN to *meso* epoxides should find extensive applications in the synthesis of chiral compounds.

Experimental Procedure

General procedure for the solid-phase synthesis of ligands: Solid-phase synthesis was carried out on the functionalized resin, FMOC-Gly-PAC (Millipore; 0.42 mmol g^{-1} loading). Reactions were performed in polypropylene Bio-Spin chromatography columns from Bio-Rad Laboratories, Inc. PAC-Gly-Fmoc resin (100 mg, 0.04 mmol) was placed in the polypropylene reaction vessel and washed with DMF (3 × 1.5 mL). The resin became swollen through by agitation in DMF (1.5 mL) for 2 h, washed with additional DMF (3 × 1.5 mL), and subsequently deprotected by washing with 20% piperidine/DMF (1.5 mL), agitation for 1.5 h in 20% piperidine/DMF (1.5 mL), and washing with DMF (10 × 1.5 mL). The FMOC-protected amino acid (0.17 mmol) was activated as a symmetrical anhydride by treatment with an excess of 1,3-diisopropylcarbodiimide (49 μL, 0.25 mmol) in DMF (1.5 mL, 20 min). The resulting solution was added to H_2N-Gly-PAC, mixed for 1 h, and then washed with DMF (10 × 1.5 mL). A sample of the resin was subjected to a ninhydrin test [10]. Samples testing positive were resubjected to the coupling conditions. FMOC-AA2-Gly-PAC was deprotected by washing with 20% piperidine/DMF (1 × 1.5 mL), mixing for 1.5 h in 20% piperidine/DMF (1.5 mL), and washing with DMF (10 × 1.5 mL). The second amino acid coupling and deprotection was performed similarly. Following coupling and deprotection, H_2N-AA1-AA2-Gly-PAC was treated with 4.0 equiv (0.17 mmol) of an *ortho*-hydroxy aldehyde (1.5 mL DMF, 2 h) and washed with DMF (10 × 1.5 mL). The ligand was cleaved from the resin by stirring with 2.0 mL of triethylamine/DMF/MeOH (1:1:9) for 60 h. The solution was filtered and the resin washed with distilled THF (3 × 2 mL). Solvent was removed in vacuo; the resulting yellow solid was taken up in CH_2Cl_2 (1.0 mL) and loaded onto a pipet packed with a cotton plug and silica gel. The ligand was eluted with EtOAc (ca. 10 mL); the product was dissolved in toluene (5 mL) and concentrated in vacuo to remove water and DMF as the azeotrope; the product was dried in vacuo to give a pale to a bright yellow solid (yields: 80–100%).

Testing of the ligands in the epoxide ring opening reaction: The ligand (0.02 mmol) prepared by solid-phase synthesis was taken up in $CHCl_3$ (1.0 mL). Toluene (2.0 mL) was added and the solution concentrated to a yellow solid in vacuo. The reaction vessel was evacuated and flushed with argon three times before $Ti(OiPr)_4$ (1 equiv of a 0.1 M solution in toluene; 200 μL, 0.02 mmol) was added; the reaction mixture and stirred for 1 h at 22 °C. Subsequently, cyclohexene oxide was added (1.0 M in toluene; 200 μL, 0.2 mmol), followed by TMSCN (1.0 M in toluene; 200 μL, 0.2 mmol). The reaction mixture was allowed to stir for 20 h (4 °C). Reactions were quenched by the addition of 1.0 mL of ether/hexanes (1:1) and forced through a silica gel plug with an additional 1.0 mL of ether/hexanes (1:1). Reaction selectivity was determined by GLC analysis (BETADEX-120 chiral column).

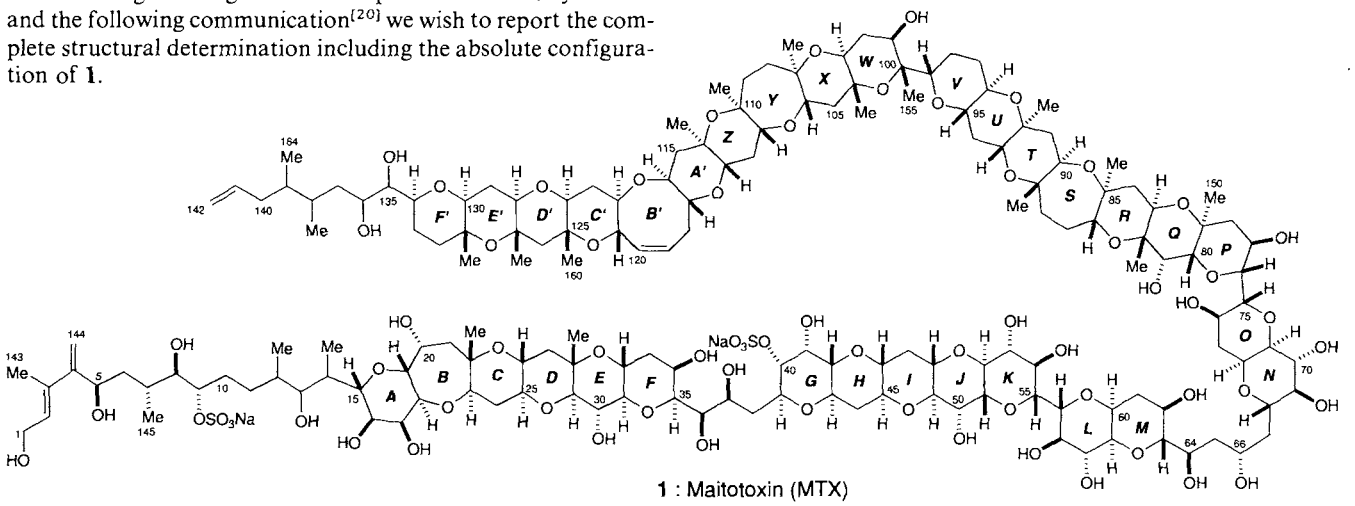
The Complete Structure of Maitotoxin, Part I: Configuration of the C1–C14 Side Chain**

Makoto Sasaki, Nobuaki Matsumori, Takahiro Maruyama, Taro Nonomura, Michio Murata, Kazuo Tachibana,* and Takeshi Yasumoto

Maitotoxin (MTX, **1**) was first discovered as one of the toxins responsible for ciguatera seafood poisoning and was afterward found to be produced by the dinoflagellate *Gambierdiscus toxicus*.[1] MTX is the largest non-biopolymer known to date (M_r = 3422),[2] thus attracting considerable attention from natural products and synthetic chemists. Additionally, MTX has remarkable biological activities; particularly, its lethality against mammalians is extremely potent (50 ng per kg, mouse, ip.) and exceeded by that of only a few proteinous toxins.[2b,3] Therefore, the elucidation of its structure has been regarded as one of the most exciting challenges in natural products chemistry. In this and the following communication[20] we wish to report the complete structural determination including the absolute configuration of **1**.



1 : Maitotoxin (MTX)

We have recently succeeded in determining the relative configuration along the polyether entity of MTX encompassing ether rings A through F'.[4] Yet the configuration of both side chains (C1–C14 and C135–C142) has remained unknown. Our strategy in previous work was based on the diastereospecific syntheses of fragment structures in combination with stereochemical analysis with use of NMR data ($^{2,3}J_{C,H}$ and $^{3}J_{H,H}$).[4] Upon determination of configuration by synthetic methods, all possible diastereomers are usually synthesized and their spectroscopic data compared with those of a derivative of the natural product. However, in the case of the C1–C14 side chain of MTX, which contains seven asymmetric carbons, the total number of the possible stereoisomers amounts to 128. In previous studies[4,5] we have demonstrated that the number of possible candidates requiring synthesis can be greatly reduced by careful examination of the NMR data of the natural product. Therefore, we first used this approach to select diastereomers of the C1–C14 side chain to be synthesized. For the C5–C9 part, the configuration was previously deduced as 5*R**, 7*R**, 8*R**, and 9*S** based on the long-range carbon–proton and proton–proton coupling constants ($^{2,3}J_{C,H}$ and $^{3}J_{H,H}$).[5] This method failed to be convincing for the C9–C12 portion mainly because of extreme overlap and broadening of the corresponding ^{1}H signals. Instead, conventional NOE analysis was informative (Fig. 1), since the C9–C12 portion appeared to take a relatively rigid conformation (1,2-disubstituted ethanes are known to be mostly in the *anti* orientation). NOEs between H-7 and H-10 (δ = 2.03) and the coupling constants $^{3}J_{H\text{-}9/H2\text{-}10}$ (7.9 and 3.2 Hz) showed that the chain C8-C9-C10-C11 takes an extended conformation, which allowed us to assign the signals for H_2-10 at δ = 1.81 and 2.03 to H_α-10 and H_β-10, respectively. NOEs arising from probable 1,3-*syn* interaction of H-9/H-11 (δ = 1.47) and H_β-10/H_3-146 indicated the extended conformation of C9-C10-C11-C12 with the following stereospecific assignments for H_2-11: H-11 (δ = 1.47) is a β-proton and H-11 (δ = 2.14) is an α-proton (Fig. 1). An intense cross peak due to C146/H_α-11 in phase-sensitive HMBC spectra (HMBC = heteronuclear multiple bond correlation)[6] suggested the dihedral angle C146-C12-C11-H_α-11 to be nearly 180°. Furthermore, the fact that $^{3}J_{H_\beta\text{-}11/H\text{-}12}$ is much larger than $^{3}J_{H_\alpha\text{-}11/H\text{-}12}$, as estimated from the intensity of the cross peaks in the DQF-COSY spectrum (double quantum filtered correlation spectrum), indicates that H_β-11 is *anti* to H-12. The relationship between C9 and C12 was therefore suggested to be 9*S**/12*R** through the double stereospecific assignments for H-9/H_2-10 and H_2-11/H-12.

Unlike the case for C9–C12, the relative configurations of C12, C13, and C14 were hardly assignable by NOE analysis

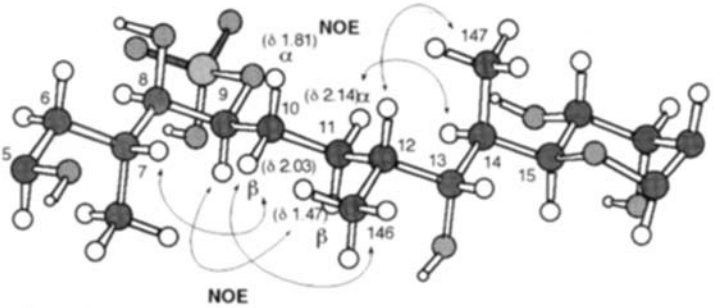


Fig. 1. Deduced conformation of the C1–C14 side chain of maitotoxin with the stereospecific assignments for H_2-10 and H_2-11. Double-headed arrows denote key NOEs necessary for deducing the conformation of the C8–C12 portion.

because of the suggested presence of two alternating conformers.[7] Nevertheless, the relationship between C12 and C13 could be established based on the coupling constants $^{3}J_{H,H}$ and $^{2,3}J_{C,H}$, since unlike the NOEs these were obtained as the weighted average of those from both conformers. As shown in Figure 2, the small value of $^{3}J_{H\text{-}12/H\text{-}13}$ of 4.0 Hz revealed that the H-12/H-13 *gauche* conformer is dominant. The large $^{3}J_{C11/H\text{-}13}$ and small $^{2}J_{H\text{-}12/C13}$ values, which were determined by HETLOC spectra,[8] were indicative of the *anti* orientation of both C11/H-13 and H-12/13-OH, respectively (Fig. 2).[15a,9] The relationship

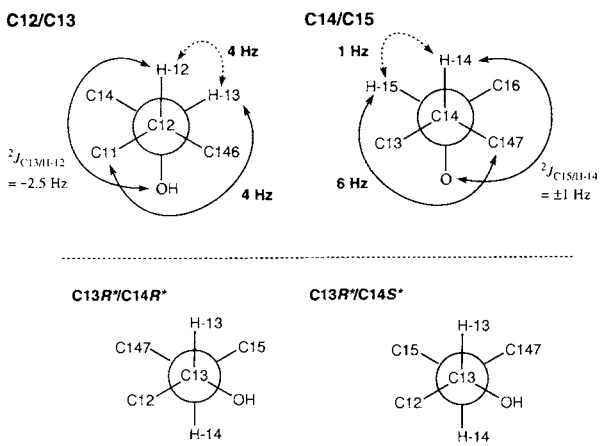

Fig. 2. Newman projections along the C12–C13 and C14–C15 bonds with vicinal H–H coupling constants ($^{3}J_{H,H}$, broken lines) and geminal/vicinal C–H coupling constants ($^{2,3}J_{C,H}$, solid lines), and Newman projections along the C13–C14 bonds of the two H-13 H-14-*anti* diastereomers. $^{2}J_{C,H}$ values are known to depend on the dihedral angle between a proton and an oxygen atom at the vicinal position and are thus utilized to deduce the rotational conformations between H-12/13-OH and H-14/15-O [9]. The value for $^{2}J_{C15,H\text{-}14}$ (±1 Hz) was obtained from phase-sensitive HMBC, in which the signs of coupling constants are not determined [6].

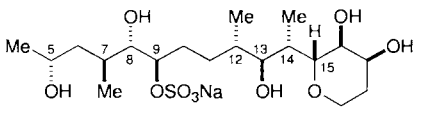
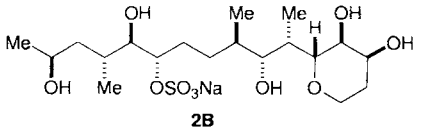
between C14 and C15 was unambiguously established by a similar method on the basis of coupling constants ($^{3}J_{H\text{-}14/H\text{-}15}$ = 1 Hz, $^{3}J_{C147/H\text{-}15}$ = 6 Hz, $^{2}J_{C15/H\text{-}14}$ = ±1 Hz). On the other hand, the relative configuration between C13 and C14 could not be assigned because of the dominant conformation with the *anti* H-13/H-14 orientation, in which the diastereomers are not distinguishable since in either case the implicated $^{3}J_{C,H\text{-}13}$ and $^{2,3}J_{C,H\text{-}14}$ couplings (due to H-13/C15, H-13/C147, H-14/C12, and H-14/13-OH) would have similar values for the *gauche* interactions (Fig. 2 bottom).

These data suggested the configuration of the side chain to be either **2A** or **2B**, in which the diastereomeric relationship is inverted at the C13–C14 bond. Thus, in order to assign this diastereomeric relationship, and also to confirm the relative configurations at C9, C12, and C13 as deduced from the NMR data, the diastereomeric fragments **2A** and **2B** were chosen to be



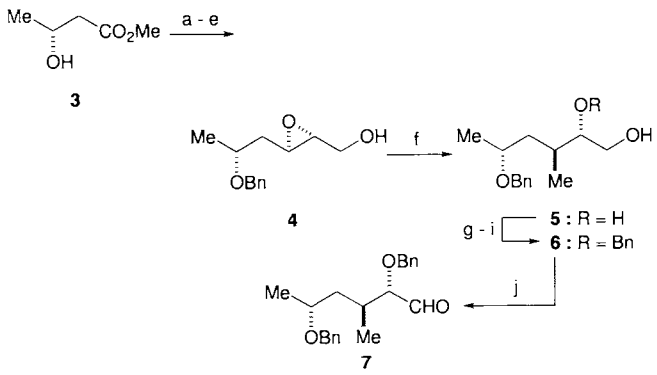
2A



2B

synthesized for comparison of their NMR data with those of MTX.[4b] These fragments were designed also to incorporate the asymmetric centers whose configuration had already been determined (C5–C8 and C15–C17) so as to reproduce the ^{1}H and ^{13}C chemical shifts of the natural product.

The synthesis of aldehyde **7**, the left half of **2A**, started with methyl (*S*)-(+)-3-hydroxybutyrate ((*S*)-(+)-**3**) (Scheme 1),

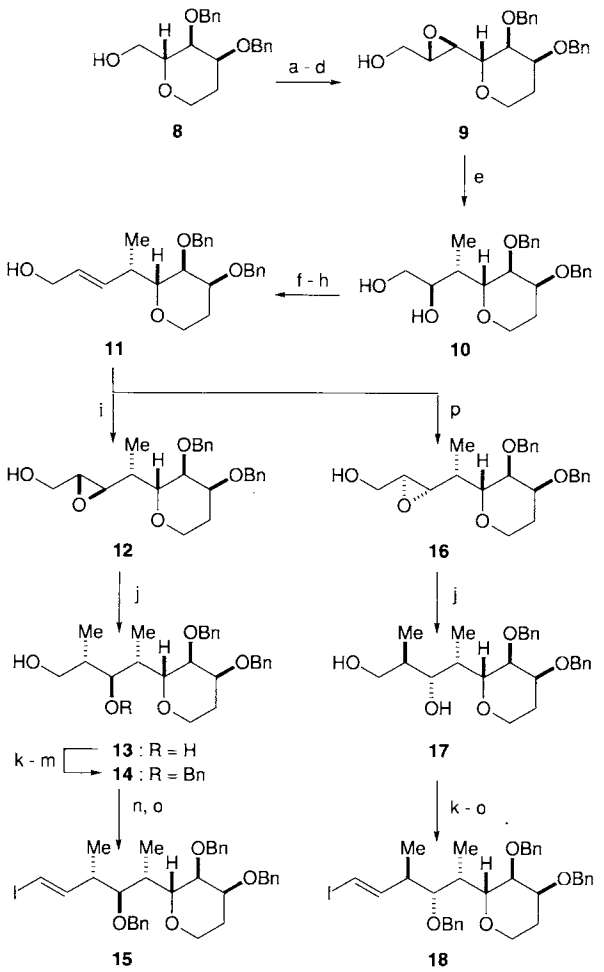


Scheme 1. Synthesis of aldehyde **7**. a) $BnOC(=NH)CCl_3$, TfOH (cat.), CH_2Cl_2/hexane (2/1), 0 °C, 84%; b) DIBAL-H, CH_2Cl_2, −78 °C; c) $Ph_3P{=}CHCO_2Me$, benzene, RT, 70% (two steps), d) DIBAL-H, CH_2Cl_2, −78 °C, 92%; e) *t*BuOOH, (−)-diethyl tartrate, $Ti(OiPr)_4$, CH_2Cl_2, 4 Å molecular sieves, −20 °C, 77%; f) $AlMe_3$, CH_2Cl_2/hexane (1/3), RT; g) MMTrCl, iPr_2NEt, CH_2Cl_2, RT, 62% (two steps); h) NaH, BnBr, DMF, RT; i) *p*TsOH (cat.), CH_2Cl_2/MeOH (1/1), RT, 72% (two steps); j) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, −78 °C→RT. Bn = benzyl, TfOH = trifluoromethanesulfonic acid, DIBAL-H = diisobutylaluminum hydride, RT = room temperature, MMTr = *p*-methoxyphenyldiphenylmethyl, DMF = *N*,*N*-dimethylformamide, *p*TsOH = *p*-toluenesulfonic acid, DMSO = dimethylsulfoxide.

which was converted into epoxy alcohol **4** by the following sequence: 1) protection as its benzyl ether, 2) reduction with diisobutylaluminum hydride (DIBAL-H), 3) Wittig homologation, 4) reduction to the allylic alcohol, and 5) Sharpless asymmetric epoxidation.[10] The C7[11] methyl group was introduced by the regioselective opening of the epoxide ring with trimethylaluminum[12] to give *vic*-diol **5**. In this transformation the regioisomeric 1,3-diol was not produced. Routine protecting group manipulations allowed the conversion of **5** into primary alcohol **6**, which was oxidized under Swern conditions to give the desired aldehyde **7**. The enantiomer of **7** was synthesized from (*R*)-(−)-**3** analogously.

Elaboration of the vinyl iodide **15**, which corresponds to the right half of **2A**, started with optically active alcohol **8**[13] (Scheme 2). Swern oxidation of **8** followed by Wittig olefination and DIBAL-H reduction gave the allylic alcohol, which was subjected to Sharpless asymmetric epoxidation to furnish epoxy alcohol **9**. Treatment of **9** with trimethylaluminum[12] provided *vic*-diol **10** as a single regioisomer, which was then converted into allylic alcohol **11** by the three-step sequence of reactions comprising periodate oxidation, Horner–Emmons olefination, and DIBAL-H reduction. Sharpless asymmetric epoxidation of **11** and regioselective opening of the resulting epoxide **12** with lithium dimethylcuprate[14] gave 1,3-diol **13** (>90% regioselectivity), which was then transformed into the primary alcohol **14**. Swern oxidation of **14** and subsequent treatment of the resulting aldehyde with iodoform and $CrCl_2$[15] provided (*E*)-vinyl iodide **15**. Similarly, the diastereomeric iodide **18** was prepared from **11** via epoxy alcohol **16**, which was produced by use of the antipodal tartrate in the Sharpless epoxidation.

The crucial $NiCl_2/CrCl_2$-mediated coupling reaction[16] of **7** and **15** provided allylic alcohol **19** in 52% yield (based on **15**, Scheme 3) as a 1:1 mixture of diastereoisomers (500 MHz



Scheme 2. Synthesis of diastereomeric vinyl iodides **15** and **18**. a) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, $-78\,^{\circ}C \rightarrow RT$; b) $Ph_3P{=}CHCO_2Me$, benzene, RT, 73% (two steps); c) DIBAL-H, CH_2Cl_2, $-78\,^{\circ}C$, 88%; d) *t*BuOOH, (+)-diethyl tartrate, $Ti(O{i}Pr)_4$, CH_2Cl_2, 4 Å molecular sieves, $-20\,^{\circ}C$, 85%; e) $AlMe_3$, CH_2Cl_2/hexane (1/2), $0\,^{\circ}C$; f) $NaIO_4$, THF/H_2O (2/1), RT; g) $(iPrO)_2POCH_2CO_2Et$, *t*BuOK, THF, $-78\,^{\circ}C$, 68% (three steps); h) DIBAL-H, CH_2Cl_2, $-78\,^{\circ}C$, 96%; i) *t*BuOOH, (−)-diethyl tartrate, $Ti(O{i}Pr)_4$, CH_2Cl_2, 4 Å molecular sieves, $-20\,^{\circ}C$; j) Me_2CuLi, Et_2O, $-20\,^{\circ}C$, then $NaIO_4$, THF/H_2O (2/1), RT, 68% (three steps); k) TrCl, iPr_2NEt, DMAP (cat.), CH_2Cl_2, RT, 82%; l) NaH, BnBr, TBAI (cat.), DMF, RT; m) *p*TsOH (cat.), MeOH, RT, 82% (two steps); n) $(COCl)_2$, DMSO, Et_3N, CH_2Cl_2, $-78\,^{\circ}C$ to RT; o) CHI_3, $CrCl_2$, THF, $0\,^{\circ}C$, 77% (two steps); p) *t*BuOOH, (+)-diethyl tartrate, $Ti(O{i}Pr)_4$, CH_2Cl_2, 4 Å molecular sieves, $-20\,^{\circ}C$. Tr = triphenylmethyl, DMAP = 4-dimethylaminopyridine, TBAI = tetrabutylammonium iodide.

^{1}H NMR spectrum). Oxidation of **19** with pyridinium dichromate gave the α,β-unsaturated ketone, which was reduced with NaHTe[17] to afford ketone **20**. Chelation-controlled $Zn(BH_4)_2$ reduction of ketone **20** proceeded in a highly stereoselective manner[18] to yield the desired alcohol **21**. Finally, sulfation of **21** followed by ion exchange to give the sodium salt and hydrogenation of the benzyl ethers with $Pd(OH)_2$/C furnished the target compound **2A**. Diastereomer **2B** was synthesized analogously from the enantiomer of **7** and iodide **18**.

In the comparison of the ^{1}H and ^{13}C NMR data of **2A** and **2B** with those of MTX, the observed chemical shifts of **2A** clearly match those of MTX (Table 1) more closely. In particular, the δ_C values of C11, C13, and C147 in **2B** deviate from those of MTX by over 1 ppm, while the relevant values of **2A** (C9–C14, C146, and C147) match those of MTX within 0.5 ppm. Furthermore, $^3J_{H,H}$ data of the C7–C9 and C12–C15 portions of **2A** alone correspond well with the those of MTX (Table 2). These results unambiguously establish the configura-

[6] For the phase-sensitive HMBC spectrum, ^{13}C-enriched MTX [2c] (ca. 4%, 9 mg) was used; the spectrum was recorded on a JEOL A-500 spectrometer (500 MHz). The pulse sequence proposed by D. G. Davis was used (*J. Am. Chem. Soc.* **1989**, *111*, 5466–5468). The acquisition data points were 2K (*F2*) vs. 512 (*F1*) and twofold zero-filling was carried out for each dimension to furnish the 2D spectrum with 4K (*F2*) and 1K (*F1*) data points. Digital resolution in the *F2* (^{1}H) dimension was 0.75 Hz.

[7] The major conformer is shown in Figure 1. In the minor conformer, C11 is thought to be *anti* to C14 along the C12–C13 bond, while C12 is *anti* to C147 along the C13–C14 bond.

[8] The HETLOC spectrum was measured with ^{13}C-enriched MTX (9 mg) on a JEOL A-500 spectrometer (500 MHz). The pulse sequence reported by U. Wollborn and D. Leibfritz (*J. Magn. Reson.* **1992**, *98*, 142–146) was used for the experiments. The data dimensions for acquisition and for 2D charts were the same as those for the HMBC spectrum [6].

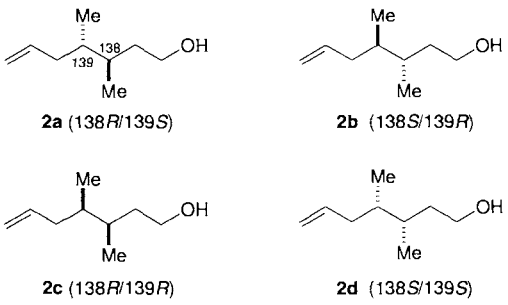
The Complete Structure of Maitotoxin, Part II: Configuration of the C135–C142 Side Chain and Absolute Configuration of the Entire Molecule**

Taro Nonomura, Makoto Sasaki, Nobuaki Matsumori, Michio Murata, Kazuo Tachibana,* and Takeshi Yasumoto

Maitotoxin (MTX, **1**; structural formula given in the preceding communication[1]) is one of the most intriguing natural products with extremely potent biological activity[1,2] and has thus attracted considerable attention. We have thus far succeeded in elucidating the relative configurations of most of the stereogenic carbon atoms in MTX; the assignment of those in the C1–C14 side chain is described in ref. [1]. In this communication we wish to report determination of the absolute configuration of MTX together with the relative configurations in the C135–C142 side chain, which results in completion of the full structural determination.

In a previous study we showed that MTX is cleaved by periodate oxidation into three pieces, the smallest of which is fragment C (3,4-dimethyl-6-hepten-1-ol) with a molecular mass of 142.[2,3] For determining the absolute configuration of this fragment, we decided to synthesize its four possible stereoisomers **2a–d** for comparison by chiral gas chromatography with fragment C obtained from the natural product. Preceding this, the relative configuration of the side chain attachment at C134 was determined with respect to the four stereogenic centers in the side chain (C135, C136, C138, and C139).



As described in the preceding communication,[1] the $^{2,3}J_{C,H}$ coupling constants provide essential information on the configuration of acyclic structures.[1,4] In the same manner the relationship between C136 and C138 could be unambiguously assigned (Fig. 1). A large value for $^3J_{H\text{-}136/H\text{-}137}$ (10 Hz) revealed the antiperiplanar relationship between H-136 and H-137 ($\delta = 1.76$), and a small value for $^2J_{C136/H-137}$ (−1 Hz) indicated 136-OH to take the *anti* position to H-137 ($\delta = 1.25$).[4,5]

[**] This work was supported in part by a Grant-in-Aid from the Ministry of Education, Science, and Culture of Japan, and by the Special Coordination Fund for Promoting Science and Technology from the Science and Technology Agency of Japan. We are grateful to Y. Kumaki and T. Hinomoto of JEOL for NMR measurements, and to Dr. M. Satake, Tohoku University, for preparation of ^{13}C-enriched maitotoxin.

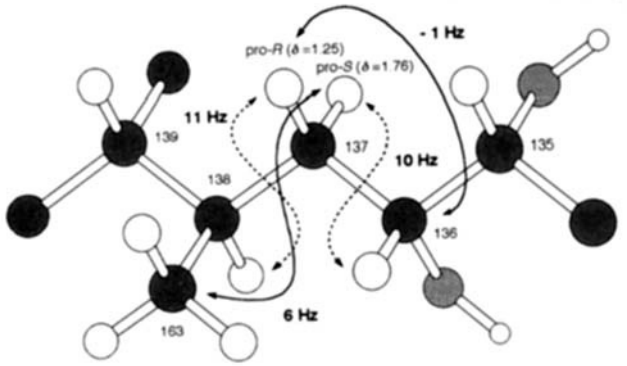

Fig. 1. The configuration and conformation of the C136–C139 portion of MTX deduced from the $^{2,3}J_{C,H}$ and $^{3}J_{H,H}$ couplings (marked with arrows).

These two relationships enabled us to determine the predominant rotational isomer with respect to the C136–C137 bond and thus to assign the prochiral protons on C137, namely, H-137$^{pro\text{-}R}$ at $\delta = 1.25$ and H-137$^{pro\text{-}S}$ at $\delta = 1.76$. We used this assignment and the analogous conformational analysis based on $^{3}J_{H\text{-}137^{pro\text{-}R}/H\text{-}138}$ and $^{3}J_{C163/H\text{-}137^{pro\text{-}S}}$ to identify the dominant rotamer around the C137–C138 bond and thus the relative configurations between C136 and C138 (Fig. 1).

The stereochemical relationships between C134, C135, and C136 were deduced in a similar manner from the results shown in Figure 2. However, NOEs together with the coupling constants $^{3}J_{H\text{-}134/H\text{-}135}$ and $^{3}J_{H\text{-}135/H\text{-}136}$, which deviate from typical values (2–3 Hz) for a *gauche* orientation, suggested that the C134–C136 portion assumes two conformations (Fig. 2), hence

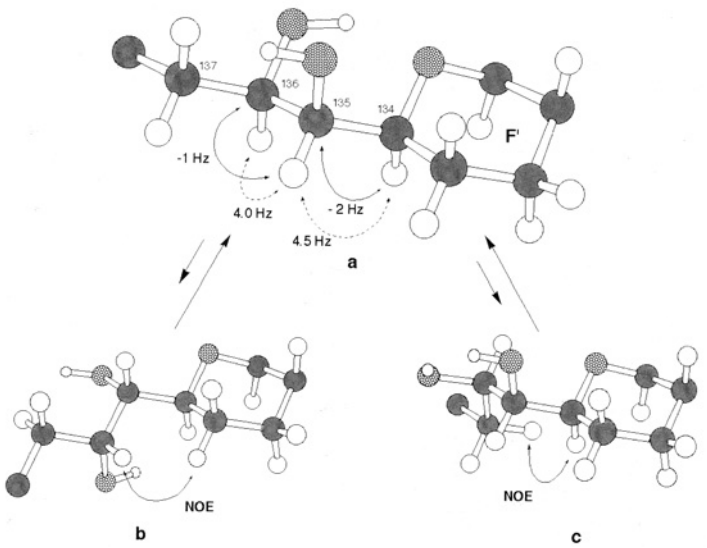

Fig. 2. Conformational changes in the C134–C137 side chain attached to the F' ring of MTX that were suggested by NOEs and $^{3}J_{H,H}$ coupling constants. a) The predominant conformer; b, c) two minor conformers with C–C *gauche* interactions at bonds C134–C135 and C135–C136, respectively.

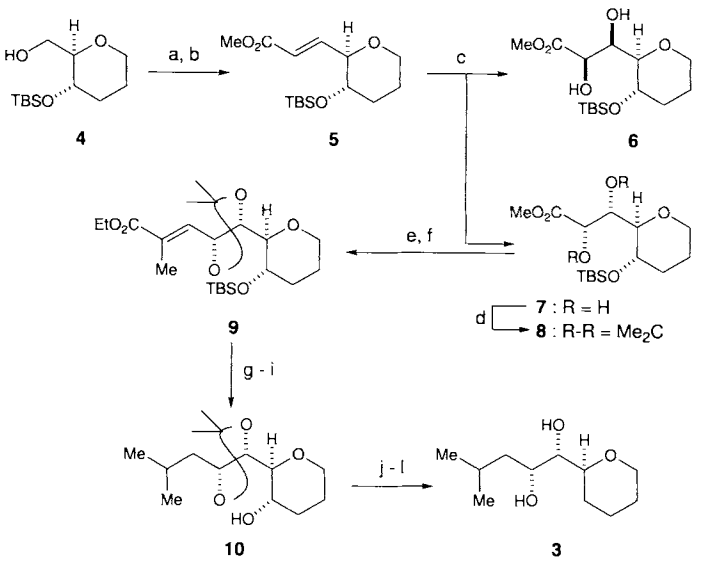
obscuring unequivocal configurational assignment. To remove this ambiguity, we proceeded to synthesize a fragment representing this portion of MTX with the proposed configurations; the $^{2}J_{C,H}$ and $^{3}J_{H,H}$ values of this synthetic fragment would then be compared with those of MTX.

The synthesis of model compound **3** started with the optically active alcohol **4**[6] (Scheme 1), which was oxidized to the aldehyde and subjected to Wittig reaction to give the α,β-unsaturated ester **5**. Asymmetric dihydroxylation of **5** with AD-mix β, which contains 1,4-bis(10,11-dihydro-7-*O*-quinidine)phthalazine as the chiral ligand,[7,8] provided a 6:1 ratio of products in favor of the desired diastereomer **7**, although the intrinsic diastereofacial preferences of **5** and the ligand used were "mismatched". Improved and reversed selectivity was obtained in the same reaction with the use of AD-mix α, containing the pseudo-enantiomeric ligand; diol **6** was then the major product with a diastereoselectivity of >10:1, thereby indicating that the stereoselectivity was controlled by the chirality of the reagent rather than that of **5**. After protection of the mixture of diols as acetonides, pure diastereoisomer **8** was separated by silica gel chromatography. Diisobutylaluminum hydride (DIBAL-H) reduction of **8** followed by Wittig homologation gave the α,β-unsaturated ester **9**, which was converted into alcohol **10** in three steps. Removal of the hydroxyl group in **10** via the phenyl thionocarbonate ester[9] and acid hydrolysis of the acetonide furnished the target compound **3** (Table 1). As shown in Table 2,[10] the $^{2}J_{C,H}$ and $^{3}J_{H,H}$ values of **3** agreed very well with those of MTX, verifying not only the deduced configuration but the presence of two conformers for the C134–C136 portion (Fig. 2).



Scheme 1. Synthesis of model compound **3**. a) SO_3·pyridine, Et_3N, DMSO/CH_2Cl_2 (1/5), 0 °C; b) $Ph_3P{=}CHCO_2Me$, toluene, 80 °C, quant. (two steps); c) AD-mix β, OsO_4 (cat.), $MeSO_2NH_2$, *t*BuOH/H_2O (1/1), RT, 75% (**6**:**7** = 1:6); d) CSA (cat.), $Me_2C(OMe)_2$, CH_2Cl_2, RT, then separation, 46%; e) DIBAL-H, CH_2Cl_2, −78 °C; f) $Ph_3P{=}C(Me)CO_2Et$, toluene, 80 °C, quant. (two steps); g) $LiAlH_4$, THF, 0 °C; h) TBAF, THF; i) H_2, Pd/C, EtOAc/MeOH (1/1), RT, 86% (three steps); j) PhOC(S)Cl, DMAP, pyridine/CH_2Cl_2 (2/1), 50 °C; k) *n*Bu_3SnH, AIBN (cat.), toluene, 80 °C; l) CF_3CO_2H, MeOH, RT, 16% (three steps). DMSO = dimethylsulfoxide, RT = room temperature, CSA = camphorsulfonic acid, DIBAL-H = diisobutylaluminum hydride, TBAF = tetrabutylammonium fluoride, DMAP = 4-dimethylaminopyridine, AIBN = 2,2'-azobisisobutyronitrile.

At this point the only diastereomeric relationship not known in the whole molecule was that between C138 and C139 because the broadened signals of H-138 and H-139 (seven-spin systems) hampered the measurement of $^{3}J_{C,H}$ and $^{3}J_{H,H}$. Therefore, in order to determine this relative configuration and the absolute configuration, the four possible stereoisomers **2a–d** were synthesized.[10] Preparation of the the *anti* isomers **2a** (138*R*/139*S*) and **2b** (138*S*/139*R*) relied on the Sharpless epoxidation, and that of the *syn* isomers **2c** (138*R*/139*R*) and **2d** (138*S*/139*S*) on the enantioselective Diels–Alder reaction. Both asymmetric reactions provided the products with about 90% enantiomeric excess, thereby securing the validity of the absolute configurations of the four isomers.

Table 1. Selected NMR data for compounds **2a**, **2c**, and **3** [a].

2a: ^{1}H NMR (500 MHz): δ = 5.67 (ddt, J = 17, 10, 7 Hz, 1H, H-141 [10]), 4.90 (br. d, J = 17 Hz, 1H, H-142), 4.88 (br. d, J = 10 Hz, 1H, H-142), 3.65 (ddd, J = 11, 8, 5.5 Hz, 1H, H-136), 3.55 (ddd, J = 11, 7.5, 7 Hz, 1H, H-136), 2.00 (m, 1H, H-140), 1.69 (m, 1H, H-140), 1.61 (m, 1H, H-137), 1.53 (m, 1H, H-138), 1.34 (m, 1H, H-139), 1.24 (m, 1H, H-137), 0.75 (d, J = 7 Hz, 3H, H-163), 0.71 (d, J = 7 Hz, 3H, H-164); ^{13}C NMR (125 MHz): δ = 139.1, 115.9, 61.2, 38.7, 38.6, 36.7, 34.5, 17.0, 16.4

2c: ^{1}H NNR (500 MHz): δ = 5.65 (ddt, J = 17, 10, 7 Hz, 1H, H-141 [10]), 4.90 (br. d, J = 17 Hz, 1H, H-142), 4.87 (br. d, J = 10 Hz, 1H, H-142), 3.63 (ddd, J = 10, 7.6, 5.8 Hz, 1H, H-136), 3.57 (dt, J = 10, 6.7 Hz, 1H, H-136), 1.94 (m, 1H, H-140), 1.75 (m, 1H, H-140), 1.62–1.52 (m, 2H, H-138, H-137), 1.42–1.28 (m, 2H, H-139, H-137), 0.68 (d, J = 6.7 Hz, 3H, H-163), 0.66 (d, J = 7 Hz, 3H, H-164); ^{13}C NMR (125 MHz): δ = 139.1, 115.8, 61.0, 40.4, 38.7, 37.8, 33.7, 14.7, 14.6

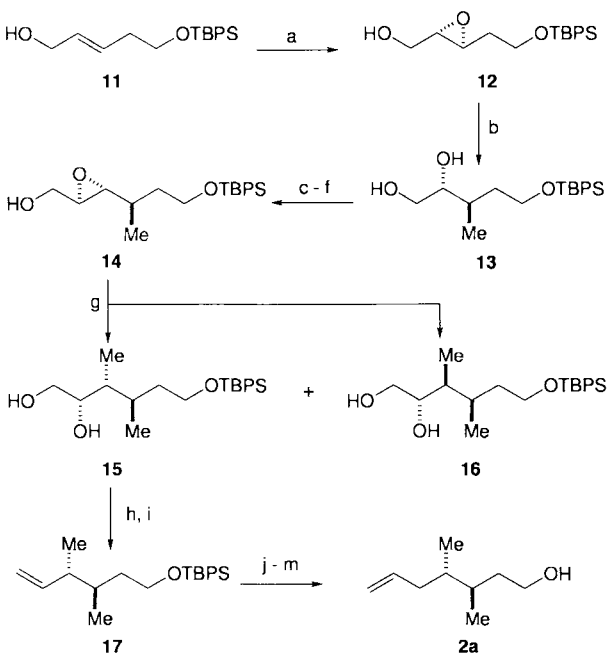
3: ^{1}H NMR (500 MHz): δ = 3.86 (m, 1H, H-130$_{eq}$ [10]), 3.81 (ddd, J = 9.2, 4.0, 3.7 Hz, 1H, H-136), 3.46 (ddd, J = 10.7, 5.2, 2.4 Hz, 1H, H-134), 3.28 (dd, J = 5.2, 3.7 Hz, 1H, H-135), 3.28 (m, 1H, H-130$_{ax}$), 1.83 (m, 1H, H-138), 1.68 (m, 1H, H-132), 1.59 (m, 1H, H-137), 1.56 (m, 1H, H-133), 1.48 (m, 1H, H-133), 1.46–1.26 (m, 4H, H-131, H-132, H-137, H-131), 0.83 (d, J = 6.7 Hz, 6H); ^{13}C NMR (125 MHz): δ = 80.3, 77.6, 70.2, 69.1, 43.7, 28.6, 26.9, 25.3, 24.12, 24.07, 22.4

[a] Recorded in [D_5]pyridine/[D_4]methanol (1/1).

Table 2. Comparison of the $^2J_{C,H}$ and $^3J_{H,H}$ values [Hz] of MTX and fragment **3**.

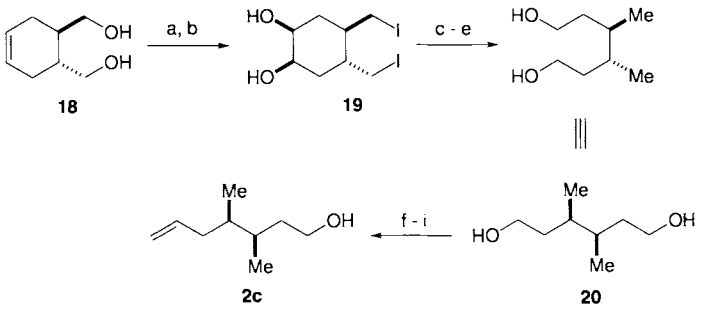
Position	MTX	**3**	Position	MTX	**3**
$^2J_{C134,H-135}$	−1	−1	$^3J_{H-134,H-135}$	5	5
$^2J_{C135,H-134}$	−2	−2	$^3J_{H-135,H-136}$	4	4
$^2J_{C135,H-136}$	0	0	$^3J_{H-136/H-137pro-R}$	3	4
$^2J_{C136,H-135}$	−1	−1	$^3J_{H-136,H-137pro-S}$	10	9

In the synthesis of **2a** (Scheme 2) starting with allylic alcohol **11**,[11] which was readily prepared from 3-butenol, Sharpless asymmetric epoxidation[12] afforded alcohol **12**. Treatment of **12** with trimethylaluminum[13] provided *vic*-diol **13** as a single regioisomer, which was then converted into epoxy alcohol **14** in four-step sequence comprising 1) periodate oxidation, 2) Wittig homologation, 3) DIBAL-H reduction, and 4) Sharpless asymmetric epoxidation. The epoxide ring opening of **14** with trimethylaluminum was expected to proceed regio- and stereoselectively to provide the *syn*-dimethylated isomer **16**. However, an approximately 7:3 mixture of *vic*-diols resulted; the unexpected *anti*-dimethylated isomer **15** predominated as indicated by the alternative synthesis of **16** described later. After purification of the mixture by column chromatography, the major isomer **15**[14] was converted into olefin **17** and thence to the (138*R*,139*S*) isomer **2a** (Table 1) by routine synthetic operations. The enantiomer of **2a** (**2b**) was prepared by the same route except the enantiomeric tartrate was used in the Sharpless epoxidation.



Scheme 2. Synthesis of the (138*R*,139*S*) isomer **2a**. a) *t*BuOOH, Ti(O*i*Pr)$_4$, (+)-diethyl tartrate, CH_2Cl_2, 4 Å molecular sieves, −20 °C, 62%; b) $AlMe_3$, hexane, 0 °C, 97%; c) $NaIO_4$, THF/H_2O (2/1), RT; d) $Ph_3P{=}CHCO_2Me$, benzene, 70 °C; e) DIBAL-H, CH_2Cl_2, −78 °C; f) *t*BuOOH, Ti(O*i*Pr)$_4$, (+)-diethyl tartrate, CH_2Cl_2, 4 Å molecular sieves, −20 °C, 78% (four steps); g) $AlMe_3$, hexane, 0 °C, 69% (**15**:**16** = 7:3); h) $NaIO_4$, THF/H_2O (1/1), RT; i) CH_2I_2, $TiCl_4$, Zn, THF, RT; j) 9-BBN, THF, RT, then 30% H_2O_2, 3 M NaOH, RT; k) SO_3·pyridine, Et_3N, DMSO/CH_2Cl_2 (1/5), 0 °C; l) $Ph_3P^+CH_3Br^-$, LiHMDS, THF, 0 °C, 17% (four steps); m) TBAF, THF, RT. 9-BBN = 9-borabicyclononane. LiHMDS = lithium bis(trimethylsilyl)amide.

To confirm the configurations assigned for **2a** and **2b** unambiguously, the (138*R*,139*R*) isomer **2c** was synthesized by the more established synthetic route (Scheme 3), instead of that originally intended from **16**. The synthesis began with the known optically active diol (−)-**18**, which was prepared by the Diels–Alder reaction of di-(+)-menthyl fumarate with 1,3-butadiene and subsequent lithium aluminum hydride reduction.[15,16] Iodination of **18** followed by catalytic osmylation gave *vic*-diol **19**, which was converted into diol **20** by a three-step sequence: 1) reductive deiodination, 2) oxidative cleavage of the *vic*-diol, and 3) sodium borohydride reduction. Monosilylation of **20**, oxidation to the aldehyde, Wittig methylenation, and desilylation furnished the desired (138*R*,139*R*) isomer **2c** (Table 1). The (138*S*,139*S*) isomer **2d** was synthesized analogously from the (+)-**18**.



Scheme 3. Synthesis of the (138*R*,139*R*) isomer **2c**. a) I_2, Ph_3P, imidazole, benzene, RT, 58%; b) OsO_4 (cat.), NMO, THF/H_2O (2/1), RT, 99%; c) nBu_3SnH, AIBN, toluene, 80 °C, quant.; d) $NaIO_4$, THF/H_2O (2/1), RT; e) $NaBH_4$, MeOH, 0 °C, 83% (two steps); f) *t*BuPh$_2$SiCl, imidazole, DMF, RT, 43%; g) SO_3·pyridine, Et_3N, DMSO/CH_2Cl_2 (1/4), 0 °C; h) $Ph_3P^+CH_3Br^-$, NaHMDS, THF, 0 °C, 90% (two steps); i) TBAF, THF, RT. NMO = 4-methylmorpholine *N*-oxide, DMF = *N*,*N*-dimethylformamide, NaHMDS = sodium bis(trimethylsilyl)amide.

The stereoisomers were separated completely by chiral gas chromatography.[17] Fragment C was prepared from MTX (50 μg) by treatment with $NaIO_4$ and then with $NaBH_4$.[2] The product was extracted with hexane and analyzed by GC-MS under the same conditions.[17] The extract gave a single peak in the gas chromatogram at 13 min 52 s; the retention time and mass spectrum for that peak are identical with those of the (138*R*,139*S*) isomer **2a** (Fig. 3). Thus we successfully determined the absolute configuration of the C135–C142 side chain as 134*S*, 135*S*, 136*R*, 138*R*, and 139*S*, which leads to the complete structure of MTX **1**[18] (Scheme 4; please note that the absolute configuration of **1** is different from that drawn in our previous publications[2,3]).

Diastereoselective C–C Bond Formation with Nonracemic Planar-Chiral η^2-Manganese Complexes**

Dieter Schinzer* and Heiko Bärmann

We report here for the first time the enantioselective preparation of planar-chiral η^2-manganese complexes and their use in diastereoselective C–C bond forming reactions.[1] In the racemic series we have already described diastereoselective alkylations and aldol reactions with η^2-manganese complexes.[2, 3]

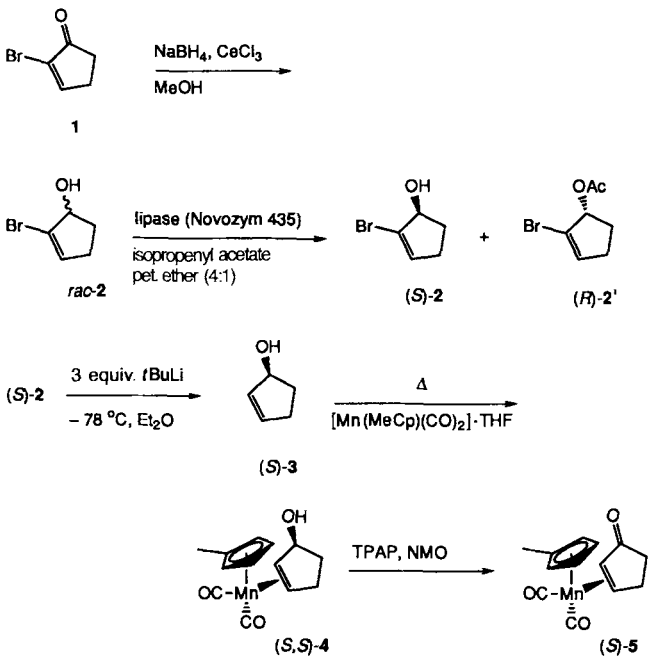
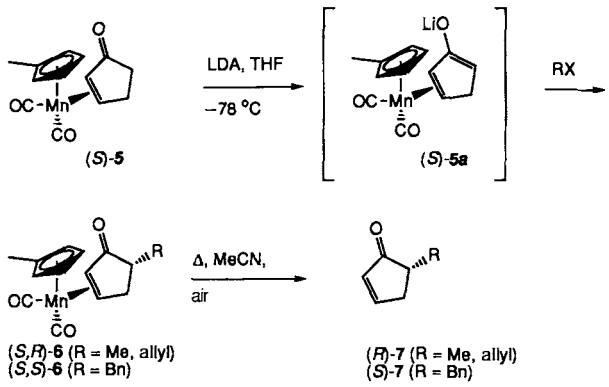
[**] This work was supported by the Deutsche Forschungsgemeinschaft (DFG) and by the Fonds der Chemischen Industrie. We also thank Schering AG, Berlin, for generous gifts of chemicals.

We have now successfully prepared these complexes enantioselectively and also utilized the reactions in the nonracemic (enantiomerically enriched) series. Bromocyclopentenone (**1**) is easily reduced to the racemic cyclopentenol *rac*-**2**,[4, 5] which reacts with an immobilized lipase (Novozym 435, *candida antarctia*) to (*S*)-**2** in 45% yield (94% *ee*) and to the corresponding acetate (*R*)-**2'** in 46% yield (94% *ee*).[6, 7] Conversion of (*S*)-**2** with *tert*-butyllithium produces (*S*)-**3** in 69% yield ($[\alpha]_D^{20} = +29.3$ ($c = 1.1$ in $CHCl_3$)).[8] The (*S*)-cyclopentenol (*S*)-**3** was then treated with the $[Mn(MeCp)(CO)_2]\cdot THF$ complex (formed in situ photochemically) to form the chiral η^2-manganese complex (*S,S*)-**4** ($[\alpha]_D^{20} = +31.0$ ($c = 0.5$ in benzene) by *syn* addition in 25% yield (50% conversion).[2, 3, 9] The oxidation of this material with tetra-*n*-propylammonium perruthenate (TPAP) as catalyst and *N*-methylmorpholine-*N*-oxide (NMO) as oxidant[10] delivered the planar-chiral η^2-manganese complex (*S*)-**5** in 90% yield ($[\alpha]_D^{20} = +78.8$ ($c = 0.5$ in benzene)).[11, 12] This oxidation is remarkable because η^2-manganese fragments are particularly sensitive towards oxidation. With the majority of modern oxidation systems tested in the course of this work, the only product obtained was a manganese dioxide.



The complex (*S*)-**5** can be deprotonated in situ with lithium diisopropylamide (LDA) in THF at $-78\,^{\circ}C$, under conditions of kinetic control, to give the enolate (*S*)-**5a**, which can be transformed diastereoselectively with alkylating agents:[2, 13] the enolate reacts exclusively on the side away from the metal atom (the *exo* side) to give the manganese complex **6**.[13] In all the examples investigated, the 100 MHz ^{13}C NMR spectrum of **6** displayed signals arising from only one diastereomer. This stereochemical result could be unambiguously determined by a crystal structure analysis from the racemic series.[2] The manganese fragment was oxidatively cleaved by warming in acetonitrile in the presence of air. The product was the alkylated α-chiral cyclopentenone **7**, which is not easily accessible by other methods.[14] The *ee* values of **7** were determined by gas chromatography on the chiral stationary phase Lipodex E (Table 1). (*S*)-**7** (R = Ph) was the only example in which enantiomers did not separate; nevertheless, the *ee* value is expected to be at least as high as that for (*R*)-**7** (R = Me, allyl), since also in the 100 MHz ^{13}C NMR spectrum of (*S,S*)-**6** (R = Bn) only one diastereoisomer was detected.



Kinetically controlled aldol reactions can be carried out analogously.[3, 13] Stereoselective aldol reactions are extremely important C–C bondforming reactions. The conversion of cyclic lithium enolates with good diastereoselectivity is particularly difficult.[15] For this reason, we investigated, for the first time, the asymmetric aldol reaction using planar, chiral η^2-manganese complexes. In this case, too, the desired *anti* aldol products **8** are obtained exclusively with a high degree of optical purity. Mild demetalation in acetonitrile in the presence of air affords the *anti* aldol product **9**. The *ee* value of (*S,R*)-**9** (R = Ph) could not be measured by gas chromatography (Lipodex E), even after derivatization to a camphanic acid ester,[16] which yielded elimination products. Nevertheless, one

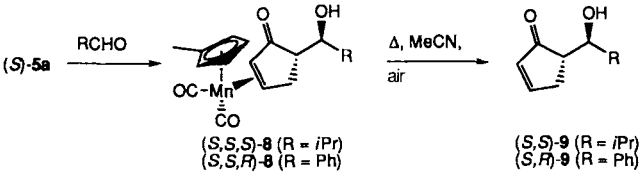


Table 1. Alkylations and aldol reaktions with the planar-chiral manganese complex (*S*)-**5** [a].

Manganese complex	$[\alpha]_D^{20}$ (*c* in benzene)	Yield [%]	Product	$[\alpha]_D^{20}$ (*c* in $CHCl_3$)	*ee* [%]	Yield [%]
(*S,R*)-**6** (R = Me)	−119.8 (1.0)	59	(*R*)-**7** (R = Me)	+41.5 (0.85)	85[b]	44
(*S,S*)-**6** (R = Bn)	−149.4 (0.5)	55	(*S*)-**7** (R = Bn)	+91.0 (0.8)	– [c]	63
(*S,R*)-**6** (R = allyl)	−103.3 (1.0)	41	(*R*)-**7** (R = allyl)	+67.5 (0.8)	85[b]	66
(*S,S,R*)-**8** (R = Ph)	−284.0 (0.5)	52	(*S,R*)-**9** (R = Ph)	−7.98 (1.05)	– [c]	75
(*S,S,S*)-**8** (R = *i*Pr)	−194.4 (1.0)	65	(*S,S*)-**9** (R = *i*Pr)	+7.35 (0.34)	88[b]	75

[a] 94% *ee*. [b] Determined by gas chromatography (baseline separation) with the chiral stationary phase Lipodex E (Macherey-Nagel, Düren). [c] The *ee* value could not be determined. The 100 MHz ^{13}C NMR spectra of (*S,S*)-**6** (R = Bn) and (*S,S,R*)-**8** (R = Ph), however, show signals from only one diastereomer.

can assume that the *ee* value is very high in this reaction, since the 100 MHz ^{13}C NMR spectrum of (*S,S,R*)-**8** (R = Ph) shows signals from only one diastereoisomer.

We can therefore access interesting synthetic building blocks in high optical yield using this new method of asymmetric C–C bond formation. In this way the principle of diastereoselective complexation of a temporarily chirally modified ligand[1] is used for enantioselective preparation of the chiral η^2-enone–manganese complex **5**, from which, after diastereoselective conversion and decomplexation, chiral, nonracemic, synthetically useful products can be obtained. Further investigations are currently underway, which focus predominantly on the use of functionalized alkylating reagents, as well as reactions at the carbonyl group of the planar-chiral enone–metal complex.

Experimental Procedure

(*R*)-**7** (R = allyl): *n*-Butyllithium (515 μL, 0.77 mmol, 1.5 M in hexane) was added dropwise to a solution of diisopropylamine (101 μL, 0.77 mmol) in THF (5 mL) at 0 °C. The resulting solution was stirred for 30 min at 0 °C. This LDA solution was then added dropwise over a period of 10 min to a solution of (*S*)-**5** (150 mg, 0.55 mmol) in THF (5 mL), precooled to −78 °C. After addition, the solution was stirred for 2 h at −78 °C. Finally allyl bromide (67 μL, 0.77 mmol) was added, and the solution allowed to warm to 0 °C over a period of about 12 h. The reaction mixture was concentrated on a rotary evaporator, and the components separated by flash chromatography with diethyl ether as eluent. Yield: 70 mg of (*S,R*)-**6**, yellow powder (41 %). $[\alpha]_D^{20} = -103$ (*c* = 1.0 in benzene); ^1H NMR (400 MHz, C_6D_6): δ = 5.65 (br., 1H), 4.93 (2H), 3.91 (1H), 3.73–3.67 (4H), 3.30 (1H), 2.66–2.52 (2H), 2.21 (1H), 1.98 (1H), 1.78 (1H), 1.24 (s, 3H); ^{13}C NMR (100 MHz, C_6D_6; * = quaternary C, + = CH_2, − = CH, CH_3): δ = 233.6 (*), 232.7 (+), 214.7 (*), 136.6 (−), 116.2 (+), 101.2 (*), 85.3 (−), 85.2 (−), 84.5 (−), 84.2 (−), 67.3 (−), 53.9 (−), 40.8 (−), 34.8 (+), 33.7 (+), 12.1 (−); IR (KBr): $\tilde{\nu}$ = 1965 (s), 1904 (s), 1699 (s), 1457 (w), 1175 (w), 917 (w), 601 (m), 573 (m) cm^{-1}; MS (CI, NH_3): *m/z* (%): 313 (9) [M^+ + H], 256 (4), 140 (44) [NH_4^+ + enone], 123 (100) [enone$^+$ + H].

(*S,R*)-**6** (R = allyl) (62 mg, 0.198 mmol) was dissolved in acetonitrile (5 mL), and the yellow solution heated under reflux for 1 h. It was then allowed to cool, and air was introduced into the flask through a needle for 20 min at room temperature. The brown precipitate that formed was separated by filtration, and the solvent removed on a rotary evaporator. After flash chromatography with pentane/diethyl ether (1/1) as eluent, 16 mg (*R*)-**7** (R = allyl) was obtained in the form of a colorless oil (66 % yield). $[\alpha]_D^{20} = +67.5$ (*c* = 0.8 in $CHCl_3$); 85 % *ee* (GC, Lipodex E); ^1H NMR (400 MHz, $CDCl_3$) : δ = 7.69 (dt, 1H, *J* = 2.6, 5.7 Hz), 6.18 (m, 1H), 5.75 (m, 1H), 5.06 (2H), 2.83 (dm, 1H, *J* = 19.3 Hz), 2.55 (m, 1H), 2.45–2.38 (2H), 2.19–2.11 (1H); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 211.6 (*), 163 (−), 135.2 (−), 133.8 (−), 116.8 (+), 43.9 (−), 35.2 (+), 34.8 (+).

[11] The absolute configuration of (*S*)-**5** was determined by conversion of the aldol product (*S,S*)-**9** to the diastereomeric Mosher esters **a** und **b** and determination of the ^1H NMR shift differences in the spectra of these compounds (I. Ohtain, Kusumi, Y. Kashman, H. Kakisawa, *J. Am. Chem. Soc.* **1991**, *113*, 4092), since we could decide the absolute configuration of (*S,S*)-**9** based on that of (*S*)-**5**. Thus, (*S,S*)-**9** (R = *i*Pr) was treated with (*R*)-(−)-α-methoxy-α-trifluoromethylphenylacetyl chloride to give **a** and with (*S*)-(+)-α-methoxy-α-trifluoromethylphenyl acetyl chloride to give **b**. The ^1H NMR signals were assigned with the H-H COSY experiments. **a**: ^1H NMR (400 MHz, $CDCl_3$): δ = 7.57 (m, 2H; H15, H19), 7.43–7.36 (m, 4H; H3, H16–H18), 6.05 (dt, 1H, *J* = 2.1, 5.8 Hz; H2), 5.16 (dd, 1H, *J* = 8.3, 3.9 Hz; H6), 3.52 (d, 3H, *J* = 1.2 Hz; H13), 2.81–2.77 (m, 1H; H5), 2.74–2.66 (dm, 1H, *J* = 19.1 Hz; H4), 2.42–2.33 (m, 2H; H4′, H7), 0.95 (d, 3H, *J* = 6.8 Hz; H8/9), 0.88 (d, 3H, *J* = 6.8 Hz; H8/9); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 207.3 (*; C1), 166.5 (*; C10), 162.6 (−; C3), 134.4 (−); C2), 131.7 (*; C11/14), 131.6 (*; C11/14), 129.6 (−), 128.4 (−), 127.6 (−) (C15–C19), 122 (*; C12), 81.6 (−; C6), 55.5 (−; C13), 45.3 (−; C5), 32.8 (+; C4), 29.6 (−; C7), 19.5 (−; C8/9), 18.8 (−; C8/9). **b**: ^1H NMR (400 MHz, $CDCl_3$): δ = 7.56 (m, 2H; H15, H19), 7.41–7.36 (m, 4H; H3, H16–H18), 6.12 (dt, 1H, *J* = 2.0, 5.9 Hz; H2), 5.18 (dd, 1H, *J* = 8.3, 3.7 Hz; H6), 3.49 (d, 3H, *J* = 1.0 Hz; H13), 2.84–2.76 (m, 2H; H4, H5), 2.53–2.47 (m, 1H; H4′), 2.41–2.32 (m, 1H; H7), 0.91 (d, 3H, *J* = 6.8 Hz; H8/9), 0.81 (d, 3H, *J* = 6.9 Hz; H8/9); ^{13}C NMR (100 MHz, $CDCl_3$): δ = 207.2 (*; C1), 166.4 (*; C10), 162.6 (−; C3), 134.4 (−; C2), 131.7 (*; C11/14), 131.6 (*; C11/14), 129.5 (−), 128.3 (−), 127.6 (−) (C15–C19), 122 (*; C12), 81.4 (−; C6), 55.3 (−; C13), 45.4 (−; C5), 32.8 (+; C4), 29.5 (−; C7), 19.4 (−; C8/9), 18.5 (−; C8/9); shift differences: $\delta_S - \delta_R = \delta$(**b**) − δ(**a**): 0.07 (H2), 0.1 (H4), 0.11 (H4′), 0.03 (H5), −0.04 (H8/9), −0.07 (H8/9).

Absolute Configurations of the Inhalation Anesthetics Isoflurane and Desflurane

Volker Schurig,* Markus Juza, Bernard S. Green, Jörg Horakh, and Arndt Simon*

The chiral inhalation anesthetics isoflurane (2-chloro-2-(difluoromethoxy)-1,1,1-trifluoro-ethane, **1**) and desflurane (2-(difluoromethoxy)-1,1,1,2-tetrafluoroethane, **2**) are clinically administered as synthetic racemic mixtures, although the stereoselective interaction of pure isoflurane enantiomers with neuronal ion channels implies the role of proteins of the central nervous system for anesthetic action.[1, 2] In the patent literature, both the (*R*) and (*S*) enantiomers of **1** and **2** (*ee* ≥ 80 %) are astoundingly claimed to be associated with less adverse effects than the racemic mixtures.[3, 4] Both documents fail to identify the enantiomers by their sign of optical rotation.[3, 4] According to another patent, (+)-**2** possesses more favorable pharmacological properties than the (−)-enantiomer or the racemate.[5] The knowledge of the absolute configurations of the commercially important haloethers **1** and **2** is therefore of general interest.

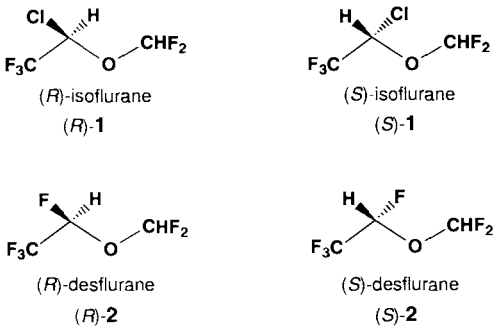
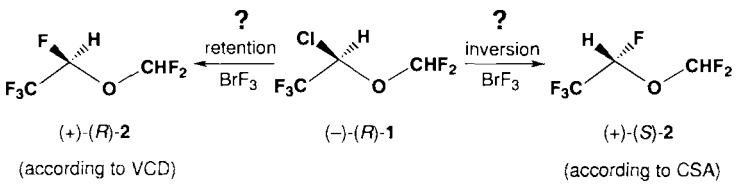
[**] V.S. thanks the Deutsche Forschungsgemeinschaft and the Fonds der Chemischen Industrie for support of this work. V. S. and B. S. G. thank The Institute of Advanced Studies at the Hebrew University, Jerusalem, for providing research facilities. We thank Professor I. Agranat and Dipl-Chem. U. Biedermann, Jerusalem, for valuable discussions and Mr. G. J. Nicholson and Mr. E. Braun, Tübingen, for assistence in the maintainance of the preparative gas chromatograph (Model APG 402, Hupe).

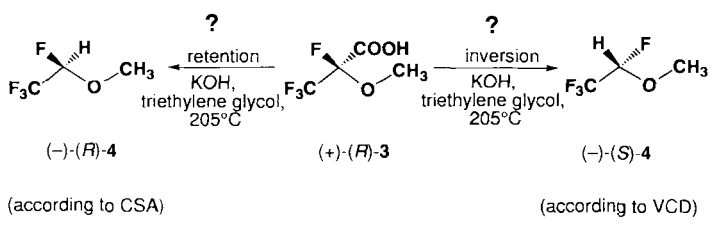


Polavarapu et al. determined the absolute configurations of **1** and **2** by vibrational circular dichroism (VCD) in the infrared region between 1400–700 cm^{-1}. Firstly, the conformations of the haloethers **1** and **2** were optimized by ab initio calculations, and afterwards the vibrational frequencies and circular dichroism intensities of the two lowest energy conformers were calculated. The theoretical spectra were then presented as the sum of the spectra of the conformers and compared with the experimental VCD spectra of the pure enantiomers of **1** and **2**. Polavarapu et al. assigned the (*S*)-configuration to dextrorotatory isoflurane, (+)-(*S*)-**1** (VCD),[6], and the (*R*)-configuration to dextrorotatory desflurane, (+)-(*R*)-**2** (VCD).[7] Although for **1** and **2** a conformer equilibrium of 80:20 and 85:15, respectively, had been calculated, a 50:50 conformer population was used for a better fit between the theoretical and experimental spectra.



Moreover, the experimental spectra were not recorded in the gas phase but in solution (**1** in CS_2, **2** in $CDCl_3$). Isomer (+)-**2** was synthesized from (−)-**1** with the expected inversion of configuration (Walden inversion) on substituting chlorine with fluorine by using BrF_3 in the solvent Br_2.[5] In light of the absolute configuration assignment by VCD, this substitution was later reinterpreted as proceeding with retention of configuration.[8]

In this journal, the decarboxylation of (+)-(*R*)-1-methoxytetrafluoropropanoic acid [(+)-(*R*)-**3**] to (−)-(*S*)-1,2,2,2,-tetrafluoroethyl methyl ether [(−)-(*s*)-**4**] was proposed to proceed



with complete inversion of configuration. The surprising stereochemical course of this reaction was based exclusively on the VCD assignment of the subsequent product desflurane as (−)-(*S*)-**2** (VCD).[9, 10]

Based on the absolute configuration assigned by VCD, the gas chromatographic elution order of the enantiomers of **1** (and two congeners) on several cyclodextrin derivatives was given as (*S*) before (*R*) while that of the enantiomers of **2** (and two congeners) was given as (*R*) before (*S*) (Table 6 in Ref. [11]). In addition, based on the absolute configuration assigned by VCD, the NMR-spectroscopic low-field shift of the proton signals of the enantiomers of **1** (and two congeners) in the presence of several cyclodextrin derivatives was greater for (*R*) than for (*S*), whereas that of the enantiomers of **2** (and two congeners) was reversed ((*S*)>(*R*), Table 6 in Ref. [11]).

The pure enantiomers of **1** and **2** can be isolated by preparative gas chromatography on two γ-cyclodextrin derivatives;[12, 13] the dextrorotatory enantiomers are always eluted first and the levorotatory enantiomers second.[12] From thermodynamic measurements it was concluded that the enantiomers of **1** and **2** with identical absolute configuration and differing only in the haloatom at the stereogenic center, possess the same sign of optical rotation and the same elution order in contrast to the chiroptical assignment (VCD).[12]

Determining the absolute configuration of **2** by anomalous dispersion of X-rays was considered impossible because the highly volatile ether was suspected to be noncrystallizable,[7] and indeed, it failed for the less volatile **1**.[2] In the present work the dextrorotatory (sodium D line) enantiomers of isoflurane, (+)-**1**, and desflurane, (+)-**2**, each obtained by preparative gas chromatography as the first fraction,[12] were investigated with X-ray crystallography. From both compounds single crystals could be grown, which were suitable for the crystal structure analysis (CSA) at −180 °C.

As seen in Figure 1 both dextrorotatory enantiomers possess the (*S*)-configuration.[16] Thus, the chiroptical assignment of dextrorotatory isoflurane as (+)-(*S*)-**1** (VCD) is confirmed,

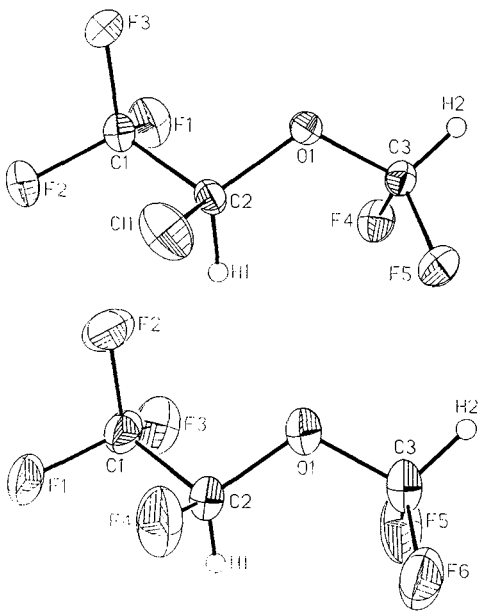


Fig. 1. Molecular structure of (+)-(*S*)-**1** (top) and (+)-(*S*)-**2** (bottom) at −180 °C; displacement ellipsoids for 50% probability; the size of the hydrogen atoms is arbitrary.

while the chiroptical assignment of dextrorotatory desflurane as (+)-(*R*)-**2** (VCD) must be revised as (+)-(*S*)-**2** (CSA). Due to the absence of heavy atoms and the low anomalous diffraction difference of the atoms hydrogen and fluorine at the stereogenic center, the determination of the absolute configuration for **2** is somewhat ambiguous. Yet, the Flack-parameter[17] of **2**[16] supports the (+)-(*S*) configuration. This result is in agreement with the following conclusions:

- Enantiomers of **1** and **2** with the same sign of optical rotation possess identical absolute configurations.
- Enantiomers of **1** and **2** with identical absolute configurations exhibit the same gas-chromatographic elution order (*S*) before (*R*) on γ-cyclodextrin derivatives (derived from D-glucose).[12]
- Enantiomers of **1** and **2** with identical absolute configurations exhibit the same NMR-spectroscopic, low-field shift of the proton resonances [(*R*)>(*S*)] on γ-cyclodextrin derivatives (derived from D-glucose).[18]
- Enantiomers of **1** and **2** are transformed into each other with inversion of configuration (Walden inversion) by halogen exchange (e.g., BrF_3 in the solvent Br_2).[5]
- (+)-(*R*)-1-Methoxytetrafluoropropanoic acid (**3**) is transformed into (−)-1,2,2,2,-tetrafluoroethyl methyl ether (**4**) with retention of configuration, and the ether possesses the (*R*) and not the (*S*) configuration.[9, 10]

The revised assignment of the absolute configuration of **2** (and of congeners[11]) has consequences for the CAS-numbering, patent literature, and the stereochemical course of reactions.[8–11]

Experimental Procedure

The sign of the optical rotation of **1** and **2** is based on the sodium D line at 20 °C (at other wavelengths no change of the sign of optical rotation was observed).

a) *Preparative enantiomer separations:* (+)-**1** (*ee*>99.9%) and (+)-**2** (*ee*=80.8%) were obtained by preparative gas chromatography on octakis (3-*O*-butanoyl-2,6-di-*O*-*n*-pentyl)-γ-cyclodextrin [15] dissolved in the polysiloxane SE-54 [12]. The enantiomers were checked before crystal sample preparation by analytical enantioselective gas chromatography for enantiomeric purity and elution order to preclude fortuitous errors.

b) *Crystal sample preparation:* An X-ray-capillary (0.2 mm diameter) was filled to a length of 1 cm by dipping its open end into the liquid. The sample was kept cold on a dry-ice block, and the capillary was sealed on both sides. Investigations with the modified Guinier technique [14] did not show any evidence of a phase transition, in the case of (+)-**2** between −185 °C and the melting point at −126 °C. (+)-**1** could not be investigated with the Guinier camera because of delayed crystallization accompanied by the destruction of the capillary.

c) *Crystal growth:* Single crystals of (+)-**1** and (+)-**2** were grown in situ on a Syntex $P2_1$ four-circle diffractometer. After cooling to a temperature below −110 °C (+)-**1** crystallized as a colorless powder. Annealing for several hours 1–2 °C below the melting point at −98 °C resulted in larger crystallites. While the temperature was carefully increased in steps of 0.1–0.2 °C, the extensive melting of a crystallite could be monitored by the decrease of a strong reflection to 1/20 of the original value of its intensity. After repeated cycles of partial melting and slow cooling, rotation and oscillation photographs showed the formation of a suitable single crystal, which could be cooled for X-ray analysis down to −180 °C without undergoing a phase transition. The growth of a single crystal of (+)-**2** was succesful by the method described above for (+)-**1** at a correspondingly lower temperature. The melting point of a (+)-**2** sample, considered to be enantiomerically pure, was −126 °C.

Influence of Anchor Lipids on the Homogeneity and Mobility of Lipid Bilayers on Thin Polymer Films

Dierk Beyer, Gunther Elender, Wolfgang Knoll, Martin Kühner, Steffen Maus, Helmut Ringsdorf,* and Erich Sackmann

Supported phospholipid bilayers were first described by McConnell et al.[1] and are supposed to be ideal systems for investigations on incorporated membrane proteins and are expected to form the basis for future biosensors.[2] They allow application of a variety of methods for the investigation of biomembranes that are restricted to planar surfaces,[3] which are generally not applicable for known model membranes.

A variety of techniques such as vesicle fusion, Langmuir–Blodgett transfer, and self-assembly can be applied on very different surfaces to establish planar model membranes.[4–9] Nevertheless, such systems are not ideally suited for investigations on membrane-spanning proteins,[1, 10, 11] because their mobility is limited due to friction with the substrate,[12, 13] which ultimately disturbs the conformation and therefore the function of the protein.[14]

Thus, an insulating barrier is required between the lipid bilayer and the substrate. This cushion layer may be achieved by using a water-swellable thin polymer layer (whose function is comparable to that of the cytoskeleton of the cell), which is covalently linked to the substrate, upon which the lipid bilayer is deposited.[15] A representation of a model biomembrane based on a polymer-supported lipid bilayer is presented in Figure 1.

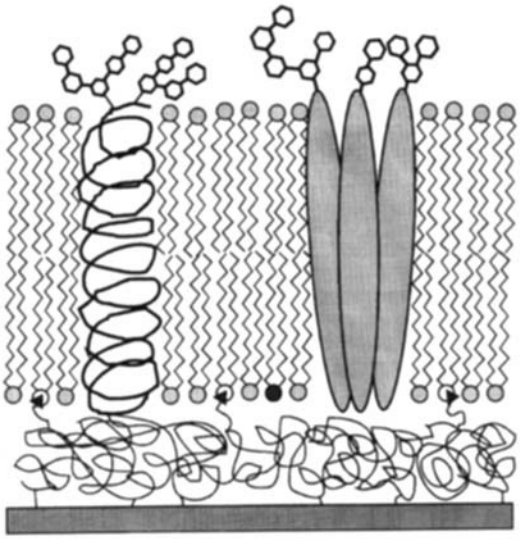

Fig. 1. Representation of a polymer-supported biomembrane (tethered supported bilayer) with membrane-spanning proteins.

The realization of such model systems still poses problems. It is still difficult to obtain homogeneous and fluid bilayers on polymer films that display long-term stability. In this communication we present an approach for covalently attaching homogeneous fluid lipid bilayers, which are stable for several days, on hydrophilic polymer films covalently attached to the substrate.

Glass slides were first functionalized with 4-aminobutyl(methoxy)dimethylsilane. Then, the alternating reactive copolymer **1** (Fig. 2), prepared from maleic acid anhydride and 1-methyl-vinylisocyanate, (poly[(1-methylvinylisocyanate)-*alt*-(maleic acid anhydride)]),[16] was chemisorbed from a solution in CH_2Cl_2/DMF.

The FTIR spectrum[17] of this reactive polymer layer is presented in Figure 2a. The bands of both the isocyanate (2272 cm^{-1}) and the anhydride (1858, 1791 cm^{-1}) remain clearly visible after reaction of the polymer on the substrate. Due to the excess of the reactive functionalities, the surface of this layer

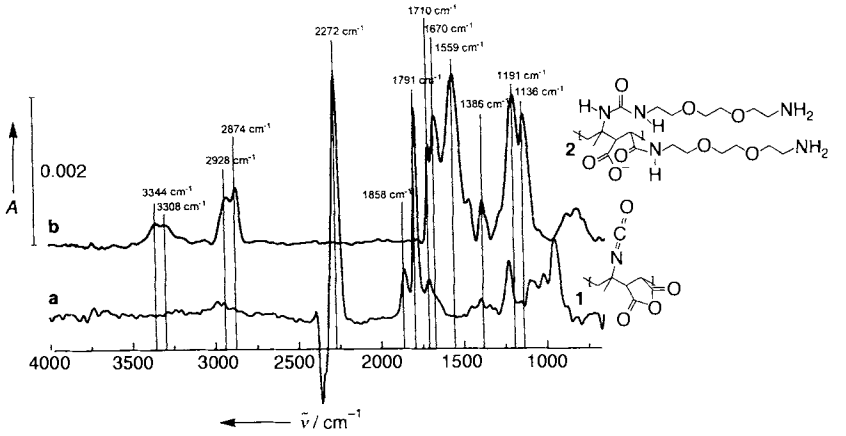

Fig. 2. FTIR spectra of the layer of reactive polymer **1** on an aminosilananized SiO_2 surface before (a) and after (b) reaction with the α,ω-diamine **3** to give **2**. A = absorbance [arbitrary units].

can be further derivatized. Reaction with an excess of α,ω-diamines such as **3** produces a polymer layer (**2**) containing

$H_2N(CH_2)_2O(CH_2)_2O(CH_2)_2NH_2$ **3**

containing hydrophilic amino groups (black triangles in Fig. 3). This layer remains stable even to extensive rinsing with CH_2Cl_2, methanol, and water. Figure 2b shows the FTIR spectrum of this amino group containing layer, which has a thickness of 81 ± 5 Å.[18, 19] The spectrum shows a strong C–O stretching vibration at 1136 cm^{-1}, as well as urea and amide bands at 1670, 1710, and 1559 cm^{-1}, which arise from the reaction of the reactive polymer layer with the α,ω-diamine. Furthermore, N–H stretching vibrations at 3344 and 3308 cm^{-1}, as well as a H–CHO alkyl stretching vibration at 2874 cm^{-1} is observed. The contact angles of layer of polymer **2** have the values $\theta_a = 15°$, $\theta_r = 10°$, whereas the contact angle of the original silanized glass slide has a value of $\theta_a = 63°$, $\theta_r = 45°$, indicating that the polymer surface formed is more hydrophilic than the hydrophobic precursor silane layer.[20]

The Langmuir–Blodgett technique was used to transfer the first lipid monolayer onto this polymer layer on the substrate. The second, outer lipid layer was deposited by dipping the substrate horizontally through a prespread monolayer of pure dimyristoylphosphatidylcholine (DMPC, **4**) on the film balance (the Langmuir–Schaefer technique). The preparation of this lipid layer system is shown schematically in Figure 3.

The composition of the lipid monolayer directly on the polymer substrate is a crucial parameter in our examination of the properties of the bilayer. In addition to the system in which pure DMPC forms the first lipid monolayer, systems with 20 mol% myristidic acid in DMPC, and 20 mol% *N*-succinimidomyristidic ester (**5**), a covalently linked anchor lipid reactive towards amino groups, in DMPC were prepared (Fig. 3). The additional incorporation of 0.8 mol% of the fluorescent lipid 7-nitrobenzo-2-oxa-1,3-diazol-dimyristoylphosphatidylethanolamine (NBD-DMPE, **6**) allowed investigation of the lipid bilayers by fluorescence microscopy.

To investigate the influence of these additional anchor lipids on the homogeneity and mobility of these "tethered, supported dilayers", three types of lipid bilayers with different compositions were prepared; their fluorescence images are displayed in Figure 4. As a reference a lipid bilayer made of pure DMPC with 0.8 mol% NBD-DMPE in the monolayer facing the substrate was prepared (Fig. 4 top). The fluorescence image record-

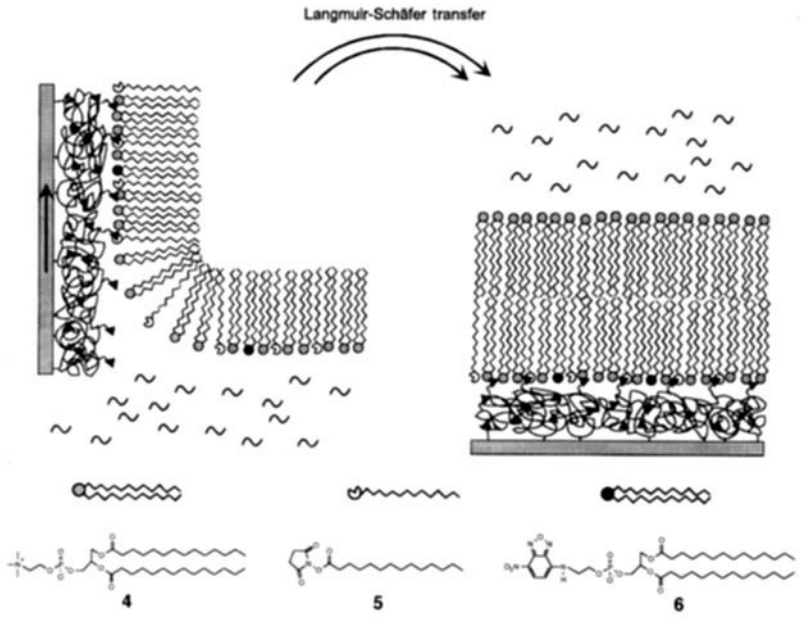

Fig. 3. Representation of the buildup of the bilayer by application of the Langmuir–Blodgett and the Langmuir–Schäfer techniques; NBD-DMPE (**6**, lipids with black headgroups), DMPC (**4**, lipids with shaded headgroups), anchor lipid (**5**, with white headgroups). Black triangles symbolize amino groups.

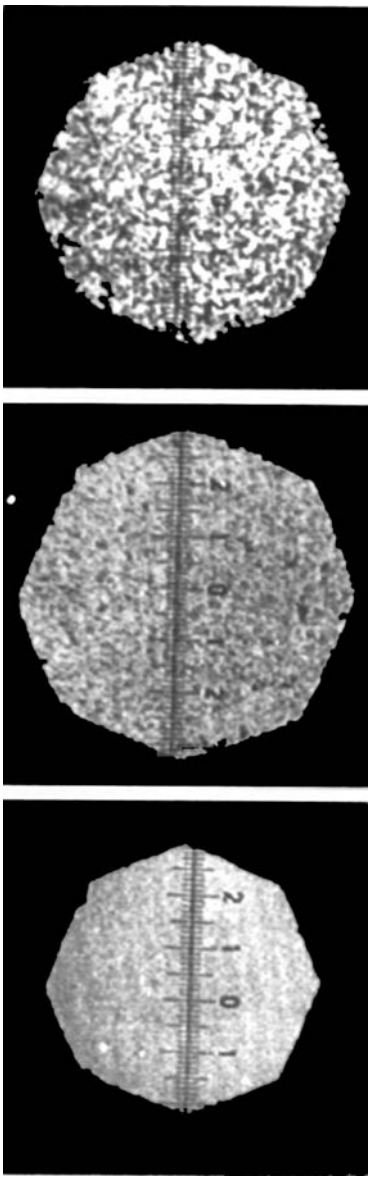

Fig. 4. Top: Fluorescence microscopy image of a lipid bilayer consisting of pure DMPC **4** without incorporation of anchor lipid into the monolayer facing the substrate. Middle: Fluorescence microscopy image of a lipid bilayer consisting of DMPC **4** with incorporation of 20 mol% myristidic acid into the monolayer facing the substrate. Bottom: Fluorescence microscopy image of a lipid bilayer consisting of DMPC **4** with incorporation of 20 mol% anchor lipid **5** into the monolayer facing the substrate. Distance between numbered lines: 13 μm, $T = 25\,^{\circ}C$.

ed directly after preparation shows a strongly inhomogeneous lipid bilayer on the polymer "cushion", as concluded from the very inhomogeneous and grainy texture. A fluorescence image of the same lipid bilayer after 24 h shows further enlargement of the inhomogeneous areas.

The incorporation of 20 mol% myristidic acid into the lipid monolayer facing the substrate leads to a bilayer displaying a more homogeneous fluorescence image (Fig. 4 middle). The homogeneity of this bilayer is significantly improved and holes appear much less frequently. This effect may be due to an ionic interaction between the myristidic acid and its anion and the partially protonated amino groups of the polymer substrate, leading to a loose attachment of the lipids on the polymer layer.

The incorporation of 20 mol% *N*-succinimidomyristidic ester (**5**) instead of the pure myristidic acid into the monolayer facing the substrate obviously leads to the covalent attachment of some of the lipids and results in a homogeneous fluorescence image (Fig. 4 bottom) without noticeable aggregation or phase separation of the lipids in the bilayer. The fluorescence image of this tethered, supported bilayer was checked over several days and did not exhibit any changes in the bilayer.

Measurements on the lateral diffusion of the fluorescence dye **6** in the monolayer of the lipid membrane facing the substrate were performed using the FRAP technique (FRAP = fluorescence recovery after photobleaching)[21] at a temperature of 25 °C. These measurements show the dependence of the diffusion constant of the dye-labeled lipid **6** upon incorporation of anchor lipid into the bilayer. A series of bilayers of different compositions was investigated. For a polymer-supported lipid bilayer of DMPC without incorporated anchor lipids or myristidic acid, a diffusion constant of $3.12 \pm 0.3\ \mu m^2 s^{-1}$ was established.[22] The value observed after incorporation of 20 mol% myristidic acid (ionic attachment) is significantly lower ($2.4 \pm 0.3\ \mu m^2 s^{-1}$). The diffusion constant of an analogously prepared lipid bilayer with the incorporation of 20 mol% anchor lipid **5** is considerably lower ($1.3 \pm 0.06\ \mu m^2 s^{-1}$) than that recorded for pure DMPC. A double layer of pure DMPC on a hydrophilic and not polymer-coated glass substrate shows a diffusion constant of roughly $4 \pm 0.3\ \mu m^2 s^{-1}$.[11, 21]

These differences in the diffusion constants are a further indication of the covalent attachment of some of the anchor lipids to the polymer film on the glass substrate. This covalent attachment forces the dye molecules to "diffuse around" the bound lipids and lowers the macroscopic diffusion constant as established by means of FRAP even further than would be achieved by the incorporation of just the myristidic acid, which is not able to form any covalent attachment with the polymer layer. The bilayer remains fluid but at the same time exhibits improved homogeneity.

The approach described here allows the preparation of homogeneous, lipid bilayers that are fluid and stable on solid substrates over several days as observed by fluorescence microscopy. Such anchored lipid bilayers (tethered supported bilayers) should, owing to the "decoupling" of the lipid bilayer from the substrate, be more suitable for the investigation of membrane proteins. Possible interactions with the substrate, which disturb the conformation and function of the protein,[14] should be reduced due to the water-swellable polymer film.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3515-1684 $ 15.00+.25/0

Experimental Procedure

The reactive polymer **1** was prepared according to the procedure of Mormnn et al. [16].

Synthesis of anchor lipid **5**: Myristidic acid (5.6 g, 24.5 mmol) and *N*-hydroxysuccinimide (3.52 g, 30.7 mmol) were dissolved in a mixture of chloroform/acetone (180 mL, volume ratio 9:1) at room temperature, and a small amount of 4-dimethylaminopyridine (DMAP) was added as catalyst. Argon was bubbled through the solution, which was then cooled to 0 °C. A solution of dicyclohexylcarbodiimide (3.09 g, 15 mmol) in chloroform (10 mL) was added slowly to the reaction mixture. The resulting solution was stirred for an additional hour at 0 °C and then for 24 h at room temperature. The precipitate formed was then filtered off and and washed with chloroform. The filtrate was concentrated to dryness in vacuo and the residue recrystallized from petroleum ether. Afterwards the crude product was purified by flash chromatography on neutral Al_2O_3 with chloroform as eluent to provide 6.6 g (82%) of the lipid. M.p. 80.5 °C; ^{1}H NMR (200 MHz, $CDCl_3$, 20 °C): $\delta = 2.85$ (s, 4H; $OCCH_2CH_2CO$), 2.58 (t, 2H; OCH_2CH_2), 1.71 (m, 2H; $OCH_2CH_2CH_2$), 1.24 (m, 20H; $(CH_2)_{10}$), 0.85 (t, 3H; CH_3).

Adsorption and reaction of the polymer: The cleaned and silanized substrate was placed in a 2.2×10^{-3} M solution of the reactive polymer **1** dissolved in DMF/CH_2Cl_2 (1:9) for 12 h. Afterwards the slides were rinsed with DMF/CH_2Cl_2 (1:9) and then placed into a 0.5 M solution of α,ω-diamine **3** in CH_2Cl_2 for 12 h. Subsequently the slides were rinsed three times each with CH_2Cl_2, methanol, water, and again methanol. The slides were then dried in vacuum.

Transfer of the lipid bilayers: The bilayers were prepared using the Langmuir–Blodgett and the Langmuir–Schäfer techniques at 25 °C and at a lateral pressure of 30 mN m^{-1} on a film balance (constructed in our institute). In all cases a complete transfer was observed. The second lipid layer was prepared by pressing the substrate with the first monolayer horizontally through a monolayer of pure DMPC compressed at 30 m Nm^{-1} onto a hollow-dip microscope slide.

$La_9Br_5(CBC)_3$: A New Superconductor**

Hansjürgen Mattausch, Arndt Simon,* Claudia Felser, and Richard Dronskowski

Dedicated to Professor Hanskarl Müller-Buschbaum on the occasion of his 65th birthday

The superconducting carbide halides $M_2X_2C_2$ of the nonmagnetic rare earth metals (M) constitute model systems which illustrate the hypothesis[1, 2] that superconductivity originates from the tendency of a pairwise localization of conduction electrons.[3, 4] In these materials, an attractive interaction between the conduction electrons is attributed to the presence of pseudomolecular C_2-π^* levels at the Fermi edge E_F. Band structure calculations[4] for $Y_2Br_2C_2$ reveal a very flat band (localization) at E_F with a significant C_2-π^* contribution, which corresponds to a maximized density of states at E_F, as well as other bands with a large slope at the Fermi edge (delocalization). This characteristic feature in the band structure may serve as a "fingerprint" in the search of new superconductors.

In the course of new investigations on quaternary compounds with Ln, B, C, and X (X = Cl, Br, I),[5] $Ce_3Br_3(BC)$[6] and $Ce_9Br_5(CBC)_3$ were obtained for the first time. The phases form as air-sensitive, rod-shaped, metallic bronze crystals after heating the corresponding mixtures of $CeBr_3$, Ce, B, and C in sealed tantalum capsules for several days.[7] The structure of $Ce_9Br_5(CBC)_3$,[9] obtained from a single-crystal study, is given as a projection along [010] in Figure 1.[11] The B atoms are surrounded by a trigonal prism of Ce atoms, while the coordination of the C atoms almost resembles a quadratic pyramid. A single prism and two pyramids constitute the central building block (highlighted in ref. [5]) that contains the pseudomolecular C-B-C unit in its interior. Such blocks are connected parallel (100) to give corrugated sheets and these are bonded to each other by Br atoms.[12] The B–C distances (151 pm) are identical within 1σ (2 pm) in both crystallographically different C-B-C

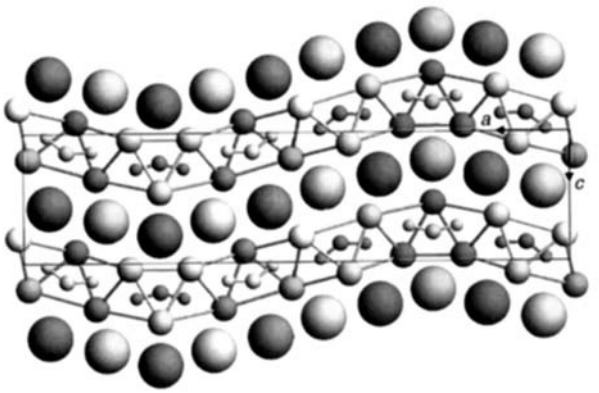

Fig. 1. Projection of the structure of $Ln_9Br_5(CBC)_3$ along [010]. Trigonal prismatic units around the B atoms, which are merged on both sides with tetragonal pyramids around the C atoms, are condensed into layers. Br atoms are found in the remaining void. Br, Ln, B, and C atoms are drawn as circles of decreasing sizes.

groups. Furthermore, the C-B-C angles are 141(3)° for C3-B1-C3 and 151(3)° for C2-B2-C2. The compound is a metallic conductor, and its specific resistance[15] is almost temperature-independent above 50 K (about 120 mΩcm).

The chemical bonding in $Ce_9Br_5(CBC)_3$ can be considered as $(Ce^{3+})_9(Br^-)_5(CBC^{7-})_3 \cdot e^-$ according to the Zintl–Klemm concept, which indicates that the CBC^{7-} ions are formally isovalence electronic with molecular SO_2. Semiempirical band structure calculations and COOP (*c*rystal *o*rbital *o*verlap *p*opulation) analyses[13] show that the excess electrons occupy bands with Ce–Ce bonding character at the Fermi edge. There is a sharp maximum in the density of states at E_F, and the COOP analysis reveals, besides the already mentioned Ce–Ce bonds, strongly bonding Ce–B, weakly bonding Ce–Ce, and antibonding B–C interactions. Thus, the characteristic "fingerprint" known from the superconducting carbide halides is present. The experiments that were performed were successful in two respects. First, the isotypical compound containing the nonmagnetic La^{3+} ion could be synthesized. This compound showed the same band structure characteristics as the Ce compound, despite having different lattice constants and atomic energy levels. Second, $La_9Br_5(CBC)_3$ exhibits superconductivity at 6 K, as supported by the appearance of diamagnetic shielding (Fig. 2)[14] and vanishing electrical resistance[15] (Fig. 2, insert).

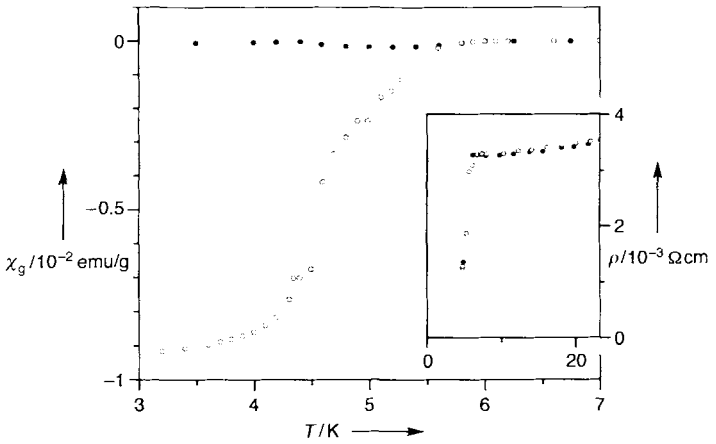

Fig. 2. Diamagnetic screening (open circles) and Meissner effect (filled circles) of $La_9Br_5(CBC)_3$ as a function of the temperature. The insert shows the electrical resistance as a function of the temperature (open circles: heating curve, filled circles: cooling curve).

The calculation of the electronic band structure[16] of $La_9Br_5(CBC)_3$ with density functional theory reveals a local maximum in the density of states at E_F. The k dependence of the bands (Fig. 3) shows that this maximum essentially arises from a flat band (van Hove singularity) with its center of gravity at the Fermi edge.

The bands' orbital character has been represented with the "fat band" technique, in which the width of the bands are drawn such as to reflect the weight of the contributing orbital. To do so, the internal coordinate system was set up such that the C-B-C unit points into the approximate x direction. The "fat band" representation confirms that the flat band at E_F arises from the covalent mixing of BC_2-centered MOs with approximate π^* symmetry and La-$d_{xz,yz}$ atomic levels. At the same time, there are bands of predominantly La-$d_{x^2-y^2}$ character at E_F, having a large absolute slope.[18] Despite the chemical and structural differences of the compounds $Y_2Br_2C_2$[4] and $La_9Br_5(CBC)_3$, their electronic structures strongly resemble each other with respect to the bands' characteristic course at E_F.

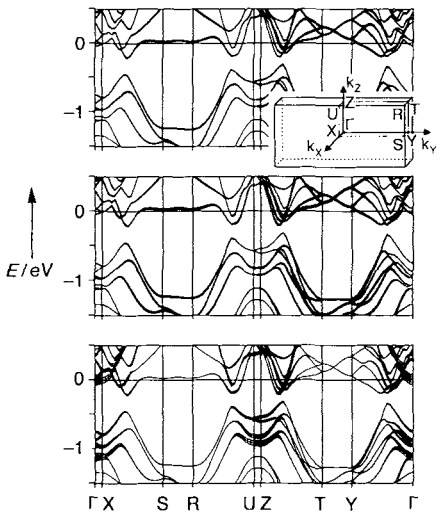

Fig. 3. Band structure of $La_9Br_5(CBC)_3$. The BC_2-centered levels of approximate π^* symmetry, the La-$d_{xz,yz}$ atomic levels, and the La-$d_{x^2-y^2}$ atomic levels (from top to bottom) are emphasized as "fat bands" [18]. The Fermi energy is the zero energy. The principal directions of the Brillouin zone are indicated.

A molecular orbital analysis of the the C-B-C units elucidates the chemical bonding of the pseudomolecular entity inside the crystal and indicates a specific electron–phonon interaction with the electrons at the Fermi edge. The result supports the formal charge assignment according to Zintl and Klemm. Within the one-electron picture, a doubly degenerate C–B antibonding π_u level is populated for a linear C-B-C unit of overall charge −7, in complete analogy to the carbide halides. The latter molecular orbital may mix with the σ_g-like LUMO through a bending vibration of symmetry π_u (Fig. 4). Such a coupling corresponds

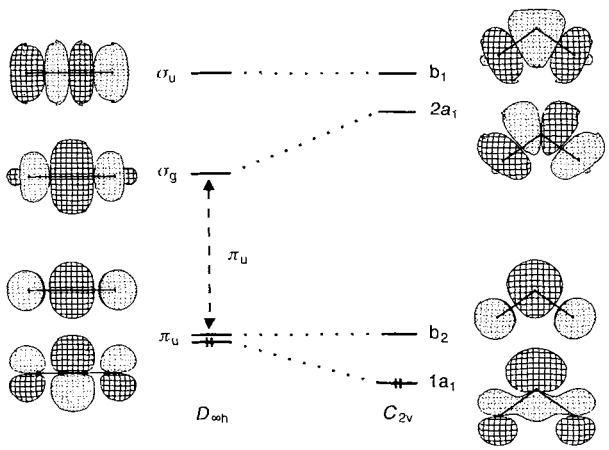

Fig. 4. Schematic Walsh diagram of a CBC^{7-} molecular anion. The molecular orbitals originate from a semiempirical (EH) calculation [23] that has been parameterized to numerical (HF) orbital energies and valence functions.

to a second order Jahn–Teller instability[19, 20] and allows the energetic stabilization/destabilization of the HOMO/LUMO under symmetry reduction from $D_{\infty h}$ to C_{2v}. This effect may be expected for all triatomic species with 18 valence electrons (O_3, SO_2, CF_2, CBC^{7-}). In the present case of CBC^{n-}, the group theory arguments are also corroborated by further ab initio calculations.[21] The influence of the matrix and the cation–anion backbonding (see above), however, is apparent from a comparison between the calculated C-B-C angle of 121° for the

isolated species and the widened angle (148°) that has been experimentally found.[22] The energy of the molecular $1a_1$ level (compared to E_F) is extremely sensitive to the size of the C-B-C angle, thus stressing the importance of the bending vibration for the appearance of superconductivity.

Superconducting boride carbides such as YB_2C_2 with $T_c = 3.6$ K[24] and $La_5B_2C_6$ with $T_c = 6.9$ K[25] have been known for a long time. Recently a lot of interest has focused on boride carbides with the composition $LnNi_2B_2C$ (T_c(max) = 16.6 K).[26–29] The bonding is complicated in all of these phases: YB_2C_2 contains B–C networks, in $La_5B_2C_6$ ($= La_5C_2(CBC)_2$) there are CBC and C_2 anions, and in $LnNi_2B_2C$ the bands carry contributions from all atoms at the Fermi edge. In comparison, the bonding conditions in the superconductor $La_9Br_5(CBC)_3$ are fairly clear. The "fingerprint" for superconductivity is similarly present for the compound $La_9Br_6(CBC)_3$,[5] which is structurally closely related. There are bands with large and negligible dispersions about 0.5 eV above and below E_F. Attempts to change E_F by substitution of La^{3+} are currently in progress.

[22] We have performed quantum mechanical optimizations (triple-zeta basis sets including two polarization functions for all valence orbitals, local density functional) of the bridging angles of CBC^{n-} molecular ions, with a fixed C–B distance (151 pm). The calculations are model-like because of the Coulomb explosions that may be expected for such high charges. $D_{\infty h}$ symmetry is only found for CBC^{3-} and CBC^{5-}, whereas CBC^{7-} and CBC^{9-} adopt C_{2v} symmetry with angles of 121 and 110°. Test calculations on SO_2 show these calculations to be better than 2°, and they strongly favor the LDA with respect to gradient-corrected functionals.

Modeling of the Chemistry of the Active Site of Galactose Oxidase**

Jason A. Halfen, Victor G. Young, Jr., and William B. Tolman*

Arrays consisting of organic free radicals proximate to metal centers recently have been identified as important components of active sites in enzymes that catalyze multielectron redox reactions.[1] An intriguing example of a functionally significant metal-radical pair is found in galactose oxidase (GAO),[2] a fungal enzyme containing a monocopper active site that effects the two-electron oxidation of primary alcohols to aldehydes. Extensive biophysical studies[2a, 3] including X-ray structures[4] have resulted in the elucidation of the topology of the active site (Fig. 1, inset) and an electronic structural description of the functionally competent form. This form (structure **A**, Fig. 1) is postulated to contain a Cu^{II} ion tightly coupled to a radical localized on an equatorial, covalently S-cys-modified tyrosinato

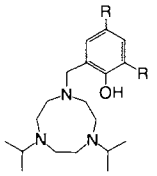
Selected bond distances [Å] and angles [°] for **4**: Cu1–O1 1.893(1), Cu1–O2 1.931(1), Cu1–N1 2.082(2), Cu1–N4 2.397(2), Cu1–N7 2.140(2), N1-Cu1-N4 80.45(6), N1-Cu1-N7 82.89(6), N4-Cu1-N7 82.29(6), N1-Cu1-O1 169.80(6), N1-Cu1-O2 92.88(6), O1-Cu1-N7 88.23(6), O1-Cu1-O2 94.85(6), O1-Cu1-N4 103.39(6), N4-Cu1-O2 107.94(6), N7-Cu1-O2 168.21(6).

ligand and stabilized by π-stacking interactions with a nearby tryptophan residue (not shown). Poised to perform two-electron redox chemistry, the free- radical-coupled copper complex **A** has been proposed to yield intermediate adduct **B** upon deprotonation of the alcohol substrate by the axial tyrosinato ligand.[2a] The subsequent alcohol oxidation has been suggested to occur by initial hydrogen atom abstraction by the appended tyrosyl radical,[5] followed by electron transfer to copper to afford the aldehyde and the reduced Cu^{I} active site (Fig. 1).[6] Two-electron oxidation by O_2 completes the hypothetical catalytic cycle.

We wish to assess the viability of this interesting mechanism by examining appropriate synthetic model complexes. Previous modeling studies have demonstrated the feasibility of phenolato–Cu^{II} units found in the inactive form of GAO (one-electron reduced form of **A**)[7] and the functional competence of free-radical-coupled copper compounds to oxidize alcohols, albeit with an abiological radical cofactor (2,2,6,6-tetramethyl-1-piperidinyloxy, TEMPO).[8] Here we report the identification of synthetic analogs of **A** and a novel mixed alcoholato–phenolato complex of Cu^{II} that models reduced **B**. Moreover, we find that one-electron oxidation of **B** induces aldehyde production.

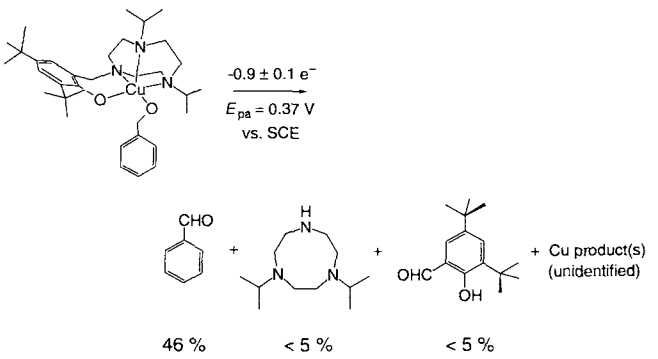
Reasoning that any attempt to generate a functional pair consisting of a phenoxyl radical and a Cu^{II} ion would be thwarted by inactivation reactions at the *ortho* and *para* positions of the arene ring, we prepared the protected monophenolato ligands $\mathbf{L^1}$ and $\mathbf{L^2}$. Deprotonation with NaH followed by treatment with the appropriate anhydrous Cu^{II} salt yielded the deep purple complexes [LCuX] (**1**: L = $\mathbf{L^1}$, X = Cl; **2**: L = $\mathbf{L^2}$, X = Cl; **3**: L = $\mathbf{L^2}$, X = O_3SCF_3), one of which (**1**) was structurally characterized by X-ray crystallography (Fig. 2, top).[9] The complex adopts a square-pyramidal geometry[10] with the chloro and phenolato ligands in *cis*-equatorial positions; spectroscopic comparisons implicate a similar arrangement in **2** and **3**.[11] The stabilizing effect of the the *tert*-butyl groups[12] is manifested in the unique electrochemical behavior of **2** and **3**, both of which exhibit reversible one-electron oxidation waves in their cyclic voltammograms (CVs) obtained with 0.25 M Bu_4NPF_6 in CH_2Cl_2 (**2**: $E_{1/2} = +0.59$ V, $\Delta E_p = 86$ mV; **3**: $E_{1/2} = +0.72$ V, $\Delta E_p = 96$ mV; both vs. SCE at 100 mV s^{-1}). One-electron oxidation of purple, EPR-active **3** could be accomplished at −40 °C electrochemically by controlled potential electrolysis at +1.0 V vs. SCE or chemically by treatment with equimolar $(NH_4)_2[Ce(NO_3)_6]$ in CH_3CN. Both procedures resulted in the production of a new green species. Consistent with the electrochemical reversibility evident in the CV of **3**, reaction of stoichiometric amounts of ferrocene [Cp_2Fe] with the green complex resulted in the quantitative regeneration of **3** and the production of $[Cp_2Fe]^+$. The green, oxidized species lacks an EPR signal and exhibits an optical absorption feature at 410 nm ($\varepsilon = 4000\ M^{-1}cm^{-1}$) similar to that observed in active GAO (445 nm, $\varepsilon = 5400\ M^{-1}cm^{-1}$)[13] and many 2,4,6-trisubstituted phenoxyl radicals.[14] These results support assignment of the green oxidized species ($\mathbf{3^{+\cdot}}$) as a magnetically coupled phenoxyl–Cu^{II} radical complex akin to GAO species **A**.



$\mathbf{L^1}$: R = CH_3
$\mathbf{L^2}$: R = $C(CH_3)_3$

In an approach toward modeling substrate interactions with the enzyme we treated **2** with $NaOCH_2Ph$ to yield [$L^2Cu(OCH_2Ph)$] (**4**) as green crystals suitable for X-ray crystallographic characterization (Fig. 2, bottom).[9, 11] The *cis*-equatorial arrangement of the alcoholato and phenolato ligands in the square-pyramidal[10] complex mimics the proposed disposi-

tion of these groups in GAO during enzyme turnover. Additional noteworthy features of **4** are the short Cu^{II}–alcoholato bond length [Cu1–O1 = 1.893(1) Å] and a 2.36 Å distance between a benzylic hydrogen (H10A) and the phenolate oxygen (O2) that implicates an O···H-C interaction of possible functional importance,[16] insofar as such an arrangement may be viewed as necessary for the hypothesized hydrogen atom abstraction that is the first step in alcohol oxidation. Indeed, the cyclic voltammogram of **4** exhibits an irreversible oxidation wave (E_{pa} = + 0.37 V vs. SCE in CH_3CN) and upon bulk electrolysis at + 0.5 V, 0.9 ± 0.1 e^- mol^{-1} was abstracted from the complex concomitant with bleaching of its EPR and UV/Vis features. ^1H NMR and GC/MS analysis of the resulting solution (after removal of copper-containing species) revealed the production of benzaldehyde (46% based on **4**) and small amounts of 1,4-diisopropyl-1,4,7-triazacyclononane[17] and 4,6-di-*tert*-butyl-2-formylphenol (Scheme 1).



Scheme 1. SCE = saturated calomel electrode.

The overall reaction whereby one-electron oxidation of **4** yields benzaldehyde and, presumably, Cu^I coproduct(s) parallels that promoted by GAO. By analogy to the electrochemical behavior exhibited by **2** and **3**, we suggest that electrolysis of **4** generates $\mathbf{4}^{+\bullet}$, a reactive Cu^{II} complex with coupling between the free radical and the copper center that binds the substrate, analogous to enzyme intermediate **B**. Hydrogen atom abstraction (cf. H10A) by the phenoxyl oxygen (O2) would initiate benzaldehyde generation, while abstraction from the activated benzylic position of the phenoxyl group would afford the byproducts.[14] Inter- or intramolecular paths are possible, although we view internal delivery of a hydrogen atom from the benzyl alcoholate to the phenoxyl oxygen as a particularly attractive alcohol oxidation route in view of the O···H–C interaction identified by crystallography for **4**.

In sum, we have obtained chemical precedents for key intermediates hypothesized in alcohol oxidation catalyzed by the unique active site of GAO comprising a monocopper center coupled to a free radical. Important findings include the identification of species derived from one-electron oxidation of phenolato–Cu^{II} compounds that model the active form of the enzyme (**A**), structural characterization of a mixed phenolato–alcoholato complex that models the reduced enzyme–substrate adduct (reduced **B**), and aldehyde evolution from the phenolato–alcoholato compound upon its one-electron oxidation, a reaction that mimics GAO function.

Experimental Procedure

All compounds yielded satisfactory mass spectra and C,H,N analyses. The copper complexes were prepared under an inert atmosphere.

L^1: A solution of the Mannich base of 1,4-diisopropyl-1,4,7-triazacyclononane (4.95 mmol) [17] and 2,4-dimethylphenol (5.16 mmol) were heated at reflux in methanol for 12 h according to ref. [18]. Addition of water to the reaction mixture caused the deposition of a colorless oily mass, which crystallized on standing. Yield: 1.22 g (71%). ^1H NMR (500 MHz, $CDCl_3$): δ = 6.81 (s, 1H), 6.60 (s, 1H), 3.73 (s, 2H), 3.02–2.96 (*m*, 4H), 2.88 (sept, J = 6.5 Hz, 2H), 2.67 (t, J = 5.0 Hz, 4H), 2.43 (s, 4H), 2.19 (s, 3H), 2.17 (s, 3H), 0.95 (d, J = 6.5 Hz, 12H); $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$): δ = 154.2, 130.0, 126.8, 126.4, 124.5, 121.9, 60.8, 54.8, 53.6, 53.4, 52.9, 20.4, 18.3, 15.6. An analogous procedure was used to prepare **L^2** from 2,4-di-*tert*-butylphenol in 90% yield. Data for **L^2**: ^1H NMR (300 MHz, $CDCl_3$): δ = 7.17 (d, J = 2.4 Hz, 1H), 6.81 (d, J = 2.4 Hz, 1H), 3.76 (s, 2H), 3.04–2.85 (overlapping multiplet and septet, 6H), 2.68 (t, J = 4.8 Hz, 4H), 2.46 (s, 4H), 1.42 (s, 9H), 1.28 (s, 9H), 0.97 (d, J = 6.6 Hz, 12H); $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): δ = 155.0, 139.6, 135.3, 123.2, 122.4, 122.1, 61.5, 54.6, 54.1, 53.7, 53.1, 34.8, 34.1, 31.7, 29.6, 18.4.

1–**3**: The sodium salt of **L^1** (prepared by the reaction of **L^1** (0.21 g, 0.60 mmol) with NaH in THF) and anhydrous $CuCl_2$ (0.081 g, 0.60 mmol) were stirred in THF (5 mL) for 2 h. The mixture was then filtered through a pad of celite, and the filtrate evaporated under reduced pressure. Recrystallization of the residue from CH_2Cl_2/pentane yielded **1** as purple crystals suitable for a single-crystal X-ray analysis, 0.189 g (70%). An analogous method was used to prepare **2** from **L^2** and $CuCl_2$ in 86% yield; complex **3** was prepared similarly using **L^2** and $Cu(O_3SCF_3)_2$ in 85% yield.

4: A solution of **2** (0.163 g, 0.31 mmol) and $NaOCH_2Ph$ (0.062 g, 0.48 mmol) were stirred in THF (5 mL) for 1 h. Pentane (10 mL) was then added, and the green mixture filtered through a pad of celite. Concentration of the filtrate and storage at −20 °C for several days caused the deposition of small green crystals of the product, 0.050 g (27%). Recrystallization from toluene/pentane at −20 °C yielded crystals of **4**·0.5 toluene suitable for a single-crystal X-ray analysis.

[9] X-ray crystal structure analysis of **1**: purple block crystal (0.50 × 0.50 × 0.20 mm): $C_{21}H_{36}ClCuN_3O$, M_r = 445.53, monoclinic, space group $P2_1/c$, a = 15.18(4) Å, b = 7.538(1) Å, c = 20.58(5) Å, β = 109.1(1)°, V = 2225(8) Å^3, Z = 4 at 298(2) K; ρ_{calcd} 1.330 g cm^{-3}; $2\theta_{max}$ = 50.00°; μ_{Mo} = 11.19 cm^{-1}. The structure was solved by direct methods; hydrogen atoms were placed at calculated positions but were not refined. A semiempirical absorption correction (DIFABS) was applied. The final cycle of full-matrix least-squares refinement (on F), based on 4319 reflections [$I > 2\sigma(I)$] and 245 variable parameters, converged at R = 0.071 and wR = 0.096 (max/min residual electron density 0.72

$-1.03\ e^{-}\ Å^{-3}$). Data were collected on an Enraf–Nonius CAD-4 diffractometer, and calculations were performed with the TEXSAN software package. X-ray crystal structure analysis of **4**·0.5toluene: green block crystal ($0.50 \times 0.50 \times 0.25$ mm); $C_{37.50}H_{59}CuN_3O_2$, $M = 647.42$, monoclinic, space group $P2_1/n$, $a = 17.5316(4)$ Å, $b = 9.3694(3)$ Å, $c = 22.1187(5)$ Å, $\beta = 91.444(1)°$, $V = 3632.1(2)$ Å^3, $Z = 4$ at 173(2) K; $\rho_{calcd} = 1.184\ g\,cm^{-3}$; $2\theta_{max} = 50.18°$; $\mu_{Mo} = 6.36\ cm^{-1}$. The structure was solved by direct methods; non-hydrogen atoms were refined anisotropically, and hydrogen atoms were placed at calculated positions and refined as riding atoms with individual isotropic displacement parameters. A semiempirical absorption correction was applied. A disordered toluene molecule was located on an inversion center; the occupancies of its atoms were fixed at 0.5 to account for the disorder. The final cycle of full-matrix least-squares refinement (on F^2), based on 6402 reflections [$I > 2\sigma(I)$] and 495 variable parameters, converged at $R1 = 0.0359$ and $wR2 = 0.0865$ (max/min residual electron density 0.264/ $-0.369\ e\ Å^{-3}$). Data were collected on a Siemens SMART system and calculations were performed using the SHELXTL V5.0 suite of programs. Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications no. CCDC-179-44. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ UK (Telefax: Int. code +(1223) 336-033; e-mail: teched(@) chemcrys.cam.ac.uk).

A Cubic (3,4)-Connected Net with Large Cavities in Solvated $[Cu_3(tpt)_4](ClO_4)_3$ (tpt = 2,4,6-Tri(4-pyridyl)-1,3,5-triazine)**

Brendan F. Abrahams, Stuart R. Batten, Hasan Hamit, Bernard F. Hoskins, and Richard Robson*

Early studies suggest that the simple trigonal building block 2,4,6-tri(4-pyridyl)-1,3,5-triazine (tpt) may provide coordination polymers with diverse structures; examples known to date reveal high symmetry, unusual topology and, as a result of the large size and rigidity of the ligand, large intraframework spaces. The mercury(II) complex $[Hg(tpt)_2](ClO_4)_2 \cdot 6C_2H_2Cl_4$ has a highly symmetrical cubic structure involving a new type of (6,3)-connected net with spacious interconnected cavities that enclose large amounts of unusually well-ordered solvent and anions.[1] The cyanozinc derivative $[Zn_3(tpt)_2(CN)_3(NO_3)_3]$· solvate, which is also cubic, consists of two infinite networks of a previously unknown topology which interpenetrate so as to produce extraordinarily large but completely sealed-off chambers capable of enclosing of the order of twenty molecules of solvent (e.g. ca. $18CHCl_3 + 4CH_3OH$ per chamber or $9C_2H_2Cl_4 + 9CH_3OH$ per chamber)—essentially minute droplets of liquid imprisoned in microscopic cells.[2] A zinc hexafluorosilicate derivative (also cubic) consists of multiply interpenetrating enantiomorphic (10,3)a nets.[3] Recently a different type of (10,3) net, namely Wells's (10,3)b net, was reported by Moore et. al. in a coordination polymer of Ag^+ ions with the related trigonal building block 1,3,5-tris(4-ethynylbenzonitrile)benzene.[4] We report here yet another highly symmetrical coordination polymer of tpt that consists of two independent and interpenetrating cubic nets, producing large, solvent-filled cavities.

Diffusion of a solution of $[Cu(CH_3CN)_4]ClO_4$ in acetonitrile into a solution of tpt in chloroform/1,1,2,2-tetrachloroethane gave very dark red, almost black crystals of solvated $[Cu_3(tpt)_4](ClO_4)_3$ whose structure was determined from single-crystal X-ray diffraction data collected at 110 K. All tpt units are equivalent and are attached to three copper centers at the corners of an equilateral triangle (edge length 12.898(3) Å). All copper centers are equivalent and are coordinated by four tpt-derived pyridine donors in a distorted tetrahedral arrangement (N-Cu-N, 111.0(3) and 106.4(5)°). This results in an infinite (3,4)-connected three-dimensional network with $(6^3)_4(6^28^4)_3$ topology.[5] A repeated structural motif immediately apparent in the network comprises six copper centers at the corners of a regular octahedron, with tpt units occupying alternate triangular faces of the octahedron. These octahedral chambers are large: the diametrically opposed copper atoms are separated by 18.241(4) Å (a unit cell length). Each copper atom is shared by two such units as shown in Figure 1. The tpt units are significantly bowed away from the center of the chamber, one consequence of which is to allow the coordination geometry of the copper atom to approach more closely the tetrahedral ideal. These chambers can be imagined to be derived from the adamantanoid cages of a diamond net by replacing the four 3-connecting centers of the adamantane unit by four trigonal nodes.

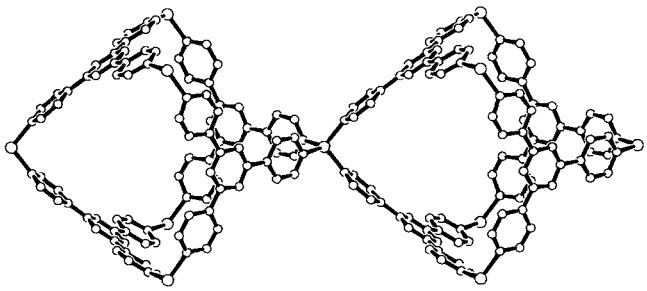

Fig. 1. Two adjacent chambers in the structure of $[Cu_3(tpt)_4](ClO_4)_3$·solvate. Each chamber comprises six Cu^{I} centers (the larger circles) at the corners of a regular octahedron and tpt units occupy alternate triangular faces. Smaller circles represent C and N. Cu–N,2.014(9) Å.

Every chamber is connected by its six copper vertices to six others whose centers are arranged octahedrally around the first. An infinite cubic collection of chambers is thereby produced as shown schematically in Figure 2. At the center of each collection

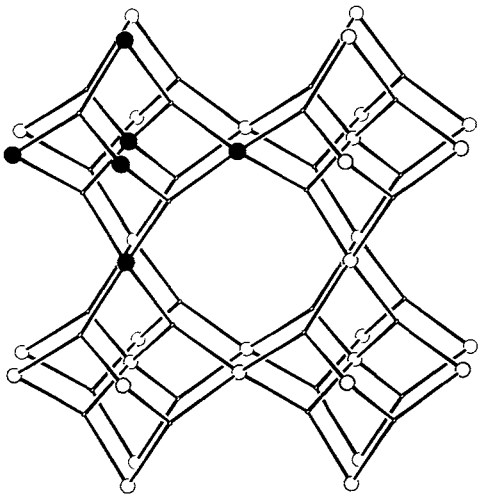

Fig. 2. A cubic tpt Cu framework. Tpt units are represented schematically by three spokes radiating from a point and Cu centers by circles. One octahedral group of Cu centers is highlighted by black circles.

of eight chambers of the type seen in Figure 2 is a cavity which is of the appropriate size, shape, and chemical character to accommodate very neatly a chamber belonging to a second completely independent but identical infinite network. A schematic representation of the two independent interpenetrating networks is shown in Figure 3. Neither framework intrudes inside

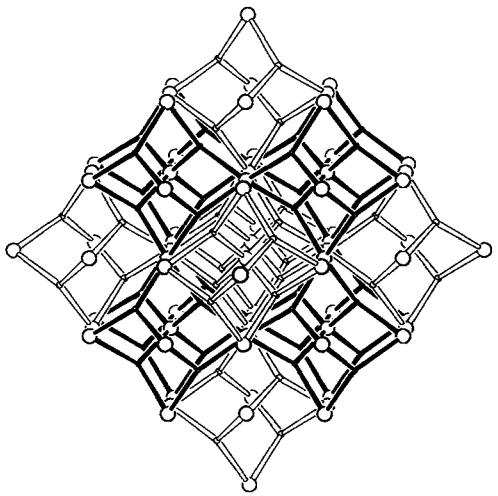

Fig. 3. Schematic representation of two interpenetrating, identical frameworks. Eight chambers of one framework ("black" connections) are disposed at the corners of a cube in the central cavity of which is a chamber of the second framework ("white"), which, in turn, is connected octahedrally to six other "white" chambers.

the octahedral chambers of the other, so the composite structure remains very spacious. Each octahedral chamber in essence has only four of its eight triangular "windows" blocked off by tpt units, the other four remaining "open". The two independent networks are so arranged that the occupied faces of one chamber butt against the occupied faces of a neighboring chamber belonging to the other framework to give discrete, centrosymmetrically related tpt pairs. Likewise the four "open windows" of a given chamber immediately face the "open windows" of four neighboring chambers belonging to the other framework. In contrast to $[Zn_3(tpt)_2](CN)_3(NO_3)_3 \cdot$solvate in which the large chambers are completely sealed off from each other by an impenetrable shell of tpt pairs,[2] $[Cu_3(tpt)_4](ClO_4)_3 \cdot$solvate allows ready access from any chamber to four of its neighbors. The bowing of the tpt ligands away from the interior of the cavity, mentioned earlier, means that within a discrete tpt pair the triazine rings are much closer together (3.29(2) Å) than the two associated Cu_3 triangles (5.27 Å).

The extremely dark red color of the crystals is unusual for Cu^I complexes (λ_{max} 420–550 nm, very broad). In those cases where visible absorption has previously been observed in Cu^I complexes this has been ascribed to metal-to-ligand charge-transfer transitions.[6]

A dark red, almost black, crystalline solid with essentially the same cubic unit cell dimensions (18.236(5) Å) as those of the perchlorate is obtained by using $CuBF_4$ in place of $CuClO_4$ following an otherwise identical procedure. The IR spectrum (KBr disc) of the tetrafluoroborate shows an anion-derived band at 1060 cm^{-1}, that of the perchlorate at 1100 and 625 cm^{-1}.

We are presently investigating whether selective incorporation of various species into the large chambers of $[Cu_3(tpt)_4](ClO_4)_3$ can be achieved.

Experimental Procedure

A buffer zone of chloroform (10 mL) was carefully layered on top of a solution of tpt (25 mg) in 1,1,2,2-tetrachloroethane (10 mL) and then a solution of $[Cu(CH_3CN)_4]ClO_4$ (45 mg) in acetonitrile (5 mL) was carefully layered on top of that. Very dark red, almost black crystals of solvated $[Cu_3(tpt)_4](ClO_4)_3$ grew on the vessel walls just below the buffer region over a period of several days. The crystals, which were sensitive to solvent loss upon exposure to the atmosphere, were transferred directly from solution to oil and cooled to 110 K on an Enraf-Nonius CAD-4MachS diffractometer for crystallographic analysis. The product obtained in this way was accompanied by a small amount of orange material and was therefore unsuitable for elemental analysis. Formation of the orange solid could be eliminated by replacing a large fraction of the acetonitrile in which the $[Cu(CH_3CN)_4]ClO_4$ was dissolved by methanol and by reducing the proportion of copper. The sample for analysis was obtained exactly as above except that the top layer consisted of $[Cu(CH_3CN)_4]ClO_4$ (22 mg) in acetonitrile:methanol (1:9, 10 mL). Even after it had been dried to constant weight at 160 C under vacuum and thereby losing 30.7% by weight, the sample still clearly retained considerable solvent. Elemental analysis calcd. for $[Cu_3(tpt)_4](ClO_4)_3 \cdot 1.5CH_3OH \cdot 1.17C_2H_2Cl_4$ ($C_{75.84}H_{56.34}Cl_{5.68}Cu_3N_{24}O_{13.5}$): C 45.9, H 2.9, Cu 9.6, Cl 13.7, N 17.0; found: C 45.4, H 2.6, Cu 9.6, Cl 13.2, N 17.1; IR (Kbr): $\tilde{\nu}$ = 1100, 625 (ClO), 1580 (CN) cm^{-1}. Crystal dimensions: 0.4 × 0.4 × 0.4 mm; cubic, space group $Pn\bar{3}m$ (no. 224), a = 18.241(4) Å, V = 6069(2) Å^3, Z = 2, ρ_{calcd} = 1.572 gcm^{-3}, $2\theta_{max}$ = 150°, $Cu_{K\alpha}$ radiation, λ = 1.5418 Å, ω:2θ scan, 1457 reflections collected, 1194 independent reflections, all reflections included in the refinement. Corrections applied for Lorentz and polarization effects. Absorption corrections were numerically evaluated by Gaussian integration (SHELX-76 [7]), μ = 75.18 cm^{-1}, min./max. transmission 0.2205/0.1069. The structure was solved by using direct methods (SHELXS-86 [8]) and refined by using a full-matrix least squares refinement based on F^2 (SHELXL-93 [9]), 62 parameters. The four unique pyridyl hydrogen atoms were located in difference electron density maps and were assigned to calculated positions. $R1$ [$I > 2\sigma(I)$] = 0.1473, $wR2$ [$I > 2\sigma(I)$] = 0.3938 [10]. Residual electron density = 0.634 e Å^{-3}. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-38. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

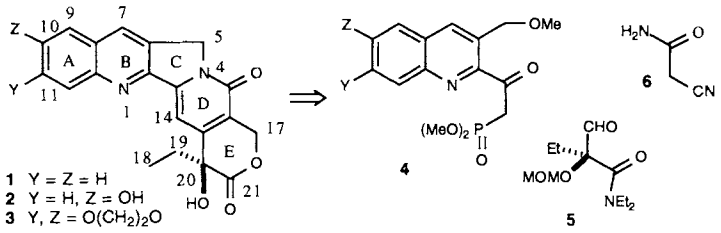
[10] The problem of relatively high R values is far from unusual in materials of this type in which highly disordered solvent constitutes a very significant fraction of the volume of the crystal. There are numbers of examples of crystal structure analyses in the literature where similar problems have been encountered and where refinements have converged with comparably high R values.

Total Synthesis of (+)-Camptothecin**

Marco A. Ciufolini* and Frank Roschangar

Camptothecin (CPT, **1**)[1] and related compounds (e.g. **2** and **3**)[2] have lately reestablished themselves as important antitumor agents.[3] Consensus has developed regarding their biomolecular target and mode of action,[4] and new biological properties of **1** have recently been discovered.[5] A good synthesis of CPT appears to be necessary in light of its biomedical significance and of its natural scarcity. As a consequence, synthetic activity in this area has experienced a major revival, and elegant new solutions have emerged.[6]

Our own interest in developing a practical synthesis of CPT and analogues led us to envision retrosynthetic dissection of the N4–C5 bond as the last stage of ring C construction. A concise synthesis might result by the merger of quinoline **4**, scalemic aldehyde **5**, and cyanoacetamide (**6**), through the agency of our recently described pyridone chemistry (Scheme 1).[7] Minor



Scheme 1. Retrosynthetic analysis of 1 and analogues. MOM = methoxymethyl.

modifications of the same general approach could also result in diverse analogues of **1**. The above mode of ring C formation is indeed facile. The strategy described here utilizes an enzymatic desymmetrization of a malonate, instead of chiral auxiliaries,[6e] Sharpless dihydroxylation,[6f-h] or resolution,[1] as a means to control absolute stereochemistry at C20.

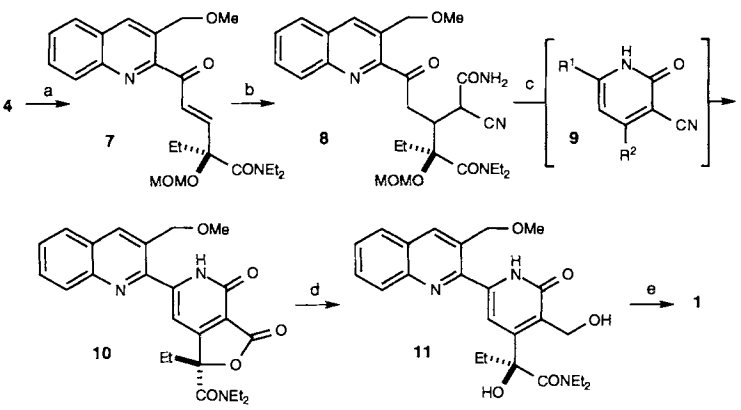
[**] We thank the National Institutes of Health (CA-55268), the National Science Foundation (CHE 95-26183), the Robert A. Welch Foundation (C-1007), and the Alfred P. Sloan Foundation, for support of our research, and Dr. Monroe E. Wall, Research Triangle Institute, North Carolina, for a gift of authentic camptothecin.

Condensation of phosphonate **4**, Y = Z = H, with aldehyde **5** (vide infra) afforded enone **7**, $[\alpha]_D^{25} = -56.1$ ($c = 4.720$ in $CHCl_3$), in 80% yield (Scheme 2). For reasons that are not yet

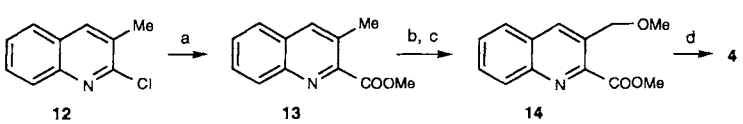


Scheme 2. a) *t*BuOK, 1,2-dimethoxyethane (DME), 5, 50 C, 12 h, 80%; b) **6**, *t*BuOK, DMSO, 25 C; c) 0.2 equiv of 5% SeO_2 on silica gel, *t*BuOOH, AcOH, 110 C, then 10% aq H_2SO_4 (see text), 68% combined yield for steps b and c; d) $NaBH_4$ (10 equiv) $CeCl_3$ (2.5 equiv), EtOH, 0 C for 20 min, then 45 C for 30 min; e) 60% H_2SO_4 in EtOH, 115 C, 94% combined yield for steps d,e.

fully understood, **7** was a poor substrate for our pyridone-forming reaction.[7] However, **7** combined with the potassium enolate of **6**[8] in DMSO to afford Michael adduct **8** in quantitative yield.[9] Subsequent oxidation with *t*BuOOH in AcOH in the presence of 20 mol% SeO_2 adsorbed on silica gel[10] gave pyridone **9**, $[\alpha]_D^{25} = -71.0$ ($c = 6.650$ in $CHCl_3$), in 74% yield. Exposure of **9** to acidic conditions induced conversion into the more synthetically useful lactone **10**, $[\alpha]_D^{25} = -38.8$ ($c = 1.025$ in $CHCl_3$). More conveniently, **10** was obtained directly from **8** simply by allowing the oxidation to reach completion (1 h), adding 10% vol/vol of 10% aqueous H_2SO_4 to the mixture, and heating at reflux for one more hour. The overall yield of **10** from **7** was thus 68%.

Lactones of the type **10** had been previously regarded as poor synthetic intermediates for **1**, because their reduction to diols like **11** is highly troublesome.[11] We confirmed these difficulties, but after much research we found that a modification of the Luche[12] protocol accomplished reduction of **10** to **11**, $[\alpha]_D^{25} = +72.1$ ($c = 1.200$ in $CHCl_3$), in over 95% yield. When crude **11** was heated at 115 °C for 5 h in 60% ethanolic H_2SO_4, fully synthetic, pure (20*S*)-(+)-camptothecin (**1**), identical in all respects including optical rotation, $[\alpha]_D^{25} = +34.8$ ($c = 0.400$ in 8:2 $CHCl_3$/CH_3OH; lit. $+35.0$[11]), to authentic samples from two different sources,[13] emerged in 94% overall yield from **10** after flash chromatography.[14] The merger of fragments **4**, **5**, and **6** to give CPT thus occurs in five steps and in 51% overall yield.

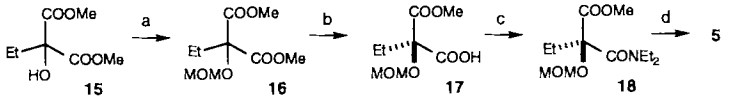
Compound **4** was obtained as follows. Readily available quinoline **12**[15] underwent smooth carbomethoxylation to **13** under catalysis by 5 mol% $[Pd(OAc)_2(dppp)_2]$ (dppp = 1,3-bis-(diphenylphosphino)propane) (Scheme 3). While aryl chlorides



Scheme 3. a) 5 mol% $[Pd(dppp)_2Cl_2]$, NaOAc, MeOH, DMF, 105 atm (1500 psi) CO, 140 C, 98%; b) *N*-bromosuccinimide (NBS), CCl_4, $(BzO)_2$, hv; c) MeOH, 5% H_2SO_4, reflux, 55% combined yield for steps b and c; d) $(MeO)_2P(O)CH_2Li$ (2 equiv), THF, −78 C, 100%.

are generally unreactive in carbonylation reactions and normally require complex catalysts,[16] the great reactivity of 2-haloquinolines seems to overcome these problems. Radical bromination and methanolysis[17] advanced **13** to **14**, which delivered phosphonate **4** upon Corey–Kwiatkowski reaction.[18]

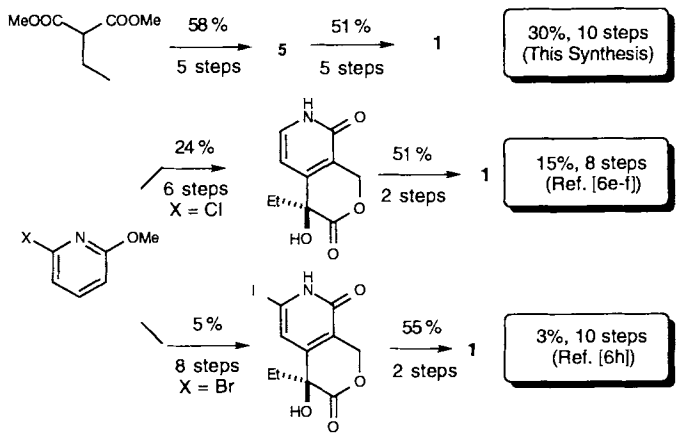
Compound **5** was prepared by the following sequence. Dimethyl 2-ethylmalonate adsorbed on silica gel was cleanly hydroxylated by ozone[19] at room temperature to give **15** (Scheme 4). Methoxymethyl (MOM) protection of the hydroxyl



Scheme 4. a) MOMCl, diisopropylethylamine, CH_2Cl_2, 25 °C, 100%; b) PLE, 25% aq DMSO, pH 6.8–7.4, 35 °C, 90%, >98% *ee* (see text); c) *N*-methyl-2-chloropyridinium iodide, Et_2NH, Et_3N, CH_2Cl_2, 25 °C, 90%; d) DIBAL, THF, −78 °C, 100%.

group[20] and enantioselective hydrolysis with pig liver esterase (PLE)[21] furnished **17**, $[\alpha]_D^{25} = +10.0$ ($c = 6.150$ in $CHCl_3$), in 90% overall yield and in >98% *ee*.[22] This carboxylic acid was converted to diethylamide **18**, $[\alpha]_D^{25} = -67.4$ ($c = 6.850$ in $CHCl_3$), under Mukaiyama conditions.[23] Subsequent exposure to diisobutylaluminum hydride (DIBAL) resulted in chemoselective and quantitative reduction of the ester to aldehyde **5**, $[\alpha]_D^{25} = -40.8$ ($c = 10.25$ in $CHCl_3$), which was spectroscopically and microanalytically pure in "crude" form and was therefore not further purified.[24]

In summary, CPT may now be obtained in ten linear steps in 30% overall yield starting from dimethyl ethylmalonate. As shown in Scheme 5, the present synthesis is twice as efficient as



Scheme 5. Comparison of published syntheses of (+)-camptothecin (**1**).

the best enantioselective alternative currently available (eight steps, 15% overall yield),[6e, f] and ten times higher yielding than the next best enantioselective protocol (ten steps, 3% overall yield).[6h] We are hopeful that our synthesis will facilitate the creation of novel CPT analogues for bioassay and for the eventual development of better anticancer resources.

[24] *ent*-**5** is readily available from **17** by reaction with excess Et_2NLi (methyl ester/diethylamide exchange) and esterification (CH_2N_2, 63% over the two steps), followed by DIBAL reduction (100%). Biologically inactive *ent*-**1** was obtained from *ent*-**5** as described above, confirming the absolute configuration of **5**.

Ancillary Ligand Dependent Shifts in Charge Distribution for Cobalt–Quinone Complexes**

Ok-Sang Jung,* Du Hwan Jo, Young-A Lee, Youn Soo Sohn, and Cortlandt G. Pierpont*

Transition metal complexes containing chelated *o*-quinone ligands have metal- and quinone-localized electronic levels that are unusually close in energy.[1] As a consequence, intramolecular charge transfer between metal and ligand occurs at low energy, and, in some cases, under conditions of thermal equilibrium.[2, 3] Structural changes that accompany shifts in metal oxidation and spin states have been applied to materials that exhibit photomechanical properties and optical switching effects.[4, 5] The most extensively studied equilibria of this type occur for complexes of cobalt with general formula [Co(N–N)(dbq)$_2$], where dbq is the semiquinonate (dbsq) or catecholate (dbcat) form of either 3,5- or 3,6-di-*tert*-butyl-1,2-benzoquinone and N–N is a bidentate nitrogen-donor ancillary ligand.[2] Temperature-dependent equilibria [Eq. (a)] may be

$$[Co^{III}(N-N)(dbsq)(dbcat)] \rightleftharpoons [Co^{II}(N-N)(dbsq)_2] \quad (a)$$

observed in the solid state as well as in solution by monitoring changes in the optical spectrum or in the magnetism for the shift from the low-spin Co^{III} ion to the high-spin Co^{II} ion.[6] The Co^{III}/Co^{II} transition temperature (T_c) is dependent upon the nature of the nitrogen coligand.[7] By defining the transition temperature as the point where concentrations of redox isomers are equal, T_c is equal to the ratio of enthalpic and entropic changes associated with the equilibrium.[6] The enthalpy change is primarily associated with changes in bond energy that occur with the shift in metal charge and spin state. Low-frequency vibrational shifts that accompany the transition to the high-spin Co^{II} ion provide the greatest contribution to ΔS, and both effects are associated with the change in population of the metal d_σ (e_g) orbitals. Donor effects of the coligands are clearly important in defining T_c through both enthalpic and entropic contributions, and the properties of ancillary ligands may be used to tune transition temperature with great sensitivity.[8] Herein we describe an unexpectedly large change in T_c associated with a minor change in coligand structure.

In an earlier study we described the properties of [Co^{III}(tmeda)(3,6-dbsq)(3,6-dbcat)] (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine).[2] The hard-donor coligand used in this case provides stabilization for the Co^{III} isomer and is responsible for the relatively high transition temperature of 310 K in solution (toluene). The T_c value for this complex is 35 K higher than that of the related bipyridine complex, even though the Co–N bond lengths are 0.1 Å longer with tmeda. Temperature-dependent changes in magnetic moment that accompany shifts in equilibrium are shown in Figure 1 for complexes prepared with *N*,*N*,*N*′,*N*′-tetramethylmethylenediamine (tmmda),

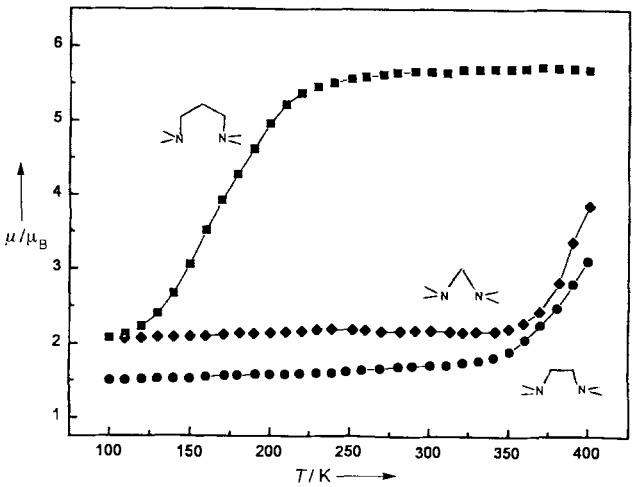

Fig. 1. Temperature dependence of the magnetic moments of complexes of the type [$Co\{Me_2N(CH_2)_nNMe_2\}(3,6\text{-dbq})_2$], $n = 1-3$.

tmeda, and *N*,*N*,*N*′,*N*′-tetramethylpropylenediamine (tmpda). The Co^{III} redox isomer has a single unpaired electron localized on the sq ligand. Metal–radical magnetic exchange that occurs for the Co^{II} isomer is responsible for values in magnetic moment that generally range between 4.5 and 5.5 μ_B. The solid-state T_c for [Co(tmeda)(3,6-dbsq)(3,6-dbcat)] lies above 400 K, and magnetic measurements made on [Co(tmmda)(3,6-dbsq)(3,6-dbcat)] indicate that it behaves similarly. In marked contrast, the related complex prepared with a propylene bridge between nitrogen donors has a solid-state T_c of 178 K, more than 200 K below the value for the corresponding complex with tmeda ligands. Solid-state equilibria have been monitored spectroscopically by observing intensity changes for a low-energy charge transfer transition that occurs characteristically for the Co^{III} redox isomers.[2] This band appears at 2500 nm for [Co(tmpda)(3,6-dbsq)(3,6-dbcat)], and temperature-dependent changes in intensity are shown in Figure 2. Structural features of [Co^{II}(tmpda)(3,6-dbsq)$_2$] in the solid state are shown in Figure 3.[9] In contrast to the features of [Co^{III}(tmeda)(3,6-dbsq)(3,6-dbcat)], Co–N and Co–O bond lengths are typical of high-spin Co^{II} ions, and dimensions of the quinone ligands are those of a semiquinone. The tmpda ligand is disordered in the structure by rotation about the Co–N2 bond. Crystallographic data collected at room temperature failed to provide clear resolution of the disordered carbon atoms, but data collected at

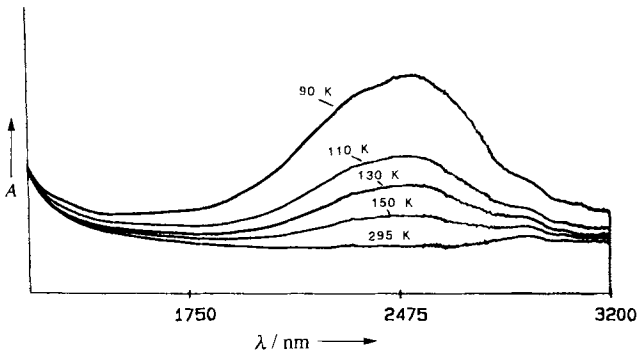

Fig. 2. Changes in the intensity of the transition at 2500 nm in [Co^{III}(tmpda)(3,6-dbsq)(3,6-dbcat)] with the equilibrium shift to [Co^{II}(tmpda)(3,6-dbsq)$_2$] at higher temperature in the solid state. Spectra were recorded on a sample prepared as a KBr disk. A = absorption.

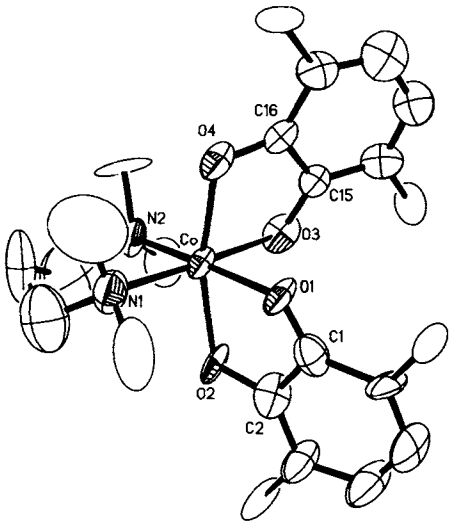

Fig. 3. View of the structure of [Co^{II}(tmpda)(3,6-dbsq)]. Carbon atoms bonded to N2 are shown in one of two disordered locations. Selected average bond lengths [Å]: Co–O 2.019(6), Co–N 2.181(10), C–O (quinone ligands) 1.29(1).

150 K gave locations for two sets of carbon atoms bonded to N2. Furthermore, data collected at 110 K has given clear resolution of the disorder and provided structural evidence for the transition to the Co^{III} isomer at low temperature.[10] The results of these structural studies will be described in a separate publication, but they show no evidence for an axially elongated low-spin Co^{II} intermediate that might appear with the high-spin Co^{II}/low-spin Co^{III} transition.

Energy changes that influence the equilibrium shown in Equation (a) provide fundamental insights on intramolecular metal–ligand electron transfer, information that is difficult to obtain directly for systems studied under conditions that are often dominated by solvation effects.[11, 12] Solid-state equilibria are of particular interest since the molecular environment can be precisely defined. Structural characterization on both [Co^{II}(tmpda)(3,6-dbsq)$_2$] and [Co^{III}(tmeda)(3,6-dbsq)(3,6-dbcat)] has shown that there are no close intermolecular contacts in the solid state. Temperature-dependent changes in both magnetism and the intensity of the band at 2500 nm in the spectrum have been used to calculate relative concentrations of Co^{II} and Co^{III} isomers present in the solid state, and from this data thermodynamic parameters have been obtained for the equilibrium.[6] The enthalpy change has been determined to be 14.2 kJ mol^{-1}, and the entropy change is 80 J mol^{-1} K^{-1}. The value for ΔS is large, but in agreement with values obtained for metal redox processes that place charge in M–L antibonding d_σ orbitals.[11] A value of 98 J mol^{-1} K^{-1} was obtained from a similar analysis on [Co(bpy)(3,5-dbq)$_2$] (bpy = 2,2′-bipyridine) in the solid state. The enthalpy change for [Co(tmpda)(3,6-dbq)$_2$] is roughly half the value of 32 kJ mol^{-1} obtained for the bipyridine complex, but within the range of values associated with Co^{II}/Co^{III} electron transfer reactions.[12] A detailed thermodynamic analysis has not been carried out for [Co(tmeda)(3,6-dbsq)(3,6-dbcat)] due to its high T_c, but the difference between complexes containing tmeda and tmpda ancillary ligands seems clearly related to the difference in chelate ring size. The six-membered chelate ring of tmpda permits greater vibrational flexibility and a N-Co-N bond angle that is more conducive to high-spin Co^{III} ions.

Experimental Procedure

[Co{$Me_2N(CH_2)_nNMe_2$}(3,6-dbq)$_2$], n = 1–3: Synthetic procedures used to prepare complexes with tmmda (n = 1) and tmpda (n = 3) coligands were similar to the synthesis of the related tmeda (n = 2) complex described previously [2].

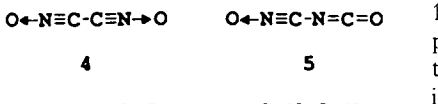
Diisocyanate**

Günther Maier,* Matthias Naumann,
Hans Peter Reisenauer, and Jürgen Eckwert

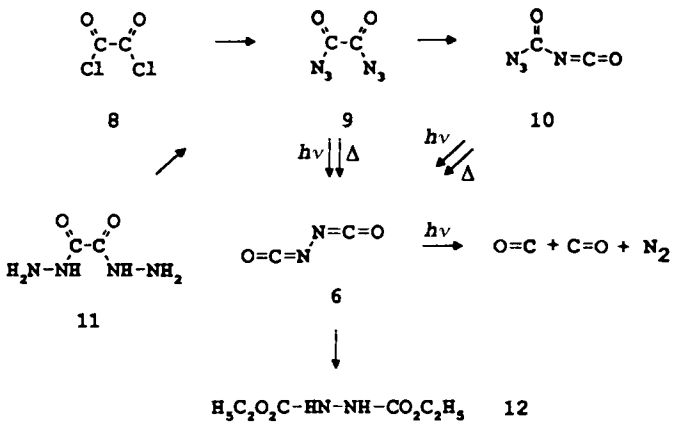
After the first synthesis of cyanogen (**1**) by Gay-Lussac in 1815[1] 173 years passed until Bickelhaupt and van der Does[2] described the formation of a second C_2N_2 isomer (**2**).[3] It took only four more years until diisocyanogen (**3**) was detected by matrix spectroscopy.[4]

In analogy to the CN radical the ambivalent fragments CNO and NCO can formally be combined to give structurally different isomers of the formula $C_2N_2O_2$. Three of a total of ten typical atomic arrangements are compounds **4**–**6**. The first species of this kind, cyanogendi-*N*-oxide (**4**), was obtained by Grundmann in 1963.[5] Here we report on the identification of the structural isomer diisocyanate (**6**).



Our aim was not only to prove the existence of **6**. In addition, we assumed that upon matrix-photolysis of **6** in argon at 10 K two CO molecules would be formed in the same rare gas matrix cage without interfering by-products. A singlet/triplet-photoexcitation of one of the ^{1}CO molecules followed by a [^{1}CO + ^{3}CO]addition might provide an access to the still unknown carbon monoxide dimer C_2O_2 (triplet ground state[6]).

Matrix-irradiation[7] of **4** does not lead to the desired diisocyanate **6** but yields—presumably via the primary, singly rearranged product **5**—nitrosyl cyanide **7**. Therefore, we had to find another route to **6**. A promising precursor for **6** is oxalic acid diazide (**9**). We first tried to obtain matrix-isolated diazide **9** by passing oxalic azid dibromide over solid sodium azide.[8] This reaction turned out to be poorly reproducible. Hence, we synthesized **9** in a reaction of oxalic azid dichloride (**8**) with tri-*n*-butyltin azide.[9] However, in this case the formation of two by-products, azidoformyl isocyanate (**10**) and the fairly explosive carbonyl diazide, is disadvantageous. In the meantime we learned that it is more convenient and safer to synthesize **9**, in a modified procedure of Roesky and Glemser,[10] by the reaction of oxalic acid dihydrazide (**11**) with nitrous acid. Utilizing this approach we isolated pure, crystalline oxalyl diazide and deposited it on a matrix window. In solution (CH_2Cl_2) at room temperature **9** loses one molecule of nitrogen, and **10** is formed. Removal of the solvent yields **10** as a colorless, pure liquid that can be safely handled, easily evaporated, and condensed on a spectroscopic window.



Irradiation of **9** and **10** in argon at 10 K with light of the wavelength 254 nm furnishes **6**. Compound **6** is also formed upon high-vacuum flash pyrolysis of **9** and **10** (quartz tube filled with quartz wool, 900 °C).

The proof of the identity of **6** is based on the following findings: Independently of the applied method of generation the IR spectrum exhibits a very intense absorption at 2201 cm^{-1}, two much weaker bands at 661 and 534 cm^{-1}, and six additional, very weak bands above 2000 cm^{-1}. All absorptions diminish simultaneously upon irradiation with 254 or 193 nm light, and CO is produced. A comparison with the spectrum of **6** calculated by ab initio methods unequivocally shows that all bands belong to diisocyanate (Fig. 1, Table 1).

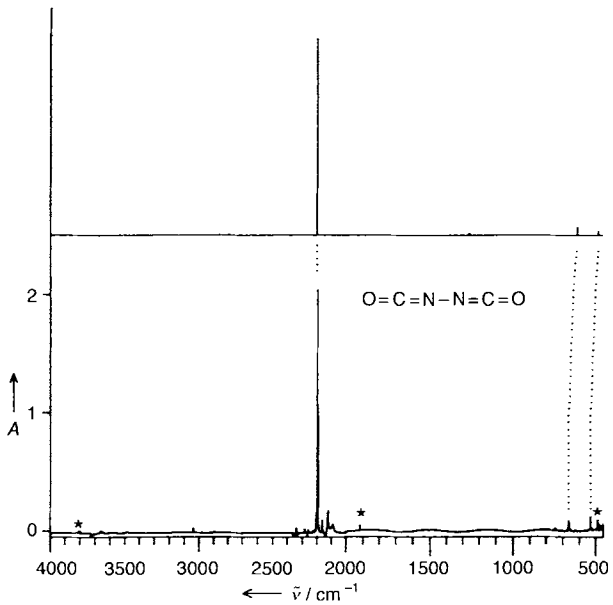


Fig. 1. IR spectrum of **6**. Top: Spectrum calculated by ab initio methods (BLYP/6-311G*). Bottom: Experimentally observed spectrum (Ar matrix, 15 K, from flash pyrolysis of **10**). The experimental spectrum is a difference spectrum of the photofragmentation of **6** into CO and N_2. *: NCO radical. A = absorbance.

The geometry optimization of **6** at the BLYP/6-311G* level[11] results in a minimum for the *s-trans*-conformation (d(C–O) = 1.178, d(C–N) = 1.233, d(N–N) = 1.387 Å, ∢(O-C-N) = 168.8°, ∢(C-N-N) = 125.9°) with C_{2h} symmetry (only real frequencies). In contrast, the C_{2v}-symmetrical molecule with *s-cis*-conformation is calculated to be a transition state (one imaginary frequency). Due to the high symmetry only six of the twelve fundamental vibrations belong to the IR-active species a_u and b_u, and only four should be found in the investigated spectral range (5000–400 cm^{-1}). The three most intense ones are readily assigned to the measured bands at 2201 (NCO

[a] Absolute intensity: 1731 km mol^{-1}. [b] Calculated from combination bands. [c] ip = in-plane. [d] oop = out-of-plane.

stretching vibration, ν_9, b_u), 661 (in-plane bending, ν_{11}, b_u), and 534 cm^{-1} (out-of-plane bending, ν_6, a_u). The missing fourth fundamental absorption (NCO stretching vibration, ν_{10}, b_u) is very weak in accordance with the calculation. Besides these fundamental vibrations six other weak bands of **6** were identified, which can, aided by the calculation, be interpreted as combination bands of IR-inactive and IR-active transitions (Table 1). The band ν_9 possesses an intensity high enough to enable the detection of the corresponding absorptions of the ^{13}C and ^{18}O isotopomers in natural abundance. The measured intensity of the ^{13}C band (2.2%) confirms that the molecule contains two symmetry-equivalent carbon atoms. Due to the breakdown of symmetry in the ^{13}C/^{12}C isotopomer the ν_1 band, which is inactive in the parent **6**, can be detected.

The photolability of **6** towards light with short (λ = 254 or 193 nm), but not towards longer wavelengths (λ > 310 nm) demands an absorption in the UV range. Indeed, an electronic transition with a λ_{max} = 220 nm can be registered in the UV spectrum. This band position shows that the bathochromic shift from an isolated monoisocyanate (HCNO: λ_{max} = 167 nm[12]) to the conjugated diisocyanate (**6**) is of the same order of magnitude as in the pair ethene (λ_{max} = 165 nm)/butadiene (λ_{max} = 217 nm).

The correctness of the identification of **6** is further supported by its reaction with ethanol: We cocondensed **6** and ethanol on a cold finger at 77 K and obtained after thawing exclusively diethyl 1,2-hydrazinedicarboxylate (**12**).

How stable is **6**? As mentioned above, **6** survives the conditions of flash pyrolysis. In this case cleavage into NCO radicals[13] was observed only to a small extent. If the thermal products of the precursor **10** are condensed without argon on a spectroscopic window at 80 K, the IR spectra reveal that **6** is viable under these conditions. Subsequent annealing results in the onset of a reaction at about 130 K. At 190 K all IR bands of **6** have vanished. While **6** does not exist in pure form at room temperature its lifetime in diluted form in the gas phase is much higher. We mixed **10** and argon (1:1000) and irradiated this sample at room temperature in an IR gas cell with 254 nm light. Spectra measured immediately thereafter exhibited the strongest absorption of **6** as a weak band with clearly visible P- and R-branches (centered at 2208 cm^{-1}). The intensity of this band decreased with a half-life of about 10 minutes.

With respect to the aforementioned C_2O_2 problem we would like to add that so far a photoinduced dimerization of the two CO molecules trapped in the same matrix cage could not be achieved.

Prenylation of Benzoic Acid Derivatives Catalyzed by a Transferase from *Escherichia coli* Overproduction: Method Development and Substrate Specificity**

Ludger Wessjohann* and Bernd Sontag

Enzyme-catalyzed reactions offer possibilities that extend beyond their obvious advantages of chemo-, regio-, and stereoselectivity, such as especially mild conditions, use in water and reproducibility on a microscale basis.[1–4] This is especially important for those reactions for which classical methods are not available. Due to their easy accessibility, hydrolases (peptidases, lipases, and esterases) now belong to the standard repertoire for organic synthesis,[1b,d] whereas enzyme-catalyzed C–C bond formations[1c,2] have not yet found widespread application. To

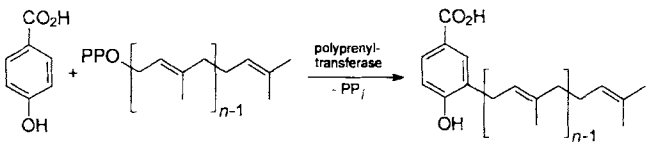
Greull for the use of their instruments and facilities.

date, only the oxynitrilase-catalyzed cyanohydrin reaction has been able to become established.[3] For more complex C–C bond formations, the aldolases have been the main focus of investigations.[1c, 2, 4]

The use of prenyltransferases in chemistry has so far been described only to a minor extent.[5] This may be because they are predominantly membrane-dependent[6–8] and therefore generally less accessible, less stable, and more difficult to characterize than globular enzymes. An important group of these enzymes catalyze the prenylation in the *ortho* position of phenols such as 4-hydroxybenzoic acid (PHB), which is a key step in the synthesis of biologically active compounds such as ubiquinone[9] and vitamin E[10] as well as many secondary metabolism products, including the Japanese drug and dye compound shikonin,[8, 11, 12] the anti-HIV-active conocurvone,[13] boviquinones,[14, 15] tridentoquinone[15–17] and others.[18, 19]

Herein we describe the regioselective prenylation of benzoic acid derivatives with a very stable and easily accessible transferase, which was first discovered in 1972 by Young et al.[20] in cell-free extracts of *Escherichia coli* and which in vivo probably catalyzes the reaction (with $n = 8$) shown in Scheme 1,[21] a



1 2 3

Scheme 1. Prenylation of 4-hydroxybenzoic acid (OPP = pyrophosphate, n = 1–12).

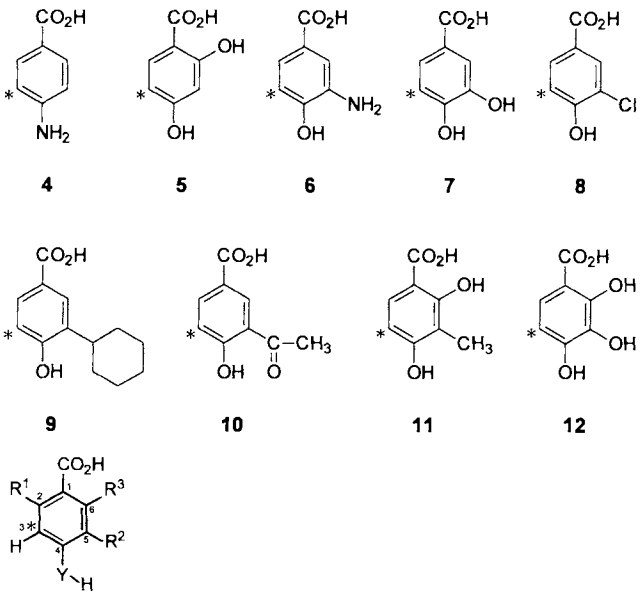
partial step in the ubiquinone biosynthesis.[6, 22] This enzyme is a polyprenyldiphosphate:4-hydroxybenzoate polyprenyl-transferase. Recently, Heide et al.[23, 24] were able to clone the corresponding gene (*ubiA*) to obtain recombinant overproducing strains, which they kindly made available to us.

The harvest of the enzyme fraction is readily accomplished in two days. A 500 mL batch yields enough material for approximately 200 prenylation experiments. The bacteria are initially grown from a main culture (glycerine culture) on an agar plate, then inoculated to a standard liquid medium (LB), where they are incubated at 37 °C to an optical density of approximately 1. The isolation of the enzyme proceeds by centrifugation and separation of the bacteria, the cell walls are destroyed with ultrasound, and the enzyme fraction is separated by centrifugation. To raise the specific activity to approximately 3 nkat mg^{-1} and to obtain better reproducibility from different batches, the membrane fractions are enriched by ultracentrifugation.[11, 24] This step, which brings about a loss of up to three quarters of the total activity of approximately 12 nkat, can be omitted for applications. The obtained membrane fraction is combined with 10 mL of a buffer solution (50 mM tris(hydroxymethyl)-aminomethane hydrochloride (TRIS·HCl; pH = 7.50), 2 mM 1,4-dithiothreitol), suspended, and immediately frozen at −25 °C. It is stable for many months without significant activity loss. After more than one year, the activity of the frozen suspension in the standard assay (see Experimental) was only approximately 20% lower than that of a fresh suspension and therefore still within the normal range of activity deviations for enzyme preparations.

The reaction of geranyl pyrophosphate (GPP) with *p*-hydroxybenzoic acid (PHB) to 3-geranyl-4-hydroxybenzoic acid (GBA) proved to be a good reference system (Scheme 1, $n = 2$). A calibration curve determined with classically synthesized GBA was used for the quantitative analysis by reversed-phase HPLC (4-ethylbenzoic acid as internal standard). For the standard assay (see Experimental) the reaction was stopped after one hour. The chemical yield for the PHB/GPP-reaction at this time was 62%; after three hours, synthetically useful yields of approximately 80% were obtained. The reproducibility of the reaction with enzyme preparations from the same batch is ±5%, excellent for these microreactions, and the deviations within one experimental series is only ±1%. Scale-up by a factor of 30 was easily accomplished and suggests no complications for larger batches.

The successful variation of the polyprenyl substituent (both GPP and geranylgeranyl pyrophosphate[27] were used) is not surprising based on the variation in the chain length in ubiquinones from *E. coli* and the resulting successful transformation of long-chain prenyl pyrophosphates.[11, 20, 24, 28] It is remarkable that the shorter GPP reacted with the highest rate, whereas, for the optimal compatibility with the chain length of the ubiquinones in *E. coli*, long-chain prenyl diphosphates such as octaprenyl[20, 29] were expected to be the best substrates. As expected, geranyl monophosphate was not converted.

The enzyme accepts a variety of 4-hydroxybenzoic acid derivates and related compounds as the substrate, of which a few are shown in Scheme 2. A systematic variation of the sub-



4 5 6 7 8

9 10 11 12

Scheme 2. Some of the successfully converted benzoic acid derivatives and a preliminary substrate model. (The prenylated position is marked with a star.) R^1 = H (other substituents are probably not allowed); R^2 = H, OH, NH_2, OCH_3, Cl, $COCH_3$, CH_3, cyclohexyl, etc., not polyprenyl or very strongly electron-withdrawing substituents like NO_2; R^3 = H, OH and others; Y = O, NH (other substituents likely to be possible).

stituents on the aromatic ring resulted in the following preliminary picture for the prenylation of the *meta*-position (C-3): 1) The acidic group is invariant: only benzoic acid derivatives are substrates. 2) The *para*-hydroxy functional group can be replaced, for example, by an amino group (**4**). Derivatives in which the hydrogen atom has been replaced, for example, by methylation to 4-methoxy- or 4-*N*,*N*-dimethylaminobenzoic acids, do not react. 3) As expected, the reaction does not take place if both *meta*-positions are blocked. However, these substances are not inhibitors either. 4) Substituents in the 5- and/or

6-position (R^2 and R^3, respectively) appear to be tolerated (**5**–**12**). Thus it is possible to carry out the one-step synthesis of 4,5-dihydroxy- and 4-hydroxy-5-methoxy-3-polyprenylbenzoic acid isolated from *Saccharomyces cerevisiae*.[18] Only very strongly electron-withdrawing substituents, such as the nitro group, lead to activity loss, whereas 5-chloro and 5-acetyl derivatives (**8** and **10**, respectively) can still be transformed at an acceptable rate. Donor-substituted substrates, such as the bulky 5-cyclohexyl-4-hydroxybenzoic acid **9**, react without any reactivity loss. 5) An additional hydroxy group in 2-position (R^1) is not acceptable.

Based on these results we have developed a model for the requirements of the enzyme with respect to the aromatic component, which has proven reliable for all of the tested compounds. The following is crucial for a successful experiment: Only those benzoic acid derivatives are transformed that bear an electron donor and a hydrogen-bond donor in *para*-position and are not substituted in the *meta*-position to be alkylated or in the adjacent *ortho*-position.

In contrast, the classical Friedel–Crafts alkylation of 4-hydroxybenzoic acid with prenyl compounds does not work. Even the reaction of methyl ester with phytol yields the 3-phytyl derivative in only 9% yield, and the important polyunsaturated all-*trans*-prenyl electrophiles did not yield the desired products at all. Not only the poor regioselectivity, but also the isomerization, overalkylation, and *O*-alkylation products were detected in these reactions.[17, 30] Such products are not formed when using the enzyme catalyst.

The investigations discussed herein for the overproduction of polyprenyl diphosphate:4-hydroxybenzoate-polyprenyltransferase from *E.-coli* demonstrate for the first time the potential of this almost unused class of C–C bond forming enzyme for the directed catalysis of a Friedel–Crafts type alkylation in water, the *meta*-prenylation of benzoic acid derivatives.

Experimental Procedure

The polyprenyl pyrophosphates were obtained from the respective polyprenyl alcohols or halides [31] according to the method of Poulter et al. [32]. Geranyl phosphate can be synthesized according to the procedure for pyrophosphates.

Enzyme assay: 100 nmol of the benzoic acid derivative (reference: PHB), 100 nmol polyprenyl pyrophosphate (reference: GPP), 50 μmol $MgCl_2$ (Mg^{2+} as the cofactor) in 50 μL of TRIS buffer (50 mM TRIS·HCl; pH = 7.5) and 50 μL of the enzyme suspension (approx. 25 pcat) were incubated for 60 min at 37 °C. The reaction was stopped by adding 2 μL of formic acid, and the reaction mixture was extracted with 500 μL of 4-ethylbenzoic acid (PEB) solution (100 μM in ethyl acetate; internal standard). After phase separation (centrifuge if necessary), a 450 μL sample of the organic phase was drawn, and the solvent removed in vacuo. The residue was dissolved in 60 μL of methanol and analyzed by HPLC (20 μL of the solution, column 250 × 4 mm, RP-18 (7 μm), 100 bar, detection at 240 nm (λ_{max} PEB) or 254 nm). The retention time of the geranylated compounds was 2.5 to 4 times that of the respective arene (eluent: methanol/water/formic acid 750/245/5, isocratic), that of geranylgeranylated compounds 6 to 7 times (eluent A (2 min), followed by gradient elution (13 min) to eluent B: methanol/isopropanol/formic acid 800/195/5). PEB elutes between the reactant and the product. The UV spectra of the prenylated benzoic acids show a bathochromic shift of 5–10 nm for the K band ($\pi \rightarrow \pi^*$) of the arene.

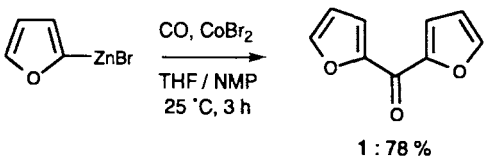
New Cobalt- and Iron-Catalyzed Reactions of Organozinc compounds**

C. Kishan Reddy and Paul Knochel*

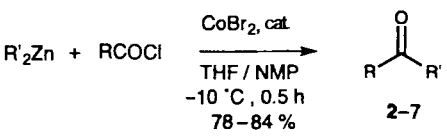
σ-Alkyl transition metal complexes are important intermediates in many transition-metal-mediated organic reactions.[1] Most of these compounds are highly unstable and undergo decomposition even at low temperature.[1, 2] It was thought that the stability of these organometallic reagents could be increased by an appropriate choice of the ligands, by using alkyl groups that do not contain β-hydrogen atoms, or by steric protection.[3] Recently we have found that the organometallic reagent used for the preparation of these transition metal alkyl species is also important for their stability. Whereas the treatment of $Co^{II}Br_2$ with highly reactive organolithium or Grignard reagents leads to decomposition even at very low temperature,[2, 4, 5] the same reaction performed with organozinc halide (RZnX) or diorganozinc (R_2Zn) reagents in THF:NMP mixtures (NMP = 1-methyl-2-pyrrolidinone) leads to deep blue solutions of RCoBr·RZnX, which are relatively stable at 0 °C.[6] Bubbling CO through these reaction mixtures (0 °C to 25 °C, 3 h) provides symmetrical ketones like **1** in excellent yield [Eq. (a)].[7] In this



(a)

work, we report several new cobalt(II)- and iron(III)-catalyzed reactions of organozinc reagents. The direct acylation of diorganozinc compounds is a low-yield reaction for which palladium-[8] and copper-catalyzed[9] reactions have been developed. The disadvantages of these methods are a lack of generality for the palladium catalysis[10] and the need for a stoichiometric amount of copper salts (CuCN·2 LiCl) for the copper-catalyzed acylations.[9-11]

We have found that $Co^{II}Br_2$ is a very efficient catalyst for the acylation of diorganozinc compounds in NMP/THF mixtures. The reaction of various functionalized diorganozinc compounds with acid chlorides in the presence of $CoBr_2$ (10 mol%) in THF:NMP (1:1) at −10 °C affords polyfunctional ketones **2**–**7** in 78–84% yield [Eq. (b) and Scheme 1]. The reactions are



(b)

complete in less than 0.5 h and proceed well with aliphatic and aromatic acid chlorides, oxalyl chloride, or even trifluoroacetic anhydride.

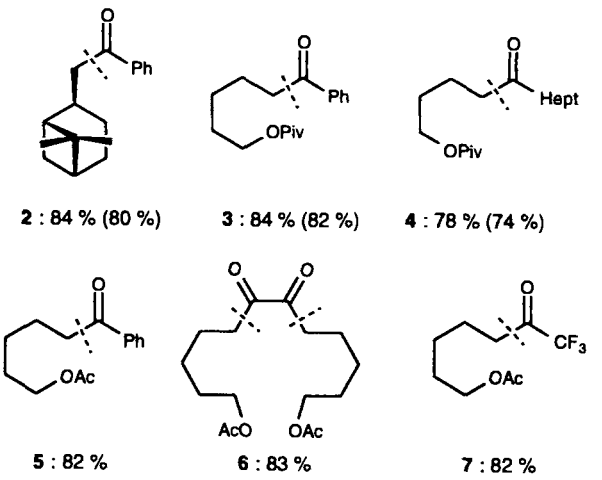
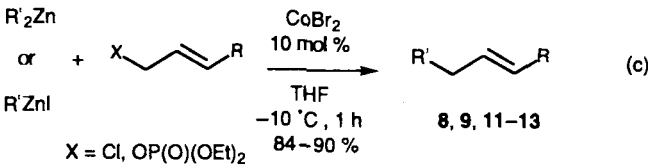


Scheme 1. Products from cobalt(II)- or iron(II)-catalyzed acylations.

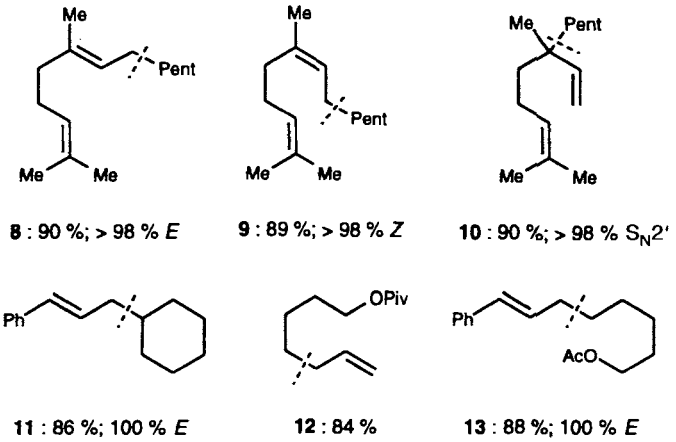
Interestingly, catalysis with $FeCl_3$ (10 mol%) can also be performed (−10 °C, 1 h). Compared to the Co^{II} catalysis, slightly lower yields (yields in parenthesis in Scheme 1) and longer reaction times are required. In the course of this work, it was found that allylations of organozinc reagents (R_2Zn or RZnX) are very efficiently catalyzed by $CoBr_2$ in THF and lead with greater than 98% selectivity to the S_N2-substitution products[12] with complete retention of the stereochemistry of the double bond [>99%, Eq. (c)]. Thus, the reaction of dipentylzinc ($Pent_2Zn$)



(c)

with geranyl chloride gives the (*E*)-diene **8** (>98% *E*; 90% yield), whereas its reaction with neryl chloride provides the isomeric (*Z*)-diene **9** (98% *Z*; 89% yield). Interestingly, the reaction of geranyl chloride with $Pent_2Zn$ in the presence of the soluble copper salt CuCN·2 LiCl (10 mol%, 0 °C, 1 h) furnishes selectively the S_N2'-substitution product **10** (90% yield, >98% S_N2'; Scheme 2).

Alkylzinc halides[9, 13] undergo the allylation reaction, giving similar yields as dialkylzinc compounds but requiring longer



Scheme 2. Products from cobalt(II)- or copper(II)-catalyzed allylations.

reaction times (about 5 h at $-10\,^{\circ}C$). Contrary to the Co^{II}-catalyzed acylation, both functionalized R′ groups from the dialkylzinc compounds ZnR'_2 are transferred in these allylation reactions (see products **11**–**13** of Scheme 2). In addition, allylic phosphates as well as allylic chlorides react, and with the same high stereoselectivity. Thus the reaction of $Pent_2Zn$ with diethyl cinnamylphosphate (THF, $-10\,^{\circ}C$, 0.5 h) furnishes the S_N2 allylated product (*E*)-1-phenyloctene (88% yield, 100% *E*, 100% S_N2 substitution). Organozinc reagents also undergo coupling reactions with benzylic bromides. In the reaction of benzyl bromide with 4-acetoxybutylzinc iodide in the presence of $CoBr_2$ (10 mol%) in THF:NMP (1:1) at $-10\,^{\circ}C$ for 5 h, 5-phenylpentyl acetate is isolated in 60% yield.

In conclusion, we have described a new and efficient cobalt(II)- and iron(III)-catalyzed acylation, which provides a general synthesis of polyfunctional ketones. Remarkably the cobalt(II)-catalyzed allylation provides exclusively S_N2 products with complete retention of the double bond geometry. Further studies involving cobalt(II)- and iron(III)-catalyzed reactions of organozinc compounds are underway.

Experimental Procedure

Typical syntheses are as follows:

Bis(4-pivaloxybutyl)zinc: A 50 mL, three-necked flask was charged with 4-iodobutyl pivalate (8.52 g, 30 mmol), CuI (60 mg, 0.3 mol%), and Et_2Zn (4.5 mL, 40 mmol, 1.3 equiv). The reaction mixture was stirred at 55 °C for 14 h. The volatiles were removed under vacuum (55 °C, 0.1 mm Hg, 2 h). After addition of decane (10 mL), all traces of Et_2Zn were removed under high vacuum (1 h). This last operation was performed twice. The resulting zinc reagent was diluted in ether (10 mL) and was ready to use.

5-Oxododecyl pivalate (**4**): A 50 mL three-necked flask was charged with $CoBr_2$ (218 mg, 1 mmol) in NMP (4 mL) and ether (2 mL). The reaction mixture was cooled to −10 °C and *n*-octanoyl chloride (1.62 g, 10 mmol) was added followed by bis(4-pivaloxy-butyl)zinc (4 mL of the solution prepared as described above, 10 mmol). The resulting deep blue solution was stirred for 0.5 h at −10 °C and worked up as usual. After evaporation of the solvents, the crude residue was purified by flash chromatography (hexane:ether = 95:5), providing **4** (2.2 g, 78% yield) as a colorless oil.

6-Heptenyl pivalate (**12**): A 50 mL three-necked flask was charged with $CoBr_2$ (218 mg, 1 mmol) in THF (5 mL). The reaction mixture was cooled to −10 °C, and allyl bromide (2.42 g, 20 mmol) followed by bis(4-pivaloxybutyl)zinc (4 mL, 10 mmol) was added. The resulting solution was stirred for 5 h at this temperature and worked up as usual to afford, after flash chromatography, 3.32 g of the ester **12** (16.8 mmol, 84% yield).

Hexakis(but-3-ynyl)benzene**

Hans-W. Marx, Françoise Moulines, Trixie Wagner, and Didier Astruc*

Interest in polyalkyne compounds has increased over the last few years[1–5] due to their use as building blocks for the construction of extended molecular frameworks needed in supramolecular assemblies[1a] and molecular electronic devices.[2] For instance, Diederich et al. have synthesized various polyalkynes with exotic shapes,[3] and Bunz et al. have devised a strategy to couple alkyne-derived transition metal complexes to form linear arrays and grids.[4] Vollhardt et al. have reported on two appealing compounds in the hexaalkynylbenzene family, hexaethynyl-[5a] and hexabutadiynylbenzene.[5b] However, little is known concerning hexaalkynylbenzenes in which methylene units separate the benzene ring and the alkyne functions.[6]

The $FeCp^+$-induced formation of multiple C–C bonds in Equation (a) proceeds readily with alkyl, allyl, and benzyl

$$[FeCp(C_6Me_6)]^+PF_6^- \xrightarrow[\text{base}]{RX} [FeCpC_6(CH_2R)_6]^-PF_6^- \qquad \text{(a)}$$

halides;[7] however, this reaction does not allow the direct introduction of alkynes. Indeed, triple bonds are not compatible with the required base. For instance, the reactions of propargyl bromide with KOH in DME or KO*t*Bu in THF with complexes of the series $[FeCp(C_6H_{6-n}Me_n)]^+PF_6^-$ give polymers. Since the $FeCp^+$-induced hexaallylation of C_6Me_6 proceeds readily,[8] we attempted to use this indirect route to synthesize hexakis(but-3-ynyl)benzene. We now report on the synthesis, structure, and reactions of this compound.

The reaction of excess allyl bromide and KO*t*Bu in THF with $[FeCp(C_6Me_6)]^+PF_6^-$ (**1**) gave the hexaallylated complex $[FeCp\{C_6(CH_2CH_2CH{=}CH_2)_6\}]^+PF_6^-$ (**2**) [Eq. (a), R = $CH_2CH{=}CH_2$; Scheme 1). Although **2** can be transformed into

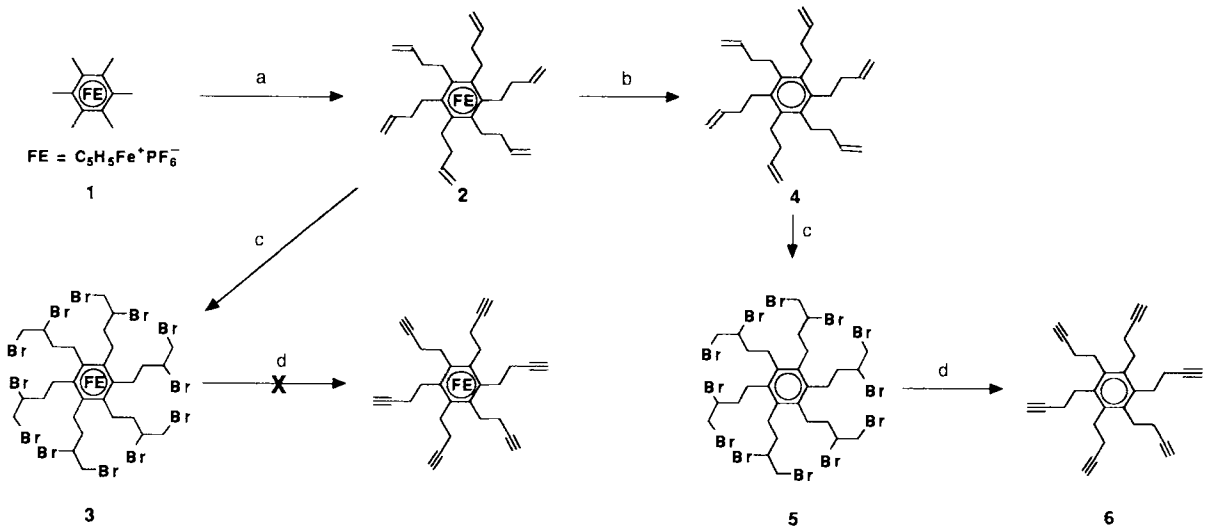

Scheme 1. Synthesis of **6**: a) CH_2=CHBr, KOH, 40 °C; b) $h\nu_{(vis)}$, CH_3CN, PPh_3, room temperature; c) Br_2 in CH_2Cl_2, room temperature; d) $NaNH_2$ in NH_3, −33 °C.

its dodecabromo derivative **3**,[8] we found that the dehydrohalogenation of the latter using $NaNH_2$ in liquid NH_3 gave a product whose ^1H and ^{13}C NMR spectra show the presence of double bonds and of several kinds of triple bonds, presumably resulting from isomerization under the reaction conditions.[9a] The analogous dehydrohalogenation of the metal-free analogue **5** was successful. Photochemical decomplexation of **2** using visible light in CH_2Cl_2 or CH_3CN quantitatively gave **4**.[8] Reaction of Br_2 with **4** in CH_2Cl_2 provided the new insoluble dodecabromo derivative **5** (negative-ion FAB mass spectrum: $[M+Br^-]$), which is also characterized by its correct elemental analysis. Dehydrohalogenation of **5** proceeded by reaction with $NaNH_2$ in liquid NH_3[9] and gave hexakis(but-3-ynyl)benzene (**6**) in 74–81% yield as a white powder (Scheme 1); this synthesis was reproduced many times.

In the pure state, **6** is air-stable at ambient temperature for weeks and thermally stable. The ^1H NMR spectrum of **6** does not change upon heating in [D_8]toluene at 100–110 °C for 18 h. The slow evaporation of a saturated THF solution of **6** provides large transparent crystals. The X-ray structure determination reveals crystallographic $\bar{1}$ symmetry for **6**.[10] The C≡CCH$_2$ units are almost linear, with angles between 176.2(1) and 177.9(1)°. The branches are alternating above and below the plane of the aromatic ring (Fig. 1). Two of the three symmetrically independent substituents have a stretched conformation (*trans* with regard to the CH_2–CH_2 bond, with torsion angles of 168.3(1) and 163.6(1)°); the third substituent has a folded conformation (*gauche* arrangement, with a torsion angle of 57.1(2)°). The C-C-C angles of the latter are larger than those of the two other branches. All equivalent C–C bonds have almost identical lengths within the limits of their estimated standard deviations.

Force-field calculations on **6** show the all-*trans* (D_{3d}) conformation to be the most stable and 11.3 kJ mol^{-1} lower in energy than the C_i arrangement found in the crystal structure (Fig. 1; four *trans* and two *gauche* conformations, Table 1). A decrease in molecular symmetry due to crystal forces is a common phenomenon. Since small energy differences like that calculated here can readily be compensated by lattice energy differences between conformers, the order of stability in the solid state may be reversed.[11]

Reactions of **6** are illustrated in Scheme 2. Addition of BuLi in hexane to **6** in THF immediately provided a white precipitate, which is only poorly soluble in *N,N,N',N'*-tetramethylethylenediamine (TMEDA). Further reactions show that this compound is the hexalithiated derivative **7**. Various electrophiles (MeI, $SiMe_3Cl$, CO_2) were added to a suspension of **7** to furnish the hexasubstituted derivatives **8**–**10** (Scheme 2, Table 2). Hexakis(pent-3-ynyl)benzene (**8**) was obtained in crystalline form in 90% yield by slow evaporation of an etheral solution of the reaction mixture. The trimethylsilyl derivative **9** was obtained as

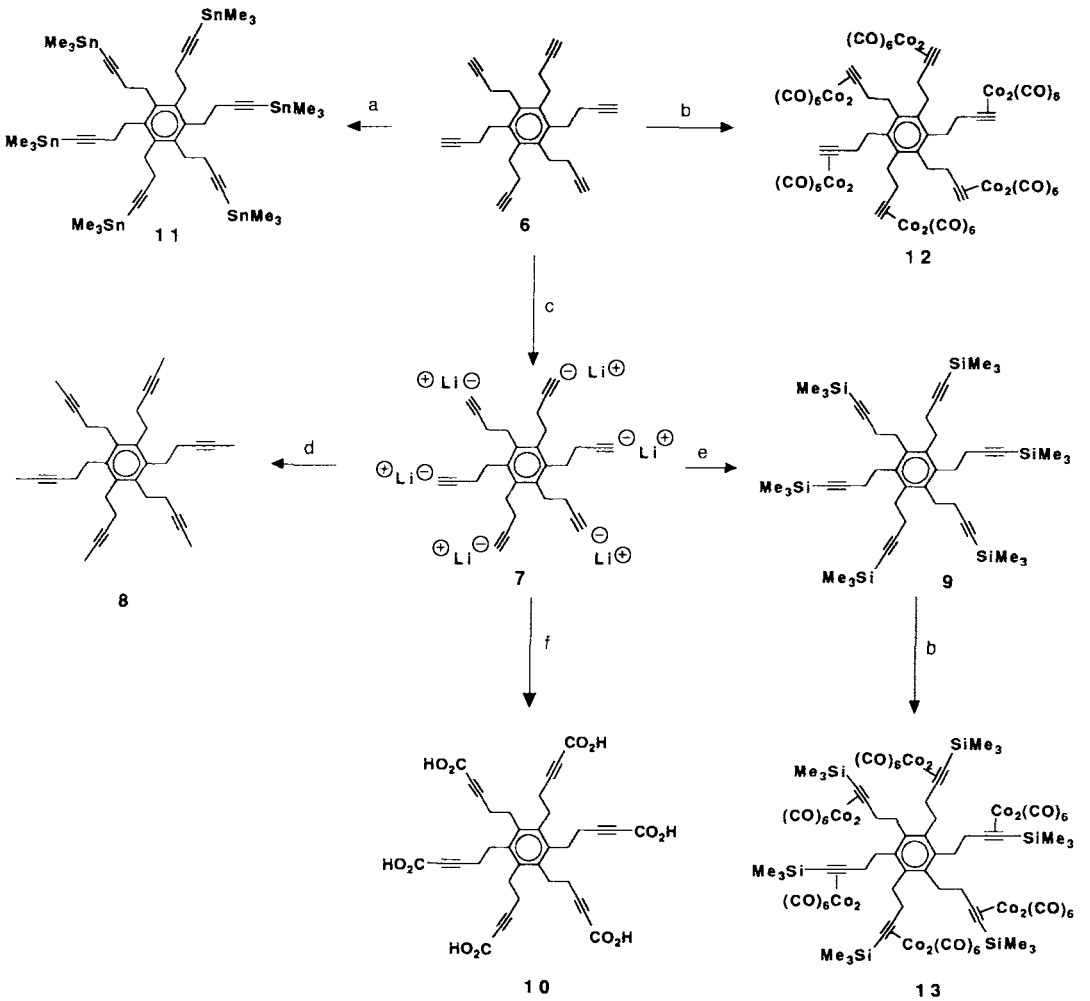
9: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.86 (pseudo-t, J = 8.1 Hz, 12H, CH_2C_{Ar}), 2.34 (pseudo-t, J = 8.1 Hz, 12H, CH_2CC), 1.50 (s, 2H, H_2O), 0.17 (s, 54H, $SiMe_3$); ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 136.3 (C_{Ar}), 106.4 (*C*CSi), 85.4 (C*C*Si), 29.1 (CH_2C_{Ar}), 21.8 (CH_2CC), 0.2 ($SiMe_3$); Anal. calcd. for $C_{48}H_{80}SiO$: 68.50 C, 9.58 H; found: 68.93 C, 9.58 H; m.p. 191–192 °C

10: ^{1}H NMR (250 MHz, [D$_6$]acetone): δ = 7.8 (br., 6H, CO_2H), 3.11 (pseudo-t, J = 7.5 Hz, 12H, CH_2C_{Ar}), 2.63 (pseudo-t, J = 7.5 Hz, 12H, CH_2CC); ^{13}C NMR (62.9 MHz, [D$_6$]acetone): δ = 154.6 (CO_2H), 137.0 (C_{Ar}), 88.6 (*C*CCO$_2$H), 75.0 (C*C*CO$_2$H), 28.3 (CH_2C_{Ar}), 20.5 (CH_2CC); IR (film): $\tilde{\nu}$ = 2230 (C≡C), 1680 (CO) cm^{-1}

11: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 2.87 (pseudo-t, J = 7.3 Hz, 12H, CH_2C_{Ar}), 2.35 (br., 12H, CH_2CC), 0.29 (s, 54H, Sn Me_3, ^{119}Sn satellites: J(Sn,H) = 59.0 Hz); ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 136.3 (C_{Ar}), 110.0 (*C*CSn), 83.2 (C*C*-Sn), 29.5 (CH_2C_{Ar}), 22.1 (CH_2CC), −7.7 ($SnMe_3$, Sn satellites of various isotopes); IR (film): $\tilde{\nu}$ = 214 (C≡C) cm^{-1}

12: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 6.19 (s, 6H, CCH), 3.07 and 2.98 (br., 12H each, CH_2CH_2); IR (film): $\tilde{\nu}$ = 2090, 2055, 2022 cm^{-1}; Anal. calcd. for $C_{66}H_{30}Co_{12}O_{36}$: 37.64 C, 1.44 H, 33.58 Co; found: 37.64 C, 1.68 H, 33.04 Co

13: ^{1}H NMR (250 MHz, $CDCl_3$): δ = 3.22 and 3.10 (br., 12H each, CH_2CH_2), 0.26 (s, 54H, $SiMe_3$); ^{13}C NMR (62.9 MHz, $CDCl_3$): δ = 200.4 (CO), 137.4 (C_{Ar}), 110.3 and 80.4 (CC), 37.2 and 31.4 (CH_2CH_2), 0.5 ($SiMe_3$); IR (film): $\tilde{\nu}$ = 2085, 2070, 2045, 2020 cm^{-1}



Scheme 2. Reactions of **6**: a) Me_2NSnMe_3; b) $[Co_2(CO)_8]$, pentane, room temperature; c) *n*BuLi, THF, room temperature; d) MeI, THF, room temperature; e) Me_3SiCl, THF, room temperature; f) CO_2, THF then aq. HCl, room temperature.

reaction was accompanied by violent evolution of CO and after a few minutes the red compound **12** formed. This compound is almost insoluble in standard solvents but gave satisfactory elemental analysis and a clean ^{1}H NMR spectrum (after 2000 scans (!), 250 MHz, $CDCl_3$). In contrast, analogue **13**, which has six $SiMe_3$ groups, is readily soluble in various solvents and was easily characterized by ^{1}H and ^{13}C NMR spectroscopy (Scheme 2, Table 2).

In conclusion, hexakis(butynyl)benzene (**6**), now easily and reproducibly accessible, is a very stable compound which shows a well-defined conformation in the solid state and a rich synthetic chemistry. Various hexaalkynylbenzenes, including functionalized derivatives and potentially useful synthetic intermediates, can be obtained from hexamethylbenzene in high yield.

Experimental Procedure

5: To a cold solution (−80 °C) of hexakis(butenyl)benzene (1.00 g, 2.48 mmol) in 50 mL of CH_2Cl_2 was added dropwise Br_2 (0.8 mL, 2.5 g, 15.6 mmol). The solution was stirred for 30 min at room temperature before the product was filtered off, washed with pentane (3 × 10 mL), and dried in vacuo. This gave 3.04–3.21 g (90–95%) of **5** as a white powder.

6: At −70 °C, 100 mL of NH_3 was condensed into a large Schlenk tube. After addition of a small amount of $Fe(NO_3)_3 \cdot 9H_2O$, Na (6.10 g, 265 mmol) was added in small portions. When H_2 evolution had ceased (the slurry was now gray), 3.00 g of **5** was added. The temperature was first raised to −60 °C (16 h), then to −35 °C (5 h). The mixture was hydrolyzed by addition of NH_4Cl (14.40 g, 269 mmol) and NH_3 was evaporated under reduced pressure. After addition of aq. HCl (pH < 4), the product was extracted with CH_2Cl_2. The organic layers were washed with water, dried over Na_2SO_4, filtered, and concentrated to dryness. Flash chromatography (Al_2O_3, 8 × 2 cm, Et_2O) yielded 640–700 mg (74–81%) of **6** as a white powder.

7: A solution of BuLi in hexane (0.92 mL, 1.6 M, 1.47 mmol) was slowly added to a cold (−70 °C) solution of **6** (95.3 mg, 0.244 mmol) in 20 mL of THF. After 15 min lithiation was complete and a white precipitate had formed. This suspension was used in subsequent reactions.

9: A twofold excess of Me_3SiCl was added to the suspension of **7** prepared as described above. The precipitate dissolved immediately. The solvent was evaporated and the product was dissolved in Et_2O. The organic phase was washed twice with water, dried over Na_2SO_4, and filtered. After evaporation of the solvent, the product was purified by flash chromatography (Al_2O_3, 5 × 2 cm, Et_2O). The white powder (97%) contained 1 equiv of water and was very soluble in Et_2O, THF, and CH_2Cl_2, but only sparingly soluble in pentane.

10: A stream of dry CO_2 was bubbled through a suspension of **7** first at −70 °C, later at room temperature. After evaporation of the solvent, water was added, the suspension was filtered, and the solution was acidified with aq. HCl. The solid that had formed was filtered, dissolved in Et_2O, and precipitated with pentane. The product (70%) was filtered and dried. It was soluble in Et_2O, acetone, and aq. NaOH, but only sparingly soluble in pentane and CH_2Cl_2.

The Novel Encapsulation of Transition Metals in a Bioctahedral Rare Earth Metal Cluster: $Cs_2La_{10}I_{17}Co_2$

Michael Lulei, Paul A. Maggard, and John D. Corbett*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

The rare earth metal halides form a remarkable variety of highly reduced phases that contain metal clusters.[1, 2] The great majority of these clusters are derived from octahedral units M_6 that are centered by an interstitial atom and are bridged over

each edge by a halide atom to form $M_6X_{12}Z$ units. Possible interstitial atoms are transition metals (i.e. elements from Groups 7–9), main group elements from the second period such as C and N, and even small diatomic C_2 units. The encapsulated elements provide not only central bonding to the cluster but also valence electrons that aid in fulfilling certain minimal electron counts necessary for cluster bonding of the electron-poor rare earth metals.

Our research in recent years has focused on the condensation of clusters into oligomers and chains, as well as on the different patterns of connectivity displayed by the halide atoms that link the clusters into diverse frameworks. Compounds in which R_6Z clusters occur isolated from each other in the structure or are condensed into infinite chains are well investigated and common. However, so far only a very limited group are known with bioctahedral clusters, such as $Gd_{10}Cl_{17}C_4$, or more recently, $CsEr_{10}I_{18}C_4$, in which two M_6 octahedra share a common edge and are each centered by a C_2 group.[3–5] In addition, there are oligomers derived from the spherical condensation of four R_6Z octahedra as in the structures of $Y_{16}I_{20}Ru_4$, $Y_{16}Br_{24}Ir_4$, and $Gd_{20}I_{28}Mn_4$.[6–8] We have also found that the introduction of alkali metal atoms into these systems leads to new quaternary compounds with different compositions and cluster arrangements, as observed in $Cs_4Pr_6I_{13}Os$ and $KPr_6I_{10}Os$ for example.[9, 10] In addition, there is a bioctahedral cluster $La_{10}I_{15}Os_2$ under further study which is apparently formed only in the presence of KI flux.[11]

We report here a novel feature in the chemistry of transition metal stabilized cluster compounds—a bioctahedral cluster unit centered by Co. The new compound with the formula $Cs_2La_{10}I_{17}Co_2$ crystallizes as irregular-shaped, black, air- and moisture-sensitive crystals.[12] As shown in Figure 1,[16] the

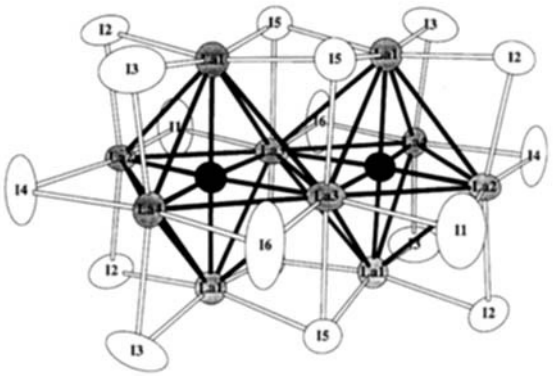

Fig. 1. Structure of the $La_{10}Co_2I_{17}^{2-}$ cluster unit (C_{2h} symmetry, ellipsoids at 99% probability with Co atoms as black circles). Selected interatomic distances [Å]: Co–Co 4.416, La1–Co 2.885, La2–Co 2.779, La3–Co 2.794/3.000, La4–Co 2.659, La1–La2 4.019, La1–La3 4.024/4.148, La1–La4 3.914, La2–La3 4.011, La2–La4 3.951, La3–La3 3.757, La3–La4 4.144.

most remarkable structural feature is a cluster of ten La atoms in the form of two edge-sharing octahedra, each centered by a Co atom. The cluster is centrosymmetric with an inversion center at the midpoint of the La3–La3 axis (site symmetry $2/m$), which is considerably shorter than the other metal–metal separations (by about 0.2 Å).

All 22 outer La–La edges of this bioctahedral cluster are bridged by one of six crystallographically distinct iodine atoms (Fig. 1), which also serve to connect the metal clusters into a three-dimensional network (Figs. 2 and 3). I1 and I4 bridge the La2–La3 and La2–La4 edges, respectively, and connect the clusters as I^{i-a}[1] into layers about (0, 0, 0) and (0, 1/2, 0) along

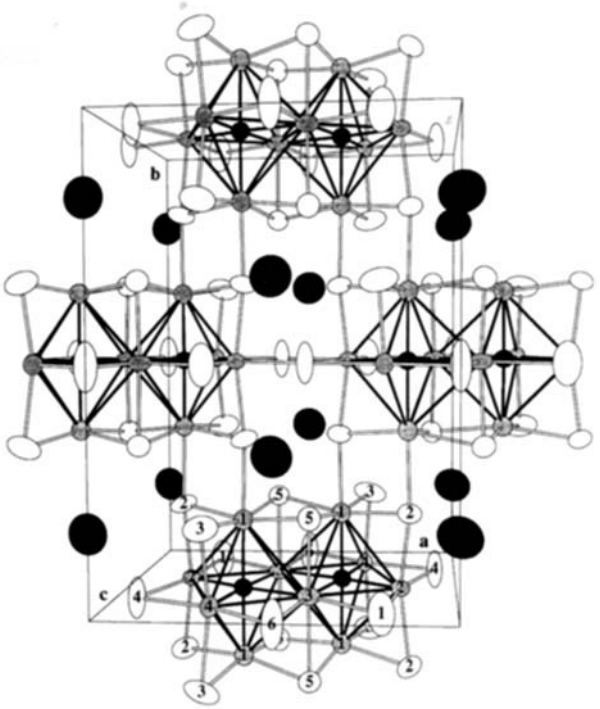

Fig. 2. Structure of $Cs_2La_{10}I_{17}Co_2$. The view of the unit cell along [001] showing the arrangement of the clusters, the iodine connectivity, and the Cs atoms (Cs: large black circles, La: gray, I: white, Co: small black circles, ellipsoids at 99% probability).

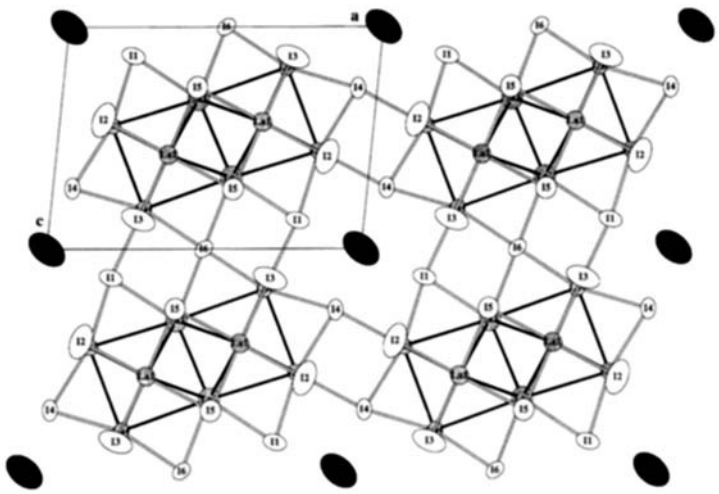

Fig. 3. Structure of $Cs_2La_{10}I_{17}Co_2$. Projection of one layer at (0, 0, 0) on (101) to show the iodine connectivity (atoms are marked as in Fig. 2).

[010] in the unit cell (Fig. 2). The I6 atoms bridge La3–La4 edges in two adjoining clusters within one layer and have, therefore, the functionality I^{i-i}. I2 atoms cover the La1–La2 edges and link the clusters as I^{i-a} along [010]. The La1–La4 edges are capped by I3 atoms (I^i) that form no bonds to neighboring clusters. Finally, two I5 atoms each bridge pairs of La1–La3 edges as I^i in the saddles of the bioctahedral cluster, and hence are each coordinated to three La atoms. All I atoms with the functionality I^{i-a} are naturally complemented by an equal number of I atoms that link the clusters as I^{a-i}. Therefore, the interconnection pattern of the structure can be formulated as $Cs_2(La_{10}Co_2)I^i_8I^{i-i}_{2/2}I^{i-a}_{8/2}I^{a-i}_{8/2}$.

The Cs atoms are located in iodine-lined, slightly distorted and somewhat oversized cuboctahedral cavities within the framework of clusters and halide atoms (Fig. 4). The inter-

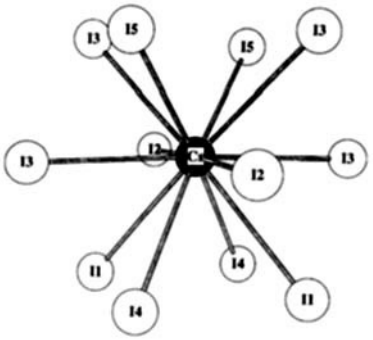

Fig. 4. Coordination polyhedron of the Cs atoms in $Cs_2La_{10}I_{17}Co_2$.

atomic distances range from 4.144 Å for Cs–I5 to 4.514 Å for the Cs–I1 separations. The electron count for $Cs_2La_{10}I_{17}Co_2$ reveals that there are 33 electrons per cluster available for metal–metal bonding. Interestingly, since there are two interstitial atoms per cluster, and an odd number of iodine atoms, it is impossible to reach an even number of cluster electrons by a complete exchange to other interstitial elements. $Cs_2La_{10}I_{17}Fe_2$ would have 31 and the Ni analogue 35 electrons available for metal–metal bonding.

The structure described here is related to those that contain the $Gd_{10}(C_2)_2$ biclusters. In all of these compounds, the halides and the interstitial species, and in case of $Cs_2La_{10}I_{17}Co_2$ also the Cs atoms, approximate a cubic close packing with the rare earth metals in the octahedral holes. Indeed, the interconnection pattern among the halide atoms for $Cs_2La_{10}I_{17}Co_2$ and $Gd_{10}Cl_{17}C_4$ is the same, although the arrangement of the bioctahedral units to each other is altered in order to accommodate the large Cs atoms. This is also reflected by the higher symmetry of the present compound.

Following up on the discovery of this new quaternary example of bioctahedral rare earth metal clusters stabilized by Co, we are exploring the range of this chemistry and also the properties of these phases. The structure pertains to other rare earth metals and interstitials such as Os as well, and preliminary magnetic data and MO calculations are consistent with the expectations (above). These aspects will be reported in a subsequent full paper.

Experimental Procedure

The synthetic and sublimation techniques for LaI_3 and the reaction procedures utilizing welded Nb tubing have been described before [17,18]. CsI (Alfa, 99.9%) was dried by slow heating under dynamic high vacuum and then sublimed. La metal (Ames Laboratory) and Co powder (Alfa, 99.95%) were used as received and were handled in a glovebox. Initially mixtures with an overall stoichiometry $Cs_2La_6I_9Co$ were heated at 800 °C for 27 days, slowly cooled at 5 °C h^{-1} to 300 °C, and then the furnace was turned off. According to Guinier powder pattern, the products were 80% $Cs_2La_{10}I_{17}Co_2$, 10% CsI and 10% LaOI (from traces of water, as usual [1]). Subsequent reactions of starting materials with the refined stoichiometry gave the compound in high yields (90%, in addition to about 10% LaOI) under the same reaction conditions.

Like on Heterogeneous Hydrodesulfurization (HDS) Catalysts, the Homogeneous HDS of Benzo[*b*]thiophene Is Achieved by the Concomitant Action of a Metal Promoter (Rh) and an Active HDS Component (W)**

Claudio Bianchini,* M. Victoria Jiménez, Carlo Mealli, Andrea Meli, Simonetta Moneti, Véronique Patinec, and Francesco Vizza

The commercial hydrodesulfurization (HDS) catalysts generally comprise metal sulfides supported on γ-alumina. Molybdenum or tungsten are essential components but the catalytic activity increases remarkably by addition of other transition metals (Ni, Co, Ru, Ir, Rh, Pt, Pd, Os, Re) as promoters.[1, 2] The role played by these promoters is still a matter of debate. According to a recent mechanistic interpretation, the active centers for thiophene activation are the promoter atoms located at the edge plane of a MoS_2 (or WS_2) single slab, whereas H_2 activation occurs on MoS_2 (or WS_2).[2] Modeling studies for the homogeneous reaction support this hypothesis since the large majority of the known C–S bond scissions of thiophenes are brought about by promoter metal complexes.[3] On the other hand, the activation of the thiophene molecules by promoter metal complexes is never followed by the desulfurization of the substrate unless polymetallic metal systems[4] or external sources of "activated" hydrogen atoms are employed.[5] We report herein that benzo[*b*]thiophene, in which a metal promoter (Rh) is inserted into a C–S bond, is desulfurized by H_2 only with the mandatory cooperation of a W center bound to the sulfur atom. For the first time, the heterobimetallic intermediate species that is formed prior to the desulfurization step has been intercepted and characterized.

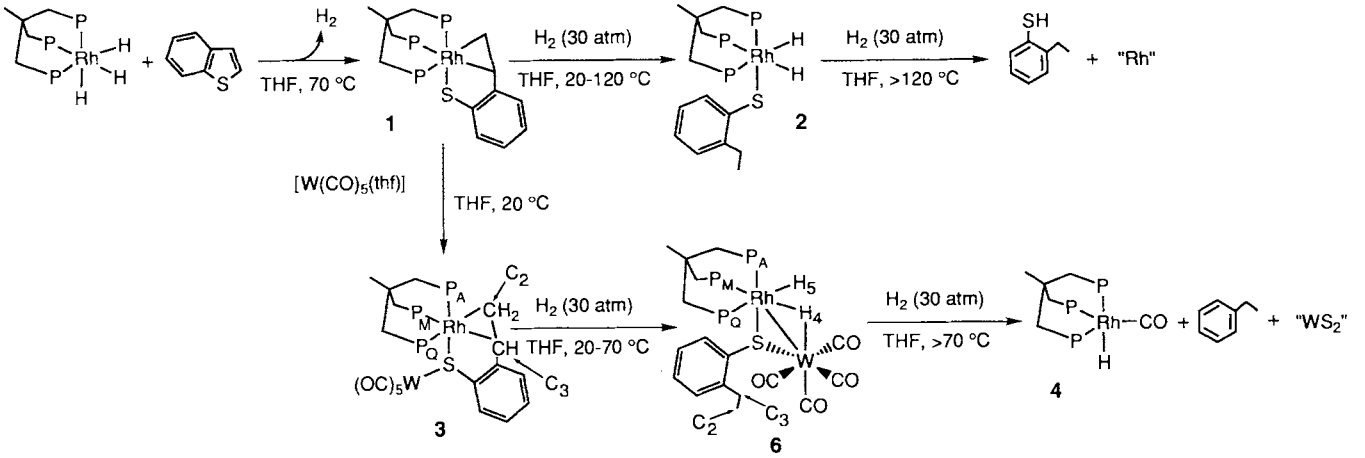
The 2-vinylthiophenolate complex [(triphos)Rh{η^3-S(C_6H_4)CH=CH_2}] (**1**), obtained by reaction of the 16-electron fragment [(triphos)RhH] (triphos = $MeC(CH_2PPh_2)_3$) with benzo[*b*]thiophene,[3h] is an efficient catalyst for the hydrogenolysis of benzo[*b*]thiophene to 2-ethylthiophenol.[6] High-pressure NMR spectroscopy (HPNMR) has shown that, under catalytic conditions, an active species is the dihydride **2**.[6] In the absence of BT, **1** in THF reacts with H_2 (30 atm, >120 °C) to give free 2-ethylthiophenol and various Rh compounds via the intermediacy of the dihydride **2** which is formed at lower temperature (20–120 °C) (Scheme 1).



Scheme 1. Synthesis of **1**–**4** and **6**.

A quite different reaction with H_2 (30 atm) is observed when **1** is previously treated with [$W(CO)_5$(thf)] to give the adduct **3**, which is isolated as orange-yellow crystals. In this case, in fact, the hydrodesulfurization of the thiolate ligand (THF, 30 atm H_2, >70 °C) occurs with formation of ethylbenzene (GC-MS), **4**,[7] and an insoluble black material that contains W and S in an approximate ratio of 1 to 2 (atomic absorption analysis). Analysis of the crude product shows that traces of $W(CO)_6$ (GC-MS) and of **5**[6] (NMR) are also formed.

[(triphos)Rh(CO){*o*-S(C_6H_4)C_2H_5}] **5**

Monitoring the reaction between **3** and H_2 by variable-temperature HPNMR shows that the degradation of **3** to **4** is traversed by an intermediate species **6**, which incorporates all the rhodium at temperatures below 70 °C. This species has been isolated as brick red crystals by reaction of **3** in THF with H_2 (30 atm) at a constant temperature of 70 °C for 3 h. The molecular structure of **6** has been elucidated in both solution and the solid state by multinuclear NMR spectroscopy and an X-ray structure analysis,[8] respectively. A Zortep drawing of this binuclear complex **6** is shown in Figure 1.

The X-ray structure analysis, carried out on crystals of **6**·CH_2Cl_2, confirms the NMR spectroscopic results: a hydride anion bridges the Rh and W metal centers (^{1}H NMR, CD_2Cl_2, 20 °C: $\delta(H_b) = -9.88$, $J(H,Rh) = 19.0$, $J(H,P)_{trans} = 100.6$, ^{183}W satellites with $J(H,W) = 34.2$ Hz). Unfortunately, the second hydrido ligand could not be located and its position is only indirectly placed (^{1}H NMR, CD_2Cl_2, 20 °C: $\delta(H_t) = -10.07$, $J(H,Rh) = 6.8$, $J(H,P)_{trans} = 181.5$, $J(H,H) = 5.4$ Hz; IR (CH_2Cl_2): $\tilde{\nu} = 1996$ cm^{-1} (νRh–H)). In fact, there is a vacant octahedral site at the Rh center, and the opposite P_1 atom is the most *trans*-influenced (d_{Rh-P1} 2.414(4), $\bar{d}_{Rh-P2,3}$ 2.293(4) Å).

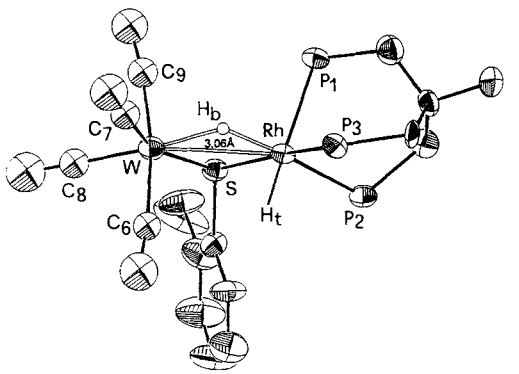


Fig. 1. Zortep drawing of the structure of **6**. Phenyl rings of the triphos ligand are omitted for clarity. The atom H_t could not be located by normal X-ray procedures and it is shown at the vacant octahedral site about the rhodium atom. The positioning is supported by the Rh–P_1 bond, which is significantly longer than the other two Rh–P bonds [2.414(4) vs. av 2.293(4) Å]. Selected bond lengths [Å] and angles [°]: W–S 2.493(4), Rh–S 2.407(4), W–C 1.93(3) (av), W–H_b 1.75(16), Rh–H_b 1.57(16); P-Rh-P 90.0(6) (av), C_6-W-C_9 170.8(7), C_7-W-C_8 91.4(7), W-S-Rh 77.1(1), S-Rh-P_3 169.9(1), S-W-C_7 159.8(5), P_2-Rh-H_b 170(5), C_8-W-H_t 172(5), W-H_b-Rh 134(3).

The overall structure can be described as follows: By initially neglecting the H_b ligand, the two formal d^6 metal centers (W^0 and Rh^{III}) appear as the central atoms of two square pyramids sharing a basal site (namely, the bridging S donor of the thiophenolate ligand). Although the H_b ligand seems to be in the proper position to complete the octahedra of both metal centers, its two electrons cannot saturate the metals (in terms of the effective atomic number (EAN) rule, the total electron count of 34 implies a M–M bond). Essentially, the situation closely resembles that of the $[M(CO)_5(\mu\text{-H})]^-$ ions (M = Cr, W),[14] which contain two isoelectronic terminal ML_5 fragments and a bent M-H_b-M bridge. The latter, also described as a three-center–two-electron bond, involves the formally empty σ-hybrid orbitals of the two ML_5 fragments and the filled H_{1s} orbital. The W–Rh distance of 3.06 Å and the W-H_b-Rh angle of 134° are consistent with the corresponding parameters of the quoted compounds.

To confirm the intermediacy of **6** in the desulfurization step, an isolated sample of this compound in THF was treated with H_2 (30 atm) at a constant temperature of 120 °C. This led to the (carbonyl)hydride **4**, ethylbenzene, and the black material

"WS_2". Also, the thermal decomposition of **6** at 120 °C under nitrogen (NMR experiment in [D$_8$]THF) gave **4** (together with some **5** and decomposition products), thus indicating that the desulfurization step involves an intramolecular hydrogen atom migration.

The overall structural motif of **6** has no experimental precedent in modeling studies on homogeneous systems, but heterobimetallic moieties with a similar structure have been suggested to form on the surface of heterogeneous HDS catalysts.[4a]

Experimental Procedure

3: A sample of $W(CO)_6$ (0.12 g, 0.33 mmol), dissolved in THF (30 mL), was placed in a quartz reactor and converted to [$W(CO)_5$(thf)] by photolysis at −10–10 °C under a flow of nitrogen. After 4 h, this solution was transferred by cannula to a flask containing **1** [3h] (0.28 g, 0.33 mmol) in THF (20 mL) and the resulting mixture stirred for 1 h at room temperature. The volume of the solvent was reduced to about 15 mL and ethanol (40 mL) added. Orange-yellow microcrystals of **3** were obtained in 85% yield after filtering and drying. $^{31}P\{^1H\}$ NMR (81.01 MHz, CD_2Cl_2, 20 °C): AMQX spin system, δ = 30.9 (ddd, $J(P_A,P_M)$ = 36.0, $J(P_A,P_Q)$ = 32.0, $J(P_A,Rh)$ = 115.8 Hz; P_A), −7.1 (ddd, $J(P_M,P_Q)$ = 42.6, $J(P_M,Rh)$ = 112.4 Hz; P_M), −10.0 (ddd, $J(P_Q,Rh)$ = 104.6 Hz; P_Q); ^1H NMR (200.13 MHz, CD_2Cl_2, 20 °C): δ = 3.84 (m, $J(H_2,H_3)$ = 9.5 Hz, $J(H_2,H_2)$ = 1.7, $J(H_2,Rh)$ = 1.8 Hz; H_2), 2.86 (m, $J(H_3,H_2)$ = 8.3, $J(H_3,Rh)$ = 0.9 Hz; H_3), 2.70 (m, $J(H_2,Rh)$ = 1.5 Hz; H_2). The J(H,H) and J(H,Rh) values were determined on the basis of $^1H\{^{31}P\}$ NMR experiments. $^{13}C\{^1H\}$ NMR (50.32 MHz, CD_2Cl_2, 20 °C): δ = 42.5 (dm, J(C,P) 35.9; C_2), 65.5 (dm, J(C,P) 28.7; C_3), 200.1 (s, ^{183}W satellites with J(C,W) = 128.7 Hz; CO_{eq}), 202.6 (s, CO_{ax}). Remaining ^{13}C resonances were obscured by those of triphos carbon atoms. IR (Nujol): $\tilde{\nu}$ = 2060 (m), 1966 (m), 1917 (vs), 1872 (s) cm^{-1} (CO). $C_{54}H_{46}O_5P_3RhSW$ (1186.7): calcd: C 54.65, H 3.91, Rh 8.67; found: C 54.55, H 3.81, Rh 8.49.

6: A solution of **3** (0.24 g, 0.2 mmol) in THF (50 mL) was treated with H_2 (30 atm) at 70 °C for 3 h in a Parr reactor. After the bomb was depressurized and vented under a nitrogen stream, the contents were transferred into a Schlenk-type flask. The solution was concentrated to about 20 mL under vacuum. Portionwise addition of *n*-heptane (10 mL) led to the precipitation of brick red crystals of **6** in 75% yield. $^{31}P\{^1H\}$ NMR (81.01 MHz, CD_2Cl_2, 20 °C): AMQX spin system, δ = 23.1 (ddd, $J(P_A,P_M)$ = 34.1, $J(P_A,P_Q)$ = 26.9, $J(P_A,Rh)$ = 109.7 Hz; P_A), 13.6 (ddd, $J(P_M,P_Q)$ = 21.7, $J(P_M,Rh)$ = 105.5 Hz; P_M), −9.2 (ddd, $J(P_Q,Rh)$ = 74.5 Hz; P_Q); ^1H NMR (200.13 MHz, CD_2Cl_2, 20 °C): δ = 2.63 (dq, $J(H_3,H_3)$ = 14.0, $J(H_3,H_2)$ = 7.4 Hz; H_3), 2.18 (dq, $J(H_3,H_2)$ = 7.4 Hz; H_3), 1.10 (t; H_2), −9.88 (dm, $J(H_4,Rh)$ = 19.0 Hz, $J(H_4,H_5)$ = 5.4 Hz, $J(H_4,P_M)$ = 100.6 Hz, ^{183}W satellites with $J(H_4,W)$ = 34.2 Hz; H_4), −10.07 (dm, $J(H_5,Rh)$ = 6.8 Hz, $J(H_5,P_Q)$ = 181.5 Hz; H_5). The J(H,H), J(H,Rh) and J(H,W) values were determined on the basis of $^1H\{^{31}P\}$ NMR experiments. $^{13}C\{^1H\}$ NMR (50.32 MHz, CD_2Cl_2, 20 °C): δ = 213.9 (s; CO), 210.6 (d, J(C,P) = 5.3 Hz; CO), 205.5 (d, J(C,P) = 3.8 Hz; CO), 205.2 (d, J(C,P) = 6.0 Hz; CO), 29.1 (s; C_2), 14.9 (s; C_3). IR (Nujol): $\tilde{\nu}$ = 1995 (s) (Rh–H), 2057 (w), 1868 (s), 1852 (s), 1811 (s) cm^{-1} (CO); (CH_2Cl_2 solution): ν = 1996 (s) (Rh–H), 2058 (w), 1872 (vs), 1860 (sh), 1822 (s) cm^{-1} (CO). $C_{53}H_{50}O_4P_3RhSW$ (1162.7): calcd: C 54.75, H 4.33, Rh 8.85; found: C 54.68, H 4.25, Rh 8.69. Crystals of **6**·CH_2Cl_2 suitable for an X-ray structure analysis were obtained by slow crystallization of **6** from CH_2Cl_2/ethanol under nitrogen at room temperature. $C_{54}H_{52}Cl_2O_4P_3RhSW$ (1246.1): calcd: C 51.99, H 4.20, Rh 8.25; found: C 51.21, H 4.22, Rh 8.12.

[8] Crystal structure data for $C_{53}H_{50}O_4P_3RhSW\cdot CH_2Cl_2$: monoclinic, space group $P2_1/n$, ρ_{calcd} = 1.607 g cm^{-3}, Z = 4, a = 15.626(5), b = 19.129(5), c = 17.270(5) Å, β = 92.33(1)°, V = 5158(3) Å^3, number of unique data = 6486, $R1$ [$I > 2\sigma(I)$] = 0.081. Data were collected on a Philips PW1100 FEBO diffractometer at 293(2) K using $Cu_{K\alpha}$ (λ = 1.5418 Å) radiation. A set of 25 carefully centered reflections having $10 < \theta < 16.5$ were used to determine the cell constants. Three standard reflections were measured every 2 h for the orientation and the intensity control. During data collection no decay for the specimen was noticed. Intensity data were corrected for Lorentz-polarization effects. Atomic scattering factors were those reported by Cromer and Waber [9] with anomalous dispersion correction taken from reference [10]. An empirical absorption correction was applied by Ψ scan with transmission factors in the range 1.001–1.46 [11]. The computational work was carried out with the program SHELXL93 [12]. The structure was solved by direct methods using the SIR92 programm [13] and all of the non-hydrogen atoms were found through a series of F_o Fourier maps. A CH_2Cl_2 solvent molecule was also introduced although affected by some disorder. Nonmetal-bound hydrogen atoms were introduced at calculated positions at the late stage of refinement. The latter was done by full-matrix least square calculations, initially with isotropic thermal parameters. In the last least square cycles anisotropic thermal parameters were used for Rh, W, S, and P, and also for the C atoms except for those of the P phenyl substituents and of the CO molecules. In the last stage of refinement a peak of 0.9 e Å^{-3} was detected in the ΔF map corresponding to the expected bridging hydrido ligand, and it was succesfully refined. No evidence was found for the terminal H ligand. In the final ΔF maps significant peaks were found close to the heavy metal (largest value ca. 1.2 e Å^{-3}), and were considered as ripples of no chemical relevance. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-71. Two-Phase Catalysis: A Strategy for Avoiding Consecutive Reactions as Exemplified in the Telomerization of Butadiene and Ammonia**

Thomas Prinz, Wilhelm Keim, and Birgit Driessen-Hölscher*

Liquid/liquid two-phase processes nowadays play a major role in homogeneous catalysis,[1–4] and are increasingly used in industrial applications.[5–7] Several homogeneously catalyzed telomerizations, that is the dimerization of a diene coupled with the addition of a nucleophile, have been carried out in two-phase systems.[8–12] One example that has already achieved

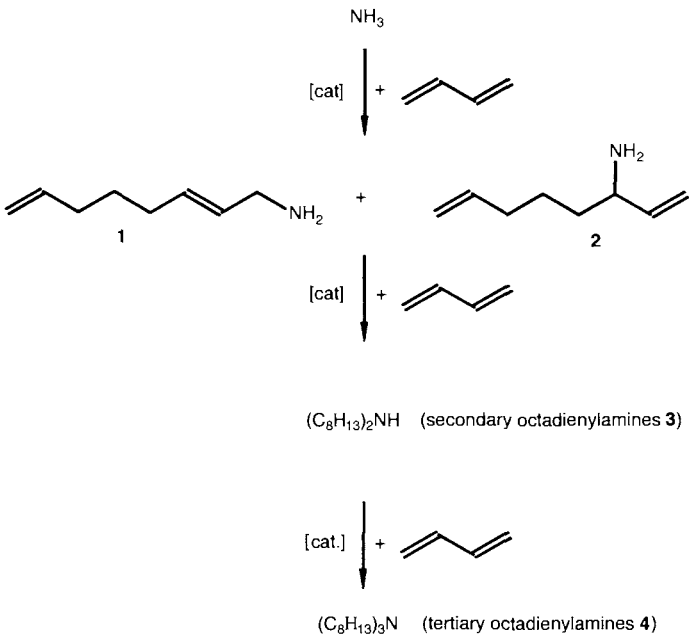
industrial significance is the synthesis of 1,7-octadienol from butadiene and water.[7] In contrast, the catalytic telomerization of butadiene and ammonia has so far only been carried out in one-phase systems,[13-15] leading to the products shown in Scheme 1.



Scheme 1. Telomerization of butadiene and ammonia.

Since the primary and secondary octadienylamines **1**/**2** and **3**, respectively, are more nucleophilic than ammonia and therefore react further, it is not possible to synthesize them in good yields and selectivities by the above-mentioned telomerization. Even at low conversions, the primary octadienylamines **1** and **2** are only obtained with poor selectivities (Table 1, entry 1). If it were possible to control this telomerization to selectively yield only the primary products **1** and **2**, a potential route for the synthesis of primary octadienylamines would be available. Hydrogenation of **1** yields the industrially important *n*-octylamine, which is used for the production of water softeners, corrosion inhibitors, and flotation agents.

We report herein that **1** and **2** can be synthesized selectively by the catalytic two-phase telomerization of butadiene and ammonia, providing that the two amines are extracted from the aqueous catalyst phase immediately after their synthesis by using a solvent with appropriate polarity. In this way, the consecutive reactions to higher amines in the aqueous phase are avoided. The catalyst system employed consists of palladium acetate/tppts (tppts = trisodium salt of 3,3′,3″-phosphanetriylbenzenesulfonic acid) dissolved in water. The second phase is an organic solvent such as toluene to which butadiene and ammonia is added. The results of the known one-phase telomerizations are listed in Table 1 together with the results of our two-phase experiments.

When the telomerization is carried out in *tert*-butyl alcohol as a single-phase process (reaction time 1 h), tertiary amines **4** are obtained as the major product with 61% selectivity in a total yield of 21% (Table 1, entry 1). In contrast, the two-phase process under otherwise identical conditions leads preferentially to the primary amines **1** and **2** (Table 1, entry 2). The high selectivity of 25.8% with which the secondary amines **3** are formed can be attributed to the high reaction temperature of 100 °C and to the small amount of ammonia present. When the two-phase telomerization is carried out at 60 °C with a large excess of ammonia and under otherwise identical conditions, the secondary amines **3** are obtained with a selectivity of only 1%. Typical results of two-phase telomerizations with various solvents are listed in Table 2. Without the organic phase—using only water as solvent—under otherwise identical conditions, the preferred products are the primary (**1**, **2**) and secondary amines **3** (Table 2, entry 1). The solubility of butadiene in the aqueous catalyst phase is sufficient to allow medium conversions. However, the octadienylamines **1** and **2** are slightly soluble in the aqueous phase and thus the consecutive reaction to the secondary amines **3** takes place to a considerable extent. Similar results are achieved when ethyl acetate is used as the organic phase (Table 2, entry 4), since it mixes better with water than the other solvents and thus compounds **1** and **2** cannot be extracted. Toluene serves as a suitable solvent for extraction; the primary amines are formed with a selectivity of 88%.

Table 1. Comparison of one-phase versus two-phase catalytic process in the telomerization of butadiene and ammonia [a].

Entry	Process	Selectivity [%]			Ratio	Total yield
		1+**2**	**3**	**4**	(**1**+**2**):**3**:**4**	[%] [b]
1	one-phase	2	4	61	1:2:31	21
2	two-phase	31.5	25.5	1.5	21:17:1	24

[a] Reaction conditions: Single-phase: $T = 100$ C, $t = 1$ h, butadiene:ammonia = 10:1, Pd : butadiene = 1:1000, 20 mL *tert*-butyl alcohol, Pd:PPh_3 = 1:3.4; two-phase: $T = 100$ C, $t = 1$ h, butadiene:ammonia = 10:1, Pd:butadiene = 1:1000, H_2O:CH_2Cl_2 = 2:1, Pd:tppts = 1:4. [b] Total yield based on ammonia.

Table 2. Influence of the organic solvent on the catalytic two-phase telomerization of butadiene and ammonia [a].

Entry	Second phase	Selectivity [%]			Total yield
		1+**2**	**3**	**4**	[%] [b]
1	–	60.5	30	·	41
2	toluene	88	6	·	55
3	pentane	79	16	·	61
4	ethyl acetate	53	18	·	40

[a] Reaction conditions: $Pd(OAc)_2$ (0.15 mmol), tppts (0.6 mmol), H_2O (20 mL), organic solvent (12.5 mL), ammonia (300 mmol), butadiene (75 mmol), $T = 80$ C, $t = 1.5$ h. [b] Total yield based on butadiene.

The total yields show that the second phase has a significant influence on the mass transfer of reactants and products between the aqueous and the organic phase. It is known that reaction rates of two-phase reactions are limited by mass transfer.[16]

In a pilot plant for batchwise operation, comprising a 900 mL reactor and a coupled separator, the catalyst phase could be recycled ten times without loss of selectivity and with only small loss of activity. Our results show that two-phase catalysis is a suitable method for avoiding consecutive reactions of primary products that are sparingly soluble in water. Further applications are conceivable such as in the hydroformylation of alkynes.

Experimental Procedure

In a typical experiment palladium(II) acetate (0.15 mmol) and tppts (0.6 mmol) (synthesized according to the procedure given by Gärtner et al. [17]) were dissolved in water (5 mL) and placed under argon into an autoclave (75 mL). Aqueous ammonia solution (300 mmol, 20 mL of a 27.13 M solution) and organic solvent (12.5 mL; mostly toluene) were added, followed by condensation of butadiene (4.1 g, 75 mmol, 5.8 mL). The autoclave was heated in an oil bath (80 C) and the mixture

stirred. After the reaction, the autoclave was cooled, degassed, and the phases were separated in a separating funnel. The aqueous phase was extracted with an organic solvent (10 mL). *n*-Hexanol was added as internal standard to the combined organic phases for analysis. A sample was dried over molecular sieves and analyzed by quantitative gas chromatography (Pona, 50 m, 1.5 bar Helium). Amines were not observed either in the aqueous phase or in the gas phase. The experimental results are given in Tables 1 and 2.

$[Mn(CO)_5]^-$, the First Square-Pyramidal Pentacarbonyl Complex in the Complex Salt $[Ph_4P][Mn(CO)_5]$, and $[Mn_3Se_2(CO)_9]^{2-}$, the First Mixed Carbonyl-Selenido Complex of Manganese**

Renate Seidel, Birgit Schnautz, and Gerald Henkel*

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

Whereas the chemistry of sulfur-containing transition metal complexes is well-developed,[1] comparatively few of the corresponding selenido and tellurido compounds are known.[2] In an approach to synthesize chalcogenido complexes with unprecedented chemical properties, we recently characterized the compounds $[Co_{11}Te_7(CO)_{10}]^{2-}$ and $[Co_4Te_2(CO)_{11}]$ obtained by oxidation of $[Co_2(CO)_8]$ with Na_2Te_2.[3] Herein we report on an unexpected disproportionation of $[Mn_2(CO)_{10}]$ that occurs when it is treated with Na_2Se in solvents like methanol or THF. Besides the mononuclear complex $[Mn(CO)_5]^-$ **2**, the trinuclear complex $[Mn_3Se_2(CO)_9]^{2-}$ **4** is formed, which is the first manganese complex with a mixed carbonyl-selenido ligand sphere. Anions **2** and **4** were isolated as tetraphenylphosphonium salts **1** and **3**, respectively, and were fully characterized by X-ray structure determinations at $-120\,^{\circ}C$.[4]

$[Ph_4P][Mn(CO)_5]$ **1** $\qquad$ $[Mn(CO)_5]^-$ **2**

$[Ph_4P]_2[Mn_3Se_2(CO)_9]\cdot THF$ **3** $\qquad$ $[Mn_3Se_2(CO)_9]^{2-}$ **4**

Very recently the mixed-metal complex $[MnFe_2Se_2(CO)_9]^-$ related to **4** was synthesized and described as isostructural with $[Fe_3Se_2(CO)_9]$.[5] The X-ray structure determination was based on a disordered model in which two of the three metal positions are statistically occupied by Mn and Fe. Because of the unexpected coordination properties of **4** (see below), the related complex $[Fe_3Se_2(CO)_9]$ **5** as well as its sulfur-containing analogue $[Fe_3S_2(CO)_9]$ **6** were prepared for comparison purposes. The structures of **5** and **6**, which were described by Dahl et al.[6] and by Bard et al.,[7] respectively, were redetermined by using high-quality low-temperature X-ray data.[4] The resulting structural parameters were used as reference material.

$[Fe_3Se_2(CO)_9]$ **5** $\qquad$ $[Fe_3S_2(CO)_9]$ **6**

Crystals of **1** are composed of discrete mononuclear anions **2** and tetraphenylphosphonium cations. The most important feature of this compound is that **2** does not possess the expected trigonal-bipyramidal structure observed in crystals of $[Ni(phen)_3][Mn(CO)_5]_2$[8] (phen = 1,10-phenanthroline) and $[Mn(thf)_6][Mn(CO)_5]_2$,[9] which is also characteristic for the isoelectronic molecule $[Fe(CO)_5]$.[10] To our surprise, the coordination polyhedron of **2** is a regular square pyramid of nearly perfect symmetry (point group C_{4v}, Fig. 1), and as such possesses a spatial distribution of the CO ligands similar to that of the protonated compound $[HMn(CO)_5]$.[11] These structural similarities might be indicative of a stereochemically active lone pair of electrons in **2**. Contrary to this hypothesis, however, the C_{ax}-Mn-C_{eq} valence an-gle (102.6(1)°) is about 5° larger than the corresponding angle in $[HMn(CO)_5]$. In the crystalline state, **2** sits on a fourfold rotation axis of the space group.

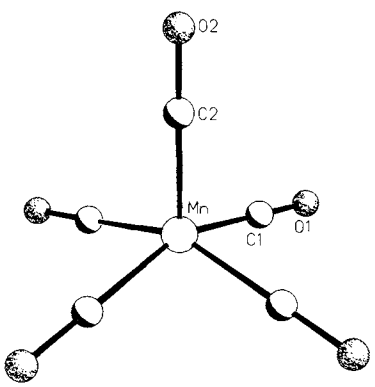

Fig. 1. Structure of **2** in crystals of **1**. Selected distances [Å] and angles [°]: Mn–C1 1.809(2) (4×), Mn–C2 1.794(3), C1–O1 1.159(2), C2–O2 1.155(4); C1-Mn-C2 102.6(1) (4×), C1-Mn-C1 154.7(1) (2×) and 87.3(1) (4×), Mn-C1-O1 179.5(2), Mn-C2-O2 180.

According to the results of the X-ray structure analysis, in addition to trinuclear mixed-valence complex anions **4** and tetraphenylphosphonium ions, crystals of **3** contain stabilizing THF molecules (ratio 1:2:1). The description of **4** as a complex anion with an odd number of valence electrons was further supported by magnetic measurements. These revealed that **4** has the expected paramagnetic properties ($\mu_{eff} = 1.8\ \mu_B$ for $[Ph_4P]_2[Mn_3Se_2(CO)_9]$ at 100 K). Paramagnetic behavior is also manifested by broadening of the resonance signals of the phenyl protons in the ^1H NMR spectrum compared to those in the diamagnetic reference compound $[Ph_4P]_2[Mn_3Se_2(SeMe)(CO)_9]$.[12]

With a total of 49 valence electrons and two Mn–Mn bonds, **4** falls short of the value required by the 18 electron rule (PSEP theory[13]) by one. The heavy atom frame is a slightly distorted square pyramid in which alternating Mn and Se atoms occupy the base, and a third Mn atom defines the top (Fig. 2).

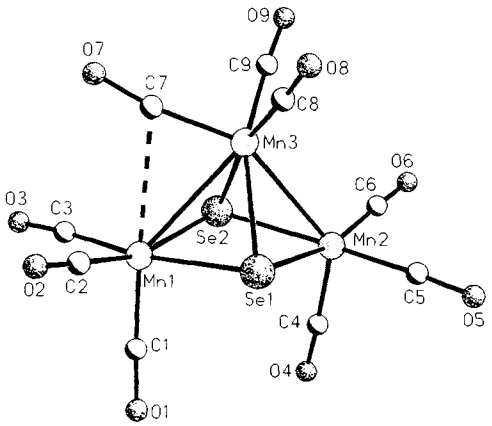

Fig. 2. Structure of **4** in crystals of **3**. Selected distances [Å] and angles [°]: Mn1···Mn2 3.647(2), Se1···Se2 3.171(2), Mn1···Mn3 2.803(3), Mn2–Mn3 2.724(2), Mn1–Se1 2.407(2), Mn1–Se2 2.402(2), Mn1–C1 1.769(9), Mn1–C2 1.805(8), Mn1–C3 1.804(6), Mn1–C7 2.726(7), Mn2–Se1 2.458(2), Mn2–Se2 2.439(2), Mn2–C4 1.768(8), Mn2–C5 1.793(6), Mn2–C6 1.793(8), Mn3–Se1 2.446(2), Mn3–Se2 2.444(2), Mn3–C7 1.794(7), Mn3–C8 1.775(7), Mn3–C9 1.783(8); Mn3-C7-O7 171.0(8).

While the heavy atom frame of **5** (50 electrons) is of comparable geometry, both compounds differ with respect to the arrangement of the carbonyl ligands around the metal atom on top of the M_3Se_2 pyramid. Evidently, an asymmetric carbonyl bridge (C7) between Mn3 and Mn1 is induced by an electronic nonequivalence of Mn1 and Mn2 in **4**, which is not observed in the structure of **5**. This nonequivalence is particularly apparent from a comparison of the Mn–Se bond lengths (Mn1–Se1 2.407(2), Mn1–Se2 2.402(2) Å; Mn2–Se1 2.458(2), Mn2–Se2 2.439(2) Å). The observed differences can be attributed to different oxidation states of the manganese atoms; the mean value is calculated to be +0.67. Based on the observed bond lengths and coordination numbers, a formal oxidation state of +1 can be assigned to the atoms Mn1 and Mn3, wheras a value of 0 seems to be appropriate for Mn2. The point symmetry of **4** is C_s; the Mn atoms define the mirror plane. All three of the Mn atoms are surrounded by three carbonyl and two selenido ligands in a square-pyramidal fashion, if the weak interaction of the asymmetric CO bridge (Mn1–C7: 2.726(7) Å) is neglected. On the other hand, if this bridge is considered to be a bond, Mn1 has a distorted octahedral ligand sphere. In contrast to Mn3 in **4**, the coordination of Fe3 in **5** is trigonal-bipyramidal (Fig. 3).

The arrangement of the carbonyl groups around Fe3 leads to identical ligand environments for both Fe1 and Fe2. Both metal atoms are chemically equivalent with similar Fe–Se bond lengths (Fe1–Se1 2.351(1), Fe1–Se2 2.359(1) Å; Fe2–Se1 2.354(1), Fe2–Se2 2.358(1) Å). The point symmetry of **5** is C_s; the mirror plane is now defined by the two Se atoms and the Fe3 center. In the mixed-valence compound **5** the formal oxidation state of Fe3 is +2, whereas Fe1 and Fe2 are monovalent.

These results support the assumption that in complexes of formula $[M_3X_2(CO)_9]^z$ (X = S, Se, Te; $z = -2, -1, 0, +1$) an asymmetric carbonyl bridge is established if the two metal atoms in the base of the M_3X_2 pyramid are electronically nonequivalent. As a consequence, the metal atom in the higher

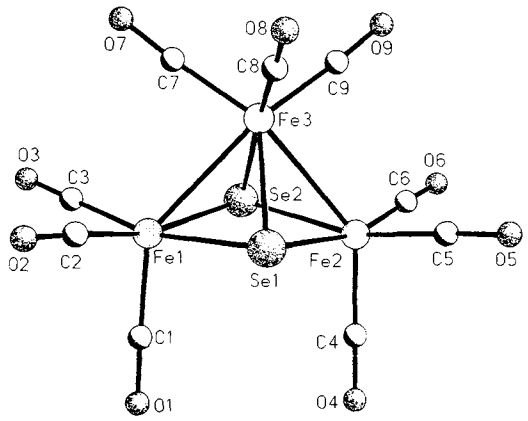

Fig. 3. Structure of **5** in the crystal. Selected distances [Å]: Fe1···Fe2 3.520(1), Se1···Se2 3.105(1), Fe1–Fe3 2.657(1), Fe2–Fe3 2.645(1), Fe1–Se1 2.351(1), Fe1–Se2 2.359(1), Fe1–C1 1.790(5), Fe1–C2 1.822(5), Fe1–C3 1.821(6), Fe2–Se1 2.354(1), Fe2–Se2 2.358(1), Fe2–C4 1.780(5), Fe2–C5 1.801(7), Fe2–C6 1.798(5), Fe3–Se1 2.354(1), Fe3–Se2 2.375(1), Fe3–C7 1.790(6), Fe3–C8 1.801(6), Fe3–C9 1.798(5).

oxidation state is stabilized probably by a $(p_\pi)_{CO}$-d_M interaction. The change from the nonbridged (**5**, Fig. 3) to the bridged state (**4**, Fig. 2) is accompanied by a rotation of the apical $M(CO)_3$ fragment by 30° around its local symmetry axis followed by a bend of this axis by about 15° in the direction of M1. At the same time, the coordination polyhedron changes from the trigonal bipyramid to the square pyramid.

Based on these results, we can now solve the problem of the Fe/Mn distribution in the complex ion $[MnFe_2Se_2(CO)_9]^-$ (see above). According to the literature, this compound is isostructural with **5**.[5] In fact, however, the complex possesses the characteristic asymmetric carbonyl bridge identified in **4** for the first time and therefore is rather built-up like **4** and not like **5**. Taking the individual metal–selenium distances into account, our analysis indicates that the metal positions in the base of the M_3Se_2 pyramid are filled most probably in an ordered fashion with manganese (position M1) and iron (position M2), contrary to the previously proposed statistical arrangement. The metal atom in the higher formal oxidation state (here Mn) is stabilized by the asymmetic carbonyl bridge in accordance with our hypothesis.

Though asymmetric carbonyl bridges are widespread in chemistry,[14] only very few other examples of the type identified in **4** with an unexpected long secondary Mn···C bond exist. A prominent example for an asymmetric bond of this type, the realization of which has only now become apparent, is found in the $[Fe_3S_2(CO)_9]$ component of the 1:1 adduct of the formula $[Fe_3S_2(CO)_9][Fe_2(S_2)(CO)_6]$, which is also known as the "King complex".[15] To our surprise, this component exhibits the same long M···C contact that is typical for **4**, although both Fe atoms in the base of the Fe_3S_2 pyramid should be chemically equivalent. The unusual orientation of the apical $Fe(CO)_3$ fragment in comparison with the expected geometry observed in **5** is described by Dahl et al. as an alternative conformation.[15] Based upon our knowledge derived from the structures of **4** and **5**, however, the existence of an asymmetric carbonyl bridge in the $[Fe_3S_2(CO)_9]$ adduct component has to be proposed. To test whether this is an exception of our hypothesis, the compound $[Fe_3S_2(CO)_9]$ **6** was crystallized and investigated at low temperatures. According to the results of an X-ray structure investigation,[4] crystals of **6** are isotypic with crystals of **5** even at −120 °C. In the structure at low temperatures no carbonyl bridges are observed. The reason for the unexpected behavior of

the $[Fe_3S_2(CO)_9]$ component within crystals of the 1:1 adduct, however, is evident on careful analysis of the packing. In fact, both components form charge transfer adducts in which trinuclear $[Fe_3S_2(CO)_9]$ and binuclear $[Fe_2(S_2)(CO)_6]$ molecules are associated alternately by intermolecular S···S bridges (3.157 Å) to form one-dimensional endless strands (Fig. 4).

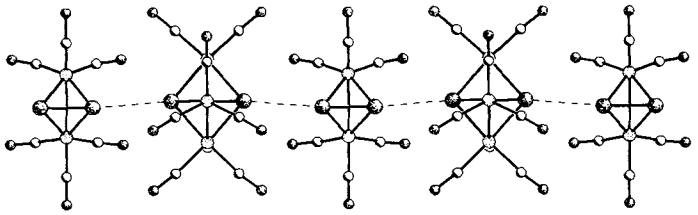

Fig. 4. Section of the alternating chain in crystals of $[Fe_3S_2(CO)_9][Fe_2(S_2)(CO)_6]$ (S···S = 3.157 Å).

Within these charge transfer adducts, electron density is transferred from the trinuclear component to the disulfide group of the binuclear complex. The resulting electron deficit in $[Fe_3S_2(CO)_9]$ is most probably stabilized by the asymmetric carbonyl bridge. This may also explain why the Mössbauer spectrum of $[Fe_3S_2(CO)_9][Fe_2(S_2)(CO)_6]$ differs significantly from that of the single complexes **5** and **6**.[16] Thorough characterization of these and related charge transfer complexes is currently in progress.

Experimental Procedure

All experiments were performed under oxygen-free nitrogen.

1 and **3**: $[Mn_2(CO)_{10}]$ (0.044 g, 0.11 mmol), Na_2Se (0.024 g, 0.19 mmol), $[Ph_4P]Cl$ (0.083 g, 0.22 mmol), and THF (1 mL) were placed in a pyrex-glass ampoule (20 cm in length, 1 cm in diameter). The ampoule was then cooled with liquid nitrogen and sealed up under vacuum (10^{-3} mbar) followed by subsequent heating of the reaction mixture for 72 h at 80 °C in an oven. After cooling the mixture to 5° C, yellow platelike crystals of **1** appeared together with dark red blocks of **3**. IR(KBr): $\tilde{\nu}$ = 1944, 1845 cm^{-1} (C=O) (**1**); $\tilde{\nu}$ = 1979, 1943, 1890, 1859 cm^{-1} (C=O) (**3**).

5 and **6** were prepared as described in the literature [17]. Crystals of **5** and **6** of better quality that were used for the X-ray structure determinations were isolated as by-products from reactions of $[Fe(CO)_5]$ with Na_2S_2 and NiI_2, and of $[Ph_4P]_2[Fe_6Se_6(CO)_{12}]$ [18] with I_2, respectively.

A Designed Non-Peptidic Receptor that Mimics the Phosphocholine Binding Site of the McPC603 Antibody**

J. Oriol Magrans, Angel R. Ortiz, M. Antònia Molins, Paul H. P. Lebouille, Jorge Sánchez-Quesada, Pilar Prados, Miquel Pons, Federico Gago, and Javier de Mendoza*

Biotechnological applications of catalytic antibodies[1] meet with considerable problems such as high cost and lability at high temperatures and in nonaqueous solvents. Potentially, most of these problems could be obviated by using synthetic molecules with similar binding properties and predicted biological activities, whose design could be guided by the binding strategy found in crystal structures of antibody–antigen complexes. We describe herein a non-peptidic abiotic receptor **1**, which binds dioctanoyl-L-α-phosphatidylcholine (DOPC) by making use of

the key interactions found in the crystal structure of the Fab domain of the McPC603 antibody complexed with phosphorylcholine (PC).[2, 3] In the McPC603–PC complex (Fig. 1) the PC phosphate group interacts with the positively charged Arg 52H residue, and its quaternary ammonium head establishes both ion–ion (Asp 97L) and cation–π interactions (Trp 107H, Tyr 33H, and Tyr 100L). Both types of interactions have been considered crucial determinants of binding specificity.[4]

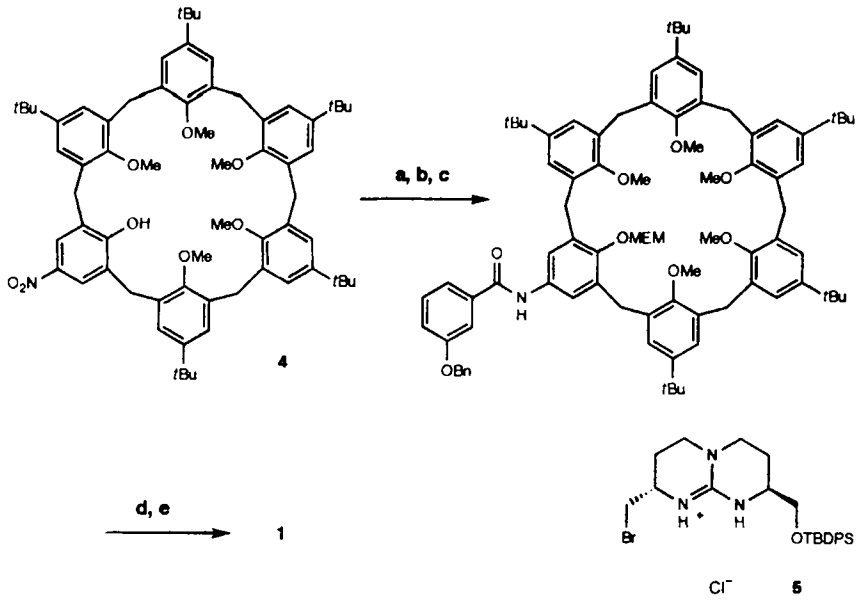
Thus, receptor **1** was designed to provide chemical complementarity to both the phosphate and trimethylammonium groups of DOPC. It contains a bicyclic guanidinium moiety for the selective complexation of phosphate monoanion and a calix[6]arene subunit for the complexation of the quaternary ammonium salt through cation–π interactions. The two subunits are linked through a short spacer containing an amide bond.

The synthesis of **1** was achieved in five steps from readily available mononitrocalix[6]arene **4**[5] and the bicyclic guanidinium compound **5** (TBDPS = *tert*-butyldiphenylsilyl)[6] with an overall yield of 30% (Scheme 1). Compound **1** was fully characterized by mass spectrometry, NMR spectroscopy (500 MHz), and microanalysis. Its NMR spectrum is consistent with the presence of an average symmetry plane bisecting the calix[6]arene macrocycle. Complete assignment of the spectrum was straightforward using a combination of COSY and ROESY experiments. ROE cross-peaks between aromatic protons on neighboring phenolic rings indicate that the *cone* conformation required for encapsulation of trimethylammonium is predominant, although the fact that methylene groups appear as singlets suggests that rapid inversion of the cone takes place at room temperature.

Addition of one equivalent of DOPC to a CD_2Cl_2 or a $CDCl_3$ solution of **1** resulted in a single set of NMR resonances substantially different from those of the component molecules. Complete assignment was also carried out by a combination of COSY and ROESY spectra. In $CDCl_3$, the important downfield shifts of $\Delta\delta = 1.76$ for the amide proton (H_A) in the side chain and of $\Delta\delta = 0.81$ for the guanidine NH proton closer to the calixarene ring (H_{G1}) were observed, indicating strong hydrogen bonds. The signal of the other guanidinium NH proton (H_{G2}) was shifted upfield by $\Delta\delta = 0.51$ in the complex.[7] Similar changes were observed in the spectra recorded in CD_2Cl_2 (Fig. 2).

The signals of the methyl and methylene protons bound to the quaternary nitrogen of the choline group were strongly shifted upfield by $\Delta\delta = 0.51$ and 0.35, respectively. This can be interpreted as being caused by the inclusion of the choline group inside the cavity formed by the aromatic groups of the calixarene. Inclusion was confirmed by the observation of a rotating-frame NOE beween the methyl group of choline and the aromatic protons ($H_{a''}$) in ring 1 in CD_2Cl_2.

A *cone* conformation of the calix[6]arene in the complex is indicated by ROE cross-peaks between aromatic protons in neighboring rings and by the chemical shifts of calixarene methylene carbons.[8] Cone inversion in the complex is slower than in the free calixarene, allowing the observation of an AB



Scheme 1. Synthesis of receptor **1**. a) K_2CO_3 (1.1 equiv), CH_3CN, room temperature, 1 h, then methoxyethoxymethyl chloride (1.5 equiv), room temperature, 24 h (yield 85%); b) H_2PtO_2 (1 equiv), THF, room temperature, 48 h (yield 100%); c) Et_3N (cat.), 3-benzyloxybenzoyl chloride (1.1 equiv), THF, reflux, 16 h (yield 88%); d) H_2, 10% Pd–C, THF, room temperature, 24 h (yield 85%); e) K_2CO_3 (1 equiv), CH_3CN, reflux, 1 h, then **5** (1.3 equiv, 20 h, 0.3 equiv, 24 h, 0.1 equiv, 24 h), 55 °C, then aq. HCl, room temperature, 16 h (yield 48%).

system for the methylene group between rings 2 and 3. However, the fact that the remaining methylenes give rise to singlets and that weak ROEs are observed between methoxy protons in ring 4 and one of the aromatic protons in rings 3 and 5 suggests that some flexibility persists.

The linker region also appears to be more structured in the complex. In particular, proton H_a shows intense ROEs to the amide proton H_A and to the methylene group (H_{h1} and H_{h2}) directly attached to the bicyclic guanidine. This indicates that the side chain is folded such that both the guanidinium and amide protons participate simultaneously in hydrogen bonding to the guest phosphate group.

Extensive molecular modeling studies were performed for the DOPC–**1** complex. In keeping with the results of the NMR experiments, the calix[6]arene moiety was initially set in an all-*syn cone* conformation, with the trimethylammonium group of DOPC docked into its cavity. Then, 500 ps restrained molecular dynamics (MD) simulations in vacuo were employed to search for low-energy conformations compatible with the NOE results. The conformation optimized in vacuo was then subjected to an unrestrained 500 ps MD simulation at 298 K in chloroform[9] (Fig. 3). In full agreement with the NMR data, the calix[6]arene moiety displays a *cone* conformation in the calculated structure; the choline head remains inside the cavity, while the phosphate group interacts through strong hydrogen bonds with proximal guanidinium (H_{G1}) and amide (H_A) protons. Structures computed for the DOPC–**1** complex

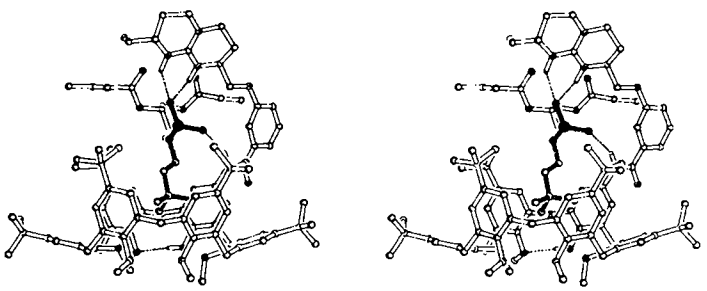

Fig. 3. Stereoview of the energy-minimized averaged structure of the DOPC–**1** complex in chloroform. For clarity the octanoyl residues have been truncated to butyroyl. Hydrogen bonds involving protons that are deshielded in the ^1H NMR spectrum are shown as dotted lines.

in chloroform are fully compatible with the relative intensities of the observed NOEs.

The structure of DOPC–**1** complex has a close resemblance to the antigen binding site in the McPC603–PC complex. In both cases the phosphocholine head adopts a linear conformation, is oriented in a similar way within the binding site, and gives rise to similar interactions: 1) the phosphate group interacts strongly with one of the nitrogens of a cationic guanidinium group (Arg52H in McPC603, the bicyclic guanidinium subunit in **1**); 2) a similarly oriented hydrogen bond is established between one of the phosphate oxygens and either the hydroxyl group of Tyr33H or the amide nitrogen of the receptor's side chain; 3) the aromatic rings are oriented toward the methyl groups on the choline head in such a way that each of the N–C vectors is perpendicular to the plane of the opposing ring; and 4) the floor of the binding site is made up of electron-rich groups, the side chain of Asp97L in the antibody, and methoxy groups and the additional hydroxyl group in the synthetic receptor.

A high binding constant K_{ass} (298 K) = 73000 ± 5000 M^{-1} ($\Delta G^\circ = -6.7$ kcal mol^{-1}) was obtained for the DOPC–**1** complex in chloroform,[10] which is very similar to that observed for the complex of McPC603 with PC in water ($\Delta G^\circ =$

-6.6 kcal mol^{-1}).[3] Since the NMR spectra of model compounds **2** and **3** did not show significant shifts upon addition of DOPC, binding was not measurable by NMR in these cases. Complexation of single quaternary ammonium salts such as acetyl choline (ACh) resulted in $K_{ass} = 730 \pm 30$ M^{-1} and 138 ± 27 M^{-1} for **1** and **2**, respectively. Weaker complexes were also formed between simple phosphodiester salts and guanidinium models. For example, triethylammonium dihexadecylphosphate is bound by guanidinium **3** with a K_{ass} of roughly 7000 M^{-1}. Thus, *both* guanidinium and calixarene subunits of **1** participate in binding DOPC, in agreement with structural data provided by the NMR studies. The fact that the experimental binding constant is still below the one estimated from model compounds of each isolated binding subunit suggests that there is still room for improvement in the design of the spacer unit. Finally, thermodynamic data were determined from titrations of **1** in tetrachloroethane with DOPC in the 330–350 K range (van't Hoff plot): ΔG° (298 K) $= -6.4$ kcal mol^{-1}, $\Delta H^{\circ} = -10$ kcal mol^{-1}, and $\Delta S^{\circ} = -12$ cal K^{-1} mol^{-1}. Thus, binding is mostly enthalpically driven.
