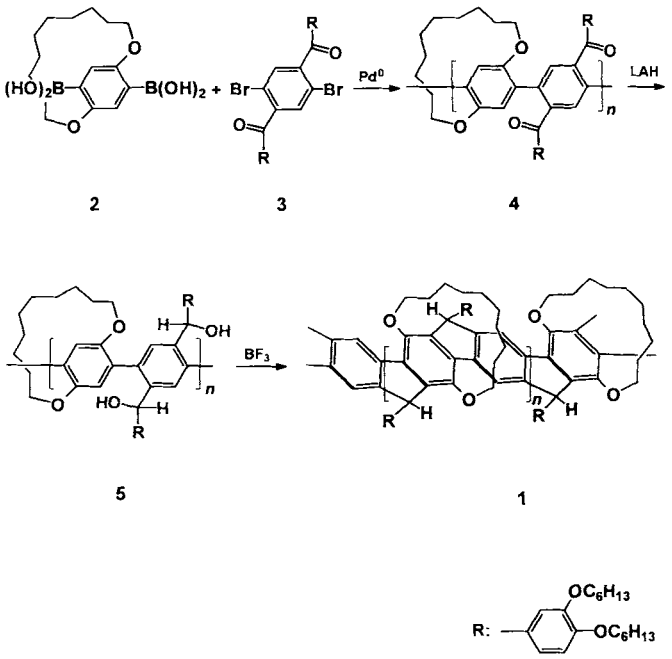
A decisive factor in the realization of our idea was the use of the $OC_{10}H_{20}O$-bridged diboronic acid **2** as one of the monomer components. We first considered the synthesis of the ladder polymer **1**, which contains these $OC_{10}H_{20}O$ bridges, with racemic **2** as the starting material (Scheme 1). The diboronic



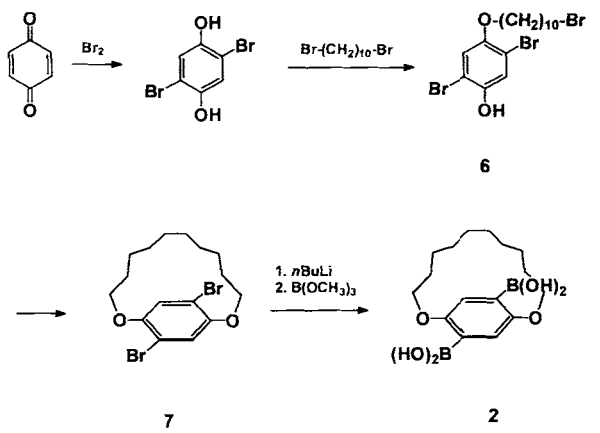
2 3 4 5 1

Scheme 1. Preparation of the $OC_{10}H_{20}O$-bridged PPP ladder polymer **1**.

acid **2** is treated with the terephthalophenone **3** to form the single-stranded PPP derivative **4** in a Suzuki aryl–aryl coupling reaction.[7] The coupling, which is catalyzed by $[Pd^0(PPh_3)_4]$, takes place in a two-phase reaction medium (THF/aqueous sodium carbonate solution). The subsequent cyclization to give the ladder polymer is carried out in a two-stage polymer-analogous reaction, the first stage of which is the reduction of the ketone functions with lithium aluminum hydride (LAH) to form **5**. This is followed the formation of **1** by ring closure, a reaction catalyzed by boron trifluoride etherate (analogous to the Friedel–Crafts reaction).[3] The transformation from the open-chain colorless **5** to the deep yellow ladder polymer **1** is accompanied by a drastic bathochromic shift of the long-wavelength absorption maximum λ_{max}.[3]

The ladder polymer **1**, with its unequivocal structure, can be prepared in yields of greater than 90% and with a molecular mass M_n of 12000–13000 (approximately 28 phenylene units in the main chain).[8] The course of the polymer-analogous cyclization of **5** to **1** was monitored by ^{13}C NMR spectroscopy. The signal from the secondary alcohol group disappears completely at $\delta = 72.5$, and the signal from the newly formed methylene bridge of **1** appears at $\delta = 53.1$. Besides the six signals from the aliphatic side chains, the $ArOCH_2$ methylene carbon atoms ($\delta = 69.8$, 70.1) are characteristic. Eleven signals for nonequivalent arene carbon atoms also appear.[8]

The diboronic acid monomer **2** is prepared in four steps (Scheme 2) from 1,4-benzoquinone. This is reductively brominated to give 2,5-dibromohydroquinone, which is treated with α,ω-dibromodecane to give the half-ether **6**. The intramolecular cyclization of **6** (at high dilution) gives a 58% yield of the dibromocyclophane **7**,[9] which, after twofold metalation with butyllithium, is treated with trimethyl borate to form **2**.[10]



6 7 2

Scheme 2. Preparation of the cyclophanediboronic acid **2**.

Because partial racemization takes place on formation of **2** from enantiomerically pure **7**,[11] we had separate the enantiomers at the stage of the diboronic acid **2** before synthesizing the optically active ladder polymers (+)-**1** and (−)-**1**, whose *ansa* substituents ($OC_{10}H_{20}O$) are located entirely on one side of the molecule. However, separation on cellulose triacetate by liquid chromatography, which is possible with the dibromide **7**,[11,12] was not successful with **2**. A suitable chiral phase, a β-cyclodextrin-modified silica gel (Chiradex, Merck), was found to be surprisingly efficient for the preparative separation of the enantiomers of **2**. This good separation can be explained by the formation of cyclodextrin/**2** inclusion compounds by hydrogen bonding.[13] Both enantiomers of **2** are obtained in high optical purity, namely 100% (+) and 97% (−) (Fig. 1). The absolute configurations of (+)-**2** and (−)-**2** can be assigned, as the structure of (+)-**7** has been determined from anomalous X-ray dispersion.[14]

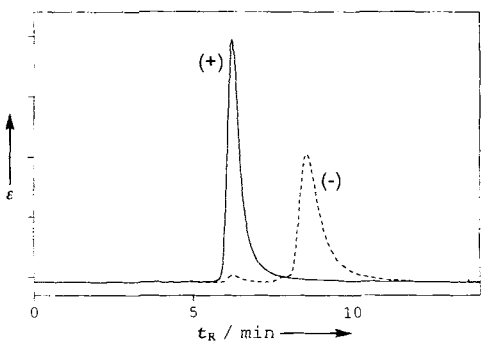


Fig. 1. Chromatograms for the determination of the enantiomeric purities of (+)-**2** and (−)-**2** [analytical separation; column material: Chiradex (Merck); solvent: methanol/water, (50/50)]. t_R = retention time, ε = absorption coefficient (310 nm).

The chiral ladder polymers (+)-**1** and (−)-**1** were obtained from the pure enantiomers of **2**.[15] Figure 2 shows the optical absorption and CD spectra of (+)-**1**. The extremely high chiroptical activity (molar ellipticity $\theta = 2.2 \times 10^6$ rad cm^2 mol^{-1}) in the long-wavelength $\pi-\pi^*$ absorption band ($\lambda_{max} \approx 461$ nm) is striking.[16] The resulting anisotropy factor $g = \Delta\varepsilon/\varepsilon$ is approximately 0.003, and is therefore only one order of magnitude less than the maximum value so far reported for chiral conjugated polymers ($g = 0.02$ for chiral aggregates of a polythiophene with a helical structure[17]). The CD spectra of (+)-**1** and

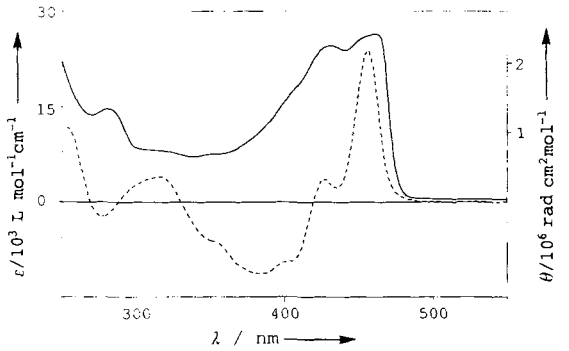

Fig. 2. UV/Vis spectrum (*continuous line*, ε = *absorption coefficient*) and CD spectrum (broken line, θ = molar ellipticity) of (+)-**1** (in dichloromethane).

(−)-**1** are mirror images of each other, the only slight differences between them being in the relative intensities of the bands.

Remarkably, hitherto only compounds of helical structure and their chiral aggregates had been considered as candidates that might display such high chiroptical activities.[1, 2, 17, 18] The cause of the surprisingly high activity of the ladder polymer **1**, whose structure is undoubtedly nonhelical, is to be investigated by temperature-dependent CD measurements and by the synthesis and characterization of model oligomers.[19]

The polymer **1**, like the achiral LPPP parent system,[20] shows very intense photoluminescence both in solution and in the solid state. This is the starting point for measurements of circular polarized luminescence (CPL) after both photoelectric and electric excitation. The detection of polarized electroluminescence in organic materials has not so far been reported. An obviously very promising candidate for this is **1**.

[19] Here we concentrate on the determination of the configuration of the new stereogenic centers of the methylene bridges (ArCHRAr'); a diastereoselective ring closure process to give an all-*trans* configuration of R relative to the cyclophane bridges could offer a plausible approach to the elucidation of the chiroptical activity.

[20] The PL quantum yields of known LPPPs, depending on the substitution pattern of the peripheral solubilizing side groups, are 65–80% (in solution, dichloromethane) and 10–25% (in the solid state [film]) [5]. The PL quantum yield of **1** is currently being determined.

Synergy between Magnetic Interaction and Spin Crossover in an Iron(III) Complex with an Organic Radical as Ligand

Jean-Pascal Sutter, Mohammed Fettouhi, Licun Li, Cécile Michaut, Lahcène Ouahab,* and Olivier Kahn*

Molecular magnetism is a novel and very active field of research that deals with the chemical and physical properties of molecular assemblies with open-shell units.[1] Two of the most important phenomena in molecular magnetism are the magnetic interaction between two spin carriers and spin crossover. We have been studying these two phenomena from both experimental and theoretical viewpoints for a few years. Here we report on the first compound in which the two phenomena occur in a synergistic way. This compound is bis(*cis*-1,2-dicyano-1,2-ethylenedithiolato)[2-(*para*-*N*-methylpyridinium)-4,4,5,5-tetramethylimidazoline-1-oxyl]iron(III) (**1**), abbreviated hereafter as [(rad)Fe(mnt)$_2$], in which rad$^+$ stands for 2-(*para*-*N*-methylpyridinium)-4,4,5,5-tetramethylimidazoline-1-oxyl, and mnt^{2-} for *cis*-1,2-dicyano-1,2-ethylenedithiolato.

Compound **1** was prepared by reacting the iodide **3** with sodium bis(*cis*-1,2-dicyano-1,2-ethylenedithiolato)iron(III) (Scheme 1).

The molecular structure of **1** is shown in Figure 1.[2, 3] The rad$^+$ unit is linked to the iron atom of [Fe(mnt)$_2$]$^-$ through the oxygen atom of the nitroxide group. The iron atom adopts square-pyramidal coordination, as observed for all the other five-coordinate bis(dithiolene) complexes;[4–9] the oxygen atom of rad$^+$ occupies the apical position. The Fe–S bond lengths are in the range 2.235(2)–2.250(2) Å, and the Fe–O bond length is 2.056(5) Å. The Fe-O1-N5 angle around the nitroxide group is 119.7(3)°. The iron atom is pulled out of the S_4 mean plane toward the apical position by Δ = 0.427(1) Å; this

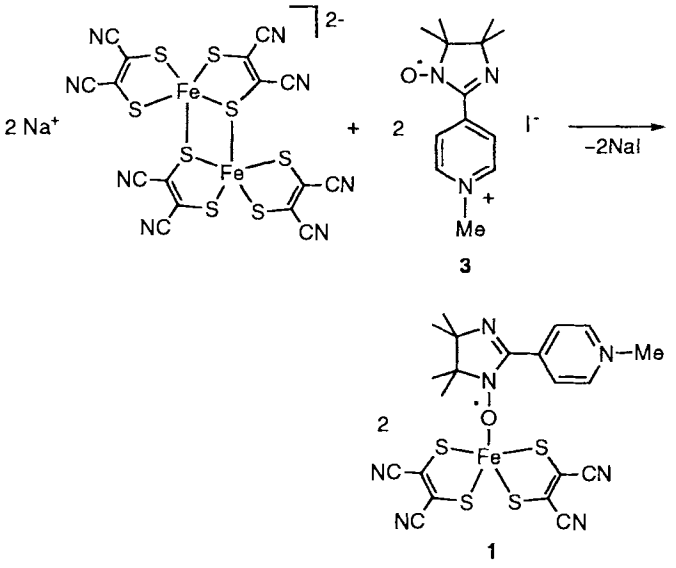

Scheme 1.

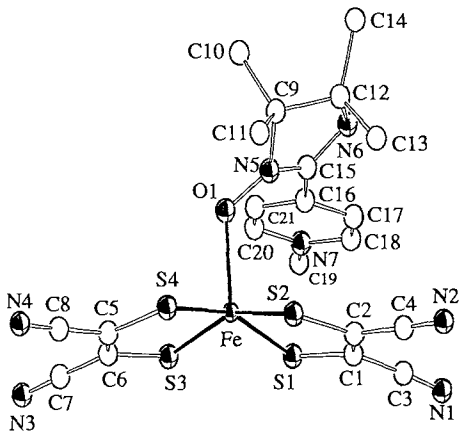

Fig. 1. Molecular structure of **1**.

value is close to that in the five-coordinate (S_4O) anionic species $\{Ph_3POFe[S_2C_2(CF_3)_2]_2\}^-$ with Fe–O = 1.957 Å and Δ = 0.434 Å.[8] The O1-N5-C15-N6 mean plane of the imino-nitroxide group makes dihedral angles of 43.6(5)° with the Fe-S1-S2-C1-C2 mean plane, and 36.7(6)° with the pyridine ring. Within the crystal lattice, the molecules are arranged in such a way that the $[Fe(mnt)]^-$ moieties are face-to-face and the rad^+ moieties are side-to-side, thus leading to the formation of columns (Fig. 2). The shortest intermolecular Fe···Fe and Fe···S separations are 5.000(2) and 4.524(4) Å, respectively, and the shortest O···O and O···N intermolecular separations between the imino-nitroxide groups are 4.703(6) and 5.357(6) Å, respectively. All the intermolecular contacts are large, thus the [(rad)-$Fe(mnt)_2$] units can be considered as being magnetically isolated within the crystal lattice.

The magnetic properties of **1** warrant a thorough investigation. The temperature dependence of both the product $\chi_m T$ and the molar magnetic susceptibility χ_m are represented in Figure 3. $\chi_m T$ is 2.33 $cm^3 K mol^{-1}$ at room temperature and remains essentially constant as the temperature is lowered to about 100 K, then decreases more and more rapidly as the temperature is lowered further, and eventually tends to zero as T approaches absolute zero. As for the magnetic susceptibility, χ_m shows a well-pronounced rounded maximum at T = 9.5 K.

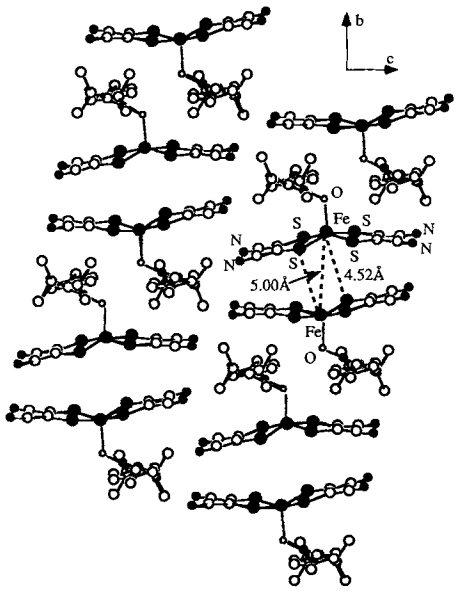

Fig. 2. Crystal structure of **1** showing the face-to-face $[Fe(mnt)]^-$ columns.

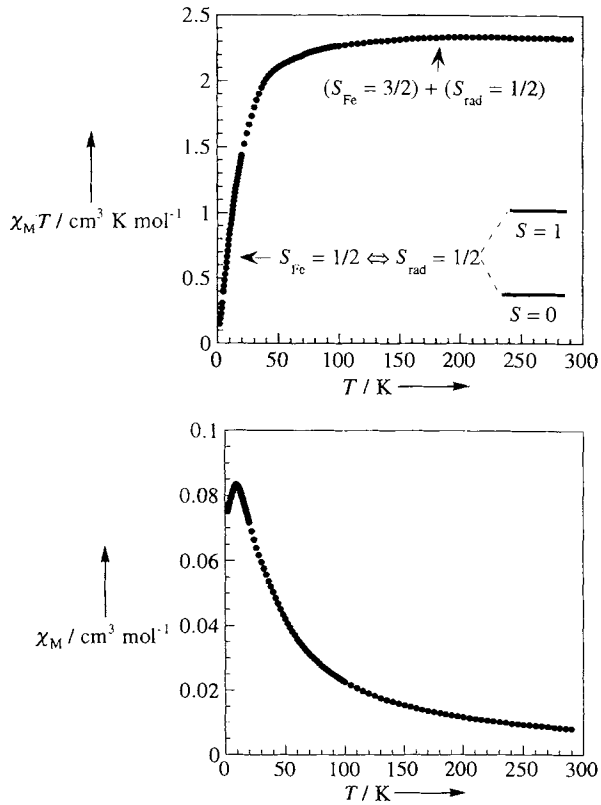

Fig. 3. Temperature dependence of $\chi_m T$ (top) and χ_m (bottom) for **1**. The applied magnetic field was 2 kOe.

To interpret these magnetic data, we will initially consider the range 100 K < T < 300 K, and then that with T < 100 K. In the high-temperature range, the magnetic susceptibility closely follows the Curie law ($\chi_m T$ = constant), which means that either the thermal energy kT is much larger than any interaction parameter between the rad^+ and $[Fe(mnt)_2]^-$ moieties, or only one molecular state is thermally populated in this temperature range. This latter hypothesis can be ruled out. Indeed, all the possible molecular states have an integer spin, and none of them

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3518-2114 $ 15.00+.25/0

can lead to a $\chi_m T$ value of 2.33 $cm^3 K mol$. This $\chi_m T$ value is therefore the sum of the two contributions arising from each of the moieties. The rad^+ moiety carries a spin $S_{rad} = 1/2$, and its contribution to the $\chi_m T$ value is 0.38 $cm^3 K mol^{-1}$;[1] thus, the contribution of $[Fe(mnt)_2]^-$ is 1.95 $cm^3 K mol^{-1}$, which exactly corresponds to what is expected for a spin quartet state, $S_{Fe} = 3/2$. In summary, the magnetic properties of the compound at high temperature correspond to the superposition of $S_{rad} = 1/2$ and $S_{Fe} = 3/2$ local states. The magnetic interaction between these two local states, which gives rise to $S = 1$ and $S = 2$ molecular states, is too small to be detectable in this temperature range.

Let us now consider the low-temperature range. The maximum in the χ_m versus T plot together with the low-temperature limit of $\chi_m T$ unambiguously indicates that the ground state of **1** is a spin singlet, $S = 0$. This nonmagnetic state can only arise from an antiferromagnetic interaction between $S_{rad} = 1/2$ and $S_{Fe} = 1/2$ local states. In other words, at low temperature the local ground state of the $[Fe(mnt)_2]^-$ moiety is a spin doublet, and not a spin quartet anymore. This moiety exhibits a spin crossover between $S_{Fe} = 3/2$ and $S_{Fe} = 1/2$ states. This very unusual magnetic behavior is shown schematically in the plot of $\chi_m T$ versus T in Figure 3.

One of the problems at hand concerning **1** is to see whether it is possible to simulate its magnetic properties. If the intermolecular interactions are neglected, the molar fraction of Fe^{III} ions in the $S_{Fe} = 3/2$ local state, $x_{S = 3/2}$, may be written according to Equation (a),[1] in which ΔH is the change in enthalpy between

$$x_{S = 3/2} = \frac{1}{1 + \exp\left[\frac{\Delta H}{R}\left(\frac{1}{T} - \frac{1}{T_{1/2}}\right)\right]} \quad (a)$$

the $S_{Fe} = 3/2$ and $S_{Fe} = 1/2$ local states, R the gas constant, and $T_{1/2}$ the inversion temperature for which $x_{S = 3/2} = 0.5$. The molar magnetic susceptibility may then be expressed according to Equation (b), in which $\chi[S_{Fe} = 1/2]$ and $\chi[S_{Fe} = 3/2]$ are the

$$\chi_M = (1 - x_{S = 3/2})\chi[S_{Fe} = 1/2] + x_{S = 3/2}\chi[S_{Fe} = 3/2] \quad (b)$$

molar magnetic susceptibilities for **1** when the Fe^{III} ion is in the $S_{Fe} = 1/2$ and $S_{Fe} = 3/2$ local state, respectively. It follows that χ_m may be according to Equation (c),[1] in which g is an average

$$\chi_M = \frac{2N\beta^2 g^2}{kT}\left\{\frac{(1 - x_{S = 3/2})}{3 + \exp(-J_{1/2}/kT)} + \frac{x_{S = 3/2}[1 + 5\exp(2J_{3/2}/kT)]}{3 + 5\exp(2J_{3/2}/kT)}\right\} \quad (c)$$

value of the Zeeman factor for all the spin carriers, and $J_{1/2}$ and $J_{3/2}$ are the rad-Fe interaction parameters when the Fe^{III} ion is in the $S_{Fe} = 1/2$ and $S_{Fe} = 3/2$ local state, respectively (the Hamiltonian operators for the interactions are defined as $-J_{1/2}\boldsymbol{S}_{rad}\cdot\boldsymbol{S}_{Fe(S = 1/2)}$ and $-J_{3/2}\boldsymbol{S}_{rad}\cdot\boldsymbol{S}_{Fe(S = 3/2)}$, respectively). Expressions such as Equations (a) and (c) can perfectly reproduce the experimental susceptibility data. However, the number of parameters involved in the model is too large to allow an unambiguous determination of their values. In any case, both the $J_{1/2}$ and $J_{3/2}$ interaction parameters are found to be rather small; $J_{1/2}$ is of the order of $-15\ cm^{-1}$. These small values may be easily rationalized in terms of orbital interactions between the $[Fe(mnt)_2]^-$ and rad^+ moieties. For instance, in the low-spin $S_{Fe} = 1/2$ local state, the unpaired electron arising from the Fe^{III} ion occupies a yz- or zx-type orbital; the z axis is colinear with the apical Fe–O direction. The overlap density between such an orbital and the singly occupied π^* orbital of the radical cation is certainly very weak in any point of space.[1]

As expected, the X-band powder EPR spectrum is strongly temperature dependent. At 9.5 K, which is the temperature of the maximum of the susceptibility, the spectrum is characteristic of a triplet state with a zero-field splitting parameter D smaller than the incident radiation. D was found to be approximately 0.15 cm^{-1}.[10] This spectrum also shows well-pronounced half-field transitions. The intensity of the triplet state signal decreases as T drops below 9.5 K.

The occurrence of an $S_{Fe} = 3/2$ intermediate spin ground state for square-pyramidal Fe^{III} species is well documented. Such a situation, for instance, has been found in halogenobis(diethyldithiocarbamato)iron(III) compounds, in which a $\chi_m T$ value of 1.90 $cm^3 K mol^{-1}$ has been determined down to 10 K.[11–14] In other respects, spin doublet–spin quartet crossovers have already been observed for a few five-coordinate iron(III) complexes, for instance for [Fe(salen)(NO)] (salen = *N*,*N*′-ethylenebis(salicylideneiminato)[15, 16] and [Fe(tmc)(NO)](BF_4) (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane).[17] Finally, recently a large number of metal–radical compounds have been found to exhibit ferro- or antiferromagnetic intramolecular interactions.[18–20] What is entirely novel as far as [(rad)Fe(mnt)$_2$] is concerned, is that three facets of molecular magnetism, namely intermediate spin state, spin crossover, and magnetic interaction, occur simultaneously within a single compound.

Experimental Procedure

3: A solution of 2-(*para*-pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide [21] (3.51 g, 15 mmol) in CH_2Cl_2 (15 mL) was added to a suspension of $NaNO_2$ (2.62 g, 38 mmol) in CH_2Cl_2 (70 mL) and CH_3COOH (8.6 mL, 150 mmol). The reaction mixture was heated to reflux for 5 min to give a bright orange solution. After filtration and neutralization with aqueous $NaHCO_3$, the organic layer was washed with water, and the aqueous phase extracted with CH_2Cl_2 (20 mL). The combined organic phase was dried over Na_2SO_4. The solution was concentrated and chromatographed over a short alumina column. Elution with a solution of CH_2Cl_2/acetone (85/15 in volume) afforded an orange fraction. The solvent was removed in vacuo and addition of hexane (10 mL) to the residue afforded the neutral 2-(*para*-pyridyl)imino-nitroxide **2** as a crystalline solid (2.20 g, 67%). IR(KBr): $\tilde{\nu}[cm^{-1}]$ = 2979, 1594, 1534, 1453, 1279, 1198, 836, 658. The quaternarization was achieved by heating a solution of **2** (2.20 g, 10 mmol) and MeI (3.8 mL, 60 mmol) in THF (25 mL) to 45 °C for 3 h. After the mixture had been cooled, the deep red suspension was filtered, the solid washed with Et_2O, and dried in vacuo to yield **3** (2.57 g, 71%) as a crystalline red solid. Anal. calcd for $C_{13}H_{19}N_3OI$: C 43.35, H 5.32, N 11.66, O 4.44; found: C 43.36, H 5.37, N 11.56, O 4.90. IR(KBr): $\nu[cm^{-1}]$ = 2980, 1644, 1546, 1458, 1278, 1190, 850, 649.

1: A suspension of **3** (75.6 mg, 0.21 mmol) in THF (8 mL) was added dropwise to a solution of Na[Fe(mnt)$_2$] [22] (71.8 mg, 0.2 mmol) in THF (8 mL). The resulting mixture was stirred at room temperature for 30 min. After filtration, Et_2O (20 mL) was slowly added. The precipitate was collected by filtration, washed with water and Et_2O, and dried in vacuo to yield **1** (35 mg, 31%) as a brown solid. Anal. calcd for $C_{21}H_{19}N_7OS_4Fe$: C 44.29, H 3.36, N 17.22, S 22.52, Fe 9.81; found: C 45.0, H 3.62, N 16.28, S 22.46, Fe 8.88. IR(KBr): $\tilde{\nu}[cm^{-1}]$ = 3247, 2976, 2203, 1637, 1490, 1148, 1108.

Surprisingly, the best-shaped single crystals of **1** were obtained in a very low yield by reaction of Na[Fe(mnt)$_2$] with 2-(*para*-*N*-Me-pyridinium)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide in ethanol. During this reaction, a very small amount of the nitronyl-nitroxide radical cation is reduced to the imino-nitroxide radical cation.

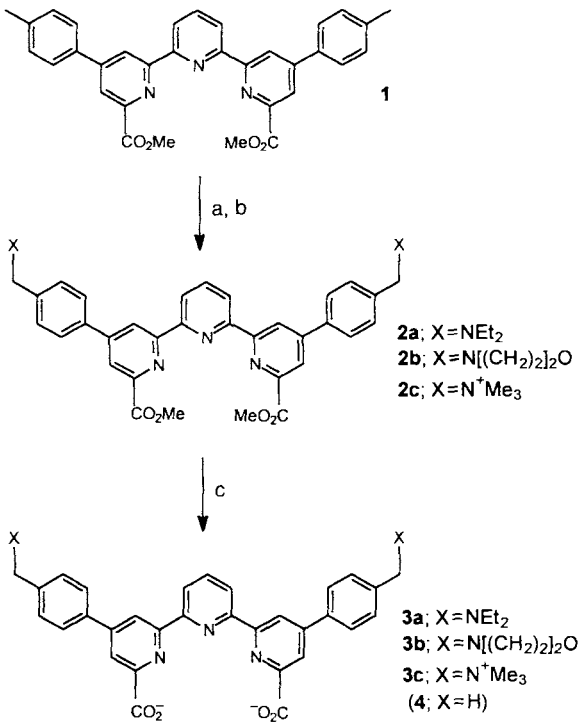
Proton-Controlled Switching of Luminescence in Lanthanide Complexes in Aqueous Solution: pH Sensors Based on Long-Lived Emission**

A. Prasanna de Silva,* H. Q. Nimal Gunaratne, and Terence E. Rice

Luminescent lanthanide complexes[1] are finding increasing use as labels for immunoassays in clinical diagnostic procedures.[2] One reason for this success is the length of their luminescence lifetimes (ms range), which permits easy temporal resolution from the short-lived (ns range) fluorescence background commonly present in biological systems. Now we show how lanthanide f–f luminescence can be exploited for the design of sensors that preserve the special features found in luminescent labels.

We[3] and others[4] have developed "fluorophore–spacer–receptor" systems which operate as ion sensors by ion-induced suppression of Photoinduced Electron Transfer (PET) from the receptor to the fluorophore. So it was a direct, logical progression to replace the organic fluorophore with a luminescent lanthanide complex. The terpyridyl derivative **4**[1r, 2f] is particularly suitable as a ligand since, besides its straightforward synthesis and its near-ultraviolet absorption, it should have a relatively electron-deficient π-system when complexed to lanthanide ions. We first modified **4** by introducing simple amino groups in the side chains, which should serve as both proton receptors and electron donors in the PET process. Of course, the PET sensor principle can be applied to many other analytes besides protons.[3, 4]

Compound **1** was converted to the desired ligand **3** according to Scheme 1. The changes in the UV absorbance A of **3** on addition of lanthanide salts were analyzed according to Equation (a)[3] to yield the binding constants β, which are listed in



Scheme 1. Reagents: a) *N*-Bromosuccinimide, dichloromethane; b) Et_2NH, $HN[(CH_2)_2]_2O$, or Me_3N; c) KOH. The structures are drawn in the metal-complexing conformation even though in the conformation of the free ligand the pyridyl dipoles are opposite to each other [13].

$$\lg[(A - A_{min})/(A_{max} - A)] = \lg[(Ln^+)_{total} - (\mathbf{3})_{total}(A - A_{min})/(A_{max} - A)] + \lg\beta \quad (a)$$

Table 1. Given the magnitude of β (roughly 10^6 at pH 6.0), mixtures of ligand **3** and lanthanide salt in hundredfold excess were used to generate the complex **3**·Ln in situ. pH Titrations of these sensor solutions resulted in small but measurable changes in the UV absorption spectra, which yielded pK_a values for the side chain amino groups (Table 1) after analysis with Equation (b).[5] Dramatic changes were found in the delayed

$$\lg[(A_{max} - A)/(A - A_{min})] = \mp pH \pm pK_a \quad (b)$$

q [i]	4.2	3.7	4.2	3.7	4.2	3.8

[a] 10^{-6} M **3a**–**c**·Ln in aerated H_2O at 22.0 °C. Lanthanide salts were used as chlorides. All of the complexes **3a**–**c**·Tb and **3a**–**c**·Eu have essentially identical UV absorption spectra with λ_{Abs} ($\lg\varepsilon$) values of 285 nm (4.74), 335 nm (4.43), and 345 nm (4.44) at pH 6.0 (ε in units of $M^{-1}cm^{-1}$). The free ligands **3a**–**c** also have essentially identical UV absorption spectra with λ_{Abs} ($\lg\varepsilon$) values of 245 nm (4.81), 272 nm (sh) (4.65), and 330 nm (sh) (3.9). Luminescence measured with a delay time of 0.1 and 0.1 ms; gate time of 0.5 and 1.5 ms for the Tb and Eu complexes, respectively. Under our conditions, the principal emission of **3a**–**c**·Eu is at 617 nm (due to the $^5D_0 \rightarrow {}^7F_2$ transition), whereas **3a**–**c**·Tb shows emission mainly at 544 nm and also at 493 nm (due to the $^5D_4 \rightarrow {}^7F_5$ and $^5D_4 \rightarrow {}^7F_6$ transitions, respectively). Corrected excitation spectra obtained during the recording of these principal emissions are very similar in shape to the corresponding absorption spectra in all cases. Due to the hydration number (q) of ca. 4, it is not surprising that hydrolytic effects at or near the metal center predominate at pH > 8. This results in luminescence decreases in both Tb and Eu systems as the pH is increased, except that the Eu cases show an increase at intermediate stages. Therefore our studies were restricted to the pH range 3 to 8. Deaeration caused 4–10% increases in the luminescence intensity of **3a**–**c**·Tb, whereas **3a**–**c**·Eu showed <2% change. Preliminary analysis of the temperature dependence of luminescence intensity[14] for **3a**–**c**·Tb yielded activation energies of 2–8 kcal mol^{-1}. The luminescence of **3a**–**c**·Eu showed virtually no temperature effect. [b] Spectral data for ligands **2a**–**c** will be presented in a full paper. [c] Obtained by analyzing the UV spectral changes seen during Eu^{3+} and Tb^{3+} variation with Equation (a) (pH 6.0). However it must be noted that the behavior is nonideal, as may be expected in such highly charged systems[15]. [d] Obtained by analyzing the small but measurable changes in the UV absorption spectra of **3**·Ln during pH variation according to Equation (b). The protonation of the two amino groups cannot be distinguished. The pK_a values have an uncertainty of ±0.2 pH units. These pK_a values are expected to be in close agreement with the pK'_a values[3]. [e] Obtained by comparison of corrected luminescence emission spectra with that of **4**·Eu[1r, 2f] and the ternary Tb complex with EDTA and sulfosalicylic acid[16] for the Eu and Tb cases, respectively. [f] Luminescence enhancement factor induced by protons = ϕ_{Lum}(acid)/ϕ_{Lum}(base). [g] Obtained by analyzing luminescence quantum yield (ϕ_{Lum}) vs pH profiles (Fig. 2), according to Equation (c). The pK'_a value corresponds to the protonation of the second amino group following the first, since both amines must be blocked before luminescence can be recovered[15]. However the corresponding pK'_a values do not differ by very much since the two amino groups behave nearly independently[17]. This is not unexpected owing to their large spatial separation and the 1,3 connections of the intervening aromatic rings. The pK'_a values have an uncertainty of ±0.1 pH units. [h] Determined by analyzing the luminescence intensity (I_t) vs delay time (τ) profile according to the equation $2.3\lg(I_t/I_{t,0}) = -\tau/\tau_{Lum}$[10]. [i] Hydration number obtained from the equation $(1/\tau_{Lum;H_2O}) - (1/\tau_{Lum;D_2O}) = (q/A)$ [18], where A is 4.2 and 1.05 for Tb and Eu, respectively.

luminescence spectra of **3a**·Tb and **3b**·Tb during pH titration (Fig. 1). These complexes show proton-induced luminescence enhancement factors (LE) of 16 and 10, respectively, without

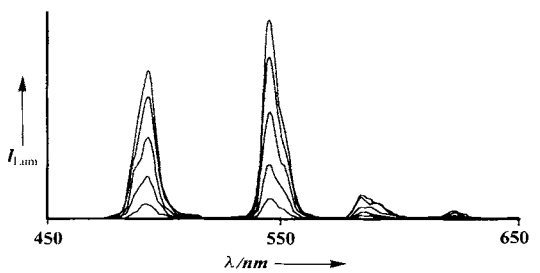

Fig. 1. Uncorrected delayed luminescence spectra of sensor **3b**·Tb as a function of pH. The pH values are (in order of decreasing intensity) 3.2, 4.4, 5.0, 5.6, 6.5.

any shift in the wavelengths of the emission bands or in their relative heights.

$$\lg[(\phi_{Lum;max} - \phi_{Lum})/(\phi_{Lum} - \phi_{Lum;min})] = pH - pK'_a \quad (c)$$

These delayed luminescence measurements completely reject intrinsic fluorescence. We note that ϕ_{Lum} vs. pH profiles (Fig. 2)

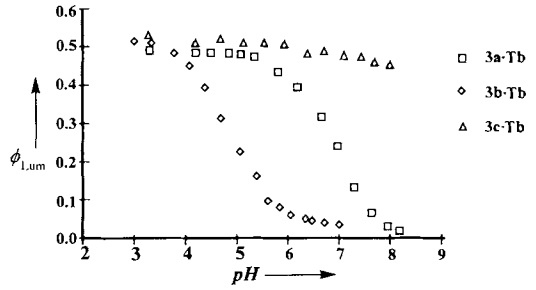

Fig. 2. Luminescence quantum yield ϕ_{Lum} versus pH for sensors **3a**·Tb, **3b**·Tb, and model compound **3c**·Tb.

are dictated by the nature of the side chain X as expected, with **3c**·Tb showing essentially pH-independent luminescence over the pH range 3–8. This also rules out any collapse of the sensor complex by hydrolysis over the pH range 3–8, since hydrolysis would remove the sensitizer/antenna effect of the ligand and extinguish the terbium luminescence. Protonation of the ligating atoms and subsequent dissociation of the complexes can also lead to pH dependence of luminescence,[1n] but this is not suitable for use in a unimolecular sensor.

Interestingly, the complexes **3a**·Eu and **3b**·Eu participate only weakly in PET processes despite the fact that aqua and edta complexes (edta = ethylenediaminetetraacetate) of Eu^{3+} are more easily reduced than those of Tb^{3+}.[6] On the other hand, because luminescence lifetimes τ_{Lum} of **3**·Eu are shorter than those of their Tb counterparts, the efficiency of the PET activity would be expected to be reduced. A further consideration is that the PET process can potentially intervene before the transfer of energy from the ligand excited state (singlet or triplet) to the lanthanide ion. This is important since previous PET sensors concern PET to or from singlet excited states of relatively high energy and nanosecond lifetime.[3, 4] In the present cases, the ligand π-electron system is spatially closer than the lanthanide ion to the electron-donating amino group in the side chain,[7] though the role of the intervening π-systems in controlling the PET rate must also be considered.[8] The π-systems in the Tb complexes appear to be marginally more electron-deficient than in **3a**·Eu and **3b**·Eu under our conditions, as judged by the relative pK'_a or pK_a values of the side chain amino groups. This should encourage more efficient PET to the π-system in **3a**·Tb and **3b**·Tb. Perhaps the most important clues to the different behavior of the Tb and Eu complexes lie in the fact that **3**·Tb shows a) a small but measurable luminescence quenching with oxygen and b) a small but measurable decrease of luminescence at increasing temperatures. The effects of oxygen and temperature on the luminescence of **3**·Eu are both negligible. Several Tb complexes are known to display more drastic examples of such effects,[1b–d] due to the equilibration of the Tb $^5D_4$ state with a ligand-centered ππ* triplet state of slightly higher energy. This situation is clearly present in **3**·Tb though to a relatively small extent (which is fortunate for the application of **3a**·Tb and **3b**·Tb as pH sensors). Thus the ligand-centered triplet state in

3·Tb would be expected to have a longer lifetime than 3·Eu. Conceptually related situations are found in E-type delayed fluorescence, for example.[9] Of course PET processes from the side chain amino group would be much more efficient when such longer lived excited states are involved.

In conclusion, we have demonstrated the pH sensing action of 3·Tb by means of its delayed luminescence. We have also developed "message in a bottle" systems which exploit room-temperature phosphorescence of all-organic π-electron systems for ion sensing.[10] These are complementary to lanthanide complexes reported here. Taken together, these sensors, which exploit relatively long-lived luminescence in the millisecond domain, should have significant potential for real-time (> ms) ion monitoring in intrinsically fluorescent environments. The relatively long emission lifetimes should also permit easy analysis of luminescence decays, which can allow ion sensing without any complications from variations in optical path, sensor concentration, and quenchers in these microenvironments.[11] A further interesting aspect of selectivity in the design of supramolecular systems like 3·Tb involves the use of a terpyridyl receptor for Tb^{3+} ions, which serves as the antenna–lumophore combination, whereas the side chain amino groups serve as receptors for the proton analyte.[12]

Maximum Functionalization of Metallocenes: Decaallylferrocene and Derivatives**

Peter Jutzi,* Christoph Batz, Beate Neumann, and Hans-Georg Stammler

Multiply functionalized metallocenes are very attractive molecules for a variety of reasons.[1] The steric and electronic properties of the parent compounds can be significantly altered by substitution at the metallocene framework. The presence of suitable substituents in the side chain enables the incorporation of the corresponding metallocenes in polymers,[2] the preparation of discotic liquid crystals,[3] or, in the context of the dendrimer strategy, the construction of highly branched systems. Furthermore, functionalization with redox building blocks could concievably lead to electron storage systems capable of simultaneously transfering several electrons at the same potential. Special properties have been predicted for such molecular electron reservoirs;[4] they are already in use for the modification of electrodes[5] and in electrochemical sensors.[6] In this context, the decafunctionalization of a metallocene is a particularly attractive goal.

Among the metallocenes, ferrocene has the largest number of known derivatives.[7] The only known decasubstituted ferrocene[8–11] capable of incorporating additional functionalities at the periphery is decabenzylferrocene, which can be additionally functionalized by Friedel–Crafts substitutions.[3] However, a disadvantage here is that the substitution reaction frequently affords mixtures comprising *ortho*- and *para*-substituted products. In this context, the route described by Astruc et al. is of special interest: starting from sandwich compounds multiple basic alkylation affords, among other complexes, hexasubstituted ferrocenyl complexes.[12, 13]

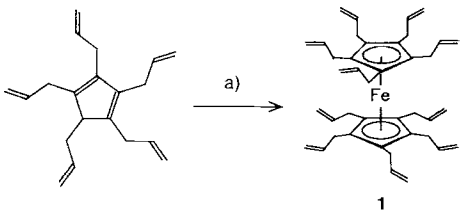
[**] We thank Dipl.-Ing. K. Hägele (Research group Prof. Przybylski, Universität Konstanz) for recording the FAB-MS spectra.

Herein we report the synthesis of the decaallylferrocene **1**, which can be readily transformed by simple subsequent reactions to yield a wide variety of functionalized ($(n \times 10)$-fold) derivatives. The key compound for the synthesis of **1** (Scheme 1)



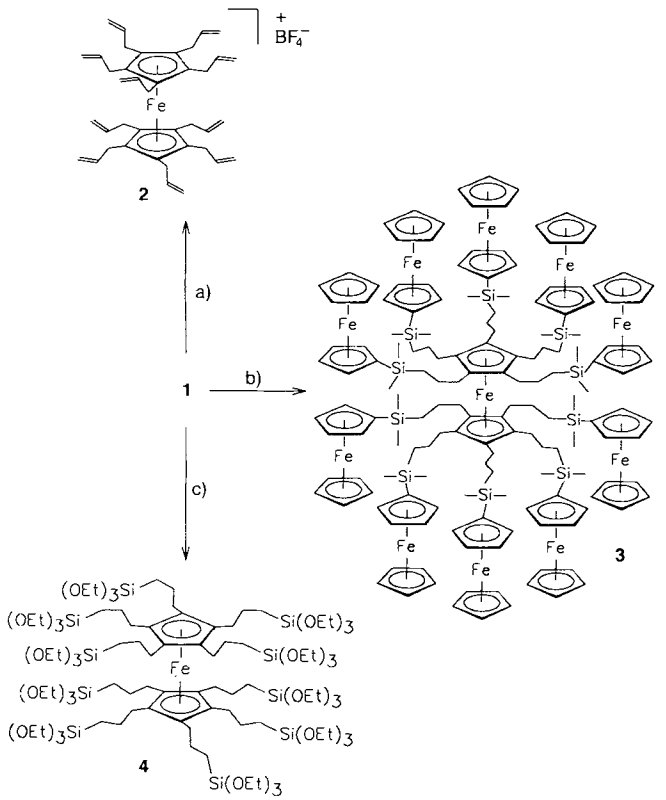
1

Scheme 1. a) 1. KH, THF; 2. $FeCl_2$ (0.5 equiv), THF, room temperature, 3 d.

is 1,2,3,4,5-pentaallylcyclopentadiene, which is prepared from cyclopentadiene and allyl bromide in a one-pot synthesis.[14] Subsequent treatment of potassium pentaallylcyclopentadienide[14] with iron(II) chloride in THF gave the decaallylferrocene **1** using standard procedures at room temperature. Product **1** is obtained as small, orange crystals; however, these crystals are not suitable for a single-crystal X-ray structure analysis. Compound **1** is air- and moisture-stable and dissolves readily in all common organic solvents; however, in polar solvents such as THF or chloroform, it decomposes slowly to give a deep red compound, which has not yet been fully characterized. Compound **1** is electrochemically oxidized in a reversible process at a potential of $E_{1/2} = 0.144$ V.[15] This value lies between those for unsubstituted ferrocene (0.337 V)[15] and decamethylferrocene (-0.163 V),[15] a finding that can be explained by steric effects and in light of the smaller inductive effect exerted by the allyl groups in comparsion to that exerted by the methyl substituents. The direct comparison with octaallylferrocene **5**, which is obtained analogously to **1** from potassium tetraallylcyclopentadienide,[14] shows that inductive effects alone cannot sufficiently explain the value of the redox potential of ferrocenes with sterically demanding substitutents.[16] The redox potential of **5** was determined to be $E_{1/2} = 0.100$ V;[15] thus, in comparison with that of **1** it is cathodically and not anodically shifted.

Chemical oxidation of **1** with $NOBF_4$ led to the decaallylferrocenium salt **2** (Scheme 2), which is very soluble in polar solvents and crystallizes from CH_3CN as blue-green needles.

Figure 1 shows the structure of the cation of **2** in the crystal.[17] The allyl groups point away from the center of the molecule in a "spider-leg-like" arrangement without a directional preference for the position of the terminal double bond. The Fe–Cp(centroid) distance of 1.715 Å is of the same magnitude as in similarly substituted ferrocenium cations.[16a, 18] Interesting, and unusual for decasubstituted ferrocene, is the almost eclipsed arrangement of the two Cp rings (twist angle 15°).



Scheme 2. a) $NOBF_4$, CH_3CN, room temperature; b) $HSi(Me_2)Fe$ (10 equiv), Karstedt-cat. (1% solution in toluene), xylene, room temperature, 1 d; c) $HSi(OEt)_3$ (excess), Karstedt-cat. (1% solution in toluene), toluene, reflux, 1 d.

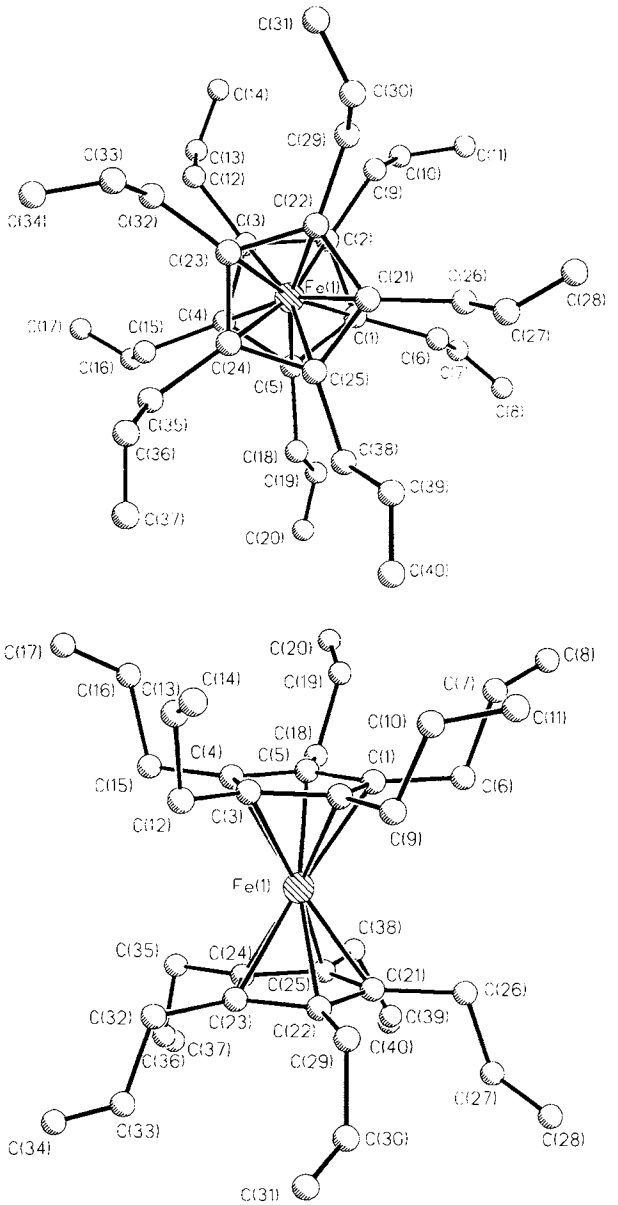


Fig. 1. Top view (top) and side view (bottom) of the cation of **2** in the crystal.

The platinum-catalyzed hydrosilylation of **1** with ten equivalents of dimethylsilylferrocene in xylene led almost quantitatively to the decaferrocenyl ferrocene **3** (Scheme 2) as an orange, waxy solid, which readily dissolves in polar and aromatic solvents. The absence of signals for the vinylic H and C atoms in the ^1H and ^{13}C NMR spectra, respectively, confirms the decasubstitution as does the detection of the molecular ion in the FAB-MS spectrum. The NMR spectra of **3** also show signals attributable to the α-hydrosilylation product (Table 1), which is formed in about 10% yield. This implies that on average one of the ten outer ferrocenyl moieties is bound to the core not by a propanediyl chain but by an isomeric methylethanediyl chain.

Table 1. Selected physical data for **1** and **3**–**5**.

1: ^1H NMR [a]: $\delta = 2.94$ (d, 2H, $^3J = 6.7$ Hz), 4.80–5.05 (m, 2H), 5.62–5.75 (m, 1H); ^{13}C NMR [a]: $\delta = 30.25$ (Fc-CH_2), 82.33 (C_5R_5), 114.96 (=CH_2), 137.96 (-CH=); MS (70 eV): *m/z* (%): 586 (100) [M^+], 546 (2) [$M^+ - C_3H_4$], 321 (2.5) [$C_5(C_3H_5)_5Fe^+$]

3: ^1H NMR [a]: $\delta = 0.19$ [c]/0.22 (2s, 60H, $SiCH_3$), 0.57 (s, 3H, CH_3 [c]), 0.65–0.80 (m, 20H, $SiCH_2$), 1.20–1.35 (m, 20H, $SiCH_2CH_2$), 1.97–2.12 (m, 20H, C_5CH_2), 4.08/4.10 (2s), 4.05–4.08 (m), 4.29 (m) (in total 90H, Fc-H); ^{13}C NMR [b] (C_6D_6): $\delta = -2.57$ [c], −1.47 ($SiCH_3$), 19.12, 28.24, 31.41 (($CH_2)_3$), 9.71 (CH_3 [c]), 68.53 (C_5H_5), 71.10, 73.40 (C_4H_4CSi), 71.20 (C_4H_4CSi), 83.8 (C_5R_5); ^{29}Si NMR [b]: $\delta = -2.8$, −0.5 [c]; FAB-MS [d]: *m/z* (%): 3029 (100) [$M^+ + H$], 2786 (89) [$M^+ - FcSiMe_2$], 2543 (37) [$M^+ - 2 \times FcSiMe_2$], 1514 (15) [M^{2+}], 1169 (58), 927 (46)

4: ^1H NMR [b]: $\delta = 0.52$ (CH_3 [c]), 1.19 (m, 2H, $SiCH_2$), 1.33 (m, 2H, $SiCH_2CH_2$), 2.12 (m, 2H, C_5CH_2), 1.21 (t, $^3J = 6.9$ Hz, 9H, OCH_2CH_3), 3.79 (q, $^3J = 6.9$ Hz, 6H, OCH_2CH_3); ^{13}C NMR [b]: $\delta = 11.95, 25.80, 29.99$ (($CH_2)_3$), 11.4 (CH_3 [c]), 82.81 (C_5R_5), 18.37, 58.18 (OEt), 17.96, 59.10 (OEt [c]); ^{29}Si NMR [b] (C_6D_6): $\delta = -45.43$; FAB-MS [d]: *m/z* (%): 2228 (90) [M^+], 2065 (100) [$M^+ - Si(OEt)_3$], 1901 (60) [$M^+ - 2Si(OEt)_3$], 1141 (37) [$FeC_5R_5^+$]

5: ^1H NMR [a] (C_6D_6): $\delta = 2.85$–2.91 (m, 16H, Fc-CH_2R), 3.65 (s, 2H, C_5R_4H), 4.91–5.05 (m, 16H), 5.76–5.96 (m, 8H); ^{13}C NMR [b]: $\delta = 30.17/31.49$ ($FcCH_2$), 82.19/83.88 (C_5R_4H), 114.78/114.90 (=CH_2), 137.52/137.84 (-CH=); MS (70 eV): *m/z* (%): 506 (100) [M^+]

The cyclovoltammetric studies of **3** show that the outer ferrocenyl moieties, which can be reversibly ($I_a/I_c \approx 1$) oxidized at $E_{1/2} = 0.40$ V (vs. Ag/AgCl), are equivalent. Furthermore, a second wave with an intensity of approximately one-twelfth of that of the dominant wave is easily discernible and attributed to the central ferrocenyl moiety ($E_{1/2} = -0.10$ V vs. Ag/AgCl) (Fig. 2). The fact that the observed ratio of intensities is not exactly 1:10 is attributed to adsorption phenomena on the electrode surface.

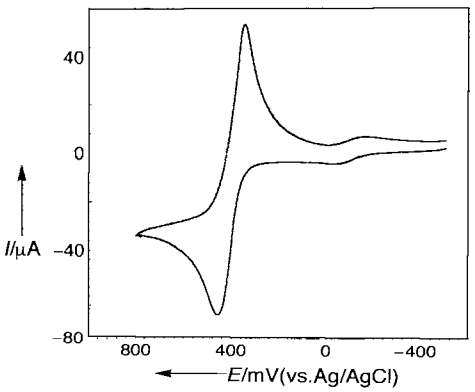

Fig. 2. Cyclovoltammogram of **3** in CH_2Cl_2 (ca. 8.8×10^{-4} mol L^{-1}, conducting electrolyte: 0.1 mol L^{-1} nBu_4NPF_6, 20 °C, Au disc electrode, scan rate 50 mVs^{-1}.

Hydrosilylation of **1** with triethoxysilane afforded the 30-fold ethoxy-substituted ferrocene **4** (Scheme 2). However, compared to the synthesis of **3**, the reaction mixture needs to be stirred for a longer period of time and heated to achieve complete addition to the ten double bonds. Here, too, the α-hydrosilylation product is formed in about 10% yield. Cyclovoltammetric studies of **4** gave a potential of $E_{1/2} = -0.055$ V (vs. Ag/AgCl) with a peak separation of $\Delta E_p = 87.6$ mV (for conditions see cyclovoltammogram of **3**).

Decaallylferrocene is an ideal substrate for further ($n \times 10$)-fold functionalization in the context of the dendrimer strategy. Hydrosilylation is one of several easily applicable reactions for the assembly of starlike organometallic molecules that can serve as building blocks for redox-active polymers (e.g. by a sol–gel process) or as molecular multielectron reservoirs. The strategy presented herein should also be suitable for the synthesis of other metallocene or cyclopentadienyl-metal compounds; it allows, generally speaking, the preparation of highly functionalized compounds.

Experimental Procedure

1: Potassium pentaallylcyclopentadienide (0.611 g, 2.00 mmol) and $FeCl_2 \cdot THF_{1.4}$ (0.303 g, 1.33 mmol) were added to THF (50 mL) at room temperature, and the resulting mixture was stirred for 3 d. The solvent was removed under vacuum and the residue was extracted with hexane. After the mixture had been filtered, the solution was concentrated and allowed to crystallize at 0 °C. Yield: 0.37 g (63%) of orange needles, m.p. 195 °C.

2: A mixture of **1** (130 mg, 0.222 mmol) and $NOBF_4$ (40 mg, 0.342 mmol) was treated with acetonitrile (5 mL), and stirred at room temperature for 12 h. The solution was concentrated and then stored under a diethyl ether atmosphere for several days, which led to the crystallization of blue-green needles of **2**. Yield: 0.13 g (87%). m.p. ≈ 350 °C (decomp.).

3: To a solution of **1** (0.10 g, 0.170 mmol) in xylene (10 mL) was added a 1% solution of the Karstedt catalyst in toluene (0.5 mL). Air was briefly passed through the solution, and then dimethylferrocenylsilane (1.00 g, 4.09 mmol) in a small amount of xylene was added dropwise. The mixture was stirred overnight at 20 °C, and then the solvent and excess ferrocenylsilane were removed under high vacuum. The residue was purified by flash chromatography (toluene, silica gel) to **3** as a dark orange, waxy solid. Yield: 0.43 g (82%).

4: To a solution of **1** (0.20 g, 0.340 mmol) in toluene (10 mL) was added a 1% solution of the Karstedt catalyst in toluene (0.8 mL). Air was briefly passed through the solution, and then an excess of triethoxysilane (2 mL) was added dropwise to the mixture. The reaction mixture was stirred for 48 h at 100 °C and then filtered through charcoal. The solvent and excess triethoxysilane were removed under high vacuum to afford **4** as a dark brown, viscous oil. Yield: 0.74 g (90%).

5: Compound **5** was prepared analogously to **1** from potassium tetraallylcyclopentadienide [14] (8.00 g, 30.2 mmol). Yield: 9.20 g (60%) as a dark orange oil.

[11] Ferrocenes substituted with functional (organic) groups are unknown; the corresponding cyclopentadienes (e.g. $(CN)_5C_5H$) are poor complexing ligands for electronic reasons [1b]. Decahalogen-substituted ferrocenes can be prepared by repeated metalation/ chlorination [9] and permercuration [10]. However, little is known about the substitution chemistry of these compounds.

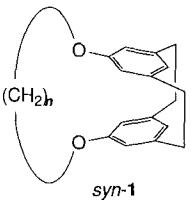
First-Generation Tethered [2.2]Metacyclophanes—Prototypes of Molecular Devices**

Graham J. Bodwell,* Tom J. Houghton, Jason W. J. Kennedy, and Michael R. Mannion*

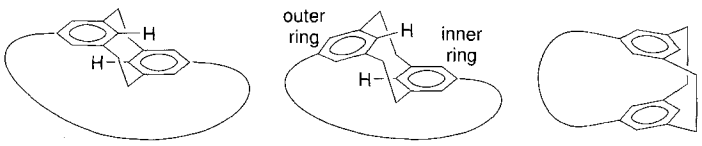
It has long since been established that the preferred conformation of [2.2]metacyclophanes is *anti*.[1] Indeed *syn*-[2.2]-metacyclophanes are relatively uncommon, as they isomerize thermally to their *anti* counterparts.[2–4] Substantial kinetic stabilization of the *syn* conformer has been achieved by introducing substituents at the internal positions.[3] The same is true, but to a lesser extent, for bridge substituents.[4] Alternately, the fusion of small rings to the bridges can fix the [2.2]-metacyclophane framework in the *syn* conformation,[5] as can the presence of a third bridge as in **1c**.[6]



syn-**1**

With respect to this latter approach, we became interested in the [*n*.2.2](1,3,5)-cyclophanes **1** because of the fascinating possibilities that they present.

First of all, it was envisaged that the conformational preference of these "tethered [2.2]metacyclophanes" would be determined by the length of the tether. A very long tether should not significantly influence the system and thus allow the [2.2]metacyclophane to behave as though it were absent; in other words, the *anti* conformation should be adopted and the two aromatic rings should be parallel (**1A**). As the length of the tether decreases, the strain in the *anti* conformer should increase, thereby lowering the difference in energy between the *anti* and *syn* conformers. In addition, the aromatic rings should now be tilted with respect to one another (**1B**). Accordingly, the internal proton of the "inner" ring will



1A **1B** **1C**

have moved further into the shielding cone of the "outer" ring than in the previous case. Exceptionally high-field ^1H NMR resonances are thus anticipated. At the same time the internal proton of the outer ring will have moved away from the shielding cone of the inner ring. Continuing to decrease the length of the tether will eventually render the *anti* conformer less stable than *syn* (**1C**). However, at some intermediate tether length, the two conformers may be close enough in energy to coexist. Modifying the constitution of the tether should ultimately provide a means of "fine-tuning" the system.

Given that *syn*-[2.2]metacyclophane itself undergoes facile isomerization to its *anti* conformer at 0 °C,[3] it does not seem unreasonable to expect an energy barrier between the two conformers low enough to allow them to interconvert at room tem-

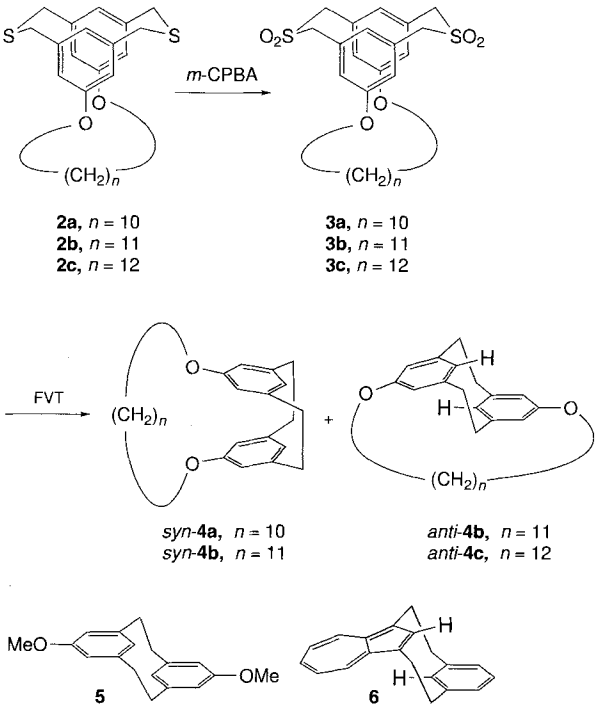
[**] Tethered [2.2]Metacyclophanes, Part 1. Support of this work from the Natural Sciences and Engineering Research Council (NSERC) of Canada is gratefully acknowledged.

perature. However, the two conformers do have markedly different structures and their interconversion will clearly involve considerable molecular reorganization, which should serve to heighten the energy barrier between them. The *syn* conformer possesses a cavity in which guest molecules or ions might be accommodated, while the *anti* conformer does not. Thus, great potential exists for the development of molecular devices based on this isomerization. Appropriate functionalization of the tether may eventually allow the system to be customized for selected guests. We now report the synthesis and conformational behavior of members of the first generation of tethered [2.2]metacyclophanes.

The dithiacyclophanes **2a–c** were prepared in analogy to a lower homologue in this series[7] by using Na_2S/Al_2O_3[8] to couple the appropriate tetrabromides (Scheme 1). Oxidation of



Scheme 1. Synthesis of tethered [2.2]metacyclophanes **4a–c**. FVT = flash vacuum thermolysis.

2a–c with *m*-chloroperoxybenzoic acid (*m*-CPBA) afforded the remarkably soluble bissulfones **3a–c** (95–100%), and these were thermolyzed in vacuo to give the tethered [2.2]metacyclophanes **4a–c** in 45–69% yield. Compound **4a** (12-atom tether, 54%) was obtained exclusively as the *syn* conformer. The ^1H and ^{13}C NMR spectra (Table 1) indicate the presence of two planes of symmetry. The signals of the internal aromatic protons are observed at $\delta = 6.19$. In contrast, compound **4c** (14-atom tether, 45%) was isolated exclusively as the *anti* conformer. The ^1H and ^{13}C NMR spectra (Table 1) indicate the presence of a single plane of symmetry, and signals of the internal aromatic protons are observed at $\delta = 4.83$ and 3.30. The higher field signal is arbitrarily assigned to the internal proton of the inner ring. With *anti*-5,13-dimethoxy[2.2]metacyclophane **5**[9] as a reference compound ($\delta(H_i) = 4.08$), $\Delta\delta$ values for the two internal protons are -0.75 (outer ring) and 0.78 (inner ring). The highest field signals of the tether are observed at $\delta = 0.50$.

The 300 MHz ^1H NMR spectrum (Table 1) of the crude pyrolysate of **3b** (13-atom tether) indicated the presence of both

Table 1. ^1H and ^{13}C NMR data for **4a–c** and **5** [a].

[a] ^1H NMR: 300 MHz, $CDCl_3$, TMS; ^{13}C NMR: 75 MHz, $CDCl_3$, TMS.

syn-**4b** and *anti*-**4b** in a ratio of roughly 2.5:1. The significant difference in their R_f values (SiO_2, 1:1 CH_2Cl_2:hexanes, R_f(*syn*-**4b**) = 0.40, R_f(*anti*-**4b**) = 0.25) allowed for straightforward chromatographic separation. The yields of isolated products were 20% (*syn*-**4b**) and 49% (*anti*-**4b**). The ^1H NMR signals of the internal protons of *syn*-**4b** are observed at $\delta = 6.17$, whereas those of *anti*-**4b** appear at $\delta = 5.07$ (outer ring) and 3.03 (inner ring). These chemical shifts are very similar to those observed in azulenophane **6**,[10] for which Mitchell[2] invoked a tilting effect akin to that in **1B**. Compared to **5**, the $\Delta\delta$ values are -0.99 (outer ring) and 1.05 (inner ring). The highest field protons of the tether are observed at $\delta = 0.37$. The conformers interconvert slowly at room temperature as seen by the gradual appearance over time of peaks corresponding to the other conformer in the ^1H NMR spectra of the original solutions of the pure conformers.[11] The equilibrium *anti*:*syn* ratio at room temperature is approximately 5.9:1, as determined by integration of the low-field aromatic signals. This ratio corresponds to a free energy difference of roughly 1.1 kcal mol^{-1}. Also worthy of note is that the isomerization of *anti*-**4b** to *syn*-**4b** is only the second documented instance of an *anti*-to-*syn* isomerization of a [2.2]metacyclophane derivative.[12]

We have established that a tether of 13 sp^3-hydridized atoms renders the two conformers of these tethered [2.2]metacyclophanes nearly equal in energy and that their interconversion takes place slowly at room temperature. Compound **4b** is thus a prototype of a molecular device, the development of which we are now actively pursuing.

Experimental Procedure

General procedure for the thermolysis of sulfones **3a–c** [13]: A solution of the bissulfone (200–300 mg per run) in CH_2Cl_2 (ca. 40 mL) in a 100 mL round-bottomed flask was evaporated on a rotary evaporator to leave a thin coating of the substrate on the surface of the flask. A cold finger was attached to the flask and high vacuum (ca. 10^{-1} mm Hg) with a nitrogen bleed was applied. The flask was then heated with a full Bunsen burner flame. The sublimate was washed back into the flask with CH_2Cl_2 and the procedure was repeated. The combined sublimate and residue thus obtained were chromatographed on SiO_2 with CH_2Cl_2:hexanes (1:4 to 1:1 gradient) as eluent to afford the products.

A Novel Catalyst with a Cuboidal $PdMo_3S_4$ Core for the Cyclization of Alkynoic Acids to Enol Lactones**

Takanori Wakabayashi, Youichi Ishii, Kazunari Ishikawa, and Masanobu Hidai*

Transition metal sulfide clusters with a cuboidal core or related structure have been found in the active sites of several metalloproteins such as nitrogenase, aconitase, and ferredoxin.[1] In order to elucidate the functions of these unique sulfide cluster structures, which are considered to be responsible for the functions of these proteins, considerable attention has been paid to the synthesis and characterization of model systems, that is cuboidal sulfide clusters containing mainly the first row transition metals.[2] Sulfide clusters of this kind have so far found little application as catalysts for organic synthesis.[3] Thus, in this context, we have prepared sulfide clusters containing metals from Group 10, which might function as catalytically active centers, and have recently synthesized and fully characterized a novel mixed-metal sulfide cluster with a cuboidal core $[PdMo_3S_4(tacn)_3Cl](PF_6)_3$ (**1**; tacn = 1,4,7-triazacyclononane).[4] Cluster **1** catalyzes the selective *trans*-addition of alcohols or carboxylic acids to acetylenes conjugated with electron-withdrawing group(s).[4b, 5] Here we report that cluster **1** is a highly effective catalyst for the cyclization of 3-, 4-, and 5-alkynoic acids to the corresponding enol lactones under very mild conditions.

Convenient and selective synthesis of enol lactones has attracted a great deal of interest because of their biological importance, and the cyclization of readily available alkynoic acids provides one of the most attractive and straightforward synthetic routes to enol lactones. Palladium and rhodium complexes such as $[PdCl_2(PhCN)_2]$ (**2**)[6] and $[RhCl(cycphos)]_2$ (**3**; cycphos = 1,2-bis(dicyclohexylphosphanyl)ethane),[7] as well as several silver[8] and mercury[9] salts have been reported to effect the lactonization of alkynoic acids. However, the catalytic activities of these monometallic catalysts are not necessarily satisfactory. For example, the cyclization of 5-hexynoic acid catalyzed by $PdCl_2$ in CH_3CN gives only a moderate yield of 6-methylene-tetrahydro-2-pyrone even under reflux,[6a] while the same reaction using **3** as the catalyst proceeds at room temperature but very sluggishly (turnover number (TON) = 21 after 50 h; where TON = mol of product per mol of catalyst).[7]

In contrast to the above catalytic systems, cluster **1** is very catalytically active in the lactonization of alkynoic acids in the presence of a small amount of NEt_3 (3 mol%) under mild conditions (20–40 °C, in acetonitrile). Figure 1 illustrates the time

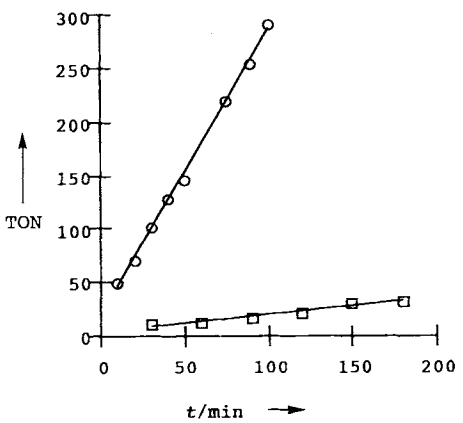

Fig. 1. Time dependence of the TON in the cyclization of **4g** catalyzed by **1** (○) and **2** (□) at 20 °C.

dependence of the TON in the cyclization of 2,2-dimethyl-5-hexynoic acid (**4g**) catalyzed by **1** and **2** at 20 °C to give 3,3-dimethyl-6-methylene-2-pyrone [Eq. (a)]. Kinetic measurements indicated that the reaction catalyzed by **1** is first order with respect to the concentration of both **1** and NEt_3. By comparing the slope of the two curves, the catalytic activity of **1** was evaluated to be 17 times higher than that of **2**. No noticeable decrease in the activity of **1** was observed during the measurement. Furthermore, the UV/Vis spectrum of the reaction solution showed no appreciable change during the catalysis, and

dilution of the reaction mixture with 1 N aqueous HCl after the reaction reproduced UV/Vis λ_{max} and ε values (463 nm (0.89×10^3), 580 nm (1.36×10^3)) essentially identical to those of **1** in CH_3CN/1 N aqueous HCl. These observations strongly support that the cluster structure of **1** is retained throughout the catalysis and that the active catalyst is a cuboidal cluster species closely related to **1**. It is noteworthy that the palladium center embedded in the molybdenum–sulfide cluster core provides a much more efficient reaction site than mononuclear palladium catalysts. γ-Lactone formation proceeded much faster than the cyclization to δ-lactones. Cluster **1** was found to be 12 times more active than **2** for the cyclization of 2,2-dimethyl-4-pentynoic acid at 20 °C. When 4-pentynoic acid (**4a**) was used as the substrate, the TON reached 100000 after 19 h at 40 °C.

The results of the catalytic cyclization of various alkynoic acids with **1** are summarized in Table 1.[10] 5-Alkynoic acids gave the corresponding δ-lactones, while 3- and 4-alkynoic acids afforded the corresponding γ-lactones as the single product, except for the reaction of 4-hexynoic acid (**4d**), which produced a mixture of γ- and δ-lactones. These reactions proceeded very rapidly under mild conditions. However, the lactonization of 6-heptynoic acid (**4h**) to the corresponding ε-lactone was rather slow and the yield was low even in CH_3CN under reflux conditions in the presence of 50 mol% of NEt_3. Mechanistically, the catalytic cycle is considered to involve intramolecular nucleophilic attack of a carboxylate anion on the C≡C bond of an acetylene coordinated to the palladium center of the cuboidal core, followed by the protonolysis of the resulting vinylpalladium species. This mechanism is basically similar to that proposed for mononuclear metal catalysts. In fact, the stereoselectivity and the ratio of the γ- and δ-lactones found in the reaction of **4d** with complex **1** is closely related to those obtained with complex **3**.[7] Although the catalytic transformation of the substrate by **1** is assumed to proceed only at the palladium center, it is particularly interesting that the palladium atom incorporated into the cuboidal sulfide cluster exhibits significantly enhanced catalytic activity in comparison with mononuclear palladium complexes.

Finally, it should also be pointed out that the above cyclization can be conducted in water, owing to the good solubility and stability of **1** in this medium. Treatment of dipropargylmalonic acid (**4i**) with catalytic amounts of **1** (0.1 mol%) and NEt_3 (1 mol%) in water led to the quick precipitation of the corresponding enol γ-lactone, which amounted to 76% yield after 10 min at 20 °C. A similar reaction catalyzed by $PdCl_2$/NaCl afforded the γ-lactone only in 8.6% yield. The catalytic activity of **1** is also considerably higher than mononuclear palladium species in aqueous media as well. Transformations of organic molecules catalyzed by metal complexes using water as solvent are of current interest in organic synthesis from an economical and environmental point of view.[11] Cluster **1** is expected to provide a new type of intrinsically water-soluble metal complex catalyst.

Table 1. Lactonization of alkynoic acids with **1** as catalyst [a].

Substrate		t [h]	Product	Yield [%] [b]
	**4a**	6 min 19 [c]		77 (100) 97
	**4b**	1 min		68 (98)
	**4c**	2		99

	4e	2		62
	**4f**	3 [d]		86
	**4g**	2		87 (98)
	**4h**	10 [e]		28
	**4i**	1 [d]		81

[a] Reaction conditions: **4** (3 mmol), NEt_3 (0.1 mmol), **1** (0.01 mmol), MeCN (5 mL), room temperature. [b] Yield of isolated product. The yield determined by GC is given in parentheses. [c] **4a** (0.1 mol), NEt_3 (1 mmol), **1** (1 μmol), 40 °C. [d] 40 °C. [e] **4i** (2 mmol), NEt_3 (1 mmol), reflux.

Experimental Procedure

The following procedure is representative for the catalytic conversion of alkynoic acids to the corresponding enol lactones. 2,2-Dimethyl-5-hexynoic acid (0.42 g, 3.0 mmol), NEt_3 (0.10 mmol, 10.5 mg), and **1** (0.010 mmol, 13.9 mg) were dissolved in acetonitrile (5 mL), and the resulting violet solution was kept at 20 °C. After 2 h, the GC analysis of the reaction mixture indicated that 3,3-dimethyl-6-methylene-2-pyrone was formed in 98% yield. Ether (25 mL) and hexane (25 mL) were added to the mixture, and the resultant violet precipitate was removed by filtration. The colorless filtrate was evaporated to dryness, and the residual oil was further purified by bulb-to-bulb distillation (100 °C/2 mmHg) to give pure 3,3-dimethyl-6-methylene-2-pyrone in 87% yield.

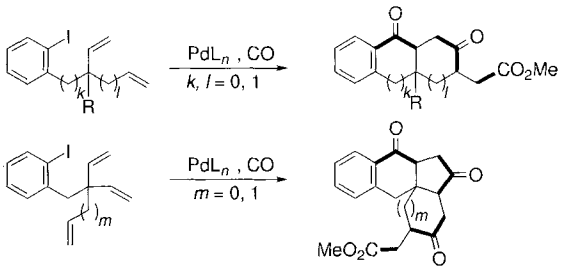
Palladium-Catalyzed Carbonylative Cyclization Cascades with Iododienes and -trienes**

Christophe Copéret, Shengming Ma, and Ei-ichi Negishi*

In memory of Wolfgang Oppolzer

We report here on a novel palladium-catalyzed cyclization cascade proceeding by carbonylation of ω-iododienes and -trienes. In this cascade, multiple carbon–carbon bonds are formed by acylpalladation cyclization,[1] with incorporation of CO in each cyclization step. The use of CO as a one-carbon unit enables the novel cyclization cascade with an angular mode of ring fusion (Scheme 1).[2]



Scheme 1. Acylpalladation cascades with an angular mode of ring fusion.

We have previously reported a series of studies delineating the scope of ring-forming acylpalladation.[3] Despite these acylpalladation reactions giving monocycles and related polymerization processes proceeding by acylpalladation,[4] no acylpalladation cascade forming polycycles appeared to be known. This prompted us to explore the feasibility of this type of reaction cascade and its applicability to the formation of five- and six-membered bicycles and polycycles. With these goals in minds, iododienes and -trienes **1a–e**[5] were subjected to palladium-catalyzed carbonylative cyclization under previously described conditions[3b] (CO (40 atm), $[Pd(PPh_3)_2Cl_2]$ (5 mol%), MeOH (4 equiv), NEt_3 (4 equiv), acetonitrile/benzene (1/1)). The results are summarized in Table 1.

The compounds **1a–c** gave the corresponding tricyclic compounds **2a–c** in good yields as a mixture of diastereomers with no sign of products arising from premature esterification.[6] Of the four possible diastereomers, only two were detected for **2b** and **2c** (Scheme 2). The major diastereomers of **2b** and **2c** showed strong NOE cross-peaks between 3-H, 9a-H, and 3a-CH_2R', strongly pointing to a *cis* ring junction and a *trans* relationship between the (methoxycarbonyl)methyl substituent and the $R'CH_2$ group. Moreover, the minor diastereomer of **2b** was shown by X-ray crystal structure analysis[7] to be the epimer with the (methoxycarbonyl)methyl substituent *cis* to the R group. In contrast, tricycle **2a** was obtained as an inseparable mixture of three diastereomers.

Table 1. Acylpalladation cascade of alkenes [a].

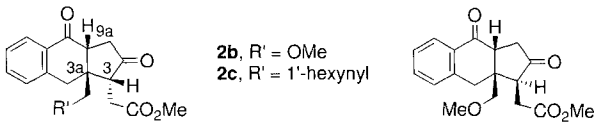
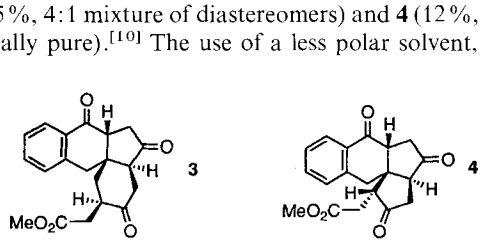


Scheme 2. The major isomers of **2b** and **2c** (left) characterized by NOE experiments, and the minor diastereomer of **2b** (right) characterized by X-ray structure analysis.

The absence of premature trapping products in the reaction of **1a–c** prompted us to investigate the corresponding reaction with iodotrienes for a tricyclization cascade. Under the previously described conditions, **1d** gave **2d** (58%, 5:1 mixture of diastereomers) and **3** (12%, 88±2% stereoisomeric purity); the structure of **3** was firmly established by X-ray crystallography.[8] The formation of **3**, albeit in low yield, is remarkable, as it involves the formation of seven carbon–carbon bonds.[9] The corresponding reaction of **1e** proceeded similarly producing a mixture of **2e** (35%, 4:1 mixture of diastereomers) and **4** (12%, >95% isomerically pure).[10] The use of a less polar solvent,



benzene, improved the yield of **4** to 22%. Further attempts to improve the yield of tricyclization are currently underway. It may be worth pointing out that the previously developed cascade with a linear mode of ring fusion[2b] involving noncarbonylative carbopalladation is not applicable to the synthesis of angularly fused polycyclic structures consisting of five- and six-membered rings. The present carbonylative procedure makes this feasible through the incorporation of CO as a one-carbon component.

Having demonstrated the feasibility of the [6-5]-cyclization cascade and its extension to the [6-5-5]- and [6-5-6]-cascades with angular ring fusion,[11] we then examined the possibility of the [5-5]-, [5-6]-, and [6-6]-cyclization cascades. Under the standard conditions, **5** gave compounds **6** (40%) and **7** (38%) both as roughly 1:1 mixtures of diastereomers. This reaction is in sharp contrast with those of **1a–e**, where premature trapping after the first cyclization was not observed. Presumably, a mixture of the *cis*- and *trans*-cyclized intermediates **8a** and **8b** is formed. The intermediate **8a** could readily cyclize to give **6**,

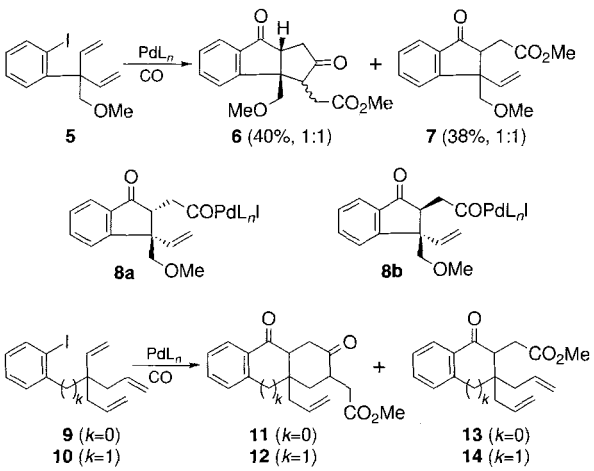
while **8b**, in which the two substituents are *trans* to each other, would preferentially react with MeOH to give **7** rather than the strained *trans*-bicyclo[3.3.0]octane ring system.[12] Finally, under the standard conditions, **9** and **10** gave **11** (54%, 2:1 mixture of diastereomers) and **12** (38%, 2:1:1 mixture of diastereomers) along with their respective products arising from premature trapping, **13** (14%) and **14** (34%). We have recently shown that



the formation of five-membered rings by acylpalladation is faster than that of six-membered rings.[3b] Consequently, if a six-membered ring is formed in the second cyclization, premature esterification would become a serious side reaction. Generally speaking, the relative effectiveness of the carbonylative cyclization cascade reactions as judged by product yields and ratios is as follows: [6-5]- > [5-6]- > [5-5]- ≥ [6-6]-cascades.

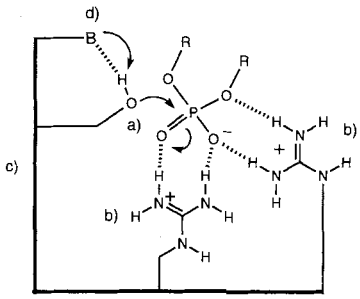
Bis(guanidinium) Alcohols as Models of Staphylococcal Nuclease: Substrate Binding through Ion Pair Complexes and Fast Phosphoryl Transfer Reactions**

Marc-Steffen Muche and Michael W. Göbel*

In memory of Wolfgang Oppolzer

For the past few years our interest has focused on the synthesis of simple, non-peptidic molecules that mimic structural and functional aspects of staphylococcal nuclease.[1, 2] The active site of this enzyme contains two arginine units, which, in conjunction with a calcium ion, lead to the electrophilic activation of phosphodiester substrates for hydrolysis.[3] The most important factor for catalysis is the optimal complexation of the pentacoordinated transition state structures by the guanidinium groups.[4] Scheme 1 illustrates our working hypothesis for the construction of metal-free "synthetic phosphodiesterases"[5, 6] along the lines of staphylococcal nuclease.



Scheme 1. Construction principle behind a synthetic phosphodiesterase. a) Nucleophile; b) guanidinium ions which contribute to the electrostatic stabilization of the transition state and to the protonation of the leaving group; c) supporting molecular framework; d) base which activates the nucleophile (not yet realized).

Since translating Scheme 1 into concrete chemical structures is not simple, we have examined individual aspects of the problem. We first studied the phosphorylation of monocationic alcohols of type **1**.[2a, d, e] Compound **1** and phosphodiesters form ion pair complexes reversibly, in which facile phosphoryl transfer to the hydroxyl

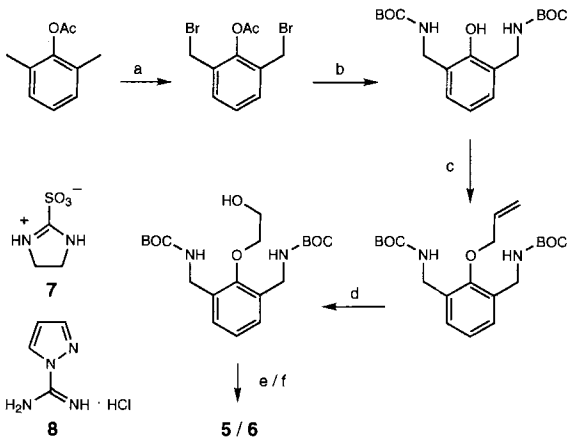
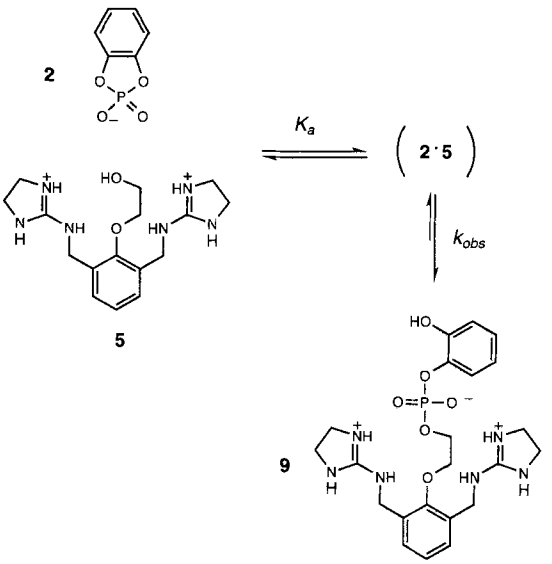
group occurs. Phosphorylation of **1** with cyclophosphate **2** is 2700 times faster than that of the uncharged alcohol **3**.[2a, d] This acceleration is explained not only by the close proximity of nucleophile and substrate in the ion pair (**1**·**2**); electrophilic activation of the phosphodiester through coordination to the amidinium ion also plays a role. This effect is observed for a variety of mono-, bis-, and tris(guanidinium) compounds.[2b, c] Thus, the rate of phosphorylation of **3** with **2** is increased by a factor of almost 5000 in the presence of bis(guanidinium) ion **4**. Compound **4** and related species are also effective catalysts for other phosphoryl transfer reactions.[7, 8] In an attempt to combine the structural characteristics of alcohol **1** and dication **4** we have now prepared compounds **5** and **6** and have studied their reaction with cyclophosphate **2**.

The syntheses of **5** and **6** are outlined in Scheme 2. The incorporation of a second cationic unit proved to increase both the reaction rates (see below) and the strength of substrate binding. ^{31}P NMR titration of **2** with **5** in the absence of base led to an association constant K_a of 2900($\pm$800) M^{-1} (DMF/[D$_7$]DMF = 2:1, 30 °C). The association constant of the ion pair (**1**·**2**) has a modest value of 190 M^{-1}. When base is added to a mixture of **2** and **5**, the hydroxyl group is phosphorylated readily giving **9** in high yield (DMF, 0.25 M diisopropylethylamine, 30 °C; Scheme 3). Compound **9**, isolable as the monopicrate salt, was characterized by ^{1}H and ^{31}P NMR spectroscopy, ESI mass spectrometry, and elemental analysis. In contrast to the phosphorylation of **1**, formation of **9** is reversible. In experiments conducted with a range of initial concentrations, equilibrium was achieved with an equilibrium constant of almost 150 M^{-1} at conversions between and 60 and 94% (Table 1, Fig. 1). The reverse reaction of **9** leading to cyclophosphate **2** can be observed directly by ^{31}P NMR spectroscopy.



Scheme 2. Synthesis of bis(guanidinium) alcohols **5** and **6**. a) *N*-bromosuccinimide (NBS), HCO_2Me, azoisobutyronitrile (AIBN), Δ, *hν*, 3 h, 69%. b) 1. $NaN(CHO)_2$, *N*,*N*-dimethylformamide (DMF), 80 °C, 3 h; 2. 3 M HCl, Δ, 7 h; 3. $(BOC)_2O$, (BOC = *tert*-butoxycarbonyl), dioxane, aq. NaOH, room temperature (RT), 16 h, 80%. c. Allyl bromide, Cs_2CO_3, DMF, 80 °C, 2 h, >95%. d) 1. O_3, MeOH, −90 °C; 2. $NaBH_4$, RT, 16 h, 75%. e) 1. HCl, MeOH, RT, 2 h; 2. **7** [11], MeOH, H_2O, NEt_3, RT, 16 h; 3. picric acid, >95%. f) 1. HCl, MeOH, RT, 2 h; 2. **8** [12], MeOH, H_2O, NEt_3, RT, 16 h; 3. picric acid, 70%.



Scheme 3. Phosphorylation of **5** to give **9** via the intermediate ion pair (**2**·**5**). Counterions employed: picrate, tetramethylguanidinium.

Table 1. Phosphorylation of bis(guanidinium) alcohol **5** to give **9**. Equilibrium concentration of **9** and pseudo-first-order rate constants depend on the starting concentrations c_0(**2**) and c_0(**5**). DMF, 0.25 M diisopropylethylamine, 30 °C; counterions: picrate, tetramethylguanidinium.

c_0(**2**)	c_0(**5**)	c(**9**)	k_{obs}
0.025 M	0.025 M	0.015 M	
0.075 M	0.025 M	0.022 M	
0.05 M	0.05 M	0.033 M	4.6×10^{-3} min^{-1}
0.15 M	0.05 M	0.047 M	8.0×10^{-3} min^{-1}

The kinetics of the forward reaction were determined by ^{31}P NMR spectroscopy and by HPLC (Table 1). For c_0(**5**) = 0.05 M and c_0(**2**) = 0.15 M the pseudo-first-order rate constant of the bis(guanidinium) compound **5** (k_{obs} = 8.0($\pm$1)$\times10^{-3}$ min^{-1}) far exceeds the values of all other alcohols we have examined up to now. Compound **5** is phosphorylated 800 times faster than

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3518-2127 $ 15.00+.25/0

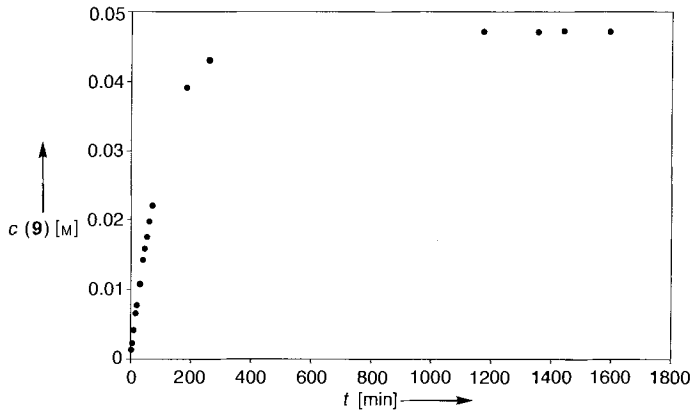


Fig. 1. Plot of the phosphorylation of **5** to give **9** versus time (c_0(**2**) = 0.15 M, c_0(**5**) = 0.05 M, DMF, 0.25 M diisopropylethylamine, 30 °C). An equilibrium is established.

the monocation **1** ($k_{obs} = 9.9 \times 10^{-6}$ min^{-1}). To compare **5** with the uncharged alcohol **3** ($k_2 = 2.4 \times 10^{-7}$ M^{-1} min^{-1}) a formal second-order rate constant can be derived ($k_{2obs} = k_{obs}/c_0$(**2**)). According to this, in the experiment with c_0(**2**) = c_0(**5**) = 0.05 M, the phosphorylation of **5** is 380000 times faster than the reaction of phenylethanol. At high dilution the limiting value of k_{2obs} is determined by $K_a k_1$. The maximum acceleration factor of 10^8, which can in theory be obtained when $k_{obs} = k_1$, is too high, because k_{obs} depends significantly on the starting concentration of alcohol **5**.[9] An acceleration factor of 10^6 to 10^7 is more realistic.

As previously observed with compound **4**,[2b] the replacement of the heterocyclic cations by unsubstituted guanidinium groups (**5** → **6**) also leads to a marked loss in reactivity of the dicationic alcohols. For the phosphorylation of **6** a value of $k_{obs} = 7.5(\pm 1) \times 10^{-4}$ min^{-1} was determined (c_0(**6**) = 0.05 M, c_0(**2**) = 0.15 M, DMF, 0.25 M diisopropylethylamine, 30 °C). The superiority of the 2-aminoimidazolinium ions over guanidinium groups is probably related to their higher acidity, as potentiometric titrations of **5** and **6** indicate. This enhanced acidity could affect the rate of reaction in two ways: a) The transition state in the addition step could be stabilized more effectively by stronger hydrogen bonding (or even protonation?). b) During the elimination the protonation of the leaving group could be facilitated.

Base concentrations of 0.25 M still appear to suffice for some deprotonation of the cations in **5**. This is evident from slight shifts in the NMR signals. Thus it cannot be excluded that the heterocycles function as general bases. N-Phosphorylated intermediates, the main products of the reaction with bis(4-nitrophenyl) phosphate, cannot be detected in even trace amounts in the ^{31}P NMR spectra of reaction mixtures of **2** and **5**. If they exist at all, they must be short-lived.

In view of the strained structure of cyclophosphate **2**, the reversibility of its reaction with **5** is remarkable. A structural aspect can be considered as a possible explanation in addition to the increased acidity of the glycolic hydroxyl group. According to molecular models, an ideal arrangement of cations and anion (four NH···O hydrogen bonds) is possible in the complex of **2** and **5** together with a correct orientation of the nucleophile. However, the hydroxylated side chain is so short that the phosphoryl group in product **9** is pulled out of the optimal position. As a result the ground state of **9** is thermodynamically destabilized, and only high-energy substrates can react.[10] Thus optimizing the side chain structure of **5** will be among the most important measures for achieving the tremendous acceleration effects obtained with cyclophosphate **2** with nonactivated phosphodiesters as well.

Experimental Procedure

4,5-Dihydro-1*H*-imidazolium 2-sulfonate (**7**) [11]: A suspension of *N*,*N*′-ethylenethiourea (2.5 g, 24.5 mmol) in 30 mL of water was treated with sodium molybdate dihydrate (18 mg, 0.075 mmol, 0.003 equiv) and cooled to 0 °C in an ice bath. To the suspension was added dropwise (temperature ≤ 5 °C) 15% hydrogen peroxide solution (16.8 mL, 74 mmol, 3 equiv). After the addition was complete, the ice bath was removed and the reaction mixture allowed to warm to roughly 20 °C. After a further 90 min the reaction solution was diluted with 50 mL of methanol and stored in a refrigerator for about 12 h. 1.56 g (42%) of **7** crystallized. M.p. 142 °C (decomp; water/methanol). ^{1}H NMR (270 MHz, [D$_6$]DMSO): δ = 3.86 (s, 4H, ethylene CH$_2$), 10.38 (br. s, 2H, NH). $C_3H_6N_2O_3S$ (150.16): calcd: C 24.00, H 4.03, N 18.66; found: C 24.10, H 4.19, N 18.46.

5: The BOC-protected alcohol (306 mg, 0.77 mmol) was dissolved in 2 mL of methanol and treated with 2 mL of methanolic hydrochloric acid. After 2 h the reaction mixture was concentrated to dryness under vacuum to give a colorless solid. This residue was dissolved in methanol/water/triethylamine (1:1:1; 6 mL), compound **7** (255 mg, 1.7 mmol, 2.2 equiv) was added, and the reaction mixture was stirred at about 20 °C for 12 h. The reaction mixture was diluted with 4 mL of 1 M sodium hydroxide and extracted twice with CH_2Cl_2. The aqueous phase was concentrated to half of its volume under vacuum, acidified with 2 M hydrochloric acid (pH 3–4), and concentrated to dryness. The dried solid residue was heated at reflux in 5 mL of methanol, the resulting mixture cooled and filtered. This procedure was repeated two more times. Water was added to the combined filtrates until a clear solution formed. A solution of picric acid (2 equiv) in methanol was added; then water was added until the solution became cloudy. The precipitating product was redissolved on heating. Slow cooling and crystallization afforded 590 mg (97%) of **5** (bispicrate). M.p. 196 °C (methanol/water). ^{1}H NMR (270 MHz, [D$_6$]DMSO): δ = 3.62 (s, 8H, ethylene CH$_2$), 3.76 (m, 2H, CH$_2$), 3.89 (t, J = 4.4 Hz, 2H, CH$_2$), 4.45 (d, J = 6.0 Hz, 4H, benzylic CH$_2$), 5.28 (br. s, 1H, OH), 7.23 (m, 3H, aromatic H), 7.45–8.45 (br. s, 4H, guanidine H), 8.51 (t , J = 6.0 Hz, 2H, benzyl NH), 8.60 (s, 4H, picrate H). $C_{28}H_{30}N_{12}O_{16}$ (790.62): calcd: C 42.54, H 3.82, N 21.26; found: C 42.58, H 4.06, N 21.49.

Dibromine Monoxide, Br_2O, and Bromine Dioxide, OBrO: Spectroscopic Properties, Molecular Structures, and Harmonic Force Fields**

Holger S. P. Müller,* Charles E. Miller, and Edward A. Cohen

The halogen oxides show great variations in structural parameters and other physical as well as chemical properties. Over a dozen chlorine oxides are known, and many of them are quite well characterized. Bromine oxides are unstable at room temperature; thus few of them are known.[1] Even fewer have been studied structurally, generally in the solid state. Structure determinations of free molecules have been confined to the BrO radical.[2]

Recently the chlorine and bromine oxides have attracted considerable attention because of their implication in reaction cycles leading to the destruction of atmospheric ozone. Of particular importance are the catalytic cycles involving ClO and BrO. Recently, bromine dioxide, OBrO, has been observed in the bromine-sensitized photodecomposition of O_3.[3, 4]

Dibromine monoxide, Br_2O, was obtained in low yields from the reaction of Br_2 with HgO.[5] Bromine dioxide was first reported by Schwarz and Schmeisser as an egg-yellow deposit from a Br_2/O_2 discharge.[6] The stoichiometry of the oxide was deduced by quantitative analysis. Its controlled decomposition below 0 °C enabled Schmeisser and Wiele to obtain pure Br_2O.[7] Later, Schmeisser and Jörger reported that the ozonolysis of Br_2 in cooled CCl_3F solution yielded OBrO.[8] In contrast, Seppelt et al. obtained single crystals of orange Br_2O_3[9] and colorless Br_2O_5[10] from that reaction but found no evidence for molecular OBrO. OBrO was detected during mass spectrometric investigations of the $O + Br_2$ reaction system,[11] ESR studies of X-ray irradiated perbromates,[12] and UV/Vis spectroscopic investigations of the $Br + O_3$ reaction system.[3, 4] The ν_1[13] and ν_3[13, 14] stretching fundamentals of the oxide were observed in Ar matrices.

Studies on Br_2O included determination of the melting point,[7] the solution[5c] and gas-phase UV/Vis spectra,[15] the solid-state Raman spectrum,[16] the solid-state structure from EXAFS (*e*xtended *X*-ray *a*bsorption *f*ine *s*tructure) data,[17] and the heat of formation.[15] The symmetric stretching vibration ν_1[14] or both stretching modes[17, 18] were observed in Ar[14, 18] or N_2 matrices.[17]

We have observed the rotational spectra of the triatomic oxides Br_2O and OBrO in the millimeter- and submillimeter-wave regions using the spectrometer described in reference [19]. We report here some of the fundamental spectroscopic constants as well as derived properties such as structure and harmonic force field.

Initially, Br_2O was obtained when Br_2 was passed through a column of HgO at room temperature, and the products were flowed through the microwave absorption cell. Although the yields were low, in agreement with earlier work,[5] many transitions were observed with no or little signal averaging.

OBrO was formed when the reaction products of an O_2 discharge plus Br_2 were condensed onto the wall of the microwave absorption cell at −20 °C. After the flow of O_2 and Br_2 was stopped, spectra of the vapor were recorded while pumping on the condensate. The identity of the product on the wall is not clear. It might be OBrO, a more complex bromine oxide, or a mixture of oxides that decompose slowly to yield OBrO. At low temperatures (≈ −20 °C) and pressures (≈0.1 Pa) essentially all absorption features were due to OBrO, although weak features of BrO were also seen. The amount of OBrO increased at higher temperatures because of a larger vapor pressure or an enhanced decomposition of its precursor. The BrO/OBrO ratio increased as well, possibly because of decomposition of OBrO. Strong absorptions of Br_2O were also seen at higher pressures (reduced flow rate) and higher temperatures. This method was subsequently used for further study of Br_2O.

The hyperfine patterns of $^{79}Br_2O$ and $^{81}Br_2O$ are consistent with their C_{2v} symmetry, whereas $^{79/81}Br_2O$ has C_s symmetry. At low J or K_a quantum numbers the splittings between single hyperfine components can be several tens of MHz, and the patterns often are complex. At high J and K_a quantum numbers usually several components overlap and symmetric triplets or quartets, or even single lines are seen, as shown in Figure 1. Additional complications arise from perturbations of the quadrupole patterns due to effects of the off-diagonal quadrupole coupling constant χ_{ab}.

The OBrO rotational spectrum is that of a C_{2v}-symmetric molecule in the $^2B_1$ electronic ground state, as is that of OClO. In general, each rotational transition is observable as a doublet of quartets. This is illustrated in Figure 2 for a transition with rather small splittings. The doublets indicate the presence of an unpaired electron, the quartets are due to one nucleus with spin 3/2 (^{79}Br or ^{81}Br).

A large number of lines was observed for Br_2O (>700) and OBrO (>1400), resulting in the precise determination of

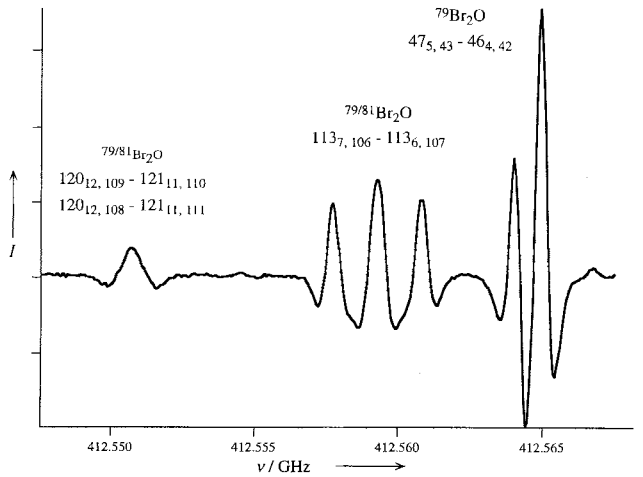

Fig. 1. Section from the submillimeter spectrum of Br_2O, which demonstrates significant intensity and quadrupole splitting for high J transitions. The asymmetric pattern of the $47_{5,43} - 46_{4,42}$ transition is caused by the off-diagonal quadrupole coupling constant χ_{ab}. I = intensity in arbitrary units.

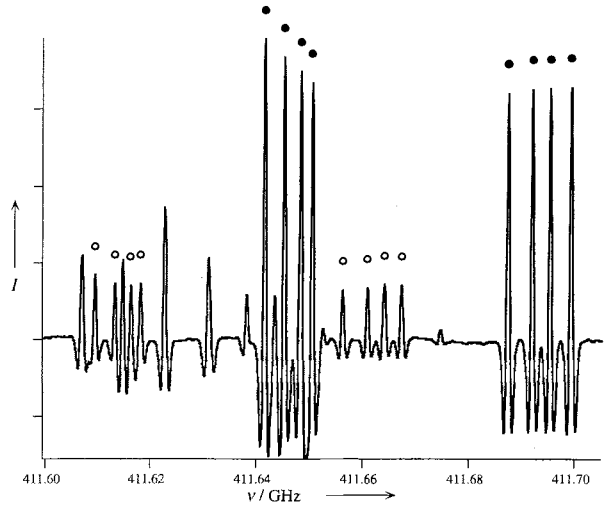

Fig. 2. Section from the submillimeter spectrum of the bromine dioxide radical. The $31_{1,30} - 30_{2,29}$ transition of $O^{81}BrO$ in the ground vibrational state (filled circles) and of $O^{79}BrO$ in the first excited bending mode (open circles) are indicated. In general each transition appears as a doublet of quartets; see text for details.

rotational, centrifugal distortion, fine (OBrO only), and Br hyperfine structure constants as well as distortion terms on fine and some hyperfine constants. Rotational and quartic centrifugal distortion constants for the vibrational ground state are given in Table 1 for $^{79}Br_2O$ and $O^{79}BrO$.

Table 1. Rotational [MHz] and quartic centrifugal distortion constants [a] [kHz] of $^{79}Br_2O$ and $O^{79}BrO$ in the ground vibrational states.

Parameter	$^{79}Br_2O$	$O^{79}BrO$

[a] Numbers in parentheses are two standard deviations in units of the least significant figures. Watson's S reduction is used in the representation I^r [20].

The principal planar moments have been used to calculate the r_0 structural parameters. They are given with data for the related chlorine compounds in Table 2. The structural parameters of different isotopomers agree well within the quoted digits. However, structural ambiguities due to vibrational effects are of up to the order of ±0.2 pm and 0.2° for Br_2O and ±0.15 pm and 0.25° for OBrO.[20] The equilibrium (r_e) structures of Br_2O and OBrO have not been determined. For both molecules the r_e bond lengths are about 0.5 pm smaller than the r_0 parameters, as estimated from the changes of related molecules; the r_e bond angles are expected to agree with the r_0 data to within the uncertainties ascribed to vibrational effects.

Table 2. Structural parameters [pm, °] [a] and harmonic force constants [N m^{-1}] of Br_2O and OBrO in comparison with related chlorine compounds.

Parameter	Br_2O [a]	Cl_2O [b,c]	OBrO[a]	OClO[b,d]
r	184.29 (20)	169.59	164.91 (15)	146.984
α	112.24 (20)	110.88	114.44 (25)	117.403
f_r	288.2	294.9	530.5	711.0
f_α	103.3	123.7	99.5	137.2
f_{rr}	38.7	50.4	−3.1	−25.0
f_r	29.6	31.2	−4.1	−2.7

[a] This work; r_0 structure with estimated upper limits for uncertainties, see text. [b] Equilibrium structure. [c] Ref. [21]. [d] Refs. [22,23].

The present structural parameters of Br_2O support the EXAFS results (185 (1) pm and 112 (2)°) for the molecular solid.[17] However, the present values are more precise and refer to the free molecule. The changes in structural parameters are smaller from Cl_2O to Br_2O than from Cl_2O to F_2O, which is in agreement with the corresponding results in the HOBr, HOCl, HOF series.[1]

The differences in bond lengths are smaller between Br_2O and Cl_2O (14.2 pm) than between OBrO and OClO (17.4 pm). This can be explained by the decreased tendency of Br compared to Cl to form double bonds. For both chlorine oxides, known r_e values were employed, for the two bromine oxides the estimates of r_e.

The quartic distortion constants have been used to calculate the harmonic force fields for both bromine oxides. Vibrational data for Br_2O were taken from reference [18]. The force constants are also given in Table 2 together with those of related molecules.

The stretching force constants f_r of Br_2O and Cl_2O are remarkably similar, possibly a reflection of the pure single-bond character. The larger stretching force constants and shorter bond lengths in OBrO and OClO compared to those of Br_2O and Cl_2O are indicative of substantial double-bond character in the dioxides.

For Br_2O both f_α and $f_{r\alpha}$ and the values of the quartic centrifugal distortion constants are strongly interdependent. The present force field indicates a value of 180 cm^{-1} for the ν_2 band center, which may be compared to 197 cm^{-1} observed for the solid.[16]

We have observed the ν_3 band of OBrO in the gas phase (Fig. 3). The Q-branch feature of $O^{79}BrO$ at 848.6 cm^{-1} and the isotopic shift of 2.4 cm^{-1} agree well with values from the force field (851.2 and 2.35 cm^{-1}) as does the position of the ν_1 band in an argon matrix (794.6 versus 794.1 cm^{-1} from reference [13]). The calculated isotopic shift for ν_1 is 1.15 cm^{-1}; an observed splitting of 2.9 cm^{-1} is more likely due to a matrix effect; see for example reference [23], where these effects have

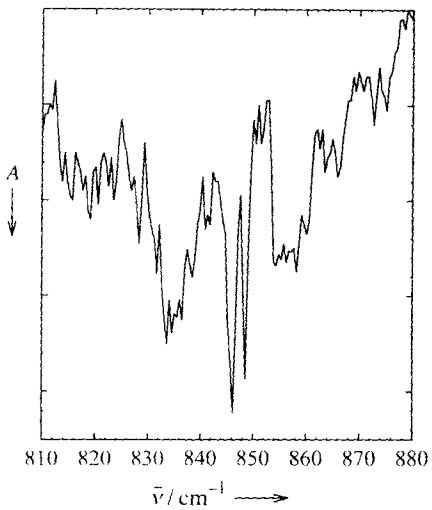

Fig. 3. The IR spectrum of gaseous OBrO in the region of the ν_3 fundamental, which shows PQR branch structure (resolution: 1 cm^{-1}).

been studied in detail for OClO. Although the bending mode has not yet been observed directly, our calculated value of 311 cm^{-1} for $O^{79}BrO$ is consistent with relative intensities observed for rotational transitions in the ground state compared to those in the $\nu_2 = 1$ state (Fig. 2).

The principal Br quadrupole constants of Br_2O have been obtained by diagonalization of the quadrupole tensor. The value $\chi_{zz} = 928$ MHz is close to that of Br_2 (810 MHz[24]), indicating a predominantly covalent Br–O bond.[20] Contributions from ionic forms Br^+OBr^- and BrO^-Br^+ are about 12% and π bonding is almost negligible (ca. 2%). The ionic character is slightly larger than in BrCl (9%)[25] and essentially the same as in HOBr,[26] which is consistent with the view that the OX group (X = H, halogen) is slightly more electronegative than the Cl atom. The quadrupolar z axis differs substantially from the Br–O bond (by ca. 2.4°; Fig. 4). If one would assume the z axis to be identical with the Br–O bond, one would derive an ionic character of about 45% for the Br–O bond in Br_2O, exceeding that of BrF (35%),[27] and a substantial degree of π bonding.

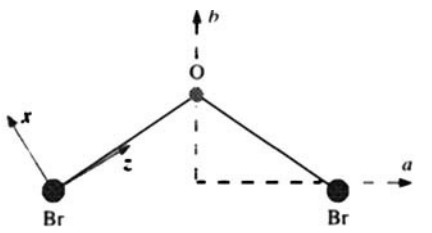

Fig. 4. The principal inertial (dashed arrows) and quadrupole axis systems (solid arrows) of Br_2O ($c \equiv y$ is perpendicular to the molecular plane).

Although a detailed discussion of the fine and hyperfine structure constants is beyond the scope of a brief communication, it should be noted that earlier ESR results[12] are consistent with those of this study. Thus, the conclusion given in reference [12] that, as in OClO, half of the spin-density is at the halogen atom, and essentially all of this in the p-orbital perpendicular to the molecular plane, remains unchanged.

In conclusion, we have used the $O + Br_2$ reaction system to study Br_2O and the OBrO radical. The presence of a mixture of bromine oxides under certain conditions indicates complex secondary chemistry that may be of atmospheric importance. We are currently investigating the spectroscopy and kinetics of these interesting molecules.

Enzyme-Catalyzed Formation of Carboxybiotin as Proved by the Measurement of $^{15}N,^{13}C$ and $^{13}C,^{13}C$ Spin–Spin Coupling**

Stefan Berger,* Annett Braune, Wolfgang Buckel,* Ulrich Härtel, and Man-Ling Lee

Dedicated to Professor Anton Rieker on the occasion of his 65th birthday

The action of biotin as a prosthetic group in carboxylating, transcarboxylating, and decarboxylating enzymes is well-known; however, the detailed mechanism of the conversion of biotin (**1**) into carboxybiotin (**2**) is still the subject of intense debate.[1] Even the proof for the occurrence of carboxybiotin during these reactions is only indirect and has been addressed very recently by the synthesis of "crippled" biotin, in which the nitrogen atom 1'-N was replaced by carbon.[2] By in situ methylation of the unstable **2** (obtained with ^{14}C-labeled hydrogen carbonate) with diazomethane, F. Lynen and co-workers were able to compare the reaction product with authentic methoxycarbonylbiotin methyl ester (**3**) and thus could show the likelihood of **2** during the enzymatic process.[3] The direct nonenzymatic synthesis of **2**, however, has to our knowledge not been demonstrated to date. We could show that **2**, when obtained by base-catalyzed hydrolysis of **3** under NMR control at 5 °C, decarboxylates within a few minutes;[4] however, a half-life of 103 min has been reported for analogous enzymatic processes.[5]

In order to obtain a better understanding of the action of biotin as a prosthetic group[6] and proof of the occurrence of **2** during the enzymatic reaction we have synthesized [1'-^{15}N]-(**1a**)[7] and [2'-^{13}C]biotin (**1b**).[8] By applying the carboxytransferase subunit GcdA of the biotin-dependent sodium ion pump glutaconyl-CoA decarboxylase (EC 4.1.1.70) for catalysis of the carboxylation of free **1b** via (*E*)-glutaconyl-CoA (**4**) to form crotonyl-CoA (**5**), we could observe a transient signal at $\delta = 160.4$. The time dependence of this signal is shown in Figure 1 and the data was fitted with a curve corresponding to the equation for consecutive reactions using one first order rate constant for the formation and one for the decarboxylation of **2**. However, the occurrence of one transient signal alone, considering background signals, impurities etc., is certainly not convincing proof of an intermediate product.

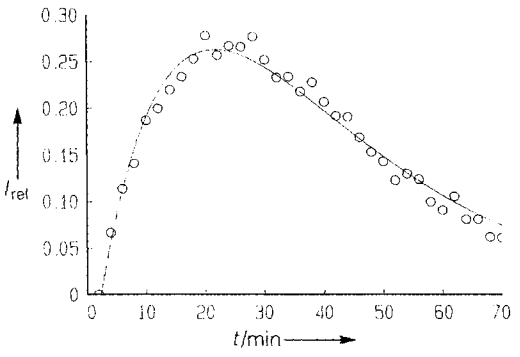

Fig. 1. Time dependence of the intensity of the 2'-^{13}C signal of carboxybiotin (**2**) during the reaction of **1b** with glutaconyl-CoA catalyzed by the carboxytransferase subunit GcdA (I_{rel} = relative intensity).

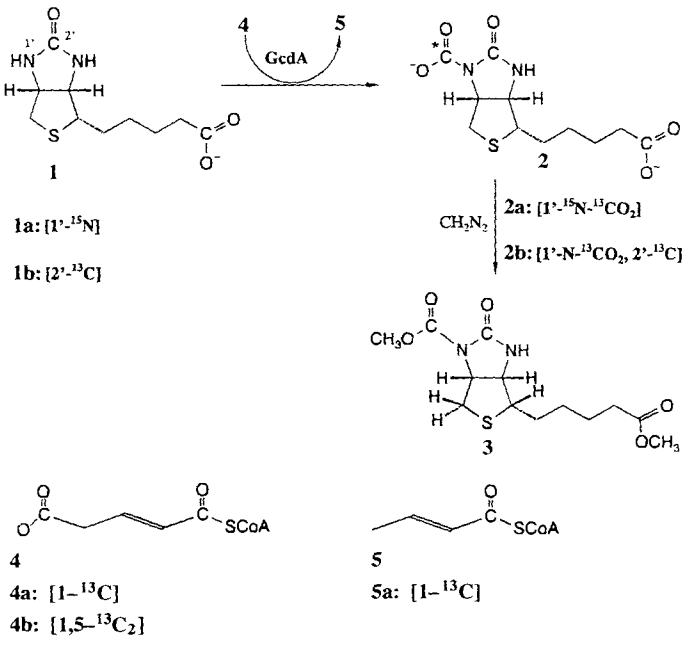
We therefore considered the use of ^{13}C-labeled glutaconyl-CoA (**4**) in this reaction. With **1b** one would expect two transient signals stemming from the newly formed product **2b**, which in addition display a $^2J(C,C)$ spin–spin coupling constant. With **1a** one would expect one transient signal displaying a $^1J(C,N)$ spin–spin coupling constant, unequivocally demonstrating that a C–N bond is formed in the enzyme-catalyzed reaction.

The synthesis of [1-^{13}C]glutaconic acid (**4a**) was unexpectedly difficult due to label scrambling and other complications. [1,5-$^{13}C_2$]Glutaconic acid (**4b**), however, was readily accessible in three steps starting from 1,3-dibromopropane-2-ol.[9] The additional ^{13}C label proved to be helpful, since the final acetate formed in the reaction [cf. Eq. (a)] could be observed.



Scheme 1. Carboxylation of labeled biotin (**1**) by (*E*)-glutaconyl-CoA (**4**) in the presence of the carboxytransferase subunit GdcA of glutoconyl CoA-decarboxylase.

The enzyme system used in the experiments was composed of the carboxytransferase subunit GcdA of glutaconyl CoA-decarboxylase from *Acidaminococcus fermentans*[10] and a mixture of auxiliary enzymes prepared from the same organism.[11] GcdA was obtained by overexpression of its gene *gcdA* harbored in the vector pJF118HE in *Escherichia coli* DH5α.[10b] GcdA from cell extracts was purified by two successive rounds of anion exchange chromatography.[12] The enzyme mixture contained glutaconate CoA-transferase (EC 2.8.3.12), crotonase [(*E*)-2-butenoyl CoA-hydratase, EC 4.1.2.17], 3-hydroxybutyryl CoA-dehydrogenase (EC 1.1.1.35), thiolase (acetyl-CoA *C*-acetyltransferase, EC 2.3.1.9), and phosphate acetyltransferase (EC 2.3.1.8). Hence, the system was able to convert glutaconate and biotin in phosphate buffer (pH 7.0) in the presence of NAD and catalytic amounts of acetylphosphate and CoASH, via the intermediates glutaconyl-CoA, crotonyl-CoA, (*S*)-3-hydroxybutyryl-CoA, acetoacetyl-CoA, and acetyl-CoA, into carboxy-

biotin, acetate, and acetylphosphate [Eq. (a)]. Finally carboxybiotin spontaneously decarboxylated to biotin and CO_2 [half-life ca. 13 min, Eq. (b)].

$$\text{glutaconate}^{2-} + \text{biotin}^{-} + H_2O + NAD^{+} + HPO_4^{2-} \longrightarrow \text{carboxybiotin}^{2-} + \text{acetate}^{-} + \text{acetylphosphate}^{2-} + NADH + H^{+} \quad (a)$$

$$\text{carboxybiotin}^{2-} + H^{+} \longrightarrow \text{biotin}^{-} + CO_2 \quad (b)$$

The experiments, which were carried out at room temperature with a Bruker AMX-500 spectrometer, fully confirmed the mechanism originally proposed by F. Lynen. ^{13}C NMR spectra were continuously recorded; each was accumulated over 2 min. Initial spectra obtained from a solution containing the incubation mixture and **1a** or **1b** but without the carboxytransferase subunit GcdA displayed only the signals of the labeled starting materials. An induction period of several minutes was observed after addition of GcdA, depending on the enzyme preparation. Figure 2 shows the transient signals, which first increased in intensity, reached a maximum after about half an hour, and then decreased and disappeared. In Figure 2a (with **1a**) a $^{13}C,^{15}N$ spin–spin coupling constant of 17.8 Hz is evident; in Figure 2b (with **1b**) a $^{13}C,^{13}C$ spin–spin coupling constant of 3.1 Hz can be seen. Both coupling constants are fully consistent with values in similar chemical environments.[13, 14]

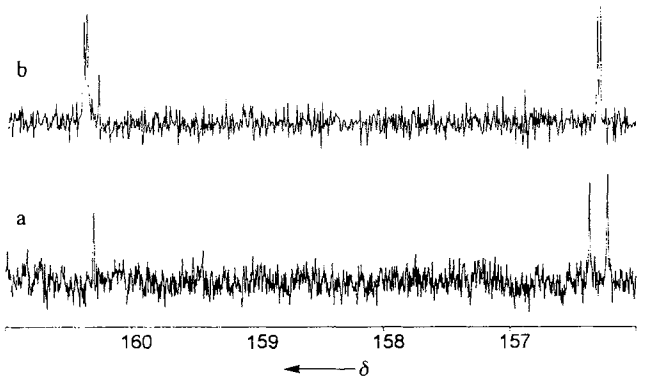

Fig. 2. Expansion of the 125 MHz ^{13}C NMR spectra of a) [1′-^{15}N-$^{13}CO_2$]carboxybiotin (**2a**) and b) [1′-N-$^{13}CO_2$,2′-^{13}C]carboxybiotin (**2b**) formed during the reaction of **1a** and **1b**, respectively, with the carboxytransferase subunit GcdA.

The method demonstrated here is also generally applicable,[15] provided that the two species that are linked by the new chemical bond can be synthesized with appropriate labels. Thus formation of a chemical bond can be proved unequivocally.

Experimental Procedure

The incubation mixture for the experiment on which Figure 1 is based contained in a total volume of 750 μL: 100 mM potassium phosphate (pH 7.0), 10% ^2H_2O, 27 mM glutaconate, 24 mM *d*-[2′-^{13}C]biotin (**1b**), 6.3 mM NAD^+, 2.1 mM acetylphosphate, 4.8 mM CoASH, 30 mM dioxane, 330 μg GcdA, and 500 μg auxiliary enzymes. The incubation mixtures for the experiments on which Figure 2 is based were essentially identical to that providing Figure 1, but unlabeled glutaconate was replaced by [1,5-$^{13}C_2$]glutaconate, and the incubation mixture for Figure 2a contained *d*-[1′-^{15}N]biotin instead of *d*-[2′-^{13}C]biotin. Since the total synthesis of [1′-^{15}N]biotin yielded the racemate [7], the biological occurring *d*-enantiomer (**1a**) was separated from the *l*-enantiomer by HPLC on a chiral column [16].

The Reaction of White Phosphorus with Lithium (Trimethylsilyl)diazomethanide: Direct Access to a New, Aromatic 1,2,3,4-Diazadiphosphole Ring

Claude Charrier, Nicole Maigrot, Louis Ricard, Pascal Le Floch, and François Mathey*

All of the possible polyphosphacyclopentadienide ions $[R_nC_nP_{5-n}]^-$ have been described,[1] and all but one of these can be prepared in a pure form and in preparative quantitities by specific syntheses. The only exception are the tetraphosphacyclopentadienides $[RCP_4]^-$, whose parent ion has been characterized by Baudler et al. as a minor by-product of the reaction of white phosphorus with sodium in diglyme.[2] We reasoned that the reaction of the synthetic equivalent of a $[RC]^-$ fragment with P_4 might provide a simple route to the $[RCP_4]^-$ ion, because of the driving force of this reaction provided by the aromatic stabilization of the final five-membered ring.[3] Thus, we decided to investigate the reaction of lithium (trimethylsilyl)diazomethanide with P_4. As expected, the reaction proceeded cleanly; however, the sole product was the previously unknown 1,2,3,4-diazadiphospholide anion **2**, which results from a formal [3+2] cycloaddition between [P≡P] and the diazomethyl anion **1** (Scheme 1).

The lithium salt of **2** displays a very characteristic ^{31}P NMR spectrum (81.01 MHz, C_6D_6+[D$_8$]THF, 25 °C, 85% H_3PO_4): $\delta = +352.5$ (d, $^1J(P,P) = 457$ Hz; P3), +231 (d, P4), and the negative ion mass spectrum confirms the formula of **2**: *m/z* (%)

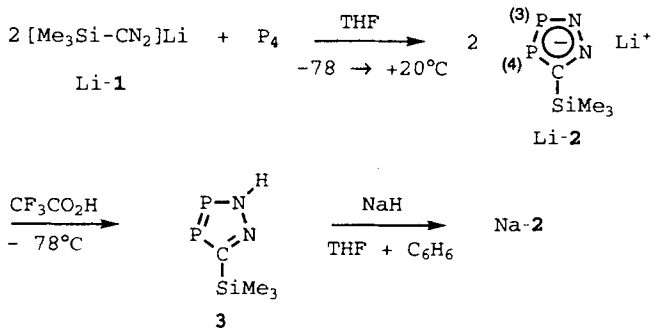

Scheme 1.

175(100) [M^-]. The protonation of **2** by trifluoroacetic acid at low temperature cleanly affords the stable 2*H*-1,2,3,4-diazadiphosphole **3**, which can be purified by chromatography on silica gel. The X-ray crystal structure analysis of **3** (Fig. 1)[4] shows that the ring is planar and that the proton resides on the nitrogen atom adjacent to the P=P unit. The double bonds are fairly well localized: the lengths of the P=P and C=N bonds are 2.07 and 1.32 Å, respectively, and these lengths are very similar to those of the corresponding bonds in a series of heterophospholes.[5] The two molecules of the asymmetric unit are connected by a N–H···N hydrogen bond, and their two planes are almost orthogonal (87.92±0.07°). The NMR parameters of **2** and **3** are surprisingly similar: **2**: $\delta(^{13}C) = 185.2$ (dd, $^1J(C,P) = 107$, $^2J(C,P) = 10$ Hz, C5); **3**: (C_6D_6): $\delta(^{13}C) = 184.45$ (d, $^1J(C,P) = 105$ Hz, C5); δ +345.8 (d, $^1J(P,P) = 489$ Hz; P3), +245 (d, P4). This resemblance suggests the existence of an equilibrium such as **3** ⇌ **2** + H^+. In C_6D_6, the signal of the proton of **3** indeed appears at $\delta = 11.4$, suggesting some weak acidic character. Consequently, **3** may be easily deprotonated by a weak base such as sodium hydride to give the sodium salt of **2** in a pure form (see Scheme 1).

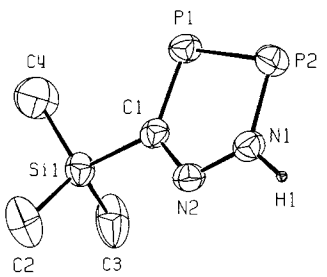

Fig. 1. Molecular structure of **3** (benzene solvate) (methyl hydrogen atoms omitted for clarity) [7]. Significant bond lengths [Å] and angles [°]: P1–P2 2.0706(6), P1–C1 1.768(2), P2–N1 1.670(1), N1–N2 1.357(2), N1–H1 0.89(2), N2–C1 1.320(2), C1–Si1 1.896(2); P2-P1-C1 92.10(5), P1-P2-N1 93.53(5), P2-N1-N2 121.7(1), P2-N1-H1 119(1), N2-N1-H1 118(1), N1-N2-C1 113.6(1), P1-C1-N2 119.1(1), P1-C1-Si1 123.39(9), N2-C1-Si1 117.5(1).

After the discoveries of pentaphosphaferrocenes by Scherer et al.[6] and the pentaphospholide ion by Baudler et al.,[2] this work underlines that white phosphorus can be an interesting starting material for the synthesis of new aromatic polyphosphorus compounds. We are currently investigating the reactivity of **2**.

Experimental Procedure

White phosphorus (2.17 g, 17.5 mmol) was dissolved in dry THF (80 mL) at 35 °C. The solution was cooled to −78 °C and a solution of lithium (trimethylsilyl)diazomethanide ((52 mmol), obtained by reaction of 1.6 M *n*BuLi in hexane with Me_3SiCHN_2 in Et_2O at −78 °C) was added dropwise. After 1 h at −78 °C, the solution was allowed to warm to room temperature and stirred for 2 h. The P_4 resonance signal completely disappeared from the ^{31}P NMR spectrum of the crude reaction solution, and only the AX system corresponding to the lithium salt of **2** was visible. Protonation of Li-**2** with trifluoroacetic acid (35 mmol) was then performed at −78 °C. The solution was evaporated at room temperature and the residue was chromatographed on silica gel with hexane/benzene 40:60 as the eluent. Traces of white phosphorus were eluted first, then the product **3** was collected: yield 1.48 g (24%), pale yellow crystals, m.p. 87 °C (benzene). ^1H NMR (200.13 MHz, C_6D_6, 25 °C, TMS): $\delta = 0.66$ (s, 9H, Me_3Si), 11.4 (s broad, 1H, NH); ^{13}C NMR (50.32 MHz, C_6D_6, 25 °C, TMS): $\delta = 0.2$ (d, $^3J(C,P) = 2.8$ Hz, Me), 184.5 (d, $^1J(C,P) = 105$ Hz, P-C-N); MS (CI, 70 eV): *m/z* (%): 176(7) [M^+], 161(13) [M^+ − Me], 149(15), 73(100) [Me_3Si^+].

The deprotonation of **3** was carried out in benzene/THF at −30 °C with one equivalent of NaH. After the mixture was allowed to warm to room temperature, the pure sodium salt of **2** was obtained: ^1H NMR (200.13 MHz, C_6D_6 + [D_8]THF, 25 °C, TMS): $\delta = 0.45$ (s, Me); ^{13}C NMR (50.32 MHz, C_6D_6 + [D_8]THF, 25 °C, TMS): $\delta = 1.4$ (s, Me), 185.2 (dd, $^1J(C,P) = 107$ Hz, $^2J(C,P) = 10$ Hz, P-C-N); MS (NCI, 70 eV): *m/z* (%): 175(100) [M^-], 160(35) [M^- − Me].

[4] X-ray structure determination for **3**: Crystals of **3**, $C_4H_{10}N_2P_2Si \cdot 0.25C_6H_6$ were grown from a cold solution of the compound in benzene. Data were collected at −150±0.5 °C on an Enraf Nonius CAD4 diffractometer using graphite-monochromated $Cu_{K\alpha}$ radiation ($\lambda = 1.54184$ Å). The crystal structure was solved and refined with the Enraf Nonius MOLEN package. The compound crystallizes in space group *C*2/*c* (no. 15), $a = 20.723(2)$, $b = 9.967(1)$, $c = 20.626(2)$ Å, $\beta = 91.50(1)°$; $V = 4258.8(1.3)$ Å^3, $Z = 16$, $\rho_{calc} = 1.221$ g cm^{-3}, $\mu = 44.3$ cm^{-1}, $F(000) = 1640$. A total of 3479 unique reflections were collected in the range $2° \le 2\theta \le 120.0°$, of which 668 were considered as unobserved ($F^2 < 3.0\sigma(F^2)$); 2811 reflections were used for solving and refining the structure. Direct methods yielded a solution for all atoms. The NH hydrogen atoms were refined with isotropic temperature factors and the methyl and benzene hydrogen atoms were included as riding atoms in the final stages of least-squares refinement while using anisotropic temperature factors for all other atoms. A nonPoisson weighting scheme was applied with a *p* factor of 0.08. The final agreement factors were $R = 0.039$, $R_w = 0.081$, GOF = 1.81. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-74. $[Cu_4Mn_4(SiC_3H_7)_{12}S]^{2-}$, a Novel Octanuclear Heterometallic Complex Consisting of a Metal Cube with an Interstitial μ_4-Sulfide Ion and Edge-Bridging Thiolate Ligands**

Hans-Oscar Stephan, Mercouri G. Kanatzidis, and Gerald Henkel*

Dedicated to Professor Peter Sartori on the occasion of his 65th birthday

Transition metal complexes with thiolate ligands have been intensively studied for about 25 years;[1] however, surprisingly few reports have emerged on heterometallic compounds.[2-4] Such species would be of particular interest with respect to their molecular structures and chemical properties because of reactivity patterns that originate from the combination of different metal atoms.

To determine the synthetic conditions under which mixed-metal thiolates may form, we have investigated the reactivity of well-defined metal thiolate precursors towards heterometal sources such as simple metal halides. This approach towards cluster build-up has been shown to be successful for the formation of homometallic systems such as $[Fe_4(SPh)_6Cl_4]^{2-}$[5] and $[Mn_4(SiC_3H_7)_6Cl_4]^{2-}$[6] as well as for the synthesis of the heterometallic complexes $[Cu_6In_3(SEt)_{16}]^{-}$[3a] and $[(PPh_3)_2CuIn(SEt)_4]$.[3b] The latter species is the only well-characterized single-source precursor to the semiconductor $CuInS_2$.

We report herein on the synthesis, structure, and magnetic properties of the novel octanuclear mixed-metal thiolate complex **2**, which is formed in the reaction of $(Me_4N)_2[Mn_2(SiC_3H_7)_6]$[6] with two equivalents of CuCl in acetonitrile at room temperature and can be isolated as the double salt of **1**.

$(Me_4N)_6[MnCl_4]_2[Cu_4Mn_4(SiC_3H_7)_{12}S]$ **1**

$[Cu_4Mn_4(SiC_3H_7)_{12}S]^{2-}$ **2**

Compound **1** is also accessible by a solvothermal reaction of the reagents in a 1:2.5 molar ratio (Mn:Cu compound) in acetonitrile at 80 °C. In both cases, a yellow microcrystalline byproduct is formed, which still has not been identified.[7]

According to the results of an X-ray crystal structure analysis,[8] **1** contains $[MnCl_4]^{2-}$ ions and the octanuclear anion **2**, whose charges are balanced by $(Me_4N)^+$ counterions. The structure of **2** is shown in Figure 1. The novel cage compound **2** contains a distorted Cu_4Mn_4 cube (mean edge length 3.092 Å), which is composed of two interpenetrating Cu_4 and Mn_4 tetrahedra of slightly different size. The center of this cube is occupied by a μ_4-S atom, which binds to the manganese atoms with a mean distance of 2.475 Å.

Because of the slightly longer edge lengths in the Cu_4 tetrahedron, the Cu–S distances are 2.853 Å (av) in length and thus

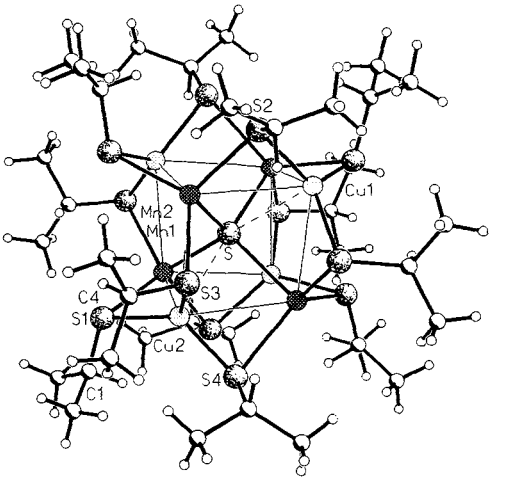

Fig. 1. Structure of **2** in crystals of **1**. Selected distances [Å] and angles [°] (mean values): Mn···S 2.506, Cu···S 2.200, Cu···S 2.853, Mn···Cu 3.092; S-Mn-S 108.8, S-Cu-S 118.6.

nonbonding in nature. In addition, each metal atom binds to three outer thiolate ligands, leading to distorted tetrahedral (manganese) or distorted trigonal-planar (copper) coordination sites. The average metal–sulfur bond lengths of 2.506 and 2.200 Å lie in the range expected for tetrahedral MnS_4[6] and trigonal-planar CuS_3[9] units, respectively.

Since each thiolate ligand is bonded to a manganese and a copper atom simultaneously, all the edges of the central metal cube in **2** are bridged by sulfur atoms. The bridging S atoms define a slightly distorted S_{12} icosahedron (Fig. 2), possibly as

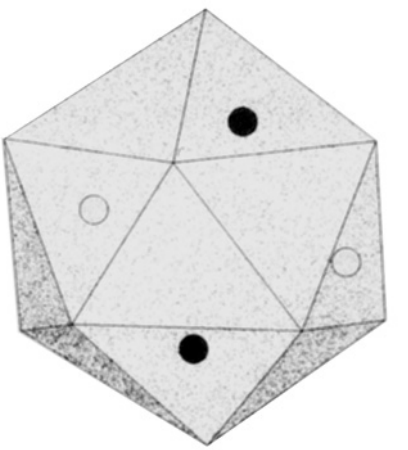

Fig. 2. Schematic representation of the $Mn_4Cu_4S_{13}$ core of **2**, showing the icosahedral arrangement of sulfur atoms.

a result of the steric requirements of the isopropyl groups. Evidently a cuboctahedral arrangement of the sulfur atoms is less favorable in this case. Taking a Mn_2Cu_2 face of the metal cube as a reference plane, the four bridging ligands thus divide equally into two sets with S–C vectors parallel and normal to the plane. As a result, the α-carbon atoms form a slightly distorted cuboctahedron.

Viewed in a different way, **2** can be considered to contain the unusual complex anion $[Mn_4(SR)_{12}S]^{6-}$, which is composed of four tetrahedral MnS_4 units sharing one common vertex. Its Mn_4S_{13} core is a minimal fragment of the cubic closest packed sphalerite-type structure, consisting of one sulfide ion surround-

[**] This work has been supported by the Deutsche Forschungsgemeinschaft (DFG), the Bundesministerium für Bildung, Wissenschaft, Forschung und Technologie (BMBF), and the Fonds der Chemischen Industrie. H.-O. S. thanks the DFG for a postdoctoral fellowship. We thank Prof. Cowen for his help and many fruitful discussions of the magnetic properties of the title compound.

ed by the complete set of 12 direct sulfur neighbors. This fragment is stabilized here for the first time as a discrete entity in a molecular complex. Other complexes containing related M_4X_{13} units as constituents of more extended M–X cores (X = S, Se) are $[Cd_{17}(SPh)_{28}(\mu_4\text{-}S)_4]^{2-}$[10] and $[Cd_8(SePh)_{16}(\mu_4\text{-}S)]^{2-}$.[11] The S_{12} polyhedron in **2** deviates slightly from the regular cuboctahedron of the sphalerite-type structure by small rotations of the atoms forming the triangular faces about their normals. The Mn^{II} ions occupy one half of the tetrahedral holes of the S_{13} fragment (T^+ set), whereas the Cu^I ions lie on triangular faces of the remaining S_4 tetrahedra (T^- set).

To our knowledge, **2** is the first complex anion that contains a metal cube with edge-bridging thiolate ligands and an interstitial μ_4-S ion. However, there are several reports on cubane complexes with thiolate-bridged Cu^I_8 skeletons and trigonal-planar Cu^IS_3 coordination centers of general composition $[Cu^{II}_6Cu^I_8(SC(Me)_2R)_{12}Cl]^{n+}$ (R = CH_2NH_2, $n = 7$ [12]; R = CO_2^-, $n = -5$;[13] R = $CH(NH_2)CO_2^-$, $n = -5$[14]), whose centers are occupied by chloride ions. In these compounds, both thiolate and amine (or carboxylate) donor functions bind to additional Cu^{II} atoms in the outer periphery of the cube. Very recently, a sulfur-bridged Cu^I_8 cube with trigonal-planar coordination of the copper atoms and an interstitial μ_8-S ion in the compound $[Cu_8(S_2P\{OiC_3H_7\}_2)_6(\mu_8\text{-}S)]$ has been reported.[15] Interestingly, similar complexes with such centered metal cubes and tetrahedrally coordinated divalent metal ions are not yet known.[16]

The metal–chalcogen framework of $[Cd_8(SePh)_{16}(\mu_4\text{-}S)]^{2-}$[11] is a rearranged extension of the framework of **2** with four additional chalcogenolate ligands. They add to the trigonal-planar coordination sites, resulting in a second set of tetrahedrally coordinated divalent metal atoms, which now are placed on the outside of the Se_{12} icosahedron.

Magnetic susceptibilities of **1** have been recorded in the temperature range from 5 to 300 K, and the Curie–Weiss law is obeyed between 200 and 300 K with $\theta = -32$ K (Fig. 3). The overall magnetic behavior is dominated by the strongly paramagnetic $[MnCl_4]^{2-}$ ions.

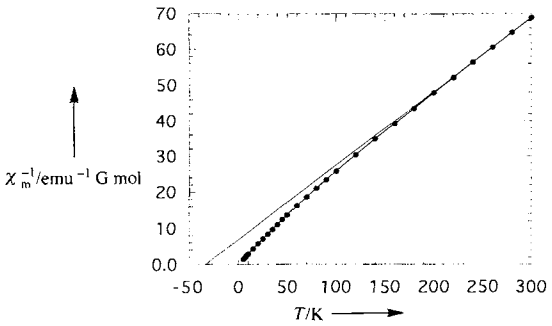

Fig. 3. Plot of the temperature dependence of the molar magnetic susceptibility of **1**.

Attempts to subtract these contributions by simply assuming perfect noninteracting paramagnets with $\mu_{eff} = 5.92\ \mu_B$ gave physically unreasonable susceptibilities for **2** at low temperatures. This observation implies that the $[MnCl_4]^{2-}$ ions interact weakly antiferromagnetically with the manganese sites in **2** and/or with themselves. Despite these limitations, however, it is possible to gain insight into the magnetic properties of **2** at higher temperatures up to about 200 K, since the weak interactions caused by the $[MnCl_4]^{2-}$ ions can then be neglected because they are small compared to the magnetic exchange interactions within complex **2**.[17] At room temperature, μ_{eff} of **1** is calculated to be 11.1 μ_B. The theoretical value for six uncoupled Mn^{2+} centers is 14.5 μ_B, indicating that the manganese atoms in **2** are antiferromagnetically coupled. This behavior is also typical for the complex ions $[Mn_4Te_4(TeiC_3H_7)_4]^{4-}$ [18] and $[Mn_2(SPh)_6]^{2-}$.[19]

In summary, we have described the synthesis and some properties of the novel octanuclear mixed-metal complex ion $[Cu_4Mn_4(SiC_3H_7)_{12}S]^{2-}$, which possesses a cubane-like Mn_4Cu_4 arrangement. This compound belongs to a new class of mixed sulfide–thiolate complexes and is the first example of a metal cube with an interstitial μ_4-S ligand.

Experimental Procedure

All manipulations were carried out in gloveboxes or with Schlenk techniques under nitrogen.

1: $(Me_4N)_2[Mn_2(SiC_3H_7)_6]$ [6] (1.42 g, 2 mmol) was dissolved in acetonitrile (50 mL). Solid CuCl (0.40 g, 4 mmol) was added to the red solution to give a yellow solution, which was stirred for 24 h. A small amount of an insoluble material was filtered off and the solution was layered with an equal volume of diethyl ether after reduction of its volume to ⅓ of its initial value. During the course of several days, orange-yellow crystals of **1** deposited along with a yellow by-product. Yield: 65% (based on Cl); C, H, N, S analysis of **1**: found (%): C 32.08, H 7.00, N 3.74, S 18.56; calc. (%): C 32.19, H 6.92, N 3.80, S 18.65.

Alternatively, **1** was accessible as follows: $(Me_4N)_2[Mn_2(SiC_3H_7)_6]$ (159 mg, 0.23 mmol) was mixed with CuCl (57 mg, 0.58 mmol), ground, and loaded into a thickwall pyrex tube. After addition of acetonitrile (1 mL), the tube was frozen with liquid nitrogen and sealed under vacuum. After 3 d at 80 °C, orange-yellow hexagonal plates were deposited together with a yellow by-product.

[7] Microanalysis (EDS method) and the odorous smell upon hydrolysis in air indicate that this material is a copper thiolate complex.

[8] Crystal structure analysis of **1**: Siemens P4RA four-circle diffractometer, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), graphite monochromator, rotating anode generator, scintillation counter, 150 K, empirical absorption corrections, SHELXTL-PLUS programs, direct methods, least-squares refinement; $C_{60}H_{156}Cl_8Cu_4Mn_6N_6S_{13}$, $M_r = 2246.09$, trigonal, space group $P\bar{3}1m$, $a = 14.814(9)$, $c = 14.164(7)$ Å, $V = 2691.91$ Å^3, $Z = 1$, $\rho_{calc} = 1.386$ g cm^{-3}, $\mu(Mo_{K\alpha}) = 1.94$ mm^{-1}, crystal dimensions about $0.65 \times 0.37 \times 0.33$ mm, ω scan, $2\theta_{max} = 54°$, 9373 reflections, of which 1536 are independent ($R_{merge} = 0.031$), R (R_w) = 0.0610 (0.0562) for 1288 observed reflections ($I > 2\sigma(I)$), 147 variables, all non-hydrogen atoms anisotropic, H atoms calculated at idealized positions, fixed and refined with one common temperature factor, one scaling factor, and one isotropic extinction parameter. Anion **2** possesses a threefold rotation axis passing through Mn1, S, and Cu1 (see Fig. 1), but the crystallographic point symmetry is $\bar{3}m$. The resulting disorder could be readily resolved and the structure was successfully refined by restricting the mean M–S bond lengths of chemically equivalent metal sites to be equal within 2σ. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-59401.

[16] In the complex ion $[Cd_8(SC_2H_4OH)_{12}(\mu_8\text{-}I)]^{3+}$, the coordination numbers of the cadmium atoms range from five to seven: H. B. Bürgi, H. Gehrer, P. Strickler, F. K. Winkler, *Helv. Chim. Acta* **1977**, *59*, 2558.
[17] For comparison, the magnetic behavior of $(Me_4N)_2[MnCl_4]$ and $(Et_4N)_2[MnCl_4]$ was also studied. $(Et_4N)_2[MnCl_4]$ ($\mu_{eff} = 5.91\ \mu_B$) behaves almost like a perfect paramagnet over the entire temperature range. In contrast, the manganese atoms in $(Me_4N)_2[MnCl_4]$ are weakly antiferromagnetically coupled, with μ_{eff} ranging from 5.1 μ_B (5 K) to the ideal value for isolated centers of 5.91 μ_B (300 K). In this compound, the shortest Mn···Mn contact is estimated to be 7.8 Å. ($(Me_4N)_2[MnCl_4]$ is isotypic with $(Me_4N)_2[ZnCl_4]$: *Acta Crystallogr.* **1959**, *12*, 611.) In crystals of **1**, this distance compares well with the shortest separations between the Mn atoms in $[MnCl_4]^{2-}$ and the Mn sites in **2** (8.6 Å) as well as those between the $[MnCl_4]^{2-}$ ions (8.5 Å). Thus, it is reasonable to assume that the $[MnCl_4]^{2-}$ ions in **1** act as pure paramagnets at room temperature, as they do in $(Me_4N)_2[MnCl_4]$.

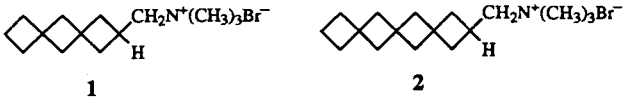
Spiro-Surfactants and -Phospholipids: Synthesis and Properties**

Fredric M. Menger* and Julia Ding

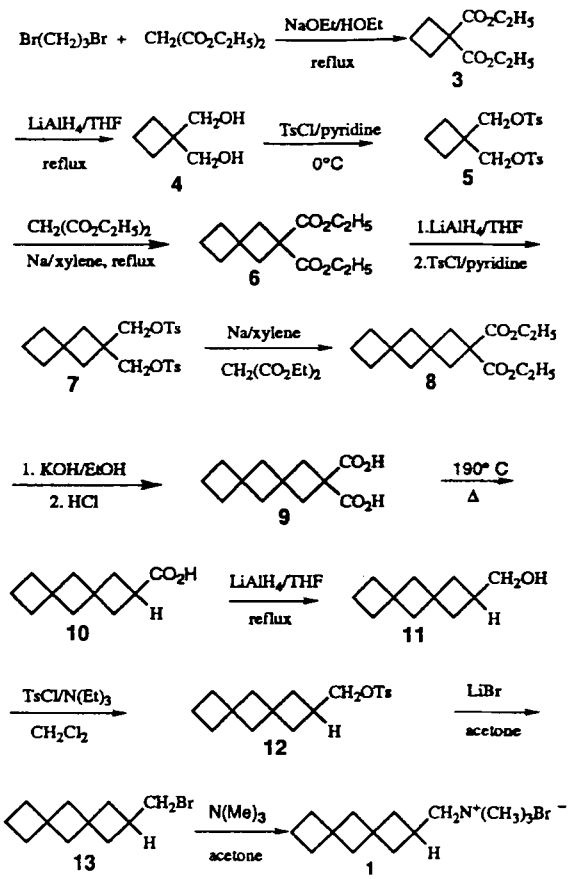
Although a micelle cross-section is often pictured as the "spokes of a wheel",[1] the micelle is in fact highly disorganized and replete with bent chains. Persuasive arguments for "brush-heap" organization range from theoretical work[2] to binding studies[3] to our ^{13}C-labeling experiments.[4] It is interesting, from an historical standpoint, that G. S. Hartley wrote in 1936, "The symmetrical asterick form...has no physical basis and is drawn for no other reason than that the human mind is an organizing instrument and finds unorganized processes uncongenial. It is easier to speak in a sentence than in a jumble of words."[5] Unfortunately, for reasons of artistic convenience, the so-called Hartley model has evolved into the "spokes of a wheel" structure. Current textbooks portraying such a model[6] perpetuate what Hartley disclaimed decades ago and, to compound matters, fix his name to it.

Recently, while musing over the disorganization of micellar chains, we asked ourselves a set of intriguing questions: What would happen if the chains of a surfactant were indeed forced to remain unbent? Would micelles even form? If micelles did form, how would their critical micelle concentrations compare with those of conventional surfactants? To answer these questions, we required a means with which to rigidify hydrocarbon chains. Introducing unsaturation might seem like the most obvious way of preventing free rotation, but this possibility was dismissed owing to uncertainty as to how electronic factors (π–π repulsion etc.) would affect micelle formation. It was necessary, clearly, to retain chains that were fully populated with sp^3 carbons. This was accomplished with the spiro systems **1** and **2** shown below. The spiro chain is vaguely reminiscent of [*n*]staffanes[7] with a main difference that the former is completely devoid of any free rotations. As described below, spiro chains were also attached to phospholipids.



1 **2**

The 13-step synthesis of surfactant **1** is presented in Scheme 1. Construction of the spirocyclobutanes was based upon past work of Rice and Grogan[8] and Buchta and Geibel.[9] Compound **3** was either prepared by means of a Perkin cycliza-



Scheme 1. Synthesis of spiro-surfactant **1**.

tion[10] or purchased (Aldrich). Reduction of the diester to dialcohol **4**[4] with $LiAlH_4$ (96%) and ditosylation (90%) gave **5** from which **6** was formed (60%) in a second Perkin reaction. Note that cyclizations with sodium alkoxide failed (< 10%), so that Na/xylene was used throughout. Repetition of the sequence on **6** produced **7** and **8**. It then remained only to convert the diester of **8** into a trimethylammoniummethyl group. This was achieved by saponifying the diester to dicarboxylic acid **9** (100%), which was decarboxylated to monocarboxylic acid **10** at 175 °C (80%). Reduction gave alcohol **11** (100%). Preparation of primary bromide **13** directly from **11** proved difficult. Neither bromination with PBr_3/pyridine nor with Br_2/Ph_3P/imidazole was satisfactory. Ultimately, success (81%) was attained by treating the corresponding tosylate with LiBr/acetone. Surfactant **1** was formed by allowing **13** to react at 80 °C (sealed tube) with trimethylamine in aqueous acetone. The final

product, obtained in a 7.5% overall yield, was characterized by ^1H and ^{13}C NMR spectroscopy and by high-resolution FAB mass spectrometry.

A 16-step synthesis of surfactant **2** (2.4% overall yield) began with **8** in Scheme 1 and continued by construction of the fourth cyclobutane ring in the usual manner. Once the four-ring analog of **8** was in hand, the chemistry corresponding to **8**→**1** was followed identically. Product **2** was characterized by ^1H and ^{13}C NMR spectroscopy and by high-resolution FAB mass spectrometry. In addition, an X-ray structure of a crystalline intermediate (the ditosylate of the tetracyclic diol) affirmed the presence of the four spiro-linked rings.

Aqueous solutions of **1** and **2** at room temperature (25 °C) were investigated tensiometrically in order to detect possible micelle formation. Conventional surfactants are known to lower the surface tension steadily as the concentration is increased below the critical micelle concentration (CMC). Upon reaching the CMC, the plot levels off since the molecules prefer to enter the micelles rather than the air/water interface. (In fact, the point at which this occurs defines the CMC.) This general behavior was observed with **1** as seen in Figure 1. An approximate CMC of 0.14 M for **1** turns out to be identical to the CMC for linear $[C_8H_{17}N(CH_3)_3]^+Br^-$ with a similar chain length.[11] On the other hand, the CMC is 3.3 times larger than that of $[C_{11}H_{23}N(CH_3)_3]^+Br^-$, a conventional surfactant[11] with the same number of chain-carbons as **1**. Clearly, the propensity of **1** to form micelles relative to its total number of chain-carbons is substantially less than normal. Micelle formation might be impaired by the rigidity of the spiro system. Alternatively, the surfactant's compactness and buried quaternary carbons might

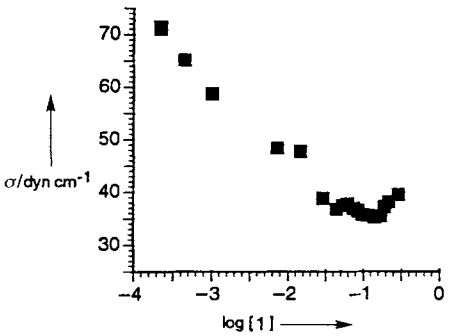

Fig. 1. Plot of surface tension σ as a function of the logarithm of the concentration of spiro-surfactant **1** [mol L^{-1}] in water at 25 °C.

reduce hydrocarbon–water contact of the monomer and thus diminish the hydrophobic forces that drive micelle formation.

Surfactant **2** lowers the surface tension effectively to less than 33 dyn cm^{-2} (Fig. 2). If a CMC exists, it must clearly exceed

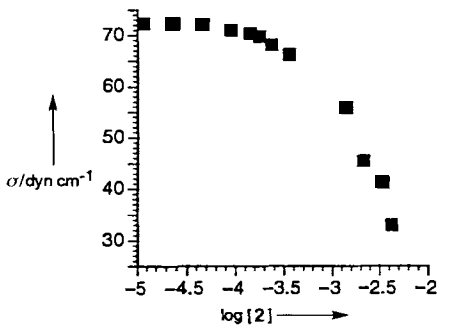

Fig. 2. Plot of surface tension σ as a function of the logarithm of the concentration of spiro-surfactant **2** [mol L^{-1}] in water at 25 °C.

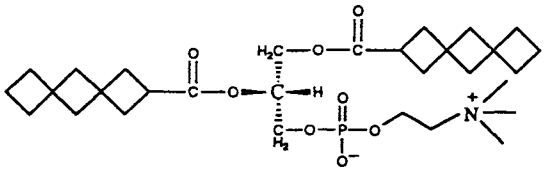
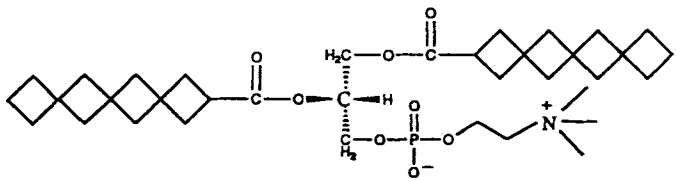
4.4×10^{-3} M (at which point our experiments ceased owing to lack of compound). The surface tension plot is anomalous in that it displays convex curvature and little change in surface tension at low concentrations. It is difficult to deduce anything conclusive here except that the spiro system has a profound effect upon the ability of the surfactant to self-assemble. Note that the presence of a CMC for **1** or **2** says nothing about the size and shape of the aggregates. Dynamic light scattering, used to address this issue, revealed that the micelle hydrodynamic diameters fall far below the detection limits of the Nicomp Model 370 laser (about 40 Å). One can conclude, therefore, that the micelles are small aggregates (perhaps only 10–20 molecules) owing, presumably, to the difficulty of packing the rigid chains into a space-filled sphere. Vesicular bilayers (which were a distinct possibility because the width of the spiro system approaches that of a double-chain) are also ruled out by the light-scattering data.

Several standard methods for preparing phospholipids **14** and **15** failed to give satisfactory yields with our hard-won spiro



14



15

compounds. These included acylation of sn-glycero-3-phosphocholine ($CdCl_2$ complex) with: spirocarboxylic acid/DCC/DMAP; spirocarboxylic acid/TFA; spirocarboxylic acid anhydride/DMAP; and spiroacylimidazolide in DMSO. Ultimately, phospholipids **14** and **15** were obtained via the spirocarboxylic acid chlorides (made from the carboxylic acids and $SOCl_2$ at −20 °C) plus pyridine in $CHCl_3$ (25 °C, 14 h). Combined yields for the two steps, following purification by column chromatography, ranged from 40–75%.

Dynamic light-scattering studies were carried out on thin films of lipids **14** and **15**, which had been deposited on glass from a solution in $CHCl_3$/MeOH and then bath-sonicated in pH 7.0 buffer at 60 °C for 30 min. The resulting vesicles were polydisperse, ranging in diameter from 200–500 Å for **14** and from 500–1300 Å for **15**. Differential scanning calorimetry (Hart Scientific DSC II) showed no detectable phase transition from −20 to 110 °C (0.5 mg lipid in 0.5 mL water or ethylene glycol/water with a scan rate of 10 K h^{-1}). Absence of an endothermic transition most likely stems from the spiro units being conformationally immobile. Conventional lipids, by contrast, undergo a thermally induced conversion from an ordered gel phase into a liquid-crystalline state replete with *gauche* linkages. It will be interesting to elaborate the transport properties of our unusual rigidified membranes.

Synthetic organic chemistry would seem to offer special opportunities for lipid chemists to explore their field. Indeed, this was the philosophy that steered the above work as well as previ-

ous syntheses of novel lipids.[12-15] It should be noted, finally, that surfactants **1** and **2** are among a growing list of new surfactants that violate the Israelachvili notions about how simple geometric factors control aggregate morphology.[16] On the face of it, the alkyl chains of **1** and **2** would seem too broad for micelle formation.

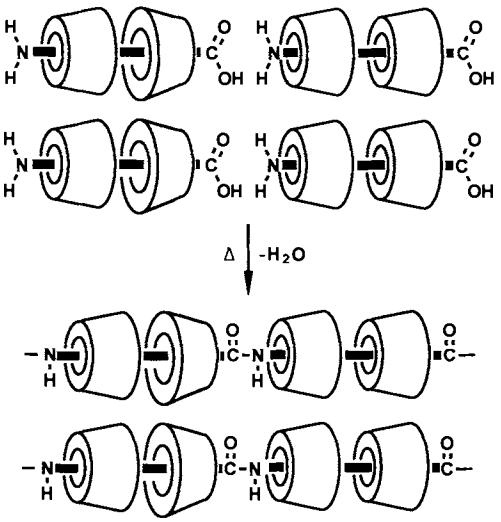
Synthesis of Water-Soluble Inclusion Compounds from Polyamides and Cyclodextrins by Solid-State Polycondensation

Marc Boris Steinbrunn and Gerhard Wenz*

Polyamides have of large practical significance because of their high form stability and high melting points. Due to strong intermolecular hydrogen bonding, these polymers are insoluble in most solvents except, for instance, in concentrated sulfuric acid.[1] Polyamides are produced technically by ring opening polymerization of the respective lactam or by bulk polycondensation of the salts formed from the amine and acid components (AH-salt) at high temperatures.[2] We now describe a method for the formation of water-soluble polymeric inclusion compounds by the polycondensation of crystalline AH-salts in the presence of cyclodextrins.

Cyclodextrins are cyclic oligomers of amylose consisting of six, seven, or eight glucose building blocks (α-, β-, and γ-cyclodextrin, respectively; **1a–1c**).[3] The inclusion of cyclodextrins in polymers was first investigated with polyethylene glycols.[4] These polymeric inclusion compounds are not water-soluble, and they dissolve in strong polar solvents only upon dissociation. The first soluble cyclodextrin inclusion compounds in polymers were obtained in our group from water-soluble poly(iminooligomethylene) compounds and ionenes.[5]

Previously the inclusion of polyamides in cyclodextrins was attempted by employing phase boundary polycondensation of diamines with dicarboxylic acid dichlorides in the presence of β-cyclodextrin.[6] The resulting products, however, were not soluble in water, which is probably due to a low coverage of the polyamide chain by cyclodextrin. With the method described herein, it is possible to obtain high coverage by solid-state polycondensation in the crystal array of the host molecule (Scheme 1). Polymerizations occurring in host crystals (clathrates) are well-established; to date, however, cyclic compounds have not been used as the matrix.[7] Cyclic matrices offer the advantage of maintaining the supramolecular order, even after dissolution of the polymeric product.



Scheme 1. Polycondensation of α,ω-amino acids in the cyclodextrin channel.

The α,ω-amino acids **2–5** that were used as reactive guest compounds were dissolved with **1a** in hot water, and the resulting solution was then rapidly cooled, upon which the inclusion compounds crystallized in high yields (Table 1). Depending on the molar ratio between the host and guest, 11-aminoundecanoic acid **2** is surrounded by either one or two cyclodextrins. The stoichiometry was determined by integration of the ^{1}H NMR signal of H-1 of the host **1a** and H-c through H-h of

6, **7**	**1a**	2:1	**6·7·(1a)$_4$**	4:2	38

[a] Initial ratio. [b] In the inclusion compound.

the guest **2** (Fig. 1a). The splitting of signals for H-c through H-h show that the guest molecule **2** is indeed present in the inner portion of the host molecule **1a**. The microcalorimetric titration of **2** with **1a** revealed a stepwise inclusion with binding constants $K_1 = 4850\,M^{-1}$ and $K_2 = 507\,M^{-1}$.[8] Similarly, a crystalline ternary inclusion compound with defined 1:1:4 stoichiometry was also obtained when α,ω-diamine **6**, α,ω-dicarboxylic acid **7**, and **1a** were allowed to crystallize together.

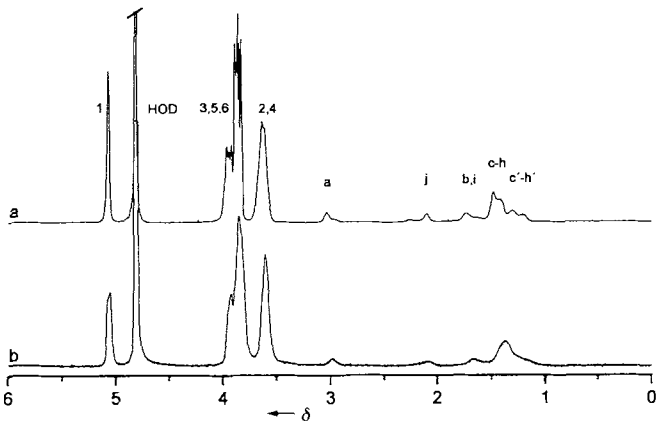

Fig. 1. ^{1}H NMR spectra of **2·(1a)$_2$** in D_2O a) before and b) after polycondensation.

The polycondensation of amino and acid groups requires a channellike packing of the cyclodextrins. The X-ray powder diffractograms of the inclusion compounds in Table 1 strongly support such a channellike packing (Fig. 2). In particular, the reflections at $2\theta = 19.63°$ ($d = 4.53$ Å) match those of known channellike inclusion compounds.[4] Only the inclusion compound **5·1b** is an exception.

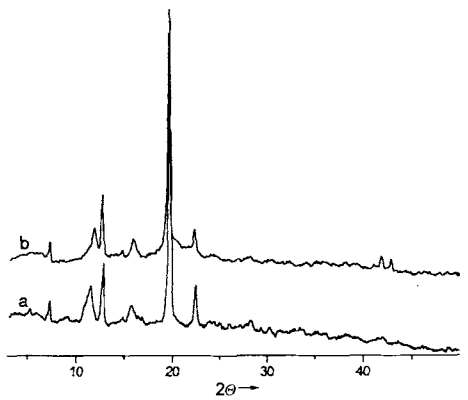

Fig. 2. X-ray powder diffractograms of **2·(1a)$_2$** in D_2O a) before and b) after polycondensation.

The polycondensation was carried out by annealing the microcrystalline inclusion compounds at 150–250 °C under vacuum. The formation of the amide can be monitored by IR spectroscopy (Fig. 3). The yield of the polyamide was independently

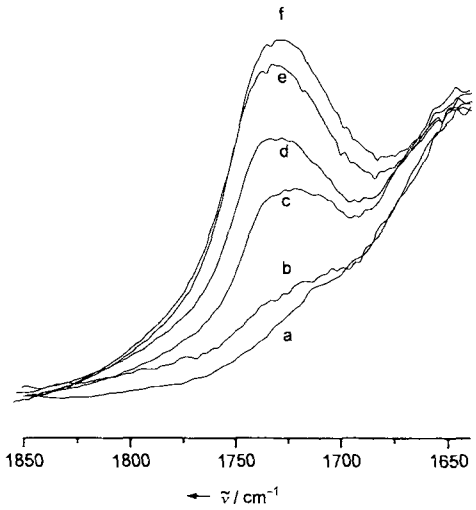

Fig. 3. IR spectra (section) of **2·(1a)$_2$** a) before and after annealing for 4 h at b) 200, c) 210, d) 220, e) 230, and f) 240 °C.

determined gravimetrically after hydrolysis of the cyclodextrin, which furthermore showed that the rate of reaction is strongly temperature-dependent: the condensation occurs at temperatures above 200 °C, a further temperature increase rapidly accelerates the polycondensation, and above 250 °C the cyclodextrin decomposes. The polycondensation of **2·(1a)$_2$** is nearly quantitative at 220 °C (Fig 4).

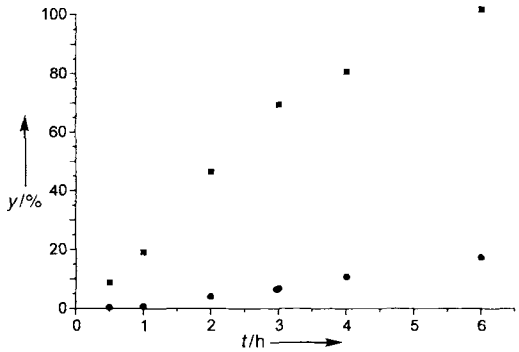

Fig. 4. Conversion y of the polycondensation of **2·(1a)$_2$** as a function of the annealing time t at 200 (●) and at 220 °C (■).

No polycondensation was observed in the case of **5·1b**. It is possible that the reactive groups are too distant from one another due to the herringbone type packing of **5·1b**. Further indications for a kind of topochemical control like that found for the solid-state polymerization of diacetylenes[9] have yet to be established. It would be interesting to investigate the impact of the alkyl chain length on the reactivity.

Based on the X-ray powder diffractogram of the product, the crystalline order is maintained during the polycondensation (Fig. 2b). An orientation reversal of the monomers can therefore be excluded. The high conversions obtained are indicative for a strictly alternating sequence of amino and acid groups in

the cyclodextrin channel, which can only be explained by strong intermolecular interactions.

Very surprising was our observation that these polyamide inclusion compounds are water-soluble. The ^{1}H NMR spectrum of $[2\cdot(\mathbf{1a})_2]_n$ in D_2O (Fig. 1b) shows the signals of cyclodextrin and polyamide. Although these are slightly broader than the corresponding signals of the monomers, they indicate the existence of a real solution. The signals of $[2\cdot(\mathbf{1a})_2]_n$ in [D$_6$]DMSO/CD$_3$COOD are better resolved, and the sharp signal for H-1 of **1a** proves that the C_6-symmetry of the α-cyclodextrin has been retained. Thus a reaction between the guest and cyclodextrin can be ruled out. The integration supports a coverage of the polyamide chain with two cyclodextrin units per repeating unit. This very high coverage explains the good solubility.

If the solution of the polyamide inclusion compound $[2\cdot(\mathbf{1a})_2]_n$ is allowed to stand for several hours, a precipitate forms in which the cyclodextrin content is reduced by 30% with respect to $[2\cdot(\mathbf{1a})_2]_n$. Apparently, the solubilizing cyclodextrins slowly unthread, with the result that free polymer chain ends can aggregate to allow the inclusion compound to precipitate. Due to the lack of mobility, the rings that are still threaded cannot slip off. The inclusion compound of polymer $[4\cdot(\mathbf{1a})_2]_n$ is soluble in water for an unlimited time. Thus the methyl substituents of the piperazine moiety seem to prevent the rings from slipping off the polymer chain.

The pure polyamides were isolated by cleaving the threaded cyclodextrins with dilute HCl. The yields of the pure polyamides, for example, polyamide-11 from $[2\cdot(\mathbf{1a})_2]_n$, was greater than 90%. The molecular masses were determined by gel permeation chromatography after N-trifluoroacylation.[10] The molecular mass of $M_w = 4500\ \mathrm{g\,mol^{-1}}$, which was obtained for **2**, corresponds to about 16 repeating units.[11]

With this solid-state polycondensation it is, in principle, possible to synthesize polyrotaxanes on any scale. Furthermore, this methodology might be applicable for the synthesis of rigid-chain, aromatic polyamides. Due to their good water-solubility, polymeric inclusion compounds could, for instance, be used for the coating of metals, polymers or textile surfaces with polyamides. Composite materials of the polyamide inclusion compounds and hydrophilic polymers, such as starch, might also be obtained.

Experimental Procedure

General: The ^{1}H NMR spectra were obtained at 400 MHz, and the X-ray powder diffractograms performed on a Siemens-WAXS-S-5000 diffractometer at 22 °C.

$[2\cdot(\mathbf{1a})_2]$: **2** (5 g, 24.9 mmol) and **1a** (125 g, 129 mmol) were dissolved in water (250 mL) and heated to 80 °C upon stirring. The clear solution was then quickly cooled to 5 °C. The resulting white precipitate was filtered, washed with water (400 mL), and dried in vacuo. Yield: 39.8 g (65%). ^{1}H NMR ([D$_6$]DMSO/CD$_3$COOD, 10:1): $\delta = 4.78$ (d, ^3J(H,H) = 1.73 Hz, 12H, H-1), 3.74 (t, ^3J(H,H) = 7.9 Hz, 12H, H-3), 3.63 (m, 36H, H-5, H-6), 3.37 (t, ^3J(H,H) = 7.86 Hz, 12H, H-4), 3.26 (dd, ^3J(H-1,H-2) = 1.73, ^3J(H-2,H-3) = 7.86 Hz, 12H, H-2), 2.73 (t, ^3J(H,H) = 7.38 Hz, 1.7H, H-a), 2.15 (t, ^3J(H,H) = 7.39 Hz, 1.7H, H-j), 1.47 (m, 3.7H, H-b, H-i), 1.225 (s, 12H, H-c through H-h); IR (KBr): $\tilde{\nu}$ = 3408 s, 2925 s, 1635 m, 1410 w, 1362 w, 1291 w, 1246 w, 1202 w, 1162 s, 1095 s, 938 m cm^{-1}.

$[2\cdot(\mathbf{1a})_2]_n$: $[2\cdot(\mathbf{1a})_2]$ (203 mg) was tempered at 230 °C and 0.1 mbar for 5 h. Yield: 196 mg (97.4%), light brown powder. ^{1}H NMR ([D$_6$]DMSO/CD$_3$COOD, 10/1): $\delta = 4.78$ (d, ^3J(H,H) = 1.73 Hz, 12H, H-1), 3.74 (t, ^3J(H,H) = 7.9 Hz, 12H, H-3), 3.62 (m, 36H, H-5, H-6), 3.36 (t, ^3J(H,H) = 7.86 Hz, 12H, H-4), 3.26 (dd, ^3J(H-1,H-2) = 1.73, ^3J(H-2,H-3) = 7.86 Hz, 12H, H-2), 2.98 (t, ^3J(H,H) = 7.38 Hz, 1.7H, H-a), 2.13 (t, ^3J(H,H) = 7.39 Hz, 1.7H, H-j), 1.44 (m, 3.7H, H-b, H-i), 1.35–1.15 (br., 12H, H-c through H-h); IR (KBr): $\tilde{\nu}$ = 3399 s, 2925 s, 2362 w, 1733 m, 1646 m, 1410 w, 1362 w, 1161 s, 1087 s, 938 m cm^{-1}; elemental analysis (%): calcd: C 46.83, H 6.68, N 0.66; found: C 46.61, H 6.96, N 1.14.

$(\mathbf{2})_n$: $[2\cdot(\mathbf{1a})_2]_n$ (1.172 g) was stirred in 1%HCl (60 mL) at 80 °C for 25 h. The resulting precipitate was filtered and washed several times with water and methanol. Yield: 103.1 mg (93.9%). For the molecular mass determination, $(\mathbf{2})_n$ (90 mg, 0.49 mmol) was added to absolute CH_2Cl_2 (15 mL) and stirred with trifluoroacetic anhydride (0.21 g, 1.0 mmol) at 25 °C for 24 h [10]. After removal of the solvent by distillation, the residue was dried at 0.1 mbar. Yield: 139 mg (96%) N-trifluoroacylated nylon-11. The soluble product was subjected to size exclusion chromatography on Styralgel columns (Waters, calibration with polystyrene standards [10]) in absolute THF.

Molecular Recognition of Cyanide by a Dicopper(II) Macrocyclic Ionophore: Construction of a Cyanide-Selective Liquid-Membrane Electrode

Benedikt Ahlers, Karl Cammann,* Sabine Warzeska, and Roland Krämer*

Over the years various types of synthetic receptors for the efficient and selective binding of anions have been developed.[1] A particularly interesting application of such compounds is their use as ionophores in potentiometric sensors.[2] There are only few examples of anion-selective microelectrodes that are based on the specific interaction of the target anion with a transition metal complex. Lipophilic metalloporphyrins[3] and alkyltin compounds[4] are selective carriers for various anions in liquid-membrane electrodes; they show a correlation between the selectivity sequence of the electrode and the strength of the coordinative bond between metal and anion.

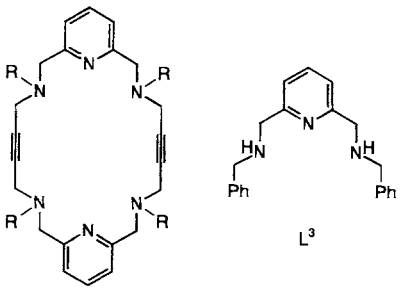
Here we present the first potentiometric anion sensor in which the dinuclear metal complex of a polyaza macrocycle acts as an ion-selective ionophore. Complexes of macrocycles that have two sites for ligation to metal centers coordinate bridging anions in a shape-selective, molecular recognition process.[5]

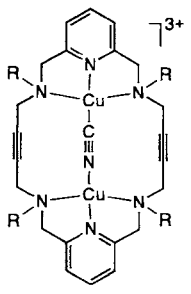
The lipophilic bis(tridentate) macrocycles L^1 and L^2 are readily available by alkylation of the secondary amino groups of a previously described ligand.[6] For a comparative study the related monotopic ligand L^3 was prepared by Schiff base condensation of pyridine-2,6-dicarbaldehyde and benzylamine, followed by $NaBH_4$ reduction of the imino groups. The crystalline complexes $[(L^1)Cu_2(NO_3)_4]$, $[(L^2)Cu_2(NO_3)_4]$,[7] and $[(L^3)Cu(NO_3)_2]$ were obtained by reaction of the ligands with $Cu(NO_3)_2 \cdot 3H_2O$ in appropriate stoichiometry.



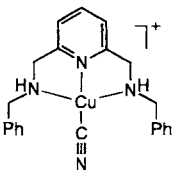
L^1: R = $C_{16}H_{33}$
L^2: R = CH_2Ph

L^3

To our knowledge the reaction of macrocyclic dicopper(II) complexes with cyanide, particularly in solution, has not yet been studied in detail. The green microcrystalline complexes $[(L^n)Cu_2(\mu\text{-}CN)(NO_3)_3]$ are obtained from $[(L^n)Cu_2(NO_3)_4]$ ($n = 1, 2$) and KCN (1 equiv). A weak ν(CN) infrared band at 2205 cm^{-1} for $[(L^1)Cu_2(\mu\text{-}CN)(NO_3)_3]$ and at 2208 cm^{-1} for $[(L^2)Cu_2(\mu\text{-}CN)(NO_3)_3]$ indicate the presence of bridging cyanide.[8] The crystal structure of the cyano-bridged dicopper(II) compound of a related ligand[9] with ν(CN) at 2235 cm^{-1}



$[(L^n)Cu_2(\mu\text{-}CN)]^{3+}$



$[(L^3)Cu(CN)]^+$

demonstrates that CN^- fits well into the central cavity defined by the relatively rigid macrocyclic framework. The cleft between the alkyne spacers is only about 6 Å wide,[6,9] which should disfavor the incorporation of bulkier (for example tetrahedral) anions for steric reasons. Addition of KCN to $[(L^3)Cu(NO_3)_2]$ yields purple $[(L^3)Cu(CN)(NO_3)]$. The rather strong ν(CN) infrared band of this complex at 2127 cm^{-1} is typical for terminally coordinated cyano ligands.[8a]

In MeOH–MeCN (1:1 v/v) solution blue $[(L^1)Cu_2]^{4+}$ (λ_{max} = 647 nm, ε_{647} = 480 $M^{-1}cm^{-1}$, ε_{400} = 290 $M^{-1}cm^{-1}$) is smoothly converted into blue-green $[(L^1)Cu_2(\mu\text{-}CN)]^{3+}$ (λ_{max} = 617 nm, ε_{617} = 550 $M^{-1}cm^{-1}$, ε_{400} = 1200 $M^{-1}cm^{-1}$) by titration with between 0 and 1 equivalent of cyanide (isosbestic point at 665 nm). Similarly, blue $[(L^2)Cu_2]^{4+}$ (λ_{max} = 656 nm, ε_{656} = 590 $M^{-1}cm^{-1}$, ε_{400} = 340 $M^{-1}cm^{-1}$) forms green $[(L^2)Cu_2(\mu\text{-}CN)]^{3+}$ (λ_{max} = 635 nm, ε_{635} = 680 $M^{-1}cm^{-1}$, ε_{400} = 1100 $M^{-1}cm^{-1}$), with an isosbestic point at 670 nm. The mononuclear complex $[(L^3)Cu]^{2+}$ (λ_{max} = 635 nm, ε = 220 $M^{-1}cm^{-1}$) reacts with between 0 and 1 equivalent of cyanide to yield purple $[(L^3)Cu(CN)]^+$ (λ_{max} = 580 nm, ε = 280 $M^{-1}cm^{-1}$, isosbestic point at 630 nm). Smooth formation of 1:1 complexes shows that the first cyanide molecule is bound with high affinity in all cases.[10] Further changes in the spectra on addition of more than one equivalent of KCN indicate coordination of more than one CN^- ion to the complexes. Thus, for 1–3 equivalents of cyanide the green solutions of the dinuclear complexes turn blue again, due to a significant decrease of 400 nm absorbance.

Evidence for the particularly efficient binding of bridging cyanide is given by the behavior of the complexes on treatment with strong acid. In a MeOH–MeCN solution (1:1 v/v) of $[(L^n)Cu_2(\mu\text{-}CN)]^{3+}$ (1 mM) λ_{max} and ε of the optical band remain unchanged upon addition of 3 equivalents of *p*-toluenesulfonic acid (TsOH) (with a very large excess of TsOH the complexes are decomposed by ligand protonation rather than by release of HCN). In contrast, treatment of $[(L^3)Cu(CN)]^+$ (λ_{max} = 580 nm) with TsOH results in protonation of coordinated cyanide to produce 70% $[(L^3)Cu]^{2+}$ (λ_{max} = 635 nm) on addition of one equivalent of TsOH and 90% $[(L^3)Cu]^{2+}$ on addition of two. Also, TsOH removes the second coordinated cyanide molecule in $[(L^n)Cu_2(CN)_2]^{2+}$ to give 55% $[(L^n)Cu_2(\mu\text{-}CN)]^{3+}$ (1 equiv. TsOH) and 80% $[(L^n)Cu_2(\mu\text{-}CN)]^{3+}$ (2 equiv. TsOH). Based on these observations we can estimate the relative affinities of the complexes for bridging and terminal cyanide ligands. The binding constant of $[(L^n)Cu_2]^{4+}$ for bridging cyanide is at least 10^2 times larger than that of $[(L^3)Cu]^+$ or $[(L^n)Cu_2(\mu\text{-}CN)]^{3+}$ for terminal cyanide.[11] It is well known that dinuclear macrocyclic copper(II) complexes have a much higher affinity for bridging anions of appropriate geometry than related mononuclear complexes.[12]

In the presence of excess cyanide $[(L^n)Cu_2]^{4+}$ ($n = 1,2$) is more stable against reduction than $[(L^3)Cu]^{2+}$. In a MeOH–MeCN solution (1:1 v/v) containing 5 mM KCN the optical absorbance of the dinuclear complex (1 mM) is unchanged for 3 min whereas reduction of Cu^{II} to Cu^{I} in the mononuclear complex (1 mM) is indicated by a complete disappearence of the absorbance around 600 nm in the same period of time.

Application of $[(L^n)Cu_2(NO_3)_4]$ ($n = 1, 2$), $[(L^3)Cu(NO_3)_2]$ and L^2 as ion-selective materials in liquid-membrane electrodes was studied by measuring the potentiometric behavior. The compounds were embedded into a plastisized PVC-membrane (PVC/*o*-nitrophenyl octyl ether/ionophore in a 33/66/1 ratio).[2a] The membranes containing $[(L^n)Cu_2(NO_3)_4]$ and $[(L^3)Cu(NO_3)_2]$ were light blue and transparent when kept in H_2O. Apparently, the $C_{16}H_{33}$ and CH_2Ph substituents anchor the complexes in the lipophilic membrane phase and prevent loss to the aqueous solution.

The membranes were implemented into a potentiometric measuring setup and the potential differences referred to a Ag/AgCl reference electrode were determined.[2a] The electrodes containing $[(L^n)Cu_2(NO_3)_4]$ exhibited fast and reversible near-Nernstian response to aqueous cyanide solutions at pH 10 with a linear working range for cyanide concentrations between 10^{-5} to 10^{-2} M. The response to CN^- is highly selective, in particular for $[(L^1)Cu_2(NO_3)_4]$ (Fig. 1). Alternating current impendance measurements[13] confirmed the interaction of membranes con-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3518-2142 $ 15.00+.25/0

taining $[(L^2)Cu_2(NO_3)_4]$ with cyanide ions. The bulk membrane resistance changed by a factor of 4 on exposure to 1 mM KCN solution in a 0.1 M $Ca(NO_3)_2$ background electrolyte. Furthermore, the bright blue membrane adopts the bright green color of $[(L^2)Cu_2(\mu\text{-}CN)(NO_3)_3]$ when kept in 0.1 M cyanide solution for 5 h.[14]

Electrodes based on $[(L^3)Cu(NO_3)_2]$ or L^1 show only a slight sensitivity to cyanide ions and behave more or less as typical anion exchangers with a selectivity pattern dependent on the lipophilicity of the sample anions (Fig. 1).[2a] Although formation of $[(L^3)Cu(CN)(NO_3)]$ is indicated by the purple color of the membrane after exposure to 0.1 M KCN, cyanide affinity of the mononuclear complex appears to be too weak to induce a selective response.

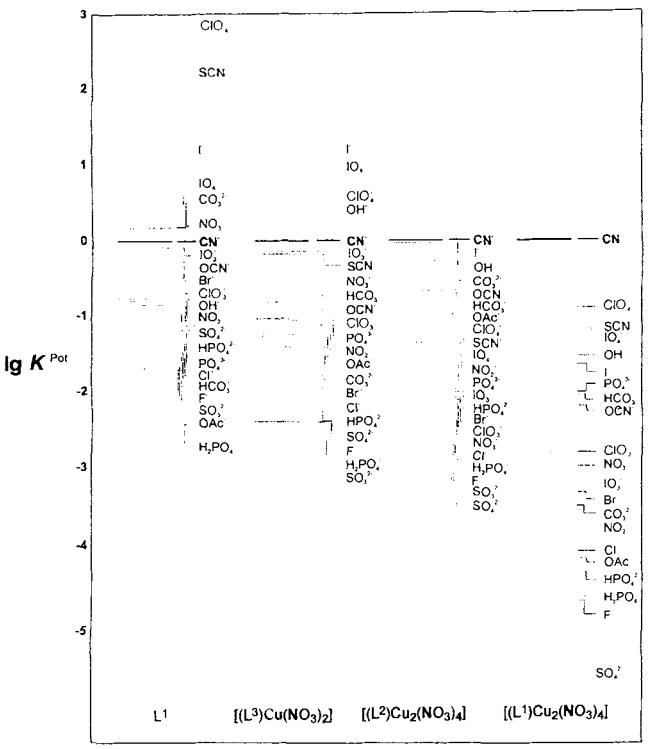


Fig. 1. Selectivity coefficients lg $K^{Pot}_{CN^-,A^-}$ of a membrane electrode containing ionophores $[(L^1)Cu_2(NO_3)_4]$, $[(L^2)Cu_2(NO_3)_4]$, $[(L^3)Cu(NO_3)_2]$, and L^2, determined according to the FIM-method.[2a] The selectivity coefficient is given by the weighting factor (K^{Pot}_{ij}) in the Nicolsky Eisenmann equation $\left(E = E^0_i + \frac{2.3\,RT}{z_i F}\,\lg\left[a_i + \sum_j K^{Pot}_{ij}\cdot(a_j)^{z_i/z_j}\right]\right)$.

In conclusion, the first cyanide-selective electrode based on a molecular recognition process was constructed. Dinuclear metal complexes of lipophilic macrocycles represent a novel class of ionophore in liquid-membrane electrodes. By variation of the metal ion and of the macrocyclic framework selective carriers for many different target anions should be available.

[14] It was not possible to follow complexation of cyanide by direct investigation of the PVC-membranes with standard UV/Vis or IR spectroscopic methods. Absorbances of the complexes are too weak and are superimposed by background absorbance of the membrane.

Structure-Directed Synthesis under Thermodynamic Control: Macrocyclic Trimers from Cinchona Alkaloids**

Stuart J. Rowan, Paul A. Brady, and Jeremy K. M. Sanders*

Covalent organic structures have traditionally been synthesized through kinetically controlled irreversible reactions, whereas noncovalent supramolecular assemblies are generally constructed with thermodynamically controlled reversible interactions.[1,2] Irreversible reactions lack the ability to proofread and repair "incorrect" bond formation, while supramolecular assemblies tend to lack the robust character associated with covalent bonds, so we have been exploring the synthetic potential of covalent chemistry under reversible conditions.[3] We now report the exceptionally efficient synthesis under thermodynamic control of macrocyclic trimers from new supramolecular building blocks derived from the cinchona alkaloids quinine (**1a**) and cinchonidine (**1b**).

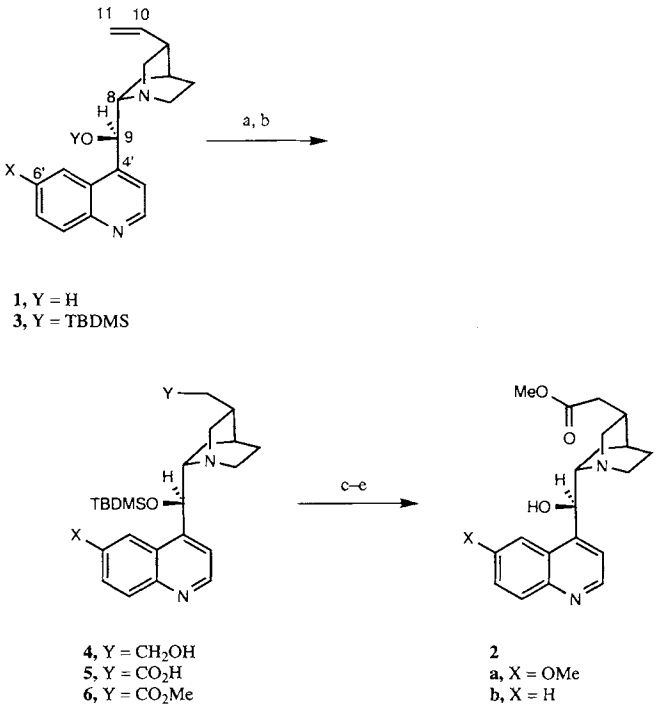
[**] We thank the Engineering and Physical Science Research Council, Merck, Sharp, and Dohme, and Rhône-Poulenc-Rorer for financial support, and the EPSRC Mass Spectrometry Service in Swansea for mass spectra.

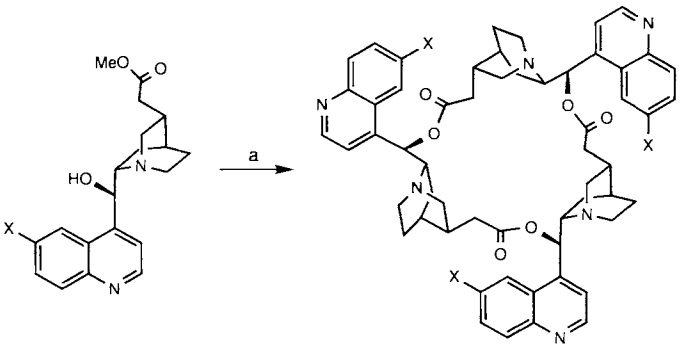
Cinchona alkaloids have recently received much attention in the field of asymmetric synthesis.[4] For example, quinine and its derivatives have been widely used in the Sharpless dihydroxylation reaction.[5] Despite all this interest, however, there has been little use of this building block in supramolecular or macrocyclic chemistry. Notable exceptions include its use as a chiral resolution agent, where quinine forms an inclusion complex with binaphthols,[6] and as a quinine-derived macrocycle, prepared by Corey and Noe[7] for use as a more rigid ligand in the Sharpless dihydroxylation reaction.

The size and relatively concave shape of quinine, together with the functionality present in the natural product, make it attractive for macrocycle synthesis. As our thermodynamic cyclizations are transesterifications,[3] we require a hydroxyl group at one end of the molecule and an ester elsewhere. There is already a hydroxyl group present at the 9-position of quinine, but an ester group had to be introduced into the system. This was achieved by modifying the vinyl group in five steps (Scheme 1)[8] to give the methyl ester **2a**. Starting with the natural product **1a** the hydroxyl group at the 9-position was protected with a *tert*-butyldimethylsilyl (TBDMS) group by reaction with Et_3N/(4-dimethylamino)pyridine (DMAP) and TBDMSCl to give **3a** in 99% yield. Hydroboration of the vinyl group with five equivalents of $BH_3 \cdot THF$ in diglyme, followed by oxidation with $Me_3NO \cdot 2H_2O$[9] yielded the terminal alcohol **4a** in 87% yield.[10] Subsequent oxidation of this alcohol with Jones' reagent gave the acid **5a** in 62% yield, which was esterified with MeOH/HCl conc. to furnish **6a** in 97% yield. Finally, deprotection by cleaving the TBDMS group with TBAF/THF yielded the monomer **2a** in 66% yield. Overall the final monomeric building block was synthesized in a 34% yield from the starting natural product. The cinchonidine monomer **2b** was prepared in an analogous manner starting from natural cinchonidine (**1b**).



Scheme 1. a) TBDMSCl, Et_3N, DMAP, DMF, room temperature; b) 1. 5 equiv $BH_3 \cdot THF$, diglyme, 0 °C, 2. Me_3NO, 100 °C; c) Jones' reagent, acetone, room temperature; d) MeOH, $HCl_{conc.}$, room temperature; e) TBAF, THF, room temperature.

Thermodynamic cyclizations of **2a** were carried out by utilizing a procedure similar to that reported previously[3] (Scheme 2). The catayst (5% KOMe/[18]crown-6) was added to a refluxing solution (5 mM) of **2a** in toluene, with azeotropic removal of the methanol produced. Initially, the extent of the reaction was followed by HPLC;[11] recently, electrospray mass spectrometry (ESMS) has proved to be a more powerful probe for following the oligomerization. Remarkably, the cyclization of **2a** gave virtually a single product: the cyclic trimer **7a** was formed in high yield (about 90% by NMR and 84% isolated yield). The reaction was virtually complete after 20 min and no significant change in distribution was seen in the following 160 minutes. Cyclization of **2b** results in the corresponding trimer **7b** in excellent yield.



Scheme 2. a) KOMe, [18]crown-6, toluene, reflux.

To demonstrate that the apparent trimer was the single product rather than a mixture of cyclic oligomers with indistinguishable NMR, MS, and HPLC characteristics, the linear dimer, trimer, and tetramer were synthesized by independent synthetic routes and subjected to cyclization under Yamaguchi-type kinetic conditions. The linear dimer and tetramer each gave the cyclic tetramer, which was indeed spectroscopically different from cyclic trimer;[12] attempts to build CPK models of the cyclic dimer suggested that this dimer would be kinetic inaccessible. Cyclization[13] of the monomer unit was also carried out under kinetic control. This yielded a mixture of cyclic trimer (37%), tetramer (23%), and other higher oligomers (40%) (according to ^1H NMR spectra). These results show that although the cyclic dimer is not kinetically accessible, higher oligomers can be formed. The narrow distribution observed in the thermodynamic reaction is thus not due to kinetic inaccessibility of the other cyclic oligomers.

Proof was then sought that the cyclization was a reversible process. To this end a mixture of the two preformed trimers **7a** and **7b** was subjected to the reaction conditions,[14] and the resulting solution was assayed by ESMS[15] after quenching with aqueous buffer (pH 7) and extraction into ethyl acetate. As Figure 1 demonstrates all four possible trimers (containing 0, 1, 2, or 3 methoxyl groups) are present, a result that is consistent only with reversible breakdown and reformation of the initial trimers. The heterotrimers appear almost immediately (20 s), and after only 2 minutes there is already a ratio of over 2:1 (heterotrimer: homotrimer). The statistically expected 3:1 is

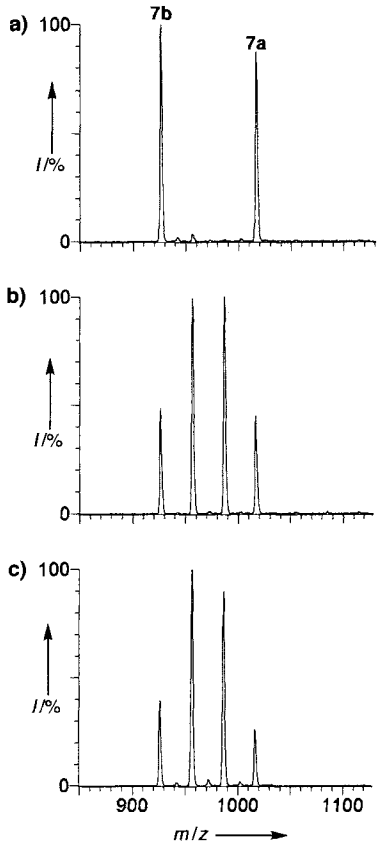

Fig. 1. Molecular ion region of the ES mass spectra of the reaction of quinine trimer (**7a**) and cinchonidine trimer (**7b**) before any catalyst was added (a), and 2 (b) and 10 minutes (c) after addition. The four peaks correspond to trimers without 6′-OMe groups (**7b**: *m/z* 925) and with one (*m/z* 955), two (*m/z* 985), or three 6′-OMe groups (**7a** 1015). The deviation from the expected 1:1 peak intensities in (a) and from 1:3:3:1 in (c) results mainly from the slight excess of **7b** used (9.5 mg, 1.03×10^{-5} mol for **7b**, 9.8 mg, 9.7×10^{-6} mol for **7a**).

reached within 10 minutes and persists beyond 1 hour.

The narrow product distributions in these cinchona alkaloid cyclizations contrast with the broader distributions observed in the cholate series,[3] when the same cyclization conditions are used, a result that must be due to a different balance of the statistical and enthalpic factors in the two systems. In the cholate series, steroid cores are linked by flexible four-carbon units, which apparently allow considerable dispersity in the ring size distribution (mainly dimer, trimer, tetramer, pentamer). In the cinchona series, rigid quinuclidine cores are connected by a flexible two-carbon unit (C_{10} and C_{11}), with some further rotation possible around the C_8-C_9 and $C_9-C_{4'}$ bonds. This rotation, however, turns out to be unexpectedly restricted: ^{1}H NMR spectra of compounds **3a–6a** show splitting of both the $(CH_3)_3CSi$ and CH_3Si proton resonances, which suggests that rotation of the bonds around the C9 carbon atom is hindered, presumably due to the bulky quinoline unit. This is also seen in the cinchonidine series **3b–6b**, although broadening of these signals suggests faster rotation due to the removal of the 6′-OMe group. The overall effect is that trimer is by far the most favored product in this reaction, with only trace amounts of the higher oligomers and no detectable dimer.

We have now shown that the thermodynamic transesterification reaction is applicable to systems other than cholates and that our new alkaloid-derived building blocks are preorganized to give cyclic trimers even though they appear to have many degrees of rotational freedom available.[16] This work is now being extended to investigate mixtures of building blocks and the effects of potential templates.

Experimental Procedure

KOMe · [18]crown-6 [17]: KOMe in methanol (0.513 mL, 0.78 M, 0.40 mmol), freshly prepared from potassium metal and methanol, was added to [18]crown-6 (106 mg, 0.40 mmol). Dried toluene (1 mL) was then added, and the mixture concentrated under reduced pressure to about 0.5 mL. More toluene (1 mL) was added, and the mixture was again concentrated under reduced pressure to 0.5 mL. This was repeated once more to ensure that all the methanol had been removed azeotropically. The catalyst mixture was then diluted with toluene (about 1.5 mL), and the solution filtered under inert atmosphere to give a KOMe · [18]crown-6 toluene solution of about 0.015–0.03 M (determined by titration).

7a: Monomer **2a** (10 mg, 2.703×10^{-5} mol) was added to a round-bottomed flask attached to a soxhlet extractor that contained molecular sieves (4 Å) and then dissolved in toluene (5.4 mL). This solution was refluxed for 30 min to remove all water from the system, and then the KOMe · [18]crown-6 catalyst solution (45 μL, 0.03 M, 1.35×10^{-6} mol) was added. To work up the reaction, the mixture was added to aqueous buffer (pH 7) and extracted with ethyl acetate. The compound was purified by column chromatography on silica (graduated elution with ethyl acetate/methanol (10/0, 9/1, 8/2, ... etc.)) to obtain **7a**. Yield. 7.7 mg (84%). TLC ethyl acetate/methanol (1/1) $R_f = 0.17$. ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 1.35$ (dd, $J = 13.4$, 7.9 Hz, 3H), 1.57 (m, 3H), 1.76 (m, 3H), 1.90 (br s, 3H), 1.97–2.18 (m, 9H), 2.24 (m, 3H), 2.62 (m, 6H), 2.99 (dd, $J = 11.2$, 14.7 Hz, 3H), 3.11 (dd, $J = 14.7$, 11.2 Hz, 3H), 3.43 (dd, $J = 18.4$, 9.0 Hz, 3H), 3.97 (s, 9H), 6.53 (d, $J = 10.6$, 3H), 7.37 (m, 6H), 7.53 (d, $J = 2.6$ Hz, 3H), 8.01 (d, $J = 9.2$ Hz, 3H), 8.76 (d, $J = 4.5$,3H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = 24.39$, 25.79, 28.17, 31.96, 38.50, 41.77, 55.71, 56.65, 59.42, 72.09, 102.26, 119.63, 121.24, 127.78, 131.88, 143.69, 144.88, 147.55, 157.88, 171.88. FAB-MS: *m/z*: 1015 $[M+H^+]$. ES-MS: *m/z*: 1015 $[MH^+]$, 508 $[MH_2^{2+}]$, 339 $[MH_3^{3+}]$.

[14] The reaction procedure is the same as before, but 15 mol % catalyst with respect to the trimers was used which corresponds to 5% per monomer unit.
[15] Positive-ion ES mass spectra were obtained on a VG BioQ triple quadrupole apparatus with a mass-to-charge (*m/z*) range of up to 4000 (VG Bio Tech Ltd, Altrincham, UK). The electrospray source was heated to 70 °C. The sampling cone voltage (V_c) was at 105 V to reduce the amount of multiply charged ions observed. The samples were introduced into the mass spectrometer source with an LC pump (Shimadzu LC-9A LC pump) at a flow rate of 4 μL min^{-1} of acetonitrile/water (1/1). Calibration was performed with protonated horse myoglobin. Scanning was performed from *m/z* 200 to 1500 in 10s. The data system was operated as a multichannel analyzer, and several scans were summed to obtain the final spectrum. Samples for ES-MS were prepared by taking aliquots from the reaction, injecting into pH 7 buffer, and extracting with ethyl acetate. The organic phase was dried (with $MgSO_4$) and concentrated to dryness by evaporation. The residue was then dissolved in acetonitrile water (1/1) and injected into the mass spectrometer.
[16] A similar narrow distribution has recently been observed by Shea and co-workers, in the cyclization of their spirocatechols with phenyltriethoxysilane to give the rigid cyclic tetramer, but they did not comment on the origin of the selectivity: J. H. Small, D. J. McCord, J. Greaves, K. J. Shea, *J. Am. Chem. Soc.* **1995**, *117*, 11588–11589.

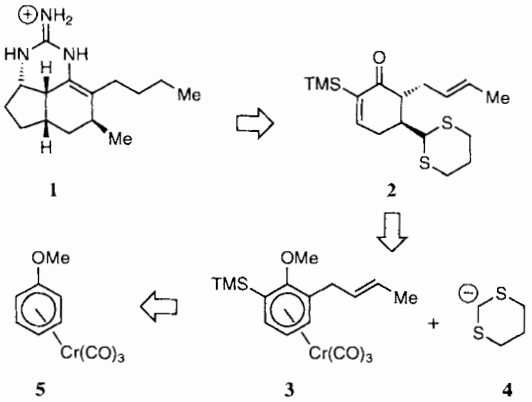
Controlling the Course of Nucleophilic Additions to *ortho*-Substituted (η^6-Anisole)tricarbonylchromium Complexes: Dienol Ether Formation versus *tele*-Substitution**

Hans-Günther Schmalz,* and Kurt Schellhaas

(η^6-Arene)tricarbonylchromium complexes, which were first described in 1958 by Fischer und Öfele,[1] enjoy a multifarious potential for organic synthesis,[2] and the chemistry of this class of compounds has been the subject of intense investigation for many years.[3] With our research we want to contribute to the acceptance of chiral arenetricarbonylchromium complexes as building blocks for the enantioselective synthesis of bioactive compounds.[4] For this purpose we pursue novel synthetic concepts based on the specific reactivity pattern of arenetricarbonylchromium complexes, and we take synthetically relevant cases as occasion to explore and tame the often subtle reactivity of these complexes and to adapt it to other synthetic applications.[5]

Recently, we aimed to synthesize the marine natural product (+)-ptilocaulin (**1**)[6, 7] following the strategy sketched in Scheme 1.[8] As the key step of the projected reaction sequence, we intended to convert complex **3**, which is accessible from anisoletricarbonylchromium (**5**), into the enone **2** by reaction with the C_1-nucleophile **4**—according to a transformation discovered by Semmelhack.[9, 10]



Scheme 1. Retrosynthetic analysis of (+)-ptilocaulin (**1**).

In contrast to all expectations, our initial attempts to achieve the conversion of **3** into **2** failed completely and led to the insight that in contrast to **5** *ortho*-substituted anisoletricarbonylchromium derivatives behave unusually, giving rise to *tele*-substituted products (e.g. **9**; see below) under the routine reaction conditions (nucleophile addition followed by protonation).[8] However, we have now succeeded in finding conditions that effectively suppress the *tele*-substitution. We report here (among other things) on the successful synthesis of the (optically active) enone **2** and demonstrate that the transformation of **3** into **2** occurs under chirality transfer without loss of stereochemical information.

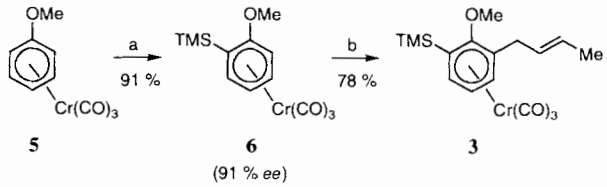
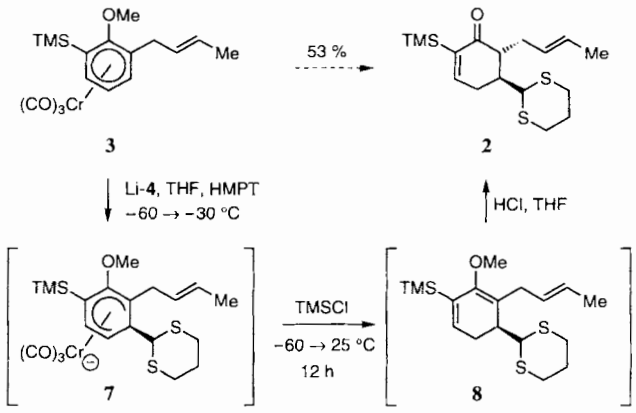
[**] This work was supported by the Volkswagenstiftung (Project I 69907) and the Fonds der Chemischen Industrie (among other things through a graduate scholarship award to K. S.). We thank the Chemetall GmbH for gifts of chemicals and Prof. M. F. Semmelhack, Princeton, for a valuable discussion.

Following the route described previously,[8] the regio- and enantioselective preparation of complex **3** was accomplished in appealing yield after optimization of all individual steps (Scheme 2).[11] Starting from the prochiral complex **5**, enantioselective deprotonation/silylation[12, 13] provides the monosilylated derivative **6** (91% *ee*[14]), which in turn is converted into complex **3** through *ortho*-deprotonation and Cu-mediated alkylation.[15]



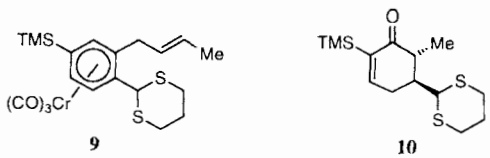
Scheme 2. Preparation of the optically active complex **3**. a) Li*N*[(*S*)-CHMePh]$_2$, TMSCl (6 equiv), THF, −100 °C, 10 min; b) *n*BuLi, THF, −60 → −20 °C, then CuCl (1.1 equiv), −50 → 0 °C, then $BrCH_2CH{=}CHCH_3$ (2 equiv), −30 → 0 °C, 2 h.

In order to prepare the enone **2**, complex **3** was treated with 2-lithio-1,1-dithiane (Li-**4**) in THF in the presence of hexamethylphosphoric triamide (HMPA) as cosolvent to give the anionic intermediate **7**, which on addition of HCl-free chlorotrimethylsilane (TMSCl), extractive workup, and oxidative decomplexation afforded a mixture containing the dienol ether **8** as the major product.[16] After acidic hydrolysis of the dienol ether moiety, the diastereomerically pure, crystalline enone **2** was isolated in 53% yield (based on **3**) (Scheme 3).[17] The enantiomeric purity of the product was greater than 95% *ee*,[14] indicating that the chirality transfer from the planar-chiral metal complex structure to the chirality center in β-position to the carbonyl function in **2** has occurred without racemization.



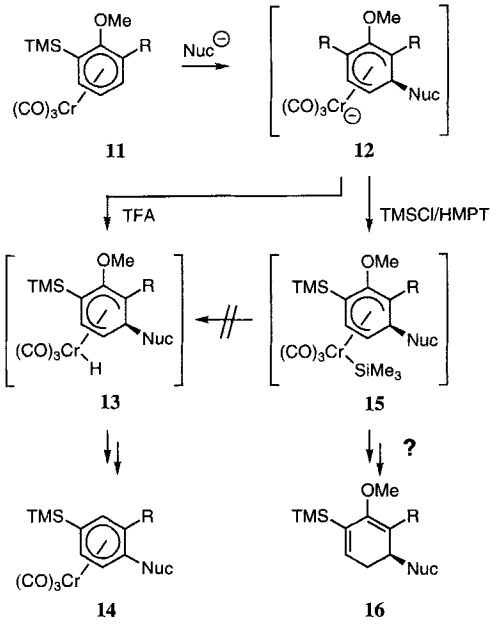
Scheme 3. Preparation of the enone **2** from the chiral complex **3**.

With this new procedure, the enantioselective synthesis of the highly functionalized ptilocaulin precursor **2** is now possible in only four steps from anisole. To demonstrate that the method is not limited to a single case, we have prepared the enone *rac*-**10**.[18] It should be emphasized that the *tele*-substituted product



9 is formed only in trace amounts under the reaction conditions described, in contrast to all other conditions tested so far (see below), where **9** always appears as the major product.

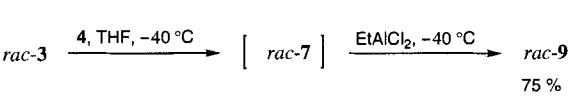
The results obtained so far provide the following picture (Scheme 4): the anionic η^5-complex **12**, which results from the stereospecific *anti*-addition of the nucelophile to the less hindered *meta*-position of the *ortho*-substituted anisoletricarbonylchromium substrate **11**, may react further by two different



Scheme 4. *anti*-Addition of a nucleophile (Nuc$^{\ominus}$) to **11** and protonation or silylation of the intermediate **12**.

modes depending on the reaction conditions. On addition of trifluoroacetic acid (TFA), protonation takes place primarily at the chromium atom (→ **13**),[9] which leads under elimination of methanol to the *tele*-substituted product (**14**),[8] probably according to the mechanism formulated by Rose et al.[19, 20] If **12** is treated with TMSCl in the presence of HMPA, however, the reaction takes a completely different course. We assume that the silylation initially takes place at the chromium atom.[21] The conversion of the resulting species **15** into the dienol ether **16** then occurs by a still unknown mechanism, however, without passing through an intermediate of type **13**, from which the *tele*-substituted product would arise. When the anionic intermediate *rac*-**7** was treated either with Bu_3SnCl followed by TFA or with $BF_3 \cdot Et_2O$, *rac*-**9** was isolated after hydrolytic workup as the sole product.[22] Also remarkable is the fact that *tele*-substitution proceeds with particular efficiency if the primary nucleophilic addition product *rac*-**7** is treated with $EtAlCl_2$. In this case the *tele*-substitution occurs even before hydrolysis of the reaction mixture (under aprotic conditions!) (Scheme 5).[23]

The protocols reported herein allow effective control of the outcome of nucleophilic additions to *ortho*-substituted anisoletricarbonylchromium derivatives of type **11**. Either dienol ether of type **16** (or the cyclohexenone derivatives) or *tele*-substituted products of type **14** can now be selectively prepared as required. Current efforts in our laboratory are directed towards the completion of the synthesis of (+)-ptilocaulin and the exploration of the scope and limitations of our general method.



Scheme 5. $EtAlCl_2$-mediated *tele*-substitution.

Experimental Procedure

All reactions were performed in anhydrous solvents in an atmosphere of argon.

6: To a solution of (*S*,*S*)-di(1-phenylethyl)amine (272 mg, 1.1 mmol) in THF (30 mL) at −70 °C was added *n*BuLi (0.74 mL, 1.16 mmol, 1.56 M in hexane), and stirring was continued for 1 h while warming to −40 °C. Then into the vigorously stirred solution at −100 °C was injected first TMSCl (0.83 mL, 6.6 mmol) immediately followed by the rapid injection of a solution of **5** (269 mg, 1.1 mmol) in 3 mL of THF. After 10 min the cooling bath was removed, and the reaction mixture was diluted with *t*BuOMe and washed twice with 2N HCl, and then with saturated aqueous solutions of $NaHCO_3$ and NaCl. The dried (K_2CO_3) organic solution was evaporated in vacuo, and the crude product was purified on a chromatotron (eluent: hexane/ethyl acetate 5/1) to give 318 mg (1.01 mmol, 91%) of compound **6** (91% *ee* [14]) as a greenish-yellow powder. M.p. 99–100 °C; $[\alpha]_D^{20} = -209$ ($c = 1.0$ in $CHCl_3$); FT-IR (KBr): $\tilde{\nu} = 1942, 1885, 1865, 1842\ cm^{-1}$; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.31$ (s, 9H), 3.73 (s, 3H), 4.79 (t, $J = 6$ Hz, 1H), 4.97 (d, $J = 7$ Hz, 1H), 5.57 (dd, $J = 6$, 1.5 Hz, 1H), 5.68 (pseudo dt, $J_t = 6$ Hz, $J_d = 1.5$ Hz, 1H); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = -0.7$(q), 55.3(q), 73.4(d), 85.0(d), 88.8(s), 95.9(d), 101.8(d), 147.5(s), 233.2(s).

3: To a solution of **6** (275 mg, 0.869 mmol) in THF (10 mL) at −60 °C was added *n*BuLi (0.59 mL, 0.913 mmol, 1.56 M in hexane), and stirring was continued for 1 h while warming to −20 °C. After cooling to −50 °C, CuCl (98 mg, 0.986 mmol) was added. While the mixture was stirred for 1.5 h and allowed to warm to 0 °C, it slowly turned greenish-black. The solution was then cooled to −50 °C, treated with crotyl bromide (0.18 ml, 1.74 mmol), and stirred for 2 h at 0 °C. The reaction mixture was then diluted with *t*BuOMe and washed several times with small portions of 2N HCl (until the green color of the aqueous layer no longer intensified). The organic solution was washed with saturated aqueous solutions of $NaHCO_3$ and NaCl, dried (K_2CO_3), and the solvent was removed in vacuo to give an orange oil. Purification on the chromatotron (hexane/ethyl acetate 10/1) afforded 252 mg (0.68 mmol, 78%) of complex **3** as a dark yellow oil, which solidified upon standing. An analytical sample was crystallized from hexane at −18 °C: M.p. 55–56 °C; $[\alpha]_D^{20} = -190$ ($c = 1.0$ in $CHCl_3$); FT-IR (KBr): $\tilde{\nu} = 1960, 1883\ cm^{-1}$; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.36$ (s, 9H), 1.75 (dd, $J = 6$, 1 Hz, 3H), 3.19 (d, $J = 6$ Hz, 2H), 3.74 (s, 3H), 4.88 (t, $J = 6.5$ Hz, 1H), 5.40 (dd, $J = 6.5$, 1.5 Hz, 1H), 5.50–5.67 (m, 3H); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = 0.1$(q), 17.9(q), 32.1(t), 62.8(q), 87.8(d), 92.6(s), 97.2(d), 99.6(d), 103.9(s), 127.8(d), 129.1(d), 146.6(s), 233.6(s).

2: To a solution of 1,3-dithiane (71 mg 0.594 mmol) in THF (1 mL) and HMPA (0.94 mL) at −60 °C was added a 1.56 M solution (0.38 mL) of *n*BuLi in hexane, and stirring was continued for 1.5 h while warming to −30 °C. At −70 °C a solution of complex **3** (200 mg, 0.54 mmol) in THF (2 mL) was added dropwise over a period of 5 min, and the mixture was allowed to warm slowly to −30 °C within 2 h. At this point freshly distilled TMSCl (0.68 mL, 5.4 mmol) was added, and the mixture was stirred for 12 h at 25 °C before it was diluted with *t*BuOMe and washed twice with 2N HCl. The organic layer was then exposed to the sunlight and air until it decolorized completely, and washed with saturated aqueous solutions of $NaHCO_3$ and NaCl. The dried (K_2CO_3) solution was filtered through a pad of Celite, and the solvent was removed in vacuo to give a clear, slightly yellow oil (dienol ether), which was dissolved in a mixture of THF (20 mL) and 2N HCl (10 mL) and heated for 1 h to 80 °C. The cooled mixture was diluted with *t*BuOMe, washed as described above, and dried with $MgSO_4$. After removal of the solvent, the crude product was purified on the chromatotron (hexane/ethyl acetate 10/1) to yield 98 mg (0.287 mmol; 53%) of the enone **2** as a colorless solid. An analytical sample was crystallized from hexane at −18 °C. M.p. 157 °C; $[\alpha]_D^{20} = 46$ ($c = 0.4$ in $CHCl_3$); FT-IR (KBr): $\tilde{\nu} = 1660, 1593, 1245, 839$; ^1H NMR (400 MHz, $CDCl_3$): $\delta = 0.10$ (s, 9H), 1.60 (d, $J = 4.5$ Hz, 3H), 1.87 (m, 1H), 2.03–2.19 (m, 2H), 2.22–2.34 (m, 2H), 2.51 (m, 1H), 2.69–2.89 (m, 6H), 4.05 (d, $J = 9$ Hz, 1H), 5.27–5.40 (m, 2H), 6.99 (dd, $J = 5$, 3 Hz, 1H); ^{13}C NMR (100 MHz, $CDCl_3$): $\delta = -1.5$(q), 17.8(q), 25.8(t), 28.3(t), 29.3(t), 29.7(t), 29.8(t), 40.6(d), 48.6(d), 49.2(d), 127.0(d), 127.8(d), 140.5(s), 154.5(d), 203.9(s); HR-MS: $m/z = 340.13508$ (as calculated for $C_{17}H_{28}OS_2Si$).

rac-**9**: To a solution of 1,3-dithiane (71 mg, 0.594 mmol) in THF (2 mL) at −60 °C was added a 1.56 M solution of *n*BuLi (0.38 mL, 0.594 mmol) in hexane. Stirring was continued for 2.5 h (→ −20 °C), the mixture was recooled to −60 °C, and a solution of *rac*-**3** (200 mg, 0.54 mmol) in THF (2 mL) was added dropwise over a period of 5 min. After 2.5 h (−60 → −30 °C) the mixture was cooled to −78 °C, and a 1 M solution of $EtAlCl_2$ (1.62 mL, 1.62 mmol) in hexane was added dropwise. The mixture was stirred for 2 h at −78 °C, quenched by careful addition of 2N HCl, and diluted with *t*BuOMe. The organic layer was washed with 2N HCl, saturated aqueous $NaHCO_3$ and brine, and dried with K_2CO_3, and the solvent was removed in vacuo. Chromatography (chromatotron; hexane/ethyl acetate 10/1) gave 186 mg of *rac*-**9** 0.406 mmol; 75%) besides some starting material (*rac*-**3**). An analytical sample of *rac*-**9** was crystallized from hexane at −18 °C. M.p. 120 °C; ^1H NMR (400 MHz, C_6D_6): $\delta = 0.23$ (s, 9H), 1.42 (m, 1H), 1.60 (m, 1H), 1.64 (d, $J = 3$ Hz, 3H), 2.26 (m, 1H), 2.45–2.58 (m, 3H), 3.14, 3.44 (each dd, $J = 8$, 3.5 Hz, 1H), 4.76

(d, $J = 3$ Hz, 1H), 5.07 (s, 1H), 5.15 (s, 1H), 5.52, 5.65 (each m, 1H), 5.86 (d, $J = 3$ Hz, 1H). For further characteristic data of *rac*-**9** see ref. [8].

[16] After extractive workup, the crude product (dienol ether) still contains significant amounts of (undefined) chromium complexes. A complete decomplexation is achieved by exposing the yellow solution to the sunlight for some time. Thereafter, GLC-MS and ^{1}H NMR analysis of the product mixture indicates that **8** is the major component (beside small amounts of **2**, some decomplexed **9**, and several unidentified by-products).
[17] The *trans*-configuration of **2** follows from the ^{1}H NMR coupling constants; the signals were assigned by means of a COSY spectrum.
[18] This product was obtained under analogous conditions in a yield comparable to that of **2**; for *rac*-**10**: m.p. 98 °C (hexane); FT-IR (KBr): $\tilde{\nu} = 1652$, 1597, 1343, 1246, 841 (s) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 0.12$ (s, 9H), 1.05 (d, $J = 7$ Hz, 3H), 1.89 (m, 1H), 2.09 (m, 1H), 2.26 (ddd, $J = 20$, 10, 2 Hz, 1H), 2.45 (pseudo sept., $J = 5$ Hz, 1H), 2.69–2.91 (m, 6H), 4.00 (d, $J = 10$ Hz, 1H), 7.06 (pseudo dd, $J = 5$, 2 Hz, 1H); ^{13}C NMR (67.5 MHz, $CDCl_3$): $\delta = -0.7$ (q), 10.3 (q), 25.9 (t), 28.3 (t), 29.7 (t), 29.8 (t), 41.1 (d), 42.9 (d), 49.3 (d), 140.2 (s), 155.5 (d), 205.1 (s); HR-MS: $m/z = 300.10378$ as calcd. for $C_{14}H_{24}OS_2Si$.

[20] There are several examples of nucleophilic *tele*- and *cine*-substitutions (S_NAr reactions) to $Cr(CO)_3$-complexed arenes [10], but only in very few cases does a methoxy group act as a leaving group. See, for instance, refs. [4b, 8, 19b].
[21] It is known that the reaction of anionic η^5-complexes of type **12** with Ph_3SnCl may lead to (isolable) stannylated products with a structure similar to **15**: E. P. Kündig, A. F. Cunningham, Jr., P. Paglia, D. P. Simmons, G. Bernardinelli, *Helv. Chim. Acta.* **1990**, *73*, 386.
[22] In these cases, a characteristic red color of the reaction mixture appeared, which is also observed when TFA is added to solutions of anionic intermediates of type **12**.
[23] This was secured by ^{1}H NMR spectroscopy of a sample that had been removed under exclusion of air (prior to the hydrolysis of the reaction mixture), freed from all volatile components in vacuo, and redissolved in C_6D_6.

Cyclopeptide Libraries as New Chiral Selectors in Capillary Electrophoresis

Günther Jung,* Heike Hofstetter, Susanne Feiertag, Dieter Stoll, Oliver Hofstetter, Karl-Heinz Wiesmüller, and Volker Schurig*

For the chromatographic separation of enantiomers a single chiral selector is added to the mobile phase or used as stationary phase. Multicomponent chiral selectors have been applied rarely, for example in inclusion gas chromatography[1] and in complexation gas chromatography.[2] Combinatorial chemistry[3] furnishes defined libraries that may be utilized as novel multicomponent chiral additives for the mobile phase or as multicomponent chiral stationary phases in pressure-driven or electrically driven separation systems. Thus, the time-consuming screening of a multitude of individual potential chiral selectors can be avoided by employing a selector library. Sublibraries with reduced heterogeneity can be employed to identify the components with the best selector properties. The search for the most efficient selectors is indicated because each component is highly dilute. Yet the use of the whole library may prove beneficial if cooperative effects between the components affect the enantioselectivity.

Capillary electrophoresis with chiral additives in the mobile phase is an efficient technique for separating water-soluble enantiomers in small sample volumes. Enantiomeric resolution has been achieved with proteins such as bovine serum albumin (BSA),[4] orosomucoid,[5] ovomucoid,[6, 7] caseine,[7] and cellulase[8] as well as with cyclic structures such as the macrocyclic antibiotics vancomycin and rifamycin B,[9, 10] crown ethers,[11] and cyclodextrins[12] serving as single chiral selectors. The mechanisms of retention and enantiodifferentiation by proteins and peptides are not yet well-understood.[13] However, the selector systems described here, which are based on cyclopeptides, may provide first hints. Firstly, as the structures of conformationally constrained cyclopeptides in solution can be determined

quickly by two-dimensional NMR spectroscopy, it should be possible to study the mechanisms of chiral recognition on the molecular level in systematic studies. Secondly, cyclopeptide libraries of high molecular diversity can be obtained by including structural variation. For example, by using the nearly 200 commercially available amino acids of defined chirality, $200^6 = 64 \times 10^{12}$ individual cyclohexapeptides are accessible. The number of cyclopeptides can be further increased by varying the ring size and by including nonpeptidic compounds, derivatives with side chain and backbone modifications, and selected building blocks with inverted chirality.

We describe here a new approach to enantiomeric resolution in which highly complex synthetic cyclohexapeptide libraries are used as chiral selectors. Three randomly chosen sublibraries were added to the mobile phase in capillary electrophoresis. These peptide libraries consist of $18^3 = 5832$ individual cyclohexapeptides which are synthesized as a mixture.[14, 15] Each sublibrary has the general formula c(OOXXXO) and is characterized by defined positions (O) and three random positions (X), which represent a mixture of 18 of the genetically encoded amino acids except cysteine and tryptophan. The synthesis of the cyclopeptide libraries is highly reproducible[14] as analyzed by electrospray mass spectrometry.[16–18]

c(DFXXXa): A 10 mM solution of the cyclopeptide library c(DFXXXa) in phosphate buffer (pH 7.4) was used to discriminate between two enantiomeric DNP-amino acids (DNP=2,4-dinitrophenyl) and Tröger's base (Table 1). The separations were performed at 20 kV. Due to very high plate numbers, Tröger's base could be separated with high efficiency despite the low separation factor α, and good resolution R_s resulted (Fig. 1a). The (+) enantiomer eluted first. The enantiomers of DNP-glutamic acid could be separated with higher selectivity and higher resolution R_s (Fig. 1b). The L enantiomer eluted first. The separation factor α of DNP-aspartic acid is lower than that of DNP-glutamic acid and baseline resolution was not achieved (Table 1), again the L enantiomer eluted first.

Table 1. Chromatographic data for the separation of enantiomers using cyclohexapeptide libraries (10 mM) in phosphate buffer pH 7.4 (20 mM); N = plate number.

Selector and selectand	α	R_S	N_1	N_2
c(DFXXXa)				
DNP-glutamic acid	1.05	3.82	40000	88000
DNP-aspartic acid	1.01	1.08	175000	133000
Tröger's base	1.01	2.94	358000	369000
c(RKXXXa)				
DNP-glutamic acid	1.13	7.2	79000	65000
c(RMXXXa)				
Fmoc-glutamic acid	1.04	1.91	22300	9430

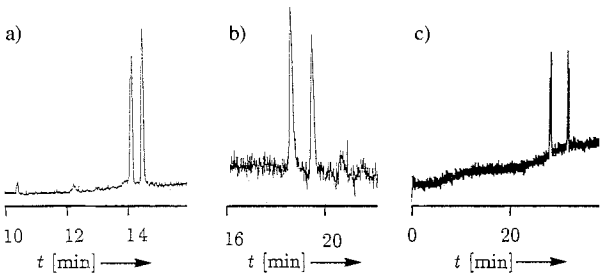

Fig. 1. Enantiomeric resolution of a) Tröger's base with c(DFXXXa), b) DNP-D,L-glutamic acid with c(DFXXXa), and c) DNP-D,L-glutamic acid with c(RKXXXa). Conditions: 10 mM cyclopeptide library c(OOXXXO) in phosphate buffer pH 7.4 (20 mM), capillary 50 µm i.d. × 50 cm effective length, 20 kV for (a) and (b), −10 kV for (c); detection at 260 nm for (a) and 340 nm for (b) and (c).

c(RKXXXa): By using a 10 mM solution of the cyclopeptide library c(RKXXXa) in phosphate buffer (pH 7.4) two enantiomers of DNP-glutamic acid could be separated (Fig. 1c). The experiments wer performed with inverse polarity at −10 kV. The separation factor α is much higher than that with the c(DFXXXa) library, and the resolution R_s is significantly improved (Table 1).

c(RMXXXa): By using a 10 mM solution of the cyclic hexapeptide library c(RMXXXa), separation of the enantiomers of Fmoc-glutamic acid (Fmoc = 9-fluorenylmethoxycarbonyl) was possible. The separation factor α is high, but the resolution R_s is rather low (Table 1). The experiments were performed at −10 kV.

These three examples demonstrate that cyclic hexapeptide libraries dissolved in the electrolyte solution can be used as chiral selectors in capillary electrophoresis. With this approach it may be possible to screen for the most effective selectors for a given enantiomeric resolution. If a mixture proves suitable, the active subunit responsible for efficient chiral separation can be pinpointed by synthesizing sublibraries of lower diversity, and several individual selectors may be precisely defined. Studies along this line are currently in progress.

Experimental Procedure

Apparatus und chemicals: Capillary electrophoresis was performed using the capillary electrophoresis system PRINCE (Bischoff, Leonberg, Germany) and one manufactured by Grom (Herrenberg, Germany), both equipped with on-line UV detectors. The cyclic hexapeptide libraries were synthesized according to ref. [14] and characterized by amino acid analysis and mass spectrometry [15, 16]. One-letter codes for these amino acids: a = D-alanine, D = L-aspartic acid, F = L-phenylalanine, K = L-lysine, M = L-methionine, R = L-arginine, X = all natural amino acids except cysteine and tryptophan. DNP-glutamic acid was purchased from Sigma (Deisenhofen, Germany), Fmoc-glutamic acid from Orpegen (Heidelberg, Germany), Tröger's base from Fluka (Neu-Ulm, Germany), DNP-aspartic acid was prepared according to ref. [19]. Water was purified with a Waters Millipore System Q (Eschborn, Germany).

Preparation of capillary columns and separations: The separations were performed in 50 µm i.d. fused-silica capillaries (Ziemer, Mannheim, Germany) with an effective length of 50 cm and a total length of 67 cm. Solutions of the peptide libraries c(DFXXXa), c(RKXXXa), and c(RMXXXa) (6.6 mg mL^{-1}) were prepared with phosphate buffer (pH 7.4, 20 mM), resulting in a total concentration of 10 mM. The solution was microfiltered (45 µm pore size; Macherey-Nagel, Düren, Germany). The capillaries were pretreated with 0.1 N NaOH for 15 min, then rinsed with water for 10 min and buffer for 10 min. This procedure was repeated after every five runs to remove peptides adsorbed to the wall of the column. Injection was performed hydrodynamically or electrokinetically. Depending on the library investigated, the experiments were carried out at +20 kv or −10 kV. The DNP-amino acids were detected at 340 nm, Tröger's base at 260 nm. The enantiomeric resolution was verified by injection of the pure enantiomers, and the elution order was determined by spiking the racemate with single enantiomers. The separation factor α was determined from $\alpha = t'_{R2}/t'_{R1}$, where t'_{R1} is the migration time of the first and t'_{R2} of the second eluted enantiomer. Water was used as a dead-time maker.

Synthesis and Structure of a Unique Monomeric σ-Bonded Aryllithium Compound Stabilized by a Weak Li–Benzene π Interaction**

Berthold Schiemenz and Philip P. Power*

Alkyl and aryllithium compounds that feature Li–C σ bonds are of major importance in both inorganic and organic chemistry.[1] Their structures[2] may be divided into two broad classes: a) uncomplexed species that are normally observed to have electron-poor, associated, frameworks and b) species complexed to Lewis bases (almost exclusively ethers or tertiary amines) that may have either associated or unassociated structures. The number of structures of organolithium compounds that are complexed by Lewis bases and contain Li–C σ bonds is now quite large,[2] whereas those for uncomplexed LiR species are limited to about a dozen examples[3, 4] most of which are alkyllithium compounds.[3] Many of these structures, for example $(LiiPr)_6$,[3c] $(LinBu)_6$,[3d] $(LitBu)_4$,[3d] and $[LiC(SiMe_3)_3]_2$,[3i] have been reported in a recent surge of interest in this area. In contrast, uncomplexed homoleptic organolithium compounds with lithium–aryl σ bonds have hardly been studied.[4] The only two currently known examples are $(LiTrip)_4$ and $(LiC_6H_3\text{-}2,6\text{-}Mes_2)_2$ (Trip = 2,4,6-$iPr_3C_6H_2$, Mes = 2,4,6-$Me_3C_6H_2$).[5a] In addition, two related, mixed aryllithium/lithium phosphide and aryllithium/alkyllithium complexes $(LiPHMes^*LiMes^*)_2$[5b] and $(LiMes^*LinBu)_2$ (Mes^* = 2,4,6-$tBu_3C_6H_2$),[5a] respectively, have also been structurally characterized. The structures of all these compounds are quite clearly different from those of alkyllithium compounds.[5] A further point of interest is that no monomeric σ-bonded aryllithium or alkyllithium compounds have been structurally characterized in the solid state without coordination of the Li^+ ion by Lewis bases.[2] In this regard we have become interested in the use of very sterically demanding *ortho*-substituted terphenyl ligands[4] in attempts to synthesize the first examples of Lewis base free monomeric organolithium compounds. Here we describe the isolation of two new aryllithium compounds, the dimer **1** (Dipp = 2,6-$iPr_2C_6H_3$) and the benzene-complexed species **2**, which has a unique monomeric structure with a Li–C(aryl) σ bond, stabilized only by steric effects and by the weakly coordinating benzene ligand.

$(LiC_6H_3\text{-}2,6\text{-}Dipp_2)_2$ **1** $C_6H_6\cdot LiC_6H_3\text{-}2,6\text{-}Trip_2$ **2**

Compounds **1** and **2** were synthesized in good yield by treatment of the appropriate aryl iodide with one equivalent of *n*Bu-Li in hexane (see Experimental Procedure). They were characterized by ^1H, ^{13}C, and ^7Li NMR spectroscopy, and X-ray quality crystals were grown from solutions in toluene (**1**) or benzene (**2**). The structures[6] of **1** and **2** are illustrated in Figures 1 and 2, respectively. In **1** each Li^+ ion is bound η^1 to the central phenyl ring of one 2,6-$Dipp_2C_6H_3$ group and η^6 to an *ortho*-Dipp substituent of the other 2,6-$Dipp_2C_6H_3$ aryl ligand. Thus **1** differs structurally from $(LiC_6H_3\text{-}2,6\text{-}Mes_2)_2$,[5a] or $[LiC(SiMe_3)_3]_2$,[3i] which have symmetric C-(μ-Li)$_2$-C bridges. The average Li–C(η^1) distance is 2.068(6) Å, the Li···C(η^6) distances range from 2.366(7) to 2.534(6) Å, and there are no close approaches between the lithium ions and the cocrystallized toluene molecules. The coordination sphere of the lithium ions is slightly distorted: for instance, the angles between the Li–C(*ipso*) bonds and the C(*ipso*)···C(*para*) vectors are 16.7° for Li1 and 21.0° for Li2. In addition, the Li–C(*ipso*) bonds subtend angles of 5.0° and 4.1° to the normals of the aromatic rings that contain C7 and C49, respectively. These distortions are undoubtedly a result of the crowded nature of the dimeric structure.

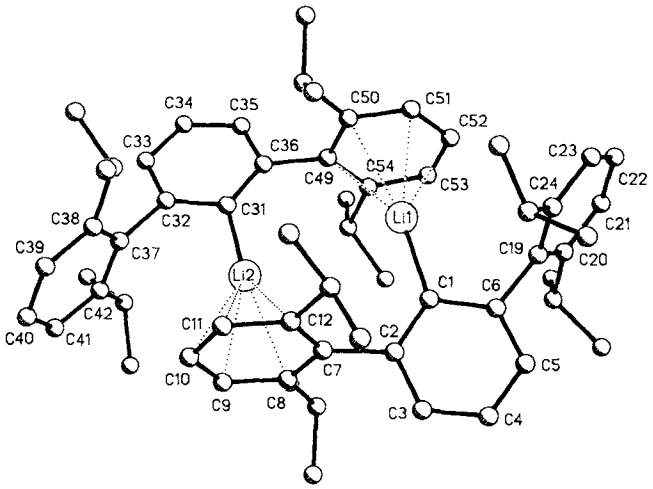

Fig. 1. Crystal structure of **1** (H atoms are not shown). Important bond lengths [Å] and angles [°]: Li1–C1 2.067(6), Li2–C31 2.069(6), Li1···C49–C54 2.534(6), 2.528(6), 2.426(6), 2.372(7), 2.366(7), 2.435(6), Li2···C7–C12 2.526(6), 2.464(6), 2.390(7), 2.385(7), 2.418(6), 2.504(6); C2-C1-C6 113.6(3), C32-C31-C36 113.7(3).

Further examination of the structure of **1** suggested that the presence of *para*-*i*Pr groups on the *ortho*-aromatic ring substituents (e.g. at C10 or C52) would result in steric interactions with the aromatic moieties that contain C37 or C19. This fea-

ture, together with the weakness (vide infra) of the Li–C(η^6) bonds (ca. 2.46 Å), led to the conclusion that the use of *ortho*-Trip rather than *ortho*-Dipp rings might effect dissociation to a monomeric structure. The structure of **2** (Fig. 2) showed that this hypothesis was essentially correct. The lithium ion is bound η^1 to the *ipso*-carbon atom of the 2,6-Trip$_2$C$_6$H$_3$ group and has an Li–C1 distance of 2.03(2) Å, which is identical to the corresponding distance found in the vapor phase structure of monomeric LiCH(SiMe$_3$)$_2$.[3h] The lithium ion is also bound η^6 to a benzene solvent molecule with an average Li···C distance of 2.35(2) Å. The C–C bonds in the benzene ring are 1.42(2) Å.

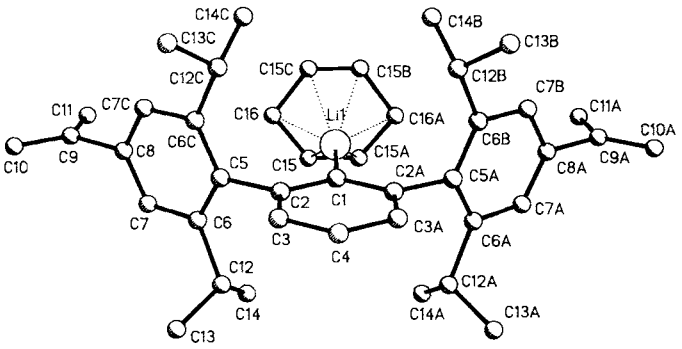

Fig. 2. Crystal structure of **2** (H atoms are not shown). Important bond lengths [Å] and angles [°]: Li1–C1 2.03(2), Li1···C15 2.36(2), Li1···C16 2.33(2), C15–C16 1.42(2); C2-C1-C2a 115.0(9).

Compound **2** is the first instance of an organometallic species in which a Li$^+$ ion interacts with a free benzene molecule in an η^6 fashion.[7] Although η^6 coordination between benzene or neutral, benzene-like rings, is well established for various main group ions[8] and the heavier alkali metals,[9, 10] it is rare for lithium and is only observed when a chelating arrangement of aromatic rings is present as, for example, in LiMesBCB(Mes)-[CH(2,3,5,6-Me$_4$C$_6$H)]$_2$[11] or [{LiN(Mes)}$_2$SiMe$_2$]$_2$,[11b] where the Li···C distances fall within the narrow range between 2.32 and 2.39 Å (cf. 2.46 Å observed in **1**).

The most important feature of the structure of **2** is not the η^6 coordination of the Li$^+$ ion with benzene, however. The structure is unique owing to the fact that it is the first example of a monomeric σ-bonded organolithium species in the solid state that is stabilized only by steric effects and by weak solvation. Thus far it has not been possible to detect the Li–η^6(aryl) complexation in either **1** or **2** by ^{1}H or ^{13}C NMR spectroscopy. The addition of Et$_2$O to **1** or **2** results in the displacement of the Li···C(η^6) ring interactions and the formation of 1:1 complexes. The species Et$_2$OLiC$_6$H$_3$-2,6-Trip$_2$ is monomeric and has been structurally characterized.[12]

In summary, the novel structure of **2** shows that monomeric organolithium species can be obtained in the solid state by using sterically demanding and weakly solvating ligands (or solvents). Moreover, the Li–C bond length in **2** is identical to the Li–C distance in LiCH(SiMe$_3$)$_2$, which contains a one-coordinate lithium ion and whose structure has been determined in the vapor phase.[3h] These results are consistent with relatively weak solvation by benzene.

Experimental Procedure

All manipulations were carried out under anaerobic and anhydrous conditions. The synthesis [12] of 2,6-Dipp$_2$C$_6$H$_3$I and 2,6-Trip$_2$C$_6$H$_3$I were carried out by modification of the procedure for 2,6-Mes$_2$C$_6$H$_3$I [13].

1: Finely powdered 2,6-Dipp$_2$C$_6$H$_3$I (2.70 g, 5 mmol) was dissolved in hexane (50 mL) and the solution was cooled to −15 °C and then treated with *n*BuLi (3.13 mL, 5 mmol of a 1.6 M solution in hexane). The solution was allowed to warm slowly to room temperature over 6 h and then stirred for a further 8 h. A colorless precipitate of **1** was formed that was allowed to settle. The solvents were removed by cannula, and the product was washed with hexane (10 mL) and dried under reduced pressure. Yield: 1.90 g (94%); m.p. 182–185 °C (decomp.). ^{1}H NMR (C_6D_6): δ = 1.125 (d, 12H, *o*-CH(CH_3)$_2$), ^3J(H,H) = 6.9 Hz, 3.21 (sept, 2H, *o*-CH(CH$_3$)$_2$), ^3J(H,H) = 6.9 Hz, 6.95–7.3 (m, several aromatic H). ^{13}C NMR (C_6D_6): δ = 24.17 (*o*-CH(CH_3)$_2$), 25.02 (*o*-CH(CH_3)$_2$), 30.02 (*m*-CH(CH$_3$)$_2$), 122.41 (*m*-Dipp), 122.70 (*m*-Ph), 123.25 (*p*-Ph), 125.84 (*p*-Dipp), 146.33 (*i*-Dipp), 147.11 (*o*-Dipp), 150.26 (*o*-Ph). ^{7}Li NMR (C_6D_6): δ = −4.08. Colorless crystals of **1** suitable for X-ray crystallography were obtained by dissolving the colorless powder in toluene (20 mL), reducing the volume to about 10 mL, and cooling in a freezer for 3 days at −20 °C. Yield: 1.53 g (68%).

2: Finely powdered 2,6-Trip$_2$C$_6$H$_3$I (2.43 g, 4 mmol) was suspended in a mixture of benzene (5 mL) and hexane (50 mL), and the mixture was cooled to −15 °C and then treated with *n*BuLi (2.5 mL, 4 mmol of a 1.6 M solution in hexane) with rapid stirring. The solution was allowed to warm to room temperature over 6 h and then stirred for a further 4 h. The finely divided suspension was allowed to settle and the supernatant liquid was removed by cannula. The colorless precipitate was dissolved in benzene (50 mL) to give a pale yellow solution. Filtration, concentration to incipient crystallization at 50 °C, and slow cooling to about 10 °C in a refrigerator yielded 1.4 g (62%) of large colorless plates of **2**. M.p. 174–176 °C (decomp.). ^{1}H NMR (C_6D_6): δ = 1.14 (d, 12H, *p*-CH(CH_3)$_2$, ^3J(H,H) = 6.9 Hz, 1.22 (d, 12H, *o*-CH(CH_3)$_2$), $^3J_{HH}$ = 6.9 Hz, 1.37 (d, 12H, *o*-CH(CH_3)$_2$), ^3J(H,H) = 6.9 Hz, 2.95 (sept, 2H, *p*-CH(CH$_3$)$_2$), ^3J(H,H) = 6.9 Hz, 3.24 (sept, 4H, *o*-CH(CH$_3$)$_2$), ^3J(H,H) = 6.9 Hz, 7.15 (s, C_6H_6), 7.16 (s, 4H, *m*-Trip), 7.19 (d,2H, *m*-Ph), ^3J(H,H) = 6.6 Hz, 7.29 (t, 1H, *p*-Ph), ^3J(H,H) = 6.6 Hz. ^{13}C NMR (C_6D_6): δ = 24.30 (*o*-CH(CH_3)$_2$), 24.80 (*p*-CH(CH_3)$_2$), 25.07 (*o*-CH(CH_3)$_2$), 30.10 (*o*-CH(CH$_3$)$_2$), 34.95 (*p*-CH(CH$_3$)$_2$), 119.96 (*m*-Trip), 122.49 (*m*-Ph), 123.16 (*p*-Ph), 128.53 (C_6H_6), 145.76 (*i*-Trip), 146.67 (*o*-Trip), 147.96 (*p*-Trip), 150.40 (*m*-Ph), 177.89 (*i*-Ph). ^{7}Li NMR (C_6D_6): δ = −3.97.

[4] The structures of a large number of uncomplexed aryllithium salts of cyclic compounds with anionic delocalized π-electron systems and Li–C π interactions have been reported. None of these have involved Li–C σ bonding to the aromatic ring, however. See ref. [2] for further discussions.

[5] The structures of (LiTrip)$_4$, (LiC$_6$H$_3$-2,6-Mes$_2$)$_2$ and the mixed alkyl/aryllithium compounds (LiMes*Li*n*Bu)$_2$ are described in the following: a) K. Ruhlandt-Senge, J. J. Ellison, R. J. Wehmschulte, F. Pauer, P. P. Power, *J. Am. Chem. Soc.* **1993**, *115*, 11353. The compounds display a variety of σ and π interactions with the aryl groups. The (LiTrip)$_4$ and (LiMes*Li*n*Bu)$_2$ (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$) structures feature almost planar Li$_4$ arrays (cf. tetrahedral Li$_4$ arrays in (LiMe)$_4$, (LiEt)$_4$, and (Li*t*Bu)$_4$). In contrast, the structure of (LiC$_6$H$_3$-2,6-Mes$_2$)$_2$ is dimeric with Li–C interactions involving only the *ipso*-carbon atoms of the central and mesityl aromatic rings. The structure of the mixed lithium phosphide/aryllithium compound (LiPHMes*LiMes*)$_2$ also displays η^1-P/η^6-C and η^1-C/η^6-C coordination modes similar to these compounds; b) S. Kurz, E. Hey-Hawkins, *Organometallics* **1992**, *11*, 2729.

[6] Crystal data for $1 \cdot C_7H_8$ and **2** ($T = 130$ K, $Cu_{K\alpha}$ ($\lambda = 1.54178$ Å): $1 \cdot C_7H_8$, $C_{67}H_{82}Li_2$, $M = 901.2$, $a = 19.906(6)$, $b = 18.120(6)$, $c = 17.251(4)$ Å, $\beta = 114.49(2)°$, monoclinic, $Z = 4$, space group $P2_1/c$, R = 0.074 for 5758 ($I > 2\sigma(I)$) data; **2**, $C_{42}H_{50}Li$, $M = 561.76$, $a = 10.929(2)$, $b = 14.097(3)$, $c = 24.581(5)$ Å, orthorhombic, $Z = 4$, space group $Cmcm$, $R = 0.102$ for 1379 ($I > 2\sigma(I)$) data. Compound **1** has no crystallographically imposed symmetry and crystallized with a disordered toluene molecule (0.5:0.5 occupancy in two orientations) in each asymmetric unit. The data for **2** require that the molecule has two mirror planes at right angles to each other along the C(1)—C(4) axis, one of which contains the plane of the C(1) ring. Crystals of **2** undergo phase changes and/or crack upon cooling below about −20 °C. They also desolvate, and this behavior, along with the disorder in the *para*-*i*Pr groups resulted in a data set that was not of the very highest quality (cf. high thermal parameters for some atoms and $R = 0.102$). Nonetheless, the structure quality is more than sufficient to substantiate the arguments made. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-80. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[7] Some Li–C, σ-bonded, organoalkali metal salts that can be obtained from solutions in benzene may contain benzene of crystallization or benzene that has weak η^1–η^2 (but not η^6) interactions with the metal. An early example of such a species is the classic structure of cyclohexyllithium [3f], which crystallizes as the hexamer $(C_6H_{11})_6 \cdot 2C_6H_2$, and contains two benzene molecules of crystallization.

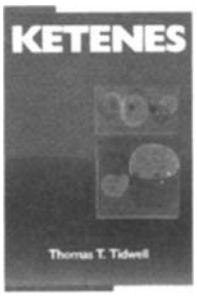
Everything You Wanted to Know about Ketenes but Were Afraid to Ask

Ketenes. By *T. T. Tidwell*. Wiley, New York, 1995. 665 pp., hardcover £ 70.00.–ISBN 0-471-57580-1

Following earlier works on ketenes, notably the classic monograph by Staudinger (1912) and the well-known reviews by Patai (1964 and 1980) and in Houben-Weyl (1968 and 1993), we now have a new up-to-date monograph by Tidwell. The first part (51 pp.) is concerned with the structure, bonding, and thermochemistry of ketenes. Aspects covered in the first chapter include orbital treatments and the latest ab initio methods, and energy calculations related to protonation, substituent effects, and stabilization of fulvenones and fulvenes, with detailed tables where appropriate. This is followed by a chapter on structure determination, in which experimentally determined bond lengths and angles are compared with calculated values. Tables giving CC, CO and CF bond lengths and angles optimized by HF/6-31G* calculations are included. These are followed by spectroscopic and physical data, including ^{13}C and ^{1}H NMR data for a large number of ketenes (and some recently measured ^{17}O chemical shifts), data from UV and photoelectron spectra, and IR spectra (including tables comparing observed and calculated CO band positions). The chapter ends with data on dipole moments, mass spectra, and gas-phase ion chemistry, including some very recent results.



The second part (47 pp.) describes the preparation of ketenes, starting with the classical synthetic routes. In addition to the best known routes (thermolysis of diketenes, pyrolysis of carboxylic acids and anhydrides, and the methods starting from acyl halides, esters, α-halogenated carboxylic acids, or diazoketenes), the author describes recently developed photochemical and thermolytic methods, and syntheses starting from alkenylcarbene-metal complexes.

The following section is the longest (294 pp.), and contains detailed descriptions of all types of ketenes, with numerous tables listing the methods of preparation, CAS numbers, and key literature references. The types of compounds covered include C-substituted ketenes (substituents: aryl, alkyl, alkenyl, alkynyl, cyano, cyclopropyl, acyl, imidoyl, cumulenyl, and fulvenones), N-, O-, and halogen-substituted ketenes, Si-, Ge-, Sn-, P-, As-, S-, and metal-substituted ketenes, bisketenes, ketenyl radicals, anions, and cations, and lastly cumulenones. The value of the book lies largely in this important central part.

The last part (211 pp.) deals with the reactions of ketenes (oxidations, reductions, photochemical and thermolytic reactions, nucleophilic and electrophilic additions to ketenes, free radical reactions, and polymerizations. As expected, considerable space is given to cycloaddition reactions of ketenes, with particular emphasis on the [2+2]-cycloadditions originally discovered by Staudinger, the [3+2]- and [4+2]-cycloadditions, and intramolecular cycloadditions, e.g. involving the carbonyl groups. The preparative methods described are accompanied by semiempirical and ab-initio calculations, discussions of the role of transition states, and stereochemical considerations. A separate subsection (5.4.1.3) is devoted to the mechanism of the addition of ketenes to alkenes; this includes tables listing rate constants for the reaction, and results from MP2/6-31G* and AM1 calculations of the transition states. The chapter ends by describing cycloadditions to N = N, N = O and N = S = O groups. 1,3-Dipolar and [4+2]-cycloadditions offer a route to many interesting types of heterocycles with a variety of applications. Intramolecular cycloadditions are attracting growing interest as novel synthetic stages, and have been discussed in three recent reviews containing recent examples of their use. The section of this book on nucleophilic additions includes a useful discussion of theoretical aspects (calculations of energy profiles and of hydration kinetics). Wittig reactions of ketenes yield allenes. Aza-Wittig reactions are only mentioned briefly, and it would have been useful to give more references on these.

I found very few errors in the monograph. It is definitely recommended, especially for its treatment of theoretical ideas and for the central chapter on the different types of ketenes with many informative tables. It lists over 2500 literature references, which are arranged in a clear and readily accessible form under the individual section headings. The index is rather meager, and it could have been enlarged to great advantage by filling the six blank pages at the end of the book. The structural formulas drawn by Pat Woodcock are large and clear; however, they are not always accurate, and the use of different styles of formulas and standards within a scheme is rather clumsy and inappropriate for a book in this price class, especially since better formula-drawing programs than ChemDraw are now available (e.g., ChemWindow).

To summarize, by its lucid, well-written, and well constructed presentation this book provides a quickly assimilable and authoritative introduction to, and up-to-date treatment of, the chemistry and theoretical aspects of ketenes. It can be thoroughly recommended for everyone involved in academic or industrial research with an interest in this class of compounds.

Heinrich Wamhoff
Institut für Organische Chemie
und Biochemie

Bonn (Germany)

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

Diazo Chemistry II. Aliphatic, Inorganic and Organometallic Compounds. By *H. Zollinger*. VCH Verlagsgesellschaft, Weinheim, 1995. 522 pp., hardcover DM 198.00.—ISBN 3-527-29222-5

Part II of this splendid monograph by Heinrich Zollinger covers aliphatic, inorganic, and organometallic diazo compounds, and, as the author explains in the introduction, its publication alongside Part I (aromatic and heteroaromatic diazo compounds) now brings together the long separated "sisters and cousins". It can be said at the outset that these two volumes certainly belong together, and the combined work is undoubtedly one of the best ever surveys of the many and remarkably varied aspects of diazo compounds.

The structure of Part II closely follows that of Part I; the author avoids unnecessary repetition of the general discussions in Part I while also not assuming too much prior knowledge. The 11 chapters treat every aspect of the chemistry of the compounds defined in the title, with comprehensive coverage of the literature up to the fall of 1994, supplemented by extensive footnotes referring to more recent work.

Chapter 1 (10 pp.) briefly outlines the history of developments in aliphatic diazo compounds and explains the recommended system of nomenclature. Chapter 2 (84 pp.) contains a very thorough and precise description of existing methods for preparing such compounds together with discussions of alternative possibilities. The author first explains the general principles of the preparative methods, then describes each individual method in turn with many examples. The methods based on diazo transfer reactions are treated especially thoroughly.

In Chapter 3 (25 pp.) inorganic diazo compounds are treated in greater detail, with special emphasis on metal complexes with N_2 ligands and diazo derivatives of boron hydrides. This chapter also includes a concise and informative survey of the chemistry of nitrogen fixation.

Chapter 4 (23 pp.) and Chapter 5 (45 pp.) are concerned with mechanistic and kinetic aspects of "aliphatic" diazotization reactions. Topics discussed include the nitrosylation of alkyl amines, the mechanisms involved in the diazoalkane synthesis, the carcinogenicity of *N*-nitrosamines, and the structure of aliphatic diazo compounds. On the latter topic there is a useful critical discussion of the large amount of spectroscopic data and theoretical results on this class of compounds, which is not available elsewhere in such a concise form.

As one expects, much space is devoted to the reactions of aliphatic diazo and diazonium compounds. Chapter 6 (49 pp.) deals with reactions in which the N_2 fragment remains intact. Here the author devotes special attention to 1,3-dipolar cycloadditions, and gives convincing evidence of the great potential value of such reactions for organic synthesis. Chapter 7 (64 pp.) discusses the often complicated situations that occur in dediazotization reactions involving diazonium intermediates. The mechanistic aspects of deamination and its synthetic applications are explained in precise detail.

The large and important group of dediazotization reactions that proceed via carbenes and carbenoids are treated in Chapter 8 (77 pp.). In discussing every aspect of the reactions of diazo compounds of carbenes the author again presents an amazing wealth of information. As well as the classical applications in organic synthesis (including the Wolff rearrangement and the Arndt-Eistert synthesis) the chapter covers recent developments such as the addition of diazo compounds to fullerenes and applications in enantioselective syntheses. The part of the book concerned with reactions is completed by Chapter 9 (37 pp.), which collects together various other reactions of aliphatic diazo compounds, such as electrophilic and nucleophilic substitutions at the α-carbon atom, electron transfer processes, and redox reactions.

In Chapter 10 (34 pp.) the author discusses the complexation of diazonium and diazo compounds with main-group and transition metals. Here one is again impressed by the comprehensive nature of this monograph. Chapter 11 is an epilog in which the author rounds off the two-volume work on diazo compounds with a broad survey of the historical development, extending from the original discovery by Peter Griess to the organometallic diazo compounds. The book is completed by a list of literature citations and a very comprehensive index, which facilitates using the work as a reference source.

In common with the first part (*Diazo Chemistry I*) this second volume too is a must for all chemists with an interest in diazo compounds, and their personal libraries should include both volumes. Moreover, the excellent presentation of the contents and the high standard of writing make both books a pleasure to read.

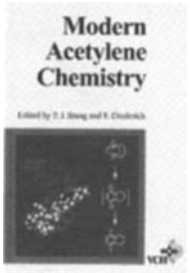
Modern Acetylene Chemistry. Edited by *P. J. Stang* and *F. Diederich*. VCH Verlagsgesellschaft, Weinheim, 1995. 506 pp., hardcover DM 168.00.—ISBN 3-527-29084-2

This book fills a gap that has existed for about twenty years. Everyone who has observed and experienced the renaissance of acetylene chemistry during the past 10–15 years has been aware of the lack of a comprehensive source of information on the subject.



The editors of the book, both of whom have themselves made important contributions to acetylene chemistry, have succeeded in persuading nearly every prominent researcher in the field to contribute an article, with the result that practically all modern aspects of compounds containing triple bonds are discussed. In the introductory chapter D. A. Plattner, V. Li, and K. N. Houk describe the latest developments in the theoretical treatment of acetylenes, diacetylenes, polyacetylenes, and linear and cyclic C_n species with *n*-values from 2 to 18. Other articles report on cyano- and halogen-substituted acetylenes (Ch. 2, H. Hopf and B. Witulski), alkynyl-iodonium salts (Ch. 3, P. J. Stang), and phosphaalkynes (Ch. 6, M. Regitz, A. Hoffmann, and U. Bergsträsser). The synthesis and reactive properties of the alkynyl-iodonium salts are treated very comprehensively, whereas in Chapters 2 and 6, after describing the synthesis of the compounds and their general reactive properties, attention is concentrated on a few special areas, such as the reaction of cyanoacetylenes with cyclophane derivatives, the use of iodoacetylenes in natural products syntheses, and the reactions of phosphaacetylenes yielding phosphorus-carbon cage compounds. Chapter 4, by G. G. Melikyan and K. M. Nicholas, is a general survey of the synthesis and reactions of metal-alkyne-π-complexes. The binuclear dicobalt-hexacarbonyl-alkyne complexes and the corresponding propargylium complexes that are described here also appear again in other chapters as synthetic building blocks. For example, the former are used in the Pauson–Khand reaction for synthesizing cyclopentenones from alkynes, alkenes, and carbon monoxide, as described in thorough detail by J. A. Casalnuovo and N. E. Schore in Chapter 5. The first part of this chapter

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3518-2154 $ 15.00+.25/0

deals with the reactions of alkynes with Fischer carbene complexes (including the Dötz reaction), which yield naphtholes, indenes, cyclobutenones, cyclopentenones, and other compounds. Chapter 7 contains a detailed survey of the "new" enediyne antibiotics, whose effectiveness depends on the Bergman cycloaromatization reaction. The diradicals formed in this reaction abstract hydrogen atoms from specific sites in the DNA. This leads to the break-up of the DNA single strand, or even of the double strand, and finally to the death of the cell. K. C. Nicolaou and A. L. Smith, discuss the structures and modes of action of the compound classes known up to now, and describe several total syntheses and some extensive studies aimed at preparing synthetic analogs. In Chapter 8 R. Gleiter and R. Merger report on the synthesis of strained cyclic alkynes and polyynes and discuss how the strain in these compounds affects their spectroscopic properties and reactivities. Of special interest here are the transannular reactions and the formation of superphanes by complexed cyclobutadienes. Chapter 10 on "Polyacetylenes" (E. J. Ginsburg, C. B. Gorman, R. H. Grubbs) and Chapter 11 on "Acetylenic Compounds as Building Blocks for High-Spin Molecules and Molecular Assemblies" (H. Iwamura, K. Matsuda) are of special interest to materials scientists.

The remaining three chapters treat various types of triple-bonded compounds in a systematic sequence that strikes one as almost playful. L. T. Scott and M. J. Cooney describe the synthesis of macrocyclic polyynes in which the acetylene and butadiyne units are separated by isopropylidene or cyclopropylidene groups. Other compounds of this general type have different bridging groups: sulfide, *tert*-butylphosphinediyl, or dimethylsilanediyl. In Chapter 12 J. K. Young and J. S. Moore describe their strategy for preparing dendrimers and macrocycles of phenylacetylene. In these each acetylene unit is flanked by two benzene rings, which in turn are linked at the *meta* and *para* or at the *meta* and *meta'* positions to continue the acetylene chain. For reasons of solubility the dendrimers have 3,3'-di-*t*-butylphenyl groups at the ends of the branches. In the ring compounds the continuation of the chain can also take place from the *ortho* positions of the flanking phenyl groups. In the last chapter F. Diederich begins by describing his three syntheses aimed at approaching as nearly as possible to the compounds cyclo-C_{18}, cyclo-C_{24}, and cyclo-C_{30}. This is followed by his syntheses of tetraethynylethenes, in which the four acetylenic end-groups are either protected by silyl groups or have their protection selectively removed. It is thus possible by a Glaser-Hay coupling reaction to prepare perethynylated dehydroannulenes, expanded radialenes, and oligomeric diyne chains.

As can be seen from this selection of topics, which is far from exhaustive, the book covers practically all aspects of current developments in acetylene chemistry (although this reviewer would have liked to see a contribution from K. P. C. Vollhardt also included). Twelve of the chapters fit fairly well into the overall scheme of the book—the only exception is the article on the enediyne antibiotics. Notwithstanding the great interest that this class of compounds holds for chemists and medical scientists, one must question whether the many approaches to their synthesis, even including, for example, that of the sugar fragment in some enediyne antibiotics, really belongs in a book on acetylenes. Despite the large number of authors the individual articles are very consistent in style, presumably because of clear guidance by the editors. In each chapter a brief introduction is followed in turn by information on synthesis, properties, and reactions. The chapter ends with additional comments (usually descriptions of a number of experiments), followed by an extensive collection of references, which also affords access to earlier work on other aspects of acetylene chemistry that are not covered in the main text.

The book is handsomely produced with a cover design showing – in a model – an enediyne antibiotic molecule entering a fold in the DNA strand, alongside a formula scheme for the Bergman cycloaromatization. There are very few printing errors that annoy one (example: in Table 8-3 the transannular distance is given as 2.09 Å instead of 2.909 Å). However, the author index needs to be thoroughly revised, as it lists only authors who are mentioned in the text, with the result that, for example, Nicolaou appears three times (including, exceptionally, the page number of his contribution to the work), whereas Regitz appears only once and Gleiter not at all.

However, this minor criticism certainly does not detract from the value of the book. It should be on every acetylene chemist's bookshelf, and will be an indispensable source for preparing lectures in advanced chemistry courses.

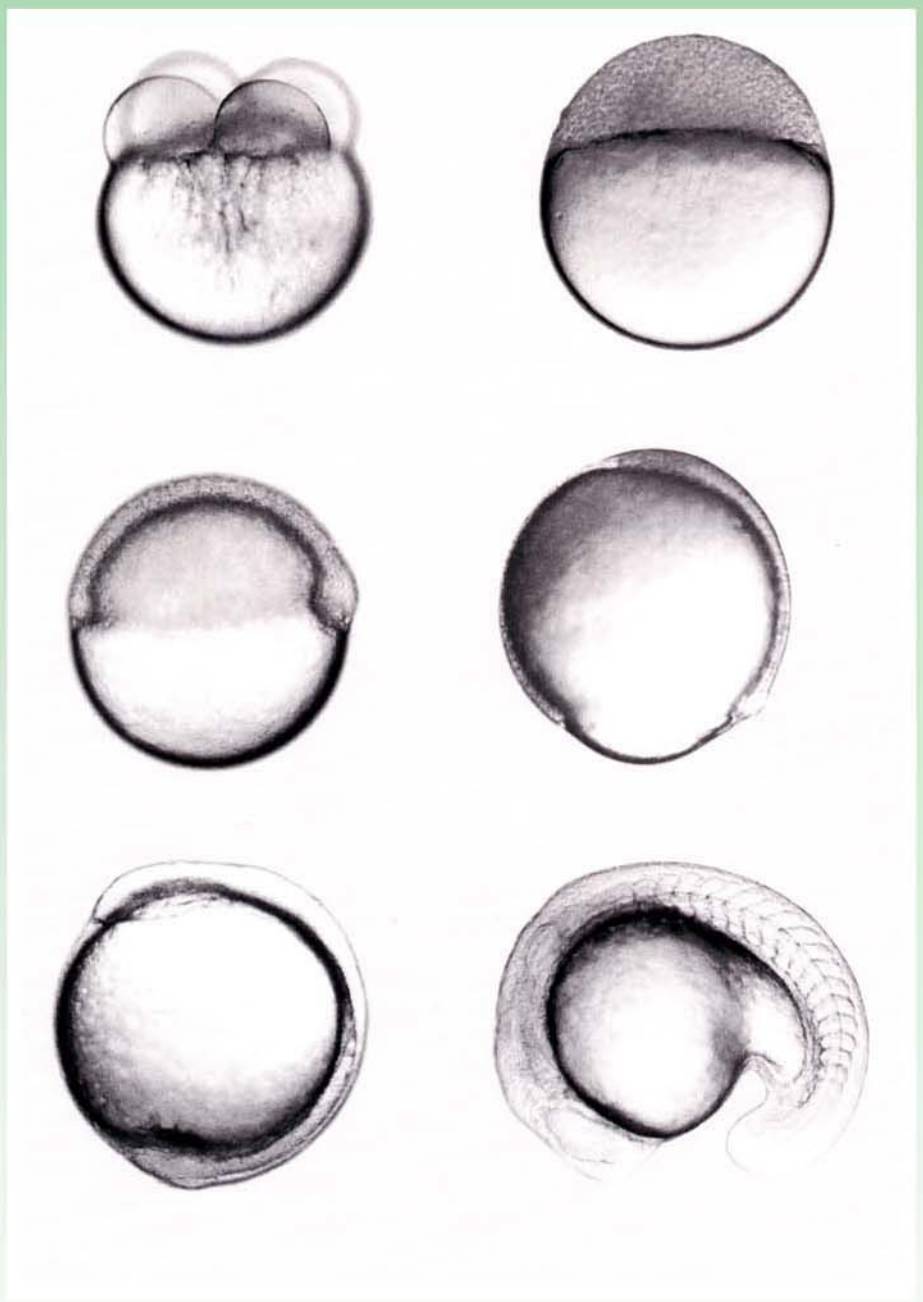
Embryogenesis of zebra fish up
to an age of 19 hours



Studies of embryonic development

The Identification of Genes Controlling Development in Flies and Fishes (Nobel Lecture)**

Christiane Nüsslein-Volhard*

In the life of animals, complex forms alternate with simple ones. An individual develops from a simple one-celled egg that bears no resemblance to the complex structure and pattern displayed in the juvenile or adult form. The process of embryonic development, with its highly ordered increase in complexity accompanied by perfect reproducibility, is controlled by a subset of the animal's genes. Animals have a large number of genes. The exact number is not known for any multicellular organism, nor is it known how many and which are required for the development of complexity, pattern, and shape during embryogenesis. Identifying these genes and understanding their functions is a major issue in biological research.

Genes can be detected by mutations, changes that affect their function. Compared with other experimental approaches, mutations provide a uniquely powerful tool for studying the role of individual components in development. Primarily, only a single component, the gene product, is removed or altered, while the remainder of the organism is left intact. The function of a gene can be deduced from the mutant phenotype, the way the animal develops in the absence of the primary gene product. The mutant phenotype provides most useful information about a gene function. Genes with similar phenotypes are likely to have similar functions, and their products are likely to cooperate in a developmental process.

Mutations occur spontaneously at a low rate, but their frequency can be increased by application of X-rays or chemicals that alter the DNA sequence. This property was first used to systematically score for mutations affecting processes of interest in bacteria and fungi.[1-3] Mutations affecting developmental processes had been collected in *Drosophila melanogaster* more or less fortuitously, starting with the bithorax mutation by Bridges in 1922.[4] In addition, a small number of embryonic mutants including *notch* had been described in detail by D. Poulson and collaborators.[5] In the 1970s, more systematic approaches were started. In the nematode *Caenorhabditis elegans* screens were begun by S. Brenner for mutations that alter the stereotyped pattern of postembryonic development.[6] E. Lewis at the California Institute of Technology collected a number of mutations causing homeotic transformations in the adult and the larva of *Drosophila*.[7] In 1979, Eric Wieschaus and I, at that time at the European Molecular Biology Laboratory (EMBL) in Heidelberg, had developed methods for the large-scale screening for embryonic lethal mutations in *Drosophila*. The screening procedure focused on the segmented pattern of the larval epidermis.[8] In this and subsequent screens, a number of new genes acting in the embryo and required for the formation of a morphologically normal larva were discovered.[9-11] Similar screens in several laboratories have led to the identification of genes that are expressed by the maternal genome, and whose products, laid down in the unfertilized egg, control the expression of the zygotic genes.[12-16] The subsequent phenotypic analysis and molecular cloning of many of these genes, and investigation of the interactions of their products, resulted in a rather complete general picture of the mechanisms establishing the anteroposterior and the dorsoventral axis of the early embryo.[17-19] These mechanisms now provide a useful paradigm for the development of complexity from a simply shaped egg cell.

Drosophila is a fly and as such has rather special properties. It is no more or less "special" than a worm or a frog, but in many respects very different from those animals. Therefore it was not clear a priori to what extent the results obtained with *Drosophila* could be generalized, and how much we could learn from them for an understanding of the development of other animals, in particular, vertebrate species. Knowledge of vertebrate embryogenesis had been collected predominantly in experiments with frogs[20] and chickens, but only to a very limited extent by genetic approaches. Because of the small size and the turgor under which *Drosophila* embryos develop, transplantation of tissues as done in frogs and chickens is hardly possible in *Drosophila*, and the power of systematic mutant searches for the analysis of complex processes, although highly desirable, cannot readily be applied to most vertebrates. Therefore, the description and understanding of the development of animals from the two phyla—arthropods with *Drosophila*, and vertebrates with frogs and chickens, mice and man—were on such different levels that for a long time a comparison seemed almost pointless. However, the development of recombinant DNA technology and with it the cloning of genes on a large scale allowed a comparison of genes from different organisms on the basis of DNA (or protein) sequences. Two most important findings emerged from these studies:

1. The biochemical function of *Drosophila* gene products, in many cases, could be deduced from a comparison of their amino acid sequences with those of related and well-characterized proteins from other organisms such as mammals, bacteria, and yeast. This revealed that many of the components controlling development are members of well-known classes of proteins, such as transcription factors, protein kinases, and secreted signaling molecules or receptors.

2. In many instances, the similarity between *Drosophila* and vertebrate proteins was found not to be restricted to their biochemical properties, but to extend to a true homology of function in a developmental process. This homology is apparent both in similar expression patterns and in the phenotypes obtained by eliminating the gene function by homologous recombination in mice. These studies lead to the surprising conclusion that the basic features of body organization, such as specification along the anteroposterior axis and polarity of gastrulation, are apparently conserved in organisms of different animal phyla.[21, 22] This conservation suggests the existence of a common basic body plan, originating from common evolutionary ancestors, the first bilaterally symmetrical organisms.

The investigation of genes discovered by their homology to *Drosophila* genes is now one of the most successful approaches to understanding the genetic control of vertebrate development. Although the elegant method of homologous recombination in the mouse allows the introduction of mutations into the chromosomal copy of any previously cloned gene,[23] there is no way of predicting which genes are indispensable in development and will therefore give an informative phenotype in "knock out" mice. An important reason for the success of the homology approach is based on the fact that the *Drosophila* genes in question represent a small fraction of the animal's genes, which were selected, through mutagenesis experiments, as being crucial and indispensable in development. Their vertebrate homologs often also have unique functions, as revealed in the mouse.[24]

Approaches based on the homology between invertebrate and vertebrate genes focus on conserved properties and therefore select against the features that make these animals different. Vertebrates have acquired specific structures and novel mechanisms during evolution. In order to identify genes affecting such functions, it is necessary to conduct mutagenesis screens directly in a vertebrate organism. Therefore, several laboratories have established methods for using the zebra fish as a model organism to analyze the genetic control of embryonic development in a vertebrate.[25–28]

In this lecture I would like to discuss the *Drosophila* screens and their most important results as well as their limitations. I will compare them with the results of a large-scale screen for mutations affecting development and pattern in the zebra fish recently performed in my laboratory in Tübingen.[29]

The *Drosophila* Mutant Screens

As a model organism for genetic studies of development, *Drosophila* has a long tradition and is by far the best established organism available.[30] Also, it proved to be quite well-suited for studying embryology. Some properties of *Drosophila* are listed in Table 1. Its small number of chromosomes enabled the development of many genetic tools such as balancer chromosomes carrying multiple inversions which prevent recombination, visible markers that allow the scoring for the absence or presence of particular progeny, and conditional lethal or sterile mutations making selection systems possible. These tools were invaluable in systematic mutagenesis screens for mutations causing lethality or sterility (Fig. 1). In combination with the giant chromosomes that provide a physical measure for the number of genes, it is possible, in *Drosophila*, to determine rather accurately the

Table 1. Properties of *Drosophila melanogaster* and *Danio rerio* for genetic and embryological research.

	Drosophila	*Danio*
Adult size	4 mm	40 mm
Space requirement	1000 per liter	10 per liter
Generation time	14 days	3 months
Lifetime	6 weeks	1–2 years

Advantages for embryological research	mechanical hatching cuticle preparations external segmentation	external fertilization synchronous development optically clear embryo

Christiane Nüsslein-Volhard began her academic career with a degree in biochemistry. Following studies of transcription in bacteria, she directed her attention in the mid-1970s at the University of Basel (Switzerland) to studies of the fruit fly Drosophila. In 1978 she worked together with Eric Wieschaus as group leaders at the European Molecular Biology Laboratory in Heidelberg (Germany), where they studied genes affecting embryological patterning. For the past ten years C. Nüsslein-Volhard has been Director of the Department of Genetics at the Max Planck Institute for Developmental Biology in Tübingen (Germany). In 1995 she received the Nobel Prize for Physiology and Medicine along with Eric Wieschaus and the geneticist Edward B. Lewis.

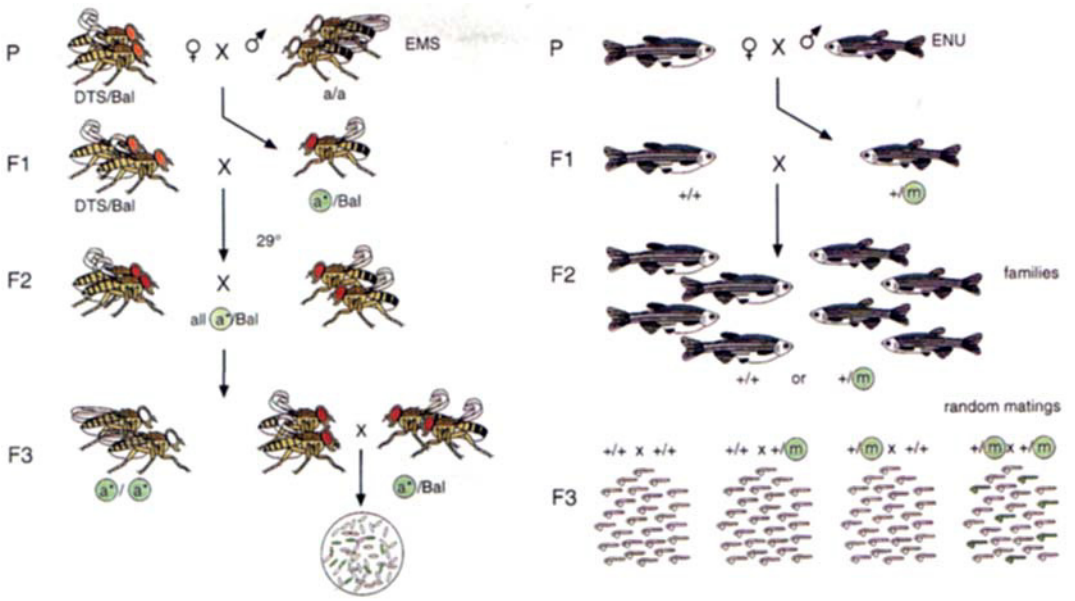

Fig. 1. Crossing schemes for isolating mutants with embryonic visible phenotypes in *Drosophila melanogaster* (left) and *Danio rerio* (right). EMS: treatment of sperm with ethyl methyl sulfonate, ENU: treatment of spermatogonia with ethylnitroso urea, DTS: dominant temperature-sensitive, Bal: balancer chromosomes. In *Drosophila*, eye colors and wing shape are markers used to distinguish carrier animals from noncarriers, which are inevitably produced in the crosses required for inbreeding. They also are useful for determining whether a lethal mutation was induced (absence of white-eyed progeny in the F3 generation). Marking and selecting systems, such as balancers, recessive mutations, and dominant temperature-sensitive mutants, useful for selection, are available for each major chromosome, but it is not easy to do screens for the entire genome all at once, because the multitude of markers significantly affects viability. *Drosophila* larvae hatch mechanically, a process that is very sensitive to perturbations. A large fraction of lethal mutations prevent hatching, although most of them do not visibly affect the embryonic pattern. Mutant embryos can be separated as unhatched from their normal siblings. In the zebra fish, the large number of chromosomes makes the development of marking systems impracticable. Instead, the entire genome is scored at once, and in each generation, carriers must be recognized by the production of mutant progeny with a visible phenotype. Mutations causing lethality without a visible mutant phenotype cannot readily be detected. In the F3 generation, only a quarter of the crosses will yield mutant embryos (25% of all embryos), as only half of the F2 fish share a particular mutation. But there is no way to distinguish carriers from noncarriers.

total number of genes essential for survival and fertility. About 5000 genes mutate to lethality. The number of genes required for fertility is less well-defined, but is probably not more than one thousand. However, the total number of genes, defined as transcription units, is much larger, about 20000. This also means that in *Drosophila* the majority of the genes do not have indispensable functions. A large fraction, about one-third of all lethal mutations, cause a failure of the embryo to hatch (embryonic lethality); however, only about ten percent of these mutations show an easily detectable and specific morphological phenotype in the unhatched differentiated larvae.

The *Drosophila* larva displays a clear axial organization with many landmarks of position and polarity, which are provided by the external cuticle shed by the larval epidermis (Fig. 2). This larval skin is derived from a large portion of the embryonic fate map, while the remainder of the blastoderm largely gives rise to internal organs which are less visible in the living embryo. Whereas an excellent and simple fixation technique was available for the skin, at the time of the mutant screens there were no efficient methods for visualizing the internal organs, which are hidden by the opaque yolk. This problem has since been overcome by the development of molecular probes and antibodies, and a number of screens have used these for the detection of mutants, albeit every screen for a rather limited range of phenotypes. The properties and advantages of *Drosophila* for the genetic analysis of embryonic pattern formation are summarized in Table 1.

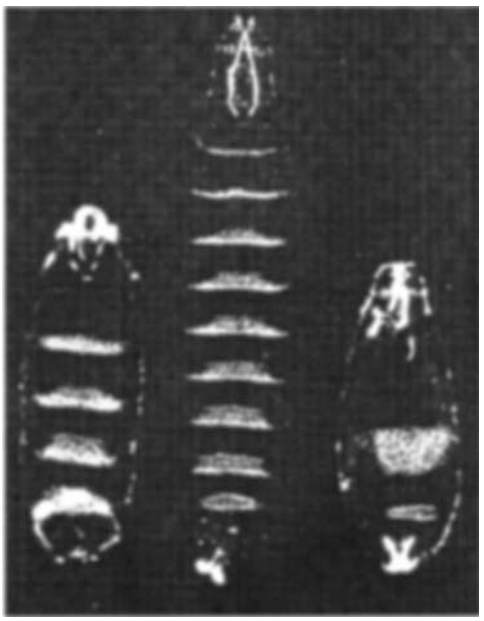

Fig. 2. The cuticular pattern of segmentation mutants. The picture shows the ventral view of a normal larva (middle), a mutant *paired* larva (left), and a *knirps* larva (right). *paired* is a pair-rule gene, and mutants produce approximately half the normal number of segments, every other segment is deleted. *knirps* belongs to the gap class of segmentation genes; most of the abdominal segments, marked by the prominent denticle belts seen in the normal larva, are deleted. Anterior is at the top of the picture.

In the Heidelberg screens[9–11] we collected mutants detectable by a distinct and significant deviation from normal patterning of the cuticle. These mutants, after complementation tests, defined about 130 genes distributed randomly over the three major chromosomes. Using similar scoring criteria, screens for maternal mutants defining about 30 genes were per-

formed in several laboratories.[12-16] Without molecular markers, most of the mutant phenotypes could not readily be analyzed and interpreted at the time. We used rather pragmatic criteria both for screening and characterizing the mutant embryos. By similarity in phenotype, several groups of genes were recognized that probably affect the same or related developmental processes. Subsequent phenotypic and genetic analysis, followed by the molecular cloning of the genes, frequently supported this notion. The groups of genes identified in the mutant screens are shown in Table 2.

Table 2. The *Drosophila* gene classes.

Class	Subclass	Genes	Cloned	Vertebrate homologs
maternal	anterior	4	4	0
	posterior	8	6	2
	terminal	6	3	1
	dorsoventral	12	12	3
zygotic	gap	9	7	1
	pair-rule	8	8	4
	segment polarity	13	8	6
	homeotic	11	9	7
	head morphology	10	4	0
	dorsalized	4	4	3
	ventralized	6	5	2
	dorsal holes	8	6	3
	others	8	2	0
	neuralized	6	6	2
	midline	5	5	1
	epithelia	4	2	2
	cell cycle	6	4	0
	denticles and hairs	4	1	0
	pigmentation	5	3	1
	tracheae	2	0	0
	hyperactive	4	1	0

In our screens, we put great emphasis on completeness, in other words, on the saturation of the genome with mutants detectable by our criteria. Several lines of evidence, such as allele frequency and comparison with phenotypes of deletion mutants, supported the notion that the majority of genes that mutate to a phenotype visible in the larval cuticle had been discovered in our screens. As an additional generation of inbreeding is required, the screens for maternal mutants were more demanding and difficult than those for embryonic lethals. Therefore, it is likely that the degree of saturation for the maternal genes is not as high as that for the zygotically expressed genes. Although the screens were successful in identifying many important genes, and screening more lines would not have significantly increased the number of genes discovered, we were aware of a number of severe intrinsic limitations of our approach.

Genetic Redundancy

At the time, the viewpoint held amongst most *Drosophila* geneticists was that genes not mutating to lethality or sterility were almost not worth studying. There was the tacit assumption that the great majority of all genes were essential for survival or fertility. Concern about redundancy and duplicated genes was a later issue, as it depended on the physical isolation of a gene by cloning, whereas in "precloning times" a gene was only detectable by a mutation causing a phenotype. However, we took redundancy as a theoretical possibility into account. Among the segmentation genes, a number of cases of gene duplications have been fortuitously discovered during the molecular analysis. As methods of reversed genetics are not generally applicable in *Drosophila*, the proportion of redundant genes cannot readily be determined. It is not at all clear why some genes are duplicated and others are not.

Maternal and Zygotic Contribution

Another limitation we were more concerned about was that genes whose products were required both maternally and zygotically would be difficult to detect in mutant screens. In cases where the product is provided maternally, the zygotic phenotype may not represent the complete lack of function. This concern applied in particular to the maternal mutants: in cases of additional functions in the embryo, mutations in genes with important maternal functions might be lethal zygotically and would therefore not be discovered in maternal screens. A number of such cases have been found. To this day, the genes required both maternally and in the zygote are not easily accessible to investigations of function.

Axis Determination in *Drosophila*

A large fraction of the genes identified in both the zygotic and the maternal screens affect either the anteroposterior or the dorsoventral axis. The pattern of the larva is composed of a series of segments that change their character from anterior to posterior. Nonsegmented terminal structures are located at both ends. The pattern also displays a clear dorsoventral difference, although the ventralmost (mesoderm) and dorsalmost (amnioserosa) structures of the embryonic fate map are not represented in the epidermal pattern.

The Anteroposterior Axis

We defined three classes of zygotic segmentation genes, which we called gap genes, pair-rule genes, and segment polarity genes.[8] In mutant embryos of the gap genes, large unique regions are deleted. In pair-rule mutants, deletions in the pattern affect homologous regions in every other segment (Fig. 2), while every segment shows a defect in mutants of the class of segment polarity genes. The phenotypes suggested that the process of segmentation involves at least three levels of spatial organization: Processes beginning during oogenesis define the large unique regions requiring the gap gene function, and the gap genes in turn control a repeat pattern with the periodicity of double segments. Finally, the individual segments are established as developmental units in response to the action of the pair-rule genes.[8]

The subsequent molecular analysis of the properties and function of the segmentation genes was carried out in many laboratories. In these studies, the method of producing transgenic flies by P element induced germline transformation, developed by

Alan Spradling and Gerald Rubin, opened up a rich repertoire of powerful approaches.[31] Many of the segmentation genes are transcription factors that control the expression domains of other segmentation genes, either within the same or of the downstream class. The pattern of expression of many segmentation genes in the first approximation corresponds to the deletion pattern displayed in cuticle preparations.[18] During early embryogenesis, a series of such molecular prepatterns, composed of the expression domains of transcription factors, which are the products of the segmentation genes, is formed. The gap genes are expressed in large unique regions early in embryogenesis; their expression patterns are controlled by maternally provided transcription factors.[18] The earliest metameric pattern, that of the pair-rule genes, has seven stripes that are each determined by the action and interaction of a particular combination of gap gene products.[32, 33] The pair-rule genes finally control the pattern of more than 14 stripes preceding the formation of the morphological pattern, the segments[34] (Fig. 3).

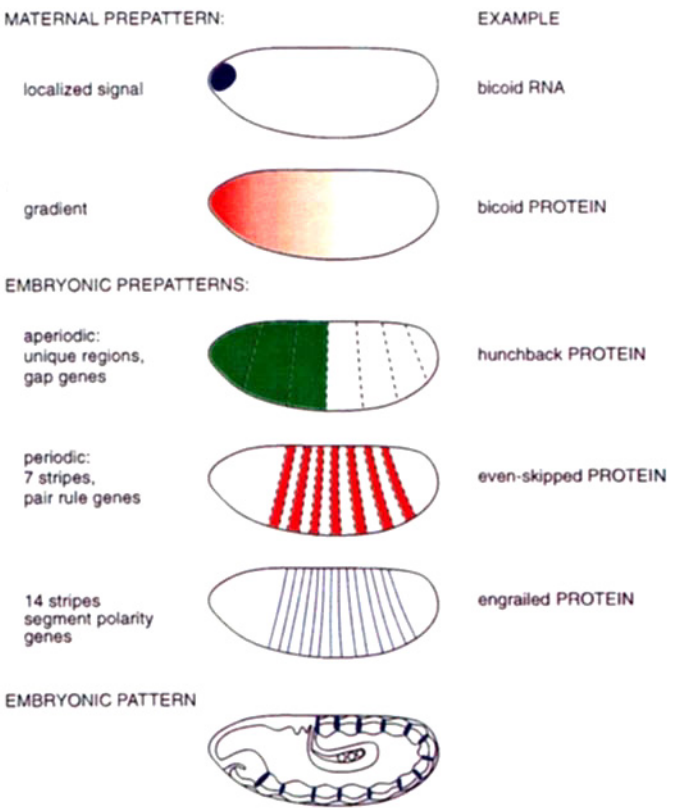

Fig. 3. The hierarchy of genes establishing the anteroposterior pattern in *Drosophila melanogaster*. In every tier, the distribution of the protein product of one representative gene of its class is shown in color. Anterior is on the left, ventral is at the bottom in each picture.

The identification and analysis of the maternal genes affecting the segmentation pattern revealed that the anteroposterior axis is controlled by three groups of genes, each independently determining a subset of the pattern, the segmented anterior or posterior, or the unsegmented terminal regions of the embryo.[35–37] Although the molecular processes by which the three groups function are largely different, they share some common features. Spatial signals are produced that are localized at the anterior or posterior egg pole. In each group, a series of molecular interactions finally results in the formation of a transcription factor gradient spanning a substantial portion of the egg length; the highest concentration is located at the site of the localized signal (Fig. 2).[38] These transcription factor gradients determine the expression of the gap genes in a concentration-dependent manner, thereby defining the first subregions of the embryo.

The Dorsoventral Axis

Two classes of zygotic genes have been identified, mutation of which cause a dorsalized or ventralized phenotype.[39] in *Drosophila*, the mesoderm is formed during gastrulation in the ventral region of the egg; its formation depends on the expression domain of two zygotic transcription factors. The refinement of the dorsoventral pattern on the dorsal side involves a long-range signaling process, unlike the series of prepatterns of transcription factors observed along the anteroposterior axis.[40] The maternal control of the dorsoventral pattern is achieved by only one group of genes that establish a nuclear localization gradient, with its maximum at the ventral side, of a transcription factor that functions both as a repressor of dorsally expressed genes and an activator of ventrally expressed genes.[17, 19] The first zygotic expression pattern divides the embryo into at least three domains along the dorsoventral axis.

Molecular Mechanisms of Pattern Formation

Despite the limitations of the mutant screens discussed above, the collection of genes within each phenotypic group and thus of components of a developmental pathway appears to be relatively complete. In several instances, the molecular interactions of the components within and between pathways have been elucidated in some detail. These examples show how complex patterns can develop from a small set of independently localized signals. A principal mechanism by which spatial complexity is increased is based on concentration gradients of morphogens, molecules that elicit different responses at different concentrations. An example of this mechanism has been discovered by studying the maternal control of the expression pattern of the gap gene *hunchback* by the morphogenic protein Bicoid.[41–43] Bicoid is the transcription factor determining the anterior pattern; it is distributed in a concentration gradient with its maximum at the anterior pole of the egg and controls the transcription of several target genes in a concentration-dependent manner. Morphogen gradients can be formed by diffusion of the protein translated from a localized mRNA source, as in the case of the anterior and posterior maternal gradients (Fig. 2).[35, 37] In other cases, gradients are apparently produced by diffusion in the extracellular space.[44] Their spatial distribution is communicated to the interior of the egg cell through a ligand/receptor-based signal transduction mechanism.[45] In the case of the dorsoventral axis, this mechanism results in the formation of a nuclear localization gradient of the initially equally distributed transcription factor Dorsal.[46, 47] During segmentation, the series of transcription factor patterns with increasing spatial complexity develops by concentration-dependent transcriptional ac-

tivation and repression, involving combinations of transcription factors.[18] The determination of the final molecular prepattern depends on short-range signaling between adjacent cells.[34, 48] This pattern immediately precedes the first morphological changes occurring during segment differentiation.

Limitations of the *Drosophila* Screens

The mechanisms by which axes are established in *Drosophila* are among the best understood examples of pattern formation to date. Because of some special features of early development in the *Drosophila* embryo, they may, however, not always have an immediate parallel in other animal classes. This restriction applies in particular to the processes requiring diffusion in a syncytial embryo, as in the case of the formation of the Bicoid gradient. On the other hand, examples such as the formation of gradients by diffusion in the extracellular space, signal transduction, and the establishment of a nuclear localization gradient, as in the case of Dorsal, may prove to have analogies in pattern-forming processes in multicellular tissues. The genetic analysis of pattern formation in *Drosophila* teaches us about the logic of pattern formation in a complex system. It also led to the discovery of some basic mechanisms that allow an increase in complexity during the development of multicellular organisms. On the other hand, many aspects of animal development, in particular the formation of organs and their functions, have not been studied as thoroughly in *Drosophila*. The reason for this restriction is the fact that we relied on the epidermal pattern in scoring mutant phenotypes in our screens. Obviously, this limitation was very apparent to us, although we tried to use it to our advantage. It limited, with rigid criteria, the number of genes we were concerned with. However, many mutations could not be recovered by the scoring of the cuticular pattern alone. To this day, a systematic screen for *Drosophila* mutants with defects in inner organs has not been performed; however, a number of genes with particular functions in inner organs have been identified in special screens using specific molecular probes[49] or by other means such as the very powerful enhancer trap screens.[50, 51] A crude classification of the *Drosophila* genes discovered in the Heidelberg screens is presented in Table 2. To date more than 60% of them have been cloned.

Many *Drosophila* genes have been shown to have homologs in vertebrates. This homology is not restricted to amino acid sequence and to their biochemical function, but extends to the biological role played in development. This remarkable conservation came as a great surprise. It had been neither predicted nor expected. One of the first indications came with the discovery of the *hox* gene clusters in vertebrates, and the conservation of the colinearity of their expression domains with the chromosomal location.[22, 52] This was soon followed by the isolation of homologs in vertebrates of other homeobox-containing genes, and it now seems that a large fraction of the *Drosophila* genes that we found in our screens have vertebrate homologs. It is difficult to give an estimate of this fraction, because not in all cases have homologs been sought. However, it may be significant that of the maternal genes very few are known so far to have vertebrate homologs (Table 2). This may reflect the very great differences observed in very early development between vertebrates and invertebrates. A large fraction of the vertebrate homologs of *Drosophila* genes have been shown to play an important role in pattern formation in the mouse. Important patterning pathways appear to be conserved, such as the signaling pathway involving TGF-β-like growth factors, and homologs of *hedgehog* and *wingless*.[21, 53, 54] Most of the components of such pathways have been detected by phenotypes visible in the segmented pattern of the *Drosophila* larva. In the vertebrate body organization they are not always required in this context. For example, genes involved in segmentation in *Drosophila* also participate in patterning the brain and limbs in *Drosophila* as well as in vertebrates. Although the collection of the *Drosophila* pattern genes provides a rich source for the study of some aspects of vertebrate development, this sample is strongly biased and probably provides only a small fraction of the genes controlling patterning in vertebrate embryos. In order to obtain a more complete collection of those genes, a direct screen for mutations in a vertebrate organism is required.

The Zebra Fish Screen

The zebra fish, *Danio rerio*, was selected as a potential model for genetic research by the late George Streisinger.[28] In the past 20 years a number of useful methods have been developed for its breeding and genetic analysis, as well as for the investigation of its embryonic development.[25–27] It is interesting to compare characteristics of flies and fishes with regard to genetic and embryological research. Obviously the long generation time and space requirement for rearing zebra fish make large-scale genetic screens difficult. In addition because of technical and logistical problems in running large numbers of aquaria, working with fish is more costly and labor-intensive than with flies. On the other hand, compared to mice, the more traditional vertebrate organism used in genetic research, zebra fish offer the advantages of extrauterine development and high fecundity. With fish, in vitro fertilization, haploid development of embryos until the larval stage, diploidization, and the freezing of sperm samples is possible (Table 1). These techniques are invaluable in the maintenance and analysis of a large number of mutants, and are not possible with flies. The greatest advantage of the zebra fish, however, lies in the nature of its embryonic development. Zebra fish eggs are fertilized synchronously, they develop rapidly outside the maternal organism, and, most importantly, they are initially completely transparent. This allows the observation of the development of many tissues and organs directly in the living embryo and at subsequent stages without the necessity of fixing, clearing, and staining[55] (Fig. 4).

The early embryogenesis of zebra fish is very different from that of flies. A period of rapid synchronous cleavages results in a three-dimensional mass of cells, unlike the two-dimensional blastoderm formed by the *Drosophila* embryo. Gastrulation in the fish involves several morphogenetic movements such as involution of mesendodermal regions and dorsal convergence.[55] Although these movements appear very different, they might be related to the invagination of mesodermal and endodermal anlagen, and ventral condensation and extension of the germ band in the *Drosophila* embryo. They result in a multilayered

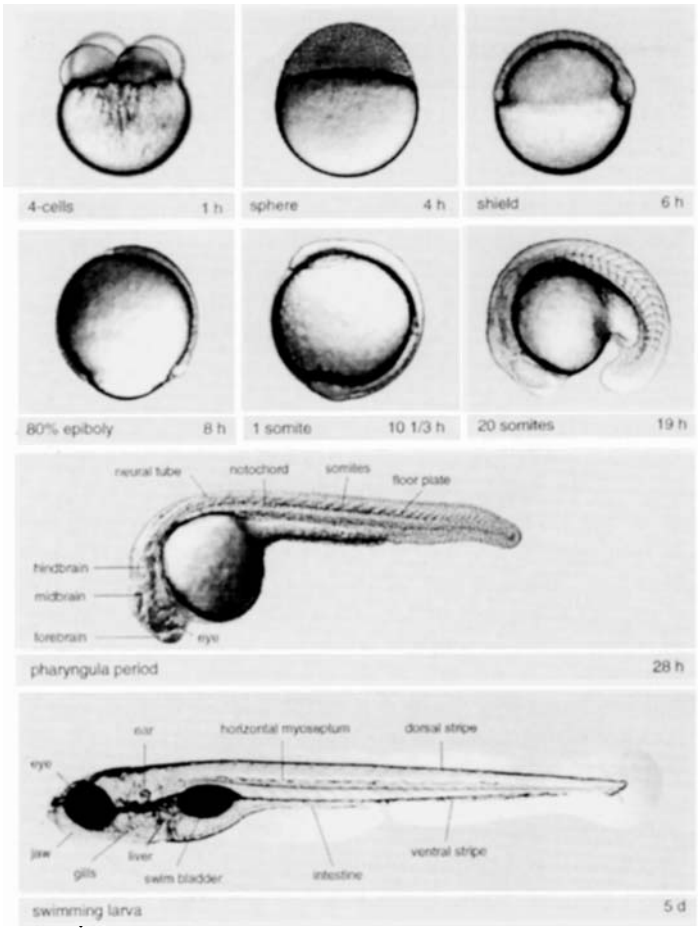

Fig. 4. Embryonic development of the zebra fish. Photographs of live embryos at different ages. With the exception of the swimming larva, the embryos were dissected out of the chorion. In the early embryos, the dorsal side is on the right. In the pharyngula and swimming larva, the dorsal side is up and the anterior to the left. Characteristic structures scored in the mutant screen are indicated. Stages are given according to ref. [55].

embryo, the pharyngula or phylotypic stage, which displays the typical vertebrate body organization (Fig. 4).

While in the *Drosophila* embryo fate mapping studies allow the construction of two-dimensional maps of the early gastrula with distinct and clearly separated anlagen, in the fish the fate of cells within particular gastrula regions is much less precisely predictable. The fish gastrula is multilayered. Large regions that later develop into different organs or tissues overlap and are superimposed. This difference may reflect quite distinct developmental mechanisms determining fate of cells in the fish and fly embryo. A comparison of fly and fish fate maps reveals further dramatic differences between the relative size occupied by the anlagen for various organs. For example in the fish the brain anlage occupies a very large fraction of the gastrula, while the epidermis is rather inconspicuous, compared to its dominance in the fly map. To a certain extent, the sizes of the anlagen reflect the importance and visibility of the structures that can be scored in a mutant screen.

The crossing scheme used to make mutants with phenotypes visible in the embryo or early fish larva is displayed in Figure 1. Treatment of fish spermatogonia with ethylnitrosourea (ENU) has been used for mutagenesis with a similar efficiency as that obtained by treatment of fly sperm with ethyl methyl sulfonate (EMS) (about one mutation per gene per 1000 genomes).[26] In contrast to the fly screens, in the fish no markers can be used to help distinguish carrier from noncarrier fish in the F2 generation. Therefore, to detect a mutation induced by the treatment of parental males, a number of crosses have to be set up, of which only 25% on average yield progeny that are homozygous for a mutation. As fish hatch enzymatically, most homozygous mutant embryos also hatch, and therefore, with few exceptions, they cannot be recognized as nonhatchers, a useful way to identify mutant embryos in the *Drosophila* screens. Mutant fish embryos can be recognized by their phenotypes only. The lack of markers and preselection is compensated somewhat by the fact that the entire genome is scored at once and not chromosome by chromosome. In the case of the fly, three separate screens on a total of more than 20000 inbred families were performed to obtain about 600 mutants in 130 genes.[9-11] For the fish, 3100 families were screened, with an average of 4.2 crosses, corresponding to the screening of 3800 genomes (Fig. 1).[29] As the breeding of such a large number of fish families is necessary to achieve a reasonable degree of saturation for any given phenotypic trait, this screen was the collaborative effort of 12 scientists. We screened as many different phenotypic traits as could be efficiently scored. We isolated a total of 1200 mutants, of which to date about 900 have been characterized both phenotypically and genetically. They define 350 genes, of which 150 have more than one allele.[29]

The different developmental features of the fish embryo were scored at different times in development, as the structures and organs became visible with age (Fig. 4). On the second day of development, the somites, notochord, and brain were scored, while after hatching heart, blood, musculature, fins, eye, ear, and other features were studied. Fish of the larval stage, the latest time scored, almost one week old, have a complete set of internal organs, liver, gut, pancreas, kidney, can see and respond to stimuli, and are pigmented with three types of pigment cells. They still display a pigment pattern characteristic for the larval stage, and the fin structure does not yet completely correspond to that of the adult fish (Fig. 4). Some structural features of the fish are recognized readily and unequivocally, while others are less conspicuous and therefore abnormalities may not always have been detected. The high degree of complexity, which is far more than that displayed in the cuticular pattern of the fly larva, allows a much broader spectrum of organs and tissues to be investigated, but it also sets considerable demands on the skill and expertise of the experimenter. The recognition of a particular phenotype is greatly enhanced if an interpretation of the phenotype is available, or if it has been seen before. Many mutants have rather general defects; they have not been kept for analysis.[29] Mutants with complex or subtle phenotypes resembling rather general defects are not always recognized as interesting or interpreted correctly. This means that the degree of saturation varies among different phenotypic classes (Table 3). On average it is certainly less than that achieved in the fly screens.

Based on their predominant phenotypic traits, the genes can be classified in a large number of groups with similar phenotypes. Classification of each mutant depends on the interpretation of its phenotype, and this in turn on the degree of phenotypic analysis that can be performed. In the fish, a number of

Table 3. The zebra fish gene classes.

Class	Subclass	Genes	Alleles	Alleles/gene
early	epiboly, arrest	11	16	1.5
	ventralized	2	4	2
	dorsalized	5	16	3
	others	13	19	1.5
mesoderm	notochord	15	67	4.5
	somites	8	26	3.2
CNS	brain	19	37	1.9
	midline	10	19	1.9
organs	blood	9	23	2.6
	heart, circulation	22	28	1.4
	liver, gut	6	6	1
	muscles	18	63	3.5
	eye	8	11	1.4
	ear	19	46	2.3
	fins	13	60	4.6
neural crest	pigment pattern	10	39	3.9
	pigment cells	61	150	2.5
	jaw and gill arches	17	30	1.8
motility	reduced	15	50	3.3
	abnormal	15	53	3.5

molecular probes are available that serve as markers for particular regions at specific developmental times. The expression patterns of such markers were very useful in characterizing many of the mutant phenotypes. The classes of fish genes identified by the mutants are shown in Table 3. A small number of classes have a parallel among the classes of fly genes, while the majority of phenotypes are novel. The collection of the fish gene classes is so different from that of the fly genes that a comparison is possible only in selected cases. With regard to the most prominent classes of fly genes, gastrulation and segmentation, however, a small number of fish genes might have similarities to fly processes.

The Zebra Fish Gene Classes

Gastrulation is affected in two gene groups, the phenotypes of which display a partial dorsalization or ventralization.[56, 57] In *dino* mutant embryos, dorsal anterior structures are reduced, while ventral posterior structures are increased in size. This results in embryos with small heads and large tails. The effect is most pronounced in the structures derived from the most ventral position in the fate map: the blood and ventral tail fin, which is increased in number in *dino*. By using molecular markers that are expressed before gastrulation in a polar manner, it is apparent that the fate map is distorted already at an early point in fish embryogenesis (Fig. 5A). As suggested by a characteristic duplication of the ventral tail fin, mutants in the *mercedes* gene have a role in the same process[56] (Fig. 5K). A phenotype complementary to that of *dino* and *mercedes* is displayed in mutants in a number of genes with a dorsalized phenotype; *swirl* embryos, for example, have much enlarged paraxial mesoderm; the forming somites encircle the entire embryo (Fig. 5F) and ventrally derived structures such as blood and the ventral tail fin are reduced or lacking entirely.[57] These groups of genes are reminiscent of genes with dorsalizing and ventralizing phenotypes also observed in *Drosophila*. For genes of both groups, homologs in the frog and fish have been cloned and shown to be expressed at opposite regions of the blastula.[58–61] These and other observations led to the revival of an old theory postulating that the orientation of the dorsoventral axis in invertebrates is inverted compared to that of vertebrates.[62–64] The fish genes are likely to provide components in these conserved pathways.

An interest in the mechanism of segmentation in vertebrates was an important incentive for the mutant screens in fish. In contrast to flies, which have a clearly segmented ectoderm, in fish the mesoderm is the primary vertebrate tissue that is organized in a metameric pattern. We did not find many genes in the fish that have similarities to fly segmentation genes. The closest are mutants in which the somites, the earliest visible repetitive structures formed in the fish embryo after ten hours of development, are fused. Five genes have a phenotype with fused somites (Fig. 5B, M, N).[65] The somite pattern in the fish embryo is much less complex than the segment pattern of the *Drosophila* larva. However, the vertebrate that develop in postlarval stages in mutant fish display characteristic mirror duplications (Fig. 5N), albeit less striking and regular than the phenotypes of the segment polarity genes in the fly, with which they may be compared. No genes with obvious resemblance to gap or pair-rule genes have been detected in the fish screens. Using molecular approaches, no clear homologs to the gap genes could be detected so far, and the homologs of the pair-rule genes do not seem to be expressed in a pair-rule fashion.[59] The failure to find mutations resembling the gap and pair-rule mutations in the fish may mean that the formation of metameric patterns differs between *Drosophila* and most other animals. On the other hand, it may be the result of redundancy.

Other mutations affect the dorsoventral subdivision of the somites by the horizontal myoseptum. Some of these also lack the notochord, while in others the notochord is apparently normal. The notochord is a vertebrate-specific structure. The gene *no tail*, a fish homolog of the mouse *brachyury* or *T* gene, is expressed in the notochord (Fig. 5C)[66, 67] (a homolog in *Drosophila* is expressed in the hindgut[68]), and mutations in *no tail* as well as in three other genes required for notochord formation have been identified (Fig. 5C).[69, 70] The structure of the somites in fish is thought to be dependent on signals derived from the notochord. The genes affecting somite subdivision by the horizontal myoseptum might represent members of these signaling processes (Fig. 5G). Their products may be involved in producing or receiving the signals.[65] For these genes, homologous processes in *Drosophila* are not obvious.

A large number of the fish genes affect structures and functions of the central nervous system and sensory organs (Table 3). This class is poorly represented in the fly screen. In our screen several aspects of CNS development have been scored. For the neurogenic genes of *Drosophila*, such as *notch* and *delta*, homologs have been detected in the vertebrate by molecular means,[71] and in our screen at least one gene with neurogenic features, *white tail*, has been found. Mutant embryos display a considerable multiplication of primary neurons at the expense of secondary neurons and certain types of glial cells (Fig. 5E).[72] Another class of genes affect structures along the midline in all three germlayers. In the mutants, the eyes are often fused. Mutant embryos display a lack of structures derived from axial mesoderm and ventral regions of the spinal cord or brain.

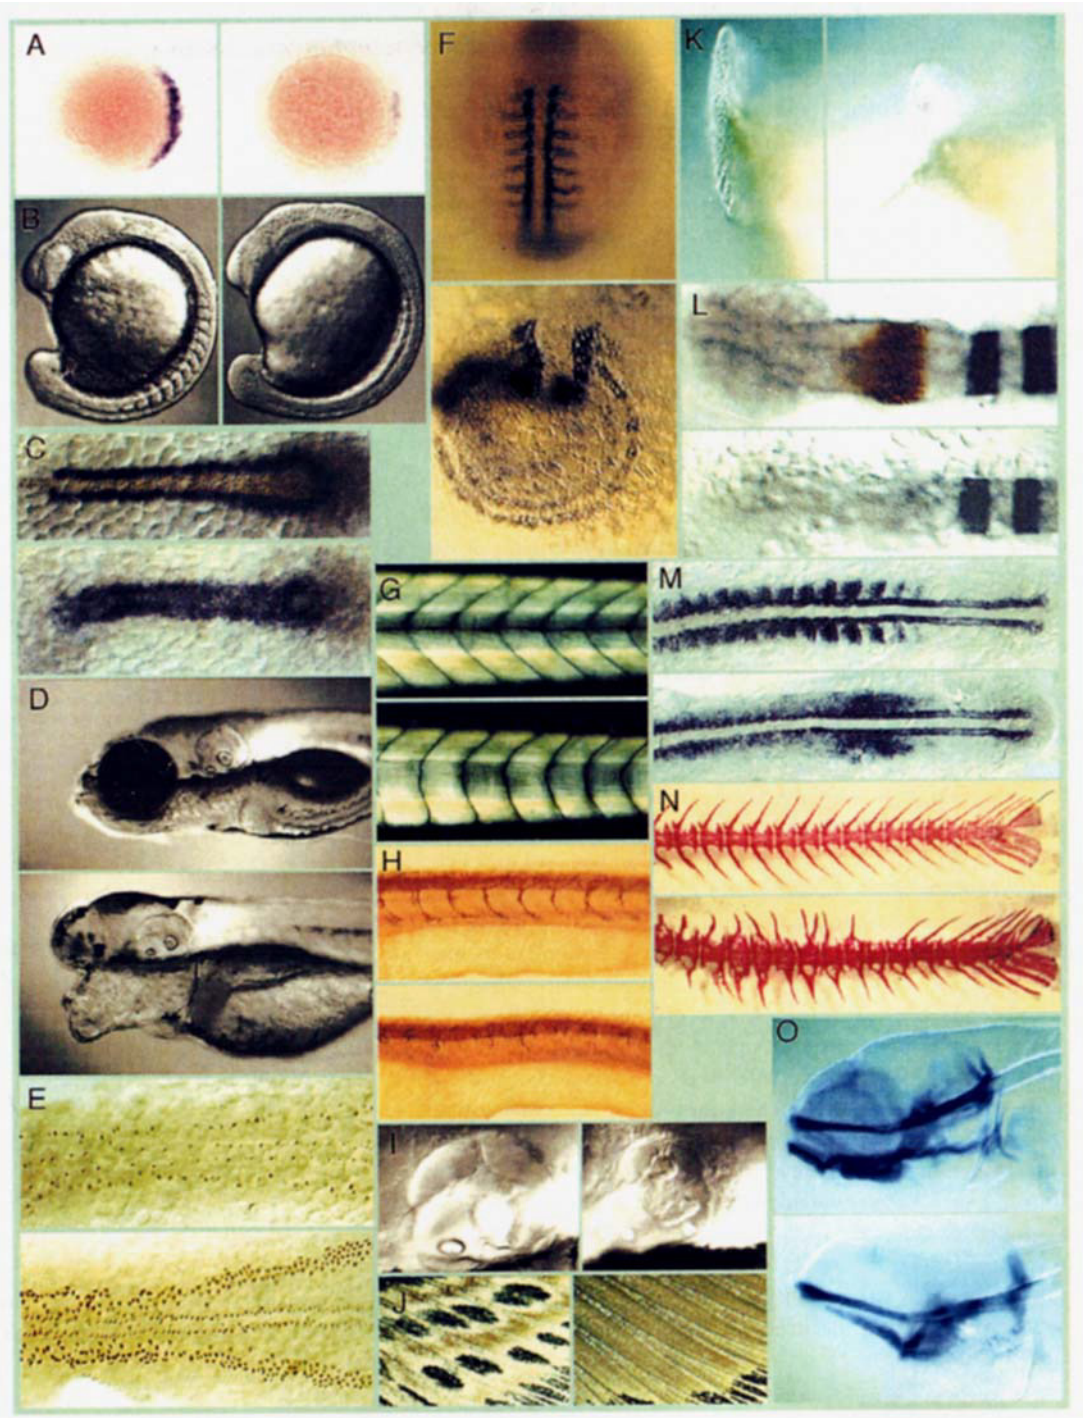

Fig. 5. Zebra fish mutants. In the pairs of panels, a wildtype embryo is shown together with a mutant embryo, which is to the right or below the wildtype. The anterior is on the left and the dorsal side up, except when otherwise noted. A) *dino*, fkd 3 in situ hybridization, shield stage. Optical section through the germ ring, dorsal right [56]. B) *fused somites*, living embryos, 12 somites stage [65]. C) *floating head*, myoD in situ hybridization, the brown staining in the wildtype marks the notochord with ntl antibody, dorsal view [69]. D) *masterblind*, living, swimming larval stage [76]. E) *white tail*, islet 1 antibody, 8 somite stage, dorsal view [72]. F) *swirl*, myoD in situ hybridization, 8 somite stage, anterior up [57]. G) *you*, living, swimming larva [65]. H) *diwanka*, znp-1 antibody, pharyngula [78]. I) *van gogh*, living, swimming larva [79]. J) *leopard, obelix*, adult fin [29]. K) *mercedes*, swimming larva, view on tail fin [56]. L) *no isthmus*, brown: 4D9 (Eng) antibody, blue: Krox 20, 8 somite stage, dorsal view [80]. M, N) *fused somites*, M myoD in situ hybridization, 14 somites, dorsal view, N) skeletal staining, adult [65]. O) *sucker* alcian blue staining of cartilage, swimming larva [81].

In some mutants the pathfinding of nerves across the midline is impaired. The most prominent and longest known representative of this class of genes is *cyclops*.[73] The eyes of mutant embryos are fused anteriorly, and the floorplate, the ventral region of the spinal cord, is lacking. There are several new members of this class of genes including *diwanka* (Fig. 5H) and *chameleon*.[74] It will be interesting to see whether the mutations that delete the midline structures (the ventral portion of the neuroectoderm and head in *Drosophila*) such as *spitz* and others[75] are homologous to the fish midline genes.

The brain morphology is affected in a number of mutants of which only some will be mentioned here. The forebrain, including the olfactory placodes and eyes, are deleted in the mutant *masterblind* (Fig. 5D). The analysis with molecular markers re-

vealed that the region that normally would develop into forebrain, instead develops into more posterior structures, similar to a homeotic transformation.[76] The midbrain–hindbrain boundary is absent in mutants of two genes, *no isthmus and* acerebellar. The *no isthmus* gene (Fig. 5L), which is also required for the formation of the kidney, is homologous to one of the *pax* genes, a family of genes first identified in the mouse by their homology to the *Drosophila* segmentation gene *paired*.[77]

A large number of zebra fish mutant classes do not have parallels in our *Drosophila* mutant collection. They will only be summarized briefly here. Of particular interest regarding their potential for medical research are mutants affecting inner organs. A number of genes affecting blood formation and circulation as well as the heart, structures easily scorable in the first two days of fish embryogenesis, have been identified. Mutants affected in organs developing later, such as liver, pancreas, and kidney, are less well-represented. Differentiation defects or degeneration of the musculature are displayed in embryos mutant for a number of genes. In addition, sensory organs such as eye and ear (Fig. 5) are affected in a number of mutants. A large number of genes are required for the formation of structures derived from the neural crest. The largest class are genes required for pigmentation, that is, pigment cell formation and pigment pattern, and a number of genes affect portions of the jaw (Fig. 5O) or branchial arches, structures specific to vertebrates (Table 3). We also isolated mutants with specific defects in motility of the larva. Mutant larvae fail to respond to touch, show reduced or no motility, and display spastic or circling behavior, as well as defects in the reciprocal inhibition across the midline of muscular contractions. In a small number of mutants, defects in the outgrowth of motoneurons were observed.[78] In *Drosophila*, our screens did not permit the recovery of motility mutants, although immotile larval phenotypes could be recognized in principle by an abnormal distortion of the larval cuticle in the unhatched embryo. Fortuitously, a small group of four genes of *Drosophila* was detected in which larvae were hyperactive, sometimes turning around in the egg case (Table 2).[9–11] These phenotypes in addition showed defective head skeleton differentiation; they have not yet been analyzed in detail.

Conclusions

Genetic research on axis determination in the *Drosophila* embryo has provided perhaps the most complete understanding of pattern formation to date. The elegance and efficiency with which mutations can be isolated and genes can be manipulated in this organism will permit further important discoveries concerning a number of basic processes of cell and developmental biology. However, mechanisms in the fly are, in several instances, likely to be unique to this specialized organism. While the approach of using fly genes to find homologs in vertebrates is a very powerful one, it emphasizes the similarities between these clearly different organisms. To understand vertebrate development, genes specific to vertebrates must be investigated in addition to those common to both flies and fishes. To find and elucidate these differences, the mutants discovered in the zebra fish will provide an important entry point for the investigation of fundamental biological and medical problems with genetic tools.

I would like to thank my collaborators, past and present, for their contributions and for their skill, understanding, thoughtfulness, brilliance, patience, enthusiasm, and support. I also wish to thank Siegfried Roth, Stefan Schulte-Merker, Stefan Meyer, Darren Gilmour, Nancy Hopkins, Peter Overath, Michael Granato, and Judith Kimble for suggestions and help with the manuscript.

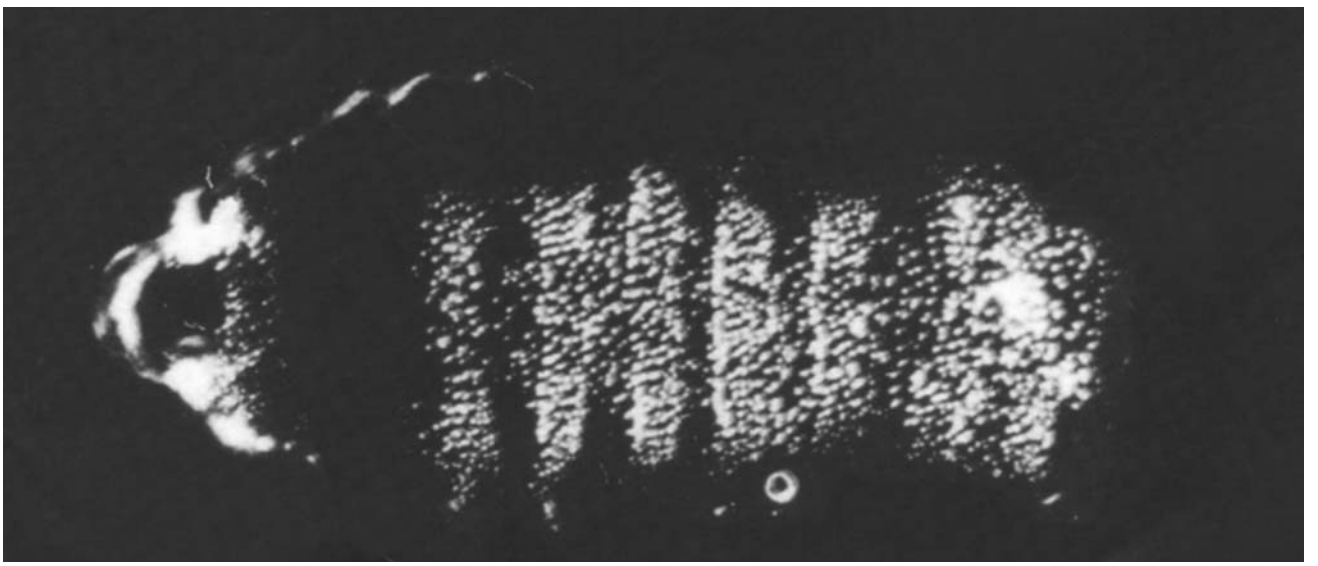
The size and spacing of the pattern deletions in mutant embryos at the end of development were used to group segmentation genes into three classes–gap, pair-rule, and segment polarity genes. One mutant embryo is shown for each class.



From Molecular Patterns to Morphogenesis—The Lessons from Studies on the Fruit Fly *Drosophila* (Nobel Lecture)**

Eric Wieschaus*

During development, cells in an embryo face two major tasks. First, they must be programmed to form specific parts of the body, and second, they must realize those fates by altering their shape, position, and patterns of gene expression. Both the determination of cell fate and the corresponding alterations in form occur progressively during development. The organism that results from this process contains a wide variety of different cell types and functions, arranged in a complex spatial pattern. In the fruit fly *Drosophila* this final pattern is achieved about 20 hours after fertilization, when the embryo has formed a larva of 40000 cells. The most obvious external feature of this larva is a segmentally repeated pattern of hairs and denticles secreted by the underlying epidermis. Beneath these hypodermal cells is a complex array of muscles also arranged in a segmentally repeated fashion. Internal to this somatic musculature are other mesodermal ddrivatives, as well as equally complex structures and organs of endodermal origin. By following the development of individual cells, it has been possible to trace the precursors for each structure in the differentiated larva back to the earliest cellular stages in the embryo.[1, 2] In *Drosophila* this stage (the blastoderm) consists of an oblong embryo about half a millimeter in length, with about 100 cells along the future anterior–posterior axis and 40 cells along the dorsal–ventral axis. The epidermis is formed by cells on the lateral side of the embryo, the muscles and other mesodermal derivatives are formed from a stripe of cells on the ventral side of the blastoderm, and the endodermal cells arise from two groups of precursors at the anterior and posterior ends of the embryo.

At the blastoderm stage, all of these cells are similar in size and morphology. A few minutes later, at the onset of gastrulation, the mesodermal precursors initiate cell shape changes that carry them into the interior of the embryo.[3] Similar changes in cellular morphology then internalize the endodermal cells. These morphogenetic movements are the first of many examples in which cells in an embryo change their shape in response to the developmental programs that control their fate. The large size of cells at gastrulation and the rapidity of these changes give gastrulation a particularly strong visual impact. The cellular mechanisms underlying these movements, however, utilize many of the same cytoskeletal and adhesive structures found in all cells. The pathway between a particular cell fate decision and the mechanisms controlling cell form have not yet been worked out in detail in any organism.

The past 15 years have seen remarkable advances in our understanding of how the changing pattern of gene activity in the *Drosophila* embryo directs cells to their final fates. These advances have been produced by an unheralded combination of molecular biology and classical genetics. At this point many of the genes that control cell fate have been cloned and their basic cellular roles are understood. In principle, this information provides an ideal starting point to address how cell fate is translated into cell form. This has proven more difficult, largely because the genetic strategies that work so well in elucidating cell fates have met unanticipated obstacles in the elucidation of cell form. Here I would like to review the general picture that has emerged from our studies on *Drosophila* about how genes control cell fate in the *Drosophila* embryo, and examine how the activity of those genes might be related to the constantly changing form of the embryo.

The Heidelberg Mutagenesis Screens

It was to address both cell fate and cell form Christiane Nüsslein-Volhard and I began the mutagenesis experiments honored in Stockholm. In the 1970s when we were finishing our graduate studies in Basel and Tübingen, it was clear that cell development, like all processes in living cells, depended on genes and gene products. Not only was the relationship between DNA, RNA, and protein known, but the analysis of several bacterial operons made it clear that gene activities could be controlled temporally and spatially. Almost everyone believed that such temporal and spatial control might explain the sequence of events giving rise to embryonic pattern. The analysis of such genes seemed formidable, however. Molecular cloning was in its infancy and there were no obvious tools for analyzing single genes in higher eukaryotes. What made the matter worse was the enormous diversity of genes and gene products present in an embryo. RNA complexity experiments estimated the number of different RNA species to be between 10000 and 50000.[4] These RNAs were expressed at varying levels and in a changing pattern as the embryo progressed through various stages. How

was one ever to sort out which gene products were essential for particular steps in development? How could the relevant genes and proteins be identified? To Christiane Nüsslein-Volhard and me, the genetic techniques that had been established in *Drosophila* over the preceding sixty years seemed to offer the best approach.

The particular mutagenesis strategy we adopted depended on two facts established about the *Drosophila* genome in the early 1970s. First, mutagenesis experiments involving small, cytologically defined chromosomal regions[5] suggested that, regardless of the total molecular complexity of the *Drosophila* genome, only about 5000 genes present in the DNA were essential for viability under laboratory conditions. This number set an upper limit on the genes essential for embryonic development. Second, a detailed analysis of flies monosomic or trisomic for various genomic regions[6] suggested that although flies are normally diploid, a single copy of most genes was sufficient for viability. This meant that most mutations leading to loss of function would be recessive and could therefore be maintained in heterozygous stocks. These two observations suggested that the requirements for gene activity during *Drosophila* embryogenesis could be surveyed in large-scale (but limited) mutagenesis experiments. If transcription of a gene was essential for embryonic development, homozygous embryos should develop abnormally when that gene was eliminated. If the gene played a specific role in patterning or cell fate, most structures in the affected embryo would be normal and the defects limited to specific regions of the body or specific tissues. Based on these defects, it should be possible to reconstruct the normal function of each gene. In that view, all that was required for a thorough survey of development was to make enough mutant lines and to be able to recognize defects by looking at embryos.

Because flies are diploid and most mutations are recessive, the mutagenesis scheme we settled on involved establishing inbred lines from single individuals carrying mutagenized chromosomes (Fig. 1). In two generations, this inbreeding produces homozygotes whose development can be compared with that of their heterozygous siblings. To obtain mutations in most or all genes in the genome, we had to establish enough mutagenized lines to hit most genes several times. Although Christiane and I carried out preliminary mutagenesis runs ourselves, the final experiments were extremely labor-intensive and were completed with the help of Gerd Jürgens and Hildegard Kluding.[7–10]

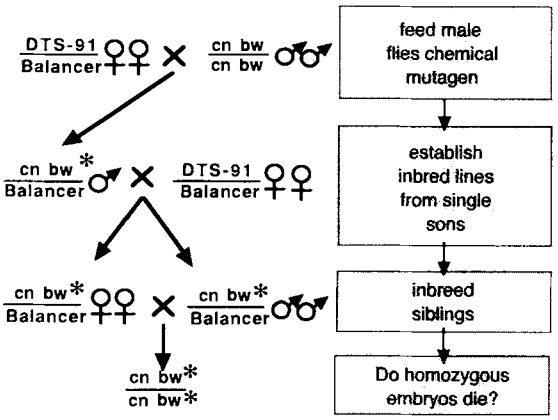

Fig. 1. Mutagenesis scheme used in Heidelberg to identify mutations on the second chromosome causing lethality in homozygous embryos. Similar crossing schemes were used for the third chromosome and the X chromosome.

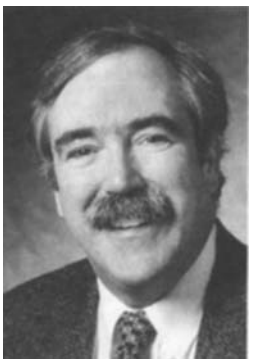
Over the course of a year, from the fall of 1979 to the summer of 1980, we established 27000 inbred lines. These lines contained an estimated 18000 independently induced mutations, each causing lethality at some point during the life cycle of the animal (Table 1). Only about a quarter of these lethal mutations prevented homozygous embryos from hatching to the larval stage,

Table 1. Results of Heidelberg mutagenesis experiments [a].

Total lines established and tested	26978
Lethal mutations	18136
Mutations causing embryonic lethality	4332
Mutations causing embryonic phenotypes	580
Complementation groups (genes)	139

[a] Numbers given are totals for experiments on the X chromosome and the two major autosomes. The number of mutations in the various classes have been corrected by using the Poisson distribution to account for those lines containing multiple mutations.

and only about 2.5% caused visible alteration of the external morphology of the embryo. These 580 mutations could be assigned by complementation tests to one of 139 different genes. The small final number of genes was an important result, since it meant that each gene could be characterized in some detail. By examining mutant embryos from the various stocks, Christiane



Eric Wieschaus was born in South Bend, IN (USA), in 1947 and grew up in Birmingham, AL. He did his undergraduate work at the University of Notre Dame and obtained his Masters degree and PhD degree from Yale University. A significant fraction of his graduate and postdoctoral research was carried out in Basel and Zurich (Switzerland). In 1978 he moved to the European Molecular Biology Laboratory in Heidelberg (Germany), where in collaboration with Christiane Nüsslein-Volhard he began the mutagenesis experiments that were recognized with the 1995 Nobel Prize for Medicine and Physiology. He is a fellow of the American Academy of Arts and Sciences and a member of the National Academy of Sciences. Since 1981 he has lived in New Jersey, where he is the Squibb Professor of Molecular Biology at Princeton University.

and I were able to establish a general picture of how gene activity in the embryo directs the development of individual cells.

In all species, many of the gene products present in the embryo are supplied by the mother during oogenesis. These include most RNAs and proteins needed for normal cell functions during early stages, as well as certain "inhomogeneities" that are used to define the initial cell axis. In our experiments, homozygous embryos are derived from mothers that have a wild-type allele. Consequently, the Heidelberg mutagenesis screens missed all maternally supplied gene products. The 139 genes identified represent only those genes whose products must be supplied by the embryo's own transcription. We therefore explained the large number of the RNA and protein species in the embryo as largely derived from maternal supplies.

The fact that zygotically required transcripts were relatively rare suggested that they might play specialized roles in development. One possibility was that zygotic transcription allows particular gene products to be expressed in one cell and not in its immediate neighbors, only at particular times. This would contrast with the ubiquitous distribution generally observed for maternally derived transcripts. In this view, the embryo would use transcription to elaborate differences between adjacent cell populations, differences that would ultimately account for the variety of cell fates and cell behaviors observed in the embryo after the blastoderm stage.

The Heidelberg Collection of Mutants: A Survey of Zygotic Gene Activities

One historical coincidence that contributed to the significance of the Heidelberg screens was the almost simultaneous development of molecular techniques that allowed genes to be cloned based on their genetic position. After we had published our experiments, a number of labs studying *Drosophila* began a concerted effort to clone the genes identified by the mutations. This effort has continued over the past ten years and is still going on today. Of the 139 lines that produce phenotypes, 20 were single hits, had relatively nondescript phenotypes, and were never given names or further characterized. Most were eventually lost. Of the remaining 119, an informal survey of the *Drosophila* database indicates that 75 have been cloned and their expression patterns examined in embryos. These molecular analyses along with the phenotypic descriptions begun in Heidelberg have generated an increasingly detailed view of the kind of functions supplied by zygotic transcripts in the *Drosophila* embryo.

In general, the greatest insights into developmental mechanism came when number of different Heidelberg genes could be grouped together because they affected the same developmental process. Sometimes, as in the series of segmentation mutants,[7] peculiarities of the phenotype of individual genes suggested regulatory hierarchies between members of the group (Fig. 2). In other cases (for example *armadillo* and *wingless*[11]), homogeneous phenotypic groups pointed to unanticipated relationships between previously characterized proteins.

One of the most striking features of the Heidelberg collection of mutants was the specificity of the phenotypes. For a given line, certain cell types or regions are affected in the mutant embryo, while other cell types and regions are normal. This

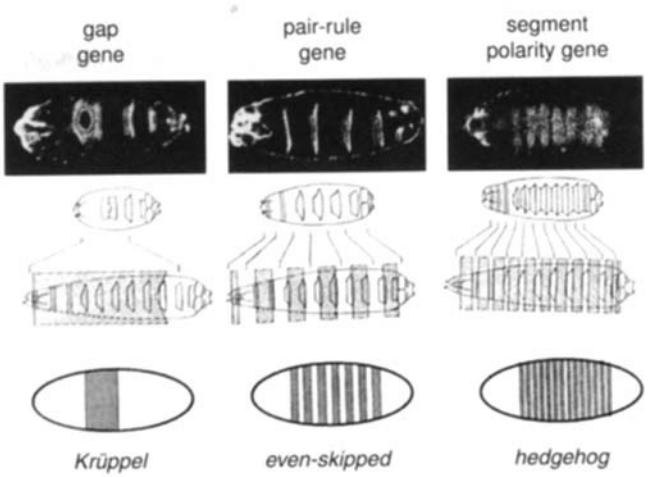


Fig. 2. Phenotypes of mutations affecting segmental pattern. The size and spacing of the pattern deletions in mutant embryos at the end of development allows extrapolation back to requirements for gene activities at the blastoderm stage. Segmentation genes can be grouped into three classes: mutations in gap genes show large contiguous deletions in the pattern; mutations in pair-rule genes show pattern deletions spaced at double segment intervals; and mutations in segment polarity genes cause pattern deletions in each segment. One example is shown for each class.

phenotypic specificity was reinforced by molecular data once the various Heidelberg genes had been cloned. Most genes show highly regulated patterns of expression such that transcripts accumulate only in those regions and cell types where they are needed. Defects associated with a given mutant stock are generally different from those of other stocks, and expression patterns show a corresponding diversity. The two observations together suggest that most of the genes play unique roles at morphologically distinct steps in development.

Mutants usually affect areas of the embryo, rather than specific cell types. These areas generally do not correspond to obvious subdivisions and could not have been predicted based on morphological considerations alone. Obvious examples of these regional specificities are the genes affecting segmentation: one could not have predicted the domains of gap gene expression, the existence of pair-rule phenotypes, or the precise structures duplicated in segment polarity mutants. Because the region affected by a particular gene ultimately gives rise to a variety of different cell types, the genes seem to define positions or spatial coordinates rather than tissues or organs.

Genes often are used several times during embryonic development. Most segmentation genes for example, are used later in the nervous system and in other tissues as well (for example the gene *Krüppel* in the Malpighian tubules[12]). This pleiotropy is not limited to genes controlling segmental pattern. Many of the genes controlling dorsal–ventral patterning at the blastoderm stage are used again at specific times in development. Even a gene like *twist*, which ultimately seems specific for muscle differentiation, shows a more complicated, broader expression pattern at the blastoderm stage, suggesting that it plays a role in determining ventral fates in general, rather than specific mesodermal identities. These features make it difficult to relate early expression patterns of particular genes to final qualities of differentiation. Again, it is consistent with a role for the genes in programming regions or fates, rather than defining differentiated cell types per se.

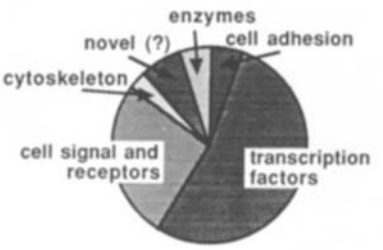

Fig. 3. Cellular functions of Heidelberg mutations. Based on the sequence of 75 cloned genes, most of the loci identified in Heidelberg encode transcription factors, or cell signals and receptors.

More that half of the 75 cloned genes encode transcription factors, judging from the presence of DNA binding motifs and/or their homology to known vertebrate or yeast transcription factors (Fig. 3). Their DNA binding properties might allow them to control expression of many different target genes. If used at various stages of development and in different combination with other genes, they might therefore affect a variety of different developmental pathways. Most of the cloned genes that are not transcription factors are cell surface signals or receptors. Some of these signaling factors may have immediate consequences for cell behavior (see below), but most of this signaling ultimately feeds back on positional identities not directly related to final differentiated states.

Genes Missed in the Heidelberg Screens: The Control of Cell Form

During the period when patterns of cell fate are being established, the embryo undergoes dramatic morphological changes. The final stages of cleavage (that is, nuclear division) occur when the embryo is still a syncytium. Once the number of nuclei have reached 6000, they stop dividing and cell membranes are pulled down between individual nuclei. This process of cellularization requires a major reorganization of the embryonic cytoskeleton and takes about an hour. When it is completed, the embryo consists of 6000 individual cells that are still morphologically identical. They are, however, molecularly different, due to expression of many of the 139 genes and transcription factors described in the previous section. At the onset of gastrulation, these differences are translated into changes of cell shape that result in the invagination of mesoderm or endoderm during gastrulation. Overall, the 90 minutes from completion of cleavage through early gastrulation represent the major period of morphological transformation that occurs in the *Drosophila* embryo.

What is the relationship between these morphological changes and the genes that were identified in the Heidelberg screens? When embryos from each of the 139 mutant stocks were examined, we found that even mutants with phenotypes identified very early in development showed no morphological defects before the onset of gastulation. This suggested that the products of the Heidelberg genes were irrelevant for the early morphological events of cleavage and cellularization, and were only required when cells in individual regions of the embryos began their regionally specific cell shape changes. One way to test this was to block all new RNA synthesis by injecting early embryos with drugs that inhibit RNA polymerase. To our consternation, work by Arking and Parente[13] as well as by Edgar et al.[14] indicated that such treatment causes embryos to become abnormal at the onset of cellularization, an hour before the earliest defects produced by any of the Heidelberg mutants. These experiments provided the first suggestion that the Heidelberg screens may have missed early acting, morphologically important genes.

To identify such genes, we developed a system of translocation crosses to generate embryos deficient for defined chromosomal regions.[15, 16] By using this system, we were able to work our way through the entire genome in a small number of crosses, examining potential mutants at early stages to detect relatively subtle deviations in morphology. These experiments identified seven regions (or genes) that together account for the defects observed in drug-treated embryos. These genes were identified because of their effects on early morphology rather than on viability or overall pattern at the end of embryonic development. They therefore represent a different sampling of the transcriptional requirements than the Heidelberg loci. Three of these seven genes have now been cloned.[17–19] Unlike the Heidelberg mutants, they do not encode transcription factors or components of a cell signaling system. Instead all three are cytoplasmic proteins associated with the cytoskeleton.[19, 20]

Genes affecting morphology during gastrulation also appear to have been missed in the Heidelberg screens.[3] For example, the two Heidelberg genes absolutely required for mesodermal programming are *twist* and *snail*. Both have been cloned and have been shown to encode transcription factors.[21, 22] Immediately before gastrulation, these genes are expressed in the nuclei of mesodermal precursors on the ventral side of the blastoderm. When either gene is mutated, no cells are programmed to mesodermal fates and no ventral furrow forms. Thus, *twist* and *snail* not only direct blastoderm cells to a mesodermal cell fate, they have an immediate read-out in terms of mesodermal cell behavior. Since they are transciption factors, they must do this by controlling the expression of other genes.

What are these downstream target genes? If they produced phenotypes visible in the final cuticle, such genes would have been detected in the Heidelberg screens. One candidate for such a target is *folded gastrulation* (*fog*). In *fog* mutant embryos, the cell shape changes of the ventral furrow are delayed and uncoordinated. Wild-type cells in the ventral furrow express *fog* immediately before changing their shape.[23] When ectopically expressed outside the ventral furrow primordium, *fog* is capable of eliciting those same initial cell shape changes, even in cells that lack *twist* or *snail* or any other factors normally affecting mesodermal fate.[24] All this makes *folded gastrulation* an excellent downstream target for *twist* and *snail*, one whose expression might account for the cell shape changes associated with mesodermal programming.

fog is the only Heidelberg gene (other than *twist* and *snail*) that affects ventral furrow formation. Because *fog* embryos make slow uncoordinated invaginations, whereas *twist* or *snail* embryos make no ventral furrow at all, *fog* cannot be the only target of *twist* and *snail*. Other genes not detected in Heidelberg must account for the difference between the *twist*, *snail*, and *fog* phenotypes, and for the delayed mesodermal invagination that still occurs in *fog* mutants. These target genes may not have been detected in Heidelberg because they may not be essential for mesoderm invagination, as long as the embryo has a wild-type allele of *fog*. They might, however, have been detected if mutant

embryos had been scored directly for morphological defects during gastrulation itself. Given the large number of stocks examined, this was not possible in the Heidelberg mutagenesis experiments. On the other hand, the relevant chromosomal regions might be identified by using translocation crosses, since only a small number of such crosses are needed to examine the effects of most chromosomal regions. Ongoing experiments of this kind in my lab suggest that there are regions that affect ventral furrow formation in ways that cannot be explained by any Heidelberg genes. Most of these morphological effects appear to be transient and similar to the case in *fog* mutant embryos; embryos that are deleted for these genes eventually internalize their mesoderm. It is therefore possible that point mutations in the genes responsible for these early morphological effects may not cause lethality or easily visible effects on final morphology.

The Relationship between Cell Fate and Cell Form

The efficiency with which mutagenesis screens identify mutations affecting cell fate but not cell form may point to a difference in the way the two processes are controlled. The existence of mutations affecting cell fate suggests that patterning functions are not redundant; each gene is absolutely essential for normal development. If only single, nonredundant factors control cell fate, ambiguity in determined states might be avoided. In this view, a precise cell-by-cell pattern of gene expression may not be as important as having at least some cells unambiguously programmed to each fate. Once a cell choice has been made, it must be realized in morphological terms. At this point there may be an enormous advantage for redundancy, since multiple pathways might ensure that a particular fate, once chosen, is actually achieved. This redundancy need not be total; elimination of a single target pathway may causes subtle deviations in the process similar in magnitude to the defects observed in the ventral furrows of *fog* embryos. In this view, cell shape changes at gastrulation would be the summed effect of various targets, each of which would be necessary for the characteristic wild-type morphology, but not for the final outcome itself.

Developmental biologists are a diverse lot; some are more interested cell fate and patterning, others in morphogenesis. Those interested in pattern might focus on genes like *twist* and *snail*, since their expression at the blastoderm stage determines the ventral cells to become mesoderm (Fig. 4 left). In this view, genes like *fog* would be just one of many downstream regulators. On the other hand, the cell shape changes that occur in mesodermal cells during ventral furrow formation are not restricted to gastrulation. Moreover, genes like *fog* are expressed in other stages and other primordia, not under control of *twist* and *snail*. Thus from the standpoint of the cellular morphology, genes like *fog* become the central players (Fig. 4 right). *fog*-Dependent cell shape changes may be activated in a variety of different developmental programs by a variety of different cell fate genes, but its role in cellular behavior would be conserved.

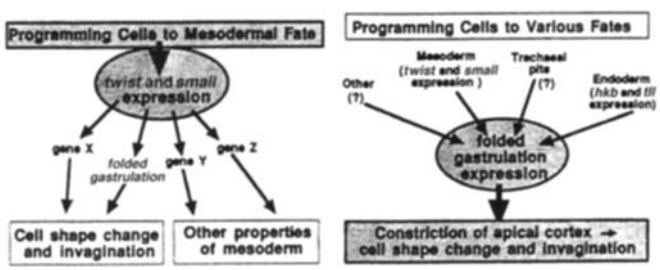

Fig. 4. Contrasting views of development. The left-hand side emphasizes programming of cells to specific cell fates; the right-hand side emphasizes the cellular mechanisms that produce changes in morphology.

Conclusions: The Powers and Limitations of the Genetic Approach

Mutagenesis experiments are a mixture of random and biased elements. Perhaps their strongest advantage is that we scientists have very little control over the kind of mutations produced. Mutations occur randomly throughout the genome, eliminating genes whether or not they have anything to do with the process of interest. This means that the production of mutants is usually not affected by biases about the kinds of molecules involved or the underlying mechanisms. Success depends on the experimenter's ability to sort through the mutations obtained and to recognize and interpret phenotypes of interest. It is this second step that introduces the major bias, in that it depends on the scientist's response to mutant phenotypes and on his or her ability to understand the nature of the defect and the proper context in which it can be described. Because we used a dual-observation microscope, Christiane and I were often simultaneously confronted with particular phenotype for the first time. It was not always easy to agree about defects or to decide why a particular stock was interesting. Because they were often the product of intense discussions, our final descriptions benefitted from a dual input. However, Christiane and I were both primarily interested in spatial patterns and gross morphological aspects of embryogenesis. Mutations affecting finer aspects of cell differentiation were certainly produced in Heidelberg, but even if they had caused embryonic lethality, they would have been discarded.

In addition to the bias introduced by experimenters, genetic screens are inherently biased by the organism. *Drosophila* embryos develop rapidly and most gene products are supplied by maternal rather than zygotic transcriptions. Development is highly regulative and cell signaling pathways ensure that a constant final morphology is achieved even when starting situations are different. One obvious limitation of the Heidelberg screen is that even though we were interested in broad aspects of morphology and early changes in cell shape, we scored only final differentiation, and there only cuticle pattern. Because the hypodermal cells that secrete cuticle represent such a large fraction of the blastoderm, we assumed that it would be not be possible to cause morphological changes at gastrulation without altering final morphology. Our later experiments suggest that this may not be true. Thus although we were not necessarily biased between mutations affecting cell fate and cell form, most genes actually detected altered fate, perhaps because effects on form in *Drosophila* are often more transient.

It is possible that different results would have been obtained had we chosen a different organism. One is curious whether

nematodes, which show an extraordinarily constant lineages, would be more subject to subtle perturbations in the movement and positioning of cells than *Drosophila*. Development in vertebrates, on the other hand, has been shown to be much more variable in terms of cell lineage and much more regulative in achieving constant final morphologies. In that respect, the ongoing screens for mutants in zebra fish and mice may produce a spectrum of genes more similar to that of *Drosophila*.

Of course, one of the important lessons from the Heidelberg experiments is that such speculations generally have little predictive value. The phenotypes and genes actually obtained by a particular mutagenesis protocol will only be known once the experiments are done. The same lesson applies to the ongoing analysis of *Drosophila* development. In spite of enormous advances made in understanding cell fates, we do not yet know how those programs produce constant morphology and structure. The morphologies assumed by *Drosophila* cells are often very similar to those in vertebrates. Moreover, the molecules and therefore the underlying mechanisms have probably been conserved over the course of evolution. By bridging the connection between cell fate and cell form in *Drosophila*, we may therefore also reinforce the bridges that connect developmental studies in all different organisms.

Crystal Packing and Molecular Geometry

J. Jens Wolff*

It is still not possible to deduce the packing of a molecular crystal from the structure of its constituent molecules. Crystal engineering, the often-stressed construction of crystal structures at will, in general remains an unrealized vision. While great strides have definitely been made since the pioneering work of Kitaigorodsky, neither computational methods[1] for the calculation of packing structures, nor experimental studies[2] can analyze this paradigm of molecular recognition in a completely satisfactory manner. This comes as no surprise—crystal packing is determined by a great number of factors, with the van der Waals energy as the dominant term. Even quite small energy differences may drastically alter a packing pattern. Parallels may be drawn to stereoselective synthesis where small differences in energies, which are more than often the sum of different effects, decide the success or failure of a particular reaction. Recurring ordering motifs in the structures of molecular crystals have at least been identified for crystals of aromatic hydrocarbons.[3a] In this class of compounds, the possible intermolecular interactions[3b] are restricted to the van der Waals type, and the molecular shape, since the occurrence of different conformers is limited,[3c] restricts the number of possible packing patterns to a few types (see Fig. 1). Even in this area, surprises are still possible as exemplified by the structural analysis of **1**, which unexpectedly crystallizes in a γ-type rather than a sandwich pattern.[3d]

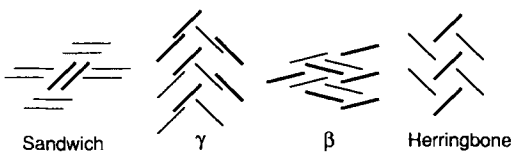

Fig. 1. Frequently occurring packing patterns for aromatic hydrocarbons.

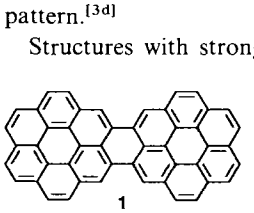
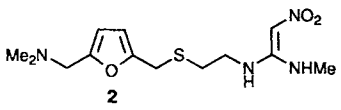
Structures with strongly directional intermolecular interactions like hydrogen bonds have also been investigated frequently.[4] This approach is akin to successful supramolecular chemistry in solution which frequently draws upon hydrogen bonds as the organizing element.[5] The statistical analysis of the contents of the Cambridge Crystallographic Database[6] has made it possible to identify a multitude of further intermolecular interactions in crystals like CH···O and Cl···Cl contacts.[2] However, it may be difficult to decide for a given case to what extent these interactions really determine the observed structure.



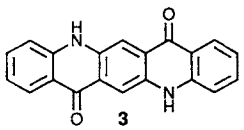
1

Special problems are presented by the phenomenon of polymorphism,[7] which arises when one molecule crystallizes in two or more geometrically different structures that are close in energy. Polymorphs may not even always be obtained reproducibly.[8] Preoccupation with the problem of polymorphism is not necessarily esoteric. For example, the acid blocker ranitidine (**2**), the active constituent of the best-selling drug worldwide in 1992, exists in two polymorphic forms of which only one is bioaccessible. Several lawsuits against the manufacturers of generic drugs, all won by the patent holder, centered around the protectability of the active polymorph, which had been discovered seven years later than the inactive form.[9]



2

Clearly, the mode of molecular packing determines the practical value of a material not only in solid-state organic syntheses[10] but also in all areas of applied research that depend on the solid-state properties of molecular crystals. Many organic pigments occur in different polymorphic forms that have different optical properties, for example quinacridone (**3**), which exists in orange to violet modifications, and copper phthalocyanine.[11] The use of crystalline materials for second-order nonlinear optics[12] requires the NLO-phores at least to crystallize in noncentrosymmetric space groups—not a trivial problem to solve, because about three-quarters of all nonchiral organic compounds adopt centric space groups in the solid state.[13] Likewise, materials with special electric[14] or (ferro-)magnetic[15] properties require well-defined molecular arrangements.



3

Polymorphic forms often occur for molecules with high conformational mobility. Frequently in different polymorphs quite different conformers are observed. At present, this interplay between packing pattern on one hand and molecular conformation on the other is also little understood. Outside the realm of crystallography, it is still common to consider one molecular

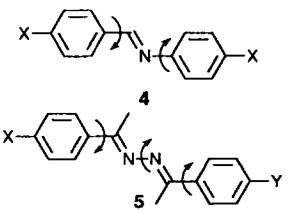
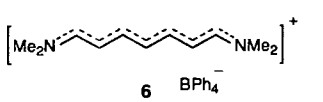
structure elucidated by diffraction methods as *the* structure of the molecule; in other words, this structure is implicitly looked upon as that of the nonperturbed, isolated molecule in the gas phase. Molecular parameters that do not agree with this perception are thought to arise from "crystal packing forces". Only in rare cases may these forces be approximately quantified. Methods available for studying these crystal fields are: the comparison with data observed or computed for the gas-phase structure, the comparison of crystallographically independent molecules within the same crystal, and the comparison of molecular parameters for different polymorphic crystal forms. Unfortunately, most molecules are either not volatile enough or too complex in structure for sufficient information to be obtained from spectroscopic methods in the gas phase. For many molecules only one crystal form with crystallographically identical molecules is obtained (or studied). Four examples taken from the recent literature (apart from the review articles cited) qualitatively illustrate the state of the art in this area, with its successes as well as its problems: a systematic study of a class of compounds and examples of structures distorted by ionic interactions, of conformational polymorphism, and of structure-dependent photochromism.

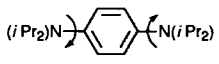
For the study of the influence of crystal packing on molecular parameters it is advantageous to use molecules with high polarizabilities and conformational mobilities. Recently, Glaser et al. have tried to employ the azines **5** as probes for the quantification of crystal packing forces.[16] Schiff bases like **4** had already proven valuable in the studies of conformational polymorphism by Bernstein,[7d] who found crystal packing effects on the order of 2 kJ mol^{-1} for the rotamers that occur in the polymorphic forms of **4**. Seventeen azines of acetophenone (**5**) were investigated. The results show that the *gauche* conformation around the N–N bond favored for the gas-phase structure according to ab initio calculations may be altered by packing effects. In some crystals the *trans* arrangement is found. However, the expectation of push–pull effects on the molecular conformation (e.g. for X = MeO and Y = CN) could not be substantiated, since the molecular parameters of symmetrically substituted compounds do not differ appreciably from those with push–pull sub-stitution. Likewise, the crystal packing effects observed could be explained solely on the basis of van der Waals contributions to the packing energy without invoking any polar contributions.



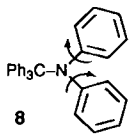
Dähne and Reck[17] succeeded in distorting the equalized C–C bond lengths along the chain of the cyanine **6** in the solid state to a maximum alternation of 0.02 Å, an effect that had not been encountered before with small counterions like tetrafluoroborate. The sterically demanding tetraphenylborate ion requires a good van der Waals contact for optimum packing. As a consequence, the distribution of negative charge in the vicinity of the cyanine cation becomes quite unsymmetrical, which leads to a much greater distortion as would be expected for a corresponding point charge.



Conformational polymorphism was observed with **7**.[18a] Two different rotamers with respect to the C–N bond are found in two polymorphs which, due to the different ability for conjugation with the π-system, also differ in the pyramidality at the nitrogen atom and in the *ipso* angles of the benzene rings. PM3 calculations indicated that the conformers are very close in energy; the differences in the packing energies between the polymorphs fall into the range of about 4 kJ mol^{-1}. Similar effects on the molecular structure had been found before for **8** for which two C–N rotamers coexist in the same crystal.[18b]

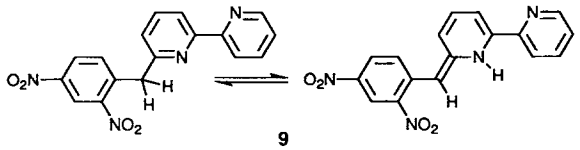


7



8

Crystals of **9**, a member of a class of compounds known to be photochromic, exist in two polymorphic forms of which only one shows photochromic behavior.[19] The arrangement of **9** in the polymorphs shows distinct differences. The inactivity of the first polymorph was ascribed to the short intermolecular contacts between the molecules, which could lead to the deactivation of the excited state and thus impede the proton transfer. This study also highlights the far-reaching consequences that even extremely subtle changes in molecular shape may have on crystallization: even deuteration of the methylene group of **9** markedly changes the ratio in which the two polymorphs occur.



9

Especially this last observation could leave doubts whether an ab initio description of the packing of organic molecular crystals will ever be possible. Certainly, a precise quantificiation of the influence of crystal fields[20] on the molecular conformation will be very useful. On the other hand, the nucleation and the kinetics of growth of molecular crystals[21] will have to be studied intensely, for example by observation of the integration of contaminants into the crystal lattice; optically anomalous crystals[2b] are suitable candidates for studies of this kind. Reducing the problem of crystallization from three to two dimensions, as offered by the investigation of the self-organization of monomolecular layers on surfaces, also promises decisive progress.

The Tricks of Ribosomal Elongation Factors**

Knud H. Nierhaus*

Elongation factors (EF) catalyze protein biosynthesis. Two classes of elongation factors can be differentiated: EF-Tu and EF-G in eubacteria and EF-1 and EF-2 in archaebacteria and eukaryotes. They can adopt at least two conformations; one when bound to GDP and another when bound to GTP. In addition, EF-Tu (EF-1) can have still other ligands.

The crystal structures of the various forms in which EF-Tu can appear[1-5] and those of EF-G with and without GDP[6, 7] have afforded exciting insights into the functions of elongation factors as well as into ribosomal mechanisms. The biggest surprise came from the crystal structure of the ternary complex aminoacyl-tRNA·EF-Tu·GTP.[4] Before we discuss the structures and some of the functional implications we will turn briefly to the process of protein biosynthesis.

In all cells ribosomes translate genetic information stored as nucleic acid (DNA or RNA) into proteins. The nucleic acids are composed of four building blocks, the nucleotides. A sequence of three nucleotides (codon) defines unequivocally one unit of a protein, an amino acid. Both nucleic acids and proteins are nonbranched molecules.

The information storage format is almost exclusively DNA; only some important virus families such as HIV store the protein sequences as RNA. To convert the information of a gene into a protein sequence, the corresponding region of the DNA is transcribed into an mRNA (transcription). The sum of all mRNAs of a cell describes the actual synthesis program for cell proteins, the central importance of which is evident—more than 99.9% of all enzymes are proteins. The synthesis program can be regulated and adjusted to changing conditions; that is the importance of this circumstantial transcription procedure: The storage medium, DNA, is very long-lived (many years), whereas the mRNA is short-lived, and thus can be easily regulated (half-life of seconds to minutes. One of the most stable mRNAs is that from globin in erythrocytes with a half-life of about 100 days.)

A ribosome "walks" in codon "steps" along an mRNA and synthesizes the corresponding protein. The ribosome cannot read the codons itself but makes use of transfer RNAs (tRNAs). tRNAs are L-shaped molecules that carry an amino acid at the end of their short arm and expose three nucleotides at the end of their long arm. The three nucleotides are complementary to the codon that codes for the corresponding amino acid. The exposed trinucleotide is therefore called an anticodon. The one-codon movement of the ribosome along the mRNA is called a translocation.

During elongation, the extension of the growing peptide chain amino acid by amino acid, there are at least two tRNAs on the ribosome. Before translocation the tRNAs are present at the A and P regions, respectively. "A" stands for aminoacyl-tRNA and "P" for peptidyl-tRNA (Fig. 1). After translocation the tRNAs are in the ribosomal P and E regions. "E" stands for exit, since the tRNA liberated from its acyl residue is released from this region of the ribosome during the subsequent occupation of the A region. The ribosomal states before (Pre) or after translocation (Post) are the main states of the active ribosome, which are separated by high energy barriers (about 80 to 90 kJ mol^{-1}[8]). The Post state is probably lower in energy than the Pre state. This is indicated by the fact that after peptide-bond formation incubation at 37 °C for a couple of minutes is sufficient to promote translocation from the Pre to the Post state in the absence of the translocation factor EF-G and GTP (spontaneous translocation[9]). In contrast, a reverse translocation has been never observed with an isolated Post state; however, a Post state can be converted into a Pre state in the presence of an A-region ligand such as *N*-acetyl-Phe-tRNA even in the absence of EF-Tu and GTP.

The elongation factors lower the activation barrier separating the two main states of the ribosome and thus dramatically accelerate protein synthesis by more than 10^4-fold. In this way they resemble enzymes, which also lower the activation energy of a reaction and lead to enormous acceleration factors of 10^6 to 10^{12}. But enzymes accelerate a reaction only until equilibrium is reached; in other words, one enzyme can catalyze both the forward and the back reaction. An elongation factor can do more: it accelerates a reaction and determines the direction of reaction as well. For example, EF-Tu catalyzes the Post → Pre transition and EF-G the Pre → Post transition. For this reason there are two elongation factors, one for each direction of reaction. Only the higher fungi such as yeast or *Candida albicans* require a third factor, EF-3, which is an E-region factor and essential for protein synthesis.[10]

Both universal elongation factors EF-Tu and EF-G are prototypes of the large superfamily of the G-proteins which regulate important processes of the cell. G-proteins are GTPases and pass through a basic GTPase cycle.[11] They can bind GTP and GDP and thus assume an "ON" and "OFF" conformation. In the "ON" conformation (GTP is bound) a G-protein can bind a protein or a complex and trigger a distinct reaction. Then the GTPase center of the G-protein is activated, the terminal phosphate residue is cleaved such that GDP is now bound, and the G-protein adopts an "OFF" conformation and dissociates from the protein or complex. A new cycle begins after the GDP has been regenerated to GTP.

Figure 1 shows the GTPase cycles of EF-G and EF-Tu which bind in the "ON" conformation to the ribosome. EF-G follows the most simple scheme possible for a G-protein. The EF-G·GTP complex binds to a ribosome which is in the Pre state and which carries the peptidyl-tRNA in the A region after peptidyl transfer. EF-G lowers the activation energy between the Pre and Post states of the ribosome (Fig. 1). Since the Post state is apparently lower in energy, the ribosome assumes this state

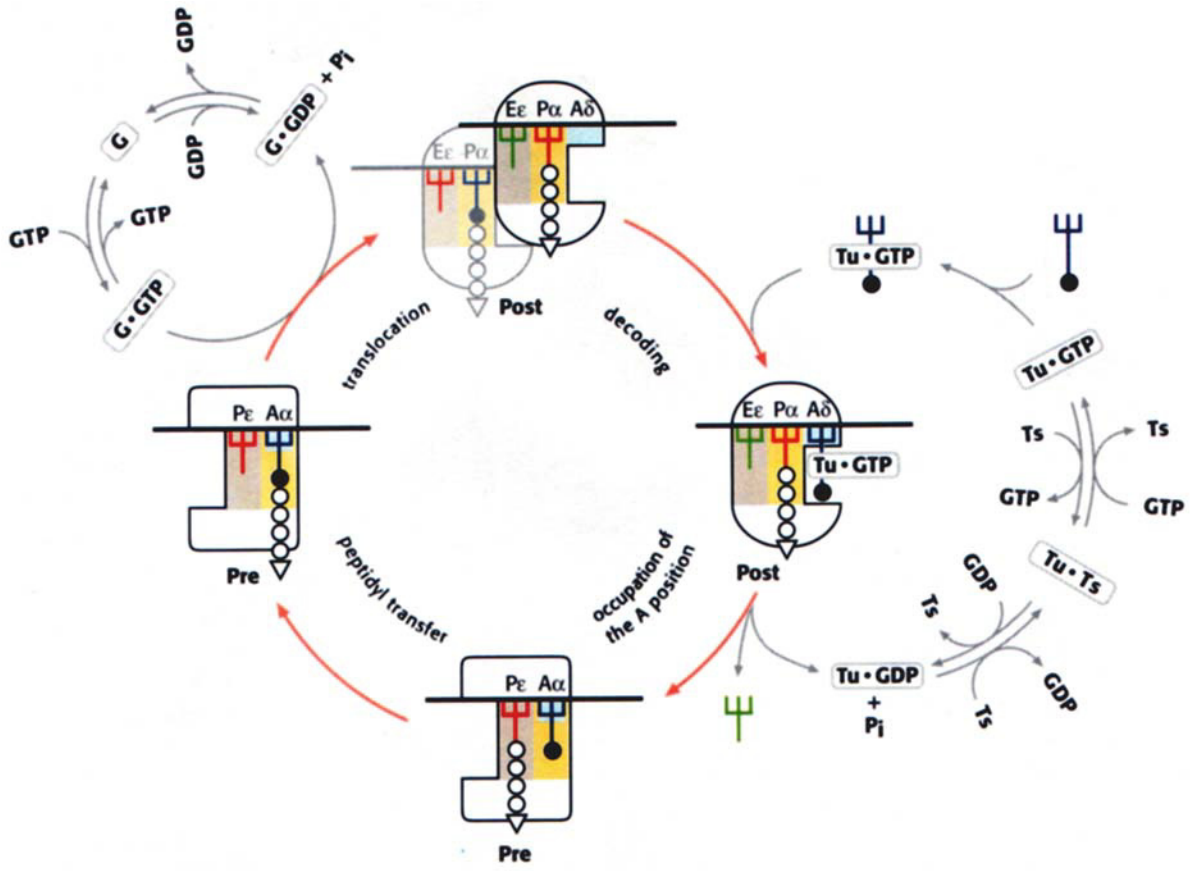

Fig. 1. The ribosomal elongation cycle (middle) and the GTPase cycles of the elongation factors EF-Tu (abbreviated as Tu, right) and EF-G (abbreviated as G, left). The elongation cycle is shown along the lines of the α–ε model, according to which the two tRNAs on the ribosome are bound to a movable domain of the ribosome. This movable domain contains two binding sites α and ε. The binding sites expose the tRNAs at the A and P regions of the ribosome in the Pre state and carries the tRNAs to the P and E regions, respectively, during translocation, thus establishing the Post state. In addition the decoding center δ is fixed at the A region; it overlaps with the α site in the the Pre state but stands alone in the Post state.

and now carries the peptidyl-tRNA at the P region and the deacylated tRNA at the E region. After the ribosome activates the GTPase center by means of an unknown mechanism, the resulting EF-G·GDP assumes the "OFF" conformation and dissociates from the ribosome. The activation barrier is raised again and keeps the ribosome stable in the Post state.

EF-G has a very low affinity to both GTP and GDP (2.7×10^4 M^{-1}[12] and 2.5×10^5 M^{-1},[13] respectively) so that the actual concentrations of GTP and GDP in the cell (ca. 1 mM and 0.1 mM, respectively[14]) are sufficient to replace GDP by GTP without the help of an additional factor, thus enabling the next round of an EF-G cycle.

The situation with EF-Tu is more complicated since EF-Tu·GTP alone cannot bind to the ribosome. It must first bind to an aminoacyl-tRNA and then form the ternary complex aminoacyl-tRNA·EF-Tu·GTP. This is a consequence of the second essential task of EF-Tu besides catalyzing the Post → Pre transition, namely to carry an aminoacyl-tRNA to the ribosome.

At this point, the X-ray crystal structure of the ternary complex (Fig. 2A[4]) is quite surprising. The ribosome is thought to use more than once the codon–anticodon interaction (proofreading) in order to achieve the accuracy of about one error per 1000 incorporated amino acids. Proposed proofreading mechanisms assume that EF-Tu uses the energy released during the hydrolysis of GTP for driving the proofreading process.[15] However, the crystal structure of the ternary complex demonstrates that EF-Tu binds the aminoacyl-tRNA at the short arm of the tRNA about 50 Å away from the anticodon (Fig. 2A), and thus EF-Tu hardly has a chance to interfere with the mechanism of codon–anticodon interaction. This conclusion is in accord with the results of recent investigations,[16] which suggest that the recognition (initial binding) of a correct codon–anticodon interaction in the ribosomal decoding center δ raises sufficient energy to explain the accuracy of 1:1000 of protein synthesis without the assumption of a proofreading mechanism. This explanation significantly simplifies the hypothesis for the selection of the correct ternary complex.

Accordingly it is probable that the correctness of the codon–anticodon interaction is checked at the decoding center δ without the participation of EF-Tu. In this view the considerable binding energy of EF-Tu and the aminoacyl-tRNA outside the anticodon region is exploited to drive the transition to the pretranslocational state only after the decoding has been completed successfully. It is generally accepted that replicases and trancriptases, which synthesize DNA and RNA, respectively, probe the stereochemoical correctness of base pairing in the course of nucleic acid synthesis and that these enzymes achieve an accuracy of better than 1:10000 without proofreading.[17]

The biggest surprise is that the X-ray crystal structures of the ternary complex and EF-G·GDP are very similar (cf. Figs. 2A

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2199 $ 15.00+.25/0

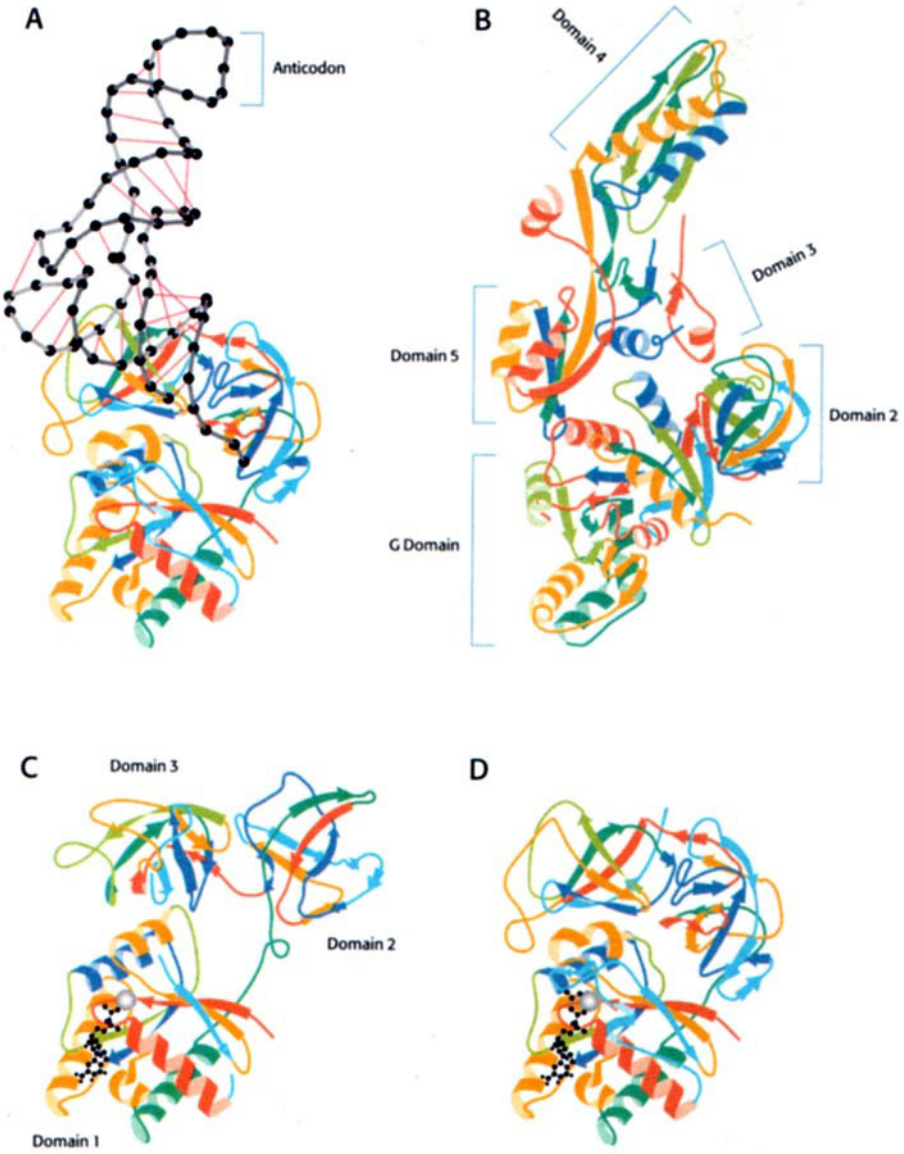

Fig. 2. X-ray crystal stuctures of elongation factors. A: Ternary complex Phe-tRNA·EF-Tu·GTP, adapted from refs. [4, 21]. B: EF-G from *T. thermophilus*, adapted from refs. [6, 7]. C and D: EF-Tu·GDP and EF-Tu·GTP, respectively. The *E. coli* sequence of EF-Tu has been modeled in analogy to the structure of EF-Tu·GTP from *Thermus thermophilus* [2]. GDP and GTP are represented as black ball-and-stick models. The Mg^{2+} ion important for the GTP/GDP binding is shown as a gray sphere; adapted from ref. [21].

and B)! The EF-G structure shows five domains (Fig. 2B); domains three to five imitate the structure of the tRNA component of the ternary complex! This is a surprising example of molecular mimicry. The ribosome model shown in Figure 1 suggests the following interpretation:[18] After EF-G·GTP has established the Post state of the ribosome, the domains of EF-G mimicking a tRNA bind to the vacant decoding center. This simple action prevents a reverse translocation of the ribosome into the Pre state as long as the presence of EF-G on the ribosome keeps the energy barrier between the two ribozome states low. After the hydrolysis of GTP, EF-G·GDP dissociates from the ribosome, the activation energy is raised again, and the ribosome is held in the Post state until the next ternary complex has finished decoding.

After EF-Tu has triggered the Pre state of the ribozyme, the ribosome activates the GTPase center of EF-Tu, probably by a similar mechanism to that in the case of EF-G. The resulting EF-Tu·GDP adopts the "OFF" conformation and dissociates from the ribosome. The structure of the "OFF" conformation of EF-Tu·GDP is more open than that of EF-Tu·GTP (cf. Figs. 2C and 2B). Upon cleavage of GTP, domains 2 and 3 move away from domain 1 as a block, and domain 2 departs from domain 1 by astonishing 40 Å.

In striking contrast to EF-G, the factor EF-Tu binds GDP with high affinity ($6 \times 10^8\ M^{-1}$) and GTP with ten times less affinity (which is still relatively high).[19] The consequence is that the concentrations of GDP and GTP in the cell do not influence the binding of the guanosine nucleotides to EF-Tu. Therefore, the special factor EF-Ts exists which regenerates EF-Tu·GTP from EF-Tu·GDP; this factor binds to EF-Tu·GDP and mediates the replacement of GDP with GTP.

The X-ray crystal structure of EF-Tu·EF-Ts[5] demonstrates that the complex is not a heterodimer as expected but rather a tetramer. In the tetramer both EF-Ts units have distinct contact areas, whereas the EF-Tu molecules hardly touch each other. Accordingly, the structure of the tetramer is best described as EF-Tu·$(EF\text{-}Ts)_2$·EF-Tu. The motif Thr-Asp-Phe-Val82, which is conserved in all structures of EF-Ts known, plays a dominant role in the replacement of GDP. The amino acids Asp80-Phe81 press into the GDP binding site and displace three amino acids of EF-Tu, which stabilize two H_2O molecules. Both water molecules are coordinated to a Mg^{2+} ion which is essential for the affinity of Ef-Tu to GDP. The disruption of the Mg^{2+} binding site causes the loss of GDP, which now can be replaced by GTP. These reactions are reversible, but for effective protein synthesis GDP must be replaced by GTP and not vice versa. The direction of the GTPase cycle (Fig. 1) is determined by the practically irreversible formation of the ternary complex, which removes EF-Tu·GTP from the equilibrium reactions.[20]

The X-ray crystal structures discussed here have afforded surprising insights into the functions of elongation factors and of G-proteins in general. The strucures shed some light on ribosomal mechanisms such as decoding and give an exciting example of molecular mimicry. Yet the ribosome, the most complicated complex in the cell, is not well understood. Exactly how the ribosome activates the GTPase centers of the elongation factors and by which mechanisms elongation fac-

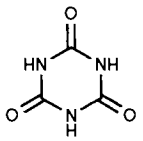
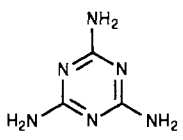
Programming a Hydrogen-Bonding Code for the Specific Generation of a Supermacrocycle**

Mark Mascal,* Nicholas M. Hext, Ralf Warmuth, Madeleine H. Moore, and Johan P. Turkenburg

The organization of matter brought about through noncovalent forces makes feats of molecular engineering possible that are virtually unthinkable from a covalent perspective. The natural world provides numerous examples of this, and yet benchtop efforts to master the behavior of molecules, apart from those immediately derived from natural systems, have been modest. The challenge lies both in the realm of information and in chemical synthesis: The conceptualization of an organized state of matter is intimately linked with the design of real components that possess the steric and functional information necessary to translate concept into substance.[1] Much of the work done along these lines has been devoted to the use of hydrogen bonds as the design principle,[2] and the structures expressed have spanned the range of dimensions, from diamondoid[3] and dendrimeric[4] (three-dimensional), to sheets (two-dimensional),[5] to various descriptions of chains,[6,7] helices,[8] and even tubes (one-dimensional).[9] Interestingly, an acknowledged challenge has been to *restrict* the dimensionality to effectively "zero",[10-12] such that the structure qualifies as a discrete, nanoscale species and not simply a crystal motif. Recently, this has taken the form of the cyclic hexameric aggregate based on the melamine (**1**)–cyanuric acid (**2**) cocrystal originally reported by Lehn et al.[6] and Whitesides et al.[7] Because the hydrogen bonding donor (D)-acceptor (A) patterns (or codes) are centrosymmetric in **1** and **2**, an ambiguity arises in the expression of the information,[13] leading to two distinct infinite chain structures besides the cyclic hexamer.[14] Although all three states of aggregation have been obtained by careful control of the steric demands of the components, the high-fidelity matching of hydrogen-bonding information which would lead exclusively to a "supermacrocycle" remained elusive.

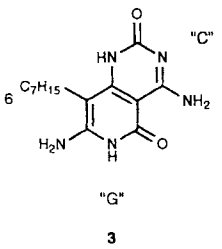


1

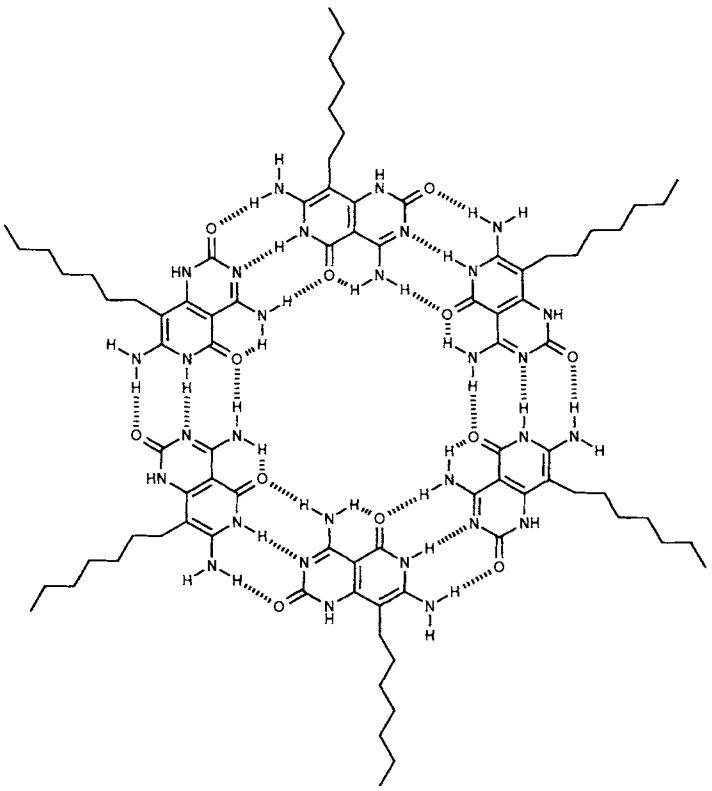


2

We now report the synthesis of a DNA-base hybrid purpose-designed to function exclusively as the cornerpiece of a hexagon: The combination of the A-A-D sequence of cytosine and the complementary D-D-A sequence of guanine at an angle of 120° to each other in pyrido[4,3-*d*]pyrimidine **3**, leads to the assembly of independent hexagonal aggregates $\mathbf{3}_6$ in the solid state (Scheme 1). This is purely the result of the communication of programmed, hydrogen-bonding information.



3



Scheme 1. The enforced self-assembly of molecules of **3** into a hexamer.

Subunit **3** was synthesized in five steps from the commercially available, inexpensive malononitrile dimer **4** (Scheme 2). Experience had shown that the final product would require a tail-group for solubility purposes,[15] and thus **4** was first alkylated by treatment with heptyl bromide and base to give **5** (71%). Cyclization with sodium methoxide gave the pyridine **6** (69%) together with the regioisomer that results from attack at the wrong cyano group (19%). Selective protection of the amino group in the 2-position was accomplished by deprotonation and subsequent treatment with dimethyl carbonate to give **7** (85%). The most difficult step proved to be formation of the second ring. After much trial-and-error, it was found that reaction of **7** with chlorosulfonyl isocyanate gave bicycle **8** in a modest 15% yield. The simultaneous demasking of both the amino and latent carbonyl functions with trimethylsilyl iodide (TMSI) proceeded smoothly to give the target material **3** in 73% yield.

The preparation of solutions of **3** in warm DMSO[16] results after several hours in the deposition of large, clear crystals of cubic habit, which show no extinction of plane-polarized light. X-ray structural data collected[17] by using synchrotron radiation indicated that **3** crystallized in the very rare cubic space group $Ia\bar{3}d$ (number 230), which possesses the highest symmetry of all space groups.[18] The unit cell contains 96 molecules of **3** and has a total volume of over 100000 Å^3. The programmed hexagonal motif (Fig. 1) can clearly be seen in the view of the

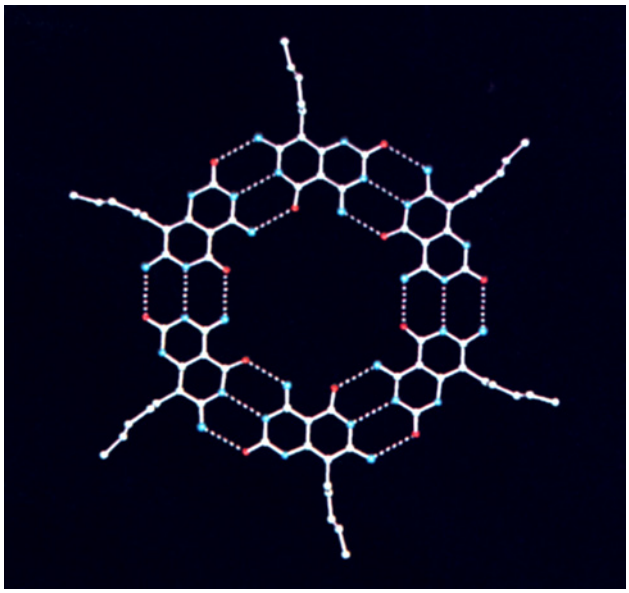

Fig. 1. The hexagonal motif $\mathbf{3}_6$ taken from the crystal structure.

unit cell (Fig. 2). The macrocycle is assembled through 18 intermolecular hydrogen bonds, (O···N (outer) 2.80, N···N 2.91, and O···N (inner) 2.91 Å); six additional intramolecular hydrogen bonds are observed between N5-H and O2 (N···O 2.66 Å). It is worth noting that the AAD–DDA interactions present in $\mathbf{3}_6$ are known to be more effective than those in **1**·**2** (ADA–DAD), the latter possessing stability constants in solution two orders of magnitude inferior to typical C–G pairs.[19]

An important feature of this structure is that the hexamers coincide with each other to describe channels with a diameter of 10.5 Å that extend through the crystal (Fig. 2). Alternate $\mathbf{3}_6$ units are rotated 24.3° in the plane of the hexagon and translated 20 Å down a perpendicular threefold axis that runs parallel to the body diagonals. The maximum deviation of the ring atoms from the plane of the hexamer is ±0.2 Å. The C_7 alkyl chains, however, extend above and below the plane in an alternating up–down arrangement related by an S_6 axis. Although the rigid core of **3** is well ordered, the alkyl chain shows dramatic progressive disorder with increasing distance from the ring atom (Fig. 3), such that the last two carbon atoms could not be located. The crystal has a calculated density of only 0.479 g cm^{-3} based on the empirical formula, which indicates that the void space (ca. 65% of the crystal) is occupied mainly by liquid solvent,[20] although partial occupancy of two solvent molecules per molecule of **3** can be modeled on the data. The presence of this solvent in the crystal prevented low-temperature data collection, but even taking this and the disorder in the structure into account, refinement gave an *R* value of 0.152 (for all $I \geq 2\sigma(I)$ data). This compares to values for the "rosette" reported by Whiteside et al. (0.112)[14d] and for the channel-forming macrocycle (0.176) reported by Moore et al.[5d]

In conclusion, we have demonstrated the value of a high-level information approach in imposing a predetermined state of order on molecular crystal components. An independent study of a related molecule has

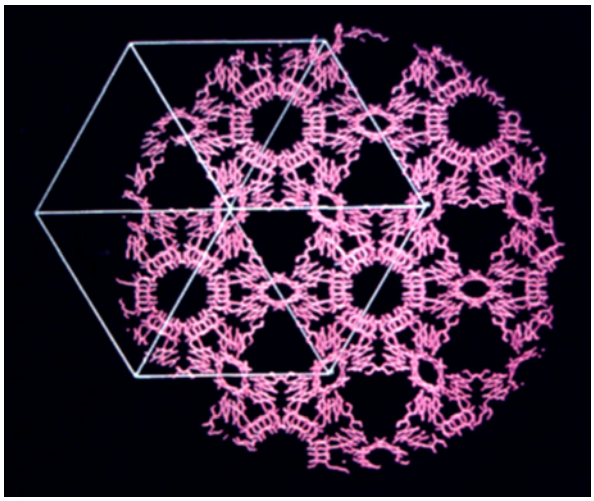

Fig. 2. A view of the cell of **3** along a body diagonal.

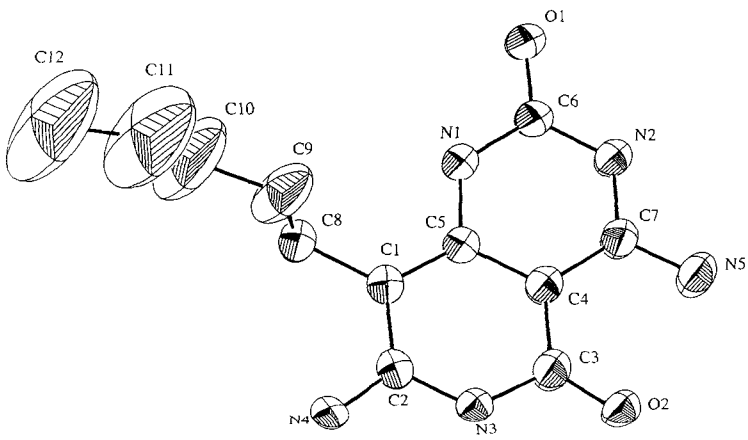

Fig. 3. An ORTEP view of **3** showing 20% ellipsoids.

provided evidence for the existence of such order also in the solution state.[21] We foresee applications of precision self-assembly to the targeted fabrication of organized states of matter of ever increasing complexity from systems of components of advanced synthetic and informational sophistication. Efforts on our part are now being directed towards the inclathration of complementary species in the channel voids of $\mathbf{3}_6$, as well as the elaboration of the periphery for the exploitation of this effective means of generating hexagonal order.

[15] A version of **3** synthesized without the tailgroup did not dissolve to an appreciable extent in any solvent.

[16] Compound **3** also gave crystals of similar appearance from DMF and DMF/DMSO mixtures. The possibility that powerful H-bond accepting solvents such as these could interfere with the assembly process was considered, but the experience has been that interbase H-bonding tends to win out over competition: J.-M. Lehn, M. Mascal, A. DeCian, J. Fischer, *J. Chem. Soc. Perkin Trans 2* **1992**, 461.

[17] X-ray structure analysis of **3**: $C_{13.42}H_{14}N_5O_{2.71}S_{0.71}$ ($M_r = 311.34$), crystal dimensions $0.7 \times 0.4 \times 0.3$ mm; cubic, space group $Ia\bar{3}d$ (no. 230), $a = 46.980(5)$ Å, $V = 103691(19)$ Å^3, $Z = 96$, $\rho_{calc} = 0.479$ g cm^{-3}, $\lambda = 0.8700$ Å, $T = 293$ K, $F(000) = 15600$. A total of 72292 reflections were measured in the range 10–0.9 Å, $0 \le h \le 27$, $4 \le k \le 50$, $0 \le l \le 35$ at the CCLRC Daresbury Laboratory Synchrotron Radiation Source, station 9.6, using a MAR image plate detector. Merging gave 5725 unique data (overall $R_{int} = 0.057$). No correction for absorption or decay was applied. The structure was solved by direct methods in SHELXS-86. Refinement was carried out against F^2 in SHELXL-93 using all 5725 reflections. Hydrogen atoms were placed in calculated positions on the appropriate N atoms and on the first four C atoms of the alkyl chain. All non-hydrogen atoms were refined anisotropically and hydrogen atoms were refined by using a riding model (C–H = 0.97, N–H = 0.86 Å) with $U_{iso}(H) = 1.2U_{eq}(C, N)$. Full-matrix least squares refinement of 247 parameters gave $R_F = 0.1701$ [$R_F = 0.1523$ on $I \ge 2\sigma(I)$ data] and $S = 1.723$. Although the overall solution is satisfactory, we are continuing to investigate the distribution of the remaining solvent molecules. Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-90. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[18] This is the first report of an all-organic molecule in this space group. Only two other molecules in $Ia\bar{3}d$ are identified in a search of the Cambridge Crystallographic Database (F. H. Allen, J. E. Davies, J. J. Galloy, O. Johnson, O. Kennard, C. F. Macrae, E. M. Mitchell, G. F. Mitchell, J. M. Smith, D. G. Watson, *J. Chem. Info. Comput. Sci.* **1991**, *31*, 187).

A Neutral, Triple-Helical, Trinuclear, Oxo-Centered Mixed-Valence Iron Complex**

Rolf W. Saalfrank,* Stefan Trummer, Harald Krautscheid, Volker Schünemann, Alfred X. Trautwein, Stefan Hien, Christian Stadler, and Jörg Daub

In memory of Gerrit L'abbé

Programming and self-assembly are key concepts underlying the design of supramolecular systems.[1] Hitherto, interest has focused on the synthesis of helicates,[2] catenanes,[3] knots,[3] and cages,[4] as well as coordination polymers.[5] However, it is in principle possible to generate a larger variety of structures selectively by using appropriate ligands and metal ions.[4, 6]

Our interest in polynuclear supramolecular iron complexes mainly stems from the importance of oxo-centered polyiron aggregates as model compounds for iron–oxo proteins, oxidation catalysts, and corrosion inhibitors.[7] In principle, oxo-centered complexes related to $[Fe_3O(O_2CR)_6(H_2O)_3]$[7] with doubly negatively charged, pentadentate, tritopic ligands L should

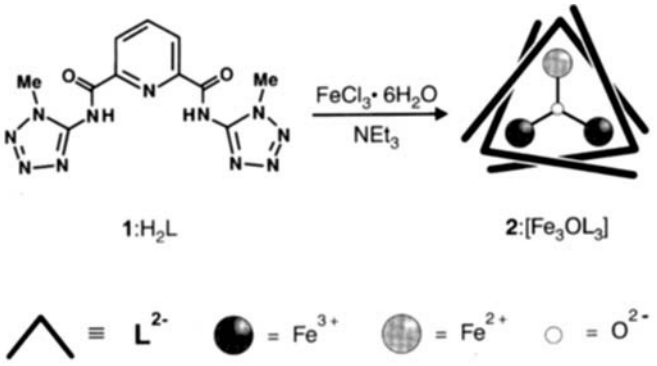
[**] Chelate Complexes, Part 7. This work was supported by the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and the Fonds der Chemischen Industrie. We are grateful to Prof. Dr. K.-P. Zeller, Universität Tübingen, for recording the numerous FAB-MS spectra. This work was initially conceived, while R. W. S. was occupying a chair at the Universität München. Part 6: R. W. Saalfrank, R. Harbig, J. Nachtrab, W. Bauer, K.-P. Zeller, D. Stalke, M. Teichert, *Chem. Eur. J.* **1996**, *2*, no. 11.

be accessible. This hypothesis is confirmed for $[Fe_3OL_3]$ by space-filling models.

We therefore doubly deprotonated H_2L (**1**)[8] at 20 °C with triethylamine, treated the corresponding dianion L^{2-} with a solution of iron(III) chloride, and after workup isolated dark green crystals. According to the microanalysis and FAB-MS data (FAB = fast atom bombardment) the product formed was a trinuclear iron chelate complex of the composition $[Fe_3OL_3]$ (**2**).



The oxygen atom in this formula apparently stems from deprotonated water of crystallization. Consequently an excess of triethylamine leads to higher yields. Furthermore under these conditions the water-soluble mononuclear by-product $[FeL_2]^-$ is formed only in small amounts.[9]

As the ^1H and ^{13}C NMR spectra of **2** do not enable unequivocal structure determination, we carried out an X-ray crystallographic analysis of the complex.[10] Compound **2** is present in the crystal as a neutral, trinuclear, iron chelate complex (Fig. 1).

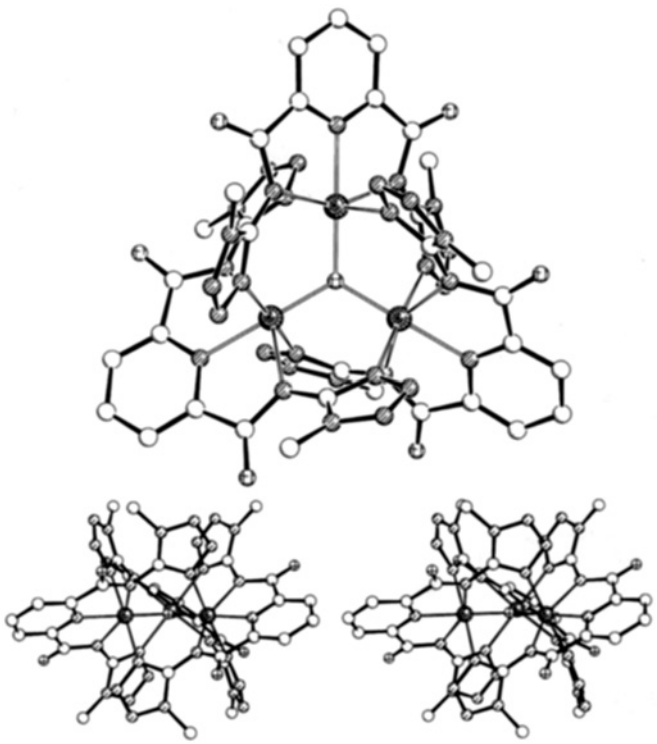


Fig. 1. Crystal structure of **2** (SCHAKAL representation). Top: view along the crystallographic C_3 axis perpendicular to the triangular plane. Bottom: stereorepresentation of a side view (for clarity H atoms have been omitted; C atoms shaded, N atoms hatched, O atoms cross-hatched, Fe atoms radially hatched). Selected bond lengths [Å] and angles [°]: (μ_3-O)-Fe 1.886(1), pyridine-N-Fe 2.070(3), amide-N-Fe 2.105(3), tetrazole-N-Fe 2.176(4); Fe-(μ_3-O)-Fe 120.0, (μ_3-O)-Fe-pyridine-N 180.0.

The core of complex **2** is generated by an equilateral triangle with a μ_3-O^{2-} ion in the center and three iron ions in the corners. Each of the three doubly negatively charged pentadentate ligands L (H_2L = **1**) links three metal centers. As a result all iron ions are distorted octahedrally, coordinated to five N donors and to a μ_3-O-ligand shared by the three iron atoms. The iron centers of the racemic complex $[Fe_3OL_3]$ (**2**) are homochiral. Since the tetrazolyl donors of the tritopic ligands attack neighboring iron ions at opposite sides of the (Fe,Fe,Fe)-triangular plain, a triple-helical, D_3-symmetric arrangement results (Fig. 2).[11]

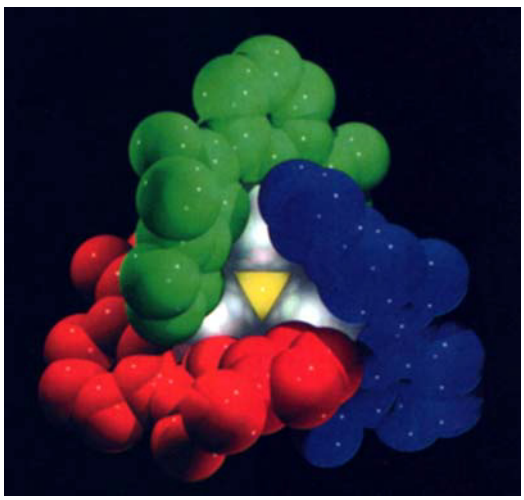

Fig. 2. Space-filling model of **2**; view along the C_3 axis perpendicular to the Fe,Fe,Fe triangular plane. To show the triple helix clearly, each ligand (H atoms omitted) is presented in a different color; oxygen atom yellow, iron atoms light gray.

The lack of a counterion implies intramolecular charge compensation and therefore mixed-valence character for $[Fe_3OL_3]$ (**2**). This is unambiguously confirmed by a Mössbauer spectrum of a powder sample of **2** recorded at 4.2 K. The spectrum exhibits two quadrupolar doublets with a peak area ratio of 1:2 (Fig. 3). The doublet with a quadrupolar splitting of ΔE_Q = 2.64(1) mm s^{-1} and an isomeric shift of δ = 0.95(1) mm s^{-1} is consistent with a high-spin iron(II) species (relative percentage: 33.7%), whereas the doublet with a quadrupolar splitting of ΔE_Q = 1.83(1) mm s^{-1} and an isomeric shift of δ = 0.53(1) mm s^{-1} is consistent with a high-spin iron(III) species

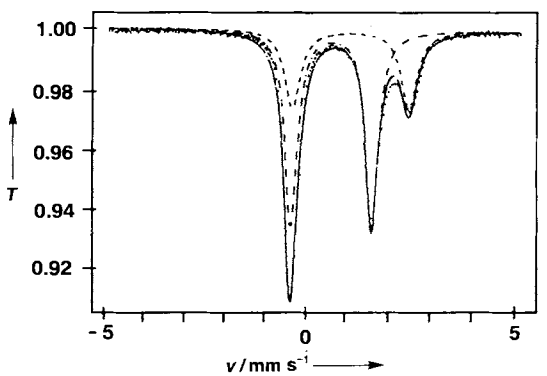

Fig. 3. Mössbauer spectrum of a powder sample of **2** recorded at 4.2 K. The connecting line is the result of an adjustment with two doublets of Lorentz lines. T = relative transmission, v = relative velocity.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2207 $ 15.00+.25/0

(relative percentage: 66.3%). It may thus be deduced that the mixed-valent trinuclear complex **2** is formed by two Fe^{III} ions and one Fe^{II} ion.

Under aprotic conditions[12] cyclic voltammetric investigation of the redox-active iron centers of neutral $[(Fe^{III})_2Fe^{II}OL_3]$ (**2**) shows two reversible one-electron transfer processes (chart speed 250 mVs^{-1}, Fig. 4). The half-wave potential $E_{1/2}$ =

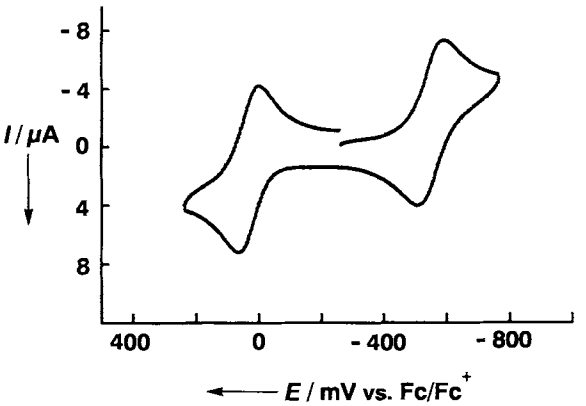

Fig. 4. Cyclic voltammogram of **2** in acetonitrile/0.1 M tetrabutylammonium hexafluorophosphate, scan rate 250 mVs^{-1}.

− 550 mV corresponds to the redox process $[(Fe^{III})_2Fe^{II}OL_3]/[Fe^{III}(Fe^{II})_2OL_3]^-$, whereas the oxidation of $[(Fe^{III})_2Fe^{II}OL_3]$ (**2**) to $[(Fe^{III})_3OL_3]^+$ occurs at $E_{1/2}$ = + 30 mV. In the reductive region at the peak potential $E_{1/2}$ = −1120 mV a further quasi-reversible pair of signals is recorded (not shown), which can be assigned to the all iron(II) species. However, this signal is not stable in a multisweep experiment, which is due to gradual decomposition of the dianion.

We will report elsewhere on the catalytic potential of $[Fe_3OL_3]$ (**2**) for the oxidation of olefins by hydrogen peroxide, and also by molecular oxygen.

Experimental Procedure

2: General procedure: To a solution of **1** (3 mmol, 988 mg) in 300 mL THF was added triethylamine (1.2 mL, 9 mmol, 911 mg) and a solution of $FeCl_3 \cdot 6H_2O$ (3 mmol, 811 mg) in 20 mL THF. The dark green mixture was stirred for 12 h at 20 °C, warmed to 66 °C during 3d, cooled to 20 °C, and filtered. The solvent was removed under vacuum, and the solid residue was dissolved in 150 mL trichlormethane. $[FeL_2]^-$ was removed by washing the organic phase eight times with 150 mL portions of warm water (40 °C). The organic layer was separated, dried over sodium sulfate, and concentrated to 30 mL. The product was crystallized by adding 50 mL of hexane, filtered off, and dried under vacuum (oil pump). Yield: 502 mg (43%), correct elemental analysis; m.p. >250 °C (decomp.); IR (KBr): $\tilde{\nu}$ = 1657, 1528, 1448 cm^{-1} (C=O, C=N, C=C, N=N); FAB-MS (3-nitrobenzylalcohol matrix): *m/z* (%): 1167.2 (100) $[M^+ + 2H]$.

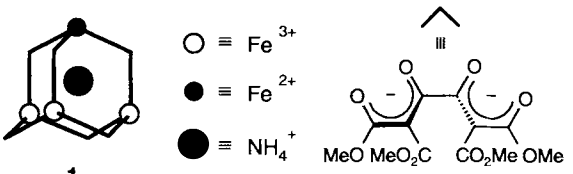
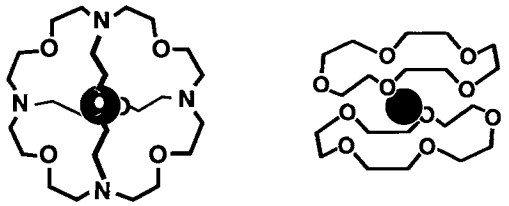
The First Metallacrown Ether Sandwich Complex**

Rolf W. Saalfrank,* Norbert Löw, Frank Hampel, and Hans-Dietrich Stachel

For some time we have been working in the field of cage compounds such as $[NH_4 \subset Fe_4L_6^1]$ (**1**), originating by the spontaneous self-assembly of preprogrammed bis(bidentate) bridging ligands and suitable metal ions.[1, 2] A notable feature of these tetranuclear adamantanoid endoreceptor complexes is their topological equivalence to cryptates (**2**).[2]

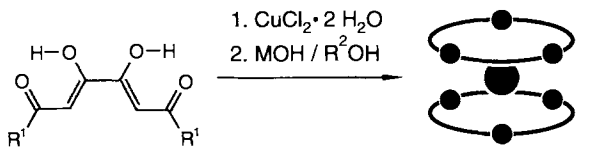


1 L^1



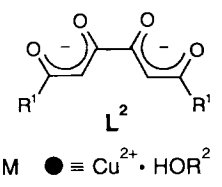
2 3

In principle, metallacrown ethers, [2]-metallacryptands, and [3]-metallacryptands[3] should exist parallel to the corresponding crown ethers, [2]-cryptands, and [3]-cryptands.[4] We were convinced that the analogy perceived between **1** and **2** is not a special case, but that the use of properly tailored ligands should give access to other metallatopomers. In order to test this hypothesis we treated dialkyl ketipinates **4a,b**[5] or tetraketone **4c**[6] with copper(II) chloride and aqueous ammonia or potassium hydroxide in methanol, obtaining dark green crystals in each case. The microanalytical data and FAB-MS spectra (FAB = fast atom bombardment) gave initial indications that the products were hexanuclear copper chelate compounds (**5**) of the general composition $[MOH(Cu_3L_3^2)_2]\cdot 6HOR^2$, constituting host guest systems topologically equivalent to well-known organocrown ether sandwich complexes **3** [for example, $KI(benzo[15]crown\text{-}5)_2$].[7] In principle, the composition of a coronate is dependent on the cavity diameter of the host. Correspondence between the size of host and guest leads to complexes with 1:1 stoichiometry, whereas "oversize" cations result in sandwich complexes with 2:1 stoichiometry.



4 5

4, 5	R^1	R^2	M
a	O*t*Bu	Me	NH_4^+
b	OE*t*	H	NH_4^+
c	*t*Bu	H	K^+



To obtain an unambiguous characterization of the molecular structure of the metallacoronates, we carried out an X-ray crystallographic structure analysis of complex $[NH_4OH(Cu_3L_3^2)_2]\cdot 6HOMe$ (**5a**).[8] According to this analysis, **5a** is indeed present as a metallacrown ether sandwich complex (Fig. 1).

The cation **5a** consists of two identical, neutral, 15-membered trimetallacrown-6 building blocks, twisted relative to each other by 60°. The ammonium ion in the center is sandwiched by the

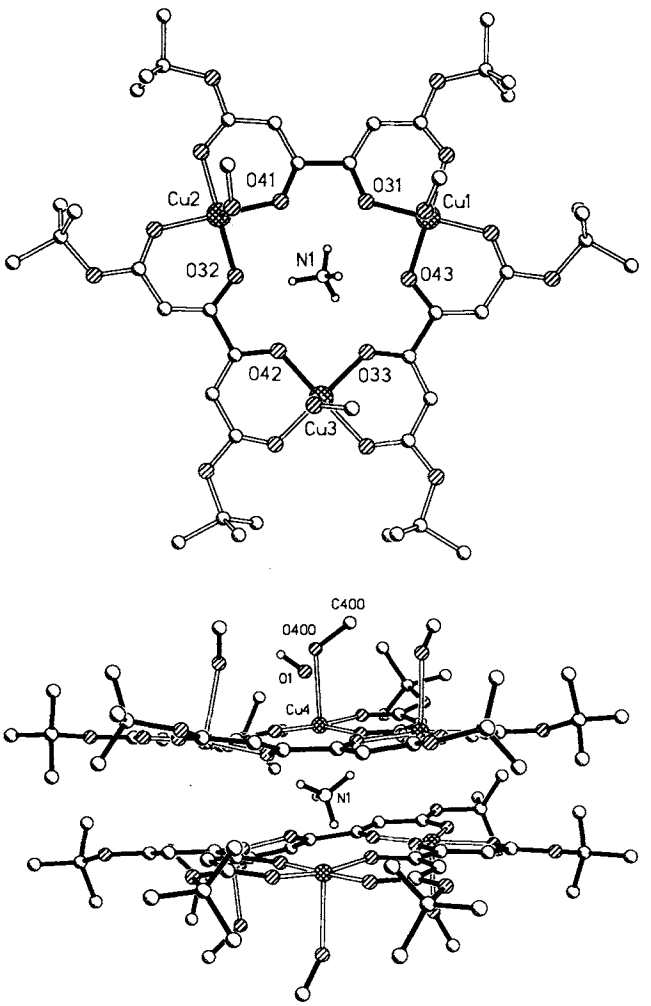


Fig. 1. Top: Structure of one 15-membered trimetallacrown-6 unit of sandwich complex **5a**, including the ammonium ion (top view: H atoms omitted, O atoms hatched, Cu atoms double hatched, C atoms shaded, N atom and ammonium-H atoms empty; counterion omitted). Bottom: Structure of **5a** (side view with counterion).

[**] Chelate Complexes, Part 8. This work was supported by the Deutschen Forschungsgemeinschaft and the Fonds der Chemischen Industrie. We thank Prof. Dr. K.-P. Zeller, University of Tübingen, for the FAB mass spectra. This work was initially conceived while R. W. S. was deputizing a chair at the Universität München. Part 7: R. W. Saalfrank, S. Trummer, H. Krautscheid, V. Schünemann, A. X. Trautwein, S. Hien, C. Stadler, J. Daub, *Angew. Chem.* **1996**, *108*, 2350–2352; *Angew. Chem. Int. Ed. Engl.* **1996**, *35*, 2206–2208.

two metallacrowns C ($\bar{d}_{C-C}$ = 375 pm). The copper(II) ions of the metallacoronands occupy the corners of two equilateral triangles ($\bar{d}_{Cu-Cu}$ = 620 pm). The copper ions are linked by bis(bidentate) di-*tert*-butyl ketipinate dianions L^2 [H_2L^2 = **4a**]. Each of the copper(II) ions is coordinated in a square-planar fashion by four O-donors. Coordination of methanol leads to a tetragonal-pyramidal oxygen environment for all copper centers. The counterion of cation $[NH_4(Cu_3L_3^2)_2]^+ \cdot 6$HOMe (**5a**) is a hydroxide ion, hydrogen-bonded to methanol.[9] Neglecting the resulting loss in symmetry, and assuming spherical symmetry for the ammonium ion, the cation **5a** has C_{6h} symmetry (Fig. 2).

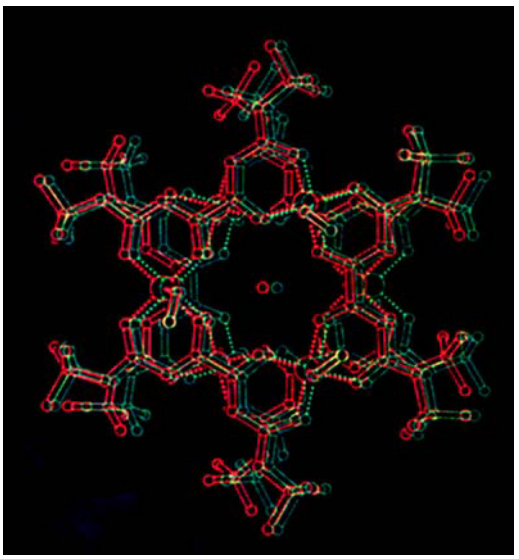

Fig. 2. Red-green stereoview of cation **5a** (top view: H atoms omitted).

Preliminary experiments indicate that use of Na^+ instead of K^+[10] or NH_4^+ leads to 1:1 metallacoronates $[\{NaCu^{II}Cl_2(Cu_3^{II}L_3^2)\}_2]$, which perpetuates the analogy with the well known organocrown ether chemistry.

Experimental Procedure

5: General procedure: Aqueous ammonia (2 mL, 12%) or potassium hydroxide (2 mL, 2N) was added dropwise to a solution of copper(II) chloride dihydrate (1.0 mmol, 171 mg) and the appropriate bis-1,3-dioxo ligand **4** (1.0 mmol) in methanol (100 mL) until no more turbidity was observed. To achieve complete precipitation of the products, water (200 mL) was added. The products were filtered off and dried under vacuum (oil pump). All new compounds gave correct elemental analyses.

All non-hydrogen atoms were refined anisotropically; the hydrogen atoms were fixed in idealized positions using a riding model. Final R values: $R1$ = 0.0773 for $F > 4\sigma(F)$ and $wR2$ = 0.2993 (all data) with $R1 = \sum|F_o - F_c| / \sum F_o$ and $wR2 = \sum w|(F_o^2 - F_c^2)^2| / \sigma w(F_o^2)^2)^{0.5}$; largest peak (1.156 e $Å^{-3}$) and hole (−0.805 e $Å^{-3}$). Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-105. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: Int. code +(1223) 336-033; e-mail: teched@chemcrys.cam.ac.uk).

[9] The positions of the hydrogen atoms could not be determined by the data set obtained. Therefore an exact assignment of the tautomeric variants [CuHOMe/OH] or [CuOMe/H_2O] is not possible.

[10] Note added in proof (4. 9. 96): According to an X-ray crystallographic structure analysis, complex $[KOH(Cu_3L_3^2)_2] \cdot 6$ HOMe is isostructural to **5a**.

Highly Selective Epoxidation Catalysts Derived from Intrazeolite Trimethyltriazacyclononane–Manganese Complexes**

Dirk E. De Vos, Julia L. Meinershagen, and Thomas Bein*

Dedicated to Professor Galen D. Stucky on the occasion of his 60th birthday

Over the last few years the development of zeolite-based catalysts for the liquid-phase oxidation of hydrocarbons has been a field of active research, and several interesting systems have been discovered.[1–8] However, the selectivities of these systems in the epoxidation of olefins may be limited by acid-catalyzed or other side reactions. This is particularly true with Ti-β and $[Mn(bpy)_2]^{2+}$–NaY catalysts (bpy = 2,2′-bypridine). Furthermore, the epoxides are frequently subject to solvolysis,[1, 3] or large amounts of less desirable products are formed, for example phenylacetaldehyde and benzaldehyde in the case of the oxidation of styrene.[8]

We now report on a novel zeolite-based catalyst, a manganese faujasite containing the cyclic triamine 1,4,7-trimethyl-1,4,7-triazacyclononane (tmtacn). This material catalyzes the oxidation of numerous olefins with H_2O_2, yielding epoxides with only minimal by-product formation. We also report on the characteristics of the corresponding homogeneously catalyzed reaction, which allows us to outline the effect of the heterogenization on the catalytic activity.

The zeolite-based oxidation catalysts were prepared by reacting a Mn^{II}NaY zeolite (0.8 wt% Mn, or about one metal ion per four supercages), dehydrated at 250 °C, with the polyamine ligand for 10 h at 150 °C under an inert atmosphere and occasional shaking. A polyamine to Mn molar ratio of 2.2 was found to be optimal for an efficient diffusion of the ligand into the zeolite pores. Homogeneous catalysts were prepared in situ by adding the ligand, dissolved in the organic reaction solvent, and $MnSO_4 \cdot H_2O$, dissolved in water, to the reaction mixture. All chemicals used were commercial products, with the exception of tmtacn and 1,4,7-triazacyclononane (tacn), which were prepared by known procedures.[9] Numerous epoxides were synthesized as reference compounds through the peracid method and identified through gas chromatograpy/mass spectrometry (GC/MS) and ^{1}H NMR spectroscopy.

Before the adsorption of the ligand by the Mn zeolite, X-band ESR spectroscopy shows the characteristic six-line signal of Mn^{II} with a total width of about 500 G, which is typical for an oxygen-coordinated Mn ion in zeolites (Fig. 1a).[10] After sorption of the ligand into the zeolite host, the intensity of this signal strongly decreases at the expense of a new Mn^{II} signal, which extends over a much wider field range, and displays a recognizable fine splitting (Fig. 1b).[11] We recently observed similar spectra for Mn^{II} ions in different A zeolites.[12] From the spectrum, the zero-field splitting parameter D can be estimated to amount to $0.06 \pm 0.015\ cm^{-1}$. Such a fine splitting is characteristic for a departure of the crystal field around Mn from cubic symmetry, with preservation of an at least threefold symmetry axis.[13] As the formation of complexes with two tmtacn ligands

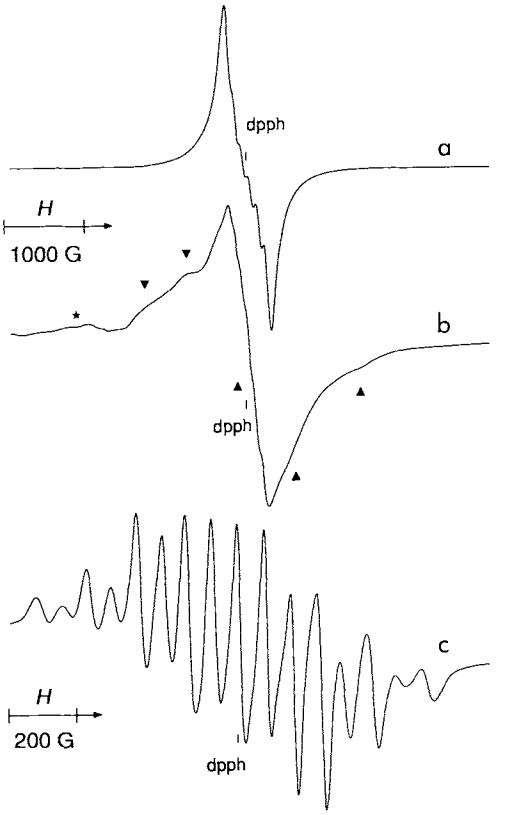

Fig. 1. X-band ESR spectra (9.44 GHz) of Mn in a) Mn^{II}NaY, before ligand adsorption, 298 K; b) $[Mn^{II}(tmtacn)]^{2+}$–NaY, under a dry N_2 atmosphere, 298 K; c) $[Mn(tmtacn)]^{2+}$–NaY, exposed for 2 h to H_2O_2 in the concentrations of catalytic experiments (see Table 1), recorded at 8 K. In a) only the central $M_S = +1/2 \rightarrow -1/2$ transition of the Mn fine structure is resolved, indicating that the symmetry of the all-oxygen Mn environment is close to cubic. The reaction with the tmtacn ligand in b) reduces the local symmetry to axially symmetric; the non-central fine transitions (involving $M_S = \pm 3/2$ and $M_S = \pm 5/2$) now also contribute to the spectrum. The resulting five fine lines ($\Delta M_S = \pm 1$) are roughly spaced by the distance D and have been marked (∇) in the spectrum. At lower magnetic field in b), half-field transitions ($\Delta M_S = \pm 2$) are observed (*). In the H_2O_2 oxidized sample c), a sixteen-line signal of the Mn^{III}–Mn^{IV} dinuclear complex is observed. dpph = 1,1-diphenyl-2-picrylhydrazyl (as reference).

per Mn ion is unlikely for steric reasons,[14] we ascribe the new ESR signal to the formation of the $[Mn(tmtacn)]^{2+}$ complex. This chelation is not observed with smaller pore MnNa-ZSM-5 or MnNa-A zeolites that have pore openings of 0.53 and 0.41 nm, respectively, which implies that the chelation in the large-pore NaY zeolite is essentially intraporous. This $[Mn(tmtacn)]^{2+}$–NaY material is used as the catalyst precursor in the catalytic reactions.

The selective epoxidation activity of the $[Mn(tmtacn)]^{2+}$–NaY zeolite is somewhat surprising. Complexes of manganese and tmtacn ligands have been observed to activate H_2O_2 at room temperature, for example for bleaching and for epoxidations.[15, 16] However, bleaching is often associated with a) the production of reactive particles such as $(OH)^{\cdot}$, $(OOH)^{\cdot}$, or singlet oxygen ($^1O_2$), which may cause the formation of side products in epoxidations, and with b) disproportionation of the peroxide to molecular oxygen and water, which leads to a reduction of the selectivity of the oxidant.[17] It is therefore understandable that the reported epoxidation of styrenes with homogeneous Mn–tmtacn catalysts requires an at least 100-fold excess of the oxidant.[15]

In our initial experiments with the zeolite-based $[Mn(tmtacn)]^{2+}$–NaY catalyst, we adopted the same conditions as used for the homogeneous epoxidation (aqueous methanol,

room temperature)[15] except that the oxidant to substrate ratio was 1:1. The epoxide yields of these reactions were very low (<1%). However, three major modifications of the procedure resulted in highly improved epoxide yields, even at close to stoichiometric H_2O_2:olefin ratios (Table 1): a) cooling the reaction mixture to 273 K or below, b) gradual peroxide addition, and c) use of acetone as a solvent. The latter produces a dramatic effect, not only for the zeolite-catalyzed reaction but also for the homogeneous reaction. For a discussion of the effect of acetone see reference [21]. The combined effects of these modifications result in a marked reduction of the undesired oxidant disproportionation, and an increase of the epoxide yield by a factor of 50.

Table 1. Effect of solvents and temperature on the epoxidation of styrene and cyclohexene with H_2O_2, catalyzed by the $[Mn(tmtacn)]^{2+}$–NaY zeolite or by homogeneous Mn–tmtacn complexes [a].

Catalyst	Substrate	T[K]	Solvent	Olefin conversion [%]	Epoxide selectivity [%] [b]
$[Mn(tmtacn)]^{2+}$–NaY					
	styrene	298	methanol	0.4	100
		298	acetone	7.0	99.1
		273	methanol	1.5	100
		273	acetone	19.3	97.7
	cyclohexene	298	methanol	0.3	100
		298	acetone	6.8	97.2
		273	methanol	2.1	100
		273	acetone	25.3	95.4
		273	acetone	47.2[c]	94.7
Mn^{II} + tmtacn					
	styrene	298	methanol	1.5	100
		273	acetone	47.1	97.8
	cyclohexene	298	methanol	1.4	100
		273	acetone	55.3	84 [d]

[a] Reaction conditions: olefin (1 mmol), H_2O_2 (1 mmol; as a 30 wt.% aqueous solution, gradually added), solvent (1 g), $[Mn(tmtacn)]^{2+}$–NaY solid catalyst (0.025 g). For homogeneous catalysis, tmtacn (22 μmol) and Mn^{II} (10 μmol) were consecutively added in organic solvent and water (0.1 mL), respectively. The homogeneous reaction conditions were chosen to match the heterogeneous experiments; they are not optimized (see ref. [21]). H_2O_2 consumption was usually complete within 12 h or less. [b] Remaining products: benzaldehyde (in case of styrene), (*E*)-1,2-cyclohexanediol (in case of cyclohexene). [c] A second aliquot of H_2O_2 (1 mmol) was added after 6 h. [d] Allylic cyclohexene oxidation products: 7%.

This yield increase does not affect the selectivity of the oxidation process. With the $[Mn(tmtacn)]^{2+}$–NaY system, side products in the reactions of styrene, cyclohexene, and *cis*-2-hexene (not listed) are minimal, if observed at all (Table 1). Products of double-bond cleavage, such as benzaldehyde, account for less than 3% of the products in the case of the oxidation of styrene. Remarkably, in the oxidation of cyclohexene with zeolite catalysts, no cyclohexenyl-2-hydroperoxide, cyclohex-2-enol, or cyclohex-2-enone was detected. This indicates that under these conditions, (HOO)$^{\bullet}$ or (HO)$^{\bullet}$ radicals, or other reactive O species, such as $^1O_2$, play no major role in the formation of cyclohexene oxidation products.[18] Epoxide solvolysis is also minimal. While in the related homogeneous systems an alkaline aqueous buffer may play a role in preventing this side reaction,[15] the excess amine adsorbed on the zeolite catalyst seems to quench effectively any acidity of the zeolite surface. This is a marked advantage of our material over catalysts such as Ti-β and $[Mn(bpy)_2]^{2+}$–faujasite; in these materials the surface pH is intrinsically acidic and further reactions of epoxides are the rule rather than the exception.[1, 3]

The structure of the tmtacn ligand seems to fulfill an essential role in making the Mn ion suited for the selective epoxidation. With the unmethylated tacn as ligand, only vigorous decomposition of the H_2O_2 oxidant is observed, resulting in the formation of the products in extremely low yields. While the methylation might protect the amine ligand against oxidation, an alternative explanation for this dramatic difference is that the methyl groups provide a hydrophobic wrapping around the Mn ion (Fig. 2). This lipophilic shield around the Mn ion probably favors the adsorption of an olefin at the peroxide-activated Mn ion, retarding the approach of new peroxide molecules and thus the catalytic H_2O_2 decomposition.

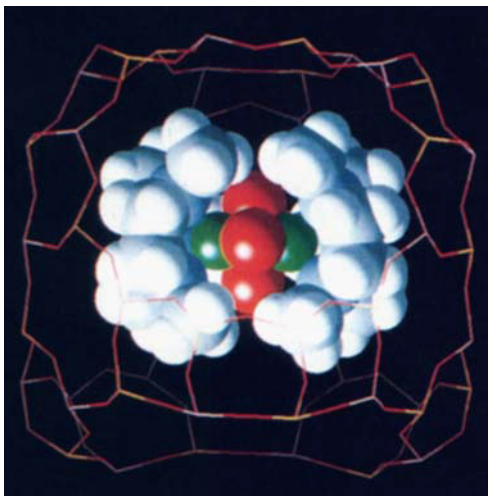

Fig. 2. Computer model (Cerius², Molecular Simulations Inc.) of a dinuclear complex of Mn and tmtacn in the supercage of a Y zeolite (Mn = green; O = red, N = blue; C = gray;, H = white).

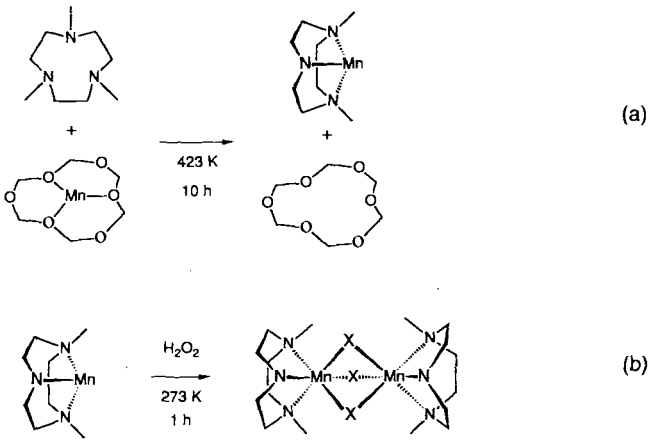
While with the homogeneous catalyst the reaction starts almost instantaneously, an induction period is observed with $[Mn(tmtacn)]^{2+}$–NaY. In the ESR spectrum (Fig. 1c), this period corresponds to the appearance of a 16-line signal with a hyperfine constant $A = 78$ G, which is typical for a Mn^{III}–Mn^{IV} dinuclear complex.[19] Although other ESR-silent species could have formed, the correlation between the induction period and the appearance of the Mn^{III}–Mn^{IV} dinuclear complex suggests that catalysis occurs in conditions that promote oxidative formation of dinuclear Mn complexes in the cavitities of the Y zeolite. Analogous spectra are not observed when MnNa-ZSM-5 or MnNa-A zeolites treated with tmtacn are contacted with H_2O_2. This failure to observe dinuclear complexes in smaller pore zeolites suggests that for the Y zeolite, the dinuclear complexes are largely confined to the inner surface. Such complexes can contain manganese in its +IV oxidation state, in which state the metal is known to have the capacity to act as an oxygen-transferring species.

The spatial interaction between a NaY supercage and a dinuclear Mn-tmtacn complex, such as $[(tmtacn)Mn^{III}\text{-}O_2(OH)\text{-}Mn^{IV}(tmtacn)]^{2+}$, was studied by molecular modeling.[20] These complexes appear to have the appropriate dimensions to reside in the large faujasite cage, suggesting their steric entrapment inside these supercages (Fig. 2). The proposed intrazeolitic complexation of the Mn^{II} ion by tmtacn, and the consecutive formation of the larger dinuclear complexes upon addition of H_2O_2, are schematically represented in Scheme 1. The zeolite-confined character of the $[Mn(tmtacn)]^{2+}$–NaY catalysis was ultimately confirmed by a filtration experiment. Two styrene oxidations were run under identical conditions, in one case, however, the catalyst powder was removed from the reaction after about 5% conversion. While in the other reaction an oxide yield of 20%



Scheme 1. Proposed reactions of Mn ions and tmtacn ligands in zeolite Y. Reaction a: In the chelation reaction, the Mn^{II} ion leaves an all-zeolite coordination, for example on a six-membered ring, to form a mononuclear $[Mn^{II}(tmtacn)]^{2+}$ chelate complex. Reaction b: The interaction of $[Mn^{II}(tmtacn)]^{2+}$–NaY with H_2O_2 in a water/acetone medium leads to intrazeolite formation of Mn^{III}–Mn^{IV} dinuclear complexes or other dimerization products (X = O^{2-}, OH^-, or other oxygen bridges).

was eventually obtained, the increase of the oxide yield stopped in the vial without catalyst.

In summary, the intrazeolite assembly of manganese complexes with cyclic amine ligands leads to novel catalytic materials for highly selective epoxidation. Dramatic effects of the ligand structure and of the solvent on the reactivity, as well as the patterns of substrate and product selectivity,[21] support the emerging picture of a sterically crowded, ligand-embedded active site in the cages of zeolite Y.

Toward the Design of Porous Organic Solids: Modular Honeycomb Grids Sustained by Anions of Trimesic Acid**

Rosa E. Melendez, C. V. Krishnamohan Sharma, Michael J. Zaworotko,* Carey Bauer, and Robin D. Rogers

The concept of design or crystal engineering of functional solids relies upon controlling the topology of crystal packing through exploitation of forces that range in the continuum from weak hydrogen bonds to covalent bonds.[1, 2] In the context of porosity, a particularly relevant functional property given the commercial importance of zeolites, it is becoming increasingly clear that even noncovalent interactions can be directional and strong enough to generate and sustain porosity.[3] Several research groups have recently demonstrated that a modular strategy to crystal engineering can propagate molecular symmetry into crystalline architecture or even space group symmetry.[4–9] Unfortunately, two- (2D) and three-dimensional (3D) frameworks typically fail to realize their full potential for porosity because of interpenetration or self-inclusion of identical frameworks.[4b, 7a, 9] In such a context, trimesic acid (1,3,5-benzenetricarboxylic acid, H_3TMA) is prototypal since it *predictably* self-assembles through the well-known carboxylic acid dimer motif into an interpenetrating honeycomb grid with 11 Å cavities.[6, 10, 11] We report herein on two compounds that illustrate two alternate modular strategies to propagate the trigonal symmetry of H_3TMA: the ammonium salt **1** forms a neutral honeycomb grid and the ammonium salt **2** has an anionic honeycomb grid based upon hydrogenbiscarboxylate hydrogen bonds.

$[NH_2(c\text{-}C_6H_{11})_2]_3[TMA]$ **1**

$[NH_2(CH_3)_2]_{12}[H_3TMA][H_2TMA]_3[HTMA]_3[TMA]$ **2**

Compounds **1** and **2**, which contain the fully and 50% deprotonated forms of H_3TMA, respectively, predictably self-assemble into honeycomb grids because of their trigonal symmetry

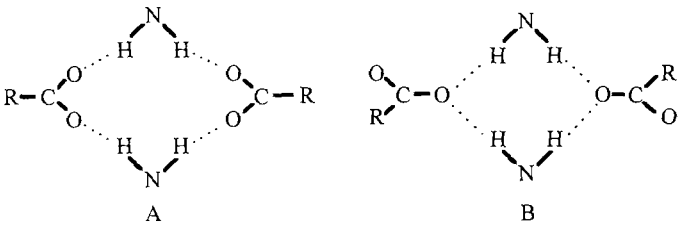
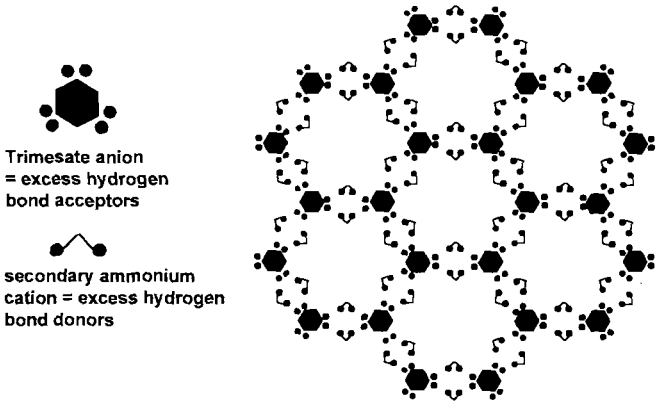
and the number and complementarity of their hydrogen bonding sites.[12] At first sight the secondary ammonium cations in compound **1** might appear to be unsuitable for facilitating propagation of the trigonal symmetry of H_3TMA or its derivatives to the crystal structure. However, as Scheme 1 reveals, there are



A B

Scheme 1.

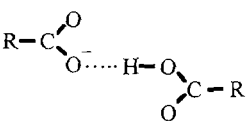
two common motifs that occur between secondary ammonium cations and carboxylate anions,[13] both of which would readily propagate TMA^{3-} into a honeycomb grid (Scheme 2). For



Scheme 2.

compound **2**, the hierarchy of hydrogen bond strengths prevents the cation from influencing the honeycomb structure that would result from self-assembly of hydrogenbiscarboxylate moieties (Scheme 3).[14]

The noncentrosymmetric crystal structure of **1**[15] reveals that the hexagonal network has an effective internal diameter of 12.7 Å. The TMA^{3-} ions are bridged by ammonium ion "spacers" in motif **B** (Scheme 1 N···O, 2.725(9), 2.837(11), 2.755(10), 2.763(10) Å, Fig. 1). The cyclohexyl groups of the ammonium ions project above and below the plane of the honeycomb sheets and almost close the cavities, thereby precluding interpenetration of the type observed in H_3TMA. The carboxylate oxygen atoms of one of the two crystallographically independent TMA^{3-} ions are hydrogen-bonded (O···O 2.727(8) Å) to three clathrated MeOH molecules that lie outside the cavity. The hydrophobic cavity enclosed by the cyclohexyl moieties contains disordered solvent molecules[15] and is reminiscent of "carceplexes".[16]



Scheme 3.

Compound **2** crystallizes as an anionic honeycomb grid. It is effectively a cocrystal of H_3TMA and, remarkably, all three of its possible deprotonated forms: H_2TMA^-, $HTMA^{2-}$, and TMA^{3-}. These components self-assemble through strong O–H···O^- hydrogen bonds to form two independent honeycomb anionic grids: $H_3TMA \cdot 3HTMA^{2-}$ and $3H_2TMA^- \cdot TMA^{3-}$ (Fig. 2).[17] The formulation of the grids was determined after hydrogen atom location and careful examination of the C–O bond lengths within the carboxylate moieties.[18] The O···O distances of the hydrogen bonds in these two sheets (2.551(5) and 2.524(5) Å, 2.535(5) and 2.523(5) Å) are contracted by 0.1 Å compared to those in H_3TMA, thereby affording a distorted hexagon with an effective internal diameter of 10.4 Å. The cations cross link adjacent hexagonal sheets (N···O, 2.711(6) to 2.808(7) Å) by donating hydrogen bonds to CO_2^- ions rather than to CO_2H moieties. This would be expected based upon the hierarchy of the donor–acceptor strengths of the hydrogen bonds of these functional groups.

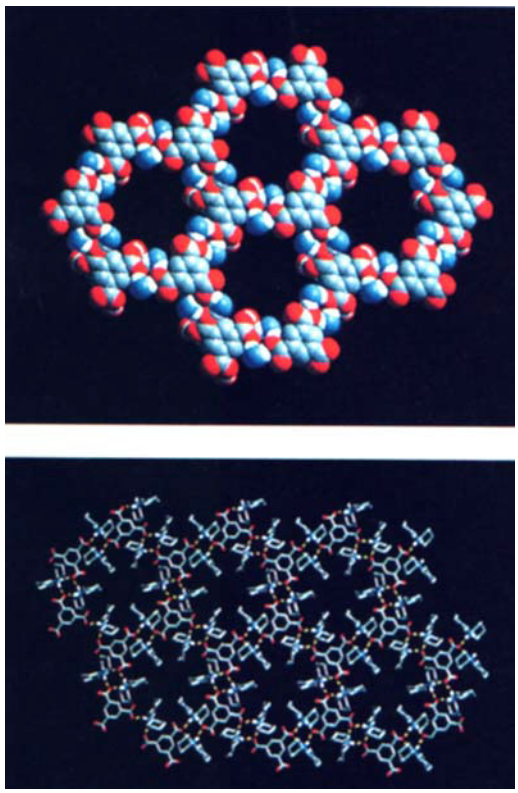


Fig. 1. Crystal structure of **1**: Top: A space-filling model of the honeycomb grid in **1**. Trimesate anions are bridged by cations through motif B (Scheme 1). Cyclohexyl groups are omitted for the sake of clarity. Bottom: A view perpendicular to the honeycomb grid, cyclohexyl groups of the cations project above and below the grid and preclude interpenetration by capping the cavity.

In summary, the crystal structures of **1** and **2** illustrate the inherent advantages of modular approaches to crystal engineering: facile synthesis, fine tuneable functional properties (i.e. cavity size), eschewing of interpenetration. Furthermore, the ionic hydrogen bonds[12] afford solids that are readily crystallized from solution yet, relative to many organic compounds, high melting. Compound **2** further illustrates that pK_a values derived from solution can be misleading in the context of predicting the location of protons in hydrogen-bonded cocrystals and/or salts.[14a] We anticipate that compounds **1** and **2** are prototypes for two new classes of host matrix based upon derivatives of H_3TMA and are presently investigating the generality of this modular strategy and the ability of such solids to selectively enclathrate moderately sized guests.

[3] Organic crystals tend to close-pack with packing coefficients in the range 0.65–0.77 [1]. However, symmetrical and rigid hydrogen bonding networks often afford less dense open structures (e.g. trimesic acid, urea, hydroquinone, and Dianin's compound) that are stabilized by enclathration of guest molecules or interpenetration. The effective cavity diameter in H_3TMA (11 Å) is determined by calculating internuclear O···O distances across the hexagon, and subtracting the van der Waal's radius of the oxygen atom. Although synthetic zeolites can have comparable or larger pores, those in naturally occuring inorganic zeolites are typically smaller than 5 Å.

Nanoclusters and colloids from the semiconducting II–V and II–VI compounds are particularly interesting with respect to their optical and electronic properties in comparison to those of the solid bulk materials.[1] The influence of the size of the molecules and particles in the nanometer scale plays an important role in determining the band-gap ("size quantization effect"). An exact interpretation of the measured effects is made more difficult by a size distribution of the particles, which is usually found to be the case for colloids. The synthesis and structural characterization of cluster molecules with a defined size and structure provide an interesting approach to this class of compounds.[2]

In the case of the cadmium chalcogenide clusters, the largest structurally characterized clusters reported to date are **1a**[3] and **1b**.[4] We have already isolated and structurally characterized

a large number of copper chalcogenide clusters,[5] amongst which is one of the largest known characterized clusters $[Cu_{146}Se_{76}(PPh_3)_{30}]$.[6] Herein we describe the first synthesis and structural characterization of mercury and cadmium selenide clusters as well as cadmium phosphide clusters **2**–**5** [Eqs. (a)–(e)].

$[Cd_{32}S_{14}(SPh)_{36}]\cdot 4DMF$ **1a**

$[Cd_{32}S_{14}(SCH_2CH(OH)CH_3)_{36}]\cdot 4H_2O$ **1b**

The reaction of $[Fe(CO)_4(HgCl)_2]$ with $PhSeSiMe_3$ in toluene [Eq. (a)] gave a red solution from which a mixture of yellow

$$[Fe(CO)_4(HgCl)_2] \xrightarrow[\text{toluene}]{PhSeSiMe_3} [Hg_{32}Se_{14}(SePh)_{36}]_{cub} + [Hg(SePh)_2] \quad \text{(a)}$$

2a

crystals of $[Hg(SePh)_2]$ and red crystals of **2a** were formed after a few days. Figures 1 and 2 show the molecular structure of the $Hg_{32}Se_{50}$ cluster of **2a**. The compound crystallizes in the cubic space group $P23$, and the cluster molecules possess T symmetry.

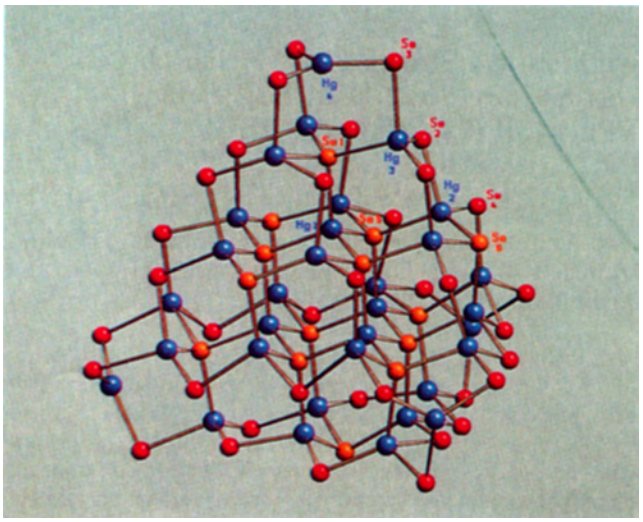

Fig. 1. Molecular structure of the $Hg_{32}Se_{50}$ cluster of **2a**. Hg: blue; Se^{2-}: orange; Se from $SePh^-$: red. Selected bond lengths [pm] and angles [°] (deviations ±0.3 pm and ±0.1°): Hg(1,2,3)–Se: 257.5–269.9, Hg4–Se3: 256.7; Se-Hg(1,2,3)-Se 91.0–130.1 (distorted tetrahedral coordination by Se); sum of the angles at Hg4 (trigonal planar coordination by Se): 360.0°

The core of the cluster, which comprises 13 HgSe adamantane cages, is a section of the sphalerite structure, which is also found in HgSe.[7] The corners of the cluster are made up of barrelanoid HgSe cages that are characteristic of the wurzite structure of HgSe. The Hg atoms Hg1–Hg3 have distorted tetrahedral environments, coordinated by the Se atoms of SePh (red) and Se ligands (orange) (Se-Hg-Se: 91.0(1)–130.1(1)°). The four Hg atoms Hg4 at the corners of the tetrahedral cluster have almost trigonal-planar coordination from the three Se atoms of the SePh ligands (Se-Hg-Se: 120.0(1)°). This is very remarkable because these Hg atoms are not sterically shielded by the phenyl groups (Fig. 2). The diameter of **2a** is thus about 2400 pm. The

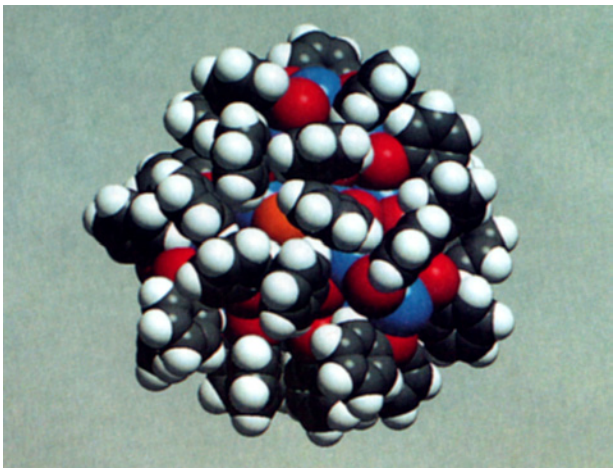

Fig. 2. Space-filling model of **2a**. Hg: blue; Se^{2-}: orange; Se from $SePh^-$: red; C: grey; H: white.

Hg–Se bond lengths lie between 256.7 and 269.9(3) pm, which correspond to those distances in HgSe (262 pm).[8] The structure of **2a** resembles that of the reported cadmium sulfide clusters[3, 4] and also that of the cadmium selenide cluster **3** (see below). However in these structures the cadmium atoms at the corners of the cluster have tetrahedral environments through additional coordination of solvent molecules or phosphane ligands.

The reaction of $HgCl_2$ with $PhSeSiMe_3$ in toluene [Eq. (b)], and subsequent layering of the red reaction solution with heptane, resulted in the formation of red needlelike crystals of **2b**,

$$HgCl_2 \xrightarrow[\text{toluene/heptane}]{PhSeSiMe_3} [Hg_{32}Se_{14}(SePh)_{36}]_{trig} + [Hg(SePh)_2] \quad \text{(b)}$$

2b

which have the same empirical formula as **2a**, but crystallize in the trigonal space group $P3_2$. The two modifications differ only in the packing of the cluster molecule in the crystal (Fig. 3). The arrangement of the cluster molecules in **2a** is such that channels with a diameter of about 700 pm are formed.

The red color of the crystals shows that the electronic structure of the cluster differs from that of the black semimetal HgSe in the macroscopic state ($\Delta E_g = -$ -0.06 eV at 300 K).[9] To obtain a more accurate analysis of the optical and electronic properties of compounds **2a** and **2b**, the absorption and luminescence spectra were measured. The absorption spectrum of **2b**, recorded in the solid state on a glass slide layered with indium tin oxide at 10 K, shows two maxima at 539 nm (2.3 eV) and 496 nm (2.5 eV) (Fig. 4). The luminescence spectrum of this sample (dotted line in Fig. 4), measured with an excitation wavelength of 436 nm at 10 K, shows a maximum at 670 nm (1.85 eV). The red solution of **2b** in THF shows weak maxima at 549 nm (2.26 eV) and 504 nm (2.46 eV) in the absorption spectrum at room temperature. In comparison to the absorption maxima of the Cd_{32} clusters,[3, 4] those for **2b** show a strong shift to larger wavelengths.

Treatment of $[CdCl_2(PPh_3)_2]$ with $PhSeSiMe_3$ in acetone afforded colorless crystals of **3** [Eq. (c)]. In analogy to the struc-

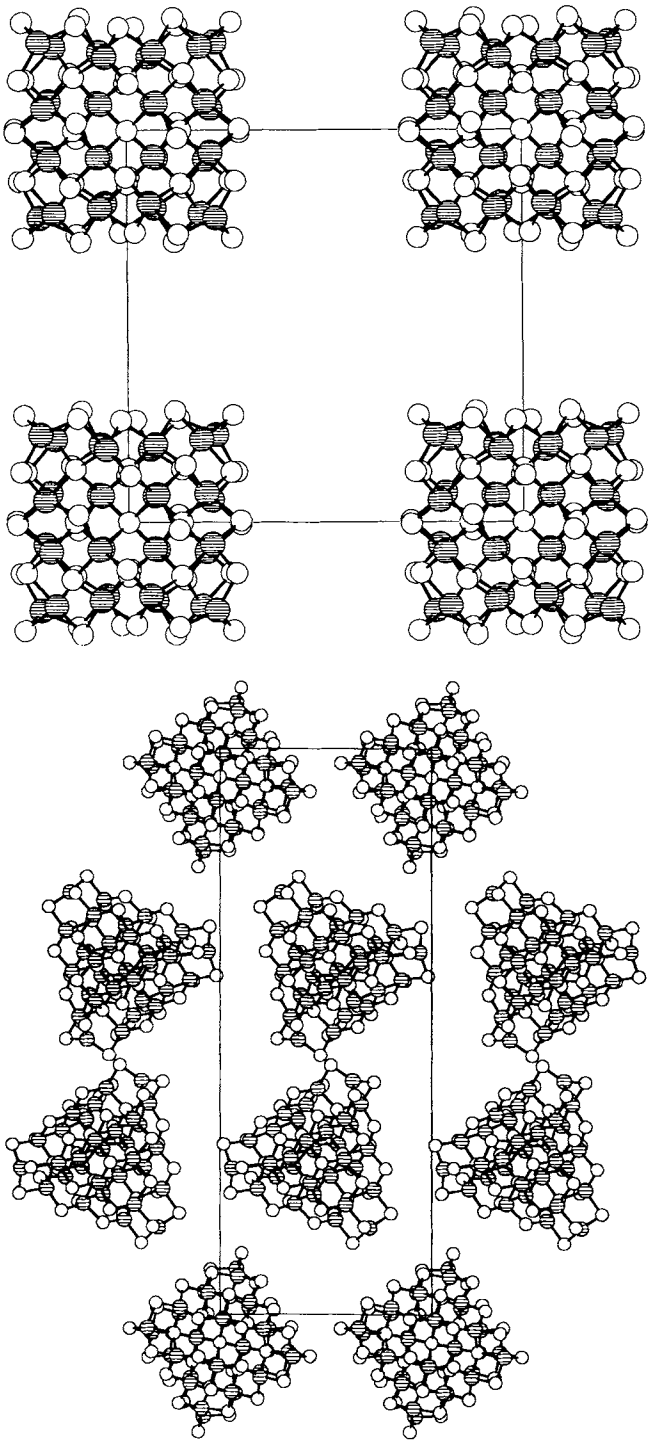

Fig. 3. Arrangement of the clusters **2a** (above) and **2b** (below) in the crystal (without C and H atoms). Hg: ◎; Se: ○.

tures of **2a** and **2b**, the skeleton of the $Cd_{32}Se_{50}$ cluster is built up from two characteristic structural units; the center of the cluster is of the sphalerite type and the corners of the cluster are formed by wurzite-analogous cages. The Cd atoms have distorted tetrahedral environments, coordinated by Se atoms from the SePh and Se ligands and by the P atoms of the PPh_3 ligands (Se-Cd-Se: 89.0–126.9(1)°, Se-Cd-P: 96.1–109.5(2)°). The Cd–Se bond lengths lie between 255.9 and 267.9(3) pm. This is comparable to the bulk material CdSe (zinc blende structure) in which the Cd–Se bond length is 262 pm.[10]

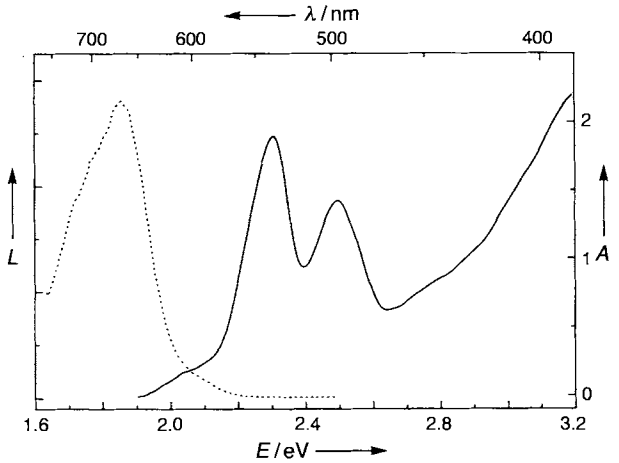

Fig. 4. Absorption (full line) and luminescence spectra (dotted line) of **2b** in the solid state on an indium tin oxide layered glass holder at 10 K. A = absorption. L = luminescence.

The reaction of CdI_2 with PEt_2Ph and $P(SiMe_3)_3$ in THF [Eq. (d)] led to the formation of a pale yellow solution, which

$$CdI_2 + 2\,PEt_2Ph + P(SiMe_3)_3 \xrightarrow[-\,ISiMe_3]{THF\,/\,RT} [PEt_2(Ph)C_4H_8OSiMe_3]_5[Cd_{18}I_{17}(PSiMe_3)_{12}] \quad \textbf{4} \qquad (d)$$

when layered with hexane produced a yellow oil (of unknown composition) and colorless, strongly refracting crystals of **4**. The analogous cluster anion also crystallized from the reaction of CdI_2 with NEt_3 and $P(SiMe_3)_3$ in THF as the compound **5** [Eq. (e)]. In both structures the cations were particularly diffi-

$$CdI_2 + NEt_3 + P(SiMe_3)_3 \xrightarrow[-\,ISiMe_3]{THF\,/\,RT} [NEt_3C_4H_8OSiMe_3]_5[Cd_{18}I_{17}(PSiMe_3)_{12}] \quad \textbf{5} \qquad (e)$$

cult to refine in the difference Fourier analysis such that for each structure only three of the cations could be localized. The two missing cations are highly disordered. The formation of the cations can be ascribed to the cleavage of THF molecules by reactive $SiMe_3$ groups, which then can attack the tertiary phosphane or amine, leading to the formation of C–P or C–N bonds, respectively.

Complex **4** crystallizes in the chiral space group $P2_12_12_1$, **5** in $P\bar{1}$. The structure of the cluster anion of **4** and **5** is shown in Figure 5 (the data for **4** are discussed). The 18 Cd atoms are μ_3-bridged by the P atoms of the 12 $PSiMe_3$ groups and the eight I atoms I10–I17, in such a way that a spherical cluster is formed. The terminal I atoms I1–I9 are coordinated to the Cd atoms Cd1–Cd9. Apart from Cd12, Cd16, and Cd17, which are coordinated by I and P atoms in a distorted trigonal planar environment, all other Cd atoms have near tetrahedral coordination. The Cd–I distances lie between 300.7 and 329.1(2) pm for the bridging I atoms and between 271.0 and 284.9(8) pm for the terminal I atoms. The Cd–P bond lengths range between 244.8 and 255.5(5) pm.

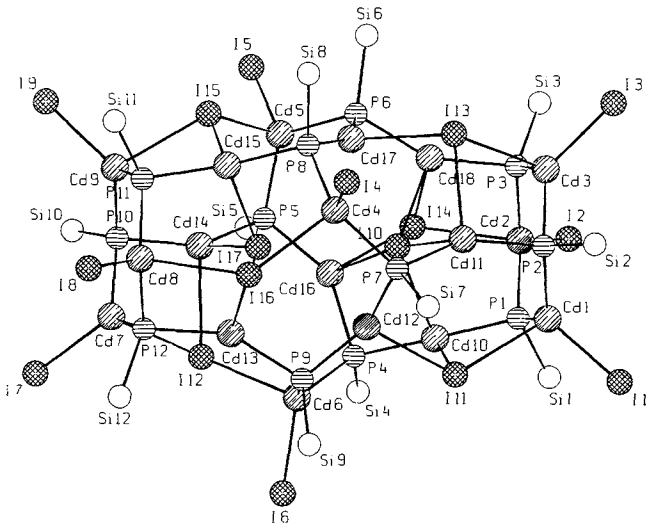

Fig. 5. Molecular structure of the cluster anion of **4** and **5**.

The cluster anions of **4** and **5** do not show any resemblance to any known bulk material structure of cadmium phosphides[11] or cadmium iodophosphides.[12] However, one might expect that the presence of the halogen atoms and the reactive $PSiMe_3$ groups could well lead to further reaction and that aggregation of the clusters to form the above-mentioned cadmium iodophosphides might be possible. Cadmium halogenophosphides are semiconductors in their macroscopic states. Sections of the solid-state structure in the form of ligand-stabilized cluster molecules would be very interesting with regard to investigations of larger quantum effects, as observed for the Q-Cd_3P_2 particles.[11]

Experimental Procedure

Preparation of compounds **2**–**5** (all steps were performed under a nitrogen atmosphere and absolute solvents were used).

2a: $PhSeSiMe_3$ (0.38 mL, 1.50 mmol) was added to a suspension of $[Fe(CO)_4(HgCl)_2]$ (0.48 g, 0.75 mmol) in toluene (25 mL). From the resulting clear red solution a yellow precipitate quickly formed. After a few days red cubes of **2a** crystallized.

2b: $PhSeSiMe_3$ (0.37 mL, 1.48 mmol) was added dropwise to a suspension of $HgCl_2$ (0.2 g, 0.74 mmol) in toluene (25 mL). The resulting clear red solution was layered with heptane and within a few hours the solution lightened in color and yellow crystals of $Hg(SePh)_2$ and red needlelike crystals of **2b** were formed.

3: $PhSeSiMe_3$ (0.46 mL, 1.86 mmol) was added to a suspension of $CdCl_2(PPh_3)_2$ (0.33 g, 0.47 mmol) in acetone (25 mL). This produced a clear, pale yellow solution, from which colorless rhomboids of **3** crystallized.

4 and **5**: A solution of CdI_2 (0.36 g 0.98 mmol) in THF (50 mL) was treated with PEt_2Ph (0.32 g, 1.96 mmol) (for **4**) or NEt_3 (0.1 g, 0.99 mmol) (for **5**). $P(SiMe_3)_3$ (0.5 g, 1.99 mmol) was added to the clear solutions. Layering the pale yellow reaction mixtures with hexane resulted in the formation of colorless crystals of **4** and **5** after three days.

The Mechanism of Class II, Metal-Dependent Aldolases**

Wolf-Dieter Fessner,* Achim Schneider, Heike Held, Gudrun Sinerius, Christiane Walter, Mark Hixon, and John V. Schloss*

Dedicated to Professor Horst Prinzbach on the occasion of his 65th birthday

The four distinct dihydroxyacetone phosphate dependent aldolases[1, 2] enjoy increasing interest for preparative asymmetric synthesis because of their capacity to build up two new stereogenic centers with high chiral induction.[3] While all DHAP aldolases have a very broad substrate tolerance for the aldol acceptor substrate, they appear to have a high substrate specificity for dihydroxyacetone phosphate (DHAP) as the aldol donor, and only few isosteric replacements of the phosphate ester moiety are tolerated.[4] Diastereoselectivity may be limited for certain cases in the control of the stereocenter at C-4, which points to occasional inverse binding of the aldehyde carbonyl group.[2e] Certainly, a detailed understanding of the contributions of active site residues in substrate recognition and in the catalytic event is highly desirable to further improve the predictive value of the method.

Aldolases have been divided into two classes according to their mode of donor activation.[5] Class I aldolases achieve stereospecific deprotonation of the substrate by means of covalent linkage to an active site lysine residue (imine/enamine formation), while class II aldolases utilize transition metal ions (usually Zn^{2+}) as essential Lewis acid cofactors to facilitate deprotonation (Fig. 1). For the class I FruA,[2] despite extensive efforts using modern techniques of enzymology, site-directed mutagenesis, and protein crystallography,[6] a conclusive model that accounts for the function of the active site residues in the individual steps of catalysis is advancing very slowly.[7] In particular, no structure with bound substrates or inhibitors is yet available.

Based on work with the class II FruA from yeast, several early hypotheses for the mechanism of Zn-dependent aldolases have been developed. According to ESR and NMR relaxation rate measurements on the Mn^{2+}-substituted holoenzyme, DHAP is bound through its phosphate group,[8] and the carbonyl is polarized by Zn^{2+} through an intervening imidazole ring (Fig. 1, **A**).[9] Subsequent FT-IR and deuterium exchange studies with native yeast aldolase[10] led to the conclusion that aldehyde activation occurs by an additional direct coordination of the carbonyl (Fig. 1, **B**). Recently, Dreyer and Schulz[11a] reported the X-ray structure for FucA (2.13 Å resolution), the first of a class II aldolase. The active site, which is located at the interface

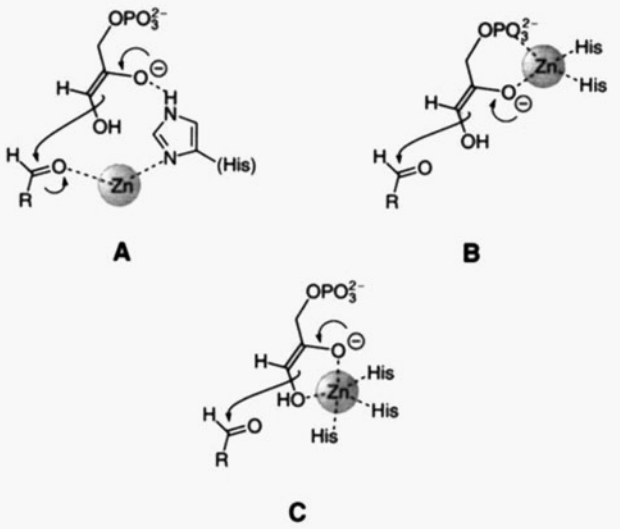

Fig. 1. Hypothetical mechanisms for catalysis by type II aldolases. **A**: Enolate stabilization by proton relay[9] and aldehyde activation by Zn^{2+}[10]. **B**: Enolate stabilization by coordination of Zn^{2+} to the carbonyl and phosphate groups[8]. **C**: Enediolate stabilization by chelate coordination to Zn^{2+}.

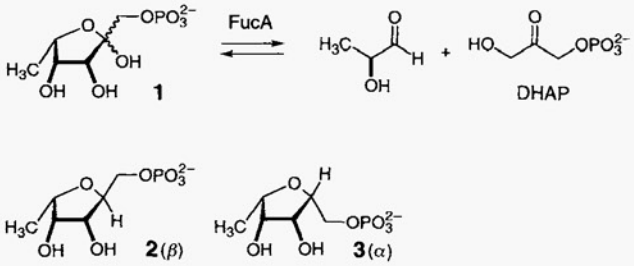
between two subunits of the homotetramer, contains the catalytically active Zn^{2+} ion tightly coordinated by three N^{ε} atoms of histidine residues (His92, His94, His155; Fig. 1, **C**). Thus, all previous mechanistic hypotheses must be rejected in light of the steric restraints imposed on the Zn^{2+} ion, which precludes coordination of more than a single substrate, and on its histidine ligands, which cannot act as a proton relay between bound substrates.

Under the slightly alkaline conditions required for FucA crystallization, the natural substrate L-fuculose 1-phosphate **1** (Scheme 1) cannot be used for X-ray analysis of the enzyme–ligand complex because it is cleaved to give the labile DHAP and



Scheme 1. Natural substrate **1** of FucA and the structurally related compounds **2** and **3**.

L-lactaldehyde. For stable substrate mimics in soaking or cocrystallization studies, we first focused on the synthesis of the structurally related anhydroalditol derivatives **2** and **3** as potential inhibitors; as they lack the anomeric hydroxyl group of **1**, ring opening and cleavage is not possible. Fucitol 1-phosphate was included as a potential mimic of the open-chain form.

L-Fuculose (**4**, obtained by enzymatic dephosphorylation of **1**[12]) was acetylated to provide a mixture of acetates **5**–**7**, from which the major product, triacetate **5** (61%), could be separated by distribution between water–ether and back extraction (Scheme 2). Silane reduction cleanly afforded a mixture of anhydroalditol esters **8** and **9** ($\geq 10:1$, 89%), which were deprotected and separated by column chromatography on Ca^{2+}-loaded ion exchange resin. Regioselective acetalization of the

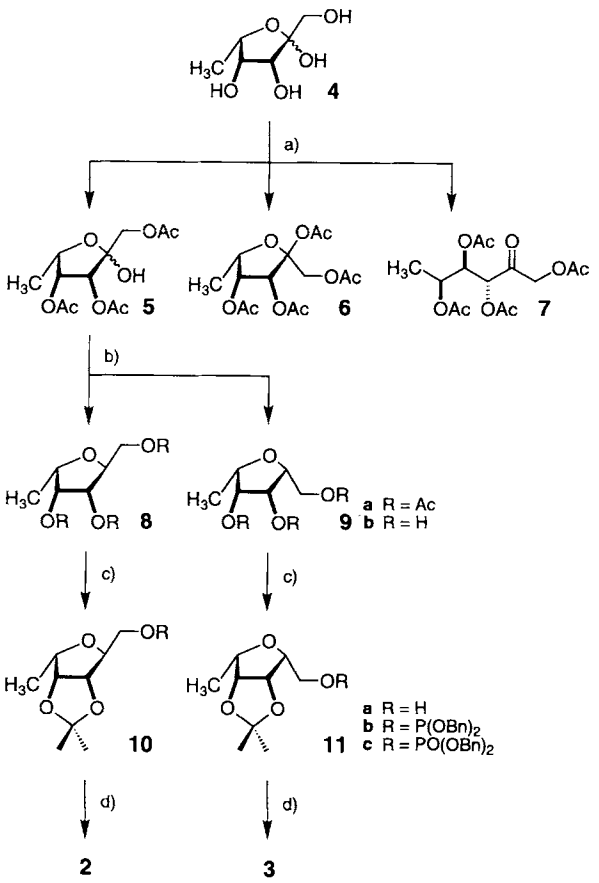
National Institutes of Health (Grants GM48568 and GM07775 to J. V. S.). We thank Prof. Dr. G. E. Schulz and Dr. M. Dreyer (University of Freiburg) for sharing their X-ray data prior to publication (see ref. [11b]). Part 11: [4b].



Scheme 2. Synthesis of FucA inhibitors. a) Ac_2O/pyridine, 93% **5**–**7** (ratio 61:17:22); b) $Et_3SiH/BF_3/(CH_2Cl)_2$, 89% **8a**/**9a** (ratio 10:1), then K_2CO_3/MeOH, 93% **8b**/**9b**; c) acetone/H_2SO_4, $Et_2NP(OBn)_2$/THF, H_2O_2, 69% **10c** (48% **11c**) for three steps; d) H_2/Pd–C/EtOH, Dowex 50W H^+/H_2O/EtOH at room temperature, 94% **2** (90% **3**).

vic-diol (**10a**, **11a**) was followed by phosphitylation/oxidation to afford the primary dibenzyl phosphate esters **10c** and **11c**, respectively, from which the target compounds were liberated by hydrogenolysis and acid-catalyzed removal of the acetal. Purification by ion-exchange chromatography provided crystalline phosphates **2** and **3** as the bis(cyclohexylammonium) salts (14% and 2% overall yield from **4**, respectively). In kinetic studies only analog **2** showed detectable FucA inhibition, albeit with low affinity (K_i = 22 mM), which indicates that the aldolase selectively binds the more abundant β-anomer of the natural substrate **1** (K_m = 0.7 mM; $\alpha:\beta$ = 2:5). In addition, the higher affinities of *sn*-glycerol 3-phosphate (K_i = 6 mM) and phosphoglycolate ($K_i \approx$ 10 mM) point to the importance of the missing anomeric OH group for specific binding. The need for the correct configuration at the anomeric center is underscored by the fact that no significant inhibition was observed for the enantiomeric *sn*-glycerol 1-phosphate or for D-glycerate 3-phosphate. The low affinity for L-fucitol 1-phosphate (K_i = 70 mM) may be interpreted as an indication of weak binding by the open-chain form of **1**.

Deprotonation of DHAP at C-3 yields an enediolate intermediate **12** closely resembling phosphoglycolohydroxamate **13** (Fig. 2). Indeed, **13** was found not only to be a potent inhibitor of FucA (K_i = 4 μM), but also a strong inhibitor of each of the class II aldolases tested so far (Table 1). Apparently the hydroxamate very effectively mimics the catalytic intermediate or transition state common to these enzymes, and seems to be bound by all Zn^{2+}-dependent aldolases in a very similar fashion.

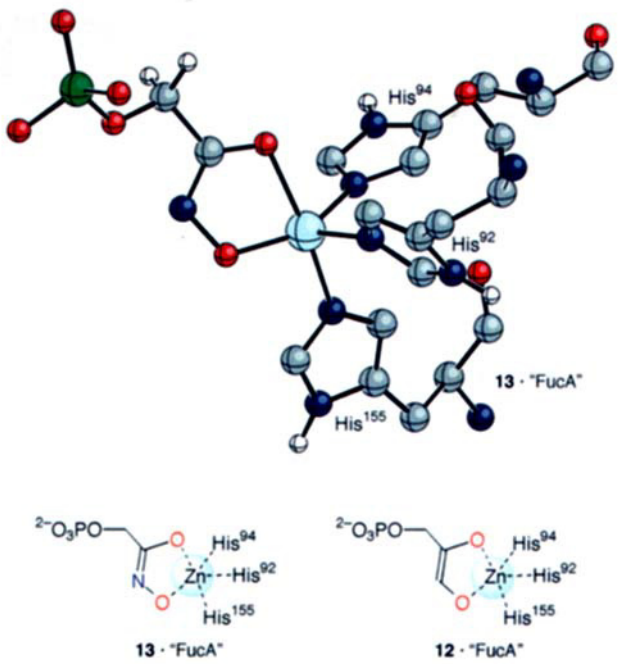


Fig. 2. Coordination of Zn^{2+} in the active site of FucA complexed with phosphoglycolohydroxamate (**13**) as determined by X-ray structure analysis[11b].

Table 1. Inhibition of zinc-dependent aldolases[a].

Enzyme [2]	Substrate K_m [M]	**13** K_i [M]	Phosphoglycolate K_i [M]
FucA	1.5×10^{-3}	$3.1 \pm 0.9 \times 10^{-6}$	$> 10 \times 10^{-3}$
RhuA	1.6×10^{-3}	$120 \pm 12 \times 10^{-9}$	$260 \pm 46 \times 10^{-6}$
FruA	6.2×10^{-6}	$15 \pm 2.5 \times 10^{-9}$	$130 \pm 26 \times 10^{-9}$

[a] Standard assays[2, 12] were based on the rate of DHAP formation from cleavage of the corresponding natural substrates by the aldolase (0.01 U), which was determined by consumption of NADH (0.2 mM) in the presence of glycerol phosphate dehydrogenase (5 U). Inhibition kinetics were determined by varying the concentrations of aldolase substrate and inhibitors. The inhibitor concentrations were chosen such that they bracketed the IC_{50} value for the aldolase at that substrate concentration. Inhibition was competitive for FucA, whereas **13** displayed slow binding kinetics with FruA and RhuA.

Very recently an X-ray structure has been determined for the complex of FucA and the substrate analog **13** (Fig. 2).[11b] The analysis reveals that the inhibitor forms a bidentate chelate in which both the enol and hydroxamate oxygens are coordinated to the Zn^{2+} ion. These results clearly indicate a role for Zn^{2+} in stabilizing the enediolate. Indeed, hydroxamates typically act as chelators in simple metal complexes[13] in which the hydroxamic acid group is in the anionic rather than the protonated form.[14] Bidentate binding of a DHAP ligand also helps to explain the natural preference of metal-dependent aldolases for an active site Zn^{2+} ion (which can be exchanged for Co^{2+} to yield highly active catalysts) because zinc (like cobalt) readily adapts to trigonal-bipyramidal coordination and is able to change its coordination state far more easily than other metals.[15] Also, zinc(II) is the most common Lewis acid in bioinorganic chemistry.

Thus, based on these considerations we propose a different catalytic cycle for FucA, with general implications for other metalloaldolases (Scheme 3). In direction of synthesis, DHAP enters as the first substrate and coordinates in an extended conformation to zinc through both hydroxyl and carbonyl oxygens initially in ground state complexes and then in intermediate

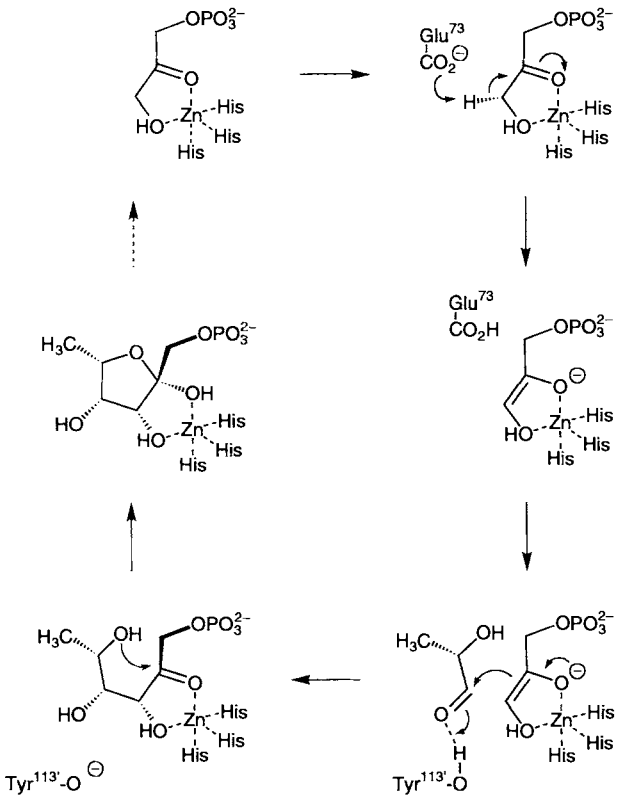

Scheme 3. Proposed catalytic cycle of FucA in direction of synthesis indicating relevant protein–substrate interactions.

states. Polarization of the carbonyl bond increases the acidity of the hydroxymethylene hydrogens and facilitates abstraction of the *pro-R* proton by a general base, which probably is Glu73. The phosphate group is rigidly held by a number of contacts to backbone amides and polar residues, most likely in order to suppress the facile enediolate fragmentation from an orthogonal conformation. Consequently, its proposed function as an intrinsic base becomes highly implausible.[16] The nucleophilic *cis*-enediolate attacks the *Si* face of an incoming lactaldehyde carbonyl, assisted by Tyr113′, which can donate a proton to stabilize the developing charge. This hydrogen bond is responsible for the asymmetric induction at C-4, while the shielding of the *Si* face of the DHAP enediolate by the protein assures the correct stereochemistry at C-3 of the product. Liberation of the product from the catalyst may be induced directly by restoring the carbonyl originating from DHAP, or may be preceded by ring closure from attack of the hydroxyl group introduced by lactaldehyde. Proton exchange with (or without) solvent prepares for the next catalytic cycle.

Previous hypotheses were based primarily on studies of enzyme–substrate interactions in the ground state, whereas our current model relies on inhibition studies and data from X-ray structure analyses with inhibitors that resemble the catalytic intermediate and/or transition state. While this model successfully explains all key stereochemical issues and the influence of the catalyst on the rate-limiting steps, it currently does not explain the high enantioselectivity for 2-hydroxyaldehydes,[12] because **13** is a model for DHAP only.

A detailed understanding of the events of molecular recognition in aldolase–substrate interactions during catalysis should develop and enable further progress, for example in the development of selective inhibitors of class I versus class II FruA enzymes for therapeutic purposes, in the design of new substrate analogs to enhance the spectrum of potential preparative applications, and in rational protein engineering towards an altered substrate tolerance and novel catalytic functions.

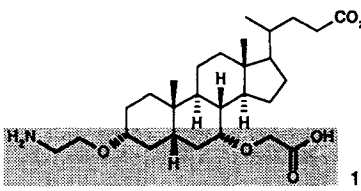
The Design and Synthesis of a Scaffold for Combinatorial Chemistry Based on Bile Acid

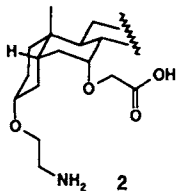
Günther Wess,* Klaus Bock, Horst Kleine, Michael Kurz, Wolfgang Guba, Horst Hemmerle, Eloisa Lopez-Calle, Karl-Heinz Baringhaus, Heiner Glombik, Alfons Enhsen, and Werner Kramer

Combinatorial chemistry opens up new possibilities for research in medicinal chemistry in both the search for lead structures and their rapid optimization.[1] Nevertheless, though many peptides are already the first milestones along this path, the optimization of sequences suitable for their combinatorial synthesis is still hardly a straightforward task.[2] The synthesis strategy must take into account the compatibility and interplay of the spacers between resin and molecular scaffold, the protecting groups, and the derivatization reactions. The number, diversity and availability of nonpeptidic scaffolds is, at present, still very limited. The design of new and structurally highly diversified nonpeptide scaffolds is a prerequisite for encompassing the widest possible range of structures.[3] We are interested in conformationally fixed amino acid units, which can be used in a variety of ways, both to generate compound libraries and to optimize targeted lead structures by means of parallel synthesis. In particular these structural elements should replace peptide sequences and/or pre-organize pharmacophores or other residues.[4, 6]

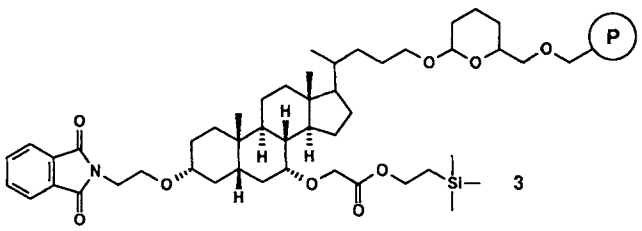
We report here on the amino acid equivalent **1**, which contains a *cis*-decalin partial structure (**2**) within a bile acid skeleton and, formally, mimics a tetrapeptide. In the form of derivative **3** it should be highly suitable for combinatorial syntheses. In **1** the two *cis*-related OH functions on the α-face of chenodeoxycholic acid (**4**) are used. Separated in each case by a spacer, the



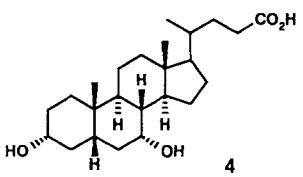
1



2



3



4

C-7 atom bears a carboxy substituent and the C-3 atom an amino group. In previous work with bile acids[5] the functions on C-3 and C-7 were the same and used either as OH groups in the form of esters or amino groups in the form of amides. In contrast to this we use different functional groups connected through spacers to C-3 and C-7 as well as an OH-group on C-24.

In **3** both the amino groups and the carboxy groups are protected but may be deprotected at any time under mild conditions on the solid support. The acid-labile tetrahydropyranyl unit acts as the connector to the polymer support.[7] After separation from the resin under very mild conditions, the C-24 alcohol is obtained, which can be easily purified and derivatized.

The synthesis of **3** is shown in Scheme 1. Preparative, selective allylation of bile acids and bile acid esters at the hydroxy groups has hitherto been a problem.[8] The use of allyl bromide/diisopropylethylamine gave satisfactory yields of the allylated product in only a few cases. Selective monoalkylation of the 3-OH-group always required protecting groups on 7-OH and 12-OH. In addition during the alkylation of 7-OH and 12-OH the other functions had to be protected, and long reaction times were necessary. We found that in allyl bromide/DMF (1/1) in the presence of powdered potassium hydroxide and with controlled temperature (10–20 °C, 8 h), allyl 3-allylchenodeoxycholate was formed selectively. Reduction of this ester with lithium aluminum hydride gave alcohol **5**, which was selectively benzylated with benzyl bromide/DMF/KOH. The 7-OH group was subsequently allylated.

Since the phthalimido group is a stable protecting group in the presence of many reagents, we chose the Gabriel synthesis[9] for the introduction of the amino function. The coupling of **10** with the polymer support was accomplished by the Ellman procedure.[7] For the coupling in dichloroethane with pyridinium-*p*-toluenesulfonate (PPTS; 18 h reflux), 1.5 g of polymer support was used (more than 2.25 mmol) and 2.65 g of the coupled product was obtained. The chlorine content, determined argentometrically after decomposition, was less than 0.76%.

The investigation of the acid conditions for cleavage from the polymer support proved that the trimethylsilylethyl group was very sensitive. The cleavage took place smoothly and without decomposition in THF with hydrochloric acid in diethyl ether (4 h, room temperature; Scheme 2). To optimize the reaction conditions the products were cleaved from the resin (THF, HCl/Et_2O, room temperature), chromatographed, and analyzed spectroscopically. The conversion of **3** to the free amine **11** under classical Gabriel conditions (hydrazinolysis)[9] did not occur; a side reaction is the formation of the carboxylic acid hydrazide from the trimethylsilyl ester. However, compound **11** is formed smoothly when **3** is treated with methylhydrazine in THF/ethanol at room temperature and is easily acylated to form **13**. Trimethylsilyl ester **3** was converted to the carboxylic acid **12** by treatment with tetrabutylammonium fluoride in DMF. Derivatization to amides was carried out with dicyclohexylcarbodiimide/1-hydroxy-1*H*-benzotriazole (DCC/HOBT)[10] in dichloromethane. Each 250 mg of **3** yielded 50 mg of **13** and 65 mg of **14** after chromatographic purification.

A library of 40 compounds of type **15** was prepared based on these results.[11]

To verify that **1** was suitable as a β-turn mimetic, the cyclic compound **16**,[16] which contains D-Pro-Ala, was prepared. This resembles a cyclic hexapeptide in which four of the amino acids have been replaced by the skeleton **1**. The interproton distances in **16** were determined from ROESY NMR spectra in $CDCl_3$ and DMSO. In DMSO two conformers, which differed in the conformation of the peptide bond between the skeleton and D-Pro, were present as an equilibrium mixture, whereas in

16

$CDCl_3$ only the *trans*-conformer was present. The distances obtained experimentally were used for a three-dimensional structure refinement by distance geometry and molecular dynamic simulations in both $CDCl_3$ and DMSO. In Figure 1 the structure of **16** is compared with that of a cyclic hexapeptide with two β-II'-turns. It is clear that the bile acid moiety occupies the positions i to $i+3$ of the upper β-turn of the hexapeptide. In contrast to the previously known turn mimetics, which usually replace positions $i+1$ and $i+2$ of a β-loop, we have here a β-turn mimetic that corresponds to a complete β-turn and enables a chain extension unambiguously in the direction of the N- and C- terminus.

Thus **1** makes available a novel scaffold for the design of combinatorial compound libraries which includes structures other than those of the previously used turn-mimetics. In addition the bile acid scaffold **1** exhibits a compact hydrophobic surface, which, if built into active peptidic substances, could have beneficial effects on their pharmacokinetic properties. We are currently synthesizing model compounds to investigate the β-fold-inducing effects of **1**. Compound libraries derived from **1** are being biologically tested for the synthesis of various targets.

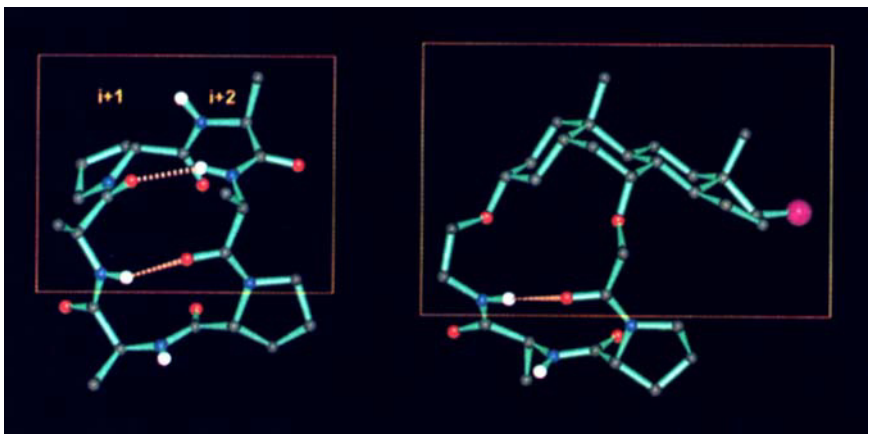

Fig. 1. Comparison of the three-dimensional structure of **16** (right) and cyclo(D-pro-Ala-Ala)$_2$ (left) [13]. The framed areas each correspond to a β-turn.

[11] The carboxylic acid function of **3** was deprotected and separately coupled with each of five different *tert*-butyl-protected amino acids (HOBT, DCC, CH_2Cl_2). After regeneration from the phthalimide ($MeNHNH_2$) the amino group was coupled with Fmoc-protected (Fmoc = fluorenylmethoxycarbonyl) amino acids (*O*-((ethoxycarbonyl)cyanomethylenamino)-*N*,*N*,*N*',*N*'tetramethyluronium tetrafluoroborate (TOTU), DMF). Finally the Fmoc groups were cleaved (piperidine) and subjected to reaction with other amino acids (Fmoc derivatives, TOTU). After cleavage from the resin and deprotection (trifluoroacetic acid (TFA), CH_2Cl_2, Et_3SiH), the products were obtained as their trifluoroacetates. Filtration through aluminum oxide (EtOAc, MeOH, H_2O, HOAc) provided the free compounds **15** in yields of 50–90% and a purity of 50–90% (determined by HPLC).

[12] Compound **9** was treated with the *tert*-butyl ester hydrochloide of D-proline (HOBT, DCCI, $EtNiPr_2$) and finally deprotected with TFA/H_2O (98/2). Reaction of the free acid with the *tert*-butyl ester hydrochloride of L-alanine (HOBT, DCC, $EtNiPr_2$), cleavage with TFA/H_2O (98/2) to form the acid, phthalimide cleavage with $MeOH/H_2NNH_2$ and finally cyclization with pentafluorophenol (DCC, CH_2Cl_2, high dilution) provides **16** in excellent yield (92%).

Synthesis and Crystal Structure of the $[Ni_{32}C_6(CO)_{36}]^{6-}$ Hexaanion: An Extended Fragment of the $M_{23}C_6$ Lattice Stabilized in a Shell of Edge-Bridging Carbonyl Ligands**

Francesca Calderoni, Francesco Demartin, M. Carmela Iapalucci, and Giuliano Longoni*

Transition metal carbonyl clusters of high nuclearity are often closely related to fragments of a metal lattice; more rarely, clusters that can be considered as an extended fragment of the lattice of a binary compound have been stabilized in a ligand shell, although some important examples of this type of cluster are known.[1, 2] Metal carbonyl clusters that exhibit the above behavior are of interest since they may provide a molecular approach to new materials,[3] and may be used as models for both experimental[4] and theoretical studies.[5]

Several years ago we reported the synthesis and crystal structure of the nickel carbide cluster **1** and its corresponding hexaanion **2**;[6] the $Ni_{32}C_6$ inner core of **1** is closely related to the

$[HNi_{38}C_6(CO)_{42}]^{5-}$ **1**

$M_{32}C_6$ truncated-octahedral fragment that is present in the $M_{23}C_6$ lattice, for example, in $Cr_{23}C_6$.[7] The method for preparing these clusters was improved recently, and thus it has now been possible to study their reactivity. As part of these reactivity studies we report here on the synthesis and crystal structure of the new $[Ni_{32}C_6(\mu\text{-}CO)_{36}]^{6-}$ hexaanion **3**, which consists of the above-mentioned $M_{32}C_6$ fragment stabilized in a shell of 36 edge-bridging carbonyl groups.

Compound **3** was obtained by degradation of **2** with carbon monoxide at atmospheric pressure [Eq. (a)], or by thermal decomposition of $[Ni_{10}C_2(CO)_{16}]^{2-}$ (**4**)[8] in diglyme at 110 °C under a nitrogen atmosphere [Eq. (b)].

$$\underset{\mathbf{2}}{[Ni_{38}C_6(CO)_{42}]^{6-}} + 18\,CO \underset{}{\overset{\text{MeCN, CO (1 atm)}}{\rightleftharpoons}} \underset{\mathbf{3}}{[Ni_{32}C_6(CO)_{36}]^{6-}} + 6\,[Ni(CO)_4] \quad \text{(a)}$$

Equilibrium (a) was shifted to the right by removal of $[Ni(CO)_4]$ under vacuum and re-exposure of the solution to a carbon monoxide atmosphere. The appearance of $[Ni(CO)_4]$ and a change in the pattern of the carbonyl absorption bands of **2** (1992 s, 1877 s, 1862 s cm^{-1}) was observed when the reaction was monitored by IR spectroscopy.[6] As the reaction proceeds, the absorption band attributed to the terminal carbonyl groups (1992 cm^{-1}) becomes progressively less intense, and the two bands attributed to the edge-bridging carbonyl ligands collapse into a single absorption band that is shifted to a slightly higher wavenumber. The intermediate IR patterns suggest the possible formation of $[Ni_{38-x}C_6(CO)_{42-x}]^{6-}$ ($x = 1-5$) species by stepwise elimination of Ni(CO) moieties. All $[Ni_{38-x}C_6(CO)_{42-x}]^{6-}$ ($x = 0-6$) clusters would constantly have $6n + 19$ filled valence orbitals, and thus, each member of the series should be possible both from a steric and electronic standpoint. A known example of such behavior is provided by the $[Ni_{34}C_4(CO)_{38}]^{6-}$ and $[Ni_{35}C_4(CO)_{39}]^{6-}$ pair of compounds.[9] The final product **3** shows a single sharp carbonyl absorption band at 1889 cm^{-1}.

Alternately, **3** can be obtained by thermal decomposition of **4** in diglyme, which proceeds approximately according to Equation (b).

$$5\,\underset{\mathbf{4}}{[Ni_{10}C_2(CO)_{16}]^{2-}} \xrightarrow{\Delta,\ 110\,^\circ C} \underset{\mathbf{5}}{[Ni_{16}C_4(CO)_{23}]^{4-}} + \underset{\mathbf{3}}{[Ni_{32}C_6(CO)_{36}]^{6-}} + 2\,[Ni(CO)_4] + 13\,CO \quad \text{(b)}$$

Owing to their very low solubility, the salts of **3** separate out, together with some insoluble inorganic material, from the reaction solution containing **5**.[10] The quaternary ammonium and phosphonium salts have been purified by extraction in MeCN and crystallized by layering the extracts with diisopropyl ether.

The unit cell of the $[PPh_3Me]_6$ salt of **3** contains one cluster anion located on a crystallographic inversion center, six cations, and four acetonitrile molecules.[11] The structure of **3**, which shows an overall idealized O_h symmetry, is shown in Figure 1.

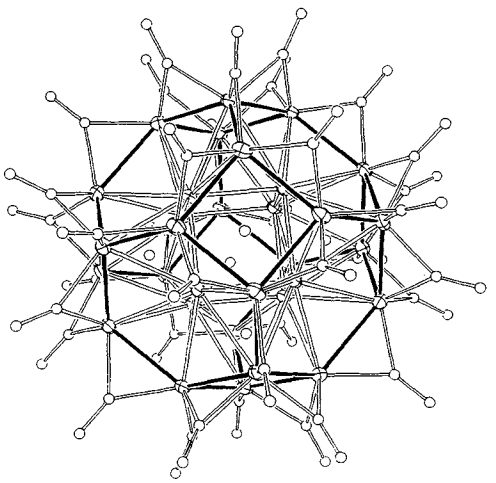

Fig. 1. Crystal structure of **3** (the Ni–Ni bonds in black highlight the outer Ni_{24} truncated-octahedron; $Ni-C_{carbide}$ bonds have been omitted for clarity).

The truncated octahedral $Ni_{32}C_6$ framework of **3** is identical to the corresponding fragment in **1**, and reveals very close interatomic separations. The structure contains an inner, empty Ni_8 cube (av Ni–Ni = 2.397 Å) whose six faces are capped by carbon atoms, which describe a C_6 octahedron without bonding interactions between the C atoms. This inner Ni_8C_6 moiety is surrounded by a truncated-octahedral Ni_{24} shell (av Ni–Ni = 2.461 Å). The Ni atoms of the Ni_{24} shell are arranged in such a way that they generate six square-antiprismatic cavities, in which the six carbide-C atoms (av Ni–C = 2.062 Å) are located. Each Ni atom of the inner cube lies approximately 0.93 Å below the center of each hexagonal face of the outer Ni_{24} shell (av $Ni_{inner}-Ni_{outer}$ = 2.634 Å) and is 12-coordinate; they are within bonding distances from six Ni atoms of the outer shell, three Ni atoms of the inner cube, and three carbide-C atoms.

The solid-state structure of **3** has exclusively edge-bridging carbonyl groups (av Ni–C = 1.917; av C–O = 1.152 Å), which span all Ni–Ni edges of the outer Ni_{24} shell. This structural feature is reminiscent of CO chemisorbed at low coverage on metal surfaces.[12] The solution IR spectrum of **3** reveals that this arrangement of the carbonyl ligands is also retained in

solution. As a result, a $Ni_{32}C_6^{6-}$ molecular ion, which is identical to the $Cr_{32}C_6$ building unit of the $Cr_{23}C_6$ carbide,[7, 13] has now been stabilized in a shell of 36 carbonyl ligands. The isolation and characterization of **3** also substantiates the linear combination of Guassian type orbitals–local density functional (LCGTO-LDF) study previously carried out on a $[Ni_{32}C_6(CO)_{36}]^{n-}$ model compound.[16]

The space-filling model in Figure 2 illustrates an interesting feature of **3**: the structure shows eight distorted hexagonal cup-shaped hollows formed by consecutive concentric rings of oxygen, carbon, and nickel atoms, and ending with an unique nickel atom belonging to the inner cube. We are currently investigating the possibility of placing sterically less demanding molecules in these cup-shaped hollows, as well as the potential use of **3** as a molecular precursor for the preparation of the unknown $Ni_{23}C_6$ alloy.

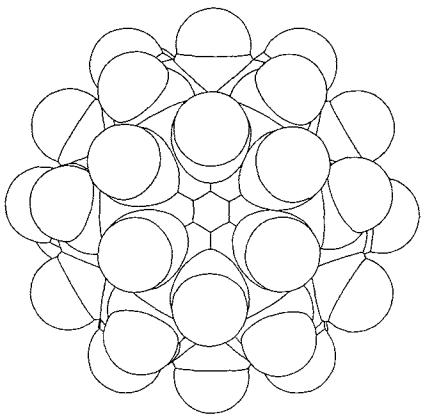

Fig. 2. Space-filling model of **3** illustrating one of the eight cup-shaped hollows.

Experimental Procedure

A solution of $[PPh_3Me]_6$-**2** (350 mg, 0.067 mmol) in acetonitrile (20 mL) was stirred under a CO atmosphere for 15 min and then evaporated under vacuum to dryness. The residue was dissolved in acetonitrile (20 mL) and stirred under a CO atmosphere for 10 min and then dried under vacuum. The resulting dark brown residue was extracted with acetonitrile (20 mL) and filtered. Precipitation by layering the extract with diisopropyl ether (40 mL) gave black crystals of $[PPh_3Me]_6[Ni_{32}C_6(CO)_{36}]\cdot 4$ MeCN (210 mg, 0.043 mmol). The salt is soluble in acetone, acetonitrile, and dimethyl sulfoxide, insoluble in THF, alcohols, and nonpolar solvents (ν_{CO} in MeCN at 1889 cm^{-1}). Elemental analysis for $[PPh_3Me]_6[Ni_{32}C_6(CO)_{36}]\cdot 4$ MeCN: calcd C 41.08, H 2.50, N 1.17; found C 40.86, H 2.41, N 1.14.

The Aluminocenium Cation $[Al(C_5H_5)_2]^+$: A Highly Effective Initiator for the Cationic Polymerization of Isobutene**

Manfred Bochmann* and David M. Dawson

Dedicated to Professor Sir Geoffrey Wilkinson on the occasion of his 75th birthday

The role of aluminum reagents as Lewis acids and as activators for olefin polymerization catalysts is well documented.[1] Very little is known, however, about the chemistry of cationic organoaluminum compounds $[AlR_2]^+$ for which very high Lewis acidity can be expected. Some donor-stablized cationic complexes such as $[AlMe_2(crown)]^+$, $[(EtAl)_2(diazacrown)]^{2+}$, and $[Al\{C(SiMe_3)_2py\}_2]^+$ have been structurally characterized,[2, 3] and recently Schnöckel et al. reported the formation of the decamethylaluminocenium cation $[AlCp_2^*]^+$ by the disproportionation of $[AlCp^*]_4$ in the presence of $AlCl_3$ ($Cp^* = C_5Me_5$).[4] The reactivity of such cationic organoaluminum complexes has to our knowledge not been explored. We report here the synthesis of the unsubstituted aluminocenium cation, $[AlCp_2]^+$, ($Cp = C_5H_5$) and its reactivity as an initiator for cationic polymerizations.

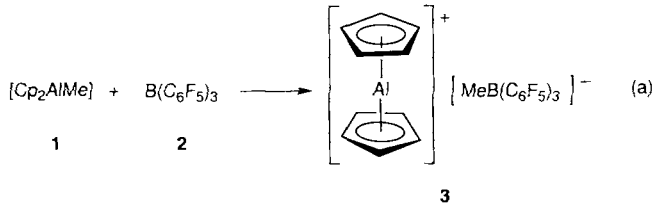
The reaction of $[AlCp_2Me]$ (**1**)[5] with $B(C_6F_5)_3$ (**2**) in dichloromethane at low temperature, followed by evaporation of the solvent affords the white microcrystalline solid **3** [Eq. (a)].[6] Compound **3** is sparingly soluble in warm benzene

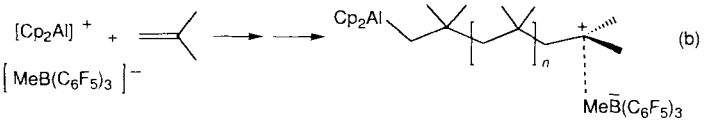


or toluene but dissolves rapidly in cold dichloromethane. Over the temperature range from -80 to $-20\,^{\circ}C$, solutions of **3** in CD_2Cl_2 show two singlets in the ^1H NMR spectrum at $\delta = 7.05$ and 0.55, consistent with the formation of the solvated ion pair $[AlCp_2]^+[MeB(C_6F_5)_3]^-$. These solutions decompose rapidly on warming them to $20\,^{\circ}C$. The ^{27}Al NMR spectrum recorded at $-60\,^{\circ}C$ for the reaction of **1** with **2** shows that the broad signal for **1** at $\delta = 72.7$ (half-width ca. 250 Hz) is replaced by a new sharp peak at $\delta = -126.4$ (half-width 30 Hz). This value is in excellent agreement with the calculated chemical shift for the $[Al(\eta^5\text{-}Cp)_2]^+$ ion ($\delta = -130.0$).[4]

1:1 mixtures of **1** and **2** in $[D_8]$toluene at $20\,^{\circ}C$ show very similar ^1H and ^{27}Al NMR spectra. The limited solubility of the reaction product in toluene leads to the formation of two phases on cooling. Although the formation of the methyl-bridged isomer $[Cp_2Al(\mu\text{-}Me)B(C_6F_5)_3]$ might reasonably be expected in less polar solvents, conclusive evidence for this was not found.

Even in the solid state **3** is highly air- and moisture-sensitive. Unfortunately crystals suitable for X-ray diffraction could not be obtained. Although **1** has been shown to contain η^2-coordinated Cp rings in the crystal and is highly fluxional in solution, the $[AlCp_2]^+$ ion most likely possesses a metallocene-type structure with η^5-bound Cp ligands. This assumption is supported by the structure of $[Al(\eta^5\text{-}Cp^*)_2]^+$, the close agreement of the observed ^{27}Al chemical shift with the one calculated assuming a D_{5d} symmetry, the narrow half-width of the ^{27}Al signal, which is typical for a highly symmetric ligand environment for Al, as well as the sandwich structures of the isoelectronic magnesiocene $[MgCp_2]$ and related Group 2 cyclopentadienyl complexes.[7] An increase in hapticity from η^1 to η^5 on forming a more Lewis acidic cationic metal center from a neutral cyclopentadienyl complex is also a common feature of boron cyclopentadienyl complexes.[8]

Starting point for the synthesis of $[AlCp_2]^+$ was the search for highly Lewis acidic compounds as initiators for carbocationic polymerizations. Compound **3** is indeed a highly active initiator for the polymerization of isobutene and isobutene–isoprene copolymerizations [Eq. (b)]. Such copolymerizations to butyl rubber are carried out on an industrial scale by using a heterogeneous initiator based on $AlCl_3$ in chloromethane at between -95 and $-100\,^{\circ}C$.[9, 10] The need to recycle large amounts of chlorinated solvents and the high energy requirements of such a low-temperature process make cleaner, less energy intensive alternatives that can be operated at higher temperatures highly desirable.



The activity of **3** as an initiator for the polymerization of isobutene has been studied over a temperature range of $-78\,^{\circ}C$ to $-25\,^{\circ}C$. The reactions proceed in dichloromethane as well as in saturated hydrocarbons. Neither **1** nor **2** on their own was found to polymerize isobutene.[11] Whereas an excess of **2** over **1** has no effect on polymer yield or molecular weight, an excess of **1** over **2** retards the polymerization. The results for isobutene homopolymerizations are given in Table 1. As expected for carbocationic polymerizations, the polymer molecular weights increase with decreasing temperature, from $M_w \approx 3 \times 10^5$ at $-30\,^{\circ}C$ to 1.8×10^6 at $-70\,^{\circ}C$, with narrow polydispersities.[12]

Table 1. Isobutene homopolymerizations initiated with **3** [a].

Entry	**1** [μmol]	**2** [μmol]	T [°C]	t [min]	Yield [g]	M_w $\times 10^{-3}$	M_w/M_n
1 [b]	40	40	−78	10	0.63	731	3.0
2 [c]	38	38	−78	10	0.28	1340	3.0
3	50	50	−70	10	0.30	1800	2.8
4	100	50	−70	10	0.02	820	3.4
5	50	50	−50	10	0.18	618	2.0
6	50	50	−30	10	0.08	318	1.8
7	50	100	−30	10	0.03	337	1.8
8	50	50	−25	10	0.05	289	1.6

[a] For reaction conditions see Experimental Procedure. Entries 3–8: Polymerizations were carried out in the presence of 1.5 mL dichloromethane. [b] Solvent: toluene (1.5 mL). [c] Solvent: methylcyclohexane (1.5 mL).

Compound **3** also initiates the copolymerization of isobutene with 2–5 vol% of isoprene, at typical reaction temperatures of -78 to $-50\,^{\circ}C$. For example, the reaction with 5% isoprene at $-70\,^{\circ}C$ gave a polymer with $M_w = 7.8 \times 10^5$ and $M_w/M_n = 3.3$. The polymer contained about 2.7% isoprene units with a 1,4-*trans* structure; there was no evidence for 1,4-*cis* or 1,2-incorporation within NMR detection limits.[13] Similar reactions with 2 vol% isoprene at $-50\,^{\circ}C$ gave copolymers with $M_w \approx 2 \times 10^5$.

It is likely that the relatively high molecular weights obtained in these reactions are not least due to the weakly basic nature of the counteranion used in this system. Isobutene homo- and copolymerizations are usually carried out with a mixture of a Lewis acidic metal halide MX_n and an alkyl halide RX capable of generating a carbocation, resulting in the formation of $R^+[MX_{n+1}]^-$. Self-ionization of the Lewis acid to $[MX_{n-1}]^+[MX_{n+1}]^-$ has also been suggested, although there is so far no direct evidence for species such as $[AlX_2]^+$ in polymerization systems.[14] Complex halide anions $[MX_{n+1}]^-$ possess rather limited stability and are prone to loss of X^- ions, which may lead to halide incorporation into the polymer and may assist deprotonation and chain transfer. In the present case we make use of the stability and very low basicity of perfluorophenylborates to generate a well-defined polymerization initiator system free of halide anions.[15, 16]

Experimental Procedure

All reactions were carried out under strictly dry and anaerobic conditions. NMR spectra were measured on JEOL EX270 and Bruker DPX300 spectrometers (reference: tetramethylsilane: ^1H and ^{13}C; $[Al(H_2O)_6]^{3+}$: ^{27}Al). Isobutene was dried over $Et_2AlOC_6H_{13}$ and recondensed; isoprene was dried over calcium hydride and distilled from sodium prior to use.

3: To a solution of **1** (400 mg, 2.3 mmol) in dichloromethane (10 mL) at $-78\,^{\circ}C$ was added **2** (1.2 g, 2.3 mmol). The mixture was stirred for 15 min, and the solution allowed to warm to $0\,^{\circ}C$ whilst the solvent was removed in vacuo. The off-white solid residue was washed with light petroleum and dried to give **3** (1.6 g, 2.3 mmol, 99%). Elemental analysis: Found: C 50.13, H 1.90, F 41.2%; calc.: C 50.87, H 1.90,

F 41.6%; ^{1}H NMR (CD_2Cl_2, −60 °C): δ = 0.55 (s, 3H, Me-B), 7.05 (s, 10H, Cp); ^{13}C NMR (CD_2Cl_2, −20 °C): δ = 10.5 (s, br, Me-B), 114.5 (s, Cp); ^{27}Al NMR (CD_2Cl_2, −20 °C): δ = −126.35; ([D$_8$]toluene, 20 °C): δ = −128.3 (half-width ca. 30 Hz).

(Co-)Polymerizations were carried out in an all-glass reactor, which was flame-dried in vacuo. Isobutene (10 mL) was condensed into the reaction vessel and magnetically stirred at 1000 rpm to allow it to equilibrate at the appropriate temperature. This was followed by injection of **2** (50 μmol) in 1 mL of solvent (cf. Table 1). The mixture was stirred for 1 min before **1** (50 μmol) in 0.5 mL solvent were injected. Polymerization took place instantaneously. The polymerization was terminated by injecting 0.5 mL methanol, and the polymer precipitated by the addition of further methanol. The product was filtered and dried in an oven at 60 °C. For copolymerizations the condensation of isobutene was followed by an injection of 2–5 vol% isoprene.

[11] In the presence of moisture **2** gives the acidic hydrate $B(C_6F_5)_3 \cdot H_2O$, which results in H^+-initiated formation of polyisobutene of variable molecular weight. Traces of moisture lead to very small amounts of high molecular weight polyisobutene (M_w = ca. $2-3 \times 10^6$), typical for very low initiator concentrations.

[12] Very similar polymerization results were obtained with the system [Al-Cp(R)Cl]/**2** (R = Me, Et). Monitoring the reaction between [AlCpMeCl] and **2** in CD_2Cl_2 at −73 °C shows the formation of $[AlCp_2]^+$ as the only identifiable product, evidently formed by Cp ligand exchange.

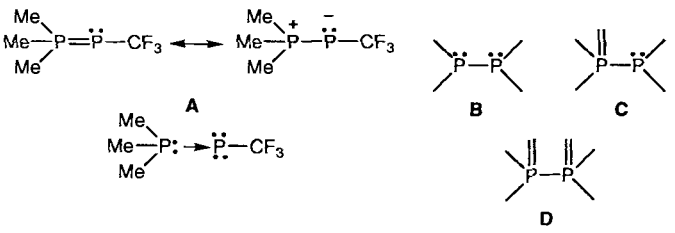
[16] Since this work was started, the cationic polymerization of isobutene with a [Cp*$TiMe_3$]/$B(C_6F_5)_3$ initiator system has been reported: F. Barsan, M. C. Baird, *J. Chem. Soc. Chem. Commun.* **1995**, 1065. The polyisobutene molecular weights reported for this system, which range from 3×10^4 (−20 °C) to 2×10^5 (−78 °C), are significantly lower than those obtained here with $[AlCp_2]^+$.

From $1\sigma^4,2\sigma^2$ to $1\sigma^4,2\sigma^n$-Diphosphetes (n = 3–6): The Surprising Persistence of the P–P bond**

Muriel Sanchez, Régis Réau, Françoise Dahan, Manfred Regitz, and Guy Bertrand*

Dedicated to Professor Miha Tišler on the occasion of his 70th birthday

The phosphanylidene-σ^4-phosphorane **A** was reported by Burg and Mahler in 1961.[1] It was the first example of a two-coordinate phosphorus atom in a neutral molecule, but more importantly, this compound opened the way to a variety of new types of P–P bonding beyond the classical ones (**B**–**D**) accepted



at that time.[2] Among other resonance forms, **A** can be regarded as a phosphane complex of a phosphinidene (phosphanediyl) unit.[3] Since phosphinidene units feature a phosphorus atom with the lowest possible coordination number, it is surprising that they have not been used more frequently to prepare phosphorus derivatives with much higher coordination states.[4] Very recently, we reported the synthesis of the $1\sigma^4,2\sigma^2$-diphosphete **1**,[5] a cyclic phosphanylidene-σ^4-phosphorane, and herein we report the conversion of the low-coordinate phosphorus center of **1** into a succession of higher coordinate phosphorus centers; the P–P interaction and the cyclic structure is retained throughout this series.

One of the rare examples of reactivity known for derivatives of type **A** is methylation.[3, 6] Thus, heterocycle **1** was treated with methyl triflate, which led to the cationic $1\sigma^4,2\sigma^3$-diphosphete **2** in 95% yield (Scheme 1); selective spectroscopic data are given in Table 1. The cyclic structure is supported by the high-field shift of the ^{31}P NMR resonance of the PMe unit (δ = + 54.9), the small $^2J(PNCH)$ coupling constants (5.2 and 4.8 Hz) typical of a diisopropylamino-substituted σ^4-phosphorus atom,[7] and by the multiplicity of the ^{1}H (δ = 1.84, dd, J(P,H) = 19.1 and 4.9 Hz) and ^{13}C NMR (δ = 11.26, dd, J(P,C) = 42.0 and 8.5 Hz) signals of the P-methyl group. Note the relatively small value of J(P,P) (107.4 Hz), which results from superimposition of the ^1J and ^3J coupling constants.

[**] This work was supported by the Centre National de Recherche Scientifique (CNRS), the Fonds der Chemischen Industrie (Graduiertenkolleg Phosphor), and the Deutsche Forschungsgemeinschaft. Editorial note: According to IUPAC recommendations, when ring atoms display a connectivity that differs from their standard bonding number, the actual bonding number is expressed as an arabic superscript to the Greek letter lambda following immediately after the appropriate locant. In this communication, however, contrary to this recommendation the Greek letter sigma has been applied to highlight the structural connection between the compounds **1**–**6**. The superscript, here gives the number of σ bonds starting from the ring phosphorus atoms.

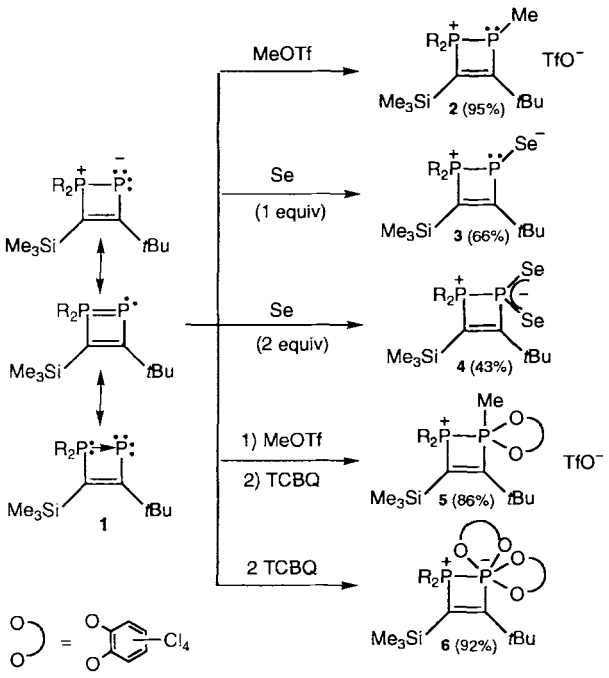
[a] Correct elemental analyses or/and mass spectra were obtained for compounds **2**–**6**.



Scheme 1. Synthesis of $1\sigma^4,2\sigma^n$-diphosphetes (n = 3–6) **2**–**6** from **1**. R = iPr$_2$N, Tf = CF_3SO_2, TCBQ = tetrachloro-*o*-benzoquinone.

The reaction of **1** with one equivalent of elemental selenium afforded the zwitterionic $1\sigma^4,2\sigma^3$-diphosphete **3** as an orange oil in 66% yield (Scheme 1). The best indications of its cyclic structure are given by the small $^2J(PNCH)$ coupling constants (4.0 and 2.7 Hz) and by the very low-field position[5] of the ^{13}C NMR signals of both ring carbon atoms (δ = 158.5 and 202.4).

A smooth reaction occurred when two equivalents of elemental selenium were added to **1**, affording the corresponding $1\sigma^4,2\sigma^4$-diphosphete **4** in 43% yield as a yellow oil (Scheme 1). Apart from the J(P,P) coupling constant (**3**: 246 Hz; **4**: 47 Hz), which is not relevant for the discussion, as mentioned above, the main difference between the spectroscopic data for **3** and **4** lies in the ^{77}Se NMR spectra (**3**: δ = – 63.0, ^1J(P,Se) = 487 Hz; **4**: δ = + 264.8, ^1J(P,Se) = 699 Hz).

For compounds **1**–**4**, ring strain is a destabilizing factor. Although ring opening through breaking the P–P bond would generate a stable phosphane on one side, a rather unstable low-coordinate phosphorus moiety[8] (a phosphinidene, a phosphenium ion, a selenoxophosphane, and a diselenoxophosphorane, respectively) would be generated on the other. If P–P bond cleavage led to stable phosphorus entities on both sides, one might expect that ring cleavage would occur. Surprisingly then, derivative **2** reacts with one equivalent of tetrachloro-*o*-benzoquinone (TCBQ) to produce the cationic $1\sigma^4,2\sigma^5$-diphosphete **5** (86% yield) as an orange oil, and addition of two equivalents of TCBQ to $1\sigma^4,2\sigma^2$-diphosphete **1** affords the $1\sigma^4,2\sigma^6$-diphosphete **6** (92% yield) as colorless crystals (Scheme 1). In addition to the arguments already used for compounds **2**–**4**, a strong indicator of a P–P bond in **5** and **6** is given by the low-field ^{31}P NMR signals of the amino-substituted phosphorus (**5**: δ = +115.5; **6**: δ = +131.5), which are inconsistent with free phosphanes. The cyclic structure has been confirmed by a single-crystal X-ray diffraction study[9] of compound **6** (Fig. 1).

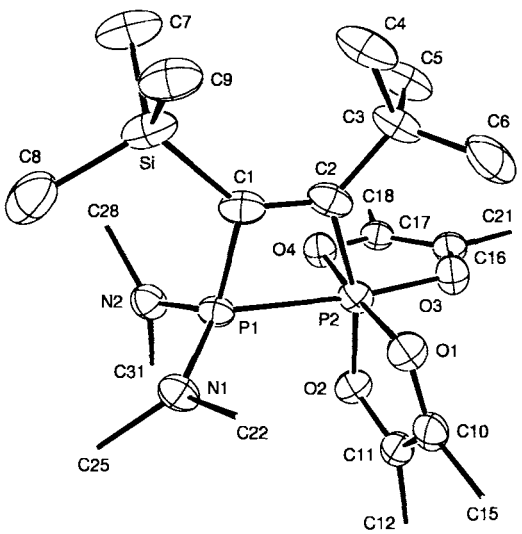


Fig. 1. Crystal structure of **6** (ORTEP view). The CH_3 groups of the diisopropylamino group and a section of the catecholate rings have been omitted for clarity. Selected bond lengths [Å] and angles [°]: P1–P2 2.2962(6), P2–C2 1.921(2), C2–C1 1.355(3), C1–P1 1.823(2); C1-P1-P2 79.66(7), P1-P2-C2 71.34(6), P1-P2-O3 173.09(5), O1-P2-O4 173.01(7), O2-P2-C2 165.44(7), P2-C2-C1 107.5(1), C1-C2-C3 129.2(2), C2-C1-P1 101.4(2), C2-C1-Si 136.1(2), P1-C1-C2-P2 1.9(2).

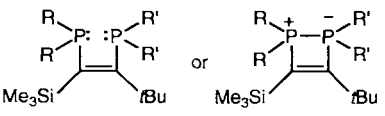
The P–P bond length of 2.2962 (6) Å is in the range of normal P–P single bonds (2.20–2.35 Å);[10] the P2 atom has a slightly distorted square-planar, bipyramidal coordination sphere, typical for hexacoordinate phosphorus.[11]

While P–P interactions between phosphanes and electron-poor polyfluorophosphoranes have been observed,[12] in marked contrast, several *cis*-1-phosphino-2-phosphonioethene derivatives exist, and none of them features a P–P interaction (P–P distances >3 Å).[13] The persistence of the P–P bond in derivatives **5** and **6** might be due to the steric repulsion between the bulky Me_3Si and *t*Bu groups, which induces small P1-C1-C2 (101.4(2)°) and P2-C2-C1 (107.5(1)°) angles. This study raises the question of a possible P–P interaction in compounds such as **7**.[14] In other words, can *cis*-$1\sigma^3,2\sigma^3$-diphosphorus-substi-



7

tuted ethene derivatives be forced to form four-membered heterocycles with a P–P bond?

Experimental Procedure

In a typical experiment, a solution of **1** (0.29 g, 0.70 mmol) in CH_2Cl_2 (1 mL) at −78 °C was added dropwise to a solution of TCBQ (0.34 g, 1.40 mmol) in CH_2Cl_2 (2 mL). The solution was allowed to warm to room temperature, and the solvent was removed under vacuum. The product was extracted from the residue with pentane (3 × 6 mL). Compound **6** was obtained from a solution in CH_2Cl_2 at −30 °C as colorless crystals (m.p. 223 °C), yield: 0.58 g (92%).

2: Orange oil from a CH_2Cl_2/pentane solution, yield: 0.34 g (95%); **3** and **4**: THF instead of CH_2Cl_2, sonication 10 min for **3** (orange oil, yield: 0.43 g (66%)) and 1 h for **4** (yellow oil, yield: 0.33 g (43%)); **5** (orange oil from a THF/pentane solution, yield: 0.41 g (86%)).

Microporous Mixed Oxides—Catalysts with Tunable Surface Polarity**

Stephan Klein and Wilhelm F. Maier*

The optimization of reaction conditions and heterogeneous catalysts is still of central importance for the improvement of selectivity in chemical production processes. The surface polarity of the catalysts has so far played a minor role. There is no detailed knowledge on the correlation of catalytic reactions and surface polarity or on catalysts whose surface polarity can be adjusted at will over a wide range, irrespective of the catalytically active centers. Here we show for the first time the preparation of microporous mixed oxide catalysts with controlled surface polarity and demonstrate their effect on selected selective oxidation reactions.

Isolated Ti^{4+} sites in an SiO_2 matrix are active centers for the selective oxidation of organic substrates with peroxides.[1] Whereas crystalline Ti zeolites like TS-1 are catalysts for selective oxidations with aqueous hydrogen peroxide but cannot utilize organic hydroperoxides such as *tert*-butylhydroperoxide (TBHP), amorphous TiO_2–SiO_2 oxides are excellent catalysts for selective oxidation with TBHP, but not with hydrogen peroxide.[2] These differences in the catalytic behavior are attributed to the difference in surface polarity of hydrophobic silicalites and hydrophilic, amorphous mixed oxides, as well as to geometric limitations in the formation of the transition state. The only exception is a TiO_2–SiO_2 oxide of unknown surface polarity and bimodal pore size distribution, which was recently reported to be active for the oxidation of arenes with hydrogen peroxide.[3]

As we have shown recently, SiO_2-based amorphous, microporous mixed oxides (AMM), prepared by an optimized sol–gel procedure in the absence of template molecules or hydrothermal synthesis conditions, are capable of catalyzing acidic and redox[4] reactions shape-selectively.[5] This synthesis concept has now been expanded to include the preparation of microporous mixed oxides, where the number of Si atoms carrying a covalently bound alkyl group is freely variable.[6] These nonhydrolyzable alkyl groups formally replace a hydroxyl group in the mixed oxide and therefore affect the surface polarity of the final catalyst.

In the following, these amorphous microporous mixed oxides are named AMM-M_x(Si-alkyl)$_y$Si. Here Si stands for the matrix materials SiO_2, x for the content of catalytically active metal oxide M (in atom %) and (Si-alkyl)$_y$ for the content (atom %) of alkyltrialkoxysilane in the Si matrix. A material named AMM-$Ti_1(SiMe)_{25}Si$ therefore has the composition of $1\,TiO_2 : 25\,H_3C\text{-}SiO_{1.5} : 74\,SiO_2$. Besides the already mentioned catalyst containing 1% Ti, any desired extent of Ti, as well as Al, Zr, Sn, and V can also be incorporated in those hybrid oxides; thus the metal as well as the alkyl content can be varied over a wide range.[7]

In the following we describe our studies on TiO_2-containg mixed oxides to illustrate the behavior of such alkyl-containing compounds. Argon adsorption–desorption isotherms con-

firmed the identical narrow micropore distribution already found in alkyl-free AMM materials.[4, 5, 8] The maxima of the pore size distribution (method of Horváth and Kawazoe) of the alkyl-containing mixed oxides (0.7 nm pore diameter) lie in the range of large-pore zeolites, comparable to the alkyl-free reference samples. The narrowness of the pore-size distribution decreases slightly with increasing methyl content in the series AMM-$Ti_1(SiMe)_ySi$ with $0 < y < 45$ (Table 1), whereas high surface areas remain a constant feature. Because the materials are all microporous, the absolute BET values from Table 1 are only

Table 1. Specific surface S_{BET}, maxima of pore size distribution D_{max} (method of Horváth - Kawazoe) and width at half height δ of the distributions of the AMM-$Ti_1(SiMe)_xSi$ materials. The values were obtained from Ar adsorption isotherms at 77 K.

Material AMM-	S_{BET} [m_2g^{-1}]	D_{max} [nm]	δ [nm]
Ti_1Si	585	0.73	0.12
$Ti_1(SiMe)_5Si$	489	0.74	0.07
$Ti_1(SiMe)_{10}Si$	627	0.73	0.06
$Ti_1(SiMe)_{15}Si$	527	0.73	0.09
$Ti_1(SiMe)_{20}Si$	545	0.72	0.07
$Ti_1(SiMe)_{25}Si$	532	0.73	0.11
$Ti_1(SiMe)_{30}Si$	539	0.74	0.36
$Ti_1(SiMe)_{35}Si$	575	0.74	0.35
$Ti_1(SiMe)_{40}Si$	625	0.73	0.30

$Ti_1(SiMe)_{50}Si$	580	0.73	0.17

important for mutual comparison and should be treated with caution. No microcrystalline areas could be detected by high resolution transmission electron microscopy. The amorphous structure of the materials must thus extend into the subnanometer region. Comparison of the elemental composition obtained from selected-area EDX-analysis (energy dispersive X-ray emission) of large and small sample areas in the nm to µm range confirms the high homogeneity of the mixed oxides already observed in the above mentioned spectroscopic studies and excludes the presence of domains. As in the methyl-free AMM-TiSi materials,[5] despite a very low Ti content a distinct IR band in DRIFT (diffuse-reflectance infrared Fourier Transform)/spectroscopic studies at 960 cm^{-1} in the AMM-$Ti_1(SiMe)_ySi$ materials confirm the isomorphic substitution of Si by Ti and thus the presence of atomically isolated Ti centers (Fig. 1). This band is absent in the Ti-free AMM-Si materials.

The incorporation of the methyl groups into the materials could be confirmed directly by DRIFT spectroscopy: the characteristic band of the structural CH_3-Si[9] unit was observed at 1280 cm^{-1}.[10] The signal intensity, which correlates with the y value of the AMM-$Ti_1(SiMe)_ySi$ (Fig. 1) did not change to 773 K. The presence of these stable methyl groups affects especially the surface polarity of these glasses. In analogy to a method employed by Weitkamp et al.[11] the polarity of materials was quantified by competitive gas-phase adsorption of octane–water mixtures.[12] From the loading x_i, obtained from the breakthrough curves of the two components, the modified hydrophobicity index $HI^* = x_{octane}/x_{water}$ was calculated as a measure of the relative affinity of the sample for these sorbates. Hydrophobic materials like Ti-silicalites of the MFI type have high HI* values greater than 1 and thus a tendency to absorb hydrocarbons, while hydrophilic materials like amorphous TiO_2–SiO_2 mixed oxides of similar composition have HI* values smaller than 1 and a preference for water absorption.

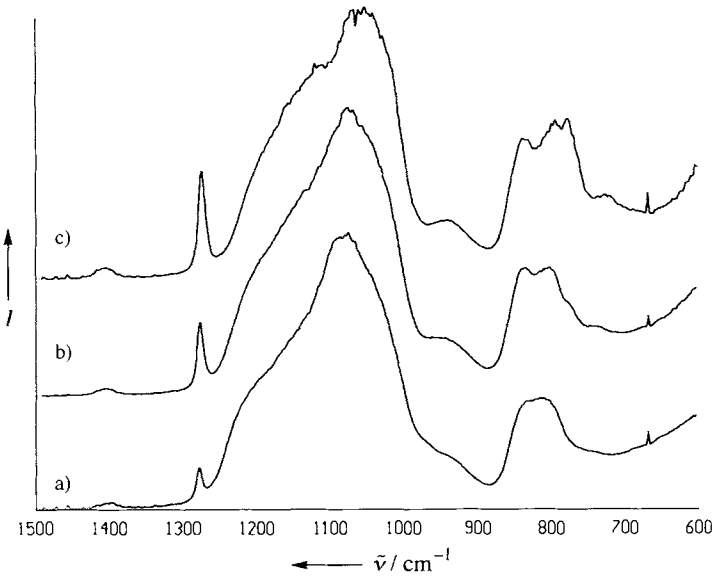

Fig. 1. DRIFT spectra of a) AMM-$Ti_1(SiMe)_{10}Si$, b) AMM-$Ti_1(SiMe)_{25}Si$, and c) AMM-$Ti_1(SiMe)_{45}Si$. The in situ measurements were performed at 303 K with calcined samples under inert atmosphere.

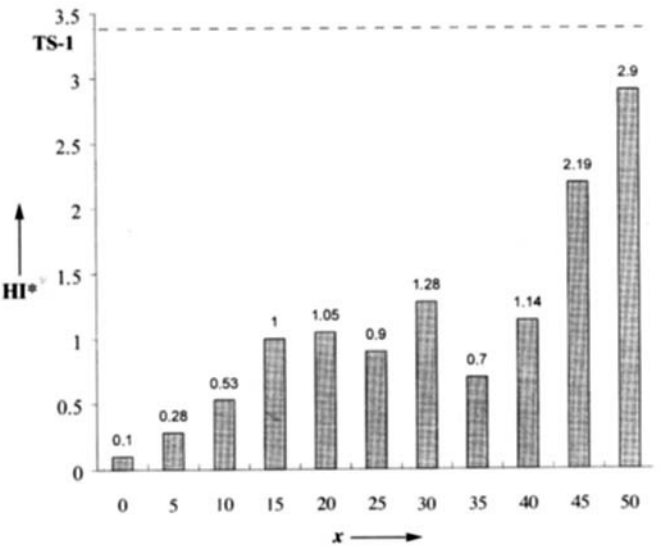

Fig. 2. The hydrophobicity index $HI^* = x_{octane}/x_{water}$ on AMM-$Ti_1(SiMe)_xSi$ as function of x. The loadings were obtained from the breakthrough curves of octane and water by competitive absorption experiments in the gas phase at 308 K.

As documented in Figure 2, the synthesis principle presented here builds a catalyst class in which the surface polarity is controlled by the number of cocondensed CH_3Si components only. The polarity can therefore be varied from hydrophilic to hydrophobic while maintaining a constant oxide composition and pore architecture.

All our observations point to a narrow correlation between catalyst surface polarity and its activity for peroxide-mediated selective oxidation reactions. As already reported, AMM-Ti_xSi materials are good catalysts for the epoxidation of olefins with a limiting concentration of TBHP.[4] During the reactions a rapid, reproducible deactivation is observed at longer reaction times or higher conversions preventing quantitative conversion (Fig. 3a). This is explained by reversible blocking (autoretardation) of catalysts through the enrichment of the reaction mixture with polar components (for example, epoxide, alcohol, water, by-products).[13] By washing with solvent and drying below the

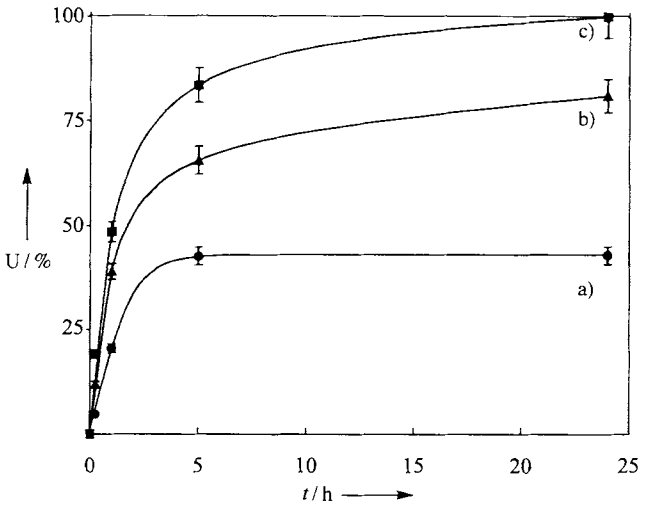

Fig. 3. Conversion–time curves (based on TBHP) of the epoxidation of 1-octene with a) AMM-Ti_1Si, b) AMM-$Ti_1(SiMe)_{25}Si$, and c) AMM-$Ti_1(SiMe)_{45}Si$. Reactions were performed in a batch reactor at 353 K with 15 mmol 1-octene, 3 mmol TBHP (3 M in isooctane), and 50 mg catalyst.

temperature of calcination, the deactivated catalyst can be completely and repeatedly regenerated. As can be seen from Figure 3b and c, the deactivation can be overcome by using more hydrophobic AMM-$Ti_1(SiMe)_ySi$ materials, and quantitative conversion is obtained at high selectivity for the first time at $y = 45\%$. We assume that in the hydrophobic mixed oxides the pores are not filled with hydrophilic components, and mass transport, even at high concentrations of polar components, is not hindered. These methyl-containing catalysts can also be regenerated thermally and reused without recognizable activity loss. The methyl groups are stable at these oxidative reaction conditions. DRIFT studies show that the used catalysts are identical to the fresh materials.

Besides the limitation of alkene conversion with TBHP because of catalyst deactivation, other disadvantages in the catalytic behavior of the mixed oxides in olefin epoxidation with TBHP can be avoided with the methylated AMM-materials. For example, the large 1,5,9-*t*,*t*,*t*-cyclododecatriene is not oxidized by TBHP with the hydrophilic AMM-Ti_xSi catalysts. Under identical reaction conditions[14] quantitative conversion to the monoepoxide is obtained with AMM-$Ti_x(SiMe)_ySi$ materials. The hydrophobicity of the methyl-containing glasses seems to facilitate the diffusion of the nonpolar triene, but the slightly increased pore size with increasing methyl content may also contribute to the improved reactivity of the system.

The most obvious effect of the surface polarity, however, is the successful catalysis of selective oxidation reactions with hydrogen peroxide. Like redox molecular sieves, the AMM-$Ti_1(SiMe)_ySi$ materials catalyze the selective oxidation of nonpolar hydrocarbons whose oxyfunctionalization with H_2O_2 could not be achieved with the methyl-free AMM-Ti_xSi materials. Besides the oxidation of olefins and hydrocarbons the oxidation of primary alcohols to the corresponding aldehydes, the oxidation of alkylarenes, and the ammoxidation of ketones has been performed (Fig. 4, Table 2).

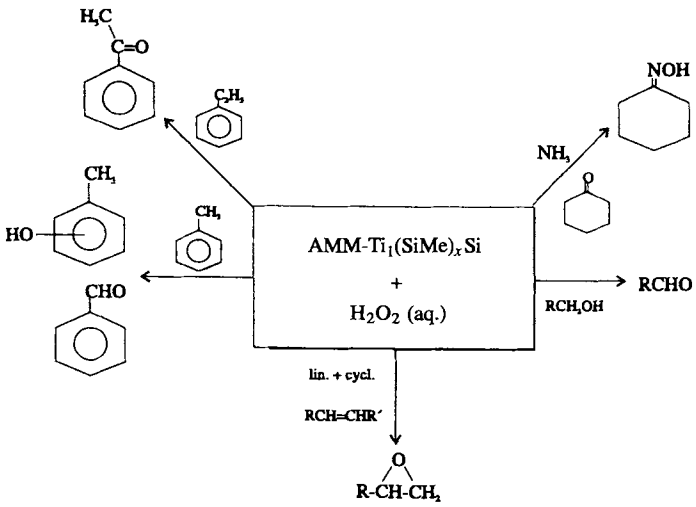

Fig. 4. Schematic overview of selective oxidations with aqueous hydrogen peroxide on AMM-$Ti_1(SiMe)_xSi$ catalysts.

The activity of the catalysts in the oxidation of polar substrates like ethanol shows no dependence on surface polarity. There is little difference in activity and selectivity between TS-1 and the AMM-$Ti_1(SiMe)_ySi$ materials with various methyl contents.

The selective oxidation of alkylarenes behaves quite differently. The toluene conversion shows a clear dependence on the catalyst polarity. The highest conversion is obtained with the most hydrophobic TS-1 zeolites, which furnish cresols as major products, whereas the AMM-$Ti_1(SiMe)_ySi$ materials catalyze exclusively side-chain oxidation (benzaldehyde, benzyl alcohol, benzyl hydroperoxide) and produce almost no cresols.

As with TS-1, AMM-$Ti_1(SiMe)_ySi$ materials oxidize ethylbenzene predominantly at the side chain, but they show higher conversion and selectivities to yield acetophenone and 2-phenylethanol. Aside from the smaller pore size of TS-1, the extreme hydrophobicities (HI* = 3.3) both of TS-1 and of AMM-

$Ti_1(SiMe)_{50}Si$ (HI* = 2.9) result in a less efficient catalysis for this reaction. More optimal parameters seem to be provided by the more balanced affinities to polar and nonpolar compounds of AMM-$Ti_1(SiMe)_{40}Si$ (HI* = 1.1).

AMM-$Ti_1(SiMe)_ySi$ is an excellent catalyst for the epoxidation of the reactive cyclohexene with H_2O_2; the activity is dependent on y and reaches a maximum for catalysts with balanced surface polarity ($HI^* \approx 1$, $y = 25-35$). Cyclohexene conversions exceed those of TS-1 by a factor of 4 to 5. Neither hydrophobic catalysts like TS-1 or AMM-$Ti_1(SiMe)_{50}Si$ nor the hydrophilic AMM-Ti_1Si can provide such optimal reactivity; their conversion is only sligthly higher than that of the uncatalyzed reaction. While the poor reactivity of TS-1 in cyclohexene epoxidation may partly be attributed to hindered diffusion because of small pore size, all AMM-$Ti_1(SiMe)_ySi$ materials have pores large enough for unhindered reactions of cyclohexene. Thus the change in surface polarity is most likely the rate-determining factor with the AMM-materials.

The ammoxidation of ketones to oximes with H_2O_2/NH_3 most likely proceeds through an intermediate formation of hydroxylamines at Ti^{4+} centers followed by oxime formation.[15] Under the reaction conditions reported in the literature,[15] we did not observe the activity and selectivity attributed to TS-1. Like with all other catalysts studied, bis(cyclohexylamine)-peroxide was the main product, indicative of a primary classical imination of the ketone followed by oxidation. However, the difference in product distribution obtained with the AMM-$Ti_1(SiMe)_ySi$ catalysts and the TS-1 show that variation of surface polarity again affects the chemical reaction. Although the AMM catalysts could not match either the activity or the selectivity of TS-1 in this reaction, a clear trend to increasing oxime selectivity with increasing hydrophobicity is evident.

With selected examples we have shown that amorphous microporous mixed oxides with adjustable surface polarity can be used for various selective oxidation reactions with polar aqueous hydrogen peroxide as well as with nonpolar TBHP. The well-known conflict in the catalytic behavior between amorphous Ti–Si mixed oxides and crystalline oxides is therefore resolved. The results document for the first time that a precisely adjusted surface polarity is as important as the presence of catalytically active sites in such microporous catalysts with high surface areas. Apparently there is an optimal surface polarity for a given reaction mixture, which affects not only reaction rate and selectivity but also conversion and catalyst lifetime. It must be assumed that there are many examples for which catalyst inactivity in a specific reaction is not an intrinsic problem of the catalytically active centers, but is attributable to the wrong surface polarity of the catalyst for the reaction conditions chosen.

The sol–gel synthesis of AMM catalysts described here allows for the first time adjustment of the monomodal microporosity, elemental composition, and surface polarity of the final catalyst material in a one-step procedure. Such catalysts can be much better tuned to the selected reaction conditions than all traditional catalysts. This sol–gel synthesis of the AMM catalysts is a new example of successful catalyst design. In contrast to zeolites, in which the surface polarity is fixed by the Al content and the pore system by the zeolite type, the extended preparation concept of the AMM catalysts offers the opportunity of adjusting the surface polarity of the catalysts precisely to the reaction of interest without affecting reaction conditions like concentration or type of solvent in the reaction mixture.

[6] The preparation procedure starts with the acid-catalyzed copolycondensation of tetraethoxysilane (TEOS), methyltriethoxysilane (MTES), and titanium tetraisopropoxide (TIPOT). In a typical reaction (AMM-$Ti_1(SiMe)_{25}Si$) ethanol (150 mmol) is added to a stirred mixture of TEOS (37.1 mmol), MTES (12.4 mmol), and TIPOT (0.5 mmol). Hydrolysis is obtained by dropwise addition of HCl (8 N, 2.2 mL). After about 3 days, gelation of the loosely covered sol–gel reaction mixture takes place. The gels are then calcined under inert atmosphere: The gels are heated at 0.5 K min^{-1} to 338 K, kept there for 5 h, then heated at 0.2 K min^{-1} to the final temperature of 523 K, and kept there for 5 h. After cooling to room temperature (1 K min^{-1}) the glasses are milled, and the sieve fraction smaller than 10 μm was used for catalysis.

[10] For confirmation of covalent methyl group incorporation the mixed oxides have been studied on a BRUKER IFS 48 IR spectrometer under diffuse reflection conditons. The finely powdered sample (20 mg) was mixed with a ten times larger amount of KBr and in a HARRICK HVC environmental cell (mounted with a diffuse-reflectance unit, type HARRICK DRA-XX) and heated over 15 h at 773 K in a slow stream of Ar. The measurement was done at room temperature under an inert atmosphere (Ar) with a spectral resolution of 2 cm^{-1}. After substraction of the KBr background the spectra were plotted as the Kubelka–Munk function for diffuse reflectance spectroscopy.

Zeolite Conference*, Montreal, July 5–10, **1992**; c) C. H. Berke, A. Kiss, P. Kleinschmit, J. Weitkamp, *Chem. Ing. Tech.* **1991**, *64*, 623.
[12] The catalyst sample was heated at 673 K for 12 h under a stream of Ar. Then a stream of Ar containing defined, comparable water and octane concentrations was used to load the sample (water and octane flow rates of about 20 mg h^{-1} were controlled by mass flow meters; Ar saturation temperature 298 K, loading temperature 308 K). The breakthrough curves of the individual components were obtained by on-line gas chromatography. Numerical integration of the normalized breakthrough curves provided the loading of water and octane. After correction for the background behavior of the total reactor the hydrophobicity index HI* was obtained as the ratio x_{octane}/x_{water}.

Isolation and Characterization of the Dimetallofullerene $Ce_2@C_{80}$

Junqi Ding and Shihe Yang*

The availability of pure metallofullerenes in milligram quantities has allowed a number of metallofullerenes to be characterized by a variety of spectroscopic means.[1] Although there have been some studies on $Sc_n@C_{2n}$,[2] the main research effort has been directed towards metallofullerenes of the type $M@C_{82}$ with a single encaged metal atom.[1] The first soluble dimetallofullerene, $La_2@C_{80}$, was reported soon after the method of synthesizing fullerenes on the macroscopic scale was developed.[3] Most recently, Achiba et al. described the first isolation and electrochemical studies of $La_2@C_{80}$.[4] This dimetallofullerene was found to be an even better electron acceptor than any metallofullerene of the type $M@C_{82}$. The first derivatization of $La_2@C_{80}$ has also been achieved by the same group.[5] Calculations have predicted that the I_h isomer of C_{80} should be able to accommodate two La atoms to form a thermodynamically and kinetically stable endohedral fullerene.[4, 6] The remarkable stability of $La_2@C_{80}$ comes from the fact that all six valence electrons of the two La atoms are transferred to the C_{80} cage; these six electrons are just enough to form a closed-shell electronic structure for the carbon cage with a large HOMO–LUMO gap. However, direct experimental confirmation for the oxidation states of the metal atoms inside the carbon cage has not yet been available.

We have recently reported a technique for the efficient separation of $Ce@C_{82}$ and also its spectroscopic characterization.[6, 7] Ce was shown to have an oxidation state of III.[8] This new method also allowed separation and characterization of the new dimetallofullerene $Ce_2@C_{80}$, which like $Ce@C_{82}$ was detected in previous laser desorption mass spectrometry experiments.[9] We report here on the separation of $Ce_2@C_{80}$ and on its characterization by UV-Vis-NIR absorption spectroscopy and X-ray photoelectron spectroscopy (XPS).

The high purity of $Ce_2@C_{80}$ isolated by HPLC can be seen from the negative-ion desorption chemical ionization (DCI) mass spectrum shown in Figure 1; a purity of >99% can be estimated.

Figure 2 shows the UV-Vis-NIR absorption spectrum of $Ce_2@C_{80}$ in the wavelength range of 300 to 2100 nm. The spectrum exhibits a monotonically decreasing absorption coefficient with increasing wavelength without well-defined, sharp features. This relatively featureless spectrum is in contrast to those of the empty fullerenes[10] as well as of the monometallofullerenes.[1c] Whetten et al. proposed that in $La_2@C_{80}$ the C_{80} cage has I_h symmetry, resulting in overall D_{2h} symmetry for the dimetallofullerene.[3, 9, 11] This is supported by a recent theoretical calculation.[6] In this and earlier work[5] it was demonstrated that $La_2@C_{80}$ can be formally represented by $La_2^{3+}@C_{80}^{6-}$, forming a closed-shell electronic structure with a HOMO–LUMO gap larger than that of $M@C_{82}$ (M = rare earth metal). As will be shown below, C_{80} in $Ce_2@C_{80}$ also acquires the six valence electrons from the two Ce atoms, presumably resulting

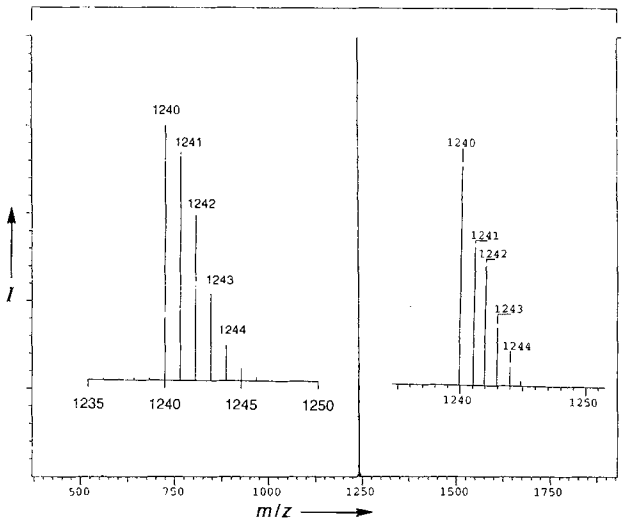

Fig. 1. Methane DCI negative-ion mass spectrum of the $Ce_2@C_{80}$ sample after HPLC separation. The insets show the calculated (left) and observed (right) isotopic distributions for $Ce_2@C_{80}$. I = intensity (arbitrary units).

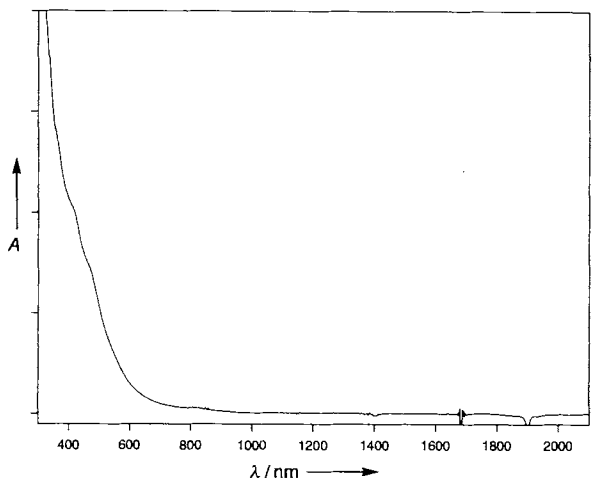

Fig. 2. UV-Vis-NIR absorption spectrum of $Ce_2@C_{80}$ in toluene. A = absorption (arbitrary units).

in the same electronic configuration as that of $La_2@C_{80}$. The closed-shell electronic structure of C_{80}^{6-} in $Ce_2@C_{80}$ is likely to account for the absence of NIR absorption peaks in the spectrum of $Ce_2@C_{80}$.

Figure 3 shows the XPS spectrum of $Ce_2@C_{80}$ in the region of the Ce $3d_{3/2}$ and $3d_{5/2}$ core levels. The spectrum is quite similar to that of $Ce@C_{82}$ with two main features for the $3d_{3/2}$ and $3d_{5/2}$ levels in order of decreasing binding energy.[8] Both features show a strong peak and a weak shoulder. For the $3d_{5/2}$ feature, the stronger peak at higher binding energy (886.57 eV) can be explained by the screening of only the surrounding fullerene orbitals, while the weak shoulder at lower binding energy (881.83 eV) may be accounted for by screening arising from charge transfer to the empty 4f shell.[12]

It is known that Ce^{4+} has a characteristic XPS (3d) peak at a binding energy of approximately 914 eV arising from a transition to the $3d^94f^0$ final state.[13] The intensity of this peak has been used for estimating Ce^{4+} concentration.[14] Since we did not observe this characteristic peak, we can rule out the presence of Ce^{4+} in $Ce_2@C_{80}$. As no characteristic peak for Ce^{2+} is known in the 3d core level region, we cannot rule out Ce^{2+} in the same way. However, the location and shape of the Ce(3d)

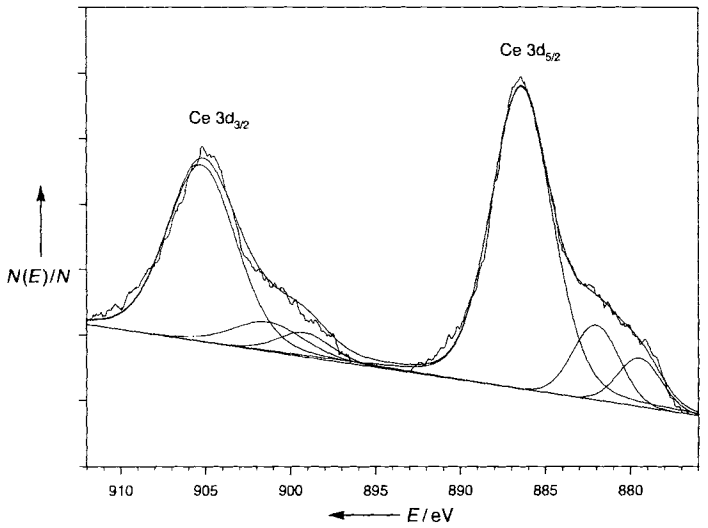

Fig. 3. XPS spectrum of $Ce_2@C_{80}$ on a gold substrate in the core level region of Ce(3d). The smooth line results from a least-square fitting of the spectral peaks using a linear baseline. The occurrence of two features ($3d_{3/2}$: signal at higher energy; $3d_{5/2}$: signal at lower energy) is due to spin–orbital splitting of the 3d core level. E = binding energy. $N(E)/N$ = photoelectron signal intensity (arbitrary units).

peak in the XPS spectrum of $Ce_2@C_{80}$ are rather similar to those of cerium trihalides,[15] suggesting that the oxidation state of Ce is III. The ratio of the intensities of the peaks at higher and lower energies is known to be very sensitive to the electronegativity of the ligands.[16] Our analysis shows that the electronegativity of the fullerene cage is somewhat less than that of chlorine. This conclusion is similar to that we drew for $Ce@C_{82}$[8] and Weaver et al. reported for $La@C_{82}$.[17]

In fact, the XPS spectram of $Ce_2@C_{80}$ is at first glance almost identical to that of $Ce@C_{82}$; however, for $Ce_2@C_{80}$ the curve-fitting can be improved by assuming more peaks. For example, Figure 3 shows the curve obtained by assuming one extra small peak at a lower binding energy. The approximation may be further improved by assuming small peaks at the high binding energy side of the two strong peaks. The presence of a few extra small peaks in addition to the strong peak and weak shoulder characteristic of Ce^{3+} may signify the interaction between the two Ce atoms in the carbon cage. Further studies are required to support this hypothesis.

We have reported the first successful separation of the new endohedral dimetallofullerene $Ce_2@C_{80}$ and its UV-Vis-NIR absorption and XPS spectra. The UV-Vis-NIR spectrum exhibits monotonically decreasing absorption as a function of wavelength without any sharp absorption features. The XPS spectrum suggests that the Ce atoms encaged in C_{80} are in the form of Ce^{3+}. This implies that in the cage one valence electron remains on each metal atom. The nature of their spin–spin coupling within the carbon cage constitutes a fascinating subject for future research.

Experimental Procedure

The procedures for isolating the metallofullerenes have been described previously[7]. Soot containing metallofullerenes was produced by the standard arc vaporization method using a composite anode which contains graphite and cerium in its oxide or carbide form. The rod was then subjected to a DC contact-arc discharge as an anode under an He atmosphere of 50 Torr. The soot was collected and extracted for 8 h in a Soxhlet extractor with *N*,*N*-dimethylformamide (DMF, 99.9%, BDH). After removal of the DMF by evaporation, a black powder (ca. 1% of the soot) was obtained. The soluble fraction was dissolved in toluene and injected into an HPLC. A buckyprep column (4.6 mm × 250 mm; Cosmosil, Nacalai Tesque Inc.) similar to a PYE column was used, and toluene served as the mobile phase. The injection volume was 1 mL and the elution rate was 1 mL min^{-1}. The sample of $Ce_2@C_{80}$ collected from HPLC was analyzed by DCI negative-ion mass spectrometry (Finnigan TSQ7000).

The UV-Vis-NIR absorption spectrum of $Ce_2@C_{80}$ in toluene was recorded with a Perkin-Elmer spectrometer (Lambda 19). For the XPS study, we prepared a $Ce_2@C_{80}$ film on a polycrystalline Au substrate. To clean the Au surface, we heated a small piece of gold foil with a natural gas torch, dipped it in methanol, and dried it in N_2 gas. Several drops of a concentrated solution of $Ce_2@C_{80}$ in toluene were transferred to the Au foil. The evaporation of the solvent left a uniform film of $Ce_2@C_{80}$, which was was dried and washed with *n*-hexane. An XPS measurement was taken using monochromatized $Al_{K\alpha}$ radiation ($h\nu$ = 1486.6 eV) with an energy resolution of roughly 0.6 eV (Perkin-Elmer PHI 5600).

Heavy Element π Donation Is Not Less Effective**

Jürgen Kapp, Christian Schade, Ahmed M. El-Nahasa, and Paul von Ragué Schleyer*

Very strong cation stabilization results from π conjugation, for example, from the interaction between empty carbon 2p orbitals and the lone pairs on nitrogen- or oxygen-based substituents.[1-3] How do the heavier group 15–17 substituent lone pair donors compare with their lighter analogs? It has been recognized for some time that π overlap arising from elements of different rows is *not* reduced due to differences in the p-orbital extensions.[4]

Conclusions from previous work are contradictory. While the amino group is the most stabilizing π-donor substituent, it is not clear if sulfur or oxygen is the better π donor.[5-11] The σ_p^+ constants, PhO = −0.62, PhS = −0.54, and PhSe = −0.47 are not very different but show a progression down the group.[12, 13] The trend in the calculated hydride affinities of $^+CH_2XH$ (X = O, S, Se, Te) is similar, with a sharp difference between oxygen and sulfur.[11] However, earlier ab initio calculations gave methyl stabilization energies [Eq. (a)] in the order OH > SeH > SH (52.6, 41.7, and 31.8 kcal mol^{-1}, respectively).[14]

$$CH_3XH_n + CH_3^+ \longrightarrow {}^+CH_2XH_n + CH_4 \qquad \text{(a)}$$

Pioneering mass spectrometric investigations by Taft, Martin, and Lampe,[2] as well as more recent experiments,[3] gave α-halomethyl cation stabilization energies that *increase* down the group: F < Cl < Br < I. In contrast, the halogen σ_p^+ constants (F = −0.07, Cl = 0.11, Br = 0.15, and I = 0.14) reveal the same trend as the chalcogen series.[15]

According to the ab initio investigation ten years ago by Bernardi et al. differences between methyl stabilization energies of second and third period lone pair donors are small within a group but more pronounced along a row.[9] We have now extended the previous studies by examining all group 15–17 π donors from the first five rows at high ab initio levels. Our objective was to compare the methyl-stabilizing effects of the lighter with the heavier elements. Schematic representations of the structures examined are given in Figure 1: neutral parent systems **15**, **15p** with planar XH_2 units (group 15), **16** (group 16), and **17** (group 17) as well as cationic species **15**$^+$, **16**$^+$, and **17**$^+$.

All structures were optimized at the restricted MP2-FC level of theory.[16] Refined energies were obtained in QCISD(T) single point calculations on the MP2-optimized structures. The GAUSSIAN94 program was employed with standard basis sets for molecules containing elements from hydrogen through chlorine during optimizations, frequency runs (6-31 + G*), and single point calculations (6-31 + + G**). Pseudopotentials (PSP) were used to replace the core electrons of systems with heavier elements: a four valence electron (Ve) PSP for carbon and 5–7 Ve PSP for Se–Br and Te–I together with the corresponding DZ + P basis sets.[17, 18] Atomic charges as well as bond orders and orbital occupancies were obtained from QCISD(T)-single point calculations according to Reed and Weinhold's NBO analysis.[19]

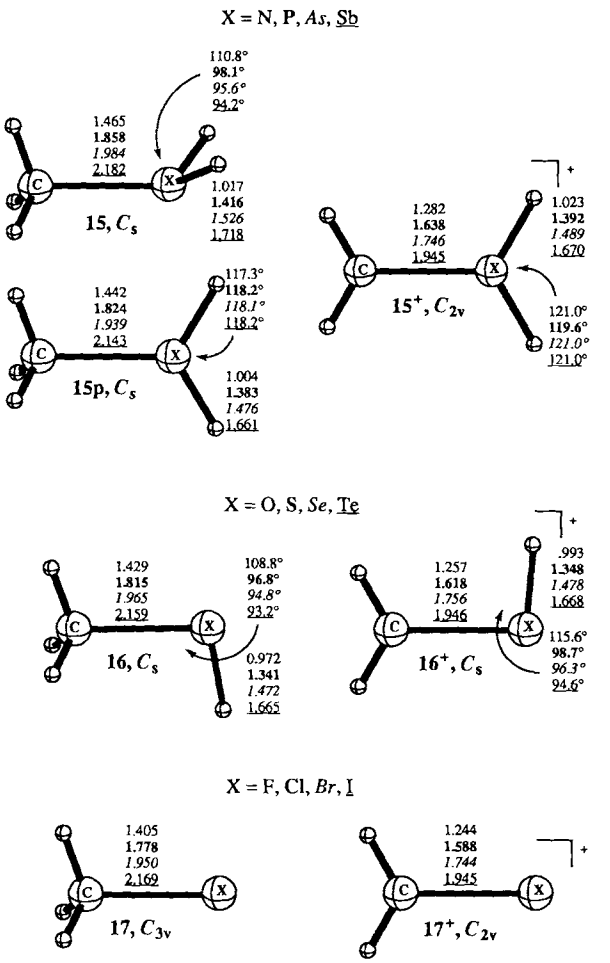

Fig. 1. Schematic representations of the structures of the neutral molecules and the cations together with selected bond lengths [Å] and angles [°]. **15p**: planar XH_2 group.

The $^+CH_2-XH_2$ cations (X = N, P, As, Sb) prefer planar structures **15**$^+$. Their isodesmic methyl stabilization energies (MSEs) [Eq. (a)] decrease in a stepwise fashion from 94 kcal mol^{-1} for NH_2 to 45 kcal mol^{-1} for SbH_2 (Table 1, column 1); although large, these MSEs are reduced due to the "cost" of planarizing the XH_2 substituents (Table 1, column 2).[20] The inversion barriers of ammonia and amines are quite low, relative to those of phosphines, arsines, and the corresponding compounds of the heavier pnictogens. The apparently superior ability of nitrogen to act as a π donor is due, in part, to the ease in achieving the optimum planar configurations with sp^2 hybridization.[4a]

However, we were interested in the *inherent* π donor ability of the heavy group 15 elements, although the idealized π interactions may have little practical relevance. The complicating influence of planarization can be eliminated and a better assessment of the "pure" π interaction be obtained by employing *planar* CXH_2 conformers **15p** of the reference CH_3XH_2 systems in Equation (a). These π stabilization energies (πSE, boldface in Table 1, column 3) are much larger than the MSEs for X = P, As, and Sb. Surprisingly, the πSEs are nearly the same for N, P, As, and Sb! In contrast, the chalcogen substituents (and, of course, the halogens) do not suffer the planarization problem. In the most favorable geometry, a pure p-orbital lone pair is

available for electron donation to the carbocation center. Indeed, the πSEs (which are identical to the MSEs for groups 16 and 17) are nearly the same for a given group, following the pnictogen >chalcogen >halogen order (Table 1, column 3)!

The calculated MSE values are in reasonable agreement with the experimentally determined values (Table 1, column 1).[2, 3] However, a complete set of MSE values is available only for group 17. These and the computed values increase from about 20 kcal mol^{-1} for F to nearly double that for I. In contrast to some previous findings,[5, 8, 9, 11] the heavier chalcogens are better π donors than oxygen, although the range of MSE values in group 16, 59 to 66 kcal mol^{-1}, is much smaller than that in group 17.

Sigma inductive effects, which also are present, can be assessed by means of Allred–Rochow electronegativity correlations. However, the πSEs [Eq. (a)] for each group reveal little electronegativity influence (Fig. 2). These results demonstrate

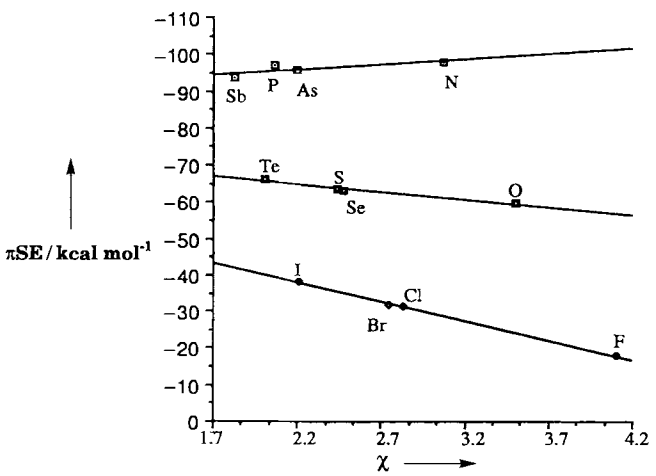

Fig. 2. $^+CH_2-XH_2$ π Stabilization energies πSE [kcal mol^{-1}] [QCISD(T)/DZ + + PP//MP2/DZ + P + ZPE, [Eq. (a)], see Table 1, column 3] versus the electronegativity χ of X.

that π interactions between the very strong π acceptor CH_2^+ and adjacent p-lone pairs do not depend on the row of the substituent. Hence, the higher period heteroatoms are just as effective π donors as their first row counterparts as assumed by Bernardi et al.[9] In group 15, most of the reduced net-stabilization and the reversed MSE variation (N >P >As >Sb) arises from the energetically costly XH_2 planarization of **15 → 15p**.[8–10, 20]

The barriers for the 90° rotation of the planar XH_2 fragments of group 15 cations also reveal strong π interactions between the carbon 2p orbital and the substituent lone pairs (Table 1, column 4): they increase from 78.0 kcal mol^{-1} (X = N) to 97.7 (X = P) and 95.7 kcal mol^{-1} (X = As), indicating powerful π bonding in the $^+CH_2-XH_2$ ground states of similar magnitude.[21]

The energies of the 90° rotation of the X–H group (X = O–Te) also should indicate the magnitude of the π interactions. However, only the rotated structure of the sulfur compound, which is 52 kcal mol^{-1} less stable than planar ^+H_2CSH (Table 1, column 4), could be located. In contrast, 90° rotated ^+H_2COH optimized directly to a C_{2v} symmetric structure with a linear C-O-H group. Hence, oxygen is readily capable of adopting an sp-hybridization with *two* p-lone pairs in the transition state (compare the small NH_2 planarization barrier) and of acting as a double-sided π donor.[22] The rotated conformers of $^+H_2CSeH$ and $^+H_2CTeH$ rearrange to H-bridged structures, which can be regarded as side-on protonated $H_2Se{=}O$ and $H_2Te{=}O$.

Natural atomic charges and orbital populations also reflect strong π interactions in all cations: while the σ-charge transfer between X and C depends on the heteroatom electronegativity, significant charge density is transferred to the formally empty carbon 2p orbital through the π bonds (0.32 e$^-$, X = F, to 1.01 e$^-$, X = Sb). Other interactions, for example, hyperconjugation between σ_{X-H} bonds or X lone pairs and σ^*_{C-H} bonds, are of minor importance. A detailed examination of the hyperconjugation contributions[23] reveals that the magnitudes of these interactions are similar in CH_3-XH_n and $^+CH_2-XH_n$ and cancel in Equation (a). The insignificant differences remaining are dominated by the π effects. Bond orders and atomic charges suggest that these cations are represented adequately by iniumion resonance structures $CH_2{=}XH_n^+$. The C–X Wiberg bond indices (WBI) are of similar magnitude for all cations (1.5–1.75); only $^+H_2C-F$ has a slightly lower WBI (1.23).

Likewise, all cation C–X bond lengths are reduced in comparison to the CH_3-XH_n reference compounds. There is an excellent correlation between C–X distances in the neutral molecules and in the cations [Figs. 1 and 3, [Eq. (b)]!

$$d_{C-X^+} = 0.92\ d_{C-X} - 6.2\ \text{pm} \qquad \text{(b)}$$

Consequently, the C–X bond shortening going from the neutral to the corresponding cation is *not* related to the πSE magnitudes. For example, the C–X bond lengths in the CH_3SbH_2, CH_3TeH, and CH_3I set (214.3, 215.9, and 216.9 pm, respectively) and those in the $^+CH_2SbH_2$, $^+CH_2TeH$, and $^+CH_2I$ set (194.5, 194.6, and 194.5 pm, respectively) are both nearly the same, despite the very large πSE differences.

While π interaction between a lone pair and the vacant orbital of an adjacent carbocation center is well recognized to be strongly stabilizing, we find that the magnitude depends on the period to a remarkably small extent. In contrast to the still common misconception that 2p-3/4/5p overlap is ineffective, our comparison emphasizes that the *inherent* π donor capabilities of the heavier elements are as large as or larger than their second row counterparts.

The First Demonstration of Molecular Queuing in Pseudo[*n*]polyrotaxanes: A Novel Variant of Supramolecular Motion**

Philip E. Mason, Ian W. Parsons,* and Malcolm S. Tolley

Pseudo[*n*]polyrotaxanes and to a lesser extent poly[*n*]rotaxanes are now well-established features of the supramolecular scene, following pioneering work by, inter alia, the groups of Wenz, Harada, Gibson, and Stoddart.[1] A particularly characteristic feature expected for pseudo[*n*]polyrotaxanes (Fig. 1), since generally the ring components cannot pass each other along the thread, is that the movement of rings is restricted by queuing as they shuffle along the central thread and eventually escape into solution. Here we report the first unequivocally identified example of such motion in supramolecular chemistry.

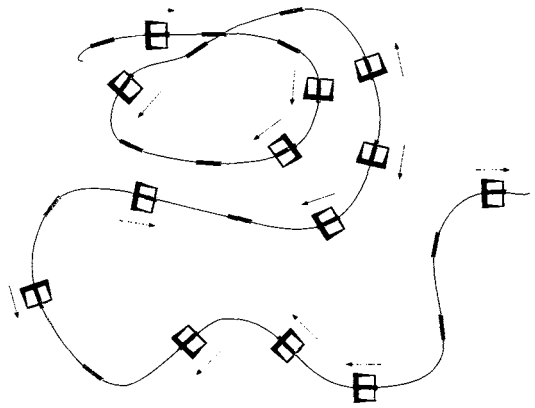

Fig. 1. Schematic representation of a pseudo[*n*]polyrotaxane.

The molecules studied in the present investigation (Scheme 1) readily self-assemble in solution[2] to provide straightforward representatives of this very simple supramolecular architecture. They are the electron-poor cyclophane **1** (Scheme 1), which moves onto, off, and along a central polymeric thread (**2**) containing alternating electron-rich 1,5-dioxonaphthalene and 1,4-dioxobenzene sites, with which **1** complexes.

For simplification we consider **1** simply as a ring and the polymer molecule as a sequence of n discrete stations, S_1 to S_n (which may or may not equate to single arene units), with each station able to accommodate only one ring. Rings threaded onto the same chain cannot pass each other, and the probability of an individual station bearing a ring is x.

We concentrate upon a particular ring complexed on the station S_m and its chances of escaping by way of the nearer end of the chain at S_1. If this ring encounters another complexed ring, it will be unable to pass and thus unable to escape into solution. Clearly, the chances of finding no other rings in attaining the chain end will be $(1 - x)^{(m-1)}$, and if the last step is equivalent the final result will be $(1 - x)^m$. The rate of intersite hopping has

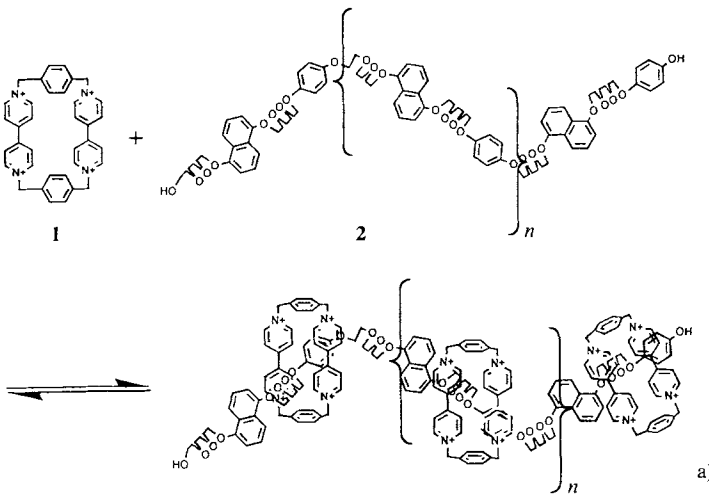

Scheme 1. Formation of the pseudo[*n*]polyrotaxane from cyclophane **1** and polymer **2**. Counterion PF_6^-.

been measured for a two-station [2]rotaxane chemically similar to the species studied here;[3] at room temperature there will be approximately 2500 hops per second between arene sites. In the system studied here x has been varied from 0.05 to 0.5.

We may define two possible ring types (states). Type A rings are in rapid exchange on the NMR timescale between existence in the solution and complexation onto a polymer chain. Type B rings are similarly in exchange, but the exchange is slow on the NMR timescale.

We can distinguish spectroscopically between **1** moving freely in solution and **1** bound onto the polymer chain by threading. The ^{1}H NMR signals arising from both the α and β protons on the 4,4′-bipyridyl unit of **1** (Fig. 2) are known to change their chemical shift values on inclusion of an aromatic guest.[4, 5] Similar results have also been reported for the signals due to the hydrogens on the guest molecules[6] and for the analogous ^{13}C NMR signals.[7] Our discussions here are limited to the ^{1}H NMR signals.

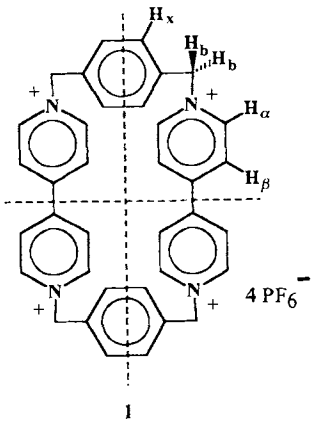

Fig. 2. Labeling of the protons of **1**.

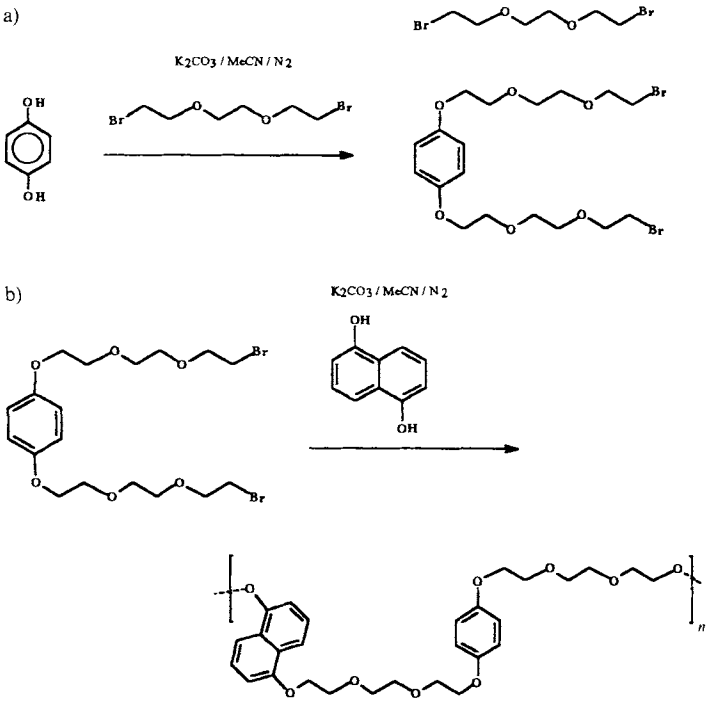
NMR signals due to particular protons exchanging between one state and another coalesce when the lifetime of the states τ is sufficiently short. For each particular proton type the explicit condition is described by Equation (a).[8]

$$\tau \leq (2^{1/2})(\pi\Delta\nu)^{-1} \qquad \text{(a)}$$

In general, since the chemical shifts of, for example, the α protons in [D$_6$]DMSO above its freezing point (Fig. 2) will be the same (or at least very similar) for all threaded **1**, a single α-proton peak will arise for all the threaded **1** molecules that escape from the thread too slowly to satisfy the above condition (that is, which are type B rings). The remaining type A molecules will give, in the usual way,[9] a coalesced NMR peak at a chemical shift that is a weighted average. Thus, with fixed concentrations of species the temperature at which a particular type of proton in **1** will give rise to a single NMR peak (in other words **1** is exclusively type A) will depend upon the value of $\Delta\nu$, the molecular weight and molecular weight distribution of the polymer, x, and the rate of intersite hopping.

The result of increasing the total concentration of **1** will be complex. The rate of exchange of bound and free **1**, as it is strongly dependent upon x, will decrease markedly. The proportion of type B rings will thus certainly increase, but the exact result depends strongly upon a number of factors. Later we use this particular effect to demonstrate "molecular queuing".

The polymers were prepared by the sequence shown in Scheme 2 by reaction of hydroquinone with an excess of the



Scheme 2. Synthesis of polymer **2**. a) and b) heated at reflux for 4 h. Higher oligomers are also formed in step a).

dibromide, isolation of the hydroquinone bis(ω-bromo)ether, and finally reaction of this intermediate with naphthalene-1,5-diol under basic conditions. The resulting alternating copolymer's general architecture, aryl groups separated by polyether chains, is designed to mimic the existing successful chemistry of rotaxanes and catenanes[10] based on **1**. Three polymers prepared by this method showed number average molecular weights of 3600, 6100, and 12000 (M_w/M_n of 2.1, 2.5, and 3.3, respectively) by size exclusion chromatography (*N*-methylpyrrolidinone (NMP) solvent, polymethyl methacrylate standards). These M_n values correspond to approximately 7, 12, and 24 polymer repeat units.

For experimental reasons the NMR studies were conducted with [D$_6$]DMSO as the solvent rather than the more usual[11] acetonitrile. Figure 3 shows ambient temperature 300 MHz spectra of the polymer (M_n = 6100), **1**, and a 1:1 (**1**:polymer repeat unit) mixture of the two in DMSO. For simplicity and brevity, in the description of the last spectrum we concentrate on the changes in the signals at $\delta > 9$, both of which we assign (by COSY and spin transfer experiments) to the α protons of **1**.

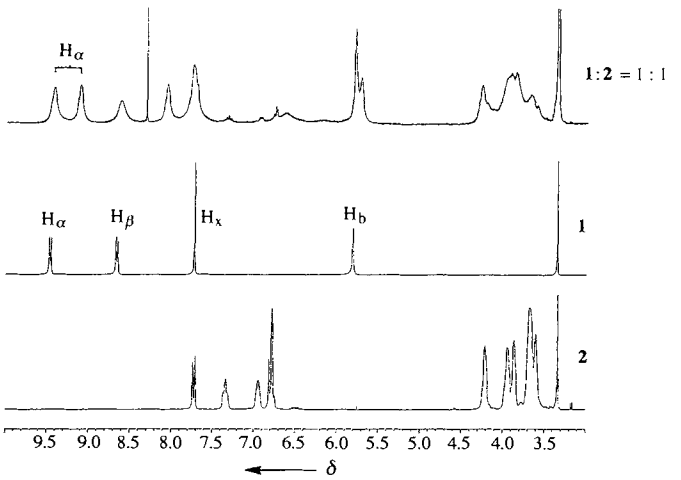


Fig. 3. Sections of the ^{1}H NMR spectra (300 MHz) of polymer **2** (M_n = 6100) (top), cyclophane **1** (middle), and a 1:1 mixture (ratio of cyclophane to polymer repeat unit) (bottom) in [D$_6$]DMSO.

There are two peaks, one at $\delta \approx 9.1$ and one at $\delta \approx 9.4$, and the fact that the upfield peak decreases rapidly in intensity as the temperature rises (Fig. 4) leads to the natural presumption that the first of these corresponds to **1** bound to the polymer, and the second to free **1**. However, this interpretation is false, as will be shown by using the (simplified) theoretical framework given above.

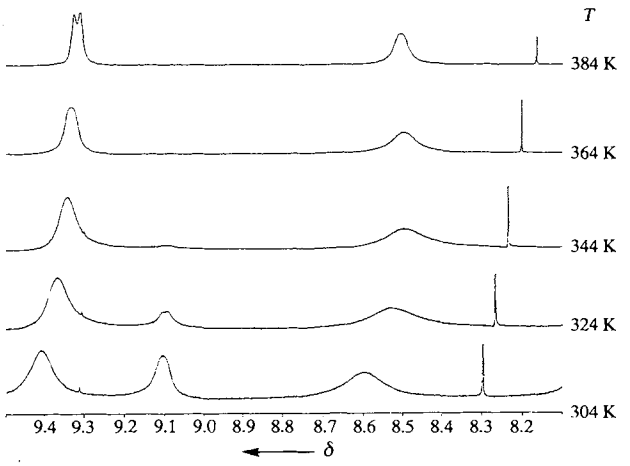

Fig. 4. Sections of the ^{1}H NMR spectra (300 MHz) of a solution containing a 1:1 mixture of **1** and **2** (M_n = 6100) (ratio of cyclophane to polymer repeat unit) in [D$_6$]DMSO at 304, 324, 344, 364, and 384 K. The sharp singlet arises from $CHCl_3$.

The two signals at $\delta > 9$ are indeed due to two different types of **1**, but they are type A and type B rings. Thus, it is perfectly possible to obtain only a single (type A) peak around δ = 9.1–9.4 whilst **1** is complexed to a substantial degree by threading on the polymer chain.

Clearly, this model predicts that the ratio of these two peaks will be dependent upon the field strength of the NMR spectrometer used. The peak at $\delta \approx 9.4$ should decrease with increasing field, since $\Delta\nu$ will thus increase. The chemical shift of this signal will also change with field, since it is an average between species of changing concentrations. Also, increasing the average polymer molecular weight (without changing the total concentration of polymer repeat unit) will result in an intensity increase for the peak at $\delta \approx 9.1$ at the expense of the peak at $\delta \approx 9.4$, and vice versa. If the concentration of **1** is increased while that of the polymer is fixed, the rings will progessively change from all type A to a mixture of types A and B, as molecular queuing makes escape from the centers of the longer chains impossible within the NMR timescale. (For even modest molecular weight polymers it may be impossible to achieve a regime in which **1** is exclusively of type A.) We have performed these experiments and here report the results.

A solution containing **1** (11.0 mg) and the polymer with M_n = 6100 (4.98 mg), which corresponds to a 1:1 ratio of **1** to the polymer repeat unit,[12] was prepared in [D$_6$]DMSO (0.700 mL; the concentration of each component is thus 14.3 mM) and its ^{1}H NMR spectrum recorded at 295 K at 90, 300, and 400 MHz (Fig. 5). The integrations of the signals due to the α protons and the derived fractions of bound and free **1**[13] are shown in Table 1.

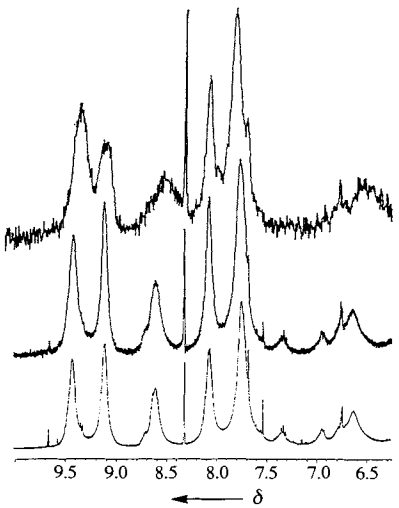

Fig. 5. Sections of the ^{1}H NMR spectra of a solution containing a 1:1 mixture of **1** and **2** (M_n = 6100) (ratio of polymer repeat unit to cyclophane) in [D$_6$]DMSO recorded at 90 (top), 300 (middle), and 400 MHz (bottom).

Table 1. Fractions of type A and type B cyclophane units, as determined by the integration of the α protons.

Spectrometer frequency [MHz]	δ (Type A)	δ (Type B)	Fraction of type A (fast exchange)	Fraction of type B (slow exchange)	Fraction in solution	Fraction bound
90 [a]	9.35	9.10	0.62	0.38	0.41	0.59
300	9.41	9.11	0.52	0.48	0.43	0.57
400	9.42	9.12	0.50	0.50	0.44	0.56

[a] Broad overlapping peaks in the 90 MHz spectrum make precise chemical shifts and integrals difficult to measure.

The results are closely in line with the predictions: as the observation frequency increases the intensity of the lower field signal decreases relative to that of the higher field signal, and its chemical shift changes. Within reasonable bounds of error this change in chemical shift is consistent with constant instantaneous fractions of bound and free **1**, as would be expected. We emphasize here that these results cannot possibly be explained by assigning one signal to bound **1** and one to free **1**.

To demonstrate molecular queuing we have kept the total concentration of polymer constant and varied the amount of **1** in solution. In the ^{1}H NMR spectra in Figure 6 the concentra-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2240 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl 1996 35 No 19

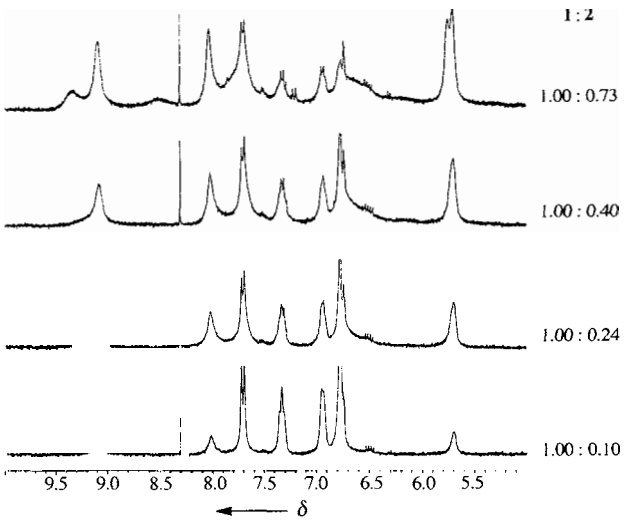

Fig. 6. Sections of the ^{1}H NMR spectra of a solution containing the shown ratios of **1** to the polymer repeat unit in **2** (M_n = 6100) in [D_6]DMSO. The sharp singlet arises from $CHCl_3$.

tion ratio varies from 0.1 to 0.73. In the first case only one peak is visible for the α protons, presumably type A species. As the concentration of **1** increases, a second peak makes its appearance, as expected, as the value of x rises to the point at which some of the **1** molecules, on the longer polymer chains, no longer exchange freely on the NMR timescale and thus become type B. At the same time the type A species spend a higher proportion of their time in solution.

These observations clearly demonstrate molecular queuing: the only reasonable explanation for the emergence and behavior of the second peak is that the rings of **1** complexed onto the polymer chain near the ends prevent the escape of rings complexed near the centers of the longer chains within the NMR time period. In mixtures with lower concentrations of **1** the rings spend nearly all of their time complexed to the polymer and their α protons have a chemical shift close to $\delta = 9.10$. As the concentration of **1** increases, the chemical shift of the type A species changes towards $\delta = 9.48$, whilst the proportion of the type B rings increases and retains a chemical shift of $\delta \approx 9.10$.

Three separate [D_6]DMSO solutions, each containing the same concentration of the polymer repeat unit and **1** (1:1) were prepared from the three polymers, and ^{1}H NMR spectra (300 MHz) were then recorded at 295 K for all three. Table 2 summarizes the findings, which are consistent with the present

Table 2. The effect of the polymer molecular weight on the relative amounts of type A and type B cyclophanes in otherwise identical solutions.

T [K]	M_r	δ (Type A)	δ (Type B)	Integral (Type A)	Integral (Type B)
295	3600	9.400	9.113	64	36
295	6100	9.418	9.105	55	45
295	12000	9.420	9.104	49	51

hypothesis. The lowest molecular weight polymer shows the greatest intensity ratio of the peak at $\delta \approx 9.4$ (due to rapid exchange) to that at $\delta = 9.10$.

A variable-temperature 400 MHz study also supports this. For the polymer with M_n = 3600 the signal of the type B protons disappears between 324 and 344 K, for the polymer with M_n = 6100 between 344 and 364 K, and for the polymer with M_n = 12000 between 364 and 384 K. At each temperature studied the three solutions showed a very similar fraction of free and complexed **1**, which generally decreased slowly as the temperature increased.

In this work we have for the first time experimentally demonstrated the existence of molecular queuing as molecules of **1** move along polymeric threads, and have shown that a simple model of this behavior serves to predict the main features of the changes wrought by altering the concentration of **1**, polymer molecular weight, and temperature. Crucially, the model's verisimilitude is confirmed by its correct prediction of the effect of changing the NMR observation frequency.

[12] Solutions were prepared by removal of solvents from carefully dispensed quantities of volumetric solutions of the cyclophane in MeCN and the polymer in $CHCl_3$. This material was then dissolved in 0.700 mL of [D_6]DMSO

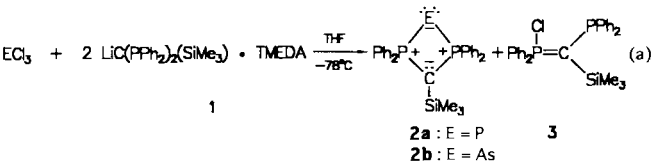
[13] The chemical shift of α protons on the free cyclophanes in [D_6]DMSO is δ = 9.48 (δf) and that for α protons on the bound cyclophanes is taken to be δ = 9.10 (δb). For the 90 MHz spectrum the chemical shift of the α protons of a type A cyclophane is 9.35. This is an average arising from the following: fraction of free type A cyclophanes × δf + fraction of bound type A cyclophanes × δb = 9.35; fraction of type A that are free = 0.66 (F); fraction of type A that are bound = 0.34 (C); Total fraction of bound cyclophanes = [(C × integral of type A α protons + integral of type B α protons)/(total integral of all α protons)] = 0.41.

A Triphosphete and a Spirocyclic Cation with a PP_4 Skeleton and a 10e Spiro P Atom

Hans H. Karsch,* Eva Witt, and F. Ekkehardt Hahn

A particularly wide variety of suitable redox processes are available for the formation of P–P bonds. For example, from the reaction of white phosphorus with phosphanes and phosphanides Schmidpeter et al. obtained cyclic and acyclic triphosphenium ions containing phosphorus(I) centers with eight electrons.[1] Diphosphinomethanides are particularly suitable for the synthesis of heterocycles containing a P_3 unit; they can react with PCl_3 to yield heterocycles with eight-,[1] seven-, or six-membered rings.[2] However, in the reaction of PCl_3 with $Li[C(PMe_2)_2(SiMe_3)]$ it was not possible to completely rule out the formation of an as yet unknown four-membered ring system (triphosphete) rather than an eight-membered ring.[2]

1,2-Diphosphetenes,[3] 1,2,3-triphosphetenes,[4] and 1,3-diphosphetes[5] have been known for some time. In order to discover whether an eight- or a four-membered ring was formed, we exchanged the methyl substituents on the phosphorus atoms of the phosphinomethanide for phenyl groups [Eq. (a)]. Indeed,



(a)

the four-membered ring compounds **2a,b** were obtained as colorless crystals from pentane, and were unequivocally characterized by elemental analysis and by mass and NMR spectra. If **2a** is formulated with formal charges, then the phosphanide nature of the divalent phosphorus atom (oxidation state +I) is evident and in agreement with the observed high-field ^{31}P NMR shift ($\delta = -86.31$). The course of the reaction can be easily understood in terms of Li/Cl exchange, subsequent elimination of LiCl, and a further substitution step. In this last step the behavior of **2a** differs from that of the methylated compound,[2] because Ph_2P-PPh_2 coupling of the phosphinomethanides as the pertinent redox step is obviously not feasible for steric reasons.[6]

If $SbCl_3$ and $BiCl_3$ are treated with **1** in an analogous manner, then the *P*-chloromethylenephosphorane **3** is obtained along with elemental antimony and bismuth, respectively. An alternative method, based on the Schmidpeter procedure,[1] yields **2a** from white phosphorus and **1**. Although only produced in moderate yields (30%), it is free of **3**. The stoichiometry was chosen based on the (hypothetical) formation of Li_3P_7 [Eq. (b)].[7]

(b)

X-ray structural analysis[8] of the isotypic compounds **2a,b** revealed that they both crystallize in the space group $P\bar{1}$ and contain two independent, but very similar molecules in the unit cell (Fig. 1). The four-membered rings are not completely planar: P3a and As1a project out of the C1a-P1a-P2a plane by 0.148(1) and 0.177(1) Å, respectively. The most striking features are the bond angles P1a-P3a(As1a)-P2a, the smallest found so far for divalent phosphorus (arsenic), and the relatively short nonbonding P1a–P2a distance, particularly in **2a**.[9] The structural parameters, especially the almost identical P1a–P3a(As1a) and P2a–P3a(As1a) bond lengths, suggest a representation as a cyclic bis(ylide) as expressed in the heteropolar notation in Equation (a).[10] Alternatively, **2a,b** can be regarded as an internally donor-stabilized phosphinidene and arsinidene, respectively. Further, a representation derived from a P^I phosphenium ion[11b] or a phosphanide ion[11] can also be considered.[12] Less convincing is a description as a cycloheterobutadiene (cf. ref.[5]) with a λ^5P-$\lambda^3P(As)\lambda^5P$ structural element. Another novel feature of **2a,b** is that these are the first bis(organo)-substituted examples of 1,3-diphosphonium four-membered rings.[26]

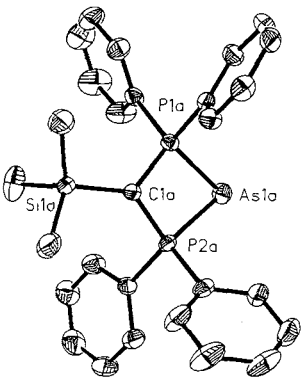


Fig. 1. Crystal structure of **2b** (the asymmetric unit contains two molecules that are identical within the limits of error). **2a** crystallizes isomorphously (exchange of As1a,b by P3a,b). Selected bond lengths [Å] and angles [°] of molecule a [molecule b] in **2a**: P1-P3 2.1489(5) [2.1526(5)], P2-P3 2.1530(6) [2.1488(5)], P1-C1 1.729(1) [1.738(1)], P2-C1 1.738(1) [1.733(1)], P1...P2 2.5483(5) [2.5347(5)]; P1-C1-P2 94.64(7) [93.83(7)], C1-P1-P3 96.44(5) [96.77(5)], C1-P2-P3 96.03(5) [97.07(5)], P1-P3-P2 72.65(2) [72.21(2)]. **2b** molecule a [molecule b]: P1-As1 2.2710(7) [2.2729(7)], P2-As1 2.2692(7) [2.2681(7)], P1-C1 1.741(2) [1.740(2)], P2-C1 1.731(2) [1.730(2)], P1...P2 2.6008(9) [2.5868(9)]; P1-C1-P2 97.0(1) [96.4(1)], C1-P1-As1 96.21(8) [96.78(8)], C1-P2-As1 96.59(8) [97.27(8)], P1-As1-P2 69.90(2) [69.45(2)].

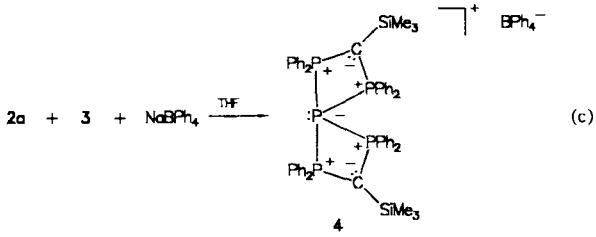
The small P1a-P3a(As1a)-P2a angle may lead to special reactivity, for example high nucleophilicity. However, large amounts of **2a,b** could not be obtained free of **3**, so that reactions of **2a,b** as nucleophiles have not yet been successful. In order to use this "disadvantage" positively, an equivalent amount of $NaBPh_4$ was added to the mixture of **2a** and **3** obtained according to Equation (a). Here **3** is converted in situ into the cation **3a**,[13] which is then attacked by the nucleophilic **2a** to yield the spirocyclic phosphorus(III) cation **4** with a PP_4 backbone [Eq. (c)].



(c)

Pale yellow crystals of **4**-BPh_4 were obtained from THF. X-ray structural analysis[14] confirmed the structure deduced from the $^{31}P\{^1H\}$ NMR spectrum (see below) (Fig. 2). As in phosphonium ions, the central phosphorus atom is tetravalent; however, it does not have a (distorted) tetrahedral environment, but exhibits a distorted pseudo-trigonal-bipyramidal frame-

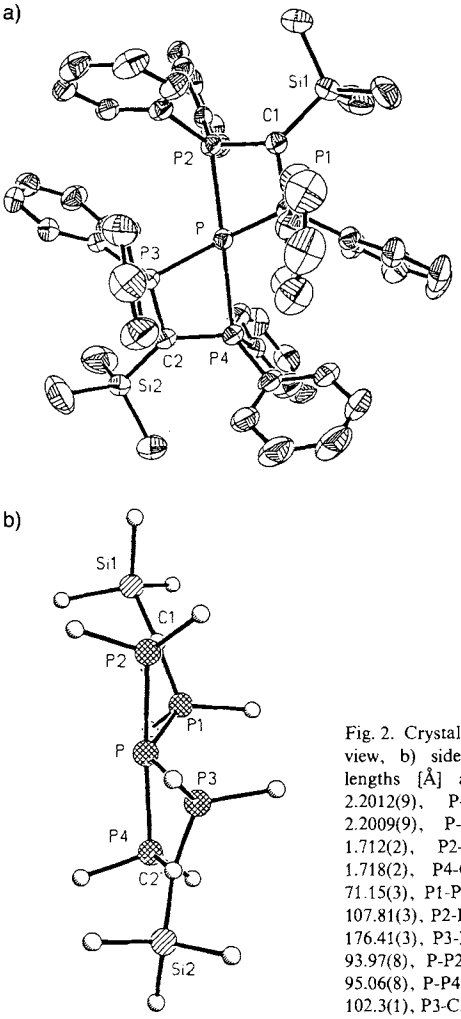

Fig. 2. Crystal structure of **4**. a) Front view, b) side view. Selected bond lengths [Å] and angles [°]: P-P1 2.2012(9), P-P2 2.4077(8), P-P3 2.2009(9), P-P4 2.4616(9), P1-C1 1.712(2), P2-C1 1.737(2), P3-C2 1.718(2), P4-C2 1.733(2); P1-P-P2 71.15(3), P1-P-P3 125.12(4), P1-P-P4 107.81(3), P2-P-P3 107.22(3), P2-P-P4 176.41(3), P3-P-P4 70.41(3), P-P1-C1 93.97(8), P-P2-C1 86.46(8), P-P3-C2 95.06(8), P-P4-C2 85.98(9), P1-C1-P2 102.3(1), P3-C2-P4 102.8(1).

work (Fig. 2a,b). The free equatorial position indicates the presence of a lone pair. Thus **4** can be included in a series, in general terms, of electronically isovalent element(II) compounds $E[C(PMe_2)_2(SiMe_3)]_2$ **5** (E = Si,[15] Ge,[16] Sn,[17] Pb[18]), with a formal isoelectronic exchange of Si by P^+. Therefore, following this type of notation, **4** can be regarded as a double phosphane adduct of a phosphenium ion (in short, a ten-electron phosphenium ion). In contrast to simple phosphenium ions (e.g. $[(R_2N)_2P]^+$, six electrons[19a]) or simple base adducts of ions of the type $[R_3N-PR'_2]X$[19b, 20] and $[R_3P-PR'_2]X$[21] (eight electrons), the chelate function of the two diphosphinomethanide ligands in **4** leads to ten electrons on the central P atom.[22] Therefore, it is possible to describe **4** as a tetraonio-substituted phosphoranide[23] with partial charge compensation by two internal carbanion functions. Although the phosphenium formalism represents the charge correctly and establishes the analogy to the systems listed above, the phosphoranide formalism describes the nature of the central phosphorus atom more accurately. Therefore, both representations are useful and should be used in conjunction.

As in the compounds **5**, the axial P–P bonds in **4** are not only longer than the equatorial P–P bonds, which are both equal in length, but they also differ slightly. The bond length differences Δd $P-P_{ax}$ and $P-P_{eq}$ (0.21 and 0.26 Å, ca. 8%) lie in the usual range for this geometry.

The chelate four-membered rings are not planar here either; the deviation of C1 from the P1-P-P2 plane amounts to 0.480(2), that of C2 from the P3-P-P4 plane, 0.467(3) Å. However, at both C1 and C2 the sum of the angles is 360°. The ring strain in the two chelate four-membered rings in **4** has a different effect on the bond angles than that expressed in compounds **5**. Not only the P2-P-P4 but also the P1-P-P3 angles are greatly expanded. Thus the P2-P-P4 axis is almost linear, whilst P1 and P3 are very clearly distorted out of the equatorial "plane" of the pseudo-trigonal-bipyramidal framework. The reason for this could lie in the interactions of the bulky phenyl groups (methyl groups in **5**).

The $^{31}P\{^1H\}$ NMR spectra of **4** in solution reveal a rapid scrambling of the equatorial and axial positions at room temperature. The signal of the central phosphorus atom is, as in **2a**, shifted to high field ($\delta = -76.26$). The average "coupling constant" $^1J(P,P)$ of 137.3 Hz is about half of that found in **2a**. On cooling to −107 °C this scrambling process is essentially frozen; an A_2B_2M spin system can be observed.

Tetravalent phosphorus(III) compounds, in which the phosphorus has ten electrons with one lone pair, have only been achieved with phosphoranide ions.[23] Compound **4** is novel as an illustration of one of the possible types of bonding in P–P systems.[24] PP_4 skeletons—be they cationic, neutral, or anionic—have not been detected to date. The formation of the novel type of structure in **4** is obviously a consequence of the nucleophilic behavior of the triphosphete **2a** and the amphiphilic character of "diphosphino carbocations" such as **3a**.

Experimental Procedure

All work was carried out under exclusion of air and moisture in an inert atmosphere of N_2.

2a: To a solution of **1**[25] (2.66 g, 4.6 mmol) in 30 mL of THF at −78 °C was added PCl_3 (0.15 mL, 1.72 mmol) by pipette. The mixture was slowly warmed to room temperature and stirred for 12 h before the solvent was removed in vacuo. The residual orange foam was extracted with pentane (2 × 40 mL). Slow evaporation of the combined pentane extracts at room temperature furnished orange crystals of **2a** (0.31 g, 37%). $^{31}P\{^1H\}$ NMR (C_6D_6, 20 °C): AB_2 spin system: $\delta P_A = -86.31$; $\delta P_B = 20.18$; $J(P_A,P_B) = 261.0$ Hz. MS(CI): $m/z = 487$ ($M^+ + 1$, 100%). ^{31}P NMR spectroscopy of the remaining oil indicates **3** along with $HC(PPh_2)_2(SiMe_3)$. $^{31}P\{^1H\}$ NMR (C_6D_6, 20 °C) of **3**: AB spin system: $\delta P_A = 0.15$; $\delta P_B = 70.15$ ($J = 164.0$ Hz).

2b: To a solution of **1** (1.76 g, 3.04 mmol) in 30 mL of THF at −90 °C was added dropwise $AsCl_3$ (0.11 mL, 1.31 mmol) in 15 mL of THF. The mixture was slowly warmed to room temperature and stirred for 12 h. The solvent was evaporated in vacuo and the residue extracted with pentane (3 × 30 mL). Evaporation of the combined pentane extracts at room temperature yielded a precipitate of product **2b** as a red crystalline solid (0.32 g, 46%). $^{31}P\{^1H\}$ NMR (C_6D_6, 20 °C): δP: −0.51, s. MS(CI): $m/z = 530$ (M^+, 100%).

4-BF_4: To a mixture of **3** (0.403 g, 0.82 mmol) and **2a** (0.398 g, 0.82 mmol) in 35 mL of THF at −78 °C was added dry $NaBPh_4$ (0.281 g, 0.82 mmol). The mixture was warmed to room temperature and stirred for 10 h before the solvent was removed by evaporation (room temperature)). Extraction with pentane gave traces of **3** and $HC(PPh_2)_2(SiMe_3)$. Extraction with THF yielded a yellow-orange oil, which when left to stand for 5 d at room temperature gave a precipitate of orange crystals of **4** (0.40 g, 39%). $^{31}P\{^1H\}$ NMR (C_6D_6 + THF, 20 °C): AB_4 spin system: $\delta P_A = -76.26$, $\delta P_B = 37.73$, $J(P_A,P_B) = 137.3$ Hz; ($C_6D_5CD_3$ + THF, −107 °C): A_2B_2M spin system: $\delta P_A = 44.39$; $\delta P_B = 26.25$; $\delta P_M = -83.71$; $J(P_A,P_B) = 172.0$ Hz, $J(P_A,P_M) = 86.0$ Hz, $J(P_B,P_M) = 172.0$ Hz.

[6] This P–P coupling determines the reaction of the P-methyl-substituted phosphinomethanide and leads eventually to the isolable bis(ylide): $(Me_2P)(Me_3Si)C{=}PMe_2\text{-}PMe_2{=}C(SiMe_3)(PMe_2)$: H. H. Karsch, B. Deubelly, G. Müller, *J. Chem. Soc. Chem. Commun.* **1988**, 517–518. In contrast to earlier reports (H. H. Karsch, B. Deubelly, G. Grauvogel, G. Müller, *J. Organomet. Chem.* **1993**, *459*, 95–105), this step can be ruled out for the analog with phenyl substituents. See also: P. Braunstein, R. Hasselbring, A. DeCian. J. Fischer, *Bull. Soc. Chim. Fr.* **1995**, *132*, 691–695. Accordingly, **3** does not react with excess **1** under the present conditions, as can be demonstrated independently.

[7] Since the reduced phosphorus species was not identified, the formulation in Equation (b) as Li_3P_7 only reflects the chosen stochiometry and is also in agreement with the corresponding formulation in ref.[1].

[8] Crystal structure determinations: Crystals of **2a** and **2b** were obtained by recrystallization from pentane. **2a** [**2b**]: $C_{28}H_{29}P_3Si$ [$C_{28}H_{29}AsP_2Si$], triclinic [triclinic], space group $P\bar{1}$ [$P\bar{1}$], $a = 9.606(1)$ [9.687(1)], $b = 16.227(1)$ [16.317(1)], $c = 17.172(1)$ [17.274(1) Å, $\alpha = 106.30(2)$ [106.35(1)], $\beta = 90.13(2)$ [90.34(1)], $\gamma = 93.12(2)$ [92.55(1)]°, $V = 2564.9(9)$ [2616.9(3)] Å^3, $Z = 4$ [4] (each contains two independent molecules in the asymmetric unit), $\rho_{calcd} = 1.260$ [1.346] g cm^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), $\mu(Mo_{K\alpha}) = 2.86$ [14.81] cm^{-1}. 11157 [9108] independent reflections measured with $\omega - 2\theta$ scans at $-120(2)$ [$-68(2)$] °C in the 2θ range [°] 2–54 [3–50]. Structure solution using direct methods, refinement of the positional parameters of all the non-hydrogen atoms with anisotropic thermal parameters, hydrogen atoms on calculated positions with $B_H[U_H] = 1.3\, B_{eq.C}$ [1.2–1.5 $U_{eq.C}$]. Refinement of the positional parameters with MolEN versus F (for **2a**) and with SHELXL-93 versus F^2 (for **2b**). $R = 0.0287$ [0.0311], $R_w = 0.0480$ [0.0747] for 8849 [7116] structural factors $F_o^2 \geq 3\sigma(F_o^2)$ [$F_o \geq 4\sigma(F_o)$] and 577 [583] variables. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-59325.

[9] This short nonbonding distance is typical for many diphosphinomethanide complexes. For example in $Br_2B[C(PMe_2)_2(SiMe_3)]$ it is 2.59(1) Å: H. H. Karsch, K. Zellner, A. Schier, unpublished results. Because of the interaction of the carbanion-like C atoms, this distance is even shorter in 1,3-diphosphetes e.g. 2.39 Å in $[C_9H_{14}N_2P(C_7H_{19}Si_2)_2]_2P_2[C(SiMe_3)]_2$ [5b].

[10] Here the extent of a possible delocalization of charges in the sense of heteroallyl cation/P anion is not considered, cf.: G. Alcaraz, A. Baceiredo, M. Niger, W. W. Schoeller, G. Bertrand, *Inorg. Chem.* **1996**, *35*, 2458–2462.

[11] Twofold coordination of a P atom with (formally) two lone pairs as in R_2P^-.

[12] This representation takes account of the (otherwise obsolete) assignment of the oxidation state of +1 between two identical elements for the bivalent P and As atoms.

[13] *P*-Chloro-methylenephosphoranes have been reported: O. I. Kolodyazhnyi, *Russ. Chem. Rev.* **1991**, *60*, 391–409; R. Appel, J. Peters, R. Schmitz, *Z. anorg. allg. Chem.* **1981**, *475*, 18–26. They can be converted into the cation e.g. with $AlCl_3$: N. Burford, R. E. v. H. Spenze, R. D. Rogers, *J. Am. Chem. Soc.* **1989**, *111*, 5006–5008; H. Grützmacher, H. Pritzkow, *Angew. Chem.* **1992**, *104*, 92–94, *Angew. Chem. Int. Ed. Engl.* **1992**, *31*, 99–101. However, C-phosphino-substituted *P*-chloro-methylenephosphoranes such as **3** and its cations, for example $[(Ph_2P)_2C(SiMe_3)]^+$ **3a**, have not yet been reported. **3a** cannot be detected by spectroscopy when **3** is treated with $NaBPh_4$. On the other hand, **4** is also produced in the reaction of a mixture of **2a** and **3** with $GeCl_2$; the counterion is $[GeCl_3]^-$. This proves that the presence of a (strong) nucleophile is essential for the abstraction of chloride from **3**. However, the reaction of **3** with the strong chloride acceptor $AlCl_3$ produces a new species, whose ^{31}P NMR signal appears at $\delta = 67.26$ and can be attributed to the "diphosphino carbocation" **3a**. A unequivocal identification of **3a** has yet to be achieved.

[14] Crystal structure determination of **4**-BPh_4: crystals of were obtained by recrystallization from THF. $C_{80}H_{78}BP_5Si_2$, monoclinic, space group $P2_1/c$, $a = 14.817(1)$, $b = 18.639(1)$, $c = 25.665(2)$ Å, $\beta = 94.08(1)°$, $V = 7070.0(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.185$ g cm^{-3}, $Mo_{K\alpha}$ radiation ($\lambda = 0.71073$ Å), $\mu(Mo_{K\alpha}) = 20.6$ cm^{-1}. 12373 independent reflections measured with ω scans at $-68(2)$ °C in the 2θ range [°] 3–50. Structure solution using direct methods, refinement of the positional parameters of all the non-hydrogen atoms with anisotropic thermal parameters, hydrogen atoms on calculated positions with $U_H = 1.2$–$1.5\, U_{eq.C}$. Refinement of the positional parameters with SHELXL-93 versus F^2. $R = 0.0403$, $R_w = 0.0950$ for 8783 structural factors $F_o \geq 4\sigma(F_o)$] and 799 variables. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany) on quoting the depository number CSD-59325.

[22] This does not conflict with the representation using formal charges, in which the central phosphorus atom is assigned a negative formal charge. For example, in the "triphosphenium ion" $[Ph_3P\text{-}\bar{P}PPh_3]^+$ [1b] the phosphorus has a negative formal charge. The representation as a phosphane–base adduct of a triono-substituted phosphane [20a] with partial charge compensation by two carbanion functions is very artificial. However, it does illustrate that **4** can also be regarded as the first phosphane–phosphane adduct—if only for very specific phosphanes.

Donor/Acceptor Complexes in Hydrogen-Bonded Networks: pH-Dependent Self-Organization**

Hans Bock,* Wolfgang Seitz, Mark Sievert, Markus Kleine, and Jan W. Bats

Donor/acceptor complexes $\{D^{\delta+} \cdots A^{\delta-}\}$[1, 2] between donor molecules of low ionization energy, which also function as Lewis bases, nucleophiles, or reducing reagents, and electron-deficient acceptor molecules with their properties as Lewis acids, electrophiles, or oxidizing reagents are kept together by weak Coulomb interactions and can be intermediates in microscopic pathways of substitution or redox reactions.[1d, 2] Their fascinating color is due to the long-wavelength excitation into short-lived charge transfer (CT) states $\{D^{\bullet+} \cdots A^{\bullet-}\}$.[1a] Structural analysis of mixed-stack aggregates between six-membered ring donors and acceptors, which can be specifically crystallized,[2c–g] proves that in their ground states, all bond lengths and angles of the components remain unchanged on π-complexation. Attempts to increase the π-interaction by shortening the donor···acceptor distance, thereby generating recognizable structure perturbations, have been the starting point for the

crystallization of donor/acceptor complexes in hydrogen-bonded networks illustrated by the following examples.[3]

1) In molecular crystals of donor/acceptor complexes exhibiting a herringbone pattern, the lattice can be planarized by additional hydrogen bonds:[2a] this is demonstrated by an exchange of the acceptor 1,2,4,5-tetracyanobenzene by the likewise tetracyano-substituted hydroquinone (Fig. 1), which, depending on the basicity of the hydrogen-bond partner, either forms a network with $-CN\cdots HO-$ ($pK_B \approx -11$) or $>NH_2^+\cdots {}^-O-$ contacts ($pK_B \approx 8$) involving cooperative effects of about 2 kJ mol^{-1} (10%) or 18 kJ mol^{-1} (32%),[4] respectively.

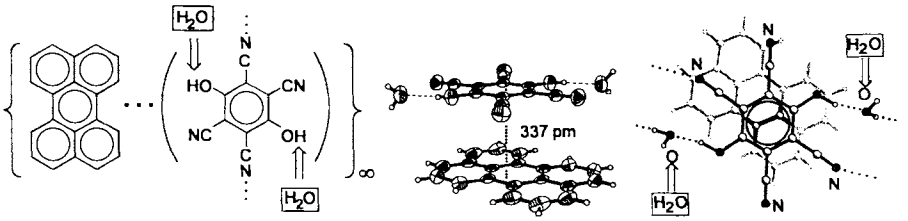

Fig. 2. Single-crystal structure of the donor/acceptor complex {perylene $\cdots$ tetracyanohydroquinone$(H_2O)_2\}_\infty$: side view (50% thermal ellipsoids) and top view; cf. {pyrene $\cdots$ 1,2,4,5-tetracyanobenzene$\}_\infty$, Fig. 1, and text.

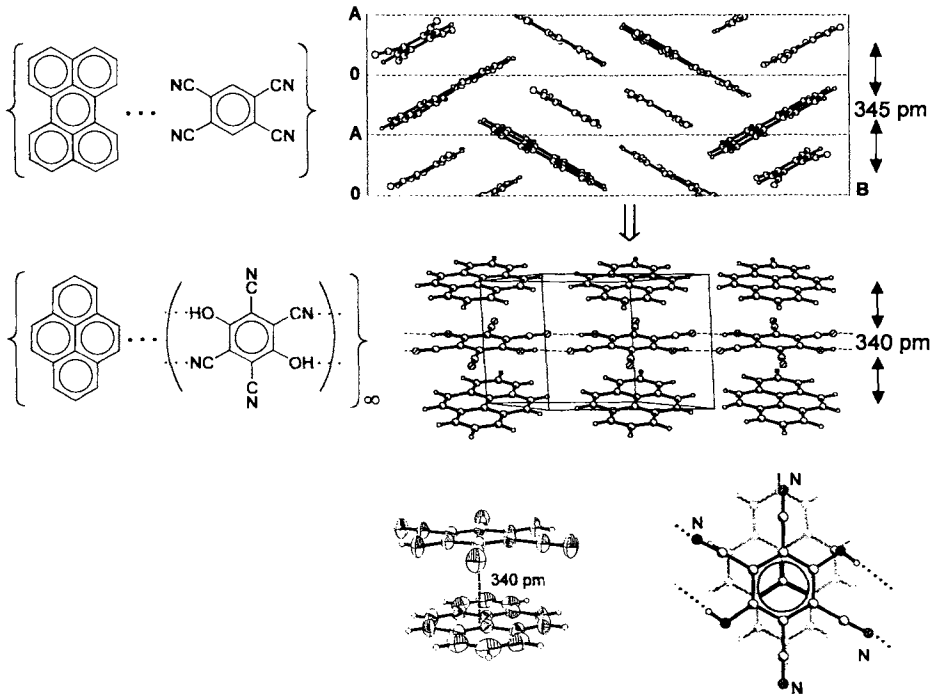

Fig. 1. Single-crystal structures of the donor/acceptor complexes {perylene $\cdots$ 1,2,4,5-tetracyanobenzene} and {pyrene $\cdots$ tetracyanohydroquinone} exhibiting lattices with either herringbone pattern or parallel layers flattened by hydrogen bonds, shown in side view (50% thermal ellipsoids) and top view (cf. text).

The herringbone pattern[1b] of the complex {perylene $\cdots$ 1,2,4,5-tetracyanobenzene}[2a] is leveled in {pyrene $\cdots$ 1,2,4,5-tetracyanohydroquinone}[5] by four additional $-CN\cdots HO-$ hydrogen bonds; simultaneously the interplanar donor $\cdots$ acceptor π-distance is shortened by 5 pm to double the van der Waals π-radius ($2\times 170 = 340$ pm).[3a] Nevertheless, no significant structural changes due to the complex formation are evident in either the donor or acceptor components. PM3/CI and AM1/CI calculations[2g] based on the crystal structure data, which approximately reproduce the long-wavelength CT-excitations of the violet or dark red dichloromethane solutions at 19000 and 21000 cm^{-1}, respectively, predict only charge transfer contributions of less than 0.1 electrons for the ground states of the individual complexes. Charge-inflicted structural perturbations, therefore, are not to be expected.

2) Crystallization of the donor/acceptor complex between perylene and tetracyanohydroquinone from a hot acetic acid solution[6] surprisingly yields the doubly hydrated polymer {perylene $\cdots$ tetracyanohydroquinone$(H_2O)_2\}_\infty$ (Fig. 2).

Lattice incorporation of two water molecules stretches the N–O distance between the hydrogen-bond pair $(CN\cdots HO-)_2$ of the pyrene adduct from 265 pm to 565 pm in the analogous perylene complex containing the contact pairs $(-CN\cdots HO-(H)\cdots HO-)_2$. Despite the comparable interplanar π-distances of 340 and 337 pm, respectively, which correspond to twice the standard van der Waals π-radius of 340 pm, the π-overlap of the polycyclic hydrocarbon donor with the tetracyanohydroquinone six-membered ring change drastically (Fig. 1 and 2). In the pyrene complex a trigonal C center and in the perylene one ring-connecting C_2 fragment is superimposed by the arene ring. Because pyrene also contains a central CC bond and perylene trigonal C centers, the energy differences between the specific overlap possibilities of six-membered rings, which are probably only small, will be explored by density functional calculations for selected model compounds,[2b] as in the case of benzene dimers in the gas phase.[7] Until proven otherwise, dominant packing effects have to be assumed, which even for small differences in lattice sublimation energies,[8] are known to determine the crystal structures. Both π-overlap situations, however, require more space for perylene (Fig. 2), and therefore the hydrate stretching of the polymer chain under comparable crystallization conditions is an interesting variation resulting from insertion of donor/acceptor complexes in hydrogen-bonded networks.

3) A third possibility of incorporating donor molecules into H-bonded layers of the acceptor tetracyanohydroquinone is observed in the complex {tetracyanohydroquinone anion $\cdots$ *N,N'*-tetramethylbenzidinium dication$(H_2O)_2\}_\infty$ (Fig. 3).[2g] Proton transfer from two hydroquinone molecules yields doubly protonated tetramethylbenzidinium dications, which are connected by hydrogen bonds to the polymer chains of likewise H-bonded tetracyanohydroquinone monoanions (Fig. 3; all H experimentally detected). After proton exchange between the donor and acceptor functions, relatively long, interplanar {benzidine$^{2+}\cdots$ hydroquinone$^-$} π-distances of 360 pm result (Fig. 3) in contrast to those of only 335 pm between the hydroquinone anions, which are arranged parallel to each other, presumably due to lattice packing. In the different hydrogen bonds the heterocenters are separated by 246 pm for $O(H)\cdots {}^-O$, 272 pm for $N^+(H)\cdots O$, and 290 pm for $N\cdots(H)O$, and form

an overall energetically favorable hydrogen-bonded network.[1b, 3c, d, 9]

Clearly, donor/acceptor complexes in hydrogen-bonded networks provide additional aspects for novel materials. The three examples presented—flattened, alternate layers of donors and acceptors (1), stretching of the hydrogen-bonded network by hydrate water inclusion for incorporation of larger π-donor molecules (2), and exchange of donor and acceptor functions by protonation/deprotonation equilibria (3)—should stimulate further exploration of the many facets of this pH-dependent molecular self-organization.

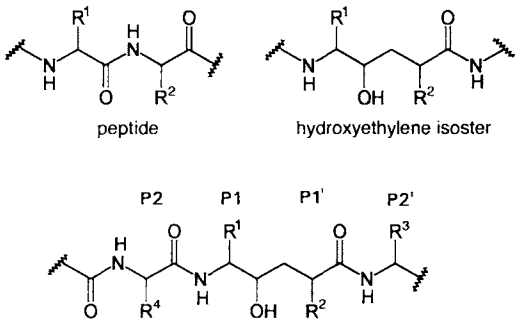
A New Chiral, Cationic β-Amino Alcohol Equivalent: A Variable Approach to Enantiomerically Pure Building Blocks for Hydroxyethylene Isosters

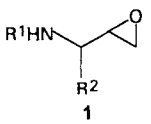
Karsten Danielmeier, Kerstin Schierle, and Eberhard Steckhan*

β-Amino alcohols are structure elements of many important peptidomimetics.[1] Numerous compounds with this subunit were synthesized in the last few years and function as inhibitors of aspartic proteases[2] such as renin[3] and HIV protease.[4] In addition to C_2-symmetric inhibitors developed by Kempf et al.,[5] hydroxyethylene isosters (HDI) have received increasing attention (Scheme 1).[4a]



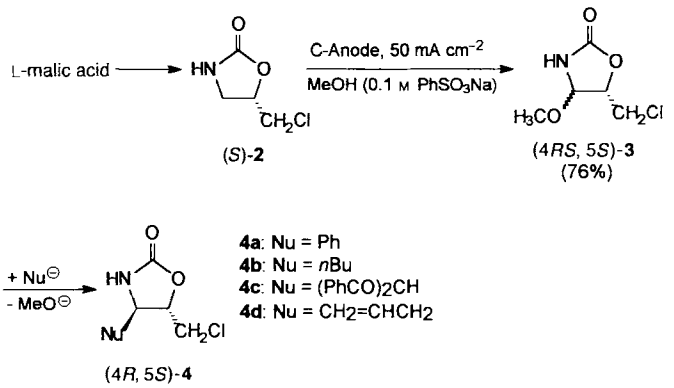
Scheme 1. Peptide and analogous hydroxyethylene isoster (top); P-nomenclature (below).

Since the pioneering work of Szelke et al.[6] a number of approaches to these compounds have been reported.[7] Often the 2,3-epoxypropylamine **1** is used as a key building block.[8, 9] Generally, **1** is synthesized from α-amino acids, for example, via chiral α-amino aldehyde[10] intermediates. The scope of these methods is limited because the substituents in the P1 position of the HDI structure are determined by the amino acid employed.[11] A hydrophobic residue in this P1 position is advantageous for achieving the optimum fit for the active center of the enzyme and thus a high inhibiting effect of the substance.[3a] Therefore, a more variable approach to the key building block that is not limited by the α-substituent of the amino acid remains an important goal. Herein we present an efficient pathway to a variable building block for chiral β-amino alcohols. We show that a variety of hydrophobic residues can be introduced easily in the P1 position of the HDI structure by using a new cationic β-amino alcohol equivalent that is not derived from α-amino acids.[12]



1

Starting from (*S*)-5-chloromethyl-oxazolidin-2-one (**2**),[13a] which is easily accessible from L-malic acid ((*R*)-5-chloromethyl-oxazolidin-2-one is available from D-malic acid), (4*RS*,5*S*)-5-chloromethyl-4-methoxy-oxazolidin-2-one (**3**) can be obtained by direct anodic oxidation in a *trans*/*cis* ratio of 5:1 in 76% yield[13b] (quasi-divided cell; anode: graphite; cathode: Pt wire; current density: 50 mA cm^{-2}; supporting electrolyte: sodium benzene sulfonate (0.1 M); solvent: methanol; $T = -10\,^{\circ}C$; c (**2**) = 2.53 mol L^{-1}). Compound **3** can be synthesized on a 10 g scale and stored at +4 °C without decomposition. This *N*,*O*-acetal is a stable form of an *N*-acyliminium ion that additionally can be further functionalized at the chloromethyl substituent in a variety of ways. Amidoalkylation reactions with **3** through exchange of the methoxy group for different nucleophiles led with high diastereoselectivity to the corresponding *trans*-disubstituted oxazolidinones **4** (Scheme 2, Table 1), which are cyclic carbamates of the desired β-amino alcohols.



Scheme 2.

Table 1. Nucleophilic exchange reactions with *N*,*O*-acetal **3**.

Nucleophile (Nu)	Lewis acid	Product [e]	Yield [%] [g]	*trans*:*cis*
Ph_3Cu_2Li	$BF_3 \cdot OEt_2$ [a]	**4a** [19]	62	>12:1
nBu_3Cu_2Li	$BF_3 \cdot OEt_2$ [a]	**4b**	59	>20:1
$nBuCu \cdot Me_2S$	$BF_3 \cdot OEt_2$ [b]	**4b**	52	7:1
dibenzoylmethane	TFA [c]	**4c** [f]	47	6:1
allyltrimethylsilane	$TiCl_4$ [d]	**4d**	79	>15:1

[a] According to Zietlow et al. [15a] the cuprate is generated at −50 °C, the Lewis acid and the substrate dissolved in absolute THF are added at −78 °C. [b] According to Wistrand and Skrinjar [17] *n*-butylcuprate is generated from one equiv Cu-Br·Me_2S and one equiv *n*BuLi, then the Lewis acid and the substrate are added. [c] According to Herborn et al. [18], first the nucleophile in dichloromethane is added, then 10 equiv TFA at 0 °C are added, and the solution is stirred for 24 h at room temperature. [d] The substrate is dissolved in dichloromethane, 2 equiv $TiCl_4$ is added at −10 °C, and the solution is treated dropwise with 1.1 equiv allyltrimethylsilane in dichloromethane. After the solution has been warmed to room temperature, it is stirred for 10 h. [e] All products were characterized by ^{13}C NMR (DEPT), ^1H NMR (NOE), IR spectroscopy, MS, high-resolution MS, and CHN analysis. An example is given in ref. [19]. [f] The product is not stable. [g] Except **4c** (*cis*/*trans*-mixture) isolated yields are for pure *trans* products.

After simple purification by column chromatography the *trans* isomers are isolated in enantiomerically pure form (GC). The relative configuration was determined by using NOE difference spectroscopy. Different cuprates, dibenzoyl methane as an example of a CH-acidic nucleophile, and allyltrimethylsilane in a Sakurai reaction[14] have been selected as nucleophiles. The best results for cuprates were obtained by using mixtures of R_3Cu_2Li and $BF_3 \cdot OEt_2$.[15, 16] But the desired products can also be obtained by amidoalkylation with nBuCu·$(H_3C)_2S$/

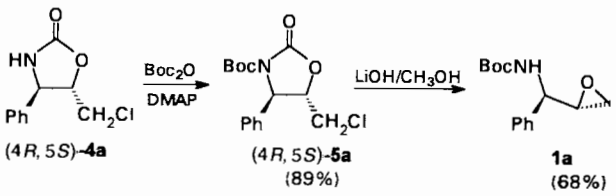
$BF_3 \cdot OEt_2$,[17] although with a lower diastereoselectivity. Remarkably, substitution at the chloro function was not detected in any example. The resulting chiral 5-chloromethyl-oxazolidin-2-ones **4** can be easily converted into the desired chiral 2,3-epoxypropylamines **1**. Using **4a**[19] as an example, the epoxide is obtained spontaneously after ring opening. To achieve this, initially the N-Boc-protected compound **5a** is formed from **4a** with Boc_2O (1 equiv) and catalytic amounts of DMAP (16 mol%) in absolute THF (0.5 h at 0 °C, 10 h at room temperature). The subsequent ring opening by LiOH (5 equiv) in methanol (1 h at room temperature, 10 mL) leads directly to the protected *threo*-(1*R*,2*S*)-1-phenyl-2,3-epoxypropylamine **1a**[20] enantomerically pure in 68% yield (Scheme 3). The enantiomeric purity was established by NMR spectroscopy in the presence of a chiral shift reagent and comparison with racemic **1a**.



Scheme 3.

The applicability of (4*RS*,5*R*)- and (4*RS*,5*S*)-5-chloromethyl-4-methoxy-oxazolidin-2-one as variable functionalizable chiral, cationic β-amino alcohol equivalent for the generation of interesting target molecules has been demonstrated by the synthesis of 4-substituted, chiral 5-chloromethyl-oxazolidin-2-ones **4** and their easy transformation to epoxides **1**, exemplified by **1a**. The application of the synthesis to other compounds of pharmacological interest like derivatives of β-blockers, and the use of functionalized nucleophiles are currently under investigation.

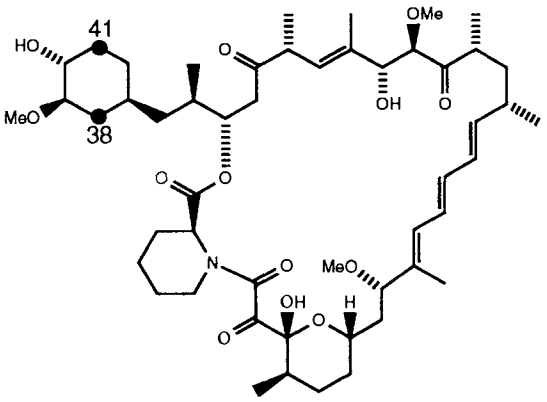
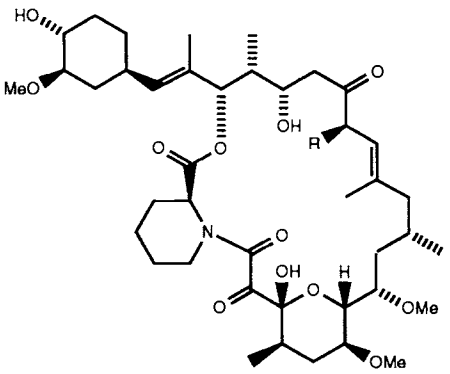
The Nature of the Starter Unit for the Rapamycin Polyketide Synthase**

Philip A. S. Lowden, Günter A. Böhm, James Staunton,* and Peter F. Leadlay

Rapamycin, FK 506, and FK 520 are structurally similar macrolide natural products of streptomycetes. Their potent immunosuppressant properties have stimulated great interest in their total synthesis[1] and in the molecular basis for their biological activity.[2] The therapeutic potential of structural analogues has also prompted research into the production of chemically modified rapamycins.[3]



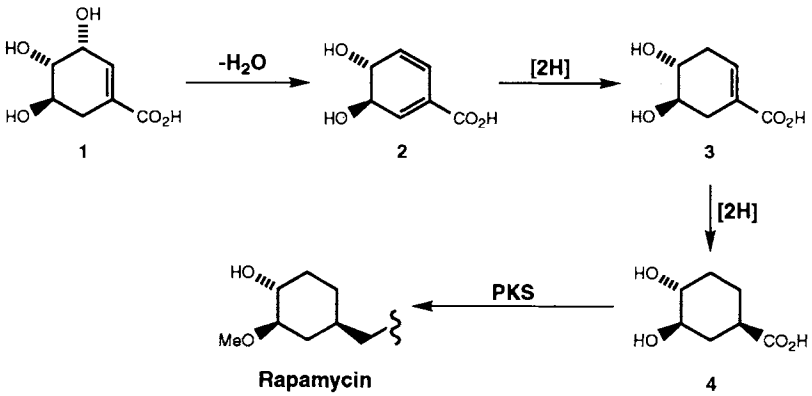
Rapamycin



FK 506, R = 
FK 520, R = Et

Biosynthetic experiments have confirmed that rapamycin is a polyketide.[4] Rapid progress has recently been made in the manipulation of complex polyketide biosynthesis to produce unnatural metabolites,[5] so a detailed knowledge of rapamycin biosynthesis at the genetic and enzymological level should provide the means to produce novel rapamycin derivatives by genetic engineering of the biosynthetic enzymes. The complete DNA sequence of the rapamycin polyketide synthase has been established.[6] Like erythromycin[7] the core of rapamycin is assembled by a modular type I polyketide synthase (PKS). In all there are 14 chain extension modules, and these are housed in three giant (M = 660–1070 kDa) multimodular polypeptides. The modules for chain initiation and termination differ markedly from those of the erythromycin PKS. Termination is effected by a specialized multidomain protein (pipecolate incorporating enzyme), which is thought to incorporate a pipecolate unit and then perform macrocyclization.[6] Chain initiation, the subject of the current report, also seems to be carried out differently than for erythromycin. Instead of an acyl transferase domain and an acyl carrier protein domain, which together transfer the starter acid from the thiol of CoA to the active thiol of the first keto–acyl synthase domain, the starter loading module of the rapamycin PKS contains a domain with amino acid sequence similarity to carboxylic acid-CoA ligases (CL), and an adjacent domain with potential for enoyl reductase activity (ER).[6] Further sequencing in our laboratory has recently shown that a putative acyl carrier protein domain lies between the ER and the keto–acyl synthase domain of the first extension module.

The nonstandard character of the starter loading module in the rapamycin PKS reflects the unusual nature of the substituted cyclohexane ring at the start of the polyketide chain in rapamycin, FK 506, and FK 520. Feeding studies with ^{13}C-labeled shikimic acid have shown that this is the source of the carbon atoms of the cyclohexane ring in rapamycin[8] and FK 520,[9] and O-methylation has been shown to occur post-PKS for FK 506.[10] A biosynthetic pathway to the starter unit can be envisaged from shikimic acid (**1**) via dehydration to **2** and reduction via **3** to dihydroxycyclohexanecarboxylic acid (**4**) (Scheme 1), which would be activated as a thioester to initiate polyketide chain extension. This pathway is related to that which has been elucidated for cyclohexanecarboxylic acid in



Scheme 1. Proposed pathway from shikimic acid (**1**) to the rapamycin starter unit **4**.

cyclohexyl fatty acids in *Alicyclobacillus acidocaldarius*[11] and in ansatrienin A from *Streptomyces collinus*.[12] The early steps of this pathway have been confirmed for FK 520,[9] but the intermediacy of the saturated dihydroxycyclohexanecarboxylic acid **4** has not been studied until now.

Before undertaking genetic engineering of the rapamycin PKS, we wished to use in vivo studies to confirm the identity of the starter acid for the PKS as **4**. The putative precursor was synthesized with four ^2H labels (**4a**), since incorporation into

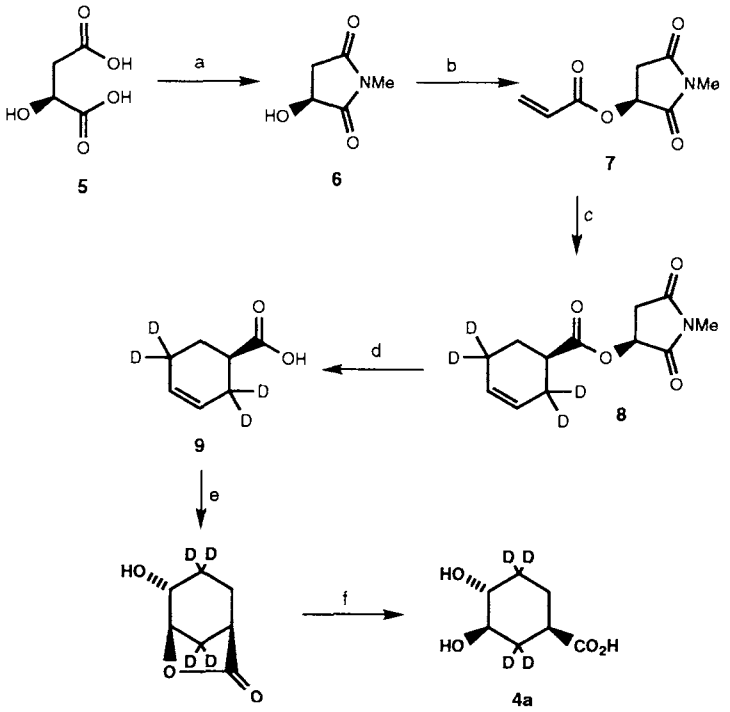
rapamycin would result in easily identifiable changes in the mass spectrum, and a characteristic ^2H NMR spectrum. The synthesis was modeled on methods developed by Ireland et al. and Corey et al.[13] in synthetic approaches toward FK 506 (Scheme 2).



Scheme 2. Synthesis of labeled precursor **4a**. a) 1. $MeNH_2$, 2. Heating in xylene at reflux (55%); b) Et_3N, acryloyl chloride, −30 °C (56%); c) $TiCl_4$, $^2H_4$-butadiene, 0 °C (93%); d) LiOH, H_2O_2 (82%); e) 1. mCPBA, 2. Et_3N, 55 °C (60%); f) KOH, H_2O, THF (100%).

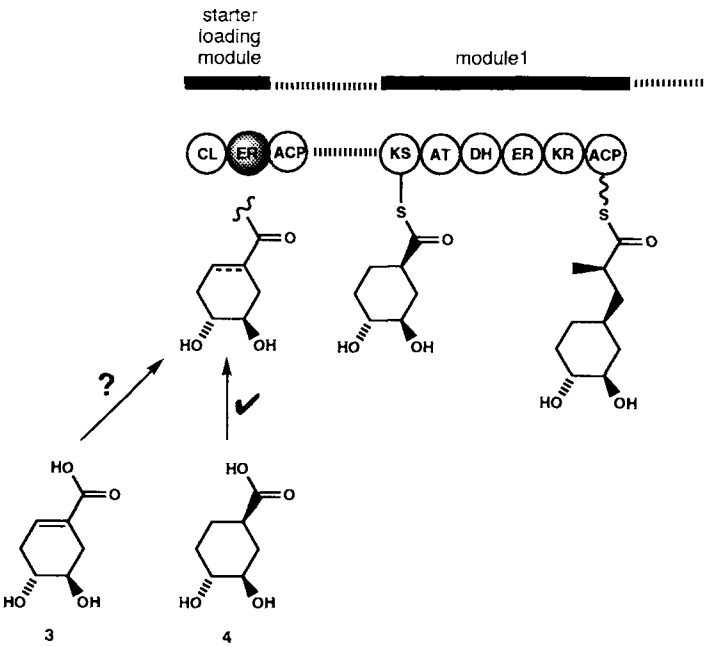
L-Malic acid (**5**) was condensed with methylamine to give imide **6**, which was acylated with acryloyl chloride to give **7**, which acted as a dienophile in a $TiCl_4$-promoted asymmetric Diels–Alder reaction with tetradeuterobutadiene (obtained by thermal decomposition of commercially available butadiene-2,2,5,5-$^2H_4$-sulfone) to afford a single diastereoisomer of Diels–Alder adduct **8**. The chiral auxiliary was removed by treatment with lithium hydroxide and hydrogen peroxide to give labeled (1*R*)-cyclohex-3-enecarboxylic acid (**9**) in 84% *ee*. Hydroxylactonization was achieved by treatment with *meta*-chloroperoxybenzoic acid (mCPBA), then triethylamine, followed by hydrolysis to afford the $^2H_4$-dihydroxycyclohexanecarboxylic acid **4a**.

This acid was fed to a growing culture (1 L) of *Streptomyces hygroscopicus* (ATCC 29253) in two 0.5 mM portions at 24 h and 48 h after inoculation. After a total of four days, the mycelia were collected, extracted with methanol, and the rapamycin (0.01 mM) purified by reverse-phase HPLC. The electrospray mass spectrum of the isolated rapamycin showed peaks at the expected masses for the unlabeled compound at 936.5 Da (Na^+ adduct), and 952.5 Da (K^+ adduct). Associated with each peak was another peak four mass units higher, due to the presence of rapamycin labeled with four deuteriums. These additional peaks were not observed in extracts of unlabeled rapamycin. Accurate mass analysis of the peak at 940.5 Da using fast atom bombardment (FAB) confirmed its derivation from the sodium adduct of tetradeuterorapamycin. Comparison of the peak intensities showed that 44% of the rapamycin was labeled. ^2H NMR analysis of the labeled rapamycin gave a spectrum that could be assigned to rapamycin in which the expected positions were equally enriched with deuterium (Table 1). The combination of the mass spectrometric and NMR evidence establishes the intact incorporation of the labeled precursor into the predicted site. A larger scale (3 L) repeat experiment gave similar results.

Table 1. ^2H NMR data for labeled rapamycin in $CHCl_3$ at 61.4 MHz. Chemical shifts (δ values) are given relative to the TMS signal. The published chemical shifts are of major and minor amide rotamers, respectively. Line widths were $\Delta\delta$ = 0.2–0.4.

Observed δ	Relative intensity	Assignment	Published δ [14]
2.01	2	38-H (eq)	2.10, 2.09
		41-H (eq)	1.99, 1.97
1.26	1	41-H (ax)	1.33, 1.30
0.64	1	38-H (ax)	0.68, 0.64

The high level of incorporation of **4a** into rapamycin demonstrates that it can compete effectively with the endogenous flow of unlabeled precursors. We conclude therefore that the saturated acid **4** is acceptable as a substrate for the CL domain. By comparison with known carboxylic acid-CoA ligases, we believe that it is activated as an acyl-adenylate. Transfer to the thiol of the first keto–acyl synthase domain may occur directly, or it may be mediated by the thiol of the 4′-phosphopantetheine prosthetic group on the nearby putative ACP domain of the PKS (Scheme 3). However, the existence of the putative ER domain next to the ligase suggests that the normal substrate of the PKS may be the unsaturated derivative **3**. This may be reduced prior to activation by the CL, in which case **4** would be the natural substrate for the CL. However, if **3** is activated before reduction, the incorporation of **4** would reflect a relaxed



Scheme 3. Relationship of the feeding results to the predicted organization of the rapamycin polyketide synthase (PKS). The N terminus of the first multienzyme polypeptide is shown with the linear arrangement of the predicted catalytically active domains. CL: carboxylic acid ligase, ER: enoyl reductase, ACP: acyl carrier protein, KS: keto–acyl synthase, AT: acyl transferase, DH: dehydratase, KR: ketoreductase.

[Rh(7-SPh-8-Me-7,8-$C_2B_9H_{10}$)(PPh_3)$_2$]: A New Rhodacarborane with Enhanced Activity in the Hydrogenation of 1-Alkenes**

Francesc Teixidor, Miquel A. Flores, Clara Viñas,* Raikko Kivekäs, and Reijo Sillanpää

The use of rhodacarboranes as homogeneous catalysts for the hydrogenation and isomerization of alkenes was first reported by Hawthorne and co-workers,[1] and their utility was later extended to other catalytic transformations.[2] A thorough mechanistic study[3] attributed the catalytic activity to the formation of B–Rh^{III}–H species by the oxidative addition of terminal B–H bonds to Rh^{I} centers in *exo-nido*-rhodacarborane derivatives. Besides, the formation of nonactive *closo*-rhodacarborane tautomers and the involvement in the catalytic cycle of B–H–Rh^{I} species attached to the less active "lower belt" of the carborane framework[3] were two reasons proposed to account for the lower activity of some of the catalysts tested (Fig. 1). For these

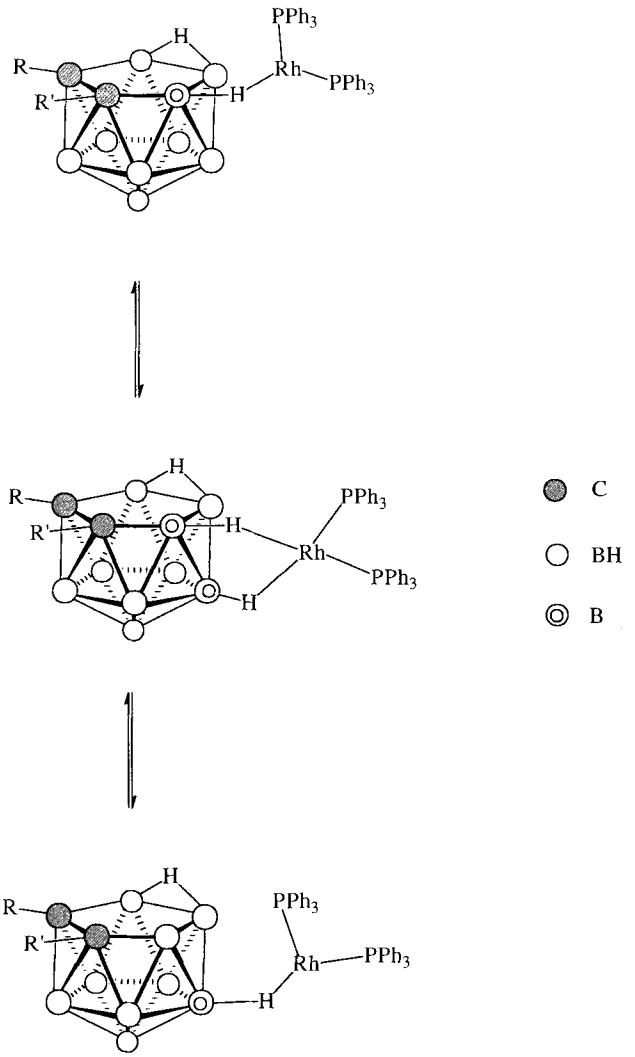

Fig. 1. Simplified description of lower belt (bottom)/upper belt (top) B–H–Rh equilibrium. R and R′ represent arbitrary alkyl or aryl groups.

reasons, two features of *exo*-monothiocarborane ligands (Fig. 2) prompted us to consider the study of their rhodium complexes: 1) the ability of such ligands to form the necessary B–H–M interactions and 2) the presence of the thioether moiety bonded to an open-face carbon atom.[4] The latter would hinder the formation of catalytically undesirable *closo* tautomers[5] and, in addition, would favor the formation of more reactive upper belt B–H–Rh^{I} species. Here we wish to report the synthesis of the first *exo*-monothiocarboranerhodium complex and its enhanced activity in the hydrogenation of 1-hexene.

Attempts to prepare [Rh(7-SPh-8-Me-7,8-$C_2B_9H_{10}$)(PPh_3)$_2$] (**1**) by heating (NMe_4)[7-SPh-8-Me-$C_2B_9H_{10}$] (NMe_4-**2**) and [RhCl(PPh_3)$_3$] at reflux in ethanol were unsuccessful and gave [RhCl(CO)(PPh_3)$_2$] as the main product. Treatment of [RhCl-

Fig. 2. *Exo-nido*-monothiocarborane ligand **2**.

$(PPh_3)_3$] with an ethanolic solution of $AgClO_4$ and subsequent reaction with NMe_4-**2** also had little success. However, reaction of the cesium salt of **2** with Wilkinson's catalyst in toluene/ethanol (8/1) at room temperature[6] resulted in the isolation of **1** as a bright red solid in 91% yield.

The IR spectrum of **1** exhibited an intense absorption at 2527 cm^{-1} characteristic of the B–H stretching of *nido*-carboranes, along with bands associated to PPh_3 and one additional band at 2112 cm^{-1} that could be attributed to B–H–Rh bridges. The $^{11}B\{^1H\}$ NMR spectrum of **1** contained eight resonances in the ratio 1:2:1:1:1:1:1:1. The $^1H\{^{11}B\}$ NMR spectrum displayed a broad resonance centered at $\delta = -4.55$ confirming the existence of B–H–Rh interactions. The remaining carborane protons appeared as a broad resonance between $\delta = 2.3$ and -0.1, and one resonance found at $\delta = -2.69$ was assigned to the B–H–B bridge. A complex series of resonances centered at $\delta = 7.4$, characteristic of phenyl protons, and a singlet at $\delta = 1.48$ assigned to the methyl protons were also observed. Finally, the $^{31}P\{^1H\}$ NMR spectrum revealed only a relatively broad doublet centered at $\delta = 42.8$ ($^1J_{Rh,P} = 176$ Hz). Low temperature (−94 °C) $^{31}P\{^1H\}$ NMR spectra (Fig. 3) exhibited two doublets of doublets centered at $\delta = 41.2$ ($^1J_{Rh,P} = 165$ Hz, $^2J_{P,P} = 40$ Hz) and $\delta = 44.0$ ($^1J_{Rh,P} = 187$ Hz, $^2J_{P,P} = 40$ Hz) characteristic of two *cis* phosphorus atoms. Variable temperature $^1H\{^{11}B\}$ NMR spectra recorded in the range between 25 °C and −94 °C exhibited a small upfield shift of the B–H–Rh resonance from $\delta = -4.55$ to −4.84. The spectroscopic data and elemental analysis are consistent with an *exo-nido*-carborane rhodium complex containing two mutually *cis* PPh_3 ligands. The variable temperature NMR experiments suggest that only one isomer exists in solution, and its PPh_3 ligands exchange readily on the NMR time scale at ambient temperatures. To determine unambiguously the nature of the interaction between the $[Rh(PPh_3)_2]^+$ fragment and the carborane cage, an X-ray crystallographic[7] study was necessary. The simplified drawing of **1** is shown in Figure 4. The carborane cage forms a chelate with the metal through a S–Rh bond and a B(11)–H–Rh bond (B(11) belongs to the cluster's open face). Two PPh_3 ligands complete the coordination sphere of the rhodium center.

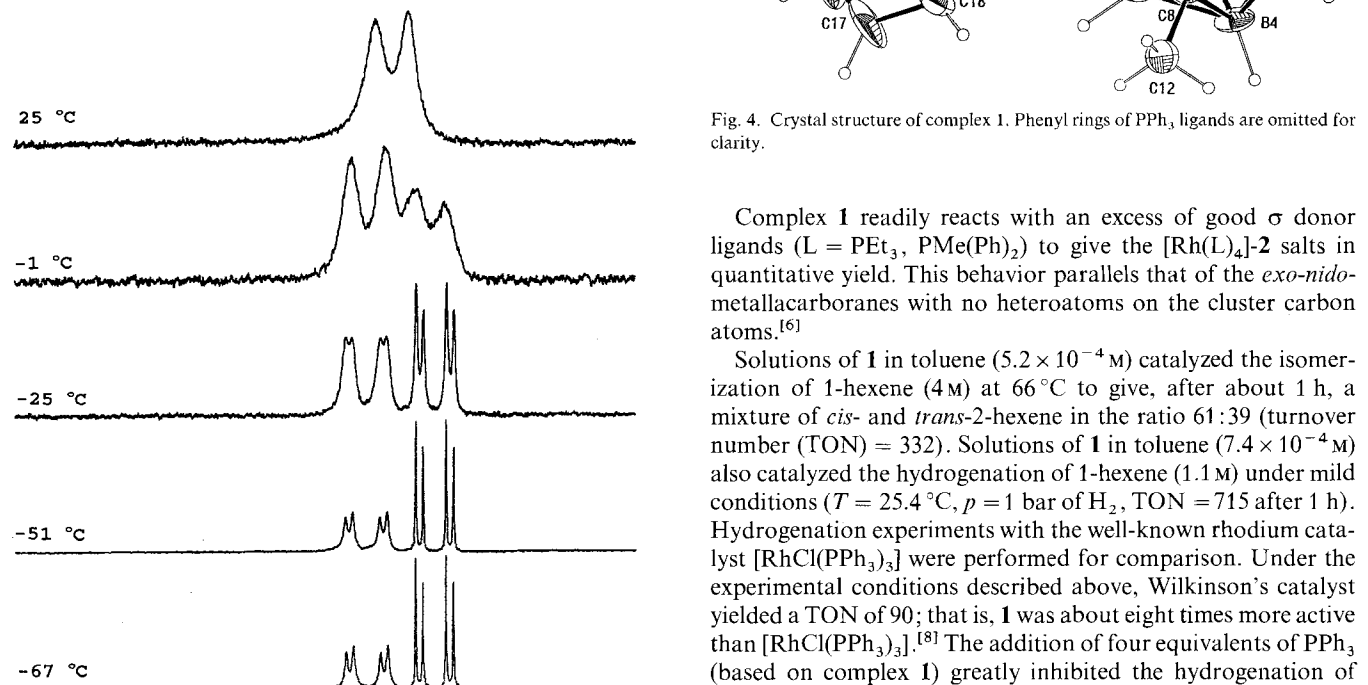

Fig. 3. Variable temperature $^{31}P\{^1H\}$ NMR spectra of complex **1** in CD_2Cl_2.

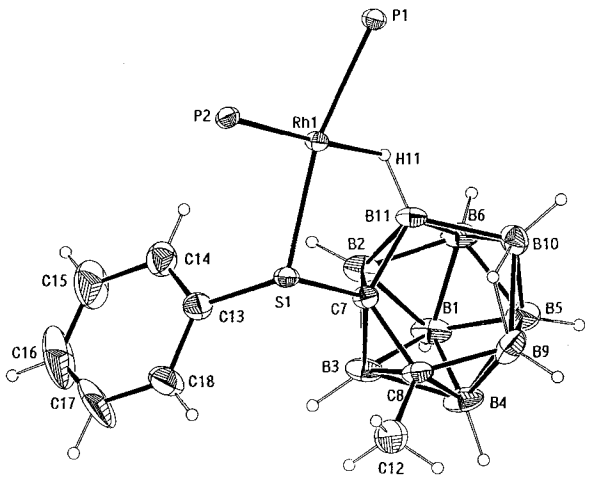

Fig. 4. Crystal structure of complex **1**. Phenyl rings of PPh_3 ligands are omitted for clarity.

Complex **1** readily reacts with an excess of good σ donor ligands (L = PEt_3, $PMe(Ph)_2$) to give the $[Rh(L)_4]$-**2** salts in quantitative yield. This behavior parallels that of the *exo-nido*-metallacarboranes with no heteroatoms on the cluster carbon atoms.[6]

Solutions of **1** in toluene (5.2×10^{-4} M) catalyzed the isomerization of 1-hexene (4 M) at 66 °C to give, after about 1 h, a mixture of *cis*- and *trans*-2-hexene in the ratio 61:39 (turnover number (TON) = 332). Solutions of **1** in toluene (7.4×10^{-4} M) also catalyzed the hydrogenation of 1-hexene (1.1 M) under mild conditions ($T = 25.4$ °C, $p = 1$ bar of H_2, TON = 715 after 1 h). Hydrogenation experiments with the well-known rhodium catalyst $[RhCl(PPh_3)_3]$ were performed for comparison. Under the experimental conditions described above, Wilkinson's catalyst yielded a TON of 90; that is, **1** was about eight times more active than $[RhCl(PPh_3)_3]$.[8] The addition of four equivalents of PPh_3 (based on complex **1**) greatly inhibited the hydrogenation of 1-hexene, which is a common feature in phosphane-containing catalysts. Hydrogenation of internal alkenes (e.g. cyclohexene) with complex **1** proceeded much more slowly than that of terminal ones.

Complex **1** could be recovered quantitatively upon completion of the catalytic reactions as shown by $^1H\{^{11}B\}$, $^{11}B\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectroscopy. Lifetime studies at high pressure in THF ([**1**] = 2.1×10^{-4} M, [1-hexene] = 7.6 M, $p = 45$ bar,

$T = 25\,^{\circ}C$, $t = 3.5$ h) also showed that complex **1** is able to perform more than 36000 turnovers[9] (yield 99.9%) without loss of activity.

In order to rule out the participation in the catalysis of free, solvated $[Rh(PPh_3)_2]^+$ or similar cationic species formed by dissociation of complex **1**, two independent experiments were made. First, the addition of four equivalents of Cs-**2** did not alter the rate of reaction, which suggests that the common ion effect is absent. Second, hydrogenation experiments with added D_2O provided further evidence to eliminate this hypothesis. If $[Rh(PPh_3)_2]^+$ or a related species were present, partially deuterated hexane would be found.[10] By GC-MS analysis it was shown that the hexane formed in the reaction was not deuterium-enriched.

The first *exo*-monothiocarborane rhodium complex has been synthesized, and it catalyzed the hydrogenation of 1-hexene eight times faster than Wilkinson's catalyst. The thioether group directly bonded to the cluster's open face enables discrimination between upper and lower belt B–H groups, leading to the formation of a B(11)–H–Rh bond. This supports the initial hypothesis that the favoring of an *exo-nido* upper-belt form would readily enhance the hydrogenation activity of a rhodacarborane molecule.

Experimental Procedure

1: $[RhCl(PPh_3)_3]$ (203 mg, 0.22 mmol) was added to a solution of Cs[7-SPh-8-Me-7,8-$C_2B_9H_{10}$] (90 mg, 0.23 mmol) in toluene/ethanol (8/1, 28 mL) under N_2 atmosphere. The solution was stirred at room temperature for 18 h until a red precipitate formed. THF was added until the red solid dissolved to give an orange solution and a white precipitate of CsCl, which was removed by filtration through Celite. The orange filtrate was concentrated in vacuo to 5 mL, and ethanol (20 mL) was added. The resulting red solid was isolated by filtration, washed with ethanol (2 × 5 mL) and ether (2 × 5 mL), and dried in vacuo. Yield: 176 mg (91%). If a lower volume of toluene is used in the synthesis, the product precipitates as an orange solid which, upon stirring, is slowly converted into the red crystalline form. IR(KBr): $\tilde{\nu} = 2527$ (s, BH), 2112 cm^{-1} (B–H–Rh); $^1H\{^{11}B\}$ NMR (300 MHz, CD_2Cl_2, 25 °C, TMS): $\delta = 7.66-7.11$ (m, 35H, aryl), 2.3–0.1 (br, BH), 1.48 (s, 3H, CH_3), −2.69 (br, 1H, BHB), −4.55 (br, 1H, BHRh); $^1H\{^{11}B\}$ NMR (300 MHz, CD_2Cl_2, −94 °C, TMS): $\delta = -4.84$ (br, 1H, B–H–Rh); $^{11}B\{^1H\}$ NMR (96.3 MHz, CD_2Cl_2, 25 °C, $Et_2O{\cdot}BF_3$): $\delta = -6.1$(1B), −9.2(2B), −12.2(1B), −16.5(1B), −21.0(1B), −22.9(1B), −27.4(1B), −34.3(1B); $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2, 25 °C, 85% H_3PO_4): $\delta = 42.8$ (br d, $^1J(Rh,P) = 176$ Hz); $^{31}P\{^1H\}$ NMR (121.5 MHz, CD_2Cl_2, −94 C, 85% H_3PO_4): $\delta = 41.2$ (dd, $^1J(Rh,P) = 165$ Hz, $^2J(P,P) = 40$ Hz), 44.0 ($^1J(Rh,P) = 187$ Hz, $^2J(P,P) = 40$ Hz). Elemental analysis for $C_{45}H_{48}B_9P_2SRh$: calcd: C 61.20, H 5.48, S 3.60; found: C 61.15, H 5.44, S 3.07.

Bimetallic Hydroformylation Catalysis: In Situ Characterization of a Dinuclear Rhodium(II) Dihydrido Complex with the Largest Rh–H NMR Coupling Constant**

Rhonda C. Matthews, Donna K. Howell, Wei-Jun Peng, Spencer G. Train, W. Dale Treleaven, and George G. Stanley*

The ability of two or more metal centers to cooperate in heterogeneous catalytic reactions is quite common and well established.[1] Bi- or polymetallic cooperativity in homogeneous catalysis, however, is much rarer and far less well understood.[2] Perhaps the most dramatic example of bimetallic cooperativity in homogeneous catalysis is the homobimetallic rhodium complex *rac*-$[Rh_2(nbd)_2(et,ph\text{-}P4)](BF_4)_2$ **1** (nbd = norbornadiene; et,ph-P4 = $(Et_2PCH_2CH_2)P(Ph)CH_2P(Ph)CH_2CH_2PEt_2$), which is a precursor for a highly active and regioselective catalyst for the hydroformylation of 1-alkenes.[3, 4] The originally proposed mechanism for this novel catalyst started with the neutral Rh^I carbonyl hydrido bimetallic complex *rac*-$[Rh_2H_2(CO)_2(et,ph\text{-}P4)]$,[3] in direct analogy with monometallic hydroformylation catalysts that have the generic formula $[RhH(CO)(P_2)]$ (P_2 = two monodentate or one chelating bis(phosphane) ligand).[5] Further reaction and spectroscopic studies have demonstrated, however, that the neutral bimetallic complex *rac*-$[Rh_2H_2(CO)_2(et,ph\text{-}P4)]$ is actually a very poor hydroformylation catalyst.[6] We report here the results of in situ spectroscopic studies that demonstrate that the active catalyst is actually the highly unusual dicationic bimetallic Rh^{II} complex *rac*-$[Rh_2H_2(\mu\text{-}CO)_2(CO)_2(et,ph\text{-}P4)](BF_4)_2$.

In situ FT-IR studies were carried out using complex **1** and *rac*-$[Rh_2(CO)_4(et,ph\text{-}P4)](BF_4)_2$ (**2**-$(BF_4)_2$), which generate the

same catalytically active species and give identical spectroscopic results (Fig. 1). The FT-IR spectra of **2**-$(BF_4)_2$ under CO (1 bar, 22 °C) is shown in Figure 1a. The $\tilde{\nu}_{CO}$ IR bands for **2**-$(BF_4)_2$ (2058 and 2006 cm^{-1}) compare well to those of other known $[Rh(CO)_2(P_2)]^+$ complexes (P_2 = chelating phosphane).[7] The ^{31}P NMR spectrum of **2**-$(BF_4)_2$ is also consistent with the proposed chelated symmetrical structure.

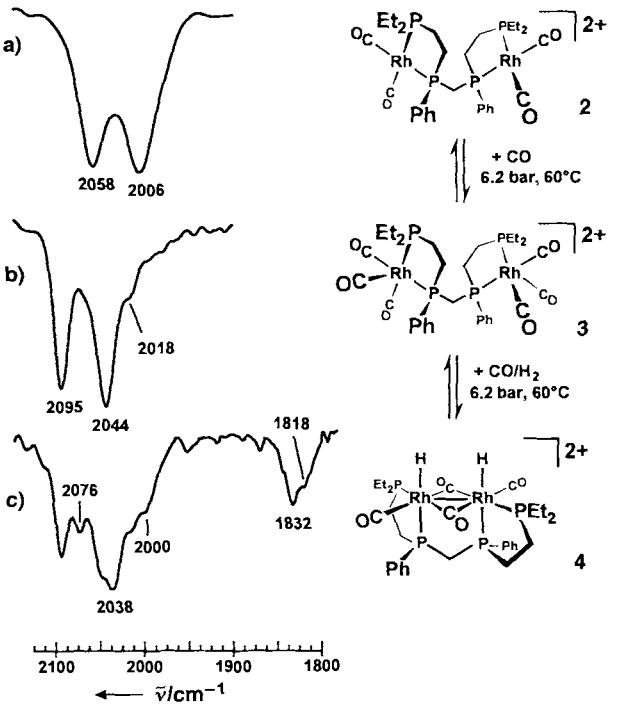

Fig. 1. In situ FT-IR spectra in acetone of a) *rac*-$[Rh_2(CO)_4(et,ph\text{-}P4)]^{2+}$ (**2**) (22 °C, 1 bar CO); b) *rac*-$[Rh_2(CO)_6(et,ph\text{-}P4)]^{2+}$ (**3**) formed when **2** is placed under 6.2 bar of CO at 60 °C; c) **3** under 6.2 bar of H_2/CO at 60 °C. Spectrum c) is a roughly equal mixture of **3** and **4**. There are also several other currently uncharacterized minor components, probably Rh^I and Rh^{III} bimetallic hydrido carbonyl complexes.

The reaction of **2** with excess CO produces the bimetallic hexacarbonyl complex *rac*-$[Rh_2(CO)_6(et,ph\text{-}P4)]^{2+}$ **3** (Fig. 1b). The addition of one additional carbonyl ligand to each rhodium center in the conversion of **2** → **3** leads to the expected shift to higher energies (by 37 cm^{-1}) for the carbonyl bands. Studies with different CO pressures indicate that **3** is stable under about 3.1 bar of CO; lower CO pressures result in CO loss and a shift back to **2**. ^{31}P NMR studies support the proposed symmetrical chelated structure and confirm a very facile equilibrium between **2** and **3** that is dependent on CO pressure.

Placing **2** under H_2/CO (4.1–13.8 bar, 20–90 °C) generates a new equilibrium mixture that contains the hexacarbonyl bimetallic complex **3** and several new hydrido species as indicated by ^1H, ^{31}P NMR, and FT-IR spectroscopy. D_2/CO studies demonstrate that all major IR bands in the region between 2200 and 1700 cm^{-1} (Fig. 1c) are due to carbonyl ligands; Rh-H/D bands are either very weak or not present. Most notable in the FT-IR spectrum is the presence of relatively intense bridging CO bands at 1832 and 1818 cm^{-1}.[8]

The in situ ^1H and $^{31}P\{^1H\}$ NMR spectra of **1** and **2**-$(BF_4)_2$ under H_2/CO (13.8 bar) at 22 °C clearly demonstrate that mainly complex **3** (92%) is present; in addition there are at least four metal carbonyl hydrido complexes, two of which are in dynamic exchange and have broad ^1H (δ = −9.8, −11.6) and ^{31}P resonances (δ = 66, 74), while the other two have relatively static (slow exchange) and well-defined ^1H NMR peaks (δ = −9.0, (dq), −18.5 (pseudo-decet). On increasing the temperature, the hydrido complex with the signal at δ = −9.0 becomes dominant (≈ 80% of the observable hydrido complexes at 90 °C) and has a simple ^{31}P and ^1H NMR spectrum, indicating a symmetrical bimetallic structure. The region of the ^1H NMR spectrum in which the hydride hydrogen atoms for this complex appear is given in Figure 2a. The ^1H and ^{31}P NMR, as well as the IR spectra do not change (apart from that the concentration of alkene decreases and that of the aldehyde product increases) on addition of 1-hexene and initiation of hydroformylation catalysis, indicating that the rate-determining step is the loss of CO and/or addition of alkene to the catalyst.

We propose the dicationic complex *rac*-$[Rh_2H_2(\mu\text{-}CO)_2(CO)_2(et,ph\text{-}P4)]^{2+}$ **4** as the active catalyst. This is an 18-electron Rh^{II} complex with a Rh–Rh bond and an edge-sharing bioctahedral structure. While there are many examples of dinuclear Rh^{II} compounds with a metal–metal bond,[9] edge-sharing bioctahedral structures are extremely rare. Theoretical studies have predicted that d^7–d^7 bioctahedral dimers with acceptor bridging ligands should have a M–M bond.[10]

The two dinuclear Rh^{II} complexes most closely related to **4** are $[Rh_2(\mu\text{-}CO)(\mu\text{-}Cl)Cl_2(dppm)_2(MeOH)]^+$ (dppm = bis(diphenylphosphano)methane), which has been structurally characterized and needs one additional terminal ligand to achieve a full edge-sharing bioctahedral coordination geometry,[11] and $[Rh_2H_2(\mu\text{-}H)_2(tripod)_2]$ (tripod = $MeC(CH_2PPh_2)_3$) that has been proposed to have a full edge-sharing bioctahedral structure, but for which there is scant spectroscopic or structural data.[12] There are also several examples of Rh^{II} complexes with one or three bridging hydrido ligands.[13] $[Rh_2(\mu\text{-}H)_3(H)(PR_3)_4]$ (R = O*i*Pr, *i*Pr) complexes have also been characterized, but both have been assigned as mixed-valent Rh^I/Rh^{III} compounds.[14] However, none of these Rh^{II} hydrido complexes have been demonstrated to be highly efficient hydroformylation catalysts like **4**.

The hydride coupling constants for the doublet of pseudo-quartets (Fig. 2a) have been determined by ^{31}P-decoupled ^1H NMR spectroscopy (Fig. 2b). The large coupling constant

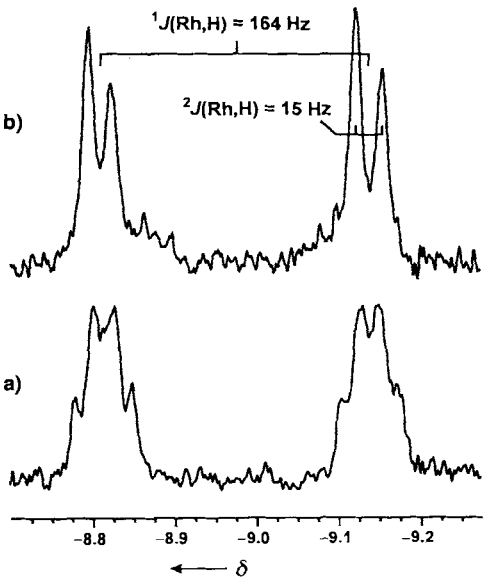

Fig. 2. a) Hydrido region of the in situ 500 MHz ^1H NMR spectrum of **4** (13.8 bar H_2/CO, 22 °C); b) broadband phosphorus-decoupled $^1H\{^{31}P\}$ NMR spectrum of **4** under the same conditions.

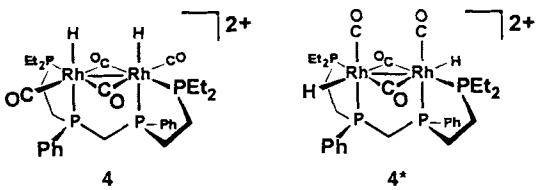
 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2254 $ 15.00+.25/0

of 164 Hz is *not* caused by *trans* ^2J(P,H) coupling, as seen in virtually all other H-Rh^{I}Rh^{III}-P complexes, but rather, is due to ^1J(Rh,H) coupling![15] There are hundreds of rhodium hydrido complexes known and their ^1J(Rh,H) coupling constants are typically small and vary from almost 0 to 50.8 Hz.[16] The ^1J(Rh,H) coupling constant of **4** (164 Hz), therefore, is by far the largest value ever seen. Large ^1J(Rh,H) coupling constants may be a distinctive feature of bimetallic Rh^{II} complexes with terminal hydrido ligands, though further examples are clearly needed to confirm this idea.

The pseudo-quartet arises from roughly equal *cis*- and *trans*-^2J(P,H) as well as ^2J(Rh,H) coupling constants of about 15 Hz. While *cis*-^2J(P,H) and ^2J(Rh,H) coupling values of 15 Hz are reasonable, this value might appear to be too small for a *trans*-^2J(P,H) coupling constant. This is an important point for elucidatng the exact structure of **4**. While there can be little doubt about the overall symmetric geometry, or the arrangement of the phosphane and bridging carbonyl ligands, the exact placement of the terminal carbonyl and hydrido ligands can be questioned. The essentially equal ^2J(P,H) coupling constants could, therefore, indicate that the hydrido ligand should be *cis* to both of the phosphane groups, placing the terminal carbonyl ligand *trans* to the internal phosphane group of the et,ph-P4 ligand (**4***).



4 **4***

A number of arguments provide strong support for the proposed structure of **4**. While *trans*-^2J(P,H) coupling constants in Rh^{I}Rh^{III} complexes are virtually always large,[17] the extraordinarily strong ^1J(Rh,H) coupling present in this dinuclear Rh^{II} hydrido complex could be attenuating the normal *trans*-^2J(P,H) interaction. In normal lantern-type dinuclear Rh^{II} compounds (e.g., $[Rh_2(O_2CR)_4]$) the ligands in axial sites *trans* to the Rh–Rh single bond are relatively labile.[9] When this D_{4h}-symmetric structure is transformed to an edge-sharing bioctahedral structure, the labile character of the axial ligands seems to be retained. In both $[Rh_2(\mu\text{-CO})(\mu\text{-Cl})Cl_2(dppm)_2(MeOH)]^+$ and $[Rh_2(\mu\text{-H})(\mu\text{-Cl})Cl_3(dppm)_2]$ one of these "axial" sites is empty.[11a, 13a] In our structural assignment for **4** we are placing the more labile CO ligands in these more weakly binding "axial" sites. It is unlikely that strongly binding hydrido ligands would occupy these positions.

Further evidence for the proposed structure of **4** comes from nuclear Overhauser effect (NOE) ^{1}H NMR experiments. Molecular modeling studies on **4** indicate that the *ortho*-hydrogen atoms on the phenyl ring are 4.4 to 5.1 Å from the hydrido ligand; for **4*** they are considerably closer (2.3–3.0 Å). The NOE ^{1}H NMR experiments on the catalyst solution demonstrate only a weak interaction between the hydrido ligands ($\delta = -9.0$) and the *ortho*-hydrogen atoms, which fits well with the expected contact distance of 4.4–5.1 Å. Finally, we know that **4** readily reductively eliminates H_2, but this should be more difficult for **4*** where one has a *trans*-like separation of the hydrido ligands.

The dicationic charge and the Rh^{II} oxidation state offer an excellent explanation for the remarkable hydroformylation activity and regioselectivity of **4**. There are no other examples of active and highly regioselective monometallic hydroformylation catalysts that have mainly alkylated, strongly donating phosphane ligands (like et,ph-P4). The reason for this is well understood. The presence of two electron-donating alkylated phosphane ligands increases the electron density on the rhodium center leading to increased π-backdonation and stronger Rh–CO bonding. This stabilizes the unreactive five-coordinate 18-electron complexes $[RhH(CO)_2(P_2)]$ and $[Rh(acyl)(CO)_2(P_2)]$ (P_2 = two monodentate or one chelating bisphosphane). Facile CO (or phosphane) dissociation is needed to generate the reactive four-coordinate 16-electron complexes needed to allow coordination of alkene or H_2 to start and/or to finish the hydroformylation catalytic cycle. The fact that **4** is a dication and the rhodium centers are in the +II oxidation state compensates for the strongly donating et,ph-P4 ligand. This makes the terminal CO ligands labile enough to allow good catalytic activity.

The high aldehyde regioselectivity of this catalyst (linear:branched = 28:1 for 1-hexene)[3] is a result of the rigid dinuclear structure of **4** and the favorable steric effects at the et,ph-P4 ligand. When an alkene coordinates to a typical monometallic square-planar rhodium hydroformylation catalyst, the other ligands bend away to form a trigonal bipyramid (or square pyramid), which is the least congested coordination geometry. This geometric reorganization results from electronic orbital rehybridization on the metal center and causes the steric directing groups on the phosphane ligands to swing away from the incoming alkene substrate. This, in turn, reduces the steric effectiveness of the phosphane ligand for orienting the alkene to insert properly into the Rh–H bond to give the desired linear alkyl intermediate species.

The catalyst **4**, however, cannot be distorted in this way on alkene coordination because the Rh–Rh bond and bridging carbonyl ligands prevent any significant movement of the ligand environment away from the alkene. Minimizing the geometric reorganization about the rhodium center maximizes the steric effect of the et,ph-P4 ligand, directing the alkene insertion into the M–H bond to form a linear alkyl group, which goes on to form the linear aldehyde. In agreement with our original proposed mechanism,[3] we still believe that an intramolecular hydride transfer plays a key role at the end of the catalytic cycle to reductively eliminate the aldehyde product and regenerate the Rh^{I} bimetallic complex **3** (or **2**).

Experimental Procedure

All synthetic procedures were carried out under an inert atmosphere with Schlenk techniques or glove boxes. FT-IR spectra were recorded on a Perkin-Elmer 1760 instrument using GRAMS/386 data collection and processing software (Galactic Software), and the NMR spectra were collected on Bruker ARX-300 or AMX-500 instruments.

2-$(BF_4)_2$: $HBF_4 \cdot OEt_2$ (0.81 g, 5.0 mmol) was added to a solution of $[Rh(acac)(CO)_2]$ (1.29 g, 5.0 mmol; acac = acetyl acetonate) in CH_2Cl_2 (30 mL) and stirred. Then *rac*-et,ph-P4 (1.16 g, 2.5 mmol in 5 mL of CH_2Cl_2) was added, which led to a red solution. The volume was reduced to about 10 mL by vacuum evaporation. CO gas was then bubbled through the solution for 5 min. The concentrated solution was then added dropwise to diethyl ether (100 mL) and stirred. The resulting red solution and precipitate were cooled to −32 °C, which afforded a red powder. Yield: 2.1 g, 90%. IR (acetone, 1 bar of CO): $\tilde{\nu}_{CO}$ = 2058 (vs), 2006 (vs) cm^{-1}; $^{31}P\{^1H\}$ NMR (124 MHz, [D$_6$]acetone, 1 bar CO, H_3PO_4): δ = 69.9 (dd, ^1J(Rh,P) = 112, ^2J(P,P) = 25 Hz, terminal P atoms), 53.5 (dd, ^1J(Rh,P) = 127, ^2J(P,P) = 25 Hz, internal P atoms). Anal. calcd for $C_{29}H_{40}P_4Rh_2B_2F_8O_4$ (M_r = 955.95): C 36.43, H 4.22; found: C 36.51, H 4.22.

3-$(BF_4)_2$: IR (acetone, 6.2 bar CO, 60 °C): $\tilde{\nu}_{CO}$ = 2095 (vs), 2044 (vs) cm^{-1}; $^{31}P\{^1H\}$ NMR (124 MHz, CD_2Cl_2, 6.9–13.8 bar CO, 22 °C, H_3PO_4): δ = 70.2 (dd, ^1J(Rh,P) = 107, ^2J(P,P) = 26.5 Hz, terminal P atoms), 59.2 (d, ^1J(Rh,P) = 117.8 Hz, internal P atoms).

4-$(BF_4)_2$: IR (acetone, 6.2 bar H_2/CO, 60 °C): $\tilde{\nu}_{CO}$ = 2095 (s), 2076 (m), 2044 (sh), 2038 (vs), 2018 (sh), 2000 (sh), 1832 (m), 1818 (m) cm^{-1}; ^{1}H NMR (500 MHz, CD_2Cl_2, 6.9–13.8 bar H_2/CO, 22 °C, TMS): δ = −9.0 (dq, ^1J(Rh,H) = 164, ^2J(Rh,H) = 15, ^2J(P,H) = 15 Hz); $^{31}P\{^1H\}$ NMR (124 MHz, CD_2Cl_2, 13.8 bar H_2/

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2255 $ 15.00+.25/0

CO, 22 °C, H_3PO_4): $\delta = 72.5$ (d, $^1J(Rh,P) = 158$ Hz, terminal P atoms), 60.8 (d, $^1J(Rh,P) = 158$ Hz, internal P atoms).

In situ FT-IR studies: A SpectraTech external sample bench was attached to the spectrometer equipped with a SpectraTech circle reaction cell (CRC) using a ZnSe crystal rod. Instrument parameters: 25 scans, resolution 4 cm^{-1}, scan speed 1.0 $cm\,s^{-1}$, scan range 4000–800 cm^{-1} (for data collection range narrowed to 2500–1400 cm^{-1}). Under these conditions we get an energy reading of 18000 to 20000 counts through the empty CRC cell; concentration of the catalyst precursor (**1** or **2**): 30–40 mM (in acetone).

In situ NMR studies: A high-pressure 5 mm NMR tube (Wilmad model 524-PV-6) with a Teflon valve was used for studying the catalyst solutions. The threads of valve were wrapped with Teflon tape to make better seals and minimize the chance of the valve being blown out of the tube. Due to the small gas volume in the NMR tube, the slow gas diffusion and reaction, and the high concentration (30–120 mM) of catalyst precursor present (**1** or **2**), the tube was shaken reasonably vigorously for at least 30–60 minutes while the tube was open to the H_2/CO gas mixture. Compound **1** is only moderately soluble in acetone giving a maximum concentration at room temperature of ≈30–40 mM; **1** is very soluble in CD_2Cl_2 giving a maximum concentration of ≈ 140 mM, but there is a considerably lower equilibrium concentration of the catalytically active complex **4** present in this solvent at room temperature.

[15] This coupling has been confirmed at a variety of different ^1H NMR frequencies (250, 300, 400, and 500 MHz), different temperatures (− 20 to +60 °C), and by both broadband and selective ^{31}P decoupling experiments. We have not, as yet, been able to perform a ^{103}Rh-decoupled ^1H NMR experiment.

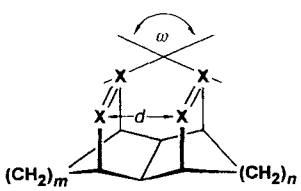
Proximate, Synperiplanar Diazene/Diazene Substrates: N=N/N=NO and ON=N/N=NO Photometathesis Reactions**

Kai Exner, Dirk Hochstrate, Manfred Keller, Frank-Gerrit Klärner, and Horst Prinzbach*

Dedicated to Professor Michael Hanack on the occasion of his 65th birthday

Studies of transannular π,π-interactions in neutral systems[1] (through-space vs. through-bond conjugation, σ-homoaromaticity, [2 + 2] photocycloaddition) as well as in four-center–three-electron (4c/3e) radical cations and 4c/2e dications[2] have greatly profited from homoconjugated bichromophores with the rigid skeleton **A**: At nearly synperiplanar orientation of the chromophores—benzo/ene, benzo/benzo,[3] ene/diazene,[4–6] benzo/diazene[7, 8]—the transannular distance *d* and interorbital angle ω were gradually modified. Investigations with bisdiazenes of this type (**A**, X = N) are scarce for the simple reason that such substrates are hardly accessible.[9–11] For the [2 + 2] photocycloaddition, particularly under stereoelectronic (*d*, ω) and energetic aspects ($\Delta\Delta H_f^\circ$), calculations (Table 1)[12]



A

Table 1. Calculated geometric [a] and energetic [a,b] data for bisdiazenes (dienes) of type **A** [X = N (CH)].

	$A_{2,2}$	$A_{1,2}$	$A_{1,1}$
d [Å]	2.93 (2.89)	2.87 (2.83)	2.83 (2.79)
ω [°]	166.3 (167.6)	171.5 (172.3)	176.4 (176.5)
$\Delta\Delta H_f^\circ$	108 (− 13.7)	88 (− 22.2)	70 (− 29.5)

[a] Data for X = N calculated by AM1, for X = CH by MM2. [b] Reaction enthalpies for the [2 + 2] cycloadditions [kcal mol^{-1}].

make the homologs with $m = n = 1$ ($A_{1,1}$) the "first choice", followed by those with $m = 1$, $n = 2$ ($A_{1,2}$) and $m = n = 2$ ($A_{2,2}$). This assessment, however, holds only if N_2 elimination, particularly in the diazabicyclo[2.2.1]heptene (DBH) subunit

DBH

$\Phi(-N_2) = 1.00$
$\lambda(\varepsilon) = 341$ nm (420)
IP = 8.96 eV

DBO

$\Phi(-N_2) = 0.02$
$\lambda(\varepsilon) = 378$ nm (187)
IP = 8.32 eV

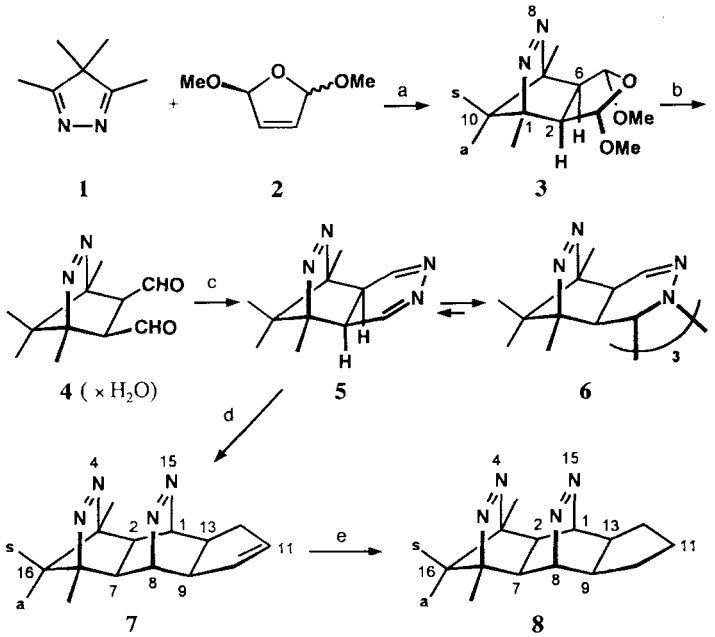
[**] Photochemical Transformations, Part 80. This work was supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the BASF AG. K. E. thanks the Studienstiftung des deutschen Volkes for a stipend and Dr. N. Bahr for stimulating discussions. We thank Prof. Dr. G. Seitz for generous support [16], Dr. D. Hunkler for NMR, and Dr. J. Wörth for MS measurements. Part 79: ref. [3a].

(cf. diazabicyclo[2.2.2]octene (DBO)[13]), does not proceed much faster than the cycloaddition.[14] Indeed, for some $\mathbf{A}_{1,1}$-, $\mathbf{A}_{1,2}$-, and $\mathbf{A}_{2,2}$-ene/diazene and -benzo/diazene systems, [2+2] cycloaddition dominates.[6, 8]

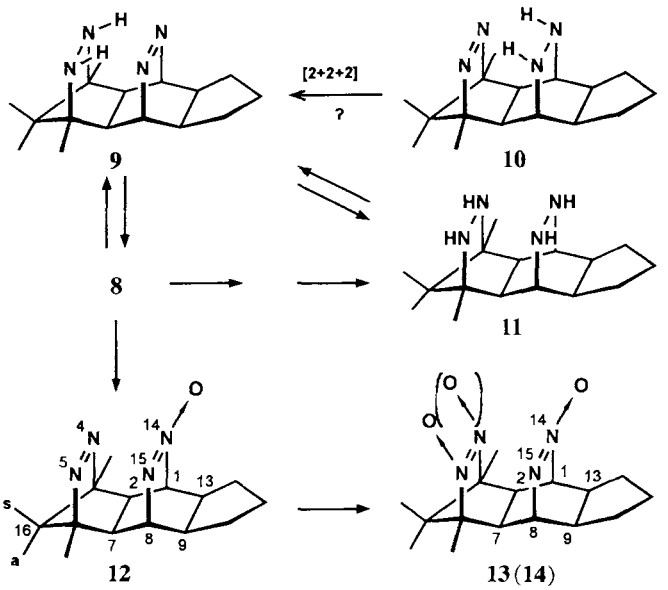
So far, only $\mathbf{A}_{2,2}$-bisdiazenes ("third choice") were available for studies.[9] Herein we present the synthesis, X-ray structural data, and photochemical results on $\mathbf{A}_{1,2}$-bisdiazenes ("second choice").[15]

The synthesis (Scheme 1) starts with the cycloaddition of tetramethyl-4*H*-pyrazole (**1**)[4] and a mixture of 2,5-dimethoxy-2,5-dihydrofurans (**2**). After attempts to perform the reaction at temperatures up to 150 °C by using microwave irradiation



Scheme 1. a) 10 kbar, 110 °C, 3 d, 74%; b) 0.22% H_2SO_4, reflux, 10 min; c) extraction with CH_2Cl_2, K_2CO_3, N_2H_4 anhydrous (10 equiv), 95–98%; d) cyclopentadiene, CH_2Cl_2, CF_3COOH (1.0 equiv based on **5**), 4 °C, 18 h, 48–52% based on **3**; e) MeOH, Pd/C (10%), 1 atm H_2, 90%.

(700 W, 3 min, decomposition) and by standard activation with trifluoroacetic acid (TFA) or lithium perchlorate had failed (decomposition of **2**),[16] high pressure was applied (10.0 kbar, 115 °C, 3 d, toluene, strict absence of any acid traces).[17] The C_s-symmetric *1*:*1* adduct **3** was obtained as the single product (*trans*-**2** was not converted) in 74% yield (gram scale) after chromatographic workup [m.p. 94 °C; λ_{max} (ε) (CH_3CN) = 197 (1335), 358 nm (195); *endo* addition confirmed by NOE experiments]. After acid-catalyzed hydrolysis of **3** in aqueous solution, the dialdehyde **4** was treated (without isolation) with hydrazine to provide the dihydropyridazine **5** nearly quantitatively in the form of its trimer **6** (stereoisomers, ^{1}H NMR).[4, 5] From the acid-catalyzed addition of cyclopentadiene[4] to **5**, only (TLC, ^{1}H NMR) the desired *exo*-1:1 adduct **7** was secured [48–52% based on **3**; yellowish plates, m.p. 273 °C (decomp.); NOEs between 16-Me_a/2-H/7-H and 2-H/7-H/9-H/13-H; λ_{max}(ε) (CH_3CN) = 213 (3140), 233 (1785), 367 nm (433)]. Catalytic hydrogenation of the C–C double bond in **7** gave **8** together with hydrazines **9** and **11** (see Scheme 2); after reoxidation of the latter (by bubbling air through the solution in the presence of a palladium catalyst) **8** was isolated by chromatography in 90% yield.[15] The n → π* band for **7** and **8** at about 370 nm can be considered as a superposition of the [2.2.1]/[2.2.2] absorp-



Scheme 2. Reactions with **8**.

tions at 358 and 384 nm. The bisdiazenes **7** and **8** remained unaltered in boiling benzene for a longer period of time (5–7 h). The catalytic hydrogenation of **8** to the bishydrazine **11** (Pt, MeOH, 1 atm H_2, room temperature) presumably started with the more strained N4–N5 double bond to give **9** as the sole detectable monohydrazine; dehydrogenation of **11** upon exposure to air occurred faster at the NH14–NH15 unit to produce **9** as an intermediate on the way to **8** (there is interest in **10** as a substrate for the as yet unknown dyotropic HNNH/N=N hydrogen transfer). Dimethyl dioxirane (DMDO, CH_2Cl_2, room temperature) neatly differentiated the two N–N double bonds of **8** to give only (TLC, ^{1}H NMR) the N14-oxide **12** [colorless crystals, m.p. 265 °C (decomp.); 94%]. The distinction from the N4-oxide is primarily based on the influence of the N–O bond on the 1-H(C) chemical shifts (e.g. $\delta_{C-1/C-8}$ = 64.2 in **8** and 74.0/58.1 in **12**); the 16s(16a)-CH_3 shifts (δ = 0.47 (0.83)) are only slightly influenced; the mass spectrum [chemical ionization (CI) with NH_3] exhibits a relatively intensive peak for the pyrazole **1**. In the UV spectrum (CH_3CN) the distinct N=NO(π,π*) maximum at 246 nm [ε = 3580; n,π*: 367 nm (370)] suggests a transannular N=N/N=NO interaction (cf. the maximum at 230 nm for an "undisturbed" [2.2.2]-N=NO chromophore, like that of DBO oxide[18, 19]).[20] Further oxidation of **12** with DMDO led to the dioxides *anti*-**13** and *syn*-**14** as a nonseparable mixture (ca. 3.9:1) [colorless crystals, λ_{max}(ε) (CH_3CN) = 228 nm (9920)]. Their differentiation on the basis of the spectral data is not unequivocal, and rests on analogy[7, 9] and on the typically divergent photochemical behavior.

Crystals of **8** suitable for X-ray analysis were obtained by diffusion of ether vapor into a solution of **8** in $CHCl_3$.[21] The four N atoms form a plane with a N_2/N_2 distance (*d*) of 2.822 Å and an interorbital angle (ω) of 174.2° (Fig. 1). The cyclopentane unit is disordered. The nonbonding distances given in Figure 1 as well as model considerations and AM1 calculations[22] suggest a considerable buttressing effect by the methyl groups (16s-, 16a-CH_3) and, to a minor extent, by the cyclopentane hydrogen atoms, which forces the N–N double bonds closer together. The transannular distance and interorbital angle are indeed "better" than that for the $\mathbf{A}_{2,2}$ analogue (2.88/2.82 Å, 168.6°).[7]

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2257 $ 15.00+.25/0

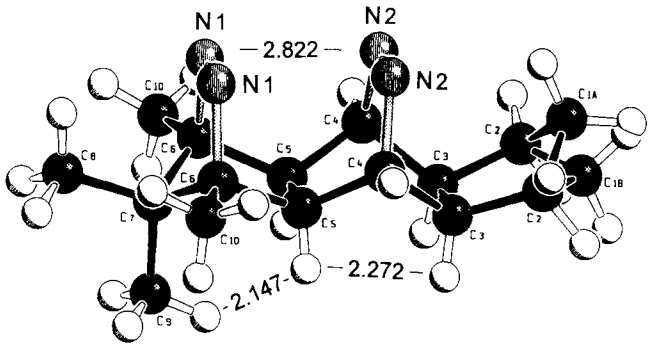


Fig. 1. Crystal structure of **8** (the numbering does not correspond to IUPAC-nomenclature).

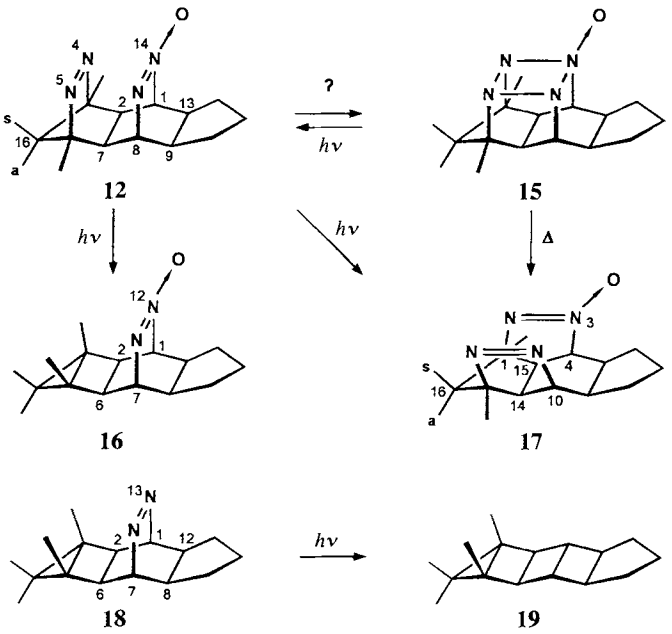
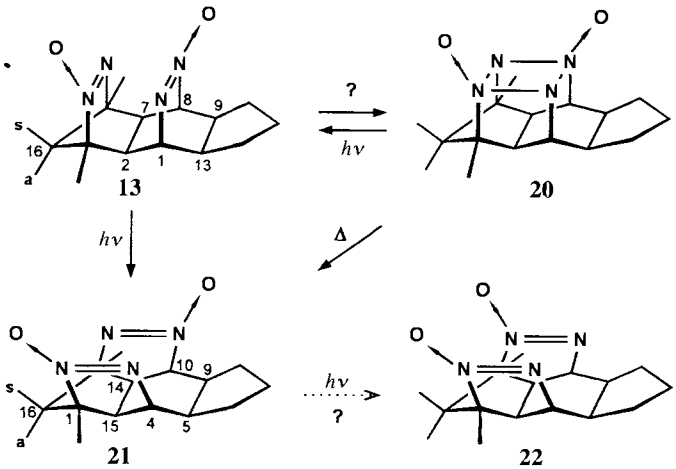
When **8** was exposed to various direct irradiation conditions between −78 °C and +30 °C (254 nm, Rayonet RUL 2537, daylight, $CHCl_3$, MeOH, or CH_3CN) only N_2 extrusion could be detected.[22] Analogous direct, monochromatic irradiation of monoxide **12** (254 nm, CH_3CN or MeOH) again caused, yet not exclusively, denitrogenation (Scheme 3): After about 75% conversion the product mixture contained, besides oligomeric material, **16** (49%), **18** (7%), possibly traces of **19**, and the metathesis isomer **17** (2–4%), which was characterized after enrichment by preparative TLC; the more flexible "open" skeleton of **17** [λ_{max} = 238 (π,π^*, NNO), 343 nm (n,π^*, NN)] is distinguished from that of **12** ($J_{1,2(7,8)} < 1.5$ Hz) for example by the $^1H,^1H$ coupling constants (**17**: $J_{4,15\ (10,14)} = 6.5-7.5$ Hz) and by the lack of peaks for [4 + 2] cycloreversion fragments in the mass spectrum.



Scheme 3. Reaction products of the monochromatic irradiation of **12**.

The picture changed significantly with the dioxides *anti*-**13**/*syn*-**14** (mixture) in that standard direct, monochromatic irradiation (254 nm, MeOH) gave rise to notable discrepancy in the rate of conversion and a high degree of metathesis; after about 50% conversion of *anti*-**13**—only 3% of *syn*-**14** was consumed—based on the conversion, 29–31% of the metathetical dioxide **21** and 1–2% of its isomer **22** (of unclear origin[23]) were present, together with other trace components and oligomeric material (in control experiments **21** was slowly decomposed) (Scheme 4). The UV spectra of **13** and **21** (purified by HPLC) are very similar; there are, as for the pair **12** and **17**, typical differences in the NMR and MS spectra (e.g. $J_{1,13} = J_{8,9} = 1.6$ Hz, $J_{1,2} = J_{7,8} = 1.6$ Hz vs. $J_{4,5} = J_{4,15} = 6.4$ Hz, $J_{9,10} = J_{10,14} = 6.3$ Hz; low-field shift of the CH_{3s}-C16 signal from $\delta = 0.74$ (**13**) to 1.43 (**21**); no retro [4 + 2] fragmentation pattern). When several experiments were carefully monitored between −78 °C and room temperature, no [2+2] photocycloadduct (**20**) nor any intermediate such as the [6+6] photocycloadduct could be seen.



Scheme 4. Reaction products of the monochromatic irradiation of **13**.

To conclude, in **8** (and **7**) the stereoelectronic and energetic prerequisites for a diazene/diazene [2+2] photocycloaddition are better than ever; nevertheless, denitrogenation remained the exclusive stabilization pathway. N-oxidation favors cycloaddition but has its price in product complexity and thermal lability of the resulting intermediate tetraazetidine oxides.[19, 24] Whether the latter can be directly observed or even isolated in low-temperature matrix experiments is currently under investigation. Doubts are justified whether the stereoelectronic advantages (Table 1) ascribed to "first choice" $\mathbf{A}_{1,1}$ skeletons—as nicely documented in the homologous benzo/benzo series **A** (X=X = C_6H_4[3])—will strongly favor N=N/N=N photocycloaddition over N_2 elimination.

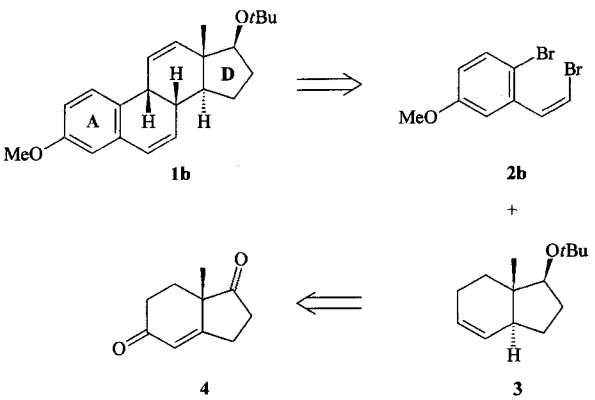
Stereoselective Synthesis of Steroids with the Heck Reaction**

Lutz F. Tietze,* Thomas Nöbel, and Maurus Spescha

Dedicated to Professor Michael Hanack on the occasion of his 65th birthday

Steroids present an attractive synthetic goal because of their biological activity and pharmacological applications. Despite the large number of known synthetic methods,[1] there is a continuous demand for new approaches that are short, generally applicable, and allow access to compounds with novel structures like **1b**. We now describe a new strategy based on the synthesis of the B-ring of the steroid structure by a double Heck reaction[2] between (*Z*)-(2-bromoethenyl)bromobenzene (**2b**) and the hexahydro-1*H*-indene derivative **3**,[3] which can be synthesized in a few steps from the ketone **4**[4] by an intramolecular Pd-catalyzed rearrangement of an allyl formate.[3] With this procedure the otherwise difficult *trans*-annelation of **3** is achieved in a stereoselective way.



Scheme 1. Retrosynthesis of **1b**.

Our initial investigations of the Heck reaction of **3** with iodobenzene (**5a**) using a catalytic amount of Pd^0 revealed that the bond formation at C-4 in **3** proceeds with high regio- and stereoselectivity in *anti*-position to the angular methyl group (Scheme 2).[5] Thus, the 4-phenyl derivatives **6a** and **7a** were

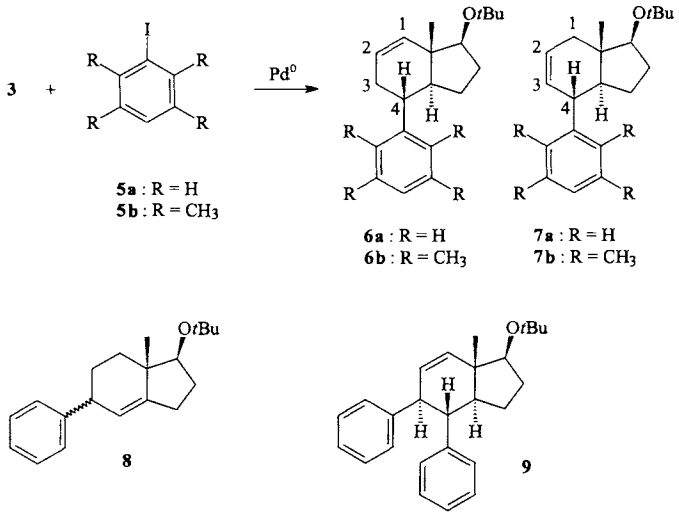
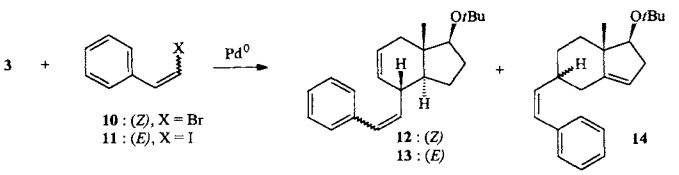
[**] This work was supported by the Deutsche Forschungsgemeinschaft (Sonderforschungsbereich 416) and the Fonds der Chemischen Industrie. We thank the Schering AG for providing a hydrindenone derivative.



Scheme 2. Heck reaction of **3** with **5**.

formed in 39% and 27% yield, respectively, and the regioisomer **8** was obtained in 16% yield;[6] at slightly elevated temperatures and in the presence of Ag_2CO_3, the diphenyl derivative **9** was also obtained (**6a**: 37%; **7a**: 26%; **8**: 8%; **9**: 4%).[7] Stereoisomers of **6** and **7** could not be identified. When the more sterically demanding 3-iodotetramethylbenzene **5b** were used in the Heck reaction with **3**, the C-4 arylated products **6b** and **7b** were formed exclusively in 90% yield and 1:1 ratio.[8] The primary products **7a** and **7b** presumably isomerize to **6a** and **6b**; the addition of silver salts[9] did not prevent the isomerization.[10]

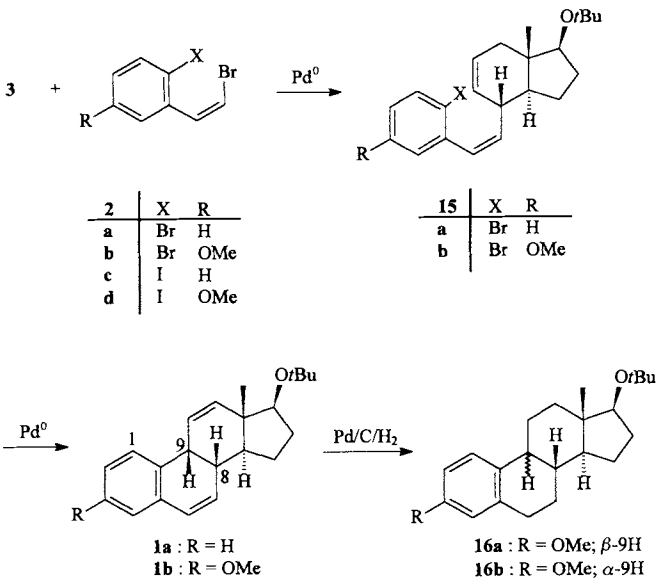
The construction of the steroid system required the introduction of two additional carbon atoms; therefore, the Heck reactions of **3** with (*Z*)-(2-bromoethenyl)benzene[11] (**10**) and (*E*)-(2-iodoethenyl)benzene[12] (**11**) were carried out; they exhibited high regio- and stereoselectivities similar to those obtained in the transformations with **5** (Scheme 3). At a conversion of about



Scheme 3. Heck reaction of **3** with **10** as well as **11**.

50%, **12** and **14** were obtained in 78% and 8% yield,[13] respectively, from the reaction of **3** and **10**, and **13** was isolated exclusively from **3** and **11** in a yield of 91%.[14] The (*Z*)-(2-bromoethenyl)bromobenzenes **2a** and **2b** as well as the (*Z*)-(2-bromoethenyl)iodobenzenes **2c** and **2d** were used for the synthesis of the estrone derivatives **1a** and **1b** (Scheme 4). Assuming that the haloethenyl substituent in **2** is more reactive than the haloarene, we expected a selective coupling to C-4 in **3**. However, the difference in reactivity in **2c** and **2d** proved to be insufficient; furthermore, in the presence of Ag_3PO_4,[15] an I/Br exchange occurred at the arene.

In contrast, the reactions of **3** with **2a** and **2b** proceeded in a highly selective fashion and resulted in the nearly exclusive formation of **15a** and **15b** in 66% and 50% yield, respectively.[16, 17] In each case 30% of **3** could be recovered. The subsequent cyclization of **15a** and **15b** under Heck reaction conditions afforded the estrone derivatives **1a** and **1b**[18] in 85% and 99% yield, respectively.[19, 20] The best results were obtained when the palladacycle recently described by Herrmann, Beller et al.[21] was used as the catalyst.



Scheme 4. Double Heck reaction of **3** with **2**.

The transformation can also be carried out as a domino reaction[22] without the isolation of **15a** and **15b**.[23] Hydrogenation of **1b** in the presence of Pd/C led to the estradiol derivatives **16a** and **16b** in 63% and 13% yield, respectively.[24]

The relative configuration of the stereogenic centers C-8 and C-9 in **1a** and **1b** was determined by 1H-1H NOESY experiments. The hitherto unknown estrone derivatives **1a** and **1b** could be used as starting materials for numerous novel steroids, for instance by hydroxylation, epoxidation, halogenation, or ene reaction. Moreover, a large number of compounds can be synthesized by variation of the hexahydro-1*H*-indene **3** and the (bromoethenyl)bromobenzene **2**. Thus, this novel Pd-catalyzed annelation of **3** provides a general and efficient access to steroidal systems.

Experimental Procedure

1b: A solution of **15b** (182 mg, 0.43 mmol), nBu$_4$NOAc (327 mg, 1.09 mmol), and *trans*-di(μ-acetato)-bis[*o*-(di-*o*-tolylphosphino)benzyl]dipalladium(II) [21] (8.1 mg, 2.0 mol%) in DMF/CH_3CN/H_2O (1/1/0.2, 5 mL) was heated for 4.5 h at 115 °C. After cooling, H_2O (30 mL) was added, and the resulting mixture was extracted with Et_2O (2 × 50 mL). Washing the combined ether layers with a saturated NaCl solution, drying over $MgSO_4$, concentration in vacuo, and subsequent purification by column chromatography (PE/CH_2Cl_2 = 3/1) afforded 145 mg (99%) of **1b**.

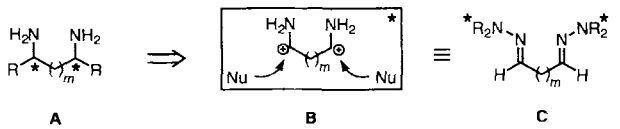
Diastereo- and Enantioselective Synthesis of C_2-Symmetric, Protected 1,*n*-Diamines from Dialdehydes**

Dieter Enders* and Michaela Meiers

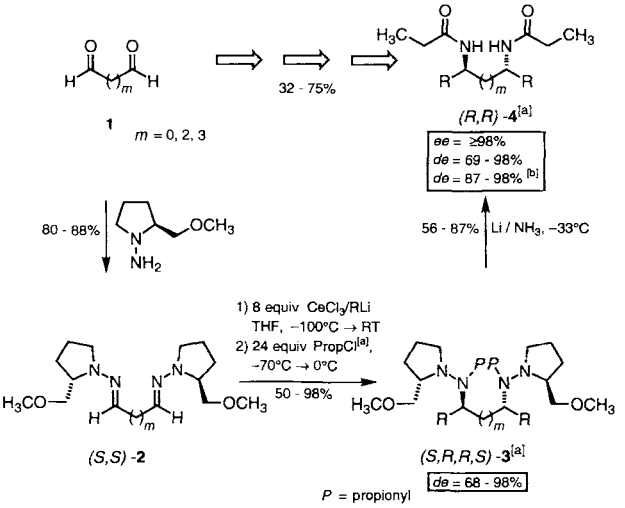
Diastereo- and enantiomerically pure diamines have a wide range of applications in organic synthesis and are characteristic structural features of numerous interesting target molecules. In particular vicinal C_2-symmetric diamines are of importance in asymmetric synthesis. They serve as chiral reagents[1] and chiral auxiliaries[2] and also as ligands[3] and ligand building blocks[4, 5] in transition metal catalyzed asymmetric synthesis. In this context salen complexes that can be employed with different transition metals are particularly well-known.[5] A class of C_2-symmetric molecules that has been found to efficiently inhibit HIV-protease contains 1,*n*-diamino functions ($n = 3-5$) as a structural feature.[6] Because of the great interest in C_2-symmetric diamines, several stereoselective syntheses have been developed; however, the majority lead to vicinal diamines.[7, 8] For this reason, we focused our attention on devising a flexible, highly diastereo- and enantioselective approach to C_2-symmetric diamines.

The retrosynthesis of diamines **A** lead to the 1,*n*-diamine synthons **B** which have an a^1-reactivity with regard to the amino group and nucleophiles (Nu). Enantiomerically pure dialdehydehydrazones **C** can be used as synthetic equivalents for **B**.



The SAMP/RAMP method has already been successfully employed for the generation of amino functions.[9, 10] The key step is the diastereoselective addition of organometallic reagents to the C=N bond of the enantiomerically pure hydrazone. Beside organolithium compounds and Grignard compounds in toluene,[11] organocerium compounds[12] proved to be particularly well-suited for the addition. We now report a flexible, diastereo- and enantioselective synthesis of N-protected diamines **A**.

Dialdehydes **1** can be converted into the corresponding bis-SAMP-hydrazones (*S,S*)-**2** in good yields by reaction with the chiral auxiliary SAMP[9] (Scheme 1). In the case of succinic dialdehyde, the dialdehyde is first liberated from 2,5-dimethoxytetrahydrofuran and then treated with SAMP. The bis-SAMP-hydrazones are treated with eight equivalents of an organocerium compound[13] formed in situ at low temperatures and the resulting lithium hydrazides then trapped with 24 equivalents of propionyl chloride (PropCl) or methyl chloroformate (MocCl)



Scheme 1. Diastereo- and enantioselective synthesis of N-protected 1,*n*-diamines **4**. [a] For the synthesis of **3b**, methyl chloroformate was used as trapping reagent. The absolute configurations of **3f** and **4f** were determined to be (*S,S,S,S*) and (*S,S*), respectively. [b] After chromatography.

f	5	Bn [e]	98	[d]	+17.8 (0.99)	(*S,S,S,S*)

[a] The *de* values were determined by gas chromatography (SE-54, FID) from (*S,R,R,S*)/(*S,R,S,S*)-**3**. [b] Configuration of the major diastereomer. [c] Trapped with MocCl. [d] The *de* value could not be determined by either gas chromatography or by NMR spectroscopy. [e] $BnMgCl/CeCl_3$ was used as the nucleophile.

The activated N–N bond is reductively cleaved without racemization by using lithium in liquid ammonia.[14] After purification by column chromatography and, if necessary, removal of the *meso* compound, the N-protected diamines **4** are obtained in moderate to good yields (56–87%) with high diastereomeric excesses (*de* = 87–98%) and very high enantiomeric excesses (*ee* ≥ 98%) (Scheme 1). The total yield (**1** to **4**) over three steps is 32–75% (Table 2).[15]

Table 2. N-protected 1,*n*-diamines **4** prepared by N–N bond cleavage of the 1,*n*-bishydrazines **3** using lithium in liquid ammonia.

4	*n*	R	Yield [%]	*de* [a] [%]	*ee* [b] [%]	$[\alpha]_D^{25}$ (c, $CHCl_3$)	Config. [c]
a	2	Me	73	98	≥98	+65.5 (0.91)	(*R,R*)
b [d]	4	Me	56	87	≥98	+20.3 (1.02)	(*R,R*)
c	4	*n*Bu	63	91 [e]	≥98	+35.1 (1.03)	(*R,R*)
d	4	nC_6H_{13}	65	98 [e]	≥96	+25.5 (0.55)	(*R,R*)
e	5	Me	87	94	≥98	−15.5 (1.06)	(*R,R*)
f	5	Bn	81	88 [f]	≥98 [f]	−30.9 (1.02)	(*S,S*)

[a] The *de* values were determined by gas chromatography (SE-54, FID). [b] According to GC analysis on chiral stationary phases, for **4b** by GC analysis of the propionyl-protected compound, for **4d** according to NMR shift experiments[16]. [c] According to correlation of the optical rotation with literature data[17]. [d] Moc-protected diamine obtained by cleavage of **3b**. [e] After separation of the diastereomers by column chromatography. [f] The *de* and *ee* values were determined by HPLC separation on a chiral stationary phases[16].

The diastereomeric excesses were determined by gas chromatography (GC) and by HPLC, the enantiomeric excesses by gas chromatography and HPLC using chiral stationary phases (CSP) and by ^1H NMR shift experiments.[16] The chiral amine (*S*)-2-methoxymethylpyrrolidine (SMP) can be recovered after cleavage of the N–N bond and converted back into the chiral auxiliary SAMP.[9] The absolute configuration was determined by comparing the optical rotation of (2*R*,3*R*)-2,3-diacetamidobutane, which can be prepared according to the same procedure using acetylchloride for trapping the lithium hydrazide and subsequent bond cleavage, with literature data. The absolute configurations were thus found to be (*R,R*) for **4a–e** and (*S,S*) for **4f**, assuming a uniform reaction mechanism for all examples.[17] This is in agreement with the relative topicity typical for the 1,2-addition to SAMP-hydrazones.

The method presented here makes possible the diastereo- and enantioselective synthesis of N-protected, C_2-symmetric diamines, since both the nucleophiles as well as the separation of the amino functions can be varied.

Experimental Procedure

Preparation of the N-protected bishydrazines **3**: Cerium trichloride heptahydrate (8 mmol) was dehydrated for 2 h at 140 °C and 0.1 Torr with cautious stirring. After cooling, the flask was filled with argon and the solid suspended in THF (35 mL) at room temperature for 2 h, during which ultrasound was applied for 1 h. The colorless suspension was cooled to −70 °C and then a solution of the organolithium reagent (8 mmol) was added slowly; in the case of **3f** a solution of benzylmagnesium chloride (8 mmol) was added. The suspension turned an intense yellow color and was stirred for another 2 h then cooled to −100 °C. The resulting organocerium reagent was treated with a solution of bishydrazone (*S,S*)-**2** (1 mmol) in 6 mL of THF, and then the reaction mixture was allowed to warm up slowly over about 15 h. The solution was again cooled to −70 °C and propionyl chloride (24 mmol) was added. The solution was stirred for 0.5 h at this temperature and for another hour at 0 °C. Alternatively, methyl chloroformate (24 mmol) was added at 0 °C and the solution stirred for 20 h at room temperature. The reaction was terminated by addition of a saturated $NaHCO_3$ solution (20 mL). The organic layer was separated and the residue extracted with ether (4 × 25 mL). The combined organic layers were then dried over $MgSO_4$ and the solvent removed on a rotary evaporator. After purification of the yellow-brown crude products by chromatography (SiO_2, ether/petroleum ether 1:1 to 4:1), colorless to light-yellow viscous oils were obtained.

Cleavage of the N–N bond to afford the N-protected diamines **4**: Lithium (4.8 mmol) was dissolved in liquid ammonia (25 mL) at −70 °C. Then a solution of the hydrazides **3** (0.5 mmol) in THF (5 mL) was added. The cooling bath was removed and the solution allowed to warm up to reflux for 3 h. Ammonium chloride (9.6 mmol) was then carefully added in order to terminate the reaction. After the ammonia had evaporated, the residue was extracted with CH_2Cl_2 (3 × 20 mL) and filtered. After removal of the solvent on a rotary evaporator and purification of the colorless, highly viscous oils by chromatography (SiO_2, ether/MeOH 8:1 to 20:1), colorless solids were obtained.

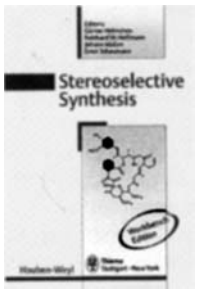
In the program of the well-known German reference work Houben-Weyl a five-volume series entitled "Stereoselective Synthesis" is fortunately now available as an English edition, which gives a complete overview over this field of chemistry. Virtually all topics of stereoselective synthesis are covered and represented in depth by more than 100 top-class authors. Both editors and authors have obviously put in great effort to produce a book of great value for chemists involved in stereoselective synthesis and stereoselective catalysis.



The chapters are mainly organized by the kind of bond formed or broken during the reaction, enabling the reader to spot specific reactions easily rather than products. A separate index facilitates the search for certain types of products. Thus these well-written books provide the natural product chemist with the ideal reference work in which he can find both product and reaction types.

After an excellent introduction into basic principles of stereochemistry and stereoselective synthesis, including nomenclature, separation, and analysis, chapters about the stereoselective synthesis of compounds with axial chirality and the formation of chiral compounds by bond disconnection follow.

After this the biggest chapter of the series (more than 2500 pages) starts, covering stereoselective synthesis by the formation of carbon–carbon bonds. Reactions of organometallic compounds, of all types of enolates, additions to carbonyls and to C–C double bonds as well as allylic substitution reactions, radical reactions, and pericyclic reactions form the main parts of this major chapter. In the remaining two volumes of the series methods for the stereoselective formation of C–H, C–Hal, C–O, C–S, C–Se, C–Te, C–N, C–P, C–Si, and C–Sn bonds are described. Substrate-induced, reagent-induced, and auxilliary-induced stereoselectivity are included in the chapters of this valuable series. As enzymatic methods are discussed in detail too, these books represent a complete work on stereoselective synthesis.

Each article is well written. Mechanistic backgrounds as well as explanations about the origin of stereoselectivity are briefly discussed where necessary and precede the well-selected examples given. The effect is to focus the attention on the specific topic.

Due to the great number of authors and reactions, some overlap seems to be inevitable; however, this concerns mainly the theoretical background of the reactions, and makes the separate articles easy to follow and a joy to read. The tabulated data and the representative experimental procedures given make these books both practical and informative for scientists working in a laboratory, too. Mistakes are extremely rare and only minor. Where they occur, they do in no way influence the clear, logical line of argumentation in this book. The high standards of these volumes are reflected in the citation of well-chosen references, including 1995. They are thus an extremely up-to-date comprehensive reference source.

In summary these books represent the present state of the art of stereoselective synthesis and are an invaluable source of information and references. They can be highly recommended and are definitely the best starting point for obtaining information about the reactions covered in these volumes. They should therefore not be missing from any chemistry library.

100 and more Basic NMR Experiments. A Practical Course. By *S. Braun, H.-O. Kalinowski* and *S. Berger*. VCH Verlagsgesellschaft, Weinheim, 1996. xii, 418 pp., paperback DM 68.00.—ISBN 3-527-29091-5

This book by Braun, Kalinowski, and Berger is the sixth joint production from these authors, following their ^{13}C *NMR-Spektroskopie* and the four volumes of *NMR-Spektroskopie von Nichtmetallen* [English-language versions: *Carbon-13 NMR Spectroscopy* (1988), and the soon forthcoming single-volume *NMR Spectroscopy of the Non-Metallic Elements*.] The present work is a collection of laboratory procedures, the NMR spectroscopist's equivalent of the organic chemist's preparative handbook, which aims to teach the user how to perform NMR experiments. Thus it is a guide through the bewildering variety of available NMR techniques, and is intended for both average and more advanced users of NMR spectrometers.

The 12 chapters cover a wide range, from the basic operations with an NMR spectrometer up to the latest multipulse experiments. The individual experiments are described in detail in subchapters which follow a standard pattern: first the purpose of the experiment, then some key literature references, the pulse sequence

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Federal Republic of Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

and phase cycle, the spectrometer settings and conditions appropriate for a specific sample solution, the processing of the recorded data, typical results including an actual spectrum (reproduced in excellent quality), and additional information about the method. Each subchapter is self-contained, so that the reader can concentrate on the method in hand without needing to have read the previous sections.

The first five chapters are concerned with basic spectrometer procedures such as tuning the probe-head, optimizing the magnetic field homogeneity, determining the pulse length, and carrying out simple NMR experiments, including recording ^{1}H and ^{13}C spectra under standard conditions, decoupling techniques, and dynamic NMR measurements. In Chapter 6 the reader learns about multiplicity selection methods (spectral "editing"), including the APT, INEPT, and DEPT techniques, about pulse sequences used as building blocks in more complicated sequences (the BIRD filter, etc.), and about methods for suppressing the water signal. Chapter 7 is devoted to experiments using selective pulses, and Chapter 8 to the use of auxiliary reagents and to quantitative measurements. Chapter 9 introduces heteronuclear NMR spectroscopy. The topics of the last three chapters are two-dimensional methods (including H,H shift correlations, C,H correlation methods using either ^{13}C or ^{1}H detection, and others), NMR experiments with pulsed field gradients, and 3D NMR experiments. The book ends with two appendices, the first listing the different names used by various instrument manufacturers to describe the recording parameters, and the second explaining the basic rules of the product operator formalism.

The authors have included here the most important and frequently used NMR methods, and their choice of experiments is appropriate for the intended readership. However, in the chapter on heteronuclear NMR spectroscopy we would have expected to find examples of measurements on ^{31}P, certainly a much more important nuclide than ^{11}B and ^{17}O, which are chosen here. Chapters 6 ("1D Multipulse Sequences") and 10 ("The Second Dimension") are especially well constructed from a teaching standpoint. All the experiments described in the book use only compounds that are readily available. In the 3D H,C,P correlation experiment the potential applications of the technique could have been demonstrated more convincingly by choosing, instead of triphenylphosphine, a compound having more than one chemical shift value in each dimension.

The methods are described in a clearly understandable way which should enable readers to perform the experiments without serious problems. However, those with little practical experience of NMR spectrometers may have a few difficulties with processing the data, especially if they are using a spectrometer of a different make from that of the authors, this despite the translations of technical terms in the appendix. Also, readers with less theoretical background would be better able to understand the pulse sequences if these were explained using the magnetization vector picture wherever possible, rather than the product operator formalism.

This book dealing with the practical aspects of carrying out NMR experiments fills a gap between the operating manuals provided by instrument manufacturers and the mainly theoretically-orientated books on the subject. It can be thoroughly recommended for purchasing by every NMR laboratory.

Solving Problems with NMR Spectroscopy. By *A.-u. Rahman* and *M. I. Choudhary*. Academic Press, San Diego, 1996. xvi, 430 pp., paperback $ 34.95.—ISBN 0-12-066320-1

The purpose of this book, according to the authors, is to provide research chemists with the practical knowledge needed to use NMR methods for determining the structures of organic molecules. They have been especially concerned to avoid making it too technical, and wherever possible they have described the underlying principles of the experiments in non-mathematical language. Like the book by Braun et al. which is reviewed above, it is concerned with the practical details of carrying out NMR experiments, but here there is more emphasis on analyzing the results.

The book begins with a long chapter (98 pp.) on the fundamentals of modern NMR spectroscopy. Aspects covered include the most important parts of the spectrometer, basic operations with the instrument, the effects of radiofrequency pulses on the magnetization vector, processing of the experimental data, and technical points related to these. Chapter 2 (57 pp.) is concerned with spin-echo and polarization transfer methods, with particular attention to the APT, INEPT, and DEPT techniques. Chapter 3 (37 pp.) introduces the basic principles of two-dimensional NMR spectroscopy, explaining how the data are recorded and subsequently processed, but not yet going so far as to describe specific experiments. In Chapter 4 (25 pp.) the authors discuss the nuclear Overhauser effect (NOE) and the practical aspects of recording NOE difference spectra. The real core of the book is Chapter 5 (131 pp.), which is devoted to various important 2D NMR experiments. These include the recording of homonuclear and heteronuclear *J*-resolved spectra, homonuclear and heteronuclear chemical shift correlation experiments, 2D nuclear Overhauser experiments (NOESY, ROESY, HOESY) and exchange spectroscopy (EXSY), the 2D TOCSY and INADEQUATE experiments, and heteronuclear correlation experiments with proton detection (HMQC, HMBC). Chapter 6 (19 pp.) introduces the principles of 3D NMR spectroscopy and describes a few of the many types of experiments that are possible. Chapter 7 (26 pp.), on recent developments in NMR spectroscopy, is mainly concerned with experiments using frequency-selective excitation pulses, with a brief mention of the use of pulsed field gradients for suppressing unwanted coherences. Lastly, Chapter 8 (19 pp.) considers how one should approach the problem of determining an unknown molecular structure, giving general recommendations as to which experiments should be performed and in what order, together with the analysis of the results. The authors then describe the sequence of events in a structural analysis, using two examples from their own research, a lupinine alkaloid and a steroid alkaloid. The book ends with a glossary of technical terms used in NMR spectroscopy (10 pp.) and a subject index of similar length.

The text is in general easy to read and understand, and gives good explanations of the most important NMR techniques in current use. However, it is not completely clear which readers the book is intended for. Beginners without any previous knowledge will find that many of the descriptions are not sufficiently detailed, whereas for experienced NMR users much of the information is superfluous. The book does not fully live up to the promise of its title. To solve structural problems without any previous knowledge of chemical shifts and coupling con-

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3519-2266 $ 15.00+.25/0

stants, neither of which is discussed in the book, may often be possible in principle, but is usually not the most efficient approach. Also some important older and well-established techniques, such as spin decoupling, are not discussed. A more honest title for the book would be something like "Modern NMR Spectroscopic Techniques".

The inclusion of exercise problems with answers in each chapter is a welcome feature. Unfortunately, however, the questions posed are not always very useful from a learning standpoint (example: "The signal-to-noise ratio can be increased by [applying] proper apodization functions. What would happen without apodization?"), and occasionally they suggest a whimsical attitude on the part of the authors. For example, to the question of what type of probe-head is most suitable for a group of preparative chemists where the problem of insufficient sample does not arise, the answer given is "a probe-head for 10-15 mm sample tubes". The book's most serious shortcoming is that many of the figures are of very poor quality. This applies especially to the reproduction of spectra, a few of which have obviously been drawn by hand. Many of the 2D spectra are much too small. Occasionally the one-dimensional spectrum is missing from one of the axes, or is shown on such a small scale that only methyl group singlets are adequately reproduced (4 mm height!), with the result that no coupling multiplets can be recognized, since they would only be a fraction of a millimeter in height. This happens even on pages whose space is not fully used. The book would have been much improved by using a larger format and taking greater care with the layout. It needs to be thoroughly reworked.

Unimolecular Reactions. Second edition. By *K. A. Holbrook, M. J. Pilling* and *S. H. Robertson*. Wiley, Chichester, 1996. 417 pp., hardcover £ 90.00.—ISBN 0-471-92268-4

The subject of unimolecular reactions has undergone much development in the last few decades. Many new types of experiments have been carried out, affording insights that could scarcely have been imagined 30 years ago. It has become possible to make remarkably precise measurements on reactions of practical importance. Alongside these advances, theoretical methods now allow one to analyze the fundamental processes with improving quantitative reliability. Consequently, monographs and review articles dealing with this fast-moving field soon become outdated. It is therefore very pleasing that K. A. Holbrook, M. J. Pilling, and S. H. Robertson have now produced a thoroughly revised and significantly enlarged new edition of *Unimolecular Reactions*, first published in 1972 under the authorship of P. J. Robinson and K. A. Holbrook. In that first edition, "Robinson and Holbrook" contained an excellent introduction to the application of the HRRKM theory, the statistical theory of unimolecular reactions developed by Hinshelwood, Rice, Ramsperger, Kassel, and Marcus, together with a detailed compilation of experimental data on classical reactions. At that time this was the most detailed introduction to the practical application of the RRKM theory available in the literature. However, in recent years it had become seriously outdated because the many later developments were not covered.

Thermal and nonthermal unimolecular reactions are often studied under conditions in which the reaction rate is determined solely or partly by intermolecular energy exchange through collisions. In retrospect it seems surprising that for many years the details of this process received so little attention. The new edition of this book remedies that omission by including descriptions based on the fundamental equations. Nevertheless, perhaps an even more detailed treatment of the energy transfer process would have conveyed a better understanding of its characteristics.

The new numerical algorithms for calculating densities of states and numbers of states are treated in detail in this book, so that the statistical analyses of the RRKM theory can be carried to completion. Thus, even a beginner should have no difficulty in learning how to treat reactions involving rigid activated complexes, for which the classical RRKM theory was mainly developed. The new edition also includes a detailed treatment of reactions involving nonrigid activated complexes. The description and comparison of the different variants of theoretical treatments of the transition state is excellent and useful. In view of this it is even more surprising that the phase space theory, which represents the limiting case of completely flexible transition states, and makes it easy to correctly take into account the conservation of angular momentum in the reaction, is almost completely ignored. To have included a treatment of this limiting case would have helped the reader to understand the detailed description of the statistical adiabatic channel model.

The book contains a wealth of information about current experimental and theoretical studies in this field. The descriptions of the kinds of investigations now possible are illustrated by informative examples, thus providing the beginner with an excellent introduction and the more advanced researcher with many stimulating ideas. It retains the spirit of the original "Robinson and Holbrook", while also bringing the treatment up to date. If the book had been completely rewritten from the start, there would probably have been some changes of emphasis. It would then have been possible to devote more space to topics such as the breakdown of molecular ions, bimolecular complex-forming reactions of neutral or charged species, trajectory calculations, calculations of adiabatic channel potentials made possible by the latest methods, anharmonic densities of states, and (as already mentioned above) phase space theory. At the same time the treatment of the classical RRKM theory could be shortened. However, to do so would have resulted in a more bulky monograph than intended. Therefore the changes have been limited to a very successful updating of the original concept. The book is well suited as a text for further reading by advanced students, and will also serve the needs of reaction kineticists who intend to work on gas phase reactions.

In combinatorial synthesis the number of products (here symbolized by the size of the spheres) increases exponentially with the number of the reaction steps and the positions that can be varied.

Combinatorial Synthesis of Small Organic Molecules

Friedhelm Balkenhohl,* Christoph von dem Bussche-Hünnefeld, Annegret Lansky, and Christian Zechel

Combinatorial synthesis has developed within a few years from a laboratory curiosity to a method that is taken seriously in drug research. Rapid progress in molecular biology and the resulting ability to determine the activity of new substances extremely efficiently have led to a change in paradigm for the synthesis of test compounds: in addition to the conventional procedure of synthesizing one substance *after* another, new methods allowing *simultaneous* creation of many structurally defined substances are becoming increasingly important. A characteristic of combinatorial synthesis is that a reaction is performed with *many* synthetic building blocks at once—in parallel or in a mixture— rather than with just *one* building block. All possible combinations are formed in each step, so that a large number of products, a so-called library, is obtained from only a few reactants. Several methods have been developed for combinatorial synthesis of small organic molecules, based on research into peptide library synthesis: single substances are produced by highly automated parallel syntheses, and special techniques enable targeted synthesis of mixtures with defined components. Many structures can be obtained by combinatorial synthesis, and the size of the libraries created ranges from a few individual compounds to many thousand substances in mixtures. This article gives an overview of the combinatorial syntheses of small organic molecules reported to date, performed both in solution and on a solid support. In addition, different techniques for identification of active compounds in mixtures are presented, together with ways to automate syntheses and process the large amounts of data produced. An overview of pioneering companies active in this area is also given. The final outlook attempts to predict the future development of this exponentially growing area and the influence of this new thinking in other areas of chemistry.

(Translated from the German)

1. Introduction

1.1. The Role of Organic Synthesis in the Search for Active Compounds

Synthesis has been the backbone of organic chemistry since Wöhler's work on production of urea from ammonium cyanate. During the last hundred years chemists have been challenged time and again to new achievements by the products of nature. The total syntheses of, for instance, vitamin B_{12}, palytoxin, and taxol are impressive demonstrations of this.[1] Today, new, ever more selective methods enable synthesis of molecules of almost any complexity. However, despite all this progress, the goal of organic synthesis has remained the same: the most efficient and selective synthesis possible of a single target molecule of defined structure.

The synthesis of biologically active compounds has, up to the present time, been influenced by this aim: once a suitable target has been selected, it is synthesized, purified, characterized, and tested for activity. The activity is then optimized, partly by systematic and partly by intuitive variation of the initial structure. A new active substance is obtained by trial and error, and many thousand molecular variations must be synthesized before a marketable product is found. Even a well-equipped and efficient synthetic laboratory can hardly produce more than *one* substance per day at present. This is one of the main factors that makes development of new pharmaceuticals or crop protection agents a lengthy, and thus expensive, process.

Rapid progress in molecular biology and gene technology has brought about fundamental changes in biomedical research in the last ten years (Fig. 1).[2] Use of molecular biological methods to identify and prepare proteins (enzymes, receptors, ion channels) that are directly associated with medical symptoms is very important in drug research. Determination of the structure of these molecules has made it possible to understand diseases at the molecular level and has opened the door to rational drug

design. Of even greater importance is the use of these targets to design efficient test systems, since this enables *thousands* of substances (with suitable automation) to be screened per day. The in vitro activity can be reliably ascertained even with minute amounts of substance. This so-called "high-throughput screening" for identification of new lead structures requires a large number of structurally diverse test substances, and this is where the concept of traditional organic synthesis (synthesizing one compound after another) reaches its limits. Preparation of test substances becomes the bottleneck in the search for active compounds. The speed of synthesis, or more precisely, the number of substances synthesized per time unit, is a new dimension in organic synthesis (high-throughput synthesis), in addition to yield and selectivity. The future goal in drug discovery will be to synthesize many structurally diverse substances rapidly so that, in combination with high-throughput screening the search for new lead structures and their optimization can be accelerated.

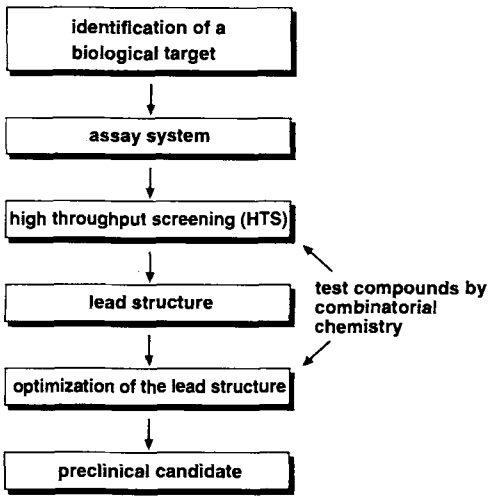

Fig. 1. The search for pharmaceuticals today.

C. von dem Bussche-Hünnefeld F. Balkenhohl A. Lansky C. Zechel

Friedhelm Balkenhohl, born in 1961 near Osnabrück (Germany), studied chemistry at the Universities of Göttingen and Hannover and finished his PhD in 1989 with Prof. E. Winterfeldt. The topic of his dissertation was the stereoselective synthesis of acceptor-substituted prostacyclins. After joining the main laboratory at BASF AG, he worked on the synthesis and process development of vitamins and their derivatives. Afterwards he investigated the use of enzyme-catalyzed reactions for the synthesis of optically active intermediates, such as amines. Since 1994 he has been the leader of the "combinational chemistry" research group.

Christoph von dem Bussche-Hünnefeld, born in 1964 in Koblenz (Germany), studied chemistry at the University of Bonn and the ETH, Zürich. His doctoral work on enantiomerically pure, fluorinated synthetic building blocks was completed in 1992 with Prof. D. Seebach. During a postdoctorial fellowship at the University of California, Los Angeles, he worked on the synthesis of cage compounds in the research group of Prof. D. J. Cram. In 1993 he joined the main laboratory at BASF AG (research area: crop-protection agents).

Annegret Lansky, born in 1965 in Offenbach am Main (Germany), studied chemistry at the Universities of Hamburg and Southampton (UK). She finished her PhD in 1992 at the University of Göttingen with Prof. A. de Meijere in the area of palladium-catalyzed multiple coupling. In 1993 she began working in the main laboratory at BASF AG, where she synthesized pharmaceutical products for the central nervous system.

Christian Zechel, born in 1958 in Berlin (Germany), studied chemistry at the University of Frankfurt am Main and finished his PhD in 1985 with Prof. H. Kessler. His dissertation was on homo- and heterodetic cyclic enkephalin analogues. During a subsequent postdoctoral fellowship with Prof. V. J. Hruby at the University of Arizona, Tucson he investigated the solid-phase synthesis of glucagon antagonists. Since 1986 he has been in the main laboratory at BASF AG and works on pharmaceutical products.

The authors have been working in the area of combinatorial chemistry in synthesis of biologically active compounds since 1994. At the center of their interest is the combinatorial synthesis of low molecular weight organic compounds on solid phase. In addition to identifying appropriate reaction sequences and synthesis of compound libraries, they are also working on automation and analytical methods for combinatorial chemistry.

1.2. The Principle of Combinatorial Organic Synthesis

The goal of combinatorial synthesis is to *simultaneously* produce many different products with defined structures.[3] The aim is no longer to produce a single, selected structure, but rather to find ways to produce many structures "in one go". Combinatorial synthesis takes its lead from nature, which succeeds in obtaining from only a few synthetic units (for example, the twenty amino acids) a large number of products with diverse functions (the peptides) by combinatorial principles. Combination of all the naturally occurring amino acids to all possible hexapeptides gives the astronomical number of $20^6 = 64\,000\,000$ substances!

Combinatorial chemistry is based on a principle that is both simple yet revolutionary: Instead of linking starting materials **A** and **B** to form one product **AB** (Fig. 2), different building blocks

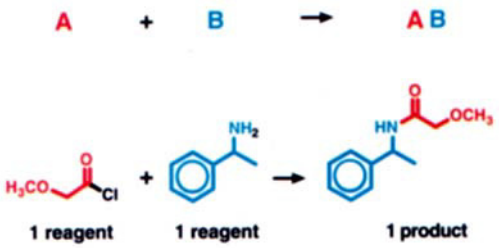

Fig. 2. Conventional organic synthesis.

of type **A** ($\mathbf{A}_1-\mathbf{A}_{10}$) are treated with different building blocks of type **B** ($\mathbf{B}_1-\mathbf{B}_{10}$) according to combinatorial principles; that is, each substance reacts with all other reactants (Fig. 3). This can take place in separate reaction vessels or compartments, or simultaneously in a mixture.

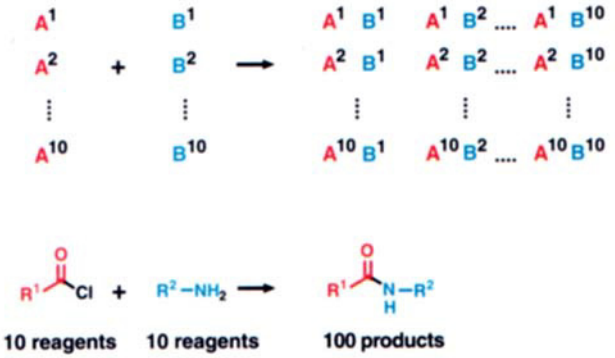

Fig. 3. Combinatorial organic synthesis.

In the above example, ten reagents of type **A** and ten reagents of type **B** give a hundred products in a combinatorial reaction. If we extend this principle of producing all possible combinations in each reaction to multiple-step syntheses, as is generally the case in drug discovery, we rapidly obtain a large number of products from only a few building blocks (Fig 4). For a three-step synthesis with ten building blocks each of type **A**, **B**, **C**, and **D**, we obtain 10 000 products.

The set of all the compounds produced in a combinatorial synthesis is known as a library, in analogy to other such collections.[4] Depending on the production method, a compound library created by combinatorial synthesis can comprise separate compounds or may be a mixture of defined composition.[5] In a multistep combinatorial synthesis, the size of such a library, which corresponds to the total number of all substances synthesized, is determined by the number of reactants or building blocks used per reaction (linear relation), and the number of reaction steps (exponential relation).

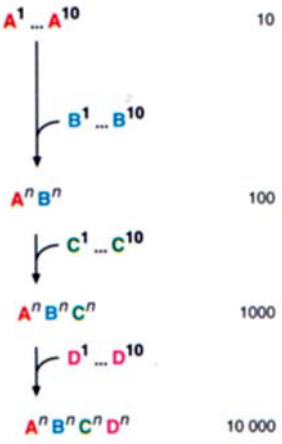

Fig. 4. Multiple-step combinatorial synthesis.

1.3. From Peptide Libraries...

That compound libraries could be created by combinatorial synthesis was first recognized by peptide chemists in the 1980s. Pioneers such as Geysen[6] (multipin method) and Houghten[7] (teabag method) led the way. They developed various methods for multiple (parallel) synthesis of peptides,[10] based on the techniques of solid-phase peptide synthesis according to Merrifield.[8, 9] Further progress was achieved in this field, among others by Frank[11] (spot synthesis) and Fodor et al.,[12] who achieved extreme miniaturization (VLSIPS method). However, combinatorial synthesis of peptides in the strict sense was made possible by the work of Furka and coworkers,[13–16] and this can be regarded as the "birth" of combinatorial chemistry. It was the use of the so-called "portioning-mixing method" ("split synthesis"[17] or the "divide-couple-and-recombine method"[18] as it was later named) that enabled technically simple and efficient synthesis of peptide libraries of almost any size[19] in the form of defined equimolar mixtures. A detailed description of this method, which is important for synthesis of libraries of small organic molecules, is given in Section 2.2.2.

1.4. ...to Small Organic Molecules

Peptides often have a number of disadvantages as drugs such as low bioavailability and ready proteolytic degradation. In addition, conversion of a peptide lead structure into a non-peptide structure is a lengthy and nontrivial undertaking. For this reason, in the last three years the focus of research in the field of combinatorial synthesis has been directed away from peptides towards libraries of "small organic molecules";[20–25] at the same time this research area has undergone a huge expansion. Until recently only a few pioneer companies and academic working groups were involved in combinatorial synthesis, whereas today probably all researching pharmaceutical firms and many academic groups are active in this field. The aim of this review is to present fundamental research on combinatorial synthesis of small organic molecules and to give a "snapshot" of this exponentially growing field. Peptides, oligonucleotides,

oligosaccharides, and pseudo-biological oligomers made up of repeating monomers (such as peptoids or oligocarbamates) are not included.[22, 24–26] The emphasis is on combinatorial synthesis,[5] regardless whether on solid phase or in solution. Syntheses of both mixtures and separate substances are included, as long as the procedure can be described as combinatorial (parallel syntheses under identical conditions according to combinatorial principles).

2. Design, Methods, and Techniques of Combinatorial Syntheses

2.1. Design

Various aspects must be considered when planning a combinatorial synthesis:

- Required is a sequence in which as many as possible of the reactions are bond-forming steps (C–C or C-heteroatom). The target molecule is thus formed by successive reactions with individual building blocks.
- The building blocks for these "construction" reactions must be available as structurally diverse sets.
- The biggest challenge, however, is the chemistry itself: Formation of a new linkage must succeed *irrespective* of the structure already synthesized and the synthetic building block to be linked; that is, the required product must be delivered with high yield and selectivity. This is, of course, the ideal, and one of the main tasks in combinatorial synthesis is to identify reaction sequences that allow the maximum variety in the building blocks ("high-fidelity reactions").
- The products should be as diverse as possible. This means that groups that can undergo noncovalent interactions (hydrophobic and ionic interactions, H-bonds) with a biological target molecule are presented in as many spatial configurations as possible (see Section 2.1.1).
- Finally, the reaction conditions for both the individual reactions and the whole sequence should be amenable to automation.

Peptide synthesis meets all these conditions. There is only a single coupling reaction that is repeated, namely formation of an amide from an activated acyl species and an amine. This reaction has been optimized over many years.

For synthesis of small organic molecules the range of application of each reaction in a chosen sequence must be examined on an individual basis. The aim is to maximize the range of application by suitable choice of reaction conditions or to identify suitable conditions for a particular set of diverse building blocks. Knowing the exact scope and limitations of each individual step in a given sequence enables a sensible choice of building blocks and thus a successful library synthesis.

Finally, there remains the question of strategy for efficient synthesis of the library (Fig. 5). Doubly functionalized monomer units are linked (**A**) in peptide synthesis, and the same is true for other oligomer syntheses. However, different strategies can be considered for synthesis of nonoligomeric small organic molecules. For example, one can start with a template that is already equipped with several functional groups. Different building blocks are attached through these groups, either in a series of separate steps or in one pot (**B**). Alternatively, one can use reactions that introduce a new functionality in the product, on which the next reaction step (**C**) takes place. The multicomponent reactions are an extreme example of this strategy in which intermediates immediately undergo further reactions under constant conditions. Examples of these different strategies and also some mixed strategies are described in the following sections.

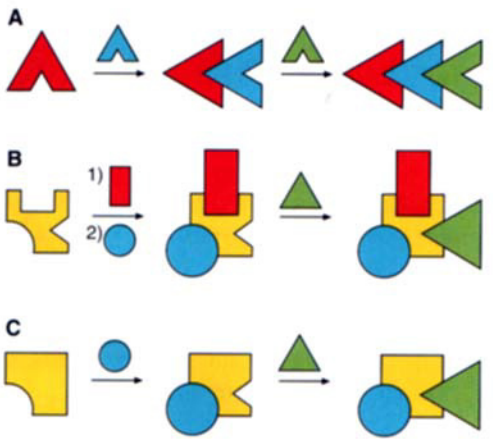

Fig. 5. Strategies for combinatorial synthesis.

2.1.1. Diversity

If one considers that the number of possible organic compounds with a molecular weight less than 750 is estimated at 10^{200},[27] it quickly becomes clear that, despite the great potential of combinatorial synthesis, it would be impossible to synthesize and test all potentially active compounds. Even in a perfect combinatorial synthesis with chemistry that, in principle, enables synthesis of libraries of any size ("virtual libraries"), there has to be a selection of the building blocks to be used and the products to be made.

Compound libraries are generally synthesized with the intention of later biological testing. The chance of finding active compounds in a library increases with the diversity and dissimilarity of the compounds in the library. The test substances should therefore be as "diverse" as possible with respect to the test system; diversity is therefore dependent on the structure of the molecular site of interaction. For example, the compounds thiorphan and *retro*-thiorphan not only have similar appearance at first glance but they also bind to the zinc proteases thermolysin and neutral endopeptidase (NEP) with almost identical affinity (Fig. 6).[28] One would accordingly class them as similar. However, at another site of action, the angiotensin-converting enzyme (ACE),[*] which is also a zinc protease, thiorphan binds about a factor of 100 more strongly than *retro*-thiorphan. Thiorphan and *retro*-thiorphan are therefore not similar relative to this enzyme.

Another example, the oligopeptide-binding protein from *Salmonella typhimurium*, puts the definition of diversity further into perspective (Fig. 7). This peptide binds dipeptides to pentapeptides without differentiation with a K_D of 10^{-6} M.[29] A library of di- to pentapeptides would therefore have no diversity in relation to this molecular target.

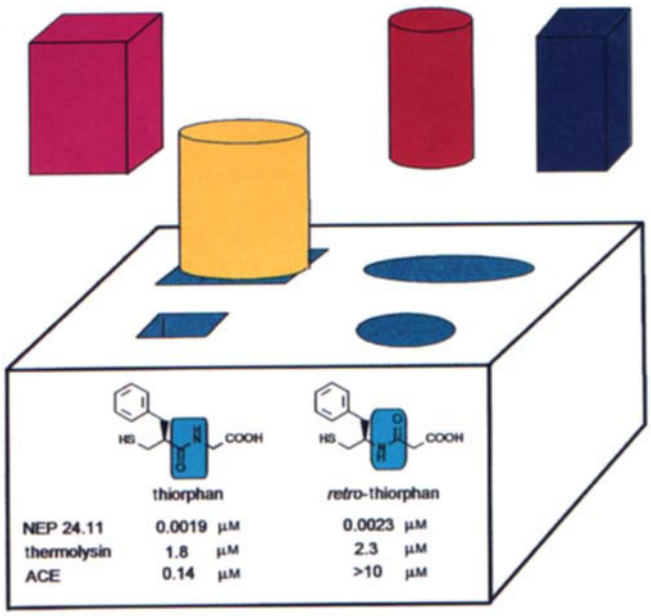

Fig. 6. As illustrated by the different activities of the inhibitors thiorphan and *retro*-thiorphan for these three metalloproteases, the similarity of any two molecules depends on the molecular target under consideration [28].

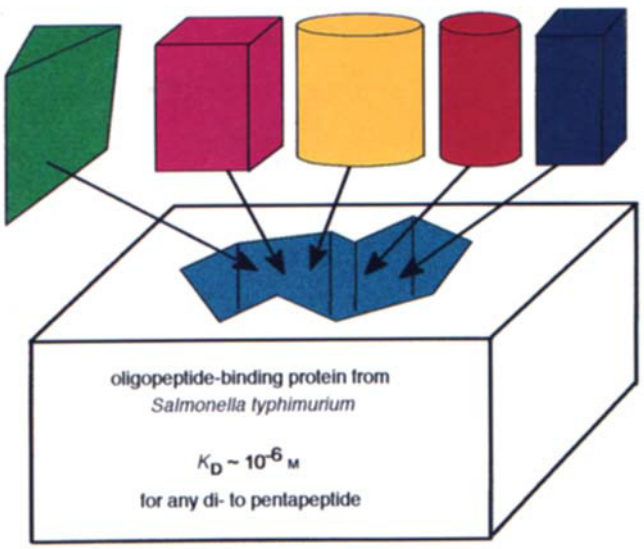

Fig. 7. The oligopeptide-binding protein from *S. typhimurium* binds all di- to pentapeptides with the same affinity [29]. A library of di- to pentapeptides would not have any diversity relative to this molecular target.

Expressing diversity with respect to the biological site of action may seem attractive, but this is not feasible in practice. The structure of the site of action is often unknown, particularly when searching for new lead structures, and a compound library should be tested on many different targets. It is thus much more useful to look for an abstract definition of diversity on an absolute scale when planning a combinatorial compound library. In the following, a collection of compounds will be defined as diverse if groups that can undergo noncovalent interactions with a receptor molecule are available in as many spatial configurations as possible, that is, if a multitude of different pharmacophoric patterns are represented.[30]

The method of Martin et al. of the firm Chiron is based on this definition of diversity. They present selected physical parameters in so-called "flowerplots" and use these to compare individual compounds graphically.[31]

A library suitable for the discovery of new lead structures should be made up of a large number of small organic molecules, which have a high degree of diversity ("random library"). However, if a known lead structure is to be optimized, or if information is available about the biological site of action, the library may have comparatively little diversity ("focused" or "biased library"; see, for example, refs. [32, 33] and Scheme 28).

2.1.2. Format

A library can comprise mixtures of low or high complexity or discrete individual compounds. The decision to use a particular format, that is, whether to test separate compounds or substance mixtures, influences both their synthesis and the procedure for biological testing. If mixtures are used, significantly more substances can be synthesized and tested per time unit. However, the synthesis must deliver all compounds in the mixture in approximately equimolar amounts. Potential problems with false positives and negatives are known in testing mixtures, and these depend on the composition of the mixture to be tested and on the test system used.[34] A common view is that one can afford to miss some active substances during screening because of the large number of test substances—a sufficient number of interesting substances will still be detected ("magic of numbers").[35] This can certainly be justified as long as no attempt is being made to determine structure–activity relationships. Experiments performed at the pharmaceutical company Pfizer[36] indicate that an optimal mixture complexity is about 20 substances per mixture. If more complex mixtures were used, detec-

tion of active compounds was no longer reliable, because the signal-to-noise factor deteriorated or false positives occurred.

Time saved by working with mixtures can, however, be partially or completely lost by the effort required for deconvolution, that is, new synthesis of less complex sublibraries or individual substances, if the active components can only be identified in this way. Since a compound library will ideally be used in a large number of tests, it is statistically possible that sooner or later each substance mixture will give a positive test result and will have to be broken down into its constituents. Taking an extreme view of the time expended long-term, it could be considered sensible to use separate substances from the beginning. However, libraries of separate compounds are unlikely to reach the size desirable for identification of lead structures. Very large libraries ($\gg 10000$ compounds) can only be efficiently produced as mixtures.

Experience shows that the optimization of lead structures yields numerous compounds displaying biological activity. In such a case it is better to use libraries of separate compounds from the start rather than to have to deconvolute all the mixtures later on. Here the reaction building blocks are selected more precisely and smaller libraries (<1000 compounds) are synthesized.

Whether the synthesis of separate compounds or mixtures will predominate is difficult to say at present. There are equally many examples of the two strategies, which will be presented in the following sections. It is unlikely that a general strategy will emerge in the future, since the choice of format will always depend on the particular problem in hand.

Another basic decision concerns investigation of the synthesized compound library in biological tests (Section 5): should the substances be tested in solution or on a support (as they are obtained initially in the case of solid-phase syntheses). The trend here is clearly to examine the test substances in solution. The results are not influenced by undesired interactions with the support, and above all, many assay systems that have already been established can be used.

2.2. Methods and Techniques of Combinatorial Synthesis

2.2.1. Synthesis in Solution; Synthesis on Solid Phase

In principle, combinatorial syntheses can be performed both in solution and on solid phase (Fig. 8). Small organic molecule synthesis on supports is nowhere near as well optimized as syntheses of peptides and nucleotides. Consequently, the effort required for development of such a synthesis is considerable. However, solid-phase synthesis has a number of advantages over conventional solution synthesis.

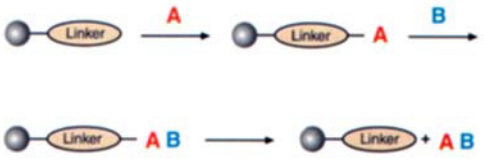

Fig. 8. Principle of solid-phase synthesis. Sphere = polymeric support, **A** = first building block, **B** = second building block, **AB** = product.

The reaction is accelerated by using an excess of the soluble reaction partner, and complete conversion can be achieved. Complex workup and purification steps are replaced by simple washing of the support at the end of each reaction. Thus, solid-phase synthesis enables full automation of all steps, even for multiple-step syntheses. It is therefore not surprising that a large proportion of combinatorial small organic molecule syntheses reported up to the present time were performed on supports. This has led to a renaissance of the solid-phase syntheses of organic molecules developed in the 1970s and 1980s, particularly those of Fréchet[37] and Leznoff,[38] and an abundance of classical organic synthetic reactions have since been carried out on solid supports.[26, 39, 40]

However, as seen from the comparison in Table 1, combinatorial synthesis in solution has advantages that should not be underestimated, especially since multiple-step organic synthesis on solid phase is still in its infancy at the moment. Combinatorial synthesis in solution does not require any additional reaction steps for linkage to or cleavage from a polymeric support. Stability and reactivity of linkers and resins do not have to be considered when choosing the reaction conditions. The biggest advantage is that the reaction conditions do not have to be adapted to the requirements of solid-phase synthesis. In addition, expensive functionalized polymeric supports are not required, and a relatively simple scale-up is possible. However, simple concepts for automated raw product purification will be important for the further development of combinatorial synthesis in solution. If side products or excess reagents could be reliably separated in this way, the number of useful reactions will be vastly increased. For this reason, combinatorial synthe-

Table 1. Comparison of combinatorial syntheses on solid phase and in solution.

Combinatorial synthesis	
On solid phase	In solution
Advantages	
Reagents can be used in excess without separation problems later, and thus reactions can be driven to completion.	All organic reactions can be used in principle
Purification of the product by washing the support	No adaption of known reaction conditions is required
Simple complete automation of reaction sequences	No additional reaction steps for linkage to and cleavage from the support
Split synthesis possible ("one bead, one compound")	Unlimited amounts of product can be produced
Pseudo-dilution	
Disadvantages:	
Not well developed → expenditure of time for development required	Reactants cannot be used in excess unless additional work is invested during purification
Additional reaction steps for linkage to and cleavage from the support	Automation of isolation and purification steps is difficult
Support and linker limit possible chemistry	
Methods for analytical monitoring of the reactions not well developed	

ses in solution are at the moment most common where only one or two steps are involved. In future, choice of solution or solid-phase synthesis will depend on the particular requirements. It may also make sense to combine solution and solid-phase reactions in a synthesis sequence, as described in recent work by Armstrong et al.[41] and Suto.[42]

2.2.2. *Synthesis of Separate Substances; Synthesis of Mixtures*

Both separate substances and defined mixtures can be synthesized according to combinatorial principles. Individual substances can be obtained by fast parallel syntheses, that is, n substances are synthesized in n reaction vessels. An efficient automated reaction process is a basic requirement for this.

Synthesis of defined mixtures requires procedures that deliver a large number of structurally defined compounds in equimolar amounts with as few reaction steps as possible. Thus mixtures of reactants could be used in each reaction step so that many reaction products are formed in one reaction vessel at the same time.

This is the usual procedure for combinatorial synthesis of mixtures in solution. However, for solid-phase synthesis this concept could be demonstrated convincingly only for synthesis of amide compounds in peptide libraries[43,44] or for synthesis of nucleotides.[45,46] Although this strategy was also employed initially for synthesis of small organic molecules,[47,48] only reactants with similar reactivity were used. Much larger differences in reactivity must usually be reckoned with in the synthesis of large libraries of small organic molecules. This may mean that certain reaction products are only formed to a lesser extent or not at all. Such reaction procedures also lack one of the big advantages of solid-phase synthesis, namely that reactants can be used in a large excess to drive the reaction to completion.

The problem of different reaction rates is elegantly avoided by the "split method" according to Furka et al.,[13-18] which furnishes an efficient synthesis of equimolar mixtures. As shown in Figure 9, the solid support is divided, for example, into three equal parts, and each of the three aliquots is treated with a

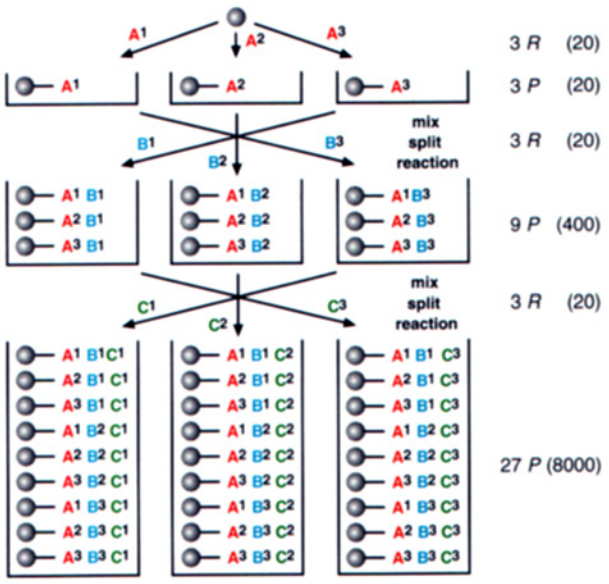

Fig. 9. Split method. Sphere = polymeric support; ***R*** gives the number of reactions performed in parallel, ***P*** is the number of different products [13-18].

synthetic unit of type **A**. The resulting product resins are mixed and divided anew, giving three mixtures in which the resin-linked components $\mathbf{A}^1$, $\mathbf{A}^2$, and $\mathbf{A}^3$ are present in equimolar amounts. These are treated with $\mathbf{B}^1$, $\mathbf{B}^2$, or $\mathbf{B}^3$, which gives nine defined products in total. Since there is only one reactant in solution in a reaction vessel at any one time that reacts with a large or small number of support-bound reaction partners depending on the synthesis plan, all reactions can proceed to completion despite possible differences in kinetics. Repetition of the cycle of division, reaction, and mixing gives, in a short time, large compound libraries in which all compounds are present in equimolar amounts. At the end of such a synthesis sequence, a compound library is obtained in which many copies of only one compound are present on each bead (one bead, one compound[17]). The obvious advantage is that 27 products are obtained in nine reaction steps with nine synthetic building blocks (in three mixtures of nine compounds each), whereas their synthesis as separate compounds would require 81 reaction steps.

All 8000 tripeptides obtained from the 20 natural amino acids can be synthesized in 20 mixtures of 400 compounds each in an analogous way using only 60 coupling reactions. These are quasi separate compounds as long as they are bound to the solid phase.

The number of all synthesized substances N is given in Equation (a), where n is the number of building blocks in each reaction (1,2, 3,... m) and m is the number of reaction steps in which new reaction building blocks are introduced.

$$N = n_1 \times n_2 \times n_3 \times \ldots n_m \qquad \text{(a)}$$

Burgess et al.[49] have thrown some light on the statistical aspects of the split method. In particular, they examined how many support particles have to be used in order that all desired compounds are present in the resulting library with a certain probability. They were able to show that with ten reactants per cycle and a total of five cycles (resulting in $10^5 = 100000$ substances), at least 500000 support particles must be used if 99% of all theoretically possible compounds are to be present in the library with 99% probability. For the commonly used synthetic resins, 1 g of support material corresponds to several million particles so that from a statistical point of view, libraries of the order of greater than 10^5 substances are possible in practice. Further statistical investigations of the split method were recently published by Zhao et al.[50] and Boutin and Fauchère.[51] A recent patent application from the company Pharmacopeia[52] describes an attempt to overcome a statistically unfavorable distribution by avoiding the mixing step in a common vessel. The support material is aliquoted from the current reaction vessel *directly* into the reaction vessel in which the next synthesis step should take place. However, synthesis of larger libraries then requires a large number of distribution steps. It is noteworthy that the split method in solution does not have this kind of statistical problem.

2.2.3. *Genetic Algorithms*

An interesting and not yet widespread approach to minimizing the number of substances to be synthesized is the use of genetic algorithms.[53] This evolutionary strategy is commonly used for efficient optimization of multiparameter systems[54]

and gives a good solution with high probability, if not necessarily the optimal solution. Using the genetic operations replication, mutation, and crossover, new solutions are generated from a set of the starting solutions, which have improved properties from generation to generation. Carrying this idea over to combinatorial synthesis, the aim is to optimize a desired substance characteristic such as biological activity whilst keeping the number of substances to be synthesized and tested as low as possible.

Weber et al.[55] used genetic algorithms to select the products to be synthesized with a four-component reaction, in order to obtain products with maximal biological activity from as few syntheses as possible. They created a library of 160000 virtual compounds by computational combination of 100 building blocks. All compounds were assigned a bit pattern (binary code) according to the building blocks they were composed of. These substance codes represented the genetic material. After parallel syntheses of 20 randomly selected reaction products, the bit patterns of these products were submitted to the genetic operations mentioned above. The new bit patterns obtained by this method coded for 20 new compounds, which were then synthesized. The biological activity was determined for the 40 compounds, and the 20 most active reaction products were selected, which now formed the parent generation for computation and synthesis of further substances. This process was carried out for 20 generations so that in total 400 (0.25% of the possible 160000) reaction products were synthesized and tested. The reaction products of the twentieth generation were 2000 times move active enzyme inhibitors than the compounds of the first generation. However, no comparison was made with the biological activity of 400 randomly selected reaction products. A further recent publication from Singh et al.[56] describes optimization of hexapeptide substrates of stromelysin by applying genetic algorithms. Model calculations of Sheridan et al.[57] show that genetic algorithms can be used for selection of suitable reagents for a combinatorial synthesis, that is, for designing a library.

2.2.4. Characterization of Test Substance Libraries

The procedure for characterization of test substance libraries depends on their format. If individual substances are produced in a parallel synthesis, the analysis is the same as for conventionally synthesized substances. The situation is similar if a compound library is synthesized by the split method. Since in this case, each particle only carries one substance (one bead, one compound), the analysis of such libraries can be reduced to that of the individual substances, as long as they are resin-bound. Since the amount of substance bound to a single support particle is usually of the order of several 100 pmol, mass spectroscopic methods are the methods of choice, despite recent progress in the fields of IR[58] and NMR spectroscopy.[59] Practical feasibility was first demonstrated with peptides,[60–62] also coupled with affinity capillary electrophoresis,[63] then with peptoids,[64] and recently with low molecular weight, non-peptide compounds.[65] Cleavage of the product-linker bond was either performed in a separate step before the measurement with trifluoroacetic acid vapor or photochemically,[61] or directly in the spectrometer under matrix-assisted, laser desorption-ionization time-of-flight (MALDI-TOF) conditions.[62]

If libraries are in the form of mixtures after cleavage from the support, a reliable analytical characterization is difficult and becomes impossible at a certain mixture complexity. The first reports of characterization of such libraries—likewise with mass spectroscopic methods—also come from the peptide field.[66] Combinatorial mixtures of low molecular weight organic molecules have also been characterized in this way since then.

Along these lines, Rebek's group examined how much of the theoretically possible product in a library synthesis was formed in solution, using combinations of different mass spectroscopic methods.[67] Meutermans et al. synthesized di- and tetrahydroisoquinolines on solid phase[47] and were able to show using ion spray MS that all the predicted compounds were present in the mixture after cleavage. Another variant, which gives reliable results particularly for characterization of smaller mixtures, is the coupling of HPLC and MS.

In addition to the *direct* methods of structural determination described above, there are also *indirect* methods, which are particularly advantageous when working with mixtures produced by split synthesis. Here, the structure is obtained by deciphering a code generated in parallel to the synthesis of the library, which represents a recording of the synthetic steps performed. Coded libraries are discussed in full in Section 5.5.

3. Combinatorial Synthesis in Solution

There are basically two strategies for combinatorial synthesis in solution. Some research groups use approaches involving synthesis of compound mixtures of varying complexity, whilst other groups use parallel synthesis, which gives a lower number of synthesized compounds but has advantages during characterization and determination of biological activity of the individual substances. Advantages and disadvantages of both strategies were discussed in Section 2.2.2.

3.1. Synthesis of Compound Mixtures

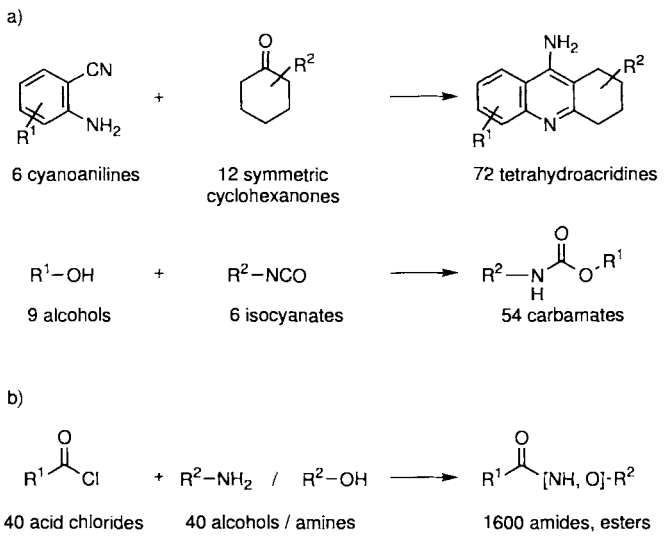
3.1.1. Random Synthesis

The synthesis of unwanted compound mixtures is a big problem in classical chemistry that every synthetic chemist has to confront. This explains the skepticism towards combinatorial chemistry often encountered especially with regard to random syntheses. The Maillard reaction[68] and research such as that of Chen and Radmer can be considered examples of random syntheses for creation of molecular diversity.[69] They treated an equimolar mixture of glucose, galactose, and inositol in pyridine with a subequimolar amount of sodium azide. According to their report, the oligomer content of the mixture obtained was increased from 14% to 27% by performing a further transformation with $Hg(CN)_2$, $HgBr_2$, and HgI_2. Subsequent reduction with hydrogen catalyzed by $Pd(OH)_2$ on carbon gave a wide variety of deoxysugars and aminoglycosides.

Since random syntheses are only a fringe area in combinatorial chemistry and are beset with major problems similar to those known from processing natural substance extracts, they will not be discussed further here.

3.1.2. One-Step Synthesis

The type of combinatorial syntheses in which per reaction step two molecules from only two different compound classes undergo a defined reaction or reaction sequence (such as acid chlorides with amines to amides) are more clear-cut than random syntheses. If sequential reactions are avoided, unwanted side products will not accumulate. However, this advantage is severely limited by the small number of products that can be obtained, since only two different components are incorporated in each molecule formed. Examples of this type of synthesis have been demonstrated by research groups at the laboratories of Duke University in the USA and at Glaxo Research and Development Ltd in Great Britain.[70, 71] They solved the problem of identification of biologically active compounds from the product mixture by using an elegant synthesis strategy. Pirrung et al. produced an "indexed combinatorial library" composed of 72 tetrahydroacridines[35] by condensing six cyanoanilines with twelve symmetrical cyclohexanones in one reaction step (Scheme 1).[71]



Scheme 1. Reactions used by Pirrung et al. [35, 71] (a) and Smith et al. [70] (b) for synthesis of indexed combinatorial compound libraries. The tetrahydroacridines are in 6 mixtures of 12 and 12 mixtures of 6 compounds [71]. The carbamates are 9 and 6 mixtures of 6 and 9 compounds, respectively [35], and the amides/esters are each 40 mixtures of 40 compounds [70].

The reactions were performed so that each of the six cyanoanilines was treated with a stoichiometric quantity of an equimolar mixture of the twelve cyclohexanone derivatives. Each cyclohexanone was also treated with a corresponding mixture of the amine components. Six mixtures of twelve components and twelve mixtures of six components were produced in total, in which the individual compounds in each mixture have half a molecule in common. In addition, each component appears in exactly two of these 18 mixtures. If a compound is biologically active, it will be detected in both of the mixtures that contain it (cf. Section 5.2). The same research group was able to use this method to identify acetylcholinesterase inhibitors in a carbamate library (Scheme 1).[35]

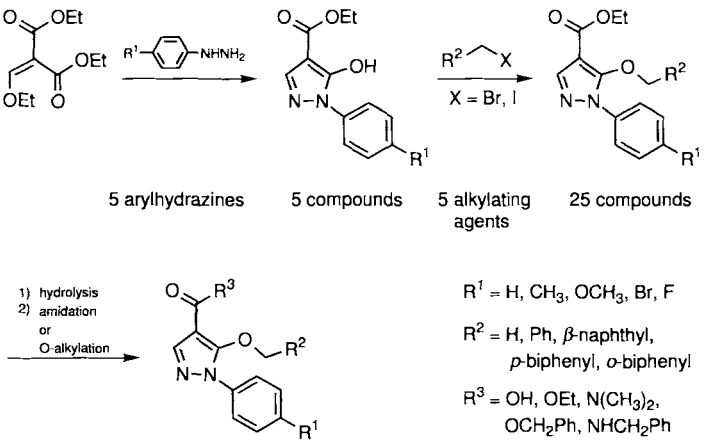
At about the same time as Pirring, Smith et al.[70] used this strategy to synthesize mixtures of esters or amides (Scheme 1) and investigated the biological activity of the mixtures with a wide range of molecular test systems. They were able to identify an inhibitor of the matrix metalloprotease-1 (MMP-1) and a neurokinin-NK_3 antagonist.

3.1.3. Two-Step Reaction Sequences

Storer of Glaxo Wellcome has worked on two-step combinatorial synthesis in solution.[72] He combined 50 amino acids, 80 carboxylic acids, and 40 amines to form a library of 160000 diamides, composed of 4000 mixtures each of 40 compounds. To achieve this, he first treated each of the 50 amino acids with a mixture of 40 amines. These 50 mixtures each of 40 compounds were subsequently treated with each of the 80 carboxylic acids. Although only 4000 reactions had to be performed rather than individual synthesis of all 160000 compounds, the use of synthesis robots was a big advantage here. This strategy saved reaction steps since, unlike in indexed libraries, each substance was not synthesized twice. However, if a mixture showed biological activity, all the individual components had to be synthesized separately for further investigation. Lead structures for different targets (HIV protease, neurokinin-1 receptor) have since been identified from this diamide library.[73]

3.1.4. Three-Step Reaction Sequences

For multiple step combinatorial synthesis sequences, MacLachlan has shown that heterocycle syntheses are possible, in addition to proven amidation reactions (Scheme 2).[74] By



Scheme 2. Synthesis of a phenylpyrazole library [74]. The 125 pyrazole derivatives are obtained as 5 mixtures each of 25 compounds.

variation of three molecule segments, he was able to synthesize a pyrazole library of 125 compounds in a three-step phenylpyrazole synthesis. Careful choice of reaction conditions and clever selection of reagents was also important here. For example, allyl bromide could not be used as an alkylation reagent for the O-alkylation, since the Claisen rearrangement would otherwise predominate. MacLachlan's work is a good example of how more complicated reaction sequences can be performed combinatorially in solution. To determine the structure of a biological-

ly active compound obtained with this synthesis scheme, three (number of variable groups) times five (number of different variants per group) sublibraries are created. The first set of sublibraries is composed of 5 mixtures each of 25 substances, which each have a defined group R^1. The groups R^2 and R^3 are identified in a similar manner.

3.1.5. *One-Pot Syntheses*

Further multiple-step reaction sequences for production of molecule libraries have been reported by Rebek, Jr., and coworkers.[67, 75–80] The reactions used were restricted to the reliable formation of amides from amines and acid chlorides, and the reaction of isocyanates with amines. They were able to link four different groups to a central molecular scaffold simultaneously in a one-pot reaction and thereby obtained a large number of highly diverse compounds. The rigid xanthene- and cubanetetracarboxylic acid chlorides **1** and **2** as well as the more flexible tricarboxylic acid chloride **3** were used as the central scaffold for their amide libraries (Fig. 10). Either the rather

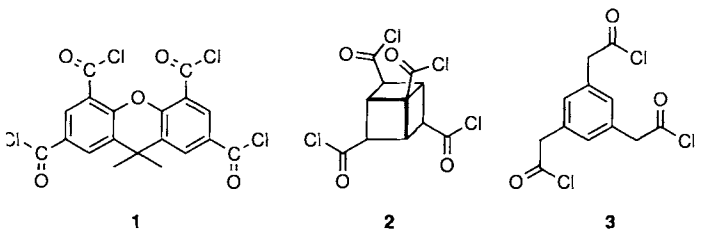


Fig. 10. Three central building blocks used by Rebek, Jr. et al. [75–80] for the synthesis of amide libraries.

more disc-shaped molecules (the derivatives of **1** and **3**) or the rather more spherical compounds (the derivatives of **2**) were obtained. At the same time, the distance between the reactive centers ensured that they had little steric influence on one another. The molecules were also chosen so that the reactivities of the functional groups were similar. To synthesize the library, templates **1**, **2**, or **3** were each treated with up to 21 amines.[75, 79, 80] The amine components chosen were mainly amino acid esters; one equivalent of an equimolar mixture of the individual amines was used.

The lower the symmetry of the central building block and the larger the number of its reactive centers, the higher the number of different products that can be formed. For example, reaction of the xanthene **1** with 4, 7, 12, and 19 amines theoretically gives mixtures of 136, 1225, 10440 and 65341 compounds (Fig. 11).

The question whether all possible reaction products are actually formed is of particular interest. HPLC chromatograms of libraries of varying complexity gave evidence that use of additional amines results in a larger number of compounds.[75] However, this question could only be answered convincingly on application of mass spectroscopic methods.[67, 77, 79] Since the analysis of a mixture of several thousand compounds is very difficult, examples of less complex libraries were synthesized by treating **4** with different sets of amines. Derivative **4** (Fig. 11) was chosen since steric interactions between the substituents at positions 4 and 5 of the xanthene, which would influence the reactivity at these positions, are unlikely. Reaction of **4** with sets

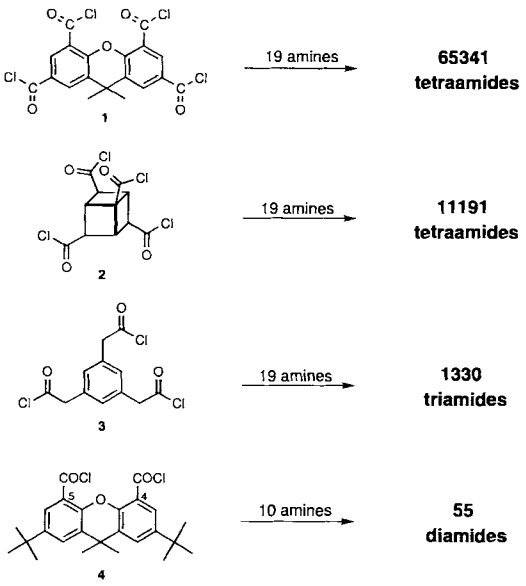

Fig. 11. Maximal number of compounds from various amide libraries. As the symmetry of the central scaffold increases, compound mixtures of lower complexity are obtained with the same number of amines [79].

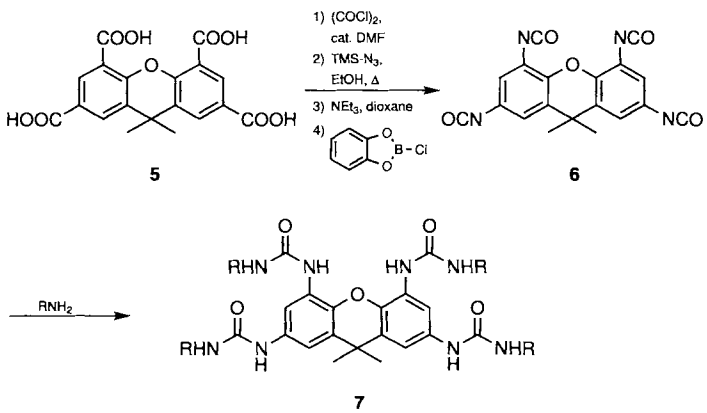
of 8, 9, and 10 amines should give 36, 45, and 55 diamide products with this simplified molecular scaffold. Suitable choice of reagents ensured that the reaction products possible from different sets of amines had different molecular weights so that their examination by mass spectroscopy gave conclusive results. These showed that for the library of 36 compounds, about 85% of the expected compounds could be identified by their molecular ion peaks compared to 78% for the 55-compound library. The experiment also permitted identification of "problem candidates" among the amine components. For example, if the arginine derivative is excluded, 93% of the expected compounds were detected in the 55-compound library. These investigations showed that a large proportion of the predicted compounds are actually present in the mixture, if the individual components are carefully chosen. At the same time, analyses indicated that about a 10% fraction of the libraries were side products.

An extension of this concept was presented by Rebek, Jr., at the fall meeting of the American Chemical Society last year (Scheme 3).[78] By using the tetraisocyanate **6** instead of the



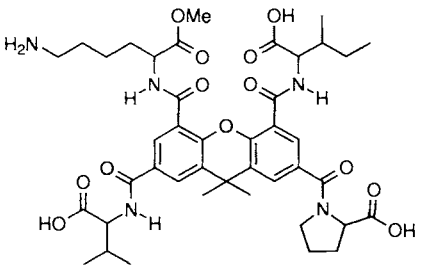
Scheme 3. Synthesis of the tetraisocyanate **6** as central building block for the urea derivatives **7** [78].

tetrachloride, urea derivatives are obtained—the reactivity of the isocyanate is so high that a 1.5-fold excess of amino acids can be used without preferential formation of any of the reaction products. This was demonstrated by examination of the reaction products of mixtures of glycine methyl ester and leucine *tert*-butyl ester with **6**.

A similar formulation was chosen by researchers at ISIS Pharmaceuticals. To increase the number of possible products, they used unsymmetrical linear and cyclic tri- and tetraamines such as azacyclophanes as templates. These were treated with acid chlorides, alkyl halides, and aldehydes.[81]

This kind of one-pot reaction enables very fast and efficient production of large substance mixtures from known reactions in solution. If the reaction components are available in highly structurally diverse forms—as is certainly the case for amines[82]—restriction to one reaction type need not result in compound libraries of reduced diversity. More serious is that only reactions that proceed reliably with reactants of very similar reactivity can be used, and that this method only permits synthesis of mixtures. This procedure has become less popular as the synthesis of large mixtures has decreased in importance.

Rebek, Jr., also presented a strategy for detection of biologically active compounds in a compound library[76, 79] and has used this to identify the trypsin inhibitor **8** ($K_i = (9 \pm 2) \times 10^{-6}$ M) (Fig. 12). The method of deconvolution used here is noteworthy in that it is not the most active compound mixture that dictates the choice of building blocks; rather the less active mixtures are used to set the exclusion criteria for the choice of building blocks.



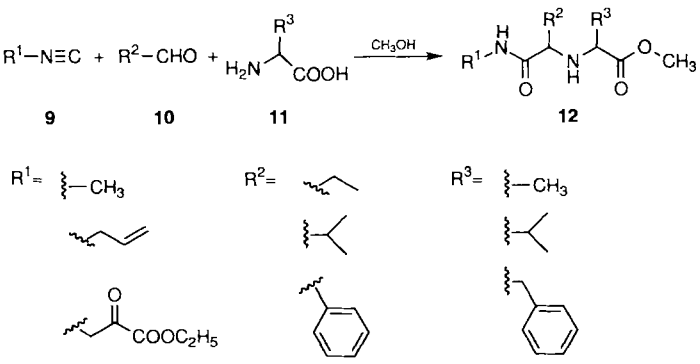
8

Fig. 12. Trypsin inhibitor found by screening a library that theoretically contains 65341 xanthenamides; $K_i = (9 \pm 2) \times 10^{-6}$ M [76].

An important limitation of this iterative process is that not necessarily the most active compounds are identified. However, Rebek, Jr., et al. presented a plausible hypothesis using computer simulation that—even if the compounds identified are not the most active—a compound which is an order of magnitude more active will not be missed.[79] Above all, groups of active compounds are identified, since a single active compound can scarcely be detected in a mixture of ten thousand inactive substances.

3.1.6. Multicomponent Reactions

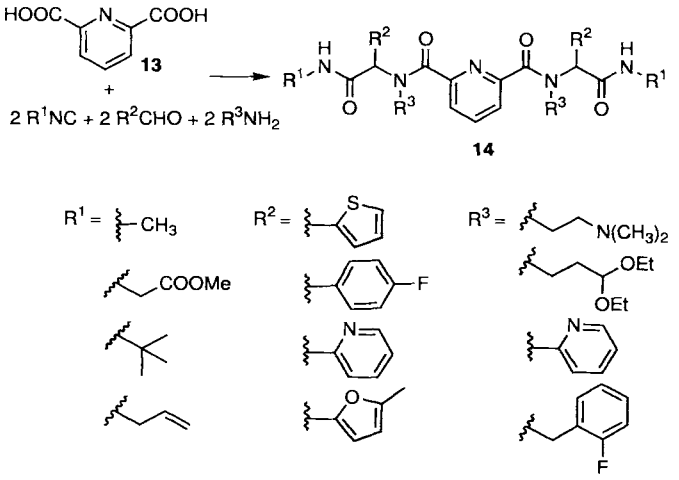
The multicomponent reactions have a unique position in combinatorial synthesis of compound libraries.[83] A particular reaction *sequence* takes place after all reaction participants have been mixed. The difference from the work described by Rebek, Jr., et al. is that a sequence of reactions of different types are used. Ugi, a pioneer in this field, has been involved in multicomponent reactions for several decades.[84] As early as 1961 (that is, many years before the term combinatorial chemistry was coined) he and Steinbrückner pointed out that it should be possible to produce an enormous number of different compounds by multicomponent reactions: "Since such condensation reactions take place between four (in exceptional cases even more than four) components, the number of possibilities are very high. The use of merely ten compounds each of the four condensation components yields 10^4 combinations. It therefore seems expedient to determine the scope and limitations with respect to the individual components by studies on simple systems in which as many variables as possible are kept constant" (translated from the German).[85] It is therefore not surprising that, almost 35 years later, after the advent of combinatorial chemistry, Ugi and his co-workers were using "Ugi Chemistry" to create compound mixtures (Scheme 4).[86]



Scheme 4. A variation of the Ugi reaction. Starting from three isonitriles **9**, three aldehydes **10**, and three amino acids **11**, a substance mixture theoretically containing 54 compounds of type **12** is obtained [86].

By treating three amino acids (**11**) with three isonitriles (**9**) and three aldehydes (**10**) and methanol, they obtained a library of type **12**, theoretically composed of 54 compounds (if possible stereoisomers are counted as separate compounds). Since only 37 compounds were shown to exist by GC-MS analysis, three daughter libraries each of 18 compounds were created. Examination of these showed that almost all of the expected products were actually formed.[86] As one-pot reactions that are simple to perform, multicomponent reactions represent an efficient way of generating compound libraries, although the products may be formed at widely differing concentrations.[86] Based on many years of experience with these reactions, Ugi selected the starting materials so that they had similar reactivities. Careful choice of reagent also ensured that the products were formed with good yield and high purity. Under these conditions, a larger library of pyridine-2,6-dicarboxylic acid derivatives (**14**) with 8256 components was successfully synthesized (Scheme 5).[86]

Libraries of carbohydrate derivatives have also been produced with multicomponent reactions.[87] However, nowhere near all the expected products were formed. In addition to this



Scheme 5. Synthesis by a variation of the Ugi reaction [86] of a library theoretically containing 8256 pyridine dicarboxylic acid derivatives **14**.

particularly bad problem, large differences in concentration of the products were obtained.

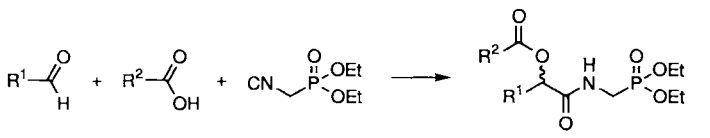
Further examples of combinatorial syntheses with multicomponent reactions are given in the following section and in the section on combinatorial syntheses on solid phase (Section 4.3.3).

3.2. Parallel Syntheses of Single Compounds

To avoid the disadvantages already mentioned of synthesis of compound mixtures, several research groups have been involved in combinatorial synthesis of single compounds in solution. The most efficient synthesis possible of a large number of defined individual compounds through combinatorial principles is the aim here. The border between classical and combinatorial chemistry is therefore fluid for these types of reaction.

3.2.1. Multicomponent reactions

Like Ugi, Armstrong[88] and Holmes et al.[89] also employ multicomponent reactions for combinatorial synthesis but they generate single compounds (the work of Weber et al.[55] was described in Section 2.2.3). Whilst Holmes's work is mostly associated with optimization of a solid-phase synthesis, Armstrong has reported synthesis of a library of 64 α-acyloxyamides **18** by systematic combination of 8 aldehydes **15**, 8 carboxylic acids **16**, and an isonitrile **17** in a Passerini reaction (Scheme 6).



R^1 = C_2H_5, n-C_3H_7, n-C_6H_{13}, CH=CHCH$_3$, CH=CHPh, Ph, p-(H_3CO)Ph, p-$((H_3C)_2N)$Ph

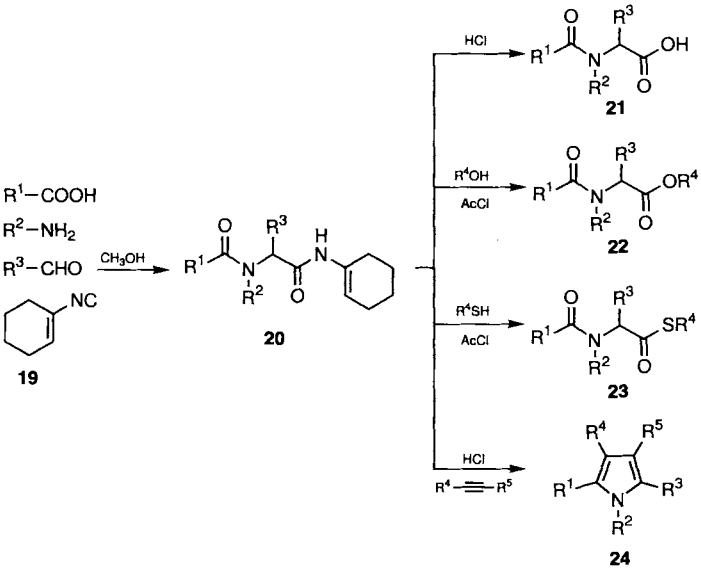
R^2 = CH_3, CH=CH, CH_2CHCl_2, CH_2Ph, $CH(Ph)_2$, CH=CHPh, Ph, α-naphthyl

Scheme 6. Passerini reaction for synthesis of a library of 64 α-acyloxyamides **18** [88].

In each of the parallel reactions, one equivalent each of the acid and the isonitrile was treated with two equivalents of the aldehyde at room temperature. The products were worked up by simple evaporation of the reaction solution. Analysis of the reaction products by ^{1}H NMR spectroscopy gave a yield of about 80% based on converted isonitrile. Armstrong's synthesis of eight azinomycin analogues also with a Passerini reaction (see also Section 4.3.3) was certainly on the border between classical derivatization and combinatorial synthesis. Although interesting compounds were obtained, these were isomeric mixtures; in addition, workup of each product required chromatographic separation.

The restrictions on the starting materials limit creation of molecule libraries with the Passerini and Ugi reactions. Although many aldehydes, carboxylic acids, and amines of differing structures are commercially available, the number of available isonitriles is much smaller.

An interesting variation of the Ugi reaction has been presented by Armstrong and Keating.[41, 90] They used 1-isonitrilecyclohexene (**19**) as the isonitrile component in the Ugi reaction and thus obtained the cyclohexenamides **20**. These were converted into further derivatives by introduction of a fourth component of molecular diversity (Scheme 7). The carboxylic acids



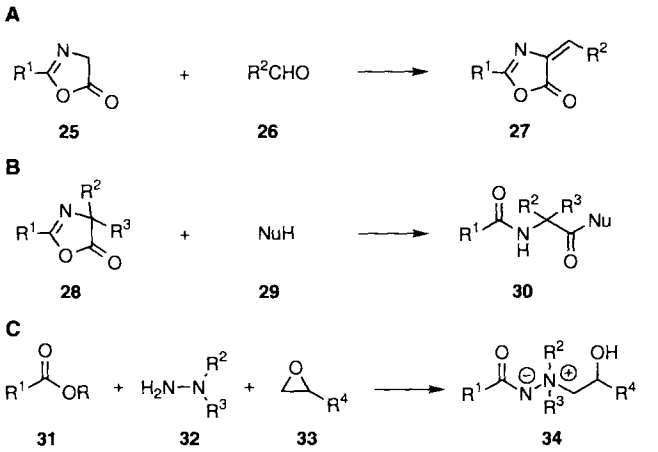
Scheme 7. The Ugi reaction with the isonitrile **19** gives the reactive enamide **20**. This can be converted by further reactions into different acid derivatives (**21**–**23**) or pyrroles (**24**) [41, 90].

21 were obtained by acid hydrolysis; alcoholysis of the reactive enamide with alcohols and mercaptanes gave the esters and thioesters **22** and **23**. Polymer-bound alcohols could also be used as the alcohol component. This so-called "resin capture" meant that the resulting esters **22** were available on a polymer support for further reactions. The pyrrole derivatives **24** were generated by [3 + 2] cycloadditions of electron-deficient alkynes on the Münchnones obtained by protonation of **20**. (A related, purely solid-phase synthesis has since been reported; see Scheme 35).[91] When anthranilic acid derivatives were used as the acid component in the Ugi reaction, the corresponding cyclohexenamides were cyclized to yield benzodiazepine derivatives.

Use of protected D-arabinose as the aldehyde component gave the corresponding lactone by cyclization of the enamide **20**.

3.2.2. *Classical Solution-Phase Reactions*

The most obvious approach for combinatorial single-substance synthesis of compound libraries is the performance of known reliable reactions in parallel. These must proceed very smoothly with high yield and preferably should not require any purification steps. In other words, any reagents remaining at the end of the reaction should be able to be removed by evaporation, as far as possible. These requirements are satisfied by so-called "snap reactions", for example as used to create compound libraries by the company ArQule (Scheme 8).[92, 93]



Scheme 8. Types of reaction used by the firm ArQule for production of compound libraries [92–94]. **A**: Knoevenagel condensation of oxazolones with aldehydes; **B**: reaction of oxazolones and nucleophiles (Nu) with ring opening; **C**: synthesis of aminimides.

By Knoevenagel condensation of oxazolone derivatives **25** with aldehydes **26**, the corresponding unsaturated compounds **27** were obtained, which with suitable choice of substituents enabled further functionalization, for example, by Michael addition (Scheme 8, **A**). Reaction of oxazolones **28** with nucleophiles **29** ran equally smoothly and led to the corresponding ring-opening products **30** (Scheme 8, **B**).[92] The aminimides **34** were another synthetic target. These can be used as peptide mimetics due to their high hydrolytic stability and improved solubility (Scheme 8, **C**).[94] Their synthesis was achieved by a 3-component reaction of ester **31**, hydrazine **32**, and epoxide **33**. Examples of libraries synthesized with this reaction include an aminimide library of type **35** composed of 5000 compounds, and a library of type **36** with 8000 compounds (Fig. 13).

Fig. 13. Structural types of individual compound libraries synthesized by the firm ArQule [92,93].

The Mannich reaction has also been used for library synthesis in solution. A library of 9000 aminophenols was produced from formaldehyde, phenols, and secondary amines.[95] Each of these three libraries were made up of single compounds synthesized on a 20 mg scale with a purity of greater than 80%. Examples of syntheses of smaller libraries each composed of 16 compounds are described in the patent literature.[96] However, both the aminimide synthesis and the Mannich reaction have since been transferred to the solid phase by ArQule researchers. The advantage gained is reported to be increased reliability of the reactions. In addition, it was noted that simpler, more uniform reaction conditions than in solution syntheses could be found for many different reactants in solid-phase syntheses.[97]

The choice of available reactions becomes much wider if simple workup steps can be used. Researchers at Panlabs[98] use excess reagents, deactivate the excess on completion of the reaction, and follow this with an extractive workup. Nevertheless, these reactions must run as quantitatively as possible. Some of the reactions used along these lines by Peterson and co-workers for combinatorial synthesis are shown in Figure 14.

Substrates	Reagents	Products
ROH	RCOCl	aldols, alcohols, amides,
RSH	ROCOCl	amines, (thio-)carbamates,
RNH_2	R_2NCOCl	(thio-)carbonates, (thio-)
$RCONH_2$	RSO_2Cl	esters, (thio-)ethers,

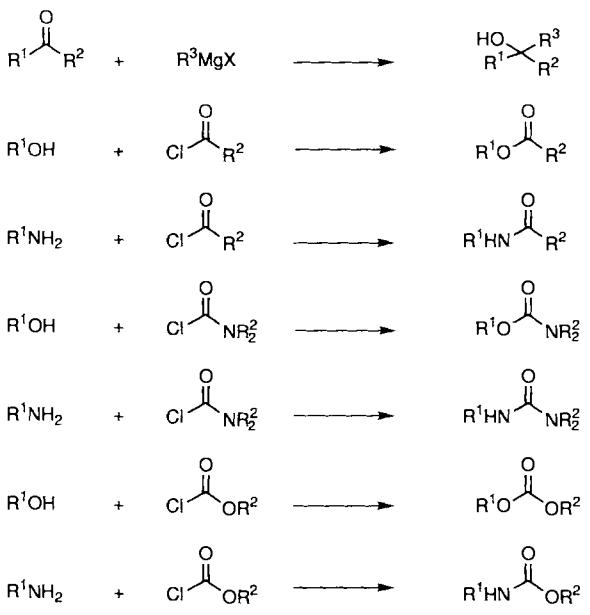
RMgX	RCH_2X	ureas, hydrazones,
RCOR	RCHO	ketones, sulfonamides,
	RCOOH	sulfones
	RCOR	

Fig. 14. Substrates, reagents, and product classes chosen by the firm Panlabs for the synthesis of libraries of individual substances [98].

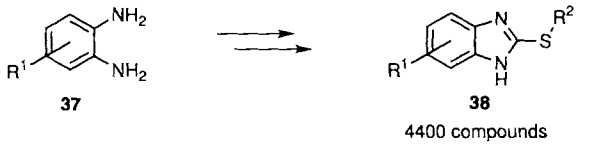
The basic difference of this procedure to the research described so far in this section is that only two building blocks are incorporated into the molecule to be synthesized. In addition, it should be pointed out that the compounds produced are crude products rather than pure substances. Seven reactions were therefore chosen to investigate the purity of the compounds, and reaction conditions were optimized for as wide a substrate spectrum as possible. With these seven reactions, 200 reaction products were produced from 40 substrates and 5 reagents, and about half of these were analyzed by mass spectrometry (Scheme 9). The analysis showed that the desired molecular ion was detected in over 92% of the samples examined. According to company reports, about 50000 compounds were produced by this method in 1995.

Panlabs researchers recently presented various two-step reactions for parallel synthesis of single compounds that extend the product diversity (for example, cyclic anhydride opening with amines and subsequent conversion into the unsymmetrical bisamide).[99] A cooperation was recently started between Panlabs and Tripos to optimize diversity of libraries obtained by this method.

A library of 4400 benzimidazole derivatives **38** synthesized as single compounds was also obtained by a two-step synthesis by Dhanoa of the company Alanex (Scheme 10).[100] A synthesizer developed by Alanex was used to produce the library.

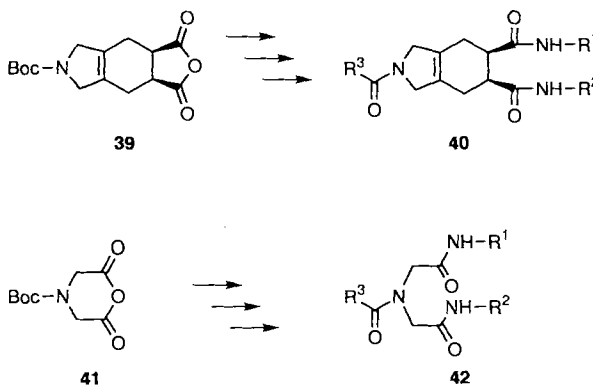


Scheme 9. Reactions used by the firm Panlabs in a validation study for synthesis of compound libraries. With these seven reactions, a library of 200 reaction products was obtained by parallel syntheses [98].



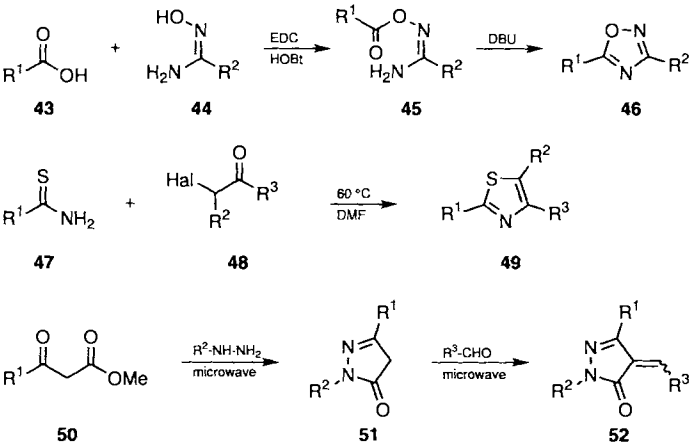
Scheme 10. With a two-step reaction sequence, a library of 4400 benzimidazole derivatives was synthesized from *o*-aminoanilines [100].

The firm Combichem has presented a library of 10000 conformationally flexible compounds as a library with a high degree of diversity. It is referred to by Combichem as a "universal library". Synthesis of a group of these compounds was recently reported by Tarby (Combichem) and Boger.[101] They converted templates **39** and **41** into the triamides **40** and **42** in three derivatization steps (Scheme 11). Purification was restricted to acidic and basic washing. Although the yields fluctuated between 3 and 89% for **40** and between 16 and 99% for **42**, the products were obtained with purities of greater than 85% and greater than 90%, respectively. The libraries synthesized so far are composed of 39 (**40**) and 125 compounds (**42**).



Scheme 11. Synthesis of substituted triamides (**40**, **42**) by successive derivatization of templates (**39**, **41**) [101].

Libraries of five-membered heterocycles (**46**, **49**, **52**) were recently reported by Merritt (Glaxo).[73] These were also produced as single substances by one- or two-step syntheses in solution (Scheme 12).



Scheme 12. Oxadiazoles (**46**), thiazoles (**49**), and pyrazolones (**52**) by combinatorial synthesis in solution [73].

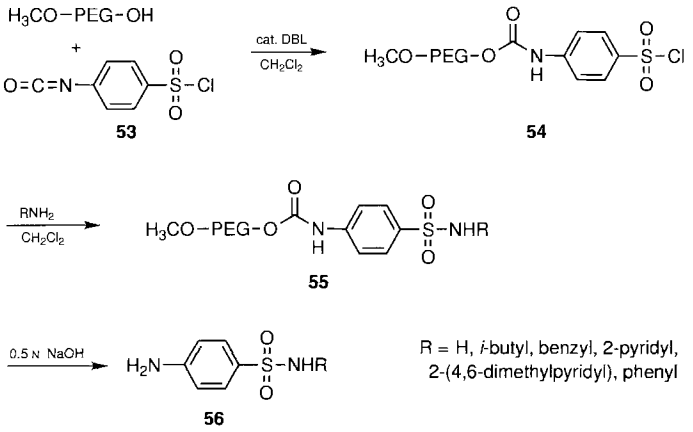
Combination of synthesis in solution and on solid phase has already been mentioned as the strategy of Armstrong,[41, 90] who attached the product of a Ugi reaction to a polymer support during a further transformation (resin capture). Another example of combination of synthesis in solution and on solid phase was reported by Suto (Signal Pharmaceuticals).[42] The reaction was performed in solution with an excess of reagent, for example acid chloride, and the excess reagent was captured by addition of an appropriately functionalized resin, for example an aminomethylated resin ("reverse use of resin"). By-products can also be removed with this procedure if the synthesis is carefully planned (for example, free acids formed by hydrolysis).

3.2.3. *Synthesis on Soluble Polymers*

Synthesis in solution was chosen as the strategy for each of the library syntheses described so far. Some of the problems of solid-phase syntheses were thereby avoided, yet at the same time, the advantages of this method were sacrificed. For this reason, Janda et al.[102] employed a strategy from the work of Bayer and Mutter,[103] which combines the advantages of synthesis in solution with those of solid-phase syntheses. Polyethylene glycol (PEG) was used as the polymeric support. This polymer is soluble in many solvents yet can be precipitated as required by addition of a large amount of diethyl ether. The reactivity of free and PEG-bound substrates can differ in individual cases;[104] however, the reaction conditions determined for synthesis in solution can often be used. This saves having to adjust a synthesis to suit solid-phase conditions. Purification of the reaction mixture can be performed by precipitation and solid-phase extraction of the PEG derivative, making use of the good crystallization properties of PEG derivatives.

An arylsulfonamide library of six individual compounds was constructed as an example library, starting by linking the iso-

cyanate **53** to PEG monomethyl ether (Scheme 13). Subsequently, the sulfonic acid chloride **54** was treated with an amine to form sulfonamide **55**. The aniline derivative **56** was released by hydrolysis of the carbamate functionality with 0.5 M sodium hydroxide.



Scheme 13. Synthesis of sulfonamides on polyethylene glycol (PEG, M_r = 5000) as a soluble polymeric support [102].

Synthesis on soluble polymers was unable to compete with solid-phase syntheses in the field of peptide synthesis. It remains to be seen if this—also in view of the problems of automation—will be the case for combinatorial synthesis of small organic molecules.

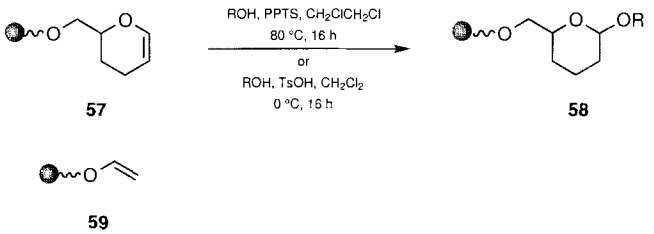
4. Combinatorial Synthesis on Solid Phase

4.1. Linkers for Organic Solid-Phase Synthesis

During organic solid-phase synthesis, the molecules to be synthesized are bound to a polymeric support through a linker (see Fig. 8). This linker largely determines the conditions under which the product is released and thus the reaction conditions suitable for the synthesis. These aspects have been discussed in a review article recently published in this journal.[26]

The support used almost exclusively in combinatorial synthesis of low molecular weight organic compounds is polystyrene crosslinked with 1–2% divinylbenzene, which is also used in peptide synthesis. The most frequently used linkers also originate from peptide synthesis, and consequently, the reactants are almost always bound to the support by an ester or amide bond. The products are generally cleaved from the resin under acidic conditions and have an acid or amide function at the former linkage site, which is not always desirable. Reactions that take place under strongly acidic conditions are therefore not feasible, and the synthesis products must be stable under the same acidic conditions during cleavage. This requirement for compatibility of the linker with the reaction conditions and for product stability precludes the possibility of a "universal linker" for all syntheses. However, it can be expected that a repertoire of linkers will be available in the future, from which a linker suitable for any synthesis sequence can be selected. The first steps in this direction are described next.

Thompson and Ellman developed the new linker **57** based on the THP protective group, which is suitable for immobilization of alcohols.[105] Binding of the alcohol takes place under the usual conditions, and cleavage is most favorable with 95% aqueous trifluoroacetic acid (Scheme 14).



Scheme 14. The THP linker **57** from Ellman et al. [105] and the polymer-bound vinyl ether **59** proposed by Wang [106] enable direct linkage of alcohols to the support.

Polymer-bound vinyl ether **59**[106] reported by Wang is structurally related but more reactive due to less steric hindrance (Scheme 14). Linkers **60**–**65**[107–111] (Fig. 15, Scheme 15) described below are suitable for linking amines to the support. Compounds **60**, **61**,[107] and **62**[108] are derived from the benzyloxycarbonyl protective group. Trifluoroacetic acid is used to

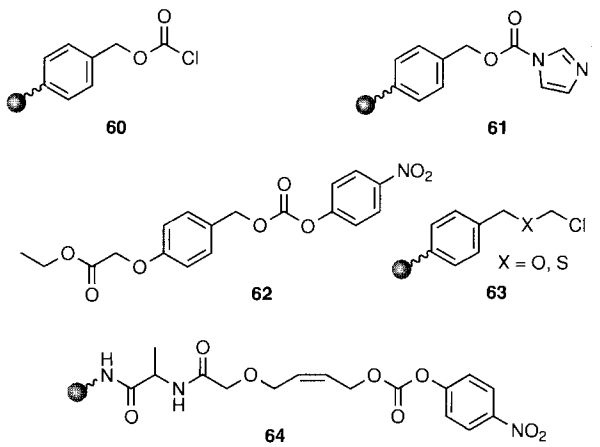


Fig. 15. Linkers for immobilization of amines. Linkers **60**, **61** [107], and **62** [108] are derived from the benzyloxycarbonyl group and are TFA-labile. The amine-linker conjugate is produced from **62** in solution and is linked to the aminomethyl resin after saponification of the ethyl ester. Linker **63** is suitable for linkage of carboxylic acids or (thio)phenols to the support [111]. Linker **64** [109] is based on the Alloc protective group, and cleavage is Pd-catalyzed.

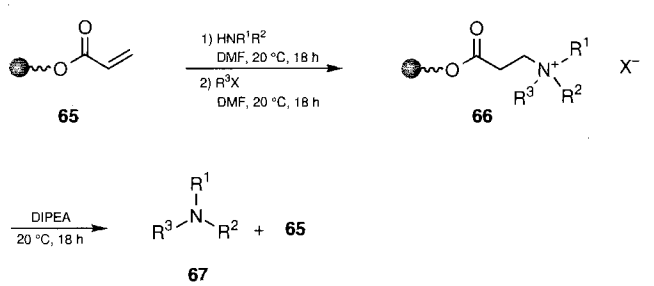
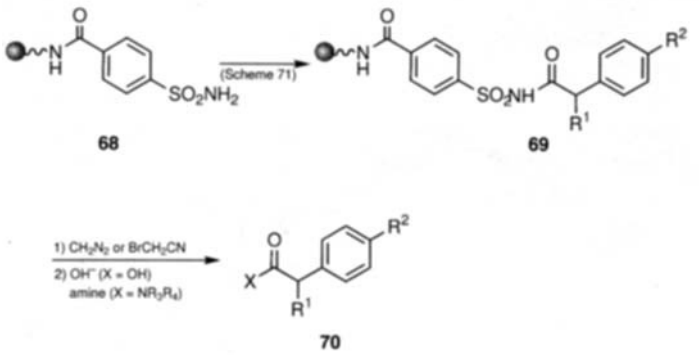


Scheme 15. Amine addition with a Michael reaction on the polymer-bound acrylic ester **65**. After the solid-phase synthesis, the product **67** is cleaved by Hofmann elimination, and **65** is recovered [110].

cleave the product from the solid phase. The cleavage is palladium-catalyzed for **64**,[109] whereas for **65**[110] the tertiary amine **67** is released by Hofmann elimination under mild conditions, thereby regenerating the polymer-bound acrylate **65** (Scheme 15).

Nucleophiles such as (thio)phenols or carboxylic acids can be immobilized with linker **63**[111] from SmithKline Beecham (Fig. 15). Cleavage occurs with 25% trifluoroacetic acid in CH_2Cl_2, for example.

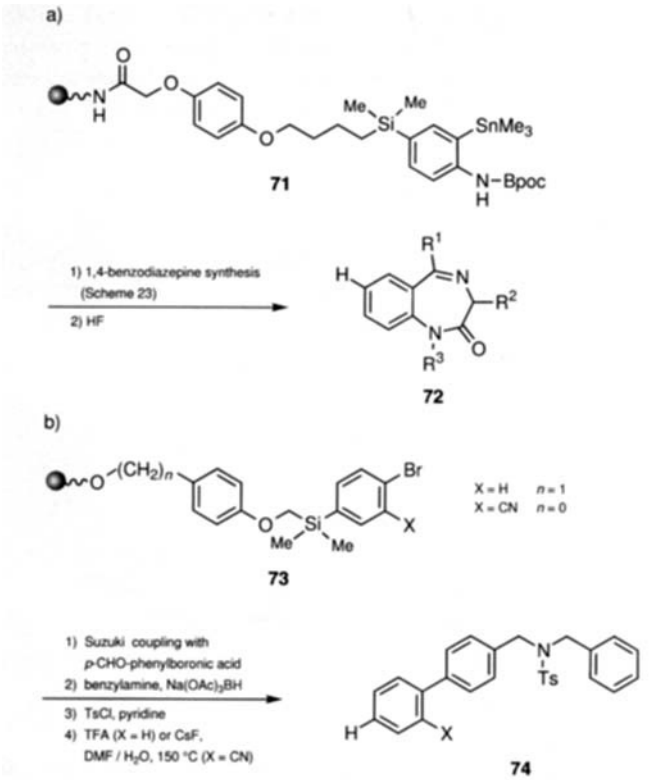
Linkers based on the "safety catch" principle seem to be particularly promising for organic chemistry on solid phase, since they are compatible with many reaction conditions in the non-activated state. Backes and Ellman[112] used the acylsulfonamide linker **68** first described by Kenner[113] for synthesis of phenylacetic acid derivatives **70** (Schemes 16 and 71). Activation takes place by methylation of the sulfonamide



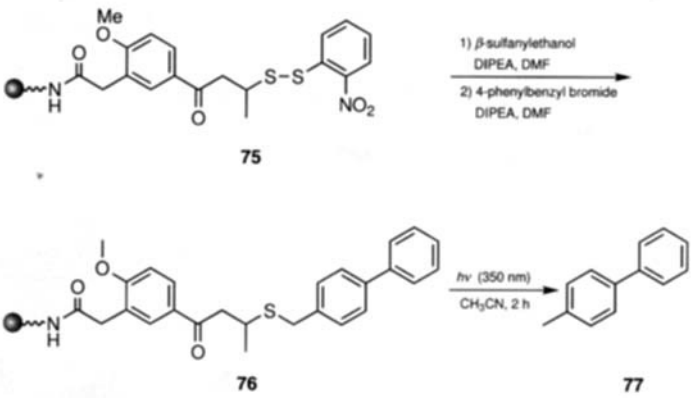
Scheme 16. Kenner's "safety catch linker" **68** [113] as used by Ellman et al. for synthesis of phenylacetic acid derivatives **70** [112, 114, 115].

nitrogen, and the resulting secondary sulfonamide can be nucleophilically cleaved under mild conditions. Anilines, however, are not sufficiently nucleophilic to bring about cleavage. This only takes place after activation of the sulfonamide bond by alkylation with bromo- or iodoacetonitrile.[114, 115]

Highly desirable linkers would not leave any functional groups behind in the target product of the combinatorial synthesis on cleavage. At the same time, the cleavage reagent should preferably be evaporable or easily separated (as in peptide synthesis), since workup that is complicated or difficult to automate is generally undesirable. These requirements are fulfilled by two chemically similar silyl linkers **71** and **73** (Scheme 17), which were developed independently by Ellman et al.[116] and Veber et al.[117] Somewhat complicated syntheses are required if these linkers are used, since the first synthetic building block cannot simply be coupled to the support-bound linker. Instead, conjugates of linker and starting material are first synthesized in solution and attached to the solid phase afterwards. This laborious synthesis has to be repeated for every new starting compound. Both silyl linkers are cleaved with trifluoroacetic acid or fluoride and do not leave any functional groups behind in the target molecule. This is also the case for the photochemically cleavable NpSSMpact linker **75**[118] (Scheme 18) developed by Sucholeiki. The linker molecules **78** described by Holmes et al.[119] and **81** from Geysen et al.[61] can also be cleaved photochemically (Scheme 19).



Scheme 17. Arylsilyl linkers **71** from Ellman et al. [116] and **73** from Veber et al. [117] that do not leave any functional groups in the product after cleavage.



Scheme 18. Photochemically cleavable NpSSMpact linker **75** according to Sucholeiki et al. [118], used in the synthesis of biaryl templates (see Scheme 73).

If the linker can be cleaved selectively, cleavage can take place in aliquots rather than releasing all the compound bound to one resin particle at once. This is of interest for structural determination of biologically active components in substance mixtures, particularly in coded libraries (see Section 5.5). Selectively cleavable linkers known at present are only usable under peptide synthesis conditions. Lebl et al.[120] described linker systems such as **84** (Scheme 20). Activation by acidic cleavage of the Boc group and subsequent dioxopiperazine formation under neutral conditions releases the first aliquot, and nucleophilic ester cleavage gives the second aliquot, both in the form of the propanol amide **87**.

Bradley et al.[121] reported multiple linkers **89** that were obtained by derivatization of aminoethyl resin with equimolar

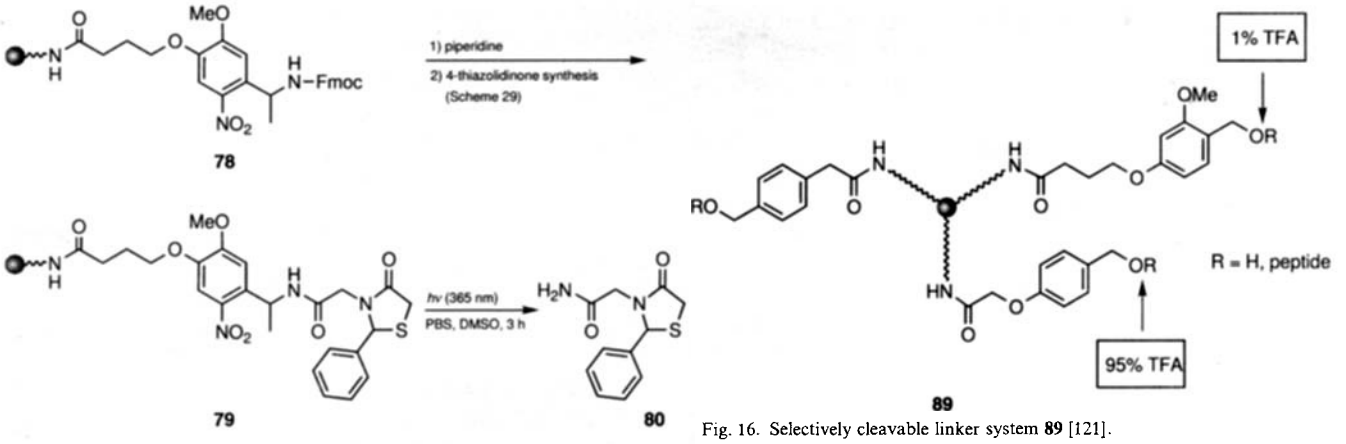


Fig. 16. Selectively cleavable linker system **89** [121].

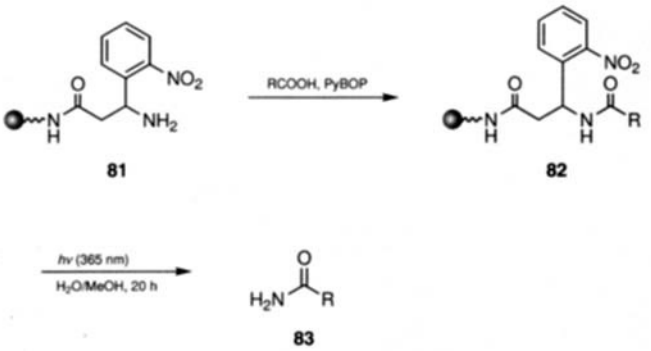
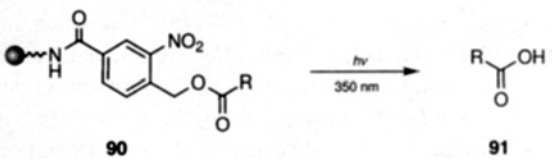


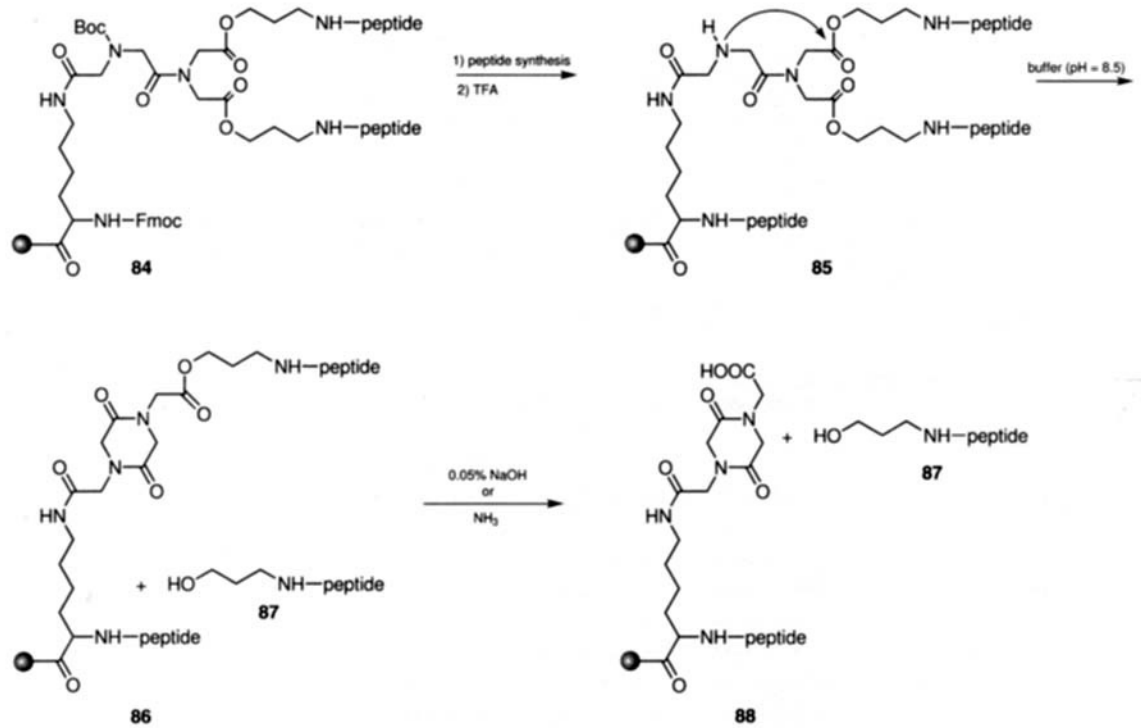
Scheme 19. Photolabile linkers **78** (Holmes et al. [119]) and **81** (Geysen et al. [61]).

amounts of linker molecules with differing acid lability (Fig. 16; R = H). After the synthesis (R = peptide), a third of the product is released with 1% trifluoroacetic acid, followed by the next third with 95% trifluoroacetic acid; the last third remains on the resin under these conditions.

Development of selectively cleavable linkers with wide applications in organic solid-phase synthesis is very difficult since the desired selectivity on aliquot cleavage must be compatible with the necessary orthogonality of the cleavage and synthesis conditions. A chemically much simpler solution has been developed by Baldwin et al.[122] of the firm Pharmacopeia. They used a photochemically cleavable *o*-nitrobenzyl linker[123] **90**, known from peptide chemistry, and achieved aliquoted cleavage by varying the irradiation time (Scheme 21).



Scheme 21. Photolabile linker **90** used at Pharmacopeia for aliquoted cleavage of product [122].



Scheme 20. Linker **84** developed by Selectide [120] that is cleaved in several steps.

In addition to those described here, linkers specially tailored to a particular synthesis are described in the literature. These linkers together with their respective synthesis sequences are described in the next section.

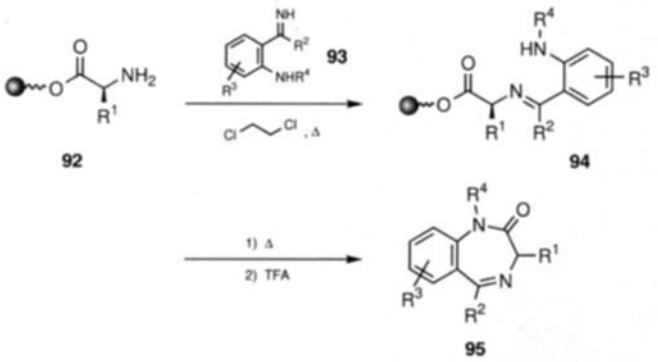
4.2. Synthesis by Ring Closure

4.2.1. Heterocycles

Experience has shown that compounds with biological activity are often derived from heterocyclic structures. It is therefore not surprising that this structural class has received special attention in combinatorial synthesis and that syntheses of heterocycles on solid phase have mushroomed. Small heterocycles, in particular, are used as rigid, highly functionalized molecular scaffolds.

4.2.1.1. Benzodiazepines and Derivatives

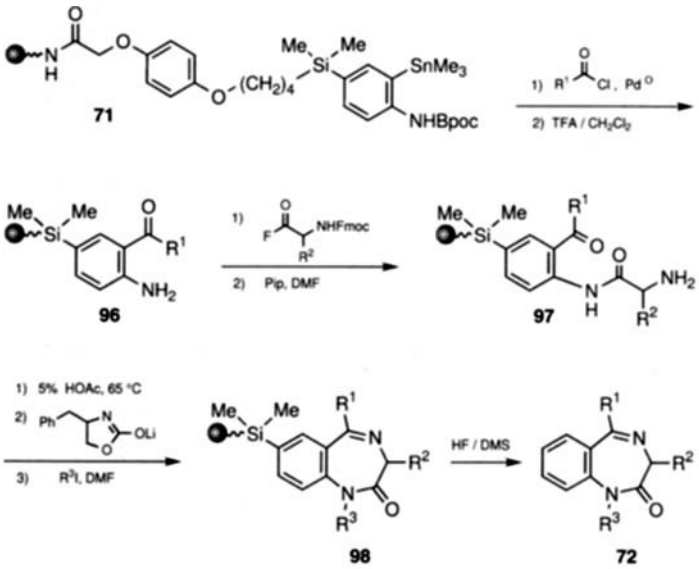
The foundation for solid-phase synthesis of non-oligomeric compound libraries was laid in 1992 with the 1,4-benzodiazepine syntheses of Ellman[124–126] and DeWitt et al.[127] (Parke Davis). This important class of heterocyclic pharmacophores is highly suitable for combinatorial syntheses, since the 1,4-benzodiazepine skeleton can be built up in two or three steps on the central, polymer-bound building block. The benzodiazepine synthesis of DeWitt et al. was based on a synthesis route developed by Camps in 1974,[128] in which amino acids bound to the solid phase (**92**) are treated either with 2-aminobenzophenones (synthesized beforehand in solution) or their imines **93** and are cyclized in the next step (Scheme 22).[129, 130] Diversity of the target compounds **95** is limited by the availability of the 2-aminobenzophenones.



Scheme 22. Solid-phase synthesis of 1,4-benzodiazepines **95** by reaction of resin-bound amino acids **92** with imines **93** and subsequent cyclization [127, 129, 130].

The company Parke Davis used the so-called DIVERSOMER technology[130–132] to synthesize individual substances in a semiautomated parallel synthesis. The apparatus has fritted glass tubes as reaction vessels. Each of these tubes contains about 100 mg resin to which Fmoc-amino acids are bound through an anchor group. Based on previous validation experiments, the reaction times were chosen so that reaction with the least reactive benzophenonimine and subsequent cyclization was successful yet degradation of the benzodiazepine derived from tryptophan was minimal. At the end of the reaction, 40 benzodiazepines were obtained with yields between 9–63% with an average purity of greater than 60% (determined by ^{1}H NMR spectroscopy).

The new synthesis from Ellman et al.,[23, 133–135] in which the 2-aminoaryl ketones **96** are assembled on the solid phase by Stille coupling of protected 2-aminoarylstannanes **71** and acid chlorides, is much more flexible than previous solid-phase benzodiazepine syntheses. This route provides elegant access to hundreds of different 2-aminoaryl ketones **96**, since over 500 acid chlorides are commercially available. 1,4-Benzodiazepines **72** can be obtained by acylation with a series of Fmoc-protected α-amino acid fluorides, deprotection, and acid catalyzed cyclization, and these can be functionalized further by N-amide alkylation (Scheme 23). The 2-aminoarylstannanes **71** are first bound



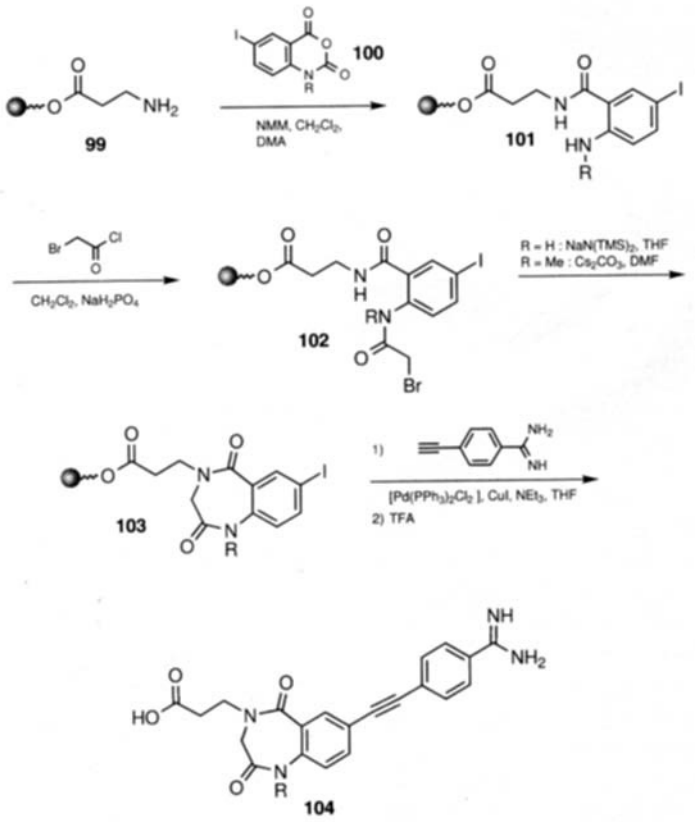
Scheme 23. 1,4-Benzodiazepine synthesis on solid phase to assemble 2-aminoaryl ketones **96** [133–136] by Stille coupling with use of a new silyl linker **71** [116].

to the support with a 4-(hydroxymethyl)phenoxyacetic acid ester linker, and the products can be cleaved after the end of the synthesis with trifluoroacetic acid to provide high-purity hydroxy-substituted benzophenones. This linker was recently modified with a silyl anchor that, after HF cleavage, only leaves a proton at the anchor site in the molecule instead of a functional group, which could interfere in biological tests.[114, 116] Extensive libraries of over 11000 compounds[136] have been synthesized on pins[6] and were examined, for example, for tyrosine kinase inhibition and binding to G-protein-coupled receptors, amongst other functions.

Another benzodiazepine synthesis was reported by Chenera et al. (SmithKline Beecham)[137] in which the benzophenones were also assembled on the solid phase by halogen–metal exchange and reaction with benzoyl chloride.

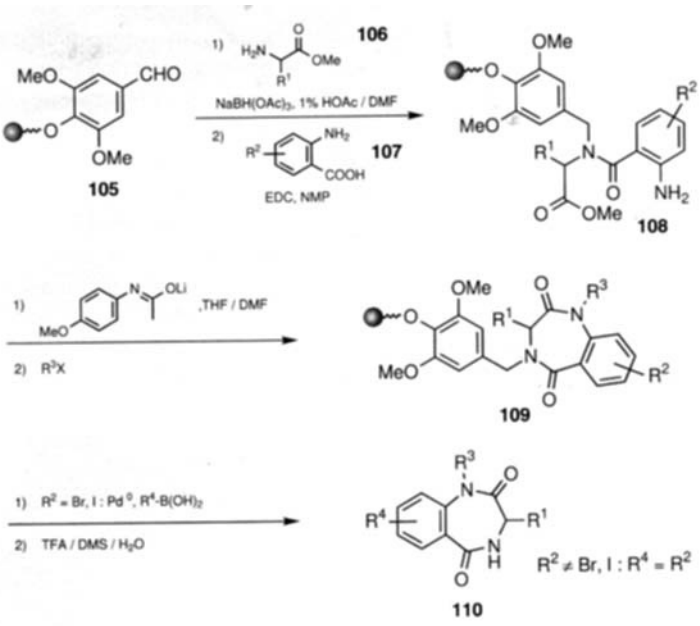
Successful 1,4-benzodiazepine syntheses certainly provided the impetus for the solid-phase syntheses of the closely related 1,4-benzodiazepine-2,5-diones published last year, and hopes are high that these will result in libraries of valuable lead compounds.[138] During the search for fibrinogen GPIIb/IIIa binding inhibitors, Phelan et al. (Genentech) developed a

four-step synthesis for 1,4-benzodiazepine-2,5-diones (**104**, Scheme 24).[139] β-Alanine-loaded Wang resin **99**[140] was converted with an iodoisatoic anhydride derivative **100** into benzamide **101**, which gave the benzodiazepinedione scaffold **103** after acylation with bromoacetic acid chloride and cyclization. Different basic nitrogen side chains were subsequently introduced at the C-7 position by palladium catalyzed coupling reactions.[141] The products were cleaved from the resin with trifluoroacetic acid and purified by reversed phase HPLC. The total yield over all steps was about 15%. No information is available about the size of the libraries or success during screening. As for many other reports on solid-phase syntheses and compound libraries, the applicability of the method is not discussed in this publication. The answer to the question "Which combinations of synthetic building blocks can reliably be used?" often remains the secret of the authors.



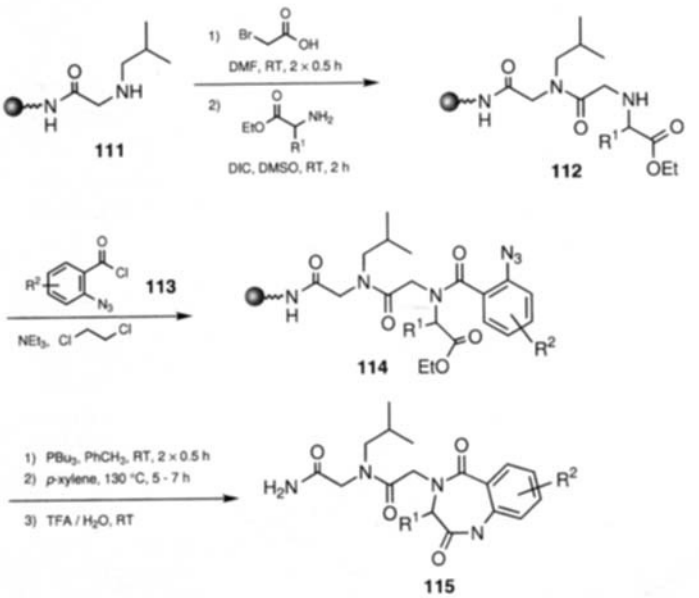
Scheme 24. Solid-phase synthesis of 1,4-benzodiazepine-2,5-diones **104**. Incorporation of basic side chains by palladium-catalyzed alkyne coupling [139].

In a benzodiazepinedione synthesis from Ellman et al.[22, 23, 142] the anthranilic acids **107** can be used as obtained commercially, since the reaction conditions do not require any protective groups (Scheme 25). α-Amino acid esters **106** are linked to dimethoxybenzaldehyde-functionalized Merrifield resin[8] **105** by reductive alkylation. Acylation of the secondary amine with anthranilic acid gives the tertiary amide **108**, which is cyclized and subsequently alkylated with lithium acetanilide in one step. A further functionalization is achieved by Suzuki coupling. Whilst in the aforementioned benzodiazepine syntheses the possibilities for variation of the aromatic substituents are limited (R^3 in Scheme 22), in this synthesis over 40 anthranilic acids can be used in the unprotected form. Racemization is observed neither during acylation nor during cyclization. The products **110** are obtained in 60–90% yield after column chromatography.



Scheme 25. Benzodiazepinedione synthesis on solid phase: reductive amination of support-bound benzaldehyde linker **105** with amino acid esters **106**, followed by acylation with anthranilic acids **107**, cyclization, and alkylation. Further derivatization by Suzuki reaction [142].

Another 1,4-benzodiazepine-2,5-dione synthesis originates from the laboratory of Goff and Zuckermann (Chiron),[143] who used the benzodiazepinedione unit to introduce a higher degree of diversity and rigidity in their peptoids (Scheme 26).[144] First, the peptoid part **112** is assembled according to established procedure,[145] and then acylation with an *o*-azidobenzoic acid chloride **113** prepares the way for an

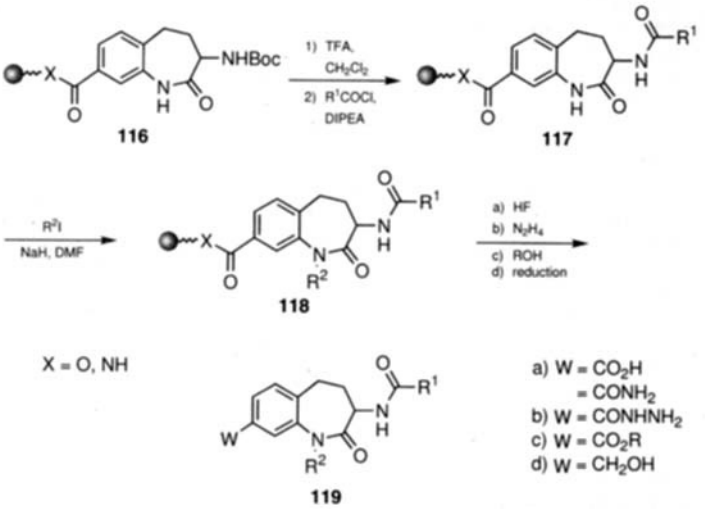


Scheme 26. Benzodiazepinedione synthesis according to Goff and Zuckermann [143]: acylation of the peptoid unit **112** [144, 145] with *o*-azidobenzoic acid chloride **113** and subsequent aza-Wittig reaction [146].

intramolecular aza-Wittig reaction. Initially, the iminophosphoranes are formed with tributylphosphane; they cyclize to the corresponding benzodiazepinediones **115** at 130 °C. Substituents on the arene offer further possibilities for derivatization. For example, a benzodiazepinedione was assembled with a triflate substituent, which was successfully used as a leaving group in a palladium-catalyzed reaction.[146] The products were obtained with 60–95% purity after cleavage (yield 34–90%). Construction of a large benzodiazepinedione library that aims for maximal diversity (!) is currently in progress.[143]

Pyrrolo-1,4-benzodiazepine-2,5-diones were also synthesized by aza-Wittig ring closure by Baldwin et al. (Pharmacopeia). However, no variation of residual groups was reported here; only the reaction of Fmoc-proline resin with unsubstituted *o*-azidobenzoyl chloride, cyclization, and cleavage.[147]

Aminobenzazepines were modified on BHA resin[148] by Chenera et al. (SmithKline Beecham) (Scheme 27).[137] First,



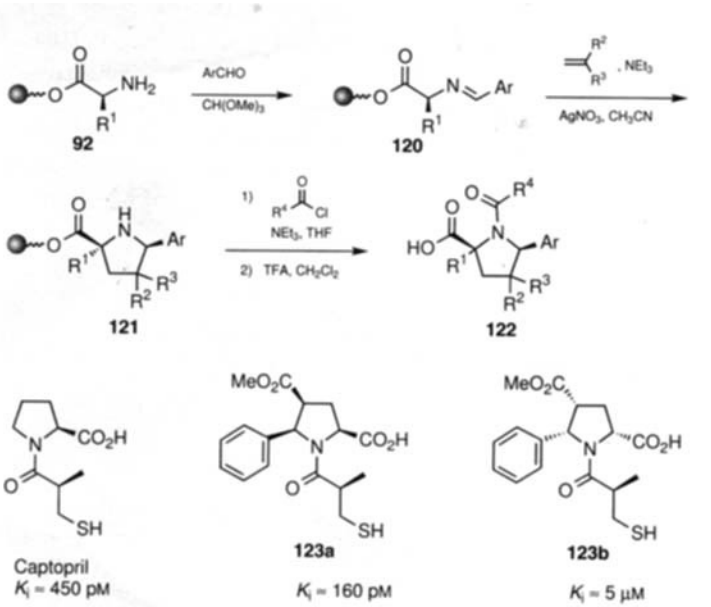
Scheme 27. Modification of 3-aminotetrahydrobenzazepinones **116** on benzhydrylamine resin. Cleavage under different conditions [137] is possible.

Boc-protected 3-amino-8-carboxytetrahydro-1*H*-1-benzazepine-2-one (**116**) was synthesized in solution (8 steps) and then bound to the polymer. After deprotection, the amino group was acylated and subsequently alkylated in DMF in the presence of sodium hydride. The finished products **119** were cleaved off the resin by acidolysis, reduction, transesterification, or hydrazinolysis.

4.2.1.2. Further Heterocycles (Cyclization on the Support)

If cyclization occurs prior to cleavage from the resin, the anchor group remains as a functionality within the molecule (see Section 4.1). This can be an acid group, an amide group, or a hydroxyl group, as exemplified by the benzodiazepines and benzodiazepinediones.

In the pyrrolidine synthesis described by Gallop and his colleagues at Affymax,[21, 32, 149] this is a carboxyl group, which is a desired element of the target structures (Scheme 28). This pyrrolidine synthesis is based upon a 1,3-dipolar cycloaddition of the support-bound azomethinylides obtained from the imines **120** under basic conditions. The imines are prepared by condensation of resin-bound amino acids with aromatic and heteroaromatic aldehydes in pure trimethylorthoformate as dehydrating solvent.[150] The substituted pyrrolidines **121** obtained after cycloaddition may be further acetylated at the nitrogen atom. In a search for new ACE inhibitors[151] a library of 500 sulfanylacyl prolines **122**, analogues of the hypotensive agent captopril, was prepared by the Split method.[13–18] After four iterative screening cycles for ACE inhibition and synthesis of partial libraries the active pyrrolidine **123** was identified, which also contains the sulfanylisobutyryl chain of captopril. It was shown that the diastereoisomer **123a** is three times more effective as an ACE inhibitor than captopril, whereas the other diastereoisomer **123b** exhibited only weak activity. The example of sulfanylacyl prolines demonstrates the possibilities a focused library offers in rapidly identifying new and even more active derivatives of a lead structure.

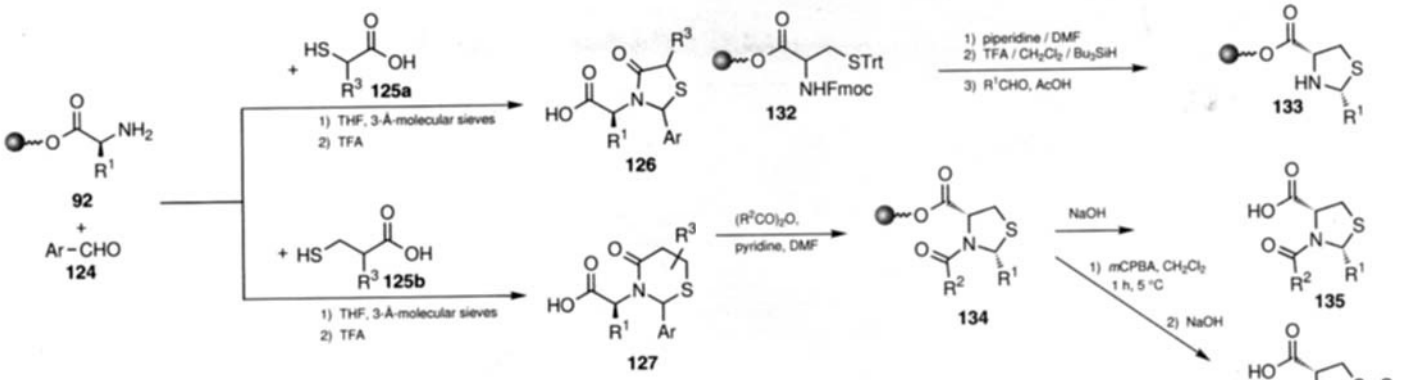


Scheme 28. Synthesis of pyrrolidines **122** by 1,3-dipolar cycloaddition of support-bound azomethinylides. Pyrrolidine **123a** was identified as a potential ACE inhibitor [32, 149].

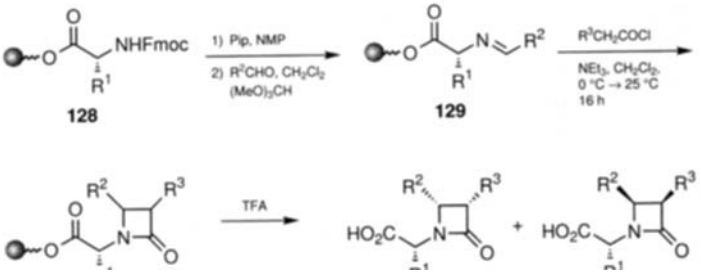
Support-bound imines were also employed by Holmes et al. (Affymax) in the synthesis of 4-thiazolidinediones **126** and 4-metathiazanones **127**.[21, 89, 152] The three-component condensation of a primary amine **92**, an aldehyde **124**, and a sulfanylacetic or propionic acid **125**, which may also be carried out sequentially, affords the corresponding heterocycles **126** and **127** in a smooth reaction (Scheme 29). 4-Thiazolidinones are known for their inhibition of cyclooxygenase-1.[153] In this manner an active inhibitor was identified in a library of 3×125 compounds prepared with the split method.[154]

This synthesis is an example of a one-pot, multicomponent reaction on a solid phase, as in this case the intermediate products undergo further reaction directly and under constant reaction conditions. Multicomponent reactions on solid phases will be discussed in more detail in Section 4.3.3.

A third application of support-bound imines, recently demonstrated by Gallop et al., is the preparation of the β-lactams **130** by [2 + 2]-cycloaddition to ketenes.[21, 155] This solid-phase β-lactam synthesis was carried out on the extremely acid-labile Sasrin resin (Scheme 30).[156] As in the previously



Scheme 29. 4-Thiazolidinones **126** and 4-metathiazanones **127** by three component condensation of a support-bound amine with aldehydes and sulfanylcarboxylic acids [89, 152].



Scheme 30. β-Lactam synthesis by [2 + 2] cycloaddition of support-bound imine **129** with ketenes [155].

Scheme 31. Preparation of thiazolidines **135** by conversion of support-bound β-sulfanylalkylamines **132** with aldehydes. Oxidation to acid-stable sulfoxide analogues **136** [157].

described pyrrolidine synthesis, the resin-bound amino acids **128** were condensed quantitatively to the imines **129** by using a large excess of alkyl, aryl, or α,β-unsaturated aldehydes in a mixture of trimethylorthoformate and dichloromethane. Following thorough optimization studies, the [2 + 2]-cycloaddition was demonstrated only to take place by slow addition of acid chlorides to a suspension of the imine resin at 0 °C in the presence of triethylamine. By using a large excess of ketene in high concentration, even the cycloaddition of imines from sterically hindered amino acids (for example valine) could be carried out with full conversion. After cleavage of the resin and preparative HPLC purification, the β-lactams **131a/b** were isolated in yields of 55–97%. The β-lactam formation occurred with high *cis* selectivity, but showed only a slight stereoinduction by the asymmetric center of the amino acid. On the other hand, induction could be achieved with an optically active ketene. The synthesis of a small model library of 25 compounds showed that most β-lactams were formed in higher than 80% purity. The course of the reaction was observed with "magic angle spinning" ^{1}H NMR spectroscopy. Subsequently a library of several thousand different β-lactams was constructed, the purity of which was suitable for direct testing. The screening results will be reported shortly.

A solid-phase synthesis of thiazolidine derivatives **135** has been developed by Patek et al. (Selectide) (Scheme 31).[157] β-Sulfanylalkylamines such as the cystein derivative **132** react with aldehydes to form a series of thiazolidines **133**. N-acylation and subsequent alkaline hydrolysis form almost exclusively the (2*R*,4*R*)-stereoisomers **134**. Strongly electron-withdrawing substituents in the *para*-position of the aromatic ring reduce the rate of acylation so much that in this case no products are obtained. Thiazolidines with aliphatic substituents, on the other hand, are readily acylated under mild conditions. A number of the thiazolidines are too acid-labile to be cleaved successfully from the resin with TFA. Oxidation with *m*CPBA, however, opens a route to the acid-stable sulfoxide analogues **136**, which after cleavage from the resin are isolated analytically pure. Derivatives with the basic thiazolidine framework are known for their antimicrobial, antihypertensive, and antitumor activity; the biological test results have currently not been reported.

Baldwin and his colleagues at Pharmacopeia are studying the synthesis of binary encoded compound libraries.[158–161] In this variant of the split synthesis, which will discussed in more detail in Section 5.5, the beads are tagged with code molecules that allow the structures of the compounds synthesized on individual beads to be elucidated.[160] The syntheses were carried out on TentaGel resin[9, 162] bearing photolabile *o*-nitrobenzyl linkers. In the construction of a dihydrobenzopyran library (Scheme 32), three dihydroxyacetophenones were initially condensed under Mitsunobu conditions with the linker **137**, which had been coupled to the resin under normal coupling conditions. Following cyclization with seven aminoketones **140**, spirodihydrobenzopyrans were obtained, which, after derivatization of the nitrogen atom, were reduced to **143** with sodium borohydride or converted into dithiolanes **144**. Similar spirocyclics **142** are known in the patent literature as Class III antiarrythmics.[163] Overall 1143 compounds were obtained, which were tested for carboanhydrase inhibition, and a compound active in the nanomolar range was identified.[158, 159]

Similarly, the encoded acylpiperidine library **145** with 6727 compounds was prepared in a three-step sequence using the photolabile nitrobenzyl linker.[158, 159] Initially seven resin-bound piperidine carboxylic acids were coupled with 31 amino acids and subsequently derivatized with 31 acylating agents to form the corresponding carboxamides, carbamates, sulfonamides, and ureas (Fig. 17). The sulfonamide **146** was found to be a carboanhydrase inhibitor, which was active in the nanomolar range.

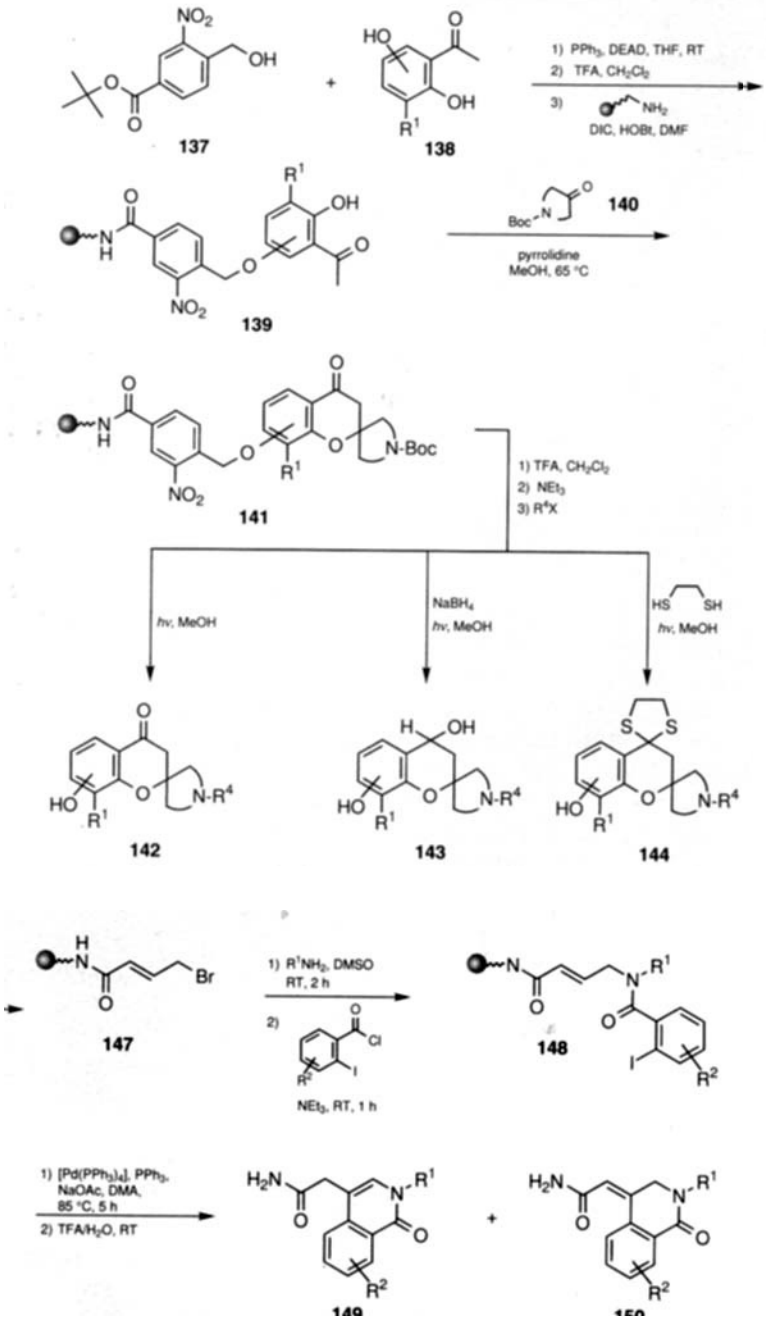


Fig. 17. Acylpiperidine library **145** containing 6727 compounds from which the carboanhydrase inhibitor **146** was identified during screening [158, 159].

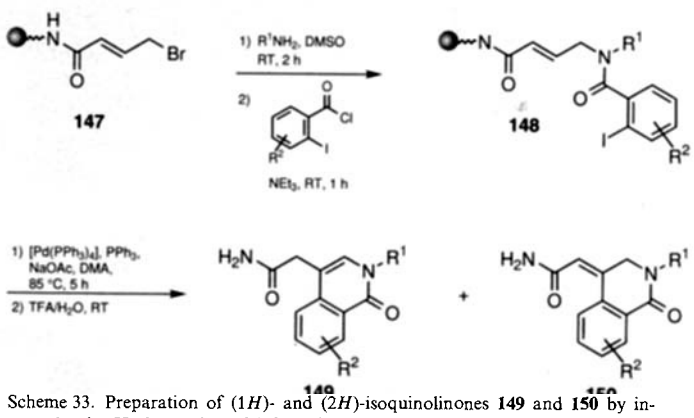
Coded sulfonamide libraries obtained by combinatorial techniques and their use are also the subject of a recent patent application of Pharmacopeia.[161]

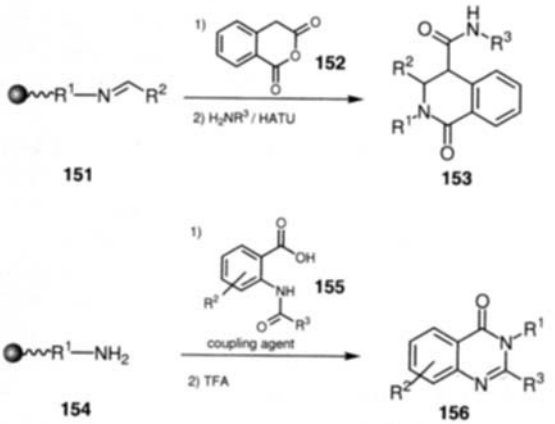
An intramolecular Heck reaction has been used by Goff and Zuckermann in the formation of 1(2*H*)-isoquinolinones (Scheme 33).[164] Acylation of a resin-bound secondary amine with *o*-iodobenzoyl chloride affords the amide **148**, which is capable of undergoing a Pd-catalyzed 6-*exo*-cyclization. Initially the 2*H*-isoquinolinone **150** is formed, which by readdition of PdH and subsequent elimination isomerizes to the thermodynamically favored 1*H*-isoquinolinone **149**. If **148** carries a substituent *ortho* to the iodine, this isomerization is totally or partially suppressed; in this case a mixture of **149** and **150** or



Scheme 33. Preparation of (1*H*)- and (2*H*)-isoquinolinones **149** and **150** by intramolecular Heck reaction of **148** [164].

exclusively **150** is obtained. After cleavage from the resin and freeze-drying, the products are isolated in good yields and with purities of 70 to 95%. Finally, a mixture of seven different peptoids **148** was cyclized. With HPLC-MS it was possible to identify all seven products, which were present in almost equimolar amounts. Apart from the initial necessity of preparing the *o*-iodobenzoic acids or the corresponding heterocyclic derivatives in solution, this reaction sequence offers rapid access to isoquinolinone systems.

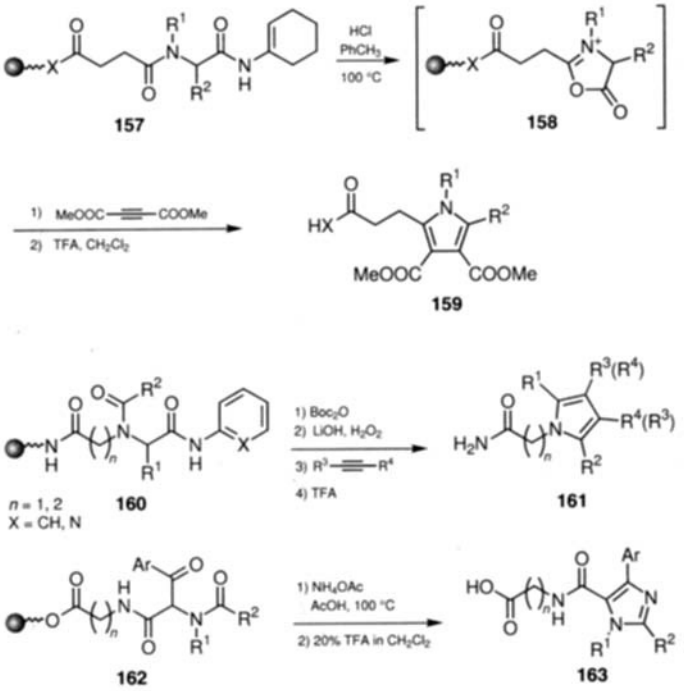
Kiely[165] and Houghten[166] have published the tetrahydroisoquinolinone and quinazolinone libraries **153** and **156** (Scheme 34). In this synthesis, which is based upon a route



Scheme 34. Synthesis of substituted tetrahydroisoquinolinones **153** and quinazolinones **156** according to Kiely [165] and Houghten [166].

devised by Cushman,[167] the tetrahydroisoquinolinones **153** are obtained by conversion of the imines **151** prepared in situ with homophthalic anhydride **152**. Coupling of the free carboxylic acid with amines affords the tetrahydroisoquinolinone carboxamides **153**, which possess three independently variable substituents. Libraries consisting of theoretically 43472 or 367200 compounds (52 sublibraries of 836 compounds and 120 sublibraries of 3060 compounds, respectively) were prepared by this synthetic pathway. Testing of these sublibraries and subsequent deconvolution in a manner analogous to that used for peptide libraries (see Section 5.3) led to compounds with affinity for the σ-receptor and for κ- and μ-opiate receptors.

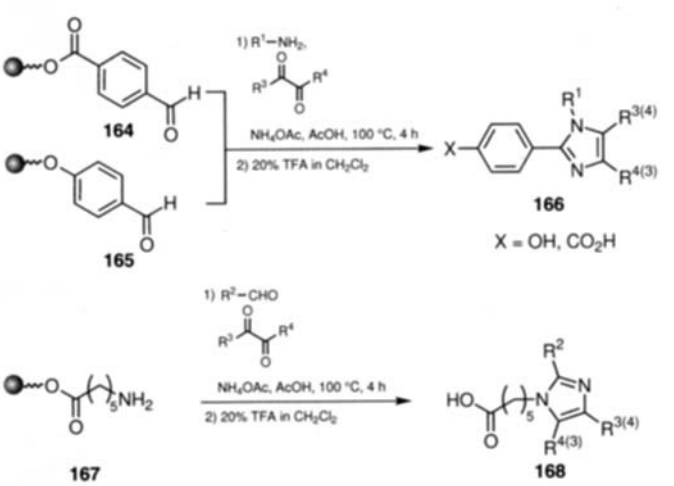
In the synthesis of the quinazolinones **156**, the immobilized amine **154** was coupled with *N*-acetylanthranilic acid **155** (R^3 = Me), and cyclization gave **156**. The C–H acidity of the R methyl group allows further chemistry; thus condensation with benzaldehydes to form the corresponding styryl compounds has been described. The currently largest quinazolinone libraries synthesized consist of 3185 compounds in subsets of 35 components each. Armstrong et al.[91] have synthesized the substituted pyrroles **159** in hitherto unsatisfactory yields (4–17%) by 1,3-dipolar cycloaddition of the münchnones **158** with esters of acetylenedicarboxylic acid (Scheme 35). The münchnones are formed under acidic conditions from the enamides **157**, which are in turn prepared by an Ugi four-component reaction.



Scheme 35. Synthesis of pyrroles **159** and **161** and imidazoles **163** from α-(*N*-acyl-*N*-alkylamino)-β-ketoamides prepared by the Ugi reaction [91, 168, 169].

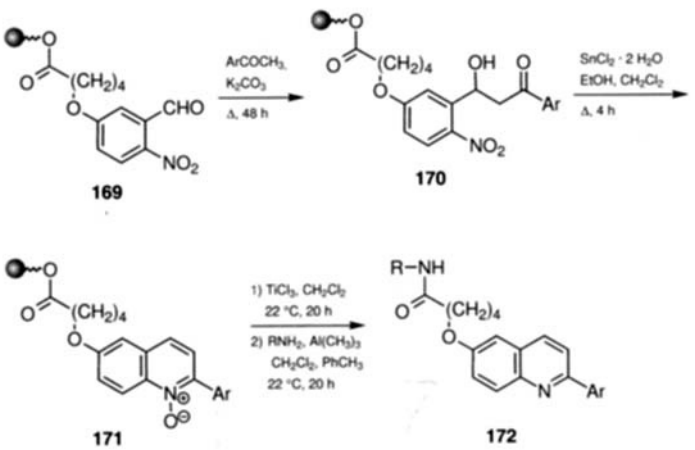
Mjalli et al. at Ontogen[168] also hydrolyzed the initial Ugi products **160**, and the intermediate münchnones were subsequently converted into the pyrroles **161** by cycloaddition with acetylenedicarboxylates (Scheme 35). They were obtained in high purity and in significantly better yields (27–72%) than in the previous work.[91] Mjalli and coworkers[169] also used the Ugi products **162** to synthesize imidazoles **163** (Scheme 35). Wang resin, which remarkably is stable under the cyclization conditions, was used as support. The products thus obtained were purified by preparative thin layer chromatography; the overall yield of Ugi reaction and cyclization lay between 16 and 56% based on the resin-bound isonitrile. It was demonstrated that the cyclization occurs in almost quantitative yields, and the Ugi reaction is the yield-determining step.

The same research group has described[170] another imidazole synthesis on Wang resin, which is based upon a known literature procedure.[171] Aldehydes, 1,2-diketones, ammonium acetate, and primary amines are used as synthetic building blocks. In two different procedures the resin-bound aldehydes **164** and **165** or the amine **167** were utilized (Scheme 36). In both cases the imidazoles **166** and **168** were obtained in very good yields (71–99%) and in very high purity (90–95%).



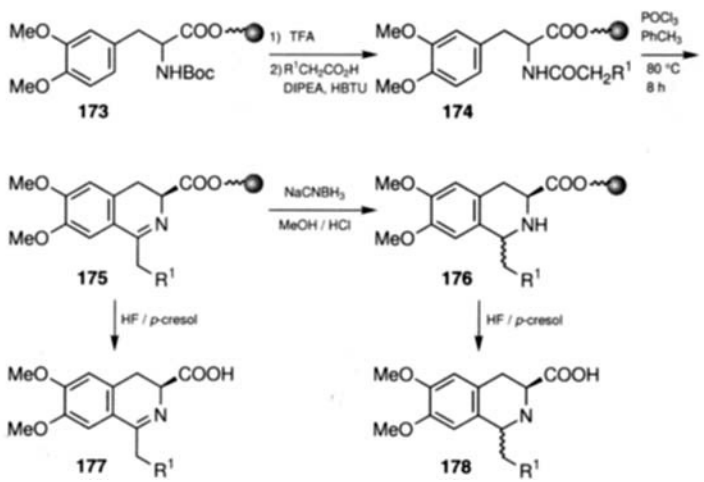
Scheme 36. Solid-phase synthesis of imidazoles **166** and **168** [170]. Either the aldehyde (top) or the amine component (bottom) can be bound to the support.

By aldol addition of support-bound hydroxynitrobenzaldehydes **169** with aryl methyl ketones, Ruhland and Künzer (Schering) have obtained the hydroxyketones **170**, which undergo reductive cyclization to give the corresponding quinoline *N*-oxides **171** (Scheme 37).[172] Deoxygenation with titanium trichloride affords the 2,6-disubstituted quinolines **172**, which may be cleaved from the resin by aminolysis.



Scheme 37. Quinoline-*N*-oxides **171** were prepared by a reaction sequence of aldol reaction and subsequent reductive cyclization, giving quinolines **172** after deoxygenation [172].

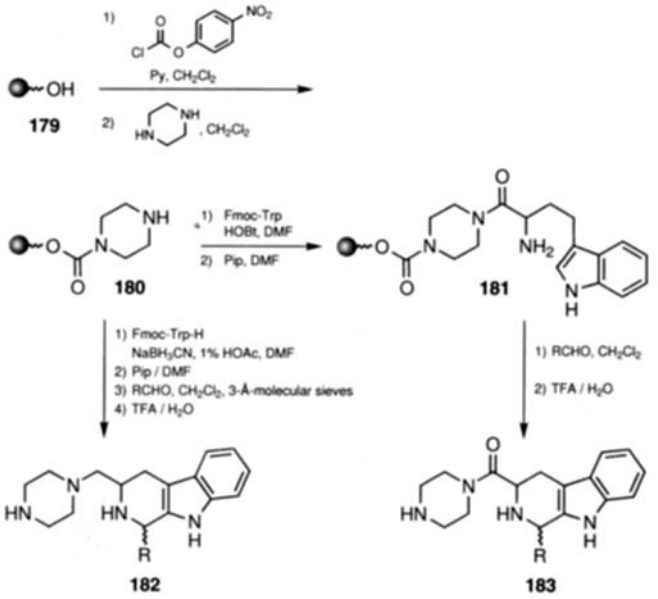
The synthesis of dihydro- and tetrahydroisoquinolines by Bischler–Napieralski reaction has been achieved by Meutermans and Alewood (Scheme 38).[47] In this reaction resin-bound L-3,4-dimethoxyphenylalanine (**173**) is acylated with acetic acid derivatives and subsequently cyclized. Considerable



Scheme 38. Synthesis of dihydro- (**177**) and tetrahydroisoquinolines (**178**) by Bischler–Napieralski synthesis on solid phase [47].

optimization work was necessary to achieve the best results. Whereas reduction of the imine **175** with sodium cyanoborohydride was possible, the use of sodium borohydride led to undesirable premature cleavage from the resin. By using equimolar mixtures of eight different acetic acid derivatives in the acylation stage, well-defined mixtures of the target products **177** and **178** were obtained after cyclization and cleavage and characterized by ion-spray MS. It was not reported whether the products were also formed in equimolar amounts.

The formation of a six-membered nitrogen heterocycle was also achieved by Kaljuste and Undén in their synthesis of tetrahydro-β-carbolines **182** and **183**.[173] In this synthesis they use the Pictet–Spengler reaction on solid phase (Scheme 39). In a two stage procedure on Wang resin[140] an aminoalkylurethane linker (**180**) is initially formed[174] and acylated with Fmoc-tryptophan or reductively alkylated with Fmoc-tryptophanal followed after deprotection by condensation with a

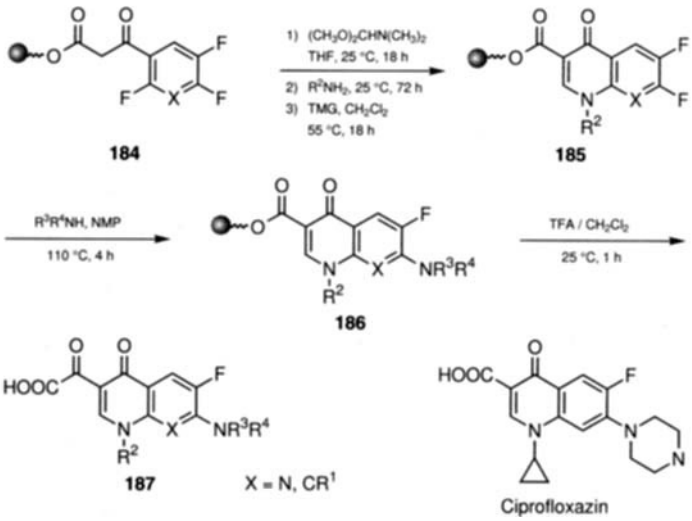


Scheme 39. Solid-phase synthesis of tetrahydro-β-carbolines **182** and **183** by Pictet–Spengler reaction [173].

large excess of different aldehydes. The tetrahydro-β-carbolines **182** and **183** are obtained in relatively high yields and high purity. Further derivatization on the nitrogen atom was not possible, since the secondary amino group in the 2-position could neither be reductively alkylated nor acylated with acid chlorides. N-protected aminoaldehydes could be used as aldehyde component, however, which allowed further acylation and reductive alkylation.

Yang (Merck) also used the Pictet–Spengler reaction for the construction of "druglike" molecules on solid phase.[175] Without using a linker he attached tryptophan directly to Merrifield resin. Following completion of the synthesis, the products were cleaved from the resin by aminolysis.

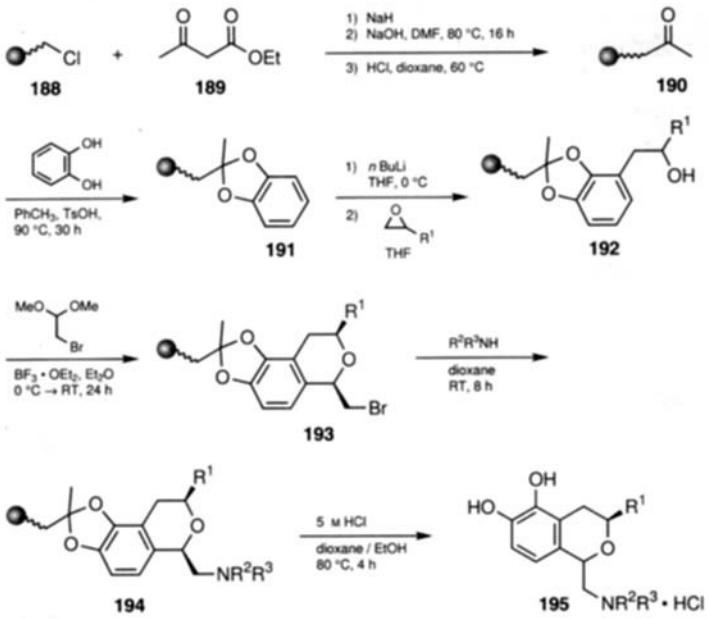
A procedure for the parallel synthesis of quinolones **187** of the ciprofloxazin type has been described by DeWitt et al.[130, 176] (Scheme 40). Here benzoylacetic acids were bound to Wang



Scheme 40. Nucleophilic aromatic substitution to form ciprofloxazin-analogous quinolones **187** on solid phase [130, 176].

resin[140] by ester exchange. Following Knoevenagel condensation with dimethylformamide dimethylacetal, reaction of **184** with a series of amines produces a number of different enamines, which undergo cyclization by nucleophilic aromatic substitution. Further nucleophilic aromatic substitution allows replacement of a second fluorine atom by cyclic secondary amines. By combining three benzoylacetic acids, three primary amines, and four cyclic amines, a focused library of 36 compounds was obtained, amongst which ciprofloxazin itself was observed. It was not mentioned whether gyrase inhibitors more effective than ciprofloxazin were found.

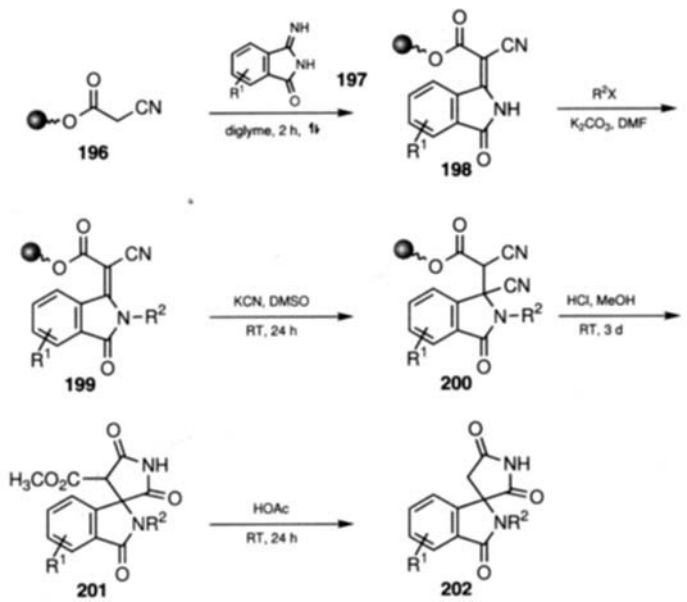
Catecholamines with a semirigid molecular framework are familiar dopamine agonists and are used, for example, against Parkinson's disease. A synthesis of 3-substituted 1-aminomethyl-3,4-dihydro-5,6-dihydroxy-1*H*-2-benzopyrans (**195**) has been devised by DeWitt et al. (Scheme 41).[130] The aromatic diol was protected as a ketal, which served as linker. Initially a catechol ketal resin (**191**) was formed by hydrolysis and decarboxylation of a support-bound β-oxoester, followed by reaction with catechol. After *ortho*-metalation **191** was converted into **192** with



Scheme 41. Preparation of aminomethyldihydroxybenzopyrans **195** starting from a catechol ketal resin **191** [130].

styrene oxide or cyclohexylethylene oxide, and the pyran ring in **193** formed with bromoacetaldehyde dimethylacetal under Lewis acid catalysis. After substitution with amines, cleavage from the resin was undertaken. Only six examples of this sequence were described. Similarly, only very few examples are found in the same patent application describing the synthesis of pilocarpine analogues, isoindolone spirosuccinimides, and pyrazoles.

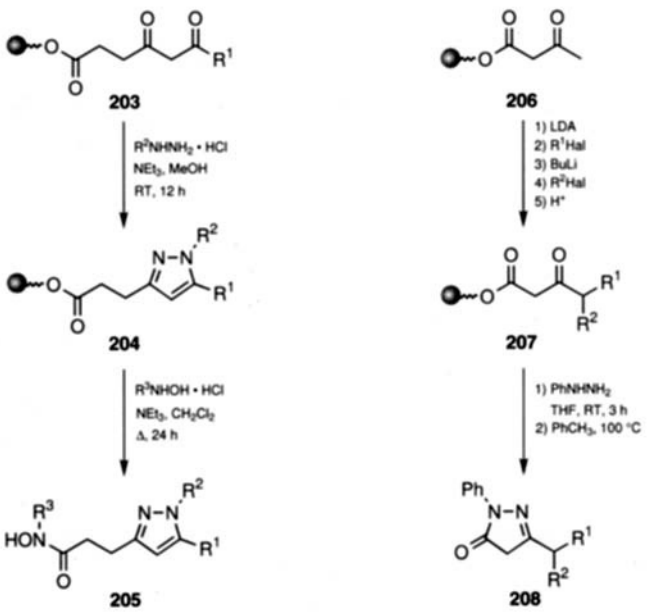
In the preparation of isoindolone spirosuccinimides[130] (**202**, Scheme 42) cyanoacetic acid bound to Wang resin (**196**) was condensed with 3-imino-1-oxoisoindolines **197**. After alkylation of the nitrogen atom and Michael addition of cyanide, **200** was hydrolyzed to the imide and concomitantly cleaved from the resin. The crude product **201** was then decarboxylated in glacial acetic acid. Spirosuccinimides of this structural type



Scheme 42. Solid-phase synthesis of isoindolone spirosuccinimides **202** [130].

are known to be aldose reductase inhibitors and antidiabetics.[177]

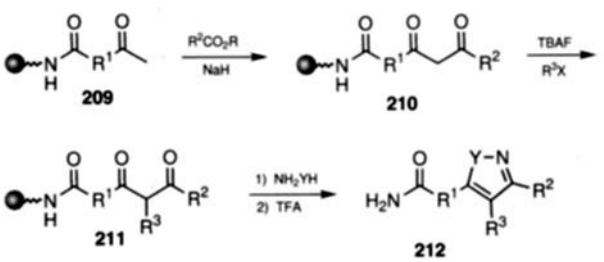
In a classical pyrazole synthesis DeWitt at al. were able to prepare a number of tepoxaline derivatives (**205**) on a polymeric support (Scheme 43).[130] In this synthesis β-diketones linked to the solid phase were condensed with a number of different hydrazines to form the corresponding pyrazoles **204**, which were cleaved from the resin by aminolysis with hydroxylamines under reflux.



Scheme 43. Solid-phase pyrazole synthesis of tepoxaline derivatives **205** (cleavage from the resin by aminolysis with hydroxylamine [130]; tepoxaline: $R^1 = p\text{-}ClC_6H_4$, $R^2 = p\text{-}CH_3OC_6H_4$, $R^3 = CH_3$) and of pyrazolones **208** (cleavage at the cyclization step [179]).

The condensation of β-dicarbonyl compounds with hydrazines has also been used by Tietze et al. in the solid-phase synthesis of 1-phenylpyrazolones **208** (Scheme 43).[178] The β-oxoesters used were obtained by selective γ-alkylation of the polymer-bound acetoacetate **206**. Since cyclization occurs during the cleavage step, and only those intermediates with the correct structure are capable of cyclization, the desired pyrazolones are obtained in very high purity.

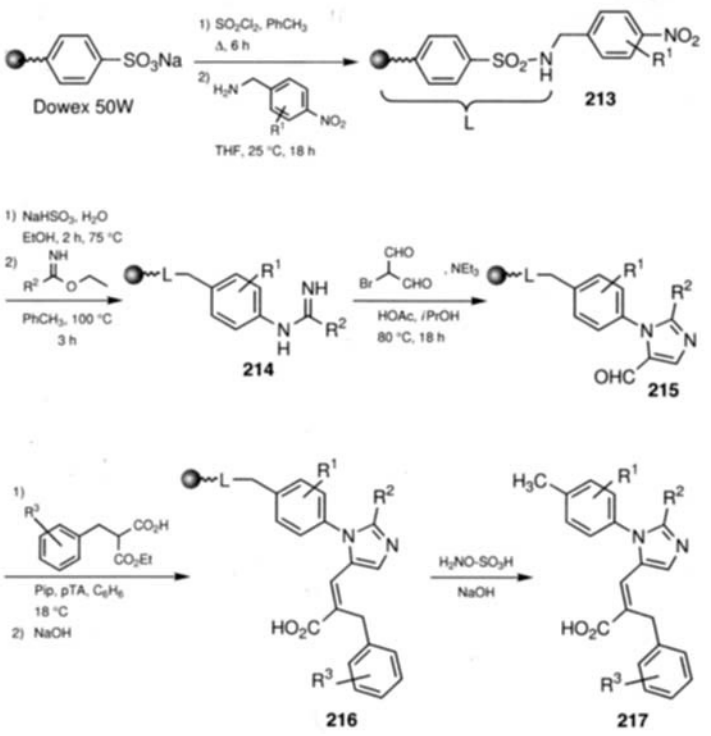
In a similar manner Felder et al. (Ciba-Geigy) were able to prepare a library of more than 10000 pyrazolones in a split synthesis (Scheme 44).[179] The β-diketone **210** was prepared by acylation of a resin-bound methyl ketone (**209**) with an ester in



Scheme 44. Solid-phase synthesis of pyrazoles **212** (Y = NR^4) and isoxazoles **212** (Y = O) [180].

the presence of sodium hydride. The subsequent alkylation was successful in the presence of TBAF. The β-diketones **211** thus obtained were cyclized both to the pyrazoles (**212**, Y = NR^4) and to the isoxazoles (**212**, Y = O). A detailed study of the scope and limitations of this reaction sequence has been recently published.[180] A further pyrazole library with about 5000 compounds has been assembled in solution by Dhanoa[100] at Alanex.

The *N*-phenylimidazolyl acrylic acid library of Chenera et al. (SmithKline Beecham) has $5 \times 5 \times 5 = 125$ members (Scheme 45).[137] In this example, the solid support is the ion

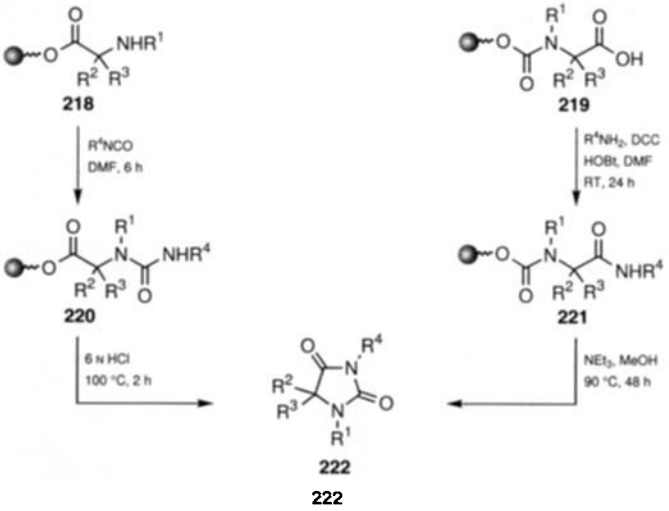


Scheme 45. Construction of a *N*-phenylimidazolyl acrylic acid library **217** through use of an ion-exchange resin with a reductively cleavable sulfonamide linker **214** [137].

exchange resin Dowex 50W. In order to ensure complete conversion a large excess of reagent was used in each reaction step. In the first step a nitrobenzylamine was bound to the resin as a sulfonamide and reduced to the aniline with sodium hydrogen sulfite. Treatment with iminoesters led to the resin-bound *N*-phenylamidines **214**, which were cyclized to the formylimidazolones **215** with bromomalonaldehyde. Conversion into the corresponding imidazolyl-5-acrylic acids **216** was achieved by a type of Knoevenagel condensation with monoethylbenzyl malonate under dehydrating conditions. After completion of the reaction, cleavage from the resin was achieved by reductive amination on heating with hydroxylamine-*O*-sulfonic acid in NaOH as reported by Nickon.[181]

4.2.1.3. Further Heterocycles (Cyclization during Cleavage from Support)

Many research groups are concerned with the development of supports that allow the mildest possible cleavage at the end of the synthesis. DeWitt and her colleagues at Parke–Davis are pursuing a somewhat different strategy in many of their syntheses; they are attempting to induce cleavage during the final cyclization step. This has a big advantage: reaction products that are not capable of cyclization and that arise from incomplete conversion in the earlier stages remain on the solid phase, so that purer products are obtained. Examples are the syntheses of 1,4-benzodiazepines illustrated in Scheme 22 and the pyrazolones **208** (Scheme 43). The same strategy was followed in the parallel synthesis of 40 hydantoins (Scheme 46).[129, 130]

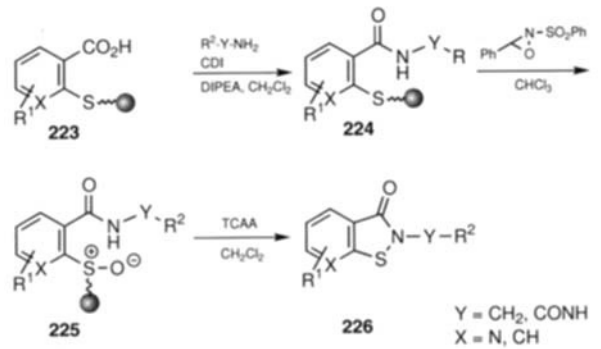


Scheme 46. Synthesis of hydantoins **222** by reaction of support-bound amino acids **218** and **219** with isocyanates and amines, respectively, and subsequent cyclization [129, 130].

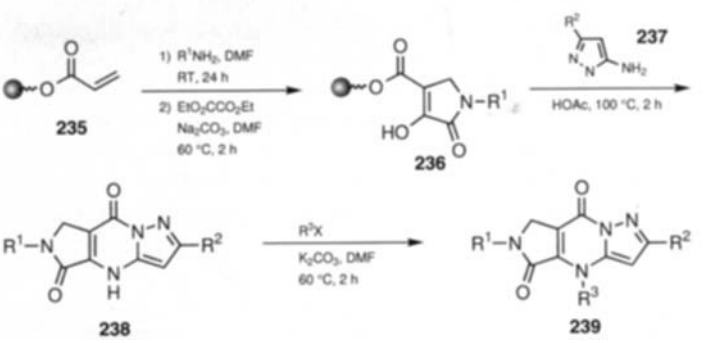
Hydantoins represent the basic structure of a number of antiepileptics, of which phenytoin is still on the market. In the hydantoin synthesis, eight different C-terminally coupled amino acids (**218**) were first deprotected and then treated with five different isocyanates. Heating the ureas (**220**) in 6 N hydrochloric acid initiated cyclization to **222**; 39 individual compounds were obtained in yields of between 4 and 81%. To achieve a greater variation in the products the amino acids may be reductively alkylated with aldehydes prior to reaction with the isocyanates.[130]

Dressman et al. (Lilly Research Lab.) have described a further hydantoin synthesis in which the amino acids are N-terminally bound to a hydroxymethyl resin through a carbamate linker (Scheme 46).[182] After amide formation to form **221**, cyclization took place under basic conditions. In this way, a library of 800 individual compounds was constructed from 20 amino acids and 80 primary amines. This hydantoin synthesis, in which a wide variety of amines may be used, has the advantage over the previous synthesis in that numerous, readily available primary amines may be used in place of the isocyanates.

The Parke–Davis research group has developed a solid-phase synthesis of benzoisothiazolones, which are known[183] for their antibacterial, antimycotic, and antifungal properties (Scheme 47). In one example, a library of nine compounds of type **226** was constructed.[130, 184] Here, aromatic thiocarboxylic acids were bound to a Merrifield resin,[8] converted into active esters, and treated with amines to form **224**. After oxidation, the sulfoxides **225** were cyclized to the benziso-



Scheme 47. Benzoisothiazolone synthesis by sulfoxide rearrangement of **225** during cleavage from the solid phase [129, 130].

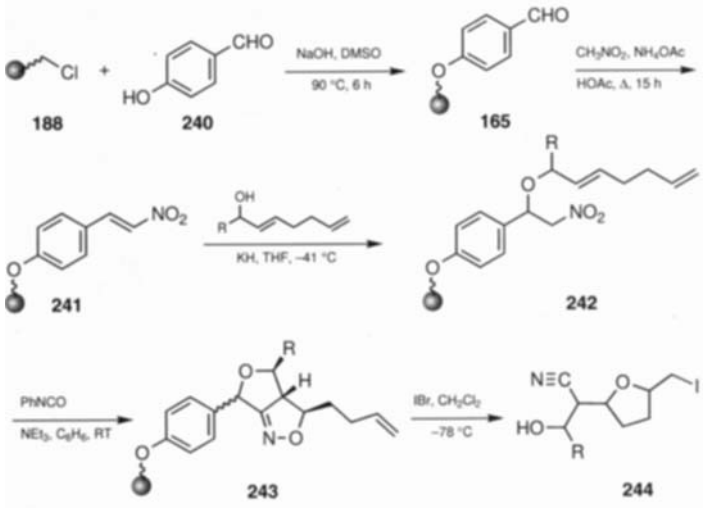


Scheme 49. Pyrimidinedione synthesis by formation of a pyrrolidinone **236** on solid phase, subsequent substitution with aminopyrazoles **237**, and cyclization during cleavage from the resin [130].

thiazolones **226** with trichloroacetic anhydride in a type of Pummerer-sulfoxide rearrangement.

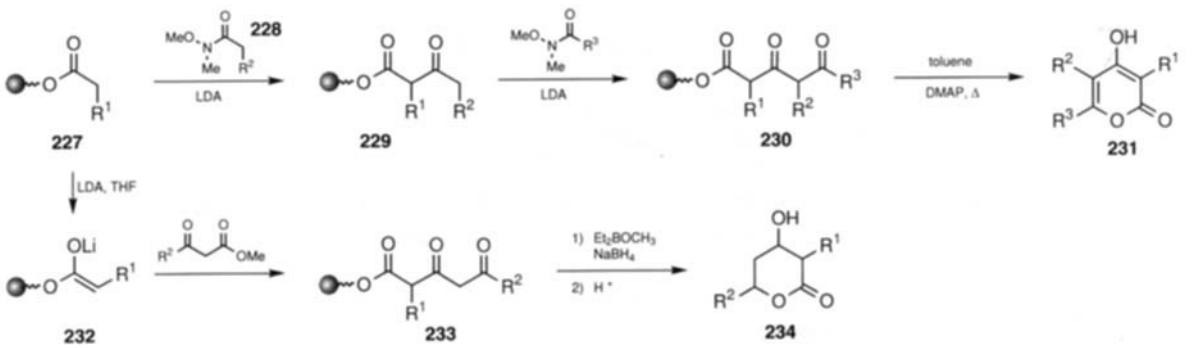
β-Oxoesters may be formed on solid phase,[185] amongst other methods, by ester enolate acylation with Weinreb amides **228** (Scheme 48).[186] The β,δ-dioxoesters **230**, formed by further acylation, cyclize to pyrones **231** on heating in the presence of DMAP. The number of products produced by this method was not reported. Three examples of the preparation of tetrahydrohydroxypyranones **234** have also been described.[130] In a five-step synthesis starting from acrylic acid substituted resin **235**, the same authors have prepared the pyrrolidinones **236** by Michael addition with amines followed by cyclization with diethyl oxalate (Scheme 49). After substitution with 3-aminopyrazoles they cyclize on treatment with 5N HCl at 80°C, with concomitant cleavage from the resin to form the pyrimidinedione systems **238**, of which eight examples were described.[130] Pyrazolopyrrolopyrimidinediones of the type **239** are known to be inhibitors of cholesterol-*O*-acyltransferase (acylCoA inhibitors).[187]

In their synthesis of cyclic ethers, Kurth et al.[188] have also made use of the strategy of cleaving the target products from the polymeric support during the cyclization stage. In a five step synthesis the nitroolefin **241** was first prepared by nitroaldol condensation and then treated with a dienol in a Michael-type reaction. The β-nitroethers **242** thus formed were converted into nitrile oxides with phenylisocyanate and immediately transformed into the tetrahydrofuroisoxazolines **243** in an intramolecular 1,3-dipolar cycloaddition. Oxidative cleavage and electrophilic cyclization of these heterocyclic systems afforded selectively the cyclic ethers **244**, as illustrated in Scheme 50. All by-products formed during this reaction sequence remained bound to the solid phase. Although various reactions were



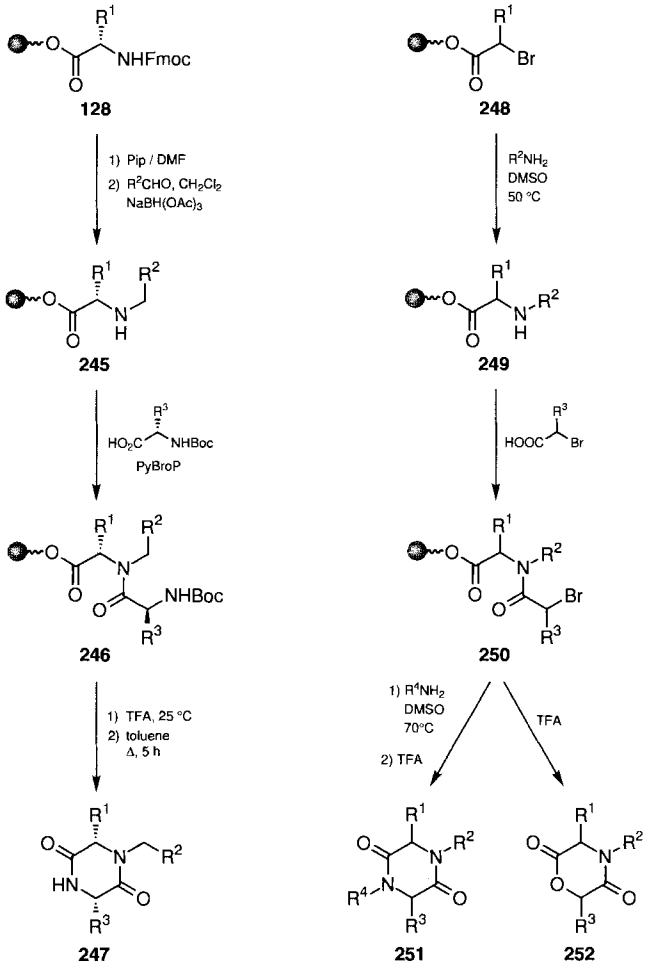
Scheme 50. Solid-phase synthesis of cyclic ethers **244** by the sequence nitroaldol condensation, Michael reaction, 1,3-dipolar cycloaddition, and subsequent oxidative cleavage from the resin by cyclization [188].

adapted for solid-phase synthesis in this reaction sequence, they are not ideally suited to library synthesis as only one moiety can be varied, since the achievable diversity of products is extremely low. The same applies to the γ-butyrolactone synthesis also developed by Kurth et al,[189] as here, too, only one substituent can be modified.



Scheme 48. Preparation of hydroxypyranones **231** on solid phase by synthesis of the β,δ-dioxoesters **230** on the resin by acylation with *N*-methoxy-*N*-methylamides **228** and cyclization during cleavage from the resin [185]. Hydroxy-δ-lactones **234** were obtained analogously by reduction before cleavage.

In contrast to the Kurth methodology, the solid-phase synthesis of a dioxopiperazine library **247** described by Gordon and Steele (Pfizer) fulfills the requirement laid down for combinatorial synthesis to a much greater extent.[190] With two readily available building blocks, amino acids and aldehydes, a heterocycle with three different substituents can be formed (Scheme 51). The key step is reductive alkylation with sodium



Scheme 51. Preparation of a dioxopiperazine library **147** by reaction of amino acids and aldehydes (Gordon, Steele [190]), and dioxopiperazines **251** and dioxomorpholines **252** from bromoacetic acids and amines (Spear et al. [191]).

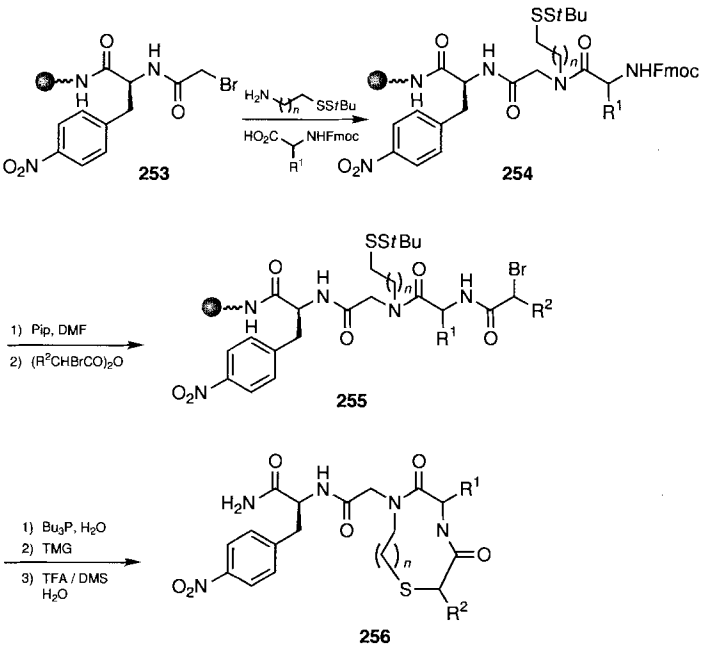
triacetoxyborohydride, which allows the use of different amino acids and aldehydes. Acylation of the secondary amine **245** is difficult and requires repeated coupling with PyBroP to obtain complete conversion. As no cyclization occurs under cleavage conditions, heating in toluene for a short while is required after evaporation of the TFA. A model library with 10×100 compounds was constructed by the split method[13–18] and characterized by HPLC-MS. By iterative screening and deconvolution of the library, several dioxopiperazines that exhibited high affinity for the neurokinin-2 receptor were identified.

Starting from α-bromocarboxylic acids and amines Spear et al. (Chiron) synthesized a library of 22540 dioxopiperazines (**251**) in 23 mixtures, each containing 980 compounds (Scheme 51).[191] Similarly, starting from the same intermediates **250**, a library of dioxomorpholines **251** was also constructed.

Dioxopiperazines, also investigated by the research group at Affymax, are subject of a recently published patent application.[192]

4.2.2. Macrocycles

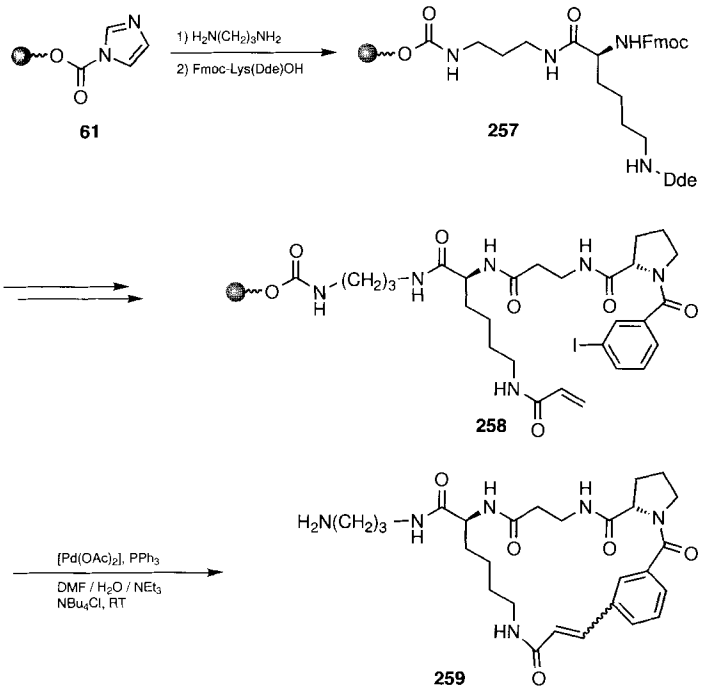
A library of macrocyclic β-turn mimetics **256** has been constructed by Virgilio and Ellman from α-amino acids, α-halocarboxylic acids, and ω-amino disulfides (Scheme 52).[134, 193, 194]



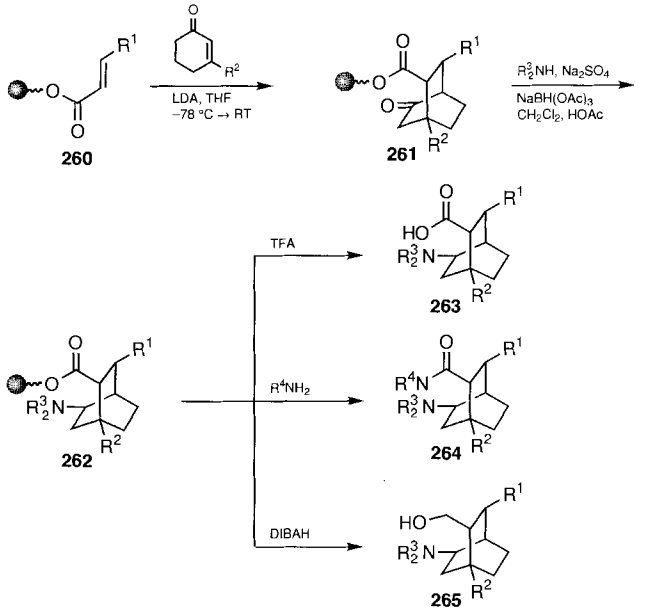
Scheme 52. Solid-phase synthesis of β-turn mimetics **256** from α-amino acids, α-halocarboxylic acids and ω-aminodisulfides [134, 193, 194].

Initially bromoacetic acid is coupled to support-bound *p*-nitrophenyl alanine, substituted with aminoalkyl disulfides, and coupled to **254** with an amino acid. Acylation with α-bromoacetic anhydride affords the precyclization product **255**. Deprotection with tributylphosphane in a 5:3:2 mixture of propanol, DMF, and water occurs successfully only on a TentaGel resin.[195] Cyclization to the nine and ten membered rings **256** occurs under strongly basic conditions in the above-mentioned solvent mixture. The β-turn mimetics, of which over 2000 examples have now been synthesized, are obtained after cleavage with TFA.[194]

Another interesting macrocyclization on a solid phase has been described by Hauske et al. (Arris, Scheme 53).[196, 197] An imidazolidine linker[107] **61** is first attached to a TentaGel support with CDI, which with diaminopropane gives an amino-functionalized resin containing an acid-labile carbamate linker. After coupling with lysine, β-alanine, and proline, *m*-iodobenzoic acid and acrylic acid are attached to the two amino termini of the tripeptides thus formed. The key step is an intramolecular Heck reaction that can only be successfully carried out on TentaGel resins, but not on conventional Merrifield resins. This macrocyclization occurs in solution at essentially "infinite" di-



Scheme 53. Macrocyclization to **259** by an intramolecular Heck reaction on a solid phase [196].



Scheme 54. Solid-phase synthesis of bicyclo[2.2.2]octanes **263**–**265** by tandem Michael addition and cleavage from the resin under different conditions [203].

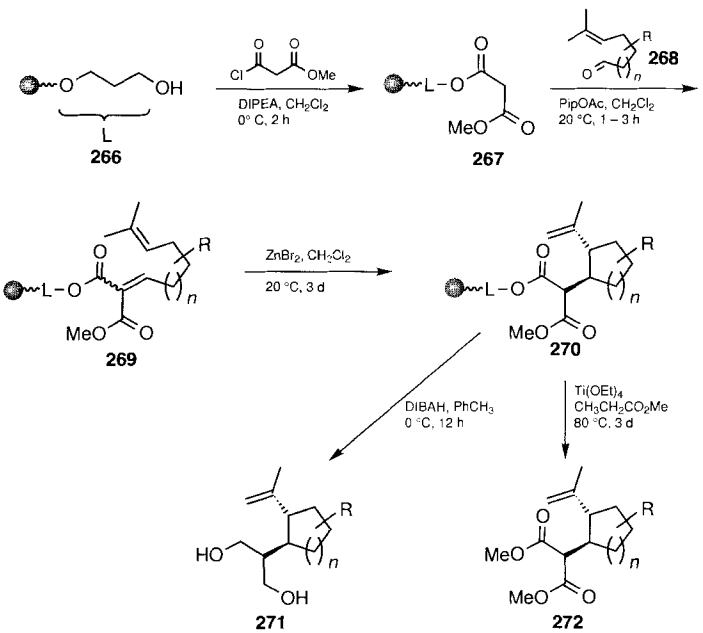
lution, because of the pseudo-dilution on the solid phase, and is clearly independent of substituents and ring size: the 20–24 membered macrocycles **259** are obtained in high purity and in remarkable overall yields (75–85%). A library with 15 members was produced by the split method. Intramolecular Wadsworth–Emmons reactions[198] have also been used by Hauske et al. for macrocyclization.[196]

4.2.3. Carbocyclic Compounds

The construction of carbocyclic compounds by Diels–Alder reaction on solid support was originally investigated by Leznoff et al. in the 1980s.[199] More recent examples of a Diels–Alder reaction are the reaction of a C_{60} fullerene with cyclopentadiene bound to a solid phase,[200] which, as expected, is reversible on heating at 180 °C, and a diastereoselective reaction of aminofurans with acrylates[201] on the solid phase. The Pauson–Khand reaction of polymer-bound alkynes with norbornadiene and norbornenone is more efficient than in solution.[202] Both cycloadditions have undeniably "combinatorial" potential, although the authors were probably not thinking of compound libraries at that time.

Until now enolate anions on a solid phase have only been used in simple alkylation reactions. Ley et al. have used them in a tandem Michael addition for the solid-phase synthesis of bicyclo[2.2.2]octanes (**262**).[203] Here, polymer-bound acrylates **260** are treated with cyclohexenone enolates (Scheme 54). After reductive amination, the bicyclo[2.2.2]octanes **262** are cleaved from the resin under reductive conditions or by aminolysis or acidolysis. This reaction sequence offers great potential for synthesis of a library of high diversity. More than 250 different acrylates and enones are currently available commercially, and the palette of amines available for reductive amination is equally extensive. One awaits further reports from this group with great anticipation.

In a further example of support-bound carbocycle synthesis, Tietze and Steinmetz have recently published a stereoselective solid-phase synthesis of the cyclopentane and cyclohexane derivatives **271** and **272** that employs a domino Knoevenagel–ene reaction (Scheme 55).[48] A Merrifield resin modified with a propandiol linker (**L**) was used as support. Subsequent reaction with monomethyl malonoyl chloride afforded the polymer-bound malonate **267**, which, for the two-component domino reaction, was treated with the unsaturated aldehydes **268** in the presence of catalytic quantities of piperidinium acetate, fol-



Scheme 55. Stereoselective solid-phase synthesis of cyclopentane and cyclohexane derivatives **271** and **272** by a domino Knoevenagel–ene reaction [48].

lowed by zinc chloride. Except with α-substituted aldehydes, the primary Knoevenagel condensation occurs without the addition of dehydrating agents. The cyclopentane and cyclohexane derivatives **270** obtained by a subsequent intramolecular ene reaction may be cleaved from the resin either by reduction or ester exchange. In either case the products were obtained not only in good yields (41–61%) and high purity (approximately 90%), but also with excellent diastereoselectivity. As expected, when geminally disubstituted aldehydes are used, only modest induced diastereoselectivity is observed. The authors did not prepare a sample library by split synthesis, but by simultaneous reaction of the polymer-bound malonate with six aldehydes in equimolar amounts (in each case 0.15 equivalents aldehyde per equivalent malonate) and subsequent by an ene reaction. With one exception, after reduction the corresponding diols could actually be obtained in almost equal concentrations. If, as here, mixtures are prepared without use of the split synthesis, one significant advantage of solid-phase synthesis is lost, namely the use of large reagent excesses. If the aldehydes used differ greatly in their reactivity, it is less likely all the compounds in the product mixture are present in equimolar amounts.

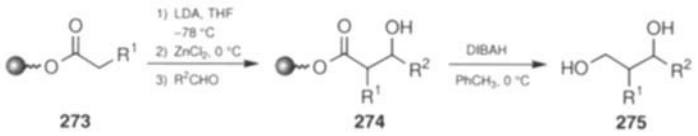
Currently these are the only carbocycle syntheses that have found application in combinatorial chemistry. It may be expected, however, that in the future the Diels–Alder and other reactions leading to carbocycles will find increasing use in library synthesis.

4.3. Further Library Syntheses

4.3.1. Modular Compound Libraries

In addition to numerous heterocyclic syntheses, several combinatorial syntheses have been described recently in which no central cyclic framework has been constructed.

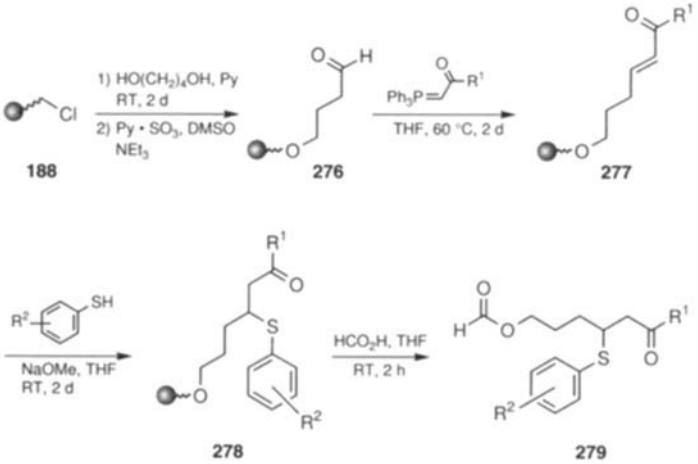
A two stage aldol reduction sequence for the 1,3-diols **275** has been developed by Kurth et al. (Scheme 56).[33] The basic ele-



Scheme 56. Synthesis of 1,3-diols **275** by solid-phase aldol reaction and reductive cleavage from the resin [33].

ment is coupled to Merrifield resin by esterification, converted into the zinc enolate and finally into **274** with a series of aldehydes in an aldol reaction. Whereas treatment with lithium aluminum hydride led to considerable retroaldol reaction, the products were reductively cleaved from the resin with diisobutylaluminum hydride. The *threo* and *erythro* isomers of **275** were obtained in a 7:5 ratio and overall yield of 26%. The progress of the reaction was monitored by IR analysis of the polymer. A model library of 27 compounds in three mixtures was prepared by the split method, purified by thin layer chromatography, and tested for their activity as antioxidants.

By means of their synthesis of β-sulfanylketones, Kurth et al. have shown[204] how a series of well-known reactions may be linked together on the solid phase (Scheme 57): the sequence begins with monosubstitution of butanediol on Merrifield resin

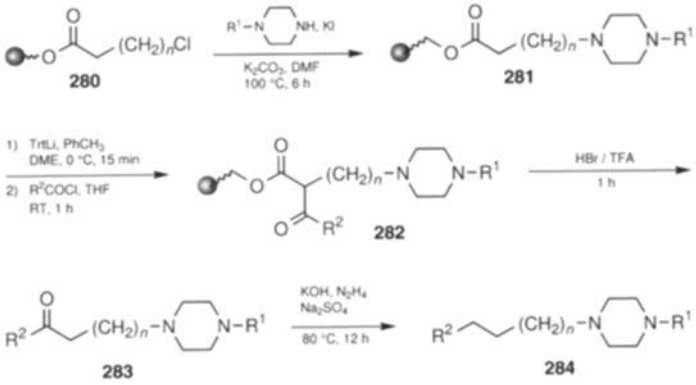


Scheme 57. Combination of several classical named reactions on solid phase. A Swern oxidation followed by a Wittig olefination with subsequent Michael reaction affords **279** [204].

188. The free hydroxyl group is oxidized with complex of sulfur trioxide and pyridine to give the aldehyde **276**, which is converted into the enones **277** in a Horner–Emmons reaction with a series of phosphoranes followed by the addition of thiophenols in a Michael type reaction. After a total reaction time of almost a week, the β-sulfanylketones **278** were cleaved from the resin with formic acid. The desired products are obtained in yields of about 20%. Here too, the course of the reaction was readily monitored by IR analysis. A small library of nine (3 × 3) compounds was prepared by the split-and-combine principles and characterized by gas chromatography. Biological testing was carried out both with the products cleaved from the resin and with the products still bound to the resin. Whether the identity of a polymer-bound compound could be determined form a single resin particle was also investigated. In this method, a single particle (200–400 mesh) was isolated under a microscope, incubated with the cleaving reagent, and analyzed by GC-MS. The structure of this and other support-bound compounds could be determined unambiguously. One problem is, however, the mechanical separation of a single resin particle. Therefore studies with larger polymer particles (20–40 mesh) are underway, as these can be separated simply without a microscope.

Dankwardt et al. (Syntex) have synthesized an aryl- and benzylpiperazine library of 190 compounds (38 × 5) by benzylation and alkylation of phenylpiperazines and investigated its biological activity.[205] However, the results of these tests have not been published.

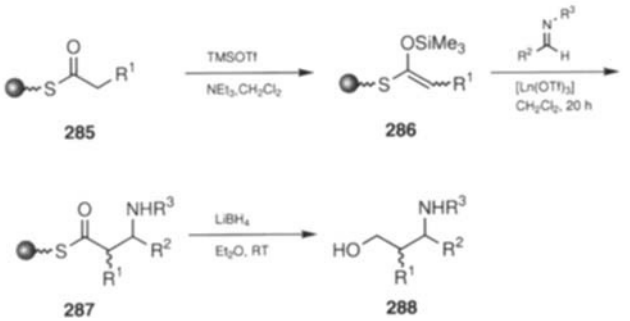
A further *N*-arylpiperazine synthesis has been described by the research group at Parke–Davis (Scheme 58).[130] Chloropropionic and butyric acids were coupled to Wang resin and converted into **281** with arylpiperazines. The enolate produced with trityl lithium could be trapped with acid chlorides. Cleavage of the product **282** from the resin under decarboxylation



Scheme 58. Preparation of *N*-arylpiperazines **283** on solid phase. Cleavage from the resin and modified Wolff–Kischner reduction to **284** [130].

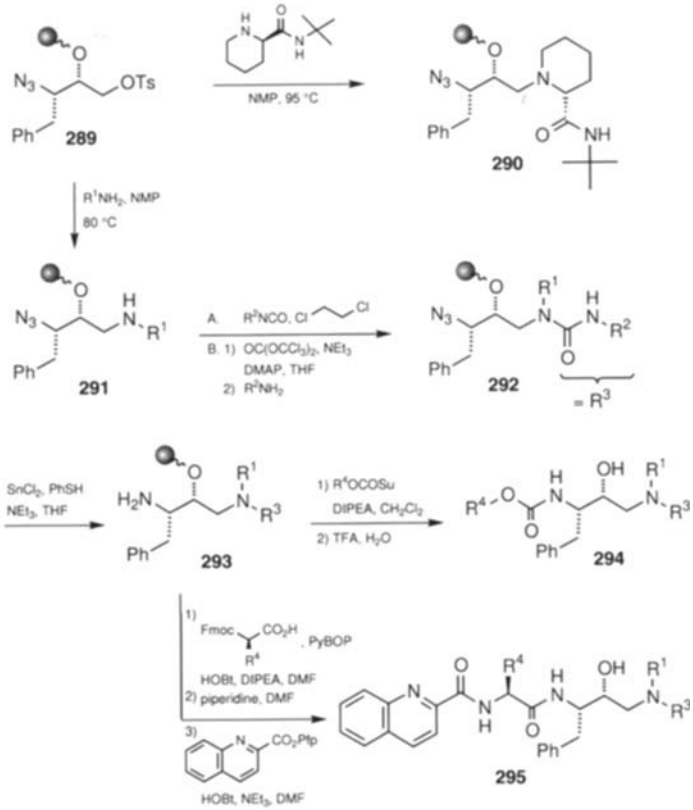
conditions was achieved by anhydrous HBr in trifluoroacetic acid. The compounds **283** thus obtained could then be reduced in a modified Wolff–Kishner reduction. In this way a library of 2×12 individual compounds was prepared, but because of the similarity of the building blocks used it exhibited only low diversity. However, further arylpiperazines should be available in an analogous manner.

Kobayashi et al. prepared silyl enol ethers **286** on solid phase from the thioesters **285** by reaction with trimethylsilyl triflate.[206] These react with imines in the presence of catalytic amounts of scandium triflate to form β-aminothioesters **287**, which may be reductively cleaved to the aminoalcohols **288** (Scheme 59).



Scheme 59. Synthesis of β-amino acid derivatives **287** by reaction of silyl enol ethers **286** with imines [206].

Aspartyl- and metalloproteases can be inhibited by hydroxyethylamines. A solid-phase synthesis of hydroxyethylamines and hydroxyethyl ureas **294** has been described by Ellman et al. (Scheme 60).[134, 207] In this method the starting material **289**, previously used as an intermediate in the synthesis of a known HIV protease inhibitor, was coupled to the resin through a dihydropyran (DHP) linker. After replacement of the tosyl group by amines, conversion into the ureas **292** was achieved with isocyanates in the case of primary amines or otherwise with triphosgene and amines. The two-stage alternative is more universally applicable because of the better availability of primary amines. The azide **292** was reduced with a cocktail of thiophe-

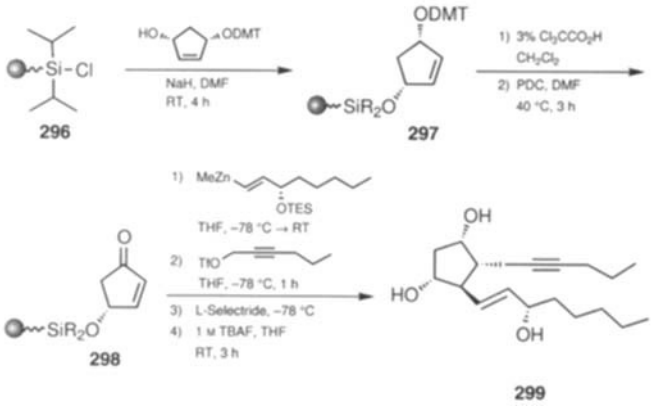


Scheme 60. Solid-phase synthesis of hydroxyethylamines and hydroxyethylureas. The key step is azide reduction with thiophenol/triethylamine/tin chloride to **193** [207].

nol/triethylamine/tin chloride[208] to yield the amine **293**, which could be acylated to the carbamate or amide. After cleavage with trifluoracetic acid and purification by column chromatography, the products were obtained analytically pure in 47–86% yield in this four- to six-stage synthesis.

Wang et al. (Abbott) proceeded in a similar manner.[209] The tosylated azide **289** was linked to benzhydryl resin by means of a bifunctional linker, and after deprotection of the two amino groups, the molecule could be extended on both sides with, for instance, carboxylic acids, sulfonyl chlorides, or isocyanates, to afford 300 individual compounds in an automated parallel synthesis. The products could only be cleaved from the resin under very drastic conditions and in purities of 20–50% in the diol series and 30–70% for the monoalcohol diamine derivative. Most of the impurities found contained linker fragments. The crude products were tested for HIV protease inhibition without further purification and gave IC_{50} values of less than 1 nM to 6.4 μM.

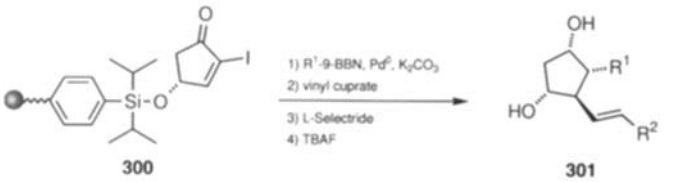
A solid phase variant of the Noyori three-component prostaglandin synthesis has been devised by Ellman et al. (Scheme 61).[210] After addition of alkylzinc derivatives to 4-hydroxy-2-cyclopentanones **298** bound to a resin, alkylation was carried out with alkyl triflates. This synthesis was originally performed with the DHP linker, but the cleavage conditions were not compatible with the target molecule. When the silyl linker **296** was used, the severe coupling conditions required that the hydroxypentane be protected with the dimethoxytrityl group. After two reaction stages the prostaglandin **299** was isolated diastereomerically pure in a yield higher than 50%. Fur-



Scheme 61. Synthesis of prostaglandin **299** on solid phase by addition of an organozinc compound to resin-bound hydroxycyclopentenone **298** and alkylation with triflate [210].

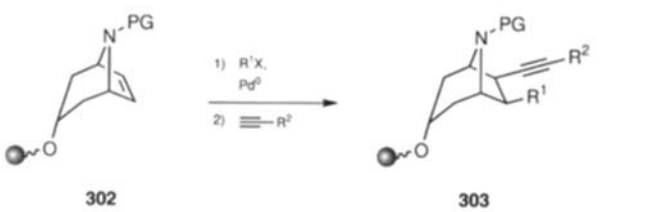
thermore, the alkylation proceeded in only poor yield on Merrifield resin. A macroporous resin proved to be a better support for this reaction sequence.

Familiar problems of this prostaglandin synthesis are the low reactivity of the initially formed enolates as well as the danger of proton exchange and subsequent elimination of the alkoxy group to form the cyclopentenone, which in this case amounts to a cleavage from the resin. Ellman has recently introduced an alternative solid phase prostaglandin synthesis[211] to overcome this problem (Scheme 62).[134] A resin-bound iodocyclopentenone (**300**), formed in three steps from **297**, is treated with an organoborane under palladium catalysis. The introduction of the ω side chain is achieved by means of Michael addition of a cuprate.



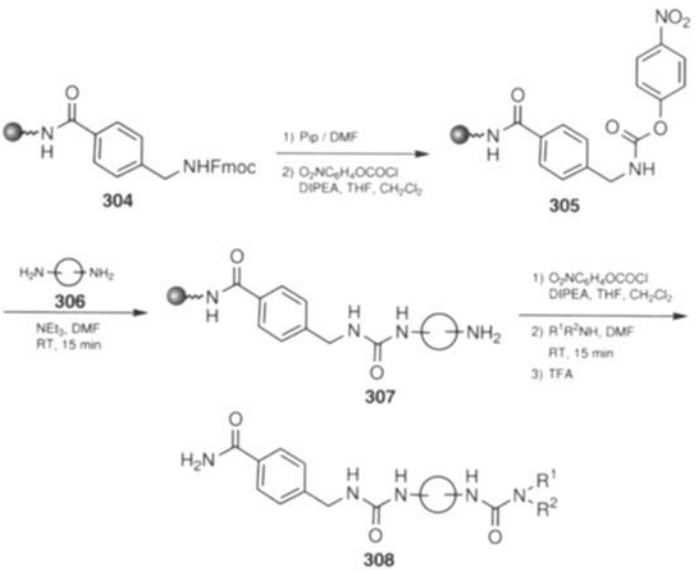
Scheme 62. Pd-mediated prostaglandin synthesis on solid phase [115b, 134].

A further reaction that proved its worth in the preparation of bicyclic prostaglandin analogues is the palladium-catalyzed three-component coupling of norbornene derivatives with bromo- or iodoolefins and alkynes.[212] Ellman has used this reaction in the solid-phase synthesis of the tropane derivatives **303** (Scheme 63).[134] Boronic acids may be coupled under these conditions in place of alkynes. Finally, after deprotection, **303** may be further derivatized on the nitrogen atom. Whether this reaction allows a wide variation in coupling partner (and hence the construction of large compound libraries) is currently being investigated.



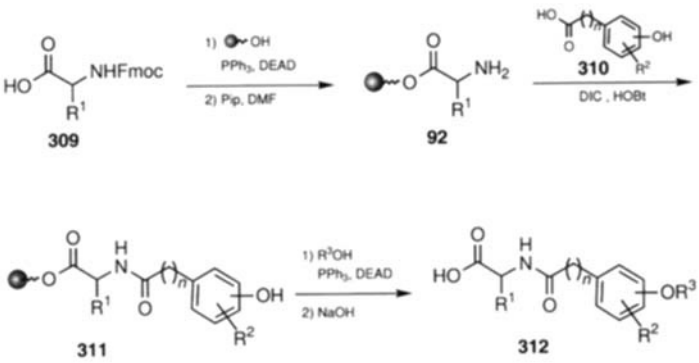
Scheme 63. Pd-mediated three-component coupling [115b, 134].

A strategy for the formation of diaminourea libraries **308** from amino acids, diamines, and amines has been developed by Hutchins and Chapman (Merck, Scheme 64).[213] The diamine unit serves to control conformatively the coupling of two molecular fragments. In this reaction, Fmoc-protected 4-(aminomethyl)benzoic acid is bound to Rink resin[214] and after deprotection is converted into the *p*-nitrophenyl carbamate.[215] The carbamate **305** forms the first urea bond with a series of unprotected primary diamines (**306**). The free amine is again converted into the nitrophenyl carbamate to allow the formation of the second urea bond with a number of amines. After cleavage with TFA the products were formed with a purity of greater than 90% and could thus be directly investigated for activity in solution. This method should be well suited for the construction of large compound libraries because of the ready availability of the reagents and the reliable chemistry.



Scheme 64. Synthesis of diaminourea libraries **308** by combination of amino acids, diamines, and amines on solid phase [213].

There have been numerous reports of solid phase Mitsunobu reactions.[216, 217] Krchnák and his colleagues at Selectide have used the Mitsunobu reaction to prepare a model library of 4200 compounds of the type **312** from amino acids, hydroxyphenyl carboxylic acids and alcohols (Scheme 65).[218] Initially an Fmoc-protected amino acid (**309**) is linked to a TentaGel resin under Mitsunobu conditions and then coupled to phenolic carboxylic acids **310**. In the final step, the reaction is carried out with a series of alcohols and benzyl alcohols, again under Mitsunobu conditions. The products **312** can be cleaved from the resin by hydrolysis with NaOH. No satisfactory results were obtained if the reaction was carried out in *N*-methylmorpholine, which has been described as the solvent of choice for the reaction of resin-bound benzyl alcohol with phenols.[217] The model library constructed from a combination of 20 amino acids, 10 aromatic hydroxy acids, and 21 alcohols was tested in biological assays whilst bound to the resin. The results are to be published later.

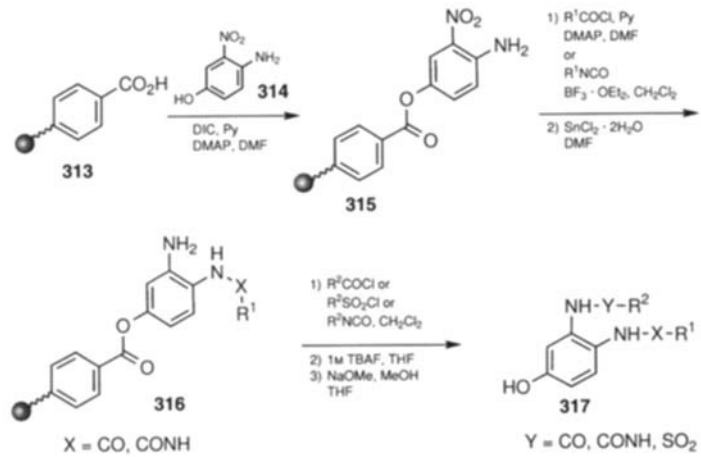


Scheme 65. Derivatization of phenolic carboxylic acids **310** to **312** by solid-phase Mitsunobu reactions [218].

4.3.2. Libraries by Derivatization of Templates

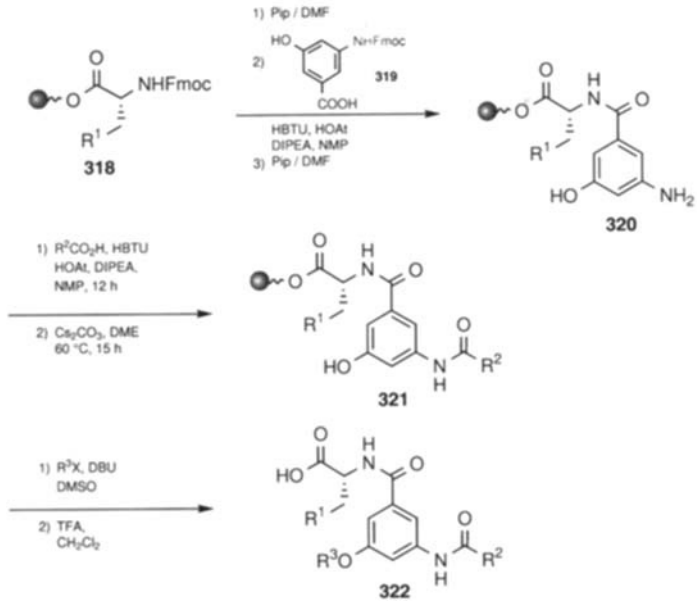
In this variant of library synthesis a template usually preformed in solution is coupled to the solid phase. There it serves as a central building block, its reactive groups being transformed during the course of the synthetic sequence.

A typical example is the bisamidophenol **317** of Pavia et al. (Sphinx):[219] the trifunctional 3-nitro-4-aminophenol (**314**) is coupled to a carboxylated resin[220] (**313**) and then acylated with acid chlorides or converted into ureas with isocyanates (Scheme 66). Finally the nitro group is reduced with tin dichloride in DMF, and the way is open for further conversions with acid chlorides, sulfonyl chlorides, or isocyanates. The products are cleaved by hydrolysis in amounts of 3–9 mg (15–45% overall yield) with purities of 60–80%. In this way a library of 600 individual compounds was prepared; it was tested in solution for protein kinase inhibition after cleavage from the resin. There are currently no reports of any lead structures having been found.



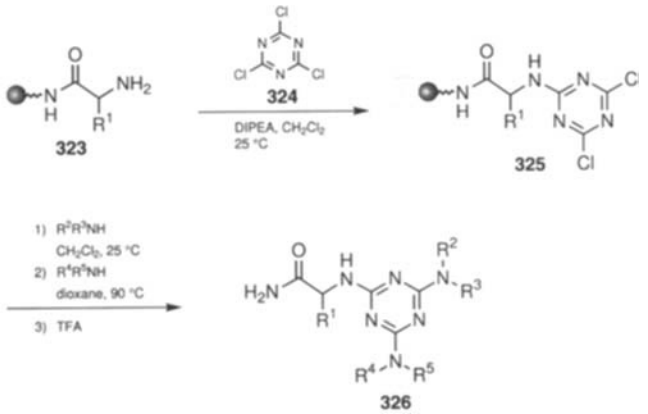
Scheme 66. Preparation of a bisbenzamidophenol library **317** by derivatization of 3-nitro-4-aminophenol **314** on polymeric support material **313** [219].

The procedure of Dankwardt et al. (Syntex) is similar.[221] Here too, a trifunctional building block, 3-amino-5-hydroxybenzoic acid (**319**), is coupled to resin and then derivatized (Scheme 67). The synthesis also starts with acylation of the amine, and the hydroxy function is concomitantly esterified. De-esterification was achieved with cesium carbonate[222] in DME, and the freed hydroxy function was further treated with alkyl halides and sulfonyl chlorides. Prior to library synthesis the scope and limitations of the reaction was first determined (criterium: greater than 70% product purity by HPLC). Each member of a model library of 5×5 compounds prepared by the split method was obtained with a purity of greater than 80 % (with less than 20% unalkylated material). To increase the diversity of the products the template was attached to the resin by means of an amino acid. Ultimately a library of 2001 (69×29) compounds (**322**) was formed (split synthesis), the biological activity of which is currently being investigated. "Fingerprints" of each mixture of 69 compounds were determined by analytical HPLC.



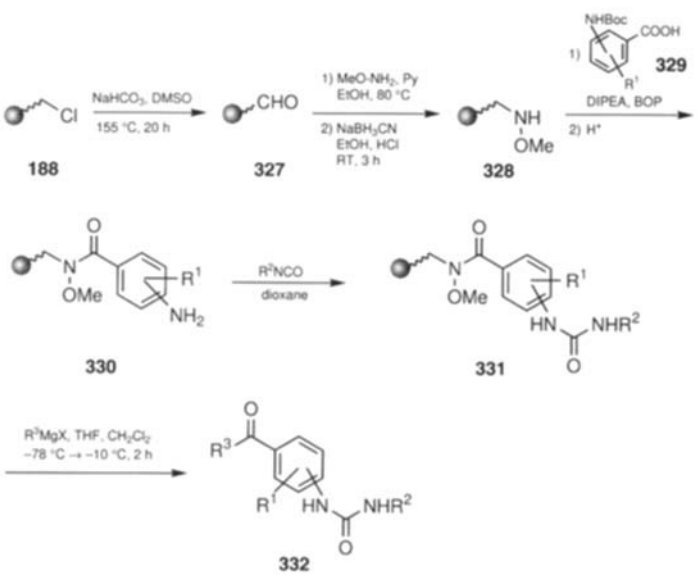
Scheme 67. Derivatization of N-protected 3-amino-5-hydroxybenzoic acid **319** to form libraries of the type **322** [221].

Researcher groups at both Affymax[223] and Selectide[224] have used the differential reactivities of the chlorine atoms of 2,4,6-trichloro-*s*-triazine (**324**) in a simple library synthesis (Scheme 68). A resin-bound amino acid (**323**) is initially treated with **324**, which smoothly causes monosubstitution of the trichlorotriazine. The remaining chlorine atoms are then sequentially substituted under more forcing conditions.



Scheme 68. Synthesis of a triazine library **326** [223, 224].

A simple bifunctional template has been derivatized by DeWitt et al. (Scheme 69).[130] Kornblum oxidation with sodium hydrogen carbonate in DMSO converted the Merrifield resin (**188**) into a support-bound benzaldehyde (**327**), which gave an



Scheme 69. Synthesis of the *O*-methylhydroxylamine resin **328** on which aminobenzoic acids **329** are converted into different ketoureas **332** [130].

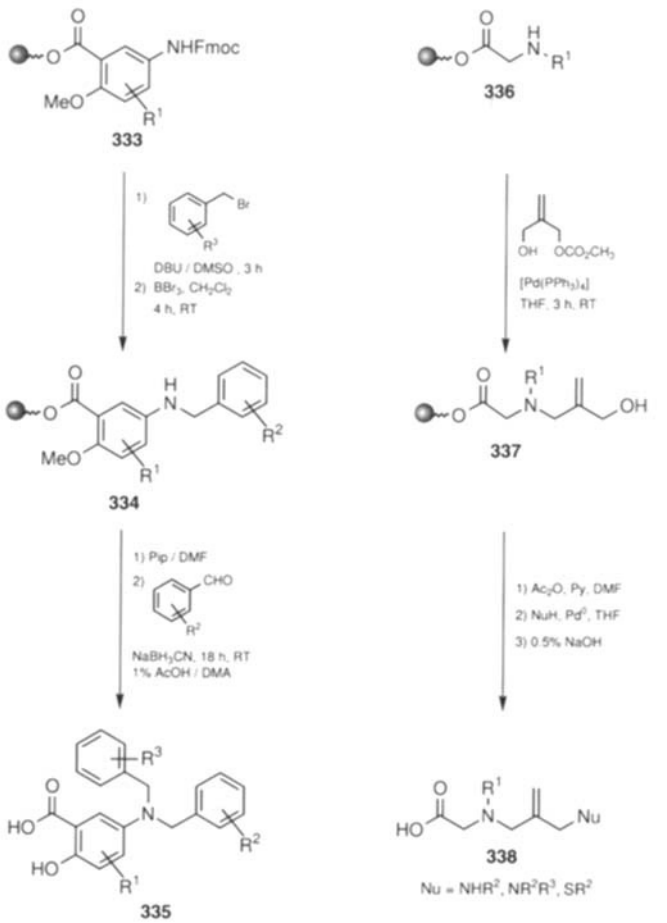
O-methylhydroxylamine resin (**328**) by heating with hydroxylamine and subsequent reduction with sodium cyanoborohydride. Coupling with aminobenzoic acids **329** followed by reaction with isocyanates afforded the corresponding ureas **331**. Treatment with alkyl- and arylmagnesium bromides led to cleavage of ketoureas **332** from the resin.

Such resin-bound Weinreb amides have also been used recently by Armstrong et al. in the synthesis of aldehydes and ketones.[225] Here, too, cleavage with Grignard compounds gave the corresponding ketones, whereas aldehydes were formed by reduction with DIBAH or $LiAlH_4$.

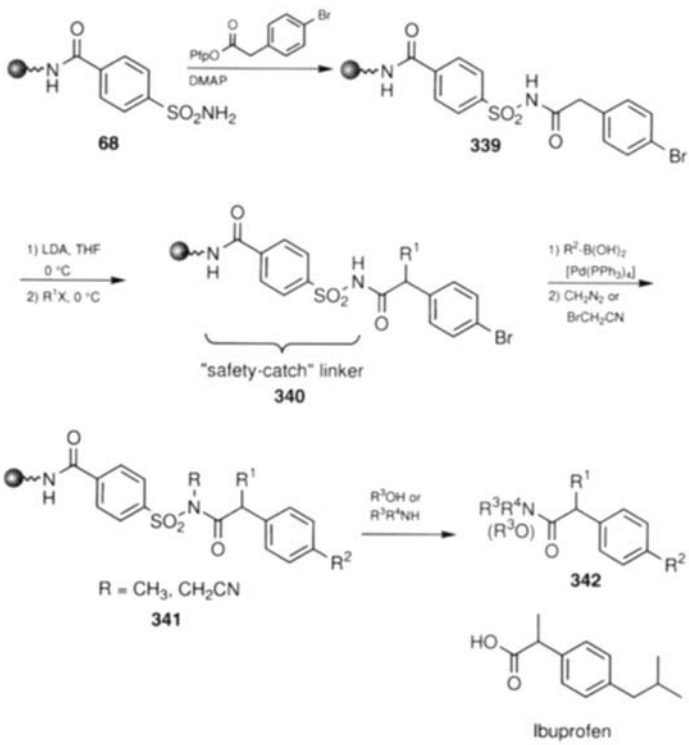
In parallel syntheses, Green (Ariad Pharmaceuticals) has prepared 60 analogues of the tyrosine kinase inhibitor lavendustin (Scheme 70).[226] In this work, methoxyaniline **333** bound to Wang or Rink resin was initially reductively alkylated to **334** with substituted benzaldehydes and subsequently treated with benzyl bromides. The tertiary amines **335** were obtained in good yields and usually with high purity after cleavage from the resin with trifluoracetic acid or boron tribromide. Cleavage from Wang resin with boron tribromide has the advantage that the methyl phenyl ethers are also cleaved to give the free polyhydroxylated target compounds.

Tertiary amines have also been the interest of Flegelová and Pátek (Selectide).[227] They have obtained the substituted products **338** by palladium-catalyzed bisallylation (Scheme 70). The reaction conditions were optimized for each of six different templates.

Arylacetic acids have been derivatized by Ellman et al. with enol alkylation and subsequent Suzuki reaction (Scheme 71).[112, 134] Certain representatives of this class, for example ibuprofen, are cyclooxygenase inhibitors. 4-Bromo-



Scheme 70. Solid-phase synthesis of the tertiary amine **335** (lavendustin A analogues [226]) and **338** (products of a Pd-catalyzed bisallylation [227]).

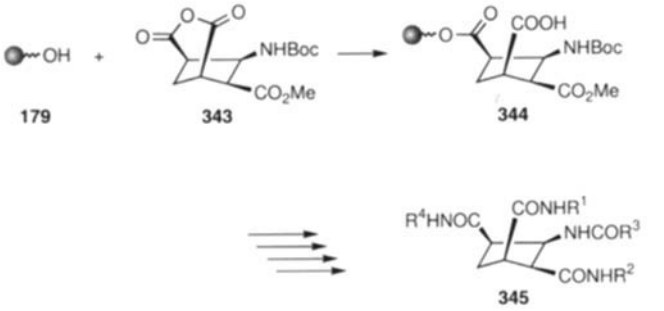


Scheme 71. Solid-phase synthesis of phenylacetic acid derivatives **342** by enolate alkylation and subsequent Suzuki reaction [112, 134] on use of the "safety catch" linker [113].

phenylacetic acid was linked to the resin through the rarely used but, under these reaction conditions, compatible "safety catch" linker.[113] The derivatives **340** were obtained by trapping the corresponding enolates with alkyl halides. A subsequent palladium-catalyzed conversion with alkyl-9-BBN derivatives or alkylboronic acids under Suzuki conditions yielded the coupled products **341**. Following N-methylation of the sulfonamide linker with diazomethane, cleavage from the resin was achieved with a series of reactive nucleophiles. Cleavage with weaker nucleophiles, such as aniline and primary amines succeeded only when the acylsulfonamide was activated by cyanomethyl substitution.[114, 115] A series of phenylacetic acids and amides **342** were obtained in high yields in a clean reaction sequence.

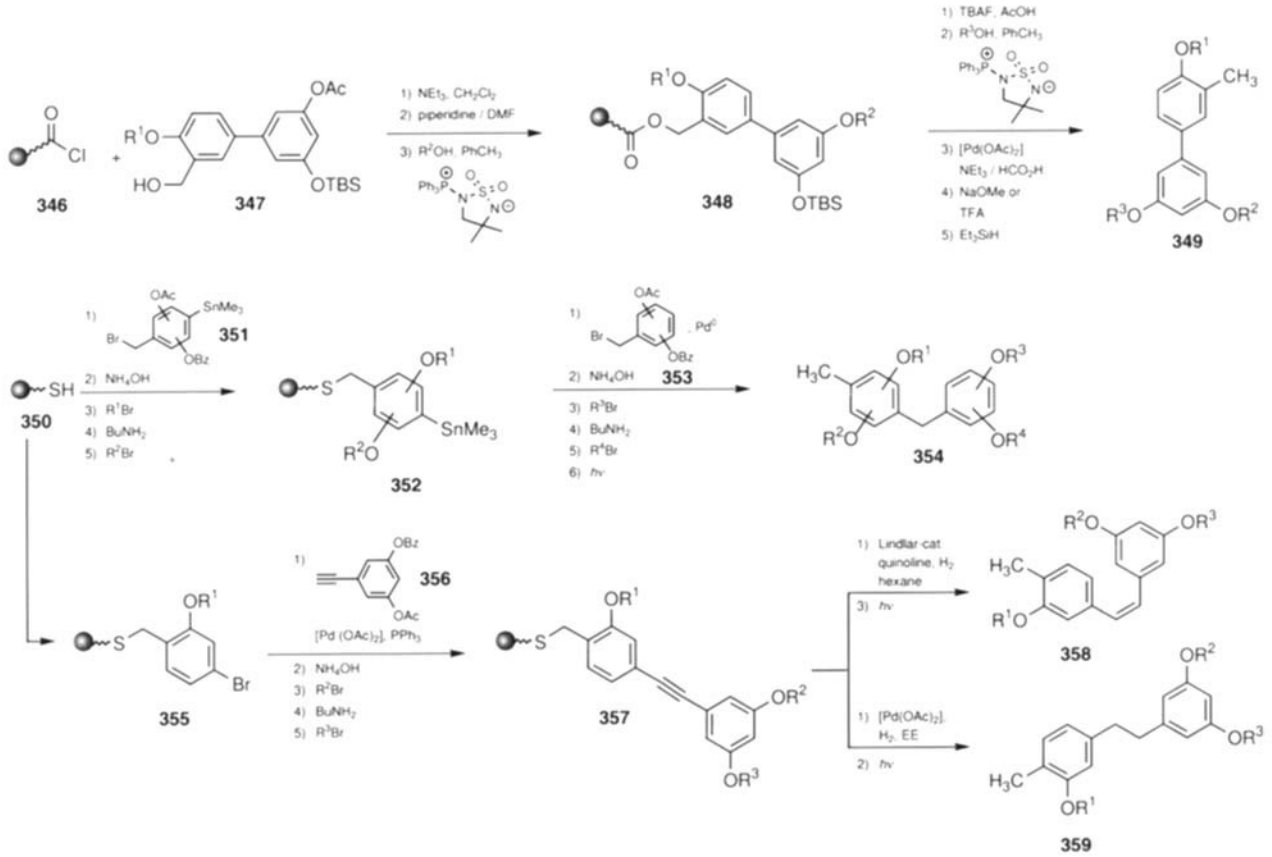
The cyclopentane template **343** was prepared in solution by Pátek et al. (Selectide) and derivatized on resin in a sequence of amide formation and protective group transformations (Scheme 72).[228] The completely substituted cyclopentanes **345** were obtained in high yields (83–90%) and purities (>90%).

The biphenyl library **349** was prepared at Sphinx Pharmaceuticals from trifunctional, alkoxy-protected biphenyl templates. These were prepared in solution, coupled to the resin, and there successively deprotected and converted into different alkoxy derivatives under modified Mitsunobu conditions (Scheme 73).[229] In a so-called "double combinatorial" procedure on a resin two aromatic templates were attached in a palladium-catalyzed coupling reaction (Scheme 73).[230] In this sequence, a protected dihydroxyarylstannane (Template 1, **351**)



Scheme 72. Conversion of the cyclopentane template **343** into compounds of type **345** [228].

was linked to a resin through the "NpSSMpact linker"[188, 231], the hydroxyl groups sequentially deprotected and etherified, and further treated with protected dihydroxybromobenzene or dihydroxybromobenzyl chloride (Template 2, **353**) in a Stille coupling reaction. The two new hydroxy groups were also derivatized before the products were cleaved photochemically. If bromoaromatics are attached to the resin as the first template, these may be converted into the tolanes **357** with the phenylacetylenes **356** by palladium catalysis and then reduced to the *cis*-stilbenes under Lindlar catalysis or to the phenylethylbenzenes with palladium acetate. In this way two functionalized aromatic templates may be connected by different flexible C-bridges. Massive libraries may be constructed by this "double combinatorial" library synthesis. With only 10 alkyl bromides in each step, 10000 compounds are obtained in which the triple



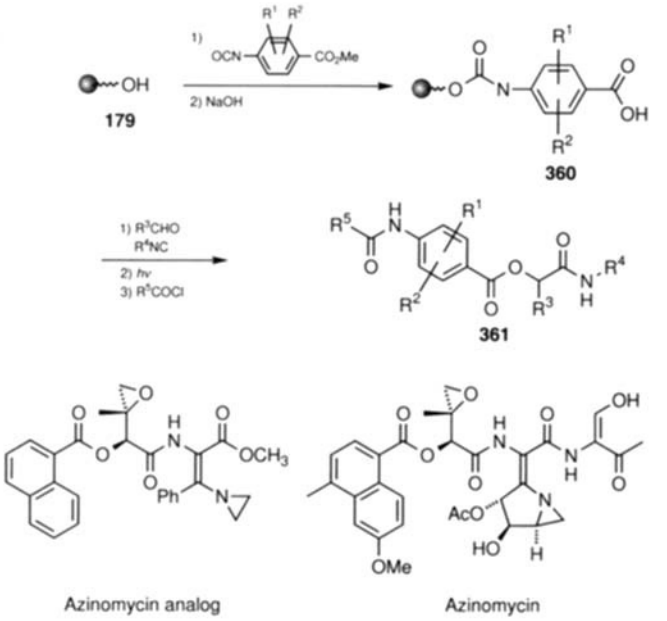
Scheme 73. Synthesis of "double combinatorial" libraries **349**, **358**, and **359** by palladium-catalyzed coupling and derivatization of two templates on a solid phase [229, 230].

bond can be partially or totally hydrogenated. Whether the biphenyls will become the templates of the 1990s—as predicted by the authors—remains to be seen.

4.3.3. *Libraries from Multicomponent Reactions*

In the syntheses previously described, the compound libraries were produced from the components by individual reaction steps in a linear synthesis. Particularly attractive, however, are reactions in which highly diverse libraries are produced in a one-pot reaction. These are multicomponent reactions[83, 84] that have previously been described in combinatorial syntheses in solution (c.f. Section 3.2.1). The Affymax thiazolidine synthesis[89] (Scheme 29) in which aldehydes and α-sulfanylcarboxylic acids were treated with amino acids in a single step was one example of a solid-phase multicomponent reaction.

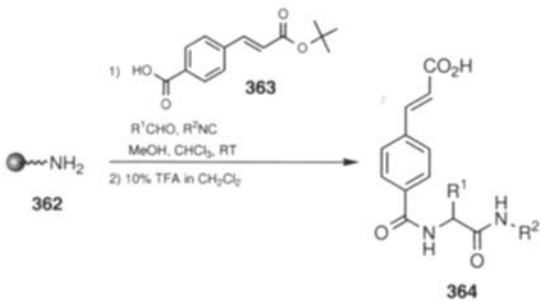
The first solid-phase multicomponent reactions were the Ugi and Passerini reactions described by Armstrong et al.[88, 232] In the three component Passerini reaction, a carboxylic acid is condensed with an aldehyde and an isonitrile. In this manner azinomycin analogues inter alia could be formed (Scheme 74).



Scheme 74. Passerini three-component reaction on solid phase and preparation of azinomycin derivatives [232, 233].

In an Ugi reaction, Rink resin[124] was condensed to α-amidoamides with three further components. To expand the range of commercially available isonitriles, additional isonitriles were prepared by lithiation of benzyl isonitrile and trapping with alkyl halides. With corresponding automation large libraries may be constructed on resin and in solution, with these two types of reaction.

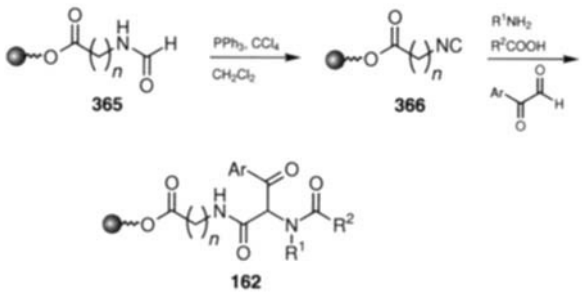
Similarly Rink resin has also been used as amine component in an Ugi reaction by Mjalli et al. of Ontogen,[234] who in this



Scheme 75. Synthesis of cinnamic acid derivatives **364** by the Ugi reaction [234]. Rink resin **362** is used as amine component.

way obtained the cinnamic acid derivatives **364** in yields and purities of over 90% (Scheme 75). These compounds represent new lead structures for inhibitors of hematopoietic protein tyrosine phosphatases (HePTP). The most active compound (R^1 = phenyl, R^2 = benzyl) inhibited this enzyme with an IC_{50} value of 3.9 μM.

A further solid-phase four-component reaction developed by this research group started from resin-bound isonitriles **366**, phenyl glyoxals, primary amines, and carboxylic acids. The products, α-(*N*-acyl-*N*-alkylamino)-β-oxoamides **162** (Scheme 76), were subsequently cyclized to imidazoles.[169] The



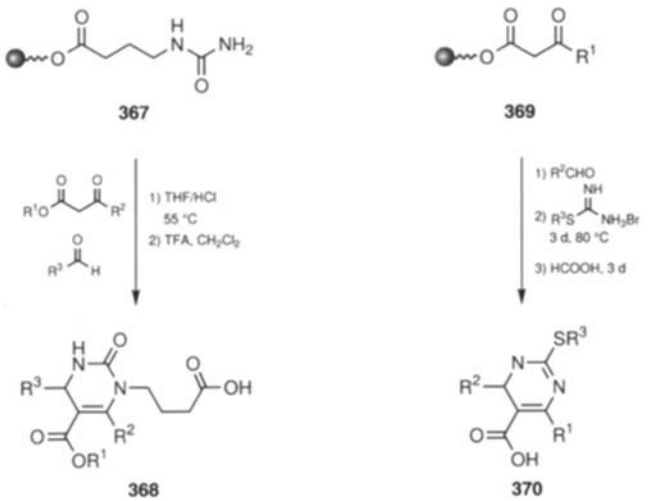
Scheme 76. Preparation of α-(*N*-acyl-*N*-alkylamino)-β-oxoamides **162** by the Ugi reaction [169]. The isonitrile **366** is produced on the solid support by dehydration of the formyl compound **365**.

required isonitriles were prepared directly on the solid support (Wang resin) by dehydration of N-formyl compounds. The Ugi reaction proceeded in moderate yields (about 50%), independent of the starting materials used; only on the use of aniline as amine component did the yield fall dramatically (16% after cyclization to the imidazole).

A further solid-phase three-component reaction has been recently reported by Wipf et al.[235] Dihydropyrimidines were obtained in high yields and purities by Biginelli condensation of β-oxoesters, aldehydes, and ureas (Scheme 77). In this sequence the resin-bound γ-aminobutyric acid (GABA) urea **367** is converted into the dihydropyrimidines **368** by heating with β-oxoesters and aldehydes under acid catalysis and isolated by simple filtration after cleavage of the benzyl ester with trifluoracetic acid. The individual products were obtained in high yields (67–98%) and excellent purity (>95%) in amounts of 10–20 mg. Since β-oxoesters are readily obtained in one step and many aldehydes

are commercially available, this reaction is applicable to the parallel synthesis of large compound libraries. The GABA linker increases the water solubility of the products and offers opportunity for further derivatization. Dihydropyrimidines are known for their wide-ranging biological effects, for instance, antiviral, antihypertensive, and antitumor activities, as well as calcium channel blockage, so libraries of this type may well contain interesting lead structures.

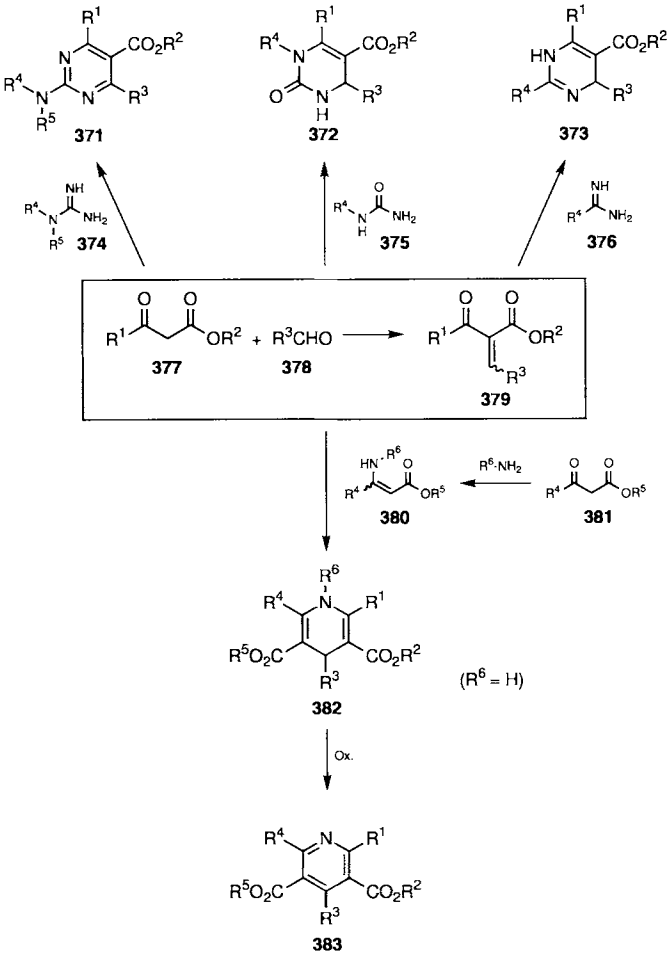
The Biginelli condensation has been carried out stepwise by Robinett (Arris Pharmaceuticals), who used the Atwal modification (basic conditions).[236] The conversion of Knoevenagel products with substituted thioureas affords thiosubstituted dihydropyrimidines **370**, which may be cleaved from the resin with formic acid (Scheme 77).



Scheme 77. Solid-phase Biginelli condensation of β-oxoesters, aldehydes, and ureas to form dihydropyrimidinones **368** [235] and synthesis of dihydropyrimidines **370** by the Atwal modification of the Biginelli reaction [236].

The Knoevenagel products **379** from β-oxoesters **377** and aldehydes **378** are ideal intermediates for the formation of a number of heterocycles (Scheme 78). Not only the thioureas **375**, but also the amidines **376**, guanidines **374**, or enaminoesters **380** may also be used as double donors to afford different pyrimidines **371**, dihydropyrimidines (**372**, **373**), and dihydropyridines **382**.

Syntheses of this type are being studied at a number of centers for their suitability for solid-phase combinatorial synthesis. Different strategies for coupling the starting building block to the solid phase are being pursued. Whereas the Chiron group starts with support-bound aldehydes, the Affymax group attaches the double donors (guanidines, enaminoesters[238]) or the β-oxoester to the solid phase, depending on the particular synthesis.[239] Resin-bound aldehydes have been used by Chiron in the synthesis of a number of heterocyclic systems (β-lactams, oxazoles, imidazoles, etc.).[237] The potential of classical heterocyclic syntheses for combinatorial chemistry is considerable; on one hand the compounds synthesized, for example dihydropyrimidines, are per se biologically active and on the other it should be possible to prepare a much greater variety of these compounds.



Scheme 78. Solid-phase synthesis of heterocycles starting from Knoevenagel products [237–239].

5. Structural Determination of Active Components in Libraries

Just as the substance library format determines the procedure for characterizing them, it is also critical in the analysis of the structure of the active compounds. If this is merely a question of a library of single compounds prepared by parallel synthesis, there is no problem in elucidating the structure of active compounds, since the site of synthesis is clearly associated with the structure being synthesized. Examples are the DIVERSOMER technique,[129, 130] photolithographic synthesis on a functionalized glass surface (VLSIPS[12]), and Ellman's synthesis[126] of benzodiazepine derivatives on a polyethylene pin matrix, which was used initially by Geysen et al. for epitope mapping.[6]

If the compound library prepared by combinatorial synthesis is tested in its support-bound form, those support particles that carry the active compounds are first sorted. Following cleavage from the support, the identity of the active substance can at least be reduced directly to a few alternative structures by mass spectrometric determination of the molecular weight (c.f. Section 2.2.4). In coded libraries the structure is determined indirectly by reading the code.

The most complicated situation for structural determination arises when mixtures are tested in solution. In these cases a

deconvolution procedure is usually required, or investigations must be carried out with indexed libraries.

In the following discussion the current methods used for structure determination during testing are reviewed. Published applications are mainly from the fields of peptides and nucleotides, but the principal procedures are essentially applicable to low molecular weight organic compounds.

5.1. Affinity Selection

Zuckermann et al. incubated peptide libraries with an antibody deficiency and, after elution of the few bound peptides, were able to elucidate the structures of the compounds of highest affinity by mass spectrometry and amino acid analysis.[240] An analogous application to low molecular weight compounds (the structures were, however, not published) has been recently reported.[241]

5.2. Indexed Libraries

In the synthesis of indexed (orthogonal) libraries, each starting material A^n is treated with an equimolar mixture of educts B^1-B^x, as is each educt B^m with A^1-A^y. Figure 18 illustrates schematically the formation of an indexed library from each of six reactants of type A (A^1-A^6) and type B (B^1-B^6).[35, 70, 71, 242] This synthetic procedure results in each compound being formed exactly twice, and every pair of mixtures has exactly one compound in common. The presence of an active compound must therefore result in activity in two mixtures. Moreover, this form of internal control allows the recognition of false positives. Assignment of activity to a certain structure is possible by simple comparison, that is, without time consuming deconvolution or new synthesis. As an example, the activity of the two mixtures $A^1-A^6B^3$ and $A^3B^1-B^6$ in Figure 18 indicates that compound A_3B_3 is active. An example of the synthesis of an indexed library is described in Section 3.1.2.

	A^1B^{1-6}	A^2B^{1-6}	A^3B^{1-6}	A^4B^{1-6}	A^5B^{1-6}	A^6B^{1-6}
$A^{1-6}B^1$						
$A^{1-6}B^2$						
$A^{1-6}B^3$			A^3B^3			
$A^{1-6}B^4$						
$A^{1-6}B^5$						
$A^{1-6}B^1$						

Fig. 18. Schematic representation of an orthogonal library (modified according to ref. [71]) synthesized from each of six components A and B. Each column and each row represents a compound mixture consisting of six components (for example, A^1B^1 to A^1B^6). The single compound responsible for the activity is derived from the correlation of two active mixtures (in this case A^3B^3).

5.3. Deconvolution

In conjunction with the split method for the preparation of equimolar mixtures of peptides, Furka[13] has outlined iterative procedures for the identification of active components (c.f. Section 2.2). A practical application to peptides bound to a solid phase has been described by Geysen,[44] and both Houghten et al.[18] and Ecker et al.[45, 46, 243, 244] were the first to report on the deconvolution of soluble peptide and oligonucleotide libraries. Initial literature examples indicate that this deconvolution method can also be used successfully for low molecular weight organic compounds, as exemplified by the pyrrolidine library described in Section 4.2.1.2.[32] This is illustrated diagrammatically in Figure 19.

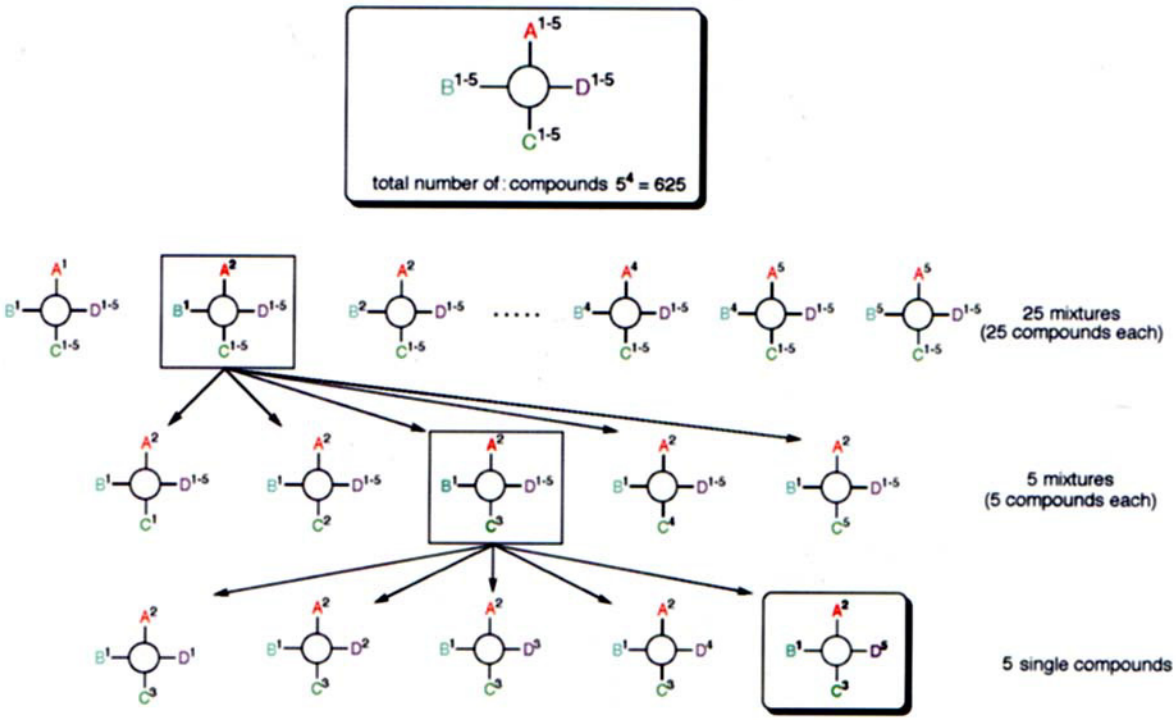


Fig. 19. Identification of the most active library component by deconvolution. In each case the most active libraries (framed) are further divided until finally the most active single compound $A^2B^1C^3D^5$ is uncovered.

A library consisting of low molecular weight organic compounds with four variable substituents (A–D) is treated formally as a tetrapeptide library. If there are, for example, five different possibilities for each substituent, the total library consists of $5^4 = 625$ compounds. In the first deconvolution round this total library can be synthesized in the form of 25 sublibraries each of 25 compounds in which in each case the substituents A and B are defined. The most active sublibrary contains the optimal combination of the substituents A and B. In Figure 19 this is the combination A^2B^1. On the basis of this result five further sublibraries in the form $A^2B^1C^nD^1-D^5$ are prepared. Each contains five compounds in which C is additionally defined. The optimal residue D is determined in the last step, the synthesis of the five individual compounds in the form $A^2B^1C^3D^n$. In the present example the most active compound is $A^2B^1C^3D^5$. One disadvantage of this iterative procedure is that the most active compound may not be necessarily found. However, Ecker et al.[243, 244] were able to show using a model calculation for oligonucleotides that even if not the most active, then at least one of only slightly less activity is selected. Moreover, it has since been demonstrated that the result is independent of the sequence in which the individual positions were iteratively optimized.[244] To what extent this may be applied to low molecular weight organic compounds is currently not clear.

Each test of the total library in another assay requires corresponding new syntheses of yet more sublibraries. In order to reduce the effort of new synthesis, Janda[102, 245] has used the procedure of recursive deconvolution. This method differs from the deconvolution described above in that an aliquot is held back after each cycle of the split synthesis. From active mixtures, similarly in one or more steps, the single active compound is identified. However, the new syntheses are not nearly so labor-intensive, because no new split syntheses are involved, merely the intermediates retained during the first split synthesis need to be elaborated further. Currently the only examples of this method of recursive deconvolution are in the peptide field.[102, 245] Application to low molecular weight organic compounds is plausible if the intermediates in the split synthesis are stable.

5.4. Positional Scanning

The noniterative method of "positional scanning" was realized for peptides by Houghten et al.[246] Using as example the library described in Section 5.3, Figure 20 illustrates how this may be carried out with low molecular weight compounds.

A total of $4 \times 5 = 20$ sublibraries in the form $A^1B^{1-5}C^{1-5}D^{1-5}$, $A^2B^{1-5}C^{1-5}D^{1-5}$, $A^3B^{1-5}C^{1-5}D^{1-5}$ to $A^{1-5}B^{1-5}C^{1-5}D^4$, $A^{1-5}B^{1-5}C^{1-5}D^5$ are synthesized. Thus for every substituent a complete library consisting of 5 sublibraries each of 125 compounds is prepared; that is, four syntheses of the total library are carried out. In the ideal situation, testing of these 4×5 sublibraries highlights immediately which substituents A–D are optimal. Thus Figure 20 illustrates how the results of the individual tests lead to the most active compound $A_2B_1C_3D_5$.

The advantage of positional scanning over deconvolution is that it is only necessary to carry out one library synthesis. However, if in one position there is no clear preference for a definitive substituent, all combinations of the preferred substituents must be synthesized in order to find the most active compound.

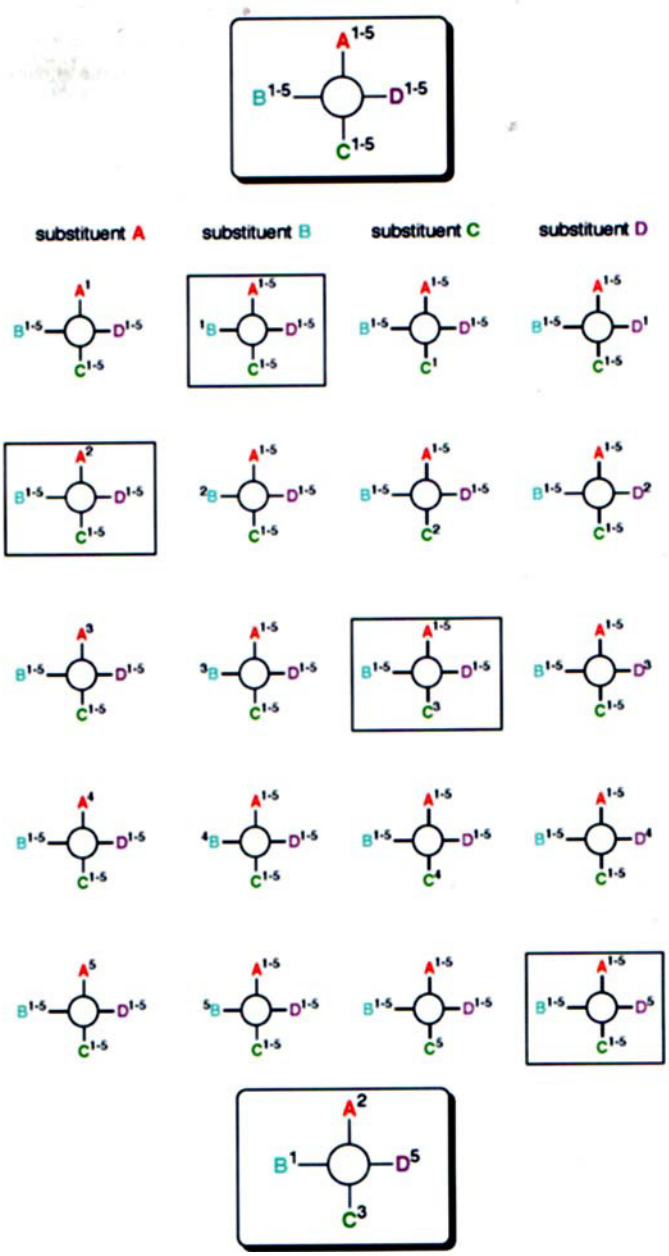

Fig. 20. Identification of the most active library component by the method of "positional scanning" (modified according to ref. [166]). The complete library is synthesized a total of four times, each time in the form of five sublibraries, and the activities of the 20 libraries thus obtained are determined. The most active libraries (framed) indicate the optimal substituents. In the illustrated example these are A^2, B^1, C^3, and D^5. The most active compound is thus $A^2B^1C^3D^5$.

5.5. Encoded Libraries

Inherent in the split synthesis ("one bead, one compound) is the problem of structural analysis of minute amounts of a substance (see Section 2.2.4). Whereas highly sensitive methods exist for the structural determination of peptides and nucleotides in the form of sequencing procedures, the direct struc-

tural determination of small amounts of low molecular weight organic compounds is comparatively less well developed. In this respect advances are to be expected in particular in mass spectrometric methods.

This problem is avoided with coded libraries,[247] in which instead of the structure of the test substance, the more accessible structure of a carefully selected—sequential or nonsequential (c.f. Section 5.5.1)—molecular code is determined. Each resin particle carries not only the respective product of the combinatorial synthesis, but also a record of the "synthetic history" in the form of this molecular code (Fig. 21). In this way, the

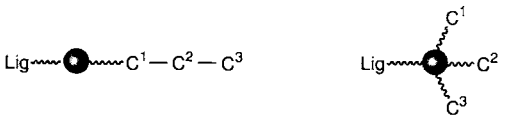

Fig. 21. In the normal case, a support particle in a coded library carries both the test substance (Lig) and the molecular codes (C^1, C^2, C^3). The code can be either sequential (left) or nonsequential (right).

reagents and the reaction conditions with which this particle has come into contact during the course of the reaction are coded. Consequently, such a procedure results in an increased complexity of synthesis. Caution must be observed, however, that the code molecules tolerate the reaction conditions used in the combinatorial synthesis and that the products of the combinatorial synthesis also remain inert during the coding reactions. This could limit the reactions available for a combinatorial synthesis.

In all cases, such a coding is of course valid only if the relationship between support, target molecules, and code molecules remains intact. This provides no problems if biological testing is carried out with the support-bound compound, not in solution. After testing and cleavage the active compound is identified by reading the code following cleavage.

However, the assay is usually carried out with dissolved material. Then, for efficient testing, cleavage of the synthetic product from the support must be able to be carried out in aliquots. Examples are the screening strategies followed by the companies Selectide[120] (Fig. 22) and Pharmacopeia.[122, 158] As Figure 22 illustrates, 500 resin particles, which can carry 500 different compounds ("one bead, one compound"), are placed in each

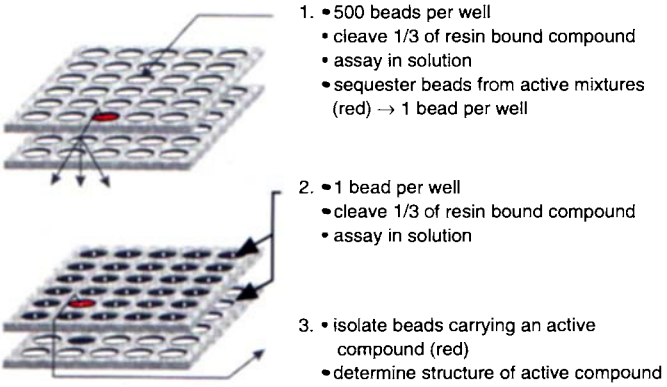

Fig. 22. Aliquot cleavage from the support and two stage testing of compound libraries (according to ref. [120c]). The procedure used by Pharmacopeia [122, 158] employs a photolabile linker and in Step 3 determines the structure of the active compounds by reading a code (see Scheme 79).

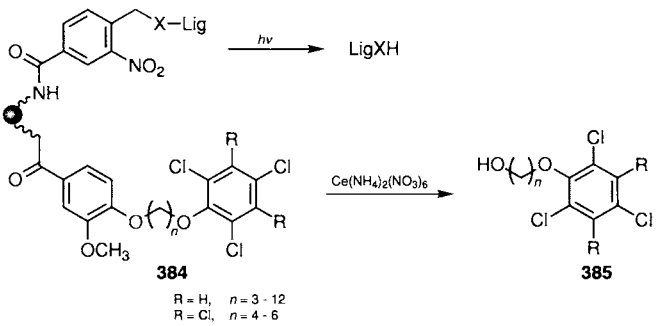
well of a microtiter plate. In the first step 1/3 of the respective compound is cleaved and transferred to a second microtiter plate. There the biological assay is then performed on dissolved substance. Since the mixtures in solution can be traced to the particle mixtures from which they were cleaved, sequestering of the particle mixtures from which the dissolved, active substance mixtures originated is possible. The individual compounds formed after cleavage of a further aliquot can be tested again and identified with the help of the resin-bound code ("single-bead assay").

In the future with the use of more effective microanalytical methods, structure determination by direct analysis of test compounds cleaved from the resin rather than by complex coding techniques should become feasible. A prerequisite for the use of these methods is, however, that an aliquot of material bound to a single resin particle is sufficient for the test. When this is guaranteed, this procedure offers ideal conditions for efficient testing.

5.5.1. Chemical Codes

The first chemical codes were peptide[248] and nucleotide[249] sequences synthesized in parallel for the construction of the library. Reading of this sequential code occurs serially by sequencing, possibly after amplification by the polymerase chain reaction (PCR) in the case of nucleotides. Unfortunately, the chemical instability of nucleotides severely limits the range of reaction conditions available for chemical synthesis.

A totally different and currently the most elegant chemical solution comes from Still et al.[160, 250] In the creation of a binary nonsequential code, they employed a number of halogenated aromatics that were coupled directly to the polymeric matrix through alkoxy spacers of varying lengths by a Rh-$(TFA)_2$-catalyzed carbene insertion reaction (Scheme 79). To



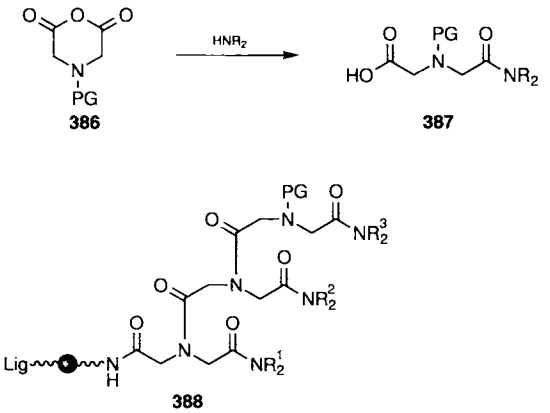
Scheme 79. Coding of compound libraries with halogenoaryloxy alcohols (according to ref. [252]). Lig = ligand.

read this code the coded aryloxyalcohols **385** were cleaved oxidatively and silylated. The presence (logic 1) or the absence (logic 0) of the different code molecules was determined by means of electron capture GC. The binary count obtained coded for the respective synthetic pathway.

The first application came again from the peptide area,[160] but more recently there have also been reports of binary coded libraries of non-peptide molecules[122, 158] (see also Section 4.2.1.2.).

A procedure very similar in principle to the Still method has been described recently by Gallop et al.[251] They used sec-

ondary amines as letters of a molecular code. Parallel to the synthesis of the test compound the oligoamide **388** was constructed from the code molecules (Scheme 80). For decoding, **388** was hydrolyzed with 6N HCl, and the secondary amines thus obtained converted into dansyl derivatives, which after HPLC separation were detected by fluorescence spectroscopy. In this way β-lactam and pyrrolidine libraries have been coded.[251]



Scheme 80. Gallop et al. [251] use secondary amines as code molecules. Parallel to the synthesis of the test compound on the support, the coded oligoamide **388** is formed from the protected amino acids **387**. Hydrolysis regenerates the free secondary amines, which can be identified after conversion into the dansyl derivatives.

A recently published patent application from SmithKline Beecham describes the coding of libraries by labeling the solid-phase particles with fluorophores.[253] This method of labeling also allows sorting of the particles with a cell sorter, during or after the split synthesis.

5.5.2. *Nonchemical Coding*

Currently the only examples of nonchemical coding are the recent papers of Nicolaou et al.[255] and Moran et al.[256] The relevant synthesis steps are recorded on a storage chip which can be written or read by high-frequency signals. Since in both cases the work was carried out with a relatively low number of particles (de facto reaction vessels), the procedure at the present state of the art may be regarded as a high-tech version of the teabag method.[7] The viability of this method was also verified by the coding of peptide syntheses.

6. Automation and Data Processing

Solving the problems of synthesis is not the end of the matter. Only an integrated concept embracing chemistry, automation, electronic data processing, and high-capacity screening promises success. One extreme position is outlined in a patent recently granted to 3-Dimensional Pharmaceuticals:[257] In a *fully automated*, computer-controlled process, optimized structures are reported to be obtained in iterative cycles that include the synthesis of test compounds, their testing, and the analysis of the biological data thus obtained.

A review of the state of automation is given by DeWitt,[258] who has also been deeply involved in the development of the now commercially available DIVERSOMER technology.[127, 129, 131, 259] The currently marketed equipment[260] is derived from multiple peptide synthesizers and is still limited in scope. For this reason venture companies have developed their own synthesizers that are used solely for their own syntheses.[261] However, developments are in progress by instrument and automation companies,[262] so systems are expected to become available in the near future that will be constructed on a modular basis that can be adapted to a number of reaction conditions. In such a system, all liquid transfers (addition of solvents or reagents, washing steps) take place in a central module constructed around a pipetting robot. The charged reaction vessels are then transferred to special incubation modules, where they remain for the duration of the reaction, while the central module is again available for the preparation of further reactions.

Another concept[263] being followed by Combichem and Argonaut Technologies totally dispenses with the use of pipetting robots: in this fully closed system, reagent and solvent vessels are permanently interconnected with the reaction vessels by means of tubes and valves.

Because of the considerable amount of data collected, combinatorial chemistry is unthinkable without the support of electronic data processing.[264, 265]

The following applications have come to the fore:

- Software for control of the synthesizer.
- Selection of reagents by search of chemical databases such as the *Available Chemicals Directory* (ACD).[266]
- Support in the selection and optimization of reactions by searching reaction databases such as *REACCS*[266] or *Crossfire Plus*.[267] With *SPORE*[39] or the solid-phase synthesis database Synopsys,[39] there are now special reaction databases for organic solid-phase synthesis.
- Management of and searches in (virtual) compound libraries. In this context programmes such as *Project Library*,[266] *Legion*,[268], *Unity*,[268] or a programme package from Daylight[269] are available.

A significant challenge is presented by programs that go beyond mere administrative functions and allow intelligent selection of the compounds to be synthesized, thus aiming to achieve a maximum diversity with the minimum number of compounds.

Significant developments are to be expected in this area in the future. A start has already been made. The programs *Selector*,[268] *Jarpat*,[269] *C²-Diversity*,[271] and *Chem-X*[271] are commercially available for assessing diversity. *Chem-X* also enables library management.

7. Venture Companies in the Field of Combinatorial Chemistry

In the 1990s the possibility of producing compound libraries by combinatorial chemistry, thus accelerating dramatically the search for novel active compounds, has led to a veritable flood of company establishments, particularly in the USA. The prospect of a drastic reduction in development time and costs of new pharmaceuticals has given rise to a gold-rush mentality, the like of which has not been experienced in chemistry since the foundation of the dye industry at the close of the last century.

These venture companies have made a major contribution to the development in the techniques of combinatorial chemistry. Many of the currently described examples of combinatorial syntheses have been published by scientists from these small companies. Without attempting to discuss the strategies of these companies in detail, the following trends are apparent:

- All companies are involved with combinatorial synthesis on solid phase, some even exclusively.
- Most companies began with the synthesis of peptide libraries, but now all are developing combinatorial syntheses of small organic molecules.
- Many companies are involved with the development of new synthesizers.
- According to the size and format of the libraries produced, the spectrum extends from parallel synthesis of individual compounds (a few hundred products) to enormous (coded) peptide libraries generated with the split method.
- Testing is carried out predominantly in solution.

At present, besides the number of products, the design of a library (diversity criteria, inclusion of pharmacophore patterns) is coming increasingly to the fore.

Without any claim to completeness, Table 2 gives an over view of a few of these companies and gives information on more recent important acquisitions and cooperations.[273] The figures show quite clearly the considerable potential the established pharmaceutical industry sees in these new techniques.

8. Outlook

"Predictions are always difficult, particularly where the future is concerned."
Niels Bohr

Combinatorial synthesis of small organic molecules is without doubt still in its infancy. The syntheses currently described do indeed start from more than one building block or reactant

Table 2. Venture companies in the area of combinatorial chemistry; research cooperations and acquisitions.

Venture Company	Partner company [a]	Project	Investment volume [mil. US$] [b]	Time period
Affymax	Glaxo	acquisition	533	February 1995
Alanex	Novo Nordisk	diabetes	n.d.	April 1996
Ariad Pharmaceuticals	Hoechst Marion Roussel	cooperation in the area of osteoporosis	40	November 1995
ArQule	Abbott Laboratories	5-year contract, development of combinatorial libraries based on lead structures of Abbott	35	June 1995
ArQule	Pharmacia Biotech	cooperation in the field of separation technology	30	March 1995
ArQule	Solvay-Duphar	5-year contract	50	November 1995
Arris Pharmaceuticals	Bayer	5-year contract new protease inhibitors against inflammatory diseases	70	January 1995
Arris Pharmaceuticals	Pharmacia Biotech	5-year contract serine protease inhibitors	40	August 1995
Chiron	Ciba Geigy	non-exclusive access to Chiron's libraries	26	November 1995
Chiron	Dow Elanco	cooperation (new lead structures in the agricultural field)	n.d.	January 1996
Chiron	Japan Tobacco	non-exclusive access to Chiron's libraries	n.d.	March 1996
Chiron	Organon	research cooperation, technology transfer	n.d.	August 1996
CombiChem	PE Sciex	instrument development	n.d.	May 1996
CombiChem	Teijin	targeted libraries	10	April 1996
Houghten Pharmaceuticals	Procter & Gamble	3-year research cooperation	n.d.	May 1995
Houghten Pharmaceuticals	Novo Nordisk	diabetes, osteoporosis	4	February 1996
Ontogen	Boehringer Ingelheim	research cooperation	41.6	August 1996
Oxford Asymmetry	Pfizer	formation of a jointly owned subsidiary company: Oxford Diversity, development of new solid-phase chemistry	5.8	March 1995
Pharmacopeia	Schering-Plough	cancer and asthma pharmaceuticals	76	January 1995
Pharmacopeia	Berlex Laboratories	multiple sclerosis	20	February 1995
Pharmacopeia	Sandoz	research cooperation for the indication area CNS, cancer, transplantations, skin	100	October 1995
Pharmacopeia	Bayer	research cooperation	20	January 1996
Pharmacopeia	Daiichi Pharmaceutical	research cooperation	22	April 1996
Pharmacopeia	Organon	research cooperation	19	June 1996
Selectide	Marion Merrell Dow	acquisition, development project: factor Xa inhibitors	58	January 1995
Sphinx Pharmaceuticals	Eli Lilly	acquisition	75	March 1994
Tripos	Menarini	cooperation in the field of inflammation inhibitors	n.d.	October 1995
Tripos	Merck	software development	n.d.	November 1995
Tripos	Panlabs	software development	n.d.	February 1995

[a] Name at time of agreement. [b] n.d. = no details.

and may therefore be termed combinatorial, but the libraries produced are frequently very small (a few to several thousand compounds).

After initial hesitation, the community of preparative chemists has ventured into combinatorial chemistry, and it may be expected that this area, until now dominated by peptide chemists, will consequently enter a new and more vigorous development phase. It is precisely these synthetic chemists, accustomed to synthesizing a specific target product, who are finding the transition to combinatorial chemistry most difficult. It is their expertise, however, which will lead to significant advances in the planning of combinatorial syntheses. Currently, reaction sequences that will in each case allow the preparation of many thousands of compounds are being worked upon in many places. Whether the perfection of peptide synthesis and hence similarly large libraries will be achieved is questionable.

Intelligent selection of individual building blocks—supported by modeling—will play an increasingly important role in library design, so that these libraries, in spite of all the limitations imposed by chemistry, will have the largest diversity possible. It remains to be seen whether in this respect the high expectations are fulfilled. Large libraries in a format suitable for wide testing will only be achievable by solid-phase synthesis, for it is only solid-phase synthesis that allows automation of all steps in a multistage synthesis and the targeted synthesis of mixtures. It is for this reason that there will be significant advances in further methodology development of solid-phase synthesis.

This will lead to new resins and linkers that will be better suited to organic reactions than the currently used materials derived from peptide synthesis. There will never be a "miracle support" upon which any organic reaction can be carried out, possibly without adjustment problems, and which will finally release the final product at the touch of a button. Most probably a selection of resins and linkers will be available from which the combination most suitable for a particular synthesis can be chosen.

The repertoire of reactions able to be carried out in the solid phase will also be considerably expanded, and in the foreseeable future a wide know-how will be available in this area.

Even more importantly, new analytical methods will ensure that we will have a better understanding of the processes on the resin and be better able to predict many results. Both NMR spectroscopy on the resin and single-bead mass spectrometry[223] are already a reality. The significance of indirect analytical methods (such as coding) will decline with the possibility of *direct* determination of the structure of products on the resin.

Finally, synthesizers will be developed that allow automated, parallel implementation of many reactions on a small scale, both on the solid phase and in solution. Moreover, methods for automated product purification (such as solid-phase extraction and preparative HPLC) will find greater use.

Miniaturization and automation of organic synthesis can no longer be restrained and will lead to the rationalization of synthesis in many areas, even outside medicinal and agricultural chemistry. This can certainly be regarded as one of the first "results" of combinatorial chemistry. However, confirmation that combinatorial chemistry in its own right leads to an acceleration in the search for active compounds has not yet been forthcoming. It may certainly be assumed that—if the peptide libraries are included—more products have already been produced by combinatorial chemistry than by conventional syntheses. There are, however, currently very few products under or close to clinical investigation that have been identified with combinatorial techniques.[166, 274]

Meanwhile the first clouds have appeared in the otherwise deep blue sky of combinatorial synthesis of small organic molecules. Is it really sensible to seek enormous compound libraries of closely related molecules in mixtures? Should not combinatorial synthesis be better used to produce a few (<1000) single compounds where prior information on a target or lead structure can be used in the planning of syntheses ("structure-based combinatorial chemistry")? It is too early for a clear answer to these questions; however, the touch of realism that is now being added to the previous euphoria will do the area more good than harm. Questions such as "single compounds versus mixtures" or "solid phase versus solution" are currently being intensively discussed. A clear path has yet to emerge, and at present rather the task and the chemistry determine strategy (Table 3).

Table 3. Characteristics of combinatorial compound libraries

Lead structure search	Lead structure optimization
random libraries (screening libraries)	focused libraries (targeted libraries)
synthesis of diverse "druglike" compounds	lead structure:target determines chemistry
many targets	one target or target class
solid-phase synthesis	solid/solution-phase synthesis
split synthesis → "compound mixtures" ("one bead, one compound")	automated parallel synthesis → single compounds
$\geqslant 10000$ products	$\ll 10000$ products
<1 mg per product	>1 mg per product
testing of mixtures (with deconvolution) or of single compounds (with decoding)	procedure for screening optional

On one hand, therefore, the opportunities for combinatorial chemistry lie in the search for lead structures, where with the help of large, diverse libraries it should be possible to access structural classes that would otherwise remain unknown in the classical approach. Here solid-phase syntheses are indispensable, and mixtures (<50 compounds) are tolerated. Innovative screening technology and analytical methods will replace coding methods, particularly where they also restrict possible chemistry. On the other hand, combinatorial synthesis will accelerate lead structure optimization. Depending upon the structure to be modified, this can be carried out both on the solid phase and in solution ("high speed analoging"). Structure–activity relationships can then be determined by testing individual compounds.

Combinatorial synthesis will not replace, merely complement, conventional synthesis. Not all structures will be accessible by combinatorial chemistry. Nevertheless it will develop into a standard method in the search for active compounds, comparable with the screening of natural products and molecular modeling. Meanwhile hundreds of scientists worldwide are working to realize the vision of the automated synthesis of new active compounds. However, whether the "laboratory on a chip" will become the standard laboratory in the search for active compounds hangs in the balance.

The perspectives of combinatorial chemistry extend beyond the search for biologically active materials; wherever the discovery and optimization of compounds with certain definitive properties is the target, combinatorial synthesis will acquire a place. Examples which have been described include new catalysts[275] and ligands,[276] complexing agents, dyes, or superconductors.[277] A requirement is, in any case, the availability of an efficient test system with high-throughput and low-substance requirement. However, the chances that combinatorial synthesis will rapidly reach maturity are favorable.[278]

We thank F. Oldenburg and K. Stüber for efficient help in the preparation of the graphics and diagrams. We are grateful to our colleagues, Drs. H. Albrecht, S. Blank, K. Ditrich, P. Eckes, G. Klebe, I. Münster, M. Puhl, and G. Steiner for their review of the manuscript and for their numerous and valuable comments.

[4] The word "*library*" is not used consistently in the literature. Often the term library is reserved for substance mixtures whereas collections of single compounds are called "*arrays*".

[5] The term *combinatorial synthesis* is strictly used only when different building blocks are treated in *one* reaction vessel, and mixtures are thus obtained. Since the boundary becomes blurred at the latest for the split synthesis (see refs. [13–15]), which also represents a compartmentalization ("one bead, one compound"), no differentiation will be made here.

Solid-State Chemistry: Restoring the Balance**

R. Schöllhorn*

Chemistry as a subject in science has two well-defined faces: a *static* face pertaining to the determination and description of the properties of a given material in terms of geometrical structure, electronic structure, chemical bonding, and physical properties, and a *dynamic* face describing any kind of time-dependent structural, compositional, or electronic reorganization in materials, in particular the *reactivity* as a functional property of chemical systems. In the area of solid-state and materials chemistry considerable progress has been achieved in the understanding of correlations between structure, bonding, and physical properties. However, understanding of the most important relationship between these static parameters and the dynamic aspects—the reactivity of solids—is far less developed.

This can be illustrated easily by analyzing (in a simplified fashion) the conventional art of synthesis in solid-state chemistry. Although synthesis is clearly an aspect of the dynamic face of chemistry, it is in fact performed essentially as a static game. If we consider the typical procedure [Eq. (a)], we find that the starting materials **A** and **B**, whose static properties are well-

$$\mathbf{A} + \mathbf{B} \longrightarrow \boxed{\text{"black box"}} \longrightarrow \mathbf{C} \qquad \text{(a)}$$

defined, are subject to certain experimental conditions based upon a combination of valuable practical experience, qualitative guidelines, intuition, and chance. This step is followed usually by a thorough examination and characterization of the static properties of the new product **C** in terms of averaged geometrical structure, chemical bonding, physical properties, and its relationship to related known materials. The next synthetic step then follows based in part upon the results of the previous experiment. The essential point here is that as a rule the "black box" located between **A**/**B** and **C** hiding the *dynamic* aspects of the chemistry involved, in other words the reaction mechanism, is not "opened" for good reasons.

The intelligent synthesis of new materials is without doubt a necessary and highly valuable task and a major source of innovation in solid-state and materials chemistry. Rational synthesis planning and modeling—essential aspects of molecular chemistry—are unfortunately hardly developed in this area with the exception of some specific domains.[1–6] In recent years "tailoring of materials" has become a fashionable term in solid-state chemistry and materials science. This promising expression suggests the existence of a predictive approach which does certainly not agree, however, with the actual reality and creates unjustified expectations about our present potential. We need to emphasize here the simple fact that without an appropriate knowledge of the contents of the "black box," that is, without a systematic investigation of *reaction mechanisms*, this ambitious goal clearly cannot be realized.

At this point we have to return to the statement made previously, that as a rule investigators avoid "opening the black box". This reality can be readily explained.

1. Most solid-state reaction mechanisms are rather complex, involving types of properties not usually found in molecular systems, for example collective behavior of solids, existence of structure-specific extended defects, and interface phenomena.
2. The detailed investigation of a single reaction mechanism in solid-state systems requires particular efforts in terms of manpower and time (frequently on the order of a decade); a combination of a large variety of specific preparative and analytical methods is frequently necessary in order to collect (mostly indirect) evidence and verify models.
3. The field is thus not attractive for younger scientists, who need rapid success to gain tenure in academic institutions and simultaneously will encounter problems in funding long-term projects under current policies in research funding. The natural trend will therefore favor synthesis-oriented short-term research projects.
4. As a consequence only a relatively small number of research groups work actively and systematically in this field, and in turn limited academic teaching staff serve to educate and motivate young scientists in this area.[6, 7]

The following paradoxical situation results: a research area representing one fundamental aspect of solid-state and materials chemistry, which is urgently required for the continued development of rational and economic synthesis strategies, has become necessarily neglected, in part for tactical reasons. We should agree that the time has come to make a serious effort to restore the balance.

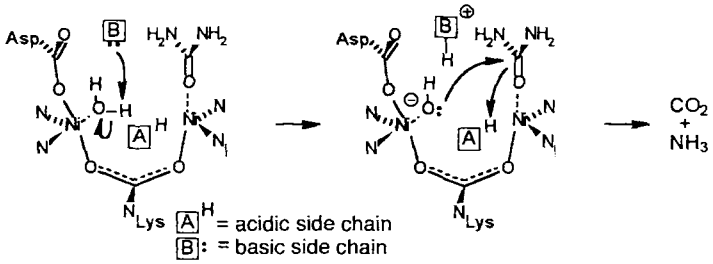
Asymmetric Two-Center Catalysis—Learning from Nature

Henning Steinhagen and Günter Helmchen*

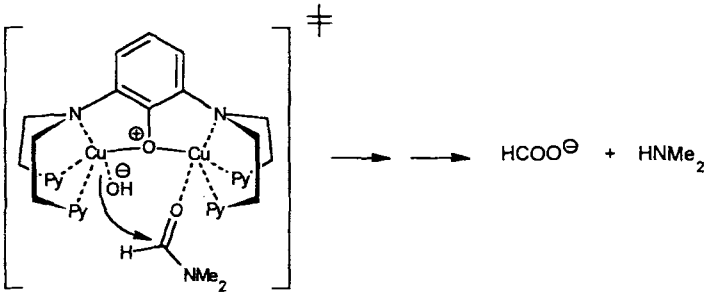
Many catalytic systems contain one reaction center in a suitable ligand environment. During catalysis one reactant is bound to, oriented, and possibly activated by this center in such a way that another reactant can attack selectively and the product is formed. Also commonly encountered are systems in which several reactants are bound to one reaction center, usually a transition metal ion, and due to their positioning they react fast and selectively. We want to point out a new and very effective principle that has not yet been studied very thoroughly: two-center catalysis.[1] In this case the reactants are bound and oriented at two different centers, which often results in both high selectivity and reactivity. This principle will be illustrated here both with recent developments and results and with well-known examples.

Urease, an enzyme for the hydrolysis of urea, provides a clear example of the principle of two-center catalysis. In 1995 Jabri and co-workers obtained an X-ray crystal stucture at 2.2 Å resolution of the urease from *Klebsiella aerogenes*[2] on which Lippard based a mechanistic model[3] (Scheme 1). The two nickel ions participating in catalysis are bridged and placed into juxtaposition by an N-carboxylated lysine (Ni–Ni distance = 3.5 Å). The entering urea substrate is bound through its carbonyl group and spatially oriented by one of the Lewis-acidic nickel centers in such a way that a hydroxide ion from the second nickel center can be added very efficiently to the carbonyl carbon. Deprotonation of the H_2O coordinated to nickel is effected by an adjacent basic histidine side chain. The resultant carbamic acid dissociates into CO_2 and NH_3, which is essential for the bacterium. As a result of the cooperative effect of the two nickel centers, the reaction rate of the hydrolysis of urea with OH^- is enhanced by a factor of 10^{14}! An analogous principle is used by the carbonylating enzyme carbon monoxide dehydrogenase (CODH). Ragsdale et al. proved both a methyl–nickel and an iron–carbon monoxide unit by resonance Raman spectroscopy in carbon monoxide dehydrogenase from *Clostridium thermoaceticum*.[4] The formation of the acetyl–metal unit probably takes place by insertion of CO into the $Ni-CH_3$ bond.



Scheme 1. Mechanism of two-center catalysis in the hydrolysis of urea by the urease enzyme of *Klebsiella aerogenes* (according to Lippard [3]); the nitrogen atoms coordinated to nickel stem from histidine. In all schemes only some of the charges are given.

A biomimetic model system for amide hydrolysis on the basis of two Cu^{2+} centers was reported by Karlin et al. in 1993.[5] Here the amide, in the example dimethylformamide, is bound to the carbonyl group and activated by one of the copper centers while a hydroxide ion is transferred by a second copper center (Scheme 2). Hydrolysis of dimethylformamide occurs within a few seconds and, thus, it is much faster than the uncatalyzed reaction, which does not proceed at room temperature.



Scheme 2. Biomimetic system for the hydrolysis of amides (according to Karlin et al. [5]).

Over the last few years several examples have been reported in the field of asymmetric catalysis that are based on the interaction of two centers. Recently, the group of Shibasaki reported particularly impressive findings.[6–9] The new catalysts (Scheme 3) consist of a central metal ion (e.g. La^{3+}, Al^{3+}), three alkali metal ions (e.g. Li^+, Na^+, K^+), and three molecules of the chiral diphenol 1,1′-(*R*)- or 1,1′-(*S*)-binaphthol [(*R*)- or (*S*)-binol, respectively]. The catalysts exhibit basic (at the oxygen of M^2-O) as well as Lewis-acidic properties (at M^1 and M^2) and are therefore multifunctional catalysts. The complexes can be prepared easily; they are stable to air and moisture and are nontoxic according to Shibasaki. In addition, binol is easy to recover.[6b] These heterobimetallic M^1-M^2-binol complexes

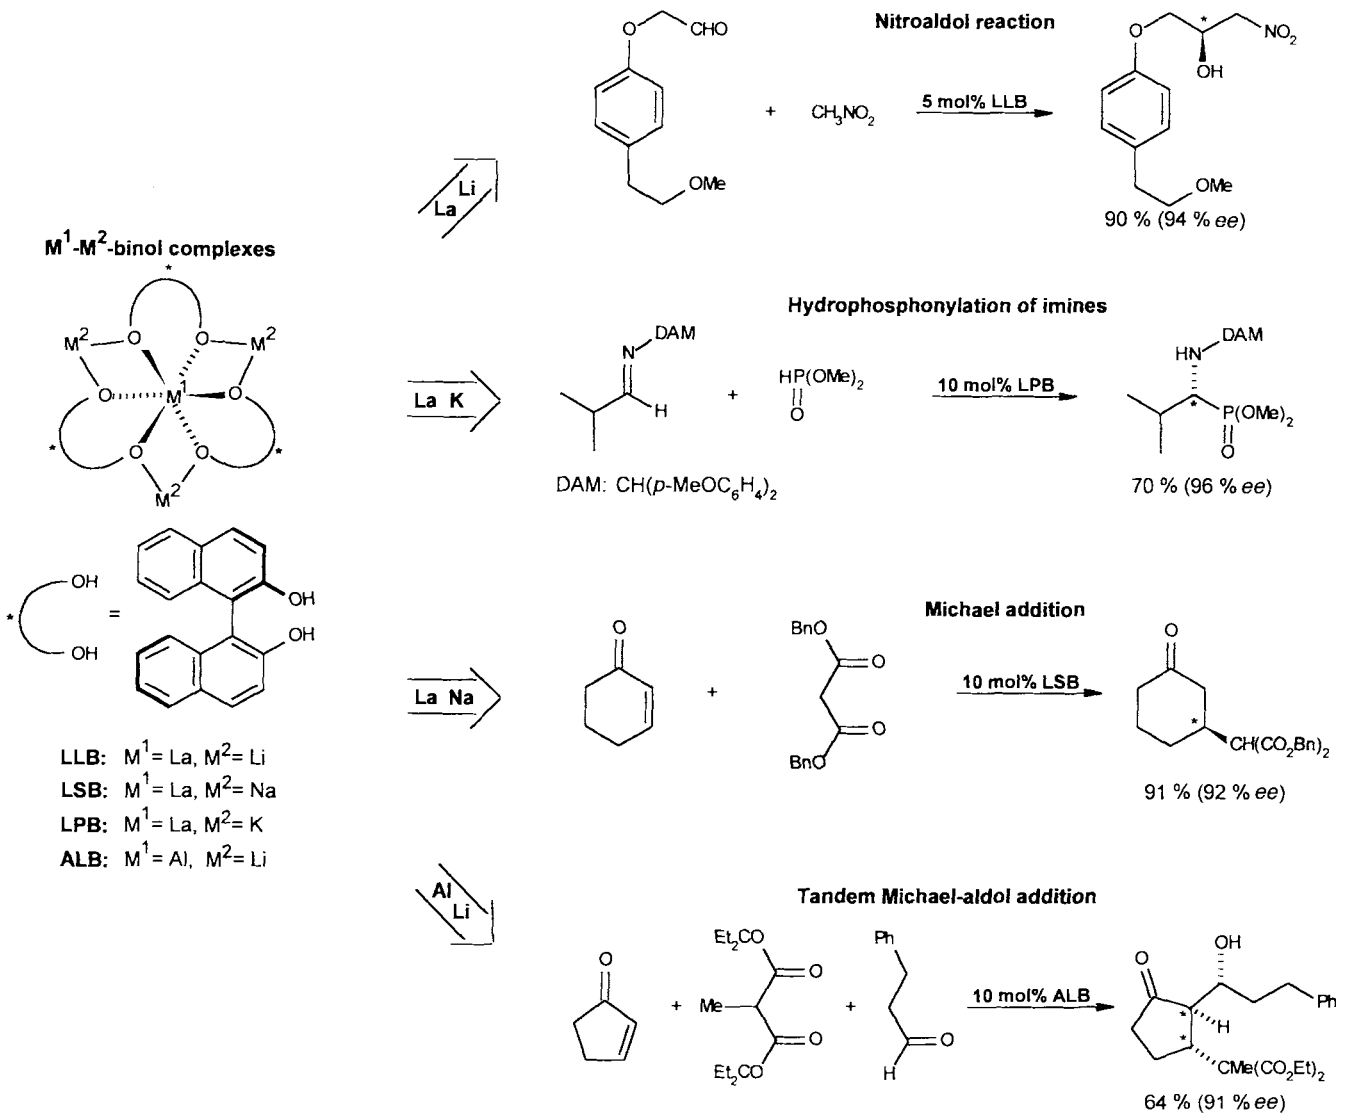

Scheme 3. Results of various reactions with specific M^1-M^2-binol complexes as catalysts (according to Shibasaki et al. [6–9]).

constitute a new class of widely applicable and versatile chiral catalysts. By careful choice of the metal centers, organic transformations of widely differing types can be catalyzed (Scheme 3).

The investigations of the Shibasaki group began with the asymmetric nitroaldol reaction.[6] When the La–Li–(*R*)-binol complex (**LLB**) was used as a catalyst, up to 94% *ee* and 90% yield were achieved[6e] (Scheme 3). By using a 6,6′-bis((trialkylsilyl)ethynyl)-substituted (*R*)-binol in the reaction of aldehydes with 2-nitroethanol, they even raised the enantiomeric excess to 97% and the yield to 97%.[6h] The nitroaldol reaction according to Shibasaki was applied both in the synthesis of the β-receptor blocking drugs (*S*)-Metoprolol,[6d] (*S*)-Pindolol,[6g] and (*S*)-Propanolol,[6c] and in the synthesis of phenylnorstatine, a building block used in the synthesis of the HIV protease inhibitor KNI-272.[6f]

Another reaction that can be catalyzed by metal–binol complexes is the asymmetric hydrophosphonylation of imines[8a] and aldehydes.[8b] This reaction is of great interest, because the products, α-amino- and α-hydroxyphosphonic acids, are potentially useful as enzyme inhibitors.[10] With the lanthanum–potassium–(*R*)-binol complex (**LPB**), it was possible to achieve enantiomeric excesses of up to 96% with yields of at most 70%[8a] (Scheme 3).

In search of further reactions that can be catalyzed by metal–binol complexes the Shibasaki group reported in 1994 the highest known enantiomeric excesses (95% *ee*, quantitative yield) for the catalytic asymmetric Michael addition.[7] In this case, not only the La–Na–(*R*)-binol complex (**LSB**) was an effective catalyst, but also the alkali-free La–(*S*)-binol complex (**LB**) (Scheme 3). The latest and most impressive discovery is a catalytic tandem Michael–aldol addition to cyclopentenones (Schemes 3, 4).[9] By varying the metals in the M^1-M^2-binol complexes, optimal conditions were found under which this multistep reaction proceeds with high selectivity (91% *ee*) and acceptable yield (64%). With regards to synthetic strategy, this reaction is a catalytic variant of a three-component coupling reaction developed in 1985 by Noyori et al. for the synthesis of prostaglandins.[11]

The mechanism according to Shibasaki (Scheme 4) clearly shows the different functions of the two metal centers in the Al–Li–(*R*)-binol complex (**ALB**) during catalysis. The nucleo-

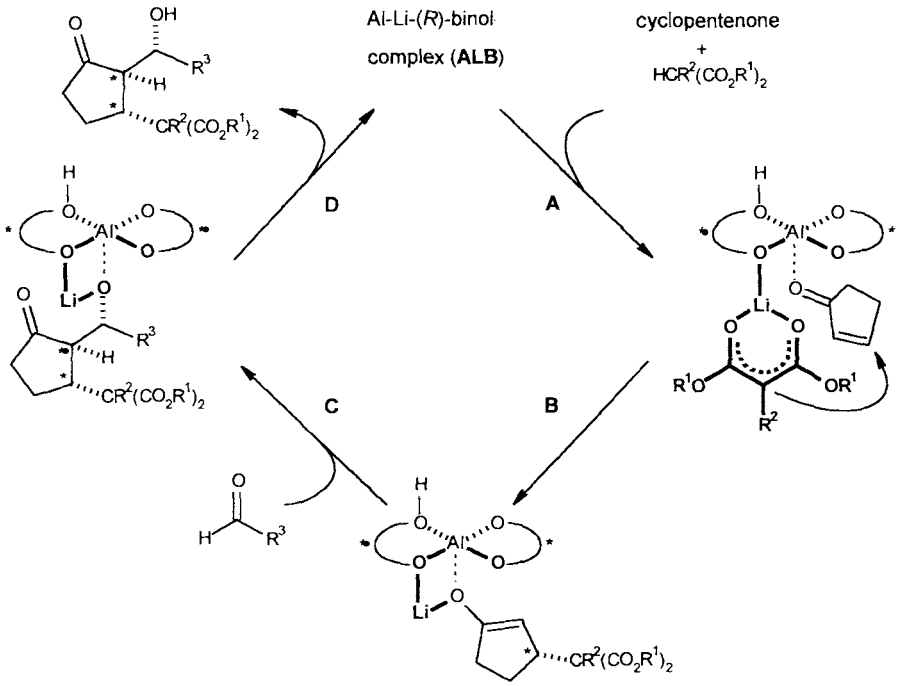


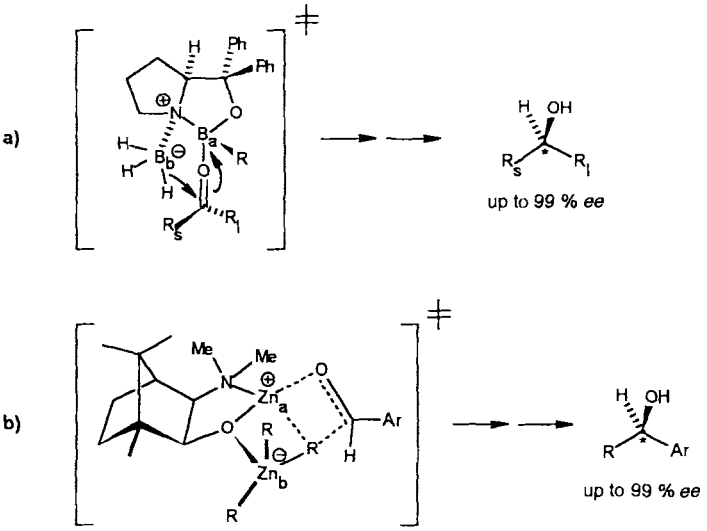
Scheme 4. Postulated catalytic cycle for the tandem Michael–aldol addition (according to Shibasaki et al. [9]).

phile to be transferred, malonate, is probably formed at the catalyst by deprotonation and is positioned by means of a Li bridge at the complex (**A**). In addition, cyclopentenone is bound and oriented at the Lewis-acidic Al^{3+} center. In the next step, the nucleophile attacks the substrate with enantioface-differentiation (**B**). The resultant enolate remains bound and positioned at the catalyst so that the subsequent aldol reaction (**C**) proceeds with both high selectivity and yield. Subsequently the products dissociate and new **ALB** enters the catalytic cycle (**D**). This system can be considered a "chemzyme" (*chem*ical en*zyme*)[12].

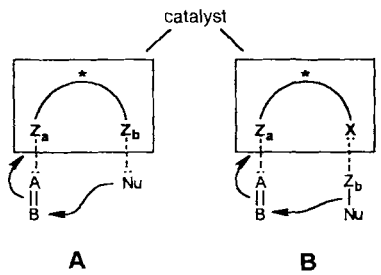
The catalysts developed by the Shibasaki group represent only one of several possible types of two-center catalysis. This is illustrated by the following classification (Scheme 5). The previously described systems belong to a particular class of the two-center catalysts (**A**) in which two Lewis-acidic centers (Z_a, Z_b) such as metal ions are available for binding after each catalytic cycle.[13] A second class (**B**) consists of catalysts that provide a Lewis-acidic (Z_a) as well as a Lewis-basic center (X). A second Lewis-acidic center (Z_b) is supplied by a reactant and appears in the product formed (see examples in Scheme 6).

In 1987 Corey, Bakshi, and Shibata introduced a very effective catalytic system for the reduction of prochiral ketones[12] based on the work of Itsuno. With oxazaborolidines as catalysts it is possible to obtain products with enantiomeric excesses of up to 99%. In this system the endocyclic, Lewis-acidic boron center B_a binds the carbonyl compound. The center atom B_b is provided by the stoichiometrically used reductant BH_3 and remains in the reaction product. With respect to two-center catalysis, B_a corresponds to the center Z_a; the second center is given by a Lewis-basic nitrogen to which the reactant BH_3 (Z_b) is bound (Scheme 6). In connection with this catalytic system terms like "molecular robot" and "chemzyme" were introduced.

On the basis of a discovery by Oguni et al.,[14] Noyori and co-workers were able to achieve enantiomeric excesses of up to 99% with chiral amino alcohols as ligands in the enantioselective addition of organozinc compounds to prochiral aldehydes (Scheme 6).[15] Again, only one metal ion (Zn_a) remains in the catalytic cycle; the second one is provided by the stoichiometrically added R_2Zn and replaced after each cycle. Thus, the two centers essential for the two-center catalysis are Zn_a and the endocyclic oxygen atom.



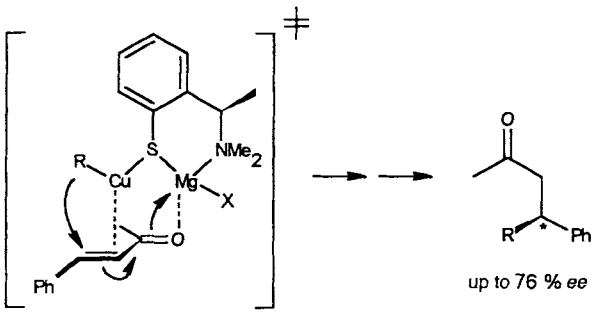
Scheme 6. Examples of two-center catalysis of type **B**: a) enantioselective reduction of prochiral ketones (according to Corey et al. [12]); b) enantioselective addition of R_2Zn to aldehydes (according to Noyori et al. [15]).



Scheme 5. Classification of two-center catalysts; A=B, Nu: reactants; Z_a, Z_b: Lewis-acidic centers; X: Lewis-basic centers.

The classification presented here should be regarded as a proposal, because with the relatively few examples available, setting up a final classification would be premature. This may be illustrated by an example taken from the copper-catalyzed 1,4-addition of Grignard reagents to α,β-unsaturated carbonyl compounds[16] (Scheme 7). Although the reaction seems to demonstrate two-center catalysis at first glance, it is a borderline

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2341 $ 15.00+.25/0



Scheme 7. Enantioselective 1,4-addition of RMgX to enones (according to van Koten et al. [16a]).

case. The enone is bound to the Cu^+ center through its double bond and also to the Mg^{2+} center through the carbonyl oxygen. The nucleophile is tranferred from the Cu^+ center. If one regards bonding and activation of the enone at the Mg^{2+} center as essential for catalysis, then the example would demonstrate two-center catalysis in the sense we have discussed. However, if one considers the Mg^{2+} center to take part only in spatial positioning and not in activation, the reaction would not be an example of two-center catalysis because both reactants are essentially attached to the Cu^+ center. This example shows the limits and the formal character of the classification because the real interactions during catalysis can often not be assessed precisely. In connection with this topic we would like to refer to hydrogenation catalysts developed by the groups of Jacobsen and Kagan, which contain a Rh^+ and a second Lewis-acidic center for additional positioning of a reactant.[17] These examples do not fit into the category of two-center catalysts as described above.

The catalytic systems and mechanisms described demonstrate the usefulness of two-center catalysis. Many, if not all of the examples were discovered empirically rather than rationally designed. In future it will be helpful to learn more about the principle of two-center catalysis and to consider it in the design of new catalytic systems. As a result the proposed classification will likely be enlarged and refined.

Not all that glitters is gold. But the powerful oxidizing agents Me_3EI_2 (E = P, As) can convert gold powder into novel complexes such as $[AuI_3(PMe_3)_2]$ (structure shown above) in an invaluable reaction. S. M. Godfrey, C. A. McAuliffe, et al. provide more details in the following article.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2343 $ 15.00+.25/0

The Oxidation of Gold Powder by Me_3EI_2 (E = P, As) under Ambient Conditions; Structures of $[AuI_3(PMe_3)_2]$, $[AuI_3(AsMe_3)]$, and $[(Me_3PO)_2H][AuI_2]$**

Stephen M. Godfrey*, Nicholas Ho,
Charles A. McAuliffe,* and Robin G. Pritchard

Historically, gold has always been considered as the most noble of all metals. It occurs naturally as the elemental metal and, unlike any other metal, is reluctant to form an oxide. Only one oxide of gold is known, Au_2O_3, and even this is unstable, decomposing to produce gold metal at moderately high temperatures (ca. 160 °C).[1] Consequently, to produce gold complexes it is necessary to solubilize the metal, usually by using rather severe reaction conditions, for example treatment with aqua regio and/or cyanide. Clearly, the development of a new reaction route starting with elemental gold to produce gold complexes under ambient conditions in a chemically inert solvent is highly desirable.

We are actively engaged in the development of certain R_3EX_2 compounds (E = P, As, Sb; $S_2 = Br_2$, I_2, IBr) as powerful oxidizing agents towards elemental metals and some zero-valent metal complexes. These compounds are capable of oxidizing crude nickel and cobalt metal powders directly to the +III oxidation state in a one-step reaction.[2-4] In addition to the surprising power of these species as oxidizing agents, their reaction with a variety of metal powders has resulted in the isolation of a number of metal complexes with unusual stoichiometries, for example $[CoI_8(PnBu_3)_3]$,[3] some which would not have been expected to exist according to the hard/soft acid/base theory, for example $[CoI_3(SbPh_3)_2]$.[5] Additionally, novel cationic species such as the linear $[Ph_3As\text{-}I\text{-}I\text{-}I\text{-}AsPh_3]^+$[6] and novel isomeric forms of known compounds, for instance the trigonal-bipyramidal $[MnI_2(PPhMe_2)]$,[2] are also available by this new synthetic route.

The chemistry of gold complexes containing tertiary phosphane ligands has been well studied and is well understood.[7-13] Two types of complex prevail, the linear gold(I) complexes $[R_3PAuX]$[9-13] and the square-planar gold(III) complexes $[R_3PAuX_3]$;[14-20] the latter are almost exclusively produced by the oxidation of a gold(I) complex, $[R_3PAuX]$, by dihalogen, X_2. The use of certain chelating agents can force the gold atom to adopt distorted trigonal-bipyramidal or, more commonly, square-pyramidal coordination geometry[21-25] due to the steric requirements of the ligand; however, no regular trigonal-bipyramidal complexes are known and, all gold(III) complexes known to date in which the ligands have no special steric requirements are square-planar.

In view of the demonstrated oxidizing power of our R_3EX_2 reagents and their versatility, we were intrigued to know if any of these species could oxidize the notoriously noble gold metal and, if this was possible, whether novel complexes could be produced. We thus treated trimethylarsinediiodine with gold metal powder according to Equation (a). The gold(III) complex

$$3\,Me_3AsI_2 + 2\,Au \xrightarrow[\text{ca. } 25\,^\circ C]{N_2,\ \text{ca. } 3\,d} 2[AuI_3(AsMe_3)] + Me_3As \qquad (a)$$

was obtained in quantitative yield; the other reaction product, Me_3As, was identified by ^1H NMR spectroscopy. Recrystallization of the dark green powder from diethyl ether at approximately 0 °C produced black crystals suitable for study by X-ray crystallography. The X-ray crystal structure of $[AuI_3(AsMe_3)]$[26] is shown in Figure 1. The gold center has the square-planar

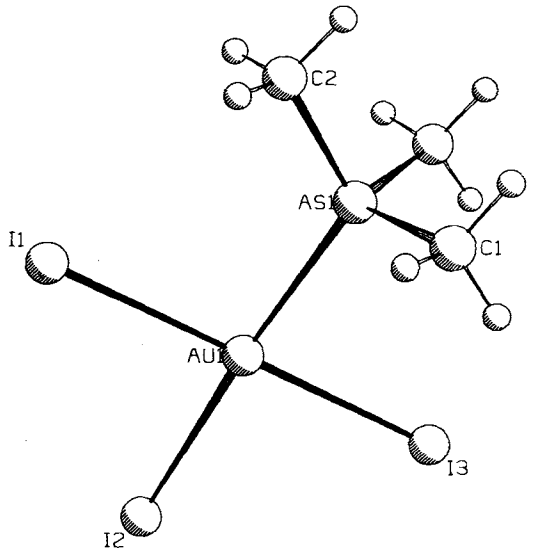

Fig. 1. X-ray crystal structure of $[AuI_3(AsMe_3)]$ (only one of the molecules in the unit cell is shown). Selected bond lengths [Å] and angles [°]: Au1-I1 2.594(7), Au1-I2 2.619(6), Au1-I3 2.651(7), Au2-I4 2.622(7), Au2-I5 2.621(7), Au2-I6 2.635(7), Au1-As1 2.41(1), Au2-As2 2.41(1); I1-Au1-I2 179.9(3), I1-A1-I3 90.0(2), I1-Au1-As1 86.4(3), I3-Au1-As1 176.3(3), I4-Au2-I5 179.8(2), I4-Au2-I6 90.7(2), I4-Au2-As2 92.7(3), I6-Au2-As2 176.6(3).

coordination geometry expected for a d^8 metal center. There are two nonequivalent molecules in the asymmetric unit. Additionally, the structure illustrates the *trans* effect; the iodo ligands that are *trans* to the trimethylarsino ligands are at an appreciably greater distance from the gold atom (2.651(7) and 2.635(7) Å) than the iodo ligands *trans* to another iodide (2.594(7), 2.619(6), 2.622(7) and 2.621(7) Å). Although this phenomenon is more pronounced in one of the molecules in the asymmetric unit than the other, the Au–As bonds for the two molecules (2.41(1) and 2.42(1) Å) are virtually identical.[26,27] These bond lengths are very similar to those found for the only other crystallographically characterized gold complexes containing an Au–As bond, $[AuI_2(diars)_2]I$ (diars = 1,2-phenylenebis(dimethylarsane)) which exhibits Au–As bonds of 2.43(3) and 2.46(2) Å.[28] The UV/Vis spectrum of $[AuI_3(AsMe_3)]$ in diethyl ether exhibits two main peaks at 355 and 621 nm, a profile similar to those of other square-planar gold(III) complexes previously investigated containing tertiary phosphane or amino donor ligands.[17]

In a second reaction Me_3PI_2 was allowed to react with gold metal powder according to Equation (b). The gold(III) complex

$$2\,Me_3PI_2 + Au \xrightarrow[\text{ca. } 25\,^\circ C]{N_2,\ \text{ca. } 3\,d} [AuI_3(PMe_3)_2] + {}^1/_2 I_2 \qquad (b)$$

was obtained in quantitative yield, and the other reaction product, I_2, was detected spectrophotometrically. Recrystallization of the dark blue powder at roughly 0 °C produced deep blue-black crystals suitable for study by X-ray crystallography; the crystal structure of $[AuI_3(PMe_3)_2]$[27] is shown in Figure 2. Remarkably, the gold center has trigonal-bipyramidal geome-

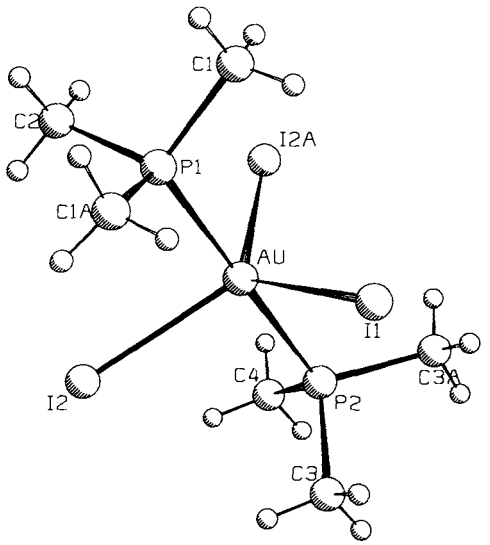

Fig. 2. X-ray crystal structure of $[AuI_3(PMe_3)_2]$. Selected bond lengths [Å] and angles [°]: Au-I1 1.709(3), Au-I2 2.761(2), Au-P1 2.333(9), Au-P2 2.347(8); I1-Au-I2 122.49(4), I1-Au-P1 89.6(2), I1-Au-P2 89.0(2), I2-Au-I2 115.01(9), I2-Au-P1 90.4(1), I2-Au-P2 90.3(1), P1-Au-P2 178.7(3).

try, although the gold(III) center has a d^8 configuration and a square-planar or square-pyramidal geometry would have been expected. This geometry is particularly surprising since there are no steric demands placed upon the gold(III) center by the ligands; in other words, the gold(III) atom is free to adopt the most stable coordination geometry. This, then, is the first trigonal-bipyramidal complex of gold(III) containing ligands that do not impose any steric demands on the metal center, and the first gold(III) complex that does not contain a chelating phosphane ligand but rather two tertiary phoshane ligands per metal center. The fact that gold halides have been treated with many tertiary phosphanes and no complex with this geometry has previously been observed indicates that our novel reaction of Me_3PI_2 with gold powder provides a new mechanistic pathway to gold complexes and thus offers the opportunity to synthesize complexes not accessible by the conventional reaction of gold halides with tertiary phosphanes.

These reactions not only indicate that even gold can be activated and oxidized by the Me_3EI_2 (E = P, As) agents, but also shows that distinctly different products form as a result of quite subtle changes in our reagents: Me_3AsI_2 yields square-planar $[AuI_3(AsMe_3)]$ and Me_3PI_2 yields trigonal-bipyramidal $[AuI_3(PMe_3)_2]$, complexes with both stoichiometric and geometric differences.

The UV/Vis spectrum of a $[AuI_3(PMe_3)_2]$ in diethyl ether exhibits two peaks at 379 and 572 nm, and is similar in profile to that of $[AuI_3(AsMe_3)]$. The $^{31}P\{H\}$NMR spectrum of $[AuI_3(PMe_3)_2]$ displays two signals at $\delta = -69.5$ and 30.1 of almost equal intensity, the former of which corresponds to the value expected for free trimethylphosphane. It therefore appears that in solution an equilibrium is set up between a four and five coordinate gold(III) complex [Eq. (c)].

$$[AuI_3(PMe_3)_2] \rightleftharpoons [AuI_3(PMe_3)] + PMe_3 \quad (c)$$

On a addition of a small quantity of water to a solution of $[AuI_3(PMe_3)_2]$ in diethyl ether, the deep blue solution turned almost colorless. After about seven days small colorless crystals had formed in the reaction vessel. A sample was removed and studied by single-crystal X-ray diffraction. From elemental analysis results the crystals appear to have the formula $[AuI_2(OPMe_3)_2]$, suggesting a gold(II) species; however, the X-ray crystal structure revealed the ionic gold(I) species $[(Me_3PO)_2H][AuI_2]$,[28] (Fig. 3). The reaction proceeds according to Equation (d). The other product from this reaction is assumed to be HI. Although this was not confirmed experimentally, evolution of a gas was observed when water was added to the diethyl ether solution of $[AuI_3(PMe_3)_2]$. Clearly the addition of water initiates reduction of the gold(III) center to form a gold(I) species accompanied by the oxidation of the PMe_3 ligands to produce $OPMe_3$. Since the interaction of a neutral oxygen donor ligand with a gold center is notoriously weak, the $OPMe_3$ ligand is released into solution. Protonation then occurs and the resulting cation, $[(Me_3PO)_2H]^+$, stabilizes the resultant gold-containing anion, $[AuI_2]^-$.

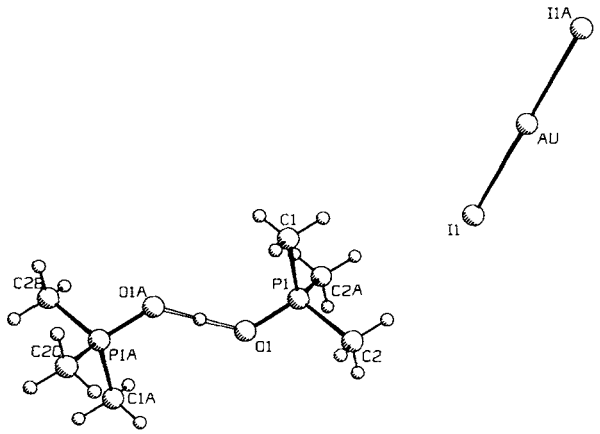

Fig. 3. X-ray crystal structure of $[(Me_3PO)_3H][AuI_2]$ (only one of the molecules in the unit cell is shown). Selected bond lengths [Å] and angles [°]: Au-I 2.616(2), P-O 1.49(2); I-Au-I 180.0(0), O-P-C(1) 111(1), O-P-C(2) 110.3(7).

$$[AuI_3(PMe_3)_2] + \text{excess } H_2O \longrightarrow [(Me_3PO)_2H][AuI_2] + HI \quad (d)$$

Experimental Procedure

Strictly anhydrous and anaerobic conditions (argon) were maintained throughout the reactions unless otherwise stated. $[AuI_3(AsMe_3)]$ and $[AuI_3(PMe_3)_2]$ were prepared by the reaction of coarse-grain gold powder (20–100 μm) and the appropriate Me_3EI_2 (E = P, As) compound. The synthesis of the Me_3EI_2 (E = P, As) compounds has been described elsewhere [29]. All reactions were performed in dry diethyl ether; reaction times were approximately 5 d at room temperature or 3 d under reflux at 60 °C in sealed tubes. The reaction of Me_3AsI_2 with gold afforded a dark green powder, which was recrystallized from diethyl ether to produce analytically pure $[AuI_3(AsMe_3)]$. Dark green – black crystals, m.p. >150 °C (decomp), correct elemental analysis (C, H, I). The UV/Vis spectrum of $[AuI_3(AsMe_3)]$ (2.71×10^{-4} M in diethyl ether) exhibits bands at $\lambda = 355$ and 621 nm. The intense color of the complex and high extinction coefficient, $\varepsilon_{max} = 9910\ dm^3 cm^{-1}$, is due to ligand–metal charge-transfer transition.

The reaction of Me_3PI_2 with gold yielded a dark blue powder, which was recrystallized from diethyl ether to produce analytically pure $[AuI_3(PMe_3)_2]$. Dark blue-black crystals, m.p. >125 (decomp), correct elemental analysis (C, H, I, P). The $^{31}P\{H\}$ NMR spectrum of $[AuI_3(PMe_3)_2]$ displays two peaks of almost equal intensity, one at $\delta = -69.5$ and the other at $\delta = 30.1$. By comparison with literature values, the former peak is assigned to free trimethylphosphane, indicating the compound dissociates in solution to form $[AuI_3(PMe_3)]$ and PMe_3. The latter peak is therefore assigned to the trimethylphosphane coordinated to the gold(III) center. The UV/Vis spectrum of $[AuI_3(PMe_3)_2]$ is similar in profile to that of $[AuI_3(AsMe_3)]$ and other square-planar gold(III) complexes, again indicating dissociation of one coordinated trimethylphosphane occurs in diethyl ether solution.

$[(Me_3PO)_2H][AuI_2]$ was prepared by the addition of a small quantity of water to a solution of $[AuI_3(PMe_3)_2]$ causing complete decolorization of the solution. After about seven days at 0 °C colorless crystals of $[(Me_3PO)_2H][AuI_2]$ formed, m.p. 185 °C, correct elemental analysis (C, H, I).

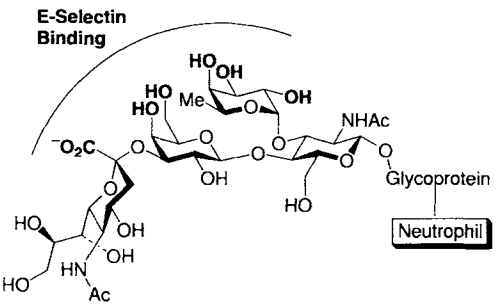
The Synthesis of Novel 6-Amido-6-Deoxy-L-Galactose Derivatives as Potent Sialyl Lewis^x Mimetics**

Michael W. Cappi, Wilna J. Moree, Lei Qiao, Thomas G. Marron, Gabriele Weitz-Schmidt, and Chi-Huey Wong*

Cell surface oligosaccharides are highly diversified in their structures and are associated with a variety of cell functions. Sialyl Lewis^x (SLe^x, Scheme 1) is found in the terminal fragment of certain glycoproteins and glycolipids as a ligand for several members of the selectin family, namely E-, L-, and P-selectin.[1] These selectins are adhesion receptors implicated in the initial interaction between leukocytes and vascular endothelium.[2] The binding of selectins to their carbohydrate ligands appears to be necessary for neutrophil extravasation and plays a major role in lymphocyte recirculation and platelet adhesion.



Scheme 1. Sialyl Lewis^x. The funtional groups necessary for binding are in bold.

Although the binding of SLe^x to the selectins under equilibrium conditions is weak, it is an effective anti-inflammatory agent in many acute disease models and is presently in second phase clinical trials.[3] Though the synthesis of SLe^x has recently been simplified by a chemo-enzymatic approach,[4] the high expense of its preparation and poor oral activity has resulted in many groups' searching for mimetics which are practical synthetically and inexpensive to produce. For the preparation of such mimetics a crystal structure of the receptor–ligand interaction would be advantageous. Unfortunately, because this connectivity is weak, no crystal structure of SLe^x bound to a selectin is available, although a crystal structure of free E-selectin has been reported.[5] Simpler working models must therefore be found, and the investigation of many structure–activity relationships has helped in the elucidation of the functional groups required for the SLe^x epitome binding to the selectins. The 2-, 3-, and 4-hydroxy groups of the fucose, the 4- and 6- hydroxy groups of the galactose, and the negative charge provided by the sialic acid in **1** proved to be crucial (bold atoms in Scheme 1).[6] With the aid of molecular mechanics calculations as well as analytical data, several groups have postulated the active-site structure of

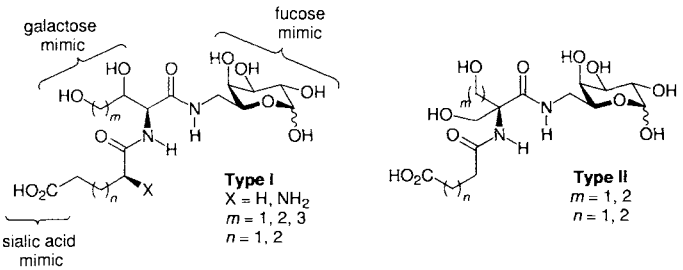
SLe^x (Scheme 1).[7] This active-site model has assisted the major effort of synthesizing SLe^x mimetics.[8] To date, several compounds show interesting in vitro activity equivalent to or better than that of SLe^x.

We have designed several SLe^x mimetics using the aforementioned structure–activity relationships for model construction. The majority of mimetics prepared to date contain the L-fucose moiety linked at the anomeric position to a suitable spacer unit.[8d, e] It was decided to replace the L-fucose unit with an L-galactose functionality to link a range of dihydroxy-α-amino acids (**3**–**7**) at the C6 position. The dihydroxy units would substitute the 4- and 6-hydroxy groups of galactose in SLe^x. Tethering a suitable alkyl side chain containing a terminal carboxylate would provide the required negative charge and afford molecules of either type **I** or **II** (Scheme 2).



Scheme 2. Two types of designed glycopeptide mimics.

Galactose amine **2** serves as the core glycoside structure for all of the mimetics and is easily prepared in high yield from L-galactose (Table 1).[9] Amino acids **3**–**5** were synthesized from threonine aldolase with methodology developed in this laboratory and subsequently protected as their *N*-Boc derivatives.[10] Amino acids **6** and **7** were prepared in four steps from serine[11] and 1-hydroxy-4-benzyloxy-2-butanone,[12] respectively.

The key amide bond was efficiently formed with EDCI/HOBt to give the derivatives in high yields (Table 1). Deprotection of the Boc group allowed introduction of the carboxylate-bearing side chain, which would act as a surrogate for the sialic acid residue. Accordingly, aminoglycosides **8**–**12** were treated with a series of activated carboxylic acids to afford the protected mimetics in high yield (Table 2). Acidic hydrolysis of the acetonides followed by hydrogenolysis of the benzyl ethers provided the fully deprotected mimetics (**13**–**25**), which were purified by Biogel P2 chromatography with water as eluent. Compounds **13**–**25** were fully characterized by ^1H NMR spectroscopy and high-resolution mass spectrometry (Table 3).

The mimetics were assayed in a system which measured the binding of SLe^x glycoconjugate to immobilized recombinant E-selectin.[13] The IC_{50} values indicate that the activity is a function of two mutually exclusive factors, the amino acid used as the galactose mimic (**3**–**7**) and the type of carboxylate tether. Mimetics **13**–**15** showed poor activity suggesting that amino acid **3** is not a good replacement for the galactose residue. In almost all cases the length of the carboxylate tether proved to be critical, as seen for compounds **16**, **22**, and **24** in contrast to **17**, **23**, and **25**. Several of the mimetics were at least as active as SLe^x (**19**, **23**–**25**), and the activity of **25** was twice that of SLe^x.

A Practical Method for the Synthesis of *N*-Acetyl-D-lactosamine Derivatives by the Tandem Use of Galactose Oxidase and β-Galactosidase**

Teiji Kimura, Shuichi Takayama, Hongmei Huang, and Chi-Huey Wong*

As the understanding of the biological role of glycoconjugates increases,[1] so does the need for an inexpensive source of synthetic oligosaccharides in large quantities. *N*-Acetyl-D-lactosamine (Galβ1,4GlcNAc, LacNAc) and its derivatives are particularly useful for the study of biological recognition processes[2] and have been the object of much synthetic effort by means of standard chemical[3] and enzymatic methods.[4] Although syntheses by chemical methods are well known, the procedures often involve many steps and are complicated. The β-1,4-galactosyltransferase-catalyzed reaction coupled with in situ regeneration of UDP-galactose has been developed for the large-scale synthesis of LacNAc; this proceeds with high regioselectivity and yield.[5] However, the limited availability of the enzymes and their high cost and instability hamper their use.[6] The β-D-galactosidase from *Bacillus circulans* also forms Galβ-1,4-linkages by reverse hydrolysis or transglycosylation.[7] The advantages of the galactosidase-catalyzed reaction are low cost, high stability, and simple reaction conditions (there is no need for sugar nucleotides).[8] There are, however, some disadvantages in using galactosidase-catalyzed reactions. Because of the hydrolytic nature of the enzyme, the yields hitherto reported were low, and the desired product was difficult to isolate from the reaction mixture containing quite similar compounds.[7–9] We report here that the *p*-nitrophenyl glycoside of 6-oxo-D-galactose (the primary OH of galactose is oxidized to an aldehyde) can be used as a donor in the reaction catalyzed by β-galactosidase. Furthermore, the transglycosylation is kinetically favored over hydrolysis.

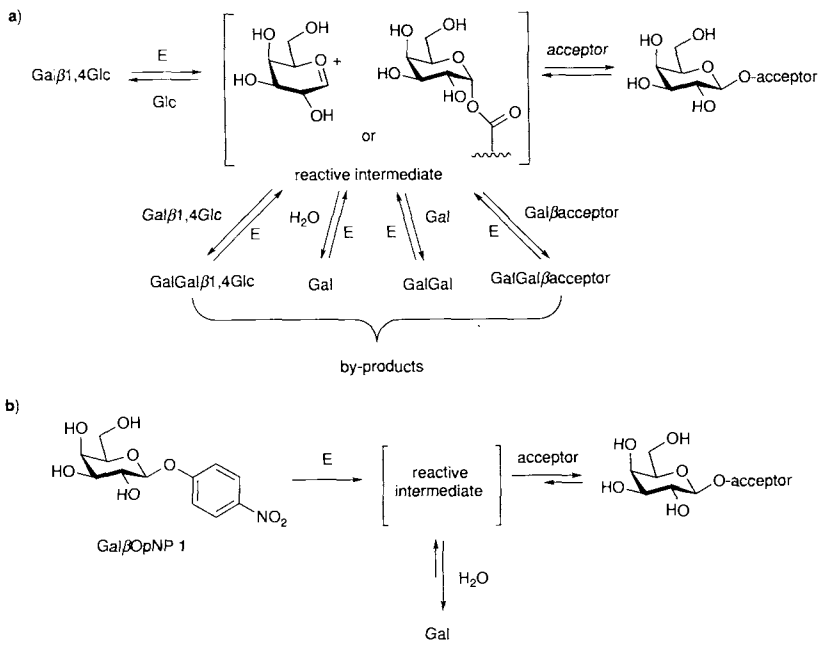
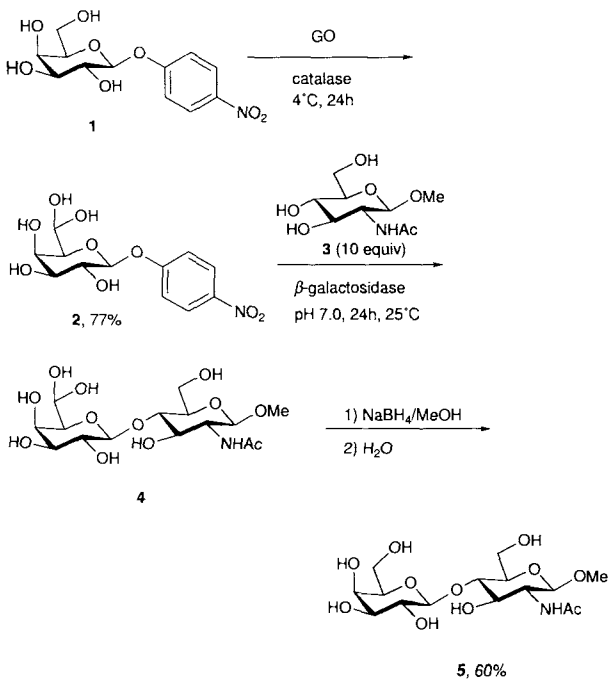
[**] Financial support of this work was provided by the National Institutes of Health (GM 44154). We thank Daiwa Kasei KK (Osaka, Japan) for providing us with β-galactosidase from *Bacillus circulans*.



Scheme 1. β-Galactosidase-catalyzed transglycosylation and hydrolysis: a) substrate with poor leaving group (e.g. Galβ1,4Glc); b) substrate with good leaving group (e.g. **1**); E = β-galactosidase.

Scheme 1 shows the reactions catalyzed by β-galactosidase. As reported,[10] the use of a glycosyl donor substrate with a poor leaving group (such as lactose) often gave a complex mixture of products including mono, di, and trisaccharides. A substrate with a good leaving group (such as *p*-nitrophenyl galactoside) and an excess of glycosyl acceptor make the reaction irreversible and minimize secondary hydrolysis and further glycosylation of the transglycosyl product, the hydrolysis product, and the donor itself. To determine which step is kinetically controlled, the effect of acceptors on initial reaction rate, v_0, was investigated (Scheme 2, Table 1). In the case of *p*-nitrophenyl galactoside (**1**, GalβOpNP), the initial reaction rate, measured by released *p*-nitrophenol, did not increase with addition of acceptor (entries 1–3), although the transglycosylation yield increased from 14% to 30%. These results suggest that the rate-determining step is perhaps the formation of an [E–S] complex. The ratio of transglycosylation to hydrolysis mainly depends on the concentrations of acceptor and H_2O. Therefore, hydrolysis is the major pathway in aqueous solution. Addition of water soluble organic solvent would reduce water activity to some extent, but it often causes substrate and/or product inhibition and makes the enzyme unstable.[11] To shift the reaction in water toward transglycosylation, it is necessary to kinetically control the partitioning step in favor of the transglycosylation reaction. When compound **1** was oxidized to the 6-oxo-derivative **2**,[12] it was found to be a relatively weak substrate for β-galactosidase. The initial rate and transglycosylation yield, however, increased with amount of the acceptor **3** (entries 4–6). This indicates that the active species generated from **2** is less reactive with water than with the acceptor **3**.

Another problem in β-galactosidase-catalyzed reactions is that the product is also subject to enzymatic hydrolysis. The improved stability of 6′-oxo-LacNAc (**4**, $t_{1/2}$ = 31 h) relative to **2** ($t_{1/2}$ = 0.4 h) toward the β-galactosidase-catalyzed hydrolysis may also contribute to the high yield of the product.[13]



Scheme 2. Synthesis of *N*-acetyl-D-lactosamine with galactose oxidase (GO) and β-galactosidase from *B. circulans*.

Table 1. Comparison of β-galactosidase-catalyzed reactions with galactopyranose (GalβOpNP, **1**) and galactohexodialdose (6-oxo-GalβOpNP, **2**)

No.	Donor	*c*(Acceptor) [M]	Yield (LacNAc) [%] [a]	v_0 [mM min^{-1}] [b]
1	**1**	0	–	5.69 ± 0.11
2	**1**	0.05	14	4.68 ± 0.08
3	**1**	0.5	30	4.16 ± 0.23
4	**2**	0	–	0.074 ± 0.008
5	**2**	0.05	29 [c]	0.137 ± 0.006
6	**2**	0.5	60 [c]	0.393 ± 0.013

[a] The reaction mixture containing 0.05 M donor and various concentrations of methyl-*N*-acetyl-D-glucosamine in 0.05 M potassium phosphate buffer (pH 7.0) was gently stirred at room temperature in the presence of the enzyme (140 U mmol^{-1} of donor) for 24 h. [b] The mixture (containing the same components as described in [a]) was incubated with shaking for 5–10 min at room temperature. Absorbance was measured at 420 nm. [c] Methyl-β-*N*-acetyl-D-lactosamine (**5**) was obtained by reduction with $NaBH_4$ followed by product isolation as described in the text.

Although the transgalactosylation reaction of **2** proceeds smoothly with excellent regioselectivity and good yield under the reaction conditions, the presence of excess acceptor may complicate product purification. The aldehyde produced, however, may be reduced with $NaBH_4$ in nonaqueous solution to form a boron complex which decomposes to the desired alcohol upon addition of water. To test the feasibility of this approach, a mixture of **3** and **4** obtained from the enzymatic reaction was reduced with $NaBH_4$ in MeOH. Afterwards, the reaction mixture was separated by silica gel column chromatography. The galactoside **3** was eluted first with nonaqueous solvent ($CHCl_3$/MeOH 1/1) and recovered in 77%. Elution with aqueous solvent ($CHCl_3$/MeOH/H_2O 5/5/1) then provided **5** in 60% yield. Other regioisomers were not observed by NMR. The recovered

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2349 $ 15.00+.25/0

compound **3** could be reused in the next cycle of the reaction without further purification. Furthermore, when the allyl, phenyl, and thiophenyl derivatives of **3** were used as acceptor, similar results were obtained.

In summary, a new method based on *Bacillus* galactosidase has been developed for the synthesis of β-galactosides using 6-oxo-GalβOpNP as donor. This method can be carried out in aqueous solution without organic solvent to give the transglycosylation product in high yield and regioselectivity.

Experimental Procedure

2: To a solution of **1** (306 mg, 1.02 mmol) in 50 mM potassium phosphate buffer (pH 7.0, 15 mL) was added galactose oxidase (135 U) and catalase (1 mg). The reaction mixture was gently stirred under an oxygen balloon for 24 h at 4 °C. After MeOH was added to terminate the reaction, the solvent was removed in vacuo. The residue was applied to a silica gel column ($CHCl_3$, then a 1:1 mixture of $CHCl_3$/MeOH) to obtain **2** (250 mg, 77%). ^1H NMR (500 MHz, D_2O): $\delta = 3.64$ (d, $J = 7.4$ Hz, 1H; H-5), 3.79 (dd, $J = 9.9$, 3.3 Hz, 1H; H-3), 3.88 (dd, $J = 9.9$, 7.7 Hz, 1H; H-2), 4.17 (d, $J = 3.3$ Hz, 1H; H-4), 5.13 (d, $J = 7.4$ Hz, 1H; H-6), 5.19 (d, $J = 7.7$ Hz, 1H; H-1), 7.26 (d, $J = 9.3$ Hz, 2H; ArH), 8.27 (d, $J = 9.3$ Hz, 2H; ArH).

To prepare **4** as an authentic sample, compound **5** was oxidized with galactose oxidase under the same conditions described for the synthesis of **2** except that $CuSO_4$ (0.5 mM) was added, and the product was purified by Biogel P-2.

4: ^1H NMR (500 MHz, D_2O): $\delta = 2.02$ (s, 3H; CH_3CO), 3.45 (d, $J = 7.5$ Hz, 1H; H-5'), 3.50 (s, 3H; OCH_3), 3.55 (dd, $J = 10.0$, 8.0 Hz, 1H; H-2), 3.57–3.63 (m, 1H; H-5), 3.66 (dd, $J = 10.0$, 3.5 Hz, 1H; H-3'), 3.67–3.74 (m, 3H; H-3, H-4, H-2'), 3.82 (dd, $J = 12.5$, 5.5 Hz, 1H; H-6), 3.98 (d, $J = 12.5$, 1.5 Hz, 1H; H-6), 4.07 (d, $J = 3.5$ Hz, 1H; H-4'), 4.45 (d, $J = 8.0$ Hz, 1H; H-1 or H-1'), 4.47 (d, $J = 8.0$ Hz, 1H; H-1 or H-1'), 5.12 (d, $J = 7.5$ Hz, 1H; H-6'). HR-MS: calcd for $C_{15}H_{25}NO_{11}Na$ ($M + Na^+$, aldehyde form) 418.1325, found 418.1310.

5: To a solution of **3** (181 mg, 770 μmol) and β-galactosidase (11 U) from *Baccilus circulans* in 50 mM potassium phosphate buffer (pH 7.0, 1.54 mL) was added **2** (24.4 mg, 77.0 μmol). The reaction mixture was gently stirred for 24 h at room temperature. After addition of MeOH (1 mL) to terminate the reaction, the solvent was removed in vacuo. The residue was dissolved in MeOH (5 mL), and $NaBH_4$ (29 mg) was added to the solution at 0 °C. After stirring for 1 h at 0 °C, the mixture was allowed to warm to room temperature within 10 h. The mixture was applied to a silica gel column and first eluted with $CHCl_3$/MeOH (1/1, 500 mL) to recover **3** (140.1 mg, 77% of starting amount). Subsequent elution with $CHCl_3$/MeOH/H_2O (5/5/1) provided **5** (18.2 mg, 60%).

[13] The half-lives of compounds **2** and **4** were determined from the pseudo first order kinetics of the β-galactosidase-catalyzed hydrolysis as follows. **2**: A 0.5 mL solution of potassium phosphate buffer (50 mM, pH 7.0) containing **2** (5 mM) and β-galactosidase (140 U per 1 mmol of **2**) was measured continuously in a plastic cell with a 1 cm light path at 420 nm against a control without enzyme. **4**: A 5 mM solution of **4** and the enzyme (140 U mmol^{-1}) in D_2O was placed in an NMR tube. The ratio between released **3** and remaining **4** was periodically determined by the integration of H-6 of **4** ($\delta = 3.98$) and H-6 of **3** ($\delta = 3.88$).

Chemoenzymatic Synthesis of a Sialylated Undecasaccharide–Asparagine Conjugate**

Carlo Unverzagt*

Dedicated to Professor Hans Paulsen on the occasion of his 75th birthday

Glycoproteins play an important role in organisms, and thus carbohydrates are involved in essential processes[1] directly or indirectly. Besides influencing proper folding and physical properties of proteins, oligosaccharides can also transfer biological information. Oligosaccharides are being discovered with increasing frequency as ligands in cellular recognition.[2] Adhesion phenomena mediated by the terminal tetrasaccharide sialyl Lewis^x[3] have stimulated great activity in the search for drugs against common diseases like rheumatoid arthritis and heart attack. The carbohydrate binding protein CD22[4] found on the surface of activated B lymphocytes recognizes the sequence α-*N*-acetylneuraminic acid-(2 → 6)-galactose present at the termini of asparagine-linked oligosaccharides (N-glycans). The following work presents the first synthesis of **1**, a fully glycosylated partial structure of glycoproteins. The key to the synthesis was the combination of chemical and enzymatic methods.

Many essential contributions on the chemical synthesis of N-glycans have been made by the groups of Ogawa[5] and Paulsen.[6] A milestone was the chemical synthesis of the entire carbohydrate moiety of **1**.[5a] The incorporation of these complex oligosaccharides into glycopeptides increases the demands on the protective groups employed in the peptide and in the sugar part, which may lead to severe complications in deprotection. To circumvent these difficulties, a novel concept was devel-

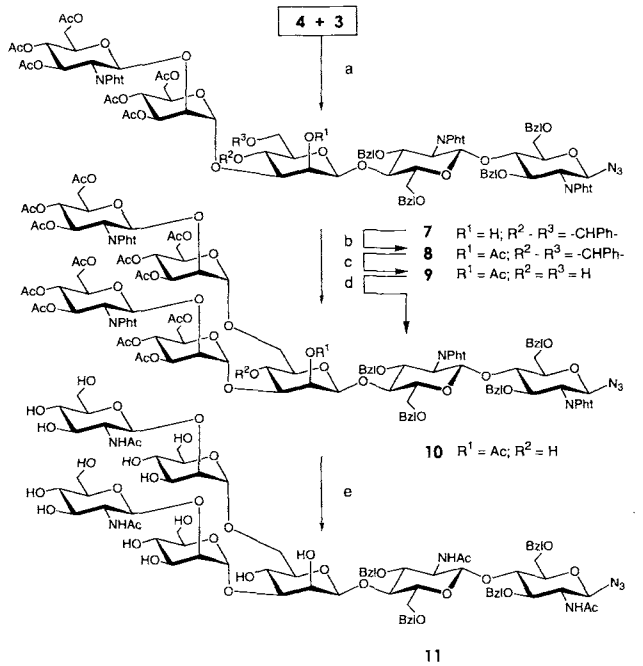
[**] This work was supported by the Deutsche Forschungsgemeinschaft and by the Leonhard-Lorenz-Stiftung, and was presented at the Eighth European Carbohydrate Symposium 1995 in Seville (Spain). I would like to thank the Hoechst AG and Boehringer Mannheim for funding and Prof. Dr. H. Kessler for his generous support.

oped for the synthesis of N-glycans and their conjugates by using the synthetic strategies of both modern carbohydrate chemistry and the elegance of enzymatic glycosylation reactions.[8] The synthesis of the biantennary undecasaccharide–asparagine conjugate **1**, a fully glycosylated partial structure of human transferrin and ribonuclease, was accomplished for the first time by combining chemical and enzymatic methods and using the building blocks **2**–**6** (Scheme 1).

An efficient route to N-glycans developed previously relied on fragment couplings.[9] The key sequence of this strategy is a double regioselective glycosylation of the benzylidene-protected β-mannoside **3** at positions 3″ and 6″. Core trisaccharide **3** synthesized according to the β-mannosylation method of Kunz[10] was glycosylated at the equatorial 3″-OH function and not at the axial 2″-OH group. Elongation of trisaccharide **3** with the highly reactive disaccharide trichloroacetimidate **4**[9, 11, 12] gave the desired α-(1 → 3)-linked pentasaccharide **7** regio- and stereoselectively (Scheme 2). The yield of 84% is about 20% higher than that resulting from reaction with the analogous acetamido-substituted donor[9] introduced by Paulsen (62%). To exclude possible side reactions of the 2″-OH group at a later state, the pentasaccharide **7** was first acetylated (→ **8**) and the benzylidene acetal removed in aqueous acetic acid (→ **9**). Pentasaccharide **9** carries two OH groups (at positions 4″ and 6″) and reacted with donor **4** under dilute conditions to afford the α-(1 → 6)-linked heptasaccharide **10** regio- and stereoselectively. With a yield of 73% this reaction proceeded significantly better than the glycosylation of the corresponding acetamido-substituted pentasaccharide.[9] This procedure was used to prepare over five grams of heptasaccharide **10**. The advantage of phthalimido residues over acetamido groups can presumably be accounted for by the smaller amount of BF_3–OEt_2 needed for activation of trichloroacetimidates. This reduces the tendency of the imido ester in the donor molecule to rearrange to the unreactive trichloroacetamide.[14]

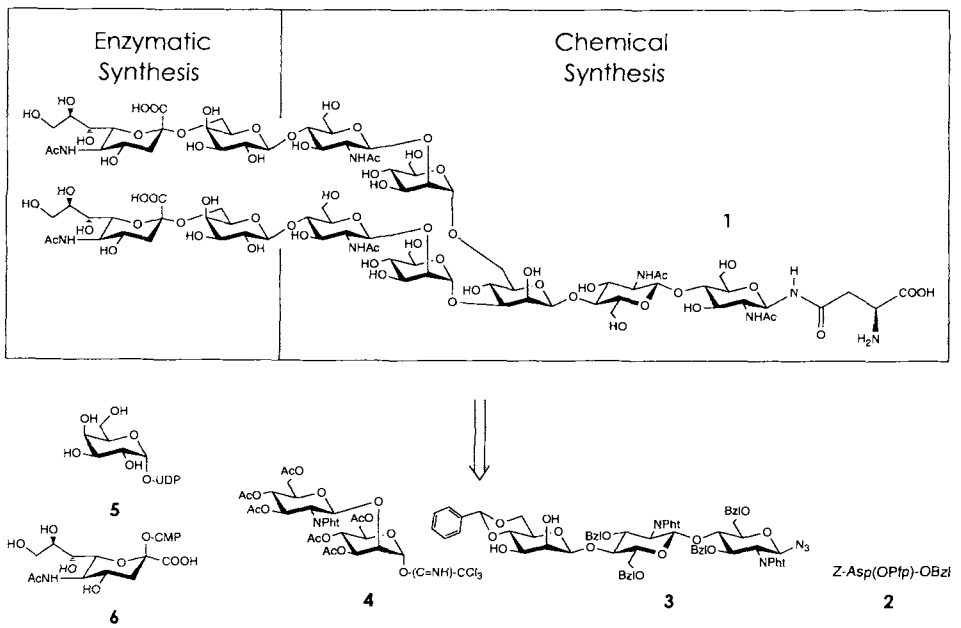
In the further conversion of the heptasaccharide **10** to the asparagine conjugate **13** the timing for connection to the amino acid and the sequence of deprotection had to be coordinated to



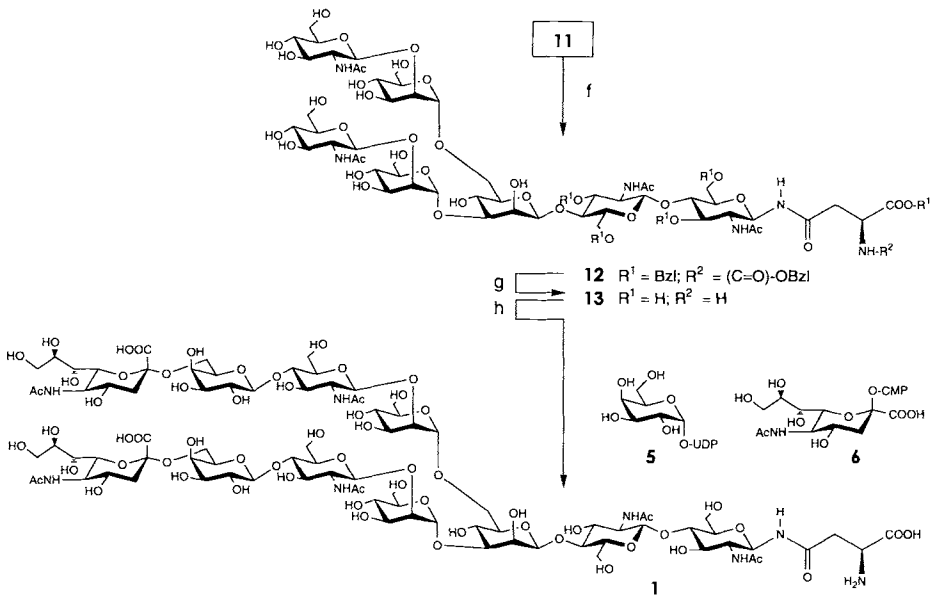
Scheme 2. BF_3–OEt_2, CH_2Cl_2 (84%); b) Ac_2O, pyridine (quant.); c) 80% AcOH, 80 °C (81%); d) **4**, BF_3–OEt_2, CH_2Cl_2 (73%); e) 1. *ethylenediamine*, *n*BuOH, 90 °C, 16 h; 2. Ac_2O, pyridine; 3. $MeNH_2$ (40%) in H_2O, (98% for steps 1–3).

accommodate the sensitive functional groups. The phthalimido groups required special attention. After the N-glycosidic linkage to asparagine was established, all attempts to remove the phthalimido residues failed. Therefore another tactic was applied. First, all acetates were removed and the phthalimido groups of **10** were replaced by acetamides. Since the four benzyl ethers of the resulting heptasaccharide **11** cannot be reduced in the presence of the anomeric azido function, the glycosylamine was generated at this point and coupled with the activated aspartic acid derivative **2**. The benzylic protective groups of the resulting heptasaccharide–asparagine conjugate **12** were removed in a single step by hydrogenolysis (Scheme 3).

The realization of this sequence required improved conditions for several reactions. Standard cleavage of the phthalimido groups of **10** with hydrazine hydrate in ethanol led to polar side products and the yields dropped to 50%. The side reactions are possibly caused by reduction of the anomeric azide by diimine,[15] which is generated from hydrazine in small amounts upon heating. When *N*-methyl hydrazine was used, the yields increased to about 70%. The best results were obtained with the conditions for dephthaloylation introduced by Hindsgaul.[16] Heating heptasaccharide **10** with ethylenediamine in *n*-butanol gave an intermediate tetraamino compound. After an acetylation–deacetylation sequence, the water-soluble heptasaccharide **11** was isolated in



Scheme 1. The undecasaccharide–asparagine conjugate **1**, a partial structure of N-glycoproteins, was obtained by convergent chemoenzymatic synthesis using the building blocks **2**–**6**. Pht = phthaloyl, Pfp = pentafluorophenyl, CMP = cytidine-5′-monophosphate, UDP = uridine-5′-diphosphate.



Scheme 3. f) 1. Propanedithiol, Et_3N, MeOH; 2. Z-Asp(OPfp)-OBzl, HOBt, *N*-methylpyrrolidone (NMP) (63%); g) Pd/H_2, MeOH, AcOH (95%); h) 1. UDP-Gal, galactosyl transferase, alkaline phosphatase; 2. CMP-*N*-acetylneuraminic acid (CMP-Neu5Ac), α-2,6-sialyl transferase, alkaline phosphatase (86%).

high yield (98%). This procedure proves to be very favorable for the deprotection of complex oligosaccharides containing azido groups. The selective reduction of the anomeric azide of **11** may be conducted by hydrogenolysis using Raney nickel or palladium on calcium carbonate. However, after acylation of the resulting glycosylamine with the pentafluorophenyl ester **2**, a mixture of the anomeric N-glycosides was obtained with an $\alpha:\beta$ ratio of 1:1. The proportion of the nonnatural α-glycoside exceeded 30% when the hydrogenation was conducted under basic conditions. Since glycosylamines anomerize rapidly in the presence of acids, it appears that in our case the noble metal catalyst accelerates the anomerization to the α-amine. Therefore we needed a reduction that proceeds under basic conditions without noble metals. These requirements were met by the reduction of the heptasaccharide azide **11** using excess propanedithiol in methanol–triethylamine.[19] After the reaction was terminated, the reagents were distilled off and the glycosylamine was coupled with **2**. The desired, β-configurated heptasaccharide–asparagine conjugate **12** was obtained in 63% yield after purification by HPLC. Glycosyl amino acid **12** is a chemically prepared building block useful for further conversion to **1** and for glycopeptide synthesis.[5c]

Prior to the the glycosyl transferase reactions the benzylic protective groups of **12** were removed by catalytic hydrogenation over palladium black. The deprotected heptasaccharide–asparagine conjugate **13** carries two terminal *N*-acetylglucosamine residues, which are known to be good substrates for galactosyl transferase (EC 2.4.1.22).[20] By using the alkaline phosphatase-enhanced glycosylation method,[21] two galactose residues were transferred onto **13** in one step. Alkaline phosphatase (EC 3.1.3.1) degraded the inhibitor uridine diphosphate formed during the reaction of UDP-galactose **5** with **13**. This increased the rate of reaction as well as the yield of the intermediate nonasaccharide–asparagine conjugate. Double sialylation was performed by subsequent incubation of the reaction mixture with α-(2 → 6)-sialyl transferase (EC 2.4.99.1), alkaline phosphatase, and the donor substrate CMP-*N*-acetylneuraminic acid. The enzymatic transfer of the four saccharide units was performed as a one-pot reaction and provided the undecasaccharide–asparagine conjugate **1** in 86% yield. Despite the preference[22] of both glycosyl transferases for the (1 → 3)-arm, the chosen reaction conditions led to nearly quantitative enzymatic glycosylation. Purification of the reaction mixture by size exclusion chromatography gave **1**, whose structure was confirmed by 500 MHz NMR spectroscopy,[23] comparison with reference spectra,[24] and electrospray mass spectrometry.[25] Thus the complex glycoconjugate **1**, which up to now could only be isolated from natural sources,[26] has been prepared by chemical synthesis for the first time.

The synthesis of *N*-glycans remains a challenging task that can be improved by combining the advantages of chemical and enzymatic methods. Currently, the incorporation of **1** into glycopeptides is being examined in the synthesis of fully glycosylated glycoprotein fragments.

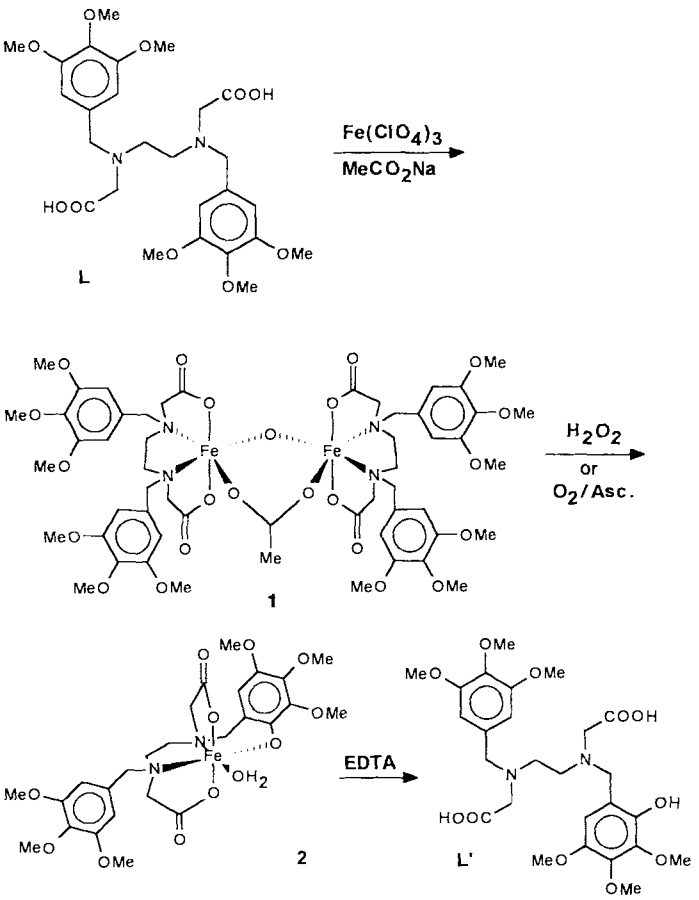
Aromatic Hydroxylation by H_2O_2 and O_2 Catalyzed by a μ-Oxo Diiron(III) Complex

Stéphane Ménage, Jean-Baptiste Galey, Georges Hussler, Michel Seité, and Marc Fontecave*

Recently a new class of enzymes, the diiron–carboxylato proteins, has emerged in which the active center contains two ferric ions linked by an oxo or hydroxo bridge and one or two carboxylato bridges of glutamate or aspartate residues.[1] Methane monooxygenase converts not only methane into methanol but reacts with a great variety of alkanes, alkenes, and aromatic compounds as well.[2] Ribonucleotide reductase oxidizes an endogeneous tyrosine to a tyrosyl radical, which initiates the conversion of ribonucleotide to deoxyribonucleotide.[3] The iron center of ribonucleotide reductase also has the potential to catalyze hydroxylation reactions as shown by the transformation of a tyrosine residue, brought into proximity of the active iron center by site-directed mutagenesis, into 3,4-dihydroxyphenylalanine (dopa).[4]

Many model compounds have been prepared but few are capable of displaying enzymatic activity such as hydroxylation of C–H bonds by molecular oxygen or hydrogen peroxide.[5, 6] Our approach here was to mimic quite closely the active center of methane monooxygenase as far as the carboxylato-rich environment of iron and the vicinity of a substrate site are concerned. An ethylenediamine tetraacetic acid (EDTA) derivative has been designed in which two carboxylato moities have been replaced by two phenyl groups which serve as substrates for the oxidation reaction.

Mixing a 1 mM solution of *N*,*N*′-bis-(3,4,5-trimethoxybenzyl)ethylenediamine *N*,*N*′-diacetic acid (ligand L)[7] with four equivalents of triethylamine in water/acetonitrile (1:1), one equivalent of $Fe(ClO_4)_3 \cdot 9H_2O$, and ten equivalents of sodium acetate led to the formation of the μ-oxo μ-acetato diferric complex $[Fe_2OL_2(CH_3CO_2)]^+$ (**1**). Its characterization in solution



was based on its UV visible spectrum,[8] which is indeed typical of μ-oxo μ-carboxylato diferric complexes.[9] Its ESI-MS spectrum[10] displays one negative ion peak at m/z 1255.5 (100%) corresponding to the pseudo-molecular ion $[Fe_2OL_2(CH_3CO_2)]^-$.[11] Assignments were confirmed by a comparison to the calculated isotopic pattern (Fig. 1). The solution was found to be EPR silent suggesting that the ferric ions are antiferromagnetically coupled through the oxo bridge. The ^1H NMR (200 MHz, CD_3CN/D_2O) spectrum of **1** in solution displays few resonances. Of interest is the resonance at $\delta = 12.5$, which is attributed to the acetate methyl protons. Such a chemical shift

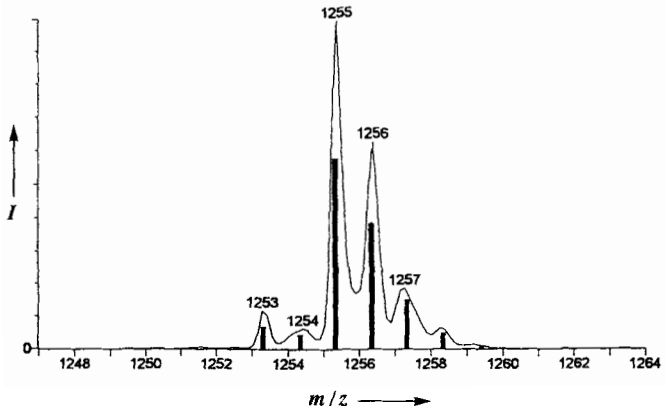

Fig. 1. Negative ionization electrospray mass spectrum of **1**. The calculated isotopic pattern for $C_{26}H_{36}O_{11}Fe$ is indicated by the bars.

indicates that the acetate is in a bridging coordination mode.[12] With a propionate as the bridging carboxylate group, the methylene protons resonated at $\delta = 11.3$ and the ring *m*-protons at $\delta = 9.03$ in the case of a benzoato bridge. All attempts to isolate and crystallize **1** were unsuccessful. However, based on the above data **1** is proposed to be a dinuclear ferric complex with one acetato and one oxo bridge. The coordination sphere for each iron is completed by two oxygen and two nitrogen atoms from the carboxylato and tertiary amino moieties of the ligand, respectively.

When three equivalents of hydrogen peroxide were added to a 1 mM solution of **1**, either in aqueous acetate buffer (pH 5.4) or acetonitrile/water (1:1), the solution turned deep blue as a result of the formation of a new chromophore with maximum absorption at 560 nm (Fig. 2). After saturation of the solution with NaCl, the new species **2** could be extracted with CH_2Cl_2. It was shown to be a monomeric ferric complex in which the ligand L is hydroxylated at position 2 of one of the phenyl groups. Monohydroxylation of L was assessed by ^1H and ^{13}C NMR spectroscopy after reduction of **2** with dithionite. The

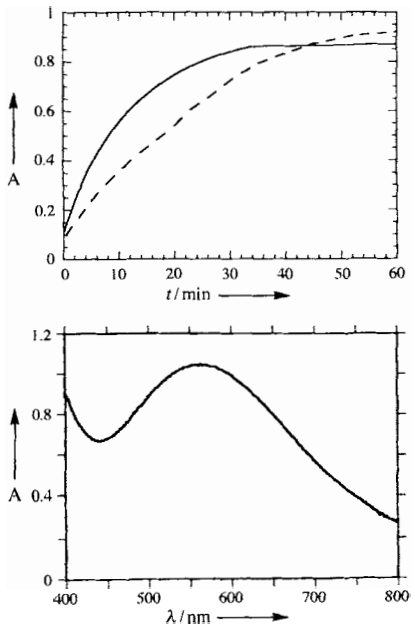

Fig. 2. Top: Absorbance at 560 nm versus time for the reaction of **1** [0.75 mM] with H_2O_2 (3 equiv, —) or O_2 (diffusing into the UV cell) and 15 equiv of ascorbate (– – –). Bottom: UV/Vis spectrum recorded at the end of the reaction.

positive mode ESI-MS analysis of **2** reveals only a signal at *m/z* 606 (90%) with the appropriate peak pattern for the pseudomolecular ion $[Fe(L') + H]^+$. No evidence was found for an ion corresponding to a binuclear species. After workup of the reaction mixture with excess EDTA to remove the metal ion, the modified ligand L′ was analyzed by HPLC/ESI-MS and confirmed to be *N*-(2-hydroxy-3,4,5-trimethoxybenzyl)-*N*′-(3,4,5-trimethoxybenzyl)ethylenediamine *N*,*N*′diacetic acid.[13] The yield of the oxidation reaction, based on the concentration of L, approached 80%. Attempts to crystallize the product were again unsuccessful due to its very high solubility in all solvents. The very intense transition at 560 nm in the visible region of the absorption spectrum of **2** can be attributed to a phenolato-to-iron charge transfer band ($\varepsilon = 1500\ M^{-1}cm^{-1}$).[14] The EPR spectrum of **2** displays a transition centered at $g = 4.3$ at 100 K for a mononuclear, hexacoordinated, high-spin iron(III) ion.[15] It is noteworthy that the EPR feature at $g = 4.3$ and the 560 nm absorption band simultaneously increased during the conversion of **1** into **2**. We thus propose that in **2** the iron(III) center is coordinated by two nitrogen atoms and four oxygen atoms (two from the carboxylato moities, one from the phenolate, and one from a water molecule).[16]

In the presence of acetate, L coordinates to iron to generate a dinuclear complex in which the ferric ions are doubly bridged by an oxo and an acetato group. The ligand L provides phenyl groups adjacent to the iron center as substrates for oxidation. Because of the well-established lability of acetato bridges,[17] reaction with H_2O_2 is possible and actually leads to aromatic hydroxylation. At the end of the reaction, the dinuclear unit is not recovered. Instead a mononuclear complex is obtained with the new phenolate moiety bound to iron. The ligand L is probably only monohydroxylated because the resulting iron–phenolato complex **2** is unable to bind and activate H_2O_2 as a consequence of the greatly decreased acidity of the ferric ion.

While alkylhydroperoxides, sodium hypochlorite, and *m*-chloroperbenzoic acid do not oxidize **1** under the conditions used with H_2O_2, monohydroxylation occurred in the absence of H_2O_2 but in the presence of molecular oxygen and excess ascorbate as a reductant (Fig. 2). The kinetics and yield of the reaction are comparable to those of the H_2O_2-dependent reaction. No reaction occurred in the absence of ascorbate. Treating **1** with ascorbate for half an hour under anaerobic conditions partially bleached the solution. Addition of O_2 then generated the 560 nm-absorbing complex **2**. This strongly indicates that ascorbate is involved in the formation of a ferrous complex which can bind and activate dioxygen. It is unlikely that the reaction depends on the formation of H_2O_2, since it is not affected by the addition of catalase.

To our knowledge, this is the first report of reductive activation of molecular oxygen resulting in aromatic hydroxylation which is promoted by a dinuclear ferric complex. This is a model for methane monooxygenase- or ribonucleotide reductase-dependent reactions. The hydroxylation of a tyrosine residue within a mutant of ribonucleotide reductase is here elegantly mimicked in that, as in the enzyme, the hydroxylated reaction product is bound to the iron center.[4] It must be noted that such chemistry is well established in the case of copper enzymes and their model compounds.[18]

A New In_4 Cluster with Short In–In Bonds in Trigonal-Planar $In(InTrip_2)_3$**

Penelope J. Brothers,* Klaus Hübler, Ute Hübler, Bruce C. Noll, Marilyn M. Olmstead, and Philip P. Power*

Homocatenation is an important feature of the chemistry of Group 14 elements, but in Group 13 it appears widely only for the lightest element, boron. Nonetheless, the synthesis and structural characterization of metal–metal bonded organoelement compounds of the heavier Group 13 metals has undergone a very rapid development since the late 1980s, and new structural and bonding types continue to be reported frequently. The simplest of these are the dimetallanes, R_2M-MR_2 (M = Al, Ga, In, Tl; R = alkyl, aryl, silyl)[1–6] and their derivatives $[R_2M-MR_2]^-$ obtained by one-electron reduction.[7] Cluster compounds $(MR)_n$ exhibit tetrahedral ($[AlCp^*]_4$, $[MC(SiMe_3)_3]_4$, M = Ga, In), octahedral ($[AlrBu]_6^-$, $[InCp^*]_6$), or icosahedral ($[AliBu]_{12}^{2-}$) geometry.[1c, 8, 9] An Al_4 ring is found in $[Al_4Br_4(NEt_3)_4]$ whereas the cyclic trigallane dianion $[Ga(2,6\text{-}Mes_2C_6H_3)]_3^{2-}$ (Mes = 2,4,6-$Me_3C_6H_2$) is a cyclopropenium ion analog.[10, 11] Chlorogallium compounds $[Ga_4Cl_4\{Si(SiMe_3)_3\}_4]$ and $[Ga_5Cl_7(OEt_2)_5]$ consist of a Ga_4Cl_4 cage containing two Ga–Ga bonds[12] and a neopentane-like $GaGa_4$ skeleton,[13] respectively.

The tetraaryl dialane and digallane $Trip_2M-MTrip_2$ (Trip = 2,4,6-$iPr_3C_6H_2$) have been shown to be useful substrates for reduction by lithium metal to yield the one-electron π-bonded compounds $[Trip_2M\cdots MTrip_2]^{\cdot -}$ with an M–M π-bond order of 0.5.[7] We undertook the synthesis of the indium analog $Trip_2In-InTrip_2$ (**1**) to investigate its reduction by similar methods. Reaction of the tetrabromodiindane $[In_2Br_4(tmeda)_2]$[4] (tmeda = tetramethylethylenediamine) with TripMgBr at low temperature afforded **1** as large, bright orange crystals [Eq. (a)].

$$(tmeda)Br_2In-InBr_2(tmeda) \xrightarrow[Et_2O,\ -15°C]{TripMgBr} \underset{\mathbf{1}}{Trip_2In-InTrip_2} \qquad (a)$$

The compound is thermally and photochemically sensitive; above −10 °C decomposition results in the deposition of indium metal. The crystal structure of **1** (Fig. 1)[14] shows it to be a highly symmetrical compound, lying on a site of 222 symmetry in the unit cell. The In–In distance of 2.775(2) Å is comparable to that of the small number of related three-coordinate diindanes (Table 1). The angle between the normals to the C-In-C planes is 47.8° and each aryl ring is oriented at 63° with respect to this plane at the corresponding indium atom.

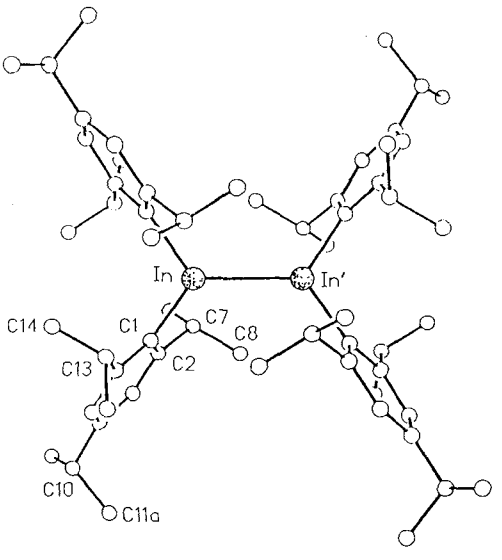

Fig. 1. Molecular structure of **1**. Selected bond lengths [Å] and angles [°]: In–In' 2.775(2), In–C1 2.184(7); In'-In-C1 121.6(2), C1-In-C1' 116.8(4).

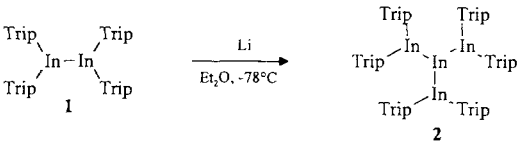
Compound **1** was reduced with lithium powder suspended in ether at −78 °C. The bright orange color rapidly darkened to give a deep red-brown solution [Eq. (b)]. Crystallization



(b)

at −20 °C resulted in the new organoindium compound **2** in low yield. The identity of **2** was determined by X-ray crystallography,[15] which showed it to be a triindylindane with the formula $In(InTrip_2)_3$ (Fig. 2).[16] The compound consists of a central

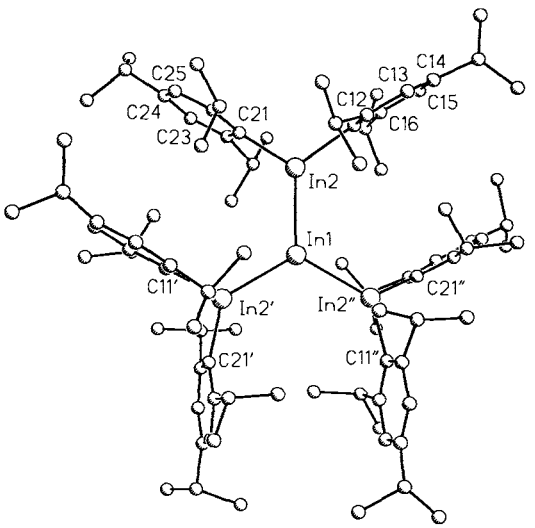


Fig. 2. Molecular structure of **2**. Selected bond lengths [Å] and angles [°]: In1–In2 2.696(2), In2–C11 2.25(2), In2–C21 2.19(2); In2-In1-In2' 120.0(1), In1-In2-C11 121.7(5), In1-In2-C21 123.0(6), C11-In2-C21 115.3(8).

indium atom bearing three $InTrip_2$ substituents, giving a trigonal-planar In_4 array with In-In-In angles of 120.0(1)° and In–In bond lengths of 2.696(2) Å. Since the molecule occupies a site of three-fold symmetry, there is just one unique $InTrip_2$ group. The C-In-C plane is tilted at an angle of 31.6° to the In_4 plane, and each aryl ring is oriented at about 77° to the C-In-C plane.

The reduction of **1** to give the new triindylindane **2** is a surprising result. When the aluminum and gallium analogs of **1** are reduced under the same conditions the only products isolated are the radical anions $[Trip_2M{\cdot\!\cdot}MTrip_2]^{\bullet-}$ (M = Al, Ga) with no change in composition of the molecules.[7] The formation of **2** (average In oxidation state +1.5) from **1** (oxidation state +2) does correspond to a formal reduction, but the overall stoichiometry is not clear due to the low yield of the isolated product and the presence of excess reducing agent. Other reduced In species may also be formed. The chemical sensitivity of **1**, which had been observed to produce small amounts of In metal upon decomposition, may also play a part in the reaction.

The trigonal $In(In)_3$ arrangement seen in the crystal structure of **2** is a geometry that is unprecedented for the heavier Group 13 elements. Catenated compounds (alkane analogs) with a σ-bonded metal–metal framework are well known for the neighboring element tin. They show chains containing up to six tin atoms, rings Sn_nR_{2n} with $n = 3$–9, branched polystannanes such as in the neopentane analog $Sn(SnMe_3)_4$, and other geometries like the propellane Sn_5Ar_6 and the cubane Sn_8Ar_8.[17] In contrast, metal–metal bonds connected by a σ-bonded framework in three-coordinate compounds of the heavier Group 13 elements have been limited to just two atoms in the dimetallanes $R_2M{-}MR_2$. Two further examples, $[Al_4Br_4(NEt_3)_4]$ containing an Al_4 ring[10] and the neopentane-like compound $[Ga_5Cl_7(OEt_2)_5]$,[13] exhibit coordination number four at the metal centers and are stabilized by NEt_3 or Et_2O donors. Al, Ga, or In compounds containing an M_4 cluster have hitherto existed in a tetrahedral arrangement with the stoichiometry M_4R_4, rather than the M_4R_6 formula existing in **2**.

Three-coordination at the metal center in **1** and its Al and Ga analogs can be attributed to the steric effect of the bulky Trip substituents. However, in **2** the central indium does not bear these bulky substituents and yet the three ether solvate molecules found in the unit cell are not coordinated to the unsaturated indium centers.

The In–In bond length in **2** (2.696(2) Å) is the shortest yet observed in a molecular indium compound and is significantly shorter than those in indium metal (3.252 and 3.377 Å,[18] Table 1). The diindane **1** and its analogs show In–In bonds ranging from 2.744(2) to 2.922(1) Å,[2–5] whereas those in the dimeric, tetrahedral, and octahedral cluster compounds $(InR)_n$ are longer than 3.0 Å.[8, 9, 19] The ternary oxide $In_{11}Mo_{40}O_{62}$, which contains linear In_5^{7+} and In_6^{8+} cations with In–In separations of 2.624–2.689 Å, is the only example exhibiting shorter In–In distances than **2**, but it is not a molecular species.[20] Since the valence electrons in **2** are fully accounted for in the $InIn_3$ σ-bonded framework, the bond shortening cannot be directly attributed to simple π-type multiple bonding and is most likely due to the lack of bulky organic substituents on the central In atom. Calculations are being undertaken to probe the bonding and properties of **2**.

Experimental Procedure

1: Under anaerobic and anhydrous conditions, $In_2Br_4(tmeda)_2$ (4.56 g, 5.83 mmol) was suspended in diethyl ether (30 mL) and cooled to −78 °C. TripMgBr (125 mL of a 0.16 M solution in diethyl ether, 20 mmol) was added dropwise through a cannula. The solution was stirred at −78 °C for 1 h and then warmed to −15 °C in an ice/salt bath, during which time the solution began to turn orange. Stirring was maintained at −15 °C for several hours. The orange solution was decanted through a cannula from the cream-colored residue, while the temperature was maintained below −10 °C. The ether was removed under reduced pressure, and the residue extracted three times with hexane (30 mL) at −10 °C. Reduction of the solvent volume to 50 mL and cooling to −20 °C resulted in large orange crystals of **1** (2.06 g, 34%). ^{1}H NMR (300 MHz, [D$_8$]toluene, −10 °C): 7.06 (s, 2H, ArH), 2.80 (sept, 1H, p-CH(CH$_3$)$_2$), 2.67 (sept, 2H, o-CH(CH$_3$)$_2$), 1.28 (d, 6H, p-CH(CH_3)$_2$), 1.25 (d, 12H, o-CH(CH_3)$_2$), ^3J (H,H) = 6.9 Hz. ^{13}C NMR (75 MHz, [D$_8$]-

toluene, −10 °C): 24.48 (*o*-CH(CH_3)$_2$), 25.01 (*o*-CH(CH_3)$_2$), 34.93 (*p*-CH(CH_3)$_2$), 41.16 (*p*-CH(CH_3)$_2$), 121.01 (*o*-C(Ar)), 148.87 (*ipso*-C(Ar)), 154.30 (*m*-C(Ar)), 160.85 (*p*-C(Ar)).

2: Compound **1** (2.09 g, 2.00 mmol) was dissolved in diethyl ether (30 mL) at −15 °C, the solution filtered onto lithium powder (0.06 g, 8 mmol) at −78 °C, and the resulting suspension stirred at this temperature. After 10 min the bright orange solution rapidly darkened to deep red-brown, and stirring was maintained for a further 3 h. The solution was filtered, concentrated under reduced pressure to 15 mL, and cooled at −20 °C to give dark red-brown crystals of **2** in about 5% yield.

[14] a) Crystal structure analysis of **1**: $C_{62}H_{92}In_2$: $M_r = 1067.0$, orthorhombic, space Group *Ccca*, $T = 130$ K, $a = 13.523(3)$, $b = 24.257(7)$, $c = 19.264(5)$ Å, $V = 6319(3)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.122$ g cm^{-3}, $F(000) = 2248$, $\mu(Mo_{K\alpha}) = 0.762$ mm^{-1}. Suitable crystals (0.16 × 0.24 × 0.32 mm) were obtained by recrystallization from hexane. Siemens R3m/V diffractometer with $Mo_{K\alpha}$ radiation ($\lambda = 0.71069$ Å); ω scan. Of 3987 reflections with $0 \le 2\theta \le 55°$, 3637 were independent. The 2198 observed reflections ($F_o > 4\sigma(F_o)$) were used to refine 143 parameters. $R = 0.066$, $R_w = 0.079$, GOOF = 0.88. Minimal and maximal remaining electron densities: −0.99 and 1.52 e Å^{-3}. One of the isopropyl groups was disordered and modeled with two sets of methyl carbon atoms of 3 to 2 occupancy and restrained geometries but free thermal parameters. Anisotropic temperature factors were used for all other non-hydrogen atoms. Hydrogen atoms (except for the disordered methyl groups) were included in calculated positions or as part of riding groups. The refinement on F was carried out by full-matrix least squares techniques (SHELXTL Plus). An XABS absorption correction was applied ($0.83 < T < 0.90$). b) The structures were solved by Patterson methods (SHELXTL Plus). Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-88. Copies of the data can be obtained free of charge on application to the Director, CCDC, 12 Union Rd, GB-Cambridge CB2 1EZ, UK (fax: int. code +(1223)336-033; e-mail: teched@chemcrys.cam.ac.uk).)

[15] Crystal structure analysis of **2** × 3 Et_2O: $C_{102}H_{168}In_4O_3$: $M_r = 1901.73$, hexagonal, space group $R\bar{3}$, $T = 130$ K, $a = 17.804(1)$, $c = 28.806(4)$ Å, $V = 7907.7(13)$ Å^3, $Z = 3$, $\rho_{calcd} = 1.198$ g cm^{-3}, $F(000) = 3000$, $\mu(Cu_{K\alpha}) = 7.215$ mm^{-1}. Suitable crystals (0.6 × 0.3 × 0.2 mm) were obtained by recrystallization from diethyl ether. Siemens four-circle diffractometer P4 with $Cu_{K\alpha}$ radiation ($\lambda = 1.54178$ Å); 2θ-ω-scan. Of 2499 reflections with $3.3 \le \theta \le 49.9°$, 2019 were independent. The 1994 observed reflections were used to refine 286 parameters and 3 restraints. $wR2 = 0.158$, $R1 = 0.064$ (using 1225 reflections with $F_o > 4\sigma(F_o)$), GOF = 1.04. Minimal and maximal remaining electron densities: −0.27 and 0.43 e Å^{-3}. Anisotropic temperature factors were used for all non-hydrogen atoms except for the diethyl ether molecule. Hydrogen atoms were included in calculated positions or as part of rigid groups (CH_3). Refinement on F^2 was carried out by full-matrix least-squares techniques (SHELXL93); see also ref. [14b]. A Difabs absorption correction was applied ($0.747 < T < 1.000$).

[16] Three disordered molecules of diethyl ether per molecule of **2** are located in cavities between the indium molecules. The possibility that a disordered lithium cation might be associated with these donors is not supported by the color of the compound, which is typical of neutral organic derivatives and is similar to that of **1**. A lithium ion was not located in the crystal structure.

Crystal Structures and Properties of Cyclic Polyenes Possessing Disulfide Units**

Toshio Shimizu, Kazuko Iwata, and Nobumasa Kamigata*

Cycloocta-1,5-diene has been the subject of considerable interest, in particular with respect to its conformational behavior[1] and role as ligand in organometallic complexes. Cycloocta-1,5-diene derivatives with heteroatom substituents at the sp^3-hybridized carbons are also of great interest in view of their conformation and reactivity. However, only a few monocyclic compounds are known. 3,4,7,8-Tetrakis(trifluoromethyl)-1,2,5,6-tetrathiacycloocta-3,7-diene[2] and the tetraselena derivative,[3] which have trifluoromethyl groups on the sp^2-hybridized carbons, are known but their chemical properties and reactivity have hardly been examined. We have successfully synthesized 1,2,5,6-tetrathiacycloocta-3,7-diene (**1**; trivial name: 1,2,5,6-tetrathiocin; see Scheme 1) and determined the crystal structure by X-ray analysis. It is very reactive in polar solvents and toward irradiation (even room light). The larger cyclic system **3** was also obtained and characterized by X-ray analysis.

Oxidation of a *cis*-disodium ethene-1,2-dithiolate with iodine/potassium iodide at −10 °C in a heterogeneous, dilute solution led to **1** in 14% yield (Scheme 1). Bicyclic trimer **2** (*meso*/*dl* = 5:2)[4] and tetramer **3** are also formed, although the monocyclic

[**] Presented in part at the 4th International Conference on Heteroatom Chemistry, Seoul, Korea, July 31, 1995.

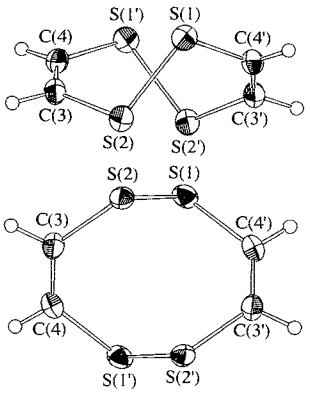

Fig. 1. ORTEP drawing of **1** with thermal ellipsoids at the 30% probability level. Selected interatomic distances [Å], bond angles [°], and torsional angles [°]: S(1)-S(2) 2.0574(8), S(2)-C(3) 1.752(3), C(3)-C(4) 1.329(3), C(4)-S(1') 1.747(3), S(1)-S(1') 3.431(1), S(2)-S(2') 3.336(1), S(1)-S(2') 3.530(1), C(4')-S(1)-S(2) 105.07(8), S(1)-S(2)-C(3) 104.55(8), S(2)-C(3)-C(4) 128.8(2), C(3)-C(4)-S(1') 129.2(2), S(2)-C(3)-C(4)-S(1') 2.5(4), C(4')-S(1)-S(2)-C(3) 108.8(1).

trimer expected for this reaction could not be detected. Based on ^{1}H NMR spectra, there is *cis* geometry at the olefin moieties in all of the products.

The structures of **1**[5] and **3**[6] were confirmed by X-ray crystallographic analysis (Figs. 1 and 2). The crystal structure of **1** shows a twist form (nearly D_2 symmetry) corresponding to the geometry calculated with a global minimum.[7] This is in contrast to the twist-boat form (C_2 symmetry) optimized as a global minimum for cycloocta-1,5-diene.[8] The bond lengths and angles of **1** are almost normal, and the dihedral angles around the olefin moieties yield strain-free geometries (2.5°). The dihedral angles around the sulfur–sulfur bonds (C-S-S-C; 109°) are slightly more extended than those of the most stable disulfide conformations (ca. 90°).[9, 10] The interesting point of the crystal structure of **1** is the nonbonding interatomic distances between sulfur atoms S(1)—S(1'), S(2)—S(2'), and S(1)—S(2') {S(1')-S(2)} are 3.43, 3.34, and 3.53 Å, respectively, and thus shorter than twice the van der Waals radius of a sulfur atom (3.70 Å). The tetramer **3** has a cage structure (approximately D_{2d} symmetry) possessing a cavity. The average distance from the center of the molecule to the sulfur atoms is 3.41 Å and that to carbon atoms is 2.53 Å. The torsional angles around the disulfide moieties (74°, average) are contracted relative to those of the most stable vertical geometry of disulfides, whereas those of **1** are extended. The cage structure of **3** indicates that it has the potential for becoming a new inclusion compound with two types of coordination sites (π-electrons of the olefins and lone pairs on the sulfur atoms).

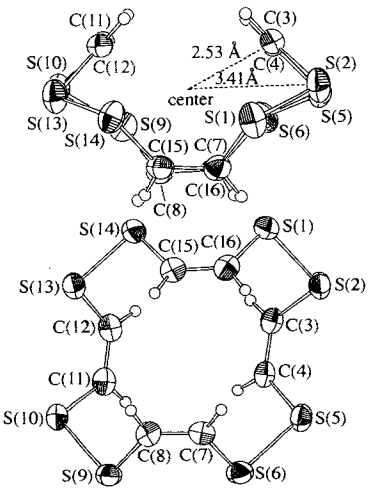

Fig. 2. ORTEP drawing of **3** with thermal ellipsoids at the 30% probability level. Selected interatomic distances [Å], bond angles [°], and torsional angles [°] as averages: S-S 2.05, S-C 1.75, C-C 1.32, S-S-C 100.4, S-C-C 123.3, C-S-S-C 73.6, S-C-C-S 0.7, S-S-C-C 133.9.

The UV spectrum of **1** shows an absorption maximum at 357 nm whereas the larger **3** has only one absorption maximum at lower wavelength (Fig. 3). The cyclic voltammograms of **1** and **3** display irreversible oxidation potentials at +150 and +50 mV, respectively, versus S. C. E. Furthermore, there are reduction potentials at −1.05 (shoulder) and −1.09 V (Fig. 4).

Tetrathiocin **1** is thermally stable: no decomposition was observed even in *p*-xylene at reflux after 3 h. Interestingly, compound **1** reacted in

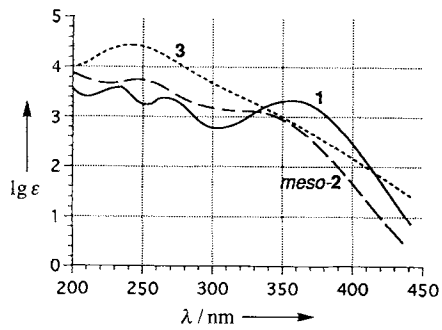

Fig. 3. UV spectra of **1**, *meso*-**2**, and **3** in cyclohexane.

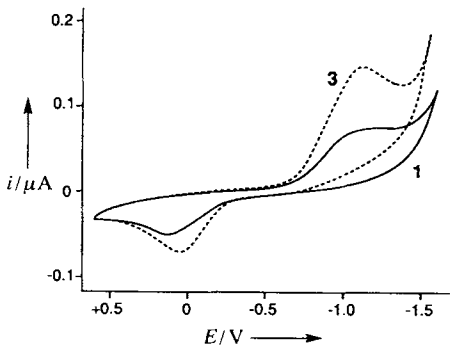

Fig. 4. Cyclic voltammograms of **1** (2.6 mM) and **3** (2.3 mM) in chloroform at 20 °C, nBu$_4$NBF$_4$ (250 mM) supporting electrolyte, glassy carbon working electrode, potential E vs. S. C. E.; scan rate, 100 mV s^{-1}.

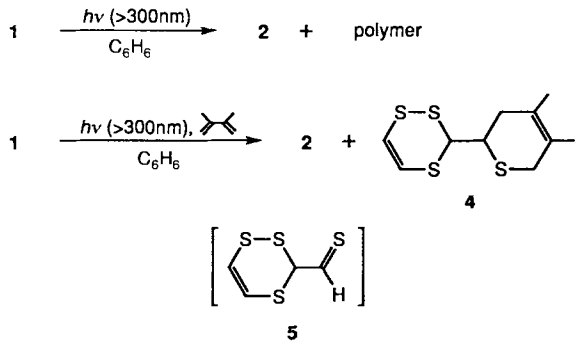
acetonitrile/chloroform (4:1) solution even at room temperature to give the ring-expanded product **3** in moderate yield (76%) after 4.5 h, whereas no change was observed in *n*-hexane/chloroform (4:1) solution under similar conditions (Scheme 2). Compound **3** was also obtained from a methanol/chloroform solution (4:1) of **1**, although the yield was low (15%) and the main product was polymer (60%). The reaction in acetonitrile/chloroform solution is considered to proceed by a nucleophilic attack of acetonitrile on the sulfur atom in **1**.

Compound **1** is also unstable toward irradiation (even room light). When a benzene solution of **1** (1.2×10^{-3} M) was irradiated with a medium-pressure mercury lamp through a Pyrex filter, a rubberlike yellow polymer formed (>60%) together with the bicyclic compound **2** (7%; *meso*/*dl* = 3:1).[4] According to combustion analysis,[11] the polymer consisted of $(CHS)_n$ units; it was insoluble in both polar and nonpolar solvents. Irradiation of **1** in the presence of a large excess of 2,3-dimethylbutadiene hindered the formation of the polymer, and bicyclic product **4**[12] was obtained in 62% yield together with a small amount of **2** (Scheme 2). This indicates that the thioaldehyde **5**, generated



Scheme 2.

by photochemical 1,3-rearrangement of **1**, is the reactive intermediate in the formation of the rubberlike polymer. Several mechanisms are plausible for the formation of **2**, which can be obtained by oxidation of ethene-1,2-dithiolate and the photochemical reaction of **1**, and are currently under investigation.

Experimental Procedure

Oxidation of *cis*-disodium ethene-1,2-dithiolate: an aqueous solution (150 mL) of *cis*-disodium ethene-1,2-dithiolate[13] (2.78 g, 20.4 mmol) and iodine (5.18 g, 20.4 mmol) in 20% aqueous potassium iodide (150 mL)[14] were added consecutively from two dropping funnels with vigorous stirring at $-10\,^{\circ}C$ under nitrogen to a heterogeneous solution of ether (300 mL) and water (250 mL) over 7 h. After additional stirring for 1 h, the products were extracted with ether and washed with 10% sodium thiosulfate solution and water. After chromatography on a short cellulose column (chloroform), purification was achieved by gel permeation chromatography (GPC).

1: 254 mg (14%); m. p. 97.5–98.5 °C (yellow prisms); ^{1}H NMR (400 MHz, $CDCl_3$) $\delta = 6.88$ (s); ^{13}C NMR (100 MHz, $CDCl_3$) $\delta = 127.6$; IR (KBr): $\tilde{\nu} = 3010$, 1515, 1170, 800, 650 cm^{-1}; UV (cyclohexane): λ (ε) = 357 (2.1×10^3), 265 (2.4×10^3), 235 (4.0×10^3) nm; EI MS: *m/z* 180 (M^+), 147, 116, 90, 57; elemental analysis for $C_4H_4S_4$ (calcd, found): C 26.64, 26.69; H 2.24, 2.24.

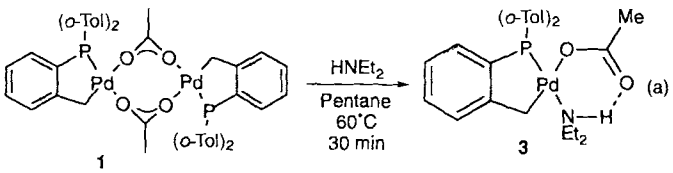
A Route to Pd^0 from Pd^{II} Metallacycles in Amination and Cross-Coupling Chemistry**

Janis Louie and John F. Hartwig*

Tri-*o*-tolylphosphane-bound palladium complexes, either isolated or generated in situ, have proven to be efficient catalysts for a wide range of coupling reactions including the Heck[1] and Suzuki[2] reactions. Amination of aryl halides has also recently been shown to be catalyzed by these palladium complexes.[3] Like the widely accepted mechanism for Heck and Suzuki reactions, the mechanism for aryl halide amination seems to involve an interconversion between Pd^0 and Pd^{II} species.[3b, d, 4] Our mechanistic and synthetic studies on such aminations led us to investigate whether the palladacycle **1** [Eq. (a)], recently reported



$[Pd\{P(o\text{-}Tol)_3\}_2]$ **2**

by Beller and Herrmann et al,[5] would operate by a mechanism different from that shown for the Pd^0 complex **2**, or whether **1** is a precursor to **2**.

[**] We would like to thank Susan de Gala for providing X-ray crystallography studies. We are grateful for support from the National Science Foundation NYI Award program, the Dreyfus Foundation for a New Faculty Award, Dupont for a Young Faculty Award, Union Carbide for an Innovative Recognition Award, and Yale University for a Junior Faculty Fellowship. J. F. H. is a fellow of the Alfred P. Sloan Foundation.

Our results delineate two different pathways for formation of Pd^0 complexes from **1**.[6] During the amination of aryl halides, formation and subsequent reaction of a palladium amide derived from the amine complex **3** gave the Pd^0 complex **2** by β-hydrogen elimination. During a cross-coupling reaction, **1** formed a Pd^0 complex containing the arylated P(*o*-Tol)$_3$ derivative P(*o*-Tol)$_2$(C$_6$H$_4$-*o*-CH$_2$Ph), which was formed by C–C bond-forming reductive elimination. As a result, the catalytic amination and some of the cross-coupling chemistry seen for **1** is strikingly similar to that of **2**.

Aryl halide palladium complexes with amine ligands catalyze the amination of aryl halides.[3b, d, 7] Metallacycle **1** was cleaved by secondary amines to form similar monometallic amine complexes such as the diethylamine complex **3** in Equation a. The ^{1}H NMR spectrum of **3** has broad signals at room temperature. These are resolved at $-80\,^\circ$C and show two singlets for the phosphane methyl groups along with two inequivalent sets of broad signals for amine ethyl groups. This indicates that the regions above and below the square plane are inequivalent, presumably due to a rigid and puckered metallacycle (vide infra). A broad singlet for the N–H proton is observed far downfield at $\delta = 9.24$. The amine N–H infrared vibration falls in the region of C–H vibrations. This assignment was confirmed by the synthesis of deuterated **3** and the observation of N–D stretching frequencies at 2238 cm^{-1} and 2163 cm^{-1}. The downfield ^{1}H NMR chemical shift and low infrared frequency corresponding to the amine N–H suggest the presence of a strong hydrogen bond, perhaps with the carbonyl oxygen.

An X-ray diffraction study was conducted on a single crystal of **3**, which was obtained by cooling a pentane solution from 60 °C to room temperature. All hydrogen atoms were located in successive difference maps and refined isotropically. The ORTEP drawing of **3**[8] shows that there is a hydrogen bond between the carbonyl oxygen and the amine proton (Fig. 1). The

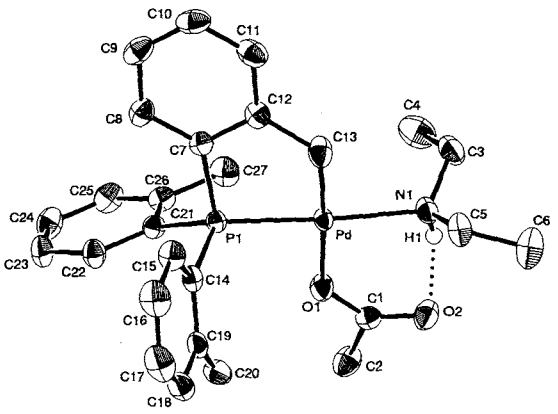

Fig. 1. Structure of **3** in the crystal. Selected bond lengths [Å] and angles [°]: O2-H1 2.10(2), Pd-P1 2.2452(5), Pd-O1 2.143(1), Pd-N1 2.150(2), Pd-C13 2.036(2), C1-O1 1.273(2), C1-O2 1.236(2), N1-H1 0.74(2); N1-H1-O2 163(2), C1-O2-H1 105.4(8), P1-Pd-O1 95.57(4), P1-Pd-C13 82.42(6), O1-Pd-N1 92.25(6), N1-Pd-C13 89.87(7), Pd-N1-H1 99(2), Pd-O1-C1 130.6(1), O1-C1-O2 126.2(2).

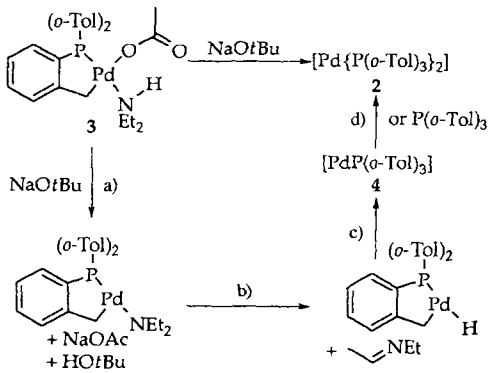
amine conformation, the C=O···H–N distance (2.15 Å), and the N1–H1–O2 bond angle (163°) are all characteristic of such a hydrogen bond.[8, 9] Moreover, the X-ray structure shows the ring pucker that was deduced from the ^{1}H NMR spectrum. The dihedral angle between the square plane, defined by N1-O1-P1-C13, and the metallacycle plane, defined by P1-C7-C12-C13, is 28.14°.

Formation of Pd^0, along with aryl amine products, has been shown to occur from amine-ligated aryl halide complexes upon addition of base to deprotonate the amine and generate a Pd^{II} amido species.[1e, 7] Amine complex **3** also reacts with base to generate Pd^0. Treatment of **3** with a slight excess of NaO*t*Bu in THF formed Pd^0 complex **2** in 48% yield, as determined by ^{31}P NMR spectroscopy. The yield of **2** was nearly quantitative based on the number of phosphanes that could be formed from **3**; an essentially quantitative yield of **2** based on palladium was obtained when the reaction was run in the presence of 3 equiv of P(*o*-Tol)$_3$.

Scheme 1 shows a rational mechanism for the formation of **2** from **3** in the presence of base. Deprotonation of the amine



Scheme 1. Postulated mechanism for the synthesis of **2**: a) deprotonation, b) β-H elimination, c) reductive elimination, d) disproportionation.

proton would lead to the formation of a short-lived amido complex, along with NaOAc and HO*t*Bu. Rapid β-hydrogen elimination, the common reaction pathway followed by palladium amides with β-hydrogens, and subsequent reductive elimination with formation of a C–H bond would provide the palladium complex **4**, which contains a single, coordinated P(*o*-Tol)$_3$.[10] Dismutation between two of these highly unsaturated species would produce **2**, as well as an unligated Pd, in a total possible yield of 50% based on the starting palladacycle.

If the reactivity described above is relevant to amination reactions catalyzed by **1**, compound **3** must catalyze the amination of aryl halides in a fashion similar to **1** and **2**. Indeed, **3** catalyzes the reaction of aryl halides with amines in the presence of NaO*t*Bu base. The coupling of 4′-bromobenzophenone and *N*-methylaniline to form **5** with **1**, **2**, or **3** as catalyst was compared. Each catalyst gave yields between 81% and 85% (Table 1) and provided turnover numbers between 350–400 per Pd center for 0.1–0.2 mol% catalyst. Thus, metallacycles **1** and **3** clearly act as precursors to P(*o*-Tol)$_3$-ligated Pd^0 complexes in the amina-

Table 1. Reaction between 4′-bromobenzophenone and *N*-methylaniline.

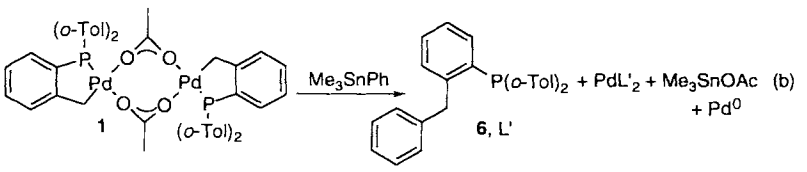
tion reactions. In order to evaluate whether the β-hydrogen elimination mechanism was necessary for activation of the catalyst, the amination of aryl bromides with diphenylamine was evaluated with **1** and **2**. Although **2** catalyzes such reactions in essentially quantitative yields, **1** was inert.

Palladacycle **1** effectively catalyzed Stille cross-coupling reactions. For example, a turnover number of 1650 was observed in the coupling of 4'-bromoacetophenone and Me_3SnPh catalyzed by 0.04 mol% catalyst **1**, as determined by ^{1}H NMR spectroscopy. An increase in catalyst concentration to 5 mol% led to complete conversion of aryl halide and a 96% yield of 4-$PhC_6H_4COCH_3$ (by ^{1}H NMR spectroscopy).

Since the reagents in these Stille reactions cannot produce ligands containing β-hydrogens, a pathway to generation of Pd^0 that is distinct from that in the amination chemistry would be required for a conventional mechanism involving Pd^0 and Pd^{II}. Palladacycle **1** and Me_3SnPh were heated to 70 °C in [D_6]benzene for 2.5 h to determine whether a Pd^0 complex formed. Monitoring of the reaction by NMR spectroscopy showed the conversion of the resonances for **1** into two new ^{31}P NMR resonances for complexed and free P(*o*-Tol)$_2$(C_6H_4-*o*-CH_2Ph) (**6**) at $\delta = -8.1$ (δ [Pd{P(*o*-Tol)$_3$}$_2$] = −6.7) and −29.9 (δ P(*o*-Tol)$_3$ = −29.1), respectively. From these reactions, the arylated *o*-tolyl phosphane **6** and P(*o*-Tol)$_3$ side product were isolated in a 5:1 ratio by column chromatography to give a total phosphane yield of 87%. As demonstrated by the two ^{31}P NMR resonances for the reaction mixture, both free and coordinated ligand **6** exist in the reaction, presumably along with unligated Pd^0 [Eq. (b)]. These results strongly suggest that Pd^0 complexes containing **5** and P(*o*-Tol)$_3$ are the active species in Stille couplings involving **1** and may be the active catalyst in Suzuki carbon–carbon bond-forming reactions.[11]



In summary, our data have shown that catalytically active Pd^0 complexes can be formed from **1** by two different routes: β-hydrogen elimination of a palladium amide or C–C bond-forming reductive elimination involving a palladium phenyl substituent. It is difficult to determine conclusively if these reactions occur in the catalytic chemistry of **1**. However, they would provide **1** with an entry into catalysis by Pd^0/Pd^{II} pathways and should be included in mechanistic considerations.

Experimental Procedure

3: Dimeric palladacycle **1** (145.0 mg, 0.155 mmol) was suspended in pentane (6 mL) under N_2. $HNEt_2$ (400 μL, 3.87 mmol) was added and the resulting mixture heated at 70 °C for 30 min. Slow cooling to room temperature produced analytically pure, air-stable, pale yellow crystals of **3** in 83.6% yield. Anal. calcd for $C_{27}H_{34}NPdO_2P$: C 59.84, H 6.32, N 2.58. Found: C 59.66, H 6.30, N 2.61; ^{31}P NMR (300 MHz, [D_8]toluene, 25 °C, H_3PO_4 standard): δ = 33.2 (s, 1P, PdP); ^{1}H NMR (300 MHz, [D_8]toluene, −80 °C, residual C_7H_8): δ = 9.24 (s, 1H, NH), 7.34–6.64 (broad m, 24H, aromatic CH), 3.16 (d, ^3J(H,H) = 14.2 Hz, 1H, $PdCH_2$), 3.06 (s, 3H, $PdC_6H_4CH_3$), 2.83 (s, 3H, $PdC_6H_4CH_3$), 2.65 (d, ^3J(H,H) = 14.9 Hz, 1H, $PdCH_2$), 2.37–2.18 (broad m, 4H, $2NCH_2$), 2.16 (s, 3H, $OCOCH_3$), 1.64 (t, ^3J(H,H) = 5.5 Hz, 3H, CH_2CH_3), 1.40 (t, ^3J(H,H) = 5.4 Hz, 3H, CH_2CH_3); ^{13}C NMR (300 MHz, [D_8]toluene, 25 °C, residual C_7H_8): δ = 179.0 (s, *C*O), 158.6 (d, ^1J(C,P) = 31.6 Hz, *P*C), 143.3 (d, ^2J(C,P) = 13.7 Hz, tolyl *C*CH_3), 137.4 (s, 2 overlapping tolyl *C*CH_3 signals), 135.2 (d, ^1J(C,P) = 53.8 Hz, 2*PC*), 132.7 (d, ^3J(C,P) = 5.5 Hz, *C*H), 132.2 (s, *C*H), 131.8 (d, ^2J(C,P) = 8.45 Hz, *C*H), 131.2 (d, ^3J(C,P) = 1.68 Hz, *C*H), 130.6 (broad s, *C*H), 128.0 (d, ^2J(C,P) = 21.0 Hz, *C*H), 125.8 (d, ^3J(C,P) = 7.3 Hz, *C*H), 125.7 (s, *C*H), 46.0 (broad s, *NCH*$_2$), 26.1 (s, *PdCH*$_2$), 25.6 (s, OC(O)*C*H$_3$), 22.6 (d, ^3J(C,P) = 10.5 Hz, 2*PC*$_6$H$_4$*C*H$_3$), 14.7 (s, 2*NCH*$_2$*C*H$_3$); IR (benzene): $\tilde{\nu}$ = 1581 cm^{-1} (C=O).

Catalytic aminations: In an inert atmosphere glove box, the palladium catalyst (0.036 mmol), P(*o*-Tol)$_3$ (0.12 mmol), 4'-bromobenzophenone (0.71 mmol), and NaO*t*Bu (1.1 mmol) were weighed into a screw-topped test tube equipped with a stir bar. Toluene (6 mL) was added, and the tube was sealed with a cap containing a Teflon septum. *N*-methylaniline (1.1 mmol) was syringed into the reaction mixture. The reaction was stirred at 80 °C for 5 h and cooled to room temperature. The product was isolated by adding brine, extracting the organic phases with ether, drying with $MgSO_4$, and removing the solvent. The product was purified by column chromatography (10:1 heptane/EtOAc).

Stille Couplings: In an inert atmosphere glove box, 4'-bromoacetophenone (0.34 or 0.042 mmol), Me_3SnPh (0.36 or 0.050 mmol), and 1,3,5-trimethoxybenzene (internal standard) were dissolved in C_6D_6 (0.6 mL). An initial ^{1}H NMR spectrum was taken. Palladacycle **1** (0.00013 or 0.0021 mmol, 0.04 mol% or 5.1 mol%) and P(*o*-Tol)$_3$ (0.00084 or 0.0072 mmol) were added to the mixture. The reaction with 0.04 mol% was heated at 120 °C overnight, while the reaction with 5.1 mol% was heated at 100 °C for 4 h. Afterwards, ^{1}H NMR spectra were obtained and compared to the initial spectra in order to determine the reaction yield and amount of remaining substrate.

Homogeneous Catalysts for Claus Chemistry: The Preparation and Structure of *cis*-$[(PPh_3)_2PtS_3O]$, a Catalytically Active Intermediate**

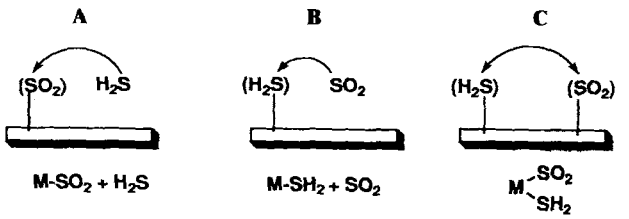
Alan Shaver,* Mohammad El-khateeb, and Anne-Marie Lebuis

The removal of sulfur from petroleum and natural gas may be the most important pollution abatement process in place today. Hydrodesulfurization (HDS)[1] of sulfur compounds gives hydrocarbons and the toxic gas H_2S, which is disposed of by the Claus process.[2] This reaction combines H_2S and SO_2, obtained by partial oxidation, over alumina at 300 °C, to give sulfur and

$$2H_2S + SO_2 \longrightarrow 3/8\,S_8 + 2H_2O$$

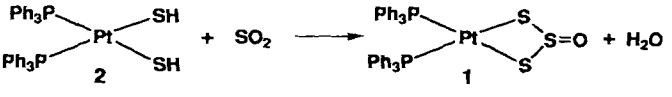
water with very high efficiencies. Many materials catalyze the reaction, which is also observed in water. Studies of the sequential adsorption and reactions of SO_2 and H_2S on alumina are, for the most part inconclusive.[3] While the details of the mechanism(s) of the Claus process are only partly understood, sulfur–sulfur bond formation and oxygen transfer must be involved—processes that have few precedents in homogeneous transition metal sulfur chemistry.

We are interested in Claus-like chemistry with soluble metal complexes and to that end have developed three conceptual models for the surface-catalyzed process and translated these into the appropriate reactions of homogeneous metal complexes. Model A depicts attack of H_2S on adsorbed SO_2, model B



represents attack by SO_2 on adsorbed H_2S, and in C both gases are adsorbed before reaction. In this report we describe the reaction of *cis*-$[(PPh_3)_2Pt(SH)_2]$ (*cis*-**2**) with SO_2 (model B) to give $[(PPh_3)_2PtS_3O]$ (**1**) and water. This represents a step in the Claus reaction. Moreover, both the complexes **1** and **2** catalyze the Claus reaction, whereas *trans*-**2** does not.

Treatment of *cis*-**2**[4] in CH_2Cl_2 with one equivalent of SO_2 gave **1** in 82% yield [Eq. (a)]. H_2O was observed in the NMR spectrum of the reaction mixture in the correct relative ratio by



integration. The structure of **1** is shown in Figure 1.[5] The Pt-S1-S2-S3 ring is not planar: the dihedral angle between the plane formed by P1-P2-Pt-S1-S3 and the plane formed by S1-S2-S3 is 22.3°.[6]

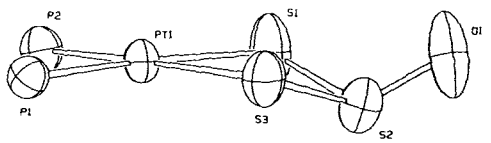


Fig. 1. ORTEP drawing of the structure of $[(PPh_3)_2Pt(S_3O)]\cdot CH_2Cl_2$ (**1**·CH_2Cl_2), excluding the phenyl rings of the PPh_3 ligands and the solvent atoms. Selected bond lengths [Å] and angles [°]: Pt–S1, 2.341(3); Pt–S3, 2.318(2); Pt–P1, 2.271(2); Pt–P2, 2.299(2); S1–S2, 2.042(2); S2–S3, 2.110(4); S2–O, 1.436(7); S1-Pt-S3, 80.73(9); P1-Pt-P2, 98.47(8); S1-Pt-P2, 88.37(8); S3-Pt-P1, 92.33(8); Pt-S1-S2, 91.3(1); S1-S2-S3, 93.2(2); Pt-S3-S2, 90.3(1).

Complex **1** reacts with H_2S at room temperature in THF to give the starting thiol complex *cis*-**2** which was identified in solution by NMR and also isolated. This regeneration prompted treatment of *cis*-**2** and of **1** with a 2:1 mixture of H_2S and SO_2. The reaction was conducted in dry CH_2Cl_2, in very dry flasks that had been previously treated with Me_2SiCl_2 (unsilylated glass catalyzes the reaction). The gases were added to the solution by syringe, and the molar ratio of the catalyst to SO_2 was 1:20. Sulfur, identified by thin layer chromatography, formed after 3 hours.[7] The yields of sulfur were high for complexes *cis*-**2**, **1**, and *cis*-$[(PPh_3)_2Pt(SCHMe_2)_2]$, whereas those for *cis*-$[(PPh_3)_2PtCl_2]$ were moderate and for *trans*-$[(PPh_3)_2Pt(SH)_2]$[8] negligible. The latter complex was recovered unchanged after treatment with pure SO_2. Addition of further aliquots of gases to solutions containing the active catalysts produced more sulfur. Peaks due to *cis*-**2** were found in the ^1H and ^{31}P NMR spectra of *cis*-$[(PPh_3)_2Pt(SCHMe_2)_2]$ upon treatment with H_2S. ^{31}P NMR spectra of the solid residues of the catalytic reactions identified the presence of the starting complex and also **1** in the cases of *cis*-**2** and *cis*-$[(PPh_3)_2Pt(SCHMe_2)_2]$; peaks due to Ph_3PS were also present.

Eller and Kubas[9] showed that treatment of $[(PPh_3)_2Pt(SPh)_2]$ with liquid SO_2 gave labile adducts of the type $[(PPh_3)_2Pt(S(SO_2)Ph)_2]$. We observed that the complexes $[(PPh_3)_2Pt(SR)_2]$, R = CMe_3, $CHMe_2$, and 4-C_6H_4Me, change color in CH_2Cl_2 from yellow to deep red upon treatment with SO_2. Addition of SO_2-saturated hexanes gave red-orange solids, which could only be characterized in solution because of facile loss of SO_2, which regenerates the thiolato complexes. These complexes are therefore formulated as bis(SO_2) adducts of the type $[(PPh_3)_2Pt(S(SO_2)R)_2]$.

Compound **1** is synthesized by a direct reaction between SO_2 and the thiolato complex **2**, which leads to sulfur–sulfur bond formation and oxygen transfer, thus mimicking a fundamental step in the Claus process.[10] The regeneration of the starting thiolato complex upon treatment of **1** with H_2S is consistent with the proposed catalytic cycle for the Claus reaction shown in Scheme 1. The first step is adduct formation between *cis*-**2** and SO_2, followed by insertion of SO_2 into the SH bond. Subsequent elimination of H_2O gives **1**, which reacts with H_2S to cleave the Pt–S bonds and regenerate *cis*-**2**. The other cleavage product is designated as "H_2S_3O" simply on the basis of the stoichiometry and was not detected. It is significant, however, that "H_2S_3O" is believed to be a key intermediate in the Claus process[11] and is expected to react rapidly with H_2S to give water and sulfur. These studies open a new chapter in the Claus process by introducing homogeneously catalyzed Claus chemistry.

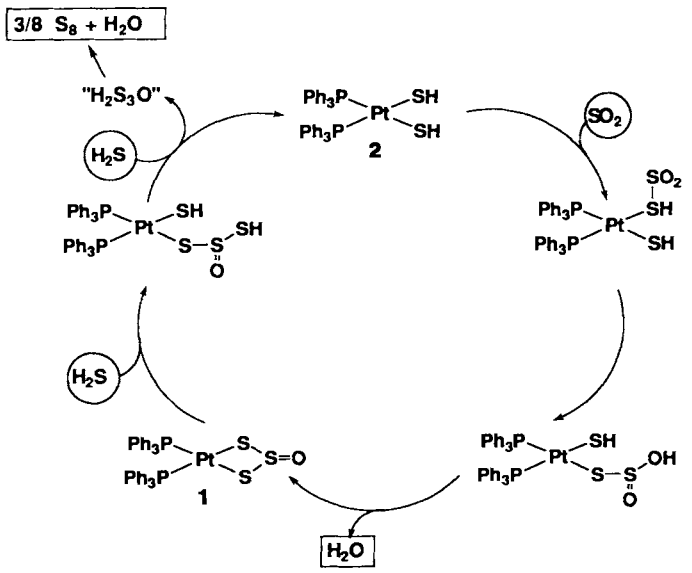

Scheme 1. Potential mechanism for Claus chemistry catalyzed by *cis*-$[(PPh_3)_2Pt(SH)_2]$.

Experimental Procedure

1: In a 100 mL Schlenk flask, *cis*-**2** (0.050 g, 0.064 mmol) in dichloromethane (5.0 mL) was treated with SO_2 gas for 30 minutes at room temperature and stirred thereafter for another 3 h. The volatiles were removed under vacuum, and the resulting yellow solid was recrystallized from in dichloromethane/hexanes. The yellow crystals were isolated by the removal of the mother liquor with a syringe (0.043 g, 82%). M.p. 262–263 °C. IR (Nujol): $\tilde{\nu}$(SO) = 1065(s) cm^{-1}. ^1H NMR ($CDCl_3$): 7.26 (m, PPh_3). ^{31}P NMR ($CDCl_3$): 18.5 (J(Pt,P) = 3200 Hz). Mass spectrum (FAB in NBA): *m/z* 832 [M^+], 784 [$M^+ - SO$], 752 [$M^+ - S_2O$], 720 [$M^+ - S_3O$]. C,H analysis calcd. for ($C_{36}H_{30}OP_2PtS_3 \cdot CH_2Cl_2$): 48.47% C, 3.52% H; found 47.98% C, 3.53% H.

Catalyzed reactions of H_2S with SO_2: H_2S was dried by passage through a column of P_2O_5, and SO_2 was purified by bubbling through concentrated sulfuric acid and then by passage through a column of P_2O_5. The Schlenk flasks (100 mL) were silylated by treatment of the flask with Me_2SiCl_2 (30 mL) for 12 h under a nitrogen atmosphere. Then the Me_2SiCl_2 was removed by syringe, and the flask dried under vacuum overnight. Sulfur produced from these reactions was identified by TLC (alumina) and mass spectroscopy.

The flask was charged with the solid catalyst (5.15×10^{-2} mmol), evacuated, filled with N_2 twice, and weighed. CH_2Cl_2 (20.0 mL) was added, and H_2S (2.06 mmol, 50.0 mL) was bubbled slowly (syringe) into the mixture, followed by the addition (by syringe) of SO_2 (1.03 mmol, 25.0 mL). The resulting solution was stirred at room temperature for 3 h, and then purged with nitrogen for 30 min. The volatiles were removed under vacuum, and the resulting solid was dried under vacuum for 4 days. The flask and its contents was weighed again to estimate the amount of sulfur formed.

Catalytic, Enantioselective Addition of Allylsilanes to Aldehydes: Generation of a Novel, Reactive Ti^{IV} Complex from TiF_4

Donald R. Gauthier, Jr., and Erick M. Carreira*

The stereoselective addition of allylmetal reagents to aldehydes is a powerful and important reaction for the preparation of homoallylic alcohols and has been extensively employed for the synthesis of stereochemically complex natural products.[1, 2] Recently, catalytic versions of this process that utilize Ti^{IV} complexes and allyl- or methallyltin reagents have been reported, which afford homoallylic alcohols with high enantioselectivities and yields.[3] However, additions involving the corresponding inexpensive, nontoxic allyltrimethylsilane to give protected homoallylic alcohols in useful yields and enantioselectivities have not been reported [Eq. (a)]. As a part of our interest in developing chiral complexes that function competently as catalysts in aldehyde additions, we have studied Ti^{IV} complexes prepared

from TiF_4.[4-6] In this communication, we report catalytic, enantioselective additions of allyltrimethylsilane to aldehydes that give homoallylic alcohols in 60–94% *ee* and in 69–93% yield. The success of these reactions is attributed to the unique reactivity of the fluorotitanium complex prepared in acetonitrile from TiF_4 and (*R*)- or (*S*)-1,1′-bi-2-naphthol (-BINOL).

Allyltrialkylsilanes are known to be significantly less reactive nucleophiles than the corresponding stannanes. In comparison to allyltributyltin, the addition of allyltrimethylsilane to various electrophiles has been shown to be 10^3-10^4 times slower.[7] The use of allylsilanes in asymmetric, catalytic additions to aldehydes is precluded by the lack of suitably reactive Lewis acids capable of activating the carbonyl group of the aldehyde towards such additions.[2f] Thus, chiral catalysts that have been developed for aldol and allyltrialkyltin additions to aldehydes are not useful with the corresponding allyltrialkylsilanes. For example, the addition of allyltrimethylsilane to the reactive methyl glyoxylate in the presence of the chiral complex generated from (*S*)-BINOL and $TiBr_4$ has been reported to afford the adduct in only 40% yield and 30% *ee*.[8] Similarly, we have investigated reactions involving the complexes derived from BINOL and $Ti(OiPr)_xCl_{4-x}$ under a variety of different conditions without success.

We assumed that TiF_4-derived complexes would be sufficiently reactive and capable of mediating the addition of allyltrimethylsilane to aldehydes. This assumption follows from the increased electronegativity of fluorine (Pauling scale = 4)[9] in comparison with chlorine (Pauling scale = 3) and bromine (Pauling scale = 2.8). Additionally, the use of a complex bearing a strong Ti–F bond (D_0(Ti–F) = 140 kcal mol^{-1})[10] was an attractive feature. The development of a catalytic allylsilane addition to an aldehyde would necessitate that the allyltrimethylsilane and the resulting Me_3SiO-ethers be stable under the reaction conditions. In this regard, we proposed that the strong Ti–F bond would disfavor desilylation of the product with formation of Me_3SiF (D_0(Si–F) = 135 kcal mol^{-1}).

Polymeric TiF_4 is commercially available as an inexpensive solid, which is insoluble in common aprotic organic solvents (Et_2O, THF, CH_2Cl_2, C_6H_6) with the exception of acetonitrile. A solution of TiF_4 in CH_3CN may be prepared and can be stored at 23 °C for weeks without evident decomposition. Treatment of (*S*)-(−)-1,1′-bi-2-naphthol (20 mol%) with a solution of TiF_4 (10 mol%) in CH_3CN produces a deep red solution, which upon evaporation of solvent yields a red-brown solid. The reaction of a mixture of this solid in CH_2Cl_2 with allyltrimethylsilane and an aldehyde at 0 °C led to the corresponding Me_3Si-protected homoallylic alcohol product.[11] Analysis of the adducts was facilitated by treatment of the silyl ethers with Bu_4NF/THF to furnish homoallylic alcohols **3** [(Eq. (b), Table 1]. For the aldehydes screened, the enantiomeric purity of the products ranged from 60–94% *ee* and the yields from 69–93%.[12] For each of the deprotected adducts, preparation of the derived (*S*)-(−)- and (*R*)-(+)-α-methoxy-α-(trifluoromethyl)-phenylacetic acid (MTPA) esters allowed the extent of asymmetric induction to be assayed by gas chromatography.[13] The absolute configuration of the products was established unambiguously by correlation with the known enantiopure homoallylic alcohols,[2] or by preparation of and comparison to authentic products synthesized by using known methods.[14, 15] For the catalytic, enantioselective process described herein, α,α-disubstituted aldehydes are ideal substrates; they afford the corresponding substituted homoallylic alcohols in high enantiomeric excess (entries 1–4). The β,β-dimethyl-substituted

Table 1. Catalytic, enantioselective allyltrimethylsilane additions to aldehydes [a].

Entry	Aldehyde	*t* [h]	Yield [%]	*ee* [%]
1		4	90	94
2		20	93	84
3	$(CH_3)_3CCHO$	4	91	94
4		20	92	93
5		20	81 [b]	74
6	PhCHO	4	85	80
7	*c*-$C_6H_{11}CHO$	4	72	60
8	$PhCH_2CH_2CHO$	4	69	61 [c]

[a] The enantiomeric excess (*ee*) was determined by preparation of the derived (*S*)-(−)-α-methoxy-α-(trifluoromethyl)-phenylacetic acid (MTPA) ester and comparison to authentic material by analysis using gas chromatography on a J&W Cyclodex-B-column. [b] Based on 25% recovered aldehyde. [c] Determined by HPLC analysis of the free alcohol on a Chiracel OD column.

secondary alcohol is a common structural motif of many bioactive natural products such as the bryostatins,[16] elfamycins,[17] aplasmomycin,[18] boromycin,[19] and mycalamides.[20] In this regard, the adducts of entries 1 and 2 serve as useful starting materials for the asymmetric synthesis of such stereochemically complex compounds.

We have established that it is important to conduct the reaction in the presence of small amounts of acetonitrile. Thus, the catalyst prepared from (*S*)-(−)-1,1′-bi-2-naphthol and TiF_4 in CH_2Cl_2 affords the adduct of pivalaldehyde in 75% *ee* and only 10% yield. As for allylstannane and aldol additions, the process described herein exhibits a nonlinear relationship between the enantiomeric purity of the 1,1′-bi-2-naphthol and the observed optical purity of the resulting homoallylic alcohol. When the allylation is conducted with 50% *ee* (*S*)-(−)-BINOL and TiF_4 in CH_3CN/CH_2Cl_2, the adduct of pivalaldehyde is isolated in 82% *ee*.

^{1}H NMR spectroscopic investigations indicate that when allyltrimethylsilane (2 equiv) is added to a solution of (*S*)-(−)-1,1′-bi-2-naphthol (1 equiv) and TiF_4 (1 equiv) in CD_2Cl_2 in the presence of 3% CH_3CN (0 °C → 23 °C) clean formation of Me_3SiF and propene is observed. Subsequent addition of excess allylsilane only leads to the appearance of resonances corresponding to allyltrimethylsilane. Upon treatment of the reaction mixture with aldehyde, new signals are observed that can be assigned to the formation of product. These findings indicate that allyltrimethylsilane initially functions as a base by consuming two equivalents of HF to give propene and Me_3SiF during the catalyst preparation; moreover, in the absence of signals

corresponding to an allyltitanium species,[21] the results indicate that transmetalation is not occurring and that the complex functions as a Lewis acid.

The new catalytic, enantioselective addition of allyltrimethylsilane to aldehydes described here is thus an alternative to methods that employ organotin reagents. The success of the reaction is attributed to the unique reactivity of a fluorotitanium complex prepared in acetonitrile from TiF_4 and (*R*)- or (*S*)-1,1′-bi-2-naphthol. The additions with allyltrimethylsilane are possible with the discovery that the TiF_4-derived catalyst is more reactive than the chloro-, bromo-, and alkoxytitanium complexes that have been previously employed. These results present new opportunities for the design and synthesis of well-defined chiral fluorotitanium complexes as catalysts in a variety of other important stereoselective processes. The study of such optically active complexes and their subsequent application are currently under investigation in our laboratory and will be reported in due course.

Experimental Procedure

To a solution of (*S*)-(−)-1,1′-bi-2-naphthol (57 mg, 0.20 mmol) in MeCN (0.5 mL) was added TiF_4 (0.20 mL, 0.10 mmol; 0.5 M solution in MeCN) to give a deep red solution that was stirred for 5 min prior to removing the solvent under reduced pressure. The residue was kept under reduced pressure (1 mm Hg) for 0.5 h and subsequently suspended in CH_2Cl_2 (0.5 mL), cooled to 0 °C, and treated dropwise with allyltrimethylsilane (0.24 mL, 1.5 mmol). After the mixture had been stirred at 0 °C for 1.5 h, the resulting red orange solution was treated with 2,2-dimethyl-4-pentenal (0.14 mL, 1.0 mmol). The reaction mixture was stirred at 0 °C for 4 h and then diluted with Et_2O/pentane (1:2; 10 mL). The mixture was filtered through a plug of silica and the filter cake washed with Et_2O/pentane (1:2; 50 mL). The filtrate was concentrated in vacuo to an oil, which was diluted with THF (2.0 mL). The resulting solution was treated with Bu_4NF (1.0 mL of a 1.0 M solution in THF), and stirred at 23 °C for 0.5 h. The reaction was quenched with Et_2O (50 mL) and washed with H_2O (20 mL). The ether extract was washed with saturated aqueous sodium chloride solution, dried over anhydrous Na_2SO_4, and concentrated in vacuo to give a colorless oil. Purification by chromatography on silica gel with Et_2O/pentane (1/10) afforded 138 mg (90%) of the product.

[11] The silyl-protected adducts are the predominant product in all of the addition reactions. Small amounts of the free alcohol products could also be isolated albeit in 5–10% yields. The % *ee* value of the alcohol product was found to be equal to that of the silyl-protected adduct for each of the aldehydes examined.

[12] As an alternative experimental procedure, we have observed that a mixture of (*S*)-(−)-1,1′-bi-2-naphthol and TiF_4 in 3% CH_3CN/CH_2Cl_2 solution works well in the addition reaction and obviates the need to remove the bulk acetonitrile solvent.

Structure of Silyl-Substituted Allenyl/Propargyllithium Reagents in Solution**

Hans J. Reich* and Johnathan E. Holladay

Theoretical studies of C_3H_3Li, which could fomally be either allenyl- or propargyllithium, have predicted a primarily allenyl structure.[1, 2] Experimentally, the question of structure has been addressed by X-Ray crystallography,[2, 3] IR spectroscopy,[1a, 4, 5] and ^{13}C NMR spectroscopy.[6a, b, 1a, 7] Both the central carbon (C_C, $\delta = 165-180$ for allenyl, $\delta = 90-100$ for propargyl) and the propargyl carbon (C_P) are very sensitive indicators of structure. Most reagents investigated have an allenyl structure; this includes compounds with alkyl groups at C_A (for example **1** and **2**, Scheme 1),[6a, b] which might destabilize the allenyl isomer. A few well-defined propargyllithium reagents are known in which C_P bears either a strained ring (**3**),[5, 6b] one or two carbanion stabilizing groups (PhS (**4**),[6b] PhSe,[6b] Ph[2, 7]), or a strong chelating group (carbamoyloxy).[6b, 8] We report results of an NMR study of silyl-substituted allenyl/propargyllithium reagents,[9] which provide insight into the thermodynamics, kinetics, and stereochemistry of the allenyl/propargyllithium interconversion, as well as the effect of lithium coordination on the electronic structure.

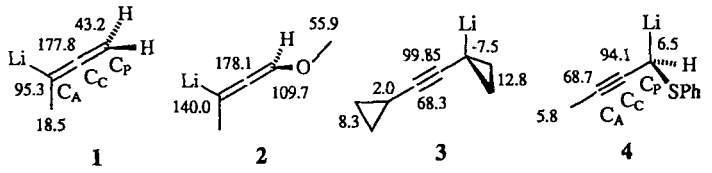
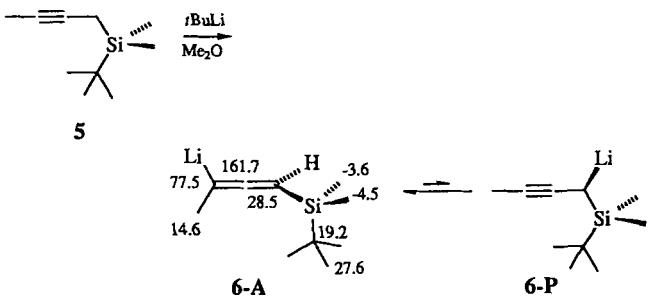


Scheme 1. ^{13}C chemical shifts of **1**–**4** in THF and Me_2O

The chemical shifts of the lithium reagent **6** (prepared by metalation of the propargylsilane **5**, Scheme 2) in THF are unambiguously allenic and essentially temperature-independent. Well-defined $^{13}C-^{7}Li$ coupling to C_A ($\delta = 77.5$, q (1:1:1:1), $J = 21$ Hz at $-152\,^{\circ}C$) and none to C_P is observed, indicating



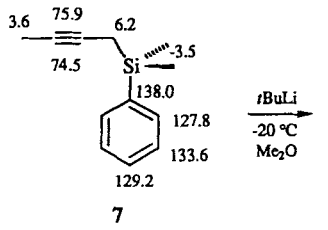
Scheme 2. Preparation and ^{13}C chemical shifts ($T = -152\,^{\circ}C$) of **6**-**A**.

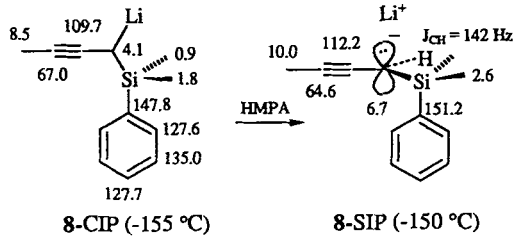
the monomeric nature of the compound and localized bonding to lithium. At $-135\,^{\circ}C$ the maximum broadening for C_P is 2 Hz more than for C_A and C_C. Thus, J_{C-Li} for C_P is less than 0.6 Hz. Assuming that this value for a propargyl isomer is at least 15 Hz, there can be no more than 4% of **6**-**P** present. Values of 16 and 18 Hz have been measured for C_P $^{7}Li-^{13}C$ couplings in **4** and its selenium analog.[6b]

Because of the chiral allenyl group, the $SiMe_2$ group of **6** is diastereotopic at low temperature. The racemization of **6** can be detected by coalescence of the signals for the $SiMe_2$ group (coalescence temperature $-135\,^{\circ}C$, $\Delta G^{\ddagger}_{-142\,^{\circ}C} = 6.3$ kcal mol^{-1}). A remarkable feature of the racemization is that it is intramolecular;[10] the $Li-C_A$ coupling persists to more than $20\,^{\circ}C$ above the coalescence temperature ($\Delta\delta = 81$ Hz between the diastereotopic Me groups).[11] A barrier to inversion could also be estimated for **8** ($k = 400\ sec^{-1}$ at $-137\,^{\circ}C$, $\Delta G^{\ddagger} =$ 6.1 kcal mol^{-1}).

The ^{13}C NMR spectra of **8** (generated from **7**, Scheme 3), the phenyl analog of **6**, are less clear-cut. The strongly temperature-dependent chemical shift values are between those expected for allenyl and propargyl isomers, and the signals show poorly resolved Li–C coupling. The propargyl-like C_C shifts at low temperature move progressively towards allenyl values at higher temperatures. Since variations in chemical shifts of over 30 ppm (between -155 and $-35\,^{\circ}C$) are unlikely to arise from altered conformer populations or extent of solvation, substantial changes in structure or equilibrium composition must occur.

Figure 1 shows chemical shifts of C_C for a range of lithium reagents, from those that appear to be allenic (such as **1**) to those that are unambigously propargyllic (such as **4**). Compounds with intermediate δ values (**8**–**11**) must either consist of significant fractions of both allylic and propargyl isomers in rapid equilibrium on the NMR time scale or have a 1,3-lithium-bridged structure such as **12** in which the asymmetry of bridging is temperature-dependent. Such bridged structures have been





Scheme 3. Preparation and ^{13}C chemical shifts of **8** in Me_2O (CIP) and Me_2O-HMPA (SIP). See text for further details.

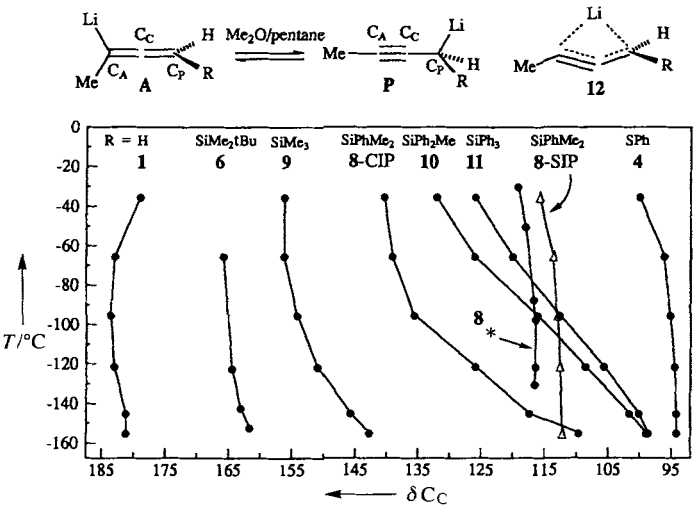


Fig. 1. Temperature dependence of the central carbon ^{13}C NMR chemical shifts of allenyl/propargyllithium reagents in THF/Me_2O (* = in 2,5-dimethyltetrahydrofuran).

predicted by calculations of unsolvated allenyllithium species, and there is evidence from HOESY experiments that dimeric 1-methoxyallenyllithium is partially bridged.[1a, 1b, 12] Since two species are detected by IR spectroscopy, we prefer an explanation involving tautomeric structures (although both could be unsymmetrically bridged). Absorptions at 1894 (strong) and 2179 (medium) cm^{-1} for **8** at $-78\,^{\circ}C$ indicate the presence of both allenyl and acetylenic structures.[1a, 4, 5] In contrast, the 2-pyridyl analog of **4** shows only an acetylenic stretch at 2164 cm^{-1}, whereas **1** shows an absorption at 1885 cm^{-1}. The ^{13}C chemical shifts of **1** and **4** are not significantly temperature-dependent; a static bridged structure such as **12** should not show the large changes in shift observed for **8**–**11**. If our interpretation of two tautomeric structures is correct, the propargyl isomer is enthalpically favored, whereas the allenyl isomer is entropically favored ($\Delta H^0 = 1.1 \pm 0.2$ kcal mol^{-1}, $\Delta S^0 = 6.1 \pm 1$ eu for **8**).[13] Solvation must play a key role in the structural changes, since the C_C chemical shifts of **8** in 2,5-dimethyltetrahydrofuran are only slightly temperature-dependent ($\delta = 119.2$ at $-30\,^{\circ}C$, 116.6 at $-130\,^{\circ}C$, Fig. 1).[14]

The temperature dependence and solvent effect suggest a difference in solvation between the allenyl and propargyl species.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2366 $ 15.00+.25/0

Perhaps the more highly directional, formally sp^2-hybridized carbanion orbital at the allenyl carbon C_A strengthens C–Li bonding and reduces the level of lithium solvation relative to that of the formally sp^3-hybridized propargyl carbanion carbon C_P. Higher temperatures would favor the isomer with the lower degree of solvation. Stronger C–Li covalency at C_A would also explain the tendency for more allenyl character in the contact ion pairs than in the solvent-separated ion pairs, as seen in most of the systems studied (see below).

When methyl groups on silicon are replaced by the more electron-withdrawing phenyl groups (compare **9** with **8**, **10**, and **11**), the fraction of propargyl isomer increases. This is consistent with the general observation that carbanion stabilizing groups (such as Ph, PhS, PhSe, or R_3Si) at the propargyl carbon favor the propargyl isomer. On the other hand, substitution of the methyl group on silicon by a *tert*-butyl group results in **6**, which has predominantly or exclusively allenyl character.

The identification of lithium reagents that are equilibrating mixtures of allenyl and propargyl isomers allowed an estimation of their rate of interconversion from D NMR line broadening. We chose the Me_3Si reagent **9** for more careful study, since it has nearly equal amounts of the two isomers at the lowest temperature investigated (Fig. 1). At $-150\,^{\circ}C$ in Me_2O/Et_2O/THF (5/2/1) the signal for C_C of **9** (estimated shifts of $\delta = 165$ and 98 in the two isomers) is 17 Hz wide. This gives a rate constant k greater than $10^5\ sec^{-1}$ and a free energy of activation $\Delta G^{\neq}$ smaller than 4 kcal mol^{-1} for interconversion of the isomers **9-A** and **9-P**. This low barrier to 1,3-lithium shift[15] has implications for the role of the isomeric lithium structures in the regioselectivity of reactions. Unless the rate of reaction for a lithium reagent with a substrate is greater than the rate of interconversion, the isomeric nature of the lithium reagent will not directly control the isomer produced (Curtin–Hammett principle). The rates of reaction for allenyl/propargyllithium reagents with typical substrates in THF are unknown. The very low barrier established here implies that the ratio of isomeric structures will directly determine regioselectivities for only the most rapid, if any, reactions of allenyl/propargyllithium reagents ($\Delta G^{\neq}_{-85\,^{\circ}C}$ for the reaction of *n*BuLi dimer and tetramer with benzaldehyde is about 9–10 kcal mol^{-1} [16]). The controlling feature will be the inherent reactivity of the individual isomers weighted by their concentrations. This conclusion is consistent with observations that a single allenyl/propargyllithium reagent can give dramatically different ratios of products with different electrophiles.[6c, 17]

HMPA titrations[6e] were carried out on most of the lithium reagents to establish the effect of lithium coordination on structure. Addition of HMPA to **8** first forms a mono-HMPA contact ion pair (CIP) followed by ion pair separation. Formation of the separated ion pair (SIP) is complete with four equivalents of HMPA. The chemical shifts are essentially temperature-independent (Fig. 1) and more propargyl- than allenyl-like. Although the C_C chemical shifts vary over 65 ppm (99 to 165 ppm) in the CIPs of **8** to **11**, the range for the SIPs is narrower (from $\delta = 106.9$ for $SiPh_3$ to $\delta = 118.7$ for $SiMe_2tBu$, $\delta(C_P)$ varies by only 2 ppm). The one-bond C–H coupling is significantly larger in the SIP (for example 146 Hz, for the $SiPh_3$ compound **11**) than in the CIP (128 Hz). Thus, there appears to be significant planarization of the carbanion carbon[6d] upon ion separation, but it is accompanied by surprisingly little change in the chemical shifts.

The significant changes in the ratio of propargyl to allenyl isomers that occur in compounds **8**–**11** can be principally ascribed to details of the interaction of the lithium cation and its associated solvent molecules with the anion. Changes in the inherent electronic structure of the carbanion play only a minor role.

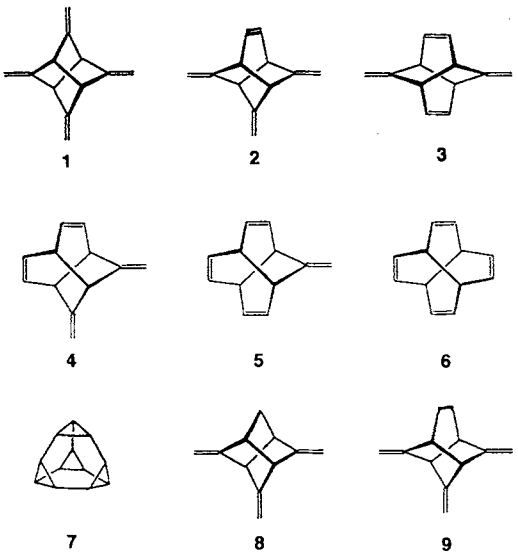
2,7,9-Trimethylenetricyclo[4.3.0.0^{3,8}]-non-4-ene**

Thilo Herb and Rolf Gleiter*

Among the many possible isomers of $C_{12}H_{12}$,[1] the family of tetraenes (**1**–**6**), in which a central tricyclic skeleton is surrounded by several 1,5-hexadiene units, is of particular interest. The double bonds can be either endocyclic or exocyclic. These attractive compounds not only offer a challenge for the synthetic chemist, but also invite studies of the interaction between the nonconjugated π-systems,[2] possible intramolecular rearrangements, and further intermolecular reactions.

There have been unsuccessful attempts to synthesize stellatetraene **1**[4] and **6**[5] (the systematic names of several compounds presented here are listed in Table 2). The latter is a potential precursor for the truncated tetrahedron **7**[6] and has, therefore, been the subject of several calculational studies. From our experience with the stellatriene **8**[7a] and its substitution products,[7b] it seems unlikely that **1** can be isolated at room temperature. However, the large increase in stability observed in going from **8** to the homologue twist-brendatriene **9**[8] suggests that species



such as **2**–**6** should be stable enough to be isolated. Calculated strain energies for the tetraenes **1**–**6** support this idea (Table 1). In this paper we report the synthesis of **2**, the first member of the series of tricyclic $C_{12}H_{12}$ isomers.

The reaction sequence leading to **2** is summarized in Scheme 1. Our studies on the synthesis of the triene **9** suggested **13** as a key intermediate for the synthesis of **2**. Compound **13** has the proper functional groups to introduce the endocyclic double bond by cleavage of the acetal protecting group and to form simultaneously one further exocyclic double bond by the opening of the oxetane ring. The synthesis of **13** can be achieved by the Diels–Alder reaction of **10**[9] with acetylallene **11**[10]. The Paternò–Büchi reaction, first introduced by Sauers et al.[11] and Nakazaki et al.[12] proved useful for the construction of the pentacyclic system in **13**. Irradiation of **12** yielded **13**, and subsequent treatment with *n*-butyllithium provided **14** (30%) and **15** (36%), as anticipated. The former was transformed into the latter by repeated treatment with *n*BuLi. Compound **15** was oxidized under Swern conditions[13] to provide the ketone **16** in 70% yield (Scheme 1).

A final Wittig reaction gave the title compound, although the yield was very low (3%). This can be ascribed to two factors: the

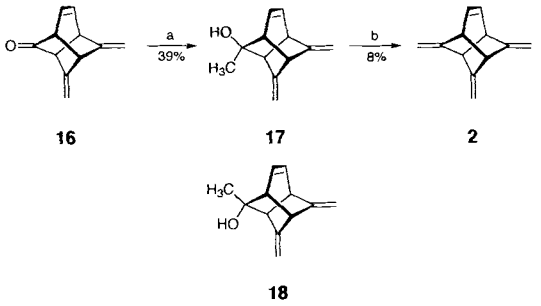
high volatility of **2** and the rearrangements of **2** and **16** at room temperature. Both compounds contain several 1,5-hexadiene units within a highly strained ring system, and it is likely that they undergo stepwise Cope rearrangements, as seen for **8**[7] and **9**.[8]

The yield of **2** in the last step of the synthesis can be increased by treating the ketone **16** with methyllithium to afford the tertiary alcohol **17** (Scheme 2). The structural assignment of **17** is



Scheme 2. a) MeLi, THF, −15 °C; b) $(COCl)_2$, DMSO, NEt_3, CH_2Cl_2, −60 °C.

based on H,H-NOESY experiments (Table 3). Comparison of the NMR data for **17** with values for similar tertiary alcohols containing such a tricyclic skeleton[7b, 14] supported the assignments for the hydroxyl and methyl groups. The epimeric alcohol **18** was not obtained by this reaction. The advantage of this protocol is the generation of a precursor (**17**) that is stable at room temperature. As shown in Scheme 2, **17** can be transformed under very mild conditions to the twist-brendatetraene **2**. This new dehydration procedure is based on the observation that the combination of $(COCl)_2$/DMSO/NEt_3, normally used for the oxidation of primary and secondary alcohols to aldehydes and ketones,[13] can be successfully applied for the elimination of water from tertiary alcohols with a β-hydrogen atom.[14] Our synthesis of **2**, one of the most strained members of the group of tricyclic tetraenes **1**–**6** (Table 1), indicates that it should also be possible to synthesize the less strained members of this series.

Side-Arm Participation in a Four-Component Template Synthesis of a [30]Crown-10 Derivative**

Andreas Merz,* Oliver Schneider, and Laszlo Parkanyi

The cation template effect often facilitates the formation of medium-sized macrocyclic crown ethers by S_N2 cycloalkylation in high yield, without requiring high dilution conditions and regardless of whether α,ω-cyclizations or manifold ring-forming reactions of smaller building blocks are used.[1] Remarkable in this respect is the selective template-assisted formation of homologous [3*n*]crown-*n* ethers directly from oxirane.[2] In the preparation of large crowns, however, the template effect is less

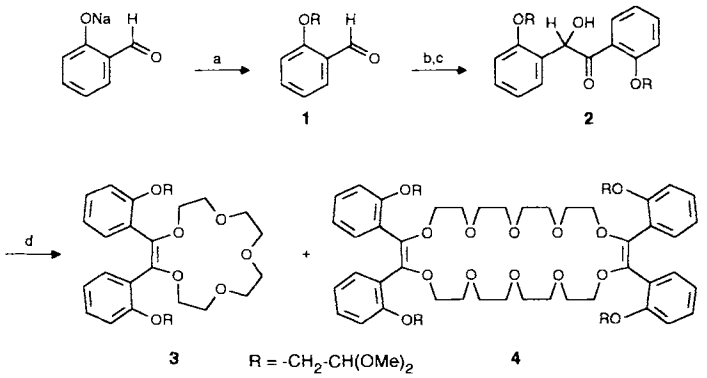
efficient and difficult to predict.[3-5] In syntheses of [15]crown-5 derivatives from two components, for example of benzocrowns from catechols and tetraethyleneglycol disulfonates, smaller amounts of the "dimeric" [30]crown-10 homologues have occasionally been found.[6, 7] Here we report on the synthesis of the 30-membered crown ether ring **4** from the substituted benzoin **2** and tetraethyleneglycol dimesylate;[8] a reaction in which we had expected to form the bibracchial ("BIBLE"[9]) [15]crown-5 **3** (Scheme 1).



Scheme 1. Synthesis of the 30-membered crown ether **4**. a) $BrCH_2CH(OMe)_2$, DMF, 100 °C, 2d; b) $Me_3SiCN/ZnBr$; 1. LDA/THF, 2. 1 equiv **1**, 3. MeOH/cat. Bu_4NF/SiO_2; d) $MesOCH_2(CH_2OCH_2)_3CH_2OMes$, KOH powder, THF.

Compound **2** was prepared according to a protocol by Hünig et al.[10] Ring closure was achieved with tetraethyleneglycol dimesylate in THF; the intermediary orange enediolate of **2** was obtained with KOH as base (Scheme 1).[11] Addition of $NaClO_4$ in THF to the oily crude mixture, which was expected to contain the crown ether **3**, resulted in the formation of a crystalline precipitate in 35% yield. This surprisingly turned out to be the disodium complex **4**·2 $NaClO_4$, which was characterized by the $[M + Na^+]$ and $[M + 2Na^+ + ClO_4]$ ions in the FAB-MS spectrum. The free [30]crown-10 **4** was subsequently obtained from the complex. Both structures were confirmed by X-ray crystal structure analyses (Fig. 1).[12] The smaller ring **3**, which was not obtained in a pure form, was identified by mass spectrometry and detected by HPLC in 2–3% yield.

Evidently, the acetal side arms are responsible for the surprising and almost complete suppression of the formation of the smaller ring **3**. We propose the complex shown in Scheme 2 as the critical intermediate: following the first alkylation step the substituted phenyl group can rotate towards the podand-like complexed cation in such a way that the enolate structure is closed to give a quasi [18]crown-6 structure. In this way the nucleophilic center is blocked for direct ring closure and the outward oriented mesyloxyethyl group can be attacked by a second enediolate nucleophile. Based on this hypothesis the size of the template cation should have an influence on the outcome of the reaction. Indeed, when the base is NaOH the yield of **4** is only 30% as opposed to 50% with KOH (HPLC analysis).

A further effect of the acetal side arms is the peculiar conformational dynamics of **4**·2 $NaClO_4$. Above room temperature the ^1H NMR signals (400 MHz) of the crown ether methylene groups are broadened. The maximal broadening is observed at −20 °C, at which temperature all the remaining signals in the spectrum are also broadened. At −60 °C the broad singlet for the eight methoxy groups splits into two singlets of equal intensity, of which the upfield one splits again at −80 °C. At −90 °C only an enhanced resolution of the signals is observed. Remarkably, the signals for the aromatic protons now appear as two sets in a 3:1 ratio.

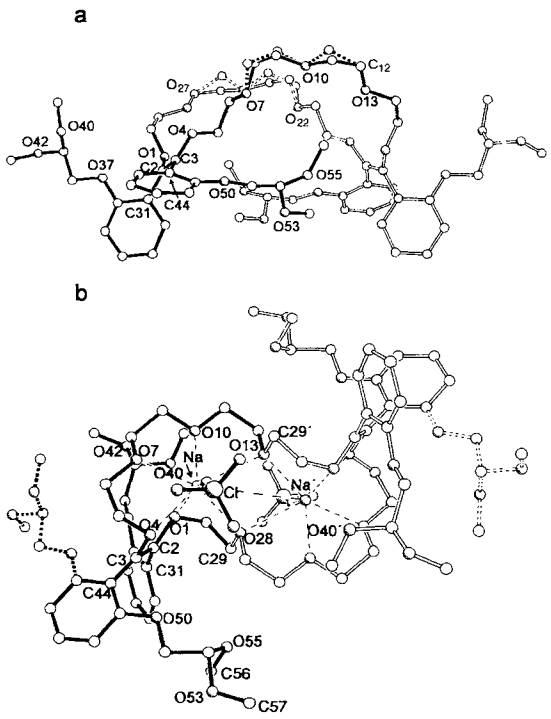


Fig. 1. Crystal structures of **4** and **4**·2 $NaClO_4$. The lightly printed parts are symmetry related to the bold ones by a C_2 axis (**4**) or an inversion center (**4**·$NaClO_4$), respectively. In the structure of **4** thermal disorder is indicated in the regions of O7 to C12 and O22 to C27. In the complex, thermal disorder exists with regard to the position of the acetal groups of the phenyl group at C3. Selected bond lengths [Å] and angles [°]: **4**: C2–C3 1.331(2), C3–O4 1.385(2), O1–C2 1.392; C2-C3-O4 123.6, C3-C2-O1 123.9, C3-C2-C31 122.9, C2- C3-C37 122.9, O1-C2-C31 113.5, O4-C3-C37 113.0. **4**·2 $NaClO_4$: Na–O1 2.430(4), Na–O4 2.508(5), Na–O7 2.413(5), Na–O10 2.392(5), Na–O13 2.736(5), Na–O(ClO_3) 2.263(3), O1–C2 1.427(2), C2–C3 1.338(2), C3–O4 1.426(2); C3-C2-O1 118.6(5), C3-C2-C31 123.9(4), O1-C2-C3 117.5(4), C2-C3-O4 116.8(5), O4-C3-C44 117.6(4), C3-C2-C31 125.6(4).

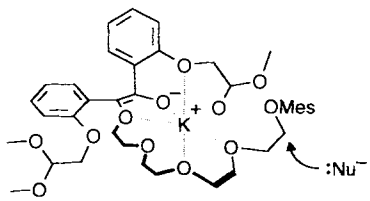
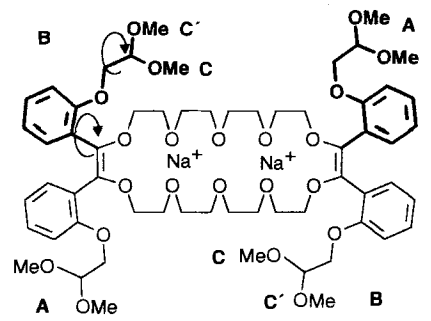


Scheme 2. Postulated reaction intermediate in the synthesis of **3** and **4**; $:Nu^-$ = enediolate of **2**.

Thus we conclude that there is a lariat interaction[9] between the acetal groups and the cations complexed in the crown ether ring. The unusual dynamic behavior above room temperature may result from an inter or intramolecular cation exchange. Apart from these conformational motions in the large crown ether ring, two important rotational processes at the periphery can be identified: the rotation of the aryl groups about the bond to the double bond and the rotation of the acetal groups about the CH_2–$CH(OCH_3)$ bond (Scheme 3).

Freezing of the rotation of the aryl groups would reduce the formal average symmetry of the crown ether from D_{2h} to C_i, as shown in Scheme 3. In this structure, two diagonal acetal groups (A and B) located above and below the crown ether plane get into a position for interaction with the nearest Na^+ ion. Freezing of the rotation of the acetal groups about the CH_2–$CH(OCH_3)$ bond will allow one of methoxy oxygen atoms in B to interact with a sodium ion, leading to the nonequivalence of

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2370 $ 15.00+.25/0 Angew. Chem. Int. Ed. Engl. 1996, 35, No. 20



Scheme 3. Two important rotational processes that take place at the periphery of the crown ether ring.

the methoxy groups C and C'. The uncomplexed external methoxy groups (A) can still freely rotate. The free ligand **4** also shows signal broadening below $-20\,^{\circ}C$, but the dynamic effects are restricted to the crown ether CH_2CH_2 signals. The aromatic signals and the OCH_3 signals of the side arms remain sharp down to $-90\,^{\circ}C$.

Interestingly, the structure of $\mathbf{4}\cdot 2\,NaClO_4$ (Fig. 1b) closely resembles the low-temperature structure deduced from the low-temperature NMR spectrum, although, in the crystal, the distance of 5.32 Å between the sodium ions and the closest methoxy oxygen atoms (O40 and O40') of the side arms are much too long for a bonding interaction. The centrosymmetric 30-membered crown ether ring is separated by a step at the O13–C29' and O28–C29 bonds into two half-crowns, which are each occupied by a sodium cation. These Na^+ ions are located outside the average planes of the five oxygen atoms pointing towards the ClO_4^- ions, which are coordinating from different sides of the ring. The oxygen atoms O13 and O28 are shared by both sodium ions. Two diagonally opposite acetal groups (O40 and O40') are bent over the ring, whereas the other two point outward. As indicated in Figure 1b the peripheral side groups (O50 to C56) are thermally disordered, which may be considered as an explanation for the observed 3:1 splitting of the signals of the aromatic protons in the ^1H NMR spectrum of the complex at $-90\,^{\circ}C$.

The C_2 symmetric free ligand **4** has a concave shape with only *gauche*-type ethylenedioxy units. The resulting cavity is filled by the acetal side groups of two diagonally arranged aryl groups on the same side of the ring (Fig. 1a).

The structures of the crown ethers most closely related to **4** and $\mathbf{4}\cdot 2\,NaClO_4$, namely dibenzo[30]crown-10[13] and its disodium complex,[14] have been known for a long time. The crystal structure of the parent, unsubstituted [30]crown-10 was determined only recently;[15] the structures of **4** and $\mathbf{4}\cdot 2\,NaClO_4$ differ significantly from the latter, which is again attributed to the supramolecular interaction of the side arms.

Experimental Procedure

1: The sodium salt of salicylaldehyde [11] (35.0 g, 0.24 mol) and bromoacetaldehyde dimethyl acetal (40.0 g, 0.24 mol) were stirred in absolute DMF (400 mL) for 48 h at 70 °C. After addition of 2 N NaOH (150 mL) the mixture was extracted with ether and the extract was fractionally distilled (b.p. 140 °C, 4×10^2 bar). Yield 14.9 g (30%), slightly yellow oil. ^1H NMR (250 MHz, $cDCl_3$): $\delta = 3.48$ (s, 6H, OCH_3), 4.13 (d, 2H, $-CH_2-$, $J = 5.2$ Hz), 4.77 (t, 1H, -HC=), 6.99 (dd, 1H, H3), 7.05 (dt, 1H, H5), 7.54 (ddd, 1H, H4), 7.84 (dd, 1H, H6), 10.51 (s, 1H, CHO). Additional coupling contants $J_{3,4} = 8.4$ Hz, $J_{3,5} = 0.8$ Hz; $J_{4,5} = 7.6$ Hz, $J_{4,6} = 1.80$ Hz, $J_{5,6} = 7.8$ Hz.

2: The O-trimethylsilyl cyanohydrin of **1** (7.80 g, 25.0 mmol) was prepared and lithiated without further purification in THF with LDA according to the procedure given in reference [10]. At $-78\,^{\circ}C$ a solution of **1** (7.80 g, 25.0 mmol) in THF was added, and the mixture was allowed to warm up to room temperature, hydrolyzed (under nitrogen) with aqueous Na_2CO_3, and extracted with ether. After the solvent had been removed, an oil (11.0 g) was obtained that was dissolved in MeOH and stirred for 48 h over tetrabutylammonium fluoride on silica (Fluka Nr. 86876) at room temperature. Pure **2** was obtained by column chromatography (silica, hexane/ethyl acetate 1:1) as a colorless oil (8.01 g, 76%). ^1H NMR (250 MHz, $CDCl_3$): $\delta = 3.45, 3.46, 3.47, 3.50$ (4s, 12H, OCH_3); 3.90, 3.92, 4.00, 4.03 (4d, 4H, Ar-O-CH_2, $J = 5.2$ Hz), 4.59 (d, 1H, CHO*H*, $J = 6.6$ Hz), 4.65, 4.76 (2t, 2H, CHOMe), 6.05 (d, 1H, C*H*OH) 6.70–7.57 (m, 8H) (the signals of the side arm are split due to different site and diastereotopy).

4: Benzoin **2** (1.26 g, 3 mmol), tetraethylenglycol dimesylate (1.05 g, 3 mmol), and powdered KOH (1.70 g, 30 mmol) in absolute THF (20 mL) were heated to reflux and stirred under nitrogen for 24 h. After most of the solvent had been removed, the mixture was taken up in CH_2Cl_2 and washed with water. Removal of the solvent left a yellowish oil (1.14 g, 67%), which was dissolved in THF (8 mL) and treated with $NaClO_4$ (171 mg, 195 mmol) in THF (5 mL). The reaction mixture was layered with pentane and the complex $\mathbf{4}\cdot 2\,NaClO_4$ crystallized overnight. $\mathbf{4}\cdot 2\,NaClO_4$: 340 mg, 30%, m.p. 153–155 °C. ^1H NMR (400 MHz, $CDCl_3$): $\delta = 3.40$ (s, 24H, OCH_3), 3.75, 3.80, 3.96, 3.91 (m, 40H, four broad signals, crown ether-H + Ar-O-CH_2), 4.70 (t, 4H, CH-$(OMe)_2$), 6.75 (t, 4H, arom.-H5), 6.76 (d, 4H, arom.-H3), 7.07 (dd, arom.-H6), 7.18 (ddd, arom.-H4). For the isolation of the free ligand **4**, the complex was dissolved in CH_2Cl_2 and the salt was washed out with water. The oil obtained after removal of the solvent slowly crystallized on addition of ether: **4**: 153 mg, 56% (m.p. 84–86 °C), ^1H NMR (400 MHz, $CDCl_3$): $\delta = 3.29$ (s, 24H, OCH_3), 3.65–3.71 (m, 24H, inner crown ether-H), 3.95 (m, 8H, =C-OCH_2), 3.98 (d, 8H, Ar-O-CH_2), 4.77 (t, 4H, CH-$(OMe)_2$), 6.65 (dt, 4H, arom.-H5), 6.76 (dd, 4H, arom.-H3), 7.02 (dd, arom.-H6), 7.11 (ddd, 4H, arom.-H4).

[12] Crystal structure data: **4** and $\mathbf{4}\cdot 2\,NaClO_4$ had rather low scattering power even at liquid N_2 temperature (77 K). Intensity data for **4** were collected at this temperature. $\mathbf{4}\cdot 2\,NaClO_4$ showed a reversible and incomplete phase transformation on cooling, therefore data collection was performed at ambient temperature. The structures were determined with an Enraf Nonius Turbo CAD4 diffractometer with $Mo_{K\alpha}$, $\lambda = 0.71069$ Å, ω-2θ scan by using direct methods (SHELXS-86), refinement on F^2 (SHELXL-93); H atoms were calculated in idealized positions. **4**: $C_{60}H_{84}O_{22}$, $M_r = 1157.3$, crystal dimensions $0.30\times0.20\times0.15$ mm, monoclinic, $P2_1/c$, $a = 14.379(3)$, $b = 15.180(3)$, $c = 17.005(3)$ Å, $\beta = 90.95(3)^{\circ}$, $V = 3711.2(13)$ Å^3, $Z = 2$, $\rho_{calcd} = 1.255$ g cm^{-3}, $T = 128(2)$ K, $\mu = 0.178$ mm^{-1}; 4596 reflections, 4445 symmetry-independent reflections of which 4392 were observed ($I > 2\sigma(I)$), 482 parameters refined, $R1 = 0.093$, $wR2 = 0.231$, max/min residual electron density 0.739 and -0.613 e Å^{-3}. Note on the disorder: the carbon atoms in the middle portion of the crown ether (C8,9,11) split into two statistically filled positions. The C52,O53.... C56 moiety is rotationally disordered, but the disorder could not be completely resolved. $\mathbf{4}\cdot 2\,NaClO_4$: $C_{60}H_{84}O_{30}Cl_2Na_2$, $M_r = 1402.2$, crystal dimensions $0.21\times0.18\times0.15$ mm, monoclinic, $C2/c$, $a = 24.017(2)$, $b = 10.101(1)$, $c = 25.012(1)$ Å, $\beta = 91.98(1)^{\circ}$, $V = 6064.2(8)$ Å^3, $Z = 4$, $\rho_{calcd} = 1.268$ g cm^{-3}, $T = 128(2)$ K, $\mu = 0.096$ mm^{-1}. 13132 reflections, 6605 symmetry-independent reflections of which 5525 were observed ($I > 2\sigma(I)$), 466 parameters refined, $R1 = 0.053$, $wR2 = 0.162$, residual electron density 0.634 and -0.361 e Å^{-3}. Due to a low data to parameter ratio the structure could only be refined when bond length constraints were applied. These include the ClO_4 tetrahedron, rigid group refinement of the phenyl groups, and C–C and C–O bonds of the crown. Note on the disorder: The O50, C51... C56 moiety is disordered, it appears in both *ortho* positions with a statistical filling of 1:1. C54 lies close to the inversion center at 0.5, 0, 0.5 and therefore makes a bond

with itself through the inversion center, that is with another side chain in statistically filled positions. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-124. Unusual Enantiomeric Resolution Phenomenon Observed upon Recrystallization of a Racemic Compound**

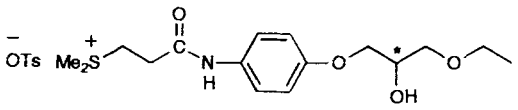
Takanori Ushio, Rui Tamura,* Hiroki Takahashi, Nagao Azuma, and Keiji Yamamoto

Since its discovery by Pasteur[1] in 1848 and its modification as "preferential crystallization" by Gernez[2] in 1866, the enantiomeric resolution of a mixture of homochiral (+) and (−) crystals (racemic mixtures or conglomerates) has been one of the most frequently used methods for separating enantiomers. In contrast, enantiomeric resolution by recrystallization of heterochiral crystals composed of a regular packing of (+) and (−) molecules (racemic compounds) has been believed to be totally infeasible.[3-8] We have found a surprising exception: Simple recrystallization of certain racemic crystals of the antiallergenic agent (±)-[2-[4-(3-ethoxy-2-hydroxypropoxy)phenylcarbamoylethyl]dimethylsulfonium *p*-toluenesulfonate (±)-**ST**[9,10] led to a remarkable enantiomeric enrichment of up to 100% *ee* in the mother liquor. More astonishing is the fact that when the



ST

slightly optically active crystals obtained by initial recrystallization of (±)-**ST** were recrystallized again without additional chiral influence, the resulting crystals displayed the opposite chirality and the **ST** remaining in the mother liquor was highly enriched with the enantiomer originally in excess. Therefore, simply collecting the mother liquors with the same chirality after each recrystallization led to efficient separation of enantiomers. Here we report this unusual enantiomeric resolution phenomenon and describe the unique properties of the **ST** crystals.

Crystallization of (±)-**ST** from a 25-fold supersaturated 2-propanol solution led to remarkable enantiomeric enrichment of up to 100% *ee* in the mother liquor (Fig. 1). As the crystallization proceeded, the enantiomeric purity of **ST** in solution gradually increased at 25 °C and could be improved further by lowering the temperature. As expected, large amounts of the deposited crystals contained the other enantiomer in small excess (Fig. 2). After more than 20 sets of recrystallizations, each conducted five times, using different samples of (±)-**ST** and various solvents, we have concluded that this enantiomeric resolution phenomenon is highly reproducible, and that the probability of obtaining one particular enantiomer in excess in the mother liquor after a number of recrystallizations of (±)-**ST** is 0.5 even if the same lot of (±)-**ST** is used. Typical examples of the time-course of the enantiomeric enrichment of the mother liquor observed during crystallization of (±)-**ST** are shown in Figure 1. More importantly, we found that when weakly optically active **ST** was recrystallized, the resulting crystals always displayed the opposite chirality (Fig. 2). This regular reversal of chirality in the deposited crystals accompanied by the enantiomeric enrichment of **ST** in the mother liquor was fully reproducible as long as optically active **ST** with less than 30% *ee* was employed. In one series of recrystallizations analogous to that described in Figure 2, weakly optically active **ST** originally en-

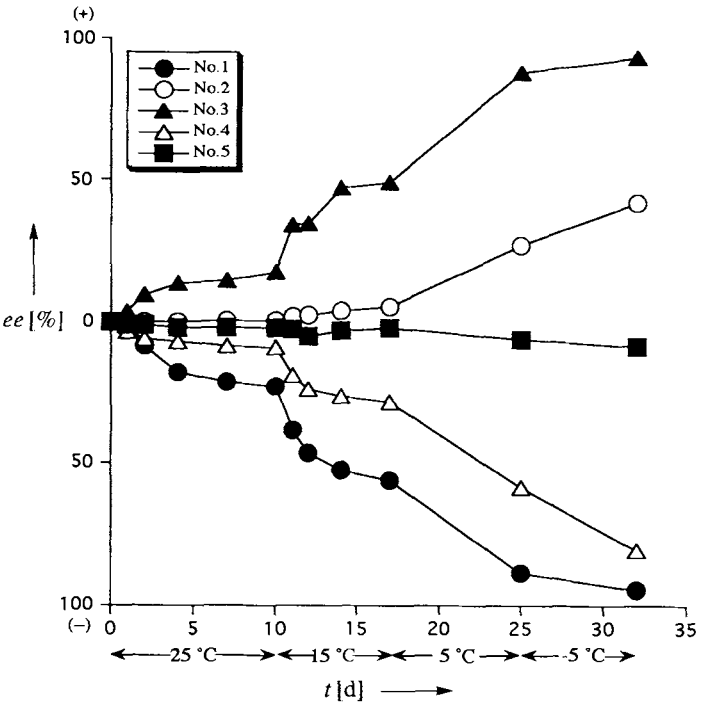


Fig. 1. Enantiomeric enrichment in aliquots of the mother liquor collected during crystallization of the same lot of (±)-**ST** carried out simultaneously in five different flasks (Nos. 1–5). The degree of enantiomeric enrichment differs each time, because it probably depends on how much and how fast the mixed crystals are deposited relative to crystals of the racemic compound. The enantiomeric excess (*ee*) [%] was determined by HPLC analysis using a chiral stationary phase (Daicel Chiralcel OD-H, hexane/EtOH/CF_3COOH/Et_2NH, 800:200:5:1). Conditions: **ST** (1.0 g) in 2-PrOH (4 mL) at 25 °C for 10 d, at 15 °C for 7 d, at 5 °C for 8 d, and at −5 °C for 7 d.

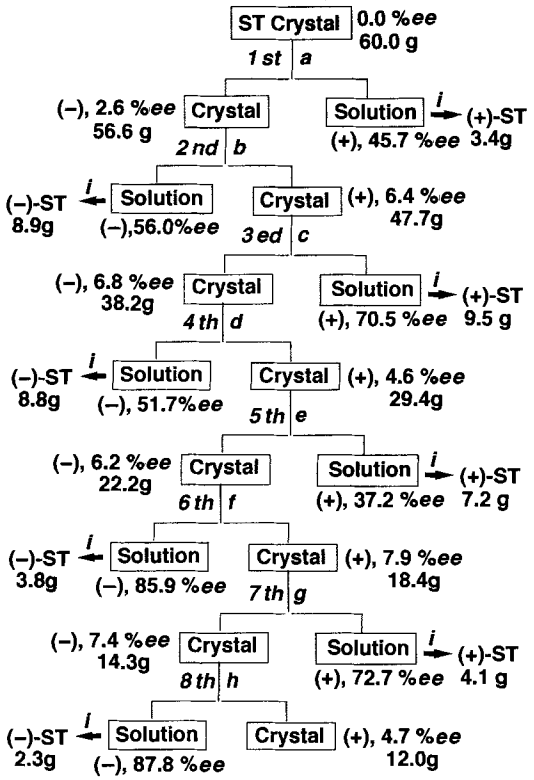

Fig. 2. Successive recrystallization of (±)-**ST** leading to the reversal of chirality in the resulting crystals and the enantiomeric enrichment in the mother liquors. The enantiomeric excess was determined by HPLC analysis. Crystallization conditions: *a*: mixed solvent system (120 mL EtOH, 60 mL iPr_2O 60 mL) at 5 °C for 18 h; *b*: EtOH (100 mL) at 5 °C for 18 h; *c*: EtOH (80 mL) at 5 °C for 3 d; *d*: EtOH (60 mL) at 5 °C for 3 d; *e*: EtOH (50 mL) at 5 °C for 15 h; *f*: mixed solvent of system (50 mL EtOH, 25 mL iPr_2O) at 5 °C for 18 h; *g*: EtOH (40 mL) at 5 °C for 2 d; h: mixed solvent system (30 mL EtOH, iPr_2O 30 mL) at 5 °C for 14 h; *i*: removal of the solvent by evaporation.

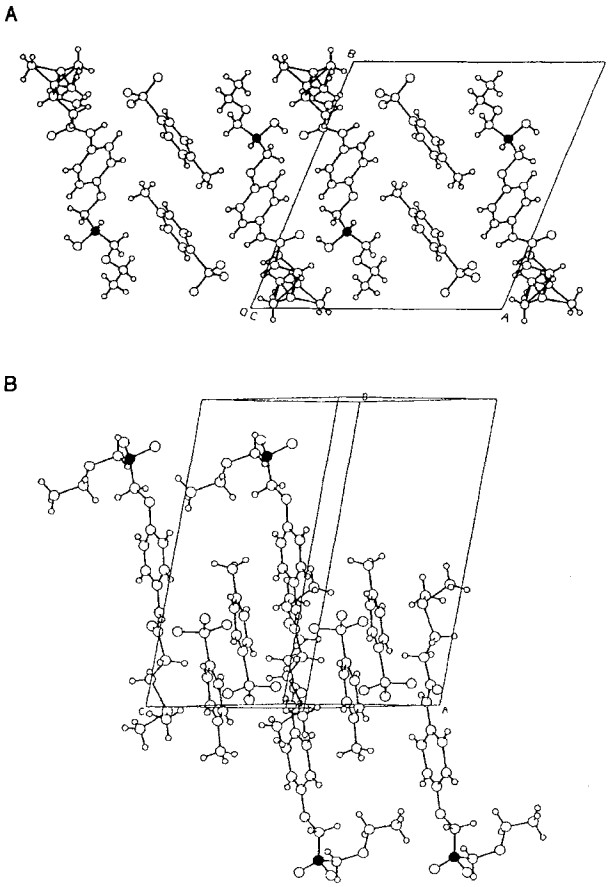

Fig. 3. Molecular and crystal structure of A) the racemic compound (±)-**ST** and B) a mixed crystal of the optical antipodes of **ST** (ca. 1% *ee*). Black circles represent the asymmetric carbon atoms. Orientational disorder was observed for the oxygen atoms in the mixed crystal; the occupancy factors were used to estimate the *ee* value.

riched in the (−) enantiomer (8.2% *ee*) was recrystallized successively from EtOH at 5 °C and then −30 °C four times in all. By simply collecting the mother liquors with the same chirality and recrystallizing the collected crystals after partial evaporation of the solvent, 4.45 g (41.1% based on the original amount of the enantiomer) and 2.96 g (32.2%) of highly optically active (+)- and (−)-**ST** crystals of 96–98% *ee*, respectively, were obtained.

In order to gain an insight into the mechanism of this unusual enantiomeric resolution phenomenon, we investigated the structure of the **ST** crystals. The X-ray crystallographic analysis of the single crystals of **ST** showed that the stable crystalline form of the racemate is a racemic compound (Fig. 3A),[11a] while the crystal of the pure enantiomer is chiral.[11b] Furthermore, it has been found that under the conditions of forced recrystallization **ST** was deposited as mixed crystals (solid solutions) of the optical antipodes with a wide range of enantiomeric purities. Namely, crystallization of **ST** with various enantiomeric purities (0 to 90% *ee*) in *i*PrOH at 25 °C by nucleation with the seed crystals of one pure enantiomer led to the deposition of the mixed crystals with the same chirality and enantiomeric purity as the original solution. The crystallographic parameters and molecular and crystal structures of these mixed crystals of various enantiomeric purities are almost identical with those of the crystals of the pure enantiomers, except that the C–OH bond is disordered in the mixed crystals (Fig. 3B).[11c] On the other hand, crystallization of (+)-enriched **ST** with low enantiomeric purity (less than 30% *ee*) in *i*PrOH by nucleation with seed crystals of the racemic compound (±)-**ST** resulted in the deposition of almost the racemic compound (somewhat (−)-rich) of less than 10% *ee* along with the enantiomeric enrichment of (+)-**ST** in the mother liquor, as confirmed by X-ray powder diffraction and HPLC analysis. In this case, as the enantiomeric purity of (+)-rich **ST** used for recrystallization increased (more than 50% *ee*), more mixed crystals were deposited with almost the same enantiomeric purity [(+)-rich] as the original solution together and fewer crystals of the racemic compound formed. From these results it was concluded that 1) the racemic form of **ST** exhibits polymorphism,[12] (in other words it forms crystals of the stable racemic compound and metastable mixed crystals (solid solutions) of 0% *ee*); 2) **ST** forms stable mixed crystals over a wide range of enantiomeric purities; and 3) mixed crystals with the same chirality and enantiomeric purity as the mother liquor and crystals with enantiomeric purities of less than 10% *ee* are liable to be deposited during recrystallization. Therefore, it is assumed that the melting point phase diagram of **ST** shows two eutectic temperatures around 10% *ee* resulting from the intersection of the phase diagrams of a racemic compound type and a mixed crystal type (Fig. 4).

Thus, it is apparent that the mechanism of this unusual enantiomeric resolution phenomenon of **ST** is quite different from that of the preferential crystallization of conglomerates, in which each deposited crystal is enantiomerically pure and the mother liquor is not as enantiomerically enriched.[1, 3] Another difference is the enantiomeric enrichment of the mother liquor resulting from the principal deposition of the racemic compound; in crystallization of nonracemates of ordinary racemic

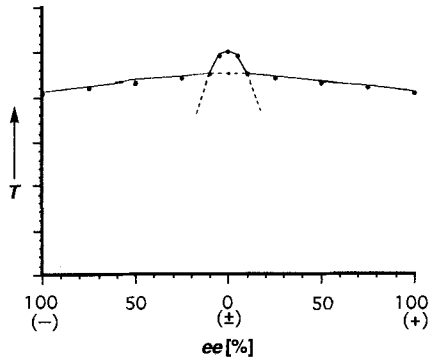

Fig. 4. Expected melting point phase diagram of **ST**; T = melting point (temperature of the end of fusion), *ee* = enantiomeric excess.

compounds the reversal of chirality in the deposited crystals never occurs. It should be emphasized that spontaneous isomerization of one enantiomer to the other one never occurred under our recrystallization conditions. Although the mechanism of the enantiomeric resolution phenomenon of **ST** is yet under investigation, it may be related to the unique polymorphism of the **ST** crystals described above. If this is true, this enantiomeric resolution phenomenon might be extended and become a powerful general method for the resolution of organic racemates showing similar polymorphism, by which both the racemic crystals and the mixed crystals are simultaneously produced.

Enantioselective Conjugate Addition of Dialkylzinc Reagents to Cyclic and Acyclic Enones Catalyzed by Chiral Copper Complexes of New Phosphorus Amidites**

André H. M. de Vries, Auke Meetsma, and Ben L. Feringa*

Conjugate addition reactions of organometallic reagents to enones are among the most widely used methods for carbon–carbon bond formation in organic synthesis.[1] A number of successful methods for stereoselective 1,4-addition based on chiral auxiliaries or stoichiometric organometallic reagents have been developed.[1, 2] Recently catalytic, enantioselective conjugate additions of organometallic reagent (RMgX, RLi, or R_2Zn) with chiral Cu^I, Ni^{II}, and Zn^{II} complexes have been demonstrated.[2, 3] All these catalysts, however, show enantioselectivity for only one specific type of enone.[3] For example, complexes prepared in situ from $[Ni(acac)_2]$ (acac = acetylacetonate) and chiral amino alcohols are enantioselective for the addition of Et_2Zn to acyclic enones, but for cyclic enones no enantioselectivity was found.[4] On the other hand chiral CuI complexes with sulfonylaryloxazoline ligands are only effective in 1,4-addition reactions of Grignard reagents to cyclic enones.[5] We now report chiral copper catalysts, capable of facilitating conjugate addition of readily available dialkylzinc reagents to cyclic and acyclic enones in high yields and with *ee* values up to 90%.

Since trivalent phosphorus compounds are known as ligands for stoichiometric conjugate organocopper additions,[6, 7] we examined the new chiral phosphorus amidite **1**, recently synthesized in our group from (*S*)-2,2′-binaphthol (**2**) and hexamethyl phosphoramide (HMPT),[8] as ligand in the CuI-catalyzed addition of Et_2Zn to cyclohexenone (**3a**) and chalcone (**5a**) [Eq. (a) and (b)].[9] Some remarkable results were observed: 1) Amidite **1** represents a new class of chiral ligands, which proved to be essential for this catalytic system. Within 3 h both substrates are converted into the 1,4-product exclusively (GC

yields greater than 95%), whereas without the ligand the copper-catalyzed reaction is very slow and many side products were found. When a larger amount of **1** (50 mol%) was employed, the reaction proceeds only at room temperature and was far less selective. These observations provide potentially striking advantages for a successful asymmetric catalysis.[10] 2) For both substrates moderate enantioselectivities were found (**4a**, 35% (*S*) and **6a**, 47% (*R*)), which indicates that this chiral catalyst is not limited to one specific type of enone.

With this knowledge we set out to determine the structure of the complex of CuI and **1**. Crystallization from benzene provided white needles (**I**) suitable for X-ray analysis.[11] The molecular structure is shown in Figure 1.[12] Three chiral ligands are bound to the copper center creating a C_3-symmetrical complex. Examination of the structure showed that crucial positions for ligand modifications are the amine moiety and the 3,3'-positions of the binaphthyl part of the ligand.

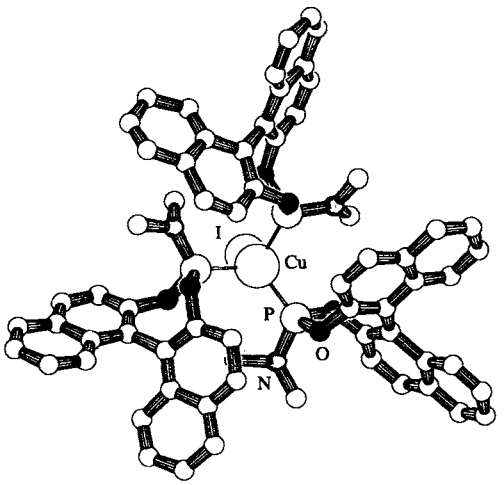

Fig. 1. Crystal structure of [CuI(**1**)] (**I**).

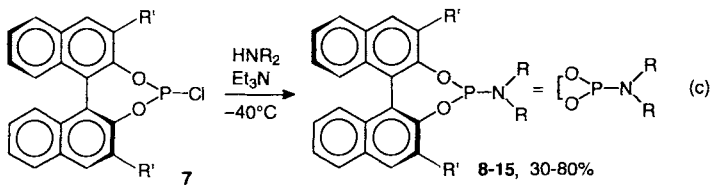
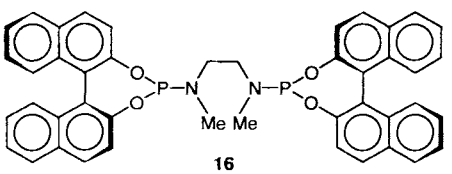
Therefore, starting from phosphoryl chloride (**7**),[13] several new phosphorus amidites **8**–**16** were prepared [Eq. (c)].[14] The



(c)



16

complexes generated in situ of these ligands and CuI gave unsatisfactory results, presumably due to low solubility. However, homogeneous catalyst solutions were obtained with CuOTf (Tf = CF_3SO_2), and the influence of the structural modifications in **8**–**15** on the enantiomeric excess of **4a** and **6a** could be determined (Table 1). For both products significant improvement in *ee* was observed when sterically demanding substituents were introduced on the ligand's nitrogen atom. The best results were obtained with the bis(*iso*-propyl)-substituted ligand **12**. Products **4a** and **6a** were isolated in high yields (>80%) and *ee* values of 60% and 83%, respectively. Ligands **13** and **14** (R' = CH_3) furnished the 1,4-products with comparable *ee* values. With ligand **15** (R' = Ph) lower enantioselectivities were found. Probably different clusters are formed with sterically demanding substituents on the 3- and 3'-position of the ligand creating less selective catalysts. In an effort to enhance the selectivity and realizing that Cu^{II} salts are used as catalyst for conjugate addition,[15] we investigated $Cu(OTf)_2$ together with **12** as chiral catalyst. Under the same conditions **4a** and **6a** were isolated with higher *ee* values (Table 2). The actual chiral catalyst is probably a Cu^{I} species, generated by in situ reduction of the Cu^{II} complex. The chiral copper complex of ligand **12** catalyzes the addition of Et_2Zn to various enones enantioselectively.

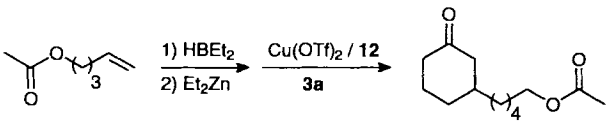
Cyclic and acyclic enones gave the corresponding 1,4-products in 55–90% *ee*. The best results were obtained for 4,4-dimethyl-2-cyclohexen-1-one (**3c**) and **5a**.

Mechanistic studies on the enantioselective catalyst are under way, and at present we emphasize the following observations. 1) With the catalyst derived from bidentate ligand **16** and copper salt (1:1) we achieve the same *ee* values as found for ligand **1**

(2:1), which indicates that during reaction two ligands are bound to the copper ion. The remaining sites in the tetrahedral coordination sphere of the copper ion are likely to be occupied by π-complexation of the enone's double bond,[17] and an ethyl fragment transfered from zinc.[18] 2) The pyridyl-substituted chalcone **5c** gave the corresponding 1,4-product in only 29% *ee*, presumably due to competitive binding of the copper catalyst to the enone's pyridine moiety.

Preliminary experiments showed that dioctylzinc, prepared directly from 1-octene by boron–zinc exchange,[19] can be used as well; it furnishes the 1,4-products with comparable *ee* values. This protocol can be extended to functionalized diorganozinc reagents. For instance, with the chiral catalyst derived from **12** and $Cu(OTf)_2$, 4-penten-1-yl acetate was added to **3a** with 56% *ee*. [Eq. (d)].



(d)

51%, 56% *ee*

In conclusion a new highly efficient catalyst for asymmetric conjugate addition of diorganozinc reagents to enones has been developed. Remarkable features are the excellent chemoselectivity to give nearly pure 1,4-products, the effective ligand acceleration by new phosphorus amidite ligands, the relatively high *ee* values for both cyclic and acyclic enones, the efficiency of a monodentate ligand in this asymmetric catalysis, and the fact that alkenes can be used as starting material.

Experimental Procedure

General procedure for ligands **8**–**16** (argon atmosphere): A warm solution (60 °C) of (*S*)-2,2′-binaphthol (**2**) (860 mg, 3 mmol) in toluene (25 mL) was added in 5 minutes to a cooled solution (− 60 °C) of PCl_3 (270 μL, 3 mmol), Et_3N (860 μL, 6 mmol), and toluene (5 mL). The reaction mixture was stirred for 2 h, warmed to room temperature, and filtered. The filtrate was treated with Et_3N (410 μL, 2.9 mmol) and 2.9 mmol of the appropriate secondary amine at −40 °C. After 16 h at room temperature, the reaction mixture was filtered, concentrated, and purified by chromatography (SiO_2, hexane:CH_2Cl_2 2:1) to give the pure amidite (yield 30–80%). (*S*)-**12**: $[\alpha]_D = +591$ ($c = 0.68$ in $CHCl_3$); ^{1}H NMR (200 MHz, $CDCl_3$): $\delta = 7.99$–7.89 (m, 4H), 7.55–7.22 (m, 8H), 3.42 (heptet, $J = 6.84$ Hz, 1H), 3.37 (heptet, $J = 6.84$ Hz, 1H), 1.24 (d, $J = 6.84$ Hz, 6H), 1.19 (d, $J = 6.84$ Hz, 6H); ^{13}C NMR ($CDCl_3$): $\delta = 150.2$, 150.1, 132.6, 131.2, 130.4, 130.0, 129.2, 128.2, 128.1, 127.0, 125.8, 125.7, 125.6, 124.5, 124.1, 122.4, 122.3, 44.6, 44.4, 24.3, 24.2; ^{31}P NMR ($CDCl_3$): $\delta = 151.7$.

Catalytic conjugate additions (argon atmosphere): A solution of $Cu(OTf)_2$ (10.9 mg, 0.030 mmol) and **12** (26.0 mg, 0.065 mmol) in toluene (3 mL) was stirred for 1 h. The colorless solution was cooled (− 20 °C) and enone (1-2 mmol) and 1.5 equivalent of dialkylzinc solution (1 M in toluene) were added. After 3 h at −15 °C the reaction mixture was poured into 25 mL of 1 N HCl and extracted with diethyl ether (2 × 25 mL). The combined organic layers were washed with brine (25 mL), dried ($MgSO_4$), filtered, and evaporated to give the crude 1,4-products. After purification by chromatography (SiO_2, hexane:diethyl ether 5:1) the *ee* values were determined. Cyclic substrates were derivatized with optically pure 1,2-diphenyl ethylene diamine and analyzed by ^{13}C NMR [20]. Acyclic substrates were studied by HPLC (Daicel OD or OJ column).

A Catalyst-Specific, Stereocontrolled Ring-Closing Metathesis**

Christoph M. Huwe, Janna Velder, and Siegfried Blechert*

Ring-closing olefin metatheses have been used increasingly for the synthesis of unsaturated carbo- and heterocycles.[1] To our knowledge, diastereoselective ring-closing metatheses have not been investigated to date.[2] We recently explored the synthesis of chiral, α-substituted heterocycles from amino acid derivatives,[3, 4] and used the chiral center for stereocontrolled secondary reactions of the double bond produced by the metathesis for the synthesis of natural products.[3]

Natural products or biologically active compounds such as various pheromones and glycosidase inhibitors contain α,α′-disubstituted pyrrolidine or piperidine units.[5, 6] To selectively ob-

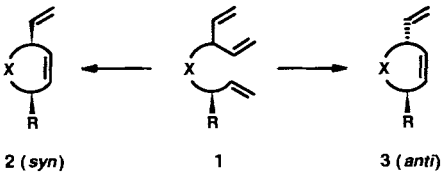
[**] This work was supported by the Fonds der Chemischen Industrie. We thank the state of Berlin for a doctoral fellowship (C. M. H.).

tain *syn*- or *anti*-α,α′-disubstituted compounds such as **2** and **3**, we were interested in ring-closing methatheses that use an existent chiral center to control the cyclization with a prochiral diene (Scheme 1). In these investigations we found that cyclization to give five-membered rings was highly catalyst-specific, and that the acyclic precursor **1** is thereby selectively converted into the *syn* or *anti* product.



Scheme 1. Principle of the generation of a new stereocenter by ring-closing metathesis.

In general, this concept of performing a diastereoselective olefin metathesis requires that the olefins at the prochiral center do not react with each other and also that the primary attack of the catalyst occurs at the double bond of the chiral center. In the case of the ruthenium catalysts[7] (abbreviated [Ru], $[Cl_2(PCy_3)_2Ru{=}CHPh]$, Cy = cyclohexyl) reported by Grubbs et al. and the molybdenum catalysts[8] (abbreviated [Mo], $[PhMe_2CCH{=}Mo{=}N\{2,6\text{-}(iPr)_2C_6H_3\}\{OCMe(CF_3)_2\}_2]$) reported by Schrock et al. which we used, the metatheses can be significantly slowed down by steric effects.[1c] Thus, we attached an additional methyl group to the prochiral olefins and precluded the ring closure between these two double bonds by using a 1,4-diene. The trienes used in the metatheses were synthesized from the known Cbz-protected amino alcohols **4**[4] and **5**[9] (Scheme 2). The prochiral diallyl moiety was readily obtained by addition of propynylborane or -borate,[10] respectively, to the tetrolimine, followed by Birch reduction. In this way, **8** and **9** were obtained in 53% and 60% yield, respectively. Since ring-closing metatheses cannot be performed with the employed catalysts in the presence of basic amines, the trifluoroacetamides **10** and **12** as well as the 2-oxazolidinone **13** were prepared. The use of the heterocycle **13** could potentially lead to different stereochemical results in the cyclization. The O-deprotected compound **11** was not converted in the attempts at cyclization. All other ring closures could be carried out in good yields, by using either the ruthenium or molybdenum catalyst.[11] In the ruthenium-catalyzed cyclization to the six-membered rings **14** and **15**, no diastereomeric excess was observed by gas chromatography (see Scheme 2 and Table 1). In contrast, the best *syn*/*anti*-selectivity we could obtain in the molybdenum-catalyzed cyclization of **10** did not exceed a ratio of 26:74. Increasing the temperature by approximately 60 K resulted in only a moderate improvement in the selectivity, and no improvement was observed when the more rigid 2-oxazolidinone **13** was employed. Presumably due to the more pronounced steric interactions, the cyclization to give five-membered rings required significantly longer reaction times, while still showing incomplete conversion in some cases. The slower cyclization resulted, however, in a significant increase in selectivity (Scheme 3 and Table 1). In the best case, the ruthenium catalyst provided the *anti*-product **16** with a diastereomeric excess of 92%, whereas the molybdenum catalyst yielded the *syn*-product preferentially with 72% *de*. We believe that this catalyst-specificity is attributed to the different spatial arrangements of the respective ligands during the cyclization. Model investigations do not offer a clear explanation for, or enable one to predict, the observed selectivities. The

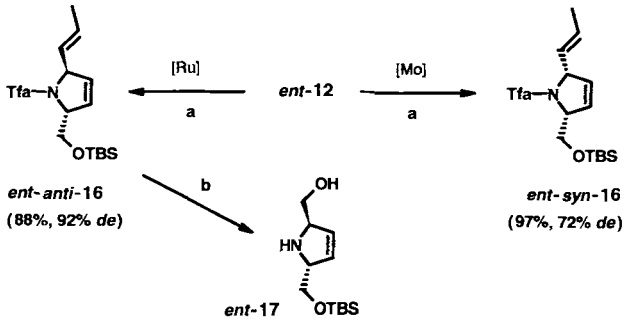

Scheme 3. Five-membered ring metathesis experiments. a) see Table 1; b) 1. O_3, CH_2Cl_2, −78 °C; 2. $LiAlH_4$, THF, RT, 18 h; 79%.

anti-**16** product can be used as an example to demonstrate the differentiation between the double bonds in the corresponding metathesis product. Careful ozonolysis of *anti*-**16** monitored by thin-layer chromatography, followed by reductive workup with lithium aluminum hydride, yielded 79% of the monoprotected aminodiol **17**, which offers a variety of possibilities for further elaboration.

Experimental Procedure

Typical procedure for the stereoselective ring-closing metathesis as exemplified by *ent-syn*-**16** (Table 1, entry 11): *ent*-**12** (50 mg, 0.13 mmol) was dissolved in anhydrous benzene (9.2 mL) under argon, [Mo] (4.9 μmol, 5 mol%) was then added, and the resulting mixture was stirred for 3 d at a bath temperature of 80 °C. The solvent was removed and the residue was purified by flash chromatography on silica gel by using *tert*-butyl methyl ether/petroleum ether (1:40) as eluent to afford 44 mg (97%) of the cyclization product (72% *de*, GC) as a yellow oil. Selected spectroscopic data: ^{1}H NMR (400 MHz, $CDCl_3$): two amide isomers, combined spectrum: $\delta = 0.05$ (s, 6H), 0.88 und 0.89 (s, 9H), 1.68 and 1.69 (dd, 3H, $J = 1.5, 6.5$ Hz), 3.82 (m, 1H), 3.87 (m, 1H), 4.76–4.97 (m, 2H), 5.11–5.45 and 5.59–5.95 (m, 4H). ^{13}C NMR (50 MHz, $CDCl_3$): two amide isomers, combined spectrum: $\delta = -5.5$ (CH_3), −5.4 (CH_3), 17.5 (CH_3), 17.7 (CH_3), 18.4 (C_q), 25.8 (CH_3), 25.9 (CH_3), 62.4 (CH_2), 67.0 (CH), 67.1 (CH), 68.2 (CH), 68.4 (CH), 126.7 (CH), 127.3 (CH), 128.1 (CH), 128.3 (CH), 129.2 (CH), 129.8 (CH), 130.0 (CH), 153.2 (C_q). HR-MS ($C_{15}H_{23}F_3NO_2Si$, $M^+ - CH_3$): calcd 334.1450, found 334.1450. IR (CCl_4): $1/\lambda = 1686$ cm^{-1}. Elemental analysis ($C_{16}H_{26}F_3NO_2Si$): calcd C 54.99 H 7.50 N 4.01, found C 55.09 H 7.50 N 4.24.

Reductive Carbon–Sulfur Bond Cleavage: A Simple Pathway to Nonstabilized (Lithiomethyl)amines**

Carsten Strohmann* and Bors Cajus Abele

(Lithiomethyl)amines are important building blocks in the synthesis of not only organic but also organoelement compounds.[1] Nonstabilized[2] α-heterocarbanions[3]—containing nitrogen or oxygen as the heteroatom—cannot ordinarily be synthesized by hydrogen–lithium or halogen–lithium exchange using either lithium bases or metallic lithium.[1] However, (lithiomethyl)amines[4] and (lithiomethyl)ethers[5] can usually be obtained by metal–lithium, typically tin–lithium, exchange. Reductive carbon–sulfur bond cleavage permits another pathway to (lithiomethyl)ethers;[6] in addition it circumvents the chromatographic separation necessary for stannylmethyl compounds.[5, 7]

During systematic investigations on the synthesis of 1,3-dimetalated compounds of general formula M–CR_2–El–CR_2–M (M = e.g. Li, MgBr; El = Group 14–16 element, when necessary containing substituents; R = H, alkyl, aryl),[8] we were also interested in the preparation of bis(lithiomethyl)amines.[9] There has only been one report[10] on the synthesis of nonstabilized, α-alkyl substituted, monometalated α-aminocarbanions using reductive C–S bond cleavage. The synthetic aspects of this reaction have not been further investigated. We report here on a simple pathway to nonstabilized mono(lithiomethyl)amines that are not substituted on the α-carbon atom by means of reductive C–S bond cleavage, as well as on the use of these synthetic building blocks in the construction of organic and organoelement compounds.

The required (phenylthiomethyl)amine starting materials can be synthesized in high yields from thiophenol, formaldehyde, and secondary amines[11] (Scheme 1). Treatment of the

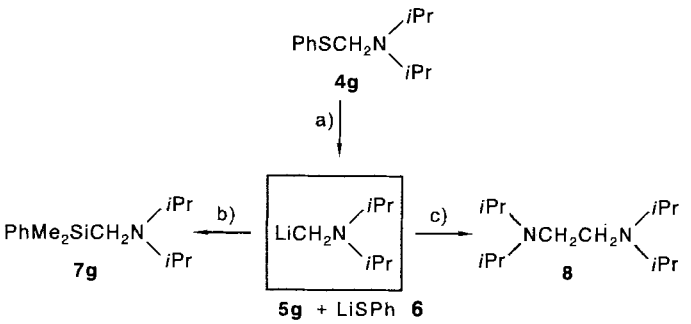
(lithiomethyl)amine had been formed, the reaction solutions were treated with two equivalents[12] of chloro(dimethyl)-phenylsilane. The corresponding pure (aminomethyl)silanes **7a–f** were isolated in 67–80% yield (Table 1).

Table 1. Yields of **7a–7h**.

7	NR_2	Yield [%]	7	NR_2	Yield [%]
a	$N(C_2H_5)_2$	80	**e**	$NC_4H_8NCH_3$	68
b	NC_4H_8	72	**f**	$N(C_2H_4OCH_3)_2$	70
c	NC_5H_{10}	74	**g**	$N(i\text{-}C_3H_7)_2$	27
d	NC_4H_8O	67	**h**	$N(C_6H_5)_2$	0 [a]

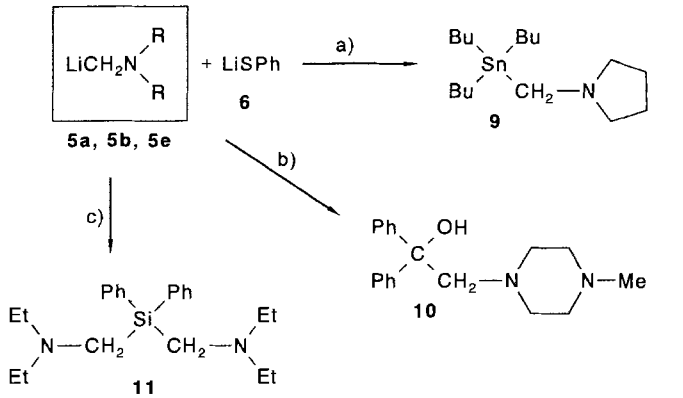
[a] Isolation of the pure entrapped products of **5h** with $PhMe_2SiCl$ has not yet been successful. The trapping reaction with Bu_3SnCl gave diphenyl(tributylstannylmethyl)amine in 56% yield.

Sterically demanding amines such as diisopropyl(phenylthiomethyl)amine **4g** and diphenyl(phenylthiomethyl)amine **4h** show a somewhat different reaction behavior. Reaction of the (lithiomethyl)amines with the starting material lead to C–C bond formation so that the $LiC_{10}H_8$ was not completely consumed. When **4g** was treated with $LiC_{10}H_8$ followed by entrapment with $PhMe_2SiCl$, both **7g** and **8** were isolated (Scheme 2). The structure of further side products has not yet been clarified. Amine **4h** reacts in a similar manner.



Scheme 2. a) $+2\ LiC_{10}H_8/-2\ C_{10}H_8$; b) $+2\ PhMe_2SiCl/-2$ LiCl, $-PhMe_2SiSPh$; c) $+$**4g**$/-2$ LiSPh.

In the reaction mixtures of the (lithiomethyl)amines obtained by reductive C–S bond cleavage, a further nucleophile, PhSLi **6**, which is not formed in the tin–lithium exchange reaction is generated. Nevertheless, **6** did not interfere with reactions with ketones, stannanes, and silanes, which furnished products in good yields (Scheme 3). Also stirring the (lithiomethyl)amines



Scheme 3. Reactions of (lithiomethyl)amines: a) **5b** $+2\ Bu_3SnCl/-2$ LiCl, $-Bu_3SnSPh$; b) **5e** $+Ph_2CO$, $+2\ H_2O/-2$ LiOH, $-HSPh$; c) 2 **5a** $+Ph_2SiCl_2/-2$ LiCl, -2 LiSPh.

for 15 min at room temperature did not lead to a change in the product composition. Protonation of the metalated carbon atoms or carbenoid reactions[11b] (for example, the decomposition into lithium amides and methylene) was also not observed. We believe the synthesis of bis(aminomethyl)silanes such as **11** is particularly interesting (Table 2). As far as we know, the only representative of this class that has been reported so far is bis-(dimethylaminomethyl)dimethylsilane.[13]

Table 2. Selected spectroscopic data of the newly synthesized compounds.

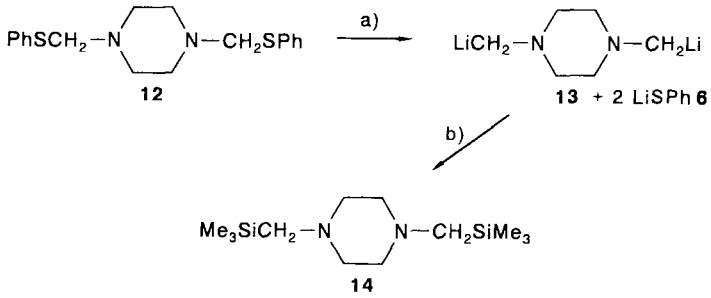
11: yield: 45%; b.p. 185 °C oven temperature/10^{-3} mbar; ^{1}H NMR (200.1 MHz, $CDCl_3$, 25 °C, TMS): $\delta = 0.83$ (t, ^3J(H,H) = 7.0 Hz, 12H; $NCCH_3$), 2.33 (q, ^3J(H,H) = 7.0 Hz, 8H; NCH_2C), 2.51 (s, 4H; $SiCH_2N$), 7.25–7.35, 7.60–7.70 (m, 10H; Ph); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): $\delta = 11.4$ (4C, $NCCH_3$), 41.8 (2 C, $SiCH_2N$), 50.0 (4C, NCH_2C), 127.6 (2C, *m*-Ph), 129.1 (*p*-Ph), 135.4 (2 C, *o*-Ph), 136.5 (*ipso*-Ph); ^{29}Si NMR (39.8 MHz, $CDCl_3$, 25 °C, TMS): $\delta = -17.5$; MS (EI, 70 eV): *m/z* (%) = 354 (2) [M^+], 268 (53) [$M^+ - CH_2N(C_2H_5)_2$], 86 (100) $[CH_2N(C_2H_5)_2]^+$; correct elemental analysis.

14: yield: 55%; b.p. 150 °C oven temperature/1013 mbar; ^{1}H NMR (200.1 MHz, $CDCl_3$, 25 °C, TMS): $\delta = -0.02$ (s, ^2J(H,Si) = 6.4 Hz, 18H; $SiCH_3$), 1.83 (s, 4H; $SiCH_2N$), 2.33 (m, 8H; NCH_2CH_2N); ^{13}C NMR (50.3 MHz, $CDCl_3$, 25 °C, $CDCl_3$): $\delta = -1.1$ (6 C, $SiCH_3$), 50.8 (2 C, $SiCH_2N$), 57.3 (4 C, NCH_2CH_2N); ^{29}Si NMR (39.8 MHz, $CDCl_3$, 25 °C, TMS): $\delta = -1.6$; MS (EI, 70 eV): *m/z* (%) = 258 (20) [M^+], 243 (12) [$M^+ - CH_3$], 229 (2) [$M^+ - CH_3 - CH_2$], 185 (100) [$M^+ - SiCH_3$], 73 (32) $[SiCH_3]^+$; correct elemental analysis.

The synthesis of multimetalated systems is also possible using this reductive bond cleavage. The product of *N*,*N*-bis(lithiomethyl)piperazine **13** entrapped by Me_3SiCl was isolated in 55% yield (Scheme 4). The preparation of further multimetalated, nonstabilized (lithiomethyl)amines is currently under investigation.

Nonstabilized (lithiomethyl)amines can be obtained in high yields by reductive C–S bond cleavage in a two-step synthesis starting from the appropriate amines and starting materials, which are both easily obtainable and inexpensive. These (lithiomethyl)amines can be used as building blocks in further synthesis reactions. The advantages of this method over tin–lithium exchange include the shortening of the synthesis by one step (which utilizes relatively expensive alkyl tin compounds) and the circumvention of chromatographic purification of the



Scheme 4. Synthesis of *N,N'*-bis(trimethylsilylmethyl)piperazine: a) $+4\ LiC_{10}H_8/-4\ C_{10}H_8$; b) $4\ Me_3SiCl/-4\ LiCl, -2\ Me_3SiSPh$.

starting materials. On account of the simple pathway to (phenylthiomethyl)amines and the wide range of applications of the metalation reaction, reductive C–S bond cleavage could develop into an important method for the synthesis of compounds containing the $-CH_2NR_2$ structural unit.

Experimental Procedure

(Phenylthiomethyl)amines: The (phenylthiomethyl)amines were prepared by reported methods [11]. Amines **7a** [14], **7b** [15], **7c** [15], **7d** [11], **8** [16], **9** [7a], and **10** [7] have already been reported.

Preparation of the (lithiomethyl)amines and their reactions: To a freshly prepared solution of lithium naphthalide from lithium granules (694 mg, 100 mmol) and naphthalene (12.8 g, 100 mmol) in 150 mL THF at −78 °C was added (phenylthiomethyl)amine (50 mmol) in 50 mL THF precooled to the same temperature. After 10 min chloro(dimethyl)phenylsilane (**7a–7h**; 17.1 g, 100 mmol), dichlorodiphenylsilane (**11**; 12.7 g, 100 mmol), or chlorotrimethylsilane (**14**; 10.8 g, 100 mmol) was added. The mixture was warmed to room temperature and then subjected to an aqueous workup. After removal of the volatiles in vacuo, the residue was purified by Kugelrohr distillation.

The Existence of Stable $Tm@C_{82}$ Isomers**

Uwe Kirbach and Lothar Dunsch*

Since the discovery of the fullerene synthesis by Krätschmer and Huffman[1] in 1990, the study of endohedral fullerenes is one of the main streams in current fullerene research[2] besides the growing field of chemical derivatization especially of C_{60}. The incorporation of metal atoms into the carbon cage results in an electron transfer from the metal atom to the carbon structure under the formation of a stable ion pair. Because of the steric hindrance by the surrounding fullerene the metal ion cannot leave the carbon cage nor react with other substances. The study of the electron transfer at such "caught" metal cations is a very new field in electrochemical research. Up till now the electron transfer to the carbon cage rather than the intramolecular transfer reactions is the main topic of these studies.

Our recent work concentrated on the preparation of several endohedral fullerenes containing different metals and their characterization by mass spectrometry, cyclic voltammetry, ex situ and in situ ESR, and UV/Vis spectroscopy.[3] New results were obtained by ex situ and in situ ESR spectroscopy on the composition of the fullerene soot extract, the differences in the redox behavior of empty and endohedral fullerenes, and the existence of different paramagnetic states at endohedral fullerenes. As metals, scandium, yttrium, lanthanum, and the rare earth metals cerium, praseodymium, samarium, holmium, thulium, and lutetium were used. In these studies the first successful mass spectrometric proof of the existence of endohedral thulium fullerene in the soot extract was reported.[3]

In this paper it will be demonstrated for the first time that three stable $Tm@C_{82}$ isomers exist, which can be isolated and structurally characterized. These isomers of an endohedral

We are particularly grateful for the special contribution of Dr. Dieter Scheller, TU-Dresden (^{13}C NMR spectra).

fullerene may have a different arrangement of pentagons and hexagons in C_{82} (nine isomers according to Fowler and Manolopoulos[4]) as well as different positions of the metal inside the fullerene cage. The isomers formed in the presented procedure have different symmetry elements and belong to different point groups (Fig. 1). Although different $M@C_{82}$ isomers (M = Sc, Y, La) have been detected by ESR spectroscopy,[5, 6] only two

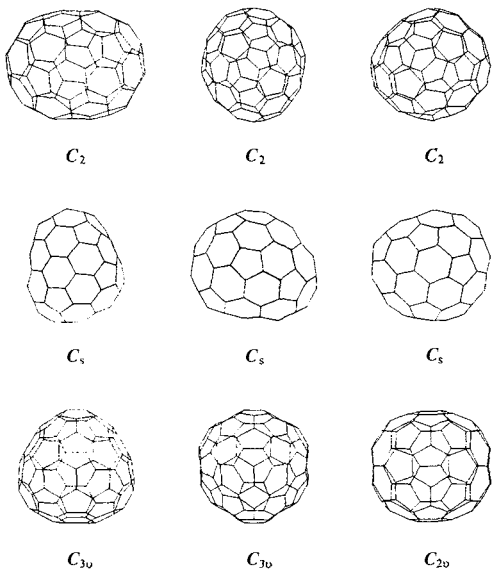

Fig. 1. The nine C_{82} isomers with isolated pentagons according to Fowler and Manolopoulos [4].

$La@C_{82}$ isomers were separated by chromatography.[7] These isomers differ markedly in their electronic properties and their stability in air. This type of isomerism is due to the positional isomerism of the lanthanum ion at the C_{82}, which can be interpreted as an endohedral or an exohedral structure.[8] In contrast the three isomers of the thulium endohedral fullerene have a similiar long-term stability but quite different electronic properties.

The fullerene soot produced by DC arc burning as well as the resulting soot extract had to be studied with high-resolution mass spectrometry as the differences in the mass of $Tm@^{12}C_x$ and $^{13}C^{12}C_{x+1}$ (x = 82, 84, 90, etc.) are very small. As already shown for the other well-known endohedral fullerenes the singly filled C_{82} was the most common structure. Furthermore the new structures $Tm@C_{84}$, $Tm@C_{90}$, $Tm@C_{92}$, $Tm@C_{94}$, $Tm@C_{96}$, $Tm_2@C_{80}$, and $Tm_2@C_{82}$ were found in addition to $Tm@C_{82}$.

By two-step HPLC separation of the soot extract with two different HPLC columns and special stationary phases, three fractions containing $Tm@C_{82}$ were obtained, all of which have the same parent mass peak at m/z 1153. This is the theoretical mass of the structure $Tm@C_{82}$. The analysis of the ^{13}C isotope peaks resulted in a ^{13}C abundance in C_{82} that was equivalent to the natural abundance.

The retention times of $Tm@C_{82}$ fullerenes in the HPLC chromatograms differ substantially from those of other endohedral fullerenes like $Sc@C_{82}$, $Y@C_{82}$, and $La@C_{82}$. The $Tm@C_{82}$ fullerenes are eluted shortly behind the peak for C_{84} in the first HPLC separation step, whereas $Sc@C_{82}$, $Y@C_{82}$, and $La@C_{82}$ appear at the beginning of the C_{88} fraction. This insignificant shift of the $Tm@C_{82}$ retention time relative to that of the empty C_{82} indicates a comparable interaction of thulium-containing fullerene with the stationary phase. The reason for this behavior is the lower electron density of the carbon cage of this endohedral fullerene. The two clearly visible peaks containing $Tm@C_{82}$ in the first separation step (Fig. 2a) split into three peaks **A**, **B**, and **C** containing the three different $Tm@C_{82}$ isomers in the second separation (Fig. 2b). The color of solutions of these isomers in toluene differs markedly even at similiar concentrations. Thus the solution of the isomers **A** is green, that of the isomers **B** yellowish brown, and that of isomers **C** brown-red. The solid samples of all three isomers do not differ and are black or black-brown microcrystalline powders.

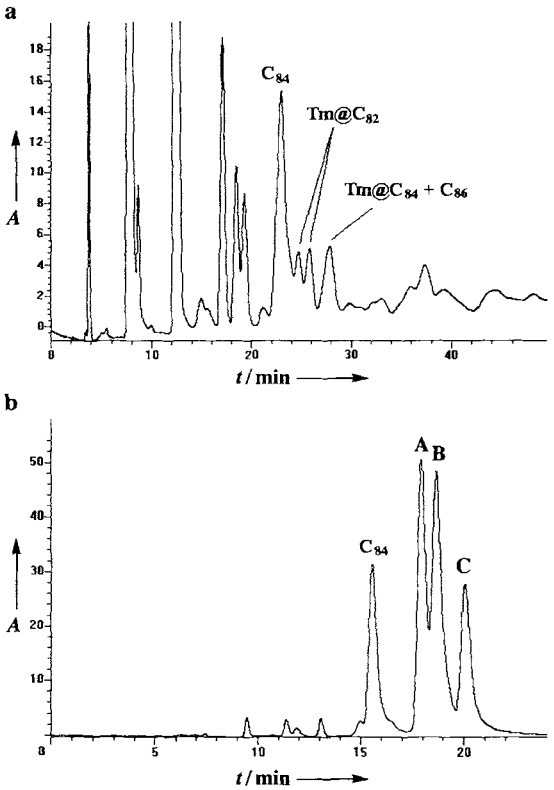

Fig. 2. a) Chromatogram of the preparative HPLC separation of $Tm@C_{82}$ soot extract (Cosmosil Buckyprep column, toluene as eluent, flow rate 10 mL min^{-1}). b) HPLC chromatogram of the preparative separation of a pre-separated thulium fullerene fraction (BuckyClutcher column, mixture of 70% toluene and 30% hexane as eluent, flow rate 2 mL min^{-1}, λ = 330 nm for both separations). For further details see Experimental Procedure. A = absorption in arbitrary units.

The existence of different $M@C_{82}$ isomers was already known and described,[5] but only one isomer seemed to have long-term stability. The concentration of the other isomers decreased rapidly during handling of the solutions in air, which pointed to exohedral fullerenes. By contrast the three $Tm@C_{82}$ isomers under study can be handled in air for several months without significant changes in their properties.

The electronic structure of these three isomers was further characterized by UV/Vis/NIR in toluene solutions, as well as by cyclic voltammetry in *o*-dichlorobenzene solutions. As expected from the different colors of the toluene solutions, the comparison of the UV/Vis/NIR spectra results in large differences especially in the visible absorption. The spectrum of isomer **A** consists of several relatively small absorption bands at 610, 660, 770, 1035, and 1200 nm. In contrast to the spectra of $La@C_{82}$, $Y@C_{82}$, $Ce@C_{82}$, $Pr@C_{82}$, and $Gd@C_{82}$,[9, 10, 11, 12] isomer **A** shows no absorptions between 1200 nm and 1700 nm. The situation changes for the isomer **B** and **C**. The number and intensity of the absorption bands are

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2381 $ 15.00+.25/0

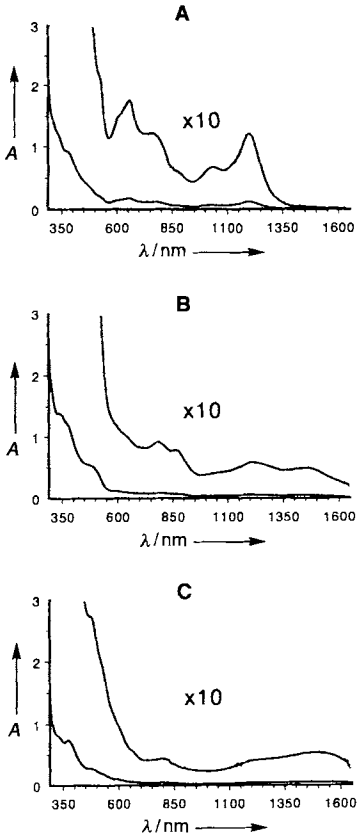

Fig. 3. UV/Vis/NIR spectra of the $Tm@C_{82}$ isomers **A**, **B**, and **C**; $c = 10^{-4}$ mol L^{-1} in toluene, room temperature, A = absorption in arbitrary units.

lower and they broaden. Furthermore new broad absorption bands appear at 1450 nm (**B**) and 1500 nm (**C**) (Fig. 3). Significant differences in the size and the number of the absorption bands are observed between the UV/Vis/NIR spectra of the $Tm@C_{82}$ isomers and the known spectra of $La@C_{82}$, $Y@C_{82}$, $Ce@C_{82}$, $Pr@C_{82}$, and $Gd@C_{82}$. These differences (for instance, several absorption bands at $\lambda < 1200$ nm for the isomer **A**) are due to a pronounced change in structural symmetry of the molecules. A higher symmetry is expected for isomer **A** than for isomers **B** and **C**, which can be explained by the C_{82} structures in Figure 1. The change of the solvent (toluene $\rightarrow CS_2$) causes a 10–15 nm bathochromic shift of the UV/Vis/NIR absorption bands. This confirms the assumption of $\pi-\pi^*$ transitions. Similiar shifts were already found for $La@C_{82}$.[9, 13]

The electron energy levels of the isomers ought to influence the electron transfer. This was tested by voltammetric measurements. The differences in the charge-transfer reactions of the three thulium-containing fullerene isomers parallel those of UV/Vis spectroscopy (Fig. 4). The change of the peak potentials of the two anodic peaks in the potential range between 0 and −350 mV is striking. At first these potentials are shifted to significantly more cathodic potentials than that of the reduction of $La@C_{82}$ and $Y@C_{82}$. Especially the isomer **A** gives peaks only at potentials more negative than −400 mV; that is, in the region where most endohedral fullerenes have two voltammetric peaks, no charge transfer occurs. The analysis of the peak currents led to the conclusion that both voltammetric peaks are attributable to one-electron transfers.

It was therefore appropriate to follow the electron transfer reactions by ESR spectroscopy too. In solution all the three isomers give no ESR signal in the magnetic field between 500 and 9000 G. Dimerization of the isomers, which could result in diamagnetic structures, was excluded by temperature-dependent measurements. The existence of an odd number of electrons at the C_{82} cage is thus less probable if splitting constants for thulium in fullerenes is assumed to be similiar to those in thulium salts. All the tests to produce a paramagnetic state by oxidation or reduction at a platinum electrode and to detect this state by in situ ESR spectroscopy failed. These results and the shift of the retention time $Tm@C_{82}$ relative to that of $La@C_{82}$ prompted us to assume the existence of the divalent $Tm^{2+}@C_{82}^{2-}$. First results of a study under progress on these isomers by ^{13}C NMR spectroscopy confirm this result. Thus the

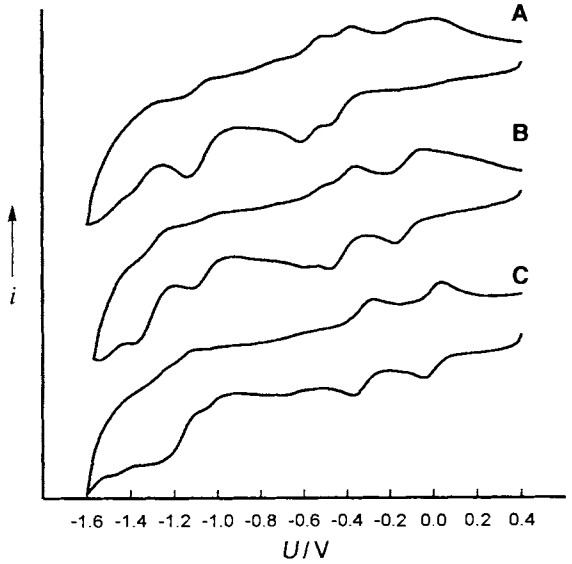

Fig. 4. Cyclic voltammograms of the three $Tm@C_{82}$ isomers **A**, **B**, and **C**; $c = 10^{-4}$ mol L^{-1} in *o*-dichlorobenzene, platinum electrode, scan rate = 100 mV s^{-1}, i = current, U = potential.

NMR spectra of $Tm@C_{82}$ isomers can be measured without any line broadening, which would seem to indicate the absence of an unpaired spin on the C_{82} cage (and consequently an even number of charges on the thulium ion). From energy considerations the +II state of the thulium is the most probable. Since the intensity of the NMR signals was very low despite a ^{13}C enrichment of 10%, 8000 accumulations per sample were required. The ^{13}C NMR measurements confirm the result that the isomer **A** has a higher symmetry than the other two isomers, as its signals were more intense and there were fewer of them. At first sight the number of lines points to a C_{3v} point group for isomer **A**. An assignment of the other isomers was impossible till now because of the low signal-to-noise ratio and the high number of lines, but C_2 or C_s symmetry is expected. The observed shift of the lines of the endohedral isomers relative to that of the empty C_{82} is due to the effect of thulium and/or its 4f magnetism. This effect is known and used in NMR shift reagents containing lanthanides.

The present study on endohedral fullerenes afforded the first preparation and separation of three stable $Tm@C_{82}$ isomers. The spectroscopic study of these new isomers shows remarkable differences between these thulium isomers that are not evident with the endohedral fullerenes of lanthanum, scandium, and yttrium. The electronic structure of the isomers is $Tm^{2+}@C_{82}^{2-}$. The isomerism is due to differences in the symmetry of the three carbon cages, as deduced from ^{13}C NMR measurements. The ^{13}C NMR spectroscopic studies will be continued to improve the resolution of the spectra in larger samples, and longer accumulation times will enable the unequivocal determination of the point groups of the $Tm@C_{82}$ isomers.

Experimental Procedure

The thulium-containing fullerenes were prepared by the arc burning method of Krätzschmer and Huffman [1]. Drilled graphite rods (Elektrokohle Lichtenberg AG, Spektralkohlestäbe TO-E, 6 × 200 mm) were filled with a mixture of thulium powder (Johnson Matthey GmbH/Alfa, 99.9%, smaller than 40 mesh) and graphite (Ringsdorf-Werke GmbH, Spektralkohlepulver RW-A). The thulium-to-carbon ratio used in the arc burning was 1:50. The current density of the arc was 175 A, and the helium pressure in the burning chamber 200 mbar. The resulting soot (4.5 to 5 g per burning) was extracted with CS_2 for 20 hours in a Soxhlet apparatus. The fullerene extract (300–350 mg) was dried and dissolved in *o*-xylene. The content of thulium-containing fullerenes was estimated by mass spectrometry

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2382 $ 15.00+.25/0

to be a maximum of 0.8% of the total amount of fullerenes. The separation of the extract was done by a two-step HPLC method. In the first step a Cosmosil Buckyprep column (20 × 250 mm, Nacalai Tesque Inc.) with a nonpolar stationary phase ([2-(1-pyrenyl)propyl]silyl-silica gel) [14] was used in a preparative HPLC apparatus (M 305, Abimed-Gilson) with toluene as eluent to enrich the $Tm@C_{82}$ fraction (injection volume 5 mL, flow rate 10 mL min^{-1}). The resulting fraction was then separated into the three fractions of the $Tm@C_{82}$ isomers in an analytical HPLC apparatus HP1050 (Hewlett Packard) equipped with a semipreparative Buckyclutcher I column (10 × 250 mm, Regis Chemicals Corp.) filled with a polar stationary phase (Trident-Tri-DNP, flow rate 2 mL min^{-1}, mixture of toluene and hexane (70:30) as eluent).

The contamination of the fractions by empty fullerenes or other $Tm@C_{82}$ isomers was tested by a sector field mass spectrometer MAT 95 (Finnigan, Bremen) and by analytical HPLC after the second separation step. In the mass spectrometric study chemical ionization by methane was used, and the negative ions were detected. The endohedral fullerene content of all three $Tm@C_{82}$ fractions was higher than 97% as measured by mass spectrometry. The isomeric purity of the fullerene fractions determined by HPLC was greater than 90%.

The UV/Vis/NIR measurements were done in toluene with a UV-3101PC spectrometer (Shimadzu). UV/Vis/NIR data: Isomer **A**: λ = 375, 485 (w), 525 (w), 610, 660, 770, 880 (w), 1035, 1200 nm. Isomer **B**: λ = 330, 375, 485, 770, 860, 1200, 1450 nm. Isomer **C**: λ = 375, 485, 525, 800, 1200, 1500 nm. For the electrochemical measurements a potentiostat PAR 273 (EG & G, USA, software PARC M270, version 3.0) and a conventional voltammetric cell were used. The latter was installed in a glovebox to ensure inert conditions (solvent *o*-dichlorobenzene, supporting electrolyte $n-Bu_4NBF_4$; either platinum or glassy carbon working electrode, large platinum sheet counterelectrode, Ag/AgCl reference electrode in the same supporting electrolyte). The in situ ESR technique for electrochemical systems has already been described in detail [15]. The ^{13}C NMR study was done in saturated CS_2 solutions of the three $Tm@C_{82}$ isomers on samples with about 10% ^{13}C enrichment (Bruker spectrometer MSL 300 with external [D_6]acetone lock; number of accumulations: 7940 (isomer **A**), 7950 (isomer **B**), 8500 (isomer **C**); no relaxation reagent).

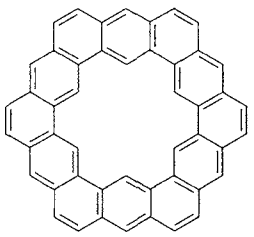
Is Kekulene Really Superaromatic?**

Haijun Jiao and Paul von Ragué Schleyer*

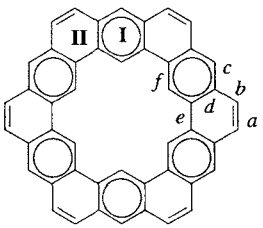
Dedicated to Professor Heinz A. Staab on the occasion of his 70th birthday

The beautiful molecule kekulene (**1**), first synthesized by Diederich and Staab[1] in 1978, is truly a superbenzene aesthetically. The twelve annelated benzene rings comprising a closed cycle also offer the intriguing possibility of enhanced stabilization. But is kekulene really superaromatic in this sense? Even before its synthesis, the electronic structure of **1** was the subject of theoretical debate.[2] The nature of kekulene has remained controversial to the present day.[2–5]

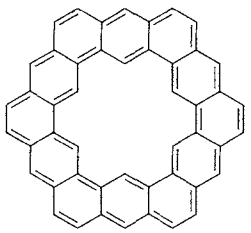
However, unlike benzene, the two principle resonance structures of kekulene are not equivalent. The D_{6h} form **1a** has benzenoid character and can be depicted more clearly by employing the Robinson sextet "circle notation" (**1a'**), whereas its D_{3h} counterpart **1b** is annulenoid. Both the [18]annulene (**2**) inner and the [30]annulene outer moieties in **1b** follow the Hückel ($4n+2$) rule. However, a variety of evidence including X-ray structure, ^1H NMR shifts,[1] and the most recent theoretical treatments[2–5] are inconsistent with the annulenoid formulation **1b**.



1a



1a' (benzenoid, D_{6h})



1b (annulenoid, D_{3h})

Nevertheless, the possible superaromaticity of kekulene has been disputed.[4, 5] Based on rather low-level ab initio calculations using an additive nodal increment method, Cioslowski et al.[4a] estimated the extra stabilization energy of kekulene to be 32.9 kcal mol^{-1} (HF/STO-3G) and 25.4 kcal mol^{-1} (HF/6-31G**) and discussed other evidence alleged to demonstrate the presence of superaromaticity in kekulene. This position was supported more simply based on the "hardness" concept.[4b]

[**] This work was supported by the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, the Volkswagen-Stiftung, and Convex Computer Corporation. We also thank Prof. J. Cioslowski for discussions.

Employing π-electron topological resonance energies, Aihara[5] reached the opposite conclusion: "Kekulene was found to be essentially non-super-aromatic with a small super-aromatic stabilization energy". Is **1a'**, with its semilocalized benzene rings, really the best representation of the bonding situation in kekulene?

We have used the Gaussian 94 program[6] to carry out ab initio and density functional theory evaluations of the superaromaticity of kekulene. Geometries were optimized first at the HF/3-21G level and then with the Becke3LYP/6-31G* functional, which includes dynamic electron correlation. Diamagnetic susceptibilities and diamagnetic susceptibility anisotropies (Becke3LYP/6-31G*) using the Continuous Set in Gauge Transformations (CSGT) method[7] and nucleus-independent chemical shifts (NICS, GIAO-SCF/3-21G)[8] were calculated with the Becke3LYP/6-31G* geometries. The computed energies, magnetic susceptibilities, and magnetic susceptibility anisotropies are summarized in Table 1.

Table 1. Computed total energies (in Hartree) for kekulene and reference molecules as well as CSGT magnetic susceptibilities (χ_{tot}, in ppm cgs) and anisotropies (χ_{anis}) at the Becke3LYP/6-31G*//Becke3LYP/6-31G* level.

Molecule	E (HF/3-21G)	E (Becke3LYP/6-31G*)	χ_{tot}	χ_{anis}
kekulene	−1821.55153	−1843.72103	−403.0	−769.7
anthracene	−533.00347	−539.53060	−114.7	−203.1
phenanthrene	−533.01572	−539.53875	−110.6	−190.5
naphthalene	−381.21581	−385.89279	−80.0	−135.0
1,2:7,8-dibenz-anthracene (**3**)	−836.60869	−846.82625	–	–
benzene	−229.41945	−232.24870	−46.1	−69.8
[18]annulene (**2**)	−688.06697 [a]	−696.64078 [b]	−320.8	−763.7

[a] At the HF/3-21G level, D_{6h} [18]annulene has one imaginary frequency (NIMAG = 1). [b] D_{6h} [18]annulene corresponds to an energy minimum at the Becke3LYP/6-31G* level.

Both HF- and Becke3LYP-optimized C–C bond lengths (Table 2) agree well with the values from the X-ray structure analysis.[1c] Comparison with the geometric parameters of

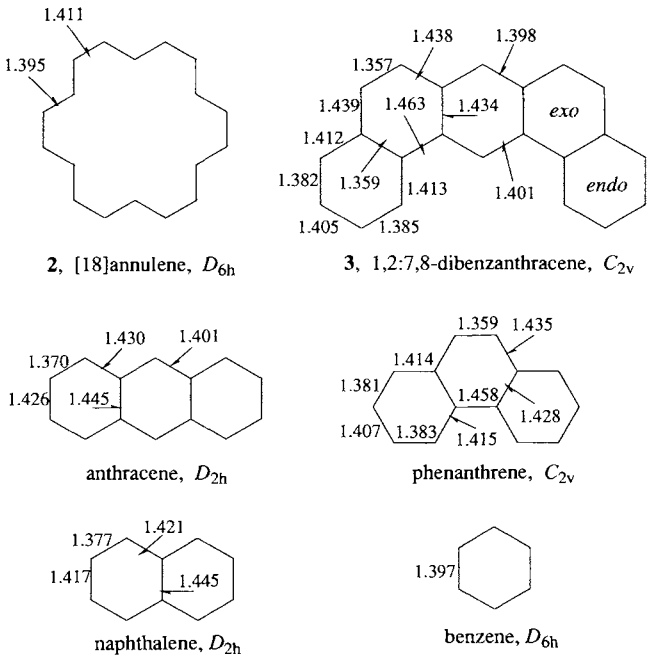
Table 2. Optimized bond lengths (in Å) calculated for kekulene compared with data from its X-ray structure analysis.

Bond [a]	HF/3-21G	HF/6-31G** [b]	Becke3LYP/6-31G*	RSA [c]
a	1.338	1.340	1.362	1.347–1.351
b	1.451	1.453	1.441	1.438–1.449
c	1.392	1.394	1.405	1.391–1.397
d	1.409	1.410	1.429	1.415–1.421
e	1.465	1.466	1.460	1.453–1.461
f	1.381	1.383	1.394	1.381–1.390

[a] The labeling system is shown in formula **1a'**. [b] Ref. [4a]. [c] Ref. [1c].

1,2:7,8-dibenzanthracene (**3**), anthracene, phenanthrene, and naphthalene (Scheme 1) confirms the description of kekulene as benzenoid (**1a**) rather than annulenoid (**1b**) but provides no evidence for superaromaticity. The alternations of the inner (0.066 Å) and outer (0.073 Å) C–C bond lengths in kekulene are larger than those (0.016 Å) in the parent [18]annulene (**2**) (Becke3LYP).

The aromatic stabilization energy (ASE) is a measure of cyclic electron delocalization in a molecule and thus of its aromaticity.[9–12] If kekulene were superaromatic, its ASE would exceed the sum of the values for its smaller benzenoid hydrocarbon



Scheme 1. Aromatic compounds used as references and their Becke3LYP/6-31G*-optimized bond lengths (in Å). Only the C–C bonds are shown.

components significantly. Since kekulene can be viewed as a set of cyclic angularly annelated benzenoid hydrocarbons, benzene, anthracene, phenanthrene, naphthalene, and 1,2:7,8-dibenzanthracene (**3**) have been employed as reference molecules. The extra aromatic stabilization energy can be evaluated simply by the homodesmic Equations (a)–(c).[12]

3[anthracene + phenanthrene − 2 benzene] = kekulene (a)

6[anthracene + phenanthrene − 2 naphthalene] = kekulene (b)

6[1,2:7,8-dibenzanthracene (**3**) − phenanthrene] = kekulene (c)

Based on Equation (a), the Becke3LYP/6-31G*-calculated extra ASE is only −3.3 kcal mol^{-1}, which is much smaller than the estimates made by Cioslowski et al.[4a] Their results were checked at the HF/3-21G level, which is also without dynamic electron correlation. Although the resulting extra ASE of −6.7 kcal mol^{-1} [Eq. (a)] is somewhat larger than the Becke3LYP value, it still is much smaller than Cioslowski's findings.[4a] Based on Equation (b), the extra ASE values are −11.6 kcal mol^{-1} (Becke3LYP/6-31G*) and −16.4 kcal mol^{-1} (HF/3-21G). With the more appropriate 1,2:7,8-dibenzanthracene (**3**) as reference molecule [Eq. (c)], the calculated extra ASE values, 2.5 kcal mol^{-1} (Becke3LYP/6-31G*) and 3.9 kcal mol^{-1} (HF/3-21G), are slightly positive but negligible. These small extra ASE values for such a large system agree with the Aihara's suggestion.[5b] We agree that the 48 π-electron kekulene does not have any appreciable extra stabilization energy and is a normal benzenoid rather than a superaromatic molecule. We thus support the conclusions that had been drawn from the original experimental work.[1b,c]

In addition to these geometric and energetic criteria, we also evaluated the magnetic criteria, specifically the diamagnetic susceptibility exaltation (Λ, ppm cgs), diamagnetic susceptibility anisotropy (χ_{anis}, ppm cgs), and the nucleus-independent chemical shifts (NICS) to characterize the superaromaticity of kekulene (Table 3). Λ, the only measurable property uniquely associated with aromaticity,[9,10,13] is defined as the difference

Table 3. GIAO-SCF NICS (ppm) and calculated magnetic susceptibility exaltations (Λ) for kekulene and reference molecules (Becke3LYP/6-31G* geometries).

Molecule	NICS (3-21G)	NICS (6-31+G* [a])	Λ [b]
kekulene			−227.8

four ring	+23.3	+22.5	
[18]annulene (**2**)	−13.4	–	−232.6

[a] From ref. [8]. [b] Calculated for the entire molecule based on an increment system (at the Becke3LYP-CSGT/6-31G* level). [c] Extra Λ evaluated with Equation (a). [d] Extra Λ evaluated with Equation (b).

between the bulk magnetic susceptibility (χ_M) of a compound and the susceptibility (χ'_M) estimated from an increment system for the same structure without cyclic delocalization ($\Lambda = \chi_M - \chi'_M$).[13] As expected from its aromatic nature and large ring size, kekulene has a large diamagnetic susceptibility exaltation ($\Lambda = -227.8$) and a large diamagnetic susceptibility anisotropy ($\chi_{anis} = -769.7$). Both of these values are close to those for [18]annulene (**2**) ($\Lambda = -232.6$ and $\chi_{anis} = -763.7$). However, if kekulene were superaromatic, both Λ and χ_{anis} would be significantly larger in magnitude than the sum of their values for the reference molecules, anthracene, phenanthrene, naphthalene, and benzene. The extra exaltation of the diamagnetic susceptibility and the extra anisotropy of kekulene can be obtained, like the evaluation of the extra ASE, by using the homodesmic Equations (a) and (b).[14] The negligibly small extra diamagnetic susceptibility exaltations of −3.7 [Eq. (a)] and −11.2 [Eq. (b)] (Table 3) further establish that kekulene is not superaromatic. In addition, the extra χ_{anis} enhancements of kekulene (−7.7 [Eq. (a)] and −28.1 [Eq. (b)]) are very small for a such large molecule.

NICS, a simple and efficient aromaticity probe,[8] is the negative of the absolute magnetic shielding constant, which can be computed easily, for example at ring centers (nonweighted mean of the heavy-atom coordinates of the ring perimeter), at the GIAO-SCF/6-31 + G* level with the Gaussian 94 program.[6] Negative NICS denote aromaticity (e.g. −9.7 for benzene) and positive NICS, antiaromaticity (e.g. 27.6 for cyclobutadiene). Nonaromatic molecules have negligible NICS (−2.2 for cyclohexane and −1.1 for adamantane). The NICS data agree with magnetic susceptibility exaltation (Λ) and serve as an additional criterion of aromaticity.[8] Furthermore, NICS has the advantage of being less dependent on ring size than the magnetic susceptibility exaltation, and can be used to analyze the ring effects of individual rings in polycyclic systems. For example, NICS for the five- (−19.7) and seven-membered (−7.0) rings of azulene resemble those of the cyclopentadienyl anion (−14.3) and the tropylium ion (−7.6). The six-ring aromaticity (−2.5) and four-ring antiaromaticity (22.5) of benzocyclobutadiene are less than the related values of benzene and cyclobutadiene (Table 3).[8]

NICS characterizes the aromaticity of individual rings in kekulene. The smaller 3-21G basis set was used, but as shown in Table 3, the 3-21G NICS values generally are very close to the 6-31 + G* results. If kekulene were superaromatic, the NICS values should be more negative than those of the reference molecules. However, this is not found. The GIAO-SCF/3-21G NICS in ring **I** of kekulene (−10.8) is less negative than that of the central ring in anthracene (−12.9) but close to the NICS of the phenanthrene outer rings (−10.3), naphthalene (−10.0), benzene (−10.0), and the central (−11.6) as well as *endo* rings (−10.1) in 1,2:7,8-dibenzanthracene (**3**). On the other hand, the NICS of the kekulene ring **II** (−4.3) is quite small in magnitude compared with the the values of the outer ring of anthracene (−8.3), the central ring of phenanthrene (−6.8), and with the *exo* rings in 1,2:7,8-dibenzanthracene (−5.4). The positive NICS (5.0) in the center of entire kekulene structure differs very significantly from the negative NICS (−13.4) in the [18]annulene (**3**) center, computed at the same level. These results agree with the ^{1}H NMR shifts for the inner hydrogens in [18]annulene (upfield shifted, $\delta = -3.0$)[15] and in kekulene (downfield shifted $\delta = 10.45$), which like NICS can be attributed to the local ring current effects of the individual rings.[1a] All these results establish kekulene to be a normal benzenoid hydrocarbon and not to be superaromatic.

The standard heat of formation (ΔH_f°) calculated at the Becke3LYP/6-31G* level for benzene (19.5 kcal mol^{-1}) on the basis of the homodesmic Equation (d) agrees with the experimental value of 19.7 ± 0.2 kcal mol^{-1}[16] (note that the zero-point vibrational energy and thermal corrections on ΔH_f° contribute only +0.2 kcal mol^{-1}).[17] Based on the experimental heat of formation[16] of anthracene (55.2 ± 0.5 kcal mol^{-1}), phenanthrene (49.6 ± 0.4 kcal mol^{-1}), naphthalene (35.9 ± 0.4 kcal mol^{-1}), and benzene, ΔH_f° for kekulene is evaluated to be 192.6 kcal mol^{-1} [Eq. (a)] and 186.0 kcal mol^{-1} [Eq. (b)]. These values are somewhat larger than Cioslowski's STO-3G estimate of 182.2 kcal mol^{-1}.

3[1,3-*trans*-butadiene −ethylene] = benzene (d)

In conclusion, the lack of significant equalization of the C–C bond lengths, the extra stabilization energy, the extra magnetic susceptibility exaltation and anisotropy, and the NICS values from the simpler benzenoid models show that kekulene is not superaromatic. The NICS of the individual rings and the fact that the bond length variations in ring **I** (0.035 Å) are smaller than those in ring **II** (0.098 Å) justify the Robinson depiction of kekulene **1a'** as the most realistic single representation of kekulene.

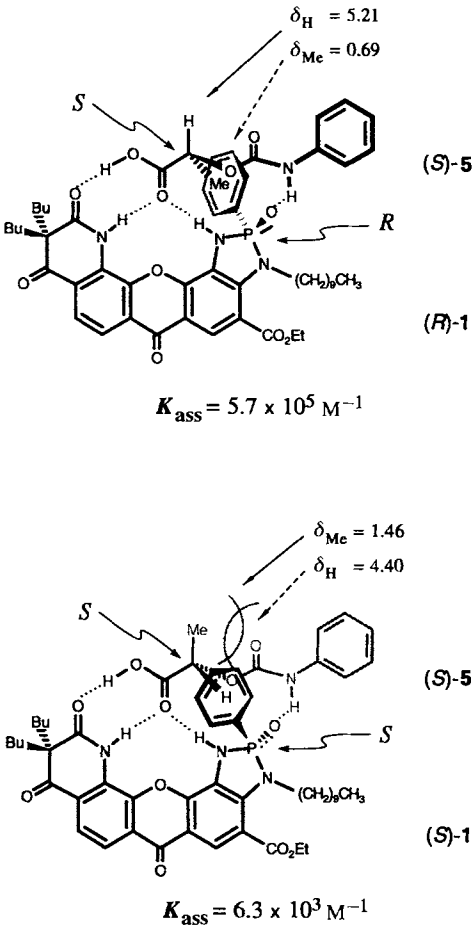
Efficient Recognition of Chiral Carbamoyl-α-Hydroxyacids with a Cleft-Type Receptor**

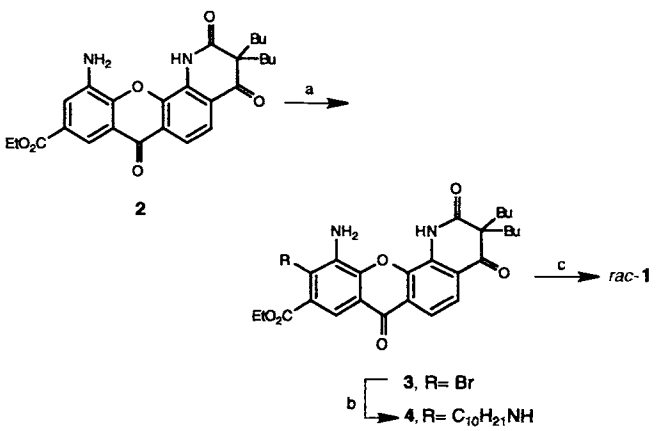
Mercedes Martín, César Raposo, Marta Almaraz, Mercedes Crego, Cruz Caballero, Manuel Grande, and Joaquín R. Morán*

Efficient recognition of small, chiral organic molecules is still a challenge for organic chemists.[1] Recognition of α-substituted chiral carboxylic acids is difficult because the chiral centers of the guest and those of the host are usually far apart. This drawback, already pointed out by Rebek, Jr., et al.,[2] can be overcome in receptor **1** by making use of a suitable xanthone spacer,[3] which provides functional groups for forming additional hydrogen bonds with an α-functionalized carboxylic acid as the guest (Scheme 1).



Scheme 1. Complexes formed by receptors (*R*)-**1** and (*S*)-**1** and the guest (*S*)-**5**.

Compound **1** was obtained as a racemic mixture from the known xanthone **2**[3] (Scheme 2). Carbamoyllactic acids should be good guests for this receptor (Scheme 1), and molecular models indicate that complexes of **1** and **5** should display chiral discrimination. When host and guest have different



Scheme 2. Synthesis of *rac*-**1**. a) $Br_2/CHCl_3$, −20 °C (75%); b) $CH_3(CH_2)_9NH_2$, 170 °C (65%); c) $PhPOCl_2/PhBr$, 130 °C (90%).

configurations ((*R*,*S*) and (*S*,*R*) complexes), four linear hydrogen bonds can form without steric hindrance. In contrast, in the (*R*,*R*) and (*S*,*S*) complexes the methyl group of the lactic acid unit collides with the carbamate carbonyl group, thus weakening the fourth hydrogen bond between the carbamate NH group and the phosphoryl oxygen atom (Scheme 1, bottom).

Experimental data confirmed these predictions. When increasing amounts of (*S*)-**5** were added to a solution of *rac*-**1** in $CDCl_3$, ^1H NMR signals of receptor **1** were split as expected for the formation of two diastereomeric complexes.[4] Initial attempts to assess the relative stability of the two complexes by plotting the ^1H NMR shifts of the receptors against each other[5] indicated an association constant ratio greater than twenty. This result suggested that formation of the complex can be used to separate the enantiomers of the receptor.[6] Neither the host nor the guest are eluted separately by TLC on silica gel plates with CH_2Cl_2/Et_2O (99/1) as eluent. However, under these conditions using TLC plates impregnated with (*S*)-**5** (1% in Et_2O), the bright yellow enantiomeric receptors were easily separated (R_f((*R*)-**1**) = 0.8, R_f((*S*)-**1**) = 0.1). This large difference in R_f values can be explained because the complex is a closed structure in which all hydrogen bond donors are saturated, and it thus has a low affinity for silica gel. Host–guest association therefore offers a way in which the receptor can be eluted with solvents of low polarity. However, this mechanism is only very efficient in the case of the (*R*) host due to its large association constant with (*S*)-**5**; the less stable complex with the (*S*) host has only a slightly increased R_f.

Both preparative TLC and Pirkle-type column chromatography[7] on SiO_2 impregnated with (*S*)-**5** provide an easy way to isolate the complexes of the enantiomeric receptors **1**. Decomplexation was accomplished either by washing an ethereal solution of the complex with aqueous sodium carbonate, by conventional chromatography on SiO_2 with petroleum ether/EtOAc (1/1) as eluent, or by crystallization from methanol, in which the (*S*)-**5** remains in the solution. The receptors isolated are enantiomerically pure (m.p. 102–105 °C; (*R*)-**1**: $[\alpha]_D = -180$ ($c = 0.55$ in $CHCl_3$); (*S*)-**1**: $[\alpha]_D = +176$ ($c = 0.60$ in $CHCl_3$).

Owing to the presence of two independent aromatic chromophores in the receptor **1**, the absolute configurations could be confirmed by CD spectroscopy by applying the exciton chirality method.[8] The xanthone moiety (complex absorption bands at λ_{max} (ε) = 347 nm (ca. 10000; ^1L_b); 236, 252, 271 (ca. 21000, ^1L_a)) interacts with the phenylphosphonic group (absorption band at λ_{sh} = 235 nm) to give rise to bisignate bands with a split Cotton effect (Davidov splitting) around 280 and 240 nm (Fig. 1). The second is stronger because the absorption bands are more intense and closer to each other. In fact, the CD spectrum of the *dextro* host shows two bisignate bands at 296/265 nm ($\Delta\varepsilon = +13/-5$) and 246/228 nm ($\Delta E = +22/-20$; Fig. 1), which is in accord with a positive dihedral angle between the xanthone and the phenyl axis and corresponds to an (*S*) configuration at the chiral phosphorus atom (see insert in Fig. 1).

A strong anisotropic effect in the (*R*,*S*) complex also supports these assignments. The ^1H NMR signal of the methyl group in complexed (*S*)-**5** ($\delta = 0.69$) is shifted upfield by $\Delta\delta = 0.88$ relative to the analogous signal of the free guest ($\delta = 1.57$); this implies that the methyl group is fixed in the shielding cone of the phosphorus phenyl ring (Scheme 1). A similar shielding effect for the signal of the α-H of the lactic unit in the (*S*,*S*) complex ($\Delta\delta = 0.78$; shift from $\delta = 5.18$ to $\delta = 4.40$) suggests that the main difference in the geometry of the diastereomeric associates is the position of the hydrogen atom and the methyl group of the guest (Scheme 1).

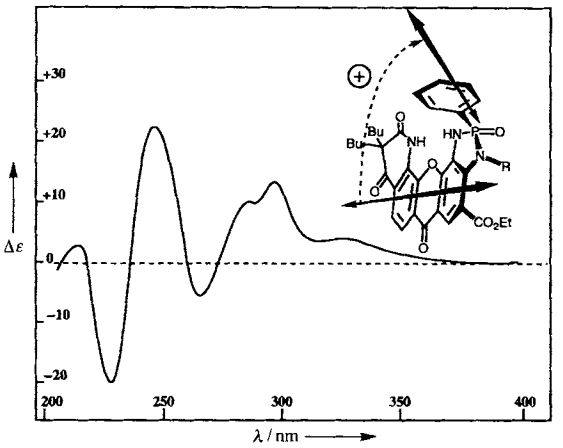

Fig. 1. CD spectrum of the receptor (*S*)-**1**.

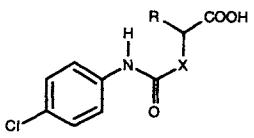
Conventional NMR titration of these receptors with (*S*)-**5** is not an accurate method for quantifying the chiral discrimination. Only the association constant of the weak (*S*,*S*) complex ($K_{ass} = 6.3 \times 10^3\ M^{-1}$) lies in the range that can be measured with the NMR method,[9] whereas the strong (*R*,*S*) associate shows a value above $10^5\ M^{-1}$. Competitive titration, however, can be used to estimate this large association constant; a scale can be constructed (Table 1) which is similar to the reactivity scales developed by Huisgen.[10]

To apply this method, complexes with stabilities lying between those of the previously discussed diastereomeric associates are necessary. Competitive NMR titrations[11] were carried out with 10^{-2} M $CDCl_3$ solutions of both guests. Increasing amounts of a 5×10^{-2} M stock solution of optically pure host **1** were added until saturation was achieved. The proton shifts of the enantiomeric guests were plotted against each other, and the ratios of the association constants were calculated by making use of a Monte Carlo nonlinear curve-fitting method.

Guests **6**–**8** were tested (Table 1). The phenyl ring in (*S*)-carbamoylmandelic acid (*S*)-**6** slightly hinders complex formation



5, R = Me, X = O
6, R = Ph, X = O
7, R = Me, X = NH
8, R = Ph, X = NH

and a competitive titration provides an association constant that is 2.3 times less than that measured for (*S*)-**5**. However, this new complex is still too strong for a precise value to be obtained

Table 1. Association constants of the complexes between guests **5**–**8** and receptor **1** (in $CDCl_3$, 20 °C).

Host/guest complex [a]	K_{ass} [M^{-1}]	K_{ass} ratio
[(*R*)-**1**·(*S*)-**5**]	5.7×10^5 [b]	2.3
[(*R*)-**1**·(*S*)-**6**]	2.5×10^5 [b]	
[(*R*)-**1**·(*S*)-**7**]	6.4×10^4 [c, d]	3.9
[(*R*)-**1**·(*S*)-**8**]	5.8×10^4 [c, d]	
[(*R*)-**1**·(*R*)-**5**]	6.3×10^3 [d]	1.3 / 12 / 13 / 21
[(*R*)-**1**·(*R*)-**6**]	4.7×10^3 [d]	
[(*R*)-**1**·(*R*)-**7**]	3.1×10^3 [b]	

[a] Data for only one of the enantiomeric complexes is given. [b] From competition experiments. [c] Average from direct measurement and competition experiments. [d] Direct titration.

in direct NMR measurements. Steric interactions between the receptor phosphorus atom and the NH of amino acid derivatives lead to further reduction in complex stability. Urea derivatives of (*S*)-alanine and (*S*)-phenylglycine, (**7** and **8**, respectively), have association constants of $K_{ass} = 6.4 \times 10^4\ M^{-1}$ and $5.8 \times 10^4\ M^{-1}$, respectively. Due to its better association, the (*S*)-alanine derivative (*S*)-**7** was selected for competitive titration against (*S*)-**6** ($K_{ass}((S)\text{-}\mathbf{6})/K_{ass}((S)\text{-}\mathbf{7}) = 3.9$). The association constant of [(*R*)-**1**·(*R*)-**6**] could be readily measured by standard NMR titration ($K_{ass} = 4.7 \times 10^3\ M^{-1}$). Competitive titration between (*R*)-**6** and (*S*)-**7** afforded $K_{ass}((S)\text{-}\mathbf{7})/K_{ass}((R)\text{-}\mathbf{6}) = 13$, a ratio that, within the experimental error, confirms the previously measured value for the association constant of compound **7**.

From the above values the association constant for [(*R*)-**1**·(*S*)-**5**] was calculated to be $K_{ass} = 5.7 \times 10^5\ M^{-1}$ (Table 1). This indicates that the chiral recognition displayed by these complexes is the best in this series: $K_{ass}((R)\text{-}\mathbf{1})/K_{ass}((S)\text{-}\mathbf{1}) = 90$. With (*S*)-**6** this ratio is reduced to 53.

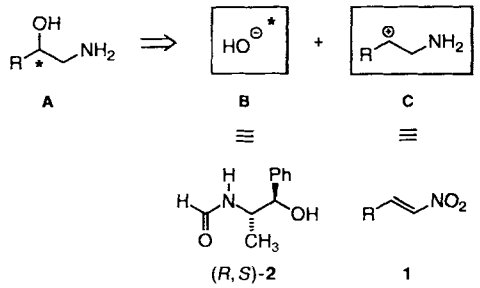
Enantioselective Synthesis of Vicinal Amino Alcohols by Oxa-Michael Addition of (−)-*N*-Formylnorephedrine to Nitroalkenes**

Dieter Enders,* Andreas Haertwig, Gerhard Raabe, and Jan Runsink

Enantiomerically pure 1,2-amino alcohols **A** are characteristic structural features of many natural products and drugs, and play an important role as chiral building blocks, auxiliaries, and ligands in transition metal catalyzed reactions.[1] They can be prepared from amino acids (for example, from the chiral pool), by resolution, or by asymmetric synthesis. Numerous diastereo- and enantioselective syntheses have been described that lead to vicinal amino alcohols for example by C–C[2] or C–N bond formation,[3] aminohydroxylation,[4] or indirectly by hydroboration of enamines.[5]

An alternative retrosynthetic analysis leads to a hydroxide synthon **B** and a β-amino cation synthon **C** by disconnection of the C–O bond. The oxa-Michael addition[6, 7] of a chiral synthetic hydroxide equivalent with a removable auxiliary, like (−)-(1*R*,2*S*)-*N*-formylnorephedrine ((*R*,*S*)-**2**), to (*E*)-nitroalkenes (**1**, as equivalents for **C**) should open a new enantioselective pathway to the title compounds **A**.



Interestingly, the oxa-analogous Michael addition was published in 1878 by F. Loydl in his work about the synthesis of malic acid from fumaric acid,[8] five years earlier than the discovery of the actual Michael reaction by Komnenos, Claisen, and Crismer. After further early work,[9] some groups tried later to find a diastereo- and enantioselective version of this reaction.[10] Some intermolecular oxa-Michael additions in which the chirality information is contained in the acceptor,[11] as well as several enzymatic variants[12] are already available. Diastereoselective intramolecular oxa-Michael addition is widely used in natural product synthesis.[13] To the best of our knowledge, the enantioselective intermolecular oxa-Michael addition with removable chirality information in the oxygen-containing nucleophile has not been reported. We have now succeeded in developing such an asymmetric oxa-Michael addition, by which vicinal amino alcohols are prepared with high asymmetric induction and in good yields by using an enantiomerically pure alcoholate.

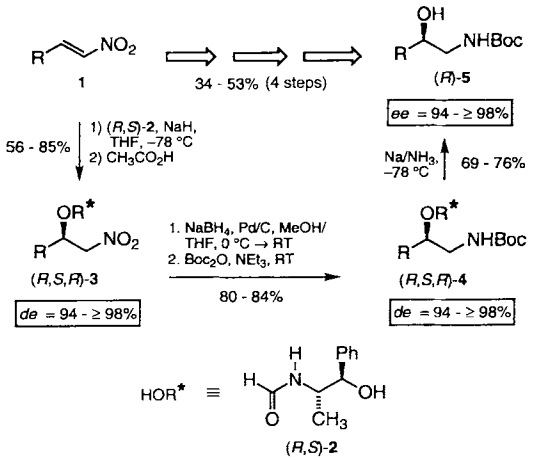
The alcoholate is obtained from (−)-(1*R*,2*S*)-*N*-formylnorephedrine ((*R*,*S*)-**2**)[14] by reaction with sodium hydride. It reacts highly diastereoselectively (*de*: 93 to ≥98%) at −78 °C with the (*E*)-nitroalkenes **1a–e** to give the nitro ethers **3a–e** in good yields (60–87%) (Table 1, Scheme 1). Virtually diastereomerically pure products (*de*: 96 to ≥98%) can be obtained for (*R*,*S*,*R*)-**3a–c** by using flash chromatography.

Table 1. Yields, diastereomeric excesses, and rotational values of the nitro ethers (*R*,*S*,*R*)-**3** obtained by asymmetric conjugated hydroxylation.

(*R*,*S*,*R*)-**3**	R	Yield [a] [%]	*de* [a, b] [%]	$[\alpha]_D^{24}$ (*c*, $CHCl_3$)
a	Me	60 (56)	94 (≥96)	−128.8 (1.1)
b	Et	75 (72)	93 (97)	−136.3 (1.1)
c	*i*Pr	87 (84)	96 (≥98)	−130.5 (1.0)
d	*t*Bu	67 [c]	≥98 [c]	−106.6 (1.5)
e	*c*Hex	85 [c]	94 [c]	−155.1 (1.1)

[a] Values in parentheses obtained after separation of the diastereomers by column chromatography (SiO_2, ether or ether/hexane 2/1 up to 1/1). [b] The *de* values are obtained by ^1H NMR spectroscopy (**3a**,**e** 300 MHz; **3b–d** 500 MHz). [c] After purification by column chromatography (SiO_2, ether/hexane 3:1), separation of the diastereomers **3e** was not possible.



Scheme 1. Enantioselective synthesis of 1,2-amino alcohols **5**.

The preferred conformation in solution and hence the relative and absolute configuration of the newly formed stereogenic center can be determined by comparison of the ^1H NMR spectra of both diastereomers—NOE measurements, coupling constants, and ring current effects—to be (*R*) in the case of the major diastereomer and to be (*S*) for the minor diastereomer. These results were confirmed by the X-ray structure determination of (*R*,*S*,*R*)-**3b** (Fig. 1).[15]

The reduction of the nitro group to the amino function is carried out with sodium tetrahydridoborate and a Pd/C catalyst in methanol/THF (1:1); the hydroxylamine is the intermediate product.[18] The introduction of the Boc protecting group is carried out in the methanol-enriched solvent with di-*tert*-butyldicarbonate (Boc_2O) and triethylamine; the isolation of the free amine is unnecessary. The N-Boc-protected amino ethers **4a–e** are obtained after flash chromatography in good yields (80–84%).

The cleavage of the ethers with sodium in liquid ammonia at −78 °C leads to the protected amino alcohols **5a–e** without racemization and in good yields (69–75%).[19] The reaction must be stopped after 15 minutes to avoid loss of products by

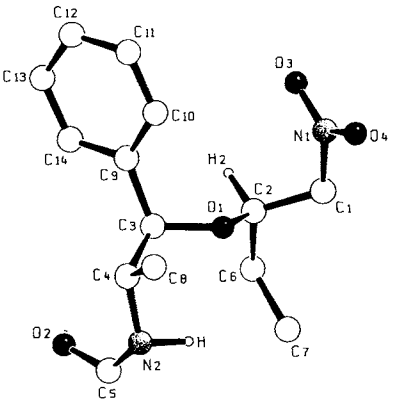


Fig. 1. Structure of the nitro ether (*R*,*S*,*R*)-**3b** in the crystal (Schakal plot) [17].

side reactions. The auxiliary is reduced to (*S*)-*N*-formylamphetamine during the ether cleavage and can be recovered. The overall yield of this procedure is 34–53% over four steps with high enantiomeric excesses (*ee*: 94 to ≥98%; Table 2).

Table 2. Yields, diastereomeric excesses, and rotational values of the *N*-Boc-protected amino alcohols **5**, and the yields of the *N*-Boc-protected amino ethers (*R*,*S*,*R*)-**4**.

[a] Determined by ^1H NMR spectroscopy with (−)-(*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol as cosolvent. [b] Determined by GC analysis on a chiral stationary phase (heptakis(2,3,6-tri-*O*-methyl)-β-cyclodextrin/polysiloxane, 25 m × 0.25 mm) and by ^1H NMR spectroscopy with (−)-(*R*)-1-(9-anthryl)-2,2,2-trifluoroethanol as cosolvent. [c] Determined after conversion to the corresponding esters with MTPA (Mosher's reagent) by ^1H NMR spectroscopy [20].

In summary, the described asymmetric oxa-Michael addition under conjugate nucleophilic hydroxylation of (*E*)-nitroalkenes opens a new efficient entry to virtually enantiomerically pure vicinal amino alcohols. Since the chiral ephedra alkaloid norephedrine is readily available, it is possible to synthesize both enantiomers of vicinal amino alcohols and thus broadly applicable chiral building blocks.[21]

Experimental Procedure

(−)-(*R*,*S*,*R*)-**3a–e**: A solution of (−)-*N*-formylnorephedrine (215 mg, 1.2 mmol) in THF (15 mL) was added at room temperature to a suspension of sodium hydride (24 mg, 1 mmol) in THF (10 mL). This suspension was cooled to −78 °C and the (*E*)-nitroalkene **1a–e** (1 mmol) in THF (1 mL) was added (the reaction was monitored by TLC). The reaction was stopped after 24–96 h by quenching with glacial acetic acid and then allowed to warm up to room temperature. After aqueous work-up, extraction with ether (4 × 20 mL), washing with saturated $NaHCO_3$ (aq), and drying with Na_2SO_4, yellow, oily crude products were obtained that could be purified by flash chromatography (SiO_2, ether or ether/hexane 3/1 up to 1/1) to give colorless oils (*R*,*S*,*R*)-**3c**,**d** or solids (*R*,*S*,*R*)-**3a**,**b**,**e**.

(*R*,*S*,*R*)-**4a–e**: To a suspension of nitro ether **3** (1 mmol) and Pd/C (50 mg, 10%) in methanol/THF (1/1, 20 mL), $NaBH_4$ (151 mg, 4 mmol) was added at 0 °C. The reaction mixture was kept at this temperature for 2 h and then allowed to warm up to room temperature and stirred for 3 d. The Pd/C catalyst was removed by filtration over Celite and washed with methanol (30 mL). Boc_2O (218 mg, 1 mmol) and triethylamine (5 mL) were added to this solution (monitored by TLC). After 1–2 h, the solvent was removed and the residue was dissolved in CH_2Cl_2, washed with water and brine, and dried with Na_2SO_4. After removal of the solvent, the obtained

crude oils were purified by flash chromatography (SiO_2, ether/hexane 1/1 up to 1/3). (*R*)-**5a**–**e**: Sodium (58 mg, 2.5 mmol) was added to liquid ammonia (25 mL) at −78 °C. Then the *N*-Boc-protected amino ether **4a**–**e** (1 mmol) in THF (10 mL) was slowly added. After 15 min the reaction was stopped by addition of saturated NH_4Cl (aq) at −78 °C. After removal of the ammonia, the residue was dissolved in CH_2Cl_2 and dried with Na_2SO_4. The solvent was removed and the crude product purified by flash chromatography (SiO_2, ether/hexane 1/1 up to 2/1) affording the compounds **5** as colorless liquids (**5a**–**c**) or solids (**5d**,**e**). The (*S*)-*N*-formylamphetamine can also be isolated in yields of 70–75%.

[15] Suitable crystals were obtained from ether/hexane mixtures at room temperature: monoclinic, space group $P2_1$ (no. 4), $a = 7.392(1)$, $b = 8.984(6)$, $c = 12.202(1)$ Å, $\beta = 106.728(6)°$; $V = 776.04$ Å^3, $Z = 2$, $M_{calc.} = 280.33$, $\rho = 1.200$ g cm^{-3}. Total number of electrons per unit cell is 300. The data were collected on an Enraf-Nonius CAD4-diffractometer, $Mo_{K\alpha}$ radiation (graphite-monochromator, $\lambda = 0.71069$ Å). The structure was solved by direct methods (GENSIN, GENTAN from XTAL3.2 [16]). The positions of the hydrogen atoms were calculated in ideal positions. 1576 observed reflections [$I > 2\sigma(I)$], 181 parameters refined, $R = 0.053$ ($Rw = 0.034$). Maximum residual electron density ± 0.3 e Å^{-3}. The configuration of C2 was obtained by using the known configuration of C3 and C4. Crystallographic data (excluding structure factors) for the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-179-91. Thiolate Bridged Nickel–Iron Complexes Containing both Iron(0) and Iron(II) Carbonyls**

Chia-Huei Lai, Joseph H. Reibenspies, and Marcetta Y. Darensbourg*

The impressive synergism developed in the last decade between synthetic inorganic and biophysical chemists with regard to understanding the function and spectroscopic signature of nickel in [NiFe] hydrogenase has gained even more momentum by the report of a protein X-ray crystal structure in 1995.[1] Crystals isolated from *Desulfovibrio gigas* in a mixture of inactive (oxidized) and ready enzymatic states were investigated. The electron density around nickel was interpreted as a two-cysteine-bridged Ni–Fe bimetallic active site, which has a Ni–Fe distance of 2.7 Å and is removed by more than 6 Å from the closest Fe_4S_4 cluster in the electron

transport chain.[1] Two other cysteine sulfur atoms about nickel complete the pseudo-square-pyramidal coordination in which the basal position is partially occupied by an undetermined ligand forming a bridge to the iron. Additional intrigue arises from the remaining groups about the octahedral iron in the bimetallic site; they are not protein donors but rather exogenous ligands. These terminal ligands on iron were modeled as water in the initial resolution of the structure, but were later suggested to refine better as diatomics.[2, 3] In view of the results of other physical techniques whose interpretation does not require the presence of such a unique iron,[4, 5] the possibility that FeL_3 arises as an artifact introduced during the isolation or crystallization of the protein cannot be overlooked. On the other hand, the potential of diatomic ligands existing in the active site of the [NiFe] hydrogenase from *Chromatium vinosum* was demonstrated by infrared spectroscopic results from Woodruff et al. in 1994.[3]

While the controversy regarding this unexpected NiFe active site mandates additional structure determination of the enzyme isolated in pure states, increasing evidence suggests that bimetallic and heterobimetallic active sites in enzymes are *not* uncommon.[6] Hence, small molecule analogs are desired as evidence of what is *chemically possible*, either in nature's design or as artifacts, and as well-characterized prototypes for spectroscopic signatures.[7] In fact, there are few bimetallic NiFe complexes reported in the literature and, to our knowledge, no carbonyl derivatives.[8, 9] Herein we report results of the synthesis of such a target molecule in which both a reduced and an oxidized form of a NiFeCO complex were discovered. Since the role of redox chemistry in [NiFe] hydrogenase activity is pivotal, these complexes were deemed worthy of detailed examination.

The S-metalation of the N,N,S,S.-coordinated nickel (II) complex **1**[10] [see Eq. (a)] has produced a number of polynuclear complexes, which have been used to demonstrate the effect of S-charge neutralization on the accessibility of the Ni^{II}/Ni^{I} couple within the NiN_2S_2 coordination sphere.[11] The structure of the dimeric $[\{(\mathbf{1})FeCl_2\}_2]$ complex (Fig. 1)[8] shows a resemblance to the purported NiFe active site,[1] although the Ni–Fe distance of 3.1 Å is 0.4 Å longer than that in the [NiFe] hydrogenase structure. Furthermore, $[\{(\mathbf{1})FeCl_2\}_2]$ lacks a third ligand present in partial occupancy in the $[NiFe]H_2$-ase structure as a Ni–Fe bridge.[1] Since attempts to replace the chloride ligands with CO or thiolates were unsuccessful, the direct route to NiFe carbonyls shown below was developed.

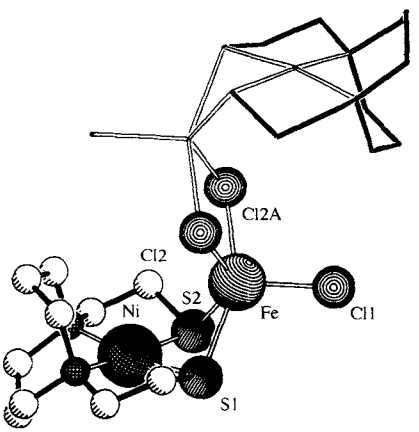

Fig. 1. PLUTON representation [21] of $[(\mathbf{1})FeCl_2]$ in the crystal [8]. Cl2 and Cl2A are bridging atoms to a second Ni–Fe unit.

On stirring a 2:1 mixture of **1** and $[Fe_2(CO)_9]$ in CH_3CN overnight at 22 °C, a moderately air-sensitive, red-brown solid precipitated [Eq. (a)]. After extraction with THF and concentration in vacuo, a crystalline compound analyzed[12] as $[(\mathbf{1})Fe(CO)_4]$ (**2**) was obtained in 70% yield by hexane diffusion into the THF solution. The $\tilde{\nu}_{CO}$ IR bands in the solution spectrum of **2**[13] are indicative of pseudo-C_{3v} symmetry about Fe [$2A_1 + E$ (split)], perturbed due to an asymmetric ligand in the axial position.[14a] Comparison with IR data of several $[LFe(CO)_4]$ complexes shows that the ligand in **1** is a σ-donor, similar to an anionic thiolate; lower $\tilde{\nu}_{CO}$ values than for ligation with thioethers or PPh_3 are observed.[13–15] This conclusion is supported by the observed CO lability of **2** which is similar to that of $[PhSFe(CO)_4]^-$.[14] For example, when THF solutions of **2** were exposed to ^{13}CO, changes in the IR spectra suggest a 50% incorporation of the labeled ligand within a few hours. The complicated spectrum indicative of multiple CO substitution reverted to the parent spectrum on removal of the ^{13}CO and replacement with a ^{12}CO atmosphere. In contrast to the CO lability, the metallothiolate ligand **1** is very slowly displaced ($t_{1/2}$ of days) from **2** by excess PPh_3 or CO at 22 °C.

The reaction of **2** and the single electron oxidant $NO(BF_4)$ in THF solution immediately led to a precipitate from which two compounds have been recovered and identified [Eq. (b)]. The red-black crystalline $[(\mathbf{1})_2Ni]^{2+}$ (10% yield of isolated product) is the result of thiolate sulfur oxidation to disulfide with loss of Ni^{2+} from one molecule of **1**. Free Ni^{2+} is known to nucleate two units of **1** rapidly and quantitatively.[16] The moderately air-sensitive, red-brown crystalline $[(\mathbf{1})_2Fe(CO)_2](BF_4)_2$ (**3**) arises from a two-electron oxidation at Fe^0 (yields ranged from 5% to 14%). These products were separated by fractional crystallization through diffusion of ether into CH_3CN solutions. Elemental analysis and $\tilde{\nu}_{CO}$ IR data[17] are consistent with the X-ray crystal structure of **3** (vide infra). In the presence of cobaltocene as reducing agent, carbon monoxide reacts with $[(\mathbf{1})_2Fe(CO)_2]^{2+}$ to re-form the Fe^0 complex **2** (eq. b); no reaction with CO occurs in the absence of a reductant.

The molecular structures of **2** and $[(\mathbf{1})_2Fe(CO)_2]^{2+}$ are shown in Figures 2 and 3, respectively.[18–21] The $Fe(CO)_4$ fragment of **2** is an almost regular trigonal bipyramid; square-planar **1** serves as a monodentate axial ligand. The $[(\mathbf{1})_2Fe(CO)_2]^{2+}$ complex is pseudo-octahedral with *cis* carbonyls and bidentate **1** thiolate ligands. The average Fe–S distance in $[(\mathbf{1})_2Fe(CO)_2]^{2+}$ is virtually the same as that of **2** and almost identical for that of $[PhSFe(CO)_4]^-$ (2.332(5) Å).[15] Consistent with earlier findings that Ni–S distances in **1** are fairly invariant with S-site modifications,[11] the two Ni–S distances of **2** are within the error limits indistinguishable from each other, from those of $[(\mathbf{1})_2Fe(CO)_2]^{2+}$, and from those of free **1** (2.16 Å).[10]

The most striking geometric variations in the structures of Ni–Fe heterometallics lie in the Ni···Fe distances. When compounds such as **1** and the similar Ni(dmpn)[22] (dmpn = *N,N'*-dimethyl-*N,N'*-bis(2-mercaptoethyl)-1,3-propanediamine) serv-

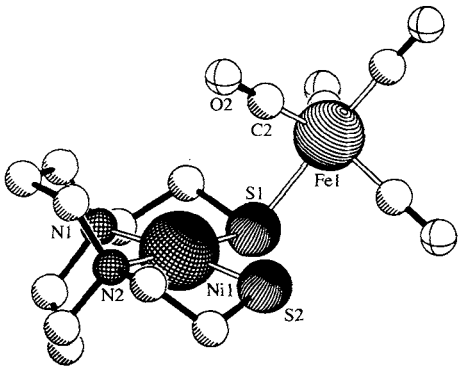

Fig. 2. Structure of **2** in the crystal. Selected distances [Å] and angles[°]: Ni···Fe 3.76(1), Ni-S1 2.172(4), Ni-S2 2.162(4), Ni-N1 1.996(1), Ni-N2 1.971(8), Fe-S1 2.332(4), Fe···S2 3.96(1), Fe-C1 1.77(2), Fe-C2 1.782(13), Fe-C3 1.754(13), Fe-C4 1.75(2), Fe-S1-Ni 113.37(14), S1-Fe-C4 175.4(4), S1-Fe-C2 89.3(4), S1-Ni-S2 90.3(2), S2-Ni-N(2) 90.8(3), N1-Ni-N2 89.7(4).

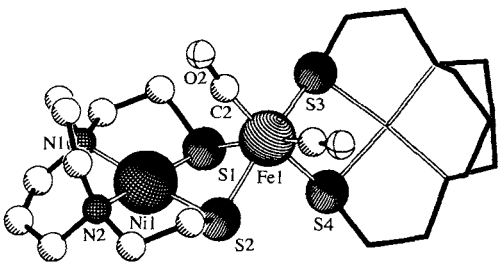

Fig. 3. Structure of the $[(1)_2Fe(CO)_2]^{2+}$ ion in the crystal. Selected distances [Å] and angles[°]: Ni1···Fe 3.088, Ni2···Fe 3.103, Ni1-S1 2.159(2), Ni1-S2 2.149(2), Ni1-N1 1.957(6), Ni1-N2 1.953(6), Fe-S1 2.345(2), Fe-S2 2.302(2), Fe-C1 1.769(8), Fe-C2 1.785(9), Fe-S1-Ni1 86.99(7), Fe-S2-Ni1 88.33(8), Fe-S3-Ni2 87.65(7), Fe-S4-Ni2 86.32(7), S1-Fe-S2 76.99(7), S2-Fe-C2 100.4(3), C1-Fe-C2 91.2(4), S1-Ni1-S2 84.39(7), S2-Ni1-N2 92.7(2), N1-Ni1-N2 89.5(2).

ing as *cis*-dithiolate, *bidentate* ligands to iron(II), this value lies in the range of 3.0–3.1 Å for the three known Ni–Fe^{II} compounds. For *monodentate* coordination of these same metallothiolates, Ni···Fe distances may vary substantially because of twisting of the planar NiS_2 unit away from the Fe center. In the case of **2** the large nonbonding Fe···S(2) distance of 3.961(4) Å correlates to a Ni–Fe distance of 3.76(1) Å and a Ni-S-Fe angle of 113°. For monodentate binding of the Ni(dmpn) ligand to Fe^{II} in $[\{(dmpn)Ni\}_3Fe^{II}]$, the analogous Ni···S (nonbonding) distance is 3.197(8) Å with a Ni–Fe distance of 3.269(4) Å and a Ni-S-Fe angle of 76.4°.[22]

While **1** is not ideal as a structural mimic of the three-dimensional nickel center in the Volbeda et al. crystal structure of [NiFe] hydrogenase,[1] the synthesis and structural results above are excellent examples of the facility with which **1** can capture iron carbonyl moieties and form robust heterometallic complexes. The isolated oxidation products of the reduced complex **2** indicate either sulfur- or iron-based but not nickel-based chemistry. Structural variations resulting from redox changes at iron do not affect the Ni–S distances, but rather incur dramatic changes in Ni-S-Fe angles and resultant Ni–Fe distances. These results are of importance for detailed X-ray absorption spectroscopic studies of *Thiocapsa roseopersicina*, which showed no change in NiK-edge spectra as the [NiFe] hydrogenase was taken through five oxidation levels. It was concluded that "No evidence to support a redox role for Ni in hydrogenase is found in the XAS data."[23] Although this conclusion is not universally accepted,[4, 5] it is supported by the "outer sphere" or non-Ni-based redox activity seen for the NiFe model complexes described above. Finally, it is within the realm of possibility that an Fe–CO moiety is present within metalloproteins that are related to CO_2 reduction chemistry in methanogenic bacteria, and demonstrations of biological Fe–CO binding are plentiful.[24, 25] Rather than completing a story or "raising more questions than it answers",[7] the Volbeda et al. crystal structure of [NiFe] hydrogenase[1] provides a focus and impetus for synthesizing interesting heterometallic complexes as structural and catalytic models.

Experimental Procedure

General procedures: Syntheses and isolation of the products was carried out under argon using standard Schlenk or glovebox techniques. Reagent grade solvents were purified according to published procedures and distilled under N_2.[11b] $[Fe_2(CO)_9]$ was purchased from Strem Chem. Co. and used as received. Infrared spectra were measured in solution cells (0.1 mm, NaCl) on an IBM IR/32 or a Mattson Galaxy 6021 instrument. Elemental analyses were carried out by Galbraith Laboratories, Knoxville, TN.

Low-Temperature Complete Combustion of Methane over Mn-, Co-, and Fe-Stabilized ZrO_2**

Vasant R. Choudhary,* Balu S. Uphade, Suryakant G. Pataskar, and Alive Keshavaraja

The concentration of methane in the atmosphere is increasing continuously.[1] Since methane has a much larger greenhouse effect than carbon dioxide, the elimination of methane emission from natural gas engines and power plants as well as petroleum and petrochemical industries by complete combustion to carbon dioxide is a must. Methane is the most inert hydrocarbon and, hence, its oxidative destruction by complete combustion at low temperature (below 600 °C, for economic reasons) is rather difficult. Noble metal catalysts show high activity in the combustion of light hydrocarbons[2–4] and methane[5–10] at low temperature. However, the use of noble metal catalysts for methane emission control is limited because of their scarcity and high cost. Worldwide efforts are, therefore, being made to replace noble metal catalysts by mixed metal oxide catalysts based on perovskite oxides[11–18] of type ABO_3 (A = La or other rare earth metal with or without partial substitution by alkaline earth metals, B = transition metal such as Mn, Fe, Co, Ni). Here we show that Mn-, Co-, and Fe-stabilized ZrO_2 (cubic) catalysts display much higher methane combustion activity at low temperature than the perovskite oxide catalysts; the activity is somewhat comparable to that of the noble metal catalysts. Furthermore, incorporation of the transition metal in the ZrO_2 bulk structure not only stabilizes the metal oxide cubic (fluorite) modification but also drastically increases the reactivity of the lattice oxygens, which can be used for low-temperature complete combustion of methane (Fig. 1).

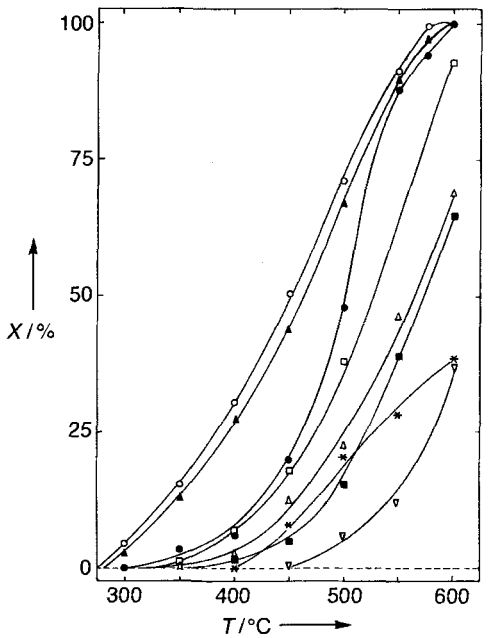

Fig. 1. Temperature dependence of the conversion of methane (X) in its complete combustion over Mn-stabilized ZrO_2 (○), Co-stabilized ZrO_2 (▲), Fe-stabilized ZrO_2 (●), Cr-stabilized ZrO_2 (□), Cu-stabilized ZrO_2 (△), Ni-stabilized ZrO_2 (■), Mn-impregnated ZrO_2 (*) and pure ZrO_2 (▽) [feed = 1 mol% CH_4 in air, gas hourly space velocity = 51 000 $cm^3 g^{-1} h^{-1}$].

The transition metals Mn, Co, Fe, Ni, Cu, and Cr are incorporated in 20 mol% concentration into the ZrO_2 bulk structure. The Mn-stabilized ZrO_2 shows the highest catalytic activity, which is much larger than that of the Mn-impregnated ZrO_2 with Mn/Zr ratio of 0.25; the latter is a mixture of MnO_2 and ZrO_2 (monoclinic). Mn-impregnated ZrO_2 with a lower Mn/Zr ratio (0.05) and pure MnO_2 (Mn/Zr = ∞) also show much lower methane combustion activity (methane conversion: 26.3 and 9.6%, respectively) at 500 °C. The Mn-stabilized ZrO_2 shows no sign of catalyst deactivation when used continuously for 50 h at 500 °C in the methane combustion process.

In the pulse reaction of pure methane over the Mn-stabilized ZrO_2 at 500 °C in the absence of free O_2, high conversion of methane to carbon dioxide is observed for the first pulse (Fig. 2, top). However, the conversion decreases with increasing pulse number and has a very low value after the 45th pulse. The initial high conversion is regained after the reoxidation of the deactivated catalyst by air (at 500 °C for 30 min). This clearly shows the involvement of the lattice oxygens of the catalyst in methane combustion and also confirms that a redox mechanism is operative in this catalytic process. The somewhat higher conversion observed for the initial few pulses after reoxidation may be due to chemisorbed oxygen on the catalyst and/or partial reduction of the virgin catalyst during storage before testing.

The Mn-stabilized ZrO_2, Mn-impregnated ZrO_2 (Mn/Zr = 0.25), and pure ZrO_2 catalysts were compared for reactivity of

their lattice oxygen atoms in methane combustion by carrying out the methane pulse reaction (in the absence of free O_2) at different temperatures (Fig. 2, bottom). The conversion of methane over Mn-stabilized ZrO_2 is very high compared to that over the other two catalysts. This reveals that the reactivity of lattice oxygens in zirconia catalysts is drastically increased due to the Mn doping, which stabilizes the cubic phase as well. Our

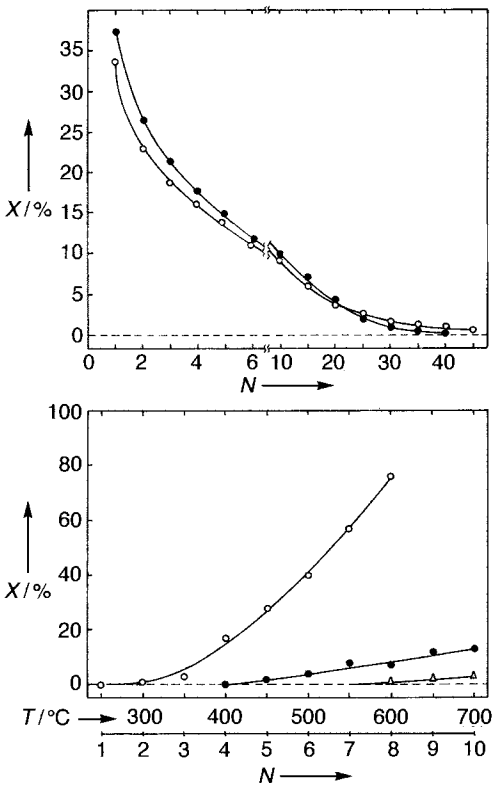

Fig. 2. Top: variation of methane conversion (X) with pulse number (N) in the pulse reaction of methane (in the absence of free O_2) at 500 °C over fresh Mn-stabilized ZrO_2 (○) and deactivated Mn-stabilized ZrO_2 after its reoxidation by air at 500 °C (●) [pulse: 0.2 cm^3 of pure methane, carrier gas: He (30 $cm^3 min^{-1}$), amount of catalyst: 0.1 g]. Bottom: temperature dependence of methane conversion (X) in the pulse reaction of methane (in the absence of free O_2) over Mn-stabilized ZrO_2 (○), Mn-impregnated ZrO_2 (●) and pure ZrO_2 (△) [amount of catalyst: 0.1 g, pulse: 0.2 cm^3 of pure methane, carrier gas: He (30 $cm^3 min^{-1}$)].

studies on the temperature-programmed reaction of pure methane (in the absence of free O_2) over the catalysts also indicate that the reactivity of lattice oxygens in all the transition metal stabilized ZrO_2 catalysts is much higher than that of pure ZrO_2 and is comparable to the observed methane combustion activity (in the presence of free O_2) shown by these catalysts. Thus, these observations reveal that the high catalytic activity in the methane combustion can be attributed to the high reactivity of the lattice oxygen atoms in the catalyst.

The methane combustion activity of the Mn-, Co-, and Fe-stabilized ZrO_2 catalysts was compared with that of the perovskite oxide catalysts (known to show high methane combustion activity) and noble metal catalysts for the same space velocity (Table 1). This clearly shows that the stabilized zirconia catalysts have much higher activity than the perovskite oxide catalysts; their activity is comparable to that of the noble metal catalysts. The stabilized ZrO_2 catalysts, particularly Mn- and Co-stabilized ZrO_2 catalysts, have a high potential for use as low-temperature combustion catalysts in methane emission control. Their high activity at low temperature is attributed to

Table 1. Comparison of Mn-, Co-, and Fe-stabilized ZrO_2 (cubic) catalysts with perovskite oxide and noble metal catalysts for complete combustion of methane (gas hourly space velocity = 51 000 $cm^3 g^{-1} h^{-1}$).

Catalyst	Surface area [$m^2 g^{-1}$]	T [°C] for 50% conversion	T [°C] for 90% conversion

the high reactivity of their lattice oxygen atoms and to the high mobility of oxygen in the stabilized zirconia. This facilitates the redox process in catalytic methane combustion. In its cubic form the Mn-doped ZrO_2 is stable up to 700 °C.[19]

The enhancement of the reactivity of the lattice oxygens as a result of stabilization of zirconia by Mn or other transitional metals may be due to creation of crystal defects. This results in the formation of low-coordinated lattice oxygens and transition metal sites on the surface and increases the mobility of oxygen both on the surface and in the bulk catalyst.

Experimental Procedure

The Cr-, Mn-, Fe-, Co-, Ni,- and Cu-stabilized ZrO_2 (cubic) catalysts were prepared by mixing aqueous solutions of zirconyl nitrate and the appropriate transition metal nitrate (transition metal/Zr mole ratio = 0.25), coprecipitating the metal hydroxide from the solution with aqueous tetramethylammonium hydroxide (25%) under vigorous stirring at 30 °C and pH 8, washing with deionized water, drying the resulting precipitate at 110 °C for 2 h, and calcining it in air at 500 °C for 8 h and then at 600° C for 1 h. The stabilization of transition metal doped ZrO_2 catalysts in their cubic form was confirmed by comparing their d-spacing values [d = 2.96(vs), 2.56(m), 1.81(vs), 1.54(vs), 1.48(w), 1.28(w), 1.17(w) and 1.15(w)] obtained by X-ray diffraction (XRD). Stabilization of ZrO_2 in its cubic phase by doping with Mn [19], Fe [20, 21], and Co [22] has been reported earlier. The pure ZrO_2 catalyst was also prepared by the above procedure but without the addition of any transition metal compound. The Mn-impregnated ZrO_2 (Mn/Zr = 0.25 and 0.05) was prepared with ZrO_2 and $Mn(NO_3)_2$ by the incipient wetness method and calcining as above. For purposes of comparison, the perovskite oxide catalysts (Table 1) were prepared by coprecipitating the metal carbonate, decomposing it at 500 °C for 4 h, powdering and pelleting, and finally calcining in air at 900 °C for 6 h. The perovskite oxide structure of the catalysts was confirmed by XRD. The methane combustion activity of all the catalysts at different temperatures was measured at atmospheric pressure in a continuous, fixed bed, quartz microreactor (i.d. 10 mm) containing 0.1 g catalyst (22–30 mesh size) mixed uniformally with 0.4 g inert α-Al_2O_3 particles (22–30 mesh size). Methane in air (1 mol%) was fed at a space velocity (measured at 0 °C and 1 atm pressure) of 51 000 $cm^3 g^{-1} h^{-1}$. The reaction temperature was measured by a Chromel-Alumel thermocouple located in the catalyst bed. The products (after condensation of water from the product stream at 0 °C) were analyzed by an on-line GC with molecular sieve and Spherocarb columns. The pulse reaction of methane over the catalyst in the absence of free O_2 was carried out with He carrier gas in a quartz pulse microreactor connected to the GC described [23]. No formation of carbon monoxide (or partial oxidation of methane) was observed in any of the methane conversion reactions.

New Course in the Search for Antitumor Agents: The Use of pH-Dependent Sources of Reactive Radicals**

Mark Vol'pin, Ilia Levitin,* and Sergei Osinsky

In our opinion, one of the most promising approaches to cancer therapy is making use of the microphysiological features of tumors that differentiate them from normal tissues. In particular, attempts to exploit the low pH values of malignant neoplasm seem attractive. This effect was thoroughly studied in the case of solid tumors.[1, 2] It is essential that their pH, which typically is 0.2–0.5 units lower than that of normal tissue, is selectively reduced by ≤ 2 units down to a value of roughly 5.5;[3, 4] this is possible first of all by glucose infusion. Hence the task consists in designing appropriate pH-dependent agents, either cytostatics that are activated under acidic conditions or pH-dependent modulators of known antitumor drugs or means.[5, 6] Several substances that generate conventional cytotoxic compounds on slight acidification have been suggested to suit this purpose. The development of this approach was reviewed by Tietze et al.[7, 8]

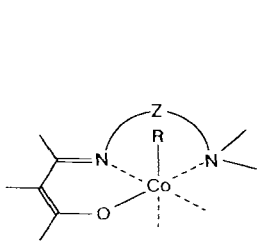
[**] We thank Dr. L. Bubnovskaya, Dr. I. Ganusevich, Dr. Yu. Istomin, Dr. E. Mironov, Dr. V. Roginsky, and M. Tsikalova for help, and Prof. R. Yakubovskaya for discussions. This work was partially supported by the Moscow City Administration, INTAS, and the Russian Foundation for Fundamental Research.

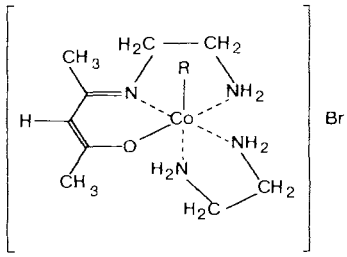
We propose a new line in the search for pH-dependent antitumor agents: the use of acid-sensitive sources of reactive radicals. This approach is based on the well-known ability of transient free radicals to damage biomolecules, in particular to cleave nucleic acids (see, for example, refs.[9, 10]). For this purpose, we have developed alkylcobalt(III) chelate complexes of type **1**, which contain tridentate Schiff bases as ligands, as a novel source of free radicals.[11] These complexes generate alkyl radicals at reduced pH under very mild conditions[12] [Eq. (a)]. Typically,

$$RCo^{III}\ldots \xrightarrow{H^+} R^{\bullet} + Co^{II}\ldots \qquad (a)$$

the plot of reaction rate versus decreasing pH displays an S-shaped curve between pH 8 and 4 at 0–50 °C. We have also observed that the decomposition of complex **2b**, the main compound used in the present work, is nearly three times faster at pH 6.5 than at pH 7.5 (aqueous phosphate buffers, 20 °C).



1



2a, R = Et; **2b**, R = *i*Pr

Furthermore, we have recently shown that alkyl radicals are not the only reactive species that may be generated by acid-induced homolytic decomposition of organocobalt complexes **1** in biological systems.[13] Although these complexes cause RNA cleavage at pH 5 under anaerobic atmosphere, this process is much more efficient in the presence of both dioxygen and ascorbic acid. Evidently, a cobalt(II) complex resulting from the homolytic decomposition of **1** catalyzes autooxidation of the biogenic reductant and generation of active oxygen species which are known[14] to cleave nucleic acids. Thus, an alkylcobalt complex with a tridentate Schiff base can serve as a source of both alkyl radicals and active oxygen species under mildly acidic conditions.

Obviously, one could expect that such sources of free radicals might selectively damage tumors since their pH is lower than that of healthy tissue. We confirmed the proposed antitumor activity of our pH-dependent sources of free radicals by examinations in vivo using several cancer models including Guerin carcinoma and sarcoma 45 in rats, and ascite L1210 leukemia and sarcoma 180 in mice. Tables 1–3 summarize some results obtained with the most thoroughly tested complex **2b**. Its direct anticancer action was noticeable in the case of ascite L1210 leukemia (Table 2, entries 1–4) and with Guerin carcinoma, provided the pH of the tumor cells was lowered (0.90 ± 0.10 units) by glucose infusion (Table 1, entries 1–3). Further, when **2b** was applied and the tumor was heated locally at 41 °C, the anticancer effect was greater than that obtained by heating alone at 43 °C (Table 1, entries 8 and 9). This result can be explained by the well-known decrease in pH when tumors are heated;[15] in our experiments the pH reduction in Guerin carcinoma was 0.30 ± 0.05 units. It is noteworthy that injection of **2b** did not substantially affect the pH decrease in tumors caused by glucose infusion or local heating.

It is particularly remarkable that complex **2b** substantially enhanced the effect of other anticancer therapeutics such as *cis*-diamminedichloroplatinum (cis-DDP; Table 1, entries 1,

10	**2b**, 60 mg/kg + cis-DDP, 2.5 mg/kg	40	22.0 ± 1.0	100	6.0 ± 0.7	45

[a] See footnotes [a, b] in Table 1. [b] Treatment was repeated after two days. [c] Increase to three treatments was mostly fatal due to toxicosis. [d] See footnotes in Table 1.

4–7, and Table 2, entries 1, 5, 6, 7, 9, 10)) and high-energy radiation (Table 3). Owing to this chemo- and radiosensitizing activity of the complex, the dose (intensity) of the drug (radiation) can be reduced by a factor of 1.7 to 4 without change in therapeutic results. Similar, though somewhat weaker effects were observed with the slightly more acid-resistant complex **2a**.

Table 3. Radiosensitizing activity of complex **2b** in rats bearing sarcoma 45[a, b].

Entry	Treatment	CR [%]	Cured rats [%]	Survival time [days]	ILS [%]
1	– (control)	0	0	35.7 ± 2.3	–
2	10 Gy	10	10	54.7 ± 5.1	53
3	15 Gy	20	20	60.2 ± 6.4	69
4	20 Gy	40	20	74.0 ± 5.4	107
5	**2b**, 20 mg/kg + 10 Gy	30	30	64.4 ± 8.3	80

[a] See footnote [a] in Table 1. [b] Complex **2b** was injected i.p. 60 min before application of a single dose of X-ray (190 kV) radiation.

Early results of pharmacokinetic experiments indicate that starting isopropylcobalt chelate **2b**, despite its high lability, enters tumor at least partially intact. This fact also agrees with the suggested mechanism of anticancer action of our complexes.

On the basis of these results, we regard the use of pH-dependent sources of free radicals as a promising line in cancer therapy. Further examinations of antitumor and other biological activities of complexes **1** are in progress.

Stereoselectivity in Reactions of 1,2-Dioxy-Substituted Radicals under Chelation Control: An Unexpected Result**

Michèle Gerster, Kurt Schenk, and Philippe Renaud*

Very recently we showed that 2-alkyl-1,2-dioxy-substituted radicals can react with substantial diastereoselectivities under chelation control.[1] For instance, treatment of the monoprotected diol **1** with trimethylaluminum,[2] followed by reaction with Bu_3SnD/azobisisobutyronitrile (AIBN) affords the *like* product *l*-**3** (Scheme 1). Presumably, the radical intermediate,

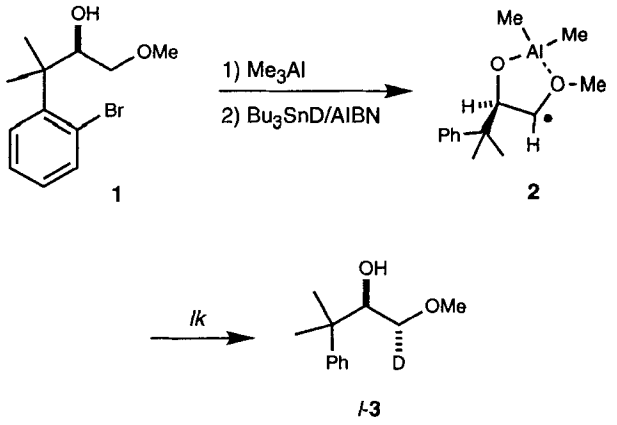
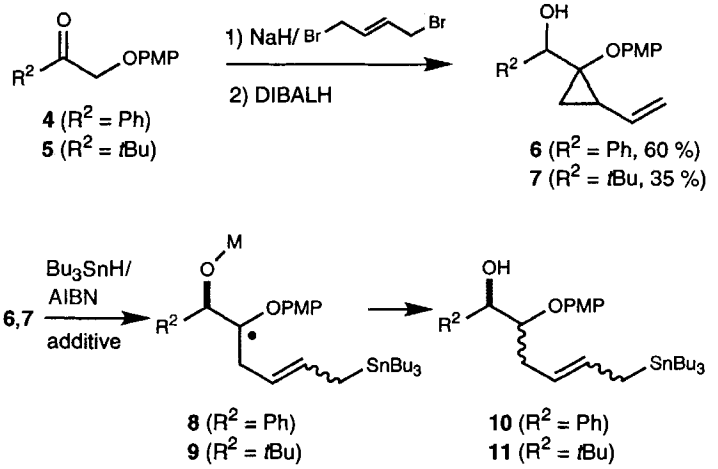
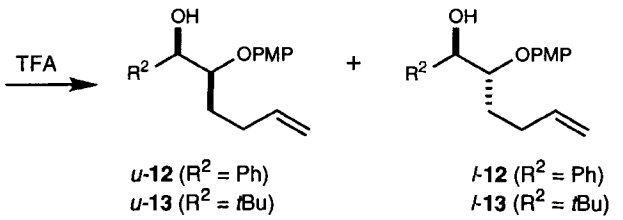


Scheme 1.

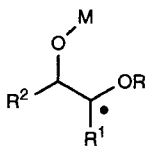




Scheme 2.

which is generated by a 1,5-shift, forms a chelate **2** and reacts with Bu_3SnD from the less hindered face, which is *anti* to the bulky vicinal $PhMe_2C$ group. This was the first example of the Cram chelation model in radical chemistry.[3-5]

We report herein that 1-alkoxy-1,2-dialkyl-2-hydroxy-substituted radicals of type **I** behave quite differently under chelation control and products with opposite configuration are formed. This is a rather rare example in which the model initially developed for ionic reactions (nucleophilic addition) is not applicable to analogous radical reactions. Our results confirm the importance of pyramidalization of the radical center in the ground and transition states.



I: M = H, AlR_2 etc.
R^1, R^2 = alkyl

Type **I** radicals have been generated from vinylcyclopropanes by using the highly efficient ring-opening reaction of cyclopropylmethyl radicals.[6] The precursors **6** and **7** were prepared from (*p*-methoxyphenoxy (PMPO))methyl ketones **4** and **5**, respectively, by a one-pot double alkylation procedure,[7] followed by reduction with diisobutylaluminum hydride (DIBALH) (Scheme 2). Irradiation of the vinylcyclopropane **6** with a sun lamp in the presence of Bu_3SnH/AIBN in dichloromethane affords the acyclic monoprotected diol **10** via the intermediate radical **8** as a *u*/*l* 1.5:1 mixture of diastereoisomers (Table 1, entry 1). The diastereomeric ratio was determined after supression of the *E*/*Z* isomerism by protodestannylation of **10** to **12** with trifluoroacetic acid (TFA). Surprisingly, addition of 1.1 equivalents of Me_3Al does not influence the stereoselectivity (entry 2). However, based on our previous results,[1] we were convinced that under these reaction conditions the radical intermediate was chelating the metal atom as depicted in structure **8.1** (see below). The use of the bulky methylaluminum di(2,6-di-*tert*-butyl-4-methylphenoxide) (MAD) additive leads after treatment with TFA to preferential formation of *l*-**12** (entry 3).

The sterically more crowded radical **9** was investigated next. In the absence of additive, the conversion of **7** to **13** was not stereoselective (entry 4). However, when the aluminum alkoxide was prepared by preliminary treatment of **7** with 1.1 equivalents of Me_3Al, the reaction was highly stereoselective (*u*/*l* 1:>20, entry 5) with unexpected preferential formation of the *like* isomer. Other additives expected to favor chelation control such as MeMgCl (entry 6) and Et_2BH (entry 7) were found to be less efficient than Me_3Al. Use of MAD (entry 8) also gave, as in the case of **6**, preferentially the *like* isomer with a moderate selectivity. The relative configurations of *u*- and *l*-**12**,**13** were deduced by their conversion to *cis*- and *trans*-**14**,**15**, respectively, upon treatment with ammonium cerium(IV) nitrate (CAN) and by NOE measurements. The *like* configuration of the major isomer of **13** was confirmed by an X-ray structure analysis of its 3,5-dinitrobenzoate (3,5-DBN) ester **16** (Fig. 1).[8]

Table 1. Radical hydrostannylation of vinylcyclopropanes **6** and **7** in the presence of additives.

Entry	Starting material	Additive (equiv)	Product	Yield [%]	*u*/*l*
1	**6**	–	**10**	80	1.5:1
2	**6**	Me_3Al (1.1)	**10**	67	1.8:1
3	**6**	MAD (1.1)	**10**	43	1:1.6
4	**7**	–	**11**	87	1:1
5	**7**	Me_3Al (1.1)	**11**	77	1:>20
6	**7**	MeMgCl (1.1)	**11**	77	1:2.7
7	**7**	Et_2BH (1.1)	**11**	58	1:2.6
8	**7**	MAD (1.1)	**11**	51	1:3.2

In order to rationalize the results, we assume that the radicals generated after Me_3Al treatment of the free alcohols **6** and **7** are chelated aluminum alkoxides of type **8.1** and **9.1**, respectively.[9] This assumption is supported by the results we have obtained with radical **2**. This reacts preferentially with a *like* (*lk*) topicity; **8** reacts with low stereoselectivity, and **9** is reduced with a high *unlike* (*ul*) topicity.[10]

Hydrogen abstraction from the tin hydride is expected to occur via a pyramidalized transition state.[11] Even the ground-state conformation of alkoxy radicals is known to be pyramidal;[12] thus, the alkoxy-substituted radicals lie in the two conformations **A** and **B**. For radical **2**, the two conformations are easily accessible and reaction occurs preferentially from the less hindered face of **2B** (Curtin–Hammet principle). The radical **8.1**, in contrast, exists preferentially in conformation **8.1A**, thus

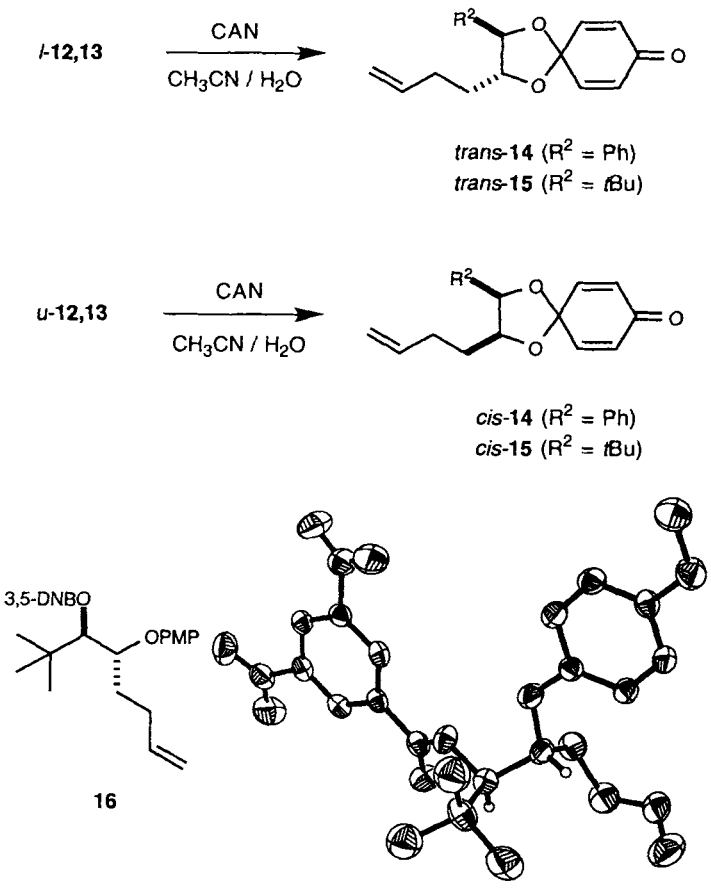


Fig. 1. Determination of the relative configurations of *u*- and *l*-**12,13**.

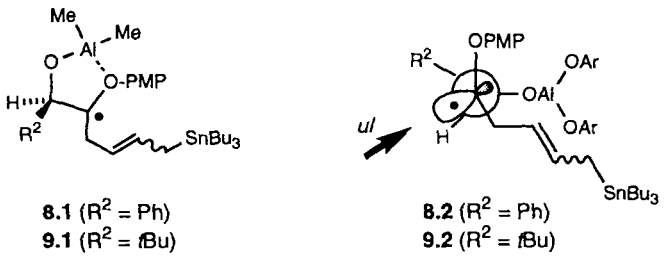
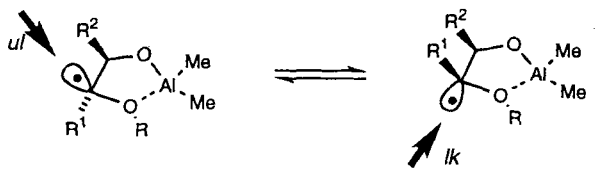
minimizing steric interactions between R^2 and R^1, but conformer **8.1B** is also accessible and presumably more reactive (less hindered). Therefore, both *lk* and *ul* topicities are observed Radical **9.1** exists exclusively in conformation **9.1A**, be-



8.1 (R^2 = Ph)
9.1 (R^2 = *t*Bu)

8.2 (R^2 = Ph)
9.2 (R^2 = *t*Bu)



2A (R^1 = H, R^2 = C(Me)$_2$Ph) **2B**

8.1A (R^1 = $CH_2CH{=}CHCH_2SnBu_3$, R^2 = Ph) **8.1B**

9.1A (R^1 = $CH_2CH{=}CHCH_2SnBu_3$, R^2 = *t*Bu) **9.1B**

cause in **9.1B** a very large eclipsing interaction between the *tert*-butyl group and the alkyl R^1 group would be present. Pyramidalization of **9.1A** forces the reduction to occur from the most shielded face with *ul* topicity (*syn* to the *tert*-butyl group).[13] The low level of stereoselectivity observed when MAD is used as an additive (entries 3 and 8) can be explained by Felkin–Ahn type transition states **8.2** and **9.2**.

In conclusion, we have demonstrated that substitution at the C1 position of 1,2-dioxy-substituted radicals is of critical importance for the sense of the stereoselectivity during chelation-controlled reactions. To our knowledge, such an effect is not observed during nucleophilic addition to carbonyl compounds under chelation control.[14] The general phenomenon is caused by strong pyramidalization in the transition state and is expected to be important in several other types of systems with pyramidal radicals such as oxiranyl,[15] tetrahydrofuran-2-yl, and aziridinyl radicals.[16] Moreover, similar effects are also expected for any type of 1,2-disubstituted cycloalkyl radicals because of pyramidalization of the transition states, and their magnitude is currently under study in our laboratory.[17]

Experimental Procedure

Ring opening: **10,11**: To a solution of **6** or **7** (1.00 mmol) and AIBN (16 mg) in C_6H_6 (3.3 mL) was added under nitrogen the additive (1.10 mmol) followed by Bu_3SnH (380 mg, 1.30 mmol). The mixture was irradiated at 10 °C with a sun lamp (300 W). Further portions of AIBN (16 mg) were added every 8 h. After completion of the reaction (TLC monitoring), the solvent was evaporated and CH_2Cl_2 (15 mL) was added followed by $Na_2CO_3 \cdot 10\,H_2O$ (1.15 g) to hydrolyze the complex. The heterogeneous mixture was stirred for 1 h, filtered through Celite, and concentrated. The residue was purified by flash chromatography (FC).

Protodestannylation: **12,13**: TFA (1.30 mmol) was added to a solution of the stannane **10** or **11** (1.00 mmol) in chloroform (1.0 mL) under nitrogen. The mixture was stirred at room temperature for 1 h. After completion of the reaction, the organic layer was washed with H_2O and then $NaHCO_3$ solution, and dried over $MgSO_4$. After filtration and concentration, the residue was purified by FC. The ratio of diastereoisomers was deduced from ^{1}H NMR spectra.

Oxidation of the PMP ethers: **14,15**: $(NH_4)_2Ce(NO_3)_6$ (CAN) (3.00 mmol) was added in one portion to a solution of the PMP ether (1.00 mmol) in CH_3CN/H_2O (4/1) at 0 °C. The reaction mixture was stirred at 0 °C for 1 h, then poured into a mixture of EtOAc and brine. The organic layer was washed with saturated aqueous $NaHCO_3$, dried over $MgSO_4$, filtered, and concentrated. The residue was purified by FC.

2,2-dimethyl-4-(*p*-methoxyphenoxy)oct-7-en-3-ol **13**. Compound **7** (276 mg, 1.00 mmol) was converted to **11** (434 mg, 77%), which after FC (Et_2O/hexane 1/5) was obtained as a mixture of diastereoisomers that were directly submitted to protodestannylation. FC (Et_2O/hexane 1/3) of the crude material gave **13** (198 mg, 93%) as a mixture of diastereoisomers (*u*-**13**/*l*-**13**), which were separated by further chromatography.

u-**13**: ^{1}H NMR (360 MHz, $CDCl_3$): δ = 6.88–6.78 (m, 4 arom. H), 5.82 (dddd, J = 17.1, 10.2, 6.9, 6.3 Hz, $H_2C{=}CH$), 5.09–4.99 (m, $H_2C{=}CH$), 4.37–4.29 (m, CH–OAr), 3.78 (s, MeO), 3.27 (dd, J = 10.3, 0.9 Hz, HO–C*H*), 2.59 (d, J = 10.3 Hz, HO), 2.26–2.09 (m, $H_2C{=}CHCH_2$), 1.94 (ddd, J = 13.8, 8.5, 5.4 Hz, O–CH–C*H*H), 1.83–1.70 (m, O–CH–CH*H*), 0.95 (s, *t*Bu). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 154.07 (s), 151.00 (s), 137.67 (d), 116.61 (d), 115.30 (t), 114.85 (d), 78.59 (d), 75.17 (d), 55.66 (q), 35.11 (s), 30.75 (t), 29.66 (t), 26.45 (q).

l-**13**: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.84 (s, 4 arom. H), 5.97–5.70 (m, $H_2C{=}CH$), 5.10–4.92 (m, $H_2C{=}CH$), 4.30 (td, J = 6.5, 3.2 Hz, CH-OAr), 3.78 (s, MeO), 3.57 (t, J = 3.5 Hz, HO-C*H*), 2.46–2.07 (m, $H_2C{=}CH{-}CH_2$), 2.05–1.67 (m, O–CH–CH_2), 1.91 (d, J = 3.9 Hz, HO), 0.97 (s, *t*Bu). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 154.14 (s), 151.88 (s), 138.53 (d), 117.56 (d), 115.01 (t), 114.83 (d), 79.24 (d), 78.97 (d), 55.72 (q), 34.22 (s), 29.74 (t), 29.16 (t), 26.90 (q). Mixture of diastereoisomers. Anal. calc. for $C_{17}H_{26}O_3$ (278.40): C 73.35, H 9.41; found: C 73.06, H 9.52.

trans-2-(But-3-en-1-yl)-3-*tert*-butyl-1,4-dioxaspiro[4,5]deca-6,9-dien-8-one (*trans*-**15**). Compound *l*-**13** (80 mg, 0.30 mmol) was converted to *trans*-**15** (60 mg, 80%), which after FC (Et_2O/hexane 1:3) was obtained as a pale yellow liquid. Starting from a mixture of *l*- and *u*-**13** a mixture of *trans*- and *cis*-**15** was prepared. The diastereoisomers were separated by chromatography.

trans-**15**: ^{1}H NMR (200 MHz, $CDCl_3$): δ = 6.72-6.53 (m, *H*C=CH–C=O, 2H), 6.22–6.04 (m, HC=C*H*–C=O, 2H), 5.82 (dddd, J = 17.2, 10.2, 7.0, 6.3 Hz, $H_2C{=}CH$), 5.13-4.92 (m, $H_2C{=}CH$), 4.01 (dt, J = 8.3, 3.2 Hz, O–*CH*–CH_2), 3.62 (d, J = 7.9 Hz, *t*Bu–*CH*), 2.45–2.06 (m, CH_2–CH–CH_2), 1.87–1.53 (m, O–CH–CH_2), 0.98 (s, *t*Bu). ^{13}C NMR (50.3 MHz, $CDCl_3$): δ = 185.36 (s), 144.77

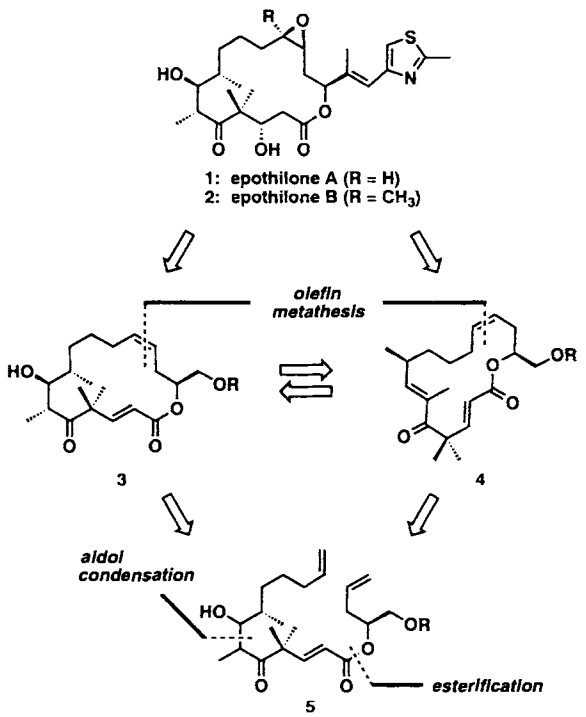
An Approach to Epothilones Based on Olefin Metathesis**

K. C. Nicolaou,* Yun He, Dionisios Vourloumis, Hans Vallberg, and Zhen Yang

Epothilones A and B (**1** and **2**, respectively; Scheme 1) represent a new class of natural products with interesting molecular architecture and considerable potential in medicine. Originally isolated by Höfle et al.[1] from myxobacteria *Sorangium cellulosum* strain 90, these compounds possess striking biological properties, for example potent antifungal activity[2] against oomyceten (*Plasmopara viticola*, *Phytopthora infestans*) both in vitro and in the greenhouse as well as cytotoxic activity against mouse fibroblasts [cell line L929, IC_{50} 2 mg mL^{-1} for epothilone B (**2**)]. Most importantly, the epothilones exhibit significant in vitro selectivity against breast and colon cell lines;[2, 3] they exert their cytotoxicity by the same mechanism as taxol,[4] namely by stabilization of microtubules. The latter observation made by Merck scientists, who also discovered the epothilones independently,[4] is both exciting and intriguing in view of taxol's success as an anticancer agent and the absence of any apparent structural similarity between taxol and epothilones. The structures of these compounds have recently been established by Höfle and his group[2] with spectroscopic



Scheme 1. Structures and retrosynthetic analysis of epothilones A (**1**) and B (**2**).

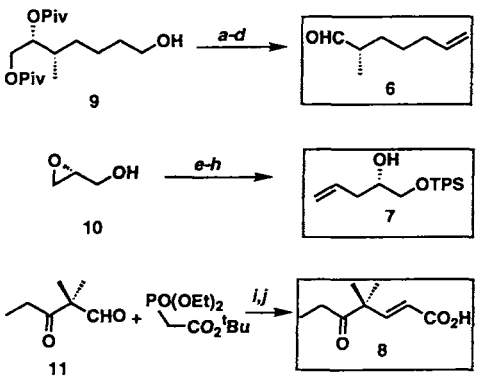
techniques and X-ray crystallographic analysis of epothilone B (**2**). In this communication we report a olefin metathesis based approach to the macrocyclic skeleton of the epothilones that may be used to construct not only the natural substances, but also a library of analogs for biological screening.

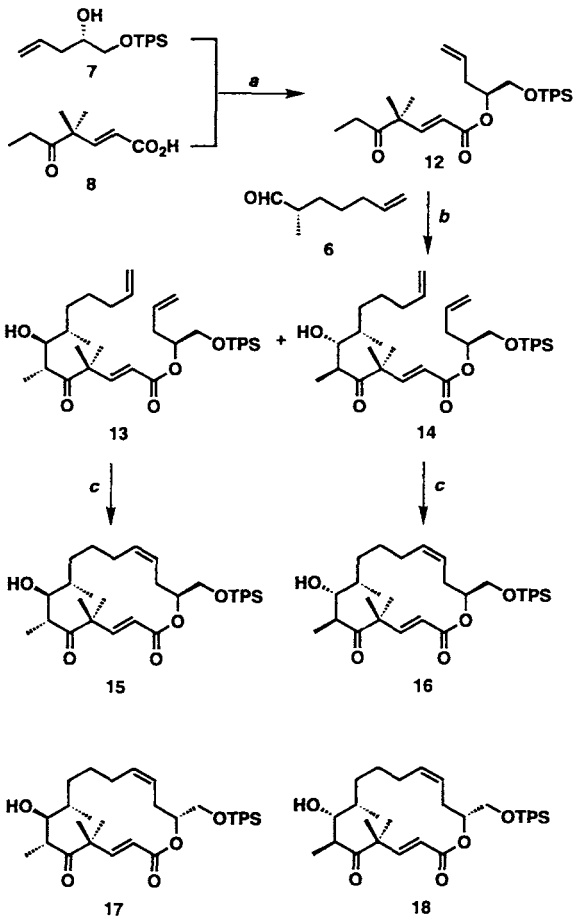
A plausible retrosynthetic strategy for epothilones is illustrated in Scheme 1. According to this metathesis-based approach, the epothilone structure is traced back to the 16-membered ring skeletons **3** or **4**, which lack, besides the side chain, a number of oxygen atoms. Further disconnection of **3** or **4** by a retro metathesis reaction reveals the open chain compound **5** as a potential precursor. Disassembly of **5** can easily be envisioned as indicated in Scheme 1, leading to three simple building blocks. Thus, though the exact sequence will have to await experimentation, the strategy evolved from this analysis will involve rapid assembly of **5**, ring closure by olefin metathesis,[5, 6] introduction of the required oxygen functions, and side chain attachment. Conformational effects of the 16-membered ring as well as neighboring group participation are expected to play important roles in setting the proper stereorelationships within the target molecules. Most importantly, the scheme is flexible enough to allow entry to all possible stereoisomers of the epothilones.

Since the stereochemical details of the epothilones A (**1**) and B (**2**) were at first unknown, we initially focused on a flexible sequence aimed at exploring a general strategy capable of delivering all possible stereoisomers and, eventually, an epothilone library of maximum diversity. To this end, the three requisite fragments **6**–**8** were synthesized as shown in Scheme 2. Construction of building block **6** involved oxidation of alcohol **9**[7] to the corresponding aldehyde, Wittig olefination, DIBAL-induced removal of the pivaloate groups, and sodium periodate cleavage of the resulting 1,2-diol (56% overall yield). Preparation of **7** proceeded smoothly from (*R*)-(+)-glycidol (**10**) through silyl ether formation, epoxide opening with the lithio derivative of dithiane, liberation of the aldehyde, and olefin formation (59% overall yield). Synthesis of **8** required selective phosphonate condensation with readily available ketoaldehyde **11**,[8] followed by acidic cleavage of the *tert*-butyl ester (87% overall yield, Scheme 2).



Scheme 2. Construction of the building blocks **6**–**8**. a) 3.0 equiv SO_3·Pyr, 5 equiv Et_3N, CH_2Cl_2:DMSO (4:1), 0 °C, 2 h, 88%; b) 1.5 equiv $Ph_3P{=}CH_2$, THF, 0 °C, 2 h, 94%; c) 2.4 equiv DIBAL, CH_2Cl_2, −78 → 25 °C, 20 h, 83%; d) 5.0 equiv $NaIO_4$, CH_2Cl_2:H_2O (4:1), 25 °C, 20 h, 81%; e) 1.1 equiv TPSCl, 1.2 equiv imidazole, CH_2Cl_2, 25 °C, 100%; f) 1.1 equiv 1,3-dithiane, 1.1 equiv *n*BuLi, THF, −30 → 25 °C, 84%; g) 1.1 equiv $Hg(ClO_4)_2$, 1.2 equiv $CaCO_3$, THF:H_2O (10:1), 12 h, 85%; h) 2.5 equiv $Ph_3P{=}CH_2$, THF, 0 °C, 1 h, 83%; 1.6 equiv NaH, THF, 0 → 25 °C, 1 h, 87%; j) CF_3COOH:CH_2Cl_2 (1:1), 25 °C, 0.5 h, 100%. TPS = $SiPh_2tBu$; Piv = $COtBu$.

The assembly of the epothilones skeleton from buidling blocks **6**–**8** is shown in Scheme 3. Coupling of **7** and **8** with dicyclohexylcarboiimide (DCC) led to **12** (99% yield) whose enolate, generated by the action of lithium diisopropylamide (LDA), reacted with aldehyde **6** to afford a mixture of diastereoisomers, **13** (29% yield) and **14** (60% yield). After chromatographic separation (silica, 20% ethyl acetate in hexanes), pure **13** was subjected to the Grubbs conditions for olefin metathesis with a $[RuCl_2(=CHPh)(PCy_3)_2]$ catalyst[5] (Cy = cyclohexyl) and furnished the 16-membered macrolide ring **15**[9] in 80% yield. Under similar conditions, diastereoisomer **14** led to cyclic system **16**[9] in 82% yield. The diastereomeric macrolide systems **17**[9] and **18**[9] were also synthesized in similar yields starting with the enantiomer of **10** and following the same sequence. The use of the enantiomer of **6** is expected to allow entry to yet another series of stereoisomers of the epothilone skeleton.



Scheme 3. Synthesis of the epothilone cyclic framework by olefin metathesis: a) 1.5 equiv DCC, 1.5 equiv 4-dimethylaminopyridine, toluene, 25 °C, 8 h, 99%; b) 1.2 equiv LDA, −78 °C, THF, 0.5 h; then **6** in THF, −78 °C, 0.5 h, **13** (29%), **14** (60%); c) substrate concentration: 0.006 M in CH_2Cl_2, 5–10 mol% $[RuCl_2(=CHPh)(PCy_3)_2]$, 25 °C, 4–12 h, 80–82%.

In conclusion, we have demonstrated the viability of a convergent and highly efficient approach to the epothilone cyclic framework through the olefin metathesis reaction. This strategy, and its many imaginable variants, pave the way for the total synthesis of both natural and designed members of this new class of compounds for biological investigations and possible therapeutic applications.[10]

[7] Compound **9** was synthesized from geraniol by standard chemistry: D. F. Taber, K. K. You, *J. Am. Chem. Soc.* **1995**, *117*, 5757–5762, and references therein. Both enantiomers of **6** may also be reached by asymmetric synthesis with chiral auxiliaries.

[8] Ketoaldehyde **11** was prepared from propionyl chloride according to a published procedure: T. Inukai, R. Yoshizawa, *J. Org. Chem.* **1967**, *32*, 404–407.

[9] Selected physical properties of compounds: **15**: $R_f = 0.29$ (silica, 20% ethyl acetate in hexanes); IR (film): $\tilde{\nu}_{max} = 3522$ (br, OH), 1718 (C(O)O), 1698 (COC), 1646 (CH=CHCO); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.67-7.35$ (m, 10H, $SiPh_2$), 7.07 (d, 1H, $J = 16.0$ Hz, $=CHCOO$), 5.85 (d, 1H, $J = 16.0$ Hz, $(CH_3)_2CH=$), 5.29 (m, 2H, $CH=CHCH_2$), 5.23 (m, 1H, $COOCH$), 3.76 (dd, 1H, $J_1 = 6.3$ Hz, $J_2 = 10.6$ Hz, CH_2OSi), 3.69 (dd, 1H, $J_1 = 5.2$ Hz, $J_2 = 10.6$ Hz, CH_2OSi), 3.26 (d, 1H, $J = 9.1$ Hz, $CH(OH)$), 3.13 (q, 1H, $J = 7.0$ Hz, $(CH_3)CHCO$), 2.87 (s, 1H, $CHOH$), 2.47 (m, 1H, $CH_2CH=CHCH_2$), 2.30 (m, 1H, $CH_2CH=CHCH_2$), 2.09 (m, 1H, $CH_2CH=CHCH_2$), 1.96 (m, 1H, $CH_2CH=CHCH_2$), 1.50 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.37 (m, 1H, $CH(CH_3)CH_2CH_2$), 1.35 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.33 (s, 3H, $C(CH_3)_2$), 1.24 (s, 3H, $C(CH_3)_2$), 1.04 (s, 9H, $C(CH_3)_3$), 1.02 (d, 3H, $J = 6.9$ Hz, $CH(CH_3)CO$), 0.96 (d, 3H, $J = 6.6$ Hz, $CH(OH)CH(CH_3)$); HRMS for $C_{36}H_{50}O_5SiCs$ ($M + Cs^+$): calcd 723.2482, found 723.2506. **16**: $R_f = 0.20$ (silica, 20% ethyl acetate in hexanes); IR (film): $\tilde{\nu}_{max} = 3520$ (br, OH), 1711 (C(O)O), 1705 (COC), 1646 (CH=CHCO); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.68-7.35$ (m, 10H, $SiPh_2$), 6.78 (d, 1H, $J = 15.8$ Hz, $=CHCOO$), 5,98 (d, 1H, $J = 15.8$ Hz, $(CH_3)_2CH=$), 5.40 (m, 2H, $CH=CHCH_2$), 5.20 (m, 1H, $COOCH$), 3.75 (dd, 1H, $J_1 = 6.0$ Hz, $J_2 = 10.7$ Hz, CH_2OSi), 3.68 (dd, 1H, $J_1 = 5.8$ Hz, $J_2 = 10.7$ Hz, CH_2OSi), 3.57 (m, 1H, $CH(OH)$), 3.05 (m, 2H, $(CH_3)CHCO$, $CH(OH)$), 2.42 (m, 1H, $CH_2CH=CHCH_2$), 2.21 (m, 1H, $CH_2CH=CHCH_2$), 2.08 (m, 1H, $CH_2CH=CHCH_2$), 1.98 (m, 1H, $CH_2CH=CHCH_2$), 1.44 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.36 (s, 3H, $C(CH_3)_2$), 1.25 (m, 1H, $CH(CH_3)CH_2CH_2$), 1.20 (s, 3H, $C(CH_3)_2$), 1.15 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.04 (s, 9H, $C(CH_3)_3$), 1.02 (d, 3H, $J = 6.9$ Hz, $CH(CH_3)CO$), 0.90 (d, 3H, $J = 6.5$ Hz, $CH(OH)CH(CH_3)$); HRMS for $C_{36}H_{50}O_5SiCs$ ($M + Cs^+$): calcd 723.2482, found 723.2508. **17**: $R_f = 0.34$ (silica, 20% ethyl acetate in hexanes); IR (film): $\nu_{max} = 3524$ (broad, OH), 1722 (-C(O)-O), 1699 (COC), 1648 (CH=CHCO); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.67-7.35$ (m, 10H, $SiPh_2$), 6.90 (d, 1H, $J = 15.8$ Hz, $=CHCOO$), 5.98 (d, 1H, $J = 15.8$ Hz, $(CH_3)_2CH=$), 5.35 (m, 2H, $CH=CHCH_2$), 5.20 (m, 1H, $COOCH$), 3.73 (dd, 1H, $J_1 = 5.7$ Hz, $J_2 = 10.7$ Hz, CH_2OSi), 3.69 (dd, 1H, $J_1 = 5.8$ Hz, $J_2 = 10.7$ Hz, CH_2OSi), 3.14 (q, 1H, $J = 6.9$ Hz, $(CH_3)CHCO$), 3.10 (d, 1H, $J = 9.6$ Hz, $CHOH$), 2.96 (s, 1H, (OH)), 2.42 (m, 1H, $CH_2CH=CHCH_2$), 2.27 (m, 1H, $CH_2CH=CHCH_2$), 2.14 (m, 1H, $CH_2CH=CHCH_2$), 1.97 (m, 1H, $CH_2CH=CHCH_2$), 1.44 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.19 (m, 1H, $CH(CH_3)CH_2CH_2$), 1.15 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.33 (s, 3H, $C(CH_3)_2$), 1.22 (s, 3H, $C(CH_3)_2$), 1.04 (s, 9H, $C(CH_3)_3$), 1.02 (d, 3H, $J = 6.9$ Hz, $CH(CH_3)CO$), 0.96 (d, 3H, $J = 6.5$ Hz, $CH(OH)CH(CH_3)$); HRMS calcd for $C_{36}H_{50}O_5SiCs$ ($M + Cs^+$): 723.2482, found: 723.2508. **18**: $R_f = 0.18$ (silica, 20% ethyl acetate in hexanes); IR (film): $\nu_{max} = 3523$ (broad, OH), 1719 (C(O)O), 1699 (COC), 1646 (CH=CHCO); ^{1}H NMR (400 MHz, $CDCl_3$): $\delta = 7.68-7.32$ (m, 10H, $SiPh_2$), 7.01 (1H, $J = 16.0$ Hz, $=CHCOO$), 5.83 (d, 1H, $J = 16.0$ Hz, $(CH_3)_2CH=$), 5.33 (m, 2H, $CH=CHCH_2$), 5.22 (m, 1H, $COOCH$), 3.73 (dd, 1H, $J_1 = 5.5$ Hz, $J_2 = 11.4$ Hz, $-CH_2OSi$), 3.69 (dd, 1H, $J_1 = 4.3$ Hz, $J_2 = 11.4$ Hz, CH_2OSi), 3.57 (m, 1H, $CHOH$), 3.04 (m, 2H, $(CH_3)CHCO$, $CH(OH)$), 2.42 (m, 1H, $CH_2CH=CHCH_2$), 2.27 (m, 1H, $CH_2CH=CHCH_2$), 2.14 (m, 1H, $CH_2CH=CHCH_2$), 1.97 (m, 1H, $CH_2CH=CHCH_2$), 1.44 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.19 (m, 1H, $CH(CH_3)CH_2CH_2$), 1.15 (m, 2H, $CH(CH_3)CH_2CH_2$), 1.33 (s, 3H, $C(CH_3)_2$), 1.22 (s, 3H, $C(CH_3)_2$), 1.04 (s, 9H, $C(CH_3)_3$), 1.02 (d, 3H, $J = 6.9$ Hz, $-CH(CH_3)CO$), 0.96 (d, 3H, $J = 6.5$ Hz, $CH(OH)CH(CH_3)$); HRMS calcd for $C_{36}H_{50}O_5SiCs$ ($M + Cs^+$): 723.2482, found: 723.2506.

[10] All new compounds exhibited satisfactory spectral and analytical and/or exact mass data. Yields refer to chromatographically and spectroscopically homogeneous materials.

Biotechnology Now—From Theory to Scale-Up

Downstream Processing of Natural Products. A Practical Handbook. Edited by *M. S. Verrall.* Wiley, Chichester, 1996. 354 pp., hardcover £ 65.00.—ISBN 0-471-96326-7

It is becoming increasingly difficult, even for those working in the field, to keep abreast with the latest developments in the methodology of natural products research, as the various specialist areas demand an ever greater degree of detailed knowledge.

This book is concerned with the production, isolation, and characterization of secondary metabolites and proteins from natural sources obtained by fermentation processes, so as to yield new active agents and lead structures for the pharmaceutical industry. In addition to a familiarity with the basic principles, such work requires specialist knowledge in the areas of microbiology, process technology, biochemistry, and physical and organic chemistry.

The various processing stages leading from the fermentation brew to the purified active agent are nowadays usually carried out as a team effort, whether in industry or in university research groups. The researchers involved rely greatly on many kinds of external support by specialist firms, which supply equipment, materials, and techniques of continually improving performance.

This book brings together a number of specialists from academic and industrial research laboratories to report on the current state of research in the downstream processing of natural products. Although certain aspects, in particular the isolation and breeding of the producing organisms, and the determination of the molecular structure of the end-product, receive little attention here, all the stages between these are treated in detail. Thus, "downstream processing" here means essentially the production, work-up, and isolation of pure secondary metabolites and proteins from biological sources.

The editor, M. S. Verrall, is a natural products expert with the British pharmaceutical company Smith-Kline-Beecham. In the first article he begins by reviewing the historical development of research on biologically active natural products and their importance as active agents and lead structures for the pharmaceutical industry, then discusses the common features and differences of the various isolation strategies, e.g. as applied to plants or to microorganisms, and for the isolation of secondary metabolites as compared with that of polypeptides. He also discusses likely future developments and technological advances (such as the increased use of molecular-biological methods for the production of secondary metabolites), thus setting the scene for the chapters that follow. These deal with the state of the art in the production, work-up, and purification of natural products with biological activity.

In addition to the editor's colleagues, the list of authors consists mainly of researchers from leading British universities, and practitioners and experts from industrial companies, both large and small. Accordingly, there are several chapters on routine technical processes such as freeze-drying, centrifuging, cell breakdown, concentration of the required product by solvent extraction or solid phase extraction, and the usual methods of fermentation analysis and process control. The individual authors discuss these topics from different points of view, while avoiding too much overlapping of subject matter.

Methods for isolating biologically active agents are covered especially thoroughly, with separate chapters describing a wide variety of available techniques. As well as detailed treatments of ion exchange chromatography, affinity chromatography, and HPLC, these chapters also discuss some innovative and less well known methods, such as radial flow chromatography and the use of supercritical liquids and liquid membranes in extraction and chromatography. Other topics covered include, for example, the properties and applications of DIAION adsorption resins for nonionic solid phase extraction (in a chapter by H. Tayakanaki et al., of the Mitsubishi research team that developed these resins), and an account by A. Thompson of the many different ways by which proteins can be modified to make their isolation easier. Although the book has a practical bias, as intended, the physical-chemical fundamentals are also covered, and the most important mathematical formulas are included where they are necessary for a basic understanding. There are also plenty of illustrations, which are well coordinated with the text. Separate chapters explain the detailed theoretical background to topics such as the integration of processes in biotechnology, the scale-up from the laboratory to industrial production, and good manufacturing practice as an important prerequisite for licencing and quality control. For the reader who needs more information on a particular topic there is a comprehensive and up-to-date list of references at the end of each chapter.

Anyone engaged in work in this field knows from reading recent literature on, for example, new biologically active natural products, that such publications usually place the main emphasis on the end-products of the evaluation process, whereas the methodology used in their discovery is given less prominence. This is probably because it is considered unnecessary to repeat descriptions of commonly used standard methods in successive publications. To complement this results-orientated type of literature, which is already plentifully available, the authors of this book have set out to provide a reference source on downstream processing methodology, and have succeeded well in that purpose. The subject matter is presented in a clearly understandable form, helped by the excellent standard of production and the numerous illustrations.

This work is an important and valuable contribution to the literature in this important area of biotechnology, not least because all the articles are thoroughly up-

This section contains book reviews and a list of new books received by the editor. Book reviews are written by invitation from the editor. Suggestions for books to be reviewed and for book reviewers are welcome. Publishers should send brochures or (better) books to the editorial office: Redaktion Angewandte Chemie, Postfach 101161, D-69451 Weinheim, Germany. The editor reserves the right of selecting which books will be reviewed. Uninvited books not chosen for review will not be returned.

to-date. It can therefore be recommended for everyone involved in the production and isolation of secondary metabolites and proteins from biological sources.

Carbohydrate Building Blocks. By *M. Bols*. Wiley, Chichester, 1996. 182 pp., hardcover £ 40.00.—ISBN 0-471-13339-6

In 1983 there appeared a book which has since become a classic work in its field: *Total Synthesis of Natural Products. The Chiron Approach*, by Stephen Hanessian. It made many chemists aware for the first time of the importance of carbohydrates as chiral building blocks for synthesizing natural products and active agents. Although that book covered the "master strategies" in the script of carbohydrates-based synthesis, it did not include details of the "opening moves". The book by M. Bols reviewed here fills that gap admirably.

Carbohydrate Building Blocks is not a textbook of carbohydrates chemistry. Instead it aims to give the reader guidelines for learning to use this group of natural products, by describing the most important and well-proven synthetic pathways that afford access to a wide variety of chiral building blocks, starting from a collection of 26 relatively cheap carbohydrates. Most of the synthetic procedures consist of three or four stages, although a few have as many as seven or eight.

The first chapter familiarizes the reader with the most important starting materials and their origins. Current trends in the choice of starting materials for synthesizing various well-known stereosequences are shown by listing quantitative data on how frequently the different sugars have been used.

The next ten chapters, which occupy about a third of the book, contain a very condensed survey of commonly used transformations in carbohydrate chemistry. The topics include acetalizations, various other important protecting group strategies, oxidations and reductions, eliminations, and skeletal rearrangements induced by acids or bases. The author includes important rules and other information intended specifically to help the chemist who is less familiar with carbohydrates. Thus, for example, data are provided on the relative reactivities of the different hydroxy groups in aldoses, ketoses, anhydro-sugars, and sugar lactones, in reactions with electrophiles or in substitution reactions.

The real core of the book is the 120-page appendix. This consists of a catalog describing 691 (!) chiral building blocks derived from carbohydrates, together with several shorter subject indexes. In the catalog, which makes no claim to be exhaustive, each structure is accompanied by a CA number, a literature reference, the sugar used as the starting material, and the number of stages in the synthesis. The list of building blocks is arranged in eleven sections which correspond to Chapters 1-11 of the book, thus forming a close connection between the two parts. Each of these sections is completed by a bibliography. However, that is not all. To help the reader wishing to plan a retrosynthesis, there follows an important additional resource, namely a stereochemical index containing 98 stereochemical sequences with up to seven stereogenic centers, shown in open-chain form. These include not only the oxygen-substituted chiral centers that one expects to find, but also others with different heteroatoms as substituents, and in particular those with carbon branching. Alongside these centers are listed the corresponding building blocks from the catalog that have the specified chain-length and absolute configuration. If the user also wants to know about all the partially oxygen-blocked, carbocyclic, and carbon-branched structures included in the catalog, this information is provided by the last three indexes in the appendix, which are structured along the same lines as the stereochemical index. These various indexes together equip the reader with a range of tools for finding a required building block.

The book contains a wealth of densely-packed information. However, in the first part a somewhat more detailed treatment, especially in Chapters 3 (partially blocked sugars) and 7 (unsaturated sugars), would have improved the book still further. Also a few of the structures contain errors (e.g., **8.23** on p. 56, **7.22** on p. 28, and Scheme 3.8), and it would have been useful to include overall yields in the details of all the building blocks.

This book will be especially useful to everyone who wishes to carry out syntheses using carbohydrates as enantiomeric starting materials with a known absolute configuration. The clear and easily understandable layout makes the subject readily accessible to the reader, and it is to be hoped that the book will overcome the inhibitions of many organic chemists towards working with this class of compounds. If it had been available ten years ago, this reviewer would have been spared a good deal of laborious effort.

Methods in Molecular Biology. Vol. 59, Protein Purification Protocols. Edited by *S. Doonan*. Humana Press, Totowa, NJ, 1996. 405 pp., loose-leaf $ 64.50.—ISBN 0-89603-336-8

This book edited by Shawn Doonan contains 36 chapters written by 33 different authors. In the first chapter the editor himself sets out some general strategies for the purification of proteins, then the following few chapters describe methods for extracting proteins from various animal and plant tissues and from bacteria and fungi. Next some articles on subcellular fractionation are followed by chapters of a more general kind on topics such as concentration and ultrafiltration. A large part of the book is devoted to various column chromatograpy procedures, then further chapters deal with the purification of membrane proteins and the use of detergents. The last part of the book contains contributions on the lyophilization and storage of proteins and on methods for electroelution from gels and electroblotting. The editor himself concludes with a chapter on practical aspects of column chromatography.

The list of the contents and the cover (in ring-binder form) lead one to expect here a handbook that belongs in every laboratory, but unfortunately the text does not live up to that promise. The separation into Methods and Notes within the individual chapters makes the book troublesome to read, and one can easily lose sight of the theme through frequent turning back and forth. It also becomes apparent that the bulkiness of the book is partly due to the fact that different authors cover the same points in their notes, for example when repeating advice about the correct use of a centrifuge and the care of rotors. It would certainly have served the newcomer better to include an introductory chapter on centrifugation, to which all the others could then refer, and would also have saved paper. Cross-references to other chapters are rare, so it is not surprising that Doonan himself, in his chapter on fractional precipitation using ammonium sulfate, again devotes nearly two pages to dialysis, despite the fact that he has already contributed a chapter on this topic.

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2404 $ 15.00+.25/0

In the first of the chapters on column chromatography, the reader who expects to learn something about ion exchange will be disappointed. The authors of this chapter, Sheehan and Fitzgerald, limit their discussion mainly to the preparation of a DE-cellulose exchange medium, and do not refer to more recent materials. There is no mention of variables such as column dimensions, capacities, gradients, etc., which are so important when planning purification strategies. These are only discussed in the final chapter, which again illustrates the book's lack of a systematic structure. However, notwithstanding these criticisms, the collection includes some very useful contributions, such as the chapters introducing the reader to the extraction of proteins from different types of tissues. Another chapter worth mentioning here is that by Bill Neville on reverse phase chromatography of proteins. The three chapters by Kay Ohlendieck on the extraction and purification of membrane proteins and the removal of detergents also certainly belong among the better examples, although it might have been better to combine these topics in a single chapter. However, the selected chapters mentioned here are again unnecessarily extended by including detailed descriptions of enzyme assay methods. The detailed description of the isolation of eggs from the sea-urchin and of the preparation of artificial sea-water is of limited interest to a broad readership, and a different example would have been more appropriate here. It would have been useful to include an article on the use of Triton X 114 for the separation of peripheral and integral membrane proteins.

The reader who hopes to find new materials or methods in this book will be disappointed. In many cases the information given is one-sided, as in the chapter on isoelectric focussing by Reiner Westermeier. This author is constrained by his admiration for a wellknown Swedish instrument manufacturer, and consequently fails to mention alternative methods of isoelectric focussing such as the Bio-Rad Rotofor cell or the high-resolution free-flow method (Octopus, Dr. Weber). The editor too is quite open about including an advertisement for the above-mentioned firm, and the last chapter even includes price information about some of the products. Here, though, the competitors are at least mentioned by name.

Finally there is the question of which readership this book is intended for. In my view it seems unsuitable for newcomers to the field, especially with regard to column chromatography. Although it contains sufficient information for these readers, they would need to hunt through the various chapters to bring it together, which is a difficult task without cross-references. The book also appears not to have been intended as a reference source for experienced protein chemists, as it does not cover new techniques and materials. This group is in any case already well served by the standard works cited in many of the chapters, such as *Methods in Enzymology*, or by the compact and informative handbooks in the *Practical Approach* series.

Sensors. Vol. 8. Micro- and Nanosensor Technology/Trends in Sensor Markets. Edited by *H. Meixner* and *R. Jones*. (Series: Sensors. A Comprehensive Survey. Series editors: *W. Göpel, J. Hesse* and *J. N. Zemel*. VCH Verlagsgesellschaft, Weinheim/VCH Publishers, New York, 1995. 565 pp., hardcover DM 410.00.—ISBN 3-527-26774-3

The final volume of this well-known work of reference has at last appeared. The publishers' original plans were revised so that the series could be extended to take into account the most recent changes in sensors research.

In the last few years research in this field has undergone some fundamental changes of direction. The main causes for this were the rapid growth of knowledge in three-dimensional microprocessing techniques (micromachining of silicon, and the LIGA technique), major advances in experimental methods for studying physical processes on the nanometer scale (STM, AFM, near-field spectroscopy), and the ability to synthesize nanostructured materials of various functionalities. This brought on the one hand new possibilities for system integration (microsystem techniques), and on the other hand the ability to control objects with dimensions in the nanometer range (nanotechnology). Also researchers in this field have become more keenly aware of needs in the market for sensors. In the new climate with regard to investment in research and development one sees a definite trend for companies to treat high-tech know-how as an essential prerequisite for strengthening their market position.

This volume is divided into two parts: Chapters 1–11 covering micro- and nanotechnologies, and Chapters 12–18 covering the markets for sensors.

Chapter 1 is a general introduction to the topics covered in this volume. Chapter 2 contains an overview of the three main types of microsystem technologies, namely the "beside-IC" type (hybrid design), "in-IC" (integrated design), and "above-IC" (design as a multilayer structure). This includes descriptions of some of the technological solutions that have resulted, such as pressure sensors and acceleration sensors (examples of "beside-IC" technology), and an electromagnetic actuator (an example of an "in-IC" design). The technologies are considered from two standpoints: firstly the needs of the market, and secondly the essential factors that contribute to the successful development of innovative microsystems.

Chapter 3 describes the design and production of microsystems within the area of integrated technologies, i.e., using only industrial IC methods, with or without additional IC-compatible production stages that are specific to the sensor concerned. In particular the chapter describes CMOS sensors for measuring humidity, magnetic fields, and electric fields.

Chapter 4 deals with the production of microsystems using the LIGA technique and several other technologies that do not belong to conventional microelectronics. The examples chosen to illustrate the LIGA method include microspectrometers and acceleration sensors. Other examples are a micropump manufactured by thermoplastic compression molding and an electrochemical microanalytical system. From this article it becomes clear that there is a distinction between microsystem technologies and microelectronic technologies. Production methods that can be used to make miniaturized sensors and control devices belong to microsystem technology.

The subject matter of Chapter 5 overlaps to some extent with the chapter on mass-sensitive detectors that appeared in Volume 2. In the present chapter the main emphasis is on the design of SAW structures, and the use of these in security passes for controlling access by a non-contact interrogator.

Chapter 6 discusses problems arising in the manufacture of miniaturized gas sensors for use at high temperatures, and possible ways of overcoming these. There is a particularly high demand for such sensors in the automobile industry. The main difficulty is that existing sensors have too short a useful life. The chapter describes attempts to overcome this problem by the use of new materials and by improving the mode of operation of such sensors. Chap-

ters 7 and 8 review the latest developments in the area of integrated optics and fiber-optic sensors.

The following three chapters are devoted to the basic concepts in the fields of nanostructured materials (Ch. 9), nanotechnologies (Ch. 11), and molecular electronics (Ch. 10). Chapter 9 emphasizes the innovative possibilities arising from the latest developments in nanostructured materials. However, the subject is treated too briefly here, covering only a few aspects of the synthesis of the materials and the production of thin films. There are no examples of applications of such materials in sensors. In Chapter 10 special attention is given to the importance of understanding the molecular and atomic processes for developing high-performance chemical sensors. Some prime examples are gas sensors based on inorganic films in which charge transfer occurs by a variety of mechanisms, other types of gas sensors depending on host–guest interactions, and the principles of function and recognition in biosensors using enzymes, antibodies, and cellular membranes. There is also a short description of the principles of molecular electronics and bioelectronics, and the use of pattern-recognition algorithms in chemical sensor technology. Chapter 11 presents a rather speculative subject-nanosensors. According to the definition given here for an nanosensor, it must have one of the following properties at nanoscale: sensitivity, surface area at which the interaction occurs or characteristic dimensions. The examples described are displacement sensors working in the nanometer and picometer ranges, force-measuring sensors based on the STM principle, optical near-field nanosensors, and Hall effect nanosensors. Apart from the optical sensors all these structures are produced by micromachining of silicon.

The purpose of the second part of this volume is to disseminate reliable information about the market for sensors. The analysis of the market for innovative sensors and microsystems is arranged under the following six key areas: aerospace industry (Ch. 13); industrial process control (Ch. 14); medical and clinical applications (Ch. 15); environment (Ch. 16); automobile industry (Ch. 17); production engineering and quality control (Ch. 18). The authors of this report describe basic requirements for measurements, and technical and commercial limitations that are specific to each of the fields discussed. They also give information about the size of the market and the commercial significance of already existing products, the requirements for new types of products in the area of sensors, and potential new markets.

The book as a whole is set out in a clear and systematic style, and has a comprehensive index. It can be recommended for all scientists and technologists who are looking for a systematic overview of the current state of sensor and microsystem technology, despite the risk that a book dealing with such a rapidly developing area of research may quickly become outdated. University and technical college students of sensor and microsystem technologies should also have access to this work, at least through a library.

Metal Complexes in Aqueous Solution. By *A. E. Martell* and *R. D. Hancock*. (Series: Modern Inorganic Chemistry. Series editor: *J. P. Fackler, Jr.*). Plenum, New York, 1996. 253 pp., hardcover $ 59.00.—ISBN 0-306-45248-0

The two authors of this book have been engaged in research in coordination chemistry for many years and have contributed greatly to the subject. They have done much detailed work on the determination of thermodynamic quantities for metal complexes and the interpretation of such data in relation to steric and electronic effects in metal–ligand interactions. These studies form the subject of the book reviewed here.

An introduction, which includes a brief historical survey and a concise summary of the most important physicochemical quantities relating to metal ions, is followed by three chapters in which the thermodynamic aspects of metal–ligand interactions are discussed in detail. Taking a representative selection of monodentate ligands as illustrative examples, the authors describe the essential characteristics of complex formation, first in the gas phase then in aqueous solution. The increased stability with multidentate ligands (chelate effect) and with macrocycles (macrocyclic effect) is explained by conformational considerations based on molecular mechanics calculations. In particular, the authors show that some commonly accepted ideas, such as the explanation of the chelate effect purely in terms of entropy, or the assumption that the selectivity of macrocyclic ligands can be predicted from the diameter of the molecular cavity, are incorrect or at least oversimplified. The second part of the book presents some topical examples from biology and medicine, such as chelate therapy, contrast agents for magnetic resonance imaging, and radiopharmaceutical applications. The authors give a survey of the various ligands that are currently used, and present some ideas for the design of new tailored ligands. The book ends with a short description of experimental methods for determining stability constants. Each chapter contains a detailed list of references to original publications, although with a definite emphasis on the authors' own work.

In view of the great importance of metal complexes in present-day medicine, biology, and environmental chemistry, the appearance of an authoritative work on the subject by two recognized experts is very welcome. Nevertheless, the wide-embracing title of the book leads one to expect more than the authors have included here. For example, reversible electron transfer processes play an important role in the chemistry of transition metal complexes (e.g., one need only think about the respiratory chain), and yet there is nothing at all here on redox reactions (with regard, for example, to the question of how the ligand shell affects the redox potential). Again, there is no discussion of hydrolytic polymerisation. One very important reaction pattern exhibited by metal complexes is the formation of polynuclear aggregates with oxo or hydroxo bridging, and should at least have been given a mention (for example, in the summary of possible types of reactions on pp. 221–222). The kinetics of ligand substitution are touched on only briefly in the introduction, and the authors do not take the opportunity to go into more detail later. One searches in vain for important keywords such as "*trans* effect" and "base catalysis". The discussion of experimental methods concentrates mainly on potentiometric techniques [including passages in Sections 7.4 to 7.7 that are mostly taken word-for-word from the book *Determination and Use of Stability Constants*, by A. E. Martell and R. J. Motekaitis (VCH Verlagsgesellschaft, 1988)]. Other methods such as NMR and ESR are mentioned briefly but are not explained in more detail.

Most of the (inevitable) printing errors are of a kind that do not interfere significantly with one's understanding. However, there are some regrettable mistakes, for example in the legend and labeling of Figure 2.19. In Sections 5.5 to 5.9 there are problems with the numbering system used for the ligands, as the numbers in the text do not agree with those in the graphics. Water ligands should be denoted by

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3520-2406 $ 15.00+.25/0

"aqua" rather than "aquo" according to IUPAC recommendations. The text as a whole could have been written somewhat more concisely. The frequent repetitions detract from the clarity of the book; for example, Tables 5.1 and 6.4 are identical. Equation 6.1, which reads: $\log K_1(\text{multidentate}) = \log \beta_n(\text{unidentate}) + (n-1)\log 55.5$ corresponds to Equation 3.1, which is identical except that there "multidentate" is replaced by "polydentate". Figures 3.16 and 6.10 show the same linear plot of $\log K(\text{DFO})$ against $\log K(OH^-)$ (relationship between the free energies), except that different values are given for Pu^{4+}! On the other hand, some of the explanations given in the introductory chapter (Ch. 1) are a little too brief. For example, in Figure 1.5 the various metal centers are classified into "hard", "soft", and "borderline" types (Pearson's HSAB principle). Here Fe and Cu are classed as "borderline", Ag as "soft", and Ga as "hard", without any indication of oxidation states. Although these assignments are appropriate for Fe^{II}, Cu^{II}, Ag^{I}, and Ga^{III}, the same is not true for Fe^{III}, Cu^{I}, Ag^{II}, and Ga^{I}.

To sum up, this book can be recommended for advanced undergraduate students, as well as for researchers working in the areas of coordination chemistry, aquatic chemistry, medicinal chemistry, and bioinorganic chemistry. It will give them a better understanding of the selectivity of metal complexing agents and provide valuable insights for the design of new tailored chelate ligands. However, the discussions are confined to thermodynamic aspects of mononuclear complexes (treated from an unconventional and also rather one-sided point of view). In this respect the book does not fully live up to its title.

Stereochemistry of Coordination Compounds. By *A. von Zelewsky*. Wiley, Chichester, 1996. 254 pp., paperback £ 24.95.—ISBN 0-471-95599-X

This book on the stereochemistry of coordination compounds goes well beyond the basic information typically found in textbooks of inorganic chemistry, and even covers recent developments in the chemistry of complexes, such as helicates, complexes of macropolycycles, and siderophores. The emphasis is on "topographical stereochemistry", an aspect that deals with the type and number of stereoisomers and their symmetry properties. The book is essentially concerned with "classical" complexes, so that organometallic compounds and clusters are not treated, for good reasons that are explained on page 9. The literature references provided (over 500) give the reader access to the original papers to study topics in greater depth.

In the introduction (Ch. 1) the author mentions the important contributions of Alfred Werner, whose coordination theory, formulated towards the end of the 19th century, was based mainly on stereochemical considerations. The clarity of this chapter could have been improved by separating the many figures and inserts more obviously from the running text, since the reader might easily lose the thread of the discussion in a few places.

Chapter 2 contains a critical discussion of the experimental methods used for investigating the stereochemical structures of coordination compounds. Chapter 3 then gives a brief survey of the most important types of coordination geometry for complexes of main-group and transition metals. Unfortunately Table 3.1 (p. 31) contains several blunders: for example, the commonest coordination geometry for Cu^{II} is the square-pyramidal, not the tetrahedral.

Chapter 4 deals with some basic concepts of topographical stereochemistry, beginning with general considerations regarding the symmetry and isomerism of metal complexes, and continuing with a classification of ligand types. In deciding which stereochemical nomenclature to use, the author opts for a sensible compromise. In general he follows the IUPAC rules for the nomenclature of inorganic compounds, but in the interests of clarity he occasionally departs from these in some details and adopts alternative principles. Thus, the introduction of several different reference systems for describing the chirality of metal complexes (pp. 67–70) seems entirely appropriate. On the other hand, it takes a little while to get used to some of the unconventional symbols introduced on pages 40-46, such as $A = A$ for planar chelate ligands and $A \approx A$ for nonplanar ones.

Chapter 5 treats the stereochemistry of mononuclear coordination compounds, illustrated by many examples. Here, if not earlier, the discussion of stereoisomeric octahedral chelate complexes (pp. 119-128) reveals one of the main strengths of the book, in that the discussions are supported by a wealth of informative examples. Even complex macrocyclic and macropolycyclic ligands and siderophore complexes are included. Here, however, I feel I must make a correction (p. 148): the first flexible polyazamacrocycle was synthesized as early as 1937 by Alphen, well before the work of Curtis in 1960. The figures in all the chapters have been prepared with much care, and I noticed scarcely any errors [although Fig. 5.73(i) on p. 159 is incorrect].

In Chapter 6 the reader is introduced to the more complex multinuclear systems, beginning with compounds having simple bridging ligands such as hydroxide, halide, or bipyrimidyl. In supramolecular coordination compounds such as the helicates and Sauvage's molecular chains and loops, the stereochemistry is of central importance.

Finally, Chapter 7 deals with stereochemical processes in the reactions of coordination compounds. Due to the complexity of this subject, only selected aspects could be covered. Here the main emphasis is on isomerizations and substitutions at the metal atom. Other topics, such as reactions of coordinated ligands and enantioselective catalysis, are treated only briefly.

To summarize, the book *Stereochemistry of Coordination Compounds* is an excellent and clearly set out reference source for chemists working on metal complexes, with a wealth of examples and many figures. The reader should be able to quickly extract information on a wide range of problems in static stereochemistry. Furthermore, the book is well written from a teaching standpoint and should be suitable for use by advanced students, although the subject matter is quite specialized for these readers.

Novolak-Diazoquinone Resists: The Imaging Systems of the Computer Chip

Arnost Reiser,* Hsiao-Yi Shih, Tung-Feng Yeh, and Jian-Ping Huang

This year some twenty billion integrated circuits will be produced worldwide. Almost all (98%) of them will be made with a photosensitive varnish, the photo resist, that allows the transfer of a fine line-pattern from an original transparency onto a silicon wafer. This photoresist has two components: one is a novolak resin, a low molecular weight phenol–formaldehyde condensation polymer; the other is a diazonaphthoquinone derivative (DNQ), which is the photoactive part of the system. Novolak–diazoquinone resists have played a crucial role in the microminiaturization of electronics. They are photographic materials of extremely high resolution, able to define features as small as 0.25 μm. Although they are now an indispensible ingredient of modern computer technology, until quite recently their molecular mechanism was not understood. We report here on work at Polytechnic University in New York aimed at solving the mystery of these important and intriguing systems. The solution, in so far as it has revealed itself to us, is rather unique and quite unexpected.

Keywords: diazonaphthoquinones · microlithography · novolak resists · percolation theory · photographic materials

1. Introduction

1.1. Initial Observations and Explanations

In the early 1940s, Oskar Süs, a leading organic chemist at Kalle in Wiesbaden, noticed that coatings of pure novolak dissolved in aqueous alkali within minutes, whereas similar coatings containing diazoquinone derivatives took an hour or more to dissolve. However, when these coatings were exposed to sunlight, they dissolved even faster than pure novolak films. It seemed that diazoquinones inhibited the dissolution of novolak, but lost their inhibiting power on exposure to light. Süs realized the potential of his observation and designed a lithographic printing plate that functioned like a film positive: irradiated and unexposed areas could be distinguished by a large differential in dissolution rate.[1] On the same principle, Süs formulated a light-sensitive varnish ("Kopierlack"),[2] which is now termed a lithographic resist.

The use of resists in the building of semiconductor devices is illustrated in Figure 1. The top of a silicon wafer carrying a layer of SiO_2 (glass) is coated with a thin resist film. The dry film is exposed to UV light through a transparency (the mask) that defines the desired pattern. The exposed film is immersed in a solution of base (the developer) long enough to remove the resist from the irradiated areas. The film is washed and dried to form a template that protects the covered areas of the wafer, but allows chemical action to take place in those areas that were uncovered by exposure and development. Thus, the SiO_2 layer may be removed image by image, and subsequently various dopants introduced in small, well-defined regions of the silicon substrate.

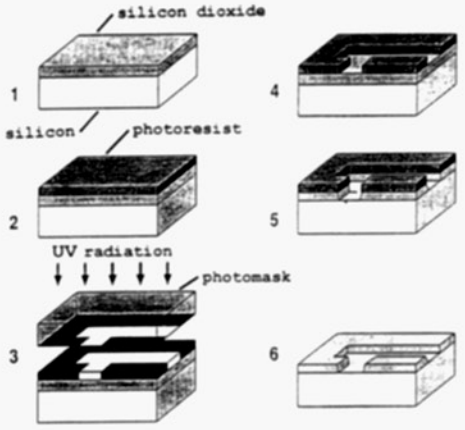

Fig. 1. The basic steps of microlithography: 1) oxidation of the silicon wafer, 2) coating with resist, 3) irradiation through a patterned mask, 4) development of the exposed film in aqueous base, 5) etching away the SiO_2 layer, 6) system ready for localized chemical action. from integrated circuits with a few hundred transistors to the 16-megabit chip.[3] They have become a crucial part of modern technology. Yet in spite of this, their molecular mechanism was not understood until quite recently.

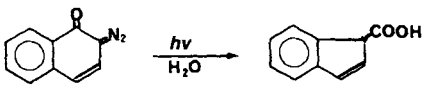
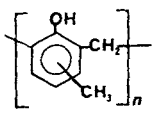
When Süs first tried to rationalize the behavior of these materials, he tested a series of diazoquinones and found that, to a varying degree, all worked as "photoactive component" in novolak resins. He surmised that image discrimination in the resists was based on a common photoreaction of diazoquinones, and he investigated their photochemistry. On irradiation with a mercury lamp (Scheme 1), diazonaphthoquinone (**1**) loses a molecule of nitrogen and, in the presence of small quantities of water, is transformed into indene carboxylic acid (**2**).[4]



1 2

Scheme 1. Photolysis of diazonaphthoquinone (**1**).

Acid **2** is soluble in alkali in contrast to DNQ, and at the time that seemed an adequate explanation for the observed behavior. Of course, the photochemistry of diazoquinone does not address dissolution inhibition in the unexposed films, nor can it account quantitatively for the behavior of exposed resists. In fact, dissolution inhibition in novolak is a unique phenomenon. Just how unusual it is can be appreciated by comparison with the effect of additives on the dissolution of common polymers. For example, the addition of 10 percent of an insoluble component to a polymethacrylate may change the dissolution rate of the polymer in acetone by 10 to 20 percent;[5] however, 10 percent of a diazonapthoquinone (DNQ) slows down the dissolution of novolak in aqueous base by more than 2000%. Several interpretations of this phenomenon have recently been proposed,[6-11] but none seems completely convincing. In this paper we present a model of novolak dissolution and dissolution inhibition based on the concepts of percolation theory.[12]



3

1.2. Novolak Dissolution and the Penetration Zone

Novolak (**3**) is a low molecular weight phenol–formaldehyde condensation polymer. The dissolution of novolak in aqueous base predicates the deprotonation of the phenolic hydroxyl groups of the polymer Ⓟ to phenolates [reaction (a)].[6] In

$$Ⓟ\,OH + OH^- \rightleftharpoons Ⓟ O^- + H_2O \qquad (a)$$

that process, base is used and a molecule of water is formed. When a novolak film is immersed in aqueous base (the developer), the base penetrates the resin matrix and a thin layer of phenolate is formed at the interface between the resin film and the developer solution. This layer is a new phase, the penetration zone. Figure 2 is a schematic representation of the zone; the

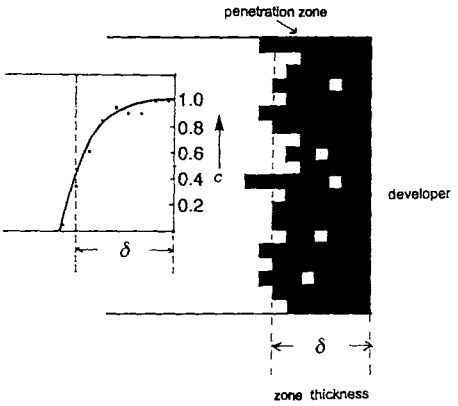


Fig. 2. The penetration zone formed at the interface of the matrix with the developer solution. The black squares represent phenolate ion sites; the white squares are phenolic OH units. The inset shows the concentration profile of phenolate ions in the zone.

phenolate ions are indicated by black squares. As soon as a sufficient number of OH groups has been ionized, the polymer chains at the back of the penetration zone become soluble in water; they disentangle and float off into the aqueous developer. When the rate of transfer of ionized novolak chains at the interface with the developer balances the rate of formation of phenolate at the front of the zone, a stationary dissolution regime is established. Without changing its thickness or its composition, the zone moves forward at a constant speed, which is identical with the dissolution rate (loss of thickness) of the novolak film.[13]

Since the deprotonation reaction is very fast, the rate of travel of the zone depends entirely on the rate at which base is supplied to the reaction site at the interface of the penetration zone with the virgin matrix. Thus, the rate of dissolution is controlled by the rate of base diffusion through the penetration zone. Arcus,

Arnost Reiser is Distinguished Research Professor and Director of the Institute of Imaging Sciences at Polytechnic University in Brooklyn, New York. Prior to that he was head of the Photochemistry Laboratory of Kodak Limited in England, where he became closely associated with the early development of photoresists. He has published extensively on polymer photochemistry and imaging, and he is the author of the book "Photoreactive Polymers: the Science and Technology of Resists", Wiley, New York, 1989. He holds the Henderson Medal of the Royal Photographic Society and was awarded a D. Sc. by the National Council for Academic Awards of Great Britain. He is a Fellow of the Society of Imaging Science and Technology.

who discovered the penetration zone and demonstrated its physical existence as a separate phase, sensed that the zone acted as a kind of control membrane,[14] and that various agents, including light, influence the permeability of this membrane to produce the unusual dissolution behavior of the system.

Since it comprises almost entirely phenolate/counterion pairs, the zone is a solid polyelectrolyte of exceptionally high ionic strength (total ionic strength as high as 10 M). The electrostatic forces between the polymer-bound phenolate anions and the countercations give it a high degree of cohesion, which has an unexpected consequence: at room temperature, the penetration zone of most resins is in a rigid glassy state. This can be demonstrated by monitoring the dissolution of resin films over an appropriate temperature range.[15] Figure 3 shows the Arrhenius plot for the dissolution of a typical novolak resin at room temperature in a 0.20 N solution of KOH. The plot has two branches separated by a discontinuity. The temperature at the discontinuity is the glass transition temperature T_g' of the zone. For the resin referred to in Figure 3 the glass transition temperature T_g' of the zone is 30 °C. In contrast, the glass transition temperature T_g of the bulk of the resin film is about 120 °C.

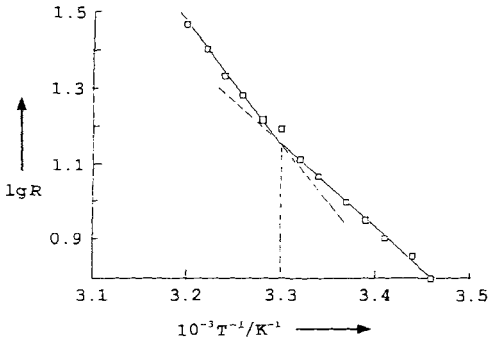

Fig. 3. Arrhenius plot of $\lg R$ vs. $1/T$ for a novolak resin dissolving in 0.2 N KOH. The discontinuity of the plot corresponds to the glass transition temperature T_g' of the penetration zone (30 °C).

Some insight into the significance of the glass transition in these systems can be gained from the activation energies calculated for the two branches of the Arrhenius plot. The activation energy of dissolution E is 4.3 kcal mol^{-1} below T_g', and 8.6 kcal mol^{-1} above T_g'. It is unusual that a higher activation energy is associated with a higher diffusion rate. The reason for this behavior is a profound change in the mechanism of base diffusion. Below the glass transition, the hydrophilic sites (OH groups and phenolate ions) are fixed in their locations, and the distribution of open bonds (that is, bonds passable by the diffusant; see Section 2) in the percolation field is independent of time. Under these conditions the activation energy corresponds to the average energy barrier between adjacent sites that form open bonds. Above the glass transition, the hydrophilic sites in the penetration zone become mobile, and site diffusion becomes the rate-determining process. The activation energy of dissolution is now associated with the movement of sites. Below T_g' the diffusant percolates in a field of stationary sites, above T_g' the sites are mobile and cooperate in the diffusional transport.

The interface of the zone with the resin matrix is a fractal surface[16, 17] (Fig. 2). The fractal nature of the interface produces a concentration profile of phenolate ions in the zone that is matched by a corresponding concentration profile of base established during the dissolution process. The form of this profile, schematically shown in the inset of Figure 2, is responsible for the nonlinear dependence of the dissolution rate on the base concentration of the developer.[18] Details on this aspect of the system can be found in references [13] and [18].

The dissolution rate R (in cm s^{-1}) is linked to the diffusional flux F of base through the zone (in mol L^{-1} cm^{-1} s^{-1}) by the mean base concentration c (in mol L^{-1}) in the zone [Fig. 4, Eq. (1)].[18] Applying Fick's law to this situation and

$$F = Rc \qquad (1)$$

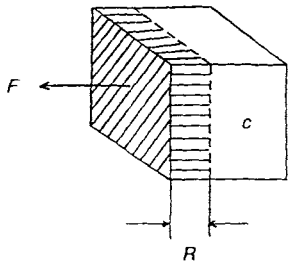

Fig. 4. Diffusional flux F of base per unit area (in mol cm^{-2} s^{-1}) of the penetration zone in a developer of base concentration c (in mol cm^{-3}). R is the rate of travel of the membrane in the direction of the concentration gradient (in cm s^{-1}).

ignoring the precise shape of the concentration profile in the penetration zone, one may in a first approximation replace the average concentration gradient $\left(\frac{dc}{dx}\right)$ in the zone by the ratio of the base concentration in the developer (c_0) to the thickness δ of the penetration zone [Eq. (2)]. This leads to a relation between

$$F = -D\frac{dc}{dx} = -D\frac{c_0}{\delta} \qquad (2)$$

the dissolution rate and the mean diffusion coefficient D of base in the penetration zone [Eq. (3)]. By inserting reasonable values

$$R = 2\frac{D}{\delta} \qquad (3)$$

for the dissolution rate ($R = 200$ A s^{-1}) and for the thickness of the penetration zone ($\delta = 100$ Å) one obtains a mean diffusion coefficient of base in the zone of approximately 10^{-12} cm^2 s^{-1}.[13]

This value is rather low compared with the diffusion coefficients of small solvent molecules in common polymers (10^{-6} to 10^{-8} cm^2 s^{-1}), but it is not unrealistic; Barker and Thomas measured the mobilities of alkali ions in cellulose films and found diffusion coefficients of the order of 10^{-18} cm^2 s^{-1}.[19]

There is a fundamental difference between the diffusion of solvent into common polymers and the diffusion of base into novolak films. The key to understanding this difference is the recognition that novolak and other phenolic resins are amphiphilic materials that contain hydrophilic as well as hydrophobic moieties. A novolak film may thus be regarded as a hydrophobic solid in which hydrophilic sites (the OH groups of the phenols) are embedded. Base ions are attracted to the hydrophilic sites and repelled by the hydrophobic regions. As a result, they migrate into the solid by transferring from one hydrophilic site to the next.[12] This mode of progression is a typical percolation process, and if our view is correct, the diffusion of base into amphiphilic solids will be governed by the rules of percolation theory.

2. Percolation Theory

Percolation theory describes the progression of a particle through a system of cells, some of which are occupied and others empty.[20-22] Figure 5 is a schematic representation of a two-dimensional square percolation field where the occupied cells are indicated by open circles. The mobile particle is allowed to reside in occupied cells, and it may transfer from one occupied cell to its occupied neighbor, but it cannot enter an unoccupied cell. As a result its movement is circumscribed by the size of the cluster of occupied cells in which it happens to find itself. The state of the percolation field is characterized by a percolation parameter p, which is simply the fraction of occupied cells. The higher the percolation parameter p, the larger the average size of the cell clusters. At some stage the cluster becomes "infinite", that is, it extends across the whole percolation field. At that point continuous diffusion throughout the system sets in. The critical p value at which this occurs is called the percolation threshold, p_c.

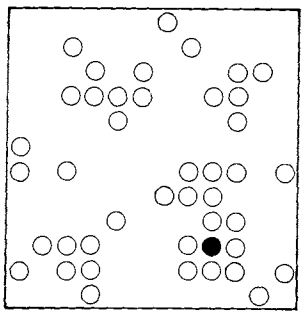

Fig. 5. Two-dimensional square percolation field in which only the occupied cells are marked by open circles. The filled circle represents the mobile particle.

It is a fundamental thesis of percolation theory that the macroscopic properties of the system are functions of the difference $(p - p_c)$. For diffusion in three dimensions this function takes the form of a quadratic scaling law [expression (4)].

$$D \sim (p - p_c)^2 \tag{4}$$

To apply the concepts of percolation theory to novolak we identify the occupied cells as those which contain either a phenol group or a phenolate ion. Both have the main attributes of a percolation site (an occupied cell): they attract, or tolerate, the (ionic) diffusant. The situation may be represented in terms of potential energy surfaces. In a hydrophobic continuum the OH group is characterized by the potential energy surface of a dipole interacting with an ion. Figure 6 shows a cross-section through the potential energy surfaces of two adjacent potassium phenolate sites (dipole moment μ = 3.0 Debye); part of the potential energy surface of a phenol site (μ = 1.5 debye) is also indicated. The potential energies were calculated based on electrostatic considerations and a Lennard-Jones potential.[23] The elementary event of base diffusion is the transfer of an ion from one potential energy trough to the next. In that transfer step the diffusant must overcome the energy barrier E_b at the intersection of the potential energy surfaces of the two adjacent sites. The probability of transfer is given by a Boltzmann factor $\exp(-E_b/RT)$, and we shall assume that above a certain critical energy barrier the transfer probability between two sites is so small that it may be neglected, while for all energy barriers below that critical value transfer will be certain. This crude device allows us to fit the dissolution problem into the established formalism of percolation theory in which a transition is either allowed or forbidden.

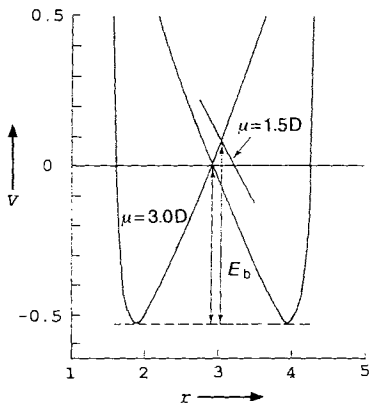

Fig. 6. Intersection of the potential energy hypersurfaces of two adjacent phenolate sites (dipole moments μ = 3.0 Debye) at a separation of about 6 Å. Part of the potential energy curve of a phenol site (dipole moment μ = 1.5 Debye) is also indicated. V: energy in eV; r: radius in Å; E_b: the energy barrier.

Figure 5 represents a site percolation field, but percolative diffusion is, in fact, a bond percolation process,[20, 21] a bond being the link between two adjacent sites. In a bond percolation field the diffusant migrates along an unbroken sequence of open bonds. The energy barrier between two sites decides whether a bond is open (that is, passable by the diffusant) or closed, and that energy barrier depends in the first place on the spatial separation of the two sites. The relationship between site separation and the energy barrier between sites can be illustrated by measuring the activation energy of dissolution in resin films in which the average site separation varies. In Figure 7 we have plotted the experimentally determined activation energy of dissolution as a function of the average intersite distance for a series of polyvinylphenol resins in which the average intersite distance had been modulated by partial methylation of the OH groups of the resin.[12]

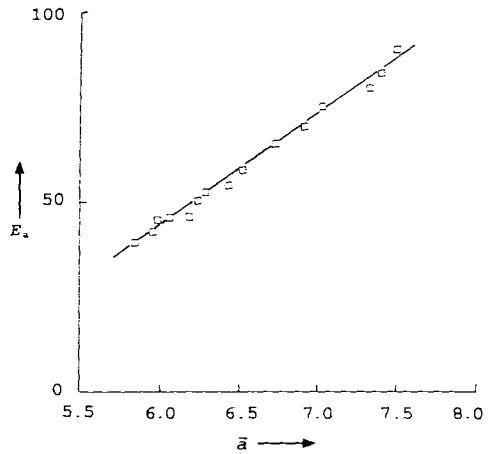

Fig. 7. Activation energies E_a (in kJ mol^{-1}) of dissolution for partially methylated poly(vinylphenol) resins, plotted as a function of the average intersite distance $\bar{a}$ (in Å).

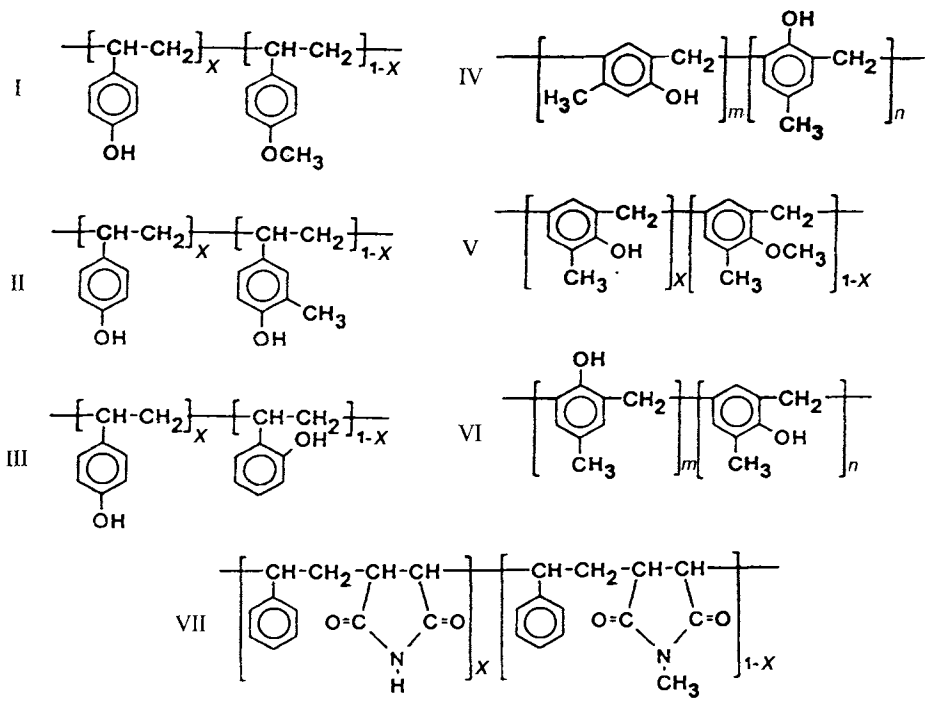
The view that percolative diffusion in amphiphilic solids is a bond percolation process is supported by a variety of observations, and also by the experimentally found value of the percolation threshold (p_c = 0.20), which is very near the theoretical percolation threshold for a cubic bond-percolation system.[15] The theoretical threshold for bond percolation in a simple cubic lattice is 0.25, and in a body-centered cubic lattice it is 0.18. (The corresponding values for a site percolation field are significantly higher: 0.312 and 0.245).[21]



Scheme 2. Amphiphilic resins: I) partially methylated poly(4-hydroxystyrene) resins [1, 5]; II) copolymers of 4-hydroxystyrene and 3-methyl-4-hydroxystyrene [9]; III) copolymers of 4-hydroxystyrene and 2-hydroxystyrene [10]; IV) novolak resins made from mixtures of *m*-cresol and *p*-cresol [11]; V) partially methylated *o*-cresol novolak resins; VI) partially methylated novolak resins made from equimolar quantities of *o*-cresol and *p*-cresol; VII) partially methylated alternating copolymers of styrene and maleimide.

2.1. A Percolation Model of Novolak Dissolution

We tested the bond percolation model of novolak dissolution by fitting the experimentally determined dissolution rates with the scaling law (5). The percolation parameter p in a phenolic

$$R \sim (p - p_c)^2 \tag{5}$$

resin is proportional to the concentration of OH groups. We selected seven amphiphilic resins (Scheme 2)[1,5] and changed their percolation parameter either by successively methylating some of their OH groups (I, V to VII), or by changing the accessibility of OH groups through steric hindrance (II to IV). Resins I to III are polyvinylphenols, IV to VI are novolak resins, and VII is an alternating copolymer of styrene and maleimide. By modifying the base resins we produced 52 amphiphilic resins with different values of p. Each resin was characterized by its fraction (x) of unaltered OH groups, and it was assumed that the unaltered base resin ($x = 1$) of each series had a percolation parameter of unity ($p = 1$). The logarithm of the dissolution rate ($\lg R$) was then plotted against $\lg(p - p_c)$. An appropriate value for the percolation threshold of all our resins was found to be $p_c = 0.20$.

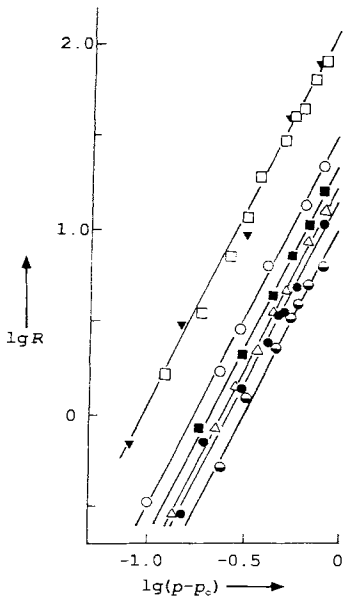


Fig. 8. Plot of $\lg R$ against $\lg(p - p_c)$ for seven series of amphiphilic resins (see Scheme 2). □ resin I, △ resin II, ■ resin III, ▼ resin IV, ○ resin V, ● resin VI, ◒ resin VII.

The results of these experiments are shown in Figure 8: the data points lie on straight lines that have a slope of 2, as demanded by the quadratic scaling law of Equation (5). Figure 8 also indicates that the dissolution behavior of these systems can be generalized. By translating the correlation lines to the left, they can be brought into superposition with the correlation line of the fastest dissolving resins, the polyvinylphenols I. In that case the experimental points fall on a single line, represented by a dimensionless scaling law [Eq. (6), where R° is the dissolution rate of the reference

$$\lg \frac{R}{R^\circ} = 2 \lg \frac{p - p_c}{1 - p_c} = f(p) \tag{6}$$

resin (unmethylated polyvinylphenol)]. The reference resin is assigned a percolation parameter of unity ($p = 1$); all other resins, including the base resins of other series, have lower values of p. In Figure 9 the dimensionless dissolution rate log R/R°

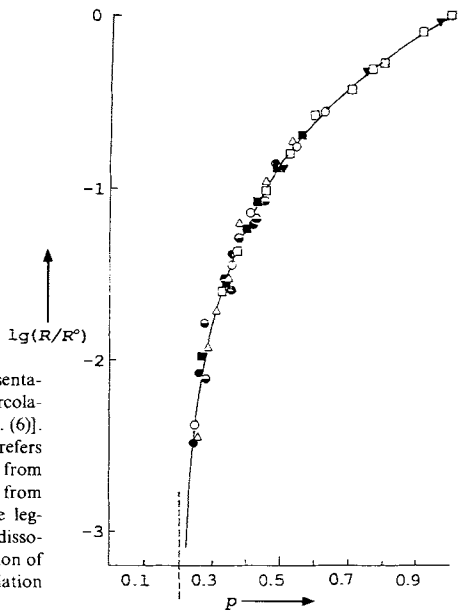

Fig. 9. Dimensionless presentation of the scaling law of percolative dissolution [Eq. (6)]. Each experimental point refers to an amphiphilic resin from one of the seven groups from Scheme 2. For symbols, see legend of Figure 8. R = rate of dissolution, R° = rate of dissolution of reference resin, p = percolation parameter.

is presented as a function of the percolation parameter p. The experimental points of all 52 resins fit the theoretical curve of the scaling law rather well.[15]

The generalized scaling law can also be used to define the percolation parameter p by an inversion of Equation 6 [Eq. (7)].

$$(p - p_c) = (1 - p_c)\sqrt{\frac{R}{R^\circ}} \tag{7}$$

This expression links the percolation parameter p directly to the dissolution rate R, rather than to the concentration of hydrophilic sites, and that is appropriate for a bond percolation process.

2.2. Dissolution Inhibition

After novolak dissolution was recognized to be a percolation process, it seemed a foregone conclusion that dissolution inhibitors function by blocking some of the hydrophilic sites (OH groups). To test this idea quantitatively we needed a measure of inhibition. In his study of the kinetics of resist dissolution Meyerhofer had found that a plot of the logarithm of the dissolution rate against the inhibitor concentration is linear over a significant concentration range (Fig. 10).[24] We used the slope

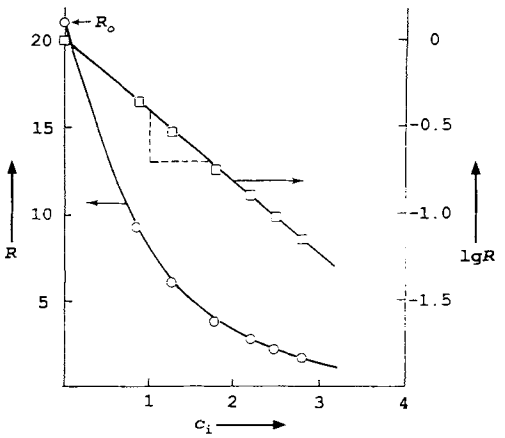

Fig. 10. Meyerhofer plot of the logarithm of dissolution rate ($\lg R$) vs. the concentration of inhibitor (c_i in wt%) in novolak films that contain a monofunctional diazonaphthoquinone inhibitor (DNQ). In addition the dependence of R (in $\mu m\,min^{-1}$) on c_i is shown.

of the Meyerhofer plot as a concentration-independent measure of the strength of the inhibition effect, and termed it the inhibition factor f_{ij} of inhibitor i in resin j [Eq. (8)]. If the inhibitor

$$f_{ij} = -\frac{d\lg R}{dc_i} \tag{8}$$

acts by changing the concentration of available hydrophilic sites, it must also change the percolation parameter of the system. The change in $\lg R$ is given by Equation (6). Accordingly, the inhibition factor f_{ij} is linked at the level of differentials to the slope of Equation (6) at the dissolution rate of the uninhibited resin. The differential at the right hand side of Equation (9) can be expanded, and on using the relation between dissolution rate and percolation parameter [Eq. (7)] it can be rewritten as Equation (10), where e is the base of the natural logarithm.

$$f_{ij} = -\frac{d\lg R}{dc_i} = \alpha\frac{d\lg R}{dp} \tag{9}$$

$$f_{ij} = \alpha_i \frac{2\lg e}{1 - p_c}\sqrt{\frac{R^\circ}{R}} \tag{10}$$

Equation 10 is a significant result. It establishes a relation between two seemingly unrelated, but directly measurable quantities: the inhibition factor of an inhibitor/resin pair and the dissolution rate of the pure, uninhibited resin. We have tested Equation 10 by plotting values of f_{ij} against the reciprocal square root of the dissolution rate ($R^{-1/2}$) of the uninhibited resins.[25] We used a standard monofunctional diazonaphthoquinone (DNQ) inhibitor (the *tert*-butyl ester of 2-diazonaphthoquinone-5-sulfonic acid) in three different types of resins: groups I and II are polyvinylphenol derivatives; group III contains partly methylated novolak resins. The results in Figure 11 show that straight lines are obtained for every group of resins, in agreement with Equation (10), but that the plots consist of two branches. The discontinuity is associated with the glass transition of the penetration zone.

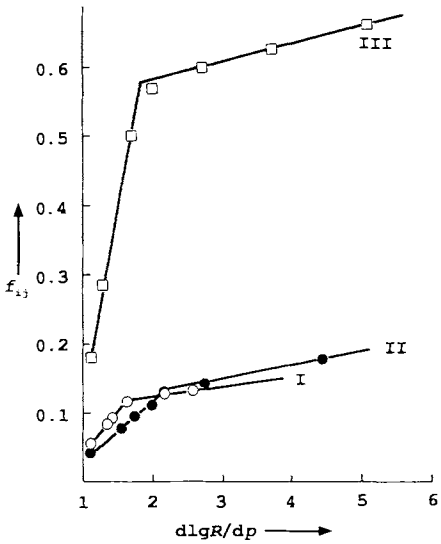

Fig. 11. Inhibition factor f_{ij} of a standard monofunctional DNQ inhibitor as a function of $d\lg R/dp$ for three series of phenolic resins: I) partially methylated poly(4-hydroxystyrenes); II) copolymers of 4-hydroxystyrene and 3-methyl-4-hydroxystyrene; III) partially methylated samples of a single novolak resin [15].

To prove this point we have determined T_g' for all the methylated novolak resins of group III by measuring the temperature dependence of their dissolution rates (Fig. 12).[25] The glass transition temperatures of the resins that give the discontinuities for group III observed in the f_{ij} plot of Figure 11 ($T_g' = 20\,^\circ C$) coincide with the temperature at which the inhibition factors were measured. As will be shown later, inhibition depends on the existence of phenolate clusters in the penetration zone. The glass transition T_g' marks the onset of site motion in the zone; above T_g' the phenolate clusters are no longer stable, and the inhibition effect does not grow any more with the slope of the scaling law function [Eq. (9)].

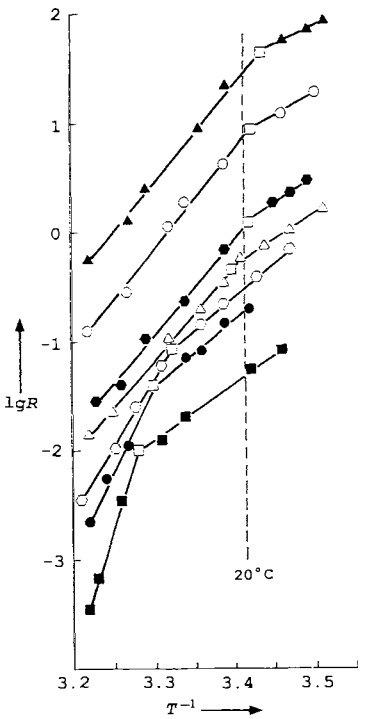

Fig. 12. Temperature dependence of the dissolution rate R (Arrhenius plot) of a group of partially methylated novolak resins (group III of Fig. 11). □: glass transition temperature T_g'.

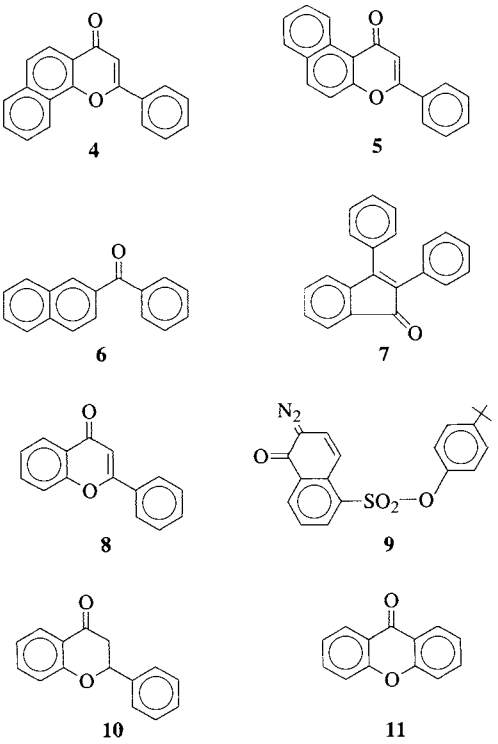
The slope of the plots in Figure 11 depends not only on the type of resin used, but also on the structure of the inhibitor. We have investigated nine aromatic ketones (inhibitors) in six partially methylated novolak resins that have different image points (Fig. 9) and slopes on the scaling law curve. All the resins had T_g' well above room temperature, so that the inhibition factors of the additives were measured in the glassy state of the penetration zone. In Figure 13 we have plotted the inhibition factors of inhibitors **4**–**11** against the reciprocal of the dissolution rate of the methylated novolak resins according to Equation (10). The experimental points for all inhibitors lie again on straight lines.[25]

The slopes of the correlation lines in Figure 13 are characterized by a proportionality constant α_i. This has the dimension of a molar volume and may be interpreted as that volume in the resin matrix that is made unavailable to percolation by the presence of one mole of inhibitor. Assuming that the least effective inhibitor, benzophenone (not shown in Fig. 13), blocks a single OH group of the resin, the ratio α_i/α_B (where α_B refers to benzophenone) measures the number of OH groups (hydrophilic sites) that a particular inhibitor would have to disable in order to produce the observed inhibition effect. Values of these "blocking numbers" (α_i/α_B) are listed in Table 1 together with the inhibition factors of the aromatic ketones.[26] According to this analysis, one molecule of the standard diazonaphthoquinone inhibitor blocks 7 OH groups, and one molecule of α-naphthoflavone eliminates some 16 phenolic sites. Clearly, inhibitors must be able to affect more than one phenolic OH to account for the inhibition effect routinely encountered in commercial resists.



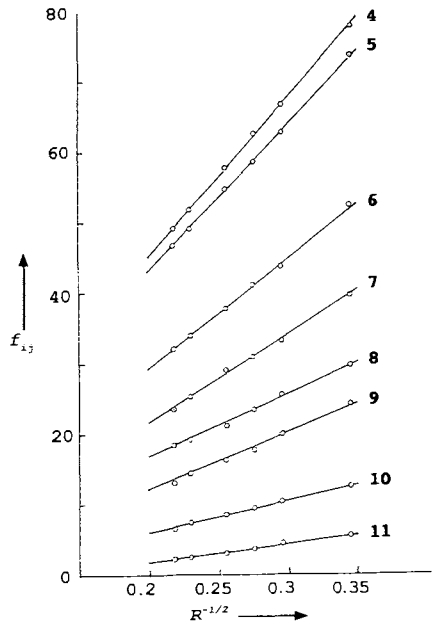


Fig. 13. Inhibition factors f_{ij} of eight additives incorporated into partially methylated novolak resins (group III of Fig. 11), plotted against $R^{-1/2}$ [25].

Table 1. Numbers of sites blocked by selected inhibitors normalized against benzophenone (given as the site blocking numbers α_i/α_B).

Inhibitor	f_{ij} [a]	M_i[b]	α_i/α_B
Benzophenone	0.55	182	1
Xanthone	2.26	196	2.13
Flavanone	6.80	223	3.78
DNQ	13.1	396	6.79
Flavone	18.3	221	7.65
2,3-Diphenylindenone	23.6	282	9.73
β-Naphthoflavone	46.6	271	16.4
α-Naphthoflavone	49.1	271	16.6

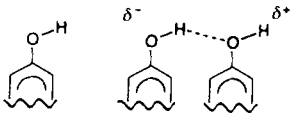
[a] f_{ij} is the inhibition factor of inhibitor i in resin j. [b] M_i is the molecular mass of the inhibitor.

Earlier, to explain this phenomenon Honda et al. had proposed the formation of a supramolecular complex in which a single inhibitor molecule could block up to 18 OH groups in a calixarene-like configuration. They termed this the "octopus pot" model.[27] The idea of supramolecular structures was also supported by Dammel and others.[28] Although the octopus pot

would explain the large inhibition factors of common diazoquinones (and such structures may be formed in special cases), it is unlikely that they arise in the typical novolak resins of practical microlithography. The most serious difficulty here is the requirement of multiple hydrogen bonding by a single center, when it is known that hydrogen bonds saturate and are formed only between single donor–acceptor pairs. We have now proposed an alternative mechanism that allows inhibitors to influence more than one phenolic OH group. It is based on the inductive polarization of hydrogen bonds.

2.3. Phenolic Clusters

Hydroxyl groups can function simultaneously as hydrogen donors and hydrogen acceptors. As a result water forms extended networks in ionic solutions, and phenols congregate in hydrogen-bonded strings or clusters. The driving force here is the autopolarization of the OH groups in hydrogen bonds. When an OH group is involved as the hydrogen donor in a hydrogen bond, the partial negative charge on its oxygen atom increases, and that oxygen becomes a stronger hydrogen acceptor than the oxygen of a free, uninvolved OH group (Scheme 3). Phenolic dimers are therefore more desirable partners for an OH group than monomeric phenols. Hydrogen bonding in phenolic solutions does not stop at the dimer, but immediately forms larger aggregates, the phenol clusters. This is illustrated by a plot of the absorbance of the IR band of free *p*-cresol (3614 cm^{-1}) as a function of the phenol concentration in solution (Fig. 14).[29] The dramatic deviations from Lambert–Beer's law at concentrations above 0.1 M indicate the formation of phenolic aggregates.



Scheme 3. Hydroxyl groups in hydrogen bonds.

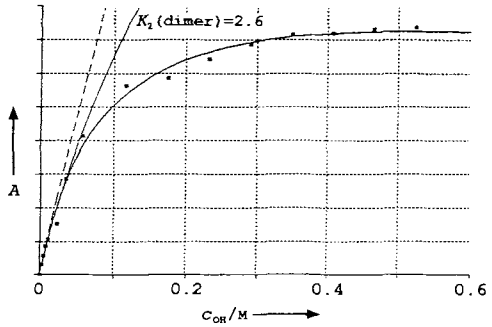


Fig. 14. Absorbance A (arbitrary units) of the OH stretching vibration at 3614 cm^{-1} in the IR spectrum of *p*-cresol as a function of the cresol concentration in CCl_4.

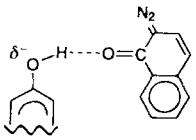
When a strong H-acceptor such as a diazoquinone or another aromatic ketone is introduced into a phenolic system, the inductive polarization effect is greatly intensified. The inhibitor forms a strong hydrogen bond with the nearest OH group, and in so doing polarizes the oxygen atom of its partner, making it a stronger hydrogen acceptor that can in turn attract other hydrogen donors (Scheme 4). In this way the stronger inductive effect of the inhibitor propagates some distance into the neighborhood and leads to the formation of larger and more tightly bound phenolic clusters. It is these clusters that are at the root of the inhibition effect.



Scheme 4. Hydrogen bonds between phenolic groups and DNQ inhibitor.

The consequences of the inductive polarization of hydrogen bonds can be demonstrated by simple bulk experiments.[28] For example, addition of strong hydrogen acceptors to novolak solutions produces a significant increase in solution viscosity (Fig. 15) caused by the polarization of OH groups adjacent to those that are directly linked to the hydrogen acceptor (inhibitor). Figure 15 shows viscosity increases in two novolak solutions to which three aromatic ketones of differing acceptor strength had been added. Similar effects were observed when the bulk glass transition temperature of dry novolak films containing strong hydrogen acceptors was measured.[26]

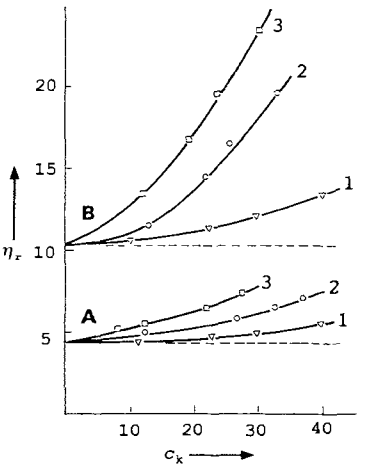


Fig. 15. The effect of the concentration c_k (in wt%) of three aromatic ketones (1: flavanone; 2: flavone; 3: α-naphthoflavone) on the viscosity η_r of two novolak solutions (A: 18.4% novolak in *iso*-amylacetate; B: 24.2% novolak in *iso*-amylacetate) at 20 °C.

How do phenolic clusters affect the dissolution rate? They concentrate some of the hydrophilic sites in small regions, depleting the surroundings of percolation sites. This creates large regions of low site density where the overall connectivity of the open bond network is reduced. Thus, the base diffusion rate is lowered and by implication also the dissolution rate. The effect may be illustrated by a simple simulation experiment.[26] Figure 16 shows a two-dimensional percolation field of a hundred cells where each cell is subdivided into nine compartments (not shown in Figure 16). One hundred sites are

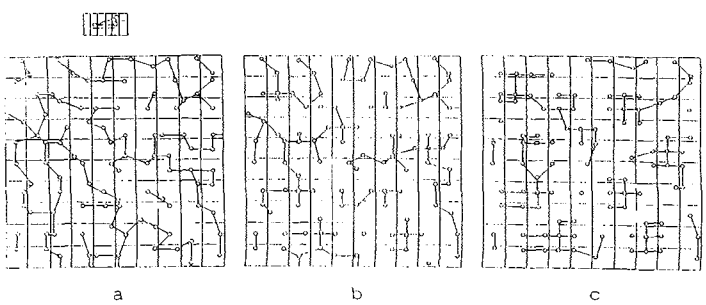

Fig. 16. Simulation experiment to illustrate the effect of clustered OH groups on the dissolution rate. The two-dimensional square percolation field represents 100 cells. One hundred sites are distributed over the 100 cells. a) The position of the sites within the cells are random. b) Ten sites (the attractors) are allowed to attract four sites each in neighboring cells, thus forming 10 four-membered clusters. c) The same attractors are allowed to attract 7 neigboring sites. For details, see text.

placed into the field, so that each cell contains one site, but the position of the sites in the compartments within the cells is random (Figure 16a). We choose a critical intersite distance (indicated in the small diagram on top of Fig. 16a), which is the separation of two neighboring sites that still constitute an open bond. We now form a network by connecting all open bonds. In the case of Figure 16a this network contains 71 sites and links opposite sides of the field, in which macroscopic diffusion is now possible. We now introduce the inhibitor by selecting ten random sites as "attractors" and allow each of these sites to attract four sites from neighboring cells. The attracted sites will move from their original compartments to the compartment nearest to the attractor site, while still remaining in their own cells (Fig. 16b). By again connecting the open bonds we find that the infinite network in this case contains only 56 sites. The connectivity of the system has clearly decreased, and diffusion will slow down since the number of opportunities for migration along open bonds has declined. Continuing in that fashion we let the same attractors as before draw to themselves up to seven sites (Fig. 16c). In this case the bond network is no longer infinite, and macroscopic diffusion ceases. We conclude that in a bond percolation field the site connectivity decreases when site clusters are formed and the fraction of sites per cluster increases.

2.4. Phenolate Ion Clusters

At this point we need to remind ourselves that the dissolution rate of novolak films is controlled by the diffusion of base through the penetration zone. If cluster formation is the controlling factor in regulating diffusion, site clusters must exist in the penetration zone. We have seen that the percolation sites in the zone are not phenolic OH groups but phenolate ions, and these are no longer connected to each other by hydrogen bonds. If the phenol clusters of the coating solution survive as phenolate clusters into the penetration zone, they do so by virtue of the glassy state of the zone.[30]

We have shown earlier that the glass transition temperature T_g' of the zone lies above the temperature of development for all useful resins.[15] Adding inhibitors to novolak increases the glass transition temperature of the zone.[26] For example, with 2% of α-naphthoflavone, T_g' increases from 30° to 43 °C for a group III resin. This increase indicates stronger cohesion in the zone. In the concentrated solid polyelectrolyte of the penetration zone, the electrostatic cohesive forces are proportional to the local charge density, which is increased at the location of the clusters. The increase in T_g' is proportional to the inhibition factor of the additive (Fig. 17); both depend on the cluster-forming capability of the inhibitor.

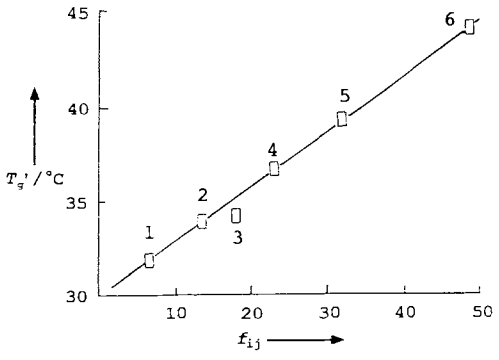

Fig. 17. The glass transition temperature T_g' of the penetration zone as a function of the inhibition factor f_{ij} of six inhibitors (1: flavanone; 2: DNQ; 3: flavone; 4: 2,3-diphenylindenone; 5: benzoylnaphthalene; 6: α-naphthoflavone).

3. The Dissolution of Exposed Resist Films

After these preliminaries we can consider the behavior of exposed resist films. When a resist film is exposed to light or UV radiation, the dissolution rate increases from a value far below that of pure novolak to a value somewhat higher than that of novolak. It is this change that makes it possible to differentiate between exposed and unexposed areas in practical applications. The situation is represented by the Meyerhofer plot in Figure 18, which depicts the dissolution rate of unexposed and exposed novolak films containing increasing quantities of a monofunctional DNQ inhibitor.[24, 30] What happens during exposure that brings about this dramatic change in behavior?

On exposure DNQ (**1**) is changed to indene carboxylic acid (**2**). That is converted into carboxylate ions in the penetration zone, where it augments the number of hydrophilic sites. However, this modest increase in the concentration of percolation sites cannot account for the large change in dissolution rate. We can demonstrate this by eliminating indene carboxylic acid from the exposed resist. Because carboxylic acids are thermally not very stable, indene carboxylic acid is decarboxylated in about one hour at 70 °C. We exposed a series of films with increasing DNQ content and kept the fully exposed films at 70 °C for two hours. When the dissolution rate of the films was measured in the usual way, all films dissolved at the same rate, irrespective of their original DNQ content, and that rate was similar to the dissolution rate of pure novolak (Fig. 18b). The small lowering of the dissolution rate relative to that of novolak is probably caused by a mild densification effect.[30]

If dissolution inhibition is caused by cluster formation, the results of these experiments must mean that exposure has, in

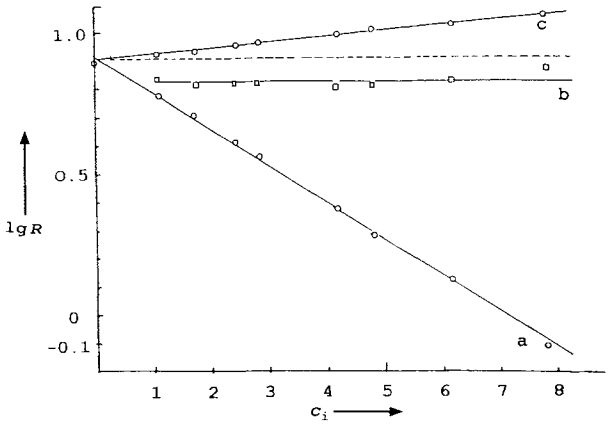

Fig. 18. Meyerhofer plot of the effect of inhibitor concentration c_i on the logarithm of dissolution rate (lg R) before (a) and after exposure to UV light (c). The experimental points indicated by squares (b) refer to films that were exposed to completion and then heated to 70 °C for two hours to decarboxylate the indene carboxylic acid produced on exposure.

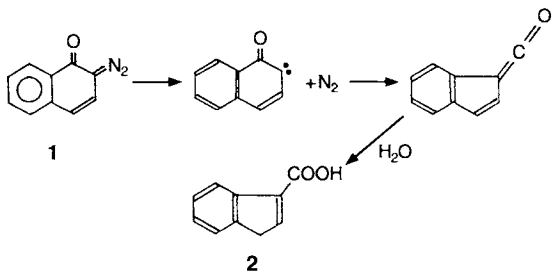
some way, dispersed the clusters and returned the system to the percolation state of novolak. It also means that the dissolution promotion effect invariably observed in exposed resists (the increase of the dissolution rate above that of pure novolak) is caused by the indene carboxylate ions which contribute their share to the overall concentration of hydrophilic sites. However, by what mechanism are the phenolic clusters dispersed on irradiation?

3.1. The Thermal Effect of DNQ Photolysis

It is known from the classical work of Süs that the conversion of DNQ **1** into acid **2** has three stages:[4] The first step is the photoreaction of diazoquinone, which releases molecular nitrogen and leads to the formation of a carbene (Scheme 5). The carbene then undergoes a Wolff rearrangement to form a ketene,[31] which is finally hydrated to give the carboxylic acid **2**.



Scheme 5. Mechanism of the transformation of DNQ (**1**) into indene carboxylic acid (**2**).

The Wolff rearrangement is not only fast, but also highly exothermic. A lower bound to the enthalpy change associated with the rearrangement of the carbene to a ketene can be estimated from bond energies and heats of atomization.[32] From these data the molar heat of reaction of the Wolff rearrangement is found to be not less than $\Delta H^{\circ}_{298} = -66\ \mathrm{kcal\,mol^{-1}}$, which corresponds to a molecular heat of reaction of $\Delta h^{\circ}_{298} = -11 \times 10^{-20}\ \mathrm{cal\,molecule^{-1}}$.

Δh° is the heat released by a single molecule of DNQ into its immediate surroundings. Let us assume that the reacting molecule is located within a cluster of ten phenolic units that occupy a volume of about $2000\ \text{Å}^3$ and represent a mass of 2000×10^{-24} g. The specific heat of the polymer is about $0.25\ \mathrm{cal\,K^{-1}}$, and therefore the heat capacity of the cluster is $c = 500 \times 10^{-24}\ \mathrm{cal\,K^{-1}}$. If the molecular heat of reaction ($q = 11 \times 10^{-20}$ cal) is released "instantaneously" into the cluster, the temperature of the cluster will increase by $\Delta T = \frac{q}{c} = \frac{11 \times 10^{-20}}{500 \times 10^{-24}} = 220\,^{\circ}\mathrm{C}$. The rate of release of heat from the Wolff rearrangement exceeds the flow of heat out of the cluster by several orders of magnitude;[30] consequently, the event has the character of an adiabatic transaction. The photoreaction and the subsequent Wolff rearrangement inject a powerful heat pulse into the cluster, and the resulting temperature spike releases the backbones of the polymer chains in the neighborhood. The phenolic clusters disperse, being no longer held together by the inductive polarization effect of the inhibitor. We believe that this is the mechanism by which phenolic clusters are eliminated from the system at the moment of exposure. This happens before development and before the penetration zone is formed.

3.2. The Effect of Indene Carboxylate in the Penetration Zone

Films that have been exposed, but not post-baked, dissolve faster than films of pure novolak. The upper trace of Figure 18 shows the dissolution promotion effect, which is absent in post-exposure baked films. The promotion effect is associated with the emergence of newly generated carboxylate ions which function as additional percolation sites. Figure 19 compares the promotion effect of indene carboxylic acid to that of 3-hydroxybenzophenone and 4-hydroxybenzophenone. Since these effects are of the same order, we conclude that dissolution promotion can be accounted for by the additional percolation sites that carboxylate ions introduce into the penetration zone.

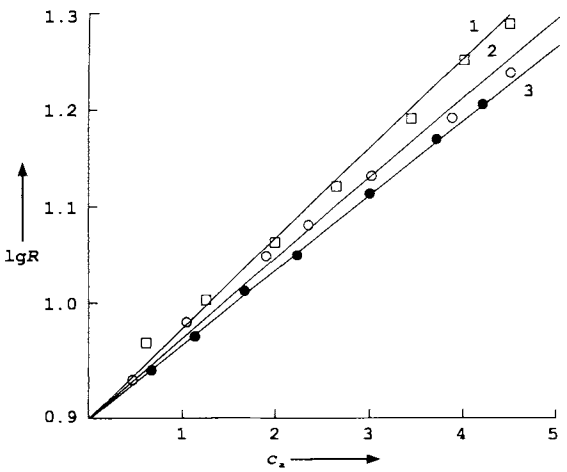


Fig. 19. Comparison of the dissolution promotion effect of 4-hydroxybenzophenone (1), 3-hydroxybenzophenone (2), and indene carboxylic acid produced in situ by exposure of the corresponding DNQ (3). The logarithm of the dissolution rate ($\lg R$) is plotted against the concentration c_a in mol%.

The presence of carboxylate has yet another effect on the penetration zone: it lowers its cohesion. We can substantiate this by determining the effect of (exposed) inhibitor on the glass transition temperature of the exposed films. Figure 20 refers to films containing 6.2% of the standard monofunctional DNQ inhibitor. It shows Arrhenius plots for the dissolution of films in 0.2N KOH before and after exposure. From the break in the traces we find that the glass transition temperature of the zone is 43 °C before exposure and 16 °C after exposure. In the exposed films the glass transition is well below the temperature of development.

The lowering of T_g in the exposed films indicates a loss of cohesion in the penetration zone. The lower cohesion is the result of the appearance of a new electrolyte, indene carboxylate. This is analogous to the behavior of aqueous solutions of

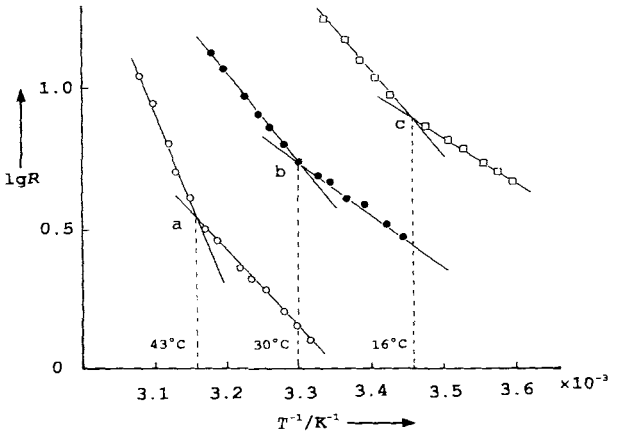

Fig. 20. Determination of the glass transition temperature T_g' of a resist containing 6.2% DNQ before (a) and after (c) exposure, as well as after irradiation and decarboxylation of the indene carboxylic acid at 70 °C (b).

polyelectrolytes, where the introduction of salt lowers the viscosity. We can demonstrate a similar effect directly in the penetration zone by adding various salts to the developer base and monitoring T_g'. For example, on addition of KCl to a 0.24 N KOH developer, the decrease in T_g' is directly proportional to the KCl concentration (Fig. 21a). The added electrolyte intercalates itself between the phenolate ions and the K^+ counterions. The intercalated ion pairs interrupt the lines of force and thereby lower the strength of the electrostatic field. If this interpretation is correct, larger anions should have a greater effect on T_g': in Figure 21b T_g' of films dissolving in 0.24 N KOH to which 0.06 N of various potassium salts was added is plotted against the size of the size of the additive ion. The effect of the added salt on T_g' does increase linearly with the ionic radius of the salt anion.

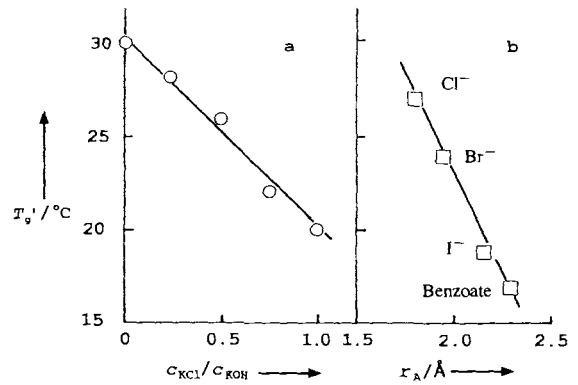

Fig. 21. The effect of concentration and size of additives in the developer solution on T_g'. a) Depression of T_g' on successive addition of KCl to a 0.20 N KOH base solution; b) depression of T_g' of a resist developing in 0.24 N KOH as a function of the radius r_A of the anion of four potassium salts (concentration 0.06 N).

4. Conclusions and Outlook

The dissolution of novolak films is controlled by the diffusion of base through the penetration zone. We have found that the transport of base through the zone can be modulated not only by changing the overall density of hydrophilic sites (for example by gradual methylation of OH groups), but also by altering their spatial distribution (that is, by site clustering). Phenolic clusters are formed in the coating solution used to make resist films by an inductive polarization effect of the diazoquinone function. They are perpetuated in the solid matrix and persist as phenolate clusters in the penetration zone by virtue of the rigid glassy state of the zone. Hydrophilic site clusters modulate the diffusive flux by an effect germane to a percolation process: they lower the connectivity of the bond percolation field and with it the diffusion coefficient of base. This is the mechanism by which diazoquinones inhibit novolak dissolution.

On exposure to light, diazonaphthoquinones produce carbenes, which subsequently undergo a highly exothermic secondary reaction, the Wolff rearrangement. This injects a heat pulse into the center of the phenolic cluster and causes a temperature spike that is intense enough to release the polymer backbones in the vicinity of the reacting DNQ. The clusters, which are no longer inductively polarized, disperse at the high temperature. Moreover, the newly created indene carboxylate ions in the penetration zone provide additional percolation sites for the base, and that is reflected in an increase of the dissolution rate of exposed resist films above that of pure novolak.

The percolation model of novolak dissolution offers an outline of the functional mechanism of novolak resists. It has begun to find acceptance in the R & D groups of industry. Several aspects of the system still await clarification, such as the effect of resin structure on photographic performance, the function of dissolution accelerators, and the surprisingly large effect of resin molecular weight on the rate of dissolution. These topics are presently under investigation at the Institute of Imaging Sciences at Polytechnic University.

Finally, the percolation approach is not limited to novolak–diazoquinone resists. Oertel et al.[33] have used it to describe the dissolution behavior of X-ray resists. In general, the method can be used effectively on any system based on dissolution inhibition, including, for example, the *t*BOC-protected polyvinylphenols introduced by Fréchet, Ito, and Willson,[34] and other systems with chemical amplification.[35]

Annelations, macrocyclizations, pinacol couplings, and heterocycle syntheses are all possible with low-valent titanium.

New Developments in the Chemistry of Low-Valent Titanium

Alois Fürstner* and Borislav Bogdanović*

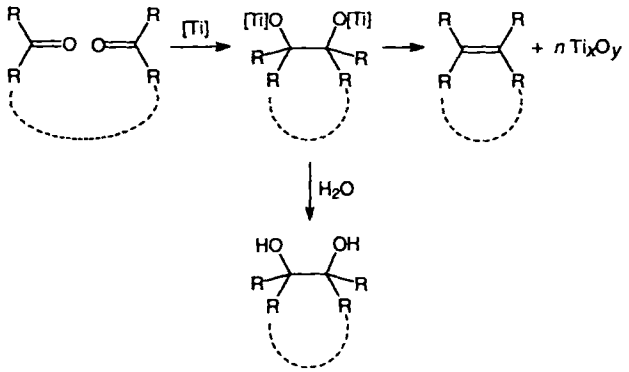
Dedicated to Professor Henri B. Kagan on the occasion of his 65th birthday

Among the applications of low-valent titanium in organic synthesis, the reductive coupling of carbonyl compounds to produce alkenes (the McMurry reaction) is particularly prominent. Discovered at the beginning of the 1970s, it has been developed and tested repeatedly, for example in numerous syntheses of natural products. This alkene synthesis has become a standard reaction in the repertoire of preparative chemists. However, the possibilities of low-valent titanium are by no means limited to this process: the last few years have brought some spectacular applications of the conventional McMurry reaction (for example the synthesis of taxol) along with a considerable extension of the scope of reductive carbonyl couplings. Thus, diverse heterocycles are now accessible following novel and efficient pathways based on intramolecular cross-coupling of functional groups—some of which were hitherto considered to be inert to titanium. The use of this method for the synthesis of indole and pyrrole alkaloids illustrates the new possibilities. At the same time, considerably simplified methods for conducting McMurry-type reactions have been developed. Examples include the particularly convenient "instant" method, the first ketone–amide coupling reactions requiring only catalytic amounts of titanium salts, and the first application of commercially available titanium powder as a coupling agent. Last but not least, the detailed investigation of diverse classical McMurry reagents has afforded a deeper understanding of the nature and mode of action of low-valent titanium. Revision of some of the current conceptions of the process of reductive carbonyl coupling is thus indispensable.

Keywords: alkenes · carbonyl compounds · heterocycles · McMurry reactions · titanium compounds

1. Introduction

The broad interest in low-valent titanium species as reagents only arose in the 1960s after Vol'pin and Shur[1] as well as van Tamelen et al.[2] recognized that these species could fix molecular nitrogen under mild conditions. Van Tamelen's group also succeeded in the reductive dimerization of alcohols to give hydrocarbons.[2f] Shortly afterwards, the research teams of Mukaiyama, Tyrlik, and McMurry independently described at about the same time the reductive coupling of aldehydes or ketones with the help of low-valent titanium to give alkenes (Scheme 1).[3–6] By lowering the temperature, it is possible to stop the reaction at the stage of the intermediate pinacol.



Scheme 1. Principle of the McMurry reaction. [Ti] = low-valent titanium.

Generally referred to as McMurry reactions after one of the discoverers, these reductive C–C couplings quickly acquired great importance in preparative organic chemistry. They have served as key steps in numerous syntheses of natural products, as well as in the preparation of sterically hindered alkenes of theoretical interest. The strong template effect of low-valent titanium deserves particular consideration: the yields of cycloalkenes obtained from intramolecular McMurry couplings are largely independent of the size of the ring formed, thus opening an efficient access to medium-sized and large rings. These applications of low-valent titanium have been summarized in several excellent reviews.[7, 8] Therefore, this account concentrates on the discussion of new developments in this field.

One of these advances concerns functional groups previously considered to be hardly reactive or even inert, for example esters, amides, urethanes, and ureas; they have been found to undergo intramolecular cross-coupling with aldehydes and ketones quite smoothly. This permits the synthesis of new types of products such as aromatic heterocycles[9–18] by reductive carbonyl coupling reactions and thus opens new entries for alkaloid synthesis and pharmaceutical research. Parallel to this increase in structural diversity, considerable methodological advances have also been made: the development of a particularly easy to perform "instant" method[17] and a catalytic variation thereof,[18] as well as the first application of commercially available titanium powder as a McMurry reagent.[18]

Furthermore, there have been new insights into the inorganic aspects of the McMurry reaction, in other words the nature and mode of action of the titanium species involved, which had aroused little interest until recently.[19] Thus, a more specific conception of the classical McMurry reagent generated from $TiCl_3$ and $LiAlH_4$[20] as well as of low-valent titanium species from $TiCl_x$ ($x = 3, 4$) and Mg[21] could be developed. Likewise, the reaction mechanism of carbonyl couplings using $TiCl_3/LiAlH_4$ and $TiCl_3/Zn(Cu)$ combinations[22] as well as $TiCl_2 \cdot 2LiCl$[22, 23] were more or less elucidated. The knowledge gained from this not only necessitates a revision of the ideas to date, but also confirmed our previous conjecture that titanium halides in solution are not reduced to metallic titanium by common reducing agents, but, depending on the method of preparation, are present as low-valent titanium species having different structures and modes of action.[24]

2. Newer Applications of Low-Valent Titanium in Organic Synthesis

2.1. Conventional McMurry Couplings: Natural Products and their Analogs

Ever since it was discovered, the McMurry reaction has served as a key step in numerous syntheses of natural products. In particular, the variety of ring systems of differing sizes found in the terpene series offers an ideal field in which to prove the advantages of intramolecular carbonyl couplings.[25] While sparcely functionalized target molecules were initially chosen, knowledge gained on the compatibility of diverse functional groups with low-valent titanium[7, 8] has led to the synthesis of more highly substituted compounds. The natural products presented in Figure 1 give an idea of the current state of the art.

(Poly)oxygenated compounds are a particular challenge because of the pronounced affinity of low-valent titanium for oxygen. A striking example of this is Clive's total synthesis of (+)-compactin (**8**, R = H, Scheme 2) and (+)-mevinolin (**9**, R = Me). Thus, the annelation of the A-ring in **12**, an advanced intermediate in this synthesis, was successful after careful optimization of the reaction conditions.[29, 30] This cyclization could only be made reproducible and high-yielding by using titanium–graphite,[24, 31] produced from $TiCl_3$ and two equivalents of C_8K.

In the same context the rather sparse reports describing cyclizations of two out of three carbonyl groups on a substrate, in which the third carbonyl group is unaffected, deserve particular mention. This semicompatibility of unprotected carbonyls towards activated titanium is documented by early syntheses of

Alois Fürstner was born in 1962 in Bruck/Mur (Austria) and studied chemistry at the Technical University in Graz (Austria), where he earned his doctorate in 1987 under the direction of Prof. H. Weidmann. After postdoctoral research with Prof. W. Oppolzer at the University of Geneva (Switzerland), he completed his "habilitation" in organic chemistry at the Technical University in Graz in 1992. Since 1993 he has been the head of a research group at the Max-Planck-Institut für Kohlenforschung in Mülheim an der Ruhr (Germany). He was a guest professor at the Université Claude Bernard - Lyon I in Villeurbanne (France) in 1994, and received a fellowship from the Fonds der Chemischen Industrie. His research interests include the development of new methods for organic synthesis with organometallic reagents and their application in natural product chemistry, the development and characterization of supported reagents, and homogeneous catalysis.

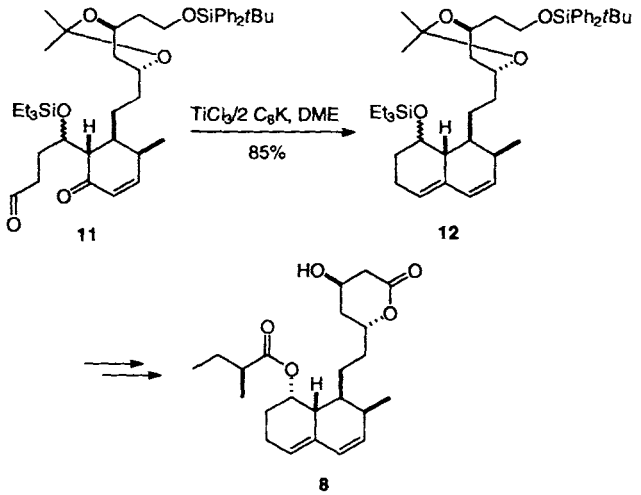
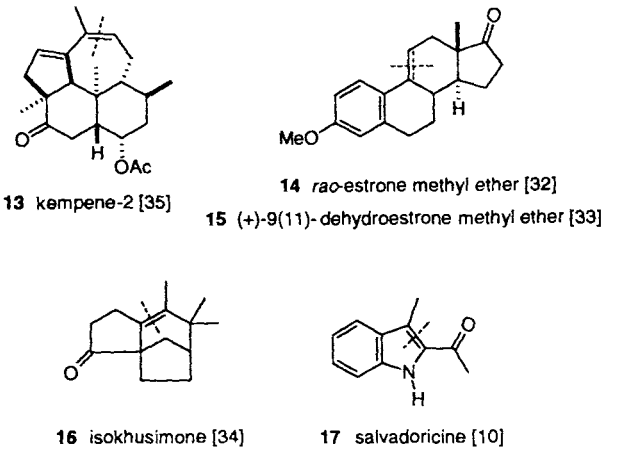


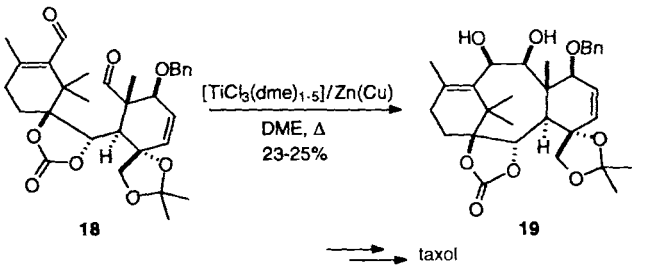
Scheme 2. Clive's synthesis of (+)-compactin (**8**).

(±)-estrone methyl ether (**14**)[32] and (+)-9(11)dehydroestrone methyl ether (**15**),[33] an efficient access to isokhusimone (**16**),[34], and an elegant preparation of the tetracyclic diterpene kempene-2 (**13**).[35]. Reference should also be made to the reductive cyclization, discussed in Section 3.4, of a diketoamide to give the simple alkaloid salvadoricine (**17**). Here the amide group, which was long considered to be inert, reacts smoothly, whilst one of the two keto groups remains unchanged.[10]



The record for the largest ring generated by the McMurry reaction in a natural product is currently held by the 36-membered diether lipid **10**, isolated from the cell membrane of archaebacteria.[36, 37]

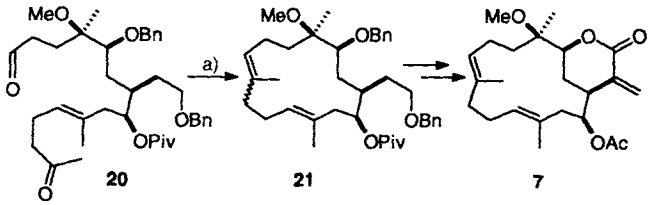
One of the most outstanding achievements in preparative organic chemistry in the last few years is, without a doubt, the total synthesis of taxol, which was successfully carried out by three teams.[38, 39] Taxol is a promising anticancer drug and already in clinical use. During the construction of the taxane skeleton, and following the work of Kende et al.,[40] the titanium-mediated cyclization of the eight-membered B-ring formed a key step of Nicolaou's synthesis[39] of this structurally exceptionally demanding target molecule. Starting from the conformationally preorganized dialdehyde **18** and using $[TiCl_3(dme)_{1.5}]/Zn$-(Cu), the desired pinacol **19** was obtained with a 23–25% yield along with three side products (Scheme 3). In spite of the



Scheme 3. Key step in Nicolaou's synthesis of taxol.

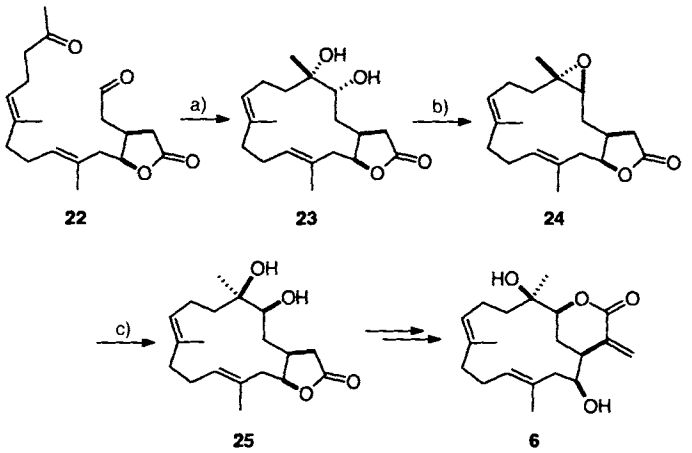
comparatively low yield, this application is a milestone in the chemistry of low-valent titanium. Similar titanium-mediated pinacol couplings were also used in the synthesis of numerous taxol analogs.[41]

The comparison of two syntheses of crassin (**6**), a diterpenoid cembranoid with antibiotic and carcinostatic activity, is instructive. Dauben's approach is based on the formation of the trisubstituted C7–C8 double bond of the macrocycle.[42] Thus, ketoaldehyde **20** is treated with low-valent titanium ($TiCl_3/Zn$-(Cu)), and the resulting compound **21** ($E:Z = 4:3$) subsequently converted into **7** in a few routine steps (Scheme 4). In contrast



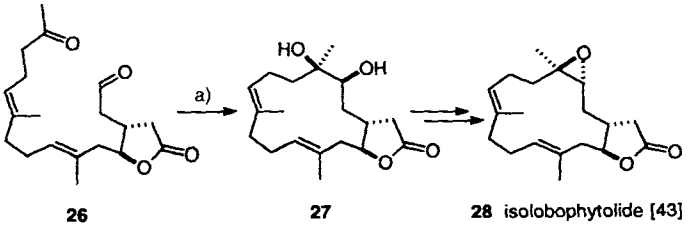
Scheme 4. Key step in Dauben's synthesis of crassin acetate methyl ether (7). a) $TiCl_3$, Zn(Cu), DME reflux, $E:Z = 4:3$, 65%.

to this, McMurry's crassin synthesis is based on an intramolecular pinacol reaction with formation of the C3–C4 diol unit of the 14-membered ring system.[43] However, the main product **23** of the cyclization of **22** proved to be an isomer of the desired diol **25**, so that a correction of the configuration on both chiral centers was necessary to complete the synthesis. This was cleverly achieved via epoxide **24** (Scheme 5).



Scheme 5. McMurry's synthesis of crassin (**6**). a) $[TiCl_3(dme)_{1.5}]$, Zn(Cu), DME, room temperature, 20% (+ isomers, 30%); b) i. MsCl, pyridine; ii. benzyltrimethylammonium hydroxide, benzene, 68%; c) H_2O, $HClO_4$, THF, 77%.

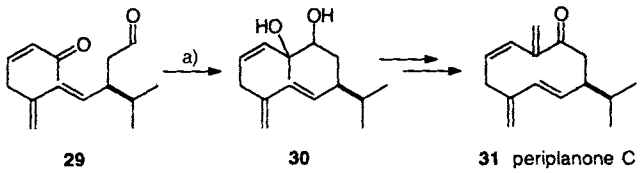
Furthermore, McMurry recognized the close relationship between crassin (**6**) and isolobophytolide (**28**):[43] whilst the precursor **22** required for the crassin synthesis has a *cis*-annelated butyrolactone structure, the analogous *trans*-annelated compound **26** undergoes an intramolecular pinacol reaction to give an advanced intermediate for the synthesis of **28** (Scheme 6). Again, all four stereoisomers are obtained. Additionally, a titanium-mediated ketone–lactone cyclization was observed as a side reaction (see Section 3.3). Even so, these syntheses prove that



Scheme 6. McMurry's synthesis of isolobophytolide (**28**) by intramolecular pinacol coupling. a) $[TiCl_3(dme)_{1.5}]$, Zn(Cu), DME, room temperature, 21% (+ isomeric diols, 37%).

(poly)oxygenated substrates can undergo selective, titanium-mediated carbonyl coupling.

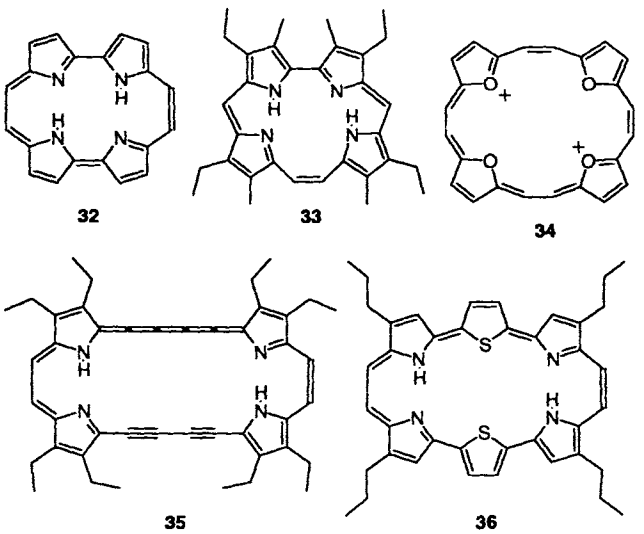
The difficulties arising in titanium-mediated pinacol formation can clearly been seen in these examples and are substantiated by some further applications. In spite of intensive efforts, the stereochemistry of a cyclic 1,2-diol formed by a reductive carbonyl coupling cannot be predicted with any certainty,[44] much less controlled. This is illustrated by the synthesis of periplanone C (**31**); the key step is the synthesis of the ten-membered ring diol **30**, which is produced in good yields but with low stereoselectivity (Scheme 7).[45] Another case is that of the pina-



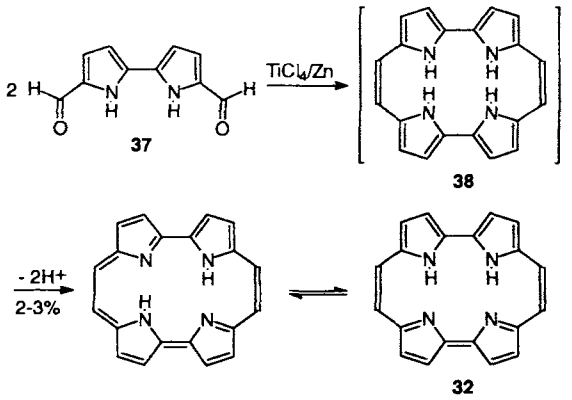
Scheme 7. Synthesis of periplanone C (**31**). a) $[TiCl_3(dme)_{1.5}]$, Zn(Cu), DME, room temperature, 60% (mixture of the four diastereomeric diols).

colization of N-protected aminoaldehydes to C_2-symmetrical diols, which are of interest as potential inhibitors of HIV protease. Again, the diastereoselectivity attained by the titanium-based method makes it inferior to the pinacol method developed by Pedersen et al., which employs $[V_2Cl_3(thf)_6]_2[Zn_2Cl_6]$ as a reagent.[46, 47]

Numerous applications of the McMurry reaction were reported in the preparation of nonnatural porphyrin derivatives. The pioneering work of the research team working with Vogel,[48] which culminated in the preparation of porphycene (**32**), corrphycene (**33**), and numerous "expanded" porphyrin analogs such as **35**, triggered many closely related syntheses. For example, porphyrin analogs were obtained in which one or several of the pyrrole units were replaced by other heterocyclic rings (furans, thiophenes, etc.) and/or were extended by an additional heteroarene ring system (e.g. **34**, **36**).[49] These compounds are used in the study of the aromaticity of expanded annulenes, and some are employed in the photodynamic therapy of tumors.



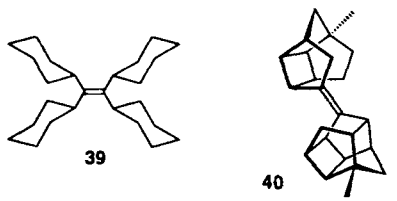
Scheme 8 gives as an example the synthesis of porphycene. The approach is based on a double (cross)coupling of suitable 1,ω-dials containing two or more heterocyclic units. Since only the (Z) isomer of the alkene formed after the first coupling can lead to ring closure, such tandem cyclizations are not usually very high-yielding.



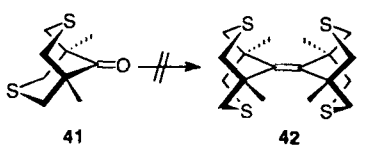
Scheme 8. Vogel's synthesis of porphycene (**32**).

2.2. Conventional McMurry Couplings: Nonnatural Products

Titanium-mediated carbonyl coupling reactions are particularly suitable for the synthesis of strained alkenes because of the high driving force resulting from the formation of titanium oxides as the inorganic by-products. Although the preparation of the long-awaited tetra-*tert*-butylethene was not successful even with the McMurry reaction, it was possible to obtain numerous theoretically interesting olefins that were inaccessible or very difficult to prepare by other means.[7, 8]

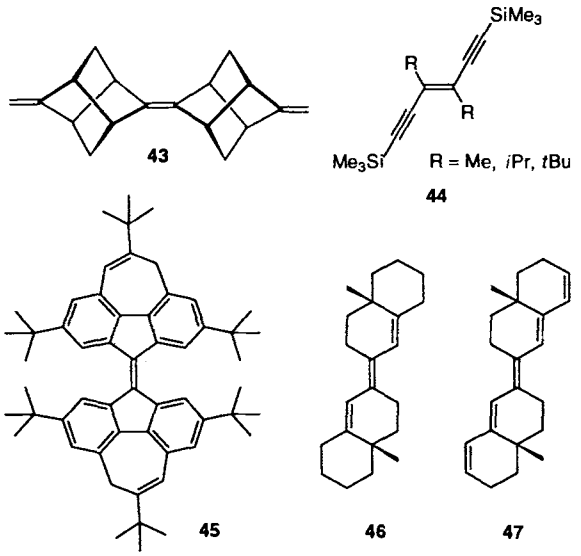


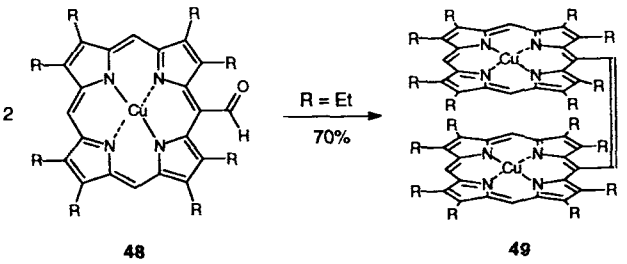
A recent example is the preparation of tetracyclohexylethylene (**39**),[50] in which the rotational barrier of the cyclohexyl groups is as high as 18.7 kcal mol^{-1}. The "cage-functionalized" alkene **40** was also obtained,[51] whilst the dimerization of **41** to the "tied-back" tetra-*tert*-butylethylene derivative **42** failed, and obviously marks the limits of this method (Scheme 9).[52] It has been estimated that products with a strain energy of $\leq$19 kcal mol^{-1} can be accessed by a McMurry coupling.[8]



Scheme 9.

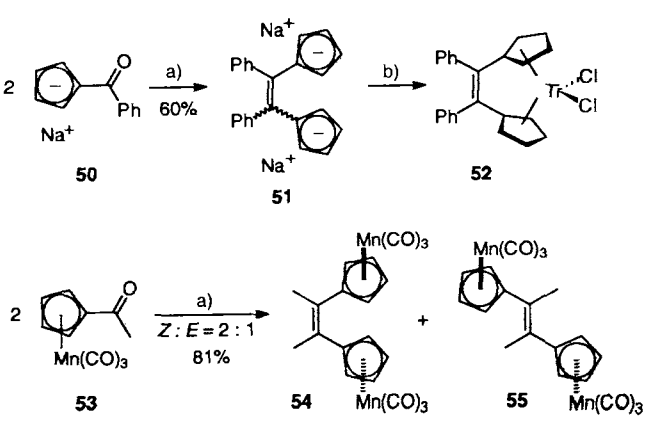
Several symmetrical alkenes were prepared in order to investigate their specific physicochemical properties. These include rod-shaped distellenes **43** (interaction of nonconjugated double bonds),[53] (E)-configurated enediynes **44** (propargyl stabilization energy),[54] triene **46**, and pentaene **47** (kinetic and thermodynamic parameters of the *anti–syn* isomerization),[55] as well as the bifluorenylidene derivative **45** with axial chirality, which was obtained from the corresponding ketone as a mixture of (E) and (Z) isomers.[56] From the thermodynamic point of view, only the (E) alkene was expected from dimerizations of 5-formylporphyrins such as **48** (Scheme 10); however, the (Z)-configurated product **49** was also produced in substantial proportions—in some cases even as the main product.[57] This points to the preorganization of the substrate by strong $\pi-\pi$ stacking interactions preceeding the C–C coupling step.





Scheme 10. Synthesis of **49**.

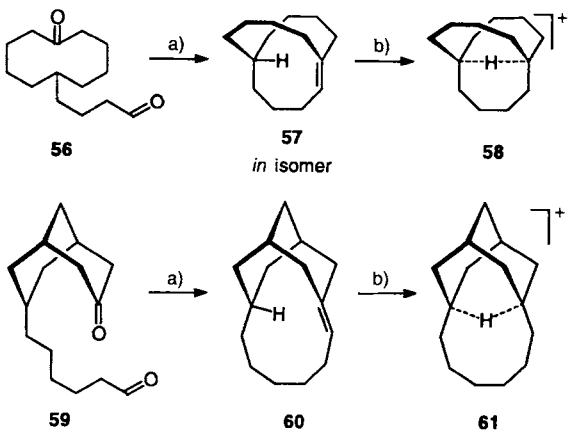
The McMurry reaction has also been used for the preparation or functionalization of organometallic compounds. For example, the acylated cyclopentadienyl derivatives **50** and **53** reacted to give the ethene-bridged *ansa*-titanocene complex **52**[58] and the binuclear cyclopentadienyltricarbonylmanganese complexes **54** and **55**,[59] respectively (Scheme 11). Diferrocenyl-



Scheme 11. Synthesis of **52**, **54**, and **55**. a) Ti-graphite; b) $TiCl_4$, 25%.

ketone can be dimerized under McMurry coupling conditions to give tetraferrocenylethene, a molecule with a strongly twisted propellerlike shape.[60] For further applications with π-complexed substrates see ref. [61].

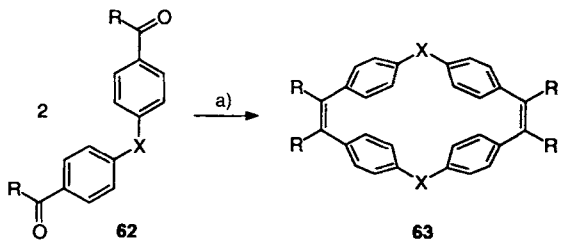
Some products that form in a series of intramolecular carbonyl-coupling reactions are also worth mentioning. The studies of bicyclic carbocations containing a three-center two-electron C–H–C bond (Scheme 12) are particularly noteworthy.



Scheme 12. Synthesis of **58** and **61**. a) $TiCl_3$, Zn(Cu), DME; b) H^+.

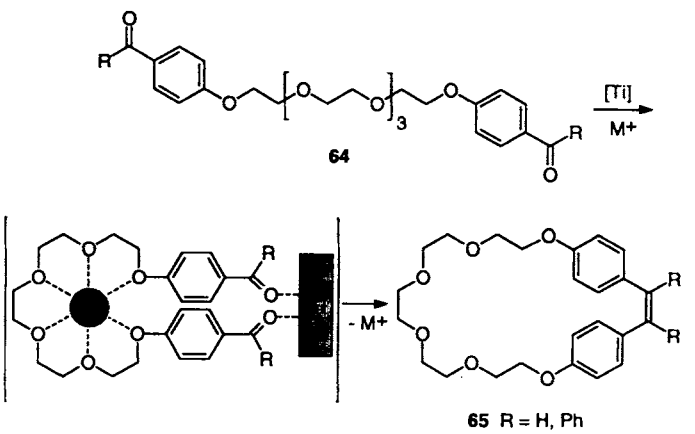
These were obtained by the McMurry coupling of suitable ketoaldehyde precursors such as **56** to give bridgehead alkenes of type **57**, which were then protonated.[62] It is remarkable that the bicyclic alkene **57** is only found as the *in* isomer, whilst the formation of the corresponding *out* isomer was not observed. Similar work by Sorensen et al. deals with the dependence of the "nonclassical" carbocation character of **61** on the chain-length of the alkyl bridge.[63]

The preparation of diverse cyclophanes such as **63** (Scheme 13)[64–66] and related crown ether bridged stilbene



Scheme 13. Synthesis of **63**. X = O, CH_2; R = H, CH_3, Ph; a) $TiCl_4$, Zn(Cu), DME, 72 h, high dilution.

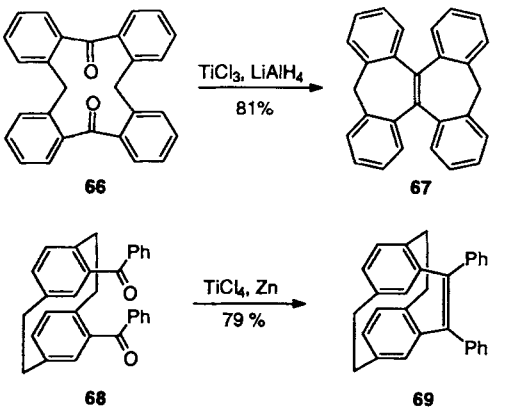
derivatives (**65**) (Scheme 14)[66–68] are representative examples of macrocycle syntheses. Since the latter are photochemically switchable, but only the (*Z*) isomer can be complexed to suitable cations, they constitute a chemical device for binary information storage. Unfortunately, they were not sufficiently stable for practical purposes. Comparison of the efficiency of different low-valent titanium species in the preparation of such "crownophanes" led to a better understanding of the template effect exerted by this metal.[68] The existence of this effect had been surmised for some time, but had hardly been probed experimentally. In some cases the preorganization of the substrate by



Scheme 14. Synthesis of **65**. [Ti] = low-valent titanium.

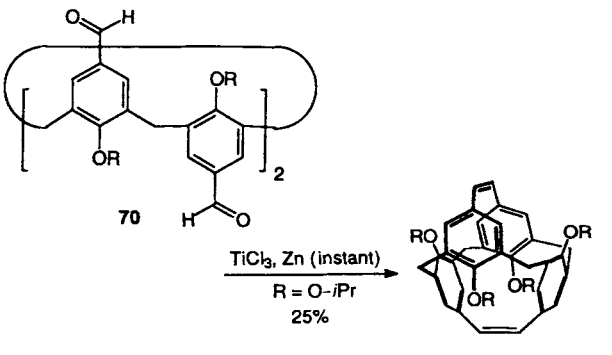
the low-valent titanium is apparently so strong that macrocycles with up to 36 members can be formed in excellent yields even without recourse to high dilution.[18, 66, 68]

A series of transannular carbonyl coupling reactions has been described (Scheme 15). These include the "tying-off" of higher



Scheme 15. Transannular carbonyl couplings.

orthocyclophane derivatives such as **66** to give **67**.[69] The reductive cyclization of diketone **68** to provide the triply bridged cyclophane **69** was successful despite considerable steric hindrance.[70] Highly strained calix[4]arene derivatives of fixed conformation could be produced from suitable diformyl precursors.[71] Even the preparation of the doubly bridged derivative **71** was successful (Scheme 16). Here it was found that the par-

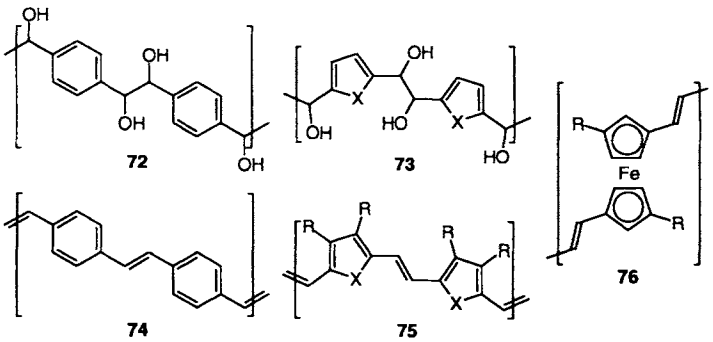


Scheme 16. Synthesis of **71**.

ticularly convenient "instant" method (see Section 3.4.1)[117] developed for the reductive synthesis of indoles is also suitable for conventional McMurry reactions.

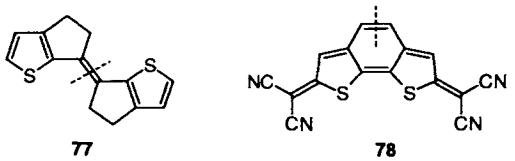
2.3. Conventional McMurry Couplings: Polymer Syntheses

Syntheses of polyvinylene derivatives or polypinacols from dicarbonyl compounds and low-valent titanium have been described in recent years. Such polymerizations are successful with substrates that are stiff enough to prevent competing intramolecular reactions. Thus, the reactions of terephthalaldehyde and 2,5-diformylfuran at 0 °C led to the corresponding polypinacols **72** and **73** (M_n = 2850 and 5540, respectively).[72] The formation of poly(1,4-phenylene-vinylene) **74** and poly(2,5-difurylene-vinylene) **75** (X = O, R = H) at reflux temperature is



impaired by the poor solubility: the mole masses achieved are low because the product precipitates prematurely out of the reaction solution.[72] This situation can be improved by attaching solubilizing side chains to the monomers. Thus, in the case of poly(3,4-dibutoxy-2,5-thienylene-vinylene) **75** (X = S, R = OBu), M_n lies at 35000,[73] and for poly(3,3'-ferrocenylene-vinylene) **76** carrying appropriate alkyl groups, M_n is still at 10000.[74]

Another possible use of the McMurry reaction in polymer chemistry lies in the synthesis of new monomers with interesting properties. For example, the symmetrical, bridged 1,2-dithienylethene **77** was prepared, which on electrochemical polymerization gave a material with a low band gap E_g and good electrochemically reversible redox behavior.[75] Compound **78** can be obtained by intramolecular McMurry coupling

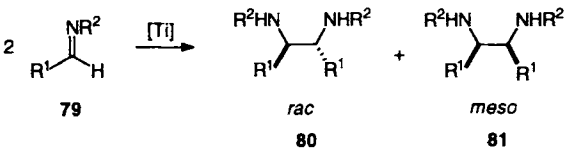


and subsequent oxidation with bromine. If it is pressed together with a typical organic electron donor such as tetrathiafulvalene, the charge-transfer complexes formed exhibit favorable electrical conducting properties.[76]

3. New Types of Substrates and Further Developments of the Method

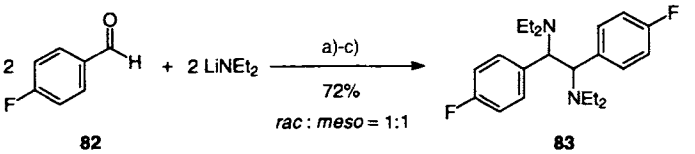
3.1. Dimerization of Imines and Iminium Salts

In close analogy to the pinacol reaction of carbonyl compounds, the reductive coupling of aldimines to give *vic*-diamines can be successfully carried out by means of low-valent titanium species (Scheme 17).[77,78] The reaction runs particularly smoothly with imines of aromatic aldehydes (R^1 = aryl) and is compatible with a series of functional groups.



Scheme 17. Synthesis of **80** and **81**. [Ti] = low-valent titanium.

The reaction of an aldehyde with a lithium amide produces a semi-aminal salt in situ. Treatment with $TiCl_4$ liberates an iminium ion; subsequent addition of low-valent titanium followed by aqueous workup furnishes the corresponding *vic*-diamine.[78] This aminative reductive C–C coupling, which can be carried out as a one-pot reaction, permits numerous structural variations of both the aldehyde and the amine components (Scheme 18).



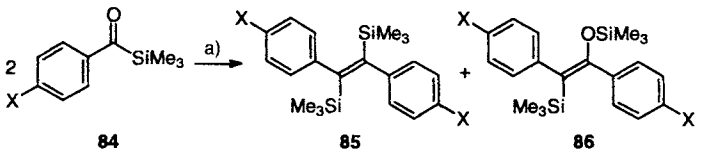
Scheme 18. Aminative reductive coupling following Seebach's method: a) $TiCl_4$; b) low-valent titanium from $TiCl_4$/Mg; c) H_3O^+.

The *vic*-diamines are usually produced as a mixture of the *meso* and *rac* forms. The latter can be removed and then separated into the optical antipodes by fractional crystallization. The enantiomerically pure diamines thus obtained have great importance in syntheses as chelate ligands for asymmetric catalysis and also as chiral auxiliaries. Reductive coupling of imines can also be carried out with reducing agents other than titanium, some of which afford more favorable *rac*:*meso* ratios.[79]

3.2. Acyl Silanes

In many respects the chemical behavior of acyl silanes mimics that of sterically hindered ketones. In spite of this close relationship, McMurry reactions of acyl silanes were unknown, except for one example of a rather inefficient intramolecular cross-coupling of an acyl silane with an aldehyde.[80] Only recently, however, it was demonstrated that aromatic acyl silanes **84** are suitable substrates for inter- and intramolecular alkene synthe-

ses.[81] The best yields of the 1,2-disilylated stilbene derivative **85** were obtained with low-valent titanium on an inorganic support (Al_2O_3, TiO_2, or NaCl)[66] (Scheme 19). Furthermore, from the observed substituent effects, it is clear that the critical step in this reaction is the deoxygenation of the C-silylated pinacol intermediates. A Brook rearrangement may interfere, which leads to silyl enol ethers of type **86** as the result of a silatropic migration.[81] Analogous McMurry reactions with aliphatic acyl silanes, however, have not succeeded to date.

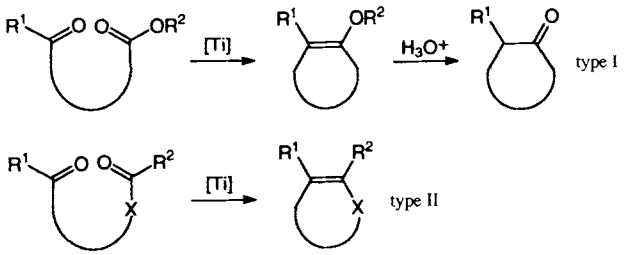


84 **85** **86**

Scheme 19. Reductive coupling of aroyl silanes. a) [Ti] on Al_2O_3 (prepared from $TiCl_3 + 2Na/Al_2O_3$). X = H: 67% + 10%; X = Br: 33% + 43% (hydrolysis product of the silyl enol ether); X = OMe: 56% + 6% (hydrolysis product of the silyl enol ether).

3.3. Ketone–Ester Cyclizations

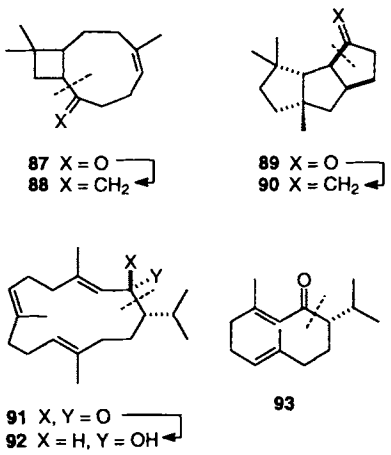
As early as 1983 McMurry et al. reported an important extension to the range of substrates for titanium-mediated cyclizations. They showed that keto esters can be coupled by low-valent titanium to give enol ethers and subsequent acidic workup of the reaction mixture provides the corresponding cyclanones (Scheme 20, type I).[82] Formally this reaction is one of the rare



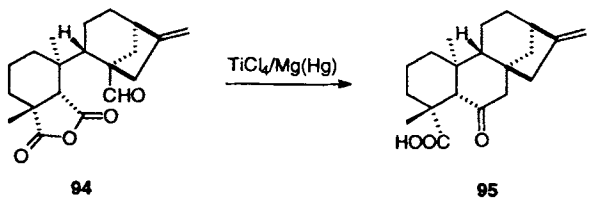
Scheme 20. Intramolecular cross-coupling reactions; see text for details. [Ti] = low-valent titanium.

examples of an intramolecular alkylidenation of an ester and is therefore particularly attractive.[83] However, success depends greatly on the careful optimization of the reaction conditions. The best results were obtained with a low-valent titanium species prepared from $TiCl_3/LiAlH_4$, which was modified by the addition of triethylamine. Titanium–graphite is also a suitable reagent.[31] In contrast to conventional couplings of diketones and dialdehydes, the formation of medium-sized rings by means of this ketone–ester cyclization gave somewhat reduced yields.[82] A strong influence is also exerted by the chain length and the steric demands of R^2.[9a]

However, this attractive process has found few applications in the synthesis of natural products. Examples include the formation of the nine-membered ring of isocaryophyllene (**88**),[84] ring closure of the C-ring of capnellene (**90**),[85] and the recent syntheses of cembrene (**92**) and acoragermacrone (**93**), which



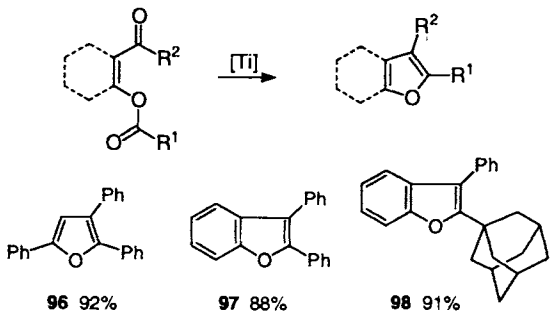
are both based on the cross-coupling of an α,β-unsaturated ester with a ketone.[86] The condensation of a cyclic anhydride with a neighboring aldehyde function is closely related (Scheme 21).[87]



94 **95**

Scheme 21. Synthesis of **95**.

A conceptual advancement is marked by the intramolecular alkylidenations of type II (Scheme 20, X = O). With this reaction aromatic heterocycles such as furans and benzo[*b*]furans can be obtained from simple precursors (Scheme 22).[9, 88] Originally titanium–graphite was used as the coupling agent, but in the meantime the considerably more convenient "instant" method has been used successfully.[17]

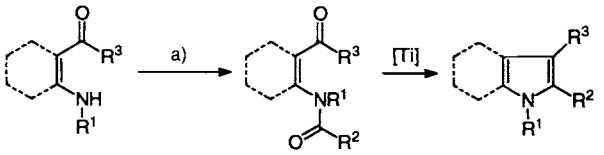


96 92% **97** 88% **98** 91%

Scheme 22. [Ti] = low-valent titanium.

3.4. Titanium-Mediated Synthesis of Pyrroles and Indoles

Although amides were considered to be inert towards low-valent titanium,[7a] intramolecular type II alkylidenation of acylamidocarbonyl compounds (Scheme 20, X = NH, NR) has proved to be a remarkably efficient entry to substituted pyrrole



Scheme 23. Reductive indole and pyrrole synthesis by intramolecular ketone–amide coupling: R^1 = H, alkyl, aryl, tosyl; R^2 = H, alkyl, aryl, heteroaryl, OR, NR_2; R^3 = alkyl, aryl, heteroaryl, (H). a) Acylation. [Ti] = low-valent titanium.

and indole derivatives.[9–18] This new heteroarene synthesis (Scheme 23), employing an intramolecular cross-coupling of two functional groups of greatly differing redox potentials, displays the following profile.

1) The reaction proved to be very flexible with regard to the substitution pattern in the enamine region of the product formed. Because all types of amides undergo reductive cyclization smoothly,[9, 17] the acylation of a parent aminocarbonyl compound with different carboxylic acid derivatives and subsequent coupling of the oxoamides thus obtained, ensures easy variation of the R^2 group (Scheme 23). Therefore, this procedure is particularly attractive, for example, in pharmaceutical chemistry for elucidating structure–activity profiles. Such variations can also be carried out as a combinatorial step.[89] Some of the products synthesized and their yields are listed in Figure 2.

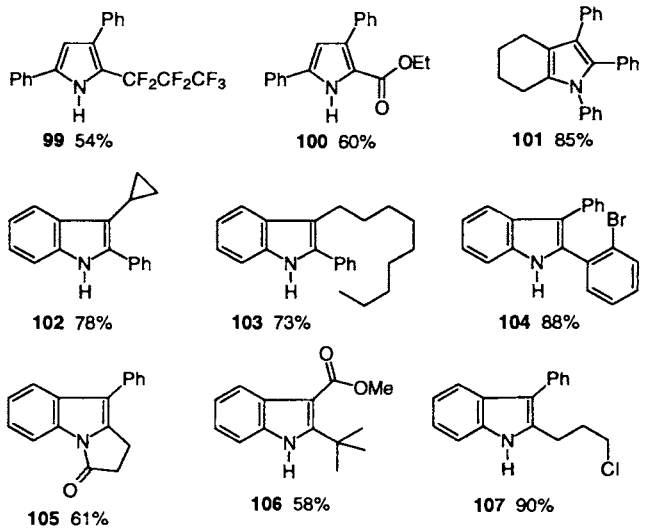


Fig. 2. Selected pyrrole and indole derivatives prepared by the McMurry reaction and their yields.

2) In contrast to many classical methods such as Fischer's indole synthesis, the substitution pattern of the product is defined unequivocally and formation of regioisomers is excluded.
3) In spite of the high reducing capacity of low-valent titanium, the method is compatible with an array of potentially reducible and/or acid-labile functional groups. Table 1 gives an overview.[9–18]
4) Preexisting stereocenters in the substrates are not racemized under the reaction conditions (Scheme 24).[17]

Table 1. Titanium-mediated heterocyclic syntheses: compatibility of functional groups.

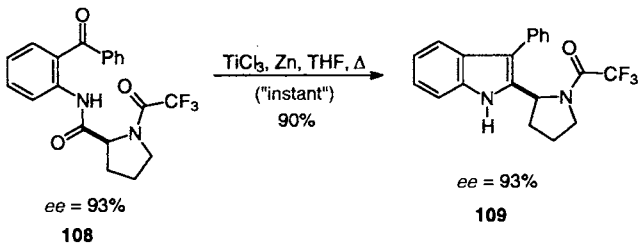
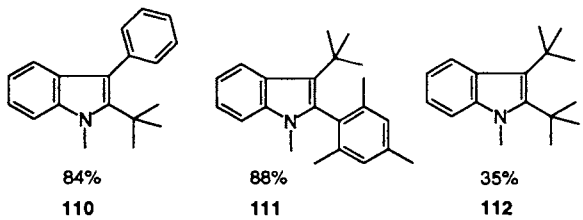


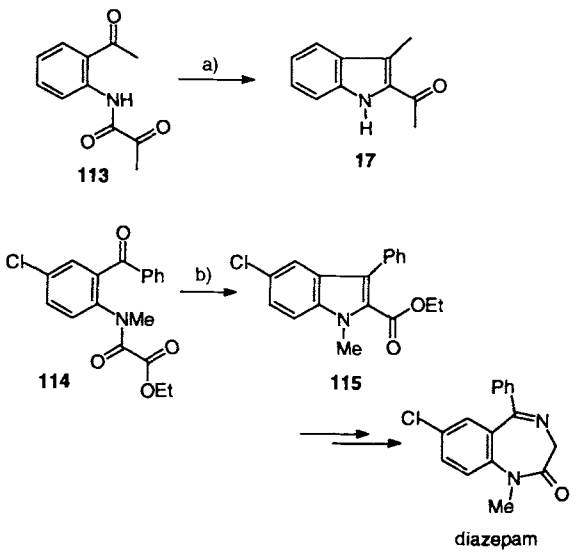
Scheme 24. Synthesis of **109**.

5) This method is also suitable for the preparation of sterically encumbered products, as illustrated by the formation of the indole derivatives **110**–**112**.[17] The 2,2-di-*tert*-butyl-3-indolinone formed as a side product (15%) during the preparation of 2,3-di-*tert*-butyl-1-methylindole **112** provides some insight into the reaction mechanism.



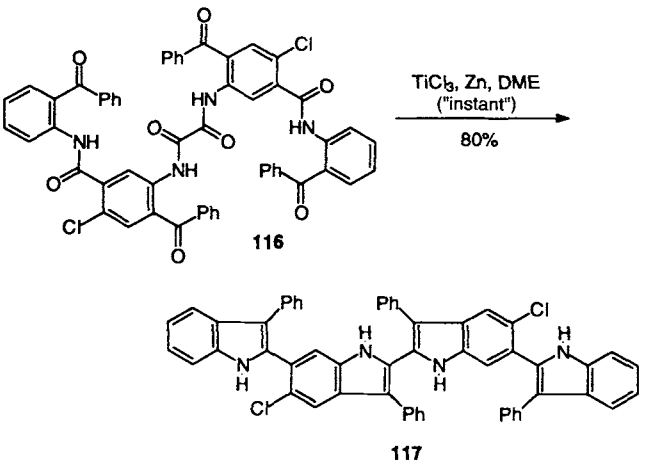
6) The reaction is probably triggered by a two-electron reduction of the carbonyl group, whereas no electrons are transferred to the amide function. The titanium-complexed "carbonyl dianion" thus formed (side-on complexation of the carbonyl group) acts as a nucleophile and attacks the neighboring amide with formation of the C–C bond. Subsequent deoxygenation of the resulting titanium diolate leads to the aromatic heterocycle.[17] This mechanism is in accord with the selectivity observed and is also supported by the results of electrochemical studies. As demonstrated by the data summarized in Section 4.1, comparable nucleophilic "dianionic" intermediates may play a more prominent role in conventional McMurry reactions than previously thought.

7) A particularly striking feature of this cyclization is its marked chemo- and regioselectivity. The formation of the indole or pyrrole ring by the coupling of a carbonyl group to a neighboring amide is highly preferred over other titanium-mediated reactions of polyfunctional substrates. However, distal amide, ester, and even keto groups are inert to [Ti]. Examples of this include the regioselective and non-racemizing cyclization of the N-trifluoroacetylated proline derivative **108** (Scheme 24),[17] as well as the preparation of **115**,[10, 17] a precursor of the drug diazepam by regioselective ketone–amide coupling (Scheme 25). In the latter case the ketone–ester cyclization, which is a possible side reaction, is not observed. This preference for indole formation is particularly apparent in the cyclization of the pyruvic acid amide **113** to salvadoricine (**17**):[10] here the ketone–amide cyclization is even superior to the conceivable McMurry coupling of the two keto groups (Scheme 25). The evident driving force of titanium-mediated formation of indoles is also responsible for the selective ketone–amide cyclizations of polyfunctional precursors, for example, in the syntheses of the alkaloids secofascaplysin (**157**)[13] and lukianol A (**165**)[15] (see Section 3.4.4).



Scheme 25. Regioselective ketone–amide coupling. a) Ti–graphite, DME, reflux, 0.5 h, 60%; b) Ti–graphite, DME, reflux, 1 h, 94%

8) This distinct selectivity accounts for polycyclization reactions with formation of oligoheteroarene structures of exactly defined length and substitution pattern such as **117** (Scheme 26).[14]
9) Because of the great driving force of titanium-mediated formation of indoles, there is no need to run the reactions under high dilution.[9, 14, 17, 18] As a rule, they proceed with good yields even at concentrations of 0.1 M for the individual substrates.
10) It is particularly significant that different titanium species with formal oxidation states of 0, +I, and +II are able to induce the cross-coupling.[17] Therefore, the reaction conditions can be simplified and/or adapted to the requirements of the given substrate.



Scheme 26. Selective polycyclization in the synthesis of **117**.

Ketone–amide couplings of this type were originally carried out with titanium–graphite[31] as the reagent, which is obtained by reducing $TiCl_3$ with three equivalents of potassium–graphite laminate C_8K (thus, formally a Ti^0 species). In C_8K the 4s electrons of potassium are delocalized in the conducting band of graphite: the reduction of a metal salt can therefore take place at any site on the large surface of the laminate, thus ensuring a high level of dispersion and excellent reactivity of the resulting particles.[24, 91] Since these particles are adsorbed on the surface of the graphite, they are also protected against premature aggregation.[92] This metal activation procedure has also been highly successful in numerous other cases.

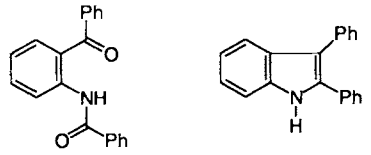
Clive et al. reported, however, that during a total synthesis of compactin (see Section 2.1) the formally monovalent titanium species formed by the reduction of $TiCl_3$ with only two equivalents of C_8K gave higher yields and more reproducible results.[29, 30] An extensive comparative study of titanium-mediated indole synthesis employing these two modifications of Ti–graphite confirmed Clive's observation, and therefore the use of the reagent prepared from $TiCl_3/2\,C_8K$ is strongly recommended.[17]

Since "Ti^0" is evidently neither essential nor necessarily the best choice, many other "low-valent" titanium samples were subsequently examined as coupling agents on a test reaction. Although they differ in their efficiency, all of the investigated titanium species with formal valencies of zero, one, or two were able to couple 2-benzamidobenzophenone (**118**) to give 2,3-diphenylindole (**119**) (Table 2).[17] This was a clear experimental confirmation of our previous assemption that different "McMurry reagents" can exist and be active.[24]

3.4.1. The "Instant" Method

With very few exceptions, McMurry reactions are carried out in two consecutive steps.[7, 8] First, $TiCl_x$ ($x = 3, 4$) is reduced to the active species by means of an appropriate reducing agent, and only then the substrate is added. Because the active species was assumed to be metallic titanium, aggressive reducing agents such as K, C_8K, Na, Li, $LiAlH_4$ etc. were often chosen; since they are incompatible with a carbonyl compound, such a two-step sequence is mandatory.

Table 2. Reductive cyclization of **118** to give 2,3-diphenylindole **119**: screening of different low-valent titanium reagents.

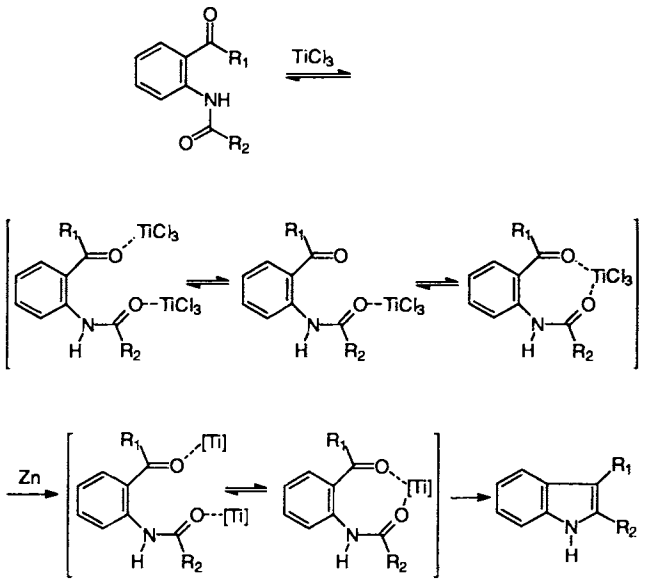


118 **119**

Reagent	Formal oxidation state	Yield [%] [a]	Reagent	Formal oxidation state	Yield [%] [a]
$TiCl_3 + 3C_8K$	0	90	$[Ti(biphenyl)_2]$	0	70
$TiCl_3 + 2C_8K$	+I	90	$[TiHCl \cdot (thf)_{0.5}]$	+II	85
$TiCl_4 + 4K[BEt_3H]$	0	67 [b]	$[Cp_2Ti(PMe_3)_2]$	+II	79
Ti cluster [c]	0	45 [b]	$[TiH_2 \cdot (thf)_2(MgCl_2)]_n$	+II	69
$[Ti(toluene)_2]$	0	75			

[a] Yield of isolated product unless otherwise stated. [b] Yield determined by GC. [c] Cluster produced by electrochemical means.

Based on the insight that carbonyl coupling reactions are by no means restricted to metallic titanium, it was possible to devise a new and significantly simplified procedure (Scheme 27). Thus, $TiCl_x$ is added to the respective substrate and reduced



Scheme 27. Reductive carbonyl coupling by the "instant" method.

to some "low-valent" titanium species within the complex formed in situ by action of a mild reducing agent such as zinc dust or iron powder. This procedure known as the "instant" method[17] combines several advantages.

1) Reagent and substrate are preorganized: the active species [Ti] is produced regioselectively at the reaction site.
2) Both steps of the carbonyl coupling process—the preparation of the active species and its subsequent reaction—are combined into a single synthetic operation. By avoiding any hazardous reducing agent, coupling reactions according to the "instant" protocol are simple to perform and easy to scale up.[90]
3) The reactions are distinguished by a high tolerance towards functional groups. The only limitations are found with acid-labile derivatives.
4) "Instant" couplings can even be carried out in nonethereal solvents such as ethyl acetate, acetonitrile, and DMF.

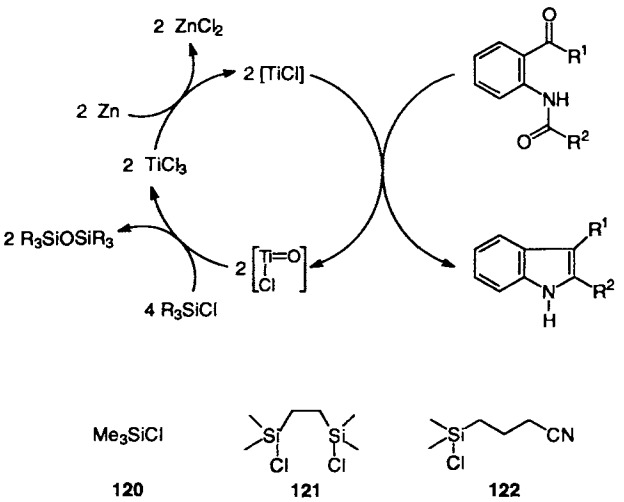
This method has proved to be particularly successful for the reductive synthesis of heterocycles. However, it can also be employed for conventional inter- and intramolecular McMurry couplings of (di)aldehydes and (di)ketones.[17] This was recently confirmed by its application to the formation of calix[4]arenes of fixed conformation (see Section 2.2).[71a]

Zinc had already been used as a reducing agent for $TiCl_x$ before the "instant" method was developed.[3, 93, 94] The conceptional difference and methodological advance lies in the deliberate avoidance of any prereduction of the titanium species.[17] This is not only fully justified in view of the preparative results obtained but also by the insight gained into the nature of low-valent titanium, which is summarized in Section 4.4. According to this work, zinc is capable of reducing $TiCl_3$ to "low-valent" titanium ($TiCl_2$) only if the redox potential of the latter has been sufficiently lowered by coordination to a carbonyl compound![22] Thus, when zinc is used as the reducing agent, a two-step procedure is futile.

3.4.2. Titanium-Catalyzed Carbonyl Coupling Reactions

The driving force of Ti-induced carbonyl coupling stems from the formation of titanium oxides as the inorganic by-products of the reaction. In the presence of reducible substrates, however, these oxides are much too stable to be reduced back to the active low-valent titanium [Ti]. As a consequence, all reactions to date have had to be carried out with at least stoichiometric amounts of titanium; in practice a (huge) excess is mandatory.[7, 8]

The "instant" method enables the generation of activated titanium [Ti] from $TiCl_x$ in the presence of the substrate. If the initial inorganic product, titanium oxychloride, can be reconverted into $TiCl_x$ in situ, then a catalytic cycle may emerge (Scheme 28).[18] The required metathetic ligand exchange may



120 **121** **122**

Scheme 28. Titanium-catalyzed indole synthesis. The catalytic cycle shown is only a formal representation of the reaction mechanism. The nature of the low-valent species involved was not investigated more closely; however, the results summarized in Section 4.4 suggest the intermediate formation of $TiCl_2$ as the active species from $TiCl_3/Zn$.

be achieved by addition of chlorosilanes as oxophilic additives. As can be seen from Table 3, a few mole% of $TiCl_3$ is in fact sufficient to couple oxoamides smoothly to yield the corresponding indoles, provided that the reactions are carried out under "instant" condititons in the presence of chlorosilanes.

Table 3. Selected titanium-catalyzed indole syntheses.

R^1	R^2	R^3	$TiCl_3$ [mol %]	Chlorosilane	Yield [%] [a]

H	*N*-trifluoroacetyl-2-pyrrolidinyl	Ph	17	**120**	67

[a] Yield of isolated product.

Control experiments proved that these transformations are indeed titanium-catalyzed.[18] Without the addition of $TiCl_3$ the substrates do react, but the desired indole is formed in only minor amounts. The quantity of $TiCl_3$ required for good yields depends on the specific chlorosilane chosen. When trimethylsilyl chloride (TMSCl, **120**) is used, 5–10 mol% of $TiCl_3$ is necessary, whereas with $ClMe_2SiCH_2CH_2SiMe_2Cl$ (**121**) as the additive 1–2 mol% of $TiCl_3$ suffices. Most likely the entropically favored intramolecular formation of siloxane is responsible for the higher turnover number in this case.

The preparation of indole derivatives with an alkyl group at C3 requires special care in the choice of the additive. Because the starting oxoamides are less likely to cyclize, the noncatalytic decomposition of the substrate competes with Ti-catalyzed carbonyl coupling. However, the latter reaction can be sufficiently accelerated by the use of $ClMe_2Si(CH_2)_3CN$ (**122**). This commercially available additive combines an affinity towards titanium, stemming from its nitrile group, with the oxophilicity of a chlorosilane. Thus, the critical transfer of oxygen from titanium to silicon is intramolecular, which favors the regeneration of $TiCl_x$ and hence the catalytic cycle.[18] The use of **122** as an additive for the catalytic method affords 3-alkylated indole derivatives in good yields (Table 3).

The insight gained in this "titanium case study"—that reactions involving early transition metals in low oxidation states can be rendered catalytic simply by the addition of chlorosilanes—nicely applies to other processes as well. Following this basic idea, Ti-catalyzed fixation of nitrogen[95] as well as Nozaki–Hiyama reactions catalytic in $CrCl_2$[96] have been successfully carried out.

3.4.3. *Commercially Available Titanium Powder as a McMurry Reagent*

The extreme passivation of commercially available titanium caused by a surface oxide layer ruled it out as a reagent for carbonyl coupling.[97] Due to this extraordinary resistance metallic titanium has gained great importance as an industrial material, but does not play any role as a chemical.

During investigations of the catalytic procedure we discerned that chlorosilanes do react with titanium oxides. This suggested a reevaluation of titanium powder as a reagent. Indeed, numerous carbonyl coupling reactions were accomplished with a combination of titanium powder (100–325 mesh) and TMSCl in good yields.[18] In spite of long reaction times, this procedure is attractive as it gives high yields and good selectivity, and is particularly simple to perform. Because only titanium compounds of no toxicological concern are involved and other metal cations are avoided, this method should be suitable for the synthesis of pharmaceutically relevant products.

It is now possible to use titanium powder/TMSCl for the reductive coupling of aromatic as well as α,β-unsaturated carbonyl compounds. The reagent exerts a pronounced template effect, which manifests itself, for example, in good yields in macrocyclizations even without slow addition of the substrate. The newly developed heterocycle syntheses based on reductive ketone–ester and ketone–amide cyclizations are also possible with Ti/TMSCl. A few representative examples are given in Table 4.[18] If catalytic amounts of $[Ti(OiPr)_4]$ or $[ClTi(OiPr)_3]$ are added, the generally long reaction times can be distinctly shortened. Unfortunately, this combination of reagents has not

Table 4. Selected carbonyl coupling reactions using commercially available titanium powder as the reagent.

Substrate	Product (yield [%])
 **123**	 **124** (94)

 **133**	 **134** (90)

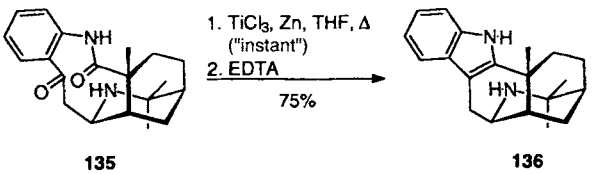
yet been successful with aliphatic aldehydes or ketones. This sharply defined profile makes chemo- and regioselective coupling reactions possible: androsta-1,4-dien-3,17-dione (**131**) is dimerized exclusively at the enone site, whilst the unprotected aliphatic keto group is not affected by the reaction.[18]

^{29}Si NMR investigations indicate that the chlorosilane not only leads to the degradation of the passivating surface layer of titanium powder, but that the observed activation is a more complex (redox) process.[18] This was confirmed by investigations with electron microscopy, which clearly show morphological changes of the titanium powder caused by the chlorosilanes.[98]

3.4.4. Titanium-Mediated Heterocycle Syntheses: Applications to Natural Products and Biologically Active Compounds

The selectivity of titanium-mediated heterocycle syntheses (see Section 3.4) is a prerequisite for application of this procedure to natural products and biologically active compounds. For example, the reaction of pyruvic acid amide **113** led to salvadoricine (**17**) (Scheme 25).[10] In this particular case the preference of the ketone–amide cyclization over the conceivable ketone–ketone coupling clearly contrasts with all the earlier findings[7, 8] in reactions employing low-valent titanium, and points to the pronounced driving force of reductive heteroarene formation. In light of this result, the selective ketone–amide coupling of the polyfunctional substrate **114** to give indole **115**, a known precursor of diazapam, is not surprising. Originally carried out with Ti–graphite,[10] this cyclization can also be accomplished with the "instant" method on a multigram scale.[17, 90]

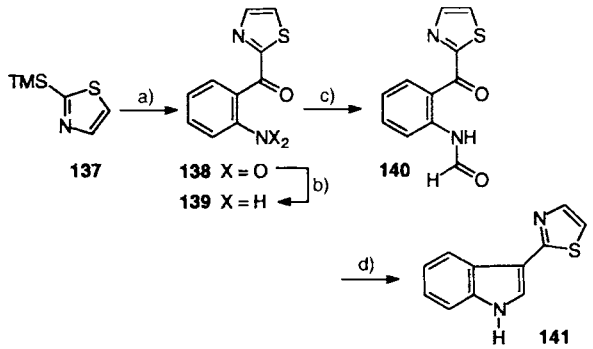
Another successful application of the "instant" procedure is the transannular coupling of **135** to afford (+)-aristoteline (**136**) (Scheme 29).[17] Because the product is strongly coordinated



Scheme 29. Synthesis of (+)-aristoteline (**136**).

through its basic nitrogen function to the Lewis-acidic titanium salt, the crude reaction mixture must be worked up by extraction with aqueous ethylenediaminetetraacetate (EDTA).

The synthesis of camalexin (**141**), a representative example of 3-(2-thiazolyl)-substituted indole alkaloids, is particularly simple (Scheme 30).[12] This phytoalexin from *Camelina sativa* is accessible in four steps with an overall yield of 50%. Acylation of the commercially available 2-trimethylsilylthiazole (**137**) with 2-nitrobenzoyl chloride affords ketone **138**, hydrogenation of the nitro group gives amine **139**, N-formylation yields **140**, and finally coupling under "instant" conditions furnishes the desired natural product. If acylation reagents other than formic acid are used, the same sequence leads to analogs of camalexin, which differ from the natural product in the substituents at C2.



Scheme 30. Synthesis of camalexin (**141**). a) 2-nitrobenzoyl chloride, CH_2Cl_2, 83%; b) H_2 (1 atm, Pd/C (5%), EtOAc, 98%; c) HCOOH/Ac_2O, 87%; d) i. $TiCl_3$ (5 equiv), Zn dust (5 equiv), DME, reflux; ii. EDTA disodium salt, H_2O, 71%.

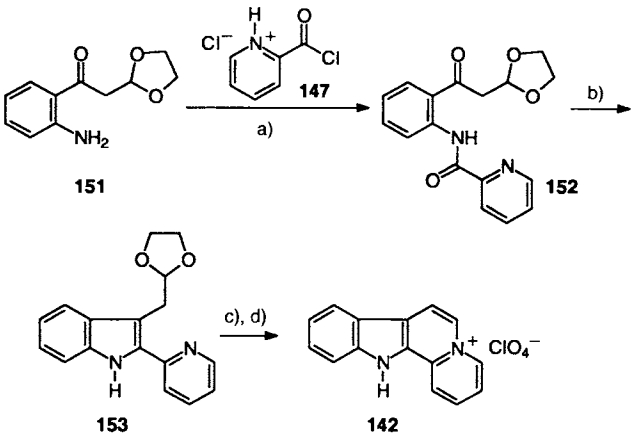
Ti-mediated indole formation led to two flexible entries to the class of indolo[2,3-*a*]quinolizine alkaloids.[12, 13] Recently, the interest in this group of natural products greatly increased after they were discovered to be physiologically active due to intercalation into DNA .

Our first synthesis[12] starts from 2-iodoaniline (**144**), which is converted into ketone **146** in two steps (Scheme 31). For the synthesis of indolopyridocoline **142**, the parent compound of this class of natural products, the amino group is acylated with pyridine-2-carboxylic acid chloride (**147**, R = H) and the resulting ketoamide **148** (R = H) subsequently coupled by using Ti–graphite to give the indole **149** (R = H). Cleavage of the methyl ether by BBr_3 leads to spontaneous cyclization of the C-ring, which can be aromatized with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (**150** → **142**, R = H). The individual representatives of this alkaloid family differ essentially in the

BBr_3, CH_2Cl_2, −78 °C (1 h) → −15 °C (5 h); ii. HCl, $CHCl_3$; iii. $NaClO_4$, H_2O, 79% (R = H), 67% (R = Me); f) i. DDQ, HOAc, reflux; ii. NaOH, $CHCl_3$; iii. $NaClO_4$, H_2O, 74% (**142**), 78% (**143**).

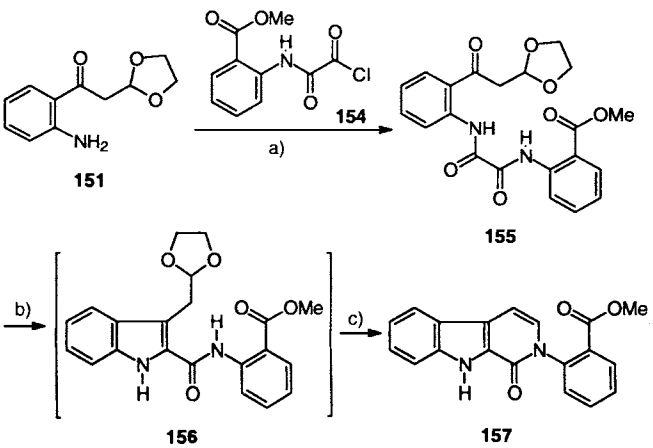
substitution pattern of the D-ring. Therefore, they can be obtained analogously by acylation of **146** with an appropriately substituted pyridine-2-carboxylic acid chloride derivative. This is demonstrated by the syntheses of 6,7-dihydroflavopereirine (**150**, R = Et) and flavopereirine (**143**, R = Et),[12] and highlights once again the flexibility of the titanium-based method with regard to the substituent at C2 of the newly formed indole derivative (cf. Section 3.4).

Alternatively, compound **151**, which is easily accessible from 2-nitroacetophenone, can be used as starting material for the synthesis of indolo[2,3-*a*]quinolizine alkaloids (Scheme 32).[13] In this case the aromatic C-ring of the desired product is formed during the hydrolysis of the acetal once the indole unit has been generated.



Scheme 32. Alternative synthesis of indolopyridocoline **142**. a) CH_2Cl_2, pyridine, DMAP cat., 0 °C → room temperature, 4 h, 89%; b) i. Ti–graphite ($TiCl_3$:C_8K = 1:2), THF, reflux, 6.5 h; ii. EDTA disodium salt, H_2O, 57%; c) HCl, THF, reflux, 8 h; d) i. Ac_2O, reflux; ii. $NaClO_4$, H_2O, 77% (for steps c) and d)).

Extracts from marine sponges of the genus *Fascaplysinopsis* have attracted attention because of their antimicrobial, cytotoxic, and antiviral activity. These properties stem from alkaloids of novel structure such as secofascaplycin (**157**). Building block **151**, already utilized in the preparation of indolopyridocoline, is a good starting material for a total synthesis of this particular natural product as well (Scheme 33). N-acylation with acyl chloride **154** (readily obtained from anthranilic acid methyl ester and oxalyl chloride) gave good yields of the polyfunctional compound **155**. Although this substrate bears five different carbonyl functions, it underwent a chemo- and regioselective coupling of the ketone with the proximate amide to produce indole **156** on treatment with Ti–graphite. The other potentially reducible groups (distal amide, ester, acetal) were not attacked.[13] Hydrolytic workup of the crude reaction mixture gave the desired alkaloid in 60% yield.



Scheme 33. Synthesis of secofascaplysin (**157**). a) CH_2Cl_2, pyridine, 20 h, 66%; b) Ti–graphite ($TiCl_3$:C_8K = 1:2), THF, 0 °C (21 h) → reflux (5 h); c) aq. HCl (5%), THF, 60 °C, 5 h, 60% (over both steps).

In the last three syntheses Ti–graphite ($TiCl_3/2C_8K$) was used as the coupling reagent.[17, 31] The aldol substructures of the individual substrates render them sensitive towards Lewis acids such as $TiCl_3$; for this reason the "instant" method is unsuitable. The same is true for the first total syntheses of the pyrrole alkaloids lukianol A (**165**) and lamellarin dimethyl ether **163** (Scheme 34). These natural products have not yet been well investigated. Although they obviously share similar structural features, these metabolites are produced by unrelated marine organisms. They have been synthesized starting from 4,4′-dimethoxychalcone, which can be converted to isoxazole **159** in two steps. Reductive cleavage of the N–O bond and acylation of the resulting ketoamine **160** with methyl oxalyl

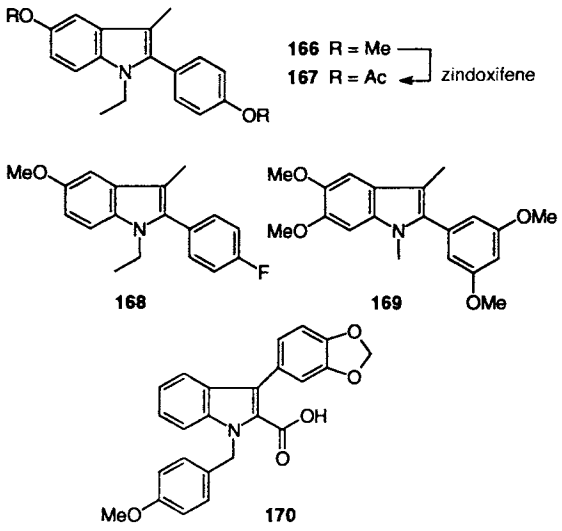
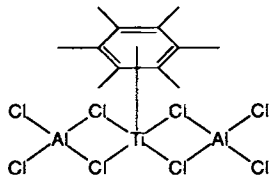
Scheme 34. chloride gives the acid-labile ketoamide **161**, which, when treated with Ti–graphite regioselectively cyclizes to give pyrrole **162**. N-Benzylation and subsequent manipulation of the protecting groups gives good yields of both lamellarin dimethyl ether (**163**) and the corresponding enol lactone lukianol A (**165**).[115]

Alongside these applications to natural products, the advantages of Ti–mediated heterocycle synthesis could also be demonstrated in the preparation of pharmacologically active compounds. For example, the indole derivative zindoxifene (**167**), which is active against estrogen-dependent tumors, was obtained in a few steps from 2-amino-5-methoxyacetophenone.[111] Once again, because of the flexibility of this method, several new analogs (e.g. **168**, **169**) of this anticancer agent are easily accessible for investigating structure–activity relationships. The indole-2-carboxylic acid derivative **170**, recently reported as an antagonist of the endothelin receptor, was also readily accessed by Ti-mediated ketone–amide coupling and, if necessary, the structure can be varied.[113] In this case, the coupling was performed by the particularly convenient "instant" method on a multigram scale.



4. Recent Results on the Structure of Low-Valent Titanium Reagents and on the Reaction Mechanism of the McMurry and Related Reactions

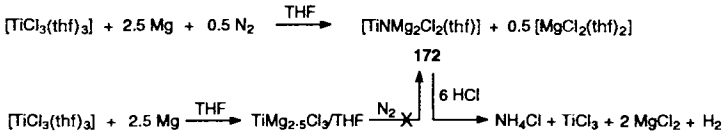
Since the discovery of the McMurry reaction[3–5] various reducing agents and methods have been used to prepare low-valent titanium reagents. The first reductive couplings of ketones and aldehydes to furnish alkenes employed Mg[4] or Zn[3] in THF to reduce titanium tri- or tetrachloride; in the former case $[TiCl_3(thf)_3]$ was "prereduced" with Mg before addition of the carbonyl compound; in the latter case $TiCl_4$ was treated with Zn powder in the presence of the carbonyl substrate. The reagent introduced by McMurry et al.[5] prepared from $TiCl_3$ and 0.5 equivalents of $LiAlH_4$ found extensive application in such reactions[99] (cf. Section 4.1.1). According to Corey et al.,[103] the combination $TiCl_4$/Mg-amalgam, as well as the discrete hexamethylbenzene–Ti^{II} π-complex **171** are favorable reagents for the coupling of aldehydes and ketones to give pinacols.[104]



171

In the 1970s the search for improvements in the effectivity and reproducibility of McMurry reactions brought the successive introduction of K,[105] Li,[106] Zn in the presence of pyridine,[94] and the Zn–Cu couple[93b] (referred to hereafter as Zn(Cu)) in THF or DME as reducing agents for $TiCl_3$ and $TiCl_4$. Tkatchenko et al.[107] demonstrated the use of the discrete Ti^0 complex bis(benzene)titanium for McMurry coupling reactions as well as for deoxygenations of unsaturated alcohols to afford alkenes (see also Table 2). The low-valent titanium species prepared from $TiCl_3$ and C_8K proved to be an excellent reagent for inter- and intramolecular coupling of aldehydes and ketones[29–31] and permitted the syntheses of furans, pyrroles, and indoles (described in Sections 3.3 and 3.4). The most efficient reagent, which is currently recommended[8] for all types of reductive coupling, is the $[TiCl_3(dme)_{1.5}]$/Zn(Cu)/DME system perfected by McMurry et al.[93a] The processes by which reductive coupling of aldehydes and ketones produce alkenes were studied by Barteau et al.[108] by temperature-programmed desorption on the surface of single crystals of TiO_2 which had been reduced by bombardment with Ar^+ ions. There is only one result as yet on the suitability of a Ti^0 colloid prepared by Bönnemann et al.[109] from $TiCl_4$ and $K[BEt_3H]$ as a coupling reagent (see Table 2).[17] The more recent developments in the methodology are discussed in Sections 3.4.1–3.4.3 and 4.1–4.4 of this review. In contrast to the widespread application of low-valent titanium reagents in organic syntheses, there have been relatively few in-depth investigations in the past on their nature and mode of action; these are summarized below.

In studies of N_2 fixation (cf. Section 1) with the $TiCl_3$/Mg/THF system, Yamamoto et al.[110] were able to isolate a complex of composition $[TiNMg_2Cl_2(thf)]$ (**172**). On hydrolysis it produced ammonia (Scheme 35). In the absence of nitrogen 2.5 moles of Mg per mole of $TiCl_3$ are consumed in the reduction of $TiCl_3$ with Mg in THF. However, the resulting THF solution proved to be inactive for N_2 fixation.[110]



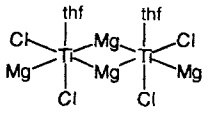
Scheme 35.

According to Sobota et al.[111] reduction of $TiCl_4$ with Mg in THF leads to a black complex $[TiMg_2Cl_2(thf)]_{2x}$ (**173**, Scheme 36). On the basis of the chemical properties and diamagnetism, a dimeric (or oligomeric) structure with direct Ti–Mg bonds was proposed for **173**.[112]

Investigations on the nature of the low-valent titanium species obtained by the reduction of $TiCl_3$ or $TiCl_4$ with Li, K, Mg,

$$2\,TiCl_4 + 6\,Mg \xrightarrow{THF} [TiMg_2Cl_2(thf)]_{2x} + [2\,MgCl_2(thf)]$$

173 ($x \geq 1$)



173

Scheme 36. Preparation and postulated structure of **173**.

and $LiAlH_4$ in refluxing THF were carried out by Geise et al.[113] in the early 1980s. The highest yields in the McMurry coupling of benzophenone or cyclohexanone were obtained when $TiCl_3$ was prereduced in molar ratios of 1:3.2 (Li, K), 1:1.7 (Mg), and 1:0.5 ($LiAlH_4$). In qualitative ESR investigations of the reduction process it was observed that the ESR signals of Ti^{III} centers disappeared after the reduction had ended. On the basis of the amount of reducing agent consumed in the reduction, and on the results of ESR and other studies, the active titanium species was suggested to consist of aggregates of metallic titanium particles adsorbed on an inorganic support (KCl, $MgCl_2$, etc.). The titanium particles formed by reaction with the various reducing agents would differ in their surface-bound ligands—H, Cl, or THF. This and the results of earlier work[93b] led to the supposition that the active titanium species in the McMurry reaction—regardless of the method of preparation—are finely divided Ti^0 particles, which differ only in the corn size, specific surface area, and morphology.[7a] The mechanism of the McMurry reaction is generally believed to be C–C coupling by dimerization of ketyl radicals, which are bound to the surface of the titanium particles, to give a pinacolate, followed by stepwise cleavage of the C–O bonds to produce the alkene and surface-oxidized titanium particles.[7a, 44]

However, in contrast to this hitherto[8] widespread[7c, d, 114] idea, there have been numerous indications for a considerable length of time [31a, b, 94, 103] that $TiCl_4$ and $TiCl_3$ in solution are not reduced to metallic titanium by common reducing agents, and that the presence of zero-valent titanium is not a prerequisite for the McMurry reaction.[108]

In the following we present a summary of more recent investigations on the structure and mode of operation of common as well as some new low-valent titanium reagents. As it turns out, reduction of $TiCl_3$ with $LiAlH_4$ (or MgH_2), Mg, and Zn(Cu) (in this case only in the presence of the carbonyl substrate) in THF or DME afford, as surmised,[24] not metallic titanium particles, but rather low-valent titanium complexes with differing structure and reactivity.

4.1. Chlorohydridotitanium $[HTiCl(thf)_{\approx 0.5}]_x$ as the Active Component of the McMurry Reagent

4.1.1. Characterization of $[HTiCl(thf)_{\approx 0.5}]_x$ and a New Formulation of the McMurry Reaction

Magnesium hydride prepared catalytically as a solid[115] or in solution [116] (in the following referred to as MgH_2^* (**174**) and MgH_2' (**175**), respectively) can be employed in both forms as a reagent for the preparation of intermetallic compounds and their hydrides in a highly reactive form.[19] $[TiCl_3(thf)_3]$ reacts with both active forms of magnesium hydride in THF at room temperature with liberation of hydrogen.[20] On close examination of the H_2 evolution it was found that as the $MgH_2'/TiCl_3$ ratio increases, the amount of H_2 increases at first and then remains constant at 0.5 H_2/Ti from a 1:1 molar ratio onwards. This result gave the first indication that under the applied conditions Ti^{III} is reduced only to (formally) Ti^{II}.

In the reaction with a 1:1 molar ratio of MgH_2^* or MgH_2' to $TiCl_3$, a highly pyrophoric black solid precipitates out of the THF solution. It is amorphous to X-rays and proved to be the new chlorohydridotitanium complex $[HTiCl(thf)_{\approx 0.5}]$ (**177**, Scheme 37); the deuterated compound **D-177** can be prepared

$$[TiCl_3(thf)_3] + MgH_2^*\ (MgH_2') \longrightarrow [HTiCl(thf)_{\sim 0.5}]\downarrow + 0.5\,H_2\uparrow + MgCl_2$$

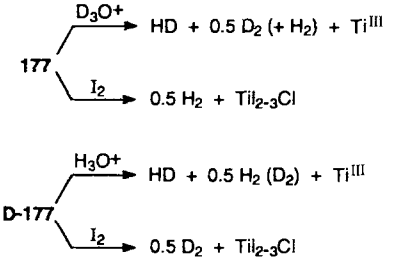
174 (**175**) **177** (70-75%)

$$[TiCl_3(thf)_3] + MgD_2^* \longrightarrow [DTiCl(thf)_{\sim 0.5}]\downarrow + 0.5\,D_2\uparrow + MgCl_2$$

176 **D-177**

Scheme 37. Synthesis of **177** and **D-177**.

in an analogous manner. Deuterolysis of **177** gives HD and D_2 (along with a little H_2) as well as Ti^{III} salts. Hydrolysis of **D-177** gives HD, H_2, and Ti^{III} salts. Iodolysis of **177** (**D-177**) gives 0.5 moles of H_2 (D_2) per mole of titanium (Scheme 38). This proves the presence of hydrogen bound as a hydride in **177**.



Scheme 38. Reactions of **177** and **D-177**.

The preparation of the McMurry reagent was repeated and it was found that **177** was the reaction product in this case too. The reduction of $TiCl_3$ with 0.5 equivalents of $LiAlH_4$ in THF produced H_2 (0.5 mole of H_2 per mole of Ti) and on addition of pentane to the reaction mixture a black, X-ray amorphous powder could be isolated in 46% yield. The IR spectrum and the composition of this powder agreed with that of **177**. As demonstrated below, **177** is a fully active reagent for the McMurry reaction. The formation of the McMurry reagent can therefore be formulated according to Equation (a).

$$[TiCl_3(thf)_3] + 0.5\,LiAlH_4 \longrightarrow \mathbf{177} + 0.5\,H_2\uparrow + 0.5\,LiCl + 0.5\,AlCl_3 \quad (a)$$

The surroundings of the titanium center in **177** was investigated with X-ray absorption spectroscopy (EXAFS).[117]

A comparison of the EXAFS spectrum of **177** with that of titanium foil rules out the possibility that **177** consists of titanium particles or nanoparticles.[113] Results of the EXAFS analysis reveal that the local environment of the titanium center in **177** consists of oxygen (0.4 atoms at 2.13 Å), chlorine (1.5 atoms at 2.44 Å), and titanium atoms at two different distances (1.3 and 1.9 atoms at 3.10 and 4.04 Å, respectively). Possible structural models compatible with the EXAFS results are represented in Figure 3.[120]

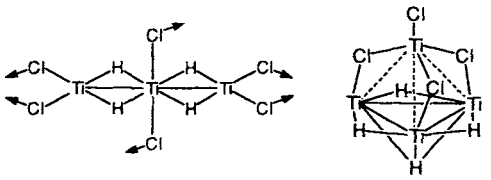


Fig. 3. Possible structures of **177** (without THF molecules).

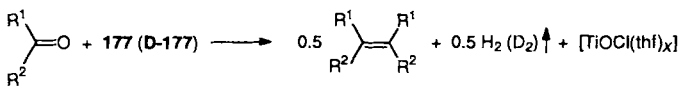
The complexes **177** and **D-177** proved to be active reagents for the reductive coupling of benzophenone to afford tetraphenylethene (**178a**) as well as of acetophenone to furnish 2,3-diphenyl-2-butene (**178b**) (Scheme 39).[118] In the course of the reaction 0.5 moles of H_2 (or D_2) are liberated per mole of titanium. Titanium(III) oxychloride was found to be the inorganic end product. The complete course of the McMurry reaction with **177** or **D-177** can therefore be described along the lines of Scheme 39.



Scheme 39.

When carried out under standard conditions, the reductive coupling of carbonyl compounds with **177** gave the same alkenes with comparable yields as those obtained with the McMurry reagent.[113a, 119] Additionally, **177** can be isolated from the $TiCl_3/0.5\,LiAlH_4$/THF reaction mixture [Eq. (a)]. Therefore, it can be considered as proved that **177**, and not finely divided metallic titanium,[113] is the active species of the McMurry reagent.

To obtain the most complete insight into the reaction process, the McMurry and related reactions were each started at low temperatures and, during the course of the reaction, the temperature was gradually increased to the boiling point of the solvent. At the same time samples were removed and quickly hydrolyzed, and the organic intermediates and end products identified and quantified by GC analysis. The reaction profile of the McMurry reaction of acetophenone with **177** as the reagent (Scheme 39) is given in Figure 4. The pinacolate forms even at low temperatures but is converted into the alkene only at higher temperatures. The appearance of 2,3-diphenyl-2-butanol (**181**, Scheme 40) as a side product of the reaction gives an experimental indication for the stepwise (radical)[7a] elimination of TiOCl from pinacolate **180**.

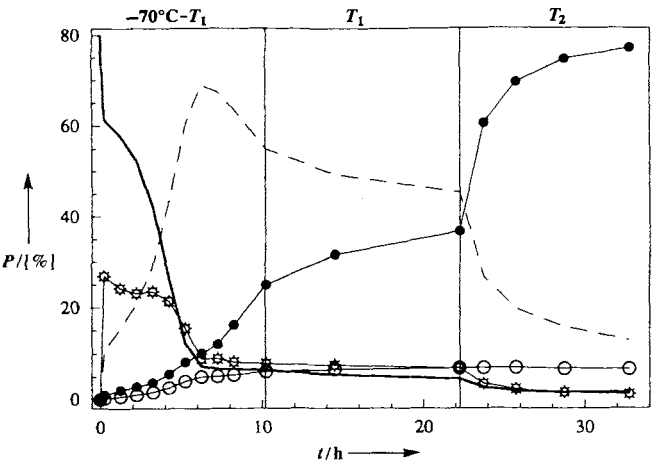


Fig. 4. The progression of the coupling reaction of acetophenone with [HTiCl(thf)$_{\le 0.5}$] (**177**) as a reagent (molar ratio 1:1) in THF; the samples were hydrolyzed with H_2O; (—) acetophenone, (●) 2,3-diphenyl-2-butene (**178b**), (✡) 1-phenylethanol (**179a**), (– – –) 2,3-diphenyl-2,3-butandiol (**180b**); (○) 2,3-diphenyl-2-butanol (**181**). T_1 = room temperature; T_2 = reflux temperature; P = product distribution.

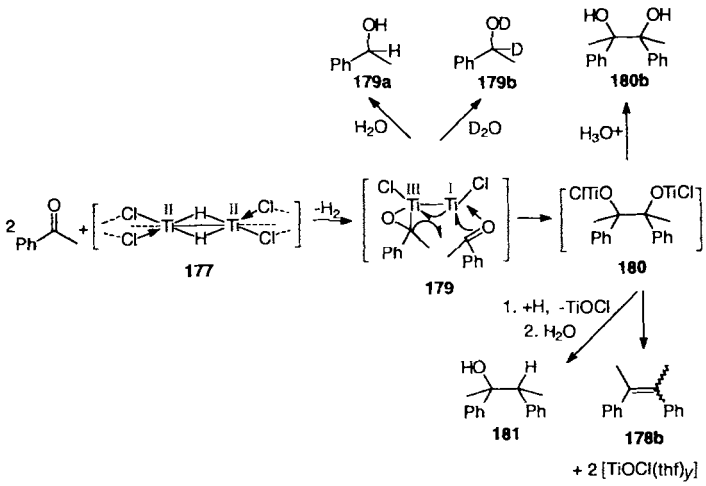
It is of particular interest that, at the beginning of the reaction, a possible precursor of the pinacolate could be intercepted, which on hydrolysis gives 1-phenylethanol (**179a**). The amount



Scheme 40. Reaction of acetophenone with **177**.

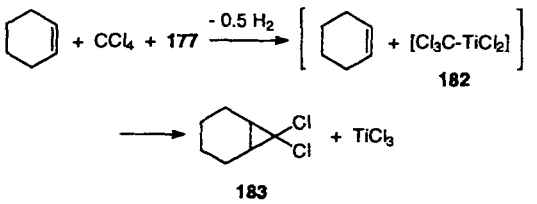
of the hydrolysis product **179a** (Fig. 4) was 20–25% at the beginning and decreased to zero as the reaction proceeded. Therefore, **179a** appears to be the hydrolysis product of the postulated[9a, 12, 16, 17, 93b, 106] "ketone dianion" intermediate (**179**) of the McMurry reaction. This hypothesis was supported by a deuterolysis experiment at low temperature. Here a 23% yield of 1-phenylethanol was produced with 98% deuterium incorporation in the 1-position (**179b**). The results thus point to a "ketone dianion" as the precursor of the titanium pinacolate **180**. The existence of "dianions" of aromatic ketones is substantiated by the X-ray structural analyses of dilithium benzophenone[120] and ytterbium benzophenone.[121] In both cases the carbonyl group is bound side-on to the metal center. Zr and Hf

complexes with carbonyl compounds coordinated side-on are also known; they occur as intermediates in C–C coupling reactions.[122]

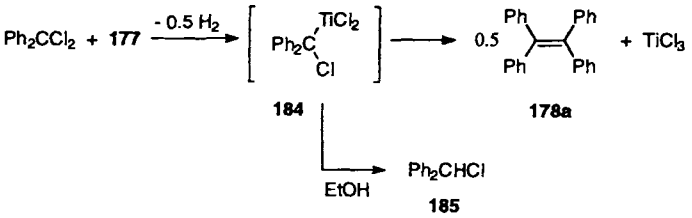
The likely appearance of the side-on coordination of acetophenone to titanium (left side of **179**, Scheme 40) as a precursor of the pinacolate in the McMurry reaction favors a nucleophilic reaction mechanism rather than a radical path for the C–C coupling step of aromatic ketones.[123] According to this mechanism, and on the basis of the structural model proposed for **177**,[20] the C–C coupling step can be envisaged to occur by the following sequence on the surface of the insoluble $[HTiCl(thf) \approx 0.5]_x$ particle (**177**, Scheme 40): After the hydride ligand in **177** has been expelled by the ketone (evolution of H_2 already starts at low temperatures![20]), the ketone coordinates side-on at the vacated coordination site of the metal. Subsequent C–C coupling to produce pinacolate **180** proceeds by nucleophilic attack of the reduced, side-on coordinated ketone at the carbonyl group of a nonreduced ketone molecule (**179**), which is coordinated to a neighboring Ti atom. Alternatively, the "ketone dianion" could nucleophilically attack a free ketone molecule (not shown in Scheme 40).

4.1.2. *Carbenoid Reactions of* $[HTiCl(thf)_{\approx 0.5}]$

Further similarities in the reaction behavior of **177** and the McMurry reagent are evident from conversions of geminal dichloro compounds. The formation of 7,7-dichloronorcarane (**183**) from cyclohexene and carbon tetrachloride, and of tetraphenylethene (**178a**) from dichlorodiphenylmethane, promoted by the McMurry reagent, was reported by Mukaiyama et al.[125] and Olah et al., respectively.[126] The analogous reactions with **177** lead to the same products in comparable yields (Schemes 41 and 42). At the onset of the reactions roughly



Scheme 41. Synthesis of **183**.



Scheme 42. Synthesis of **185** and **178a**.

0.5 moles of H_2 per mole of **177** evolved[124] and $TiCl_3$ is the inorganic end product. Therefore, the reactive intermediates can be postulated as titanium-based carbenoids[127,128] **182** and **184**, respectively. In the reaction presented in Scheme 42, intermediate **184** could be trapped with ethanol to give chlorodiphenylmethane (**185**) (Fig. 5). Thus, intermediate **184** could clearly be demonstrated as the precursor to alkene **178a**.[124]

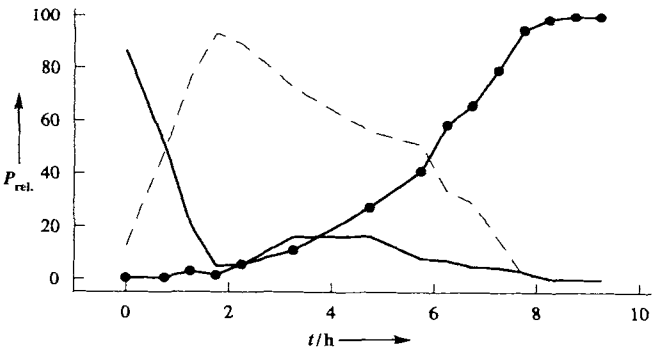


Fig. 5. The progression of the coupling reaction of dichlorodiphenylmethane with $[HTiCl(thf)_{\approx 0.5}]$ (**177**) as a reagent (molar ratio 1:1) in THF; the samples were quenched with EtOH; (—) dichlorodiphenylmethane, (•) tetraphenylethene (**178a**), (– – –) diphenylchloromethane (**185**). P_{rel} = relative product distribution.

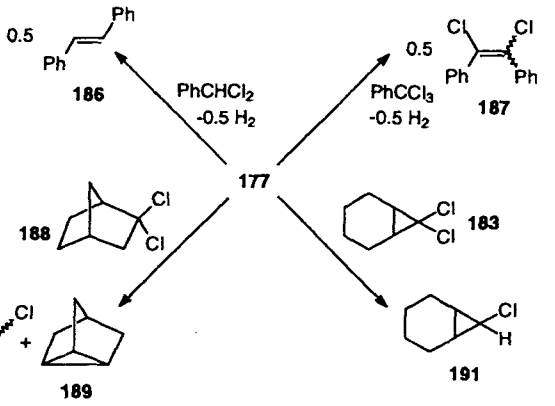
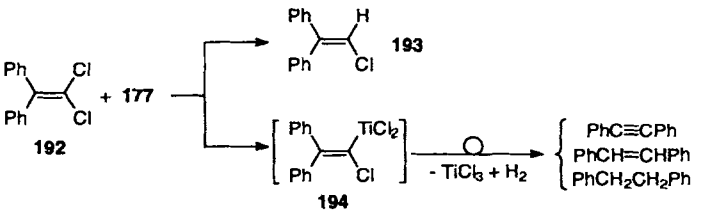
The conversions of benzal chloride into (*E*)-stilbene (**186**, 97%, Scheme 43) and of benzotrichloride into 1,2-dichlorostilbene (**187**, 81%) in the presence of **177** both probably



Scheme 43.

proceed via titanium-based carbenoid intermediates as well. In the reaction of 2,2-dichloronorbornane (**188**) with **177** a rearrangement typical for carbenes, producing nortricyclane (**189**) (in a mixture with 2-chloronorbornane **190**), was observed. In contrast, 7,7-dichloronorcarane (**183**) on reaction with **177** only gave the monodehalogenated product 7-chloronorcarane (**191**).

The products diphenylacetylene, stilbene, and 1,2-diphenylethane (total yield ca. 25%) from the reaction of 1,1-dichloro-2,2-diphenylethene (**192**) with **177** (Scheme 44) proved



Scheme 44. Fritsch–Buttenberg–Wiechell rearrangement of carbenoid intermediate **194**.

that a Fritsch–Buttenberg–Wiechell rearrangement,[127] a characteristic reaction of carbenoids (**194**), had taken place. However, the main product of the reaction (ca. 75%) was 1-chloro-2,2-diphenylethene (**193**).[124]

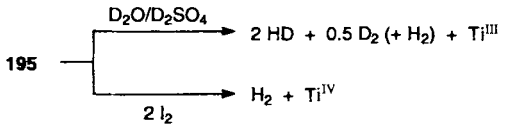
4.2. $[TiH_2 \cdot (MgCl_2 \cdot 2thf)_{0.2-0.3}]$: A New, Highly Reactive Titanium Dihydride

If the reaction of $TiCl_3$ with MgH_2*[115] in THF is carried out with a 1:1.5 molar ratio instead of in a 1:1 molar ratio (Section 4.1), then a solid of composition $[TiH_2 \cdot (MgCl_2 \cdot 2thf)_{0.2-0.3}]$ (**195**, Scheme 45) is isolated in 77% yield. This

$$[TiCl_3(thf)_3] + 1.5\ MgH_2^* \xrightarrow[-0.5\ H_2]{THF} \underset{\mathbf{195}}{[TiH_2 \cdot (MgCl_2 \cdot 2thf)_{0.2\text{-}0.3}]\downarrow} + 1.2\text{-}1.3\ MgCl_2$$

Scheme 45. Synthesis of **195**.

solid is black, highly pyrophoric and amorphous to X-rays. Deuterolysis of **195** produces 2.5 moles of a mixture of HD, D_2, and a little H_2 per mole of titanium, with an H/D ratio of 2/3; iodolysis of **195** produces 1.0 mole of H_2 per mole of titanium (Scheme 46). Consequently, **195** is a titanium(II) dihydride. Since **195** is produced with a relatively constant proportion of 0.2–0.3 moles of $MgCl_2$ per mole of Ti, which can barely be reduced by washing with THF, it must be assumed that $MgCl_2$ and $MgCl_2 \cdot 2thf$ are chemically bound in **195**.[129]

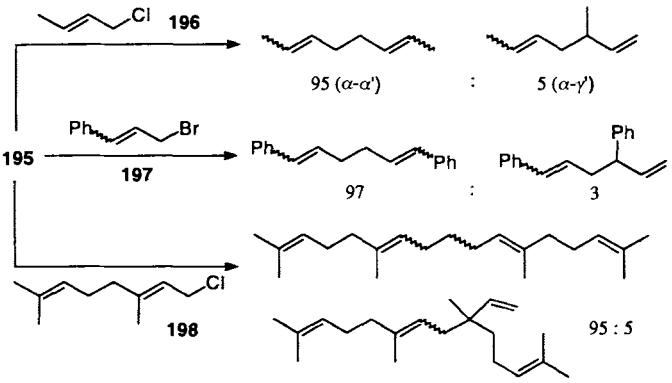


Scheme 46. Reactions of **195**.

The properties of the new titanium dihydride strongly deviate from those of the inorganic solid TiH_2 known to date.[130] In contrast to TiH_2, **195** has a certain—if only slight—solubility in THF ($\approx 0.015\ mol\,L^{-1}$ at 20 °C), which is probably due to the solubilizing action of $MgCl_2 \cdot 2thf$. **195** is much less thermally stable than TiH_2.[130] In boiling THF, 1,4-dioxane, toluene, or tetramethylethylendiamine **195** loses hydrogen quantitatively within a few hours. The dehydrogenation products are finely divided titanium and $MgCl_2$ or a $MgCl_2$–donor adduct. Solid **195** must be handled with care as it is highly pyrophoric and decomposes *explosively* (!) at temperatures above 90 °C. The strongly exothermic decomposition of solid **195** is probably due to the reaction of the low-valent titanium with the bound THF.[129]

Preliminary investigations[129] indicate that **195** is suitable as a reagent for deoxygenation or dehalogenation of organic compounds. Thus, the use of **195** in a McMurry reaction with acetophenone or benzophenone produces the corresponding alkenes, whilst diisopropyl ketone, cyclohexanone, and 3,3,5,5-tetramethylcyclohexanone are reduced to the corresponding secondary alcohols, and benzaldehyde is reduced to toluene. 1,2-Diols and epoxides are deoxygenated by **195**, in some cases with quite high yields. Furthermore, it is worth mentioning that **195** reduces *n*-hexanol to *n*-hexane, cyclohexanol to cyclohexane, and 1,6-hexanediol and 1,8-octanediol to mixtures of *n*-alkanes and monoalcohols. However, these reactions have proceeded with only modest conversions of 40–50% so far.

1,2-Dichloro-, 1-chloro-2-hydroxy-, and 1,2-dibromocyclohexane could be dehalogenated in the presence of **195** to give cyclohexene in high yields. It was interesting to observe that in some cases the use of **195** caused the regioselective coupling of allyl halides to afford 1,5-dienes. Thus, (*E*)-crotyl chloride (**196**), cinnamyl bromide (**197**), and geranyl chloride (**198**) could be dimerized in this way to give the corresponding 1,5-dienes with total yields of 85–98% and with α–α'/α–γ' selectivities of 95/5 and 97/3 (Scheme 47).[131] Highly regio- and stereoselective reductive couplings of allyl halides to 1,5-dienes have been made possible recently by use of activated barium.[132]



Scheme 47. Coupling of allyl halides **196**–**198**.

4.3. Low-Valent Titanium Complexes from Titanium Halides and Magnesium in THF: $[Ti(MgCl)_2(thf)_x]$ as an Inorganic Grignard Compound

As discussed at the beginning of Section 4, the reaction of titanium chlorides with magnesium in THF was intensively investigated in the past, in particular with respect to the preparation of catalysts and reagents for the McMurry reaction,[113], N_2 fixation,[110], H_2 fixation, and other reactions.[111, 112] According to our investigations,[21] the reduction of α-$TiCl_3$ (or $TiCl_4$) with excess magnesium in THF at room temperature proceeds in two steps (Fig. 6 and Scheme 48). In the first, relatively fast step of the reaction, 1.5 moles of magnesium per mole of titanium are consumed, so that the Mg:Ti ratio in solution increases to a value of 1.5 (in the case of $TiCl_4$ to 2.0) (Fig. 6). During protolysis of the black solution (Scheme 48) 1.5 moles of H_2 per mole of titanium as well as Ti^{III} are produced. This indicates that titanium is present in the reaction mixture in the formal oxidation state 0. If the reaction is carried out up to this step in THF saturated with $MgCl_2$, then 0.5 moles of $MgCl_2$ per mole of titanium crystallize out of the supersaturated solution. This indicates that 0.5 moles of free $MgCl_2$ per mole of titanium are produced in the reaction. Therefore, the first step of the reaction furnishes 0.5 moles of $MgCl_2$ and 1 mole of the bimetallic complex $[TiMgCl_2(thf)_x]$ (**199**, Scheme 48)[19, 21, 133].

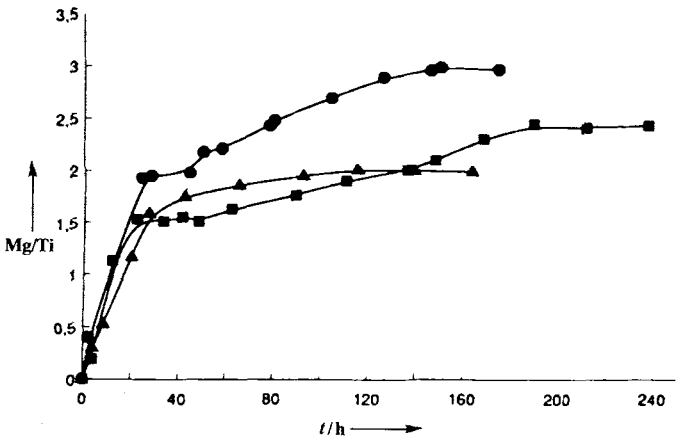


Fig. 6. The increase of the Mg/Ti ratio in solution during the reaction of α-$TiCl_3$ (■), $TiCl_4$ (●), and $[TiCl_2(tmeda)_2]$ (▲) with magnesium turnings (Mg/Ti molar ratio ≈ 10:1) in THF at room temperature.

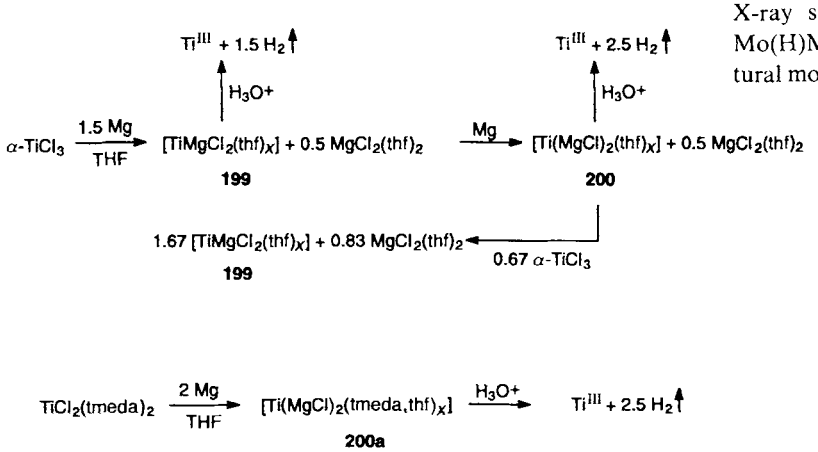

Scheme 48.

In the second, considerably slower step of the reaction, a further mole of magnesium per mole of titanium is consumed (Fig. 6). The existence of the more strongly reduced complex $[Ti(MgCl)_2(thf)_x]$ (**200**) is supported by hydrolysis, which produces 2.5 moles of H_2 per mole of titanium and Ti^{III} (Scheme 48). This corresponds to a formal oxidation state of −II for titanium in **200**. As the reaction with $TiCl_3$ proves, the reduction of **199** to give **200** is reversible. The consumption of a total of 2.5 moles of magnesium per mole of titanium in the reaction of $TiCl_3$ with Mg, and the formation of a complex with the Ti:Mg:Cl ratio of 1:2:2 from $TiCl_4$ and Mg (Scheme 48) confirm the earlier results of Yamamoto et al.[110] (Scheme 35) and Sobota et al. (Scheme 36).[111, 112]

The complex system **200a** with a Ti:Mg:Cl ratio of 1:2:2 is also accessible from $[TiCl_2(tmeda)_2]$[134] and Mg in THF, although no $MgCl_2$ is produced as a side product in this case. Accordingly, the plateau of the Mg/Ti ratio (Fig. 6) is reached after the consumption of 2.0 moles of magnesium per mole of titanium, and hydrolysis produces once again 2.5 moles of H_2 per mole of titanium (Scheme 48). Complexes **199**, **200**, and **200a** can be obtained after removal of the solvents as black, X-ray amorphous powders with variable THF or TMEDA content.

The structure of complex **200** in the solid state and in solution was investigated by EXAFS methods[117] (titanium K-edge). Complex **200** was found to have the shortest Ti–Mg distance (2.72 Å) yet observed. When compared to the corresponding distances in other transition metal/magnesium complexes[135–137] determined by X-ray crystal structure analysis, this distance was found to correspond to a covalent Ti–Mg bond. Evaluation of the EXAFS spectrum reveals that the local environment around the Ti center in **200** consists of 1.4(4) oxygen atoms (2.03 Å), 5(2) carbon atoms (3.02 Å), 2.2(4) magnesium atoms (2.72 Å), and 3.6(7) chlorine atoms (4.05 Å). The results of the EXAFS analysis indicate that there are two THF ligands and two Mg atoms bound to chlorine atoms in the coordination sphere of the titanium center in **200**. On the basis of the EXAFS data, the simplest structural model for **200** is that of a dimer, in which two titanium units are joined by bridging chlorine atoms (Fig. 7a). A comparable dimeric structure containing bridging halogens was previously determined by Green et al.[135] by X-ray structure analysis of the crystalline complex $[\{Cp_2Mo(H)MgBr(OEt_2)MgBr(C_6H_{11})\}_2]$ (**201**, Fig. 7b). The structural model of **200**, based on EXAFS analysis, comparison with **201**, and chemical reactivity (vide supra), differs from the structure originally proposed (**173**),[112] among other features, by the absence of direct Ti–Cl bonds.

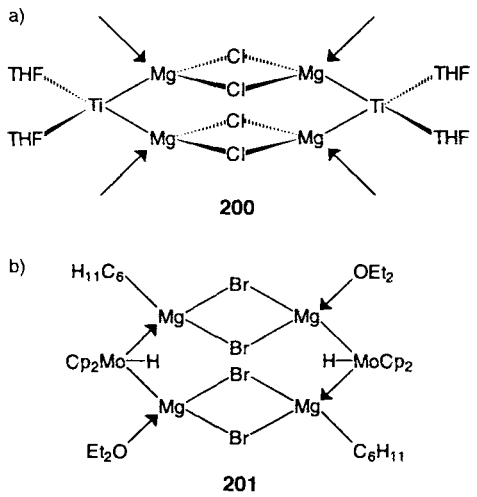

Fig. 7. a) Proposed structural model for $[Ti(MgCl)_2(thf)_x]$ (**200**) based on the results of chemical and spectroscopic studies. b) X-ray crystal structure of the inorganic Grignard complex $[\{Cp_2Mo(H)MgBr(OEt_2)MgBr(C_6H_{11})\}_2]$ (**201**)[135].

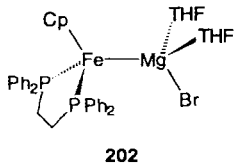
The molybdenum complex **201**[135] as well as Felkin's[136] iron complex [CpFe(diphos)MgBr(thf)$_2$] (diphos = 1,2-diphenylphosphinoethane) (**202**) were discovered 20 years ago and have been described as inorganic analogs of a Grignard compound or "inorganic Grignard compounds".



202

Complex **200**, as well as some other purely inorganic complexes recently described by us[133] with the general formula $[\{M(MgCl)_n(thf)_x\}_p]$ (M = Ni, Fe, Pd, Pt, Ru, Rh, Ir; $n = 1, 2, 3$), can also be described as inorganic Grignard analogs. The $[\{M(MgCl)_n(thf)_x\}_p]$ complexes are suitable as inorganic

Grignard reagents for the wet-chemical synthesis of highly active, nanocrystalline metals, intermetallic compounds, and alloys.[19, 133] For example, **200** reacts with $FeCl_2$ in THF to yield a finely divided, highly active powder, which according to its Mössbauer spectrum consists of a mixture of the intermetallic phases TiFe and $TiFe_2$ in a ratio of roughly 2:1; elemental iron could not be detected in the samples. The formation of the two intermetallic compounds can be described by the equations in Scheme 49, whereby the soluble Ti^0 complex **199** is formed as a side product in the reaction yielding $TiFe_2$.[133]

$$[Ti(MgCl)_2(thf)_x] + FeCl_2 \longrightarrow TiFe\downarrow + 2\,MgCl_2$$
200

$$2\,\mathbf{200} + 2\,FeCl_2 \longrightarrow TiFe_2\downarrow + [TiMgCl_2(thf)_x] + 3\,MgCl_2$$
199

Scheme 49.

It was interesting to investigate the behavior of the soluble Ti complexes **199** and **200** as reagents for carbonyl coupling. From the profile of the reaction of acetophenone with complex **200** (molar ratio 1.1:1; Fig. 8) it can be seen that only a few percent of the expected 2,3-diphenyl-2-butene is produced because the reaction stops at the pinacol stage. The reaction of acetophenone with the Ti^0 complex **199** follows an almost identical course. Additionally, the distribution of the reaction products changes insignificantly if the molar ratio **199** or **200** to acetophenone is varied between 2:1 and 1:2.

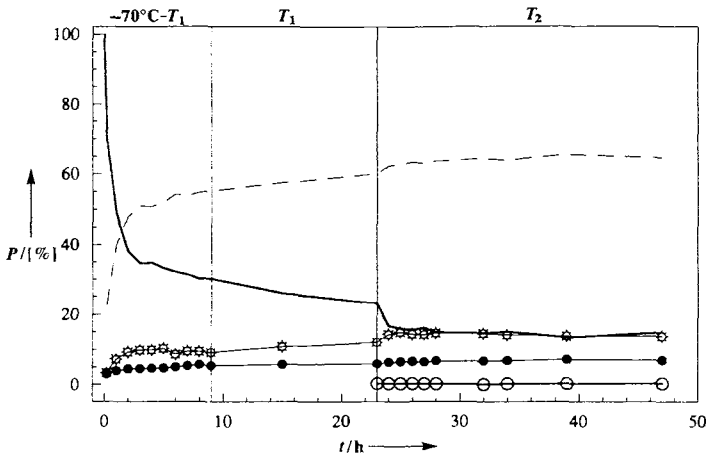


Fig. 8. The progression of the coupling reaction of acetophenone with $[Ti(MgCl)_2(thf)_x]$ (**200**) as a reagent (molar ratio 1.1:1) in THF; the samples were hydrolyzed with H_2O; (—) acetophenone, (· · ·) 2,3-diphenyl-2,3-butanediol (**180b**), (✡) 1-phenylethanol (**179a**), (●) 2,3-diphenyl-2-butene (**178b**), (○) 2,3-diphenyl-2-butanol (**181**). T_1 = room temperature; T_2 = reflux temperature; P = product distribution.

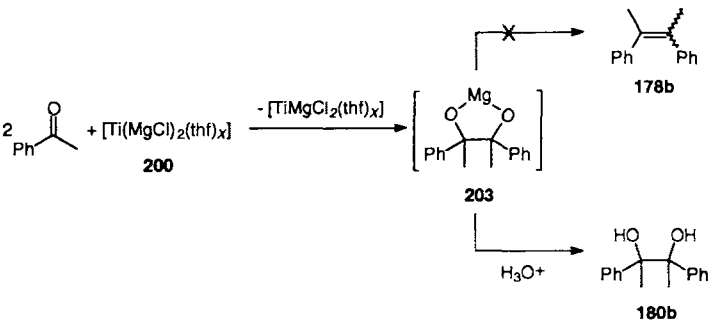
A possible explanation for this unexpected behavior in the reaction of **200** (and of **199**) with acetophenone might be that it is not the titanium pinacolate but the magnesium pinacolate (**203**, Scheme 50) which is formed. It is known that it is not possible to cleave magnesium oxides from magnesium pinacolates to form alkenes.



Scheme 50.

Nevertheless, it turned out that the McMurry coupling of acetophenone to give alkenes using the system $TiCl_3$/Mg/THF can proceed in high yields. Instead of prereducing $TiCl_3$ with Mg in refluxing THF as previously reported[113a] or at room temperature to give the soluble complexes **199** and **200** (Scheme 48), $TiCl_3$ was treated with Mg powder in the presence of acetophenone, according to the "instant" method[17] (Section 3.4.1). As shown in Figure 9, alkene **178b** was produced

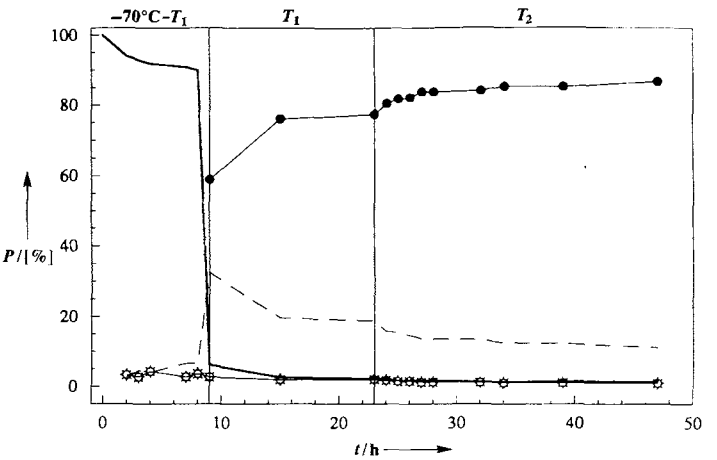


Fig. 9. The progression of the coupling reaction of acetophenone in the $TiCl_3$/Mg system under "instant" conditions (molar ratio 1:1.1:4.4) in THF; the samples were hydrolyzed with H_2O; (—) acetophenone, (· · ·) 2,3-diphenyl-2,3-butandiol (**180b**), (●) 2,3-diphenyl-2-butene (**178b**), (✡) 1-phenylethanol (**179a**). T_1 = room temperature; T_2 = reflux temperature; P = product distribution.

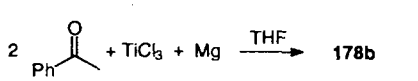
via the intermediate pinacolate even at room temperature. The yield of **178b** increases to over 80% at reflux temperature (Scheme 51).[138]

A comparison of Figures 8 and 9 shows that the reductive coupling of acetophenone under otherwise identical conditions can lead to different products depending on the method used: prereduction gave pinacol **180b** and the "instant" method alkene **178b**. In the experiment with the "instant" method (Scheme 51) it is conceivable that Ti^I and/or Ti^{II} species are involved (cf. Sections 4.1 and 4.4 and refs. [103, 104]).[139]



Scheme 51.

4.4. Comparison of $[TiCl_3(dme)_{1.5}]/Zn(Cu)$ and $TiCl_2 \cdot LiCl$ as Coupling Reagents in the McMurry Reaction

According to the procedure described in 1989 by McMurry et al.[93a] for the McMurry reaction, the $[TiCl_3(dme)_{1.5}]$ complex in boiling DME is prereduced by the Zn(Cu) couple; the resulting active titanium suspension is subsequently treated at reflux temperature with the carbonyl substrate to produce the alkene. It has been proposed[7a, 8] that the active species is finely divided metallic titanium in this case as well.

As an alternative to the prereduction of titanium halides with zinc, the "instant" method[17] (cf. Section 3.4.1) was recently suggested, particularly for titanium-induced pyrrole and indole syntheses.[9–18] The prereduction step is deliberately omitted and a solution of $TiCl_3$ in DME is treated directly with zinc powder in the presence of the carbonyl substrate. One of the reasons for the excellent results of the synthesis of indoles by this method is thought to be that the reduction of Ti^{III} occurs within the $TiCl_3$–substrate complex, which was detected by IR spectroscopy (cf. Scheme 27).

4.4.1. Attempted Reduction of $[TiCl_3(dme)_{1.5}]$ with Zn in DME

In order to explain the mode of action of the $[TiCl_3(dme)_{1.5}]$/Zn and Zn(Cu) reagents (which are now of considerable preparative importance) the attempt was made to discover the nature of the active species produced in this system by the prereduction method. Mixtures of $[TiCl_3(dme)_{1.5}]$ with Zn(Cu), with Zn(Cu) in the presence of pyridine, and with active zinc (Zn*)[140] were refluxed in DME for 20 hours. The solids and filtrates were separated and then tested for their activity in the McMurry coupling of acetophenone to give 2,3-diphenyl-2-butene (**178b**). All three isolated solids were found to be completely active as coupling reagents, whilst only the filtrate obtained from the experiment with Zn* exhibited slight activity.[141] Surprisingly, combined TEM-EDX analyses (*T*ransmission *E*lectron *M*icroscopy/*E*nergy *D*ispersive *X*-ray analysis), powder X-ray analyses, and IR spectra of the isolated solids only showed mixtures of the starting materials; in other words, there was no indication for the formation of low-valent titanium species! Therefore, refluxing the $[TiCl_3(dme)_{1.5}]/Zn(Cu)$ mixture for several hours before adding the carbonyl substrate is totally unnecessary in the McMurry coupling affording pinacols or alkenes.[22, 124]

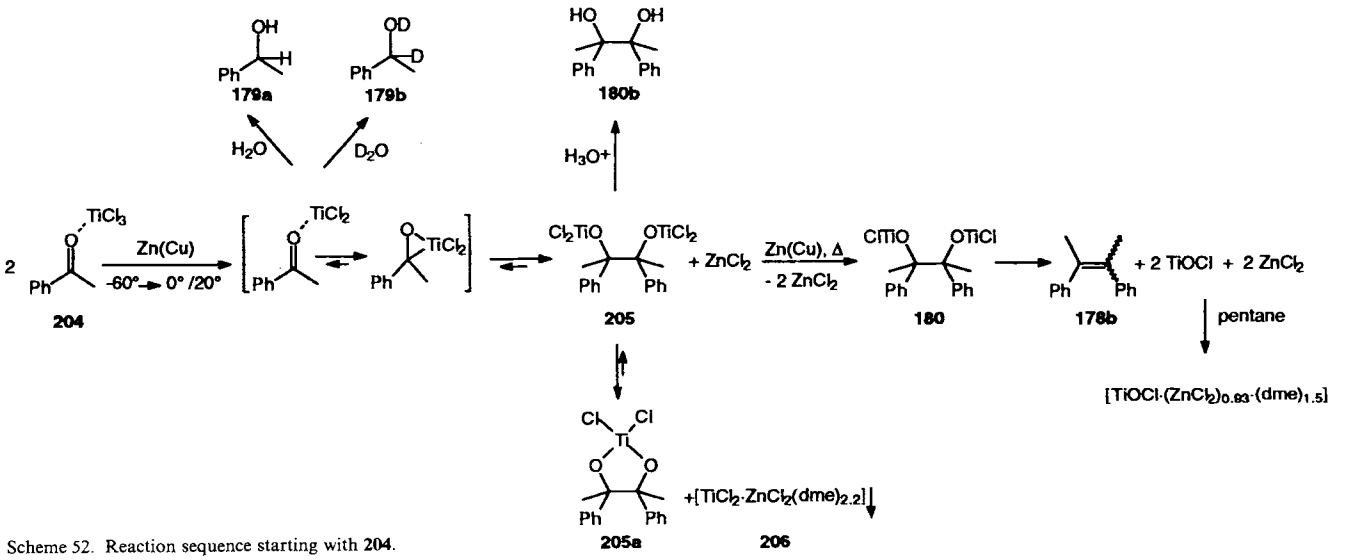
As the experiments described in the following section prove, the reduction of $TiCl_3$ by Zn only takes place in the presence of (coordinated) acetophenone; that is, the McMurry reaction in this system proceeds along the lines of the "instant" method anyway.[17]

4.4.2. Stoichiometry and Reaction Mechanism of the McMurry Coupling of Acetophenone with the $[TiCl_3(dme)_{1.5}]/Zn(Cu)$ Reagent in DME

The formation of a donor–acceptor complex between acetophenone and $TiCl_3$ in DME is proved by the shift of the carbonyl stretching frequency from 1680 cm^{-1} for free acetophenone to 1620 cm^{-1} for the solid acetophenone–$TiCl_3$ adduct (**204**, Scheme 52). Since the reduction of $TiCl_3$ by Zn(Cu) takes place only in the presence of acetophenone, it can be assumed that the reduction potential of the $TiCl_3$–acetophenone system is lower than that of $TiCl_3$. Therefore the reaction begins with the reduction of a $TiCl_3$–acetophenone complex by Zn(Cu) (Scheme 52). This hypothesis is supported by findings (vide supra) that the McMurry reaction of acetophenone succeeds even with metals such as Fe or Sn as the reductant for $TiCl_3$, metals whose standard potentials are considerably lower than that of Zn.

The reaction profile of the McMurry reaction of acetophenone with the $[TiCl_3(dme)_{1.5}]/Zn(Cu)$ system is shown in Figure 10 for the temperature range from −60 °C to the boiling point of DME. An obvious feature of the reaction between 0 °C and room temperature is that the reaction stops at the pinacol step. The pinacol is converted quantitatively into 2,3-diphenyl-2-butene (**178b**) only when the reaction mixture is refluxed for several hours. This situation permitted the elucidation of the stoichiometry of the two reaction steps.

For this purpose $[TiCl_3(dme)_{1.5}]$, acetophenone, and Zn(Cu) (molar ratio 1:1:2.3) in DME were stirred in the temperature



Scheme 52. Reaction sequence starting with **204**.

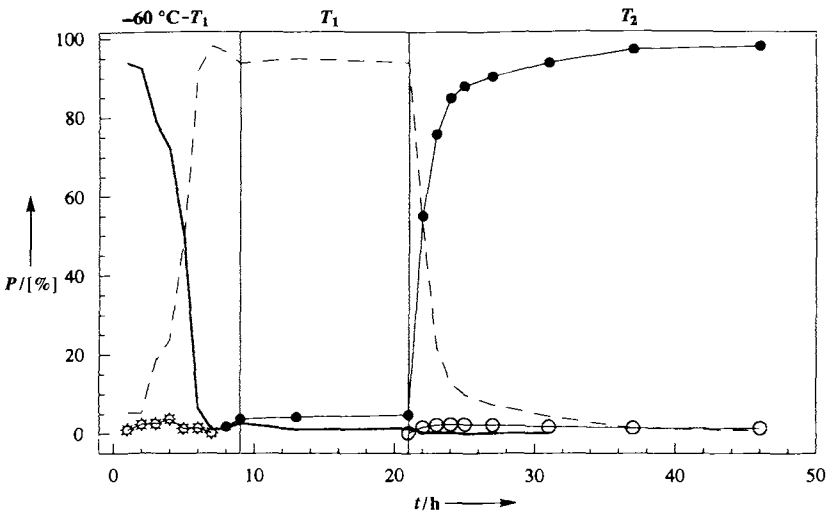


Fig. 10. The progression of the coupling reaction of acetophenone with $[TiCl_3(dme)_{1.5}]$/Zn(Cu) (molar ratio 1:4:16) in DME; the samples were hydrolyzed with H_2O; (—) acetophenone, (– – –) 2,3-diphenyl-2,3-butandiol (**180b**), (●) 2,3-diphenyl-2-butene (**178b**), (✡) 1-phenylethanol (**179a**), (○) 2,3-diphenyl-2-butanol (**181**). T_1 = room temperature; T_2 = reflux temperature; P = product distribution.

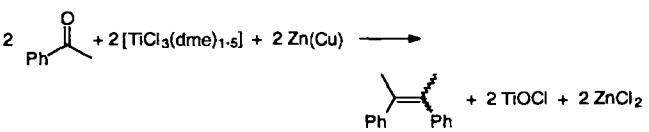
range from −50 to 0 °C. The reaction solution was subsequently separated from the unreacted Zn(Cu) and the precipitated $[TiCl_2 \cdot ZnCl_2(dme)_{2.2}]$ (**206**, Scheme 52). If the solution was left to stand at 0 °C, then further violet **206** precipitated whilst the complex **205a** and a little $ZnCl_2$ remained in solution. The low solubility of complex **206** appears to favor the disproportionation of the initially formed titanium pinacolate **205** to the Ti^{IV} and Ti^{II} complexes **205a** and **206** (Scheme 52). Based on the amount of complexes **205a** and **206** formed, it can be concluded that the composition of the reaction mixture in the pinacolate step corresponds to **205** + $ZnCl_2$, and that the disproportionation (**205** → **205a** + **206**) is virtually complete. Furthermore, these results show that the reaction up to the pinacolate stage consumes one mole of Zn(Cu) per mole of **205**. This represents a formal temporary reduction of Ti^{III} to Ti^{II} (Scheme 52), because Ti^{III} is present once again in pinacolate **205**. In another experiment, acetophenone, $[TiCl_3(dme)_{1.5}]$, and Zn(Cu) (molar ratio 1:1:1) in DME were refluxed for 48 h (Table 5, entry 3), which resulted in an 84% yield of alkene **178b** and complete consumption of Zn(Cu). After addition of pentane to the reaction solution, a solid precipitated with the composition $[TiOCl \cdot (ZnCl_2)_{0.9}(dme)_{1.5}]$ (Scheme 52). The total consumption of approximately two moles of Zn(Cu) per mole of **178b** and the composition of the inorganic end product of the reaction (TiOCl) indicate that the conversion of the pinacolate into the alkene requires a further mole of Zn(Cu) per mole of **178b**. The overall reaction of acetophenone with the $[TiCl_3(dme)_{1.5}]$/Zn(Cu) system is shown in Scheme 53.

The course of the reaction (Schemes 52 and 53) is supported by experiments in which the molar ratio acetophenone:$[TiCl_3(dme)_{1.5}]$:Zn(Cu) was varied (Table 5). If the molar ratio 1:0.5:0.5 (entry 1) is employed, then a high yield of the pinacol (93.8%) is obtained but an alkene yield of at best ≈50% can be reached. If a molar ratio of 1:1:1 or higher is used (entries 2–6), then excellent yields of the alkene are obtained in every case; this is in agreement with Scheme 53. However, if the amounts of the titanium and zinc reagents used are increased, then the conversion of the pinacolate into alkene accelerates. A large excess of the reagents (entry 6) is not necessarily required since a yield of 95% alkene after 16.5 h is already attained with a 1:2:2 ratio (entry 5). It is interesting here that when the starting materials are in a 1:2:2 molar ratio, high yields of alkene **178b** (90–92%) can also be achieved with Fe or Sn powders as the reducing agent.[22, 124]



Scheme 53. **178b**

4.4.3. *McMurry Coupling of Acetophenone with the $TiCl_2 \cdot LiCl$ Reagent*

Further support of the course of reaction displayed in Schemes 52 and 53 was provided by comparative experiments in which the $TiCl_2 \cdot LiCl$ reagent proposed by Eisch et al.[23] was used for the McMurry coupling of acetophenone (Table 6). The reaction profile of the 1:1 reaction (Fig. 11) shows that a high

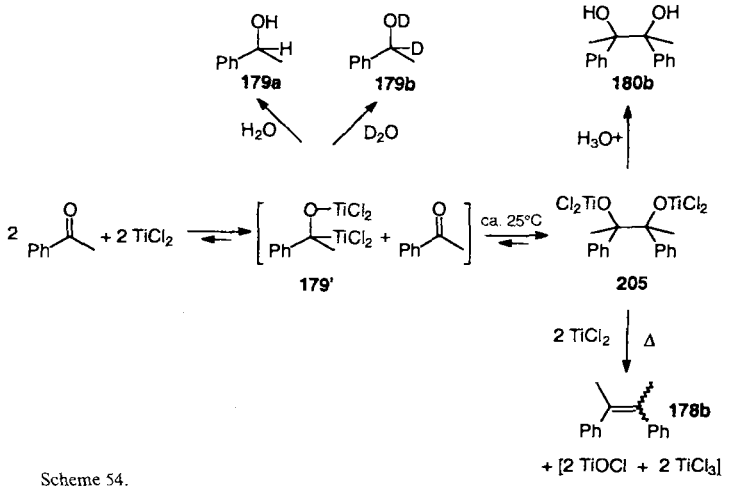

Scheme 54.

yield (91.4%) of pinacolate (**205**, Scheme 54) is produced at room temperature. When the mixture is heated at refluxed (Table 6 and Fig. 11) in the absence of a further amount of $TiCl_2$, then the maximum yield of alkene is 46%. The formation of the alkene **178b** (Fig. 11) is accompanied by a partial regeneration of acetophenone; this indicates that the formation of the pinacolate is reversible.[142] The partial reversal of pinacolate formation probably liberates the required amount of $TiCl_2$ for the conversion of the remaining pinacolate into the alkene (Scheme 54). This implies that $TiCl_2$ can only act as a one-electron reducing agent for the formation of alkene from the pinacolate. In agreement with this, when acetophenone:$TiCl_2 \cdot LiCl$ is used in a 1:2 or 1:4 molar ratio (Table 6), high yields of alkene are achieved in both cases.

Once again the intermediate appearance of the hydrolysis product 1-phenylethanol (**179a**, Scheme 54) at the beginning of the reaction is interesting (Fig. 11). In this case too (cf. Fig. 4, Section 4.1.1) a deuterolysis experiment yielded a quantitatively deuterated 1-deutero-1-phenylethanol (**179b**, Scheme 54). Therefore, the side-on coordinated acetophenone–$TiCl_2$ complex **179'** (Scheme 54) could be either a formal Ti^{IV} (as in Scheme 52) or a Ti^{III} complex.

4.5. Final Remarks and Outlook

The results summarized above on the stoichiometry and course of the reductive coupling reaction of acetophenone using different types of low-valent titanium reagents permits new, refined insights into the mechanism of the McMurry and related reactions. If complex **177** is used as a reagent, then the titanium center is oxidized during the reaction from formally Ti^{II} (in **177** and in pinacolate **180**) to Ti^{III} (in **179** and TiOCl). On account of the homolytic dissociation of the hydride ligand, an additional electron is available for the reaction. Therefore, complex **177** behaves as a (strong) two-electron reductant and a 1:1 molar ratio of ketone to **177** is sufficient to produce alkenes in high yields. In contrast, $TiCl_2$ acts as a one-electron reductant in the formation of the alkene ($\approx$50% yield of alkene for a 1:1 molar ratio of the reactants), whereby Ti^{II} is oxidized to Ti^{III} during the reaction (Scheme 54). The results obtained from the coupling reaction with the $[TiCl_3(dme)_{1.5}]/Zn(Cu)$ system (Scheme 52) indicate quite clearly that each of the two reaction steps involves a one-electron reduction of Ti^{III} by Zn. Therefore, there are short-lived Ti^{II} intermediates taking part in the reaction. The reduction of Ti^{III} to Ti^{II} with weak reducing agents such as Zn, Fe, and Sn is only possible in the presence of the (complexed) carbonyl substrate.

As these investigations demonstrate, the low-valent titanium complexes $[HTiCl(thf)_{\approx 0.5}]$,[20] $[TiH_2 \cdot (MgCl_2 \cdot 2thf)_{0.2-0.3}]$,[129] $[TiMgCl_2(thf)_x]$, $[Ti(MgCl)_2(thf)_x]$,[21] and $[TiCl_2 \cdot LiCl]$[22,23] have specific reactivities. In future, the use of such defined low-valent titanium complexes instead of the reagents produced in situ may lead to improved reproducibility and yields. Additionally, it is possible, for example by varying the ligands of the Ti^{II} complexes or by the choice of the reducing agent, of directly influencing the course of the reaction and thus increasing the selectivity. New impetus for preparative chemistry can be expected from the reactions of the reactive intermediates, for example the proposed ketone–titanium chloride complexes **179** and **179'** and the carbenoids such as **182** and **184**, with reaction partners other than those used to date.

We would like to thank our co-workers listed in the references for their valuable contributions resulting from their personal initiative and excellent teamwork. One of us (B. B.) thanks Prof. J. Rozière and Dr. D. J. Jones, University of Montpellier, France, for the EXAFS investigations. We thank the Volkswagen-Stiftung and the Fonds der Chemischen Industrie for financial support.

Electron Transfer and Chemical Reactions—Stepwise or Concerted? *On the Competition between Nucleophilic Substitution and Electron Transfer* **

Bernd Speiser*

Dedicated to Professor Michael Hanack on the occasion of his 65th birthday

Reaction mechanisms are important concepts for our comprehension of chemical transformations: mechanisms allow not only a pictorial description of reactions but also their classification into some fundamental types. Sometimes, however, it is asked whether our list of mechanisms is sufficient to explain experimental data, whether explanations of a particular mechanism are correct, and how we can distinguish between similar pathways.

Recently, it has been asked whether the nucleophilic substitution of a leaving group X^- by a nucleophile Nu^- can proceed by mechanisms other than the well-known[1] S_N1 [two elementary steps, Eq. (1)] and S_N2 variants [one elementary step, Eq. (2)]. In particular, electron transfer (ET) reactions[2] have

$$R\text{-}X \longrightarrow R^+ + X^- \xrightarrow{Nu^-} R\text{-}Nu + X^- \quad (1)$$

$$Nu^- + R\text{-}X \longrightarrow [Nu\cdots R\cdots X]^- \longrightarrow R\text{-}Nu + X^- \quad (2)$$

been proposed, in which Nu^- acts as a single electron donor. This is in contrast with the classical characterization of Nu^- as an electron pair donor.

In many instances when the electron transfer is separated from the subsequent step (monomolecular cleavage of the bond to the leaving group) by a substrate radical anion intermediate (outer sphere ET, definition in ref. [3]), an $S_{RN}1$ chain reaction [Eq. (3)] has been found[4, 5] (initiation by photo- or electrochemical means, by a chemical reducing agent, or "thermally" by Nu^- itself; termination reactions not included here).

$$\begin{aligned}
&\text{Initiation:} && R\text{-}X + e^- \longrightarrow R\text{-}X^{\bullet -}\\
&\text{Propagation:} && R\text{-}X^{\bullet -} \longrightarrow R^\bullet + X^-\\
& && Nu^- + R^\bullet \longrightarrow R\text{-}Nu^{\bullet -}\\
& && R\text{-}Nu^{\bullet -} + R\text{-}X \longrightarrow R\text{-}Nu + R\text{-}X^{\bullet -}\\
&\text{Overall reaction:} && Nu^- + R\text{-}X \longrightarrow R\text{-}Nu + X^-
\end{aligned} \quad (3)$$

An inner sphere process (definition in ref. [3]) with ET, bond breaking, and bond formation occurring in a single step corresponds to the classical S_N2 mechanism [Eq. (2)]. In a hypothetical third variant (dissociative outer sphere ET[5] [Eqs. (4) and (5)]), ET and cleavage of the R–X bond occur concertedly,

$$Nu^{\bullet -} + R\text{-}X \longrightarrow Nu + R^\bullet + X^-;\ R^\bullet + Nu^{\bullet -} \longrightarrow R\text{-}Nu^- \quad (4)$$

$$Nu^- + R\text{-}X \longrightarrow Nu^\bullet + R^\bullet + X^- \longrightarrow R\text{-}Nu + X^- \quad (5)$$

while product (bond) formation constitutes a second elementary step. In contrast to the S_N2 case, the nucleophile does not bind to the reaction center in the transition state: with regards to Nu^-, both (4) and (5) are outer sphere reactions.

The question of alternatives to the classical view of S_N reactions is thus intimately linked to the theory of ET (Marcus theory)[6] and its extension to dissociative ET[7] by Savéant.[8] Both Marcus's and Savéant's theories apply to ET reactions between an electron donor and an electron acceptor as well as to electrochemical reactions between a donor or acceptor and an electrode. In the latter case, cyclic voltammetry can be used to determine the free energy of activation $\Delta G^\ddagger$ for the electron transfer.[7, 9–12] Important experimental features are peak broadening in the voltammograms, quantitatively expressed by the half-peak width $E_p - E_{p/2}$ and the peak shift with the scan rate v, $dE_p/d\log v$ (for a definition of the peak parameters, see Fig. 1). Theoretical predictions have been tested experimentally

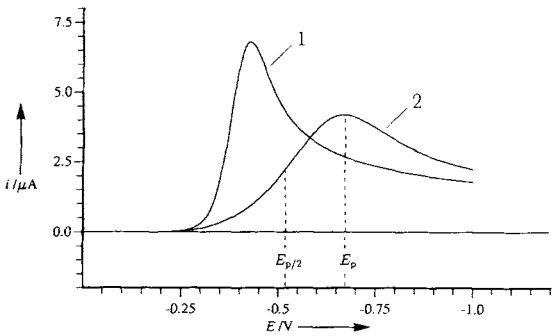

Fig. 1. Cyclic voltammetric peaks for a reversible diffusion-controlled process (curve 1) and for a quasi-reversible process controlled by diffusion and ET (curve 2). E_p: peak potential; $E_{p/2}$: potential at which the current reaches half its peak value; both potentials are shown here for curve 2; $E_p - E_{p/2}$: half-peak width; simulated voltammograms with $E^0 = -0.4$ V, concentration $c = 10^{-4}$ M, electroactive area $A = 0.08\ cm^2$, diffusion coefficient $D = 10^{-5}\ cm^2 s^{-1}$, $v = 1.0\ V s^{-1}$; additional parameters for curve 2: transfer coefficient $\alpha = 0.3$, rate constant of the heterogeneous ET $k_s = 10^{-3}\ cm\,s^{-1}$.

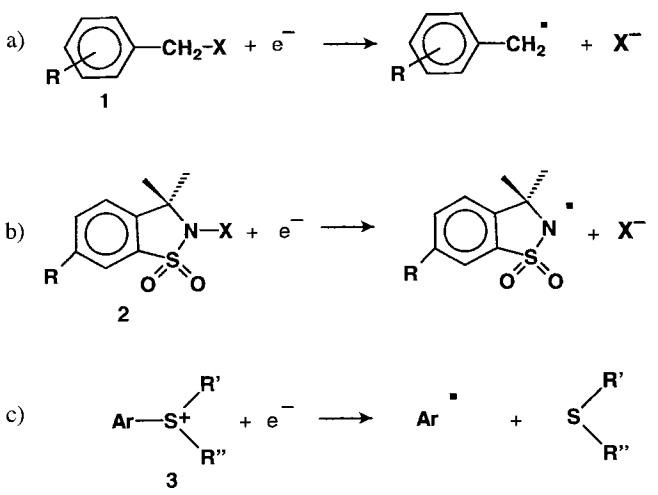
and confirmed for several electrochemical cleavage reactions [e.g. Scheme 1, a)–c)].



Scheme 1. Reductive cleavage of benzyl halides **1**, *N*-halosultams **2**, and sulfonium cations **3**.

Several factors have been identified that control the transition between a stepwise sequence [Eq. (6)] and a concerted reaction [Eq. (7)] (Fig. 2). For the reduction of benzyl halides **1**, *N*-halo-

$$R{-}X + e^- \longrightarrow R{-}X^{\bullet -} \longrightarrow R^\bullet + X^- \quad (6)$$

$$R{-}X + e^- \longrightarrow R^\bullet + X^- \quad (7)$$

sultams **2**, and sulfonium cations **3**, the energy of the π^* LUMO, which accomodates the incoming electron, and the bond dissociation energy of the R–X bond are most important (Figs. 2b and 2c). Thus, nitro-substituted benzyl halides **1** (R = NO_2; X = Cl, Br) with a low-lying π^* LUMO react according to Equation (6), since reduction to the radical anion proceeds easily (not very negative formal potential $E^0_{RX/RX^{\bullet -}}$). Cyano- or unsubstituted benzyl halides (R = CN, H; X = Cl, Br) with a higher energy π^* LUMO, on the other hand, undergo concerted cleavage according to Equation (7).[10] Although characterized by LUMO energies similar to those found for the benzyl halides, sultams **2** (R = NO_2; X = Br, Cl) react concertedly [Eq. (7)][10] since the N–X bond is weaker than its C–X counterpart. Only the fluorosultam (R = NO_2; X = F), which has a high N–F bond dissociation energy, returns to stepwise cleavage [Eq. (6)]. Analogous results were found for the reductive cleavage reactions of alkyl halides (weaker C–X bond: concerted) and aryl halides (stronger C–X bond: stepwise).[7]

In the reduction of aryldialkyl sulfonium cations **3**[11] the mechanism for two compounds (R′ = CH_3, R″ = $CH_2{-}C_6H_5$, Ar = phenyl or naphthyl) changes when the cyclic voltammetric scan rate is increased: for small v the data agree with a concerted, for large v with a stepwise mechanism. This difference is related to the v-dependent peak shift in the voltammograms. With smaller v (slower timescale) the peaks move to less negative potentials E in agreement with the fact that the ET is kinetically controlled. If the reaction proceeds at more positive E, however, the energy of $RX + e^-$ and thus the thermodynamic driving force[8] of the reaction decreases. This leads to a concerted reaction (Fig. 2d). An increased driving force is expected for an ET induced by pulse radiolysis. Indeed, the reaction of 3-cyanobenzyl bromide in water is stepwise under such conditions, while its electrochemical reduction in CH_3CN is concerted.[11]

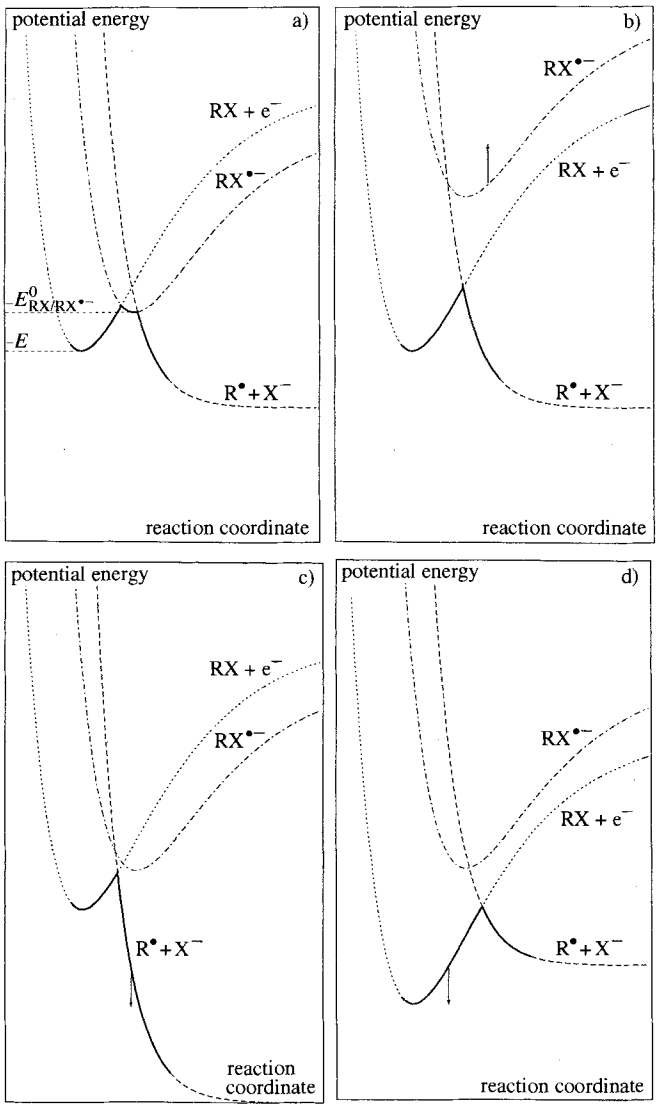


Fig. 2. Influences on an ET reaction with coupled bond cleavage; potential energies of substrate R–X (---), its reduction products $R{-}X^{\bullet -}$ (– · – · –), and the cleavage products $R^\bullet + X^-$ (– – –) given as function of the reaction coordinate (simplified: distance R–X); the energetically favored pathway for the reaction (energy profile) follows the thick line. The arrows indicate changes of the potential curve relative to situation a) (stepwise mechanism, two transition states, outer sphere ET); b) increase of $R{-}X^{\bullet -}$ LUMO energy, more negative $E^0_{RX/RX^{\bullet -}}$; c) decrease of dissociation energy, weaker R–X bond; d) decrease of driving force, more positive electrode potential E. All three variations lead to the concerted pathway (one transition state, outer sphere dissociative ET).

Solvent effects could also play a role. Consequently, the influence of different solvents on the reductive cleavage of CF_3Cl has been estimated by ab initio calculations.[13] Polar solvents were found to favor the concerted reaction, and the minimum for $CF_3Cl^{\bullet -}$ on the potential energy surface for "gas-phase" calculations disappears.

Can we apply these electrochemical results to homogeneous reactions? The cathode as an electron source is then replaced by a one-electron donor $D^{\bullet -}$. During the ET according to Equations (8) (stepwise, outer sphere) and (9) (concerted, outer

$$D^{\bullet -} + R\text{–}X \longrightarrow D + R\text{–}X^{\bullet -} \longrightarrow D + R^{\bullet} + X^{-} \quad (8)$$

$$D^{\bullet -} + R\text{–}X \longrightarrow D + R^{\bullet} + X^{-} \quad (9)$$

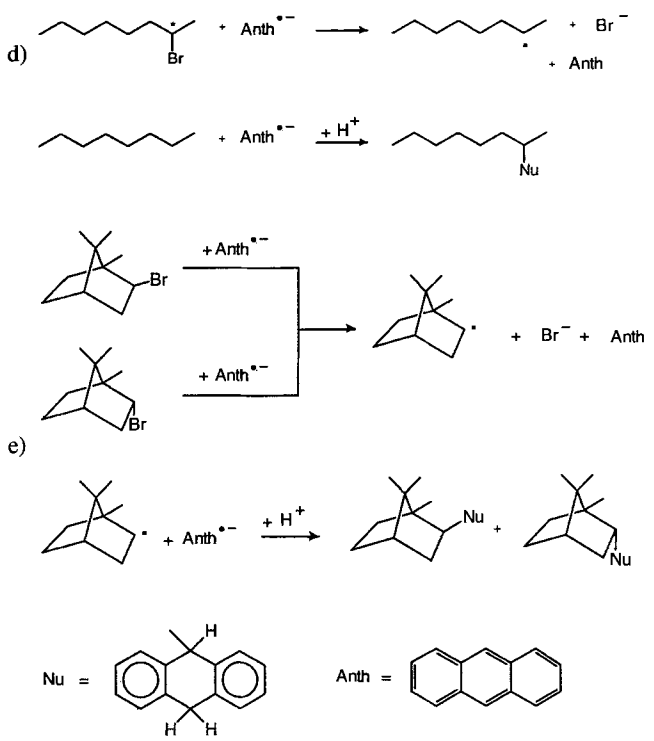
sphere dissociative) $D^{\bullet -}$ does not bind to the reaction center. Examples of donor molecules are anion radicals of aromatic hydrocarbons and heteroarenes. These species are persistent in DMF, and their reactions with acceptors have been well characterized.[14] Experimentally, the reactions are followed again by cyclic voltammetry,[15] but studies with rotating disk electrodes and ultramicroelectrodes have also been conducted.[16] The radical anion $D^{\bullet -}$ is formed at the electrode and reacts with R–X according to Equation (8) or (9)[17] to regenerate the neutral donor. The redox couple $D/D^{\bullet -}$ serves as the mediator in an indirect electrolysis.[18]

Lund's group has tested extensive series of substrates such as alkyl and aryl halides, activated olefins, CO_2, and anhydrides.[14] The driving force of the reaction and hence its rate is affected by the reduction potential of the donor. Stepwise [Eq. (8)] and concerted pathways [Eq. (9)] are observed as before for direct ET at an electrode.[7]

The transition to the S_N2 reaction is reached if $D^{\bullet -}$ and R interact. Then $D^{\bullet -}$ corresponds to a nucleophile and is bound to RX in the transition state. The outer sphere ET becomes an inner sphere process, and formation and cleavage of the two bonds occur simultaneously. The dissociative outer sphere and S_N2 variants are expected to differ in their stereochemical results, their activation entropy ΔS^{+}, and their activation enthalpy ΔH^{+}. A S_N2 reaction [Eq. (2)] at a carbon atom proceeds with inversion of configuration (Walden inversion).[19] The nucleophile attacks the reaction center as an electron pair donor from the side opposite to the leaving group for electronic and steric reasons. The resulting transition state has strict requirements for the relative alignment of Nu, R, and X, which explains the observed high activation entropy (for example $\Delta S^{+} = -67.3\ J\,K^{-1}\,mol^{-1}$ for the reaction between *n*-butyl bromide and anthracene radical anion).[20] Since the nucleophile and the reaction center form a bonding interaction, ΔH^{+} is relatively small ($37.4\ kJ\,mol^{-1}$ for the example mentioned[20]).

Nevertheless, in a series of bimolecular nucleophilic substitutions at least partial racemization has been observed (Scheme 2),[14, 21] a fact that can be explained easily by formation of an intermediate radical R$^{\bullet}$ through dissociative ET (for further examples, see ref. [5]). In these cases, the nucleophile does not have to attack along the C–X axis. Rather, the bond cleavage may proceed through action of the nucleophile as one-electron donor without directional preference. This results in a smaller absolute value of ΔS^{+} (for example $-36\ J\,K^{-1}\,mol^{-1}$ for the reaction of bornyl bromide with anthracene radical anion).[14] The intermediate R$^{\bullet}$ reacts with a second molecule $Nu^{\bullet -}$ and forms the product anion [Eq. (4)], which is subsequently protonated.[22] If the nucleophile itself does not have radical character, the product is formed directly according to Equation (5).

The influence on ΔG^{+} is usually determined by the "kinetic advantage" technique.[14, 23] The rate constants k_{ET} for ET reactions of the substrate with donors having various redox potentials and thus different driving forces are compared to the rate constants k_{SUB} for the substitution reaction. If the value of k_{SUB} is within the range expected for an ET reaction with the particular driving force, an ET pathway like that in Equation (9) is assumed. For an S_N2 reaction with a stabilizing interaction in the transition state, k_{SUB} has appreciably higher values. The latter effect is found for sterically less demanding alkyl halides, while in the case of isobornyl bromide $k_{ET}/k_{SUB} \approx 1$.



Scheme 2. Examples of bimolecular nucleophilic substitutions that proceed with (partial) racemization; d) 92% racemization, e) 1:1 ratio of isomers independent of the bromide employed.

The following picture emerges from these considerations and experiments: If the reaction center can be approached by the nucleophile easily from the back side, the concerted S_N2 pathway is energetically advantageous. A sterically hindered reaction center, however, may still form products by a less direction-specific reaction which is favored by ΔS^{+}.

The question whether the ET and the S_N2 reactions have to be described by two separate transition states is still controversial.[2, 5, 14] Alternatively, a spectrum of reaction pathways through a single transition state with a variable proportion of ET could exist whose extremes correspond to the two mechanisms.[14] Put in another way:[24, 25] is there an activated complex different from the S_N2 transition state that leads to a substitution and where the reaction is initiated by dissociative outer sphere ET?

Lund and co-workers argue in favor of a spectrum of mechanisms.[14, 16, 26] Since the logarithm of the rate constant depends linearly on the driving force, a change of the transition state is unlikely. Other results (D = anthracene, R–X = methyl halides;[27] D = 1,4-naphthalenedicarbonitrile, R–X = benzyl bromide[28]) also point to a competition between mechanisms; in the latter example it is controlled by the solvent (CH_3CN vs. DMF).

Sastry and Shaik tried to locate the transition states for S_N2 and ET reactions on the calculated potential energy surface of the reaction between $CH_2{=}O^{\bullet -}$ and CH_3Cl. They found, how-

ever, only inner sphere variants with bonding of the donor.[25] Similarly, for the reaction between $CHY{=}O^{\bullet -}$ and CH_3X (Y = H, CH_3, CN; X = Cl, Br, I) only one transition state could be characterized, from which either inner sphere ET or substitution may occur depending on X and Y[29] (spectrum of mechanisms).

In a most recent manuscript, Savéant and co-workers,[30] on the other hand, used ab initio calculations to identify two transition states (S_N2, ET) for the reaction of $CH_2{=}CH_2^{\bullet -}$ with CH_3F and three transition states (S_N2 at the O atom and at the C atom of the formaldehyde radical anion, ET) for the reactions of $CH_2{=}O^{\bullet -}$ with CH_3F or CH_3Cl. The relative energies and entropies closely correspond to those expected from the discussion above.

Calculations for more complex systems may contribute further to the understanding of the S_N2 reaction; however, more sophisticated experiments are needed for the final verdict. Already in 1987, Eberson predicted that the alternatives to the classical S_N reaction "in all likelihood ... will create vigorous discussion in parts of the scientific community, and agreement about their mechanism will be slow to come to."[31] Almost ten years later the question has not yet been fully resolved. Despite current criticism,[2, 25] the outer sphere dissociative ET must be regarded as a supplementary pathway for S_N2-like substitutions,[2, 25] just as the $S_{RN}1$ mechanism is discussed for monomolecular reactions. Even textbook reaction mechanisms are not immune to changes.

Marcus computes the standard free energy of activation $\Delta G_0^{\ddagger}$ of an ET reaction as the sum of an inner (λ_i) and an outer (λ_o) reorganization energy [Eq. (10)] [6]. These energies result from changes in bond angles and lengths, and reorientation of solvent molecules, respectively. Saveant [7] substitutes the harmonic oscillator parabola by a Morse curve for the case of an ET with concerted bond cleavage. This results in Equation (11), where D corresponds to the dissociation energy of the cleaved bond. In both cases the activation energy $\Delta G^{\ddagger}$ shows a quadratic dependence on the driving force of the reaction, $-\Delta G^0$, according to Equation (12) [32] (+ for forward, − for reverse reaction; work terms for the formation of precursor and successor complexes are neglected [32]). The standard value $\Delta G_0^{\ddagger}$ follows for $\Delta G^0 = 0$.

$$\Delta G_0^{\ddagger} = \frac{\lambda_i + \lambda_o}{4} \tag{10}$$

$$\Delta G_0^{\ddagger} = \frac{D + \lambda_i + \lambda_o}{4} \tag{11}$$

$$\Delta G^{\ddagger} = \Delta G_0^{\ddagger}\left(1 \pm \frac{\Delta G^0}{4\Delta G_0^{\ddagger}}\right)^2 \tag{12}$$

[3] In an outer sphere electron transfer either no bonds are formed or cleaved on the timescale of the experiment or this happens in an elementary step separate from the ET [5, 23]. The inner sphere case, on the other hand, describes an elementary step corresponding to an ET with a concerted change in bonding.

Late Transition Metal Complexes: Catalysts for a New Generation of Organic Polymers

Adnan S. Abu-Surrah and Bernhard Rieger*

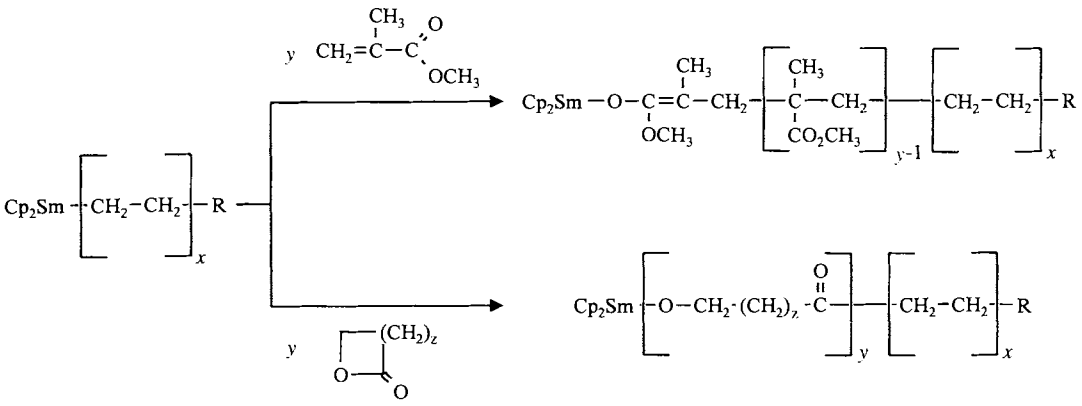
Since the pioneering by Karl Ziegler and Giulio Natta in the the early 1950s on the polymerization of simple olefins,[1] there has been intense interest in the application of early transition metal catalysts for the selective polymerization of inexpensive olefins. Current studies on metallocene-based catalysts have far-reaching implications for the development of new poly(α-olefin) materials as well as for an understanding of basic reaction mechanisms responsible for the growth of polymer chains at a catalyst center and for the control of polymer microstructures and molecular weights.[2] However, due to the sensitivity of early transition metal complexes to electron-donating functional groups, this catalyst generation allows only the use of a limited number of polar monomers bearing sterically hindered functionalities.[3] Thus, copolymers of readily available polar monomers with ethene are exclusively produced by radical routes in high-pressure processes.[4]

The corresponding α-olefin copolymers are not accessible by these techniques; related structures have been achieved by applying grafting reactions of acrylates on an isotactic polypropene backbone. Controlled copolymerization of ethene and propene with polar olefins such as readily available acrylates, their derivatives, and vinyl ethers is still a long-standing goal in polyolefin engineering, since copolymers of this type might endow a new generation of materials with remarkably high adhesive, dyeing, and moisture adsorption properties.

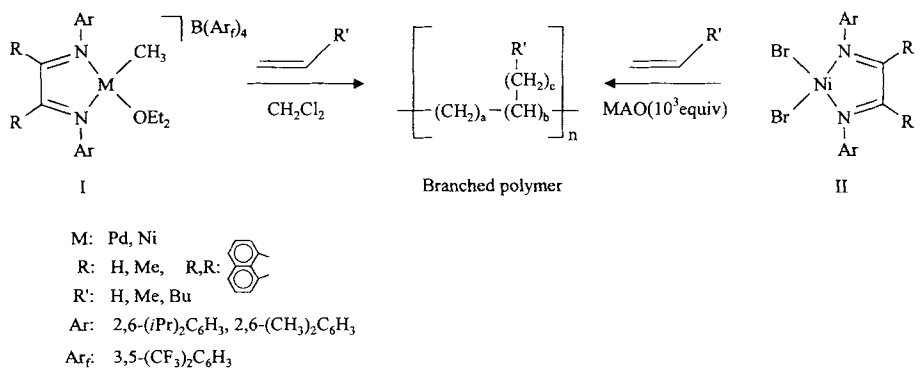
The first successes in this direction were recently achieved by using rare earth transition metal compounds. Lanthanide complexes were used to prepare block copolymers comprising a polyethene and a polar polyacrylate or polyester moiety. In this reaction, ethene is first polymerized by a samarocene complex. The second block is then introduced by a consecutive group-transfer polymerization of methyl methacrylate or by ring-opening polymerization of a lactone[5] (Scheme 1).

It was established in the 1970s that alkyl complexes of late transition metals such as iron and cobalt could also be applied for the insertion polymerization of acrylic acid derivatives.[6] Yamamoto et al. used diethylbis(bipyridine)iron(II) and related cobalt complexes for the homopolymerization of acrylonitrile. The observed low monomer conversion is probably due to a labile coordination of the bipyridine ligands, which leads to a facile deactivation of the catalyst by β-H-migration and reductive elimination of the growing polymer chain.[7] In 1995 Brookhart et al. reported that certain Pd^{II} and Ni^{II} catalysts can convert ethene and α-olefins to high molecular weight polymers at low pressure.[8] These late transition metal compounds are either monocationic alkyl complexes of the type $[(N\cap N)M(CH_3)(solvent)][B(Ar_f)_4]$ or methyl aluminoxane (MAO)-activated nickel(II) dibromide complexes bearing a bidentate imine ligand[9] with a sterically demanding substitution pattern (Scheme 2).

The counteranion $[\{3,5\text{-}(CF_3)_2C_6H_3\}_4B]^-$ increases the solubility of these catalyst systems, and the bulky substituents on the aryl groups of the diimine ligands block an associative olefin exchange, thus effectively retarding chain transfer processes. Both aspects are important prerequisites that make such palladium(II) complexes the first transition metal catalyst systems capable of copolymerizing ethene or propene with readily avail-



Scheme 1. Synthesis of AB block copolymers with samarocene catalysts. R = polymer chain.



Scheme 2. Olefin polymerization with sterically hindered Ni^{II} and Pd^{II} catalysts.

were prepared from the corresponding monoalkyl complex $[(N\cap N)Pd(CH_3)Cl)]$, acrylate monomer, and $NaB(Ar_f)_4$, are suitable precursors of the catalytically active species in the copolymerization reactions. The resulting ethene copolymers are amorphous, highly branched materials, in which the ester groups are predominantly located at the end of the branches.

Similar Pd^{II} catalysts (**IV**, Scheme 4) bearing enantiomerically pure, C_2-symmetric bis(dihydrooxazole) ligands have also been

Scheme 4. Synthesis of isotactic, optically active polyketones with chiral bis(dihydrooxazole)palladium(II) catalysts. Ar_f see Scheme 2.

applied by Brookhart et al. for asymmetric polymerization reactions.[12] Optically active, isotactic polyketones are formed by an alternating insertion of bulky olefins (e. g. 4-*tert*-butylstyrene) and carbon monoxide.

Comparable alternating polymers comprising more simple olefins are accessible by using palladium(II) phosphane complexes. Sen et al.[13] and Takaya et al.[14] obtained highly isotactic, optically active alternating propene/carbon monoxide copolymers by using Pd^{II} complexes of (*R*)-Me-DUPHOS (**V**) or the asymmetric ligand (*R*,*S*)-BINAPHOS (**VI**)[15] (Scheme 5). These polyketones are a new and versatile class of polymers, whose property profiles range from crystalline thermoplastics[16] to high molecular weight elastomers.[17] In contrast to regio- and stereoregular poly(α-olefins), which possess a mirror plane perpendicular to the main chain, the polyketones are chiral polymers that can show optical activity when enantiomerically pure catalysts are applied. Only time will tell whether the formation of complexes with other chiral polymers, such as

Deposition of Data from X-ray Structure Analyses

In order to make life easier for authors and referees the Cambridge Crystallographic Data Centre (CCDC) and the Fachinformationszentrum Karlsruhe (FIZ) have unified their procedures for the deposition of data from single-crystal X-ray structure analyses.

From now on prior to submitting your manuscripts please deposit the data for your compound(s) **electronically** at the appropriate data bank, that is, at the CCDC for organic and organometallic compounds and at the FIZ for inorganic compounds. Both data banks will be pleased to provide help (see our *Notice to Authors* in the first issue of this year). In general, you will receive a depository number from the data bank within one working day after electronic deposition; please include this number with the appropriate standard text (see our *Notice to Authors*) in your manuscript. This will enable the referees to retrieve the structure data quickly and efficiently if they need this information to reach their decision.

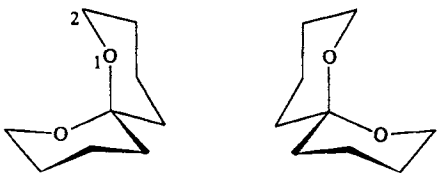
This is now the uniform procedure for manuscripts submitted to the journals *Angewandte Chemie, Chemische Berichte, Chemistry—A European Journal*, and *Liebigs Annalen*.

Chiral Recognition of (*R*)-(−)-1,7-Dioxaspiro-[5.5]undecane by Hexakis(2,3,6-tri-*O*-methyl)-α-cyclodextrin**

Konstantina Yannakopoulou, Dimitris Mentzafos, Irene M. Mavridis,* and Konstantina Dandika

The principles underlying the mechanism of chiral recognition, a process essential in all living systems, have been approached in studies with various model host–guest systems. Cyclodextrins (CDs), one class of chiral hosts,[1] were recognized early on as capable of binding guests with chiral discrimination,[1b,c] and this selective binding is the basis for enantiomeric resolution by chiral gas and liquid chromatography.[2] Enantiomeric species can also be differentiated in solution by NMR spectroscopy after addition of cyclodextrins and formation of diastereomeric inclusion complexes.[2e,3] Moreover, enrichment in one of the enantiomers during crystallization of CD inclusion complexes of racemic guests has been observed by X-ray crystallography.[4] Although these findings document the propensity of CDs for chiral discrimination, reliable predictive rules have not been set forth so far. Armstrong's model[5] adequately explains the observed enantioselectivity in some cases[6] but not in others.[4c,7]

We have investigated the enantioselective complexation of 1,7-dioxaspiro[5.5]undecane (**1**), the primary constituent of the sex pheromone of the female olive fly *Bactrocera oleae* and other *Bactrocera* species, by CDs.[8] Natural **1** isolated from the



(*R*)-(−)-1 (*S*)-(+)-1

glands of the insect has been identified as the racemic mixture, and synthetic (±)-**1**[9] has the same biological activity as the natural extract. Further entomological studies, however, have suggested that the individual enantiomers may affect the behavior of male and female insects differently.[10] Several multistep enantioselective syntheses of (*R*)-(−)-**1** and the (*S*)-(+)-**1**, have established the absolute configuration of the pure enantiomers.[11] We report here on the totally selective separation of (*R*)-**1** from its (*S*) enantiomer through simple complexation with hexakis-(2,3,6-tri-*O*-methyl)-α-cyclodextrin (TMαCD), as determined by X-ray crystallography[12] and NMR spectroscopy.

A complex precipitated from an aqueous solution containing equimolar amounts of TMαCD and (±)-**1**. The precipitate was redissolved in water and stirred vigorously with *n*-pentane (TMαCD was recovered from the aqueous phase). The organic layer afforded a colorless liquid; its ^1H and ^{13}C NMR spectra are identical to those of **1**, and its optical rotation ($[\alpha]_D^{21} = -115$ ($c = 0.172$ in *n*-pentane)) is close to the literature value[11b] for (*R*)-**1** ($[\alpha]_D^{21} = -121$ ($c = 1.84$ in *n*-pentane)).[13] Additional confirmation of this remarkable resolution was obtained by chiral GC using a capillary column[14] coated with heptakis-(2,3,6-tri-*O*-methyl)-βCD (TMβCD). The chromatogram of the racemate showed two peaks but that of the extracted spiroacetal showed only one. This liquid was also examined by ^{13}C NMR spectroscopy in D_2O in the presence of two equivalents of αCD as a chiral solvating agent.[15a] Only one signal was detected for C2 (presumably due to (*R*)-**1**) at an excellent signal-to-noise ratio, indicating complete enantioselectivity, whereas the racemate displayed two distinct signals for C2 (Fig. 1). A ^{13}C NMR

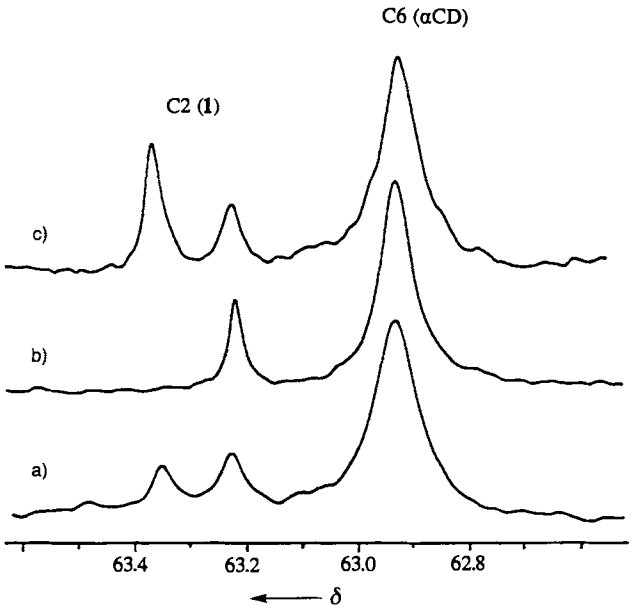


Fig. 1. Section of the ^{13}C NMR spectrum of 1,7-dioxaspiro[5.5]undecane (**1**) in D_2O in the presence of a twofold excess of αCD at 298 K (routine experiment, relaxation delay = 1 s). a) (±)-**1**, b) (*R*)-**1** only, c) **1** enriched in the (*S*) enantiomer.

titration study of (±)-**1** with TMαCD in aqueous solution showed that the exchange of the guest between free and complexed states was fast on the NMR timescale. In an inverse gated decoupling experiment the racemic guest gave rise to two ^{13}C NMR signals of the same intensity for C2.[16] Thus, the preferential binding of (*R*)-**1** by TMαCD could not be detected owing to the conditions of fast exchange for the guest, according to which the initial enantiomeric ratio (of the racemate) is detected. The chemical shift difference of the C2 signals in the racemate in the presence of αCD was much greater than in the presence of TMαCD.

The TMαCD/(*R*)-**1** complex is stable in aqueous solution; even after several days no racemization was evident by additional peaks in its ^{13}C NMR spectrum. This complex can be prepared in high yields exceeding the theoretically possible 50% owing to conversion of (*S*)-**1** to (*R*)-**1**. Gradual increase of the concentration of each reactant in the aqueous solution, from 20 mM to 80 mM led to increased yields of the (*R*)-**1** complex. The maximum yield of 77% was obtained at a concentration of 80 mM after 48 h at ambient temperature. Clearly, in aqueous solution the two enantiomers of **1** equilibrate, presumably via an open form, but only (*R*)-**1** is isolated from the precipitate. To exclude the possibility that the enantioselectivity of TMαCD

towards (*R*)-**1** results from the differential solubility of the diastereomeric complexes TMαCD/(*R*)-**1** and TMαCD/(*S*)-**1**, we measured the binding constants $K_{(R)}$ and $K_{(S)}$. We prepared a TMβCD/(±)-**1** complex enriched in (*S*)-**1**. The ^{13}C NMR spectrum of its extract indicated that it contained at least 80% of the (*S*) enantiomer. However, in the presence of one equivalent of TMαCD in D_2O the guest racemized within a few days without formation of a precipitate. Its NMR spectrum was then similar to that of (±)-**1**, thus indicating that the (*R*) enantiomer is much more stable than its antipode. The approximate binding constant[15b] of (*R*)-**1** (6800 M^{-1}) is greater than that of the (*S*)-enriched-**1** (4000 M^{-1}); however, the latter value is only indicative since the sample was not enantiomerically pure. Therefore, (*R*)-**1** is very stable in the presence of TMαCD, whereas (*S*)-**1** converts to its enantiomer, which forms a much more stable complex. These experiments were carried out in clear solutions to eliminate solubility effects. The remarkably enantioselective binding found in aqueous solution results in the complete separation of (*R*)-**1** by precipitation as its complex with TMαCD.

The crystal structure of the precipitate[12] shows that only (*R*)-**1** guest exists in the complex. Attempts to refine the structure with complexed (*S*)-**1** alone or with a mixture of complexed (*R*)- and (*S*)-**1** failed. The complex is situated on a twofold axis. (*R*)-**1** is located at the secondary side of TMαCD and exhibits statistical disorder in the crystal. Only two of the primary methoxy groups (C63–O63 and the corresponding symmetry equivalent) of TMαCD are directed towards the exterior of the cavity; the rest are directed towards the interior, thus blocking the primary entrance (Fig. 2). As a result, the

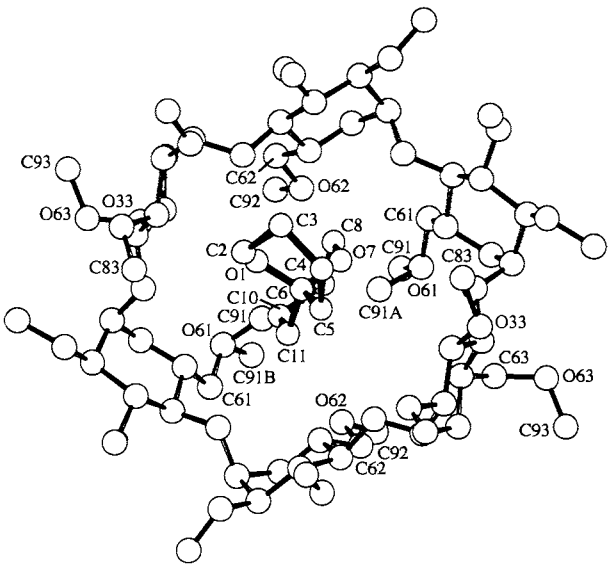

Fig. 2. ORTEP diagram of the TMαCD/(*R*)-**1** complex as viewed from the secondary side of the cyclodextrin. Note the methoxy groups O61–C91 and O62–C92 extending into the cavity on the primary side and the O33–C83 methoxy group (and its symmetry equivalent) pointing inside the cavity and interacting with O1 and O7 of the guest.

free space left to the guest, if we take into account the van der Waals radii of the host, is small (Fig. 3), and (*R*)-**1** enters the cavity only partly. The thermal parameters of the guest atoms are of the same order of magnitude as those of the host, a rather rare feature for CD complexes, implying a tight fit of the guest. Indeed, the TMαCD geometry is distorted in order to better accommodate the guest (induced fit).[17] The six glucosidic oxygen atoms form a distorted hexagon (Fig. 2), and the tilting of the glucose units with respect to the molecular axis is very uneven. These features combined with the orientation of the methoxy groups result in numerous van der Waals contacts between the guest atoms (except for the central C6) and atoms of the methoxy groups of either the host molecule or neighboring CDs; these distances range from 3.29 to 4.04 Å. The shortest distances are between the O1 and O7 atoms of (*R*)-**1** and the methoxy group C83 and its symmetry equivalent (3.29 and 3.31, respectively, Fig. 3); C–H···O interactions where O is an ether oxygen are involved. It is worth noting that most of the other contacts also involve the same kind of interactions, which are quite common in solid-state structures of carbohydrates.[18] Chiral recognition of (*S*)-**1** by a modified αCD has been attributed previously[4c] to the asymmetry imposed by the unusual substitution of the host. In the present case it is shown that a symmetrically substituted βCD is sufficiently flexible to undergo conformational changes to better accommodate the same guest. The time-averaged structure proposed for the complex TMαCD/**1** in solution[15b] from NMR studies resembles the solid-state structure in that only one ring of the guest is included.

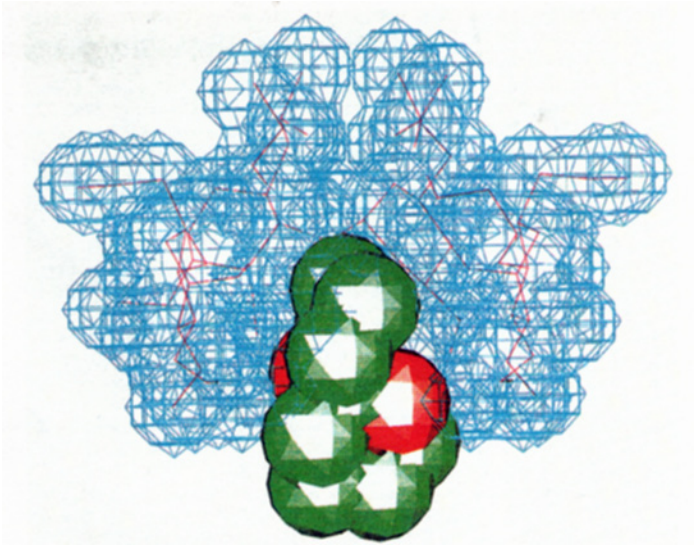

Fig. 3. Side view of the inclusion complex TMαCD/(*R*)-**1**. Van der Waals surfaces computed for the host show the free space left for the guest (CPK model, radius 1.5 Å; O1, O7 in red). The front atoms of the host have been removed for clarity [19].

In conclusion, we have observed that the inclusion of (*S*)-**1** in TMαCD is completely enantioselective in solution and in the solid state. The main requirement for chiral recognition as indicated by the crystal structure is the tight fit of host and guest achieved without the aid of conventional hydrogen bonds. In addition, (*R*)-**1** can be separated from its enantiomer in high yields and on a large scale by means of recyclable materials (TMαCD) and simple laboratory techniques. Furthermore, TMαCD can be used to store (*R*)-**1** and prevent its racemization.

A Ferrimagnetic Manganese Oxide with a Layered Perovskite Structure: $YBaMn_2O_5$**

Jon P. Chapman, J. Paul Attfield,* Michele Molgg, Chris M. Friend, and Tim P. Beales

There is renewed interest in perovskite-type $Ln_{1-x}A_xMnO_3$ phases (Ln = trivalent lanthanide; A = Ca, Sr, or Ba), following the discovery of giant negative magnetoresistances (GMR) at the transition between their conducting ferromagnetic and insulating paramagnetic states.[1] GMR has been found in both thin film[2] and sintered polycrystalline samples[3] with $x \approx 0.3$, and anisotropic GMR phenomena have recently been reported in layered Ruddlesden–Popper type perovskites $(Ln,A)_{n+1}Mn_nO_{3n+1}$ for $n = 2$.[4] Similar effects have also been observed in the oxygen-deficient cubic pyrochlore $Tl_2Mn_2O_{7-\delta}$.[5]

The chemical features common to these materials are a highly connected Mn-O-Mn network, with a three-dimensional or multilayered structure, and a mean Mn oxidation state between +3 and +4, that is hole-doped Mn^{III}. The hole-doping suppresses the long-range cooperative Jahn–Teller distortion found in the parent Mn^{III} structure and gives rise to the ferromagnetic conducting phase at low temperatures through a "double exchange" mechanism.[6] This shows some similarities to the hole-doping of layered Cu^{II} oxide perovskites which enables superconductivity to occur.[7] The structural similarities between these two groups of materials suggests that new Mn analogues of the high-temperature superconducting Cu oxides may be prepared. There are also chemical analogies, for example, Cu^{II} forms many oxocarbonates with Ba or Sr, such as $(Ba,Sr)_2CuO_2CO_3$,[8] and a Mn^{III} oxocarbonate, $Sr_5Mn_4O_{10}CO_3$, has recently been reported.[9] We have attempted to prepare a Mn analogue of $YBa_2Cu_3O_{7-\delta}$, in which Y^{III}/Ba^{II} cation ordering gives rise to oxygen vacancy ordering and hence anisotropic electronic properties.[10] This has resulted in the discovery of the new phase $YBaMn_2O_5$.

Attempts to prepare triple perovskite "$YBa_2Mn_3O_{9-x}$" phases by sintering mixtures of $BaMnO_{3-\delta}$ and $YMnO_3$ at 900–1100 °C under a variety of atmospheres were unsuccessful. However, a new perovskite-related phase was observed in samples treated under reducing conditions, for example at 1000 °C under argon containing less than 1 ppm O_2, and this has been identified as $YBaMn_2O_5$. This double perovskite phase is difficult to prepare in a pure form and long reaction times, in excess of a week, are required at 1000 °C under a controlled oxygen atmosphere. We have found syntheses in sealed, evacuated, silica glass tubes to be the most reliable (see Experimental Procedure).

The Rietveld-fitted X-ray powder diffraction pattern of $YBaMn_2O_5$ is shown in Figure 1 and the refined parameters and

distances and angles are presented in Table 1. The structure (Fig. 2) shows that a layered arrangement has been formed due to the presence of oxygen vacancies in the yttrium plane, reducing the yttrium coordination number to 8, while barium occupies a typical 12-coordinate perovskite site. The manganese–oxygen network consists of double layers of identical MnO_5 square pyramids linked through all their apices, and the basal and apical Mn–O distances are almost equal. The $YBaMn_2O_5$ structure is derived from the $YBa_2Cu_3O_7$ arrangement by removal of the chains of CuO_4 square planes between the two sheets of CuO_5 square pyramids. This structure type is not found in the Y-Ba-Cu-O system, but is adopted by $YBaCuFeO_{5+\delta}$[11] and by $YBaCo_2O_{5+x}$ $(0 < x < 0.5)$.[12]

The oxygen stoichiometry of $YBaMn_2O_5$ is confirmed by thermogravimetric reduction in H_2/N_2 (see Experimental Procedure). In air or oxygen, $YBaMn_2O_5$ decomposes irreversibly into $YMnO_3$ and $BaMnO_{3-\delta}$ above 220 °C. Attempts to intercalate additional oxygen into the yttrium plane to give $YBaMn_2O_{5+x}$ compositions analogous to those of the above isostructural materials were unsuccessful. For example, after heating the sample in air at 200 °C for 6 h, both the unit cell parameters determined by Rietveld analysis and the magnetic ordering temperature measured by alternating current (AC) susceptometry were unchanged.

Both direct current (DC) and AC susceptibility measurements show a magnetic ordering transition at 167 K. A ferromagnetically ordered component is clearly revealed by the peak in the imaginary susceptibility (Fig. 3) and by the observation of hysteresis loops at 10 K (Fig. 4) and 130 K, but not at 250 K. However, the saturated moment obtained from both the DC susceptibility and hysteresis measurements is only about 0.5 μ_B per $YBaMn_2O_5$ formula unit, compared to the total moment of about 9 μ_B that would result from a ferromagnetically ordered

array of $S = 5/2$ Mn^{II} and $S = 2$ Mn^{III} spins. Hence, the overall order is ferrimagnetic, with a small ferromagnetic component due to the inexact cancellation of antiferromagnetically ordered sublattices.

The ferrimagnetic order in $YBaMn_2O_5$ is consistent with ordering of the Mn^{II} and Mn^{III} valences, as the high electrical resistivity shows that the d-electrons are localized below at least 300 K. Valence ordering in perovskite-related structures results in an alternation of valence states (a commensurate charge density wave), as is found in the perovskite $Ba_2Bi^{III}Bi^{V}O_6$.[13] This will give rise to the arrangement shown in Figure 5 for

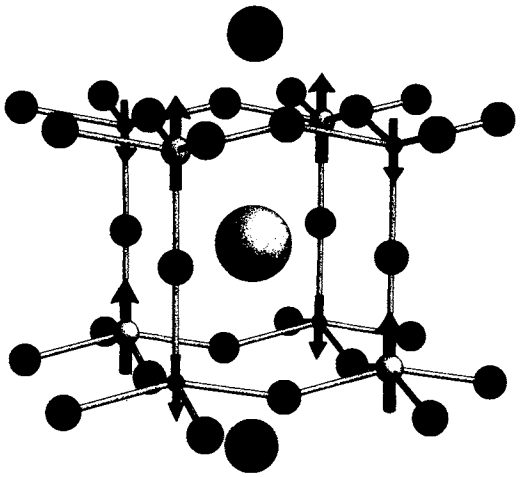

Fig. 5. Proposed valence and magnetic ordering model for $YBaMn_2O_5$ showing an alternation of Mn^{II} (large, lightly shaded spheres) with $S = 5/2$ spins (up) and Mn^{III} (small, filled spheres) with $S = 2$ spins (down). The other atoms are labeled as in Figure 2.

$YBaMn_2O_5$, in which each Mn^{II} ion is linked through Mn-O-Mn bridges to five Mn^{III} ions, and vice versa. These near-linear Mn^{II}-O-Mn^{III} linkages will give rise to antiferromagnetic interactions between the cation spins, due to both σ and π superexchange, hence in the magnetically ordered state all the $S = 5/2$ Mn^{II} spins will be antiparallel to the $S = 2$ Mn^{III} spins. This results in a net spin of 1/2 per $YBaMn_2O_5$ formula unit, ideally giving a saturated moment of 1 μ_B. This is consistent with the small observed value of about 0.5 μ_B allowing for moment reduction due to Mn–O covalency.[14] If extended over long distances, the proposed valence ordering will give rise to a $\sqrt{2}a \times \sqrt{2}a \times c$ superstructure which is not observed in the present X-ray data, and powder neutron diffraction will be needed to detect this and confirm the ordered magnetic arrangement.

In conclusion, we have prepared a new, layered perovskite $YBaMn_2O_5$. This phase appears only to be stable with an oxygen content close to the stoichiometric value, at which the mean Mn oxidation state is +2.5. This is an unusually low oxidation state for Mn in a perovskite oxide, as values between +3 and +4 are normally found, and so opens up the possibility of preparing electron-doped phases (relative to Mn^{III}) with conducting and magnetic properties similar to those of the hole-doped phases. In $YBaMn_2O_5$, the exact +2.5 oxidation state leads to Mn^{II}/Mn^{III} valence ordering and insulating electronic behavior below 300 K, which results in a ferrimagnetic state with a small resultant moment below the ordering transition at 167 K.

Experimental Procedure

An almost phase pure sample of $YBaMn_2O_5$ (2 g) was synthesized from an equimolar mixture of $YMnO_3$, BaO, and MnO. $YMnO_3$ was prepared by heating Y_2O_3 and $MnCO_3$ in air at 1350 °C. BaO and MnO were produced by decomposing BaO_2 and $MnCO_3$ under flowing H_2/N_2 at 900 °C. All the reactants were found to be phase pure by powder X-ray diffraction. The reaction mixture was ground, pelleted, sealed in an evacuated silica glass tube, and heated for four days at 1000 °C. This treatment was repeated three times.

Thermogravimetric reduction of $YBaMn_2O_5$ (51.8 mg) under a $0.05H_2 + 0.95N_2$ mixture (flow rate 58 $cm^3 min^{-1}$, heating rate 2 °C min^{-1}) showed a single-step reduction starting at 400 °C. X-ray analysis showed the product to be a mixture of Ba^{II}, Y^{III}, and Mn^{II} oxides. The 1.9% mass loss for this process corresponds to that calculated for 5.0 oxygen atoms per formula unit. Oxidation of $YBaMn_2O_5$ under flowing O_2 resulted in a single weight uptake between 220 and 400 °C to give $YMnO_3$ and $BaMnO_{3-\delta}$. The observed 3.0% weight change is less than the theoretical value for this reaction (3.8%) which may be due to a significant oxygen deficiency (δ) in the latter phase.

X-ray powder diffraction data were recorded for $2\Theta = 20$–$110°$ on a Philips PW1710 diffractometer using $Cu_{K\alpha}$ radiation, counting for 15 s per 0.02° step. Rietveld analysis [15] using the GSAS package [16] enabled the structural model to be refined, and the contributions from traces of secondary phases ($YMnO_3$ and MnO) to the profile were also fitted (Fig. 1). The refined model for $YBaMn_2O_5$ (Table 1 and Fig. 2) gave residuals $R_{WP} = 0.047$, $R_P = 0.033$, and $R_F = 0.073$. No significant Y/Ba cross-substitution or Mn deficiency was found by X-ray refinement, confirming the cation stoichiometry.

Magnetic measurements between 4 and 300 K were performed on a Quantum Design DC SQUID magnetometer and AC susceptometer. The DC magnetization was measured in a field of 2.0 T and the AC measurement used a field of 0.1 mT at a frequency of 105 Hz. DC hysteresis loops were recorded at 10, 130, and 250 K, while the applied field was swept continuously at 10 mTs^{-1}. The resistivity of a sintered pellet of $YBaMn_2O_5$ was found to be greater than 10^5 Ωcm between 30 and 300 K.

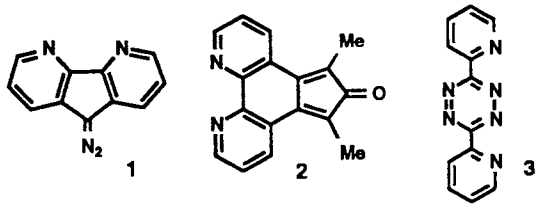
Space-Separated 1,10-Phenanthroline, 4,5-Diazafluorene, or 3,6-Di(2-pyridyl)pyridazine Units as Ligands in Diruthenium Complexes: Preliminary Studies of Metal–Metal Interactions**

Ronald N. Warrener,* Aurélio B. B. Ferreira, Austin C. Schultz, Douglas N. Butler, F. Richard Keene,* and Laurence S. Kelso

There has been much activity in the field of intramolecular energy transfer and electron transfer in large molecular assemblies, and the next advances will clearly require sophisticated molecular design. Where metal complexes are involved as the light-harvesting chromophore[1] the design and construction of ligands becomes an important component. Studies on intramolecular electron transfer have been reported in which metal complexes have been tethered to redox-active chromophores, but almost all of these systems contain flexible linkages.[2] Elegant syntheses have been reported recently for fully conjugated diad systems incorporating the 1,10-phenanthroline moiety as the bidentate ligand,[3] and we have described the first molecular rack (molrac) in which two units of the same ligand are spatially separated.[4] We report here on the preparation of a new set of rigid bis(bidentate ligand) structures in which the individual bidentate ligands (1,10-phenanthroline, 4,5-diazafluorene, or 3,6-di(2-pyridyl)pyridazine) are fused to an alicyclic framework.

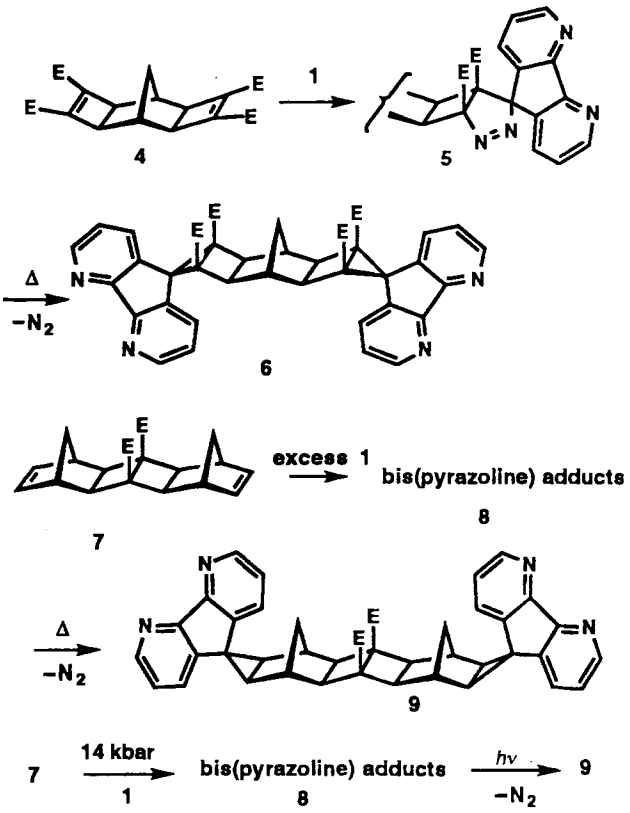
The versatile spacers in molracs permit the development of bridging ligands in which the ligating groups are placed at a set distance and relative orientation in space. These compounds should allow assessment of the factors controlling intramolecular energy- and electron-transfer processes in polymetallic species, as well as lead to new reagents for the study of self-assembly processes.[5] Rigid alicyclic frameworks have been used in molrac systems since they have proven their worth in diad and triad systems devoid of metal centers[6] and are available in an increasing range of shapes and sizes.[4, 7–10]

The typical olefinic spacers in the molracs have norbornene or cyclobutene diester end groups (or mixtures thereof), and these offer different dienophilic character. When the cycloaddition reagents **3**, **2**, and **1** (Scheme 1) are used to deliver the specific ligand center, it is possible to introduce 3,6-di(2-pyridyl)-pyridazine,[9] 1,10-phenanthroline,[4] and 4,5-diazafluorene groups, respectively,[10] to the norbornene end, and 1,10-phenanthroline and 4,5-diazafluorene functionalization to the cyclobutene diester end of molracs. Given that these bidentate ligands can be attached in homo or hetero pairs as shown herein, and that the 4,5-diazafluorene is linked orthogonally to the plane of the spacer whereas the other two ligands are fused in a coplanar fashion, numerous ligand and geometric variants are available by this procedure.



Scheme 1. Ligand-delivery agents used in this study.

For the production of molrac systems containing two diazafluorene (DAF) ligands, 9-diazo-4,5-diazafluorene (DADAF) **1** was employed as the delivery agent for 4,5-diazafluorene. Reaction of the known bis(cyclobutene) **4**[11] with excess **1** (Scheme 2) produced a regiomeric pair of pyrazolines of type **5**, which were not separated but thermally deazotized to form the bisligand **6** (63% yield) (bisligand = a molrac having two ligand groups).[12] The ^{1}H NMR resonances[13] of the bisligand **6** are entirely in keeping with the assigned structure. This reaction is general and more extended spacer bis-DAF ligands have been produced in our laboratory.[14]



Scheme 2. Synthesis of molracs **6** and **9** in which the ligand units are coplanar with and orthogonal to the central spacer, respectively.

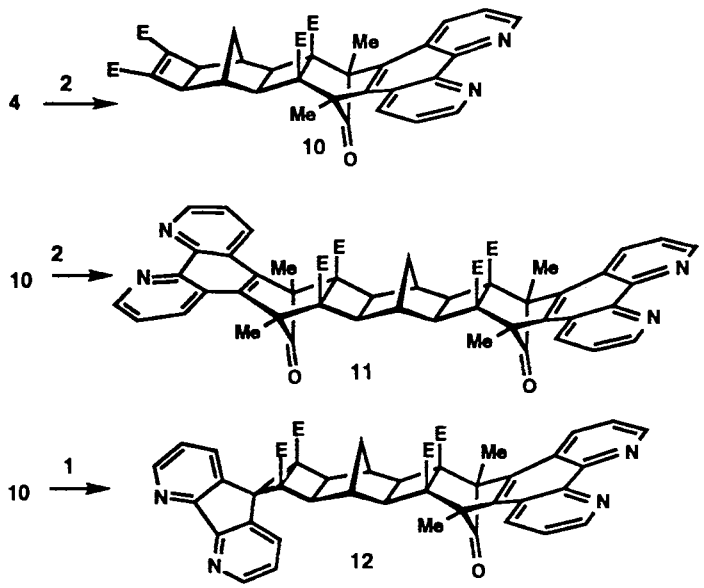
Addition of DADAF **1** to the norbornene π-bonds of bis(olefin) **7**[9] (Scheme 2) was sluggish and required prolonged heating (toluene, reflux, 60 h). Addition of DADAF **1** (fourfold excess) in three portions to **7**, over a period of 60 h, afforded **9** in 68% yield. Alternatively, **9** could be produced by photochemical deazotization of the bis(pyrazolines) **8**, themselves generated under high-pressure conditions (14 kbar, room temperature, CH_2Cl_2 from **7** and **1**.

While an X-ray structure of a mono-DAF-substituted molrac has been reported,[10] the bisligand described herein has only been obtained as microcrystals unsuitable for single-crystal structure analysis. Since the results of molecular modeling (SPARTAN, AM1) are in good agreement with the X-ray derived parameters in molrac systems, computational techniques (AM1) can be used to obtain structural parameters such as separation distances and shapes.

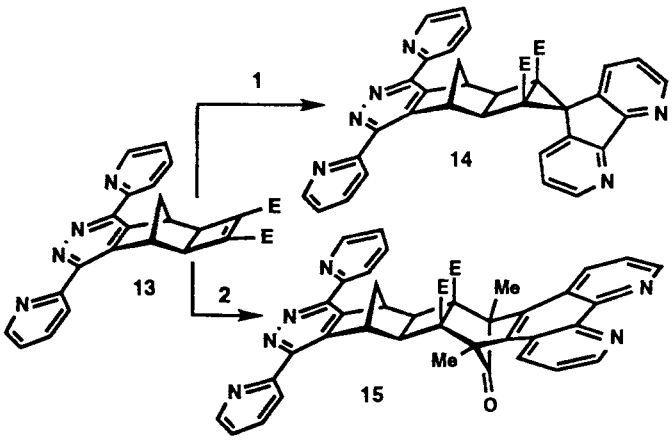
Cyclopentadienone **2**[4] was used as the delivery agent for the 1,10-phenanthroline ligand; it served as a standard electron-demand diene in Diels–Alder reactions with olefins in the order of reactivity cyclobutene-1,2-diesters > benzonorbornenes > nor-bornenes.[4] Diels–Alder addition of **2** to bis(cyclobutene) **4** occurred stereospecifically to produce first the monoadduct **10** and then the bisadduct **11** (Scheme 3). The C_s symmetry of **11**



Scheme 3. Reaction of cyclopentadienone **2** with diene **4** produces the monoadduct **10**; reaction with more **4** provides the bisligand **11**. Reaction of **10** with DADAF **1** yields the mixed bisligand **12**.

was supported by its ^1H and ^{13}C NMR spectra and the assigned stereochemistry by the upfield position of the ester methyl proton resonances ($\delta = 3.14$). Separate reaction of **10** with DADAF **1** to form **12** led to the first of the mixed ligand systems. The two ligands bear an orthogonal relationship to one another, which is reflected in the ^1H NMR shifts of the two sets of methyl ester resonances; the phenanthroline ligand shields the proximate ester groups ($\delta = 3.16$), whereas the diazafluorene ring lying orthogonal deshields the other set ($\delta = 3.60$).

Reaction of Smith's diene[15] with 3,6-di(2-pyridyl)-*s*-tetrazine/DDQ (DDQ = 2,3-dichloro-5,6-dicyanobenzoquinone) according to our reported procedure[9] occurred preferentially at the norbornene π-center to produce the fused dpp molrac **13** (Scheme 4). Treatment of **13** with **1** gives the mixed bisligand **14**,



Scheme 4. Synthesis of mixed bisligands in which the two ligand units are orthogonal (**14**) and roughly parallel to each other (**15**).

where the two ligands again have an orthogonal relationship. The alternative reaction of **13** with DAPC **2** produced the bisligand **15** in which the two ligands are now parallel.

In conclusion, the versatile ligand-delivery agents **1** (for 4,5-diazafluorene), **2** (for 1,10-phenanthroline), and **3** (for 3,6-di-(2-pyridyl)pyridazine) can be attached to bis(olefins) to produce an array of doubly(bidentate ligand) molracs of varied size and geometry through simple cycloaddition reactions.

The bridged diruthenium species $[\{Ru(bpy)_2\}_2(\mu\text{-BL})]^{4+}$ (BL = **6**, **9**, **11**; bpy = 2,2′-bipyridine) were synthesized by reaction of the respective ligands with excess $[Ru(bpy)_2(CF_3SO_3)_2]$ in chloroform/2-methoxyethanol mixtures under microwave conditions.[16, 17] In all three cases, electrochemical studies

(cyclic voltammetry and differential pulse voltammetry) indicated a single oxidation (n = two electrons, by coulometry). Similarly, careful spectroelectrochemical studies at $-32\,^{\circ}C$ in acetonitrile solution provided no evidence for the transient accumulation of a Ru^{II},Ru^{III} state. Accordingly, the Ru^{II},Ru^{III} form of these complexes appears to be thermodynamically disfavored with respect to disproportionation.

These results indicate a weak interaction between the metal centers and are consistent with results reported recently for a complex in which the bridging ligand is composed of two diazofluorene units linked by an adamantane spacer.[18] As noted previously,[18, 19] such weak interactions do not preclude the existence of rapid intercomponent energy or electron transfer, and photophysical studies are in progress on Ru/Ru, Ru/Os, and Os/Os analogues of the complexes described here to assess the consequences of spatial separation on such processes.

Highly Diastereoselective Synthesis and Epoxidation of Chiral 1,2-Dihydronaphthalenes**

Torsten Linker,* Karl Peters, Eva-Maria Peters, and Frank Rebien

Epoxidations are one of the most important methods for the formation of carbon–oxygen bonds.[1] Catalytic enantioselective processes, which have been studied particularly intensively, were first developed for allylic alcohols[2] and have been extended to unfunctionalized olefins in the last few years.[3] The diastereoselective epoxidation of chiral alkenes is also very important with regard to the directing effect of various functional groups.[4] Although epoxidations of monocyclic alkenes have attracted the most attention,[5] the analogous reactions of chiral 1,2-dihydronaphthalenes have not been investigated in detail.[6] This is surprising, since achiral dihydronaphthalenes and structurally related chromenes are prime substrates for asymmetric epoxidations.[3] We were interested in the synthesis and epoxidation of chiral 1,2-dihydronaphthalenes in the context of the synthesis of podophyllotoxin analogues.[7]

Oxazolines (dihydrooxazoles) **2**, which are easily accessible starting from 2-naphthoic acid (**1**), have proven themselves to be good precursors for 1,2-dihydronaphthalenes[8] (Scheme 1). The nucleophilic addition of phenyllithium occurs with high regioselectivity at the 1-position and the trapping of the azaenolate intermediate with trifluoroacetic acid (TFA) gives the salt *rac*-**3** in good yield. The use of TFA has been shown to be especially important here, since with other proton sources isomerization to 1,4-dihydronaphthalenes occurs. The exclusive formation of the *trans* product is due to rapid and complete epimerization at the 2-position and is in accordance with additions to 1-naphthyloxazolines.[8b] To examine the influence of different substituents on the stereoselectivity of the epoxidations, the salt *rac*-**3** was transformed into the derivatives *rac*-**4** (Scheme 1).

The oxidations were first performed with *m*-chloroperbenzoic acid (MCPBA), which smoothly led to the epoxides *rac*-**5** (Scheme 2; Table 1, entries 1–3). The yields could be improved

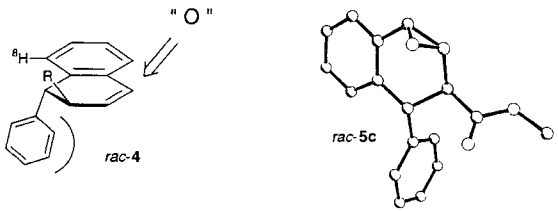
8	*rac*-**4c**	CO_2Me	DMD [d]	>95	26	67

[a] Diastereoselectivities (*ds*, in %) determined from ^1H NMR spectra (250 MHz) of the crude product. [b] Yields (in %) of isolated product after crystallization or column chromatography. [c] Isolated as the ester after reaction with diazomethane. [d] Water and perchloric acid added.

by using dimethyldioxirane (DMD) as oxidant, which allows epoxidations to be conducted under milder conditions.[9] The surprising formation of the diol *rac*-**6c** in the reaction of the ester *rac*-**4c** (entry 4) is due to acid-catalyzed opening of the epoxide in the presence of traces of water. By using dimethyldioxirane (DMD), which was synthesized under anhydrous conditions,[9c] the desired epoxides *rac*-**5** could be successfully prepared in excellent yields (entries 5–7). The postulated acid-catalyzed epoxide opening was supported by a control experiment in the presence of water (entry 8).

Interestingly, only one diastereomer was formed in all reactions, regardless of the oxidant and the substituents R. The assignment of the relative configurations of the epoxides *rac*-**5** was not possible from the NMR data; however, the signals of 1-H to 4-H of the ring-opened product *rac*-**6c** had a characteristic coupling pattern, which confirmed the assigned configuration. The structure of epoxide *rac*-**5c** was assigned unequivocally by X-ray structure analysis.[10]

The oxidant attacks *cis* to the substituents R in all reactions. However, a *syn*-directing effect of the hydroxy groups,[4, 5a, b] which has often been observed previously, can be excluded for the 1,2-dihydronaphthalenes investigated, since the homoallylic alcohol *rac*-**4a** and the ester *rac*-**4c** show the same stereoselectivity. Rather, it is the phenyl group that controls the reaction, irrespective of the substituents R. From this point of view, the observed selectivities are surprisingly high, since sterically controlled epoxidations previously reported proceed with only moderate diastereomeric excesses.[5c, d, 6b] Apparently, the preferred conformation of 1,2-dihydronaphthalenes[11] is responsible for the high stereoselectivities. In AM1 calculations[12] we found that in the most favorable rotamer of *rac*-**4** the phenyl group is orthogonal to the plane of the dihydronaphthalene. Consequently the steric requirements of this substituent is particularly large and the bottom face of the dihydronaphthalene is effectively shielded (Scheme 3). The high-field shift of 8-H, which is due to the induced magnetic field of the phenyl group, is also in accordance with these calculations.



Scheme 3. Preferred conformation of the 1,2-dihydronaphthalenes *rac*-**4** and crystal structure of *rac*-**5c**.

In summary, the reaction sequence Meyers oxazoline synthesis, nucleophilic addition of phenyllithium, and epoxidation, starting from 2-naphthoic acid (**1**), gives easy access to the diastereomerically pure epoxides *rac*-**5**. The selectivities of the reactions are strongly controlled by the steric requirements of the phenyl group, whereas polar substituents have no influence on the epoxidations. As 1,2-dihydronaphthalenes can be prepared enantioselectively,[8] this new epoxidation protocol may find application in the synthesis of optically active podophyllotoxin analogues.

Experimental Procedure

Oxazoline **2** [8b] (22.53 g, 100 mmol) was dissolved in anhydrous THF (180 mL) under argon at −40 °C. To this was added dropwise a solution of PhLi in hexane/diethyl ether 7/3 (2.06 M, 60 mL, 124 mmol). The reaction mixture was stirred for 3 h at this temperature, then a mixture of TFA (30 mL, 389 mmol) and THF (20 mL) was added. After 10 min the reaction mixture was poured into a saturated ammonium chloride solution (200 mL) and extracted with diethyl ether (3 × 80 mL). The combined organic phases were dried over Na_2SO_4 and crystallized at 0 °C, directly yielding the salt *rac*-**3** (29.6 g, 68%; m.p. 155–156 °C). Upon concentration of the mother liquor a further crop of the product was obtained (7.4 g, 17%). Under argon atmosphere a solution of *rac*-**3** (13.06 g, 30 mmol) in 3 N HCl (200 mL) was heated at reflux for 7.5 h, cooled, and then extracted with ethyl acetate (4 × 50 mL). The combined organic phases were dried over Na_2SO_4 and then concentrated under vacuum. Filtration through a short column of silica gel (hexane/ethyl acetate 6/4) yielded the acid *rac*-**4b** in the form of white crystals (7.35 g, 98%; m.p. 121–122 °C). To a solution of *rac*-**4b** (2.5 g, 10 mmol) in dichloromethane (50 mL) at 0 °C was added a solution of diazomethane in diethyl ether until the yellow color persisted. After 12 h at 20 °C the solution was concentrated and filtered over a short column of silica gel (hexane/ethyl acetate 8/2) to yield the ester *rac*-**4c** (2.62 g, 99%). Anal. calcd. for $C_{18}H_{16}O_2$: C 81.79, H 6.10; found: C 81.47, H 5.97; ^1H NMR (200 MHz, $CDCl_3$): δ = 3.63 (s, 3H, OMe), 3.70 (ddd, J = 8.6, 4.3, 2.1 Hz, 1H, 2-H), 4.64 (d, J = 8.6 Hz, 1H, 1-H), 5.94 (dd, J = 9.6, 4.3 Hz, 1H, 3-H), 6.66 (dd, J = 9.6, 2.1 Hz, 1H, 4-H), 6.89 (d, J = 7.2 Hz, 1H, 8-H), 7.12–7.32 (m, 8H, aromat. H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 45.8, 48.5, (2d, C-1, C-2), 52.1 (q, CO_2Me), 123.6, 126.5, 126.8, 127.0, 128.0, 128.3, 128.5, 128.6, 129.1 (9d, C-3, C-4, C-5, C-6, C-7, C-8, C-Ph), 132.4, 136.2, 142.8 (3s, C-9, C-10, C-Ph), 173.6 (s, CO_2Me).

The ester *rac*-**4c** (2.12 g, 8.02 mmol) was dissolved in anhydrous dichloromethane (120 mL). A solution of DMD [9c] in acetone (0.06 M,150 mL, 1.1 equiv) was added dropwise to this solution at 0 °C over 30 min. After 2 h at 0 °C the reaction mixture was concentrated directly on a rotary evaporator. Crystallization from diethyl ether gave the epoxide *rac*-**5c** as white needles (2.2 g, 98%; m.p. 97–98 °C). Anal. calcd. for $C_{18}H_{16}O_3$: C 77.12, H 5.75; found: C 76.86, H 5.63; ^1H NMR

(200 MHz, $CDCl_3$): δ = 3.20 (dd, J = 12.0, 0.8 Hz, 1H, 3-H), 3.61 (s, 3H, OMe), 3.96 (dd, J = 4.3, 0.8 Hz, 1H, 2-H), 4.06 (d, J = 4.3 Hz, 1H, 1-H), 4.33 (d, J = 12.0 Hz, 1H, 4-H), 6.56 (dd, J = 7.4, 1.0 Hz, 1H, 5-H), 7.12–7.49 (m, 8H, aromat. H); ^{13}C NMR (50 MHz, $CDCl_3$): δ = 43.1, 48.1, (2 d, C-3, C-4), 52.2 (q, CO_2Me), 53.0, 55.6 (2 d, C-1, C-2), 126.5, 127.3, 128.4, 128.7, 128.8, 129.7, 129.8 (7 d, C-5, C-6, C-7, C-8, C-Ph), 131.4, 139.1, 140.1 (3 s, C-9, C-10, C-Ph), 172.7 (s, CO_2Me).

Catalytic Activation of C–H Bonds in Aromatic Hydrocarbons, Ethene, and Methane by the Naphthalene/Sodium System in Tetrahydrofuran**

Siegbert Rummel,* Margarita A. Ilatovskaya, Evgeny I. Mysov, Vladimir S. Lenenko, Helmuth Langguth, and Vladimir B. Shur

Radical anions formed from naphthalene and alkali metals are classical objects of chemical research, frequently used because they can efficiently transfer electrons to organic and inorganic substrates. They have achieved particular importance as catalysts for the polymerization of 1,3-dienes and some monoenes, in which "living" polymers are formed.

One of the characteristic reactions of the radical anion adducts of alkali metal ions with naphthalene and other aromatic hydrocarbons is the rapid and reversible electron transfer between the anionic species and the hydrocarbon [Eq. (a)]. Analogous elec-

$$ArH^{\bullet -} + ArH \rightleftharpoons ArH + ArH^{\bullet -} \quad (a)$$

tron transfer processes can also take place between the radical anions themselves [Eq. (b)]. Although there are already numer-

$$2\ ArH^{\bullet -} \rightleftharpoons ArH + ArH^{2-} \quad (b)$$

ous publications on electron transfer of this type,[1] to the best of our knowledge no one has hitherto investigated the reversible hydrogen transfer reactions between C–H bonds of hydrocarbons in these and similar systems. To clarify this question we chose the naphthalene/sodium system, which is formed by addition of sodium to an equimolar mixture of [D_0]naphthalene and [D_8]naphthalene in [D_0]THF, and investigated whether hydrogen isotope exchange takes place between the naphthalene rings.

The experiments were carried out under argon with careful exclusion of air and moisture. The molar ratio of sodium to naphthalene was 0.5:1, 1:1, and 2:1. In the last case some of the sodium remained undissolved because of the excess employed. After removal of the solvent by distillation in vacuum at 20 °C we analyzed the sublimed naphthalene by mass spectrometry.[2, 3] In addition to the H/D exchange in naphthalene we investigated whether analogous isotope exchange processes take place with other hydrocarbons, for example, with benzene, toluene, ethene, and methane.[3]

In our earlier work we had found[4, 5] that adducts of active carbon with metallic potassium, and also graphite–potassium lamellar compounds, are able to activate C–H bonds in various hydrocarbons and to catalyze the hydrogen isotope exchange at room temperature. Herein we report that analogous H/D exchange reactions take place in the naphthalene/sodium system in THF.

In a typical experiment, metallic sodium and [D_0]THF were added under argon to a 1:1 mixture of [D_0]naphthalene and

$[D_8]$naphthalene (mole ratio Na:naphthalene = 2:1, $c_0(C_{10}H_8 + C_{10}D_8) = 2$ M). The resulting dark-green solution of naphthalene–sodium was then stirred at room temperature. Mass spectroscopic analysis of the naphthalene obtained showed that redistribution of hydrogen isotopes between the naphthalene rings had taken place. After 7 h the isolated naphthalene had the following isotopic composition: $[D_0] = 22.9\%$, $[D_1] = 16.0\%$, $[D_2] = 7.1\%$, $[D_3] = 4.4\%$, $[D_4] = 6.3\%$, $[D_5] = 11.2\%$, $[D_6] = 14.5\%$, $[D_7] = 12.3\%$, and $[D_8] = 5.3\%$. At the same time, the total D-content (f_D) of the naphthalene had decreased—apparently as a result of isotope exchange with the undeuterated THF—from 50.8 to 42.5 atom%. The formation of deuterated naphthalene ($[D_0] = 9.8\%$, $[D_1] = 24.5\%$, $[D_2] = 29.9\%$, $[D_3] = 21.7\%$, $[D_4] = 10.1\%$, $[D_5] = 3.2\%$, $[D_6] = 0.7\%$, $[D_7] = 0.1\%$, $f_D = 26.3$ atom%, 22 °C, 3.5 h) from $[D_0]$naphthalene and sodium in $[D_8]$THF (99.9 atom%) supports this assumption. A reduction in the ratio Na:naphthalene from 2:1 to 1:1 or 0.5:1 led to a reduction in the rate of the isotope exchange in our test system.

A remarkable feature of the isotope exchange observed here is the strong dependence on the type of reagent used. For example, if sodium is replaced with potassium or lithium, no isotope exchange occurs. The same result is observed on the addition of [15]crown-5 and also by using dimethoxyethane (DME) in place of THF. On the other hand, one can significantly increase the rate of the H/D exchange in this system if alkanes or cycloalkanes, for example, cyclohexane, are added to the THF. By increasing the amount of cyclohexane in the mixture the rate of isotope exchange passes through a maximum, which lies at a THF/cyclohexane volume ratio of about 1:1, as shown clearly in Figure 1. If the isotope exchange is carried out in this solvent

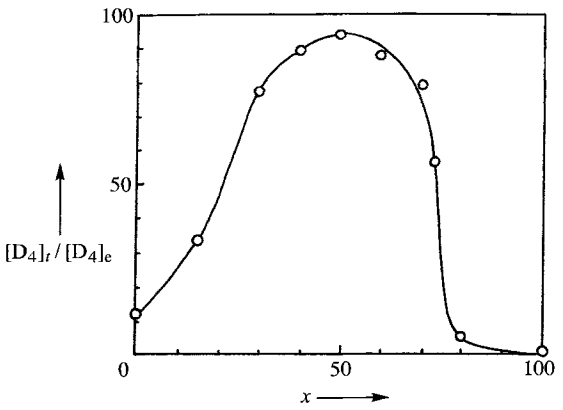

Fig. 1. Influence of the volume ratio x of cyclohexane in $[D_0]$THF on the rate of the H/D exchange in the system $[D_0]$naphthalene + $[D_8]$naphthalene + Na, given as the ratio $[D_4]_t/[D_4]_e$ in percent (22 °C, 3.5 h; mole ratio Na:naphthalene = 2:1; isotope composition of the initial naphthalene: $[D_0] = 48.6\%$, $[D_7] = 1.6\%$, $[D_8] = 49.8\%$, $f_D = 51.3$ atom%; initial naphthalene concentration = 2 M). $[D_4]_t$ = content of $[D_4]$naphthalene at time t, $[D_4]_e$ = content of $[D_4]$naphthalene in deuterated naphthalene after reaching the statistical isotope equilibrium.

mixture (Fig. 2, curve 1), a mixture of $[D_0]$naphthalene and $[D_8]$naphthalene leads, after only 3.5 h at room temperature, to that mixture of isotopomers ($[D_0] = 2.7\%$, $[D_1] = 10.7\%$, $[D_2] = 21.3\%$, $[D_3] = 25.9\%$, $[D_4] = 21.3\%$, $[D_5] = 12.4\%$, $[D_6] = 4.6\%$, $[D_7] = 1.1\%$, $f_D = 39.2$ atom%) that nearly corresponds to the statistical isotope equilibrium.[6] Under otherwise identical conditions, but without cyclohexane (Fig. 2, curve 2), only 11.6% of the statistical isotope equilibrium (based on $[D_4]$naphthalene) is reached. An even more pronounced accelerating effect of cyclohexane on the H/D exchange is observed when the reaction is carried out with a mole ratio of Na:naphthalene of 1:1 or 0.5:1 ($c_0(C_{10}H_8 + C_{10}D_8) = 2$ M).

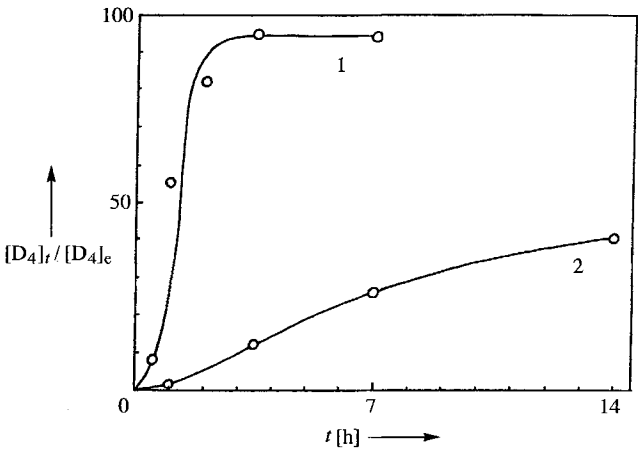

Fig. 2. Time-dependence of the H/D exchange in the system $[D_0]$naphthalene + $[D_8]$naphthalene + Na in cyclohexane/$[D_0]$THF 1/1 (curve 1) and in pure $[D_0]$THF (curve 2) (22 °C, Na:naphthalene = 2:1, initial naphthalene concentration = 2 M).

Further experiments showed that the sodium/naphthalene system in THF is not only able to activate the C–H bonds in naphthalene but also in a series of other hydrocarbons. For example, if one adds $[D_6]$benzene and metallic sodium to $[D_0]$naphthalene ($c_0 = 1.47$ M) in $[D_0]$THF (mole ratio $C_{10}H_8$:Na:$C_6D_6 \approx 1:2:2$), an efficient hydrogen isotope exchange takes place between C_6D_6 and the naphthalene–sodium even at room temperature. After 3.5 h the deuterium content in the naphthalene (obtained from the naphthalene–sodium) had increased from zero to 21.5 atom% (isotope composition: $[D_0] = 15.6\%$, $[D_1] = 30.8\%$, $[D_2] = 29.2\%$, $[D_3] = 16.6\%$, $[D_4] = 6.3\%$, $[D_5] = 1.5\%$) and that in benzene had decreased from 99.2 to 77.1 atom% (isotope composition: $[D_0] = 0.2\%$, $[D_1] = 0.8\%$, $[D_2] = 3.0\%$, $[D_3] = 10.6\%$, $[D_4] = 25.9\%$, $[D_5] = 36.5\%$, $[D_6] = 23.0\%$). In addition to benzene and naphthalene, THF is also involved in the isotope exchange, which was demonstrated by an experiment involving $[D_8]$THF and a mixture of $[D_0]$naphthalene and $[D_0]$benzene. Reduction in the ratio of sodium to naphthalene leads in this system, too, to a decrease in the rate of the isotope exchange.

Analogous isotope exchange processes in the naphthalene/sodium system can also be observed with toluene and ethene. In the case of toluene the exchange involves both the hydrogen atoms of the ring and of the methyl group. Finally, it could be shown that even methane can be drawn into the isotope exchange with this system, albeit with a lower rate. The experiments with ethene and methane were carried out in sealed glass ampoules ($V \approx 10$ mL) at an initial gas pressure of 600 Torr. Under these conditions a mixture of deuterated ethene ($[D_1] = 12.0\%$, $[D_2] = 22.9\%$, $[D_3] = 37.6\%$, $[D_4] = 27.5\%$) with a D-content of about 70.2 atom% was obtained after only 0.5 h with $[D_0]$ethene, $[D_8]$naphthalene (1.5 mmol, $c_0 = 2$ M, 99.9 atom% D), and sodium in $[D_8]$THF at room temperature (Na:$C_{10}D_8$ = 2:1); after 1.5 h the deuterium enrichment in the ethene was 89.6 atom% ($[D_1] = 0.8\%$, $[D_2] = 5.3\%$, $[D_3] = 28.6\%$, $[D_4] = 65.2\%$). The reaction of $[D_0]$methane with the $[D_8]$naphthalene/sodium system in $[D_8]$THF (3 mmol of $C_{10}D_8$, $c_0(C_{10}D_8) = 2$ M, Na:$C_{10}D_8$ = 2:1) gave a mixture of $[D_1]$methane (14.7%), $[D_2]$methane (0.8%), and $[D_3]$methane

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3521-2490 $ 15.00+.25/0

(0.1%) after 70 h at 22 °C. The addition of dodecane to the [D_8]THF (in a volume ratio of 1:1) increased the rate of isotope exchange with methane: after 70 h under otherwise identical conditions we obtained 20.2% [D_1]methane, 1.6% [D_2]methane, and 0.1% [D_3]methane—in contrast there was no deuterium enrichment in the dodecane.

An interpretation of our results using "simple" exchange mechanisms presents considerable difficulties. This is particularly the case for those mechanisms that involve a reversible $H^{\bullet}(D^{\bullet})$ or $H^{+}(D^{+})$ abstraction from the hydrocarbon by naphthalene–sodium with formation of the corresponding free radicals or carbanions. The first of these two mechanisms appears to be unlikely from a thermodynamic point of view, as the abstraction of a hydrogen atom from a hydrocarbon would lead to a much less stable radical (Ph$^{\bullet}$, Me$^{\bullet}$, etc.) than the radical anion of naphthalene. In addition, on the basis of this mechanism it is not easy to understand why cyclohexane and dodecane, in contrast to methane, are not involved in the H/D exchange, because it is well-known that the rate of $H^{\bullet}$ abstraction from alkanes and cycloalkanes by radicals decreases in the order *tert*-CH > *sec*-CH > *prim*-CH > methane.[7]

Attempts to interpret the experimental data by means of the proton abstraction mechanism also present serious difficulties. In particular, it is not clear whether naphthalene–sodium is at all capable of removing protons from such weak CH acids as, for example, methane at room temperature. Another difficulty in this case lies in explaining the accelerating effect of cyclohexane and the excess sodium present on the H/D exchange.[8]

However, there is a mechanistic interpretation—although also hypothetical—that satisfactorily describes the experimental observations. This is based on the assumption that atomic sodium, which can aggregate to form sodium clusters Na_n,[9] is formed in the naphthalene(ArH)/sodium system in THF by the reactions (c)–(e). These clusters are stabilized by the formation

$$Na_{met.} + ArH^{\bullet-}Na^{-} \rightleftharpoons Na^{+}ArH^{\bullet-} + Na_{at.} \quad (c)$$

$$ArH^{\bullet-}Na^{+} + ArH^{\bullet-}Na^{+} \rightleftharpoons ArH + Na^{+}ArH^{\bullet-} + Na_{at.} \quad (d)$$

$$ArH^{\bullet-}Na^{+} \rightleftharpoons ArH + Na_{at.} \quad (e)$$

of surface complexes with naphthalene. We now assume that activation of the hydrocarbon C–H bonds takes place on the surface of these sodium clusters, the result of which is an observable H/D exchange.

With sodium/naphthalene ratios of 0.5:1 and 1:1 atomic sodium could be formed by reactions (d) and (e). In addition, the conditions required for reaction (c) could be satisfied in the presence of excess metallic sodium: the resulting higher content of sodium clusters would cause the observed increase in rate of the H/D exchange.

Addition of nonpolar solvents such as alkanes and cycloalkanes to THF shift the equilibria (d) and (e), by a reduction in the solvation of the sodium cations, apparently in the direction of formation of atomic sodium. Thus, it can be explained why the addition of certain amounts of cyclohexane to the naphthalene/sodium system in THF initially led to an acceleration of the H/D exchange. If the amount of added hydrocarbon becomes too large, however, the system is deactivated by destruction of the naphthalene–sodium with formation of naphthalene and metallic sodium.[10] As a result, the rate of H/D exchange passes through a maximum with increasing content of cyclohexane in the mixture.

The H/D exchange itself takes place apparently by reversible cleavage of the hydrocarbon C–H bonds with formation of surface groups Na_{surf}–Ar, Na_{surf}–H, Na_{surf}–R, and Na_{surf}–D, where Ar is naphthyl and R is either naphthyl or another hydrocarbon group that undergoes exchange with naphthalene. A requirement for this mechanism to be valid for the isotope exchange appears to be direct contact of the sodium atoms on the surface with the naphthalene or other hydrocarbon molecules. This means that the intermediate complexes formed from the hydrocarbon molecules and the sodium atoms must have the character of contact ion pairs and not that of solvent-separated ion pairs. Presumably, this is the reason why the systems naphthalene/lithium in THF, naphthalene/potassium in THF, naphthalene/sodium in THF in the presence of [15]crown-5 and naphthalene/sodium in DME show no isotope exchange, in contrast to the naphthalene/sodium system in THF. In this connection, according to literature data[1, 11, 12] only contact ion pairs are present in naphthalene/sodium in THF at room temperature, whereas naphthalene/lithium and naphthalene/potassium in THF, and naphthalene/sodium in DME, form solvent-separated ion pairs.

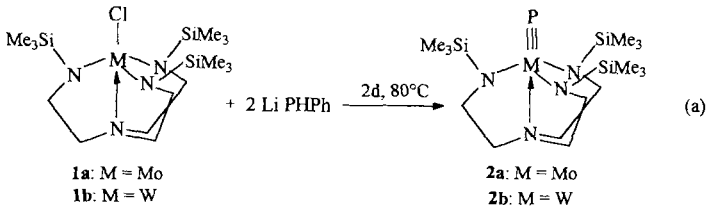
Complexes Containing Phosphorus and Arsenic as Terminal Ligands**

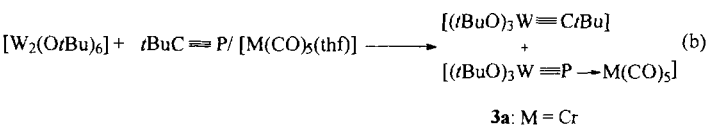
Manfred Scheer,* Jan Müller, and Marco Häser

Alkali metal bis(trimethylsilyl)phosphanides react with different halogenophosphorus compounds to form multiple P–P bonds.[1] The alkali metal phosphanide serves as a reagent for metalation of silylphosphorus functionalities with the elimination of $P(SiMe_3)_3$ and as a source for the central phosphorus atom in the resulting tri- and isotetraphosphanes. Our interests have focused on the extension of the above concept by the use of transition metal halides and the heavier homologues $[E(SiMe_3)_2]^-$ (E = As, Sb, Bi).[2] The paramagnetic W^{IV} halogenide $[(N_3N)WCl]$[3] **1b** $[(N_3N) = N(CH_2CH_2NSiMe_3)_3]$ serves as an ideal starting material in both respects. With this species and the corresponding molybdenum compound **1a**,[4] Schrock et al. were able to synthesize the first examples of compounds containing a metal–phosphorus triple bond (**2**) [Eq. (a)] that were structurally characterized.[5] At the same time Cummins et al. reported the synthesis of a complex containing a Mo–P triple bond by using $[Mo(NAr'R)_3]$ (Ar' = 3,5-$C_6H_3Me_2$, R = $C(CD_3)_2CH_3$) and white phosphorus as starting materials.[6]

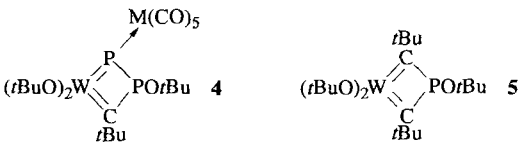


(a)

The $^{183}W,^{31}P$ coupling constant of **2b** (138 Hz) differs significantly from the coupling constants determined for the stabilized phosphido complexes **3a,b** (**3a**: 536 Hz, **3b**: 554 Hz), which we synthesized according to the methathesis reaction given in Equation (b).[7] Limited amounts of **3**, as well as alkylidyne complexes, react under cycloaddition with the phosphaalkyne to form four-membered ring derivatives. A subsequent 1,3-O*t*Bu shift yielded the corresponding phosphaalkoxy-substituted compounds **4** and **5**. Due to decomposition of the alkoxides on the column material, chromatographic separation of the reaction mixture has not been possible, nor have we been able to obtain single crystals of **3** suitable for structural analysis. It has been possible, however, to enrich solutions of **3** by fractional crystallization.

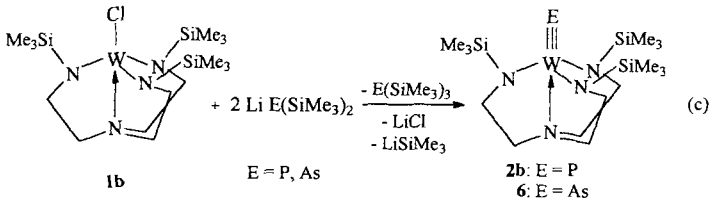


(b)



In an effort to find an explanation for the different $^{183}W,^{31}P$ coupling constants, we decided to synthesize **2b**, starting with lithium bis(trimethylsilyl)phosphanide and subsequent complexation with $[W(CO)_5(thf)]$. Furthermore, it should be possible to use bis(trimethylsilyl)pnictides $[E(SiMe_3)_2]^-$ (E = As, Sb, Bi) to synthesize complexes containing the heavier homologues of phosphorus.[8]

The reaction of **1b** with $[P(SiMe_3)_2]^-$ at 80 °C for two days afforded the phosphido complex **2b** in 65% yield [Eq. (c)]. To prepare the corresponding arsenido complex **6** temperatures of 110 °C are needed. Whereas Schrock et al. observed and isolated the phosphanido complex $[(N_3N)W-PPh(H)]$ as an intermediate in reaction (a), no corresponding Me_3Si-substituted phosphanido derivative could be detected by monitoring reaction (c) by ^{31}P NMR spectroscopy.[9] Instead, with growing amounts of **2b** an increase in the amount of $P(SiMe_3)_3$ is detected. Evidently, the rate-determining step of reaction (c) is the formation of the phosphanido complex $[(N_3N)W-P(SiMe_3)_2]$, which is subsequently metalated by a second equivalent of $LiP(SiMe_3)_2$ with the elimination of $P(SiMe_3)_3$, forming the phosphido complex **2b**, presumably, by the metal-catalyzed elimination of $LiSiMe_3$. These conclusions are in accordance with our results on the reaction pathway of multiple P–P bond formation[1] as well as with findings by Schrock et al., who emphasize the need for a base (LiPPhH or LiR) in the transformation of phosphanido to phosphido complexes **2** by the elimination of LiPh.[10]



(c)

The phosphido complex **2b** first reacts with $[M(CO)_5(thf)]$ (M = Cr, W) to form complexes **7**, although a second substitution in the *trans*-position is preferred, leading to the $M(CO)_4$ complexes **8**, which can be isolated in 68 to 74% yield [Eq. (d)].[11] Complexes **6** and **8** are yellow and red crystalline materials, respectively, which are moderately soluble in *n*-hexane, although well soluble in toluene and THF. These compounds were completely characterized by spectroscopic methods.[12] The mass spectrum of **6** reveals the molecular peak, whereas for **8** the peak of the $[(N_3N)W\equiv P\rightarrow M]^+$ fragment is the highest one observed. In the range of CO vibrations, IR spectra show a strong band at 1912 (**8a**) and 1896 cm^{-1} (**8b**), respectively, corresponding to local D_{4h} symmetry of the $M(CO)_4$ unit. A discussion of the W≡E vibrations in the Raman spectra of **2a** and **6**, can be found in a publication by Schrock et al.,[13] who synthesized **6** and the corresponding Mo derivative by reaction (a) starting with LiAsPhH.

The crystal structure analyses of **1b** and **6** (Fig. 1)[14] confirm their isostructural relationships with **2b**. All compounds exhibit

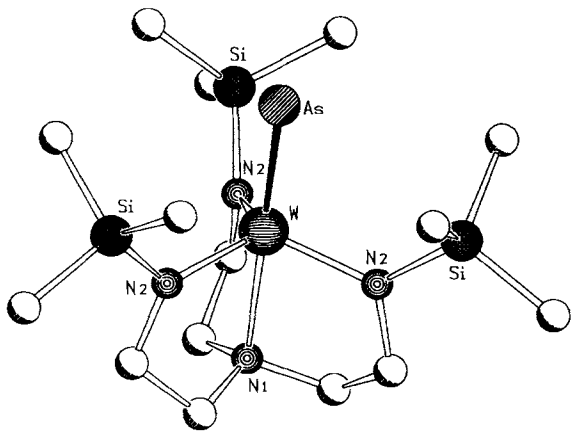

Fig. 1. Molecular structure of **6** (without H atoms).

a linear N_{ax}-W-E axis with a distorted trigonal-bipyramidal geometry at the central W atom. The W–As distance in **6** is 2.290(1) Å and is therefore 13 pm longer than the analogous W–P distance in **2b** (2.16 Å). The corresponding Mo–As bond length is reported to be 2.25 Å.[10] The distortion of the trigonal bipyramid is most pronounced for the As derivative **6** (E-W-N2 angle in Table 1 and 2) and lessens for the phosphido complex **2b** and still further for the chloro derivative **1b**. Whereas the W–N2 distances are almost not influenced by the substituent E, the extent of intramolecular N1 → W coordination is strongly dependent on it. In accordance with the higher electronegativity, this distance in the chloro-substituted compound **1b** (2.182(6) Å) is shorter than that in the As derivative **6** (2.336(6) Å), which is almost identical to the distance found for the phosphido complex **2b**.

Complex **8b** (Fig. 2)[14] exhibits a linear N_{ax}-W-P-W-P-W-N_{ax} axis. The W1 atoms are coordinated in a trigonal-bipyramidal fashion, the W2 atom resides in an octahedral environment. In comparison with **2b** the coordination of the phosphido ligands at the W^0 center causes a lengthening of the W–P triple bond by 4 pm to 2.202(2) Å (Table 1 and 2). The mean W2–P distance is 2.460 Å and is therefore shorter than that observed in $[(CO)_5W(PMe_3)]$[15] (2.516 Å), although it is within the same region as that in *trans*-$[(CO)_4W(PR_3)_2]$ (2.458 Å).[16] π Back donation of the central W^0 atom to the phosphido ligand weakens the triple bond.

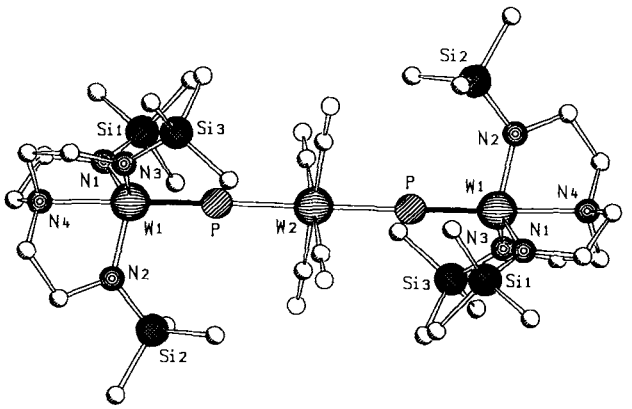

Fig. 2. Molecular structure of **8b** (without H atoms).

The comparison of the ^{31}P NMR data[12] of **2b**, **7**, and **8** indicates that the additional coordination of a metal center by the phosphido substituent leads to a high-field shift and to a considerable increase in the $^1J(^{183}W,^{31}P)$ values.[12] Thus, ^{31}P NMR chemical shifts and the $^1J(^{183}W,^{31}P)$ values in **3** (**3a**: $\delta = 595.4$, $J = 535.8$ Hz; **3b**: $\delta = 544.6$, $J = 554$, 163 Hz) are within the range of those found for complexes **7** and **8**.

The following points were investigated by theoretical methods: 1) For which ligands E is reaction (c) thermodynamically favored? 2) Why does **2b** react with $[M(CO)_5(thf)]$ to afford **8** instead of **7**? 3) Which ligating properties does **2b** have? 4) What causes the considerable change in the $^1J(^{183}W,^{31}P)$ value on linear coordination of tungsten complexes with terminal phosphido ligands to Lewis acids? In order to discuss these points, equilibrium structures of all compounds in question were calculated by applying the B-P86/SVP density functional approximation (see Tables 1 and 2).[17] There is good agreement between the calculated and experimentally observed structural parameters, with exception that the distance between W and the axial nitrogen atom is calculated to be 0.17–0.25 Å longer (the corresponding bond is rather weak).[18]

Electronic energies, calculated with the B-P86/SVP approximation, show reaction (c) to be slightly exothermic (exception: E = N; cf. Table 3). These calculated reaction energies are

Table 3. Calculated reaction energies (without correction of zero point vibrations) of reaction (c) in kJ mol^{-1} as a function of the terminal ligands E.

E	Method B-P86/SVP	B3-LYP/SVP
N	+61	+104
P	−14	+26
As	−30	+13
Sb	−25	+19

based upon the assumption that all lithium compounds appear in a partially aggregated state: $LiE(SiMe_3)_2$ as a dimer with D_2 symmetry,[19] LiCl as a tetramer,[20] and $LiSiMe_3$ as a hexamer.[21] Interactions with the solvent (toluene) and with donor compounds ($E(SiMe_3)_3$, THF) that are present in low concentration are ignored.[22] Reaction (c) is supposed to be favored by entropy due to an increase in the number of particles.

Reaction energies were also determined by the B3-LYP/SVP density functional approximation[23] at fixed B-P86/SVP equilibrium geometries (Table 3). This yields reaction energies that are shifted by $+42 \pm 2$ kJ mol^{-1} into the endothermic region. The reason for this systematic difference is the different spin multiplicity of starting materials and products: compound **1b** exhibits a triplet spin state. A more accurate calculation of the spin coupling energies for molecules of this size is currently not feasible. Nevertheless, the following conclusions can be drawn: A) Reaction (c) is equally favored from a thermodynamic point of view for E = P, As, or Sb, but not for E = N. This is surprising since compounds containing nitrido ligands have been known for a long time. The probable explanation lies in the high stability of the amide $LiN(SiMe_3)_2$, which would be a starting material in reaction (c). B) Reaction (c) is most exothermic when E = As. C) From a purely thermodynamic point of view, since reaction (c) had been carried out successfully for E = P, it should work for E = Sb as well.

To establish why **2b** and $[W(CO)_5(thf)]$ form **7b** only as an intermediate, which then preferentially yields **8b**, reaction energies for the reactions **2b** + $[W(CO)_5(thf)]$ → **7b** + THF, and **2b** + **7b** → **8b** + CO were calculated. In the B-P86/SVP (B3-LYP/SVP) approximation these reaction energies are −51 (−40) kJ mol^{-1}, and +66 (+58) kJ mol^{-1}, respectively. Evidently, CO is a more strongly binding ligand than **2b**. The apparent contradiction with experimental findings can be resolved if the reaction $[W(CO)_5(thf)] + CO \rightarrow [W(CO)_6] + THF$ is taken into account. With the formation of $[W(CO)_6]$ acting as a driving force,[24] the overall reaction **2b** + **7b** + $[W(CO)_5(thf)]$ → **8b** + $[W(CO)_6]$ + THF has a reaction energy of −19 (−14) kJ mol^{-1}. Further reaction of **8b** with elimination of CO is not feasible for steric reasons.

The characteristics of bonding in **2b** and in the other complexes were investigated by PESHO analysis[25] (PESHO = *p*air of *e*lectron *s*haring *h*ybrid *o*rbitals).[26] The W≡P bond in **2b** largely consists of one d_σ–p_σ bond and two d_π–p_π bonds (Table 4, Fig. 3); there are only small contributions from the 6s

Table 4. Bonding in **2b** and its complexes characterized by PESHOs. For further explanations about the information given in the Table see reference [25]. The η_h values associated with the radii R_A, R_B are recorded in columns 5–8.

[a] Dominant electron sharing mechanism. [b] See Figure 3. [c] The fourth PESHO with its significantly smaller shared electron number η_h signals that electron sharing between W and P is qualitatively described by a triple bond (as opposed to a "quadruple bond"). [d] $\eta_h(A,R_A;B,R_B)$ for A = P and B = B cannot be directly compared to $\eta_h(A,R_A;B,R_B)$ for A = P and B = W2, because typical valence radii of W and B are different (PESHO analysis does not rely on empirical data). [e] Electron sharing between P and B in $[(N_3N)WP \rightarrow BH_3]$ is dominantly of σ type; π contributions are smaller by a factor of 5. [f] σ and π contributions to electron sharing between P and W2 in **8b** differ by a factor of 2.5. A comparison of radial electron densities $\rho_P(r,l,m)$ (not shown) reveals that s and p_σ densities at phosphorus in **2b** are larger than in **8b**, while the reverse holds for p_π densities. This may be interpreted as σ donation and π acceptance of **2b** in **8b**.

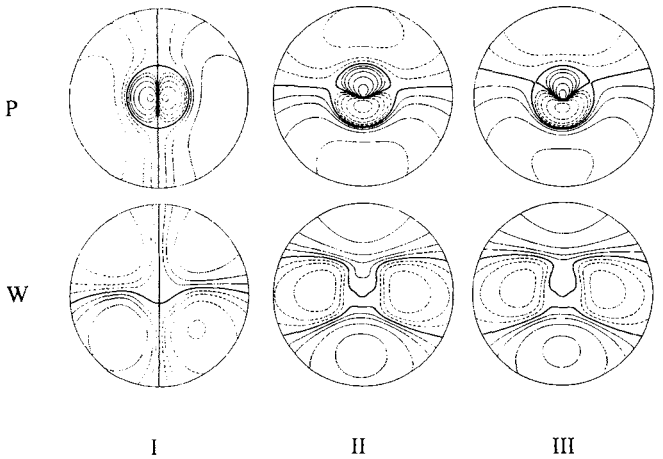

Fig. 3. PESHOs $|A,R_A;\tilde{h}\rangle$ and $|B,R_B;\tilde{h}\rangle$ with A = W and B = P; $R_A = R_B$ = 100 pm (radii of the circles drawn) for compounds **2b** (I: $h = 2$; II: $h = 1$) and $[(N_3N)W{\equiv}P\ \ BH_3]$ (III: $h = 1$). The amplitudes of the PESHOs were multiplied by η_h (cf. Table 4) and subsequently plotted as contour lines. Bold lines correspond to nodal lines (zero amplitude); other contour lines represent amplitudes of ± 0.02, ± 0.04, ± 0.08, etc (in $a_0^{-3/2}$). The centers of the circular frames are occupied by the corresponding nuclei (not drawn), their vertical distances are to scale. Since an effective core potential has been used at W, its valence orbitals exhibit few if any inner nodes. Otherwise, I corresponds to a typical p_π–d_π bond between P and W. Comparison of II and III shows the increasing contribution from the phosphorus 3s orbital to the p_σ–d_σ bond upon coordination to BH_3.

orbital of tungsten and the 3s orbital of phosphorus to the $d_\sigma - p_\sigma$ bond (Fig. 3). Coordination of **2b** to an σ acceptor, for example BH_3, leads to formation of a weak σ bond between P and B (Table 4), with simultaneous *shortening* of the W≡P bond (cf. calculated values in Tables 1 and 2). This effect can be explained by increased participation of the 3s orbital of phosphorus in covalent interactions with its partners (Fig. 3). The energy of the reaction $[(N_3N)WP] + H_3B(thf) \rightarrow [(N_3N)WP{-}BH_3] + THF$ is calculated to be $-22\ (-2)$ kJ mol^{-1} by using the B-P86/SVP approximation (B3-LYP/SVP approximation). Accordingly, a possible borane adduct of **2b** would be much less stable than the complex with $[W(CO)_5]$, which compares with our experimental observations. This can probably be explained by the π acceptor ability of ligand **2b**, which is shown, for example, by PESHO analysis of **8b** (Table 4). Since the W≡P-π bond is thereby weakened, the W≡P distance in **8b** is 2.4 pm (calculated) or 4.0 pm (observed) greater than in **2b**. Thus, the phosphido complex **2b** is characterized by similar, but less pronounced, ligating properties than CO.

The increase of the $^{183}W,^{31}P$ coupling constant upon linear coordination of **2b** to a σ acceptor may be rationalized by the stronger phosphorus 3s orbital involvement in W≡P bonding upon complex formation (Fermi contact term).

Experimental Procedure

2b, **6**: **1b** (103 mg, 0.18 mmol) and $LiE(SiMe_3)_2 \cdot 2THF$ (0.37 mmol) (E = P [27], As [28]) in toluene (10 mL) were stirred for 48 h at 80 and 110 °C, respectively. The deep red suspension was reduced to dryness in vacuum and the residue was extracted twice with hexane (40 mL). The solvent was removed in vacuum until the onset of crystallization. Compounds **2b** and **6** crystallized at −20 °C as yellow-orange cubes. The compounds could be recrystallized from Et_2O (**2b**: 67 mg, 65%; **6**: 53 mg, 48%).

8: To a solution of **2b** (104 mg, 0.18 mmol) dissolved in toluene (10 mL), $[M(CO)_5(thf)]$ (M = Cr, W) (9 mL of a 0.02 M solution in THF), prepared by irradiating $M(CO)_6$ in a UV-apparatus, was added and stirred for 60 h at ambient temperature. The solvent was removed in vacuum until crystals began to form. At −20 °C **8a** (81 mg, 68%), **8b** (96 mg, 74%), respectively, crystallized as red rhombuses from deep red solutions.

[9] In a sealed NMR tube, reaction (c) was monitored for 48 h by ^{31}P NMR spectroscopy in [D$_8$]toluene starting at ambient temperature and heating to 60 and 80 °C. Measurements were taken every 2 h in the beginning, later every 8 h. Small amounts of **2b** and $P(SiMe_3)_3$ could already be detected after 2 h. The increase in the amount of **2b** formed is accompanied by a decrease in the amount of $LiP(SiMe_3)_2$ and an increase in that of $P(SiMe_3)_3$. The trace amounts of $HP(SiMe_3)_2$, evidently caused by hydrolysis at the inner wall of the tube, remain constant.

[10] R. R. Schrock, lecture at the 211th ACS Meeting, New Orleans **1996**, see INOR 517 in book of abstracts.

[11] The reaction was monitored by ^{31}P NMR spectroscopy between −40 °C and ambient temperature. Intensities of the products showed that the complexes **7** are only intermediates; complexes **8** are formed as the main products with an increase in temperature and time. After 48 h **8** is formed quantitatively.

[17] Structure optimizations were performed by using the TURBOMOLE set of programs with the RI-*J* approximation (K. Eichkorn, O. Treutler, H. Öhm, M. Häser, R. Ahlrichs, *Chem. Phys. Lett.* **1995**, *242*, 652–660). For definition of the B-P86 density functional see A. D. Becke, *Phys. Rev. A* **1988**, *38*, 3098; J. P. Perdew, *Phys. Rev. B* **1986**, *33*, 8822; *ibid.*, **1986**, *34*, 7046. The acronym SVP refers to TURBOMOLE split valence basis sets, augmented by a shell of polarization functions, cf. A. Schäfer, H. Horn, R. Ahlrichs, *J. Chem. Phys.* **1992**, *97*, 2571. Quasi-relativistic pseudopotentials were used for the elements W and Sb (D. Andrae, U. Häussermann, M. Dolg, H. Stoll, H. Preuss, *Theor. Chim. Acta* **1990**, *77*, 123; A. Bergner, M. Dolg, W. Küchle, H. Stoll, H. Preuss, *Mol. Phys.* **1993**, *80*, 1431). The corresponding SVP basis sets optimized for W and Sb by F. Weigend, K. Eichkorn and R. Ahlrichs are unpublished.

[18] Results are not improved upon switching to the MP2/SVP approximation ($SiMe_3$ in **2b** replaced by Me).

[19] D_2-symmetric $(LiE(SiMe_3)_2)_2$ corresponds to the crystal structures of $[LiP(SiMe_3)_2(thf)]_2$ (cf. G. Becker, H.-M. Hartmann, W. Schwarz, *Z. Anorg. Allg. Chem.* **1989**, *577*, 9–22) and $[LiAs(SiMe_3)_2(dme)]_2$ (cf. G. Becker, C. Witthauer, *Z. Anorg. Allg. Chem.* **1982**, *492*, 28–36). The analogous antimony compound prefers a slightly different mode of aggregation (cf. G. Becker, A. Münch, C. Witthauer, *Z. Anorg. Allg. Chem.* **1982**, *492*, 15–27).

[20] In the experiment, LiCl is formed as a solid in reaction (c).

[21] The difference in energy between the hexamer and the tetramer was calculated to be 4.5 kJ per mol of $LiSiMe_3$ (B-P86/SVP). The crystal structure of the hexamer is known: T. F. Schaaf, W. Butler, M. D. Glick, J. P. Oliver, *J. Am. Chem. Soc.* **1974**, *96*, 7593–7594; W. H. Ilsley, T. F. Schaaf, M. D. Glick, J. P. Oliver, *ibid.* **1980**, *102*, 3769–3774.

[22] Calculated reaction energies will be correct as long as solvation and aggregation of the lithium compounds are considered in a similar approximation for the starting materials and for the products. Relative reaction energies amongst pnictido ligands E are supposed to be very reliable, since they are not influenced by errors associated with lithium aggregation.

[23] For a concise definition of the B3-LYP density functional see C. W. Bauschlicher, H. Partridge, *Chem. Phys. Lett.* **1994**, *231*, 277. The calculations were performed by using the TURBOMOLE set of programs (R. Ahlrichs, M. Bär, M. Häser, H. Horn, C. Kölmel, *Chem. Phys. Lett.* **1989**, *162*, 165; O. Treutler, R. Ahlrichs, *J. Chem. Phys.* **1995**, *102*, 346).

Becker, *Phosphorus, Sulfur, Silicon*, **1994**, *93–94*, 391–392; M. Scheer, C. Troitzsch, L. Hilfert, M. Dargatz, E. Kleinpeter, P. G. Jones, J. Sieler, *Chem. Ber.* **1995**, *128*, 251–257; M. Scheer, U. Becker, J. C. Huffman, M. H. Chisholm, *J. Organomet. Chem.* **1993**, *461*, C1–C3.

[25] M. Häser, *J. Am. Chem. Soc.* **1996**, *118*, 7311–7325. A PESHO is a pair of atomic hybrid orbitals $|A,R_A;\tilde{h}\rangle$ and $|B,R_B;\tilde{h}\rangle$; here "atomic" means $|A,R_A;\tilde{h}\rangle$ and $|B,R_B;\tilde{h}\rangle$ are contained within spherical neighborhoods of the nuclei A and B, respectively, with radii given by R_A and R_B, respectively; the PESHOs are obtained by requiring the closest description of electronic delocalization between the atomic neighborhoods of A and B (thus approximating the oneelectron density operator) for any pre-set number of PESHOs ($h=1,2,3,\ldots$). Each PESHO ($|A,R_A;\tilde{h}\rangle$, $|B,R_B;\tilde{h}\rangle$) is characterized by a number $0\leq\eta_h(A,R_A;B,R_B)\leq 2$ of electrons shared between $|A,R_A;\tilde{h}\rangle$ and $|B,R_B;\tilde{h}\rangle$. The number of PESHOs with values $\eta_h(A,R_A;B,R_B)$ significantly different from zero relates to the number of covalent bonds between A and B, while η_h itself refers to the extent of the corresponding electron sharing phenomenon. Entries in Table 4 are values of $\eta_h(A,R_A;B,R_B)$ for $R_A=R_B=60$, 80, 100, and 120 pm.

[26] The analysis of bonding was based on Kohn–Sham orbitals from the B-P86/SVP calculations. Conclusions regarding electronic delocalization remain valid only in as far as electronic correlations are of minor importance.

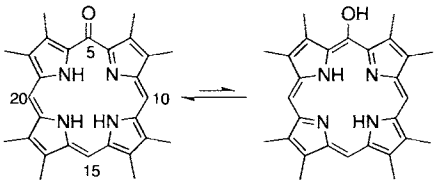
Self-Assembling Covalently Linked Supramolecular Arrays of Defined Structure: The Remarkable Redox Reactivity of 15-*meso*-Substituted 5-Oxyporphyrins**

Richard G. Khoury, Laurent Jaquinod, Daniel J. Nurco, Ravindra K. Pandey, Mathias O. Senge, and Kevin M. Smith*

The synthesis and chemistry of organized supramolecular assemblies have received considerable attention recently, particularly with regard to self-assembly of macromolecules to give supramolecular arrays possessing, or potentially possessing, biological or other catalytic activity.[1, 2] It is hoped that such biofunctional assemblies might show unique biomimetic function, demonstrate molecular discrimination enabling unique catalytic activity, or act as selective transport agents. In the present paper we show that, based on their redox properties, certain carefully designed oxyporphyrins (oxophlorins) can be induced to reversibly self-assemble, by way of covalent carbon–carbon bonds, to give supramolecular assemblies with defined structures.

Iron complexes of oxophlorins **1** have been postulated as intermediates in the catabolism of heme leading to bile pigments.[3] Oxophlorins are porphyrinoids that have a *meso* carbonyl group, and exist in the keto form **1** rather than in the enol form **2** in neutral solution.[4] In acidic solution or in the presence



1 **2**

of divalent metals, the enol structure predominates, but with trivalent metal ions such as iron(III), either the keto or enol form can predominate, depending upon pH.[4] Based on the known radical chemistry of metallooxophlorins (due to their low oxidation potentials)[5] and the tendency of the radicals to dimerize to give unique structures,[6] we chose to synthesize a number of *meso*-substituted oxophlorins and then investigate their chemical oxidation to provide regio- and stereochemically pure oligomers. All known radical dimerizations of 5-oxophlorins[5, 6] involve the 15-position, and thus the largest oligomer that can be obtained is a dimer. In order to investigate access to oligomers (and therefore supramolecular assemblies), we targeted 15-substituted 5-oxophlorins in the hope that radical oligomerization reactions of these substrates would take place

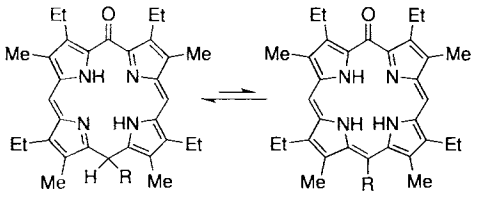
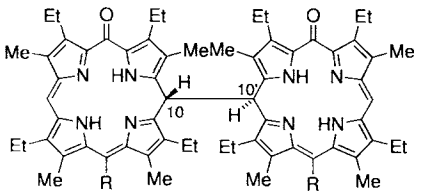
at both the 10- and 20-positions. Moreover, the electronic nature of the substituent at C-15 should enable facile control over the oxidation potential of the oxophlorin, and therefore over the ease of formation of the supramolecular assembly.

Several approaches have been developed for the synthesis of oxophlorins;[7, 8] we selected the MacDonald-type 2+2 condensation of 1,9-diformyldipyrroketones and dipyrromethane-1,9-dicarboxylic acids,[8] because this approach would enable us to readily prepare a series of 15-substituted 5-oxophlorins. Condensation of a 1,9-diformyldipyrroketone with a 5-ethyldipyrromethane-1,9-dicarboxylic acid[9] predominantly afforded the 15-ethyl-5-isooxophlorin **3**, which existed as the iso tautomer rather than the expected oxophlorin form **4** owing to steric congestion between the substituents at positions 13, 15, and 17.[8b] However, another product was isolated more recently in smaller amounts from this reaction, and is identified as 10,10′-bis-(15-ethyl-10*H*-5-oxophlorin). This compound exists in the isomeric forms **5** and **6**, each of which demonstrate that 15-substituted-5-oxophlorins do indeed dimerize at the 10,10′-positions. Stereoisomers **5** and **6** are stable as a solid

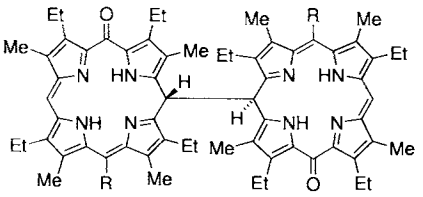


3, R = Et

4, R = Et
7, R = C_6H_5
10, R = C_6F_5



5, R = Et
8, R = C_6H_5
11, R = C_6F_5



6, R = Et
9, R = C_6H_5
12, R = C_6F_5

and in solution, and are separable. The molecular structure of **5** was confirmed by X-ray crystallography (Fig. 1).[10a, c] Molecules of **5** pack in a crystalline lattice with alternating columns of stacked dimers and ordered molecules of cyclohexane (not shown).

The 15-phenyl-5-oxophlorin **7** was synthesized by using the same conditions as those in the attempted preparation of **4**; under the acidic conditions, both the mono- and dications of the oxophlorin **7** were observed spectrophotometrically. Basic workup of this reaction product, followed by exposure to air in

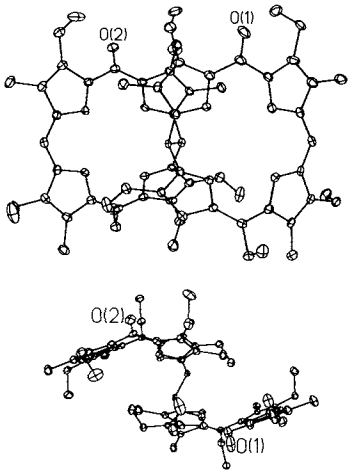


Fig. 1. Molecular structure of isooxophlorin dimer **5** (35% probability thermal ellipsoids) in the crystal. The lower portion shows an edge-on view of the same dimer. Hydrogen atoms have been omitted for clarity.

CH_2Cl_2 and daylight (which accelerates the dimerization) afforded, in 89% yield, the novel isooxophlorin dimer as a mixture of regioisomers **8** and **9**. Figure 2 shows the UV/Vis spectrum ($CHCl_3$). The ^1H NMR spectrum (in $CDCl_3$) indicates

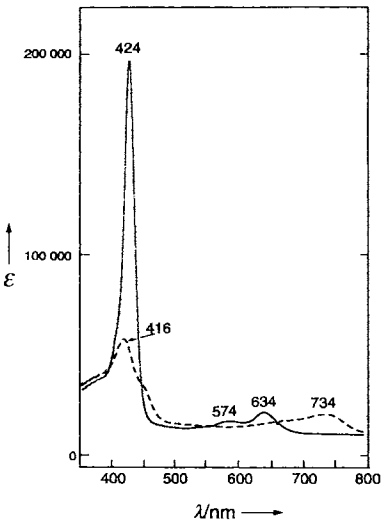

Fig. 2. UV/Vis spectra ($CHCl_3$) isooxophlorin dimer **8/9** (– · –) and the salt of diprotonated **7** (—).

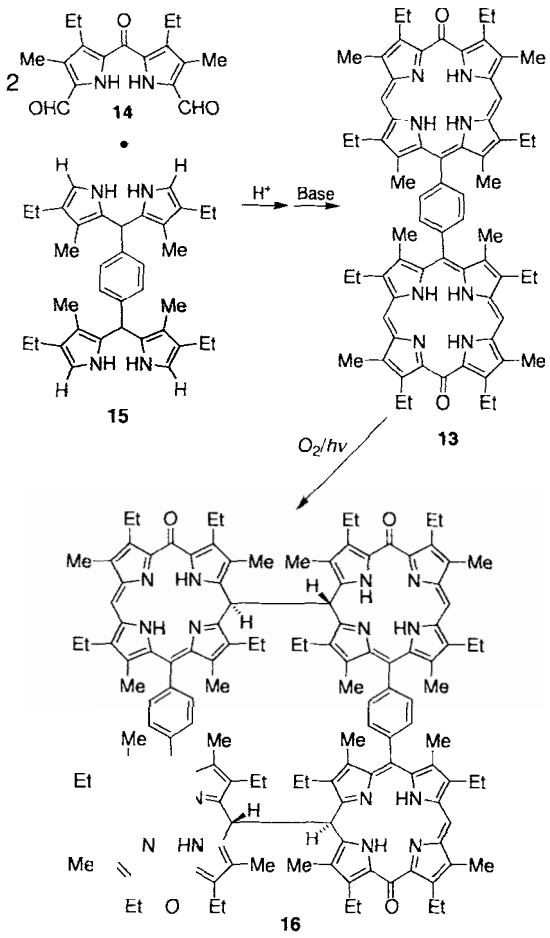
interrupted conjugation and features signals for exchangeable NH protons at $\delta = 13.46$, 13.27, 13.25, and 13.18 (each 2H); the 10-H protons give rise to signals at $\delta = 5.35$ and 5.30 (each 2H, two isomers). Dimerization of 15-phenyl-5-oxophlorins required a longer period of time than that of the 15-ethyl analogue, confirming that the 15-*meso* substituent plays a role in moderating the oxidation potential of the oxophlorin macrocycle. Synthesis of 15-pentafluorophenyl-5-oxophlorin **10** and further treatment as described above resulted in even a slower rate of dimerization; treatment with an oxidizing agent such as $[K_3Fe(CN)_6]$ resulted in complete dimerization to give the mixture of regioisomers **11** and **12** in 20 minutes.

Having established the oxidative dimerization of the 15-substituted 5-oxophlorins, we next attempted to synthesize an oxophlorin supramolecular array. 5-Oxophlorin dimer **13** was prepared by condensing diformyldipyrroketone **14** with a symmetrical bis(dipyrromethane) **15**.[12] Oxidative dimerization of **13** afforded a 93% yield of the macromolecule **16** consisting of four



isooxophlorin-type subunits connected in a stereochemically unique fashion. The UV/Vis spectrum of **16** resembles that shown in Figure 2A, but the major bands are blue-shifted (λ_{max} = 378, 654 nm). The ^{1}H NMR spectrum (in $CDCl_3$) of **16** again demonstrates interrupted conjugation in the macrocycle, with signals for exchangeable NH groups at δ = 13.20 and 12.85 (each 4H), as well as the 10-H signal at δ = 5.41 (4H). The molecular structure of **16** was confirmed by X-ray crystallography (Fig. 3).[10b,c] The molecule has an overall helical structure

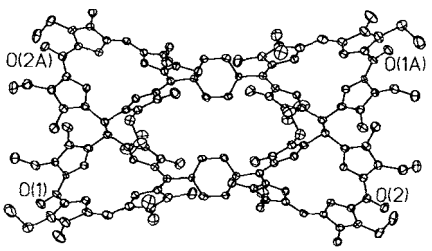


Fig. 3. Molecular structure of isooxophlorin tetramer **16** in the crystal (35% probability thermal ellipsoids). Hydrogen atoms have been omitted for clarity.

with disordered molecules of *n*-hexane fitting into the groove of the helix (not shown).

The radical dimerizations to afford the regioisomeric pairs **8**/**9**, **11**/**12**, and tetramer **16** are reversible, and involve the extremely facile reduction of oxophlorin radicals;[5] treatment with acid serves to regenerate the protonated oxophlorins (see Fig. 2), which can be quantitatively transformed back into the dimers or tetramer as already described above. ^{1}H NMR signals for the internal NH groups are shifted downfield $\Delta\delta$ = 15 upon dimerization of **4**, **7**, **10**, and **13** (indicating a disruption in the porphyrin-type ring current) and are exchangeable with D_2O/Et_3N. The protons at the 10-positions give rise to ^{1}H NMR signals around δ = 5.30 and the ^{13}C NMR signal of C-10 occurs at about δ = 40.0.

The structural features of **16** are unique. We consider compound **16** to be a remarkable example of a robust, self-assembled supramolecular array having a defined structure composed of versatile chromophores linked by covalent bonds. Studies of metal-binding and other chemical characteristics of a series of compounds such as **16** will be reported in due course. Most other synthetic supramolecular arrays of which we are aware are either irreversibly linked through covalent bonds or are only tenuously associated by way of relatively weak dative or hydrogen bonding interactions.

Dedicated to Professor Hans Georg von Schnering on the occasion of his 65th birthday

Compounds of the Al/B/C system are of great importance for the development of light, nonoxidic ceramics because of their high chemical and thermal stability,[1] which has led to a great number of recent publications and patents in this field.[2] While boron-rich compounds such as $B_{51}Al_2C_8$ ("AlB_{10}",[3]) and $B_{48}Al_3C_2$ ("diamond-like boron", "β-AlB_{12}" [4]) have been known for a long time, an aluminum-rich phase $Al_4B_xC_4$ with variable boron content ($x = 1-3$) was first reported in 1964.[5] Later the composition $Al_8B_4C_7$ was proposed without data on a crystal structure of the compound.[6] A detailed characterization was thus desirable, because this phase plays an important role in the investigation of hard materials ("cermets") based on boron carbide "B_4C" and aluminum.[7] The structure analysis of single crystals, which were obtained from the synthesis in molten aluminum, showed[8] that the correct composition is Al_3BC_3, that is a carbidecarboborate of aluminum.[9] Vibrational spectra confirm that the linear CBC group in Al_3BC_3 can be formulated as a complex anion $(C{=}B{=}C)^{5-}$ and thus represents the 16-electron system isoelectronic to CO_2 with the highest negative charge.

Single crystals of Al_3BC_3 in the form of hexagonal light yellowish transparent platelets were prepared from the elements at 1500 °C (see Experimental Procedure). The light yellow color is attributed to a weak and very broad absorption band at 380 nm in the UV/Vis spectrum. Single crystals of Al_3BC_3 are not sensitive to hydrolysis, and are stable in air up to about 600 °C. With the exception of HF and HNO_3 they are not attacked by dilute acids and bases at room temperature.

In the structure of Al_3BC_3 (Fig. 1), Al_5C trigonal bipyramids are linked by common corners of the basal plane to give layers of the composition Al_3C ($=CAl_2Al_{3/3}$), similar to Al_4C_3.[10] The most striking structural feature of the compound is located between these layers, namely isolated linear CBC groups with a B–C distance of 1.44 Å.

[**] We thank Prof. Dr. G. Thiele (Freiburg) for the generous support of our work.

These CBC units are parallel to each other and connect the Al_3C layers. Hitherto, comparable linear CBC groups were only found for Sc_2BC_2.[11] In the latter, the B–C distance (1.48 Å) is longer than in Al_3BC_3, possibly as a result of the metallic properties of Sc_2BC_2.

If the crystal structure is described based on the coordination polyhedra of the C atoms, corner-shared double tetrahedra Al_3CBCAl_3 in a staggered orientation with the boron atom as common corner connect the Al_3C layers of CAl_5 bipyramids through the terminal Al atoms, which are thus also tetrahedrally coordinated (Al–C: 2.00–2.06 Å). As a result of the formation of the superstructure,[8] the equatorial Al atoms (shaded in Fig. 1) are coordinated as slightly distorted tetrahedra with Al–C distances of 1.98 Å (3×) and 2.23 Å. In contrast to some of the conclusions drawn by Matkovich et al.,[5] the boron content does not vary. Therefore, Al_3BC_3 is the only stoichiometric ternary compound of the Al/B/C system.

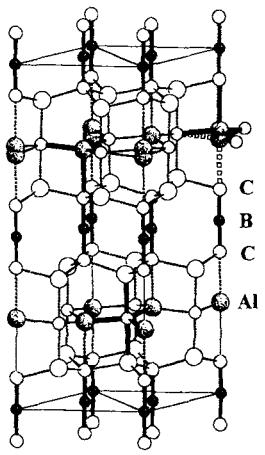

Fig. 1. Crystal structure of Al_3BC_3 with Al_3C layers and CBC groups. The Al atoms of the distorted AlC_5 trigonal bipyramids are shaded.

The structural similarity of Al_3BC_3 to Al_4C_3 and Al_5C_3N is a good reason for an ionic formulation as $(Al^{3+})_3(C^{4-})$-$(CBC)^{5-}$. According to this the CBC group can be interpreted as an anion $(C{=}B{=}C)^{5-}$ with 16 valence electrons. The analogy to CO_2 is confirmed by the vibrational spectra (Fig. 2). The

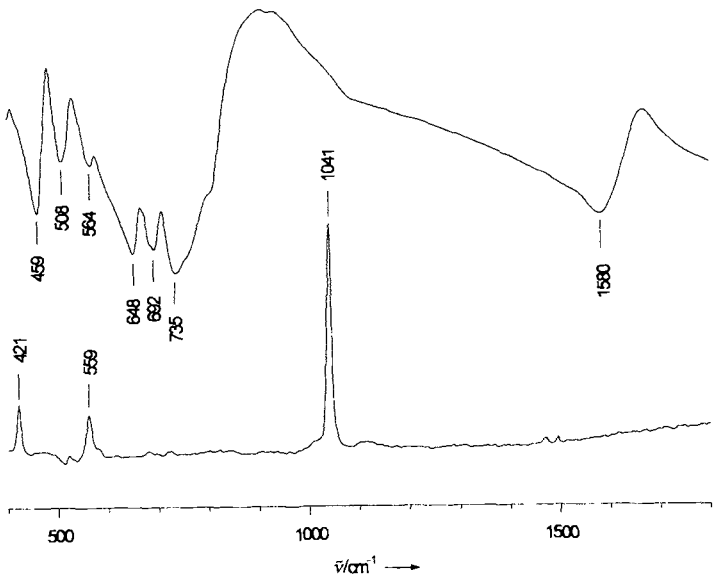

Fig. 2. FT-IR (top) and FT-Raman spectrum (bottom) of Al_3BC_3 (Bruker IFS66v, KBr and PE pellets, respectively).

predicted spectrum of a linear group YXY with $D_{\infty h}$ symmetry consists of three bands (symmetric stretching mode ν_s, Raman active; antisymmetric stretching mode ν_{as}, IR active; doubly degenerate bending mode δ, IR active). The strong band at 1041 cm^{-1} in the Raman spectrum of Al_3BC_3 can be assigned to the ν_s mode of the CBC group. The bands at 421 cm^{-1} and 560 cm^{-1} can be interpreted as Al–C stretching modes.[12] IR

 © VCH Verlagsgesellschaft mbH, D-69451 Weinheim, 1996 0570-0833/96/3521-2499 $ 15.00+.25/0

active modes at 1580 cm^{-1} (ν_{as}) and 735 cm^{-1} (δ) complete the vibrational spectrum of the CBC group. The calculation of the three force constants led to values of $f = 6.59\ N cm^{-1}$ (stretching force constant), $f' = 1.05\ N cm^{-1}$ (interaction force constant), and $f_d = 0.60\ N cm^{-1}$ (bending force constant). The quite high value of f_d results from the interaction between the C atoms of the CBC group and the surrounding Al atoms. As shown for the anion $(N{=}B{=}N)^{3-}$ f_d rises with the charge/radius ratio of the countercation.[13] Because of the broad signals and the low ^{10}B content (20%), the isotope splitting expected for the IR active modes is not observed.

According to Pauling[18] a bond order of 1.6 is calculated on the basis of the B–C distance. This is in good agreement with a value of 1.7 calculated from the force constant f according to the method of Siebert.[19] As expected the formal double bond is weakened significantly by the high negative charge. The effective charge of the CBC group is difficult to estimate because of the covalency of the Al–C bonds and will be investigated in more detail in the course of calculations. The comparison of bond lengths and force constants of anions with 16 valence electrons and boron as central atom shows (Table 1) that the results for the CBC group fit excellently in this series.

Table 1. Distances and force constants of 16-electron systems.

ref.	[13, 14]	[13, 15]	[16, 17]	this work

In summary, we have characterized the anion $(C{=}B{=}C)^{5-}$ for the first time by vibrational spectroscopy and by a structure analysis of Al_3BC_3. In terms of the maximum negative charge, the series of linear systems isoelectronic to CO_2 appears to be completed with $(C{=}B{=}C)^{5-}$. With respect to the ionic description, Al_3BC_3 can be regarded as the first carbidecarboborate.

Experimental Procedure

Single crystals of Al_3BC_3 were prepared from the elements. In an atmosphere of Ar the precursors (molar ratio Al/B/C = 40:2:3) were heated in a corundum crucible to 1500 °C, followed by slow cooling at a rate of 10 $K h^{-1}$ to 600 °C and then to room temperature by turning off the heat. Excess Al was removed with dilute aqueous HCl. By-products (AlB_2, Al_4C_3) were separated under the microscope.

[8] Structure analysis: No structure model could be developed on the basis of the unit cell as determined by film methods (a = 5.90 Å, c = 15.9 Å). However, a structure model was found for the subcell with a' = 3.405 Å ($= a/\sqrt{3}$), constituted by the reflections of high intensity (space group $P6_3/mmc$, $wR_2(I) = 0.048$, $R_1(F) = 0.020$, 122 reflections, 14 parameters). In this structure one Al atom is coordinated in a trigonal bipyramidal way [Al–C: 1.97 Å (3×), 2.53 Å (2×)]. As well known for similar structures (Al_4C_3, Al_5C_3N, ..) the Al atom is not located in the plane of the triangle, but moved to one of the tops of the bipyramid, thus forming a distorted tetrahedron. In the subcell this shift can be simulated by a disorder of Al in the z direction ($wR_2(I) = 0.030$, $R_1(F) = 0.013$). On the basis of this structure model a number of superstructure models were developed with tetrahedral coordination of Al. A satisfactory refinement was possible in the space group $P\bar{3}c1$ [dimensions of the crystal: 0.7 × 0.7 × 0.03 mm, M_r = 383.34, a = 5.900(2), c = 15.900(2) Å, V = 479.0(2) Å^3, space group $P\bar{3}c1$ (no. 165), Z = 6, ρ = 2.66 gcm^{-3}, CAD4 (Nonius), $Mo_{K\alpha}$ radiation, graphite monochromator, $\omega/2\theta$ scan, $2° < \theta < 32.5°$ ($\pm h$, $\pm k$, l), no absorption correction, structure solution: SHELXS86, refinement: SHELX93, 584 independent reflections (439 with $I > 2\sigma(I)$), 36 parameters, $wR_2(I) = 0.057$, $R_1(F) = 0.023$]. Four of the six trigonal bipyramidally coordinated Al atoms are located on a fourfold position (4d) in an ordered way, while the two remaining Al atoms occupy half of a fourfold position (4c). In that way a partial resolution of the disorder is possible. The symmetry reduction to space group $P3c1$ and the assumption of twinning (inversion twins, merohedral twins) led to unsatisfactory refinements. The complete separation of all Al atoms according to a 1:1 pattern is impossible on the basis of this unit cell if a trigonal space group is assumed. However, more complex patterns of ordering with orthorhombic or monoclinic symmetry and/or enlarged unit cells can be developed, but on the basis of the present data a satisfactory refinement seems to be impossible. The refinement in $P\bar{3}c1$ should be seen as a good approximation to the real structure. Further details of the crystal structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, D-76344 Eggenstein-Leopoldshafen (Germany), on quoting the depository number CSD-380116.
[9] Single crystals were analyzed by WDX (wavelength dispersive X-ray). No foreign elements heavier than boron were detected. Quantitative analysis gave the values: Al: calc. 42,8%, obs. 42,5%; B: calc. 14,3%, obs. 10,2%; C: calc. 42,8%, obs. 47,3%. The deviations for B and C are attributed to technical problems associated with the higher uncertainties for light elements.

Asymmetric Cyclization of α-Silyl Esters to Give Functionalized Hydrindanones**

Dieter Schinzer,* Thorsten Blume, and Peter G. Jones

Intramolecular additions of α-silyl esters to carbonyl groups, also known as intramolecular Peterson olefinations,[1] are rarely observed.[2, 3] In general, the starting materials for these reactions must be carefully selected so that the base does not remove one of the acidic protons adjacent to the carbonyl group. These competing deprotonations limit the utility of the Peterson olefination for cyclization reactions. We here report on the first

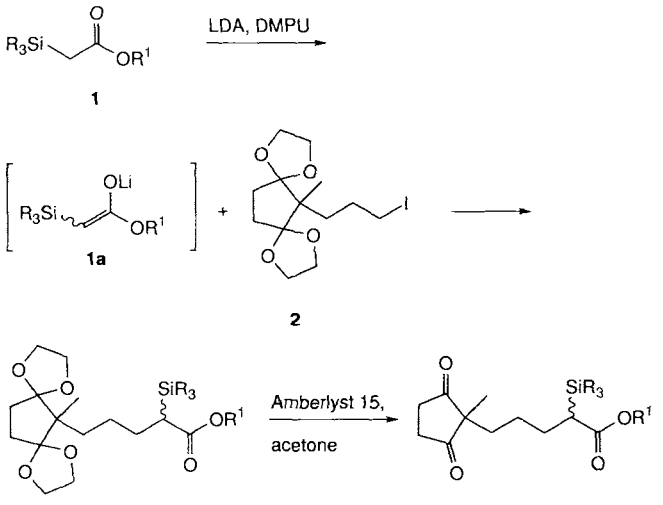
desilylations of alicyclic tricarbonyl compounds in which ester enolates are selectively formed and react further to yield functionalized hydrindanones (**5**, **6**) by means of a crossed, intramolecular aldol reaction. The cyclization products of these transformations are extremely important building blocks for the synthesis of steroids (for example the Hajos–Wiechert ketone).[4]

The required starting materials can be prepared readily in simple syntheses. The reaction of α-silyl ester **1** with **2**[5] afforded diketal **3**, which was hydrolyzed in the presence of amberlyst 15 to yield diketone **4** (Scheme 1, Table 1).[6] When **4a**

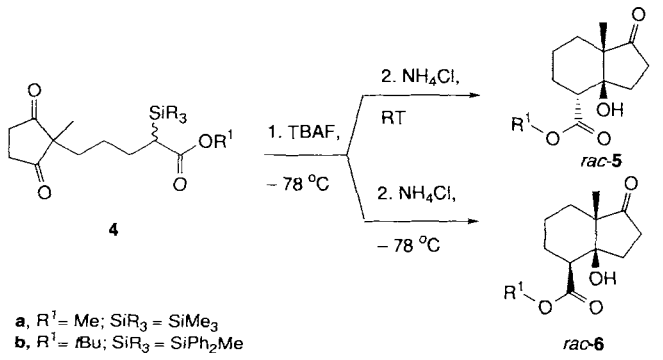


Scheme 1. Synthesis of **4**. R^1 = Me, *t*Bu, (−)-menthyl, (−)-, (+)-phenylmenthyl; SiR_3 = $SiMe_3$, $SiPh_2Me$.

Table 1. Yields of the syntheses of **3** and **4** and of the cyclization giving *rac*-**5** and *rac*-**6**.

	Starting compound				Yield [%]	
	SiR_3	R^1	**3**	**4**	*rac*-**5**	*rac*-**6**
1a	$SiMe_3$	Me	70	77	41	64
1b	$SiPh_2Me$	*t*Bu	73	62	40	68
1c	$SiPh_2Me$	(−)-menthyl	59	62		
1d	$SiMe_3$	(−)-phenylmenthyl	72	71		
1e	$SiMe_3$	(+)-phenylmenthyl	69	71		

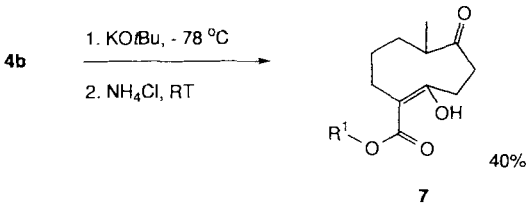
(R^1 = Me; SiR_3 = $SiMe_3$) was treated with one equivalent of tetra-*n*-butylammonium fluoride (TBAF) at −78 °C, the functionalized hydrindanones *rac*-**5** and *rac*-**6** were exclusively



a, R^1 = Me; SiR_3 = $SiMe_3$
b, R^1 = *t*Bu; SiR_3 = $SiPh_2Me$

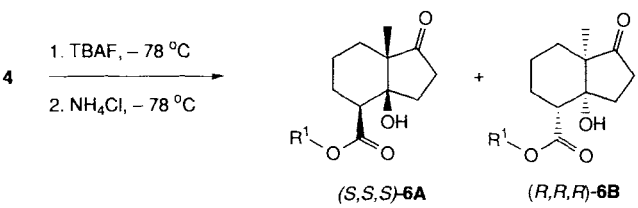
formed depending on the workup conditions (hydrolysis at −78 °C and at room temperature (RT), respectively) (Table 1; the relative configurations were determined by COSY and NOE NMR experiments). When less than one equivalent of TBAF was used, the reaction did not go to completion, implying that this reaction corresponds to a desilylation/aldol sequence.[7] The transformation with lithium diisopropylamide did not yield any cyclization product. When potassium *tert*-butoxide was used, however, *rac*-**5** was isolated in 23% yield.

The corresponding reaction of the *tert*-butyl ester **4b** (R^1 = *t*Bu; SiR_3 = $SiPh_2Me$) proceeds in a different way. Depending on the workup conditions (hydrolysis at −78 °C or at RT), treatment of **4b** with TBAF resulted in the formation of the expected hydrindanones *rac*-**5** and *rac*-**6** (R^1 = *t*Bu), respectively. In contrast, however, the transformation of **4b** with potassium *tert*-butoxide surprisingly led to the medium-sized ring **7** (R^1 = *t*Bu) in 40% yield.[6] In this case, the nine-membered ring β-oxo ester, which exists exclusively in the enol form, is presumably formed by a retro-aldol reaction[8] following the cyclization step.



Since substrates **4** contain a prochiral center with diastereotopic groups, they can potentially be exploited in asymmetric syntheses. To explore this possibility, we prepared the optically active esters **4c–e** (R^1 = (−)-menthyl, (−)- and (+)-phenylmenthyl, respectively). For the synthesis of **4c**, commercially available (−)-menthyl acetate was first C-silylated with diphenylmethylsilyl chloride as described in the literature;[9] the trimethylsilyl derivatives were prepared according to the silyl ketene acetal method.[10] The resulting α-silyl ester was then alkylated with the diacetal iodide **2**, and the acetal groups were subsequently cleaved to form an inseparable 60:40 mixture of diasteromers (**4c** (R^1 = (−)-menthyl, SiR_3 = $SiPh_2Me$)).

Treatment of **4c** with TBAF in THF at −78 °C afforded the all-*cis* compounds (*S*,*S*,*S*)-**6A** and (*R*,*R*,*R*)-**6B** as an inseparable mixture of diastereomers in a total yield of 61% and a ratio of 35:65.[6]



The transition from (−)-menthol to (−)-phenylmenthol as a chiral auxiliary generally results in enhanced stereochemical discrimination.[11] Hence we synthesized the phenylmenthyl esters **4d** and **4e** (R^1 = (−)- and (+)-phenylmenthyl, respectively, SiR_3 = $SiMe_3$) to investigate their cyclization behavior. Compound **4d** reacted with TBAF in THF at −78 °C to form the cyclization products (*S*,*S*,*S*)-**6A** and (*R*,*R*,*R*)-**6B** (R^1 = (−)-phenylmenthyl) in a somewhat improved diastereomeric ratio relative to that resulting from the corresponding menthyl ester (Table 2). An additional preparative advantage is that the

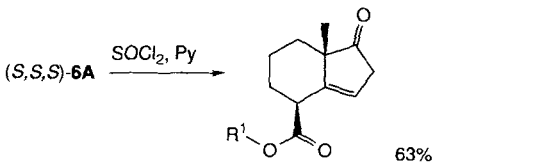
[a] Hexamethylphosphoric triamide.

diastereomers (*S,S,S*)-**6A** and (*R,R,R*)-**6B** (R^1 = (−)-phenylmenthyl) can be separated easily by flash chromatography. The transformation with the (+)-phenylmenthyl ester **4e** yielded the (*S,S,S*)-phenylmenthyl ester **6A** as the major product. The absolute configurations of (*S,S,S*)-**6A** and (*R,R,R*)-**6B** (R^1 = (−)-phenylmenthyl) were confirmed by X-ray crystallography.[12]

Compounds such as **6A** and **6B** are interesting synthetic C–D ring intermediates for the biologically active cardiac glycosides.[13] In order to obtain the equally important *trans*-annulated C–D building blocks necessary for the synthesis of vitamin D_3,[14] the tertiary OH group must be eliminated. The transformation of (*S,S,S*)-**6A** in pyridine (Py) and thionyl chloride affords exclusively the β,γ-unsaturated compound (*S,S*)-**8**, which can then be hydrogenated to furnish the desired *trans*-hydrindanone.[5]



(*S,S*)-**8**, R^1 = (+)-phenylmenthyl

Experimental Procedure

A solution of TBAF in THF (1.1 M, 0.289 mmol, 0.26 mL) was stirred in anhydrous THF (2 mL) for 20 min at room temperature with activated molecular sieves to bind any residual water in the TBAF solution. The resulting anhydrous TBAF solution was then added dropwise to a solution of diketone **4d** (120 mg, 0.241 mmol) in THF (3 mL) cooled to −105 °C. The solution was stirred for 20 min at −105 °C and subsequently hydrolyzed with NH_4Cl. The mixture was extracted twice with diethyl ether, the combined organic layers were washed with NaCl solution and dried over $MgSO_4$, and the solvent was removed. Purification by flash chromatography with pentane/ether (5/1) yielded 62 mg of (*R,R,R*)-**6B** (R^1 = (−)-phenylmenthyl; 60%) and 24 mg of (*S,S,S*)-**6A** (R^1 = (−)-phenylmenthyl; 23%).

Model Calculations on the Stereoselectivity of the Triplet Photoreaction of 1,2-Dimethyltrimethylene

Marcus Böckmann and Martin Klessinger*

In a nonadiabatic photoreaction, excitation from the ground state (S_0) into the lowest singlet state (S_1) or triplet state (T_1) brings about geometrical changes followed by return from S_1 to S_0 by a conical intersection or from T_1 to S_0 by intersystem crossing (ISC), and thermal equilibration in the ground state.[1] Although the structures of the products and the efficiencies of their formation depend on the nature of the motions in the excited state, on the geometry of return to the S_0 state, and the final steepest descent motion on the S_0 surface, the geometry of return is of a paramount importance in solution reactions. For a nonadiabatic singlet reaction, this is the conical intersection, which from a mechanistic point of view plays a similar role as the transition state in a thermal reaction.[2] In triplet photoreac-

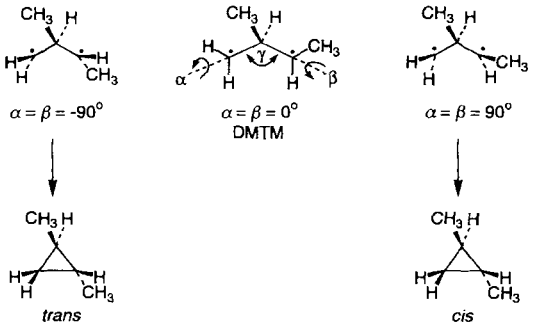
tions the geometries most favorable for ISC may be considered to be of similar relevance.[3]

Thus, the knowledge of the "reactive structure", that is the transition structure of a thermal reaction, the structure of the conical intersection accessible on the excited state potential energy surface (PES) of a singlet photoreaction, or the geometries favorable for ISC in a triplet photoreaction, is decisive for the discussion and prediction of the stereochemical outcome of the reaction. Triplet stereoselectivity has recently been exploited mainly in synthetic applications of the Paternò–Büchi reaction.[4]

Herein we present a general procedure for determining the reactive structure and discussing the stereoselectivity of triplet photoreactions. The ring-closure reaction of 1,2-dimethyltrimethylene (DMTM) will be used as an example to show that on the basis of the PES of the ground state S_0 and the lowest triplet state T_1 in combination with SOC surfaces, where the spin-orbit coupling value SOC rather than the energy E is plotted as a function of the reaction coordinates, it is possible to locate the regions of large SOC and small singlet–triplet separation E_{ST} that are most favorable for ISC.[5] All calculations are based on recently developed methods to treat SOC within the framework of the semiempirical configuration interaction (CI) approach.[6]

Computational results for unsubstituted trimethylene (TM) have been reported,[6, 7] and the structural dependence of SOC has been discussed previously[6, 7a, b] and rationalized on the basis of the two-electron two-orbital model and symmetry considerations.[8] It was shown that conrotatory ($\beta = \alpha$) and disrotatory ($\beta = 180° - \alpha$) motions of the terminal methylene groups yield similar results. On the basis of a combined analysis of PES and SOC surfaces, ISC and the ring-closure reaction could be discussed: the minimum energy valley of the triplet PES that corresponds to nearly free rotation of the radical centers is unfavorable for ISC since the S_0 state lies energetically above the T_1 state. However, in the region of large SOC, in which the terminal methylene groups are rotated by $\alpha > 45°$ toward a face-to-face arrangement (Scheme 1), decreasing the C-C-C valence



Scheme 1. Definition of the rotational angles α and β, and of the bond angle γ. $\alpha = \beta = 0$ corresponds to a side-to-side arrangement of the radical centers, and $|\alpha| = |\beta| = 90°$ to a face-to-face arrangement.

angle γ to a value of 105° raises the energy only slightly (1–2 kcal mol^{-1}) and leads to singlet–triplet degeneracy ($E_{ST} = 0$) and therefore to geometries very favorable to ISC.[6]

In DMTM there are two different modes of conrotatory motion ($\beta = \alpha$) of the radical centers, leading to stereoisomeric cyclization products: rotation by positive ($\alpha > 0$) and negative ($\alpha < 0$) values of the rotational angle yields *cis*- and *trans*-dimethylcyclopropane, respectively (see Scheme 1). S_0 and T_1 PES together with SOC surfaces are shown for both modes of rotation in Figure 1.[9] From a comparison of these results with

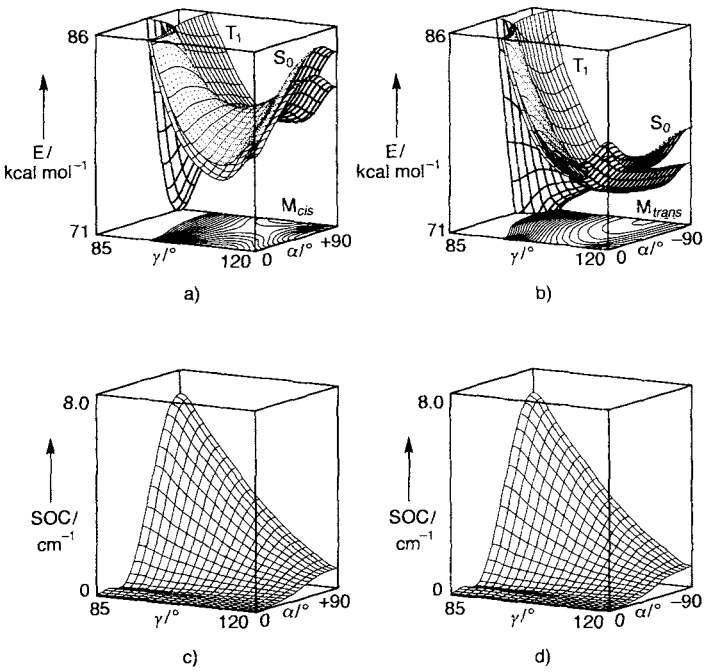


Fig. 1. The ring-closure reaction of 1,2-dimethyltrimethylene. Lowest singlet and triplet PES for conrotatory motion of the radical centers toward a) the *syn* ($\alpha > 0°$) and b) the *anti* conformation ($\alpha < 0°$), as well as SOC surfaces c) for $\alpha > 0°$ and d) for $\alpha < 0°$.

those of TM[6] it is evident that to a first approximation the methyl substituents do not at all affect the SOC values, while steric effects appreciably change the appearance of the valley on the T_1 PES. For the *syn* mode of rotation a barrier of approximately 3.4 kcal mol^{-1} is found to separate the local minimum M_{cis} at $\alpha = 90°$ from the planar structure ($\alpha = 0°$) that is 1.0 kcal mol^{-1} lower in energy than the barrier. For the *anti* mode of rotation, however, the valley descends practically without a barrier toward the minimum M_{trans} at $\alpha = -90°$, 5.0 kcal mol^{-1} lower in energy than M_{cis}. Some data for selected geometries including the singlet–triplet intersection line ($E_{ST} = 0$), are collected in Table 1. By decreasing the bond angle γ, geometries are accessible both from M_{cis} and M_{trans} at which S_0 and T_1 are degenerate ($E_{ST} = 0$) and SOC is appreciable (SOC > 2 cm^{-1}); the necessary energies are less than 1 kcal mol^{-1}. For rotational angles $|\alpha| < 45°$, however, much larger energies (> 10 kcal mol^{-1}) are required and geometries with SOC < 1 cm^{-1} are reached.

Table 1. 1,2-Dimethyltrimethylene. State energies and SOC values for selected geometries from MNDOC-CI calculations [a].

Geometry [γ, α] [b]		Energy [kcal mol^{-1}] ^3E [c]	E_{ST} [d]	SOC [cm^{-1}]
[111, −90]	M_{trans}	0	1.5	1.778
[112, 0]		2.6	1.1	0.002
[109, 60]	B	6.0	1.0	1.090
[110, 90]	M_{cis}	5.0	1.3	1.912
[105, 90]		5.4	0	2.631
[105, 75]		5.8	0	2.315
[103, 60]		6.6	0	1.613
[96, 45]		0.6	0	0.923
[106, −90]		0.6	0	2.612
[105, −75]		0.7	0	2.316
[103, −60]		1.5	0	1.627
[96, −45]		6.8	0	0.930

[a] Singlet open-shell 3-3′ CI. [b] $\beta = \alpha$. [c] Relative to $\Delta H_f(^3M_{trans}) = 73.4$ kcal mol^{-1}. [d] $E_{ST} = {}^1E - {}^3E$.
